Sugar 6.—This material (15 mg) was obtained from the paper chromatographic separation of sugars 5 and 6. The syrup had an R_f value identical with that of 2,4-di-*O*-methyl-D-xylose in solvents (A), (B), and (C). The syrup failed to crystallize or yield a crystalline aniline derivative.

Sugar 7.—This material (10 mg) was obtained from the separation of sugar 2. The syrup yielded arabinose after demethylation and had an R_f value in solvents (A) and (B) of 0.91 and 0.85 respectively. The data suggest that it is either 2,3,4-tri-*O*-methyl-L-arabinose or 2,5-di-*O*-methyl-L-arabinose (45); crystalline derivatives could not be obtained.

Investigation of the Alcohol-soluble Smith-type Degradation Products

1. Acetone Separation

The syrup (2.1 g) was extracted three times with boiling acetone. The acetone solutions were decanted, combined, and concentrated to a syrup (1.1 g).

2. Separation of the Acetone-insoluble Material

The syrup (1.0 g) in water (3 ml) was absorbed on a column of Dowex 50W resin 2% crosslinked (lithium salt) (46). Water was used as the developing solvent and six fractions were collected. Chromatography of the first three fractions indicated the presence of higher molecular weight material. Hydrolysis of portions of each fraction indicated a mixture of glycerol and one or two sugars.

3. Separation of the Acetone-soluble Material

This material (1.1 g) was separated in the same manner as the acetone-insoluble material and the following fractions were obtained.

Fraction	Tube No.	Component (R_{rham}, solvent (B))	Weight (mg)
A	0–81	0.22, 0.16	110
B	82–100	1.52, 1.14, 0.93 0.75, 0.60, 0.30, 0.14	230
C	101–146	1.50, 1.11, 0.90 0.75, 0.60	317
		Total	657

Fraction A.—This fraction was not investigated.

Fraction B (230 mg).—This fraction was separated on cellulose using butan-1-ol half saturated with water as eluant to give seven fractions.

Fraction B_3 (30 mg).—This fraction had an R_f value corresponding to glycerol in all solvents. The syrup was characterized as the tri-*O*-*p*-nitrobenzoate, m.p. 190–191° C undepressed on admixture with authentic glycerol-tri-*O*-*p*-nitrobenzoate (9). All the other fractions were hydrolyzed and appeared to be glycerol glycosides of arabinose and galactose.

Fraction C (317 mg).—This fraction was fractionated in a manner similar to that used for fraction B to yield five fractions.

Fraction C_1.—This syrup was separated into two components (R_{rham} 1.64 and R_{rham} 1.24) using solvent (A). The fast-moving component (R_{rham} 1.64) yielded glycerol and a trace of arabinose after hydrolysis. The slow-moving component (R_{rham} 1.24) yielded glycerol and traces of arabinose and galactose after hydrolysis.

Fraction C_2.—This syrup had $[\alpha]_D^{22}$ +13° (*c*, 1.3) and yielded equal amounts of glycerol and arabinose after hydrolysis. The material had an R_{glyc} value of 0.87 in solvent (A) and 0.92 in solvent (B). When oxidized with metaperiodate, the syrup consumed 1.80 moles of periodate and released 0.81 mole of formic acid per sugar molecule. Hydrolysis of the periodate-oxidized material followed by chromatography in solvent (A) indicated that no monosaccharide was present but confirmed the presence of glycerol. The material did not crystallize but possessed optical rotation and R_f values similar to those of 2-*O*-α-L-arabinosyl glycerol glycoside obtained by Jones (14).

Fraction C_3.—This material was not further investigated.

Fraction C_4.—This fraction was separated into three components by paper electrophoresis. The zones (α, β, and γ) were eluted with water and concentrated to syrups.

Fraction α.—This syrup (48 mg) had $[\alpha]_D^{22}$ +29° (*c*, 0.94) and R_{rham} value 0.61 in solvent (A) which was identical with that of arabinose. The syrup was treated with saturated benzoyl hydrazine solution for 48 hours. The derived L-arabinose benzoyl hydrazone had m.p. and mixed m.p. 189–191° C (47).

Fraction β.—This material (27 mg) had $[\alpha]_D^{22}$ +18° (*c*, 1.38) and R_{rham} value 0.68 in solvent (A). The syrup yielded arabinose and glycerol after hydrolysis.

Fraction γ.—This syrup (27 mg) was a mixture and consisted of two components (R_{rham} 0.68 and 0.77) in solvent (A). Hydrolysis of the mixture followed by chromatography indicated the presence of arabinose, galactose, and glycerol.

Fraction C_5.—This syrup (5 mg) had $[\alpha]_D^{27}$ +23° (*c*, 0.38) and R_{gal} values of 1.10 in solvent (A) and 1.2 in solvent (B). The material gave a dark brown color with *p*-anisidine and yielded about equal amounts of arabinose and galactose after hydrolysis. Sufficient material was not available for further study.

Partial Hydrolysis of the Neutral Fraction

The neutral material (1 g) in sulphuric acid solution (0.5 *N*, 10 ml) was heated on a boiling-water bath. Samples were removed at hourly intervals for a period of 9 hours and examined chromatographically in solvents (A) and (B). The maximum yield of oligosaccharides was obtained at about 5 hours. These conditions were therefore chosen for a large-scale partial hydrolysis.

The neutral fraction (29 g) was swollen in sulphuric acid solution (0.5 *N*, 290 ml) and heated on a boiling-water bath for 5 hours. The hydrolyzate was neutralized ($BaCO_3$) and the precipitate removed by centrifugation. The centrifugate was passed through IR-120(H) resin and A-4(OH) resin. The neutral eluate was concentrated to a small volume (75 ml) and dialyzed against distilled water for several days. The water used in the dialysis was concentrated to a syrup (23 g). The dialyzate was concentrated and then poured into alcohol to yield the degraded polysaccharide (1.79 g) which had $[\alpha]_D^{21}$ −15° (*c*, 0.23). Hydrolysis of this material (30 mg) followed by chromatography in solvents (B) and (C) indicated the presence of xylose and galactose but the absence of arabinose; trace amounts of rhamnose and galacturonic acid were also detected. The disaccharides were separated from the monosaccharides in the syrup (23 g) on a charcoal–celite (1:1, w/w) column (48) using water as eluant. The disaccharides were removed with ethanol in water and yielded a syrup (2.1 g) upon concentration.

Column Separation of the Oligosaccharides

The syrup (2.1 g) was adsorbed on a cellulose column previously equilibrated with the developing solvent (*n*-propanol:ethyl acetate:water) (7:1:1, v/v). Thirteen fractions were collected, all of which were mixtures. All but fractions 12 and 13 were further separated on paper, using solvent (A).

Identification of the Disaccharide Fragments

Disaccharide 1

This material (352 mg) had $[\alpha]_D^{22}$ +84° (*c*, 1.75) and showed R_{gal} values of 1.18, 1.29, and 1.33 in solvents (A), (B), and (D) respectively. Hydrolysis of the syrup followed by chromatography indicated equal amounts of arabinose and xylose. Bromine oxidation showed that arabinose was the reducing end-group.

A small portion (20 mg) of the disaccharide was dissolved in water (3 ml). Redistilled phenylhydrazine (0.18 ml) and glacial acetic acid (0.20 ml) were added and the mixture heated for several hours at 40–45° C. Upon cooling of the solution, yellow crystals appeared, which were collected and recrystallized from water. The crystals rapidly turned a dark brown color and had m.p. 121–125° C.

A further portion of the syrup (25 mg) was dissolved in borate buffer (0.1 *M*, pH 7) and reduced with potassium borohydride solution (3 mg in 1 ml) for 1 day (49). The excess borohydride was destroyed with dilute acetic acid and the solution was then passed through IR-120(H) resin and A-4(OH) resin. The eluate was concentrated and codistilled several times with methanol. The dried syrup was treated twice with acetic anhydride (3 ml) and pyridine (5 ml) at room temperature for 40 hours. The acetate was isolated in the usual manner but failed to crystallize. The syrup had $[\alpha]_D^{22}$ +6° (*c*, 1.27 in chloroform). The disaccharide acetate was dissolved in acetone (20 ml) and the solution refluxed with sodium hydroxide solution (0.1 *N*, 5 ml) for 5 hours. The solution was cooled and passed through IR-120(H) resin. The eluate was then concentrated to a syrup. Paper chromatography indicated a trace of unreduced disaccharide (R_{gal} 1.2) and the syrupy sugar alcohol derivative which was separated using solvent (A). The zone (R_{gal} 0.70) was eluted with water and finally yielded a syrup (14.5 mg) which had $[\alpha]_D^{23}$ +46° (*c*, 1.45). When the material was oxidized with lead tetraacetate in a Warburg apparatus, 1.5 moles of formic acid were released. The reduced

disaccharide consumed 3.47 moles of periodate and liberated 1.60 moles of formic acid and 0.70 mole of formaldehyde (50) per mole of sugar when oxidized with sodium metaperiodate. Disaccharide 1 when chromatographed in solvents (A) and (B) had R_{gal} 1.16 and in solvent (C) had R_{gal} 1.31. This material had R_{gal} values which differed from those of 5-*O*-β-D-xylopyranosyl-L-arabofuranose, 3-*O*-α-D-xylopyranosyl-L-arabinose, and 2-*O*-β-D-xylopyranosyl-L-arabinose.

Disaccharide 2

This material (125 mg) had $[\alpha]_D^{17}$ +94° (*c*, 1.23). The R_{gal} values in solvents (A), (B), and (D) were respectively 1.00, 0.88, and 1.02. The syrup was not identical with 3-*O*-α-D-xylopyranosyl-D-xylose and the xylobiose already identified. Hydrolysis of a small portion indicated only xylose. The syrup (7 mg) was treated with phenylhydrazine to yield yellow crystals which darkened in color very rapidly. After recrystallization from hot water the crystals had m.p. 154–156° C. When oxidized with sodium metaperiodate, the disaccharide consumed 3.10 moles of periodate and released 1.60 moles of formic acid per sugar molecule.

Disaccharide 3

This syrup (41 mg) had $[\alpha]_D^{17}$ −16° (*c*, 2.04). The R_f value in all solvents was identical with that of 4-*O*-β-D-xylopyranosyl-D-xylose. Hydrolysis of a portion of the syrup showed only xylose. When seeded the material crystallized. It was recrystallized from methanol and had m.p. 194–196° C, undepressed on admixture with authentic 4-*O*-β-D-xylopyranosyl-D-xylose (40). The derived phenylosazone had m.p. and mixed m.p. 210–212° C (decomp.).

Disaccharide 4

A small amount of this material (3 mg) was available. The syrup had $[\alpha]_D^{17}$ +34° (*c*, 0.29). Hydrolysis followed by chromatography indicated arabinose and galactose. Bromine oxidation left the galactose unit untouched. The R_{gal} values on chromatograms in solvents (A) and (B) were 0.92 and 0.65 respectively.

Disaccharide 5

This material (5 mg) possessed R_{gal} 0.42 in solvent (A) and R_{gal} 0.65 in solvent (B). The syrup had $[\alpha]_D^{17}$ +25° (*c*, 0.48) and was shown to be a galactosyl-arabinose from the results of hydrolysis and bromine oxidation.

Disaccharide 6

This syrup (164 mg) had $[\alpha]_D^{18}$ +14° (*c*, 8.2). Hydrolysis followed by chromatography indicated the presence of xylose and arabinose. Bromine oxidation indicated arabinose to be the reducing end-group. The derived phenylosazone had m.p. 185–187° C. The disaccharide consumed 4.34 moles of periodate and produced 1.95 moles of formic acid. The material had R_{gal} values of 0.90 in solvents (A) and (C) and 0.80 in solvent (B).

Resin Separation of Fractions 12 and 13

The combined fractions 12 and 13 (155 mg) were placed on a column of Dowex 50W resin, 2% cross-linked (46). Aqueous ethanol (50%) was used as the developing solvent, to give four fractions. All fractions proved to be mixtures. Fraction 4 crystallized and was recrystallized from ethanol containing a trace of water. The crystals had m.p. 238–240° C. Hydrolysis followed by chromatography indicated only xylose. The sugar had R_{glu} values in solvent (E) of 0.13 and R_{malt} value of 0.20.

ISOTOPE RATE EFFECTS IN THE ENOLIZATION OF OXALACETIC ACID

GEORGE W. KOSICKI
Department of Chemistry, Essex College, Assumption University of Windsor, Windsor, Ontario
Received February 16, 1962

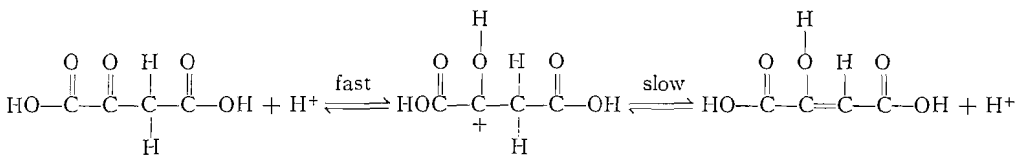
ABSTRACT

Acid-catalyzed enolization of oxalacetic acid in H_2O and D_2O gives rise to a constant isotope rate effect k_{H_2O}/k_{D_2O} of 2.4 over the pH (pD) range of 5.5 to 7.5. Base-catalyzed enolization of oxalacetic acid in H_2O and D_2O gives rise to a constant isotope rate effect k_{H_2O}/k_{D_2O} of 4.5 over the pH (pD) range of 7.0 to 8.0. The percentage of enol form of oxalacetic acid was calculated to be 15.3% at pH 8.0, using the absorption of the enol form in ether at 255 mμ and the absorption of the keto form at pH 0.5 in an aqueous system. The spectrophotometric measurement of the isotope rate effect involved in the enolization of oxalacetic acid gives direct evidence for the rate-determining step in both the acid- and the base-catalyzed reactions without subsequent reactions.

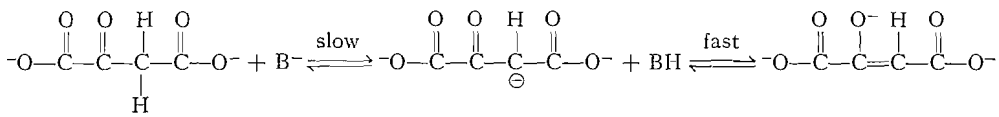
INTRODUCTION

During the study of the isotope rate effects of the citrate-condensing enzyme we observed certain spectral changes in the assay involving the enolization of oxalacetic acid (1). Oxalacetic acid has been found to exist in the enol form to the extent of 15.2 to 15.8% in aqueous systems from pH 5 to 10 (2). Enolizations of this type are general acid- and base-catalyzed reactions (3, 4):

Acid-catalyzed:



Base-catalyzed:



The step involving the C—H bond cleavage has been shown to be rate limiting by following the rate of enolization by subsequent bromination (5, 6), racemization, and deuteration (7) of the resulting enol. The rate of the base-catalyzed bromination is proportional to the concentrations of the ketone and base but is independent of the concentration of bromine. The acid-catalyzed halogenation has properties similar to those of the base-catalyzed reaction, i.e. the rate is proportional to the concentration of the ketone and acid but independent of the concentration of the halogen. This means that although halogen is consumed in the overall reaction of both acid- and base-catalyzed enolizations, it becomes involved after completion of the rate-determining step.

The rate of enolization of oxalacetic acid can also be followed spectrophotometrically because the enol form has a markedly increased absorption at 255 mμ. This increased absorption is due to the conjugated bond system of the enol form. In this paper the rate

of enolization of oxalacetic acid is measured spectrophotometrically as a function of pH and pD. The results show an isotope rate effect in both the acid- and base-catalyzed enolizations, indicating directly that C—H bond cleavage is involved in the rate-determining step.

EXPERIMENTAL

The following materials were commercial preparations: reduced diphosphopyridine nucleotide (DPNH), oxalacetic acid, and malate dehydrogenase (C. F. Boehringer and Son, Mannheim, Germany). The D_2O (99.78 atom% excess D) was purchased from Atomic Energy of Canada Limited, Ottawa. Tris(hydroxymethyl)aminomethane (THAM) was primary standard grade.

Oxalacetic acid concentrations were measured enzymatically using malate dehydrogenase and DPNH in 0.1 *M* potassium phosphate buffer, pH 7.2 (8). In these cases, however, the malate dehydrogenase reaction was followed to completion in the presence of an excess of enzyme (200 units) and a limiting concentration of oxalacetic acid. In a 1.0-ml volume and 1.0-cm light-path reaction cell, 1.0 μmole of DPNH consumed, which is equivalent to 1.0 μmole of oxalacetic acid, gives a change of 6.22 absorbancy units at 340 mμ. Freshly dissolved oxalacetic acid samples were stored in ice during the time of running a given series of readings in order to minimize decarboxylation.

The pH of each reaction cell was measured at the end of the assay by a Beckman Model G pH meter. For the D_2O systems the numerical reading of pH was converted to pD by adding 0.4 units as described by Lumry *et al.* (9, 10). This calculation received experimental confirmation by Glascoe and Long (11). For the assays in D_2O the same reagents used in the H_2O systems were made up in D_2O. The D_2O concentrations were routinely above 98% in the reaction cell.

The rates of reaction were measured with a Beckman Model D.U. spectrophotometer. The temperature of the reaction cell was kept at 25±0.2° C by a water-circulating bath.

RESULTS

Figure 1 shows the absorbancy of the equilibrium mixture of enol and keto forms of oxalacetic acid measured in the direction of enol formation. The equilibrium mixture at pH 8.0 contains 15.3% enol as calculated from the 255-mμ absorption of oxalacetic acid in ether; the ketoacid in ether is known to be in the enol form (12). The molar absorbancy index at 255 mμ is 5.60×10^3. The aqueous absorption at pH 8.0 was corrected for the

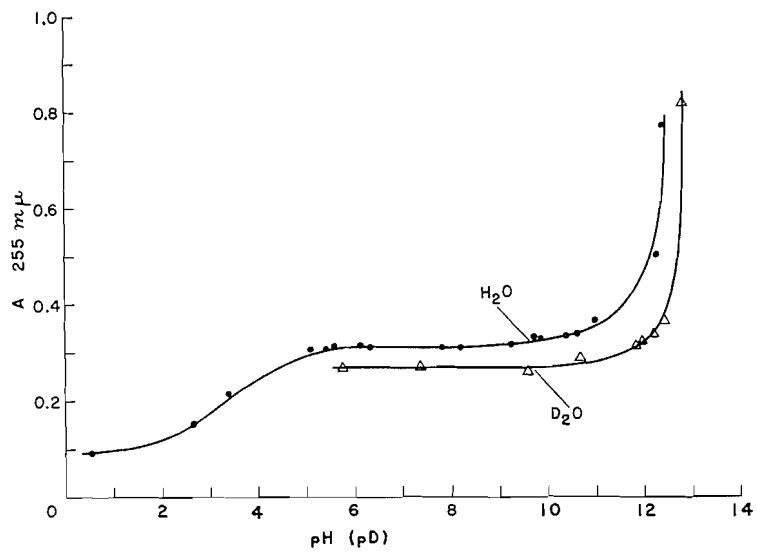


FIG. 1. Equilibrium absorbancy of oxalacetate. Each cell (0.5-cm light-path) contained 0.795 μmole of oxalacetic acid and sufficient NaOH (or HCl) to give the resulting pH (pD) values, and water to make the final volume 1.5 ml. For D_2O systems the reagents were made up in D_2O. The absorbancy values are the highest readings reached for each reaction.

absorption of the keto form by using the absorption of oxalacetic acid at pH 0.5, where the molar absorbancy index is 0.41×10^3. At pH 2.5 oxalacetic acid in H_2O is 2.8% in the enol form and at pH 12.4, 49%. The equilibrium absorption is approximately constant from pH 5 to 10.

The equilibrium absorption in D_2O is decreased, corresponding to 12.7% enol form from pD 5 to 11. Above pD 11 the absorption in D_2O is shifted about 0.5 pD units.

The same equilibrium values are reached by ketonization. Oxalacetic acid in NaOH (pH 12.5) or in ethanol, where the enol form predominates, was neutralized with varying amounts of HCl or NaOH to give a range of resulting pH and equilibrium values. At 25° C the rate of ketonization is too fast to be followed by our method.

Figure 2 shows the rate of absorbancy change as a function of pH in the range of acid-catalyzed enolization. The solid acid (enol form) equilibrated in H_2O (pH 2.5) corresponds

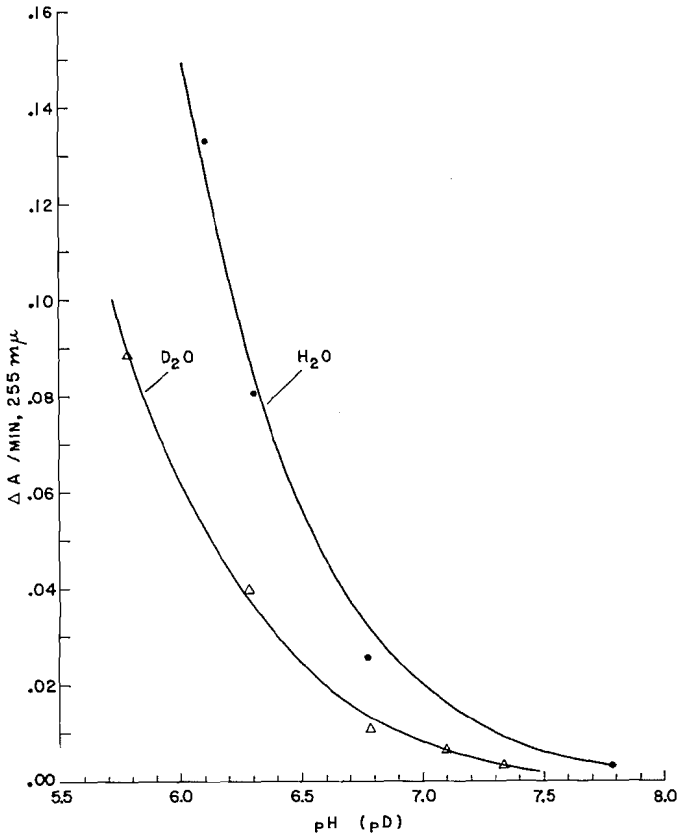

FIG. 2. Acid-catalyzed enolization. Each reaction cell (0.5-cm light-path) contained 0.765 μmole of oxalacetic acid, sufficient NaOH to give the resulting pH (pD) values, and water to make the final volume 1.5 ml. The reactions were started by additions of 0.10 ml of a solution of oxalacetic acid in H_2O (pH 3) or in D_2O (pD 2.5). The curve for the H_2O system is drawn with a constant isotope rate effect of k_{H_2O}/k_{D_2O} of 2.4.

to 2.8% enol form. This solution of the keto form of oxalacetic acid was added to a solution of NaOH of varying concentrations so that the resulting pH values would be within the range of pH 5.5 to 7.5. The initial rates of absorbancy increase were measured at 255 mμ and expressed as absorbancy change per minute.

The rate of absorbancy change as a function of pD (Fig. 2) shows a similar acid-catalyzed enolization. The D_2O system was measured under identically corresponding conditions, replacing H_2O with D_2O. The rate of enolization in D_2O depends on a higher concentration of acid, giving rise to a constant isotope rate effect k_{H_2O}/k_{D_2O} of 2.4.

In Fig. 3 the base-catalyzed enolization is shown for both H_2O and D_2O systems. A solution of the keto form (pH 3.0) was added to 0.67 *M* THAM–HCl, with the HCl

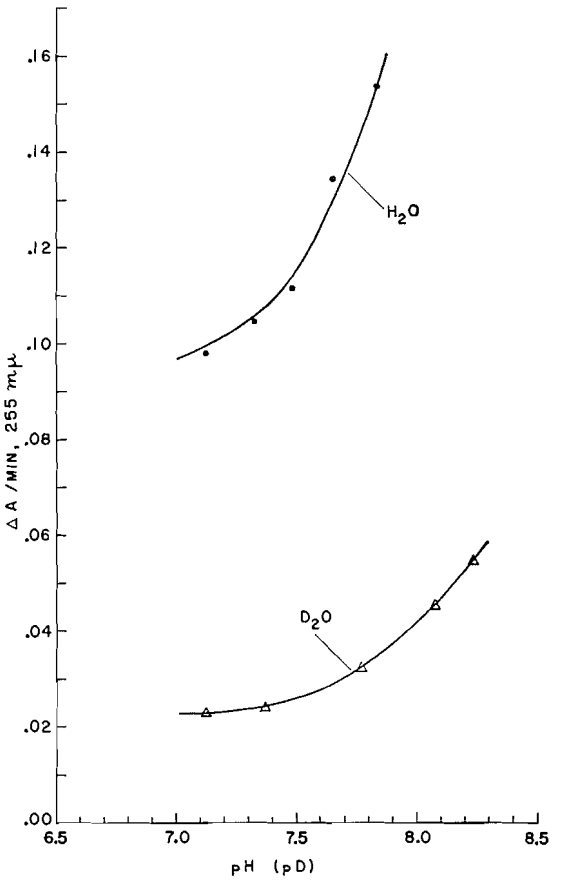

FIG. 3. Base-catalyzed enolization. Each reaction cell (0.5-cm light-path) contained 0.680 μmole of oxalacetic acid, 100 μmoles of basic THAM, sufficient HCl to give the resulting pH or pD values, and water or D_2O to make the final volume 1.5 ml. The curve for H_2O is drawn with a constant isotope rate effect k_{H_2O}/k_{D_2O} of 4.5.

concentrations varying so as to adjust the resulting pH or pD values. The rate of base-catalyzed enolization was similarly followed by the absorption increase at 255 mμ. The isotope rate effect of k_{H_2O}/k_{D_2O} is a constant value of 4.5. Additions of salts of weak acids such as $KHCO_3$ or THAM–acetate increased the rate of enolization, thus shifting the rate curve of the base-catalyzed reaction to lower pH values.

DISCUSSION

Approximately the same equilibrium value of 15.3% enol for the pH range of 5 to 10 is reached by acid or base catalysis whether approached from the enol or keto side of

the equilibrium. In the pH (pD) ranges where the rate of reaching the equilibrium is comparatively slow the equilibrium absorption is slightly variable and decreases because of decarboxylation of oxalacetic acid to pyruvic acid (13, 14). In the strongly basic region the equilibrium absorption increases because of the formation of the enolate. The magnitude of the shift of the absorption curve for D_2O to a higher pD value corresponds well to shift of pK values of weak acids in D_2O as compiled by Glascoe and Long (11).

In the strongly acid range the absorption of equilibrated oxalacetic acid decreases because full protonation of the carboxyl groups decreases any tendency to a conjugated double-bond system which is responsible for the 255-mμ absorption. This is borne out by the fact that the 255-mμ absorption of oxalacetic acid at pH 0.5 can be used as the absorption of the keto form.

The isotope rate effects in both acid- and base-catalyzed enolizations of oxalacetic acid indicate that proton cleavage is involved in the rate-limiting step of both reactions. When the oxalacetic acid is equilibrated in D_2O prior to the experiment it quickly exchanges to form the fully deuterated substrate (15). The C—D bond is then cleaved in the slow step.

These data give further and direct evidence that the proton–carbon bond cleavage is the rate-limiting step in acid- and base-catalyzed enolizations.

A NUCLEAR MAGNETIC RESONANCE INVESTIGATION OF MOLECULAR COMPLEXES OF POLAR MOLECULES IN AROMATIC SOLVENTS*

J. V. HATTON† AND W. G. SCHNEIDER
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received February 14, 1962

ABSTRACT

In order to confirm the existence of specific molecular complexes in solutions of polar solutes in *aromatic* solvents previously proposed, the temperature variation of the proton resonance shifts of the solutes acetonitrile, *p*-benzoquinone, and N,N-dimethylformamide in 5 mole% concentration in toluene were measured. The large temperature coefficients of the solute shifts observed strongly support molecular complex formation. For the same solutes dissolved in methylcyclohexane the temperature coefficients were negligibly small. The temperature at which onset of free rotation of the N-dimethyl group of N,N-dimethylformamide occurs is solvent and concentration dependent. These observations are consistent with the proposed geometry of the molecular complex in the aromatic solvents.

INTRODUCTION

The proton chemical shifts of solute molecules in solution may be affected by a number of factors (1). The observed shift, δ, can be written

$$\delta = \delta_G + \delta_B + \delta_A + \delta_W + \delta_E + \delta_C,$$

where δ_G is the shift of an isolated gaseous molecule, δ_B is the shift due to the bulk diamagnetic susceptibility of the solvent, δ_A is the shift arising from the solvent magnetic anisotropy, and the term δ_W is the shift due to the van der Waals interaction between solute and solvent molecules. These contributions are important in the interpretation of the shifts of non-polar solute molecules, but, for polar molecules, an additional term, δ_E, must be taken into account. This is the shift arising from the reaction field of the solvent. Finally, δ_C is the shift due to specific molecular interaction or complex formation in solution. Theoretical calculations of the magnitude of δ_A have been made for the disk-shaped aromatic molecules, and the observed high-field dilution shifts of non-polar solutes in aromatic solvents agree reasonably well with theory (2–4).

Of particular interest is the exceptional behavior shown by polar solutes in aromatic solvents. Very large "high-field" dilution shifts have been observed (5–8). These have been tentatively interpreted in terms of complex formation between the polar solute and aromatic solvent molecules. Further supporting evidence for this interpretation would be highly desirable. The present paper describes an investigation of the temperature coefficient of the chemical shift of solute protons for three selected systems, each comprising a polar solute in an aromatic solvent. The large temperature variations observed provide strong evidence for molecular complex formation in these systems.

EXPERIMENTAL

The proton chemical shifts of dilute solutions of N,N-dimethylformamide, acetonitrile, and *p*-benzoquinone in toluene and methylcyclohexane have been measured at different temperatures on a Varian spectrometer operating at 60 Mc/sec. The variable temperature probe previously described (9) was used throughout the work and this gives temperatures which are accurate to $\pm 1/2°$ C.

*Issued as N.R.C. No. 6893.
†*National Research Council Postdoctorate Fellow, 1961–63.*

The solutions were made up by weight and contained 5 mole% solute. At this dilution, solute-solute interactions may be ignored. The strongest solution of *p*-benzoquinone in methylcyclohexane that could be obtained was 1 mole%.

All the liquids used were of White label or Research grade purity; the *p*-benzoquinone was purified by repeated sublimation.

Chemical shifts were measured by the side-band technique using T.M.S. (tetramethylsilane) as internal reference. These are accurate to ±0.1 cycle/sec. Tetramethylsilane was chosen because of its sharp resonance over the entire temperature range studied, −100° C to +140° C.

RESULTS AND DISCUSSION

The variation of chemical shift with temperature of dilute solutions of acetonitrile, *p*-benzoquinone, and N,N-dimethylformamide in methylcyclohexane and toluene are shown in Figs. 1 to 3 respectively. It is observed that in all three systems the proton

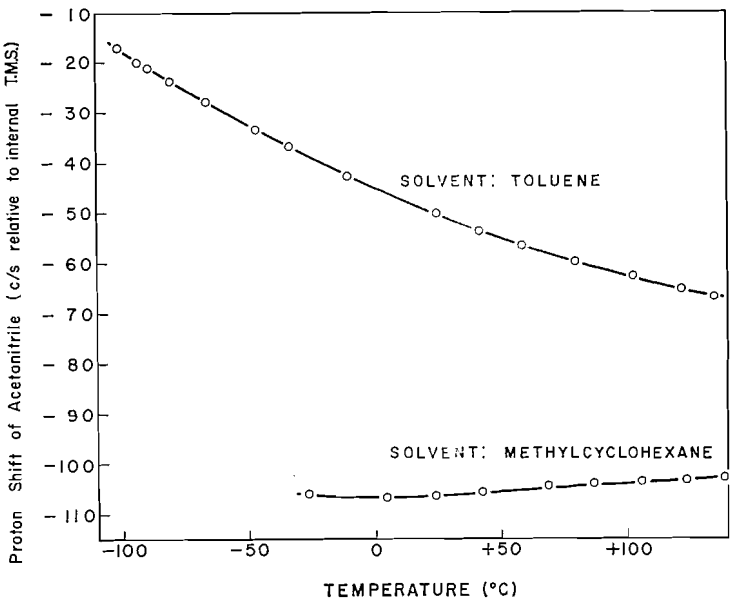

FIG. 1. The temperature dependence of the proton chemical shift of acetonitrile in toluene and methylcyclohexane. The negative sign indicates a displacement of the signal to the low-field side of the reference, T.M.S.

shifts are almost completely independent of temperature when methylcyclohexane is used as solvent, confirming the absence of solute–solvent complex species in these solutions. On the other hand, there is a progressive high-field shift of the solute protons in toluene solutions as the temperature is reduced.

Large shifts to high field occur in the *p*-benzoquinone–toluene system below +10° C. This is the result of the solution becoming more dilute as the solubility of the solid decreases. For this reason, the temperature coefficients of the shifts have been calculated using +10° C as the lower limit. The upper limit, +90° C, is fixed by the internal rotational behavior of N,N-dimethylformamide just above this temperature. The temperature coefficients are shown in Table I.

The methyl derivatives, toluene and methylcyclohexane, rather than the parent hydrocarbons, were chosen as solvents since their much lower freezing points enable a wide temperature range to be investigated. In addition, certain physical properties, i.e.

*The negative sign indicates a shift to low field on raising the temperature.

shape, molar volume, and dielectric constant, of these two molecules are so similar that we are justified in making the following two assumptions:

(*a*) The van der Waals interactions between solute and solvent molecules will be comparable for both solvents.

(*b*) The electric "reaction field" experienced by polar solute molecules will also be small and comparable in toluene and methylcyclohexane.

Furthermore, the use of an internal reference eliminates the effect of the bulk susceptibility of the solvent. Thus, we can neglect the terms δ_B, δ_W, and δ_E, and the observed difference between the solute shifts in toluene and methylcyclohexane, $\Delta\delta$, will be a direct measure of the effect of $(\delta_A+\delta_C)$ on the solute molecule.*

The formation of the complexes can be represented by the equilibrium

$$\text{solute} + \text{toluene} \rightleftharpoons \text{toluene:solute}. \qquad [1]$$

At sufficiently high temperatures complex formation is very unfavorable and the distribution of molecules is completely random. Here, $\Delta\delta$ is small and, in the limit, tends to zero. At lower temperatures the distribution of solvent molecules around each solute molecule becomes increasingly more ordered as a result of complex formation, causing an increase in $\Delta\delta$.

Under the present experimental conditions the complexes are short-lived and it is not possible to isolate a pure species† and to measure the chemical shift. Thus, the actual value of $\Delta\delta$ at any temperature will depend, not only upon the geometry of the complex, but also upon the averaged configuration determined by the equilibrium constant of equation [1].

We have previously proposed, independently, that the complexes are planar and that the molecular interaction is dipolar‡ in nature (5, 6). The values of the temperature coefficients of the proton shifts (Table I) are consistent with the structure of these complexes, shown schematically in Fig. 4. The temperature coefficients decrease in the order $CH_3CN > \alpha\text{-}CH_3$ (N,N-dimethylformamide) > *p*-benzoquinone > $\beta\text{-}CH_3$ (N,N-dimethylformamide). This is also the order of the magnitudes of the anisotropic high-field shifts at each of these proton sites.

Since $\Delta\delta$ is observed to be positive, and δ_C may be expected to make a negative contribution, δ_A, the contribution due to the magnetic anisotropy, is responsible for the large "high-field" shifts of the solute protons in aromatic solvents.

†*A solid phase compound with an incongruent melting point in the acetonitrile–benzene system has recently been reported (10) and observed independently in this laboratory.*

‡*The complexes formed by p-benzoquinone with aromatic solvents may be regarded as arising from quadrupole-induced quadrupole interaction.*

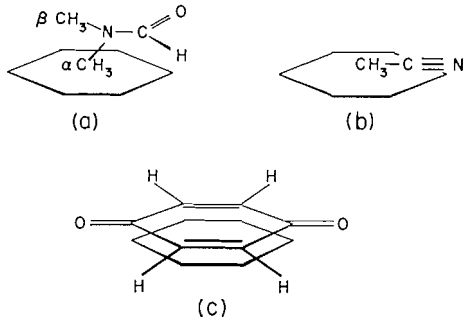

FIG. 4. Schematic representation of the complexes formed between toluene and (*a*) N,N-dimethylformamide, (*b*) acetonitrile, and (*c*) *p*-benzoquinone.

According to Gutowsky and Holm the potential barrier to free rotation of the NMe_2 group of N,N-dimethylformamide about the C—N bond is 7 kcal/mole (11). In Fig. 3 it is observed that onset of "free" rotation of the NMe_2 group (sufficient to cause averaging of the methyl chemical shifts) in the dilute solution in methylcyclohexane occurs at a temperature of 99° C. However, in the toluene solution, free rotation (in the above sense) does not begin until a temperature of 125° C is reached. The temperatures at which onset of free rotation occurs in toluene solutions of different N,N-dimethylformamide concentrations are shown in Table II. At first sight it would appear that, since

TABLE II

The temperatures at which free rotation of the N-dimethyl group of N,N-dimethylformamide occurs

Solvent	Concentration of solute (mole%)	Temperature (°C)
Methylcyclohexane	5	99
Toluene	5	125
	10	121
	25	112
Nitrobenzene	10	103

molecular interaction of the type considered here may be expected to hinder internal rotation in the solute, these values are consistent with the existence of complexes in the aromatic solvent. However, since the separations of the N-dimethyl resonances in the toluene solutions are larger than those in the methylcyclohexane, the faster exchange rates required in the former may well account for the higher temperatures at which free rotation sets in.* From the broadening of the resonance lines of N,N-dimethylformamide (below the coalescence temperature) in toluene and in methylcyclohexane, values of τ, the average time spent by each methyl group in a given environment, have been calculated. For the toluene solution these are $\tau = 0.078$ second (99° C) and 0.014 second (125° C). In methylcyclohexane, the value of τ at coalescence is 0.06 second (99° C). The larger value of τ at 99° C in toluene compared to that in methylcyclohexane could arise from the association postulated to occur between amide and aromatic molecules. However, this conclusion cannot be definitely confirmed since the present data were not sufficiently extensive to make an adequate assessment of errors and to establish the level of significance of the observed difference in τ values.

**We are indebted to the referee for drawing our attention to this point.*

The calculation of thermodynamic quantities governing the formation of these complexes is possible from the shape of the curves but their usefulness is questionable. The method involves a number of assumptions, which can introduce large errors.

The very weak molecular interaction proposed suggests a small heat of formation. This has been confirmed by calculations of ΔH for these systems, which imposes lower and upper limits of -1 and -2 kcal/mole respectively. Recently, Abraham has proposed that methyl iodide forms a complex with toluene in which the C—I bond lies along the sixfold symmetry axis of the ring, with the methyl protons nearest the ring center (12). We venture to suggest that the interaction could equally be one in which the C—I bond lies parallel to the plane of the ring. It may be that halogenated methanes do associate with a T-shape geometry, but numerous polar unsaturated solutes almost certainly associate with the aromatic ring, so that the planes of both molecules are parallel (5–8). Moreover, there is no doubt that in complexes between polar solutes and non-polar aromatic hydrocarbons the solute protons tend to be located above the plane of the ring and adjacent to the axis of symmetry.

The situation existing in solutions of polar aromatic molecules is more complicated. The shift of the methyl protons of N,N-dimethylformamide in a dilute solution of nitrobenzene is to low field from their position in a dilute solution of cyclohexane. Furthermore, the temperature at which onset of free rotation of the NMe_2 group occurs in a 10 mole% solution of N,N-dimethylformamide in nitrobenzene is 103° C. This is very much lower than the value of 121° C observed for the corresponding solution in toluene.

EFFECT OF ADDED AMMONIA ON THE REACTIONS OF ACTIVE NITROGEN WITH CH_4, C_2H_6, AND C_2H_4[1]

A. N. WRIGHT[2] AND C. A. WINKLER

Upper Atmosphere Chemistry Research Group, Physical Chemistry Laboratory, McGill University, Montreal, Que.

Received March 7, 1962

ABSTRACT

The small HCN yield from the CH_4 and C_2H_6 reactions in an unheated, cylindrical reaction vessel is greatly reduced in the presence of added NH_3. The addition of NH_3 completely quenches the flame emission from the CH_4 reaction, and greatly reduces that from the C_2H_6 and C_2H_4 reactions. Both flame emission and HCN production from the CH_4 and C_2H_6 reactions appear to be initiated, at reaction temperatures of about 83° C, by an excited nitrogen molecule similar to that responsible for NH_3 decomposition.

INTRODUCTION

The quenching effect of added NH_3 on the flame emission from the reactions of active nitrogen with compounds of the type XCN, where X represents a halogen atom, and also with CCl_4, recently led Bayes (1) to conclude that the CN light emission from these reactions is initiated by $N_2(A^3\Sigma_u^+)$ molecules. Since it is known (2) that NH_3 is quite efficient in removing from active nitrogen the excited molecule responsible for its decomposition, a brief study has been made of the effect of NH_3, not only on the flame emission, but also on the HCN production, from the reactions of active nitrogen with CH_4 and C_2H_6, which, according to earlier suggestions (3, 4), might be initiated by excited N_2 molecules. At the same time, a brief examination has been made of the effect of NH_3 on the flame from the C_2H_4 reaction, where it has been established (5) that addition of NH_3 does not reduce the production of HCN.

EXPERIMENTAL

The experiments were made in apparatus (II) of a previous paper (5). The apparatus was poisoned against surface recombination of N atoms by the introduction of a minute amount of water vapor. This treatment avoided ambiguity due to the poisoning effect of NH_3 itself (5, 6). The operating pressure was 3 mm and the products from a reaction of 100 seconds duration were trapped at liquid air temperature. The amount of NH_3 in the products was estimated by titration with standard sulphuric acid while HCN was analyzed by titration with silver nitrate in the presence of added NH_3, with potassium iodide as indicator.

To study the effect of added NH_3 on HCN production from the hydrocarbons, various flow rates of hydrocarbon were introduced through a mobile jet at levels 15 and 30 cm below a fixed NH_3 jet at the "0-cm" or reference level. A glass-encased thermocouple on the mobile jet column permitted a measure of the reaction temperature at a point 3.0 cm below the position at which the hydrocarbon was introduced.

Changes in the intensity of light emission in the active-nitrogen stream upon introduction of hydrocarbon, or hydrocarbon plus added NH_3, were measured with a 1P21 photomultiplier tube (hereafter referred to as PM) coupled to an Eldorado photometer. The PM was positioned so as to view the active nitrogen stream at a level corresponding to the maximum light intensity for medium flow rates of hydrocarbon, i.e., at a point 2 cm below a fixed jet at the 0-cm level through which, in these experiments, the hydrocarbon was introduced. Another fixed reactant inlet, 0.5 cm above the jet at the 0-cm level, permitted the simultaneous introduction of NH_3, when its effect on the light emission was to be studied. Although the PM readings are only proportional to the light intensity in the active-nitrogen stream, and no resolution of the emission into the red and violet systems (7, 8) of CN was attempted, the quenching effect of added NH_3 on the hydrocarbon reaction flames was readily observed.

RESULTS

Although HCN and H_2 were previously reported (9) to be the only significant products of the CH_4 and C_2H_6 reactions in a spherical reaction vessel, NH_3 was found to be a product from both reactions in an unheated cylindrical vessel. The very small NH_3 yield increased with flow rate of reactant, as illustrated in Table I for the CH_4 reaction at the 15-cm level.

The Effect of NH_3 on HCN Production from CH_4 and C_2H_6

The extent of HCN production from the CH_4 reaction was very small* (Table I) but increased as the flow rate of reactant was increased. Even with the highest flow rates of CH_4 alone, there was no significant change in the temperature of the active nitrogen (87° and 78° C at the 15- and 30-cm levels respectively), no visible reaction flame, and no visible diminution of the nitrogen afterglow downstream. In the presence of NH_3 added upstream, there was a slight (1° to 2° C) decrease in the temperature of the active nitrogen, and a marked decrease in HCN production, as shown in Table I.

Although the HCN yield from the C_2H_6 reaction (Table II) was also small, it was considerably larger than that obtained from CH_4† and approached the extent to which NH_3 was decomposed (5) by the active nitrogen at the same levels. The HCN yield remained dependent upon C_2H_6 flow rate, up to the highest flow rate of the hydrocarbon used. Even at the highest flow rates of C_2H_6, there was a negligible temperature change in the active-nitrogen stream and, although the eye could distinguish a weak reaction flame that extended about 8 cm downstream, the afterglow did not appear to be diminished to any large extent further downstream. When NH_3 was added, at various flow rates

The N-atom flow rate, inferred from maximum HCN production from C_2H_4 (5), was 22.6×10^{-6} and 20.2×10^{-6} mole sec^{-1} at the 15- and 30-cm levels respectively.

†*The small production of HCN from CH_4 was apparently not due to a trace of C_2H_6 as an impurity in the CH_4 (9), since mass spectrometric analysis, kindly performed by Dr. Leon Phillips of this department, showed that, in the CH_4 used for the present experiments, C_2H_6 could not have been present to an extent greater than 1 part in 250.*

TABLE II

Effect of added NH_3 on HCN production from C_2H_6

through the fixed jet, the temperature of the active-nitrogen stream, 3 cm below the C_2H_6 inlet, was decreased by about 1° C, and the HCN production was significantly reduced, as shown in Table II.

The Effect of NH_3 on the Reaction Flames from CH_4, C_2H_6, and C_2H_4

When NH_3, at flow rates of 6.3×10^{-6} and 12.7×10^{-6} mole sec^{-1}, was introduced above CH_4, the PM reading was decreased (Table III) to the same value as that* observed when NH_3 alone was added to the active nitrogen. With C_2H_6 as reactant, however, addition of NH_3 did not completely reduce the PM reading to that obtained in the absence of hydrocarbon. As shown in Table III, the overall increase in the PM reading became greater, for either flow rate of added NH_3, as the flow rate of C_2H_6 was increased. Finally, although NH_3 reduced the light emission from the C_2H_4 reaction, the results in Table III indicate that its effectiveness was considerably less than with either CH_4 or C_2H_6. It may be noted that, for the highest flow rate of C_2H_4 (7.0×10^{-6} mole sec^{-1}), the PM reading could be reduced to values of 380, 330, and even 200 (i.e. lower than with 12.7×10^{-6} mole sec^{-1} of NH_3 alone) by adding NH_3 at flow rates of about 26×10^{-6}, 31×10^{-6}, and 40×10^{-6} mole sec^{-1} respectively.

DISCUSSION

Although the extent of NH_3 production from the CH_4 and C_2H_6 reactions was quite small, it amounted to about one-third of the small HCN yield. It appears that some NH_3 formation may be a fairly general characteristic (10) of active nitrogen reactions

**A decrease in intensity of the active-nitrogen afterglow has been observed (6) down to the 45-cm level for introduction of various flow rates of NH_3 at the 0-cm level in the poisoned system.*

*The upper limit of the PM was reached at a reading of 1000.
†The smaller PM readings for these higher flow rates of C_2H_6 are probably due simply to a shift in position of the flame to a position closer to the inlet jet.

(5) and that its extent may depend on the structure of the reactant, as found by Dewhurst and Cooper (11) for the methyl-substituted silanes.

The low HCN yields from the CH_4 and C_2H_6 reactions, in the unheated cylindrical reaction vessel, indicate that these hydrocarbons react directly with N atoms only to a very limited extent, if at all, at the low temperatures involved. This is perhaps not surprising, since a change of spin must occur before HCN can be produced from N-atom attack on these saturated hydrocarbons. Moreover, the persistence of the nitrogen afterglow downstream, in the presence of large amounts of CH_4 and C_2H_6, suggests that, as with the C_2H_4, *n*-butane, and but-2-ene reactions in an unheated cylindrical reaction vessel (5), there is little or no loss of N atoms through rapid recombination catalyzed by reactant, such as appears to occur at low reaction temperatures in a spherical reaction vessel (4). These results offer evidence, then, that the CH_4 and C_2H_6 reactions may be induced, at low reaction temperatures, by a second reactive species present in active nitrogen. It is not possible to calculate, as for the NH_3 reaction (5), the lifetime of the reactive species responsible for initiating the CH_4 and C_2H_6 reactions since, although the extent of HCN formation was less for reaction at the 30-cm than at the 15-cm level, it showed some dependence on the flow rate of reactant, even at high flow rates.

Although addition of NH_3 reduces the amount of HCN produced during the CH_4 and C_2H_6 reactions, no similar reduction is observed (5) when NH_3 is added to the C_2H_4 reaction. It would appear that, in an unheated cylindrical reaction vessel, destruction of the added NH_3, and formation of HCN from CH_4 and C_2H_6, are competitive reactions. The competitive nature of these reactions is also indicated by the further observation

that when NH_3 was added at the 0-cm level its extent of destruction was progressively reduced when CH_4 or C_2H_6 was added at the 30- or 15-cm level. It seems reasonable to conclude, therefore, that the reactions of these hydrocarbons, like the destruction of NH_3, involve an excited nitrogen molecule, presumably $N_2(A^3\Sigma_u^+)$. It is suggested that a collision of the Second Kind between CH_4 or C_2H_6 and the excited nitrogen molecule leads to some fragmentation of the hydrocarbon, followed by rapid reaction (3) of these fragments with N atoms to produce HCN. Since CH_4 produces considerably less HCN than C_2H_6, it is apparently less effective in competition with NH_3 for the excited nitrogen molecule involved. The small increase in HCN production at higher flow rates of the hydrocarbons might be due partly to reaction initiated by small amounts of $N_2(A)$ molecules formed by the recombination of N atoms in the presence of reactant (2), and partly to a slow direct reaction of N atoms with the hydrocarbon. The much higher maximum HCN yield at higher reaction temperatures (approximately equal to that from C_2H_4 at about 400° C in either a spherical or cylindrical vessel (9, 4, 5)) is almost certainly due to a much faster rate of the direct N-atom attack under such conditions.

The PM measurements indicate that the reaction flames from all three of the CH_4, C_2H_6, and C_2H_4 reactions are also initiated by $N_2(A)$ molecules. In this respect their behavior is similar to the reactants investigated by Bayes (1). However, the actual mechanism leading to the emission of the CN flame remains unresolved.

Since there is no effect of increased temperature (5, 12), or of NH_3 added upstream (5), on HCN production from C_2H_4 in a cylindrical reaction vessel, HCN formation from this reactant need not be initiated by excited nitrogen molecules. Nevertheless, the results indicate that the C_2H_4 reaction flame is reduced in intensity in the presence of NH_3, although the quenching efficiency of NH_3 is less than with CH_4 or C_2H_6. This reduced efficiency of NH_3 might be due to a greater ability of C_2H_4 to compete with NH_3 for $N_2(A)$ molecules. On the other hand, part of the flame emission from the C_2H_4 reaction might result from a direct reaction, at a considerable rate even at the low temperature involved, between N atoms and the unsaturated hydrocarbon molecule. This is indicated by the similar rate constants obtained for the active nitrogen – C_2H_4 reaction by measuring the extent of HCN production (2), or by application of flame diffusion techniques (13, 12).

THE REACTIONS OF ACTIVE NITROGEN WITH BORON TRICHLORIDE AND GERMANE[1]

ROSEMARY STORR,[2] A. N. WRIGHT,[3] AND C. A. WINKLER
Upper Atmosphere Chemistry Research Group, Physical Chemistry Laboratory, McGill University, Montreal, Que.

Received March 7, 1962

ABSTRACT

Chlorine and tetrachlordiborine were the main products from the reaction of active nitrogen with boron trichloride. The maximum flow rate of chlorine recovered, about 4% of the available N-atom flow rate, was essentially independent of temperature in the range 100° to 395° C. It is suggested that the reaction is initiated by $N_2(A^3\Sigma_u^+)$, and that this is followed by N-atom attack on the resulting BCl_2 radical. A similar mechanism is suggested for a slight extent of reaction observed with germanium tetrachloride.

Hydrogen and germanous nitride (Ge_3N_2) were the products of the reaction of active nitrogen with germane. The amount of germane decomposed increased with an increase of temperature from 100° to 200° C; at the higher temperature it corresponded to not more than two-thirds of the N-atom flow rate used. It is suggested that the reaction involves the direct and complete displacement of hydrogen by atomic nitrogen.

INTRODUCTION

Of the many reactions of active nitrogen that have been studied, those with inorganic reactants have revealed several points that appear to be of interest in any consideration of the nature of active nitrogen. For example, the experimental data available at present indicate that the maximum extent to which NH_3 is decomposed by active nitrogen is only about one-sixth of the maximum extent to which HCN may be produced from hydrocarbons or hydrocarbon derivatives (1–3). This, in turn, is comparable with the maximum extents to which active nitrogen reacts with O_2 (4) and NO_2 (5), but is considerably less than the maximum extent to which it reacts with NO (5, 6). Again, at least some of the reactions with inorganic molecules, e.g. PH_3 (7), HBr (8), SiH_4 (9), apparently involve hydrogen abstraction by atomic nitrogen, whereas this does not seem to occur with any of the organic molecules yet studied.

In the continuing program of investigations into the behavior of active nitrogen that has been in progress in this laboratory for several years, part of the effort is devoted to the study of reactions for which little or no information is yet available, but which might conceivably reveal interesting aspects of the nature of active nitrogen. Of these, the reactions with BCl_3 and GeH_4 have now been examined, the first as a convenient inorganic halide, the second for comparison with the data available for SiH_4 and CH_4.

Jevons (10) believed that he observed three intense bands due to BN in the spectrum of BCl_3, excited with active nitrogen, while BN was deposited on the wall of the vessel. Mulliken (11) later showed that Jevons had really observed the spectrum of BO, due to oxygen impurity in the nitrogen used. However, evidence for a band system around 3600 Å, due to BN, has been obtained by Douglas and Herzberg (12), by passing a trace of BCl_3 into a discharge through helium containing a small amount of nitrogen.

The reaction of active nitrogen with SiH_4 (9) yields no condensable product. Presumably the silane is decomposed to yield H_2 and, possibly, SiN. It was suggested that the reaction proceeded by a hydrogen-abstraction mechanism,

$$SiH_4 + N \rightarrow SiH_3 + NH,$$

followed by

$$2NH \rightarrow N_2 + H_2 \text{ or } NH + N \rightarrow N_2 + H.$$

On the other hand, the products from the reaction of active nitrogen with CH_4, in an unheated cylindrical vessel, are about two-thirds HCN and one-third NH_3, and the reaction appears to be initiated by excited nitrogen molecules (6).

EXPERIMENTAL

The apparatus and procedures of the present study were similar in all essentials to those outlined in the earlier papers from this laboratory. The reactions occurred at 1.45 mm pressure, in a spherical reaction vessel.

The products of the reaction with BCl_3 were separated with the Le Roy still (13). Chlorine distilled at $-110°$ C, at 3 mm pressure; BCl_3 at $-80°$ C, at 4 mm pressure; and tetrachlordiborine at room temperature. Chlorine was analyzed by absorption in distilled water and titration with sodium thiosulphate, with thyodene as indicator (14). Unreacted BCl_3, and the tetrachlordiborine, were both estimated by hydrolysis and titration with standard NaOH in the presence of mannitol to increase the extent of ionization of the boric acid formed (14). This method was used in preference to the less simple $AgNO_3$ titration of the chloride, but concordant results were obtained by the two methods.

The amount of unreacted GeH_4, following an experiment, was determined from its pressure in a known volume at room temperature. Germanium nitride, formed as a solid on the wall of the vessel, was treated in a manner that will be described later.

RESULTS

Reaction with BCl_3

With this reactant, the yellow afterglow of active nitrogen was completely replaced by a pale green reaction flame, and a small amount of white solid was deposited on the wall of the reaction vessel.

In Fig. 1 are plotted the yields of Cl_2 at 100, 353, and 395° C, and of B_2Cl_4 at 395° C. These yields are obviously very low in comparison with the active-nitrogen flow rate of 9.5×10^{-6} mole/sec, estimated from the maximum amount of HCN produced from C_2H_4

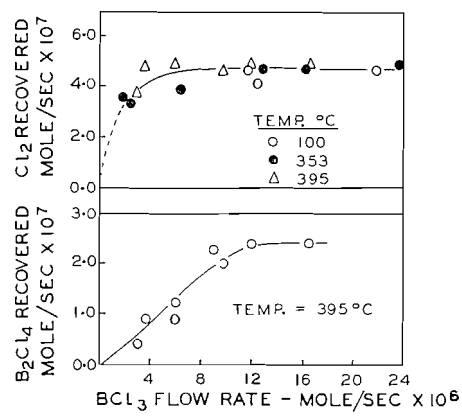

FIG. 1.

at 350° C. It might be noted that the ratio of the B_2Cl_4 yield to that of Cl_2 increased from about 1:10 at low flow rates of BCl_3 to 1:2 at the highest flow rates of reactant used.

The amount of solid deposited on the wall of the reaction vessel was insufficient for analysis. It was assumed to be BN. If it is assumed that the only chlorine-containing compounds in the products were BCl_3 and B_2Cl_4, it may be estimated that, since the Cl_2 plateau (0.5×10^{-6} mole/sec) corresponds to 1×10^{-6} mole/sec of Cl, and the B_2Cl_4 plateau (0.25×10^{-6} mole/sec) also corresponds to 1×10^{-6} mole/sec of Cl, the total rate of Cl recovery is 2×10^{-6} mole/sec, equivalent to BCl_3 destruction of 0.66×10^{-6} mole/sec. Hence, the amount of boron not accounted for in the trap is 0.66×10^{-6} mole/sec minus 0.5×10^{-6} mole/sec appearing as B_2Cl_4, or 0.16×10^{-6} mole/sec. This would, presumably, correspond to the amount of BN formed on the wall.

Reaction with $GeCl_4$

A few experiments were made with $GeCl_4$, instead of BCl_3, but even less reaction occurred. The nitrogen afterglow was completely quenched, and a reaction flame was observed. This was pale blue at low flow rates of $GeCl_4$ and a beautiful royal blue at higher flow rates. No noticeable amount of solid material was deposited on the wall of the vessel, and the maximum yield of Cl_2 at 65° C was only about 0.13×10^{-6} mole/sec, even at relatively high flow rates of $GeCl_4$ (of the order of 20×10^{-6} mole/sec). Accordingly, study of this reaction was not pursued further.

Reaction with GeH_4

This reaction produced a yellowish-orange flame and destroyed the nitrogen afterglow completely. No NH_3 or other condensable product was obtained in the cold trap, but a dark brown solid was deposited on the wall of the reaction vessel and of the tube connecting the reaction vessel to the cold trap. Reproducible results were obtained only after several experiments had been made and a uniform layer of the solid deposited on the wall. Data were then obtained for the amount of GeH_4 that reacted with active nitrogen at 100° and 200° C, as illustrated in Fig. 2. Higher temperatures were avoided, since

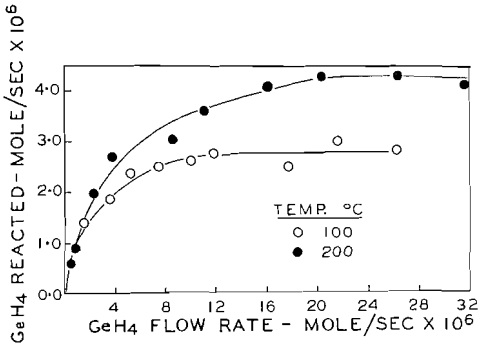

FIG. 2.

GeH_4 decomposes thermally at about 280° C (15). The flow rate of active nitrogen was obtained by titration with NO (16–18), in the presence of the brown solid, and found to be about 10×10^{-6} mole/sec (corresponding to about 6×10^{-6} mole/sec if based on HCN production from C_2H_4 (6)).

The solid product was insoluble in H_2SO_4 or HCl, but dissolved in H_2O or dilute NaOH to give a colorless solution from which the brown solid could be reprecipitated on acidification. Ammonia was evolved when the alkaline solution was heated. The color of the solid slowly became lighter when it was left exposed to air. These observations agree with the behavior of Ge_3N_2 (19), but not with that of Ge_3N_4, which is insoluble in H_2O and common organic solvents, and is not affected by air at ordinary temperatures (20). Hence, the product from the GeH_4 – active nitrogen reaction appeared to be mainly Ge_3N_2. Analysis of the solid by the micro-kjeldahl method gave a value of 5.3% N (theoretical for Ge_3N_2, 11.4%). The discrepancy was almost certainly due to air oxidation of the nitride. Accordingly, a known weight of the material was treated with $HClO_4$ to convert it completely to oxide, and from the change in weight it was found that 37% of the germanium in the original sample was converted from the nitride to oxide. This may be compared with a calculated value of 41% for a material containing 5.3% N and assumed to be Ge_3N_2. Again, the data indicate that the solid product from the GeH_4 – active nitrogen reaction was mainly Ge_3N_2. Examination of the solid by X-ray methods showed only that it was amorphous.[4]

DISCUSSION

Reactions with BCl_3 and $GeCl_4$

Of three possible modes of attack of N atoms on BCl_3, two may be ruled out from energy considerations. These are

$$BCl_3 + N \rightarrow BCl_2 + NCl, \Delta H = +63 \text{ kcal};$$

and

$$BCl_3 + N \rightarrow BN + Cl_2 + Cl, \Delta H = +175 \text{ kcal}.$$

The third possibility is a "catalyzed" atom recombination (21), which may be represented by

$$BCl_3 + N \rightarrow BCl_3.N \xrightarrow{N} N_2 + BCl_2 + Cl. \quad [1]$$

Such a sequence would probably have a negative temperature coefficient, since, without any other energetically favorable path available to it, the complex can only suffer reversion to the original reactants, and its lifetime (hence the rate of the overall reaction) should decrease with increase of temperature. Moreover, an initial reaction such as [1], followed by similar reactions with BCl_2 and BCl, or by direct attack of N on BCl to form BN + Cl, would be expected to cause much more destruction of BCl_3 than that observed, unless back reactions, probably involving a third body, occurred to a considerable extend, e.g.

$$Cl + BCl_2 + W \rightarrow BCl_3$$
$$Cl_2 + BCl + W \rightarrow BCl_3.$$

However, Holliday and Massey (22) and Frazer and Holzmann (23) have shown recently that B_2Cl_4 may be efficiently produced, at pressures less than 4 mm, from the decomposition of BCl_3 in a microwave discharge, which suggests that such back reactions should be quite unimportant at the pressures used in the present experiments. Catalyzed recombination of N atoms on the reactant therefore does not seem to provide an adequate mechanism for the reaction.

[4]*We are indebted to Dr. A. J. Frueh for the X-ray study of the solid product.*

The small extent of BCl_3 decomposition, relative to the concentration of N atoms available, and the negligible temperature coefficient of the reaction would both be consistent with an assumption that BCl_3 is decomposed by energy transfer from an excited nitrogen molecule, e.g. $N_2(A^3\Sigma_u^+)$:

$$BCl_3 + N_2(A^3\Sigma_u^+) \rightarrow BCl_2 + Cl + N_2. \quad [2]$$

The increase in the ratio of Cl_2:B_2Cl_4 in the products is then readily explained if the BCl_2 formed in [2] suffered extensive reaction with N atoms at low flow rates of BCl_3, but dimerized to a progressively larger extent as the flow rate of BCl_3 was increased. It is interesting to note that, since the ground state of BN appears to be a triplet (24), the reaction

$$BCl_2 + N \rightarrow BN + Cl_2, \Delta H = -18 \text{ kcal}$$

may be both energetically and spin favorable.

The reaction of active nitrogen with $GeCl_4$ is probably also initiated by excited molecules, but to a lesser extent than BCl_3, owing to the greater number of degrees of freedom into which the energy might pass.

Reaction with GeH_4

Since an increase of temperature from 100 to 200° C increased the plateau value for the amount of GeH_4 decomposed by only about 25%, it seems reasonable to assume that the plateau value at 200° (4.2×10^{-6} mole/sec) represents roughly the maximum extent of reaction possible with the flow rate of active nitrogen used (ca. 6×10^{-6} mole/sec on the basis of HCN production from C_2H_4). If this be true, there would seem to be far too few N atoms available for the reaction to proceed by stepwise hydrogen abstraction, followed by disproportionation of NH radicals, since this would require 4 N atoms per GeH_4 decomposed (i.e. 16.8×10^{-6} mole/sec of N atoms) plus 2.8 N atoms to convert 4.2 Ge atoms to Ge_3N_2, or a total flow rate of 19.6×10^{-6} mole/sec of N atoms.[5]

Decomposition of GeH_4 by excited N_2 molecules alone also seems to be an unsatisfactory explanation, since this would require at least 4.2×10^{-6} mole/sec of such a species, which would probably require a flow rate of active nitrogen much greater than that measured even by NO titration (6). To achieve the observed extent of reaction, following initiation by excited molecules, a sequence of reactions involving H- and N-atom reactions might be suggested, e.g.

$$GeH_4 + N_2^* \rightarrow GeH_3 + H$$
$$GeH_4 + H \rightarrow GeH_3 + H_2$$
$$GeH_3 + N \rightarrow GeN + H + H, \text{ etc.}$$

However, the last reaction would be less favorable energetically than the direct and complete displacement of H_2,

$$GeH_4^* + N \rightarrow GeN + 2H_2,$$

which is almost certainly exothermic.[6] It is suggested, therefore, that this represents the most acceptable mechanism for the reaction of GeH_4 with active nitrogen. It is interesting,

[5]*The data given in ref. 9 are inadequate for detailed analysis, but this argument does not seem to apply with nearly the same force to the silane reaction. Approximately 1.65×10^{-7} mole/sec of SiH_4 seems to have been decomposed, apparently with little SiN formation, and this would require some 6.5×10^{-7} mole/sec of N atoms. Actually, the HCN production from C_2H_4 indicated about 5×10^{-7} mole/sec of N atoms available (about 8.5×10^{-7} mole/sec on the basis of a NO titration).*

[6]*No value for the bond strength of GeN is available in the literature. A rough, and probably exaggerated, estimate of 80 kcal may be made by considering nitrides of other elements in neighboring groups in the periodic table. An average of 70 kcal may be similarly estimated for the GeH bond in GeH_4.*

perhaps, though obviously no argument in its favor, that such a mechanism would not seem to be applicable to any other active nitrogen reaction previously studied.

Regardless of the mechanism assumed for its formation, it does seem reasonable that GeN is a precursor to Ge_3N_2, the main solid product of the reaction. Transformation of the simpler to the more complex nitride is probably accomplished in wall reactions, which might be relatively simple, e.g.

$$3GeN \rightarrow Ge_3N_2 + \tfrac{1}{2}N_2,$$

or might be considerably complicated by the attack of N atoms on the nitride film.

CONSTITUENTS OF THE OLEORESIN OF THE MALE FERN (DRYOPTERIS FILIX MAS L.)

PART I. ALCOHOL AND STEROL FRACTIONS[1]

TELFER LAWSON THOMAS[2] AND ALFRED TAURINS
Department of Chemistry, McGill University, Montreal, Que.

Received in original form December 23, 1960; as revised March 27, 1962

ABSTRACT

The solid alcohol fraction of the oleoresin of the male fern was shown to contain two higher primary alcohols, 1-tricosanol and 1-docosanol. The sterol fraction was found by means of chemical and spectrographic evidence to be 5,11(?)-stigmastadien-3β-ol.

1-Tricosanol was synthesized from behenic (docosanoic) acid via tricosanoic acid, the latter being the product of Arndt–Eistert synthesis. 1-Docosanol was synthesized by $LiAlH_4$ reduction of behenic acid.

DISCUSSION

The oleoresin of the rhizome of the male fern, *Dryopteris filix mas* L. (or *Aspidium filix mas* L.), has been used as an anthelmintic since the time of Ancient Greece, although its composition was not investigated until the end of the nineteenth century. The anthelmintic activity of the oleoresin was ascribed to a group of related compounds commonly known as "phenol fraction of the oleoresin" which were derivatives of 2-acylcyclohexane-1,3-dione. Recently a review on these compounds has been published by Hassal (1), who gives a number of references to the previous work.

In addition to the phenolic fraction, the oleoresin of the fern rhizome contains a large amount of glycerides of fatty acids. Maizite (2–4) has investigated oleoresins of several fern species, including *D. filix mas* L. Upon saponification of the fat fraction, *n*-butyric and linoleic acids as well as glycerol were isolated from all the fern oleoresins. From *Nephrodium filix mas* L. Maizite isolated, in addition, palmitic and stearic acids. He also obtained an unsaponifiable fraction which he thought was phytosterol, but did not investigate further.

The present paper describes the study of the solid alcohol and sterol fractions obtained from the male fern (*D. filix mas* L.) oleoresin. When the phenol fraction had been separated by the method described in the experimental part, the phenol-free residue was hydrolyzed and petroleum ether soluble and insoluble fractions were obtained. The former was found to consist of higher aliphatic alcohols, and the latter of a sterol.

Alcohol Fraction

The crude solid alcohol fraction was recrystallized from petroleum ether and esterified with *p*-phenylazobenzoyl chloride in order to facilitate the separation of substances by chromatography. Two main products were isolated from the chromatogram, and these esters were hydrolyzed to the original substances.

The major product melted at 73.4–73.7°, showed no ultraviolet absorption, and had a molecular weight of 343. Analysis indicated that the compound had the empirical formula $C_{23}H_{48}O$. The infrared spectra of the alcohol, its acetate, and azoate indicated that the substance was a straight-chain primary alcohol with little, if any, branching. A monolayer of the alcohol was tested on a film balance of the vertical pull type, similar to that used

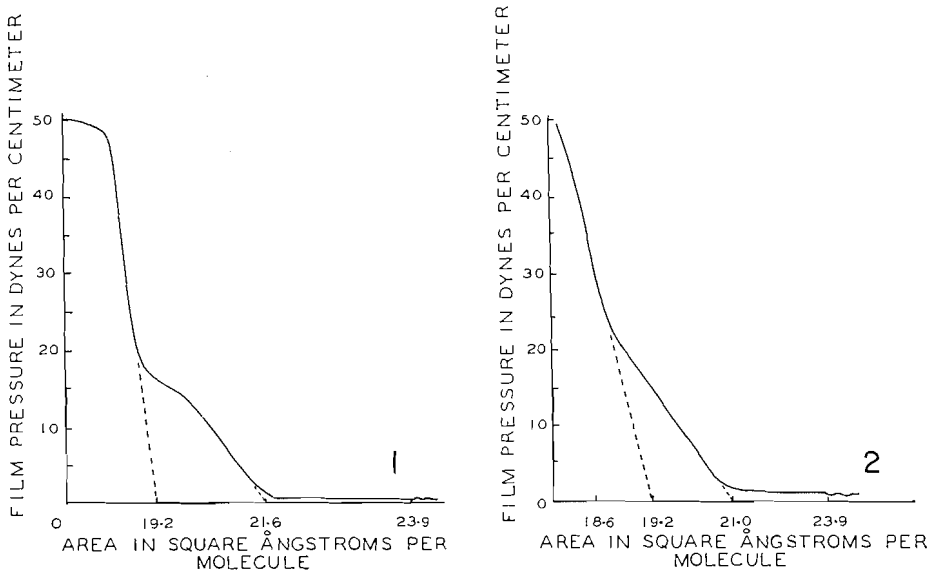

Fig. 1. Pressure–area isotherm of major product extracted from alcohol fraction of oleoresin.
FIG. 2. Pressure–area isotherm of 1-tricosanol.

by Harkins and Anderson (5). The change in pull on the immersed plate was recorded electrically. The shape of the pressure–area isotherm (Fig. 1), the area of the methylene chain, and the area of zero compression (area of the polar group in this case) all indicated that the substance was a high molecular weight, saturated, straight-chain, primary alcohol.

On the basis of the foregoing evidence, the substance was believed to be 1-tricosanol (6). In order to obtain further proof, an authentic sample of 1-tricosanol was prepared from erucic acid. Erucic acid was hydrogenated, using Adams catalyst, to behenic or docosanoic acid, $CH_3(CH_2)_{20}COOH$, and the latter was converted via an Arndt–Eistert synthesis to tricosanoic acid, $CH_3(CH_2)_{21}COOH$. The methyl ester of tricosanoic acid was reduced with lithium aluminum hydride to 1-tricosanol, $C_{23}H_{47}OH$. Comparison of the infrared spectra, pressure–area isotherms (Figs. 1 and 2), and determination of the mixed melting point showed that 1-tricosanol and the naturally occurring product were indeed identical. The spectra and melting points of 1-tricosanyl acetate and 1-tricosanyl azoate and the corresponding esters prepared from the natural product also were in complete agreement.

The second product isolated from the chromatogram melted at 72–73.3° and gave no precipitate with digitonin. The infrared spectrum of this material and that of an authentic sample of 1-docosanol (6) were found to be identical. A mixed melting point determination of the two substances showed no depression.

1-Tricosanol and 1-docosanol were found to be present in the original fern rhizome oleoresin to the extent of approximately 0.16–0.25% and 0.02–0.03% respectively.

Sterol Fraction

The petroleum ether insoluble portion of the unsaponifiable fraction of the oleoresin was recrystallized from ethanol. It was further purified via the digitonide, followed by recrystallization. Infrared absorption spectra of the crude and purified material, taken in Nujol, were identical, and it was concluded that only one sterol was present in the fraction.

The pure product melted at 136.1–137°, and had the empirical formula $C_{29}H_{50}O_2$. The sterol was tested for unsaturation with tetranitromethane, and the presence of at least two double bonds was indicated. The absence of absorption in the ultraviolet region of the spectrum led to the conclusion that the double bonds were not in conjugation. The material was found to contain 1 molecular equivalent of water of crystallization. Two derivatives, the azoate and the benzoate, were synthesized and characterized (Table I).

TABLE I

Comparison of analytical data for sterol isolated from male fern oleoresin and 5,11(?)-stigmastadien-3β-ol (10)

Physical constants	Sterol isolated from male fern oleoresin	5,11(?)-Stigmastadien-3β-ol from oats
M.p.	136.1–137° (corr.)	137°
$[\alpha]_D$	−36.7±2° at 18° C	−37.6±3° at 26° C
Benzoate derivative m.p.	148.8–149°	157°
Benzoate derivative $[\alpha]_D$	−11.0±2° at 20° C	−11.8±2° at 26° C
p-Phenylazobenzoate derivative m.p.	189–191°	191°

The presence of the hydroxyl group in the molecule was further verified by the existence of bands in the infrared at 3610 and 1050 cm^{-1} (in CS_2 solution). Since the sterol formed a digitonide, the hydroxyl group was considered to be in the 3β-position. When the spectrum was taken in chloroform solution, two distinct bands appeared in the C=C stretching region at 1665 and 1600 cm^{-1}. The higher-frequency band could be due to a double bond in either the 5- or 7-position of the steroid nucleus (7, 8). It was believed that the absorption at 1600 cm^{-1} was due to the existence of a double bond at either position 11 or 16, although bands due to double bonds in these two positions generally absorb at somewhat higher frequencies (9). Since the steric strain of a double bond in the five-membered D ring of the steroid nucleus usually results in an intense absorption in the olefinic C—H stretching region (3100–3000 cm^{-1}), and this phenomenon was absent in the present case, it was felt that the double bond was likely located at position 11. In the region 790–850 cm^{-1}, in which the characteristic bands due to the out-of-plane bending vibrations of an olefinic C—H occur, there was absorption at 837 and 782 cm^{-1} (in CS_2 solution).

The infrared spectrum of the fern sterol (Table II and Fig. 3) was found to be identical

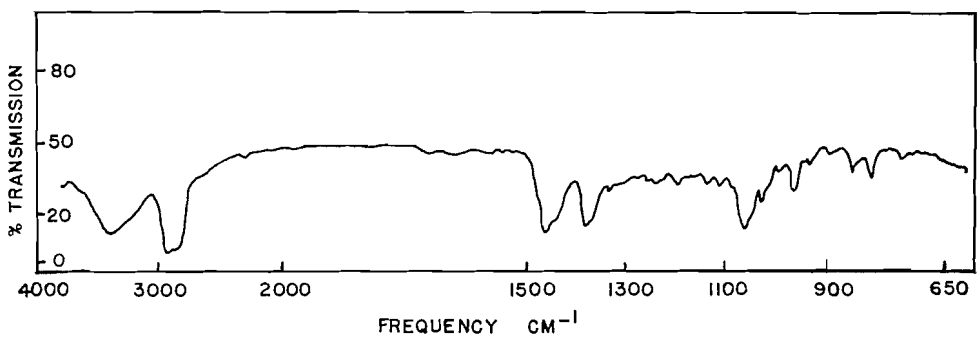

FIG. 3. The infrared spectrum of the sterol from fern (in KBr pellet).

with the spectrum obtained by Idler and his co-workers (10) for the sterol from oats. The analytical data and physical constants of the fern sterol and its derivatives were found to correspond quite closely with those of 5,11(?)-stigmastadien-3β-ol (Table I) which had been isolated from oats.

A quantitative Liebermann–Burchard reaction was run on the male fern oleoresin sterol. The graph of the reaction taken at 420 mμ was identical with that published by Idler and co-workers (10) (Fig. 4). Unfortunately it was not possible to obtain a sample of 5,11(?)-stigmastadien-3β-ol from oats for further comparison purposes. The sterol comprised approximately 0.17–0.25% of the oleoresin.

EXPERIMENTAL

The melting points below 200° were determined in an electrically heated Scientific Glass Apparatus Company No. 1855 interjoint melting point apparatus containing dibutyl phthalate. Melting points above 200° were carried out in a melting point block constructed according to the specifications given by Fieser (11). All melting points are corrected. Carbon, hydrogen, nitrogen, and oxygen analyses for all compounds except the benzoate of the sterol were carried out in the Schwarzkopf microanalytical laboratory, Woodside,

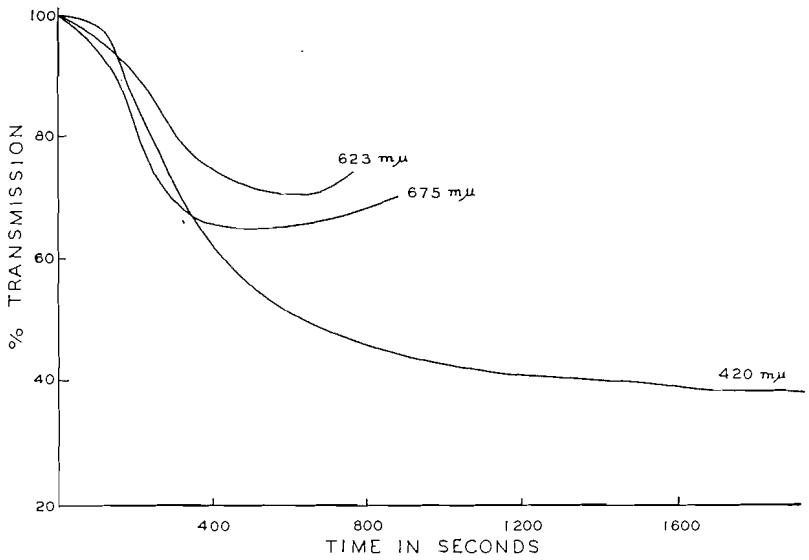

FIG. 4. Liebermann–Burchard reaction of sterol isolated from oleoresin of male fern.

N.Y., U.S.A. The analysis of the benzoate derivative was performed in the laboratory of W. Manser in Zurich, Switzerland. The infrared absorption spectra were determined by means of a Perkin–Elmer Model 21 double-beam spectrophotometer equipped with a sodium chloride prism, and the ultraviolet absorption spectra were determined using a Beckman DK-1 spectrophotometer.

Isolation of the Phenolic Fraction

Previous methods (12, 13) used for the separation of the phenol fraction of the oleoresin were excessively laborious and the method following was devised. Male fern oleoresin (453 g) was dissolved in diethyl ether and the solution was added to magnesium oxide (900 g), enough ether being present to form a thick paste with the oxide. More magnesium oxide was then added to this paste until "solidification" occurred. The ether was then allowed to spontaneously evaporate from the mixture. The magnesium phenolates were removed from the ether-free mixture by leaching with water (5×5 liters). The aqueous solution (about 25 liters) was acidified with dilute sulphuric acid, filtered, and a red-brown amorphous product separated. This material, consisting of the phenolic substances, was washed with water until the washings were neutral. The anhydrous phenolic material was obtained in a yield of 26.4 g, i.e. 5.9% based on the original oleoresin.

Isolation and Separation of Alcohols and Sterols

The oil (200 g) remaining after removal of the phenol fraction was hydrolyzed with 4% ethanolic potassium hydroxide (1500 ml) in a nitrogen atmosphere. The mixture was refluxed for 5 hours, then the ethanol was removed under reduced pressure. The residual material was diluted with water (1000 ml). The slightly turbid solution which formed was extracted continuously with diethyl ether for 12 hours. The aqueous solution was discarded and the ether extract was dried over anhydrous magnesium sulphate. The ether was removed, leaving a semisolid residue (1.9 g). This residue was triturated with petroleum ether (30–60°) and the insoluble fraction (0.75 g) was recrystallized from ethanol. The soluble fraction (1.15 g), after recrystallization from a minimum volume of petroleum ether, weighed 0.9 g. Ethanolic digitonin had no effect on the petroleum ether soluble portion but produced a flocculent precipitate with the insoluble fraction.

Esterification and Identification of the Components of the Alcohol Fraction

The recrystallized petroleum ether soluble material (0.9 g) was mixed with pyridine (10 ml) and azoyl chloride (0.9 g). The orange-colored solution was refluxed gently for 2 hours. It was then cooled, poured into cold 2% sodium bicarbonate solution, filtered, washed with water, and dried *in vacuo* over phosphorus pentoxide.

The ester mixture was chromatographed using a Pyrex glass column 5 cm in diameter, the sides of which had been treated with a solution of silicone oil in chloroform. The adsorbent employed was 3:1 silicic acid: Celite 503. The chromatograms were carried out in a nitrogen atmosphere, using as eluent a mixture of petroleum ether (b.p. 90–120°) and benzene, which was gradually changed from 3:1 to 5:1 petroleum ether: benzene. The change was completed when the lowest band had reached the middle of the column. Three bands were obtained in this way. The column was extruded and the colored sections were separated. Each band was extracted with hot benzene. The top band was found to contain mainly pyridinium compounds

and unesterified alcohols. About 2 cm below the top of the column was a very narrow band of azoyl ester and at the bottom of the column there was a large band of ester. The chromatographed esters were recrystallized from benzene and dried *in vacuo* over phosphorus pentoxide.

1-Tricosanyl Azoate

The azoyl ester from the lower band (0.45 g) melted at 82.0–82.2° after three recrystallizations from benzene. The infrared spectrum of the ester was determined in potassium bromide pellets (Table III). Molecular weight (Rast), 548. A mixed melting point determination with an authentic sample of 1-tricosanyl azoate showed no depression. Anal. Calc. for $C_{36}H_{56}N_2O_2$: C, 78.83; H, 10.30; N, 5.11. Found: C, 79.30; H, 10.03; N, 4.81%.

Isolation of 1-Tricosanol

The azoyl ester (150 mg) from the lower band was dissolved in benzene (5 ml) and treated with 8% potassium hydroxide in 70% aqueous ethanol (3 ml). The mixture was refluxed for 1 hour, and then was cooled and extracted with benzene. The benzene extract was dried, and the solvent removed *in vacuo*. The solid residue was recrystallized from methanol and melted at 73.4–73.7°. Both bromine and potassium permanganate tests for unsaturation in the molecule were negative. The substance showed no absorption in the ultraviolet region of the spectrum. A monomolecular film of the alcohol was tested on a film balance similar to that used by Harkness and Anderson (5). The balance was of the vertical pull type, and the pull on the immersed plate was electrically recorded on a Minneapolis-Honeywell Brown continuous recorder. The film was spread on 0.1 *N* hydrochloric acid from dilute benzene solution. The pressure–area isotherm is shown in Fig. 1. The area of zero compression was 21.6 $Å^2$, and the area per molecule at the liquid–solid film phase transition was 19.2 $Å^2$. Molecular weight determinations by the Rast and gravimetric methods indicated that the compound had a molecular weight of 343. A mixed melting point determination with the authentic sample of 1-tricosanol remained undepressed. The infrared spectrum of 1-tricosanol was taken in KBr (Table III). Anal. Calc. for $C_{23}H_{48}O$: C, 81.07; H, 14.22. Found: C, 81.09; H, 13.78%.

1-Tricosanyl Acetate

1-Tricosanol (0.5 g) was refluxed with acetyl chloride (4 ml) and pyridine (3 drops) for 30 minutes. The solution was cooled and poured into ice water and allowed to stand for 1 hour. The precipitate which formed

was filtered, recrystallized from ethanol, and dried. The substance melted at 52.0–52.5°, and a mixed melting point determination with the authentic sample of 1-tricosanyl acetate showed no depression. The infrared spectrum of 1-tricosanyl acetate is recorded in Table III.

Isolation of 1-Docosanol

The material from the middle band of the chromatogram (0.16 g), after recrystallization from benzene, melted at 79–82°. The azoate (185 mg) was refluxed with 8% potassium hydroxide in 70% ethanol (3.8 ml), ethanol (8.7 ml), water (2.6 ml), and benzene (9.0 ml) for 1 hour. The product was isolated, and after recrystallization from ethanol it melted at 71–72°. A mixed melting point with the authentic sample of 1-docosanol was not depressed. The infrared spectrum of the alcohol (Table III) was identical with that of the authentic 1-docosanol.

Synthesis of 1-Tricosanol

Behenic or docosanoic acid, $CH_3(CH_2)_{20}COOH$ (10 g) (m.p. 79.5–80°) was converted by means of thionyl chloride to the acid chloride. The latter was added to an excess of ethereal diazomethane, and the solvent and excess diazomethane were removed *in vacuo* at 10°. The crude diazoketone was dissolved in 1,4-dioxane (100 ml), and the solution was added dropwise to a stirred mixture of sodium thiosulphate (11 g) and freshly precipitated silver oxide (7 g) in water (200 ml). The mixture was heated at 75° for 90 minutes, then the solid residue was filtered and washed with water. The precipitate was treated with dilute nitric acid, refiltered, washed with water, and dried. The material was then extracted with four 500-ml portions of boiling ether, each extraction lasting 1 hour. The ethereal solution was decolorized with Norite, concentrated to 250 ml, dried over anhydrous magnesium sulphate, and concentrated further until crystals precipitated. The crystalline material, after five recrystallizations from ligroin and finally from benzene, yielded tricosanoic acid, m.p. 79.5–80.5°. The tricosanoic acid was converted with diazomethane to methyl 1-tricosanoate (3 g). The ester was reduced with ethereal lithium aluminum hydride, yielding 1-tricosanol, which after recrystallization from isopropyl alcohol – ethanol (1:1) melted at 73.4–73.5° (reported m.p. 73.5–74.5 (6)).

Synthesis of 1-Docosanol

Methyl behenate was prepared by esterification of behenic acid with diazomethane. The ester was reduced with lithium aluminum hydride to 1-docosanol, which after recrystallization from isopropyl alcohol – ethanol (1:1) melted at 71.0–72.0° (reported m.p. 70.5–71.5° (6)).

Sterol Fraction

The unsaponifiable, petroleum ether insoluble fraction (410 mg) was recrystallized from ethanol.

The filtrate from the recrystallization was treated with digitonin, and the precipitate which formed was filtered and washed with cold 1,4-dioxane. The digitonide was decomposed in pyridine solution, and ether was added to precipitate the free digitonin, which was then removed by filtration and washed with diethyl ether. The pyridine–ether solution was evaporated *in vacuo* at 30°, leaving the sterol residue (140 mg). After three recrystallizations from ethanol, the melting point of the material remained unchanged at 135–136°.

The recrystallized sterol (m.p. 127–130°; 200 mg) which had been obtained from the petroleum ether insoluble fraction was also purified via the digitonide as above. The sterol (124 mg) obtained in this case, after three recrystallizations from ethanol, melted at 136.1–137°, and remained unchanged on further recrystallization.

A mixed melting point determination of the two sterols showed no depression and their infrared spectra (Nujol) were identical.

The sterol was tested for unsaturation with tetranitromethane (12). Cetyl alcohol was used as a blank. The color produced by the sterol was compared to, and found to be considerably deeper than, that produced by cholesterol. The cetyl alcohol – tetranitromethane mixture remained colorless. It was concluded that the sterol contained at least two double bonds. The ultraviolet absorption spectrum was taken, and there was no absorption in this region.

Attempts to determine the molecular weights by the Rast method gave unsatisfactory results due to the fact that the sterol underwent a considerable amount of decomposition above its melting point.

A sample of the sterol (25.16 mg) was heated at 110° under 0.005 mm pressure until a constant weight was achieved. The loss of weight was 1.03 mg, indicating the presence of 1 molecular equivalent of water of crystallization for a compound of molecular weight 439. There was no change in melting point after dehydration.

A quantitative Liebermann–Burchard reaction was run on the sterol using the Beckman ultraviolet and visible spectrophotometer. The sterol concentration was 0.097 mg/ml in chloroform. One-centimeter cells were used. There was absorption at 420 mμ (Fig. 4), and at 623 mμ and 675 mμ as well. At 623 and 675 mμ the rate of decrease of light transmission was slightly faster at first, but on standing for a short time the transmission began to increase again. The initial rate of decrease of transmission was greatest at 675 mμ, next at 623 mμ, and slowed at 420 mμ. $[\alpha]_D^{18}$ $-36.7\pm2°$ (*c*, 6.4, $CHCl_3$). Infrared spectrum (Table II). Anal. Calc. for $C_{29}H_{48}O.H_2O$: C, 80.87; H, 11.70; O, 7.43. Found: C, 80.91; H, 11.75; O, 7.99%.

5,11(?)-Stigmastadien-3β-yl Benzoate

5,11(?)-Stimastadien-3β-ol (25 mg), freshly distilled benzoyl chloride (7 ml), and pyridine (3 drops) were heated together for 4 hours on a steam bath. Then the reaction mixture was poured into cold water. When the excess benzoyl chloride had decomposed, the solid product was filtered, and the benzoic acid was removed by extraction with ethanol. The insoluble benzoate was separated by filtration, washed with ethanol, and recrystallized from acetone. The 5,11(?)-stigmastadien-3β-yl benzoate obtained in this way melted at 148.8–149°. $[\alpha]_D^{18}$ $-11.0\pm2°$ (*c*, 1.6, $CHCl_3$). Infrared spectrum was taken in KBr (Table II). Anal. Calc. for $C_{35}H_{52}O_2$: C, 83.68; H, 10.15. Found: C, 83.30; H, 10.54%.

5,11(?)-Stigmastadien-3β-yl Azoate

5,11(?)-Stigmastadien-3β-ol (40 mg), *p*-phenylazobenzoyl chloride (36 mg), and pyridine (0.4 ml) were refluxed together in an oil bath for 2 hours. The orange-colored solution was cooled and added to ice water. The material which precipitated was filtered and dried. Then the product was dissolved in benzene and the insoluble pyridinium salts were filtered and discarded. The filtrate was evaporated under reduced pressure, and the solid residue was recrystallized from benzene–ethanol. The recrystallized material softened at 180° and melted at 190–200°. The crude ester was chromatographed on a 20-mm column using 3:1 silicic acid: Celite 503 as the adsorbent. The eluent was a petroleum ether (90–120°) – benzene mixture, the ratio of which was changed rapidly from 4:1 to 6:1. The column was extruded when the main band reached about 2 cm from the bottom of the column. The center section of this band was cut out, extracted with benzene, and recrystallized from benzene–ethanol. After two recrystallizations, the ester softened at 181° and melted at 191–193°. Infrared spectrum (Table II).

ACKNOWLEDGMENTS

The authors wish to thank Dr. W. A. Rabinovitch for his aid in the film balance work, and Dr. Barbara G. Ketcheson for the editing of the manuscript.

THE PYROLYSIS OF TOLUENE

S. J. PRICE
Department of Chemistry, Essex College, Assumption University of Windsor, Windsor, Ontario
Received September 28, 1961

ABSTRACT

The pyrolysis of toluene has been studied in a flow system from 913 to 1143° K. First-order rate constants are independent of the toluene concentration but decrease approximately 9% when the contact time is reduced from 1.0 to 0.41 second. Increasing the contact time from 1.0 second to 2.07 seconds does not affect the rate constant. The overall rate has been resolved into homogeneous and heterogeneous components. It is suggested that the activation energy of the homogeneous process, 85 kcal/mole, may be associated with $D(C_6H_5CH_2—H)$.

INTRODUCTION

Attempts to determine $D(C_6H_5CH_2—H)$ by pyrolysis, photobromination, and mass spectrometric methods have led to values differing by 15 kcal/mole. The mechanisms proposed for all three types of studies have been questioned and it seemed possible that none of these methods could be used to obtain this bond dissociation energy.

The initial research on the pyrolysis of toluene was carried out by Szwarc (1). He reported a first-order homogeneous process represented by $\log k = 13.3 - 77{,}500/2.3RT$ and associated the activation energy with $D(C_6H_5CH_2—H)$. The mechanism proposed by Szwarc has been extensively reviewed (2–5) and seems to be substantially correct, although it does not explain the formation of solid products other than dibenzyl.

A second pyrolytic study was carried out by Blades, Blades, and Steacie (2). Their work disagreed with that of Szwarc in several important details. First, the rate constant was found to double when the contact time was increased from 0.068 to 0.568 second. Second, the rate was slightly increased by an increase in toluene pressure. Thirdly, the solid and involatile liquid products reported by Szwarc to be dibenzyl were shown to be only 50 to 75% dibenzyl, the bulk of the remainder being a mixture of dimethyl diphenyls. Fourthly, they found that the decomposition was partly heterogeneous. Blades *et al.* did confirm the constancy of the $CH_4:H_2$ ratio, but their ratio of 30:70 is considerably lower than the 40:60 ratio reported by Szwarc. Blades *et al.* preferred not to associate their activation energy of 90 kcal/mole with any single bond rupture process.

Anderson *et al.* (6) have tried to establish $D(C_6H_5CH_2—H)$ by studying the photobromination of toluene. They obtained a value of 89.5 kcal/mole, but this has been criticized by Sehon and Szwarc (3), who point out that the reaction of the benzyl radical with bromine, which was assigned zero activation energy by Anderson *et al.* in their calculations, may have an activation energy of 5–8 kcal/mole, giving $D(C_6H_5CH_2—H)$ a value of 81.5 to 84.5 kcal/mole.

Sehon and Szwarc (3) have also reviewed the mass spectrometric studies on toluene. It must be concluded that these studies cannot be used to obtain $D(C_6H_5CH_2—H)$.

Recently Takahasi (4) has studied the pyrolysis of toluene prepared from *o*-toluidine. Following Takahasi's suggestion (private communication), his results using a reaction zone of only 6.4 cc have been disregarded. It therefore appears that, qualitatively at least, his rate constants do seem to decrease with decreasing contact time. Although his results are somewhat scattered, it would also appear that his rate constants are independent of toluene concentration. Identification of the main solid products seems to agree

with the results of Blades *et al.* Takahasi reports, however, that the Arrhenius plot of the rate constants is curved and he assigns activation energies from 74 to 105 kcal/mole to different portions of the curve. His results do not seem sufficiently accurate to warrant such detailed analysis and for the present work his results will be represented by a best straight line giving an activation energy of approximately 86 kcal/mole.

EXPERIMENTAL

Materials

(*a*) Unprepyrolyzed toluene: Fischer reagent grade toluene dryed over sodium, fractionally distilled twice, degassed by bulb-to-bulb distillation, and stored over sodium.

(*b*) 1.5% prepyrolyzed toluene: reagent grade toluene passed through a quartz tube at 828° C with a contact time of approximately 1 second and then treated as in (*a*).

(*c*) 30% prepyrolyzed toluene: reagent grade toluene passed through a quartz tube at 900° C with a contact time of 3 to 4 seconds and then treated as in (*a*).

(*d*) Toluene from *o*-toluidine: toluene prepared by the diazotization of *o*-toluidine followed by deamination with sodium hypophosphite. The organic layer was fractionally distilled. The fraction boiling between 109–110° C (uncorrected) was dried over sodium and then treated as in (*a*).

Apparatus and Procedure

The apparatus used was a modified Szwarc toluene carrier system. Toluene pressures were measured using a mercury – dioctyl phthalate differential manometer. The volume of the reaction zone in the unpacked quartz vessel was 179 cc except as noted in the tables of results. The reaction vessel used to test for heterogeneity was packed with thin-walled vitrosil tubing approximately 2-mm O.D. It had a volume of 150 cc and a surface area approximately 10 times that of the unpacked vessel. Care was taken to completely fill the cross section of the reaction zone so that flow would occur evenly through the tubes and not above them. The contact time was varied by changing the flow controlling the capillary sealed into the line on the outlet side of the reaction vessel. A dry ice – acetone trap removed toluene, dibenzyl, and similar products. The remaining products were transferred by a diffusion pump to a Le Roy still kept at −160° C to remove traces of toluene and then to a pump-down trap (−200° C) to remove C_2H_6 and C_2H_4. The remaining H_2 and CH_4 were transferred with the aid of a Toepler pump, at intervals, past a non-return valve into a gas burette. After the $CH_4 + H_2$ mixture had been measured samples were taken for combustion over CuO and/or chromatographic analysis. The burette was then cleared, the pump-down trap was brought to room temperature, and the C_2 hydrocarbons were similarly measured and then collected for chromatographic analysis. The products which can be condensed by a dry ice – acetone trap have been well characterized and were not analyzed in the present work.

The chromatographic analyses were carried out using a 1-m silica gel column at 40° C with a flow rate of helium of approximately 20 cc/min. Internal standards were run with each set of analyses, so that peak heights could be used. In the $CH_4 + H_2$ mixtures the CH_4 was determined and the H_2 calculated by difference. Experiments with known CH_4–H_2 mixtures showed that this method yielded satisfactory results.

RESULTS

Tables I, II, and III give the results of the three major divisions of this investigation. In addition, two experiments were carried out at 845° K using unprepyrolyzed toluene. Rate constants calculated from the usual first-order rate expression assuming

$$\text{fraction decomposed} = \frac{\text{moles } CH_4 + \text{moles } H_2}{\text{moles toluene}}$$

were approximately eight times as large as those subsequently found at this temperature using toluene from *o*-toluidine.

Quantities of C_2 hydrocarbons were observed in all experiments. These ranged from 1 to 40 mole% of the $CH_4 + H_2$. In runs with 30% prepyrolyzed toluene this ratio was never above 10%, while in runs with toluene from *o*-toluidine it was rarely more than 2–3%. Analysis showed that the C_2 products were 0 to 5% C_2H_6, the remainder being C_2H_4. When prepyrolyzed toluene is used, C_2H_6 and C_2H_4 are undoubtedly produced by the decomposition of impurities. In experiments using toluene from *o*-toluidine, C_2H_4

probably arises from secondary reactions of the benzyl radical and possibly from rupture of the aromatic ring, while C_2H_6 is assumed to be formed by the recombination of two CH_3 radicals. The fraction of decomposition in experiments using toluene from *o*-toluidine should therefore be calculated from the moles of $H_2 + CH_4 + 2C_2H_6$. However, the quantities of C_2H_6 were often so small that they could not be detected chromatographically and even the largest quantities of C_2H_6 found would increase the calculated rate by less than 0.5%. The fraction of decomposition has therefore been calculated from moles $CH_4 + H_2$.

*Volume of reaction zone 195 cc.
†Packed vessel, volume 150 cc, surface approx. 2500 cm^2.

The results in Table I show that the rate constants obtained with 1.5% prepyrolyzed toluene are badly scattered. All attempts to reduce this scatter were unsuccessful. Furthermore, the percentage of CH_4 in the CH_4:H_2 mixture was generally higher than expected and very erratic (43±8%), although excellent agreement between chromatographic analysis and CuO combustion was always obtained on any one mixture.

Table II shows the results using toluene that had been approximately 30% decomposed in prepyrolysis. The rate constants from these experiments are included in Fig. 1. Reproducibility was satisfactory and the CH_4 percentage was lower and less scattered (36±4%). However, the quantities of C_2 hydrocarbons were still larger than expected.

Following the work of Takahasi (4) toluene prepared from *o*-toluidine was used for the experiments recorded in Table III. The percentage of CH_4 in the $CH_4 + H_2$ mixtures was slightly lower and more consistent (33±2%) than in runs with 30% prepyrolyzed toluene. Closer consideration of the results is therefore restricted to the results in Tables II and III, with major emphasis on those in Table III.

Runs at 1106° K (Table II) and 1053° K (Table III) show that over the range studied the first-order rate constants are unaffected by changes in the toluene concentration. Table IV shows that the rate constant apparently decreases approximately 9% when the contact time is reduced from 1.0 to 0.41 second, although increasing the contact time from 1.0 second to 2.07 seconds does not affect the rate constant. The effect of contact time

TABLE IV

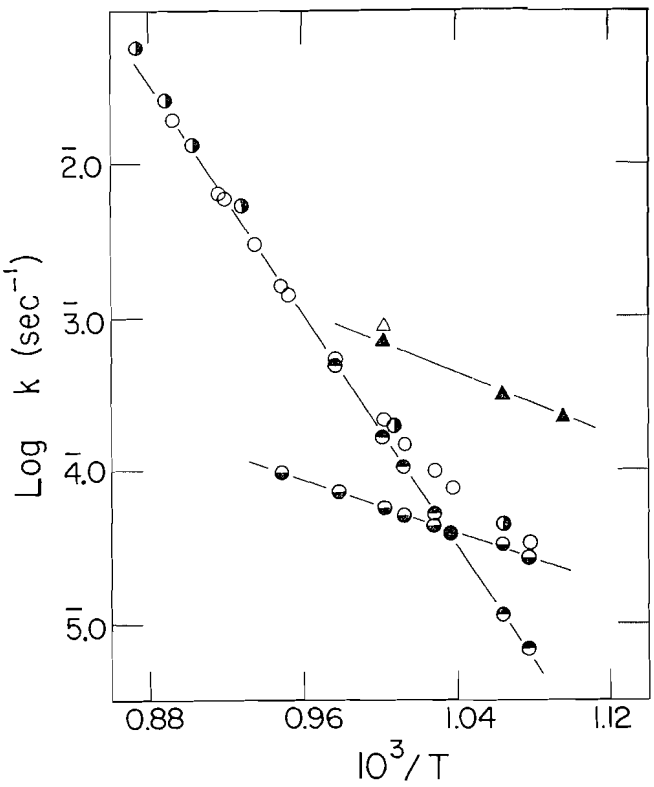

FIG. 1. Arrhenius plot for the pyrolysis of toluene. All points calculated assuming fraction decomposed given by moles H_2 plus moles CH_4 divided by moles toluene. ○ overall reaction (*o*-toluidine toluene); ◑ overall reaction (30% prepyrolysis toluene); ◓ homogeneous component; ◒ heterogeneous component; △ overall reaction in packed vessel; ▲ heterogeneous component in packed vessel.

will be discussed in detail later in this paper. Rate constants calculated on the basis of the Szwarc mechanism are shown as open circles in Fig. 1. The curvature in the lower portion of the plot was attributed to a competing surface reaction. The slope of this lower portion indicated that above approximately 1050° K the rate constants should be effectively those of the homogeneous reaction. Therefore the upper portion of the Arrhenius curve was linearly extrapolated and used as a basis for several approximations. The results of these calculations are shown by the resolved Arrhenius plots in Fig. 1. To confirm the heterogeneous nature of the competing process, the surface-to-volume ratio was increased by a factor of approximately 12. As may be seen from Table III and Fig. 1, the rate constants in the packed vessel increased by roughly the same ratio as the increase in surface to volume. The Arrhenius equation for the homogeneous process is given by $\log k = 14.8 - 85{,}000/2.3RT$.

DISCUSSION

Before any simple mechanism for the thermal decomposition of toluene can be considered, the effect of contact time on the rate constant observed both in this and previous work (2, 4) must be explained. Surface effects would appear to be unimportant under the experimental conditions used to check the effect of contact time, and it is unlikely that

any homogeneous process could cause the observed effect unless benzyl radicals are undergoing extensive side reactions. The decomposition of dibenzyl has been studied by Blades *et al.* (2). They report that no CH_4 was formed, although considerable quantities of hydrogen were produced. The invariance of the CH_4:H_2 ratio with contact time would therefore indicate that under the conditions used to study the thermal decomposition of toluene little breakdown of benzyl or dibenzyl is occurring. This is further substantiated by an experiment at 788° C carried out in the study of the pyrolysis of dimethyl zinc in a toluene carrier system (7). The quantity of hydrogen found in the products was essentially that expected from the decomposition of toluene, even though methane, and therefore benzyl radicals, were being produced at approximately 12 times the rate at which they would be produced in the decomposition of toluene under the same experimental conditions.

One further possibility is that as the contact time is decreased thermal equilibrium is not achieved in the initial part of the reaction zone, thus effectively reducing the reaction volume. It is tentatively suggested that this is the case and that the rate constants obtained in the present work using contact times of approximately 1 second are within 3 to 5% of the true first-order rate constants. Accepting this postulate, the thermal decomposition of toluene may be represented by the following mechanism:

$$C_6H_5CH_3 \rightarrow C_6H_5CH_2 + H \quad [1]$$

$$H + C_6H_5CH_3 \rightarrow C_6H_5CH_2 + H_2 \quad [2]$$

$$H + C_6H_5CH_3 \rightarrow C_6H_6 + CH_3 \quad [3]$$

$$CH_3 + C_6H_5CH_3 \rightarrow C_6H_5CH_2 + CH_4 \quad [4]$$

$$H + C_6H_5CH_3 \rightarrow C_6H_4CH_3 + H_2 \quad [5]$$

$$CH_3 + C_6H_5CH_3 \rightarrow C_6H_4CH_3 + CH_4 \quad [6]$$

$$2CH_3 \rightarrow C_2H_6 \quad [7]$$

plus the dimerization of benzyl and the various methyl phenyl radicals to give dibenzyl, dimethyl diphenyl, etc. and the breakdown of small quantities of these products to form the other solid and liquid products observed by Blades, Blades, and Steacie (2).

Whether reactions [5] and [6] occur at a sufficient rate to explain all the dimethyl diphenyl formation is uncertain. Blades and Steacie (5) indicate that at 1000° K approximately 10% of the radicals may be abstracting from the ring. Takahasi's work with deuterated toluene (8) would indicate considerable reactivity for the meta and para positions at least. Berezin *et al.* (9), using tritium labeling, find reaction [6] insignificant compared to reaction [4]. However, Berezin's work was carried out at much lower temperatures and may not be particularly relevant to the present study.

The possibility that reactions [8] and/or [9] occur to any appreciable extent seems

$$C_6H_5CH_3 \rightarrow C_6H_5 + CH_3 \quad [8]$$

$$H + C_6H_5CH_3 \rightarrow C_6H_5 + CH_4 \quad [9]$$

unlikely in view of the results of Leigh and Szwarc on the decomposition of *n*-propylbenzene in the presence of normal toluene (10) and of Blades and Steacie (5) on the decomposition of *n*-propylbenzene in the presence of "toluene-d_3".

The activation energy of the homogeneous process, 85 kcal/mole, may therefore be associated with $D(C_6H_5CH_2—H)$ within the limits of the kinetic method. This would

give a resonance energy of 17.5 kcal/mole to the benzyl radical. It should perhaps be pointed out that the observed frequency factor is within the limits expected in unimolecular processes (11).

Finally it is of interest to compare the results of the four kinetic studies of the pyrolysis of toluene. This has been done in Fig. 2. The results of Szwarc are of the same order as

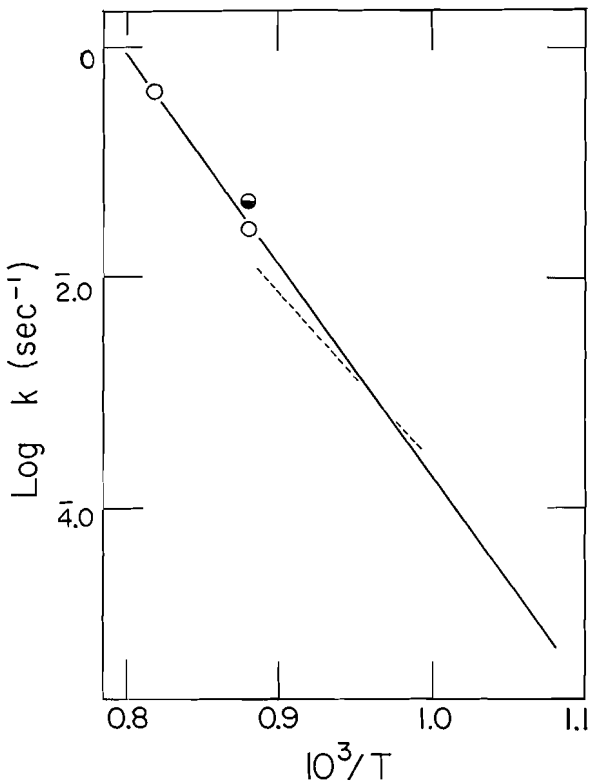

FIG. 2. Comparison of the present results with those of previous investigations. Broken curve, Szwarc; open circle, Blades, Blades, and Steacie using contact time of 0.068 second (half-fitted circle, correction of open circle to 1 second contact time); solid curve from $10^3/T = 0.875$ to $10^3/T = 1.08$, present work; solid curve from $10^3/T = 0.800$ to $10^3/T = 0.990$, Takahasi.

those of the other three investigations but detailed agreement is lacking. The agreement between the present results and the present author's interpretation of Takahasi's work is good. The agreement with the results of Blades *et al.* is somewhat unexpected. Both Blades *et al.* and the present work report decreasing rate constants as the contact time is decreased. Yet, agreement has apparently been obtained using contact times differing by a factor of 15. The effect of contact time in any one investigation seems real and it must be presumed that the agreement observed is due to systematic errors in either Blades' work or in both Takahasi's work and the present results.

ACKNOWLEDGMENTS

The author wishes to thank Mr. M. Jacko and Mr. M. Krech for carrying out preliminary experiments. This work has been supported by a grant from the National Research Council of Canada.

PERIODATE-OXIDIZED PHOSPHOMANNAN Y-2448: STRUCTURAL SIGNIFICANCE OF ITS REACTION WITH ALKALI[1]

ALLENE JEANES AND P. R. WATSON

Northern Regional Research Laboratory, Northern Utilization Research and Development Division, Agricultural Research Service, U.S. Department of Agriculture, Peoria, Ill., U.S.A.

Received January 29, 1962

ABSTRACT

The diesterphosphomannan produced by *Hansenula holstii* NRRL Y-2448 was shown by periodate-oxidation analysis to have 20% of its D-mannose units linked through carbon-1 only (or carbons-1 and -6), 33% through carbons-1 and -2, and 47% through carbons-1 and -3. Information regarding branching in this macromolecular polysaccharide derivative was not established. The periodate-oxidation product neutralized dilute alkali rapidly at pH 8.5–10.0, with elimination of about 30% of the phosphorus as inorganic orthophosphate. About 80% inorganic orthophosphate was obtained by longer treatment at pH 10.1–10.5. These observations are shown to support the hypothesis that diesterorthophosphate groups (0.20 mole/mole mannose unit) are held between carbon-6 of units otherwise linked only through carbon-1, and carbon-1 of 60% of the carbon-2-linked units. After periodate oxidation, both phosphoester bonds may undergo β-aldehydo elimination by alkali; the unit having phosphate in hemiacetal linkage and a mannosidic attachment at carbon-2 is presented as the more reactive site. Periodate oxidation also produces sites for β-dealkoxylation by alkali.

The exocellular polysaccharide derivative synthesized by the yeast *Hansenula holstii* NRRL Y-2448 and isolated as the neutral potassium salt has the constituents D-mannose, phosphorus, and potassium in the ratio of 5:1:1 (1). This phosphomannan is sensitive to overoxidation by sodium metaperiodate unless the reaction is conducted in the cold; after neutralization of the formic acid liberated, the oxidized product shows activity with mild alkali unusual for a polysaccharide. We have sought an explanation for these behaviors in relation to the structure of phosphomannan Y-2448.

It is reasonable to consider overoxidation of this substance possible since it seems characteristic of yeast mannans to have a significant proportion of their mannose units (MU) linked glycosidically at carbon-2 and/or carbon-3 (2–5). If in a reducing end position, such units are known to be susceptible to overoxidation (3–5). Phosphate groups in sugar phosphates (6) and in a polyribose phosphate (7) do not cause overoxidation unless the position of the phosphate results in formation of an active methylene group (6).

There are indications in the literature, however, that the presence of phosphate groups might be involved in the high activity of periodate-oxidized phosphomannan with alkali. Phosphates of β-aldehydo alcohols readily undergo phosphate elimination by mild alkali (8). Possibly closer parallels are provided by the smooth β-elimination, under mild alkaline conditions, of the phosphate moiety from dialdehydes produced by periodate oxidation of substances such as ribonucleoside-5′-phosphate (9) and by the adaptation of this procedure to oligo- and poly-nucleotides (9, 10).

Previously a fading end point during alkaline titration for formic acid in periodate-oxidation solutions of carbohydrates usually has been associated with the presence of *O*-formyl esters derived from reducing end groups (11–13), although other interpretations have been made (14, 15). *O*-Formyl groups appear to be excluded as the source of "ester" acidity in phosphomannan Y-2448 by the high proportion of ester-type acidity in relation

[1]*Presented before the Division of Carbohydrate Chemistry at the 139th Meeting of the American Chemical Society, St. Louis, Missouri, March 1961.*

to the reducing power of the polymer (1), and also by the relatively slow rate of reaction we have observed at pH 8.5–10.0. Since *O*-formyl esters saponify in the pH range 5.7–7.6 (11) or 5.0–9.5 (12) they should react almost instantaneously under our conditions for titrating ester-type acidity.

EXPERIMENTAL

Materials

The phosphomannan Y-2448 used, and the procedure for assuring samples of known dry weight, have been described previously (1). Visking tubing,[2] from which soluble matter had been removed by soaking in water, was used for dialysis.

Phosphorus Analysis

Carbohydrate-bound phosphate and inorganic phosphate were determined by adapting the method of Dryer, Tammes, and Routh (16). In the digesting of samples to determine carbohydrate-bound phosphorus, nitric acid was used instead of hydrogen peroxide (17). Since this method does not detect pyrophosphate under the conditions for inorganic phosphate (18, 19), any inorganic phosphate reported here is the ortho form.

Paper Chromatography

Solvent systems used for separating the inorganic components of dialyzates obtained from periodate-oxidation products after treatment with alkali or glycine buffer and neutralization were: *n*-propyl alcohol – water – aqua ammonia (6:1:3, v/v) (20); and the upper phase of *n*-butyl alcohol – pyridine – 1.5 *N* ammonium hydroxide (2:1:2, v/v) (21).

Phosphate was detected by dipping chromatograms in an ammonium molybdate – perchloric acid reagent (22) and using ultraviolet light (2537 Å) to bring out the spots (23).

Periodate Oxidation

For convenience in calculation and expression of periodate-oxidation results, sample weights of the phosphomannan (which is considered to have a repeating unit, $(C_6H_{10}O_5)_{10}(PO_3K)_2$) were calculated on the basis of $(C_6H_{10}O_5)_{10}$.

Oxidations were carried out in the dark; after a preliminary run of unbuffered solution at 25° C all subsequent oxidations were made at 4° C. Solutions for periodate oxidation contained phosphomannan Y-2448 and sodium metaperiodate at concentrations of 0.1% and 0.0074 *M* respectively, giving a ratio of 1.2 mole periodate ion per mole MU.

Analytical data for structural analysis were from unbuffered oxidation mixtures in which initial and final pH values were 5.0 and 4.0, respectively. For studies on quantitative elimination of phosphate groups from periodate-oxidized phosphomannan, periodate oxidations were conducted without buffer, in 0.065 *M* acetate buffer (pH 5.0), and in 0.025 *M* phthalate buffer (pH 6.0).

Periodate was measured by the method of Fleury and Lange as described by Jackson (24). Solutions were cooled to 4° C before and during titration with iodine (25).

Free Acidity

Ethylene glycol (1 ml) was added to aliquots (10 ml) of unbuffered oxidation mixtures and then the free acidity was titrated rapidly to the first phenolphthalein end point with 0.01 *N* barium hydroxide under an atmosphere of nitrogen. Comparable results were obtained by potentiometric titration. Acid titration values were corrected for a reagent blank. Evidence that this free acid was formic was obtained by subjecting 25-ml aliquots from a 400-hour oxidation mixture to distillation and finding 91% of the titratable free acidity in the distillate.

"Ester"-type Acidity

Measurement for ester-type acidity was made after titrating free acid in the oxidation reaction solution. When titrating for free acid, the first phenolphthalein end point faded within a few minutes and the pH decreased steadily. A more permanent end point was achieved by adding 0.2- to 1.0-ml portions of barium hydroxide solution at about 5-minute intervals during about 1.5 hours to maintain pH within the lower and upper limits of 8.5 and 10.0. Throughout this time, air was excluded by use of nitrogen gas.

Measurements on periodate-oxidation solutions showed inorganic phosphate present after titrating ester acidity but not before, and thus indicated that alkali was breaking some phosphate bonds. Conditions then were sought for more complete elimination of phosphate.

Elimination of Phosphate from Periodate-oxidized Phosphomannan

Except as stated otherwise, this procedure was applied to periodate-oxidation-reaction solutions after 240 hours' oxidation, when further change had become very slow. The pH of unbuffered oxidation solutions

[2]*Mention of trade names should not be construed as a recommendation or endorsement by the Department of Agriculture over those not mentioned.*

was made to about 5 before adding, to both buffered and unbuffered oxidation reaction mixtures, 1.01 times the calculated amount of ethylene glycol to reduce excess periodate. The solutions then were dialyzed (4° C) against distilled water until free of iodate and buffer salts. All phosphate remained in the residue.

Dialysis residues were treated (25° C) with dilute potassium hydroxide solution under an atmosphere of nitrogen, or with glycine buffer at pH 10.3–10.5 to eliminate the phosphate combined in the periodate-oxidized phosphomannan. Conditions for treatment with 0.1 *N* potassium hydroxide were (A) adding alkali to pH 11.90 and allowing to stand 1.5 hours, (B) adding alkali during 0.5 hour to pH 11.35 and allowing to stand 18 hours, and (C) adding alkali during 36 hours to maintain pH 10.45 and then allowing to stand 14 hours. Treatment with 0.02 *M* glycine buffer consisted of combining dialysis residue and 0.08 *M* glycine buffer in ratio of 10:3 by volume and allowing to stand 18 hours. The solutions then were neutralized with hydrochloric acid and analyzed for phosphate. At times the neutralized solutions were dialyzed and dialyzates and residues were analyzed separately for phosphate.

RESULTS

Oxidation in Unbuffered Solution

Oxidation of phosphomannan Y-2448 with sodium metaperiodate (1.2 mole/mole MU) in unbuffered solution at 25° C resulted in extensive overoxidation. Eventually all periodate was reduced and iodine was liberated. Unbuffered oxidation at 4° C apparently followed a normal course of reaction which, however, did not reach a sharp end point but continued to progress very slowly. Oxidation for 400 hours at 4° C resulted in essentially the same measured values as 24 hours' oxidation at 25° C.

As seen in Table I, reduction of periodate at 4° C was rapid during the first 24 hours,

TABLE I

Sodium metaperiodate oxidation of phosphomannan Y-2448 in unbuffered solution at 4° C

	Time, hours:			
	24	72	240	400
	Mole/mole MU

Free acid	0.072	0.096	0.154	0.201
Single cleavage (A)*	0.326	0.378	0.332	0.328
"Ester"-type acidity (B)	0.293	0.293	0.329	0.337
(A)−(B)	0.033	0.085	0.003	−0.009

*Calculated from: IO_4^- reduced minus two times the free acid produced.

but proceeded more slowly thereafter. Liberation of formic acid occurred slowly; only 35% of the final amount was found at 24-hour reaction time. In contrast, when the neutral polysaccharide dextran B-512 is oxidized under the same conditions, it liberates 63% of the final amount of formic acid (0.60 mole/mole glucose unit) within the first 24 hours. In contrast to the slow liberation of free acid from the phosphomannan, 87% of the total ester-type acidity was obtained in 24 hours, and the value remained relatively constant the rest of the time. Cleavage of individual bonds (in 1,2-linked units) also was very rapid, and for each mole MU oxidized in this way there appears to be approximately one mole of ester acidity. The difference in these values, shown in Table I as (A)−(B), might represent the first, relatively rapid cleavage of MU from which formic acid would be liberated after the second, apparently much slower, cleavage was accomplished. The value, −0.009, suggests that by 400-hour reaction time some formic acid was being liberated by oxidation of only one bond. This reaction would result if reducing end groups became available by acid hydrolysis.

Oxidation in Buffered Solutions at 4° C

Curves for oxidation of phosphomannan in solutions buffered at pH 5.0 and pH 6.0 paralleled that for unbuffered solution after the rapid, initial stages, but the rate increased with pH. Thus, mole periodate reduced per mole MU was 0.59 for unbuffered solution at 122 hours, but at 85 hours it was 0.62 for pH 5.0 and 0.68 for pH 6.0. These values at pH 5.0 and 6.0 seemed to be approaching the 0.73 mole periodate reduced per mole MU observed for unbuffered solutions at 400 hours (Table I).

Elimination of Inorganic Phosphate from Periodate-oxidized Phosphomannan

Analysis for inorganic phosphate in solutions of phosphomannan Y-2448 oxidized 400 hours in unbuffered solution at 4° C (Table I) showed none before or after titrating free formic acid, but 0.06 mole per mole MU after titrating ester-type acidity.

Investigation of conditions for maximum elimination of phosphate in inorganic form showed the influence of rate of addition of alkali, maximum pH reached, and duration of reaction with alkali. Complete conversion to inorganic phosphate was accomplished only by adding the periodate-oxidation product to 1 *N* alkali. Milder treatment under conditions (A) and (B) resulted in 64% inorganic phosphate. Application of condition (C) to products of unbuffered and buffered periodate oxidation (Table II) shows that the

TABLE II

Elimination of phosphate from periodate-oxidized phosphomannan Y-2448 by treatment at pH 10.10–10.45

	Oxidation with $NaIO_4$

*If it be assumed that the amount of free acid was the same as for the unbuffered reaction, the mole OH^-/mole free PO_4^{3-} would be 5.1 for the acetate-buffered and 4.4 for the phthalate-buffered reaction. Since from these buffered reactions the free acid may be expected to be greater than from the unbuffered, their ratios actually would be lower than those shown.

amount of phosphate eliminated increased directly in relation to the pH at which periodate oxidation was conducted, that is, directly in relation to the extent of oxidation. Essentially no change in results were observed when glycine buffer was used to maintain mild pH conditions for phosphate elimination. Our use of glycine buffer was an application of the procedure previously reported for elimination of phosphate from periodate-oxidized nucleotides (9).

DISCUSSION

Previous work on phosphomannan Y-2448 has established that the molar ratio of phosphorus to mannose is 1:5 (1), that phosphate occurs in diester linkage between the carbon-6 position of one mannose unit (26) and the carbon-1 hemiacetal position of another (1, 26), and that the phosphate appears to cross-link chains (1, 26). We now have strong evidence that phosphate is present in the ortho rather than in the pyro form.

Our analytical measurements and paper chromatography of dialyzates of the dephosphorylated periodate-oxidized phosphomannan (19) demonstrated that orthophosphate was the only inorganic form present. The experimental conditions for these reactions appear to preclude hydrolysis of pyrophosphate if it had been present in the phosphomannan.

The nature and proportion of the mannosidic linkages, as determined by periodate oxidation, are shown in Table III. On the basis of all these experimental findings, the

TABLE III

Linkages of mannopyranose units as indicated by periodate oxidation

%	Out of 10	Carbon atoms bearing linkages

types and proportions of groups constituting the average hypothetical repeat unit are depicted in Fig. 1. A total of 10 MU are present, distributed on an average of 5 between

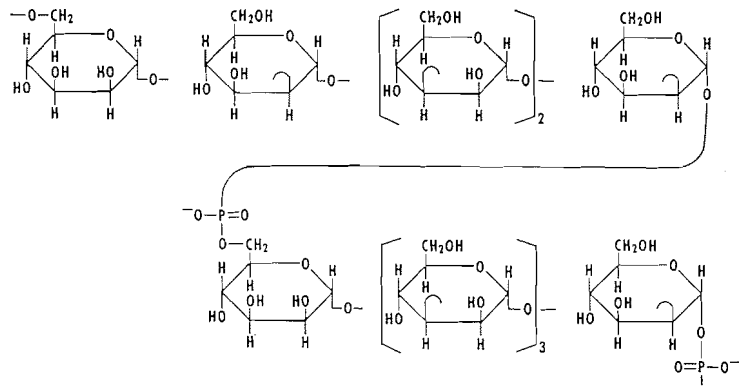

FIG. 1. Structural types and relative proportions of constituent mannose units in phosphomannan Y-2448. Absence of branching and some details of sequence have not been established.

a diesterorthophosphate group linked between carbon-6 of one MU and carbon-1 of another which appears to be mannosidically linked at carbon-2. As an average, phosphate is linked to 20% MU at carbon-6 and to 20% at carbon-1. The presence of sequences of 1,3-linked mannose units has been established by isolation of neutral di- and tri-saccharides containing this linkage from partial hydrolyzates of the periodate-oxidized phosphomannan (27). Evidence indicating 1,2-linkages rather than 1,4- will be discussed later in this article. The relative positions of 13% of the units linked through carbons-1 and -2 and of the sequences of 1,3-linked units are not established, nor is it known whether branching occurs. Therefore, linkages are not shown between the types of groups comprising the hypothetical repeating unit (Fig. 1).

These structural relationships (Fig. 1) appear to be compatible with all our observations relating to periodate oxidation and subsequent elimination of phosphate by alkali. Formic acid is believed to come from the unit linked through carbon-6 to phosphate.

Cleavage of the ring between cis hydroxyls would be rapid; subsequent cleavage between carbons-3 and -4 might be retarded by the electron-shielding effect of the phosphate ion, especially in unbuffered solution. Neutralization of this charge in buffered solution should permit an increased rate of oxidation, as was observed. In unbuffered solution, formic acid would be released slowly. Single ring cleavages presumably occur in units linked through carbons-1 and -2, and the rate of completion of this oxidation is striking (Table I). If the acid-sensitive hemiacetal-phosphate linkage should be hydrolyzed from one of these units, as might occur during unbuffered oxidation, overoxidation would occur and continue down the chain until a linkage through C_6 was encountered.

The structural representation is compatible with our observations that the native phosphomannan yields no inorganic phosphate under the conditions used for measuring ester acidity, nor even when heated at 60° C for 12 hours in 1 *N* sodium hydroxide solution. After this heating in 1 *N* alkali, the product showed no secondary phosphoryl hydrogen ions and no change in the primary ones. However, in the presence of weak acid, the native phosphomannan readily yields a secondary phosphoryl hydrogen ion, but no inorganic phosphorous is produced (1, 26). Direct correlation between the extent of periodate oxidation and the subsequent susceptibility of the phosphate to elimination by dilute alkali (Table II), as well as the high percentage of phosphate which can be eliminated, shows that both ester linkages of the phosphate become activated.

After periodate oxidation both phosphoester bonds are in β-aldehydo positions (Fig. 2, units I and II). The phosphoester attachment in I is directly analogous to that in

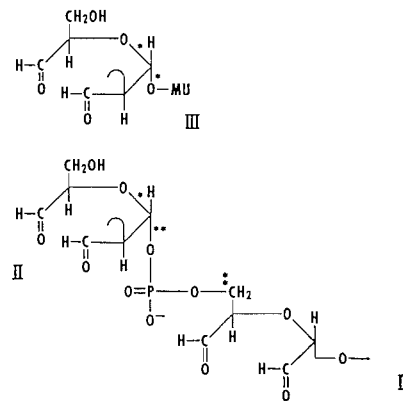

FIG. 2. Types of units from periodate-oxidized phosphomannan Y-2448 susceptible to β-alkoxy carbonyl (*) and β-phospho carbonyl (**) reaction with alkali.

periodate-oxidized adenosine-5′-phosphate. From this dialdehyde nucleotide, phosphate is eliminated in 85–90% yield by consumption of 2 equivalents of alkali per mole of phosphate liberated (9); we have employed the same manner of treatment with alkali.[3] There is analogy also btween the phosphoester attachment in I and that of the carbon-3 alkoxy group in 2:3-di-*O*-methyl D-glucose, which is eliminated readily by dilute alkali (28). There appears to be no previous report of a phosphoester attachment entirely comparable with that in II. However, the 3-carbon aldehyde to which the phosphate is attached is similar to the systems which react with alkali in 2:3-di-*O*-methyl D-glucose

[3]*An improved method for eliminating phosphate from dialdehyde nucleotides, reported recently by J. X. Khym and W. E. Cohn, J. Biol. Chem.* **236**, *PC9 (1961), also should be applicable to a system such as ours.*

and in periodate-oxidized methyl cellobioside (29) in having substituents at carbons-2 and -3 and in the absence of an α-hydroxyl. High activity might be expected at the carbon-3 position of this aldehyde fragment (originally the carbon-1 position of MU) since it is the site from which either (or both) the phosphoryl or α-glyceraldehyde group might undergo β-elimination.

Periodate-oxidized phosphomannan Y-2448 has still other alkali-sensitive bonds. In units glycosidically linked through carbons-1 and -2 (III), β-dealkoxylation might split out either of the two alkoxy groups attached at the original carbon-1 position. An additional postulated source for β-dealkoxylation would be a unit linked at carbon-3 if it were to become a reducing end group (30, 31).

The moles alkali consumed per mole inorganic phosphate eliminated from periodate-oxidized phosphomannan Y-2448 is 5.5 under the conditions of Table I (400 hour) and 4–5, or less, as estimated in Table II. These ratios are high in relation to the value 1 expected for normal dealkoxylation from a reducing sugar (32), 2 as observed for phosphate from periodate-oxidized adenosine-5′-phosphate (9), and 0 expected from a β-alkoxy aldehyde having no α-hydroxyl (28). Conditions contributing to our apparently high values might be conversion of some phosphate merely to the monoester state (81% being the maximum inorganic obtained), and the presence of alkali-sensitive groups other than phosphate.

The ester-type acidity observed stems from bonds which become labile to alkali during periodate oxidation and which, at least in part, are phosphate bonds. However, this lability is not all of equal degree. The main liberation of inorganic phosphate occurred relatively slowly or required strong alkali. Much more active was the ester acidity which apparently reached its full value within 24 hours' oxidation time, which showed a strikingly constant ratio of near unity to single bond cleavages by periodate, and which reacted relatively rapidly with alkali under mild conditions but resulted in elimination of only about 30% of the phosphate (Table I). These observations support our belief that this more active ester acidity arises from unit II rather than I.

These observations and the fact that both phosphoester attachments become activated support our hypothesis of a mannosidic bond at carbon-2 rather than at carbon-4 of unit II. Cleavage of a carbon-4-linked unit would result in a substituted α-phosphoglycol aldehyde, which would be expected to be much less reactive with alkali than the β-phosphoglyceraldehyde postulated (8, 29, 32, 33).

Additional evidence of a mannosidic bond at carbon-2 of the unit carrying phosphate in hemiacetal linkage (II) is the low reducing activity with alkaline copper reagents observed after mild acid hydrolysis of the native phosphomannan (26).

ACKNOWLEDGMENT

We are indebted to Jay E. Pittsley for paper chromatographic separation and identification of orthophosphate and of the mannose oligosaccharides.

THE FERMENTATION OF LONG-CHAIN COMPOUNDS BY TORULOPSIS MAGNOLIAE

I. STRUCTURES OF THE HYDROXY FATTY ACIDS OBTAINED BY THE FERMENTATION OF FATTY ACIDS AND HYDROCARBONS[1]

ABSTRACT

The yield of extracellular glycolipid produced by *Torulopsis magnoliae* is increased three- to five-fold by the addition of suitable compounds to the growing culture. The supplement, which can be a long-chain acid, ester, hydrocarbon, or glyceride, is hydroxylated and converted to hydroxy fatty acid sophorosides. Fatty esters of all chain lengths from C_{16} to C_{22}, including several unsaturated esters, and even-numbered hydrocarbons from C_{16} to C_{24} are readily fermented. Shorter-chain compounds are used poorly or not at all. With compounds of 16 to 18 carbon atoms, hydroxylation occurs at the terminal or penultimate carbon atom, depending on degree of unsaturation and chain length. Substrates of more than 18 carbon atoms are mainly reduced in chain length by one or more two-carbon units and hydroxylated, giving C_{17} or C_{18} acids with the hydroxyl group on the penultimate carbon atom. The various enzymic reactions which occur during the fermentation are discussed.

The extracellular oil produced by a particular strain of *Torulopsis magnoliae* in submerged culture has been the subject of an earlier investigation (1). It is heavier than water and consists of a mixture of hydroxy fatty acid glycosides of partially acetylated sophorose. The major components of the fatty acid portion of this "normal product" were 17-L-hydroxyoctadecanoic acid and 17-L-hydroxy-9-octadecenoic acid. Several minor components have since been identified as described below.

It has now been found that many long-chain compounds can be fermented by *Torulopsis magnoliae* with a substantial increase in the yield of glycolipid. The products are partially acetylated glycosides of hydroxy fatty acids as before, but the composition of the fatty acid portion varies with the substance added. To study this variation the glycolipids were subjected to acid methanolysis and the hydroxy fatty acid esters produced were analyzed by gas–liquid chromatography (GLC).

The compositions found when various fatty acid esters are incorporated into the medium are compared in Table I with that of the "normal product". Two hydroxy palmitic acids are the major components of the hydroxy acids obtained from the fermentation of methyl palmitate and also occur as minor components of the "normal product". One was shown to be 16-hydroxypalmitic acid by oxidation to hexadecanedioic acid. The other was thought to be 15-hydroxypalmitic acid by analogy with the 17-hydroxy C_{18} acid previously found (1). Bromination–dehydrobromination followed by oxidation with permanganate–periodate gave tetradecanedioic acid (2), and the derived oxo acid was shown to be identical with synthetic 15-oxopalmitic acid. The starting material for preparation of the latter was erucic acid; cis hydroxylation gave *threo*-13,14-dihydroxybehenic acid, which, after lead tetraacetate oxidation and hydrogenation, gave 13-hydroxytridecanoic acid. The ω-hydroxy acid was brominated to yield 13-bromotridecanoic acid,

Linoleate	1	2	4	37	56	—	0.60
11-Eicosenoate	2	3	9	56	11	19	0.52
Erucate	2	4	5	65	12	12	0.51
None	9	10	21	50	6	4	0.16

which was converted to 15-oxopalmitic acid by the method of Bergström *et al.* (3). 15-Hydroxypalmitic acid is dextrorotatory and is assumed to have the L-configuration (1). The other minor component of the normal product examined was an unsaturated 18-hydroxy C_{18} acid, hydrogenation and oxidation of which yielded octadecanedioic acid.

On addition of ethyl stearate and methyl oleate to the culture the principal fatty acid components of the glycosides are 17-hydroxystearic and 17-hydroxyoleic acids respectively. The acids obtained from the fermentation of methyl linoleate were shown to be mainly a mixture of 17- and 18-hydroxy C_{18} diunsaturated acids, since on hydrogenation followed by oxidation with chromium trioxide they yielded a mixture of 17-oxooctadecanoic and octadecanedioic acids. Also, the known 18-hydroxyoctadecanoic acid was isolated from the mixture of hydrogenated acids. The double bonds in all the unsaturated hydroxy acids derived from the various fermentation products start at the ninth carbon atom since azelaic acid is the only dicarboxylic acid isolated on permanganate–periodate oxidation (4, 5).

It appears from these results that the substrate largely determines the structure of the hydroxy acid portion of the product; thus when stearate is added the fatty acids are more saturated and when oleate is added they are more unsaturated than in the "normal product". The hydroxy acids are probably produced by direct hydroxylation of the substrate and not by breakdown to acetate and resynthesis. Convincing evidence for this view was obtained by fermenting selectively hydrogenated soya bean oil methyl esters. Since this material contains isomeric mono- and di-enoic esters produced during hydrogenation, permanganate–periodate oxidation yields a number of other dicarboxylic acids besides azelaic acid. Oxidation of the hydroxy fatty acids obtained after fermentation gave the same mixture of dicarboxylic acids as did oxidation of the soya esters, showing that direct hydroxylation had occurred.

When methyl 11-eicosenoate and methyl erucate were fermented another aspect of the reaction appeared. The major acid produced from both is 17-L-hydroxyoleic acid as shown by hydrogenation to 17-L-hydroxystearic acid and oxidation to azelaic and 8-hydroxypelargonic acids. Since the double bond in the added esters is in the 11,12- or 13,14-positions respectively and is in the 9,10-position in the product, two or four carbon atoms must have been removed from the carboxyl end of the molecule. A hydroxy C_{20} acid is a minor component of eicosenoate fermentation, and is probably 19-hydroxy-11-eicosenoic acid, since undecanedioic acid was found in the oxidation products of the fatty acid mixture in an amount corresponding to the amount of C_{20} acid present. A small percentage of a hydroxy C_{20} acid appears to be produced from erucate, but no hydroxy C_{22} acid was found. The methyl esters of linolenic, pentadecanoic, and myristic acids were poorly utilized by the organism, and the products were complicated mixtures. Lower fatty acids were even less readily fermented.

Table II shows the composition of the fatty acid portion of the product obtained when some esters of odd-numbered fatty acids are fermented. Heptadecanoate gives 16-L-hydroxyheptadecanoic acid and some 17-hydroxy acid. The former acid is also obtained from nonadecanoate by loss of two carbon atoms, through 18-L-hydroxynonadecanoic acid is the major component of the hydroxy acids. With heneicosanoate, reduction in chain length by four carbon atoms is the principal reaction leading to 16-L-hydroxy- and 17-hydroxy-heptadecanoic acids but some 18-L-hydroxynonadecanoic acid is also produced by loss of two carbon atoms. Only a very small amount of hydroxyheneicosanoic acid is obtained. The location of the hydroxyl group was established for 16-hydroxyheptadecanoic and 18-hydroxynonadecanoic acids by hypoiodite oxidation to yield iodoform and hexadecanedioic and octadecanedioic acids respectively.

It appears likely that the production of "normal product" usually proceeds slowly at the same time as the supplement is fermented, which would account for the presence of C_{18} acids in the palmitate, nonadecanoate, and heneicosanoate fermentations and the presence of unsaturated acids in the stearate fermentation.

The hydroxy acids derived from the products of fermentation of some hydrocarbons are listed in Table III. The results are similar to those obtained with esters of the same chain length; chain shortening occurs with eicosane, docosane, and tetracosane, and the principal acid produced is 17-L-hydroxystearic acid. 19-L-Hydroxyeicosanoic acid was isolated as a minor component of eicosane fermentation. The hydroxyl group was shown to be at C_{19} by the formation of nonadecanedioic acid on oxidation with hypoiodite and the formation of a mixture of nonadecanedioic and octadecanedioic acids on oxidation with permanganate in acetic acid (6). However, no hydroxy C_{22} acid could be detected in the products of the docosane fermentation.

Finally the fermentation of substituted fatty acid esters was examined. Methyl 12-hydroxyoctadecanoate is much less readily utilized than the other supplements but a small amount of dihydroxy acid, which is probably 12,17-L-dihydroxyoctadecanoic acid, is obtained. Methyl 10-methyloctadecanoate is readily fermented to products assumed to be 17-L-hydroxy-10-methyloctadecanoic acid and minor amounts of 15-L-hydroxy-methylpalmitic acid and the corresponding ω-hydroxy acids.

Methyl 8-hydroxyoctadecanoate, which was isolated from hydrogenated isano oil, is also easily fermented, giving a good yield of 8,17-L-dihydroxyoctadecanoic acid. The positions of the hydroxyl groups in the starting material and in the product were confirmed by permanganate oxidation (6), the former yielding mainly pimelic and suberic acids, and the latter azelaic and sebacic acids, in addition to the other two acids. The configuration of the hydroxyl group in the hydroxy acid of isano oil does not appear to have been determined.

Glycerides such as olive oil and tallow, and free fatty acids such as tall oil acids, are also fermented easily and the products are very similar to those obtained before. The mixture of hydroxy acids produced is always that expected from the composition of the substrate. Thus, the product from tall oil acids contains ω-hydroxy C_{18} acids corresponding to the amount of linoleic acid in the tall oil.

The possibility that the "normal product" is produced by direct hydroxylation of glycerides in the yeast cells has been examined. If this occurs the composition of the acids of the "normal product" should be similar to that of the cell glycerides in chain length and degree of unsaturation. Cells grown on a low-nitrogen medium, when no extracellular oil is obtained but appreciable amounts of intracellular lipid are produced, and cells recovered after isolation of "normal product" were extracted and the fatty acid composition of the lipids determined. They were quite similar to each other, with a high percentage of oleic acid and more palmitoleic than palmitic acid. Oils with this composition would be expected to give a considerably higher percentage of unsaturated hydroxy acids than actually found in the "normal product". Therefore, the glycolipid is probably not produced in this way.

The fermentation reaction may have practical applications, as quite good yields of hydroxy acids can be obtained. With hydrocarbons and C_{20} and C_{22} esters 50–60% of the supplement is converted to hydroxy fatty acids and with palmitate and C_{18} esters 70–80%. No supplement is recovered unchanged. Except for ricinoleic, long-chain hydroxy acids are not readily available and not easily synthesized. Unsaturated hydroxy acids, which can be prepared by fermenting inexpensive materials such as inedible tallow or tall oil fatty acids, might be useful in resin or polymer preparation.

TABLE II

Hydroxy acids obtained by fermentation of esters of fatty acids with an odd number of carbon atoms

Added compound	Percentage of hydroxy acid							Yield of hydroxy esters from 1 g of ester (g)
	15-Hydroxy C_{16}	16-Hydroxy C_{16}	16-Hydroxy C_{17}	17-Hydroxy C_{17}	17-Hydroxy C_{18}	18-Hydroxy C_{19}	20-Hydroxy C_{21}

TABLE III

Hydroxy acids obtained by fermentation of normal hydrocarbons

Added compound	Percentage of hydroxy acids							Yield of hydroxy esters from 1 g of hydrocarbon (g)
	15-Hydroxy C_{16}	16-Hydroxy C_{16}	17-Hydroxy C_{18}	Unsaturated 17-hydroxy C_{18}	Unsaturated 18-hydroxy C_{18}	19-Hydroxy C_{20}	Others	
Hexadecane	36	43	5	13	2	—	1	0.56
Octadecane	2	4	85	4	—	—	5	0.55
Eicosane	8	7	57	8	2	14	4	0.54
Docosane	8	9	67	9	3	—	4	0.64
Tetracosane	8	8	63	16	5	—	—	0.51

From a practical point of view the most important result of the chain-shortening reaction is that compounds with an even number of carbon atoms greater than 18 are converted to 17-hydroxy C_{18} acids and compounds with an odd number of carbon atoms greater than 17 are converted to 16-hydroxy C_{17} acids. Therefore, the hydroxy fatty acid portion of the glycolipid obtained by fermenting a mixture of compounds of various chain lengths should consist largely of only one or two components. Preliminary experiments, using rapeseed oil and a crude petroleum fraction containing normal hydrocarbons with from 13 to 23 carbon atoms, have indicated that this is in fact the case.

Enzymic Reactions Involved

Since this type of fermentation has not been observed before, it is useful to consider the mechanism by which the added compounds are converted to hydroxy acids. As the carboxyl group is free in the end product and esters are readily utilized the first stage may be hydrolysis by an esterase to the free acid. The next stage would probably be oxidation of $-CH_3$ to $-CH_2OH$ or $\rangle CH_2$ to $\rangle CHOH$. This reaction is similar to that occurring in the well-known microbiological hydroxylation of steroids. The enzyme appears to be fairly specific in its action since the relative amounts of hydroxylation at the terminal and penultimate carbon atoms, which are shown in Tables I and II, can be correlated with the length of the substrate molecule. Figures derived from the work of Nicolaides and Laves (7), who measured the lengths of fatty acids and esters as urea complexes, were used. ω-Hydroxylation does not occur with stearic acid (25.05 Å), but with the shorter oleic (24.22 Å) and heptadecanoic acids (23.80 Å) it occurs to a small extent (13%). Elaidic acid (24.91 Å), very close to stearic acid in length, was also not terminally hydroxylated. With linoleic (23.31 Å) and palmitic (22.55 Å) acids, which are both shorter still, considerable ω-hydroxylation occurs but to a lesser extent with palmitic than with linoleic acid, suggesting that palmitic acid is shorter than the most favorable length for ω-hydroxylation. Pentadecanoic and myristic acids are apparently too short for appreciable hydroxylation of any type to occur. Since linolenic acid (calculated length 22.51 Å) is about the same length as palmitic acid it is probable that it is not hydroxylated readily because the 15,16-double bond is too close to the site of the reaction. Also, 12-hydroxyoctadecanoic acid probably does not react easily because the hydroxyl group is too near the reaction site. However, substituents in the 10- and 8-positions appear to be too far away to interfere. It may be that there are two active sites on the enzyme, one which can hold the carboxyl group and one which is involved in the oxidation, and only substrates of a certain critical length can fit onto these sites.

In the case of esters of more than 18 carbon atoms another enzyme system must be involved as the chain is reduced in length before hydroxylation. Since two carbon units are removed from the carboxyl end of the molecule, the reaction probably proceeds by β-oxidation similar to that occurring in fatty acid metabolism. The results of the fermentation of methyl erucate, for example, where about 50% is converted to hydroxyoleic acids, can be explained by assuming that the chain-shortening reaction and the hydroxylation reaction are proceeding independently. When the erucic acid has been reduced to 18 carbon atoms it can be hydroxylated by the other enzyme system, but part is broken down too far and metabolized in other ways, accounting for the lower percentage conversion.

In the utilization of hydrocarbons yet another type of oxidation probably occurs, that is the conversion of $-CH_3$ to $-COOH$. A number of examples are now known in which

Nocardia and other bacteria oxidize long-chain hydrocarbons to fatty acids of the same chain length (8, 9) and it is assumed that this type of terminal oxidation takes place. Hydrocarbon oxidation to acids of shorter chain length has also been observed (10) and apparently proceeds by β-oxidation. With *Torulopsis magnoliae* the probable course of reaction is oxidation to the fatty acid, and for longer-chain substances reduction to 18 carbon atoms and then hydroxylation as before.

Linday and Donald (11), who studied hydrocarbon oxidation by *Pseudomonas* and *Nocardia*, found the percentage conversion to long-chain fatty acids to be very low and suggested that this was due to further oxidation to short-chain acids. In the present work this degradation does not occur to any great extent probably because rapid hydroxylation followed by formation of the sophoroside effectively protects the fatty acid. Stewart and co-workers (8) found a gram-negative coccus which converted hexadecane to cetyl palmitate in moderately good yield. Also Raymond and Davis (9), working with *Nocardia*, obtained nearly 50% conversion of octadecane to cell lipids which were partly glycerides and partly ester waxes. Here the fatty acids may be protected by the formation of esters either with long-chain alcohols or with glycerol.

EXPERIMENTAL

Melting points were determined using a Leitz hot-stage microscope. Optical rotations were measured at 25° C in a 1-dm tube. Davison silica gel, 60–200 mesh, was used without activation for column chromatography. Petroleum of boiling range 60–80° C was used except where other boiling ranges are mentioned.

Preparation of the Substrates

Methyl palmitate, ethyl stearate, methyl oleate, methyl linoleate, methyl 11-eicosenoate, and methyl erucate were prepared from vegetable oils and purified by the usual methods. These esters were shown by gas–liquid chromatography to be more than 99% pure. Ethyl linoleate was prepared by fractional crystallization of the ethyl esters of safflower seed oil and contained 20% of ethyl oleate. Selectively hydrogenated soya bean oil esters were obtained from Dr. C. G. Youngs.

Methyl heptadecanoate was prepared as follows. 1-Octadecene was hydroxylated (12) and the diol crystallized four times from methanol. 1,2-Octadecanediol (10 g), m.p. 75–80° C, was dissolved in glacial acetic acid (150 ml), and lead tetraacetate (ca. 22 g) added. After 45 minutes benzene (150 ml) was added, the mixture was poured into water (600 ml) and shaken, the aqueous layer was further extracted with benzene (100 ml), the extract was washed twice with water, and the solvent was removed. The residual aldehyde was taken up in glacial acetic acid (80 ml) and a solution of chromium trioxide (3.17 g) in water (5 ml) and acetic acid (20 ml) added in portions. After 30 minutes the mixture was poured into water, sulphur dioxide passed in to reduce excess oxidant, and the precipitated acid filtered off. The acid, m.p. 60–61° C after crystallization from petroleum, was converted to methyl heptadecanoate by refluxing with 4% methanolic hydrogen chloride.

Methyl nonadecanoate was prepared by the method of Levene and Taylor (13).

Methyl heneicosanoate was prepared as follows. A mixture of tridecanoic acid (16 g) and methyl hydrogen sebacate (14) (8 g) was dissolved in methanol (130 ml) containing sodium (0.09 g) and electrolyzed, and the reaction mixture worked up as described by Greaves *et al.* (15). The neutral product (8.1 g) was extracted with petroleum and the acids (8.5 g) extracted with ether after acidification. Purification of the neutral fraction by distillation (b.p. 150° C at 0.1 mm) and crystallization from methanol (1500 ml) gave pure tetracosane (3.9 g), m.p. 50.5° C. The acid fraction after crystallization from methanol (100 ml) gave crude heneicosanoic acid (3.4 g), m.p. 67–72° C (lit. (16) gives 74.3° C). The acid (3 g) was esterified with methanolic hydrogen chloride and the ester, crystallized from methanol (75 ml), had m.p. 46–47° C (lit. (16) gives 47.2° C).

Hexadecane, octadecane, eicosane, and docosane were pure commercial products. Tetracosane was obtained as a by-product of the synthesis of methyl heneicosanoate.

Methyl 12-hydroxystearate was prepared from commercial 12-hydroxystearic acid.

Methyl 10-methyloctadecanoate was prepared as described by Linstead and co-workers (17).

Methyl 8-hydroxyoctadecanoic acid was prepared from isano oil (18) obtained from the Pacific Vegetable Oil Corporation. Isano oil (65 g) was hydrogenated at 40° C and 1800 p.s.i. over 5% palladium on charcoal (6 g) in ethanol (100 ml) for 5 hours. The product was saponified and the acids distributed between 85% methanol and petroleum in two separating funnels. The polar fraction, after two crystallizations from acetone, gave 8-hydroxyoctadecanoic acid (6.5 g), m.p. 77.5–79° C. The methyl ester was prepared as usual and distilled, $[\alpha]_D$ −0.4° (c, 12.7, MeOH).

Method of Fermentation

An oil-producing strain of *Torulopsis magnoliae* was used. The medium consisted of glucose (10%), yeast extract (0.8%), and urea (0.1%). The medium (50 ml) was put in a 500-ml conical flask and agitated on a shaker of 230 r.p.m. and a radius of 1 inch. The flask was shaken for 1 day after inoculation, then the supplement (1 g) added as a stable emulsion or suspension in water, and the shaking continued for 2–3 days. The oil was isolated by allowing it to separate from the medium in a 50-ml centrifuge tube. The product formed a layer at the bottom of the tube, from which the yeast cells and medium could be siphoned off. The mixture was not centrifuged because if this was done the yeast cells were mixed with the product. The fermentation conditions and the yields obtained from a number of fermentations which were carried out on a larger scale are described elsewhere (19).

Isolation of the Methyl Esters

The product was taken up in ethyl acetate, separated from the water, liberated, and dried over sodium sulphate. The dry oil was refluxed overnight with 4% methanolic hydrogen chloride (25 ml) poured into water, and the methyl esters of the hydroxy acids extracted with chloroform. The yield of methyl esters obtained from 50 ml of inoculated medium without supplement was the average of two separate fermentations. Exact figures for the percentage conversion cannot be obtained because the results varied slightly with different fermentations and the amount of "normal product" produced at the same time can not be measured accurately.

Gas–Liquid Chromatographic Analysis

The apparatus used was described previously (20, 21). For routine analysis of the hydroxy acid methyl esters a 2-ft×1/4-in. copper column packed with 1:6 silicone grease on 60–80 mesh acid-washed celite was used. The apparatus was operated at 200° C with injector at 250° and a flow rate of 60 ml of helium/min. A typical result of the analysis of esters from the "normal product" is shown in Fig. 1.

Not very much work has been done on the gas chromatography of hydroxy acids (22) and apparently none at all on the quantitative aspects of the results or on mixtures of hydroxy acids of the same chain length. As shown in Fig. 1 there is a good separation between ω-hydroxy esters and esters with the hydroxyl

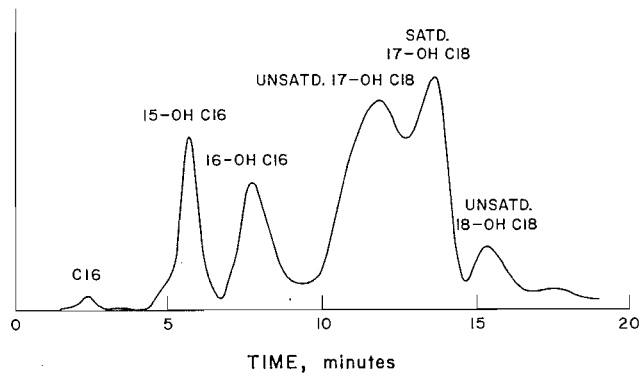

FIG. 1. Gas–liquid chromatographic analysis of hydroxy fatty acid esters using a silicone column.

group on the penultimate carbon atom. When the equivalent chain lengths (E.C.L.) (22) for the hydroxy esters are calculated the difference between the two types of ester amounts to almost 1 unit. The figures for the saturated hydroxy methyl esters obtained in the fermentations are as follows: 15-hydroxypalmitate 18.0, 16-hydroxypalmitate 18.8, 16-hydroxyheptadecanoate 19.0, 17-hydroxyoctadecanoate 20.0, 18-hydroxyoctadecanoate 20.8, and 19-hydroxyeicosanoate 22.0. The corresponding oxo esters had the same E.C.L.'s: 15-oxopalmitate 18.0, 17-oxooctadecanoate 20.0, 19-oxoeicosanoate 22.0. When the more polar fluorinated silicone QF-1 (23) is used the E.C.L.'s of the hydroxy esters are increased by 2 units compared to the results with the ordinary silicone: 15-hydroxypalmitate 20.0, 16-hydroxyheptadecanoate 21.0, 18-hydroxynonadecanoate 23.0. This difference in E.C.L. on the two types of silicone columns may be used as another way of distinguishing oxygenated esters from normal esters which have the same E.C.L. on one column. The column used was 18-in.×1/4-in. stainless steel, was packed with 1:6 silicone QF-1 on Gas-Chrom P (40–60 mesh), and was operated at 200° C.

Figure 1 also shows that the silicone column can give a partial separation of saturated and unsaturated hydroxy esters (20), sufficient to allow a rough estimation of the relative amounts present. It was not possible to use a polyester column to separate the saturated and unsaturated hydroxy esters, as can be done with ordinary esters (21, 24), because extensive decomposition or reaction with the liquid phase occurred.

Accordingly the following procedure was used in the analysis of the products. The ratio of the combined area of the saturated and unsaturated 17-hydroxy C_{18} peaks to the area of one of the hydroxy C_{16} peaks (the C_{16} esters are almost entirely saturated) is calculated. The spread between the saturated and unsaturated ester peaks can be much reduced by using a chart speed of one quarter of that used to give Fig. 1. A portion of the esters is oxidized with the permanganate–periodate reagent and separated into neutral and acidic fractions. From the analysis of the former by GLC the ratio of the area of the saturated 17-hydroxy C_{18} peak to the area of the hydroxy C_{16} peak is calculated. The complete composition of the ester mixture can then be worked out. The quantitative results obtained by gas chromatography agreed with the known values for a made-up mixture of saturated hydroxy esters and also with the percentages obtained by fractional crystallization, distillation, and chemical separations, within 5%. Some decomposition occurs on the column but since all the components are hydroxy compounds it is assumed that they all decompose to the same extent.

To separate azelaic acid and other products obtained by oxidation of the unsaturated esters or in permanganate – acetic acid oxidations a 10-ft×3/16-in. copper column packed with ethylene glycol – *o*-phthalate (24) 1: 4.5 on 40–60 mesh acid-washed firebrick was used. The oven temperature was 209° C and the flow rate 60 ml helium/min. To separate dicarboxylic esters of 16 or more carbon atoms obtained in hypoiodite oxidations the oven temperature was raised to 230° C.

Chemical Analysis of the Hydroxy Acids Produced by Fermentation

Palmitate Fermentation

The percentage of unsaturated esters was determined by two methods. (1) By oxidation: Esters (1.03 g) were dissolved in tertiary butanol (40 ml) and added to a mixture of permanganate–periodate solution (0.097 *M* in sodium metaperiodate and 0.0025 *M* in potassium permanganate) (40 ml), 0.25% potassium carbonate solution (40 ml), and tertiary butanol (80 ml), and the solution shaken for 6 hours. Ethylene was then passed in to destroy the excess oxidant, several milliliters of the carbonate solution added to raise the pH to 9, the butanol removed under vacuum at 50° C, and the saturated esters (0.89 g, 87%, measured by GLC 85%) extracted with ether. The amount of saturated C_{18} esters in this fraction was measured by GLC. After acidification the acidic products (0.16 g) were extracted with ether, converted to methyl esters with diazomethane, and found by GLC to be mainly azelaic and 8-hydroxypelargonic acids. (2) By hydrogenation: Esters (4.99 g) were hydrogenated in ethanol (65 ml) over 5% palladium on charcoal (0.5 g) and took up 59 ml hydrogen, corresponding to 14% monoene (theoretical volume required for monoene is 412 ml). The percentage of ω-hydroxy ester was determined by quantitative chromium trioxide oxidation (25). The hydrogenated and distilled ester consumed 1.46 atoms of oxygen, corresponding to 46% ω-hydroxy compound (calculated by GLC 44%).

Isolation of 16-Hydroxypalmitic Acid

A seven-stage fractional crystallization of the crude methyl esters (4.20 g) from acetone at −10° C gave pure methyl 16-hydroxypalmitate (0.57 g), m.p. 55.5–56° C (lit. (26) gives 55–55.5° C). Calculated for $C_{17}H_{34}O_3$: C, 71.3%; H, 12.0%. Found: C, 71.3%; H, 11.95%. Saponification gave 16-hydroxypalmitic acid, which, after crystallization from acetone, had m.p. 95–96.5° C (lit. (26) gives 95° C). Calculated for $C_{16}H_{32}O_3$: C, 70.5%; H, 11.8%. Found: C, 70.8%; H, 11.8%. On chromium trioxide oxidation the acid consumed 1.96 atoms of oxygen and gave hexadecanedioic acid, m.p. 119–122° C. The mixed melting point with the synthetic acid, m.p. 124–127° C, prepared by the method of Greaves *et al.* (15) was 121–125° C. 15-Hydroxypalmitate could not be obtained in pure form from the mother liquors of the fractional crystallization due to the presence of hydroxy C_{18} esters.

Isolation of 15-L-Hydroxypalmitic Acid

Partial acetylation of the crude esters, by refluxing with 85% acetic acid for 2 hours, and distribution of the product between petroleum and 80% ethanol in two separating funnels gave a polar fraction in which the concentration of the desired ester had been increased to 60%. This material was chromatographed on a silicic acid column and elution with petroleum containing 4% acetone gave an ester of 84% purity. The main impurity was 17-hydroxy C_{18} esters. The ester was acetylated by treatment with acetic anhydride at 100° C for 2 hours and finally purified by preparative gas chromatography. Batches of 42 mg were put through an 8-ft×5/16-in. copper column containing 1:6 silicone grease on acid-washed celite (60–80 mesh) operated at 240° C with injector at 290° and a flow rate of 60 ml helium/min. The recovery was about 88%. Deacetylation and crystallization from petroleum (b.p. 60–80° C) yielded pure methyl 15-L-hydroxypalmitate, m.p. 46–47° C. Calculated for $C_{17}H_{34}O_3$: C, 71.3%; H, 12.0%. Found: C, 71.1%; H, 12.1%; $[\alpha]_D$ +5.0° (*c*, 10.0, MeOH). 15-L-Hydroxypalmitic acid was obtained by hydrolysis and crystallization from acetone at 0°, m.p. 74–75° C. Calculated for $C_{16}H_{32}O_3$: C, 70.5%; H, 11.8%. Found: C, 70.45%; H, 11.7%; $[\alpha]_D$ +5.4° (*c*, 6.5, CH_3COOH). On oxidation with chromium trioxide the acid consumed 1.14 atoms of oxygen and gave 15-oxopalmitic acid, m.p. 81–82° C, after one crystallization from petroleum. The melting point was not depressed by the synthetic acid.

Synthesis of 15-Oxopalmitic Acid

Methyl erucate (25 g, prepared from rapeseed oil) was stirred with a mixture of 100% formic acid (60 ml) and 30% hydrogen peroxide (9 g) at 40° C, and propionic acid (20 ml) was added to give a homogeneous solution. After 3 hours' reaction the solvent was removed, the residue saponified with 10% potassium

hydroxide, and the acid isolated. Methyl *threo*-13,14-dihydroxybehenate was prepared by esterification with methanolic sulphuric acid (2%) and crystallized from petroleum, m.p. 77–79° C. The ester glycol was oxidized with lead tetraacetate, as described for the oxidation of octadecanediol above, and the aldehyde hydrogenated over Raney nickel at 100° C in ethanol. Saponification and crystallization from benzene gave 13-hydroxytridecanoic acid (7 g), m.p. 72–77° C (lit. (26) gives 79° C). The acid was brominated with 30% hydrogen bromide in acetic acid, esterified with diazomethane, and converted to the iodoester by refluxing with sodium iodide in dry acetone. After crystallization from ethanol the methyl 13-iodotridecanoate had m.p. 32–34° C. The iodoester (1.00 g), acetoacetic ester (0.36 g), potassium carbonate (1.15 g), and 2-pentanone (10 ml) were refluxed for 22 hours (3). Water was added and the product was extracted with ether and hydrolyzed with 10% methanolic potassium hydroxide (20 ml) at 50° C for 24 hours. After dilution with water and acidification crude 15-oxopalmitic acid (0.77 g) was extracted with ether. Two crystallizations from ethanol gave the pure acid, m.p. 81–82° C. Calculated for $C_{16}H_{30}O_3$: C, 71.1%; H, 11.2%. Found: C, 71.2%; H, 11.3%.

Isolation of Minor Components of the "Normal Product"

Crude hydrogenated hydroxy acids, prepared as before (1), were crystallized from acetone to remove most of the C_{18} acids (19.5 g). The residue (4.1 g) in the mother liquors was converted to methyl esters, acetylated, and separated in batches with a silicone column similar to that used above to give the two hydroxypalmitic acids. The 15-L-hydroxypalmitic acid had m.p. 75° C, $[\alpha]_D$ +4.6° (*c*, 4.6, CH_3COOH). Bromination of the acid (15 mg) with hydrogen bromide in acetic acid (1 ml) followed by dehydrobromination, by refluxing with S-collidine, and oxidation with aqueous permanganate–periodate reagent gave a dicarboxylic acid product. This material was found to be mainly tetradecanedioic acid when the methyl esters were analyzed on the polyester column and also on the silicone column at 200° C. Oxidation of the hydroxy acid with chromium trioxide gave 15-oxopalmitic acid, m.p. 80–81.5° C, undepressed on admixture with the synthetic acid, the X-ray powder photographs of the two acids were indistinguishable. Calculated for $C_{16}H_{30}O_3$: C, 71.1%; H, 11.2%. Found: C, 70.7%; H, 11.1%. The 16-hydroxypalmitic acid had m.p. 81–88° C, and oxidation yielded hexadecanedioic acid, m.p. 123–124° C, which did not depress the melting point of the synthetic acid, and the X-ray photographs of the two were indistinguishable. The hydrogenated crude acids were oxidized with chromic oxide and the oxo acids were removed by crystallization from ethanol. Hexadecanedioic and octadecanedioic acids were isolated from the mother liquors by crystallization from hexane and separated as methyl esters on the silicone column. Thus purified the octadecanedioic acid had m.p. 122–123° C and did not depress the melting point of a synthetic sample (15). The X-ray powder photographs were indistinguishable.

Stearate Fermentation

The crude ester was hydrolyzed and the acid crystallized once from acetone, m.p. 79–81° C, no depression with authentic 17-L-hydroxyoctadecanoic acid.

Oleate Fermentation

The crude esters were distilled, b.p. 168–170° C at 0.07 mm, $[\alpha]_D$ +3.2° (*c*, 8.0, MeOH). A portion was oxidized with the permanganate–periodate reagent and separated into saturated material (10%) and oxidation products as described for the palmitate product. The saturated material was analyzed by GLC to estimate the percentage of saturated C_{18} esters in the original product. GLC of the methyl esters of the oxidation products showed the presence of only azelaic and 8-hydroxypelargonic acids. Another portion of the esters was hydrogenated and 17-L-hydroxyoctadecanoic acid isolated, m.p. 77–80° C; the melting point of the authentic acid was not depressed.

Linoleate Fermentation

On permanganate–periodate oxidation in tertiary-butanol (5) the esters used 7.8 atoms of oxygen; the products were azelaic acid and short-chain hydroxy acids. The esters for this experiment were prepared by the fermentation of pure methyl linoleate but all the other reactions were carried out on esters derived from ethyl linoleate containing 20% ethyl oleate. The esters were distilled, b.p. 170–180° C at 0.08 mm, $[\alpha]_D$ +2.1° (*c*, 10.1, MeOH). During hydrogenation over 5% palladium on charcoal (0.36 g) the distilled esters (3.06 g) in ethanol (55 ml) took up 359 ml of hydrogen (calculated for 1.8 double bonds 398 ml). The hydrogenated esters (5 g) were oxidized with chromic oxide (3 g) in acetic acid (60 ml) as described before. The product (4.33 g) was crystallized from petroleum (b.p. 40–60° C) (150 ml) at 25° C and gave crude methyl hydrogen octadecanedioate (1.73 g, 40%). The pure half ester was obtained by crystallization from petroleum, m.p. 74–76° C (lit. (27) gives m.p. 72–74° C). Octadecanedioic acid was obtained by saponification and crystallized from ethyl acetate, m.p. 123–125.5° C, mixed melting point with the synthetic acid 124–127.5° C. The mother liquors, after separation of the half ester, yielded crude methyl 17-oxooctadecanoate (2.60 g), which gave the pure ester after crystallization from petroleum at 0° C, m.p. and mixed m.p. with the synthetic ester (1) 53–55° C. 17-Oxooctadecanoic acid was obtained by hydrolysis and crystallized from ethanol, m.p. and mixed m.p. with synthetic acid 85.5–87.5° C (1).

Isolation of 18-Hydroxyoctadecanoic Acid

Hydrogenated esters (20 g) were acetylated, by treatment with acetic anhydride (250 ml) at 100° C for 2 hours, and the reagent was removed under vacuum at 70° C. The acetate ester was taken up in methanol (200 ml), urea (34 g) added, and the mixture warmed to give a solution. The solid (33 g) was collected after 18 hours, decomposed with water, extracted with ether, and deacetylated with sodium methoxide in

methanol. The methyl esters (7.66 g) so obtained, contained about 75–80% ω-hydroxy ester. A portion (4.9 g) was chromatographed on a silicic acid column and eluted with petroleum containing 6% acetone. Methyl 17-hydroxyoctadecanoate came off first followed by pure methyl 18-hydroxyoctadecanoate (2.91 g), which was obtained as very long colorless needles after crystallization from petroleum, m.p. 61–62° C (lit. (3) gives 62.5° C). 18-Hydroxyoctadecanoic acid was prepared by saponification and crystallized from acetone, m.p. 97–99° C (lit. (3) gives 99° C). Calculated for $C_{18}H_{36}O_3$: C, 71.95%; H, 12.1%. Found: C, 71.8%; H, 12.0%.

Selectively Hydrogenated Soya Bean Oil Methyl Esters Fermentation

The composition of the original esters was palmitic 11.8, palmitoleic 0.2, stearic 5.6, oleic and isomers 62.7, linoleic and isomers 19.5%. Oxidation of these esters with the permanganate–periodate reagent (5) gave the following dicarboxylic acids expressed as molar percentages: C_6 1.2, C_7 1.6, C_8 5.1, C_9 58.7, C_{10} 10.3, C_{11} 10.7, C_{12} 9.6, C_{13} 2.8. Oxidation of the hydroxy methyl esters obtained after fermentation gave: C_6 2.3, C_7 2.0, C_8 3.8, C_9 57.6, C_{10} 11.8, C_{11} 9.6, C_{12} 10.6, C_{13} 2.2.

11-Eicosenoate Fermentation

Crude hydroxy esters (0.162 g) were oxidized as described for the palmitate fermentation and gave neutral product (0.018 g, 12.5% of original material). The oxidation products were 8-hydroxypelargonic acid and azelaic acid (85%, as a molar percentage of the total dicarboxylic acids) and undecanedioic acid (15%). Part of the esters was hydrogenated, purified by GLC as the acetate, and saponified, giving 17-L-hydroxyoctadecanoic acid, m.p. and mixed m.p. 79–81° C.

Erucate Fermentation

The acidic products obtained by the oxidation procedure used above were almost entirely azelaic and 8-hydroxypelargonic acids. A portion was hydrogenated and hydrolyzed to give 17-L-hydroxyoctadecanoic acid, m.p. and mixed m.p. 78–80° C.

Heptadecanoate Fermentation

Esters (0.63 g) were chromatographed on a silicic acid column and eluted with petroleum containing 4% of acetone, giving methyl 16-L-hydroxyheptadecanoate (0.44 g) free from the ω-hydroxy compound, m.p. 51.5–52.5° C, $[\alpha]_D$ +4.8° (*c*, 4.75, MeOH). Calculated for $C_{18}H_{36}O_3$: C, 71.95%; H, 12.1%. Found: C, 71.95%; H, 12.1%. The ester was saponified, giving 16-L-hydroxyheptadecanoic acid, which after crystallization from acetone had m.p. 86.5–87.5° C, $[\alpha]_D$ +5.2 (*c*, 4.0, CH_3COOH). Calculated for $C_{17}H_{34}O_3$: C, 71.3%; H, 12.0%. Found: C, 71.1%; H, 11.9%. Acid (10 mg) was dissolved in dioxane (2 ml), 5% aqueous potassium hydroxide (1 ml) added, followed by a solution (ca. 1 ml) of iodine in aqueous potassium iodide (10 g iodine in 50 ml of 30% potassium iodide solution) until the brown color persisted when heated to 60° C. The mixture was kept at 60° C for 2 minutes, potassium hydroxide added to dissolve excess iodine, and water (5 ml) added. Iodoform crystallized on standing. The solution was evaporated to a volume of 3–4 ml, acidified with 4 *N* sulphuric acid, sodium metabisulphite added, the acids extracted with ether, and treated with diazomethane. The principal dicarboxylic acid was shown by GLC to be hexadecanedioic acid together with a very small amount of the C_{15} acid.

Nonadecanoate Fermentation

Batchwise separation of the acetylated esters by GLC, as described under 15-hydroxypalmitate purification, and working up as usual yielded 18-L-hydroxynonadecanoic and 16-L-hydroxyheptadecanoic acids. Crystallization of the former from acetone gave pure 18-L-hydroxynonadecanoic acid, m.p. 91.5–92.5° C, $[\alpha]_D$ +4.4° (*c*, 2.8, CH_3COOH). Calculated for $C_{19}H_{38}O_3$: C, 72.6%; H, 12.2%. Found: C, 72.7%; H, 12.3%. Oxidation with hypoiodite as described above yielded mainly octadecanedioic acid and a small amount of the C_{17} acid. Treatment with diazomethane yielded methyl 18-L-hydroxynonadecanoate, m.p. 56–57° C, $[\alpha]_D$ +3.4° (*c*, 3.5, $CHCl_3$). Calculated for $C_{20}H_{40}O_3$: C, 73.1%; H, 12.3%. Found: C, 73.1%; H, 12.35%. The 16-L-hydroxyheptadecanoic acid was also crystallized from acetone and had m.p. 86–88° C. Calculated for $C_{17}H_{34}O_3$: C, 71.3%; H, 12.0%. Found: C, 71.5%; H, 12.2%. The X-ray powder photographs of this acid and of the 16-L-hydroxy C_{17} acid described earlier were indistinguishable.

Heneicosanoate Fermentation

Chromatography of the esters on silicic acid and elution with petroleum containing 4% of acetone yielded a fraction largely free from ω-hydroxy esters. This fraction was acetylated and separated into C_{17} and C_{19} ester acetates on the silicone column by GLC as above. After working up and crystallizing from acetone, 16-L-hydroxyheptadecanoic acid was isolated, m.p. and mixed m.p. 86.5–88° C. The 18-L-hydroxynonadecanoic acid had m.p. and mixed m.p. 90.5–92° C.

Hexadecane Fermentation

The products were identified by comparison of the GLC results with those obtained by palmitate fermentation.

Octadecane Fermentation

On hydrolysis the esters yielded 17-L-hydroxyoctadecanoic acid, m.p. and mixed m.p. 80–81° C. Oxidation of the esters as above gave 93% of neutral material.

Eicosane Fermentation

The crude hydroxy esters were first purified by rapid distillation, b.p. 160–180° C at 0.1 mm, then C_{16} and C_{18} compounds removed by fractional distillation through a spinning band column. Saponification of

a portion of the distillate and two crystallizations from acetone yielded 17-L-hydroxyoctadecanoic acid, m.p. and mixed m.p. 78–80° C. The distillation residue consisted of polymeric material, produced during the prolonged heating, and hydroxy C_{20} esters. The latter were largely separated from polymer by rapid distillation at 200° C and 0.04 mm. The ester so obtained was separated from a small amount of ω-hydroxy ester by chromatography on a silicic acid column and elution with petroleum containing 6% acetone. After hydrolysis 19-L-hydroxyeicosanoic acid was obtained and crystallized from acetone, m.p. 86.5–87.5° C, $[\alpha]_D$ +5.2° (*c*, 1.4, CH_3COOH). Calculated for $C_{20}H_{40}O_3$: C, 73.1%; H, 12.3%. Found: C, 73.3%; H, 12.4%. Esterification with 4% methanolic hydrogen chloride gave methyl 19-L-hydroxyeicosanoate, which was crystallized from petroleum, m.p. 58–60° C, $[\alpha]_D$ +3.6° (*c*, 2.4, MeOH). Calculated for $C_{21}H_{42}O_3$: C, 73.6%; H, 12.4%. Found: C, 73.75%; H, 12.3%. When the acid was oxidized with potassium permanganate in acetic acid (6) the principal acids produced were nonadecanedioic and octadecanedioic in about equal amounts; minor amounts of shorter-chain acids were also found. Chromium trioxide oxidation of the acid yielded 19-oxoeicosanoic acid, which crystallized from ethanol, m.p. 88.5–90.5° C. Calculated for $C_{20}H_{38}O_3$: C, 73.6%; H, 11.7%. Found: C, 73.4%; H, 11.5%. Oxidation of the oxo acid with hypoiodite gave mainly nonadecanedioic acid with small amounts of C_{18} and C_{17} dicarboxylic acids.

Docosane and Tetracosane Fermentations

17-L-Hydroxyoctadecanoic acid was isolated from both products by saponification and crystallization from acetone, m.p. and mixed m.p. 78–80° C.

12-Hydroxyoctadecanoate Fermentation

The ester product (0.49 g, derived from 2 g supplement) was saponified and chromatographed on silicic acid; elution with chloroform removed monohydroxy acids and elution with acetone gave a dihydroxy acid (0.19 g). Crystallization from ethyl acetate – hexane yielded 12,17-L-dihydroxyoctadecanoic acid, m.p. 71–72° C, $[\alpha]_D$ +8.2 (*c*, 4.9, CH_3COOH). Calculated for $C_{18}H_{36}O_4$: C, 68.3%; H, 11.5%. Found: C, 68.2%; H, 11.5%. Chromic acid oxidation gave 12,17-dioxooctadecanoic acid, which crystallized from ethyl acetate, m.p. 53–56° C. Calculated for $C_{18}H_{32}O_4$: C, 69.2%; H, 10.3%. Found: C, 68.9%; H, 10.3%.

10-Methyloctadecanoate Fermentation

ω-Hydroxy esters were removed from the product (0.53 g, from 1 g supplement) by silicic acid column chromatography as described for the heptadecanoate fermentations. Saponification yielded gummy 17-L-hydroxy-10-methyloctadecanoic acid (0.2 g), containing about 10% of a 17-hydroxymethyl C_{16} acid, $[\alpha]_D$ +3.2° (*c*, 7.5, CH_3COOH). Chromic acid oxidation gave 10-methyl-17-oxooctadecanoic acid, which was purified by GLC as the methyl ester. The acid, after crystallization from petroleum, had m.p. 35–36° C. Calculated for $C_{19}H_{36}O_3$: C, 73.0%; H, 11.6%. Found: C, 72.95%; H, 11.5%.

8-Hydroxyoctadecanoate Fermentation

The crude esters (1.01 g, from 1 g supplement) were extracted with boiling petroleum, and crystalline dihydroxy ester (0.49 g) was obtained on cooling. This ester was saponified and the product crystallized from acetone to give 8,17-L-dihydroxyoctadecanoic acid, m.p. 82–83° C. Calculated for $C_{18}H_{36}O_4$: C, 68.3%; H, 11.5%. Found: C, 68.05%; H, 11.45%, $[\alpha]_D$ +3.9° (*c*, 5.0, CH_3COOH). Methyl 8,17-L-dihydroxyoctadecanoate was prepared by treatment with methanolic hydrogen chloride and crystallized from acetone, m.p. 77–78° C, $[\alpha]_D$ +3.9° (*c*, 2.4, MeOH). Calculated for $C_{19}H_{38}O_4$: C, 69.0%; H, 11.6%. Found: C, 69.0%; H, 11.6%. Oxidation of the acid with permanganate in acetic acid yielded the following dicarboxylic acids: C_7 and C_8, lesser amounts of C_9 and C_{10}, and minor amounts of C_6, C_5, and C_4. Oxidation of 8-hydroxystearate in the same way gave mainly C_7 and C_8 dicarboxylic acids.

Composition of the Oil of Torulopsis magnoliae Cells

The yeast was grown on the following "low-nitrogen" medium: glucose 10%, yeast extract 0.2%, and urea 0.1%. The air flow was 1 liter per minute per fermentor, the agitator speed 400 r.p.m., and the temperature 30° C. No extracellular oil was produced. The yeast was also grown on the usual medium for oil production and the oil produced was separated. In both cases the cells were collected by centrifuging, washed twice with distilled water, and dried *in vacuo* at room temperature. The dry cells were ground and extracted with petroleum using the modification of Troéng's method (28) developed for use with fungus spores (29). The oil content of the cells grown on the "low-nitrogen" medium was 11%. Methyl esters were prepared in the usual way and analyzed by GLC (30). The fatty acid composition was: myristic 0.5, palmitic 12.9, palmitoleic 15.4, stearic 6.7, oleic 62.8, linoleic 0.7, and unidentified 0.9%. The extract from the oil-producing cells was 2.4% and only about 20% of this was fatty acid esters. The fatty acid composition was: palmitic 6.7, palmitoleic 16.5, stearic 2.7, and oleic 74.1%.

ACKNOWLEDGMENTS

The authors are indebted to Dr. C. G. Youngs for suggesting the fermentation of, and supplying, selectively hydrogenated soya bean oil esters. The authors wish to thank Mr. N. R. Gardner, Mr. L. L. Hoffman, and Miss S. F. Lubin for technical assistance, Miss I. M. Gaffney for the X-ray powder photographs, and Mr. M. Mazurek for the microanalyses.

THE GAS–LIQUID PARTITION CHROMATOGRAPHY OF CARBOHYDRATE DERIVATIVES

PART II. THE SEPARATION OF METHYL GLYCOSIDES AND OF ACETYLATED DISACCHARIDES

H. G. JONES AND M. B. PERRY

Department of Organic Chemistry, Queen's University, Kingston, Ontario

Received March 15, 1962

ABSTRACT

Gas–liquid partition chromatography has been used to separate anomeric methyl glycosides and also fully acetylated disaccharides.

DISCUSSION

Earlier work in this laboratory (1, 2) showed that gas–liquid partition chromatography (G.L.P.C.) provided an excellent method for the separation of glycitol and glycose acetates. These results encouraged us to investigate the possibility of extending the method to the analysis of unsubstituted monosaccharides and of acetylated carbohydrates of higher molecular weight. This paper describes the separation of unsubstituted methyl glycosides and of acetylated disaccharides by G.L.P.C.

The recorded separations were obtained using samples (5–20 γ) of the methyl glycosides in dry methanol and of the acetylated disaccharides in dry chloroform solution developed on a Pye Argon Chromatograph fitted with an ionization detector (3), and in cases where larger amounts of material (50–150 mg) were separated and collected, the Burrell Kromo-Tog K-2 apparatus was used.

Bishop *et al.* (4, 5) and Kircher (6) have shown that G.L.P.C. can be applied to the separation of methyl *O*-methyl glycosides but that under the conditions used, methyl mono-*O*-methyl hexopyranosides and methyl hexopyranosides (5) have such large retention volumes that resolution of these compounds was not satisfactory. In our work it was found that the substitution of part of the usual Chromosorb W support material by glass beads coated with a suitable non-polar liquid phase greatly reduced the retention volumes of these compounds, thus making their separation by G.L.P.C. practical.

For the separation of methyl glycosides the two most suitable column packing materials found, from many trial experiments, were (*a*) a column made up of an intimate mixture of Apiezon M grease on Chromosorb W and butanediol succinate polyester on Chromosorb W packed on top of a column of methyl silicone rubber gum on glass beads (column packing I), and (*b*) an intimate mixture of Apiezon M grease on Chromosorb W, butanediol succinate polyester on Chromosorb W, and Apiezon M grease on glass beads (column packing II). Typical separations of glycosides on column packing I are shown in Fig. 1, and on column packing II in Fig. 2. The retention volumes of glycosides on these column packings are given relative to methyl β-L-arabinopyranoside (= 1.00) in Table I.

The most suitable operating temperature was found to be 200–210°, under which condition good separations were obtained on the Pye Argon Chromatograph without apparent decomposition of the compounds. However, although methyl pentosides were recovered unchanged from the effluent gas stream from preparative separations using the Burrell Kromo-Tog K-2 apparatus, methyl glucosides and methyl galactosides collected were found to be contaminated with β-glucosan (?) and β-galactosan respectively. It is

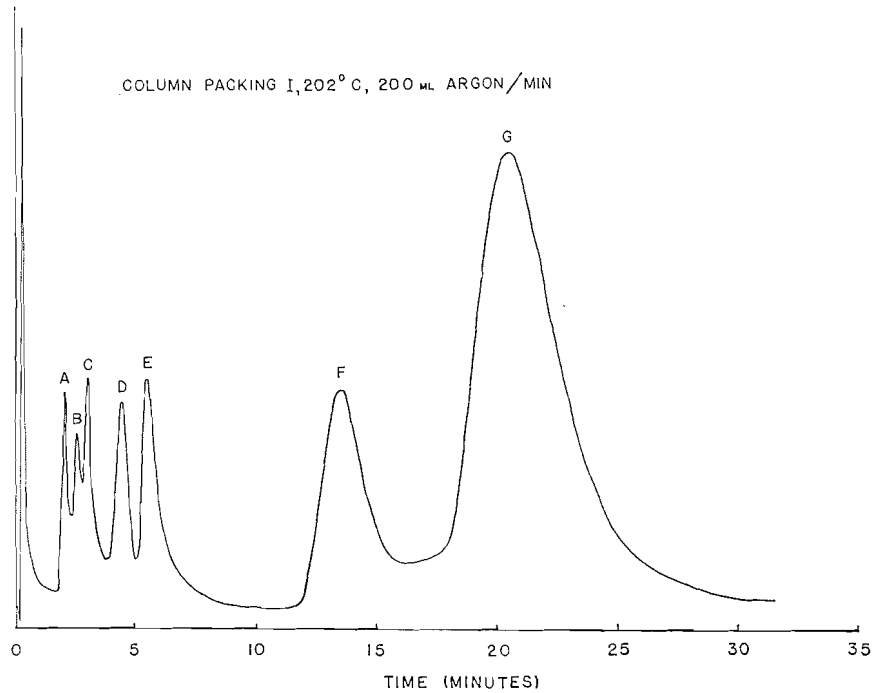

FIG. 1. Separation of glycosides: (A) methyl α-L-fucopyranoside, (B) methyl β-L-arabinopyranoside, (C) methyl β-D-xylopyranoside, (D) methyl α-L-arabinofuranoside, (E) β-galactosan, (F) methyl (methyl β-D-glucopyranosid) uronate, and (G) methyl β-D-galactopyranoside.

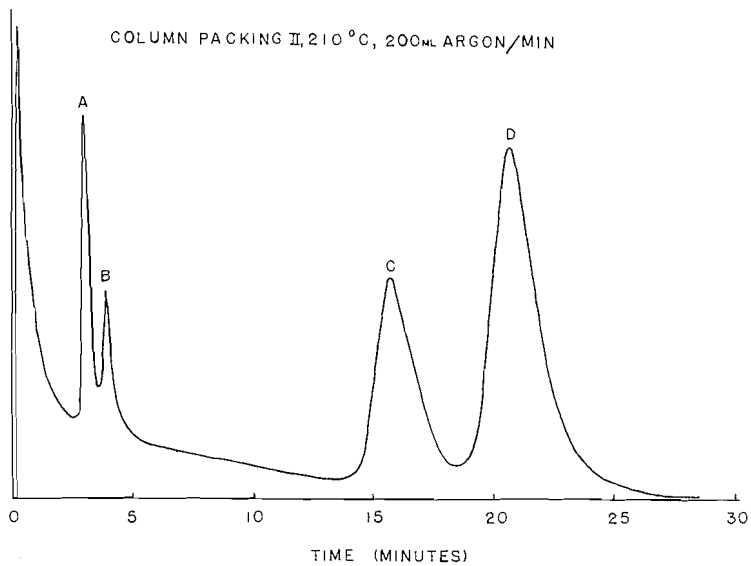

FIG. 2. Separation of methyl glycosides: (A) methyl β-L-arabinopyranoside, (B) methyl β-D-xylopyranoside, (C) methyl α-D-glucopyranoside, and (D) methyl β-D-glucopyranoside.

considered that the decomposition of the methyl hexosides takes place in the heated part of the collection device and not on the column packing material. A general relationship between the structures of the methyl glycosides and their relative retention volumes

TABLE I

Retention volumes of glycosides relative to methyl β-L-arabinopyranoside

Glycoside	Column packing	
	I (202°)	II (210°)
Methyl α-L-fucopyranoside	0.77	0.79
Methyl β-L-arabinopyranoside	1.00 (2.5 min)	1.00 (3 min)
Methyl α-L-rhamnopyranoside	1.06	1.00
Methyl β-D-xylopyranoside	1.20	1.25
Methyl β-D-ribofuranoside	1.70	1.75
Methyl α-L-arabinofuranoside	1.73	1.56
Methyl α-D-arabinopyranoside	2.20	—
β-Galactosan	2.30	1.00
Methyl α-D-glucopyranoside	5.50	5.40
Methyl (methyl β-D-glucopyranosid) uronate	5.60	2.53
Methyl α-D-galactopyranoside	5.70	5.34
Methyl α-D-altropyranoside	6.40	6.13
Methyl β-D-glucopyranoside	7.11	7.00
Methyl α-D-mannofuranoside	7.40	6.90
Methyl β-D-glucofuranoside	—	7.21
Methyl α-D-mannopyranoside	8.30	7.10
Methyl β-D-galactopyranoside	8.52	7.74
Methyl β-D-glycero-D-gulopyranoside	31.8	—
Phenyl β-D-glucopyranoside	39.0	—

could not be made since it was found that reversal of the order of elution occurred in some cases on changing the nature of the liquid phases. In the case of each glycoside investigated it was found that the anomers showed fairly wide separation and it is considered that the G.L.P.C. method will provide a convenient procedure for the detection, quantitative analysis, and preparative-scale separation of these compounds. In general, paper chromatography has not provided a successful method for the separation of anomeric methyl glycosides (6, 7), although some success has been achieved using cellulose column chromatography (8) separations on Florex XXX (9) and on Dowex-1 resin in the chloride and borate forms (10).

Attempts to separate oligosaccharide acetates by G.L.P.C. were successful only when glass beads were used as the inert support material for the liquid phases. Two of the most successful columns were prepared using (*a*) a mixture of polyphenylether on glass beads and D-C silicone oil 710 on glass beads (column packing III) and (*b*) methyl silicone rubber gum on glass beads (column packing IV) at 236–238°. Typical separations of disaccharide acetates are shown in Fig. 3 (column packing III) and in Fig. 4 (column packing IV), and the retention volumes of these derivatives, relative to octa-*O*-acetyl sucrose (= 1.00), are recorded in Table II.

The acetates of reducing disaccharides gave broad peaks under the conditions described above, and good separations of the anomers were not achieved. The best results were obtained with the acetates of non-reducing disaccharides and with glycosyl-glycitol derivatives prepared by acetylation with pyridine and acetic anhydride of reduced ($NaBH_4$) reducing disaccharides.

EXPERIMENTAL

Apparatus

Separations were carried out using the Pye Argon Chromatograph fitted with an ionization detector (80 μc radium D) and employing straight glass columns (117×0.5-cm I.D.) packed with the appropriate support, enclosed at each end by small glass-wool plugs. The samples (5–20 γ) in dry methanol or chloroform solution were placed on the top of the columns using a micropipette, and development was made using dry argon as the carrier gas.

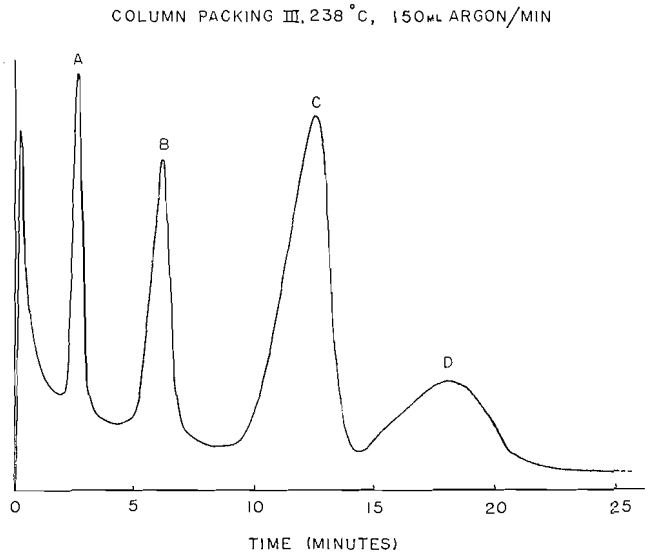

FIG. 3. Separation of disaccharide acetates: (A) α-D-xylopyranosyl α-D-xylopyranoside, (B) 5-*O*-β-D-xylopyranosyl-L-arabitol, (C) sucrose, and (D) cellobiitol.

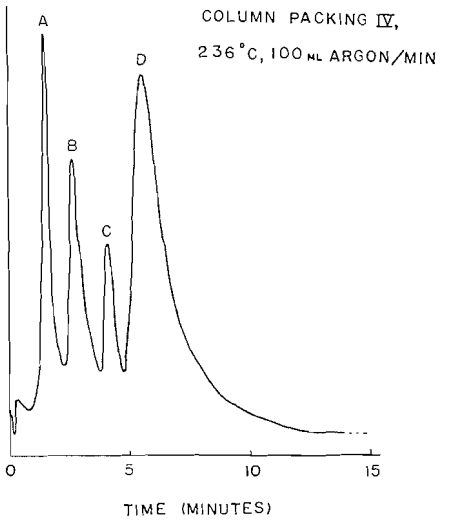

FIG. 4. Separation of disaccharide acetates: (A) α-D-xylopyranosyl α-D-xylopyranoside, (B) 5-*O*-β-D-xylopyranosyl-L-arabitol, (C) sucrose, and (D) maltitol.

Preparative-scale separations (50–150 mg) were made on U-shaped glass columns (250×1.3-cm I.D.) filled with the support material, using the Burrell Kromo-Tog K-2 apparatus fitted with a thermal detector and employing helium as the carrier gas.

Column Packings

Chromosorb W (Johns-Mansville), 60–80 mesh, was washed with 2 *N* hydrochloric acid and then with distilled water until the washings were neutral, was dried at 110°, and was then screened to remove fines. Glass beads, 60 plus mesh (MS-H; Microbeads Inc., Jackson, Mississippi), were washed with chloroform, acetone, water, hot dilute nitric acid, and then with distilled water and dried at 150°.

TABLE II

Retention volumes of fully acetylated disaccharides relative to octa-*O*-acetylsucrose

Disaccharide acetate	Column packing	
	III (238°)	IV (236°)
α-D-Xylopyranosyl α-D-xylopyranoside	0.21	0.34
5-*O*-β-D-Xylopyranosyl-L-arabitol	0.47	0.62
α,α-Trehalose	0.88	1.22
Sucrose	1.00 (12.5 min)	1.00 (4 min)
3-*O*-β-D-Mannopyranosyl-D-mannitol	1.09	1.00
Maltitol	1.30	1.38
Lactitol	—	1.35
Cellobiitol	1.46	1.72
Melibiitol	1.46	1.50
Gentiobiitol	1.74	1.60

The following liquid phases were used: (*a*) Apiezon M vacuum grease (Fisher Scientific Co.), (*b*) butanediol succinate polyester (m.p. 107–109°) prepared according to the directions of Bishop *et al.* (4), (*c*) polyphenylether (F & M Scientific Corp.), (*d*) D-C silicone oil 710 (F & M Scientific Corp.), and (*e*) methyl silicone rubber gum SE-30 (General Electric Co.). The packing materials were prepared by stirring a slurry of a weighed amount of the liquid phase dissolved in chloroform with a weighed amount of the inert support while the bulk of the solvent was removed by stirring the mixture, which was heated on a boiling-water bath. The last traces of the solvent were removed by heating the material *in vacuo* at 140°.

The packing materials were prepared as described below.

(1) Column packing I.—A column constructed of 40 cm of (*a*) a 1:1 v/v mixture of 20% w/w Apiezon M grease on Chromosorb W, 60–80 mesh, and 20% w/w butanediol succinate polyester on Chromosorb W, 60–80 mesh, placed on top of a 77-cm column of (*b*) column packing IV.

(2) Column packing II.—A 1:1:2 v/v intimate mixture of (*a*) 20% w/w Apiezon M grease on Chromosorb W, 60–80 mesh, (*b*) 20% w/w butanediol succinate polyester on Chromosorb W, 60–80 mesh, and (*c*) 0.1% w/w Apiezon M grease on 60 plus mesh glass beads.

(3) Column packing III.—A 1:2 w/w intimate mixture of (*a*) 1% w/w polyphenylether on 60 plus mesh glass beads and (*b*) 1% w/w D-C silicone oil 710 on 60 plus mesh glass beads.

(4) Column packing IV.—Methyl silicone rubber gum SE-30, 1% w/w, on 60 plus mesh glass beads.

The dried column packings were run into the glass columns under gravity, with gentle tapping to ensure even packing and the absence of any cavities. The packed columns were purged with argon gas for 3–4 hours at 20–30° above the operating temperatures before use. The columns could be used for at least 100 analyses before any noticeable deterioration in their resolving power became apparent.

ABSTRACT

The method of timed precipitations has been used to measure the half-lives of Cs^{141}, Cs^{142}, and Cs^{143}, which were found to be 24 ± 2 sec, 2.3 ± 0.2 sec, and 2.0 ± 0.4 sec respectively.

(A) INTRODUCTION

The occurrence of Cs^{141}, Cs^{142}, and Cs^{143} among the fission products of U^{235} was implied by the discovery of their respective xenon precursors (1–3). Recently Wahl *et al.* (4) reported a half-life of 25 ± 3 sec for Cs^{141} and also gave evidence that the half-life of Cs^{142} is less than 8 sec.

To measure the decay periods of the three cesium isotopes the method of timed precipitations (5) was used. Cesium is precipitated from a fission-product solution and the resulting compound is later analyzed for a suitable daughter isotope. For this purpose 32-day Ce^{141}, 92-min La^{142}, and 14-min La^{143} were selected. Their activity will be proportional to the number of cesium-parent atoms which were present at the time of the precipitation. By correlating the results of several runs with the time schedule of the precipitations, it is possible to obtain the half-life of each of the three cesium isotopes. Each half-life determination requires a separate set of experiments since it is necessary to optimize precipitation times and counting conditions. Employing perchloric acid as the precipitation agent, this method has been used earlier to measure the half-lives of Rb^{92}, Rb^{93}, and Rb^{94} (6, 7). Because of the very similar chemical behavior of rubidium and cesium, only minor changes had to be made to adopt the principal part of the procedure for the work on the cesium isotopes.

(B) Cs^{141}

Samples of 200 μg U^{235} were irradiated in the pneumatic-rabbit system of the McMaster Reactor in a flux of 3×10^{12} neutrons $cm^{-2}sec^{-1}$ for 20 seconds. The irradiated uranyl nitrate solution (2 ml) was mixed with 25 ml carrier solution containing 900 mg cesium and divided into two approximately equal portions. Cesium was then precipitated as the perchlorate by the addition of the first portion of the fission-product solution to 10 ml perchloric acid (20%) contained in a large membrane-filter assembly. Upon formation of the cesium perchlorate, which occurred immediately, the time was recorded and simultaneously the suction pump was started to draw off the liquid. The precipitate was washed once with dilute perchloric acid. This procedure was then repeated with the second portion of the fission-product solution. The two cesium perchlorate samples were dissolved in 3 *M* hydrochloric acid and small aliquots withdrawn for the later determination of the chemical yield of the cesium precipitation. After the addition of Ba, La, and Ce carriers the main portions were set aside for 2 days. During this time all the Cs^{141} and the intermediate members of its decay chain (18-min Ba^{141} and 3.9-hr La^{141}) decayed to 32-day Ce^{141}. The cerium was then isolated and purified using the method of Glendenin *et al.* (8). The resulting cerium oxalate was β-counted for several days in an automatic low-level unit to determine the relative quantities of Ce^{141} in the two samples.

The chemical yields were obtained by ashing the cerium oxalate and weighing the resulting cerium dioxide. The chemical yields of the cesium precipitations were usually measured by bringing the small aliquots of the perchlorate solutions to complete dryness, dissolving the cesium perchlorate in water, passing the solution over a cation-exchange column, and titrating the resulting acid with 0.05 *M* sodium hydroxide solution. In one case (run No. 4) the Cs^{141} was carried down on rubidium perchlorate and the relative cesium yields were determined by analyzing the small aliquots for their contents of Cs^{137}, which had been added to the rubidium-carrier solution.

Table I shows the results of four half-life measurements for Cs^{141}. The average value

TABLE I

Summary of Cs^{141} half-life data

Run	U^{235} (μg)	Flux (neutrons cm^{-2} sec^{-1} 10^{12})	Duration of irradiation (sec)	$CsClO_4$ precipitation times (sec)		Cs^{141} half-life (sec)
				1st ppt.	2nd ppt.	
1	200	3	20	23.8	47.2	23.7
2	200	3	20	31.4	41.8	21.2
3	200	3	20	24.0	69.6	26.4
4	300	3	20	24.0	48.0	25.6

of 24±2 sec is in very good agreement with the half-life of 25±3 sec obtained by Wahl *et al.* (4).

(C) Cs^{142}

A preliminary estimate had indicated that the half-life of Cs^{142} would be around 5 sec. This was based on an experiment completely analogous to the kind described for Cs^{141}. The two perchlorate precipitates were analyzed for La^{142} using γ-ray spectroscopy. Further work, however, indicated a considerably lower value. In fact, it was found impossible to perform two precipitations in a sufficiently short time interval. The quantity of Cs^{142} in the second precipitate was so small that the amount of the lanthanum daughter could just be detected and not properly measured. Therefore, it was decided to modify the method in the following manner: samples of a mixture of uranyl nitrate and cesium nitrate dissolved in 5 ml water were irradiated. The quantities of U^{235} (300 μg) and cesium (300 mg) were the same for all experiments and the irradiation time of 10 seconds was kept constant within 0.1 second. The recording of the precipitation time was achieved by connecting an electric stop watch to the rabbit-control system. This timer was started by the "reverse air-flow" signal which marks the end of the irradiation and was stopped when the cesium precipitate appeared. Filtration and washing were done as described in Section (B). Besides analysis of the cesium perchlorate for La^{142}, determination of the amount of Cs^{131} which resulted from the (n,γ) reaction on the cesium carriers was carried out. The latter analysis permits the calculation of a correction factor which takes into account both the cesium yields and the possible day-to-day variations in the neutron flux. In other words the method is based on the assumption that the number of Cs^{142} atoms produced is constant for each irradiation and that the quantity of Cs^{142} in the cesium precipitate is only a function of the precipitation time.

Each cesium perchlorate sample was dissolved in dilute hydrochloric acid, and barium and lanthanum carriers were added. Forty minutes after the end of the irradiation

lanthanum hydroxide was precipitated and reprecipitated in the presence of barium-hold-back carrier. The collected supernatants were set aside for the later determination of the correction for the cesium yield and flux variations. The lanthanum hydroxide was dissolved and further purified using tributyl phosphate (9). The lanthanum was finally counted as the oxalate.

The counting of the La^{142} is hampered by the presence of much larger quantities of La^{141}. A gross β-decay curve shows practically no deviation from the 3.9-hr half-life of La^{141}. Associated with the decay of La^{142} is a strong γ ray at 640 Kev (10). In contrast, the only γ line of La^{141} (1.37 Mev) is quite weak (10). The lanthanum samples were therefore γ-counted for 40 minutes through a 2 g cm^{-2} polyethylene absorber using a shielded 3×3 in. NaI (Tl) crystal in connection with a 256-channel analyzer. The area of the 640 Kev peak was determined by numerical integration. Finally, the lanthanum oxalate samples were ashed and the lanthanum oxide weighed to obtain the chemical yields.

From the collected supernatants of the first and second lanthanum hydroxide precipitations, barium was removed as the carbonate and the filtrates were γ-counted under identical geometrical conditions. The γ spectra were quantitatively analyzed for Cs^{134} and gave the correction factor for the chemical yield of the cesium precipitation and the neutron-flux variations.

A total of seven cesium perchlorate precipitations were carried out. The precipitation times ranged from 4.9 to 12.3 seconds, measured from the end of the respective irradiations. Figure 1 shows the resulting decay curve, indicating a half-life of 2.3±0.2 sec for Cs^{142}. The value is consistent with the upper limit of 8 sec given by Wahl *et al.* (4).

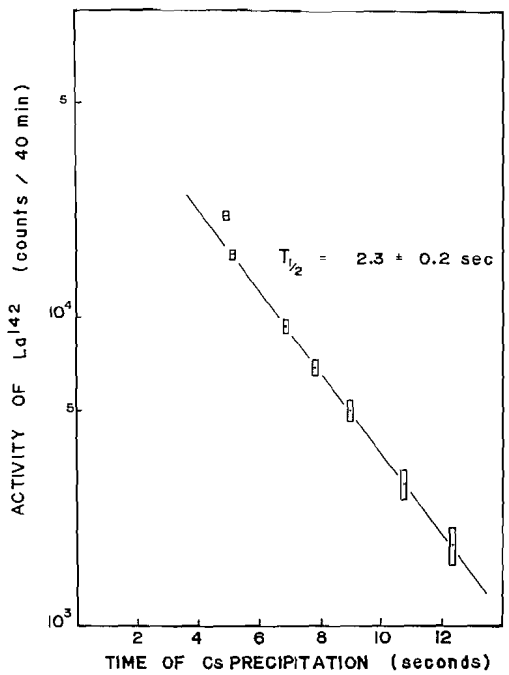

FIG. 1. Half-life of Cs^{142} from the timed precipitation of fission-product cesium. The normalized activity of La^{142} found during the later analysis of each cesium precipitate is plotted against the time of the cesium perchlorate precipitation as measured from the end of the respective irradiation.

(D) Cs^{143}

The half-life of Cs^{143} was determined using the same procedure as outlined for Cs^{142}. Since the fission yield of Cs^{143} is lower (4), the amount of U^{235} was increased to 500 μg. The cesium perchlorate samples were analyzed in the following manner. The precipitate was rinsed off the membrane filter into a 50-ml centrifuge tube containing barium and lanthanum carriers. Lanthanum hydroxide was precipitated and centrifuging was started at exactly 2 minutes after the end of the irradiation. At this time the intermediate member of the decay chain, 12-sec Ba^{143} (4), had decayed completely. On the other hand, only relatively small quantities of La^{142} and La^{141} had been formed, due to the holdup by the 11-min Ba^{142} and the 18-min Ba^{141}. From then on the purification of the lanthanum, as described in Section (C), was carried out as rapidly as possible and the counting was usually started at 21 minutes after the end of the irradiation.

The lanthanum oxalate samples were β-counted with a unit consisting of a 2×2 in. plastic scintillator coupled with an EMI 9536 photomultiplier tube, a DD2 amplifier, and a single-channel analyzer. Only β rays with energies in the interval 2.6 to 3.2 Mev were recorded, in 200-second intervals automatically for about 4 hours. In this way the conditions for the analysis of the La^{143} having a β energy of 3.3 Mev (9) were optimized. The β energies of La^{141} and La^{143} are 2.4 and 4.4 Mev respectively (10). The resulting decay curves were analyzed for their 14-min La^{143} and 92-min La^{142} components. The contribution of La^{142} to the initial counting rate ranged from approximately 10 to about 20%, depending on the time of the original cesium perchlorate precipitation. The initial counting rate itself was 450 c.p.m. for the strongest lanthanum sample (corresponding to the earliest cesium precipitation) and only about 70 c.p.m. for the weakest lanthanum sample. Consequently the statistics of the individual points which make up the decay curve of Cs^{143} were fairly poor. The preparation and analysis of five cesium perchlorate precipitates was done over a period of 3 days. A test of the counting unit over a similar time showed that there was a random drift of the window. No pattern in the shifting could be detected. For example, the unit would be perfectly stable for hours, then fairly slowly drift in one direction, remain constant, and after many hours return slowly to more or less the original position. The total spread of the shifting did not exceed 1%. However, the counting of a Ru–Rh^{106} standard, which has a spectrum similar to that of La^{143}, showed that this can cause fluctuations of approximately 10% in the counting rate. An effort was made to correct for this by storing the events which passed through the window in a 256-channel analyzer concurrently with the decay measurement. From the position of the window an estimate of the correction term was made and applied to the result of the decay-curve analysis. But since this is only an estimate the uncertainty in each point of the Cs^{143} decay curve is necessarily increased.

The corrections for the chemical yields were carried out using identical procedures as described above for Cs^{142}. The decay curve of Cs^{143} is shown in Fig. 2, giving a half-life of 2.0 ± 0.4 sec. It was pointed out above that in the lanthanum samples the amount of La^{142} increased relative to the quantity of La^{143} with increasing time of precipitation. Knowing the half-life of Cs^{142}, it is, in principle, possible to calculate the half-life of Cs^{143} from these data. In practice the errors of these ratios are too large to permit a meaningful calculation. However, the trend of the ratio values indicates that the half-life of Cs^{143} is shorter than that of Cs^{142}, even though the errors are such that the individual measurements overlap (Cs^{142} = 2.3 ± 0.2 sec and Cs^{143} = 2.0 ± 0.4 sec).

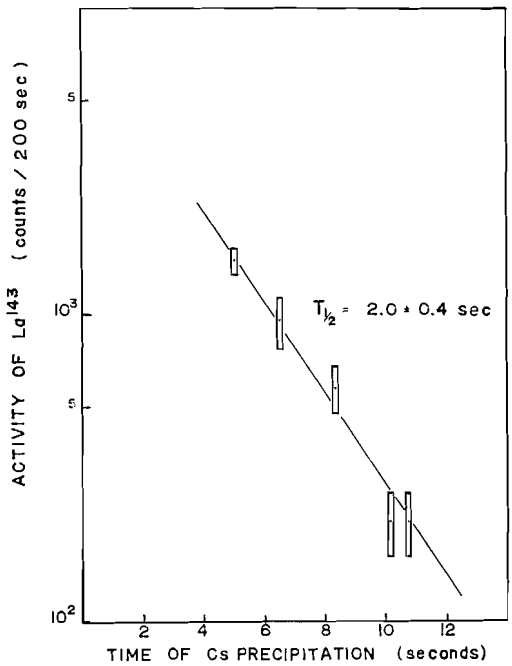

FIG. 2. Half-life of Cs^{143} from the timed precipitation of fission-product cesium. The normalized activity of La^{143} found during the later analysis of each cesium precipitate is plotted against the time of the cesium perchlorate precipitation as measured from the end of the respective irradiation.

(E) DISCUSSION

All features and possible limitations of the method of timed precipitations have been discussed previously (5–7). One would usually expect that the largest errors originate from the uncertainty of the timing and particularly from the assumption that the formation process of the precipitate is identical from sample to sample. Furthermore, it has been shown that daughter atoms (i.e. Sr and Ba) are easily extracted from the precipitate by the washing solution (6). This effect should have the most serious consequences in cases of short half-lives (<10 sec) since it is, in practice, impossible to exactly duplicate the precipitation and washing procedure on a time scale involving fractions of seconds. The very good agreement of the results of Wahl *et al.* (4) and those of this work for the half-life of Cs^{141} (25 ± 3 sec and 24 ± 2 sec) indicates that these effects are at least not too serious for somewhat longer half-lives. Although Wahl's method was similar, it was based on the timed removal of the Ba^{141} daughter (as the nitrate) rather than on the direct precipitation of the cesium.

Recently Stehney and Perlow (11) detected a delayed-neutron precursor among the decay products of fission-product krypton and found its half-life to be about 6 sec. This value agrees with the 5.3 ± 0.5-sec half-life of Rb^{92} and the 5.6 ± 0.5-sec half-life of Rb^{93} (6). Although certain other considerations favor Rb^{93} as a delayed-neutron precursor, the measurements of Stehney and Perlow indicate, in any case, that the method of timed precipitations is quite reliable for short half-lives.

For the case of very short half-lives (<3 sec), which require a new irradiation for each point of the decay curve, no independent check is available at present. Here an additional source of error is introduced by the possibility that the production of the nuclide in

question is not constant from sample to sample. Experimental evidence, however, indicates that the errors in the counting of the respective daughter isotopes are more serious. This is mainly due to the fact that these nuclides themselves are fairly short-lived and that their relative quantities must be determined in the presence of the large amounts of other isotopes of the same element.

ACKNOWLEDGMENTS

The author wishes to thank T. J. Kennett for many helpful discussions and W. V. Prestwich and T. Erme for assistance during the course of the experimental work. The financial assistance given by the National Research Council and the cooperation of the reactor staff are greatly appreciated.

COORDINATION COMPLEXES OF METAL ALKOXIDES

PART I. METAL ALKOXIDE – HYDRAZINE COMPLEXES

M. S. BAINS[1] AND D. C. BRADLEY[2]
Department of Chemistry, Birkbeck College, Malet Street, London, W.C.1, England

Received February 1, 1962

ABSTRACT

The field of metal alkoxide coordination compounds is surveyed briefly. The preparation of moderately stable complexes of hydrazine with aluminum isopropoxide, titanium ethoxide, titanium isopropoxide, and zirconium isopropoxide is described. Some reactions of these new complexes are reported.

INTRODUCTION

An interesting feature of the metal alkoxides is their preference for auto complex formation (i.e. polymerization) rather than the formation of addition complexes with typical donor molecules. A general rule stating that the metal alkoxide strives to achieve covalency expansion of the metal with the minimum degree of polymerization has been proposed to explain this behavior in terms of structural models (1). Another property of these compounds is the formation of double alkoxides (alkoxide salts), such as: $Li[Al(OEt)_4]$; $Ca[Al(OEt)_4]_2$; $K_2[Be(OEt)_4]$; $K[Li(OC_3H_7)_2]$. More than 50 such compounds were isolated by Meerwein and Bersin (2) and these formulations were supported by appropriate titrations of the reactants in non-aqueous solvents, using conventional indicators.

In spite of this great tendency on the part of the metal to attain its covalency maximum, no coordination complexes resulting from the simple union of an alkoxide and a neutral molecule were reported prior to 1951 (3), and among the large number of new alkoxides of transition metals prepared in recent years only the following complexes have been reported: $Ti(OBu^i)_4,Bu^iOH$; $Zr(OPr^i)_4,Pr^iOH$; $Zr(OPr^i)_4,C_5H_5N$; $Zr(OC_6H_5)_4,C_6H_5OH$; $Ce(OPr^i)_4,Pr^iOH$; $Ce(OPr^i)_4,C_5H_5N$; $Ce(OC_4H_6Cl_3)_4,C_5H_5N$; $Pu(OPr^i)_4,Pr^iOH$; $Pu(OPr^i)_4,C_5H_5N$; $Hf(OPr^i)_4,Pr^iOH$; $Th(OC_4H_6Cl_3)_4,2C_5H_5N$; $Sn(OPr^i)_4,Pr^iOH$.

The lack of complex formation in boron and aluminum alkoxides was discussed on the basis of X-ray crystallographic data, and the difference in the reducing power of boron and aluminum alkoxides in the Meerwein–Ponndorf–Verley reduction was attributed to their relative ability to coordinate with carbonyl compounds in solution (3).

It has been suggested (4) that oxygen in the alkoxide group attached to a metal atom has a greater electron density and hence can be a better donor than oxygen in the typical organic donor molecules (e.g. alcohols, ethers, esters, ketones, etc.). This may well explain why metal alkoxides polymerize instead of complex with donor molecules. The alkoxide salt formation is readily interpreted as due to the greater negative charge on the oxygen of the alkoxide group attached to the more electropositive metal. It also appears from experimental observation that even nitrogen bases rarely form complexes with metal alkoxides. Zirconium isopropoxide, which forms fairly stable addition compounds with isopropyl alcohol and pyridine, would not coordinate with donors such as diethyl ether, triethylamine, thiourea, dimethylamine, or α,α-dipyridyl (5). We have also found that aluminum alkoxides do not form stable complexes with bases such as ammonia, pyridine,

[1]*Present address: Department of Chemistry, Panjab University, Chandigarh 3, India.*
[2]*Present address: Department of Chemistry, The University of Western Ontario, London, Ontario.*

diethylamine, dimethylamine, triethylamine, quinoline, and picolines; ether; or acetone. However, the fact that the donor character of the solvent lowered the degree of polymerization of tantalum alkoxides (6) under ebullioscopic conditions coupled with Chelinzev's evidence (7) based on thermal data gives strong support to the view that addition complexes may be formed in solution. Moreover, coordination is proposed as the first step in the mechanism of certain organic reactions which are catalyzed by polymeric alkoxides. An interesting example of the formation of weak complexes was revealed by the existence of an insoluble ammoniate of ferric ethoxide, $Fe(OEt)_3,xNH_3$, where $x = 1$–3, which was coprecipitated with ammonium chloride in the synthesis of ferric ethoxide by the ammonia method (8).

A consideration of the addition complexes of metal chloride alkoxides (4) suggested that as chlorines are successively replaced by alkoxide groups, the acceptor ability of the central metal atom decreases. Polymerization due to metal–oxygen intermolecular bonding increases and the coordination of the nucleophilic reagent to the metal atom of the alkoxide steadily decreases. Thus in the case of zirconium, the compounds $ZrCl_4$,-CH_3COOEt; $ZrCl_3OEt,EtOH$; $ZrCl_2(OPr^i)_2,Pr^iOH$; $ZrCl(OEt)_3,EtOH$; and $Zr(OEt)_4$ were obtained. The compound $ZrCl_3(OEt),EtOH$ is so stable that the alcohol of addition cannot be removed from it but zirconium ethoxide does not form an addition complex.

If an electron-attracting group is substituted in the alkyl group of the alkoxide group, the electron density on the oxygen atom can be decreased and thus coordination of a ligand is enhanced. For example, when zirconium isopropoxide was treated with anhydrous chloral (5) the tetrakis-(trichloroethoxy)-zirconium produced retained 2 molecules of acetone in the complex $Zr(OCH_2CCl_3)_4,2(CH_3)_2CO$. This emphasizes the electronic arguments for the absence of coordination complexes of metal alkoxides. The chlorine atoms in the trichloroethoxide group have made the chloroalkyl group electron attracting instead of electron releasing. This has consequently drawn on the electron density of the oxygen atom on the one hand and to a diminished extent made the metal more electrophilic. Thus the oxygen in the trichloroethoxide group is a weaker donor than the oxygen in acetone. Gal *et al.* (11) have shown that certain insoluble carbonyl compounds would dissolve in the presence of aluminum monochloride diisopropoxide, but not in the presence of aluminum triisopropoxide. It appears that the carbonyl compound coordinates more readily with the monochloride and thus goes into solution.

Besides these electronic factors, the steric factors cannot be ignored in the formation of addition complexes, although it seems likely that in many cases steric factors would favor the addition of a ligand rather than polymerization. The monomeric nature of certain alkoxides was interpreted in terms of steric arguments (9).

In a recent publication (10) it was reported that the complex $Ti(OPr^i)_4,EtNH_2$ crystallized from a concentrated mixture of the alkoxide and excess ethylamine in *n*-decane. It was also established by the vapor pressure method that both $Ti(OPr^i)_4$,-$2EtNH_2$ and $Ti(OPr^i)_4,EtNH_2$ existed in solution as unstable complexes.

In attempts to find insoluble complexes of aluminum alkoxides we have found that hydrazine forms stable soluble complexes with metal alkoxides. The compounds isolated and the related reactions are described and discussed in this communication.

EXPERIMENTAL

Materials

The alkoxides used for this research were prepared by the methods described in the literature and were purified by distillation under reduced pressure: aluminum isopropoxide (12, 13); aluminum *tert*-butoxide (14); titanium ethoxide (15); titanium isopropoxide (16); zirconium isopropoxide isopropylate (17). The purity of the above compounds was checked by the standard analytical methods given in the cited literature.

Solvents

The solvents used were of "Analytical Reagent" grade. Benzene, diethyl ether, and petroleum ether (b.p. 40–60; 60–80°) were dried over freshly extruded sodium wire. Sodium-dried benzene was further dried by azeotropic distillation.

Bases

Pyridine, diethylamine, triethylamine, quinoline, α-picoline, and β-picoline were kept over potassium hydroxide pellets and then refluxed over a fresh batch of potassium hydroxide and fractionally distilled. A second distillation was performed if it was thought necessary. Dimethylamine was used as such from the ampoule.

Hydrazine (98%) was kept over potassium hydroxide for 2 days and then three successive distillations over potassium hydroxide through a small reflux column were performed. The liquid thus obtained was titrated against potassium iodate solution in strong hydrochloric acid, when 100±0.5% hydrazine was estimated. This purified hydrazine was kept in a desiccator and if left for more than a week was freshly distilled before use.

Analytical Methods

Zirconium and titanium were determined using the method described in the source describing the preparation of their alkoxides. Aluminum was determined by precipitating and weighing as the oxinate (18).

The alkoxide content of the pure metal alkoxides was determined by the method described by Bradley *et al.* (19) in the case of pure alkoxides.

The hydrazine content of the complexes was determined by the following iodate method. Hydrochloric acid (conc., 30 ml) and water (20 ml) were taken in an iodine flask (250 ml), and carbon tetrachloride (5 ml) was added as indicator. A sample containing about 0.05 g of hydrazine was added and the solution titrated with 0.15 *N* potassium iodate solution with shaking between the addition until the organic layer (CCl_4) was first decolorized. This method was reliable even in the presence of alkoxide groups, since under the conditions described, blank experiments with known amounts of hydrazine and excess alcohols showed no interference by the alcohol. However, the alkoxide content could not be estimated by the usual chromic acid method due to interference by the hydrazine.

1. Reaction between Aluminum Isopropoxide and Hydrazine

To a solution of aluminum isopropoxide (4.7 g) in anhydrous petroleum ether (40–60° C) in a flask (100 ml) an excess of hydrazine (8.5 g) was added and caused the precipitation of a white solid. The reaction mixture was mildly refluxed and allowed to cool, when a crystalline product separated. The excess of solvent and hydrazine was evaporated off at low pressure and the product was dried under 0.1 mm pressure. The crystalline product on analysis corresponded to aluminum isopropoxide hydrazinate, $Al(OPr^i)_3,N_2H_4$. Found: Al, 11.4, 11.5; N_2H_4, 13.50, 13.54%. $Al(OPr^i)_3,N_2H_4$ requires: Al, 11.47; N_2H_4, 13.56%.

In another experiment hydrazine (1.5 g) was added to a benzene solution (50 g) of aluminum isopropoxide (9.4 g). On shaking, a small precipitate appeared, and a sticky product was obtained on evaporation of the benzene under reduced pressure. An effort to crystallize it from benzene failed but when an excess of hydrazine was added to the petroleum ether solution heat was evolved and a precipitate appeared. The product gave the same results as before. Found: Al, 11.4, 11.4; N_2H_4, 13.52%. The above product on further evacuation at 0.1 mm pressure for 5–6 hours corresponded to $Al(OPr^i)_3,\frac{1}{2}N_2H_4$. Found: Al, 12.5, 12.7; N_2H_4, 7.51, 7.48%. $Al(OPr^i)_3,\frac{1}{2}N_2H_4$ requires: Al, 12.3; N_2H_4, 7.30%. The final product did not lose any further amount of hydrazine.

2. Reaction between Aluminum tert-Butoxide and Hydrazine

To a solution of aluminum *tert*-butoxide (1.82 g) in ether, hydrazine (0.5 g) was added. The clear supernatant solution was decanted off and the solvent removed under low vacuum. The analysis of the product corroborated with the empirical composition $Al(OBu^t)_3,2\frac{1}{2}N_2H_4$. Found: Al, 8.6, 8.5; N_2H_4, 25.50, 25.70%. $Al(OBu^t)_3,2\frac{1}{2}N_2H_4$ requires: Al, 8.30; N_2H_4, 24.54%.

The above product fumed strongly in the air. It was subjected to evacuation at 0.1 mm pressure for half an hour. On analysis the product was found to have no hydrazine. Found: Al, 11.8, 11.9%. $Al(OBu^t)_3$ requires: Al, 10.95%.

Attempts to isolate coordination complexes of quinoline, pyridine, diethylamine, triethylamine, dimethylamine, ether, or ammonia with aluminum isopropoxide failed. The product on removal of volatile contents always corresponded to aluminum isopropoxide.

3. Reaction between Titanium Ethoxide and Hydrazine

To a solution of titanium ethoxide (2.2 g) in ether (60 ml) hydrazine (0.75 g) was added. A colorless precipitate appeared, which turned light yellow after some time. Then the crystals redissolved until a very small amount remained. On evaporation of the solvent under water pump pressure a colorless crystalline product was obtained. It was then dried at 0.1 mm pressure for a while, and left a product whose analysis suggested that $Ti(OEt)_4,\frac{1}{2}N_2H_4$ was formed. Found: Ti, 21.0, 20.9, 21.1; N_2H_4, 6.3%. $Ti(OEt)_4,\frac{1}{2}N_2H_4$ requires: Ti, 19.65; N_2H_4, 6.56%.

4. Reactions of Titanium Isopropoxide and Hydrazine

Titanium isopropoxide (7.7 g) in diethyl ether (100 ml) was caused to react with an excess of hydrazine and the solution was shaken during mixing. After being allowed to stand for a few minutes the clear solution was decanted off from the excess of hydrazine, which remained as a lower layer. Ether was removed under water pump pressure and a colorless crystalline product obtained gave an analysis corresponding with the composition $Ti(OPr^i)_4,N_2H_4$. Found: Ti, 15.3, 15.0, 15.0; N_2H_4, 9.8, 9.7%. Calculated for $Ti(OPr^i)_4,N_2H_4$; Ti, 15.16; N_2H_4, 10.13%.

In another experiment titanium isopropoxide (2.39 g) and hydrazine (3.4 g) were heated by means of an oil bath for about 3 hours at about 130° C. An explosion took place when the temperature was raised a little further. The green material collected from the side of the condenser did not react even with hot chromic acid. In these experiments it was noted that the addition of hydrazine to the alkoxide was an exothermic process.

5. Reactions between Zirconium Isopropoxide Isopropylate and Hydrazine

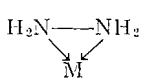
Hydrazine (0.33 g) in diethyl ether (50 ml) was allowed to react with zirconium isopropoxide isopropylate, $Zr(OPr^i)_4,Pr^iOH$ (2.5 g). Removal of the solvent and excess hydrazine by evaporation under 0.1 mm pressure left zirconium isopropoxide hydrazinate. Found: Zr, 25.9; N_2H_4, 8.3%. $Zr(OPr^i)_4,N_2H_4$ requires: Zr, 25.4; N_2H_4, 8.9%.

DISCUSSION

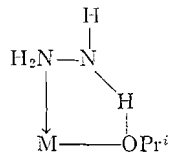
The situation in the coordination complexes of metal alkoxides has been briefly surveyed in the introduction. This study has shown that hydrazine forms some interesting, moderately stable complexes with metal alkoxides. The following complexes appear to be established by analytical evidence: aluminum isopropoxide hydrazinate, $Al(OPr^i)_3,N_2H_4$; aluminum isopropoxide hemihydrazinate, $Al(OPr^i)_3,\frac{1}{2}N_2H_4$; titanium isopropoxide hydrazinate, $Ti(OPr^i)_4,N_2H_4$; titanium ethoxide hemihydrazinate, $Ti(OEt)_4,\frac{1}{2}N_2H_4$; zirconium isopropoxide hydrazinate, $Zr(OPr^i)_4,N_2H_4$.

Although it is clear that more work must be done in order to elucidate the structure of these complexes a few comments now are not out of place. For example, it is noteworthy that aluminum isopropoxide has a much greater affinity for hydrazine than has aluminum *tert*-butoxide. The failure of $Al(OBu^t)_3$ to coordinate hydrazine is presumably not due to steric factors, since the *tert*-butoxide is dimeric and there is less steric hindrance to the coordination of a molecule of hydrazine than to dimerization. We assume that bridging by *tert*-butoxide groups is favored by the high electron density on the oxygen which results from the large electron release of the Bu^t group.

The ability of hydrazine to form complexes with metal alkoxides is at first sight surprising in view of the fact that this ligand is a fairly weak base. It is tempting to suggest that the hydrazine behaves as a chelating ligand, thereby enhancing the stability of the complex. This would require the unusual arrangement (I) of a three-membered ring involving the metal and two nitrogens.



(I)



(II)

Alternatively the hydrazine might behave as a monodentate ligand but with additional stabilization due to ring formation in the hydrogen-bonded structure (II). We were unable to determine accurate molecular weights on any of the new complexes due to their instability in solution. Therefore it is not possible to assign structures to these complexes at present.

During this work it was observed that the hydrazine complexes with titanium and zirconium alkoxides underwent further chemical reaction on standing in solution and on being heated. The details of these reactions have not yet been elucidated but preliminary results suggest that alkoxide groups may be replaced by hydrazine, giving compounds of the type $M(OR)_{4-x}(N_2H_{4-x})$. This is remarkable because it has been found that amines do not as a rule displace alkoxide groups whereas alcohols displace amines very vigorously from dialkylamino derivatives (21). However, it was found that the "titanium hydrazinate" prepared by means of the following reaction:

$$x\mathrm{Ti(NEt_2)_4} + x\mathrm{N_2H_4} \rightarrow [\mathrm{Ti(N_2)}]_x + 4x\mathrm{Et_2NH},$$

exploded violently after the removal of volatile products at room temperature (20). Thus it seems reasonable to suggest that the explosion in experiment 4 was due to an unstable compound, $Ti(OPr^i)_{4-x}(N_2H_{4-x})$, where $x \rightarrow 4$.

ACKNOWLEDGMENT

One of the authors (M. S. Bains) wishes to thank S. Bhagar Singh Bains for the financial support which enabled him to carry out this research.

ABSTRACT

Reactions involving $TaCl_5$ and LiX (where X = NMe_2, NEt_2, NPr^n_2, NBu^n_2, $NMeBu^n$, and NC_5H_{10}) were shown to produce substantially the pentaderivatives TaX_5. The thermal decomposition of TaX_5 (X = NMe_2, NEt_2, NPr^n_2, NBu^n_2, and $NMeBu^n$) was studied and only $Ta(NMe_2)_5$ could be sublimed unchanged. In other cases the main product of decomposition was a quinquevalent compound $RN{=}Ta(NR_2)_3$ and the secondary amine R_2NH. Some olefin and quadrivalent $Ta(NR_2)_4$ were also detected and it is believed that decomposition involves the following sequence:

$$Ta(NR_2)_5 \rightarrow Ta(NR_2)_4 + NR_2 \rightarrow RN{=}Ta(NR_2)_3 + HNR_2 + (R{-}H, \text{olefin}).$$

This is in contrast to the behavior of niobium compounds, which appears to be:

$$Nb(NR_2)_5 \rightarrow Nb(NR_2)_4 + NR_2 (\rightarrow HNR_2, \text{imine, etc.}).$$

INTRODUCTION

In a previous communication (1) we reported that lithium dialkylamides reacted with the tetrachlorides of titanium or zirconium and formed the corresponding tetrakis-(dialkylamino)-metal compounds:

$$MCl_4 + 4LiNR_2 \rightarrow M(NR_2)_4 + 4LiCl;\ M = Ti, Zr.$$

Aminolysis reactions (viz. $M(NR_2)_4 + HNR'_2 \rightarrow M(NR'_2)(NR_2)_3 + HNR_2$) revealed that the dialkylamino groups exerted considerable steric hindrance to nucleophilic attack on the central metal atom. In a recent communication (2) we reported on the reactions involving niobium pentachloride and several lithium dialkylamides. It appeared that the very powerful steric effects of the dialkylamino groups precluded the formation of stable pentakis-(dialkylamino)-niobium compounds except in the cases of the least bulky ligands, such as —NMe_2, —$NMeBu^n$, and —NC_5H_{10} (piperidide). With the more bulky ligands (—NR_2, where R = Et, Pr^n, Bu^n) the final products of distillation *in vacuo* were the tetrakis-(dialkylamino)-niobium(IV) derivatives. Preliminary results on the reactions of tantalum pentachloride with lithium dialkylamides (3) showed that tantalum resembled niobium in forming a stable pentakis-(dimethylamino) compound. However, with lithium diethylamide the final products obtained by distillation *in vacuo* contained mainly the surprising compound $EtN{=}Ta(NEt_2)_3$. In this paper we report the results from a detailed study of the reactions of tantalum pentachloride with various lithium dialkylamides, with special attention to the composition of the initial products of reaction.

RESULTS AND DISCUSSION

In these reactions the tantalum pentachloride was added to a suspension of the equivalent quantity of lithium dialkylamide in pentane at room temperature. After removal of the insoluble lithium chloride by filtration the tantalum product was isolated

[1]*For Part II see ref. 2.*
[2]*Present address: Stauffer Chemical Company, Anderson Division, Weston, Michigan, U.S.A.*

by evaporation of the solvent *in vacuo*, thus avoiding the heating involved in our earlier technique (3). By this means it was demonstrated that pentakis-(dialkylamino) derivatives $Ta(NR_2)_5$ (R = Me, Et, Pr^n, Bu^n) and also $Ta(NMeBu^n)_5$ and $Ta(NC_5H_{10})_5$ were initially formed in a substitution reaction:

$$TaCl_5 + 5LiNR_2 \rightarrow Ta(NR_2)_5 + 5LiCl.$$

This is in contrast to the behavior of niobium pentachloride, which under comparable conditions (2) gave products which contained increasing proportions of quadrivalent niobium as the size of the dialkylamino group was increased.

The thermal stability of $Ta(NMe_2)_5$ was demonstrated by the recovery of 73% of the compound as a pale yellow sublimate (100° C at 0.1 mm). After heating a sample at 180° C for an hour about 60% was recovered by sublimation *in vacuo*.

The impure $Ta(NEt_2)_5$ decomposed when heated and a volatile product distilled over at 120° C at 0.1 mm. From the tantalum and nitrogen analyses and a chemical determination of the valency it was deduced that the product consisted of $Ta(NEt_2)_4$ (55%), $Ta(NEt_2)_5$ (10%), and $EtN{=}Ta(NEt_2)_3$ (35%). In a repetition of the experiment the final distillate appeared to be $Ta(NEt_2)_4$ (38%), $Ta(NEt_2)_5$ (15%), and $EtN{=}Ta(NEt_2)_3$ (47%). These results are significantly different from those obtained when the reaction was conducted in diethyl ether (3) and the final distillate appeared to be substantially pure $EtN{=}Ta(NEt_2)_3$. Repetition of the reaction in ether has confirmed the earlier work, since the final distillate appeared to consist of $Ta(NEt_2)_4$ (20%) and $EtN{=}Ta(NEt_2)_3$ (80%). Further experiments showed that the product obtained by distillation from the reaction in petrol, when heated in diethylamine solution, was also converted to a mixture of $Ta(NEt_2)_4$ (20%) and $EtN{=}Ta(NEt_2)_3$ (80%). This suggests that the tetrakis-(diethylamino)-tantalum is slowly oxidized by loss of an ethyl group from one diethylamino group and converted to $EtN{=}Ta(NEt_2)_3$. This behavior underlines the lower stability of the quadrivalent tantalum compound relative to $Nb(NEt_2)_4$, which does not appear to be converted to $EtN{=}Nb(NEt_2)_3$.

The principal product from the reaction involving lithium di-*n*-propylamide and tantalum pentachloride was pentakis-(di-*n*-propylamino)-tantalum contaminated with about 10% of tetrakis-(di-*n*-propylamino)-tantalum. Heating the product *in vacuo* gave an orange liquid which distilled at 150° at 0.1 mm and contained 93% quinquevalent tantalum. Analysis showed that this product was substantially $Pr^nN{=}Ta(NPr_2^n)_3$. Treatment of this product with isopropanol liberated both primary-propylamine and di-*n*-propylamine and converted the tantalum to tantalum pentaisopropoxide. In addition to forming $Pr^nN{=}Ta(NPr_2^n)_3$ the thermal decomposition of $Ta(NPr_2^n)_5$ gave two more volatile fractions. One fraction, which condensed at ca. −78° C, was shown by gas chromatographic analysis (g.c.a.) to be 95% di-*n*-propylamine. The amount of di-*n*-propylamine was approximately 1 molecule per molecule of $Ta(NPr_2^n)_5$. The most volatile fraction, which condensed at ca. −180°, was shown by g.c.a. to contain propylene with some propane and butane or isobutylene.

A similar sequence of reactions occurred following the addition of $TaCl_5$ to lithium di-*n*-butylamide. The initial product was substantially $Ta(NBu_2^n)_5$ and this when heated at 180° *in vacuo* gave two volatile fractions. The most volatile was predominantly 1-butene (85%) with small proportions of isobutylene (or butane) and *cis*- and *trans*-2-butene. The other fraction was di-*n*-butylamine (95%) in an amount corresponding to 1 molecule per molecule of $Ta(NBu_2^n)_5$. Besides the two organic fractions a third, least volatile fraction (b.p. 180° at 0.1 mm) was predominantly $Bu^nN{=}Ta(NBu_2^n)_3$. The presence of both primary butylamino and di-*n*-butylamino groups in the latter was

confirmed by gas chromatographic analysis of the products of *n*-butanolysis, by means of which the tantalum was converted to tantalum pentabutoxide.

It appears that the overall products of thermal decomposition of tantalum pentadialkylamides conform to the following equation (for the di-*n*-propylamide):

$$Ta[N(CH_2CH_2CH_3)_2]_5 \rightarrow CH_3CH_2CH_2N{=}Ta[N(CH_2CH_2CH_3)_2]_3 + HN(CH_2CH_2CH_3)_2 + CH_2{=}CHCH_3.$$

This behavior is in striking contrast to that of the corresponding niobium compounds, which are converted to tetrakis-(dialkylamino) compounds. We are inclined to the view that the primary cause of decomposition of $M(NR_2)_5$ (M = Nb, Ta) is the same in both cases, namely intramolecular congestion due to the steric effect of dialkylamino groups. It is tempting to suggest that a dialkylamino radical is released from the pentakis compounds and that in the case of niobium a relatively stable tetrakis-(dialkylamino)-niobium(IV) is produced together with the products of reaction of the R_2N radical (amine, imine, etc.). However, in the case of tantalum the quadrivalent $Ta(NR_2)_4$ is unstable and interacts with the R_2N radical to produce $RN{=}Ta(NR_2)_3$, R_2NH, and olefin. It is noteworthy that the ligands (NMe_2, $NMeBu^n$, and NC_5H_{10}) which gave relatively stable pentacompounds with niobium also gave stable pentacompounds with tantalum. The thermal decomposition of $Ta(NMeBu^n)_5$ was considered likely to furnish further information on the mechanism of decomposition since there was the possibility that either $MeN{=}Ta(NMeBu^n)_3$ or $Bu^nN{=}Ta(NMeBu^n)_3$ would be formed. A sample heated *in vacuo* at 160–180° gave one volatile fraction which was predominantly N-methylbutylamine in the proportion of 1 molecule per molecule of $Ta(NMeBu^n)_5$. The volatile tantalum product was a mixture of $Bu^nN{=}Ta(NMeBu^n)_3$ (major fraction) and $Ta(NMeBu^n)_4$, which was separated by fractional distillation. It thus appears that in the cleavage of the BuMeN group it is the methyl group which is detached.

Work in this field is still in progress and further results on magnetic and spectroscopic properties of these and related compounds will be reported when complete.

EXPERIMENTAL

General Techniques

All reactions were conducted in carefully dried all-glass apparatus under an atmosphere of oxygen-free dry nitrogen.

Amines were stored over sodium wire and distilled from freshly cut sodium as required. The purity of the amines was checked by gas chromatographic analysis (g.c.a.).

Alcohols were dried azeotropically with benzene, and stored in contact with "molecular sieve" drying agent until required.

Commercially available tantalum pentachloride was used without further purification.

Analytical Techniques

Tantalum.—Samples of the dialkylamido compound were weighed directly into weighed platinum crucibles, allowed to hydrolyze, and finally ignited to tantalum pentoxide.

Nitrogen.—Weighed samples were hydrolyzed in caustic soda solution and the liberated amine steam-distilled into an excess of standard acid. The excess acid was back-titrated with standard alkali.

Valency.—The average valency of the tantalum in these compounds was deduced by determining the equivalent weight of the tantalum by oxidation of quadrivalent tantalum with ceric sulphate solution. To avoid premature oxidation of Ta(IV) whilst effecting solution of the sample prior to titration with ceric sulphate the following procedure was developed: Weighed samples were added to 10-ml aliquots of a solution containing anhydrous ferric chloride (15 g) in absolute ethanolic (150 ml) sulphuric acid (15 ml). When a clear solution was obtained (usually within 10 seconds), dilute sulphuric acid was added and the solution then titrated against standard ceric sulphate. A "blank" determination was made on the alcohol – ferric chloride – sulphuric acid reagent.

Preparation of Pentakis-(dimethylamino)-tantalum

Tantalum pentachloride (14.4 g) was added to a stirred suspension of lithium dimethylamide (0.202 g-equiv) in pentane. A rapid reaction occurred with the transient appearance of an orange solid and the formation of a pale yellow solution. After the mixture had been stirred for 18 hours it was filtered and the filtrate

evaporated *in vacuo*. A yellow solid (15.4 g, theory for $Ta(NMe_2)_5$, 16.1 g) remained. Found: Ta, 43.4; Me_2N, 50.1; Cl, trace; Li, zero; valency of Ta, 5.0. $Ta(NMe_2)_5$ requires: Ta, 45.1; Me_2N, 54.9%. A sample (14.2 g) was sublimed at 100° C at 0.1 mm, giving a pale yellow solid (10.8 g). Found: Ta, 44.8; Me_2N, 53.5%. Another sample (3.74 g) was heated at 180° for 1 hour under an atmosphere of nitrogen. The yellow solid melted to an orange liquid. A red sublimate (2.12 g) was recovered at 80–90° at 0.1 mm. Found: Ta, 45.4%. Gas chromatographic analysis of the amine liberated by isopropanolysis showed that only dimethylamino groups were present.

Reactions between $TaCl_5$ and Lithium Diethylamide

Tantalum pentachloride (13.8 g) was added over a period of 30 minutes to a stirred suspension of lithium diethylamide (0.215 g-equiv) in pentane. A slow reaction occurred and the system became light brown in color. After 20 hours' stirring it was filtered and an orange liquid (20.0 g) remained after the removal of volatile products and solvent *in vacuo*. Found: Ta, 33.9; Et_2N, 63.1; Li, trace; Cl, trace; valency of Ta, 4.92. $Ta(NEt_2)_5$ requires: Ta, 33.4; Et_2N, 66.6%. Gas chromatographic analysis of the product of *n*-butanolysis showed that only diethylamine was liberated.

A sample (17.2 g) of the foregoing product was heated *in vacuo* and gave a red distillate (12.7 g; b.p. 125° at 0.1 mm). Found: Ta, 38.8; N, 12.2; valency of Ta, 4.45. Calc. for a mixture of $Ta(NEt_2)_4$ (55%), $Ta(NEt_2)_5$ (10%), and $EtNTa(NEt_2)_3$ (35%): Ta, 38.8; N, 12.3%. Gas chromatographic analysis of the amines liberated by *n*-butanolysis showed that both primary ethylamine and diethylamine were present.

In another experiment under essentially the same conditions as before the $Ta(NEt_2)_5$ was decomposed to give a liquid (b.p. 120° at 0.1 mm) with the composition $Ta(NEt_2)_4$ (38%), $Ta(NEt_2)_5$ (15%), $EtNTa(NEt_2)_3$ (47%). Found: Ta, 39.0; N, 12.1%; valency of Ta, 4.63; ratio N:Ta, 4.01. The product was then heated under reflux at 120° at 0.1 mm for 3 hours and then distilled. Found: Ta, 39.6; N, 12.4%; valency of Ta, 4.75; ratio N:Ta, 4.04. The product was then refluxed in diethylamine for 24 hours and finally recovered by distillation *in vacuo*. Found: Ta, 40.2; N, 12.35%; valency of Ta, 4.77; ratio N:Ta, 3.99. Finally the product was refluxed in diethylamine for 4 days and the tantalum compound isolated as before. Found: Ta, 40.0; N, 12.5%; valency of Ta, 4.81; ratio N:Ta, 4.04. It is noteworthy that the five tantalum compounds analyzed in the foregoing sequence of experiments had a constant nitrogen-to-tantalum ratio (4.02 ± 0.02) but a steadily increasing valency. The constancy of the N:Ta suggests that very little $Ta(NEt_2)_5$ was present and that the change in analysis corresponds to the conversion of $Ta(NEt_2)_4$ to $EtN{=}Ta(NEt_2)_3$.

In a repetition of the previous experiment the product of the thermal decomposition of $Ta(NEt_2)_5$ (9.10 g; Ta, 39.2; N, 12.0%; valency of Ta, 4.66) was refluxed with diethylamine (20 ml) in pentane (20 ml) for 40 hours. Removal of solvent and diethylamine left a light brown liquid (9.00 g; found: Ta, 39.2%; valency of Ta, 4.72). Distillation of some of this liquid (7.22 g) gave a light brown distillate (7.10 g; b.p. 110° C at 0.1 mm; found: Ta, 39.7%; valency of Ta, 4.71).

In an earlier experiment in which $TaCl_5$ was added to lithium diethylamide in diethyl ether the solvent was removed and a tantalum compound (found: Ta, 40.0%) distilled out *in vacuo*. Gas chromatography of the amines liberated by *n*-butanolysis showed that the compound contained both primary-ethylamine and diethylamine. Redistillation of the product gave at 100–105° at 0.05 mm a compound with an analysis (Ta, 40.3; N, 12.2%; N:Ta, 3.91) similar to those of the final products of the previous two experiments. It thus appears that in the reaction carried out in ether the formation of $EtN{=}Ta(NEt_2)_3$ is facilitated. Following the development of the technique for determining the valency of the tantalum we repeated the experiment carried out in ether as follows: Tantalum pentachloride (17.7 g) was added to a stirred ethereal solution of lithium diethylamide (250 ml of 1.1 *N* solution). The ether was evaporated off and replaced by an equal amount of benzene and the system was then refluxed for 3 hours. After being allowed to cool overnight the mixture was filtered and the filtrate evaporated to dryness. Distillation of the residue gave a light brown liquid (11.6 g; b.p. 120° at 0.1 mm). Found: Ta, 40.6; N, 12.4%; valency of Ta, 4.80; ratio N:Ta, 3.94. Calc. for a mixture of $EtN{=}Ta(NEt_2)_3$ and $Ta(NEt_2)_4$: Ta, 40.5; N, 12.6%. It is evident that the $TaCl_5$–$LiNEt_2$ reaction gives reproducible products whether it is carried out in pentane or in ether.

Reactions between $TaCl_5$ and Lithium Di-n-propylamide

Tantalum pentachloride (13.7 g) was added to a stirred suspension of lithium di-*n*-propylamide (0.200 g-equiv) in pentane and the fast reaction was accompanied by the development of an orange color. After the system had been stirred at room temperature for 6 hours the crude $Ta(NPr_2^n)_5$ was isolated in the usual manner as a deep orange viscous liquid (25.9 g). Found: Ta, 25.6; Pr_2^nN, 67.7; Li, trace; Cl, trace; valency of Ta, 4.89. $Ta(NPr_2^n)_5$ requires: Ta, 26.5; Pr_2^nN, 73.5%. Distillation *in vacuo* of this product (19.4 g) gave an orange distillate (14.7 g, i.e. 93% recovery of Ta; b.p. 150° at 0.1 mm). Found: Ta, 31.7; N, 10.0; valency of Ta, 4.93; ratio N:Ta, 4.07. $Pr^nNTa(NPr_2^n)_3$ requires: Ta, 33.6; N, 10.4%. To a sample of the distillate (5.86 g) was added isopropanol (10 ml) cooled to 0° C. After refluxing, the volatile products were shown by g.c.a. to contain both primary-*n*-propylamine and di-*n*-propylamine. Removal of the volatile products and isopropanol followed by vacuum distillation afforded tantalum pentaisopropoxide (see also ref. 4) in quantitative yield (4.87 g, 98% of theory; m.p. 100° C, b.p. 110° at 0.1 mm). Found: Ta, 38.0; N, zero. $Ta(OPr^i)_5$ requires: Ta, 38.0%.

In a repetition of this experiment there was obtained from $TaCl_5$ (14.5 g) and $LiNPr_2^n$ (0.22 g-equiv) an orange liquid (26.3 g): Found: Ta, 27.4; N, 9.69%; valency of Ta, 4.92. A sample of this product (24.5 g) was heated *in vacuo* and volatile fractions were trapped at −78° and −180°. The most volatile fraction

(0.5 ml colorless liquid) was shown by g.c.a. to contain propylene, propane, and isobutylene or butane. The less volatile fraction (4.0 g) was shown by g.c.a. to be 95% Pr_2^nNH. Titration with acid gave the equivalent weight of the base as 121.6 (Pr_2^nNH requires 113). The ratio of molecules Pr_2^nNH produced per molecule of $Ta(NPr_2^n)_5$ was 1.0 based on the g.c.a. and 0.88 based on the volumetric analysis. The least volatile fraction was the tantalum compound, which was redistilled to give an orange liquid (16.6 g, 78% recovery of original Ta; b.p. 150° at 0.1 mm). Found: Ta, 32.1; N, 9.88%; valency of Ta, 4.90; ratio N:Ta, 3.98. Both primary-*n*-propylamine and di-*n*-propylamine were identified by g.c.a. as products of ethanolysis of the foregoing product.

Reactions of $TaCl_5$ with Lithium Di-n-butylamide

Tantalum pentachloride (12.0 g) was added to a stirred suspension of lithium di-*n*-butylamide (0.188 g-equiv) in pentane. During the fast reaction a yellow color developed. Afer refluxing for 6 hours and working up in the usual manner a red liquid tantalum compound (26.4 g) was obtained. Found: Ta, 21.7; Bu_2^nN, 74.4; valency of Ta, 4.89. $Ta(NBu_2^n)_5$ requires: Ta, 22.0; Bu_2^nN, 78.0%. Only di-*n*-butylamine was identified by g.c.a. as the product of *n*-butanolysis of this compound. When heated *in vacuo* a sample of $Ta(NBu_2^n)_5$ (22.8 g) gave a yellow liquid distillate (10.5 g, 57% recovery of Ta; b.p. 180° at 0.1 mm). Found: Ta, 27.6; N, 8.58; valency of Ta, 5.00; ratio N:Ta, 4.01. $Bu^nNTa(NBu_2^n)_3$ requires: Ta, 28.4; N, 8.80%. To this product (4.67 g) was added *n*-butanol (10 ml) and after refluxing the solution both primary-butylamine and di-*n*-butylamine were identified by g.c.a. as products of the reaction. Removal of the amines and excess *n*-butanol gave a near-quantitative yield of tantalum penta-*n*-butoxide as a pale yellow distillate (3.74 g; 83% recovery of Ta; b.p. 200° at 0.05 mm). Found: Ta, 33.2; N, zero. $Ta(OBu^n)_5$ requires: Ta, 33.1%.

From another reaction involving $TaCl_5$ (16.8 g) and $LiNBu_2^n$ (0.25 g-equiv) the red liquid product (40.3 g) was predominantly $Ta(NBu_2^n)_5$. Found: Ta, 20.9; N, 8.20%; valency of Ta, 4.92; ratio N:Ta, 5.07. A sample (38.8 g) was heated under reflux at 180° at 0.1 mm for 1 hour and the volatile products were condensed into two fractions at −78° and −180°. The most volatile fraction (0.5 ml) was shown by g.c.a. to be predominantly 1-butene (85%) with a small amount of isobutylene (or butane) (10%) and traces of *cis*- and *trans*-2-butene. The less volatile fraction (6.40 g) was shown by g.c.a. to be mainly di-*n*-butylamine (95%) and by titration to have an equivalent weight of 133.1±1.0 (di-*n*-butylamine requires 129). The molar proportion of Bu_2^nNH to $Ta(NBu_2^n)_5$ was calculated to be 1.05 (by g.c.a.) or 1.07 (by titration). The residual tantalum compound was then distilled and gave a yellow liquid (14.6 g; 50% recovery of Ta; b.p. 175° at 0.1 mm). Found: Ta, 27.7; N, 8.60; valency of Ta, 4.98; ratio N:Ta, 4.01. $Bu^nNTa(NBu_2^n)_3$ requires: Ta, 28.4; N, 8.80%. Ethanolysis of the product was shown by g.c.a. to liberate both Bu^nNH_2 and Bu_2^nNH.

Preparation of Pentakis-(piperidino)-tantalum

Tantalum pentachloride (10.9 g) was caused to react with lithium piperidide (0.155 g-equiv) in petrol (boiling range 35–60° C). After refluxing for 4 hours the system was allowed to cool and was then filtered. Evaporation of the filtrate to dryness gave impure pentakis-(piperidino)-tantalum as a light brown solid (19.4 g). Found: Ta, 27.1; $C_5H_{10}N$, 62.3; valency of Ta, 4.90; ratio N:Ta, 4.96; Li, trace; Cl, trace. $Ta(NC_5H_{10})_5$ requires: Ta, 30.1; $C_5H_{10}N$, 69.9%. Some of this product (16.5 g) was fractionally crystallized from petrol (boiling range 35–60°). The first crop of light brown crystals (4.75 g) were still contaminated by impurities (found: Ta, 26.7; $C_5H_{10}N$, 57.0; Li, trace; Cl, trace; valency of Ta, 4.99; ratio N:Ta, 4.58). The second crop appeared to be pure pentakis-(piperidino)-tantalum (6.90 g; found: Ta, 30.1; $C_5H_{10}N$, 69.2%; valency of Ta, 5.00). The third fraction was a red paste (4.31 g; Found: Ta, 27.7; $C_5H_{10}N$, 61.0%; valency of Ta, 4.75).

The pentakis-(piperidino)-tantalum was also prepared by aminolysis as follows: Piperidine (7.5 g) was added to $Ta(NMe_2)_5$ (4.32 g) in petrol (boiling range 35–60°), and dimethylamine was rapidly evolved. The system was refluxed for 3 days, the solvent then evaporated off, and the crude product recrystallized from petrol to give a pale yellow solid (1.62 g; 25% recovery of Ta). Found: Ta, 30.3; $C_5H_{10}N$, 70.2%.

Reaction of $TaCl_5$ with Lithium N-Methyl-n-butylamide

From the reaction involving $TaCl_5$ (19.0 g) and $LiNMeBu^n$ (0.27 g-equiv) in pentane at room temperature (4 hours), the pentakis-(N-methyl-*n*-butylamino)-tantalum was isolated after removal of lithium chloride as an orange liquid (32.2 g). Found: Ta, 29.7; N, 11.23; valency of Ta, 5.00; ratio N:Ta, 4.90; Li, zero; Cl, trace. $Ta(NMeBu^n)_5$ requires: Ta, 29.6; N, 11.45%. Butanolysis of a sample was shown by g.c.a. to liberate only N-methyl-*n*-butylamine.

Some $Ta(NMeBu^n)_5$ (29.7 g) was refluxed at 160–180° at 0.1 mm for 1 hour and the volatile products were condensed at −180°. The volatile fraction (4.50 g) was shown by g.c.a. and by titration (equiv. wt., 94.5±0.2; Bu^nMeNH requires: equiv. wt., 87) to be mainly a secondary amine and the molar ratio of amine to $Ta(NMeBu^n)_5$ was 0.98. The residual red liquid tantalum compound (25.0 g) was distilled to an orange liquid (22.5 g, b.p. 150° at 0.1 mm). Found: Ta, 34.8; N, 10.72; valency of Ta, 4.69; ratio N:Ta, 3.98. $Ta(NMeBu^n)_4$ requires: Ta, 34.4; N, 10.67%. $Bu^nNTa(NMeBu^n)_3$ requires: Ta, 35.4; N, 10.79%. These analytical data suggested that the orange liquid was a mixture of $Bu^nNTa(NMeBu^n)_3$ and $Ta(NMeBu^n)_4$. Fractional distillation of the substance (15.9 g) gave two fractions: An orange liquid (9.00; b.p. 150–155° at 0.1 mm) which appeared to be $Bu^nNTa(NMeBu^n)_3$; found: Ta, 35.3; N, 10.9; valency of Ta, 4.95; ratio N:Ta, 4.0. $BuNTa(NMeBu^n)_3$ requires: Ta, 35.4; N, 10.8%. The less volatile fraction was a red liquid (6.80 g; b.p. 155–180° at 0.1 mm) which according to its tantalum and nitrogen analysis was $Ta(NMeBu^n)_4$, but the valency determination indicated the presence of a considerable proportion of quinquevalent material.

Found: Ta, 34.4; N, 10.57; valency of Ta, 4.75; ratio N:Ta, 3.97. $Ta(NMeBu^n)_4$ requires: Ta, 34.4; N, 10.67%. A sample (5.31 g) of the $Bu^nNTa(NMeBu^n)_3$ was refluxed in *n*-butanol (9.0 g) and it was shown by g.c.a. that both primary-butylamine and N-methyl-*n*-butylamine were liberated, but no primary-methylamine was detected. After the removal of amines and butanol the residue was distilled *in vacuo*, giving a quantitative yield of tantalum penta-*n*-butoxide (5.40 g, 95% recovery of Ta; b.p. 200° at 0.1 mm). Found: Ta, 33.1; N, zero. $Ta(OBu^n)_5$ requires: Ta, 33.1%.

A SIMPLE THERMOBALANCE FOR STUDIES OVER A PRESSURE RANGE OF 0 TO 60 ATMOSPHERES

WENDELL J. BIERMANN AND MENNO HEINRICHS
Parker Chemical Laboratories, University of Manitoba, Winnipeg, Manitoba
Received January 15, 1962

ABSTRACT

A design is presented for a thermogravity balance usable to a pressure of 1000 p.s.i. The mass sensitive element is a tool steel cantilever rod, the displacement of which is measured by a linear variable differential transformer. Thermograms for the pyrolysis of calcium oxalate, chromium (VI) oxide, and Mohr's salt are included to show typical performances.

A search of the literature to find a thermogravity balance design which would enable us to study solid–gas reactions over an extended temperature and pressure range disclosed only one design, that reported by Rabatin and Card (1). This design employs a modified torsion balance as the mass sensitive element and an optical lever – photoelectric cell transducer system to develop a voltage proportional to mass, for automatic recording. While there is no question of the intrinsic excellence of their design, the construction of their balance would seem to offer a major challenge to the machine shop facilities available in most university laboratories.

In the present design, the mass sensitive element is a tool steel cantilever rod, rigidly fixed on one end and undergoing varying displacement on the free end as the sample, supported on the free end, changes mass. The amount of displacement is determined by a linear variable differential transformer (LVDT), whose output is demodulated and fed to a recording potentiometer. Easy zero adjusting of the transducer after closing and pressurizing the system is incorporated in the design, overcoming the major criticism of Rabatin and Card to the application of an LVDT as a displacement transducer.

The cross-sectional drawing of Fig. 1 shows the mechanical construction of the thermobalance. Since recent papers by Newkirk (2) and Garn (3) outline in detail various general considerations regarding the design of thermogravity balances, it would seem superfluous to repeat them here. Suffice it to say that the present design is in harmony with their various suggestions.

DESCRIPTION OF THE APPARATUS

The Pressure Vessel

The pressure vessel consists of three cylindrical chambers. An upper chamber M, with a removable top plate, houses the furnace and sample. Communicating with the upper chamber through a tube is the transducer chamber S, from the side of which projects the third cylindrical chamber, housing the cantilever rod and its associated adjustment mechanisms. A removable bottom plate and a removable end plate permit access to these latter chambers. The entire construction was from type 304 stainless steel, employing wall thickness of 0.25 inch for the chambers, 0.50 inch for the flanges welded onto the open ends of the chambers, and 0.75 inch for the access plates. These plates were secured by hardened steel cap screws, and gas-tight closure was effected with Teflon "O" rings.

Instead of using flat plates on the ends of the pressure chambers, they could alternately be machined to spherical segments which would permit the same pressures to be contained

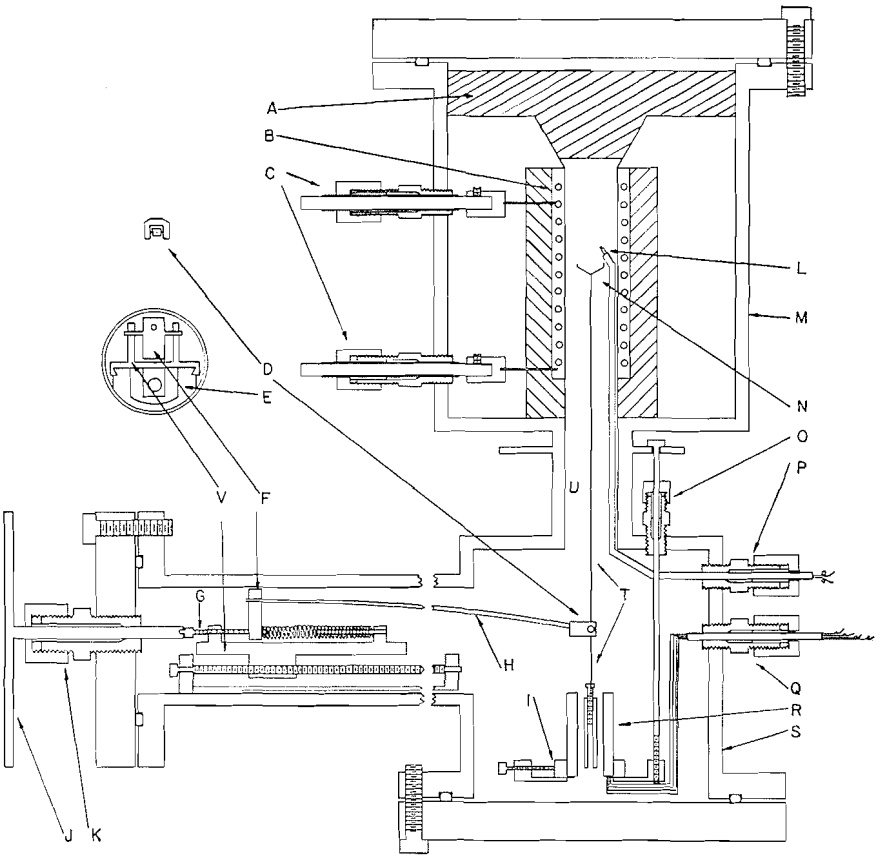

FIG. 1. Mechanical construction of the thermobalance.

with thinner walls. It would also be better practice to use radius cuts on the terminations and joinings of the chambers rather than the right-hand cuts which are shown on the drawing.

A tripod support, not shown on the drawing, holds the pressure vessel about 6 inches off the vibration pad on which it rests, permitting adjustments to be made through the lower access port, using a mirror for vision. The vibration pad consists of several layers of lead and cork, sandwiched between plywood, and mounted onto a concrete block wall by rigid brackets and was originally intended to support an analytical balance.

Calculations indicate that the pressure vessel should safely hold a pressure of about 1500 p.s.i., and it has been tested up to 1100 p.s.i. by applying oxygen from a cylinder.

A vertical quartz rod T supports the dish-shaped platinum foil sample pan on a tripod support N in the center of an electrically heated furnace. Fixed on the bottom of the quartz rod is the core of a Schaevitz Type 175 ES-L LVDT. This particular LVDT was chosen because we had anticipated more vibration background than was actually experienced; the amount of deflection needed is much less than the linear range of this unit. A much shorter range LVDT can therefore be substituted.

Immediately above the core, the quartz rod is supported by the cantilever rod H, a jewel-bearing supported pivot D allowing the quartz rod to remain vertical as the angle between it and the cantilever rod changes as a result of displacement. As displacements

of only a few thousandths of an inch are used, this assembly is essentially a strain gauge. Originally it had been planned to use a quartz rod for the cantilever, but experience showed that a rod thin enough to give adequate sensitivity was subject to frequent breakage. A 10-inch length of alloy steel drill rod (3/32-inch diameter) was then substituted and it has proved to be highly satisfactory both as regards mechanical strength and retention of calibration.

The furnace in the upper chamber was wound with Kanthal A-1 wire, backed with Alundum cement to give a rigid, cylindrical heating element B, which surrounds the sample. Asbestos fibers were packed in the space between the heating element and the wall of the pressure vessel. Closure of the top was effected with a lid A, fabricated from an insulating firebrick, which sits on the packed asbestos fibers. When the furnace is operated at 1000° C, very little heating of the outer vessel takes place. Two platinum foil radiation shields, in the vicinity of U in Fig. 1, minimize heat transfer to the lower sections of the pressure vessel.

Electrical connection to the heating element was made by slipping a cover of Teflon tubing over brass rods and then leading them through the wall of the pressure vessel with Conax sealants (Conax Corporation, Buffalo, N.Y.) with Teflon seals, as shown at C on Fig. 1.

Temperature in the vicinity of the sample is measured by means of a conventional high-temperature thermocouple L, led in through a Conax sealant P and having an exposed platinum, platinum–rhodium junction for low thermal lag. A similar thermocouple employing a chromel–alumel junction has also been employed. Placement of the thermocouple in different positions gives no change in the temperatures at which mass changes occur, indicating that no important thermal gradients exist in the vicinity of the sample pan.

The LVDT R in the lower compartment was mounted on a triangular brass plate, supported near each corner by an adjusting screw, one of which is shown at O, permitting leveling and approximate vertical positioning of the transducer body. Conax pressure sealants with neoprene seals were used to pass the adjusting screws through the wall of the pressure vessel. Three adjusting screws, one of which is shown at I, were used to center the transducer case about the core. Once the transducer case has been positioned, it requires no further adjustment between runs, vertical adjustment of the core for zeroing being done with the cantilever rod adjustment.

The fixed end of the cantilever rod H is anchored in a small brass plate, shown in both side and front view as F, which is in turn supported on a pivot which can rotate in ball bearing assemblies fixed to the carriage V. The angular position of this small plate is fixed by the end of the threaded rod G, against which it is pressed by a firm coil spring. This rod can be moved horizontally by rotation, being threaded through a block on the end of the carriage (40 threads/inch). A conax sealant, with a neoprene seal, passes this adjusting rod through the end plate with a gas-tight seal, and permits it to be turned with the 3-inch handwheel J after pressure buildup. This very simple system permits surprisingly precise adjustments of core position with no difficulty whatever.

The entire carriage assembly can be moved horizontally along the dovetail track E by means of a drive screw. This adjustment was intended to allow coarse adjustments of sensitivity by changing the length of the cantilever rod. Thus far it has been superfluous, the linear range of the LVDT being sufficiently long, and the stability and sensitivity of the other components sufficiently high that a change in range is more easily accomplished by taking greater or lesser fractions of the demodulator output.

Demodulator

Although the output of the LVDT is greater than would be required for full-scale deflection of a 10-mv recorder, the output signal is put through an amplifier stage before rectification to circumvent the difficulty of finding a rectifier with linear characteristics at low voltages. Following half-wave rectification of the amplified signal, a portion, usually 1/12, is selected by a variable potential divider network for feeding to a 10-mv recorder. The demodulator circuit is shown as Fig. 2. It will be noticed that the recorder

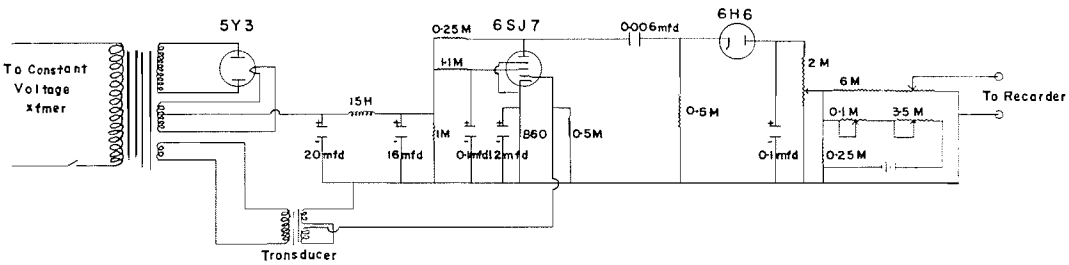

FIG. 2. Demodulator circuit.

output voltage fed to the recorder is opposed by a variable voltage taken from a mercury cell. This is a convenient way of setting the recorder to zero when beginning a run with the transducer slightly removed from its null point to get into a more linear region, and also to eliminate the effects of any constant inductive effects before the rectifier.

This demodulator is probably more complex than required. In principle, as there is adequate voltage from an LVDT in this situation to drive a recorder directly, it should only be necessary to follow the rectifier, even though non-linear, with an RC circuit having a time constant several times as long as the duration of a cycle in the LVDT output. We have not yet explained our failure to achieve satisfactory operation with the simpler circuit.

The recorder used was a two-pen, 10 mv/channel ServoRiter recording potentiometer (Texas Instrument Company, Houston, Texas) which permitted simultaneous recording of the LVDT and thermocouple outputs with 10-inch deflections on a common time axis.

Temperature Programmer

When the power supplied to the furnace was varied by linear variation of the voltage across the heater with time, the resulting time–temperature plots showed only moderate changes of slope. As this curvature was not great enough to be a handicap in any work we have in mind, a relatively simple motor and gear box drive was used to turn a variable autotransformer, with a limit switch at the end of its range. This was fed by a second variable autotransformer, much in the manner used by Reisman (4). By selecting suitable gear combinations a wide range of heating rates can be selected.

PERFORMANCE OF THE THERMOBALANCE

Operation

With the bottom plate removed, the transducer case is centered coaxially about the core in the vicinity of the null point by manipulation of the six adjusting screws which determine its position. As mentioned previously, this adjustment seldom needs to be repeated.

As the demodulator is not phase sensitive, deflections on either side of the null point are not distinguishable by the recorder. It is, therefore, easy to locate the null point by moving the cantilever rod with the handwheel until minimum deflection of the recorder is noted. Because an LVDT is generally non-linear in the immediate vicinity of its null point, it is most convenient to displace the core downward sufficiently to come into a linear region, the displacement with this apparatus being equivalent to about 40 mg in the sample pan. The region of linearity of the LVDT, in this apparatus, extends over a sample mass in excess of 1 g and the voltage developed across the 2-meg potential divider in the 6H6 plate circuit is about 1.0 mv/mg load in the sample pan. Since the recorder used gave full-scale deflection with 10-mv input, it was found convenient in most cases to use 1/12 of the demodulator output and to choose samples of such size that the mass change would be of the order of 0.1 g.

When set up as above, calibration was done directly by the addition of a succession of fractional weights, and the resultant sensitivity was 1.23 mg/chart division (0.1 inch), linear within the uncertainty of interpolating between chart markings. Greater or lesser sensitivity can be obtained, if experimentally convenient, by using a different fraction of the demodulator output. Zeroing of the recorder at different positions within the linear range is accomplished by applying a counter voltage in series with the demodulator output. The magnitude of the counter voltage, obtained from a mercury cell, is determined by the settings of the 3.5- and 0.1-meg potentiometers functioning as variable resistors and giving a coarse and fine control, respectively.

With the transducer core positioned at the beginning of the linear region, an appropriate-sized sample is then placed on the sample pan. If mass is to be lost, the recorder is set near full-scale deflection, and where mass is to be gained by reaction with the atmosphere within the pressure vessel, the recorder is set near zero deflection. While it would be possible to record the absolute mass of the sample, greater use is made of the sensitivity of the apparatus by weighing the sample on a balance and, using the above method of setting the recorder and an appropriate setting of the sensitivity selector, recording only the loss or gain in mass.

Results

Typical plots of mass and temperature as functions of time were traced from the recorder charts of the apparatus described above, and are reproduced as Figs. 3, 4, and 5. The temperature curve is easily distinguished from the loss of weight curve by the absence of inflection points. Calibration of the thermocouples by conventional calibration at invariant points served to fix the temperature axis.

Figure 3 shows the pyrolysis of a 0.2-g sample of calcium oxalate. The first plateau, representing completion of drying, begins at a temperature of 230° C, and the third plateau, completion of conversion to calcium oxide, occurs at 860° C, both temperatures being in substantial agreement with Newkirk (2). The center plateau, formation of calcium carbonate by the loss of carbon monoxide, is apparently reached at 435° C, substantially lower than Newkirk's value, but the irregularity in the temperature curve in this vicinity suggests that oxidation of the carbon monoxide is probably responsible for the rise in sample temperature, and served to underline the stress laid by Newkirk and by Garn and Kessler (5) on the effect of atmosphere and venting on the shape of the thermogram.

Figure 4 is a thermogram for the pyrolysis of chromium (VI) oxide under an oxygen atmosphere of 200 p.s.i. A precision potential divider allowed all, half, or one fifth of the

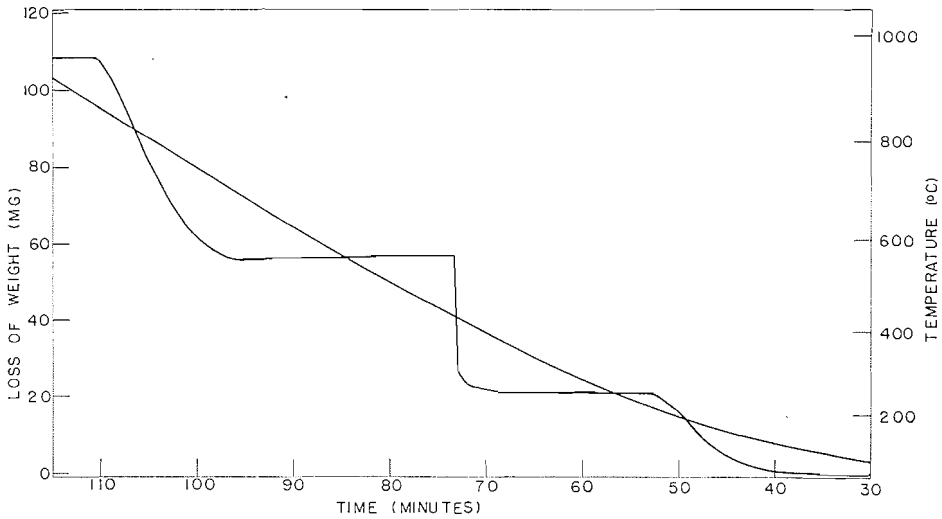

FIG. 3. Thermogram obtained by heating calcium oxalate.

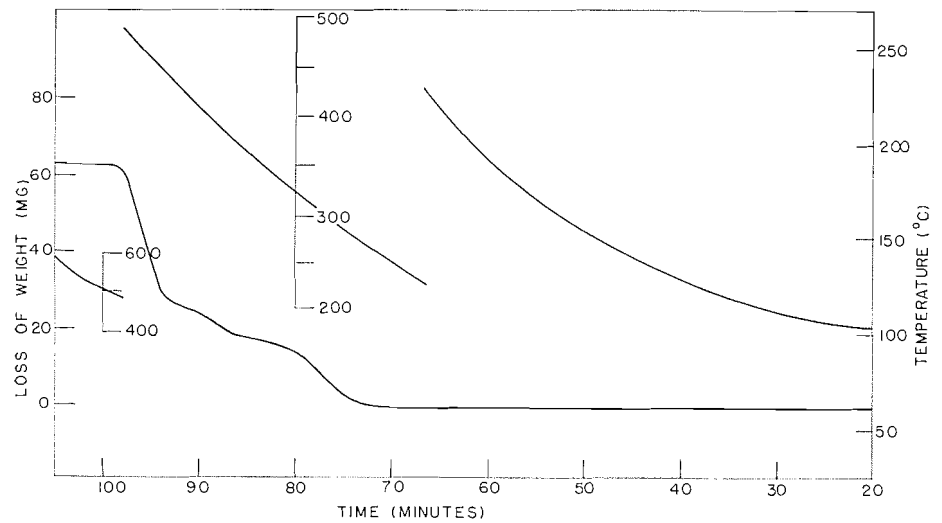

FIG. 4. Thermogram for heating chromium (VI) oxide under oxygen pressure of 200 p.s.i.

chromel–alumel thermocouple output to be fed into the recorder, thus leading to the three temperature axes shown on this thermogram. Oxygen is lost in three steps, the weight losses in these steps being in the ratio 4.10:1.97:9.00, which agrees with the successive formation of Cr_5O_{13}, Cr_5O_{12}, and Cr_2O_3, as reported by Mellor (6). The 258.2-mg sample gave a residue of 194.8 mg, compared to the theoretical value of 196.1 mg.

Figure 5 is a pyrolysis curve for Mohr's salt. This thermogram can be tentatively interpreted by postulating a decomposition in the following steps:

(1) a loss of 4, and subsequently 2 more, moles of water per mole of Mohr's salt, with the loss of mass being 34.68% of the sample weight (34.58% theoretical);

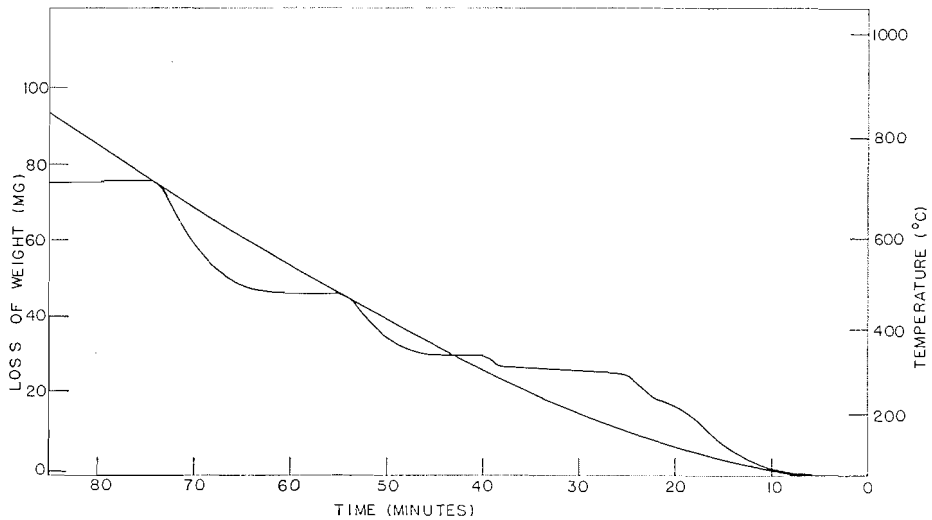

FIG. 5. Thermogram obtained on heating Mohr's salt.

(2) a loss of 1 mole of ammonia and $\frac{1}{2}$ mole of hydrogen simultaneously, the loss of mass being 5.64% (5.69% theoretical);

(3) the simultaneous loss of 1 mole of ammonia and $\frac{1}{2}$ mole of sulphuric acid, the mass loss being 21.29% (21.19% theoretical);

(4) the loss of $1\frac{1}{2}$ moles of sulphur trioxide, corresponding to a mass loss of 38.39% (38.42% theoretical).

LIQUID–LIQUID EXTRACTION OF BERYLLIUM

I. A STUDY OF FACTORS AFFECTING EXTRACTION

WENDELL J. BIERMANN AND ROBERT MCCORKELL
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received March 7, 1962

ABSTRACT

A consideration of factors known to govern the formation of coordination compounds with metal ions led to the conclusion that the best ligands to use in attempting to separate beryllium from other metal ions of inert gas configuration by liquid–liquid extraction would be easily polarizable, monofunctional ligands. It is suggested that the thiocyanate ion, as ammonium thiocyanate, is particularly promising for metallurgical application.

The organic solvent was shown to play an active role in the extraction, ketone or hydroxy groups on chains containing six to eight carbons giving good extraction with low solvent loss.

INTRODUCTION

Most of the existing literature concerning the chemical metallurgy of beryllium is directed towards the processing of beryl, until recently the only commercially important beryllium mineral, to produce beryllium oxide, destined for use mainly as a ceramic oxide or for production of beryllium–copper alloy (1–3). Recently there has been a resurgence of interest in the extractive chemistry of beryllium as a result of the discovery of new types of mineralization, extensive and rich enough to be more attractive than the traditional hand-cobbed beryl (4). The requirements of the nuclear energy field have also placed a far greater emphasis on purity than has heretofore existed.

A variety of studies has been in progress in this laboratory, designed to establish process information useful in meeting these new requirements. A series of communications, of which this is the first, will describe one aspect of this work—the separation of beryllium from other elements which might coexist in natural deposits by liquid–liquid extraction techniques.

In order to be useful on a commercial production scale, several criteria must be met. First, and most obvious, costly reagents and solvents must be avoided, otherwise there will be no practical advantage over existing practice. Recovery of reagents and solvents, by economical means, likewise is an advantageous situation. Second, some selectivity of the extraction system for beryllium is necessary if anything is to be accomplished. Third, after partition of the beryllium between the liquid phases, it must be easily possible to strip the beryllium-rich phase.

In principal, any reagent or group of reagents which can react with the aquated beryllium ion and, by displacement of water molecules in the primary hydration layer, produce an uncharged structure would enhance the solubility of the beryllium ion in "organic" solvents and could thus serve as the basis of a solvent extraction system. A brief consideration of some of the principals involved shows, however, that most of the potential systems will be of little practical value.

Various classifications of liquid–liquid extraction systems have been proposed (5, 6), a broad classification into ion association systems and coordination complexes being common.

Whether the ion association aggregate has any physically real distinction from the more common interaction involving coordination of ligands to the central atom is debatable. Generally, members of the ion association groups are those in which one would predict

weak coordination bonds between the central atom and the ligands. Since there seemed to be no possible advantage to maintaining these categories in planning a search for practical extraction systems, we considered that all extractions of beryllium would be of species containing coordinately bonded ligands with two associated negative charges, required to give an electrically neutral species.

A large amount of the modern solvent extraction literature is concerned with the coordination of polyfunctional bases to the central atom, giving the generally very stable chelate complexes. It has been shown by various investigators that the formation constants of chelates with a given ligand but various central ions can be, at least qualitatively, related to the charge of the central ion and its radius. Beryllium is often an exception to this generalization, the formation constants being too low, presumably because of steric hindrance effects arising from its very small radius. Advantage is frequently taken of this effect, as when beryllium is separated from ions with similar or smaller charge-to-radius ratios, notably aluminum, by chelating agents such as ethylenediaminetetraacetic acid or 8-quinolinol. Where a stable chelate is formed with beryllium ion, the 1,3-diketones being familiar examples, almost all other cations except those of groups I*a* and II*a* form equally, or more, stable complexes. We therefore rejected polyfunctional ligands as generally not meeting our criterion of specificity and, secondarily, as generally being on the expensive side.

This left us with only monofunctional ligands as potential extraction agents. Here we restricted most of our experimental work to those systems in which a priori considerations and reagent costs together established at least an hypothetical basis for an efficient and reasonably selective extraction system.

While the orbital theories of chemical bonding are useful in predicting formulae and geometry of coordination compounds, the electrostatic approach was far more useful in attempting to predict the usefulness of various ligands. In general the strength of the bonds, and hence the formation constant, will be determined by Coulomb's law (7). In the case of small, noble gas configuration cations and small anions one generally can get at least semiquantitative results by the simple use of conventional ionic charges and radii. When dealing with larger anions, particularly when the central cation shows a high effective charge-to-radius ratio, polarization effects can completely alter the expectations derived from the simple picture. The inversion of the order of stabilities of the halo complexes of the elements at the ends of the transitional series has been successfully explained on this basis, it being postulated that the effective charges on these ions are unduly high because of the ineffectual screening of the nucleus by the electrons in the *d* orbitals.

We now have two possible paths, regarding selectivity, for a solvent extraction system to follow. We might employ small ligands, such as fluoride ion, and use a basic solvent to supply the remaining two ligands to give an uncharged beryllium complex with the usual coordination number of four satisfied, or we might seek a large negatively charged anion and rely on the polarizing power of beryllium to distort the anion sufficiently to give a sufficiently stable bond to permit extraction.

The first would not be expected to give good separation from aluminum, lithium, or other elements of fairly high charge-to-radius ratio, but might be effective with some of the heavier elements, which are, however, seldom a difficulty in the metallurgy of beryllium. Because of the large energy of such coordinate bonds, for example between beryllium and fluoride ions, it is difficult to avoid a negatively charged, hence less extractable, ion.

Using large, hence deformable, anions seems to be the more promising approach. Since the polarizing power of an ion varies with the ratio of the charge to the square of the radius, such an easily polarizable ion should give good selectivity from elements with inert gas configurations, because the beryllium ratio is much larger than for other commonly coexisting ions like aluminum and lithium. Interference would be expected from those elements which occur about the ends of the transitional series, but since it seems to us that interference is inevitable, this would at least constitute the less objectionable type of interference. The fact that formation constants with ligands of this type would be lower than for small, or highly charged, ligands can also be advantageous in that it becomes easier to avoid anionic forms of beryllium and that stripping should be facilitated.

Because this picture includes the solvent as a coligand to the actual anionic reagent, the basic nature and water solubility of the solvent should be closely related to the extraction of beryllium. Solubility in water should, by a mass-law effect, increase extractability, and some strongly basic functional group should be necessary for appreciable extraction.

The systems studies were chosen in accordance with the above considerations, and the results were completely consistent with expectation.

EXPERIMENTAL

In essence, the experimental work consisted of taking water solutions of known beryllium concentration and any other reagents whose effects were to be studied and equilibrating with an appropriate organic solvent. The actual extractions were made in glass-stoppered separatory funnels, shaking until extraction was complete. It was assumed that when the beryllium concentration of the aqueous phase was reproducible after longer shaking intervals, equilibrium had been reached. In no cases studied were more than 1 or 2 minutes required to reach such equilibrium. For simplicity of comparison, equal volumes (40 ml) of aqueous and organic phases were used. Analysis of the aqueous phase after extraction then permitted calculation of the percent beryllium extracted, which is simply related to the distribution coefficient by D = (percent extraction)/(100-percent extraction) in the equal volume situation, provided the two solvents show little miscibility, as was generally the case.

Where extraction was sufficiently high to be promising, the experiments were repeated using an equivalent amount of aluminum ion in place of the beryllium, the distribution coefficients of aluminum and beryllium serving as a measure of the selectivity of the extraction for inert gas configuration ions.

A major part of the experimental work was analysis of aqueous and organic phases for beryllium and aluminum, and some complications were encountered here because of the coordination of beryllium and aluminum ions to thiocyanate and solvent. There seemed to be a tendency to prevent complete precipitation of the beryllium in some gravimetric methods, and in the determination of beryllium by optical absorption of beryllium–reagent complexes, results were similarly often low.

Ultimately two standard methods were adopted, a photometric method using *p*-nitrobenzeneazoorcinol (8) which proved applicable in some cases, and the precipitation of beryllium as NH_4BePO_4 (9), followed by ignition to $Be_2P_2O_7$ at 900° C. The latter method proved to be generally reliable, the uncertainty being no worse than $\pm 0.5\%$.

Aluminum was determined by EDTA titration using hematoxylin as an indicator (10). The reliability was shown to be within $\pm 0.5\%$ under the prevailing conditions.

The aqueous aluminum solutions were prepared from reagent grade aluminum sulphate, with no further purification. Beryllium solutions were prepared from beryllium sulphate tetrahydrate, supplied by A. D. MacKay, Inc., and whose purity was verified by chemical analysis. A range of grades of solvents, determined mostly by availability, was used and, when the results were thought to be significant, the solvents were purified by fractional distillation.

EXPERIMENTAL RESULTS

Our attempts to extract a solvated hydroxy complex of beryllium, using solvents with oxygen donor atoms in various functional groups, proved uniformly unpromising and were soon discontinued. The percentages of beryllium extracted were generally less than 0.1%.

Commercial di-*n*-butyl phosphate proved to be a fairly able extractant for beryllium when used in kerosene suspension, but as shown by representative results collected in Table I, it is not notably selective. Since, in addition, we encountered some difficulty in

TABLE I

The extraction of beryllium and other metals from 1.0 *M* aqueous nitric acid solution by kerosene suspensions of commercial di-*n*-butyl phosphate
(Initial metal concentration 0.050 *M*, extraction time 5 minutes, equal volumes of organic and aqueous phases)

Metal ion	Butyl phosphate concentration (moles/liter)	Percentage metal extracted
Be^{+2}	0.10	18.6
Be^{+2}	0.20	50.8
Be^{+2}	0.40	72.9
Be^{+2}	0.60	75.3
Be^{+2}	1.00	91.1
Ti^{+4}	0.10	48.6
Al^{+3}	1.00	45.5

getting clean separations of the liquid phases, due to emulsion formation, we discarded this as an impractical system.

In Table II are collected results of extractions using anions of various weak aliphatic acids as ligands. The aqueous layer was prepared by raising the pH until the beryllium

TABLE II

Extraction of 0.2 *M* beryllium solutions, in the presence of various carboxylic acids, with chloroform

Acid	Acid concentration (moles/liter)	Percentage extraction	Percentage Al^{+3} extraction
Acetic	5.0	3.3	
Propionic	5.0	21.9	95
Butyric	2.0	87.5	100
Butyric	3.0	92.3	100
Butyric	4.0	91.7	100
Butyric	5.0	94.7

Octanoic		100	100

*Used instead of chloroform as organic phase.

precipitated as an hydroxide, after which it was redissolved by addition of an excess of the acid being tested. While the results showed good beryllium extraction, little differentiation from aluminum was noted, so no further attempts were made to develop this as a practical system.

As would be predicted from the introductory considerations the large, polarizable, halide-type anions proved to be particularly suitable for extraction. Table III shows the extractability of chloride, bromide, iodide, and thiocyanate complexes of beryllium and aluminum under similar experimental conditions. Of these ions, the low cost of ammonium thiocyanate made this reagent look particularly attractive, and seemed to justify a concentration of work on thiocyanate extraction systems.

TABLE III

Extraction of metal ions from solutions of halide-type ions with *n*-amyl alcohol (Initial metal concentration 0.100 *M*, pH = 3.00)

Metal	Salt	Percentage metal extracted
Be	4 *M* NH_4Cl	0.0
Be	4 *M* KBr	1.3
Be	4 *M* KI	66.6
Be	3 *M* NH_4CNS	81.0
Al	3 *M* NH_4CNS	41.2

Since we postulated that the solvent would play an active role in forming the co-ordination compound, which is the actual extracted species, distribution coefficients were determined with a variety of solvents.

The standard conditions of comparison were: an initial beryllium concentration of 0.100 *M*, as beryllium sulphate; an initial thiocyanate concentration of 3.00 *M*, as ammonium thiocyanate; and a pH of 3.00±0.01. It was noted that the distribution coefficient was pH sensitive, probably because a high proton concentration lowers the concentration of the somewhat basic thiocyanate ion, and a low proton concentration lowers extraction, presumably because of the formation of species like $BeOH^+$. The results of the solvent studies are tabulated in Table IV.

TABLE IV

The distribution ratios between the organic and aqueous phases of beryllium and aluminium ions in the presence of thiocyanate ion, for various organic phases (Initial concentration of metal in the aqueous phase 0.100 *M*, of thiocyanate ion as ammonium thiocyanate 3.0 *M*, pH = 3.00+0.01)

	Distribution ratio			Distribution ratio

DISCUSSION

These results seem to be consistent with our analysis of the problem. The degree of differentiation that thiocyanate ion shows between the extraction of aluminum and beryllium is generally more than adequate to serve as the basis of a liquid–liquid extraction system for beryllium.

The best organic solvents to use seem to be six- to eight-carbon alcohols, or solvents containing double-bonded oxygens associated with five or six carbon atoms. Probably the lower efficiency of longer-chain compounds is merely a lowering of the concentration in the water phase as a result of the lower solubility.

It would seem that polarizability of the solvent is not an important contribution to the stability of the complex, as noted by the very poor extraction by the thioalcohols. This seems reasonable because the charge seen by the ligand should be quite low after the negative thiocyanate ions have been coordinated.

With cost considerations, as well as effectiveness of extraction and separation considered, methyl isobutyl ketone, 1-hexanol, isoamyl acetate, and 2-octanol seemed to be particularly promising solvents. A detailed investigation of beryllium–thiocyanate extraction systems using these solvents has therefore been undertaken, and a description of this work will constitute the second paper in this series.

The emphasis given to the thiocyanate ion in this work raises the question of the uniqueness of thiocyanate ion, implied by the failure to investigate the numerous other negatively charged ions which could coordinate to beryllium ions. If polarizability of the anion is an essential factor, then it seems evident that the negative ligand must be produced by dissociation of an acid in which the proton is associated with some element other than oxygen, since the nucleophilic atom would be more subject to polarization than atoms more remote from the coordinate bond. The cyanide ion, for example, would seem to meet our basic requirements of a ligand, but it does not exist as a free ion in the pH region where beryllium is free of hydroxylation. Other ions, such as selenocyanate, might work as well, or better than, the thiocyanate, but those which have occurred to us were rejected either on the basis of toxicity or economic consideration.

A SYNTHESIS OF MIMOSINE

IAN D. SPENSER AND ALBERT D. NOTATION
Department of Chemistry, McMaster University, Hamilton, Ontario
Received March 9, 1962

ABSTRACT

DL-Mimosine has been synthesized by debenzylation and detosylation of the product obtained by condensation of 3-benzyloxy-4-pyrone with β-amino-α-tosylaminopropionic acid. A new method for the isolation of mimosine from *Leucaena glauca* Benth. is described.

The amino acid mimosine (VIII ↔ XV) was first isolated (1) from the sap of *Mimosa pudica* L. Investigation of its structure (1, 2) and of the structure of leucaenol (leucaenine) (3–9), isolated somewhat later (10) from *Leucaena glauca* Benth. (Kao Haole), made it likely that the two compounds were identical (1, 3–7). Direct comparison (11) confirmed this identity[1] and a synthesis of mimosine has been reported (12).

In connection with an investigation of the biosynthesis of mimosine, we required the compound in quantities which could not be conveniently obtained from *M. pudica*. Attempts to repeat the reported synthesis were disappointing. By reaction of 3-methoxy-4-pyridone (III) with α-acetamidoacrylic acid (IV), Adams and Johnson (12) had obtained an uncharacterized adduct, regarded as *O*-methyl-*N*-acetylmimosine (V), which gave mimosine (VIII) in 25% yield on vigorous hydrolysis with hydriodic acid. We were unable to obtain the amino acid by this method. The final product of the reaction was a mixture which, on the basis of paper chromatographic analysis, did not contain mimosine but appeared to consist mainly of 3-hydroxy-4-pyridone (VI) and alanine.

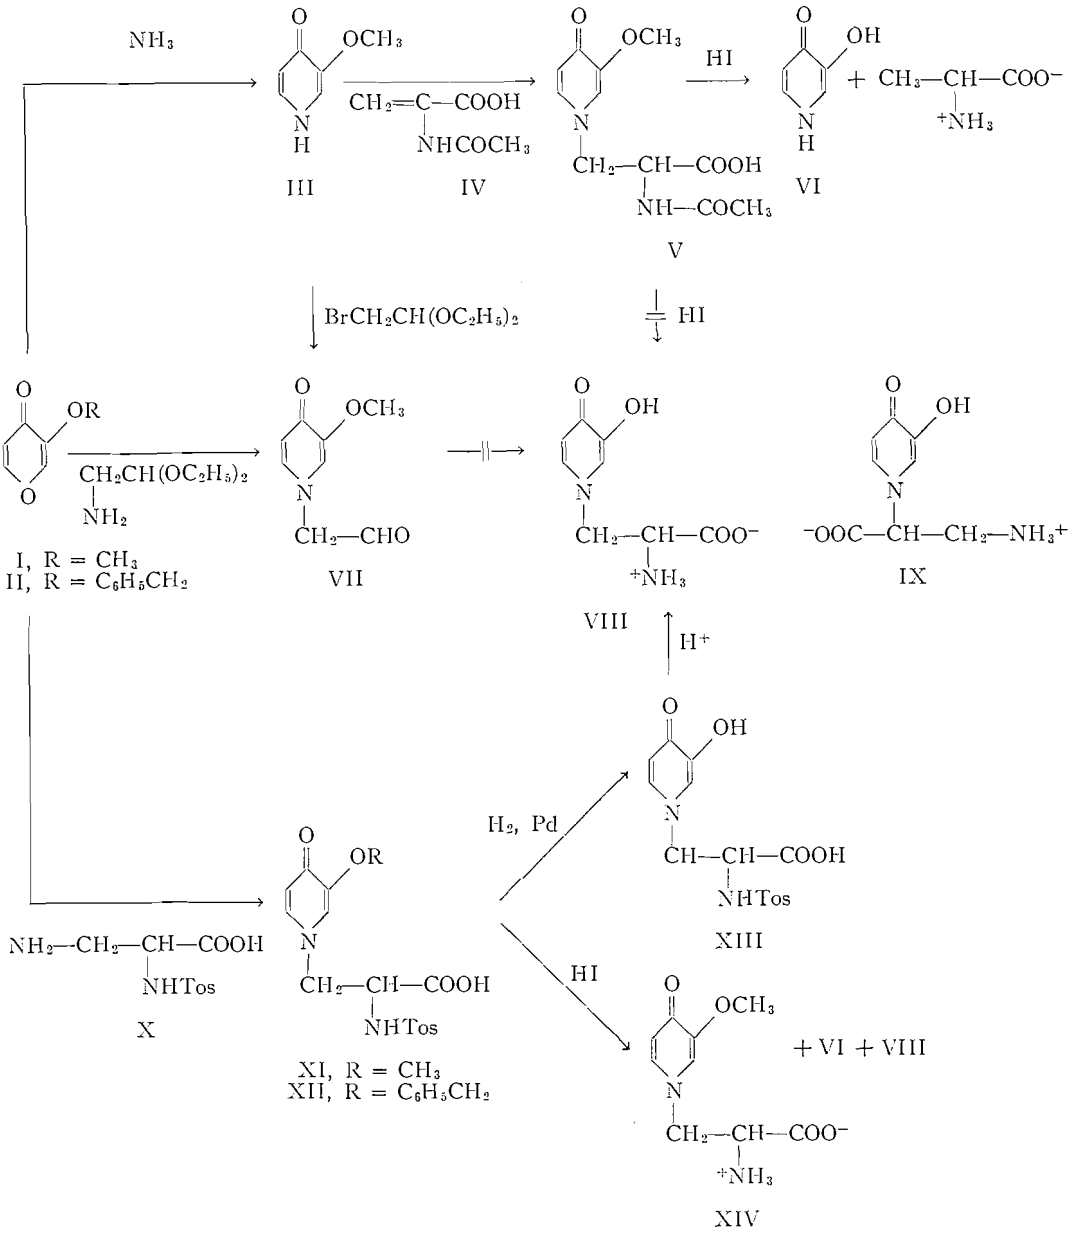
Another approach to synthesis, which had failed, was by the Strecker route. Although condensation of 3-methoxy-4-pyridone (III) with bromoacetaldehyde diethylacetal (13) and condensation of 3-methoxy-4-pyrone (I) with aminoacetaldehyde diethylacetal (14) gave derivatives of the requisite aldehyde (VII), further conversion of these to mimosine proved unsuccessful (13, 15).

The present synthesis was based on the condensation of suitably substituted derivatives of 3-hydroxy-4-pyrone and α,β-diaminopropionic acid. It had been reported earlier that 3-hydroxy-4-pyrone or 3-methoxy-4-pyrone did not react with glycine, α,β-diaminopropionic acid, β-amino-α-bromopropionic acid (15), or with β-amino-α-hydroxypropionic acid (12). Since the crucial step in the pyrone–pyridone conversion is generally regarded as analogous to carbinolamine formation (16), a nonprotonated amine is required as the nucleophilic reactant, and it was likely that the failure of these amino acids to condense was due to their zwitterion structure, in which the amino group is protonated. No attempt had been made to control the ionic state of the reactants (12, 15). Indeed, it was subsequently shown (17) that condensation of glycine with a number of 4-pyrone derivatives takes place only in the presence of an equimolar amount of base.

The desired condensation of a pyrone with α,β-diaminopropionic acid requires the species $NH_2—CH_2—CH(NH_3^+)COO^-$ of the latter. The assignment of pK values (pK_2, 6.69 (α-NH_2); pK_3, 9.50 (β-NH_2)) (18) indicates that in aqueous solutions this species in unobtainable in significant amounts. The species $NH_3^+—CH_2—CH(NH_2)COO^-$,

[1]*Since the name "mimosine" was the first to be coined (1), proof of identity makes the names "leucaenol" (10), "leucenol" (4), and "leucaenine" (5) redundant.*

which overwhelmingly predominates in the isoelectric range of the amino acid, would on condensation with 3-hydroxy-4-pyrone yield an isomer (IX) of mimosine. Condensation of the pyrone with the amino acid at pH > 11, i.e., with the species $NH_2—CH_2—CH(NH_2)COO^-$, would lead to a mixture of mimosine (VIII) and its isomer (IX). For an unequivocal synthesis of mimosine, protection of the α-amino group was therefore required.

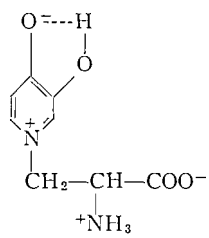


The chosen derivative was DL-β-amino-α-tosylaminopropionic acid (X), which was prepared, according to Rudinger (19), by Hofmann rearrangement of α-*N*-tosylasparagine.

Condensation of the tosylamino acid with 3-methoxy-4-pyrone in the presence of an equimolar quantity of sodium hydroxide gave β-(1,4-dihydro-3-methoxy-4-oxo-1-pyridyl)-*N*-tosylalanine (*O*-methyl-*N*-tosylmimosine) (XI) in 46% yield. Hydrolysis with hydrobromic or hydriodic acid under a variety of conditions gave mimosine (VIII), but was accompanied by considerable *N*-alkyl cleavage. It would appear that whereas mimosine itself is stable towards halogen acids (4, 5), derivatives of its *O*-methyl ether are not; this was presumably the reason why Adams and Johnson obtained a poor yield in their synthesis (12), and why we could not repeat their work. Under conditions where removal of the alanyl side chain from XI was minimal, detosylation did take place, but ether cleavage was incomplete. The product was a mixture of mimosine (VIII) and its *O*-methyl ether (XIV), fractionation of which proved to be tedious.

The difficulty was overcome by a minor variation in the route of synthesis. Condensation of DL-β-amino-α-tosylaminopropionic acid (X) with 3-benzyloxy-4-pyrone (II) gave β-(3-benzyloxy-1,4-dihydro-4-oxo-1-pyridyl)-*N*-tosylalanine (*O*-benzyl-*N*-tosylmimosine) (XII) in 70% yield, which on catalytic debenzylation yielded β-(1,4-dihydro-3-hydroxy-4-oxo-1-pyridyl)-*N*-tosylalanine (*N*-tosylmimosine) (XIII) in yields of 80%. Hydrolysis of the tosyl group by hydrogen bromide in glacial acetic acid gave DL-β-(1,4-dihydro-3-hydroxy-4-oxo-1-pyridyl)-alanine (VIII),[2] melting at 228–230° (decomp.). The melting point and infrared absorption of this synthetic material were very similar to the melting point (11, 12, 20) and infrared absorption[3] (9, 12, 20) of samples of natural mimosine, obtained from *M. pudica* L. and from *L. glauca* Benth. The ultraviolet absorption curves of the synthetic and the natural (4, 9) material were identical.

Synthetic and natural mimosine showed identical dissociation constants (pK_1, 2.1 (COOH); pK_2, 7.2 (NH_3^+); pK_3, 9.2 (OH)). The values for pK_2 and pK_3 are in good agreement with those calculated (7.28 and 9.19 respectively) from reported potentiometric data (5). The dissociation, pK_2, was the only one depressed in the presence of formaldehyde and must therefore be assigned to the α-amino group of mimosine. Its value, unusually low for the α-amino group of an amino acid, corresponds to reported values of the dissociation constants of similar NH_3^+ groups in 1,2-diammonium derivatives (e.g., $NH_3^+CH_2CH(NH_3^+)COO^-$, pK_2, 6.69 (α-NH_3^+) (18); $NH_3^+—CH_2—CH_2—NH_3^+$, pK_1, 6.98 (22)). The factor which lowers the basicity of the NH_2 group in these compounds is the polar effect of the proximal, charged NH_3^+ group. Since the pK_a of the α-amino group of mimosine is of similar magnitude, it is likely that the species XV is an important resonance contributor.



XV

[2]*An attempt to synthesize the* L-*isomer, starting from* L-α-*tosylamino-*β-*aminopropionic acid, failed, since condensation of this compound with 3-benzyloxy-4-pyrone under our conditions was accompanied by racemization.*

[3]*The observation that the infrared spectrum of a* DL-*amino acid in the solid state (*KBr*) differs from the spectra of the individual* D- *and* L-*isomers has been repeatedly confirmed (e.g., ref. 21).*

Unequivocal proof of identity, and incidentally, confirmation of structure, were obtained by comparison of the nuclear magnetic resonance spectra of synthetic and natural mimosine, recorded on samples dissolved in deuterium oxide containing sodium deuteroxide. A trace of water (H_2O) was present for internal reference. The two spectra were superimposable and showed four signals (chemical shift in parts per million from water): (*a*) a triplet +1.20, +1.12, +1.03 (—CH—); (*b*) a doublet +0.71, +0.63 ($—CH_2—$); (*c*) a doublet −1.57, −1.67 (C_5—H); (*d*) a singlet −2.49 (C_2—H) superimposed on a doublet −2.52, −2.62 (C_6—H). The areas of the signals were in the ratio 1:2:1:2. This spectrum fully accounts for the structure of the amino acid.

Extraction of mimosine from the seeds of *L. glauca* Benth. by reported methods (3–6) requires large volumes of solvent and the removal from the extracts of considerable quantities of protein and polysaccharides (23). Partial hydrolysis of the latter in the course of extraction leads to gummy intractable residues from which the desired product is obtainable only with great difficulty.

A simple but effective method for the separation of mimosine from the seeds of *L. glauca* has now been developed. Finely powdered seeds were dialyzed against distilled water. When the dialyzate was concentrated and allowed to stand overnight, almost pure mimosine crystallized in high yield.

Mimosine was also isolated from the exudate obtained on cutting the stems of *M. pudica*.

In biosynthetic experiments with *M. pudica*, radioactivity from carbon-14 dioxide and DL-3-C^{14}-aspartic acid was incorporated into mimosine. Degradation of the labelled mimosine from the latter experiment is in progress.

EXPERIMENTAL

3-Hydroxy-4-pyrone (Pyromeconic Acid)

3-Hydroxy-4-pyrone, melting at 116–118°, was prepared (24) in 66% yield by pyrolysis of anhydrous meconic acid and was purified by sublimation at 110° and 10^{-3} mm.

3-Methoxy-4-pyrone (I)

3-Methoxy-4-pyrone, melting at 93–95°, was obtained in 84% yield by methylation of pyromeconic acid with diazomethane in ether solution (24). It was purified by distillation at 5×10^{-3} mm and 100–110°.

3-Benzyloxy-4-pyrone (II)

A mixture of 3-hydroxy-4-pyrone (2.24 g, 0.02 mole), potassium iodide (0.30 g, 0.00019 mole), anhydrous potassium carbonate (2.67 g, 0.019 mole), and benzyl chloride (2.70 g, 2.45 ml, 0.022 mole) in dimethylformamide (100 ml) was heated for 8 hours on the steam bath with continuous stirring. The hot mixture was filtered, the residue washed repeatedly with ethanol, the combined filtrates evaporated to dryness, and the residual solid exhaustively extracted with ether. The extract was dried (Na_2SO_4) and concentrated to yield crystals of *3-benzyloxy-4-pyrone* (3.30 g, 81%), melting at 84–85° after recrystallization from ether. (Found: C, 71.0; H, 5.0. $C_{12}H_{10}O_3$ requires: C, 71.3; H, 5.0%.)

L- *and* DL-*β-Amino-α-tosylaminopropionic Acid (X)*

This was prepared according to Rudinger *et al.* (19) from L- and DL-*α-N*-tosylasparagine respectively.

β-(1,4-Dihydro-3-methoxy-4-oxo-1-pyridyl)-N-tosylalanine (O-Methyl-N-tosylmimosine) (XI)

3-Methoxy-4-pyrone (1.39 g, 0.011 mole) in water (10 ml) was added to a solution of DL-β-amino-α-tosylaminopropionic acid (2.58 g, 0.01 mole) in 0.1 *M* sodium hydroxide (100 ml, 0.01 mole). The mixture was heated for 3 hours on the steam bath and then concentrated to a volume of 50 ml, when the pH, originally above pH 11, had dropped to pH 9. The pH was adjusted to pH 7 by dropwise addition of concentrated hydrochloric acid and the solution was allowed to stand at 5° for several hours. Unreacted tosylamino acid (0.31 g, 0.0012 mole) was filtered off and the pH of the filtrate was adjusted to pH 2 with concentrated hydrochloric acid. Crystallization of the product started almost immediately and was complete after 12 hours at 5°, yielding DL-*β-(1,4-dihydro-3-methoxy-4-oxo-1-pyridyl)-N-tosylalanine* (1.51 g, 47%), melting at 200–201° (decomp.) after recrystallization from water. (Found: C, 52.7; H, 5.1; N, 7.6; S, 9.0. $C_{16}H_{18}N_2O_6S$ requires: C, 52.5; H, 5.0; N, 7.7; S, 8.7%.)

Condensation of 3-methoxy-4-pyrone with L-β-amino-α-tosylaminopropionic acid in place of the DL-compound was accompanied by racemization, also yielding optically inactive condensation product.

β-(3-Benzyloxy-1,4-dihydro-4-oxo-1-pyridyl)-N-tosylalanine (O-Benzyl-N-tosylmimosine) (XII)

3-Benzyloxy-4-pyrone (2.24 g, 0.011 mole) in ethanol (15 ml) was mixed with a solution of DL-β-amino-α-tosylaminopropionic acid (2.58 g, 0.01 mole) in 0.1 *M* sodium hydroxide (100 ml, 0.01 mole). The mixture was warmed and shaken until homogeneous, and the solution was heated on the steam bath under reflux for 8 hours. Concentrated hydrochloric acid (3 ml) was added with rapid stirring and the solution allowed to stand at 5° overnight, when *β-(3-benzyloxy-1,4-dihydro-4-oxo-1-pyridyl)-N-tosylalanine* (3.25 g, 74%), melting at 203–205° (decomp.) after recrystallization from ethanol, was obtained. (Found: C, 59.5; H, 5.3; N, 6.3; S, 7.4. $C_{22}H_{22}N_2O_6S$ requires: C, 59.7; H, 5.0; N, 6.3; S, 7.2%.)

β-(1,4-Dihydro-3-hydroxy-4-oxo-1-pyridyl)-N-tosylalanine (N-Tosylmimosine) (XIII)

O-Benzyl-*N*-tosylmimosine (1.00 g, 0.0023 mole) in dimethylformamide (100 ml) was shaken 45 hours at room temperature under hydrogen at 18 p.s.i. in the presence of 5% palladium on charcoal (1.00 g), the catalyst having been prehydrogenated at 25 p.s.i. in ethanol (50 ml) at room temperature for 3 hours. The reaction mixture was heated and filtered and the catalyst exhaustively washed with hot ethanol. The filtrate was evaporated to dryness and the residue crystallized from ethanol, yielding *β-(1,4-dihydro-3-hydroxy-4-oxo-1-pyridyl)-N-tosylalanine* (0.64 g, 80%), melting at 203–205° (decomp.). (Found: C, 51.0; H, 4.8; N, 7.8; S, 9.3. $C_{15}H_{16}N_2O_6S$ requires: C, 51.1; H, 4.6; N, 8.0; S, 9.1%.)

β-(1,4-Dihydro-3-hydroxy-4-oxo-1-pyridyl)-alanine (DL-Mimosine) (VIII)

The tosyl derivative (XIII) (0.40 g) was dissolved in sufficient glacial acetic acid (approximately 25 ml) to give a homogeneous solution. Phenol (0.40 g) was added and the solution was saturated at room temperature with dry hydrogen bromide and left at 60–65° in a stoppered flask. The reaction mixture was repeatedly monitored by ascending paper chromatography (phenol–ethanol–water, 3:1:1) and incubation was continued until the phenolic spot corresponding to *N*-tosylmimosine (R_f 0.78) failed to appear and only that corresponding to mimosine (R_f 0.27) was observed on development of the chromatogram with ferric chloride solution. This generally required 2–3 days but in some runs additional hydrogen bromide was passed into the solution after 3 or 4 days in order to complete hydrolysis. The cooled solution was diluted with dry ether (400 ml) and allowed to stand at 5° until the separation of mimosine hydrobromide was complete. The supernatant liquid was decanted and the residue repeatedly extracted with ether and then dissolved in water. The aqueous solution was basified with concentrated ammonium hydroxide and evaporated to dryness under reduced pressure. The remaining solid was repeatedly moistened with water and evaporated to dryness under reduced pressure to remove excess ammonia, and finally dissolved in hot water, decolorized with charcoal, and allowed to crystallize, yielding DL-mimosine (0.10 g, 45%) melting at 222–225° (decomp.). For analysis a sample was recrystallized from boiling water and the product filtered from the hot solution, to give anhydrous DL-mimosine, melting at 228–230° (decomp.). (Found: C, 48.7; H, 5.4; N, 14.1. Calculated for $C_8H_{10}N_2O_4$: C, 48.5; H, 5.1; N, 14.1%.) Dissociation constants (determined by half-titration of mimosine in 0.04 *M* aqueous solution with 0.10 *M* sodium hydroxide and 0.10 *M* hydrochloric acid, and application of water correction): pK_1, 2.1 (—COOH); pK_2, 7.2 (α-NH_3^+); pK_3, 9.2 (phenolic —OH). Only pK_2 was depressed in the presence of formaldehyde. Ultraviolet absorption (λ_{max}, mμ (log ε)): in water: 283 (410); in 0.07 *M* HCl: 277 (3.87); in 0.07 *M* NaOH: 309 (4.04). Infrared absorption (KBr) (cm^{-1}): 3400 (broad) (OH), 2900 (broad) (NH), 1640 (s) (C=O), 1588 (s) (COO^-), 1490 (s) (NH_3^+).

Mimosine from the Seeds of Leucaena glauca

Coarsely crushed dried seeds were pulverized to a fine powder in a ball mill. The powdered seeds (50 g) were placed into a dialysis bag (length 35 cm, cross section 3 cm) which was then filled with distilled water and completely immersed in distilled water (1 l.). After three changes of external solvent the dialyzate showed only a weak phenolic reaction. Each dialyzate was concentrated at reduced pressure to 25 ml, when almost pure product crystallized. Mimosine (0.61 g, 1.2%), melting at 227–228° (decomp.), after recrystallization from water, was obtained from 50 g of seeds. Dissociation constants: pK_1, 2.1; pK_2, 7.2 (α-NH_3^+); pK_3, 9.2 (OH). Ultraviolet absorption: (λ_{max}, mμ (log ε)): in water: 283 (4.11); in 0.07 *M* HCl: 277 (3.86); in 0.07 *M* NaOH: 309 (4.04). Infrared absorption (KBr) (cm^{-1}): 3400 (broad) (OH), 2850 (broad) (NH), 1640 (s) (C=O), 1590 (s) (COO^-), 1530 (s), 1490 (s) (NH_3^+).

Mimosine from Mimosa pudica (cf. Ref. 1)

The exudate from freshly cut green stems and petioles of *Mimosa* was aspirated into a lambda pipette. A sample (250 μl) was rubbed with ethanol (5 ml), when crude mimosine (12 mg) precipitated, which after treatment with charcoal and recrystallization from water melted at 224–226° (decomp.). A sample of exudate (250 μl) was evaporated to dryness in a vacuum desiccator to give a brown residue (39 mg) which was dissolved in water, decolorized with charcoal, and yielded mimosine, melting at 221–223° (decomp.).

A sample of exudate (250 μl) was dissolved in phthalate buffer (pH 4, 0.2 *M*) (3 ml), and applied to a cation exchange column (Dowex 50-X4) in the hydrogen form. Water eluted a fluorescent material which was not further investigated. Mimosine was displaced with ammonia (0.02 *M*). The eluate was concentrated *in vacuo* and dried in a vacuum desiccator over concentrated sulphuric acid, yielding mimosine (9 mg), melting at 225–226° (decomp.).

Paper Chromatography

Reaction mixtures and plant extracts were monitored by ascending paper chromatography on Whatman No. 1 paper, using phenol–ethanol–water, 3:1:1, as the solvent. Spots were developed with ferric chloride (1%) and/or ninhydrin (3% in acetone). Before development the papers were dried for 1 hour at 80° to ensure complete removal of phenol.

Under these conditions the following R_f values were found: 3-hydroxy-4-pyrone, R_f 0.83; 3-hydroxy-4-pyridone, R_f 0.70; *O*-methylmimosine, R_f 0.61; *N*-tosylmimosine, R_f 0.78; mimosine, R_f 0.27.

ACKNOWLEDGMENTS

We are greatly indebted to Professor R. Adams, University of Illinois, for a gift of *L. glauca* seeds; to Dr. H. Matsumoto, University of Hawaii, for a generous supply of ground seeds of Kao Haole; and to Dr. C. Lamoureux, University of Hawaii, for a gift of dried Kao Haole plants. We are also grateful to Mr. B. Lipinski, who, as a visiting fellow, took part in the early stages of this investigation.

Financial assistance by the National Research Council of Canada and by the Ontario Research Foundation is gratefully acknowledged.

ABSOLUTE YIELDS IN THE γ-RADIOLYSIS OF GASES[1]

R. A. BACK, T. W. WOODWARD,[2] AND K. A. MCLAUCHLAN[3]
Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received March 27, 1962

ABSTRACT

Absolute yields of hydrogen from the γ-radiolysis of hydrocarbon gases have been obtained by relating the hydrogen produced to saturation ion currents measured in the radiolysis vessel. Values for G_{H_2} of 1.28, 1.20, 6.25, 5.40, and 5.00 have been estimated for ethylene, propylene, propane, *n*-butane, and isobutane respectively. These values are consistently lower than those obtained previously with α-rays, and this is discussed as an effect of radiation quality. Arguments are advanced for the use of M/N, the yield per ion pair, rather than G, as a measure of yields in the radiolysis of gases.

Despite the very considerable amount of work done in recent years on the γ-radiolysis of gases, the dosimetry of these systems, especially the absolute dosimetry, is very far from satisfactory. Most workers have calculated G-values by a comparison with other gas-phase "dosimeters", such as ethylene, acetylene, or nitrous oxide, using a correction for differences in stopping power (usually simply an electron-density correction), although these "dosimeters" have never been well calibrated for gamma radiation. Others have simply estimated the energy absorbed from the measured γ-ray flux, with some assumption about an energy absorption coefficient for the gas, which can lead to large errors for gases at atmospheric pressure or lower. The basic difficulty in γ-ray dosimetry at these pressures is that in most cases the direct absorption of γ-radiation in the gas is quite negligible, and almost all the chemical effects are due to secondary electrons ejected from the walls of the irradiation vessel. The accurate estimation of absorbed energy becomes very difficult in this situation, especially in the absence of precise knowledge of the energy distribution of the electrons, and of their rate of energy loss in the gas.

Surprisingly little use has been made in the radiation chemistry of gases of the measurement of saturation ion currents in the gases themselves during irradiation. Essex and co-workers (1), using very weak sources of α-rays, have related chemical yields to saturation ion currents for a few gases, but the method has never been applied to γ-radiolysis systems. It appears to offer a very simple way to obtain absolute yields in the γ-radiolysis of gases, and the present paper describes the results of some measurements made with simple hydrocarbons.

EXPERIMENTAL

Unlike α-rays, γ-radiation cannot be restricted conveniently to a region between two parallel plates, so a cylindrical reaction vessel, shown in Fig. 1, was used in which the cylindrical wall itself was the collecting electrode. The vessel was made of 60-mm o.d. Pyrex tubing, while the cathode and guard ring consisted of graphite coatings, originally applied as colloidal graphite in aqueous suspension. The anode was a tungsten wire of 1.5-mm diameter, while tungsten leads through the glass walls made connections to the cathode and guard ring. The vessel was thoroughly baked under vacuum before its initial use, and before each experiment. In the initial baking at 400° C, a tarry material slowly distilled out, presumably formed from the decomposition of the suspension agent mixed with the graphite. After the first several hours of baking, no further material was ever evolved.

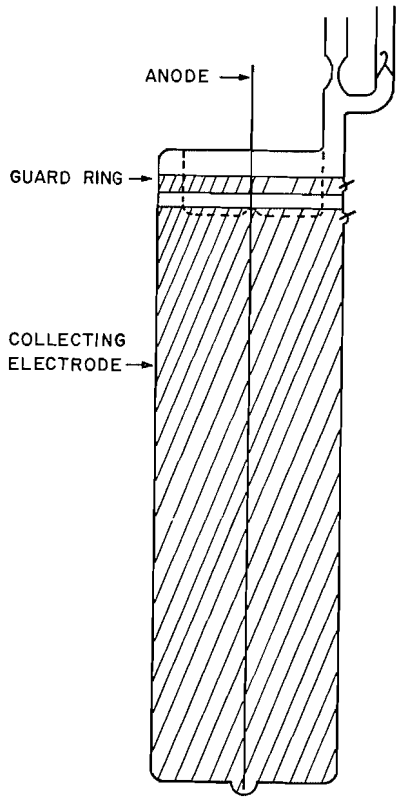

FIG. 1. Vessel used for γ-radiolysis of hydrocarbon gases, and for measurement of saturation ion currents

The preparation of the reaction vessel and the hydrocarbon gases, and the analytical techniques, were similar to those previously described (2). The hydrocarbons were all Phillips Research Grade, and showed no change in behavior upon careful treatment with sulphuric acid to remove any olefin present. Hydrogen was the only product accurately measured, and conversions were always low enough so that the yields were close to true initial values (2).

Ion currents were measured by passing the current from the collecting electrode to earth through a calibrated Rubicon spot galvanometer equipped with a suitable shunt. The guard ring was held at the same potential as the collecting electrode, while a variable high potential, up to 5 kv, could be applied to the central anode. Saturation ion currents were always measured at the beginning of the irradiation, and the time during which the field was applied was always negligible compared to the total time of irradiation, which was usually about 16 hours, and sometimes much longer. In a few experiments, ion currents were also measured at the end of the radiolysis period, and were found to be unchanged.

The source of γ-radiation was a Co^{60} unit, nominally of about 200 curies. The radiolysis vessel was mounted in an approximately reproducible position, end-on to the source, and about 8 inches away.*

RESULTS AND DISCUSSION

Figure 2 shows typical plots of ion current against applied voltage for ethylene and *n*-butane at 800 mm pressure. The slower approach to saturation in the latter is probably due partly to the higher electron density, with consequent higher rate of absorption of energy, higher ion concentrations, and hence faster gas-phase recombination, and partly to a slower diffusion of electrons and ions to the electrodes through the heavier gas. Similarly good saturation behavior was found with all the gases studied.

We are grateful to the Division of Applied Physics of these Laboratories for the use of the Co^{60} source.

‖Taken to be the same as n-butane.

shown are values of W, the average energy absorbed per ion pair, taken from the literature, and values of G_{H_2} calculated from the relation $G = (M/N) \times 100/W$. All the pure hydrocarbons in Table I were studied at 800 mm pressure and room temperature, and each of the values of $(M/N)_{H_2}$ represents an average of at least two experiments agreeing to $\pm 2\%$ or better. To all the data in Table I, a correction of about 5% was applied to take

into account the "dead space" around the guard ring and in the side arm from which ions were not collected and measured.

The systems with added ethylene scavenger, ranging from 3 to 10 mole%, were maintained at constant electron density, equal to that of the pure paraffin at 800 mm and 25° C. The data were then extrapolated back to 0% scavenger in a way similar to that described previously (2). The W-values then used in computing G_{H_2} for unscavengable hydrogen were those for the pure paraffin. The similarity of the values of W for paraffins and olefins, and the almost unchanged ion currents observed with added scavenger, justify this procedure.

Several features of the results in Table I deserve comment. The ratio of G-values obtained with and without scavenger for propane, butane, and isobutane are almost identical with those found previously by simple measurements of relative hydrogen yields (2). This indicates that olefin impurities were not affecting the results, and shows that the saturation ion current method at least yields reasonable relative values in the presence and absence of olefin scavenger.

The values of W shown in Table I, and used in the calculation of G_{H_2}, were estimated by a variety of means, as indicated, and while probably not very reliable, they are unlikely to be grossly in error. There is no direct information available about W-values for γ-radiation, as their measurement is practically impossible. The values of W appropriate to the secondary electrons which are effective in the present systems are probably close to those measured for β-radiation.

In the last column of Table I are some values of G_{H_2} taken from the literature. The agreement between our measured values for ethylene and propane and the more recent literature values for γ-radiation is quite good. The values of G_{H_2} for α-radiolysis of propane, *n*-butane, and isobutane are consistently much higher than our present measured values for γ-radiation. This may be a true effect of radiation quality, and, if so, is one of the few examples of such an effect to be observed in gases. The larger hydrogen yield found in the α-radiolysis might be explained by the neutralization of a large fraction of the hydrocarbon ions in the α-ray tracks, with subsequent decomposition of the highly excited neutral species. With γ-rays, especially at the low intensities used in the present work, neutralization could be predominantly at the wall, with stabilization of the resultant fragment or molecule, and a decreased yield of products. In some recent experiments (12), it has been found that a saturation field applied during the course of the γ-irradiation of *n*-butane and isobutane causes a decrease in $(M/N)_{H_2}$ of about 30%, which supports the suggestion that neutralization at a surface could cause a reduction in hydrogen yield. This also suggests that at least 30% of the ions in the γ-radiolysis normally do *not* reach the wall, but this would still allow enough neutralization at the wall to account for the difference between α- and γ-radiolysis.

The absolute values of G_{H_2} for α-radiolysis found by Back and Miller (11) depend essentially upon a single measurement of the strength of their polonium source, and while this is reasonably certain, some confirmation of these values would be very desirable. Freeman and Ramaradhya (13), in the only comparable work,* have reported a similarly

*It should be noted that all the early work on the α-radiolysis of hydrocarbons (3), using radon, was done at such high conversions that the reported values of hydrogen yields are undoubtedly much lower than the initial ones, due to scavenging effects of products, and cannot be usefully compared with more recent measurements. Even in the work of Essex and Williams (14), using the saturation-current method in the α-radiolysis of ethane, and from which $G_{(H_2+CH_4)} = 5.7$ can be computed, the conversion of about 0.05% which was attained was high enough so that much of the original scavengeable hydrogen must have been lost, so that the higher value of $G_{H_2} = 8.8$ found recently by Yang and Gant (8) for the γ-radiolysis of ethane at much lower conversions probably does not represent a reversal of the dependence on radiaton quality discussed above.

"high" value of $G_{H_2} = 8.0$ for the α-radiolysis of cyclohexane vapor, which is again much higher than the values reported for β- and γ-radiation, although the latter data are very uncertain. Thus while there is some confirmation of a strong dependence on radiation quality in these systems, further measurements with both α- and γ-radiation, particularly the former, would be very useful.

Finally, some cogent arguments may be advanced for the general use of M/N rather than G as a measure of absolute yields in the radiolysis of gases. Both quantities are empirical, but G depends upon the measurement of total energy absorbed in the gas, which is almost impossible to determine directly for γ-radiation, and is usually estimated by some rather arbitrary, indirect, and uncertain method of dosimetry. M/N, on the other hand, when measured by the saturation-current method, is obtained directly from two well-defined and easily measured quantities. The saturation-current method is applicable to most gases, and to all types of radiation, and should be very useful in the comparison of results in different systems and from different laboratories. The use of M/N was, of course, common in the early days of radiation chemistry, when it was regarded as somewhat akin to a quantum yield. It fell into disrepute when it became evident that processes other than ionization could be important in radiolysis. However, M/N is still a more fundamental quantity than G, and a more directly useful one, especially for relating radiolysis products to mass spectra, as has become very popular recently. It is generally realized today that radiolysis mechanisms are undoubtedly very complex, and there seems to be little danger now that anyone would assume that the use of M/N implied a one-to-one relation between ion pairs and product molecules. Thus the reinstatement of M/N as a respectable quantity in the radiolysis of gases appears to offer few drawbacks and several distinct advantages. If W, the average energy dissipated per ion pair, could be more easily measured, then M/N and G would of course be readily interchangeable.

HYDROGEN FORMATION IN γ-IRRADIATED HYDROGEN CHLORIDE

D. A. ARMSTRONG

Department of Chemistry, University of Alberta, Calgary, Calgary, Alberta

Received March 9, 1962

ABSTRACT

Hydrogen yields from pure liquid and solid hydrogen chloride irradiated with Co^{60} γ-rays were G_{H_2}(liquid) = $6.5_0 \pm 0.1_0$ and G_{H_2}(solid) = $3.3_0 \pm 0.1_0$ at −79° C and −196° C respectively. The yield from solid hydrogen chloride was only slightly reduced by the addition of chlorine; but the yield from liquid samples was reduced sharply by low concentrations of chlorine to a value of about 4.5, and then much more gradually by larger concentrations. A G_{H_2} value of 2.1 persisted at 10 mole% chlorine. The results were interpreted in terms of the formation of hydrogen in the reactions

$$H + HCl \rightarrow H_2 + Cl \quad [11]$$

and

$$H\ (hot) + HCl \rightarrow H_2 + Cl. \quad [11^*]$$

Reduction of the hydrogen yields by chlorine was attributed to the reactions

$$H + Cl_2 \rightarrow HCl + Cl \quad [15]$$

and

$$H\ (hot) + Cl_2 \rightarrow HCl + Cl. \quad [15^*]$$

Values of k_{11}/k_{15} and k_{11}^*/k_{15}^* were estimated to be 1.7×10^{-3} and 0.10 respectively, while those of G_H and $G_{H(hot)}$ were 2.4 ± 0.2 and 4.0 ± 0.2. Electron scavenging by chlorine was considered as a less likely mechanism for reduction of the hydrogen yield. Sources of the thermal and hot hydrogen atoms were examined and it was suggested that the decomposition of electronically excited molecules might be an important mode of decomposition.

INTRODUCTION

The decomposition of hydrogen halides by ionizing radiation has long been a subject of interest. Most of the earlier work was carried out with radon α-particles (see for example ref. 1), but more recently, Zubler, Hamill, and Williams (2) have irradiated gaseous hydrogen bromide with X rays. In this study the results were interpreted according to the mechanism of Eyring, Hirshfelder, and Taylor (3). Although it was suggested that the dissociation of electronically excited molecules might make a small contribution, most of the observed decomposition was considered to result from the ionization of hydrogen bromide molecules. Very few studies of the radiolysis of hydrogen halides in the liquid and solid states have been reported, and it seems that the effects of free-radical scavengers on the hydrogen and halogen yields have never been investigated. The present work was therefore initiated with the intention of extending our knowledge of the radiation chemistry of these compounds to condensed phases, and of determining the effect of scavengers on the product yields. This paper describes the results of an investigation of the radiolysis of liquid and solid hydrogen chloride (hereafter referred to as HCl). The effect of chlorine and ethylene on the hydrogen yields is also reported.

EXPERIMENTAL

Apparatus

A mercury-free vacuum line for purifying and storing HCl and chlorine was fitted with an oil diffusion pump and constructed so that samples of hydrogen and other volatile gases could be transferred from it via the oil diffusion pump to a conventional hydrogen analysis system. This feature permitted repeated irradiations of the same sample of hydrogen chloride without its being contaminated with mercury vapor from the analysis system. Pyrex bulbs and traps were provided for purifying the gases and storing them at liquid

nitrogen temperature, and a set of calibrated bulbs was used for measuring out samples of chlorine. These were connected to one side of a differential diaphragm manometer, the other side of which was attached to an auxiliary vacuum line with a conventional mercury manometer. Chlorine pressures were read on the mercury manometer, the differential manometer being used as a "null" instrument to equate the pressure in the auxiliary line to that of the chlorine in the calibrated bulb. The measured quantity of chlorine was distilled into the irradiation cell prior to the introduction of the HCl.

The 16-mm O.D. pyrex irradiation cells were cleaned by standard techniques and attached to the vacuum line via capillary "seal off" tubes. They were provided with "break seals" for re-entry into the vacuum line after radiolysis and were flamed to the sodium emission temperature under vacuum before the reagents were introduced. After they had cooled a small quantity of HCl was introduced and left in them for about 30 minutes to displace or react with possible contaminants adsorbed on the walls. The cells were then reflamed while the HCl was pumped out to an ultimate pressure of 5×10^{-6} mm of Hg.

A 200-curie Co^{60} source, housed in a concrete cave, was used for the radiolysis. Liquid HCl samples were irradiated at $-79°$ C in a dry ice – alcohol bath. Solid samples were irradiated at $-196°$ C in liquid nitrogen. The Fricke dosimeter was used and corrections were made for the different electron density of HCl. Chlorine molecules would undoubtedly have contributed a certain fraction of the total primary absorption of γ-rays in the system. However, they should also have absorbed a roughly equivalent fraction of the energy of the electrons set in motion in the medium. In solutions containing chlorine, the dose was therefore calculated for HCl alone, and energy absorption by chlorine was neglected.

Materials

Chlorine (99.5% minimum purity) from a Matheson lecture bottle was purified by bulb-to-bulb distillation and stored in a liquid nitrogen trap. Degassed hydrogen chloride of 99.0% minimum purity, also obtained from Matheson, was purified from hydrogen bromide and other impurities by preirradiation for a day or by treatment with chlorine. Both procedures oxidized the hydrogen bromide to bromine, which (together with excess chlorine) was subsequently removed by passage through copper foil. The hydrogen chloride was then stored in a liquid nitrogen trap. Samples for irradiation were further purified by sublimation from a trap at $-100°$ C through a second trap at the same temperature into a liquid nitrogen trap. A second sublimation from $-100°$ C to a calibrated bulb followed. The required quantity of this HCl was then roughly measured out as a liquid at its melting point and sublimed into the irradiation cell. Ethylene was purified in the same way as the chlorine.

Analytical Apparatus and Technique

The hydrogen analysis system, consisting essentially of a McLeod Gauge and Toepler pump, was similar to that described by Allen and co-workers (4) except that a palladium thimble was used, in place of the combustion technique, for identification of the hydrogen.

The liquefied HCl samples were shaken after irradiation to equilibrate the dissolved hydrogen with that in the vapor phase, and then frozen. All the non-condensable gas was introduced into the analytical apparatus by either connecting the irradiation cells directly to it or by connecting them to the purification system and transferring the gas with the diffusion pump. There was no difference between hydrogen yields measured by these two methods, and the hydrogen content of this first sample of gas was usually 95% or better. After melting and refreezing the hydrogen chloride a second portion of non-condensable gas was taken off. Its hydrogen content was usually about 10% of the first, and that of further degassings was negligible.

After the hydrogen had been extracted the HCl was either purified from halogen and transferred to another cell for a second irradiation or absorbed in water and titrated with standard sodium hydroxide to determine accurately the size of the sample. The latter was the eventual fate of all HCl samples except those with an appreciable concentration of chlorine. These were absorbed in standard sodium hydroxide and "back-titrated" to determine the total chloride. The original molecular chlorine content was then determined from the hypochlorite formed by iodimetry, and the HCl by difference. The chlorine content determined in this way agreed within a few percent with the gas phase measurement. The quantity of HCl used was usually in the range 2.4 to 2.7 g.

RESULTS

Hydrogen yields from pure liquid HCl and from solutions of ethylene and chlorine in liquid HCl have been plotted as a function of dose in Fig. 1. In all cases they were linear with dose over the range used, and for pure HCl repeated irradiation of the same sample to a total dose of 5×10^{19} ev/g produced no change in the hydrogen yield. The yields were reproducible to within $\pm1\%$ when reasonably large doses were used. The absolute accuracy is probably ±0.1 G units.

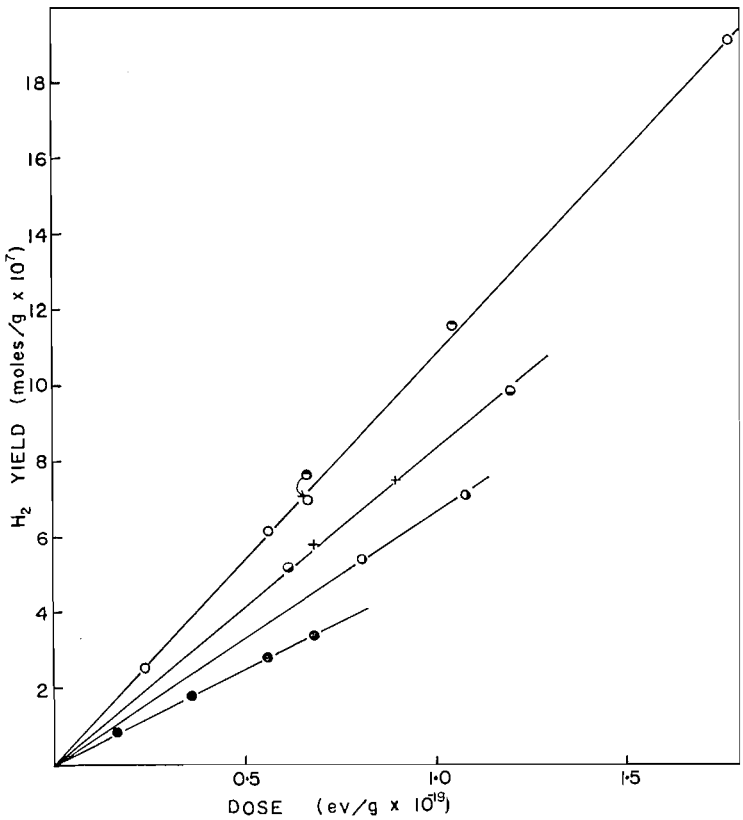

FIG. 1. Hydrogen yields from liquid HCl at −79° C plotted against absorbed dose: ○ pure HCl; ◓ HCl + NO (10^{-2} *M*); ◒ HCl + C_2H_4 (5.6×10^{-1} *M*); + HCl + Cl_2 ($7.1_7\times10^{-2}$ *M*); ◑ HCl + Cl_2 (4.65×10^{-1} *M*); ● HCl + Cl_2 (1.52 *M*).

It can be seen from Fig. 1 that ethylene was by far the less efficient of the two scavengers, and very high concentrations of it would have been required to reduce the hydrogen yield to the levels achieved with chlorine. In view of this and of the fact that there is a free-radical chain addition reaction between ethylene and HCl (5), which would have consumed the olefin, chlorine was chosen as the scavenger most suitable for detailed study. In the two experiments which were conducted with ethylene a small quantity of nitric oxide was added to inhibit the chain reaction. This quantity of nitric oxide was shown to be without effect on the hydrogen yield, but its efficiency as an inhibitor can only be presumed until a detailed study of the reaction is made.

The results for solutions of chlorine at several different concentrations in HCl have been summarized in Fig. 2. The hydrogen yields have been plotted as G_{H_2} values against the corresponding solute concentrations and it can be seen that an abrupt decrease in hydrogen yield from 6.5 to 4.5 resulted over the concentration range $0\text{-}2\times10^{-4}$ mole chlorine/g HCl. Further addition of chlorine caused a much more gradual decrease. A G_{H_2} value of 2.1 was finally reached at a chlorine concentration of 2.9×10^{-3} mole/g or about 10 mole%. Obviously, two hydrogen-forming species, which are scavenged with different efficiencies by chlorine, must be present.

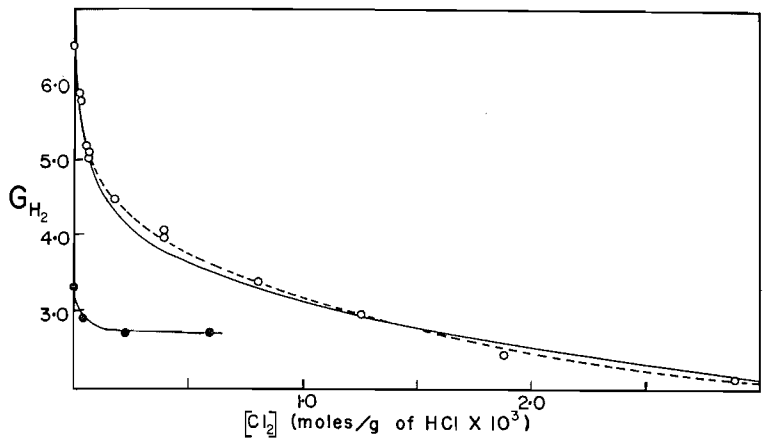

FIG. 2. Values of G_{H_2} plotted against chlorine concentration, which is expressed in moles/g HCl: ○ liquid HCl at −79° C; ● solid HCl at −196° C.

Note: The curves are theoretical and were calculated on the basis of equation [ii]: —— values of G_H, G_{H^*}, k_{15}/k_{11}, and k_{15}^*/k_{11}^* uncorrected; - - - values of G_H, G_{H^*}, k_{15}/k_{11}, and k_{15}^*/k_{11}^* corrected by successive approximation.

Hydrogen yields from pure HCl samples irradiated in the solid state were much lower than those from liquid HCl, and showed a tendency to decrease with dose. Yields were therefore measured at the minimum practical dose ($\sim 2\times10^{18}$ ev/g), and these have been presented in Fig. 2. The addition of chlorine to these samples had a much less pronounced effect than in the liquid samples. A concentration of 2×10^{-4} mole chlorine/g HCl caused a decrease in G_{H_2} from 3.3 to 2.7 and further addition of chlorine appeared to have little or no effect. It may be concluded from this that the more readily scavenged species does not produce much hydrogen in the solid state. Experiments with still larger amounts of chlorine (10 mole%) would have shown whether the second species was scavenged by chlorine with the same efficiency in the solid state as in the liquid state. This information is obviously highly desirable, but such experiments were not conducted because of the difficulty of obtaining homogeneous solid solutions of high concentration.

DISCUSSION

At this point it will be convenient to review briefly the ionic reactions which are likely to occur in irradiated HCl. Mass spectrometric studies (6, 7) have demonstrated the formation of the following positive ions on bombardment of HCl with electrons: HCl^+, HCl^{++}, Cl^+, Cl^{++}, and H^+. From the data of reference 7 the approximate relative abundances of the first four of these may be estimated to be 100:2:10:12 respectively at electron impact energies of 150 ev. The parent ion (HCl^+) is thus by far the most abundant ion in the mass spectrum, and it may be inferred that this will also be the predominant ionic species formed in irradiated HCl:

$$HCl \text{ —}\sim\sim\rightarrow HCl^+ + e. \qquad [6]$$

A consideration of the electron-stopping power and electron density (3.5×10^{23} electrons/ml) of HCl in the liquid state at −79° C leads to the conclusion that the L.E.T. (and hence the distribution of ions along the radiation tracks) should not be very different from that occurring in liquid water for the same type of radiation.

Secondary electrons ejected from the ionized molecules would lose energy to the liquid medium and might eventually become thermalized. Because of the comparatively small dielectric constant of HCl (approx. 10 at −79° C (8)), interionic forces would be large and thermalized electrons would be unlikely to escape recombination with positive ions. They would probably give rise to energetic radicals through dissociative combinations:

$$e + HCl^+ \rightarrow HCl^* \rightarrow H + Cl + \text{energy.} \qquad [7]$$

As usual, the time required for the thermalization and return to the positive ions cannot be determined with any degree of certainty. However, as a first approximation it may be assumed that this period will be similar to that estimated by Samuel and Magee for electrons in liquid water ($\sim 10^{-13}$ sec, see ref. 9). Obviously, other ionic processes which could occur within this time and lead to alternative decomposition mechanisms must also be considered.

The reaction

$$HCl^+ + HCl \rightarrow H_2Cl^+ + Cl \qquad [8]$$

has been shown to proceed with a rate constant of 4.4×10^{-10} ml/molecule sec in the gas phase (10). Assuming the same rate constant in liquid HCl, where the concentration of HCl molecules is $1.9_7 \times 10^{22}$/ml, it can readily be shown that the lifetime of HCl^+ ions with respect to this reaction should be of the order of 10^{-13} sec. Hence reaction [8] could conceivably precede ion recombination, and reactions [9*a*] and [9*b*]:

$$e + H_2Cl^+ \rightarrow H + HCl + \text{energy} \qquad [9a]$$

$$\rightarrow H + H + Cl + \text{energy,} \qquad [9b]$$

must be regarded as alternatives to reaction [7].

Several investigations of the electron resonance capture reaction:

$$e + HCl \rightarrow H + Cl^-, \qquad [10]$$

have recently been reported (11–13). The value of the energy threshold in the gas phase is virtually the same as the calculated endothermicity (0.65 ev), and most studies indicate that the capture cross section passes through a maximum at about 0.8 ev and then falls to a very low value at 1.5 ev. Obviously during the course of their thermalization in liquid HCl the secondary electrons must pass through this energy range. Their lifetime with respect to capture while in it can be estimated using the data of Buchelnikova (mean cross section for the above energy range $\simeq 2 \times 10^{-18}$ cm^2/molecule in the gas phase) and the concentration of molecules in liquid HCl. This lifetime again turns out to be of the order of 10^{-13} sec. Thus the possibility of capture cannot be excluded. Furthermore, there is strong evidence for hydrogen bonding (14) in the condensed phases of the hydrogen halides, and Cl^- ions are known to associate strongly with HCl molecules (15–17). Thus the reaction

$$e + H\text{—}Cl \cdots H\text{—}Cl \rightarrow H + Cl\text{—}H\text{—}Cl^- \qquad [10a]$$

should replace reaction [10] in liquid HCl. Because of the greater thermodynamic stability of the $ClHCl^-$ ion, the endothermicity of this reaction should be less than that of reaction [10]. Electron capture would therefore be extended to lower energies than in the gas phase, and could in fact be the exclusive fate of secondary electrons in liquid HCl. If formed in reaction [10*a*] the $ClHCl^-$ ions would diffuse relatively slowly. There would

then be no doubt that reaction [8] would occur prior to neutralization. The H_2Cl^+ and $ClHCl^-$ ions would react according to the equation

$$H_2Cl^+ + ClHCl^- \rightleftharpoons 3HCl. \qquad [10b]$$

This reaction is the reverse of the self-ionization process in HCl, for which there are now at least two independent sources of evidence (16, 17).

From the preceding discussion it can be seen that several reaction paths of the "Samuel–Magee" type are possible in liquid HCl: reactions [6]–[7]; reactions [6]–[8]–[9*a*]; and reactions [6]–[8]–[9*b*]. These are all likely to produce "hot" hydrogen atoms. As in the case of HBr the decomposition of electronically excited molecules must be included, and present knowledge (18) of the energy levels of the HCl molecule indicates that dissociation to H and Cl atoms in their ground states would occur, with the fragments gaining a considerable excess of kinetic energy (up to about 50 kcal). Most of this energy would again be acquired by the hydrogen atoms (cf. the photolysis of HBr and HI, ref. 20). The fraction of the hot hydrogen atoms from these sources which would be thermalized before reacting with HCl (see reaction [11*] below) should be comparatively small. "Hot-atom effects" similar to those observed in other irradiated systems are therefore to be expected. In contrast to the above processes the alternative "Lea" type decomposition path involving reactions [6], [8], [10*a*], and [10*b*] should produce hydrogen atoms of thermal or comparatively low energies.

Hydrogen and chlorine atoms may undergo the following reactions in HCl:

$$H + HCl \rightarrow H_2 + Cl \qquad [11]$$

$$H\ (hot) + HCl \rightarrow H_2 + Cl \qquad [11^*]$$

$$H + Cl + M \rightarrow HCl + M \qquad [12]$$

$$H + H + M \rightarrow H_2 + M \qquad [13]$$

$$Cl + Cl + M \rightarrow Cl_2 + M. \qquad [14]$$

The activation energy of reaction [11] is considered to be about 5 kcal (19). Assuming identical steric factors for all of the above reactions and activation energies of zero for the last three, simple calculation shows that the ratio of k_{11} to k_{12} or k_{15} at $-79°$ C should have a value of about 10^{-5}. The excessively large concentration of HCl in the pure liquid at $-79°$ C would be more than sufficient to compensate for this, and only a few hydrogen atoms would be expected to take part in reactions [12] and [13]. At $-196°$ C, however, the ratio of k_{11} to k_{12} or k_{15} would be of the order of 10^{-11} and hardly any thermal hydrogen atoms would react with HCl. Hot hydrogen atoms on the other hand should react almost exclusively with HCl at both temperatures. The large difference between the hydrogen yields in the solid and liquid samples of HCl can thus be attributed largely to loss of the hydrogen which is formed in reaction [11] at the higher temperature. The slight effect of chlorine in the solid phase may be due to the scavenging of thermal hydrogen atoms, which would otherwise have undergone reaction [13]. The remainder of the hydrogen yield, $G_{H_2} = 2.7$, at $-196°$ C must be formed in reaction [11*], and therefore gives a measure of the yield of hot hydrogen atoms, G_{H^*}. It seems that this is considerably less than in the liquid (see below).

As products accumulated in the system, reactions [15] and [16] would have been expected:

$$H + Cl_2 \rightarrow HCl + Cl \qquad [15]$$

$$Cl + H_2 \rightarrow HCl + H. \qquad [16]$$

In pure HCl their occurrence would have resulted in a decrease in the hydrogen yield at higher doses. Since the yields in liquid HCl were linear, we may consider that reactions [15] and [16] were negligible for the small chlorine and hydrogen concentrations which accumulated during the radiolysis. However, in the more concentrated synthetic solutions of chlorine in HCl reaction [15] must have been occurring, but it appears that reaction [16] was still insignificant since the yields remained linear. Hence in all cases the hydrogen yields from liquid HCl may be regarded as true "initial" yields unaffected by secondary radical reactions. The tendency for the yields from solid HCl to decrease with dose may be attributed in part to reaction [15], and also to reaction [12] since chlorine atoms would have been trapped in the solid matrix and their concentration should have built up to a fairly high level at the larger doses.

At the concentration employed ethylene could only have reacted with the thermal hydrogen atoms:

$$H + C_2H_4 + M \rightarrow C_2H_5 + M. \qquad [17]$$

Reduction of the hydrogen yield by it may be taken as further evidence for the formation of hydrogen in reaction [11]. Chlorine, on the other hand, may react with electrons:

$$e + Cl_2 \rightarrow Cl^- + Cl, \qquad [18]$$

as well as with thermal hydrogen atoms. Reduction of the hydrogen yield might then arise in three ways: (*a*) a competition between reaction [18] and reactions [7] or [9]; (*b*) a competition between reactions [18] and [10*a*]; and (*c*) a competition between reactions [15] and [11]. If it is assumed that the last competition (*c*) is responsible for the reduction in the hydrogen yield, then the usual steady-state approximation leads to the equation

$$\frac{1}{\Delta G_{H_2(S)}} = \frac{1}{G_H}\left\{1+\frac{k_{11}(HCl)}{k_{15}(Cl_2)_S}\right\}. \qquad [i]$$

$\Delta G_{H_2(S)}$ is the reduction of the total hydrogen yield at chlorine concentration $(Cl_2)_S$ and G_H is the yield of thermal hydrogen atoms, which in the absence of chlorine would have undergone reaction [11]. A similar treatment of alternative (*b*) above would have yielded an analogous expression except that G_e, k_{10}, and k_{18} would have replaced G_H, k_{11}, and k_{15} respectively. A plot of $1/\Delta G_{H_2}$ against $1/(Cl_2)$ for all but the two very dilute solutions of chlorine in HCl, which have very large possible errors in ΔG_{H_2} ($\pm 10\%$) and do not warrant inclusion, has been given in Fig. 3. This plot resolves into two parts: a linear portion corresponding to the low chlorine concentrations at which the abrupt decrease in hydrogen yield occurred and a second steeply curving portion which intercepts the Y axis at about 0.15. As would have been expected this intercept corresponds to a total ΔG_{H_2} of 6.5 at infinite chlorine concentration. The intercept for the linear portion, $1/G_H$, gives a value of 2.6 for the yield of thermal hydrogen atoms in the system and from the slope a value of $1.9\pm0.2\times10^{-3}$ was calculated for k_{11}/k_{15}. Klein and Wolfsberg (21) have recently shown that the ratio of k_{11} to k_{15} for thermal hydrogen atoms in the gas phase is given by the equation $k_{11}/k_{15} = (0.14_3\pm0.03)\exp -(1540/RT)$. Extrapolation of their data to the temperature used in this study predicts a value of 2.5×10^{-3}. The substantial agreement of this figure with the present result strongly supports the assumption made above, and the calculations in the following paragraph are based on it. However, as already indicated, electron scavenging could give rise to entirely analogous effects. It should not, therefore, be categorically excluded at this time.

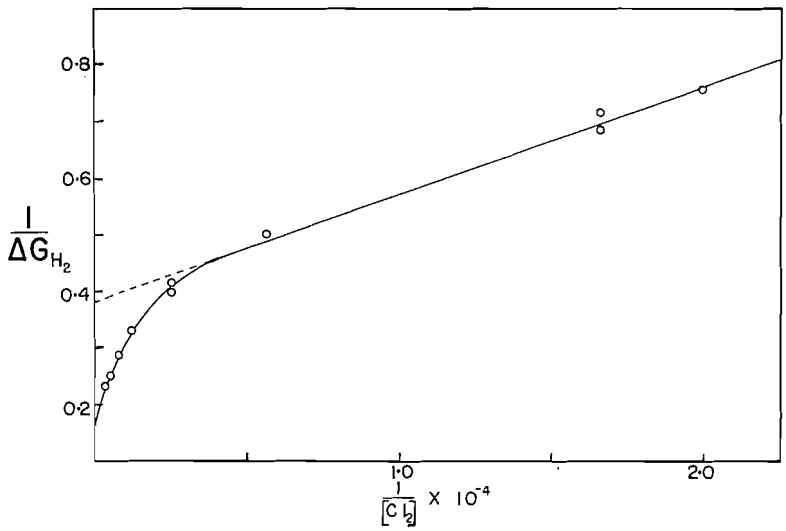

FIG. 3. The reciprocal of the reduction in the hydrogen yield ($1/\Delta G_{H_2}$) plotted against the reciprocal of the chlorine concentration ($1/(Cl_2)$).

Reaction [11*] appears to be the most reasonable process which can account for the relatively large hydrogen yield persisting in the presence of 10 mole% chlorine. On the assumptions that a competition between reaction [15*]:

$$H\ (hot) + Cl_2 \rightarrow HCl + Cl, \qquad [15^*]$$

and reaction [11*] is responsible for the reduction in the hydrogen yield at the higher chlorine concentrations, and that H and H (hot) are formed and react independently, equation [ii] may be derived:

$$G_{H_2(total)} = G_{H_2} + G_{H_2^*} = G_H \frac{1}{1+\frac{k_{15}(Cl_2)}{k_{11}(HCl)}} + G_{H^*} \frac{1}{1+\frac{k_{15}(Cl_2)}{k_{11}(HCl)}}. \qquad [ii]$$

Here G_H and G_{H^*} represent the yield of H and H (hot) in the system and are assumed to be independent of chlorine concentration. G_{H_2} and $G_{H_2^*}$ are their contributions to the total hydrogen yield, $G_{H_2(total)}$. Using this equation along with G_H and k_{15}/k_{11} determined above, G_{H_2} may be calculated and subtracted from $G_{H_2(total)}$ to give $G_{H_2^*}$. The values of $G_{H_2^*}$ determined in this way remained constant until a Cl_2 concentration of 2×10^{-4} mole/g Cl_2 was reached, and only then did they decrease in a regular manner. The initial constancy is no doubt due to the assumption which was implicit in the calculation of G_H and k_{15}/k_{11}, namely that the entire ΔG_{H_2} at the lower chlorine concentrations was due to thermal hydrogen atom scavenging. By substituting the values of $\Delta G_{H_2^*}$ for the higher chlorine concentrations into an equation analogous to [i] and using $G_{H^*} = 6.5_0 - 2.6_0 = 3.9_0$, the rate constant ratio k_{15}^*/k_{11}^* can be evaluated. The figure obtained, 0.13, was then used to correct ΔG_{H_2}, and thus to evaluate G_H, G_{H^*}, k_{11}/k_{15}, and, in turn, k_{15}^*/k_{11}^* more accurately. This method of successive approximation gave: $G_H = 2.3$; $G_{H^*} = 4.2$; $k_{15}/k_{11} = 1.7\times10^{-3}$; and $k_{15}^*/k_{11}^* = 0.1_0$. These values differ little from the original ones and k_{15}^*/k_{11}^* is still comparable to the pre-exponential factor of Klein and Wolfsberg, which would seem to be a reasonable ratio for the rate constants concerned.

The validity of equation [ii] was further tested by inserting the values of the four parameters and calculating the total hydrogen yield, $G_{H_2(total)}$. The "solid curve" in Fig. 2 was obtained with the uncorrected parameters and the "dashed curve" with those found by successive approximation. The agreement in the latter curve is a clear indication that the results can be explained on the basis of chlorine scavenging first thermal hydrogen atoms and then highly energetic ones.

Although an unequivocal choice of the origin of the hot hydrogen atoms is not at present possible, it should be pointed out that at high concentrations chlorine would be expected to react both with electrons and with positive ions in the exothermic charge-transfer reaction:

$$HCl^+ + Cl_2 \rightarrow HCl + Cl_2^+. \qquad [19]$$

If reactions [7] and [9] are responsible for the formation of the hot hydrogen atoms, chlorine should then behave as a dual scavenger, removing both the hot atoms and their precursors. A much more drastic reduction in the hot-hydrogen yield would therefore have been expected in the presence of 10 mole% chlorine. In view of this it may be suggested that electronically excited molecules and not ions are the precursors of the hot atoms. As indicated earlier in the discussion, reaction [10*a*] is a very likely source of the thermal hydrogen atoms.

Further work with other scavengers of different types is now in progress and the effects of these on the chlorine yield will also be investigated.

ACKNOWLEDGMENTS

The author wishes to express his appreciation to the Chemistry and Metallurgy Division of Atomic Energy of Canada Ltd. for a summer appointment in 1960. He also acknowledges many helpful discussions with Dr. F. C. Adam and other members of the University of Alberta, Calgary, Chemistry Department.

SULPHONIUM SALT SOLVOLYSIS

PART III. NUCLEOPHILIC ROLE OF ANIONS IN SOLVOLYSIS OF DIMETHYL-*t*-BUTYL SULPHONIUM SALTS

J. B. HYNE AND J. H. JENSEN
Department of Chemistry, University of Alberta, Calgary, Alberta

Received March 22, 1962

ABSTRACT

The effect of variation of added anion type (I^-, Cl^-, NO_3^-, ClO_4^-, CH_3COO^-) on the kinetics of solvolysis of dimethyl-*t*-butyl sulphonium ions is interpreted as evidence supporting a nucleophilic role for the anion in low-polarity solvents. The specific case of acetate is discussed in terms of its relation to biochemical transmethylation reactions involving methionine.

INTRODUCTION

In the previous paper of this series (1) it was suggested that the anion plays an increasingly important role as a nucleophilic species in the solvolysis of sulphonium salts as the polarity of the solvent medium is reduced. In the particular case of solvolysis of dimethyl-*t*-butyl sulphonium salts in ethanol–water mixtures, it has been shown (1, 2) that in highly aqueous media the rate of solvolysis is independent of anion character, in keeping with the S_N1-type mechanism involving the production and subsequent fast solvolysis of the *t*-butyl carbonium ion. As the solvent polarity is decreased by increasing the ethanol content the observed rate of solvolysis becomes increasingly dependent on anion type. The form of this dependence has been analyzed in terms of a kinetic expression involving the onset of both ion pairing and a nucleophilic role of the anion (2) as solvent polarity diminishes. Previous experimental study of such solvolyses has been limited to a narrow range of anions of relatively similar nucleophilicities (e.g. the halides). In order to investigate further the possible nucleophilic role of the salt anions in solvolysis we report here a series of kinetic studies of the solvolysis of dimethyl-*t*-butyl sulphonium salts in highly ethanolic solvent media with variation of anion over the series I^-, Cl^-, NO_3^-, ClO_4^-, and CH_3COO^-.

EXPERIMENTAL

All kinetic studies were carried out by the radiochemical gas flow counting technique used in previous work (1, 2) and described by Hyne and Wolfgang (3). Labelled (C^{14}-methyl) dimethyl-*t*-butyl sulphonium iodide was prepared as described previously (3) and metathesized with the corresponding silver salts. In a few cases this metathesis was not carried out so that the kinetic system contained 10^{-3} *M* iodide in addition to the anion concentration of the added salt. It was found that the effect of this iodide ion was very small at the high concentrations of added salt used and was within the experimental uncertainty of the kinetic data. All working solutions were 10^{-3} *M* sulphonium salt in 0.945 mole fraction ethanol–water mixtures. Added anions were I^-, Cl^-, CH_3COO^-, NO_3^-, and ClO^-_4 in the form of their lithium salts. In a few selected runs potassium salts were used instead of lithium to check the independence of rate on cation type. This was found to be true in every case tested. All salts were vacuum-dried and assayed for water of crystallization. Since our primary interest in this work was in the dependence of k_{ip}' (see equation [1]) on anion nucleophilicity, rate investigations were limited to the linear portion of the k_{obs} vs. $[X^-]$ relationship, i.e. higher added salt concentration. In the acetate case, however, rate studies were carried out over the complete range of added salt concentrations. All rates were run at 69.46° C and rate analysis from the log (counts/min) versus time plots (see ref. 3) were made by least mean square analysis on an IBM-1620 computer. Rate data are presented in tabular form in Table I and plotted in Fig. 1.

TABLE I

Overall rate of solvolysis (rate of production of dimethyl sulphide) for dimethyl *t*-butyl sulphonium salts in 0.945 mole fraction ethanol in water at 69.46° C as a function of added anion (LiX) concentration

$[X^-]\times10^3$ (molar)	$k_{obs}\times10^4$ (sec^{-1})	$[X^-]\times10^3$ (molar)	$k_{obs}\times10^4$ (sec^{-1})	$[X^-]\times10^3$ (molar)	$k_{obs}\times10^4$ (sec^{-1})
CH_3COO^-		I^-		NO_3^-	
3.39	2.84	22.4	3.39	13.39	2.30
5.83	3.08	28.1	3.45	25.90	2.29
10.17	3.12	28.2	3.35	44.63	2.40
10.54	3.39	44.7	3.66	50.96	2.38
14.60	3.51	56.6	3.90	75.00	2.48
19.02	3.69	56.6	3.88		
24.92	3.73				
25.36	3.67	Cl^-		ClO_4^-	
36.07	3.96	13.01	2.91	13.88	2.31
46.98	4.12	26.55	3.05	25.20	2.35
58.10	4.28	39.57	3.20	44.94	2.32
58.85	4.12	53.72	3.22	66.91	2.37
69.77	4.42	71.47	3.31	74.21	2.36
70.70	4.50				
83.04	4.68				

NOTE: No added salt $k_{obs} = 2.34\pm0.02\times10^{-4}$ sec^{-1}.

DISCUSSION

A rate equation was previously derived (1) which described the observed solvolytic rate behavior (k_{obs}) as a function of anion concentration $[X^-]$. This equation has the form

$$[1] \qquad k_{obs} = \frac{k_+ + k_{ip}K_A[X^-] + k_{ip}'K_A[X^-]^2}{1+K_A[X^-]},$$

where k_+ is the rate of S_N1 solvolysis of the sulphonium ion predominating in high-polarity solvent media; k_{ip} is the rate of reaction of the sulphonium ion pair (association constant K_A) and is possibly associated with an S_Ni mechanism where the ion-pair anion acts internally as a nucleophile; and k_{ip}' is the rate of nucleophilic attack of an external anion on the ion pair and predominates at high added anion concentration, accounting for the observed linear dependence of k_{obs} on $[X^-]$ (see Fig. 1). As was shown in the previous paper (1), equation [1] reduces to the approximate form [2] at higher $[X^-]$, where $K_A[X^-]$ becomes large compared with unity and k_+:

$$[2] \qquad k_{obs} \doteq k_{ip} + k_{ip}'[X^-].$$

According to equation [2] approximate values for both k_{ip}' and k_{ip} can be obtained from the slope and intercept of the linear sections of the plots in Fig. 1. The rate values thus obtained are tabulated in Table II. If the postulated mechanism involving a nucleophilic role for the anion in both the k_{ip}' and k_{ip} rate steps is correct, we would expect the k_{ip}' and k_{ip} values to be related to the nucleophilicity of the anion.

In Table II nucleophilicity **n** values (4) are recorded for the anions used. Since the nucleophilicity constants are derived from a free-energy type of relationship ($\log k/k_0 = S\mathbf{n}$), $\log k_{ip}'$ rather than k_{ip}' is plotted against **n** in Fig. 2. The precise value of the nucleophilicity constant for ClO_4^- is not known but it is generally assumed to be less than zero on the arbitrary scale used here (4). A value of -1.2 would place the ClO_4^- point on the straight line established in the plot of Fig. 1 based on the three points for

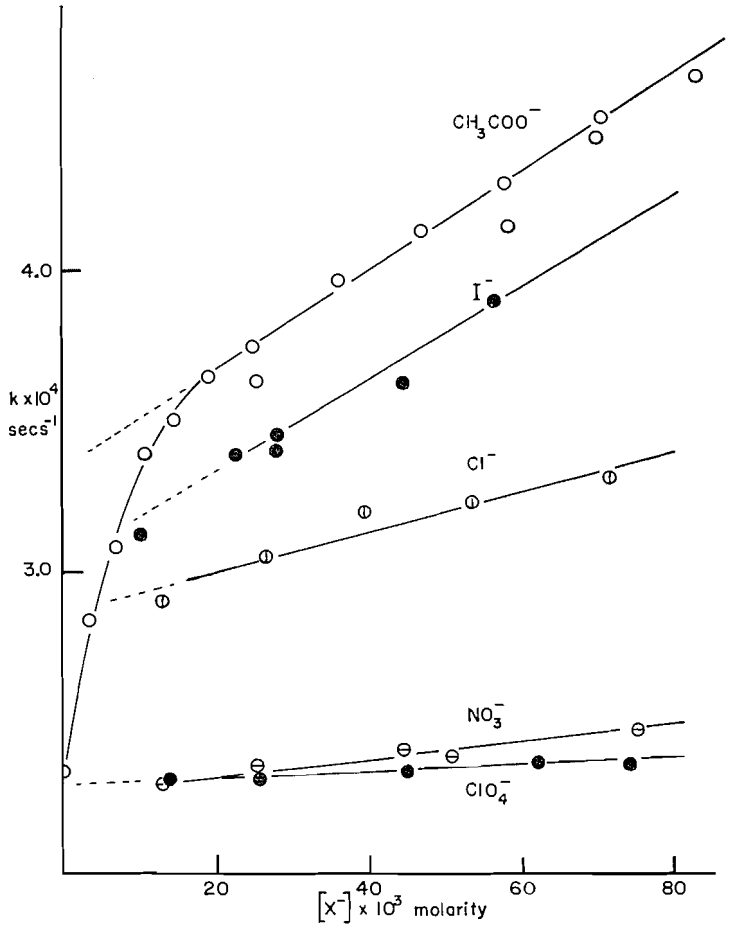

FIG. 1. Observed rate of solvolysis of dimethyl-*t*-butyl solphonium salts in 0.945 mole fraction ethanol in water at 69.46° C as a function of added anion concentration.

ClO_4^-	~2.30	0.12	0.0 (−1.12)†

*Values of **n** from ref. 4.
†Bracketed value is that required for linearity in Fig. 2.

I^-, Cl^-, and NO_3^-. It is, however, not critical to the argument that this linear relationship should hold precisely. It appears justifiable to claim that the rate constant (k_{ip}') does in fact depend on the nucleophilicity of the added anion, X^-, thus constituting further support for the claim that this step involves the nucleophilic attack of the anion on the ion pair.

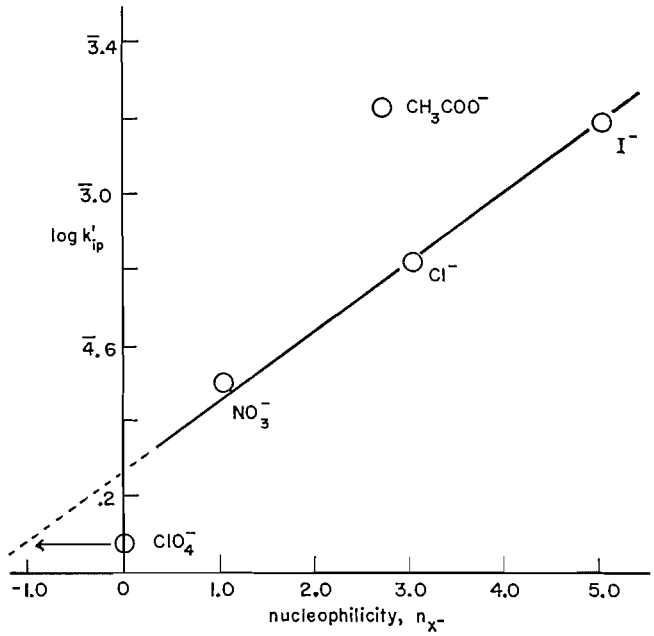

FIG. 2. Log k_{ip}' rate values (equation [2]) versus nucleophilicity constants (**n**) for various added anions.

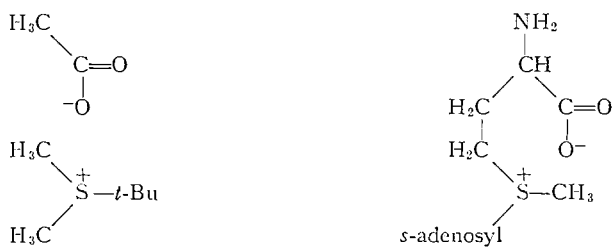
The failure of the acetate anion to conform to the relationship apparently obeyed by the other anions is of particular interest on several counts. The apparent enhancement of nucleophilicity of the acetate anion in this particular mechanism over that expected from the **n** value may be related to the fact that in its nucleophilic role in sulphonium salt solvolysis the duality of the carboxylate group as a nucleophile, due to the two resonance forms possible, is of importance. This would suggest that the precise configuration of the ions with respect to one another in the transition state of the nucleophilic attack is of importance. It should also be noted that this enhanced nucleophilicity of acetate is also reflected in the higher k_{ip} value for acetate. Since this rate is presumably associated with the internal nucleophilic attack of the acetate anion of the ion pair on the *t*-butyl entity of the sulphonium ion, it is to be expected that the duality of the carboxylate anion as a nucleophile would enhance the number of favorable configurations possible for internal nucleophilic attack. It is also noteworthy that the carboxylate anion is probably involved in the analogous sulphonium salt reaction of methionine in biological transmethylations. The particular facility of acetate anion in enhancing the rate of cleavage of the sulphonium salt therefore raises the interesting question as to the possibility of a



similar role of the methionine carboxylate anion in biological transmethylation. Further investigation of this aspect of anion involvement in transmethylation is now in progress.

In the NO_3^- and ClO_4^- cases it would appear from the values of k_{ip} obtained by back extrapolation that these ionic entities are such weak nucleophiles that cleavage of the sulphonium ion by internal nucleophilic attack within the ion pair is kinetically unimportant. The value of k_{ip} obtained by back extrapolation in these cases is virtually identical with the observed rate in the absence of added anion.

By virtue of the fact that the approximate form of the rate expression (equation [2]) has been used in the analysis of the rate data presented here, no reference has been made to the effect of variation of the ion-pair association constant K_A as the anion character is changed. It should be noted, however, that the major effect of changes in K_A on the observed rate of reaction is in determining how rapidly the linear relationship between k_{obs} and $[X^-]$ is attained as $[X^-]$ is increased. The larger the value of K_A the greater will be the effect of initial increases in $[X^-]$ in converting the sulphonium ion essentially completely to ion pairs. The effect of K_A variation on the k_{ip} and, particularly, the k_{ip}' values obtained by equation [2] will therefore be small.

CONCLUSIONS

The kinetic effect of variation of anion type in the solvolysis of dimethyl-*t*-butyl sulphonium salts in low-polarity media is clearly related to the nucleophilicity of the anion. This observation represents further evidence for the nucleophilic role of the salt anion under conditions where the S_N1-type mechanism is suppressed. The failure of the kinetic effect of the acetate anion to conform with the nucleophilicity of that species as observed in other reactions is suggestive of the fact that in sulphonium salt reactions the specific orientation of the anion nucleophile is important. This observation is in keeping with the involvement of ion pairs in the kinetic mechanism proposed and suggests possible interesting extensions to the case of biological transmethylation mechanisms involving methionine.

5,6-DIMETHYLBENZ[*a*]ANTHRACENE AND 5,6-DIMETHYLBENZO[*c*]PHENANTHRENE

P. M. G. BAVIN[1]
Chemistry Department, the University, Hull, England

Received March 12, 1962

ABSTRACT

5,6-Dimethylbenz[*a*]anthracene and 5,6-dimethylbenzo[*c*]phenanthrene have been synthesized, the latter by a novel route.

The synthesis of benzo[*c*]phenanthrene and its derivatives has presented interesting problems, largely overcome by the use of partially hydrogenated intermediates (1, pp. 158–160; 2; 3). The successful ring expansion of benzo[*c*]fluorenone by the Schmidt reaction (4) and our earlier work with benzo[*b*]fluorene (5) prompted experiments with benzo[*c*]fluorene.

7-Acetylbenzo[*c*]fluorene (I*a*) was prepared by the Claisen condensation and was methylated in the usual way (cf. fluorene (6) and 9-acetylfluorene (7)). Reduction and subsequent dehydration–rearrangement by heating with phosphorus pentoxide under xylene (8) gave crude 5,6-dimethylbenzo[*c*]phenanthrene (II*a*) in 80% yield. Purification through the trinitrobenzene complex and by chromatography gave the pure hydrocarbon, m.p. 98–99°, characterized by comparison of its ultraviolet spectrum with those of benzo[*c*]phenanthrene and its methylated derivatives (9, 10). The availability of benzo[*c*]-fluorenones from arylpropiolic acids (11, 12 and references quoted therein) may make this novel route to benzo[*c*]phenanthrenes and other sterically hindered hydrocarbons an attractive one.

To extend the above synthesis methyl benzo[*c*]fluorene-7-carboxylate (I*c*) was prepared and methylated by a general method (5). Reduction gave the alcohol (I*e*) as an oil, the tosylate (I*f*) not being obtained pure. The acetate (I*g*) crystallized during 18 months and was recrystallized only with difficulty. Sufficient experiments were carried out to show spectroscopically that dehydration–rearrangement of I*e* gave a mixture of approximately equal amounts of 5- and 6-methylbenzo[*c*]phenanthrenes (II*b* and II*c*).

[1]*I.C.I. Fellow, 1958–60. Present address: Smith Kline and French Laboratories Ltd., Mundells, Welwyn Garden City, England.*

5,6-Dimethylbenz[*a*]anthracene (III), of interest because its carcinogenic index has been predicted from the results of quantum mechanical calculations (13), has been synthesized by a more conventional route (cf. 5-methoxybenz[*a*]anthracene (14)). The Friedel–Crafts reaction of 1,2-dimethylnaphthalene with phthalic anhydride gave a good yield of keto acid, assigned structure IV*a* by analogy with other substitution reactions of 1,2-dimethylnaphthalene (bromination, sulphonation (15); chloromethylation (16); acetylation (15, 17)). Cyclization of the reduced acid (IV*b*) using a variety of reagents has not been achieved in satisfactory yield. However, reduction of the crude cyclization product and careful purification gave pure 5,6-dimethylbenz[*a*]anthracene, m.p. 111–112°, in 5–10% yield. The hydrocarbon was characterized as its trinitrobenzene complex and by comparison of its ultraviolet spectrum with those of benz[*a*]anthracene and its methylated derivatives (18–20).

EXPERIMENTAL

Microanalyses marked SKF are by Miss Doreen Hardiman, Smith Kline and French Laboratories Ltd; others are by Weiler and Strauss, Oxford. Melting points are uncorrected.

7-Acetyl-7-methylbenzo[c]fluorene (Ib)

Benzo[*c*]fluorene (4 g) (21) was acetylated in the usual way (6).* The crude ketone was unstable (cf. 9-acetylfluorene (6)) and was immediately methylated (7). The *ketone* crystallized from acetone–methanol as lustrous plates (0.9 g), m.p. 170.0–170.5°. Found: C, 88.41; H, 5.97. Calc. for $C_{20}H_{16}O$: C, 88.20; H, 5.92%. Carbonyl stretching frequency: 1702 cm^{-1}.

5,6-Dimethylbenzo[c]phenanthrene (IIa)

The ketone (0.3 g) was reduced with lithium aluminum hydride to give the alcohol as an oil. Dehydration–rearrangement by boiling in xylene (10 ml) with phosphorus pentoxide (1 g) for 4 hours gave crude II*a*. Preliminary purification by passage of a solution in hexane through a column of activated alumina gave a colorless oil showing an intense blue fluorescence. The *1,3,5-trinitrobenzene complex* separated as bright orange needles (0.42 g, 82%) from ethanol, m.p. 145.0–145.5° after sintering at 144°. Found (SKF): C, 67.0; H, 4.26; N, 8.76. Calc. for $C_{26}H_{19}N_3O_6$: C, 66.52; H, 4.08; N, 8.95%. The hydrocarbon was regenerated by passage of a solution of the complex in hexane through a column of alumina, crystallization of the eluted material from methanol giving small, colorless, lustrous plates, m.p. 98–99°. Found (SKF): C, 93.6, 93.8; H, 6.30, 6.50. Calc. for $C_{20}H_{16}$: C, 93.71; H, 6.29%.

Benzo[c]fluorene-7-carboxylic Acid

Prepared in the usual way (5), the *acid* crystallized from benzene–hexane as colorless needles (81%), m.p. 212–214° with decomposition. Found: C, 83.21; H, 4.59. Calc. for $C_{18}H_{12}O_2$: C, 83.06; H, 4.65%. Equivalent wt. found: 262; calc.: 260.3.

The *methyl ester* (Ic), prepared by esterification in methanol–chloroform (1:1) saturated with hydrogen chloride, crystallized from acetone–methanol as colorless, glistening plates (86%), m.p. 129–130°. Found: C, 83.40; H, 5.11. Calc. for $C_{19}H_{14}O_2$: C, 83.20; H, 5.15%.

Methyl 7-Methylbenzo[c]fluorene-7-carboxylate (Id)

Methylation of the preceding ester by a general method (5) gave the *ester* (Id) as glistening plates (92%), m.p. 184–185°. Found: C, 83.46; H, 5.59. Calc. for $C_{20}H_{16}O_2$: C, 83.31; H, 5.59%.

**For alternative syntheses of 9-acetylfluorene from methyl 9-hydroxyfluorene-9-carboxylate and 9-ethinyl-9-fluorenol see refs. 22, 23; for the product of the reaction between acetyl chloride and fluorenyl lithium see refs. 24, 25.*

Hydrolysis and decarboxylation by boiling with potassium hydroxide in ethylene glycol (26) gave 7-methylbenzo[*c*]fluorene, which crystallized from acetone–methanol as white needles, m.p. 85–86°. (Lit. m.p. 80.2–82.0° cor. (21).) Found: C, 92.35; H, 7.86. Calc. for $C_{18}H_{14}$: C, 92.26; H, 7.74%.

7-Methyl-7-benzo[c]fluorenylmethyl Acetate (Ig)

Reduction of the ester (I*d*) with ethereal lithium aluminum hydride gave alcohol (I*e*) as an oil, not obtained crystalline during 2 years. The tosylate (I*f*), prepared in the usual way (26), was not obtained pure. It was obtained after several crystallizations from benzene–hexane as an amorphous powder which sintered between 80 and 120° and finally turned black at 180°. Found: C, 76.48, 76.49; H, 5.57, 5.60. Calc. for $C_{26}H_{22}O_3S$: C, 75.33; H, 5.35%.

Esterification of the alcohol with acetic anhydride containing a trace of concentrated sulphuric acid gave the *acetate* (I*g*) as a yellow gum. Material eluted from alumina with hexane–benzene (10:1) was colorless and crystallized during 18 months. Two recrystallizations from hexane, which required careful seeding, gave colorless needles, m.p. 79.5–81.0°. Found: C, 83.66; H, 5.85. Calc. for $C_{21}H_{18}O_2$: C, 83.42; H, 6.00%. Reduction with lithium aluminum hydride gave alcohol (I*e*) identical (infrared spectra) with that obtained from ester (I*d*).

5- and 6-Methylbenzo[c]phenanthrenes (IIb and IIc)

The alcohol (II*d*) (0.2 g) and xylene (10 ml) were boiled under reflux for 6 hours with phosphorus pentoxide (1 g). The product remaining after evaporation of the xylene was dissolved in hexane and passed through a column of activated alumina. The eluted oil (0.17 g) was colorless. Examination of the ultraviolet and infrared spectra suggested the presence of approximately equal amounts of 5- and 6-methylbenzo[*c*]phenanthrenes. The ultraviolet spectra have been reported elsewhere (9, 10); infrared spectra were obtained from small samples of authentic specimens (2) provided by Professor M. S. Newman. Attempts to separate the hydrocarbons through complexes with trinitrobenzene, picric acid, or trinitrofluorenone were not successful.

2-(1',2'-Dimethyl-4-naphthoyl)-benzoic Acid (IVa)

Finely powdered anhydrous aluminum chloride (14.8 g) was added to a solution of 1,2-dimethylnaphthalene (7.8 g) (15) and phthalic anhydride (7.4 g) in dry sulphur-free benzene (100 ml), maintained at 5°. After being kept at room temperature for 12 hours the mixture was poured onto ice, acidified, and steam-distilled. The residual solid acid was dissolved in aqueous sodium bicarbonate solution, clarified with charcoal, and poured into excess hydrochloric acid. One crystallization from benzene–hexane gave pale yellow prisms (10.5 g, 71%), m.p. 187–189°. Found: C, 78.71; H, 5.52. Calc. for $C_{20}H_{16}O_3$: C, 78.93; H, 5.30%. Equivalent wt. found: 310; calc.: 304.3.

2-(1',2'-Dimethyl-4-naphthylmethyl)-benzoic Acid (IVb)

The preceding acid (10 g) was reduced by stirring and boiling under reflux for 15 hours with aqueous sodium hydroxide (250 ml, 10%) and zinc dust (30 g) activated with copper. Aqueous ammonia solution (5 ml, *d* 0.88) was added every half hour for the first few hours. The *acid* separated from benzene–hexane as colorless prisms (7 g), m.p. 211–212°. Found: C, 82.46; H, 6.37. Calc. for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%. Equivalent wt. found: 285; calc.: 290.3.

5,6-Dimethylbenz[a]anthracene (III)

The reduced acid (1.45 g) was dissolved in concentrated sulphuric acid (10 g, 98%) containing boric acid (0.5 g) (27). The dark solution, protected from atmospheric moisture, was left at room temperature for 12 hours and then poured onto ice. The precipitated yellow gum was reduced by boiling and stirring for 15 hours with aqueous sodium hydroxide solution (250 ml, 10%), toluene (50 ml), and zinc dust (30 g) activated with copper, aqueous ammonia (5 ml, *d* 0.88) being added at half-hourly intervals for the first few hours. The crude hydrocarbon was dissolved in hexane and the solution passed through a column of activated alumina. Eluted material readily crystallized from methanol as colorless needles (0.15 g, 11%), m.p. 111–112°. Found: C, 93.40; H, 6.57. Calc. for $C_{20}H_{16}$: C, 93.71; H, 6.29%. The *1,3,5-trinitrobenzene complex* crystallized from methanol as deep orange needles, m.p. 179–180°. Found: C, 66.93; H, 4.13. Calc. for $C_{26}H_{19}N_3O_6$: C, 66.52; H, 4.08%.

Attempts were made to improve the cyclization, using hydrogen fluoride, aluminum chloride and the acid chloride, benzoyl chloride, zinc chloride, and acetic acid – acetic anhydride, but without marked success.

Ultraviolet Spectra

The ultraviolet spectra were obtained using a Beckmann DK-2 recording spectrophotometer, with ethanol as solvent. Shoulders are marked by an asterisk. Wavelengths are in mμ; intensities are recorded as log ϵ.

STRUCTURES OF CYCLOHEXANONE–UREA CONDENSATION PRODUCTS[1]

C. PODESVA, E. J. TARLTON, AND A. F. MCKAY
L. G. Ryan Research Laboratories of Monsanto Canada Limited, Lasalle, Que.

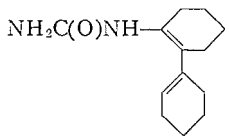
Received March 9, 1962

ABSTRACT

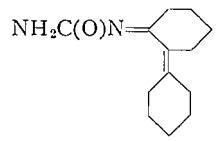
A new series of urea derivatives was prepared by condensing cyclohexanone with urea, thiourea, and their monosubstituted derivatives.

A new series of urea derivatives was prepared by condensing urea, thiourea, and their monosubstituted derivatives with cyclohexanone in the presence of acid. The derivatives formed by the condensation of 2 mole equivalents of cyclohexanone with the ureas and thioureas were formed also by condensing 2-cyclohexylidene-cyclohexanone with the same ureas and thioureas. The new compounds prepared in this study are described in Table I.

Two structures (I and II) were considered for the product from the condensation of



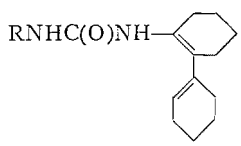
I



II

cyclohexanone with urea. If one assumes the substituted N atom to be equivalent to carbon for calculating the ultraviolet λ maxima of these unsaturated structures then the calculated values for structures I and II are 239 mμ and 326 mμ respectively (1). The observed λ_{max} of 238.5 mμ given in Table II is in good agreement with the calculated value for structure I. This structure was confirmed by an n.m.r. spectrum of the compound. The vinylic proton peak at 4.67 p.p.m. definitely excluded structure II from consideration. A peak at 7.99 p.p.m. is assigned to the four hydrogens of the methylene groups which are unshielded by the diene system. The rest of the hydrogen atoms of the remaining methylene groups gave a peak at 8.4 p.p.m.[2]

The infrared spectra listed in Table III show that all of the urea and thiourea derivatives possess this same general structure III. The bands between 3060 and 3080 cm^{-1} are



III

R = hydrogen, aryl, cyclohex-1-enyl, or alkyl

assigned to C—H stretching vibration of the —C=C—H group. The strong absorption band between 1673 and 1685 cm^{-1} is tentatively assigned to the stretching vibrations

[1]*Contribution No. 36.*
[2]*Sixty-megacycle n.m.r. spectrum was measured with Varian model HR-60 high-resolution spectrometer.*

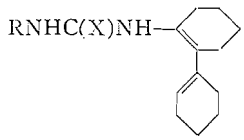
TABLE II

Ultraviolet absorption[a]



R	X	λ_{max} (mμ)	ϵ_{max}
Hydrogen	O	238.5	3,865
Cyclohex-1-enyl	O	233	6,670
Phenyl	O	247[b]	5,850
		220	End absorption
Hydrogen	S	275	9,020
		256	9,580
		220	End absorption
Phenyl	S	305[b]	10,280
		220	End absorption

[a]The ultraviolet spectra were determined on ethanolic solutions of the compounds with a Beckman DK-1 recording spectrophotometer.
[b]These absorption bands were broad and unsymmetrical. The phenyl groups contribute to the general absorption in the region covered by these broad bands.

of the —NH—C=C—C=CH or —NH—C=C— group. The CRR=CHR group gives an absorption band around 1670 cm^{-1} (2). This absorption is generally weak. Conjugation in a diene system shifts the absorption some 30 cm^{-1} to a lower frequency but the intensity of the band is generally increased considerably. In aliphatic conjugation of C=C bonds splitting of the two double-bond absorption bands usually occurs (2). In most of the compounds in Table III the band assigned to the —C=O group appears as a strong, separate band while in 2-cyclohex-1-enyl cyclohex-1-enyl-urea, 1-(cyclohex-1-enyl)-3-(2-cyclohex-1-enyl cyclohex-1-enyl)-urea, and 1-(4-hydroxyphenyl)-3-(2-cyclohex-1-enyl cyclohex-1-enyl)-urea the C=O absorption band has coalesced with the strong band tentatively assigned to the conjugated unsaturated group.

During this study 1,2-dicyclohexylisourea was prepared. This compound gave a strong, broad infrared absorption band at 1630 cm^{-1} which includes the C=N stretching and N—H bending modes.

EXPERIMENTAL[3]

2-Cyclohexylidene-cyclohexanone

2-Cyclohexylidene-cyclohexanone (b.p. 153–155° at 20 mm) was prepared in 69% yield by the method of Gault *et al.* (3).

3,4-Dichlorobenzylurea

3,4-Dichlorobenzylurea (m.p. 164–165°) was prepared in 82% yield from 3,4-dichlorobenzylamine hydrochloride and sodium cyanate by the general procedure described by Vogel (4). Anal. Calc. for $C_8H_8Cl_2N_2O$: C, 43.86; H, 3.68; Cl, 32.37; N, 12.79%. Found: C, 44.04; H, 3.77; Cl, 32.38; N, 12.55%.

Ethylenediurea

Ethylenediurea (m.p. 199° decomp.) was prepared in 73% yield by a modification of Volhard's (5) method. Sodium cyanate was used in place of silver cyanate.

Preparation of 2-Cyclohex-1-enyl cyclohex-1-enyl Derivatives of Ureas and Thioureas

The compounds described in Table I were prepared by either of the processes given in detail below for the preparation of 1-(3,4-dichlorobenzyl)-3-(2-cyclohex-1-enyl cyclohex-1-enyl)-urea.

[3]*All melting points were determined on samples sealed in evacuated capillary tubes. This technique was essential in obtaining reproducible melting points. Microanalyses were determined by Micro-Tech Laboratories, Skokie, Illinois.*

[a]Absorption spectra on Nujol mulls of the crystalline compounds.

Method A

A mixture of 3,4-dichlorobenzylurea (10.25 g, 0.047 mole), cyclohexanone (49 g, 0.5 mole), and concentrated hydrochloric acid (5 g, 0.05 mole) was refluxed for 30 minutes. Crystals separated from the solution during the refluxing period. These were separated and washed with ethanol, yield 15.4 g (86.8%). The melting point (243–244°) was not altered by further crystallization.

Method B

This procedure was the same as given in Method A with the exception that 2-cyclohexylidene-cyclohexanone (17.8 g, 0.1 mole) was used instead of cyclohexanone. The yield of product (m.p. 243–244°) was 13 g (73.3%).

1,2-Dicyclohexylisourea

A solution of bromocyanogen (5.3 g, 0.05 mole) in ether (50 ml) was added dropwise over a period of 35 minutes to a cold (−5 to 0°) solution of freshly distilled cyclohexylamine (9.9 g, 0.1 mole) in ether (50 ml). After the mixture was stirred for an additional 30 minutes, the precipitate of cyclohexylamine hydrobromide was removed by filtration and the filtrate at 0° was treated with cyclohexanol (50 g, 0.5 mole). The solution was stirred for 90 minutes, after which dry HCl gas (5.7 g) was added. This solution was allowed to stand at room temperature for 5 days and then the ether and excess cyclohexanol were removed *in vacuo*. The residue was suspended in water (20 ml) and the pH of the suspension was adjusted to 10 with sodium hydroxide solution. A crystalline suspension was obtained after the mixture had remained at room temperature for 4 days. The crystals (m.p. 78°) were recovered by filtration, yield 11.2 g (100%). Two crystallizations from petroleum ether (b.p. 65–110°) (5 ml/g) raised the melting point to 96°, yield 73.3%. Anal. Calc. for $C_{13}H_{24}N_2O$: C, 69.60; H, 10.78; N, 12.49%. Found: C, 69.80; H, 10.76; N, 12.51%.

1,1'-Bis-(2-cyclohex-1-enyl cyclohex-1-enyl)-ethylenediurea

Ethylenediurea (14.6 g, 0.1 mole), cyclohexanone (58.8 g, 0.6 mole), and concentrated hydrochloric acid (0.2 mole) were heated under reflux for 75 minutes. The crystals were removed from the cool solution by filtration, yield 35.1%. These crystals did not melt below 300° and they were very insoluble in the common organic solvents. Anal. Calc. for $C_{28}H_{42}N_4O_2$: C, 72.05; H, 9.07; N, 12.00%. Found: C, 72.18; H, 9.06; N, 12.32%.

1-(Cyclohex-1-enyl)-3-(2-cyclohex-1-enyl cyclohex-1-enyl)-urea

Urea (60 g, 1 mole), cyclohexanone (98 g, 1 mole), and concentrated hydrochloric acid (100 g, 1 mole) were heated under reflux for 90 minutes. After cooling of the mixture to room temperature the organic layer was separated and the unreacted cyclohexanone, together with some water, was removed *in vacuo*. The oily residue was diluted with ethanol (25 ml) and the solution poured into water (400 ml). This mixture was neutralized with aqueous sodium hydroxide, after which the oil solidified. The product (m.p. 180–200°) was separated by filtration and washed with water, yield 98 g (98%). Two crystallizations from ethanol–benzene (1:1) raised the melting point to a constant value of 221–223°. In some preparations a crystalline modification melting at 238° was obtained. The infrared spectra of these two crystalline modifications were identical. Anal. Calc. for $C_{19}H_{28}N_2O$: C, 75.96; H, 9.39; N, 9.33%. Found: C, 75.62; H, 9.40; N, 9.14%.

ACKNOWLEDGMENT

The infrared and ultraviolet spectra were determined by Dr. C. Sandorfy of the University of Montreal, Montreal, Quebec.

THE REACTION OF SULPHURYL CHLORIDE WITH REDUCING SUGARS

PART I

H. J. JENNINGS AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario

Received February 13, 1962

ABSTRACT

The reaction of sulphuryl chloride with D-glucose, with D-xylose, and with maltose is described. The products were fully substituted compounds containing both chlorodeoxy and chlorosulphate groups. Formation of the methyl glycosides and subsequent removal of the chlorosulphate groups enabled structural investigations to be carried out on the resultant chlorodeoxy methyl glycosides.

INTRODUCTION

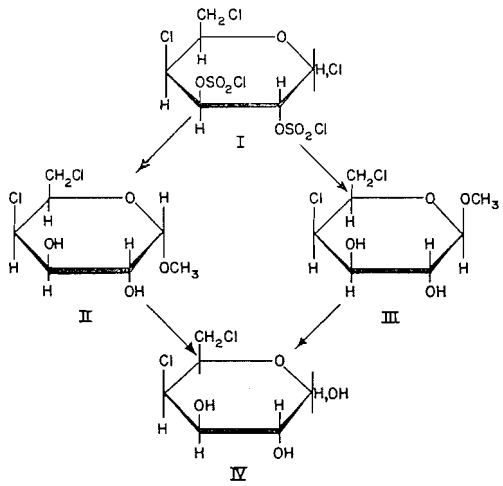
Previous communications (1, 2) on the reaction of sulphuryl chloride with methyl glycosides have described the isolation of fully substituted glycosides containing chlorodeoxy and cyclic sulphate groups. In the case of methyl α-D-glucopyranoside the 2,3-cyclic sulphate derivative was desulphated to yield substances characterized as methyl 4,6-dichloro-4,6-dideoxy-α-D-galactoside and 4,6-dichloro-4,6-dideoxy-D-galactose (2). When conditions similar to those described by Bragg *et al.* (1) were employed the reaction of sulphuryl chloride with reducing sugars produced considerable degradation of the carbohydrate, and a crystalline product, tentatively identified as a dichloro pyridine derivative, was isolated. When the reaction was carried out at a much lower temperature degradation of the sugar was reduced and good yields of carbohydrate derivatives were obtained. Changes in reaction conditions also produced a new range of carbohydrate derivatives which contained the chlorosulphate group.

DISCUSSION

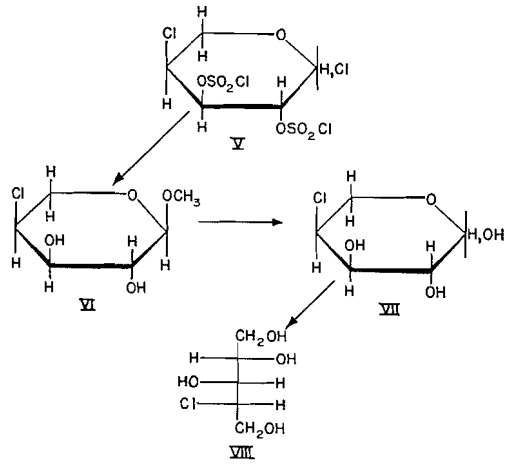
In view of the work of Bragg *et al.* (1, 2) it was considered likely that sulphuryl chloride would react with reducing sugars in pyridine solution to yield cyclic sulphate derivatives with the possible replacement of the hydroxyl group of C_1 by a chloro group. Analysis of the crystalline derivative from maltose indicated that such a reaction had in fact occurred but that the cyclic sulphate grouping was absent. Further examination of the crystalline derivative from maltose and of the syrupy products from D-glucose and D-xylose showed that chlorosulphate residues as well as chlorodeoxy groupings were present in the products. The infrared spectra of the compounds had two characteristic strong absorption frequencies, at 1431–1435 cm^{-1} and 1195–1200 cm^{-1}, the values of which compared well with the frequencies of absorption of the O—SO_2—Cl group reported by Robinson (3). The spectra also showed the absence of hydroxyl absorption. The presence of the chlorosulphate group was further substantiated by the reaction of the compounds with aniline and pyridine (4) to give a characteristic red dye. This dye was previously reported by König and Bayer (5) and was prepared by them from a wide range of inorganic acid chlorides.

The reactions of sulphuryl chloride with D-glucose (experiments i and ii) gave syrupy products which were probably mixtures of the α- and β-chlorodeoxy compounds (I). The formation of the methyl glycosides and the simultaneous dechlorosulphation with methanol alone produced, as the main product, methyl 4,6-dichloro-4,6-dideoxy-α-D-

galactopyranoside (II). The corresponding β-anomer (III) was obtained when methanol and silver oxide were employed. This was evident because both II and III gave on hydrolysis 4,6-dichloro-4,6-dideoxy-D-galactose (2) (IV). The reason for the isolation of both the α and β methyl glycosides is not clear and could be attributed to either a preponderance of the α- or β-1-chloro compound in the original product (I) due to different reaction conditions, or to the different methods used for the formation of the methyl glycosides from I. If it is assumed that in all these reactions the chlorosulphate group is substituted and removed without inversion, discounting the less likely process of double inversion; then compound I was 4,6-dichloro-4,6-dideoxy-D-galactopyranosyl chloride 2,3-dichlorosulphate.



The reaction of sulphuryl chloride with D-xylose gave a syrup (V) which was dechlorosulphated with great difficulty using silver oxide and aqueous methanol. Analysis indicated the presence of one chlorodeoxy group in the dechlorosulphated methyl glycoside (VI) and periodate oxidation of VI gave results (1 mole/mole uptake) consistent with the presence of adjacent hydroxyl groups. Hydrolysis of VI yielded a monochloropentose (VII) which formed a phenylosazone which still contained chlorine. D-Xylose may have reacted in the pyranose or furanose form and the chlorodeoxy group could be assigned to positions C_4 or C_5 depending whether V was a pyranose or furanose derivation. Periodate oxidation of the monochloropentitol (VIII) (produced by reduction of VII) liberated 0.9 mole of formic acid and proved that the chlorodeoxy group was on position C_4 of the molecule, thus establishing that the original sugar had reacted in the pyranose form. The high positive rotation of VI (+237°) suggested that inversion of configuration had taken place at C_4, forming an L-arabinose derivative, and this was supported by the fact that VI remained unchanged when treated with sodium hydroxide solution. If inversion had not occurred the compound would have remained in the D-xylose configuration, and it is known that under alkaline conditions chlorine is eliminated from methyl 4-chloro-4-deoxy-α-L-xyloside to give the 3,4-anhydro compound (2). Compound VI was found to have a specific rotation similar to that of methyl β-L-arabinopyranoside (+245.5°) (6) and therefore it was characterized as methyl 4-chloro-4-deoxy-β-L-arabinopyranoside. On this evidence V was probably 4-chloro-4-deoxy-L-arabinopyranosyl chloride 2,3-dichlorosulphate.

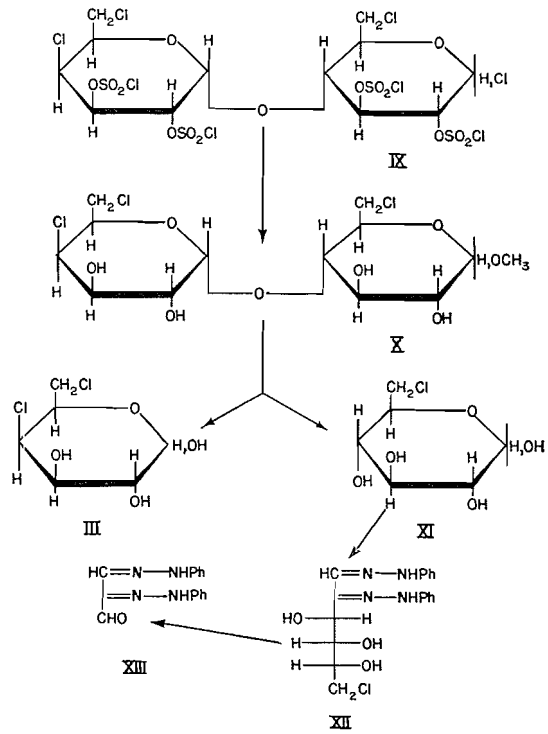


The reaction of sulphuryl chloride with maltose gave a crystalline product (IX) ($C_{12}H_{14}O_{15}Cl_8S_4$). Formation of the methyl glycoside and dechlorosulphation using sodium iodide gave two crystalline products, one of which was shown by analysis to be a trichlorotrideoxy methyl glycoside (X). Sodium iodide was employed because of the difficulty encountered in dechlorosulphating this product by the previous methods. Hydrolysis of X produced a syrup from which two main products were separated and identified as chlorodeoxy hexoses (III and XI). The crystalline dichlorodideoxy hexose (III) was characterized as 4,6-dichloro-4,6-dideoxy-D-galactopyranose (2). The other chlorohexose (XI), which could not be obtained crystalline, was identified as 6-chloro-6-deoxy-D-glucopyranose on the following evidence. It was found to have a specific rotation similar to that of the equilibrium value obtained for crystalline 6-chloro-6-deoxy-D-glucopyranose (7) and gave a phenylosazone (XII) identical with the phenylosazone of 6-chloro-6-deoxy-D-glucopyranose obtained by a synthetic route (8). The phenylosazone (XII) was oxidized with periodate by the method of Hough, Powell, and Woods (9) and initially consumed 1.93 moles of periodate, releasing 0.64 mole of formic acid and no formaldehyde, with an immediate precipitation of the 1,2-bisphenylhydrazone of mesoxaldehyde (XIII). The low yield of formic acid agreed with the findings of Hough, Powell, and Woods, who obtained similar results from the periodate oxidation of phenylosazones (9), but the gradual loss of formic acid with time cannot be satisfactorily explained. The initial results, however, are consistent with the presence of a chlorodeoxy group on position C_6 of the molecule. Accordingly compound X was characterized as methyl 4-*O*-α-4′,6′-dichloro-4′,6′-dideoxy-D-galactopyranosyl 6-chloro-6-deoxy-D-glucopyranoside, and the fully substituted compound (IX) from which it was obtained would be 4-*O*-α-4′,6′-dichloro-4′,6′-dideoxy-D-galactopyranosyl-6-chloro-6-deoxy-D-glucopyranosyl chloride 2,3,2′,3′-tetrachlorosulphate.

The other crystalline compound obtained from IX gave, on hydrolysis, products similar in properties to those observed when X was hydrolyzed. Failure to obtain a sharp melting point and a consistent analysis of the crystalline product from IX indicates that it is probably a mixture containing the α- and β-anomers of compound X.

EXPERIMENTAL

Melting points were determined on a Kofler hot stage and were uncorrected. Optical rotations were measured at 21±3° C. Solutions were concentrated under reduced pressure below 50° C. Paper chromatography was carried out by the descending method on Whatman No. 1 filter paper using the following



solvent systems (v/v): (*a*) ethyl acetate, acetic acid, formic acid, water (18:3:1:4) and (*b*) butan-1-ol, ethanol, water (3:1:1). Sugars were located on chromatograms by *p*-anisidine hydrochloride (10) or alkaline silver nitrate (11) sprays and the rates of movement are quoted relative to that of D-xylose (R_x). Sugars containing the chlorosulphate group were located specifically with a spray made of a butan-1-ol solution of aniline and pyridine (4). Infrared absorptions were measured as solutions in chloroform or as a powder suspended in a potassium bromide pellet on a Perkin–Elmer Model 21 spectrophotometer. All solutions were deionized by passage through Amberlite IR120 (H form) and Duolite A4 (OH form) unless otherwise stated.

General Method

The reducing sugar (10 g), previously dried over phosphoric oxide, was partially dissolved in dry pyridine (40 ml). Chloroform (100 ml), dried over anhydrous sodium sulphate, was added to the pyridine solution, and precipitation of some of the reducing sugar occurred. The heterogeneous reaction mixture was cooled in a solid carbon dioxide – acetone bath, and an excess of redistilled sulphuryl chloride was added drop by drop over a period of half an hour with vigorous stirring (21 ml of sulphuryl chloride for a pentose and 26 ml for a hexose or disaccharide). Cooling was continued for a further 2 hours and the reaction mixture was then allowed to come to room temperature. During this rise in temperature the viscosity of the solution decreased rapidly and a white precipitate, possibly of pyridine salts, was formed. The precipitate was filtered from the chloroform solution, and the chloroform solution was washed successively with 10% sulphuric acid, saturated sodium bicarbonate solution, and distilled water. The final chloroform solution was dried over anhydrous sodium sulphate, filtered, and the filtrate was concentrated to a syrup which crystallized on standing, in the case of maltose.

D-*Glucose (i)*

The general method was applied and the reaction mixture was allowed to stand for 24 hours at room temperature. D-Glucose gave a pale yellow syrup (8.8 g) which could not be obtained crystalline. It had $[\alpha]_D$ +66° (*c*, 2.8 in chloroform) and paper chromatography in solvent (*a*) gave one spot that moved with the solvent front (aniline/pyridine spray).

*Methyl 4,6-Dichloro-4,6-deoxy-α-*D*-galactopyranoside*

The above syrup (8.2 g) was refluxed in anhydrous methanol (200 ml) solution for 12 hours. The methanolic solution was passed through Duolite A4 (OH form) ion exchange resin and concentrated to a pale yellow syrup (4.5 g) which crystallized on standing. The crude crystals were dissolved in water, the solution was continuously extracted with chloroform, and the chloroform solution on concentration gave a crystalline

mass. Recrystallization from chloroform – light petroleum (b.p. 40–60° C) gave long colorless needles (2.5 g) of m.p. 157° C and $[\alpha]_D$ +179° (*c*, 2.1 in water). The mixed melting point with an authentic sample of methyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside (1, 2) was 157° C. The crystals gave an infrared spectrum identical with that of the authentic specimen of the galactoside derivative.

D-*Glucose (ii)*

The same method was applied as in the previous case (i) except that the reaction product was isolated immediately after the reaction mixture had attained room temperature. D-Glucose gave a pale yellow syrup (8 g) which could not be obtained crystalline and paper chromatography in solvent (*a*) gave one spot that moved with the solvent front (aniline/pyridine spray).

Methyl 4,6-Dichloro-4,6-dideoxy-β-D-galactopyranoside

The above syrup (6 g) was dissolved in anhydrous methanol (150 ml) and the solution was shaken in an aluminum foil covered flask with silver oxide (10 g), 'drierite' (5 g), and glass beads for 24 hours. Distilled water (10 ml) was then added to the reaction mixture, which was shaken for a further 24 hours. The heterogeneous mixture was filtered and the filtrate was deionized and concentrated to a syrup (2.5 g) which crystallized immediately. Two recrystallizations from chloroform – light petroleum (b.p. 40–60° C) gave colorless needles (0.5 g) of m.p. 154° C and $[\alpha]_D$ −8° (*c*, 0.8 in water). Analysis: Calc. $C_7H_{12}Cl_2O_3$: C, 36.4%; H, 5.2%; Cl, 30.7%. Found: C, 36.3%; H, 5.5%; Cl, 30.4%.

The crystals were hydrolyzed with *N* sulphuric acid and the solution was neutralized with barium carbonate, filtered, and the filtrate was deionized to give a syrup which crystallized on standing. Recrystallization from methanol gave colorless crystals of m.p. 184° C (decomp.), $[\alpha]_D$ +130° (30 minutes) → +97° (equilibrium, 24 hours) (*c*, 0.98 in methanol), and mixed melting point with authentic 4,6-dichloro-4,6-dideoxy-D-galactose (2) 184° C (decomp.).

D-*Xylose*

The reaction was carried out by the general method and the reaction product was isolated after the reaction mixture had been allowed to stand at room temperature for 4 hours. D-Xylose gave a yellow syrup (9.5 g) which had $[\alpha]_D$ −41° (*c*, 5.8 in chloroform) and did not crystallize. Paper chromatography in solvent (*a*) gave one spot that moved with the solvent front (aniline/pyridine spray).

Methyl 4-Chloro-4-deoxy-β-L-arabinopyranoside

The above syrup (5.5 g) was treated in the same way as the syrup from D-glucose (ii). Dechlorosulphation of the syrup using silver oxide, methanol, and distilled water was found to be incomplete even after 96 hours. Therefore, the sulphur-containing syrup (3.75 g) was dissolved in chloroform and the chloroform solution was extracted with distilled water. The distilled-water fraction was concentrated to a syrup (0.75 g) which partially crystallized and which was found to be free of sulphur. The semicrystalline mass was then dissolved in water and continuously extracted with ether. The ether extract on concentration produced a crystalline product (0.7 g). Recrystallization from ethyl acetate gave needle-shaped crystals of m.p. 152° C and $[\alpha]_D$ +237° (*c*, 0.96 in methanol). Analysis: Calc. $C_6H_{11}ClO_4$: C, 39.4%; H, 6.0%; Cl, 19.5%. Found: C, 39.4%; H, 6.3%; Cl, 19.1%.

4-Chloro-4-deoxy-L-arabinose

The above crystals (0.36 g) were refluxed in *N* sulphuric acid solution (50 ml) for 10 hours. The solution was neutralized with barium carbonate, filtered, and the filtrate was deionized and concentrated to a syrup (0.33 g) which crystallized on standing. Recrystallization from ethanol gave colorless crystals of m.p. 150° C and $[\alpha]_D$ +155° (10 minutes) → +119° (equilibrium, 36 hours) (*c*, 0.4 in water). Analysis: Calc. $C_5H_9ClO_4$: C, 35.6%; H, 5.4%; Cl, 21.0%. Found: C, 35.6%; H, 5.6%; Cl, 20.4%.

The phenylosazone of the above compound was made and purified by three successive precipitations from methanol solution using distilled water to give fine yellow crystals of m.p. 123° C (decomp.). Analysis: Calc. $C_{17}H_{19}ClN_4O_2$: Cl, 10.3%; N, 16.2%. Found: Cl, 10.0%; N, 15.8%.

4-Chloro-4-deoxy-L-arabitol

The crystalline monochloropentose (0.15 g) was dissolved in distilled water (50 ml) and an excess of sodium borohydride (0.15 g) was added. When the solution became non-reducing acetone was added to decompose the excess sodium borohydride. The solution was deionized and concentrated to a syrup which was codistilled (×10) with methanol. The resultant colorless syrup (0.14 g) did not crystallize and had $[\alpha]_D$ +10° (*c*, 0.9 in water). The syrup contained chlorine and gave one spot with alkaline silver nitrate (11) at R_x 1.0 on paper chromatograms when developed in solvents (*a*) and (*b*).

Periodate Oxidations

The oxidations were carried out in the dark at 25° C, using a small sample (20 mg) of the compounds in distilled water (25 ml) containing 0.3 *M* sodium metaperiodate (1 ml). Aliquots (1 ml) were removed at intervals and the consumption of periodate (12) and the production of formic acid (13) were measured.

Oxidation of Methyl 4-Chloro-4-deoxy-β-L-arabinopyranoside

The moles of periodate consumed were as follows: 0.37 (3.25 hours); 0.37 (5 hours); 1.01 (23 hours); 1.13 (68 hours). No formic acid was produced.

Oxidation of 4-Chloro-4-deoxy-L-arabitol

The moles of periodate consumed and moles of formic acid produced were respectively as follows: 2.04, 0.89 (0.5 hour); 2.08, 0.9 (9.5 hours).

Reaction of Methyl 4-Chloro-4-deoxy-β-L-arabinopyranoside with Sodium Hydroxide

The crystals (18 mg) were dissolved in 0.1 *N* sodium hydroxide solution (2 ml) and the solution was left to stand for 8 hours. Titration of the solution with 0.1 *N* sulphuric acid, using phenolphthalein as the indicator, indicated that only a negligible quantity of the sodium hydroxide solution had been spent in the reaction (0.02 ml). The solution was deionized and concentrated to a crystalline mass (18 mg) which was recrystallized from ethyl acetate to give a product with m.p. 151° C and mixed melting point with the starting material 150–151° C.

Maltose

The general method was applied except that the reaction product was isolated immediately after the reaction mixture had attained room temperature. Maltose gave a pale yellow syrup (11.6 g) which crystallized on standing. Recrystallization was carried out by cooling a saturated solution of the crude crystalline product in chloroform in an acetone – solid carbon dioxide bath. The crystals (6.8 g) were isolated by filtration and washed with chloroform – light petroleum (b.p. 40–60° C) (1:1, v/v). The crystals had m.p. 203° (decomp.) and $[\alpha]_D$ +143° (*c*, 1.28 in chloroform). Analysis: Calc. $C_{12}H_{14}Cl_8O_{15}S_4$: C, 18.2%; H, 1.8%; Cl, 35.8%; S, 16.1%. Found: C, 18.0%; H, 2.0%; Cl, 35.4%; S, 15.7%. Paper chromatography in solvent (*a*) gave one spot that moved with the solvent front (aniline/pyridine spray).

Methyl 4-O-α-4′,6′-dichloro-4′,6′-dideoxy-D-galactopyranosyl 6-chloro-6-deoxy-D-glucopyranoside

The above crystals (10 g) were dissolved in anhydrous methanol and refluxed for 8 hours to form the methyl glycoside. Sodium iodide (10 g) was added to the solution and an immediate evolution of iodine and sulphur dioxide was noticed. The reaction mixture was left to stand for 8 hours. Iodine was removed from the solution by passing hydrogen sulphide through it and the excess hydrogen sulphide was removed by aeration. The solution was neutralized with barium carbonate and filtered. Silver nitrate was added to remove the iodides from solution and after filtration of the silver iodide, potassium chloride was added to the solution to remove the excess silver nitrate. Finally the silver chloride was filtered from the solution and the solution was concentrated to a semicrystalline mass, which was extracted with cold acetone (×3). Evaporation of the acetone solution gave a colorless syrup (5 g). The syrup was dissolved in water and extracted continuously with chloroform for 4 hours and then for a further 4 hours, giving two fractions, A and B.

Fraction A

Concentration of the chloroform solution gave a colorless syrup (2 g) which did not crystallize. Crystallization occurred from ethyl acetate – chloroform and recrystallization from *n*-propanol gave colorless needles (0.25 g) of m.p. 184–186° C and $[\alpha]_D$ +174° (*c*, 0.58 in methanol). Analysis: Calc. for the monohydrate $C_{13}H_{24}O_9Cl_3$: C, 36.2%; H, 5.6%; Cl, 24.7%. Found: C, 36.0%; H, 5.0%; Cl, 24.6%. The sample above was dried to constant weight at 60° C *in vacuo* over phosphoric oxide. Analysis: Calc. for $C_{13}H_{22}O_8Cl_3$: C, 37.8%; H, 5.3%; Cl, 25.8%. Found: C, 37.8%; H, 5.1%; Cl, 26.1%.

6-Chloro-6-deoxy-D-glucose and 4,6-Dichloro-4,6-dideoxy-D-galactose

The crystals of the monohydrate above (0.25 g) were dissolved in *N* sulphuric acid (50 ml) and the solution was refluxed for 16 hours. The reaction mixture was neutralized and deionized as described for previous hydrolyzates. Concentration of the resultant solution gave a syrup (0.2 g) which was shown by paper chromatography in solvents (*a*) and (*b*) to contain two major reducing components at R_x 1.7 and R_x 2.5. A minor reducing component at R_x 0.63 cochromatographed with D-glucose in solvents (*a*) and (*b*). The syrup was fractionated on Whatman 3MM paper using solvent (*b*). End strips of the chromatogram were sprayed with alkaline silver nitrate and the areas of paper corresponding to the two components at R_x 1.7 and R_x 2.5 were eluted with water to give solutions of the two components.

Component at R_x 2.5

The solution was filtered and concentrated to give a crystalline mass (120 mg) which was recrystallized from ethanol. The crystals had m.p. 183–184° C (decomp.) and mixed melting point with an authentic sample of 4,6-dichloro-4,6-dideoxy-D-galactose (2) 184° C (decomp.). The crystals also cochromatographed with the authentic specimen in solvents (*a*) and (*b*).

Component at R_x 1.7

The solution was filtered and concentrated to give a syrup (100 mg) which could not be obtained crystalline. It had $[\alpha]_D$ +34° (*c*, 0.98 in water), and formed a phenylosazone which was recrystallized from methanol–

water to give yellow needles of m.p. 167–168° C (decomp.). Analysis: Calc. $C_{18}H_{21}ClN_2O_3$: C, 57.2%; H, 5.6%; Cl, 9.4%; N, 14.9%. Found: C, 57.6%; H, 5.7%; Cl, 9.1%; N, 15.0%.

Preparation of 6-Chloro-6-deoxy-D-glucose

This was carried out essentially by the method of Wiggins and Wood (8). 6-*O*-Tosyl methyl α-D-glucoside (0.5 g) was heated with anhydrous lithium chloride (0.25 g), absolute methanol (10 ml), and anhydrous acetone (10 ml) at 150° C in a sealed tube for 60 hours. The solution was concentrated to a syrup which was dissolved in water, deionized, and reconcentrated to a syrup (0.35 g) which did not crystallize and gave no spots on paper chromatograms developed in solvents (*a*) and (*b*). The syrup was refluxed with *N* sulphuric acid for 8 hours, and the solution was neutralized and deionized as in previous hydrolyses. The solution was concentrated to a syrup which was shown to consist of one major reducing component (R_x 1.9) and two minor reducing components (R_x 0.65 and R_x 1.35) by paper chromatography in solvents (*a*) and (*b*). The syrup was fractionated on Whatman 3MM paper in solvent (*b*) and the component at R_x 1.9 was isolated by the method used in the previous fractionation by chromatography on 3MM paper. Concentration of the aqueous solution gave a syrup (0.17 g) which could not be obtained crystalline. The syrup gave a phenylosazone of m.p. 165° C (decomp.) and had a mixed melting point with the phenylosazone from above of 166–167° C (decomp.). The two phenylosazones also gave identical infrared spectrums.

Periodate Oxidation of 6-Chloro-6-deoxy-D-glucose Phenylosazone

The crystalline phenylosazone (above) (14.7 mg) was oxidized with sodium metaperiodate in 50% aqueous ethanol by the method of Hough, Powell, and Woods (9). A yellow-orange precipitate was filtered from the solution after 30 minutes and the moles of periodate consumed and the formic acid produced were respectively as follows: 1.93, 0.64 (0.66 hour); 2.06, 0.62 (2.66 hours); 2.09, 0.17 (29.5 hours). No formaldehyde was produced.

1,2-Bisphenylhydrazone of Mesoxaldehyde (9)

The yellow-orange precipitate was recrystallized from 50% aqueous ethanol and gave crystals of m.p. 189° C. An authentic specimen had m.p. 193–194° C and the mixed melting point was 187–189° C. The infrared spectra of the authentic and derived specimens were identical over the range 4000–600 cm^{-1}.

Fraction B

The chloroform solution gave on concentration a syrup (2 g) which crystallized on the addition of hot chloroform. Recrystallization from chloroform – ethyl acetate gave non-reducing colorless crystals (1 g) of m.p. 98–102° C and $[\alpha]_D$ +76° (*c*, 1.0 in methanol). A consistent analysis could not be obtained for this compound even after repeated recrystallizations; therefore it was considered to be a mixture.

6-Chloro-6-deoxy-D-glucose and 4,6-Dichloro-4,6-dideoxy-D-galactose

The crystals from fraction B gave results similar to those observed when the crystalline product from fraction A was hydrolyzed under the same conditions. Paper chromatography produced reducing spots of the same intensities with similar R_x values at R_x 0.63, R_x 1.7, and R_x 2.5. The hydrolysis product was fractionated as described for the crystalline product from fraction A and both 6-chloro-6-deoxy-D-galactose and 4,6-dichloro-4,6-dideoxy-D-glucose were isolated and characterized.

ACKNOWLEDGMENTS

The authors wish to thank Mr. J. C. Turner for the sample of 6-*O*-tosyl methyl α-D-glucoside. They would also like to thank the National Research Council for financial assistance (grant N.R.C./T19).

CONSTITUTIONS OF POLYSACCHARIDES FROM SERRATIA MARCESCENS[1]

H. C. SRIVASTAVA[2] AND G. A. ADAMS
Division of Applied Biology, National Research Council, Ottawa, Canada

Received March 1, 1962

ABSTRACT

Constitutional studies of three polysaccharides prepared from *Serratia marcescens* cells by a sequence of phenol extraction, ultracentrifugation, and fractionation by Cetavlon are described. Methylation of the polysaccharides followed by acid hydrolysis yielded 2,3,4,6-tetra-*O*-methyl-D-glucose, 2,4,6-tri-*O*-methyl-D-glucose, 2,4,6-tri-*O*-methyl-D-mannose, 4,6-di-*O*-methyl-D-glucose, 2,6-di-*O*-methyl-D-glucose, and an unidentified di-*O*-methyl-glucose. The acidic components found were: 2,3,4-tri-*O*-methyl-D-mannuronic acid, 3-*O*-(2,3,4-tri-*O*-methyl-D-mannuronosyl)-2,4,6-tri-*O*-methyl-D-glucose, and *O*-2,3,4-tri-*O*-methyl-D-mannuronosyl-(1 → 3)-*O*-2,4,6-tri-*O*-methyl-D-glucosyl-(1 → 3)-2,4,6-tri-*O*-methyl-D-glucose. The polysaccharides are composed of a main chain of D-glucose and D-mannose residues joined by 1,3-glycosidic bonds. Some glucose residues carry branches at C_2 and C_4 which terminate in either D-glucose or D-mannuronic acid residues. The three polysaccharides studied had similar chemical structures but varied in the amounts of component sugars and degree of branching.

Because of the tumor-necrotizing properties of the polysaccharides of *Serratia marcescens* (*Bacillus prodigiosus*), much work has been carried out during the last two decades on isolation from their culture filtrates as well as from the cells, on analysis, and on biological properties (1–8). However, only one attempt has been made to investigate the chemical structure of the carbohydrate polymer. Thus, Rathgeb and Sylven (9) carried out structural studies on a glucan isolated by fractionation of Shear's polysaccharide (1) with trichloroacetic acid and ethanol followed by treatment with hot picric acid (7). On the basis of methylation and periodate oxidation, data suggested that the polysaccharide was composed of glucose residues combined mutually by alternating 1,4- and 1,6-glycosidic bonds. However, a weakness in this work is that identification of the methylated sugar fragments was based solely upon paper chromatographic analysis. It is now known that methyl ethers of different sugars having the same degree of methylation can have the same R_f value in a particular solvent. It is rather speculative to assign any structural significance to the periodate-oxidation data unless some reasonable idea about the inter-sugar linkages in the polysaccharide is available. The present communication describes constitutional studies on polysaccharides (or lipopolysaccharides) isolated from the cells of *S. marcescens* by phenol–water extraction followed by fractionation of the polysaccharide mixture by (i) high-speed centrifugation and (ii) by complex formation with cetyltrimethylammonium bromide (Cetavlon) (10). Figure 1 shows an abbreviated scheme of the preparative procedures for polysaccharides used in the present study (for details see ref. 10).

Graded hydrolysis of a main polysaccharide fraction (6NR) with *N* sulphuric acid produced three uronic acid components (A, B, and C), which were separated from neutral sugars by ion-exchange resins and from each other by chromatography on thick filter paper sheets. Component A was identified as D-mannuronolactone. Component B had an equivalent weight of 356 and proved to be an aldobiouronic acid. It turned dark rapidly, thus precluding optical rotation measurements. The aldobiouronic acid was converted to its methyl ester methylglycoside and the latter was reduced with lithium aluminum

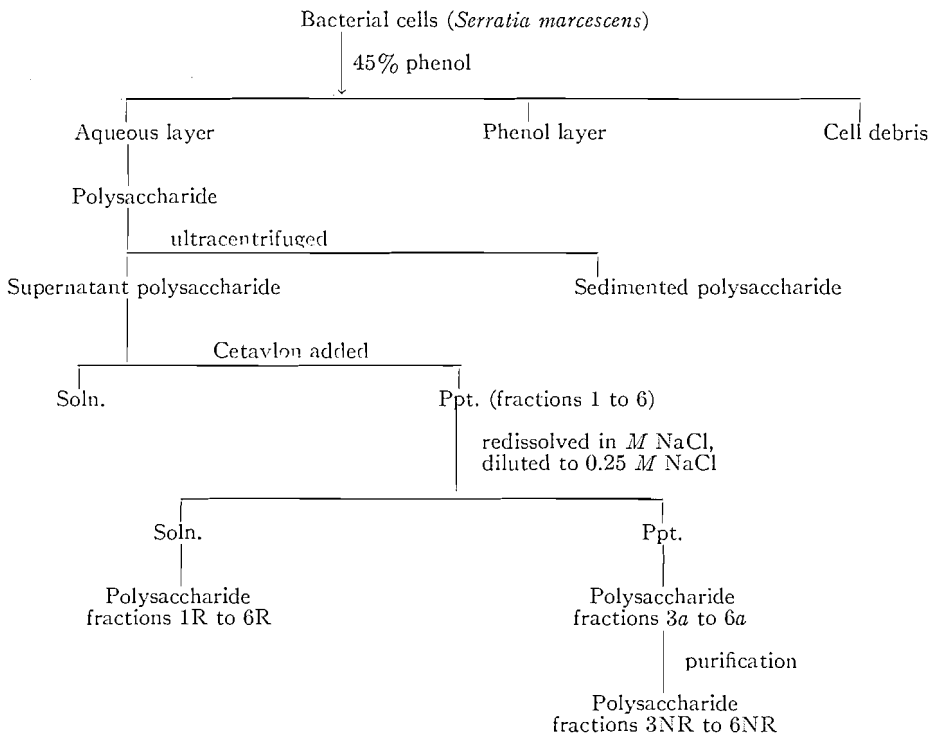

FIG. 1. Preparation of polysaccharides. Fractions 3R, 4R, and 5R were combined for methylation study; fraction 6NR was studied by methylation methods.

hydride to produce the methyl glycoside of a neutral disaccharide. Hydrolysis of the glycoside with acid produced D-glucose and D-mannose in equal proportions. The sugars were characterized as their *p*-nitroanilides. Similar experiments with component C revealed that it was an aldotriouronic acid in which a mannuronic acid residue was combined with two glucose units.

Fractions 6NR and combined fractions 3R, 4R, and 5R (see Fig. 1) were methylated separately with dimethyl sulphate and alkali and the methylation was completed by methyl iodide and silver oxide. The methylated polysaccharides were fractionated and the fractions having the highest methoxyl values were examined.

Methanolysis of 6NR methylated polysaccharide produced a mixture of methylated glycosides, a portion of which was separated by gas–liquid chromatography (11, 12) into three components. One of them crystallized and was shown to be methyl 2,4,6-tri-*O*-methyl-β-D-glucoside, m.p. 68–69° (13).

The methyl glycosides were hydrolyzed with acid to give a mixture of methylated sugars and methylated uronic acids. The uronic acids were converted to their barium salts and separated from the methyl glycosides by selective solvent extraction. The mixture of neutral methylated sugars was resolved by cellulose-column chromatography and the components were weighed and then identified as follows: (i) 2,3,4,6-tetra-*O*-methyl-D-glucose, characterized as *N*-phenyl 2,3,4,6-tetra-*O*-methyl-D-glucosylamine, m.p. 134–135°, $[\alpha]_D$ +240° in chloroform (14); (ii) 2,4,6-tri-*O*-methyl-D-glucose, m.p. and mixed m.p. 123–125° (15), identified as anilide, m.p. 162–165° (16); (iii) 2,4,6-tri-*O*-methyl-D-mannose, m.p. 63–65°, $[\alpha]_D$ +17.6° in water (17); the identity of the compound

was confirmed by ionophoresis and by its characteristic crystalline aniline derivative, m.p. and mixed m.p. 132°, $[\alpha]_D$ +7.8° in methanol (18), (iv) 4,6-di-*O*-methyl-D-glucose, m.p. and mixed m.p. 157–158°, $[\alpha]_D$ +62° in water (15); (v) 2,6-di-*O*-methyl-D-glucose, $[\alpha]_D$ +58° (19); and (vi) 2,3- or 2,4-di-*O*-methyl-D-glucose; the lack of sufficient material prevented complete identification of this component. The identification of 2,6-di-*O*-methyl-D-glucose, which was obtained as a sirup, is based upon the following evidence. Demethylation gave glucose and its mobility on paper chromatogram and paper electrophoretogram was the same as that of an authentic specimen of 2,6-di-*O*-methyl-D-glucose. It gave a negative color reaction with alkaline triphenyltetrazolium chloride (20, 21), indicating that C_2-hydroxyl of the sugar was substituted. The sugar was therefore 2,3-, 2,4-, or 2,6-di-*O*-methyl-D-glucose. Periodate oxidation of the sugar on paper followed by benzidine spray (22) showed that oxidation had taken place. Since, of the three possibilities, only 2,6-di-*O*-methyl-glucose is oxidizable, its identity is established.

Three methyl ether derivatives of acidic components were isolated from the hydrolyzate of the methylated polysaccharide. They were shown to be 2,3,4-tri-*O*-methyl-D-mannuronic acid (I), 3-*O*-(2,3,4-tri-*O*-methyl-D-mannuronosyl)-2,4,6-tri-*O*-methyl-D-glucose (II), and *O*-2,3,4-tri-*O*-methyl-D-mannuronosyl-(1 → 3)-*O*-2,4,6-tri-*O*-methyl-D-glucosyl-(1 → 3)-2,4,6-tri-*O*-methyl-D-glucose (III) on the basis of the following experimental evidence. The components I, II, and III were each transformed into their methyl ester methyl glycoside derivatives, which were reduced with lithium aluminum hydride and hydrolyzed. Component I gave only 2,3,4-tri-*O*-methyl-D-mannose, $[\alpha]_D$ +1° in water (23), which was identified by paper and gas chromatography and by preparation of the crystalline derivative 2,3,4-tri-*O*-methyl-D-mannonophenylhydrazide, m.p. 166° (24), via 2,3,4-tri-*O*-methyl-D-mannono-δ-lactone. Component II afforded a mixture of 2,3,4-tri-*O*-methyl-D-mannose and 2,4,6-tri-*O*-methyl-D-glucose (in approximately equal proportions), the methylated sugars being identified by the methods described earlier. Component III also yielded 2,3,4-tri-*O*-methyl-D-mannose and 2,4,6-tri-*O*-methyl-D-glucose but the proportion of the two sugars in this case was approximately 1:2.

Two methylated polysaccharides (S_0,S_I) which were isolated by fractionation of the methylated combined polysaccharides 3R, 4R, and 5R (Fig. 1) were also analyzed in the manner described for methylated 6NR polysaccharide. Both methylated fractions gave upon hydrolysis 2,3,4,6-tetra-*O*-methyl-D-glucose, 2,4,6-tri-*O*-methyl-D-glucose, 2,4,6-tri-*O*-methyl-D-mannose, and di-*O*-methyl sugars, besides the methylated aldobiouronic acid 3-*O*-(2,3,4-tri-*O*-methyl-D-mannuronosyl)-2,4,6-tri-*O*-methyl-D-glucose. There was also evidence for the presence of small amounts of methylated glucuronic acid, indicating thereby that some D-glucuronic acid residues were present in the polysaccharide in addition to the main acid component, D-mannuronic acid. The ratios of the methylated sugars produced upon hydrolysis of the methyl ethers of different polysaccharide fractions are given in Table I.

TABLE I

Mole ratios of methylated sugars

Methylated sugar	Fraction 6NR	Fraction S_0	Fraction S_I
2,3,4,6-Tetra-*O*-methyl-D-glucose	4.5	1.0	1.0
2,4,6-Tri-*O*-methyl-D-glucose	21.0	20.0	10.0
2,4,6-Tri-*O*-methyl-D-mannose	11.0	9.0	3.0
4,6-Di-*O*-methyl-D-glucose	2.5	1.0	1.0
2,6-Di-*O*-methyl-D-glucose	2.0		
Di-*O*-methyl-D-glucose (?)	1.0	—	—

6NR and 4R polysaccharides were oxidized with sodium metaperiodate, when 0.52 and 0.50 mole of periodate were consumed and 0.122 and 0.125 mole of formic acid were produced respectively per anhydrohexose unit.

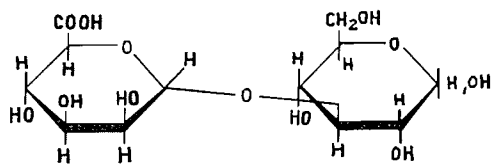
DISCUSSION

Polysaccharide (6NR)

Isolation of D-mannuronolactone from the hydrolyzate of the polysaccharide and 2,3,4-tri-*O*-methyl-D-mannuronic acid from the products of hydrolysis of the methylated polysaccharide established beyond doubt that D-mannuronic acid was a component part of this polymer. As far as the authors are aware, this is the second polysaccharide in which D-mannuronic acid occurred as a building unit of the polymer, the other well-known example being that of alginic acid. D-Mannuronic acid has been suggested by Barker *et al.* to be a constituent of the capsular polysaccharide of *Aerobacter aerogenes*; however, definitive identification of the acid has not been made (25).

Although the methylation data were not sufficient for the formulation of a unique structure for the polysaccharide, the following points of constitutional significance emerged from these studies. The isolation of 2,4,6-tri-*O*-methyl-D-glucose and 2,4,6-tri-*O*-methyl-D-mannose showed that the polysaccharide had a backbone of D-glucose and D-mannose residues linked by 1,3-glycosidic bonds. Some of these glucose residues carried branches at C_2 or C_4 which terminated either in D-glucose or D-mannuronic acid residues, as indicated by the identification of 2,6-di-*O*-methyl, 4,6-di-*O*-methyl, 2,3,4,6-tetra-*O*-methyl ethers of D-glucose and 2,3,4-tri-*O*-methyl-D-mannuronic acid. Di-*O*-methyl sugars may arise from undermethylation and/or demethylation of the polysaccharide, but the isolation of tetra-*O*-methyl-glucose and the fact that no di-*O*-methyl ethers of mannose were obtained showed that the di-*O*-methyl-glucoses have definite structural significance.

Isolation of the aldobiouronic acid (B) from the polysaccharide and the identification of 3-*O*-(2,3,4-tri-*O*-methyl-D-mannuronosyl)-2,4,6-tri-*O*-methyl-D-glucose (II) as one of the methylated fragments from the methylated polysaccharide proved that the D-mannuronic acid was combined to the rest of the polymer through D-glucose residues and by 1,3-glycosidic bonds. It also proved that the D-mannuronic acid was in a terminal position. In the same way, the isolation of an aldotriouronic acid composed of mannuronic acid and two glucose residues and its corresponding methyl ether from the methylated polysaccharide provided evidence that the D-mannuronic acid is joined to one of two continuous D-glucose residues in the molecule.



B

A high positive specific optical rotation of the polysaccharide as well as of its methyl ether indicated that the majority of the intersugar linkages had an α-configuration. The low consumption (0.5 mole) of periodate per anhydrohexose unit indicated that most of the sugar residues in the polysaccharide are immune to periodate oxidation and those which were oxidized were the non-reducing end groups of D-glucose and D-mannuronic

acid. The interpretation of the periodate-oxidation data was complicated by the presence of uronic acid residues, which tend to become oxidized, and also by the possibility that some of the sugar residues might be esterified by the phospholipid moiety of the lipopolysaccharide.

Polysaccharides (Combined 3R, 4R, 5R)

These polysaccharides were built up of similar sugar residues and the sugars were linked in the same manner as in the 6NR polysaccharide. However, they differed from the latter polysaccharide in the degree of branching and in their glucose:mannose ratio.

EXPERIMENTAL

All evaporations were carried out under diminished pressure below 40° unless otherwise stated.

Paper chromatograms were run by the descending method using the following solvent systems (v/v): (A) pyridine – ethyl acetate – water (2:1:2); (B) butanone–water azeotrope containing ammonia; (C) benzene–ethanol–water–ammonia (200:47:14:1); (D) 1-butanol–ethanol–water (40:11:19); and (E) ethyl acetate – acetic acid – formic acid – water (18:3:1:4). *p*-Anisidine hydrochloride was used to detect the sugars and their methyl ethers on paper chromatograms (26). R_g and M_G represent rates of movement of sugar paper chromatographically and electrophoretically in relation to 2,3,4,6-tetra-*O*-methyl-D-glucose and D-glucose respectively.

Hydrolysis of the Polysaccharide and Isolation of Uronic Acid Components

Polysaccharide (2.37 g) was heated in *N* sulphuric acid (50 ml) at 70° C for 23 hours and then at 100° C for 8 hours. The hydrolyzate was neutralized with barium hydroxide and barium carbonate, and the barium sulphate was removed by filtration. The barium ions were removed by Amberlite IR-120 and the acidic components were adsorbed on a column of Dowex 1 resin (acetate form). After the neutral sugars were washed off with water, the acids were eluted with *N* formic acid (yield of uronic acids 1.003 g). Chromatography on paper in solvent E showed three spots; one spot (component A) had the same mobility as mannuronolactone, the other two spots (components B and C) had $R_{\text{mannurone}}$ values of 0.22 and 0.36 respectively. The acids were separated on Whatman No. 3 MM paper using solvent E and gave the following yields: A, 82 mg; B, 334 mg; and C, 76 mg.

Attempts to crystallize A, $[\alpha]_D^{25}$ +91° (*c*, 1 in water), were unsuccessful. Reduction of its methyl ester methyl glycoside yielded a sugar which was identified chromatographically (solvent A) as mannose.

Component B, which appeared to be an aldobiouronic acid (acid equivalent: calculated 340, found 356), turned dark rapidly on standing and optical rotation measurements were impossible. Component B (134 mg) was heated for 10 hours at 75° C with 2% methanolic hydrogen chloride (3 ml). The methyl glycoside methyl ester was dissolved in tetrahydrofuran (25 ml) and reduced with lithium aluminum hydride (27). The recovered disaccharide glycoside (130 mg), $[\alpha]_D^{25}$ +34.8° (*c*, 2.3 in methanol), was hydrolyzed with *N* sulphuric acid. Chromatographic examination on paper using solvent A showed glucose and mannose in approximately equal amounts.

The sugars were separated on sheets of paper using solvent A, when mannose (53.6 mg) and glucose (57.9 mg) were obtained. The sugars were converted to their *p*-nitroanilides by heating with *p*-nitroaniline in methanol. The recovered *N*-*p*-nitrophenyl-D-mannopyranosylamine dihydrate had a melting point of 219° and the *N*-*p*-nitrophenyl-D-glucopyranosylamine dihydrate a melting point of 184° C, which are in good agreement with the reported values (13).

Similar examination of the derived neutral glycoside of component C showed that it was composed of mannose and glucose in the proportion of approximately 1:2.

Methylation of Fraction 6NR

The polysaccharide (4.01 g) was methylated three times by dimethyl sulphate and alkali (28) to yield chloroform-soluble (0.76 g) and chloroform-insoluble (5.03 g) fractions. These two fractions were then methylated five times by Purdies reagents (29); the chloroform-insoluble fraction yielded a product (0.85 g) with OCH_3 26.9%, and the chloroform-soluble material gave a product (4.73 g) with OCH_3 32.6%. Further methylation of this latter product did not increase its methoxyl content. The methylated polysaccharide (4.7 g) was dissolved in a mixture of chloroform – ethyl ether (60 ml, 1:5, v/v) and fractionated by addition of petroleum ether (b.p. 30–60°). A total of nine fractions were recovered and their specific rotations and methoxyl values are given in Table II. On the basis of similarity of these values, fractions 1, 2, and 3 were combined for methanolysis studies.

Methanolysis of Methylated Polysaccharides

The combined methylated polysaccharides (2.8 g) were refluxed on a water bath in 8% methanolic hydrogen chloride (80 ml). The course of methanolysis was followed by the changes in specific rotation: $[\alpha]_D$ initial (not observable); +75.5° (2 hours); +88° (6 hours); +90° (12 hours, constant value).

TABLE II

Fractionation of methylated polysaccharide from chloroform solution by petroleum ether

Fraction	Weight (g)	$[\alpha]_D^{27}$ in $CHCl_3$	OCH_3 value (%)
1	0.1535	+118°	36.1
2	1.5274	+100°	36.4
3	1.1200	+108°	38.4

A small portion of the mixture of methyl glycosides, after neutralization (Ag_2CO_3), was examined by gas–liquid chromatography (11, 12) using Apiezon M at 150° C and a flow rate of 75 ml of argon/min. Three distinct peaks were observed and the components of the mixture were collected separately. One of the components from the column crystallized as needles, which were recrystallized from ethyl – petroleum ether. The crystals had m.p. 67.5–69° and showed no depression when mixed with an authentic sample of methyl 2,4,6-tri-*O*-methyl-β-D-glucoside.

Acid Hydrolysis

A portion (65 mg) of the mixture of methyl glycosides was reserved and the remainder was hydrolyzed with hydrochloric acid (60 ml, 0.8 *N*) on a steam bath for 8 hours. The solution became dark upon hydrolysis and had a final $[\alpha]_D$ of +50° (*c*, 5). The hydrolyzate was neutralized (Ag_2CO_3), filtered, and silver ions were removed by H_2S. Evaporation of the solution afforded a light brown, clear syrup (2.67 g) which upon chromatography using solvent B gave spots with the following M_G values: 0.24; 0.59; 0.66; 1.00. From the chromatographic analysis the following sugars were tentatively identified: (i) 2,3,4,6-tetra-*O*-methyl-D-glucose; (ii) 2,4,6-tri-*O*-methyl-D-glucose; (iii) 2,4,6-tri-*O*-methyl-D-mannose; (iv and v) two di-*O*-methyl-hexoses; and (vi) uronic acid containing material which remained on the starting line.

The mixture of methylated sugars and uronic acids was passed over IR-120 and the acids were converted subsequently to their barium salts by heating with barium hydroxide at 65°. The neutral sugars were removed by continuous extraction with ethyl acetate for 4 days. The extract was evaporated to a sirup (1.734 g) which partly crystallized. The aqueous solution left after ethyl acetate extraction was acidified with *N* sulphuric acid and the extraction was continued with ethyl acetate for 48 hours. The extract was dried (Na_2SO_4) and evaporated to give a mixture of methylated uronic acid as a sirup (0.615 g). Examination of the acids by chromatography (solvent E) showed that there were three main components having R_g values 1.0, 0.8, and 0.55 respectively. They were separated from each other by sheet-filter-paper chromatography using solvent E and were designated fractions I, II, and III respectively.

Separation of the Mixture of Neutral Methylated Sugars on a Cellulose Column

The mixture (1.484 g) was put on a cellulose column and the column was developed with 1-butanone–water azeotrope. Ten-milliliter fractions were collected every 20 minutes. The appropriate fractions were combined and identified as described below.

Identification of Methylated Sugars

2,3,4,6-Tetra-O-methyl-D-glucose

The sirupy product (253 mg), $[\alpha]_D$ +83° in water (*c*, 1), was dissolved in 50% aqueous methanol and the insoluble material removed by filtration. Chromatographic examination in three different solvent systems (B, C, and D) showed that the sugar moved as a single spot and had the same mobility as 2,3,4,6-tetra-*O*-methyl-D-glucose. Examination of the methyl glycoside of the sugar by gas–liquid partition chromatography (11, 12) gave the same retention time as methyl 2,3,4,6-tetra-*O*-methyl-α,β-D-glucoside. Demethylation with boron trichloride (30) showed that glucose was the only parent sugar. The methylated sugar was identified as *N*-phenyl 2,3,4,6-tetra-*O*-methyl-D-glucosylamine, m.p. and mixed m.p. 134–135°; $[\alpha]_D$ +240° ±3° in chloroform (*c*, 0.3) (14).

The tri-*O*-methyl fraction, which was a mixture, was resolved into two components by chromatography on Whatman No. 3MM paper using solvent C. The two methylated sugars were identified as follows.

2,4,6-Tri-O-methyl-D-glucose

This sugar gave a bright red color with *p*-anisidine spray and yielded only glucose on demethylation. Its R_g (solvent C) was 0.47, which is the same as that of an authentic sample of 2,4,6-tri-*O*-methyl-D-glucose. The sirup crystallized and, after recrystallization from ethyl ether, had m.p. and mixed m.p. 123–125° (15).

Refluxing with aniline in ethanolic solution yielded *N*-phenyl 2,3,6-tri-*O*-methyl-D-glucosylamine, m.p. 162–165° (16). Examination of the methyl glycoside of the sugar by gas–liquid partition chromatography showed that it had the same retention time as that of authentic methyl 2,4,6-tri-*O*-methyl-α,β-D-glucoside.

2,4,6-Tri-O-methyl-D-mannose

This sugar had R_g 0.61 (solvent C) and M_G 0.0 in borate buffer, values which are in agreement with those of an authentic sample of 2,4,6-tri-*O*-methyl-D-mannose. On demethylation with boron trichloride it gave only mannose. Upon seeding with 2,4,6-tri-*O*-methyl-D-mannose, the sirup crystallized and, after recrystallization from ether–hexane, had m.p. and mixed m.p. 63–65° and showed $[\alpha]_D$ +17.6° in water (*c*, 1). These values are in good agreement with those reported for this sugar (17). The anilide, after recrystallization from ethyl ether, had m.p. and mixed m.p. 132° and $[\alpha]_D$ +7.8° in methanol (*c*, 0.35). The reported values for *N*-phenyl 2,4,6-tri-*O*-methyl-D-mannosylamine are m.p. 134° and $[\alpha]_D$ +8° (18).

The di-*O*-methyl sugar fraction did not give satisfactory separation of its components on paper using solvents B, C, and D. However, it was separable by electrophoresis on paper strips in 0.05 *M* borate buffer at 800 volts for 2 hours. Two main components (X, Y) and a minor one (Z) were separated. The methylated sugars were recovered from the paper by elution with water. Sodium ions were removed by Amberlite IR-120 and boric acid was removed by repeated distillation with methanol. The M_G values of the fractions were: X, 0.17; Y, 0.071; Z, 0.00 and the colors produced with the *p*-anisidine spray were: X, brown; Y, pink; and Z, bright red. Identifications of the sugars were made as follows.

4,6-Di-O-methyl-D-glucose

The rate of movement of the sugar on paper chromatogram (solvents B and C) was the same as that of 4,6-di-*O*-methyl-D-glucose and the brown color given by the *p*-anisidine spray was the same as that of an authentic specimen. Demethylation of this component produced only glucose. The sugar crystallized as fine needles from ethyl acetate solution, and after recrystallization from the same solvent, the crystals had m.p. 157–158° and showed $[\alpha]_D$ +62° in water (*c*, 1.9). The reported melting point and $[\alpha]_D$ for 4,6-di-*O*-methyl-D-glucose are 156–158° (19) and +62.4° (15) respectively.

2,6-Di-O-methyl-D-glucose

The sugar gave glucose on demethylation. Its mobility on paper in solvents B and C and by electrophoresis in borate buffer were the same as that of an authentic sample of 2,6-di-*O*-methyl-D-glucose. The specific rotation, +58° in water (*c*, 1), agreed closely with the reported value of +58.3° (19). The sugar gave a negative reaction with triphenyltetrazolium chloride (20, 21) but was detectable on the paper with periodate–benzidine spray (22).

Di-O-methyl Sugar (Component Z)

Its M_G value in borate buffer was 0.0, and upon demethylation, the sugar yielded glucose. It gave a negative triphenyltetrazolium test, showing thereby that C_2 was substituted. It was not oxidized by periodate. From these results the component appeared to be either 2,3- or 2,4-di-*O*-methyl-D-glucose. Scarcity of material precluded further investigation.

Identification of Methylated Uronic Acid Components

Fractions I, II, and III (10 mg each) were converted to their methyl ester methyl glycoside derivatives by heating with 2.5% methanolic hydrogen chloride (2 ml) at 100° in a sealed tube for 15 hours. Reduction with lithium aluminum hydride (50 mg) in tetrahydrofuran (40 ml) yielded sugars, which, after recovery by extraction with chloroform, were hydrolyzed with *N* sulphuric acid for 15 hours. The hydrolyzates were neutralized ($BaCO_3$) and chromatographed in solvent C. Fraction I yielded one main component, R_g 0.61; fractions II and III gave two components each, R_g 0.61 and 0.47 respectively. Chromatography of the sugars on paper using solvents B and C indicated that the sugar having R_g 0.61 (solvent C) and R_g 0.71 (solvent B) was 2,3,4-tri-*O*-methyl-D-mannose and the other sugar (R_g 0.47 (solvent C) and R_g 0.60 (solvent B)) was 2,4,6-tri-*O*-methyl-D-glucose.

Thus, fraction I yielded only 2,3,4-tri-*O*-methyl-D-mannose and fractions II and III yielded a mixture of this sugar and 2,4,6-tri-*O*-methyl-D-glucose. The mixtures were resolved by sheet-filter-paper chromatography and the sugars identified in the following manner.

2,4,6-Tri-O-methyl-D-glucose

The sugar crystallized and, after recrystallization from ethyl ether, had m.p. and mixed m.p. 123–125° (15). It gave an anilide, m.p. 162–165° (16). The identification was further confirmed by examination of its methyl glycosides by gas–liquid chromatography as described earlier.

2,3,4-Tri-O-methyl-D-mannose

The sirup, $[\alpha]_D$ +1° in water (*c*, 1), when examined on paper chromatograms in solvents B and C showed the same rate of movement as an authentic sample of 2,3,4-tri-*O*-methyl-D-mannose. Gas–liquid partition chromatography of the methyl glycoside of the sugar gave the same retention time as an authentic specimen of methyl 2,3,4-tri-*O*-methyl-α-D-mannoside.

The sugar (107 mg) was dissolved in water (2 ml), and barium carbonate (90 mg) and bromine (0.5 ml) were added. The oxidation was allowed to take place in the dark for 48 hours, after which time the excess of bromine was expelled by aeration. The reaction mixture was filtered, the filtrate acidified and extracted with chloroform. Evaporation of the chloroform extract gave 2,3,4-tri-*O*-methyl-D-mannonic acid, which

was distilled, b.p. (bath temp.) 110–120° (0.005 mm), to afford 2,3,4-tri-*O*-methyl-D-mannono-δ-lactone. Treatment of methanolic solution of the lactone (63 mg) with phenylhydrazine (33 mg) for 3 hours at 100° yielded crystalline 2,3,4-tri-*O*-methyl-D-mannonophenylhydrazide, which on recrystallization from ethyl acetate had m.p. 166° (reported value 166°) (26).

Methylation of Combined Fractions 3R, 4R, and 5R

The combined fractions (2.0 g) were methylated three times with dimethyl sulphate and alkali, using each time 50 ml of dimethyl sulphate and 150 ml of 45% potassium hydroxide. The first methylation was done in an atmosphere of nitrogen; acetone was added in subsequent methylations to keep the methylated product in solution. The rest of the procedure was the same as that described for 6NR. The chloroform-soluble material was methylated five times with methyl iodide and silver oxide, acetone being added in the first methylation to dissolve the partially methylated product. The methylated polysaccharide was recovered as a light brown friable glass (1.2 g; OMe 41.55%). The methylated polysaccharide was fractionated from chloroform – ethyl ether solution with petroleum ether and the analytical data on the fractions are given in Table III.

TABLE III

Analytical data of fractions of methylated polysaccharide

Fraction*	Weight (g)	$[\alpha]_D^{27}$ in $CHCl_3$	OCH_3 (%)
P I	0.1582	+106°	43.56
P II	Negligible	—	—
P III	0.0860	+109°	35.76
P IV	0.2536	+110°	38.8
S I	0.5704	+ 62°	41.34
S II	0.1000	+ 67°	25.95
S III	0.0396	+ 10°	2.4
S IV	0.0522	+ 11.5°	7.6

*P I, P II, P III, and P IV were combined to give S_0.

Examination of Methylated Fractions S_0 and S_I (See Table III)

Methanolysis and Hydrolysis

Fraction S_0.—This had $[\alpha]_D$ +114° (*c*, 1.18 in methanol) and was heated for 12 hours in 8% methanolic hydrogen chloride (20 ml). A portion of the methyl glycosides was hydrolyzed by heating with 0.5 *N* hydrochloric acid for 10 hours at 100° (final $[\alpha]_D$ +69°).

Fraction S_I.—This showed $[\alpha]_D$ +83° (*c*, 0.93 in methanol). It was treated the same way as described for S_0. After hydrolysis it had $[\alpha]_D$ +66°.

Chromatographic Examination of Methylated Sugars

The hydrolyzate of S_0 when examined by chromatography using solvents B and D showed the following components: 2,3,4,6-tetra-*O*-methyl-D-glucose; 2,4,6-tri-*O*-methyl-D-glucose; 2,4,6-tri-*O*-methyl-D-mannose; dimethyl sugar fraction; and uronic acid fraction.

Hydrolysis of fraction S_I gave the same components as S_0. The uronosides and glycosides from S_0 were separated by converting the former into their barium salts, from which the neutral glycosides were extracted with chloroform.

Examination of Neutral Sugar Fractions

The neutral glycosides of fraction S_0 were examined by gas–liquid partition chromatography and the retention times were compared with those of known sugar glycosides. By this means, the following sugars were found: 2,3,4,6-tetra-*O*-methyl-D-glucose; 2,4,6-tri-*O*-methyl-D-glucose; 2,4,6-tri-*O*-methyl-D-mannose; and an unresolved dimethyl fraction. Paper electrophoresis of the dimethyl fraction in borate buffer showed the presence of 4,6-di-*O*-methyl-D-glucose, 2,6-di-*O*-methyl-D-glucose, and an unidentified dimethyl spot.

Examination of fraction S_I by the same means as described for fraction S_0 showed that the same sugars were present, although the proportions were different. The ratios of the methylated fragments are given in Table I. Since it was clear from chromatographic evidence that the same sugars were present in all three fractions (6NR, S_0, and S_I) of the methylated polysaccharide and identification had been made of those in fraction 6NR, it was considered unnecessary to identify those in fractions S_0 and S_I further.

Methylated Uronic Acid Components of Fractions S_0 and S_I

The amounts of material were small and the whole quantity of each was treated as in the case of 6NR methylated polysaccharide. Reduction of the methyl ester methyl glycosides with lithium aluminum hydride yielded disaccharides which were subjected to acid hydrolysis. The sugars were separated by paper chromatography using solvent C and were found to be 2,3,4-tri-*O*-methyl-D-mannose and 2,4,6-tri-*O*-methyl-D-glucose. A portion of the sugars in the acid hydrolyzate was treated with methanolic hydrogen chloride

and the methyl glycosides thus formed were examined by gas–liquid chromatography. In addition to the above-mentioned sugars, there was present in the mixture a small amount of the glycosides of 2,3,4-tri-*O*-methyl-D-glucose.

Periodate Oxidation

Samples 4R (0.0854 g) and 6NR (0.0864 g) were each dissolved in water (50 ml), and 0.1 *M* sodium periodate (50 ml) was added. The samples and the blanks were put in brown, 250-ml glass-stoppered flasks and stored in the refrigerator (5° C). From time to time aliquots were taken out and periodate consumption and formic acid production were determined in the following manner.

Periodate Consumption

To 5 ml of aliquot, sodium bicarbonate (1.7 g), sodium arsenite solution (10 ml), and potassium iodide (1 ml) were added. The flasks were stored in the dark for 15–20 minutes and then titrated against 0.0203 *N* iodine using starch as indicator.

Formic Acid Production

To 10 ml of aliquot, seven drops of 2-methyl-1,2-propanediol were added. After 20 minutes, 1 ml of 20% potassium iodide was added and the liberated iodine was titrated against 0.01 *N* sodium thiosulphate.

Since the rate of oxidation was very slow during the first 24 hours, the samples were removed from the refrigerator and stored in a room maintained at 15° C. The results are given in Table IV.

TABLE IV

Periodate oxidation of fractions 4R and 6NR

Sample	Time (hours)	IO_4^- consumption (moles)	HCOOH produced (moles)
4R	5	0.27	0.076
	24	0.32	—
	48	0.29	0.080
	72	0.37	0.096
	196	0.50	0.125
6NR	5	0.17	0.071
	24	0.19	—
	48	0.38	0.086
	72	—	0.095
	196	0.52	0.122

ACKNOWLEDGMENTS

The authors wish to record their grateful thanks to Professor F. Smith for the specimens of 2,4,6-tri-*O*-methyl ethers of D-glucose and D-mannose, to Dr. C. T. Bishop and Mr. F. P. Cooper for gas-chromatographic analyses, and to Mr. W. R. Rowsome for valuable technical assistance.

ABSTRACT

The thermal decomposition of diazomethane (DM) into singlet methylene radicals and nitrogen has been studied from 225° to 450° in 10:1 olefin–diazomethane mixtures. At 2.5 cm pressure, $k = 1.2\times10^{12} \exp(-34{,}000/RT)$ sec^{-1}. The methylene radicals have similar reactivity to methylene generated from photolytic decomposition of DM, as judged by the follow-up reactions with ethylene and *cis*-butene-2. The structural isomerization reactions of energized cyclopropane and the structural and geometric isomerization of 1,2-dimethylcyclopropane (DMC), formed from the addition of the thermally generated methylene to the olefins, were measured from 250° to 450° over a wide range of pressures. For comparison, cyclopropane formed from photolysis at 4358 Å and 25° of DM and ethylene was studied. As judged from comparison of the experimental isomerization rate constants, the energy of the cyclopropanes formed at 350° in the thermal DM system is about the same as for cyclopropanes formed by photolysis at 4358 Å of DM at 25°. The experimental rate constants obtained on the assumption of strong collisions are compared with calculated rate constants which are based on quantum statistical models for k_E which fit literature data on conventional thermal isomerization of cyclopropane and DMC. From this comparison, the average energies of the formed molecules in the thermal systems are estimated to be between 107 and 115 kcal/mole, depending upon the temperature. Photolysis at 25° of the ketene–ethylene system (3200 Å) and of DM–ethylene system (4358 Å) give cyclopropane characterized as being at 103 and 111 kcal/mole respectively. These energies deduced from kinetic data are compared with available thermochemical quantities; the existing value of $\Delta H_f^0(CH_2N_2)$ is questioned. Further support for fast intramolecular relaxation of vibrational energy in DMC, relative to the relaxation process for reaction, is noted. Comparison of data in the literature on the ketene and DM photolytic systems strongly suggests that a larger fraction of the excess light energy resides with methylene from ketene (0.65–0.8) than with methylene from DM (0.3–0.5). Various approximations for the calculation of k_E are examined and are compared with accurate quantum statistical evaluation.

In a preliminary communication (1), we reported that thermal decomposition of diazomethane (DM) (2–4) proceeds with conservation of spin angular momentum to give singlet methylene radicals and nitrogen, in contradistinction to the thermal decomposition of the isoelectronic molecule nitrous oxide (5). The studies have now been extended to include more data on the thermal decomposition of DM; on the follow-up reactions of methylene with *cis*-butene at three temperatures, and with ethylene at two temperatures; and on the photolysis (6) of DM at 25° in the presence of ethylene, which was done for comparison.

The predominant reactions of singlet methylene with olefins, insertion across C—H bonds (7) and addition to the double bond (8), give vibrationally excited molecules which may either decompose or be deactivated through collisions with bath molecules (8 (*c* and *e*), 9). (Reference 9 is most closely related to this work.) Recent explanation (10) of the pressure dependence of methylene radical in terms of singlet–triplet transitions of the methylene are not believed to apply in this work for reasons we have previously presented (1), and which are further supported here.

The use of singlet methylene radicals arising from photolysis of ketene and DM at various wavelengths with different substrates offers the possibility, beautifully exploited by Butler and Kistiakowsky (9(*c*)), of producing relatively monoenergetic molecules at variable, high vibrational energies. Unfortunately, due to the uncertainty in $\Delta H_f(CH_2)$ and in the fraction of excess light energy carried by the methylene, the energy of the hot cyclopropanes has not been well known. In the present work, utilizing a DM *thermal* decomposition source of CH_2 radicals, the energy of the formed cyclopropanes may, in principle, be changed in known manner by variation of temperature. The situation turns out not to be so simple; but by use of all these data, together with a relatively accurate quantum statistical formulation for the magnitude and energy dependence of the structural isomerization rate constants of the energized molecules, an attempt has been made to rationalize the various experimental rate constants and energies of cyclopropane and dimethylcyclopropane formed via these different sources of methylene radicals.

EXPERIMENTAL

Materials

DM prepared from N,N′-nitrosomethylurea was stored in butyl phthalate at −196° (9(*b*)). Ethylene and *cis*-butene-2 were Phillips research grade. The *cis*-butene-2 was distilled and corrections were applied for the remaining 0.4% *trans*-butene impurity.

Apparatus

A conventional vacuum system was used for gas handling. Pyrolyses were performed in seasoned pyrex bulbs of various sizes. Temperature gradients across the bulbs were less than 2°.

A G.E. AH-6 high-pressure (quartz-jacket) mercury lamp was used in the photolysis of DM. A combination of Dow Corning No. 5543 and No. 3389 filters isolated the 4358 Å line with the following distribution of absorbed radiation: 75% at 4450–4250 Å, 11% at 4450–5000 Å, and 14% at 4250–4000 Å.

All analyses were performed by gas–liquid phase chromotography.[2]

Procedure

Vessels were conditioned by treating with air at 375° for several hours, evacuating, and seasoning with *cis*-butene (5–10 cm Hg) for 8 hours at 300°; a run was done and discarded. The vessel was then, usually, properly seasoned. Data from unseasoned vessels were characterized by excess stabilization products (cyclopropanes).

Runs were performed by flash-distilling a liquid mixture of DM and olefin into the furnace as with butene, or by premixing the two gases and expanding in the gaseous mixture as with ethylene. Most runs were made with 1:10 mixture of DM to olefin; at the lowest pressure and highest pressure, the ratios approached 1:5 and 1:50, respectively. For photolysis, the ratios were at least 1:10.

RESULTS AND DISCUSSION

Thermal Decomposition of DM

Temperature Dependence of Products from DM Decomposition with Butene

Principal products from thermal decomposition of DM with *cis*-butene-2 above 220° are the expected C_5H_{10} compounds (9(*b*)). Figure 1 shows the variation of the C_2H_4/C_5H_{10}

$$CH_2N_2 \xrightarrow{k_1} CH_2 + N_2 \qquad [I]$$

$$CH_2 + C_4H_8 \longrightarrow C_5H_{10}$$

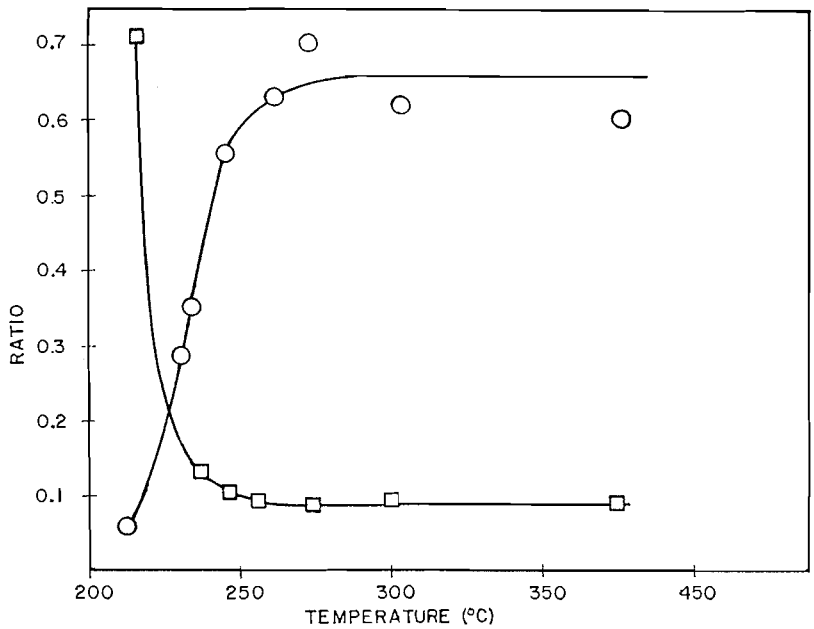

FIG. 1. Variation of the C_5H_{10}/DM ratio, ○, and of the C_2H_4/C_5H_{10} ratio, □, with temperature, for DM with *cis*-butene-2; total pressure = 2.5 cm.

product ratio and the C_5H_{10}/DM ratio with temperature. These runs were made with 1:20 mixtures of DM to *cis*-butene, at constant concentration of 7.4×10^{-7} mole/cc (~2.5 cm) of butene. In all cases complete decomposition of DM occurred. The deficit in material balance in Fig. 1 is due to deposition of polymethylene upon the reactor walls. Below 250°, ethylene product predominates; above 250°, only ~10% of the products are ethylene and propene and their production is directly dependent upon the DM/butene ratio. This suggests that ethylene arises at lower temperatures mainly by the molecular reaction [II*a*] reported by Steacie (3), and by attack mainly of methylene upon DM (reaction [II*b*]) (6(*a*)) at higher temperatures. Products formed in trace

$$2CH_2N_2 \longrightarrow C_2H_4 + 2N_2 \qquad [II a]$$

$$CH_2 + CH_2N_2 \longrightarrow C_2H_4 + N_2 \qquad [II b]$$

quantities were ethane, propane, butane, pentane, and isopentane, which may arise from reactions of CH_3 radicals resulting from H abstraction by methylene (7(*b*), 9(*b*)); these products were not followed quantitatively.

Kinetic Order and Activation Energy

C_5H_{10} production, i.e. the rate law for DM decomposition, followed first-order kinetics (Fig. 2). The data were obtained under the same conditions as those in Fig. 1. At low temperatures (below 225°) reproducible data could not be obtained in our system; it also appeared that at the lower temperatures the rate constants were high, suggesting heterogeneity. In view of the low C_5H_{10} yields and importance of C_2H_4 production below 250°, the activation energy determination here is based upon the three higher temperatures (Fig. 3). The rate constant $k_1 = 1.2\times10^{12}\exp(-34{,}000/RT)$ sec^{-1} for the thermal homogeneous decomposition of DM was obtained. Shantarovich (4) has reported $k_1 = 8\times10^{10}\exp(-31{,}400/RT)$ sec^{-1} in a nitrogen flow system; we prefer our value. E_a

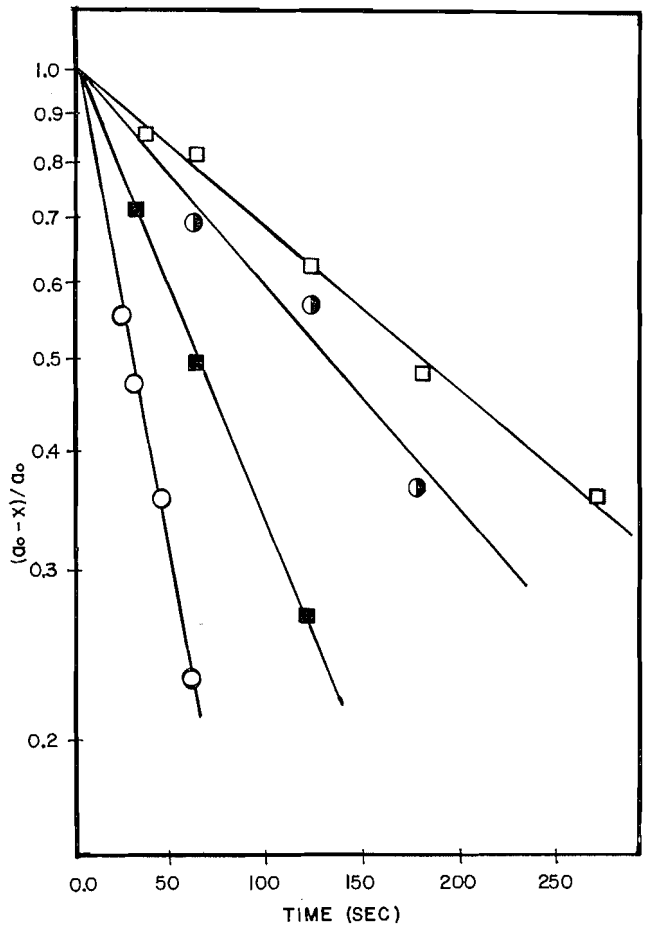

FIG. 2. Illustration of kinetic first-order behavior for formation of methylene-derived C_5H_{10} products: 212°, □; 232°, ◑; 245°, ■; 257°, ○.

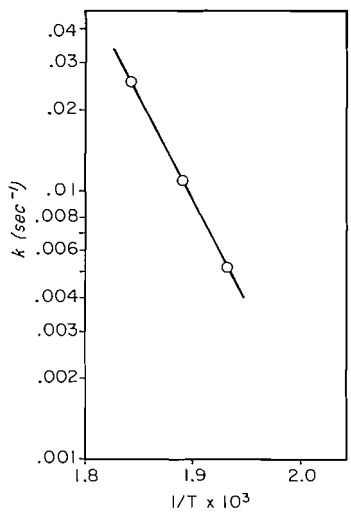

FIG. 3. Arrhenius plot for the three highest temperatures.

was measured here in a region of falloff which is estimated theoretically, and also by comparison with results for CH_3NC (11) (a molecule having somewhat similar complexity, structure, reaction temperature, and activation energy) to be ~1 kcal/mole below E_∞. A_∞ should also rise to the value of $\sim 10^{13}$ sec^{-1}, normal for many cases in which no change in electronic multiplicity is involved.

Homogeneity of Reactions of Methylene

The homogeneity of the methylene reactions that form cyclopropanes was tested in a 110-cc vessel packed with glass wool to give a tenfold increase in surface area. The results for *cis*-butene-2 at 1.3 cm pressure and 300° are as follows:

Product	Unpacked, seasoned (%)	Packed, seasoned (%)	Packed, unseasoned (%)
trans-DMC[a]	15.8	15.2	11.0
cis-DMC[a]	17.2	20.6	38.0
2-Methylbutene-2	18.2	17.4	13.7
trans-Pentene-2	8.9	8.5	7.1
cis-Pentene-2	36.8	35.1	27.9
2-Methylbutene-1 / 3-Methylbutene-1	3.1	3.2	2.3

[a]1,2-Dimethylcyclopropane.

Wall reactions are obviously important in unseasoned vessels and are characterized by formation of excess stabilized *cis*-DMC. However, in properly seasoned vessels above 250°, wall reactions[2] account for not more than 1–3% of the total C_5H_{10} products.

Temperature Variation Due to Self-Heating

The possibility of the true reaction temperature being significantly higher than the measured temperature of the furnace, due to the exothermicity of the reaction of methylene radicals with olefins, must be considered. The overall exothermicity for methylene-derived C_5H_{10} or C_3H_6 products is shown later to be ~80 kcal/mole. At 250°, the half-life, $t_{1/2}$, for DM decomposition is 90 sec; the theoretical equations (12) predict an insignificant temperature rise of <10°.

At 300° and 2.5 cm, it was shown by experiment with *cis*-butene that self-heating did not give rise to detectable effects: Runs made with DM/butene ratios of 1/40 and 1/8 resulted in no change of the observed rate constants for structural or geometric isomerization of DMC.

At an apparent temperature of 375°, DM decomposition is practically instantaneous. Experiments with various DM/butene ratios between 1/60 and 1/8 gave a variation in the measured values of the rate constants. Most experiments were done with DM/butene ratios of 1/10, and the average self-heating was estimated as ~25° for the butene system and ~50° for the ethylene system. Nominal temperatures of 375° and 400° thus correspond more closely to 400° and 450° for the *cis*-butene and ethylene systems, respectively, *and will be referred to as such, hereafter*. At these temperatures, conventional thermal isomerization reactions of the cyclopropane products are negligible for the short residence times employed (<3 min).

Reaction of Methylene with Ethylene

Products of Reaction and Variation with Pressure

Major products were cyclopropane and propene. Side products were ethane, propane, butane, butene-1, and unidentified compounds in trace quantities. The total quantities

of all side products increased from a few percent to 20% at lowest pressure. In general, the pyrolysis system gives less side reactions than the corresponding photolysis system.

The percent of cyclopropane product increases at higher pressures (Fig. 4). These data are characteristic of an energized cyclopropane molecule (8(*c*), 9), which can either

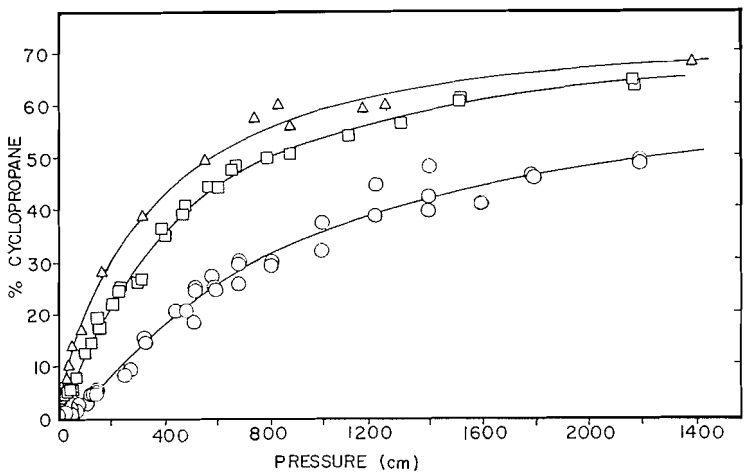

FIG. 4. Percent cyclopropane at different pressures; DM + C_2H_4 at 325°, □; DM + C_2H_4 at 450°, ○; photolysis (4358 Å) of DM with C_2H_4 at 25°, △. In the interest of clarity, a considerable amount of data was omitted from Figs. 4, 6, 7, 8, in the lower-pressure region especially.

isomerize to propene or be stabilized through collisions with bath molecules. Limiting high-pressure values of <100% cyclopropane reflect the direct insertion of methylene across C—H bonds to give propene:

$$\begin{array}{lcccl} & \xrightarrow{k_{11}} & \triangledown^* & \xrightarrow[M]{\omega} & \triangledown \\ CH_2+C_2H_4 & & \Big\downarrow k_a & & \\ & \xrightarrow{k_{12}} & CH_3CH{=}CH_2^* & \xrightarrow[M]{\omega} & CH_3CH{=}CH_2. \end{array} \qquad [III]$$

The asterisk represents a vibrationally excited molecule resulting from chemical reaction. At higher pressures no reaction of $CH_3CH{=}CH_2^*$ is expected; at low pressures it may decompose, and this may in part explain the increase in side reactions at low pressure.

Extrapolations (9(*c*)) of plots of propene/cyclopropane vs. ω^{-1} to infinite pressure gave the relative magnitudes of k_{12} and k_{11} in Table I. Such plots[2] of the 325° and photolysis data show little curvature and illustrate the relatively monoenergetic character of the energized cyclopropane molecules. The 450° data shows considerable scatter,[2] but no significant curvature either. Discussion of Table I is delayed until presentation of the butene data.

Experimental Average Rate Constants k_a

For the ethylene–cyclopropane systems, average experimental rate constants for structural isomerization of $\triangledown^*$ were computed according to the expression (13) $k_a = \omega \cdot D/S$

TABLE I

Summary of rate constants of cyclopropanes produced by chemical activation from methylene plus olefins

Olefin	CH_2 source	Relative CH_2 addition rates per C—H bond			Experimental rate constants ($10^8 sec^{-1}$)			E_{min} (kcal/mole)	E_{av} (kcal/mole)
		C=C	Allyl H	Vinyl H	k_a	k_{g1}	k_{g2}/k_{g1}

[a]This work.
[b]Ref. 9(*b*). For photolysis in liquid phase (−70°) Frey (7(*b*)) found ratios of CH_2 addition to C=C:allylic C—H:vinylic C—H of 1.00:0.13:0.99 for *trans*-butene-2.
[c]Ref. 9(*c*).
[d]Ref. 14.
[e]Ref. 9(*a*) with corrected (14) estimate here of effective radiation involved.
[f]Corrected temperature as described in text earlier.
[g]Average values: DMC, Fig. 9, S/D between 0.2 and 1.5 for the 400° case, and between 0.2 and 3 for the lower temperatures; cyclopropane, average of all values shown in Fig. 5.
[h]For internal consistency, Butler and Kistiakowsky's (9(*c*)) data have been converted to the collision cross sections used here (Appendix I).
[i]In selecting E_{av}, the magnitude of k_E (Fig. 13) was set equal to k_a, since the distribution in wavelengths is small; for a similar system, DM photolysis with C_2H_4, where the distribution of absorbed radiation was used, this was shown to be a good approximation.
[j]Values of k_a (9(*b*)) range from 1.4×10^8 sec^{-1}, at $S/D = 3.8$, to 0.9×10^8 sec^{-1}, at $S/D = 0.5$; an intermediate value of 1.1×10^8 sec^{-1} was taken by the present authors.
[k]An average value of 1.6×10^8 sec^{-1} was taken by the present authors.
[l]In his higher-energy radiation studies with ketene and cyclobutene, Frey (9(*d*)) does not find the inversion of lifetimes, shown here for 3130 Å and 2600 Å as reported by Butler and Kistiakowsky.
[m]Given as sum of $\Delta E_0' + \bar{E}_{ex}$.
[n]True values for thermal DM systems may be lower by ~3 kcal/mole if allowance is made for inefficient collisional deactivation, particularly for C_2H_4 system.

and are presented in Fig. 5; S is the stabilized cyclopropane, D is the propene isomerization product, and ω is the specific collision rate (Appendix I).

Lifetimes of Cyclopropane from Different Sources

The similarity in magnitudes of k_a obtained from photolysis work at 4358 Å and from thermal DM decomposition at 325° indicates that the cyclopropane derived from these two sources have similar energy.

The average lifetimes of reacting molecules in conventional thermal structural isomerization of cyclopropane at 445° is $\sim10^{-7}$ sec (9(*a*)). This may be contrasted with the shorter lifetimes ($<10^{-10}$ sec) of the chemically activated molecules (Table I). The cyclopropanes obtained with ketene as the methylene precursor have longer lifetimes

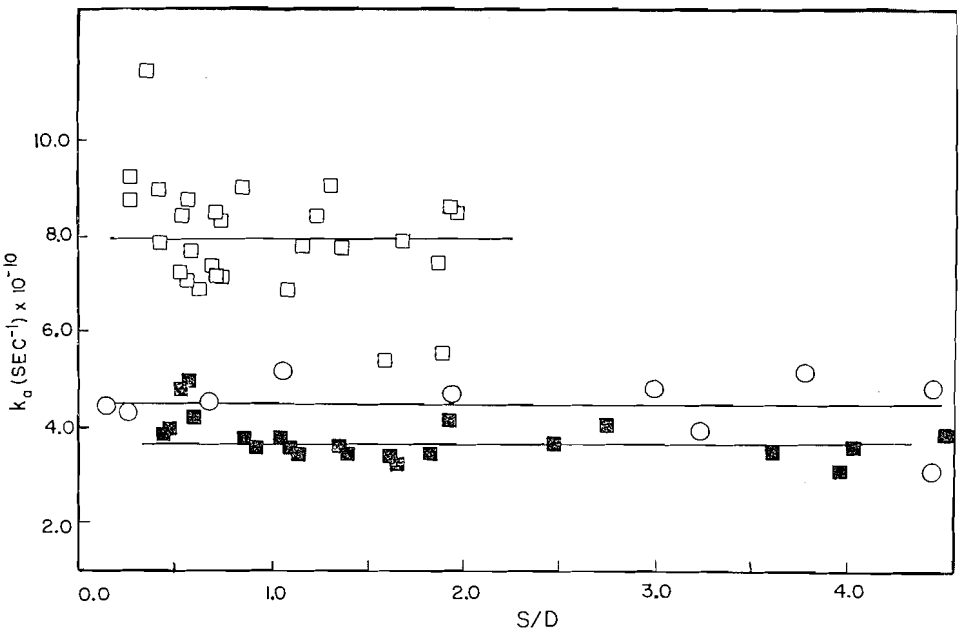

FIG. 5. Rate constants for isomerization of cyclopropane to propene: DM + C_2H_4 at 450°, □; DM + C_2H_4 at 325°, ■; photolysis (4358 Å) DM with C_2H_4 at 25°, ○.

than those derived from DM. Similar results have been found earlier for other systems (9(*c* and *d*)). Quantitative interpretation of these magnitudes is presented later. In this connection, it is desirable to mention now some different k_a data from the photolysis of ketene with ethylene. The data of Kistiakowsky and Frey (8(*e*)) give $k_a = 1.3\times10^{10}$ sec^{-1} for photolysis at 3130 Å. For a similar study with ethylene-d_2 (9(*a*)) $k_a = 1.1\times10^{10}$ was reported. For the photolysis at 3200 Å of ketene with ethylene (14), k_a[5] is 1.8×10^{10} sec^{-1}. The latter value will be used later for estimation of the energy of the formed cyclopropane molecules, while the variation of k_a with wavelength in the ketene–ethylene-d_2 system (Table I) will be used as a test of the energy dependence of the calculated rate constants.

Reaction of Methylene with *cis*-Butene-2

Variation of Products with Pressure and Methylene Source

Methylene adds to butene to give chemically energized DMC, or inserts across the allylic and vinylic C—H bonds to give *cis*-pentene-2 and 2-methylbutene-2, respectively. These energized molecules undergo characteristic isomerization reactions or are deactivated by collisions with bath molecules:

$$\begin{aligned} & \xrightarrow{k_{21}} \quad H_3C\bigtriangledown CH_3^* \\ CH_2 + CH_3CH{=}CHCH_3 \quad & \xrightarrow{k_{22}} \quad cis\text{-}CH_3CH_2CH{=}CHCH_3^* \\ & \xrightarrow{k_{23}} \quad CH_3CH{=}C(CH_3)_2^*. \end{aligned} \qquad [IV]$$

[5]*An isotope effect accounts in part for the difference between the cyclopropane-d_2 and cyclopropane values.*

Figures 6, 7, and 8 illustrate the product dependence upon pressure; the approach to constant limiting percentages at high pressure verifies reactions [IV]. The relative magnitudes of these processes (Table I) were again determined from ω^{-1} extrapolations of

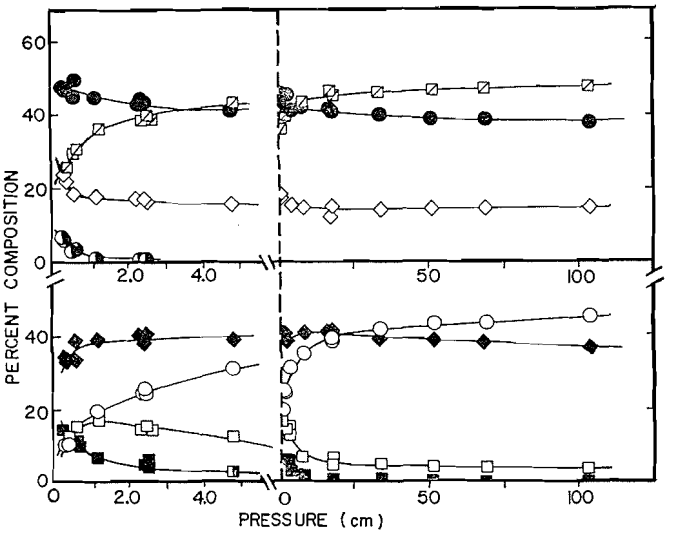

FIG. 6. Variation of the product composition with pressure, DM + *cis*-butene system, 250°: □, *trans*-DMC; ○, *cis*-DMC; ◆, *cis*-pentene-2; ■, *trans*-pentene-2; ◑, 2- and 3-methylbutene-1; ◇, 2-methylbutene-2; ⊠, total DMC; ●, total pentene-2. See Fig. 4.

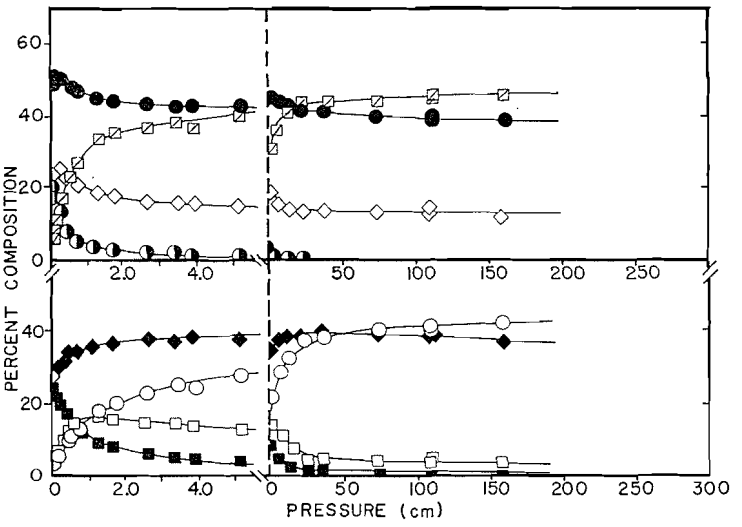

FIG. 7. Variation of the product composition with pressure, DM + *cis*-butene system, 300°: □, *trans*-DMC; ○, *cis*-DMC; ◆, *cis*-pentene-2; ■, *trans*-pentene-2; ◑, 2- and 3-methylbutene-1; ◇, 2-methylbutene-2; ⊠, total DMC; ●, total pentene-2. See Fig. 4.

product ratios: total pentene/DMC; (*cis* + *trans* + pentene-2)/DMC; and (2-methylbutene-2 + 2- and 3-methylbutene-1)/DMC. Due to the greater energy spread of the excited DMC relative to cyclopropane (*cf.* $f(E)$, Fig. 13), these plots[2] at 300° and

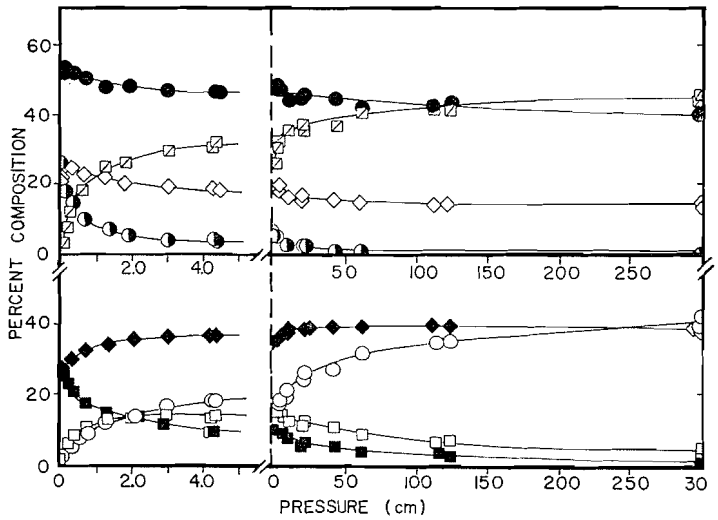

FIG. 8. Variation of product composition with pressure, DM + *cis*-butene system, 400°: □, *trans*-DMC; ○, *cis*-DMC; ◆, *cis*-pentene-2; ■, *trans*-pentene-2; ◑, 2- and 3-methylbutene-1; ◇, 2-methylbutene-2; ⊠, total DMC; ●, total pentene-2. See Fig. 4.

especially 400° show considerable curvature at higher pressures, in contrast with the cyclopropane plots.

For both ethylene and *cis*-butene the reactivity of methylene generated from thermal decomposition of DM is similar to that from photolytic (4358 Å) decomposition of DM (Table I). Both sources give nearly the same degree of discrimination between C=C and C—H bonds; any apparent trend is within experimental error. As was reported by other workers (9(*c*), 10), in the gas phase CH_2 from DM was found much less selective than CH_2 from ketene, both in regard to C—H insertion vs. double-bond addition and in regard to discrimination between different types of C—H bonds. Within experimental error (Table I), methylene derived from DM is indiscriminate in its attack on vinylic and allylic C—H bonds in the gas phase (note footnote *b*, Table I). The apparent difference (10, 7(*b*)) for alkanes, i.e. random insertion in the liquid phase and selective insertion (tert. > sec. > prim.) in the gas phase for methylene produced from photolysis of DM, does not hold for vinylic and allylic C—H bonds.

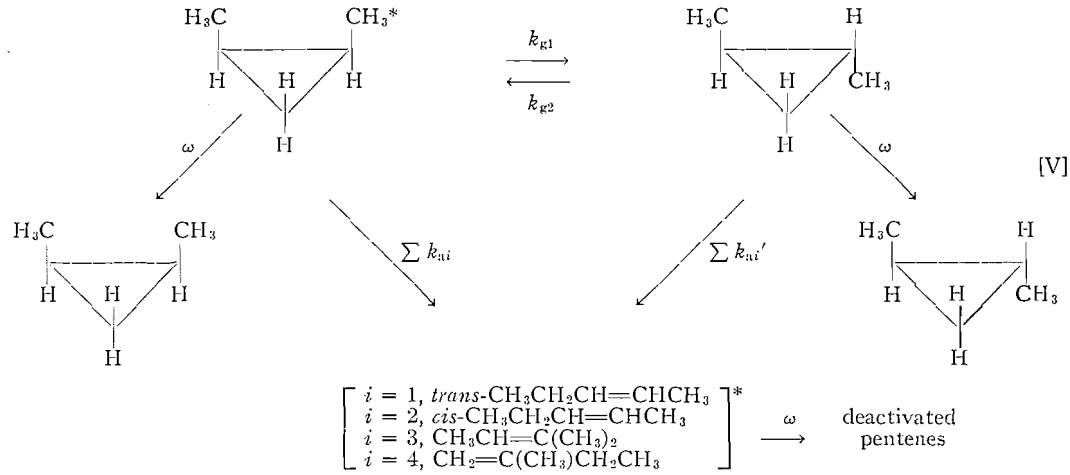
The constancy in this work of the relative magnitudes of k_{21}, k_{22}, and k_{23} from 250° to 400°, as shown in Table I, indicates that little difference in activation energy exists for addition of methylene to the double bond vs. C—H insertion; or, alternatively, the methylene carries excess translation energy, which negates small activation energy differences. Methylene from photolysis of DM is thought to carry excess translational energy (9(*b*)).

Reactions of Energized Product Molecules

A. Dimethylcyclopropane

The vibrationally excited *cis*-DMC, *cis*-pentene-2, and 2-methylbutene-2 species may undergo further reactions. *cis*-DMC may isomerize to the trans isomer, undergo intramolecular H migration in the ring to give *cis*- and *trans*-pentene-2, 2-methylbutene-2, and 2-methylbutene-1, or be de-energized by collisions with bath molecules. Still another possible reaction suggested by the data, and which involves the CH_3 substituent, will

be considered later. The *trans*-DMC also undergoes these reactions unless collisionally deactivated. These processes are defined in the manner of Frey (9(*b*)):



Consider the variation of the products with the total pressure under this scheme. The percent *trans*-DMC should go through a maximum when plotted as a function of pressure, since k_{g1} is approximately ninefold greater than $\sum_i k_{ai}$, as shown below (15).[6] Also, the percent of pentenes should increase from their high-pressure limits given by equations [IV], as total pressure is reduced. Figures 6, 7, and 8 exhibit these features.

The above mechanism also predicts that as the reaction temperature, and consequently the energy of the formed molecules, is increased, then k_{g1}, $\sum_i k_{ai}$, and $\sum_i k_{ai}'$ should increase. Indeed, at 400°, 300°, and 250° approximately one-half of the *cis*-DMS had isomerized to the *trans* isomer at 2.2 cm, 1.0 cm, and 0.6 cm, respectively; one-half of the total DMC had decomposed to pentenes at 1.2 cm, 0.5 cm, and 0.35 cm, respectively. This aspect of the data further supports an excited molecule mechanism.

B. Reactions of cis-Pentene-2

The energized *cis*-pentene-2 may isomerize to *trans*-pentene-2 unless de-energized by collisions with bath molecules. This is illustrated by the decline in *cis*-pentene-2 at lower pressures as reaction k_{g1}' of eq. [VI] overtakes reactions k_{a2} and k_{a2}' of eq. [V] (Figs. 6, 7, and 8).

$$cis\text{-}CH_3CH_2CH{=}CHCH_3^* \underset{k_{g2}'}{\overset{k_{g1}'}{\rightleftarrows}} trans\text{-}CH_3CH_2CH{=}CHCH_3^* \qquad [VI]$$

Pentene-1 was found only in trace quantities, indicating that rearrangement of pentene-2 to pentene-1 did not occur.

C. Reactions of 2-Methylbutene-2

Isomerization reactions [VII],

$$CH_3CH{=}C(CH_3)_2^* \longleftrightarrow CH_2{=}CHCH(CH_3)_2^* \qquad [VIIa]$$
$$CH_3CH{=}C(CH_3)_2^* \longleftrightarrow CH_2{=}C(CH_3)CH_2CH_3^*, \qquad [VIIb]$$

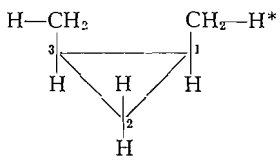
[6] *Flowers and Frey (15) find* $k_{g1} = 23 \sum_i k_{ai}$ *in thermal studies.*

between 3-methylbutene-1, 2-methylbutene-1, and 2-methylbutene-2 are known (16), and indeed the experimental data at the lowest pressures and highest temperature suggest that some 2-methylbutene-2 may be disappearing. For reactions [VII] at 1500°, roughly the "temperature" of these energized molecules, the equilibrium constants (17) for the formation of 3-methylbutene-1 and 2-methylbutene-1 from 2-methylbutene-2 are 0.25 and 3.7, respectively. This suggests that 2-methylbutene-1 could be formed from 2-methylbutene-2, and reaction [VII*b*] explains the decrease in percentage of 2-methylbutene-2 at the lowest pressures (Figs. 7 and 8).

D. Formation of 3-Methylbutene-1 and Possible Occurrence of Triplet Methylene

All products and their pressure dependence, except for 3-methylbutene-1, are reasonably explained by the above mechanism.

Within the pressure range 1 to 300 cm, the ratio of 3-methylbutene-1/2-methylbutene-1 was constant and slightly greater than unity. At the lowest pressure this ratio increased to nearly 3. In contrast to Frey (9(*b*), 19), we also find that photolysis of DM with *cis*-butene-2 gives 3-methylbutene-1 in similar amounts. Neither heterogeneity nor the intervention of triplet methylene (as discussed below) is thought to be primarily responsible for 3-methylbutene-1 formation. Also, thermodynamic considerations weigh against reaction [VII*a*] as a source. Indeed, Frey (9(*b*)) found evidence for the *reverse* of [VII*a*] in his studies of methylene with isobutene. Possible modes for its formation are the additional paths [VIII] and [IX]:



$$\xrightarrow{k_{a5}} \quad CH_2{=}CHCH(CH_3)_2 \qquad [VIII]$$

$$:CH_2 + CH_3CH{=}CHCH_3 \longrightarrow \cdot CH_3 + \cdot CH_2CH{=}CHCH_3 \qquad [IXa]$$

$$\cdot CH_2CH{=}CHCH_3 \longleftrightarrow CH_2{=}C\dot{H}CHCH_3 \qquad [IXb]$$

$$\cdot CH_3 + CH_2{=}C\dot{H}CHCH_3 \longrightarrow CH_2{=}CHCH(CH_3)_2$$

$$\cdot CH_3 + \cdot CHCH_2{=}CHCH_3 \longrightarrow CH_3CH_2CH{=}CHCH_3. \qquad [IXc]$$

Reaction [VIII] involves intramolecular hydrogen transfer from a methyl group to carbon atom 2 with rupture of C_1—C_2 or C_3—C_2. (Hydrogen transfer from a methyl to carbon atoms 1 or 3 with rupture of C_1—C_3 or C_2—C_3, respectively, would give pentene-1, or ethylcyclopropane; pentene-1 was not formed and unfortunately no search was made for ethylcyclopropane.) Alternatively, transfer of a methyl group between carbons 1 and 3 would also give this same result as well as some others to be mentioned next; isotopic studies could distinguish these possibilities. Other experimental evidence is cited now to support these transfer reactions.

Flowers and Frey (16) have earlier suggested methyl–hydrogen transfer, with an estimated activation energy as high as 68 kcal/mole, to explain small quantities of 2-methylbutene-2 in the thermal decomposition of 1,1-dimethylcyclopropane. In another study of energized 1,1-dimethylcyclopropane (9(*b*)) from CH_2 + isobutene, this methyl–hydrogen transfer reaction was not mentioned; however, a possible interpretation of this data at the lowest pressures could also include it. Again, Frey (9(*d*)) has found ethylacetylene to be one of the products of energized methylene cyclopropane from CH_2 + allene, and he has explained it by the migration of two hydrogen atoms; alternatively, it could also result from methylene hydrogen transfer.

Scheme [IX] remains to be considered. A minor reaction of singlet methylene radicals is abstraction of H from hydrocarbons (7(*b*), 9(*d*)) (reaction [IX*a*]). Equation [IX*b*] represents two resonance structures of the butenyl radical. Combination with methyl radical, reactions [IX*c*], gives 3-methylbutene-1 or pentene-2 in the ratio 1:2.5 at 25° (18), and 1:6 at 200° (19).

Since the proportions of DM and *cis*-butene are held constant, the relative amount of products arising through scheme [IX] would tend to be only weakly dependent on pressure. Figures 6, 7, and 8 show, instead, that the methylbutene-1 fraction goes to zero at high pressure, which suggests that an abstraction scheme, [IX], involving singlet methylene is not operative in an important way.

It is important, therefore, to consider again the proposal of Richardson *et al.* (10): Methylene radicals in the gas phase undergo singlet–triplet transitions before they react with the olefins; the lower the pressure the larger is the fraction converted to the triplet state; important reactions of triplet methylene radicals are non-stereospecific addition to the double bond (20) as well as postulated abstraction of H, followed by recombination of the methyl and hydrocarbon radical to give both *apparent* C—H insertion products and *apparent* cyclopropane isomerization products.

Now Frey (20) has found that *triplet* methylene reacts with *cis*-butene to give *cis*- and *trans*-DMC, 3-methylbutene-1, and *cis*- and *trans*-pentene-2, but not 2-methylbutene-2 or 2-methylbutene-1, as occur here. In addition, the following arguments pertaining to our reaction system, as well as previous evidence cited above and earlier (1), weigh further against involvement of triplet methylene in the main course of reaction: (*a*) The dependence of the methylbutene-1 fraction upon temperature at a given pressure (0.5 cm: 400°, 13%; 300°, 9%; and 250°, 4%) is clearly consistent with the reactions of energized molecules whose energy content varies somewhat with temperature. (*b*) Frey's studies of triplet methylene (20) at 25° show that at butene partial pressures of 2–10 mm, inert gas to butene ratios of 300:1 are necessary to convert 50% of the singlet methylenes to the triplet state and inert gas addition is necessary to produce characteristic "triplet" products. Therefore, at the same low butene pressures in our system, but with no intervening inert gas perturbing collisions, spontaneous singlet–triplet transitions cannot be important. (*c*) As noted above, the combination of methyl and butenyl radicals gives more pentene-2 than 3-methylbutene-1 (18). No such proportionate rise in the total pentene-2 fraction accompanies the rise in the 3-methylbutene-1 fraction (Figs. 6, 7, and 8) at lower pressures.

Thus reaction [VIII], whether methyl H or methyl group migration, fits best as the process giving 3-methylbutene-1. Reaction [IX] may conceivably explain the small (less than 1%), nearly constant amounts of *trans*-pentene-2 and methylbutene-1 fractions at high pressures, as well as the ethane, propane, and similar products.

Experimental Rate Constants k_a and k_g for Activated DMC

Individual values of the overall structural isomerization rate constant k_a are shown in Fig. 9. The previous definition of k_a is again used: $k_a = \omega(D/S)$, where S is stabilized *cis*- and *trans*-DMC and D is the total olefins, including 3-methylbutene-1, derived from excited cyclopropanes; ω is the specific collision rate (Appendix I). The above definition gives an *average* rate constant for both *cis*- and *trans*-DMC. The study of *trans*-DMC and of *cis*-DMC thermal isomerization reactions (15) indicates for our purposes a minor, although real, variation between $\sum_i k_{ai}$ and $\sum_i k_{ai}'$.

At 250° and 300°, the k_a values were quite reproducible. An upward trend with increasing S/D (i.e. increasing pressure) is evident, and is consistent (13) with a larger

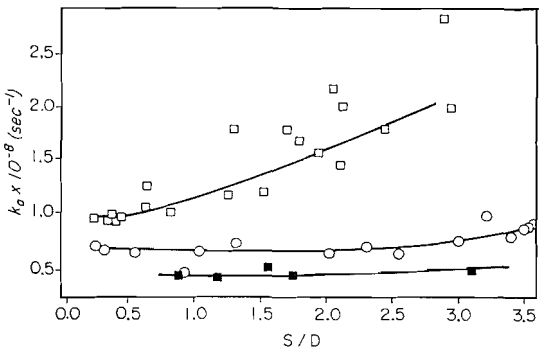


FIG. 9. Rate constant for isomerization of DMC to pentene: ■, DM and *cis*-butene-2 at 250°; ○, DM and *cis*-butene-2 at 300°; □, DM and *cis*-butene-2 at 400°.

energy spread in the formed DMC molecules. Values of k_a at very high pressure are more unreliable due to their sensitivity to the detailed choice of extrapolated high-pressure limits; thus a quantitative estimate of the energy spread is not available on this basis. At the highest temperature, 400°, there is more scatter in k_a at high S/D. This is possibly due to different degrees of self-heating in the various runs. The considerable rise in k_a at 400° with increase of S/D is also indicative of a greater energy spread of the formed molecules. However, the apparent increase is too large to be explained by this effect alone and may reflect, in part, the inaccuracy of the ω^{-1} extrapolation to $p = \infty$; such error becomes less important in the determination of k_a at the lower range of S/D.

Experimental values for k_{g1}^{-1} and k_{g2}/k_{g1} were calculated by least-squares analysis (Fig. 10) of the linear, low-pressure portion of the function

$$cis\text{-DMC}/trans\text{-DMC} = (k_{g2}/k_{g1}) + \omega \cdot (1 + D/S) \cdot k_{g1}^{-1}.$$

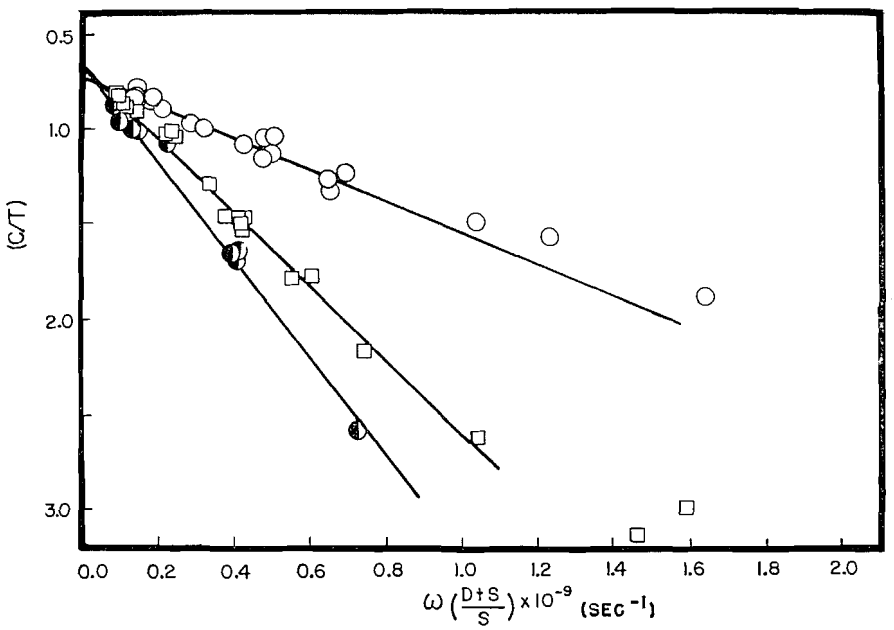

FIG. 10. Plot of *cis*-DMC/*trans*-DMC against $\omega \cdot (D+S)/S$: 400°, ○; 300°, □; 250°, ◐.

This relation follows (9(*b*))[2] from the steady-state expression for energized *trans*-DMC, on setting $k_a = \sum_i k_{ai} = \sum_i k_{ai}'$. The least-squares results for k_{g1} and k_{g2}/k_{g1} are 3.5×10^8 sec^{-1} and 0.66, 4.45×10^8 sec^{-1} and 0.66, 1.15×10^9 sec^{-1} and 0.72, at 250°, 300°, and 400°, respectively. Figure 11 illustrates the magnitude of k_{g1} for all S/D.

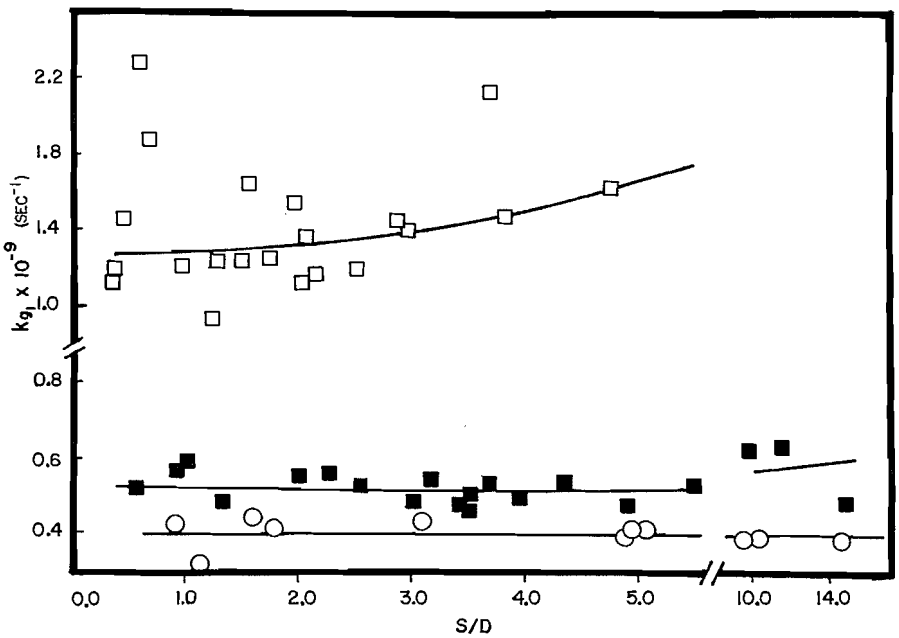

FIG. 11. Rate constants for *cis–trans* isomerization of *cis*-DMC: ○, DM and *cis*-butene at 250°; ■, DM and *cis*-butene at 300°; □, DM and *cis*-butene at 400°.

To obtain a ratio of k_{g1}/k_a, the least-squares value of k_{g1} was compared to k_a evaluated at $S/D = 1.0$. The ratio k_{g1}/k_a is 8 at 250°, 7.4 at 300°, and 11 at 400°; an average of 9 is taken; this is in agreement with related earlier findings that geometric isomerization of cyclopropanes proceeds faster than structural isomerization (9(*a*)).

k_g' for Pentene-2

The following expression obtained from the steady-state equation was used to calculate k_{g2}':

$$(k_{a1}/k_{g2}')(S/T_p) - (\omega/k_{g2}) + (k_{g1}'/k_{g2}') \cdot (C_p/T_p) = 1.0,$$

where S is the total DMC product, T_p is *trans*- and C_p is *cis*-pentene-2 product. The equilibrium constant for cis $\rightleftharpoons$ trans, i.e. k_{g1}'/k_{g2}', was calculated as 1.1 at these high vibrational "temperatures" from thermodynamic data (17). The values for k_{a1} and k_{g2}' were obtained by trial and error procedure with an IBM 709 computer for the data in Figs. 7 and 8, in conjunction with estimation of the contribution of k_{a1} to k_a. The best fit was given by $k_{a1}/k_{g2}' = 1\pm0.2$, and $k_{g2}' = 1.6\pm0.5\times10^7$ sec^{-1} and $3\pm1\times10^7$ sec^{-1} for 300° and 400° respectively.

The average ratio obtained for k_{g1}'/k_a was 0.27. Since the isomerization of *cis*-pentene-2 (i.e. k_{g1}') is expected to have an activation energy nearly equal to that for *cis*-butene-2 ($\geq$62.8 kcal/mole), which in turn is closely the same as that for the overall structural isomerization of *cis*-DMC (15), the ratio of 0.27 *may* largely reflect a difference in reaction path degeneracy—which is 8 for *cis*-DMC and only 2 for *cis*-butene-2 (21).

Some Remarks on Experimental Rate Constants

(a) Comparison of Energy of Chemically Activated DMC

Table I lists the average rate constants for geometric and structural isomerization in different DMC systems. The correspondence between the photolysis of a DM + *trans*-butene-2 mixture at 4358 Å and the thermal decomposition of a DM + *cis*-butene-2 mixture at 400° indicates that the energized DMC product molecules have nearly the same energy in both cases. A similar correspondence has been noted above for cyclopropane produced by DM pyrolysis at 325°. Sources of error in such comparisons include some uncertainty in the effective average wavelength for photolysis, and in the estimation of the change of the effective collision cross section with temperature by use, for example, of the Sutherland constant.

(b) Equilibrium Constant for cis–trans-DMC

For DM with *trans*-butene at 4358 Å Frey has found a low-pressure limit for k_{g2}/k_{g1} of 0.33 (9(*b*)). Within the validity of the approximation, $\sum k_{a\,i} = \sum k_{a\,i}'$, the low-pressure ratio of k_{g2}/k_{g1} corresponds to the apparent equilibrium constant of the *activated cis–trans*-DMC molecules (equation [V]). In view of the small differences in the heats of formation (1.02 kcal/mole) of *cis*- and *trans*-DMC (15), and in consideration of the high vibrational "temperatures" of these energized molecules, our present average of 0.68 for k_{g2}/k_{g1} seems more valid. In some work on DM photolysis, we obtain 0.80, again closer to unity.

(c) Evidence for Intramolecular Relaxation of Energy

The ratios of k_{g1}/k_a from the thermal isomerization of *cis*-DMC (15) and from this work are ~23 and ~9, respectively. This difference can be explained by the appreciable activation energy difference (15) (2 kcal/mole) between structural and geometric isomerization of *cis*-DMC. At the comparatively low energies of the conventional thermal system, this difference is important; at the higher energies here (Appendix IV) k_{g1}/k_a *tend* to approach the ratio of the pre-exponential factors. This reconciliation of the actual change in k_{g1}/k_a for these two different methods of activation provides additional support for fast intramolecular relaxation of vibrational energy relative to the relaxation process for decomposition (9(*c*), 22).

Calculation of k_a Values. Evaluation of Energy of Chemically Activated Cyclopropanes

In this section, a model for k_a is constructed which gives good fit of conventional thermal unimolecular data, i.e. systems of known energy. Values of k_g will not be computed here. The model is applied to the estimation of the cyclopropane energies involved in chemical activation work by treating the unknown energies as parameters which give fit of experimental and calculated values of k_a. This procedure is useful in view of the uncertainty in many of the thermochemical quantities involved and, together with all experimental data, also provides a test of various "thermochemical" assumptions and data.

Thermochemical Quantities. Distribution Function of the Formed Cyclopropanes

In order to calculate a value for k_a the energy distribution function of the formed cyclopropane molecules $f(E)$ must be obtained. Figure 12 illustrates and defines the thermochemical quantities.[7] The cyclopropane molecules are formed in an energy range

[7]*All quantities refer to 0° K. Although many quantities must be estimated, so that almost any reference should be sufficiently accurate, it seems best to adopt this base.*

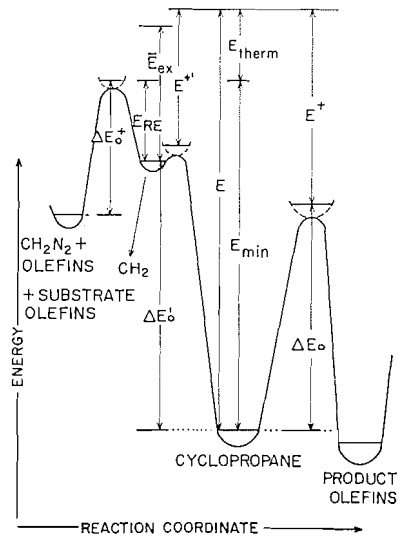

FIG. 12. Illustration and definition of thermochemical quantities for the addition of methylene to olefins. $\bar{E}_{ex}$ pertains only to photolysis systems and is that part of the excess light energy captured by the methylene and assumed to be retained up to reaction.

above E_{min} and isomerize to produce olefins unless their energy is reduced below ΔE_0 by collisions with heat bath molecules. E_{min} is the sum of $\Delta E_0'$, the heat of the addition reaction of CH_2 to the substrate olefin, and E_{RE}, the fraction of reorganization energy in the DM decomposition associated with methylene (Appendix III). E_{RE} is assumed to be largely retained by the methylene, which adds efficiently to olefins (8(*c*)). This is supported by the ability of CH_2 to carry from its genesis excess photolysis light energy (of varying amount) into the product cyclopropanes (9). The activation energy for addition of methylene to olefins is small (8(*c* and *d*), 23) (<2.0 kcal/mole) and, for simplicity, *relative translational* energy of the reacting methylene and olefin is simply lumped into E_{RE}.

The formed cyclopropanes are not in equilibrium with the heat bath. For the calculation of $f(E)$, the principle of detailed balancing is applied as before (13). As a reasonable approximation (and a desirable one, also, due to our ignorance of the spread in E_{RE}) we shall take E_{RE} to be a constant quantity, which can be added to the heat of reaction $\Delta E_0'$, but which does not affect the form of $f(E)$. $f(E)$ spans a large range of energies at the high temperatures used here in any case. Details are given in Appendix II and the form of $f(E)$ is illustrated for two cases in Fig. 13. Neither $\Delta E_0'$ or E_{RE} is well known, so that the procedure adopted here means that $f(E)$ is started at a value of E_{min} that gives agreement between experimental and calculated rate constants.

Formulation of k_E and k_a

The chemically activated cyclopropane molecules, $\triangledown$, with energy $E = E_{min} + E_{therm}$, may isomerize to olefin product with specific rate constant k_E, or may lose energy by collision with bath molecules with specific probability ω (equation [XI]). The asterisk denotes a cyclopropane molecule having energy above ΔE_0, and capable of undergoing

$$\triangledown (E') \xleftarrow{\omega} \triangledown (E)^* \xrightarrow{k_E} \text{olefin product} \qquad [XI]$$

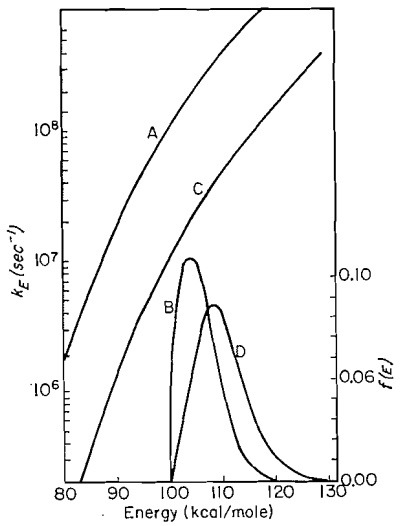

FIG. 13. Plots of k_E and $f(E)$ as a function of energy: (A) k_E for cyclopropane; all values have been multiplied by 10^{-2} to show them on the graph. (B) $f(E)$ for cyclopropane at 325° C. (C) k_E for DMC. (D) $f(E)$ for DMC at 300° C. Both distribution functions were started at 100 kcal/mole only for purposes of comparison.

isomerization. We consider only the case of strong collisions, i.e. $E' \leqslant E_0$. Detailed low-pressure experimental data and more refined collisional transition probabilities, including inefficient energy transfer, to be presented elsewhere, indicate that little error results here for this case.

The observed average rate constant is (13)

$$k_a = \omega \,.\, (D/S) = \omega \,.\, \frac{\int_{E_{min}}^{\infty} \{k_E/(k_E+\omega)\} f(E)dE}{\int_{E_{min}}^{\infty} \{\omega/(\omega+k_E)\} f(E)dE}, \qquad [a]$$

where the expression for k_E is (24)

$$k_E = P_1^+ N_E^+ / h P_1^* N_E^*. \qquad [b]$$

N_E^+ is the total sum over the active energy states of the activated complex up to its energy E_v^+; N_E^* is the total density of the active rotational and vibrational states at the energy E for the energized molecule; P_1^+/P_1^* is the residue of the partition function ratio for adiabatic degrees of freedom of overall rotation, including reaction path degeneracy. Reference 13 may be consulted for more detailed description of these equations and others of Appendix II.

The molecular and activated complex models used, as well as further calculational details, are summarized in Appendix II. Resulting k_E values for cyclopropane and DMC at various high energies are shown in Fig. 13. Combination of k_E with $f(E)$ gives k_a at different pressures (ω), according to equation [a]. With use of the strong collision model Table I lists the values of E_{min} and of the average energy of the formed cyclopropanes, $E_{av} = E_{min} + \bar{E}_{therm}$, necessary to give a magnitude of k_a that matched the observed rate

constant. $\bar{E}_{\text{therm}}$ was calculated from $f(E)$. On the basis of the agreement with conventional thermal data described in Appendix III, supported somewhat by the comparisons of the following section, the E_{av} values are considered known to within 5 kcal/mole. The remark may be added that inefficient collisional energy transfer indicates a lowering of the energies in Table I by 2–3 kcal/mole in some cases (thermal DM), which for cyclopropane, particularly, is opposed in effect by neglect of anharmonicity (11).

Energy Dependence of k_a

The calculational models predict that above 100 kcal/mole a change in excitation energy of 4–5 kcal/mole produces a twofold variation in k_E for both cyclopropane and DMC (Fig. 13). At lower energies, the energy dependence is somewhat stronger. The calculated change in k_E is compared to experimentally observed change in k_a for known energy change in Table II. Comparison of k_a with k_E is adequately valid since the energy dispersion (13) of the activated cyclopropanes is actually quite small in view of the large values of E_{min}.

TABLE II

Variation of rate constants with energy change, ΔE

System	ΔE (kcal/mole)	Observed change in k_a (factor)	Predicted change in k_E (factor)
DMC (DM, 250°)	1.7	1.4	1.3
DMC (DM, 300°)	1.7	1.4	1.3
DMC (DM, 400°)	5.4[a] 3.7[a]	2.3[a] 1.7[a]	2.1 1.6
Cyclopropane (DM, 325°)	2.7	2.0[b]	1.4[b]
Cyclopropane (DM, 450°)	2.7	2.0[b]	1.4[b]
Cyclopropane-d_2 (ketene, 3320 Å)	3	1.76	1.6
Cyclopropane-d_2 (ketene, 3200 Å)	3	1.76	1.6

[a]For 250–400° and 300–400°, respectively.
[b]Consideration of inefficient collisional deactivation reduces this discrepancy.

For the thermal DM–*cis*-butene systems the agreement between predicted and observed changes in the rate constants is well within experimental error. In these thermal DM systems, although E_{min} is treated as an unknown to be evaluated empirically, the increment in $\bar{E}_{\text{therm}}$ with temperature is reasonably well known.

The comparison of the cyclopropane results at 325° and 450° is less rewarding due to larger self-heating and to less efficient collisional deactivation for this smaller molecule.[2] Considerations of more inefficient stepwise deactivation from low-pressure studies bring the cyclopropane data within experimental error.

Since Fig. 13 shows closely similar *relative* energy dependence of k_E for both cyclopropane and DMC, it would be expected that k_E for methylcyclopropane should display similar energy dependence. Butler and Kistiakowsky (9(*c*)) have measured the rate constants for structural isomerization of energized methylcyclopropane formed from photolysis of ketene and of DM with propene and with cyclopropane, to make three pairs of systems: The exothermicity of the reaction of methylene with cyclopropane is known to be 7.9 kcal/mole greater than the reaction with propene. Using the present collision cross sections (Appendix I) the average ratio of rate constants for their three

pairs of systems is 3.8±0.4, and dependent a little upon the choices of collision cross sections. Around 100 kcal/mole, a change in energy of 7.9 kcal/mole changes k_E by a calculated factor of 3.5 and 3.3 for DMC and cyclopropane, respectively.

Pressure Dependence of k_a

As shown in Fig. 9, the values of k_a increase at higher pressures due to the rather large energy spread (Fig. 13) of the formed molecules. However, quantitative experimental measurement is difficult due to the sensitivity of the k_a values to the extrapolated high-pressure limits. It is sufficient to note that on the unit deactivation efficiency model the calculated $k_{a\infty}/k_{a0}$ ratio for the 300° DMC system is 1.45, and for the 325° cyclopropane system is 1.2. An inefficient collisional deactivation model would reduce these calculated ratios, but in any case these are sensible magnitudes of the energy dispersion (13).

Comparison of Calculated E Values with Those Based on Existing Thermochemical Quantities. $\Delta H_f^0(CH_2N_2)$

A comparison may now be made of the E_{min} values determined above with estimates of E_{min} from thermochemical data (17). A commonly used value of $\Delta H_f^0(CH_2)$ is 67 kcal/mole (25); $\geq$80 kcal/mole[8] may be a better estimate (8). The heat of reaction of CH_2 with ethylene to form cyclopropane ($\triangledown$) is $\Delta E_0' = [\Delta H_f^0(C_2H_4)+\Delta H_f^0(CH_2) - \Delta H_f^0(\triangledown)]$. Taking $\Delta H_f^0(C_2H_4)$ = 14.5 kcal/mole, $\Delta H_f^0(\triangledown)$ = 15.5 kcal/mole, and $\Delta H_f^0(CH_2)$ = 67–80 kcal/mole, limits of 66 and 79 kcal/mole for $\Delta E_0'$ are set. Since $E_{min} = \Delta E_0' + E_{RE}$ is ~101 kcal/mole (Table I, footnote *n*), E_{RE} is required to be between 35 and 22 kcal/mole. A significant part of the reorganization energy in DM decomposition should actually be in the nitrogen ($r(CH_2N{=}N)$ = 1.18 Å, $r(N{\equiv}N)$ = 1.094 Å) (27, 28), and E_{RE} would be expected to be less than the total reorganization energy.

The maximum possible value of E_{RE} is $\{\Delta H_f^0(CH_2N_2)+\Delta E_0^+ - \Delta H_f^0(CH_2)\}$. The activation energy ΔE_0^+ for DM decomposition seems here established at ~35 kcal/mole. Electron impact data (26) give $\Delta H_f^0(CH_2N_2)$ as 46 kcal/mole; this value of $\Delta H_f^0(CH_2N_2)$ leads to a range of E_{RE} of 1–14 kcal/mole, which is incompatible with the kinetic data and the above discussion on E_{RE}. This suggests that $\Delta H_f^0(CH_2N_2)$ must be >67 kcal/mole. Hence, high values for both $\Delta H_f^0(CH_2)$ and for $\Delta H_f^0(CH_2N_2)$ best fit the kinetic data; in terms of present evidence, $\Delta H_f^0(CH_2) \geq 80$ kcal/mole is favored and is used henceforth. Even if the models for k_E were in error by a factor of two and E_{min} were to be lowered by about 5 kcal/mole, this would not change the nature of the above arguments.

The Fraction of Excess Light Energy, $\bar{E}_{ex}$, Carried by the Methylene in Photolysis Systems

A. Ketene

The observed structural isomerization rate constant for cyclopropane formed from photolysis (3200 Å, 25°) corresponds to $E_{av} \simeq 100$ kcal/mole (Table I). At 25°, $\bar{E}_{therm}$ is 2 kcal/mole, so $\Delta E_0' + \bar{E}_{ex}$ = 98 kcal/mole.[9] Since $\Delta E_0'$ is 79 kcal/mole, $\bar{E}_{ex}$ = 19

[8]*We cite here three examples favoring a higher $\Delta H_f^0(CH_2)$: First, the existence of close-lying singlet and triplet states make interpretation of electron impact data difficult; Herzberg (Proc. Roy. Soc. (London), A,* ***262****, 291 (1961)) has reported an ionization potential of 10.4 ev for methylene ($^3\Sigma_g^-$), as opposed to the previous value of 11.9 ev (25), and a value for $\Delta H_f^0(CH_2)$ of $\leqslant$ 93 kcal/mole^{-1}. Second, Gesser and Steacie (Can. J. Chem.* ***34****, 113 (1956)) interpret the reaction of methylene with hydrogen to give $\Delta H_f^0(CH_2) \simeq$ 80 kcal/mole. Third, a recent value of 93 kcal/mole for the activation energy of the reaction $CH_4 \rightarrow CH_2 + H_2$ (where $CH_2(^1A_1)$ is presumably formed according to spin conservation) leads to $\Delta H_f^0(CH_2) \simeq$ 76 kcal/mole (V. Kevorkian, C. E. Heath, and M. Boudart. J. Phys. Chem.* ***64****, 964 (1960)).*

[9]*Due to the wavelength distribution of the incident radiation and some distribution in fraction of excess light energy retained by the methylene, we use only an average excess energy $\bar{E}_{ex}$, and do not define an E_{min} quantity for photolysis systems.*

kcal/mole. The *total* excess light energy is $\{\Delta H_f^0(CH_2CO)+h\nu-\Delta H_f^0(CH_2)-\Delta H_f^0(CO)\}$, and for $\Delta H_f^0(CH_2) = 80$ kcal/mole, this quantity is 23.8 kcal/mole. It follows that $\bar{E}_{ex}$, the fraction of the excess light energy in the methylene when it reacts, is $\simeq 0.80$ of the total excess light energy.

B. DM

We set $\Delta H_f^0(CH_2N_2) = 70$ kcal/mole for purposes of discussion. The kinetic data suggest $(\Delta E_0' + \bar{E}_{ex}) \simeq 107$ kcal/mole for the DM–ethylene system, and $\bar{E}_{ex}$ is here 28 kcal/mole. The total excess light energy is $\{\Delta H_f^0(CH_2N_2)+h\nu-\Delta H_f^0(CH_2)\}$ and equals 55 kcal/mole at 4358 Å ($h\nu$ = 65 kcal/mole). Hence $\bar{E}_{ex} \sim 0.50$ of the total excess light energy. A higher value for $\Delta H_f^0(CH_2N_2)$ would reduce this fraction.

Frey (9(*d*)) has studied energized methylcyclobutane and methylenecyclopropane formed from photolysis of DM + cyclobutane and DM + allene, respectively, at 4358 Å and 3660 Å. Assuming that the average wavelength absorbed was indeed the mentioned values, then the maximum energy difference of each pair would be 12 kcal/mole. The observed change in the structural isomerization rate constants was only a factor of 1.5 for both the methylenecyclopropane and the methylcyclobutane. This strongly suggests that the real energy change of the formed molecules was even less than $12\times0.50 = 6$ kcal/mole and that $\bar{E}_{ex} < 0.4$ of the total excess light energy.

In the same paper, Frey (9(*d*)) reported methylcyclobutane formed by photolysis of ketene and cyclobutane with 3130 Å, and with unfiltered, radiation in a quartz vessel (effective radiation was mainly 3000 Å and 2800 Å), and found an increase in the isomerization rate constant by a factor of 2. The maximum difference in absorbed wavelength was 3130 Å and 2800 Å, or a difference in total excess light energy of ~11 kcal/mole and probably somewhat smaller. Comparison of this data with that for Frey's DM system just described also supports the above finding that an appreciably greater fraction of the excess light energy remains with the reacting methylene from ketene photolysis than from DM photolysis.

If a high value for $\Delta H_f^0(CH_2)$ of 90 kcal was used, many of the quantities calculated above would change appropriately. The estimated fractions would decrease from 0.8 to 0.65 for ketene and from 0.5 to 0.4 for DM so that the relative relations and previous conclusions are unchanged. In addition, if the arbitrary estimate of $\Delta H_f^0(CH_2N_2) = 70$ kcal was raised to 80 kcal, this latter value when coupled with $\Delta H_f^0(CH_2) = 90$ kcal would reduce the fraction for DM further to 0.33.

Little information on the electronically excited DM and ketene states is available. However, it is of interest to compare r(C—O) in ground-state ketene and in the carbon monoxide product (1.15 Å (28) and 1.13 Å, respectively) with r(N—N) in ground-state DM and in the nitrogen product (1.18 Å (28) and 1.094 Å, respectively). The relative invariance of r(C—O) may help to explain the higher fraction of excess light energy that remains with the methylene in ketene photolysis.

The present study has benefited greatly from the related work of Dr. H. M. Frey.

APPENDIX I

Calculation of the Specific Collision Frequency

A Sutherland correction was used to obtain the effective collision frequency at the different temperatures. Furthermore, it was necessary to apply molecular volume and

self-shielding corrections to the experimental ideal gas pressure at the high pressures used in the DM–ethylene systems (9(*a*)). For the cyclopropane system, DM and/or its products were counted fully in the calculation of the total ω. For the DMC system, DM and/or its products were counted in arbitrarily as one-half their value (to allow for decreased deactivation efficiency relative to *cis*-butene-2). The following tabulation lists the constants employed.

Molecule	Diameter (Å)	Sutherland constant
Ethylene	4.95	226[a]
Cyclopropane	4.92	
Diazomethane	6.4	
Propene	5.9	
cis-Butene-2	6.5	500[b]
Methylcyclopropane	5.9	
Dimethylcyclopropane	7.0

APPENDIX II

Computation of k_a

Formulation of f(E)

The process of interest for the calculation of $f(E)$ in the thermal DM system is the reverse dissociation of cyclopropane into methylene and substrate olefin (13). Then we may define

$$f'(E)dE = \frac{k_E'K(E)dE}{\int_{E_{\min}}^{\infty} k_E'K(E)dE}, \qquad [c]$$

where $K(E)$ is a Boltzmann distribution function for cyclopropane molecules at the reaction temperature, and k_E' is the specific rate at which energized molecules would decompose into methylene and substrate olefins. On substitution of equation [*b*] into [*c*], the distribution function $f'(E)$ takes the form

$$f'(E)dE = \frac{N_E^{+\prime}e^{-E/RT}dE}{\int_{E_{\min}}^{\infty} N_E^{+\prime}e^{-E/RT}dE} \qquad [d]$$

and $f'(E)$ becomes $f(E)$ upon superposition of E_{RE}.

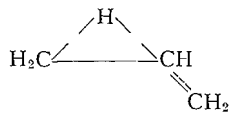
For the photolysis system the energy distribution of the formed activated molecules corresponds to the combination of the thermal distribution at the reaction temperature, usually 25°, with the wavelength distribution of the absorbed light.

Numerical Calculations and Vibrational Models

Values of N_E^*, N_E^+, $N_E^{+\prime}$ were calculated directly with an IBM 709 (29). In order to do the sums of quantum states it is economical to group the molecular frequencies somewhat; in this case, five frequency groups (each group a degenerate oscillator with frequency equal to the geometric mean of the molecular frequencies of the group) give an accurate representation of the species concerned. Comparison of the zero-point energy

and partition function for the molecular cyclopropane frequencies (30) to that from the present model indicates that less than 10% error is introduced by this simplification.[2] *All vibrational and internal rotational degrees of freedom of molecules and complexes were taken as active.* The molecular frequencies for DMC were estimated. The grouped molecular frequencies are shown below.

For the activated complex for structural isomerization of cyclopropane, the previously described model (31, 32) (the representation of the activated complex in ref. 32 contains a slight typographic distortion) was used:



Relative to cyclopropane, the principal changes are the elimination of one C—H stretching frequency, and lowering of three frequencies corresponding to two new torsional modes of the methylene groups and a whole molecule bending frequency. These frequencies and bond lengths were chosen in accord with bond order rules. In formulation of the activated complex for structural isomerization of DMC, no distinction was made between either the two geometric isomers of DMC or between the formation of different structural isomers. The frequencies of this activated complex were obtained by changing the DMC frequencies in analogy with the above treatment of cyclopropane. As has been shown (32, 33), calculational results are fairly insensitive to variations in the assignment of frequencies for the activated complex. This is particularly true for large molecules whose frequency pattern is little affected by such variations. The assignment of vibrational frequencies for the methylene plus olefin *association* complex is, again, not a critical feature of these calculations. Methylene addition to olefins is stereospecific (8) and no internal rotation in the association activated complex is postulated.

[a]Frequencies for cyclopropane molecule as given most recently by S. J. Cyvin, Spectrochim. Acta., **16**, 1022 (1960), would be slightly different, but the calculational results would be virtually unchanged.

The ratio $[(I_A{}^+I_B{}^+I_C{}^+)/(I_AI_BI_C)]^{1/2}$ was calculated to be 1.21 for cyclopropane and estimated as 1.1 for DMC. Combination of these models and the observed activation energies give 60.0 and 62.7 kcal as the values for ΔE_0 for DMC and cyclopropane respectively.

Fit of the Cyclopropane Models to Thermal Isomerization Data

The frequency assignments and calculational methods employed here do, in fact, provide an excellent fit of thermal unimolecular isomerization data, where $E_{\min} \equiv E_0$ is a known quantity: For k_∞ for cyclopropane, we have already found (32) with these models A_∞(calc.) = $10^{15.32}$; A_∞(exptl.) (34) = $10^{15.30}$. In addition, the model was shown to give the correct curvature for the experimental falloff curve of cyclopropane (35, 36). The absolute pressure fit is given to within a factor of $\sim$2, depending somewhat on the calculation of collision cross sections and on the particular experimental data. These models also satisfy (32) the observed (37) pressure dependence of the intermolecular isotope effect, (k_H/k_D), between cyclopropane and cyclopropane-d_6. This involved simultaneous fit of the observed activation energy difference, frequency factor ratio, and reasonable satisfaction of the Teller–Redlich product rule.

The models employed for DMC and its activated complex give $A_\infty = 7.0\times10^{14}$ sec^{-1} for the high-pressure frequency factor for thermal isomerization at 740° K. The theoretical rate is given by factors of 1.8 and 1.2 for *cis*-1,2-DMC and *trans*-1,2-DMC, respectively, relative to experimental values (15), and by a factor of 0.6 relative to 1,1-DMC (16).

The agreement described above supports the validity of the application here of these k_a calculational models to the chemical activation data for the evaluation of $E_{\min}$ and E_{av} by using these as parameters which bring k_a (calc.) into correspondence with k_a (exptl.).

APPENDIX III

Potential Surface for the Decomposition of DM

Herzberg[8] has shown from spectroscopic evidence that the triplet ($^3\Sigma_g^-$) rather than the singlet ($^1A_1$) is the ground state of methylene. Similar conclusions have been drawn from stereochemical evidence (20). The separation of these levels is not known but is believed to be small (Fig. 14).

The decomposition of DM is similar in principle to that of N_2O, for which (38) $k_\infty = 10^{11.9}\exp(-60{,}000/RT)$ and the decomposition proceeds (5) on surfaces I and III of Fig. 14 to give O(^3P). Gill and Laidler (39), using Stearn and Eyring's analysis (5(*a*)) together with an estimated normal frequency factor of 3×10^{13} sec^{-1}, find a separation of 500 cal/mole at the crossing of the $N_2O(^1\Sigma)$ surface with the $N_2(^1\Sigma)$–O(^3P) surface. This is of the magnitude given by McClure (40)[10] for N and O atom spin–orbit interactions and by Stearn and Eyring (5(*a*)) for O(^1D) and O(^3P) interaction.

The thermal decomposition of diphenyldiazomethane (ϕ_2DM) into diphenylmethylene radicals has recently been investigated (41) in an inert solvent; a rate constant of $10^{11.64}\exp(-26{,}000/RT)$ was reported at 100°. This low pre-exponential factor is similar to that for N_2O and is suggestive that the thermal decomposition gives triplet radicals. (Diphenylmethylene radicals from the photolysis of ϕ_2DM (42) may be produced in the triplet state.) Assuming this interpretation to be correct for the sake of this discussion, while subject to further investigation,[11] a "normal" frequency factor for the high-pressure decomposition would be $\gtrsim10^{13}$, and the transmission coefficient for the ϕ_2DM decomposition would be $\sim10^{-2}$. The Landau–Zener relation gives[12] in

[10]*McLure (40) estimates 28 cm^{-1} (80 cal/mole), 70 cm^{-1} (200 cal/mole), and 152 cm^{-1} (430 cal/mole) for the spin–orbit coupling parameters of atoms* C, N, *and* O, *respectively.*

[11]*The cautionary remarks of Fielding and Pritchard (J. Phys. Chem.* **74**, *278 (1960)) should be kept in mind.*

[12]*Based on tables from Stearn and Eyring (5(a)), with $|s_1-s_2|$, the difference in slopes of the two intersecting potentials, arbitrarily set the same as for* N_2O.

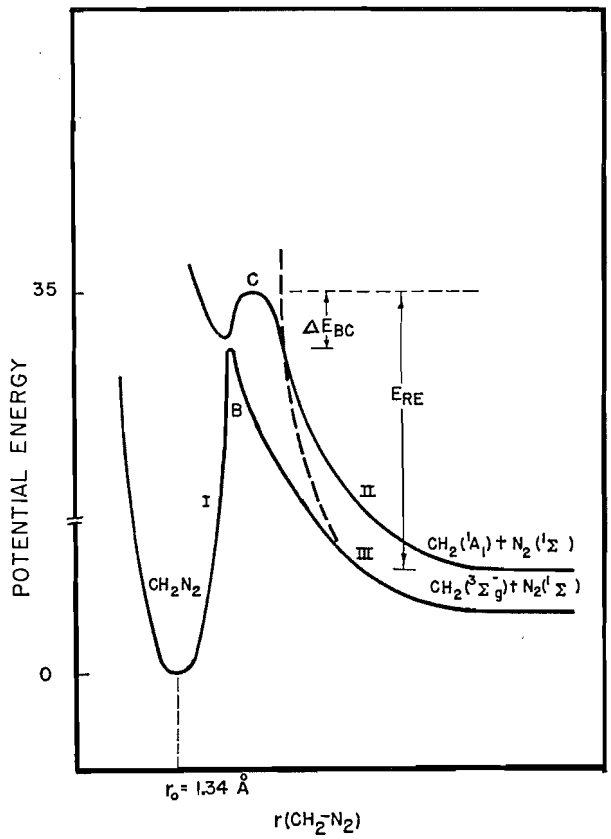

FIG. 14. Two-dimensional schematic representation of potential surfaces for diazomethane, singlet and triplet methylene. Zero-point energies have been omitted for simplicity. Variation of energy along the HCH angle coordinate may be inferred from the text, corresponding to the dotted curve for $CH_2(^3B_1)$.

this case a resonance separation of ~80 cal/mole. This would be a reasonable order of magnitude for the spin–orbit interaction.

For DM, it would not have been unexpected, therefore, had the reaction followed surface III rather than II. Without prejudice to factors that may alter the splitting at B as between ϕ_2DM and DM, we consider here only one other factor: The HCH bond angle in DM is around 120° while those in $CH_2(^1A_1)$ and $CH_2(^3\Sigma_g^-)$ are 103° and 180°, respectively.[8] As noted by Thrush (43), the energy of surface III with reduction of HCH angle from 180° toward 120° should follow the dotted line which lies in large part outside of the plane of Fig. 14. The latter represents, for surfaces I and II, a cut at a slightly varying HCH angle (120°–103°). After this paper was submitted, some calculations by Pedley (44) on the variation of CH_2 energy with HCH bond angle have appeared; these suggest that the dotted line could lie closer to the solid curve, and might cut surface I above B (Fig. 14) and within a few kcal of C, as would be required by our kinetic results and the Landau–Zener relation.

The explanation of the behavior of ϕ_2DM, if triplet product is indeed formed, would involve consideration both of a changed magnitude of separation of the singlet–triplet energies of the substituted methylene, and of the characteristic ϕ—C—ϕ angle in both states.

APPENDIX IV

Comparison of k_E Calculated from Quantum, Semiclassical, and Classical Models

Clarification of the relation of alternative expressions for the calculation of k_E may be worthwhile. Cyclopropane is used as a practical example. The well-known classical equation [*e*] of RRK has been widely used for estimation of k_E,

$$k_E = A\left\{\frac{E-E_0}{E}\right\}^{s-1}. \qquad [e]$$

A is a semiempirical constant; E_0 has its customary significance and is 62.7 kcal/mole for cyclopropane (32). The classical statistics give highly inaccurate results unless the index s is arbitrarily reduced to a fraction of the total number of vibrational modes (29, 33). For cyclopropane studied thermally at 500° C, $s \simeq 10.5$ (36).

By application of the Marcus–Rice semiclassical statistical approximation (24), Rabinovitch and Diesen (13) indicated an improved expression (equation [*f*]),

$$k_E = A'\left\{\frac{E-E_0+a^+E_z^+}{E+aE_z}\right\}^{s-1}. \qquad [f]$$

Here all vibrational modes are customarily to be taken (29, 33) as active ($s = 21$); E_z and E_z^+ are the zero-point energies of energized molecule (49.04 kcal/mole) and activated complex (42.8 kcal/mole), respectively. A' is evaluated from the properties of the species in question and is equal to $\sigma \cdot P_1^+ \cdot \Pi_{i=1}^{n} \nu_i^* / h \cdot P_1^* \cdot \Pi_{i=1}^{n-1} \nu_i^+$; for cyclopropane A' (Appendix II) is $10^{15.80}$. The quantities a^+ and a are empirical correction factors that bring the semiclassical expression for the sum of the vibrational states into agreement with exact count for the activated complex and energized molecule, respectively; values of a for cyclopropane have been given (29). Expression [*f*] has been applied previously (45).

Equation [*f*] has also been used in simplified form (9(*a*)) (denoted here as eq. [*f'*]) with $a = a^+ = 1$ and with A' simply set equal to A_∞ ($10^{15.30}$), as evaluated experimentally (34) from the high-pressure limit of thermal reaction as representing the correct order of magnitude. The approximation $a = 1$ is tolerable, but a^+ only approaches unity for E values much above E_0. The present experimental system represents a favorable case since $E-E_0 > 40$ kcal.

The results for cyclopropane given by eq. [*e*] and [*f'*] are compared to the results from the accurate direct quantum count for k_E (eq. [*b*]) in Table III. The Table shows that [*e*] is a gross underestimate of k_E at all energies and that [*f'*] becomes a good order of magnitude approximation to the direct count k_E at moderately high excess energies, but does not have the proper energy dependence. Use of tabulated values for a and a^+ shown in Table III provide a fit of eq. [*f*] to the accurate value of k_E given by eq. [*b*].

TABLE III

Values of k_E compared in various approximations (sec^{-1})

INFLUENCE OF TEMPERATURE ON THE ELECTROLYTIC SEPARATION FACTOR OF HYDROGEN ISOTOPES[1]

L. P. Roy[2]

Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario

Received August 12, 1960

ABSTRACT

An electrolysis cell and a tritium counting system are described for the study of the influence of temperature on the electrolytic separation of hydrogen isotopes on a mild steel cathode in alkaline solution. By careful control of the conditions for electrolysis, the separation factors could be determined with a probable error of ±4%. From the temperature coefficients of the three separation factors α, β, and γ, differences in activation energy of −1680, −2260, and −580 cal/mole have been calculated for electrolysis in the H–D, H–T, and D–T systems respectively. When conditions were less stringently controlled, the separation factor β was found to be a linear function of the separation factor α according to an equation of the form $\beta = D\alpha - E$. This relationship is of importance in the use of deuterium as a tracer in the electrolytic concentration of natural tritium. Some empirical equations showing the temperature influence on the variation of β as a function of α are also included.

INTRODUCTION

The study of the mechanisms of the cathodic evolution of hydrogen and the importance of obtaining an efficient separation of the hydrogen isotopes in the commercial production of heavy water by electrolysis have led investigators to determine the influence of factors which affect the separation of protium from deuterium. Among these factors may be cited: current density, overvoltage, nature of the electrode surface, presence of impurities in the electrolyte, time of electrolysis, and the influence of temperature on the separation of protium and deuterium. The efficiency of such a separation is usually expressed by its separation factor, which is defined by the ratio of the isotopic forms in the gaseous phase to that in the liquid phase. For the three hydrogen systems, protium–deuterium, protium–tritium, deuterium–tritium, the separation factors are:

$$\alpha = \frac{(h/d)_{\text{gas}}}{(h/d)_{\text{liquid}}}, \qquad [1]$$

$$\beta = \frac{(h/t)_{\text{gas}}}{(h/t)_{\text{liquid}}}, \qquad [2]$$

$$\gamma = \frac{(d/t)_{\text{gas}}}{(d/t)_{\text{liquid}}}, \qquad [3]$$

where h, d, and t represent the number of atoms of protium, deuterium, and tritium in the specified phase. The three separation factors are related to one another by the equation

$$\gamma = \beta/\alpha. \qquad [4]$$

Thus a knowledge of any two of these factors enables the third one to be calculated.

The results of previous workers have shown that the electrolytic separation factor of the hydrogen isotopes varies somewhat with temperature. Bell and Wolfenden (1) have reported a value of 4.3 at 10° C and 3.8 at 100° C for the separation factor α on a nickel cathode in alkaline solution. Walton and Wolfenden (2) have investigated the temperature

[1]*Issued as A.E.C.L. No. 1534.*

[2]*Present address: Laval Industrial Association (Incorporated), P.O. Box 124, Pointe-aux-Trembles, Montreal, Que.*

influence on five cathode materials. They have found a negative effect, i.e. a decrease of the separation factor α for an increase in temperature for Ni, Ag, Pt, and Hg, the temperature effect with the latter cathode being hardly detectable, while for Sn there seemed to be a slightly positive effect. They have reported a separation factor α of 7 at 15° C and 5.9 at 95° C on a nickel cathode in acid solution.

More recently, Brun and Varberg (3) have studied the temperature influence on the separation factor of protium and deuterium on a mild steel cathode in alkaline solution. They observed a decrease from 17.5 to 5.8 in the separation factor α for an increase of temperature from −19° C to +97° C. In such experiments carried out at various temperatures, it is possible to calculate the difference of activation energy for the rate-controlling step in the liberation of hydrogen isotopes by means of the Arrhenius equation applicable to the protium–deuterium system in the following way:

$$\frac{d \log \alpha}{dT} = \frac{\Delta H_\alpha}{2.3RT^2} \qquad [5]$$

where α is the separation factor at absolute temperature T, R is the molar gas constant, and

$$\Delta H_\alpha = E_H - E_D, \qquad [6]$$

where E_D is the free activation energy for the transfer of a deuteron to the cathode and E_H is the same activation energy for the transfer of a proton to the cathode.

Applying the above equation to the results of Brun and Varberg, an activation energy difference of −1800 cal/mole has been calculated for the H–D system on a mild steel cathode in alkaline solution.

On the other hand, the data available in the literature on the protium–tritium separation factor are very limited and do not involve any investigations of temperature dependence. Eidinoff (4) has observed a value of 14 on a smooth platinum cathode at 20° C in alkaline solution. Horiuti and Nakamura (5) have obtained, by theoretical calculations, values of 15.1 and 16.1 for nickel and platinum cathodes. Kaufman and Libby (6) have observed wide fluctuations for successive determinations of β and α but the ratio of β/α was found to be essentially constant at 2.1 ± 0.1. This ratio has been used by them and later workers to calculate, for purposes of low-level tritium measurements, the tritium recovery of an electrolytic enrichment from the observed deuterium recovery.

We observed a wide range of values in the electrolytic separation factors α and β during the first part of our investigation, and these results are discussed more fully below. Östlund and Werner observed the same behavior (7). We eventually improved our technique to the extent that reproducible results were obtained. This paper describes the electrolysis method finally adopted to study the influence of temperature on the electrolytic separation factors α and β on a mild steel cathode in alkaline solution. From our results and the relation given in equation [4] it was possible to calculate γ as a function of temperature. Linear Arrhenius relationships (equation [5]) allowed deduction of the activation energy differences of the three systems.

EXPERIMENTAL

(a) Electrolytic Cell and Oxidation Apparatus

The apparatus used is shown in Fig. 1. The electrolytic cell A, made of Pyrex glass, had a capacity of about 15 cc and was equipped with a ground-glass joint so that it could be opened readily. Two U traps, D, cooled with liquid nitrogen, kept the water of the electrolyte from contaminating the electrolytic gases. The simple manual Toepler pump E allowed quantitative transfer of the electrolytic gases from the cell

to the Vycor oxidation chamber L, which was filled with cupric oxide and kept at 750° C by means of an electric furnace. A second Toepler pump K was used to discard sweep gases while the water produced in the furnace was collected in the removable trap N, kept at liquid nitrogen temperature.

(b) Electrodes and Electrolyte

The 0.25 mm thick mild steel cathode containing 0.2±0.05% manganese and 0.1±0.05% carbon and the nickel anode were mounted as shown in Fig. 2. Two thin slots, cut in a small Teflon block located at

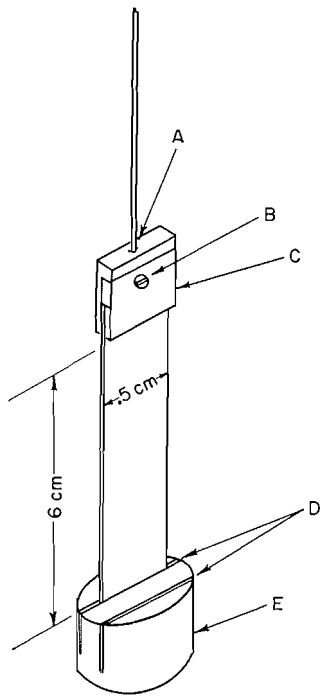

FIG. 2. Electrode arrangement.

B = clamping screw
C = stainless steel clamp
D = slots for positioning electrodes
E = teflon block

the bottom of the cell, kept the electrodes in a fixed position. The electrical metal leads, extending about 3 cm from the top of the cell through small holes, were fastened to the glass with Armstrong cement. The direct current was supplied by a dry cell and was measured with a milliammeter. A variable resistance was inserted into the circuit to restore the small drop in current following the first one or two minutes of electrolysis.

The water used to make up the electrolyte was distilled three times from an alkaline permanganate solution. Some heavy water of known concentration was added to make the solution 2% in HDO and about 20 to 25 μc of tritium (as THO) was introduced into the water. The electrolyte was 4.4 weight% KOH.

(c) Reduction Apparatus and Tritium Counter

Figure 3 shows the reduction apparatus and the vacuum line associated with the operation of the tritium gas counter F. The water produced by the electrolysis and collected in the trap N (Fig. 1) was vacuum-distilled into E, with the Zn furnace at room temperature. Reduction was carried out by allowing the

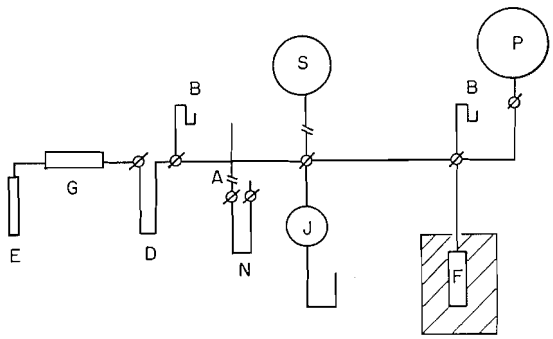

FIG. 3. Schematic representation of the reduction apparatus and of tritium gas counting system.

sample to pass through a few grams of 20-mesh zinc metal at 375° C. Trap D served to recover any unreacted water. The hydrogen was transferred from the reduction system to the counter by the manual Toepler pump J.

Counter F, which was 8 cm in length and 1.8 cm in outside diameter, had a sensitive volume of 8.7 ml. The anode consisted of a 0.025-mm diameter tungsten wire, while the copper walls constituted the cathode. The use of an electronic quench unit (an A.E.C.L.-designed unit, number AEP 1702) with a self-quenching gas mixture of argon and ethylene provided a plateau with a slope of about 2%/100 v over a 400-v region. Six inches of lead were used for shielding, and this kept the background to about 12 counts/min. The counting gas mixture, consisting of 6 parts of argon to 5 parts of ethylene by volume, was stored in bulb P.

(d) Procedure

The electrodes were polished with 2/0 and 4/0 emery paper, cleaned with ethanol and benzene, inserted into the Teflon holder, and clamped to the connecting leads. The electrolyte was poured into the cell, the solution frozen with liquid nitrogen, and the air removed by pumping for a few minutes. Two or three freezing and pumping operations were sufficient to remove the last traces of dissolved air, which was then replaced by some 10 cm pressure of helium or argon. The electrolyte was purified by a pre-electrolysis at a current density of 15 ma/cm^2 for 1 hour, after which the solution was frozen by liquid nitrogen and the electrolytic gases along with the inert gas were removed by the series of operations outlined above. A fresh portion of inert gas was then added to the electrolytic cell and the pressure was maintained at 60 cm of Hg throughout the experiment by lowering of the mercury reservoir E. The solution, kept at constant temperature, was then electrolyzed for 30 to 60 minutes at a current density of 8 ma/cm^2. Current efficiencies of 95 to 98% were calculated from the hydrogen gas yield. At the end of the electrolysis, the solution was frozen with liquid nitrogen and the electrolytic gases, well mixed with the inert gas, were transferred, at a reduced pressure for safety purposes, to the evacuated cupric oxide furnace L by means of the mercury bulb E. (Fig. 1). The resulting water was collected in removable trap N, which was connected to the reduction apparatus at A (Fig. 3), and the water transferred into E. The reduction was carried out in the manner already described. Complete reduction of the water was very important in order to avoid a possible fractionation of the hydrogen isotopes at this stage. The presence of any unreacted water was detected by an increase of pressure when the evacuated, liquid nitrogen cooled trap D was heated gently to room temperature. In such a case, a second reduction was carried out. However, it was found that the incomplete reaction could be avoided by changing the zinc furnace frequently, e.g. after 5 or 6 runs. A portion of the hydrogen gas was put into a removable sample bulb, S (Fig. 3), for measurement of the protium–deuterium

ratio with a Model 21-610 Consolidated mass spectrometer. The remaining fraction of the hydrogen gas was transferred to the tritium counter F (Fig. 3) by the manual Toepler pump J and mixed four or five times with a constant amount of counting gas mixture supplied from P (Fig. 3). The hydrogen pressure varied between 10 and 15 cm of mercury while the argon–ethylene pressure was kept constant at 10.0 cm of mercury. A plateau was run for every tritium determination and the average activity over a 300-v interval was used as the true activity.

RESULTS AND DISCUSSION

The protium–deuterium separation factor α was calculated by means of equation [1], where the $(h/d)_{gas}$ and $(h/d)_{liquid}$ ratios were measured by a mass spectrometer after the water from the electrolyte (liquid phase) and the water from the electrolysis (gas phase) had been reduced to hydrogen gas. Two methods were used for the determination of the protium–deuterium separation factor. The first one consisted of calibration of the instrument with protium–deuterium mixtures of known composition so that the h/d ratios of the gaseous and liquid phases could be determined absolutely. The second method consisted of comparison of the HD peak height of the hydrogen derived from the electrolyte (liquid phase) to that derived from the electrolytic waters (gas phase) for the same hydrogen peak height in both phases. The ratio of the two peak heights under these conditions gave the separation factor of the protium–deuterium system. Both methods agreed within 2%.

A relative method was used to determine the protium–tritium separation factor β. The specific activity of the hydrogen derived from the electrolyte, relative to the specific activity of the hydrogen released during electrolysis, gave the separation factor directly. No absolute calibration of the counter was required. When the technique described in (*d*), Experimental, was followed carefully, the reproducibility was reasonable, as illustrated in Table I.

The errors shown in Table I refer to the probable error obtained by a statistical treatment of the experimental data and lie well within the estimated combined errors of the individual measurements which were used to calculate the separation factors. Thus, uncertainties in the D content of the electrolyte and electrolytic water led to an error of ±2% in the separation factor, while a possible variation in temperature might produce an error of ±1%; finally, possible isotopic fractionation in the oxidation and reduction steps amounted to an error of ±3%. The latter value was obtained experimentally by

comparing the h/d ratio of the electrolytic hydrogen before and after it had undergone oxidation and reduction steps. The errors in the protium–tritium system were assessed as follows: statistical error due to tritium counting of the electrolyte and the electrolytic water amounted to ± 1 and $\pm 2\%$ in the final value of β, while measurement of hydrogen and of counting gas pressures introduced an error of $\pm 2\%$ in β. A possible variation in temperature might produce an error of $\pm 1\%$ while an error of $\pm 4\%$ in β was expected from the possible fractionation of hydrogen isotopes in the oxidation and reduction steps.

The results for the temperature effect on the electrolytic separation factors α, β, and γ are summarized in Table II. The separation factor γ has been calculated by the relation

TABLE II

Temperature effect on the electrolytic separation factors of hydrogen isotopes

	T (°C)	α	β	γ	log β/log α
	0.5	11.7±0.4	31.8±1.3	2.7_2±0.14	1.41

ΔH (cal/mole)		$\Delta H_\alpha = -1680$	$\Delta H_\beta = -2260$	$\Delta H_\gamma = -580$	

given in [4]. The error quoted for over 15 determinations at each temperature refers to the most probable error. From Fig. 4, it can be seen that the Arrhenius relationship is obeyed in the temperature range studied. From the plots of Fig. 4, differences of activation energy of -1680, -2260, -580 cal/mole have been calculated for the H–D, H–T, and D–T systems, respectively. The value of -1680 cal/mole for the protium–deuterium system compares reasonably well with the value of -1800 cal/mole calculated from the results of Brun and Varberg (3). The ratio of log β/log α was found to be constant at 1.41±0.01, in agreement with the value of 1.40±0.01 reported by Bigeleisen (8) and of 1.40±0.09 reported by Kaufman and Libby (6).

When the technique described in (*d*), Experimental, was not followed, the agreement between successive runs was not very good, as shown in Fig. 5, in which the values of α varied from 6.7 to 12.7 at 0.5° C. This lack of reproducibility appears to arise from one or more of the following factors: nature of the electrode surface, impurities in the electrode or in the solution, omission of pre-electrolysis, presence of dissolved air in the electrolyte.

As a matter of practical interest in connection with measurement of tritium concentration in natural waters, it was desirable to determine whether or not β varies systematically with α. The practical usefulness of such a correlation will be evident when it is remembered that for determination of low levels of tritium in water, extensive preliminary electrolyses are necessary to concentrate the tritium (see for example ref. 6). In such electrolyses, β cannot be measured directly, i.e. only the H–D separation factor can be determined. Accordingly, all of the data obtained in the present work have been examined from this point of view. Table III summarizes the results. At all four temperatures, good empirical

TABLE III

Empirical equations at various temperatures

T (°C)	Limits		Number of determinations	Empirical equation
0.5	$6.7 < \alpha < 12.7$	$12.2 < \beta < 34.8$	45	$\beta = 3.80\alpha - 13.2$
22.5	$5.4 < \alpha < 10.5$	$9.2 < \beta < 29.8$	28	$\beta = 3.53\alpha - 9.7$
40.0	$3.5 < \alpha < 8.8$	$5.5 < \beta < 21.4$	26	$\beta = 3.16\alpha - 6.0$
60.0	$3.4 < \alpha < 7.4$	$5.8 < \beta < 18.6$	34	$\beta = 3.04\alpha - 5.4$

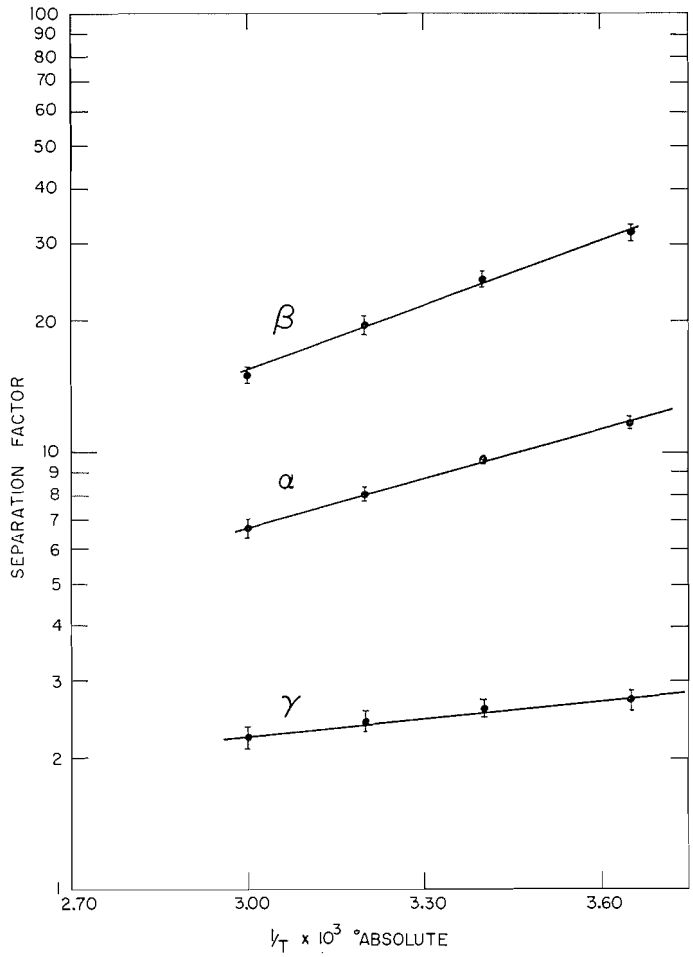

FIG. 4. Temperature variation of the separation factors α, β, and γ.

correlations of the form $\beta = D\alpha - E$ were observed between corresponding values of α and β. These are shown in the last column of Table III, and were derived from the data at each temperature by a least-squares analysis. The probable error in D and E was found to be 6% and 15% respectively.

The solid line in Fig. 5 represents the empirical correlation equation for 0.5° C. Correlations for other temperatures were fully as good as that shown in Fig. 5. Östlund and Werner (7) have also obtained a similar form of correlation between α and β for electrolysis at 10° C.

It is worthwhile emphasizing that γ, i.e. β/α, is not constant; for example, over the range of α observed at 0.5° C, γ was found to vary from 1.8 to 2.8, in contrast with the constant value of 2.1 ± 0.1 adopted by Libby and Kaufman (6) but in agreement with the values of 1.6 to 2.5 obtained by Östlund and Werner as reported by Bigeleisen (8).

CONCLUSION

When experimental conditions are carefully controlled, a good degree of reproducibility can be achieved in measurement of the isotopic separation which occurs during the electrolysis of alkaline water. For these conditions, a systematic increase of each separation

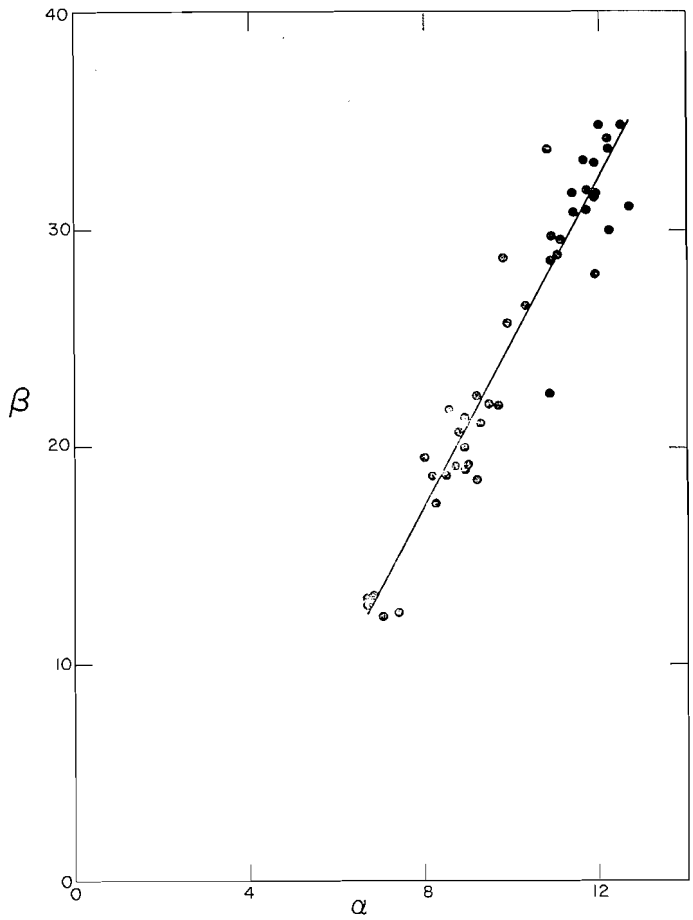

FIG. 5. Variation of separation factor β as a function of separation factor α, for $T = 0.5°$ C.

factor with decreasing temperature is observed; this effect can be expressed formally as an Arrhenius activation energy. The highest value observed for any separation factor was 34.8 for the H–T separation at 0.5° C.

When experimental conditions are less stringently controlled, variations up to a factor of 2 in the values of α occur, at a fixed temperature. For these less well defined conditions, it has been demonstrated that at each temperature a good empirical relationship of the form $\beta = D\alpha - E$ exists between corresponding values of α and β; D and E are temperature-dependent constants. As a consequence, γ is not a constant, as has been assumed previously, but varies with the value of α. These correlations have practical application in estimating the retention of tritium in the residual water after the extensive preliminary electrolyses frequently required as a concentration step in the determination of tritium in natural waters.

FREE-RADICAL REACTIONS WITH AROMATIC ETHERS

PART I. BENZOYL PEROXIDE WITH ANISOLE[1]

BRIAN M. LYNCH[2] AND RALPH B. MOORE[3]

Chemistry Department, Memorial University of Newfoundland, St. John's, Newfoundland

Received January 22, 1962

ABSTRACT

A re-examination of the products of thermal decomposition of benzoyl peroxide in anisole has resolved anomalous findings by previous workers. The expected phenylation of the substrate is accompanied by appreciable benzoyloxylation, and the distribution of isomers in the phenylation and benzoyloxylation products has been examined; the theoretical implications of the results are discussed.

INTRODUCTION

Phenylation of aromatic substrates by benzoyl peroxide, discovered by Gelissen and Hermans (1) in 1925, was recognized as a free-radical process by Hey and Waters (2), and continues to receive much attention (for general reviews, see Augood and Williams (3), Dermer and Edmison (4), Walling (5), and Williams (6, 7)). In a series of some 20 papers, Hey and Williams and their co-workers (8, and previous papers cited therein) have applied Ingold's competitive method (Ingold and Shaw (9)) to evaluate the relative reactivities of many aromatic compounds towards the aryl radicals liberated by decomposing benzoyl peroxides.

Recently, it has been pointed out (5, 10–12) that there is considerable uncertainty attached to the application of the competitive method in such reactions, since many side reactions occur, and their importance varies markedly for different aromatic substrates. Further reservations have been expressed since the phenylation process does not occur by any one mechanism; differing processes may be dominant at different concentrations (Eliel *et al.* (13)). It is apparent that selection of the relative yields of substituted biphenyls as a measure of reactivity towards free-radical attack must be regarded with considerable reserve; a more acceptable procedure involves consideration of the distribution of products among the various possible reaction paths (cf. Lynch and Pausacker (11, 12)).

In the present paper, we have used this approach in a study of the various reaction products obtained when benzoyl peroxide decomposes in hot anisole, and we have resolved suggestions (14; 6, p. 65) that anisole is in some way anomalous in its behavior. A previously published study of this reaction system (15) neglects the occurrence of benzoyloxylation of the substrate.

EXPERIMENTAL

Analyses are by the Schwarzkopf Microanalytical Laboratory, Woodside, N.Y., and the Australian Microanalytical Service at the Chemistry Department, University of Melbourne. Infrared spectra were measured using a Unicam SP100 prism-grating spectrometer, and ultraviolet spectra were recorded with a Beckman DK2A spectrophotometer.

Materials

Anisole (Matheson, Coleman, and Bell) was redistilled before use, b.p. 154°, n_D^{25} 1.5151; the various samples contained from 0.02–0.08% phenol. Benzoyl peroxide was purified (minimum purity, 98%) by reprecipitation from ice-cold chloroform by methanol. Reference samples of the isomeric methoxybiphenyls, methoxyphenols, and methoxyphenyl benzoates, and of phenol and phenyl benzoate, were obtained by purification of commercially available samples or by established common syntheses; the physical constants of these samples agreed with those recorded in the literature.

General Procedure

Benzoyl peroxide and anisole were heated together under varying conditions (see Table I). After completion of reaction, the various products were separated and isolated as follows: the *carbon dioxide* evolved was estimated by passage through a gas-absorption train. *Free benzoic acid* was isolated by extraction with saturated sodium hydrogen carbonate solution, followed by acidification. Excess of substrate was removed under reduced pressure, and the residue was heated under reflux with 5% potassium hydroxide in ethanol (16 hours). The ethanol was removed under reduced pressure, and the residue was acidified to pH 2 and extracted with ether. The *phenolic fraction* and an additional quantity of benzoic acid (*benzoic acid from hydrolysis*) were obtained from the extract by standard methods, and the *methoxybiphenyls* were isolated, after evaporation of the ether, by careful distillation under reduced pressure, or by steam distillation. Any involatile residue was weighed and reserved. This procedure is based on that employed by Lynch and Pausacker (11).

The Phenolic Fractions: Distribution of Isomers in Benzoyloxylation

Element analysis, and infrared and ultraviolet spectra, indicate that the phenolic fractions isolated from the various experiments consist largely of methoxyphenols, with little phenol being present. The following infrared absorption bands were noted for the three methoxyphenols, and for a typical phenolic fraction (from expt. 2): guaiacol (capillary film) (cm^{-1}, intensity): 745 vs, 835 m, 920 w, 1005 w, 1022 s, 1040 m, 1112 s, 1220 m, 1265 s, 1380 m, 1440 m, 1480 m, 1510 vs, 1610 vs, 1620 m, 2840 m, 2960 m, 3010 m, 3430 s, 3500 s; *m*-methoxyphenol (capillary film): 690 s, 770 s, 840 m, 925 m, 996 w, 1045 s, 1080 w, 1160 vs, 1200 vs, 1290 s, 1445 m, 1470 m, 1500 s, 1600 vs, 1615 vs, 2835 m, 2950 m, 3000 m, 3400 s; *p*-methoxyphenol (KCl disk): 733 s, 825 vs, 1033 vs, 1105 s, 1151 w, 1170 w, 1182 m, 1240 s, 1280 s, 1302 m, 1379 s, 1455 s, 1510 vs, 1608 s, 2830 m, 2950 s, 3015 w, 3035 w, 3400 s; phenolic fraction from expt. 2 (capillary film): 690 vw, 735–760 s, 820 s, 840 s, 920 w, 1030 s, 1040 s, 1110 s, 1155 s, 1180 m, 1225 s, 1270 s, 1380 m, 1460 m, 1480 m, 1510 vs, 1600 vs, 1620 s, 2840 m, 2955 s, 3010 w, 3430 s, 3500 s. Virtually all of these bands can be assigned without difficulty, following the lines of previous work by Katritzky *et al.* (16, and previous papers cited therein). It is evident that guaiacol and *p*-methoxyphenol are major constituents of the phenolic fraction examined (the infrared spectra of the phenolic fractions were all closely similar), but the differences in the spectra of the three isomers are not sufficient for accurate analysis of the ratios of isomers.

Similarly, although the ultraviolet spectra of the mixtures of phenols from expts. 1–3 and 6–8 corresponded well to that of guaiacol, the differences between the spectra of the various isomers are small (in water containing 1% methanol by volume, guaiacol has λ_{max} 216 and 275 mμ, log ε 3.76 and 3.33; *m*-methoxyphenol has λ_{max} 217, 273, and 279 mμ, log ε 3.83, 3.28, and 3.23; *p*-methoxyphenol has λ_{max} 223 and 289 mμ, log ε 3.83 and 3.41; phenol has λ_{max} 211, 270, and 276 mμ, log ε 3.75, 3.18, and 3.08; and the various phenolic fractions showed λ_{max} 216 and 275 mμ, log ε 3.9 and 3.32). The infrared spectra of the three methoxyphenyl benzoates were recorded, and it was found that the meta and para isomers had characteristic absorption bands in the aromatic C—H deformation region. The following absorption bands were observed (bands characteristic of an isomer are italicized): guaiacyl benzoate (KCl disk) (cm^{-1}, intensity): 710 vs, 760 s, 810 w, 1025 s, 1040 m, 1065 vs, 1080 m, 1110 s, 1155 w, 1170 s, 1200 s, 1260 vs, 1310 w, 1450 s, 1585 w, 1600 s, 1735 vs, 2835 m, 2940 s, 2975 vs, 3000 s, 3065 s; *m*-methoxyphenyl benzoate (KCl disk): *690* s, 710 vs, *744* w, *782* s, 870 s, *930* s, *996* w, 1023 s, 1063 vs, 1081 vs, 1142 vs, 1160 m, 1175 m, 1190 s, 1270 vs, 1318 s, 1450 s, 1490 s, 1589 vs, 1605 vs, 1736 vs, 2825 m, 2930 s, 2950 s, 3000 s, 3065 m; *p*-methoxyphenyl benzoate (KCl disk): 710 vs, 765 m, *815* s, 870 m, 1030 m, 1040 m, 1070 s, 1075 s, 1115 w, 1185 m, 1205 s, 1255 s, 1280 s, 1320 w, 1440 m, 1520 vs, 1605 m, 1735 vs, 2835 s, 2935 s, 2960 s, 2995 vs, 3065 m. Samples of mixed methoxyphenyl benzoates, prepared by benzoylation of the phenolic fractions from expts. 1 and 2, showed the following bands (KCl disk): 710 vs, 760 m, 815 w, 870 w, 1024 s, 1040 m, 1065 vs, 1077 s, 1113 m, 1170 s, 1200 s, 1265 vs, 1315 w, 1450 s, 1520 s, 1600 s, 1735 vs, 2830 s, 2940 s, 2970 s, 2998 s, 3065 m. The absence of absorption at 690, 744, 782, 930, and 996 cm^{-1} in the samples of mixed benzoates indicated that very little *m*-methoxyphenyl benzoate was present; comparison with synthetic mixtures containing the other isomers showed that as little as 3% of the meta isomer could be detected readily by the above absorption bands. Comparison of the intensities of the 710 cm^{-1} and 815 cm^{-1} bands in the mixed benzoates with those in a series of synthetic mixtures (the 710 cm^{-1} band is common to all three isomers; the 815 cm^{-1} band is characteristic of the para isomer) indicated ortho:para ratios of from 20–25:1, suggesting that very little *p*-methoxyphenyl benzoate was present. However, a referee has drawn attention to bands in the infrared spectra of the phenolic mixtures (at 1155 cm^{-1}, and at 1180 and 820 cm^{-1}) indicating the presence of significant amounts of both *m*-and *p*-methoxyphenols; it thus appears possible that some fractionation of isomers occurred during esterification.

Consequently, further examination of the various phenolic mixtures was made by gas–liquid chromatography using a Beckman GC-2A gas chromatograph with a "Carbowax 4000 Dioleate"-on-firebrick column No. 70007, operated using helium at an inlet pressure of 30 p.s.i. (outlet pressure, atmospheric), at a column temperature of 160° C. Trial experiments established that the three methoxyphenols were satisfactorily resolved under these conditions, (the order of elution being ortho, para, meta), and that the ratio of peak areas was accurately proportional to the quantities of the isomers. The following isomer percentages were deduced: mixture from expt. 1: ortho, 65; para, 35%; from expt. 2: ortho, 70; para, 30%; from expt. 3: ortho, 82; para, 18%. No *m*-methoxyphenol was detected, confirming in part the results deduced from the infrared spectra of the mixed methoxyphenyl benzoates. The results of the trial experiments indicate that the individual experimental error is ±2%.

The Methoxybiphenyls: Isomer Ratios in Phenylation

The mixtures of methoxybiphenyls isolated from expts. 1 and 2 were analyzed by gas–liquid chromatography and by differential ultraviolet spectrophotometry.

In the gas–liquid chromatography, a Beckman GC-2A gas chromatograph was used, with the standard silicone-on-firebrick column No. 74346; helium at an inlet pressure of 30 p.s.i. (outlet pressure, atmospheric) was the carrier gas, and the column temperature was 190° C. Under these conditions, the three isomers were satisfactorily resolved (the order of elution being ortho, meta, para), and experiments with synthetic mixtures showed that the ratio of peak areas was proportional to the isomer ratios. The results obtained were: mixture from expt. 1: ortho, 76.2; meta, 10.5; para, 13.3%; mixture from expt. 2: ortho, 77.4; meta, 10.7; para, 11.9%. Results obtained with the synthetic mixtures indicate that the experimental error is ±2%.

The ultraviolet absorption spectra of the various methoxybiphenyls differed sufficiently for analysis of the mixtures by a standard method (cf. Lynch and Pausacker (17), Cadogan, Hey, and Williams (18)). Calibration spectra in 95% ethanol were recorded in the wavelength range 220–360 mμ, with the following results: *o*-methoxybiphenyl showed λ_{max} 246 and 285 mμ, log ε 4.09 and 3.70; *m*-methoxybiphenyl showed λ_{max} 250 and 280 (shoulder) mμ, log ε 4.18 and 3.62; *p*-methoxybiphenyl showed λ_{max} 261 mμ, log ε 4.28. The proportions of ortho, meta, and para isomers were found to be 80, 10, and 10% for the mixtures from expts. 1 and 2 (the two mixtures gave identical ultraviolet spectra). The experimental error is probably ±5%.

The infrared spectra of the various methoxybiphenyl mixtures were consistent with the isomer ratios as determined above, and no bands other than those due to the three isomers were present. The following absorption bands were noted for the methoxybiphenyls: (*a*) *o*-methoxybiphenyl (capillary film) (cm^{-1}, intensity): 700 vs, 732 s, 755 vs, 915 m, 937 w, 998 w, 1012 s, 1031 s, 1060 s, 1078 m, 1126 s, 1166 m, 1182 s, 1241 vs, 1264 vs, 1300 m, 1433 vs, 1465 m, 1485 vs, 1508 s, 1585 s, 1600 s, 2830 m, 2935 s, 2955 s, 3000 m, 3025 m, 3060 s; *m*-methoxybiphenyl (capillary film): 699 vs, 755 vs, 790 m, 860 m, 998 w, 1020 m, 1038 m, 1053 m, 1077 w, 1180 s, 1215 vs, 1270 sh, 1298 s, 1420 s, 1480 vs, 1570 s, 1600 vs, 2832 m, 2935 s, 2950 s, 3000 m, 3030 m, 3060 s; *p*-methoxybiphenyl (KCl disk): 688 m, 759 vs, 832 vs, 909 w, 1001 w, 1015 m, 1038 s, 1042 m, 1120 m, 1186 m, 1202 s, 1253 vs, 1271 m, 1290 s, 1441 m, 1450 m, 1466 m, 1490 vs, 1527 m, 1582 w, 1609 vs, 2835 m, 2935 s, 2960 s, 3000 m, 3030 m, 3070 m.

Infrared Spectra of Involatile Residues

These were recorded for the products from the various experiments, using the potassium chloride disk technique for sample preparation; all spectra were closely similar. A typical example (a sample prepared from the involatile residue from expt. 7) showed the following strong bands: 700, 755, 830, 1035, 1080, 1120, 1180, 1230, 1250, 1300, 1410, 1480, 1500, 1590, 1600, 2830, 2930–2960, 3000, 3030, 3060 cm^{-1}.

DISCUSSION

In most experiments, the sums of the yields of carbon dioxide, free benzoic acid, and benzoic acid from hydrolysis account almost quantitatively for the reacted benzoyl peroxide, and the yields of other products are quite reproducible. Although some losses are inevitable in the working-up processes, it appears that reasonably quantitative estimates of the various reaction products have been made.

In the following discussion, we interpret the anomalous behavior reported by previous workers, and attempt to show that anisole actually behaves in a typical manner in its reactions with the radicals from decomposing benzoyl peroxide.

The "Anomalous" Behavior of Anisole

The distribution of products in the present work differs from that reported previously (Suehiro (15)). Under conditions similar to those of expts. 4 and 5, Suehiro obtained the following yields of products (mole/mole peroxide): carbon dioxide, 0.51; free benzoic

acid, 1.22; methoxybiphenyls, 0.36. Thus, the contribution of the stoichiometric expression (A) to the total reaction is greater for our experiments.

$$Ph.OCH_3 + Ph.CO.O.O.CO.Ph \rightarrow Ph.C_6H_4.OCH_3 + CO_2 + Ph.CO_2H \quad (A)$$

Results similar to Suehiro's, in that yields of benzoic acid well in excess of 1 mole/mole peroxide were obtained, have also been reported by Augood (14) and Rondestvedt and Blanchard (19). Since the stoichiometric equations (A), summarizing phenylation, and (B), summarizing benzoyloxylation by benzoyl peroxide, predict a *maximum* yield of free benzoic acid of 1 mole/mole peroxide, processes other than (A) and (B) must account for the abnormally high yields of free benzoic acid.

$$Ph.OCH_3 + Ph.CO.O.O.CO.Ph \rightarrow Ph.CO.O.C_6H_4.OCH_3 + Ph.CO_2H \quad (B)$$

Augood and Williams (3) and Williams (6, p. 65) suggest that the high yields of benzoic acid noted in their reactions result from hydrogen abstraction from anisole by a benzoate radical, yielding the phenoxymethyl radical and benzoic acid (process (C)):

$$Ph.CO_2\cdot + Ph.OCH_3 \rightarrow Ph.CO_2H + Ph.OCH_2\cdot; \quad (C)$$

this radical is assumed to be incorporated in the high-boiling residues. If this suggestion is correct, it might be expected that 1,2-diphenoxyethane (formed by dimerization) and/or phenoxymethylanisoles (by nuclear substitution in anisole) would occur in the "methoxybiphenyl" fractions.* However, there were no indications of the presence of these substances in the methoxybiphenyls (see Experimental); furthermore, the infrared spectra of the involatile residues from the various experiments, and their methoxyl content (cf. Table I), indicate that these residues are probably of the quaterphenyl or tetrahydroquaterphenyl type to be expected from dimerization of the adduct between a phenyl radical and anisole (cf. Lynch and Pausacker (11), Pausacker (21), DeTar and Long (22)). Thus there is little supporting evidence for suggestions involving the extensive participation of process (C) in the total reaction scheme.

The key to an explanation of the anomalous yields of free benzoic acid obtained previously is simple; it is provided by the fact that although in the present work there is still an excess of free benzoic acid over the isolated nuclear substitution products, it is far less marked than reported previously. This implies that the anisole samples used in the various sets of experiments differ in some way. Since we noted in the course of the present work that our anisole samples contained traces of free phenol (which reacts extremely readily with benzoyl peroxide, yielding benzoic acid and other products (cf. refs. 23–25), it seems evident that the much higher yields of free benzoic acid obtained by previous workers are a result of the presence of higher proportions of free phenol as a contaminant in their anisole samples, and are not a consequence of any anomalous behavior of the anisole itself. Confirmation is afforded by the results of expts. 9 and 10, where deliberate addition of phenol to reaction mixtures markedly increased the yields of free benzoic acid.

It is also feasible that hydrolysis of the peroxide by small amounts of water present in the solvent might lead to increased yields of free benzoic acid (cf. the behavior of iodosobenzene dibenzoate and of lead tetrabenzoate (17, 26, 27); however, added water had no appreciable effect (expt. 11).

**Pfordte and Leuschner (20) have obtained 1,2-diphenoxyethane in low yield by irradiation of anisole with ultraviolet light, and Henbest, Reid, and Stirling (20(a)) have isolated phenoxymethylanisoles from the thermal decomposition of t-butyl peroxide in anisole.*

It is possible that another process may contribute to some of the excess of free benzoic acid noted in the present series of experiments, although there is no direct evidence in its favor: demethylation of anisole to phenol could occur by a route analogous to that commonly postulated for the dealkylation of tertiary amines (5, 28), i.e.

$$\mathrm{Ph.\ddot{O}{-}CH_3 + Ph.CO_2\cdot \rightarrow (Ph.\dot{O}{-}CH_3)^+ + Ph.CO_2^-}$$

$$\mathrm{(Ph.\dot{O}{-}CH_3)^+ + Ph.CO_2\cdot \rightarrow (Ph.\overset{+}{O}{=}CH_2) + Ph.CO_2H}$$

$$\mathrm{(Ph.\overset{+}{O}{=}CH_2) + H_2O \rightarrow Ph.OH + CH_2O + H^+.}$$

In unpublished experiments, we have shown that this reaction path is significant when substituted benzoyl peroxides react with anisole, since free phenol is generated from the substrate in sufficient amount for ready isolation from completed reaction mixtures. Cowley, Norman, and Waters (29) have found that methyl radicals effect dealkylation of anisole, and Kharasch and Huang (30) have shown that many phenol ethers can be dealkylated by free radicals, thus lending some support to this suggestion.

Nuclear Substitution Products

(a) Methoxyphenyl Benzoates

When benzenoid aromatic compounds react with benzoyl peroxide, benzoyloxylation (process (B) above) generally accompanies phenylation (process (A)) as a side reaction of varying importance.

Thus, benzoyloxylation has been observed when benzoyl peroxide decomposes in benzene (31), chlorobenzene (12, 31), nitrobenzene (12, 17), biphenyl (27, 31), *p*-dichlorobenzene (27), 1,2,3-trimethoxybenzene (32), pyridine (33), quinoline (33), and *p*-dimethoxybenzene (34). With the monosubstituted compounds, the extent of benzoyloxylation is small, and in some instances, the products (generally determined after hydrolysis to the corresponding substituted phenols) could have been formed by nucleophilic substitution of excess substrate during the hydrolysis step (e.g., nitrobenzene is converted into *o*- and *p*-nitrophenols by treatment with alkali in the presence of air (35, 36)).

However, in our present work we find that at 80° (expts. 6 and 7), the yields of methoxyphenyl benzoates are approximately one-half those of methoxybiphenyls; at higher temperatures, the extent of benzoyloxylation decreases, since the benzoyloxy radicals decarboxylate more rapidly.

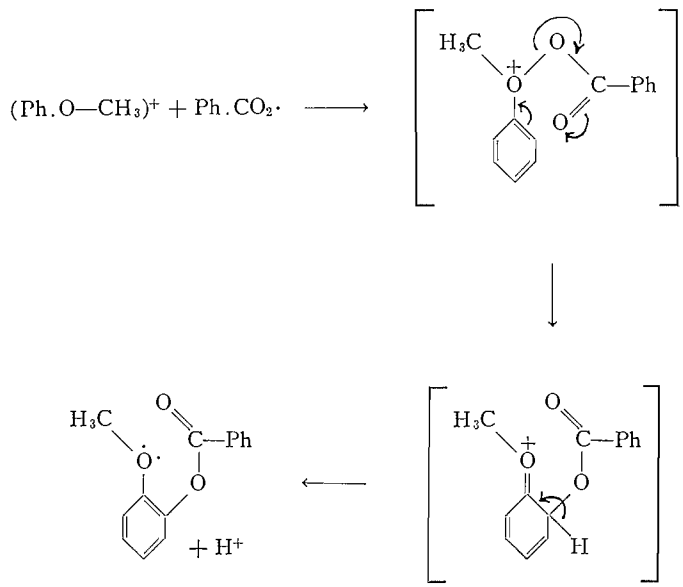
These results imply that anisole is more reactive towards decomposing benzoyl peroxide than any monosubstituted benzene examined previously (since in a more reactive solvent, the benzoyloxy radical is more likely to react with the substrate before decarboxylating), conflicting with findings in previous studies employing the competitive method (3, 19, 37). Further discussion of this point is given below.

Acyloxylation of anisole under conditions favoring free-radical attack has been reported previously: with lead tetraacetate in acetic acid at 80°, *p*-methoxyphenyl acetate is a major product (38), while electrolysis of aqueous acetic acid in the presence of anisole gives mixed methoxyphenyl acetates (ortho:para ratio, 7:3) (39, 40).

In the present work, the most reliable values for the isomer distribution range from 65–82% *o*-methoxyphenol and from 18–35% *p*-methoxyphenol; no *m*-methoxyphenol could be detected. The large scatter in the isomer distributions for the various experiments (far beyond errors of analysis) probably reflects the occurrence of some preferential oxidation of the *p*-methoxyphenol during the hydrolysis of the methoxyphenyl benzoates

(which is effected under conditions known to oxidize phenols having electron-donating substituents (cf. ref. 40(*a*))). The apparent selectivity may thus result from the more rapid oxidation of *p*-methoxyphenol (for recent evidence indicating that *p*-methoxyphenol is oxidized more rapidly than *o*-methoxyphenol, see McClure and Williams (40(*b*))).

The occurrence of extensive ortho benzoyloxylation is in contrast to the results noted for thermal acetoxylation by Cavill and Solomon (38); it is suggested that the mechanism of ortho benzoyloxylation of anisole is analogous to that proposed for the benzoyloxylation of phenols by benzoyl peroxide (Walling and Hodgdon (41)). Thus, the second stage of the suggested dealkylation reaction (p. 1466) is replaced by coupling between the anisole ion–radical and a benzoate radical, followed by a cyclic rearrangement, i.e.



Walling and Hodgdon found that the reaction rates of phenols were increased by electron-donating substituents, and we find (34) that *p*-dimethoxybenzene is benzoyloxylated rapidly and almost quantitatively by benzoyl peroxide at 80° (apparent first-order rate constants for 0.125 *M* peroxide are (10^5k, sec^{-1}): *p*-dimethoxybenzene, 58.8; anisole, 8.3; benzene, 3.8), thus lending some slender support to the suggested mechanism.

A re-examination of the acetoxylation of anisole by lead tetraacetate in acetic acid, using infrared spectroscopy in the examination of products (42), further confirmed Cavill and Solomon's finding (38) of preferred para substitution (we could detect no *o*-methoxyphenyl acetate). It is possible that the differences in orientation between benzoyloxylation and acetoxylation reflect the occurrence of *polar* acetoxylation by lead tetraacetate (cf. Mosher and Kehr (43)).

Free phenol, present in our anisole samples, could lead to the occurrence of catechol in the phenolic fractions (arising from the above ortho benzoyloxylation, followed by hydrolysis), thus lessening the significance of the isomer ratios deduced above. This possibility was checked by extracting any phenolic material from completed reaction mixtures with aqueous sodium hydroxide, and brominating the extracted material; only

very small quantities (0.02 g from a reaction under conditions similar to expt. 6) were isolated. Therefore, this potential source of error is not significant (see also Experimental, p. 1462.

(b) Methoxybiphenyls

The isomer ratios for the free-radical phenylation of anisole at 154° (present work) and 100° (Suehiro (15)) and for methylation at 140° (Cowley *et al.* (29)) are assembled in Table II.

TABLE II

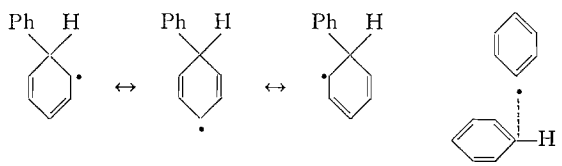
Percentages of isomers in the phenylation and the methylation of anisole

	Ortho	Meta	Para
Phenylation			
At 154°: analysis by gas–liquid chromatography	76.8	10.6	12.6
analysis by ultraviolet spectrophotometry	80	10	10
At 100°: analysis by infrared spectroscopy	67	18	15
Methylation			
At 140°: analysis by gas–liquid chromatography and infrared spectroscopy	74	15	11

Changes in orientation with temperature probably do not account for the differences between our results and Suehiro's, since isomer ratios in free-radical substitutions are not greatly temperature dependent. In our experience, infrared spectroscopy did not prove very suitable for the analysis of the isomer ratio in the phenylation of anisole, since considerable overlapping occurred among the various characteristic bands in the C—H out-of-plane deformation region (see Experimental); we believe that the figures based on gas–liquid chromatography are more reliable. However, the general pattern of the results is similar, and the agreement is reasonable on an absolute basis, although any revision of isomer distributions will have a large effect on partial rate factors.

Comparison of our results for phenylation of anisole with those for methylation reveals little difference in the behavior of the two radicals; in particular, no significant differences in the proportions of ortho isomer are noted, although it has been suggested (6, 29) that there may be slightly less steric hindrance to methylation than to phenylation. Since recent work (Weingarten (44)) indicates that the phenyl radical approaches almost perpendicularly to the plane of the aromatic ring in the substrate, steric effects will normally be insignificant. The appreciably lower meta:para ratio noted for phenylation probably reflects the greater electrophilicity of the phenyl radical.

High ortho:para ratios are typical of free-radical phenylations (for a summary, see Williams (7)), yet still await satisfactory explanation. Although preferred ortho–para orientation is to be expected from resonance theory if a σ-complex (the "Wheland intermediate" I*a*–I*b*–I*c*) is regarded as the transition state (since a σ-complex will be stabilized by conjugation or hyperconjugation by all substituents ortho or para to the site of attack), it is doubtful whether the formation of a σ-complex can be regarded as rate controlling in phenylations.



(Ia) (Ib) (Ic) (II)

The lack of selectivity noted in the phenylation and the methylation of naphthalene (12, 45–47) indicates that in the transition states for these reactions, the aromatic carbon being attacked is still partly conjugated with the rest of the system and the attacking radical is weakly bonded. Since the free-radical phenylations of all aromatic substrates are certainly very fast reactions with very low activation energies, showing low selectivity between the various possible positions of attack, and very little contrast in relative reaction rates (which, although derived using the somewhat suspect "competitive" method, possess empirical significance), a transition state involving a long "π-like" bond between radical and substrate (i.e., (II)) is probably appropriate for all phenylations (Walling (5, pp. 312, 434) has suggested that analogous "π-complexes" may be involved in other reactions involving the interaction of radicals with aromatic molecules). If so, however, the explanation of preferred ortho–para orientation noted above loses much of its force, although the relative stabilities of the various "π-complexes" may parallel those of the Wheland intermediates.

General Comments on the Significance of Partial Rate Factors and Relative Reactivities towards Phenyl-Radical Attack

Recent downward revisions of the scale of relative reactivities of aromatic compounds towards phenyl-radical attack (8), as evaluated by application of the "competitive" method, indicate that calculations of partial rate factors may not be meaningful for these reactions. Partial rate factors which are appreciably less than unity are noted for the meta positions of nitrobenzene (0.86), toluene (0.71), ethylbenzene (0.76), and isopropylbenzene (0.81). Further, if a relative reactivity of ca. 1.6 is assigned to anisole (cf. refs. 3, 6, 8, 14), then the calculated partial rate factor for a meta position is ca. 0.5. It is difficult to suggest a mechanism for *deactivation* of the *meta* positions relative to a benzene position.

Olah and his co-workers, in a study of another reaction (48) presenting a similar problem of low selectivity between different substrates, together with non-statistical isomer distribution (i.e., nitration of alkylbenzenes by nitronium tetrafluoroborate), suggest that partial rate factors are meaningless under such conditions, since the primary competition between substrates involves their molecular π-electron systems as entities, and not the individual positions of these molecules.

Unfortunately, such an interpretation accentuates the difficulty in suggesting a satisfactory explanation of the marked preference for ortho substitution found with phenylations. Waters' naive but remarkably fruitful suggestion that free radicals are essentially electrophilic (49–51) may be relevant, together with Rondestvedt and Blanchard's suggestion (19) that ortho substitution in nitrobenzene and benzonitrile results from preliminary radical complexing at the substituent (the region of highest electron density), followed by ready rearrangement to ortho product.

Further comment on the occurrence of concurrent benzoyloxylation and phenylation of anisole is pertinent. It has been noted previously (12, 19, 52) that application of the competitive method can lead to meaningful results only where side reactions are unimportant. This criterion is not satisfied for anisole, so that previously quoted relative reactivities (14, 19) can have little significance.

ACKNOWLEDGMENTS

Grateful acknowledgment is made to the donors of the Petroleum Research Fund, administered by the American Chemical Society, for support of this research, and also to the National Research Council of Canada, for an equipment grant.

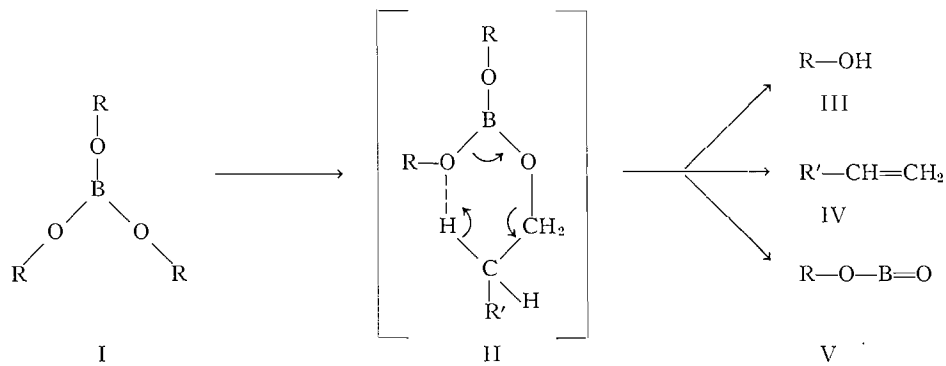
NOTES

DÉCOMPOSITION PYROLYTIQUE DE BORATES D'HEPTYLE

J. M. LALANCETTE

Brandenberg et Galat (1) rapportent que la déshydratation d'alcools peu volatils en présence d'acide orthoborique conduit aux alcènes correspondants avec de bons rendements. Ces auteurs expliquent cette réaction par formation initiale d'un orthoborate qui se décomposerait par la suite pour donner l'hydrocarbure non saturé. Cependant, O'Connor et Nace (2) postulent plutôt l'existence d'un métaborate comme intermédiaire à la formation de l'hydrocarbure. Leur argument s'appuie sur le fait qu'un orthoborate est relativement stable au traitement thermique et se transforme en métaborate en présence d'acide orthoborique. Récemment, Young et Anderson (3) ont pu montrer que l'on pouvait éliminer la possibilité de formation d'un métaborate comme intermédiaire à la déshydratation et apportent des évidences en faveur d'un intermédiaire orthoborique. Le mécanisme que proposent ces derniers auteurs, consiste en une décomposition de l'ester orthoborique en alcène et acide orthoborique suivie d'une déshydratation graduelle de l'acide orthoborique en anhydride borique. Cependant, j'ai constaté que la pyrolyse de l'orthoborate d'heptyle, en phase liquide et sous des conditions expérimentales permettant un dégagement rapide des produits volatils de la masse réactionnelle, a donné un mélange de deux moles d'hydrocarbure et d'une mole d'alcool par mole d'ester orthoborique décomposé. Le pourcentage relativement élevé d'alcool dans le distillat peut être expliqué en postulant un mécanisme d'élimination interne, la forme cyclique intermédiaire II constituant l'étape initiale de la réaction.



L'existence de II est d'ailleurs facilité par le caractère de lien double partiel que présente la liaison B—O (4). Un déplacement électronique concerté, du type postulé par Hurd et Blunck (5) pour expliquer la pyrolyse des acétates, conduit alors à la production d'une mole d'alcool III, d'hydrocarbure IV et de métaborate V. Ce métaborate, instable à la température de la réaction (6), se décompose par la suite pour donner une mole supplémentaire d'hydrocarbure.

Le mécanisme proposé justifie donc la proportion relative d'alcool et d'alcène dans le distillat donné par la pyrolyse. On conçoit cependant que si l'alcool est peu volatil ou si le temps de contact entre l'alcool généré *in situ* et le milieu réactionnel est trop long, une déshydratation subséquente de cet alcool viendra augmenter la proportion d'hydrocarbure jusqu'aux valeurs rapportées par Brandenberg et Galat (1). C'est probablement pour ces raisons que Young et Anderson ne retrouvent que peu d'alcool (0.040 mole par mole de borate) à la pyrolyse de l'orthoborate d'octyle.

Le mécanisme postulé incluant un métaborate, il a semblé indiqué d'effectuer une pyrolyse de cet ester afin d'étudier la composition du mélange d'hydrocarbure ainsi obtenu en regard de la composition trouvée à la pyrolyse de l'orthoborate correspondant. La grande divergence de composition (42% d'alcène monosubstitué pour l'orthoborate et 62% avec le métaborate, sous les mêmes conditions expérimentales) montre bien que la décomposition de l'ester orthoborique ne s'est pas accomplie par simple transformation de l'orthoborate en métaborate, ce qui vient s'ajouter aux arguments de Young et Anderson (3). Cependant, une contribution partielle d'une forme métaborique à l'élimination demeure possible en regard du mécanisme proposé.

PARTIE EXPÉRIMENTALE

1. Préparation de l'orthoborate d'heptyle

L'ester du titre a été préparé à partir d'heptanol "Reagent" et d'acide orthoborique "U.S.P." en quantités stoïchiométriques (distillation azéotropique de l'eau formée avec du benzène) et redistillé sous vide. P.é.: 175° sous 0.5 mm; n_D^{23}: 1.4300. Décrit (7): p.é.: 185° sous 2 mm; n_D^{20}: 1.4280. Spectre infrarouge (CCl_4): pas de bandes dans la région de 3400 cm^{-1}; bandes à 1415 cm^{-1} (forte), à 1330 cm^{-1} (très forte), 1050 cm^{-1} (moyenne), 1030 cm^{-1} (moyenne).

2. Pyrolyse

La pyrolyse de l'orthoborate d'heptyle a été effectuée dans un ballon Claisen d'une capacité de 50 ml muni d'une colonne haute de 10 cm, permettant de maintenir un reflux de l'ester sans en provoquer la distillation. Le système, préalablement purgé par de l'azote sec, a été gardé sous atmosphère inerte, à la pression atmosphérique au cours de la réaction qui dure de trois à quatre heures. La température de la masse réactionnelle demeure à 315–325° tout au cours de la réaction qui est arrêtée lorsqu'on voit apparaître un début de solidification. Le distillat brut est fractionné par distillation, en hydrocarbure et alcool. La nature de l'alcool est établie par ses constantes physiques et son spectre infrarouge. Le mélange d'hydrocarbure est analysé par chromatographie en phase gazeuse (colonne de 4 m, 15% éther benzylique sur Chromosorb No. 154-0262 Perkin–Elmer, élution par hélium, 50 cc/min, température: 100° C) et les pics identifiés par comparaison avec des chromatogrammes d'heptène synthétiques (8) de structure connue. Heptène-1: p.é.: 93° sous 750 mm; n_D^{23}: 1.4002. Décrit (9): p.é.: 94.9° sous 760 mm; n_D^{20}: 1.3999. Heptène-2 (mélange cis et trans): p.é.: 95° sous 750 mm; n_D^{23}: 1.4043. Décrit (9): p.é.: 98.1–98.4° sous 760 mm; n_D^{20}: 1.4041. Le distillat présente un indice de réfraction constant tout au cours de la pyrolyse et renferme des traces d'eau qu'on n'a pu évaluer avec précision. Une expérience de ce type effectuée à partir de 0.0241 mole d'orthoborate donne 0.0195 mole d'alcool et 0.0400 mole d'hydrocarbure. À la chromatographie en phase gazeuse, la fraction hydrocarbure indique 42% de monosubstitution, 25% d'alcène disubstitué cis et 33% d'alcène disubstitué trans. On assume ici que conformément aux mentions de la littérature (10), l'isomère trans sort le premier. Spectre infrarouge de la fraction hydrocarbure (CCl_4): bandes 990 cm^{-1} (faible), 965 cm^{-1} (moyenne), 905 cm^{-1} (moyenne).

3. Préparation du métaborate de n-heptyle

Le métaborate a été préparé à partir d'heptanol "Reagent" (0.240 mole) et d'acide orthoborique "U.S.P." (0.240 mole), l'eau formée étant éliminée par distillation azéotropique avec du toluène. Le toluène est distillé sous pression réduite et l'ester est maintenue à 100° C sous 0.7 mm, pendant 2 heures, sous bonne agitation pour enlever les dernières traces de solvant. Ce mode de purification a été adopté du fait que les métaborates sont rapportés instables à la distillation (6). On obtient ainsi une huile incolore, visqueuse; n_D^{23}: 1.4415. Spectre infrarouge (CCl_4): pas de bandes dans la région de 3400 cm^{-1}; bandes à 1470 cm^{-1} (moyenne), 1410 cm^{-1} (forte), 1335 cm^{-1} (très forte), 1080 cm^{-1} (moyenne). Calculé pour $BO_2C_7H_{15}$: C, 59.20; H, 10.64; B, 7.62. Trouvé: C, 59.22; H, 10.88; B, 7.72.

4. Pyrolyse

La pyrolyse du métaborate est faite suivant la méthode décrite précédemment, sauf que la température de la masse réactionelle demeure à 300° C et que l'opération dure 2 heures. Le distillat (15.9 g à partir de

35.0 g de métaborate) est fractionné en hydrocarbure (n_D^{23}: 1.4015; p.é.: 85–130° sous 750 mm; 10.3 g) et alcool (n_D^{23}: 1.4252; p.é.: 175–185° sous 750 mm; 3.6 g). Analyse chromatographique en phase gazeuse de la fraction hydrocarbure (méthode décrite plus haut): alcène monosubstitué: 62%; alcène interne: 19% cis; 19% trans.

Je désire remercier le Conseil National de Recherches du Canada de l'aide financière qu'il m'a accordée dans la poursuite de ce travail.

THE UNIT CELL, SPACE GROUP, INDEXED X-RAY POWDER PATTERN, AND MAGNETIC SUSCEPTIBILITY OF $VCl_3.2N(CH_3)_3$*

L. D. Calvert and C. M. Pleass†

This note records magnetic susceptibility measurements and X-ray data for the solid complex $VCl_3.2N(CH_3)_3$. The study was undertaken with the hope of showing that the vanadium atom was five-coordinated in solid $VCl_3.2N(CH_3)_3$. A trigonal bipyramidal coordination is not yet established for a solid vanadium complex and there is considerable interest in the structures of vanadium complexes (1). Recent measurements (2, 3) of magnetic susceptibility and molecular weight of $VCl_3.2N(CH_3)_3$ in nitrobenzene and chlorobenzene solutions have shown the vanadium to be five-coordinated. Since solid $VCl_3.2N(CH_3)_3$ sublimes readily at $\approx$100° C a non-ionic, molecular, five-coordinated structure seemed possible. Fivefold coordination in solution has been established for similar compounds such as $TiCl_3.2NMe_3$ (4), $NiBr_3.2PEt_3$ (5), $CoCl_3.2PEt_3$ (6), $VCl_3(OPr_3)_2$, etc. (7) but in no case is the solid structure known.

Magnetic Susceptibility Measurements

The magnetic susceptibility of a powdered sample of $VCl_3.2N(CH_3)_3$ sealed into a thin-walled glass ampoule was measured between 100 and 300° K using the Curie method with Henry pole-pieces (8). No decomposition was detected on an X-ray powder photograph of the sample after the measurements were completed. The results are plotted in Fig. 1. The effective magneton number, assuming no orbital contribution, is $\mu_{eff} = 2.49$ B.M. This is somewhat less than that calculated for two unpaired spins (2.83 B.M.) or that observed for $VCl_3.2N(CH_3)_3$ in chlorobenzene, 2.72 B.M. (2). This value does not establish a trigonal bipyramidal coordination for the vanadium since an ionic arrangement, as in solid PCl_5 (9), or shared octahedra would also have two unpaired spins.

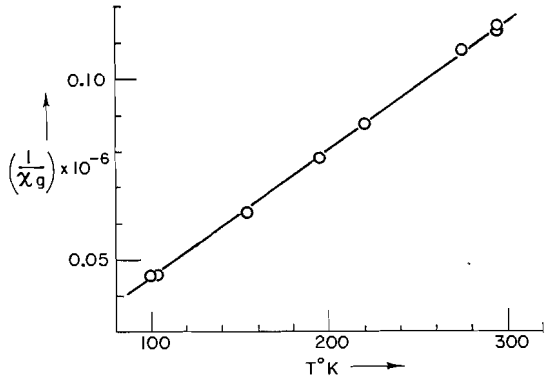

FIG. 1. Reciprocal mass susceptibility values plotted against absolute temperature.

A reversible reproducible color change from a "permanganate pink" to a pale green, without change of crystal form, was observed at about 170° K. Since there is no corresponding change in the χ/T curve the electron distribution must remain substantially unaffected.

Crystallographic Observations

$VCl_3.2N(CH_3)_3$ is strongly deliquescent, so the crystals used were slowly sublimed under reduced pressure into thin-walled glass capillaries which were then sealed off. Rosette-shaped aggregates were the most common form but a few, apparently hexagonal, tablets and one or two pyramidally terminated needles were found. Most crystals proved to be imperfect or multiple on X-ray examination. One selected crystal (0.15×0.15×0.10 mm) proved to be perfect and was used to record the bulk of the X-ray data; a second, less perfect, was used to confirm the data. Optical goniometry of the enclosed crystals was not possible but comparison of the X-ray precession photographs with the hexagonal tablet selected showed that the tablet face was (100) and that {010}, {110}, and {111} were the other forms present. The hexagonal outline is only superficial and arises from the angles $111 \wedge 010 \wedge \bar{1}1\bar{1} \wedge \bar{1}\bar{1}\bar{1}$ being 52°, 52°, and 76°.

The crystals were orthorhombic, *mmmPn—a*, a = 9.838 Å, b = 10.14 Å, c = 13.14 Å (all ±0.3%), vol. = 1311 Å^3, Z = 8, D_c = 2.79 g/cm^3, D_m 2.9 ±0.2 g/cm^3 (pycnometrically in dry varsol), F.W. = 275.55. The possible space groups are $Pnma(D_{2h}^{16})$ and $Pn2_1a(C_{2v}^{9})$ but no choice was made, although *Pnma* was the more probable.

X-Ray powder photographs were obtained from separate samples crushed, loaded, and sealed into thin-walled glass capillaries in an argon-filled dry box. Photographs of coarsely and finely powdered specimens were compared and no evidence of decomposition detected. Although Cu K radiation gave acceptable results, Cr K radiation gave a pattern more suitable for indexing. The powder pattern, indexed to d = 2.30 Å is given in Table I. The pattern, as observed, is given down to d = 1.439 Å; beyond this, the lines present are too weak to be of value in identification. The powder pattern of $TiCl_3.2N(CH_3)_3$ (4), which is almost identical, is given in columns 5 and 10 of Table I. It can also be indexed on a similar orthorhombic unit cell with a = 9.8 Å, b = 10.2 Å, and c = 13.1 Å. (The original data (4) do not allow greater precision in the axes.) $TiCl_3.2N(CH_3)_3$ is thus isomorphous with $VCl_3.2N(CH_3)_3$ and also has the diffraction symbol *mmmPn—a*.

†Data of Antler and Laubengayer (ref. 4).
‡b = broad line.
§Line barely visible, d-value not accurate.
‖Plus other, weak lines at lower d-values.

In the case of $SbCl_5$ (10) the space group and unit cell contents were sufficient to establish trigonal, bipyramidal coordination around the antimony atom. Unfortunately this is not the case for $VCl_3.2N(CH_3)_3$ and a full structural study was not possible in the limited time available. It is hoped that this study will be undertaken later.

The authors wish to acknowledge with gratitude the help of Dr. F. R. Ahmed, who calculated the d-values using an IBM650 program and Miss M. McLellan, who prepared the X-ray powder photographs.

THE MEASUREMENT OF STREAMING POTENTIALS

G. H. E. SIMS AND R. G. GILSON

Many workers who have measured the streaming potentials of powders have used a layer of filter paper supported on a perforated platinum disk at each end of the cell to contain the powder. An exception has been Buchanan (1), who relied solely on perforated disks. This was possible with the materials he used since they were all available in large particle sizes, i.e. up to 500 μ; but with fine powders it is impracticable to drill sufficiently small holes in platinum. During some experiments in which the streaming potentials of phosphor particles of size 10–20 μ were being measured it was found that the pores of the filter paper were becoming clogged with powder as the experiments proceeded and thus the rate of flow of the streaming solution was being seriously reduced. This effect would give low values of E/P, where E is the streaming potential and P is the applied pressure, since the pressure drop in passing through the filter paper would be disproportionately high compared with the pressure drop through the powder. Also, the potential produced at the compacted interface between the powder and the cellulose fibers of the filter paper could produce unwanted results.

This difficulty was appreciated by Edelberg and Hazel (2), who measured the streaming potential of the filter paper used in their experiments. Then by assuming that the filter paper in an ordinary cell accounted for not more than 1% of the total hydrodynamic resistance they were able to calculate that the error introduced by it into the calculation of zeta potentials was well under 1%. It was felt that the arbitrary figure of 1% may not be justified even in the case of fairly large particles, e.g. −60 to +150 mesh, and certainly not in the case of very small particles. Accordingly a cell was constructed to determine the effect of filter paper on streaming potential measurements.

EXPERIMENTAL

The basic cell was that of Lauffer and Gortner (3) and consisted of two B14 ground-glass sockets joined end to end and fitted with two B14 cones. Perforated platinum disks (A and D) were placed over the ends of the cones and were connected by platinum leads to a valve voltmeter. The powder was contained in the cell formed by the two electrodes. Two platinum tubes (B and C) of 0.5-mm bore and 1.5-mm O.D. were sealed into the side of the cell at approximately equal spacing. The outer ends of the tubes were sealed into 1-mm-bore capillary tubing, which in turn was connected to mercury manometers. The bare platinum between the capillary tubing and the wall of the cell was connected to the potential measuring circuit. Thus we now have a cell in which the ratio E/P may be determined for three sections, A–B, B–C, and C–D, as well as the overall ratio A–D.

The material used in the cell was willemite phosphor which had been sintered at 1200° C for 4 hours in air and then ground to give a particle size fraction between 60 and 150 mesh. The material was elutriated several times in distilled water before use to remove 'fines' and was finally dried at 120° C.

The cell was filled by pouring into it a sludge of the material in distilled water, under a slightly reduced pressure and with the ends of the capillaries plugged to prevent loss of the powder through the side arms. The plugs were removed after filling and the capillary tubes were connected to two mercury manometers.

The streaming solution was distilled water and it was found that by increasing the streaming pressure slowly and continually adjusting the height of the mercury in the manometers, it was possible to obtain an air-free liquid/mercury interface in the manometer limbs close to the end of the capillary tubes. There was usually very little loss of material through the platinum tubes while these adjustments were being made. The streaming solution flows up through the cell from A to D.

When the streaming potential between the two perforated electrodes (A–D) had reached a steady value, potentials and pressures between points A–B, B–C, C–D, and A–D were measured. In order to allow for the polarization of the platinum electrodes the pressure was returned to zero and the potentials were measured again.

RESULTS

Several cells were prepared using filter paper (Whatman No. 54) and 200-mesh silk gauze to contain the powder, and several runs were made with each cell. Typical results for the ratio E/P are given in Table I for the two methods of containing the powder.

TABLE I

Ratios of E/P for two different methods of containing the powder

Containing material					
Filter paper (Whatman No. 54)			Silk gauze (200 mesh)		
Expt. No.	Measurement points	E/P (mv/cm Hg)	Expt. No.	Measurement points	E/P (mv/cm Hg)
1	A–B	26.3	3	A–B	63.2
1	B–C	64.0	3	B–C	61.2
1	C–D	11.1	3	C–D	43.8
1	A–D	34.4	3	A–D	56.8
2	A–B	25.3	4	A–B	63.1
2	B–C	61.3	4	B–C	62.4
2	C–D	10.0	4	C–D	43.7
2	A–D	32.8	4	A–D	55.0

It is to be expected that if the filter paper or gauze are contributing to the hydrodynamic resistance to any extent, then the effect will be most apparent at the upper end (C–D), where the powder is being forced against the containing material. It will be less evident at A–D, and at B–C a true value of E/P will be obtained. This is shown to be so by the experimental results.

Perhaps the most notable feature is the extent of the pressure drop at D when filter paper is used. It is also appreciable when 200-mesh gauze is used.

These results indicate that great care must be taken when comparing results by different workers using different methods of containing the material of their plugs. None would appear to give absolute values unless no hydrodynamic constraint is used. The best condition for accuracy would be the use of a filter of the same mesh size as the particles.

Due to difficulties associated with setting up the apparatus (particularly the fragility of the platinum/glass seals) it has not been possible to make extensive measurements of streaming potentials using the apparatus described above, and in further experiments it was decided that the error involved in using 200-mesh silk gauze would be accepted. The good agreement which has been subsequently found in measurements on different cells of the same material has shown that this error is constant.

Two interesting consequences arise from these experiments. The first is that a comparison of electrokinetic potentials derived from streaming or electroosmotic measurements with those obtained from electrophoretic measurements will show a poor correspondence if the potentials of the former are measured in a cell in which there is an extraneous hydrodynamic constraint. Bull (4) has found that the zeta potentials of quartz and cellulose derived from a streaming method were much lower than those derived from electrophoretic measurements.

The second consequence is that it is difficult to measure true zeta potentials of particles in the size range between say 5 μ and 50 μ. Below 5 μ an electrophoretic method can be used but for larger particles the effect of gravity becomes increasingly troublesome.

Above 50 μ it is possible to use an electroosmotic or streaming method by containing the particles in a cell by means of a fine-mesh gauze, as has been done in these experiments. The results, however, will become increasingly affected by the containing material as the particle size of the powder decreases, so that in the intermediate range 5–50 μ there is no easy method of electrokinetic measurement which will provide a true zeta potential.

ACKNOWLEDGMENT

THE CONSTITUTION OF A SYNTHETIC XYLAN

I. GENERAL STRUCTURAL FEATURES

G. G. S. DUTTON AND A. M. UNRAU[1]

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received March 19, 1962

ABSTRACT

The polysaccharide was obtained by polymerization of D-xylose at 140° C in the presence of phosphorous acid. Complete hydrolysis of the xylan followed by bromine oxidation showed that the synthetic polymer contained only xylose. Periodate oxidation resulted in formation of a considerable quantity of formaldehyde, the origin of which is not known. Periodate oxidation of borohydride-reduced xylan gave additional formaldehyde and, from this, the average D.P. of the polymer was estimated to be about 55. Complete hydrolysis of the polyalcohol gave ethylene glycol, glycerol, and xylose in a ratio of 2:9:1. Partial hydrolysis gave ethylene glycol, glycerol, and at least seven non-reducing components. Hydrolysis of the fully methylated xylan gave tri-, di-, mono-methyl xyloses and xylose in a 32:32:18:5 ratio, and a carbonyl band was evident in the infrared spectrum of the hydrolyzate. No such band was evident in the hydrolyzate of the unsubstituted xylan. The xylan is highly branched and contains some D-xylofuranose units.

In contrast to the relatively ordered structures of naturally occurring enzymatically synthesized polysaccharides, it has usually been found that synthetic polysaccharides have highly random and branched structures (1–5). Recent investigations (6) on a synthetic glucan (7) have shown that almost all possible linkages were present and that glucofuranose residues occurred in the polymer. In contrast to the apparently simpler structure of a synthetic xylan investigated by Bishop (8), the results reported in this paper from experiments on a synthetic xylan prepared by Mora and associates (9) indicate that its structure is complex.

Complete hydrolysis of the xylan gave only D-xylose, which was obtained in crystalline form. Bromine oxidation of the hydrolyzate followed by adsorption of the xylonic acid on anion exchange resin left no residue that reacted with *p*-anisidine trichloroacetate or ammoniacal silver nitrate spray reagents, thus indicating the absence of any polyols. The facile partial hydrolysis of the xylan suggested the presence of some xylofuranose units (Table I). The oligosaccharides surviving the mild acid hydrolysis were presumed to consist primarily of xylopyranose units. The specific rotation of the xylan, $[\alpha]_D^{22}$ 45°, suggested that both alpha and beta glycosidic linkages were probably present, but if some of the D-xylose residues were present as open-chain acetals this point is less certain.

The rapid production of formaldehyde (1.52 mg per xylose unit after 20 minutes and 2.35 mg after 210 minutes, with no significant change thereafter) upon periodate oxidation of the xylan under controlled conditions (pH 4.0–4.5, 5° C) indicated the oxidation of some primary hydroxyl groups. A structural feature to accommodate this observation cannot

48	53.0	12.5	3.3	5.9	78

be suggested with certainty at this point. Under the conditions of the oxidation, it does not seem probable that any appreciable overoxidation would have occurred. A possible explanation may be that there are present some open-chain xylose residues in which the C_4 and C_5 hydroxyls are not substituted. Periodate oxidation would result in the formation of formaldehyde from C_5 and the acetal system would be readily hydrolyzed by dilute acid. Periodate oxidation of the reduced ($NaBH_4$) xylan resulted in the liberation of additional formaldehyde, and by application of a reported procedure (10), the average degree of polymerization was estimated to be a minimum of 55. The assumption is made that the reducing end-group is not substituted at C_2 and hence gives 1 mole of formaldehyde on reduction and treatment with periodate.

The periodate uptake (0.91 mole per sugar residue, constant after 18 hours) indicated the presence of periodate-resistant xylose units in the xylan. Reduction ($NaBH_4$) of the xylan polyaldehyde followed by complete hydrolysis of the polyalcohol gave ethylene glycol (from non-reducing xylopyranose end-units and $1 \rightarrow 2$ linked pyranose units), glycerol (from internal xylopyranose and xylofuranose units, also from external xylofuranose units), and xylose in an approximate ratio of 2:9:1. About 7–8% xylose was not degraded. Since non-reducing xylofuranose end-units are present, the quantity of ethylene glycol formed in the periodate degradation compared to the estimated D.P. of the xylan cannot be used to calculate the approximate number of branch points in the molecule.

The controlled hydrolysis (11) of the polyalcohol gave ethylene glycol, glycerol, xylose, and at least seven oligosaccharide fragments with varying R_{xylose} values in several solvent systems. Free xylose is believed to have originated from relatively labile furanoside linkages. The oligosaccharides were composed of xylose and glycerol in varying ratios and further details concerning these will be reported later.

Methylation of the xylan was accomplished by employing successively the Haworth, Kuhn, and Purdie procedures. Only after extended and vigorous treatment with Purdie's reagents was the xylan fully methylated; methoxyl content 39.2%, no hydroxyl band in the infrared spectrum. The methylated xylan, $[\alpha]_D^{22}$ 42° (*c*, 8.2 in $CHCl_3$), was soluble in petroleum ether containing 4.5–5% chloroform. Hydrolysis of the methylated xylan gave tri-, di-, and mono-methyl xyloses and free xylose in a molar ratio of 32:32:18:5, respectively. The identity of the methylated sugars will be reported in a separate communication but it may be noted that the rotation, $[\alpha]_D^{22}$ 22.3° in water, of the trimethyl fraction indicated the presence of 37.5% 2,3,5-tri-*O*-methyl-D-xylofuranose; hence non-reducing xylofuranose end-units were present in the xylan. Since the methylated xylan was hydrolyzed with sulphuric acid under conditions known to minimize demethylation (12), the presence of xylose in the hydrolyzate indicates the occurrence of fully substituted residues in the xylan.

The infrared spectrum of the hydrolyzate of the methylated xylan showed absorption bands at 3400, 2930, 2825, 1725, 1650, 1460 cm^{-1}. The definite absorption at 1725 cm^{-1} suggested that aldehydic carbonyl groups might be present. It seemed unlikely that this absorption was due to furfural degradation products, since when a sample of the original xylan was hydrolyzed under similar conditions the band at 1725 cm^{-1} was absent. Xylose residues methylated at C_4 and C_5 would exist in the aldehyde form and could conceivably be responsible for absorption in the carbonyl region. As suggested previously, xylose residues occurring in the xylan in the open-chain form and not substituted at C_4 and C_5 would explain the rapid formation of formaldehyde upon periodate oxidation. The above spectroscopic observation lends support to this proposal.

EXPERIMENTAL

Chromatographic separations were carried out using the descending technique and Whatman No. 1 and 3MM paper. Solvent systems employed were A, ethyl acetate:acetic acid:water (8:2:2); B, ethyl acetate:pyridine:water (9:2:2); and C, butanone:water azeotrope. Spray reagents were D, *p*-anisidine trichloroacetate and E, ammoniacal silver nitrate solutions. Unless otherwise stated, evaporations were carried out under reduced pressure at a bath temperature of 40° C. Melting points are uncorrected and specific rotations were taken at 22±2° C.

Hydrolysis of Xylan

A quantity (750 mg) of xylan, $[\alpha]_D$ 45° (*c*, 2.0 in water), was dissolved in 0.2 *N* sulphuric acid (30 ml), and the solution boiled for 10 hours. The solution was neutralized ($BaCO_3$), deionized, and evaporated to a thick sirup which crystallized upon standing. After recrystallization from ethanol, D-xylose had m.p. and mixed m.p. 143–145°, $[\alpha]_D$ 18° (*c*, 1.8 in water).

Bromine Oxidation of Xylan Hydrolyzate

A portion (about 500 mg) of the hydrolyzate was oxidized with bromine in the usual manner until an aliquot of the solution no longer reduced Fehlings solution. After removal of excess bromine from the solution by aeration, the solution was passed through anion exchange resin. Evaporation of the neutral effluent left no residue which would react with either spray reagent D or E.

Partial Hydrolysis of Xylan

An aliquot (80 mg) of the polymer in 0.1 *N* hydrochloric acid (3 ml) was left at room temperature. The appearance of hydrolysis products was followed by paper chromatographic analysis in solvent A using the phenol – sulphuric acid method (13) to determine xylose and xylose oligosaccharides. The course of the hydrolysis was also followed polarimetrically. The change in the optical rotation and the extent of hydrolysis are summarized in Table I.

Periodate Oxidation, Reduction ($NaBH_4$), Complete Hydrolysis

Xylan (176 mg, 1.325 mmoles) was dissolved in water (20 ml) and the solution acidified with 6 *N* acetic acid (2 ml). After the solution was cooled, 0.5 *M* sodium periodate (5 ml) was added and the oxidation allowed to proceed at 5° C. Formaldehyde was determined (10) after $\frac{1}{3}$, $3\frac{1}{2}$, 12, 48, and 72 hours. After $\frac{1}{3}$ hour, 1.52 mg formaldehyde was produced per xylose unit and 2.43 mg after $3\frac{1}{2}$ hours, with no significant increase thereafter. After 72 hours, periodate consumption was determined and the xylan had consumed 0.905 mole of periodate per xylose unit. To the solution was added barium chloride and barium carbonate, and after filtration, sodium borohydride (200 mg) was added. The reduction was allowed to proceed overnight at room temperature, after which time the solution was acidified with hydrochloric acid and evaporated to dryness. Borate was removed by several evaporations with methanol and the residue hydrolyzed with sulphuric acid. The solution was deionized, concentrated, and the sirupy product chromatographed. Compounds corresponding to glycerol, ethylene glycol, and xylose were detected. The ratio of these was determined chromatographically using the periodate – chromotropic acid procedure (10) for the alcohols and the phenol – sulphuric acid method (13) for the determination of xylose. The ratio of ethylene glycol:glycerol:xylose thus found was about 2:9:1. A further quantity (650 mg) of xylan was treated as described above and the combined hydrolyzates resolved by paper chromatography (Whatman 3MM paper) using solvent A. The three compounds were located by spraying guide strips, and subsequently eluted. *Ethylene glycol*, 47 mg, was reacted with *p*-nitrobenzoyl chloride in pyridine solution to give the corresponding di-*p*-nitrobenzoate, m.p. and mixed m.p. 139–141° C. *Glycerol*, 435 mg, was similarly converted to the corresponding tri-*p*-nitrobenzoate, m.p. and mixed m.p. 188–190° C. D-*Xylose*, 70 mg, crystallized spontaneously and after recrystallization from ethanol had m.p. and mixed m.p. 143–144° C, $[\alpha]_D$ 17.7° (*c*, 1.4 in water).

Periodate Oxidation of Reduced ($NaBH_4$) Xylan and Determination of D.P. (10)

Xylan (230 mg) was dissolved in water (20 ml) and to the solution was added sodium borohydride (100 mg). The reduction was allowed to proceed at room temperature for 24 hours. The solution was acidified with acetic acid (2 ml), cooled to 5° C, and 0.5 *M* sodium periodate (5 ml) was added. Formaldehyde was determined (10) after $\frac{1}{3}$, $3\frac{1}{2}$, 12, 48, and 72 hours. After $3\frac{1}{2}$ hours, 4.20 mg formaldehyde had been formed per xylose unit, with no significant change thereafter. On the assumption that the extra formaldehyde formed in the periodate oxidation of the reduced xylan arose from the xylitol end-groups and that each such group produced 1 molecular proportion of formaldehyde, the approximate D.P. of the xylan was 55. The periodate consumption was determined after 72 hours and 0.92 mole of periodate had been consumed per pentose unit. The oxidation mixture was subsequently treated in the same manner as described in the previous section. Chromatography of the final product showed the presence of ethylene glycol, glycerol, and xylose. The ratio of these was determined and found to be about 2:10:1.

Partial Hydrolysis of Polyalcohol (11)

A quantity (100 mg) of xylan was dissolved in water (20 ml), cooled to 5° C, and 0.5 *M* periodic acid (5 ml) was added. After 72 hours, when 0.91 mole of periodate had been consumed per xylose unit, the solution was neutralized ($BaCO_3$), filtered, and sodium borohydride (75 mg) was added. The solution stood at room temperature overnight and was evaporated to dryness. Borate was removed by treatment with methanol containing 1% hydrogen chloride (14) and the residue was finally dissolved in 0.1 *N* sulphuric acid (30 ml) and left for 8 hours. The solution was neutralized ($PbCO_3$) and evaporated. Chromatographic examination of the sirupy residue indicated the presence of ethylene glycol, glycerol, xylose, and at least seven non-reducing components with a considerable range of R_{xylose} values. Further details of these periodate degradations will be reported separately.

Methylation of the Xylan

A quantity (4.0 g) of xylan was treated in the usual way with the Haworth methylating reagents, followed by two successive methylations using methyl iodide, silver oxide, and dimethylformamide (15). The product (4.59 g), a brittle, yellow glass, showed an OH band in the infrared spectrum and was therefore methylated three times with Purdie's reagents over extended periods (3–4 days). The final product (4.35 g) was dissolved in petroleum ether (30–60°) containing 5% chloroform, and a small quantity of insoluble material was removed by filtration. Evaporation of the solvent left a yellow, resinous solid which showed no OH character in its infrared spectrum and contained 39.2% methoxyl. Hydrolysis of a portion (80 mg) was effected using sulphuric acid (12). After neutralization ($BaCO_3$) and deionization, the solution was evaporated. Chromatographic examination using solvent C indicated the presence of tri-, di-, and mono-methyl xyloses and a small amount of free xylose. The ratio of the above-mentioned xylose methyl ethers was estimated chromatographically using the phenol – sulphuric acid reagent (13). The approximate molar ratio of tri-, di-, mono-methyl xyloses and xylose thus found was 32:32:18:5. The components of the hydrolyzate were subsequently separated by passage through a cellulose–hydrocellulose column using solvent C as the irrigant. The trimethyl fraction had a specific rotation of 22.3° in water, indicating that it was composed of 2,3,4- and 2,3,5-tri-*O*-methyl-D-xyloses in the ratio of 62.5:37.5. The identification of the other components will be reported later.

ACKNOWLEDGMENTS

This investigation was supported by a research grant (RE 7652) from the Division of General Medical Science, U.S. Public Health Service, to whom we express our thanks. We are also indebted to Miss J. Hunter for skillful technical assistance.

RELATIVE SIGNS OF GEMINAL AND VICINAL PROTON–PROTON COUPLING CONSTANTS IN α,β-DIPHENYLPROPIONIC ACID AND ITS METHYL ESTER

ROBERT R. FRASER
Department of Chemistry, University of Ottawa, Ottawa, Ontario
Received March 13, 1962

ABSTRACT

It has been shown that the geminal and vicinal coupling constants are of opposite sign in α,β-diphenylpropionic acid and its methyl ester. The significance of the results is discussed.

We recently reported the findings that from analysis of the n.m.r. spectra of a series of dioxolane derivatives (see Fig. 1) the sign of the geminal coupling constant J_{BC} was

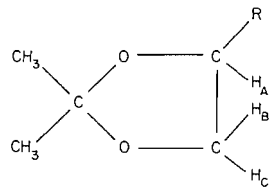

FIG. 1. The structures of the dioxolane derivatives from which the signs of the coupling constants between protons A, B, and C were determined.

opposite to that of the vicinal coupling constants J_{AB} and J_{AC} (1). Since the theoretical calculations of vicinal coupling constants by Karplus (2) and of geminal coupling constants by Karplus, Gutowsky, and Grant (3, 4) predicted the geminal and vicinal coupling constants to have the same sign as long as the bond angle between the geminal hydrogens is less than 125°, our results were surprising. Previously, in styrene oxide (3, 5), β-*p*-nitrophenyl-β-propiolactone (3), and several monosubstituted ethylene oxides (5, 6) the relative signs had been in accord with theory. Now, further examples of compounds in which the geminal and vicinal coupling constants have opposite signs have been reported, namely diethyl sulphite (7), epichlorohydrin (8), and hexadeuteriocyclohexanol (17), and prompts us to report our analysis of the spectra of α,β-diphenylpropionic acid and methyl α,β-diphenylpropionate.

In order to determine with any degree of certainty the relative signs of coupling constants between protons in a three-spin system from a complete analysis of the spectrum it is necessary that each of the three protons be slightly shifted in resonance position from one another. This is by definition an ABC system. Then the correctness of the parameters obtained by analysis is judged from a comparison of the theoretical and experimentally measured intensities. Final proof of the results is provided by comparing the spectrum measured at a lower frequency with that predicted from analysis of the original spectrum. It should be mentioned that a second, very useful method of determination of relative sign exists. This is the method of spin-decoupling, which has been described in detail by Freeman (9). We wished to examine the relative signs of coupling constants in open-chain aliphatic compounds and so examined a number of ethane derivatives of the general

structure XCH_2CHXY, where X and Y are substituents possessing appreciable magnetic anisotropy. Styrene dibromide, styrene glycol dibenzoate, α-bromobibenzyl, and α,β-diphenylpropionitrile produced spectra in which the aliphatic protons appeared as an ABX or AX_2 pattern and so were not studied in detail. On the other hand both α,β-diphenylpropionic acid and its methyl ester gave good ABC spectra.

A detailed description of a rigorous method of analysis of this type of spectrum has been given by Waugh and Castellano (10, 11). We have followed this method in our analysis, using an IBM 650 to perform the calculations. Any terms used subsequently, such as *arrangements*, *groupings*, *sets* of eigenvalues, will appear in italics and have the exact meaning defined by Waugh and Castellano (10). The spectrum of α,β-diphenylpropionic acid measured at 60 Mc/sec is shown in Fig. 2. Eleven transitions in all are

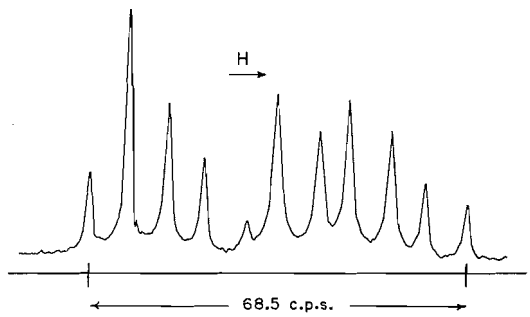

FIG. 2. Spectrum of a 25% solution (w/v) of α,β-diphenylpropionic acid in carbon tetrachloride at 60.0 Mc/sec.

visible and are assigned from the repeated spacings as being, in the first-order approximation, a triplet at low field (proton A) adjacent to two quartets (protons B and C), each at successively higher field. Since there are no visible combination bands,* there is no ambiguity in the assignment of this *grouping*. From the four possible *arrangements* four *sets* of eigenvalues are obtained. And from each *set* of eigenvalues two sets of chemical shifts, $\Delta\nu$'s, and coupling constants, J's, are calculated. In all, six sets of $\Delta\nu$'s and J's were obtained, two sets being discarded by failure to satisfy the condition of real roots. The theoretical intensities of all 15 transitions were then calculated for each of the six sets. From the obvious discrepancy between calculated and observed intensities three of the sets were immediately eliminated. The remaining three sets gave calculated intensities in fair agreement with the observed intensities, as is shown in Table I. To determine which set of parameters was correct the spectrum of the acid was also measured at 24.288 Mc/sec. This spectrum is compared in Fig. 3 with the spectra predicted from each of the three sets of chemical shifts and coupling constants given in Table I. Only for set I does the predicted spectrum agree with the observed spectrum to within 0.2 cycle/sec. It should be pointed out that although the chemical shifts and coupling constants are given to two decimal places they are estimated to be accurate only to ±0.08 cycle/sec.

The spectrum of methyl α,β-diphenylpropionate measured at 60 Mc/sec is shown in Fig. 4. Utilization of the same method of analysis provided three sets of chemical shifts and coupling constants compatible in theoretical intensities with the observed intensities. The comparison is shown in Table II. The spectrum of the ester was then measured at

A combination band arises from a transition which is forbidden in the first-order limit. It becomes increasingly intense when the chemical shifts between the nuclei become smaller.

line positions to within 0.4 cycle/sec for set I. Errors greater than 1 cycle/sec are found in the spectra predicted by the other sets. Thus in both compounds J_{BC} is opposite in sign to J_{AB} and J_{AC}.

Unambiguous assignment of the proton alpha to the carboxyl was made by measuring the spectra of the α-deuterated acid and ester. Exchange of the proton for deuterium was performed by heating the methyl ester with sodium in O-deuterated methanol. The spectrum of the aliphatic protons of the α-deuteroester was a pair of doublets of spacing 13.6 cycles/sec. Although the lower-field doublet was partially obscured by absorption of the ester methyl group, the spectrum was clearly devoid of absorption in the low-field region of the A proton. Hydrolysis of the deuterated ester in heavy water gave the α-deuterated acid, whose spectrum showed a pair of doublets of spacing 13.8 cycles/sec and no absorption in the region of the A proton. It is therefore concluded that in both compounds the proton attached to the alpha carbon atom appears at lowest field. The

magnitude of the spacing of the doublets agrees with the coupling constant obtained by the ABC analysis for each compound and serves to confirm its correctness.

To determine which of the remaining two protons represent signal B, deuterium gas was added to an aqueous solution of the sodium salt of *trans*-α-phenylcinnamic acid using 10% palladium on carbon as catalyst. The spectrum of the product showed only a single broadened peak whose chemical shift corresponded to that of proton C. If we assume that the deuterium added cis, the three protons can be assigned the positions shown in Fig. 6.

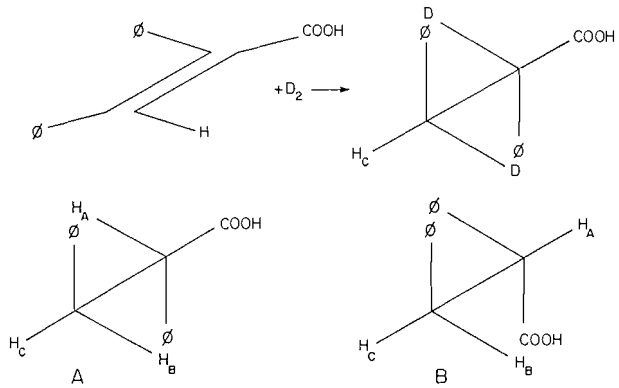

FIG. 6. Perspective formulae of the dideutero acid and the two most probable conformations of α,β-diphenylpropionic acid. The protons are labelled according to the conclusions of the deuteration experiments.

The two most probable conformations for the acid are shown. Since a phenyl group is larger than carboxyl,* conformation A would be more populated, as is indicated by J_{AB} being larger (7.96) than J_{AC} (7.29). This follows from the relation of the magnitude of J to the dihedral angle θ defined by two hydrogens on adjacent carbon atoms (2). When the two hydrogens are trans to each other ($\theta = 180°$) the coupling constant is three times as large as when the two hydrogens are gauche ($\theta = 60°$). Since carbomethoxyl is smaller than carboxyl, even less of conformation B should be present in the methyl ester. The larger difference between J_{AB} (8.85) and J_{AC} (6.50) in the methyl ester is attributed to this increase in the proportion of conformation A. Since proton A is in the alpha position, J_{BC} represents the geminal coupling constant. Thus in both α,β-diphenylpropionic acid and its methyl ester the geminal coupling constant is opposite in sign to the vicinal coupling constants.

It is now apparent that this opposition of sign is not simply peculiar to dioxolane derivatives. The question arises as to whether it is the theoretical calculations of the vicinal or of the geminal coupling constants which are at variance with the experimental evidence.

It would be most satisfying if all the experimental results could be accommodated by the present theory in a necessarily modified form. An indication of the point at which modification is required is most strikingly illustrated by Reilly's analysis of epichlorohydrin (8). For this compound the coupling constants were reported as shown in Fig. 7. Between protons 1, 2, and 3 all coupling constants are positive, as has been found in other epoxides. For protons 3, 4, and 5 the geminal and vicinal coupling constants are of opposite sign, as is the case in our substituted ethanes and diethyl sulphite. And further, it can be seen that this difference in relative sign is due to a change in sign of the *vicinal*,

**The A value, the difference in Gibbs free energy between axial and equatorial position of the substituent on a cyclohexane ring, has been found to be 2.6 for phenyl (12), 1.7 for carboxyl (13), and 1.1 for carbethoxyl (14). Presumably the carbomethoxyl group would have an A value slightly less than 1.1.*

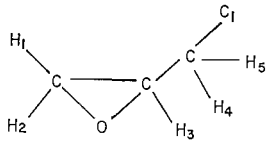

FIG. 7. Results of Reilly's analysis of epichlorohydrin.

$J_{1,2} = 5.0$	$J_{3,4} = -6.6$	$J_{1,4} = -0.2$
$J_{1,3} = 2.4$	$J_{3,5} = -4.0$	$J_{2,4} = 0.6$
$J_{2,3} = 4.0$	$J_{4,5} = 11.7$	$J_{2,5} = -0.1$
		$J_{1,5} = -0.1$

not the geminal, coupling constants $J_{1,2}$ and $J_{4,5}$, which both have the same sign. It must be realized that the possibility of other solutions of the spectrum of epichlorohydrin quite different in relative signs could exist, for this compound requires an exceedingly complex analysis. More results must be obtained before too much reliance can be placed on the above analysis.

EXPERIMENTAL

All 60.0 Mc/sec spectra were measured on a Varian V-4302 high-resolution n.m.r. spectrometer. The line positions in each spectrum were determined by the side-band technique and are reported as the average of 10 spectra. Intensities were obtained from peak heights and are also reported as the average of 10 spectra. They are generally considered to be accurate to within 10% of the reported value. The 24.288 Mc/sec spectra were recorded on a Varian V-4300B high-resolution n.m.r. spectrometer. The line positions reported are the average of four spectra.

α,β-Diphenylpropionic Acid

Condensation of benzyl chloride with phenylacetonitrile gave α,β-diphenylpropionitrile, m.p. 56–57.5° (lit. m.p. 58° (15)). Acid hydrolysis of the nitrile gave α,β-diphenylpropionic acid, which after two recrystallizations from heptane was seen to be a mixture of crystalline forms, m.p. 79–84° C (lit. m.p., plates 95–96°, prisms 88–89°, fused solid 82° (15)).

Methyl α,β-Diphenylpropionate

The above acid was converted to methyl α,β-diphenylpropionate, m.p. 31.5–32.5° (lit. m.p. 34° (15)), by treatment with diazomethane.

trans-α-Phenylcinnamic Acid

This acid was prepared by the procedure of Buckles and Hausman (16) in 45% yield. The product was a white solid, m.p. 169–170.5° (lit. m.p. 172° (16)).

ACKNOWLEDGMENTS

The author is grateful to the National Research Council of Canada for financial assistance. The technical assistance of Mrs. N. Stojanac is also appreciated.

COMPLEX TELLURATES OF COBALT AND MANGANESE

M. W. LISTER AND Y. YOSHINO[1]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received February 19, 1962

ABSTRACT

Complex tellurates of manganese and cobalt have been prepared by oxidizing mixtures of manganous or cobaltous sulphate with potassium (or sodium) tellurate by means of an alkaline hypochlorite solution. Cobalt gives $K_3H_6Co(TeO_6)_2.2H_2O$ as a dark green powder. The formula was confirmed by its oxidation equivalent with ferrous sulphate, by its displacement of chloride ions from an anion exchange resin, and by its magnetic susceptibility (-154×10^{-6} e.m.u./g-mol). The behavior of the compound on acidification is reported. Manganese gives $K_6H_8Mn(TeO_6)_3.5H_2O$ and $Na_7H_7Mn(TeO_6)_3.5H_2O$ as dark red crystals. The formula was confirmed as for the cobalt complex: its magnetic moment is 3.30 Bohr magnetons, which is reasonable for Mn(IV). The acid–base properties of the compound were examined. The ion is not very stable in solution, as shown by changes in its absorption spectrum; measurements of this gave evidence for the nature of the decomposition, and the equilibrium constant for this reaction. The main reaction is

$$H_7Mn(TeO_6)_3^{-7} + H_2O \rightleftharpoons H_4Mn(TeO_6)_2^{-4} + H_4TeO_6^{-2} + OH^-,$$

for which $K = 4\times10^{-5}$ (g-mol/l.)^2 at 25° C.

In recent papers (1), the present writers described the preparation and properties of complex periodates of cobalt and manganese. It seemed reasonable to expect that the same elements would give complex tellurates, especially in view of the behavior of trivalent copper, which has rather similar complex tellurates and periodates (2, 3). Issa, Khalafalla, and Issa (4) have deduced, from observations on the reduction of permanganate ions in the presence of sodium tellurate, that complex ions of manganese(IV) and tellurate must be formed, but they did not suggest any definite formula. The present paper reports the preparation of complex tellurates of cobalt and manganese, and gives an account of some of their properties. As will be seen, there is (as with copper) a general similarity between the complex periodates and tellurates, at least so far as the number of ligands attached to the metal is concerned; but the hydration of the salts, and the number of alkali metal ions present, are not the same. There can be no doubt that these are compounds of manganese(IV) and cobalt(III), as are the periodates.

Since it is perhaps rather more convenient to have all the information on the compounds of each central metal atom together, the cobalt compounds will be described first, followed by the manganese compounds.

Potassium Tellurato-cobaltate(III)

1. Preparation

Various rather similar methods were tried, but the most satisfactory proved to be as follows. A solution was prepared containing 2.0 g of cobalt chloride hexahydrate, 4.8 g of telluric acid, 1–2 ml of 6 *M* nitric acid, and 40 ml of water. A second solution contained 5 g of potassium hydroxide dissolved in 40 ml of 1.5 *M* potassium hypochlorite. These solutions were rapidly mixed, and allowed to stand while a dark green precipitate formed. Eighty milliliters of ethyl alcohol was added, and the solution allowed to stand. The supernatant liquid was poured off, and the precipitate was washed with 50% alcohol. The precipitate was then redissolved in 50 ml of 0.1 *M* potassium hydroxide, and an equal

[1]*Present address: College of General Education, University of Tokyo, Tokyo, Japan.*

volume of alcohol was added to the mixture. The new precipitate was then centrifuged off. This reprecipitation was repeated two or three times, and the final product was filtered off and dried over calcium chloride.

The yield was 3.7 g in a typical preparation. The compound is a dark green, microcrystalline powder. The precipitate was liable to be sticky; use of acetone instead of alcohol, or treatment of the solution with active charcoal, gave no improvement. It was necessary to add the alcohol very slowly, with stirring.

A similar preparation using sodium instead of potassium gave a somewhat similar precipitate, but analysis gave rather variable compositions and it appeared to contain sodium tellurate as an impurity.

Analysis of the potassium salt was carried out by dissolving a sample in concentrated hydrochloric acid, and adding first sulphur dioxide solution (to help it to dissolve) and then a solution of hydrazine chloride. The hydrochloric acid was now about 3 *M*. After 5 minutes' boiling, the precipitated tellurium was filtered off and weighed. The solution was evaporated to dryness, the hydrazine salts were destroyed by nitric acid, and after re-evaporation the residue was dissolved in very dilute hydrochloric acid. The metals were absorbed in a column of Dowex 50W-X8 in its hydrogen form; then the sodium was eluted by 0.4 *M* hydrochloric acid, and cobalt by 2 *M* hydrochloric acid. The potassium was weighed as K_2SO_4, and the cobalt was converted to $CoSO_4$. The cobalt content was also checked by EDTA titration. The water content of the compound was found from the loss in weight at 130° C.

The results of the analyses were: K 18.5, Co 8.94, Te 37.2, H_2O 5.97%; calculated for $K_3H_6Co(TeO_6)_2.2H_2O$: K 17.6, Co 8.86, Te 38.35, H_2O 5.42%. This formula assumes the presence of Co(III), which will be substantiated by other evidence below.

A check on this formula was obtained by dissolving a known weight of the compound, passing it through an anion exchange resin (Dowex 1-X4) in its chloride form, and titrating the potassium chloride liberated with silver nitrate. It was found that 1 g-mol of potassium chloride was liberated by 214 g of the compound; the calculated value is 221.8 g if the reaction is (R represents the resin)

$$K_3H_6Co(TeO_6)_2 + 3RCl \rightarrow R_3H_6Co(TeO_6)_2 + 3KCl.$$

2. Properties

Since telluric acid is not nearly as strong an oxidizing agent as periodic acid, it is not possible to check the formula of the complex tellurates by measuring the equivalent weight with a variety of reducing agents, as it is with complex periodates. However, an equivalent weight could be found by adding a known amount of ferrous ammonium sulphate in excess to a weighed sample of potassium tellurato-cobaltate, and the excess was titrated with decinormal potassium permanganate. The equivalent weight so found was 663; if $K_3H_6Co(TeO_6)_2.2H_2O$ is reduced by one oxidation step (i.e. Co(III) to Co(II)), the calculated equivalent weight is 665.4.

The most convincing evidence for the valency of the cobalt comes from the magnetic susceptibility of the compound. Measurements with a Goüy magnetic balance of the usual type gave a value for the susceptibility of -154×10^{-6} e.m.u./g-mol, at room temperature. Since the compound is diamagnetic, the cobalt is presumably trivalent. The susceptibility is a little lower than would be expected for this compound using, for instance, Angus' estimates (5) of the magnetic susceptibility of the atoms it contains: this gives a calculated value of -258×10^{-6} e.m.u./g-mol; but this is certainly not enough difference to cast any doubt on the trivalency of the cobalt.

3. Acid–Base Properties

A solution containing 2 g of potassium tellurato-cobaltate, on acidification with 5 ml of 3 *M* sulphuric acid, gave a dark green precipitate. The supernatant solution was pale pink, so some decomposition to Co(II) had occurred. The precipitate was washed, dried, and analyzed. It evidently contained a different Te/Co ratio, and in fact was approximately $KH_5Co_4(TeO_6)_3.10H_2O$. Addition of a weighed amount to a standardized ferrous ammonium sulphate solution and titration of the excess ferrous ion showed that the cobalt was still entirely trivalent. This substance has a sufficiently surprising formula that one might be inclined to dismiss it as a mixture. However, Malaprade (6, 7) has reported complex cobalt periodates with the same ratio of cobalt to ligand (e.g. $Na_3Co_4(IO_6)_3.10H_2O$).

If a solution of potassium tellurato-cobaltate was titrated with dilute perchloric acid (0.117 *N*) and the pH followed, the compound gave a normal pH curve. The pH curve makes pK_1 (the first stage of ionization) about 3.5, followed by considerably higher values of p*K* for the next two stages: roughly pK_2 is 7 and pK_3 is 9. This means that ionization to $Co(H_4TeO_6)_2^-$ is fairly easy, followed by two ionization steps to give $Co(H_3TeO_6)_2^{-3}$.

4. Absorption Spectrum

Like other complex tellurates or periodates, potassium tellurato-cobaltate gives an absorption spectrum with high absorption in the violet, falling to a minimum, followed by a single maximum as the wavelength is increased. The extinction coefficients at different wavelengths are: λ (mμ) 500, ϵ 139.1; 520, 95.6; 540, 74.7; 560 (min.), 68.0; 580, 71.0; 600, 75.4; 620, 80.0; 635 (max.), 81.6; 640, 81.1; 660, 75.9; 680, 63.7; 700, 49.9; 720, 34.5; 740, 23.7; 760, 14.7; 780, 9.9; 800, 6.9. These results were obtained from a 0.00435 *M* solution of the compound in 0.1 *M* potassium hydroxide. It was found that the addition of potassium tellurate caused no detectable change in the absorption curve, indicating that there is virtually no dissociation of the complex in a solution of this concentration.

Sodium and Potassium Tellurato-manganate(IV)

1. Preparation

After various preliminary trials, the most satisfactory methods devised were as follows. For the potassium salt, two solutions were made, one containing 2.0 g of manganous chloride tetrahydrate, 8.2 g of telluric acid, and a little nitric acid in 40 ml of water; the second contained 12 g of potassium hydroxide in 50 ml of 1.5 *M* potassium hypochlorite. The solutions were mixed, and, after standing, 100 ml of ethyl alcohol was added. The rather sticky red precipitate was separated by centrifuging and decantation. It was redissolved in 50 ml of 0.2 *M* potassium hydroxide, and reprecipitated by an equal volume of alcohol. This was repeated several times, and the final product was dried over calcium chloride or sulphuric acid. The yield on various occasions was 7.5 to 9.1 g of dark red crystals. In some preparations somewhat different ratios of manganese to tellurium were used.

The sodium salt was made similarly from sodium hydroxide and hypochlorite. It was less easy to purify, as sodium tellurate precipitated more easily than the potassium salt. However, the sodium tellurato-manganate is also less soluble.

The salts were analyzed by virtually the same methods as for the cobalt compound. The results for the potassium salt were: K 20.9, Mn 5.24, Te 36.5, H_2O 8.59%; calculated for $K_6H_8Mn(TeO_6)_3.5H_2O$: K 22.1, Mn 5.19, Te 36.2, H_2O 8.48%.

The results for the sodium salt were: Na 14.83, Mn 5.37, Te 39.2, H_2O 9.31%; calculated for $Na_7H_7Mn(TeO_6)_3.5H_2O$: Na 16.38, Mn 5.59, Te 38.9, H_2O 9.16%.

As with the cobalt compound, a check on the formula was made by passage of a weighed amount of the potassium salt in solution through an anion exchange resin in its chloride form; the liberated chloride ion was titrated. One gram-molecule of chloride ion was liberated by 185 g of the potassium salt. This is a little higher than the calculated value of 176 g for $K_6H_8Mn(TeO_6)_3.5H_2O$.

2. Valency of Manganese

This was obtained from equivalent weights in redox reactions, and from magnetic properties. The reducing agent that was found to give the best results was ferrous ammonium sulphate: excess of this was added, and the excess titrated with potassium permanganate. The equivalent weight so obtained was 518 for the potassium salt, and 534 for the sodium; if the ferrous ions reduced Mn(IV) to Mn(II), the calculated values are 529, and 492. Any other valency of manganese would give a very different equivalent weight, and, though the results are not very precise, there can be no doubt that the manganese is changing its valency by two.

The magnetic susceptibility of $K_6H_8Mn(TeO_6)_3.5H_2O$ was found to be 5230×10^{-6} e.m.u./g-mol at 25.1° C, and 4910×10^{-6} e.m.u./g-mol at 39.6° C. The correction for the diamagnetism of the various atoms is about 383×10^{-6} e.m.u./g-mol, making the corrected susceptibilities 5613×10^{-6} at 25.1° C, and 5293×10^{-6} at 39.6° C. If these susceptibilities obey the Curie–Weiss law, then the Weiss constant is −58°, and the Curie constant is 1.348. Hence the magnetic moment ($2.84C^{1/2}$) is 3.30 Bohr magnetons. This is somewhat lower than the calculated "spin only" value of 3.87 Bohr magnetons, but still near enough that it most probably indicates three unpaired electrons.

3. Acid–Base Properties

The potassium salt proved stable enough in solution to be titrated with dilute perchloric acid; or the solution on acidification could be back titrated with potassium hydroxide. The pH curve was the same in both directions. Starting at the acid end, the pH of 0.00204 *M* $H_{14}Mn(TeO_6)_3$ was 2.62. This corresponds to between one and two hydrogen ions/molecule, meaning that ionization is easy up to $Mn(H_4TeO_6)_3^{-2}$. When these acid hydrogens had been neutralized the pH rose steeply, and thereafter gave no marked rise until three more hydrogens had been neutralized. The third to fifth ionization steps, which cannot be clearly distinguished, have pK values about 7.5, corresponding to ionization as far as $Mn(H_3TeO_6)_3^{-5}$. The next ionization constant after this has pK about 11.5. These constants are consistent with the formula of the compound.

Stability of Tellurato-manganate Ion

Like other compounds of this type, sodium or potassium tellurato-manganate ions in solution gave an absorption spectrum which was high at the violet end, low at the red end, with a single minimum and maximum in between. The minimum was at about 420 mμ, and the maximum at 470 mμ. However, the absorption was considerably altered by addition of excess sodium tellurate, and it was evident that an equilibrium existed between ions differing in their content of tellurium. The absorption curves so obtained are shown in Fig. 1.

In the presence of excess sodium tellurate, the chief ion present contains three tellurate residues to each manganese atom. The evidence for this partly comes from the fact that the solid salts which were prepared contained this ratio of atoms, and partly from the following experiment. If a constant amount of manganese sulphate was mixed with varying

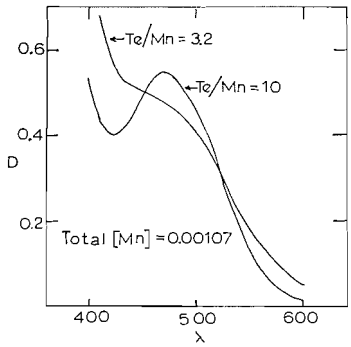

FIG. 1. Optical density of solutions with constant manganese and varying tellurium content.

amounts of sodium tellurate in solution, and the mixture oxidized by sodium hypochlorite, then some (or all) of the manganese was converted into a solution of sodium tellurato-manganate (the rest was precipitated as manganese dioxide). The amount in solution was determined by diluting the solution to a given volume, and measuring its optical density. The optical density increased steadily until the ratio of tellurium to manganese reached 3, and thereafter it levelled out.

Mixtures with various concentrations of manganese sulphate and sodium tellurate were oxidized by sodium hypochlorite, and the optical densities of the resulting solutions were measured at various wavelengths. The concentration of sodium hydroxide present was also varied. The temperature in all cases was 25° C. The results are summarized in Table I, which, however, only gives data for 470 mμ and 420mμ, which were the wavelengths where the greatest change in the optical density occurred. As indicated in Fig. 1, measurements were also made over most of the range 400–600 mμ.

In the interpretation of the results in Table I it was assumed that the equilibrium was of the type

$$\text{Mn(tellurate)}_3 \rightleftharpoons \text{Mn(tellurate)}_{3-n} + n.\text{tellurate}.$$

Let

Mn_0 = total manganese present,
R = tellurium/manganese ratio,
ϵ_1 = extinction coefficient of Mn(tellurate)_3,
ϵ_2 = extinction coefficient of $\text{Mn(tellurate)}_{3-n}$,
$A = \epsilon_1\text{Mn}_0$,
$B = \epsilon_2\text{Mn}_0$,
D = optical density.

Then it follows from the equations for the total manganese and tellurium present, and the Beer–Lambert law, that

$$K = \frac{D-A}{B-D}\,\text{Mn}_0\left[R-3+\frac{n(D-A)}{B-A}\right]^n.$$

K is the equilibrium constant of the reaction. If R is large, almost all the manganese will be converted to Mn(tellurate)_3, so $D = A$; hence a reasonably good value of A can be obtained by extrapolation of D at high values of R. Values of K were calculated

TABLE I

Run	[Mn]×10³ (*M*)	Ratio Te/Mn	Optical density 470 mμ	Optical density 420 mμ	[NaOH] (*M*)

		3.7	0.349	0.346	
		4.0	0.352	0.308	
		5.0	0.362	0.282	
		7.0	0.367	0.273	
		10.0	0.367	0.272	
5	0.713	3.7	0.338	0.321	0.295
		4.0	0.340	0.309	
		5.0	0.354	0.291	
		7.0	0.355	0.273	
		10.0	0.357	0.271	
		10.0	0.354	0.275	

from the data for different values of R, assuming various values of B and n. The value B was taken to be that for which the average deviation in K was least, and this deviation was compared for different values of n. Run 1, for instance, gave:

n	1	2	3
Average deviation in K (%)	3.8	13.2	22.2

Hence $n = 1$, and the equation for K reduces to

$$K = \mathrm{Mn}_0\left(\frac{D-A}{B-D}\right)\left(R-3+\frac{D-A}{B-A}\right).$$

The procedure adopted to find K was to select values of A and B for any one run, until the values of K obtained from that run showed a minimum average deviation (expressed as a percentage of K). This was done for both wavelengths studied, with the results given in Table II.

The values of K are fairly consistent, but tend to fall as the concentration of hydroxide ions rises. This drift is not quite as much as is required on the assumption that the equilibrium constant is inversely proportional to $[OH^-]$. Assuming that the ion in solution is the same as in the solid, and that tellurate is dissociated to $H_4TeO_6^{-2}$ in moderately alkaline solution, then the main reaction is

$$H_7Mn(TeO_6)_3^{-7} + H_2O \rightleftharpoons H_4Mn(TeO_6)_2^{-4} + H_4TeO_6^{-2} + OH^-.$$

TABLE II

Run	Wavelength (mμ)	A	B	$K\times10^4$	ϵ_1	ϵ_2
1	470	0.52	0.31	1.70	485	290
	420	0.40	1.10	1.71	375	1030
2	470	0.265	0.16	1.62	495	300
	420	0.194	0.55	1.55	365	1030
3	470	0.55	0.30	1.40	515	280
	420	0.39	1.10	1.42	365	1030
4	470	0.37	0.20	0.87	520	280
	420	0.26	0.75	0.98	365	1050
5	470	0.362	0.21	1.30	510	295
	420	0.255	0.75	1.16	360	1050

The equilibrium constant for this reaction will be the value of K given in Table II multiplied by the hydroxide ion concentration; this is about 4×10^{-5}. Hence this complex tellurato-manganate ion is of rather moderate stability. The extinction coefficients are also consistent, and average as follows:

$H_7Mn(TeO_6)_3^{-7}$: 470 mμ, $\epsilon_1 = 505$; 420 mμ, $\epsilon_1 = 290$;
$H_4Mn(TeO_6)_2^{-4}$: 470 mμ, $\epsilon_2 = 365$; 420 mμ, $\epsilon_2 = 1040$.

The absorption maximum found for $H_7Mn(TeO_6)_3^{-7}$ at 470 mμ seems to be absent for $H_4Mn(TeO_6)_2^{-4}$.

INTERFACE KINETICS

HYDROGEN PEROXIDE OXIDATION OF CUPROUS ION

D. W. COLCLEUGH[1] AND W. F. GRAYDON[2]

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario

Received March 9, 1962

ABSTRACT

It has been established (D. W. Colcleugh and W. F. Graydon. J. Phys. Chem. In press) that hydrogen peroxide is produced during the dissolution of polycrystalline copper in dilute aqueous solutions. The hydrogen peroxide formed during the dissolution further attacked the metal, producing additional cupric copper in solution. The kinetics of this heterogeneous reaction was investigated in aerated sulphuric acid solutions. Under these experimental conditions the ratio of the increase in concentration of cupric ion to the decrease in concentration of hydrogen peroxide was constant at the value of 2. In deaerated sulphuric acid this stoichiometric ratio was constant at the value of 1 under similar experimental conditions.

Rate equations for the formation of cupric ion in solution and for the decomposition of hydrogen peroxide in the solution were determined as a function of sample area, corroding solution volume, temperature, hydronium ion concentration, cupric ion concentration, and hydrogen peroxide concentration.

A reaction mechanism was suggested to describe the empirical rate equations and the stoichiometry obtained experimentally.

EXPERIMENTAL

Apparatus

The apparatus consisted of a cylindrical sample of polycrystalline copper rotating in a solution of sulphuric acid. The solution was kept saturated with either pure nitrogen or an oxygen–nitrogen mixture by continually bubbling the gas into the acid solution during an experimental run. The apparatus was described in full previously (1) and no modifications were made.

Analysis

A polarographic method of analysis was used for cupric ion, hydrogen peroxide, and, occasionally, dissolved oxygen determinations. Dissolved oxygen determinations were carried out prior to the start of a run to ensure that deaeration was complete.

The supporting electrolyte used was 1 M sodium acetate and the maximum suppressor was a 0.01% gelatin solution. The capillary had "m" and "t" values of 3.24 mg/sec and 3.19 sec respectively at 0.0 volts versus the saturated calomel electrode.

Procedure

The corroding solution consisted of a sulphuric acid solution containing cupric ion (dissolved cupric sulphate pentahydrate) and hydrogen peroxide. The gas stream was bubbled through the solution for several hours before the metal sample was immersed into the solution and the run was begun. The copper sample, before immersion in the solution, was polished mechanically with various grades of emery paper, progressing from rough to fine, and then cleaned thoroughly with distilled water and absolute alcohol.

Periodically, during the course of a run, samples of corroding solution were removed and analyzed for cupric ion and hydrogen peroxide content polarographically.

Unless otherwise stated in the discussion of the results the operating conditions were: a sulphuric acid concentration of 0.2 mole/liter, an ambient temperature of 25.8° C, a sample surface area of 11.4 cm^2, a corroding solution volume of 500 ml, partial pressure of oxygen in the gas stream of 0.21 atm, and a sample rotation speed of 880 r.p.m. In Section B of Discussion of Results, the oxygen concentration in the gas stream was zero.

DISCUSSION OF RESULTS

Introduction

Hydrogen peroxide was produced during the dissolution of polycrystalline copper in dilute aerated sulphuric acid solutions (2). At hydrogen peroxide concentrations less

[1]*N.R.C. Bursary 1959–60; N.R.C. Studentship 1960–61.*
[2]*Professor of Chemical Engineering, University of Toronto.*

than about 5×10^{-4} mole/liter the ratio of cupric ion concentration in solution to hydrogen peroxide concentration in solution was constant at the value of 2 under all experimental conditions. The plots of cupric ion concentration and hydrogen peroxide concentration to the one-half power versus time gave straight lines below this limit in hydrogen peroxide concentration.

It seemed logical to assume that the hydrogen peroxide, an active oxidizing agent, would be involved in the dissolution process. If the dissolution was allowed to continue beyond a hydrogen peroxide concentration of about 5×10^{-4} mole/liter, a marked increase in the ratio of cupric ion concentration to hydrogen peroxide concentration was observed. The slopes of the plots of cupric ion concentration and hydrogen peroxide concentration to the one-half power versus time began to increase and decrease respectively with increasing hydrogen peroxide concentration, as seen by Table I.

TABLE I

Time	$[H_2O_2]\times10^4$	$\frac{d[Cu^{++}]^{1/2}}{dt}\times10^4$	$\frac{d[H_2O_2]^{1/2}}{dt}\times10^4$	$\frac{[Cu^{++}]}{[H_2O_2]}$
7.5	0.97	11.4	7.80	2.0
15.0	2.54	11.3	7.67	2.1
25.0	5.29	12.2	6.82	2.3
35.0	8.39	13.0	5.35	2.6
45.0	11.35	14.2	3.85	3.3
58.5	12.73	16.4	0.60	5.1

These observations indicated that the copper dissolution process in aerated sulphuric acid solutions consisted of two oxidation steps, the oxidation of copper by dissolved oxygen (2) and the oxidation of copper by dissolved hydrogen peroxide formed in the first reaction.

The following empirical equations were postulated to explain the aforementioned phenomenon in a solution of constant sulphuric acid concentration and at a constant reaction temperature:

$$\frac{d[Cu^{++}]}{dt} = k_1[O_2]^{1/2}[Cu^{++}]^{1/2}+k_2[Cu^{++}]^{1/2}[H_2O_2] \quad [1]$$

$$2\times\frac{d[H_2O_2]}{dt} = k_1[O_2]^{1/2}[Cu^{++}]^{1/2}-k_2[Cu^{++}]^{1/2}[H_2O_2] \quad [2]$$

$$2\times\frac{d[Cu^{++}]^{1/2}}{dt} = k_1[O_2]^{1/2}+k_2[H_2O_2]. \quad [3]$$

At very low concentrations of hydrogen peroxide the equations above would reduce to the form of the rate equations reported previously (2):

$$2\times\frac{d[H_2O_2]}{dt} = \frac{d[Cu^{++}]}{dt} = k_1[O_2]^{1/2}[Cu^{++}]^{1/2}. \quad [4]$$

To test the validity of the above proposed equations [1], [2], and [3], several runs with initially added cupric ion and hydrogen peroxide were completed in aerated sulphuric acid solutions. Experiments of this sort were also carried out in deaerated sulphuric acid solutions. The exclusion of dissolved oxygen from the solution in contact with the metal

would serve to isolate part of the reaction for closer and more detailed examination. The data from these experiments were compared with the simplified forms of the equations [1] and [2] at zero oxygen concentration.

The dependence of the rate constants on dissolved oxygen concentration, sample area, corroding solution volume, rotation speed of the sample, temperature, and acid concentration was determined.

A. Experiments in Aerated Sulphuric Acid

Rate Dependence on Cupric Ion and Hydrogen Peroxide Concentrations

The basis of the proposed one-half-order dependence of rate with respect to cupric ion concentration and the first-order dependence of the rate with respect to hydrogen peroxide concentration was a series of experiments carried out under normal operating conditions with varying amounts of initially added cupric ion and hydrogen peroxide. These so-called normal operating conditions were specified in the Experimental Procedure.

The data obtained from these experiments when fitted to equations [1] and [2] gave constant values of k_1 and k_2 over the wide range of cupric ion and hydrogen peroxide concentrations used. The rates obtained, the average cupric ion and hydrogen peroxide concentrations over a run, and the calculated rate constants k_1 and k_2 are tabulated in Table II.

From Table II it can be seen that a wide selection of cupric ion concentrations and hydrogen peroxide concentrations were used in this part of the work. Average cupric ion concentrations in solution ranged from a low of 12.2×10^{-4} mole/liter to a high of

61.3×10^{-4} mole/liter, and the average hydrogen peroxide concentrations ranged from a low of 6.82×10^{-4} mole/liter to a high of 50.6×10^{-4} mole/liter. The ratio of average cupric ion concentration in solution to average hydrogen peroxide concentration in solution ranged from about 6.4 to 0.3. With these quite wide ranges in conditions the rate constants calculated from the proposed rate equations remained essentially constant with no observable trends.

Perhaps the most convincing part of the argument for acceptance of the proposed rate equations was the fact that at high enough concentrations of hydrogen peroxide, that is, concentrations above about 28×10^{-4} mole/liter, it was observed that the rate of formation of hydrogen peroxide was negative. At these high concentrations of hydrogen peroxide more hydrogen peroxide was being used up in reaction with the copper than was being produced in the reaction of the copper with dissolved oxygen. Again the rate constant remained at the same value without any significant trends.

It should also be noted that in run No. 8 a rate of hydrogen peroxide formation of zero was observed at a constant hydrogen peroxide concentration of 28.0×10^{-4} mole/liter. The cupric ion concentration increased throughout the run with no apparent change in the hydrogen peroxide concentration. The amount of hydrogen peroxide produced by the reaction of dissolved oxygen with copper discussed previously (2) was exactly balanced by the amount of hydrogen peroxide used up in reaction with the copper.

Rate Dependence on Dissolved Oxygen Concentration

A set of runs with initially added cupric ion and hydrogen peroxide was carried out in aerated 0.2 *M* sulphuric acid solutions with varying partial pressures of oxygen in the saturating gas phase.

The partial pressure of oxygen in the gas phase was found to be directly proportional to the concentration of dissolved oxygen in the condensed phase. The Henry's law constant for this concentration of solution at 25.8° C was found experimentally to be 8.00×10^{2} atm-liter/mole.

The values of the rate constants k_1 and k_2 calculated from the rate data and equations [1] and [2] and the corresponding partial pressures of oxygen in the gas phase are given in Table III. From this data it was observed that the rate constants k_1 and k_2 were independent of the oxygen concentration in the corroding solution.

TABLE III

0.20	0.120	0.60
0.50	0.122	0.31

Rate Dependence on Sample Area and Corroding Solution Volume

A linear relationship between the rate constant k_2 and the ratio of sample area to

corroding solution volume was found as seen by Fig. 1. A similar dependence was previously found for the rate constant k_1 (1, 2), and was substantiated by this work.

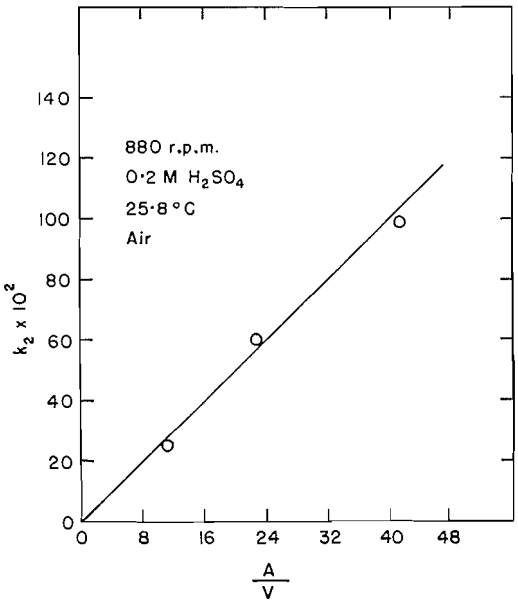

FIG. 1. Effect of sample area and corroding solution volume. Variation of rate constant from equations [1] and [2] with the ratio of sample area to dissolving solution volume.

Rate Dependence on Sample Rotation Speed

The cylindrical copper sample was rotated at three widely different speeds and the rate constants measured. Any dependence of rate on the rotation speed of the sample would indicate that the rate of diffusion of a reacting species to the copper surface played an important part in the control of the dissolution process.

The results shown in Table III clearly indicated that the rate constant k_2 was independent of sample r.p.m. and the reaction of hydrogen peroxide with copper was chemically controlled under these experimental conditions.

Rate Dependence on Sulphuric Acid Concentration

The variable in this series of experiments was sulphuric acid concentration. All other operating conditions were kept constant.

The variation in the values of k_1, as seen by Table III, was as expected from the previous work (2). The values of k_2 also showed a dependence on sulphuric acid concentration. The values of k_2 measured showed an inverse dependence on acid concentration, decreasing as the sulphuric acid concentration increased.

B. Experiments in Deaerated Sulphuric Acid

If the dissolved oxygen concentration in the solution is zero, equations [1] and [2] become

$$\frac{d[Cu^{++}]}{dt} = k_2[Cu^{++}]^{1/2}[H_2O_2], \qquad [5]$$

$$2\times\frac{d[H_2O_2]}{dt} = -k_2[Cu^{++}]^{1/2}[H_2O_2]. \qquad [6]$$

Thus one would expect, from the results in Section A, that the ratio of the increase in concentration of cupric ion in solution to the decrease in concentration of hydrogen peroxide in solution for the condition of no dissolved oxygen in solution would be constant at the value 2. However, it became increasingly evident as the path of the reaction between hydrogen peroxide and polycrystalline copper in deaerated sulphuric acid was followed that this stoichiometric ratio was in fact 1 and not 2.

Also, it was found that both the rate of formation of cupric ion and the rate of decomposition of the dissolved hydrogen peroxide were dependent upon the concentration of cupric ion in solution and upon the hydrogen peroxide concentration in solution to the one-half power and the first power respectively.

The results given in Table IV illustrate the above statements concerning the stoichiometry and the independence of the rate constant on cupric ion concentration and hydrogen

TABLE IV

No.	$[Cu^{++}]_{av}\times10^4$	$[H_2O_2]_{av}\times10^4$	K	$-\frac{\Delta[Cu^{++}]}{\Delta[H_2O_2]}$

15	24.8	12.6	0.55	0.93

peroxide concentration. The sample surface area was 11.4 cm², the corroding solution volume was 500 ml, the sample rotation speed was 880 r.p.m., and the ambient temperature was 25.8° C for all the runs given in Table IV.

The rate constant K given in Table IV was an average value over the length of the run and was defined by the following equations:

$$\frac{d[Cu^{++}]}{dt} = K[Cu^{++}]^{1/2}[H_2O_2] \qquad [7]$$

$$-\frac{d[H_2O_2]}{dt} = K[Cu^{++}]^{1/2}[H_2O_2]. \qquad [8]$$

The results from a typical run were illustrated graphically in Fig. 2, which corresponds to run No. 5 in Table IV.

It can be seen from the values of K that they are identical with the values of k_2 obtained in aerated solutions (Table II).

Rate Dependence on Sulphuric Acid Concentration

Figure 3 illustrates the effect of changing the acid concentration on the rate constant K. As was the case in Section A a decrease in the acid concentration increased the value of the rate constant k_2. The values of k_2 obtained from the experiments in aerated solutions

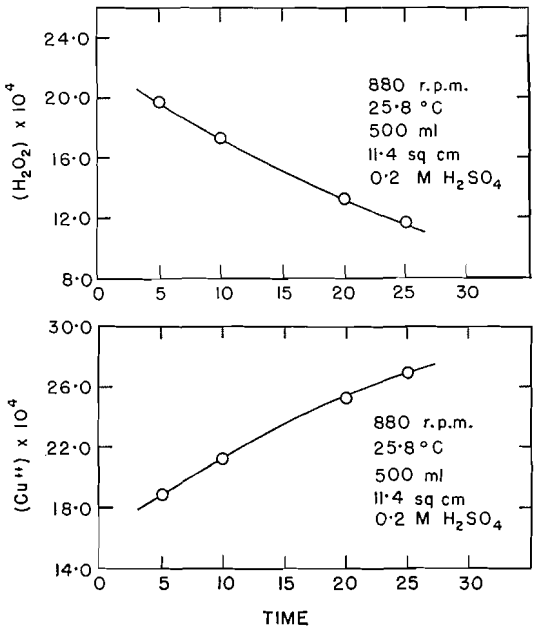

FIG. 2. Variation of concentration (mole/liter) with time (hours) in deaerated solution.

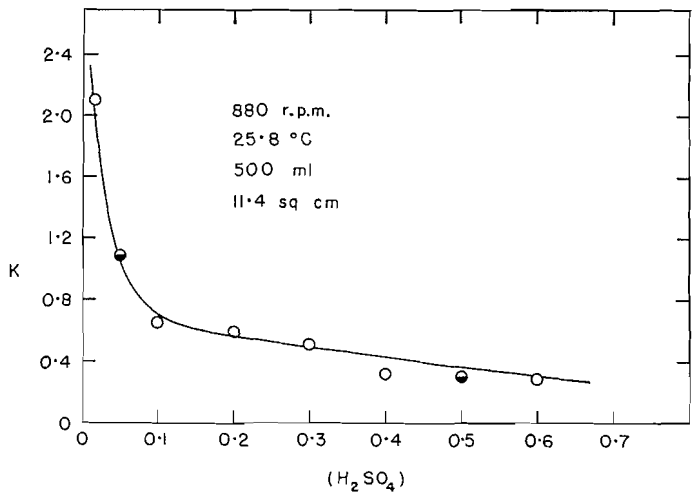

FIG. 3. Effect of sulphuric acid concentration. Variation of rate constant K from equations [7] and [8] with acid concentration (mole/liter) in deaerated solutions; ◒ shows variation of k_2 from equations [1] and [2] with acid concentration in aerated solutions.

and calculated from equations [1] and [2] were superimposed on Fig. 3, and found to agree well with the values of K obtained in deaerated solutions and calculated from equations [7] and [8].

The dependence of the rate constant K on sulphuric acid concentration did not appreciably affect the stoichiometry of the reaction, which remained at the value 1, as seen by Table V.

"	"	"	"	2300	1.05

The data in Fig. 3 when replotted as the reciprocal of the rate constant versus hydronium ion concentration (Fig. 4(*a*)) resulted in a good linear correlation. Similar data to that described above were obtained at ambient temperatures of 15.0° C (Fig. 4(*b*)), 36.0° C (Fig. 4(*c*)), and 45.0° C (Fig. 4(*d*)).

This data substantiated the linear relationship between hydronium ion concentration and the reciprocal of the rate constant.

Thus

$$K = \frac{K_1}{K_2 + [H_3O^+]}. \qquad [9]$$

Rate Dependence on Temperature

This series of experiments carried out with temperature as the variable was designed to determine the temperature dependence of the rate constants as well as to test the linear correlation of the reciprocal of the rate constant versus acid concentration as discussed above.

At the temperatures used, the stoichiometric ratio of the increase in concentration of cupric ion to the decrease in concentration of hydrogen peroxide remained at the value unity.

From the slopes and intercepts of Fig. 4(*a–d*) values of the rate constants K_1 and K_2 were determined and plotted as in Fig. 5. Arrhenius activation energies calculated from the slopes of Fig. 5 were 20.6 kcal/g-mole and 11.8 kcal/g-mole for the rate constants K_1 and K_2 respectively.

Rate Dependence on Sample Area and Corroding Solution Volume

As was the case in the experiments in aerated sulphuric acid solutions, a linear relationship between the rate constant K and the ratio of sample area to corroding solution volume was found as seen by Fig. 6.

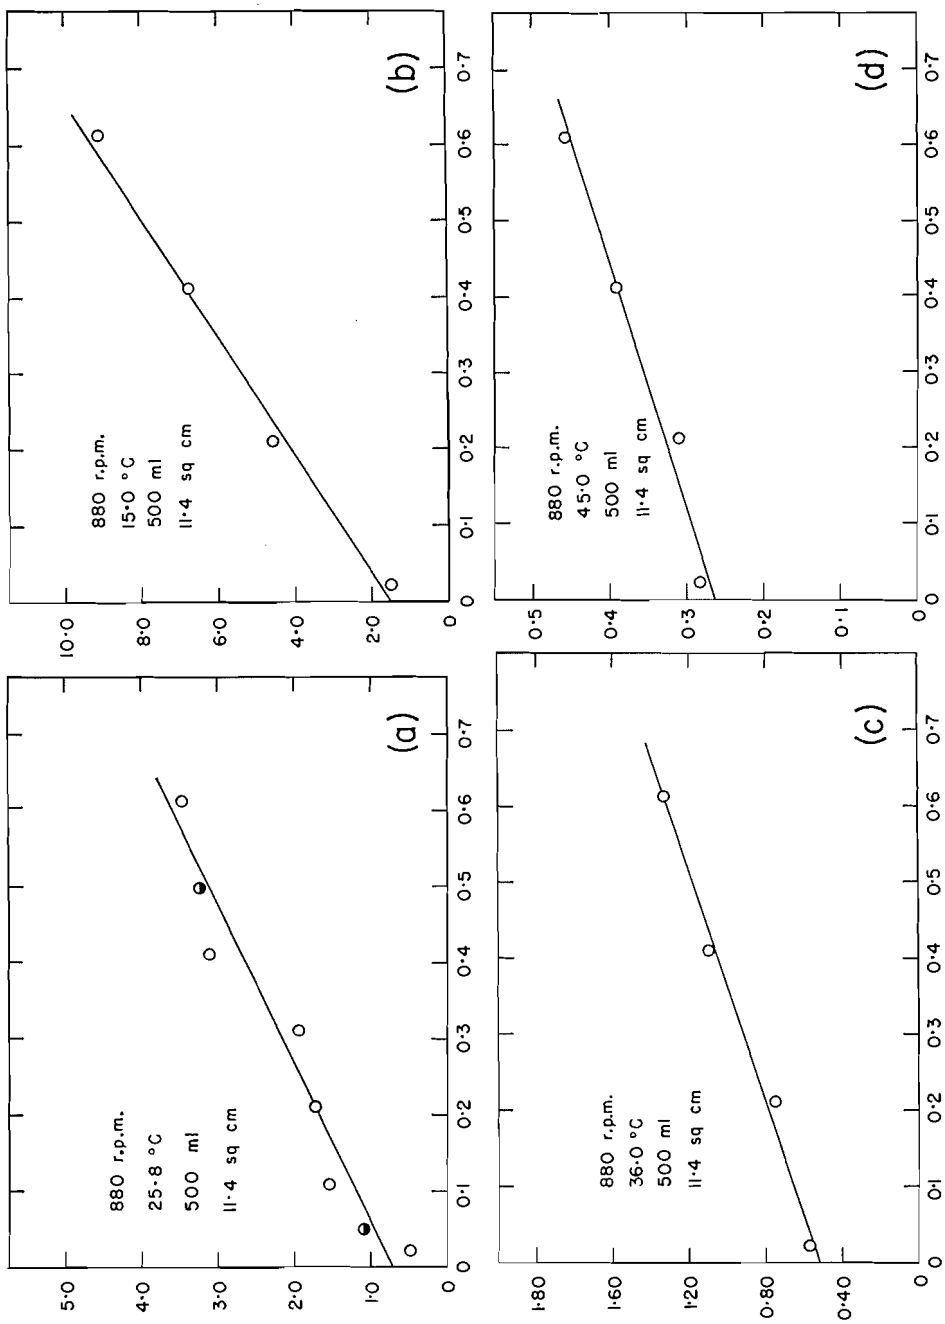

FIG. 4. Effect of hydronium ion concentration. Reciprocal of rate constant K from equations [7] and [8] versus hydronium ion concentration (mole/liter) in deaerated solutions at (*a*) 25.8, (*b*) 15.0, (*c*) 36.0, (*d*) 45.0° C. In Fig. 4(*a*) ◑ shows variation of reciprocal rate constant k_2 from equations [1] and [2] versus hydronium ion concentration in aerated solutions.

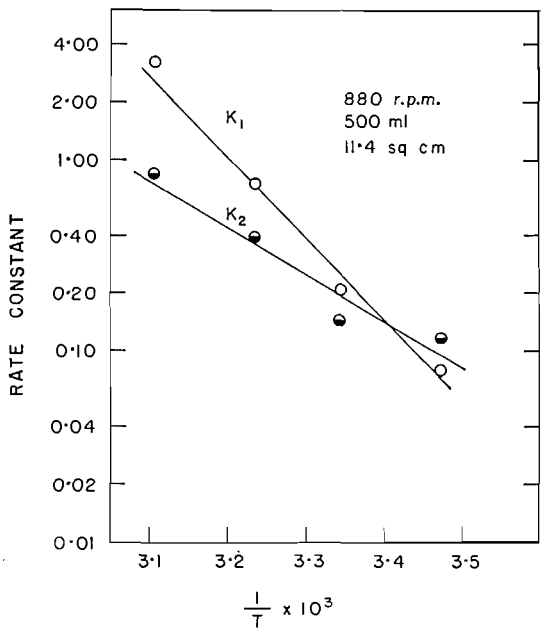

FIG. 5. Effect of temperature. Logarithms of rate constants K_1 and K_2 as defined by equation [9] versus the reciprocal of the corresponding absolute temperature in deaerated solutions.

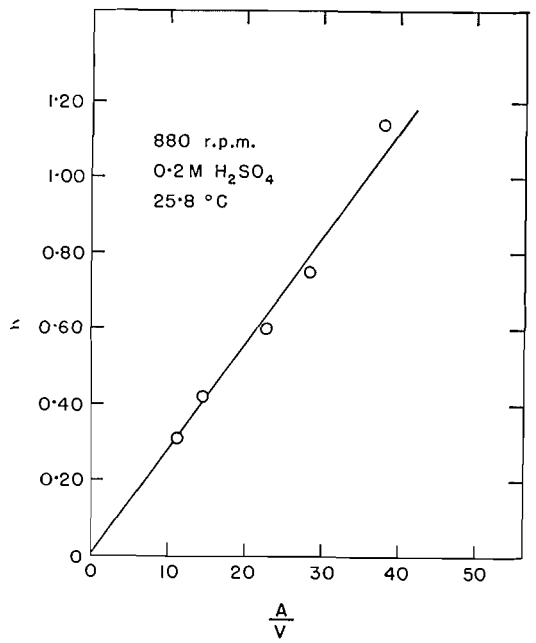

FIG. 6. Effect of sample area and corroding solution volume. Variation of rate constant K as defined by equations [7] and [8] with ratio of sample area to dissolving solution volume in deaerated solutions.

The stoichiometric ratio was unaffected by the variation in sample area and corroding solution volume, as illustrated in Table V.

Rate Dependence on Sample Rotation Speed

Variation in the rotation speed of the sample did not affect the value of the rate constant or the stoichiometric ratio and therefore the reaction must be chemically controlled under the existing experimental conditions.

Summary

From the discussion of the results obtained in this work and the results of previous work (1, 2), the overall rates of formation of cupric ion and hydrogen peroxide during the dissolution of polycrystalline copper in dilute sulphuric acid solutions could each be represented by the sum and difference, respectively, of two component rates:

$$\frac{d[Cu^{++}]}{dt} = R_1 + \frac{9.08\times10^{-3}(A/V)[Cu^{++}]^{1/2}[H_2O_2]}{0.145+[H_3O^+]}$$

$$\frac{d[H_2O_2]}{dt} = \frac{1}{2}R_1 - \frac{1}{\beta}\frac{9.08\times10^{-3}(A/V)[Cu^{++}]^{1/2}[H_2O_2]}{0.145+[H_3O^+]}.$$

The contribution to the overall rates of formation through the attack of the copper by dissolved oxygen, represented above by R_1, was discussed previously (1, 2). The rate constant obtained previously (2) for R_1, at 25.8° C in a sulphuric acid solution of 0.2 M, was $5.44\pm0.48\times10^{-3}$. The hydrogen peroxide concentrations were low enough so that the second term in each overall rate equation was negligible with respect to R_1.

In this investigation, in aerated solutions, the hydrogen peroxide concentration and the second term in each overall rate equation were not negligible with respect to R_1. The value of the rate constant for R_1 at 25.8° C in 0.2 M sulphuric acid, under these conditions of high hydrogen peroxide concentrations was $5.32\pm0.56\times10^{-3}$.

The value of β, the stoichiometric ratio, was 2 in aerated sulphuric acid solutions and 1 in deaerated sulphuric acid solutions.

At 25.8° C and a sulphuric acid concentration of 0.2 M the rate constant for the hydrogen peroxide oxidation of cuprous ion in aerated solutions was $26.3\pm3.71\times10^{-3}$ and in deaerated solutions was $26.3\pm2.11\times10^{-3}$.

Proposed Mechanism

The following reaction scheme was suggested as a possible reaction mechanism for the oxidation of polycrystalline copper by dissolved hydrogen peroxide in dilute acid solution under aerated or deaerated conditions.

In formulating the reaction mechanism the experimentally established facts were adhered to.

1. Both the rate of formation of cupric ion and the rate of decomposition of hydrogen peroxide were one-half order with respect to cupric ion and first order with respect to hydrogen peroxide.

2. One mole of cupric ion was formed for every mole of hydrogen peroxide reacted in deaerated solutions and 2 moles of cupric ion were formed for every mole of hydrogen peroxide reacted in aerated solutions.

3. The reaction was inhibited by increasing concentration of acid.

The following reactions were assumed to take place at the solid–liquid interface:

$$Cu + Cu_i^{++} \overset{K_a}{\rightleftharpoons} 2Cu_i^{+} \text{ (equilibrium)} \qquad [i]$$

$$Cu_i^{+} + H_2O_{2i} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Cu^{+}.H_2O_2 \qquad [ii]$$

$$Cu^{+}.H_2O_2 \xrightarrow{k_3} Cu_i^{++} + OH + OH^{-} \qquad [iii]$$

$$Cu^{+}.H_2O_2 + H_3O^{+} \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} Cu_i^{+} + H_3O_2^{+} + H_2O \qquad [iv]$$

$$H_3O_2^{+} + H_2O \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} H_2O_2 + H_3O^{+}. \qquad [v]$$

Reaction [iv] represents the inhibition step. The hydronium ion enters into competition for and returns the cuprous ion, hydrogen peroxide transitory species to its original uncombined form of free cuprous ion and molecular hydrogen peroxide.

It is suggested that the hydroxyl free radical formed in reaction [iii] reacted predominantly in one of two ways depending upon the condition with respect to dissolved oxygen concentration.

In aerated solutions:

$$OH + O_s \xrightarrow{k_5} O_s.OH$$

$$O_s.OH + OH \xrightarrow{k_6} H_2O_{2i} + O_s.$$

In deaerated solutions:

$$OH + OH \xrightarrow{k_7} H_2O + \tfrac{1}{2}O_2.$$

The direct recombination of hydroxyl free radicals to form H_2O_2 was discounted by Weiss (3) because of dipolar repulsion, but he felt recombination in solution to form H_2O_2 was possible under the catalytic influence of various molecules or ions, such as dissolved oxygen (4). Stein (5) has suggested that many free radicals show a great tendency to combine with oxygen. Hydroxyl free radical, in this system, is thought to combine with surface oxygen in aerated sulphuric acid solutions; the product is subsequently rapidly reacted upon by more hydroxyl free radicals to form molecular hydrogen peroxide and regenerate the surface oxygen.

In the absence of surface oxygen, dismutation of hydroxyl radicals takes place by reaction at the solid–liquid interface, forming water and oxygen. The oxygen is removed from the solid–liquid interface by diffusion into the oxygen-free corroding solution and is swept out of the solution by the nitrogen stream bubbling through the solution.

The concentration of each of the four transitory species postulated was assumed to be small and in a stationary state with respect to time.

$$\frac{d[Cu^{+}.H_2O_2]}{dt} = 0 \qquad [10]$$

$$\frac{d[OH]}{dt} = 0 \qquad [11]$$

$$\frac{d[O_s.OH]}{dt} = 0 \qquad [12]$$

$$\frac{d[H_3O_2^{+}]}{dt} = 0 \qquad [13]$$

Therefore from equation [10] and assuming $k_{-4}[H_3O_2^+][H_2O]$ is much smaller than $k_1[H_2O_2]$

$$[Cu^+.\,H_2O_2] = \frac{k_1[Cu^+]_i[H_2O_2]_i}{k_{-1}+k_3+k_4[H_3O^+]}.$$

From the cuprous, cupric, copper equilibrium existing at the solution–solid interface,

$$[Cu^+]_i = K_a'[Cu^{++}]_i^{1/2}. \qquad [14]$$

There was no rate dependence on sample rotation speed so the diffusion gradient existing from bulk solution to interface is negligible.

$$[Cu^{++}]_i = [Cu^{++}] \qquad [15]$$

$$[H_2O_2]_i = [H_2O_2] \qquad [16]$$

In aerated solutions (from equations [11]–[16]):

$$\frac{d[Cu^{++}]}{dt} = \frac{k_3K_a'k_1[Cu^{++}]^{1/2}[H_2O_2]}{k_{-1}+k_3+k_4[H_3O^+]} \qquad [17]$$

$$\frac{d[H_2O_2]}{dt} = -\frac{1/2k_3K_a'k_1[Cu^{++}]^{1/2}[H_2O_2]}{k_{-1}+k_3+k_4[H_3O^+]}. \qquad [18]$$

In deaerated solutions (from equations [11]–[16]):

$$\frac{d[Cu^{++}]}{dt} = \frac{k_3K_a'k_1[Cu^{++}]^{1/2}[H_2O_2]}{k_{-1}+k_3+k_4[H_3O^+]} \qquad [19]$$

$$\frac{d[H_2O_2]}{dt} = -\frac{k_3K_a'k_1[Cu^{++}]^{1/2}[H_2O_2]}{k_{-1}+k_3+k_4[H_3O^+]}. \qquad [20]$$

Equations [17]–[20] are of the same form as those found experimentally for the rate of formation of cupric ion and the rate of decomposition of hydrogen peroxide due to the attack of the copper by dissolved hydrogen peroxide.

The rate constants in equations [17], [19], [20] are identical in form with those found empirically and the rate constant in equation [18] differs from the other three only by the factor 1/2, which was found experimentally.

Notation

[ ] —concentration in mole/liter;
A —exposed surface area of copper sample in cm²;
V —volume of corroding solution in liters;
i —denotes solid–liquid interface;
O_s —oxygen at surface of metal;
Time, t —reaction time in hours.

THE POLYMERIZATION OF 1-BUTENE BY $TiCl_3$–$Al(i\text{-}Bu)_3$ CATALYSTS

M. H. JONES AND M. P. THORNE
Department of Chemistry, Ontario Research Foundation, Toronto, Ontario

Received March 14, 1962

ABSTRACT

An investigation has been made of the polymerization of 1-butene by $TiCl_3$–$Al(i\text{-}Bu)_3$ catalysts in heptane solution at 40° C. The polymerization curve has two segments covering initial and steady-state periods at which the rate increases several fold. The change in rate, which occurs after the formation of a constant amount of polymer for a given concentration of $TiCl_3$, is interpreted as an increase in surface area due to breakdown of the catalyst particles. For the steady-state period, it has been shown that the rate of polymerization is proportional to the monomer and titanium trichloride concentrations and approaches a constant value as the aluminum triisobutyl concentration increases.

The intrinsic viscosity of the bulk polymer and the crystallinity, as determined by infrared analysis, were found to be essentially independent of the concentrations of the catalyst components and the extent of polymerization.

The results are considered in terms of current theories on the mechanism of heterogeneous polymerization.

INTRODUCTION

Since the development of Ziegler–Natta type catalysts for the polymerization of α-olefins and dienes, many instances have been reported of the polymerization of 1-butene using, for the most part, catalysts prepared from aluminum alkyls and titanium tetrachloride or trichloride. However, kinetic studies (1, 2) have been confined to titanium tetrachloride systems, where problems have been encountered in making reproducible rate measurements. In part, this is understandable from the fact that the activity of these catalysts is believed to be associated with the formation of metal–organic complexes, involving titanium in a lower valency state, which are ill-defined and result from a series of complex reduction reactions between the tetrachloride and the metal alkyl (3–5). With propylene as the monomer, it has been found (6) that the use of titanium trichloride in place of the tetrachloride gives catalysts which are more reproducible and which yield polymers of greater stereoregularity. Similar observations have been reported (7) in a kinetic investigation of the polymerization of styrene by titanium trichloride – aluminum alkyl catalysts.

The present work is concerned with a kinetic study of the polymerization of 1-butene with aluminum triisobutyl – titanium trichloride catalysts and an examination of the effect of catalyst concentration and component ratio on the molecular weights and crystallinities of the polymers obtained.

EXPERIMENTAL

Polymerizations

The polymerization reactions were carried out in heptane solution at 40±0.2° C using Boston round bottles which were rotated end over end in a thermostatically controlled water bath. The methods employed for the purification of the solvent, catalyst components, etc., and the technique of catalyst preparation have been described previously (5).

For each series of reactions using the same ratio of catalyst components but different total concentrations, a single catalyst preparation was made and suitable samples withdrawn by a hypodermic syringe for injection into the monomer–solvent mixture. With bottle polymerizations it was not possible to follow the complete course of any single polymerization experiment because of the heterogeneous nature of the reaction mixture, and the fact that the polymer forms a gel around the catalyst particles, preventing effective sampling. Consequently, rates were determined from the amount of polymer formed during a

standard polymerization time. For each catalyst condition, duplicate reaction mixtures were prepared and the reactions stopped by the addition of ethanol at 24 and 48 hours respectively.

In several cases, the whole polymerization reaction for a given catalyst condition was followed by preparing a number of identical reaction mixtures and terminating them at suitable time intervals.

The polymers were recovered by precipitation in a 20-fold excess of ethanol while stirring in a Waring Blendor. After filtration and drying under vacuum, the crude products had ash contents of 1–2%. Further removal of the catalyst residue to an ash content of less than 0.5% was effected by reprecipitation and subsequent digestion in acidified 90% aqueous ethanol from a hot tetralin solution containing dibutyl *p*-phenylenediamine as antioxidant.

Viscosity Measurements

The intrinsic viscosities of the various polymer samples were determined in tetralin solution at 135° C using an Ubbelhode viscometer having a large bulb to permit dilution of the sample *in situ*. Polymer solutions (0.2 g/100 cc) were prepared at the bath temperature with a solvent containing 0.2% by weight of the antioxidant to prevent degradation. Under these conditions, solution flow times remained constant over a period of 3–4 hours and agreement between consecutive readings was found to be within 0.2 sec. It was established that the antioxidant had no detectable effect on the flow time of the pure solvent.

Polymer Fractionation

The polymer samples were separated into three fractions by extraction in a Soxhlet apparatus with ether and heptane. The ether extraction was continued until the solution failed to produce cloudiness when added to ethanol. The ether-soluble fraction was then obtained by evaporation of the solvent.

The extraction with heptane was continued for a standard time (4 hours) and the dissolved polymer recovered by precipitation in ethanol. Prolonged extraction with heptane resulted in complete removal of the polymer from the Soxhlet thimble in the form of a well-dispersed gel. The infrared absorption spectra of the separate fractions showed that the 4-hour extraction period was sufficient to increase the crystallinity of the residue to a constant level, which was assumed to be 100%.

The residue from the heptane extraction was dissolved in tetralin at 135° C, and reprecipitated from ethanol.

Crystallinity Measurements

The crystalline contents of the polymers were determined by infrared analysis on KCl pellets using the absorption peak due to crystallinity at 923 cm^{-1}. The samples were prepared by mixing a hot tetralin solution of the polymer with freeze-dried KCl at 120° C, the temperature of the mixture being maintained above 70° C while the solvent was removed by pumping under vacuum. The pellets, having an average thickness of 0.13 cm and containing a known concentration of polymer in the range 2.5–3.0%, were obtained by pressing the dried mixture under vacuum at a pressure of 100,000 p.s.i.

RESULTS

The results of a series of polymerization experiments covering a range of catalyst concentrations and component ratios are given in Table I. These were obtained using a single sample of titanium trichloride which, after pumping in vacuum, showed a residual tetravalent titanium content of 3%. Other samples from the same production lot were found to give lower rates of polymerization and also to contain lower amounts of tetravalent titanium. However, it was established that the addition of titanium tetrachloride to various samples of the trichloride to bring the Ti^{4+} content to a constant level resulted in comparable rates of polymerization. This method was employed to prepare reaction mixtures to study the course of the polymerization reaction under conditions in which the overall rates were similar to those reported in Table I.

Plots of the amount of polymer formed as a logarithmic function with respect to time for various catalyst concentrations are shown in Fig. 1. It is apparent that there are two segments to the rate curves. Both of these are essentially linear, indicating that the polymerization reaction is first order with respect to monomer concentration up to conversions of at least 85–90%. Values of the rate constants for the initial and final periods (k_1 and k_f) for different catalyst conditions are given in Table II. These data provide preliminary evidence that both rates increase progressively with the titanium trichloride concentrations and are independent of the ratio of catalyst components. More detailed information on these points has been obtained by calculating the values of k_f

for the experiments listed in Table I, using the fact that the ratio of the initial and final rates, k_1/k_f, is constant for all polymerization conditions.

The dependence of the rate constant k_f on the concentration of titanium trichloride is shown in Fig. 2. Although there is some scatter in the data the rate is essentially independent of the Al:Ti ratio at values of 2 and above, and approaches a linear relationship with respect to titanium trichloride concentration in the high concentration range. Essentially the same result is obtained if the overall reaction rate is used, as determined from the amount of polymer formed after the standard polymerization times of 24 and 48 hours, although the curvature of the plot is greater.

A plot of the rate constant per unit concentration of titanium trichloride, k_f/[$TiCl_3$], as a function of the aluminum triisobutyl concentration is given in Fig. 3. It follows

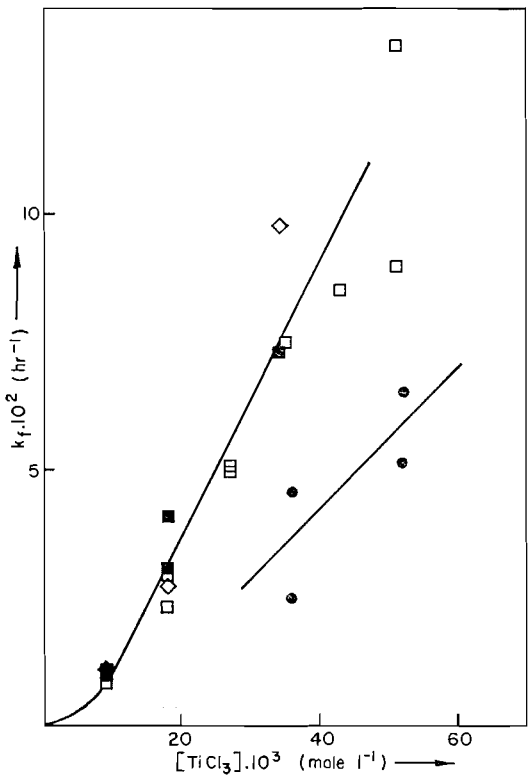

FIG. 2. Plot of k_f versus $[TiCl_3]$; Al:Ti: ● 1.0, □ 2.0, ■ 3.0, ◇ 5.0.

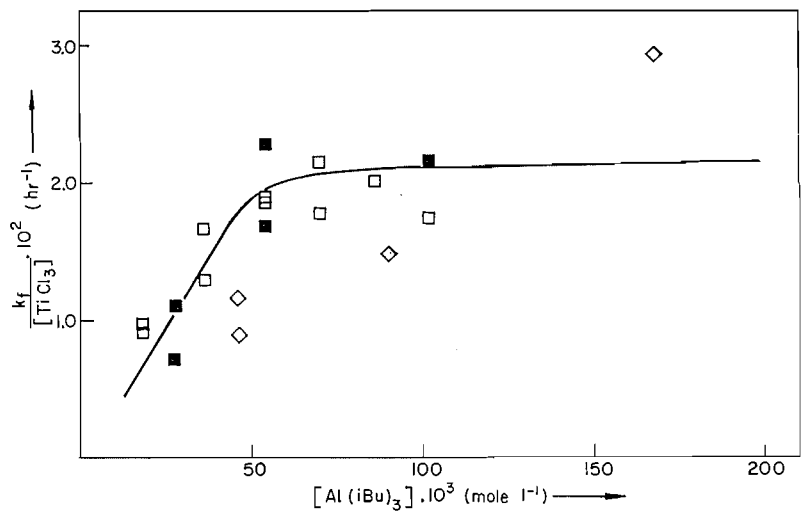

FIG. 3. Plot of $k_f/[TiCl_3]$ versus $[Al(i\text{-}Bu)_3]$; Al:Ti: □ 2.0, ■ 3.0, ◇ 5.0.

that the rate is dependent on $[Al(i\text{-}Bu)_3]$, approaching a constant value in the high range. This provides an explanation for the curvature of the plot of k_f versus $[TiCl_3]$,

since experiments in which the [Al(*i*-Bu)$_3$] is in the low range are also generally those in which the [TiCl$_3$] is in the low range. It may be assumed, therefore, that the rate of polymerization is essentially a linear function of the titanium trichloride concentration.

The apparent dependence of rate on the Al:Ti ratio below values of 2 may also be attributed, at least in part, to the effect of rate dependence on the [Al(*i*-Bu)$_3$] in the low concentration range.

Molecular Weights

The intrinsic viscosities of a number of unfractionated polymer samples are recorded in Table I. In the absence of data on a molecular weight – intrinsic viscosity relationship for poly-1-butene, approximate values of molecular weight for these samples have been calculated from that obtained by Moraglio (8) for polypropylene under identical conditions of solvent and temperature, viz.

$$[\eta] = 1.93.10^{-4}\bar{M}^{0.74}.$$

The effect of polymerization conditions on the molecular weight of the bulk polymer, expressed as a logarithmic function of the intrinsic viscosity ($\log [\eta] \propto \log \bar{M}$), is illustrated in Fig. 4. It is apparent that the molecular weight is essentially independent of

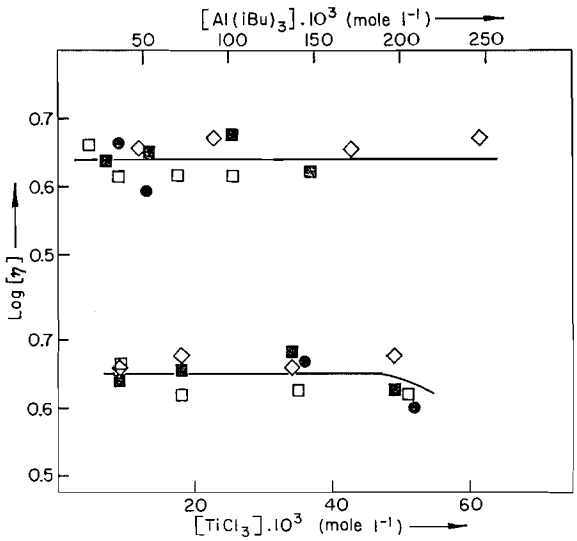

FIG. 4. Plots of log [η] versus [TiCl$_3$] and [Al(*i*-Bu)$_3$]; Al:Ti: ● 1.0, □ 2.0, ■ 3.0, ◇ 5.0.

both the concentration of titanium trichloride and aluminum alkyl. Similarly, it has also been found that the molecular weight is independent of the extent of polymerization, as shown in Fig. 5. In this case the individual points are for reactions carried out under widely different catalyst concentrations and ratios, and the constancy of molecular weight is dependent on the prior condition of no effect of catalyst variables as established above.

An example of the change in molecular weight with the fractions obtained by solvent extraction of a bulk polymer is given in Table III.

Crystallinities

The infrared absorption spectra in the solid and molten states of the tetralin-soluble fractions of poly-1-butene, which should contain the greatest degree of isotacticity, were essentially identical with those reported by Natta (9). Two modifications exist in the solid state, the stable form having absorption bands at 1328, 1060, 1028, 1014, 976, 923, 848, 817, and 799 cm^{-1} which may be attributed to crystallinity. It was confirmed that the unstable modification is obtained on rapid cooling from the melt and it was found that conversion to the stable modification is not complete even after a period of several weeks. Some difficulty was experienced initially in the preparation of samples for optical density measurements in that as much as 40% of the unstable modification could be present if the polymer solution – KCl mixture was allowed to cool too rapidly during removal of the solvent. This is somewhat surprising in view of the pressure used in preparing the pellets, which was well in excess of that reported (9) to give rapid transformation to the stable modification.

The spectra of the ether-soluble fractions showed a complete absence of the crystalline peaks and the samples were assumed, therefore, to consist entirely of amorphous or atactic poly-1-butene. However, it was noted that the spectra were not identical with

those of the molten tetralin-soluble fractions, small differences being observed in the 900–1300 cm^{-1} region. In particular, a broad absorption band occurs at 937 cm^{-1}. This could not be attributed to solvent or catalyst residues and is unlikely to represent an end-group effect, in view of the comparatively high molecular weight of these fractions.

The crystalline contents of a series of unfractionated polymers are given in Table I. These were determined from optical density measurements using the strongest crystalline absorption band at 923 cm^{-1}. The calibration curve was prepared from synthetic mixtures of the ether-soluble or atactic polymer and the tetralin-soluble polymer. The latter was assumed to be 100% isotactic and, hence, to exhibit the maximum degree of crystallinity under the conditions of measurement. The optical densities of these fractions from different polymerization experiments were constant within the experimental accuracy (Table III).

The effect of polymerization conditions on crystallinity is shown in Fig. 6. Essentially, it is independent of both the titanium trichloride and aluminum triisobutyl concentration. There is some evidence of a trend to higher values with increasing concentration

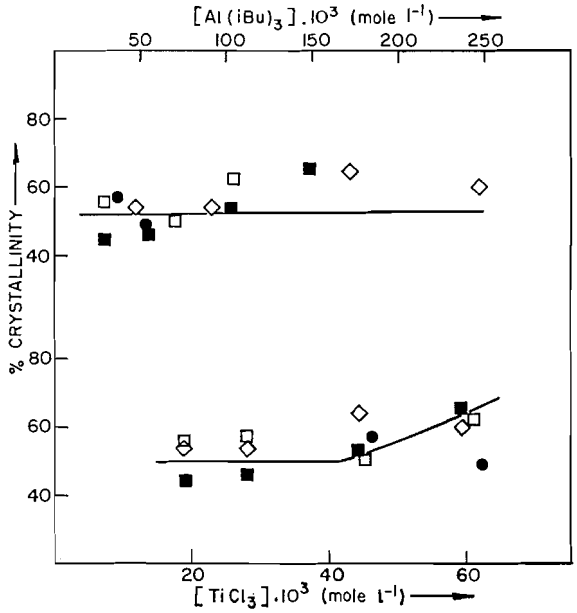

FIG. 6. Plots of % crystallinity versus $[TiCl_3]$ and $[Al(i\text{-}Bu)_3]$; Al:Ti: ● 1.0, □ 2.0, ■ 3.0, ◇ 5.0.

of the catalyst components but this probably represents a reflection of the small increase in crystallinity with the extent of polymerization as illustrated in Fig. 5. Higher yields of polymer were obtained with increasing titanium trichloride concentration.

Infrared analysis of some of the heptane-soluble fractions, Table III, gave crystallinity values of 60–70%, and the presence of the absorption band at 937 cm^{-1} indicated that the samples contained atactic polymer or atactic segments in the polymer chains. On the assumption that the crystalline content of these fractions is 65% and that of the tetralin-soluble fractions is 100%, crystallinity values have also been determined from the fractionation data listed in Table I. These fall in the range 58–72% and, as with the results for unfractionated polymer samples, are essentially independent of the polymerization conditions.

DISCUSSION

For the present catalyst system it has been shown that there are two segments to the overall polymerization curve, which may be termed the initial and steady-state periods, the rate during the latter being several fold greater. Also, the length of the initial period is determined by the amount of polymer formed for a given titanium trichloride concentration and is independent of the concentration of aluminum alkyl (Table II).

With heterogeneous catalysts of this type it is generally considered that polymerization occurs at active sites on the surface of the trichloride crystals (3, 10, 11). Thus, the increase in rate constant on the change to the steady-state period can be attributed to a breakup of the titanium trichloride crystals, revealing fresh surfaces at which additional polymerization centers can form by adsorption and complex formation with the excess aluminum alkyl present in the solution. The fact that the change in rate occurs at a fixed ratio of polymer to titanium trichloride suggests that cleavage of the crystals results from forces exerted by the polymer as it builds up on the catalyst surface, once a critical level is exceeded. This process of particle breakdown appears to take place in a uniform manner to provide a constant increase in surface area (more specifically of active sites) since the ratio of the rate constants for the initial and steady-state periods is independent of both the absolute rate and the titanium trichloride concentration. The occurrence of an initial adjusting period after which the rate of polymerization reaches a steady value has been noted with comparable catalyst systems (7, 12) and has been attributed to a similar cause (12).

For the steady-state period, it has been established that the rate is proportional to both the concentration of monomer and that of the titanium trichloride. In the case of the latter it is obvious that the relationship is not one of concentration but of surface area, since the system is heterogeneous, and the linear dependence of rate can be interpreted as the formation of a constant number of catalytic sites for each unit of available surface. Similarly, the trend in the values of $k_t/[TiCl_3]$ towards a constant level with increasing $[Al(i\text{-}Bu)_3]$ may be attributed to an approach to the condition of saturation of all potential polymerization sites on the surface. A similar kinetic pattern has been reported for the polymerization of propylene and styrene with $TiCl_3$–$AlEt_3$ catalysts (6, 7, 13), although the limiting condition of independence of rate on the metal alkyl concentration extends to much lower levels.

The higher rates observed with titanium trichloride samples containing residual amounts of tetravalent titanium appear to be related to the formation of a greater number of active sites on the trichloride base, as catalysts prepared from titanium tetrachloride at the impurity levels encountered are inactive.

Polymerization by Ziegler–Natta type catalysts is generally considered to proceed by an anionic mechanism and several possible steps have been suggested for the termination of growing polymer chains (13), viz.,

(i) direct intramolecular termination at the catalyst site by hydride ion transfer:

$$\overset{\delta+\ \delta-}{\text{cat. } CH_2CH(C_2H_5)\cdots} \rightarrow \overset{\delta+\ \delta-}{\text{cat. H}} + CH_2{=}C(C_2H_5)\cdots;$$

(ii) hydride ion transfer involving monomer:

$$\overset{\delta+\ \delta-}{\text{cat. } CH_2CH(C_2H_5)\cdots} + CH_2{=}CH(C_2H_5) \rightarrow \overset{\delta+\ \delta-}{\text{cat. } CH_2CH_2C_2H_5} + CH_2{=}C(C_2H_5)\cdots;$$

(iii) chain transfer involving metal alkyl:

$$\overset{\delta+\ \delta-}{\text{cat. CH}_2\text{CH}(\text{C}_2\text{H}_5)\cdots} + \text{AlR}_3 \rightarrow \overset{\delta+\ \delta-}{\text{cat. R}} + \text{R}_2\text{AlCH}_2\text{CH}(\text{C}_2\text{H}_5)\cdots;$$

(iv) a chain transfer process that is kinetically dependent on $[TiCl_3]$.

Process (iv) may be neglected, as the intrinsic viscosities of the polymers and, consequently, the molecular weights were found to be independent of the concentration of titanium trichloride. Hence the average polymeric chain length can be expressed in the form

$$\bar{P} = k_p[M]/(k_{t_1}+k_{t_2}[M]+k_{t_3}[A]),$$

where k_p, k_{t_1}, k_{t_2}, and k_{t_3} are the rate constants for propagation and termination by steps (i) to (iii), and [M] and [A] are the concentrations of monomer and aluminum alkyl. It follows that the reciprocal of the chain length is

$$1/\bar{P} = k_{t_1}/k_p[M]+k_{t_2}/k_p+k_{t_3}[A]/k_p[M].$$

This expression applies strictly to instantaneous rates or, in practice, to low polymer yields. However, the effects of the different termination steps will be apparent in the molecular weight of the polymer, at least qualitatively, over the range of yields encountered. As no significant influence on the intrinsic viscosity was noted with changes in the aluminum alkyl concentration, it may be assumed that the predominant termination reactions are processes (ii) and (iii) and that

$$k_{t_2}+k_{t_1}/[M] \gg k_{t_3}[A]/[M]$$

for the conditions employed. The range of average monomer concentrations encompassed, as reflected in the extent of polymerization, is small, but the constancy of molecular weight with polymer yield suggests that termination by monomer transfer (process (ii)) is favored.

In this simple analysis it has been assumed that the concentrations of the species involved in termination processes are those of the solution phase. The same conditions will be met for adsorbed species provided the concentrations in solution are linearly related to those in the adsorbed phase. This situation will apply for the limiting condition of low surface coverage in a Langmuir-type adsorption isotherm. The fact that the rate of polymerization is proportional to the monomer concentration supports this contention.

The influence of polymerization conditions on the crystallinity of the poly-1-butene is small. In this particular case, crystallinity is considered to represent the degree of stereoregularity in the polymer chains, although there may be no simple relationship between the two factors. Thus, the isotactic content of the polymer is also largely unaffected by polymerization variables. Similar observations have been reported for the polymerization of propylene (6). Chemical and X-ray analyses of the solid phase of the present catalyst system have shown (5) that it consists essentially of unchanged titanium trichloride with a small residual content of aluminum and alkyl groups, and it has been proposed (3, 10, 11) that the active sites for polymerization with such catalysts are locations on the crystal surface where the metal alkyl is adsorbed or enters into complex

formation with a particular configuration which provides steric control during the propagation step. In terms of this model, the relative constancy of the crystalline content of the polymer with the extent of polymerization implies that the configuration of the active centers formed on the new surfaces, revealed by breakdown of the titanium trichloride crystals during polymerization, is essentially the same as that present initially. Similarly, the nature of the sites is not affected by the aluminum alkyl concentration. The slight increase in crystallinity at high conversions may reflect a change in the nature of the complexes due to transfer.

IONIZATION OF ORGANIC COMPOUNDS

IV. STUDIES OF ETHANOL AND ETHYL ETHER IN SULPHURIC ACID BY NUCLEAR MAGNETIC RESONANCE

J. T. EDWARD, J. B. LEANE,[1] AND I. C. WANG
Department of Chemistry, McGill University, Montreal, Que.

Received March 20, 1962

ABSTRACT

The chemical shift of the methyl protons relative to the methylenic protons of an ethyl group attached to a basic center increases with the acidity of the medium. This increase may be attributed to two effects: over a relatively narrow range of acidity function (H_0) values, to protonation of the basic center; over the complete H_0 range investigated, to a general solvent effect, which may be due to changing strengths of hydrogen bonds between the basic center or its conjugate acid and solvent water molecules. Protonation constants (pK_{BH^+}) of -1.1 for propionamide and -6.9 for propionic acid have been calculated, in good agreement with values obtained by the ultraviolet spectrophotometric method; the constants calculated for diethyl ether (-6.2) and ethanol (-4.8) are much less certain, because of the greater magnitude of the solvent effect with these compounds.

INTRODUCTION

The basicities of many aromatic compounds in aqueous acids have been determined since 1935 by Hammett's spectrophotometric method (1). However, the application of this method to aliphatic compounds has been restricted by their feeble absorption in the conveniently accessible range of ultraviolet frequencies (2–4), and new methods for following the ionization of such compounds are needed. Arnett and Wu (5) have made use of solubility changes attendant on the protonation of ethers for determining their basicities, and in the present work we have attempted to use nuclear magnetic resonance to follow the ionization of compounds having an ethyl group attached to the ionizing center. It is known that the difference in chemical shift of the methyl and methylenic protons of ethyl compounds CH_3CH_2X (which, following Stone (6), we shall term the "internal chemical shift" and symbolize by δ_1) is an approximately linear function of the electronegativity of the atom of X directly bonded to the ethyl group (7). Consequently, it can be expected that protonation of X will lead to a large increase in this difference. This expectation has been realized,* although it has become apparent that δ_1 is not only a sensitive index of protonation but also of other forms of interaction with the solvent.

EXPERIMENTAL

Materials

The purification of propionamide and propionic acid have already been described (4). Reagent grade ethanol, ethyl ether, and ethylamine were used without further treatment.

Procedure

Nuclear magnetic resonance spectra of approximately 3% solutions of the organic compounds in acid were measured at room temperature (ca. 23°) as soon as possible (10–15 minutes) after mixing of the solutions, using a Varian V4300-B high-resolution spectrometer operating at 60 Mc/sec. The chemical shift (δ_1) between the centers of the methyl triplet and the methylene quadruplet was measured to ± 0.5 c.p.s., the recorder trace being calibrated by the side-band technique using a Hewlett–Packard frequency counter. In most cases four to six measurements of δ_1 were made, alternately with increasing and decreasing

**Stone and his collaborators (6) have recently observed a similar effect when X is coordinated with a Lewis acid.*

field. The concentration of acid in the solutions was determined by titration, and the H_0 values read from large-scale plots of H_0 against acid concentration constructed from the data of Paul and Long (8).*

RESULTS AND DISCUSSION

The internal chemical shifts of ethanol, ethylamine, and propionic acid in dilute aqueous solution (Table I) are close to the values found by Dailey and Shoolery (7) for the compounds in 50% benzene solution. As expected, δ_i of these and the other compounds

increases with increasing acidity of the medium, and, furthermore, plots of δ_i against the acidity function H_0 (8) of the solvent give sigmoid curves, characteristic of the protonation of neutral Brønsted bases, as shown in Figs. 1 and 2. The pK_{BH^+} values in Table I have

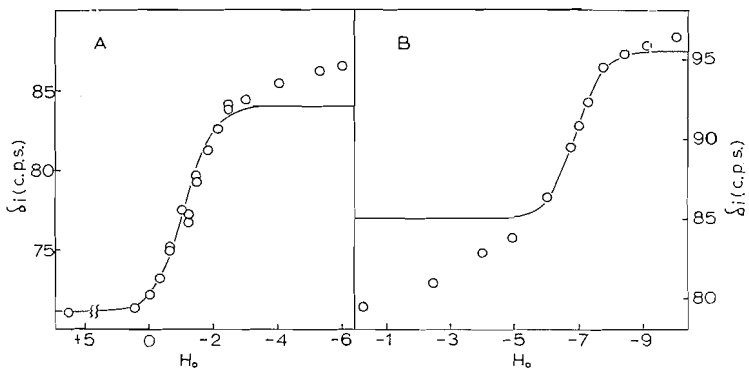

FIG. 1. Change in internal chemical shift (δ_i) with acidity. Points: experimental; curves: theoretical for equation [1], with parameters shown. A. Propionamide: $pK_{BH^+} = -1.1$, $\delta_i^{EtX} = 71.2$ c.p.s., $\delta_i^{EtXH^+} = 84.0$ c.p.s. B. been obtained from the H_0 values of the inflection points of these curves, this method having been shown previously to give the most reliable values (4). The protonation

**Such H_0 values strictly refer to aqueous solutions of acid containing extremely small concentrations of Brønsted base, comparable to the concentrations of indicators used in determining them (8). In the present studies the sulphuric acid is diluted by water plus organic compound, rather than water alone; when the organic compound is a stronger base than water (e.g. propionamide), this should cause the acidity of the solution to be less than that indicated by the data of Paul and Long. The low concentration of organic compound should make this effect a small one.*

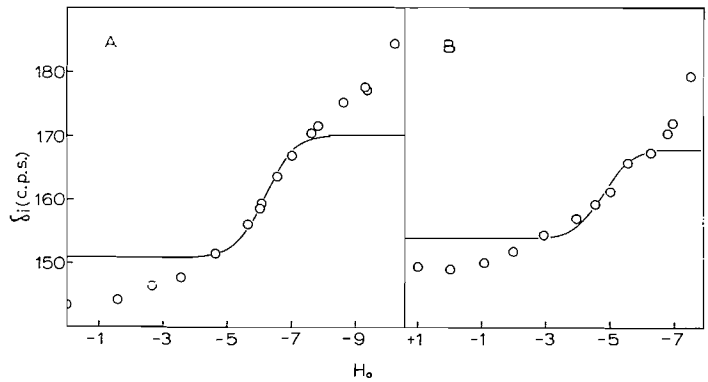

FIG. 2. Change in internal chemical shift (δ_i) with acidity. Points: experimental; curves: theoretical for equation [1], with parameters shown. A. Ethyl ether: $pK_{BH^+} = -6.2$, $\delta_i^{EtX} = 151.0$ c.p.s., $\delta_i^{EtXH^+} = 170$ c.p.s. B. Ethanol: $pK_{BH^+} = -4.8$, $\delta_i^{EtX} = 154.0$ c.p.s., $\delta_i^{EtXH^+} = 168$ c.p.s.

constants thus obtained for propionamide and propionic acid (Fig. 1) are close to the values previously obtained by the spectrophotometric method (4); the slightly weaker basicities found in the present study may be due in part to slight errors in the H_0 values caused by the fact, mentioned above, that the organic compound is present in higher concentrations than usual.

While these results with propionamide and propionic acid show the sigmoid shape of the δ_1–H_0 curves to be due to protonation of the compounds, the curves are very far from the ideal sigmoid shape (Fig. 1) required by the equation

$$[1] \qquad \log (\delta_1-\delta_1^{EtX})/(\delta_1^{EtXH^+}-\delta_1) = pK_{BH^+}-H_0,$$

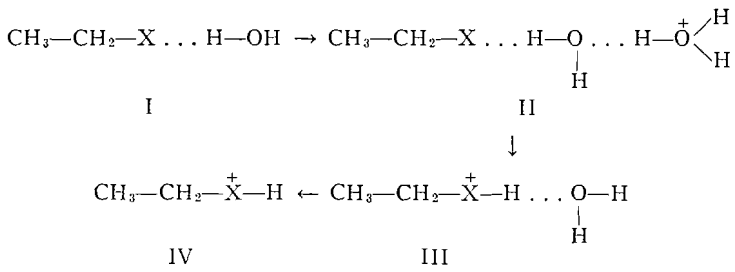
which should describe (with fair precision (4)) the increase in δ_1 with H_0 if it were due to protonation alone. It is evident that, in addition, δ_1 of both neutral and protonated molecules increases continuously with increasing acidity of the medium. A possible explanation of this "solvent effect" is given later. Unfortunately the effect appears even more strongly in the curves for ethyl ether (Fig. 2A) and ethanol (Fig. 2B), and makes the estimation of precise pK_{BH^+} values for these compounds very uncertain; furthermore, the experimental points for ethanol in solutions more acidic than $H_0 = -6$ become progressively less reliable because esterification of the alcohol starts to become appreciable even in the short time required for making n.m.r. measurements after the mixing of the solutions (9). (Ethyl ether, however, is stable under the conditions of these experiments in the most strongly acidic solutions employed (5, 10).) Consequently the pK_{BH^+} value reported in Table I for diethyl ether and, even more, for ethanol can be considered only as highly tentative.

The divergence of our value for the basicity of ethyl ether from that of Arnett and Wu (5) is very large. It is possible that the changes in solubility observed by Arnett and Wu and attributed by them to formation of the protonated species Et_2OH^+ are in fact due to formation of a relatively stable hydrogen-bonded complex $Et_2O \ldots H_3O^+$. Dramatic increases in the solubility of nitrobenzene in sulphuric acid with increasing acidity were noted long ago by Hammett and Chapman (11), and shown not to be due to protonation; they are also probably due to the formation of hydrogen-bonded complexes. Arnett and Wu give reasons for rejecting this possibility, but for the moment it is reasonable to

consider the pK_{BH^+} values of aliphatic ethers unsettled, in the absence of further independent evidence. A pK_{BH^+} of -4.8 for ethanol is of about the magnitude expected from values reported for isopropyl alcohol (-3.2, -4.1) (12) and for *t*-butyl alcohol (-3.8) (13) from kinetic evidence.

The values in Table I of δ_1 of the protonated bases (except ethylammonium) are the values used in the calculation of the theoretical curves of Figs. 1 and 2, and hence, in view of the solvent effect, do not represent the maximum values of δ_1 for $EtXH^+$. However, accepting the values of the table, the increase in δ_1 accompanying protonation of the oxygen atom of ethyl ether (0.44 p.p.m.) is close to the increase accompanying its coordination with boron trifluoride (0.38 p.p.m.) (6). Further, the increase accompanying protonation of the nitrogen atom of ethylamine (0.22 p.p.m.) is almost identical with the increase accompanying the coordination of the nitrogen atom of triethylamine with boron trifluoride (0.23 p.p.m.) (6). It seems likely that about the same positive charge is developed by complexing with boron trifluoride and by protonation. The larger change in δ_1 accompanying the appearance of a positive charge on oxygen, as compared with nitrogen, is perhaps explained by the shorter carbon–oxygen bond length (14).

It is evident from the present work that the protonation of organic compounds may be followed by measurements of the internal chemical shift, but that the usefulness of the method is impaired by the magnitude of the solvent effect. Some understanding of this effect is, in consequence, desirable. At the moment only a tentative explanation for it can be advanced. It has been observed in spectrophotometric studies that donor molecules such as aliphatic ketones (3), propionic acid (4), and propionamide (4) form progressively stronger hydrogen bonds with the solvent as the acid concentration is increased, possibly with water molecules occupying the first (e.g. II) or second hydration layer of the oxonium ion. The increased strength of the hydrogen bond in going from I to II would be expected



to increase the inductive effect of X, and hence to increase δ_1 of the unprotonated molecules. On the other hand, after protonation, the group XH^+ becomes the acceptor, and the oxygen of the free water molecules, the donor, as in III. With continued increase in acid strength the activity of the water decreases (15) and the hydration of protonated bases decreases (4, 16), shown schematically in III $\rightarrow$ IV. The hydration of XH^+ in III represents a slight neutralization of the partial positive charge on the hydrogen, and hence a diminution of the electron pull of the XH^+ group, so that progressive decrease in hydration (III $\rightarrow$ IV) should lead to an increase in δ_1 of the protonated molecule. The smaller solvent effects noted with the conjugate acids of propionic acid and propionamide may be due to the greater degree of charge dispersal in these compounds, with the result that hydration is less important.

Very recently Taft and Levins (17) have determined the pK_{BH^+} of *p*-fluorobenzamide and *p*-fluoroacetophenone from the change with increasing acidity in the position of the

F^{19} nuclear magnetic resonance lines, measured relative to an external standard. It was evident that the unshielding of the fluorine nuclei with increasing acidity was due to a solvent effect in addition to protonation of the carbonyl groups.

THE HYDROGEN ISOTOPE EFFECT IN THE PYROLYSIS OF ETHYL-1,1,2,2-d_4 CHLORIDE[1]

ARTHUR T. BLADES, P. W. GILDERSON, AND M. G. H. WALLBRIDGE
Research Council of Alberta, Edmonton, Alberta

Received February 16, 1962

ABSTRACT

The hydrogen isotope effect in the pyrolysis of ethyl-1,1,2,2-d_4 chloride has been investigated in the temperature range 758–989° C, yielding the relative rate constant expression

$$k_H/k_D = 1.16e^{985\pm50/RT},$$

where k_H and k_D are the rate constants for the production of C_2D_4 (and HCl) and of C_2D_3H (and DCl) per β-deuterium atom respectively.

The isotope effect is pressure dependent, its value increasing with decreasing pressure. The pressure effect in ethyl chloride has also been studied, and a qualitative explanation is given for the pressure dependence of intermolecular and intramolecular isotope effects.

The data are compared with the isotope effects in ethyl-d_4 bromide and ethyl-d_4 acetate, and the conclusion is reached that the evidence supports a four-centered transition-state complex in the case of the halides.

INTRODUCTION

The thermal decomposition of ethyl chloride is believed to be an example of a unimolecular reaction. Barton and Howlett (1) have shown that it decomposes into ethylene and hydrogen chloride in the stoichiometric ratio, and that increases in surface area and addition of propylene have no influence upon the kinetics. They concluded, therefore, that the mechanism does not involve a radical chain, but rather is a simple, homogeneous, unimolecular process. Further investigation by Howlett (2) has revealed that the rate constants are pressure dependent in the pressure region below 1 cm Hg.

The deuterium isotope effect in the pyrolysis of ethyl chloride is of interest because a carbon–hydrogen bond is being broken in the course of the reaction, and because the reaction is pressure dependent. In recent years, a number of isotope effects have been shown to be pressure dependent. R. E. Weston, Jr. (3), investigating the decomposition of cyclopropane-*t*, has observed a decrease in the isotope effect with lowering of pressure, and Langrish and Pritchard (4) have found a similar pressure effect in the pyrolysis of cyclobutane and octadeuterocyclobutane. Further, Blades (5) has demonstrated that the isotope effect in the cyclopropane–cyclopropane-d_6 decomposition is pressure dependent, the isotope effect at 482° C decreasing from 1.96 at 75 cm Hg to 1.35 at 0.0178 cm Hg.

The present work involves a re-examination of the pressure effect in the decomposition of ethyl chloride, and a study of the isotope effect in ethyl-1,1,2,2-d_4 chloride from the standpoint of its variation with pressure and temperature coefficient. If the generally accepted mechanism involving a four-centered transition state is correct, elimination from the ethyl-1,1,2,2-d_4 chloride molecule can yield two product ethylenes—C_2D_4 and C_2D_3H—from whose ratio the intramolecular isotope effect may be derived. The pressure dependency of this isotope effect is especially interesting because all the previously reported variations of isotope effects with pressure have involved intermolecular comparisons.

[1]*Contribution No. 175.*

EXPERIMENTAL

A conventional toluene carrier gas flow system, as has been described previously (6), was used for the investigation of the pressure effect in the pyrolysis of ethyl chloride. The hydrogen chloride produced was trapped at −196° C and titrated with standard 0.1 *N* sodium hydroxide, and the pressures, ranging from 1 to 6 cm Hg, were measured on a mercury – dibutyl phthalate magnifying manometer.

In the pyrolysis of ethyl-1,1,2,2-d_4 chloride, the same apparatus was used, with a large reaction cell being substituted at low temperatures to increase the contact time, as was done in the ethyl acetate study (7). In this flow system, the pressure was varied from 0.68 to 2.88 cm Hg. To extend the pressure range, a number of uninhibited static runs were performed in a seasoned vessel between the average pressures of 0.067 and 16.61 cm Hg.

The reaction products for all the flow runs were passed successively through traps at −80° C and −196° C. The contents of the latter trap, and all the contents of the reaction cell in the case of the static runs, were chromatographed on a silica gel column, using hydrogen as the carrier gas. It was shown by a separate experiment that the ratio of product ethylenes (C_2D_3H/C_2D_4) was unchanged by this treatment.

The ethylenes produced were analyzed on a mass spectrometer using the parent peaks 31 and 32 in the spectrum and correcting for the carbon-13 content of the ethylenes. A further small correction was introduced, as in the ethyl-1,1,2,2-d_4 acetate investigation (7), for production of C_2D_3H from impurities in the "99% deuterated as indicated" reactant.

RESULTS

(a) Ethyl Chloride

The effect of pressure on the first-order rate constant of ethyl chloride at 922.5° K is shown in Fig. 1.

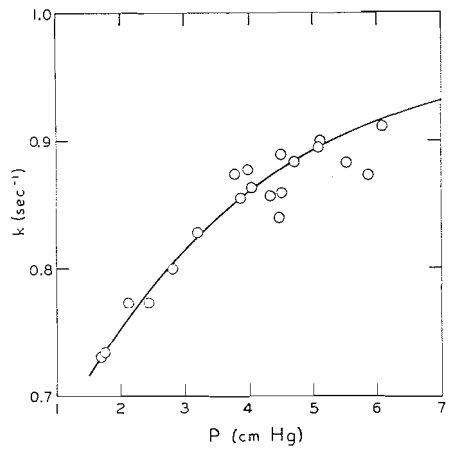

FIG. 1. The effect of pressure on the first-order rate constant (sec^{-1}) of ethyl chloride at 922.5° K.

(b) Ethyl-1,1,2,2-d_4 Chloride

The data for the effect of pressure on the isotope effect in ethyl-1,1,2,2-d_4 chloride are plotted in Fig. 2, indicating an increase in the isotope effect as the pressure is lowered. In this graph, the isotope effect, equivalent to twice the ratio of C_2D_4/C_2D_3H due to the multiplicity of β-deuterium atoms, is shown for both static and flow experiments. The flow experiments, being carried out at 857.6° K, have been corrected to the same temperature as the static experiments (831.9° K) by the use of the temperature coefficient of the isotope effect,

$$k_H/k_D = 1.22e^{985\pm50/RT},$$

derived from the data shown in Fig. 3. These data were obtained over the temperature range 758–989° K and has been normalized to a pressure of 1.80 cm Hg. Indications from

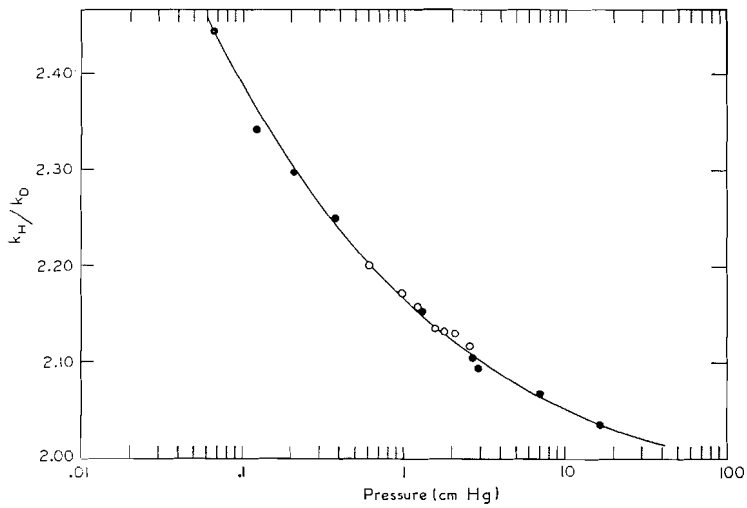

FIG. 2. The effect of pressure on the intramolecular isotope effect in ethyl-1,1,2,2-d_4 chloride at 831.9° K. ○, flow runs; ●, static runs.

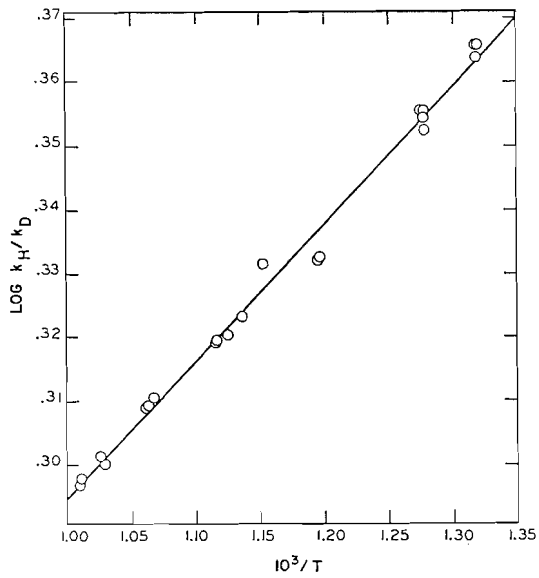

FIG. 3. The temperature dependence of the isotope effect in ethyl-1,1,2,2-d_4 chloride at 1.80 cm Hg pressure.

the pressure effect curve suggest that this effect is about 5% above that at infinite pressure, and the effect at infinite pressure would be given by

$$k_H/k_D = 1.16e^{985\pm50/RT}.$$

DISCUSSION

The Pressure Effects

Throughout our pressure range, the first-order rate constant for ethyl chloride is affected by pressure. However, the results from above 4 cm Hg are erratic, suggesting that the high-pressure limit of our technique has been reached at this pressure. This is

rather unfortunate, for the so-called critical pressure falls outside the range of not only our technique, but also that of Howlett, for he says (2) "that with (his) apparatus, the critical pressure was too low to allow a more quantitative study of the low pressure region". The critical pressure of 8 mm Hg that he does tentatively put forward is considerably lower than what might be expected from our data, which indicates that there is still curvature in the k vs. p plot at 6 cm Hg. Indeed, the fact that the isotope effect is still changing in the pressure region between 7 and 17 cm Hg suggests a "critical" pressure in excess of the former value and possibly greater than the latter. It is also significant that the falloff of the rate constant in ethyl chloride with decreasing pressure is essentially parallel to that observed for ethyl bromide (8).

At this stage it is relevant to give a qualitative explanation that will progressively explain, first the ordinary pressure effect as in ethyl chloride, then the pressure dependence of intermolecular isotope effects, and finally the pressure dependence of intramolecular isotope effects as in ethyl-d_4 chloride.

It has long been known that, if a sufficiently low pressure is attained, any unimolecular reaction will show an apparent increase in order, or, in other words, the value of the first-order rate constant will fall with decreasing pressure. This has been explained by indicating that below a certain pressure, molecular collisions are unable to maintain the equilibrium concentration of highly energized molecules in the energy region above the minimum energy required for reaction. According to the Rice, Ramsberger, and Kassel (R.R.K.) Theory and using Benson's (9) notation:

$P(E)$ = the energy distribution of the reactant molecules,
$k(E)$ = the reaction rate function,
$k(E)P(E)$ = the energy distribution of the chemical product,
E^* = the minimum energy required for the molecule to react,

when the pressure is drastically reduced, $P(E)$ is diminished in the energy region above E^* since the energetic molecules lost by reaction are not maintained at their equilibrium concentration by the decreased rate of collisional processes. Hence, the product distribution $k(E)P(E)$ is reduced below the high-pressure value, and thus the first-order rate constant decreases with decreasing pressure below the so-called critical pressure, as was found in the case of the ethyl chloride decomposition.

This simple model can be extended to account for the pressure effect in an intermolecular isotope effect (see Fig. 4). The areas under the product curves $(k(E)_HP(E)_H$

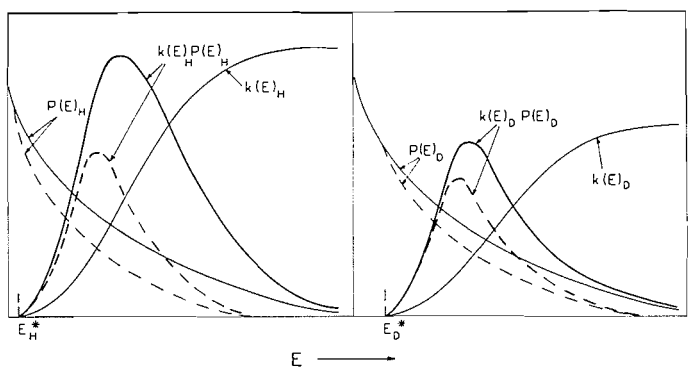

FIG. 4. The effect of pressure on an intermolecular isotope effect—graphical representation of the reaction rate functions for a hydrogen compound, $k(E)_H$, and for a deuterium compound, $k(E)_D$, the classical energy-distribution functions for the hydrogen and deuterium reactants, $P(E)_H$ and $P(E)_D$, in the region of E^*, and their products: $k(E)_HP(E)_H$ and $k(E)_DP(E)_D$.

and $k(E)_D P(E)_D$, solid lines) represent the rates for the hydrogen and deuterium compounds respectively at high pressure; their ratio is the isotope effect. At lower pressures (broken lines), the energy distribution curves, $P(E)_H$ and $P(E)_D$, deviate from the equilibrium high-pressure curves, this deviation becoming increasingly important with increasing energy due to the increase in the $k(E)$ curves with increasing energy. This results in product curves of similar shape, but with the maxima shifted to lower energies, the change in relative areas determining the direction of the trend of the isotope effect with pressure. Since the distortion of the $P(E)$ curves is due to reaction, the relative change in $P(E)_H$ and $P(E)_D$ depends on the relative shapes of the $k(E)_H$ and $k(E)_D$ curves. In the region of these curves of importance here, the value of $k(E)$ is influenced by the value of "s", the number of classical oscillators contributing to activation. As suggested by Rabinovitch, Setser, and Schneider (10), the "s" value for the deuterium compound (s_D) would be higher than that for the hydrogen compound (s_H) due to its more classical behavior and hence the $P(E)_H$ curve is more strongly influenced than the $P(E)_D$ curve by the pressure decrease, and the isotope effect would consequently decrease. This explanation is confirmed by all the available data on the subject.

In the intramolecular isotope effect, the situation is slightly different. The single energy distribution curve (Fig. 5), coupled with the two rate constant curves $k(E)_H$ and $k(E)_D$,

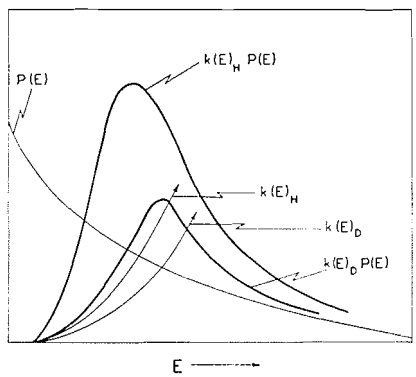

FIG. 5. The effect of pressure on an intramolecular isotope effect—graphical representation of the reaction rate functions $k(E)_H$ and $k(E)_D$ for the rupture of a carbon–hydrogen or a carbon–deuterium bond, the classical energy-distribution function $P(E)$, and their respective products: $k(E)_H P(E)$ and $k(E)_D P(E)$.

combine to give two product curves $k(E)_H P(E)$ and $k(E)_D P(E)$, the deuterium product curve being displaced to higher energies due to the higher activation energy required for this reaction. As the pressure is reduced, the energy distribution curve is more severely affected towards higher energies; the deuterium product, being more dependent on this part of the distribution curve, is thereby proportionately more reduced than the hydrogen product and an increase in the isotope effect results.

While this explanation, based on the R.R.K. Theory, adequately explains the behavior of intramolecular isotope effects, it should also be pointed out that a rate constant independent of the energy in excess of the minimum required for reaction also allows a rise in isotope effect with decreasing pressure, and indeed the arguments are not unrelated. It is also noteworthy that, although the isotope effect increases with decreasing pressure, the overall, and individual, rate constants decrease; in contradistinction to the intermolecular effect, however, s_H is now greater than s_D. This may be qualitatively explained in that when hydrogen is involved in reaction, vibrations involving four deuterium atoms

provide a more classical sink for energy than the three deuteriums and one hydrogen when deuterium is involved in reaction.

The Temperature Coefficient

The magnitude of the isotope effect at 500° C may be compared with the values obtained for similar reactions at the same temperature (see Table I). These values are approximately

TABLE I

High-pressure isotope effects at 500° C

Compound	Isotope effect	Ref.
Ethyl-d_4 chloride	2.20	—
Ethyl-d_4 bromide	2.17	11
Ethyl-d_4 acetate	2.00	7

equal to the "maximum" value to be expected for a reaction in which a carbon–hydrogen bond is essentially broken in the activated complex. From the extreme similarity between the effects in the bromide and chloride, and from the fact that an intermolecular isotope effect is observed in ethyl bromide (8), it may be assumed that this effect occurs in the rate-determining step in the decomposition. This serves as direct support for the generally accepted four-center mechanism for this reaction, in which the carbon–hydrogen and carbon–chlorine bonds are breaking simultaneously with bond formation between hydrogen and chlorine.

To assess the reasons for the differences in the magnitudes of the isotope effects for the ethyl-d_4 chloride, bromide, and acetate, it would be most instructive to consider the individual relative rate expressions:

$$\text{ethyl-}d_4\text{ chloride},\ k_H/k_D = 1.16 \exp(985/RT);$$
$$\text{ethyl-}d_4\text{ bromide},\ k_H/k_D = 1.18 \exp(925/RT);$$
$$\text{ethyl-}d_4\text{ acetate},\ k_H/k_D = 0.99 \exp(1145/RT).$$

Unfortunately, the experimental errors are such that only the differences in isotope effects can be stated with certainty, whereas the differences in the relative rate expression parameters between the halides and the acetate can merely be stated to be probable. It is tempting to associate this latter difference with the fact that the activated complex for the halides is four centered, while the complex for acetate is six centered. The lower temperature coefficient would then imply greater residual and (or) incipient bonding in the activated complex for the halides; this also has the effect of increasing the frequency factor ratio in accordance with observation. However, this would also require a reduced isotope effect, which is not consistent with the facts. Further discussion on this point is fruitless due to the wide variety of sometimes conflicting effects which may come into play.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Mr. J. Stauffer and Mr. F. Vaneldik for their valuable assistance in the mass spectrometric analyses, and to Dr. H. Habgood for his many helpful comments.

THE HYDROGEN ISOTOPE EFFECTS IN THE PYROLYSIS OF ETHYL-1,1,2,2-d_4 BROMIDE AND OF ETHYL-d_5 BROMIDE[1]

ARTHUR T. BLADES, P. W. GILDERSON, AND M. G. H. WALLBRIDGE

Received February 16, 1962

ABSTRACT

The relative rate constant expression has been obtained for the decomposition of ethyl-1,1,2,2-d_4 bromide under inhibiting conditions in the temperature range 697.6 to 999.1° K,

$$k_H/k_D = 1.18e^{925\pm50/RT}.$$

The pressure dependence of the isotope effect has been investigated both with and without inhibitor, and in each case it has been shown that the isotope effect increases with decreasing pressure.

The relative rate constant expression for the ethyl-h_5, ethyl-d_5 bromide comparison was also obtained in the temperature range 730.9 to 964.8° K,

$$k_H/k_D = 0.502e^{2300\pm200/RT}.$$

The isotope effect is again pressure dependent, falling to lower values as the pressure is decreased.

The data are used to demonstrate that the inhibited decomposition of ethyl bromide is primarily a molecular process, and that the rate-controlling step involves a carbon–hydrogen bond break.

A side reaction that produces small amounts of ethane has been observed.

INTRODUCTION

Recent investigations (1–3) of the thermal decomposition of ethyl bromide have suggested that the reaction consists of two components, the first of which is a unimolecular splitting into ethylene and hydrogen bromide, the second being a faster chain reaction initiated by bromine from the interaction of hydrogen bromide and ethyl bromide. The rate of reaction may be reduced to a limiting value by the use of various inhibitors such as cyclohexene, propylene (2), and toluene (4), the conclusion being drawn that by this procedure the second component is eliminated. Further, the fact that no bibenzyl is found in the toluene-inhibited decomposition products has been interpreted (4) as evidence for the absence of radical reactions in the inhibited decomposition.

The results of these investigations have led to the belief that the reaction in the observed induction period in the uninhibited decomposition is identical with the reaction under the influence of inhibitors. Goldberg and Daniels (1) have pointed out that the initial rate during the induction period in their uninhibited experiments is in good agreement with the rate, under inhibited conditions, found by Blades and Murphy (4). Again, Blades (3) has shown that the rate constant of Goldberg and Daniels, when extrapolated to zero pressure, is comparable to the inhibited rate.

Although the relationship of the initial process to the inhibited decomposition may have been established, nevertheless the molecular nature of these reactions has not been unequivocally proved, and has in fact been cast in doubt recently by Wojciechowski and Laidler (6). These authors have suggested that inhibition limits such a reaction, not to a molecular component, but rather to a special type of radical process in which the inhibitor is involved in both the initial and final steps. Thus the absence of bibenzyl in the toluene-inhibited reaction products does not necessarily rule out such a limited chain in this

[1]*Contribution No. 176.*

reaction; neither does the finding of an isotope effect in ethyl-d_5 bromide by Blades (5), for an effect would in all probability be observed in the radical step

$$Br + C_2H_5Br \rightarrow HBr + C_2H_4Br.$$

If it can be shown that the initial step is indeed molecular, there is still a problem to be solved from the current literature on the nature of the transition state. Maccoll and his co-workers (7) have drawn an analogy between the gaseous decomposition of alkyl halides and S_N1 and E1 reactions in solution, concluding that the process is essentially heterolytic. Furthermore, Ingold (8) has gone as far as to suggest that the activated complex is a carbonium ion – halide ion pair, and that in its formation there is "no hydrogen loosening of any kind". However, the finding, by Blades (5), of an intermolecular hydrogen isotope effect on ethyl bromide (2.26 at 500° C) would appear to invalidate Ingold's argument. On the other hand, Maccoll and Thomas (9) have suggested that the β-hydrogen atom acts in a stabilizing capacity similar to the solvent in solution phase S_N1 and E1 mechanisms, allowing the transition state to be represented in essentially the same form as the often-proposed, four-centered complex.

The work reported in this paper is an investigation of the isotope effect in two deuterium-substituted ethyl bromides. In ethyl-1,1,2,2-d_4 bromide the isotope effect has been studied in an inhibited system from the standpoint of its pressure dependency and its temperature coefficient. Further, the isotope effect was examined over a wide range of pressures in an uninhibited system. In the second compound, ethyl-d_5 bromide, the influence of temperature and pressure variations on the isotope effect has again been studied in an inhibited system, using a technique different from that used previously (5) in order to check the unexpected Arrhenius parameters that have been reported.

EXPERIMENTAL

(a) Ethyl-1,1,2,2-d_4 Bromide

The apparatus and experimental procedure were essentially the same as for the ethyl-1,1,2,2-d_4 chloride as reported in the preceding paper.

In the inhibited pressure effect investigation the flow runs were conducted in the range 0.71 to 2.89 cm Hg, while one static run was performed at 20.4 cm Hg using *cis*-butene-2 as the inhibitor. Without an inhibitor, a further six runs were carried out between the average pressures of 0.0424 and 23.4 cm Hg. Data for the temperature coefficient were obtained over the range 697.6 to 999.1° K using the toluene flow system.

The hydrocarbon products were separated on a 24-inch silica gel column by vapor phase chromatography at room temperature, and the product ethylenes (C_2D_4 and C_2D_3H) were collected and analyzed on a mass spectrograph using the parent peaks (32 and 31) in the spectrum. Corrections to the ratios of the peak heights were made for the contributions of carbon-13 to the ethylenes, and for impurities in the reactants, as before (10).

(b) Ethyl-h_5 Bromide/Ethyl-d_5 Bromide Comparison

A gaseous mixture of ethyl-h_5 bromide and ethyl-d_5 bromide was prepared in the approximate ratio 5:1, and introduced from a graduated gas burette through a capillary into the toluene stream. The remainder of the apparatus and technique was essentially the same as for the 'd_4' pyrolyses, one static run (utilizing *cis*-butene-2 as inhibitor) being conducted at 11.4 cm Hg to extend the pressure range in the case of the pressure effect studies. For the temperature coefficient determination, two flow cells were used to enable the decomposition to be studied over the range 730.9 to 964.8° K.

The parent peaks 28 and 32 were used in the mass spectrum to measure the C_2H_4/C_2D_4 ratio. Successive corrections were made for the carbon-13 content of the ethylenes, for the contribution of C_2D_4 to the mass 28 peak, and for the reactant conversions, which were controlled to below 10%. In order to determine the contribution at 28 made by C_2D_4, a sample of C_2D_4 was prepared by pyrolyzing the 99% deuterated ethyl-d_5 bromide (Merck and Co.) in a large excess of toluene and separating as before. The contribution in question was then found on the mass spectrometer for the ionization potential that was used in the analysis of the C_2H_4, C_2D_4 mixtures.

RESULTS

(a) Ethyl-1,1,2,2-d_4 Bromide

The effect of pressure on the intramolecular isotope effect for ethyl-1,1,2,2-d_4 bromide is shown in Fig. 1, where the curves A and B show, respectively, the results of the inhibited

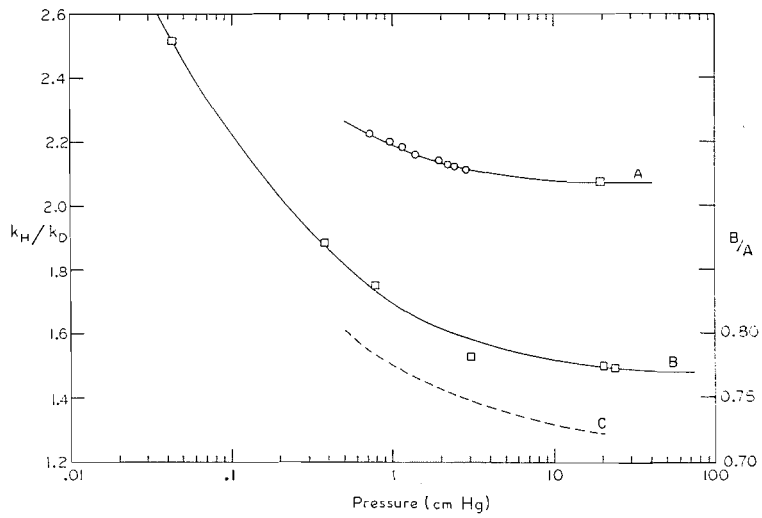

FIG. 1. The effect of pressure on the intramolecular isotope effect in ethyl-1,1,2,2-d_4 bromide at 826.4° K. Curve A shows the effect under inhibiting conditions; curve B, without inhibitor; and curve C is the ratio B/A.

and uninhibited decompositions. Curve C represents the variation in the ratio B/A with pressure, and demonstrates that the isotope effects under inhibiting and uninhibiting conditions converge at low pressures.

Figure 2 is a plot of the temperature coefficient of the isotope effect at 1.80 cm Hg, which may be expressed as

$$k_H/k_D = 1.22e^{925\pm50/RT}.$$

To obtain this expression, the data above 900° K were omitted from the least-squares process, for it is evident that these runs are consistently displaced above the linear plot.

At infinite pressure, the pre-exponential term in the above expression would be lower by about 3%, as indicated by curve A in Fig. 1. Thus the true relative rate expression is

$$k_H/k_D = 1.18e^{925\pm50/RT}.$$

(b) Ethyl-h_5/Ethyl-d_5 Bromide Comparison

The effect of pressure on the isotope effect in this comparison is shown in Fig. 3, which includes data from the previously published pressure effect curves for ethyl bromide and ethyl-d_5 bromide (5). The latter data, obtained at 889° K, were reduced to the temperature of the present investigations (826.4° K) by utilizing the coefficient reported below.

The relative rate constant expression for this comparison at 2.00 cm Hg is

$$k_H/k_D = 0.494e^{2300\pm200/RT},$$

from the data plotted in Fig. 4. The expression at infinite pressure is

$$k_H/k_D = 0.50e^{2300\pm200/RT}.$$

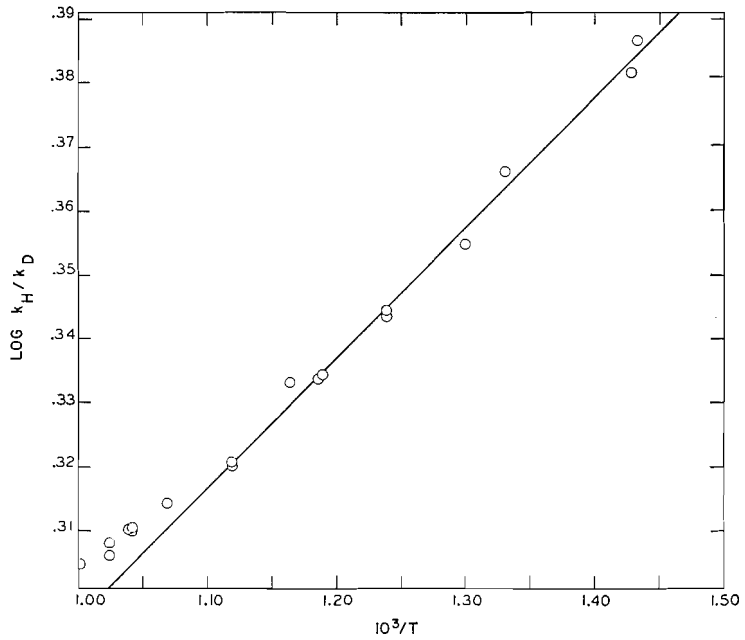

FIG. 2. The temperature dependence of the isotope effect in ethyl-1,1,2,2-d_4 bromide at 1.80 cm Hg pressure.

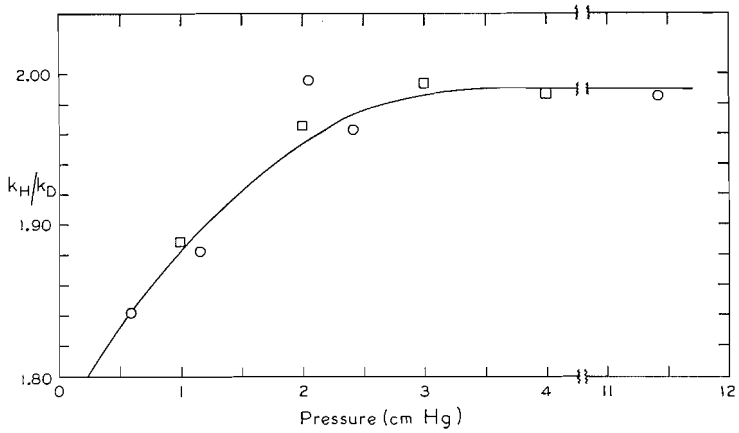

FIG. 3. The effect of pressure on the intermolecular isotope effect in the ethyl-h_5 bromide/ethyl-d_5 bromide comparison at 826.4° K. □, data from ref. 5; ○, results of present investigations.

(c) Ethane

Besides the ethylene, another product appeared in the chromatography of the hydrocarbon products. It was identified as ethane and was found to occur only to the extent of 1 or 2% of the total hydrocarbon products. Samples taken from the pyrolysis products of ethyl-d_5 bromide in toluene vapor were found to be approximately equimolecular mixtures of C_2D_5H and C_2D_6. In the few cases that were examined, no consistent trend could be established between the ratio of ethanes on the one hand, and either the temperature or the partial pressure of the bromide on the other.

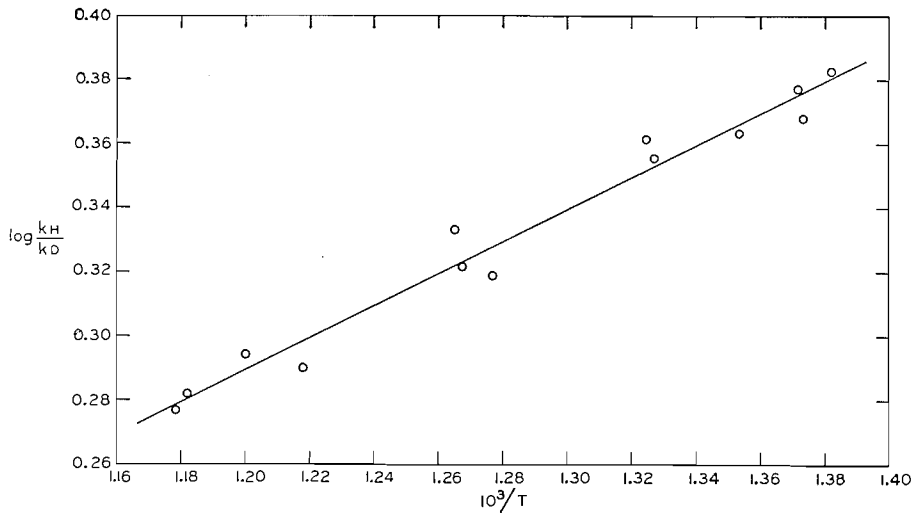

FIG. 4. The temperature dependence of the isotope effect in the ethyl-h_5 bromide/ethyl-d_5 bromide comparison at 2.00 cm Hg pressure.

DISCUSSION

Ethyl-1,1,2,2-d_4 Bromide

There is a great similarity between the isotope effects in the inhibited decomposition of ethyl-1,1,2,2-d_4 bromide and in the uninhibited decomposition of ethyl-1,1,2,2-d_4 chloride. The effects themselves at 500° C are 2.17 for the bromide and 2.20 for the chloride, while the relative rate expressions are:

$$\text{ethyl-}d_4 \text{ bromide, } k_H/k_D = 1.18e^{925/RT};$$
$$\text{ethyl-}d_4 \text{ chloride, } k_H/k_D = 1.16e^{985/RT}.$$

Further, it was demonstrated in the preceding paper that the pressure effects in ethyl bromide and ethyl chloride are almost identical, and this similarity is reflected in the pressure dependences of the isotope effects in the ethyl-d_4 bromide and in the ethyl-d_4 chloride. Not only do the isotope effects rise with falling pressure in both cases (in agreement with the theory postulated for intramolecular isotope effects in the preceding paper), but they do so in an essentially parallel fashion. Furthermore, the combination of these similarities sheds appreciable light on the mechanism of the ethyl bromide reaction.

If the ideas of Wojciechowski and Laidler (6) are applicable to the decomposition of ethyl bromide, then under the influence of inhibitors the reaction is limited to a special type of free-radical process. On this basis, and in addition, assuming the ethyl chloride decomposition to be a truly unimolecular reaction, it would be expected that there would be an appreciable difference in the isotope effects in the inhibited decomposition of ethyl-d_4 bromide and in ethyl-d_4 chloride. It has been shown here that this is not the case. Nevertheless, before rejecting the applicability of Wojciechowski and Laidler's ideas to this system, it is well to question the molecular nature of the ethyl chloride decomposition.

The pyrolysis of ethyl chloride has been considered to be a unimolecular process on the grounds that inhibitors do not affect the rate. It might be argued, however, that in this decomposition a special kind of radical chain is operating which is uninfluenced by inhibitors. Such a process must at the same time explain not only the intramolecular

isotope effect in ethyl-d_4 chloride but also its pressure dependence. Thus, although the chain-propagation reaction

$$Cl + C_2H_5Cl \rightarrow HCl + C_2H_4Cl$$

could produce the former, it would not be expected to account for the latter. It now seems inconceivable that any reasonable reaction scheme can be contrived which will explain the rise in k_H/k_D with decreasing pressure without the major reaction being intramolecular.

Thus far we have shown that the ethyl chloride decomposition is at least a predominantly unimolecular reaction, and it may now be inferred that the great similarities between the ethyl chloride and the maximally inhibited ethyl bromide decompositions indicate that in the latter a molecular reaction at all events has the preeminence. Hence, the only difference between the modes of decomposition of ethyl bromide and ethyl chloride is that in the bromide a radical chain reaction is known to exist in uninhibiting conditions. It now remains to be shown how the results of the uninhibited decomposition of ethyl-d_4 bromide fit into this scheme.

The isotope effect in the decomposition of ethyl-d_4 bromide increases with decreasing pressure over the pressure range studied, and curve C in Fig. 1 indicates that as the pressure is decreased, the isotope effects for the inhibited and uninhibited reactions approach one another. These observations are entirely in agreement with the previously noted (3) tendency for the uninhibited rate in ethyl bromide to approach the inhibited rate at low pressures due to the diminishing importance of the chain reaction. Again, the fact that the isotope effects at high pressure in the inhibited and uninhibited decompositions of ethyl-d_4 bromide are appreciably different adds further weight to the argument that distinct types of mechanism are predominant in each case, for if the source of both isotope effects was the radical-abstraction reaction

$$Br + C_2H_5Br \rightarrow HBr + C_2H_4Br,$$

and if the only difference between the inhibited and uninhibited decompositions was to be found in the length of the chain, then no estimable difference in the isotope effects should be seen.

If the above reaction does represent the chain-carrying step, it is apparent from Fig. 1 that the isotope effect in this reaction is less than 1.5 at 831.9° K. This would suggest that the curvature noted in the temperature coefficient (Fig. 2) cannot arise from a change to a free-radical mechanism in the temperature range above 900° K since this would result in the opposite curvature. If real, this effect may be due to the predicted curvature of such plots at high temperatures (10).

Ethyl-h_5/Ethyl-d_5 Bromide Comparison

The effect of pressure upon this intermolecular isotope effect (Fig. 4) is in accordance with the theory postulated in the preceding paper. It is satisfying that the results of our present investigations are in agreement with data obtained directly from previous work (5), which employed a different technique.

In the temperature coefficient studies there is also good agreement with the earlier results, and it would appear that there is indeed a large secondary isotope effect in this comparison, and that the carbon–hydrogen bond is being broken in the activation process in accordance with a four-centered activation complex.

Ethane

The production of C_2D_6 and C_2D_5H in approximately equal proportions in the inhibited decomposition of ethyl-d_5 bromide suggests that a small side reaction is occurring. The

two ethanes may be formed by a mechanism that involves an exchange reaction between DBr and toluene, occurring via a benzyl radical intermediate:

$$C_2D_5Br \rightarrow C_2D_4 + DBr$$
$$DBr + C_6H_5CH_3 \rightleftharpoons HBr + C_6H_5CH_2D$$
$$DBr + C_2D_5Br \rightarrow C_2D_6 + Br_2$$
$$HBr + C_2D_5Br \rightarrow C_2D_5H + Br_2.$$

The alternate mechanism of ethane production from ethyl radicals arising from the split of ethyl bromide cannot be definitely ruled out. It seems unlikely, however, since the amount of ethane is considerably higher than would be predicted from this reaction, and in any case ethyl radicals are known to decompose under these experimental conditions (11).

In conclusion, it has been shown that the ethyl bromide decomposition involves a radical and a molecular component, the former being largely eliminated under inhibiting conditions. The isotope effects reported are pressure dependent, following the general pattern laid down for such pressure effects in the preceding paper. The isotope effects are also consistent with the four-centered activated complex in which a hydrogen atom is transferring from a carbon atom to a bromine atom in the transition state. A side reaction producing small quantities of ethane has also been observed, and an explanation for the isotopic distribution of the ethane is suggested.

ACKNOWLEDGMENTS

The authors wish to thank Mr. J. Stauffer and Mr. F. Vaneldik for carrying out the mass spectrometric analysis.

DITERPENOID QUINONES OF INULA ROYLEANA D.C.[1, 2]

O. E. EDWARDS, G. FENIAK,[3] AND M. LOS[3]
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received March 16, 1962

ABSTRACT

Three related diterpenoid quinones, royleanone, 9-acetoxyroyleanone, and 9-dehydroroyleanone, have been isolated from the roots of *Inula royleana* D.C. These have been assigned structures on the basis of degradation studies and the synthesis of royleanone from ferruginol.

The plant *Inula royleana* D.C. is a perennial shrub that grows in the western Himalayas at altitudes of 7,000 to 11,000 ft above sea level. It is considered to be poisonous and has been used as an insecticide and a disinfectant (1). Its roots have been shown to be rich in derivatives of the diterpenoid alkaloid lycoctonine (2–4). In addition, the presence of a yellow pigment has been reported (5). This pigment we now show to consist mainly of a mixture of diterpenoid quinones which we call 'royleanones'. The major component was an acetoxyroyleanone (I) ($C_{22}H_{30}O_5$). Small quantities of royleanone (IV) ($C_{20}H_{28}O_3$) and a dehydroroyleanone (III) ($C_{20}H_{26}O_3$) were also present. That these compounds were structurally closely related will become apparent in the sequel.

We first concerned ourselves with establishing the nature of the chromophoric system in royleanone. The compound was acidic (pK_a 8.5 in 50% aqueous methanol) and its alkaline solution was magenta in color. It reacted with diazomethane to give a monomethyl derivative. Royleanone took up 1 mole of hydrogen on catalytic hydrogenation and the colorless product was converted back to royleanone on standing in the presence of air. These properties, and the ultraviolet spectrum of royleanone, which was very similar to those of hydroxybenzoquinones (6), suggested that royleanone contained this unit. The hydrogen-bonded hydroxyl band ($\nu_{max}^{CHCl_3}$ 3350 cm^{-1}) and the two low-frequency carbonyl bands ($\nu_{max}^{CHCl_3}$ 1672 and 1632 cm^{-1}) in the infrared spectrum fitted this assignment. Finally, the reductive methylation of royleanone methyl ether (IX) to a trimethoxybenzene (VII) (λ_{max}^{EtOH} 208 mμ, ϵ 49,000, 281 mμ, ϵ 740) furnished conclusive evidence that royleanone was a hydroxybenzoquinone.

The structural relationship between royleanone, the dehydroroyleanone, and the acetoxyroyleanone was established as follows. Catalytic hydrogenation of the dehydroroyleanone (2 moles of hydrogen were taken up) followed by oxidation of the product by air gave royleanone. This indicated that dehydroroyleanone differed from royleanone only in having an additional double bond. A comparison of the ultraviolet spectra of royleanone (λ_{max}^{EtOH} 277, 283 (shoulder), and 403 mμ) and the dehydroroyleanone (λ_{max}^{EtOH} 212, 247 (shoulder), 330, and 459 mμ) showed that this double bond was conjugated with the quinone ring.

The similarity between the ultraviolet absorption spectra and many features of the infrared absorption spectra of acetoxyroyleanone and royleanone led us to believe that these compounds were related. The presence of an ester grouping in the acetoxyroyleanone was indicated by the carbonyl band at 1748 cm^{-1} in its infrared spectrum. In addition

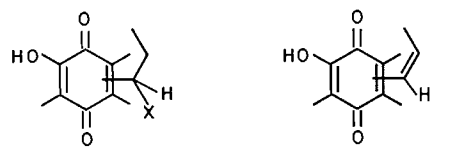
[3]*National Research Council of Canada Postdoctorate Fellow.*

the n.m.r. spectrum of acetoxyroyleanone methyl ether had an unsplit methyl signal[4] at τ 8.05 and a signal from a strongly deshielded single hydrogen at τ 4.25. These are consistent with the presence of a secondary acetoxyl group. The presence of the acetoxyl was confirmed by hydrolysis of the acetoxyroyleanone to acetic acid and an alcohol (II). Dehydration of II with *p*-toluenesulphonic acid in boiling xylene gave a compound identical with the natural dehydroroyleanone described above. Hence the acetoxyl was probably α or β to the quinone ring. Catalytic hydrogenation of acetoxyroyleanone (2 moles of hydrogen were taken up) followed by oxidation of the product with air gave royleanone. Such facile hydrogenolysis of the acetoxyl is compatible only with its being allylic or benzylic. Since there was no evidence for any unsaturation other than that in the quinone system, the acetoxyl was assigned to a carbon directly attached to this ring.

We were surprised to find that the acetoxy group of acetoxyroyleanone could be removed not only by catalytic hydrogenation but also by the action of sodium borohydride in methanol at room temperature. To our knowledge such a cleavage has not been previously reported.

There were no signals at lower field that τ 5.95 in the n.m.r. spectrum of royleanone methyl ether, showing that there were no hydrogens attached to the quinone ring. This evidence combined with the correlations described above allowed us to assign the following partial structures to the royleanones. As has been shown above, the differences in the partial structures are the only differences between these compounds.



ROYLEANONE X = H
ACETOXYROYLEANONE X = OAc

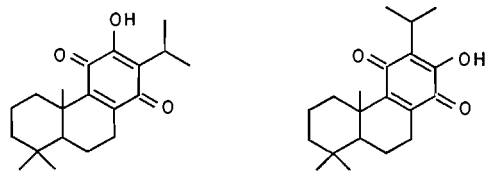
DEHYDROROYLEANONE

Evidence for the remaining structural features was obtained by oxidation of dehydroroyleanone and royleanone. Alkaline hydrogen peroxide oxidation of either of these compounds gave rise to isobutyric acid. Since the oxidation conditions were relatively mild, this proved that an isopropyl group was attached to the quinone ring. Since isobutyric acid was obtained in both cases, the double bond in the dehydroroyleanone and consequently the acetoxyl group in the acetoxyroyleanone were not associated with the isopropyl group.

Oxidation of the dehydroroyleanone with alkaline potassium permanganate resulted in low yields of 1,3,3 trimethylcyclohexane-1,2-dicarboxylic acid (V). The assignment of structure to the latter compound was based on the n.m.r. spectrum of its methyl ester. The significant features of the latter were three unsplit C—CH_3 signals (τ 9.2, 9.15, 8.95), an unsplit signal (τ 7.1) which corresponded to a single hydrogen, and two unsplit O—CH_3 signals (τ 6.4, 6.35).

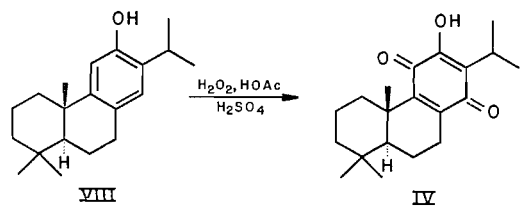
Only two structures for royleanone are compatible with the degradation products described above and the presence of signals due to an allylic hydrogen (τ 7.8) and two vinyl hydrogens (τ 3.4, 3.2) in the n.m.r. spectrum of the methyl ether of the dehydroroyleanone. The two possibilities are shown below.

[4]*The chemical shifts are given in τ values, following G. D. Tiers, J. Phys. Chem.* **62**, *1151 (1958). The n.m.r. spectra were of ca. 10% carbon tetrachloride or chloroform solutions with tetramethylsilane as an internal reference.*



An attempt to distinguish between these two by dehydrogenation of royleanone was unsuccessful. Under the conditions required to complete the dehydrogenation the isopropyl group was lost. The isolation of small amounts of 1-methylphenanthrene (VI), however, supplied confirmation that one of these two structures was correct.

The structure of royleanone was finally proved to be IV by synthesis from ferruginol (VIII), a substance whose structure and absolute configuration have been firmly established (for leading references, see ref. 7). Oxidation of ferruginol with 98% hydrogen peroxide in acetic acid with sulphuric acid as catalyst gave a 7% yield of royleanone with optical rotation and other physical properties identical with those of the natural substance. The low conversion is probably due to the presence of two benzylic positions



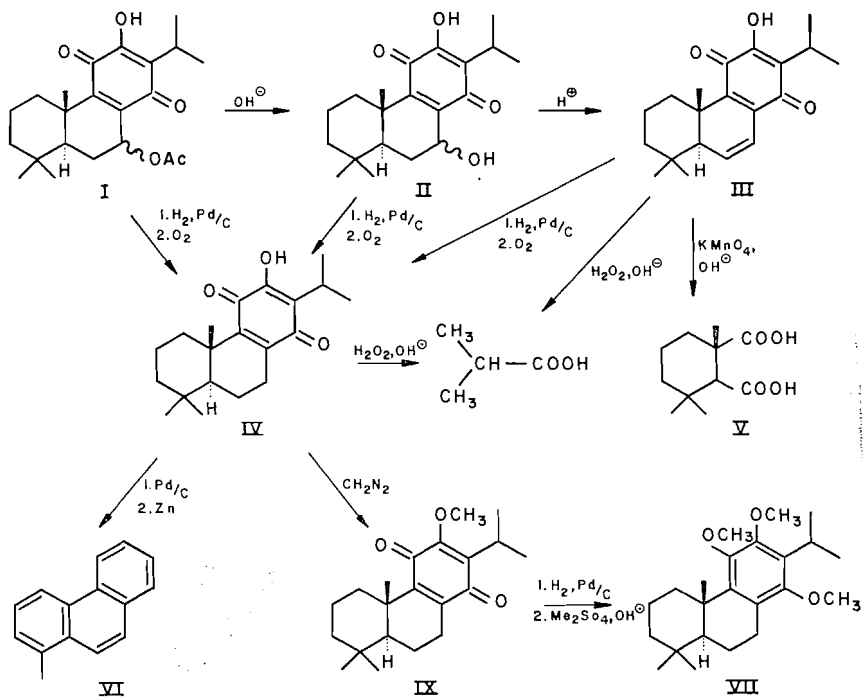
VIII IV

in ferruginol, which are known to be susceptible to oxidation (8). It follows that the companion quinones are 9-acetoxy- and 9-dehydro-royleanone, and that the reactions of these are as shown on the flowsheet.

The royleanones, thus, have the same trans A/B ring fusion and absolute configuration as all natural steroids and most diterpenes. The absolute configuration at the A/B junction bears a mirror image relationship to that found in lycoctonine (9), which, as was mentioned earlier, is found in the same plant. This indicates that although lycoctonine and the royleanones are both diterpenoid they are probably not closely linked biogenetically. Their syntheses in the plant must enter different pathways before the formation of the A/B junction.

After the structures of the royleanones had been established and their relationship to ferruginol recognized we considered the possibility that ferruginol is a direct royleanone precursor in the plant. Further examination of *Inula royleana* extracts indeed led to the isolation of small amounts of ferruginol from them. This leads us to suggest that the plant produces a 6-hydroxy diterpene by the route discussed by ApSimon and Edwards (10) and that this is isomerized and aromatized to ferruginol, which in turn is converted in stages to royleanone, 9-acetoxyroyleanone, and 9-dehydroroyleanone.

Examination of molecular models has convinced us that it is at present not possible to assign the configuration to the acetoxyl group in 9-acetoxyroyleanone on the basis of infrared (11) or n.m.r. (12) data because of the quasi-axial and quasi-equatorial configuration of the C_9 substituents and because of the proximity of the quinone carbonyl. This point, therefore, is still unsettled.



EXPERIMENTAL

Rotations were of chloroform solutions and melting points were taken in capillaries and are corrected.

Isolation of Royleanones

The dried ground roots of *Inula royleana* D.C., obtained from the S. B. Penick Company, N.Y., were extracted with methanol. During concentration of the extracts a dull yellow solid crystallized. This solid was predominantly 9-acetoxyroyleanone containing small quantities of royleanone. The mother liquors contained royleanone, 9-dehydroroyleanone, and ferruginol.

9-Acetoxyroyleanone (I)

The crude solid obtained above was purified by four recrystallizations from 2-butanone, a sublimation at 140° and 10^{-4} mm, and a final recrystallization from ethanol. It had m.p. 212–214.5°; $[\alpha]_D$ −14° (*c*, 1.07); $\nu_{max}^{CS_2}$ 3360, 1748, 1675, and 1645 cm^{-1}; λ_{max}^{EtOH} 272 mμ, ε 13,300, 407 mμ, ε 840. Neut. equiv. 378, 383. Found: C, 70.48; H, 7.86; OAc, 11.34. Calc. for $C_{22}H_{30}O_5$ (374.5): C, 70.56; H, 8.08; OAc, 11.49.

For most purposes material that had been recrystallized from ethanol three times (m.p. 208.5–212°) was used. The yield was approximately 1% of the weight of the dried roots.

The acetyl derivative of 9-acetoxyroyleanone, which was prepared by the treatment of 9-acetoxyroyleanone with acetic anhydride in the presence of sulphuric acid, melted at 122–122.5° (recrystallized from methanol–water); $[\alpha]_D$ +32° (*c*, 0.67); λ_{max}^{EtOH} 262 mμ, ε 14,900, 327 mμ, ε 320; $\nu_{max}^{CS_2}$ 1773, 1741, 1665, 1655 (shoulder), and 1607 cm^{-1}. Found: C, 69.06; H, 7.39; OAc, 20.38. Calc. for $C_{24}H_{32}O_6$: C, 69.21; H, 7.74; OAc, 20.66.

Treatment of a methanolic solution of 9-acetoxyroyleanone with excess ethereal diazomethane resulted in the formation of a monomethyl ether; m.p. 182.5–184.5° (recrystallized from methanol); $[\alpha]_D$ −121° (*c*, 1.32), λ_{max}^{EtOH} 270 mμ, ε 12,500, 375 mμ, ε 590; $\nu_{max}^{CS_2}$ 1740, 1660, 1645, and 1602 cm^{-1}. Found: C, 70.98; H, 8.21; OCH_3, 8.06. Calc. for $C_{23}H_{32}O_5$: C, 71.10; H, 8.30; OCH_3, 7.99.

Royleanone (IV)

A benzene solution of the solid that crystallized from the concentrated *Inula royleana* extract (see above) was chromatographed on silica gel. The first colored fractions that were eluted from the column with benzene were concentrated under reduced pressure and the residue was crystallized from hexane. Two different types of crystals separated, one yellow and the other orange in color. They were separated manually. The orange-colored crystals were recrystallized from glacial acetic acid until their melting point had risen to 181.5–183°. The yield was 0.008% of the weight of dried root extracted. $[\alpha]_D$ +134° (*c*, 1.03); $\lambda_{max}^{CCl_4}$ 277 mμ, ε 15,900, 283 mμ (shoulder), ε 15,200, 403 mμ, ε 510; $\nu_{max}^{CHCl_3}$ 3350, 1672, 1632, and 1602 cm^{-1}. Neut. equiv. 287, 306. Found: 75.93; H, 8.65. Calc. for $C_{20}H_{28}O_3$ (316.4): 75.91; H, 8.92.

The methyl ether of royleanone was prepared by treatment of a methanolic solution of royleanone with excess ethereal diazomethane. It melted at 119–120.5° (recrystallized from methanol); $[\alpha]_D$ −82° (*c*, 1.18), λ_{max}^{EtOH} 275 mμ, ε 12,300, 372 mμ, ε 460; $\nu_{max}^{CHCl_3}$ 1657 (shoulder), 1642, and 1602 cm^{-1}. Found: C, 76.03; H, 9.01; OCH_3, 9.75. Calc. for $C_{21}H_{30}O_3$: C, 76.32; H, 9.15; OCH_3, 9.39.

9-Dehydroroyleanone (III)

This material was obtained in pure form from 9-acetoxyroyleanone (*vide infra*). Evidence for its presence in the plant was obtained in the following manner. The mother liquors obtained after removal of the 9-acetoxyroyleanone from the plant extracts described above were concentrated until most of the methanol had been removed. The dark viscous mass was extracted with benzene. The benzene extracts were concentrated under reduced pressure, the residue was taken up in 1:1 benzene–hexane, and this solution was chromatographed on a silica gel column. The second colored band eluted with 1:1 benzene–hexane was collected, the eluate was concentrated, and the residue was recrystallized twice from ethanol. The yield of bright-orange-colored plates (m.p. 168–171°) was 0.07% of the weight of dried root. The infrared and ultraviolet spectra, the melting point, and the optical rotation of this material were identical with those of a ca. 45:55 mixture of royleanone and 9-dehydroroyleanone. We were unable to separate this mixture into its components.

This material, on hydrogenation over palladium on charcoal in glacial acetic acid, took up 1.6 equivalents of hydrogen. The product was oxidized by air to royleanone (mixed melting point and infrared spectrum).

Ferruginol (VIII)

The mother liquors obtained after the removal of the 9-acetoxyroyleanone from the plant extracts were concentrated until most of the methanol had been removed. The residue was extracted with hexane. The hexane extracts were concentrated, the residue was taken up in benzene, and the solution was washed well with 0.5 *N* aq. sodium hydroxide. The benzene layer was concentrated and the residue was chromatographed on silica gel. The fractions eluted with 1:1 hexane–benzene were combined, concentrated, and distilled. Material distilling below 140° at 10^{-3} mm was collected. The purification steps described above, i.e. the washing of a benzene solution of this material with 0.5 *N* aq. sodium hydroxide, the chromatography, and the distillation, were repeated. This time the material distilling below 125° at 10^{-3} mm was collected. The crude ferruginol, which was obtained as a viscous bright orange oil was characterized as the benzoate. After a crystallization from methanol and three recrystallizations from hexane, the benzoate was obtained as white needles that melted at 154–155.5°. It was identical with authentic ferruginyl benzoate (mixed melting point and infrared spectrum). The yield corresponded to 0.04% of the weight of the dried root.

Conversion of 9-Acetoxyroyleanone (I) to Royleanone (IV)

A suspension of 0.198 g of 9-acetoxyroyleanone in 30 ml of glacial acetic acid was hydrogenated over Adams' catalyst at atmospheric pressure. The reduction was complete within 2 hours. The uptake of hydrogen was 26.7 ml. The catalyst was removed by filtration, the filtrate was warmed to 90° and swirled for 20 minutes to promote aerial oxidation of the hydroquinone. The solution was concentrated under reduced pressure and the residue was recrystallized from glacial acetic acid, giving 0.123 g, m.p. 179–182.5°. The product was identical with natural royleanone (mixed melting point and infrared spectrum).

The catalytic reduction described above could be replaced by reduction with sodium borohydride in methanol at room temperature without any change in the course of the reaction.

9-Hydroxyroyleanone (II)

To a boiling solution of 0.513 g of 9-acetoxyroyleanone in 25 ml of ethanol was added 63 ml of 0.10 *N* aq. sodium hydroxide. The resulting magenta-colored solution was refluxed gently for 2 hours, cooled in an ice bath, and acidified with 15% phosphoric acid. The solid that separated was collected by filtration and air dried. It was purified by chromatography on silica gel followed by recrystallization from methanol–water, giving 0.23 g, m.p. 171–174°. After two additional recrystallizations from methanol–water the gold-colored plates melted at 172.5–174.5°, $[\alpha]_D$ −132° (*c*, 1.24). λ_{max}^{EtOH} 273 mμ, ε 11,900, 408 mμ, ε 800; $\nu_{max}^{CHCl_3}$ 3540, 3360, 1670, 1648, 1627, and 1604 cm^{-1}. Neut. equiv. 309, 325. Found: C, 72.46; H, 8.32. Calc. for $C_{20}H_{28}O_4$ (332.4): C, 72.26; H, 8.49.

In one run the acid liberated during the above hydrolysis was separated from the reaction mixture by codistillation with water. It was converted to the *p*-bromophenacyl ester, which was identical with authentic *p*-bromophenacyl acetate (mixed melting point and infrared spectrum).

9-Hydroxyroyleanone was converted to royleanone by catalytic reduction followed by air oxidation as is described above for the conversion of 9-acetoxyroyleanone to royleanone.

Treatment of a methanolic solution of 9-hydroxyroyleanone with excess ethereal diazomethane resulted in the formation of a monomethyl ether; m.p. 138.5–139.5° (recrystallized from methanol–water); $[\alpha]_D$ −310° (*c*, 1.05); λ_{max}^{EtOH} 270.5 mμ, ε 10,000, 372 mμ, ε 500; $\nu_{max}^{CHCl_3}$ 3550, 1661, 1640, and 1600 cm^{-1}. Found: C, 72.67; H, 8.54; OCH_3, 8.89. Calc. for $C_{21}H_{30}O_4$: C, 72.76; H, 8.73; OCH_3, 8.95.

Dehydration of 9-Hydroxyroyleanone (II) to 9-Dehydroroyleanone (III)

A mixture of 0.20 g of 9-hydroxyroyleanone, 10 ml of *p*-xylene, and 0.002 g of *p*-toluenesulphonic acid (monohydrate) was heated under reflux for 3½ hours. It was concentrated to a volume of ca. 0.5 ml under

reduced pressure, the residue was taken up in 1:1 hexane–benzene and the solution was poured onto a silica gel column. The column was eluted with 1:1 hexane–benzene and then with benzene. The benzene eluate was concentrated under reduced pressure and the residue was recrystallized from ethanol–water, giving 0.158 g; m.p. 166–168.5°; $[\alpha]_D$ −620° (*c*, 0.21); λ_{max}^{EtOH} 212 mμ, ε 16,700, 247 mμ (shoulder), ε 8,400, 330 mμ, ε 7,700, 459 mμ, ε 770; $\nu_{max}^{CHCl_3}$ 3340, 1666, 1635, 1615 (shoulder), 1595 (shoulder) cm^{-1}. Neut. equiv. 316. Found: C, 76.18; H, 8.30. Calc. for $C_{20}H_{26}O_3$ (314.4): C, 76.40; H, 8.34.

9-Dehydroroyleanone was converted to royleanone by catalytic reduction followed by air oxidation as is described above for the conversion of 9-acetoxyroyleanone to royleanone.

The methyl ether was prepared by the treatment of a methanolic solution of 9-dehydroroyleanone with excess diazomethane. It melted at 106.5–107.5° (recrystallized from methanol–water); $[\alpha]_D$ −615° (*c*, 0.21); λ_{max}^{EtOH} 212 mμ, ε 14,300, 246 mμ (shoulder), ε 8,400, 320 mμ, ε 5,600, 429 mμ, ε 770; $\nu_{max}^{CHCl_3}$ 1642, 1615 (shoulder) cm^{-1}. Found: C, 76.81; H, 8.49; OCH_3, 9.48. Calc. for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59; OCH_3, 9.45.

Reductive Methylation of the Methyl Ether of Royleanone (IV) to VII (cf. ref. 13)

A solution of 0.185 g of royleanone methyl ether in 50 ml of methanol was hydrogenated over Adams' catalyst until the solution was colorless. The reaction mixture was left in the hydrogen atmosphere at room temperature, and during a period of 40 hours a total of 15 ml of 30% aq. sodium hydroxide and 13 ml of dimethyl sulphate was added to it. These were added in 1-ml portions; shaking was continued for 24 hours after the completion of the addition. The catalyst was removed by filtration, 50 ml of water was added, and the mixture was concentrated under reduced pressure to remove most of the methanol. The residue was extracted with benzene (75 ml). The benzene extract was washed with water (2×50 ml), dried over anhyd. magnesium sulphate, and passed through a column of alumina (activity I, 4 g). The colorless eluate was concentrated and the residue was crystallized from ethanol (0.11 g, m.p. 89–90.5°). After two additional recrystallizations from ethanol the product melted at 95–96.5°; $[\alpha]_D$ +99° (*c*, 0.91); λ_{max}^{EtOH} 208 mμ, ε 49,000, 281 mμ, ε 740. Found: C, 76.78; H, 10.09; OCH_3, 25.70. Calc. for $C_{23}H_{36}O_3$: C, 76.61; H, 10.07; OCH_3, 25.82.

Oxidation of 9-Dehydroroyleanone (III) with Alkaline Hydrogen Peroxide

To a solution of 0.200 g of 9-dehydroroyleanone in 81 ml of 0.10 *N* aq. sodium hydroxide at 70° was added 1.0 ml of 30% aq. hydrogen peroxide. The temperature was held at 70° for 3 hours. During this period three additional 1.0-ml portions of 30% aq. hydrogen peroxide were added. (The purple color of the sodium salt of the hydroxyquinone was completely discharged after the reaction had been in progress for 1½ hours.) The resulting pale yellow solution was made acid to Congo red with phosphoric acid and distilled. The volume of the pot residue was maintained at 30–90 ml by the addition of portions of water. Approximately 100 ml of distillate was collected. A small amount of oily material present in the distillate was removed and the residue was titrated with 0.100 *N* aq. sodium hydroxide (4.1 ml required). The resulting solution was concentrated to a volume of ca. 2 ml, made acid to Congo red with phosphoric acid, and extracted with ether (5×2 ml). The ether extracts were dried over anhydrous sodium sulphate, concentrated, and distilled. A colorless liquid, b.p. ca. 150°, 0.031 g, whose infrared spectrum was identical with that of isobutyric acid was obtained.

The oxidation of royleanone with alkaline hydrogen peroxide was carried out in the same fashion as was used with 9-dehydroroyleanone. The yield of isobutyric acid was comparable in the two cases.

Oxidation of 9-Dehydroroyleanone (III) with Alkaline Potassium Permanganate

Four percent aq. potassium permanganate was added to a solution of 1.22 g of 9-dehydroroyleanone in 100 ml of 2% aq. sodium hydroxide at such a rate that an excess of potassium permanganate was maintained in the reaction mixture. The temperature was held at 40–45° for 2 hours and at 65–70° for 1 hour. The solution was cooled to 30°, made acid to Congo red with conc. sulphuric acid, and the manganese dioxide was decomposed with sodium bisulphite. The volume of the solution was reduced to ca. 40 ml. The insoluble oil was separated and the residual aqueous layer was extracted continuously with ether. A yellow oil (0.44 g) was obtained when the ether extracts were concentrated. This oil was taken up in ether and treated with a slight excess of ethereal diazomethane at 5°. After 15 minutes at 5° the mixture was filtered through anhydrous sodium sulphate and the filtrate was concentrated under reduced pressure. The residue was taken up in 1:1 benzene–hexane and the solution was passed through a column of alumina (activity III, 10 g). The eluate was concentrated and distilled; the fraction distilling at 60–65° at 0.1 mm was collected; 0.130 g, $[\alpha]_D$ +26.5° (*c*, 1.83), $\nu_{max}^{CS_2}$ 1732 cm^{-1}. Found: C, 64.66; H, 9.06. Calc. for $C_{13}H_{22}O_4$: C, 64.44; H, 9.15.

Dehydrogenation of Royleanone (IV)

Royleanone (0.33 g) was passed through a heated column (100×8 mm) of 0.50 g of 30% palladium on charcoal supported on finely cut glass wool. The column was supported in a horizontal position in a furnace which was 20 cm in length and heated to 350°. The royleanone was distilled into the heated column with a small, movable furnace. A slow stream of hydrogen was used to sweep it through the catalyst bed. The product was passed through the catalyst bed in this manner five more times. It was then passed twice through a heated column (50×8 mm) of a mixture of zinc dust (Mallinckrodt Analytical Reagent) and pumice powder (B and A No. 2157) (2:1 by weight). The column was heated in the furnace described above.

Again a slow stream of hydrogen was used to carry the material through the column. Each of the passes described above required approximately 1 hour.

The material obtained from three such runs (0.54 g) was combined, dissolved in hexane, and chromatographed on 17 g of alumina (activity I). The column was eluted with hexane, hexane–benzene, and finally with benzene. The fractions eluted with hexane (0.14 g) were liquid and probably consisted of a mixture of naphthalenes (λ_{max} 228 mμ (strong), 280 mμ (medium), and ca. 320 mμ (weak doublet)). These fractions were not investigated further. The fractions eluted with hexane–benzene and with benzene were solid or semisolid (0.135 g). Their ultraviolet spectra were similar to those of phenanthrenes. These fractions were combined and fractionally recrystallized from ethanol. A total of 0.021 g of material with m.p. 118–120° was obtained. A mixed melting point with 1-methylphenanthrene (m.p. 119.5–121.5°) was not depressed (mixed m.p. 118–120.5°). Contamination of the 1-methylphenanthrene obtained by dehydrogenation of royleanone was indicated by a weak absorption band at 762 cm^{-1} in its infrared spectrum and a weak absorption band (ϵ 56) at 376 mμ in its ultraviolet spectrum. The spectra of the two samples were identical in all other respects.

Conversion of Ferruginol to Royleanone (IV)

To a solution of 0.360 g of ferruginol (liberated from the benzoate which melted at 156.5–157.5°) in 4 ml of glacial acetic acid at room temperature was added a drop of conc. sulphuric acid followed by 0.50 ml of 98% hydrogen peroxide. The reaction mixture quickly turned yellow and after an hour a solid began to separate. It was allowed to stand at room temperature for 12 hours. Water was added until the supernatant liquid was almost colorless. The gummy yellow precipitate was taken up in benzene, the solution was filtered through anhydrous sodium sulphate and concentrated under reduced pressure. The residue was chromatographed twice on silica gel. In each case the yellow band that was eluted with benzene–hexane was collected. The eluate was concentrated and recrystallized from acetic acid, giving 0.031 g, m.p. 176–180°. After an additional recrystallization from glacial acetic acid the product melted at 179–182°, 0.028 g, $[\alpha]_D$ +134° (*c*, 1.34). The melting point was not depressed by the admixture of authentic royleanone (mixed m.p. 179–182°). The infrared spectra of the two samples were identical (in chloroform).

ACKNOWLEDGMENTS

We wish to thank Mr. A. Knoll for the extractions and preliminary separations, Mr. H. Seguin for the analyses, Mr. J. Nicholson for the n.m.r. spectra, and Mr. R. Lauzon for the infrared spectra. We are grateful to Dr. P. K. Grant for a generous sample of ferruginol.

OXIMES

I. THE SYNTHESIS OF SOME SUBSTITUTED 2-OXIMINOACETOPHENONES[1]

J. J. NORMAN,[2] R. M. HEGGIE, AND J. B. LAROSE
Defence Research Chemical Laboratories, Ottawa, Canada

Received March 16, 1962

ABSTRACT

The preparation of some *p*-(ω′-dimethylaminoalkyl)- and *p*-(ω′-dimethylaminoalkoxy)-2-oximinoacetophenones and their methiodides is described.

No general method was found for synthesis of short-chain (C_0, C_1, C_2) *p*-(ω′-dimethylaminoalkyl)-2-oximinoacetophenones. The longer-chain compounds (C_3, C_4) were prepared by a method which would appear to be general. ω-Phenyl-1-haloalkanes undergo Friedel–Crafts acylation to yield *p*-(ω′-haloalkyl)-acetophenones. These were converted to the dimethylamino compounds, which, subsequently, yielded 2-oximinoacetophenones. No method of preparation of *p*-(2′-dimethylaminoethyl)-2-oximinoacetophenone was found.

Synthesis of *p*-(ω′-dimethylaminoalkoxy)-2-oximinoacetophenones was accomplished using mixed α,ω-dihaloalkanes and *p*-hydroxyacetophenone. The *p*-(ω′-haloalkoxy)-acetophenones from these reactants were first converted to oximes and then to the dimethylamino compounds. Syntheses of *p*-(ω′-dimethylamino-ethoxy, -propoxy, -butoxy, and -pentoxy)-2-oximinoacetophenones were achieved. That of *p*-(dimethylaminomethoxy)-2-oximinoacetophenone was unsuccessful.

In the last few years, it has been shown that oximes are particularly effective reactivators of cholinesterases which have been inhibited by organophosphorus compounds (1–5). These inhibitors phosphorylate a group in the enzymatically active portion of the molecule, thus blocking hydrolysis of the normal substrate molecule (6–8). Kinetic and other studies with both inhibitors and substrates have revealed considerable detail regarding the structure of the active center of the enzyme (9, 10*). In this manner, it has been shown that both acetylcholinesterase (true cholinesterase) and pseudocholinesterase have a very similar "esteratic" site responsible for the actual hydrolysis of the substrate and that phosphorylation occurs at some point in this site (11, 12). The two enzymes, however, differ in the position and number of "anionic" sites which assist hydrolysis by aligning substrate molecules into positions favorable for interaction with the esteratic site (13, 14). For reactivation then, the enzyme must be dephosphorylated. With oximes, this results from nucleophilic attack of the oximate ion upon the phosphorus atom, with a resulting cleavage of the enzyme–phosphorus bond (15).

Incorporation into the reactivator molecule of a group capable of interaction with the anionic sites should assist dephosphorylation by aligning the oximate ion into a favorable position for attack on phosphorus. This would be entirely analogous to the substrate–enzyme interaction. Reasoning in this way, Wilson (16) and Davies and Green (17) tested pyridinium-2-aldoxime methiodide and found that it was both an effective reactivator of inhibited cholinesterase and, in conjunction with atropine sulphate, an excellent antidote for organophosphorus poisoning. By varying the distance of this interacting group from the oximino portion of the molecule, it should be possible to produce reactivators showing considerable specificity towards one or the other of the two types of cholinesterase and to map the enzyme surfaces by correlating the specificity patterns

[1]*Received as D.R.C.L. Report No. 372.*
Presented in part before the 5th Western Regional Conference of the CIC, Regina, 1960.

with the geometry of the oximes. Such an approach had been tried previously by Wilson (18, 19) in a much more limited way, using pyridinium-2-, -3-, and -4-aldoxime methiodides.

It has been shown previously (20) that the protonated dimethylamino group interacts with the anionic site nearly as well as the trimethylammonium group present in the choline portion of substrates. These two groups, therefore, were chosen for incorporation into the oxime molecule. The oxime portion chosen was based upon work by Childs, Davies, and Green (4, 5), who had shown that potent reactivators are obtained when a 1-oximino-2-oxo grouping is present in a wide variety of compounds. This grouping is present in 2-oximinoacetophenone, which itself is not an outstanding reactivator. It would be expected then that compounds related to 2-oximinoacetophenone carrying a trimethylammonium group or a dimethylamino group of suitable basicity would be better reactivators than the parent compound if they were specifically aligned for attack on the phosphorus atom, and any enhanced reactivity would reflect the fit of the oxime to the enzyme.

In this paper, the synthesis of the various oximes used in this study will be presented. Infrared spectra of the oximes and the results of reactivation studies will be reported in subsequent papers.

The first series of oximes synthesized had the general formula I, where n = 0, 1, 3,

I

and 4, and R = $(CH_3)_2N$— and $I^-.(CH_3)_3\overset{+}{N}$—.

I (n = 0, R = $(CH_3)_2N$—) was synthesized from aniline. This was accomplished by a Friedel–Crafts acylation of acetanilide, followed by hydrolysis of the resulting *p*-acetaminoacetophenone to the free base.

Dimethyl sulphate converted this to the dimethylamino compound, which was treated with alkaline butyl nitrite to yield the required oxime. *p*-Aminoacetophenone was obtained in 40% yield from the starting materials but dimethylation and oximation resulted in low yields, about 20% in each case.

The following reaction scheme was utilized for synthesis of I (n = 1; R = $(CH_3)_2N$—). *p*-Toluidine was diazotized and treated with cuprous cyanide to form *p*-toluonitrile. This, on treatment with N-bromosuccinimide, yielded α-bromotoluonitrile, which in turn was converted to the dimethylamino compound. The cyano group was allowed to react with methylmagnesium iodide to form a methyl ketimine and, after hydrolysis, *p*-dimethylaminomethylacetophenone was obtained. This was treated with butyl nitrite to form *p*-(dimethylaminomethyl)-2-oximinoacetophenone.

The method of preparation of the *p*-alkyl compounds I (n = 3, 4; R = $(CH_3)_2N$—) was as follows. The ω-phenylalkanol-1 was converted to the bromide, which was acetylated with acetyl chloride in the presence of aluminum chloride. The resulting *p*-(ω'-bromoalkyl)-acetophenone was treated with dimethylamine to form the *p*-(ω'-dimethylaminoalkyl)-acetophenone, which, upon reaction with butyl nitrite in the presence of alkali, formed the oxime. Yields of bromoketones generally were good, about 80%, while those of the dimethylamino compounds were variable and poor, between 5 and 30%. The oximes were formed in about 25% yield.

It was found impossible to synthesize the compounds where n = 2, all attempts yielding only styrene derivatives.

As the length of the side chain increased, suitable starting materials became increasingly more difficult to obtain. A second series of compounds, therefore, was prepared from the readily available mixed α,ω-dihalides and *p*-hydroxyacetophenone. The resulting *p*-alkoxy compounds, II, where R = $(CH_3)_2N$— and $I^-.(CH_3)_3\overset{+}{N}$—, contain an ether link in the

II

side chain, but such a substitution should have little effect upon the geometry of the system.

The synthesis of these compounds was accomplished in the following way. The mixed dihalide was treated with *p*-hydroxyacetophenone in the presence of potassium carbonate to yield a *p*-(ω'-haloalkoxy)-acetophenone. This, on reaction with butyl nitrite in the presence of sodium methoxide, formed the halooxime, which, subsequently, was treated with dimethylamine to yield the desired compound. Yields of the ω'-halo ketones were fair, 64–76%, while those of ω'-halooximes were variable, 30–70%. Yields of the ω'-dimethylaminooximes were poor, about 25%. In this manner, the compounds II (n' = 2, 3, 4, and 5; R = $(CH_3)_2N$—) were prepared. An attempt to prepare the compound II (n' = 1; R = Cl) was unsuccessful.

The dimethylamino compounds of both series I and II were quaternized with methyl iodide in absolute methanol, except for I, n = 0, where excess methyl iodide was used as solvent. Yields were approximately 50%.

Infrared spectra were run routinely to identify the products of reaction but are not reported here.

EXPERIMENTAL

Since methods were identical for many of the compounds prepared, only representative examples of the preparations will be given in detail. Starting materials for these preparations were commercially available C.P. grade chemicals.

Preparation of p-(ω'-Substituted alkyl)-2-oximinoacetophenones

p-Dimethylaminoacetophenone

p-Aminoacetophenone.—Acetanilide (0.2 mole) and aluminum chloride (0.3 mole) were suspended in carbon disulphide (250 ml), then acetyl chloride (0.2 mole) was added dropwise, with vigorous stirring. The reaction mixture was refluxed for 2 hours and then stirred overnight. Carbon disulphide and excess acetyl chloride were removed by distillation and the syrupy residue was poured onto ice. The solid material so obtained was suspended in 10% sodium hydroxide (200 ml) and the mixture was refluxed for 2 hours. After cooling, the solution was extracted with chloroform, the extracts were combined, and solvent was removed *in vacuo*. The residue was recrystallized from 50% aqueous ethanol. Yield: 0.082 mole, 41%, m.p. 103–105° C, lit. m.p. 105.8° C (28).

p-Dimethylaminoacetophenone.—*p*-Aminoacetophenone (0.74 mole) was added to warm water (500 ml, 70–80° C) and the stirred solution was treated dropwise with dimethyl sulphate (2.54 mole). A solution of 50% sodium hydroxide (135 ml) was placed in a dropping funnel and added at such a rate that the reaction mixture was kept mildly alkaline. When all the dimethyl sulphate had been added, the remainder of the alkali solution was run into the mixture and the whole was stirred for 10 minutes. The solid product was filtered, recrystallized from 70% methanol, and dried *in vacuo*. The dried material was shaken with warm (50° C) 10% sodium hydroxide (700 ml) and twice its weight of *p*-toluenesulphonyl chloride until the odor of the sulphonyl chloride had disappeared. The residual solid was separated and washed with 5% hydrochloric acid (5×50 ml). The acid extract was made alkaline (pH 9) with 10% sodium hydroxide and the precipitate was removed by filtration. This material was recrystallized from 65–110° C petroleum ether. Yield: 0.092 mole, 20.6%, m.p. 105–106° C, lit. m.p. 105° C (29).

p-(Dimethylaminomethyl)-acetophenone

α-Bromo-p-toluonitrile.—Toluonitrile (0.50 mole) (21) in carbon tetrachloride (200 ml) was added slowly, with stirring, to a mixture of N-bromosuccinimide (0.5 mole) and benzoyl peroxide (1 g) in a flask fitted with

a condenser. After refluxing for 45 minutes, half the solvent was removed by distillation and the mixture was allowed to cool. The precipitate was removed, washed three times with water, and dried. Yield: 0.30 mole, 60%, m.p. 114–116° C, lit. m.p. 114–115° (30).

p-(Dimethylaminomethyl)-benzonitrile.—α-Bromo-*p*-toluonitrile (0.30 mole) was dissolved in a mixture of ether (400 ml) and benzene (100 ml), the solution was chilled to −70° C, dimethylamine (0.3 mole) was added, and the flask was sealed and allowed to warm to room temperature. After 48 hours, the flask was cooled in an ice–salt bath to −10° C and opened. The solvent was removed *in vacuo* and the residue was dissolved in the minimum quantity of water. This solution was ether extracted, the extracts were combined and dried with anhydrous sodium sulphate, then distilled. Yield: 0.25 mole, 83.5%, b.p. 90–91° C at 0.6 mm, n_D^{25} 1.5234.

p-(Dimethylaminomethyl)-acetophenone.—*p*-(Dimethylaminomethyl)-benzonitrile (0.25 mole) was added dropwise to methylmagnesium iodide (0.50 mole) in toluene (400 ml) and the mixture was refluxed 48 hours. The reaction mixture was poured onto crushed ice, and 6 *N* hydrochloric acid was added until the precipitate just dissolved. This solution was heated on a steam cone for 2 hours, cooled, and extracted with ether. The aqueous layer was made basic with sodium carbonate and ether-extracted. The combined ether extracts were dried and distilled. Yield: 0.188 mole, 75%, b.p. 90° C at 0.05 mm, n_D^{25} 1.5248.

p-(4′-Dimethylaminobutyl)-acetophenone and p-(3′-Dimethylaminopropyl)-acetophenone

3-Bromopropylbenzene and 4-bromobutylbenzene.—3-Hydroxypropylbenzene and 4-hydroxybutylbenzene, prepared by lithium aluminum hydride reduction of ethyl 3-phenylpropionate and ethyl 4-phenylbutyrate (22), were converted to the corresponding bromides according to the procedure of Marvel (23).

p-(4′-Bromobutyl)-acetophenone.—Aluminum chloride (0.7 mole) was suspended in carbon disulphide (350 ml) in a 1-liter round-bottomed flask fitted with a stirrer, dropping funnel, and condenser with drying tube, then acetyl chloride (0.7 mole) was added over 10–15 minutes to the vigorously stirred mixture. This was cooled in an ice–salt bath, and a solution of 4-bromobutylbenzene (0.8 mole) and acetyl chloride (1.5 mole) was added as fast as possible. Stirring was continued until hydrogen chloride was no longer evolved. The complex was decomposed by pouring the reaction mixture onto crushed ice, the organic layer was separated, and the aqueous layer was extracted with benzene. The combined organic phases were dried and then distilled under reduced pressure. Yield: 0.16 mole, 20.3%, b.p. 125–127° C at 0.01 mm.

p-(3′-Bromopropyl)-acetophenone.—This compound was prepared in an analogous manner from 3-bromopropylbenzene in 70% yield.

p-(4′-Dimethylaminobutyl)-acetophenone.—*p*-(4′-Bromobutyl)-acetophenone (0.15 mole) was dissolved in anhydrous methanol (150 ml) in a pressure flask. The solution was chilled to −70° C, dimethylamine (0.35 mole) was added, and the flask was sealed. The solution was allowed to warm to room temperature and to stand for 24 hours. The flask was opened, the solvent was removed *in vacuo*, and the residue was dissolved in water. The dimethylamino compound was ether-extracted, the extracts were dried and distilled. Yield: 0.077 mole, 53%, b.p. 100° C at 0.005 mm, n_D^{25} 1.5195.

p-(3′-Dimethylaminopropyl)-acetophenone.—This compound was prepared similarly in 78% yield.

Preparation of Oximes

All the above acetophenones were converted to oximes in the same manner and one representative procedure only is given.

p-(4′-Dimethylaminobutyl)-2-oximinoacetophenone.—Butyl nitrite (0.08 mole) was added to a stirred, ice-cold solution of sodium ethoxide (from 0.088 mole of sodium) in absolute ethanol (100 ml). *p*-(4′-Dimethylaminobutyl)-acetophenone (0.077 mole) was added dropwise over 25–30 minutes, the solution was allowed to warm to room temperature and then to stand until the following day. The precipitate was filtered, washed with ether, and then dissolved in the minimum quantity of water. The solution was acidified with glacial acetic acid and the resulting yellow solid was filtered, recrystallized from ethanol, from isopropanol, and finally, from ether–acetone. Yield: 0.027 mole, 35%, m.p. 125° C. Other oximes were recrystallized twice from ethanol.

Preparation of p-(ω′-Substituted alkoxy)-2-oximinoacetophenones

Mixed α,ω-dihalides.—1-Chloro-3-bromopropane was prepared from 3-chloropropanol-1 and phosphorus tribromide (24), 1-chloro-4-idobutane from 1,4-dichlorobutane and sodium iodide (25), and 1-chloro-5-bromopentane from 5-chloro-*n*-amyl acetate and phosphorus tribromide (26). 1-Chloro-2-bromoethane was obtained from Fisher Scientific Co. Ltd.

p-(4′-Chlorobutoxy)-acetophenone.—*p*-Hydroxyacetophenone (1.5 mole) and potassium carbonate (2.0 mole) were suspended in 2-butanone (700 ml). To this vigorously stirred suspension, 1-chloro-4-bromobutane (1.5 mole) was added dropwise over 1 hour, then the mixture was refluxed for 5 hours. Inorganic solids were removed and the solution was taken to dryness *in vacuo*. The residue was taken up in ether, washed with 10% sodium carbonate, with water, then dried and distilled at reduced pressure. Yield: 0.98 mole, 64%, b.p. 131–132° C at 0.07 mm.

Other p-(ω′-chloroalkoxy)-acetophenones.—These compounds were prepared in a similar manner from 1-chloro-2-bromoethane, 1-chloro-3-bromopropane, and 1-chloro-5-bromopentane.

p-(ω'-Chloroalkoxy)-2-oximinoacetophenones.—These were prepared from the corresponding *p*-(ω'-chloroalkoxy)-acetophenones and butyl nitrite following the procedure outlined above for *p*-(4'-dimethylaminobutyl)-2-oximinoacetophenone.

p-(ω'-Dimethylaminoalkoxy)-2-oximinoacetophenones.—All the above chloroalkoxyacetophenones were converted to dimethylamino compounds in a fashion analogous to that described for *p*-(4'-dimethylaminobutyl)-acetophenone.

Quaternizations

The dimethylaminooxime (1.0 g) was dissolved in absolute methanol (10 ml), and then methyl iodide (15 ml) was added. The mixture was kept in a sealed tube at room temperature for 48 hours. The solvent was removed *in vacuo* and the residue was recrystallized from ethanol or acetonitrile. Yields varied from 18 to 97% but, in general, were 40% or better.

Derivatives

2,4-Dinitrophenylhydrazones were prepared for most acetophenone compounds, following the general procedure given in Shriner and Fuson (27, p. 171). When the acetophenone contained a dimethylamino group, this procedure had to be modified slightly, since the precipitate obtained was the hydrosulphate. This was treated with 15% sodium carbonate solution to regenerate the free base, which was recrystallized in the normal manner.

In one instance, the hydrazone did not form. The semicarbazone, however, was obtained readily (27, p. 170).

Analyses

Yields and anlyses for the various compounds prepared are listed in Tables I and II. Unfortunately, these compounds were all quite unstable and the analyses reported are the best obtained. It is realized that deviations between calculated and experimental values, in some instances, are somewhat larger than the generally accepted limits but further attempts at purification led to loss of nitrogen. The materials, however, are believed to be the oximes claimed because of their behavior in biological tests, which will be reported at a later date.

ACKNOWLEDGMENTS

The authors would like to thank Mr. I. G. Wright and Mr. R. Miller for their assistance in the preparation of some of these compounds, and Mr. J. Helie for performing the microanalyses.

INVESTIGATIONS IN THE BICYCLOHEPTANE SERIES

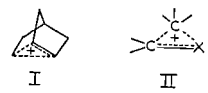
PART I. THE ELECTRONIC EFFECT OF METHYL GROUPS ON C_6 OF THE NORBORNYL CATION

DONALD E. MCGREER
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received March 21, 1962

ABSTRACT

The addition of acetic acid to camphenilene has been carried out. The major products are the two expected from normal addition without rearrangement. From the product ratio it is possible to conclude that the difference between the electronic effect of a methyl and a hydrogen at C_6 of the norbornyl cation is small.

Winstein (1–3) and Roberts (4, 5) have proposed that a non-classical carbonium ion (I) is obtained in the norbornyl system by solvolysis of derivatives of *exo*-norborneol. This is analogous to the type of intermediate (II) proposed in a number of migration reactions (6). For many such reactions, i.e. the Baeyer–Villiger and pinacol rearrangement reactions,

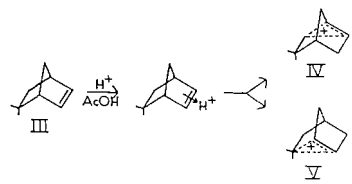


I II

a definite order of migrational aptitude of *t*-butyl > ethyl > methyl has been observed (7, 8) and this order has been partly attributed to electronic influence of the methyl groups on the migrating carbon. It is of interest to see if such pronounced effects are also present in the norbornyl system.

In our laboratories, we are studying the electronic and steric effects of substitution at C_6 of the norbornyl system and in this paper will report evidence concerning the electronic influence of two methyl groups at C_6.

Addition of acetic acid to camphenilene (apoisofenchene (III)) can potentially yield a simple norbornyl cation (IV) and/or a 6,6-dimethylnorbornyl cation (V) (the non-classical ion is used here for convenience since we do not have definitive evidence for or against its formation). Neglecting any steric differences (which are shown below to be small)

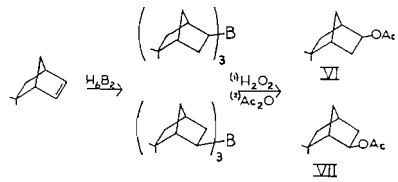


III IV V

and provided the product is not equilibrated, the product ratio should be a measure of the electronic influence of the methyl groups on the intermediate ion.

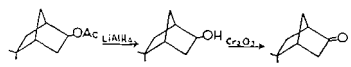
Beckmann and Bamberger (9) in 1953 reported the addition of acetic acid to camphenilene. They observed as the major product the acetate from IV (5-*exo*-camphenilanyl acetate (*β*-isofenchocamphoryl acetate) (VI)). Two other minor products resulting from

rearrangement were also found but there was no evidence for the acetate from V (6-*exo*-camphenilanyl acetate) (VII). We now have repeated this work and find that 5-*exo*-camphenilanyl acetate (VI) and 6-*exo*-camphenilanyl acetate (VII) are the major products and are formed in the ratio of 2:1 respectively.



The acetate mixture from the addition of acetic acid to camphenilene was chromatographed by vapor chromatography and two major peaks were found to be present. These components were isolated and found to be identical with the pair of acetates prepared from camphenilene by the hydroboration method of Brown and Subba Rao (10). Hydroboration of camphenilene followed by oxidation and then acetylation gave two acetates, b.p. 211° and 214°, in a ratio of 45:55 respectively. From studies by Brown *et al.* on bicyclic systems and related structures (11, 12) it is unlikely that rearrangement of the carbon skeleton has occurred and it is probable that the two acetates are *exo*. It is important to note that for a reaction which has been shown to be sensitive to steric effects the ratio of acetates formed is close to 1. It is based on this observation that we feel that steric effects are minor in the addition reaction with acetic acid.

Further identification of the products has been based on the transformation of the acetates to the alcohols and derivatives and then to the ketones and derivatives. The



pertinent melting points of these and related compounds are given in Table I. From these data it can be concluded that the acetate, b.p. 214°, is 5-*exo*-camphenilanyl acetate (VI) and the acetate, b.p. 211°, is 6-*exo*-camphenilanyl acetate (VII).

TABLE I

Source	Melting point (°C)			
	Alcohol	Hydrogen phthalate	Ketone	Semicarbazone
5-*exo*-Camphenilanyl	60–61 (13)	130–131 (13)	64–65.5 (14)	193 (14)
3-Camphenilanyl "1"	103–104 (15)	178–179 (15)	38 (16)	223 (16)
3-Camphenilanyl "2"	75–76 (15)	154–155 (15)	38 (16)	223 (16)
α-Isofenchocamphoryl	132–133 (15)	174–175 (15)	109 (17)	220 (17)
6-*exo*-Camphenilanyl	—	—	b.p. 197 (18)	—
Acetate, b.p. 211°	30	138.5–140	55–56, b.p. 195	183–184
Acetate, b.p. 214°	55–56	130–131	—	189–190

Beckmann and Bamberger (9) missed the derivatives of the 6-*exo*-camphenilanyl system for the following reasons. In the attempted separation by crystallization of the hydrogen phthalates of the alcohol mixture the hydrogen phthalate of 6-*exo*-camphenilanol was

not obtained since it is more soluble than the 5-isomer in the solvents used. The ketone mixture of 6-camphenilanone and 5-camphenilanone under standard conditions yields the pure semicarbazone of the 5-isomer since the 6-isomer forms a semicarbazone at a much slower rate. The slow reactivity of the 6-ketone is presumably due to the large steric effort of an *endo*-methyl group at the 2-position.

There are two possible explanations for the observed product ratio from the addition of acetic acid to camphenilene. The first is that the presence of methyl substitution at C_6 of I (V) provides no additional stabilization over structure IV and thus the product ratio is close to 1. The ability of methyl attached to the carbon of a migrating group to give stabilization by electronic induction or hyperconjugation has been questioned in the case of the Wagner–Meerwein rearrangement reaction (19). Cram and Knight based their arguments on an observed migrational aptitude for methyl and ethyl of 35:1 respectively in the solvolysis of 3,4-dimethyl-4-phenyl-3-hexyl *p*-bromobenzoate. Unfortunately, there have been no other migrational aptitudes measured for the Wagner–Meerwein rearrangement reaction.

The second possible explanation is that C_6 does not participate during the addition and thus the effect of methyl substitution on C_6 is long range. It is hoped that further studies on the effect of substituents at C_6 of the norbornyl system will provide additional information from which our understanding of the factors involved will be increased.

EXPERIMENTAL

Melting points and boiling points are uncorrected. Boiling points of analytical samples were determined by the micro inverted capillary method.

Camphenilene

The camphenilene, m.p. 33–34°, b.p. 131°, and n_D^{35} 1.4525, used in this study was prepared by methods similar to those reported by Berson (20).

Addition of Acetic Acid to Camphenilene

A solution of 18 g (0.15 mole) of camphenilene in 70 ml of acetic acid containing 1 ml of 50% sulphuric acid was heated at 100° for 1 hour. The solution was poured into 500 ml of cold water and the two layers which formed were separated. The water layer was washed with ether and the ether washing combined with the organic layer. The resulting ether solution was washed with water, 10% sodium carbonate solution, and water and then dried over anhydrous magnesium sulphate. The ether solution was filtered and distilled to give 21 g of acetate product, b.p. 106–122° at 30 mm. Chromatographic separation of the two major components which comprised 90% of the product was carried out, first with a Megachrom instrument fitted with six 8-ft apiezon J columns fitted in parallel to give two acetate products which were shown by chromatography to be 95% pure. Further purification of the acetates with an Aerograph unit fitted with a 10-ft dinonyl phthalate column gave the two components pure.

Acetate, b.p. 211° and n_D^{21} 1.4597. Calc. for $C_{11}H_{18}O_2$: C, 72.53; H, 9.89. Found: C, 72.45; H, 9.66.

Acetate, b.p. 214° and n_D^{21} 1.4611. Calc. for $C_{11}H_{18}O_2$: C, 72.53; H, 9.89. Found: C, 72.41; H, 9.77.

The lower-boiling acetate was eluted first, on both columns.

The addition of acetic acid was carried out under a variety of conditions to determine the effect of time and temperature on the product ratio. For these experiments 1 g of camphenilene and 5 ml of acetic acid containing 1% of sulphuric acid were used. The results are given in Table II. A pure sample of the acetate,

TABLE II

Time (min)	Temp. (°C)	% acetate of b.p. 211°	% acetate of b.p. 214°	Comment
20	60	36	64	Reaction incomplete
60	60	39	61	5% camphenilene remaining
5	100	35	65	Reaction complete
30	100	39	61	
240	100	43	57	

b.p. 214°, was heated 5 minutes at 100° in acetic acid with sulphuric acid added. Work-up of the solution showed that there had been no isomerization of this acetate into the acetate, b.p. 211°. The product ratio is therefore kinetically controlled.

Hydroboration of Camphenilene

In a 200-ml 3-necked flask fitted with two gas adapters and a pressure-equalized dropping funnel was placed a solution of 10.73 g (0.088 mole) of camphenilene in 20 ml of purified diglyme. The flask was flushed with nitrogen, and 25 ml (0.025 mole) of 1 *M* sodium borohydride solution in diglyme was added. To the magnetically stirred solution was added dropwise a solution of 4.73 g (0.033 mole) of boron trifluoride etherate in 20 ml of diglyme over a 1-hour period. The solution was allowed to stand an additional hour and there was then added 7 ml of water and 14 ml of 3 *N* sodium hydroxide. The addition funnel was replaced by a condenser and 14 ml of 30% hydrogen peroxide was added in portions to maintain a steady reflux. The solution was cooled and added to 100 g of ice and extracted four times with water, and the ether extract was washed with ice water and dried over magnesium sulphate.

The ether solution was filtered and the ether removed by distillation. To the residual alcohol was added 40 ml of pyridine and 20 ml of acetic anhydride. The mixture was heated 3 hours on a steam bath and then poured into ice containing 15 ml of concentrated sulphuric acid. The resulting solution was extracted with ether and the ether solution washed with dilute sulphuric acid and water and then dried over magnesium sulphate. Distillation gave 9 g of acetate, b.p. 95–100° at 17 mm.

Vapor chromatographic separation of the product using a dinonyl phthalate column showed only 2 peaks. The first peak, n_D^{24} 1.4583, representing 45% of the total, was identical by infrared with the acetate, b.p. 211°, isolated from the addition reaction of acetic acid to camphenilene. The second peak, n_D^{24} 1.4600, representing 55% of the total, was identical with the acetate, b.p. 214°.

5-exo-Camphenilanol (β-Isofenchocamphorol)

A 15.1-g (0.0825 mole) sample of the acetate, b.p. 214°, which contained 5% of the acetate, b.p. 211°, was reduced in ether with 2.0 g of lithium aluminum hydride. After work-up in the usual way the dry ether solution of the alcohol product was reduced in volume to 20 ml, and 75 ml of pyridine was added. The resulting mixture was heated until all of the ethanol had distilled. Phthalic anhydride (11.3 g, 0.0825 mole) was added to the solution, which was then refluxed for 4 hours. The reaction mixture was poured into 1 liter of 10% sulphuric acid and extracted five times with 50-ml portions of benzene. The benzene solution was washed with water and dried. Evaporation of the benzene gave 23.3 g of product, m.p. 124–128°. Recrystallization from ethyl acetate and petroleum gave 10 g of the pure hydrogen phthalate of 5-*exo*-camphenilanol, m.p. 130–131° (lit. (13) m.p. 130–131°).

A solution of 9.4 g of the hydrogen phthalate of 5-*exo*-camphenilanol and 12.5 g of sodium hydroxide in 50 ml of water was steam-distilled to give 3.9 g of 5-*exo*-camphenilanol, m.p. 53–54° (lit. (13) m.p. 60–61°). Sublimation raised the melting point to 55–56°.

Semicarbazone of 5-Camphenilanone

To a solution of 0.5 g of 5-*exo*-camphenilanol in 1.5 ml of acetone at 5° was added dropwise 1.3 ml of chromic acid solution containing 10.3 g of chromium trioxide and 8.7 ml of concentrated sulphuric acid in 30 ml of water. After 1 hour at 5°, addition was complete, and the reaction was diluted with 13 ml of water and extracted with ether. The ether extract was washed and dried and then concentrated to give 0.5 g of an oil. The oil was treated with 0.5 g of sodium acetate, 0.5 g of semicarbazide hydrochloride, 5 ml of water, and 5 ml of methanol and heated at 65° for 20 minutes. After addition of 10 ml of water and cooling, the semicarbazone separated. Recrystallization from methanol gave 0.25 g, m.p. 189–190°, of the semicarbazone of 5-camphenilanone.

6-exo-Camphenilanol

A pure sample of 4 g of the acetate, b.p. 211°, was reduced with 1 g of lithium aluminum hydride in ether. After work-up in the usual way the product was distilled to give 2.8 g of 6-*exo*-camphenilanol, m.p. 30°, n_D^{31} 1.4187, and b.p. 200°. Calc. for $C_9H_{16}O$: C, 77.09; H, 11.50. Found: C, 77.13; H, 11.79.

The acid phthalate was prepared from a sample of the acetate, b.p. 211°, which contained 5% of the acetate, b.p. 214°, by the procedure used for the preparation of the hydrogen phthalate of 5-*exo*-camphenilanol. After three crystallizations from ethyl acetate and petroleum ether a constant melting point of 138.5–140° was obtained. Calc. for $C_{17}H_{20}O_4$: C, 70.81; H, 6.99. Found: C, 71.02; H, 7.13.

6-Camphenilanone

A solution of 2.6 g of 6-*exo*-camphenilanol in 20 ml of ether was treated at 20° with 8.8 ml of a solution made up from 5.00 g of sodium dichromate dihydrate and 3.75 ml of concentrated sulphuric acid diluted to 25 ml by the procedure of Brown and Garg (21). Chromatography of the product showed two peaks. The major peak, representing 82% of the total, was collected to give 1.0 g of 6-camphenilanone, m.p. 55–56° and b.p. 194° (lit. (18) b.p. 197°). Calc. for $C_9H_{14}O$: C, 78.21; H, 10.21. Found: C, 78.22; H, 9.95.

Semicarbazone, m.p. 183–184°, mixed m.p. with the semicarbazone of 5-camphenilanone 159–172°. Calc. for $C_{10}H_{17}N_3O$: C, 61.51; H, 8.78; N, 21.52. Found: C, 61.46; H, 8.66; N, 21.50. The semicarbazone, which

was prepared in methanol–water with semicarbazide hydrochloride and sodium acetate at room temperature, precipitated over a period of 4 weeks.

2,4-Dinitrophenylhydrazone, m.p. 164–165°. Calc. for $C_{15}H_{18}N_4O_4$: C, 56.59; H, 5.70; N, 17.60. Found: C, 56.65; H, 5.53; N, 17.61. The 2,4-dinitrophenylhydrazone took 3 weeks to form by the procedure of Shine (22). Camphor under the same conditions yields the derivative in 3 days.

The minor peak was collected but not identified. Analysis gave C, 72.09; H, 8.08.

THE GAS–LIQUID PARTITION CHROMATOGRAPHY OF CARBOHYDRATE DERIVATIVES

PART III. THE SEPARATION OF AMINO GLYCOSE DERIVATIVES AND OF CARBOHYDRATE ACETAL AND KETAL DERIVATIVES

H. G. JONES, J. K. N. JONES, AND M. B. PERRY
Department of Organic Chemistry, Queen's University, Kingston, Ontario

Received April 24, 1962

ABSTRACT

Gas–liquid partition chromatography has been used to separate the anomeric acetates of 2-amino-2-deoxy-D-glucopyranose (D-glucosamine) and of 2-amino-2-deoxy-D-galactopyranose (D-galactosamine) and also their fully acetylated reduction products, 2-acetamido-2-deoxy-1,3,4,5,6-penta-*O*-acetyl-D-glucitol and 2-acetamido-2-deoxy-1,3,4,5,6-penta-*O*-acetyl-D-galactitol. The gas–liquid partition chromatographic method has also been successfully applied to the separation of unsubstituted carbohydrate acetal and ketal derivatives and to those derivatives in which the free hydroxyl groups have been substituted by *O*-acetyl, *O*-benzoyl, O-benzyl, carbonate, *O*-methanesulphonyl, *O*-methyl, and *O*-toluene-*p*-sulphonyl groups.

The Separation of Amino Glycose Derivatives

The present methods available for the analysis of amino glycoses mainly involve paper chromatographic procedures (1, 2) in which the compositions of the solvent systems have to be carefully chosen in order to prevent the decomposition of the free glycoses, which results in tailing, and the production of double spots. The *N*-(2,4-dinitrophenyl) (3) and *N*-acetyl derivatives of amino glycoses, however, behave like non-nitrogenous glycoses in the usual paper chromatographic solvent systems and their separations present no difficulties. Quantitative paper chromatographic procedures for the analysis of amino glycoses have been developed which use 2,3,5-triphenyl-2-*H*-tetrazolium hydroxide or ninhydrin as the detecting reagents (4). Methods involving ion-exchange chromatography have also been used in the separation of amino glycoses (5).

A variety of amino glycoses are now known to occur in nature (6), particularly in bacteria, lower fungi, and their soluble metabolites, and as components of mucopolysaccharides and glycoproteins. It was considered that a successful gas–liquid partition chromatographic procedure for their separation which would have the advantages of greater selectivity, speed, and simplicity and which could be used in the investigation of microamounts of material would provide a valuable supplement to the existing analytical methods.

The present investigations were confined to the two common naturally occurring amino glycoses 2-amino-2-deoxy-D-glucose (D-glucosamine) and 2-amino-2-deoxy-D-galactose (D-galactosamine). It was found that the acetates of these glycoses had such large retention volumes on the columns previously used for the analysis of non-nitrogenous glycose and glycitol acetates (7) that their successful resolution was not achieved. However, when a column packing made up of 5% w/w neopentylglycol sebacate polyester on Chromosorb W placed on top of a column approximately twice its length of 1% w/w SE-30 methyl silicone polymer on glass beads (column packing 3) at 214° C was used, good resolution of the anomers of 2-acetamido-2-deoxy-1,3,4,6-tetra-*O*-acetyl-D-glucose and of 2-acetamido-2-deoxy-1,3,4,6-tetra-*O*-acetyl-D-galactose and also of their acetylated reduction products 2-acetamido-2-deoxy-1,3,4,5,6-penta-*O*-acetyl-D-glucitol and 2-aceta-

mido-2-deoxy-1,3,4,5,6-penta-*O*-acetyl-D-galactitol were obtained. Table I records the retention volumes of these derivatives relative to penta-*O*-acetyl-L-arabitol (= 1.00) and a typical separation of the derivatives of 2-amino-2-deoxy-D-glucose is shown in Fig. 1.

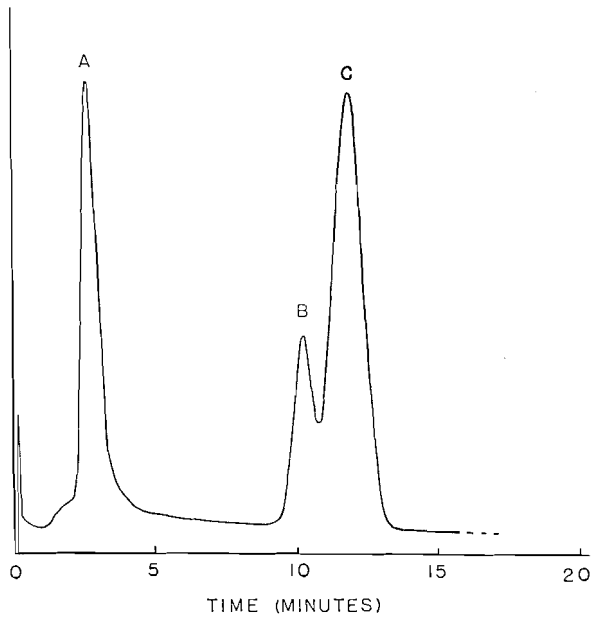

FIG. 1. Separation of 2-amino-2-deoxy-D-glucose derivatives: (A) 2-acetamido-2-deoxy-1,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose, (B) 2-acetamido-2-deoxy-1,3,4,5,6-penta-*O*-acetyl-D-glucitol, and (C) 2-acetamido-2-deoxy-1,3,4,6-tetra-*O*-acetyl-α-D-glucopyranose. (Column packing 3, 214° C, 150 ml argon/min.)

TABLE I
Retention volumes of amino glycose derivatives relative to penta-*O*-acetyl-L-arabitol (= 1.00)

Amino glycose derivative	Retention volume column packing 3 214° C
2-Acetamido-2-deoxy-1,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose	1.82
2-Acetamido-2-deoxy-1,3,4,5,6-penta-*O*-acetyl-D-glucitol	6.92
2-Acetamido-2-deoxy-1,3,4,6-tetra-*O*-acetyl-α-D-galactopyranose	7.93
2-Acetamido-2-deoxy-1,3,4,6-tetra-*O*-acetyl-α-D-glucopyranose	7.95
2-Acetamido-2-deoxy-1,3,4,6-tetra-*O*-acetyl-β-D-galactopyranose	8.12
2-Acetamido-2-deoxy-1,3,4,5,6-penta-*O*-acetyl-D-galactitol	8.14

Preliminary studies on the quantitative analysis of mixtures of 2-amino-2-deoxy-D-glucose and 2-amino-2-deoxy-D-galactose have been obtained by the G.L.P.C. separation of their fully acetylated glycitol derivatives (prepared by the sodium borohydride reduction of the 2-acetamido-2-deoxyglycoses followed by acetylation using pyridine and acetic anhydride) and measurement of the areas under the peaks obtained on the separation curves. Column packing 3 also resolved the acetates of non-nitrogenous pentitols and hexitols, and since the 2-acetamido-2-deoxy-penta-*O*-acetylhexitol derivatives investigated have much larger retention volumes than the former derivatives, it has been possible to analyze mixtures of neutral and basic glycoses on a single separation curve in a way analogous to that previously described for the analysis of neutral sugars alone

(8). The method has proved useful in this laboratory for the analysis of the hydrolyzates of glycoproteins and their lower molecular weight fragmentation products.

The Separation of Carbohydrate Acetal and Ketal Derivatives

The acetal and ketal derivatives of carbohydrates have proved to be important derivatives (9) which can be used for the characterization of glycitols, and as intermediates of known constitution from which substituted derivatives can be made and from which the protective alkylidene or arylidene groups may be subsequently removed under mild conditions. Hitherto, for acetal and ketal carbohydrate derivatives, there have been no generally satisfactory chromatographic methods of separation with the exception of a method developed by Barnett and Kent (10) using ascending chromatography on cellulose acetate strips. Our present results show that the G.L.P.C. method provides a sensitive micromethod for the detection and separation of carbohydrates containing one or more alkylidene or arylidene groups and also for such derivatives in which free hydroxyl groups have been substituted by *O*-acetyl, *O*-benzoyl, *O*-benzyl, carbonate, *O*-methanesulphonyl, *O*-methyl, and *O*-toluene-*p*-sulphonyl groups.

The most generally useful column packing was made up of an intimate mixture of Apiezon M grease on Chromosorb W and butanediol succinate polyester on Chromosorb W packed on top of a column of SE-30 methyl silicone polymer on glass beads (column packing 1), which at 206° C gave good separations of carbohydrate acetal and ketal derivatives. A representative group of derivatives separated on column packing 1, with their retention volumes quoted with reference to 1,2:5,6-di-*O*-isopropylidene-D-glucose (= 1.00), is recorded in Table II. Typical separations of D-fructose derivatives are shown in Fig. 2 and separations of 1,2:5,6-di-*O*-isopropylidene-D-glucose, 4,6-*O*-ethylidene-2,3-*O*-isopropylidene-D-mannose, and 1,2-*O*-isopropylidene-D-glucofuranose are shown in Fig. 3.

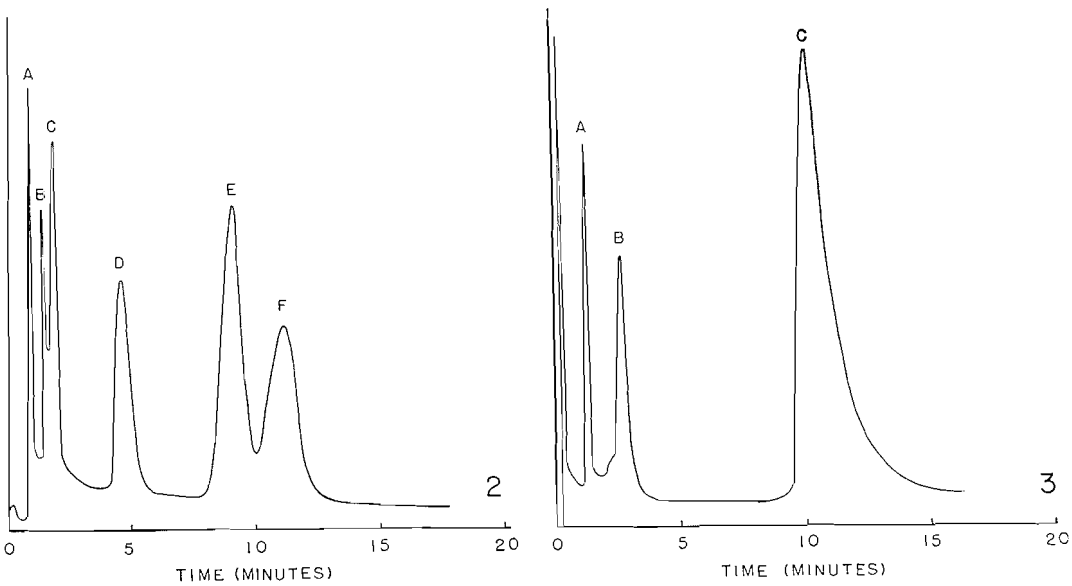

FIG. 2. Separation of D-fructose derivatives: (A) 1,2:4,5-di-*O*-isopropylidene-3-*O*-methyl-D-fructose, (B) 1,2:4,5-di-*O*-isopropylidene-D-fructose, (C) 2,3:4,5-di-*O*-isopropylidene-D-fructose, (D) 1,2-*O*-isopropylidene-D-fructose, (E) 3-*O*-benzyl-1,2:4,5-di-*O*-isopropylidene-D-fructose, and (F) 1,2:4,5-di-*O*-isopropylidene-3-*O*-methanesulphonyl-D-fructose. (Column packing 1, 206° C, 150 ml argon/min.)

1,2:3,4-Di-*O*-isopropylidene-6-*O*-methanesulphonyl-D-galactose	6.64
2-*O*-Benzyl-3,4:5,6-di-*O*-isopropylidene-D-mannose dimethylacetal	7.46
1,3:2,4-Di-*O*-methylene-D-glucitol	8.88
2,3:5,6-Di-*O*-isopropylidene-4-*O*-toluene-*p*-sulphonyl-D-glucose dimethylacetal	8.92
3,5-Di-*O*-acetyl-2,4-*O*-benzylidene-D-xylose dimethylacetal	12.8
2,3:4,5-Di-*O*-isopropylidene-1-*O*-toluene-*p*-sulphonyl-D-fructose	16.7
1,3,5-Tri-*O*-acetyl-2,4-*O*-benzylidenexylitol	17.8
Methyl 3,4-*O*-isopropylidene-2-*O*-toluene-*p*-sulphonyl-β-D-arabinoside	18.0
1,2:5,6-Di-*O*-isopropylidene-3-*O*-toluene-*p*-sulphonyl-D-glucose	25.6
Methyl 4,6-*O*-isopropylidene-2,3-di-*O*-methanesulphonyl-α-D-glucoside	40.1
Methyl 4,6-*O*-isopropylidene-2,3-di-*O*-benzoyl-α-D-glucoside	42.7
4,6-*O*-Ethylidene-1,2-*O*-isopropylidene-3-*O*-toluene-*p*-sulphonyl-D-galactose	54.0
3,4-*O*-Ethylidene-1,2-*O*-isopropylidene-6-*O*-toluene-*p*-sulphonyl-D-galactose	56.8
Penta-*O*-acetyl-L-arabitol	2.46

In general it is found that substitution of free hydroxyl groups in carbohydrate acetal and ketal derivatives by *O*-methyl or *O*-acetyl groups reduces the retention volume below that of the parent compound whereas replacement by *O*-benzyl, *O*-methanesulphonyl, *O*-benzoyl, and *O*-toluene-*p*-sulphonyl groups causes increase in the retention volumes above that of the parent derivative, in the order listed.

Carbohydrates substituted by only one arylidene group, such as methyl 4,6-*O*-benzylidene-α-D-glucoside (retention time 2 min, column packing 2), and those derivatives containing two or more *O*-toluene-*p*-sulphonyl groups had such large retention volumes on column packing 1 that their separation proved impractical. However, a column made up of a very short length of a 1:1 v/v intimate mixture of (*a*) 20% w/w Apiezon M grease on Chromosorb W and (*b*) 20% w/w butanediol succinate polyester on Chromosorb W placed on top of a column of 1% w/w SE-30 methyl silicone polymer of glass beads at 206° C gave good separations of those compounds which had impractically high retention volumes on column packing 1.

EXPERIMENTAL

Apparatus

Separations were carried out using a Pye Argon Chromatograph fitted with an ionization detector (80 μc radium D) and employing straight glass columns (117×0.5-cm I.D.) packed with the support material and enclosed at each end by small glass wool plugs. The samples (3–5 γ) in dry methanol or chloroform solution were placed on the top of the columns with the aid of a micropipette and development was made using dry argon as the carrier gas.

Column Packings

Chromosorb W (60–80 mesh) and glass beads (60 plus mesh) were prepared and coated with the liquid phases under the previously described conditions (7). The columns were prepared as described below.

(1) Column packing 1.—A column was constructed of 40 cm of (*a*) a 1:1 v/v intimate mixture of 20% w/w Apiezon M grease on 60–80 mesh Chromosorb W and 20% w/w butanediol succinate polyester on 60–80 mesh Chromosorb W placed on top of a 77-cm column of (*b*) 1% w/w SE-30 methyl silicone polymer on 60 plus mesh glass beads.

(2) Column packing 2.—A column was constructed of 1.8 cm of (*a*) a 1:1 v/v intimate mixture of 20% w/w Apiezon M grease on 60–80 mesh Chromosorb W and 20% w/w butanediol succinate polyester on 60–80 mesh Chromosorb W placed on top of a 113-cm column of (*b*) 1% SE-30 methyl silicone polymer on 60 plus mesh glass beads.

(3) Column packing 3.—A column was constructed of 40 cm of (*a*) 5% w/w neopentylglycol sebacate (Applied Science Laboratories Inc., State College, Penna.) on 60–80 mesh Chromosorb W placed on top of a 74-cm column of (*b*) 1% w/w SE-30 methyl silicone polymer on 60 plus mesh glass beads.

The fresh columns were purged with argon gas for 6 hours at 15° above their operating temperatures before use. The columns could be used for several hundred analyses before any noticeable deterioration in their resolving power became apparent.

ANIONIC POLYMERIZATION OF STYRENE

EFFECT OF TETRAHYDROFURAN[1]

S. BYWATER AND D. J. WORSFOLD
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received March 16, 1962

ABSTRACT

The propagation step in the butyllithium-initiated polymerization of styrene in benzene solution is thought to be due to a small concentration of highly active free ion-pairs in equilibrium with unreactive dimeric ion-pairs. This work shows that these dimers may be broken down by the addition of tetrahydrofuran. Small quantities of tetrahydrofuran form, first, a low concentration of a monoetherate of the ion-pair with a high reactivity, and this augments the propagation reaction without changing the kinetic order with respect to the initiator. This, at higher tetrahydrofuran concentrations, is followed by the complete breakdown of the dimers to give a dietherate in much higher concentration and lower reactivity compared with the initial ion-pair and monoetherate. The kinetic order with respect to the initial initiator species changes from one half to one during this process, and a maximum appears in the rate as the ether concentration increases.

Small amounts of ethers and amines have been found to cause a great increase in the rate of polymerization of styrene initiated by lithium alkyls in hydrocarbon solution (1, 2). Welch, and Tobolsky and O'Driscoll, have postulated the formation of a stable complex of the lithium alkyl or active chain end with two molecules of ether, when the ether is tetrahydrofuran (THF), and Welch made an estimate of the equilibrium constant for the association from the variation of rate with ether concentration.

Later data (3, 4), however, have indicated that the kinetic scheme used has to be modified. It is now thought that the lithium polystyryl salts formed in the polymerization in benzene solution are dimerized, because the rate of propagation is proportional to the half power of polystyryl anions present. Confirmation of this hypothesis could be sought by looking for the breakdown of the dimers by preferential coordination with THF, with a resultant change in the kinetic behavior. The more detailed study that is necessary has now been made, and although the formation of etherates is confirmed, the whole behavior is more complex than was previously thought.

EXPERIMENTAL

The experimental procedures were those used before (4). The THF was added via further fragile bulbs into which either a known volume of vapor was condensed or, for the highest concentrations, a known volume of liquid. Benzene was used as solvent throughout. All concentrations are in moles/liter, the time is in minutes, and except for the temperature dependence measurements the experiments were done at 20°.

RESULTS AND DISCUSSION

The first series of kinetic runs was designed to study the behavior of the reaction in the presence of a large excess of THF over *n*-butyllithium, the initiator used throughout. The first major effect of the THF is apparent in the initiation reaction. In the presence of 0.15 *M* THF the initiation step is completed virtually instantaneously on mixing of the reagents, in sharp contrast to the behavior in the absence of THF, where it is possible to follow the initiation reaction by the increase in optical density at 335 mμ over a period

[1]*Issued as N.R.C. No. 6889.*

of an hour or more. The optical density at 335 mμ attained a maximum before any measurements could be taken, and then declined at such a slow rate compared with that of the propagation reaction that the decline was negligible.

The shape of the ultraviolet absorption peak of the polystyryl anion in this benzene–THF mixture differs somewhat from that in pure benzene (4). Although the position of the maximum is still at 335 mμ the peak is broader and more akin to the spectrum in pure THF. There also appears to be a small increase in the integral extinction coefficient as found from the relative areas under the curves, and the area is closer to that of the absorption of the sodium polystyryl salt in THF solution. The extinction coefficient at 335 mμ changed from 1.30×10^4 in benzene to 1.20×10^4, and compares with 1.18 found in THF at 343 mμ. In subsequent series of experiments it was found that on the addition of smaller amounts of THF the spectrum was closer to that in pure benzene. When the [THF]/[butyllithium] ratio is about 2, at a butyllithium concentration of 10^{-3} M, the spectrum is almost identical with that in pure benzene solution. On addition of further THF the spectrum changes up to a ratio of 30/1 and then remains constant.

Even at the lowest concentration of THF used initiation was complete in a few seconds and no attempt was made to measure its kinetics. It is possibly this greatly increased rate of initiation that has caused other workers to comment on the greater overall rate of polymerization in the presence of THF. The propagation rate is generally increased as well, but far less markedly. Because of the fast initiation step, the concentration of polymerizing chain ends could always be taken to be the same as the initial butyllithium concentration.

The propagation reaction gives a normal first-order disappearance of styrene over several half-lifetimes, and good logarithmic plots of the decrease in optical density at 291 mμ were obtained as far as the limitations of the analysis would allow. The order with respect to the initial butyllithium concentration is changed from one half in the absence of THF to one in the presence of 0.15 M THF (Fig. 1). This is consistent with the breakdown by THF molecules of the dimerized active chain ends postulated to explain the half-order dependence in benzene. The actual increase in the rate of polymerization,

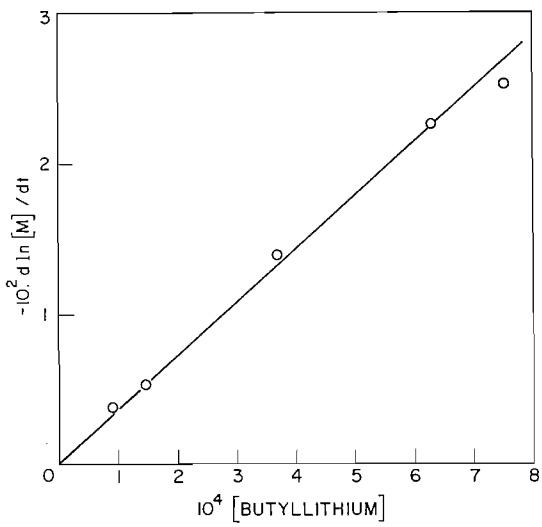

FIG. 1. The dependence of the propagation rate on the initial concentration of butyllithium in the presence of 0.15 M THF.

however, is only a few fold, and not at all proportional to the great increase in the number of monomeric active chain ends that must occur as all the chain ends separate. This can be explained by a sharp decrease in the intrinsic reactivity of the chain ends when complexed with THF. Alternatively, the reaction could be directly with the dimer instead of the single lithium polystyryl ion-pairs in equilibrium, but this view is not consistent with the rest of the data.

The next series of experiments was designed to find how the rate of propagation varied with the THF concentration. Propagation rates were measured over a wide range of THF concentrations, keeping the butyllithium nearly constant, at each of two median butyllithium concentrations (Fig. 2). It is seen that, although for small ratios of [THF]/

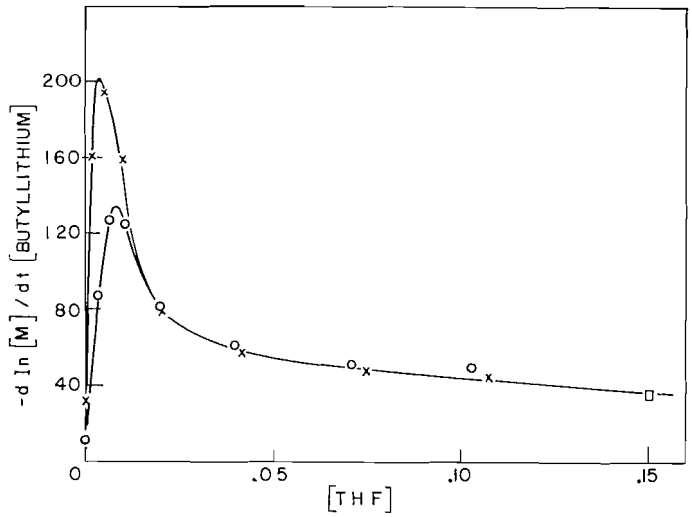

FIG. 2. The effect of wide variations in the tetrahydrofuran concentration on the propagation rate at two median butyllithium concentrations: O, [BuLi] = 0.96–1.2×10^{-3} M; ×, [BuLi] = 1.2–1.8×10^{-4} M.

[butyllithium] there is a sharp increase in rate, at ratios above about 10:1 the rates begin to decline.

The variation of the rate with the butyllithium and THF concentrations at the initial rising portion of these curves was next determined. Figure 3 is a plot of rate against the square root of half the initial butyllithium concentration at constant [THF] of 10^{-3} M, demonstrating that at this low THF concentration the order is still very close to a half in initiator. The difficulty of accurately reproducing this low THF concentration under these conditions is responsible for the rather undesirable scatter of the points.

Figure 4 shows a plot of rate/([butyllithium]/2)$^{1/2}$ vs. [THF] for low values of the latter, over a narrow range of initial butyllithium concentration. It is seen that the increase in rate approaches a linear dependence on the THF concentration as this decreases.

Hence at low [THF]/[butyllithium] ratios the propagation rate seems to be governed by the rate expression

$$-d \ln [\text{styrene}]/dt = ([\text{butyllithium}]/2)^{1/2}[\text{styrene}](k^{\text{I}}+k^{\text{II}}[\text{THF}]). \qquad [1]$$

At high ratios of [THF]/[butyllithium] it is possible to obtain a linear plot of rate against 1/[THF] with an intercept on the ordinate (Fig. 5). Hence as it has already been

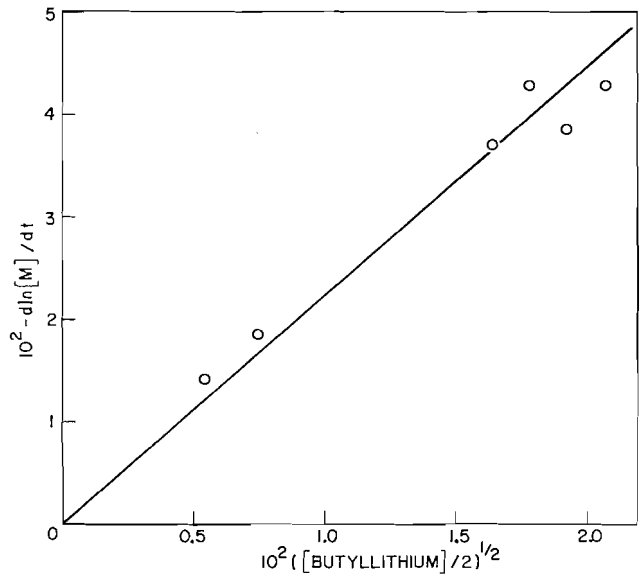

FIG. 3. The dependence of the propagation rate on the initial concentration of butyllithium in the presence of 1×10^{-3} M THF.

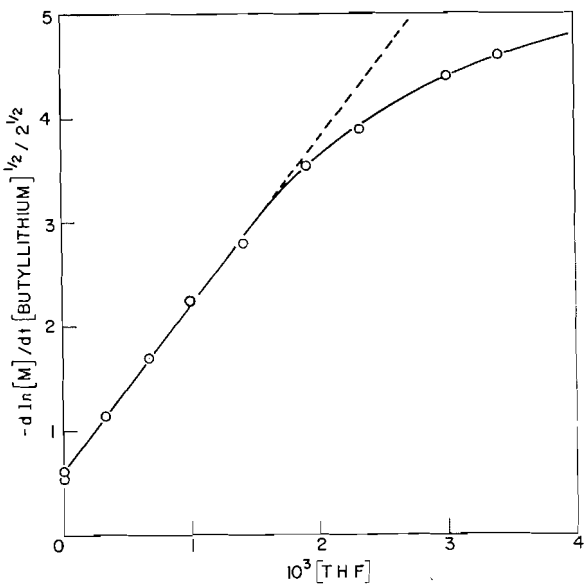

FIG. 4. The dependence of the propagation rate on low concentrations of THF. [BuLi] = $4.2\text{–}6.4\times10^{-4}$ M.

shown that the rate is of first order in initial [butyllithium], the propagation rate is governed by the equation

$$-d\ln[\text{styrene}]/dt = [\text{butyllithium}](k^{\text{III}}+k^{\text{IV}}/[\text{THF}]). \qquad [2]$$

These kinetics are consistent with a reaction scheme whereby the initial unreactive dimer ion-pair is in equilibrium with the free chain end ion-pair, which in turn is in equilibrium with a complex of this ion-pair with one molecule of THF, and this in turn can

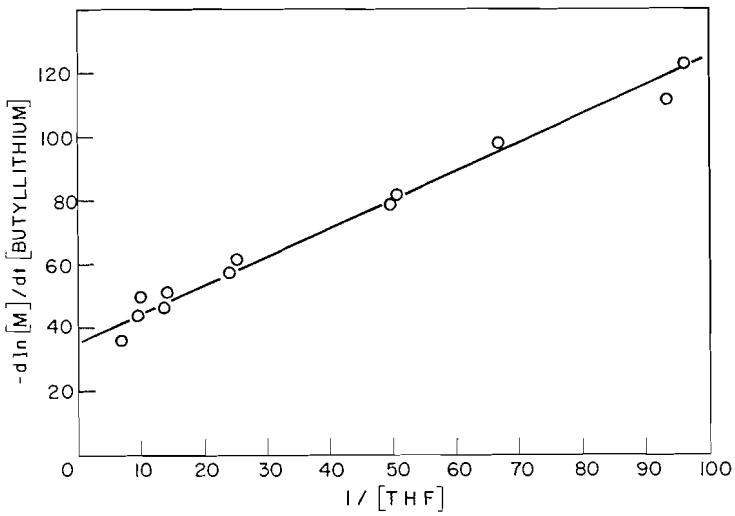

FIG. 5. The dependence of the propagation rate on higher concentrations of THF.

complex with one more molecule of THF to form a dietherate of comparatively low reactivity compared with the monoetherate or the bare ion-pair.

Hence,

$$(P_i)_2 \overset{K_1}{\rightleftarrows} 2P_i, \qquad P_i + M \overset{k_1}{\rightarrow} P_{i+1} \qquad [3]$$

$$P_i + THF \overset{K_2}{\rightleftarrows} P_i.THF, \qquad P_i.THF + M \overset{k_2}{\rightarrow} P_{i+1}.THF \qquad [4]$$

$$P_i.THF + THF \overset{K_3}{\rightleftarrows} P_i.2THF, \qquad P_i.2THF + M \overset{k_3}{\rightarrow} P_{i+1}.2THF \qquad [5]$$

At low THF concentrations only [3] and [4] will be of importance; hence,

$$-d \ln [M]/dt = k_1[P_i]+k_2[P_i.THF]$$
$$-d \ln [M]/dt = k_1K_1^{1/2}[(P_i)_2]^{1/2}+k_2K_1^{1/2}K_2[(P_i)_2]^{1/2}[THF].$$

Under these conditions both $[P_i]$ and $[P_i.THF]$ are small and $[(P_i)_2]$ is given by [butyllithium]/2. This is identical with [1] if $k^{I} = k_1K_1^{1/2}$ and $k^{II} = k_2K_1^{1/2}K_2$.

At high THF concentration, only [4] and [5] are of importance; hence,

$$-d \ln [M]/dt = k_2[P_i.THF]+k_3[P_i.2THF]$$
$$-d \ln [M]/dt = k_2[P_i.2THF]/K_3[THF]+k_3[P_i.2THF].$$

Under these conditions $[P_i.THF]$ is small, and in the limit $[P_i.2THF]$ is the total concentration of chain ends and hence equal to the initial butyllithium concentration. This is equivalent to [2] when $k^{III} = k_3$ and $k^{IV} = k_2/K_3$.

The overall reaction is governed by the equation

$$-d \ln [M]/dt = k_1[P_i]+k_2[P_i.THF]+k_3[P_i.2THF],$$

and if $[P_i]$ and $[P_i.THF]$ are assumed always small, then $2[(P_i)_2]+[P_i.2THF] = [c]$, where $[c]$ is the initial butyllithium concentration, and

$$-d \ln [M]/dt = k_1K_1^{1/2}\{(c-B)/2\}^{1/2}+k_2B/K_3[THF]+k_3[B], \qquad [6]$$

where

$$B = \{(A^2+4Ac)^{1/2}-A\}/2,$$
$$A = K_1K_2^2K_3^2[\mathrm{THF}]^4/2,$$
$$c = [\text{butyllithium}],$$

for all concentrations of THF.

The values $k_1K_1^{1/2} = 0.548$, $k_2K_1^{1/2}K_2 = 1.59\times10^3$, $k_2/K_3 = 0.89$, and $k_3 = 35.5$ can be derived from the slopes and intercepts in Figs. 1, 4, and 5, and from them it is possible to evaluate equation [6]. The calculated contributions of the three simultaneous propagation rates are given in Table I, together with their sum and the experimental value for all runs. Reasonable agreement is found, considering the range covered, which suggests that the approximations made were valid.

Because of the different rates of propagation of the three reactive species, if the establishment of the equilibria is not rapid, the polymer produced would not have the Poisson distribution expected from the fast initiation and slow propagation rates. To check this, two polymers were made under different conditions and their viscosity-average molecular weights found (5). The agreement shown in Table II with the number-average molecular weight calculated from the expression D.P. = [M]/[c] is sufficiently good to conclude that the equilibria must be very labile.

TABLE II

Measured and calculated molecular weights

			Molecular weight	
10^3[BuLi]	[Styrene]	10^3[THF]	Calc.	Visc.
1.24	0.452	3.95	37,900	39,600
1.38	1.050	6.05	79,100	82,800

The temperature coefficient of the reaction of the dietherate with styrene at a THF concentration of 0.15 M was found over the range 10° to 30°, and was equivalent to an activation energy of 10.4 kcal. This compares with the value of 9.2 kcal found by Gee, Allen, and Stretch (6) for the propagation reaction in the polymerization of styrene by sodium naphthalene in dioxane solution. The dielectric constants of the two solvents are similar, and both reactions have the same kinetics. No doubt the reactive species in dioxane is again an etherate.

It is not possible to determine the absolute concentration of the monoetherate from the data, but the assumption that it is small seems valid. The concentration of the dietherate can be calculated and shows that the tendency to complex is not very strong, since for an initiator concentration of 10^{-3} M nearly a 10-fold excess of THF is necessary before over 90% of the chains are in this form. Even then the rate is still largely governed by the small equilibrium concentration of monoetherate. The weakness of the complex is also illustrated by the slow change in appearance of the absorption peak in the ultraviolet with increasing THF concentration. It would seem that the ion-pair would prefer to associate with itself than with the THF. The interaction between two ion-pairs would be expected to be greater than that between one ion-pair and a polar molecule.

It should be noted that this analysis does not preclude the possibility of higher etherates forming at even higher THF concentration. Even in the range covered small amounts of such complexes would be overlooked unless they had again a markedly different reactivity.

γ-FLUOROGLUTAMIC ACID

R. L. BUCHANAN, F. H. DEAN, AND F. L. M. PATTISON
Department of Chemistry, University of Western Ontario, London, Ontario
Received March 27, 1962

ABSTRACT

The synthesis of γ-fluoroglutamic acid, $HOOCCHFCH_2CH(NH_2)COOH$, was achieved by two independent methods, both of which involved the Michael reaction: (1) methyl α-fluoroacrylate and diethyl acetamidomalonate gave the transesterified intermediate, which on hydrolysis produced γ-fluoroglutamic acid (31% yield); (2) ethyl α-acetamidoacrylate and diethyl fluoromalonate reacted under mild conditions to give, after hydrolysis, the required amino acid in 56% overall yield. Of the two procedures, the second is preferable, since it is based on more readily available starting materials and gives a higher yield.

Virulent *Mycobacterium tuberculosis* var. *hominis* has a glutamic acid content averaging 50% higher than that of non-infective strains. The infective strain's virulence might thus conceivably be related in some way to its content of glutamic acid. From this it follows that antimetabolites of glutamic acid might have some chance of being effective against the tubercle bacillus. Because of the spatial similarity of fluorine and hydrogen atoms in organic compounds (1), γ-fluoroglutamic acid (I) was considered to be a promising candidate agent, and its synthesis was therefore undertaken.

The two routes which were examined initially proved to be unsuccessful. These are summarized below:

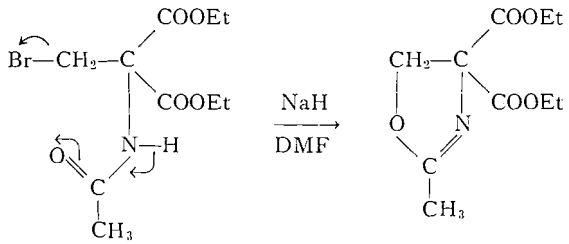
$$EtOOC\overline{C}HF + BrCH_2COCOOEt \rightarrow EtOOCCHFCH_2COCOOEt$$
$$\rightarrow EtOOCCHFCH_2CH(NH_2)COOEt \rightarrow \underset{\text{I}}{HOOCCHFCH_2CH(NH_2)COOH}, \quad [1]$$

$$\underset{\text{II}}{(EtOOC)_2CHF} + \underset{\text{III}}{BrCH_2C(NHAc)(COOEt)_2} \rightarrow (EtOOC)_2CFCH_2C(NHAc)(COOEt)_2$$
$$\rightarrow \underset{\text{I}}{HOOCCHFCH_2CH(NH_2)COOH}. \quad [2]$$

The first of these failed because the enolate of ethyl fluoroacetate (2) was found to attack the keto group of the ethyl bromopyruvate rather than effect nucleophilic substitution; attempts at blocking the keto group were no more successful.

For the second route, the preparation of diethyl bromomethylacetamidomalonate (III) proved to be unexpectedly difficult. Direct alkylation of diethyl acetamidomalonate using excess dibromomethane gave none of the desired product. Alkylation of diethyl acetamidomalonate with chloromethyl methyl ether gave the expected diethyl methoxymethylacetamidomalonate, but attempted cleavage of the ether with hydrobromic acid resulted either in no reaction or in extensive hydrolysis of the ester and amide groupings; this is in contrast to the behavior of diethyl methoxymethylmalonate, which readily forms diethyl bromomethylmalonate under similar treatment (3). The required diethyl bromomethylacetamidomalonate (III) was finally synthesized in satisfactory yield from diethyl acetamidomalonate by hydroxymethylation using formaldehyde and Amberlite IR-4B anion exchange resin at 30–35° (4), followed by treatment with excess phosphorus tribromide. However, on attempted reaction with diethyl fluoromalonate (II) (5), the

basic medium promoted ring closure of the bromo compound rather than the desired alkylation shown above; thus 4,4-dicarboethoxy-2-methyl-2-oxazoline (IV) was formed.



III IV

While oxazolines are susceptible to attack by some nucleophiles, trial runs indicated that 4,4-dicarboethoxy-2-methyl-2-oxazoline was resistant to ring opening by malonic ester anion.

Attention was next directed to schemes involving the Michael reaction:

$$\underset{\text{V}}{\text{ROOCCF=CH}_2} + \text{CH(NHAc)(COOEt)}_2 \rightarrow \underset{\text{VI}}{\text{EtOOCCHFCH}_2\text{C(NHAc)(COOEt)}_2}$$

$$\rightarrow \underset{\text{I}}{\text{HOOCCHFCH}_2\text{CH(NH}_2\text{)COOH}}, \quad [3]$$

$$\underset{\text{II}}{\text{(EtOOC)}_2\text{CHF}} + \underset{\text{VII}}{\text{CH}_2\text{=C(NHAc)COOEt}} \rightarrow \underset{\text{VIII}}{\text{(EtOOC)}_2\text{CFCH}_2\text{CH(NHAc)COOEt}}$$

$$\rightarrow \underset{\text{I}}{\text{HOOCCHFCH}_2\text{CH(NH}_2\text{)COOH}}. \quad [4]$$

While the first of these (scheme [3]) (6) was being studied, Hudlický (7, 8) described the identical procedure starting from ethyl α-fluoroacrylate (V, R = Et) (8, 9). Our work differed only in the use of methyl α-fluoroacrylate (V, R = Me) (10). Details of the synthesis may be obtained from Hudlický's reports. The only additional point of interest is that, during the Michael reaction, treatment with sodium ethoxide in ethanol caused the methyl ester grouping associated with the α-fluoroacrylate to be transesterified to the ethyl ester; thus both methyl and ethyl α-fluoroacrylate gave diethyl α-acetamido-α-carboethoxy-α′-fluoroglutarate (VI) as the Michael intermediate.

The above synthesis (scheme [3]) was based on α-fluoroacrylic esters, which are not readily available, and gave a rather low overall yield of γ-fluoroglutamic acid (31%, crude). Hence the second Michael reaction (scheme [4]) was next examined. Both starting materials are fairly easy to prepare. Diethyl fluoromalonate (II) (5) was obtained from ethyl fluoroacetate and ethyl chloroformate. Ethyl α-acetamidoacrylate (VII) (11) was synthesized from the half ethyl ester of acetamidomalonic acid by reaction with formaldehyde and dimethylamine; the resultant Mannich base gave the desired product at pH 8. The Michael reaction proceeded smoothly at room temperature to yield diethyl α-acetamido-α′-carboethoxy-α′-fluoroglutarate (VIII) and a small amount of 3,5-dicarboethoxy-3-fluoro-2-pyrrolidone by ring closure of VIII (12); the formation of the latter was inferred from the presence of traces of ethyl acetate in the reaction mixture. That the main product was VIII was indicated by a comparison of its amide carbonyl stretching frequency (1681 cm^{-1}) with that of diethyl α-acetamido-α-carboethoxy-α′-fluoroglutarate

(VI) (1686 cm^{-1}) and of 5,5-dicarboethoxy-2-pyrrolidone (1718 cm^{-1}). A separation was not attempted, because hydrolysis of the pyrrolidone and of VIII would give the desired γ-fluoroglutamic acid in both instances. The crude intermediate was heated under reflux with 6 *N* hydrochloric acid. Isolation and purification gave the pure material (I) in 56% overall yield, based on diethyl fluoromalonate. This procedure is the method of choice, in terms of yield, convenience, and availability of starting materials.

γ-Fluoroglutamic acid was non-toxic to mice ($LD_{50} > 80$ mg/kg by intraperitoneal injection). It was inactive in vitro at 20 γ/ml against the following bacteria: *Lactobacillus arabinosus*, *Lactobacillus casei*, *Streptococcus faecalis*, *Streptococcus pyogenes*, *Staphylococcus aureus*, *Proteus mirabilis*, *Pseudomonas aeruginosa*, *Salmonella typhimurium*, and *Mycobacterium tuberculosis* (H37Rv). It was inactive against the following important human pathogenic strains of virus (tissue culture test): polio, measles, herpes, and a virus isolated from respiratory infections (hemagglutinating virus No. 1). It showed weak activity against malignant cells (Eagle–Foley tests) in tissue culture (ED_{50}, 30 γ/ml). In short, no significant biological activity of any sort has been observed so far. The lack of positive results has led us to interrupt the synthesis of the isomeric β-fluoroglutamic acid, $HOOCCH_2CHFCH(NH_2)COOH$.

EXPERIMENTAL

Ethyl Fluoroacetate

This compound was prepared from technical sodium fluoroacetate (compound 1080) (13).

Diethyl Fluoromalonate (II)

This compound was prepared by the method of Bergmann, Cohen, and Shahak (5), but modified as follows: (*a*) The reaction was carried out on four times the scale (i.e. 2 *M*). (*b*) Sodium hydride dispersion (56.5%) in mineral oil was used in place of pure sodium hydride. (*c*) Ethyl fluoroacetate was added over 19 hours instead of 4 hours. (*d*) At the completion of the reaction, the ether extracts were washed with 1% sodium bicarbonate. Crude diethyl fluoromalonate (72.1 g, 27.7%) was obtained, b.p. 86–94° at 9 mm, and n_D^{25} 1.4063, which on fractionation through a platinum-plated spinning-band column yielded the pure fluoro ester (61.5 g, 23.6%), b.p. 97–97.5° at 12 mm, n_D^{25} 1.4056. Calc. for $C_7H_{11}FO_4$: C, 47.19; H, 6.22. Found: C, 46.82; H, 6.46.

Diethyl Methoxymethylacetamidomalonate

Sodium (4.6 g, 0.20 g-atom) was cut into small pieces under dry xylene, was washed with dry ether, and was added to 100 ml of anhydrous ethanol in a 1-liter, three-necked flask fitted with a stirrer, reflux condenser, and addition funnel. When all the sodium had reacted, diethyl acetamidomalonate (43.5 g, 0.20 mole) was added together with a further quantity of anhydrous ethanol (25 ml). The mixture was stirred at room temperature for 14 hours. Dry benzene (100 ml) was added to complete the precipitation of the enolate. The solid was filtered, was washed with dry benzene and dry ether, and was dried in a vacuum desiccator over P_2O_5; yield 37.6 g, 78.5%, m.p. 188–192° (decomp.). The dry enolate was transferred to a 1-liter, three-necked flask, fitted with a stirrer, reflux condenser, and addition funnel. Dry ether (150 ml) was added, and chloromethyl methyl ether (24.2 g, 0.3 mole) in dry ether (30 ml) was added over 15 minutes with vigorous stirring. The mixture was stirred at room temperature for an additional 4 hours, was heated under reflux for 2 hours, and was allowed to stand for 12 hours at room temperature. The precipitated sodium chloride was removed by filtration, and the filtrate was concentrated by evaporation on a steam bath. A small quantity (4.2 g) of diethyl acetamidomalonate crystallized, and the residual viscous liquid was distilled *in vacuo* through a short Vigreux column to yield the required product (10.4 g, 22.0%), b.p. 106–111° at 0.20 mm, n_D^{25} 1.4507. Infrared spectrum in $CHCl_3$, cm^{-1}: 3448 (NH) s, 3012 (CH) s, 2950 (CH) s, 2833 (OCH_3) m, 1745 (ester C=O) vs, 1681 (amide C=O) vs, 1497 s, 1479 s, 1449 m, 1393 m, 1374 s, 1304 s, 1222 s, 1110 s, 1078 m, 1022 s, 858 m. Calc. for $C_{11}H_{19}NO_6$: C, 50.65; H, 7.33. Found: C, 50.37; H, 7.20.

Diethyl Hydroxymethylacetamidomalonate (4)

A slurry of 12 ml of Amberlite IR-4B anion exchange resin in 95% ethanol was placed in a chromatographic column (0.9-cm internal diameter) which was maintained at 30–35° by means of heating tape. Diethyl acetamidomalonate (4.4 g, 22 mmoles) was dissolved in 95% ethanol (100 ml), and 37% formalin solution (2.6 g, 32 mmoles) was added. This solution was added dropwise to the column over 2 hours. The eluate was collected, and about 70 ml of 95% ethanol was passed through the column at the same rate to elute the remainder of the product. The ethanol was removed on a steam bath using a rotatory evaporator; the

resultant viscous syrup was dissolved in benzene, and petroleum ether (b.p. 60–80°) was added. On scratching and cooling, colorless crystals of the hydroxymethyl compound (3.4 g, 62.5%) separated, m.p. 61–65°. Yamada *et al.* (4) quote m.p. 64–65°. Calc. for $C_{10}H_{17}NO_6$: C, 48.57; H, 6.93. Found: C, 48.83; H, 7.13.

Diethyl Bromomethylacetamidomalonate (III)

To diethyl hydroxymethylacetamidomalonate (23.92 g, 96.8 mmoles) in the minimum quantity of benzene was added pyridine (two drops) and then, dropwise and with stirring, phosphorus tribromide (26.2 g, 97 mmoles). The mixture was stirred at 70° for 3½ hours. An equal volume of cold water was added and the resultant layers were separated. The aqueous layer was extracted four times with benzene, and the extracts were added to the original organic layer. The benzene solution was washed with 5% sodium bicarbonate and then with water, and was dried over anhydrous sodium sulphate. The solution was concentrated to a small volume, which on cooling deposited colorless crystals (17.5 g, 58.2%), m.p. 68.5–71.5°. Infrared spectrum in $CHCl_3$, cm^{-1}: 3448 (NH) s, 3021 (CH) s, 1751 (ester C=O) vs, 1681 (amide C=O) vs, 1497 vs, 1449 m, 1427 m, 1395 m, 1376 s, 1304 vs, 1247 s, 1196 s, 1163 m, 1100 m, 1063 m, 1014 s, 946 m, 881 m, 860 s, 630 (C—Br) s. Calc. for $C_{10}H_{16}BrNO_5$: C, 38.72; H, 5.20; Br, 25.77. Found: C, 38.92; H, 5.36; Br, 25.64.

4,4-Dicarboethoxy-2-methyl-2-oxazoline (IV)

Sodium hydride dispersion (56.5%) in mineral oil (137 mg, 3.23 mmoles) was suspended in dry dimethylformamide (25 ml). The bromoester III (1.0 g, 3.23 mmoles) was added, and the mixture was stirred at 65–70° for 7 hours. By this time evolution of hydrogen had ceased and the solution was clear. After standing at room temperature for a further 12 hours, the mixture was poured into water. Extraction with ether, washing the extracts with water, drying (Na_2SO_4), and distillation gave the oxazoline (0.40 g, 54.2%), b.p. 85–87.5° at 0.01 mm, n_D^{25} 1.4489. Infrared spectrum in CCl_4, cm^{-1}: 2985 (CH) s, 1745 (ester C=O) vs, 1667 (C=N) s, 1471 m, 1447 m, 1389 s, 1370 s, 1351 m, 1299 vs, 1247 vs, 1200 vs, 1103 vs, 1029 s, 1001 s, 917 s, 861 m. Calc. for $C_{10}H_{15}NO_5$: C, 52.39; H, 6.60; N, 6.11. Found: C, 52.21; H, 6.74; N, 6.25.

Methyl α-Fluoroacrylate

This compound (V, R = Me) (10) was kindly provided by Dr. J. J. Baron, Jr., General Aniline and Film Corporation, Easton, Pa.

γ-Fluoroglutamic Acid (I) (Scheme [3])

The method was essentially the same as that described by Hudlický (8), but with minor modifications. Methyl α-fluoroacrylate was used in place of the ethyl ester. However, this gave the transesterified Michael intermediate VI, m.p. 99–100.5°. Calc. for $C_{14}H_{22}FNO_7$: C, 50.14; H, 6.61; N, 4.18; F, 5.67; M.W., 335. Found: C, 50.42; H, 6.52; N, 4.22; F, 5.38; M.W. (Rast), 326. It is essential that vigorous and complete hydrolysis of the Michael intermediate be carried out; mild hydrolysis leaves the amide grouping intact, which in turn causes difficulty in the subsequent purification. The free amino acid had m.p. 188–192°. Calc. for $C_5H_8FNO_4$: C, 36.37; H, 4.88; N, 8.48. Found: C, 36.50; H, 5.17; N, 8.70.

Ethyl Hydrogen Acetamidomalonate

This compound was prepared by the method of Hellmann *et al.* (11).

Ethyl α-Acetamidoacrylate (VII)

This compound was prepared by the method of Hellmann *et al.* (11). To ensure the required decarboxylation, it is important to acidify the formalin–dimethylamine solution to a pH of ca. 8 by the addition of dilute hydrochloric acid before adding the acetamidomalonate half ester.

γ-Fluoroglutamic Acid (I) (Scheme [4])

Sodium (41.2 mg, 1.79 mg-atom) was dissolved in absolute ethanol (10 ml) contained in a 50-ml three-necked flask fitted with a stirrer, reflux condenser, and addition funnel. Diethyl fluoromalonate (3.78 g, 21.2 mmoles) was added, and the resultant mixture was stirred for 10 minutes. Ethyl α-acetamidoacrylate (3.2 g, 22.3 mmoles) in absolute ethanol (5 ml) was added dropwise and with stirring, causing a rise in temperature. The mixture was stirred for a further 30 minutes, and then was allowed to stand for 11 hours. The mixture, which had a distinct odor of ethyl acetate, was acidified with dilute hydrochloric acid, and the solvent was removed on a steam bath. The residue (5.65 g), a viscous oil, afforded a satisfactory infrared spectrum for VIII, cm^{-1}: 3413 (NH) s, 2985 (CH) s, 1742 (ester C=O) vs, 1681 (amide C=O) s, 1502 m, 1468 m, 1445 m, 1372 s, 1302 s, 1263 vs, 1159 s, 1096 (C—F) s, 1068 s, 1024 s, 942 m, 858 m.

The viscous oil (5.65 g) was heated under reflux with concentrated hydrochloric acid (14 ml) for 5¾ hours. The resultant solution was evaporated *in vacuo* on a steam bath, and was diluted with water and evaporated twice more. The syrup was dissolved again in water and treated with an excess of freshly prepared silver oxide to remove chloride ions, and filtered through "Supercel" to remove residual traces of silver chloride. The filtrate was evaporated at 70° in a water bath to a volume of about 50 ml. Further evaporation at 35° caused the amino acid to crystallize. After the solid had been collected by filtration, the remainder of the product was precipitated by the addition of 95% ethanol. The fluoroglutamic acid was obtained as a light brown solid (1.96 g, 56%). Two recrystallizations from water and drying *in vacuo* over P_2O_5 gave the pure

acid, m.p. 189–191°. The samples obtained by the two methods (schemes [3] and [4]) gave, on mixing, a melting point of 188–191°. Calc. for $C_5H_8FNO_4$: C, 36.37; H, 4.88; N, 8.48. Found: C, 36.10; H, 5.13; N, 8.28.

The nuclear magnetic resonance spectrum (Table I) of the γ-fluoroglutamic acid (10% w/v in redistilled trifluoroacetic acid) was obtained with a Varian 60 Mc/sec V-4302B spectrometer, using tetramethylsilane as internal standard. The data for DL-glutamic acid, obtained under the same conditions, agree with those already published (14).

TABLE I

N.M.R. spectrum of $HOOCCHFCH_2CH(\overset{+}{N}H_3)COOH$

Group	Chemical shift (τ)		Coupling constants (cycles/sec)
—COOH	−1.60	(under solvent signal)	—
$-\overset{+}{N}H_3$	2.36	(broad)	—
—CHF—	4.47	(doublet of triplets)	J_{HF} 47.3; J_{HH} 5.6
$-CH(\overset{+}{N}H_3)-$	5.25	(multiplet)	—
$-CH_2-$	6.99	(doublet of triplets)	J_{HF} 23.5; J_{HH} 5.6

ACKNOWLEDGMENTS

We wish to express our indebtedness to the National Research Council for financial support and for a studentship (R. L. B.), and to Canadian Industries Limited for the award of a fellowship (F. H. D.). We wish also to acknowledge with thanks the gift of a sample of methyl α-fluoroacrylate from Dr. J. J. Baron, Jr., Central Research Laboratory, General Aniline and Film Corporation, Easton, Pa. We are grateful to Dr. J. B. Stothers of this department for help with the nuclear magnetic resonance spectra, to Dr. M. K. McPhail, Suffield Experimental Station, Ralston, Alberta, for determining the toxicity, and to Parke, Davis and Co., Research Laboratories, 2800 Plymouth Road, Ann Arbor, Michigan, for carrying out or arranging for the bacterial, viral, and anticancer screening of γ-fluoroglutamic acid.

INFRARED ABSORPTION STUDIES ON PEROXY TITANIUM SULPHATE

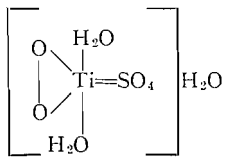
G. V. JERE AND C. C. PATEL
Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 12, India

Received February 23, 1962

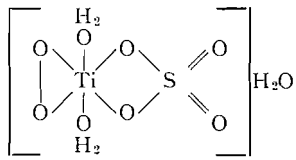
ABSTRACT

The infrared absorption spectrum of peroxy titanium sulphate has been studied in the region from 2 to 23 μ and the various bands are characterized. The sulphate group in the compound is shown to have C_{2v} symmetry, indicating its bidentate nature.

Orange-red peroxy titanium sulphate, $TiO_2SO_4.3H_2O$, was prepared in the solid state by Mohan and Patel (1). The compound was subjected to various physicochemical studies and assigned the structure (A). No infrared absorption studies were, however, carried out on the complex.



(A)



(B)

The infrared spectrum was taken with a single-beam Perkin–Elmer IR spectrometer, model 112, with a KBr prism, employing the mull technique. The absorption curve in the region from 2 to 23 μ is given in Fig. 1. The observed bands with group assignments are listed in Table I. The assignments of the frequencies are based on the available data in the literature. Wherever the bands are broad, the frequency at the center of gravity of the band is given.

The sulphate ion has a regular tetrahedral structure belonging to the point group T_d (2). In its ionic state, SO_4 has nine vibrational degrees of freedom, distributed in four normal modes of vibration. Out of these, only two are infrared active (2). When SO_4 functions as a unidentate ligand, the oxygen coordinating to a metal atom is no longer symmetrically equivalent to the other three oxygens and the effective symmetry of SO_4 is lowered to C_{3v} (3). In C_{3v} symmetry, six infrared absorption bands are observed. When SO_4 functions as a bidentate group, its effective symmetry is further lowered to C_{2v}. In C_{2v} symmetry, eight modes of vibration, out of the total of nine, are infrared active (3). It is thus possible to arrive at the symmetry of the SO_4 group in peroxy titanium sulphate from the observed bands. The observed infrared absorption bands of the SO_4 group for different point group symmetries are listed in Table II, along with the observed bands of the sulphate group of peroxy titanium sulphate. The results of Table II show that the sulphate group in peroxy titanium sulphate has a point group symmetry C_{2v} and the bands agree fairly well with those reported by Nakamoto and co-workers (3) for SO_4 having C_{2v} symmetry. This shows that the SO_4 group functions as a bidentate ligand in peroxy titanium sulphate, confirming the earlier observation of Mohan and Patel (1, 4). In peroxy titanium sulphate, two of the oxygens of the sulphate group are coordinated to the central titanium atom, as given in formula (B).

The band at 3030 cm^{-1} is attributed to the O—H stretching vibration and the one at 1681 cm^{-1} to O—H bending of H_2O groups in the complex. The lowering of the stretching frequency and the raising of the bending frequency from the corresponding frequencies

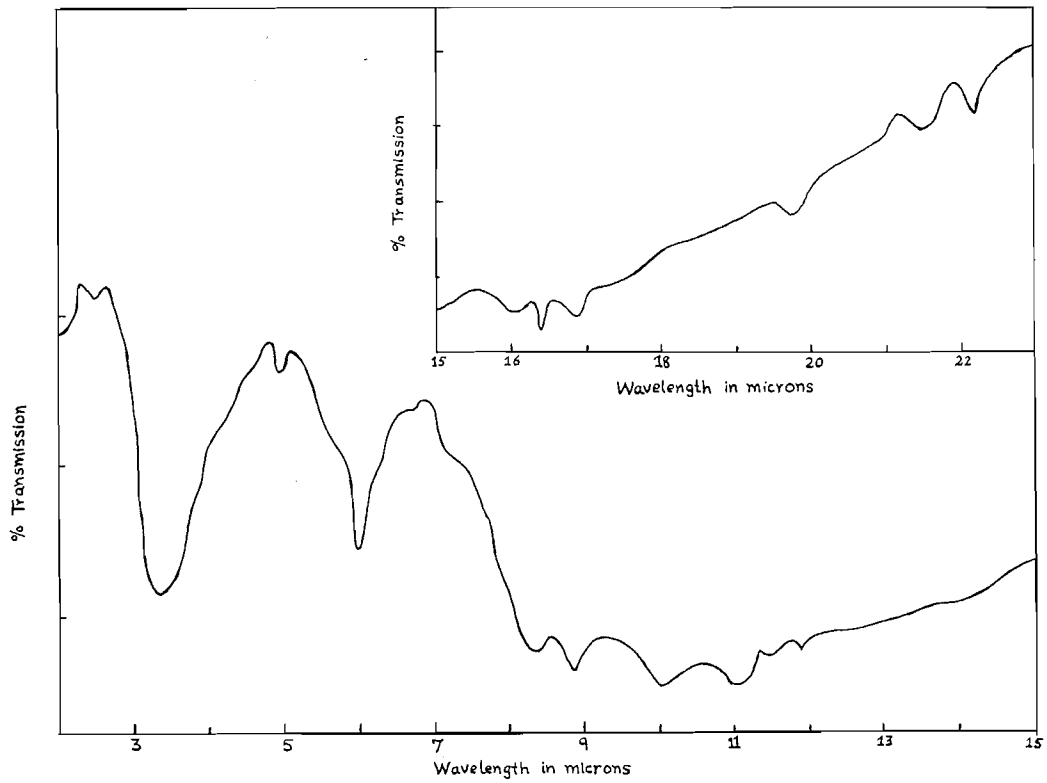


FIG. 1. Infrared spectrum of peroxy titanium sulphate.

TABLE I
Assignments of observed frequencies in the infrared spectrum of peroxy titanium sulphate

Frequency (cm^{-1})		Assignment
3030	(vs)	$\nu(H_2O)$
1681	(vs)	δ (H_2O)
1199	(vs)	(SO_4)

peroxy titanyl group, Ti$\begin{smallmatrix} O \\ | \\ O \end{smallmatrix}$. This assignment is based on the observation of similar bands in titanium peroxide (6), $TiO_2(OH)_2$, and the absence of the same bands in meta-titanyl hydroxide, $TiO(OH)_2$. The peroxy titanyl group bands are also found in the same region in peroxy titanium oxalate, maleate, and malonate complexes (our unpublished data). Unlike the peroxy bands in other peroxy titanium compounds, the band at 1005 cm^{-1} in peroxy titanium sulphate overlaps with one of the SO_4 bands in the same region, resulting in the broadening of the band. The bands at 506 and 448 cm^{-1} are due to the fundamental modes of vibration of Ti—O, as assigned earlier by Narayanan (7) and by Last (8) in rutile and several titanates respectively.

It has been observed, in the infrared spectra of a number of peroxy and deperoxygenated compounds including titanyl peroxide and hydroxide, investigated by the present authors, that there is a broad shallow absorption band extending from about 1000 to 700 cm^{-1}. Nyholm and co-workers (9) have also observed very broad absorption between 800 and 900 cm^{-1} in $TiOSO_4$ and $K_2TiO(C_2O_4)_2$. Kendall (10) has also found continuous absorption in the region 700–1200 cm^{-1} in the spectra of TiO_2 in its three polymeric forms. Narayanan (7) has also observed a broad absorption band extending from 1000 to 1200 cm^{-1} in the Raman spectrum of the rutile. The average region of absorption thus extends from 700 to 1200 cm^{-1} in various compounds having the Ti—O group. This broad absorption seems to be a characteristic feature of the Ti—O system of various titanium compounds. In the infrared spectrum of peroxy titanium sulphate, some of the bands due to the sulphate and the peroxy groups are superimposed on this broad absorption band.

ACKNOWLEDGMENTS

The authors are thankful to Professor M. R. A. Rao for his interest and to the authorities of the Physics Department of this Institute for taking the spectrum.

ISARIIN, A NEW DEPSIPEPTIDE FROM ISARIA CRETACEA[1]

L. C. VINING AND W. A. TABER
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received April 2, 1962

ABSTRACT

One of the metabolic products of the fungus *Isaria cretacea* has been found to yield four different amino acids and a hydroxyacid on acid hydrolysis. The amino acids were identified as glycine, L-alanine, L-valine, and D-leucine, and a quantitative analysis showed them to be present in the molar ratio of 1:1:2:1, respectively. The hydroxyacid was identified as D-β-hydroxydodecanoic acid. These units appear to be combined in a simple cyclic structure by means of peptide bonds and an ester linkage between the hydroxyl of hydroxydecanoic acid and the carboxyl of the C-terminal amino acid. The sequence valine $\rightarrow$ β-hydroxydodecanoic acid $\rightarrow$ glycine has been established.

In an earlier study (1) it was reported that two strains of *Isaria cretacea* van Beyma had been isolated from the heterokaryotic parent organism. The most noteworthy difference between them was the ability of strain A to produce phototropic synnemata under suitable conditions of growth, whereas strain B formed only a highly branched aerial mycelium. Nutritional differences were also discovered, and the ability to develop synnemata was correlated with a low rate of growth.

During an examination of the metabolic products of the two strains a new depsipeptide, which has been named isariin, was isolated. It was found to be present in both strains A and B as well as the parent heterokaryon.

Isariin was obtained as colorless needles, m.p. 249.5–250.5° C, after repeated recrystallization from aqueous ethanol. Analyses and molecular weight estimations indicated the molecular formula $C_{33}H_{59}O_7N_5$. The infrared absorption spectrum provided evidence for ester and secondary amide groups. Isariin possessed neither acidic nor basic functions, but could be hydrolyzed in mild alkaline conditions to the monobasic isariic acid $C_{33}H_{61}O_8N_5$. That the infrared absorption maximum at 1727 cm^{-1} in this product was that of a carboxyl and not the unchanged ester carbonyl was shown by converting it to the sodium salt, when the maximum was shifted to 1603 cm^{-1}.

Vigorous acid hydrolysis of isariin yielded an ether-soluble product which was separated into neutral and acidic fractions. The acid, m.p. 62.8–63.2° C, gave analyses and a neutralization equivalent indicating the molecular formula $C_{12}H_{24}O_3$. The infrared spectrum showed maxima attributable to an aliphatic hydroxyacid, and upon distillation *in vacuo* a product was obtained which had infrared maxima consistent with those of an unsaturated aliphatic acid. This was converted with the uptake of approximately 1 mole of hydrogen, over palladium catalyst, to lauric acid. From the ease with which the hydroxyacid was dehydrated and from the properties of the unsaturated acid the hydroxyl group was thought to be in the β-position. This was confirmed by synthesis and resolution of DL-β-hydroxydodecanoic acid. Fractional crystallization of the D-amphetamine salt of the racemate afforded a levorotatory acid which was indistinguishable from the hydroxyacid of isariin. The dextrorotatory isomer was also separated and on admixture with an equal part of the natural acid or synthetic levorotatory isomer gave a product which was identical with the synthetic DL-racemate. The dextrorotatory isomer was also

[1]*Issued as N.R.C. No. 6898.*
Presented, in part, before the 41st Annual Conference of the Chemical Institute of Canada in Toronto, Ontario, May 26-28, 1958.

indistinguishable from a sample of authentic L-β-hydroxydodecanoic acid kindly furnished by Dr. K. Serck-Hanssen, who synthesized the compound by anodic chain extension (2) of methyl L-β-acetoxy-γ-carboxybutanoate. Admixture of the authentic L-isomer with the natural acid or the levorotatory isomer obtained by resolution of the racemate gave a product indistinguishable from the racemate. It is therefore concluded that the compound present in isariin is D-β-hydroxydodecanoic acid.

The neutral fraction from acid hydrolysis of isariin was an oil with an infrared maximum at 1765 cm^{-1}, suggestive of a lactone group. Upon alkaline hydrolysis β-hydroxydodecanoic acid was obtained as the only product, indicating that the material was a lactide formed by interesterification of the hydroxyacid.

Paper chromatographic examination of the aqueous solution from the acid hydrolyzate detected glycine, alanine, valine, and leucine. These were separated on a cellulose column; alanine and valine were found to be of the L- and leucine of the D-configuration. Quantitative analysis of the hydrolyzate showed that glycine, alanine, valine, leucine, and β-hydroxydodecanoic acid were present in the ratio 1:1:2:1:1, respectively.

Hydrazinolysis of isariic acid indicated that one of the two molecules of valine possessed a free carboxyl group and must, therefore, have been esterified with the hydroxyacid in isariin. This result was confirmed by subjecting isariic acid to the Dakin–West reaction (3). Vigorous acid hydrolysis of the product showed all four amino acids to be present in equimolecular amounts. Carboxypeptidase also released valine, but no other amino acid. Absence of enzymatic hydrolysis after the removal of valine suggests that the D-leucine may then have been in the penultimate position. It is unlikely that D-leucine was the newly formed C-terminal unit since its initial presence in the penultimate position should have prevented any action by carboxypeptidase on isariic acid. Less probably the lack of further action on the peptide by carboxypeptidase might have been due to the appearance of alanine in the terminal position, thus providing a relatively poor substrate for continued hydrolytic cleavage (4).

Partial hydrolysis of isariin gave an ether-extractable fraction which, on complete hydrolysis, yielded mainly glycine and β-hydroxydodecanoic acid. It was concluded that these two components were directly linked in the original compound. Five ninhydrin-reacting products, in addition to the constituent amino acids, were separated paper chromatographically from the partial hydrolyzate. In each instance they were found to contain all five amino acids and probably also the hydroxyacid. They are presumed to have been formed by ring opening of isariin at the various peptide bonds. For the depsipeptide a partial structure which is supported by the evidence at present available is shown in Fig. 1.

During the early part of this investigation it was noted that analysis of the components in various preparations of isariin did not yield whole numbers of amino acids. In particular, the content of alanine was frequently higher, and of valine lower, than found in samples which had been repeatedly recrystallized from aqueous ethanol. The presence of traces of an amino acid with an R_f corresponding to that of α-aminobutyric acid was also noted. Attempts to separate the crude material into components by paper chromatography were unsuccessful, but these observations suggested that *I. cretacea* produced a mixture of depsipeptides related to isariin, and that the latter was not the major constituent under all conditions of culture.

Depsipeptides containing a β-hydroxyacid are relatively uncommon. To the authors' knowledge, they have been reported only in esperin (5), an antibiotic containing β-hydroxytridecanoic acid obtained from *Bacillus mesentericus*, and in serratamolide,

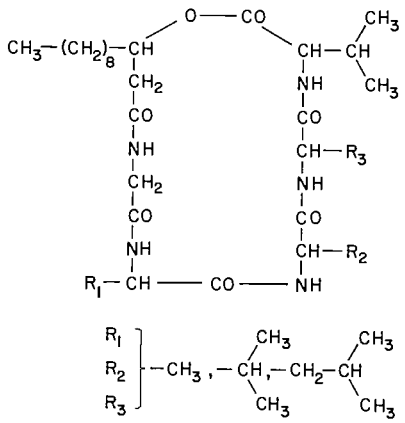

FIG. 1.

recently isolated (6) from *Serratia* strains and shown (7) to possess D-β-hydroxydecanoic acid. β-Hydroxydodecanoic acid appears not to have been previously isolated and unequivocally identified from a natural source, although Bergström and co-workers (8) appear to have obtained some evidence for its presence in the fatty acid components of crude pyolipic acid from *Pseudomonas pyocyanea*.

EXPERIMENTAL

Production of Isariin

In a typical experiment a covered glass tray (9×15 inches) containing 400 ml W.G.A. medium (9) supplemented with neomycin (5 mg) was seeded with the parent strain of *I. cretacea* van Beyma by flooding the surface of the agar with a suspension (27 ml) of a standard spore inoculum (1) and incubated at 28–30° C for 16 days. The mycelium (wet weight 1.1 g) was then scraped from the agar surface, suspended in ethanol (100 ml), and macerated in a Waring blender. The slurry was filtered and the residue re-extracted twice in the same manner. The extracts were combined and evaporated to dryness. The residual solid thus obtained was twice extracted with ethyl acetate (250 ml) under reflux for 30 minutes. The solution was concentrated to dryness and the gummy residue triturated with several portions of petroleum ether, b.p. 30–60° C. The insoluble white solid was crystallized from ethyl acetate as fine needles and constituted crude isariin (18 mg), m.p. 250–252° C. Found: C, 60.84%; H, 8.88%; N, 11.85%.

Strains A and B grown in the same manner yielded 1.6 and 1.0 g of wet mycelium from which 44 and 21 mg, respectively, of crude isariin were isolated.

In an alternative procedure 250-ml Erlenmeyer flasks containing W.G.B. medium (50 ml) were inoculated with 0.5 ml of a standardized spore suspension (1) of strain A incubated at 28–30° C on a rotary shaker for 8 days. The mycelium was then separated and extracted with ethanol as above. The filtrate was extracted with three portions of one-half volume each of *n*-butanol. The ethanolic and butanolic extracts were combined, evaporated to dryness, and the residue worked up, as described above. The yield of crude isariin in a typical experiment was 250 mg/liter of culture medium used.

Purification and Properties

Crude isariin was recrystallized twice from ethyl acetate, and then six times from aqueous ethanol to give fine, colorless needles, m.p. 249.5–250.5° C. Found: C, 62.12%; H, 9.11%; N, 11.14%; molecular weight (Rast in D-borneol) 551, (isothermal distillation in ethanol) 609; saponification equivalent, 638. Calculated for $C_{33}H_{59}O_7N_5$: C, 62.11%; H, 9.32%; N, 10.98%; molecular weight, 637.8. The ultraviolet spectrum in ethanol showed end absorption. Principal infrared maxima (KBr disk) were at 3300, 3060 (w), 2950 (shoulder), 2920, 2855, 1735, 1650 (broad), 1533 (broad), 1470, 1450 (shoulder), 1380 (broad), and 1190 cm^{-1}. Isariin is easily soluble in ethanol, methanol, or chloroform, less readily in acetone, poorly in ether or ethyl acetate, and insoluble in benzene, petroleum ether, water, 2 *N* sodium hydroxide, or hydrochloric acid solution.

Alkaline Hydrolysis of Isariin

Isariin (31.6 mg) was dissolved in methanol (4 ml), and 0.1 *N* KOH solution (1 ml) added. After 48 hours at 40° C the solution was acidified with 0.1 *N* HCl (2 ml) and cooled to 0° C. The gelatinous precipitate was separated, washed with water, and dried. The residue (24 mg) was crystallized twice from aqueous ethanol

as fine needles, melting indefinitely from 194 to 200° C. Found: C, 60.35%; H, 9.37%; N, 10.49%; molecular weight (Rast in D-borneol) 570; neutralization equivalent, 651. Calculated for $C_{33}H_{61}O_8N_5$: C, 60.43%; H, 9.38%; N, 10.68%; molecular weight, 655.9. Infrared maxima (KBr disk) for the free acid were at 2600 (broad, w), 1727, 1635 (broad), and 1543 (broad) cm^{-1}; for the sodium salt at 1655 (broad), 1603, and 1542 (broad) cm^{-1}.

Acid Hydrolysis

Isariin (98.5 mg) was heated for 48 hours at 100° C in a sealed tube with 20% (w/v) HCl (5 ml). The reaction mixture, which contained a brownish oil at the surface, was diluted with water to 20 ml and extracted thoroughly with ether. The ethereal extracts, on evaporation, left a partially crystalline oil (25.8 mg). Calculated for formation of 1 mole of $C_{12}H_{24}O_3$: 33.2 mg. This was separated into acidic (18.7 mg) and neutral (6.8 mg) fractions by distribution between ether and 0.5 *N* Na_2CO_3 solution.

The acidic fraction was crystallized twice from petroleum ether as colorless needles, m.p. 62.8–63.2° C, $[\alpha]_D^{25} - 15.2°$ ($c = 3.4$ in $CHCl_3$). Found: C, 66.42%; H, 11.06%; neutralization equivalent, 218. Calculated for $C_{12}H_{24}O_3$: C, 66.63%; H, 11.18%; molecular weight, 216.3. Principal infrared maxima (KBr disk) were at 3525, 3425, 3090, 2920, 2850, 2660 (broad), 1735, 1706, 1675, 1472, 1436, 1416, 1395, 1365, and 1295 cm^{-1}.

The neutral fraction was hydrolyzed by being heated for 3 hours under reflux in a mixture of ethanol (4 ml) and 4 *N* NaOH (1 ml). The acidic product (7 mg) was crystallized from petroleum ether to give fine needles, m.p. 62.5–63.0° C, undepressed on admixture with the acid obtained directly from hydrolysis of isariin.

The aqueous solution from the acid hydrolysis was evaporated to dryness over solid NaOH. It gave a strongly positive ninhydrin test and paper chromatography in several common solvent systems showed four ninhydrin-reacting substances to be present. These were identified by direct comparison with standards as glycine, alanine, valine, and leucine.

The residue dissolved in a mixture of *sec*-butanol (12 ml) and 3% aqueous ammonia (4 ml) was chromatographed on a column (2.5×60 cm) of powdered cellulose developed with the same solvent system. Fractions (10 ml) were collected and tested for the presence of amino acids by paper chromatography. Appropriate fractions were combined and evaporated to dryness. The residue from each was crystallized from aqueous ethanol and then sublimed under high vacuum for analysis.

The first yielded glistening, colorless plates from aqueous ethanol, $[\alpha]_D^{27} -13.0°$ ($c = 0.67$ in 6 *N* HCl). Found: C, 54.96%; H, 9.84%; N, 10.58%. Calculated for $C_6H_{13}O_2N$: C, 54.94%; H, 9.99%; N, 10.68%. The infrared spectrum (KBr disk) was indistinguishable from that of authentic D-leucine.

The second compound crystallized as colorless plates, $[\alpha]_D^{28} +30.0°$ ($c = 0.61$ in 6 *N* HCl). Found: C, 51.34%; H, 9.50%; N, 11.96%. Calculated for $C_5H_{11}O_2N$: C, 51.26%; H, 9.47%; N, 11.96%. The infrared spectrum (KBr disk) was indistinguishable from that of authentic L-valine.

The third compound crystallized as colorless prisms, $[\alpha]_D^{27} +17.0°$ ($c = 0.56$ in *N* HCl). Found: C, 40.44%; H, 7.60%; N, 15.49%. Calculated for $C_3H_7O_2N$: C, 40.44%; H, 7.92%; N, 15.72%. The infrared spectrum (KBr disk) was indistinguishable from that of authentic L-alanine.

The fourth compound crystallized as colorless needles, m.p. 232° C (decomp.). Found: C, 32.10%; H, 6.54%; N, 18.43%. Calculated for $C_2H_5O_2N$: C, 32.00%; H, 6.71%; N, 18.66%. A mixed melting point with authentic glycine showed no depression, and the infrared spectra (KBr disk) of the two substances were indistinguishable.

Lauric Acid

When the ether-soluble acid from the acid hydrolysis of isariin was distilled *in vacuo* (10^{-2} mm Hg) in a sublimation block at a block temperature of 100° C a discrete fraction was collected which, on cooling in an ice bath, formed a white crystalline solid, m.p. 25–26° C, with infrared maxima (film) at 2920, 2850, 2680 (broad), 1695, 1650, 1470, 1423, 1380, and 983 cm^{-1}. The substance took up hydrogen equivalent to 0.91 mole/mole, calculated on the basis that it was dodecenoic acid, and yielded an acid, m.p. 40–41° C, which gave a single peak on gas–liquid partition chromatography, using a column containing diethylene glycol succinate as liquid phase, with the same retention time as lauric acid. A mixture with authentic lauric acid, m.p. 42.5–43° C, gave m.p. 41.5–43° C. The infrared spectra of the two substances were indistinguishable.

Synthesis and Resolution of β-Hydroxydodecanoic Acid

Ethyl β-ketododecanoate was prepared in a yield of 70% by condensing caproyl chloride with the sodio derivative of ethyl acetoacetate and hydrolyzing the intermediate with sodium methylate in methanol, according to the procedure of Hunsdiecker (10). The keto ester was hydrogenated for 2½ hours at 1600 p.s.i. and 300° F over Raney nickel, as described by Skogh (11), hydrolyzed with alcoholic KOH under reflux, and the product crystallized from petroleum ether (b.p. 60–80° C) to yield DL-α-hydroxydodecanoic acid, m.p. 68.3–69.2° C, in an overall yield of 47% based on caproic acid.

To the racemic acid (1.22 g) in ether (120 ml) was added a solution of D-amphetamine prepared by treating D-amphetamine sulphate (2 g) with *N* NaOH (20 ml) and extracting the base into ether (25 ml). The precipitated salt was redissolved by adding just sufficient ethanol to the refluxing mixture, and allowed

to cool slowly to 10° C. The mass of fine needles (776 mg, m.p. 125–129° C) which separated was removed by filtration and recrystallized twice from ether–ethanol to give 360 mg of material of m.p. 119–121° C. The free acid was regenerated by shaking the product with dilute HCl and ether; the ethereal solution was dried over anhydrous sodium sulphate and evaporated to dryness. The residue, after crystallization from petroleum ether (b.p. 60–80° C), gave needles (172 mg), m.p. 62.5–63.25° C, $[\alpha]_D^{25}$ $-15.2(\pm 1)°$ (c = 1.6 in $CHCl_3$). Found: C, 66.38%; H, 10.94%. A mixture of equal parts of this substance and the hydroxyacid from isariin melted at 62.5–63.25° C. The infrared spectra (KBr disks) of the two compounds were indistinguishable.

The mother liquor from the initial crystallization of the D-amphetamine salt was cooled to −40° C to yield a crop of feathery needles (581 mg) melting mainly at 78–79° C. After two recrystallizations from ether at low temperature the material (495 mg) gave a sharp m.p. of 78–79° C. The free acid, regenerated as before, yielded 249 mg of small needles, m.p. 61–63.25° C, $[\alpha]_D^{25}$ $+14.4(\pm 1)°$ (c = 2.8 in $CHCl_3$). Found: C, 66.70%; H, 11.28%. The infrared spectrum of a sample in a KBr disk, prepared by evaporating an ethereal solution to dryness on KBr powder, was identical with that of the levorotatory isomer examined similarly.

No depression of melting point was observed when a sample was mixed with authentic L-β-hydroxydodecanoic acid, m.p. 62.2–63.2° C, $[\alpha]_D^{25}$ $+15.6(\pm 1)°$ (c = 2.1 in $CHCl_3$), and the two samples had virtually identical infrared spectra (KBr disk). When admixed with an equal amount of the hydroxyacid from isariin and recrystallized from petroleum ether (b.p. 60–80° C), the compound melted at 69–69.75° C. A similar mixture of authentic L-β-hydroxydodecanoic acid with the natural acid melted at 68–69.5° C. Mixtures of this compound or the authentic L-isomer with the levorotatory product from resolution of the racemate melted at 68.7–69.7° C and 69–69.75° C, respectively. All such mixtures of compounds with opposite optical rotations gave no depression when admixed with the unresolved racemate, and had infrared spectra (KBr disks from ether) which were indistinguishable from each other and from the racemate, but different from that of the optically active substances.

A comparison of authentic L-β-hydroxydodecanoic acid with the acids from isariin and from resolution of the racemate carried out by Dr. Serck-Hanssen yielded results similar to those obtained in this laboratory.

Quantitative Amino Acid Analysis

A sample of isariin (6.00 mg), hydrolyzed in a sealed tube with 25% w/v HCl at 110° for 2½ days, was extracted with ether, the aqueous phase freed of excess hydrochloric acid and made to 2 ml with water. Measured amounts of this solution were applied in triplicate to paper strips and chromatographed in *n*-butanol – acetic acid – water (4:1:1) at the same time as mixtures containing known amounts of leucine, valine, alanine, and glycine. The developed chromatograms were dried, treated with ninhydrin, the density of the spots measured with a densitometer, and the amount of each amino acid estimated by comparison with the standards, according to the procedure of Redfield and Guzman Barron (12).

The values obtained for a sample of crude isariin showed the content of glycine, alanine, valine, and leucine to be (to the nearest 0.05 mole/mole) 0.95, 1.30, 1.75, and 0.90, respectively. In addition, there was a trace of an amino acid with R_f values in several solvent systems corresponding to those of α-aminobutyric acid. For preparations of isariin purified by repeated crystallization from aqueous ethanol the content of amino acids was 1.0, 0.95, 2.05, and 1.0 mole/mole, respectively.

Hydrazinolysis of Isariic Acid

Isariic acid (1.5 mg), hydrazine sulphate (30 mg), and hydrazine (1 ml) were heated in a sealed tube at 60° C for 16 hours. Excess hydrazine and hydrazides were removed by the method of Bradbury (13). Paper chromatography of an aliquot of the aqueous solution showed only a single ninhydrin-reacting substance with R_f values in several solvent systems corresponding to valine. When the remainder of the solution was treated with 1-fluoro-2,4-dinitrobenzene and the dinitrophenylamino acids were separated and paper chromatographed in *n*-butanol – 3% aqueous ammonia (9:1), a spot corresponding in R_f value with 2,4-dinitrophenylvaline was obtained.

Dakin–West Reaction

The procedure described by Turner and Schmerzler (14) was used. Isariic acid (2.5 mg) was heated in a sealed tube at 135° C with pyridine (0.25 ml) and acetic anhydride (0.625 ml). The contents of the tube were then evaporated to dryness and hydrolyzed by heating under reflux with 6 *N* HCl for 24 hours. Excess acid was removed in a desiccator containing solid NaOH, and the amino acid composition of the product estimated quantitatively by paper chromatography as described above. Glycine, alanine, valine, and leucine were present in the ratio 1.0:1.0:1.05:1.0.

Action of Carboxypeptidase on Isariic Acid

Isariic acid (4.75 mg) was dissolved in water (4.5 ml) by adding 0.1 *N* NH_4OH to pH 9.0. A suspension of carboxypeptidase (2 mg) in water (0.1 ml) was added, the pH adjusted with dilute acetic acid to 7.8, and the final volume made up accurately to 5 ml with water. The suspension was agitated gently at room temperature and aliquots removed for quantitative paper chromatographic amino acid analysis at 0.5, 1, 2, 4, 8, and 24 hours. The only amino acid detected was valine in amounts of 0.58, 0.62, 0.73, 0.75, 0.86, and 0.88 mole/mole of isariic acid.

Partial Acid Hydrolysis of Isariin

Isariin (10 mg) was dissolved in glacial acetic acid (1.5 ml), and concentrated HCl (1.5 ml) added. The solution was kept at 40° C in a stoppered flask. At intervals, 0.5-ml aliquots were removed, evaporated to dryness, and the residue distributed between equal volumes of ether and water. At 4 days the ether-soluble fraction contained no products reacting with ninhydrin, but gave a strong positive test after further hydrolysis of the material with 6 *N* HCl under reflux for 18 hours. Paper chromatographic examination showed this to be due mainly to glycine, although small amounts of alanine, valine, and leucine were also present. After 6 days, only glycine could be detected in the hydrolyzate of this fraction. Paper chromatography of the aqueous fraction showed small amounts of all four amino acids present after 4 days with traces of ninhydrin-reacting material having R_f values higher than leucine in all solvent systems examined. The proportion of the latter substances appeared highest after 6 days. No compounds with R_f values lower than leucine, other than single amino acids, were detected during the 10-day period in which the hydrolyzate was examined.

The remaining water-soluble products from all sampling times were combined and separated by paper chromatography on a preparative scale. The mixture was applied as a line along the origin of a sheet of Whatman 3 MM paper and the chromatogram developed ascendingly with *n*-butanol – pyridine – 3% w/v aqueous ammonia (2:1:1). Marker strips cut from each edge of the paper and treated with ninhydrin showed, in addition to the expected single amino acids of R_f values 0.09 (gly), 0.16 (ala), 0.27 (val), and 0.37 (leu), five distinct purple zones at R_f values of 0.50, 0.58, 0.65, 0.78, and 0.87. Segments corresponding to these were cut from the untreated paper and eluted with 50% aqueous methanol. Each was evaporated to dryness and the residue hydrolyzed with 20% w/v HCl in sealed tubes for 24 hours at 110° C. The hydrolyzates all gave the characteristic odor associated with the presence of β-hydroxydodecanoic acid and, upon paper chromatographic examination, were found to contain all of the four amino acids present in isariin.

ACKNOWLEDGMENTS

The authors are indebted to Dr. B. M. Craig of this laboratory for the identification of lauric acid by means of gas–liquid partition chromatography, and to Dr. K. Serck-Hanssen of the Medicinsk–Kemiska Institutionen, Göteborgs Universitet, Sweden, for the gift of a sample of L-β-hydroxydodecanoic acid expressly synthesized for comparison with the acid from isariin. We also wish to express our thanks to Dr. Serck-Hanssen for communicating the results of comparisons carried out in his laboratory. Expert technical assistance was provided by Misses M. J. A. Gates and C. Marshall. Miss I. M. Gaffney and Mr. M. Mazurek of this laboratory performed microanalyses and prepared infrared spectra, respectively.

SOME 5,5′-FREE PYRROKETONES[1]

J. M. OSGERBY[2] AND S. F. MACDONALD
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received February 23, 1962

ABSTRACT

5,5′-Dicarbethoxypyrromethanes are oxidized to the pyrroketones by lead tetraacetate – lead dioxide in acetic acid. The 5,5′-free pyrroketones obtained by decarboxylating the latter have not yet proved synthetically useful.

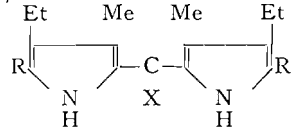
INTRODUCTION

Redistribution reactions may complicate the synthesis and further reactions of pyrromethenes and pyrromethanes. In this respect pyrroketones (2,2′-dipyrrylketones) should be more reliable intermediates in the synthesis of polypyrranes and porphyrins (1), although the behavior of some benzophenones (2) suggests that the difference might be relative rather than absolute. To explore their synthetic possibilities, we prepared some 5,5′-free pyrroketones corresponding to pyrromethanes which had proved synthetically useful (1).

Fischer's only general route to 5,5′-free pyrroketones lay in converting the 5,5′-dimethyl derivatives to dicarboxylic acids with sulphuryl chloride and decarboxylating these (3). 5,5′-Dimethylpyrroketones have been prepared by ring synthesis (4). More generally, they have been obtained by combining 5-methyl-2-free pyrroles with phosgene or with derivatives of 5-methyl-2-carboxypyrroles by the Grignard (5, pp. 361 ff.), Friedel–Crafts (5, pp. 361 ff.), or Vilsmeier (6) methods. It is uncertain whether this general approach could be usefully modified, avoiding both methyl groups for blocking. Both a 5-carbethoxy- (3) and a 5-free pyrrole-carboxylic acid chloride (7) had been used as the acylating component, though there is no general route to the latter. However, the use of a 2,5-free pyrrole as the other component was ambiguous (3), and the less reactive 5-carbethoxy-2-free pyrroles have not been used.

We found that the pyrroketones I*b*, II*b*, III*b*, and IV*b* (5, pp. 361 ff.) are easily obtained from the corresponding pyrromethanes I*a* (1), II*a* (1), III*a* (8), and IV*a* (5, p. 343) by oxidizing with lead tetraacetate in the presence of lead dioxide. Under similar conditions porphyrins have been oxidized to xanthoporphinogens (5, Vol. II/2, pp. 423 ff.). Selenium

I,	A	P	P	A
II,	P	A	A	P
III,	A	P	A	P
IV,	Me	Et	Et	Me
V,	Et	Me	Me	Et



A = $CH_2.COOEt$
P = $CH_2CH_2.COOEt$

a,	X = H_2,	R = COOEt
b,	X = O,	R = COOEt
c,	X = O,	R = H
d,	X = H_2,	R = Me
e,	X = O,	R = Me
f,	X = H_2,	R = CHO

[2]*National Research Council Postdoctorate Fellow, 1960–62.*

dioxide, manganese dioxide, and permanganate left the pyrromethanes unchanged. The 5,5′-carbethoxy groups may be essential for this oxidation for, although pyrromethenes may reasonably be assumed to be intermediates, our attempts to oxidize 3,3′,5,5′-tetramethyl-4,4′-diethylpyrromethene to its ketone (5, pp. 361 ff.) were unsuccessful. Further, other reagents had oxidized both the 3,3′- and the 4,4′-dicarbethoxytetramethylpyrromethanes to pyrromethenes rather than to pyrroketones (9, 10). Also, 5-positions in pyrromethenes which bear hydrogen or carboxy and other labile groups there (like the methyl group in 2-methylpyrroles (11)) may be hydroxylated by lead tetraacetate (12, 13).

Four 5,5′-free pyrroketones have been previously prepared, the parent dipyrrylketone directly from pyrryl magnesium bromide and phosgene (5, pp. 361 ff.). Representing Fischer's general route, sulphuryl chloride converted the 5,5′-dimethyl pyrroketone V*e* into the 5,5′-dicarboxylic acid corresponding to V*b*, which at 180° *in vacuo* decarboxylated to V*c*; analogous transformations giving IV*b* and IV*c* from IV*e* were carried out but not described (3). Finally, a compound formulated as 3,4-dichlor-3′-methyl-4′-ethyl-5-carbethoxypyrroketone has been decarboxylated in 10% sodium hydroxide at 190° (3), essentially the conditions under which the pyrromethanes I*a*, II*a*, and III*a* lose their 5,5′-carboxyls (1). The free acetic acid groups of pyrrole-acetic acids, unlike their salts, are relatively easily decarboxylated by heat. Consequently we heated the free acids corresponding to I*b*, II*b*, III*b*, and IV*b* with 10% sodium hydroxide at about 160° to obtain acids corresponding to the 5,5′-free pyrroketones I*c*, II*c*, III*c*, and IV*c*.

In general, Fischer's general route and ours will lead to isomeric 5,5′-carboxy- and 5,5′-free pyrroketones from given pyrroles, e.g. to V*b*, V*c* and IV*b*, IV*c* respectively from 2,4-dimethyl-3-ethylpyrrole or its 5-carbethoxy derivative. Although our sequence gives symmetrical ketones more directly, unsymmetrical ones are reached through pyrromethane intermediates whose purity must be scrutinized (8).

The reduction of the ketones was studied both to confirm their structures and as a model for the conversion of derived intermediates into natural products. Xanthoporphinogens had been reduced to porphyrins (5, Vol. II/2, pp. 423 ff.) and the parent dipyrrylketone had been reduced to dipyrrylmethane (5, p. 335). The statements that V*e* was reduced to the pyrromethane are hard to reconcile with the experimental work (14). We reduced the ketone I*b* by Clemmensen's method to the dipyrrylmethane I*a* after catalytic methods had failed.

The carbonyl groups of dipyrrylketones were known to be unusual (5, pp. 361 ff.). In the absence of absorption at normal carbonyl frequencies in the infrared, it is reasonable to assume that exceptionally low frequencies are associated with the carbonyl groups of the ketones: 1627 cm^{-1} in I*b*, 1582 cm^{-1} in I*c*, 1543 cm^{-1} in IV*c*, 1522 cm^{-1} in V*e*.* This last, V*e*, was prepared for comparison from 2,4-dimethyl-3-ethylpyrryl magnesium bromide and phosgene (5, pp. 361 ff.).

The ketone V*e* gives a dibromo derivative (3) and our 5,5′-free pyrroketones all gave Ehrlich's reaction strongly in the cold. However, under conditions which had been successfully applied to the corresponding pyrromethanes (1), they were unreactive or gave no pure products. Attempts to introduce formyl groups into II*c* by the Gattermann–Hoesch method led to recovered starting material, by the Vilsmeier method to intractable tars. Nothing was isolated following attempts to condense II*c* with the methyl ester corresponding to II*f*, with 5,5′-di(bromomethyl)-3,3′-dimethylpyrromethene-4,4′-dipropionic

*NOTE ADDED IN PROOF: *The carbonyl groups in dipyrrylketone and its 4-methoxy derivative absorb at 1597 and 1595 cm^{-1} respectively (H. Rapoport and C. D. Willson. J. Am. Chem. Soc. **84**, 630 (1962)). That of 4,4′-bis(dimethylamino)-benzophenone absorbs, we find, at 1598 cm^{-1}.*

acid, or with formic and hydrobromic acids. Also, heating with formaldehyde in acid solution, which converts rather unreactive pyrroles into pyrromethanes (15), left II*c* unchanged.

There is no pronounced general deactivation peculiar to pyrroketones, for 3,3′,5,5′-tetramethylpyrroketone can be acylated in the 4,4′-positions (5, pp. 361 ff.). Also, we found that the pyrroketones were insoluble in hydrochloric acid and showed no evidence of forming presumably unreactive meso-chloropyrromethenes (5) therein. However, the expected interaction (16) between the 2- and 5- (or 2′- and 5′-) positions may be greater in pyrroketones than in monopyrroles. Thus, in contrast to the 5,5′-free pyrroketones, 2-carbethoxy- and 2-cyano-pyrroles have given 5-aldehydes by the Gatterman–Hoesch (5, pp. 162 ff.) and Vilsmeier (17) methods respectively, and 2,5-diacylpyrroles have been obtained otherwise (5, p. 206). Conversely, nucleophilic attack on 5-bromo-2-carbethoxy-pyrroles is apparently not facilitated (18).

In pyrromethenes there is definitely interaction between the 2- and 5- (or 2′- and 5′-) positions which is incidental to strong interaction between the 5- and 5′-positions. Fischer thus explained the extremely easy acid-catalyzed exchange of halogen for hydroxyl in 5-carbethoxy-5′-bromo- as opposed to 5,5′-dibromo-pyrromethenes (19). Other reactions can be rationalized in the same way. Thus under alkaline conditions the halogen of 5-methyl-5′-bromo- but not of 5-methoxy-5′-bromo-pyrromethenes is exchanged for methoxy (19). Conversely, 5-methoxy-5′-free pyrromethenes condense rapidly with formaldehyde in the presence of acid at room temperature (19) whereas a 5,5′-free pyrromethene condensed slowly at 125° (20).

EXPERIMENTAL

The infrared spectra and their interpretation are by Dr. R. N. Jones and Mr. R. Lauzon, the microanalysis by Mr. H. Séguin. Melting points (block) are corrected.

5,5′-Dicarboxypyrroketone-3,3′-dipropionic acid-4,4′diacetic acid Hexaethyl Ester (Ib)

A solution of 5,5′-dicarboxypyrromethane-3,3′-dipropionic acid-4,4′-diacetic acid hexaethyl ester (1) (2 g) in glacial acetic acid (75 ml) was treated with lead tetraacetate (2.9 g) and stirred at room temperature for 4 days. Lead dioxide (90%, 2.3 g) was then added and stirring continued for 2 days. The mixture was then centrifuged and the supernatant poured into ice water (500 ml). The colorless precipitate was separated, washed with water, and dissolved in ether. The ethereal solution was washed successively with water, 5% aqueous sodium bicarbonate, and water, then dried (sodium sulphate) and concentrated. The crystals which separated (1.27 g, 62%) were recrystallized from ether, affording colorless prisms, m.p. 152.5–153.5°, λ_{max} (log ϵ) in 95% ethanol: 251 mμ (4.35), 303 mμ (4.17), 336 mμ (4.29). Found: C, 58.34; H, 6.34; N, 4.40. Calc. for $C_{33}H_{44}O_{13}N_2$: C, 58.57; H, 6.55; N, 4.14.

Attempted Oxidation of a Pyrromethene

When 1.54 g of 3,5,3′,5′-tetramethyl-4,4′-diethylpyrromethene hydrobromide in 70 ml of acetic acid and 0.45 g of anhydrous sodium acetate was oxidized exactly as above, the product was a black precipitate insoluble in organic solvents.

Reduction of Ib to the Pyrromethane Ia

The ketone I*b* (0.668 g) in 5 ml of ethanol was added to water (1 ml), concentrated hydrochloric acid (1 ml), and amalgamated zinc (0.78 g). The mixture was refluxed for 3 hours, cooled, and filtered. When the filtrate was concentrated and then refrigerated, the pyrromethane I*a* (146 mg, 20%) crystallized; m.p. and mixed m.p. 94° after recrystallization.

5,5′-Dicarboxypyrroketone-3,3′-diacetic acid-4,4′-dipropionic acid Hexaethyl Ester (IIb)

This was prepared from 5,5′-dicarboxypyrromethane-3,3′-diacetic acid-4,4′-dipropionic acid hexaethyl ester (1) (7.91 g), acetic acid (200 ml), lead tetraacetate (11.7 g), and lead dioxide (9.2 g) as described for the isomer I*b* above. The ketone formed colorless prisms (5 g, 62%) after recrystallization from ether (thimble), m.p. 156°, λ_{max} (log ϵ) in 95% ethanol: 250 mμ (4.34), 304 mμ (4.17), 336 mμ (4.29). Found: C, 58.13; H, 6.60; N, 4.39.

5,5′-Dicarboxypyrroketone-3,4′-diacetic acid-4,3′-dipropionic acid Hexaethyl Ester (IIIb)

This was prepared from 5,5′-dicarboxypyrromethane-3,4′-diacetic acid-4,3′-dipropionic acid hexaethyl

ester (8) (1.56 g), lead tetraacetate (2.3 g), and lead dioxide (1.5 g) as described for I*b* above. The crude product (0.694 g, 43.5%) was recrystallized from ether (thimble), affording colorless microneedles, m.p. 149–150°. Found: C, 58.45; H, 6.37; N, 4.12.

4,4′-Dimethyl-3,3′-diethyl-5,5′-dicarbethoxypyrroketone (IVb)

This was prepared from 4,4′-dimethyl-3,3′-diethyl-5,5′-dicarbethoxypyrromethane (5, p. 343) (1.065 g), glacial acetic acid (35 ml), lead tetraacetate (1.45 g), and lead dioxide (1.2 g) as described for I*b*. The product formed colorless rods (300 mg, 27%) from ethanol, m.p. 190–191°. Found: C, 65.04; H, 7.08; N, 7.34. Calc. for $C_{21}H_{28}N_2O_5$: C, 64.92; H, 7.27; N, 7.21.

5,5′-Dicarboxypyrroketone-3,3′-dipropionic acid-4,4′-diacetic acid

Aqueous sodium hydroxide (10%, 3 ml) was added to a solution of the corresponding ester I*b* (400 mg) in ethanol (4 ml) and the mixture heated to dryness on the steam bath in an open flask (about 4 hours). Water (5 ml) was added to the residue. The resulting clear solution was brought to pH 1 with dilute hydrochloric acid, heated to dissolve the colorless precipitate, and allowed to cool. The crystals which separated were washed with water, with ether, then recrystallized from 5 ml of hot water. The product formed colorless needles (170 mg, 56%), m.p. (softening from 159°) 164–168°, Ehrlich's reaction negative in the cold. Found: C, 49.61; H, 4.24; N, 5.41. Calc. for $C_{21}H_{20}N_2O_{13}$: C, 49.61; H, 3.96; N, 5.51.

Pyrroketone-3,3′-dipropionic acid-4,4′-diacetic acid (Compare Ic)

A solution of the ketone I*b* (1.186 g) in ethanol (10 ml) and sodium hydroxide (10%, 5 ml) was hydrolyzed by heating to dryness in an open flask on the steam bath. The residue in water (4 ml) and sodium hydroxide (10%, 4 ml) was heated for 10½ hours at 155–158° in a Teflon-lined closed metal tube. The crude product (0.654 g, 89%) precipitated when the cooled solution was acidified to Congo red with sulphur dioxide. When recrystallized from acetone (thimble) it formed colorless needles, m.p. 203–205°, Ehrlich's reaction positive cold. Found: C, 54.11; H, 5.43; N, 6.51. Calc. for $C_{19}H_{20}N_2O_9$: C, 54.28; H, 4.80; N, 6.66.

Pyrroketone-3,3′-diacetic acid-4,4′-dipropionic acid (Compare IIc)

The ester II*b* (1.14 g) was hydrolyzed and then decarboxylated like the isomer above, giving the crude product (0.583 g, 82%). From aqueous acetone it formed colorless cubes, m.p. 272° (decomp.), Ehrlich's reaction positive cold. Found: C, 54.18; H, 4.94; N, 6.58.

The Tetraethyl Ester (IIc)

The above acid (145 mg) was left at room temperature overnight in 10 ml of 5% ethanolic hydrogen chloride. The solvent was removed *in vacuo* (<50°), leaving a red oil. This was extracted with hot *n*-hexane, from which the product separated as fine colorless plates (60 mg, 33%), m.p. 94–95°, λ_{max} (log ϵ) in 95% ethanol: 297.3 mμ (4.01), 334.5 mμ (4.23). Found: C, 60.64; H, 6.70; N, 5.21. Calc. for $C_{27}H_{36}N_2O_9$: C, 60.89; H, 6.82; N, 5.27.

The same ester (72%) was obtained by treating an ethereal suspension of the acid with freshly distilled ethereal diazoethane.

Pyrroketone-3,4′-diacetic acid-4,3′-dipropionic acid (Compare IIIc)

The ester III*b* (0.873 g) was hydrolyzed and decarboxylated like its isomers. The crude product (255 mg, 47%) was recrystallized from acetone (thimble) as colorless cubes, m.p. 260–262° (decomp.), Ehrlich's reaction positive cold. Found: C, 54.24; H, 4.88; N, 6.51.

4,4′-Dimethyl-3,3′-diethylpyrroketone (IVc)

The ester IV*b* (0.2 g) was heated to dryness with ethanol (25 ml) and sodium hydroxide (10%, 3 ml). The residue was heated in a closed tube for 10 hours at 155–160° with water (4 ml) and sodium hydroxide (10%, 3 ml). The cooled solution was extracted with chloroform. The chloroform extract was washed with dilute hydrochloric acid and then with water, dried (sodium sulphate), and evaporated. The residue was dissolved in ether, and *n*-hexane added, precipitating the products as colorless fluffy rods (108 mg, 86%), m.p. 180–180.5° (lit. 166° (3)), Ehrlich's reaction strongly positive cold, λ_{max} (log ϵ) in 95% ethanol: 344 mμ (4.26), 295 mμ (3.96), 207 mμ (3.95). Found: C, 74.02; H, 8.04; N, 11.36. Calc. for $C_{15}H_{20}N_2O$: C, 73.73; H, 8.25; N, 11.47.

3,5,3′,5′-Tetramethyl-4,4′-diethylpyrroketone (Ve)

This was prepared by the method of Fischer and Orth (5, pp. 361 ff.). The crude product (68%) was recrystallized from ethanol, giving slightly yellow needles, m.p. 208.5–210° (lit 207°), λ_{max} (log ϵ): 301 mμ (3.92), 364 mμ (4.44).

Attempted Reactions with IIc

(*a*) It was added to a mixture of phosphorus oxychloride and dimethylformamide, then left at 20° for 18 hours or at 100° for 10 minutes. In both cases working up gave a black tar from which nothing was isolated.

(*b*) It was dissolved in hydrogen cyanide – ether – chloroform, and dry hydrogen chloride passed in at 0°. Evaporation left ether-soluble material, from which the starting ketone (25%) was recovered, but no water-soluble aldimine hydrochloride.

(*c*) It was refluxed for 1 hour in 5% ethanolic hydrogen chloride containing formaldehyde (2 moles). Only the starting ketone (57%) was recovered.

(*d*) Like II*b* it was recovered quantitatively after attempted reduction by hydrogen over palladium black in ethanol or acetic acid.

(*e*) It was recovered (85%) after refluxing with hydroxylamine hydrochloride and sodium acetate in 90% ethanol.

STEREOCHEMISTRY OF ARSENIC

PART IV. CHLORODIPHENYLARSINE

J. TROTTER

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received March 28, 1962

ABSTRACT

Crystals of chlorodiphenylarsine, $(C_6H_5)_2AsCl$, are monoclinic with four molecules in a unit cell of dimensions $a = 11.09$, $b = 8.55$, $c = 11.93$ Å, $\beta = 95.0°$. The crystals are isomorphous with crystals of the corresponding bromo derivative, and the structure has been determined by the isomorphous replacement method. The mean values of the bond lengths and valency angles (with standard deviations) are: As—Cl = 2.26±0.02 Å, As—C = 1.97±0.04 Å, C—C = 1.39±0.02 Å, ∠ Cl—As—C = 96±1°, ∠ C—As—C = 105±2°, ∠ As—C—C = 120±2°, ∠ C—C—C = 120±2°. The general molecular configuration and the intermolecular separations are very similar to those in bromodiphenylarsine.

INTRODUCTION

Crystals of chlorodiphenylarsine are isomorphous with crystals of bromodiphenylarsine, whose structure has been determined (1), but it has been considered useful to carry out a complete analysis of the chloro derivative to provide further details of the stereochemistry of arsenic, and to measure the As—Cl bond distance. The investigation has followed similar lines to that of Ph_2AsBr, and details of the molecular dimensions and of the intermolecular contacts have been obtained.

EXPERIMENTAL

The colorless crystals of chlorodiphenylarsine used in this investigation were removed from the walls of a bottle, where they had been deposited by very slow sublimation. The unit cell dimensions, space group, and density were determined as for the bromo derivative (1).

The crystal data were: Chlorodiphenylarsine, $C_{12}H_{10}AsCl$; M, 264.6; m.p. 38–40°. Monoclinic, $a = 11.09 \pm 0.04$, $b = 8.55 \pm 0.03$, c = 11.93±0.04 Å, $\beta = 95.0 \pm 0.5°$. Volume of the unit cell = 1127 Å^3. d_c (with $Z = 4$) = 1.550, $d_m \sim 1.5$ g cm^{-3}. Absorption coefficient for X rays: $\lambda = 1.542$ Å, $\mu = 69$ cm^{-1}. Total number of electrons per unit cell = $F(000) = 528$. Absent spectra: $h0l$ when h is odd, $0k0$ when k is odd. Space group is C_{2h}^5—$P2_1/a$.

Intensity data for the $0kl$ and $h0l$ zones were recorded as for bromodiphenylarsine, but a small crystal was used and no absorption corrections were applied.

Structure Analysis

The signs of most of the $h0l$ and $0kl$ structure factors were determined by comparison with the bromo derivative, using the isomorphous replacement method; refinement then proceeded by Fourier methods. After two cycles of F_o syntheses no further sign changes were indicated, and the discrepancy factors were $R_{h0l} = 14.8\%$ and $R_{0kl} = 15.8\%$; the scattering factors for As and C and an overall isotropic temperature factor were similar to those for Ph_2AsBr, and the scattering factor used for Cl was that of Tomiie and Stam (2). Measured and calculated structure factors are listed in Table I, and final electron-density maps are shown in Fig. 1.

Coordinates and Molecular Dimensions

The final positional parameters are listed in Table II, x, y, and z being fractions of the monoclinic cell axes, and X', Y, and Z' coordinates in Å units referred to orthogonal axes a', b, and c.

The bond distances and valency angles are shown in Fig. 2. The closest intramolecular C . . . C contacts between phenyl groups are: C_1—C_{12} = 3.29 Å; C_6—C_{12} = 3.43 Å; C_6—C_7 = 3.59 Å. The distance between the hydrogen atoms attached to C_6 and C_{12} (assuming C—H = 1.08 Å) is 2.87 Å.

The equations of the planes of the aromatic rings are:

$$C_1—C_6: \quad 0.2597X' - 0.5498Y + 0.7939Z' - 1.7213 = 0$$
$$C_7—C_{12}: \quad 0.6965X' + 0.6410Y - 0.3226Z' + 0.1296 = 0$$

TABLE I

6	0.206	0.062	0.165	2.271	0.526	1.771	−0.02	—
7	0.071	0.167	0.418	0.781	1.430	4.914	—	+0.01
8	0.031	0.275	0.489	0.347	2.350	5.806	—	+0.01
9	0.083	0.275	0.599	0.913	2.350	7.070	—	−0.01
10	0.176	0.167	0.638	1.944	1.430	7.438	—	0
11	0.213	0.059	0.559	2.351	0.500	6.464	—	0
12	0.159	0.059	0.450	1.761	0.500	5.208	—	0

and the deviations of the atoms from these planes are listed in the final columns of Table II. The angle between the planes is 65°.

The standard deviations of the atomic positions (3) are $\sigma(x) = \sigma(y) = \sigma(z) = 0.007$ Å for As, 0.014 Å for Cl, and 0.05 Å for C.

The intermolecular separations correspond to van der Waals interactions, and are very similar to those in bromodiphenylarsine.

DISCUSSION

Differences between chemically equivalent bond lengths and valency angles are not significant, the mean values being (with standard deviations):

$$\text{As—Cl} = 2.26 \pm 0.02 \text{ Å}$$
$$\text{As—C} = 1.97 \pm 0.04 \text{ Å}$$

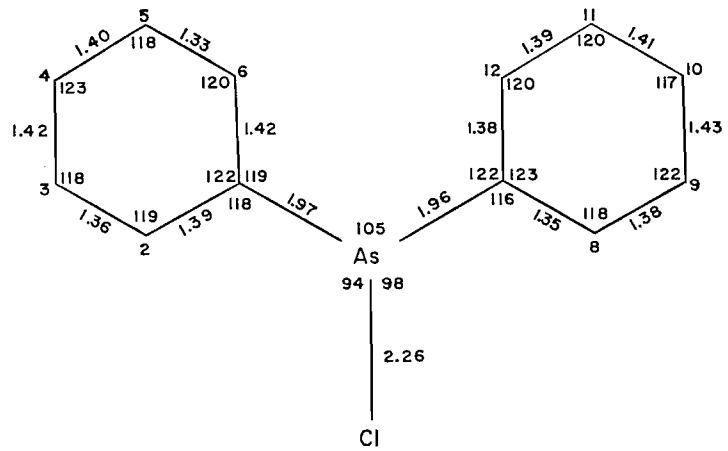

FIG. 2. Measured bond lengths (Å) and valency angles (degrees).

$$\text{C—C} = 1.39 \pm 0.02 \text{ Å}$$
$$\angle \text{ Cl—As—C} = 96 \pm 1°$$
$$\angle \text{ C—As—C} = 105 \pm 2°$$
$$\angle \text{ As—C—C} = 120 \pm 2°$$
$$\angle \text{ C—C—C} = 120 \pm 2°.$$

Apart from the shorter As—Cl distance in comparison with As—Br, these dimensions are very similar to those of bromodiphenylarsine (1). The molecular configuration of chlorodiphenylarsine is also almost identical with that of the bromo derivative; in comparison with an ideal model similar to that described for Ph_2AsBr, ring I (C_1—C_6) is rotated 76°, and is therefore in a position where interaction with the arsenic lone pair is almost at a minimum, while ring II (C_7—C_{12}) is twisted by 35°, so that interaction is still appreciable.

The author thanks the National Research Council of Canada for financial support, and Dr. W. R. Cullen for the crystal samples and for helpful discussion.

AN APPARATUS FOR THE STUDY OF SHORT-LIVED FISSION PRODUCT RARE GASES

D. W. Ockenden[1] and R. H. Tomlinson
Department of Chemistry, McMaster University, Hamilton, Ontario
Received April 4, 1962

ABSTRACT

A procedure is described for the isolation, separation, and study of short-lived krypton and xenon isotopes formed by thermal fission of uranium. The gases are swept out from a thin film of uranium-235 stearate, rapidly separated by gas chromatography, and examined by gamma-spectrometric techniques. Krypton isotopes have been studied within 10 seconds of their formation in the reactor and xenon isotopes within 25 seconds. Spectra are reported for krypton-89 and -90, xenon-137, -138, and -139.

INTRODUCTION

Although the first uranium chain reaction took place 20 years ago, the amount of information available on the short-lived fission products ($T_{1/2}$ < a few minutes) is still relatively small. The main difficulty has been the development of extremely rapid and complete separation procedures. The fission product rare gases krypton and xenon have been examined more than most elements since, although they are difficult to separate from each other, they may easily be isolated from other fission products. Dillard and co-workers (1) measured the half-lives of several krypton and xenon nuclides without separation, by passing an active rare gas mixture at a known flow rate through a tube containing a coaxial charged wire. By measuring the distribution of the decay products along the wire, these workers were able to calculate half-lives.

In 1951, Kofoed-Hansen and Kristensen (2, 3) used an isotope separator for the isolation of particular species, and reported β-ray-energy end-point values and half-lives for the krypton and rubidium isotopes of mass numbers 89–91.

Wahl (4), in 1958, determined the cumulative yields of short-lived krypton and xenon isotopes from the thermal neutron fission of uranium-235, using the emanating properties of certain inorganic stearates for the isolation of the gases. Rubidium and cesium isotopes formed from the decay of some of the fission product gases were reported by O'Kelley *et al.* (5) and by Bunker *et al.* (6).

In 1960, Prakash (7) reported a study of krypton-89 and xenon-137, which were obtained by gas sweeping an irradiated uranyl nitrate solution. These were separated from each other by an adsorption–desorption technique which took 4 minutes. From an examination of the gamma-ray spectra and the relative intensities of the gamma rays in each, provisional decay schemes for the two isotopes were presented.

In 1961, Koch and Grandy (8) described an apparatus for the determination of radioactive fission gases, the radioisotopes being separated by gas chromatography, using charcoal as the fixed phase and helium as the carrier gas. The quickest separation obtained by these authors took 20 minutes, the xenon elution being accelerated by column heating. The shortest-lived isotopes studied, 3.2-min Kr-89 and 17-min Xe-138, were determined indirectly by study of their immediate decay products. Little gamma-spectrometric data was given.

[1]*Present address: Chemical Services Department, Windscale Works, U.K.A.E.A., Sellafield, Seascale, Cumberland, England.*

Wahlgren (9) has described the first extended study of the short-lived fission product rare gases. He has studied the gases evolved from solid uranium nitrate using a hypodermic needle sampling system which drew the gas mixture slowly through a thin charcoal bed. This produced pure radiokrypton in the gas phase and left radioxenon on the charcoal. Each phase was then examined separately, the minimum time from reactor to detector being 24 seconds for krypton and 30 seconds for xenon. Gamma-ray spectra of several short-lived nuclides were reported, together with some beta-ray spectra and a few beta–gamma and gamma–gamma coincidence measurements.

EXPERIMENTAL

Apparatus

The apparatus used in this work, for the preparation, isolation, and study of the rare gas fission products, may be discussed under the following headings: (*a*) beam port irradiation facility; (*b*) irradiation cell, with its neutron shutter; (*c*) gas chromatography; and (*d*) gas handling system.

(a) Beam Port Irradiation Facility

A beam port of the McMaster University reactor was used as a source of neutrons. The arrangement, including shielding, is shown in Fig. 1 along with the capped tube for containing the apparatus in the beam

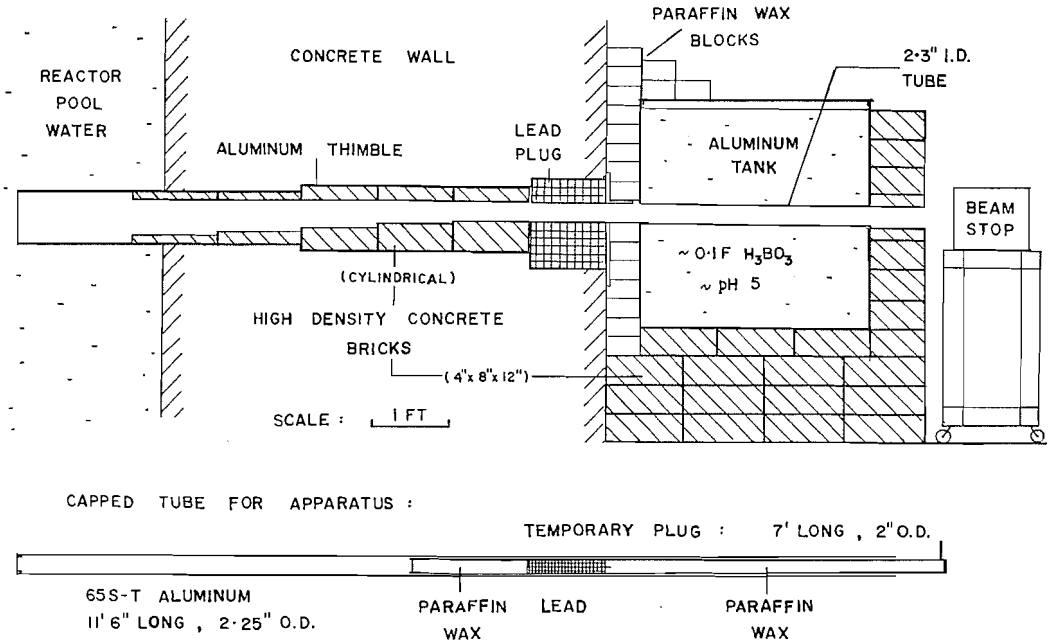

FIG. 1. Section through beam port No. 2, McMaster University swimming pool reactor. Main tube for the apparatus, and its associated plug also shown.

port, and the beam plug. The short space between the reactor core and the end of the beam port thimble contained, besides water, a 1 ft thick plug of graphite, a 6-in. can of air, and a 6-in. canned plug of bismuth. With the reactor operating at 1 MW, the thermal neutron flux at the reactor end of the beam port was found to be 2×10^{10} neutrons $cm^{-2}sec^{-1}$.

(b) Irradiation Cell and Neutron Shutter

The irradiation cell with its thermal neutron shutter is shown in Fig. 2. This apparatus fits inside the capped tube and beam port shown in Fig. 1. It is made in three interlocking aluminum sections and allows a fast stream of helium to flush out the emanated fission product rare gases. The gas leads are coiled throughout the length of the apparatus and also pass through sections of paraffin wax and lead. The hemispherical inside surfaces of the irradiation cell are coated with a uranium-235 stearate film approximately 2 mg cm^{-2} thick, and containing about 70 mg of uranium-235. The production of radioactivity from a short-lived isotope, rather than that from a long-lived one, is favored by a short irradiation. Hence, the

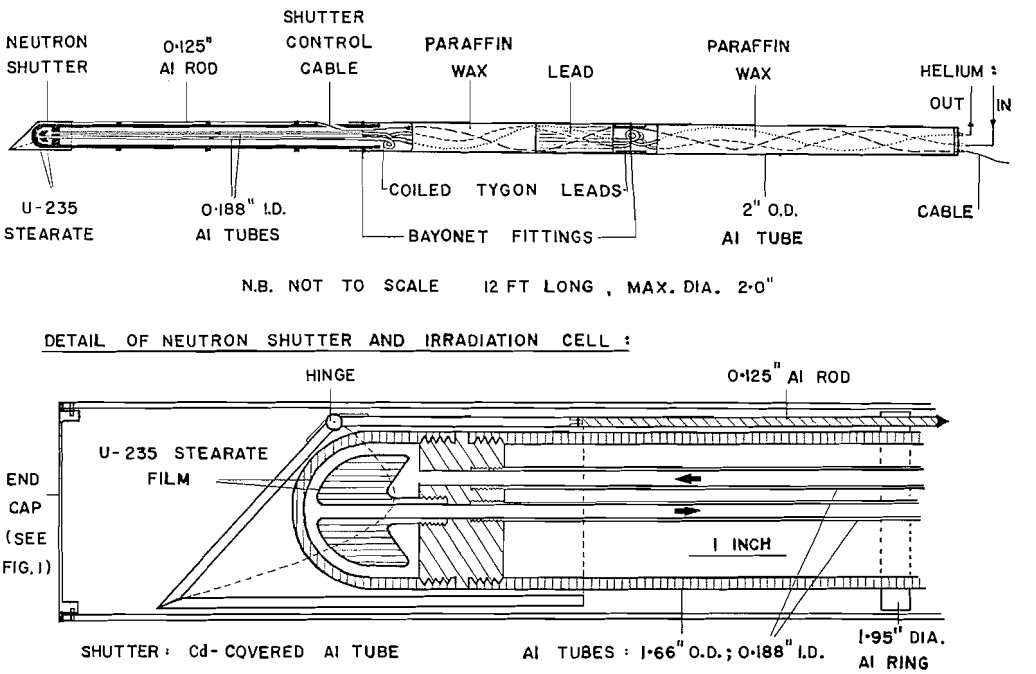

FIG. 2. Apparatus for the production and sweeping out of short-lived fission product rare gases.

irradiation cell is surrounded by a moveable thermal neutron shutter, which can be pulled back to expose the cell to the neutron beam for any predetermined length of time. The shutter is made from the aluminum tube covered with 1/32-in. cadmium sheet, and has a hinged, curved flap on the front, so that when the whole unit is drawn backwards by means of the rod and control cable, the flap fits snugly between the irradiation cell tube and the outer capped tube. The observed fission rate is reduced by a factor of about 80 when the shutter is in the closed position. The shutter is operated by a pneumatic barrel and plunger system, which is shown in Fig. 3. By means of the solenoid-operated valves, the compressed air system opens or closes the thermal neutron shutter in a fraction of a second.

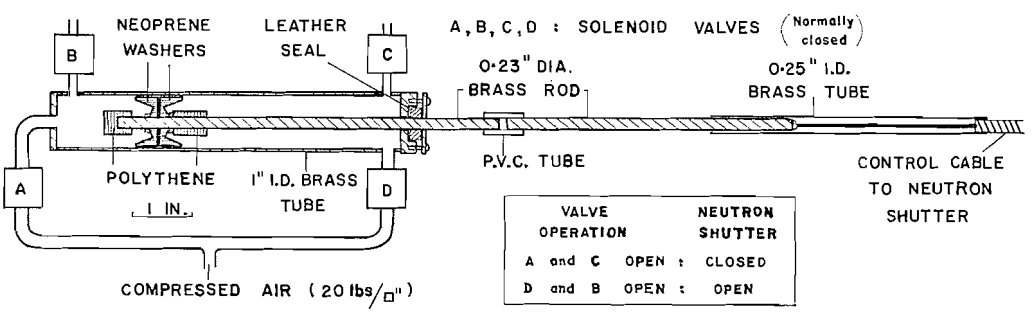

FIG. 3. Pneumatic system for the consistent and quick operation of the neutron shutter.

(c) Gas Chromatography

Separation of the active krypton and xenon isotopes outside the beam port was achieved by gas chromatographic means. Considering the relatively small number of radioactive atoms involved, it seemed likely that previous workers had used too much solid adsorbent in their separations. Accordingly, a gas chromatographic column was prepared which had the advantages of providing a high flow rate of carrier gas through a column containing only a small amount of activated charcoal.

The column packing was made by shaking up short pieces of glass wool, 2–3 cm long, with a small amount of very fine (200–400 mesh) activated charcoal, until the glass wool became a dark grey color without

retaining any obviously free charcoal. This packing was then tamped gently into several 4-mm bore glass tubes, varying in length from 5–30 cm at 5-cm intervals. The performance of these columns was tested at room temperature (70° F) using helium as carrier gas, and krypton–xenon mixtures from the irradiation cell. A shielded geiger tube, operating a rate meter and pen recorder, was used at the end of the column as the detector.

Excellent separations were obtained from all but the shortest columns, the best performance being from a 15-cm column which, at a helium flow rate of 310 cc/min, showed a krypton peak after 4 seconds and a xenon peak after 27 seconds. A typical trace is shown in Fig. 4, and the effect of helium flow rate on the performance of the 15-cm column is indicated in Table I.

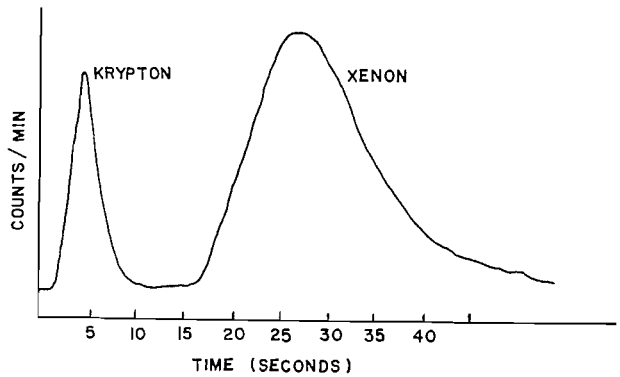

FIG. 4. High-speed gas chromatographic separation of radio-krypton and -xenon.

TABLE I

Effect of helium flow rate on krypton–xenon separation

Flow rate (cc/min)	Time to emergence of peak (seconds)	
	Krypton	Xenon
130	7	48
175	6	40
220	5	34
270	4.5	30
310	4	27
360	3.5	23
400	3.5	22
450	3.5	21

The fastest flow rates gave elution peaks which were even closer together, but in which tailing started to occur. For most of the work described subsequently, the 310 cc/min flow rate was used. Some improvements could, no doubt, be made on this separation by further adjustment of charcoal particle size, column length, flow rate, and temperature.

(d) Gas Handling Apparatus

The apparatus used for sweeping out the rare gas fission products from the irradiation cell is shown diagrammatically in Fig. 5. This enables either krypton or xenon isotopes to be studied by the gamma-ray spectrometer. The system is controlled by several solenoid-operated valves, which are normally closed. Commercial helium, at 15 lb/in^2 pressure, is used to flush out the irradiation cell and is used also as carrier gas for the chromatographic separation.

When valves E, G, and H are opened together, the mixture of rare gas isotopes from the irradiation cell is swept out through the sampling tube and on towards the trap, which contains activated charcoal granules cooled in liquid air. The flow is adjusted so that after 2 seconds the maximum amount of radioactivity is passing through the sampling tube. The flow is then stopped, trapping the sample between valves G and H. After any predetermined time the valves F and J are opened together and allow the sample to be swept into the gas chromatographic column, the separation being shown by the geiger-operated pen recorder. Depending on which gas is to be studied, valves K and L are operated so that one is swept into the trap, and the other into a replaceable 50-cc bulb, supported at the center of a 2×2×2-ft cave made from high-density concrete bricks. The outlet leads from the bulb return to the trap. The bulb, which is flattened on

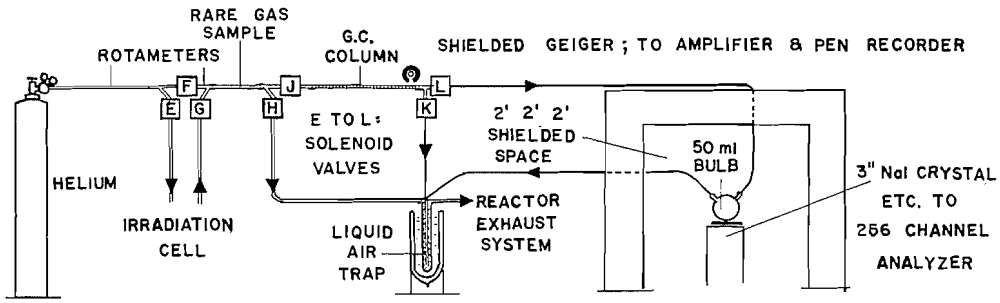

FIG. 5. Diagram of apparatus outside beam port.

one side, is fixed with the flat side facing a 3-in. sodium iodide (T1) γ-scintillation crystal connected via a photomultiplier to an R.C.L. 256-channel pulse height analyzer.

The bulb system was chosen to contain the gas sample rather than a cooled trap, since it allows the rapid removal of the gas and rapid study of the solid decay products deposited on the walls. It is housed in a small concrete cave in order to reduce reactor background and back-scattered radiation. While not as large or as effectively shielded as that suggested by Heath (10), it was found to be adequate for the relatively active samples counted in this work. The gas sweeping and gas chromatographic operations of any experiment were worked either manually or automatically by means of an electronic timing mechanism. This unit was designed to provide (i) a variable sweeping-out time (T_1), although this was always set at 2 seconds; (ii) a hold-up time (T_2) outside the beam port, varying from 2–81 seconds; and (iii) a chromatographic time (T_3) which could be set from 1–10 seconds, or to continuous running. By this means, reproducible samples could be obtained. The manual and automatic controls were usually used in conjunction with each other as outlined below.

Procedure

The procedure used in all experiments was as follows:

1. The irradiation cell was swept free of all gases for 10 seconds, using manual control.
2. The stearate sample was irradiated for a given period by opening and finally closing the thermal neutron shutter.
3. The emanated gases were allowed to "cool" for a predetermined time inside the cell. This time could, of course, be zero.
4. Automatic operation: the gases were swept out for 2 seconds ($T_1 = 2$), the maximum amount of activity being trapped in the sampling section.
5. The gases were held up in the sampling section (T_2 from 2–81 seconds).
6. Chromatographic separation: for krypton samples, T_3 was set at 10 seconds, or less if very fast flow rates were used. For xenon samples, T_3 was set for continuous running and the krypton was diverted to the trap by manual switching.
7. Gamma-spectrometric examination of the gas sample in the bulb.
8. If necessary, the bulb was flushed out with helium and the solid decay products examined.

Using this procedure, several fission product rare gas isotopes were studied and also a few of their decay products.

RESULTS

Krypton-89

After a 1-minute irradiation, the emanated gases were allowed to decay for 5 minutes inside the cell in order to allow krypton-90 to decay completely, and then treated by the above procedure. The time settings were $T_1 = 2$, $T_2 = 30$, $T_3 = 10$ seconds. The krypton sample was then counted by the 256-channel analyzer through a 1.5 g cm^{-2} aluminum absorber for a predetermined time. In the first experiments, the instrument was set for 0–1.0 Mev operation, and half-life determinations were made on the major photopeaks in this region. The results showed that these all decayed with a half-life of 3.2±0.2 min in agreement with previous work (1–3).

In order to obtain a gamma spectrum relatively free from the contributions of other longer-lived krypton isotopes or decay products, an accumulation technique was used.

Several identical samples were produced and counted for 1 minute only, the spectra being allowed to accumulate, and the sample bulb being changed for each count. The accumulated spectrum from five such samples of krypton-89 is shown in Fig. 6. The

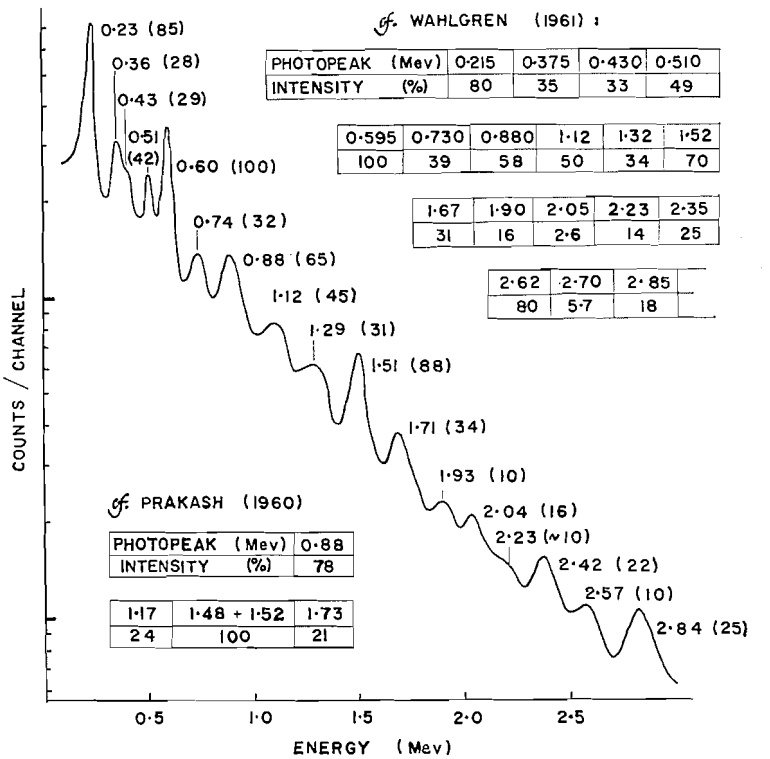

FIG. 6. Gamma spectrum of krypton-89.

energies of the photopeaks are shown, together with their relative intensities, which were calculated from the respective peak areas and an empirical efficiency curve. This was produced by study of isotopes with known decay schemes. The agreement with Wahlgren's data is seen to be reasonably good. On close examination, the photopeak at 1.51 Mev did appear to be composed of two very closely spaced peaks, as suggested by Prakash, but since they are normally unresolved, the photopeak was treated as a single one, with a single intensity. The incompleteness of Prakash's data make it unlikely that his proposed decay scheme for krypton-89 is valid.

It is probable that some of the low-intensity photopeaks may be sum or escape peaks. Coincidence measurements, which are currently being conducted, should elucidate this decay scheme.

A sample of short-lived krypton was produced as in the above experiments, allowed to decay for 5 minutes in the sample bulb, and then blown out by a stream of helium. The solid decay products were then studied from 0–1.5 Mev. The only photopeaks were at 0.66, 1.06, and 1.25 Mev, and, since all decayed with a half-life of 15.0 min, were due to the well-studied rubidium-89 (5, 9). It was not, therefore, examined any further.

Krypton-90

In order to minimize the effects of krypton-89, irradiations of 5 seconds were used.

The emanated gases were allowed to cool in the cell for 30 seconds and then treated according to the timing periods $T_1 = 2$, $T_2 = 30$, $T_3 = 10$ seconds. The major photopeaks were found to be at 0.125, 0.55, and 1.12 Mev and all decayed with a half-life of 35 ± 3 sec. A lower-intensity photopeak at 0.24 Mev was obscured by the 0.23 Mev peak of krypton-89.

To obtain a gamma spectrum relatively free from this effect, the accumulation technique was used. The krypton-90 samples were isolated as above and each was counted by the analyzer for 10 seconds only. The spectrum accumulated from 20 such samples is shown in Fig. 7. Under these conditions the effect of krypton-89 was negligible and the intensity

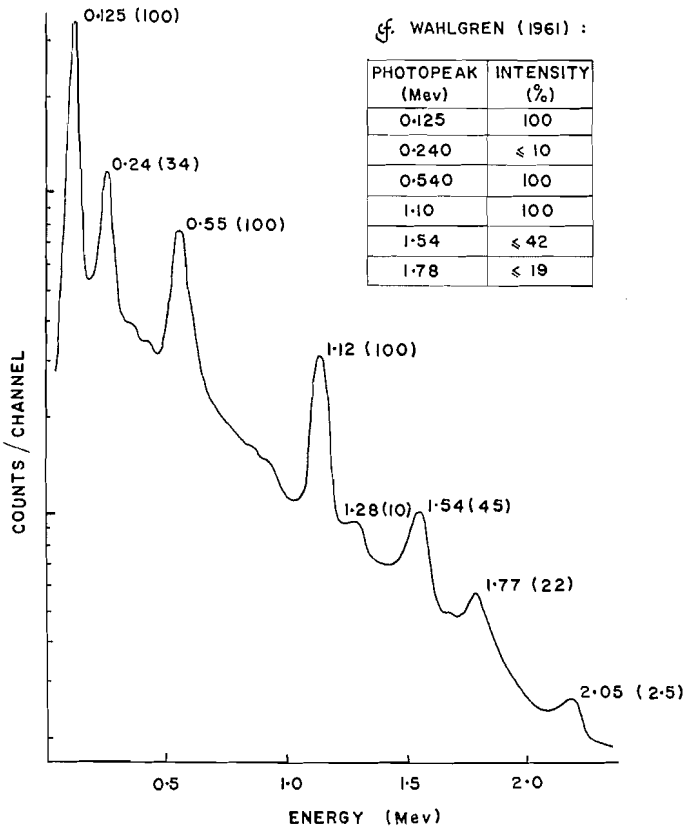

FIG. 7. Gamma spectrum of krypton-90.

of the 0.24 Mev photopeak was calculated to be 34%, much higher than the $\leq 10\%$ estimated by Wahlgren in allowing for krypton-89 interference. Otherwise the agreement is excellent.

In exactly the same way as described for the study of rubidium-89, a sample of krypton-90 was produced and allowed to decay for 90 seconds to rubidium-89. The krypton was then blown out of the cell and the decay products examined. The only photopeak which it was possible to study was the 0.84 Mev peak of rubidium-90, which decayed with a half-life of 2.8 ± 0.2 min, in agreement with O'Kelley (5) and Wahlgren (9). Other photopeaks were noted at 0.51 and 0.61 Mev, as stated by O'Kelley, but these were too small for half-life determinations.

Krypton-91

Although the half-life of this isotope is reported to be 10 sec (1, 2), no gamma rays of this period could be detected. Using 2-second irradiations and the fastest possible processing, such that the krypton sample was being counted only 9 seconds after leaving the reactor, the spectra produced were identical with that of krypton-90. The accumulation technique also failed to show evidence of this isotope, the final spectrum from 20 samples, each counted for only 5 seconds, again being identical with that of krypton-90.

This result is unusual in view of the energy available for the decay of krypton-91.

Xenon-137

This isotope, for which a half-life of 3.8 min is quoted (11), was produced by a 1-minute irradiation followed by a 2-minute cooling period, and was obtained in the cell by the separation procedure outlined above.

The gamma spectrum of the sample was similar in shape to that noted by Prakash (7) and showed photopeaks at 0.16, 0.26, 0.44 (a complex of three: 0.42, 0.44, and 0.46), and 0.53 Mev. However, only the single photopeak at 0.44 Mev showed a half-life of 3–4 min, the others being due either to xenon-138 ($t_{1/2}$ = 17 min) or its daughter cesium-138 ($t_{1/2}$ = 32 min). Only an approximate value of the 0.44 Mev half-life could be obtained because of the proximity and similar decay rates of the neighboring photopeaks.

The accumulation technique was used to establish that the 0.44 Mev photopeak did originate from xenon-137. Short-lived xenon samples were produced after 1-minute irradiations and 5-minute cooling periods, and counted for 1 minute only. Eight such samples were accumulated and showed a major photopeak at 0.44 Mev superimposed on a xenon-138 spectrum (*q.v.*). No other photopeaks of xenon-137 were noted.

The decay scheme for xenon-137 suggested by Prakash (7) must therefore be regarded as incorrect.

Xenon-138

Manual operation of the apparatus was used to obtain samples of this isotope, which was examined after 5-minute irradiations and 45 minutes' cooling outside the reactor.

The gamma spectra of these samples showed photopeaks mainly at low energies, at 0.16, 0.26, 0.42, 0.44 (trace Xe-137), 0.46, and 0.53 Mev. Those at 0.16 and 0.26 Mev decayed with a half-life of 17.5±0.5 min while the 0.42 Mev peak decayed with a half-life of 18±1 min. These are therefore attributed to xenon-138. The photopeaks at 0.46 and 0.53 Mev showed half-lives of 32±3 min and belong to cesium-138. Further proof of the xenon photopeaks was shown when a typical xenon-138 sample was allowed to decay for 30 minutes, then swept out of the cell by a stream of helium. The residual activity showed only the gamma spectrum of cesium-138, which has been thoroughly studied by Bunker *et al.* (6).

Thulin (12) had noted the 0.42 Mev peak of xenon-138 together with others at 0.51, 1.78, and 2.01 Mev. In order to establish the existence of these photopeaks, the accumulation technique was used over the energy range 0–2.5 Mev. The gamma spectrum from five xenon-138 samples is shown in Fig. 8 together with a cesium-138 spectrum produced under similar conditions. A low-intensity photopeak was produced at 0.51 Mev which had a relative intensity ratio of 0.2 compared to the 0.42 Mev peak, as found by Thulin. Since cesium-138 consistently showed a photopeak at 0.53 Mev, 0.51 Mev was assigned to xenon-138.

The photopeaks at 1.78 and 2.02 Mev are shown to be prominent in the xenon-138 spectrum and are missing from that of cesium-138.

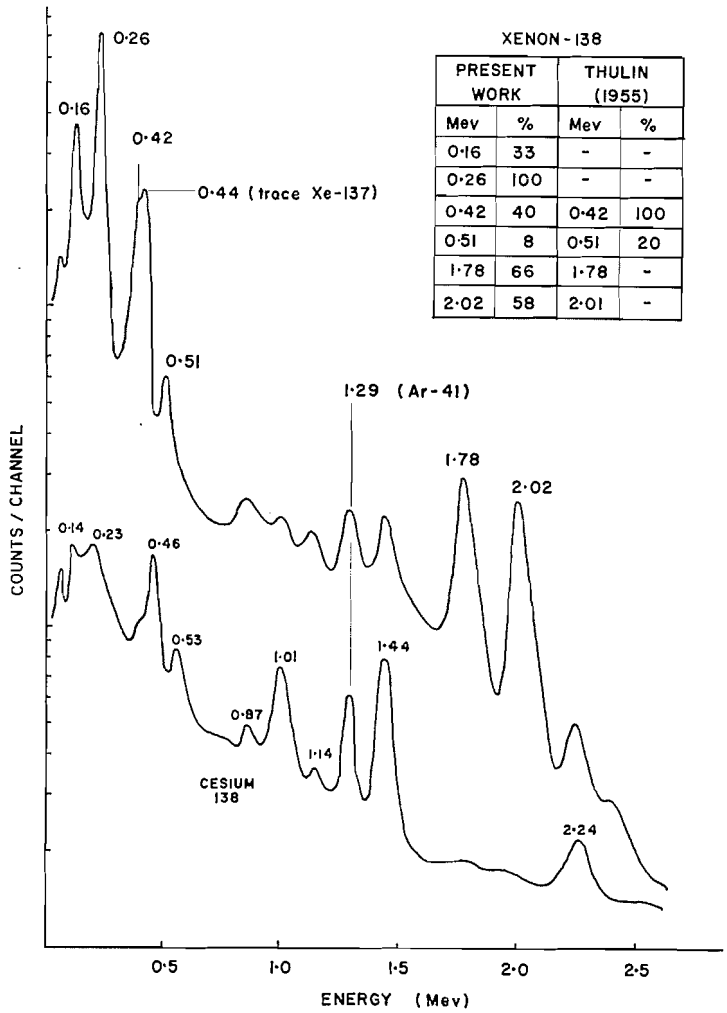

FIG. 8. Gamma spectra of xenon-138 and cesium-138.

Those attributed to xenon-138, therefore, are: 0.16, 0.26, 0.42, and 0.51±0.01 Mev; 1.78 and 2.02±0.02 Mev; their approximate relative intensities are shown in Fig. 8.

Xenon-139

In order to minimize the effect of xenon-138, a gamma spectrum of 41-sec xenon-139 was produced by the accumulation technique. Irradiations of 15 seconds were made, followed by the cycle $T_1 = 2$ seconds, $T_2 = 2$ seconds, $T_3 = \infty$ and with the xenon fraction being flushed into the cell. The spectrum, after 10×20 second counts, showed photopeaks at 0.18, 0.22, 0.30, 0.40, and 1.15 Mev as well as others due to other xenon and cesium isotopes. Subsequent half-life determinations on the 0.18, 0.22, 0.30, and 1.15 Mev peaks showed a decay period of 43±2 sec and these are all attributed to xenon-139, the first three being in agreement with Wahlgren (9). The photopeak at 0.40 Mev was too weak to study, although this also was attributed to xenon-139 by Wahlgren. The accumulated spectrum is shown in Fig. 9, with the calculated relative intensity values for the xenon-139 photopeaks. Agreement with Wahlgren's figures is good.

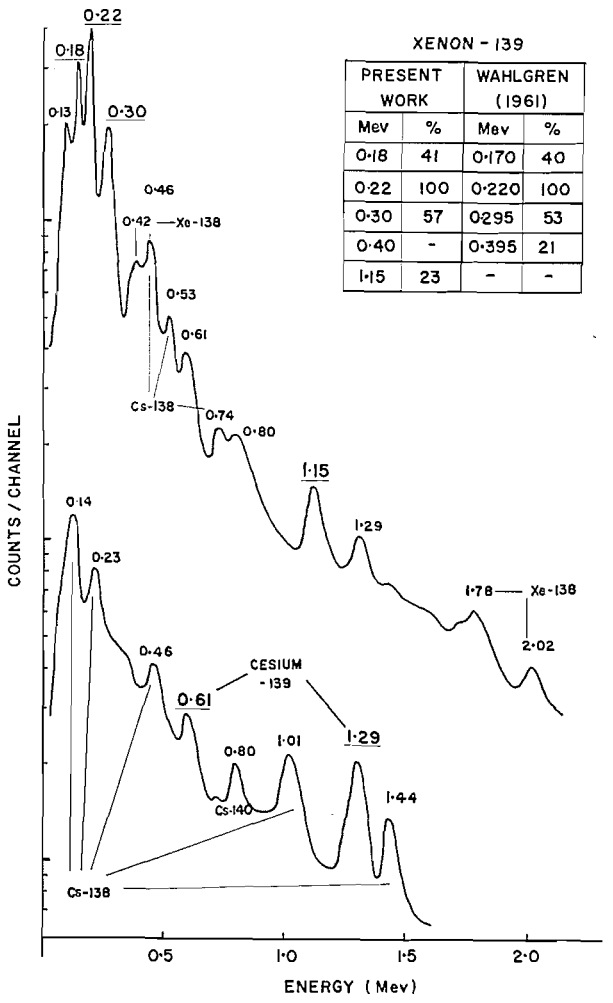

FIG. 9. Gamma spectra of xenon-139 and cesium-139.

The gamma-ray spectrum showing cesium-139 was also produced by accumulation. Xenon-139 samples were produced as described above and allowed to decay for 90 seconds, after which the xenon was blown out of the cell and the radiocesium counted for 5 minutes. Six samples were accumulated, and the resulting spectrum is shown on the lower part of Fig. 9.

Of all the photopeaks shown, only those at 0.61 and 1.29 Mev were attributed to cesium-139, the others being mainly due to cesium-138. Half-life studies confirmed this, values of 10 ± 1 min being obtained from both peaks. The 1.29 Mev peak contained a contribution from argon-41 ($t_{1/2}$ = 110 min) in the air, but a correction was made for this. Again these results are in agreement with those of Wahlgren (9).

Xenon-140

In all the gas samples containing xenon-139, a photopeak appeared at 0.13 Mev which decayed with a half-life of approximately 15 sec. This is due to xenon-140. No other gamma rays from this isotope could be detected, even when using the accumulation

technique in conjunction with 2-second irradiations and the quickest gas chromatographic separation.

CONCLUSION

The apparatus described has allowed the production of a large number of rare gas fission product samples, and the rapid gas chromatographic separation has enabled them to be studied within very short times. The results so far have confirmed recent studies (9) on krypton-89 and -90. No gamma rays from krypton-91 could be detected. New data have been obtained on xenon-137, -138, and -140, and previous work on xenon-139 has been corroborated. Some rubidium and cesium decay products have also been studied.

Coincidence measurements and decay scheme studies are being made on several of the above nuclides, and will be reported later.

THE RANGE OF Cs^{137} IONS OF KEV ENERGIES IN GERMANIUM[1]

J. A. DAVIES, J. D. MCINTYRE,[2] AND G. SIMS
Research Chemistry Branch, Atomic Energy of Canada Ltd., Chalk River, Ontario

Received April 25, 1962

ABSTRACT

The range of Cs^{137} ions in germanium has been measured at 4-, 20-, and 40-kev bombardment energy. Two independent methods of determining the depth of penetration were used. The results are in reasonable agreement with our previous range measurements in aluminum, and with the recently published theoretical treatment of Lindhard and Scharff. A possible explanation has been found for the abnormally large value reported by Bredov for the penetration depth of 4-kev Cs^{134} ions in germanium.

INTRODUCTION

Some years ago, Bredov and co-workers (1–3), reported an anomalously large penetration depth for alkali metal ions in germanium. They observed that a 4-kev Cs^{134} beam had a median penetration depth in germanium of approximately 35 $\mu g\ cm^{-2}$; in contrast with this, our recent experimental value (4) for 5-kev Cs^{137} ions in aluminum is only 0.9 $\mu g\ cm^{-2}$. The theoretically predicted increase in range in changing from an aluminum to a germanium target is somewhat less than a factor of 2; hence, Bredov's result is at least an order of magnitude higher than one would expect.

There are several completely different experimental techniques now available for measuring the range of atomic particles of kev energies in solid targets (5–7); the experimental results, except those of Bredov for germanium, are in reasonable accord with one another, and with the recent theoretical treatment of Lindhard and Scharff (8). However, most of this work has been confined to targets of low atomic number, particularly to aluminum. Hence, it was decided that a further investigation of germanium as a target material was necessary in order to determine whether an anomalously large range actually exists.

Bredov's experimental technique was to bombard a germanium target with a beam of Cs^{134} ions, and then to immerse the target for various periods of time in an aqueous H_2O_2 solution. From the observed decrease in the counting rate of the target after each immersion, and the known rate of etching of germanium in aqueous H_2O_2, he calculated the depth of penetration of the embedded radioactivity. Such a calculation involves two rather doubtful assumptions: (i) that the rate of etching is uniform over the target surface, and (ii) that it is unaffected by the Cs ion bombardment. The latter assumption is particularly questionable in view of the known effect of ionic bombardment on the electrical properties of semiconductors such as germanium and silicon (9–12).

EXPERIMENTAL

The present investigation may be divided into two parts:

(1) Duplication of Bredov's technique, using as small a beam intensity as possible in order to minimize any effect of radiation damage on the etching rate.

(2) Measurement of the transmission of Cs ions through thin germanium films in order to eliminate completely the above assumption about the rate of etching.

(1) Etching of Germanium Disks

Disks of pre-etched transistor-grade germanium were bombarded in a specially constructed electrostatic

[1]*Issued as A.E.C.L. No. 1538.*

[2]*Present address: Department of Chemistry, Princeton University, Princeton, N.J., U.S.A.*

ion accelerator (13) with a beam of 4-kev Cs^{137} ions. The beam was swept back and forth over the target in order to bombard as large an area as possible. The integrated flux in each case was about 3×10^{13} Cs ions per cm^2 of surface. After bombardment, the amount of radioactivity in each disk was measured with an end-window proportional β-counter of the methane flow type. The disks were then subjected to several successive immersions in aqueous H_2O_2. After each immersion, the disks were carefully weighed on a microbalance to determine the average thickness of the germanium layer removed, and then counted in order to obtain the residual Cs^{137} content. The results are illustrated in Fig.1. In one run, the $[H_2O_2]$, and hence

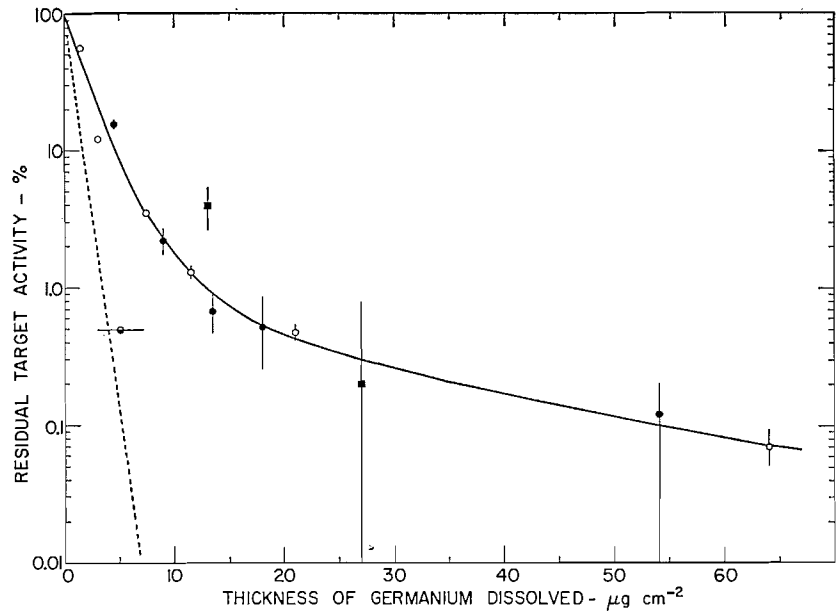

FIG. 1. Apparent depth of penetration of 4-kev Cs^{137} ions in germanium disks: ●, ○ using 0.3% aqueous H_2O_2 etch; ■ using 3% aqueous H_2O_2 etch; ◒ using the transmission method; – – – distribution curve for 5-kev Cs^{137} ions in aluminum.

the rate of etching, was increased 10-fold; this did not markedly affect the observed distribution curve. The broken line represents the observed distribution for 5-kev Cs^{137} ions in aluminum, using a previously established technique for removing *uniform* layers of accurately known thickness: viz. anodic oxidation at constant voltage, followed by dissolution of the oxide layer (5). The shape of the distribution curve in germanium approaches that observed in aluminum targets asymptotically. The observed shape of the curve might suggest the existence of an extremely penetrating component in the case of germanium. However, this penetrating "tail" was not found in the case of aluminum, and may be due merely to non-uniform etching of the germanium surface. It would require only a few percent of the incident beam to have become embedded in a corrosion-resistant region to account entirely for this "tail". The set of experiments described below provides considerable support for such an explanation.

(2) Transmission Through Thin Germanium Layers

Since the assumption of uniform etching of a germanium surface by aqueous H_2O_2 is subject to doubt, the range of Cs ions in germanium was also determined by a completely independent technique: viz. by measuring the transmission of Cs^{137} through thin films of germanium. The method consisted of three steps: (i) deposition of a thin film of germanium on an aluminum target by vacuum sublimation; (ii) bombardment of the target by a beam of Cs^{137} ions; and (iii) complete removal of the germanium layer by a 10-minute immersion in 3% aqueous H_2O_2 solution. By counting the target immediately before and after step (iii), the fraction of the Cs^{137} beam penetrating through the germanium film into the aluminum was obtained. Since the germanium film is completely dissolved in this experiment, no assumption about uniform etching rate is required. A similar technique has been used by Jech (14) to obtain approximate penetration depths for 4- to 6-kev Kr^{84} ions in nickel films.

Vacuum sublimation of the germanium was carried out slowly, with the collecting surface at least 20 cm from the heated filament, in order to obtain a fairly uniform layer. The rate of deposition was approximately 5 $\mu g\ cm^{-2}\ min^{-1}$.

The thickness of each germanium layer was determined radiochemically, using germanium containing a small amount of the 12-hr Ge^{77} isotope. This enabled extremely thin sublimed layers to be measured accurately by comparison of the counting rate of each target with that of a germanium standard of known weight. This radiochemical analysis was complicated by one factor: the Ge^{77} isotope decays to As^{77}, which in turn decays, with a 39-hr half-life, to the stable isotope Se^{77}. Since arsenic is much more volatile than germanium, it was found that the As^{77} content of the sublimed layer was considerably greater than that of the standard source. A suitable correction term for this effect was obtained by following the decay of each target for several days. With this procedure, it was possible to determine the average thickness of the germanium to ±15%. Some of the thicker layers were also measured by observing the increase in weight of the aluminum targets. There was no significant difference between the two methods (see Table I).

TABLE I

Transmission of Cs^{137} ions through germanium

	Film thickness ($\mu g\ cm^{-2}$)		
E_1 (kev)	Radiochemical analysis	Weight change	% transmission of Cs^{137}
4.0	—	5±2	0.5
20	1.8	—	95.5
	8.3	—	48
	18	14±2	4.0
40	11	—	47
	32	38±2	0.6
	58	—	0.1

After the film thickness was obtained, the (Ge^{77}+As^{77}) activity was allowed to decay to a negligible level before proceeding with the Cs^{137} bombardment.

Two additional tests were carried out in order to confirm that the aqueous H_2O_2 solution dissolves the germanium completely, without attacking the underlying aluminum.

To determine whether the aqueous H_2O_2 treatment dissolves the germanium film completely, a blank run was made with radioactive germanium of high specific activity and using the inactive Cs^{133} isotope in step (ii). After a 10-minute immersion in aqueous H_2O_2, it was found that less than 0.05% of the germanium activity remained on the aluminum foil. Hence, the dissolving of germanium was essentially quantitative.

To verify that the peroxide solution does not attack the underlying aluminum surface, another blank run was performed in which the Cs^{137} ions were injected directly into the aluminum target, i.e. before the germanium film was added. Any decrease in counting rate of the target after the germanium film was dissolved would indicate that the H_2O_2 solution was dissolving some of the underlying aluminum. The Cs^{137} ions were injected into the aluminum at 10-kev energy, and a thin, uniform layer of aluminum of known thickness (1.6 $\mu g\ cm^{-2}$) was then dissolved away by the standard anodizing and film stripping technique (5). This thickness corresponds roughly to the "most probable range" of 10-kev Cs^{137} ions in aluminum; hence, its removal effectively exposes a surface layer of aluminum with maximum Cs^{137} content. After measuring the target activity, a layer of inactive germanium approximately 30 $\mu g\ cm^{-2}$ in thickness was deposited on the surface, and subsequently dissolved by immersion in 3% aqueous H_2O_2. The decrease in Cs^{137} content was less than 1%. From this experiment, and the known distribution of the embedded Cs^{137} ions in the aluminum (13), it is estimated that the amount of aluminum dissolved by the aqueous H_2O_2 treatment was less than 0.05 $\mu g\ cm^{-2}$, i.e. less than one atom layer.

These preliminary experiments have shown that a thin layer of germanium of known thickness can be sublimed onto an aluminum surface, bombarded with Cs ions, and then removed completely without removing a significant amount of the underlying aluminum. Hence, the major sources of error for obtaining range data in germanium by chemical etching have been eliminated in the "transmission method".

Three different bombardment energies have been investigated—4, 20, and 40 kev; the results are summarized in Table I. The 4-kev result has been included in Fig. 1; the extremely small transmission through a 5 $\mu g\ cm^{-2}$ layer confirms our earlier suggestion that the "tail" observed above in Fig. 1 is not an abnormal penetration phenomenon but is due to a non-uniform rate of etching across the germanium surface.

A completely unexpected, direct observation of this non-uniformity in etching rate across a germanium surface occurred in several of these transmission experiments. During the dissolving of the sublimed layers, it was noticed that the bombarded area of the germanium dissolved somewhat more slowly than the unbombarded area; in fact, the last part to disappear resembled closely the shape of the bombarding beam. In subsequent runs, this effect was confirmed by obtaining an autoradiograph of the bombarded foil, and then comparing this autoradiograph visually with the appearance of the aluminum surface during the

dissolving of the germanium. In every case, immersion in the aqueous H_2O_2 produced on the aluminum surface a fleeting pattern of undissolved germanium which was identical in shape with the distribution of Cs^{137} atoms in the autoradiograph. Evidently, the ionic bombardment inhibits very markedly the rate of dissolution of the germanium layer—in the present case, the reduction in rate corresponded roughly to a factor of 3.

DISCUSSION

Depth-of-penetration curves for each of the energies studied are plotted in Fig. 2, together with the earlier results of Bredov *et al.* (2). No evidence of an abnormally large

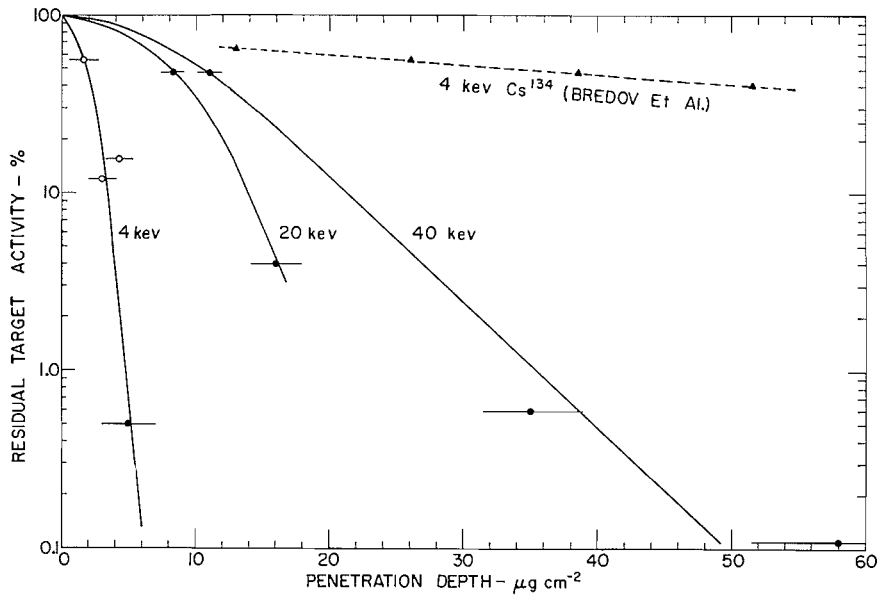

FIG. 2. Depth of penetration of Cs^{137} ions in germanium as a function of energy: ○ using method (1); ● using method (2); ▲ Bredov's data for 4-kev Cs^{134}.

penetration of germanium by Cs ions has been observed in the present investigation; in fact, even the 40-kev beam penetrated only a small fraction of the depth reported by Bredov for 4-kev ions.

A probable explanation for this discrepancy may be found in the marked reduction in etching rate that accompanies Cs ion bombardment. Bredov *et al.* determined their rate of etching, not on the bombarded specimen, but by weight loss of a control specimen which had not been subjected to the Cs ion bombardment. Consequently, the actual rate of etching of the bombarded surface (and hence, the penetration depth of the Cs ions) would be considerably less than the values calculated from the etching rate of an unbombarded specimen. It is, nevertheless, surprising that the discrepancy should have been so large, and suggests that chemical etching is not a reliable method of determining small depths of penetration.

Values of the median range obtained from the penetration curves of Fig. 2 are listed in Table II together with corresponding values for Cs^{137} ions of similar energy in aluminum targets.

In order to compare the aluminum and germanium results on a common basis, Lindhard and Scharff's recent theoretical treatment (8) has been used. They define a suitable

range parameter ρ and an energy parameter ϵ, such that all range–energy data expressed in terms of these parameters should fall on the same curve. The expressions for these two parameters may be written

$$\rho = R_m\left(1 + \frac{A_2}{3A_1}\right)\cdot\frac{166}{(Z_1^{2/3}+Z_2^{2/3})}\cdot\frac{A_1}{(A_1+A_2)^2}\ \mu g\ cm^{-2}$$

and

$$\epsilon = \frac{a}{b} = \frac{32{\cdot}5}{Z_1Z_2(Z_1^{2/3}+Z_2^{2/3})^{1/2}}\cdot\frac{A_2}{A_1+A_2}\cdot E_1,$$

where the subscripts 1 and 2 refer to the projectile and target atom respectively, a is the appropriate screening distance, b the collision diameter, and E_1 is the projectile energy in kev. By substituting the appropriate range–energy data from Table II into

TABLE II

Range of Cs^{137} ions in germanium and aluminum

E_1 (kev)	R_m, median range ($\mu g\ cm^{-2}$)	
	In aluminum	In germanium
2	0.6±0.3	—
4	—	1.8±0.5
5	0.9±0.3	—
20	4.8±0.3	8.1±1.2
30	7.4±0.4	—
40	—	10.5±1.6
50	9.0±0.5	—

the above equations, the ρ–ϵ plot shown in Fig. 3 is obtained. An earlier approximate treatment by Nielsen (15) is included for comparison. It will be noted that the germanium

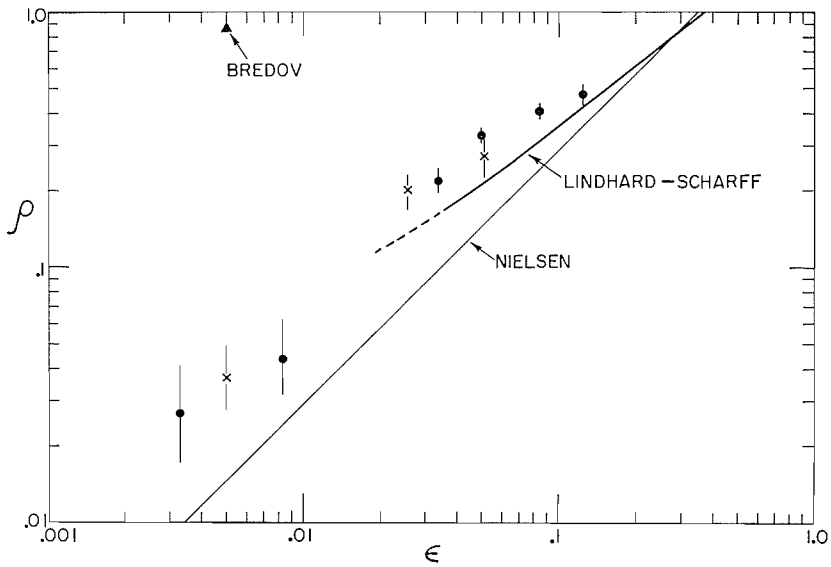

Fig. 3. ρ–ϵ plot for Cs^{137} ions: ● in aluminum; × in germanium; ▲ Bredov *et al.*

and aluminum results do in fact agree extremely well with one another, and that deviations from the theoretical $\rho-\epsilon$ curve predicted by Lindhard and Scharff, although significant, are not unreasonable and are within the limitation of the theory. In a future paper, the application of this $\rho-\epsilon$ plot to all our previous experimental measurements will be considered in detail.

SOME REACTIONS INVOLVED IN THE PHOTOBROMINATION OF SIMPLE ALCOHOLS AND KETONES IN THE VAPOR PHASE

E. BUCKLEY* AND E. WHITTLE
Department of Chemistry, University College, Cathays Park, Cardiff, Wales
Received April 2, 1962

ABSTRACT

The vapor phase brominations of methanol, ethanol, formaldehyde, and acetaldehyde are all photosensitive. The products have been identified and mechanisms postulated to explain their formation. The vapor phase reactions between formaldehyde and HBr, acetaldehyde and HBr, acetaldehyde and acetyl bromide, and ethanol and acetyl bromide have also been studied.

The vapor phase reactions between bromine and simple organic compounds containing oxygen have received little attention. We are currently studying the kinetics of reactions of this type and have obtained considerable information about the chemistry involved, which will now be described. Unless otherwise stated, all reactions involve mixtures of the vapors of the reactants at room temperature.

We have shown previously (1) that the reaction between bromine and methanol is photosensitive and is given by

$$CH_3OH + 2Br_2 \rightarrow CO + 4HBr. \qquad [1]$$

A mechanism was proposed for this overall process involving successive stripping of hydrogen atoms from methanol by bromine atoms, thus giving formaldehyde as an intermediate. This was subsequently confirmed by kinetic studies (2). From separate experiments (1) it was found that the bromination of formaldehyde is also photosensitive and is given by

$$CH_2O + Br_2 \rightarrow CO + 2HBr. \qquad [2]$$

If more formaldehyde is used than is required by eq. [2] the yield of HBr falls considerably and separate experiments showed that formaldehyde and HBr react immediately with a 1:1 stoichiometry, producing drops of liquid on the walls of the container. If condensation is prevented the number of moles of products may be estimated from the pressure change. The results of two experiments are given in Table I. The products are water and *sym*-dibromodimethyl ether, and if the reaction is

$$2CH_2O + 2HBr \rightarrow BrCH_2OCH_2Br + H_2O, \qquad [3]$$

TABLE I
The reaction between formaldehyde and HBr

HBr	CH_2O	Total products
120	81	118
113	87	115

NOTE: all quantities are in μmoles.

**Present address: Department of Chemistry, University of British Columbia, Vancouver, British Columbia.*

then the number of moles of products should equal the number of moles of HBr reacted. If there is an excess of HBr, the final moles of products including unreacted HBr should still equal the initial moles of HBr, and this is confirmed by the data of Table I.

Tischtschenko (3) has shown that reaction [3] occurs when HBr reacts with solid polyoxymethylene and that similar reactions occur when HI or HCl is used. We have prepared the ethers $(XCH_2)_2O$, where X = Cl, Br, I, and have measured their infrared spectra, which are of interest, since Bellamy (4) has pointed out that the influence of α-halogenation on the C—O stretching vibration has not been studied. The following wave numbers of this vibration were found for solutions of the ethers in carbon disulphide: $(CH_3)_2O$, 1164; $(CH_2Cl)_2O$, 1099; $(CH_2Br)_2O$, 1080; $(CH_2I)_2O$, 1057 cm^{-1}.

The vapor pressure of the dibromoether was measured in the temperature range 284–307° K and is given by the equation

$$\log P_{mm} = 9.24 \pm 0.20 - 2420 \pm 60/T.$$

The unknown compound methyl hypobromite could be produced by

$$CH_3OH + Br_2 \rightarrow CH_3OBr + HBr, \qquad [4]$$

a reaction frequently postulated to occur in solutions of bromine in methanol. It could also be formed by

$$CH_2O + HBr \rightarrow CH_3OBr. \qquad [5]$$

However, we could detect no trace of it in the products of the vapor phase reactions. In 1894, Henry (5) isolated an unstable compound which he claimed to be $BrCH_2OH$. We have repeated his experiment, which consists of passing HBr into aqueous 40% formalin at room temperature. After about 90 minutes, an oily liquid separated but its infrared spectrum was the same as that of *sym*-dibromodimethyl ether and indeed this is a convenient way of making the compound.

Bromine and Acetaldehyde

The reaction between bromine and acetaldehyde is almost instantaneous in daylight but there is no dark reaction. A series of experiments was done using progressively increasing amounts of bromine measured photometrically. The following result is typical: initial acetaldehyde 29.1 mm, initial bromine 34.9 mm, residual bromine 6.7 mm. Clearly the stoichiometry is close to 1:1 when using excess bromine. Infrared analysis indicated that acetyl bromide and HBr are the only major products, with traces of acetic acid, CO, and CH_4. Hence the overall reaction is

$$CH_3CHO + Br_2 \rightarrow CH_3COBr + HBr. \qquad [6]$$

This was confirmed by dissolving the products in water and titrating the H^+ liberated. In one experiment 40.6 μmole of bromine reacted with 46.0 μmole of acetaldehyde, and 118.6 μmole of H^+ was found, compared to the expected value of $3 \times 40.6 = 121.8$ μmole.

In view of these facts the probable mechanism of reaction [6] is

$$Br_2 + h\nu \rightarrow 2Br \qquad [7]$$

$$Br + CH_3CHO \rightarrow HBr + CH_3CO \qquad [8]$$

$$CH_3CO + Br_2 \rightarrow CH_3COBr + Br \qquad [9]$$

plus a suitable termination step, e.g.

$$Br + Br + M \rightarrow Br_2 + M. \qquad [10]$$

The traces of CO and CH_4 amounted to less than 0.4% of the acetaldehyde reacted and could be owing to the breakdown of the acetyl radical:

$$CH_3CO \rightarrow CH_3 + CO \quad [11]$$

$$CH_3 + CH_3CHO \rightarrow CH_4 + CH_3CO. \quad [12]$$

The formation of acetic acid is discussed later.

If more acetaldehyde is used than is required by reaction [6], additional products are obtained, the main one being an ester, and it seems likely that the excess acetaldehyde reacts with the products of reaction [6]. This was confirmed by reacting 42.3 μmole of bromine with 79.7 μmole of acetaldehyde. The products were dissolved in water and on rapid titration (to avoid appreciable hydrolysis of the ester by reaction [14]) the measured H^+ was 56.1 μmole compared with the expected 3×42.3 μmole. We have therefore studied the reactions of acetaldehyde with acetyl bromide and with HBr.

Reaction between Acetaldehyde and Acetyl Bromide

On mixing equimolar amounts of the vapors of these compounds, both react completely and no HBr is liberated. The product has a fruity smell and an infrared spectrum rather like that of ethyl acetate. The carbonyl absorption is at 1773 cm^{-1} compared to 1745 cm^{-1} for ethyl acetate.

The product of the reaction was shown to be α-bromoethyl acetate, produced by the reaction

$$CH_3COBr + CH_3CHO \rightarrow CH_3COOCH(Br)CH_3. \quad [13]$$

The bromoester is unstable and is difficult to free from acetic acid as it is fairly readily hydrolyzed by water according to the equation

$$CH_3COOCH(Br)CH_3 + H_2O \rightarrow CH_3COOH + HBr + CH_3CHO, \quad [14]$$

and the fact that this reaction was found to be quantitative plus the information given above are strong proof of the identity of the compound.

The bromoester has been little studied since Tawildarow (6) made it by heating a mixture of acetaldehyde and acetyl bromide to 130° and distilling the product. We find that, on mixing the liquids at 20°, heat is liberated and good yields of the ester are obtained. Its infrared spectrum is identical with that of the ester formed when bromine reacts with excess acetaldehyde; clearly the acetyl bromide formed reacts with excess acetaldehyde.

The Reaction between Acetaldehyde and HBr

On mixing gaseous acetaldehyde and HBr, the changes seen are the same as when formaldehyde is used. The lower layer of the two liquids produced has an infrared spectrum characteristic of an ether, with two intense absorptions at 1076 and 1128 cm^{-1} compared with a single band at 1120 cm^{-1} in diethyl ether. By analogy with reaction [3], the ether could be *di-α-bromoethyl ether*, produced by

$$2CH_3CHO + 2HBr \rightarrow CH_3CH(Br)OCH(Br)CH_3 + H_2O. \quad [15]$$

This compound is unstable and is rapidly hydrolyzed by water, which reverses reaction [15]; this has been used to check the assigned formula. It does not seem to have been reported previously, although the corresponding dichloroether was made by Moffett (7) from acetaldehyde and HCl in the liquid phase.

If reaction [15] occurs to some extent when bromine reacts with acetaldehyde, then the water formed could react with the acetyl bromide present to give the traces of acetic acid mentioned earlier.

The Bromination of Ethanol

The reaction between bromine and aqueous ethanol has been studied in detail (8, 9) and it was found that in concentrated aqueous ethanol the only products are ethyl acetate and hydrobromic acid, whereas in dilute solution acetic acid is formed rather than ethyl acetate. The mechanism has not been definitely established.

In the vapor phase, we find that ethanol and bromine react only in light. The results of two experiments are shown in Table II and it is clear that the stoichiometry is close to 1:1. The main products are ethyl acetate and HBr, so the overall reaction is

$$2C_2H_5OH + 2Br_2 \rightarrow CH_3COOC_2H_5 + 4HBr. \qquad [16]$$

TABLE II

The reaction between bromine and ethanol

Initial pressure (mm)		Final pressure (mm)	Br_2 reacted (mm)
C_2H_5OH	Br_2	Br_2	
26.6	35.0	7.4	27.6
29.1	44.6	14.4	30.2

When methanol is brominated, formaldehyde is formed as an intermediate so it is likely that ethanol will give acetaldehyde on bromination. But acetaldehyde is rapidly brominated to acetyl bromide, which could react with residual ethanol. If the vapors of ethanol and acetyl bromide are mixed there is an immediate reaction which gives only ethyl acetate and HBr, presumably by

$$C_2H_5OH + CH_3COBr \rightarrow CH_3COOC_2H_5 + HBr. \qquad [17]$$

In view of the above facts the following mechanism is postulated to explain reaction [16]:

$$Br_2 + h\nu \rightarrow 2Br \qquad [7]$$

$$Br + CH_3CH_2OH \rightarrow HBr + CH_3CHOH \qquad [18]$$

$$CH_3CHOH + Br_2 \begin{cases} \nearrow \; CH_3CHO + HBr + Br & [19a] \\ \text{or} & \\ \searrow \; CH_3CH(Br)OH + Br & [19b] \end{cases}$$

$$CH_3CH(Br)OH \rightarrow CH_3CHO + HBr \qquad [19c]$$

followed by reactions [8], [9], and [17]. The termination step of this chain sequence has not been identified. Reaction [19*a*], and the alternatives [19*b*] and [19*c*] are analogous to those discussed by Buckley and Whittle (1) in connection with the bromination of methanol. If each molecule of acetyl bromide produced is converted to ethyl acetate, the above mechanism gives reaction [16] as the overall result.

A minor product of the bromination of ethanol is acetic acid, probably because of hydrolysis of some of the intermediate acetyl bromide. The necessary water could be produced by reaction [15] or by

$$C_2H_5OH + HBr \rightarrow C_2H_5Br + H_2O. \qquad [20]$$

There would also be traces of water in the original ethanol. Any ethyl bromide formed by this reaction would be very difficult to detect.

EXPERIMENTAL

Materials

Br_2 and CH_2O were treated as described previously (1). HBr was made from Br_2 and tetralin. B.D.H. spectroscopic ethanol was dried with anhydrous Na_2SO_4, distilled, and finally subjected to bulb-to-bulb distillations on a vacuum line. A middle cut was stored at −80°. May and Baker acetaldehyde was subjected to several bulb-to-bulb distillations on the vacuum line and a small middle cut stored at −80°.

Procedure

The reactions took place in a conventional high vacuum apparatus and all materials were thoroughly degassed before mixing.

sym-Dibromodimethyl Ether

This was made by (*a*) mixing the vapors of CH_2O and HBr or (*b*) treatment of paraformaldehyde with HBr. In each case the products were two immiscible liquids, the lower one being the ether and the upper layer aqueous HBr. The ether was dried with anhydrous Na_2SO_4. It fumes and decomposes in air and reacts very rapidly with aqueous NaOH. Because of this instability the ether cannot be obtained completely pure. A Carius estimation gave 74% Br (theor. 78.4%). A sample was hydrolyzed with dilute NaOH, and the H^+ and Br^- ions liberated were estimated independently and were found to be equivalent. Two samples of the ether, weighing 0.046 and 0.042 g respectively, gave 0.034 and 0.031 g of HBr (theor. HBr from reverse of eq. [3], 0.0365 and 0.0335 g). This is satisfactory in view of the instability of the compound.

Procedure (*b*) above was also used to make $(CH_2Cl)_2O$ and $(CH_2I)_2O$ starting with HCl and HI respectively. There is no apparent reaction between HCl and CH_2O vapors, and HCl gas must be left in contact with paraformaldehyde for several days at 100° C before liquid products are formed.

α-Bromoethyl Acetate

This was made (*a*) by mixing the vapors of CH_3CHO and CH_3COBr or (*b*) more conveniently by mixing the corresponding liquids, using a slight excess of CH_3CHO. When reaction was complete, the mixture was cooled to 20° and any excess CH_3CHO pumped away. The residue was distilled and a fraction with boiling point range of 108–132° was collected. This was rapidly washed with dilute aqueous $NaHCO_3$ followed by water and it was dried with anhydrous Na_2SO_4. The final product could not be freed of traces of acetic acid, probably because of the ready hydrolysis of the ester; this was studied with the following results.

Ester (0.329 g, 1.97 mmole) was dissolved in water and left until hydrolysis was complete. On the basis of eq. [14] we expect 1.97 mmole Br^-, 1.97 mmole CH_3CHO, and 3.94 mmole H^+. The Br^- and H^+ were determined volumetrically as 1.74 and 3.66 mmole respectively. The CH_3CHO should equal the Br^- and was found to be 1.73 mmole using a gravimetric determination based on the 2,4-dinitrophenylhydrazone. The results are satisfactory since the ester could not be completely freed of acetic acid.

Di-α-bromoethyl Ether

This was made by mixing the vapors of CH_3CHO and HBr. The subsequent results and procedure were similar to those given above under *sym*-dibromodimethyl ether. A sample of 0.088 g of di-α-bromoethyl ether was hydrolyzed with excess aqueous NaOH, and 0.056 g of HBr was liberated (theor. on the basis of the reverse of reaction [15], 0.061 g).

One of us (E. B.) wishes to thank the D.S.I.R. for a maintenance grant.

NOVEL DEVIATIONS FROM THE 'MIXTURE LAW' IN THE RADIOLYSIS OF HYDROCARBON MIXTURES[1]

P. J. DYNE AND J. DENHARTOG
Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario

Received April 10, 1962

ABSTRACT

The 'mixture law' states that, if the radiolysis of material A gives a product M with yield G_M, then, in a mixture where the mole fraction of A is X_A, the yield of M is $G_M X_A$.

In the radiolysis of dilute mixtures of cyclohexane-d_{12} or of methylcyclohexane-d_{14} with other aliphatic hydrocarbons D_2 is formed in a process which is first order with respect to the deutero compound. As a consequence these mixtures provide a sensitive method of detecting deviations from the mixture law.

Experimentally the yield of D_2 and the yield of HD vary widely from one solvent to another amongst the C_5 to C_{10} hydrocarbons selected. The yields of D_2 and HD are, approximately, linearly related. The solvents have similar quantitative effects on the yields for both deuterated hydrocarbons.

These deviations from the mixture law cannot be explained in terms of kinetic effects (variations in rate constants caused by differing bond strengths), because the D_2 yield measures a process without free radical intermediates. Mechanisms involving excitation transfer, ion–molecule reactions, and subexcitation electrons are discussed.

INTRODUCTION

An effective method of exploring mechanisms of radiolysis is to examine the radiation chemistry of mixtures. Here effects and interactions unsuspected from the radiolysis of a pure compound may be clearly revealed.

The first expectation about the radiolysis of a binary mixture is that the product yields will follow a simple mixture law. Suppose G^0_M is the yield of M derived from a material A, and suppose that X_A is the fraction of energy absorbed by A in a binary mixture of A and B. The yield of M in the mixture is then expected to be $G^0_M X_A$. Put another way, the yield G_M *per 100 ev absorbed in component A* is expected to be independent of composition.

In practice, mixtures obeying this simple law are the exception. Many physical and chemical interactions are possible between the compounds in the mixture and the intermediates in the decomposition, and, as a consequence, the yields depart widely from the simple mixture law. This is hardly surprising considering the diversity of compounds studied in a single mixture, e.g. cyclohexane–benzene (1–3), carbon tetrachloride and diphenyl-picryl-hydrazyl (4), hexane and methyl methacrylate (5). Mechanisms of energy transfer, charge transfer, and radical scavenging have been proposed for these interactions and have been demonstrated with varying degrees of rigor.

If the components of the mixture are similar, interactions are expected to be small or non-existent, as shown, for instance, by the hydrogen yield from mixtures of benzene (10) and toluene (6). The present paper describes experiments on mixtures of aliphatic and alicyclic hydrocarbons where large deviations from the simple mixture law are observed.

In these experiments we measure the yield of D_2 and HD from mixtures of cyclohexane-d_{12} (or methylcyclohexane-d_{14}) with other hydrocarbons (called "solvents"). Kinetic analysis (7, 8) shows that, at low concentrations of the deuterated hydrocarbon, the D_2 comes exclusively from the first-order decomposition

$$c\text{-}C_6D_{12} \longrightarrow D_2 + \text{products},$$

[1]*Issued as A.E.C.L. No. 1543.*

in which both deuterium atoms come from the same hydrocarbon molecule. The yield of D_2 is equivalent to the yield of M referred to in an earlier paragraph. We calculate the yield of this first-order decomposition, $G_1(D)$, from the relation

$$G_1(D) = G(D_2)/100 \text{ ev absorbed in cyclohexane-}d_{12}.$$

We assume that the fraction of energy absorbed by the cyclohexane-d_{12} is equal to its mole fraction.* We find that $G_1(D)$ is not a constant, as expected from the mixture law, but varies widely from solvent to solvent.

The use of a deuterated hydrocarbon as one component of a mixture gives, via the analysis of D_2 and HD, a sensitive method of detecting the reactions of one component in a mixture. Consequently we call the deuterated hydrocarbon molecule 'the detector molecule' and the other, non-deuterated hydrocarbon 'the solvent' since it is always present in large excess.

EXPERIMENTAL

The techniques of irradiation (Co-60 γ-rays), dosimetry, and isotopic analysis of the hydrogen have been described previously (7, 8). In cases where the methane yield is appreciable the total amount of gas, not condensed in liquid N_2, was measured and analyzed mass spectrometrically for methane and the hydrogen isotopes.

Cyclohexane-d_{12}, methylcyclohexane-d_{14}, and benzene-d_6 of >99% isotopic purity were obtained from Merck & Co. The isotopic purity was confirmed by mass spectrometric analysis.

The hydrocarbon solvents were: Fisher Spectrograde: *n*-hexane and cyclohexane; Phillips Pure Grade: methylcyclopentane, *n*-decane, methylcyclohexane, cyclopentane, *n*-pentane, and *n*-octane; Phillips Research Grade: *n*-hexane, cyclohexane, cyclopentane, neohexane, isopentane, isohexane, and *n*-pentane; Anachemia: (purified with H_2SO_4) methylcyclohexane, ethylcyclohexane, *n*-nonane, and *n*-decane; Matheson, Coleman and Bell: (purified with H_2SO_4) isooctane and decalin. The Phillips chemicals were used as received after we had found that refluxing with sulphuric acid to remove olefins, according to the method of Hardwick (5), did not increase $G(H_2)$. With the exception of *n*-hexane, which will be discussed later, no significant difference was found in the behavior of solvents from different manufacturers.

In general, measurements were made at two concentrations of the deuterated hydrocarbon, one at about 3 mole% and one at about 6 mole%. These gave yields of HD and D_2 which lay on a line passing through the origin. The estimated uncertainty in the percentage of D_2 and hence in $G_1(D)$ amounts to about ±5%; the uncertainty in the percentage of HD is less than this and amounts to ±3%. The values of $G(H_2)$ in Table I were obtained from 20-ml samples at a dose of 5×10^{22} ev/l. Values of G(total hydrogen) for the

TABLE I

Summary of D_2 and HD yields in hydrocarbon solvents

Hydrocarbon solvent	$G(H_2)$ (pure solvent)	Solutions of cyclohexane-d_{12}		Solutions of methylcyclohexane-d_{14}	
		$G_1(D)$	g(HD)	$G_1(D)$	g(HD)
1. *n*-Pentane	4.5	2.6	11.5	2.1	14.5
2. Isopentane	4.0	1.3	6.5	1.0	7.9

16. Decalin	3.9	0.08	1.6	0.075	1.72

**In the mixtures studied the mole fraction is approximately equal to the electron fraction, the parameter chosen by many workers. The effects reported in this paper are much larger than the differences between mole fraction and electron fraction.*

smaller isotopic samples containing the heavy hydrocarbon gave results of somewhat lower precision, deviating by as much as 5% from the results obtained with the larger samples. The values of $G_1(D)$ and $g(HD)$ are based on the amounts actually measured on the small samples. These, again, will be somewhat lower than the limiting values at zero dose.

This study is essentially a survey; observations were made at fewer concentrations of the deuterated hydrocarbon than in the earlier studies (7, 8). The reliability and reproducibility of all these experiments is good and so the smaller number of experimental points does not materially reduce the significance of the data.

Experiments with *n*-hexane showed that while Fisher Spectrograde material and Phillips Research Grade gave essentially the same $G(H_2)$, the values of $G_1(D)$ and $g(HD)$ from the isotopic mixtures with the Fisher material were about half those found in the Phillips material. We naturally looked for this type of variation with other hydrocarbons. However, cyclohexane from several manufacturers, viz. Phillips Pure and Research grades, Fisher Spectrograde, all gave essentially identical results. This impurity effect is, so far as we know, restricted to *n*-hexane: it is noteworthy that this 'impurity' does not markedly affect $G(H_2)$ although it affects both $g(HD)$ and $G_1(D)$ proportionately.

THE KINETIC ANALYSIS

The kinetic scheme used has been given previously (7, 8) and is summarized below for the reader's convenience. In essence it separates hydrogen-forming processes into two classes: those which are first order with respect to the hydrocarbon and those which are second order.

The scheme is:

$$\left.\begin{aligned} C_H &\xrightarrow{\sim\sim} H_2 + P \\ C_D &\xrightarrow{\sim\sim} D_2 + P \end{aligned}\right\} \text{first-order yields} \quad \begin{matrix} G_1(H) \\ G_1(D) \end{matrix}$$

$$\left.\begin{aligned} C_H &\xrightarrow{\sim\sim} X_H + P \\ C_D &\xrightarrow{\sim\sim} X_D + P \end{aligned}\right\} \text{second-order yields} \quad \begin{matrix} G_2(H) \\ G_2(D) \end{matrix}$$

$$\begin{aligned} X_H + C_H &\rightarrow H_2 + P \quad \text{rate constant } k_1 \\ X_D + C_H &\rightarrow HD + P \quad \text{" " } k_2 \\ X_H + C_D &\rightarrow HD + P \quad \text{" " } k_3 \\ X_D + C_D &\rightarrow D_2 + P \quad \text{" " } k_4 \end{aligned}$$

where C_H is the light hydrocarbon, C_D the deuterated hydrocarbon, P is any residue, and X_H and X_D the reactive intermediates in the bimolecular, second-order processes. We have shown that in mixtures containing C_D moles of the heavy hydrocarbon and C_H moles of the light hydrocarbon the yield of D_2 is given by:

$$G(D_2) = G_2(D) \times k_4/k_2 \times (C_D/C_H)^2 + G_1(D) \times C_D/C_H \qquad [1]$$

when $C_H > C_D$, and that in the limit $C_H \gg C_D$,

$$G_1(D) = G(D_2) \times (C_H/C_D). \qquad [2]$$

The yield of HD is given by

$$G(HD) = C_D/C_H[(k_3/k_1) \times G_2(H) + G_2(D)] \qquad [3]$$

when $C_H \gg C_D$.

We define

$$g(HD) = G(HD) \times (C_H/C_D) = (k_3/k_1) \times G_2(H) + G_2(D). \qquad [4]$$

This analysis assumes that the excitation is partitioned between the components according to their mole fraction, and the simple expectation is that $G_1(D)$ is independent

of the nature of C_H, the solvent. As will be seen, $G_1(D)$ varies with the solvent and we interpret this in terms of interaction of the detector molecule with the solvent.

RESULTS AND CORRELATIONS

(a) Aliphatic Solvents

The results are tabulated in Table I and are plotted in Figs. 1–3. The range of values of $G_1(D)$ and $g(HD)$ is large: values of $G_1(D)$ for C_6D_{12} in decalin and in *n*-pentane differ

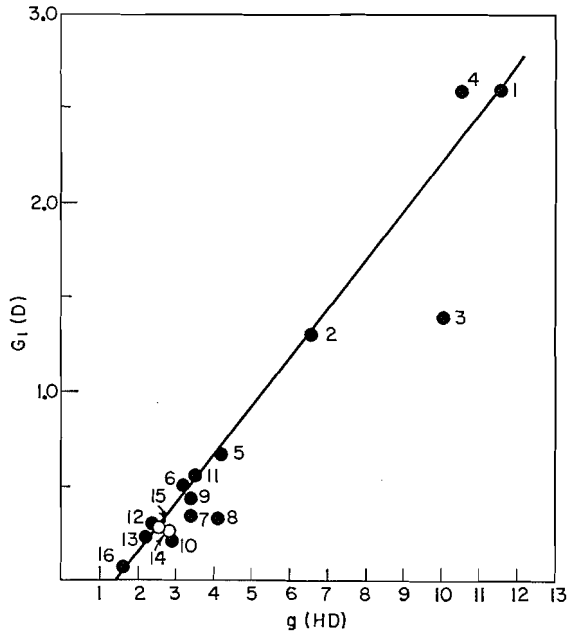

FIG. 1. Variation of $G_1(D)$ with $g(HD)$ for solutions of cyclohexane-d_{12} in various solvents. The key to the numbers identifying the solvents is in Table I.

by a factor of 30, values of $g(HD)$ for the same mixture differ by a factor of 7. In its simplest experimental terms the percentages of D_2 and HD differ by these amounts, since the yield of total hydrogen is relatively constant. The range in G(total hydrogen) for these same mixtures amounts to 15%. The effect we are studying is consequently of much greater magnitude than the variations in hydrogen yield between one hydrocarbon and another. It is also much greater than any corrections which might be made to the calculation of mole fraction due to non-ideality of the solution and other corrections which might alter the initial estimate of the energy partitioning.

There is a correlation between $G_1(D)$ and $g(HD)$. Solvents in which $G_1(D)$ is large are also solvents in which $g(HD)$ is large. This is shown in Figs. 1 and 2, where values of $g(HD)$ are plotted against $G_1(D)$. To a first approximation this correlation is linear, i.e. it can be expressed by

$$g(HD) \simeq AG_1(D)+B, \qquad [5]$$

where B is a constant.

There is also a correlation between $G_1(D)$ for cyclohexane-d_{12} solutions and $G_1(D)$ for methylcyclohexane-d_{14} solutions. Solvents in which $G_1(D)$ is large for one detector molecule also give large values for the other detector molecule. This is shown in Fig. 3.

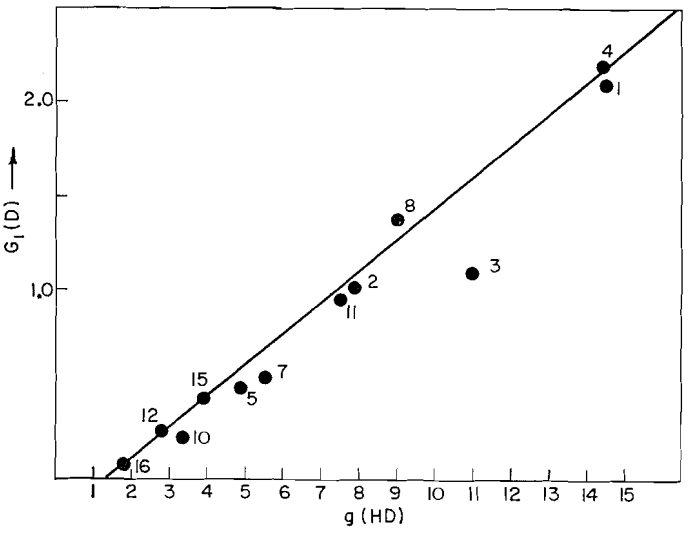

FIG. 2. Variation of $G_1(D)$ with $g(HD)$ for solutions of methylcyclohexane-d_{14} in various solvents. The key to the numbers identifying the solvents is in Table I.

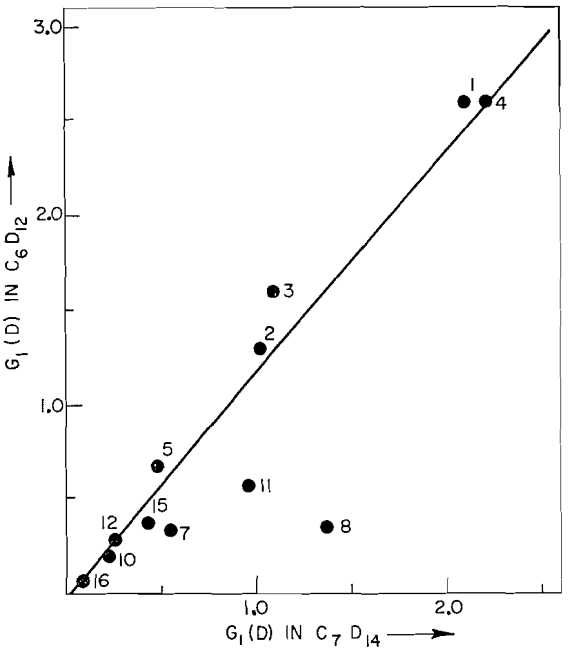

FIG. 3. The effect of solvent on $G_1(D)$ from C_6D_{12} (abscissa) against $G_1(D)$ from C_7D_{14} (ordinate). The key to the numbers identifying the solvents is in Table I.

These results show that the effective reactivity of the detector molecule, as measured by HD and D_2 yields, varies widely from solvent to solvent. This variation in reactivity must appear in the yields of all the other products derived from the detector molecule. To take an example, the yields of cyclohexene and high molecular weight hydrocarbons with a C_6 ring must differ between mixtures in pentane or in heptane. Muccini and Schuler (9)

have studied mixtures of cyclohexane and cyclopentane, analyzing the $(C_6)_2$, (C_6,C_5), and $(C_5)_2$ hydrocarbons. They conclude that the solutions are regular and show no evidence of energy transfer. These product yields are not symmetric with concentrations; they attribute this to reactions changing the identity of free radicals:

$$C_6H_{11} + C_5H_{10} \rightarrow C_6H_{12} + C_5H_9. \quad [6]$$

No measurements were made of the yields of olefins. If this change of identity reaction occurred it could mask the effects of the interaction we observe through the yields HD and D_2. While Muccini and Schuler's experiment gives no inkling of the interaction we observe we do not consider that it is in conflict with our data.

A further conclusion from the experimental results is that, since $G_1(D)$ varies with solvent, no unique significance can be placed on the value obtained from solutions of C_6D_{12} in C_6H_{12} (7). There is no reason to suppose that it gives the first-order yield in 'pure' C_6D_{12}, since we cannot assume that there is no interaction between molecules which differ only in isotopic substitution.

(b) Solutions of Aromatic Hydrocarbons

Experiments were carried out with benzene-d_6 as the detector molecule in both aromatic and aliphatic solvents.

From a complete analysis of mixtures of benzene and benzene-d_6 we have shown (10) that, within experimental error, the mixtures are regular. The isotopic composition of hydrogen evolved from a 50:50 benzene–benzene-d_6 mixture can be accurately predicted from the kinetic analysis which is confined to the two ends of the concentration range, $C_H \gg C_D$ and $C_D \gg C_H$.

Values of $G_1(D)$ and $g(HD)$ for benzene-d_6 in four aromatic solvents are shown in Table II.

TABLE II

Solutions of benzene-d_6 in aromatic hydrocarbons

Solvent	$10^3 G_1(D)$	$10^2 g(HD)$
Benzene	3.2	2.7
Toluene	3.2	5.2
Cumene	3.2	5.7
p-Xylene	2.6	6.2

The extreme errors in $G_1(D)$ amount to $\pm 5 \times 10^{-4}$ G(unit), in $g(HD)$ to $\pm 2 \times 10^{-3}$ G(unit). Values of $G_1(D)$ show little variation with solvent. In view of the wide variations observed with aliphatic mixtures it is reassuring to find some mixtures in which the simple expectation, the invariance of $G_1(D)$, is realized. Variations in $g(HD)$ due to kinetic effects are to be expected in these systems because of the aliphatic side chains in the solvents other than benzene.

Data on solutions of benzene-d_6 in aliphatic hydrocarbons are more difficult to interpret. The percentage of D_2 in the radiolytic gas is very small so that $G_1(D)$ can only be determined with low precision. $G(HD)$ is a markedly non-linear function of the concentration of the deutero compound, so $g(HD)$ can only be estimated from the limiting slope of the yield curve. Solutions of benzene-d_6 in cyclohexane, *n*-hexane, cyclopentane, isopentane, and *n*-octane have these points in common: firstly, the limiting value of $g(HD)$ is about 3

in all cases, showing a reactivity of benzene which is fully comparable to that of cyclohexane-d_{12}, and, secondly, $G_1(D) \geqslant G(D_2)$ for pure benzene-d_6. This last observation was first made by Patrick and Burton (11), who commented that it was apparently inconsistent with the amount of HD obtained from mixtures of benzene and benzene-d_6. It is likely that a solvent interaction is affecting the value of $G_1(D)$ (10).

THE MECHANISM OF THE INTERACTION

Any proposed mechanism must predict:

(1) changes in that yield of D_2 which is first order with respect to the deuterated hydrocarbon;

(2) the empirical relation $g(HD) = AG_1(D)+B$.

Let C_H and C_D represent the concentrations of these hydrocarbons and I_H and I_D the concentration of intermediates derived from them. I_H and I_D symbolize any ion, excited state, or molecular fragment derived from C_H and C_D.

The dominant terms in the rate equation describing the first-order D_2 yield cannot be of the form kC_D^2, kC_DI_D, or kI_D^2, since these will give a second-order dependence of $G(D_2)$ on C_D. A first-order dependence will be given by algebraic terms of the form kC_D, kC_DC_H, kI_DC_H, kC_DI_H, and kI_DI_H. The first term does not contain any explicit interaction with the solvent, and the second describes a reaction which would take place in the absence of radiation. The first two terms can therefore be discarded. Speculating on the reactions which would generate the last three rate expressions, we see that these would arise from

$$I_D + C_H \rightarrow D_2 + \ldots \quad [7]$$

$$C_D + I_H \rightarrow D_2 + \ldots \quad [8]$$

$$I_D + I_H \rightarrow D_2 + \ldots \quad . \quad [9]$$

Conventional free radical reactions, in particular H atom reactions, of the form of [7] and [8] provide paths for the formation of HD but not of D_2. Reaction [9] is implausible.

We have therefore to speculate on novel reactions of the forms of [7] and [8]. We present two possibilities: in the first the intermediates are unspecified excited states, in the second the intermediate is specifically identified as an ion.

An Excitation Transfer Mechanism

Writing the intermediates as excited states C_D^* and C_H^*, reaction [8] becomes

$$C_D + C_H^* \rightarrow C_D^* + \ldots \quad . \quad [10]$$

We follow an earlier suggestion (8) that C_D^* decomposes by two parallel routes:

$$C_D^* \xrightarrow{\alpha} D_2 + P \qquad C_D^* \xrightarrow{\beta} X_D + P \quad [11]$$

i.e., the first-order process giving D_2 and the second-order process giving HD have a common precursor. Algebraic treatment of steps [10] and [11] combined with the kinetic scheme of the section "The Kinetic Analysis" yields a relation of the form of equation [5]. This can be seen directly as follows:

The rates of the first- and second-order decompositions will be given by $\alpha k_{11}C_D^*$ and $\beta k_{11}C_D^*$. If α and β are constant and independent of the solvent, then $G(D_2)$ and $G(HD)$ will vary proportionately. We can write

$$g(HD) = k_3/k_1G_2(H)+G_2(D) = k_3/k_1G_2(H)+\beta/\alpha G_1(D).$$

Comparing with equation [5] we see $A = \beta/\alpha$, $B = k_3/k_1G_2(H)$. The solvent effect appears in the variation of $G_1(D)$, which is given by

$$G_1(D) = \alpha\left[G_D + \frac{k_{10}G_H C_H}{k_{12}+k_{10}C_D}\right], \qquad (C_H \gg C_D)$$

where G_D and G_H are the primary yields of C_D^* and C_H^*, and k_{12} is the sum of the rate constants of the concurrent processes:

$$C_H^* \begin{cases} \nearrow H_2 + P \\ \searrow X_H + P \end{cases} . \qquad [12]$$

At low concentrations of C_D the effective variable is k_{10}/k_{12}.

If this mechanism is correct and our identification of equation [5] is valid, this implies that the constant term is $k_3/k_1G_2(H)$. This does seem possible.

If an excitation transfer mechanism is operating then the magnitude of the interaction must be, in part, determined by the relative energies of the excited species involved. Now the order of the solvents in decreasing values of $G_1(D)$ (approximately the order of Table I) is roughly the order of increasing carbon number. Since the ionization potential of hydrocarbons decrease with increasing carbon number this correlation is qualitatively in agreement with the supposition of excitation transfer. However, the ionization potential is also a measure of the energy levels of excited states so this argument alone does not favor charged excited species over uncharged excited species. It would appear from these results that the net probability of excitation transfer increases as the difference between the energy levels of the solvent and detector molecule increases.

Taking this excitation transfer picture we note that $G_1(D)$ for C_6D_{12} in cyclohexane is greater than it is in methylcyclohexane. Methylcyclohexane is therefore an energy acceptor relative to cyclohexane. It follows that $G_1(D)$ for methylcyclohexane-d_{14} should be higher in cyclohexane than it is in methylcyclohexane and also higher than $G_1(D)$ for cyclohexane in methylcyclohexane. Both these differences are observed.

It is also possible that this effect is produced by subexcitation electrons. This is briefly discussed in the last section.

An Ion–Molecule Mechanism

Williams (12) has argued that ion–molecule reactions play a significant role in the radiolysis of liquid alkanes. The major point of Williams' paper is that ion–molecule reactions are allowed thermochemically.

The mechanism proposed by Williams for the formation of the dimer is

$$C_nH_{2n+2} + C_nH_{2n+2}^+ \rightarrow C_nH_{2n+3} + C_nH_{2n+1}^+ \qquad [13]$$

by either H atom or hydride ion transfer, followed by

$$C_nH_{2n+3} \rightarrow C_nH_{2n+1} + H_2$$

$$2C_nH_{2n+1} \rightarrow C_{2n}H_{4n+2}.$$

If this reaction is written for two hydrocarbons, one of them deuterated, the reaction path for H atom transfer is

$$C_nH_{2n+2}^+ + C_eD_{2e+2} \rightarrow C_nH_{2n+1}^+ + C_eD_{2e+2}H \text{ (H atom transfer).} \qquad [14]$$

Elimination of hydrogen from the $C_eD_{2e+2}H$ radical may take two paths:

$$C_eD_{2e+2}H \rightarrow HD + C_eD_{2e+1} \qquad [15a]$$

$$C_eD_{2e+2}H \rightarrow D_2 + C_eD_{2e}H \qquad [15b]$$

In reaction [15*b*] we have a process giving D_2 which will be first order with respect to the concentration of the deuterated hydrocarbon. The possibility of D_2 elimination rather than HD elimination depends on the extent to which the transferred H atom keeps its identity in the radical. This reaction also says that HD is formed by molecular elimination. Since $G(HD) \sim 10G(D_2)$ we have simply to assume that only 1 in 10 of the eliminations gives D_2. This is a relatively small amount of randomization compared with the statistical reaction in which D_2 would be greatly in excess since $(2e+2) \gg 1$.

The effect of solvent appears through the relative probabilities of reactions [14] and [15]. It can be shown that a scheme based on reactions [13], [14], and [15] can give relations of the form of our correlation equation [5].

This argument neglects contributions to the first-order hydrogen yield by the ionic molecular elimination

$$C_nH_{2n+2}^+ \rightarrow C_nH_{2n}^+ + H_2.$$

The yield of this reaction, in an isotopic experiment, could change with solvent due to preferential charge exchange. This is a mechanism which is formally equivalent to the first mechanism discussed in the first part of this section.

Possible Mechanisms of Excitation Transfer or Preferential Excitation

The formation of excited states by ionizing radiation has always raised the intriguing possibilities of energy transfer playing a dominant role in radiation-induced reactions. For energy transfer to be efficient the time-constant characteristic of the transfer process must be at most as long as the lifetime of the excited state. This often requires the energy transfer cross section to be appreciably greater than the gas-kinetic cross section.

One mechanism which permits the energy transfer cross sections to be large has been outlined by Lipsky and Burton (13) and Nosworthy, Magee, and Burton (14). In simple terms the idea is this: molecules in liquids are geometrically ordered over small distances and electronic excitation of one molecule may, to some extent, be delocalized and be more accurately described as a state of the ordered group of molecules. This delocalization will give the excitation a mobility and range greater than that expected for molecules with interaction and collision cross sections comparable to their gas-kinetic cross sections.

Again, while the chemical nature of the molecules has little effect on their initial probability of excitation it may affect the process in which the delocalized energy is focused onto one particular molecule prior to the molecular dissociation.

This hypothesis could be tested by examining the radiolysis of isotopic mixtures in the vapor phase: we are planning to do this.

It is also possible that these experiments reveal the effects of subexcitation electrons whose properties have been outlined by Platzman (15). Secondary electrons with energies greater than the minimum electronic excitation energy of the irradiated substance lose their energy rapidly: below this energy they lose their energy by relatively slow thermal processes. Another substance, with a lower electronic excitation energy will, however, act as an efficient sink for the energy of these 'subexcitation' electrons. Chemical effects resulting from this excitation of the second substance would be apparent at low concentrations ($\sim$1%) and would appear as a greater sensitivity to radiation than expected. It is clear that, in a qualitative sense, our observations follow this pattern: this model permits us to accept the observation that very small differences in excitation energy, as measured by the ionization potential, can have a large effect on the reactivity.

SYNTHÈSES DE DÉRIVÉS DE LA LYSINE[1]

LOUIS-MARIE BABINEAU ET LOUIS BERLINGUET
Département de Biochimie, Faculté de Médecine, Université Laval, Québec, Qué.

Reçu le 26 mars 1962

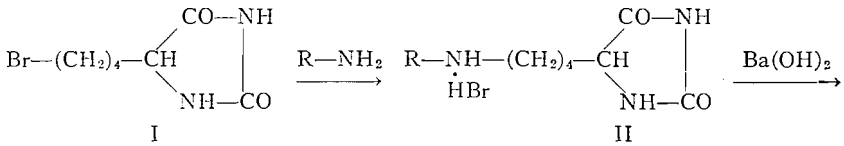
ABSTRACT

New N-ε-substituted lysines have been synthetized as follows: by condensing 5-δ-bromobutylhydantoin with different primary amines, 5-δ-alkylaminobutylhydantoins were obtained, the alkaline hydrolysis of which gave the corresponding N-ε-substituted lysines. N-α-Substituted hexahomoserines have also been prepared by acid hydrolysis of the reaction product between α,ε-dihydroxycaproic nitrile and primary amines. 5-Amino-5-carboxypentane sulphonamide has been prepared in the following way: 5-δ-bromobutylhydantoin was reacted with thiourea, and the resulting isothiouronium salt was oxidized with chlorine. Gaseous ammonia was then bubbled through an ethereal suspension of the 5-δ-chlorosulphonyl butylhydantoin and the resulting sulphonamide was hydrolyzed under pressure with barium hydroxide. 5-Amino-5-carboxypentane sulphonamide was then isolated and crystallized.

À l'heure actuelle, le métabolisme de la lysine est passablement bien connu même si l'on n'a pu encore démontrer de façon certaine la présence de quelques intermédiaires dont on a postulé l'existence (1). Cependant, on est loin d'avoir précisé tous les aspects de ce métabolisme. Ainsi, on rencontre encore peu d'études biochimiques des dérivés de cet acide aminé: on n'a en effet synthétisé jusqu'à présent qu'un petit nombre d'analogues de la lysine. Au cours de ce travail, nous avons synthétisé plusieurs nouveaux dérivés de la lysine. Nous en avons fait une étude biologique préliminaire et nous publierons ailleurs les résultats de cette étude.

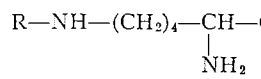
On peut classifier en deux groupes les analogues de la lysine déjà existants: les uns sont porteurs de radicaux alkylés situés sur l'un ou l'autre atome d'azote ou sur les deux à la fois; les autres sont des dérivés de la lysine où l'on a greffé des chaînes latérales ou encore des composés où on a remplacé l'un ou l'autre des groupements aminés de la lysine par un radical quelconque. Nous avons synthétisé quelques représentants de ces deux groupes: les acides N-ε-méthyl-, N-ε-éthyl-, N-ε-cyclohexyl- et N-ε-pipéridyl-lysine et les acides éthylamino-2 hydroxy-6 et cyclohexylamino-2 hydroxy-6 caproïques. Enfin, au cours de ce travail, nous avons préparé un nouvel acide aminé porteur d'un groupement sulfonamide en ε: l'acide amino-5 carboxy-5 pentanesulfonamide.

Voici maintenant les modalités de notre synthèse de dérivés de la lysine porteurs de groupements alkylés sur l'azote en ε. La condensation de la δ-bromobutylhydantoïne-5 (I) avec différentes amines primaires donne une δ-alkylaminobutylhydantoïne-5 (II). L'hydrolyse de cette hydantoïne soit en milieu alcalin et sous pression, soit en milieu acide donne un acide alkylamino-6 amino-2 caproïque (III). Les rendements de la condensation sont de l'ordre de 45%; par contre, les rendements de l'hydrolyse de l'hydantoïne en acide aminé sont meilleurs (75%). À l'exception de la N-ε-méthyl-lysine et de la N-ε-pipéridyl-lysine, les produits obtenus sont relativement faciles à purifier. Le schéma suivant résume le processus suivi:



I II

[1]*Présenté en partie au congrès de l'ACFAS à Montréal en novembre 1959.*



III

Enger et Steib (2), Neuberger et Sanger (3) et Poduska (4) ont déjà synthétisé la N-ε-méthyl-lysine mais en utilisant comme produit de départ l'acide ε-aminocaproïque qu'ils ont méthylé en ε. Pour la synthèse de dérivés N-α-alkylés de la lysine, d'autres auteurs (5) utilisent comme produit de départ la lysine ou l'acide ε-aminocaproïque. Dans ce dernier cas, ils procèdent de la façon suivante: la fonction ε-aminée étant protégée, ils greffent sur le carbone alpha de la molécule une fonction aminée puis remplacent cette dernière fonction aminée par un halogène et enfin, l'halogène par l'amine choisie.

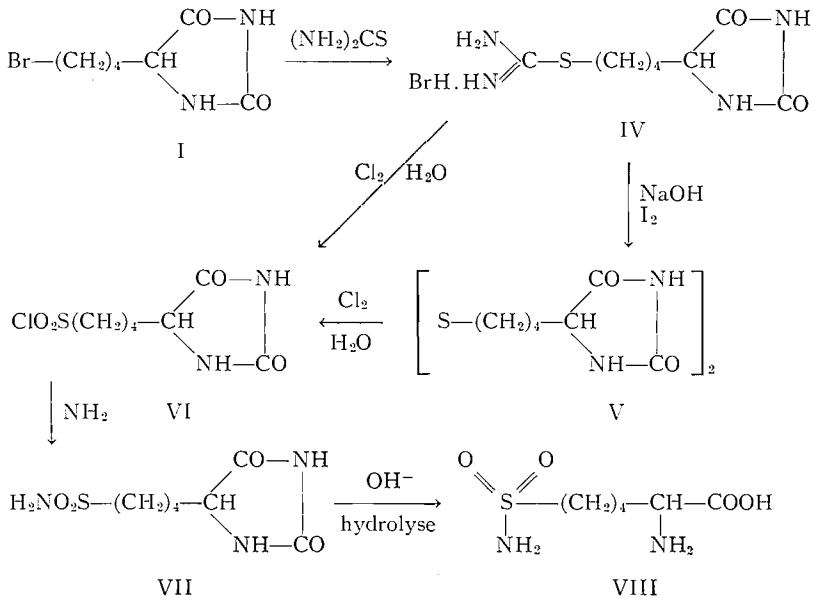
Nous avons voulu obtenir ces dérivés par synthèse totale à partir de produits facilement accessibles comme le dihydropyranne. Gaudry a déjà publié (6) une synthèse de la lysine à partir de cette substance. L'hydrolyse acide du dihydropyranne donne la δ-hydroxy-valéraldéhyde dont le traitement par la méthode classique de Bucherer et Lieb (7) conduit à la formation de la δ-hydroxybutyl-5 hydantoïne et finalement à l'acide amino-2 hydroxy-6 caproïque. En remplaçant dans cette synthèse l'ammoniac par des amines primaires, nous espérions obtenir des dérivés de l'hexahomosérine à azote substitué en position alpha. Il était toutefois à prévoir que le traitement au carbonate d'ammonium des aminonitriles substitués entraînerait un remplacement du groupe alkylé par l'ammoniac. En effet, on avait déjà observé (8) que le traitement au carbonate d'ammonium de l'aminonitrile du cyclopentane donnait la spirohydantoïne non substituée sur l'azote. De plus, on avait noté que l'hydrolyse acide à chaud dissociait l'aminonitrile pour redonner la cyclopentanone de départ et non l'acide aminé attendu.

Dans notre cas, nous avons réussi à obtenir, à partir de la δ-hydroxyvaléraldéhyde et de l'éthylamine ou de la cyclohexylamine, deux alkylaminonitriles que nous avons isolés et dont l'hydrolyse par l'acide sulfurique concentré à froid a finalement donné deux acides alkylamino-2 hydroxy-6 caproïques.

Pour transformer ces deux acides hydroxylés en dérivés de la lysine, il ne restait plus qu'à protéger le groupement alpha aminé soit par acylation, soit par la formation d'une hydantoïne substituée et qu'à remplacer l'hydroxyle terminal par le brome. Une amination de l'hydantoïne ou du dérivé acylé ainsi préparé, suivie d'une hydrolyse, aurait alors donné l'acide particulier recherché. Nous n'avons pu, cependant, obtenir de cette façon des dérivés alkylamino-2 de la lysine. Il a été impossible, en effet, d'isoler une hydantoïne cristalline par traitement à l'isocyanate de phényle ou au cyanate de potassium du nitrile cyclohexylamino-2 hydroxy-6 caproïque.

Au cours de ces recherches, nous avons préparé un nouvel acide α-aminé contenant un groupement sulfonamide en position 6. Reisner (9) a déjà synthétisé plusieurs acides γ-sulfonamide α-aminés qui sont des analogues de l'acide glutamique. L'un de ces acides, l'amino-3 carboxy-3 propane sulfonamide, est un bon inhibiteur in vitro de la croissance de *Escherichia coli* T_2 et supprime la multiplication du coliphage T_2. Comme il n'existe aucun analogue de la lysine à groupement ε-sulfonamide, nous avons pensé en préparer un. Nous avons réussi de la façon suivante la synthèse de l'acide ε-sulfonamide α-amino-caproïque ou amino-5 carboxy-5 pentane sulfonamide.

On transforme d'abord la δ-bromobutylhydantoïne-5 (I) en un sel d'isothio-uronium (IV) au cours d'une réaction presque quantitative et d'exécution facile. On peut préparer ensuite le chlorure de sulfonyle de la butylhydantoïne-5 (VI) de deux manières différentes:



(*a*) On soumet le sel d'isothio-uronium (IV) à une hydrolyse alcaline modérée que l'on fait suivre d'une oxydation à l'iode. On obtient ainsi le dérivé dithio (V) que l'on traite au chlore après l'avoir suspendu dans l'eau.

(*b*) On dissout le sel d'isothio-uronium (IV) dans l'eau et l'on traite immédiatement la solution aqueuse par le chlore. On obtient aussitôt le chlorure de sulfonyle de la butylhydantoïne-5 (VI) avec un rendement beaucoup plus élevé dans ce cas que dans le premier. Après avoir préparé la sulfonamide (VII) par traitement à l'ammoniac gazeux d'une suspension éthérée du chlorure de sulfonyle (VI), on obtient facilement l'acide aminé recherché (VIII) par une hydrolyse alcaline et sous pression de la sulfonamidebutylhydantoïne-5 (VII). Le rendement final en acide ϵ-sulfonamide α-aminocaproïque est de 22.5% ou de 35.8% selon que l'on utilise ou non la bis(thio-δ-butylhydantoïne-5) (V), le rendement étant calculé à partir de la δ-bromobutylhydantoïne-5.

PARTIE EXPÉRIMENTALE

δ-Bromobutylhydantoïne-5 (I)

On prépare ce produit selon la méthode décrite par Gaudry (6). À partir de 0.2 mole (34.4 g) de δ-hydroxybutylhydantoïne-5, on obtient finalement, après recristallisation, 47 g de δ-bromobutylhydantoïne-5. Rendement: 70%; p.f. 126–127° (lit. 129–131°) (6). Anal. Calc. pour $C_7H_{11}O_2N_2Br$: N, 11.97%. Obtenu: N, 11.81%.

Bromhydrates de δ-alkylaminobutylhydantoïnes-5 (II)

Premier cas: On dissout 0.1 mole (23.5 g) de δ-bromobutylhydantoïne-5 dans un excès de méthylamine à 30% ou d'éthylamine à 70%.

Deuxième cas: On dissout la même quantité de δ-bromobutylhydantoïne-5 dans 55 ml d'éthanol chaud et on ajoute, lentement, 0.2 mole de cyclohexylamine ou 0.3 mole de pipéridine. La réaction est passablement exothermique avec la méthyl- ou l'éthyl-amine, légèrement exothermique avec la cyclohexylamine et la pipéridine. On laisse reposer le mélange réactionnel à la température ambiante pendant 2 jours. Des cristaux n'apparaissent qu'avec la cyclohexylamine. On se débarrasse du solvant et de l'excès d'amine par une évaporation à sec du mélange, sous vide et à basse température. Dans le cas de la réaction avec la pipéridine, il faut dissoudre le résidu dans l'eau et l'extraire plusieurs fois à l'éther pour le débarrasser de toute trace d'amine.

On dissout l'hydantoïne substituée dans l'éthanol absolu à l'exception du bromhydrate de la δ-méthylaminobutylhydantoïne-5 que l'on dissout dans le méthanol. On laisse la solution alcoolique plusieurs jours

à la glacière. On filtre des cristaux blancs que l'on recristallise de l'éthanol absolu ou du méthanol (cas de la δ-méthylaminobutylhydantoïne-5).

On trouvera au Tableau I la liste des δ-alkylaminobutylhydantoïnes-5 préparées.

Bromhydrates d'acides amino-2 alkylamino-6 caproïques

On hydrolyse ces hydantoïnes au moyen de $Ba(OH)_2.8H_2O$ en solution aqueuse, sous pression, à 170° pendant une demi-heure (6), ou encore, au moyen de HBr à 48%, à reflux pendant 15 heures. Les rendements de l'hydrolyse acide sont toutefois très inférieurs à ceux de l'hydrolyse alcaline. On recristallise de l'eau et de l'alcool les divers bromhydrates de la lysine à l'exception du bromhydrate de la N-ε-cyclohexyl-lysine qui recristallise de l'alcool absolu. On trouvera au Tableau II la liste des dérivés de la lysine ainsi préparés.

Ces acides amino-2 alkylamino-6 caproïques migrent vers la cathode à l'électrophorèse sur papier à pH 8.6 et donnent une coloration violette à la ninhydrine.

Phénylcarbamates des acides amino-2 alkylamino-6 caproïques

On a caractérisé les divers acides amino-2 alkylamino-6 caproïques en en préparant les phénylcarbamates par la méthode habituelle (Tableau III).

Alkylamino-2 hydroxy-5 capronitriles

(a) Ethylamino-2 hydroxy-5 capronitrile

On dissout 0.77 mole (100 g) de dihydroxy-2,5 capronitrile dans 2 moles d'éthylamine à 70%. On abandonne le mélange pendant 3 jours à la température ambiante. On évapore l'excès d'amine sous vide et à basse température. On dissout le résidu dans l'éther anhydre et l'on extrait la solution éthérée au moyen de l'éther de pétrole bouillant. On refroidit cette dernière solution et l'on filtre des cristaux de nitrile éthylamino-2 hydroxy-5 caproïque. P.f. 44–45°. Rendement: 36.5 g (30%). Anal. Calc. pour $C_8H_{16}ON_2$: N, 17.93%. Obtenu: N, 17.58%. L'acétylation de ce produit a donné une huile que nous n'avons pas caractérisée.

(b) Cyclohexylamino-2 hydroxy-5 capronitrile

On laisse tomber lentement 1.6 moles de cyclohexylamine dans 0.8 mole (104 g) de dihydroxy-2,5 capronitrile. On note un fort dégagement de chaleur et le produit de la réaction ne tarde pas à cristalliser. On le

Acides alkylamino-2 hydroxy-6 caproïques

On hydrolyse pendant 15 heures 0.1 mole de l'un ou de l'autre nitrile au moyen d'un excès d'acide chlorhydrique concentré. On évapore à sec et l'on chasse toute trace d'eau. On dissout le résidu dans l'alcool anhydre, l'on filtre le NH_4Cl formé et l'on ajoute un excès de pyridine. On porte à la glacière et l'on obtient dans les deux cas un précipité amorphe. On recristallise de l'acétone l'acide éthylamino-2 hydroxy-6 caproïque. P.f. 184–185°. Rendement: 7 g (40%). Anal. Calc. pour $C_8H_{17}O_3N$: N, 7.99%. Obtenu: N, 7.30%. Quant à l'acide cyclohexylamino-2 hydroxy-6 caproïque, on peut le purifier en en préparant le chlorhydrate que l'on traite à nouveau par la pyridine. P.f. 210–211°. Rendement: 16.8 g (73%). Anal. Calc. pour $C_{12}H_{23}O_3N$: N, 6.11%. Obtenu: N, 5.87%.

Le traitement de ces deux acides aminés à l'isocyanate de phényle ne donne que des huilles non cristallisables.

Bromhydrate de la δ-isothio-uronium butylhydantoïne-5 (IV)

On prépare ce dérivé en modifiant comme suit la technique de Snyder et Cannon (10). On dissout dans un minimum d'alcool absolu et bouillant 23.5 g (0.1 mole) de δ-bromobutylhydantoïne-5 et 7.6 g (0.1 mole) de thiourée. On fait bouillir le tout à reflux au bain-marie pendant 21 heures. Le dérivé cristallise dans le ballon. On porte à la glacière pour quelques heures. On filtre des cristaux blancs qu'on lave à l'acétone. Les cristaux, très solubles dans l'eau et le méthanol, fondent à 176–177°. Rendement: 28.6 g (92%). Anal. Calc. pour $C_8H_{15}O_2N_4BrS$: N, 18.00%. Obtenu: N, 18.03%.

Bis(thio-δ-butylhydantoïne-5) (V)

On dissout 73 g (0.23 mole) d'isothio-uronium de la butylhydantoïne-5 dans un minimum d'eau bouillante et on y ajoute, lentement, 100 ml d'une solution de soude à 18.8%. On agite le tout pendant une heure. On oxyde (11) ensuite le produit par addition d'une solution d'iode ioduré (0.23 mole) jusqu'à apparition d'une coloration brune permanente. On filtre le précipité et on le dissout dans 250 ml de cellosolve bouillant. On purifie la solution par addition de noir animal et on lui ajoute 300 ml d'eau. On porte à la glacière. On obtient 28.0 g (63.0%) de cristaux blancs fondant à 178–180°. Anal. Calc. pour $C_{14}H_{27}O_4N_4S_2$: N, 14.96%. Obtenu: N, 14.64%.

δ-Chlorosulfonylbutylhydantoïne-5 (VI)

(*a*) On réduit 26.8 g (0.07 mole) de bis(thio-δ-butylhydantoïne-5) en une poudre fine que l'on suspend ensuite dans 100 ml d'eau. On place le ballon dans un bain de glace et l'on agite la suspension. On fait passer un courant de chlore pendant 80 minutes. Une masse solide se forme. On décante, on dissout la masse dans l'acétate d'éthyle et l'on traite l'eau cinq fois avec ce même solvant. On sèche l'acétate d'éthyle avec du sulfate de sodium anhydre, on le filtre et on le distille sous vide. On dissout le résidu dans l'acétate d'éthyle, on ajoute de l'éther de pétrole et on place le tout dans la glacière. On filtre 25.0 g (69%) de cristaux blancs fondant à 128–130°. Anal. Calc. pour $C_7H_{11}O_4SCl$: N, 11.00%. Obtenu: N, 10.82%.

(*b*) On prépare la δ-chlorosulfonylbutylhydantoïne-5 en traitant directement par le chlore, après une élimination préliminaire du brome sous forme de bromure d'argent, le bromhydrate de la δ-isothio-uronium butylhydantoïne-5 (12). En partant de 31.0 g (0.1 mole) du sel d'isothio-uronium de la butylhydantoïne-5,

on obtient 18.0 g (72%) de cristaux blancs fondant à 123–125°. Anal. Calc. pour $C_7H_{11}O_4SCl$: N, 11.00%. Obtenu: N, 11.30%.

δ-Sulfonamidebutylhydantoïne-5 (VII)

On prépare ce dérivé selon la méthode décrite par Reisner (9). On utilise 24.0 g (0.094 mole) de δ-chlorosulfonylbutylhydantoïne-5 et l'on obtient finalement, après recristallisation, 14.0 g (63%) de δ-sulfonamidebutylhydantoïne-5 sous forme de cristaux blancs fondant à 159–160°. Anal. Calc. pour $C_7H_{13}O_4N_3S$: N, 17.88%. Obtenu: N, 17.93%.

Acide DL-*amino-5 carboxy-5 pentane sulfonamide (VIII)*

L'hydrolyse alcaline, suivant la méthode de Gaudry (6), de 8.2 g (0.035 mole) de δ-sulfonamidebutylhydantoïne-5 a donné 6.5 g (89%) de cristaux blancs d'acide DL-amino-5 carboxy-5 pentane sulfonamide fondant à 243–245°. Anal. Calc. pour $C_6H_{14}O_4N_2S$: N, 13.33%. Obtenu: N, 13.45%.

Le traitement de ce nouvel acide aminé par l'isocyanate de phényle a donné un dérivé non cristallin qui se transforme par une hydrolyse acide avec HCl 6 *N* en une δ-sulfonamidebutyl-[(phényl-3)hydantoïne-5] recristallisable de l'alcool. P.f. 146–148°. Anal. Calc. pour $C_{13}H_{17}N_3O_4S$: N, 13.46%. Obtenu: N, 13.26%.

REMERCIEMENTS

Les auteurs remercient Monsieur Benoit Mercier de sa précieuse collaboration technique à ce travail. Ils remercient également le Conseil National de Recherches Médicales du Canada d'y avoir participé par l'octroi de subventions (octroi MA-831).

TERPENOIDS

II. CEANOTHENIC ACID: A C_{29} A-NORLUPANE DERIVATIVE

P. DE MAYO AND A. N. STARRATT
Department of Chemistry, University of Western Ontario, London, Ontario

Received April 9, 1962

ABSTRACT

Extraction of *Ceanothus americanus* (Jersey Tea) has afforded a new pentacyclic triterpenoid of the empirical formula $C_{29}H_{42}O_4$. It is a dicarboxylic acid containing two ethylenic linkages. The environment of one carboxyl group and one ethylenic linkage has been shown by diagnostic transformations characteristic of ring E of the lupeol–betulin series. The other ethylenic linkage has been shown to be present in a contracted ring A from which one carbon atom has been lost. The position of the second carboxyl group has been established by introduction of the 11-oxo-12-ene system, when monodecarboxylation occurred under mild conditions. This and other evidence establishes ceanothenic acid to be A-norlupa-1,22-diene-14,17-dicarboxylic acid.

Investigations of the triterpenoid constituents of *Ceanothus americanus* (Jersey Tea) were first initiated by Julian, Pikl, and Dawson (1), who reported the presence of ceanothic acid, a hydroxy dicarboxylic acid. Subsequent investigations (2) established the structure and stereochemistry of ceanothic acid to be as in (I) and have also established its identity with emmolic acid (3–5).

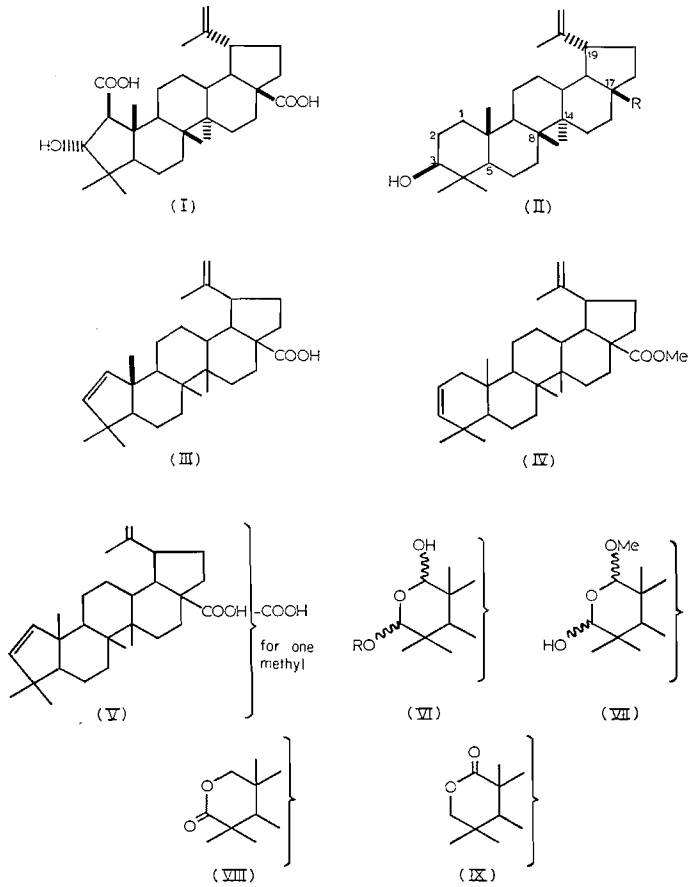
During the isolation of ceanothic acid a number of simple aromatic acids were isolated (see Experimental) together with the triterpenoids lupeol, betulin, and betulinic acid (II, R = CH_3, R = CH_2OH, and R = COOH respectively). In addition there was obtained a new acid, ceanothenic acid.[1]

Ceanothenic acid analyzed for $C_{29}H_{42}O_4$ or $C_{30}H_{44}O_4$, and was a dicarboxylic acid. It gave a non-crystalline dimethyl ester, reconverted to the acid on lithium iodide halolysis (6), and gave a tetrahydro acid on hydrogenation over platinum oxide. This, in turn, gave a crystalline dimethyl ester. Both the tetrahydro acid and its ester were optically transparent in the ultraviolet in the region 195–220 mμ and gave no color with tetranitromethane. No points of unsaturation other than the carboxyl functions therefore remained in the molecule: ceanothenic acid thus contained two ethylenic linkages and was pentacarbocyclic. The tetrahydro acid was converted into the acid chloride and thence, with lithium aluminum hydride, to the saturated diol characterized as the diacetate and, by oxidation, as the dialdehyde. The dicarboxylic acid recovered by oxidation of the diol had properties identical with those of the starting material, thus confirming its homogeneity.

In the infrared, ceanothenic acid exhibited two bands, at 893 and 753 cm^{-1} (nujol mull). The former band was in the position expected for the methylene out-of-plane deformation in an isopropenyl group. This assignment was confirmed by the obtention of formaldehyde on ozonolysis of ceanothenic acid and by the presence, in the n.m.r. spectrum of dimethyl ceanothenate (Fig. 1(*b*)), of bands at τ 5.29 and 5.41 (two multiplets, 2 H, $\diagdown$C=CH_2[2]) and 8.34 (singlet, 3 H) (7, p. 57) for the methylene and methyl moieties of the isopropenyl group.

[1]*The isolation of this acid was reported in the experimental section of Part I of this series. An improved isolation procedure is here presented.*

[2]*In an earlier paper (2) this was inadvertently referred to as a doublet. We wish to thank Dr. J. B. Stothers and a Referee for drawing this to our attention.*



The band at 753 cm^{-1} was suggestive of a cis disubstituted ethylenic linkage. In the n.m.r. spectrum there were two doublets, at τ 4.66 and 4.11 ($J \sim 5.7$) (2 H), in accord with the presence of vicinal vinyl hydrogen atoms. Further, the similarity of this pattern to that obtained from the substance (III)—derived from ceanothenic acid (see Fig. 1(*a*)) by dehydration–decarboxylation—was indicative of a like environment for the double bond in ceanothenic acid. Methyl anhydrobetulinate (IV), in contrast, showed no such pattern (Fig. 1(*c*)).

If such were the case it seemed plausible that the extruded ring A carbon in ceanothic acid (I) had been eliminated in ceanothenic acid. This should, therefore, contain only 29 carbon atoms. The molecular weight, determined mass spectroscopically on dimethyl tetrahydroceanothenate, confirmed the hypothesis.[3] At this point it was possible to consider the part structure (V) for ceanothenic acid. Chemical evidence, in confirmation, was then sought.

Methyl ceanothenate, on treatment with osmium tetroxide gave the expected tetrol. Cleavage with periodic acid in methanolic solution, with the appropriate oxygen uptake, gave, however, a crystalline product differing from the expected analysis by the elements of methanol. Methanol of crystallization could be discounted since the process of purification involved chromatography and subsequent crystallization from ether and light

[3]*We are much indebted to Dr. K. Biemann (M.I.T.) for this determination.*

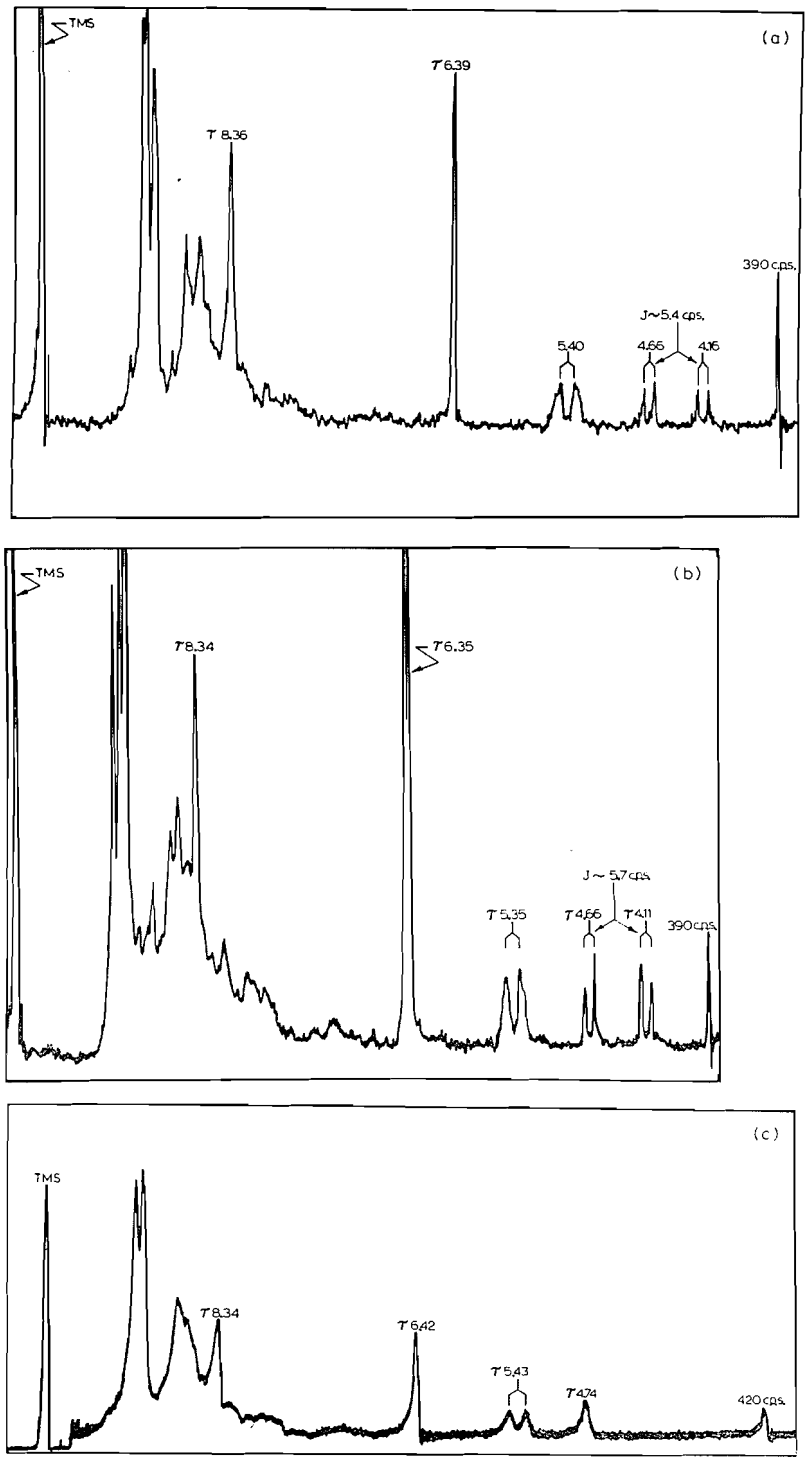


FIG. 1. N.M.R. spectra of (*a*) methyl decarboxyanhydroceanothate, (*b*) dimethyl ceanothenate, and (*c*) m ethyl anhydrobetulinate.

petroleum. Finally, any aldehydic structures could be rejected, since no low-field bands attributable to such hydrogen (7, p. 62) could be discerned in the n.m.r. spectrum.

The presence of the expected acetyl group was indicated by a singlet (3 H) at τ 7.84. A singlet (3 H) at τ 6.57 confirmed the presence of a methoxyl function. In addition there was, clearly discernible, bands (1 H each) at τ 5.84 and 5.43 in addition to the two methyl esters, which, at such low field, were required to be attributed to the environment of the moiety of the molecule under discussion. This pattern was compatible with expectation for the acetal and hemiacetal hydrogens of structures (VI; R = Me) or (VII) and this interpretation was confirmed, as follows.

Under the acidic conditions of 2,4-dinitrophenylhydrazone formation, the hemiacetal, being in equilibrium with the aldehyde, would be expected to react, and, in the event, the cleavage product gave the predicted tris-2,4-dinitrophenylhydrazone. Cleavage of the tetrol was then carried out in aqueous dioxane. The product, which was, however, not crystalline, showed bands at τ 0.85 and 0.73 compatible with aldehydes bearing no α hydrogen atoms. Since the infrared spectrum exhibited hydroxyl absorption at 3360 cm^{-1} it appeared possible that the product might be a mixture of aldehyde and hemiacetal (VI, R = H). Treatment with 2,4-dinitrophenylhydrazine in acid gave the same tris-2,4-dinitrophenylhydrazone obtained previously.

When the aqueous dioxane cleavage product was heated in aqueous methanol containing 2% of sodium hydroxide for 30 minutes the resultant product was almost entirely acidic. Acidification of the alkaline solution, however, gave material which was neutral. Such behavior and spectral properties (ν_{max} 1708 cm^{-1}) are compatible with those of a δ-lactone such as (VIII) or (IX). In agreement there was present, in the n.m.r. spectrum ($\tau \sim 5.85$, $J \sim 11$ c.p.s.), one half of the non-equivalence quartet expected for the lactonic methylene group, the other half being obscured by the ester methoxyl groups. The same substance was obtained by allowing the cleavage product to stand at room temperature with methanolic sodium methoxide. The formation of the lactone, an internal Cannizzaro reaction, has analogy in the chemistry of the monoterpenoid iridodial (8).

The above transformations establish the nature of ring A and, further, exclude from consideration positions 23, 24, and 25 for the unplaced carboxyl group. Had it been present at any one of these points a very facile deformylation would have been expected in the cleavage product, in view of its nature as an α-formyl ester, under the conditions of the Cannizzaro reaction: none was observed. Two positions, C_8 and C_{14}, remained.

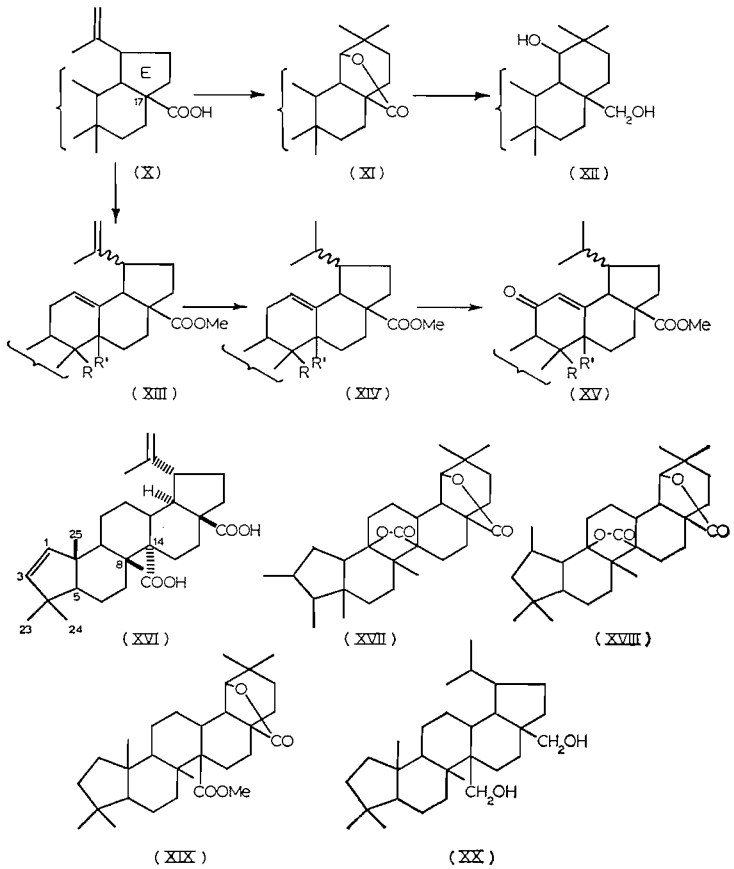
A characteristic and diagnostic test for the terminal ring E in the lupeol–betulin series is the acid-catalyzed expansion of this ring with, in the case of substances having a carboxyl at C_{17}, subsequent lactonization (9). When a solution of ceanothenic acid was refluxed in 98% formic acid or in hydrochloric–acetic acids the product recovered was neutral, both carboxyl groups evidently having been involved in lactonization. The band at 893 cm^{-1}, indicative of the isopropenyl methylene, was no longer present in the infrared spectrum as was the allylic methyl in the n.m.r. spectrum, observations expected for the ring E expansions. In an attempt to achieve this transformation whilst leaving ring A untouched, dimethyl ceanothenate was dissolved in benzene, and a solution of sulphuric acid in acetic acid added (9). After 5 days at room temperature the same dilactone was obtained.

The part structure (V) now having been substantiated, it was required to place the remaining carboxyl group. Since the formation of the dilactone involved a rearrangement both in ring E and ring A no information could be forthcoming from it. The simplest approach appeared to be the introduction into ring C of a functional group so as to

effect a selective decarboxylation. A route to the introduction of such a group lay in the well-known conversion of substances of the lupeol–betulin class into that of β-amyrin (9), but a prerequisite for such an approach was the removal of the unsaturation from ring A.

Attempted selective hydrogenation, bromination, and peracid oxidation were unavailing in attempts to discriminate between the two ethylenic linkages. Recourse to diimide (11) as the reducing agent was successful and, in fact, under the conditions of the reaction the isopropenyl group was entirely resistant. A brief survey of other ethylenic systems showed that, whilst norbornylene was reduced to norbornane, lupeol, α-amyrin benzoate, cholesterol, and cholest-2-ene were largely unaffected.

With dihydroceanothenic acid (X) available, the β-amyrin conversion now appeared feasible. Treatment with formic acid gave the expected acid lactone (XI), characterized as the methyl ester, which was reduced to the diol (XII) with lithium aluminum hydride. It was intended to dehydrate the secondary alcohol (10) and oxidize further with selenium dioxide (12), but preliminary tests indicated that these later steps proceeded in too poor yield for the quantity of material available.



At this point the recently reported oxidation of compounds of the lupeol–betulin class with mercuric acetate became available (13). With this reagent the direct introduction of a Δ^{12} ethylenic linkage has been shown to be possible. Oxidation of methyl

dihydroceanothate with mercuric acetate, in the manner described (13), gave the dehydro compound (XIII; R or R′ = COOMe, R′ or R = Me). Hydrogenation over platinum oxide saturated the isopropenyl group, giving (XIV; R or R′ = COOMe, R′ or R = Me) characterized as the acid by lithium iodide halolysis (6). Although evolving gas at the melting point, as to be expected of a β,γ-unsaturated acid, the product of this decarboxylation could not be obtained crystalline. Oxidation of (XIV) with chromic acid in acetic acid gave the desired 11-ketone (XV; R or R′ = COOMe, R′ or R = Me).

The keto diester, unlike its precursor (XIV) and in keeping with its nature as a vinylogous β-ketoester, was readily hydrolyzed by 5% potassium hydroxide to a non-crystalline dicarboxylic acid monoester (14). This decarboxylated at 145° to give the crystalline monoester (XV; R = Me, R′ = H). The carboxyl unallocated in (V) must therefore be placed at C_{14}. Any possibility that the ethylenic linkage might have moved β,γ into the C_{13}—C_{18} position and that the C_{17} carboxyl had been lost could be discounted since the monoester retained its α,β-unsaturated ketone. Ceanothenic acid is, therefore, to be represented as (XVI), a disposition of carboxyl groups paralleled in the α-amyrin series by quinovic acid (15).

Although no direct evidence is available, it seems possible that the configuration of the isopropenyl group in (XIII)–(XV) may be opposite that (α) in lupeol, ceanothic acid, or ceanothenic acid. The n.m.r. spectrum shows a significant change, the original two multiplets now appearing as a single broad band at τ 5.24. In addition, on mechanistic grounds, since it has been shown (13) that the isopropenyl group is required for oxidation, inversion would seem necessary to allow approach of the reagent to C_{12}.

Since the direct lactonization from C_{27} to C_1 or C_3[4] is not possible, rearrangement must occur on dilactonization. Two more probable structures may be considered, (XVII) and (XVIII), the formation of both of which involves only the generation of tertiary carbonium ions after the initial migration. These are derived by protonation at either end of the cyclopentene ethylenic linkage. These two formulations differ in the number of potential acetic acid molecules obtainable by Kuhn–Roth oxidation. The monolactone (XI), now to be represented as (XIX), has two methyl groups and two geminal dimethyl groups. The same obtains in formulation (XVIII) for the dilactone. The alternative (XVII) has, in contrast, four methyl groups and one geminal dimethyl group. Since geminal dimethyl functions are known to give only a small fraction of a molecule of acetic acid, (XVII) would be expected to have a greatly increased Kuhn–Roth yield of acetic acid over (XIX). In fact, (XIX) gave 2.3 C—Me and the dilactone 2.2,[5] and, on this basis, (XVII) may be excluded. The position of the lactone is that found in the acid-catalyzed lactone from quinovic acid, novic acid (16).

EXPERIMENTAL

For general experimental details see Part I (2). Nuclear magnetic resonance spectra were determined in carbon tetrachloride solution. Silica gel was B.D.H. grade except where specified differently.

Extraction of Ceanothus americanus

(*a*) The ground root bark (10 kg) was extracted by standing with alcohol for approximately 24 hours, after which time the solvent was drained off. This was repeated seven times. The combined alcohol extract (30 l.) was concentrated to about 2 l., diluted with water, and extracted with ether. The ethereal solution was extracted exhaustively with potassium hydroxide solution, the insoluble potassium salts removed by filtration, and the defatted acids derived from the soluble salts isolated as previously described (2).

The larger benzene-soluble portion of the acid mixture was chromatographed on silica gel (730 g; Davison). Elution with benzene–ether (19:1) yielded a material which, after recrystallization of a portion from ether–benzene followed by ether–methanol, gave ceanothenic acid, m.p. 350–354° (decomposition) undepressed

[4]*In numbering ceanothenic acid it has been assumed that* C_2 *is extruded.*

[5]*We are greatly indebted to Mr. J. M. L. Cameron (Glasgow) for these determinations.*

on admixture with the acid from the earlier isolation (2), $[\alpha]_D$ +39° (*c*, 1.25; pyridine). Calc. for $C_{29}H_{42}O_4$: C, 76.61; H, 9.31; O, 14.08%. Found: C, 76.45; H, 9.23; O, 14.43%. Further elution produced the previously reported triterpenoids, betulinic acid, and ceanothic acid (I).

Additional amounts of ceanothenic acid were obtained upon addition of alcohol to the benzene-insoluble portion of the acid mixture. This then crystallized (m.p. 340–346°) and combination of this with the ceanothenic acid obtained upon chromatography yielded 8 g of crude acid.

The ether solution remaining after removal of the acidic material was washed with aqueous hydrochloric acid (2 *N*; 5×300 ml) and the neutral fraction isolated by evaporation.

The neutral material (17.6 g) from 19 kg root bark was refluxed for 3 hours under nitrogen with aqueous alcoholic (1:8) potassium hydroxide solution (5%; 300 ml).[6] The neutral fraction (30 g) from this, separated by ether extraction, was chromatographed on silica gel (650 g). Elution with light petroleum – benzene (3:7) afforded lupeol, identified by melting point (207–208°), mixed melting point, rotation ($[\alpha]_D$ +27°), and infrared spectrum. Elution with benzene–ether (9:1) produced a fraction which was recrystallized to give β-sitosterol, m.p. 136–137°, identical in every respect with authentic material. Further elution with benzene–ether (3:1) gave betulin, identified by melting point and mixed melting point. Acetylation gave the acetate identical in every respect with authentic betulin diacetate.

Acidification of the aqueous phase of the hydrolysis mixture followed by ether extraction of the acidic material afforded a fraction (9.9 g) which was chromatographed on silica gel. Elution with benzene–ether (1:3) gave a substance shown by melting point, mixed melting point, ultraviolet and infrared spectra to be phthalic acid.

(*b*) After alcoholic extraction of the root bark (10 kg) with alcohol, a further extraction was carried out using chloroform (3×4 l.).[6] After evaporation of the chloroform the residue was extracted exhaustively with refluxing light petroleum, dissolved in ether, the acidic fraction isolated by extraction with potassium hydroxide solution (2%), acidification, and ether extraction. The residue (7.2 g) was chromatographed on silica gel (210 g). Elution with benzene–ether (9:1) gave crystalline material, m.p. 201–202°. Calc. for $C_8H_8O_4$: C, 57.14; H, 4.80%. Found: C, 57.52; H, 4.79%. Methylation with diazomethane gave a crystalline compound, m.p. 58–59°. The substances were identified as vanillic acid and its methyl ether, and their melting points were undepressed on admixture with authentic specimens.

Elution with benzene–ether (4:1) gave material, m.p. 184–185°, raised to 207–208° after further purification. Calc. for $C_9H_{10}O_5$: C, 54.54; H, 5.09; O, 40.37%. Found: C, 54.22; H, 5.20; O, 40.78%. Methylation with diazomethane produced a compound, m.p. 80–81°. The original compound was identified as syringic acid by melting point, mixed melting point, and infrared spectrum.[7]

Dimethyl Ceanothenate

Ceanothenic acid was methylated with diazomethane to yield a non-crystalline ester, $[\alpha]_D$ +32° (*c*, 0.81), ν_{max} 1720, 1642, 890 cm^{-1} (CCl_4). Calc. for $C_{31}H_{46}O_4$: C, 77.13; H, 9.61%. Found: C, 77.17; H, 9.20%.

Tetrahydroceanothenic Acid

Ceanothenic acid (33 mg) absorbed 2.0 mole of hydrogen when hydrogenated in glacial acetic acid over platinum oxide catalyst. Recrystallization from ether gave tetrahydroceanothenic acid, m.p. 340° (decomposition), $[\alpha]_D$ −34° (*c*, 0.51; pyridine), ν_{max} 1686 cm^{-1} (nujol mull). Calc. for $C_{29}H_{46}O_4$: C, 75.94; H, 10.11%. Found: C, 75.88; H, 9.90%.

Dimethyl Tetrahydroceanothenate

Tetrahydroceanothenic acid (20 mg) was methylated with diazomethane to give the dimethyl ester, m.p. 159–163°, $[\alpha]_D$ −21° (*c*, 1.2). Calc. for $C_{31}H_{50}O_4$: C, 76.50; H, 10.36; OCH_3, 12.72%. Found: C, 76.58; H, 10.17; OCH_3, 11.52%. The molecular weight (mass. spec.) was 486 (calc. 486.7).

Ozonolysis of Ceanothenic Acid

Ozonolysis of ceanothenic acid (56 mg) in acetic acid solution at room temperature for 30 minutes followed by distillation into aqueous dimedone gave formaldehyde, characterized as the dimedone derivative, in 12% yield. A similar ozonolysis of undecylenic acid (21 mg) produced a 21% yield of formaldehyde as the dimedone derivative. Addition of alkali (10% potassium hydroxide solution) to the non-crystalline acidic product from ozonolysis followed by I_2–KI solution produced a precipitate of iodoform.

Ceanothenic Acid Dilactone

(*a*) Ceanothenic acid (68 mg) was refluxed 5 hours with formic acid (10 ml; 98%). The residue, obtained upon evaporation of the formic acid *in vacuo*, was chromatographed on alumina (Grade 1; 3 g). Elution with light petroleum – benzene (1:1) afforded crystalline material which gave, after recrystallization from chloroform–methanol, ceanothenic acid dilactone (19 mg), $[\alpha]_D$ −17° (*c*, 1.04). Calc. for $C_{29}H_{42}O_4.0.5MeOH$: C, 75.32; H, 9.36%. Found: C, 75.33; H, 9.20%. The dilactone possessed a complex melting point, undergoing transition in the range 250–285°, before finally completely melting, at 285°.

[6]*We wish to express our thanks to Mr. M. P. Li for this experiment.*

[7]*We are grateful to Dr. Irwin A. Pearl (The Institute of Paper Chemistry, Wisconsin) for a specimen of syringic acid.*

(*b*) Ceanothenic acid (110 mg) was refluxed with a mixture of acetic acid (36 ml) and concentrated hydrochloric acid (4 ml) for 2 hours. Additional hydrochloric acid (2 ml) was added and the refluxing continued for 3 hours. Dilution with water and ether extraction yielded a neutral product which gave, after recrystallization from ether, ceanothenic acid dilactone (42 mg).

(*c*) Methyl ceanothenate (22 mg) was dissolved in benzene (1 ml), and acetic acid (5 ml) and sulphuric acid (1 ml) added. After 5 days' standing at room temperature, ether extraction followed by chromatography on alumina yielded ceanothenic acid dilactone identical in every way with the material described above.

Conversion of Tetrahydroceanothenic Acid to the Diol (XX)

Tetrahydroceanothenic acid (32 mg) was refluxed 1 hour with thionyl chloride (3 ml). The thionyl chloride was removed under reduced pressure, then dry benzene (5 ml) added and likewise removed. The residue was dissolved in dioxane, an excess of lithium aluminum hydride added, and the mixture refluxed for 12 hours. After working up in the usual manner and filtering through alumina (Grade 4; 1 g), crystalline material (25 mg) was obtained which, after recrystallization from ether–methanol, afforded the diol (XX), m.p. 253–254°, $[\alpha]_D$ −41° (*c*, 0.99; pyridine), ν_{max} 3330 cm^{-1} (nujol mull). Calc. for $C_{29}H_{50}O_2$: C, 80.87; H, 11.70%. Found: C, 80.51; H, 11.56%.

Oxidation of the diol with an acetic acid solution of chromic anhydride at room temperature regenerated tetrahydroceanothenic acid identical in every respect with that obtained directly.

The crude diol (400 mg) was acetylated (30 minutes at 100° with acetic anhydride – pyridine (1:2)), and the isolated product chromatographed on alumina (8 g; Grade 1). Light petroleum – benzene (19:1) eluted crystalline material which, after recrystallization from ether–methanol, gave the diacetate, m.p. 121–122°, $[\alpha]_D$ −31° (*c*, 0.99), ν_{max} 1730 cm^{-1}. Calc. for $C_{33}H_{54}O_4$: C, 76.99; H, 10.57%. Found: C, 76.98; H, 10.51%.

Methyl Anhydrobetulinate

Methyl betulinate benzoate (134 mg) was heated under nitrogen for 30 minutes on a metal bath at 320–330°. The crude product was refluxed under nitrogen with alcoholic potassium hydroxide (10%) followed by isolation of the neutral material with ether and chromatography on alumina (2 g; Grade 1). Elution with light petroleum and crystallization from chloroform–methanol gave methyl anhydrobetulinate, m.p. 154–157°, $[\alpha]_D$ +25° (*c*, 2.44), ν_{max} 1720, 1642, 889 cm^{-1}. Calc. for $C_{31}H_{48}O_2.0.5MeOH$: C, 80.76; H, 10.62%. Found: C, 80.33; H, 10.62%.

Osmic Acid Oxidation

Methyl ceanothenate (195 mg) was dissolved in dioxane (2.5 ml), and pyridine (3.5 ml) and osmic acid (350 mg) added. This mixture was kept in the dark at room temperature for 9 days, when the osmic ester was decomposed with sodium bisulphite (17). The crude product was isolated by ether extraction and filtered through alumina with methanol–benzene (1:5). Recrystallization from methanol afforded the tetrol (112 mg), m.p. 254–260°, $[\alpha]_D$ −25° (*c*, 0.62; alcohol), ν_{max} 3440, 1712 cm^{-1}. Calc. for $C_{31}H_{50}O_8$: C, 67.61; H, 9.15%. Found: C, 67.75; H, 9.16%.

Periodic Acid Titration of the Tetrol in Methanol

The tetrol (114 mg), dissolved in methanol (24 ml) and water (3 ml), was titrated with periodic acid (3 ml; approx. 0.4 *N*). After 4 hours the uptake of oxidant had ceased, with consumption of 2.3 moles. The product was isolated by ether extraction and chromatographed on alumina (6 g; Grade 1). Elution with benzene–ether (19:1) gave a compound, m.p. 185–190° after recrystallization from ether – light petroleum. The substance showed ν_{max} 1708 cm^{-1}, and n.m.r. bands at τ = 7.87, 6.60, 6.37, 6.21, and 5.88. Further elution gave a second compound ((VI; R = Me) or (VII)), m.p. 184–186° after recrystallization from ether – light petroleum, $[\alpha]_D$ −10° (*c*, 0.54), ν_{max} 3400, 1720 cm^{-1}, n.m.r. bands at τ = 7.84, 6.57, 6.35, 6.22, 5.84, and 5.43. Calc. for $C_{31}H_{48}O_8$: C, 67.85; H, 8.82; OMe, 16.95%. Found: C, 67.91; H, 8.92; OMe, 16.61%.

To the cleavage product ((VI; R = Me) or (VII)) (16 mg) in alcohol (35 ml) was added a solution of 2,4-dinitrophenylhydrazine (45 mg) in alcohol (4 ml) containing hydrochloric acid (6 drops). After refluxing for 4.5 hours, the product was isolated and chromatographed on alumina. Benzene removed some non-crystalline material and on further elution with chloroform a substance was obtained which was recrystallized from chloroform–methanol to give the tris-2,4-dinitrophenylhydrazone, m.p. 281–282°. Calc. for $C_{48}H_{56}O_{16}N_{12}$: C, 54.56; H, 5.30; N, 15.90%. Found: C, 55.03; H, 5.88; N, 15.68%.

Periodic Acid Titration of the Tetrol (XXI) in Dioxane

The tetrol (35 ml) was titrated with periodic acid in the same manner as above, using dioxane (8 ml) and water (1 ml) as solvent. At the end of 4 hours, reaction was complete, with the consumption of 2.1 moles of oxidant.

Chromatography of the product did not afford any crystalline material. The n.m.r. spectrum of the oil showed bands at τ = 7.94, 6.34, 6.18, 0.85, and 0.73 and the compound possessed ν_{max} 3360 and 1708 cm^{-1}. Reaction of this product with 2,4-dinitrophenylhydrazone afforded the same derivative, m.p. 281–282°, as was obtained from the methanolic titration.

Cannizzaro Reaction

Sodium hydroxide solution (2 ml; 10%) was added to the periodic acid – dioxane cleavage product (20 mg), dissolved in methanol (8 ml). The solution was refluxed under nitrogen for 0.5 hours. Ether extraction yielded a trace of neutral material (3 mg). Acidification of the alkaline solution followed by re-extraction with ether gave crystalline material (16 mg). This material could not now be extracted from the ethereal solution with aqueous potassium hydroxide (2%). Recrystallization from ether–petrol gave the δ-lactone, m.p. 212–215°, $[\alpha]_D$ −18° (*c*, 1.04), ν_{max} 1708 cm^{-1}, τ = 7.80, 6.28, 6.21. Calc. for $C_{30}H_{44}O_7$: C, 69.74; H, 8.58%. Found: C, 70.28; H, 8.30%. The periodic acid – dioxane cleavage product (24 mg) in a sodium methoxide solution (2%) maintained overnight at room temperature afforded the same lactone.

Dihydroceanothenic Acid

Potassium azodicarboxylate (200 mg; 1.1 mmoles) prepared from azodicarbonamide was added to a solution of ceanothenic acid (20 mg) in methyl cellosolve (2 ml). Acetic acid (155 mg; 2.2 mmoles) was added and the mixture stirred under nitrogen until the disappearance of color (approx. 10 minutes). Recrystallization from ether–methanol gave dihydroceanothenic acid, m.p. 340° (decomposition), $[\alpha]_D$ +15° (*c*, 0.99; pyridine), ν_{max} 1692, 1646, 888 cm^{-1} (nujol mull). Calc. for $C_{29}H_{44}O_4.0.5MeOH$: C, 75.00; H, 9.76%. Found: C, 75.01; H, 9.72%. In the same manner norbornylene (220 mg) was reduced with potassium azodiformate (4 g) and acetic acid (3.6 g). The product was identified as norbornane by melting point and infrared spectrum.

Dihydroceanothenic Acid Lactone

Dihydroceanothenic acid (84 mg) was refluxed 3 hours with formic acid (25 ml; 97%). The product, after removal of the formic acid *in vacuo*, was chromatographed on silica gel (4.5 g). Elution with benzene–ether (19:1) yielded material which was recrystallized from ether – light petroleum to give dihydroceanothenic acid lactone, m.p. 289–291°, $[\alpha]_D$ +47° (*c*, 1.21), ν_{max} 1764, 1695 cm^{-1}. Calc. for $C_{29}H_{44}O_4$: C, 76.27; H, 9.71%. Found: C, 76.11; H, 9.47%.

Methyl Dihydroceanothenate Lactone (XIX)

Methylation of the acid with diazomethane gave methyl dihydroceanothenate lactone, recrystallized from ether – light petroleum, m.p. 179–180°, $[\alpha]_D$ +43° (*c*, 1.05), ν_{max} 1760, 1712 cm^{-1}. Calc. for $C_{30}H_{46}O_4$: C, 76.55; H, 9.85%. Found: C, 76.44; H, 9.79%.

Methyl Dehydrodihydroceanothenate

Methyl dihydroceanothenate (106 mg) in chloroform (4 ml) was refluxed with mercuric acetate (2 g) in acetic acid (20 ml) for 5 hours. The residue obtained after chloroform extraction was dissolved in pyridine and hydrogen sulphide passed through it for 1 hour. The precipitated sulphide was removed by filtration and the pyridine removed *in vacuo*. The residue, in ether, was washed with ammonium sulphide solution and the remaining material was chromatographed on alumina (2 g; Grade 1). Elution with benzene–ether (19:1) afforded material (47 mg) which recrystallized from ether–methanol to give methyl dehydrodihydroceanothenate, m.p. 160–161°, $[\alpha]_D$ +54°, (*c*, 1.09), ν_{max} 1723, 1669, 1625, 902 (shoulder), 894 cm^{-1} (CCl_4). Calc. for $C_{31}H_{46}O_4$: C, 77.13; H, 9.61%. Found: C, 76.70; H, 9.49%.

Methyl Dehydrotetrahydroceanothenate

Methyl dehydrodihydroceanothenate (332 mg) in acetic acid (18 ml) was hydrogenated over platinum oxide catalyst (82 mg). Recrystallization of the product from ether – light petroleum gave methyl dehydrotetrahydroceanothenate, m.p. 190–192°, $[\alpha]_D$ +8° (*c*, 0.93), ν_{max} 1716 cm^{-1}. Calc. for $C_{31}H_{48}O_4$: C, 76.81; H, 9.98%. Found: C, 77.33; H, 10.03%.

Lithium Iodide Halolyses

(*a*) Methyl ceanothenate (31 mg), in 2,4,6-collidine (2.8 ml), was refluxed for 8 hours with anhydrous lithium iodide (114 mg). The cooled solution was poured into a mixture of 2 *N* HCl (15 ml) and ether – methylene chloride (15 ml; 2:1). The aqueous portion was twice washed with ether – methylene chloride (2:1). The combined organic extract was then washed with dilute hydrochloric acid and water before evaporation of the solvent. Recrystallization of the product gave ceanothenic acid (22 mg), m.p. 347–351°.

(*b*) Methyl dehydrotetrahydroceanothenate (XIV; R = Me, R′ = COOMe) (57 mg) with lithium iodide (200 mg) in 2,4,6-collidine (4 ml) was refluxed for 8 hours. The reaction mixture was worked up as above. The product was recrystallized from ether–methanol to give the corresponding acid (28 mg), m.p. 320–330° (gas evolution), $[\alpha]_D$ −4° (*c*, 0.75; pyridine), ν_{max} 1692 cm^{-1} (nujol mull). Calc. for $C_{29}H_{44}O_4$: C, 76.27; H, 9.71%. Found: C, 76.09; H, 9.56%. Methylation of the acid gave back methyl dehydrotetrahydroceanothenate, identified by melting point, mixed melting point, and infrared spectrum.

Methyl 11-Oxodehydrotetrahydroceanothenate

An acetic acid solution of methyl dehydrotetrahydroceanothenate (50 mg) was allowed to stand overnight at room temperature with an excess of chromic acid solution (10 ml; 0.16 *N* in acetic acid). Isolation of the product and recrystallization from ether – light petroleum gave methyl 11-oxodehydrotetrahydroceanothenate, m.p. 217–219°, $[\alpha]_D$ −34° (*c*, 1.04), λ_{max} 239 mμ (ϵ = 12,200), ν_{max} 1718, 1699, 1615 cm^{-1}. Calc. for $C_{31}H_{46}O_5$: C, 74.66%; H, 9.30%. Found: C, 74.74; H, 9.43%.

Hydrolysis and Decarboxylation of the Ketone (XV; R = Me, R′ = COOMe)

Methyl 11-oxotetrahydrodehydroceanothenate (52 mg) was refluxed under nitrogen for 4 hours with methanolic potassium hydroxide (20 ml; 5%). The mixture was worked up as usual and the crude acidic fraction (22 mg) in methanol (10 ml) titrated with *N*/100 sodium hydroxide to a phenolphthalein end point. A titration value of 82% of the calculated was obtained.

This acid material was decarboxylated by heating 10 minutes at 145° under nitrogen. Filtration through alumina with benzene and recrystallization from ether–methanol afforded the neutral ketoester (XV; R = Me, R′ = H), m.p. 182–185°, $[\alpha]_D$ −95°, (*c*, 1.11), λ_{max} 241 mμ (ϵ = 13,200), ν_{max} 1717, 1690, 1614 cm^{-1}. Calc. for $C_{29}H_{44}O_3$: C, 79.04; H, 10.07%. Found: C, 79.07; H, 9.78%.

Oxidation of the Diol (XX) with Chromic Acid

The diol (62 mg) in Analar acetic acid (3 ml) was oxidized by standing overnight at room temperature with 0.17 *N* chromic acid in acetic acid (5.8 ml). Following isolation, the product was separated into acidic and neutral fractions. The neutral fraction was chromatographed on alumina (2 g), elution with light petroleum – benzene (19:1) affording crystalline material in poor yield. Recrystallization from ether–methanol gave the dialdehyde, m.p. 138–142°, $[\alpha]_D$ −22° (*c*, 0.75), ν_{max} 2740, 1715 cm^{-1}. Calc. for $C_{29}H_{46}O_2$: C, 81.63; H, 10.87%. Found: C, 81.52; H, 10.16%.

Reduction of Dihydroceanothenic Acid Lactone (XI)

Dihydroceanothenic acid lactone (97 mg) in tetrahydrofuran (9 ml) was refluxed with an excess of lithium aluminum hydride (300 mg) for 0.5 hour. The product was isolated in the usual manner and methylated with diazomethane. The crude product was filtered through alumina (2 g; Grade 1) in benzene and recrystallized from ether – light petroleum to yield the diol (XII), m.p. 236–238°, $[\alpha]_D$ +23°, (*c*, 0.90), ν_{max} 3350, 1709 cm^{-1}. Calc. for $C_{30}H_{50}O_4$: C, 75.90; H, 10.62%. Found: C, 76.05; H, 10.50%.

ACKNOWLEDGMENTS

The authors wish to thank Mr. R. E. Klinck for the determination of the n.m.r. spectra. Grateful acknowledgment is made to the National Research Council of Canada and to Abbott Laboratories for financial support.

INFLUENCE OF THE DEFECT CENTERS ON THE SZILARD–CHALMERS ANNEALING

IRINA NEGOESCU AND T. COSTEA
Laboratory of Radiochemistry, Institute of Atomic Physics, Bucharest, Roumania

Received December 19, 1961

ABSTRACT

Reactor-irradiated copper and cobalt oxinates were studied for the behavior of Cu^{64} and Co^{60} atoms produced by radiative thermal neutron capture. The annealing processes associated with the Szilard–Chalmers effect were followed by means of retention. Both substances exhibit annealing at room temperature, formally following first-order kinetics. The retention was found to increase with reactor exposure time, following kinetics similar to that for post-irradiation thermal annealing. The interpretation of experimental data relies on the assumption that fractions annealed at room temperature decrease with increasing density of defect centers containing an annealable Szilard–Chalmers atom.

INTRODUCTION

The mechanism of the processes occurring in radiation-damaged solids is still considered to be in question in spite of the number of works published hitherto on this topic. In this connection the usefulness and importance of the Szilard–Chalmers method, which by its very simple radiochemical procedures obtains many results hardly available by the use of other methods, are well known.

The complexity of these processes is shown by the lack of reproducibility of experimental data. Attempts were made to follow the influence of various factors such as crystal fragment size, irradiation conditions (dose, dose rate, temperature), sample type (treated or untreated), etc. As a matter of fact most of these factors determine in a straightforward manner the crystal damage range along with the retention value, as shown by Maddock and Vargas (1), although variations were found not only in a unique direction. Certainly, definite conclusions may not be drawn until new experimental data can lead to a more precise knowledge of the way crystal defects act on recombination of recoil species.

The discussion of experimental results will rely on Harbottle and Sutin's hot-zone model (2); the processes arising after hot-zone cooling will be examined according to Vand–Primak's hypothesis on processes group distributed in activation energy (3).

Oxinates were chosen for the investigation of processes associated with the Szilard–Chalmers effect because, on the one hand, for chelate compounds, the exchange reaction between the recoil and complexed atom does, properly, not occur; on the other hand, owing to the solubility of oxinates in organic solvents there appears the possibility of carrying out the separation of recoil atoms through water extraction, without using more intricate analytical methods which may eventually change the original distribution of recoil fragments. Moreover, oxinates exhibit radiation and thermal stability against irradiation decomposition as well as radiation and thermal sensitivity against annealing. In the present work copper and cobalt oxinates were chosen. Cobalt (4), tungsten, calcium (5), copper, manganese, and nickel oxinates (6) were also studied but only in order to obtain high specific activity radioisotopes.

EXPERIMENTAL

Irradiation

Samples contained in quartz tubes were irradiated in the thermal column of the I.F.A. reactor. The irradiations were carried out in air at hole temperature (30–35° C); irradiation times ranged from 15 minutes

to 10 hours for copper oxinate and from 1 hour to 8 hours for cobalt oxinate. Irradiation conditions were as follows: thermal neutron flux 1.2×10^{11} $cm^{-2}sec^{-1}$, fast neutron flux 6.3×10^{9} $cm^{-2}sec^{-1}$, gamma dose rate 3.5×10^{6} r hr^{-1}.

Extraction

Irradiated 1-mg samples were dissolved in freshly distilled chloroform. Cobalt oxinate dissolution was carried out at a temperature of 45–50° C, *m*-toluidine traces being present. The recoil atoms were water-extracted at pH = 6 with Cu^{2+} and Co^{2+} respectively as carriers.

To test the separation method the following operations were performed: (*a*) Extraction of Cu^{64} synthetized copper oxinate from chloroformic phase to aqueous phase at pH 6; no active copper ions were found in the aqueous phase. (*b*) Extraction of active copper ions from aqueous solution at pH 6 to chloroformic phase; no activity was found in the chloroformic phase. (*c*) No exchange reaction was found between complexed active copper in the chloroformic phase and inactive Cu^{2+} used as carrier in the aqueous phase. Similar procedures were used for cobalt oxinate.

Counting

Both phases activity was measured using an immersion G.M. counter. Measurements were made after Cu^{66} (5.18 minutes) and Co^{60m} (10 minutes) activities had decreased to a negligible value. Retention was computed from the ratio between chloroformic and total activity of both phases. Each result consists of the average value obtained for two or three irradiation sets, with similar irradiation conditions. The uncertainty affecting the average value is ±1.5%.

RESULTS AND DISCUSSIONS

Copper Oxinate

The retention of samples reactor-irradiated for 15 minutes–9.5 hours was determined at room temperature and found to increase with time. In a few hours it reached a value of 94%, which remained constant even 24 hours after irradiation. An exception was found for the 9.5-hours irradiated sample, which exhibited from the very beginning a retention of 94%. Therefore, the conclusion may be drawn that in neutron-irradiated copper oxinate a fast annealing characterized by the decrease in annealing rate with time and by the appearance of a pseudo plateau occurs at room temperature. The following step, the slow annealing process taking place with constant annealing rate, was not yet tested owing to the short life of recoil radioactive atoms (7).

It must also be pointed out that for samples treated immediately after irradiation, the shorter the irradiation time the smaller the retention value, the existence of various original retention values hence depending on reactor exposure time. The ordinary plot of $R(t)$ could not account for this assumption because retention values in the range of greatest annealing rates were unknown, as determinations could only be made during the first few minutes after irradiation. The uncertainty affecting the retention value did not even allow the plot of a curve representing exactly the annealing kinetics, by extrapolation of which the retention at the end of irradiation might be obtained. The question was solved in another way.

As Harbottle and Sutin (8) pointed out, annealing of radiative neutron capture damages may be treated according to Vand–Primak's concept of group of processes distributed in activation energy (3). On the other hand it was demonstrated (9) that in first approximation, fast annealing may be formally considered as a first-order process characterized by apparent rate constants. The approximation is allowed for owing to the existence of a Primak spectrum consisting of a narrow band of activation energy.

In the present work a plot of log (ΔR) versus t is given, where $\Delta R = R_\infty - R$, R_∞ being the retention value at the pseudo plateau and R the retention value at time t. Straight lines exhibiting equal slopes were obtained, as was expected. Figure 1*a* shows the variation of annealing fraction with time at room temperature, for two samples irradiated with various integral neutron fluxes. The plot gives, by extrapolation, the original retention

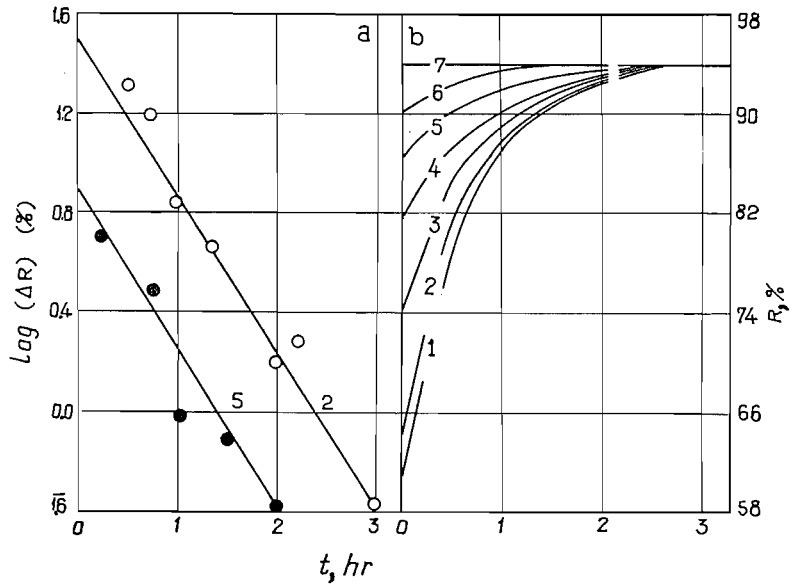

FIG. 1. The annealing at room temperture of copper oxinate irradiated as follows: 1, 15 minutes; 2, 30 minutes; 3, 1 hour; 4, 2 hours; 5, 3 hours; 6, 4 hours; 7, 9.5 hours.

R_0, i.e., the retention at the end of irradiation. R_0 increases with irradiation time; its values are given in Table I. The log (ΔR) versus t plot allowed also for the computation

TABLE I

Variation of the retention R_0 with the time of irradiation t' for copper oxinate

t', min	15	30	60	120	180	240	570
R_0, %	60.9	63.8	74.1	81.4	86.1	90.4	94.0

of a set of thermal annealing kinetic curves for various samples (Fig. 1*b*). The formal kinetic equation characterizing the process is:

$$[1] \qquad \Delta R = (\Delta R)_\infty \exp(-kt),$$

where $(\Delta R)_\infty = R_\infty - R_0$. The apparent rate constant has the value $k = 4.03 \times 10^{-4}$ sec^{-1}.

Similar considerations led to the description of the annealing during the irradiation. Reactor annealing is marked by prime superscripts; therefore $R_\infty' \equiv R_0$ and $(\Delta R)' = R_\infty' - R'$. A plot of log $(\Delta R)'$ versus irradiation time t' is a straight line, as shown in Fig. 2*a*. Hence, the annealing during irradiation may be formally considered as a first-order process. The kinetic curve of the annealing during irradiation corresponds to an equation of the same type as the former:

$$[2] \qquad (\Delta R)' = (\Delta R)_\infty' \exp(-kt'),$$

where $(\Delta R)_\infty' = R_\infty' - R_0'$. The numerical values obtained by graphical means from the plot in Fig. 2*a* are $k' = 1.73 \times 10^{-4}$ sec^{-1} and $R_0' = 54.6\%$. The condition $k \neq k'$ does not agree with the assumption that annealing could occur only under the influence of the temperature, although in this circumstance the temperature plays an important part.

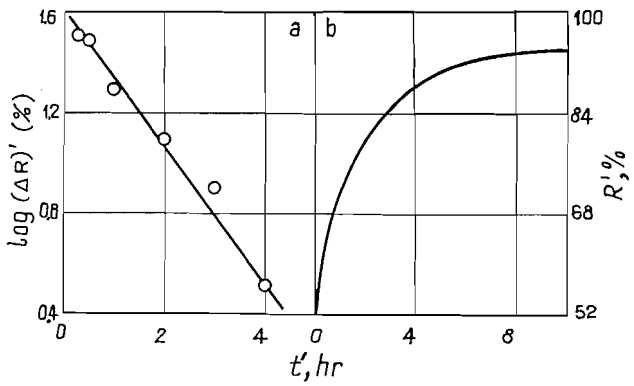

FIG. 2. The annealing concomitant with the irradiation of copper oxinate.

Moreover, curves similar to those plotted in Fig. 2*b* were reported for potassium chromate (10) and for hexammino-cobaltic nitrate (11); an equation of the type of eq. [2] was also found. It is worthwhile to point out the great original retention value R_0', which may be accounted for by applying only the hot-zone model because both the lack of nuclear inefficiency of gamma-ray emission and the lack of a Suess effect do not succeed in explaining the fact that about a half of the whole activity is retained by the original chemical compound or by compounds exhibiting a similar structure. However, it may be assumed that original retention results from recombination processes occurring in 10^{-11} second in the melt, which behaves as a cage for the recoil atom (12). Thus, the original retention arising from spontaneous recrystallization may quite possibly remain constant during the whole irradiation time. To this may be added the secondary retention, which also varies with time and which is due to radiation and thermal annealing of recoil atoms not yet rearranged and trapped in the hot zone during recrystallization. These processes require, also, activation energies as pointed out for thermal annealing, though radiation annealing might be accounted for by the appearance of hot spots behaving like hot zones.

Cobalt Oxinate

Cobalt oxinate behaves like copper oxinate. Annealing process at room temperature may be observed and the retention increases with time until reaching a saturation value, which is found to be constant even after 50 hours. However, the pseudo plateau is not the same for all samples, smaller values being found for samples irradiated with stronger integral neutron fluxes. The saturation retention values R_∞ for samples reactor-irradiated for 2–8 hours are given in Table II.

TABLE II

Variation of the retentions R_0 and R_∞ with the time of irradiation t' for cobalt oxinate

t', min	120	240	300	480
R_0, %	32.9	35.5	41.4	48.8
R_∞, %	83.0	71.0	67.0	64.0

According to reasons similar to those for copper oxinate, annealing curves are studied on a log (ΔR) versus time plot. Figure 3*a* shows that thermal annealing follows eq. [1]

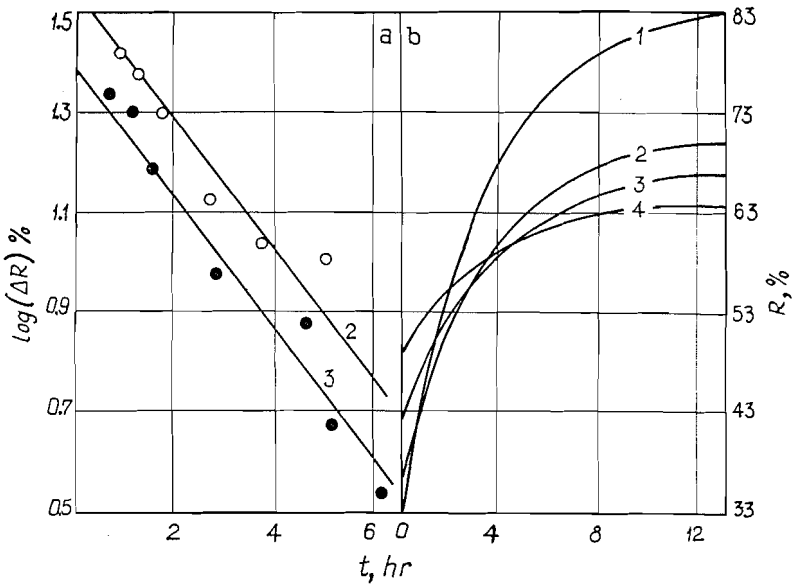

FIG. 3. The annealing at room temperature of cobalt oxinate irradiated as follows: 1, 2 hours; 2, 4 hours; 3, 5 hours; 4, 8 hours.

with $k = 0.80 \times 10^{-4}$ sec^{-1}. Figure 3*a* also allows computation of the original retention values R_0 (Table II), and thus a plot for thermal annealing kinetic curves is obtained. As shown in Fig. 3*b*, the curves cross one another according to their radiation history. As for copper oxinate, R_0 increases with reactor exposure time, attesting annealing during irradiation.

Influence of Defect Centers

Now two questions arise: saturation retention value depends on the one hand on heating temperature (room temperature) and on the other hand on irradiation time. An answer may be found by studying the variation of the annealable fraction at room temperature $(\Delta R)_\infty = R_\infty - R_0$ for the samples irradiated with various integral neutron fluxes. Moreover, the differences in crystal damages are also accounted for by various integral neutron fluxes. It may be shown that $(\Delta R)_\infty \propto 1/N$, where N is the density of defect centers.

Such a dependence was also found for hexammino-cobaltic nitrate (9). In a study of thermal annealing at various temperatures for various irradiation conditions it was found that, for a given heating temperature T, the annealable fraction $(\Delta R)_\infty$ may be written:

$$[3] \qquad (\Delta R)_\infty = \alpha_0 N^{1-\beta}(T - T_0),$$

where α_0 and β are constants characterizing the compound and T_0 is also a constant representing the characteristic annealing temperature, i.e., the temperature from which annealing begins and which is related to the minimum activation energy of Primak's spectrum (3) by the equation $E_0 = kT \ln (Bt)$. In eq. [3] N is the number of annealable defects, i.e., the number of cooled hot zones containing an annealable recoil atom.

For the present case, in which annealing occurs at room temperature, $T - T_0 = \Delta T$ is a constant; therefore,

[4] $$\alpha_0 \Delta T = c_1$$

[5] $$\beta - 1 = c_2,$$

so that eq. [3] may be written

[6] $$(\Delta R)_\infty = c_1 N^{-c_2}.$$

In Table III values of $(\Delta R)_\infty$ and N are given for copper and cobalt oxinates. It is noteworthy that an approximately linear relation is found between the logarithm of the change

TABLE III

The values of the fraction destined to be annealed and of the number of defect centers, for different irradiation times

	Copper oxinate		Cobalt oxinate	
t', min	$(\Delta R)_\infty$, %	N	$(\Delta R)_\infty$, %	N
15	33.1	1.35×10^{12}	—	—
30	30.2	3.47×10^{12}	—	—
60	19.9	6.84×10^{12}	—	—
120	12.6	1.33×10^{13}	50.1	2.95×10^{13}
180	7.9	1.94×10^{13}	—	—
240	3.6	2.53×10^{13}	35.5	5.68×10^{13}
300	—	—	25.6	6.45×10^{13}
480	—	—	15.2	9.02×10^{13}

in retention from the zero-time value to pseudo-equilibrium value and the logarithm of the density of the defect centers, although the slope between two successive points increases by degrees with the growth of the number of defect centers (Fig. 4). This proves

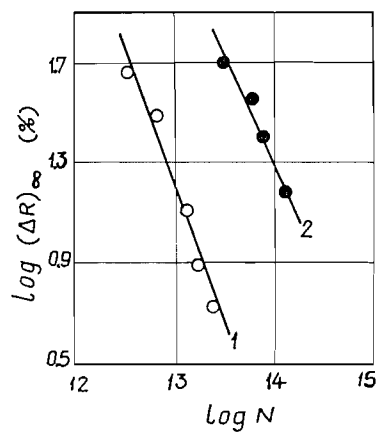

FIG. 4. The fraction destined to anneal at room temperature, as a function of the density of the defect centers: 1, copper oxinate; 2, cobalt oxinate.

the validity of eq. [6] for copper and cobalt oxinates. However, the imperfect linearity denotes that the phenomenon is more complex and we are under no illusions that the results are sufficient to generalize our equation, but hope that further studies will be suggested by them and that a theoretical consideration of this experimental evidence

will resolve the problem of the dependence between the annealing and the density of defect centers.

CLAM POISON

III. PAPER ELECTROPHORESIS OF CLAM POISON[1]

R. A. B. Bannard and A. A. Casselman
Defence Research Chemical Laboratories, Ottawa, Ontario

Received April 19, 1962

ABSTRACT

In paper strip electrophoretograms on Whatman 3MM paper, clam poison migrated toward the cathode when formic acid (1 *N* and 0.1 *N*), acetic acid (1 *N*), sodium acetate – acetic acid (0.1 *M*), monosodium dihydrogen phosphate – disodium monohydrogen phosphate (0.1 *M*), and sodium tetraborate (0.1 *M*) were used as electrolytes. Formic acid (1 *N*) proved the most suitable of these for examination of the quantitative electrophoretic behavior of clam poison. A method of pretreatment for the paper was developed to minimize introduction of extractable impurities into material recovered after electrophoresis by aqueous elution. Pure clam poison, on electrophoresis for 1.75 hours at 900 v on an 8×18-in. sheet of pretreated paper, migrated as a single, positively charged, Weber-positive band with apparent mobility 18.1 cm, which exhibited no fluorescence. Recovery was quantitative on both a weight and toxicity basis, and the toxicity, specific rotation, and infrared spectrum of the recovered toxin were identical with those of the starting material, thus providing an additional check on the homogeneity of the sample. Quantitative electrophoresis of toxin from clam poison tailings which had been purified by paper chromatography removed impurities which the latter method was incapable of eliminating, with resultant improvement in both the specific rotation and toxicity. Two such treatments provided toxin possessing a toxicity and specific rotation within the accepted limits for pure clam poison.

INTRODUCTION

The purification of clam poison by ion exchange followed by chromatography on acid-washed alumina, by chromatography on Norit A followed by crystallization as the helianthate, by countercurrent distribution (1), or by paper chromatography (2), provided material concluded to be chemically homogeneous because of the close correspondence in chemical, physical, and biological properties of the resultant specimens. Nevertheless, the fact that this exceedingly toxic substance of low molecular weight has not been obtained in a crystalline form possessing a definite melting point (2) makes it desirable to examine its purity by methods other than those mentioned above. Recently, we described a heavy-paper technique by means of which the toxin in clam poison tailings was enriched approximately fourfold in toxicity to 5000–5800 mouse units (MU)/mg in 67% yield. The recovered toxin exhibited physical, chemical, and biological characteristics which agreed in all respects with those reported previously for pure clam poison (1, 2), except that the specific rotation ($+98\pm4°$) was approximately 25% below normal. Since paper chromatography proved incapable of producing further improvement in the toxicity and rotation it was uncertain whether the low rotation referred to above was caused by the presence of impurities or whether the toxin recovered from the tailings differed from clam poison in some subtle manner. It therefore seemed worthwhile to examine the homogeneity of pure clam poison and tailings toxin by a method different from those previously employed, and the behavior of these materials during quantitative paper strip electrophoresis is reported herein.

RESULTS AND DISCUSSION

The paper strip electrophoresis of pure clam poison was examined in a series of electrolytes ranging in pH from 1.8 to 9.25 using Whatman 3MM paper and results are given

[1]*Issued as D.R.C.L. Report No. 367.*

in Table I. In all these electrolytes, the toxin migrated toward the cathode as a single, Weber-positive spot. In the first four electrolytes there was no ultraviolet fluorescence

TABLE I

Paper electrophoresis of clam poison

Electrolyte	pH	Time (hr)	True distance* (cm) migrated by: Toxin	UV-fluorescent material
HCOOH, 1 *N*	1.80	1.75	15.7

*Migration toward cathode designated as positive.

coincident with the toxin spot and none was anticipated since paper chromatograms performed on the same sample in the usual manner (2) revealed it to be free of fluorescence.* In the phosphate and borate buffers, however, there was ultraviolet fluorescence coincident with or overlapping the Weber-positive spot, together with two additional ultraviolet-fluorescent spots. The explanation for this phenomenon cannot be stated with certainty but could well be related to the frequent observation that the toxicity of clam poison decreases with increasing pH of its aqueous solutions (4–6), thus implying some destruction of the poison under these conditions. In this connection we have found that clam poison kept at 25° in aqueous solution at pH 6 for 11 days decomposed to the extent of 40%, with formation of a second Weber-positive substance of low toxicity and two additional ultraviolet-fluorescent substances, one of which is highly toxic (7). The appearance of multiple fluorescent spots in the phosphate and borate buffers makes these electrolytes less suitable for quantitative examination of the electrophoresis of clam poison than those electrolytes which do not cause such abnormalities. The sodium acetate – acetic acid buffer, although satisfactory for qualitative experiments, was not considered suitable for quantitative work because of the difficulty of removing salt from the recovered toxin. The 1 *N* formic acid proved the most satisfactory of the remaining acidic electrolytes, since it gave the most compact spots and the mobility of the poison was high. Whatman No. 1 and Reeve Angel No. 934-AH glass fiber papers gave more diffuse spots than No. 3MM paper and could not be loaded as heavily as the latter. Experiments with Whatman No. 17 and seed-test papers revealed them to be unsuitable for strip electrophoretic work, at least in this application, since 1-mg spots of toxin streaked very badly.

Earlier work on the purification of clam poison by quantitative paper chromatography in the acidic solvent system *t*-butanol:acetic acid:water (2:1:1) on Whatman No. 1, No. 17, and seed-test papers established the importance of extensive pretreatment of the papers to minimize introduction of impurities into the recovered toxin (2, 3). It was therefore necessary to ascertain the quantities of impurities introduced into toxin recovered by aqueous elution after electrophoresis on Whatman 3MM paper in 1 *N* formic

**Previously, samples of partially purified clam poison obtained from both the U.S. Army Chemical Corps Biological Laboratories and the U.S. Army Chemical Research and Development Laboratories exhibited fluorescence coincident with the Weber-positive toxin in paper chromatograms in t-butanol:acetic acid:water (2:1:1). This fluorescence proved separable from the toxin on electrophoresis in the first four electrolytes listed in Table I and was concluded to be a minor impurity present in partially purified samples, since pure specimens from both of the above-mentioned sources did not contain it.*

acid and, if possible, to develop a method of pretreatment for the paper capable of minimizing such impurities. To this end, 8×18-in. sheets of untreated 3MM paper were subjected to electrophoresis in blank runs under conditions identical with those described in the experimental section for electrophoresis of clam poison. Strips were removed from the dried sheet at preselected mobilities corresponding to the components in clam poison tailings, eluted with water, treated with Amberlite IRA-400 (Cl) resin, and filtered (2, 3). The filtrates were lyophilized and residues weighed. The experiments were repeated using Whatman 3MM papers which had been chromatographically pretreated by the procedure previously found to be most effective for removal of impurities from Whatman No. 1, No. 17, and seed-test papers (2, 3). Finally, 8×18-in. sheets of 3MM paper which had been chromatographically pretreated were conditioned further, by elution with 1 *N* formic acid and prolonged electrophoretic treatment as described in the experimental section, before the quantities of extractable impurities were determined. Results of these experiments are given in Table II, from which it is clear that untreated paper yields

TABLE II

Impurity recovered from Whatman 3MM paper

Mobility of band (cm)	Weight recovered (mg/in²) from:		
	Untreated	Pretreated	Pretreated and electrophoretically conditioned
5.1	0.074	0.046	0.024
6.7	0.076	0.060	0.024
8.2	0.075	0.068	0.036
18.0	0.057	0.044	0.025
18.8	0.103	0.079	0.031
22.5	0.106	0.069	0.034

substantial amounts of impurities which can be reduced appreciably by chromatographic pretreatment (2, 3). A further reduction can be effected by prolonged washing of the pretreated papers with 1 *N* formic acid, followed by electrophoretic conditioning. Preliminary experiments revealed the apparent mobility of clam poison under the experimental conditions used to be 18–19 cm and that the maximum loading attainable to confine the toxin to a 1×8-in. band after electrophoresis is 8–10 mg. It was concluded from the data in Table II that use of electrophoretically conditioned pretreated paper would introduce 2–3% of impurity into the recovered toxin, and although this level was somewhat greater than that realized by use of heavy-paper chromatography (3) it was still acceptable for the purpose of the present study.

A sample of pure clam poison dihydrochloride (5.02 mg, toxicity 6000 MU/mg, $[\alpha]_D^{25}$ +127°) was applied to an 8×18-in. sheet of electrophoretically conditioned pretreated paper and subjected to electrophoresis in 1 *N* formic acid at 900 v for 1.75 hours. Examination of a reference strip from the electrophoretogram under ultraviolet irradiation revealed no ultraviolet-fluorescent material. Spraying with Weber reagent revealed only one pink spot with apparent mobility 18.1 cm and ninhydrin produced a single yellow spot characteristic of the toxin (2) with the same mobility as the Weber-positive material. The substance was recovered by aqueous elution and the toxicity (5700 MU/mg) and specific rotation (+126°) were identical, within experimental error, with those of the starting material. The infrared spectrum was also identical with that reported previously for clam poison (2, 8). Since recovery was quantitative on both a weight (102%) and

toxicity (97.5%) basis it is evident that paper electrophoresis provides further support for the view that clam poison which possesses the physical constants delineated by Schantz and co-workers (1) is homogeneous.

Electrophoretograms on samples of tailings toxin (toxicity 5400±400 MU/mg, $[\alpha]_D^{25}$ +98±4°) on Whatman 3MM paper in 1 *N* formic acid at 900 v for 1.75 hours revealed the presence of Weber-positive toxin at an apparent mobility of 18–19 cm, ninhydrin-positive spots at 21 and 30 cm, and ultraviolet-fluorescent spots at 6.5 and 8 cm. These results indicated that electrophoresis is capable of separating components in the tailings toxin which are not separable by paper chromatography.

A sample of tailings toxin (8.40 mg, toxicity 5100 MU/mg, $[\alpha]_D^{25}$ +102°) was applied to an 8×18-in. sheet of electrophoretically conditioned pretreated Whatman 3MM paper and subjected to electrophoresis at 900 v for 1.75 hours in 1 *N* formic acid. A reference strip was examined under ultraviolet irradiation, then sprayed with Weber-reagent and ninhydrin for location of the components, which were recovered by aqueous elution. The eluates were lyophilized, weighed, and bioassayed as described in the experimental section. The results given in Table III clearly show that recovery on a weight basis is quantitative

TABLE III

Quantitative electrophoresis of tailings toxin*

Fraction No.	Chromogenic agent	Apparent mobility (cm)	Corrected weight (mg)	Toxicity (MU/mg)	Total MU
1	Ultraviolet	6.6	0.168	200	34
2	Ultraviolet	8.0	0.148	250	37
3	Weber	18.5	6.662	5,500	36,600
4	Ninhydrin	21.8	0.580	550	320

			8.199 (101%)		37,000 (89.6%)

*Theoretical recovery 8.10 mg (41,300 MU).

whereas recovery on a toxicity basis is 90% of theoretical. Approximately 99% of the toxicity accounted for is contained in fraction 3, the specific rotation of which rose by 14% to +116° and the toxicity of which increased 8%. The infrared spectrum of the fraction was indistinguishable from that of clam poison (3). Because of the marked increase in rotation on electrophoretic treatment it appeared that the anomalous rotations of enriched tailings toxin (3) owe their origin to the presence of impurities (fractions 1, 2, 3, and 5) which possess low-order toxicities and little or no optical activity. (Fractions 1, 2, and 5 had no optical activity and fraction 4 had specific rotation +8.2°.) This point of view was confirmed by a second experiment in which fraction 3 was repurified by the same method. The recovered toxin had specific rotation +127° and toxicity 5800 MU/mg, which is within the range of values reported by Schantz and co-workers for pure clam poison (1), and the infrared spectrum of the sample remained unchanged. Recovery in the toxin fraction was 97% on a weight basis and 96% on a toxicity basis. The discrepancy between the recovery on a weight and toxicity basis in the experimental results given in Table III is ascribed to the difficulty of obtaining accurate bioassays on fractions possessing low-order toxicity, particularly when the latter contain rather large amounts of impurities from the paper. It is possible that such impurities may suppress the toxicity since it has been shown by Wiberg and Stephenson (6) that the presence of sodium chloride produces such an effect.

It is evident, therefore, that the toxin obtained by paper chromatographic purification of clam poison tailings (3) is clam poison containing toxic impurities with little or no optical activity and which are removable by paper electrophoresis. Clearly, the method described herein for electrophoretic purification of clam poison, although useful as a research tool, is quite impractical for purification of large quantities of tailings. However, it seems quite likely to us that a continuous electrophoretic apparatus would circumvent this drawback.

Schantz and co-workers (8) have reported clam poison to contain periodate-cleavable groups, the precise nature of which is unknown. The periodate-labile moiety could contain one or more of several well-known functional groups (9) and it is conceivable that one of these might be a 1,2-diol. It occurred to us that it might be possible to demonstrate the presence of the latter if it was present in a cis configuration in a five- or six-membered ring by the behavior of clam poison on paper electrophoresis in borate buffer, since under such circumstances a negatively charged borate–diol complex would be formed which would migrate toward the anode (10, 11). The observation (Table I) that clam poison migrates toward the cathode on electrophoresis in borate buffer could, therefore, be construed as evidence against the presence of the type of 1,2-diol group referred to above. However, it was also considered possible that the effect of borate in producing a negatively charged complex might have been masked by concomitant formation of ammonium-type ions on the basic centers known to be present (8). A brief examination of two model compounds demonstrated that masking of the borate-complexing effect with diols can indeed occur in the presence of a basic nitrogen atom. It was previously shown (12) that the N-*p*-nitrobenzoyl derivatives of *dl*-3α-amino-1α,2β-cyclohexanediol and *dl*-3β-amino-1α,2α-cyclohexanediol had M_G values of 0 and 0.34 respectively on electrophoresis in 0.1 M sodium tetraborate at 435 v; i.e., as anticipated, the *cis*-diol formed a borate complex which migrated toward the anode, whereas the *trans*-diol did not. Under identical conditions, the corresponding aminediols *dl*-3α-amino-1α,2β-cyclohexanediol and *dl*-3β-amino-1α,2α-cyclohexanediol behaved quite differently. Both migrated toward the cathode and the M_G values for the *cis*- and *trans*-diols were -0.24 and -0.49 respectively. These results suggest that the *trans*-diol formed only an onium-type ion and thus migrated toward the cathode more rapidly than the *cis*-diol, which in addition contained a negatively charged center due to borate complex formation. Thus, conclusions reached on the basis of paper electrophoresis in borate buffer regarding the stereochemical configuration of 1,2-diols in five- or six-membered ring compounds which also contain a basic nitrogen atom may be erroneous unless the basic center is protected from salt formation. It is therefore not possible to conclude from the present experiments whether or not clam poison contains a 1,2-diol function.

EXPERIMENTAL

All experiments were performed in a water-cooled closed strip-type apparatus (E.C. Apparatus Co., Model 401) containing the appropriate electrolyte. For qualitative experiments 10 λ (200 γ) of a 2% aqueous solution of clam poison was applied to strips of Whatman 3MM paper (6.3×46 cm) and placed in the apparatus, which was equipped with wicks of Whatman 3MM paper extending the strips to which the toxin was applied into the electrolyte (total path length of current = 60 cm). A voltage of 900 was applied (i.e. 15 v/cm) for the length of time given in Table I. The paper strips were dried for 7 minutes on a glass plate at 100°,* cut in half longitudinally, and the portion containing the clam poison sprayed with Weber reagent,

**Excessive heating of the paper strips must be avoided since it was found that heating at 100° for periods exceeding 10 minutes causes the appearance of ultraviolet-fluorescent material coincident with the toxin. Unlike other ultraviolet-fluorescent material which is observed to be coincident with the toxin in paper chromatograms of partially purified toxin, the fluorescent substance produced by action of heat on pure clam poison is not separable electrophoretically.*

after examination under ultraviolet irradiation to locate fluorescent material. The remainder of the electrophoretogram was sprayed with a chromogenic agent to reveal the particular reference compound used to define the electroendosmotic migration. *i*-Inositol was used as reference compound for the first four electrolytes shown in Table I and was revealed by spraying with ammoniacal silver nitrate, followed by heating. L-Proline (isoelectric point pH 6.3) was used as reference compound in the phosphate buffer and revealed by spraying with ninhydrin. The glucose and tetramethylglucose used with borate buffer were revealed by ammoniacal silver nitrate and by iodine in petroleum ether (0.2% w/v) respectively. Acid electrolytes were prepared from reagent grade acids, the strengths of which were determined by titration. The other buffers were prepared from appropriate reagent grade salts.

For the experiments with *dl*-3α-amino-1α,2β-cyclohexanediol and *dl*-3β-amino-1α,2α-cyclohexanediol in 0.1 *M* sodium tetraborate, 1% aqueous solutions were spotted on strips of Reeve Angel No. 934-AH glass fiber paper (6.3×46 cm) together with glucose and tetramethylglucose and subjected to electrophoresis under conditions identical with those previously described for the N-*p*-nitrobenzoyl derivatives (12). The strips were dried at 100° on a glass plate and sprayed with alkaline permanganate (13).

Pretreatment of Papers

Whatman 3MM papers were pretreated by chromatographic washing according to the method described previously (2) for Whatman No. 1 paper. For preparation of electrophoretically conditioned paper, the pretreated paper was eluted with 1 *N* formic acid for 2 days, with water for 2 days, air-dried, and cut into 8×18-in. sheets. The latter were subjected to electrophoresis in 1 *N* formic acid at 900 v for 5 hours, dried for 1.5 minutes at 100° then in air at room temperature, washed for 2 days with water, and air-dried.

Blank Runs on Pretreated Paper

Wicks used in all quantitative experiments were pretreated Whatman No. 1 paper. Whatman 3MM papers (8×18-in.), untreated, pretreated, and electrophoretically conditioned, were subjected to electrophoresis in 1 *N* formic acid at 900 v for 1.75 hours. The sheet was dried for 1.5 minutes at 100° and suspended horizontally at room temperature until completely dry. Bands (1/2 to 1 in. wide) were cut from the "electrophoretogram" in locations corresponding to the mobilities displayed by components in tailings toxin in qualitative experiments under equivalent conditions and eluted with water (3–5 ml). The eluates were passed through Amberlite IRA-400 (Cl) resin (1.5–2 ml), filtered through a fine-porosity sintered-glass funnel, lyophilized, and weighed. From the areas of the strips, the weights of residues recoverable per sq. in. of paper at the mobilities indicated in Table II were determined.

Paper Electrophoretic Purification of Tailings Toxin

Clam poison tailings toxin (8.40 mg, toxicity 5100 MU/mg, $[\alpha]_D^{25}+102°$) was applied as 28 spots from a 1% solution along a start line 4 in. from one end of an 8×18-in. sheet of electrophoretically conditioned Whatman 3MM paper. The sheet was subjected to electrophoresis under conditions identical with those for the blank runs. After drying as described above, a reference strip was examined under ultraviolet irradiation, sprayed with Weber reagent and ninhydrin for location of the components, and the bands removed. The latter were extracted as described in the blank runs and the weights of residues determined. From the weights thus obtained, the weights of impurities known to be introduced as a result of blank runs on the same batch of paper were subtracted to give the corrected weight of each fraction, as shown in Table III. Bioassays were performed on all the fractions as described previously (3, 5). The infrared spectrum of fraction 3 was recorded (KBr pellet) and the specific rotation (1% aqueous solution) was found to be $[\alpha]_D^{25}$ +116°. Fraction 3 was repurified in the same manner, yielding toxin with specific rotation +127° and toxicity 5800 MU/mg (recovery, 96% on a toxicity basis and 97% on a weight basis).

Paper Electrophoresis of Pure Clam Poison Dihydrochloride

Pure clam poison dihydrochloride (5.02 mg, toxicity 6000 MU/mg, $[\alpha]_D^{25}$ +127°) was subjected to quantitative electrophoresis as described for the tailings toxin. Only one Weber-positive band of apparent mobility 18.1 cm was obtained. Elution gave 4.78 mg (102% on a weight basis, 97.5% on a toxicity basis) of pale yellow glass with toxicity 5700 MU/mg and $[\alpha]_D^{25}$ +126°. The infrared spectrum was identical with that of the starting material.

ACKNOWLEDGMENTS

We are indebted to Dr. E. J. Schantz of the U.S. Army Chemical Corps Biological Laboratories for providing the sample of pure clam poison dihydrochloride used in this work. Thanks are also due Dr. A. D. Tennant and Mr. R. Tuszynski of the Laboratory of Hygiene, Department of National Health and Welfare, Ottawa, for performing the bioassays and to Dr. R. N. Jones and Mr. R. Lauzon, Division of Pure Chemistry, National Research Council, Ottawa, for measurement of infrared spectra.

KINETIC SOLVENT EFFECT IN ETARD'S REACTION

R. A. STAIRS
Department of Chemistry, Queen's University, Kingston, Ontario
Received July 28, 1961

ABSTRACT

The rate of the reaction of chromyl chloride with toluene has been measured in a number of halogenated solvents. The data were correlated with the solubility parameters of the solvents and also with their dielectric constants. The results were taken as evidence against an ionic mechanism for the reaction.

INTRODUCTION

The initial stage of Etard's reaction may involve ionic or molecular attack upon the hydrocarbon by a species containing chromium VI. However, the kinetic study reported previously (1) was unable to discriminate between these two possibilities. In an attempt to subject this point to experimental scrutiny, we have now examined the effect of solvent on the rate of reaction of chromyl chloride with toluene. The influence of solvent on the rate of a chemical reaction has been discussed by Frost and Pearson from two points of view (2, pp. 132, 140). Following Hildebrand (3) they derive a relation between the rate constant and the molar volumes and solubility parameters of the various species (2, p. 132), which can be rearranged:

$$RT \ln (k/k_0) = (V_A\delta_A^2 + V_B\delta_B^2 - V_{\neq}\delta_{\neq}^2) - 2(V_A\delta_A + V_B\delta_B - V_{\neq}\delta_{\neq})\delta_l + (V_A + V_B - V_{\neq})\delta_l^2. \quad [1]$$

Here V represents a molar volume and δ a solubility parameter (related to internal pressure). The subscripts refer to the two reactants (A, B), the activated complex ($\neq$), and the solvent (l), and k_0 and k are the rate constants in a hypothetical ideal solution and in the real solution. For a given reaction at constant temperature, in different solvents having a range of values of the solubility parameter δ_l, by fitting an equation of the form $\log k = a + b\delta_l + c\delta_l^2$ to the data, it should be possible to evaluate $V_{\neq}$ from the coefficient of δ_l^2, and then $\delta_{\neq}$ from the coefficient of δ_l, if V_A, V_B, δ_A, δ_B are known or can be estimated. With imprecise data it should still be possible, by making an assumption about the volume of activation ($\Delta V_{\neq} = V_{\neq} - V_A - V_B$), to arrive at an estimate of $\delta_{\neq}$, and hence obtain some idea of the molecular character of the activated complex.

The other approach (2, p. 140), following Kirkwood (4), considers all the species A, B, and $\neq$ as more or less polar, ignores all but electrostatic forces, and yields

$$RT \ln (k/k_0) = \frac{N(\epsilon-1)}{2\epsilon+1}\left(\frac{\mu_A^2}{r_A^3} + \frac{\mu_B^2}{r_B^3} - \frac{\mu_{\neq}^2}{r_{\neq}^3}\right). \quad [2]$$

Here k is the rate constant in the real solvent of dielectric constant ϵ, and k_0 is that in a hypothetical solvent of dielectric constant unity, but otherwise identical with the first. N is Avogadro's number, and μ represents the electric dipole moment and r the molecular radius of the species indicated by the subscript. Thus, if estimates can be made of the dipole moments and the radii of the reactant species and of the radius of the activated complex, an estimate of the dipole moment of the complex can be obtained from the slope of a graph of $\log k$ against $(\epsilon-1)/(2\epsilon+1)$.

METHOD AND RESULTS

Kinetic measurements were made on the reaction between chromyl chloride and toluene (Etard's reaction), using the method already described (1), in a number of solvents. The solvents are listed in Table I, together with values of their dielectric constants and

TABLE I

Solvent properties

Solvent	ϵ_{298}*	δ_{298}
1,2-Dichloroethane	10.13	9.8‡

Chloroform	4.96	9.3‡
1,1,2-Trichloro-*f*-ethane	2.48†	7.2§
Carbon tetrachloride	2.23	8.6‡
Pentachloroethane	3.60	9.4‡

*Values from International Critical Tables, unless otherwise indicated.
†Value from "Freon" Technical Bulletin B-2, E.I. du Pont de Nemours and Co. (Inc.), Wilmington 98, Delaware (adjusted to 25° C).
‡Value from ref. 2, p. 436.
§Value estimated by methods from ref. 2, chap. XXIII.

solubility parameters at 25° C. All the solvents were purified by treatment first with concentrated H_2SO_4 and then with water, followed by drying over $CaCl_2$, and distillation through a short column. The most satisfactory test of purity was found to be the clarity of the CrO_2Cl_2 solutions. Slow reaction of CrO_2Cl_2 with the solvent was observed, and roughly corrected for, in the case of dichloroethane.

Table II contains the results, in the form of second-order rate constants, each being the average of three to six determinations in each solvent at each temperature. Estimates of

*Stairs and Burns (1).

the Arrhenius activation energies and steric factors are also listed. The steric factors appear to be normal (2, p. 94) for a bimolecular reaction between two fairly complex molecules, except for the reaction in 1,2-dichloroethane, which may be anomalously slow, or in error owing to reaction with the solvent. The constants were based on initial rates

only, and are assumed to refer to the first stage of the complex overall reaction, i.e. to the reaction

$$PhCH_3 + CrO_2Cl_2 = PhCH_2OCrCl_2OH. \qquad [i]$$

DISCUSSION

Equation [i] may represent a molecular reaction, going essentially as written, or it may involve attack by a cation derived from CrO_2Cl_2. In the latter case it is necessary to assume a bimolecular ionization step, e.g.

$$2CrO_2Cl_2 = CrO_2Cl^+ + CrO_2Cl_3^-,$$

in order to explain the observed (1) partial order of unity with respect to CrO_2Cl_2. The activated complex would be cationic, but associated with an anion, and the dipole moment of this ion pair would be large, possibly as large as 10 debyes. If a meaningful solubility parameter could be assigned to such a polar entity, it would be large number. On the other hand, the molecular reaction would be expected to have an activated complex resembling a moderately polar molecule. It should be pointed out that the kinetic ambiguity between ionic and molecular mechanisms demonstrated by Weil and Morris (5) in the urea reaction does not apply here, owing to the distinctly different character of the activated complex postulated for the two mechanisms.

Figure 1(*a*) shows the results of plotting the logarithms of the observed rate constants versus the solubility parameters (δ_l) of the various solvents, all at 25° C. The data did not

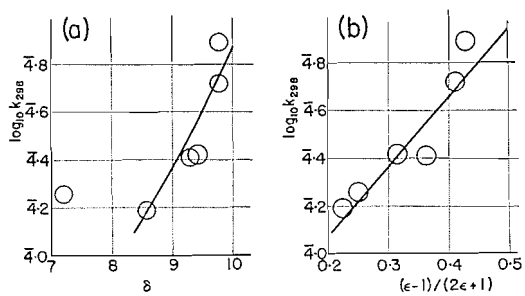

FIG. 1. Rate constants at 25° C in various solvents (as common logarithms) plotted (*a*) against the solubility parameters of the solvents, δ_l, and (*b*) against the function $(\epsilon-1)/(2\epsilon+1)$ of the dielectric constant.

appear to fit equation [1] well enough to justify calculation of the volume of activation, so the curve in the figure was drawn with an assumed value of $\Delta V_{\neq} = -10$ ml/mole. The point for the solvent $CF_2ClCFCl_2$ is the only one seriously off the curve.

The positive slope means that the activated complex has a higher solubility parameter than the reactants. Using molar volumes and solubility parameters of 107 ml and 8.9 for toluene (3, p. 437) and 81.0 ml and 10.4 for CrO_2Cl_2 (estimated by methods of ref. 3, chap. XXIII), the value of $\delta_{\neq}$ estimated from the slope is 11.5 ± 0.5, which represents only a moderate increase in intermolecular forces, and presumably in polarity.

In Fig. 1(*b*) the logarithms of the observed rate constants are plotted against $(\epsilon-1)/(2\epsilon+1)$ at 25° C. The positive slope of the line means that the activated complex is more polar than the reactants. Using radii estimated from the molar volumes used above, and the dipole moments 0.47 for CrO_2Cl_2 (6) and 0.4 (7) for toluene, one may calculate from the slope, using equation [2], $\mu_{\neq} = 2.0$. This value is typical of moderately polar molecules.

Analysis of the data by the two methods has shown that, in this case at least, the data are more compatible with the electrostatic than with the solubility parameter theories. However, within their limitations both approaches lead to the same conclusion, namely that the activated complex in Etard's reaction is somewhat more polar than the starting materials, but probably not polar enough to be described as ionic, even though in these relatively non-polar media an ionic activated complex would probably exist as an associated ion pair.

ACKNOWLEDGMENTS

The author wishes to acknowledge the assistance of Messrs. D. R. Morton and E. G. Dewar and Miss M. G. Gillies in making the measurements, a gift of 1,1,2-trichloro-*f*-ethane (Freon 113) from the Dupont Company of Canada, and a grant from the National Research Council.

NITRONIUM SALTS

I. NEW METHODS FOR THE PREPARATION OF $NO_2^+BF_4^-$, $NO_2^+PF_6^-$, $NO_2^+AsF_6^-$ [1]

S. J. KUHN
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received April 13, 1962

ABSTRACT

Two new methods are presented for the preparation of complex salts of NO_2F using easily available starting materials such as nitric acid, HF, BF_3, etc. These methods produce very pure materials in a one-step reaction.

There is an increasing interest in the chemistry of nitronium salts since it has been proved that the attacking species in the nitration of aromatic compounds in many cases is the NO_2^+ ion which forms before or during the nitration. In the nitronium salts, the NO_2^+ ion is already present before the interaction with the aromatics. The nitronium salts are excellent nitrating agents (1–4) for aromatics, sometimes showing nitrating ability superior to that of the mixed acids or other nitrating agents. N- and O-nitrations have also been carried out with nitronium salts (5). The most frequently used nitronium salts for nitrations are $NO_2^+BF_4^-$ and $NO_2^+PF_6^-$ because of the ease of handling; generally, no side reaction occurs during nitrations by these compounds.

Most of the known nitronium salts other than the complex salts of NO_2F were prepared in pure state and studied by Goddard, Hughes, and Ingold (6).

The first nitronium salts of NO_2F were prepared by Woolf and Emeléus (7) in 1950 by the interaction of NO_2 together with BrF_3 on suitable non-metallic compounds like B_2O_3, As_2O_5, etc. With this method, they obtained $NO_2^+BF_4^-$, $NO_2^+PF_6^-$, $NO_2^+AsF_6^-$, and $NO_2^+SbF_6^-$. Since that time, other new methods have become known for the preparation of nitronium salts of NO_2F and a number of new salts have been prepared. Schmeisser and Elisher (8) prepared $NO_2^+BF_4^-$ and $(NO_2^+)_2SiF_6^{--}$ by adding the appropriate fluoride to a mixture of N_2O_5 and anhydrous HF in nitromethane. A number of nitronium salts have been prepared by reacting NO_2F (9, 10) with non-metallic elements or with their fluorides. Nitronium tetrafluoroborate has also been prepared by the ozone oxidation of the nitrozonium salt (11).

All of the above-mentioned methods present some difficulties. Some of them do not produce pure materials, others require separate preparation of sensitive starting materials.

In this work, two new possibilities were investigated for the preparation of nitronium salts of NO_2F. The aim of this investigation was to find methods which can produce large quantities of pure nitronium salt in a simple, one-step reaction using available starting materials.

The first reaction investigated was the interaction between nitric acid, anhydrous HF, and Lewis acid fluorides.

According to Gillespie and Millen (12), the following equilibrium exists if anhydrous HF is added to nitric acid:

$$2HF + HNO_3 \rightleftharpoons NO_2^+ + 2F^- + H_3O^+.$$

[1]*Contribution No. 46.*

In the infrared and Raman spectra of solutions of HNO_3 in liquid HF spectral features attributed to nitronium ion have also been observed by Del Gseco and Gryder (13). It was found in this investigation that if a sufficient amount of Lewis acid fluoride is added to an equimolar mixture of nitric acid and anhydrous HF, solid nitronium salt can be separated. The reaction proceeds without solvent but is easier to handle in nitromethane solution:

$$HNO_3 + HF + nBF_3 \rightarrow NO_2^+BF_4^- + H_2O.(n-1)BF_3.$$

The yields depend on the amount of Lewis acid used in the reaction, as it is shown in Tables I and II.

TABLE I

BF_3 (mole)	HNO_3 (mole)	HF (mole)	CH_3NO_2 (g)	Yield of NO_2BF_4 (g)	(%)
0.75	0.5	0.5	60.0	51.4	77.4
0.85	0.5	0.5	60.0	55.4	83.4
1.00	0.5	0.5	60.0	61.0	91.8
1.25	0.5	0.5	60.0	55.6	83.7

TABLE II

PF_5 (mole)	HNO_3 (mole)	HF (mole)	CH_3NO_2 (g)	Yield of NO_2PF_6 (g)	(%)
0.75	0.5	0.5	60	75.6	72.2
0.75	0.5	0.25	60	75.1	71.7
1.00	0.5	0.25	60	91.0	95.9
1.10	0.5	0.25	60	91.0	95.9
1.25	0.5	0.25	60	91.0	95.9

It was found that optimum yield was obtained if enough ($n = 2$) BF_3 is added to form the complex salt and HBF_3OH with the by-product water:

$$HNO_3 + HF + 2BF_3 \rightarrow NO_2^+BF_4^- + HBF_3OH.$$

The reaction is more complex if PF_5 or AsF_5 are used in the place of BF_3 because these compounds undergo hydrolysis with the water formed in the reaction.

It can be seen from Table II that maximum yield can be obtained if enough PF_5 is added to give the nitronium salt and POF_3 with the water formed in the reaction. It can also be seen that only a small amount of HF is necessary to start the reaction because the hydrolysis of PF_5 supplies more than a sufficient amount of HF for the reaction:

$$HNO_3 + 2PF_5 \xrightarrow{HF} NO_2^+PF_6^- + POF_3 + HF.$$

If the reaction is carried out under pressure a better utilization of the PF_5 can be achieved according to the following equation:

$$4HNO_3 + 5PF_5 \rightarrow 4NO_2PF_6^- + HF + H_3PO_4.$$

By using the described methods, $NO_2^+BF_4^-$, $NO_2^+PF_6^-$, $NO_2^+AsF_6^-$ were prepared with good purity and $NO_2^+SbF_6^-$, $(NO_2^+)_2SiF_6^{--}$ contaminated with hydrolysis by-products.

Later it was found that nitric acid can be replaced by esters of nitric acid in these reactions. Kuhn (14) investigated the solutions of ethyl nitrate in sulphuric acid and concluded that esters undergo ionization, yielding NO_2^+. He also found that the ultraviolet spectrum of this solution is almost identical with that of a solution of nitric acid in the sulphuric acid. Probably the same situation exists in the presence of anhydrous HF. This method is limited to the preparation of $NO_2^+BF_4^-$, $NO_2^+PF_6^-$, and $(NO_2^+)_2SiF_6^{--}$ because SiF_5 and AsF_5, being strong oxidizing agents, gave explosions when brought together with nitrate esters. It was found again (Table III) that optimum yield can be obtained if sufficient amount of BF_3 is added to produce the nitronium salt and remove the alcohol by-product in a form of $ROH.BF_3$:

$$R—O—NO_2 + HF + 2BF_3 \rightarrow NO_2^+BF_4^- + R—OH.BF_3.$$

TABLE III

BF_3 (mole)	$CH_3CH_2—ONO_2$ (mole)	HF (mole)	CH_3NO_2 (g)	Yield of NO_2BF_4 (g)	(%)
0.75	0.5	0.5	60.0	49.5	74.9
0.875	0.5	0.5	60.0	55.8	84.2
1.0	0.5	0.5	60.0	62.0	93.4
1.25	0.5	0.5	60.0	60.5	91.0

Methyl, ethyl, *n*-propyl, and butyl esters of nitric acid were used in these reactions and all of them gave similar results. The advantage of this second process is that the salts prepared in this way are extremely pure, ideal for kinetic investigations.

All of the described reactions can be carried out without the use of solvent or in excess HF. In these cases the ionization of nitric acid or the esters may occur before the addition of the Lewis acid fluoride. The situation is probably different in nitromethane solution, although the cryoscopic and spectroscopic properties of the solutions of HF and HNO_3 or HF and $R—ONO_2$ in nitromethane have not been investigated yet. An equilibrium probably exists between the unreacted acid and the protonated nitric acid or esters, and the formation of nitronium ion is promoted by the addition of the fluorides. The complex nitronium salts precipitate from the nitromethane solution, although $NO_2^+PF_6^-$ and $NO_2^+AsF_6^-$ are soluble in nitromethane, and for this reason it is advisable to use only a small amount of solvent. The optimum temperature for all these reactions is between -20 and $0°$. The HNO_3 content of the acid used is important because, in the case of dilute acid, large amounts of fluorides are needed to remove water and the yields are smaller due to the solubility of the salt in the by-product formed. Best results were obtained using 95–100% nitric acid. All these nitronium salts were prepared earlier by other methods. They are stable, white crystalline compounds if kept dry but hydrolyze in the presence of moisture. Only a few solvents can be found to dissolve these compounds because they interact with most of the usual solvents or they are not soluble at all. In previous work (12), it was found that tetramethylene sulphone is a good solvent for all of the salts. Solutions up to 10% can be made of this solvent. Nitromethane is an excellent solvent for $NO_2^+PF_6^-$ and $NO_2^+AsF_6^-$, especially for the latter ($\approx$50%). All of nitronium salts are soluble in anhydrous HF.

The infrared spectra of the nitronium salts (15) prepared by these methods were compared to the infrared spectra of nitronium salts prepared by other methods and were found to be identical.

EXPERIMENTAL

Reagents

The nitric acid used was either fuming nitric acid (HNO_3 assay 90%) or red fuming nitric acid (HNO_3 assay 100%). The HF used in the process was (HF assay 96–100%) supplied by the Matheson Co. The BF_3 and SiF_4 were also supplied by the Matheson Co. (BF_3 assay 99%, SiF_4 assay 99.5%). PF_5 and AsF_5 were supplied by Ozark and Mahoning Co. SbF_5 was supplied by Stauffer Chemicals Co. The alkyl nitrates and nitromethane used were Eastman white label chemicals or supplied by K and K Laboratories, Inc.

The HNO_3 Method

A solution of 40 g of anhydrous HF (2 moles) and 126 g of red fuming nitric acid (2 moles) in 250 g of nitromethane was placed in a 1-liter silica or polyethylene flask, and 271.3 g of BF_3 (4 moles) was introduced into this solution. The temperature was kept between −15 and 0° and the flask was shaken during the reaction. After the BF_3 addition, the precipitated white solid was filtered, washed twice with 40 g of nitromethane, then twice with 50 ml of Freon 113, chloroform, methylene chloride, or carbon tetrachloride. The complex was dried by pumping off the volatile washing solvents. Yield 91.8%, based on HNO_3 used. N% found, 10.55, calculated, 10.5.

NO_2PF_6, NO_2AsF_6 were made essentially in the same way using PF_5 or AsF_5 instead of BF_3 but the mole ratio of reagent used is different: $HF:HNO_3:PF_5(AsF_5) = 0.5:1:2$. In the preparation of NO_2BF_4, the $HF:HNO_3:BF_3$ mole ratio was 1:1:2. $(NO_2)_2SiF_6$ and NO_2SbF_6 can also be prepared by this method but the products are contaminated with SiO_2 and antimony oxide impurities.

The R—O—NO_2 Method

A solution of 20 g of anhydrous HF (1 mole) and 1 mole of alkyl nitrate in 120 g of nitromethane were placed in a 500-ml silica flask, and 2 moles of BF_3 were introduced into the reaction mixture. The temperature was kept between −20 and 0° C during the reaction. The product was filtered, washed twice with 25 g of nitromethane, then twice with 25 ml of low-boiling halogenated aliphatic hydrocarbon (Freon 113, chloroform, etc.).

Yield 93.4%, based on alkyl nitrate used. The product is very pure. N% calculated, 10.5, found, 10.5.

NO_2PF_6 and $(NO_2)_2SiF_6$ can also be made by this process.

The author is very grateful to Mrs. S. H. Flood for carrying out some of the experimental work and to Dr. Denys Cook and Miss C. D. Anderson for taking the infrared spectra of the compounds.

ortho-DIQUATERNARY AROMATIC COMPOUNDS

I. THE SYNTHESIS OF *ortho*-DITERTIARYBUTYLBENZENE. SOME REACTIONS OF SIDE CHAIN SUBSTITUTED DERIVATIVES

L. R. C. BARCLAY, C. E. MILLIGAN, AND N. D. HALL
Department of Chemistry, Mount Allison University, Sackville, New Brunswick

Received April 24, 1962

ABSTRACT

1,1,4,4-Tetramethyltetralone (I) was converted by oxidative procedures into *o*-phenylene-diisobutyric acid (III). Hydride reduction of the dimethyl ester of III yielded β,β'-dihydroxy-*o*-di-*t*-butylbenzene (IV). The ditosylate of IV was converted by hydride reduction into *o*-di-*t*-butylbenzene (VI) (44%) together with rearrangement products. Ultraviolet spectral evidence indicated a slight distortion of the benzene ring in VI and its various side chain derivatives. Side reactions were encountered in the synthesis of III, which involved the conversion of this acid by periodate or lead tetraacetate oxidation into a lactone (X) and the anhydride (XI). A mechanism is postulated to account for the formation of X. The structures postulated for the various compounds were confirmed by n.m.r. spectral studies.

INTRODUCTION

The considerable interest in strained aromatic compounds bearing *o*-*t*-butyl groups has culminated in several recent syntheses of this system through the cyclization of *t*-butylacetylenic compounds with organometallic catalysts. Hubel and co-workers have successfully applied this method to the synthesis of 1,2,4-tri-*t*-butylbenzene (1), 1,2-di-*t*-butylbenzene (2), and 1,2,4,5-tetra-*t*-butylbenzene (3). Similarly Arnett and co-workers synthesized tetra-*t*-butylbenzene (4) and an impure version of *o*-di-*t*-butylbenzene (5). Earlier unsuccessful attempts to synthesize this system have been discussed (4–6).

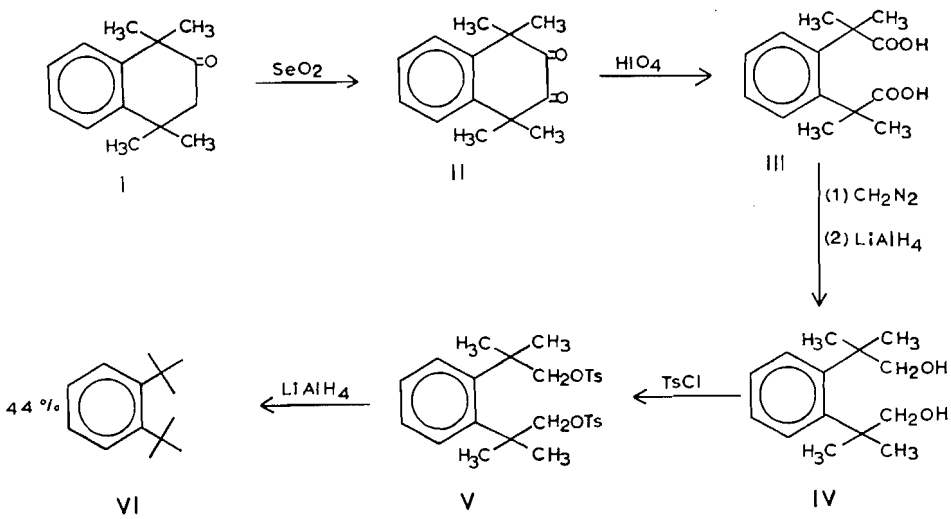
In 1958 Bruson and co-workers (7) reported the syntheses of *o*-phenylene-diisobutyric acid, the first derivative of *o*-di-*t*-butylbenzene reported in the literature. In a preliminary communication (8) we reported the conversion of this acid into β,β'-dihydroxy-*o*-di-*t*-butylbenzene. We now wish to report on the details of this synthesis as well as the conversion of this diol to *o*-di-*t*-butylbenzene and some interesting reactions of side chain derivatives of *o*-di-*t*-butylbenzene. This strained system represents the initial research undertaken in our laboratory into the chemistry of various *o*-diquaternary aromatic systems.

DISCUSSION OF RESULTS

Bruson's procedure for the cyclialkylation of benzene with 2,2,5,5-tetramethyltetrahydrofuranone to produce 1,1,4,4-tetramethyltetralone* (I) was the starting point in our synthesis. The structure assigned to I was confirmed by its n.m.r. spectrum. A peak at 8.69 p.p.m. was attributed to the two methyl groups on carbon 4, while a peak at 8.56 of equal intensity was attributed to the two methyls on carbon 1, adjacent to the carbonyl function. The two methylene hydrogens appeared at 7.36 and a peak at 2.74 corresponded in relative intensity to the four aromatic protons. The conversion of I to *o*-phenylene-diisobutyric acid (III) by permanganate oxidation according to Bruson's procedure (7) was not very successful. A low yield of the acid (III) was obtained with a melting point of 218–219°. On the other hand Bruson reported a melting point of

**This synthesis actually yields a mixture of I and rearrangement products such as 1-acetyl-1,3,3-trimethylindan and 2,2,4,4-tetramethyl-1-indanone. These rearrangements will be the subject of a later publication.*

181–183° for this acid. In order to establish the identity of our acid, an alternate synthesis was carried out. In this synthesis I was oxidized with selenium dioxide to produce the yellow diketone (II) in high yield. Periodic acid oxidation of II at 70° readily yielded the acid (III). Treatment of III with diazomethane yielded the corresponding diester, dimethyl-*o*-phenylene-diisobutyrate. The structure of this ester (and therefore of the acid III) was confirmed by its n.m.r. spectrum. This spectrum showed a single band for C-methyl at 8.40 p.p.m. of relative intensity corresponding to the four C-methyls. The absorption for the two O-methyls appeared at 6.39 p.p.m. and the four aromatic protons absorbed at 2.73 p.p.m. On expansion of the spectrum, this band was resolved into the two groups of bands of the A_2B_2 type of pattern. The above diester was reduced with lithium aluminum hydride to yield β,β'-dihydroxy-*o*-di-*t*-butylbenzene (IV). The diol (IV) showed the expected n.m.r. spectrum. This spectrum showed a single peak attributable to C-methyl at 8.51 p.p.m. and of relative intensity corresponding to four such groups. A peak at 8.21 p.p.m. was assigned to the two hydroxyl hydrogens and one at 6.22 p.p.m. to the four methylene hydrogens. The aromatic protons showed the usual two groups of bands of the A_2B_2 pattern near 2.55 and 2.78 p.p.m. The infrared spectrum of a KBr pellet of this compound showed hydroxyl absorption at 3350 cm^{-1}, a strong band at 1037 cm^{-1} due to the $—CH_2OH$ groups, and a strong band at 750 cm^{-1} due to *o*-disubstitution. The relationships between these compounds are illustrated below.

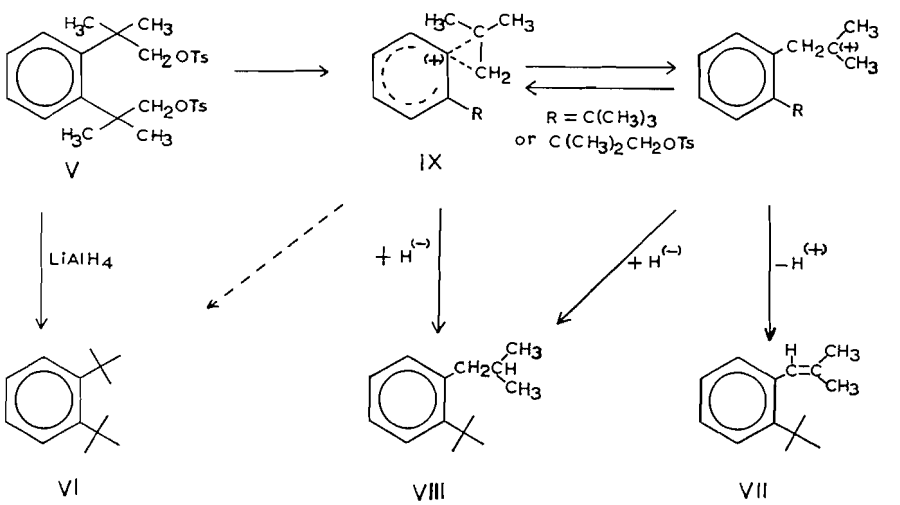


Treatment of the diol (IV) with *p*-toluenesulphonyl chloride in pyridine gave the corresponding ditosylate (V). Reduction of an ethereal solution of V with lithium aluminum hydride yielded a mixture of hydrocarbons showing parent masses of 190 and 188 in a high-temperature inlet mass spectrometer. Vapor phase chromatography indicated three major components in this mixture and, using this technique, *o*-di-*t*-butylbenzene (VI) (m.p. 24–27°) was separated in 44% yield. The structure of this hydrocarbon was confirmed by its n.m.r. spectrum, which showed one strong band for the C-methyls at 8.49 p.p.m. corresponding to the six such groups and the two groups of bands for the four aromatic protons near 2.63 and 3.09 p.p.m. The infrared spectrum of VI showed bands at 1390, 1360, 1230, and 1195 cm^{-1} attributed to the *t*-butyl groups, and a strong band for *o*-disubstitution was present at 755 cm^{-1}.

The two other major components formed by hydride reduction of V were found to consist of an unsaturated hydrocarbon (VII) and a hydrocarbon (VIII) of the same skeletal structure, since VII was converted to VIII by catalytic reduction. The structure of VII was established by its n.m.r. spectrum. This spectrum showed a band at 8.63 p.p.m. corresponding to the nine protons of a *t*-butyl group. There was a series of partially resolved symmetrical bands at 7.98, 8.10, 8.44, and 8.59 p.p.m. of relative intensity corresponding to six protons. The observed splitting can be explained by examination of a molecular model of *o*-*t*-butyl-β,β-dimethylstyrene, the structure postulated for VII. The bulky *t*-butyl group forces the ortho-situated unsaturated side chain out of the plane of the benzene ring. As a result one of the methyl groups on the olefinic carbon lies directly over the plane of the benzene ring, thereby causing a shielding effect on the protons in this group which is absent in the other methyl group on the olefinic carbon. An A_3B_3-type pattern is therefore observed for these two methyl groups. Absorption at 3.43 p.p.m. was attributed to the olefinic proton and a series of bands between 2.58 and 3.00 p.p.m. to the four aromatic protons.

Hydrocarbon VII showed the expected infrared spectrum with a band at 837 cm^{-1} attributed to the out-of-plane deformation of the olefinic proton and a band at 765 cm^{-1} due to *o*-disubstitution. On the other hand VII did not show the typical ultraviolet spectrum expected of an alkyl styrene. There was only comparatively weak general absorption, with no maxima observed. This can be attributed to steric inhibition of resonance whereby the olefinic double bond has been twisted out of the plane of the benzene ring.

Hydrocarbons VII and VIII undoubtedly formed by rearrangement accompanying the hydride reduction of V. In this case the nucleophilic displacement of the tosyl group may take place by an ionizing mechanism. The benzene ring can participate in this displacement (anchimeric assistance) through formation of a phenonium ion intermediate (IX). The relief of strain in the rearranged compounds VII and VIII would be a contributing driving force for this rearrangement. This is an interesting case of rearrangement accompanying hydride reduction; Winstein and co-workers (9) demonstrated that ethyl ether becomes a good ionizing medium in the presence of an added salt. It is possible that lithium aluminum hydride similarly promotes the ionization of V in ethyl ether.



The ultraviolet absorption spectra of *o*-di-*t*-butylbenzene and derivatives are summarized in Table I. *o*-Di-*t*-butylbenzene and its derivatives all show a broad general

TABLE I

Ultraviolet absorption spectra

Compound	λ_{max} (mμ)	ϵ
1,1,4,4-Tetramethyltetralin	271, 264, 257	398, 457, 324
o-Phenylene-diisobutyric acid (III)	262	233
Dimethyl-*o*-phenylene-diisobutyrate	264	252
β,β'-Dihydroxy-*o*-di-*t*-butylbenzene (IV)	265	225
o-Di-*t*-butylbenzene	262.5	214

band in the region 262–265 mμ. The characteristic aspect of this absorption is the loss of aromatic vibrational fine structure typical of *o*-disubstituted benzenes such as 1,1,4,4-tetramethyltetralin. This effect has been the subject of some discussion (3–5, 8) including a detailed discussion of the infrared and ultraviolet spectrum of 1,2,4-tri-*t*-butylbenzene by Dale (10). The absence of vibrational fine structure has been attributed to a slight twisting of the benzene ring. This would result in a small decrease in overlap of the associated aromatic π-orbitals, which could account for the washing out of the aromatic fine structure in the ultraviolet spectrum. On the other hand the effect is a very subtle one compared to a seriously distorted benzene ring. Rapoport and Smolinsky (11) synthesized a highly strained 6,5,5,5-tetracyclic hydrocarbon which showed a much more dramatic change in ultraviolet absorption. In this case the spectrum was not only completely devoid of fine structure but showed a bathochromic shift of at least 8 mμ and approximately one-half the intensity of the corresponding unstrained analogue. A strikingly different behavior was shown by benzo[1,2:4,5]dicyclobutene examined by Cava and co-workers (12). The ultraviolet spectrum of this strained hydrocarbon showed a bathochromic displacement of 8–10 mμ from durene but the vibrational fine structure was preserved and furthermore the extinction coefficient of the strained hydrocarbon was 10 times *greater* than that of durene. Perhaps the strain in benzo[1,2:4,5]dicyclobutene manifests itself in an opening of the angles of the benzene ring which remains essentially planar, while the ring is actually slightly distorted in *o*-di-*t*-butylbenzene and derivatives.

If the *o*-*t*-butyl groups are seriously distorted from the plane of the ring, it is conceivable that derivatives of *o*-di-*t*-butylbenzene could exist in optically active forms (assuming the more likely "trans" distortion). Attempts to resolve *o*-phenylene-diisobutyric acid (III) through its brucine salt were completely unsuccessful. The salt was entirely homogeneous rather than consisting of diastereoisomeric forms. An attempt is being made to obtain detailed quantitative information on the "structure" of β,β'-dihydroxy-*o*-di-*t*-butylbenzene (IV) by X-ray analysis.* Unfortunately the crystal structure is a complex one with a large unit cell (approximately a cube of 17 Å) containing 16 molecules. The space group was found to be *Iba*2 with no center of symmetry and with two molecules in the asymmetric unit.

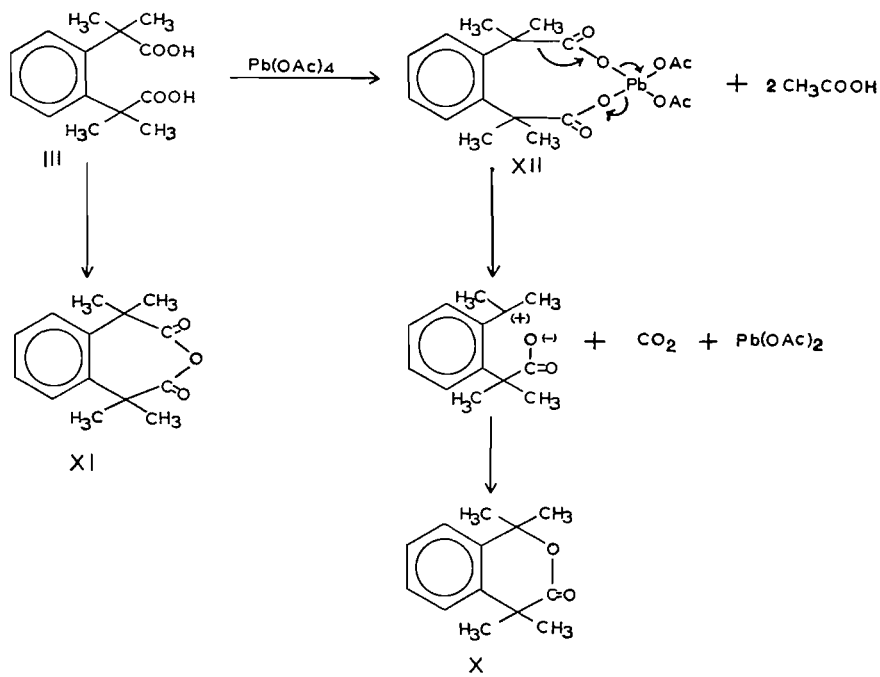
Periodic acid oxidation of 2,3-dioxo-1,1,4,4-tetramethyltetralin proceeded normally in aqueous dioxane at 70° to yield (64%) the acid (III). However a new neutral compound accompanied the formation of this acid and when the oxidation was carried out at the

*The authors are indebted to Dr. A. W. Hanson, Division of Pure Physics, National Research Council, for the X-ray measurements.

boiling point of the solvent this neutral product was formed in 90% yield. This neutral compound analyzed for $C_{13}H_{16}O_2$ and was shown to have the lactone structure (X) on the following evidence. Carbonyl absorption was shown in the ester region of the infrared at 1729 cm^{-1} and a strong band for *o*-disubstitution was present at 760 cm^{-1}. The ultraviolet spectrum of X showed characteristic aromatic absorption at 262.5 mμ, ϵ = 271 and 270 mμ, ϵ = 236 which was almost identical with that of 1,1,4,4-tetramethyltetralone (I). Mass spectral analysis of X showed the theoretical parent mass of 204, and fragment masses corresponding to loss of CH_3, CO_2, and $CO(CH_3)_2$ were observed. The n.m.r. spectrum of X showed two bands for C-methyl absorption. One appeared at 8.40 p.p.m. corresponding in intensity to six protons. The other band of equal intensity was shifted downfield to 8.30 p.p.m. due to the adjacent oxygen function. The four aromatic protons absorbed at 2.74 p.p.m.

Experiments on the mechanisms of formation of X showed that it formed from the acid (III). This acid was oxidized with periodic acid in aqueous dioxane to yield X. Treatment of III with lead tetraacetate in anhydrous dioxane or with periodic acid in glacial acetic acid yielded a mixture of approximately equal amounts of lactone (X) and the acid anhydride (XI) (m.p. 98–99°). The same anhydride resulted from dehydration of III with acetic anhydride. Colonge and Lagier earlier reported (13) the preparation of this anhydride with a melting point of 116°. Their compound probably has a different structure than XI since we have independent evidence that their starting material for oxidative degradation was not the proposed 1,1,5,5-tetramethyl-6,7-benzosuberane but rather was 1-isopropyl-4,4-dimethyltetralin. The acid (III) was recovered unchanged from heating with mineral acids or with hydrogen peroxide or benzoyl peroxide in various solvents. It appears that this reaction is specific for periodic acid and lead tetraacetate.

McCoy and Zagalo (14) reported a decarboxylation and lactonization of 2,3-diphenylglutaric acid with lead tetraacetate. Because the more stable (trans) lactone formed,



they favored a non-concerted mechanism, either radical or carbonium ion. Other workers (15) favor ionic mechanisms for the decarboxylation of organic acids by lead tetraacetate. It is possible that formation of the lactone (X) from the acid (III) involves intermediate formation of a cyclic compound such as XII. The latter could decompose by an ionic mechanism to the lactone. Anhydride formation which occurred in anhydrous solvents may take place prior to formation of the cyclic intermediate. A free radical mechanism can also be written for these reactions but the expectation that a free radical reaction could be catalyzed by peroxides was not realized.

EXPERIMENTAL

The melting points were obtained on a hot stage equipped with a microscope and are uncorrected. Ultraviolet spectra were recorded on a Beckman DK-2 spectrophotometer and infrared spectra on a Perkin–Elmer Model 136 Infracord. Reaction products were analyzed on a Perkin–Elmer Model 154-D vapor fractometer. The mass spectroscopic and nuclear magnetic resonance spectra were obtained in independent laboratories. The 1,1,4,4-tetramethyltetralone used was prepared by a procedure similar to that reported (7). The purified compound had m.p. 76.5–77.5°; λ_{max} 263.5 mμ, ϵ = 259 and 271 mμ, ϵ = 223. The infrared spectrum showed carbonyl absorption at 1700 cm^{-1} and a band for *o*-disubstitution at 755 cm^{-1}.

2,3-Dioxo-1,1,4,4-tetramethyltetralin (II)

1,1,4,4-Tetramethyl-2-tetralone (25.0 g, 0.12 mole) was dissolved in 200 ml of freshly purified dioxane, and selenium dioxide (14.0 g, 0.125 mole) was added. The reaction mixture was stirred and refluxed for 44 hours. After cooling and filtering, the solvent was removed under reduced pressure on the steam cone to yield a crude crystalline product. Recrystallization from petroleum ether yielded 22.3 g (86% yield) of yellow crystals (m.p. 61.5–63°). The ultraviolet spectrum of this compound had bands at 267 mμ, ϵ = 429 and 273 mμ, ϵ = 369. The infrared spectrum had a strong carbonyl band at 1700 cm^{-1} and a band for *o*-disubstitution at 755 cm^{-1}. Anal. Calc. for $C_{14}H_{16}O_2$: C, 77.74; H, 7.46; O, 14.80. Found: C, 77.85, 77.85; H, 7.57, 7.62; O, 14.89, 14.80.

The Action of Periodic Acid on II

(A) Preparation of o-Phenylene-diisobutyric Acid (III) and Methyl Ester

2,3-Dioxo-1,1,4,4-tetramethyltetralin (41.0 g, 0.19 mole) was dissolved in 435 ml of dioxane–water, and 50.1 g (0.22 mole) of paraperiodic acid was added. The reaction mixture was stirred and heated at 70° for a total of 40 hours. The solvent was removed under reduced pressure on the steam cone to leave a solid residue. This solid was taken up in ether and extracted with 10% sodium hydroxide. On acidification of the alkaline extract, a flocculent white precipitate was obtained. Recrystallization from ethyl acetate yielded 30.2 g (64% yield) of *o*-phenylene-diisobutyric acid (III) (m.p. 218–219°). The ultraviolet spectrum of this acid had a broad band at 262 mμ, ϵ = 233 (methanol). The infrared spectrum showed carbonyl absorption at 1680 cm^{-1} and *o*-disubstitution at 755 cm^{-1}. Anal. Calc. for $C_{14}H_{18}O_4$: C, 67.16; H, 7.25; neut. equiv., 125. Found: C, 67.03, 67.15; H, 7.32, 7.32; neut. equiv., 123.9, 124.4.

The neutral material from the preparation of the acid (III) was a viscous liquid (6.7 g). Vapor phase, infrared, and ultraviolet analyses of this material showed it to be identical with the neutral lactone (X) described below (B).

o-Phenylene-diisobutyric acid (25.0 g, 0.10 mole) was dissolved in ethyl ether and an ethereal solution of excess diazomethane was added slowly with stirring. The reaction mixture was allowed to stand in the refrigerator overnight. The solvent was then distilled, leaving a crude crystalline product. Recrystallization from petroleum ether yielded colorless crystals (27.3 g, 98%), m.p. 102–103°. Anal. Calc. for $C_{16}H_{22}O_4$: C, 69.03; H, 7.97; O, 23.00. Found: C, 69.33; H, 8.01; O, 23.39.

The ultraviolet spectrum of this ester showed a strong band at 264 mμ, ϵ = 252 (methanol). The infrared spectrum showed carbonyl absorption at 1720 cm^{-1} and a strong band at 752 cm^{-1} attributed to *o*-disubstitution (carbon disulphide).

(B) Formation of Lactone (X)

The diketone (II) (25.0 g, 0.12 mole) was oxidized with paraperiodic (31.0 g, 0.14 mole) in 250 ml of aqueous dioxane under similar conditions as above (A) except that the reaction mixture was refluxed (100°). On working up the reaction mixture as before, only 2.03 g (7%) of acidic material (III) was isolated. The major part of the reaction was a neutral product (22 g, 77%). This neutral compound was purified by chromatography of a petroleum ether solution on alumina. The compound crystallized on vacuum distillation from a Späth tube. Recrystallization from petroleum ether yielded colorless crystals, m.p. 50–51°. Anal. Calc. for $C_{13}H_{16}O_2$: C, 76.44; H, 7.89; O, 15.67. Found: C, 76.63, 76.49; H, 7.75, 7.85; O, 15.67,15.76.

The ultraviolet spectrum of this compound showed bands at 262.5 mμ, ϵ = 271 and 270 mμ, ϵ = 236 (cyclohexane). The infrared spectrum showed carbonyl absorption at 1729 cm^{-1} and a strong band attributed

to *o*-disubstitution at 765 cm^{-1} (carbon disulphide). High-temperature mass spectroscopic analysis showed a parent mass of 204. Large peaks for fragment masses were present at 189, 161, and 145.

β,β′-Dihydroxy-o-di-t-butylbenzene (IV)

Lithium aluminum hydride (14.8 g, 0.39 mole) was dissolved in 750 ml of dry ethyl ether in a three-necked flask equipped with a dropping funnel and a reflux condenser protected by a calcium chloride drying tube. Dimethyl-*o*-phenylene-diisobutyrate (27.1 g, 0.097 mole) was dissolved in 750 ml of dry ethyl ether and added dropwise to the reaction mixture over a period of 1.5 hours. The reaction mixture was refluxed for 27 hours. It was decomposed in ice water and made just acid with hydrochloric acid. The ether layer was separated, washed free from acid with water, and dried over sodium sulphate. Evaporation of the solvent left a white crystalline compound which, on recrystallization from petroleum ether – acetone, yielded 18.5 g (86% yield) of colorless crystals, m.p. 115–116°. Anal. Calc. for $C_{14}H_{22}O_2$: C, 75.63; H, 9.98; O, 14.39; active hydrogen, 0.90. Found: C, 75.34, 75.92; H, 9.98, 9.94; O, 15.12; active hydrogen, 0.90.

The infrared spectrum of this diol in a KBr pellet showed broad hydroxyl absorption at 3350 cm^{-1}. A strong band at 1037 cm^{-1} was attributed to the $—CH_2OH$ groupings and a strong band at 750 cm^{-1} to *o*-disubstitution. In chloroform solution the hydroxyl absorption appeared as two bands, at 3400 and 3570 cm^{-1}. The ultraviolet spectrum showed a broad band at 265 mμ, $\epsilon = 225$ (methanol).

Ditosylate (V) of IV

β,β′-Dihydroxy-*o*-di-*t*-butylbenzene (18.5 g, 0.083 mole) was dissolved in 100 ml of pyridine and cooled to 0°. Tosyl chloride (47.4 g, 0.249 mole) was similarly dissolved in 100 ml of pyridine and cooled to 0°. The tosyl chloride solution was then added to the diol solution and the resulting mixture left at room temperature for 24 hours. About 200 ml of water was then added and a white solid came out of solution. This was extracted with chloroform, washed with ice-cold 15% sulphuric acid, saturated sodium bicarbonate solution, and finally with water. After drying over sodium sulphate, the solvent was removed under reduced pressure at 38° to yield a white crystalline solid. Two recrystallizations from petroleum ether – chloroform yielded 36.7 g (83% yield) of ditosylate (V) (m.p. 110–111°). Anal. Calc. for $C_{28}H_{34}S_2O_6$: C, 63.37; H, 6.46; O, 18.09; S, 12.08. Found: C, 63.36, 63.32; H, 6.57, 6.67; O, 17.80, 17.79; S, 12.38, 12.49.

The ultraviolet spectrum of this compound showed bands at 262 mμ, $\epsilon = 1293$ and 273 mμ, $\epsilon = 1082$.

Lithium Aluminum Hydride Reduction of V, o-Di-t-butylbenzene

The ditosylate (V) (18.0 g, 0.034 mole) was dissolved in 1800 ml of anhydrous ethyl ether, and lithium aluminum hydride (14.2 g, 0.37 mole) was added all at once. The reaction mixture was stirred at room temperature for 2 days. It was then decomposed in ice water, made slightly acidic with hydrochloric acid and the resulting mixture extracted continuously with ethyl ether for 2 days. The extract was dried over anhydrous sodium sulphate and the solvent distilled to leave 6.3 g of a liquid residue. Vapor phase analysis at 198° of this product on a column of apiezon L grease (column "Q") indicated that there were three major components present (A, B, and C). These components were cleanly separated on this column with retention times of A = 95.5, B = 112.5, and C = 147 respectively. Quantitative vapor phase analysis indicated that the relative amounts of the components present were 19% A, 21% B, and 44% C. The original reaction product was reduced in methanol solution with hydrogen over a palladium – calcium carbonate catalyst at 50 p.s.i. Vapor phase analysis of the reduced material showed that component A had disappeared and component B was correspondingly increased. The proportion of component C was unchanged.

Larger quantities of the three components produced in the hydride reduction of V were obtained by vapor chromatography. This was accomplished by repetitive runs on an apiezon L grease column at 198° and by superheating the outlet from the vapor fractometer to 240° with electric heating tape. In this way the components were distilled into the collector as they eluted from the column rather than condensing and remixing.

The major component (C; *o*-di-*t*-butylbenzene) was a crystalline compound, m.p. 24–27°. Anal. Calc. for $C_{14}H_{22}$: C, 88.35; H, 11.65. Found: C, 88.13, 88.22; H, 11.60, 11.64.

The infrared spectrum of this compound showed a strong band at 755 cm^{-1} attributed to *o*-disubstitution. Bands at 1390, 1360, 1230, and 1195 cm^{-1} were assigned to *t*-butyl groups. The ultraviolet spectrum showed one band without fine structure at 262.5 mμ, $\epsilon = 214$.

Component A (unsaturated hydrocarbon) was similarly isolated by vapor phase analysis. This compound was obtained as a colorless oil. Anal. Calc. for $C_{14}H_{20}$: C, 89.29; H, 10.71. Found: C, 89.28, 89.15; H, 10.78, 10.72.

The infrared spectrum of this compound showed a strong band at 760 cm^{-1} attributed to *o*-disubstitution and a strong band at 837 cm^{-1} assigned to the out-of-plane deformation of an olefinic proton. The ultraviolet spectrum showed only general absorption (260 mμ, $\epsilon = 1055$).

Component B from the vapor phase analysis (also the reduction product of A) was not isolated for detailed analyses. However, the ultraviolet spectrum of B showed absorption typical of *o*-disubstituted aromatic hydrocarbons with vibrational fine structure.

The Action of Periodic Acid on o-Phenlyene-diisobutyric Acid (III)

(A) In Aqueous Dioxane

The acid (III) (1.0 g, 0.004 mole) and paraperiodic acid (0.91 g, 0.004 mole) were dissolved in a mixture of 15 ml of dioxane and 9 ml of water. The reaction mixture was stirred and refluxed for 45 hours. The solvent was removed under reduced pressure on the steam cone and the residue treated with ether. The ether extract was washed with 10% sodium hydroxide but no acid was recovered from the alkali extract. Distillation of the solvent from the ether extract left a semisolid residue (0.80 g). Ultraviolet, infrared, and vapor phase analyses of this material indicated it to be the lactone (X).

(B) In Glacial Acetic Acid

The acid (III) (0.50 g, 0.002 mole) and paraperiodic acid (0.46 g, 0.002 mole) were dissolved in glacial acetic acid and the solution heated at 100° for 2 days. The solvent was distilled under reduced pressure on the steam cone and the residue treated with ethyl ether. Some unreacted acid (III) (0.07 g) was recovered from this ether extract by extraction with 10% sodium hydroxide. The ether extract yielded 0.33 g of solid material. This material was analyzed on the vapor fractometer and found to contain 41% of the lactone (X) and 59% of the anhydride of *o*-phenylene-diisobutyric acid. The same anhydride was prepared for comparison purposes as described below.

o-Phenylene-diisobutyric acid (0.35 g, 0.0014 mole) was dissolved in 6.0 ml of acetic anhydride and the solution refluxed for 3 hours. The solvent was distilled under reduced pressure to yield 0.30 g (92%) of colorless crystals. Recrystallization from petroleum ether produced colorless crystals of m.p. 98–99°. Anal. Calc. for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94; O, 20.67. Found: C, 72.28; H, 6.87; O, 20.41.

The infrared spectrum of this anhydride showed a doublet at 1770 and 1725 cm^{-1} for carbonyl absorption. A band at 765 cm^{-1} was attributed to *o*-disubstitution. The ultraviolet spectrum did not show definite maxima but exhibited shoulders at 260 mμ, ϵ = 339 and 267 mμ, ϵ = 212.

The Action of Lead Tetraacetate on III

o-Phenylene-diisobutyric acid (8.00 g, 0.032 mole) was dissolved in 300 ml of purified anhydrous dioxane, and lead tetraacetate (14.24 g, 0.032 mole) added. The mixture was stirred and heated at 75° for 21 hours. The solvent was distilled under reduced pressure on the steam cone and the organic residue dissolved in ethyl ether. The product from the ether extract was found to contain a mixture of approximately equal amounts of the lactone (X) and the anhydride (m.p. 98–99°) by vapor phase analysis.

ACKNOWLEDGMENTS

The authors express their appreciation to the National Research Council for financial support of this research. One of us (C. E. M.) was a recipient of a N.R.C. Studentship.

LIGNIN MODEL COMPOUNDS

II. PREPARATION AND PROPERTIES OF 1-HYDROXY-1-(4-HYDROXY-3-METHOXYPHENYL)-2-PROPANONE*

J. A. F. Gardner, D. W. Henderson, and Harold MacLean

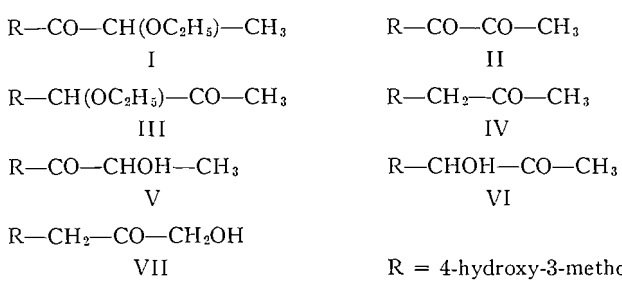
Vancouver Laboratory, Forest Products Research Branch, Department of Forestry of Canada, Vancouver, British Columbia

Received April 3, 1962

ABSTRACT

Modern concepts of lignin structure suggest that the ketol 1-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone, VI, should be detectable in the hydrolysis products of lignin and wood. A reference sample of VI, previously unavailable, has now been prepared by catalytic hydrogenation of the diketone 1-(4-hydroxy-3-methoxyphenyl)-1,2-propanedione, II. Both fermentative and catalytic hydrogenation of II gave mixtures of, according to paper chromatography, mainly 2-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone, V; the desired ketol, VI; small amounts of vanillic acid; and traces of guaiacyl acetone and an unknown phenolic compound. The ketol VI was isolated from the catalytic hydrogenation products by solvent fractionation and was identified by absorption spectra, derivatives, and comparison with the other two possible isomeric ketols. Dilute alkali converted VI to the isomeric ketol V. Both ethanolysis and acidolysis of VI gave the same monomeric products as lignin.

Since the discovery by Hibbert and co-workers (1) that the four guaiacylpropane derivatives I–IV were produced by refluxing extractive-free coniferous wood with ethanol containing a small percentage of hydrogen chloride, extensive studies have been conducted on related monomers and dimers as model compounds for lignin reactions. In this way significant new knowledge of lignin structure and behavior has been acquired.

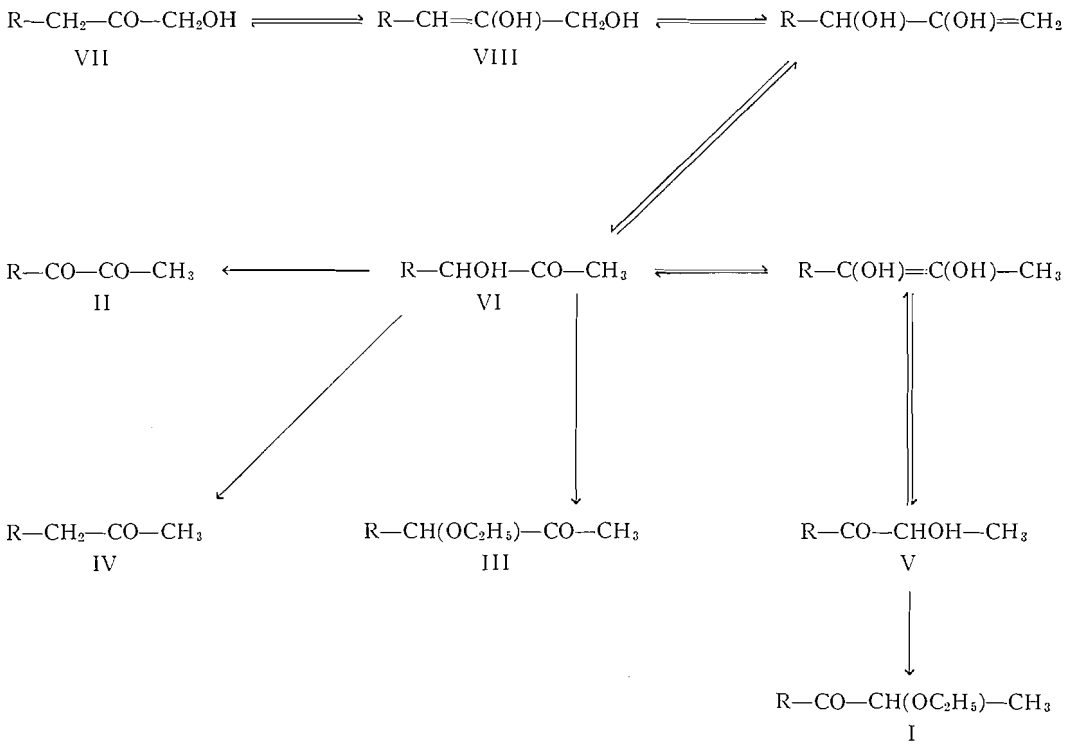


In seeking an explanation for the formation from lignin of the "ethanolysis" products, the synthesis and study of the three isomeric α-ketols V, VI, and VII were undertaken by the Hibbert group. The synthesis of V, 2-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone, and VII, 3-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone, was accomplished (2, 3) but repeated attempts failed to provide VI, 1-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone, and therefore it was necessary to perform ethanolysis and other reactions on its diacetate (4). Wacek and Horak (5) also attempted to prepare VI but found, as had Mitchell (6), that even very mild deacetylation techniques applied to the diacetate of VI invariably resulted in rearrangement to the more stable V. These findings were in accord with the results obtained with related alkylaryl α-ketols by Auwers and Noll (7) and Temnikova (8). Thus methylbenzoyl carbinol (V, R = phenyl) rearranged with a variety of reagents to phenylacetyl carbinol (VI, R = phenyl) whereas

*Paper presented at the 44th Annual Conference, Chemical Institute of Canada, Montreal, Quebec, August 3–5, 1961.

substitution of a methoxyl or hydroxyl group into the para position of the benzene ring stabilized the methylbenzoyl carbinol and completely reversed the order of stability. In the guaiacylpropane series, therefore, the para hydroxyl group stabilizes the 2-hydroxy derivative V and accounts for the difficulties experienced in attempts to prepare the 1-hydroxy derivative VI.

In a previous paper (9) strong experimental support was provided for Hibbert's proposal that the ethanolysis products, I–IV, are derived from lignin via a more reactive β-hydroxyconiferyl alcohol unit, VIII, by a series of rearrangements:



R = 4-hydroxy-3-methoxyphenyl

The relatively small amount of the ethyl ether, III, of the ketol VI compared to that of I of the ketol V obtained in lignin ethanolysis is consistent with the above scheme and the apparent relative stability of the ketols.

The same explanation applies to the formation of the lignin ethanolysis products by ethanolysis of guaiacylglycerol and its β-guaiacyl and β-coniferyl ethers, substances which have been found to be excellent model compounds for the study of characteristic lignin reactions (10). A primary α–β dehydration would yield an enol ether which would hydrolyze to β-hydroxyconiferyl alcohol, VIII. According to this scheme small amounts of the intermediate 1-hydroxy ketone VI should occur in the hydrolysis and acidolysis products of lignin and lignin model compounds. Goldschmid (11) suspected that an unknown substance detected among the products of aqueous hydrolysis of extractive-free western hemlock woodmeal was the 1-hydroxy derivative VI but this awaits confirmation. Adler *et al.* (12) showed that refluxing guaiacylglycerol-β-guaiacyl ether and two isolated lignins with dioxane–water containing 0.2 *N* hydrogen chloride ("acidolysis") gave a mixture

of products containing the 2-hydroxy ketone V, the diketone II, and guaiacyl acetone, IV. Other guaiacylpropane derivatives, if present, were not identified. The purpose of the present work was to prepare a sample of the 1-hydroxy compound VI for reference purposes in lignin hydrolytic studies and to permit a study of its properties in relation to lignin and related propylphenols.

In seeking methods that would avoid the chance of acid- and base-catalyzed rearrangements in the final stages, the possibility of preparing VI by treating vanillin with fermenting sugar solutions was investigated. Neuberg and Hirsh (13) had found that addition of benzaldehyde to sugar solutions yielded some phenylacetyl carbinol as well as benzyl alcohol. Application of this technique to vanillin showed that as well as the main product, vanillyl alcohol, minor amounts of vanillic acid, and two unknown compounds were produced. Paper chromatographic examination showed that neither of these was the known 2-hydroxy derivative V. While it was considered possible that some of the desired 1-hydroxy compound VI was present, this technique as a method of preparation was abandoned because of the obvious difficulties in purification. Subsequently, reports of the similar work of Higuchi *et al.* (14) came to hand. These workers also found that vanillyl alcohol, vanillic acid, and small amounts of the diketone II were formed from vanillin in fermenting sugar solution. Another minor product detected by paper chromatography (15) was believed to be the 1-hydroxy derivative VI but no confirmation has been published.

The hydrogenation of the diketone II as a means of preparing a sample of VI was investigated. This approach would eliminate contamination of the products with reduction products of vanillin. Both phytochemical and catalytic reduction methods were examined.

Addition of the yellow diketone to fermenting sucrose solution resulted in rapid decolorization. Descending paper chromatography in two solvent systems showed the presence of six phenolic substances: the ketol V (the main component), vanillic acid, unchanged diketone (trace), guaiacyl acetone, IV (trace), and two unknown compounds. One of these ($R_f = 0.89$ in butanol–ethanol–ammonia–water, 40:10:1:49 v/v) gave a pink color with diazotized sulphanilic acid (DSA) and was present in traces. The other ($R_f = 0.76$), present in substantial quantities, gave an orange color with DSA.

When the diketone II was treated in ethanol with 1 mole of hydrogen at room temperature and pressure over a palladium–barium sulphate catalyst prepared according to Kuhn (16), a very similar mixture of phenolic products was obtained according to paper chromatography. In this case the mixture was not contaminated with yeast and sugar fermentation products and it crystallized on standing. Recrystallization from benzene gave the pure 2-hydroxy derivative V. Attempts to isolate the other products by chromatography on celite and cellulose columns were unsuccessful. However, extraction of an ether solution of the mixture with aqueous bisulphite solution gave a bisulphite-soluble fraction containing the substance $R_f = 0.76$, believed to be the desired 1-hydroxy derivative, VI, contaminated with unreacted diketone, II. Distribution of this fraction between benzene and water gave a good separation, the diketone being retained in the benzene layer.

The product isolated from the aqueous layer as a colorless oil gave a strongly positive test for *p*-hydroxybenzyl alcohols with quinone monochloroimide (17) and exhibited only one spot on paper chromatograms using several solvent systems. It slowly crystallized and after recrystallization from ether–petroleum ether had a melting point of 53–54° C. The ultraviolet and infrared absorption spectra were consistent with a 1-aryl-2-propanone structure. Proof that it was the expected 1-hydroxy derivative, VI, was

provided by preparing the diacetate, which, obtained in high yield, was identical with an authentic sample of the diacetate of VI synthesized by the method of Mitchell and Hibbert (4).

It was of interest to determine the relative proportion of the two α-ketols V and VI produced by catalytic hydrogenation of the diketone. By quantitative paper chromatography (18), the mixture was found to consist of 73% 2-hydroxy derivative, V; 13% 1-hydroxy derivative, VI; 14% unchanged diketone; 2.6% vanillic acid; and a trace of guaiacyl acetone, IV, and an unknown ($R_f = 0.89$).

No systematic investigation of the effect different solvents or catalysts might have on the hydrogenation of the diketone was undertaken. However, after this paper was presented, the results of Adler and Marton (19) on the hydrogenation of a series of lignin model compounds became available. Using 93% acetic acid as solvent and a palladium chloride – barium sulphate catalyst, unwashed after prehydrogenation, they found that carbonyl groups conjugated to the guaiacyl ring, as in the ketol V and the diketone II, were reduced rapidly, whereas those in the position β to the ring, as in IV, were practically unaffected. Thus rapid addition of 2 moles of hydrogen to the diketone was reported to yield guaiacyl acetone, IV, via hydrogenation and then hydrogenolysis, the β-carbonyl not being reduced. This report prompted us to hydrogenate the diketone with Kuhn's catalyst (16) in 95% acetic acid instead of ethanol. After addition of 1 mole of hydrogen, the products were approximately the same as when ethanol was used as solvent, the main product being, as before, the 2-hydroxy derivative V. The indicated marked effect of the catalyst on the course of the reaction is now being investigated.

Ethanolysis of 1-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone, VI, gave the same propylphenol products, I–IV, as lignin, in accord with the prior work on the diacetate (4).

Treatment of VI with dilute alkali at 95° C rapidly brought about complete conversion to the 2-hydroxy derivative V, a result predictable from the findings of Mitchell (6) and of Wacek and Horak (5).

Acidolysis of VI in dioxane–water according to the method of Adler *et al.* (12) gave a mixture consisting of mainly the 2-hydroxy derivative V and the diketone II with traces of vanillic acid, vanillin, and an unknown phenol. Both V and II were obtained by Adler *et al.* by the acidolysis products of wood and isolated lignin. After 4 hours of acidolysis, roughly 10% of the ketol VI was unchanged. This measure of stability indicates that there is a good possibility of detecting the occurrence of the ketol VI in the acidolysis and hydrolysis products of lignins and wood.

The preparation of 1-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone, VI, completes the syntheses of the three possible α-ketols in the guaiacylpropane series and provides reference samples for use in lignin degradation studies. Its behavior in ethanolysis and acidolysis reactions confirms conclusions based on prior studies with derivatives and isomers.

EXPERIMENTAL

Solvent systems for paper chromatographic examinations were butanol–ethanol–ammonia–water (40:10:1:49 v/v) (BEAW) and tetrahydrofuran – petroleum ether (65–110°) – water (3:7:5 v/v) (THF). In the case of the latter system R_f's depended to a marked extent on the care exercised in equilibrating the paper with the solvent and therefore are not quoted.

Preparation of Diketone 1-(4-Hydroxy-3-methoxyphenyl)-1,2-propanedione, II

Two methods were used: 2-hydroxy-1(4-hydroxy-3-methoxyphenyl)-1-propanone was prepared from guaiacol and oxidized with copper sulphate by the method of Brickman *et al.* (20), or propiovanillone (22)

was converted with isobutyl nitrite by the method of Fodor *et al.* (21) to the α-oximino ketone, which was hydrolyzed to the diketone with 2% HCl at reflux or with 12 *N* H_2SO_4 at room temperature. The yellow diketone was extracted with benzene and recrystallized from petroleum ether, m.p. 62–63° C.

Preparation of 1-Hydroxy-1(4-hydroxy-3-methoxyphenyl)-2-propanone, VI

Kuhn's catalyst (16) (0.5 g) was added to 95% ethanol (50 ml), the flask evacuated, and the contents equilibrated with H_2 (13.7 ml) by mechanical shaking at slight pressure. The diketone (3 g = 0.0155 mole) was added, the flask again evacuated, and H_2 (348 ml = 0.0155 mole) added with mechanical shaking over 21 minutes. The catalyst was filtered and washed with ethanol, the filtrate and washings being evaporated under reduced pressure to yield a yellow oil (3 g). This oil gave a positive color test for *p*-hydroxybenzyl alcohols with quinone monochloroimide (17), and descending paper chromatographic examination showed the presence of six substances giving positive color reactions with DSA. The use of reference samples established the presence of vanillic acid (orange, R_f 0.22 BEAW); 2-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone, V (tan, R_f 0.54); diketone II (tan, R_f 0.60); guaiacyl acetone, IV (red, R_f 0.89); and two unknowns (strong orange, R_f 0.76; and weak red, R_f 0.89). The unknown with the same R_f on paper as guaiacyl acetone using BEAW was readily separated from it with the other solvent (THF).

The unknown with the orange color reaction, which also gave a positive 2,4-dinitrophenylhydrazone test, was isolated by the following fractionation, each step being monitored by paper chromatography. A diethyl ether solution (100 ml) was extracted with 15% sodium bisulphite solution (4×20 ml), then was back-extracted with diethyl ether (4×25 ml) to ensure removal of the 2-hydroxy derivative V and vanillic acid from the bisulphite-soluble compounds. The bisulphite solution was acidified to pH 3 with 6 *N* H_2SO_4, stripped of SO_2 using partial vacuum and a nitrogen bubbler, and then extracted with chloroform (5×25 ml). After drying, the chloroform was evaporated to leave a yellow oil which in benzene solution (50 ml) was extracted with water (5×25 ml). The water after back extraction with benzene (2×25 ml) was extracted with chloroform (7×25 ml). Drying and removal of the chloroform left a colorless oil (280 mg; 9% yield) which slowly crystallized. This material showed only one spot (orange, R_f 0.76 BEAW) on a papergram. Recrystallization from ether – petroleum ether gave colorless crystals, melting point 53–54° C. The infrared absorption spectrum, ν_{KBr}^{max} in cm^{-1} 3450, 3325, 2950, 2860, 1700 (unconjugated carbonyl), 1610, 1516, 1470, 1433, 1355, 1270, 1150, 1125, 1080, 1030, 866, 814, 735, was consistent with structure VI being very similar to that of the isomeric α-ketol VII (9). The ultraviolet absorption spectrum in ethanol (max. 282 mμ; min. 261 mμ; shoulder 234 mμ) was also consistent with this formulation. The semicarbazone, m.p. 170.5–172° C from hot water, differed from those of authentic specimens of the two α-ketols V and VII, m.p. 147–148 and 194–196° C respectively, prepared by identical procedures. The diacetate prepared in high yield (80%) by a 5-minute reflux in acetic anhydride – pyridine was identical by mixed melting point, 95.5–96° C, and infrared spectra with an authentic sample of 1-acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone synthesized by the method of Mitchell and Hibbert (4).

If the oily hydrogenation product from the diketone was seeded with the 2-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone, V, partial crystallization occurred. Trituration with cold benzene followed by recrystallization from benzene gave colorless crystals, m.p. 110–111° C, identical with authentic V.

The presence of vanillic acid in the diketone hydrogenation product was proved by extraction of the ether solutions with cold 5% sodium bicarbonate solution. Acidification gave crystalline material identical with an authentic sample of vanillic acid.

Quantitative Estimation of Diketone Hydrogenation Products

A quantitative paper chromatographic method (18) with BEAW as developing solvent and Folin–Ciocalteu reagent for phenols was used, the spots being detected with ultraviolet light. Optical densities were measured at 750 mμ on a Beckman DK-2.

Ethanolysis of 1-Hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone

A sample (20 mg) was refluxed with ethanol – 3% HCl (1.5 ml) for 24 hours in a carbon dioxide atmosphere. After cooling, the mixture was added to water (10 ml) and filtered. The filtrate was extracted with ether, the extract dried, and solvent removed. Paper chromatographic examination of the residue in comparison with synthetic mixtures of authentic specimens using BEAW, 20% aqueous KCl, and isopropanol–ammonia–water (8:1:1 v/v) as solvents showed the presence of the ethanolysis products I–IV.

Alkaline Rearrangement of 1-Hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone

A sample (36 mg) was dissolved in 1% NaOH (15 ml), forming a yellow-colored solution which turned orange on warming under a nitrogen atmosphere on a steam bath (95° C) for ½ hour. Acidification and extraction with chloroform yielded, after removal of the solvent, a yellowish oil (30 mg) which slowly crystallized. It was shown to be the isomeric 2-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone by infrared absorption spectrum and chromatographic comparison with an authentic sample in BEAW and 20% aqueous KCl.

Acidolysis of 1-Hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone

The ketol VI (10 mg) was refluxed in dioxane–water (9:1) (15 ml) containing 0.2 *N* hydrogen chloride by weight for 4 hours (12). The mixture was neutralized with sodium bicarbonate, evaporated to remove

most of the dioxane, diluted with water (10 ml), and extracted with chloroform (3×20 ml). Removal of the chloroform yielded a yellow oil (9 mg). Paper chromatography with BEAW solvent, THF solvent, and 20% aqueous KCl using DSA and ultraviolet light for detection showed, besides unchanged starting material (roughly 10%), the 2-hydroxy isomer V and the diketone II with traces of vanillin, vanillic acid, and an unknown phenol.

THE PROTON RESONANCE SPECTRUM OF 2-FURANACROLEIN

T. SCHAEFER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received April 30, 1962

ABSTRACT

The proton resonance spectrum of 2-furanacrolein consists of two effectively independent ABX spectra, that due to the ring protons and that due to the side-chain protons. The solvent effects are such that the latter reduces to an AA^1X case. The ABX and AA^1X cases are discussed as deviations from the A_2X case. The difference is simply that forbidden singlet–triplet transitions in the A_2X case become allowed in the ABX case because the singlet and triplet states are uncoupled as the A_2 nuclei become nonequivalent. Energy level diagrams are given to illustrate this situation.

INTRODUCTION

Abraham and Bernstein give a detailed discussion of the analysis of deceptively simple high-resolution n.m.r. spectra (1). These arise, in the simplest instance, when a given nucleus, X, is coupled differently to two other nuclei, A and B, which themselves are strongly coupled. The observed splittings in the spectra of the three nuclei are then equal to the average of the coupling constants J_{AX} and J_{BX}. J_{AB} is unobservable in this case.

Musher (2) has recently remarked on this phenomenon in connection with an anomalous interpretation of certain fluorine–fluorine coupling constants (3) and calls it "virtual coupling". In the course of a study of solvent effects on proton resonance spectra we have noticed a good example of this. It appears profitable to discuss this example in terms of a general theorem on high-resolution n.m.r. spectra. It supplements the treatment of Abraham and Bernstein in an interesting way and should perhaps be read together with it.

The ABX, AA^1X, A_2X Systems

A pair of spins can be said to be isochronous if they have the same chemical shift. If, in addition, the spins have the same coupling constant with every other spin of the molecule they are said to be equivalent. A pair of spins can be equivalent only if they are isochronous. There is a well-known theorem stating that scalar couplings between equivalent spins are unobservable in a nuclear resonance experiment (4, 5). The proof of this theorem does not depend on symmetry in any way.

By definition the A protons of the A_2X system satisfy the theorem. The positions of the two A protons can usually be made to coincide through an operation of the symmetry group of the molecule. In that case their spin functions combine to form singlet and triplet states. Since singlet–triplet transitions are forbidden none of the observed transitions depend on the coupling constant between the A protons.

If the A protons are isochronous but unequally coupled to proton X they are nonequivalent and the theorem no longer applies. This situation is usually designated as AA^1X. The effect is to uncouple partially the singlet and $F_z(A) = 0$ triplet states of the A protons. This is also so if the A protons are not isochronous, but are equally coupled to proton X. When the nonequivalence arising in either of these two ways is large enough the coupling between the A protons becomes observable.

The two situations are intermediate stages in the conversion of an A_2X system, which gives rise to 5 lines, to the general ABX system, which has 14 lines in its spectrum. This is illustrated in Fig. 1, where the energy levels are given for six different cases as follows:

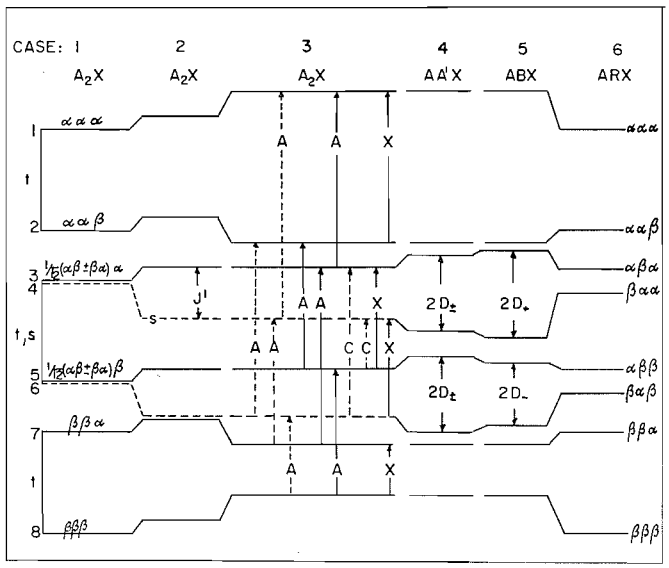

FIG. 1. The energy level diagram for a system of three-spin $\frac{1}{2}$ nuclei with one nucleus having a large relative chemical shift from the other two. The letters s and t indicate singlet and triplet states for the latter nuclei. Transitions are given by vertical arrows and those marked A are for the coupled nuclei. The various cases are described in the text.

(1) $\delta = 0 = J_1 = J_2 = J^1$;
(2) $\delta = 0 = J_1 = J_2, J^1 > 0$;
(3) $\delta = 0, J_1 = J_2 = J^1 > 0$;
(4) $\delta = 0, J_1 - J_2 > 0, J_1 + J_2 = 2J^1$ or $\delta > 0, J_1 = J_2 = J^1 > 0$;
(5) $\delta > 0, J_1 - J_2 > 0, J_1 - J_2 < \delta, J_1 + J_2 = 2J^1$;
(6) $\delta > 0, J_1 = J_2 = J^1 = 0$.

Here δ is the shift between the two A protons, J_1 and J_2 are the coupling constants between the A and X protons, and J^1 is the coupling constant between the A protons. We assume, of course, that the shift between A and X protons is so large that it does not affect the shape of the spectra. We take $J_1 + J_2 = 2J_1$, all positive, without too great a loss of generality.

In Fig. 1 the antisymmetric singlet levels are indicated by horizontal broken lines. The maximum number of 14 transitions in systems of this kind is indicated. There are eight transitions which are always allowed and six of these become pairwise isoenergetic in the A_2X limit. The other 6 of the 14 are singlet–triplet transitions in the A_2X limit and are forbidden. They are indicated by broken vertical arrows. In the AA^1X or ABX limit they no longer have singlet–triplet character and become allowed. But two of them involve a spin flip of all three nuclei and are usually very weak. Their occurrence, however, allows one to determine the relative signs of J_1 and J_2. They are marked C in Fig. 1. As can be seen from the figure we cannot observe J^1 when $2D_\pm - J^1$ is less than the resolution of a good spectrometer, presently about 0.3 cycle/sec. D_+ and D_- are defined by

$$2D_\pm = \{[\delta \pm 1/2(J_1 - J_2)]^2 + (J^1)^2\}^{1/2}.$$

Abraham and Bernstein derive the condition $[\delta \pm 1/2(J_1 - J_2)]^2/2J^1 < 0.3$. Physically

this condition describes the point at which singlet–triplet states are sufficiently strongly uncoupled to be detectable experimentally.

The various spectra for such three-spin systems are very easily deduced from Fig. 1 and three of them are reproduced in Fig. 2. Here broken lines indicate forbidden transitions. Otherwise the figure is self-explanatory. For the ABX case the two quartets in the

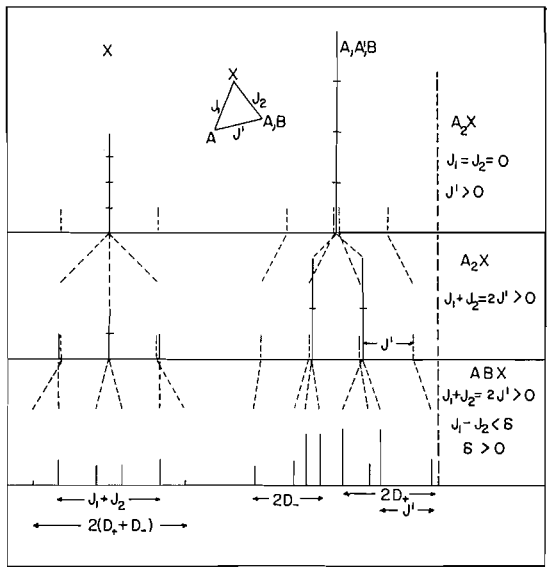

FIG. 2. The spectral shapes expected for three of the cases whose energy levels are illustrated in Fig. 1 and described in the text. Broken vertical peaks indicate forbidden transitions, allowed in the ABX case.

AB region corresponding to the two X spin states are easily picked out. It is, of course, the two outside lines of each quartet which disappear in the A_2X limit, and by comparison with the AB case it becomes perfectly obvious why J' should no longer be observable. In the more general ABR_pX_q . . . cases we would have $(p+1)(q+1)$ . . . such quartets, as discussed by Pople and Schaefer (6). Energy level diagrams for such cases could be constructed by simple extensions of Fig. 1.

EXPERIMENTAL

Proton spectra were taken of 2-furanacrolein at 60 Mc/sec at various concentrations in acetone and benzene. Peak separations were obtained by the side-band technique, taking averages of up to 10 spectra. Internal and external references were not used and concentrations were adjusted to obtain the desired spectral effects. The concentrations are therefore not known accurately but this is of no consequence for our purpose. τ values in chloroform have been given by Bhacca *et al.* (7). Figures 3 and 4 give the observed and calculated spectra in acetone and benzene solutions.

DISCUSSION

The spectrum is a superposition of two effectively independent ABX spectra, one due to the ring protons and one due to the side-chain protons. In Fig. 3 the calculated spectra are given as arrived at by the standard analysis (4). The peaks of the ring protons are indicated by broken lines. Table I presents the spectral parameters obtained from spectra run more slowly than that shown in Fig. 3.

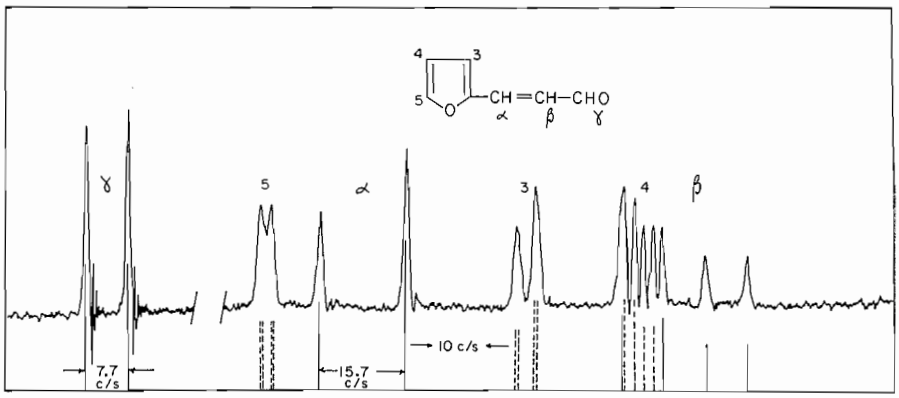

FIG. 3. The proton magnetic resonance spectrum of 2-furanacrolein as a saturated solution in acetone at 60 Mc/sec.

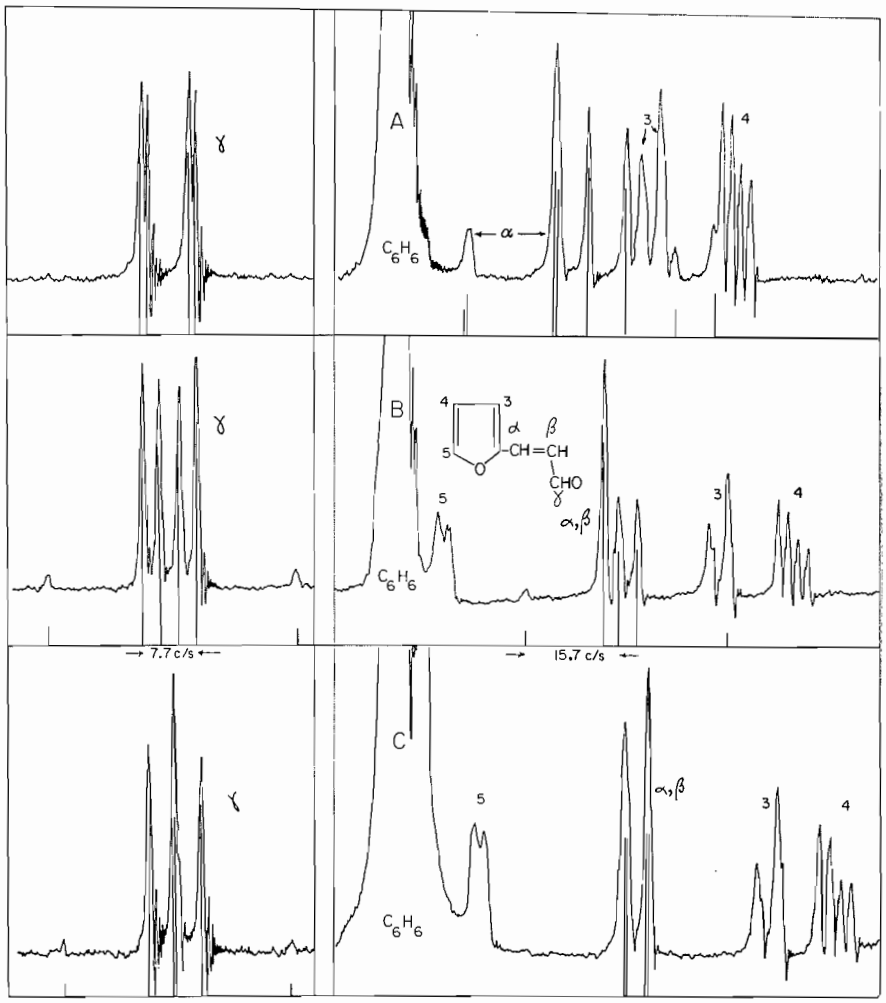

FIG. 4. The proton magnetic resonance spectrum of 2-furanacrolein at 60 Mc/sec at three concentrations in benzene, varying from a saturated solution in A to the most dilute solution in C.

					$J_{\alpha 5}$ = 0.38±0.1

*See Fig. 3 or 4 for labelling of protons.
†All coupling constants are assumed to be positive.

(a) Ring Protons

There is no startling change in the shape of this ABX spectrum because the chemical shifts never become small compared to the coupling constants. The values of the latter agree well with the average values found for a large number of substituted furans (8) and also with those of furan itself, obtained by means of $C^{13}H$ patterns (9). Preferential shifts are discussed below.

(b) Side-chain Protons

As can be seen from Table I and Fig. 4, increasing dilution in benzene results in a preferential shift to high field of the α-ethylenic proton such that $\eta H_0(\sigma_\beta-\sigma_\alpha) = \delta$ decreases to about zero. The energy levels in Fig. 1 lead us to expect a transition from a 14-line ABX pattern to a 5-line AA^1X pattern if $D_\pm$ becomes indistinguishable from $J_{\alpha\beta}$. This will be so if $(\delta+1/2J_{\beta\gamma})^2/2J_{\alpha\beta} < 0.3$.

In the most concentrated benzene solution, A, there are 10 ABX lines. The two combination lines in the X region are too weak to be observed and since $J_{\alpha\gamma}$ is effectively zero there are only two α lines instead of four. These two lines are broadened by a weak coupling to proton 5 on the ring.

In benzene solution B the ABX situation still holds but δ is small enough that all six possible X lines are observable, including the two combination lines. In the AB region two of the weak transitions which become singlet–triplet transitions in the A_2X limit are already too weak to be observed.

Finally, in benzene solution C we are just on the borderline between AA^1X and ABX. δ is just a little less than zero and all AB transitions which become singlet–triplet transitions in the A_2X limit are too weak to be observed, but the two combination lines are detectable. Even if δ were zero we would still have a 0.4 cycle/sec splitting of the lines in the AB region. The combination lines would not be observable, however. Presumably because of the small coupling of proton α to proton 5 this is not observable in Fig. 4C. It is clear, of course, that the size of $J_{\alpha\beta}$ determines the rate at which one approaches a 5-line spectrum. Physically this means that the size of $J_{\alpha\beta}$ relative to δ and $J_{\alpha\gamma}-J_{\beta\gamma}$ determines the tightness of the coupling of the AB protons. We have the curious situation that the larger the relative magnitude of $J_{\alpha\beta}$ the sooner it becomes unobservable.

(c) Preferential Solvent Shifts

In going from acetone solution to the most dilute benzene solution the α-ethylenic proton shows a preferential shift to high field relative to the β-ethylenic proton of almost

1 p.p.m. Crotonaldehyde shows a similar behavior (6). In the ring it is proton 3 which shows the largest solvent shift and it is almost as large as that of the α-ethylenic proton. Some conformations of the molecule will have the α and 3 protons quite near. The implication is that the benzene molecules pack around the solute molecule in such a way as to avoid the oxygen atoms as far as possible. The shifts in Table I lend some support to this idea. Why this should be so is a problem.

THE EXTRACTION OF THORIUM AND SOME LOWER LANTHANIDE NITRATES BY DIBUTYL BUTYL PHOSPHONATE

P. G. MANNING*

Mineral Sciences Division, Mines Branch, Department of Mines and Technical Surveys, Ottawa, Canada

Received April 3, 1962

ABSTRACT

The distribution of thorium and a number of lanthanides between nitric acid and solutions of dibutyl butyl phosphonate in odorless kerosene has been examined as a function of the aqueous nitric acid concentration. Experiments were conducted at trace metal concentration using radioisotopes. Separation factors (denoted by S and defined as the ratio of the distribution coefficients, K, for two metal species) have been measured for some lanthanide–lanthanide couples and also for some thorium–lanthanide couples. Results indicate that separation factors between successive lanthanides (given by $S = K_{Z+1}/K_Z$) at the lower end of the rare-earth series are superior to those obtained with either tributyl phosphate (TBP) (D. Scargill *et al.* J. Inorg. & Nuclear Chem. **4**, 304 (1957)) or trioctyl phosphine oxide (TOPO) (J. M. Schmitt. Oak Ridge National Laboratory. Unpublished data), but as Z increases, $S_{DBBP} \sim S_{TBP} > S_{TOPO}$. For thorium–lanthanide couples, $S'_{DBBP} > S'_{TBP}$. Measurements over a range of extractant concentrations indicate that the lanthanides are extracted as trisolvates.

INTRODUCTION

Much work is being pursued at the present time in elucidating the metal-extractive properties of organophosphorus reagents. Of the neutral esters, tributyl phosphate (TBP) has found widespread application in the large-scale separation of metals, while a number of analytical procedures for the determination of metals with trioctyl phosphine oxide have also been devised (3). Siddall (4) and Madigan and Cattrall (5) have shown that dibutyl butyl phosphonate (DBBP) is a more efficient extractant for uranium and thorium than TBP. Other workers in these laboratories have produced uranium of nuclear-grade purity by a process, employing DBBP, which competes successfully with TBP in giving a product of high purity and in economy of operation (6, 7). Since DBBP can also compete with TBP in availability and initial cost, it possesses great potential in the large-scale separation of these metals. Some measurements have also been reported for the extraction of thorium and lanthanides with diphosphonates, these compounds being β-diketones (8). Radioisotopes of the rare-earth elements were used as tracers to obtain accurate values for the distribution coefficients achieved.

EXPERIMENTAL

DBBP was obtained from the Virginia–Carolina Chemical Corporation. Infrared spectra and titration against standard alkali indicated the presence of about 1% hydrogen-bonded acidic impurities. All organic solutions were, therefore, scrubbed with sodium hydroxide and then washed several times with distilled water prior to use. A 58% (v/v) solution of DBBP in kerosene was used in all distribution experiments. Trioctyl phosphine oxide (TOPO) was an Eastman Kodak White Label product and was used without further purification. The nitric acid used was Mallinckrodt analytical reagent grade and the kerosene was supplied by Anachemia.

La^{140} and Pr^{142} were obtained as carrier-free isotopes from Oak Ridge National Laboratory, $Eu^{152/154}$ from Atomic Energy of Canada Ltd., Chalk River, Ontario, and Tb^{160} from the Radiochemical Centre, Amersham, England. For the thorium measurements, carrier-free Th^{234} was prepared according to the method described by Berman *et al.* (9). The γ-emitting lanthanides were assayed using a NaI (Tl) scintillation assembly, and the β-active Th^{234} using a Geiger–Müller counter.

The distribution coefficient is defined as

$$K = \frac{\text{concentration of nuclide in organic phase}}{\text{concentration of nuclide in aqueous phase}}.$$

**National Research Council Postdoctorate Fellow.*

Ten milliliters of both phases were shaken together in Erlenmeyer flasks for a period of 1 hour, preliminary runs having shown that equilibration was attained in less than 30 minutes. All organic phases were pre-equilibrated. The temperature was 27±3° C; under these conditions the variation in K with temperature is well within experimental error (±3%).

RESULTS AND DISCUSSION

The Nature of the Species Extracted

To determine the nature of the species extracted, K was measured as a function of the neutral ester concentration in the organic phase. The application of dilute solutions of DBBP (desirable to maintain ideality in the organic phase) would involve the measurement of very low distribution coefficients. It was decided, therefore, to carry out this investigation, using another neutral organophosphorus reagent, trioctyl phosphine oxide (TOPO), since, according to Weaver (10), readily measurable distribution coefficients may be obtained at low extractant concentration. $Eu^{152/154}$ was employed as a tracer, and the aqueous phase was 0.316 M HNO_3. The results are listed in Table I, and are presented graphically in Fig. 1. The limiting slope is 2.9, which indicates the formation of the species

$Eu(NO_3)_3(TOPO)_3$. Since it has been established previously that lanthanides are extracted by TBP as trisolvates (1), and since DBBP is intermediate between TBP and TOPO in both structure and electron-donor properties, it is reasonable to assume that the species extracted is $Eu(NO_3)_3(DBBP)_3$.

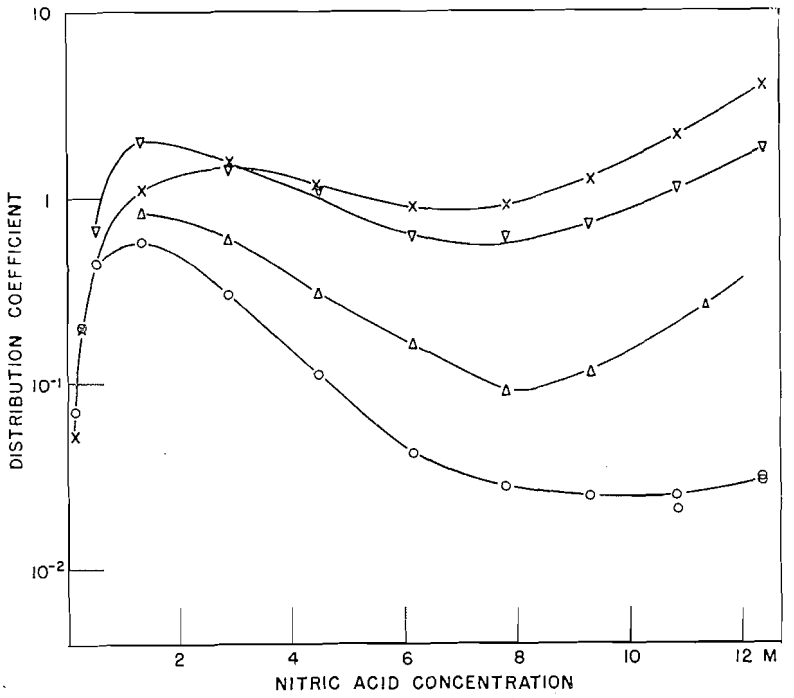

FIG. 2. Lanthanide nitrate distribution coefficients at varying nitric acid concentrations: ○ La^{140}; △ Pr^{142}; ▽ $Eu^{152/154}$; × Tb^{160}.

Although the plots follow the general pattern exhibited by the analogous lanthanide – HNO_3–48% TBP–kerosene system (1), the "valleys" are seen to be much deeper. Scargill *et al.* (1) and Hesford *et al.* (11) have discussed the shapes of the TBP curves, and stated that the important factors in operation are:

(*a*) The salting-out effect of the nitrate ion. This effect produces the initial increase in K with increasing nitric acid concentration.

(*b*) Lanthanide–nitrate complexing and HNO_3 competition for TBP molecules. These reactions would operate over the second portion of the curves and offer an explanation for the decreasing partition coefficients.

(*c*) Activity coefficients. According to Scargill *et al.*, this effect is responsible for the rising partition coefficients at the higher acidities.

That these factors are primary in determining the shapes of the rare earth – DBBP extraction curves is apparent from a qualitative comparison of the plots of Fig. 2 with the corresponding plots of Scargill *et al.* (1). As metal–nitrate complexing in both systems is identical under given aqueous conditions, the deeper "valleys" observed in the DBBP system may be attributed to greater DBBP–HNO_3 interaction, with the formation of the species DBBP.$(HNO_3)_n$. That the extraction of europium by TOPO also passes through a maximum has been demonstrated by Weaver (10).

Some K_{HNO_3} values between aqueous and DBBP phases are listed in Table II.

The non-parallel nature of the lanthanide–DBBP curves at very high acidities (Fig. 2) would suggest that another mechanism is operative in this region. Marcus and Abrahamer (12) have shown that the lanthanides are extracted by long-chain amines from nitrate solutions as anionic complexes, and, therefore, at the higher acidities employed in the present investigation, considerable lanthanide–nitrate complexing can be expected, the degree of which depends upon the hydration number of the ion. Since the ionic radii of the lanthanides decrease with increasing atomic number (the "lanthanide contraction"), the rare earths become progressively more hydrated, and, therefore, less prone to nitrate interaction.

This latter effect may account for the fact that the slope of the lanthanum distribution curve (Fig. 2) is much smaller, at higher nitrate concentration, than for Eu and Tb.

Allowing for the small difference in extractant concentration, DBBP is seen to be a better extractant for lanthanides than TBP.

At nitric acid concentrations greater than 4 *M*, distribution coefficients increase with *Z*, as is to be expected from the gradation in the ionic radii of the rare earths, but under no experimental conditions are the curves regularly spaced. At lower acidities, however, distribution coefficients increase with atomic number from La to Eu, but at this point in the lanthanide series a discontinuity occurs, and $K_{Tb} < K_{Eu}$. These points are illustrated in Fig. 3, which is a plot of *K* against *Z* at a number of nitric acid concentrations. Some TBP data have been included (1), and it is apparent in this system also that partition

coefficients are not proportional to the atomic number, although the authors state otherwise.

Separation Factors

couples and also for some thorium–lanthanide couples determined in the present investigation. S' and S are separation factors defined as follows.

$$S' = K_{M_1}/K_{M_2}, \text{ where } M_1 \text{ and } M_2 \text{ represent any two nuclides,}$$

and

$$S = \text{separation factor between successive lanthanides}$$

$$= \frac{K_{Z+1}}{K_Z} = \left(\frac{K_{Z_2}}{K_{Z_1}}\right)\frac{1}{Z_2 - Z_1}.$$

The TBP figures have been computed from the data of Scargill *et al.* (1), while the TOPO figures are those of Schmitt (2) and Ross *et al.* (13). As Table III indicates, DBBP is superior to TBP and TOPO in the separation of lanthanum from other lanthanides, but for all three extractants S decreases as Z increases, and for the Gd–Sm pair $S_{TOPO} < 1$. At the middle reaches of the rare-earth series, S_{DBBP} and S_{TBP} are comparable, $S_{DBBP} \sim S_{TBP} \sim 1.4$. For thorium–lanthanide mixtures, DBBP affords a higher degree of specificity of extraction than TBP, but it is difficult to compare directly the separation factors obtained with DBBP and TOPO as quantitative data are not available.

Lewis and Ingles (14), in these laboratories, from investigations involving the preferential adsorption of lanthanides on cation-exchange resins from sulphate solutions, obtained maximum separation factors of 6 between thorium and lanthanum.

CONCLUSIONS

Although the separation factors between successive lanthanides determined in this investigation are inferior to those obtained with acidic organophosphorus reagents (15, 16), the high S' values measured for the thorium–lanthanide system, coupled with the ready availability and relative cheapness of DBBP, would suggest that DBBP might

find ready application in the separation of thorium from rare earths on the industrial scale.

TOPO is among the best extractants of metals of all organophosphorus reagents, but it suffers from the disadvantage that it is expensive, and although TOPO has found application in the analytical separation of metals, its cost would preclude its use in large-scale processes.

Further investigations are being pursued to assess the influence on the magnitude of S' and S, by introducing acidic extractants into the organic phase in conjunction with DBBP. As thorium is known to complex more strongly than the lanthanides with such cation-exchangers as thenoyltrifluoroacetone, it is possible that any synergic effects which might occur would produce an enhancement of the separation factors.

ACKNOWLEDGMENT

This work was done while holding a National Research Council Postdoctorate Fellowship, the award of which is gratefully acknowledged.

ELECTROCHEMISTRY OF THE NICKEL OXIDE ELECTRODE

PART III. ANODIC POLARIZATION AND SELF-DISCHARGE BEHAVIOR

B. E. CONWAY AND P. L. BOURGAULT*

Department of Chemistry, University of Ottawa, Ottawa, Ontario

Received March 26, 1962

ABSTRACT

Further evidence that the rate-controlling process in self-discharge of the nickel oxide electrode is the anodic partial reaction of oxygen evolution is reported and is based on: (*a*) comparison of the heats of activation for open-circuit oxygen evolution and for d-c. anodic polarization with oxygen evolution; (*b*) comparison of the current potential behavior for d-c. anodic polarization and for rates of oxygen evolution on open circuit as a function of potential; and (*c*) comparison of H/D isotope effects for open-circuit and d-c. polarization behavior. In the latter cases, an unusual and characteristic inverse isotope effect is observed.

True Tafel slopes are deduced and interpreted in terms of possible mechanisms of oxygen evolution, taking account of the dependence of activation energy upon surface coverage by adsorbed intermediates.

INTRODUCTION

In previous papers (1, 2) we have discussed the mechanism of the self-discharge behavior of electrodes in a state of oxidation approaching and exceeding "Ni III" and have given some evidence that the rate-controlling process in self-discharge is a step in the anodic partial reaction of oxygen evolution. Since the converse view, that the cathodic step is rate limiting (but without a full appreciation of the electrochemical factors involved), has been presented elsewhere (3), we give, in the present paper, further unequivocal evidence for the identity of the rate-controlling process on open-circuit self-discharge, and hence of mechanism, by comparing the kinetics of the oxygen evolution process on open circuit and on driven anodic polarization of the charged (i.e. in a state of oxidation approximating to "$NiO_{1.5}$") nickel oxide electrode. Related data for the adsorption pseudocapacity associated with the surface layer at the nickel oxide electrode are also presented.

EXPERIMENTAL

Techniques used in the preparation of electrodes and solutions, in the e.m.f. measurements, and in the determination of oxygen evolution rates on open circuit (4) have been described in detail in our previous publications (1, 2). Evidence has also been given elsewhere (5) that ordinarily prepared aqueous solutions (made up from recrystallized analytical grade KOH and twice-distilled "conductance" water) give results identical, within experimental error, with those obtained using ultrapurified solutions prepared from potassium amalgam and pre-electrolyzed anodically before carrying out the kinetic runs at the nickel electrode. The ordinarily prepared solutions were hence used in the present work.

The following matters of experimental procedure require further mention:

(a) Steady-state Current-potential Behavior

A number of experiments were carried out in order to compare the kinetic parameters (viz. the apparent heats of activation and the exchange currents) for steady-state d-c. anodic oxygen evolution and open-circuit oxygen evolution. Since the nickel oxide electrode behaves electrically as a large capacitance (2, 5) due to discharge or desorption of O-containing radicals at its surface, normal procedures for examining steady-state polarization behavior at various current densities must be modified to allow for pseudo-Faradaic effects in charging the adsorption capacity (5, 6) which lead to time variation of the electrode potential when the current density is varied.

The impregnated plaques (7) were given three cycles of charging and discharging at 25° C before being used in the kinetic polarization measurements. The initial charging rate was at 38.5 ma g^{-1} of $Ni(OH)_2$

**Present address*: *Johnson Matthey and Mallory Co., Toronto, Ontario.*

for 30 hours and subsequent discharge and charge cycles were at about 55 ma g^{-1} for 5 hours. This conditioning of electrodes was necessary to obtain the best reproducibility (± 5 mv in polarization measurements; it is of interest that this figure is three or four times better than is normally attainable with pure solid metal electrodes). The electrodes were then transferred to the experimental cell containing two Hg/HgO reference electrodes and the KOH solution prepared from the recrystallized monohydrate. Final charging was then carried out at 38.5 ma g^{-1} $Ni(OH)_2$ for 30 hours and then at various higher and lower current densities until steady values of oxygen overpotential were attained.

The criterion of what constitutes a "steady state" is dependent upon the current density used. At high current densities (300 ma g^{-1}), e.m.f. was considered to be "constant" when it changed at a rate not exceeding 0.01 mv sec^{-1}. However, at a current density of 3 ma g^{-1} a rate of change of e.m.f. of 10^{-4} mv sec^{-1} is quite significant. This arises as follows: following a change of current density and polarization, the total current i_T passing into the electrode will be made up of a Faradaic contribution i_F (due to oxygen evolution) and a component i_C due to the change of charge held by the surface capacitance. Thus

$$i_T = i_F + i_C = i_F + C dV/dt.$$

The measured current i_T will thus only be equal to i_F, which is of significance in the kinetics of oxygen evolution, when the charging current has fallen to a negligible value. At low current densities, it is hence necessary to wait for a relatively greater constancy of e.m.f. with time (i.e., a low value of dV/dt) than would be the case at high current density, in order to obtain the same degree of accuracy in i_F. Estimates of the capacity were obtained from the slopes of electrode potential vs. volume of oxygen evolved on open circuit (1, 5) and from the θ values (1, 8) obtained in e.m.f. decay studies.

At the lowest current densities, several days* would be required for CdV/dt to become less that 1% of i_T. In order to overcome this difficulty, the value CdV/dt was obtained at various times and when it reached a value i_C' less that 10% of i_T, the current i_C' was subtracted from i_T, giving the required i_F for oxygen evolution. Allowing for a possible error of 10% in the estimate of CdV/dt, the error introduced into the corresponding estimate of i_F when $i_C = i_C' = i_T/10$ was only 1%. At higher current densities, the value of CdV/dt becomes negligible compared with i_T in a few minutes.

(b) Apparent Heats of Activation

The apparent (9, 10) heats of activation for the driven anodic oxygen evolution process and for the evolution of oxygen on self-discharge were evaluated by conducting the above steady-state measurements over a range of temperatures and also following the oxygen evolution rates on open circuit at various temperatures. In calculating the heat of activation, allowance was made for the e.m.f. of the Hg/HgO electrode and its temperature coefficient, so that the heats of activation would refer, in the usual way, to the oxygen evolution process at the *reversible* oxygen potential.

(c) Deuterium Isotope Effects

The effect of complete deuterium substitution in the "hydrated" oxide, the solvent and the electrolyte, on the kinetics of open-circuit decay of e.m.f. and on the rate of anodic oxygen evolution was investigated by examining the behavior of electrodes prepared from anhydrous nickel sulphate by precipitation of $Ni(OD)_2$ by means of KOD in D_2O. Control experiments were carried out using ordinary H-containing reagents but retaining the $NiSO_4$ instead of the normally used $Ni(NO_3)_2$ hydrate, which cannot be prepared anhydrous without decomposition. The purpose of this experiment was to obtain further confirmation of our previous evidence (1) that the open-circuit self-discharge process is controlled by the anodic oxygen evolution partial process rather than by the cathodic partial process of reduction of the higher oxide to $Ni(OH)_2$, as claimed by Pitman and Work (3).

(d) E.M.F. Decay and Surface Capacitance

Electromotive force decay studies were made as described previously (1), and from the evaluation of the term θ in the logarithmic decay of potential with time, the capacitance of the electrode was evaluated (1, 8, 5). Tests were performed (see Results) to check the validity of the estimates of θ and of the assignment of slopes of e.m.f. decay lines in log [time]. Surface capacitance values were also obtained from the slopes of the lines relating e.m.f. of the electrode to volumes of oxygen evolved, as described previously (1); new data were obtained at various temperatures and KOH concentrations which extend the range and applicability of our previous considerations (1).

RESULTS

(a) Steady-state d-c. Polarization Behavior

The steady-state Tafel lines obtained by the procedure described above are shown in Fig. 1 for 7 M (molal) aqueous KOH at five temperatures. Current densities are expressed

**It should be noted that the adsorption or pseudocapacitance of the nickel oxide electrodes is very large, e.g. of the order of 100 F g^{-1} (1, 5). It is for this reason that the charging currents, which are negligible at most other kinds of electrodes, except at the very lowest current densities, are important in the present work.*

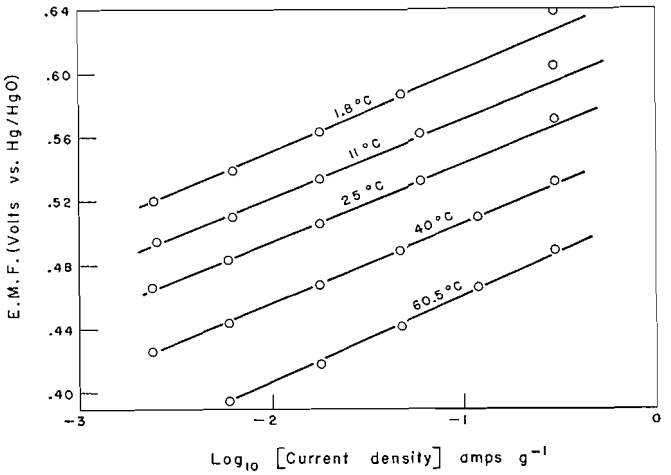

FIG. 1. Steady-state Tafel lines for d-c. anodic polarization of the nickel oxide electrode in 7 *M* KOH at various temperatures.

in amp g^{-1} as discussed previously (1, 2) since the real areas of the wet electrodes cannot be precisely determined (B.E.T. areas of the charged nickel oxide electrodes in the dry condition are about 40 m^2g^{-1} and of the uncharged electrodes 30 m^2g^{-1}; these values cannot be safely identified with the electrochemically accessible real areas of wet electrodes, although it is likely that areas of similar orders of magnitude are involved). The points shown are the mean values obtained from a series of measurements at increasing and decreasing current densities and are also averaged for runs with several electrodes. Reproducibilities of points are about ± 5 mv at a given current density. The slopes of the lines (calculated for 25° C) are 0.049 ± 0.002.

(b) Rates of Oxygen Evolution on Open Circuit

Typical plots of oxygen evolution rate as a function of electrode potential on open circuit are shown in Fig. 2 for various KOH solutions at 1°, 25°, and 60.5° C. Depending on concentration and temperature, these lines exhibit either one or two linear regions, as previously discussed, corresponding to the inflections in the e.m.f. decay lines (1, 5). The changes of slope in the latter plots of e.m.f. vs. log [time] are hence not due to incidental changes of capacitance with potential but must reflect a true change of mechanism (or rate-controlling step) in the oxygen evolution reaction. When a change of slope in the plot of e.m.f. vs. log [oxygen evolution rate] occurs, the two corresponding exchange currents can be evaluated and are shown, for 25° C, in Fig. 3 as a function of the log of the molal activity of KOH. It is seen that while the slopes of the e.m.f. – log [rate] plots vary significantly with KOH concentration, the exchange currents i_0 for oxygen evolution are not dependent, within the reproducibility* of the data, upon KOH activity (Fig. 3); however, the *difference* between the mean i_0 values for the processes in the upper and lower potential regions is certainly quite significant (Fig. 3). The datum for the steady-state anodic polarization in 7 *M* KOH at 25° C, indicated by the square point in Fig. 3, is also consistent with the other data obtained from the open-circuit measurements. The exchange currents for various temperatures are summarized in Table I.

**The reproducibility of the i_0 values appears to be less satisfactory than the claimed reproducibility (± 5 mv) for the overpotential values. This arises, however, since a relatively long extrapolation of the log [rate] plot is necessary down to the reversible oxygen potential, and the Tafel slopes are small.*

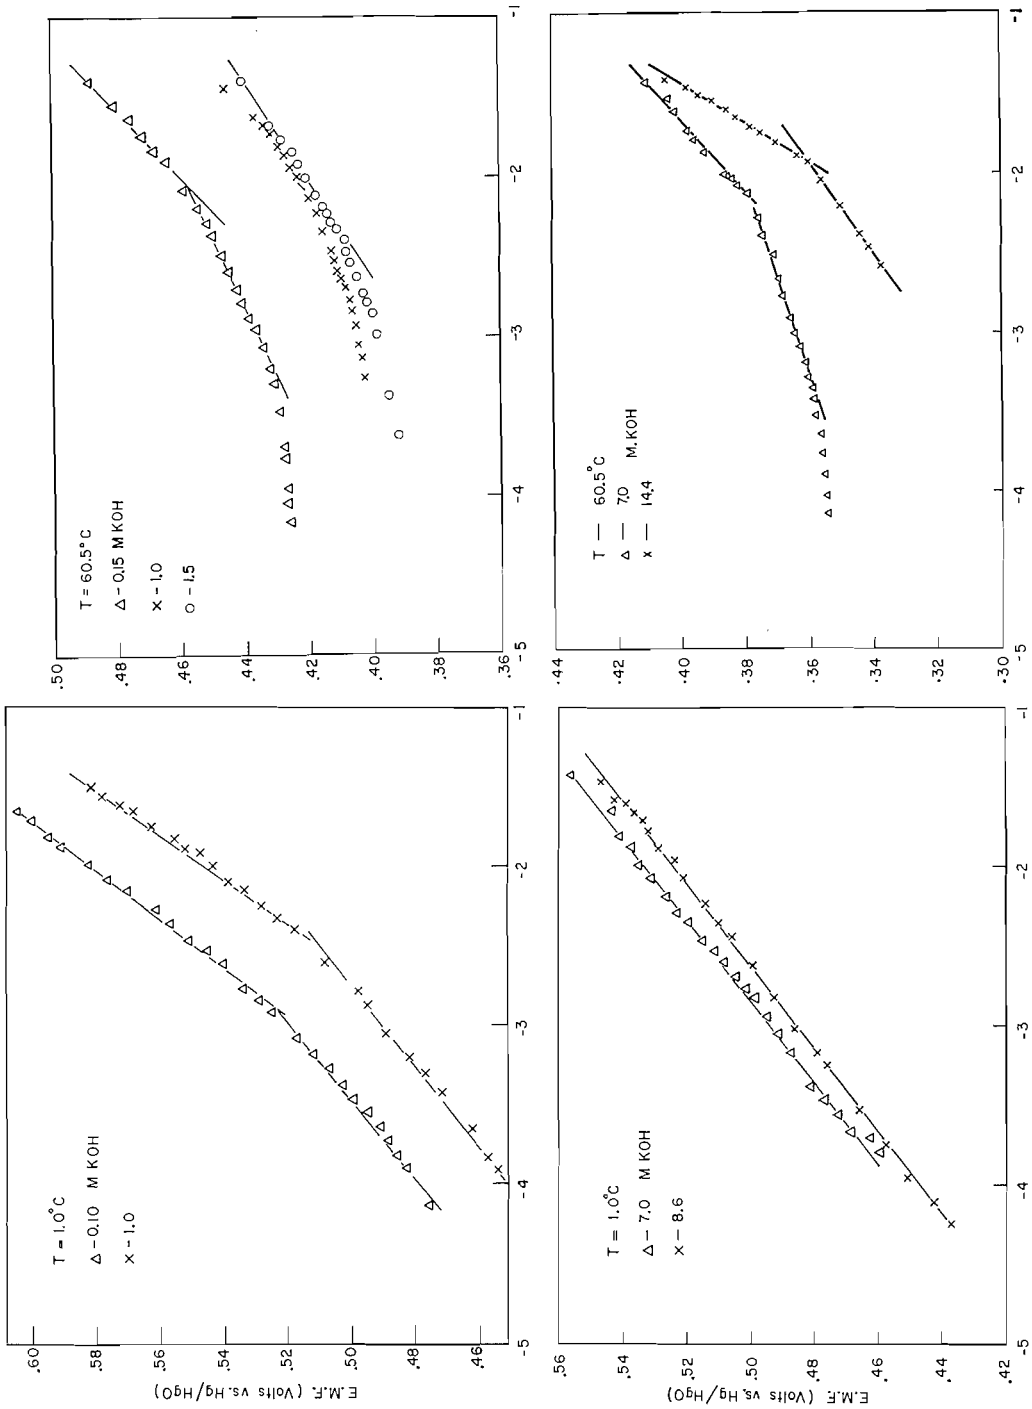

FIG. 2. Rates of oxygen evolution on open-circuit in KOH solutions at various concentrations and at 1° C, 25° C, and 60.5° C.

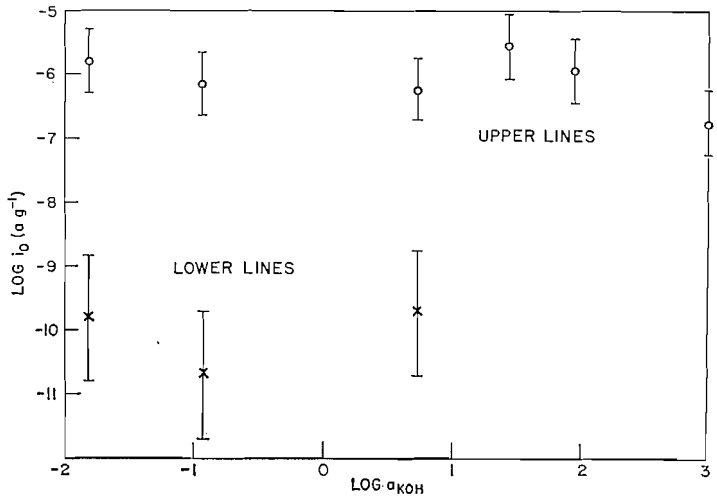

FIG. 3. Exchange currents for the two processes in oxygen evolution at high and low anodic overpotentials for various KOH activities at 25° C.

TABLE I

Exchange currents in amp g^{-1} from extrapolation of e.m.f. – log [rate of oxygen evolution] lines

Temp. (°C)	Concn.	Region I	Region II	Region III
−25	4.5		5×10^{-10}	
	8.2		6×10^{-10}	
	11.8		3×10^{-10}	
1.0	0.10	$[8\times10^{-7}]$*	1.4×10^{-8}	
	1.0	$[5\times10^{-6}]$	4.5×10^{-8}	
	7.0		2.7×10^{-8}	
	8.6		1.7×10^{-8}	
25	0.015		1.6×10^{-6}	1.5×10^{-10}
	0.15		7×10^{-7}	2.0×10^{-11}
	2.9		5.6×10^{-7}	2.2×10^{-10}
	7.0		2.7×10^{-6}	†
	9.4		1.2×10^{-6}	†
	14.6		2×10^{-7}	†
60.5	0.15		1.4×10^{-6}	
	1.5		5×10^{-6}	
	7.0		4×10^{-5}	
	14.4		8×10^{-5}	
	15.4		4×10^{-5}	

*These i_0 values correspond to the two values of b obtained for these conditions in the plots of oxygen evolution rate against potential.
†Values for i_0 for these concentrations cannot be obtained since no second region of the oxygen evolution rate line appears.

(c) Identity of Open-circuit and Steady-state Kinetic Behavior

(i) Current-potential Behavior

Direct comparison between the current-potential relationships obtained for steady-state d-c. and open-circuit oxygen evolution in 7 *M* aqueous KOH at 25° C is made in Fig. 4 and it is evident that, provided the electrode is conditioned by several cycles of charging and discharging, the kinetic behavior on open circuit is identical with that for steady d-c. polarization provided due allowance is made, as described above, for pseudo-Faradaic effects in charging the surface capacitance (2). In the plot for the open-circuit behavior in Fig. 4, the current density is identified with the self-discharge current

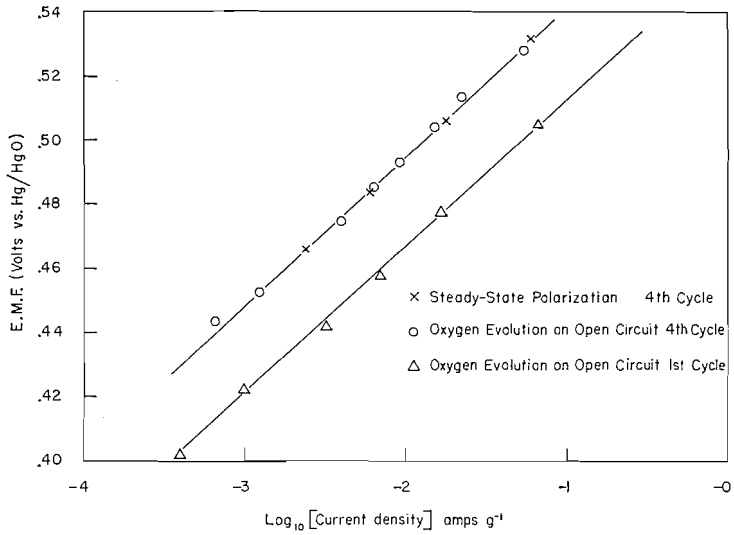

FIG. 4. Comparison of steady-state d-c. polarization behavior with that deduced from rates of oxygen evolution on open circuit (7 *M* KOH, 25° C).

expressed as $4F.dV_{O_2}/dt$, where V_{O_2} is the volume of oxygen evolved at N.T.P. (corrected for partial pressure of water vapor over the KOH solution (18)) as a function of time t.

From Fig. 4, it is evident that previous cycling history is of importance in determining the position of the Tafel line (i.e. the i_0 value) but not the slope and hence the rate-controlling mechanism. A number of experiments made at various times have indicated that the electrodes give reproducible behavior after the second or third cycle of charging and discharging. It is seen that fourth-cycle data for both open-circuit and steady-state kinetic behavior are identical within the experimental reproducibility (5 mv).

(ii) Apparent Heats of Activation

The apparent heat of activation (in the sense of Temkin (9, 10)) for steady-state d-c. polarization in 7 *M* KOH is derived from the Arrhenius plot shown in Fig. 5 by calculating $(\partial(\ln i)/\partial(1/T))_E$ at an oxygen overpotential of $E_{O_2} = 0.18$ v and is found to be 15.2 (± 1) kcal mole^{-1}. This corresponds, with the observed Tafel slope of 0.049 ± 0.002, to a heat of activation at the reversible oxygen potential of 20.2 (± 1.6) kcal mole^{-1}. In this calculation, allowance is made for the fact that the e.m.f. measurements were made with respect to the Hg/HgO electrode, which has a temperature coefficient of standard e.m.f. of -0.55×10^{-3} v (°C)$^{-1}$ (11).

The corresponding heat of activation for the evolution of oxygen on *open circuit* is identical with this value (see Fig. 5), although the Arrhenius plot is slightly shifted towards higher rates at a given temperature compared with that for the d-c. polarization. This may be due to slightly different electrode preparations used in these two experiments; in the oxygen evolution work, electrodes having maximum degree of impregnation (achieved by three successive vacuum impregnations (1, 2)) were used in order to achieve the highest possible extent of oxygen evolution with a given electrode.

(iii) Direction of H–D Isotope Effects

Open-circuit decay measurements were made in H_2O/KOH and D_2O/KOD solutions using electrodes prepared from anhydrous Ni_2SO_4 as described. Related experiments on oxygen evolution under d-c. polarization at nickel wires were also carried out in D_2O and H_2O. In both cases, the mercuric oxide reference electrode was used so that the

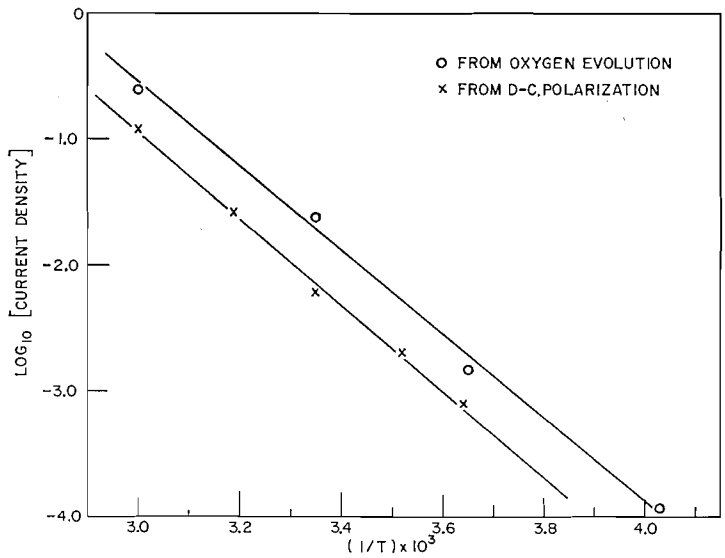

FIG. 5. Arrhenius plots for the apparent electrochemical heat of activation for the oxygen evolution reaction at nickel oxide electrodes (7 *M* KOH; overpotential for O_2 evolution = 0.18 v).

oxygen overpotential at a given current density or after a given time of decay could be compared directly in H_2O and D_2O, since the standard free energy and hence e.m.f. associated with the reaction

$$Hg + 1/2\,O_2 \rightleftharpoons HgO$$

is independent of the nature or activity of the water species.

Both for the open-circuit decay process and the d-c. polarization behavior, the H/D isotope effect on the rate of oxygen evolution is an *inverse* one having a magnitude of about 1/5, the reaction in the D-solvent being the faster at a given oxygen overpotential. This direction of the isotope effect has also been found at the partially charged electrodes in a formal state of oxidation "$NiO_{1.25}$" and has been referred to previously (2). The identity of the direction of the isotope effects for open-circuit and d-c. polarization behavior is further evidence that the rate-controlling process is the same in the two cases and is hence associated with oxygen evolution. The direction of the isotope effect observed is also important negative evidence that the cathodic reduction step* involving proton transfer, viz.

$$NiO.OH \xrightarrow{H^+, e} Ni(OH)_2,$$

which must occur in self-discharge, is *not*, as has been suggested by Pitman and Work (3), the rate-controlling partial process. The inverse isotope effect probably arises from preferential discharge of O from OD^- in D_2O than from OH^- in H_2O on account of different solvation energies of the isotopically analogous ions (12, 13).

(d) Open-circuit Decay of E.M.F., and Electrode Capacitance

Further (see ref. 1) e.m.f. decay studies have been made at various temperatures and the capacitance involved in the associated self-discharge process has been evaluated from

**The cathodic reduction step during relatively short times (less than about 1 day) and at room temperature mainly involves reduction of the surface phase (5) rather than the bulk phase, although self-discharge of the latter can be significant at elevated temperatures (e.g. 60° C) or over longer times (2).*

the θ constant defined (8) and discussed (1, 5) previously. The self-consistency of the e.m.f. decay data obtained was checked by establishing that:

(i) the θ term was inversely proportional to the current density prior to interruption of the current (see Fig. 6(*a*));

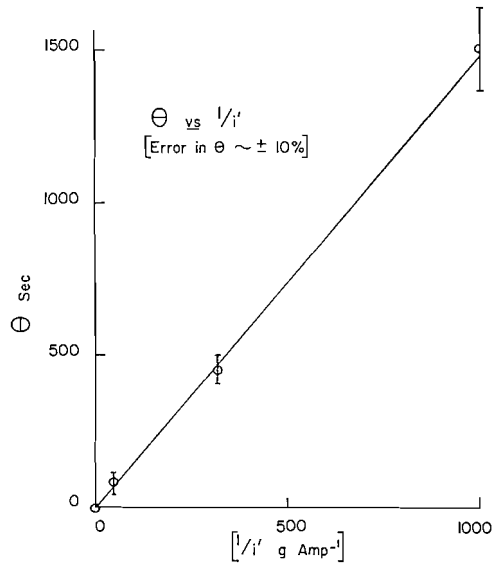

FIG. 6(*a*). θ values plotted against initial polarizing current density (0.72 *M* KOH, 25° C).

(ii) the e.m.f. decay lines taken from a series of different initial polarizing current densities were (almost) coincident (see Fig. 6(*b*));

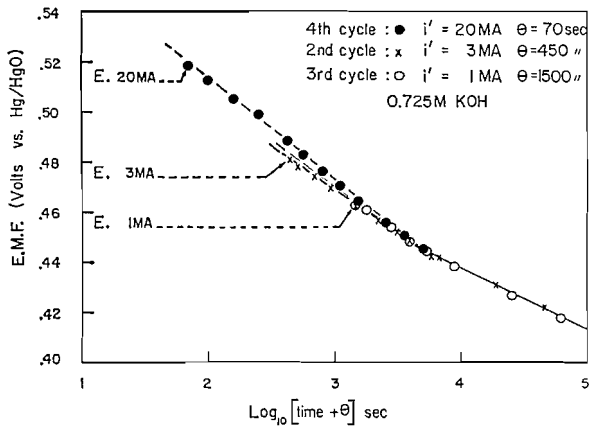

FIG. 6(*b*). Coincidence of e.m.f. decay lines taken from different initial polarizing current densities (0.72 *M* KOH, 25° C).

(iii) the same slope of the e.m.f. decay line was obtained by making an e.m.f. decay plot by the "difference" procedure (see Fig. 6(*c*)); this type of plot merely eliminates any arbitrariness in the estimation of θ. It is particularly useful in cases where it is suspected that a change of mechanism may occur with falling electrode potential at a potential near the starting value, i.e. after a time on open circuit comparable with θ.

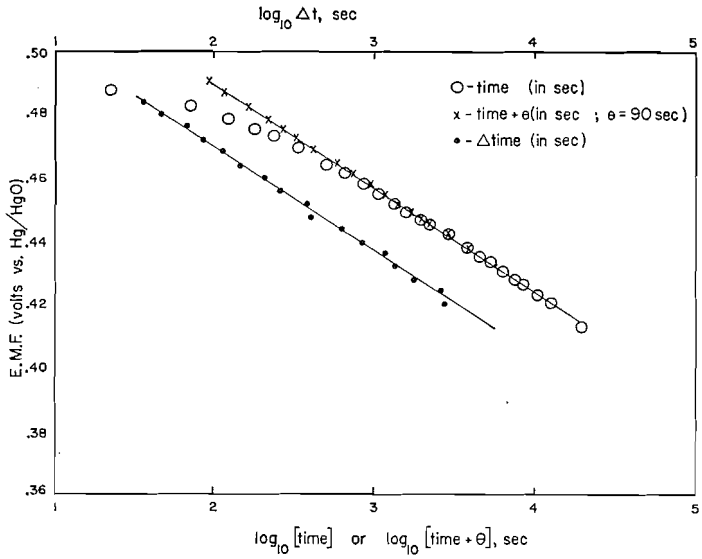

FIG. 6(*c*). Application of the difference method for evaluation of e.m.f. decay slopes without evaluation of θ (9.1 *M* KOH, 25° C); Δt values are the times required for successive falls of potentials of 4 mv, as a function of mean potential during these times. Log t and log $[t+\theta]$ plots for comparison.

The e.m.f. decay lines plotted in terms of E vs. log $[t+\theta]$ are shown in Fig. 7 for various concentrations at −25°, 1°, and 60.5° C. The behavior at 25° C, previously published (1), is included for comparison. The associated θ values lead (8, 1) to the capacities listed in Table II, where they are compared with the (initial) capacities deduced (cf. ref. 1) from

TABLE II

Surface capacitance and active oxygen content of electrodes as a function of temperature and KOH concentration

Temperature (°C)	Concn. (*M*/liter)	Surface capacitance ($F\,g^{-1}$)		Active O atom per Ni atom

	15.4	280	320	0.66	0.035

*The margins of error indicated are the maximum deviations from the mean values observed between replicate runs done under the same conditions of temperature and concentration.

†The values recorded here are of "initial" capacitance at the highest anodic potential at the beginning of the e.m.f. decay. Substantially higher values arise at lower e.m.f.'s after the decay has proceeded for some time, particularly in the more dilute solutions at higher temperatures.

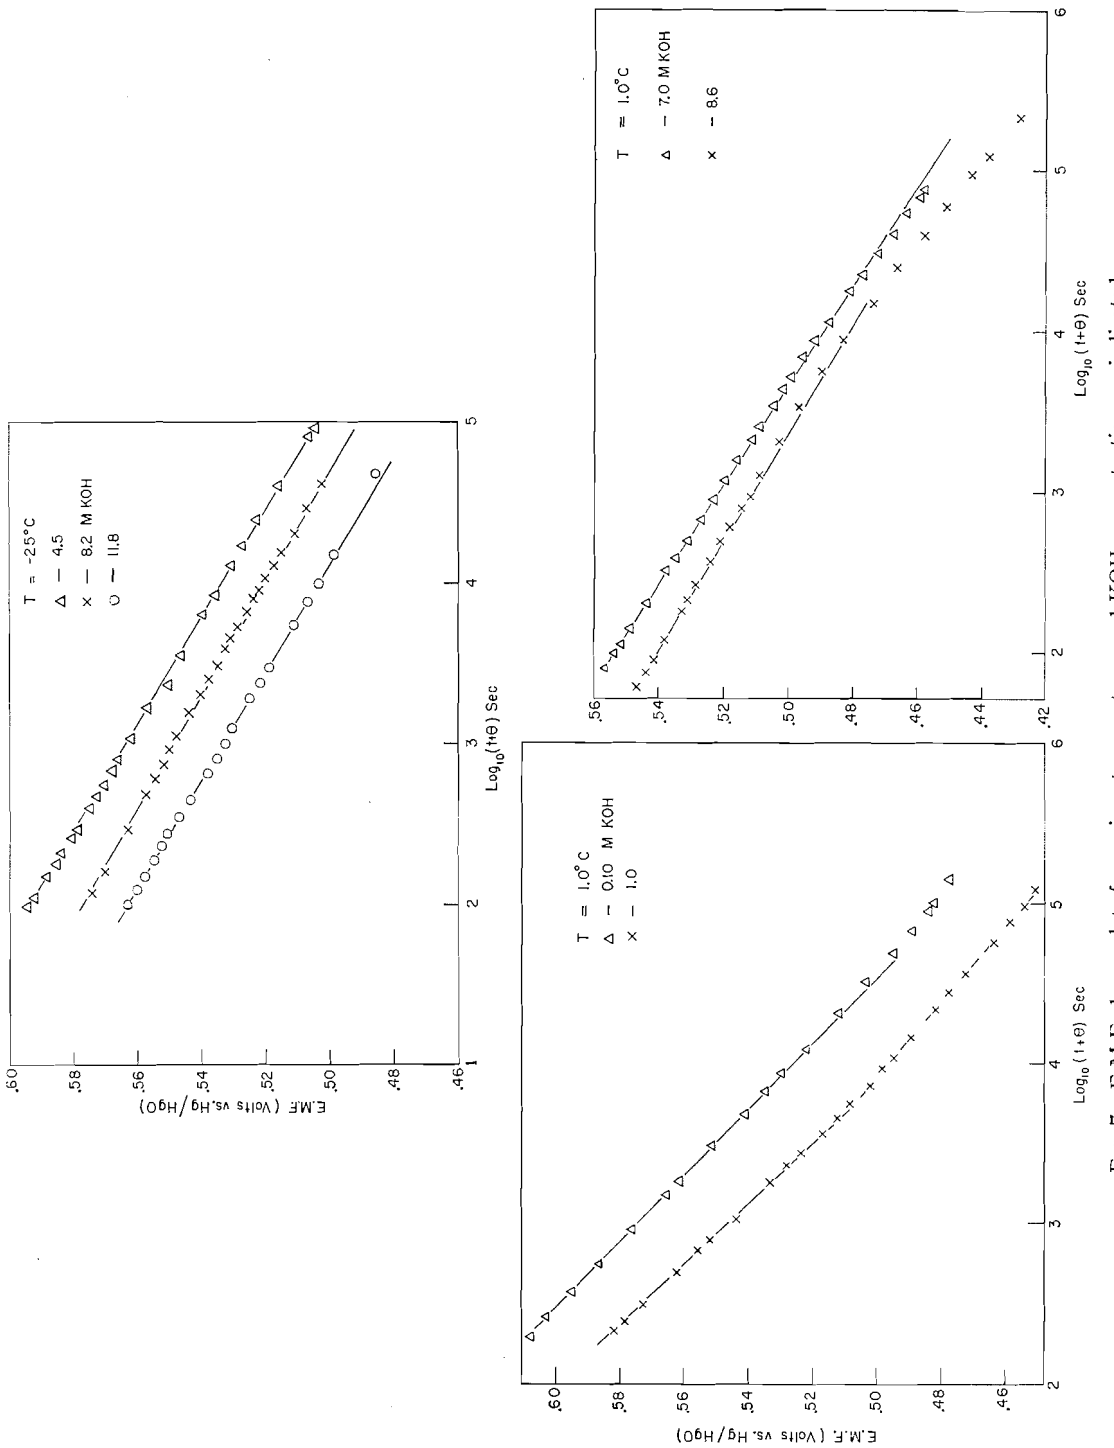

FIG. 7. E.M.F. decay plots for various temperatures and KOH concentrations as indicated.

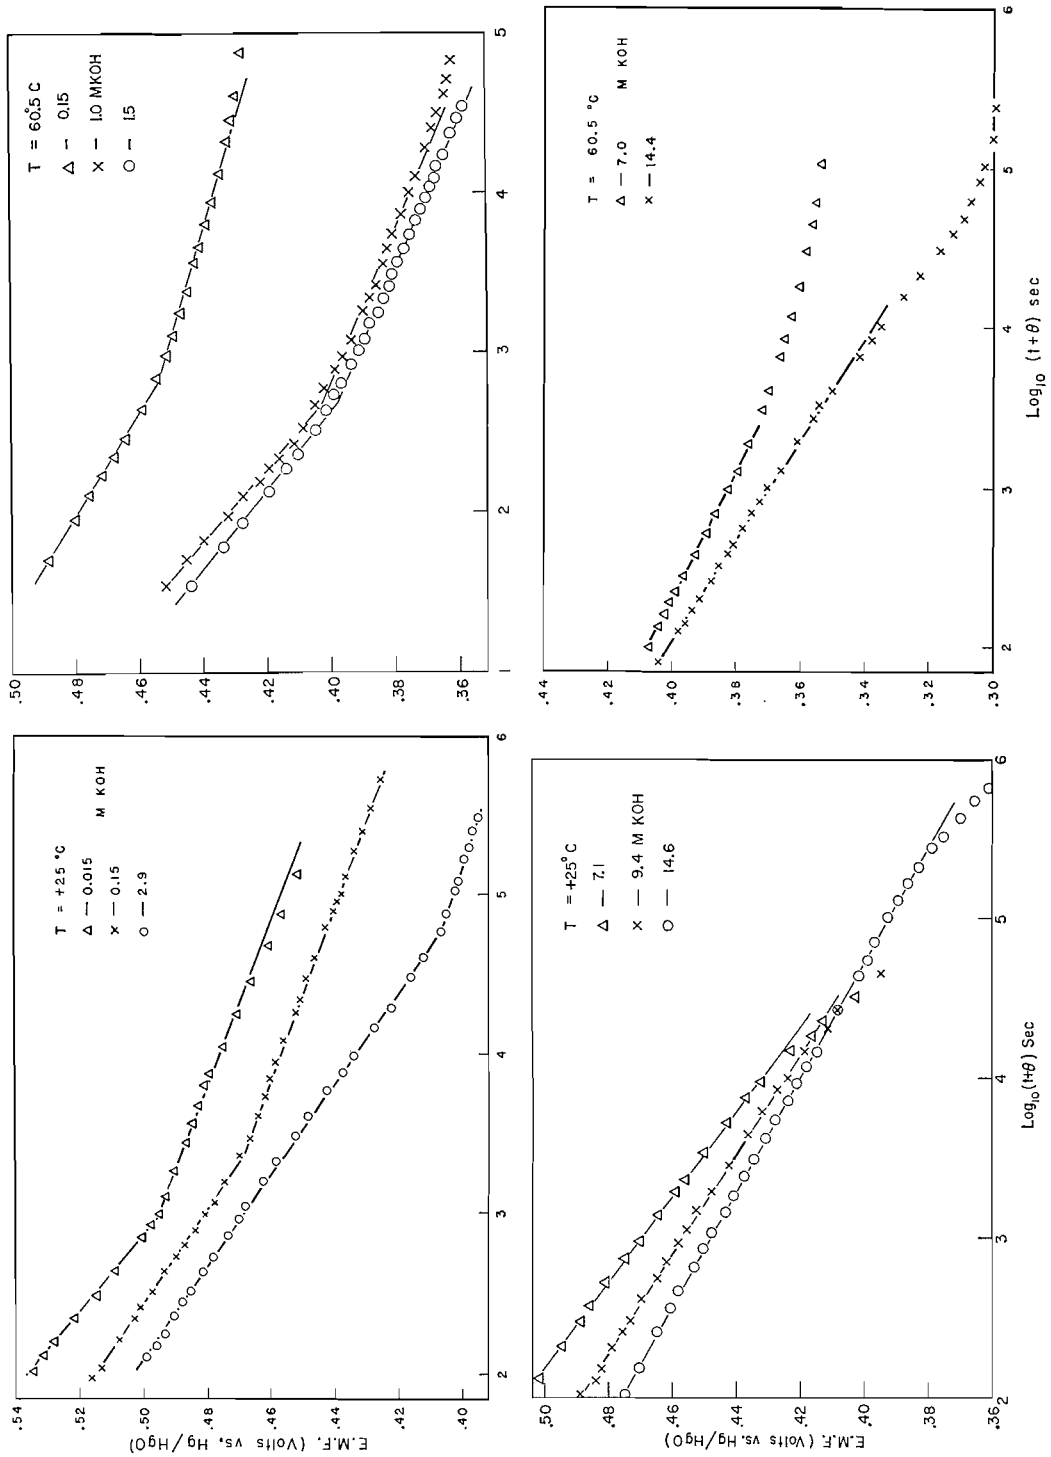

FIG. 7.

the volumes of oxygen evolved on open circuit as a function of electrode potential (as shown in Fig. 8). The corresponding total active oxygen to nickel ratios have been calculated from coulombic discharging and charging curves and are given in the last column of Table II.

DISCUSSION

(a) Rate-determining Mechanism in Self-discharge

From the above results, it is clear that three distinct lines of evidence strongly indicate that the self-discharge process is controlled by the *anodic* partial reaction of oxygen evolution rather than the cathodic one of reduction of nickel oxide in the bulk (or the surface) phase as suggested by Pitman and Work (3). Their differing conclusion evidently arises from the fact that *average* rates of oxygen evolution were estimated over a long time and hence over an appreciable range of falling potentials without making a proper allowance for the relation of the rate to the electrode potential. It may also be noted that the marked increase of the self-discharge rate at various given electrode potentials with increasing KOH activity cannot be related in a simple way to the nature of the self-discharge mechanism, since it is now evident that the effect arises mainly from the dependence of Tafel slopes of the rate-determining oxygen evolution reaction on the KOH activity; the corresponding i_0 values (see Fig. 3) are, in fact, almost independent of KOH activity within the reproducibility indicated.

The possibility that the self-discharge process in the overcharge region is simply a non-electrochemical decomposition or desorption from the surface phase at the interface of the nickel oxide particles (i.e. a process analogous to the decomposition reactions of the chemically prepared higher nickel oxide discussed by Howell (23)) can be eliminated on the basis of the identity of oxygen evolution rate and d-c. polarization Tafel slopes. Such a dependence of rates upon potential could only arise in a non-electrochemical decomposition if there was a remarkable and coincidental dependence of free energy of the surface phase (and hence associated electrode potential) upon coverage by adsorbed species leading to an apparent dependence of rate of decomposition on electrode potential. All the characteristics of the self-discharge process are consistent with an electrochemically controlled reaction, as also occurs for the partially charged material where an electrochemically controlled self-discharge process can quantitatively account for the steady-state mixed potential (2).

(b) E.M.F. Decay Slopes and Current-potential Behavior

Elsewhere (5) we have shown how the e.m.f. decay slopes ($dE/d \ln t$) may be related in a formal way to the mechanistically significant Tafel slopes when the surface capacitance (2, 5) involved in the self-discharge process is potential dependent. This case arises with the nickel oxide electrode only at room and higher temperatures but not at all at low temperatures in quite strong KOH solutions. When the e.m.f. decay slopes b_1 are obtained, the true Tafel slope b_3 follows (5, 14) from

$$b_1 = \frac{b_2 b_3}{b_3 - b_2},$$

where b_2 is the Nernst factor relating surface charge q_s or corresponding capacity dq_s/dE to potential E in the equation

$$q_s = ke^{E/b_2}$$

as we have shown previously (5).

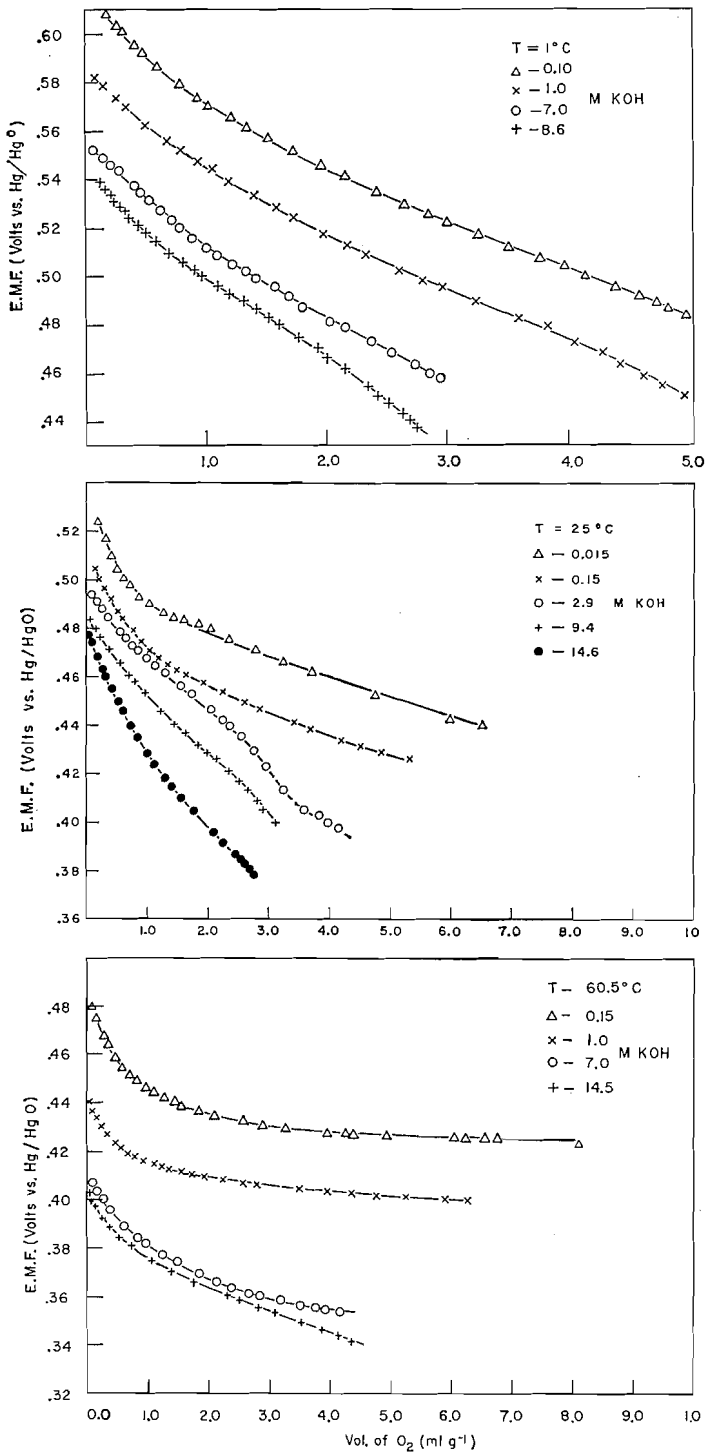

FIG. 8. Volumes of oxygen evolved on open circuit as a function of potential in various KOH solutions and at three temperatures.

In the dilute solutions (<1 M KOH) at 25° C, the *true* Tafel slopes may be calculated from the slopes of the e.m.f. decay lines (Fig. 7) using the observed dependence (1, 5) of surface charge upon potential (deduced from oxygen volume measurements (Fig. 8) as a function of potential (1)). The following values are obtained:

0.15 M KOH (25° C) upper potential region	$b_3 = 0.045$
0.15 M KOH (25° C) lower potential region	$b_3 = 0.022$
7 M KOH (25° C) upper potential region	$b_3 = 0.045$
7 M KOH (25° C) d-c. polarization (upper region)	$b_3 = 0.049$
0.15 M KOH (60.5° C) upper potential region	$b_3 = 0.051$
0.15 M KOH (60.5° C) lower potential region	$b_3 = 0.027$
1.5 M KOH (60.5° C) upper potential region	$b_3 = 0.044$
1.5 M KOH (60.5° C) lower potential region	$b_3 = 0.021$

We now consider the mechanistic significance of these true Tafel slopes in relation to our previous discussion (1) of rate-controlling mechanisms. By comparison with the steady-state Tafel lines for d-c. polarization (in 7 M KOH), it is seen that the Tafel slopes derived from the e.m.f. decay slopes in the upper potential region are now fairly consistent with the d-c. polarization values (viz. 0.049±0.002). In all cases, the Tafel slope in the lower potential region (corresponding to the lower i_0 values in Fig. 3) is approximately one half that for the mechanism occurring at higher potentials in cases where both the e.m.f. decay and oxygen evolution rate lines show a clear inflection.

Elsewhere (1) we have suggested consecutive mechanisms of oxygen evolution at the nickel oxide electrode that are consistent with limiting Tafel slopes of $\frac{2}{3}.2.3RT/F$ (0.038 v at 25° C), followed by either $\frac{2}{3}.2.3RT/F$ (0.023 v) or $2.3RT/3F$ (0.020 v). The true Tafel slopes (for the upper potential region) discussed above are seen to be between $2.3RT/F$ (0.059 v) and $\frac{2}{3}.2.3RT/F$. Thomas (15) has shown, by taking into account the variation of activation energy with surface coverage of intermediates, that the former value can arise in a simple radical recombination step, e.g. $H + H \rightarrow H_2$, in cathodic hydrogen evolution, when the activation energy for desorption in a molecule-producing step is greater than the net desorption energy, i.e., in the present case when the reverse process of chemisorption of O_2 as M—O is "activated". Inspection of the following possible oxygen-producing mechanisms involving recombination steps:

$$\text{I}\begin{cases} OH^- + M \rightarrow MOH + e & \text{(i)} \\ 2MOH \rightarrow MO + H_2O & \text{(ii)} \\ 2MO \rightarrow M + O_2 & \text{(iii)} \end{cases}$$

or

$$\text{II}\begin{cases} OH^- + M \rightarrow MOH + e & \text{(i)} \\ OH^- + MOH \rightarrow MO + H_2O + e & \text{(ii)} \\ 2MO \rightarrow M + O_2 & \text{(iii)} \end{cases}$$

where M refers to the surface of the nickel oxide, indicates (1, 19) that the final step in either case must be associated with a Tafel slope of $2.3RT/4F$ for low coverage by MO or MOH, with the Langmuir isotherm applying (15, 20). At appreciable coverages, different results can arise as discussed below. Since we have also to account for a lower slope of either $\frac{2}{3}.2.3RT/F$ or $2.3RT/3F$, which appears at lower potentials in dilute solutions, the scheme previously suggested (1), viz:

$$\text{III}\begin{cases} M + OH^- \rightarrow MOH + e & \text{(i)} \\ MOH + OH^- \rightarrow MO + H_2O & \text{(ii)} \\ MO + MOH \rightarrow MHO_2 & \text{(iii)} \\ MHO_2 + MOH \rightarrow M + H_2O + O_2 & \text{(iv)} \end{cases}$$

must still be considered under certain conditions.

Case 1: General Equations for the Recombination Mechanisms I(ii), I(iii), or II(iii)

Elsewhere (21) we have developed the treatment of Thomas (15) and applied it to steps similar to the recombination reactions I(ii), I(iii), or II(iii), allowing for variation of the free energy of activation of the various steps with coverage; analogous calculations of surface coverage effects have previously been carried out with regard to electrochemical H/D isotope effects (16). In another paper (5), we have shown from the direction of potential dependence of the adsorption pseudocapacity that the nickel oxide surface is appreciably covered with O-containing radical intermediates except at low anodic potentials.

The coverage by the adsorbed OH species at the surface must hence be considered sufficient to cause variation of the heat of adsorption ΔH of OH with coverage θ, according to the equation

$$\Delta H = \Delta H^0 - r_1\theta, \qquad [1]$$

per g radical of OH; then with I(i) or II(i) in quasi-equilibrium and with $\theta_{MOH} \doteqdot \frac{1}{2}$ (cf. ref. 15) and $\theta_{MOH} \gg \theta_{MO}$* so that the main effect of variations of θ is in the exponentials, we obtain (15, 24)

$$\Delta G_{-1} - \Delta G_1^{\neq} + VF = r_1\theta + K, \qquad [2]$$

where K is a constant at constant concentration and temperature, and the $\Delta G^{\neq}$ values are the standard free energies of activation for the indicated forward and backward reactions I(i) or II(i) proceeding at an interfacial p.d. of V.

The rate equation for rate-controlling I(ii) is

$$v_2 = k_2(\theta_{MOH})^2 \exp -[\Delta G_2^{\neq} - 2\gamma r_1\theta + (1-\gamma)r_2\theta]/RT, \qquad [3]$$

where γ is a symmetry factor similar to the usual β and r_2 refers to MO species in an equation similar to [1]. For intermediate coverage ($\theta \doteqdot 0.5$) the variation of v_2 with θ_{MOH} will be mainly due to variation of the exponentials with θ in the terms involving $r_1\theta$ and $r_2\theta$. For most examples of chemisorption, the heat of adsorption varies by at least 10 kcal (g-atom)$^{-1}$ over the range of fractional coverage 0 to say 0.9, so that r is of the order 10 kcal. A variation of θ from $\theta = 0.1$ to say 0.9 as potential is varied would change the velocity of a recombination step by a factor of 81 due to variation of the pre-exponential term in θ_{MOH}^2; however, the corresponding effect in the exponential, through the r term taken as 10 kcal, would give a rate factor of

$$\exp\left[\frac{2\,0.9r}{RT}\right] \Big/ \exp\left[\frac{2\,0.1r}{RT}\right].$$

This ratio is approximately exp [26.6] or $10^{11.6}$ so that the exponential θ term, even when θ varies over as large a range as 0.1–0.9, can be by far the principal factor determining the dependence of rate upon coverage. In practice, this means that the variation of θ

**In the original treatment (15) for hydrogen evolution the only intermediate is adsorbed* H. *When several consecutive steps are involved, as in the present case, limiting assumptions must be made about the* total *coverage by intermediates and about the relative values of coverage, e.g. by* O *and* OH *etc. Such assumptions are also the basis of the previous general analysis of oxygen evolution slopes (19) but neglecting coverage effects in exponential terms. In the present case, with I(ii) or II(ii) rate determining, θ_{MOH} will be much greater than θ_{MO}.*

with potential occurs over a much wider range of potential than is possible if only the pre-exponential terms in θ are involved in the rate expression (21).

Substitution of θr_1 from [2] into [3] leads to the Tafel slope of

$$dV/d \ln i = 2RT/F$$

when $r_1 = r_2$, as is likely for the similar chemical species OH and O at the water-covered surface (21). No activated adsorption case (cf. ref. 15) can arise with I(ii) since molecular oxygen is not a product (to be desorbed) of this step. The Tafel slope can hence never be $RT/2F$ for this step and the lowest Tafel slope obtainable is RT/F when $r_1 \gg r_2$.

If I(iii) or II(iii) were rate determining, the low coverage Tafel slope is obviously $RT/4F$ and the intermediate coverage slope is now $RT/2F$ (15) for non-activated adsorption conditions. However, since in I(iii) or II(iii), the molecular oxygen produced is the final product and must be desorbed, the activated adsorption case (cf. ref. 15) must be considered here and corresponds to the substitution of a term $2\gamma r\theta$ instead of $2r\theta$ in the rate equation similar to [3] for reactions I(iii) or II(iii), leading to a Tafel slope of RT/F when $\gamma = 0.5$, and r now refers to coverage effects due to MO + MOH if I(iii) or II(iii) is rate controlling. For I(iii) or II(iii) the Tafel slope could hence change in the sequence

$$RT/4F \text{ (low coverage)} \rightarrow RT/2F \text{ (intermediate coverage)} \rightarrow RT/F \text{ (intermediate coverage, "activated" adsorption).}$$

We may note that when surface coverage terms are introduced into the exponentials in the rate expressions the lowest Tafel slope that can arise is $RT/2F$ when the exponential terms in θ are more important that the pre-exponential θ terms. Steps such as I(iii) or II(iii), which give a slope less than $RT/2F$ at low coverage (1, 19), cannot hence be distinguished, under conditions of intermediate coverage, from steps I(ii) or II(ii) at low coverage. The same arises for ion–radical recombination steps which, independent of their position in the consecutive sequence of steps, will not give slopes less than RT/F when coverage by intermediates is appreciable (21, see below) except when they are terminal desorption steps for which the minimum slope will normally be $2.3(2RT/3F)$.

Case 2: Ion–Radical Rearrangement—Mechanism II(ii) or III(ii)

Here, following the same methods as above, the theoretically possible Tafel slopes are:

Langmuir adsorption	(low coverage)	$2.3(2RT/3F)$;
Temkin adsorption	(intermediate coverage)	$2.3(2RT/F)$ $(r_1 = r_2)$,
		$2.3(RT/F)$ $(r_1 \gg r_2)$.

Since molecular O_2 is not a product in these reactions, neither of the terminal desorption cases considered above are relevant to this case.

(c) Conclusions on Reaction Mechanism

If the observed slope of 0.049 in the upper potential region is to be identified with that considered above for recombination in reactions I(iii) or II(iii) with "activated" desorption, γ will be 0.6 while if the slope were to be identified with that for the desorption reactions II(ii) or III(ii) at low coverage, the symmetry factor β in

$$dV/d \ln i = RT/(1+\beta)F$$

would vary from 0.22 to about 0.33 depending on the value of the slope considered, which varies to some extent with concentration (e.g. see refs. 1, 5). At the present time, we cannot make a final distinction between the several above possibilities but we note that the low values of β which would now be required to account for the observed slopes with the radical–ion desorption mechanism (Langmuir case) are unusual, while the value of γ (which has a similar significance to that of β) required to account for the observed slopes in the upper potential region on the basis of a recombination reaction has the more reasonable value of 0.6, nearer to the normal expected value of about 0.5.

Under conditions corresponding to activated adsorption of oxygen, it is seen that the observed slope for the upper potential region must preferably be explained in terms of the radical recombination mechanism II(iii) or III(iii), with $\gamma \doteqdot 0.6$ since II(ii) or III(ii) at appreciable coverage can never give slopes less than $2.3RT/F$ ($r_1 \gg r_2$) (21). The lower slope of $2.3(2RT/5F)$ or $2.3(RT/3F)$ observed at lower potentials in dilute solutions still follows in terms of the same consecutive mechanisms previously suggested (1), although it must be noted that for these slopes to arise, the coverage must be low, since at intermediate coverage III(iii) cannot give a slope less than $2.3RT/F$ for the same reasons as those which determine the slope of I(ii) or II(ii). Similarly, if III(iv) were rate determining, only slopes of $2.3RT/2F$ or $2.3RT/2\gamma F$ could arise as in the case of I(iii) or II(iii).

Since the lower slopes are observed only after an appreciable volume of oxygen has been desorbed in the self-discharge, this requirement of low coverage is not inconsistent with the experimental situation; we have in fact shown (5) that the total amount of oxygen desorbed over about a day corresponds to about a monolayer, based on the B.E.T. area of the dry oxidized electrode. Also with decreasing potential, the pseudocapacitance increases, indicating a trend (5) from high to lower coverage.

For the oxygen-producing reactions at the nickel oxide electrode, the low coverage Langmuir case is almost certainly only applicable after appreciable desorption of oxygen on self-discharge, since we have shown (5) from the direction of the potential dependence of the adsorption pseudocapacitance (viz. decreasing capacitance with increasing anodic oxygen overpotential) that the adsorbed layer of O-containing radicals at the surface is approaching full coverage at high anodic potentials. Under these conditions, where the heat of adsorption of O-containing radicals will be far removed from the "initial" or zero-coverage value, it is likely that the condition of "activated" adsorption (15) will hold, corresponding to a slope of $2.3RT/F$ for the final desorption step.

We hence conclude that the observed slope in the upper potential region could correspond to the final recombination step at appreciable coverages under "activated adsorption" conditions and the change of slope with decreasing potentials (and coverage) could correspond to a real change of mechanism to process III(iii) or to the alternative process $MO + OH^- \rightarrow MHO_2 + e$, as previously suggested (1), corresponding to a slope of $2.3(2RT/5F)$ under conditions of low coverage.

(d) Electrode Surface Capacity and Active O:Ni ratio

Elsewhere (2, 5) we have discussed the significance of the surface capacitance in relation to the e.m.f. decay behavior and to the mechanism of charging of the electrode. The results in Table II extend the previous observations (1) to higher and lower temperatures. The capacitance values given are "initial" values corresponding to the highest anodic potential involved at the moment of commencement of e.m.f. decay on open-circuit oxygen evolution; the variation of capacitance with temperature at a given concentration is not significant but the active O:Ni ratio generally increases with increasing KOH

concentration at 25° C and 60.5° C and the extent of self-discharge measured by the oxygen evolved is larger at the higher temperature on account of the greater rate of the process at elevated temperatures, as indicated by the kinetic data given above. The actual surface capacitance values vary appreciably probably on account of the difficulty of reproducing surfaces of the same real area from one run to another. The trend of the active O:Ni ratios with increasing KOH concentration may reflect stabilization of the surface layer of higher degree of oxidation by adsorbed KOH. The trend of true reversible potentials for the "$NiO_{1.25}$" electrode with KOH concentration requires participation of adsorbed KOH (2); elsewhere (25) it will be shown that the reversible potentials for the nickel oxide electrode, even in a low state of charge, are determined by the surface phase at the nickel oxide – solution interface.

We may conclude by noting that from equation [2] we can write

$$d\theta/dV = F/r.$$

Since the pseudocapacity associated with the coverage θ by radicals is

$$C = dq/dV,$$

where q is the adsorbed charge corresponding to θ and given by

$$q = k\theta,$$

it is clear that a constant pseudocapacity contribution C arises, associated with the linear dependence of θ on V, given by

$$C = kF/r$$

and is determined by the rate of change of adsorption energy with coverage (cf. ref. 22). When the heat of adsorption varies with θ by some power other than unity, potential-dependent capacitance can be shown (21) to result, as is also the case (24) for Langmuir conditions when the pre-exponential θ terms are taken into account. When pre-exponential and exponential terms in θ are combined, a more complex expression for C can be shown to result (21).

NOTES

THE X-RAY POWDER DIFFRACTION PATTERNS OF AMMONIA – NICKEL CYANIDE COMPLEXES

V. M. BHATNAGAR[1] AND J. A. R. CLOUTIER[2]

Clathrate compounds of ammonia – nickel cyanide complexes can be prepared from a small group of organic molecules. The composition of this series of clathrates is represented by $[Ni(CN)_2.NH_3.M]$, where M is aniline, benzene, furan, phenol, pyridine, pyrrole, or thiophene. An X-ray structural investigation of benzene clathrate has been made by Rayner and Powell (1).

The three clathrates were prepared by the method described by Palmer (2). The hydrated ammonia – nickel cyanide complex was obtained as stated by Bhatnagar (3). The following code has been used for these compounds in this note:

JA = $[Ni(CN)_2.NH_3.C_4H_5N]$, pyrrole clathrate;
VM = $[Ni(CN)_2.NH_3.\frac{1}{4}H_2O]$, hydrated ammonia – nickel cyanide complex;
QR = $[Ni(CN)_2.NH_3.C_6H_5NH_2]$, aniline clathrate;
AB = $[Ni(CN)_2.C_5H_5N]$, pyridine clathrate.

The unground powder, except when indicated, was introduced into a 0.2-mm glass capillary tube of 0.01-mm wall thickness. Diffraction patterns were obtained using Philips Debye–Scherrer powder cameras, diameter 114.83 mm, and Cu K_α radiation. Exposures from 5 to 10 hours at 30 kv and 10 ma were used. Line positions were corrected for film shrinkage and converted into d-values using tables (4). Relative intensities were estimated visually on a scale of 100. The I/I_1 values, as recorded, take into account the widths of the lines.

The X-ray powder diffraction patterns of the four complexes studied are presented in Figs. 1(*a*), 1(*b*), 1(*c*), and 1(*e*). The corresponding diffraction data are given in Table I. Letters are used to report on the condition of some of the observed lines. A diffuse line is indicated by the letter "d". An unresolved doublet which appeared as an unusually wide line is marked "w".

The four patterns of Figs. 1(*a*), 1(*b*), 1(*c*), and 1(*e*) are different from one another and could be used to characterize the corresponding compounds. However, under close inspection, a number of lines repeat with about the same relative intensities in each of these powder diagrams. These lines are, limiting the discussion to the ones of larger d-values: 3.60, 3.21, 2.54, 2.27, and 2.19 Å. Qualitatively, it would therefore appear that these four complexes have some common structural feature.

The effect of mechanical grinding on the powder diagrams was studied. The patterns from complexes AB and JA remained unaffected. Many lines disappeared on the pattern from complex QR, as illustrated in Fig. 1(*d*). Complex VM showed the presence of some additional doublets in its pattern, Fig. 1(*f*). However, these changes attributed to the

grinding of the powder were not predictable, since several patterns were obtained which were similar to Figs. 1(*c*) and 1(*e*), the diagrams from the unground QR and VM powders respectively.

The heat stability of the complexes was investigated. It was not possible to correlate the changes observed in the patterns with the expected ones associated with either the loss of the enclathrated organic molecules or the removal of NH_3 from the solid matrix. Therefore, it is not known how the initial dissociation of these complexes with heat takes place. However, it was observed that at 200±10° C the four complexes turned to a light brown color and yielded an X-ray diffraction pattern, Fig. 1(*g*), which was identified as that from anhydrous nickel cyanide (5). When the temperature was raised to 300±10° C, the four complexes gave the cubic pattern characteristic of nickel oxide, Fig. 1(*h*).

VANADIUM TRIALKOXIDES AND SOME ALCOHOLATES OF VANADIUM TRICHLORIDE

D. C. Bradley* and M. L. Mehta†

In attempting to prepare vanadium trialkoxides with vanadium trichloride as a starting material we have found that the lower aliphatic alcohols coordinate with vanadium trichloride, forming green solid alcoholates which are sparingly soluble in benzene, ether, toluene, carbon tetrachloride, or petrol, but more soluble in dimethylcellosolve. Methanol formed a 1:4 complex, VCl_3,4MeOH, whilst ethanol gave VCl_3,3EtOH, but neither complex could be crystallized from the alcohol. Isopropanol also gave a 1:4 complex, VCl_3,4Pr^{i}OH, which was recrystallized from boiling isopropanol. These alcoholates were readily oxidized on exposure to the air. It is noteworthy that chromium and iron trichlorides also form alcoholates (viz. $CrCl_3$,3ROH (1); $FeCl_3$,2ROH (2)).

The preparation of vanadium trialkoxides proved to be very difficult due to their ease of oxidation. Only the trimethoxide and triethoxide could be obtained in a reasonably pure state as green non-volatile solids. They were both prepared by the reaction involving vanadium trichloride and the appropriate lithium alkoxide:

$$VCl_3 + 3LiOR \rightarrow V(OR)_3 + 3LiCl.$$

Several methods for preparing vanadium triisopropoxide were tried but the product always contained vanadium in a higher valence state than three. In one experiment the quinquevalent vanadyl compound $VO(OPr^i)_3$ was obtained whilst in another the quadrivalent vanadium tetraisopropoxide $V(OPr^i)_4$ was isolated. Similarly, attempts to prepare vanadium tri-*tert*-butoxide were unsuccessful because of oxidation. In view of the precautions taken to avoid atmospheric oxidation it seems probable that the vanadium trialkoxides are sufficiently powerfully reducing to liberate hydrogen from the alcohols (cf. action of alkali metals). Moreover, it seems likely that we succeeded in isolating $V(OMe)_3$ and $V(OEt)_3$ only because they are sparingly soluble and hence less prone to oxidation. It is noteworthy that a similar facile oxidation has been observed with cerium (III) (3), uranium(IV) (4), and niobium(IV) (5) alkoxides. The insolubility and nonvolatility of vanadium trimethoxide and vanadium triethoxide strongly suggest that these compounds are polymeric. Vanadium triethoxide thus differs from ferric ethoxide and aluminum ethoxide, which can both be volatilized under reduced pressure.

EXPERIMENTAL

Apparatus

All-glass apparatus specially adapted to exclude atmospheric moisture and oxygen was used. The apparatus was rinsed with ethanol, dried at 120° C, and allowed to cool *in vacuo*. All operations were conducted under an atmosphere of pure dry nitrogen. The gas was finally deoxygenated by scrubbing with a solution of the sodium ketyl of benzophenone in diphenyl ether. The gas was conducted to the apparatus through polyethylene tubing since the latter is less permeable to oxygen than P.V.C. tubing.

Chemicals

Vanadium trichloride was prepared as follows: vanadium metal was chlorinated at 130–150° C to form the tetrachloride, which was dissociated at 160–170° C to give the trichloride. Methanol was dried by refluxing for 24 hours over magnesium methoxide and then distilled. Ethanol was first dried azeotropically with benzene and then chemically with sodium ethoxide and diethylphthalate followed by distillation. Isopropanol was dried azeotropically with benzene. *tert*-Butanol was dried first over freshly ignited calcium oxide, then distilled over sodium, and finally subjected to azeotropic distillation with benzene. In the preparation of the vanadium(III) alkoxides the alcohols were passed through a column of dry chromatographic alumina to remove traces of peroxides.

Benzene, toluene, petrol, and diethyl ether were dried over sodium and distilled. Carbon tetrachloride was dried by distillation over phosphoric oxide.

Analytical Methods

Vanadium was determined volumetrically, after reduction to V(II) in a Jones Reductor, by titration with ceric ammonium sulphate using ferroin indicator. This gave the titer for "total" vanadium; the average valency of the vanadium in a compound was deduced by comparing the equivalent weight of vanadium given by the titration of total vanadium with the equivalent weight determined by direct titration of the sample with ceric ammonium sulphate. In the vanadium alkoxides the "total" vanadium was checked gravimetrically as follows: The sample (ca. 0.2 g) was weighed directly into a crucible and hydrolyzed with dilute nitric acid. After careful evaporation to dryness (infrared lamp) the residue was treated with a few drops of concentrated nitric acid, dried, then ignited to V_2O_5. Chlorine was determined gravimetrically by precipitation of silver chloride in acid solution. Methoxide, ethoxide, and isopropoxide were determined volumetrically using the chromic acid method (6) with corrections for the concomitant oxidation of V(III) to V(IV).

Preparation of VCl_3,4MeOH

Vanadium trichloride (4.4 g; V, 32.8; Cl, 67.5%; valency, 3.01) appeared not to react with methanol (30 g) even on shaking. Heating under reflux for 3 hours gave a green solution but the cooled solution did not crystallize. Evaporation of the excess methanol under reduced pressure at room temperature left a green solid (8.0 g). Found: V, 18.72, 18.57; Cl, 36.8, 36.8; MeOH, 45.9, 46.8; valency, 3.04. VCl_3,4MeOH requires: V, 17.89; Cl, 37.3; MeOH, 44.8%. Attempts to recrystallize the product from methanol were unsuccessful.

Preparation of VCl_3,3EtOH

Vanadium trichloride (5.2 g) appeared not to react with ethanol (38.5 g) at room temperature. After refluxing the mixture for 4 hours the excess alcohol was removed, leaving a green solid (9.4 g). Found: V, 17.6, 17.6; Cl, 33.66, 33.60; EtOH, 45.9, 46.1; valency, 3.24. VCl_3,3EtOH requires: V, 17.3; Cl, 36.01; EtOH, 46.7%.

Preparation of VCl_3,4Pr^{i}OH

Vanadium trichloride (11.5 g) was refluxed with isopropanol (105 g), and on cooling deposited green crystals which were separated by decantation and recrystallized from isopropanol. The green crystalline product (26.6 g) was dried *in vacuo* at room temperature. Found: V, 13.12, 13.15; Cl, 26.50, 26.50; Pr^{i}OH, 60.01, 59.96; valency, 3.05. VCl_3,4Pr^{i}OH requires: V, 12.83; Cl, 26.80; Pr^{i}OH, 60.4%.

Preparation of Vanadium Trimethoxide

Vanadium trichloride (10.2 g) was dissolved in methanol (150 ml) and to this solution was added a solution of lithium methoxide (from 1.36 g Li) in methanol (100 ml). Vanadium trimethoxide was precipitated as a green solid, which was filtered off and washed with methanol (800–1000 ml) until the washing was free from chloride. The final residue (6.8 g) was analyzed. Found: V, 34.8 (volumetrically), 34.7 (gravimetrically); MeO, 64.2, 64.6; valency, 3.08; ratio MeO:V, 3.04; Cl, 0; Li, 0. $V(OMe)_3$ requires; V, 35.4; MeO, 64.6%. The trimethoxide was heated to 150° at ca. 10^{-4} mm in a molecular still and a trace of greenish-yellow sublimate was obtained, but the green solid was non-volatile. Found: V, 35.4; MeO, 64.4; valency, 3.05; MeO:V, 2.96. The trace of sublimate was probably the quinquevalent vanadyl trimethoxide.

Preparation of Vanadium Triethoxide

From the reaction involving VCl_3 (12.8 g) and lithium ethoxide (from 1.7 g Li) in ethanol (500 ml) a green solid (9.1 g) was finally obtained after filtration and exhaustive washing with ethanol. Found: V, 27.1, 27.2; EtO, 70.0; Cl, 0; Li, 0; valency, 3.1; EtO:V, 2.93. $V(OEt)_3$ requires: V, 27.4; EtO, 72.6%. A sample of the triethoxide was heated to 250° at ca. 10^{-4} mm in a molecular still but gave only a trace of yellow sublimate (probably $VO(OEt)_3$). The non-volatile residue (found: V, 40.2%; valency, 4.8) was not the triethoxide.

Attempts to Prepare Vanadium Triisopropoxide

(a) From VCl_3 and Sodium Isopropoxide

The trichloride (8.2 g) suspended in isopropanol (175 ml) was refluxed in the boiler of a Soxhlet apparatus, which also contained sodium (3.59 g) in the extraction compartment. The sodium isopropoxide was thus extracted into the vanadium trichloride solution in an atmosphere of hydrogen. After filtration the green solution was evaporated under reduced pressure but gave a brown solid residue (12.1 g). Found: V, 24.4, 23.3; Pr^{i}O, 44.1, 43.7; valency, 4.58, 4.60; Pr^{i}O:V, 1.56. $V(OPr^i)_3$ requires: V, 22.4; Pr^{i}O, 77.6%.

(b) From $V(OMe)_3$ and Isopropanol

The trimethoxide (8.4 g) was suspended in isopropanol (200 ml) and benzene (20 ml) and then refluxed under a fractionating column. During 5 days of reaction the trimethoxide went into solution and the liberated methanol was removed as the methanol–benzene azeotrope. Removal of excess isopropanol from the green solution left a green solid (6.8 g). Found: V, 23.9 (volumetrically), 23.7 (gravimetrically); Pr^{i}O, 71.0; valency, 4.54, 4.52; Pr^{i}O:V, 2.57. When the foregoing product was heated to 100–120° at 0.5 mm a green liquid distilled over. Found: V, 20.1; Pr^{i}O, 66.0, 70.0; valency, 4.98; Pr^{i}O:V, 2.93. $VO(OPr^i)_3$ requires: V, 20.9; Pr^{i}O, 72.5%.

(c) From VBr_3 and Lithium Isopropoxide

The tribromide (15.8 g) was dissolved in isopropanol (200 ml) and mixed with lithium isopropoxide (from 0.587 g Li) in isopropanol (200 ml). Nothing precipitated, so the green solution was evaporated to dryness and the residue heated *in vacuo*. At 140° and 0.2 mm a green distillate was obtained. Found: V, 20.7; 20.4; Pr^{i}O, 72.2; valency, 4.95, 4.75. $VO(OPr^i)_3$ requires: V, 20.9; Pr^{i}O, 72.5%.

(d) From VCl_3 and Sodium in Isopropanol

The trichloride (11.8 g) was suspended in isopropanol (52.5 g) and benzene (74.7 g), and sodium (4.91 g) was added. The mixture was refluxed for 12 hours, giving a green solution which was evaporated to dryness, and the residue distilled at 100–110° at 0.1 mm. The green distillate solidified. Found: V, 17.3; Pr^{i}O, 79.8; valency, 4.17; Pr^{i}O:V, 3.89. $V(OPr^i)_4$ requires: V, 17.7; Pr^{i}O, 82.3%.

Attempts to Prepare Vanadium Tritertiary Butoxide

(a) From Vanadium Trimethoxide and Lanthanum tert-Butoxide

Vanadium trimethoxide (1.6 g) was mixed with lanthanum tri-*tert*-butoxide (4.49 g) in benzene (50.2 g). During 12 hours of refluxing a faint green color developed in the solvent. After filtration the filtrate was taken to dryness, giving a light green solid (0.2 g). Found: V, 17.9. $V(OBu^t)_3$ requires: V, 18.9%. The product was heated at 0.01 mm but nothing volatilized up to 340°.

(b) From Vanadium Trimethoxide and Aluminum tert-Butoxide

Vanadium trimethoxide (4.2 g) and aluminum tri-*tert*-butoxide (7.2 g) were mixed with petrol (20 ml, boiling range 40–60°) and well shaken. After evaporating off the solvent the residue was heated *in vacuo*. A green liquid distilled over (1.3 g; b.p. 140° at 0.3 mm). Found: V, 17.4; valency, 4.98. $VO(OBu^t)_3$ requires: V, 17.8%.

(c) From the Action of tert-Butanol on Vanadium Amide

Potassium amide was prepared in liquid ammonia (1000 ml) from potassium (8.27 g). Vanadium trichloride (10.6 g) was added, causing an exothermic reaction. After the mixture had stood overnight, *tert-*

butanol–benzene azeotrope (80 ml) was slowly added and the solvents were then evaporated off. The residue was extracted with petrol (200 ml, 40–60° boiling range) and gave a green solution which, upon evaporation and drying, left a violet solid (1.32 g). Found: V, 16.1, 16.3; valency, 5.0.

TRANSFORMATION OF ACONITINE TO AN ISOMER OF HYPACONITINE*

ROBERT E. GILMAN† AND LÉO MARION

Hypaconitine, $C_{33}H_{45}O_{10}N$, $[\alpha]_D = +23°$ ($CHCl_3$), m.p. 198°, has long been considered to be closely related to aconitine in structure. Majima and Tamura have reported that hypaconitine contains an N-methyl group rather than the N-ethyl group that is present in aconitine (1). They also found that hypaconitine is very resistant to chromic acid oxidation. It is known that aconitine (I) is oxidized with ease by chromic acid to a ketone, aconitinone, which readily loses the elements of methanol to form the α,β-unsaturated ketone aconitoline, and that it is a secondary hydroxyl in ring A that is oxidized in this reaction (2). Hence, if hypaconitine possesses the same ring structure as aconitine, it cannot contain a similarly placed hydroxyl in ring A.

It was then assumed as a working hypothesis that hypaconitine had the same structure as aconitine except that it contained an N-methyl instead of an N-ethyl group, and that it lacked the hydroxyl of ring A. An attempt to convert aconitine into the assumed structure II of hypaconitine was started in this laboratory by Dr. N. V. Riggs. By treatment of aconitine with thionyl chloride, anhydroaconitine ($C_{34}H_{45}O_{10}N$) was obtained, which, on catalytic hydrogenation, absorbed 1 mole of hydrogen and produced deoxyaconitine ($C_{34}H_{47}O_{10}N$). It has now been demonstrated that the ring A hydroxyl was the one that was removed in these reactions. Pyrolysis of deoxyaconitine gave pyrodeoxyaconitine, $C_{32}H_{43}O_8N$ (III). Transesterification of the pyro compound gave pyrodeoxyaconine (IV), which was isolated as the perchlorate. The infrared spectrum of pyrodeoxyaconine contained carbonyl absorption at 1705 cm^{-1}, like pyraconine, and it can thus be concluded that a secondary hydroxyl group must be present in ring D of deoxyaconitine (cf. ref. 3). If this ring D hydroxyl had been the one removed in the formation of deoxyaconitine, the pyrolysis product would have been an olefin like pyrodelphinine (4) instead of being a ketone.

TRANSFORMATION OF ACONITINE TO AN ISOMER OF HYPACONITINE*

ROBERT E. GILMAN† AND LÉO MARION

Hypaconitine, $C_{33}H_{45}O_{10}N$, $[\alpha]_D = +23°$ ($CHCl_3$), m.p. 198°, has long been considered to be closely related to aconitine in structure. Majima and Tamura have reported that hypaconitine contains an N-methyl group rather than the N-ethyl group that is present in aconitine (1). They also found that hypaconitine is very resistant to chromic acid oxidation. It is known that aconitine (I) is oxidized with ease by chromic acid to a ketone, aconitinone, which readily loses the elements of methanol to form the α,β-unsaturated ketone aconitoline, and that it is a secondary hydroxyl in ring A that is oxidized in this reaction (2). Hence, if hypaconitine possesses the same ring structure as aconitine, it cannot contain a similarly placed hydroxyl in ring A.

It was then assumed as a working hypothesis that hypaconitine had the same structure as aconitine except that it contained an N-methyl instead of an N-ethyl group, and that it lacked the hydroxyl of ring A. An attempt to convert aconitine into the assumed structure II of hypaconitine was started in this laboratory by Dr. N. V. Riggs. By treatment of aconitine with thionyl chloride, anhydroaconitine ($C_{34}H_{45}O_{10}N$) was obtained, which, on catalytic hydrogenation, absorbed 1 mole of hydrogen and produced deoxyaconitine ($C_{34}H_{47}O_{10}N$). It has now been demonstrated that the ring A hydroxyl was the one that was removed in these reactions. Pyrolysis of deoxyaconitine gave pyrodeoxyaconitine, $C_{32}H_{43}O_8N$ (III). Transesterification of the pyro compound gave pyrodeoxyaconine (IV), which was isolated as the perchlorate. The infrared spectrum of pyrodeoxyaconine contained carbonyl absorption at 1705 cm^{-1}, like pyraconine, and it can thus be concluded that a secondary hydroxyl group must be present in ring D of deoxyaconitine (cf. ref. 3). If this ring D hydroxyl had been the one removed in the formation of deoxyaconitine, the pyrolysis product would have been an olefin like pyrodelphinine (4) instead of being a ketone.

Issued as N.R.C. No. 6896.

I: $R = Et; R^1 = OH; R^2 = OAc; R^3 = OH,H; R^4 = COC_6H_5$
II: $R = Me; R^1 = H; R^2 = OAc; R^3 = OH,H; R^4 = COC_6H_5$
III: $R = Et; R^1 = R^2 = H; R^3 = O; R^4 = COC_6H_5$
IV: $R = Et; R^1 = R^2 = R^4 = H; R^3 = O$

The N-ethyl group of deoxyaconitine was then removed by oxidation with mercuric acetate in 3% acetic acid solution. This method has been used previously in this laboratory to remove the N-ethyl group of delcosine (5). The oxidation of deoxyaconitine proceeded smoothly and yielded two products. The desired secondary amine was extracted into chloroform from the reaction mixture as its acetate salt. Conversion of the acetate to the free base gave an amorphous compound which could not be crystallized even after careful chromatography over Grade III alumina. The n.m.r. spectrum did not contain the triplet characteristic of an ethyl group at τ 8.9. The second product was obtained by chloroform extraction of the residual reaction mixture after it had been made basic. The base was crystallized from acetone–hexane to a melting point of 168–175°, but was not examined further, since its n.m.r. spectrum indicated that the N-ethyl group was still present.

A small quantity of the amorphous secondary amine was converted back to deoxyaconitine by treatment with ethyl iodide. Hence only the ethyl group attached to the nitrogen had been removed by the oxidation.

The secondary amine was then converted to the desired N-methyl compound by treatment with methyl iodide. The product was recrystallized from methanol until it had a constant melting point of 172–178° decomp.

This compound, which has structure II, has an infrared spectrum which is nearly superimposable on that of hypaconitine, but there are slight differences in the region between 950 and 1050 cm^{-1}. The X-ray powder patterns of the two compounds are also nearly identical, although definite differences are observable. Hence, although the compound derived from aconitine is very similar to hypaconitine, it is definitely different.

In the compound derived from aconitine there are 14 asymmetric centers, many of which have a fixed configuration because of the rigidity of part of the structure. A difference of configuration at any one of the remaining centers, however, could account for the slight differences observable in the infrared spectra and the X-ray patterns. It is probable that the ring structure of hypaconitine is the same as that of aconitine, but that the configuration of either a ring, or one or more of the substituents, is different. To determine what the difference is will necessitate degradative work with hypaconitine, which cannot be undertaken until a supply of the alkaloid becomes available.

EXPERIMENTAL

All melting points were measured on a hot-stage under the microscope. The infrared spectra were obtained in nujol mulls on a Perkin–Elmer model 21 double-beam instrument.

*Anhydroaconitine Perchlorate**

Aconitine (3 g) and redistilled thionyl chloride (10 ml) were refluxed for 3 hours, initial gas evolution apparently ceasing after 40 minutes. The mixture was evaporated at the water pump on a water bath at 60° to a dry froth which was evaporated twice similarly with methanol (5 ml). The residue dissolved in methanol (5 ml) was neutralized by the dropwise addition of 70–72% perchloric acid, the solid mass obtained diluted with methanol (5 ml), and the mixture set aside. The crystal crop (2.5 g) was recrystallized several times from methanol–ether, from which it separated as clumps of prisms, m.p. 200–204°, $[\alpha]_D^{25} = +12.9°$ (*c*, 1.90 in acetone). The material was dried at 100° and 0.4 mm for 16 hours for analysis. Found: C, 55.40; H, 6.38; Cl, 4.53; OCH_3, 17.66%. Calc. for $C_{34}H_{45}O_{10}N.HClO_4.0.5H_2O$: C, 55.39; H, 6.43; Cl, 4.81; $4\times OCH_3$, 16.84%. The water of crystallization was not removed by drying at 100° and 0.01 mm. Found: C, 55.51; H, 6.46%.

*Deoxyaconitine**

A solution of anhydroaconitine perchlorate (151 mg) in purified ethanol (20 ml) absorbed hydrogen (4.89 ml at 25° and 760 mm; calc. for 1 mole, 5.01 ml) in the presence of 5% palladium–95% barium sulphate catalyst during 5 hours, uptake then ceasing. Evaporation of the filtrate and crystallization of the residue from methanol with addition of ether gave prisms, m.p. 180° after softening at 165°, $[\alpha]_D^{25} = -11.7°$ (*c*, 2.33 in acetone). The material was dried at 100° and 0.5 mm for 16 hours. Found: C, 55.87; H, 7.16; Cl, 4.80. Calc. for $C_{34}H_{47}O_{10}N.HClO_4$: C, 55.92; H, 6.63; Cl, 4.86%.

The perchlorate was shaken with cold saturated sodium carbonate solution and the mixture extracted three times with chloroform. The combined extract was dried over sodium carbonate and evaporated to a froth which rapidly crystallized in contact with a little methanol. Recrystallization from acetone–water gave colorless leaves, m.p. 173–176°. The material was dried at 100° and 0.4 mm for 4 hours. Found: C, 64.84; H, 7.52; OCH_3, 19.43. Calc. for $C_{34}H_{47}O_{10}N$: C, 64.84; H, 7.52; $4\times OCH_3$, 19.71%.

Pyrodeoxyaconitine

Deoxyaconitine (85 mg) was placed in a sublimation tube and the tube evacuated to 5×10^{-4} mm. The tube was then placed in a block heater at 200–205° C and held at that temperature for 30 minutes while the pyrolysis product distilled slowly. Yield of faintly colored distillate, 70 mg. All attempts to crystallize the distillate were unsuccessful and it was redistilled for analysis. $[\alpha]_D^{20} = -82°$ (*c* = 1.0 in ethanol). Calc. for $C_{32}H_{43}O_8N$: C, 67.46; H, 7.61; N, 2.46. Found: C, 67.40; H, 7.49; N, 2.44%.

Pyrodeoxyaconine Perchlorate

Distilled pyrodeoxyaconitine (150 mg) was dissolved in dry methanol (10 cc). Sodium (1–2 mg) was added and the solution was kept at 0° for 1 hour. The methanol was then removed by distillation at 30° under reduced pressure. Chromatography of the residue over Grade IV alumina gave 66 mg of product that crystallized from a concentrated ether solution, m.p. 85–90°. Since the crystals could not be obtained in pure form, the base was converted to the perchlorate salt. Recrystallized from methanol–ether, m.p. 250–260° decomp., $[\alpha]_D^{20} = -86°$ (*c* = 0.6 in water). The infrared spectrum has a strong band at 1705 cm^{-1}. Calc. for $C_{25}H_{39}O_7N.HClO_4$: C, 53.05; H, 7.12; N, 2.47. Found: C, 53.11; H, 7.24; N, 2.45%.

N-Desethyl-deoxyaconitine

Deoxyaconitine (750 mg) was dissolved in 3% acetic acid (25 cc), and mercuric acetate (1.25 g) was added. The solution was heated on the steam bath for 1 hour. The crystalline mercurous acetate that formed was then removed from the cooled reaction mixture by filtration. The filtrate was extracted with three portions of chloroform and the combined chloroform extracts were washed with 5% potassium carbonate solution and then with water. Concentration of the dried chloroform solution to dryness left a white foam. Yield: 350 mg. All attempts to crystallize this material failed.

Chromatography over Grade III alumina gave a main fraction of 210 mg when the column was eluted with 50% benzene–chloroform. The lack of a triplet in the n.m.r. spectrum at a τ value of 8.9 indicated that the ethyl group attached to the nitrogen was absent.

Attempts to prepare crystalline salts of the secondary amine were also unsuccessful.

The original aqueous reaction mixture, which had been extracted with chloroform, was then made basic and extracted again with chloroform. Concentration of the washed and dried chloroform extract left a residue that was crystallized from ether – *n*-hexane, m.p. 168–175°. The n.m.r. spectrum indicated that the N-ethyl group was still present, so this product was not investigated further.

Ethylation of N-Desethyl-deoxyaconitine

The chromatographed secondary amine (50 mg) was dissolved in ether and treated with excess ethyl

**Experiments performed by Dr. N. V. Riggs.*

iodide. The solution was refluxed for 30 minutes. Excess ethyl iodide and ether were distilled off and the residue was dissolved in water. The aqueous solution was made basic with potassium carbonate and the precipitate was extracted with chloroform. Concentration of the washed and dried chloroform extracts left a white foam which was crystallized from ether – *n*-hexane to a constant melting point of 167–174° decomp. The melting point was not depressed when the product was mixed with deoxyaconitine. The infrared spectrum was identical with that of deoxyaconitine.

Methylation of N-Desethyl-deoxyaconitine

The chromatographed secondary amine (300 mg) was dissolved in ether and treated with excess methyl iodide. The solution was refluxed for 30 minutes and then concentrated to dryness *in vacuo*. The residue (370 mg) was worked up exactly as above and yielded a white foam (240 mg) that crystallized on contact with ether. This was recrystallized from methanol to a constant melting point of 172–178° decomp., $[\alpha]_D^{20} = +18°$ (*c*, 1.2 in $CHCl_3$). Calc. for $C_{33}H_{45}O_{10}N$: C, 64.37; H, 7.37; N, 2.27. Found: C, 64.57; H, 7.29; N, 2.33%.

ACKNOWLEDGMENTS

We acknowledge with thanks the kindness of Professor H. Suginome, who supplied us with a small sample of hypaconitine. We thank Dr. M. Przybylska for the X-ray patterns, Mr. R. Lauzon for the infrared spectra, and Mr. H. Seguin for the analyses.

A NEW SPRAY FOR THE DETECTION OF HIGHLY SUBSTITUTED ACETALS AND KETALS OF CARBOHYDRATES

J. W. BIRD

The detection of highly substituted acetals and ketals of carbohydrates on paper chromatograms is often difficult or impossible with the commonly used spray reagents (i.e. alkaline silver nitrate (1), *p*-anisidine hydrochloride (2)) unless vicinal hydroxyl or reducing groups are present. Pacak and Cerny (3) report the use of ceric ammonium nitrate for the detection of isopropylidene compounds. However, the author has found this reagent (2–3% aqueous solution heated at 120° C for 2–3 minutes) to give difficultly reproducible results and now reports a modification giving a more sensitive, reliable, and permanent method of detection.

The chromatograms developed in basic, acidic, or neutral solvent systems were dried (chromatograms from acidic solvents were air dried for 1 hour) and sprayed, first with a freshly prepared aqueous solution of ceric ammonium nitrate (2–3%) then immediately with a 2% solution of silver nitrate in acetone (1). The chromatograms, after drying at 120° C for 2–3 minutes, were sprayed with a 2% ethanolic solution of sodium hydroxide, and after 2–3 minutes the background color was bleached by immersion of the chromatogram in sodium thiosulphate solution. After application of the sodium hydroxide spray reagent, a further overspraying with the ceric ammonium nitrate solution was found to give improved definition.

THE STRUCTURE OF CARBOLINES AND RELATED COMPOUNDS

LEONELLO PAOLONI

In a recent paper Abramovitch and Adams (1) have made some remarks concerning the work of this author (2) on the concept of valence state and the electronic structure of carbolines and their anhydronium bases. They state in the footnote on p. 2518 of reference 1: ". . . his conclusion that it is unnecessary to represent the carboline anhydrobases as hybrids of dipolar and quinonoïd structures in view of the fact that his results '*illustrate eloquently the compromise between the tendency to form the (aromatic) sextet and that to neutralize the charges*' seems a contradiction in ideas".

The wording in italics, written by the Authors (1) between quotation marks, does not represent a *verbatim* translation of any sentence in the original paper (2), but it is, on the best, the abstract of their interpretation of the last paragraph of p. 1532 of reference 2.

The compounds listed in Table I were detected as light brown to black spots on a light background after following the procedure above.

THE STRUCTURE OF CARBOLINES AND RELATED COMPOUNDS

LEONELLO PAOLONI

In a recent paper Abramovitch and Adams (1) have made some remarks concerning the work of this author (2) on the concept of valence state and the electronic structure of carbolines and their anhydronium bases. They state in the footnote on p. 2518 of reference 1: ". . . his conclusion that it is unnecessary to represent the carboline anhydrobases as hybrids of dipolar and quinonoïd structures in view of the fact that his results '*illustrate eloquently the compromise between the tendency to form the (aromatic) sextet and that to neutralize the charges*' seems a contradiction in ideas".

The wording in italics, written by the Authors (1) between quotation marks, does not represent a *verbatim* translation of any sentence in the original paper (2), but it is, on the best, the abstract of their interpretation of the last paragraph of p. 1532 of reference 2.

Because the quotation is in fact wrong and misleading, we give here its correct English version: "One consequence of this (valence state) interpretation is that it is no longer necessary to use two formulas (one with charge separation) in exchange equilibrium with one another to denote, for example, anhydronium bases. The balance between the *tendency to sextet formation* and the *tendency to charge neutralization*, used by Robinson (3) to justify the double formula, is indeed the consequence of the change which has taken place in the potential field where the electrons move. Since such a changed situation is clearly reflected in the classical formula, this is in itself completely adequate to describe the properties of anhydronium bases."

We would like also to remark that the emphasis of our paper (2) was not on the exact calculation of the pK_a or of the spectrum of the carboline anhydronium bases (whose general trend is correctly predicted), but rather on the relationship between the valence state of atoms in molecules and the chemical symbolism.

It may be convenient to point out, for those who do not read Italian, that an English translation of the paper (2) has been published recently (4).

REACTIONS OF ALIPHATIC ARYLHYDRAZONES AND OF ANILINE WITH CARBON MONOXIDE TO YIELD UREAS

ALEX ROSENTHAL

It has been recently reported (1–3) that the cyclization of Schiff bases and of aromatic ketone phenylhydrazones with carbon monoxide yields N-phenylphthalimidines and phthalimidine-N-carboxyanilides, respectively. In this paper we wish to report the extension of the carbonylation reaction to aliphatic arylhydrazones and to aniline. Slightly modified conditions to those reported by Murahashi and Horiie (1, 2) were used.

When a solution of acetone phenylhydrazone in benzene was reacted with about 4000 p.s.i. of carbon monoxide at about 250° in the presence of preformed dicobalt octacarbonyl, the main products isolated were *sym*-diphenylurea, monophenylurea, and diphenyl. In addition, a crystalline organocobalt complex which, on degradation with molten sodium hydroxide, yielded aniline and ammonia was obtained. An unstable substance (B), having an empirical formula of $C_{10}H_{10}N$ (approximate), was separated from the mixture of products by chromatography on alumina. As the latter substance was present in low yield, and rapidly changed in the presence of air, further work on it was abandoned.

Similarly, acetaldehyde phenylhydrazone also reacted with carbon monoxide to yield *sym*-diphenylurea and monophenylurea.

Because the quotation is in fact wrong and misleading, we give here its correct English version: "One consequence of this (valence state) interpretation is that it is no longer necessary to use two formulas (one with charge separation) in exchange equilibrium with one another to denote, for example, anhydronium bases. The balance between the *tendency to sextet formation* and the *tendency to charge neutralization*, used by Robinson (3) to justify the double formula, is indeed the consequence of the change which has taken place in the potential field where the electrons move. Since such a changed situation is clearly reflected in the classical formula, this is in itself completely adequate to describe the properties of anhydronium bases."

We would like also to remark that the emphasis of our paper (2) was not on the exact calculation of the pK_a or of the spectrum of the carboline anhydronium bases (whose general trend is correctly predicted), but rather on the relationship between the valence state of atoms in molecules and the chemical symbolism.

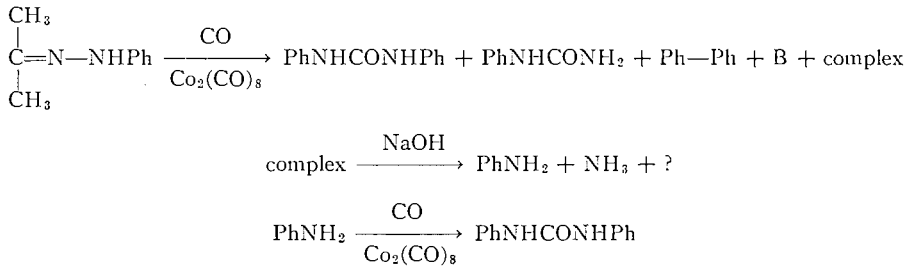
REACTIONS OF ALIPHATIC ARYLHYDRAZONES AND OF ANILINE WITH CARBON MONOXIDE TO YIELD UREAS

ALEX ROSENTHAL

It has been recently reported (1–3) that the cyclization of Schiff bases and of aromatic ketone phenylhydrazones with carbon monoxide yields N-phenylphthalimidines and phthalimidine-N-carboxyanilides, respectively. In this paper we wish to report the extension of the carbonylation reaction to aliphatic arylhydrazones and to aniline. Slightly modified conditions to those reported by Murahashi and Horiie (1, 2) were used.

When a solution of acetone phenylhydrazone in benzene was reacted with about 4000 p.s.i. of carbon monoxide at about 250° in the presence of preformed dicobalt octacarbonyl, the main products isolated were *sym*-diphenylurea, monophenylurea, and diphenyl. In addition, a crystalline organocobalt complex which, on degradation with molten sodium hydroxide, yielded aniline and ammonia was obtained. An unstable substance (B), having an empirical formula of $C_{10}H_{10}N$ (approximate), was separated from the mixture of products by chromatography on alumina. As the latter substance was present in low yield, and rapidly changed in the presence of air, further work on it was abandoned.

Similarly, acetaldehyde phenylhydrazone also reacted with carbon monoxide to yield *sym*-diphenylurea and monophenylurea.



The fact that diphenyl was present in the reaction product suggests strongly that during the reaction phenyl free radicals were produced and these subsequently combined. It is possible that the phenyl free radicals were produced by thermal decomposition of the azo tautomer of acetone phenylhydrazone. Support for this hypothesis is provided by the recent work of Connor (6), who found that the phenylhydrazones of aldehydes and ketones rapidly tautomerize to benzene azoalkanes. The homolytic cleavage of the latter compound to yield nitrogen and free radicals is well known (7, 8).

Since *sym*-diphenylurea was produced by the reaction of aliphatic arylhydrazones with carbon monoxide, it was decided to determine if under similar conditions aniline would also yield the same product. The expected result was realized, although in much lower yield. Presumably the dicobalt octacarbonyl dehydrogenated the aniline, yielding *sym*-diphenylurea and possibly cobalt hydrocarbonyl. A similar dehydrogenation of aniline was recently reported by Franz and co-workers (4, 5), who found that aniline reacted with carbon monoxide in the presence of sulphur to yield *sym*-diphenylurea and hydrogen sulphide.

The explanation of the mechanism of the reaction is complicated by the fact that acetone phenylhydrazone is known to be thermally decomposed into aniline and ammonia (9). As the rate of formation of *sym*-diphenylurea from aniline was much slower than that from acetone phenylhydrazone, it would appear that the reaction must proceed by at least two independent mechanisms.

EXPERIMENTAL

General Considerations

The equipment was described previously (10).

Reaction of Acetone Phenylhydrazone with Carbon Monoxide

A mixture of 10 g (0.065 mole) of acetone phenylhydrazone (11) and 2 g of preformed dicobalt octacarbonyl in 40 ml of thiophene-free anhydrous benzene and carbon monoxide (1980 p.s.i. at 20°) was placed in the high-pressure bomb. The reactants were heated with rocking at 250–265° for 2 hours. An observed pressure drop of 50 p.s.i. at 20° was obtained. After the residual gases were vented, a blue crystalline residue (1.65 g) was removed by filtration. The residue was insoluble in ether, benzene, or acetone and very slightly soluble in N,N-dimethylformamide. Infrared (KBr): 3150–3450 (broad, m), 1715 (s), 1480 (m), 1330–1410 (broad, w), 1150 (w), 1065 (w), 1010 (w), 825 (m). Anal. Found: C, 44.22; H, 4.16; N, 16.44.

Combustion of 14.190 mg of blue crystals yielded 3.486 mg of cobalt residue. Reaction of the organocobalt complex with molten sodium hydroxide pellets produced basic gaseous and liquid nitrogen containing substances. The gaseous component was shown by means of infrared analysis to contain ammonia. The liquid component was converted to a bromo derivative, and shown to be identical with an authentic sample of 2,4,6-tribromoaniline. Reaction of the liquid component with gaseous hydrogen chloride produced aniline hydrochloride. Another compound in trace amount was shown, by nuclear magnetic resonance studies, to be present in the liquid.

After removal of the organocobalt complex, an aliquot of the filtrate containing 1.5 g of the product was subjected to exhaustive chromatographic fractionation on alumina (110×30-mm diam.). Petroleum ether (b.p. 65–80°) eluted traces of residual catalyst. A 1:1 mixture of benzene–petroleum ether (35–60°) yielded

0.32 g (20%) of substance A, which on recrystallization from petroleum ether at −50° yielded diphenyl, m.p. 68–70°; mixed m.p. with an authentic sample of diphenyl was 68–70°. The infrared spectra of both compounds were identical.

Substance B (0.16 g) was then eluted from the column with benzene. Fraction B (oil) turned red on addition of an acid (or after standing in the air for a few hours) and yellow on addition of a base. Infrared (KBr): 3400 (m), 3080 (w), 2950 (m), 1700 (w), 1620 (w), 1600 (w), 1550 (m), 1460 (s). The n.m.r. spectrum of fraction B in chloroform showed two main peaks at 2.15 and 7.32 τ having approximate areas of 22:18. Anal. Found: C, 81.45; H, 6.95; N, 9.70.

Substance C (*sym*-diphenylurea) was then eluted with a 1:1 mixture of benzene–chloroform. Recrystallization of compound C from chloroform gave pure material; m.p. 251–252°; mixed m.p. with an authentic sample (12) of *sym*-diphenylurea was 251–252°. The infrared spectra of both compounds were identical.

Compound E (monophenylurea) was eluted with a 9:1 mixture of benzene–ethanol; yield, 0.33 g. Recrystallization from chloroform gave pure monophenylurea, m.p. 146–148°; mixed m.p. with an authentic sample of monophenylurea (13) was 146–148°. The infrared spectra of both compounds were identical.

Reaction of Acetaldehyde Phenylhydrazone with Carbon Monoxide

A mixture of 8.3 g of acetaldehyde phenylhydrazone (14), m.p. 98–101°, was carbonylated at 250–260° for 70 minutes. The reaction products consisted of a highly intractable gum in addition to a blue-black solid (0.5 g). After removal of the solid and gum, the benzene filtrate was freed of catalyst and then subjected to chromatographic fractionation on alumina according to the procedure described previously in the experimental section. *sym*-Diphenylurea (55%) and monophenylurea 17% (based on the chromatographed material) were the chief products of the reaction.

Reaction of Aniline with Carbon Monoxide

A mixture of 1.5 g of aniline and 0.4 g dicobalt octacarbonyl in 15 ml of benzene was reacted with 3900 p.s.i. of carbon monoxide at 250–260° for 1.5 hours. The product was chromatographed on Florisil, as described previously in the experimental. *sym*-Diphenylurea was obtained; 0.04 g, m.p. 250–252°; mixed m.p. with an authentic sample of *sym*-diphenylurea 250–252°.

ACKNOWLEDGMENTS

This research was supported by a grant from the Petroleum Research Fund administered by the American Chemical Society. Grateful acknowledgment is hereby made to the donors of said fund.

The author wishes to thank Dr. D. McGreer of this department for carrying out the nuclear magnetic resonance studies. The phenylhydrazones were prepared by Mr. J. Matson.

Thanks are also due Dr. W. R. Cullen for determining the ammonia in the organocobalt complex.

SOME DIELECTRIC PROPERTIES OF CARBONYL CHLORIDE[1]

D. W. DAVIDSON

Recent spectroscopic (1), crystal structure (2), and calorimetric (3) studies of carbonyl chloride (phosgene) seem to rule out the possibility of the existence of residual entropy in the stable solid form (1) of carbonyl chloride, in contrast with earlier suggestions (4). However, the identification by Giauque and Ott (3) of two additional, relatively unstable, solid forms (II and III) prompted a dielectric study with the aim of determining whether the residual disorder in these forms was accompanied by dipolar relaxation processes of appreciable rate. In addition, the static dielectric constant of the liquid between −132 and +20° and the dipole moment of the gas were measured.

Gas Measurements

These were undertaken primarily to check the performance of a recently constructed apparatus for measurements of dipole moments of substances in the vapor state. The apparatus is of the classical LC oscillator type in which the cell capacitance is connected in parallel with a series arrangement of a small fixed capacitor (C_s = ~23 pf) and a General Radio Type 722 variable air capacitor. Deviations of the oscillator frequency from 1 Mc/sec, shown directly on a General Radio Frequency Deviation Meter, are adjusted to zero (to within a fraction of a cycle/sec) with the variable capacitor. Readings of this capacitor (corrected by calibration) are taken with the cell evacuated (C_0'), filled with sample at a known pressure (C_g), and evacuated again (C_0'').

The gas cell consists of three coaxial cylindrical electrodes of gold-plated nickel, suspended in a stainless steel vessel. The intermediate (high-potential) electrode is slightly shorter than the other two and is held in circular grooves in Teflon rings which fit tightly between the ends of the inner- and outer-most (grounded) electrodes. The rings are backed with perforated nickel disks, grooved to receive the ends of the grounded electrodes. The electrode assembly is held rigid by bolts which bear on the backing disks and are threaded on a nickel shaft attached to the top of the cell vessel. A vacuum-tight seal between the top and body of the vessel, which are bolted together, is provided by a thin 2S0 aluminum gasket, placed between a 1/16-in. circular bead machined on the lower edge of the top and the highly polished upper edge of the body wall. The lead from the high-potential electrode is brought out through a double Kovar-glass seal and connected to the oscillator via a rigid Teflon-insulated coaxial cable. The cell is connected to the sample line via a Kovar-glass seal. The cell constant (C_{cell}) is ~170 pf.

Dielectric constants ϵ were determined from

$$\frac{(\epsilon-1)C_{cell}}{C_s^2} = \frac{C_0-C_g}{(C_0+C_s+C_p)(C_g+C_s+C_p)}$$

in which $C_0 = (C_0'+C_0'')/2$ and C_p = small effective capacitance in parallel with the variable capacitor. Values of the two constants, viz. C_s^2/C_{cell} and C_s+C_p, were determined from measurements with standard non-polar gases at different pressures and with the cell in parallel with a small variable condenser in which capacitance variations were known to 0.001 pf.

[1]*Issued as N.R.C. No. 6877.*

The cell is mounted in a thermostated oil bath. Temperatures are measured with a calibrated thermocouple located in a blind hole in the wall of the cell.

Gaseous phosgene from a cylinder (Matheson of Canada, Limited) was condensed into a cooled, evacuated flask. Vapor pressures of the original samples considerably exceeded the vapor pressure of carbonyl chloride itself, but after about one quarter of the samples had been distilled off at dry-ice temperatures the vapor pressures at 0° had fallen to within a few tenths of a millimeter of the value (564.3 mm) obtained from the equation of Giauque and Jones (4) for carbonyl chloride at 0°. The samples studied were obtained from the middle one third of the distillate.

Values of dielectric constant of the vapor were determined at 7 to 10 pressures between 40 and 600 mm at each of five temperatures between 20 and 180°. We obtain a dipole moment ($1.17_9 \pm 0.015$ debyes) almost identical with that of Smyth and McAlpine (5) (1.19 ± 0.01) as re-evaluated (6, 7) with modern constants. Our value of the polarizability contribution (A) to the molar polarization is 18.3 ± 0.5 cm^3 (vs. 18.4 ± 0.4 cm^3).

Liquid Measurements

Carbonyl chloride was distilled under vacuum into the dielectric cell. The electrical measurements and temperature control and measurement were essentially as previously described (8). Values of the static dielectric constant for two samples were obtained at 28 temperatures between +20° and −132°. At the latter temperature the sample is undercooled by some 4° below the melting point of the stable solid form I. Measurements were made at each temperature at 10 and 100 kc/sec. Direct-current conductivities ranged from $\sim 7 \times 10^{-10}$ at the melting point to $\sim 4 \times 10^{-8}$ ohm^{-1}cm^{-1} at 20°.

The results can be expressed as a function of T (°K) by

$$\epsilon_0 = -1.01_3 + \frac{1678.2}{T}$$

to within a standard deviation of ±0.36%. The temperature dependence of the dielectric constant is shown graphically in Fig. 1.

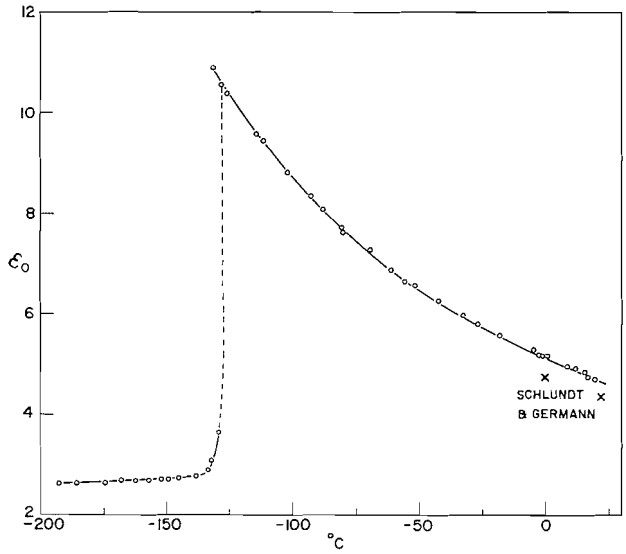

FIG. 1. Dielectric constant of carbonyl chloride. Solid data at 10 kc/sec, temperature increasing.

The only previous dielectric measurements on liquid carbonyl chloride are those reported in 1925 by Schlundt and Germann (9) at temperatures of 0 and 22°. Their dielectric constants, viz. 4.72 at 0° and 4.34 at 22°, are smaller by 7 to 8% than those found for corresponding temperatures in the present study. It appears that most of this difference may be attributed to the use by Schlundt and Germann of Drude's values (10) of the dielectric constants of acetone–benzene solutions for calibration of their apparatus. Comparison of Drude's values with those of more recent workers (e.g., those of Syrkin and Shedlovskaya (11)) in the range of concentration corresponding to dielectric constants between 3.5 and 5 shows the former values to be too low by almost 6%.

Dipole moments of carbonyl chloride have been calculated at different temperatures from the above values of the static dielectric constant of the liquid by use of the Onsager equation. For this we have taken values of ϵ_∞ derived from $A = 18.4$ cm^3 (6) and density values from the formula of Davies (12). The dipole moments obtained are effectively independent of temperature: at 0°, for example, the Onsager moment is 1.175 ± 0.014 debyes, at −100° 1.165 ± 0.038 debyes. The indicated uncertainty at 0° is primarily due to a standard deviation of 0.4 cm^3 in the value of A (6). That at −100° includes as well the possibility that the density given by the formula of Davies is in error by as much as 2%; this temperature is well below the range of the data on which the formula was based.

It is worth noting that, although the Onsager moment of carbonyl chloride is, within experimental error, the same as the moment of the gas, values obtained from measurements of the dielectric constants of dilute solutions in non-polar solvents are considerably smaller. Measurements of Le Fèvre *et al.* (13, 7) gave 1.11 debyes for carbonyl chloride in CCl_4 at 0° and 1.13 debyes in benzene at 25°.

Solid Measurements

Numerous dielectric constant and loss measurements were made on solid phosgene of different thermal histories in an attempt to determine whether solids II and III are characterized by rotational disorder of the type contributing to the dielectric constant. No disorder of this type was found within the considerable uncertainties of the quantities measured.

Dielectric constants were 2.7 ± 0.1 below the freezing point, and decreased by about 0.1 unit on cooling to liquid nitrogen temperature, probably because of some contraction of the sample away from the electrodes at very low temperatures. In general the dielectric losses in the solid were considerably less than those due to d-c. conductivity in the liquid at the same frequencies. No consistent differences were observed in the dielectric behavior of samples frozen slowly and rapidly (with, for example, the thermal histories specified by Giauque and Ott (3) for formation of solids II and III), except that samples frozen rapidly tended to show pronounced loss maxima at 10 kc/sec and lower frequencies at the onset of freezing.

Of seven cooling curves run on four samples of phosgene at cooling rates between 0.1°/min and 2°/min, five froze sharply into III, one into II, and one directly into I. Form III had a waxy appearance and, with further cooling or heating, frequently was observed to change into white crystals which grew from nucleation centers. It could only be melted without being converted into another form if it were immediately heated just after freezing was completed. Otherwise all samples melted as I. One or two showed signs of starting to melt as II, conversion to I, and melting as I. These observations are in general agreement with those of Giauque and Ott (3).

In view of the instability of III, it is possible that none of the dielectric measurements

was made on this form. However, since the freezing process was followed a number of times dielectrically with the invariable observation of only a monotonic fall in dielectric constant and loss, even when freezing started in the range of 130 to 135° K, it is probable that form III, like the other two forms, exhibits no appreciable dipolar polarization. Another possibility, that III has dielectric properties very similar to those of the supercooled liquid, may be excluded. All dielectric samples melted at the melting point of I.

Mention should be made of the occurrence in one sample (which had a d-c. conductivity in the liquid some 2.5 times as great as the best samples) of a broad loss maximum at temperatures near 118° K. This maximum developed some hours after the sample had frozen, and was subsequently observed on passing through this temperature range in either direction, on heating to the melting point of I and recooling, and on melting the sample completely and refreezing. The maximum must be attributed to solid I, but its origin is not clear. The magnitude of the maximum increases with decreasing frequency (change of the frequency from 10 kc/sec to 100 cycles/sec increased it by a factor of 20) and at low frequencies a maximum in the dielectric constant is also apparent. There appeared to be no dependence of the temperature of the maximum on frequency. It is possible that these effects were due to the presence of some HCl or water in the sample, and that the maximum corresponded to a eutectic temperature.

THE PREPARATION AND RAMAN SPECTRUM OF DIPHOSPHORYL TETRAFLUORIDE: COMPARISON WITH THE SPECTRUM OF DIPHOSPHORYL TETRACHLORIDE

E. A. ROBINSON

Department of Chemistry, University of Toronto, Toronto, Ontario

Received May 10, 1962

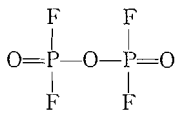
ABSTRACT

Diphosphoryl tetrafluoride has been prepared by the dehydration of difluorophosphoric acid with phosphoric anhydride. The Raman and F^{19} n.m.r. spectra have been determined and are consistent with a symmetric structure $F_2P(O)—O—P(O)F_2$. The Raman spectrum is compared with that of diphosphoryl tetrachloride and partial assignments of the frequencies to normal modes of vibration are made by comparison with the spectra of POF_3 and $POCl_3$.

The compound $P_2O_3F_4$ has been reported previously (1) as a decomposition product of a white solid of approximate composition $P_7O_{10}F_{15}$ which was obtained at −75° C by the action of an electrical discharge on an equimolar mixture of oxygen and phosphorus trifluoride. In the present work, $P_2O_3F_4$ was prepared by the dehydration of difluorophosphoric acid with phosphoric oxide:

$$2HPO_2F_2 = P_2O_3F_4 + H_2O.$$

The F^{19} n.m.r. spectrum consisted of two peaks of equal intensity, indicating that all four fluorine atoms in the molecule are equivalent, the two peaks being due to spin–spin coupling between F^{19} and P^{31}. The method of preparation of the compound and its n.m.r. spectrum are consistent with its formulation as difluorophosphoric acid anhydride, I.



I

The spectrum is shown in Fig. 1. Table I gives the frequencies of the 22 observed lines and a comparison is made with the spectrum of $P_2O_3Cl_4$ (2, 3). The infrared spectrum of $P_2O_3Cl_4$ was checked and the measurements are also shown in Table I. The formulation of $P_2O_3Cl_4$ as dichlorophosphoric anhydride is reasonable since this acid is reported (4) as the product of hydrolysis of $P_2O_3Cl_4$ at −60°.

Gerding and co-workers (3) and Baudler and co-workers (2) attempted only a partial assignment of frequencies. Their conclusions are summarized in Table II. Gerding (3) made his assignment mainly by comparison with his previous assignment of the spectrum of $S_2O_5Cl_2$ (5), which has since been criticized (6).

halides $S_2O_5X_2$ to those of the sulphuryl halides SO_2X_2 (6). Partial assignments for the molecules $P_2O_3Cl_4$ and $P_2O_3F_4$ which are shown in Table IV were made in this way and it is necessary therefore to comment on only a few of them.

For a molecule $P_2O_3X_4$ the maximum number of fundamental vibrational frequencies is 21. Baudler and co-workers report a total of 26 lines in the Raman and infrared spectra of $P_2O_3Cl_4$ and we have found 22 lines in the Raman spectrum of $P_2O_3F_4$. Some of the observed frequencies must therefore be combination or overtone bands. Since we expect only two frequencies greater than 1000 cm^{-1} (the in-phase and out-of-phase P—O stretches), we assign 1270, 1170, and 1083 cm^{-1} in the spectrum of $P_2O_3F_4$, and 1248 and 1135 cm^{-1} in the spectra of $P_2O_3Cl_4$, as combination or overtone bands.

Theoretically three vibrations are expected to be associated with the P—O—P bridging group and these are conveniently described as symmetric and asymmetric stretches, and a bend. The bend is assigned at 159 and 160 cm^{-1} (polarized), respectively, for $P_2O_3Cl_4$ and $P_2O_3F_4$, by comparison with the S—O—S bends near 150–160 cm^{-1} in disulphuryl

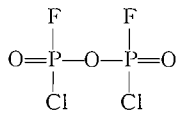
halides (6) and the Si—O—Si bend in, e.g., $[(CH_3)_3Si]_2O$ at 180 cm^{-1} (7). The P—O—P asymmetric stretches are assigned at 962 cm^{-1} ($P_2O_3Cl_4$) and 987 cm^{-1} ($P_2O_3F_4$), and the symmetric stretches at 425 cm^{-1} ($P_2O_3Cl_4$) and 480 cm^{-1} ($P_2O_3F_4$). Bands near 950 cm^{-1} have been assigned to the P—O—P asymmetric stretches in the infrared spectra of pyrophosphates and pyrophosphate esters (8). The P—O—P stretches are to be compared with the assignment of Si—O—Si stretches at 500–600 cm^{-1} (symmetric) and approximately 1050 cm^{-1} (asymmetric) in several disiloxanes (7), and with our recent assignment of S—O—S stretches at approximately 300 cm^{-1} (symmetric) and approximately 800 cm^{-1} (asymmetric) in the spectra of disulphuryl halides (6).

The only other assignment which requires special comment is that of the lines at 713 cm^{-1} (polarized) and 649 cm^{-1} in the spectrum of $P_2O_3Cl_4$, and 721 cm^{-1} (polarized) and 700 cm^{-1} in the spectrum of $P_2O_3F_4$, to P—O wagging modes. These are to be compared with our recent assignment of 716 cm^{-1} (polarized) and 621 cm^{-1} in the spectrum of $S_2O_5Cl_2$, and 733 cm^{-1} (polarized) and 630 cm^{-1} in the spectrum of $S_2O_5F_2$, to SO_2 rocking modes (6). The relatively high values of these frequencies may be attributed to the close proximity of the $POCl_2$ groups.

Recently Stolzer and Simon (9) have reported the preparation of diphosphoryl difluoride dichloride, $P_2O_3F_2Cl_2$, by the reaction between P_4O_{10} and $POFCl_2$. They claim that the compound has the symmetrical structure II and have found bands at 1360 cm^{-1} (P—O stretch), 1020 cm^{-1} (P—O—P asymmetric stretch), 930 cm^{-1} (PF stretch), and 600 cm^{-1} (PCl stretch) in the infrared spectrum. It is of interest to note that the P—O stretching frequency is close to the mean of the frequencies of the similar vibrations in $P_2O_3Cl_4$ (1320 cm^{-1}) and $P_2O_3F_4$ (1390 cm^{-1}), which provides additional support for the symmetric formulation II.



II

EXPERIMENTAL

Diphosphoryl tetrafluoride was prepared by the reaction between difluorophosphoric acid (Ozark-Mahoning Co.) and phosphoric anhydride. Difluorophosphoric acid (1.0 mole) and P_4O_{10} (0.25 mole) were heated under gentle reflux for 1 hour and the mixture was then distilled. The fraction boiling below 75° was collected and purified by fractional distillation using an efficient column. The product had b.p. 71°.

The Raman spectrum was measured with the apparatus previously described (6) and polarization measurements were carried out using polaroid cylinders to polarize the incident light perpendicular to and parallel to the axis of the Raman tube.

The n.m.r. measurements were carried out using a Varian Associates high-resolution n.m.r. spectrometer operating at 56.4 Mc.

ACKNOWLEDGMENTS

Professor R. J. Gillespie of the Chemistry Department, McMaster University, is thanked for discussion of the manuscript, and Dr. W. E. White of the Ozark-Mahoning Company, Tulsa, Oklahoma, for a gift of difluorophosphoric acid. The National Research Council of Canada is thanked for financial support.

AN ELECTRON IMPACT STUDY OF CHLOROMETHYL AND DICHLOROMETHYL DERIVATIVES

A. G. Harrison and T. W. Shannon
Department of Chemistry, University of Toronto, Toronto, Ontario
Received May 3, 1962

ABSTRACT

The appearance potential of the CH_2Cl^+ ion has been measured from methyl chloride, dichloromethane, bromochloromethane, and ethyl chloride. The results lead to $\Delta H_f(CH_2Cl^+) = 230\pm3$ kcal/mole. The heat of formation of $CHCl_2^+$ is estimated to be 215 ± 3 kcal/mole from the appearance potential of this ion in the mass spectrum of chloroform and of bromodichloromethane. By the indirect mass spectrometric method $\Delta H_f(CH_2Cl) = 29\pm3$ kcal/mole and $\Delta H_f(CHCl_2) = 15\pm3$ kcal/mole are obtained. The ionization potentials of a number of chlorine-containing compounds have been measured.

INTRODUCTION

The literature contains little consistent information on the heats of formation of chloromethyl and dichloromethyl radicals and ions, and hence on bond dissociation energies involving these radicals. Reed and Sneddon (1) have reported the electron-impact ionization potential of CH_2Cl radical to be 9.70 ev and have combined this with $A(CH_2Cl^+) = 12.89$ ev from dichloromethane to give $D(CH_2Cl—Cl) = 74$ kcal/mole. However, their appearance potential is considerably higher than the value 12.3 ev reported by Gutbier (2), and, further, the radical ionization potential is in disagreement with the value 9.32 ev measured by Lossing, Kebarle, and deSousa (3).

The results for dichloromethyl derivatives are equally contradictory. Reed and Sneddon have reported $I(CHCl_2) = 9.54$ ev and have combined this with $A(CHCl_2^+) = 13.00$ ev from dichloromethane and 12.43 ev from chloroform to give respectively $D(CHCl_2—H) = 80$ kcal/mole and $D(CHCl_2—Cl) = 67$ kcal/mole. It should be noted that their ionization potential is again in disagreement with that reported by Lossing *et al.* (3), and also that the appearance potentials lead to mutually inconsistent values for $\Delta H_f(CHCl_2^+)$ when combined with standard thermochemical data.

Recently, Goldfinger and Martens (4) have estimated $D(CH_2Cl—H) = 98$ kcal/mole and $D(CHCl_2—H) = 95$ kcal/mole on the assumption of a monotonic decrease in bond dissociation energies from methane to chloroform. As justification for this assumption they refer to estimates of $D(C—Br)$ by Sehon and Szwarc (5) for the various chlorobromomethanes. Sehon and Szwarc obtained $D(CH_2Cl—Br) = 61.0$ kcal/mole and $D(CHCl_2—Br) = 53.5$ kcal/mole from the pyrolysis of the bromides by the toluene-carrier technique. However, the activation energies and hence the bond dissociation energies were estimated from rate measurements at one temperature on the basis of a pre-exponential factor of 2×10^{13} and, furthermore, the rates were found to be dependent on the toluene pressure. Hence the results obtained must be accepted with reservation.

The present work reports the measurement by electron-impact methods of the appearance potentials of CH_2Cl^+ and $CHCl_2^+$ from suitable derivatives to obtain further information concerning the heats of formation of these ions. In view of the lack of consistent information on bond dissociation energies we have also applied the indirect mass spectrometric method (6) to the determination of the heat of formation of the chloromethyl and dichloromethyl radicals.

The principles of the indirect method of obtaining radical heats of formation can be outlined briefly. The appearance potential for the process

$$RR_1 + e \rightarrow R^+ + R_1 + 2e,$$

where R_1 is the radical of interest, can be equated to standard heats of formation as follows.

$$A(R^+) = \Delta H_f(R^+) + \Delta H_f(R_1) - \Delta H_f(RR_1) + E,$$

where E is any excess energy which may be associated with either the charged or uncharged fragments. If E can be measured or can be assumed to be zero then the heat of formation of the radical can be evaluated provided $\Delta H_f(R^+)$ and $\Delta H_f(RR_1)$ are known independently. The main experimental difficulty lies in the estimation of the excess energy and consequently it is usually assumed to be zero. The large body of consistent results thus obtained (7) affords some justification for this assumption. It is apparent, however, that the presence of excess energy in any ionization process, if undetected, would lead to erroneous conclusions. Somewhat more reliable results can be obtained by measuring the appearance potentials of ions of known heat of formation from a number of derivatives where R_1 is the common neutral fragment. If consistent results for $\Delta H_f(R_1)$ are obtained then either the excess energy is the same in all cases or it is zero. Economy of hypothesis would suggest the latter. However, the method can only lead to upper estimates for radical heats of formation in the absence of accurate excess energy measurements.

EXPERIMENTAL

The ionization and appearance potentials were measured using an Associated Electrical Industries MS-2 mass spectrometer, which has been described previously (8). Tungsten filaments were used throughout this work since rhenium filaments were found to deteriorate rapidly in the presence of chlorinated compounds. The ionization efficiency curves for the unknown and standard were plotted in the semilogarithmic manner (9). For molecular ions these curves were parallel and the voltage difference could be determined directly. For the fragment ions these curves were frequently non-parallel and in these cases the threshold voltage was evaluated by extrapolation of the voltage difference curve to zero ion current.

In the dissociative ionizations studied in this work the postulated neutral fragment frequently contained a halogen atom. Since the formation of negative halide ions is frequent in electron impact the possibility of ion-pair processes cannot be neglected. The mass spectra of the compounds studied were therefore examined for negative ions. In many cases small negative ion currents were found. To check that this low abundance was not completely due to instrumental factors the O^- formation in oxygen was studied. The ratio $O^-/O^+ = 0.016_9$ was obtained at 35 volts electron energy, compared to the value of 0.04 obtained by Lozier (10) in a system presumably devoid of discrimination effects. We therefore conclude that the mass spectrometer is approximately 42% efficient in collecting negative ions, although this is undoubtedly a rather rough estimate.

The samples used were commercially available samples of high purity.

RESULTS AND DISCUSSION

Ionic Heats of Formation

The results obtained for the appearance potential of the CH_2Cl^+ ion from a number of derivatives are recorded in Table I and compared with previous results. The appearance potential of CH_2Cl^+ from methyl chloride obtained in the present work is in good agreement with the earlier result by Irsa (11). Both results are somewhat lower than the value obtained by Gutbier (2), although the discrepancy is not serious. The present result for $A(CH_2Cl^+)$ from dichloromethane is in essential agreement with Gutbier's result and in disagreement with the higher result obtained by Reed and Sneddon (1). There does not appear to have been any previous study of bromochloromethane. The appearance potential curve for CH_2Cl^+ from ethyl chloride showed a large curvature and led to a somewhat

lower result than that reported by Irsa. The error, however, is large due to the extrapolation involved.

The last three columns of Table I record values for $\Delta H_f(CH_2Cl^+)$ calculated from the present data and the literature data using the heats of formation recorded in column 4 for the neutral molecules and the following heats of formation (12): $H = 52.1$, $Cl = 29$, $Br = 27$, and $CH_3 = 32$, all in kcal/mole. With the exception of the results for ethyl chloride and the one high value for dichloromethane the calculated ionic heats of formation are in reasonable agreement and lead to $\Delta H_f(CH_2Cl^+) = 230\pm3$ kcal/mole. It would appear that the formation of CH_2Cl^+ from ethyl chloride involves considerable excess energy.

The alternative ion-pair process

$$CH_2ClX + e \rightarrow CH_2Cl^+ + X^- + e$$

would lead to much lower values for the ionic heats of formation. For methyl chloride the negative ion would be H^-, which could not be detected. Ion-pair processes involving H^- formation appear to be quite rare. For dichloromethane and bromochloromethane small ion currents for Cl^- and Br^-, respectively, were found. Using the collection efficiency of 42% discussed above, these negative ion currents were estimated to be less than 1% of the CH_2Cl^+ ion current in each case. This abundance, if arising from an ion-pair process involving CH_2Cl^+ as the positive fragment, would lead to considerable tailing of the appearance potential curves. For the chloro and bromo derivatives this tailing was relatively small, suggesting that negative ion formation was not interfering seriously with the measurements. For methyl chloride the appearance potential curve for CH_2Cl^+ was parallel to the standard krypton curve, lending further support to the conclusion that H^- was not formed. The agreement of the ionic heats of formation calculated from the three results suggests that ion-pair formation in the chloro and bromo compounds also is not interfering.

The appearance potential of the $CHCl_2^+$ ion was measured from chloroform and bromodichloromethane. The results are summarized in Table II. The appearance potential of the ion from dichloromethane could not be determined accurately because of the low abundance of the ion. The appearance potential of $CHCl_2^+$ from chloroform obtained in the present work is 0.73 ev lower than the value reported by Reed and Sneddon (1). Assuming the ionization process

$$CHCl_2X + e \rightarrow CHCl_2 + X + 2e$$

and, further, assuming that no excess energy is involved, the present results lead to consistent values for $\Delta H_f(CHCl_2^+)$, as shown in Table II, suggesting that the earlier appearance potential is in error. The alternative ionization process leading to ion-pair formation would result in ionic heats of formation 80–90 kcal/mole lower than the value 215 kcal/mole obtained. This does not appear possible by comparison with the well-established $\Delta H_f(CCl_3^+)$ = 216 kcal/mole (13, 14) and the low (about 1%) abundance of the corresponding negative ions.

Radical Heats of Formation

The ionic heats of formation reported above lead to $D(CH_2Cl—H)$ = 79 kcal/mole and $D(CHCl_2—H)$ = 68 kcal/mole when combined with $I(CH_2Cl)$ = 9.70 ev and $I(CHCl_2)$ = 9.54 ev as reported by Reed and Sneddon (1). When combined with the ionization potential of 9.3 ev reported for both radicals by Lossing *et al.* (3), they lead to $D(CH_2Cl—H)$ = 89 kcal/mole and $D(CHCl_2—H)$ = 74 kcal/mole. These results appear quite unlikely when compared with $D(CH_3—H)$ = 102 kcal/mole and $D(CCl_3—H)$ = 89 kcal/mole (15) and suggest that the radical ionization potentials reported by both groups may be in error. To obtain further information the indirect mass spectrometric method was used to obtain estimates for the radical heats of formation.

Table III records the results obtained by the indirect method for the chloromethyl

radical. These appearance potentials do not appear to have been measured previously. Column 5 gives the values calculated for $\Delta H_f(CH_2Cl)+E$, assuming the following ionization process:

$$RCH_2Cl + e \rightarrow R^+ + CH_2Cl + 2e.$$

The alternative ionization process involving $CH_2 + Cl$ as the neutral fragments is of considerably higher energy. For example, using $\Delta H_f(CH_2) = 93$ kcal/mole, calculated from $D(CH_2—H) = 113$ kcal/mole (16), the appearance potential for the ionization process

$$CH_2ClCH_2Cl + e \rightarrow CH_2Cl^+ + CH_2 + Cl + 2e$$

is calculated to be 16.6 ev compared to the experimental value of 12.52 ev. On the other hand, the ion-pair process

$$RCH_2Cl + e \rightarrow R^+ + CH_2 + Cl^- + 2e$$

would lead to appearance potentials only slightly higher than the experimental values. To check this possibility the ratio Cl^-/R^+ was measured for each of the compounds studied. Over the range 20–50 volts electron energy this ratio was about 0.01 for dichloroethane and less than 0.0008 for all other compounds listed in Table III. The ionization efficiency curves for the negative ion were complex and could not be used to obtain information on the mechanism of formation of the ion. It would appear that ion-pair formation by the process indicated above is occurring to only a slight extent, if at all. The assumption of the simple ionization process leading to CH_2Cl as the neutral fragment is therefore justified.

With exception of the result for the $C_3H_7^+$ ion from *n*-butyl chloride the calculated values for $\Delta H_f(CH_2Cl)+E$ are in essential agreement. Neglecting this value, which must involve considerable excess energy, the results lead to an upper limit $\Delta H_f(CH_2Cl) = 29\pm3$ kcal/mole on the assumption that $E = 0$ for the other ionization processes.

The application of the indirect method to the estimation of the heat of formation of the dichloromethyl radical is hindered by the lack of accurate heat of formation data. The study was necessarily limited to two derivatives, 1,1,2,2,-tetrachloroethane and pentachloroethane, with the results shown in Table IV. The appearance potentials obtained,

when combined with the thermochemical data given in the table, yield consistent results leading to $\Delta H_f(CHCl_2) = 15\pm3$ kcal/mole on the assumption that no excess energy is involved in the ionization processes. Again small amounts of Cl^-, amounting to about 1% of the R^+ peak, were formed; however, the possible mechanisms of formation in the

polychlorinated derivatives are abundant. The low abundance of the negative ion would suggest that the ion-pair process

$$RCHCl_2 + e \rightarrow R + CHCl + Cl^- + e$$

is not occurring to a significant extent, and that calculations on the basis of the dissociation process

$$RCHCl_2 + e \rightarrow R + CHCl_2 + 2e$$

are justified.

Bond Dissociation Energies and Radical Ionization Potentials

The radical heats of formation reported above may be combined with standard thermochemical data to yield bond dissociation energies. Table V gives the results of these

TABLE V

CCl_3*	89	68	50–55

*Values for methyl and trichloromethyl derivatives from ref. 15.

calculations and compares the results with bond dissociation energies for methyl and trichloromethyl derivatives (15). The following heats of formation, all in kcal/mole, were used in the calculations: CH_3Cl = −20.6 (17), CH_2Cl_2 = −21 (12), $CHCl_3$ = −24.4 (12), CH_2ClBr = −12 (18), $CHCl_2Br$ = −14 (18), H = 52.1 (12), Cl = 29 (12), and Br = 27 (12).

Within experimental error the calculated bond dissociation energies for the chloromethyl derivatives are identical with the well-established values for the methyl derivatives. The value $D(CH_2Cl—H)$ = 102±3 kcal/mole is indistinguishable from the estimated value, 98 kcal/mole (4), within the combined limits of error, although $D(CH_2Cl—Br)$ = 68±3 kcal/mole is considerably higher than the value of 61 kcal/mole reported by Sehon and Szwarc (5). The present value for $D(CH_2Cl—H)$ is in reasonable agreement with $D(CH_2Br—H)$ = 99 kcal/mole at 0° K, obtained from photobromination experiments (19). This agreement suggests that the present results are not greatly in error, although the lower limit of error is more likely to apply than the upper limit.

The bond dissociation energies obtained for dichloromethyl derivatives do not fit a picture involving an even gradation of bond energies in the series from methyl to trichloromethyl. The present results indicate that the bond dissociation energies of dichloromethyl derivatives are identical with the bond dissociation energies of trichloromethyl derivatives. If the value $D(CCl_3—H)$ = 93 kcal/mole (4) is used the present results for dichloromethyl derivatives are lower than for trichloromethyl derivatives. It is interesting to note that recent measurements (4) of the activation energy of the reaction $Cl + RH \rightarrow HCl + R$ indicate that the activation energy for chlorine atom reaction with dichloromethane is somewhat less than that for reaction with chloroform. The present value $D(CHCl_2—Cl)$ = 68±3 kcal/mole is in agreement with an earlier result $\geqslant$ 72 kcal/mole obtained from the kinetics of the thermal decomposition of chloroform (20), although this result has been questioned (15). The result $D(CHCl_2—Br)$ = 56±3 kcal/mole is also in agreement with

$D(CHCl_2—Br)$ = 53.5 kcal/mole (5), although this value too must be accepted with reservations. The present results should represent an upper limit to the bond dissociation energies of dichloromethyl derivatives. The available experimental results are therefore in reasonable agreement and indicate that the bond dissociation energies of dichloromethyl derivatives are identical with or less than the bond dissociation energies of trichloromethyl derivatives.

From the radical and ionic heats of formation obtained in this work $I(CH_2Cl)$ and $I(CHCl_2)$ are calculated to be 8.72±0.26 and 8.67±0.26 ev respectively. The large error in these calculated values makes detailed comparison with $I(CH_3)$ = 9.95 ev (21) and $I(CCl_3)$ = 8.78 ev (13) of little value; however, it would appear that the ionization potentials of the three chloromethyl radicals do not differ greatly. The calculated ionization potentials are considerably lower than the experimental values reported by either Reed (1) or Lossing (3), suggesting that the vertical ionization potential reported by these workers is considerably above the adiabatic ionization potential.

Ionization Potentials of Parent Molecules

During the course of this investigation the appearance potentials of the molecular ions were determined wherever the parent ion was of sufficient intensity. The results are presented in Table VI and compared, where possible, with previous electron-impact

THE DISULPHONATION OF 2,6- AND 2,7-DI-*t*-BUTYLNAPHTHALENE

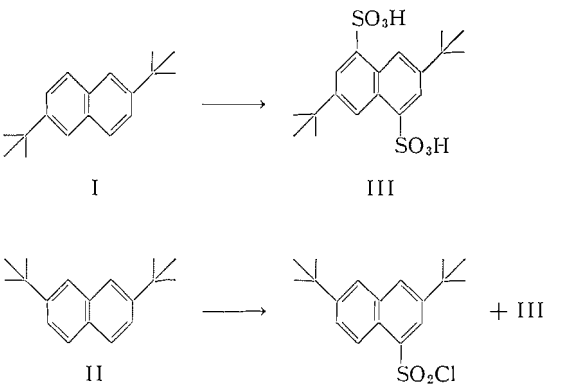
MARCEL MENARD, DENNIS AWANG, AND FRANCIS L. CHUBB
Research Laboratories, Frank W. Horner Limited, Montreal, Que.

Received March 21, 1962

ABSTRACT

It has been found that both 2,6- and 2,7-di-*t*-butylnaphthalene form the same disulphonic acid when treated with 2 molar equivalents of chlorosulphonic acid. It is suggested that this acid is 2,6-di-*t*-butylnaphthalene-4,8-disulphonic acid. The evidence, including the n.m.r. spectrum, on which the proposed structure is based is presented.

In a previous paper (1) it was shown that sulphonation of 2,6- and 2,7-di-*t*-butylnaphthalene (I and II) with 1 molar equivalent of chlorosulphonic acid gave high yields of the corresponding 4-sulphonic acids. It has now been found that I and II behave differently when treated with 2 molar equivalents of chlorosulphonic acid. From I a disulphonic acid, III, was obtained in high yield, whereas from II two products were obtained—a neutral product, 2,7-di-*t*-butylnaphthalene-4-sulphonyl chloride, and the disulphonic acid III. Thus in one of the above reactions a rearrangement must have occurred.



The structure of the disulphonic acid III, shown as 2,6-di-*t*-butylnaphthalene-4,8-disulphonic acid, was assigned from the following considerations. The ease of formation of III from I, as well as the fact that the ultraviolet absorption spectrum of the dimethyl ester of III was similar to that of ethyl 2,6-di-*t*-butylnaphthalene-4-sulphonate and different from that of ethyl 2,7-di-*t*-butylnaphthalene-4-sulphonate (Fig. 1), indicated that III was a 2,6-di-*t*-butylnaphthalene derivative. Since the low-temperature disulphonation of naphthalene yields the 1,5- (or 4,8-) disulphonic acid (2, 3) and since the 4 and 8 positions in I are the only available positions free of steric hindrance, it was believed that the sulphonic acid group entered these positions. Finally, the n.m.r. spectrum of the dimethyl ester of III (Fig. 2) was in excellent agreement with the proposed structure. The spectrum showed peaks at 510 and 534 c.p.s., due to the aromatic protons. These protons, occupying meta positions, revealed characteristic two-cycle coupling. The protons in the α position of the naphthalene nucleus, being less shielded, showed resonance lines at 534 c.p.s., while those located between the methyl sulphonate and *t*-butyl groups, being

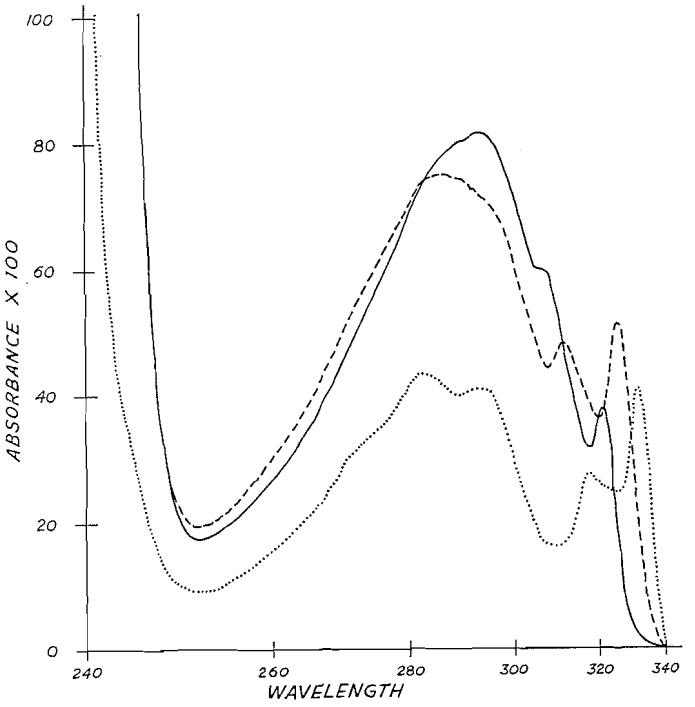


FIG. 1. The ultraviolet absorption spectra of: ethyl 2,7-di-*t*-butylnaphthalene-4-sulphonate (——) in methanol solution; ethyl 2,6-di-*t*-butylnaphthalene-4-sulphonate (- - -) in methanol solution; and dimethyl 2,6-di-*t*-butylnaphthalene-4,8-disulphonate (· · ·) in chloroform solution.

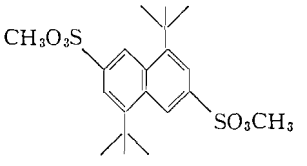
more shielded, showed resonance lines at 510 c.p.s. The spectrum would fit the isomeric dimethyl 1,5-di-*t*-butylnaphthalene-3,7-disulphonate (IV) equally well but this structure seems very unlikely. Apart from the evidence of the ultraviolet spectra it would require the shift of both *t*-butyl groups in both sulphonation reactions to relatively more hindered positions.



IV

Thus the disulphonation of 2,7-di-*t*-butylnaphthalene is accompanied by the rearrangement of one of the *t*-butyl groups. This may be a new example of the well-known Jacobsen rearrangement, although no evidence in favor of any particular mechanism has been obtained.

EXPERIMENTAL

Melting points are uncorrected. Ultraviolet absorption spectra were measured on a Beckman Model DK 2 recording spectrophotometer. Microanalyses were performed by E. Thommen, Thannerstrasse 45, Switzerland, and Dr. Claude Daesslé, 5757 Decelles, Montreal, Que.

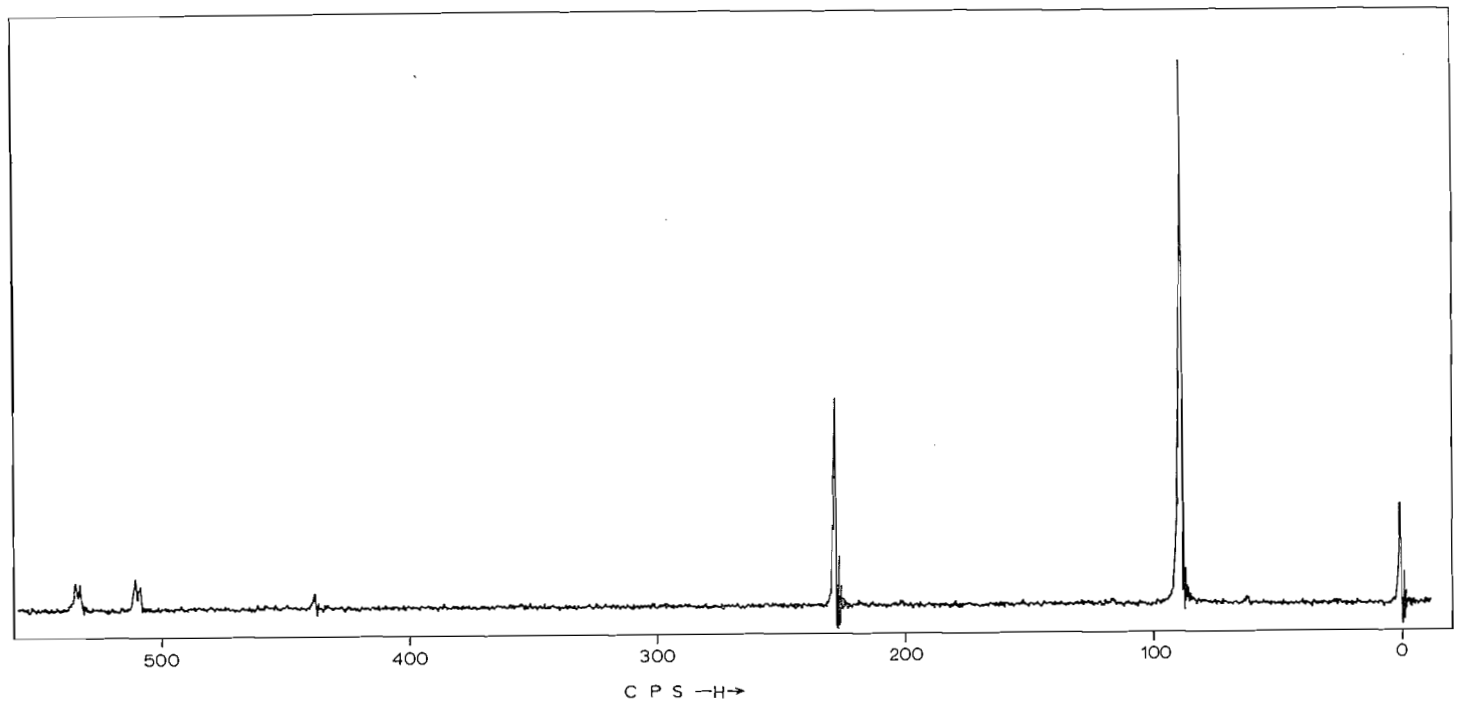


FIG. 2. The n.m.r. spectrum of dimethyl 2,6-di-*t*-butylnaphthalene-4,7-disulphonate in $CDCl_3$ solution with tetramethylsilane as the internal reference.

2,7-Di-t-butylnaphthalene (II)

A mixture of sodium 2,7-di-*t*-butylnaphthalene-4-sulphonate monohydrate (256 g) (1), water (100 ml), and concentrated sulphuric acid (750 g) was heated in an oil bath at 200–210° C and steam-distilled. Filtration of the distillate and recrystallization of the solid from ethanol gave 133 g (80%) of the hydrocarbon, m.p. 102–103° C (4).

2,6-Di-t-butylnaphthalene-4,8-disulphonic Acid (III)

To a stirred and cooled slurry of 2,6-di-*t*-butylnaphthalene (10 g, 0.042 mole) (4) in carbon tetrachloride (25 ml), chlorosulphonic acid (10.8 g, 0.094 mole) was added dropwise so that the temperature was maintained below 5°. The mixture was then stirred at room temperature for 2 hours and the white precipitate filtered and washed with petroleum ether. Recrystallization from acetic acid gave 14.4 g (86%) of the crude disulphonic acid III, m.p. 204° decomp. (5). Further recrystallization from acetic acid raised the melting point to 264–266°. No sulphonyl chloride could be isolated from the combined filtrates, the only contaminant being the corresponding monosulphonic acid (1). Analysis: Calc. for $C_{18}H_{24}O_6S_2.H_2O$ (418.52): C, 51.65; H, 6.26; S, 15.32%. Found: C, 52.03; H, 6.12; S, 15.42%. Neut. equiv.: Calc.: 209.3. Found: 209.9.

Dimethyl ester (from diazomethane).—M.p. 248–250°. Analysis: Calc. for $C_{20}H_{28}O_6S_2$ (428.56): C, 56.05; H, 6.59; S, 14.96%. Found: C, 56.30; H, 6.70; S, 15.00%. Ultraviolet spectrum ($CHCl_3$): maxima at 283, 317, and 331 mμ (ϵ = 635, 405, and 595). N.M.R. spectrum: peaks at 535, 533, 511, 509, 238, and 88 c.p.s.

Disulphonyl chloride.—Prepared by the method of Bosshard *et al.* (6), m.p. 260–263°. Analysis: Calc. for $C_{18}H_{22}O_4S_2Cl_2$ (437.40): C, 49.42; H, 5.07; S, 14.66%. Found: C, 49.98; H, 5.33; S, 14.34%.

Sulphonation of 2,7-Di-t-butylnaphthalene

Pure 2,7-di-*t*-butylnaphthalene (10 g) was treated, as described for the 2,6-isomer, with 2.2 molar equivalents of chlorosulphonic acid. Recrystallization of the solid gave pure 2,6-di-*t*-butylnaphthalene-4,8-disulphonic acid (8.5 g, 30%). The identity of this material with the dibasic acid described above was ascertained by a comparison of melting points and ultraviolet spectra.

Concentration of the combined filtrates and extraction of the solid residue with boiling ligroin (2×100 ml) gave 7.5 g (31%) of 2,7-di-*t*-butylnaphthalene-4-sulphonyl chloride, m.p. 167–169°, undepressed on admixture with an authentic sample (1).

ACKNOWLEDGMENT

The authors wish to thank Dr. N. S. Bhacca of Varian Associates, who obtained and analyzed the n.m.r. spectrum for us.

SYNTHESIS OF CARBON-14 LABELED DEOXYRIBONUCLEOSIDES[1]

D. L. WILLIAMS
Los Alamos Scientific Laboratory, University of California, Los Alamos, New Mexico
Received May 10, 1962

ABSTRACT

The enzymatic transfer of deoxyribose from a purine or a pyrimidine deoxyriboside to a carbon-14 labeled purine or pyrimidine base affords an efficient means of preparing labeled deoxyribonucleosides. Deoxyadenosine-8-C^{14}, deoxyguanosine-8-C^{14}, deoxycytidine-2-C^{14}, and thymidine-2-C^{14}, with the natural β-configuration, were prepared in good yields and isolated in radiochemically pure form by large-scale paper chromatography.

INTRODUCTION

Carbon-14 labeled deoxyribonucleosides are not, as yet, commercially available. Strictly chemical syntheses of 2′-deoxyribosides (*a*) by the reduction at C2′ of ribofuranosylpurines (1) and -pyrimidines (2, 3); (*b*) through condensation of acylated 2-deoxyribosyl halides with suitably substituted purines (4–6) and pyrimidines (7); or (*c*) by the direct condensation of 2-deoxyribose with purines and pyrimidines catalyzed by polyphosphoric acid ester (8) are, in general, attended by requirements for difficultly obtainable intermediates, low yields, or the formation of both the α- and β-anomers. The β-anomer is the desired natural product.

In terms of high yields of solely the desired β-anomer and probable time consumption, enzymatic methods of synthesis appear much more of interest than the above chemical methods. The phosphorylase enzymes (9–13) give excellent yields of deoxyribosides from deoxyribose-1-phosphate and certain purines and pyrimidines, but the enzyme from a given tissue and species of organism is too specific and a number of enzyme preparations would be required to obtain the desired products. The *trans-N*-glycosidase first described by MacNutt (14), which was more specifically named *trans-N*-deoxyribosylase and further characterized by Roush and Betz (15), appeared to be the enzyme of choice, since it is nonspecific and transfers 2-deoxyribose from any deoxyriboside to a new purine or pyrimidine base, according to the following equilibrium:

$$\text{base}_1 + \text{base}_2 \text{ deoxyriboside} \rightleftarrows \text{base}_2 + \text{base}_1 \text{ deoxyriboside}.$$

This communication describes the enzymatic synthesis and isolation of 2′-deoxyadenosine-8-C^{14} (I), 2′-deoxyguanosine-8-C^{14} (II), 2′-deoxycytosine-2-C^{14} (III), and thymidine-2-C^{14} (IV).

EXPERIMENTAL

Carbon-14 Assays

Radiochemical yields were determined, with a Tri-Carb spectrometer,* by liquid scintillation counting of suitable aliquots in 15 ml of a dioxane system (naphthalene, 125 g/l.; 2,5-diphenyloxazole (PPO), 7.5 g/l.; and 2,2′-*p*-phenylenebis-(5-phenyloxazole) (POPOP), 0.375 g/l.) (16).

Paper Chromatography

Reaction mixtures were separated by chromatography on 18×44-in. sheets of Whatman No. 3 paper, and the chromatograms were developed with Hems' (17) solvent (85% saturated ammonium bicarbonate) in a combined descending and ascending manner. The paper was attached at both ends to supports in a

[1]*Work performed under the auspices of the U.S. Atomic Energy Commission.*
**Model 314EX, Packard Instrument Company, Inc., LaGrange, Illinois.*

Chromatocab. This procedure gave good separation of all components, including the pairs thymine–thymidine and cytosine–deoxycytidine. Upon rechromatography of aliquots of the isolated products on $1\frac{1}{2}\times44$-in. strips of Whatman No. 3 MM paper, only one ultraviolet-absorbing spot was observed, in each case. The only radioactivity which was observed with a windowless gas-flow strip scanning device* was concentrated in these spots.

R_f values for the compounds encountered in this work are shown in Table I.

TABLE I

NOTE: Paper, Whatman No. 3. Solvent, 85% saturated ammonium bicarbonate.

Enzymes

trans-N-Deoxyribosylase enzyme was extracted from sonically disrupted *Lactobacillus helveticus* (ATCC 12046) bacteria with 0.1 *M* phosphate buffer (pH 6) and was partially purified, through the first ammonium sulphate precipitation step, as described by Roush and Betz (15). The protein which precipitated between 35% and 70% of saturation was redissolved in distilled water and dialyzed against distilled water at 4° C until free of sulphate ion. The final solution contained 6 mg of protein per ml, as determined by the method of Lowry *et al.* (18).

An auxiliary enzyme, xanthine oxidase, was prepared from fresh, whole cream according to the procedure of Horecker and Heppel (19). Oxidase activity was determined spectrophotometrically with hypoxanthine as substrate. The uric acid produced absorbs strongly at 293 mμ, and there is no interference from purines or pyrimidines or their deoxyribosides at this wavelength.

The specific activity of the transferase enzyme was also determined spectrophotometrically by a modification of the auxiliary enzyme procedure of Kalckar (20). In the transfer reaction between deoxyadenosine and hypoxanthine to form deoxyinosine, the rate of disappearance of hypoxanthine was measured with xanthine oxidase. At a hypoxanthine concentration of 101.3 μg/ml and a molar ratio of deoxyriboside to free purine base of 5 to 1 in pH 6.1 phosphate buffer at 37° C, the initial rate of disappearance of hypoxanthine was 13.13 μmoles per mg of protein per hour. These conditions were similar to those anticipated in subsequent synthesis experiments.

Transfer Reactions

(a) Deoxyadenosine-8-C^{14} (I)

A solution of adenine-8-C^{14} (300 μc, sp. act. 8.5 mc/mmole) and thymidine (42.8 mg, 0.1765 mmole) in 25 ml of 0.1 *M* phosphate buffer (pH 6.1) was incubated with 1 ml of enzyme solution at 37° C for 2 hours. The solution was overlaid with 5 drops of toluene to prevent bacterial growth. At the end of the incubation period, the solution was heated in boiling water for 5 minutes to denature the enzyme, cooled in ice, filtered, and chromatographed. The buffer salts, which moved with the solvent front, did not interfere with the complete separation of adenine-8-C^{14} and deoxyadenosine-8-C^{14}. The radioactive, ultraviolet-absorbing bands of residual adenine-8-C^{14} and the deoxyadenosine-8-C^{14} were cut from the large sheets and eluted with dilute ammonium hydroxide. The radiochemical yield of pure product was 91.4%; 2.7% of the initial adenine-8-C^{14} was also recovered. The results are shown in Table II.

Both the thymine and thymidine bands on the chromatogram were radioactive. The total activity in the two bands was 5.62 μc. This finding suggests that the commercial adenine-8-C^{14}, which is obtained from biologically labeled DNA, contained a small amount of C^{14}-thymine.

(b) Deoxyguanosine-8-C^{14} (II)

Guanine-8-C^{14} (300 μc, sp. act. 9.8 mc/mmole) was suspended in 100 ml of deionized water and heated in a boiling-water bath to dissolve as much of the guanine as possible. To the resulting suspension at 37° C was added 25 ml of 0.1 *M* phosphate buffer (pH 6.1), thymidine (37.1 mg, 0.153 mmole), and 1 ml of enzyme solution. A few drops of toluene were added, and the mixture was magnetically stirred in a stoppered flask for 24 hours at 37° C. After 24 hours, some guanine-8-C^{14} was still undissolved; 1 ml of enzyme solution was added, and incubation was continued an additional 24 hours with stirring. The reaction mixture was heated in boiling water for 7 minutes to coagulate protein and cooled to room temperature. The mixture was then desalted, prior to chromatography, by adsorption of the organic components on a mixture of 80-mesh

*Abbreviations used are: thymidine, t; deoxyadenosine, a.
†Phosphate buffer salts not removed prior to chromatography.
‡Phosphate buffer salts removed prior to chromatography.
§Buffer was not used in this and subsequent thymidine runs.
‖This is percentage of activity recovered in the residual base and the deoxyriboside formed.

Fishers' activated charcoal (1 g) and Celite (1 g). The charcoal bed was washed free of phosphate ion with three 10-ml portions of distilled water.* The purines and deoxyribosides were eluted with 50% aqueous ethanol containing 5% pyridine (by volume). The eluate (ca. 1500 ml) was concentrated to ca. 30 ml on a rotary vacuum evaporator at 35° C. The components of the mixture were then separated by chromatography, as described above. The radiochemical yield of pure product was 80%; 7.2% of the initial guanine-8-C^{14} was also recovered. The results are given in Table II.

The thymine and thymidine bands, which were both radioactive, were eluted together and rechromatographed. When the two bands were eluted and assayed, the thymine contained 2.34 μc of activity and the thymidine contained 4.16 μc. As in the adenine-8-C^{14} case above, the guanine-8-C^{14} apparently contained C^{14}-thymine.

(c) Deoxycytidine-2-C^{14} (III)

A solution of cytosine-2-C^{14} (300 μc, sp. act. 5.07 mc/mmole) and deoxyadenosine (74.3 mg, 0.296 mmole) in 25 ml of distilled water was adjusted to pH 5.8 with carbon dioxide. One milliliter of enzyme solution and 5 drops of toluene were added, and the solution was incubated at 37° C for 6 hours. The reaction mixture was then heated in boiling water for 5 minutes, cooled in ice, filtered, and chromatographed as described above. As shown in Table II, it was necessary to treat the residual cytosine-2-C^{14} several times in this manner in order to approach quantitative conversion to the deoxyriboside. The total radiochemical yield of pure product was 83.3%; 11.7% of the initial cytosine-2-C^{14} was also recovered.

The pooled deoxyadenosine from all the deoxycytidine runs contained 5.16 μc of radioactivity, which was probably cytosine-2-C^{14}, since the adenine was not active.

(d) Thymidine-2-C^{14} (IV)

A solution of thymine-2-C^{14} (300 μc, sp. act. 5.0 mc/mmole) and deoxyadenosine (75.5 mg, 0.3 mmole) in 25 ml of 0.1 *M* phosphate buffer (pH 6.1) was incubated with 1 ml of enzyme solution for 2 hours. The reaction mixture was heated, cooled, and desalted, as described for II above, prior to chromatography. As illustrated in Table II, it was necessary to treat the residual thymine-2-C^{14} several times to effect a high degree of conversion to deoxyriboside. In the second thymidine run (Table II), the reaction was run in distilled water, but the pH was 6.7 due to a trace of residual ammonium bicarbonate. This is higher than the enzyme pH optimum of 5.8 (15), and apparently the 2-hour incubation was too short for equilibrium to be established. Subsequently, the reaction was run 6 hours in distilled water adjusted to pH 5.8–6 with carbon dioxide. The total radiochemical yield of pure product was 74.6%; 9% of the initial thymine-2-C was also recovered.

The pooled deoxyadenosine from all the thymidine runs contained 11.9 μc of radioactivity. This activity is probably all due to thymine-2-C^{14}, since the adenine was free of activity.

**The filtrate and washings contained 3.1 μc of C^{14} activity, which was not absorbed on an additional 1 g of charcoal.*

DISCUSSION

The *trans-N*-deoxyribosylase enzyme offers an efficient means of obtaining labeled deoxyribosides, with the natural configuration, providing the labeled bases or a deoxyriboside with the label in the deoxyribose moiety are available. Since the enzyme has no requirement for phosphate, the transfer reaction can be run in neutral aqueous medium or one adjusted with carbon dioxide to the optimum pH of 5.8, thus eliminating the need for a desalting step prior to chromatography.

Although guanine is only slightly soluble in a neutral or slightly acidic (pH 6) aqueous medium, high yields of deoxyguanosine are obtained by stirring a suspension of guanine in thymidine solution for an extended reaction period. Guanine dissolves as the reaction proceeds.

As indicated by the work of Roush and Betz (15), at equilibrium, in a reaction mixture containing the enzyme, a purine, a pyrimidine, and their deoxyribosides, the reaction rates greatly favor the formation of purine deoxyriboside. Therefore, thymidine is an excellent donor of deoxyribose in the preparation of labeled deoxyadenosine and deoxyguanosine. Comparison of the concentrations of deoxycytidine and thymidine in equilibrium with deoxyadenosine (Table II) and the equilibrium data of Roush and Betz (15) suggests that a pyrimidine deoxyriboside as deoxyribose donor would afford higher yields of labeled thymidine or deoxycytidine than does deoxyadenosine. However, separation of the resulting four-component mixture by paper chromatography or by cellulose column chromatography would be extremely difficult because of the narrow spread in R_f values for most solvents. In any case, it appears that several successive treatments of the pyrimidine bases are required in approaching quantitative conversion to their deoxyribosides.

ACKNOWLEDGMENT

The author is grateful to Dr. I. U. Boone of this laboratory for the *Lactobacillus helveticus* bacteria used in this work and for assistance and technical advice in the preparation of the *trans-N*-deoxyribosylase enzyme.

ISOTOPIC COMPOSITION OF RADIOLYTIC HYDROGEN EVOLVED FROM MIXTURES OF BENZENE AND CYCLOHEXANE WITH THEIR DEUTERATED ANALOGUES[1]

P. J. DYNE AND W. M. JENKINSON
Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario

Received May 16, 1962

ABSTRACT

We have measured the isotopic composition of radiolytic hydrogen evolved from mixtures of benzene and cyclohexane with their deuterated analogues. The data are interpreted in terms of first-order processes of the kinetic form (for C_6D_{12}) $C_6D_{12} \rightarrow C_6D_{10} + D_2$ and second-order processes $C_6D_{12} \rightarrow X_D + R$, $X_D + C_6H_{12} \rightarrow HD + R$.

A complete kinetic analysis for the system C_6D_6–C_6H_6 has been made from measurements at the two ends of the concentration range. This gives a satisfactory prediction of the isotopic composition of hydrogen evolved from an equimolar C_6H_6–C_6D_6 mixture. A first-order yield of D_2 is found in solutions of C_6D_{12} in benzene which persists to 'zero' C_6D_{12} concentration. The mechanisms of the first-order process studied in these experiments, and of the 'unscavengeable' or 'molecular' yields of radiolytic hydrogen, are discussed.

INTRODUCTION

Studies (1–3) of the isotopic composition of hydrogen formed in the radiolysis of light and heavy hydrocarbons have shown the existence of two radiolytic processes: a decomposition in which both hydrogen atoms in the H_2 molecule come from the same hydrocarbon molecule,

$$RH \text{—}\sim\sim\rightarrow H_2 + \text{residue}, \qquad [1]$$

and a decomposition which occurs via a reactive intermediate X_H,

$$RH \text{—}\sim\sim\rightarrow X_H + \text{residue} \qquad [2]$$

$$X_H + RH \longrightarrow H_2 + \text{residue}, \qquad [3]$$

where the hydrogen atoms in the H_2 molecule come from two hydrocarbon molecules. We call the first 'the first-order process' since its existence is shown, in our experiments, by a yield of D_2 which is first order with respect to the concentration of the deuterated hydrocarbon. The second we call 'the second-order process' since the yield of D_2 formed by it has a second-order dependence on the concentration of the deuterated hydrocarbon.

The yield of the first-order process is calculated with the assumption that the amount of energy absorbed by the deuterated hydrocarbon is proportional to its mole fraction in the mixture. We have previously called the first- and second-order yields the 'unimolecular' and 'bimolecular' yields. The new terminology emphasizes the operational definition and avoids confusion in discussion.

In reference 3 we have described experiments on hydrocarbon mixtures in which the variation of the first-order yield with solvent demonstrates that the energy absorbed by the deuterated hydrocarbon is not determined simply by its mole fraction. The major part of this paper is concerned with mixtures of heavy and light benzene in which the deviations from the mixture law as described in reference 3 appear to be absent. Experiments on other mixtures of benzene and cyclohexane, variously deuterated, are also described.

[1]*Issued as A.E.C.L. No. 1416.*

EXPERIMENTAL

The experimental techniques have been previously described (1, 2). Cyclohexane-d_{12} and benzene-d_6 of >99% isotopic purity were obtained from Merck and Co; the isotopic composition was confirmed by mass spectrometric analysis.

Cyclohexane and benzene were Fisher Spectrograde. Benzene samples (~2 ml) were irradiated for 40 hours at a dose rate of $\sim 3\times10^{22}$ ev/l. hr to give 1–2 μmoles of gas.

KINETIC ANALYSIS

It is convenient to use the kinetic analysis given previously (1, 2). The following steps are proposed:

$$\left.\begin{array}{ll} C_H \rightsquigarrow H_2 + P & \text{yield } G_1(H) \\ C_D \rightsquigarrow D_2 + P & \text{" } G_1(D) \end{array}\right\} \text{first-order yields}$$

$$\left.\begin{array}{ll} C_H \rightsquigarrow X_H + P & \text{" } G_2(H) \\ C_D \rightsquigarrow X_D + P & \text{" } G_2(D) \end{array}\right\} \text{second-order yields}$$

$$\begin{array}{ll} X_H + C_H \rightarrow H_2 + P & \text{rate constant } k_1 \\ X_D + C_H \rightarrow HD + P & \text{" " } k_2 \\ X_H + C_D \rightarrow HD + P & \text{" " } k_3 \\ X_D + C_D \rightarrow D_2 + P & \text{" " } k_4 \end{array}$$

where C_H refers to the 'light' hydrocarbon and C_D to the 'heavy', i.e. completely deuterated, hydrocarbon.

We have shown that when $C_H \gg C_D$ (1, 2) and putting $C_D/C_H = F$:

$$G(D_2) = G_1(D)\times F + (k_4/k_2)\times G_2(D)\times F^2 \quad \text{(i)}$$

$$G(HD) = F[G_2(D) + (k_3/k_1)\times G_2(H)]. \quad \text{(ii)}$$

It can readily be shown that when $C_D \gg C_H$ the analogous equations hold where $F' = C_H/C_D$:

$$G(H_2) = G_1(H)\times F' + (k_1/k_3)\times G_2(H)\times F'^2 \quad \text{(iii)}$$

$$G(HD) = F'[G_2(H) + (k_2/k_4)\times G_2(D)]. \quad \text{(iv)}$$

In equation (i) the second term is considerably smaller than the first and $G_1(D)$ can be obtained from the slope of the line obtained by plotting $G(D_2)$ vs. F. Alternatively, the function $G(D_2)/F$ can be plotted against F when $G_1(D)$ is obtained as the intercept of $G(D_2)/F$ when $F = 0$. This is the graphical method given in reference 1. The values of the bracketed terms in equations (ii) and (iv) are the slopes of the plot of $G(HD)$ vs. C_D/C_H and C_H/C_D respectively. We have defined (2) the slope of (ii) as

$$g(HD) = G_2(D) + (k_3/k_1)G_2(H). \quad \text{(v)}$$

We now define

$$g'(HD) = G_2(H) + (k_2/k_4)G_2(D). \quad \text{(vi)}$$

This analysis contains six independent quantities, $G_1(H)$, $G_2(H)$, $G_1(D)$, $G_2(D)$, k_3/k_1, and k_2/k_4. Noting that, for the pure compounds C_H and C_D, $G(H_2) = G_1(H) + G_2(H)$ and $G(D_2) = G_1(D) + G_2(D)$, measurements of $G_1(D)$ and $G_1(H)$ using equations (i) and (iii) and measurements of $g(HD)$ and $g'(HD)$ will determine all six quantities.

MIXTURES OF C_6H_6 AND C_6D_6

In this system all the constants in our kinetic analysis have been established using data obtained at both ends of the concentration range. Within our experimental precision no very large interactions occur in this mixture or in other mixtures of aromatic hydrocarbons (3). Small positive deviations in G(total hydrogen) are observed from that predicted on the basis of a simple mixture law: these differ in sign from deviations reported by Gordon and Burton (4), who made the first studies on this system.

(a) Mixtures where $C_6H_6 \gg C_6D_6$

Data on the isotopic composition of hydrogen evolved from benzene (C_6H_6) containing small amounts of C_6D_6 are given in Table I. The yields are shown in Fig. 1. A plot of $G(D_2)/F$ gives an intercept:

$$G_1(D) = (3.2 \pm 0.4) \times 10^{-3}, \qquad (C_6H_6 \gg C_6D_6)$$

TABLE I

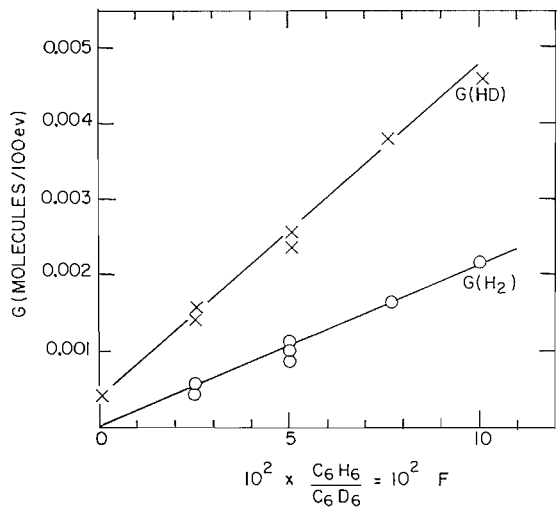

FIG. 2. Yields of HD and H_2 from dilute solutions of C_6H_6 in C_6D_6.

not isotopically pure this material gives gas containing 2.88% HD. The plot of G(HD) vs. mixture composition does not go through the origin: we have, however, taken g'(HD) to be the slope of this line. The mass spectrum of 'pure' D_2 contains about 1% of the D^+ ion, $m/e = 2$. The mass spectrometric results given in Table II have been corrected for this. In this connection we went to some trouble to avoid the accidental introduction of hydrogenous impurities into these samples. Rigorous exclusion of water vapor by handling materials and preparing samples in a 'dry' dry box and using 'Kel F' grease

(a perfluorinated hydrocarbon) in the vacuum lines made no noticeable difference to the amounts of H_2 or HD observed nor to the experimental scatter.

From these data we obtain

$$G_1(H) = 0.02 \pm 0.002 \qquad (C_6D_6 \gg C_6H_6)$$
$$g'(HD) = k_2/k_4G_2(D) + G_2(H) = 0.045.$$

(c) Mixtures where $C_6H_6 \sim C_6D_6$

Data on a few samples in the intermediate concentration region are given in Table III and plotted in Fig. 3. These data fit smoothly to the data given above for the two ends

TABLE III

Isotopic composition of hydrogen from C_6H_6–C_6D_6 mixtures ($C_H \sim C_D$)

Mole% C_6D_6	$G(H_2)$	G(HD)	$G(D_2)$	G(hydrogen)
20	0.0276	0.0052	0.00089	0.0337
50	0.0166	0.0102	0.00406	0.0308

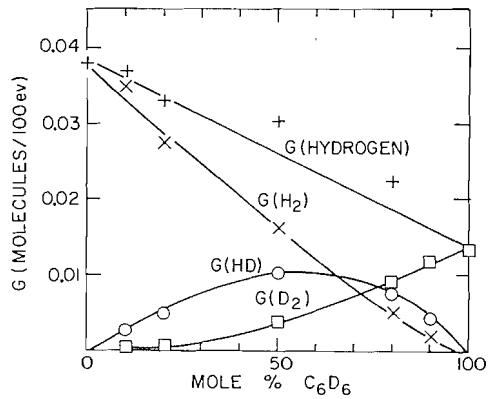

FIG. 3. Yields of H_2, HD, D_2, and total hydrogen from mixtures of C_6H_6 and C_6D_6.

of the concentration range. However, the values of G(hydrogen) = $G(H_2 + HD + D_2)$ differ significantly from the previously published data of Gordon and Burton (4), although there is good agreement in the percentage isotopic composition. At 50 mole% C_6D_6, for instance, we found G(hydrogen) = 0.03, whereas they report 0.02. The percentage composition we found was 53.8% H_2, 33.1% HD, and 13.1% D_2. They report 52.1% H_2, 33.1% HD, and 14.8% D_2. Our values of G(hydrogen) lie above the 'mixture line' for C_6H_6–C_6D_6 mixtures. Their results lie below the 'mixture line' and they concluded that C_6D_6 and C_6H_6 were in effect protecting one another. We have no explanation of this experimental discrepancy.

(d) Other Parameters of the System

Combining the values of G_1(H) and G_1(D) with the values of $G(H_2)$ and $G(D_2)$ we found for pure C_6H_6 and C_6D_6, viz.

$$G(H_2) = 0.038$$
$$G(D_2) = 0.0135,$$

and recalling that $G(H_2) = G_1(H)+G_2(H)$, $G(D_2) = G_1(D)+G_2(D)$, we find

$$G_2(H) = 0.018 \text{ and } G_2(D) = 0.01.$$

From the values of $g(HD)$ and $g'(HD)$ we find

$$k_3/k_1 = 0.95 \text{ and } k_2/k_4 = 2.7.$$

With the equations given above, these numbers can be used to calculate the isotopic composition of radiolytic hydrogen evolved from mixtures of any composition.

For a 50–50 mixture the calculated percentage composition is 56.5% H_2, 31.1% HD, and 12.1% D_2, which is in reasonable agreement with the observed compositions (see above). The calculated G(hydrogen) is 0.025, which is midway between the experimental results of Gordon and Burton and ourselves.

While this agreement in isotopic composition is satisfactory, it is probably not very significant since the kinetic analysis can be regarded as a curve-fitting procedure. As the parameters have been chosen to give a fit at the two ends of the composition range, it is not surprising that an interpolation at the midpoint of the composition is in good agreement with experiment.

MIXTURES OF C_6D_{12} AND C_6H_6

Data on mixtures of benzene with small amounts of cyclohexane-d_{12} are given in Table IV and plotted in Fig. 4. The dotted line, $G_0(H_2)\times$electron fraction, shows the

TABLE IV

Isotopic composition of hydrogen from C_6H_6–C_6D_{12} mixtures

Mole% C_6D_{12}	$F = C_6D_{12}/C_6H_6\times10^2$	G(hydrogen)	% HD	% D_2	$G(HD)\times10^3$	$G(D_2)\times10^3$	$G(D_2)/F$	$G(H_2)$
1.95	1.98	0.045_6	8.15	2.90	3.71	1.32	0.066	0.040_6
3.96	4.12	0.047_5	14.4	5.78	6.84	2.74	0.066	0.037_9
5.82	6.17	0.048_9	19.8	8.03	9.68	3.92	0.0635	0.035_3
7.60	8.22	0.052_7	23.7	10.61	12.48	5.58	0.072	0.034_6

decrease in $G(H_2)$ expected from simple dilution, neglecting any interactions such as the formation of HD. It can be seen that $G(D_2)$ is a linear function of the C_6D_{12} concentration and there is a finite first-order yield of D_2. For these mixtures

$$G_1(D) = 0.06\pm0.01 \qquad (C_6H_6 \gg C_6D_{12})$$
$$g(HD) = 0.17.$$

This first-order decomposition of C_6D_{12} in benzene is analogous to "$g_c(H_2)$", the unquenchable yield of H_2 from c-C_6H_{12}, which persists at "infinite benzene concentration", observed by Burton, Chang, Lipsky, and Reddy (5). This "unquenchable yield" was obtained by calculation from values of $G(H_2)$ in benzene–cyclohexane mixtures of the yield of H_2 from cyclohexane per 100 ev absorbed in the cyclohexane fraction. This yield, $g_c(H_2)$, extrapolated to 0.5 molecule/100 ev in pure benzene. While this yield is considerably greater than our value of $G_1(D)$ the experiments agree on the existence of this unquenched decomposition.

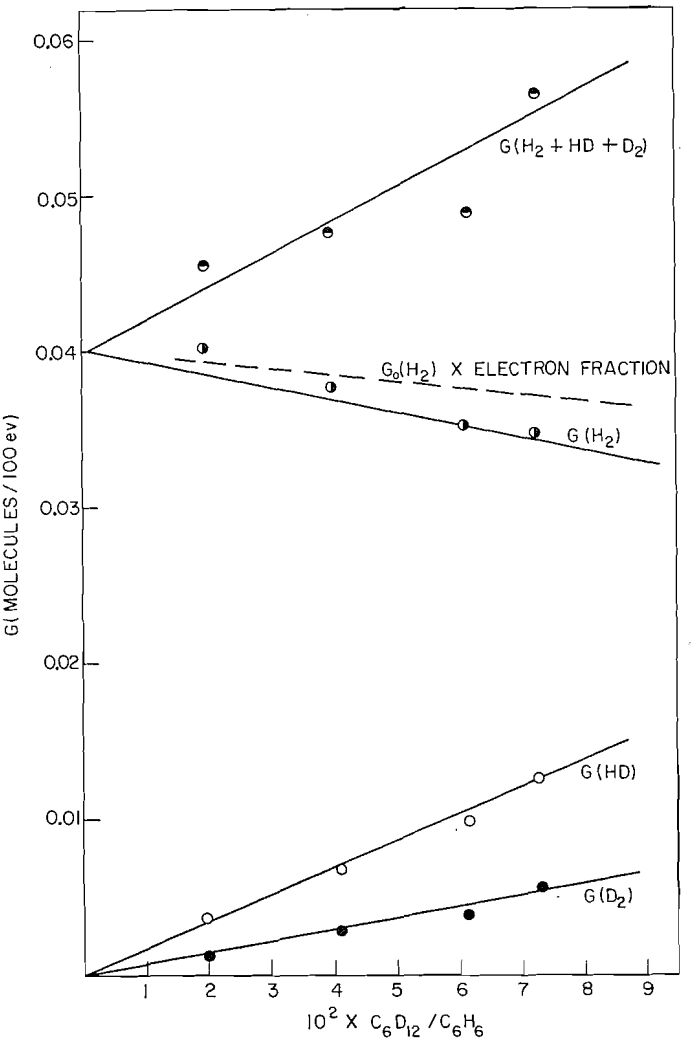

FIG. 4. Yields of HD, D_2, and total hydrogen from dilute solutions of C_6D_{12} in C_6H_6.

Burton and his co-workers suggest that this decomposition occurs via a precursor which cannot be quenched by benzene. It is not, however, necessary to make this assumption because the simple quenching scheme can lead to a finite yield. The sequence

$$C \sim\sim\sim\rightarrow C^x \text{ (yield } G) \qquad [4]$$

$$C^x \longrightarrow \text{products including hydrogen} \qquad [5]$$

$$C^x + B \longrightarrow \text{products excluding hydrogen,} \qquad [6]$$

where C ≡ cyclohexane, B ≡ benzene, leads to:

$$G(H_2) = \frac{GX_c}{1+k_6/k_5[B]},$$

where X_c is the mole fraction of cyclohexane. Burton's quantity $g_c(H_2)$ and our quantity $G_1(D)$ are both of the form $G(H_2)/X_c$. If $k_6/k_5 \sim 1$ and X_c is small (i.e. $[B] \rightarrow 10$ moles/liter) then $G/(1+k_6/k_5[B]) \sim G/10$, which is still a finite fraction of the yield in pure cyclohexane. From a more detailed analysis of the variation of $G(H_2)$ with composition Freeman (6) concluded that, at high benzene concentrations, the main interaction between benzene and the excited precursors C^x was a charge or energy-transfer step like [6] and that, in fact, $k_6/k_5 \sim 1$ ($k_6/k_5 \equiv k_3''/k_4''$ in Freeman's terminology). This correlation only shows, however, that similar kinetic treatments of the system lead to similar numerical values of the parameters.

At present it is only possible to make qualitative, comparative comments on the value of $g(HD)$. In solutions of c-C_6D_{12} in C_6H_6, $g(HD) = 0.17$, in solutions of C_6D_6 in C_6H_6 $g(HD) = 0.027$, so the deuterium atoms on a cyclohexane molecule are considerably more labile in benzene solutions than deuterium atoms on a benzene molecule.

MIXTURES OF C_6D_6 IN C_6H_{12}

The isotopic composition of hydrogen evolved from these mixtures has been previously studied by Burton and Patrick (7) and by Chang (8). In the present work more data were obtained in the low concentration range. These data are given in Table V and plotted in Fig. 5,

TABLE V

Mixtures of C_6D_6 with C_6H_{12}

82.92	—	0.106	33.56	10.93	0.034	0.109

together with some data for $G(HD)$ from C_6D_{12}–C_6H_{12} mixtures. The yield of HD from these solutions is not a linear function of C_6D_6 concentration, due mainly to the large reduction in G(hydrogen) on the addition of benzene. The initial slope of $G(HD)$, i.e. the limiting value of $g(HD)$ as $[C_6D_6] \rightarrow 0$, is 2.94 as measured from the lowest concentration point; conventional extrapolation techniques of the differential slope show that the limiting value may be as great as 3.5.

The experimental result is therefore

$$g(HD) \geqslant 2.9. \qquad (C_6H_{12} \gg C_6D_6)$$

The value of $g(HD)$ can only be subjected to a qualitative discussion. The main point of interest is that the value $g(HD) = 2.9$ where benzene-d_6 is the source of the D atoms in cyclohexane solutions is close to the value $g(HD) = 3.7$ (1, 2) where cyclohexane-d_{12} is the source of D atoms. The comparable reactivities of benzene and cyclohexane in this respect is somewhat surprising when one recalls the very low hydrogen yield from pure benzene. It must, however, be noted that in these solutions the absolute yield $G(HD)$ is a small fraction of the total hydrogen yield and is also a small fraction of the decrease in hydrogen yield from pure cyclohexane. At the lowest concentration of benzene-d_6,

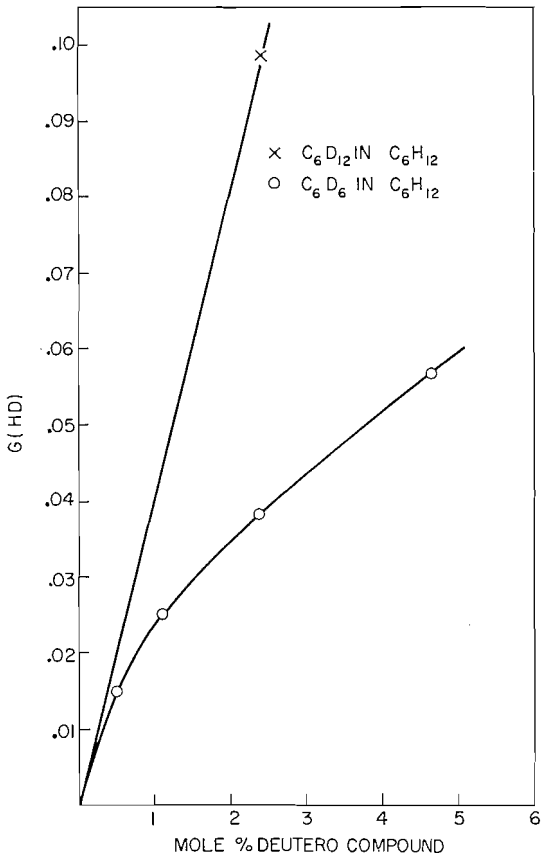

FIG. 5. Yields of HD from dilute solutions of C_6D_6 in C_6H_{12} and C_6D_{12} in C_6H_{12}.

$G(HD) \approx 0.015$, $\Delta G(\text{hydrogen}) \approx 1.4$, so there is a factor of the order of 100 between the efficiency (rate) of the abstraction reaction and that of the scavenging/quenching reactions which are responsible for the decrease in hydrogen yield.

A second point of interest is the variation of $G(D_2)$ at high benzene concentration: Burton and Patrick (7) reported that $G(D_2)$ is a linear function of mole% C_6D_6. Our results for D_2 yields plotted in Fig. 6 confirm this. We have also plotted values of $G(D_2)$ in C_6H_6–C_6D_6 mixtures, together with the extrapolated limiting slope measured at low C_6D_6 concentration which we have identified with $G_1(D)$. The measurements in cyclohexane solution show a linear slope such that $G_1(D)$ equals the yield of D_2 from pure benzene-d_6. This suggests that the deuterium from pure C_6D_6 (or hydrogen from C_6H_6) is produced wholly by the first-order mechanism. However, this cannot be since mixtures of C_6H_6 and C_6D_6 give appreciable amounts of HD.

This paradox is partially resolved if the results of reference 3 are recalled. It was noted that $G_1(D)$ varies with solvent; it could be greater or less than the first-order yield in the pure deuterated hydrocarbon and could very well be greater than the total yield of D_2 from the deuterated hydrocarbon. If it were greater, the curve of $G(D_2)$ vs. concentration would be concave to the concentration axis, a behavior which is shown in some of the data obtained by Chang (8) from C_6D_6–C_6H_{12} mixtures containing iodine. If the results

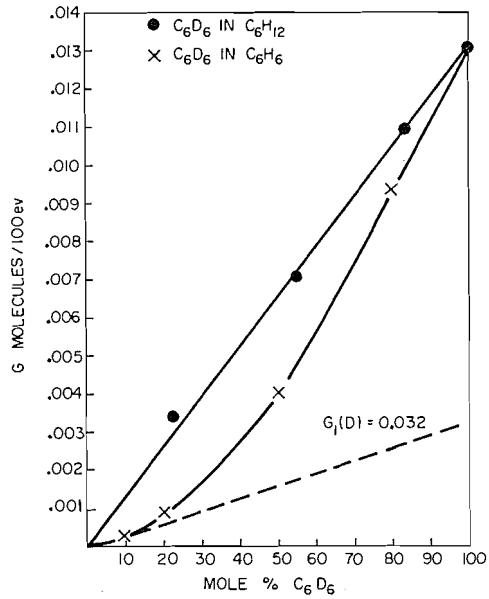

FIG. 6. Yields of D_2 from mixtures of C_6D_6 in C_6H_{12} and C_6D_6 in C_6H_6.

of reference 3 are taken to indicate energy transfer then this result apparently indicates energy transfer from cyclohexane to benzene-d_6.

MIXTURES OF C_6D_{12} AND C_6H_{12}

This section is a brief account of some experiments on 'pure' C_6D_{12}. This material has a 99.5% isotopic purity and consequently contains about 5–6% $C_6D_{11}H$. Radiolysis of this material gives hydrogen containing 6.4% HD. This result indicates an apparently 'infinite' isotope effect for the liberation of H atoms from $C_6D_{11}H$; if excitation is partitioned between components as their mole fraction, then this result implies that every $C_6D_{11}H$ molecule dissociates to give the X_H precursor with something approaching 100% efficiency. The gas obtained from the radiolysis of 'pure' $C_6D_{11}H$ contained 26% HD and 2.2% H_2. This compound contains 8% hydrogen atoms and the amounts of H_2 and HD found do not suggest any abnormal effects in the lability of H atoms. The amount of HD from 'pure' C_6D_{12} is equivalent to a material containing ~25% $C_6D_{11}H$.

This anomaly makes the interpretation of the data on mixtures of C_6D_{12} with small amounts of C_6H_{12} uncertain. Making a simple subtraction of the yield of H_2 from 'pure' C_6D_{12} our experiments show a wide experimental scatter but indicate $G_1(H) \sim 4.0 \pm 1.0$. This value is very close to the total hydrogen yield and apparently greater than the initial yield of cyclohexene, viz. 3.2 (9). Comparable experimental observations have been made by Burton and Chang (10).

THE MECHANISM OF THE 'FIRST-ORDER' PROCESS

Part of the hydrogen yield from alkanes is rapidly reduced by materials expected to have a high reactivity towards hydrogen atoms (11). As a consequence this part is often referred to as the 'scavengeable' hydrogen. The residue, which is "unscavengeable", is often called the 'molecular' hydrogen. Our first isotopic experiments (1) demonstrated the existence of the molecular detachment process formalized in eq. [1]. We have later

shown that benzene and iodine reduce the first-order yield with an efficiency closely comparable to the efficiency with which the total hydrogen yield is reduced. We have analogous results for solutions of benzoquinone and carbon tetrachloride in C_6D_{12}–C_6H_{12} mixtures and for benzene and iodine in mixtures of methylcyclohexane-d_{14} and methylcyclohexane (12). Since the 'molecular' process, observed in the isotopic experiments, is reduced concurrently with the bimolecular process (which would be reduced by a hydrogen atom scavenger) interpretations of the type given by Hardwick (11) and Freeman (20) need modification.

It is of interest to discuss possible mechanisms for the first-order yield.

For alkanes, these are:

(i) A true unimolecular decomposition mechanistically described by

$$C_H \text{—}\sim\sim\rightarrow C_H{}^X \rightarrow H_2 + \text{olefin.}$$

The excited precursor $C_H{}^X$ may be an ion or a neutral molecule. Williams (13) has argued that, for *n*-alkanes, this unimolecular decomposition of an ion is exothermic and may account for part of the olefin formation. Forrestall and Hamill (14) have suggested that the intermediate $C_H{}^X$ (our nomenclature) is formed following electron capture by the $C_6H_{12}{}^+$ ion. Sauer and Dorfman (15) have shown, for ethylene and *n*-butane, that a considerable amount of photolytic hydrogen is produced in a unimolecular decomposition via non-ionic precursors.

(ii) A bimolecular ion–molecule reaction, e.g.

$$CH_3{}^+ + CH_4 \rightarrow C_2H_5{}^+ + H_2$$

or, more generally (13),

$$C_nH_{2n+2}{}^+ + C_nH_{2n+2} \rightarrow C_{2n}\text{-hydrocarbon} + H_2. \qquad [7]$$

These reactions would not be affected by a radical scavenger and would consequently contribute to the unscavengeable hydrogen (or 'molecular' hydrogen) in contrast to the scavengeable hydrogen which, by definition, occurs via a radical reaction. If reaction [7] is rewritten for a mixture of isotopic hydrocarbons:

$$C_nH_{2n+2} + C_nD_{2n+2}{}^+ \rightarrow C_{2n}\text{-hydrocarbons} + \begin{cases} H_2 \\ HD \\ D_2 \end{cases} \qquad [8]$$

we see that there is no certainty as to the isotopic composition of the molecular hydrogen. Williams suggests that this reaction may proceed via hydride ion transfer—to give $C_nD_{2n+2}H$, which then eliminates 'hydrogen', which, in this case, could be D_2 or HD. The amount of D_2 formed by this process would be proportional to the concentration of the deutero compound and would contribute to the first-order yield.

(iii) A bimolecular radical–radical reaction

$$C_6D_{12} \text{—}\sim\sim\rightarrow C_6D_{11} + D \qquad [9]$$

$$D + C_6D_{11} \longrightarrow D_2 + C_6D_{10}, \qquad [10]$$

where the second step is a diffusion-controlled reaction between the species formed in the first step. We have discussed (15) the possibility of benzene acting as a radical scavenger in dilute benzene–cyclohexane solutions and competing with step [8], and conclude that the gas-phase values for the reactivity of H atoms with benzene are not large enough for effective competition at low benzene concentrations. We concluded that the mechanism

by which benzene reduces the 'molecular' yield must be a 'quenching' or energy-transfer type of mechanism.

Somewhat surprisingly, the gas-phase reactivity is not large enough to exclude this radical–radical reaction even in pure benzene solutions. In the equation given by Roy, Williams, and Hamill (16) the probability of a scavenger competing with a diffusion-controlled reaction is determined by the product P_2X (where, in this case, P_2 is the collision efficiency of the reaction of D atoms with benzene and X is mole fraction of benzene). Their data show that if $P_2 \sim 1$ a 50% efficiency of scavenger is observed when $X \sim 10^{-2}$. When the reaction occurs in pure scavenger ($X = 1$) P_2 must be $\sim 10^{-2}$ for effective competition. Since the collision efficiency P_2 for the reaction between hydrogen atoms and benzene in the gas phase is $1.3\text{–}7.9 \times 10^{-4}$ (17), it is still possible for the first-order yield to be occurring by a sequence like reactions [9] and [10] in pure benzene. This observation reinforces our conclusion (3, 15) that, at low benzene concentrations, benzene acts by 'quenching' precursors of the 'unimolecular' decomposition.

Smith (18), in this laboratory, has observed a first-order yield of D_2 in the radiolysis of C_6D_{12}–C_6H_{12} mixtures in the vapor phase which is somewhat greater than that in the liquid phase. The diffusion-controlled atom–radical reaction cannot occur in the vapor phase and consequently, one of the first two mechanisms must be occurring in the vapor. This again argues that they may be expected to occur in the liquid.

In benzene the situation is different. The total hydrogen yield is very small so while the first-order yield is a significant fraction of the total yield it corresponds, by comparison with cyclohexane, to a much less efficient process. It is, therefore, quite possible that the diffusion-controlled radical–radical reaction is significant in benzene whereas it is relatively insignificant in cyclohexane. Ingalls (19) has suggested that the radical–radical reaction is the mechanism for the first-order yield which he measured in toluene.

From the balance of this evidence it is our opinion that, in cyclohexane, the first-order yield measures a true molecular detachment. The ionic process discussed in (ii) is an interesting and provocative speculation. In benzene, the first-order yield could be a true molecular detachment or a diffusion-controlled radical–radical reaction.

C^{13} SPLITTINGS IN SOME SUBSTITUTED BENZENES

H. M. HUTTON,* W. F. REYNOLDS,† AND T. SCHAEFER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received May 4, 1962

ABSTRACT

C^{13} sidebands in the proton spectra of some symmetrically substituted benzenes have been used to obtain carbon–hydrogen coupling constants as well as proton coupling constants.

A long-range carbon–hydrogen coupling constant has also been found. Substituents which act as electron acceptors in an inductive manner are found to increase the $C^{13}H$ coupling constants by as much as 20 c.p.s. The patterns of the sidebands are discussed and possible errors in first-order analyses are indicated.

INTRODUCTION

The carbon–hydrogen spin–spin splittings in a wide variety of compounds have been measured, either by C^{13} resonances or from sidebands in proton resonances. They have been reviewed by Lauterbur (1). It has been proposed that they are mainly determined by the *s* character of the carbon-bonding orbital (2, 3). Long-range carbon–hydrogen coupling constants have been measured by Karabatsos *et al.* by means of C^{13} enrichment (4). A few carbon–hydrogen coupling constants for benzene rings have been reported from C^{13} measurements (1). We have measured these for a dozen substituted benzenes by means of proton spectra. All compounds were chosen so that the main proton resonance was a single line. In such cases the sidebands occurring due to splitting by C^{13} present in natural abundance are observable. The separations of the centers of gravity of the sidebands give the carbon–hydrogen coupling constants directly. The sidebands show interesting fine structure and these are discussed.

EXPERIMENTAL

The C^{13} sidebands of the proton resonance at 60 Mc/s were measured in natural abundance in the pure liquid or saturated solution. Peak separations were determined by the standard techniques using a frequency counter and sidebands obtained from the main proton resonance. Averages were taken of up to 10 spectra. The spectra were taken with a radio-frequency power of about 50 db below 0.5 watt. A compromise had to be reached between saturation effects and a rate of sweep of the field such that fine structure could be observed.

RESULTS AND DISCUSSION

In Table I the coupling constants are given for the various compounds run either as liquids or as saturated solutions in the solvents listed. The standard deviations are given. In Fig. 1 typical spectra are presented for symmetrically substituted benzenes as well as that of benzene itself. The different types of spectra will now be discussed in turn.

Pentasubstituted Benzene

The spectrum of molecules of 2,3,5,6-tetrachloronitrobenzene containing a C^{13} nucleus bonded to the hydrogen is of course a simple doublet, Fig. 1(*a*). The separation of the peaks is 175.0 ± 0.4 c.p.s. in carbon tetrachloride and 176.9 ± 0.6 c.p.s. in acetone. The difference is just larger than the standard deviations but it is not certain that this is significant.

The two peaks marked I in Fig. 1(*a*) are due to impurities. The unmarked peak next to the main proton resonance, however, is not caused by an impurity. It is one peak in

TABLE I

Coupling constants in some symmetrically substituted benzenes in c.p.s.

Compound	State	$J_{C^{13}H}$*	Other coupling constants*
2,3,5,6-Tetrachloronitrobenzene	In CCl_4	175.0±0.4	$J_{C^{13}CH} = 4.9\pm0.3$
	In acetone	176.9±0.6	or $J_{C^{13}CCH} = 4.9\pm0.3$
2,4,6-Tribromophenol	In acetone	172.5±0.8	$J_m^{HH} = 2.3\pm0.2$
2,4,6-Trichlorophenol	In acetone	171.3±0.5	$J_m^{HH} = 2.5\pm0.2$
2,4,6-Trinitrophenol	In acetone	175.8±0.5	$J_m^{HH} = 2.8\pm0.2$
2,6-Dinitro-4-chlorophenol	In ether	174.1±0.4	$J_m^{HH} = 2.8\pm0.2$
2,6-Dibromo-4-nitrophenol	In acetone	172.8±1.3	$J_m^{HH} = 3.3\pm0.3$
1,3,5-Trichlorobenzene	In CCl_3Br	172.2±0.4	$J_m^{HH} = 2.1\pm0.2$
1,3,5-Tribromobenzene	In CCl_3Br	174.3±0.5	$J_m^{HH} = 1.7\pm0.3$
1,3,5-Trinitrobenzene	In acetone	179.5±1.5	$J_m^{HH} = 1.9\pm0.2$
p-Dichlorobenzene	In acetone	169.0±1.0	
p-Dimethoxybenzene	In acetone	161.1±1.0	
Benzene	Liquid	158.7±0.8	
2,4,6-Trimethylpyridine	Liquid	158.5±0.7	$J_{C^{13}H}(CH_3) = 126.4\pm0.5$

*Errors given are standard deviations.

the doublet due to long-range carbon–hydrogen coupling in those molecules where C^{13} is in the position ortho or meta to the proton. A spectrum run in reverse reveals the other peak of the doublet. Ringing of the large proton peak obscures the second peak of the doublet in each case. The coupling is 4.9±0.3 c.p.s. Since the intensity of the peaks in this doublet is greater than that of the peaks in the other doublet (the exact ratio is very hard to decide because of the proximity of the large ring resonance), we conclude that this coupling is either $J_{C^{13}CH}$ or $J_{C^{13}CCH}$. In less heavily substituted benzenes the peaks due to such coupling will be obscured by the more intense central hydrogen peak.

The only other value for a long-range coupling constant in benzenes is the one of 5 c.p.s. between the methyl protons and, presumably, the neighboring ring carbon in toluene (10). It is of the same order of magnitude as those found by Karabatsos *et al.* in molecules containing sp^2 hybridized carbon (4).

Tetrasubstituted Benzenes

All four of this type have the two protons in the meta position. A typical spectrum is shown in Fig. 1(*b*). Neglecting long-range coupling constants between carbon and hydrogen, we have, in first order, that the separation of the doublets is $J_{C^{13}H}$ and the doublet spacing is J_m^{HH}.

Consider now an exact approach to this three-spin system. The two ring protons and the C^{13} nucleus constitute an AA′X system (5). It follows that the separation of the outermost peaks of the doublets is $J_m^{HH}+1/2(J_{C^{13}H}+J_{C^{13}CCH})+2D$ and the separation of the innermost peaks is $-J_m^{HH}+1/2(J_{C^{13}H}+J_{C^{13}CCH})+2D$. Here $2D = \{[1/2(J_{C^{13}H}-J_{C^{13}CCH})]^2+(J_m^{HH})^2\}^{1/2}$. Only if both J_m^{HH} and $J_{C^{13}CCH}$ are much smaller than $J_{C^{13}H}$ do we make no error in a first-order analysis. Assuming a maximum long-range coupling constant of about 5 c.p.s. and a J_m^{HH} of 2 c.p.s. the error in $J_{C^{13}H}$ is only about 0.1 c.p.s. The error can reach significant proportions where J^{HH} is not small, as in cis and trans disubstituted ethylenes for instance.

Trisubstituted Benzenes

A typical spectrum is shown in Fig. 1(*c*). In first order we expect two triplets with spacings equal to J_m^{HH} and centers separated by $J_{C^{13}H}$. If J_m^{HH} and $J_{C^{13}CCH}$ cannot be neglected with respect to $J_{C^{13}H}$ we have the $AA_2'X$ case. The energy levels for this are written down rather easily. It is immediately clear that there are strong A transitions between antisymmetrical triplet states which are separated by $J_{C^{13}H}$. This constant can

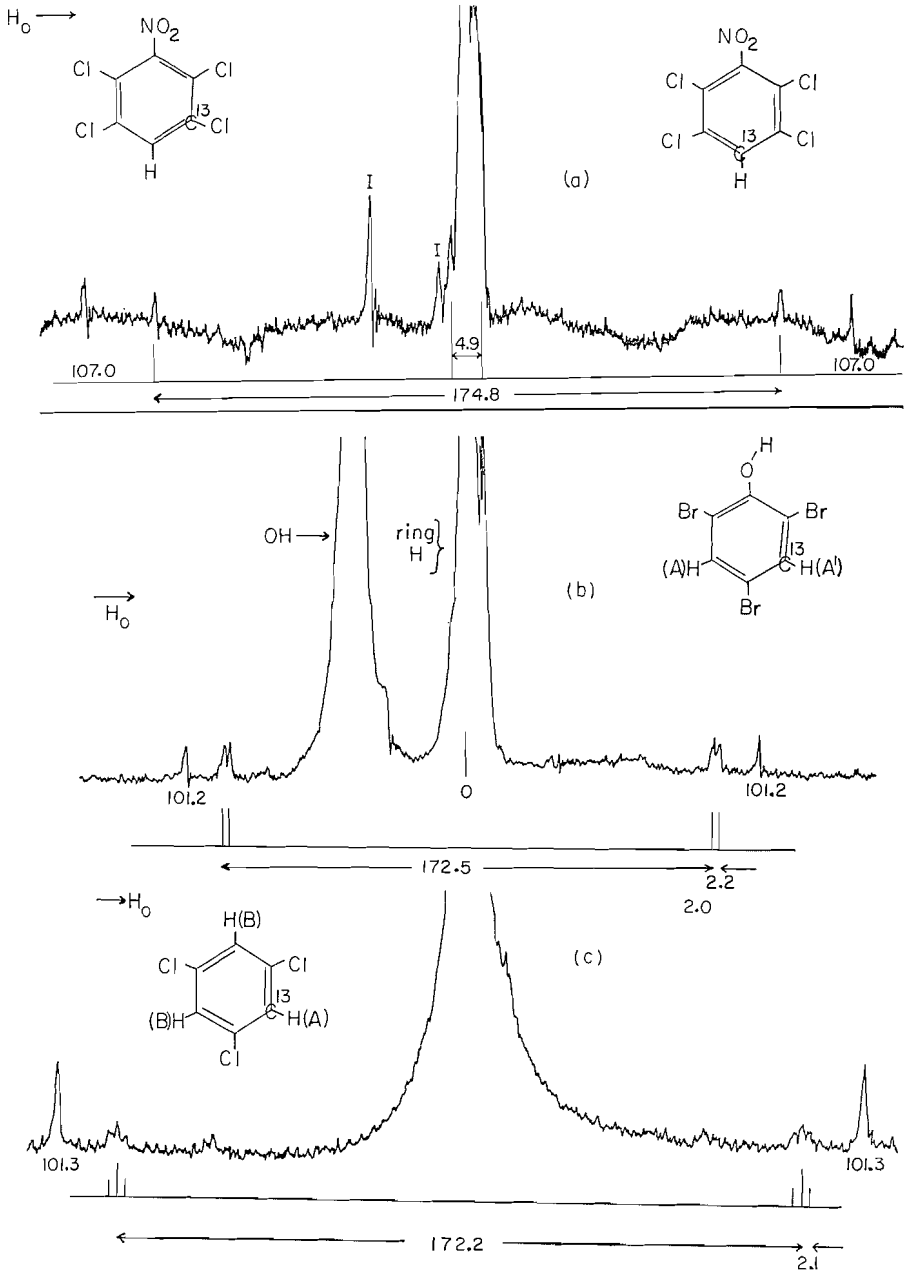

FIG. 1. The 60 Mc/s proton resonance spectrum at high radio-frequency power, showing the C^{13} sidebands in saturated solutions of (*a*) 2,3,5,6-tetrachloronitrobenzene in acetone, (*b*) 2,4,6-tribromophenol in acetone, (*c*) 1,3,5-trichlorobenzene in trichlorobromomethane. Peak separations in the observed and calculated spectra are given in c.p.s.

immediately be derived from the separation of the strong central lines of the triplets. In contrast to the tetrasubstituted benzenes the peak separations in the multiplets themselves deviate from J_m^{HH}, depending on the relative sizes of J_m^{HH}, $J_{C^{13}CCH}$, and $J_{C^{13}H}$. In our examples the error is less than the experimental one.

Disubstituted Benzenes

The spectrum obtained from a paradisubstituted benzene is typified by Fig. 2(*a*). It is

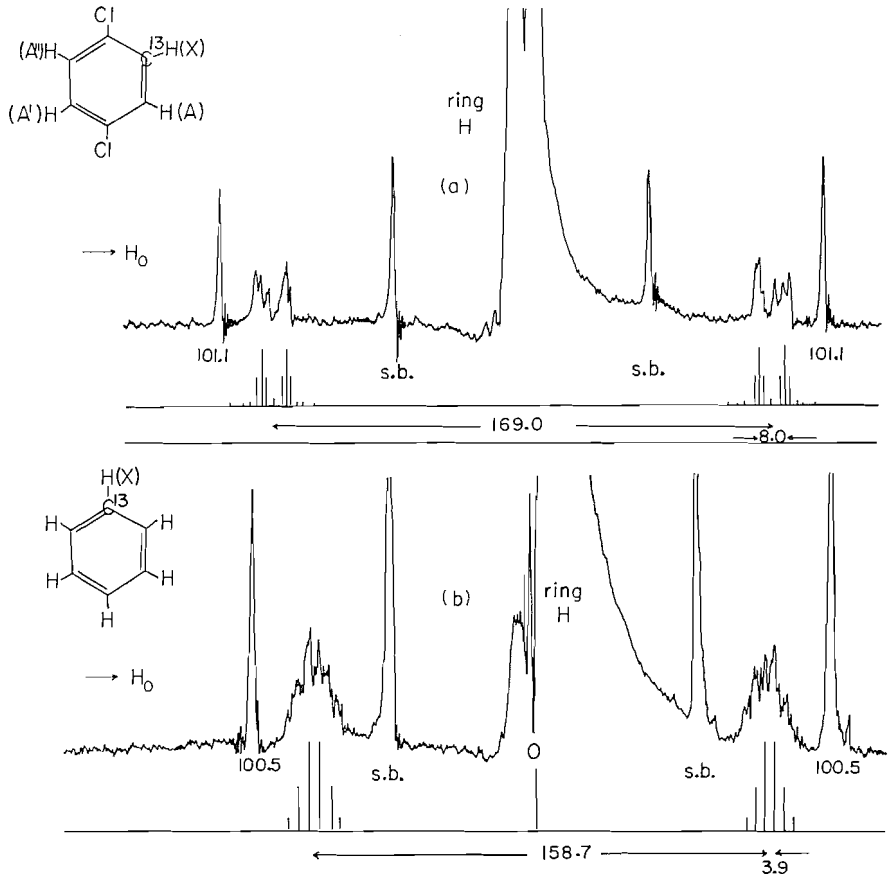

FIG. 2. The 60 Mc/s proton resonance spectrum at high radio-frequency power, showing the C^{13} sidebands of (*a*) paradichlorobenzene as a saturated solution in acetone, (*b*) liquid benzene. Peak separations in the observed and calculated spectra are given in c.p.s. The peaks marked s.b. are spinning sidebands.

immediately clear that it is not a first-order spectrum. The best approximation to the actual situation, for which explicit values for the transitions in terms of spectral parameters can be obtained, is AA'A''X, where long-range carbon–hydrogen coupling constants are neglected. The highest order of the submatrices is three and orthogonal matrices can be found which diagonalize them. This was done.

Taking $J_o^{HH} = J_{AX} = J_{A'A''} = 8$ c.p.s., $J_m^{HH} = J_{AA'} = J_{A''X} = 2$ c.p.s., and $J_p^{HH} = J_{AA''} = 0$ c.p.s., the calculated spectrum which results is shown in Fig. 2(*a*). This is exactly what one expects as soon as one realizes that proton X and proton A as well as protons A' and A'' are relatively tightly coupled.

The deviation from the calculated spectrum can result from the fact that $2J_o^{HH} \approx 0.1J_{C^{13}H}$. If the $J_{C^{13}H}$ values are large enough, they could aggravate the deviation from the case AA'A''X. We conclude that we are in fact dealing with the case AA'A''A'''X, where X is now a carbon nucleus. These systems show no symmetry and this is really where the difficulty lies. However, our analysis has accounted for the spread of the spectrum and we can extract a value of $J_{C^{13}H}$ which is accurate to about 1 c.p.s.

Benzene

The calculated spectrum in Fig. 2(*b*) is that resulting from the assumed case A_5X, where X is the proton bonded to C^{13}. This assumption is justified if (*a*) $J_{C^{13}H}$ is large compared to any J^{HH} and (*b*) J_o^{HH} is large compared to a fraction, about one quarter, of $J_o^{HH}-J_m^{HH}$. These conditions, hard to specify more closely in this complex situation, are roughly true here. In that case each half of the spectrum should be a sextet with separations between the multiplet peaks of $1/5(2J_o^{HH}+2J_m^{HH}+J_p^{HH})$. This is 3.9 c.p.s. on an average and it is seen that the calculated spectrum reproduces the shape of the observed spectrum. The situation is somewhat similar to that of fluorobenzene (6). A good general discussion of similar systems is given by Abraham and Bernstein (7). Further progress in the analysis of C^{13} sidebands in the proton spectra of substituted benzenes will no doubt involve enrichment of the carbon isotope in these molecules.

The Carbon–Hydrogen Coupling Constants

All the carbon–hydrogen coupling constants lie above that of benzene itself. If the relation $\rho_{CH} = 0.20J_{C^{13}H}$ is correct, as suggested by Muller and Pritchard (2), then the percentage of *s* character, ρ_{CH}, of the carbon atomic orbital of the CH bond varies from about 32% for benzene to about 36% for 1,3,5-trinitrobenzene. The carbon atomic orbital deviates only slightly from sp^2 hybridization. If, further, the linear relation between r(C—H) and percentage of *s* character of C—H is correct, the bond length shortens by 0.01 Å in going from benzene to 1,3,5-trinitrobenzene.

Lauterbur has obtained $J_{C^{13}H}$ coupling constants for a number of methyl-, hydroxy-, and methoxy-substituted benzenes from the C^{13} spectra (8). They are the same as that in benzene within experimental uncertainties. These substituents are all electron donors in an overall manner. Most of the substituents in the present set of compounds are electron acceptors in an inductive manner, including the halogens. The electron-withdrawing groups cause an increase in $J_{C^{13}H}$ and this is an indication of an increase in *s* character of the C—H bond if Muller's ideas are correct (2). The trinitrobenzene has the highest $C^{13}H$ coupling constant and it is one of the strongest meta-directing groups. No simple additivity relation is evident for the various substituents, such as the one found for substituted methanes (9), and this is probably due to resonance interactions among the substituents.

The $C^{13}H$ coupling constant in the pyridine is the same as in benzene and since the carbon is meta to the nitrogen this is perhaps not surprising.

DETERMINATION OF FREE FORMALDEHYDE BY VAPOR DIFFUSION TECHNIQUE: A STUDY OF THE GLYCINE–FORMALDEHYDE REACTION

JOHN L. MORRISON,[1] AUDREY S. LEE, AND PETER J. MOLONEY
Connaught Medical Research Laboratories, University of Toronto, Toronto, Ontario

Received May 8, 1962

ABSTRACT

A vapor diffusion technique has been modified to give absolute values of the free formaldehyde in glycine–formaldehyde mixtures. The equilibrium constant for the formation of the monomethylol addition compound of glycine and formaldehyde was found to be 40, which coincides with that calculated from Levy's measurements which were made with a hydrogen electrode. Values of the equilibrium constant for the formation of the dimethylol compound were variable and much higher than a single value reported by Levy. This uncertainty may be due to polymerization.

INTRODUCTION

The reaction of formaldehyde with glycine has been studied with the hydrogen (1) and glass (2) electrodes. Levy (1) has proposed addition reactions of one and two formaldehyde molecules on the amino group. Further support of Levy's assumptions would be given by a determination of the amount of free or unbound formaldehyde in the aqueous solution. Isolation procedures such as distillation or even precipitation of the formaldehyde as, for example, by dimedon reagent, do not avoid the rapid reversal of the reactions. It was found here that Nash reagent (3) gives a complete reversal of the reaction. Phloroglucinol reagent (4) probably gives a partial reversal.

In the present paper, a vapor diffusion technique (5, 6) has been modified to give an absolute measure of the free formaldehyde, and the equilibria proposed by Levy and others are applied to the measurements.

EXPERIMENTAL

Aqueous solutions of pure formaldehyde were obtained by fractional distillation from paraformaldehyde into water (7). The glycine was analytical grade. The aqueous mixtures were adjusted to various pH values by HCl and NaOH of 0.1 and 1.0 normalities; pH was measured on a Radiometer pH meter.

Formaldehyde was analyzed by means of the Nash test (3) at 420 mμ on a Coleman Universal spectrophotometer. Contrary to what Nash reports, it was found that his reagent retains its full strength for several months, provided that no pipette is dipped into the original reagent bottle. It was noted that standard formaldehyde solutions of over 0.03% concentration are stable for at least 1 month.

The vapor diffusion bottle, Fig. 1, was adapted from diffusion flasks described by Ward Smith (5). Exactly 0.1 ml of a known formaldehyde concentration is added to the small cup by a blowout T.D. type pipette and 5 to 10 ml of the glycine–formaldehyde mixture is measured into the bottle. Several concentrations of formaldehyde (5–8) are placed in the cups of a series of the vapor diffusion bottles above a fixed volume of glycine–formaldehyde mixture. The concentrations in the cups are chosen so as to bracket the free formaldehyde concentration in the mixture. The bottles are rotated on an *inclined* rotating machine (9) in a constant-temperature room. All solutions, bottles, and pipettes are allowed to come to thermal equilibrium in the room before the various additions are made. This precaution is necessary to prevent mass distillation of liquid to or from the small cups. After about 3 to 4 hours' rotation, the complete contents of each cup are carefully washed into separate volumetric flasks and made up to a volume suitable for formaldehyde analysis by the Nash test. Then for each cup the absolute change in formaldehyde concentration is plotted against the original concentration. Usually lines drawn through the increasing and decreasing concentration points are linear and meet at the point of zero change (Fig. 2). The concentration of formaldehyde represented by this point is a measure of the free formaldehyde in the glycine–formaldehyde mixture.

[1]*Present address: Ontario Research Foundation, Toronto, Ontario.*

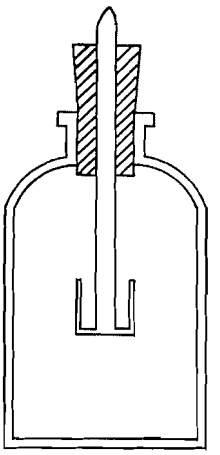

FIG. 1. Vapor diffusion bottle: 50 ml total capacity, No. 00 rubber stopper, borosilicate glass, small cup volume of 0.4 ml.

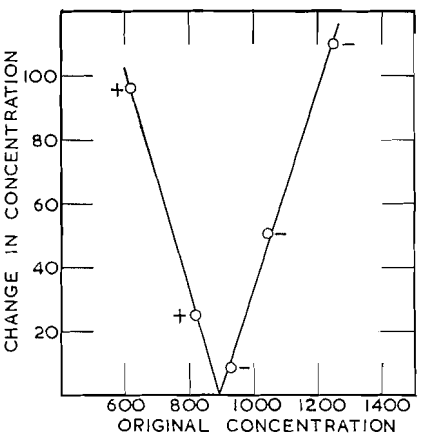

FIG. 2. Determination of free formaldehyde by vapor diffusion bottles; all concentrations and changes in concentration refer to solutions in the small cups; concentrations in parts per million.

It is the point of equal "escaping tendency" or activity (8) of the formaldehyde in the cup and in the mixture.

Blank experiments in which the concentrations in the cup and bottle were the same showed no change in the analysis of formaldehyde in the cup. This shows that during the course of an experiment thermal equilibrium is maintained between the formaldehyde solution and the glycine–formaldehyde mixture. All experiments were carried out in a room at 31.5±0.3° C.

Fixed amounts of 1% glycine and 0.1% formaldehyde were used in most of the experiments. The pH was varied from 2.8 to 9.7. In a few experiments, the ratio of glycine to formaldehyde was varied for both a fixed formaldehyde and a fixed glycine content at a pH of 8.30. This pH was chosen in a region where the free formaldehyde changes rapidly with pH change.

RESULTS AND DISCUSSION

The free formaldehyde values in 0.1% formaldehyde and 1% glycine mixtures at various pH values are given in Table I and plotted in Fig. 3. The only similar experiments in the literature were those of Hobohm (4). In general, except for the 90% free formaldehyde values below pH 7, his results were higher than ours. This is to be expected since he determined the free formaldehyde directly on the *bulk mixture* by the phloroglucinol

TABLE I

Free formaldehyde at various pH values

pH	Free formaldehyde, %	K_3	pH	Free formaldehyde, %	K_3
9.70	6.0		7.40	85	3,800
9.30	8.5		7.04	90	4,500
9.10	12	27,700	6.55	90	
8.55	23	19,700	5.63	90	
8.40	28	17,100	4.10	90	
7.99	52	7,750	2.8	90	
7.40	74	8,050			

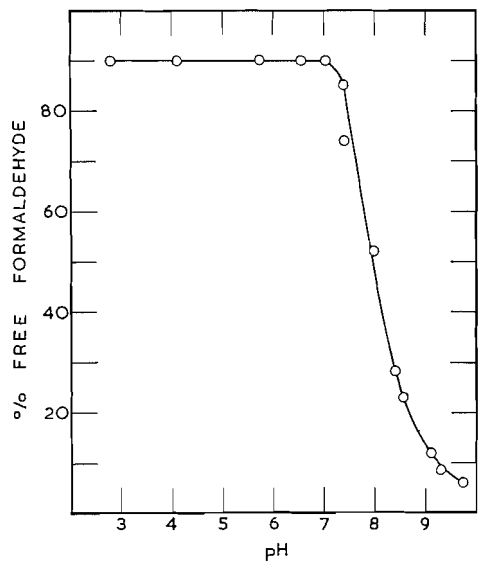

FIG. 3. The variation of free formaldehyde with pH for solutions of 1% glycine and 0.1% formaldehyde.

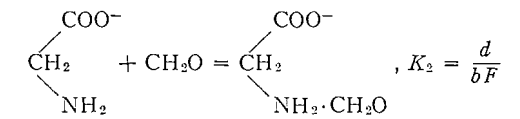
colorimetric method. Hobohm evidently assumed that phloroglucinol does not even partially reverse the reaction of glycine–formaldehyde compound formation. Our results suggest that this assumption is not valid. In fact, in the case of Nash reagent, there is a complete recovery of formaldehyde from glycine–formaldehyde mixtures at all pH values tested. Apparently phloroglucinol only partially reverses the reaction.

The effect of varying the formaldehyde concentration for a fixed glycine concentration, and the converse, are given in Table II. In order to treat the data theoretically it is necessary to consider the experimental measurements and theoretical calculations of Levy for the same system (1).

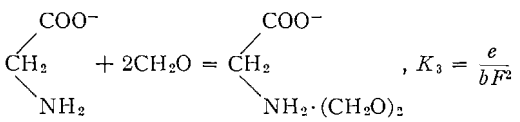
Levy considered that glycine reacted very rapidly with formaldehyde to form mono- and di-methylol addition compounds.

He postulated that the following equilibria determine the behavior of the system:

$$\underset{a}{\mathrm{CH_2(COOH)NH_2}} = \underset{b}{\mathrm{CH_2(COO^-)NH_2}} + \mathrm{H^+},\ K_1 = \frac{bh}{a} \qquad [1]$$



[2]



[3]

K_1 is the hydrogen ion dissociation constant of glycine.

TABLE II

Total formaldehyde, %	Total glycine, %	Free formaldehyde, %	Apparent K_2	K_3
A. Variation of free formaldehyde with formaldehyde concentration at pH 8.30 and 1% glycine				
0.0125		73	58.6	3,400
0.0250		64	90.5	4,650
0.0500		50	167.5	7,500
0.100		30*	444	18,250
0.150		27	585	17,000
B. Variation of free formaldehyde with glycine concentration at pH 8.30 and 0.1% formaldehyde				
	2.0	24		7,200
	1.0	30*		18,250
	0.5	55		14,300

*This value was obtained from an interpolation in Fig. 3.

Levy used the hydrogen electrode to measure the equilibrium relations. The pH values of half-neutralized amino acid at various formaldehyde concentrations were measured and designated pG_f. In order to obtain a simple relationship between the constants K_1, K_2, and K_3, he used the approximation that, when the amino acid concentration is small compared with the formaldehyde concentration, the amount of combined formaldehyde becomes negligible compared with the total formaldehyde. Then the total formaldehyde concentration can be substituted for F, the concentration of free formaldehyde. On the basis of this approximation, Levy obtained the equation

$$\left(\frac{G_f}{K_1}+1\right)\frac{1}{F} = K_2+K_3.F = M. \qquad [4]$$

An examination of Levy's results for some amino acids other than glycine indicates that his approximation is valid. However, in the case of glycine he extrapolated from results (in his Fig. 2) in which an appreciable amount of the total formaldehyde is combined with the glycine. For example, at $M = 100$, and on the assumption that the glycine is combined with 2 moles of formaldehyde, it is found that 13% of the formaldehyde has been combined. His extrapolation of the straight line for glycine to zero formaldehyde concentration gave a value of 60 for K_2. Our estimation of K_3 from the slope of his straight line gives a value of 520. He reported in his Table II a value of 290 for 0.01 M glycine only.

By using Levy's graphical data for glycine as given in his Fig. 1, we calculated the results given in our Fig. 4. These results are plotted over a range of pH values and formaldehyde concentrations similar to those of his other amino acids. From the graph, K_2 is

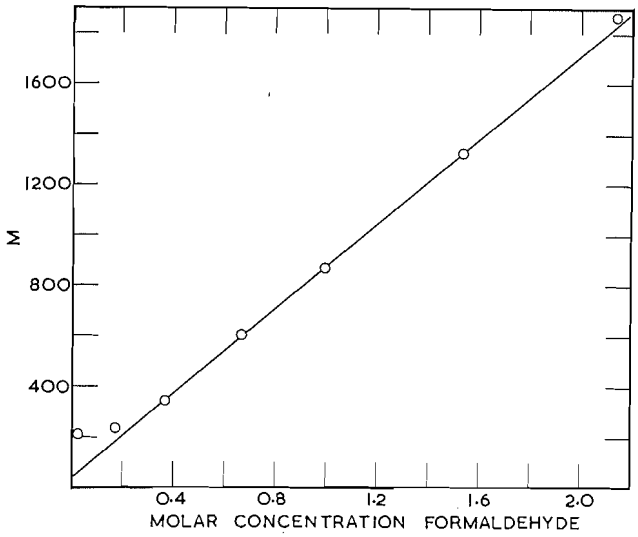


FIG. 4. A graph of calculations made from Levy's results (1) for glycine and formaldehyde. $M = K_2+K_3F$.

found to be 40 instead of 60. It is interesting to note that the points begin to depart from linearity at a formaldehyde concentration below which Levy's approximation is no longer valid. From the slope of the graph, the value of K_3 is found to be 830.

Most of Levy's measurements were made in a region of relatively high formaldehyde concentration; in contrast, the present measurements were made in a region of relatively low formaldehyde concentration. Levy's equilibrium equations can be applied directly to our measurements. In order to obtain K_2, equation [2], apparent values of K_2 were calculated on the assumption that no dimethylol compound was formed (reaction [3] not involved). Apparent K_2 values at various formaldehyde concentrations were calculated at pH 8.30 for a fixed glycine concentration (Table II, A). These were plotted against the total formaldehyde concentration (Fig. 5) and the curve was extrapolated to zero formaldehyde concentration, at which the assumption (no dimethylol compound formed) can be considered valid. The value of $K_2 = 40$ was obtained, which coincides with that obtained by the present calculations from Levy's results. In these calculations of K_2, the value of 9.6 for pK_1 was used.

K_3 was calculated in the following manner: The ratio of b to a is given by the ratio of pK_1 to pH from equation [1]. The total glycine equals $a+b+d+e$. The bound formaldehyde equals $d+2e$. With $K_2 = 40$, one obtains the ratio of b to d. Then one solves for b and e, thus obtaining K_3.

Values of K_3 are included in Tables I and II. K_3 varies from 3,400 to 27,700, in all cases much larger than the values calculated from Levy's data. An analysis of our data showed that when e, the molar concentration of dimethylol compound, was small, K_3 was small, and conversely, when e was large, K_3 was large. Separate calculations on the assumption that $K_2 = 60$ change the values of K_3 by less than 10%.

There are obviously anomalies in the reaction between glycine and formaldehyde. Not

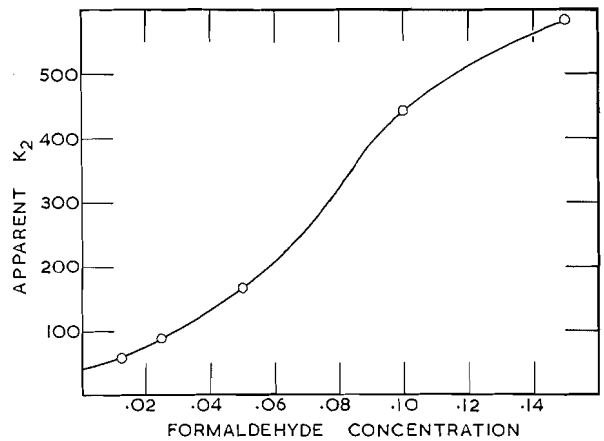

FIG. 5. Apparent K_2 values versus % total formaldehyde concentration for 1% glycine solutions.

only are the calculated values of K_3 variable both for the present results and for those of Levy, but our K_3 values are much larger than those of Levy. It is apparent that the three equations postulated by Levy do not completely describe the reactions between glycine and formaldehyde.

Also, some other experimental results are not accounted for by Levy's equations. For example, the fixed percentage of bound formaldehyde below pH 7.0 is not explained. Hobohm (4) also observed about the same magnitude of binding below pH 7.0.

Moreover, a slow, irreversible binding occurs between formaldehyde and glycine at pH values greater than 7.0. For example, at pH 8.7, 94% of the original formaldehyde remains after 5 days at 31.5° C, as shown by the results of the Nash test on the bulk mixture; after 6 weeks, only 65% can be accounted for by the Nash test. On the other hand at pH 5.65, 94% remains after 2 months.

Levy had reservations concerning the interpretation of his glycine results. He suggested by way of explanation that "there is evidence in this case that the formaldehyde compound is polymerized to a marked extent and the values of the constants are dependent to some extent on the actual glycine concentration" (1). Perhaps one or more of the many possible compounds suggested in the review by French and Edsall (10) is slowly being formed.

HIGH-TEMPERATURE STUDIES OF METALLURGICAL PROCESSES

PART II. THE THERMAL REDUCTION OF CALCINED DOLOMITE WITH SILICON

J. M. Toguri and L. M. Pidgeon
Department of Metallurgy, University of Toronto, Toronto, Ontario

Received May 18, 1962

ABSTRACT

The production of magnesium by the following reaction has been studied:

$$2CaO_{(s)} + 2MgO_{(s)} + Si_{(s)} = 2Mg_{(g)} + Ca_2SiO_{4\,(s)}. \qquad (a)$$

The rate of reaction (*a*) was followed by continuous weight loss measurements of the reactants. Keeping the particle size of the reactants and size and shape of the charge constant, the following factors which affect the yield of magnesium were investigated: (1) temperature, from 1050–1560° C; (2) pressure, from less than 1 μ to 261 mm of Hg; (3) catalysts, CaF_2, BaF_2, and MgF_2; and (4) ferrosilicon grade, from 18.7% to 96.7% Si.

It was found that the yield increased by a factor 1.55 for a 50° increase in temperature over the temperature range investigated. At temperatures below 1300° C the yield falls linearly with increase in pressure, while at temperatures above 1300° C the yield remains relatively constant until the pressure exceeds the equilibrium magnesium pressure. All fluoride additions were found to increase the yield, CaF_2 being the most effective. The rate of the reaction was also found to have a direct relationship with the silicon activity.

INTRODUCTION

The problem of extracting magnesium from its ores has resolved itself into two general methods: (1) electrolysis of fused magnesium chloride and (2) direct thermal reduction of magnesium oxide.

In the direct thermal reduction of magnesium oxide, various reducing agents are available. However, only three have been used commercially: carbon (1–4), calcium carbide (5), and silicon (6–11). Of these three, only the thermal reduction of calcined dolomite with silicon has survived. The overall reaction that occurs in this process can be expressed by the equation

$$2CaO_{(s)} + 2MgO_{(s)} + (Fe)Si_{(s)} = 2Mg_{(g)} + Ca_2SiO_{4(s)} + (Fe)_{(s)}. \qquad [1]$$

This reaction is endothermic, and CaO, the more basic of the two alkaline earth oxides, combines with the silica to form the dibasic silicate. Pidgeon and King (12) have measured the eqilibrium pressure of magnesium over this reaction by means of the entrainment method, obtaining a value of 10.1 mm of Hg at 1100° C, which has been confirmed recently by Rosenqvist and Ellingsaeter (13). This is to be compared with 1.9 mm Hg and 1200° C, obtained by Schneider and Hesse (14), for the reaction pressure of Mg over the system MgO and Si in the absence of CaO. In addition to the higher equilibrium pressure, the presence of CaO makes possible the use of dolomite as a raw material. This mineral is abundant and contains one molecule each of $CaCO_3$ and $MgCO_3$, frequently in a state of high purity.

To effect completion of this reaction, the ambient pressure must be below the equilibrium pressure and this can be accomplished by either a vacuum system or by sweeping out the magnesium by a stream of inert gas.

In one commercial application, this reaction takes place in vacuum (less than 0.1 mm of Hg) at a temperature of 1180° C in a horizontal tubular alloy steel retort (6, 7, 8, 15). Calcined dolomite is intimately mixed with silicon in the form of ferrosilicon. This mixture

is pressed into briquettes, which are then charged into the retort. Since magnesium is the only volatile component in the system, it is distilled from the reaction mixture and condensed as a dense, coherent deposit in the water-cooled end of the retort. The operation is essentially a vacuum distillation, and yields metal of high purity (99.97%). The magnesium crystals produced in this manner are melted and cast into ingots.

While this process has resulted in the production of substantial amounts of magnesium, relatively little has been published on the factors controlling reaction rates, and in fact little is known of the reaction mechanism. There are many variables in the reaction, and only by arbitrarily holding constant a few can the effect of others be examined. This paper describes experiments in which the effect of temperature (1050–1560° C), pressure, and composition of silicon alloys was examined and under conditions in which the reaction mixture was of uniform composition.

EXPERIMENTAL PROCEDURES

The experimental procedure adopted for the determination of the reaction rate has been previously described (16). Briefly, the method consisted of determining the weight loss with time of a briquetted reaction mixture due to the evolution of magnesium, by means of a calibrated helical steel wire spring suspended in a vacuum furnace. Since the particle size of the reactants and size and shape of the briquettes were held constant, the effect of factors such as temperature and pressure could be determined. These standardized experimental conditions permitted a direct comparison of the yields. However, because of the heterogeneous nature of the reaction concerned, the experimental results may not be interpreted in terms of exact kinetic laws.

The composition of the calcined dolomite used in these tests is shown in Table I. The dolomite was commercially calcined.

TABLE I

Analysis of calcined dolomite

Loss on ignition	1.38%
Insoluble	0.48
R_2O_3	0.40
CaO	57.5
MgO	38.8

The ferrosilicon used was 74.1% Si, −200 mesh, unless otherwise stated.

The charge was made up by mixing intimately the fine calcined dolomite with ferrosilicon. Fifteen percent excess of silicon was added to that required by the stoichiometry of equation [1]. All briquettes of the reaction mixture were made in a 1-inch-diameter mold at a pressure of 3000 p.s.i. without a binder. The weight of each briquette was approximately 17 g. Three briquettes were used for each experiment and these were arranged as previously described (16).

Blank runs using only calcined dolomite prepared in the same manner as the reaction mixture showed negligible weight loss when heated over the temperature range 1050–1356° C in the graphite retort. When briquetted calcined dolomite and ferrosilicon mixture were reacted in the graphite retort, weight losses of the retort were observed at temperatures exceeding 1300° C. At 1568° C, the highest temperature used in this investigation, the weight loss of the graphite accounted for 5.85% of the total loss in weight. Below 1300° C, however, the weight loss of the reactants and the weight of magnesium collected was found to be in good agreement within ±2.0%.

A. Effect of Temperature

Typical results are shown in Fig. 1, where percentage yield of Mg, based on the initial weight of MgO, is plotted against time in minutes. In Fig. 2, the results are summarized by plotting percentage yield after 10 minutes against temperature.

B. Effect of Pressure

The main function of vacuum in this process is to displace the equilibrium in such a way that the metal may be distilled or sublimed from the reaction mixture. A secondary function is to permit the formation of a dense solid condensate (17).

Figure 3 shows the result of the effect of pressure on the yield at various temperatures. At the lower temperatures, an increase of pressure has a marked effect on the yield, the yield appearing as a linear function

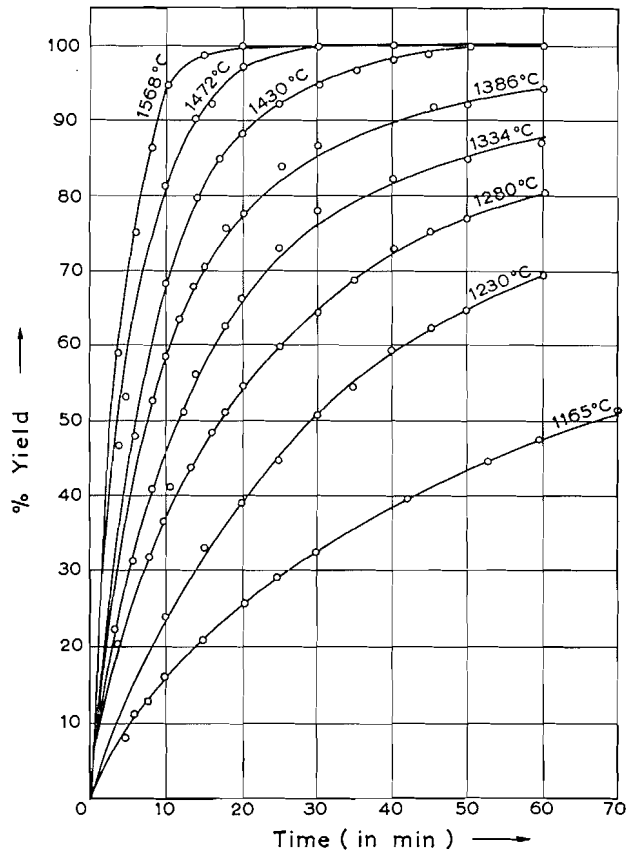

FIG. 1. Reaction rates for calcined dolomite and FeSi (74.1% Si).

of pressure. However, at the higher temperature, 1370° C, an increase in the pressure has much less effect on the yield until the equilibrium pressure (209 mm of Hg, calculated from an extrapolation of Pidgeon and King's measurement (12)) is reached, at which point the yield falls off rapidly.

The beneficial effect of high temperature is quite apparent from this curve. However, as expected, the physical nature of the condensate was found to be affected by the pressure. The results obtained were similar to those reported by Betcherman and Pidgeon (17). Under high-vacuum conditions, a very dense condensate is obtained regardless of the temperature of the reactor, but as soon as the pressure is increased, numerous loosely compacted dendrites are formed. Further increase in pressure caused a lacy network of innumerable fragile dendrites to appear. With a combination of high temperature (1370° C) and increased argon pressures, the condensate appeared to collect in a partly liquid state.

C. Effect of Ferrosilicon Grade

While theoretical considerations favor the use of 100% Si as a reducing agent, its cost is prohibitive in most cases and ferrosilicon is preferred. An examination of the iron–silicon phase diagram shows that in the region 60–100% silicon no solid solubility exists and solid alloys in this range consist of a mixture of free silicon and ferrosilicon alloy.

A range of alloys has been examined between 18.7% and 96.7% Si, as shown in Fig. 4, to ascertain the effect of ferrosilicon grade on the reaction rate at 1228° C. The weight percentages of free silicon, as calculated from the phase diagram, are shown in Table II. In Fig. 5, the initial rate constants are plotted against the mole fraction of silicon. The similarity of the plot with the activity curve of FeSi, as determined by Rosenqvist and Ellingsaeter (13), at 1200° C, is evident. It appears that the initial rate constant is a direct function of the activity of silicon. The decrease of the rate in the case of the 90% and 74.1% alloys after 15 minutes of reaction is to be attributed to the decrease in availability of silicon. While the decrease in the 46.7% and 18.7% alloys can be attributed to the activity of Si and to the formation of a liquid phase at 1128° C, which tends to agglomerate and decrease the effective reaction surface. Evidence that the liquid particles

coalesce was afforded by the existence in the residue of ferrosilicon balls of about 1.5-mm diameters. The initial size of the ferrosilicon was −200 mesh.

D. Effect of Catalyst

Alkali and alkaline earth fluorides are known to accelerate solid-state reactions in oxide systems. CaF_2 is commonly used as a catalyst in the calcined dolomite – ferrosilicon reaction (7, 18). In this investigation, the effects of CaF_2, BaF_2, and MgF_2 were studied. The amount of fluoride added in all cases was 2.5% of the charge. The results are summarized in Fig. 2, where the percentage yield after 10 minutes is plotted against temperature. CaF_2 is the most effective, while MgF_2 and BaF_2 appear to have approximately the same catalytic effect.

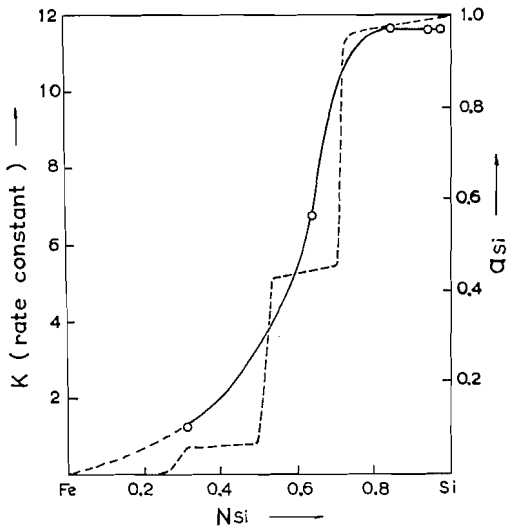

FIG. 5. Initial rate constant vs. N_{Si} at 1228° C. Solid line shows the initial rate constant while the broken line shows the activity of Si in FeSi as measured by Rosenqvist and Ellingsaeter (13).

E. Effect of Temperature on Purity of Magnesium Condensate

Magnesium was produced at temperatures between 1165° C and 1588° C. Magnesium crystals representative of the bulk of the condensate at any temperature were analyzed, with results shown in Table III.

TABLE III

Effect of temperature on purity

Temp.	Ca	Al	Ni	Cu	Mn	Zn	Pb	Sn	Si	Fe

NOTE: Analyses by spectrographic method—courtesy of Dominion Magnesium Ltd.

No effect of temperature is detectable. The metal produced from the dolomite used in these experiments is known to be of high purity (7) and the independence of temperature suggests that such impurities as appear are either absent in the original raw materials, completely distilled at all temperatures (impossible conclusions for Ca, Al, Si, and Fe), or are not a part of the distillation process as such (a few "high" values suggest salting).

DISCUSSION

It has been shown that small samples of calcined dolomite are reduced by silicon at extremely rapid rates at high temperatures. Between 1200 and 1500° C the increase in yield with temperature is approximately linear and involves a factor of 1.55 per 50° C. The presence of small amounts of certain catalysts (2.5% of the charge) was found to increase the rate. For example, at 1200° C, calcium fluoride increased the percentage

yield after 10 minutes from 21.5% to 27.0%. This effect was even more noticeable at 1400° C, where the corresponding values are 62.5% and 87.0%. In the presence of alkaline earth halides the residue showed a glassy appearance under the microscope, regardless of the temperature of the reaction. This suggests the formation of a liquid phase which may account for the catalytic effect (19). In finely divided reactants, the formation of a liquid phase may decrease the effective reaction surface and thus decreases the rate of reaction; however, it also creates a faster diffusion media and thereby increases the reaction rate. The phase diagram of the system CaF_2–$CaO.SiO_2$ shows a low-melting eutectic at 1125° C (20). It may be possible that, as small amounts of silicates appear, they form a eutectic with neighboring CaF_2, thus explaining the glassy appearance of the residue. Another possible explanation for the catalytic effect is that the fluorine anions tend to surround the highly charged silicon cations and thereby increase the silicon diffusion rate.

These factors seem insufficient to account for the rapid reaction rates which are observed, and it is natural to suggest that other gaseous or liquid intermediaries are present.

The vapor pressure of silicon seems too low to account for the rates measured. At 1370° C, the vapor pressure of silicon is approximately 3×10^{-3} mm Hg; yet the silicon was almost half reacted in 8 minutes at this temperature. A plausible gaseous intermediary is SiO. SiO gas is stable at these temperatures according to a number of investigators (23, 24). In a previous publication (16), it was shown that SiO is distilled from the reaction mixture of MgO + Si at temperatures above 1300° C. In the present work, where CaO was present, no SiO was distilled, even at 1565° C. Thus, if SiO is formed at all, it must be assumed that the presence of the basic CaO prevented loss of SiO from the system. (In the calculations shown, the thermodynamic values recommended by Kubaschewski and Evans (25) have been used.)

If the following reaction takes place:

$$MgO + Si = Mg_{(g)} + SiO_{(g)} \qquad [2]$$

$$P_{SiO} \text{ at } 1550° \text{ K} = 3.26\times10^{-1} \text{ mm Hg},$$

it may be followed by reaction [3]:

$$2SiO + 2CaO = Ca_2SiO_4 + Si \qquad [3]$$

$$\Delta G^0_{1550° \text{ K}} = -35.2 \text{ kcal/mole CaO}.$$

The calculated P_{SiO} over [3] at 1550° K is 8.24×10^{-3} mm Hg. This is too low to produce appreciable distillation, and reaction [3] should take place since P_{SiO} for reaction [2] is greater than P_{SiO} for reaction [3] (different from the case of MgO alone). Reaction [3] also offers a mechanism for depositing free silicon throughout the reaction system, acting as nuclei for further reaction.

Schneider *et al.* (21) have suggested that the primary reaction is the formation of calcium silicide by reaction between CaO and Si. At the temperature concerned, this silicide would be in the liquid state. Similarly, Kroll (22) has suggested the formation of calcium–magnesium silicides. X-Ray analysis of residues was carried out in this investigation at various stages of the reaction. No positive identification of either calcium or magnesium silicide was found in the diffractograms. It is possible that the large number of lines from the calcium orthosilicate had concealed those of the silicide; also, under the

condition of rapid reaction which existed the calcium silicide reacted as rapidly as it was formed. Current work indicates that calcium silicide is a likely intermediate in this reaction.

ACKNOWLEDGMENTS

Financial support in the form of a fellowship (to J. M. T.) from the Steel Company of Canada is gratefully acknowledged. The authors are also indebted to Dominion Magnesium Limited for supplying the dolomite and ferrosilicon used throughout this investigation.

THE PROTON RESONANCE SPECTRA AND STRUCTURES OF SUBSTITUTED AZULENES IN TRIFLUOROACETIC ACID[1]

S. S. DANYLUK[2] AND W. G. SCHNEIDER
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received March 28, 1962

ABSTRACT

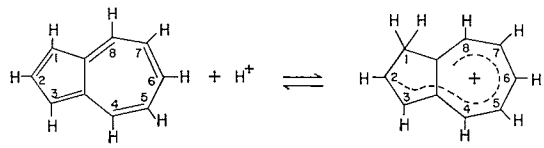
The proton resonance spectra for a number of substituted azulenes and their conjugate acids are reported at 22° C. From the spectra for the conjugate acids it is confirmed that monoprotonation occurs in the five-membered ring in each case. The unit electron deficiency is shown to be mainly localized in the seven-membered ring of the ion.

Chemical shift changes on protonation are interpreted qualitatively in terms of changes in local π electron charge densities on the carbon atoms.

Unusually large values are noted for the coupling constants between protons on the five-membered ring of the cations and are attributed in part to hyperconjugative effects.

INTRODUCTION

Aromatic hydrocarbons, both alternant and non-alternant, dissolve readily in strong protonic acids with formation of their conjugate acids. Proton addition is generally favored at the carbon atom with the greatest excess electron charge density. For example, molecular orbital calculations (1, 2) indicate the highest π electron density in positions 1 and 3 for the non-alternant hydrocarbon azulene, I. Protonation would therefore be favored as follows:



(I) (II)

with the formation of a methylenic carbon at position 1 and a delocalization of the unit charge deficiency in the five- and seven-membered rings. The proton resonance spectrum for the azulenium cation in trifluoroacetic acid, reported previously (3), strongly supports structure II for the conjugate acid.

In an earlier work Mclean *et al.* (4) confirmed from proton resonance spectra that proton addition occurs almost entirely in the 9 position when 9,10-dimethyl-1,2-benzanthracene is dissolved in CF_3COOH–$H_2O \cdot BF_3$ mixtures. Proton resonance spectra are therefore capable of providing useful information about the structures and charge distribution in the conjugate acids of aromatic hydrocarbons. In this paper proton resonance spectra are reported for several substituted azulenes in strongly acid media and the structures of the conjugate acids are confirmed. The possibility of monopositive ion–radical formation in oxygenated solutions has also been investigated and some preliminary observations on the effects of dissolved oxygen are also included.

[2]*National Research Council Postdoctorate Fellow 1958–1960. Present address: Department of Chemistry, University of Toronto, Toronto, Ontario.*

EXPERIMENTAL

The proton resonance spectra were measured at 22±0.5° C with a Varian 4300 high-resolution spectrometer equipped with a superstabilizer and operating at 60 Mc/s. Signal separations from the reference, CH_2Cl_2, were measured by the side-band technique and are accurate to ±0.2 c.p.s. Closely spaced multiplets were bracketed with side bands as the spectrum was recorded.

Reagent grade trifluoroacetic acid was redistilled through a fractionating column and the middle portion retained for use. Commercial, high-purity azulene, 4,6,8-trimethylazulene, and guaiazulene were used without further purification.

Solutions, approximately 7 mole% in the hydrocarbon, were prepared under a nitrogen atmosphere and were sealed in 5-mm spinning tubes. Spectra were recorded immediately after preparation of the solutions. A slow, irreversible reaction was noted recently by Lauterbur (5) for solutions of azulene in trifluoroacetic acid. In the present investigation the spectra of oxygen-free acid solutions of the cations did not alter appreciably over a period of several days.

All measurements were referred to methylene chloride as internal standard. The methylene chloride signal, measured relative to internal tetramethylsilane, was shifted only very slightly (less than 5 c.p.s.) on dilution from pure methylene chloride to a 10 mole% solution in trifluoroacetic acid.

The electron spin resonance spectra were recorded with a Varian 4500 spectrometer equipped with a 100 kc field modulation unit. Solutions were prepared as described previously and oxygen was bubbled directly into the samples prior to measurements. The "g" value was measured relative to diphenyl picryl hydrazyl (D.P.P.H.) radical as reference.

RESULTS

Azulene and Azulenium Cation

The proton resonance spectra for azulene and the azulenium cation are shown in Fig. 1. The five-membered-ring protons of azulene show a characteristic AB_2 spectrum

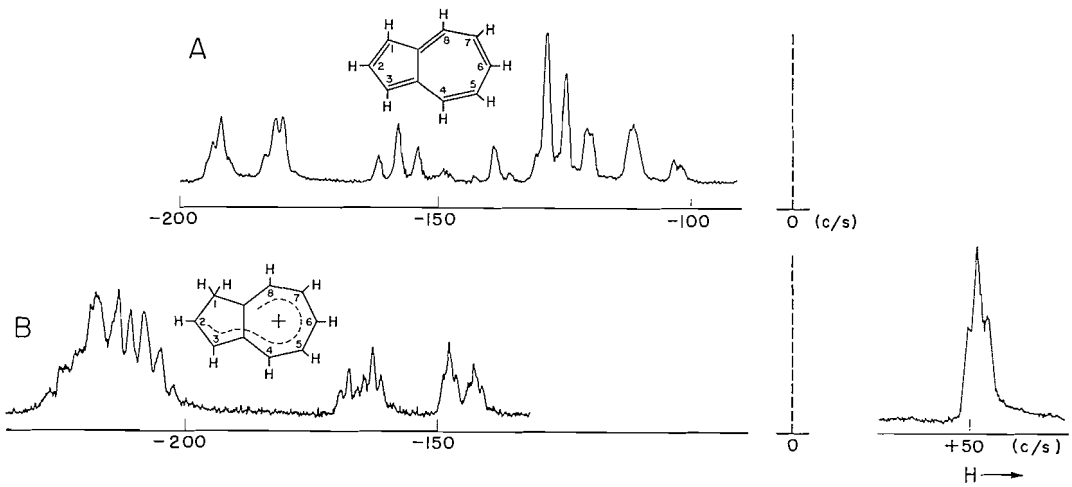

FIG. 1. Proton magnetic resonance spectra. A. 7 mole% solution of azulene in CH_2Cl_2. B. 7 mole% solution of azulene in CF_3COOH. CH_2Cl_2, internal reference.

and analysis gives a value of 3.9±0.2 c.p.s. for the coupling constant J_{12} (J_{23}) and 0.486±0.005 p.p.m. for the relative chemical shifts. A detailed analysis of the seven-membered-ring proton signals was not attempted, although it is of interest to note the displacement of proton 2 from the center of the signal for proton 4 (8), i.e.,

$$\delta_2 - \delta_4 = 0.448 \pm 0.005 \text{ p.p.m.}$$

Figure 1B reproduces the azulenium ion spectrum under somewhat higher resolution than previously reported (3). A typical ABX_2 type of spectrum is observed for the five-membered-ring protons and a first-order analysis of the splitting for the methylene signal

at 51.8 c.p.s. gives coupling constants of 1.8±0.2 c.p.s. and 1.3±0.2 c.p.s. for $J_{11',2}$ and $J_{11',3}$ respectively.[3] Analysis of the AB portion of the spectrum centered at −155.7 c.p.s. gives a value of 0.372 p.p.m. for the relative chemical shift between protons 2 and 3 and 5.5±0.2 c.p.s. for J_{23}. A further splitting of the AB spectrum into triplets (relative intensity, 1:2:1) is due to spin coupling with the methylene protons. The slightly larger splitting, 1.8±0.2 c.p.s., is attributed to interactions with proton 2, while the smaller splitting, 1.3±0.2 c.p.s., involves coupling with proton 3.

The broad unresolved bands at low field, −208 c.p.s. to −240 c.p.s., are assigned to the five non-equivalent protons on the seven-membered ring.

4,6,8-Trimethylazulene and Trimethylazulenium Cation

Figure 2 shows the proton resonance spectra for 4,6,8-trimethylazulene and its conjugate acid. Analysis of the AB_2 spectrum for the five-membered-ring protons in trimethylazulene gives a relative chemical shift of 0.300±0.005 p.p.m. and spin–spin coupling constant of 3.9±0.1 c.p.s. The resonance band at −110.3±0.3 c.p.s. is assigned to the protons in the 5 and 7 positions while the bands at 141.0±0.2 c.p.s. and 156.8±0.2 c.p.s. are assigned to the methyl groups in the 4 and 8 positions and the 6 position respectively.

The spectrum for the trimethylazulenium ion shows a band at 66.5 c.p.s. corresponding to the methylene protons in position 1 (or 3). A quadruplet, Fig. 2C, centered at −145.0 c.p.s. is due to non-equivalent protons in the 2 and 3 positions with a relative chemical shift of 0.181±0.005 p.p.m. and coupling constant, J_{23}, of 5.7±0.2 c.p.s. Spin coupling with the methylene protons further splits the components of the quadruplet into triplets with $J_{11',2} = 1.6\pm0.1$ c.p.s. and $J_{11',3} = 1.1\pm0.1$ c.p.s.

The broad bands at −192.5 c.p.s. and −199.8 c.p.s. are due to the two non-equivalent protons (5, 7) in the seven-membered ring while the three non-equivalent methyl groups account for the bands at 130.0, 132.1, and 134.8 c.p.s.

Guaiazulene and Guaiazulenium Ion

Proton resonance spectra for guaiazulene and its conjugate acid are shown in Fig. 3. An assignment and analysis of the proton spectrum for pure guaiazulene has been reported previously (7). Analysis of the spectrum for a 7 mole% solution in methylene chloride gives the following values:

$$(\delta_1-\delta_2) = 0.433\pm0.005 \text{ p.p.m.}$$
$$J_{12} = 3.8\pm0.2 \text{ c.p.s.}$$
$$(\delta_7-\delta_6) = 0.406\pm0.005 \text{ p.p.m.}$$
$$J_{76} = 11.0\pm0.2 \text{ c.p.s.} \qquad J_{46} = 2.0\pm0.2 \text{ c.p.s.}$$

An appreciable increase in magnitude of the relative chemical shifts is noted for both sets of protons (1,2 and 6,7) in the dilute solution as compared with pure guaiazulene. Furthermore the separation between the five-membered-ring and seven-membered-ring protons increases with dilution. Thus the separation between the midpoints of protons 1 and 2, and 4, increases from 0.753 p.p.m. for pure guaiazulene to 0.847 p.p.m. in a 7 mole% solution in methylene chloride.

Assignment of the remaining bands is straightforward with the septet (129 c.p.s.) and doublet (227, 236 c.p.s.) due to the isopropyl group and the two bands at 146.2 and 150 c.p.s. arising from the two non-equivalent methyl groups. The displacement of proton 2 relative to proton 4, 0.61 p.p.m., is significantly greater in guaiazulene as compared

[3]*The methylene protons on the protonated azulene have been labelled as 1,1'.*

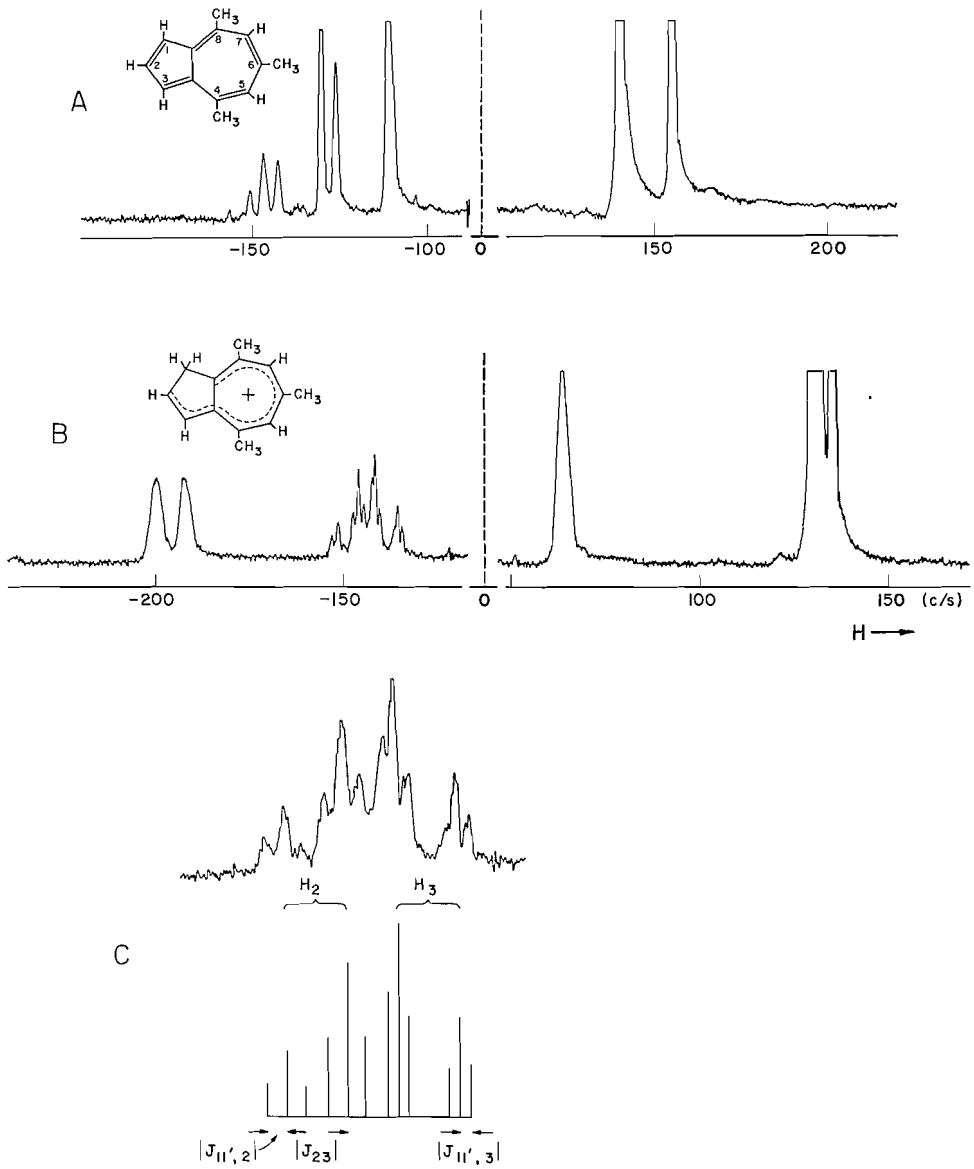

FIG. 2. Proton magnetic resonance spectra. A. 7 mole% solution of 4,6,8-trimethylazulene in CH_2Cl_2. B. 7 mole% solution of 4,6,8-trimethylazulene in CF_3COOH. C. Quartet centered at −118.7 c.p.s. CH_2Cl_2, internal reference.

with azulene. Since the azulene and guaiazulene solutions were relatively dilute (7 mole%) the larger $(\delta_2-\delta_4)$ value in the latter cannot be attributed to solvent effects solely but may reflect small changes in electron distribution brought about by the substituent alkyl groups.

Several distinct features are apparent in the spectrum of the guaiazulenium ion shown in Fig. 3B. The methylene protons in position 1 appear as a symmetric quintet, Fig. 3C (relative intensity 1:4:6:4:1), at 75.5 c.p.s. In order to account for the latter the spins of the methylene protons must interact equivalently with the proton in the 2 position and

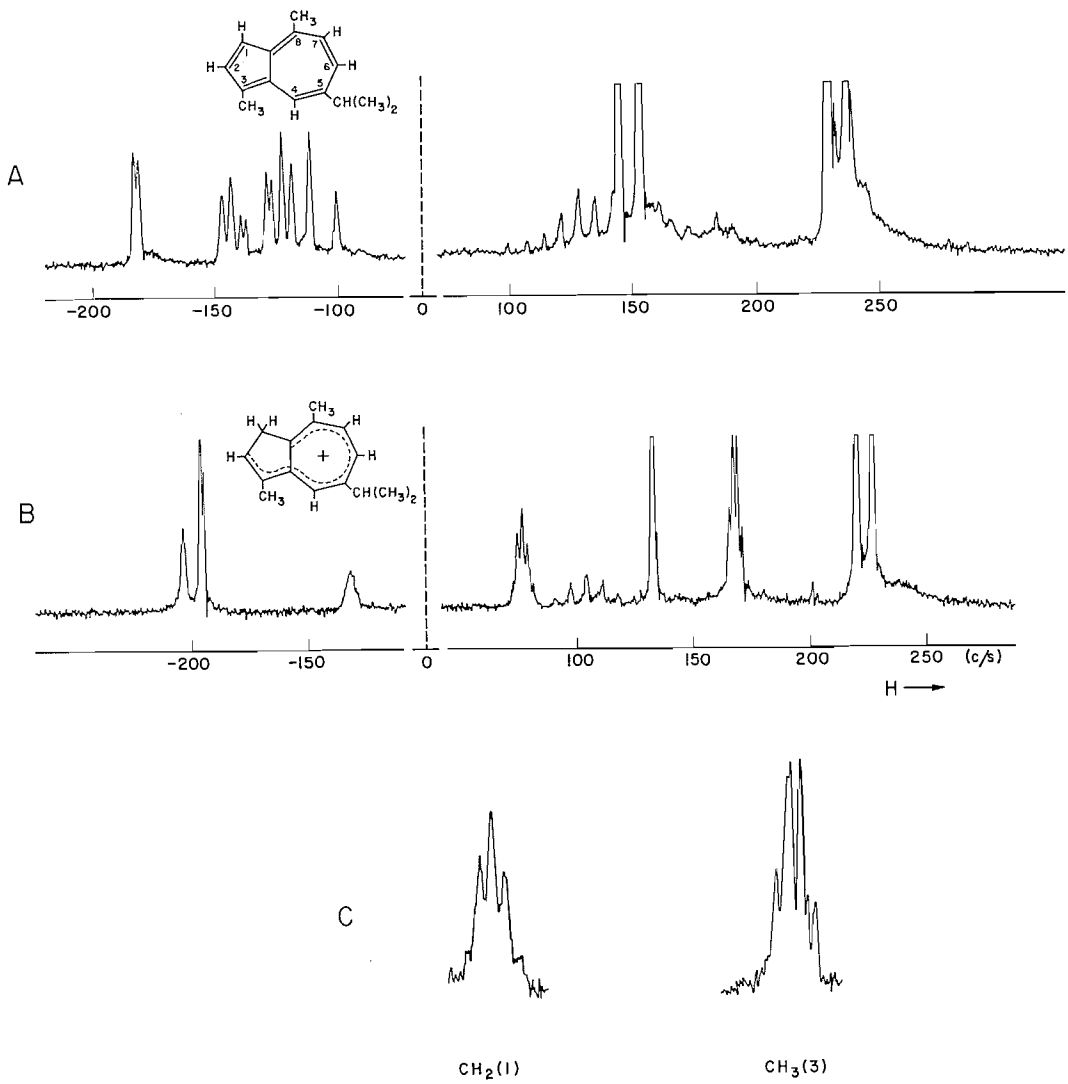

FIG. 3. Proton magnetic resonance spectra. A. 7 mole% solution of guaiazulene in CH_2Cl_2. B. 7 mole% solution of guaiazulene in CF_3COOH. C. Methylene protons in position 1 and methyl group in position 3 of guaiazulenium. CH_2Cl_2, internal reference.

the methyl protons attached to the 3 position, the coupling constant having a value of 2.0 ± 0.2 c.p.s. On this basis the quadruplet at 166.0 c.p.s. is assigned to the methyl group at position 3. Although long-range spin–spin coupling has been noted previously (8, 9), the magnitude of the spin interaction extending over five bonds in the guaiazulenium ion is unusually large.

An assignment of the bands at low field can be made from a comparison of relative intensities. Thus the broad unresolved multiplet at -133.5 c.p.s. is attributed to proton 2 while the bands at -197.6 and -204.0 c.p.s. arise from protons in positions 6 and 7 and 4 respectively. Both the methyl and isopropyl group on the seven-membered ring in the ion are shifted downfield slightly.

The addition of oxygen to 7 mole% solutions of azulene and guaiazulene in trifluoroacetic acid produced in both cases significant changes in the proton resonance spectra and led to the appearance of an electron spin resonance band. A noticeable broadening of the proton resonance lines associated with the cations occurred in the oxygenated solutions. In addition the electron spin resonance spectra show a single band with a half-band width of 5 ± 0.5 gauss and a "g" value of 2.0031. No evidence of hyperfine splitting is apparent under the present conditions.[4] The intensity of the e.s.r. band increases rapidly with time for freshly prepared solutions until equilibrium is attained, generally within 24 hours. An increase in the concentration of oxygen also increases the intensity of the e.s.r. signal, while a degassing of equilibrated solutions leads to a disappearance of the signal.

DISCUSSION

The values of the coupling constants J_{12} are identical for the three azulenes and in agreement with previous results (7, 10). No change in the coupling constants is noted when alkyl groups are present on the five- or seven-membered rings.

Comparison of the relative chemical shifts for the dilute solutions shows that the values of $(\delta_1-\delta_2)$ for guaiazulene, 0.433 p.p.m., and trimethylazulene, 0.300 p.p.m., are appreciably lower than for azulene, 0.486 p.p.m. This decrease is attributable primarily to changes in the local π electron charge densities on the carbon atoms induced by alkyl substituents. It has been demonstrated previously (10) that ring currents alone do not account for the shifts satisfactorily in azulene.

Both the trimethylazulene and guaiazulene show anomalous dilution shifts, the former being of slightly smaller magnitude than the dilution shift observed for azulene. For guaiazulene the anomalous shift leads to an increase of 0.094 p.p.m. in the separation between the protons in the five- and seven-membered rings.

The proton resonance spectra for the three ions show that monoprotonation takes place in the five-membered ring with formation of a characteristic methylene group in each case. Further proton addition does not occur under the present experimental conditions. Recent conductivity measurements by Long and Schulze (11) on acid solutions of azulene confirm monoprotonation in this system.

Protonation of the azulenes brings about pronounced changes in the chemical shifts and coupling constants, as is apparent from the proton resonance spectra. From Table I it is evident that protons in the seven-membered ring are shifted as much as 1.50 p.p.m. to low field in the ions.

Two effects might be expected to contribute to the chemical shift changes.

(1) Any alteration in the aromatic ring currents would result in a shift of the proton signals. In the azulenium ions the formation of a CH_2 group will alter the ring currents in the five-membered ring considerably. Information about ring currents in analogous rings, such as cyclopentadiene, is lacking and the effect on chemical shifts is uncertain. If it is assumed, however, that the ring current is hindered completely in the protonated ring, then relatively large changes in chemical shifts, amounting to 1.66 p.p.m., would be expected for protons in the 2 and 3 positions. Protons in the seven-membered ring would be shifted much less due to ring current change since the introduction of an excess charge into a ring does not affect the ring currents appreciably. In the tropylium ion, for example, the shift due to ring current changes amounts to 0.41 p.p.m. per unit electron deficiency

[4]*No e.s.r. absorption was noted for the original oxygen-free solutions. Furthermore, addition of oxygen to solutions of azulenes in methylene chloride and to pure trifluoroacetic acid does not affect the proton resonance spectra nor do these solutions show any e.s.r. band.*

TABLE I

Chemical shifts for ring protons in protonated and unprotonated azulenes

Compound		$\delta_{CH_2Cl_2}$*	δ_{acid}†
Azulene	5-membered (1,3)	−2.13	(3) −2.40
	(2)	−2.62	(2) −2.77

*Chemical shifts are given in p.p.m. relative to CH_2Cl_2 as internal standard, with CH_2Cl_2 as the solvent.
†Chemical shifts in trifluoroacetic acid in p.p.m. relative to CH_2Cl_2 as internal standard.
‡Estimated.

(12). Since the unit electron deficiency is distributed between the two rings in the azulenium ion its effect on the seven-membered-ring currents is difficult to estimate. The effect would be less than 0.41 p.p.m., however, and assuming that an electron deficiency of 0.60 electron is localized on the seven-membered ring the shift change would amount to 0.25 p.p.m. to low field. The contributions of neighbor-ring currents to the chemical shifts range from 0.12 to 0.65 p.p.m., with protons in the 3 and 4 positions affected more than protons in the other positions.

(2) A second effect contributing to chemical shifts results from differences in local π electron charge densities. In particular, introduction of a positive charge into a ring generally produces shifts of the ring protons to lower fields (12–14). Surprisingly large shifts were noted by Fraenkel *et al.* (12) when a unit electron deficiency was present in aromatic rings ($C_7H_7^+$). In the present case the large decrease in screening and the near equivalence of the seven-membered-ring protons in the ions indicate a significant localization of the electron deficiency in the seven-membered ring. This suggests a configuration analogous to the tropylium ion and it is of interest to note that signals of the seven-membered-ring protons are in the same region as proton signals of the tropylium ion, −3.10 p.p.m. (12) relative to methylene chloride.

An estimate of the effect of protonation on the chemical shifts of ring hydrogens has been made recently (15) for a number of alternant aromatic carbonium ions on the assumption that ring currents and excess charges are the only significant factors affecting the shift. In each case the unit electron deficiency was found to be distributed fairly uniformly in the ion.

A similar uniform distribution of positive charge is noted in the azulenium ion. The π electron densities, ρ, for azulene and the azulenium ion have been calculated using the calibration equation $\delta = 10.6\rho$ (16) and the results are summarized in Table II and Fig. 4. Corrections due to the neighbor-ring current have been applied to the protons in the five- and seven-membered rings of azulene. The charge densities for azulene agree with the values reported earlier (16). In the case of the azulenium ion an estimate has been made of charge densities in the seven-membered ring, assuming the absence of a neighbor-ring current in the five-membered ring. A deficiency of approximately 0.7 electron charge is localized in the seven-membered ring and is distributed uniformly around the ring. The

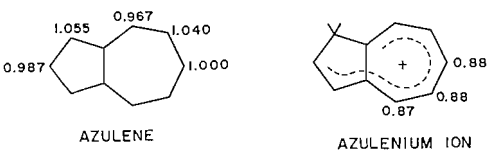

FIG. 4. Charge densities in azulene and the azulenium ion.

charge densities in the five-membered ring cannot be determined satisfactorily because of the uncertainty in the magnitude of the ring current and the change in hybridization at the carbon atom in the 1 position. However, a comparison of the chemical shifts for the five-membered-ring protons in the ion, Table II, with the chemical shift for the olefinic protons in cyclopentadiene, +0.84 p.p.m. relative to benzene, indicates a significant decrease in screening in the ion.

The magnitudes of the spin–spin coupling constants between protons in the five-membered rings are of considerable interest. Long-range proton spin–spin coupling extending over three and four bonds for both saturated and unsaturated hydrocarbons have been reported previously (9, 10, 18, 19). Values for these long-range coupling constants are generally less than 1 c.p.s. and decrease as the number of intervening bonds increases. Interactions between protons separated by five bonds have been reported recently (8). Fraser observed coupling constants of 1.46 c.p.s. and 1.17 c.p.s. between the protons of the methyl groups in angelic and tiglic acids respectively. In the present work, $J_{11',3}$ extending over four bonds has values of 1.3 and 1.1 c.p.s. for the azulenium and trimethylazulenium ions. A surprisingly large coupling constant, 2.0 c.p.s., extending over five bonds is noted between the methylene protons in the 1 position and the methyl group in the 3 position for the guaiazulenium ion. Long-range spin–spin interactions have been interpreted theoretically (17) in terms of a delocalization of electrons in the C—H bond and it is probable that this effect accounts at least qualitatively for the magnitude of the coupling constants observed in the five-membered ring of the ion. The magnitude

of J_{11',CH_3} in guaiazulenium suggests, in addition, the likelihood of a significant contribution to the delocalization of electrons due to hyperconjugation (1). Similar effects have been noted previously for substituted allenes (18), thiophenes (19), and mesitylene (20).

The electron paramagnetic resonance of oxygenated acid solutions of the azulenes can be accounted for by the additional formation of monopositive ions of the hydrocarbons along with the protonated ions. The formation of monopositive ions has been noted previously for solutions of perylene (21, 22), anthracene (22, 23), and other polycyclic aromatic compounds (23) in strongly acidic and oxidizing media. Although the mechanism is not clear it is likely that the paramagnetic monopositive ion $C_{10}H_8^+$ (as distinct from the protonated species $C_{10}H_9^+$) is formed by transfer of an electron from the azulene to the oxygen molecule, acting as an electron acceptor, to form the O_2^- ion. The width of the e.s.r. absorption band and the lack of hyperfine splitting indicate a rapid exchange reaction between the monopositive ion and the free hydrocarbon.

ABSTRACT

The kinetics of protein–dye and antibody–hapten reactions were studied with the temperature-jump method. The systems used consisted of (i) bovine serum albumin (BSA) and the dye 1-naphthol-4-[4-(4′-azobenzene azo)phenyl arsonic acid], referred to as N—R′, (ii) BSA and the dye 1-naphthol-2-sulphonic acid-4-[4-(4′-azobenzene azo)phenyl arsonic acid], referred to as NS—R′, and (iii) rabbit antibodies to phenyl arsonic acid [Ab] and the hapten N—R′.

Each of the systems exhibited a single relaxation time. From the analysis of the concentration dependence of the relaxation times, it was concluded that each system could be represented by the reactions

$$P + D \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} PD,$$

where P refers to BSA or Ab, and D to N—R′ or NS—R′. The following rate constants were calculated for the three systems at 25° C:

(i) BSA – N—R′ : $k_{12} = 2.1\times10^6\ M^{-1}\text{sec}^{-1}$; $k_{21} = 35\ \text{sec}^{-1}$
(ii) BSA – NS—R′ : $k_{12} = 3.6\times10^5\ M^{-1}\text{sec}^{-1}$; $k_{21} = 2.5\ \text{sec}^{-1}$
(iii) Ab – N—R′ : $k_{12} = 2\times10^7\ M^{-1}\text{sec}^{-1}$; $k_{21} = 50\ \text{sec}^{-1}$.

The effects of temperature and pH on the rate constants of the system BSA – N—R′ are discussed.

INTRODUCTION

In most biological reactions, such as in enzyme–substrate, antibody–antigen, or antibody–hapten reactions, at least one of the reactants is a macromolecule. Antibody–hapten systems are particularly suitable for the elucidation of the nature of the forces which are responsible for the specificity of these reactions, their main advantage being that antibodies to a variety of chemically well-defined substances can be produced. From equilibrium studies it has been shown that the free energy change for many antibody–hapten associations is of the order of -7 to -12 kcal/mole (1, 2). This means that even at high dilutions the extent of association is still appreciable.

Information about the mechanisms of chemical reactions can be obtained from kinetic studies. However, in the case of antibody–antigen and antibody–hapten associations only very few such studies have been performed so far. For some systems, containing polyvalent antigens and divalent antibodies (3–5), the rates were followed by measure-

ments of the light scattered as a function of time. Such systems involve complex, overall reactions leading to the formation of aggregates of different size. Therefore, it is conceivable that the initial reaction between the specific combining sites was obscured by re-equilibration steps resulting in some statistical redistribution of these aggregates with respect to their size. In other instances, such as the kinetic studies of the inhibition of luciferase (6) and the neutralization of bacteriophage (7) by the corresponding antibodies, rates of combination between antigen and antibody molecules were not measured directly. Only Berson and Yallow (8) have actually determined rate constants from the direct measurements of the rates of association between insulin and the corresponding antibodies; I^{131}-labelled insulin in concentrations as low as 10^{-9} M was used for this purpose and the values reported for the rate constants ranged from 10^4 to 10^6 $M^{-1}\text{sec}^{-1}$ (8).

Only two studies of the kinetics of antibody–hapten reactions have been reported so far. Schneider and Sehon (9) attempted to study the kinetics of the reaction between the reducible hapten 4-(4′-aminophenylazo)phenyl arsonic acid and its homologous antibody with the aid of cathode-ray polarography. They reported that the reaction had gone to completion within the time of mixing, which was estimated to be 1–2 seconds. Although rate measurements could not be made directly, lower limiting values of 10^6 $M^{-1}\text{sec}^{-1}$ and 1 sec^{-1} were calculated for the rate constants k_{12} and k_{21}, respectively, for the reaction

$$\text{Ab} + \text{H} \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} \text{AbH}. \qquad [1]$$

While the present investigation was in progress, Sturtevant *et al.* (10) studied the association between a dinitrobenzene derivative and its homologous antibodies using a stopped flow technique. These authors have shown that about two thirds of the reaction had gone to completion within the dead time of their instrument. Nevertheless, they were able to compute a rate constant of 10^6 $M^{-1}\text{sec}^{-1}$ for k_{12} for the slower region of the reaction, and suggested a value as high as 10^8 $M^{-1}\text{sec}^{-1}$ for the faster portion of the reaction.

In the present paper, studies of the kinetics of antibody–hapten interactions by means of the temperature-jump method are reported. This technique is generally applicable to rapid reactions involving a change in enthalpy and which occur within the range of 1 microsecond to 1 second. The reaction system is perturbed by a sudden jump in temperature (of about 10° C), which is achieved within 0.1–1 microsecond by discharging a condensor through a conducting solution containing the system to be studied. The rate of readjustment of the system to the new equilibrium conditions at the higher temperature is then determined by following the change in an appropriate physical parameter, which represents the concentration of one of the reactants. Provided the deviations from equilibrium are small, for a one-step reaction the linearized rate equation can be expressed as

$$\tau \frac{d(\Delta C)}{dt} + \Delta C = \Delta \bar{C}(t),$$

where $\Delta \bar{C}(t)$ is the change in equilibrium concentration of a given reactant, ΔC the concentration change from the original equilibrium value at any time t, and τ is the relaxation time (11). With the help of appropriate relations which are characteristic for a given reaction mechanism, τ yields the rate constants determining the new equilibrium. Thus, for a reaction of the type represented by equation [1] the relaxation time is expressed by

$$\frac{1}{\tau} = k_{21}+k_{12}[(\overline{\mathrm{Ab}})+(\overline{\mathrm{H}})],$$

where $(\overline{\mathrm{Ab}})$ and $(\overline{\mathrm{H}})$ represent equilibrium concentrations of the antibody and hapten, respectively.

In view of the scarcity of specific antibodies, the applicability of this relaxation technique to the present investigation was first established with a model system consisting of bovine serum albumin (BSA) and the two colored hapten molecules 1-naphthol-4-[4-(4′-azobenzene azo)phenyl arsonic acid] and 1-naphthol-2 sulphonic acid -4-[4-(4′azobenzene azo)phenyl arsonic acid. This system was chosen as a model since the results of equilibrium measurements for BSA–dye interactions are similar to those of antibody–hapten reactions (12, 13).

EXPERIMENTAL

Materials

Crystalline bovine serum albumin (BSA) was obtained from Armour Pharmaceutical Co., Kankakee, Ill. The molecular weight of BSA used for various calculations was taken as 69,000 (14).

Antibodies to the phenyl arsonate group were prepared by immunizing rabbits with the protein–hapten conjugates as described elsewhere (15). The antibody preparations used in this study were isolated by precipitation of the γ-globulin fraction according to the procedure of Marrack *et al.* (16).

The haptens used for the kinetic studies with both BSA and specific antibodies were the dyes 1-naphthol-4-[4-(4′-azobenzene azo)phenyl arsonic acid] and 1-naphthol-2 sulphonic acid-4-[4-(4′-azobenzene azo)phenyl arsonic acid], referred to hereafter as N—R′ and NS—R′, respectively. These compounds were prepared by coupling the diazonium salt of 4-(4′-aminobenzene azo)phenyl arsonic acid to 1-naphthol and 1-naphthol-2 sulphonic acid, respectively (17).

The buffers used were borate–KNO_3 (pH 8.0, 8.5, 9.0, $\Gamma/2 = 0.1$), borate–NaCl (pH 8.0, $\Gamma/2 = 0.1$), Tris[4]–KNO_3 (pH 7.5, $\Gamma/2 = 0.1$), and phosphate (pH 7.0, $\Gamma/2 = 0.1$).

Methods

The concentrations of the BSA solutions were determined spectrophotometrically at a wavelength of 280 mμ ($E^{1\%}_{1\,\mathrm{cm}} = 6.8$). Antibody concentrations were determined by the quantitative precipitin method of Heidelberger and Kendall (18), and the nitrogen contents of the precipitates were obtained by the micro-Kjeldahl procedure of McKenzie and Wallace (19).

The concentrations of bound and free dyes were determined spectrophotometrically (20, 21). If the molar extinction coefficients of the bound and free forms of the dye are known, the fraction of the free dye can be calculated from the equation

$$\alpha = \frac{\epsilon_{\mathrm{app}}-\epsilon_{\mathrm{b}}}{\epsilon_{\mathrm{f}}-\epsilon_{\mathrm{b}}},$$

where ϵ_{app} is the apparent molar extinction coefficient of the dye, and ϵ_{f} and ϵ_{b} are the molar extinction coefficients of the free and bound forms of the dye, respectively. The molar extinction coefficient of the free dye was calculated from the optical densities of solutions of known dye concentrations in appropriate buffers. To obtain ϵ_{b} the method of Westphal *et al.* (21) was used. Values for the apparent molar extinction coefficient were determined for a series of solutions containing a constant amount of dye and varying amounts of BSA or of the specific antibodies. For the calculation of ϵ_{b}, values of ϵ_{app} were plotted versus the ratios of dye/protein concentrations of the corresponding solutions, and ϵ_{b} was identified with the molar extinction coefficient of the solution for infinite protein concentration. All spectrophotometric measurements were made with a Zeiss spectrophotometer.

The number of binding sites on the BSA molecule was calculated with the help of the equation used previously by Nisonoff and Pressman (22) for antibody–hapten systems,

$$\frac{1}{b} = \frac{1}{K(\mathrm{P})c} + \frac{1}{(\mathrm{P})},$$

where b and c are the concentrations of bound and free dye, (P) is the total molar concentration of the protein binding sites, and K is the equilibrium constant. For this purpose varying amounts of dyes were added to a constant amount of BSA and the concentrations of bound and free dye were calculated from optical density measurements. The number of binding sites on the antibody molecules was taken as two (1, 23).

[4]*Tris refers to tris-(hydroxy methyl)-amino methane.*

Relaxation time measurements were made with the aid of the temperature-jump apparatus described elsewhere (11, 24), and the rate of re-equilibration at a higher temperature was followed spectrophotometrically at a wavelength of 590 mμ.

RESULTS AND DISCUSSION

(a) BSA–Dye Interactions

The rationale for synthesizing the particular dyes N—R′ and NS—R′ was that these compounds incorporated the antigenic determinant, the phenyl arsonate group, and had a structure similar to that of Orange I, which is a pH indicator. The pK values of these pH indicators as determined by spectrophotometric measurements in buffer solutions of various pH values were 8.7 and 7.2 for N—R′ and NS—R′, respectively. An increase in pH resulted in a shift of the absorption spectra of the dyes to longer wavelengths, which was considered to be due to the ionization of the naphtholic OH group. Similar shifts were observed when BSA or the specific antibody solutions were added to the dye solutions. To obtain maximum shifts in wavelength due to the binding of the dyes, experiments were performed in buffer solutions of pH values which were mainly below the pK values of the dyes. The effect of BSA on the absorption spectrum of N—R′ in borate–KNO_3 buffer (pH 8.0, $\Gamma/2 = 0.1$) is shown in Fig. 1, from which it is evident that the absorption maximum was shifted from 510 mμ (which corresponded to the free dye) to 610 mμ for the bound dye. Spectral shifts for the interaction of NS—R′ with BSA in phosphate buffer (pH 7.0, $\Gamma/2 = 0.1$) were not nearly as pronounced (Fig. 2).

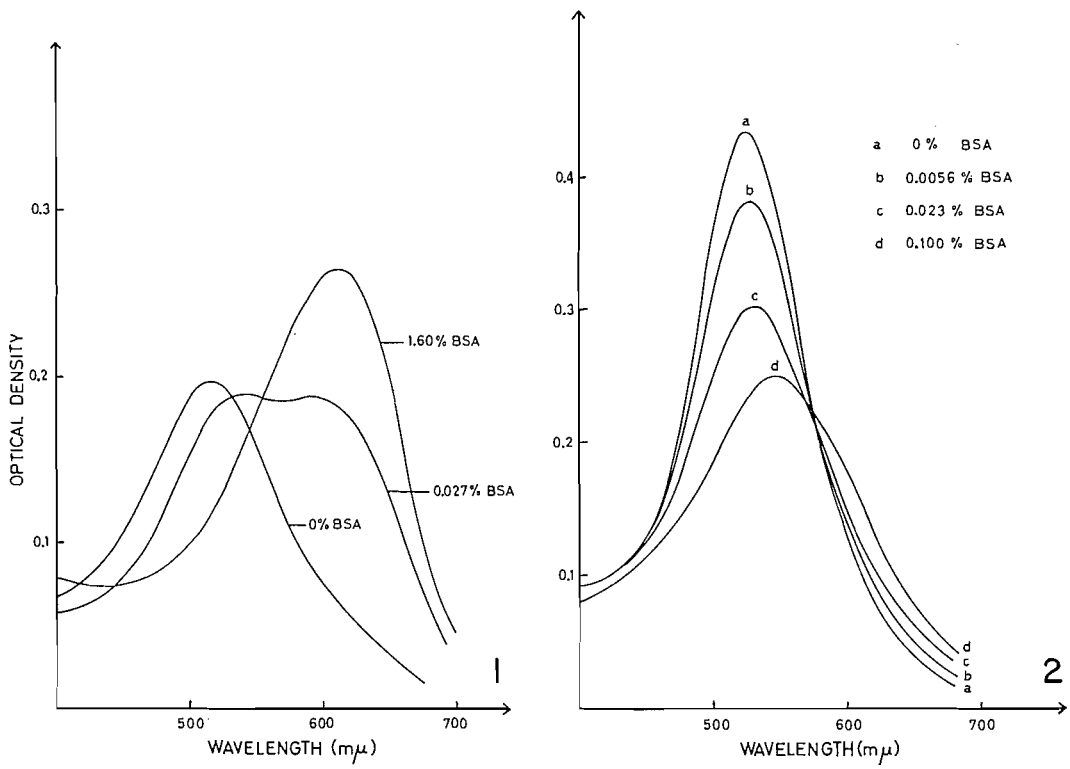

FIG. 1. The effect of BSA on the absorption spectrum of a 9.1×10^{-6} M solution of N—R′ in borate–KNO_3 buffer (pH 8.0, $\Gamma/2 = 0.1$).

FIG. 2. The effect of BSA on the absorption spectrum of a 9.1×10^{-6} M solution of NS—R′ in phosphate buffer (pH 7.0, $\Gamma/2 = 0.1$).

In the present study equilibrium dialysis could not be employed, since both dyes showed an extremely high affinity for the dialysis membranes. Therefore, only spectrophotometric methods were used for the determinations of free and bound reactants, as described under Methods. The molar extinction coefficient ϵ_f was determined as 0.58×10^4 M^{-1}cm^{-1} at 610 mμ and the value for ϵ_b was calculated (at pH 8.0, borate–KNO_3 buffer) from the plot shown in Fig. 3 as 2.80×10^4 M^{-1}cm^{-1}. The corresponding extinction

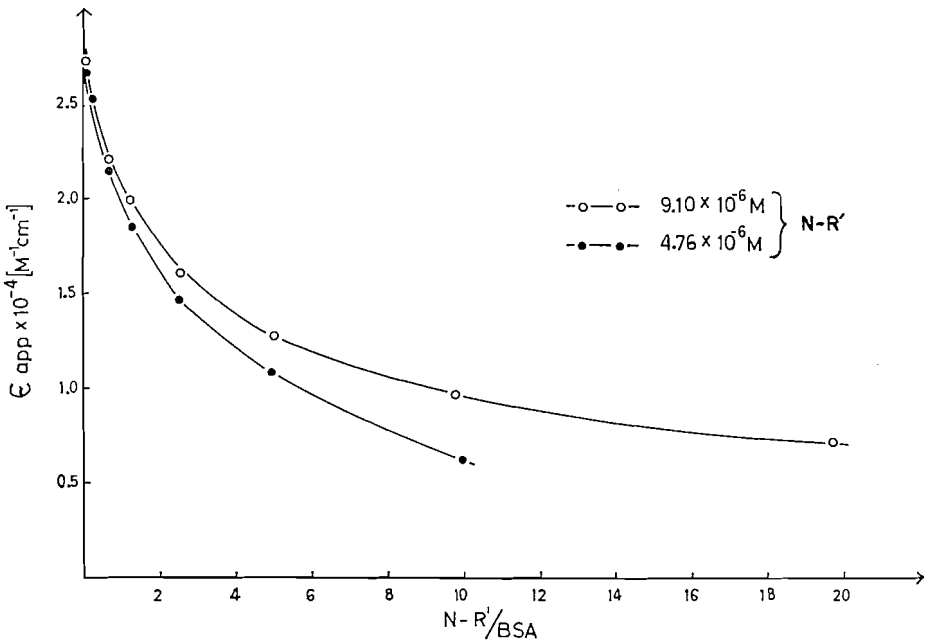

FIG. 3. Determination of ϵ_b of N—R′ bound by BSA for two different dye concentrations in borate–KNO_3 buffer (pH 8.0, $\Gamma/2 = 0.1$).

coefficients for NS—R′ in phosphate buffer (pH 7.0) were determined as 2.10×10^4 M^{-1}cm^{-1} and 1.04×10^4 M^{-1}cm^{-1} for ϵ_b and ϵ_f, respectively.

Binding curves for BSA with the dyes N—R′ and NS—R′ are shown in Figs. 4 and 5, respectively, and the corresponding number of binding sites per molecule of BSA for N—R′ and NS—R′ were calculated as five and one. The deviation of the curve from a straight line in Fig. 4 indicates that the binding sites on BSA have different affinities for N—R′ and a heterogeneity index (a) of 0.6 was calculated using the method of Nisonoff and Pressman (22). The average equilibrium constant K_0 for the association between N—R′ molecules and BSA was computed as 1×10^5 M^{-1}. On the other hand the plot in Fig. 5 suggests that the sites of BSA involved in the binding of NS—R′ were homogeneous. The equilibrium constant for this reaction was calculated as 5.5×10^4 M^{-1}.

To simplify the evaluation of the relaxation time measurements, it was assumed that all the binding sites on the BSA molecule were identical and independent of one another. Relaxation time measurements were performed on different solutions of varying dye/protein concentration ratios. A relaxation curve for the interaction between N—R′ and BSA is shown in Fig. 6. In all cases the curves were characterized by a single relaxation time. From the analysis of the concentration dependence of the relaxation time it was found that the relation

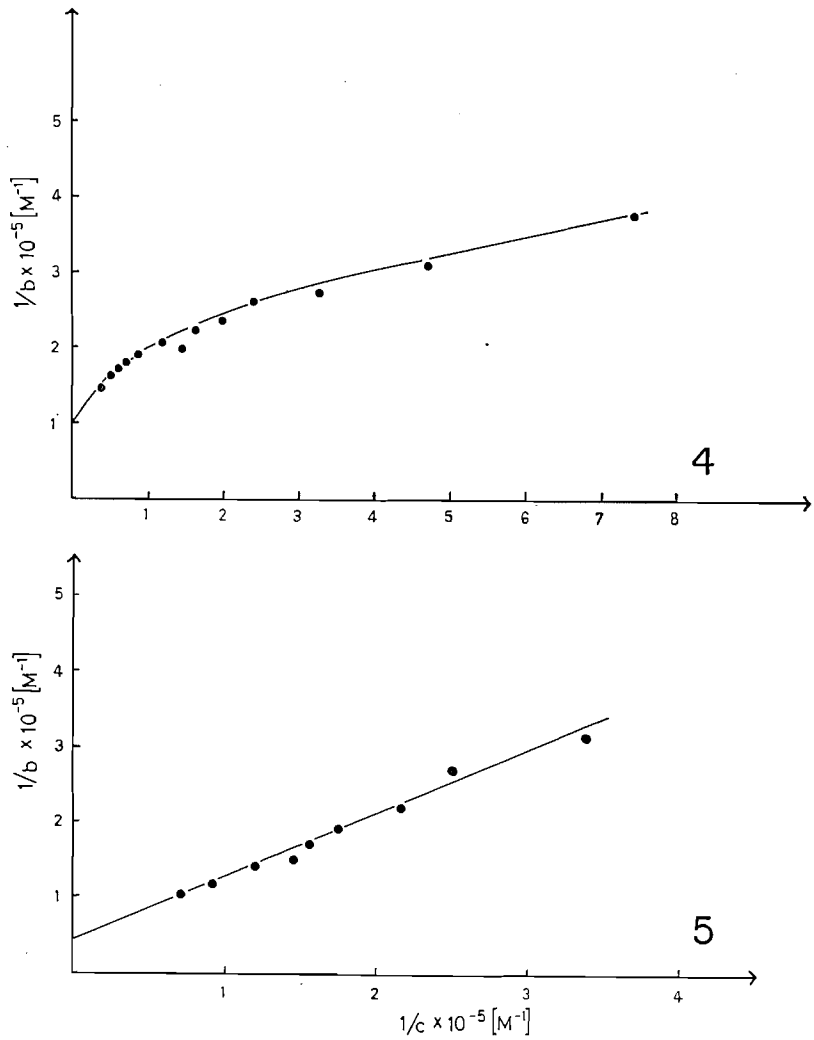

FIG. 4. The binding of N—R′ by BSA in borate-KNO_3 buffer (pH 8.0, $\Gamma/2 = 0.1$) at 25° C. Here c and b represent the free and bound dye concentrations, respectively.

FIG. 5. The binding of NS—R′ by BSA in phosphate buffer (pH 8.0, $\Gamma/2 = 0.1$) at 25° C. The symbols c and b represent the free and bound dye concentrations, respectively.

$$\frac{1}{\tau_{ii}} = k_{21}+k_{12}[(\overline{P})+(\overline{D})]$$

described the behavior of the system (11). In consequence it is suggested that the overall mechanism for the interaction of BSA with N—R′ is represented by the reactions

$$P + D \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} PD.$$

In Fig. 7 are given the plots of $1/\tau$ versus $[(\overline{P})+(\overline{D})]$ for 25, 30, and 35° C. The corresponding rate constants k_{12} and k_{21} at these temperatures are listed in Table I. It was shown also that the values for k_{12} and k_{21} were almost independent of the buffer ions used.

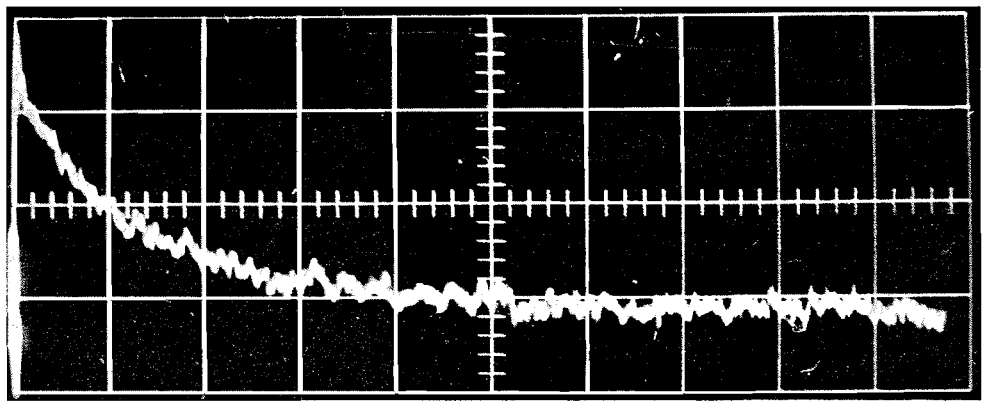

FIG. 6. Relaxation curve for the reaction between BSA and N—R′ (sweep rate 5 msec/cm).

TABLE I

Temperature (°C)	$k_{21}\times10^{-1}$ (sec^{-1})	$k_{12}\times10^{-6}$ ($M^{-1}sec^{-1}$)
25	3.5	2.1
30	7.0	3.2
35	13.6	3.7

The same relationship was found to be valid for the concentration dependence of the reaction between NS—R′ and BSA at 25° C (Fig. 8), and the appropriate rate constants were calculated as $k_{12} = 3.6\times10^5\ M^{-1}sec^{-1}$ and $k_{21} = 2.5\ sec^{-1}$. Thus, the equilibrium constants obtained from the ratio k_{12}/k_{21} for the systems consisting of BSA and N—R′ and NS—R′ are respectively $6\times10^4\ M^{-1}$ and $1.4\times10^5\ M^{-1}$ at 25° C. These values are of the same order of magnitude as the equilibrium constants calculated from static experiments, i.e. $1\times10^5\ M^{-1}$ and $5.5\times10^4\ M^{-1}$ for the N—R′ and NS—R′ systems, respectively (see also above).

In view of the different approaches used for obtaining these values, which represent only averages of the distribution of complex constants for the different binding sites, this agreement is considered satisfactory. Moreover, it ought to be stated that in the static experiments (Figs. 4 and 5) the concentration of the dyes had to be varied within wide limits, some of which were outside the range where the dye N—R′ obeyed Beer's law. This effect was probably caused by micelle formation and might introduce a serious error in the calculation of both the equilibrium constant and the number of binding sites. The latter error is carried over to the kinetic experiments in as much as the relaxation times are related to the total number of active sites.

In view of the heterogeneous population of the binding sites with respect to their affinity for the dye, which results in a distribution of equilibrium values (Fig. 4), it is reasonable to expect that there should be also a statistical distribution of the corresponding rate constants, k_{12} and k_{21}, rather than single values. From the equilibrium experiments with N—R′ an average value for the binding constant was determined. However, on the basis of the calculated heterogeneity coefficient of 0.6, the actual equilibrium constants for the different binding sites would vary over a wide range of values, differing by as much as two orders of magnitude (22). No account was taken of this complication in

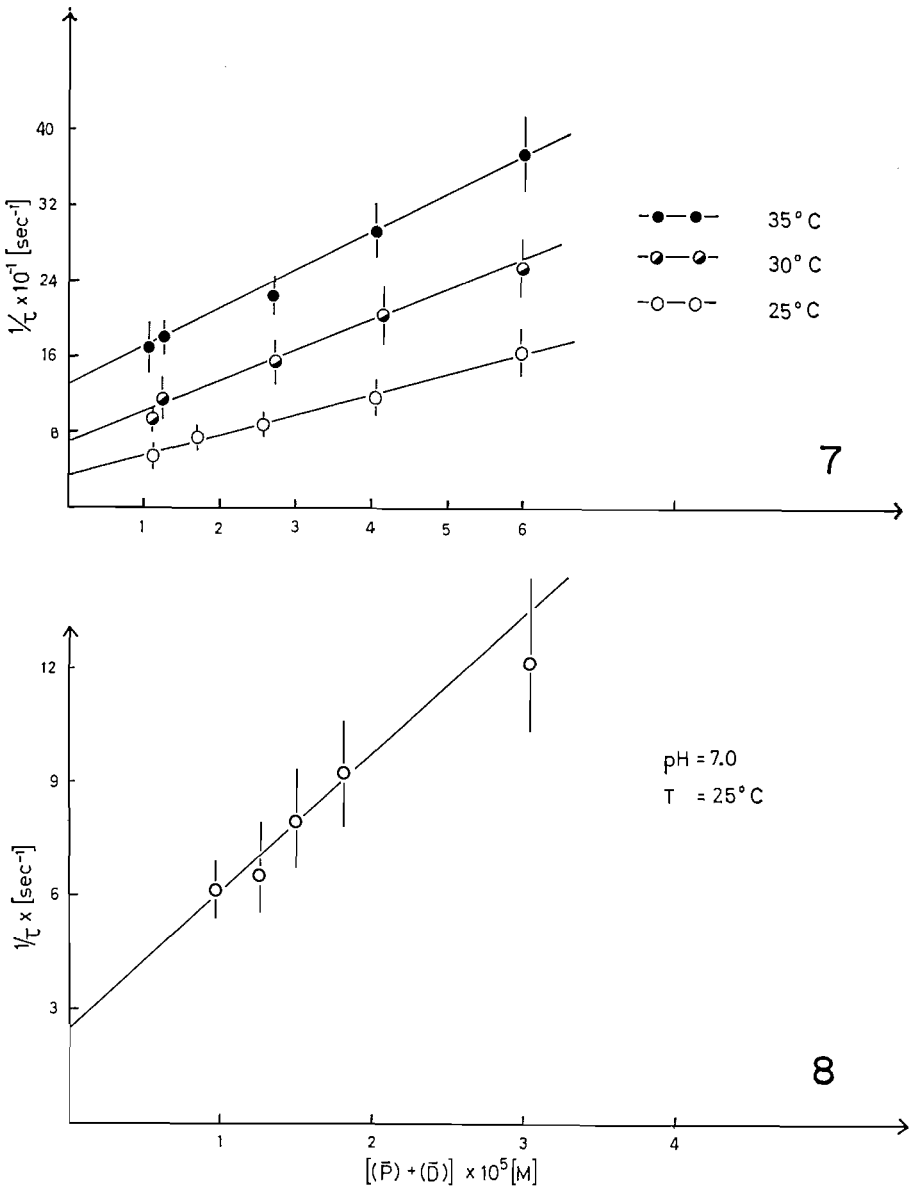

FIG. 7. Concentration dependence of $1/\tau$ for the reaction between BSA and N—R′ in borate–KNO_3 buffer (pH 8.0, $\Gamma/2$) at 25, 30, and 35° C.

FIG. 8. Concentration dependence of $1/\tau$ for the reaction between BSA and NS—R′ in phosphate buffer (pH 7.0, $\Gamma/2 = 0.1$) at 25° C; $k_{12} = 3.6 \times 10^5$ [M^{-1}sec^{-1}], $k_{21} = 2.5$ [sec^{-1}].

plotting the concentration dependence of τ from which the values of k_{12} and k_{21} were calculated. In consequence, at the lower concentrations of the dye, the contribution of the binding sites with the higher affinities will be more pronounced, and on increasing the concentration of the dye the binding sites having weaker affinities will come into play. Because of all these considerations it is obvious that the temperature dependence of the rate constants could not be obtained with the high degree of accuracy required for the

determination of an activation energy. Moreover, due to technical reasons, the present studies were restricted to a narrow temperature range of 10° C, so that relatively small errors in rate constants would have led to considerable uncertainties in activation energies, particularly in determining the activation energy of the dissociation step from the temperature dependence of k_{21}, which is obtained by extrapolation of $1/\tau$ to zero concentration of the free reactants. Therefore, the estimated activation energies, $E_{12}\simeq 10$ kcal/mole and $E_{21}\simeq 20$ kcal/mole, should be regarded as preliminary values and considered with some reservation. Studies over a wider temperature range are in progress and more definite values for these activation energies will be given later. From the difference in activation energies for the association and dissociation steps, it would appear that the reaction is exothermic to the extent of about 10 kcal/mole.

Because of the great number of protolytic equilibria involved, it is conceivable that the rate of dye–albumin interactions is affected greatly by pH. Relaxation time measurements at the three different pH values of 8.0, 8.5, and 9.0 at 25° C are shown in Fig. 9,

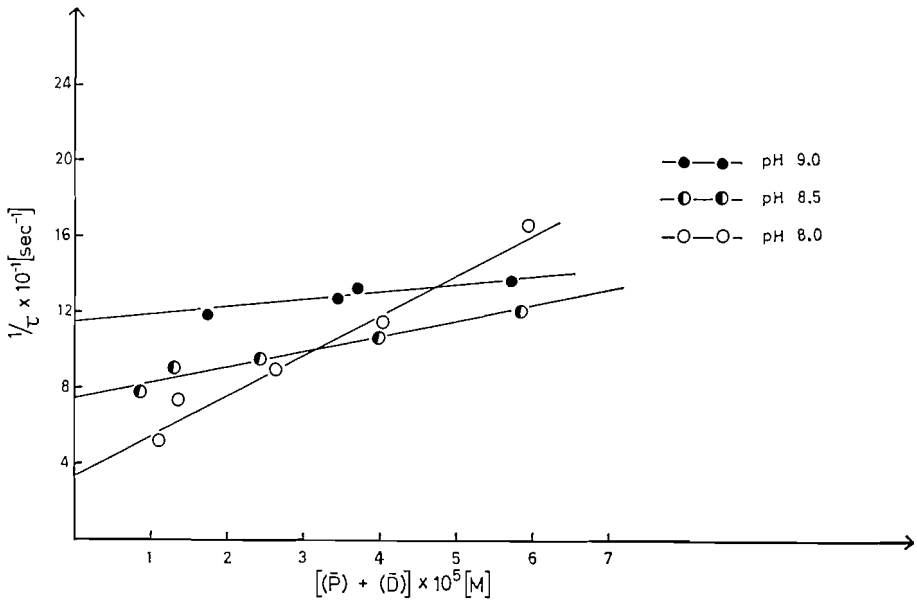

FIG. 9. Concentration dependence of $1/\tau$ for the reaction between BSA and N—R′ in borate–KNO_3 buffer at three different pH values.

from which it can be inferred that dissociation rates increase and association rates decrease with increasing pH. This could be explained partly by the increased repulsion between the negatively charged reactants, which becomes more pronounced at the higher pH values.

(b) Antibody–Hapten Interactions

Reactions between the haptens NS—R′ and N—R′ and the antibodies to the phenyl arsonate group resulted in a shift of the spectra of both dyes to longer wavelength. However, addition of normal rabbit gamma globulin to these dyes did not result in a detectable spectral shift. The change in the absorption spectrum of the NS—R′ dye due to the addition of antibody in Tris buffer at pH 7.5 is shown in Fig. 10.

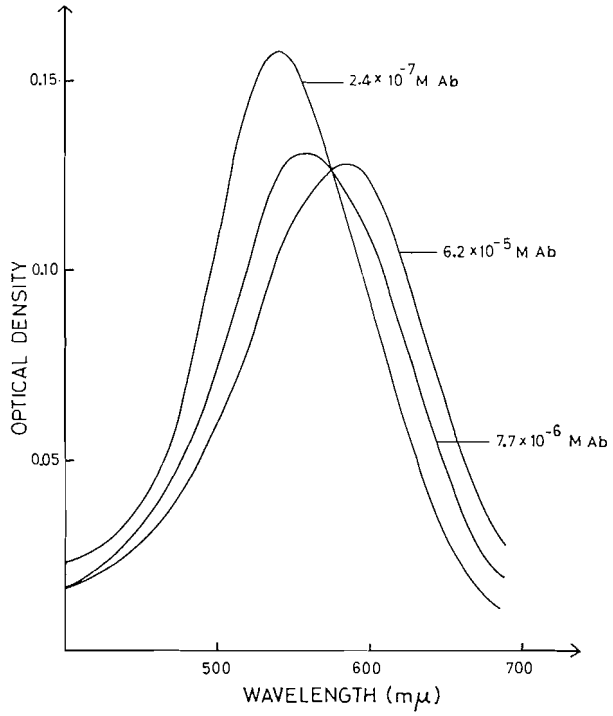

FIG. 10. The effect of anti-R antibodies on the absorption spectrum of a 4.8×10^{-6} M solution of NS—R′ in Tris–NaCl buffer (pH 7.5, $\Gamma/2 = 0.1$).

Unfortunately, it was not possible under the present experimental conditions to measure relaxation times for the reaction between NS—R′ and the antibodies in Tris buffer, because of the large temperature coefficient of the latter. This in turn led to a large change in the protolytic equilibrium of the dye, which masked any effect due to the dye–antibody interaction. Phosphate buffer could not be used either, since it was found to inhibit the reaction.

In spite of the fact that the N—R′ was univalent, precipitation was observed at some antibody-to-hapten ratios. This precipitation was most likely due to the aggregation of the hapten into micelles, an effect which was previously referred to. For this reason no binding studies were done with N—R′. Nevertheless, relaxation time measurements could be made with this system in borate buffer at pH 8.0 in a concentration range where no precipitation occurred. The value for ϵ_b for N—R′ was assumed to be 2.8×10^4 $M^{-1}cm^{-1}$, by analogy with the value determined for the BSA – N—R′ system.

From the concentration dependence of $1/\tau$ (Fig. 11) the rate constants k_{12} and k_{21} were calculated as $\sim2\times10^7$ $M^{-1}sec^{-1}$ and ~50 sec^{-1}, respectively. These values are higher by one order of magnitude than the lower limits estimated by Schneider and Sehon for the phenyl arsonate system (9). The value of k_{12} exceeds also the lower limit reported by Sturtevant *et al.* for the dinitrophenyl system (10) by one order of magnitude. Although rate constants as large as 10^9 $M^{-1}sec^{-1}$ could have been determined with the method used in the present investigation, no further second-order step representing the formation of specific complexes could be detected. The equilibrium constant calculated from the values of k_{12} and k_{21}, i.e. $\sim4\times10^5$ M^{-1}, agrees well with the equilibrium constants calculated for similar antibody–hapten reactions (9, 25).

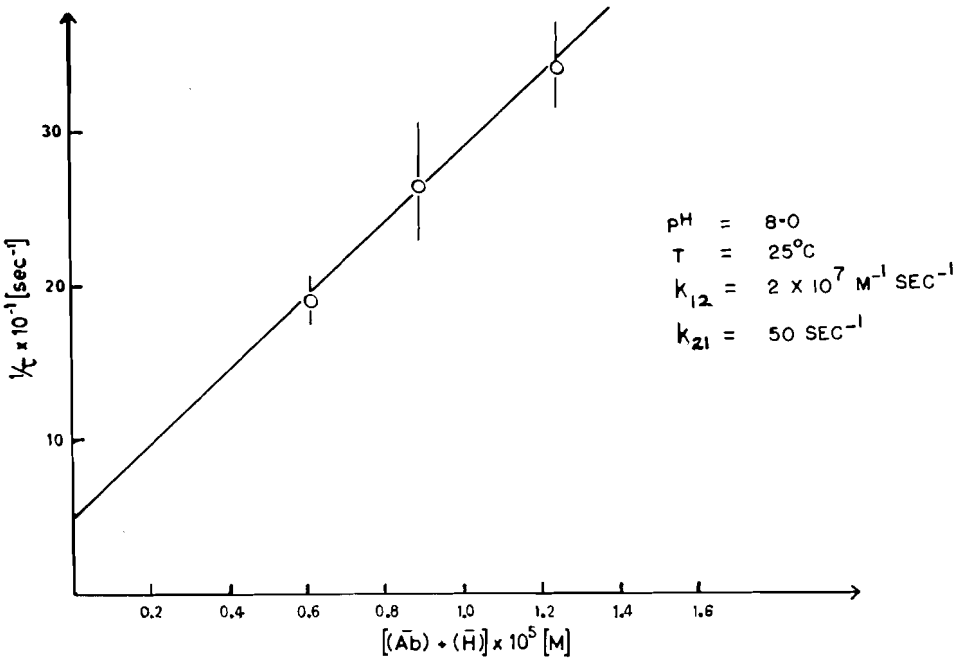

FIG. 11. Concentration dependence of $1/\tau$ for the reaction between anti-R antibodies and N—R′ in borate–NaCl buffer (pH 8.0, $\Gamma/2 = 0.1$) at 25° C.

GENERAL REMARKS

This study has demonstrated the applicability of the temperature-jump method to the investigation of the kinetics of protein–dye and antibody–hapten reactions. In view of the complicated mechanisms underlying these systems, the error limits of the rate constants obtained in these first studies might still be quite large. However, additional support for the kinetic values derived in this study is provided by the good agreement between the equilibrium constants calculated from the ratios of k_{12}/k_{21} and the equilibrium values computed from static experiments, both in this and other studies (1, 9, 25). The rate constant for the association between the hapten and the specific antibody at 25° C was found to be larger than that for the reaction between the hapten and BSA (by a factor of at least 10), but it is still more than one order of magnitude below the limit to be expected for a diffusion-controlled reaction. The fact that BSA reacts more slowly is not surprising since one might expect that repulsion between the negatively charged dye and albumin molecules is larger and that the extent of complementariness between the combining sites in the antibody–hapten system is more pronounced.

BIOSYNTHESIS OF SUGARS FOUND IN BACTERIAL POLYSACCHARIDES

PART II. BIOSYNTHESIS OF D-*glycero*-D-*manno*-HEPTOSE

J. K. N. JONES, M. B. PERRY, AND R. J. STOODLEY
Department of Organic Chemistry, Queen's University, Kingston, Ontario

Received May 17, 1962

ABSTRACT

Azotobacter indicum was grown in media which contained D-glucose-1-C^{14}, D-glucose-2-C^{14}, D-glucose-6-C^{14}, D-mannose-1-C^{14}, or D-galactose-1-C^{14}. Each radioactive polysaccharide produced was hydrolyzed and the specific activity of the isolated D-*glycero*-D-*manno*-heptose was determined. The distribution of activity in the heptose molecule was determined by chemical degradation procedures.

The results suggest that the D-*glycero*-D-*manno*-heptose is formed from hexose precursors by pathways which involve the action of transaldolase, transketolase, and aldolase

INTRODUCTION

The role of D-*altro*-heptulose (sedoheptulose) 7-phosphate in cellular metabolism has been amply demonstrated. It has been detected as an early product of photosynthesis (1) and as an intermediate in the pentose phosphate cycle (2, 3). Aldoheptoses have been found in the polysaccharides of a number of Gram-negative bacteria (4), although there is little information about the structures of such polymers. The mode of biosynthesis of these 7-carbon sugars has not been reported, but it is logical to expect that they may be derived from D-*altro*-heptulose 7-phosphate.

Knight and his co-workers (5) have shown that *Azotobacter indicum* can produce a heptose-containing extracellular polysaccharide. Sowa (6) in this laboratory, has characterized the 7-carbon sugar as D-*glycero*-D-*manno*-heptose. The results of growing *A. indicum* in media containing a number of C^{14}-labelled sugar substrates were reported in Part I of this series (7). The polysaccharides produced were hydrolyzed and the distribution of activity in the isolated D-glucose and L-rhamnose was determined and possible origins of L-rhamnose were discussed. In this communication the results of the heptose degradations are reported and possible pathways for the biosynthesis of D-*glycero*-D-*manno*-heptose are presented.

EXPERIMENTAL

Azotobacter indicum was grown in media which contained D-glucose-1-C^{14}, D-glucose-2-C^{14}, D-glucose-6-C^{14}, D-mannose-1-C^{14}, or D-galactose-1-C^{14}. The methods for the production and hydrolysis of the polysaccharide, the isolation of the component monosaccharides, and the counting procedures were the same as those described earlier (7).

Paper chromatography was carried out by the descending method on Whatman No. 1 filter paper using the following solvent systems (v/v): (*a*) 1-butanol, ethanol, water (3:1:1), (*b*) ethyl acetate, acetic acid, formic acid, water (18:3:1:4), and (*c*) 1-butanol, pyridine, water (10:3:3). Sugars were located on the developed chromatograms by the *p*-anisidine hydrochloride spray (8).

The weights of D-*glycero*-D-*manno*-heptose isolated from the polysaccharide hydrolyzates were determined by the colorimetric phenol – sulphuric acid method (9); the estimated specific activities of the heptose are shown in Table I. The samples of radioactive D-*glycero*-D-*manno*-heptose were diluted with inactive heptose prior to their degradations.

Degradation of D-glycero-D-manno-*Heptose*

The heptose was degraded according to the reactions outlined in Fig. 1.

Determination of C^{14} in C1–6 and C7

D-*glycero*-D-*manno*-Heptose (20 mg) was dissolved in pH 8 phosphate buffer (10 ml), and 0.3 *M* sodium metaperiodate solution (2 ml) was added. Barium acetate solution was added after 2 hours and the precipitated barium salts were removed by filtration. The filtrate was acidified with acetic acid and dimedon was

TABLE I

Specific activities of D-*glycero*-D-*manno*-heptose

Sugar substrate	Specific activity of sugar substrate (μc/mmole C)	Specific activity of heptose (μc/mmole C)
D-Glucose-1-C^{14}	3.00	3.40
D-Glucose-2-C^{14}	3.00	3.22
D-Glucose-6-C^{14}	3.00	2.85

added. The precipitated formaldehyde dimedon (C7) was collected after 20 hours and was recrystallized from aqueous ethanol prior to the determination of its specific activity; m.p. 188° C. Mercuric acetate solution was added to the filtrate obtained after removal of the formaldehyde dimedon and the formic acid (C1–6) was oxidized to carbon dioxide (10), the specific activity of which was determined.

Determination of C^{14} in C1+7 and C2–6

The heptose (15 mg) was reduced with 1% sodium borohydride solution (2 ml). The excess borohydride was destroyed after 12 hours by the addition of 2 *N* sulphuric acid and the specific activity of C1+7 (formaldehyde) and of C2–6 (formic acid) were determined as described above.

Determination of C^{14} in C1–7, C1–2, C3–6, and C7

D-*glycero*-D-*manno*-Heptose *p*-nitrophenylhydrazone was prepared in the usual manner in 80% yield; m.p. 176–177° C. The hydrazone (40 mg) was dissolved in pH 8 phosphate buffer (10 ml) and was oxidized with excess sodium metaperiodate. Glyoxal *p*-nitrophenylhydrazone precipitated almost immediately and, after recrystallization from aqueous acetone, it was obtained in 65% yield; m.p. 199–200° C. The specific activity of C1–2 was then determined. The solution remaining after the removal of the glyoxal *p*-nitrophenylhydrazone was acidified with acetic acid, and dimedon was added. After 20 hours the formaldehyde dimedon was removed by filtration, and, after recrystallization from aqueous ethanol, it was obtained in 70% yield; m.p. 188° C. The material was plated and the specific activity of C7 was determined. The filtrate was acidified with sulphuric acid and distilled. The formic acid in the distillate was oxidized with mercuric acetate (10) and the specific activity of C3–6 was determined. The specific activity of C1–7 was determined by directly counting the heptose *p*-nitrophenylhydrazone.

Oxidation of D-glycero-D-manno-*Heptose p-Nitrophenylhydrazone with 1 Mole of Periodate*

D-*glycero*-D-*manno*-Heptose *p*-nitrophenylhydrazone (300 mg) was dissolved in hot water (20 ml). The solution was cooled in ice water, and periodic acid (198 mg) in water (10 ml) was added. Glyoxal *p*-nitrophenylhydrazone precipitated within a few seconds and was collected by filtration after 10 minutes. The material had m.p. 199–200° C and was obtained in 55% yield. Barium acetate solution was added to the filtrate and the precipitated barium salts were removed by filtration. The filtrate was evaporated to dryness under reduced pressure and the residue was examined by paper chromatography using solvents *a*, *b*, and *c*. A reducing component corresponding to ribose was detected with the *p*-anisidine hydrochloride spray (8). Minor amounts of other components were also detected.

The residue (170 mg) was fractionated on Whatman 3MM filter paper using solvent *a*. The area of paper containing ribose was eluted with water and the solution was evaporated to a pale yellow syrup (40.5 mg, 31%). The material was paper chromatographically homogeneous in solvents *a*, *b*, and *c*.

Determination of C^{14} in C3+7 and C4–6 of the Heptose

The ribose (15 mg) isolated above was reduced with sodium borohydride and then oxidized with sodium metaperiodate as described for D-*glycero*-D-*manno*-heptose. Formaldehyde dimedon (C3+7) was obtained in 65% yield after recrystallization from aqueous ethanol; m.p. 188° C. The formic acid (C4–6) was oxidized to carbon dioxide with mercuric acetate (10).

The specific activities of the fragments obtained during the degradation of D-*glycero*-D-*manno*-heptose are recorded in Table II.

The percentage distribution of activity in the carbon chain of D-*glycero*-D-*manno*-heptose is summarized in Table III.

The total activity of the heptose was determined by summing the individual activities of C1, C2, C3, C4–6, and C7. The isotope content of C1 was obtained by difference (activity of C7 subtracted from that of C1+7), while the activity of C2 was calculated by subtracting C1 from C1+2. When a negative value resulted, the activity of C2 was assumed to be zero. The activity of C3 was determined by subtracting C4–6 from C3–6 (in the cases when D-glucose-1-C^{14} or D-galactose-1-C^{14} were the substrates) or by subtracting C7 from C3+7 (when D-glucose-2-C^{14} and D-mannose-1-C^{14} were substrates). In the calculations the average isotope content of C7 (mean of determinations by two methods) was used.

TABLE II

Specific activities of heptose fragments (c.p.m./mmole C)

Heptose carbon	Sugar substrate				
	G-1-C^{14}	G-2-C^{14}	G-6-C^{14}	M-1-C^{14}	Gal-1-C^{14}
C1–6	—	15,750	4,040	29,540	16,560
C7*	—	10,080	112,350	6,720	16,590

TABLE III

Distribution of C^{14} in individual carbon atoms of D-*glycero*-D-*manno*-heptose

Sugar substrate	C^{14} as % total in the aldoheptose						
	C1	C2	C3	C4	C5	C6	C7
D-Glucose-1-C^{14}	72	0	15	←	5	→	8
D-Glucose-2-C^{14}	15	49	4	←	25	→	7
D-Glucose-6-C^{14}	16	←		2		→	82
D-Mannose-1-C^{14}	67	0	27	←	3	→	3
D-Galactose-1-C^{14}	59	0	25	←	7	→	9

DISCUSSION

There have been no reported degradations of C^{14}-labelled aldoheptoses. Preliminary studies were aimed at cleaving the heptose to a 6-carbon sugar, which could then be degraded by conventional methods. Antia and Perry (11) prepared methyl β-D-gulopyranoside by oxidizing methyl β-D-*glycero*-D-*gulo*-heptopyranoside with 1 mole of sodium metaperiodate followed by borohydride reduction of the resulting aldehyde. It was hoped to convert methyl α-D-*glycero*-D-*manno*-heptopyranoside to methyl α-D-mannopyranoside by this method; however, in practice only poor yields of mannose (ca. 15%) were obtained.

D-*glycero*-D-*manno*-Heptose *p*-nitrophenylhydrazone could be prepared in 80% yield and was used to determine the isotope content of C1+2, C3–6, and C7. Oxidation of the hydrazone with 1 mole of periodate under unbuffered conditions gave fair yields (ca. 30%) of a compound characterized chromatographically as ribose. The isolated ribose was reduced to ribitol and oxidation with sodium metaperiodate gave formaldehyde (C3+7) and formic acid (C4–6), from which the specific activities of C3+7 and C4–6 of the original heptose were determined.

The D-*glycero*-D-*manno*-heptose *p*-nitrophenylhydrazone would be expected to adopt the stable zig-zag conformation if it existed in the open-chain form, in which case the C2—C3 glycol system would be trans and unfavorable for attack by the periodate ion. The present results suggest that the heptose *p*-nitrophenylhydrazone exists mainly in a furanose ring form in which cleavage of the C2—C3 glycol system by the periodate ion is more favored than cleavage of the exocyclic C6—C7 glycol group.

The isotope contents of C1–6, C7, C1+7, and C2–6 were determined by periodate oxidation of the D-*glycero*-D-*manno*-heptose and its reduction product D-*glycero*-D-*manno*-heptitol according to the reactions outlined in Fig. 1.

Perry and Pietak (12) in an investigation of the periodate oxidation of aldoheptoses found that the production of an intermediary malondialdehyde derivative about C5 resulted in partial overoxidation, with the subsequent release of some carbon dioxide from C5. However, under the alkaline conditions used, the overoxidation is minimized and only a small proportion (0.08 mole) of carbon dioxide is released from C5 and the degradation proceeds essentially as illustrated in Fig. 1.

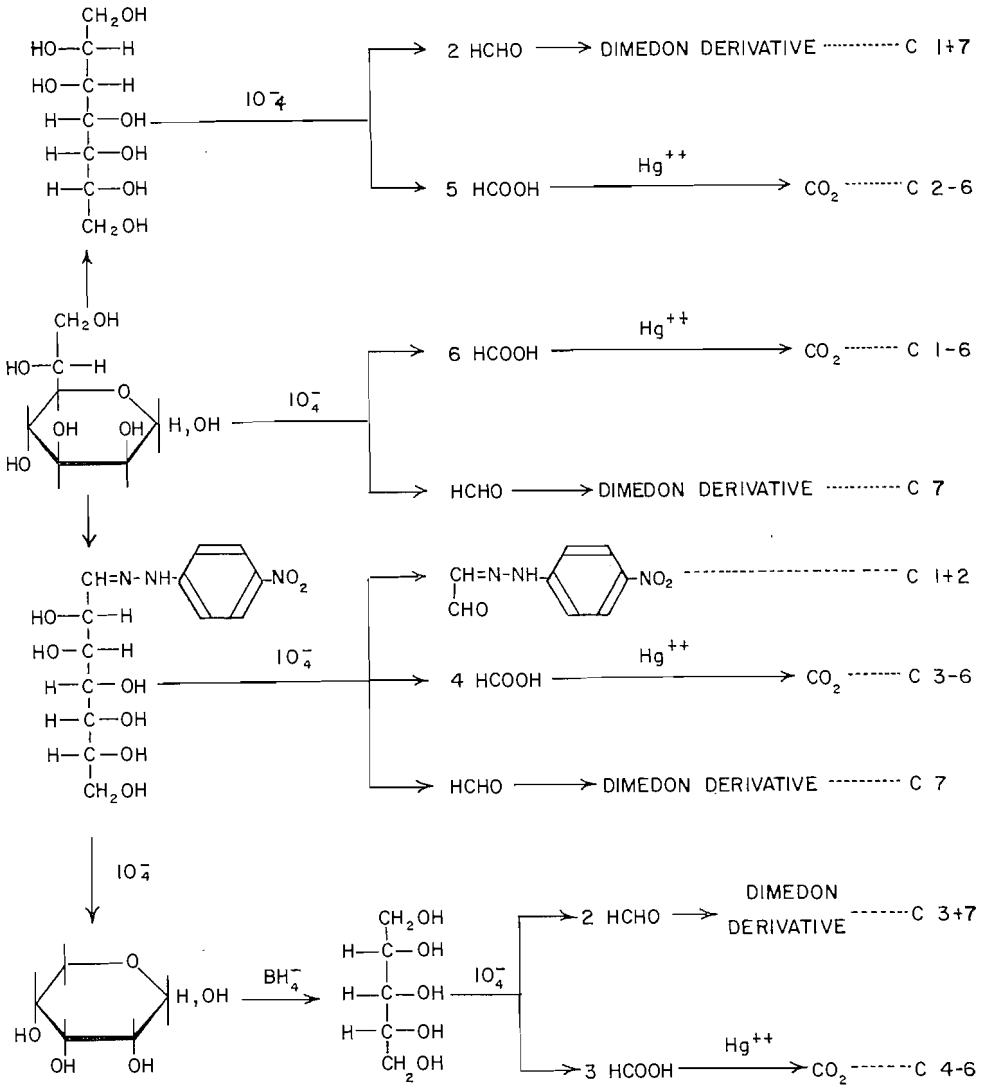

FIG. 1. Degradation of D-*glycero*-D-*manno*-heptose-C^{14}.

In this investigation the isotope contents of C4–6 and C7 were determined directly while those of C1, C2, and C3 were calculated by difference, using 2 mmoles of heptose.

It is generally unwise to determine activities of carbon atoms indirectly, since the errors are magnified. However, the objection is not so serious as it may first appear. When D-glucose-1-C^{14}, D-glucose-2-C^{14}, and D-mannose-1-C^{14} were substrates for extracellular polysaccharide synthesis by *A. indicum*, the isolated heptose samples contained very little activity in C7. The determination of C1+7 and C3+7 is, therefore, almost as satisfactory as a direct determination of C1 and C3.

When D-glucose-1-C^{14}, D-mannose-1-C^{14}, and D-galactose-1-C^{14} were substrates about $65\pm7\%$ of the activity was located in C1 of the isolated heptose. The majority of the remaining radioactivity was located in C3 ($21\pm6\%$). Most of the activity (82%) was found in C7 of the heptose when D-glucose-6-C^{14} was the substrate and the remaining activity was located in C1. When D-glucose-2-C^{14} served as the substrate about 50% of the activity was recovered in C2 of the heptose, 25% in C4–6, and 15% in C1. This latter result indicates that C1 decarboxylation is occurring and suggests that some of the pentose thus formed in the hexose monophosphate shunt is utilized for heptose synthesis.

The specific activities of the 7-carbon sugars isolated from the polysaccharide hydrolyzates were quite similar to each other ($\pm8\%$) and also to those of the corresponding hexose-1-C^{14}, -2-C^{14}, or -6-C^{14} substrates, indicating that C1, C2, and C6 of D-glucose make similar contributions to the heptose carbon skeleton.

The distribution of activity in the heptose samples may be largely interpreted in terms of the known reactions of the pentose phosphate cycle (13), which are summarized in Fig. 2. The routes which may be responsible for aldoheptose biosynthesis are shown in

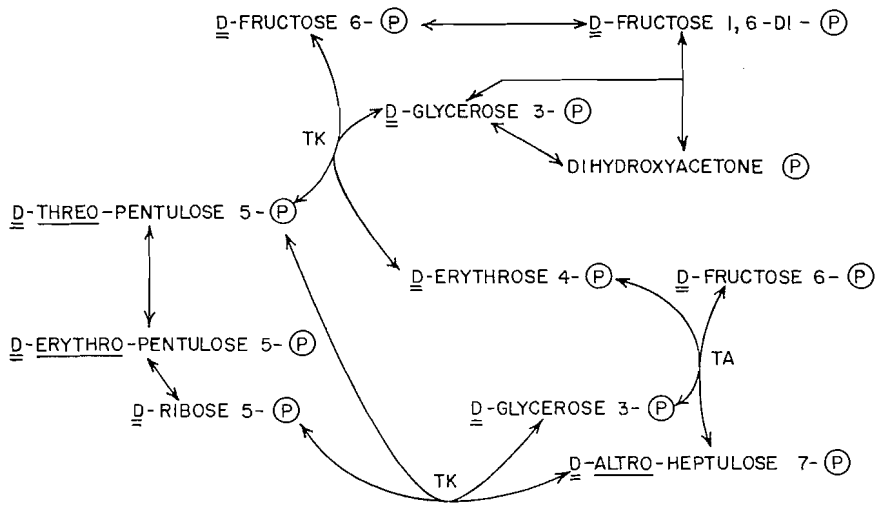

FIG. 2. Reactions of the pentose phosphate cycle.

Fig. 3. If reactions B and C (Fig. 3) are the sole pathways, the specific activity of the heptose isolated from the D-glucose-6-C^{14} substrate should be only 50–60% as much as the specific activities of the heptose samples isolated from the other substrates. In practice

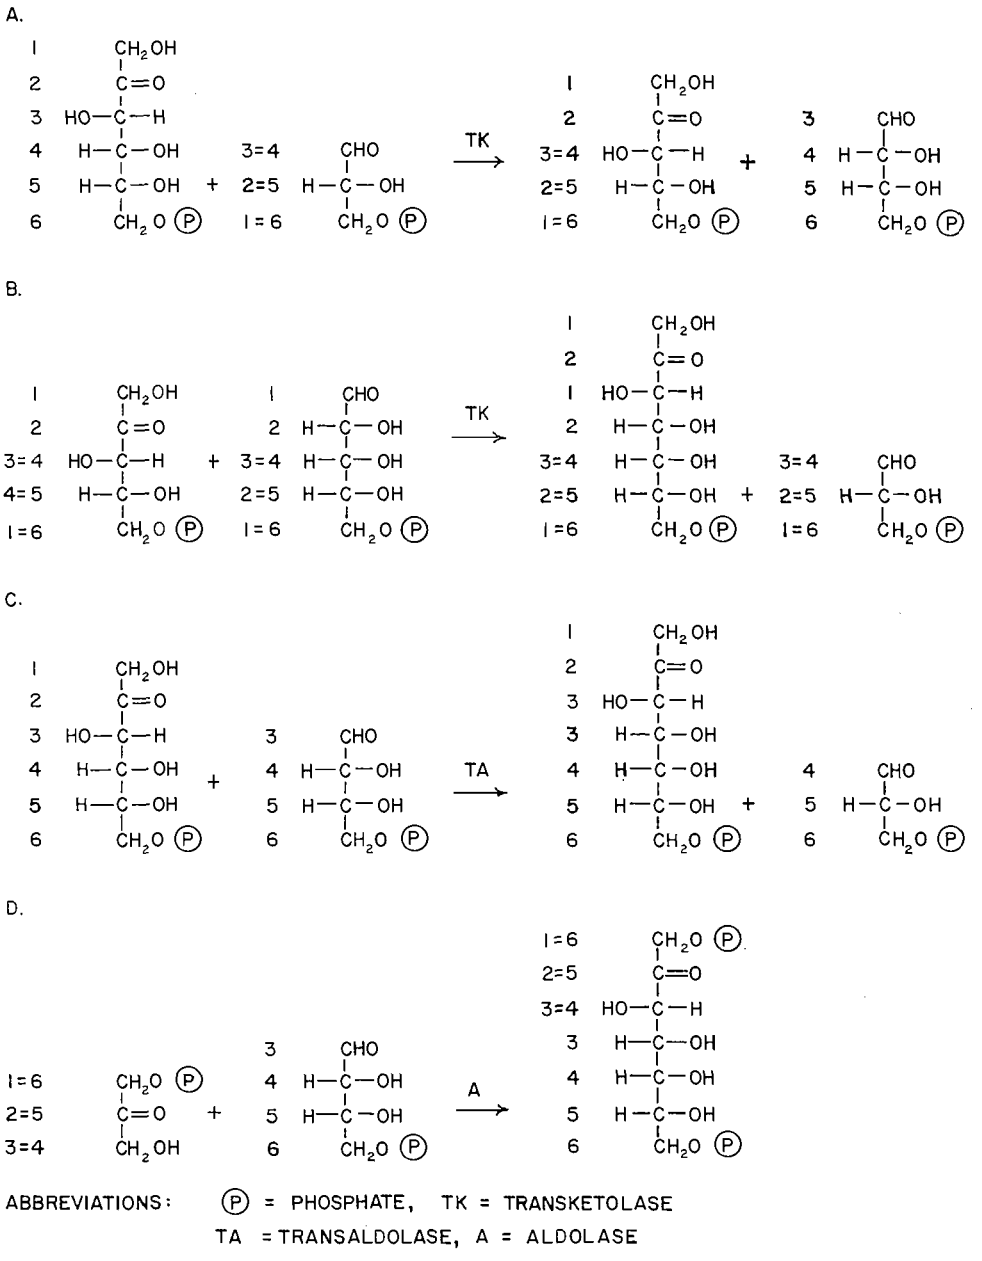

FIG. 3. Possible routes of heptose biosynthesis.

there was little difference between these specific activities, suggesting that there is an additional route for heptose synthesis in which C6 of D-glucose makes more of a contribution than C1 or C2.

Horecker *et al.* (14) and Ballou *et al.* (15) have shown that aldolase can catalyze the condensation of dihydroxyacetone phosphate with D-erythrose 4-phosphate to form D-*altro*-heptulose 1,7-diphosphate (route D, Fig. 3). If it is assumed that 25% of the heptose synthesized by *A. indicum* is formed by this route, 25% by route B, and 50%

by route C, the observed specific activities and the distributions of activity in the heptose can be explained.

There have been no previous investigations on the mechanism of formation of aldoheptoses found in polysaccharides. The present study suggests that D-*glycero*-D-*manno*-heptose may be synthesized by the action of transketolase on D-*threo*-pentulose 5-phosphate and D-ribose 5-phosphate. The pentoses may be derived from hexose and triose phosphates by the action of transketolase, or from hexonic acid phosphate via the hexose monophosphate shunt. The action of transaldolase on hexose and tetrose phosphates probably makes a significant contribution to the 7-carbon sugar biosynthesis. D-*altro*-Heptulose 7-phosphate is probably formed by these reactions while D-*altro*-heptulose 1,7-diphosphate may also be produced by the action of aldolase on dihydroxyacetone phosphate and D-erythrose 4-phosphate.

The heptulose phosphates are probably converted to aldoheptose phosphates, which are then transformed into the appropriate nucleotides, prior to incorporation into the polysaccharide. Palleroni and Doudoroff have shown that D-*altro*-heptulose and D-*glycero*-D-*manno*-heptose are interconvertible in the presence of a mannose isomerase from *Pseudomonas saccharophila* (16). Ginsburg (17) has recently isolated the guanosine diphosphate derivative of D-*glycero*-D-*manno*-heptose from bakers' yeast.

ACKNOWLEDGMENTS

The authors are greatly indebted to Dr. N. K. Richtmyer for a generous sample of D-*glycero*-D-*manno*-heptose hexaacetate. They thank Dr. G. B. Krotkov and Dr. C. D. Nelson of the Biology Department of Queen's University for making available the counting apparatus. They would also like to thank the National Research Council of Canada for financial assistance (Grants T-39 and NRC 706) and for the award of a Studentship to one of them (R. J. S.).

TRIMETHYL ORTHOBORATE – AMINE INCLUSION COMPOUNDS[1]

D. M. YOUNG AND C. D. ANDERSON
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received May 17, 1962

ABSTRACT

A new class of non-stoichiometric crystalline inclusion compounds has been discovered, having the general formula

$$(CH_3O)_3B.(\text{amine})_n.(\text{solvent})_x,$$

where $0.5 < n < 1.0$ and $0 < x < 3$ depending on the method of preparation and on the nature of the amine and solvent. Such compounds have been prepared with ammonia and a variety of primary and secondary amines. Among the solvents which can be incorporated into the crystals are alcohols, ketones, ethers, esters, nitriles, nitroparaffins, and hydrocarbons. Such compounds are also formed by triphenyl orthoborate, with $1.7 < n < 2.4$ and $1.2 < x < 1.6$.

The incorporated solvent has been shown to exert a definite vapor pressure. Furthermore, many of the compounds sublime at room temperature to form large transparent crystals which also contain incorporated solvent. The mechanism probably involves dissociation, followed by reassociation on the walls of the vessel. Preliminary X-ray diffraction measurements suggest that the trimethyl orthoborate – ammonia inclusion compounds have essentially the same crystal lattice as pure trimethyl orthoborate – ammonia.

INTRODUCTION

In a discussion of various methods for preparing the compound $(CH_3O)_3B$, Schechter (1) reported that treatment of the trimethyl orthoborate – methanol azeotrope with ammonia afforded crystals with incorporated methanol. The present work was undertaken to determine whether this phenomenon is a general one and, if so, to make a preliminary study of the properties of these inclusion compounds.

The literature on adducts of orthoboric acid esters and amines is scant. As recently as 1950, these esters were thought (2) to be insufficiently acidic (in the Lewis sense) to form such compounds.

In a series of papers on the reaction of trimethyl orthoborate with ammonia and amines, Goubeau *et al.* (3–5) described the preparation of $(CH_3O)_3B.NH_3$ and its reactions with excess ammonia and with excess orthoborate. They also prepared and characterized the 1:1 addition compounds of trimethyl orthoborate with mono-, di-, and tri-methylamine (5). Urs and Gould (6) reported the formation of solid addition compounds on mixing trimethyl orthoborate with dimethyl-, diethyl-, di-*n*-propyl-, di-*n*-butyl-, di-*n*-amyl-, triethyl-, and tri-*n*-butyl-amine. The compounds formed with ethylenediamine, piperidine, methylamine, and *t*-butylamine were stable enough to be purified by sublimation *in vacuo*; melting points and analytical results were given for these 1:1 addition compounds. The addition reactions were strongly catalyzed by the lower aliphatic alcohols. No solids separated on mixing amines with triethyl, tri-*n*-butyl, and tri-*n*-amyl orthoborates, although considerable heat evolution was noted with the ethyl ester. Urs and Gould (6) found no evidence of interaction between trimethyl orthoborate and pyridine or quinoline, but a stable 1:1 adduct of tris(1,1,1-trifluoroethyl) orthoborate and pyridine has since been characterized by Gerrard *et al.* (7).

Horn and Gould (8) studied the interaction of trimethyl orthoborate with 19 aliphatic and 5 heterocyclic amines, by measuring partial vapor pressures of the borate over

[1]*Contribution No. 68.*

equimolar borate–amine mixtures. Departures from ideality, which were greatest for ethylenediamine, piperidine, and triethanolamine and least for trimethylamine, di-*i*-propylamine, and pyridine, afforded a measure of the degree of interaction. As found previously (6), methanol markedly increased the borate–amine interaction.

Addition compounds between triaryl orthoborates and amines have been prepared and characterized by Colclough, Gerrard, and Lappert (9, 10). Stable 1:1 adducts were obtained in most cases, but where steric hindrance was severe the adducts were found to be deficient in amine. Ammonia formed 3:1 and 2:1 adducts respectively with tris(2,4,6-trichlorophenyl) and triphenyl orthoborates.

EXPERIMENTAL

Materials

Trimethyl orthoborate – methanol azeotrope was prepared by fractionating orthoboric acid and methanol (1:4 mole ratio) at a 10:1 reflux ratio. Trimethyl orthoborate was separated by shaking the azeotrope with anhydrous lithium chloride (11) and purified by fractionation. The purity was checked by titrating a weighed sample with 0.1 *N* sodium hydroxide to the phenolphthalein end point in the presence of mannitol.

Triphenyl orthoborate was prepared by distilling orthoboric acid and phenol (1:5.3 mole ratio), the water formed being removed azeotropically with the excess phenol (9). The crude product was purified by vacuum distillation, the fraction boiling at 154–167° at 0.2 mm being used for subsequent experiments.

The ammonia was Dow refrigeration grade. The gaseous amines were supplied by the Matheson Company and the liquid amines and solvents were Eastman Kodak "White Label" quality.

Preparation of Inclusion Compounds

(i) Trimethyl Orthoborate plus Gaseous Amines

Trimethyl orthoborate (5 ml) and the solvent to be incorporated (10 ml) were mixed in a 50-ml Erlenmeyer flask and saturated with the amine under slight excess pressure. Cooling the mixture in an ice bath helped to initiate crystallization and was useful in controlling the subsequent temperature rise. The crystals were separated by filtration on a sintered-glass funnel, in a dry box, washed with the same solvent if sufficiently volatile, otherwise with methanol, acetone, or *n*-pentane. After drying by suction, samples of the solid were transferred to tared weighing bottles for analysis. A small quantity was crushed on a porous plate and placed in a melting point tube which was sealed immediately after removal from the dry box.

(ii) Trimethyl Orthoborate plus Liquid Amine

Trimethyl orthoborate, solvent, and amine (5 ml of each) were added in turn to a 50-ml Erlenmeyer flask cooled in an ice bath. The resultant crystals were filtered in the dry box as described above.

(iii) Trimethyl Orthoborate plus Liquid Ammonia

A few inclusion compounds were formed using liquid ammonia, in an attempt to obtain an exactly 1:1 ratio of B:N. A mixture of trimethyl orthoborate, solvent, and ammonia in the mole ratio 1:8:5 was found to provide a sufficient excess of ammonia and enough solvent to prevent the trimethyl orthoborate from freezing. One part of trimethyl orthoborate and four parts of solvent were cooled to −28° C (boiling CF_2Cl_2) and a mixture of five parts of liquid ammonia and four parts of solvent added cautiously with stirring. A soda lime trap was attached to the flask and the contents were allowed to warm to room temperature. Filtration was carried out in a dry box, as usual.

(iv) Triphenyl Orthoborate

Triphenyl orthoborate – ammonia compounds were made by dissolving the ester in the solvent to be incorporated (using a slight excess of solvent over that required to effect solution) and saturating the solution with ammonia.

Analysis of Inclusion Compounds

Weighed samples of the inclusion compounds were dissolved in water and titrated against 0.1 *N* hydrochloric acid to the methyl red end point. Mannitol was added and the solution then titrated against 0.1 *N* sodium hydroxide to the phenolphthalein end point. The first titration gives the amount of amine, the second gives the amount of boric acid liberated on hydrolysis.

The methanolysis procedure of Thomas (12) was used to determine the boron content of the triphenyl orthoborate inclusion compounds. Later experiments, however, showed that direct titration gives the correct answer despite the presence of free phenol.

All inclusion compounds were assumed to correspond to the formula

$$(RO)_3B.(amine)_n.(solvent)_x.$$

The values of n and x could be calculated from the above analytical results.

RESULTS

Trimethyl Orthoborate – Ammonia Compounds

Analytical and other data for inclusion compounds involving trimethyl orthoborate, ammonia, and a series of alcohols are given in Table I. The solvents used to wash the

crystals are listed in column 6 ("col. 1" means that the crystals were washed with the same alcohol). The appearance of the crystals is noted in column 7. These compounds were generally quite wet and sticky, so that it was not possible to measure melting points. Thus the compound containing ethanol became practically liquid on storage. Many of the compounds showed a marked tendency to sublime at room temperature. After a few weeks' storage in weighing bottles, large transparent crystals were deposited on the upper surfaces of the bottles. In some cases, such crystals were found buried in the original powder at the bottom of the bottles. The tendency for crystal growth by sublimation is indicated in column 8 (x = slight, xx = moderate, xxx = pronounced). The compounds with *t*-amyl and *n*-decyl alcohols formed large, dry crystals, which were removed with tweezers and analyzed (see Table IX).

In Table II are listed the results obtained for inclusion compounds containing trimethyl orthoborate, ammonia, and a series of saturated and unsaturated hydrocarbons. All these compounds were fine, dry powders. For all the alkanes except neopentane and cyclohexane, x is equal to zero within the experimental error. In contrast, significant values of x were found for all the unsaturated hydrocarbons except isoprene. Benzene and cyclohexane gave almost identical x values. Melting points (sealed tube) for some of these compounds are recorded in the last column.

Results for compounds containing trimethyl orthoborate, ammonia, and a variety of organic solvents are given in Table III. Some of these compounds were prepared using liquid ammonia and are designated "liq." in column 6. Crystals of the compound containing 1,1-dimethoxyethane, which had sublimed on storage, were removed and analyzed (Table IX). The compound containing CF_2Cl_2 (b.p. −28° C) was prepared as follows.

A mixture of approximately equal volumes of trimethyl orthoborate and liquid CF_2Cl_2 (they are not completely miscible) was held at −28° C in a boiling-CF_2Cl_2 bath and saturated with ammonia gas. Extensive precipitation was observed in both gas and liquid phases. The mixture was warmed to room temperature, whereupon all the uncombined CF_2Cl_2 and ammonia evaporated. The weight of the residual solid was measured as a function of time; the sample lost weight continuously over a period of 24 hours. The same results were obtained in a subsequent experiment in which $(CH_3O)_3B.NH_3$ (1.785 g) was treated with excess liquid CF_2Cl_2 at its boiling point. After warming to room temperature and allowing the excess CF_2Cl_2 to boil off, the solid was reweighed and found to

have occluded 0.172 g of CF_2Cl_2 ($x = 0.096$). This sample also lost weight slowly at room temperature.

Trimethyl Orthoborate – Methylamine Compounds

Results for compounds of trimethyl orthoborate, monomethylamine, and alcohols are shown in Table IV. Under the conditions used, no crystals could be obtained in the

presence of ethanol, *n*-propanol, *n*- and iso-butanol; with isoamyl alcohol, *n*-decanol, and *n*-dodecanol, the crystals were not stable enough to permit filtration. The remaining alcohols in Table IV formed stable compounds having substantial values of x, comparable (excepting methanol) to those found for the corresponding ammonia adducts (Table I). Values of n showed far less variation than those in Table I. In the case of methanol and *n*-hexanol, the crystals formed by sublimation during storage were hand-picked and analyzed (Table IX).

The results shown in Table V, for compounds involving trimethyl orthoborate, monomethylamine, and hydrocarbons, are remarkably similar to those for the corresponding

TABLE V

$(CH_3O)_3B.(CH_3NH_2)_n.(hydrocarbon)_x$

(Prepared by saturating a hydrocarbon solution of trimethyl orthoborate with methylamine gas. Crystals washed with the same hydrocarbon)

Hydrocarbon	% N	% B	n	x	Crystal growth	M.p. (°C)
n-Pentane	8.90	8.54	0.81	−0.03		73.5–76

CCl_4	8.06	7.65	0.81	0.08		64–66

compounds made with ammonia (Table II). The values of x are almost identical except for 2-methylbutane, which is occluded with methylamine but not with ammonia, and

for cyclohexane, for which the reverse is true. With methylamine, the values of n are slightly lower than with ammonia. Results for CH_2Cl_2 and CCl_4 are also included in Table V. These solvents give very low x values, in contrast to their behavior with ammonia (cf. Table III).

Trimethyl Orthoborate – Higher Amine – Methanol Compounds

In Table VI are given the results for compounds involving trimethyl orthoborate and higher amines, methanol being the incorporated solvent in each case. The first five

TABLE VI

n-Heptyl	No crystals formed						
Piperidine	5.93	4.76	0.96	1.29	Mod. dry	xx	65–69

amines were added as gases. The data for ammonia and methylamine (from Tables I and IV) are listed for the sake of completeness. All the compounds analyzed contained substantial amounts of included methanol ($0.95 < x < 1.79$) and exhibited B:N ratios close to unity ($0.96 < n < 1.16$). The trimethyl orthoborate – diethylamine – methanol compound showed a pronounced tendency to sublime, producing spectacular clusters of large crystals on the walls of the weighing bottle in which it was stored. A photograph of the crystals is shown in Fig. 1; the black strip on the outside of the weighing bottle is 1 cm in length. These crystals were hand-picked and analyzed (Table IX).

In order to determine the effect of solvent concentration on the value of x, a number of preparations of the methyl borate – piperidine – methanol compound were made, by adding 5 ml of piperidine to 5 ml of methyl borate dissolved in 1–10 ml of methanol. The results, given in Table VIII, will be discussed later.

Sublimed Crystals

The n and x values for large sublimed crystals, which were hand-picked and analyzed, are compared in Table IX with the corresponding values for the fine crystals from which they were grown.

Triphenyl Orthoborate – Ammonia Compounds

Results for compounds involving triphenyl orthoborate, ammonia, and solvent are summarized in Table VII. The amounts of pentane, benzene, and methylene chloride incorporated are much larger than with the trimethyl orthoborate – amine compounds. Furthermore, n is nearer 2 than 1, in accord with the work of Colclough, Gerrard, and Lappert (10), who found $n = 2$ for the pure compound triphenyl orthoborate – ammonia.

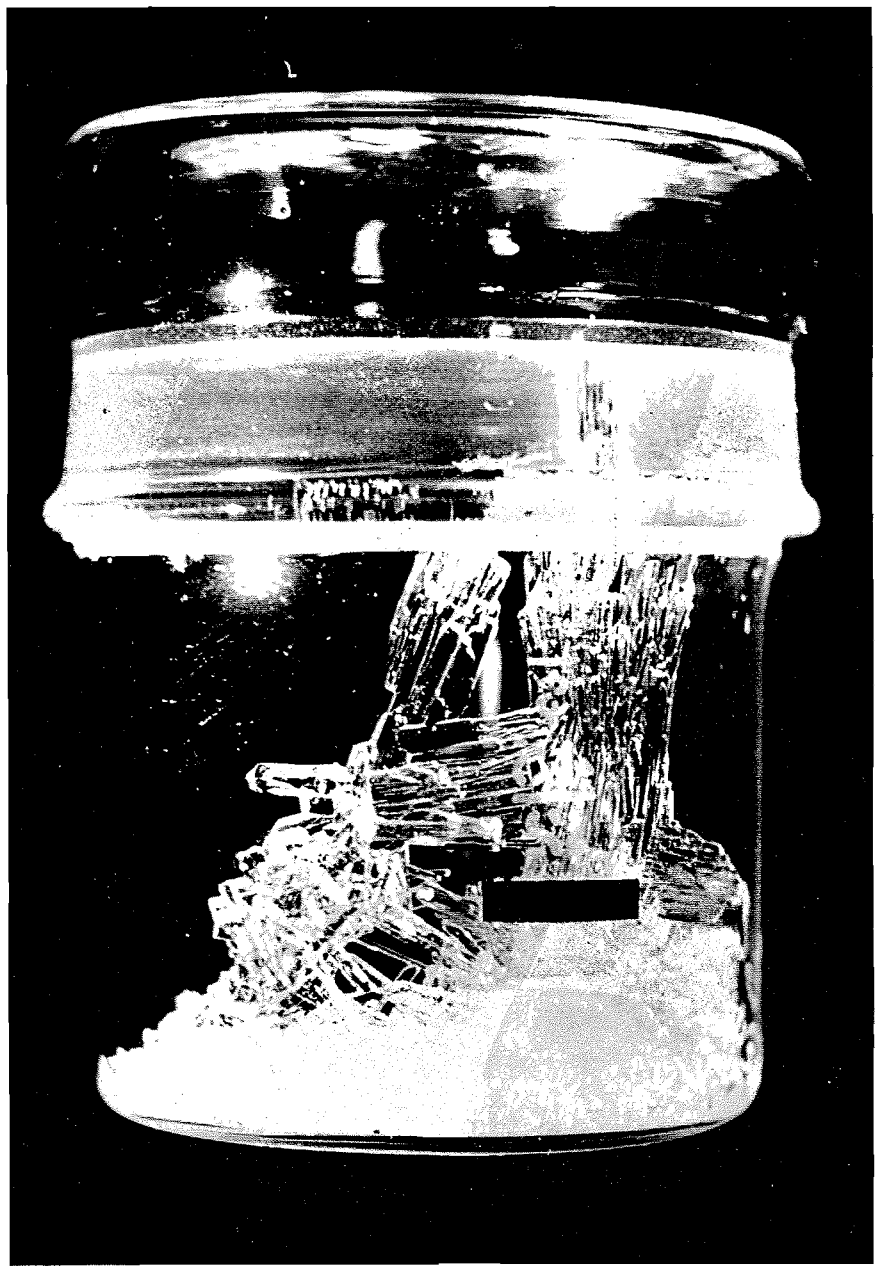

FIG. 1. Sublimed crystals of the trimethyl orthoborate – dimethylamine – methanol compound. The black strip is 1 cm long.

CH_2Cl_2	5.90	2.54	1.80	1.24	84–88

DISCUSSION

In the absence of any detailed physicochemical or crystallographic information on the pure inclusion-free borate–amine compounds, there is little hope of being able to give a satisfactory interpretation of the mass of results obtained in this work. It may be worthwhile, however, to assemble the facts which theory must eventually explain.

The most striking feature of the compounds is that they are non-stoichiometric with respect to the B:N ratio. Thus with trimethyl orthoborate – ammonia – heptanol, n is as low as 0.35, while with the first member of the same series, trimethyl orthoborate – ammonia – methanol, $n = 1.16$. Triphenyl orthoborate – ammonia inclusion compounds also exhibit wide variations in n.

Considering now the values of x, it must be borne in mind that this parameter is sensitive to the method of preparation and time of drying with suction on the filter. In a number of instances, x and n have been determined as a function of time of drying. In all cases, long drying causes a decrease in x, but n remains constant. Care was therefore taken to prepare the compounds under similar conditions; indeed, duplicate preparations have shown x and n to be fairly reproducible.

The series trimethyl orthoborate – ammonia – alcohol (Table I) merits detailed examination, because it is the largest group and exhibits the widest range of x and n values. The results indicate a rough correlation between x and n, as shown in Fig. 2. Excluded from this graph are the data for ethanol, which exhibits an abnormally high affinity for trimethyl orthoborate – ammonia, the results for the methanol compound prepared using liquid ammonia, and those for the resublimed compounds. It should be emphasized that in all cases a constant volume of solvent was used. If the value of x is a function of the mole fraction of the solvent in the mixture during precipitation, more meaningful values of x might have obtained if in all preparations a constant initial mole fraction of solvent had been used.

In order to determine the dependence of x on the mole fraction of solvent in the mixture at the start of the reaction, a series of preparations of the compound $(CH_3O)_3B.(\text{piperidine})_n.(\text{methanol})_x$ was made, using varying amounts of methanol. This system was selected because liquid amines form adducts more rapidly than gaseous amines and because moderately dry crystals with high x values could be obtained. The variation of x with the amount of methanol used followed no regular pattern in this case (Table VIII). However, the results are of unusual interest in that they show very clearly the relation between x and n (see Fig. 3) and confirm the correlation inferred from Fig. 2.

If the incorporated solvent molecules occupy holes in the trimethyl orthoborate – amine crystal lattice, one would expect x to be high for small molecules and zero for large ones. This general behavior is found in the series trimethyl orthoborate – ammonia – alcohol. In Fig. 4, the value of x is plotted against the number of carbon atoms in the

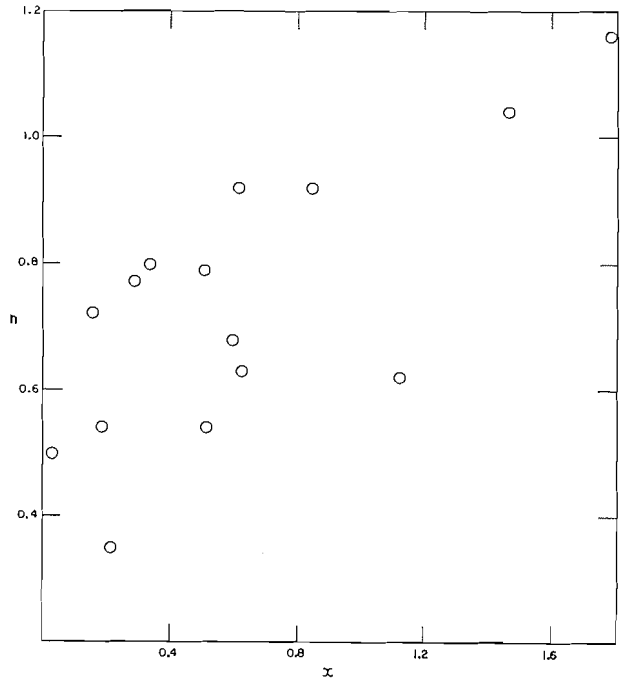

FIG. 2. Plot of n versus x for the series of compounds $(CH_3O)_3B.(NH_3)_n.(alcohol)_x$.

TABLE VIII

$(CH_3O)_3B.(piperidine)_n.(MeOH)_x$

(Prepared by adding 5 ml of piperidine to 5 ml of trimethyl orthoborate dissolved in methanol)

MeOH (ml)	% N	% B	n	x

7	6.34	5.16	0.95	0.78
10	6.45	5.54	0.90	0.47

alcohol, for primary straight-chain alcohols. Since it has been shown that x does not exhibit a systematic variation with the mole fraction of alcohol in the mixture (see above), the results in Fig. 4 may be cited as partial evidence for this "molecular sieve" effect.

The marked tendency of the trimethyl orthoborate – amine inclusion compounds to sublime is most probably due to dissociation, migration of the volatile components through the vapor space, and reassociation on the cooler parts of the vessel. The same behavior has been found with pure trimethyl orthoborate – ammonia. It is interesting to note (Table IX) that the sublimed crystals have substantially higher values of n and x than

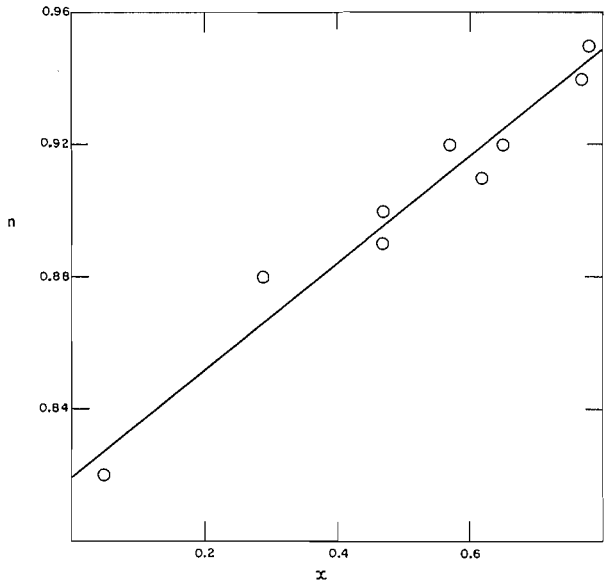

FIG. 3. Plot of n versus x for the series of compounds $(CH_3O)_3B.(piperidine)_n.(CH_3OH)_x$.

TABLE IX

Amine	Incorporated solvent	Original crystals		Large sublimed crystals	
		n	x	n	x

	n-Decanol	0.72	0.16	0.93	0.24
	$1,1\text{-}(CH_3O)_2C_2H_4$	0.78	0.66	0.90	0.71
Monomethyl	Methanol	0.83	0.67	0.78	0.60
	n-Hexanol	0.97	0.95	0.97	0.95
Diethyl	Methanol	1.01	1.23	0.98	1.02

the original crystals, when ammonia is the amine, whereas with methylamine and diethylamine n and x are unchanged or lower than in the original crystals.

From the behavior of the CF_2Cl_2 inclusion compound it is clear that CF_2Cl_2 is incorporated into the crystal lattice of trimethyl orthoborate – ammonia in such a way that it is in equilibrium with a definite partial pressure of CF_2Cl_2, as if it were adsorbed on charcoal, for example. The same undoubtedly holds true for the other incorporated solvents. The problem of measuring this equilibrium partial pressure is complicated, however, by the fact that trimethyl orthoborate and the amine also exert appreciable equilibrium partial pressures. If a compound could be prepared from an involatile orthoborate ester and an involatile amine, this solid could be treated as the sorbent and the solvent to be incorporated as the sorbate, sorption isotherms could be measured, and the thermodynamic functions for the system calculated in the usual way.

The melting points of the inclusion compounds are thought to be dissociation temperatures rather than true melting points; therefore little significance is attached to the fact that those for the trimethyl orthoborate – ammonia compounds lie close to that (72° C) reported by Goubeau and Link (5) for the pure compound trimethyl orthoborate – ammonia. In contrast, the melting point of the methylene chloride inclusion compound

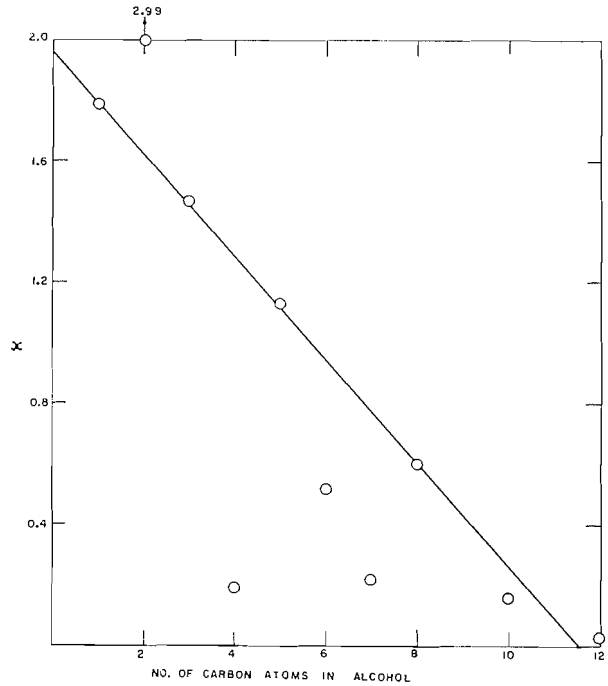

FIG. 4. Dependence of x on the number of carbon atoms in the alcohol, for the series of compounds $(CH_3O)_3B.(NH_3)_n.(\text{alcohol})_x$.

of triphenyl orthoborate – ammonia (84–88°) is much lower than the value (125°) reported for the pure adduct (10).

The finding that alkanes are not occluded by trimethyl orthoborate – ammonia and trimethyl orthoborate – methylamine forms the basis for a proposed method (13) for making these compounds, free from incorporated solvent, avoiding the disadvantages of the vapor phase method (1). It is interesting to note that, although the alkanes are not incorporated, the crystal growth of the pure amine compounds prepared from alkane solutions depends on the nature of the alkane. Thus (Table II), crystals of trimethyl orthoborate – ammonia prepared in 2-methylbutane or *n*-heptane show a pronounced tendency for crystal growth, whereas those prepared in other alkanes do not. In all these cases $x = 0$ within experimental error. The same general behavior is exhibited with trimethyl orthoborate – methylamine compounds prepared from alkane solutions (Table V).

Preliminary X-ray diffraction measurements on some trimethyl orthoborate – ammonia inclusion compounds have indicated that the crystal lattice is essentially the same as that of pure trimethyl orthoborate – ammonia, confirming the idea that the included solvent molecules occupy holes in the crystal lattice.

ABSTRACT

A galactomannan containing D-galactose (16%) and D-mannose (84%) has been isolated from the water-soluble polysaccharides of *Trichophyton granulosum*. Methylation studies showed that the structure was highly branched, the predominant structural feature being a chain of α-D-mannopyranose units joined together by an equal number of $1 \rightarrow 2$ and $1 \rightarrow 6$ linkages. About 22% of the D-mannose units were doubly substituted at positions 2,6; 2,4; and 2,3 to form branch points. The branches were terminated by D-mannopyranose and D-galactofuranose residues, the latter accounting for all of the D-galactose present in the polysaccharide.

An earlier investigation (1) showed that the skeleton of the cell wall of dermatophytes is made up of chitin, a water-insoluble polysaccharide. However, the cells of these organisms also contain other polysaccharides which, when isolated, are soluble in water. These water-soluble polysaccharides are of considerable immunochemical importance because Bloch *et al.* (2) have shown them to be an essential part of "trichophytin". The latter is an antigenic material derived from cultures of dermatophytes and is used clinically in diagnostic skin tests.

Water-soluble polysaccharides from a number of dermatophytes have now been isolated as part of a program to determine if species differences occur and to test their antigenic properties. The present paper describes the isolation and constitution of the first of these to be studied, a water-soluble polysaccharide from *Trichophyton granulosum* Sabouraud, 1909.

A crude mixture of polysaccharides was isolated in 10% yield from powdered cells of *T. granulosum* by the procedure given in the experimental section. The product contained no nitrogen and hence was free from any proteinaceous material. On hydrolysis the mixture yielded large amounts of mannose with smaller amounts of glucose and galactose. Examination of the crude polysaccharides by moving-boundary electrophoresis in borate buffer (3) gave the separation pattern shown in Fig. 1A. In both separations shown in Fig. 1 the non-migrating peak was shown to be a false boundary. The peak of greatest mobility in Fig. 1A was sharp and symmetrical and obviously represented the major polysaccharide component of the mixture. The less mobile peak in Fig. 1A was low, broad,

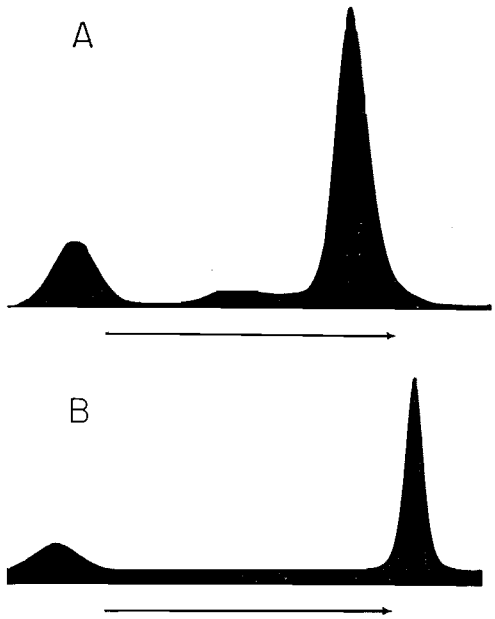

FIG. 1. Moving-boundary electrophoresis of polysaccharides from *T. granulosum*: A. Crude polysaccharides. B. Purified galactomannan (fractions 3+4, Fig. 2). Buffer: 0.05 *M* sodium tetraborate.

and diffuse, indicative of heterogeneity, and showed that the major polysaccharide was admixed with probably more than one minor component.

The mixture of polysaccharides was resolved by chromatography on diethylaminoethyl (DEAE) cellulose (4) into two fractions, as shown in Fig. 2; fractions 2 and 4 proved to be the same as fractions 1 and 3 respectively. On electrophoresis fractions 1+2 gave a broad, diffuse peak corresponding in mobility to the minor component in

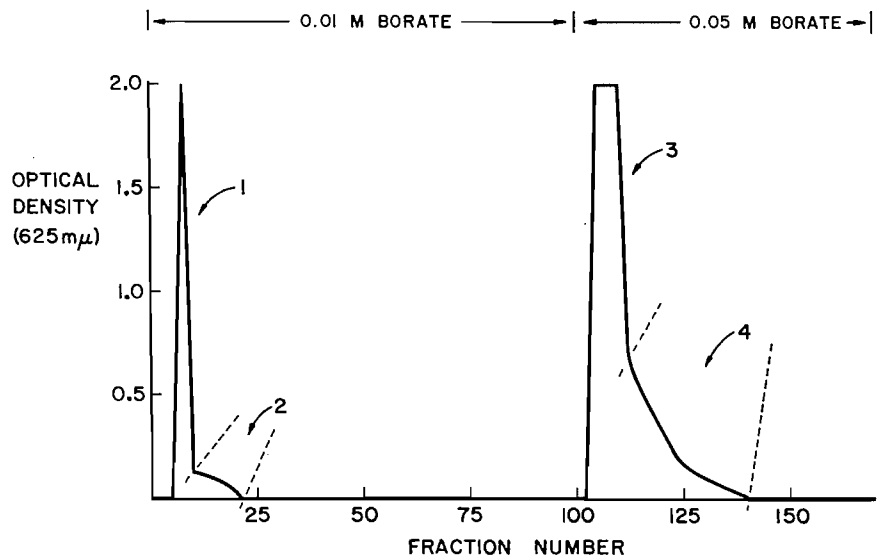

FIG. 2. Separation of *T. granulosum* polysaccharides on DEAE cellulose.

Fig. 1A and on hydrolysis yielded approximately equal amounts of glucose, galactose, and mannose. Fractionation of fractions 1+2 in ethanol–water mixtures yielded a small amount of material which gave only glucose on hydrolysis, and other fractions were enriched with respect to mannose and galactose. The material in fractions 1+2 was therefore a mixture of a glucan and a galactomannan or a glucogalactomannan. Fractions 3+4, Fig. 2, gave the electrophoresis pattern shown in Fig. 1B, and the single, sharp, symmetrical peak had the same mobility as the major component in Fig. 1A. Hydrolysis of fractions 3+4 yielded a large amount of mannose, a smaller amount of galactose, and a trace of glucose. Reprecipitation of this polysaccharide in 50% aqueous ethanol left the glucose-containing material in solution and yielded a pure galactomannan on which the balance of this work was done.

The galactomannan had a number-average degree of polymerization of 55 ± 1. On hydrolysis its specific rotation changed from $+71\pm1°$ to $+22\pm1.5°$, indicative of a predominance of α-glycosidic linkages. Three independent estimations of the monosaccharide composition gave the average values of 16% galactose and 84% mannose. Isolation of crystalline derivatives confirmed the identities of the two sugars and showed that both were present as the D-enantiomorphs.

The galactomannan was methylated and hydrolyzed; the *O*-methyl sugars in the hydrolyzate were isolated and estimated by a combination of gas–liquid chromatography (5, 6), liquid–liquid chromatography on cellulose (7), and paper electrophoresis (8). Thus, gas–liquid chromatography of the mixture of *O*-methyl sugars, as their methyl glycosides, gave the separation shown in Fig. 3. Although only one peak, the third,

3. Methyl 3,4-di-*O*-methyl-α-D-mannoside (1).

1 part

4. Methyl 3,6-di-*O*-methyl-α-D-mannopyranoside (1).
   Methyl 4,6-di-*O*-methyl-α-D-mannoside (1).

represented a single compound, this separation provided the overall quantitative ratio of di- to tri- to tetra-*O*-methyl hexosides as 2:5:2. The tetra-*O*-methyl hexoses were separated from the other components and from each other by liquid–liquid chromatography on cellulose, which gave 2,3,4,6-tetra-*O*-methyl-D-mannose (1 part) and 2,3,5,6-tetra-*O*-methyl-D-galactose (3 parts); both compounds were identified by formation of crystalline derivatives. The tri-*O*-methyl hexoses were separated from the other components but not from each other by liquid–liquid chromatography on cellulose. However,

paper electrophoresis of the tri-*O*-methyl fraction yielded 3,4,6-tri-*O*-methyl-D-mannose (1 part) and 2,3,4-tri-*O*-methyl-D-mannose (1 part), both of which were identified as crystalline derivatives. Individual components in the di-*O*-methyl fraction could not be resolved by paper chromatography or paper electrophoresis. They were separated by gas–liquid chromatography under the conditions given in Fig. 4. A portion of the 3,4-di-

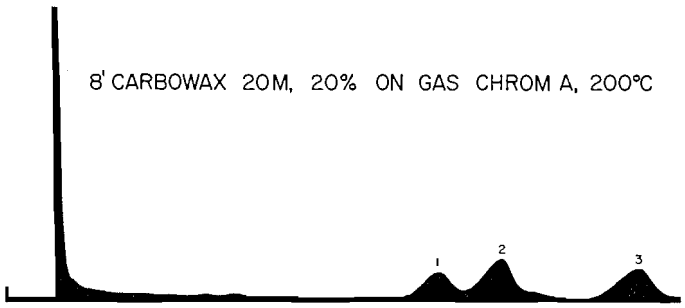

FIG. 4. Gas–liquid chromatogram of methyl-di-*O*-methyl-α-D-mannosides from methylated galactomannan of *T. granulosum*.

2 parts
1. Methyl 3,4-di-*O*-methyl-α-D-mannoside.

1 part
2. Methyl 3,6-di-*O*-methyl-α-D-mannopyranoside.

1 part
3. Methyl 4,6-di-*O*-methyl-α-D-mannoside.

O-methyl-D-mannose had crystallized from the di-*O*-methyl fraction and was removed for identification prior to this separation. This did not disturb the quantitative data because the ratio of 3,4-di-*O*-methyl-D-mannose to the other components was established by the separation shown in Fig. 3. Identifications of the three components shown in Fig. 4 were based on the following evidence. The di-*O*-methyl fraction obtained from chromatography on cellulose yielded 2,3,4,6-tetra-*O*-methyl-D-mannose exclusively on complete methylation, thus limiting the possibilities to di-*O*-methyl-D-mannopyranoses. The di-*O*-methyl fraction migrated as one component on paper electrophoresis and its mobility (M_G 0.38) showed that all components had a free hydroxyl at C_2. The three components shown in Fig. 4 were collected from the effluent gas stream and the first was identified as crystalline methyl 3,4-di-*O*-methyl-α-D-mannoside. The other two components then had to be the glycosides of 3,6- and 4,6-di-*O*-methyl mannose because these were the only possible remaining di-*O*-methyl mannopyranoses with a free hydroxyl at C_2. Distinction between the two possibilities was made by periodate oxidation of the glycosides collected from the gas–liquid chromatogram. The glycoside from peak 2 was resistant to periodate oxidation and was therefore the 3,6-di-*O*-methyl isomer; the compound from peak 3 was readily oxidized by periodate and was therefore the glycoside of 4,6-di-*O*-methyl-D-mannose. The separation shown in Fig. 4 gave a ratio of 3,6- to 4,6-di-*O*-methyl-D-mannoses of 1:1. Figure 3 showed that the amount of 3,4-di-*O*-methyl-D-mannose was equivalent to the sum of the other di-*O*-methyls. The ratio of 3,4- to 3,6- to 4,6-di-*O*-methyl-D-mannose was therefore 2:1:1.

Table I contains a summary of the methylation results which give some idea of the gross structure of the polysaccharide. The predominant feature was a chain of D-mannose units joined together by an equal number of $1 \rightarrow 2$ and $1 \rightarrow 6$ linkages. The polysaccharide was highly branched with about 22% of the D-mannose units being doubly substituted at positions 2,6; 2,4; and 2,3: the branches were terminated by D-manno-

TABLE I

Hydrolysis products from methylated galactomannan of *T. granulosum*

3,4,6-Tri-*O*-methyl-D-mannose	5
3,4-Di-*O*-methyl-D-mannose	2
3,6-Di-*O*-methyl-D-mannose	1
4,6-Di-*O*-methyl-D-mannose	1

pyranose and D-galactofuranose residues. A polysaccharide such as that just described should consume 1.39 moles of periodate with production of 0.33 mole of formic acid per mole anhydrohexose unit. When the galactomannan was oxidized by periodate the results indicated extensive overoxidation and the data did not permit a valid extrapolation. The overoxidation was probably caused by α-hydrogen oxidation in the malondialdehyde-type structure (9) which would be formed by oxidation of the terminal D-galactofuranoside residues. The units giving rise to the methyl ethers in Table I could, of course, be joined together in many different ways. Fragmentation analysis is required to provide more detailed information, such as the sequence of $1 \rightarrow 2$ and $1 \rightarrow 6$ linkages along the mannan chain and the size of the branches.

The galactomannan from *T. granulosum* appears to be unique among the naturally occurring polysaccharides of this type. In the plant kingdom galactomannans occur most widely in the endosperms of the *Leguminosae* and have the general structure of a chain of $1 \rightarrow 4$ linked β-D-mannose units, some of which are substituted at the C_6 position by single α-D-galactopyranose residues (10). To the authors' knowledge, the polysaccharide from *T. granulosum* is the first galactomannan to be isolated from a microorganism but some of its structural features can be related to those occurring in other microbial polysaccharides. Thus, the mannan chain bears some resemblance to the mannan isolated from *Candida albicans* (11) in having both $1 \rightarrow 2$ and $1 \rightarrow 6$ but no $1 \rightarrow 3$ linkages. This absence of $1 \rightarrow 3$ linkages serves to distinguish both of these polysaccharides from the mannans isolated from *Saccharomyces cerevisiae* (12–14) and *Saccharomyces rouxii* (15).

The occurrence of all of the galactose units as terminal non-reducing furanoside residues was another distinguishing feature of the galactomannan from *T. granulosum*. D-Galactose appears to have been found in the furanose form in only three other polysaccharides, galactocaralose from *Penicillium charlesii* (16), an extracellular polysaccharide from *Gibberella fujikuroi* (= *Fusarium moniliforme*) (17), and the specific substance from type 34 *Pneumococcus* (18).

EXPERIMENTAL

Paper chromatograms were run by the descending method using the following solvent systems (v/v):

(A) pyridine:ethyl acetate:water—1:2.5:2.5 (upper phase);

(B) butanone saturated with water;

(C) *n*-butanol:ethanol:water—3:1:1;

(D) benzene:ethanol:water:concentrated ammonium hydroxide—200:47:14:1 (upper phase).

Paper electrophoreses (8) were done on Whatman 3 MM paper in 0.1 *M* sodium tetraborate at 750 v (potential gradient, 25 v/cm) and 25–40 ma for 2 1/2 hours. Unsubstituted sugars were detected on paper chromatograms by silver nitrate – sodium hydroxide sprays (19); methylated sugars were detected on the papers by the *p*-anisidine hydrochloride spray reagent (7). Gas–liquid chromatography (5, 6) was done on a Pye

Argon Chromatograph equipped with an ionization detector and on an F and M Model 500 Chromatograph which had a thermal-conductivity detector. All evaporations were at 35–40° C under diminished pressure; melting points are corrected; specific rotations are equilibrium values unless otherwise specified. R_g values represent movement relative to 2,3,4,6-tetra-*O*-methyl-D-glucose on paper chromatograms and M_G values refer to movement relative to glucose on paper electrophoresis.

Isolation of Crude Polysaccharides

Trichophyton granulosum was grown in 500-ml Erlenmeyer flasks containing 250–300 ml of a liquid medium consisting of the following nutrients: 4% maltose (technical grade), 1% neopeptone "Difco", 0.05% yeast extract "Difco", 0.001% thiamine, 0.005% inositol made up in tap water. The incubation period was 3–4 weeks at 25° C, after which the cultures were autocalved at 121° C for 20 minutes. The mycelium was collected and washed three times in boiling water to remove adhering medium. The washed mycelium was freeze-dried, ground in a ball mill, and extracted continuously with light petroleum (b.p. 30–60° C) in a Soxhlet apparatus for 8 days. The extracted mycelium (730 g) was suspended in 0.8% aqueous sodium carbonate (8500 ml) and the pH of the mixture was adjusted to 8.1 by addition of *N* hydrochloric acid. Trypsin (3.0 g, "Difco") was added to the mixture, which was then protected from contamination by a layer of toluene (10 ml per flask). The trypsin digests (four equal lots) were kept at 37° C and were shaken vigorously once every 24 hours during an incubation period of 14 days. The insoluble residue was centrifuged, washed three times with distilled water, and freeze-dried. Crude polysaccharides were removed from the freeze-dried material (510 g) by extraction with hot, 3% aqueous sodium hydroxide (10,200 ml) for 15–16 hours. The extract was clarified by centrifugation, neutralized with acetic acid, and dialyzed to remove salts and other low molecular weight impurities. The non-dialyzable polysaccharides were precipitated by ethanol, dissolved in water, reprecipitated, and dried by solvent exchange with ethanol, ether, and light petroleum (b.p. 30–60° C). The polysaccharide preparation thus obtained was a light tan powder (10% of the dried, powdered mycelium) which contained no nitrogen, as shown by microanalysis. A sample (5 mg) of this material was hydrolyzed by *N* sulphuric acid (0.5 ml) at 97° C in a sealed tube for 12 hours. Paper chromatography (solvent A) of the hydrolyzate showed the presence of a large amount of mannose with smaller amounts of glucose and galactose. Another sample (150 mg) of the polysaccharide preparation was dissolved in 0.05 *M* sodium tetraborate, equilibrated with the buffer by dialysis, and examined by moving-boundary electrophoresis (3). Figure 1A shows the separation obtained by this procedure. The first peak was a false boundary because the removal and hydrolysis of a sample yielded no sugars. The second peak was broad and diffuse, indicative of heterogeneity; it had an average mobility (μ) of 8.33×10^{-5} cm²/volt sec. The peak of greater mobility ($\mu = 11.28\times10^{-5}$ cm²/volt sec) was sharp and symmetrical and obviously represented the major component of the mixture.

Purification of Galactomannan

The mixture of crude polysaccharides (300 mg) was resolved on a column (32×3 cm) of diethylaminoethyl (DEAE) cellulose by stepwise elution with increasing concentrations of sodium tetraborate (4). Fractions (18 ml each) were collected automatically every 15 minutes; aliquots (1 ml) of each fraction were mixed with 2 ml of anthrone reagent (0.5% anthrone in 95% sulphuric acid) and the optical densities at 625 mμ were read on a colorimeter. Figure 2 shows the result of this separation, which gave four fractions. Each fraction was passed over Amberlite IR-120 exchange resin to remove sodium ions and was then evaporated until boric acid began to crystallize. Six volumes of methanol were then added and the precipitated polysaccharides were washed successively with methanol, ethanol, ether and were then dried. This procedure yielded fractions 1 (76.2 mg), 2 (16.3 mg), 3 (128.2 mg), and 4 (25.8 mg); recovery, 246.5 mg, 82%. The losses were accountable in part by the 5.5% of each fraction of eluate used for the anthrone test and in part by the irreversible absorption of highly pigmented impurities on the DEAE cellulose. The recovered polysaccharides were white, water-soluble powders and yielded the following sugars on hydrolysis, as shown by paper chromatography (solvent A): fractions 1 and 2—glucose, mannose, galactose; fractions 3 and 4—mannose, galactose, trace of glucose. On moving-boundary electrophoresis under the conditions described above, fractions 1+2 gave a broad, diffuse peak corresponding in mobility to the minor component shown in Fig. 1A. Fractions 3+4, under the same conditions, gave a sharp symmetrical peak (Fig. 1B) which had the same mobility as the major component in Fig. 1A. The above results showed that fractions 2 and 4 were the same as fractions 1 and 3 respectively and probably represented the normal elution pattern of these polysaccharides from DEAE cellulose.

The separation was repeated a sufficient number of times on a larger scale (2 g of crude polysaccharide on a column (7.6×50 cm) of DEAE cellulose, 230 g) to yield 5.0 g of fractions 3+4. Reprecipitation of this product from aqueous solution by addition of ethanol to a concentration of 50% yielded a pure galactomannan; the trace of glucose-containing material remained in solution. The number-average degree of polymerization of the galactomannan was 55±1 based on estimation of reducing end group by hypoiodite oxidation (20).

Estimation and Identification of Constituent Sugars

A sample (64.0 mg) of the galactomannan in *N* hydrochloric acid (5 ml) showed an initial specific rotation of +71±1°. When this solution was heated at 85° C the specific rotation changed to a constant value of

+22±1.5° after 11 hours. The calculated specific rotation for a mixture containing 13% galactose and 87% mannose is +22.7°. The sugars in the hydrolyzate were resolved by paper chromatography (solvent A) and estimated by the phenol–sulphuric acid method (21), which gave 18% galactose, 82% mannose. The amounts of *O*-methyl mannose and galactose derivatives (Table I) from hydrolysis of the methylated polysaccharide showed 16.5% galactose and 83.5% mannose. The average of these three estimations was 16% galactose, 84% mannose.

The two sugars in a hydrolyzate of 100 mg of the polysaccharide were isolated by preparative paper chromatography (solvent A), and identified as D-galactose and D-mannose by preparation of the phenylosazone (22), m.p. and mixed m.p. 194–196° C, and the *p*-nitroanilide (23), m.p. and mixed m.p. 217–218° C, respectively.

Methylation of Galactomannan

Galactomannan (3.0 g) was methylated five times by dimethyl sulphate and 30% sodium hydroxide (24). The partially methylated product (2.96 g), isolated by extraction into chloroform, was methylated three times by silver oxide and methyl iodide (25) to yield a product (2.6 g; OCH_3, 41.5%) showing weak hydroxyl absorption in its infrared spectrum. A portion of this material was insoluble in absolute ethanol and was removed by centrifugation. The ethanol solution was then evaporated to dryness and a small oily impurity was removed from the residue by extraction with hot light petroleum (b.p. 30–60° C). The residue from this extraction was the fully methylated galactomannan, a cream-colored powder; 2.23 g, $[\alpha]_D^{25}$ +42 ±1° (*c*, 2.3% in chloroform); OCH_3, 44.8%; calc. OCH_3, 45.6%.

Hydrolysis Products from Methylated Galactomannan

The methylated galactomannan (2.1 g) was dissolved in ice-cold 72% sulphuric acid (16 ml) and the solution was left at room temperature for 45 minutes. Water (112 ml) was added and the solution (now 12% sulphuric acid) was heated on a boiling-water bath for 4 hours (26). Acid was removed by Amberlite IR-45 exchange resin and the neutral solution was evaporated to dryness. A portion of the residue was refluxed with 2% methanolic hydrogen chloride for 6 hours and the solution was then neutralized with silver carbonate. The methyl glycosides in this solution were examined by gas–liquid chromatography to give the separation shown in Fig. 3. Subsequent identifications of the components showed that all but one of the peaks in Fig. 3 represented more than one compound. However, the areas of the peaks, determined by triangulation, gave the gross quantitative ratios of di- to tri- to tetra-*O*-methyl sugars as 2:5:2. Detailed quantitative ratios of individual components within each of these groups were obtained as described below.

The mixture of reducing *O*-methyl sugars was chromatographed in solvent B on a column of powdered cellulose to yield the following fractions:

Fraction 1

Fraction 1, 160 mg, gave R_g values (1.04, 0.99, and 1.07 in solvents B, C, and D respectively) identical with those given by an authentic sample of 2,3,5,6-tetra-*O*-methyl-D-galactose prepared by methylation and hydrolysis of methyl β-D-galactofuranoside (27), m.p. 66–67° C, $[\alpha]_D^{25}$ −113.5±1.0° (*c*, 2.94% in water). Oxidation by bromine yielded a lactone having an infrared spectrum identical in all respects with that of authentic 2,3,5,6-tetra-*O*-methyl-D-galactonolactone. Both spectra showed carbonyl absorption at 1775 cm^{-1} indicative of 5-membered (1765–1790 cm^{-1}), as opposed to 6-membered (1726–1760 cm^{-1}), lactone rings (28). The lactone yielded an amide which, after three recrystallizations from acetone, had $[\alpha]_D^{25}$ +7.7±1.0° (*c*, 4.92% in water) and a melting point of 157–158° C, unchanged on admixture with an authentic sample of 2,3,5,6-tetra-*O*-methyl-D-galactonamide (29).

Fraction 2

Fraction 2, 50.7 mg, contained two components with R_g values (1.04 and 0.98) in solvent B the same as those of 2,3,5,6-tetra-*O*-methyl-D-galactose and 2,3,4,6-tetra-*O*-methyl-D-mannose respectively. The two compounds were separated by preparative paper chromatography and the amounts obtained gave a ratio of 4 parts 2,3,5,6-tetra-*O*-methyl-D-galactose to 1 part 2,3,4,6-tetra-*O*-methyl-D-mannose.

Fraction 3

Fraction 3, 60.3 mg, contained one component with R_g values (0.98, 0.99, and 1.00 in solvents B, C, and D respectively) the same as those of 2,3,4,6-tetra-*O*-methyl-D-mannose and had $[\alpha]_D^{27}$ +44.7±0.6° (*c*, 3% in methanol). The derived anilide, recrystallized from ether:methanol (98:2), had $[\alpha]_D^{27}$ −11±2° (*c*, 0.88% in methanol) and a melting point of 146–147° C, unchanged on admixture with N-phenyl-2,3,4,6-tetra-*O*-methyl-D-mannosylamine (30).

Portions of fractions 1 and 3 were converted to their methyl glycosides by methanolic hydrogen chloride and examined by gas–liquid chromatography under conditions given in Fig. 3. The two sugars were not separated under these conditions and had the same retention time as peak 1, Fig. 3. The quantitative ratio of 3 parts 2,3,5,6-tetra-*O*-methyl-D-galactose to 1 part 2,3,4,6-tetra-*O*-methyl-D-mannose was obtained from the relative amounts of fractions 1, 2, and 3. Thus, 2,3,5,6-tetra-*O*-methyl-D-galactose = fraction 1 (160 mg) + 4/5 fraction 2 (4/5×50.7) = 200 mg and 2,3,4,6-tetra-*O*-methyl-D-mannose = fraction 3 (60.3 mg) + 1/5 fraction 2 (1/5×50.7) = 70.4 mg (ratio = 2.84:1).

Fraction 4

Fraction 4, 249 mg, showed only one spot on paper chromatograms in solvents B and C (R_g values 0.72 and 0.88 respectively) but gave two spots, not separated completely, of R_g 0.58 and 0.47 in solvent D.

Paper electrophoresis gave a separation of two components with M_G values of 0.00 and 0.31. Methylation (31) and hydrolysis of the mixture yielded only 2,3,4,6-tetra-*O*-methyl-D-mannose, as shown by chromatography in solvent B. R_g values in this solvent were 2,3,5,6-tetra-*O*-methyl-D-galactose (1.04), 2,3,4,6-tetra-*O*-methyl-D-mannose (0.98), and 2,3,4,6-tetra-*O*-methyl-D-galactose (0.81). Both components were therefore mannopyranose derivatives and the R_g values indicated that they were tri-*O*-methyl mannoses. Since the component with M_G 0.31 probably had a free hydroxyl at C_2 the mixture was seeded with crystalline 3,4,6-tri-*O*-methyl-D-mannose, which induced crystallization of that component. Crystallization from ether:hexane (2:1) yielded three crops of crystals which were combined and recrystallized from the same solvent to yield 3,4,6-tri-*O*-methyl-D-mannose (32), m.p. and mixed m.p. 102–104° C, $[\alpha]_D^{25}$ +36±1° (*c*, 1.15% in methanol).

The component with M_G 0.00 was separated from the 3,4,6-tri-*O*-methyl-D-mannose remaining in the mother liquors from the above crystallization by preparative paper electrophoresis (Whatman 3 MM paper 14×46 cm). The area of the paper containing the non-migrating component was eluted with water and the eluate was passed over Amberlite IR-120 exchange resin and evaporated. Boric acid was removed from the residue by repeated evaporation with methanol. The sirupy product was oxidized by bromine to yield a lactone which showed carbonyl absorption at 1715 cm^{-1} in its infrared spectrum, indicative of a 6-membered lactone ring (28). The lactone yielded an amide which was recrystallized from ethyl acetate and had m.p. 142–143° C, $[\alpha]_D^{25}$ = +4.5±1° (*c*, 1.3% in water), in good agreement with the reported values for 2,3,4-tri-*O*-methyl-D-mannonamide (33).

Small samples of 3,4,6- and 2,3,4-tri-*O*-methyl-D-mannose were refluxed with 2% methanolic hydrogen chloride for 6 hours and the products were examined by gas–liquid chromatography. The two components were not separated under conditions given in Fig. 3 and had the same retention time as peak 2. Small peaks from both of these samples had the same retention time as the small peaks following peak 2, Fig. 3. It is known that D-mannose yields predominantly the α-methyl glycoside on methanolysis and these small peaks were probably the β-anomers. The small amounts and the close similarity of their retention times precluded more positive identification.

The quantitative ratio (1:1) of the two tri-*O*-methyl-D-mannoses was established by the amounts recovered from a preparative paper electrophoresis carried out before crystallization of the 3,4,6-tri-*O*-methyl isomer. The two products were recovered as described above to yield 2,3,4-tri-*O*-methyl-D-mannose (14.9 mg) and 3,4,6-tri-*O*-methyl-D-mannose (14.1 mg) (ratio = 1.05:1.0).

Fraction 5

Fraction 5, 208 mg, showed one spot in solvents C and D (R_g 0.69 and 0.21 respectively) and a double spot (R_g 0.40 and 0.35) in solvent B. On paper electrophoresis the mixture migrated as an elongated spot with M_G 0.38 (center of spot). Methylation (31) and hydrolysis yielded only 2,3,4,6-tetra-*O*-methyl-D-mannose, as shown by chromatography in solvent B. The R_g values indicated di-*O*-methyl derivatives, the M_G value showed that there were free hydroxyls on C_2, and methylation proved that all components were derivatives of mannopyranose; this left only the 3,4-, 3,6-, and 4,6-di-*O*-methyl mannoses as possibilities. Peak 3, Fig. 3, had the same retention time as an authentic sample of methyl 3,4-di-*O*-methyl-α-D-mannoside so the mixture of reducing di-*O*-methyl mannoses was seeded with crystalline 3,4-di-*O*-methyl-D-mannose. The sirup crystallized partially and three crops of the product were obtained by crystallization from ethyl acetate. Recrystallization of this material from the same solvent yielded 3,4-di-*O*-methyl-D-mannose (15, 34), m.p. and mixed m.p. 71–73° C, $[\alpha]_D^{24}$ +32±1.5° (*c*, 1.55% in methanol).

The components in the mother liquors from crystallization of the 3,4-di-*O*-methyl-D-mannose were converted to their methyl glycosides and examined by gas–liquid chromatography. Under the conditions given for Fig. 4 a separation of three components was obtained and they were collected from the effluent gas stream. The material from peak 1, Fig. 4, crystallized when seeded with methyl 3,4-di-*O*-methyl-α-D-mannoside (13) and had m.p. and mixed m.p. 86–87° C. The material from peak 2, Fig. 4, was resistant to periodate oxidation when tested as follows. The compound was spotted on glass fiber paper, which was then sprayed with a saturated solution of sodium metaperiodate. The oxidation was allowed to proceed for 1 hour and the paper was then sprayed successively with acetonic silver nitrate and alcoholic sodium hydroxide (19), which showed up any oxidation products as dark brown spots. Because peak 1, Fig. 4, had been identified as the 3,4-di-*O*-methyl isomer, peak 2, Fig. 4, could only be the glycoside of 3,6- or 4,6-di-*O*-methyl-D-mannose. The negative periodate oxidation test showed that this component was the glycoside of 3,6-di-*O*-methyl-D-mannose. This compound does not appear to have been reported and attempts to prepare a crystalline derivative were unsuccessful. No crystalline osazone could be obtained from 2,3,6-tri-*O*-methyl-D-mannose and acetylation of the methyl 3,6-di-*O*-methyl-α-D-mannopyranoside yielded a sirupy product. Lack of sufficient material precluded attempts to prepare other derivatives.

The compound giving peak 3, Fig. 4, was readily oxidized by periodate under the test conditions described above, and by similar reasoning, was thereby proved to be the methyl glycoside of 4,6-di-*O*-methyl-D-mannose. An attempt to prepare 2,3-*O*-isopropylidine 4,6-di-*O*-methyl-D-mannose (35) from the reducing sugar did not yield sufficient material for characterization.

The glycosides of 3,6- and 4,6-di-*O*-methyl-D-mannose, as collected from peaks 2 and 3 respectively (Fig. 4) were not separable under the conditions cited in Fig. 3 and had the same retention time as peak 4, Fig. 3. No anomeric pairs were observed in these di-*O*-methyl mannosides and the α-configuration, proved for the 3,4-di-*O*-methyl isomer, was assumed for the other two.

Quantitative relationships between the three di-*O*-methyl mannoses were obtained from Figs. 3 and 4. Thus, the areas of peaks 3 and 4, Fig. 3, were in a 1:1 ratio (1 part of 3,4-di-*O*-methyl-D-mannose to 1 part 3,6- + 4,6-di-*O*-methyl-D-mannose). The separation in Fig. 4 showed that 3,6- and 4,6-di-*O*-methyl-D-mannose were present in a 1:1 ratio; some of the 3,4-di-*O*-methyl-D-mannose had been removed by crystallization from the mixture shown in Fig. 4. The overall ratio of 3,4- to 3,6- to 4,6-di-*O*-methyl-D-mannose was therefore 2:1:1.

The amounts of the five fractions recovered from the cellulose column gave a ratio of di- to tri- to tetra-*O*-methyl sugars of 1.00:1.25:1.3, which was different from that (2:5:2) obtained by gas–liquid chromatography. The recoveries from the cellulose column were regarded as unreliable, first because the above ratio, in disagreement with the results of gas–liquid chromatography, did not satisfy theoretical requirements and second because it would give a galactose content of 29% (4/5 of the tetra-*O*-methyl was galactose), quite different from the average value of 15.5% found by two other methods. There was no ready explanation for these anomalous recoveries from the cellulose column. However, it was apparent that compounds with hydroxyl groups (di-*O*- and tri-*O*-methyl isomers) were lost, possibly by irreversible adsorption on the particular batch of cellulose used. There was no evidence that a single isomer was lost preferentially and ratios of components within a single fraction were regarded as valid.

Periodate Oxidation

The galactomannan (118.9 mg, 0.734 mmole) was dissolved in water (125 ml), and 0.25 *M* sodium periodate (25 ml) was added. A reagent blank was also prepared and the oxidation was allowed to proceed at 25° C in the absence of light. At intervals samples were removed for estimation of formic acid by iodometric titration and of periodate by the excess arsenite procedure (36). The results, given below in moles per mole anhydrohexose unit, were indicative of extensive overoxidation.

Time (hr)	Formic	Periodate
72	0.57	1.05
96	0.63	1.58
144	0.68	1.85
168	0.72	2.05

ACKNOWLEDGMENT

The authors are grateful to Mr. F. P. Cooper for carrying out the gas–liquid chromatographic separations.

THE KINETICS OF THE ALKALINE HYDROLYSES OF DIMETHYL TEREPHTHALATE AND THE TRANS ISOMER OF DIMETHYL 1,4-CYCLOHEXANEDICARBOXYLATE IN DIOXANE–WATER MIXTURES[1]

W. J. Svirbely and Patricia A. Cunniff

Received March 29, 1962

ABSTRACT

The kinetics of the alkaline hydrolyses of dimethyl terephthalate and *trans*-dimethyl 1,4-cyclohexanedicarboxylate was studied in dioxane–water mixtures varying in dielectric constant from 60 to 11. The effect of the medium on the mechanism and rate constants is, in general, similar to that previously observed in the study of the alkaline hydrolyses of aliphatic diesters.

INTRODUCTION

Recently (1) a study was made on the effect of the medium on the rate constant ratios of diester hydrolysis. Three diesters in the aliphatic series differing markedly in length, namely, diethyl malonate, diethyl succinate, and diethyl sebacate, were used. It was observed that as the dielectric constant decreased (or as the dioxane content in dioxane–water media increased), the two rate constants in each of the two-step competitive–consecutive second-order reactions approached each other, i.e. the rate constant ratio in each diester reaction approached unity. The observations can be explained on the basis that both steps of each reaction are proceeding by essentially the same mechanism in low-dielectric media. This situation would arise if one were dealing under such circumstances with solvated ion pairs or aggregates. One would expect the same general variation in the rate constants for the alkaline hydrolyses of cyclic diesters in low-dielectric media if structural features did not complicate the picture.

Consequently, in order to determine the effect of the medium on the alkaline hydrolyses of cyclic diesters, studies were made of the alkaline hydrolysis of *trans*-dimethyl 1,4-cyclohexanedicarboxylate and of dimethyl terephthalate in dioxane–water mixtures varying in dielectric constant from 60 to 11.

EXPERIMENTAL

Materials and Apparatus

Dioxane, water, sodium hydroxide solutions, and hydrochloric acid solutions were prepared or purified as before (2).

The dimethyl terephthalate was obtained from Eastman Kodak Co. Two recrystallizations from diethyl ether yielded a product which melted at 139.6–140.4° (corr.). Literature values are 140.5–141° and 140°. The saponification equivalent indicated 99.9±0.1% purity.

The trans isomer of dimethyl 1,4-cyclohexanedicarboxylate was obtained from a cis–trans mixture furnished by the Eastman Kodak Co.[2] which had an approximate isomer concentration of 60% cis and 40% trans. The solid material was filtered from the mixture and recrystallized five times from petroleum ether, m.p. 69.1–69.4° (corr.). Further recrystallization did not produce a change in the melting point. The saponification equivalent indicated 99.9±0.1% purity.

Procedure

The procedure has been described (1).

[1]*Abstracted in part from a thesis by Patricia A. Cunniff to the Graduate School of the University of Maryland in partial fulfillment of the requirements for the degree of Master of Science.*

[2]*Acknowledgment is hereby made to the Eastman Kodak Company for their grant of two pounds of the mixture.*

DATA AND CALCULATIONS

Evaluation of Rate Constants

The alkaline hydrolyses of the diesters used in this research may be represented by the equations

$$A + B \xrightarrow{k_1} C + E$$

$$A + C \xrightarrow{k_2} D + E,$$

where A, B, C, and D represent hydroxyl ion, diester, monovalent ion of the ester, and divalent ion of the ester respectively. The procedure for calculating the rate constants, based on the Frost and Schwemer method (3), has been described (1). Tables I and II summarize the calculations for two of our runs. In some of our calculations, the Burkhard (4) extension of the τ (defined $= B_0k_1t$) and time-ratio tables of Frost and Schwemer were used.[3]

TABLE I

Data for the dimethyl terephthalate reaction at 25.22°;
$D = 25.82$; $A_0 = 11.055\times10^{-3}$ mole/l.; $B_0 = 5.527\times10^{-3}$ mole/l.

80.00	3.9909	0.3610	75.10	4.0433	0.3657
90.00	3.8511	0.3484	85.00	3.9559	0.3578
100.00	3.6589	0.3310	95.00	3.7638	0.3405

Table III summarizes the data at 25.22°. A_0 (starting hydroxide concentration) varied from 10.825×10^{-3} to 11.075×10^{-3} mole/l. in the various runs. Thus the data in Table III were obtained under essentially the same stoichiometric ionic strength conditions as far as the reactants were concerned. Solubility limitations prevented the study of the dimethyl terephthalate reaction over the same dielectric range as was used in the trans 1,4-cyclohexanedicarboxylate reaction.

Table III also summarizes the data obtained when KCl was added to the reaction mixtures.

[3]*In order to obtain the time-ratio derived data from the experimental data, values of α (defined as A/A_0) for duplicate runs were plotted against time on a large sheet of graph paper. From the resulting smooth curve, the times for fixed percentages of completion were determined. Time-ratios were then calculated from these times for the various percentages of reaction.*

	10.70	80	3.06	1.37	2.23			

*Duplicate runs were made in all cases. Average deviation from the mean of the $1/K$ values in each pair of runs was between 0.1% and 2.2%.
†Reading down the column, KCl added was = 0.1253 and 0.1398 mole/l. respectively.

DISCUSSION

Reference to Fig. 1 and to the literature (1) shows quite similar behavior in the effect of the medium on the rate constants obtained for the alkaline hydrolyses of cyclic diesters and aliphatic diesters in dioxane–water mixtures. These may be summed up as follows: (1) While there is a marked difference in the rate constants for the two steps of each reaction in high-dielectric media, this difference is markedly less in lower-dielectric media. (2) With the exception of the dimethyl terephthalate reaction, the curves of log k_2 vs. $1/D$ for the reactions go through a minimum in a narrow dielectric range, i.e. between 25 and 33. A minimum for the dimethyl terephthalate reaction could not be demonstrated because of solubility limitations. Our previous conclusion (1) "that this could be the point at which ion-pair formation becomes important and the second step of each reaction is changing from an ion–ion reaction to one involving ion-pairs" is thus also applicable to these cyclic diester reactions.

Since both of the diesters used in this research had, as substituents, the same electron-withdrawing groups, i.e. carbomethoxy groups, the larger values of k_1 obtained in the terephthalate reaction compared to the values of k_1 obtained in the cyclohexanedicarboxylate reaction can be accounted for by the assumption of greater electrophilicity of the carbonyl carbon atom in the terephthalate compound as the result of structural differences in the two ring structures. However, on examining the results for the second step

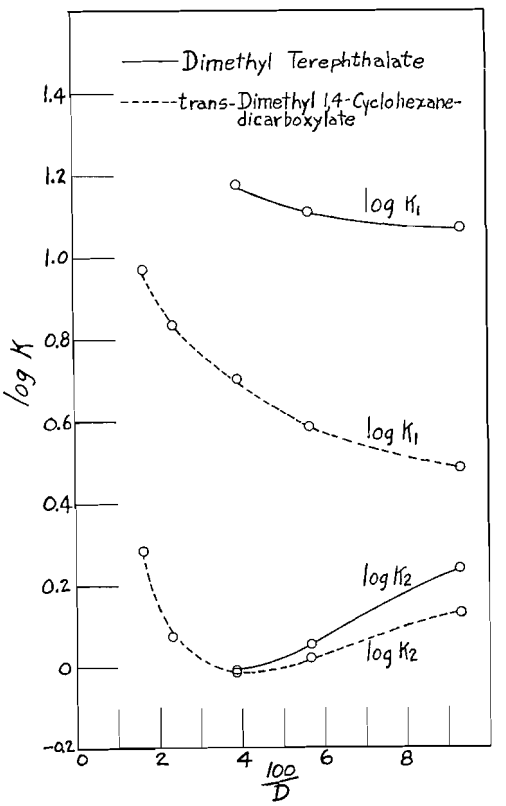

FIG. 1. Log K versus $100/D$ at 25.2°.

of each reaction, one observes that the k_2 values of the two esters are considerably closer to one another under similar environmental conditions. If structural differences can account for the differences in the k_1 values, they should also lead to differences in the k_2 values. Such is not the case. We can explain the above observations by the following argument. If one examines the k_2 values of aliphatic diesters (1) along with the k_2 values of the cyclic diesters, one observes that in low-dielectric media, i.e. $D \sim 11$, the magnitudes of the k_2 values are in the inverse order to the distances separating the substituents in the original compounds. If one assumes that an increase in electrophilicity of the carbonyl carbon atom in the second step of the reactions depends both on the distance between the residual charge on the so-called monovalent ion and its remaining carboxylate group and on the medium surrounding the ion rather than on any effect through the ion due to its structure, then one can rationalize the variation in the k_2 values. Since the residual charge on the so-called monovalent ion is affected by the extent of ion-pair or other aggregate formation, then a change in slope in the log k_2 vs. $1/D$ curve should occur as the composition of the medium is changed. This is in agreement with the observations.

THE HYDROGEN-ABSTRACTION REACTIONS IN THE PHOTOLYSIS OF PENTAFLUOROPROPANAL AND HEPTAFLUOROBUTANAL[1]

G. O. PRITCHARD, G. H. MILLER, AND J. K. FOOTE
Department of Chemistry, University of California, Santa Barbara, Goleta, Calif., U.S.A.

Received April 16, 1962

ABSTRACT

The main products of the photolysis of the aldehydes at 3130 Å were determined and the rates of H-atom abstraction relative to radical recombination were measured. They are $k_1/k_2^{\frac{1}{2}} = (3.09\pm0.12)10^3 \exp(-4500\pm200/RT)$ mole$^{-\frac{1}{2}}$cc$^{\frac{1}{2}}$sec$^{-\frac{1}{2}}$ for C_2F_5CHO, and $k_1/k_2^{\frac{1}{2}} = (1.86\pm0.14)10^3 \exp(-4000\pm300/RT)$ mole$^{-\frac{1}{2}}$cc$^{\frac{1}{2}}$sec$^{-\frac{1}{2}}$ for C_3F_7CHO. The derived Arrhenius parameters are compared with those determined in the photolysis of CF_3CHO, and also with the non-fluorinated aldehydes.

INTRODUCTION

The photolysis of the two aldehydes C_2F_5CHO and C_3F_7CHO was undertaken with a view to testing their suitability as convenient sources of $C_2F_5\cdot$ and $C_3F_7\cdot$ radicals for studying the rates of hydrogen abstraction from various hydrogen-containing compounds RH. It was first necessary to determine the rates of the self-abstraction reaction [1] in the systems, e.g.,

$$R_fCHO + h\nu \rightarrow R_f\cdot + CHO\cdot \qquad [I]$$

$$R_f\cdot + R_fCHO \rightarrow R_fH + R_fCO\cdot \qquad [1]$$

$$R_f\cdot + R_f\cdot \rightarrow R_{f_2}, \qquad [2]$$

where $R_f\cdot$ denotes $C_2F_5\cdot$ or $C_3F_7\cdot$, relative to the respective radical recombination reaction [2].

Our values of the Arrhenius parameters for reaction [1] showed a marked difference from those expected from the earlier work of Dodd and Smith (1) on the photolysis of trifluoroacetaldehyde ($R_f\cdot = CF_3\cdot$). A discussion of these differences constitutes the scope of this paper. Reactions of $R_f\cdot$ with other RH will be presented subsequently.

EXPERIMENTAL

A standard vacuum apparatus for this type of study was used. The light source was a British Thomson-Houston ME/D 250-watt high-pressure mercury arc. The beam was collimated by a quartz lens, and passed through a Corning 9863 blue-glass into the 10 cm long, cylindrical, quartz reaction vessel, volume 152.6 ml, fully illuminating it. It was connected to the remainder of the system with a mercury cutoff; the dead space was less than 10 ml. The temperature in the surrounding furnace was controlled to $\pm1°$ during the period of a run.

The aldehydes were obtained as the hydrates from K and K Laboratories and Columbia Organic, and dehydrated with P_2O_5 and H_2SO_4 (2). After low-temperature fractionation, their purity was established mass spectrometrically (3). They were stored in blackened bulbs at $-195°$, for decomposition and polymerization occurred at room temperature. The ultraviolet absorption spectra were taken on a Cary Model 14 recording spectrophotometer. They were identical in shape, with a maximum at 3190 Å. The C_3F_7CHO extinction coefficient ($\log_{10} I_0/I = \epsilon cl$), 22.8 l. mole^{-1}cm^{-1}, is about 50% higher than that for C_2F_5CHO, 15.5 l. mole^{-1}cm^{-1}.

After photolysis, product analysis was effected by low-temperature fractionation on Ward – Le Roy stills and mass spectrometry. The CO and H_2 were collected at $-195°$ and measured; after treatment in a CuO furnace at 300°, the CO was determined as CO_2, and the H_2 by difference. The remainder of the reaction products and the undecomposed aldehyde were condensed into a tube containing a solution of phenylhydrazine in carefully out-gassed, distilled water, made acid with HCl or H_2SO_4. The tube was allowed

[1]*Presented at the XVIIIth International Congress of Pure and Applied Chemistry, Montreal, August, 1961.*

to warm to room temperature, and left until the aldehyde had completely reacted. If pure water only is used, an equilibrium is established, and the aldehydes are volatile enough to interfere in the subsequent analysis. In our procedure they are removed, probably as hydrates, hydrazones, and polymer.

In the C_2F_5CHO experiments, C_2F_5H was collected at $-150°$, and C_4F_{10} at $-120°$. The separation of these two products by low-temperature distillation is tedious, and in many cases they were collected together and analyzed on the mass spectrometer, using the CF_2H^+ (51) ion peak for C_2F_5H, and the residual CF_3^+ (69) ion peak for C_4F_{10}. Pure standards were obtained by prolonged photolysis of the aldehyde, and careful fractionation. The mass spectra were identical with those previously recorded (4, 5). No disparity was found between the two methods.

In the C_3F_7CHO photolyses, C_3F_7H was collected at $-120°$, and C_6F_{14} at $-80°$. Their purity was checked from the mass spectra (5, 6).

RESULTS

The results are presented in Table I for C_2F_5CHO and in Table II for C_3F_7CHO.

Hydrogen was a minor product, and it was not determined in all experiments. Differentiation between CO and H_2 is made only in Table II. The relative amounts of H_2 formed increased with temperature, as would be expected from the activation energy required for the decomposition of the formyl radical (7). No thermal decomposition

occurred up to 315° C, and no fluorocarbons resulting from F-atom abstraction reactions were detected. The absence of SiF_4 in the products shows that fluoroalkyl radicals do not react with silica at these temperatures.

The Arrhenius plots for $k_1/k_2^{\frac{1}{2}}$ mole$^{-\frac{1}{2}}$cc$^{\frac{1}{2}}$sec$^{-\frac{1}{2}}$ versus $10^3/T°$ K are given in Fig. 1.

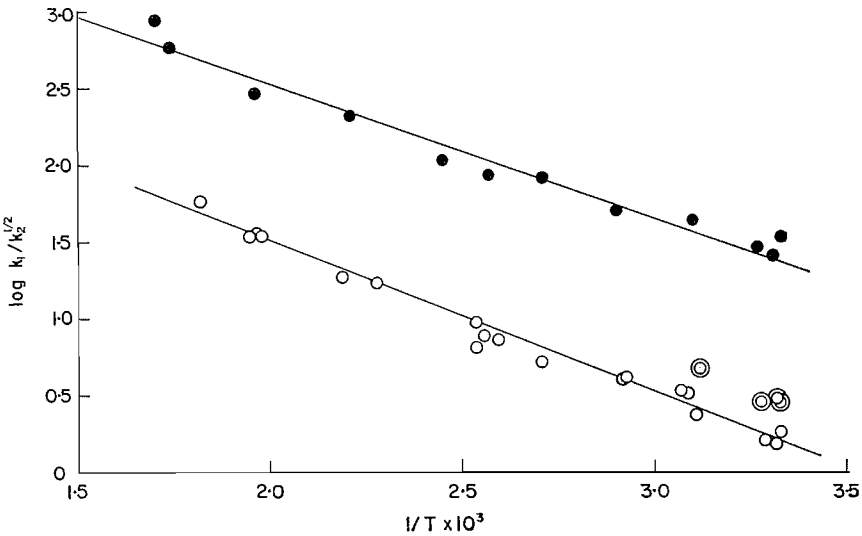

FIG. 1. Plot of log $k_1/k_2^{\frac{1}{2}}$ versus $1/T\times10^3$. ○ C_2F_5CHO photolysis; for double circles, see text. ● C_3F_7CHO photolysis; displaced upward by one log unit for clarity.

There was some scatter in the low-temperature end of the C_2F_5CHO plot (double circles), but as the run numbers indicate, it was random. However, there is a suggestion of curvature, and Dodd and Smith (1) found a distinct curvature of this kind in the CF_3CHO photolysis. As there is no other plausible source of R_{f_2}, other than reaction [2], they suggest the following possible reactions of low activation energy as competing sources of fluoroform, which are important at low temperatures:

$$CF_3\cdot + \cdot CHO \rightarrow CF_3H + CO \qquad [3]$$

and

$$CF_3\cdot + CF_3CHO \text{ (wall)} \rightarrow CF_3H + \text{products} \qquad [4]$$

and the intramolecular split:

$$CF_3CHO + h\nu \rightarrow CF_3H + CO, \qquad [II]$$

They discount [3], and contend that their results provide evidence for the occurrence of [4] and some mode [II] fission. It is certain that at higher temperatures, and at our intensities, the aldehyde decomposition is mainly due to the chain-propagating step, reaction [1], which is the only significant source of R_fH, and the absence of curvature in the plots in Fig. 1 indicates that reactions comparable to [3], [4], and [II] are relatively unimportant in this work. It may be noted, however, that due to the high value (see Discussion) found for the activation energy of reaction [1] for $CF_3\cdot$, competing sources of fluoroform formation of low activation energy will be more apparent.

A least-squares treatment of the results yields for C_2F_5CHO $k_1/k_2^{\frac{1}{2}} = (3.09\pm0.12)10^3\times \exp(-4500\pm200/RT)$ mole$^{-\frac{1}{2}}$cc$^{\frac{1}{2}}$sec$^{-\frac{1}{2}}$ exclusive of the double circles; including them,

$k_1/k_2^{\frac{1}{2}} = (1.64\pm0.25)10^3 \exp(-4000\pm600/RT)$ mole$^{-\frac{1}{2}}$cc$^{\frac{1}{2}}$sec$^{-\frac{1}{2}}$. For C_3F_7CHO we obtain $k_1/k_2^{\frac{1}{2}} = (1.86\pm0.14)10^3 \exp(-4000\pm300/RT)$ mole$^{-\frac{1}{2}}$cc$^{\frac{1}{2}}$sec$^{-\frac{1}{2}}$.

Values of $k_1/k_2^{\frac{1}{2}}$ were calculated from the steady-state approximation $(\bar{R}_{R_fH}/\bar{R}_{R_{f_2}}^{\frac{1}{2}} \times [\text{Ald.}]_{av})$, where $\bar{R}$ is the mean rate of formation, and the average aldehyde concentration is the arithmetic mean of the initial and final concentrations (assumed percentage decomposition = $(R_fH+2R_{f_2})/(\text{Ald.})_0$). Correction factors to the above approximation to allow for time fluctuations and cell gradients in the radical concentration have been discussed (8, 9). Some of the percentage decompositions in the C_2F_5CHO results are well beyond the normal limit of a steady-state condition, suggesting that we take cognizance of these factors in discussing these experiments. It is noticeable, however, that we have not observed any deviation from the Arrhenius plots for the high percentage decomposition runs; e.g., compare numbers 7 and 22 in Table I. Perhaps more important is the fact that the approximation is put to severe limitations if the two measured products can be consumed by secondary reactions, or produced from alternative sources, as the decomposition progresses. This is not the case in our system, for we have established that reactions other than [1] and [2] are unimportant, and the products, once formed, are not removed by subsequent reaction. Hydrogen transfer, e.g.,

$$C_3F_7\cdot + C_3F_7H \rightarrow C_3F_7H + C_3F_7\cdot,$$

does not disturb the product balance, and R_{f_2} is stable and not subject to radical attack. It is surprising that Henderson and Steacie (10) found no variation in the ratio $\bar{R}_{CH_4}/\bar{R}_{C_2H_6}^{\frac{1}{2}}[\text{Ac.}]_0$ from the photolysis of acetone above 10% decomposition, as this system must incorporate some of these limitations.

DISCUSSION

We may compare our results with the value of $k_1/k_2^{\frac{1}{2}} = (1.95\times10^4)T^{1/4} \exp(-8200/RT)$ mole$^{-\frac{1}{2}}$cc$^{\frac{1}{2}}$sec$^{-\frac{1}{2}}$ given by Dodd and Smith (1) from CF_3CHO photolysis, and it is seen that there is a large variation in the Arrhenius parameters. The values of $k_1/k_2^{\frac{1}{2}}$ differ much less markedly; at 182° C they are 10.6 (CF_3CHO), 21.1 (C_2F_5CHO), and 22.7 (C_3F_7CHO), all in mole$^{-\frac{1}{2}}$cc$^{\frac{1}{2}}$sec$^{-\frac{1}{2}}$. Variations between A and E can be accounted for by compensation between the two, but if rate data are to be interpreted in terms of the Arrhenius equation, reasons must be sought for significant differences in these parameters.

It has been demonstrated (11) that E_2 does not vary for simple perfluoroalkyl radicals, so that the variation in E_1 is real. The absolute magnitude of E_2 is uncertain; for $CF_3\cdot$ it has been suggested that it may be as high at 2 kcal/mole, due, in part, to the polarity of the radical (12). This result has been questioned (13), but recent studies by Szwarc and his co-workers (14, 15) on the "cage" recombination of $CF_3\cdot$ radicals from the photolysis of $(CF_3)_2N_2$ in isooctane solution at 65° C indicate a value of about 1.5 kcal/mole. The only direct determination of $CF_3\cdot$ radical recombination has been made by Ayscough (16), using a rotating sector, giving $k_2 = 2.34\times10^{13}$ mole^{-1}cc sec^{-1} at 400° K. From collision theory, we find at 400° K ($\sigma CF_3\cdot = 4.0$ Å) the collision number $Z_2 = 7.5\times10^{13}$ mole^{-1}cc sec^{-1} (not 1.5×10^{14} mole^{-1}cc sec^{-1}, as given by Ayscough, as Z_2 is one half of this value for combination between identical species). These values yield limits of E_2 and the steric factor P_2 of 0 kcal/mole and 0.31, and 0.93 kcal/mole and 1, respectively. The evidence favors the latter picture, especially if $CF_3\cdot$ is planar.

The recombination rates of $C_2F_5\cdot$ and $C_3F_7\cdot$ radicals have not been determined directly; the respective collision numbers are 1.1×10^{14} and 1.3×10^{11} mole^{-1}cc sec^{-1} at 400° K ($\sigma C_2F_5\cdot = 5.5$ Å, $\sigma C_3F_7\cdot = 6.5$ Å). If $P_2 = 1$ for all three radicals, we may equate

Z_2 with A_2. Using these values in conjunction with the experimental $A_1/A_2^{\frac{1}{2}}$ ratios, and assuming the following collision diameters: σCF_3CHO = 5.7 Å, σC_2F_5CHO = 7.2 Å, and σC_3F_7CHO = 8.2 Å, yields values of $P_1 = 3.8\times10^{-3}$ ($CF_3\cdot$), 1.2×10^{-4} ($C_2F_5\cdot$), and 6.8×10^{-5} ($C_3F_7\cdot$) at 400° K. If $P_2 < 1$, which may well be so for the larger radicals,[2] the values of P_1 will be further reduced.

The calculated steric factors for $C_2F_5\cdot$ and $C_3F_7\cdot$, which are maximum values, are lower than those generally expected in free-radical H-abstraction reactions, i.e., about 10^{-3}, but this might be expected, due to the smaller number of available hydrogen atoms in the molecule undergoing radical attack. As an example, we may consider the competing reactions

$$CD_3\cdot + CF_3H \rightarrow CD_3H + CF_3\cdot \quad [5]$$

and

$$CD_3\cdot + CD_3COCD_3 \rightarrow CD_4 + \cdot CD_2COCD_3 \quad [6]$$

where it was found (17) that $A_5/A_6 = 0.013$. Taking $A_6 = 6.3\times10^{11}$ $mole^{-1}cc\ sec^{-1}$ (18), this gives $P_5 = 1.3\times10^{-4}$ at 400° K (σCD_3 = 3.5 Å, σCF_3H = 4.0 Å).

A comparison of Dodd and Smith's value (1) with other known activation energies for H-abstraction reactions indicates that it is improbably high. A survey of these values (19) for $CH_3\cdot$ (E_m) and $CF_3\cdot$ (E_f) radicals shows a reasonably constant difference of $E_m - E_f = 3$ kcal/mole, suggesting that $E_7 = 8.2+3 = 11.2$ kcal/mole (for reaction

$$CH_3\cdot + CF_3CHO \rightarrow CH_4 + CF_3CO\cdot \quad [7]$$

[7]), which compares unfavorably with the established value of $E_8 = 7.5$ kcal/mole (18) (for reaction [8]).

$$CH_3\cdot + CH_3CHO \rightarrow CH_4 + CH_3CO\cdot \quad [8]$$

However, Dodd and Smith (1) do report $k_9/k_2^{\frac{1}{2}} = (2.5\times10^3)T^{\frac{1}{4}}\exp(-4000/RT)$ for the reaction

$$CF_3\cdot + CH_3CHO \rightarrow CF_3H + CH_3CO\cdot, \quad [9]$$

which is very compatible with our results, and $E_m - E_f = 3.5$ kcal/mole for reactions [8] and [9].

The main factors which determine the activation energies of simple metatheses of the type we are discussing are the strengths of the bonds broken and formed, and the repulsive forces between the attacking radical and molecule, and those between the new molecule and radical that are produced in the reaction (20). If the respective C—H bond strengths do not vary in the R_fCHO and R_fH series of molecules, we may anticipate a constant activation energy for reaction [1], provided that the repulsive forces do not vary with R_f. The constancy of E_2 with $R_f\cdot$ suggests that they do not, so that a value of $E_1 = \sim4$ kcal/mole may be expected for reaction [1]. The result of reaction [9] suggests that this may well hold true for aldehydes in general. A similar correspondence has been found for methane and ethane (4, 11) and cyclohexane (21, 22) subjected to $R_f\cdot$ radical attack.

[2]*In systems containing two radicals* A *and* B, *it is frequently found that the cross-combination ratio* $k_{AB}/k_{AA}^{\frac{1}{2}}k_{BB}^{\frac{1}{2}}$ *equals about 2, independent of temperature. As the collision number ratio* $Z_{AB}/Z_{AA}^{\frac{1}{2}}Z_{BB}^{\frac{1}{2}}$ *is also close to 2, it has been suggested that this is an indication that radical combination in the gas phase occurs on every collision (reference 13). We have found (reference 11) for* A = $CF_3\cdot$ *and* B = $C_3F_7\cdot$ *that* $k_{AB}/k_{AA}^{\frac{1}{2}}k_{BB}^{\frac{1}{2}} = 1.77\pm0.1$, *independent of temperature. This shows that* $E_{AB} = \frac{1}{2}(E_{AA}+E_{BB})$, *but the values are not necessarily zero, and that* $P_{AB} = (P_{AA}\cdot P_{BB})^{\frac{1}{2}}$, *but again not necessarily that* $P_{AB} = P_{AA} = P_{BB} = 1$. *We may cite an extreme case of* $P_{AB} = 0.1$, $P_{AA} = 1$, *and* $P_{BB} = 0.01$. *Further complexities can arise if disproportionation reactions occur; see A. R. Blake, J. F. Henderson, and K. O. Kutschke, Can. J. Chem.,* ***39****, 1920 (1961).*

For these compounds the rate constants at 182° C vary as $CF_3\cdot \gg C_2F_5\cdot > C_3F_7\cdot$, which indicates increasing steric effects with the larger radicals.

Trotman-Dickenson and his co-workers (13) have established the Arrhenius parameters of the reactions

$$R\cdot + RCHO \rightarrow RH + RCO\cdot \quad [10]$$

and

$$CH_3\cdot + RCHO \rightarrow CH_4 + RCO\cdot \quad [11]$$

compared to the relevant recombination reaction

$$R\cdot + R\cdot \rightarrow R_2, \quad [12]$$

where R· is Me·, Et·, *n*-Pr·, or *n*-Bu·. The rate constants for these reactions are remarkably constant. For reaction [11], $k_{11}/k_{12}^{\frac{1}{2}}$ ranges from 13 to 20 $mole^{-\frac{1}{2}}cc^{\frac{1}{2}}sec^{-\frac{1}{2}}$ (mean 17), which indicates that the alkyl group has little effect on the reactivity of the aldehydic hydrogen.

Our values of $k_1/k_2^{\frac{1}{2}} = 21.1$ ($C_2F_5\cdot$) and 22.7 ($C_3F_7\cdot$) compare favorably with those for $k_{10}/k_{12}^{\frac{1}{2}} = 16$, and appear to be quite constant, as in the case of the alkyl radicals.

The general pattern of the results suggests that the potential barrier to perfluoroalkyl radical H-abstraction reactions will be lower than that for the corresponding alkyl radical reaction. The reason for Dodd and Smith's result (1) is not clear.

THE KINETICS OF THE FORMATION OF THE MONOSULPHATO COMPLEX OF IRON (III) IN AQUEOUS SOLUTION

G. G. DAVIS[1] AND W. MACF. SMITH
Department of Chemistry, Queen's University, Kingston, Ontario

Received May 31, 1962

ABSTRACT

The kinetics of formation of the monosulphato complex of iron (III) has been examined spectrophotometrically using a continuous-flow technique over the range of temperatures 15.6 to 34.5° C in an aqueous medium of ionic strength 0.5 and a range of concentrations of hydrogen ions 0.05 to 0.30 *M*. The experimental data may be interpreted on the assumption that the significant reactions are a bimolecular association opposed by a first-order dissociation ($Fe^{+++} + SO_4^{=} \rightleftharpoons FeSO_4^{+}$). For the forward reaction $\Delta H^{\mp}$ is 18.0 kcal mole^{-1} and $\Delta S^{\mp}$ is 19.4 cal mole^{-1}deg^{-1}.

INTRODUCTION

The kinetics of the association reactions of ferric ion with thiocyanate and chloride have been investigated by Connick and co-workers (1, 2), that of ferric ion with fluoride by Pouli and Smith (3). Although the equilibria involved in the reactions involving ferric and sulphate ions have been considerably studied, there has been no account of studies of the kinetics. This work was carried out to provide more information about the nature of the association reactions involving ferric ions.

EXPERIMENTAL

Reagents and Solutions

All solutions used in the spectrophotometric observations relating to solutions at equilibrium were prepared from triply distilled water, the second distillation being from alkaline permanganate. The solutions used for the kinetic studies were prepared mainly from singly distilled water. Checks of the absorption spectra of solutions of acidified ferric perchlorate in singly and triply distilled water were made and showed no indication of any difference. Sodium perchlorate (anhydrous), perchloric acid (70%), and ferric perchlorate (non-yellow) were reagent grade and obtained from G. Frederick Smith Chemical Company. The perchlorate was tested for chloride content by nephelometric methods and shown to contain less chloride than would correspond to a concentration of 10^{-5} *M* in any of the solutions used. The stock solutions of ferric perchlorate in perchloric acid were analyzed for acid and iron content by the method previously discussed (3). Sodium sulphate was Baker anhydrous reagent and was dried for 2 to 3 hours at 120° C before weighing. The *o*-cresol red was obtained as 0.02% solution from Fisher Scientific Company. In all solutions the acidity was adjusted with perchloric acid, the ionic strength to 0.5 with sodium perchlorate.

The Measurement of Equilibrium Constants

The spectrophotometric measurements on solutions at equilibrium were carried out with a Beckman DU spectrophotometer using Beckman quartz cells of 10-mm path length which were housed in a thermostating block permitting temperature control to ±0.10°.

The Kinetic Measurements

The kinetic measurements were carried out spectrophotometrically using a continuous-flow technique. Essentially this involves means of rapidly mixing two reactant solutions and of following the change in composition along the length of a reaction tube down which the mixed and reacting solution flows at a velocity which is constant and sufficiently high to prevent streamlining. The design of our apparatus is based on principles evaluated by Hartridge and Roughton (4), involves some features of a design by Dalziel (5), and is such as to permit its incorporation in a Beckman DU spectrophotometer. The reaction tube is quartz about 2 mm in inside diameter and 40 cm long. One end of this tube fits into a plexiglass mixing block containing the mixing chamber, which is continuous with the reaction tube and identical in diameter. The reactant solutions are forced from thermostated storage flasks by controlled gas pressure and enter the mixing chamber via two pairs of 0.5-mm jets whose axes are nearly tangential to the circumference of the chamber. The spectral character of the reacting mixture at various points along the reaction tube is determined by standard photometric techniques, and these measurements are then interpreted to yield the composition of the solution for reaction times equal to the times of flow between the regions of mixing and

[1]*Holder of an Ontario Research Council Scholarship 1960–61.*

observation. The reaction tube is held firmly in an aluminum housing which slides in a metal collar attached to the portion of the Beckman normally carrying the cell holder and the assembly is carefully constructed so that any part of the reaction tube may be slid reproducibly into the beam of radiation emerging from the monochromator. The beam is collimated by slits 1 mm wide and 4 mm long before and after passage through the reaction tube and, consequently, only the radiation passing through the central portion of the tube (an effective path length of just under 2 mm) reaches the photomultiplier unit. Flow rates of the solution were controlled to $\pm 2\%$ and tests involving the mixing of a solution of the acid form of *p*-nitrophenol with a solution of sodium hydroxide and examination of the resulting solution for optical homogeneity and completeness of transformation to the basic form indicated that mixing of the solutions was complete at the region of observation which is closest to the mixing chamber. This corresponded to a reaction time of about 5 milliseconds. No attempt was made to thermostat the reaction tube. A Sargent Thermistor Thermometer was used to measure the temperature of the solution leaving the exit of the reaction tube and also leaving the mixing chamber with no reaction tube attached. A temperature gradient of 0.4° occurred over the length of the tube under conditions of maximum difference in temperature between the solution and environment, and the average of the extremes was taken as the reaction temperature.

Details about Measurements Made with the Flow Apparatus

A kinetic run involved measurements of relative intensity of the beam of λ 305 mμ transmitted through the flow tube at various positions along its length while the mixed, reacting solution was flowing through it at uniform velocity. At λ 305 mμ, $FeSO_4^+$ has a maximum in its extinction coefficient (6). Uncomplexed iron has an effective coefficient which is constant at the constant acidity of a run but is dependent on the acidity (due to varying proportion of $FeOH^{++}$ to Fe^{+++}). The effective extinction coefficient is, however, substantially less than that of $FeSO_4^+$ over the range of our experimental conditions. Immediately before and after the kinetic run reference intensities were obtained at the same positions along the flow tube, which now contained a solution of the same ionic strength, acidity, and iron (III) content as that in the kinetic run but no sulphate. Since sulphate is transparent these intensities correspond to mixed but unreacted solution. If the predominant species involved in the reaction are Fe^{+++}, $SO_4^=$, and $FeSO_4^+$, and if the ratio $[Fe^{+++}]/[FeOH^{++}]$ remains constant, the difference (ΔD) in optical densities or absorbances of the two solutions at the same position along the flow tube is

$$\Delta D = x(\epsilon_{FeSO_4^+} - \epsilon_{Fe,\,eff})l,$$

where

$\epsilon_{FeSO_4^+}$ is the molar extinction coefficient of $FeSO_4^+$;

$\epsilon_{Fe,\,eff}$ is the effective molar extinction coefficient of the Fe (III) (in the forms Fe^{+++} and $FeOH^{++}$);

x is the concentration of $FeSO_4^+$ (moles liter^{-1});

l is the length of the optical path in centimeters;

and consequently

$$[1] \qquad \frac{\text{Concentration of } FeSO_4^+ \text{ at time } t}{\text{Concentration of } FeSO_4^+ \text{ at equilibrium}} = \frac{x}{c} = \frac{\Delta D_t}{\Delta D_\infty}$$

and

$$\frac{c-x}{c} = \frac{\Delta D_\infty - \Delta D_t}{\Delta D_\infty},$$

where c is the concentration of $FeSO_4^+$ at equilibrium; ΔD_t and ΔD_∞ the values of ΔD at times of observation and equilibrium.

For most runs reaction was nearly complete within the flow tube (i.e. within a time of 250 milliseconds) and the transmission (and absorbance) remained nearly constant over a range of positions near the exit. First approximations of the values of the rate constants for the reaction were made assuming that the values of ΔD_t obtained from readings close to the exit were those of ΔD_∞. The rate constant so obtained and the values of the time corresponding to positions near the exit when inserted into the integrated rate expression [7] given below indicated the fractional progress to equilibrium and also a correction to this first approximation for ΔD_∞. The corrected value for ΔD_∞ was used to estimate a corrected value for the rate constant.

The correlation between distance along the flow tube and time of reaction depends on cross section and volume rate of flow. The average cross section was determined by measuring the length of known weights of mercury in the tube and was found to be 0.0377 cm², and there was a maximum variation in average cross section for various 1-cm lengths of $\pm 1\%$. The rate of flow was determined by direct observation of the volume of liquid collected at the exit (checked by observation of the volumes leaving the storage flasks) over definite times. As indicated above, the two conditions which must apply before simple interpretation of the flow measurements may be made are (1) effective mixing at the point where the jets enter the mixing chamber and (2) flow along the flow tube at such a rate that it is turbulent and not significantly streamlined. The rate of flow in our kinetic runs was about 8.5 cc/sec, a value well in excess of the minimum value required to attain turbulence. To confirm that the conditions of flow and mixing were satisfactory, we have carried out runs using identical reacting solutions and different flow rates between 2.7 cc/sec and 9.1 cc/sec. The

temperature was 15° C, the total iron (III) concentration 1.0×10^{-2} M, the total sulphate concentration 2.0×10^{-3} M.

The results are given in Fig. 1 as plots of ΔD_t (called change of absorbance) against time and in Fig. 2

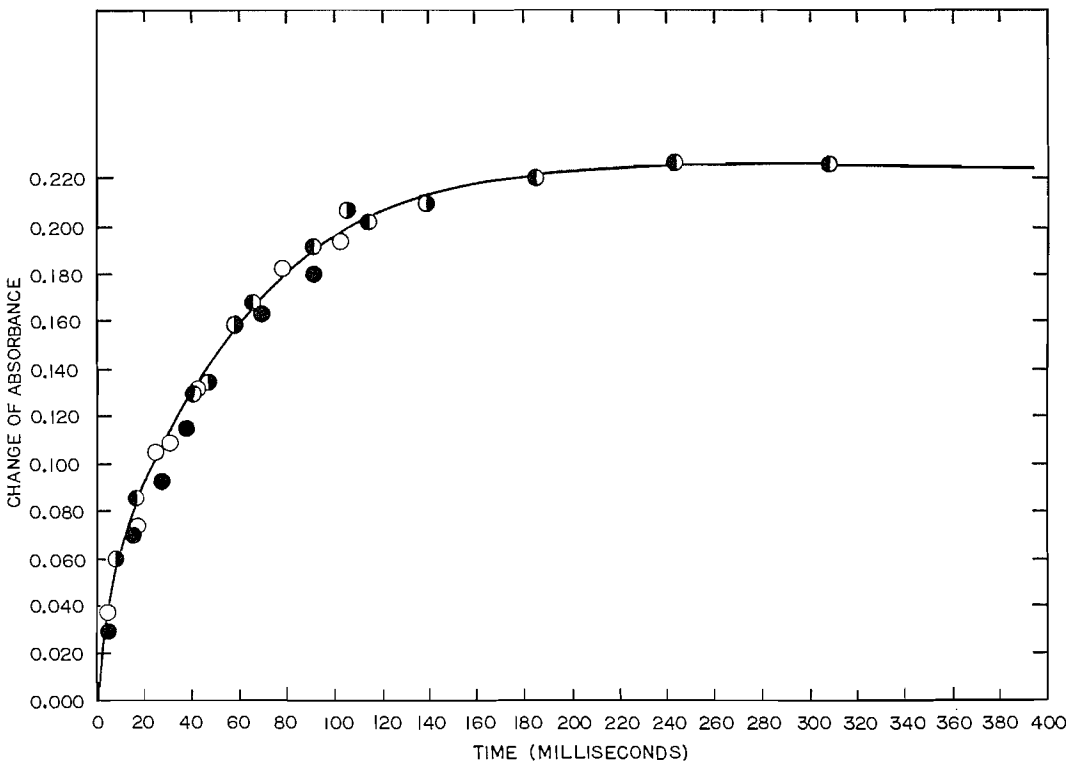

FIG. 1. Change of absorbance plotted against time for four different kinetic runs differing only in flow rate. Temperature 15.6° C, ionic strength 0.50, total iron (III) concentration 0.010 M, total sulphate concentration 0.0020 M, perchloric acid concentration 0.15 M. Flow rate: run 1 ● 9.09 cc/sec, run 2 ○ 8.69 cc/sec, run 3 ◑ 5.97 cc/sec, run 4 ◐ 2.68 cc/sec.

in partially reduced form as a plot of log $(c-x)$ against time, where c is the concentration of $FeSO_4^+$ at equilibrium and x its concentration at time t. This plot should be linear according to the integrated rate expression [7] developed below. Concentration c was determined using the relationship (5) given below and x was determined using the relationship $x = c\Delta D_t/\Delta D_\infty$. In Fig. 1 only one point of every three measured for runs 1, 2, and 3 and one of every two for run 4 are plotted. In Fig. 2 all data for run 2 for times up to 100 milliseconds are included. It will be noted that there is no significant dependence on the flow rate of the correlation between amount of reaction and time, and also that the data appear to extrapolate smoothly to $\Delta D = 0$ at $t = 0$. We had anticipated that there might be some immediate change in optical density on mixing, during which time ion pairs (with solvent between the positive and negative ions) but not complexes between ferric and sulphate ions might be formed. Experiments using higher concentrations of reactants and covering a wider range of wavelengths might indicate such an effect.

The Significance of the Species $FeHSO_4^{++}$ and $Fe(SO_4)_2^-$

The assumption implied above that ΔD is proportional to x would not be valid if the species $FeHSO_4^{++}$ or $Fe(SO_4)_2^-$ was in concentration comparable to that of $FeSO_4^+$ or in relatively small amounts if their contributions to optical density were appreciable.

Whiteker and Davidson's measurements (6) suggest that the extinction coefficient of the species $Fe(SO_4)_2^-$ is not greatly different from that of $FeSO_4^+$ at the wavelength used in our kinetic study. They indicate a value for the second association quotient $[Fe(SO_4)_2^-]/[FeSO_4^+][SO_4^=]$ of about 10 at ionic strength 1.0 and temperature 27°. We estimate that the maximum concentration of free sulphate ions existing under our experimental conditions is about 3×10^{-4}, and this implies a value for $[Fe(SO_4)_2^-]/[FeSO_4^+]$ of 0.003 if the value 10 is assumed to apply to ionic strength 0.5. The figure 0.003 must be considered as a very rough estimate, but as under most of our experimental conditions the formation of $Fe(SO_4)_2^-$ relative to $FeSO_4^+$ is much less favored than in this example, it seems justifiable to ignore its influence on free sulphate concentra-

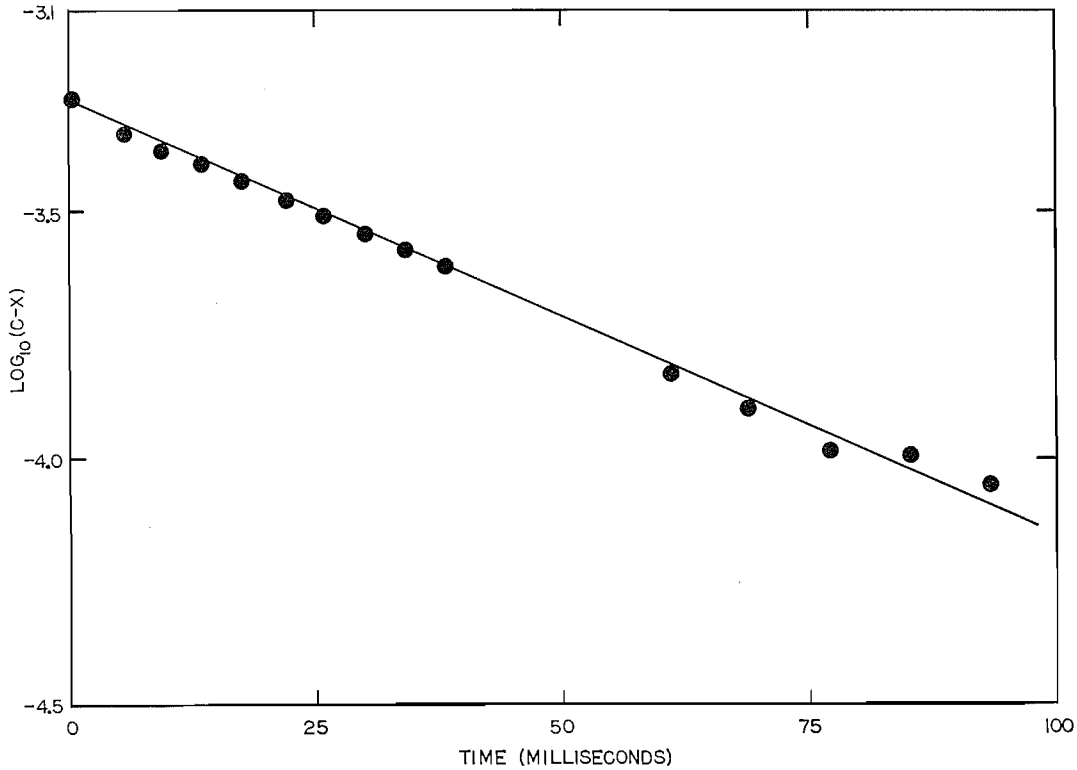

FIG. 2. Plot of log $(c-x)$ against time for data of run 2 of Fig. 1.

tion. Also, as the molar extinction coefficient of $Fe(SO_4)_2^-$ appears to be less than 50% greater than that for $FeSO_4^+$ (6), its contribution to optical density should be negligible.*

Whiteker and Davidson found no positive evidence for the formation of $FeHSO_4^{++}$ but Lister and Rivington (7) and Sykes (8) suggest values for the formation constant which, while applying to conditions different from ours, suggest that this species might be formed in significant amount under our experimental conditions. We have, therefore, attempted experimental evaluation of this constant along with those applying to the formation of $FeSO_4^+$ and the acid ionization of HSO_4^- at ionic strength 0.5.

The acid dissociation quotient of HSO_4^- at ionic strength 0.5 and temperatures between 1.4 and 35° C was determined spectrophotometrically using *o*-cresol red to indicate the hydrogen ion concentration in solutions containing sulphate and bisulphate. These solutions were prepared by adding perchloric acid to sodium sulphate and adjusting the ionic strength with sodium perchlorate. Values for the concentration of the hydrogen ion and of the total sulphate permitted estimation of the concentration of $SO_4^=$ and HSO_4^- and so of the ionization quotient. The ionic strength of these solutions depends on the extent to which H^+ and $SO_4^=$ associate, and to permit approximate adjustment to the ionic strength 0.5, we have calculated compositions on the basis of approximate values for the ionization constant for HSO_4^- determined from Monk's value at ionic strength zero (9) and the application of the Davies activity function. The relation between the absorbance of the *o*-cresol red solution and hydrogen ion concentration was determined at λ 520 mμ (where the indicator is the only significant absorber and its acidic and basic forms have marked differences in their extinction coefficients) with standards prepared from perchloric acid and sodium perchlorate. As the acid concentration was in the range 0.02 to 0.06 *M* it was legitimate to consider the concentration of hydrogen ions equal to that of perchloric acid. The *o*-cresol concentration in all solutions corresponded to 34.0 ml of 0.02% cresol red solution per liter. The values of acid ionization quotient

$$K_a \left(= \frac{[H^+][SO_4^=]}{[HSO_4^-]} \right),$$

which we have measured, are given in Table I.

**Lister and Rivington (7) suggest that the formation quotient* $([Fe(SO_4)_2^-]/[FeSO_4^+][SO_4^=])$ *at ionic strength 1.2 and temperature 25° C may be about 100. If this value is correct then the concentration of* $Fe(SO_4)_2^-$ *is higher at ionic strength 1.0 than we have estimated. Our data (discussed below) obtained from experiments designed to yield information about* $FeSO_4^+$ *and* $FeHSO_4^{++}$ *are generally more consistent with Whiteker and Davidson's with regards to the formation quotient of* $FeHSO_4^{++}$ *and the molar extinction coefficient of* $FeSO_4^+$*, although the difference in ionic strength makes strict comparison of the formation constants impossible.*

TABLE I

The acid ionization quotient (K_a) for bisulphate (ionic strength = 0.5)

Temperature (°C)	$K_a \times 10^2$ (mole liter^{-1})
35.0	3.36±0.09
25.0	4.33±0.05
15.0	5.40±0.10
1.4	7.40±0.10

The formation quotients of $FeSO_4^+$ (K_c) and of $FeHSO_4^{++}$ (K_m) at ionic strength 0.5 were measured using a method similar to that described by Lister and Rivington (7). The essential data involved the optical densities of solutions containing substantial excess of iron (III) over sulphate and adjusted for ionic strength and acidity, relative to a blank which differed in that it did not contain sulphate. Groups of solutions of different acidity were examined, with members of each group containing the same small concentrations of sulphate (1×10^{-3} M), the same relatively large concentration of perchloric acid, and varying concentrations of iron (III) (between 1×10^{-2} and 3×10^{-2} M). Our data for temperatures 1.4 and 15° C interpreted using the value of K_a given in Table I indicated the values for K_c given in Table II and were

TABLE II

The association quotients (K_c) for the monosulphato iron (III) complex (ionic strength = 0.5)

Temperature (°C)	K_c (mole^{-1} liter)
35.0	280±22
25.0	205±18
15.0	149±10
1.4	95±6

consistent with $K_m = 0\pm1$. The data for 25° and 35° were less consistent and suggested somewhat negative values for K_m. We have assumed that $K_m = 0$ in interpreting the data and obtain the values of K_c for 25.0 and 35.0° C given in the table. These values of K_c yield a fair linear plot of log K_c against $1/T$ and values of $\Delta H^0 = 5.5$ cal mole^{-1} and $\Delta S^0 = 29$ cal mole^{-1} deg^{-1}.

It appears then that the value for the formation quotient for $FeHSO_4^{++}$ is less than 0.01 that for $FeSO_4^+$ at ionic strength 0.5. The maximum value of $[HSO_4^-]/[SO_4^=]$ under our experimental conditions is about 8/1. Since

$$\frac{[FeHSO_4^{++}]}{[FeSO_4^+]} = \frac{K_m}{K_c}\frac{[HSO_4^-]}{[SO_4^=]}$$

the concentration of $FeHSO_4^{++}$ is probably less than 8% of that of $FeSO_4^+$ under the conditions most favoring its formation. Sykes estimates that the extinction coefficient at λ 305 mμ for $FeHSO_4^{++}$ is 850 mole^{-1}liter cm^{-1} and for $FeSO_4^+$ is 2160. Whiteker and Davidson find a value of 2200 for $FeSO_4^+$ (6). Our data do not cover the range of compositions or wavelengths which would permit an estimate of these quantities. However, our results, implying a small degree of formation of $FeHSO_4^{++}$, along with the reasonable assumption that $\epsilon_{FeHSO_4^{++}}$ is less than $\epsilon_{FeSO_4^+}$, suggest that the influence of $FeHSO_4^{++}$ on optical density is small under the conditions of our experiments.

We have, therefore, interpreted our kinetic data on the assumptions that the only species of importance are the absorbing species Fe^{+++}, $FeOH^{++}$, and $FeSO_4^+$ and the non-absorbing species HSO_4^- and $SO_4^=$. Additional support for this procedure is provided by the approximate proportionality between the overall change in absorbance during a kinetic run and the concentration of the species $FeSO_4^+$ calculated for the final equilibrium conditions, using the data from the equilibrium studies outlined above. In the kinetic runs the light path in the reacting solution had an effective length just under 2 mm and the change in absorbance ΔD_∞ due to reaction should be approximately

$$\Delta D_\infty = c(\epsilon_{FeSO_4^+} - \epsilon_{Fe,\,eff})l,$$

where c is the concentration of $FeSO_4^+$ at equilibrium, and l, the effective length of the optical path, is approximately 0.2 cm.

Consequently

$$\Delta D_\infty + c\epsilon_{Fe,\,eff}d = c\epsilon_{FeSO_4^+}l. \qquad [2]$$

Concentration c was calculated for the equilibrium conditions attained in the kinetic runs at 25° C using the value of the association quotient for $FeSO_4^+$ given in Table II and the value for the acid ionization quotient for HSO_4^- given in Table I and ignoring all effects due to $FeHSO_4^{++}$. The value for the left side of equation [2] was then evaluated and plotted against c. The plot was consistent with a straight line passing through the origin ($\Delta D = 0$ for $c = 0$) with a slope indicating $\epsilon_{FeSO_4} = 1940$ if the length of the light path be taken as 2 mm or $\epsilon = 2155$ if the path be taken as 1.8 mm. Richards and Sykes' value for this extinction coefficient (λ 305 mμ) is 2160, Whiteker and Davidson's 2210.

The Reduction of the Kinetic Measurements

We have found that our kinetic data may be satisfactorily interpreted on the assumption that the following rate equation applies:

$$[3] \qquad (d/dt)[FeSO_4^+] = k_1[Fe^{+++}][SO_4^{=}] - k_1/K_c[FeSO_4^+],$$

corresponding to a second-order association opposed by a first-order dissociation.

$$Fe^{+++} + SO_4^{=} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} FeSO_4^+$$

K_c is the association quotient of the complex ($=k_1/k_{-1}$).

If

a = total concentration of iron (III)
$= [Fe^{+++}]+[FeOH^{++}]+[FeSO_4^+]$;

b = total sulphate concentration
$= [SO_4^{=}]+[HSO_4^-]+[FeSO_4^+]$;

K_a = acid ionization quotient of HSO_4^-;

$$s = \frac{[SO_4^{=}]}{[SO_4^{=}]+[HSO_4^-]} = \frac{K_a}{K_a+[H^+]};$$

K_h = hydrolysis quotient of ferric ion;

$$r = \frac{[Fe^{+++}]}{[Fe^{+++}]+[FeOH^{++}]} = \frac{[H^+]}{K_h+[H^+]};$$

x = concentration of $FeSO_4^+$ at time t;

c = concentration of $FeSO_4^+$ at equilibrium;

then equation [3] becomes

$$[4] \qquad \frac{d}{dt}x = k_1rs(a-x)(b-x) - \frac{k_1}{K_c}x,$$

also

$$[5] \qquad K_c = \frac{c}{rs(a-c)(b-c)}.$$

Substituting [5] into [4] and solving yields

$$[6] \qquad \ln\frac{c-x}{ab-cx} = \frac{k_1sr}{c}(c^2-ab)t + \ln\frac{c}{ab}.$$

Under our experimental conditions, where a is present in considerable excess over b, cx is small relative to ab and equation [6] reduces to

$$[7] \qquad \log\frac{c-x}{c} = -k_1rs\frac{(ab-c^2)}{2.3c}t$$

but

$$\frac{c-x}{c} = \frac{\Delta D_\infty - \Delta D_t}{\Delta D_\infty}.$$

So

$$[8] \qquad \log(\Delta D_\infty - \Delta D_t) = \text{constant} - \frac{k_1rs(ab-c^2)}{2.3c}t$$

and a plot of log $(c-x)$ or log $(\Delta D_\infty - \Delta D_t)$ against time should yield a straight line with slope $[k_1 rs(ab-c^2)]/[2.3c]$, and knowledge of the values of a, b, c, r, and s permits evaluation of k_1. The value r has been estimated from values of K_h given by Connick and co-workers (10), s has been estimated from the values for K_a given in Table I, and c was estimated using the values of K_c given in Table II.

Results of the Kinetic Measurements

The values obtained for the rate constant k_1 under all conditions which we have examined in the kinetic measurements are given in Table III. Although the scatter in the values of k_1 is considerable, there seems

to be no significant dependence on the concentrations of the reactants or the acidity, with the possible exception of the values for the highest temperature and lowest acidity. This is in contrast with the result obtained by Connick and co-workers for the reactions of thiocyanate and chloride with ferric ion, where the species $FeOH^{++}$ was contributing appreciably to the overall rate and apparent rate constant at hydrogen

ion concentrations of 0.05, and is also in contrast with the findings of Smith and Pouli for the reaction between fluoride and iron (III) that there is a significant increase in apparent rate constant with hydrogen ion concentration over the range 0.1 to 0.4 *M*.

We have taken the arithmetic mean of all values at one temperature as the value of the bimolecular rate constant for the association reaction at that temperature. The values are given in Table IV, and are the basis of the log k_1/T against $1/T$ plot of Fig. 3.

$$\Delta S^{\ddagger} = 19.4 \pm 6.7 \text{ cal mole}^{-1}\text{deg}^{-1}.$$

DISCUSSION

Pearson (11) has emphasized that for displacement reactions second-order kinetics (first order in both interacting species) may result from both an S_N2 mechanism

$$M(H_2O)_n + X \rightarrow X - - - - M(H_2O)_n \rightarrow M(H_2O)_{n-1}X + (H_2O)$$

or an "intermediate" S_N1 mechanism where the partially desolvated intermediate $M(H_2O)_{n-1}$ reacts to re-form $M(H_2O)_n$ much more rapidly than to form $M(H_2O)_{n-1}X$:

$$M(H_2O)_n \underset{k_b}{\overset{k_a}{\rightleftharpoons}} M(H_2O)_{n-1} + H_2O$$

$$M(H_2O)_{n-1} + X \xrightarrow{k_c} M(H_2O)_{n-1}X.$$

k_b is a first-order constant which involves the concentration of water.

Assuming that stationary-state conditions apply it may be shown that

$$\frac{d}{dt}[M(H_2O)_{n-1}X] = \frac{k_a k_c [M(H_2O)_n][X]}{k_b + k_c[X]}$$

and if $k_c[X] \ll k_b$,

$$\frac{d}{dt}[M(H_2O)_{n-1}X] = \frac{k_a k_c}{k_b}[M(H_2O)_n][X].$$

If $k_c[X] \gg k_b$ then the reaction becomes zero order in X with a first-order rate constant equal to k_a.

Our finding that the reaction is first order in sulphate implies that the mechanism is either S_N2 or intermediate S_N1 with $k_c[X] \ll k_b$ over the range of concentrations of sulphate (X) investigated. The rate constant is therefore identifiable with $k_a k_c/k_b$ if the mechanism is intermediate S_N1.

We find a value of 6.4×10^3 mole^{-1}liter sec^{-1} for the second-order constant for the ferric sulphate association at 25° C. Taube (12) has, from n.m.r. measurements, estimated that the first-order rate constant of water exchange from ferric ions is probably 1×10^4 sec^{-1} at 25° C, the assignment of this value being somewhat indefinite because of the possibility that the mean life of the magnetic spin state rather than the life of the freely solvated ferric ion is being measured.

If it is assumed that the value of k_a is that for water exchange and that the intermediate S_N1 mechanism operates, then

$$\frac{k_c k_a/k_b}{k_a} = \frac{6.4 \times 10^3}{1 \times 10^4} \quad \text{and} \quad \frac{k_c}{k_b} = 0.64.$$

Recalling that k_b involves the concentration of water, i.e. $k_b = k_b'[H_2O]$, then $k_c/k_b' = 0.64[H_2O] = 35$, where k_c and k_b' are both second-order rate constants. The implication that the rate constant for the association of sulphate with $Fe(H_2O)_5^{+++}$ is 35 times that for the association of water with this species seems reasonable. The concentration

of water is 2.7×10^4 times the maximum concentration of sulphate in our kinetic work. Consequently the rate of attack of water relative to that of sulphate on the five-coordinated intermediate would be $(2.7\times10^4)/35 = 770/1$, and the concentration of five-coordinated intermediate would remain close to its equilibrium value and a second-order rate law is implied. It would appear then that Taube's and our data are consistent with an intermediate S_N1 mechanism. They do not, however, rule out the S_N2 mechanism.

The absence of any considerable contribution to the rate by the species $FeOH^{++}$ does favor the assumption that the mechanism approaches S_N2. Decrease of positive charge associated with loss of a proton from the hydrated ferric ion should lead to enhancement of the rate constant if the mechanism were pure S_N1 and could lead to partially compensating effects if the mechanism were S_N2 (12). At a concentration of hydrogen ions of 0.05 *M* at 25° C, $FeOH^{++}$ is contributing appreciably to the rate of the reactions with chloride and thiocyanate but not to the reaction with sulphate. The facts concerning the first two associations do not alone rule out the possibility of predominately S_N2 mechanisms applying but the added fact of absence of significant reaction involving $FeOH^{++}$ and sulphate does suggest greater interaction of the entering ligand in the transition state involving sulphate than with those involving chloride or thiocyanate (i.e. that the reaction involving sulphate has more S_N2 character than do those involving thiocyanate and chloride).

The transition state should be a seven-coordinate configuration $(SO_4 \ldots Fe(H_2O)_6)^+$ if the S_N2 mechanism applies and a six-coordinate configuration $(SO_4 \ldots Fe(H_2O)_5)^+$ if the intermediate S_N1 applies. The decrease in charge accompanying the formation of the transition state should yield markedly positive entropies of activation for both mechanisms, with the value for the S_N1 mechanism being the larger and approaching the value for the overall association reaction. The observed value for $\Delta S^{\ddagger}$, i.e. 19.4, is less than the value ΔS^0, i.e. 29, and this fact is at least consistent with an S_N2 mechanism.

ACKNOWLEDGMENTS

We are particularly grateful to Mr. R. D. Bradfield, Instrument Maker of Queen's University, for his assistance with both the design and construction of the continuous-flow apparatus. We acknowledge helpful advice from Dr. Anthony C. Davies and one of us (G. G. D.) wishes to thank the Ontario Research Council for a scholarship.

This work was carried out with financial assistance from the National Research Council of Canada.

THE ELECTROLYSIS OF ω-BROMOCARBOXYLIC ACIDS

R. G. WOOLFORD
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received May 29, 1962

ABSTRACT

The first successful preparation of ω,ω′-dibromides from the electrolyses of a series of ω-bromocarboxylic acids, $Br(CH_2)_nCOOH$ ($n = 5$ to $n = 11$), is reported. Under conditions of fairly low temperature and current density, yields from 54 to 71% of these dibromides were obtained.

The electrolysis of 11-bromoundecanoic acid is discussed as an example of how a small change in experimental conditions can produce a considerable change in the products of reaction. At 50°, the product was mainly 1,20-dibromoeicosane, whereas at 65° the products were mainly the esters methyl 11-bromoundecanoate and methyl 11-methoxyundecanoate.

It has been reported (1) that ω-bromocarboxylic acids with chain lengths of 10 carbons or less do not electrolyze normally to yield ω,ω′-dibromides, while those with greater chain lengths behave as expected (the acids used were of formula $Br(CH_2)_nCOOH$, where n = 1–5, 7, 9, 10, 15). No products were isolated and identified in these non-coupling reactions. Later, a successful mixed coupling reaction involving 3,5-dimethyl-6-bromohexanoic acid (I) was run (2), but no experimental details regarding conditions, yields,

$$\underset{\text{I}}{BrCH_2\underset{CH_3}{CH}CH_2\underset{CH_3}{CH}CH_2COOH} + HOOC(CH_2)_{16}CH_3 \rightarrow BrCH_2\underset{CH_3}{CH}CH_2\underset{CH_3}{CH}(CH_2)_{17}CH_3$$

etc. were given. Also, 11-bromoundecanoic acid, which has been electrolyzed normally on more than one occasion (1, 3), has been known (4) to split out bromine under a high temperature of reaction, to yield a neutral product not identified further.

In view of these unexpected and sometimes conflicting results, a thorough investigation of the electrolyses of ω-bromocarboxylic acids seemed necessary. This investigation has produced the first successful anodic couplings of 6-bromohexanoic acid, 7-bromoheptanoic acid, 8-bromooctanoic acid, 9-bromononanoic acid, 10-bromodecanoic acid, and 12-bromododecanoic acid, giving the corresponding ω,ω′-dibromides in yields of 54–71%. These dibromides, while known compounds, have not been made previously by the Kolbe reaction.

The work reported is part of a study being carried out on electrolyses of ω-bromocarboxylic acids which may or may not electrolyze normally, i.e. produce ω,ω′-dibromides in reasonable yield. The results show that ω-bromocarboxylic acids of chain lengths from 6 to 12 will electrolyze to give the expected symmetrical coupling products. The best experimental conditions seem to be a low temperature of reaction (at least below 50° and often below 40°) and not too high a current density. Normally such factors as concentration of acid, current density, temperature of reaction, etc. are not nearly so critical for electrolyses in absolute methanol as they are for electrolyses in aqueous media (5, 6). However, for the ω-bromocarboxylic acids, it appears that these factors may be much more critical than for various unhalogenated acids and half-esters. Certainly, temperature of reaction seems to be quite critical if a good yield of the dibromide is desired. So, while the results in the experimental section (Table I) reflect reasonably

good conditions for the production of ω,ω′-dibromides from the corresponding ω-bromocarboxylic acids, there are yet insufficient data to define more closely the best experimental conditions.

As an example of how the course of an electrolysis may change markedly with a relatively small change in experimental conditions, consider the electrolysis of 11-bromoundecanoic acid (II).

$$\underset{\text{II}}{Br(CH_2)_{10}COOH} \xrightarrow[CH_3OH\ \text{solvent}]{65^\circ} \underset{\text{III}}{Br(CH_2)_{10}COOCH_3} + \underset{\text{IV}}{CH_3O(CH_2)_{10}COOCH_3}$$

(71%) (2.4%)

$$\text{II} \xrightarrow[CH_3OH\ \text{solvent}]{50^\circ} \underset{\text{V}}{Br(CH_2)_{20}Br}$$

(64%)

At 50°, the major product in good yield is 1,20-dibromoeicosane (V). At 65°, no dibromide seems to be produced, but only the two esters, methyl 11-bromoundecanoate (III) and methyl 11-methoxyundecanoate (IV). These esters would be expected as possible side products in this electrolysis at any temperature but the almost complete production of esters under a slightly higher temperature of reaction is rather startling. A control reaction, in which an identical electrolytic solution was heated under reflux (65°) in the absence of an electric current, yielded a negligible conversion of 11-bromoundecanoic acid to any esters. Obviously, more details about the electrolysis of 11-bromoundecanoic acid and other ω-bromocarboxylic acids under varying experimental conditions are necessary before any conclusions can be drawn. It should be noted that the ω-bromocarboxylic acids behave rather sluggishly in the electrolyses (current efficiencies are low: reactions are often incomplete even after three times the theoretical time for the electrolysis). This sluggishness increases as the chain length of the acid increases. So it is not unreasonable that side reactions, such as ester formation, might play a greater role with the brominated acids than with their unsubstituted analogues, which do not possess the heavier bromine atoms, and which, therefore, are attracted faster to the electrodes.

The bromoacids necessary for the present work were either purchased commercially or synthesized by standard means. The preparation of 10-bromodecanoic acid by a Barbier–Wieland degradation of 11-bromoundecanoic acid is described in the experimental section; it is a modification of the work of Paulshock and Moser (7), who were not too explicit on details of the final oxidation step, which turned out to be the critical one. Not much is known of the stability of bromoacids under strong oxidizing conditions but in at least one instance (the conversion of 10-bromodecanol to 10-bromodecanoic acid in 31% yield (1)) the yields seem to be lower than those for their unsubstituted counterparts. More vigorous oxidizing conditions for the production of 10-bromodecanoic acid than those described always resulted in considerably lower yields and in greater difficulties in purification.

Recent speculations in print (2, 8) have suggested or implied that it is surprising that the ω-bromoacids with a chain length of 6 to 10 carbon atoms do not couple normally. The present work now shows that they do couple normally, provided the proper experimental conditions are used. These reactions represent a convenient synthetic route for some of the rarer long-chain ω,ω′-dibromoalkanes.

EXPERIMENTAL

General

All melting points were recorded on a Leitz hot-stage microscope. The melting points are corrected. The boiling points are uncorrected. The analyses were performed by Spang Microanalytical Laboratory, Ann Arbor, Michigan, and by Schwarzkopf Microanalytical Laboratory, Woodside, New York.

6-Bromohexanoic acid, 8-bromooctanoic acid, 9-bromononanoic acid, and 12-bromododecanoic acid were purchased from Sapon Laboratories, Lynbrook, New York. 11-Bromoundecanoic acid was purchased from Eastman Organic Chemicals, Rochester, New York. These bromoacids were all redistilled before use, and then recrystallized from low-boiling petroleum ether.

7-Bromoheptanoic Acid

7-Bromoheptanonitrile (150 g, 0.79 mole), 48% hydrobromic acid (300 ml), and glacial acetic acid (300 ml) were heated under reflux for 16 hours. The mixture was cooled, diluted with water (500 ml), and extracted with ether. The ether extract was washed with water and dried over anhydrous magnesium sulphate. The ether and acetic acid present were distilled at atmospheric pressure, and the residual liquid was fractionally distilled under reduced pressure. 7-Bromoheptanoic acid (126 g, 80%) of b.p. 112–116° (0.3 mm) and m.p. 28–29° was obtained. Ames *et al.* (9) report b.p. 140–142° (1.5 mm) and m.p. 29°.

Methyl 11-Bromoundecanoate

11-Bromoundecanoic acid (90.0 g, 0.34 mole) was dissolved in methanol (300 ml), and concentrated sulphuric acid (5 ml) was added. The solution was heated under reflux for 8 hours, cooled, and diluted with water (300 ml). The ester layer was separated, washed with 10% sodium carbonate solution, then water, and dried over anhydrous sodium carbonate. Distillation under reduced pressure yielded methyl 11-bromoundecanoate (76.0 g, 81%), b.p. 170–175° (12 mm), n_D^{25} 1.4630. Geiger-Berschandy (10) reports b.p. 175–176° (14 mm), n_D^{16} 1.4665.

1,1-Diphenyl-11-bromo-1-undecene

Methyl 11-bromoundecanoate (76.0 g, 0.27 mole) in anhydrous ether (150 ml) was added dropwise over a period of 2 hours to an ethereal solution of phenylmagnesium bromide (0.60 mole), made from 94.2 g of bromobenzene and 14.5 g of magnesium in 250 ml of ether. The reaction mixture was heated under reflux for 8 hours, and then poured into a mixture of 500 ml of 10% sulphuric acid and 300 g of ice. The ether layer was separated, washed with water, and dried over anhydrous magnesium sulphate. After removal of the ether, the residue was fractionated under reduced pressure to yield 1,1-diphenyl-11-bromo-1-undecene (80.0 g, 76%), b.p. 210–214° (1.2 mm), n_D^{25} 1.5596. Paulshock and Moser (6) report b.p. 190° (0.5 mm), n_D^{25} 1.557.

10-Bromodecanoic Acid

A solution of chromium trioxide (80.0 g, 0.80 mole) in 90% acetic acid (800 ml) was slowly added to a solution of 1,1-diphenyl-11-bromo-1-undecene (80.0 g, 0.21 mole) in glacial acetic acid (500 ml) at 90°, over a period of 3 hours. The solution was stirred for 5 hours at 90° and allowed to stand at room temperature overnight (10 hours). Ten-percent hydrochloric acid (2000 ml) was slowly added, and the reaction mixture was ether-extracted five times with 400 ml of ether each time. To separate the bromoacid from any benzophenone produced, the combined ether extract was washed with saturated sodium carbonate solution; the carbonate washings were separated, acidified with hydrochloric acid, and extracted with ether. After drying over anhydrous magnesium sulphate and removal of the ether, the residue was fractionated to yield 10-bromodecanoic acid (34.5 g, 65%), b.p. 134–138° (0.3 mm), m.p. 37–38°. Pattison *et al.* (1) report m.p. 37–38°.

Anodic Syntheses of ω,ω'-Dibromoalkanes

The cell used for all electrolyses was a water-jacketed, thick-walled test tube of dimensions 5×23 cm. A rubber stopper fitted with a reflux condenser held two platinum foil electrodes (2.5×5 cm) in place; these were spaced about 2 mm apart. A 50-volt d-c. supply produced the electrical current.

The ω-bromocarboxylic acid (10–15 g) was dissolved in absolute methanol (100 ml) along with sufficient sodium to neutralize 5% of the acid. A current of 1.0–1.5 amp was passed for about two to three times the theoretical time. Sometimes the end of the reaction was indicated when the electrolyte turned alkaline to litmus. In most cases, however, the solution remained slightly acid, either because the starting acid was too sluggish to react completely in the time allotted, or because traces of bromine were produced which seemed to keep the solution acidic even though electrolysis was complete. To isolate the products the current was stopped, sufficient glacial acetic acid was added to neutralize any sodium salt of unreacted starting material, and the bulk of the methanol was evaporated on a steam bath. The residue was diluted with water (100 ml) and extracted with ether several times. The combined extracts were washed with 10% sodium carbonate solution to remove any unreacted bromoacid, and then dried over anhydrous magnesium sulphate. Unreacted starting material was recovered by acidifying the carbonate washings, extracting with ether, and drying the extract over anhydrous magnesium sulphate. After removal of the

*Recrystallized from petroleum ether (30–60°).

†In most cases, as the reactions proceeded the solid product settled on the electrodes, causing the current to drop; frequent changes of polarity were necessary to maintain the current. The current indicated and the temperature of the system (which varied with the current and depended on the heat of the electrodes) represent maximum values in these cases.

‡Boiling point 107–109° (0.45 mm), n_D^{28} 1.4914.

ether, the neutral and acidic products were purified by fractional distillation or by recrystallization. Table I lists the details of the electrolyses of the ω-bromocarboxylic acids containing from 6 to 12 carbon atoms.

Non-coupling Electrolysis of 11-Bromoundecanoic Acid

11-Bromoundecanoic acid was electrolyzed to yield 1,20-dibromoeicosane under conditions described above, the details being recorded in Table I. When the temperature of the reacting solution was increased from 50° to reflux (65°) the course of the reaction changed and different products were obtained. This non-coupling electrolysis is described here, along with the identification of the major products.

11-Bromoundecanoic acid (26.5 g, 0.10 mole) was dissolved in absloute methanol (200 ml) to which sodium (0.12 g, 0.005 mole) had been added. This solution was electrolyzed at 1.0 amp for 18 hours at reflux temperature (65°). Small amounts of bromine were liberated continuously during the electrolysis. The current was stopped and glacial acetic acid (1 ml) was added. Approximately 90% of the methanol was distilled off on a steam bath, and the residue was dissolved in 100 ml of ether. Any unreacted bromo-acid was removed from the ether solution by washings with 10% sodium carbonate. On acidification and ether extraction, only a trace of impure starting acid was recovered. The neutral ether extract was dried over anhydrous magnesium sulphate. On removal of the ether, a yellow-orange oil, which did not solidify, remained. Distillation under reduced pressure yielded two main fractions, both colorless liquids: (i) b.p. 100–102° (0.3 mm), n_D^{25} 1.4356, 0.54 g, and (ii) b.p. 112–116° (0.3 mm), n_D^{25} 1.4630, 20.0 g. These fractions were identified as follows.

Fraction (i).—This fraction proved to be methyl 11-methoxyundecanoate. Its physical constants and infrared spectrum were identical with those of authentic methyl 11-methoxyundecanoate prepared as described below. Its behavior in gas chromatography, using a column of diethylene glycol succinate on Chromosorb-W, was identical with that of the authentic ester. Hydrolysis (10% NaOH) of small samples of fraction (i) and the authentic ester yielded acids, both of which had m.p. 34–35° (recrystallized from low-boiling petroleum ether) and whose mixed melting point was undepressed. Bowman and Mason (11) report, for 11-methoxyundecanoic acid, m.p. 34.5–35°.

Fraction (ii).—This fraction proved to be methyl 11-bromoundecanoate. Its physical constants and infrared spectrum were identical with those of the authentic methyl 11-bromoundecanoate prepared previously. Its behavior in gas chromatography, as above, was identical with that of the authentic ester. Hydrolysis (10% NaOH) of a small sample yielded an acid of m.p. 49–50° (recrystallized from low-boiling petroleum ether), undepressed by admixture with authentic 11-bromoundecanoic acid. Analysis of fraction (ii): Calculated for $C_{12}H_{23}BrO_2$: C, 51.61; H, 8.30; Br, 28.62. Found: C, 52.07; H, 8.29; Br, 28.65.

The yields of these esters were: methyl 11-methoxyundecanoate, 2.4%; methyl 11-bromoundecanoate, 71%.

Methyl 11-Methoxyundecanoate

Methyl 11-bromoundecanoate (37.4 g, 0.13 mole) was added dropwise to a solution of sodium (3.0 g, 0.13 mole) in dry methanol (100 ml) over a period of 1 hour. The solution was heated under reflux for an additional 4 hours. Most of the methanol was evaporated on a steam bath and 50 ml of 10% hydrochloric acid was carefully added. The mixture was ether-extracted, and the ether extract washed with 10% sodium carbonate solution and dried over anhydrous magnesium sulphate. Removal of the ether and fractional distillation yielded methyl 11-methoxyundecanoate (25.0 g, 81%) of b.p. 109–112° (0.8 mm), n_D^{25} 1.4356. Bowan and Mason (11) report b.p. 104–105° (0.5 mm), n_D^{20} 1.4375.

THE INHIBITED AUTOXIDATION OF STYRENE

PART I. THE DEUTERIUM ISOTOPE EFFECT FOR INHIBITION BY 2,6-DI-*tert*-BUTYL-4-METHYLPHENOL*

J. A. HOWARD† AND K. U. INGOLD

Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received May 29, 1962

ABSTRACT

Most previous work on the inhibition of autoxidation by phenols has indicated that the reaction involves abstraction of the phenolic hydrogen. However, the apparent absence of any appreciable deuterium isotope effect made it difficult to believe that abstraction could be rate controlling. The present work using styrene as the substrate, 2,6-di-*tert*-butyl-4-methylphenol as the inhibitor, and azo-bis-isobutyronitrile as the initiator has shown that this reaction has an unexpectedly large isotope effect, e.g. ~10.6 at 65° C. Previous failures to detect an isotope effect are attributed to the rapid exchange of deuterium which takes place between deuterated phenols and traces of moisture or other hydroxyl-containing compounds present in the substrate. Rate constants and activation energies for some of the elementary reactions in the inhibited and uninhibited oxidation of styrene have been measured. It is suggested that a compound which functions in the same way as a weak phenolic inhibitor is formed in the apparently uninhibited oxidation.

INTRODUCTION

Although the ability of phenolic compounds to inhibit the autoxidation of organic substances in the liquid phase has been known for many years, the exact mechanism by which this process occurs is still far from certain (1). Autoxidation is a free radical chain process which, for most organic substrates, can be described by the following simplified reaction scheme:

Initiation:	production of $R\cdot$ or $RO_2\cdot$	[1]
Propagation:	$R\cdot + O_2 \rightarrow RO_2\cdot$	[2]
	$RO_2\cdot + RH \rightarrow ROOH + R\cdot$	[3′]
	$RO_2\cdot + RH \rightarrow ROO\dot{R}H$	[3]
Branching:	$ROOH \rightarrow RO\cdot + \cdot OH$	[4]
Termination:	$RO_2\cdot + RO_2\cdot \rightarrow$ inactive products.	[5]

RH represents the organic substrate and $RO_2\cdot$ its peroxy radical. Hydroperoxides are produced by the majority of organic compounds (reaction [3′]) but certain polymerizable olefins yield, instead, polyperoxides (reaction [3]) (2).

The chain-breaking step by which phenolic inhibitors reduce oxidation rates has generally been considered to involve the hydrogen abstraction process

$$RO_2\cdot + AH \rightarrow ROOH + A\cdot, \qquad [6]$$

where AH is the inhibitor and $A\cdot$ is its resonance stabilized, comparatively unreactive, phenoxy radical. The radical $A\cdot$ will, in general, be destroyed by reaction with a second peroxy radical (1),

$$RO_2\cdot + A\cdot \rightarrow ROOA. \qquad [7]$$

If reaction [6] is truly a simple hydrogen abstraction process, replacement of the phenolic hydrogen by deuterium should reduce its rate, i.e., AD should be a less efficient inhibitor than AH. The magnitude of such an isotope effect would be expected to be larger than

Issued as N.R.C. No. 6922.

†*N.R.C. Postdoctorate Fellow 1961–62.*

that observed in reaction [3′] when RH is replaced by RD, since the transfer of a hydrogen atom between two identical atoms should, in general, proceed through a transition state in which the zero-point energy of the hydrogen is lost (3). Under these conditions the isotope effect will tend to be a maximum (3). The abstraction of a hydrogen atom from cumene (which is isoelectronic with a phenol) by peroxy radicals (E = 6.7 kcal/mole) has an isotope effect k_H/k_D = 5.5 (4). It might therefore be expected that deuteration of a phenol would decrease its efficiency by a factor of more than 5.5. However, several workers have either failed to detect any isotope effect with 2,6-di-*tert*-butyl-4-methylphenol (BMP)* (7) and similar hindered phenols (8), or else have found only comparatively small isotope effects, i.e. 1.3 with 3% BMP in butadiene – styrene rubber (9) and 1.6–1.7 in methacrylonitrile (10). The situation with other inhibitors—both of the phenolic and of the aromatic amine type—is similar. That is, either no isotope effect has been observed (11–13) or else only a very small one ~1.0–1.3 (9, 14–16). It should also be noted that abstraction of the phenolic hydrogen from BMP by diphenylpicrylhydrazyl radicals (E = 5.3±0.5 kcal/mole) has a reported kinetic isotope effect of 1.95 (7) whereas abstraction from 2,6-di-*tert*-butylphenol by the same radical (E = 6.0 kcal/mole) has a reported isotope effect of 8.1 (17).

Many of the above facts appear to be mutually contradictory unless it is assumed that the mechanism of reaction [6] (with phenols) is quite dissimilar to the mechanism of reaction [3′] (with hydrocarbons). That is, the very small, or even non-existent, isotope effect that has been reported for reaction [6] could only be a secondary isotope effect, which would imply that a straightforward hydrogen abstraction process is not rate determining. This is both unexpected and contrary to the fact—based on product analysis (1)—that the phenolic hydrogen is actually removed by peroxy radicals. Moreover, replacement of this hydrogen by an alkyl group completely destroys the antioxidant properties of the phenol.

We considered that the question of the existence of an isotope effect in reaction [6] was worth reinvestigating since the previous work is open to some criticism (1) owing to the fact that a phenolic hydrogen, even when sterically well protected, as in BMP, can exchange extremely rapidly if the phenol is dissolved in an organic liquid saturated with D_2O (15). It seems likely, therefore, that deuterated phenols can also exchange rapidly with the hydroperoxides that are the normal products of autoxidation. If this is the case, there is little hope of observing any appreciable isotope effect unless the deuterated phenol is used at such a high concentration that reaction [3′] is nearly completely suppressed. In this way, significant rate measurements might be made before appreciable exchange occurred but it would, of course, be very difficult to estimate how high the concentration should be under any given set of oxidative conditions. This difficulty can, however, be overcome by using as the substrate certain polymerizable olefins which form polyperoxides rather than hydroperoxides, i.e., reaction [3]. Styrene was chosen as the substrate in the present work since its products and also its kinetics for oxidation initiated by α,α'-azo-bis-isobutyronitrile (AIBN) have previously been examined in some detail (18). Moreover, among this type of olefin, styrene undergoes a minimum amount of side reactions leading to hydroxyl- or hydroperoxide-containing compounds. A further advantage that may be expected is that the peroxy radicals will probably be complexed with the aromatic π electron system of one or more adjacent styrene molecules (19) (cf. chlorine atoms in aromatic media (20)). Such complexing

**The activation energy for the reaction of* BMP *with various peroxy radicals has been reported to be 5.0±1.0 kcal/mole (5, 6).*

will reduce the reactivity of the peroxy radicals, which will tend to raise the activation energy for hydrogen abstraction from the added inhibitor, thereby increasing the magnitude of any isotope effect. That is, an isotope effect of this type is more likely to be observable in aromatic, than in aliphatic, media.

BMP was chosen as the inhibitor both because of the large amount of work already done with this phenol and also because the steric protection afforded to the OH group by the two adjacent *t*-butyl groups tends to suppress otherwise troublesome side reactions, e.g., the direct reaction of the phenol with peroxides, chain transfer processes, etc. A further advantage in using BMP is that these same steric factors may also directly increase the magnitude of the hydrogen isotope effect (21).

EXPERIMENTAL

The apparatus has been described previously (22). Styrene was degassed and distilled several times under vacuum before use. It was stored at −30° C under vacuum. α,α'-Azo-bis-isobutyronitrile (AIBN) was used as a thermal initiator of oxidation. It was stored in carbon tetrachloride solution at −15° C. The required volume of solution was added to the reaction vessel and the CCl_4 removed under vacuum. Following this, a BMP solution in CCl_4 was added and the solvent was again removed under vacuum. The styrene was then distilled into the reaction vessel.

Deuterated BMP (i.e., BMP-*d*) was very simply prepared by adding a small quantity of D_2O to a CCl_4 solution of BMP and shaking at room temperature for a few hours. The solution was stored under D_2O since it was found that back exchange with atmospheric moisture occurred extremely rapidly. Infrared analysis indicated that it contained >96% OD, and it might be noted that exchange was fairly rapid even in a dry, stoppered, infrared cell.

The oxidation was studied under 1-atm pressure of dry oxygen from 45–70° C at 5° temperature intervals with 5-ml samples of dry styrene. The AIBN and BMP concentrations were in the range 10^{-1} to 10^{-4} M and 2×10^{-2} to 2×10^{-5} M respectively.

RESULTS AND KINETICS

The Uninhibited Oxidation

At the temperatures used in this work initiation by peroxide decomposition (reaction [4]) can be neglected and therefore the only important initiation process is the unimolecular decomposition of AIBN. That is, reaction [1] can be represented by

$$I_2 \rightarrow 2I\cdot. \qquad [1]$$

Measurements of the rate of nitrogen evolution from AIBN dissolved in styrene under oxygen-free helium at six temperatures from 45° to 70° C give

$$k_1 = 1.99\times10^{15} \exp(-30{,}900/RT)$$

in excellent agreement with previous work in benzene and toluene (23).

The general shape of both the uninhibited and inhibited oxygen uptake curves are shown in Fig. 1. In the absence of BMP the rate of oxidation is constant for several hours. This rate was measured over quite a large range of AIBN concentrations at each temperature and was found to be proportional to $[AIBN]^{0.60\pm0.02}$. The results obtained at 50° and 65° demonstrating this relationship are shown in Fig. 2. Assuming a bimolecular chain termination step (i.e., reaction [5]) the rate should be proportional to the square root of the initiator concentration. That is, the rate of the uninhibited oxidation $(\rho)_0$ is given by:

$$(\rho)_0 = 2ek_1[I_2]+k_3[RH][RO_2\cdot]-k_1[I_2], \qquad [I]$$

where e is the efficiency of chain initiation by AIBN and the last term corrects for nitrogen evolution from the AIBN. The usual steady-state treatment yields the relation

$$(\rho)_0 = (2e-1)k_1[I_2]+k_3[RH]\left(\frac{ek_1[I_2]}{k_5}\right)^{1/2}. \qquad [II]$$

Since the first term is negligible compared with the second, this equation predicts that $(\rho)_0$ should be proportional to $[I_2]^{1/2}$. The observed rate law can be most easily explained by assuming that there is a concurrent first-order chain termination process even in the apparently uninhibited oxidation.* If this reaction is simply represented as

$$RO_2\cdot \rightarrow \text{inactive products}, \qquad [8]$$

then,

$$(\rho)_0 = k_3[RH]\left(\frac{(k_8^2+16ek_1k_5[I_2])^{1/2}-k_8}{4k_5}\right). \qquad [III]$$

Let

$$\frac{k_3k_8[RH]}{4k_5} = \alpha \qquad \text{and} \qquad \frac{ek_1k_3^2[RH]^2}{k_5} = \beta$$

then,

$$(\rho)_0 = (\alpha^2+\beta[I_2])^{1/2}-\alpha \qquad [IV]$$

and

$$\frac{[I_2]}{(\rho)_0^2} = \frac{1}{\beta}+\frac{2\alpha}{\beta}\cdot\frac{1}{(\rho)_0}. \qquad [V]$$

A plot of $[I_2]/(\rho)_0^2$ against $1/(\rho)_0$ should yield a straight line whose slope and intercept can be used to derive α and β. This procedure was followed at each temperature. Although the straight lines are not particularly good the oxidation rates calculated from α and β by equation [IV] represent the experimental results just about as well as the 0.60-order rate law over a wide range of AIBN concentration (see dotted curves in Fig. 2). The assumption that a unimolecular chain-terminating reaction occurs in the uninhibited oxidation of styrene is therefore not unreasonable. This assumption also receives some support from the experiments on the effects of light and heavy water on this oxidation (see below). However, the possibility that the non-integral rate law is due to some other cause cannot be ruled out.

The following activation energies were derived from the values of α and β obtained at each temperature and given in Table I:

$$E_\alpha = E_3+E_8-E_5 = 11.0\pm1.0 \text{ kcal/mole},$$

$$E_\beta = E_1+2E_3-E_5 = 46.0\pm1.0 \text{ kcal/mole}.$$

**Some other explanations which have been put forward in the past to account for non-integral kinetics in similar systems such as the mutual termination of geminate chains (24) or the radical-induced decomposition of* AIBN *can be ruled out since they would also apply to other substrates, whereas we have found that the rate of oxidation of cumene is accurately proportional to* $[AIBN]^{0.50}$ *under similar experimental conditions (25).*

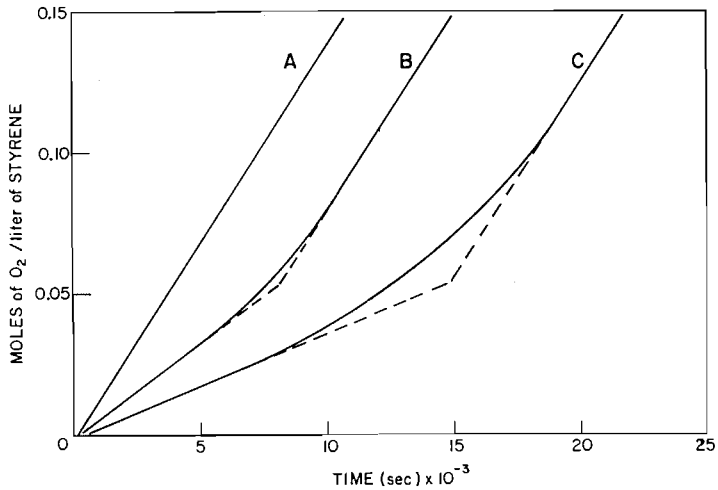

FIG. 1. Oxidation of styrene initiated by 0.01 mole/liter of AIBN, at 50° C. Key: A, no inhibitor; B, 1.38×10^{-4} mole/liter of BMP; C, 2.38×10^{-4} mole/liter of BMP.

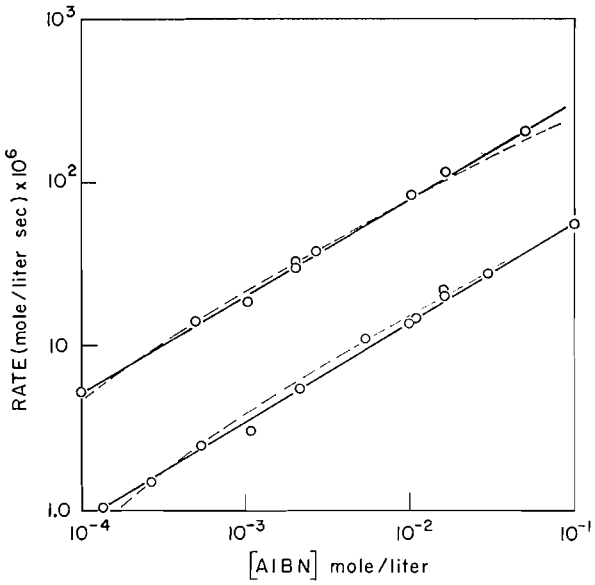

FIG. 2. Uninhibited oxidation of styrene at 50° C and 65° C.

Understandably, E_β compares very well with the activation energy derived directly from the measured oxidation rates at a given AIBN concentration. That is, from equation [II]:

$$E_{p_0} = \tfrac{1}{2}E_1 + E_3 - \tfrac{1}{2}E_5 = 23.3 \pm 0.5 \text{ kcal/mole.}$$

The Inhibited Oxidation

Figure 1 shows that the addition of BMP to the styrene–AIBN system reduces the initial rate to a smaller, but still constant, value. Thereafter, the rate increases slowly until it becomes the same as for the uninhibited oxidation, at which point all the BMP

70.5	21.3	6.5	19.9	0.24	27.2	186

must have been consumed. The intersection of the extrapolated linear regions of the inhibited oxidation curves (see Fig. 1) gives an induction period which corresponds to the time at which the BMP would have been completely consumed had its rate of consumption remained constant. That is, this procedure makes allowance for the steady decrease in the concentration of BMP. The efficiency of chain initiation, e, can therefore be determined since the amount of AIBN decomposed during this induction period is known from k_1 and since each molecule of BMP is known to react with two peroxy radicals (26, 27). An average value of e at 50° equal to 0.67 ± 0.02 was obtained in this way. This value of e compares favorably with values obtained in benzene (0.61), chlorobenzene (0.57), and nitrobenzene (0.73) by the same technique (28) when it is remembered that in the present case the solvent is also the reactant. Rather similar values of e have been obtained in aromatic solvents by using iodine as the radical trap (28) and by using an isotopic dilution method (29). It is also interesting that e for the AIBN-initiated polymerization of styrene(0.66–0.82) is also in this range (30).

The kinetics applicable to the BMP-inhibited oxidation depend on the relative concentrations of BMP and AIBN. That is, at low concentrations of inhibitor,

$$(\rho)_{[AH]\to 0} = k_3[RH]\left(\frac{((k_8+2k_6[AH])^2+16ek_1k_5[I_2])^{1/2}-(k_8+2k_6[AH])}{4k_5}\right), \qquad [VI]$$

since reaction [7] will be very fast compared with reaction [6] for the inhibitor BMP (8). Therefore, the rate is approximately proportional to the square root of the initiator concentration. Subtracting equation [VI] from equation [III] we obtain

$$(\rho)_0 - (\rho)_{[AH]\to 0} \approx \frac{k_3k_6[RH][AH]}{2k_5}. \qquad [VII]$$

On the other hand, in the presence of sufficiently high concentrations of inhibitor, reactions [5] and [8] can be neglected. Therefore,

$$(\rho)_{[AH]\to max} = 2ek_1[I_2] + \frac{ek_1k_3[RH][I_2]}{k_6[AH]} - k_1[I_2] \qquad [VIII]$$

and the rate is proportional to the initiator concentration and inversely proportional to the inhibitor concentration.

Equation [VII] predicts that at a given temperature the decrease in rate produced

by the addition of a small concentration of inhibitor will be independent of the initiator concentration, i.e., independent of the uninhibited rate. This is confirmed by the results shown in Fig. 3 for the rates obtained at four AIBN concentrations at 65° C. Within the limits of experimental error the tangents to the curves at zero BMP concentrations are of equal slope. The activation energy derived from these slopes at each temperature is:

$$E_{VII} = E_3+E_6-E_5 = 9.4\pm1.0 \text{ kcal/mole.}$$

Owing to the difficulties which are always inherent in measuring tangents to experimental curves this activation energy is somewhat less accurate than the others obtained in this work.

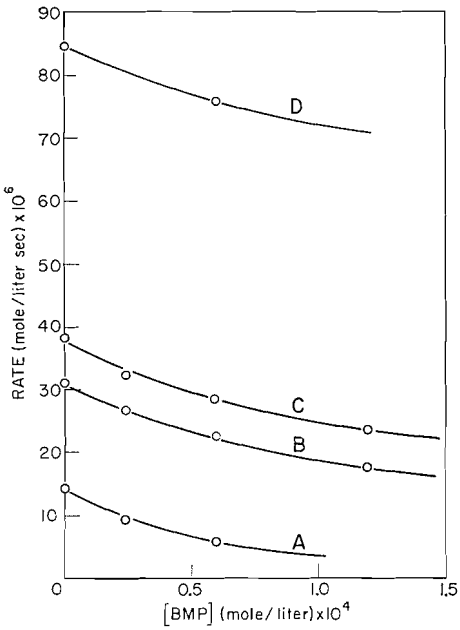

FIG. 3. Effect of low concentrations of BMP on the rate of oxidation of styrene at 65° C. Key: A, 5.0×10^{-4} mole/liter of AIBN; B, 2.0×10^{-3} mole/liter of AIBN; C, 2.63×10^{-3} mole/liter of AIBN; D, 1.0×10^{-2} mole/liter of AIBN.

Figure 4 shows that at high inhibitor concentrations a straight line is obtained by plotting $(\rho)_{[AH]\to max}/[I_2]$ against $1/[AH]$ as predicted by equation [VIII]. This line passes very close to the origin, but the expanded area of the graph shows that it actually has a finite intercept on the vertical axis. From equation [VIII], this intercept $= (2e-1)k_1 \approx 1.2\times10^{-5}$ sec^{-1} and therefore $e = 0.8$ at 65°, in fairly good agreement with the method based on induction periods. The slopes of these lines at different temperatures (see Fig. 5) give

$$E_{VIII} = E_1+E_3-E_6 = 36.9\pm0.5 \text{ kcal/mole.}$$

Both the low and the high concentrations of inhibitor can be treated together by using the same method as was used in deriving equation [V]. That is, neglecting reaction [8], the inhibited rate is given by

$$\rho_{AH} = (2e-1)k_1[I_2]+(\alpha^2[AH]^2+\beta[I_2])^{1/2}-\alpha[AH], \qquad [IX]$$

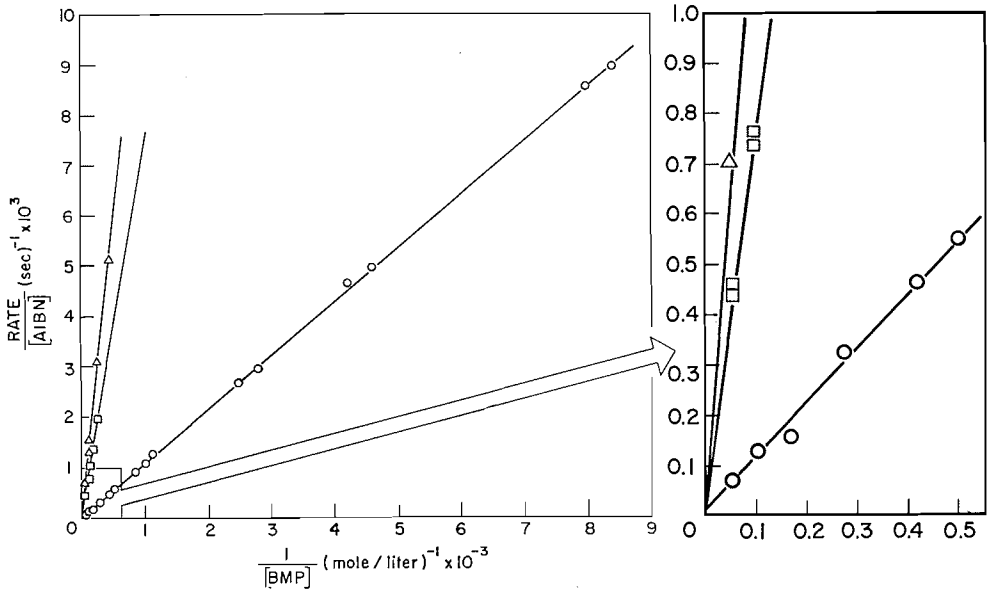

FIG. 4. Effect of high concentration of BMP on the rate of oxidation of styrene at 65° C. Key: ○ BMP; □ BMP-*d*; △ BMP-*d* + D_2O.

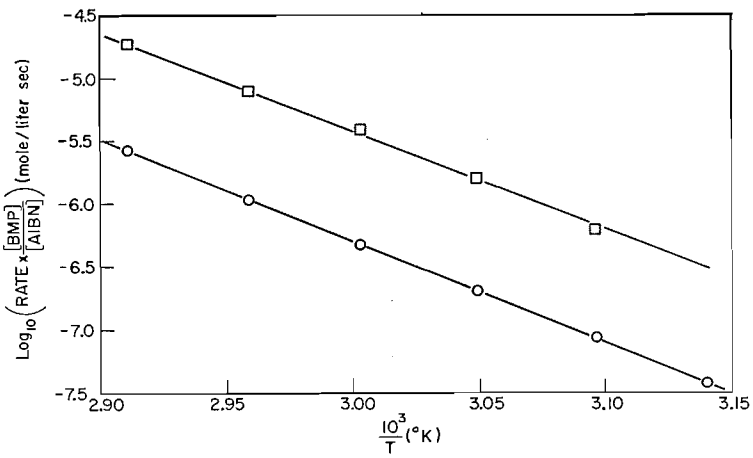

FIG. 5. Oxidation of styrene inhibited by high concentrations of BMP and BMP-*d* plotted against the reciprocal of the absolute temperature. Key: ○ BMP; □ BMP-*d* (92–95%, see text).

where $\alpha = k_3k_6[RH]/2k_5$ and $\beta = ek_1k_3^2[RH]^2/k_5$. Good straight lines yielding α and β are obtained by plotting $[I_2]/\rho_{AH}^2$ against $[AH]/\rho_{AH}$, and the activation energy derived from α is in good agreement with E_{VII}.

The Effect of BMP-d and Heavy Water on the Oxidation

Preliminary experiments showed that deuterated BMP was a much less efficient inhibitor than the undeuterated phenol, but that considerable precautions had to be taken to obtain reproducible results. For example, the temporary admission of air to the system just prior to a run or the use of low concentrations of BMP-*d* could result in rates little different from those obtained with an equivalent concentration of the

undeuterated phenol. Even with fairly high concentrations of BMP-*d* ($\sim 10^{-2}$ to 10^{-3} mole/liter) the rate of oxygen uptake decreases markedly with time (Fig. 6). That this is due to a fairly rapid loss of deuterium by the BMP was proved both by infrared analysis during the oxidation and by adding 1.0–2.0 ml of heavy water to the system.* The effect of this heavy water is to increase the rate by about two thirds based on the initial rate at the same BMP-*d* concentration (see Fig. 4). The rate remains unchanged at this high value throughout the reaction (see Fig. 6). The occurrence of a rapid exchange of the phenolic hydrogen during the oxidation was further confirmed by showing that, although H_2O has a small accelerating effect ($\sim 10\%$) on the rate of a normal BMP-inhibited reaction, D_2O causes the rate to rise towards that of the BMP-*d* + D_2O reaction a short time after oxidation commences. The addition of H_2O to the BMP-*d*-inhibited reaction rapidly reduces the rate to that of the normal BMP + H_2O reaction. The oxygen uptake curves obtained in all these experiments are shown in Fig. 6. It should be added that for both light and heavy water the effects on the rate were independent of the amount of water added and were the same whether the water was pipetted or vacuum distilled into the reaction vessel. The accelerating effects of H_2O and D_2O are therefore not due to traces of transition metal contaminants.

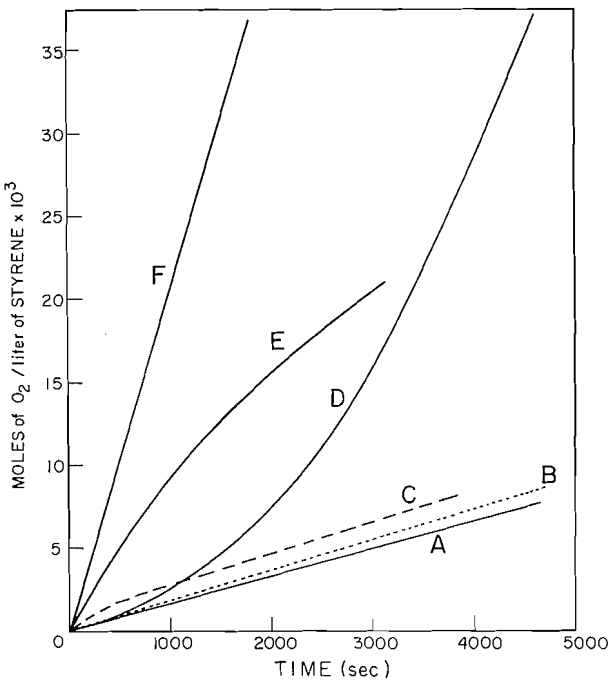

FIG. 6. Effect of H_2O and D_2O on the inhibited oxidation of styrene at an AIBN concentration of 1.32×10^{-2} mole/liter and a BMP concentration of 1.0×10^{-2} mole/liter. Key: A, BMP; B, BMP + H_2O; C, BMP-*d* + H_2O; D, BMP + D_2O; E, BMP-*d*; F, BMP-*d* + D_2O.

The initial rates of the BMP-*d*-inhibited oxidation in the absence of D_2O are compared with the rates of the normal BMP-inhibited reaction at 65° C in Fig. 4. The isotope effect, which is given by the relative slopes of the two lines (equation [VIII]), should probably be regarded as a lower limit, since some exchange occurs before sufficient

**Infrared spectra suggest that small quantities of water are produced in the uninhibited oxidation.*

measurements have been made to obtain an accurate rate. The infrared spectra of reaction samples inhibited by BMP-*d* at a number of stages from preparation to fairly extensive oxidation indicated that this exchange amounted to about 5–8% during the initial linear region of the oxidation curve. The approximately 67% increase in the rate produced by D_2O is, therefore, probably largely due to the maintenance of fully deuterated BMP in the oxidizing system. A lesser part of the increase is probably due to the same factors that cause H_2O to have a small accelerating effect, ~10%, on the inhibited reaction. That is, the measured isotope effect at 65° C in the absence of D_2O is 7.1. On the basis that 5–8% of the deuterium has already exchanged, the true isotope effect will be about 50% greater than this, i.e., $7.1 \times 1.5 = 10.6$. The measured isotope effect in the presence of D_2O is 11.7, which, after applying the 10% correction based on the effect of H_2O, gives an isotope effect of 10.5, in agreement with the value calculated for fully deuterated BMP. In view of the large effect of D_2O on the uninhibited oxidation (see below) it was considered to be safer to estimate the isotope effect from the experimental slopes of the lines obtained in the absence of D_2O rather than in its presence. These slopes are compared at each temperature in Fig. 5 with the slopes obtained with the undeuterated phenol, and they give the minimum isotope effect since they would probably be about 50% greater if allowance were made for deuterium loss. The activation energy with BMP-*d* is $(E_{VIII})_D = 35.8 \pm 0.5$ kcal/mole. Therefore, $(E_6)_D - (E_6)_H = 1.1 \pm 1.0$ kcal/mole.

In view of the catalytic effects of light and heavy water on the inhibited oxidation their effect on the uninhibited oxidation was also examined. H_2O increased the rate by about 12–15% and D_2O by nearly 50%. The increases appeared to be independent of temperature and AIBN concentration and were not due to metal catalysts.

DISCUSSION

From this study of the deuterium isotope effect of the autoxidation inhibition reaction it is apparent that styrene has certain advantages over many of the more usual oxidizable substrates. The most notable advantage is the very low concentration of hydroxyl-containing compounds in the products. On the other hand, the non-integral kinetics of uninhibited oxidation is very surprising, particularly in view of earlier reports about this reaction (18). As was discussed in the previous section, these kinetics can be most readily explained by assuming that a first-order termination process is competing with the usual bimolecular termination. The exact nature of this reaction is unknown but the effect of H_2O and D_2O on the "uninhibited" oxidation suggests that a free radical inhibitor containing a replaceable hydrogen is responsible. Since the rate of oxidation is constant for the "uninhibited" oxidation up to fairly high conversions the concentration of such an inhibitor must rapidly reach a steady state. That is, the inhibitor must be formed throughout the oxidation and must react with a small but constant percentage of the peroxy radicals produced by the decomposing AIBN. In view of the reaction conditions, it seems a reasonable assumption that such a compound contains a hydroxyl group and is therefore, quite probably, a phenol. If this is the case, the small catalytic effect of H_2O could be due to surface adsorption of some of the phenol on the water droplets. This would decrease its effective concentration, since the active centers would be oriented away from the peroxy radicals present in the organic phase. The larger catalytic effect of D_2O would be due to the decreased reactivity of the exchanged but unadsorbed deuterated phenol.

The suggestion that an inhibitor, which is probably a phenol, is produced in the AIBN-initiated oxidation of styrene receives further support from the observation (31)

that the AIBN-initiated oxidation of benzene gives a product which inhibits the thermal polymerization of styrene. Moreover, the fact that H_2O is a catalyst in the present system implies that some rather unusual reaction is occurring, since water generally has either no effect on a substrate (25) or else behaves as an inhibitor. Its usual inhibiting effect is most probably due both to the solvation of small initiating radicals and to the surface adsorption of the larger peroxy radicals.

Although the activation energies and rate constants of the uninhibited propagation and termination reactions cannot be separately evaluated from the present measurements, it is possible to determine $E_3-\frac{1}{2}E_5$ and $k_3/k_5^{1/2}$ from both ρ_0 and β. The two sets of data are in good agreement, as would be expected, and the average values can be represented by

$$E_3-\tfrac{1}{2}E_5 = 7.7\pm0.5 \text{ kcal/mole}$$

$$\frac{k_3}{k_5^{1/2}} = 2.6\times10^3 \exp(-7700/RT) \text{ (liter/mole sec)}^{1/2}.$$

Both these quantities compare very well with the values previously reported by other workers for a variety of fairly reactive substrates containing activated secondary hydrogen atoms, e.g., ethyl linoleate (32) and tetralin (33). It is interesting that a very similar relationship holds for the thermal polymerization of styrene (34), i.e.,

$$\frac{k_{\text{propagation}}}{(k_{\text{termination}})^{1/2}} = 4.17\times10^3 \exp(-6370/RT) \text{ (liter/mole sec)}^{1/2}.$$

Hydrocarbon structures appear to have little effect on the self-termination rate constant of secondary peroxy radicals, since all determinations of k_5 by non-stationary-state methods in substrates which yield these radicals lie fairly close to 10^7 liter/mole sec (5, 6, 32, 33, 35, 36). It therefore seems not unreasonable to assign this same value of k_5 to polystyryl peroxy radicals. Making the further assumption that $E_5 = 0$ within experimental error, we obtain

$$k_3 = 8.1\times10^6 \exp(-7700/RT) \text{ (liter/mole sec)}.$$

The corresponding values for thermal polymerization are (34)

$$k_{\text{propagation}} = 4.5\times10^6 \exp(-7300/RT) \text{ (liter/mole sec)}$$
$$k_{\text{termination}} = 5.8\times10^7 \exp(-1900/RT) \text{ (liter/mole sec)}.$$

An activation energy and an *apparent* first-order rate constant for the postulated first-order termination reaction in the uninhibited oxidation can be derived from α. That is,

$$E_8-\tfrac{1}{2}E_5 = 3.3\pm1.5 \text{ kcal/mole}$$

$$\frac{k_8}{k_5^{1/2}} = 4.4\times10^{-6} \exp(-3300/RT) \text{ (mole/liter)}^{1/2} \text{ sec}^{3/2}$$

or

$$k_8 = 1.4\times10^{-2} \exp(-3300/RT) \text{ sec}^{-1}.$$

The activation energy of this reaction is of the right order of magnitude for the reaction of a polystyryl peroxy radical with a phenolic inhibitor that is rather less reactive than BMP (see below).

At low concentrations of BMP we obtain from E_{VII} and the average value of $E_3-\frac{1}{2}E_5$:

$$E_6-\tfrac{1}{2}E_5 = 1.7\pm1.5 \text{ kcal/mole},$$

and hence,

$$\frac{k_6}{k_5^{1/2}} = 21.8 \exp(-1700/RT) \text{ (liter/mole sec)}^{1/2}$$

or

$$k_6 = 6.9\times10^4 \exp(-1700/RT) \text{ (liter/mole sec)}.$$

At high concentrations of BMP we obtain from E_{VIII} and equation [VIII]

$$E_6-\tfrac{1}{2}E_5 = 1.7\pm1.0 \text{ kcal/mole}$$

$$\frac{k_6}{k_5^{1/2}} = 33.8 \exp(-1700/RT) \text{ (liter/mole sec)}^{1/2}$$

or

$$k_6 = 1.0\times10^5 \exp(-1700/RT) \text{ (liter/mole sec)}.$$

The two sets of data derived by independent experiments are in excellent agreement, but it is probable that the results obtained at high concentrations are more accurate (Figs. 3 and 4). The absolute value of k_6 is in excellent agreement with the values reported for this reaction with cyclohexane and some methyl-substituted cyclohexanes as substrates (5). The activation energy is, however, less than half of the previous reported values but within the limits of accuracy of both methods, and considering the different substrates employed the agreement is satisfactory. Moreover, it is interesting to note that this activation energy is quite close to the value of 1.0 ± 0.5 kcal/mole recently found for the transfer of a hydrogen atom between 2,4,6-tri-*tert*-butylphenol and its phenoxy radical (37).

The present result is also in excellent agreement with the rate constant obtained for the reaction of 2,4,6-trimethylheptylperoxy radicals with the comparatively poor inhibitor diphenylamine (16), i.e.,

$$k = 6.0\times10^4 \exp(-3500/RT) \text{ (liter/mole sec)}.$$

This suggests that there is no fundamental difference in the mechanism of inhibition between phenols and secondary aromatic amines.

At high concentrations of BMP-*d* in the absence of D_2O, we obtain

$$(E_6)_D-\tfrac{1}{2}E_5 = 2.8\pm1.0 \text{ kcal/mole}.$$

Under these conditions maximum rate constants will be obtained, since no correction has been made for the fact that the BMP-*d* was no longer fully deuterated by the time

these measurements were made. On making this correction the pre-exponential factors will be decreased by one third to give minimum rate constants, since the correction factor (1.0/1.5) may have been somewhat overestimated. In the following expressions the first number represents the uncorrected pre-exponential and the second the corrected pre-exponential factor. The true values should lie between these limits.

$$\frac{(k_6)_D}{k_5^{1/2}} = 24.6\ (16.4)\ \exp\ (-2800/RT)\ (\text{liter/mole sec})^{1/2}$$

$$(k_6)_D = 7.8\ (5.2)\times 10^4\ \exp\ (-2800/RT)\ (\text{liter/mole sec})$$

Therefore,

$$\frac{(k_6)_H}{(k_6)_D} = 1.3\ (2.0)\ \exp\ (1100/RT).$$

The difference in activation energy for normal and deuterated BMP can be calculated on the basis of a simple zero-point energy effect from the O—H and O—D fundamental stretching frequencies (38). In styrene, $\nu_{O-H} = 3634\ cm^{-1}$ and $\nu_{O-D} = 2682\ cm^{-1}$ for BMP and hence,

$$(E_6)_D - (E_6)_H = 1.36\ \text{kcal/mole},$$

in excellent agreement with the measured value. The ratio of the pre-exponential factors should lie between 1.0 and $\sqrt{2.0}$ (38), giving a calculated isotope effect of 7.6 and 10.6 respectively at 65° C compared with an uncorrected measured value of 7.1 and a corrected measured value of 10.6. These values should also be compared with the rather smaller isotope effect, $(k_6)_H/(k_6)_D = 4.2\pm0.5$, which we have obtained very recently from the initial rates of the AIBN-initiated oxidation of cumene inhibited by BMP at 65° C (25).

The present results indicate that the rate-determining step for the inhibition of the autoxidation of aromatic substrates by BMP involves a straightforward abstraction of the phenolic hydrogen by peroxy radicals. There is therefore no need to postulate the formation of an intermediate complex as the rate-determining step with this particular inhibitor in an aromatic substrate. This result can probably be generalized to all strong phenolic inhibitors which show first-order kinetics but it is possible that complexing will be rate determining in non-aromatic media.

The determination of rate constants and activation energies would be greatly improved by using a photochemical method of initiation instead of the thermal method, since this would eliminate the large activation energy E_1 from the calculations. Moreover, a direct determination of k_5 could then be made by the rotating sector technique.

It might be added, in conclusion, that comparisons of deuterated and undeuterated inhibitors by measurements of the induction periods produced in a given substrate are extremely unlikely to detect appreciable isotope effects under either initiated or thermal conditions. In the first case, if the reaction is initiated by a compound such as AIBN it is obvious that the length of the induction period will not be affected by deuteration of the inhibitor. In the second case, where initiation is due to the thermal decomposition of hydroperoxide products, the hydroperoxide concentration which builds up during the induction period will generally be quite sufficient to ensure a virtually complete exchange of the deuterium before the end of the induction period. This will lead to nearly equal induction periods for the two inhibitors. That is, if deuteration reduces inhibitor efficiency

by a factor of 10 it will increase the chain length by an equal factor. Therefore, from the very beginning of the reaction, at least 10 molecules of inhibitor (and probably many more since this assumes a chain length of only one for the undeuterated compound) can lose deuterium by exchange with the product hydroperoxide for each molecule that reacts with a peroxy radical. That is, nearly all the deuterium can be lost by exchange in the early part of the induction period so that the measured induction periods will appear to be nearly identical for the deuterated and undeuterated inhibitor. This difficulty might be overcome either by extremely careful measurements at very low degrees of oxidation, although even these would not give the true isotope effect, or alternatively, by the addition of D_2O, provided the D_2O had no effect on the oxidation other than to maintain the inhibitor in its fully deuterated state.

ACKNOWLEDGMENT

The authors wish to thank Dr. I. E. Puddington for his continuing interest and advice throughout the course of this work.

THE CHEMICAL SHIFT OF AROMATIC ALKOXY GROUPS

CLAYTON HEATHCOCK[1]
Research and Development, Humble Oil & Refining Co., Baytown, Texas, U.S.A.
Received May 31, 1962

ABSTRACT

The nuclear magnetic resonance (n.m.r.) spectra of 42 variously substituted anisoles and phenetoles have been obtained. The chemical shifts of the alkoxy hydrogens have been assembled in charts for ready use in interpreting the n.m.r. spectra of unknown compounds. For meta- and para-substituted anisoles, a reasonably good correlation has been shown to exist between the methyl resonance and the corresponding Hammett σ parameter. With anisole itself, a preferential solvent effect has been noticed which suggests a specific type of interaction between solute molecules.

In the interpretation of high-resolution nuclear magnetic resonance spectra, two features are of prime importance: the chemical shift and the spin–spin multiplicity pattern. Spin coupling shows the relative positions of various protons within a molecule, and the chemical shift derives its usefulness from its ability to "see" various functional groups which may be present. Chamberlain (1) has shown that the chemical shift can be a powerful tool in the identification of functional groups. Chamberlain's chemical shift charts contain the complete data on more than 400 organic compounds. By using these charts, the organic chemist is often able to identify an unknown resonance peak with a specific functional group.

In these data, however, only two compounds containing aromatic alkoxy groups are included. The only specific study of compounds of this type which has appeared in the literature is the work of Kun and Cassidy (2), who report the spectra of a number of methylated 1,4-dimethoxybenzenes.

In light of the fact that this functional group is very common in organic compounds, especially those of biological origin, we have obtained the n.m.r. spectra of 42 variously substituted anisoles and phenetoles and condensed the data into a chemical shift chart patterned after those of Chamberlain (1).

EXPERIMENTAL

Nuclear magnetic resonance spectra were produced with a modified Varian V-4300B spectrometer operating at a frequency of 60 Mc. The magnetic field was stabilized to a high degree by proton-resonance control in addition to the Varian Super Stabilizer. All spectra were run at room temperature (ca. 30° C) at an r.f. amplitude of 0.04 milligauss and a scan rate between 1.5 and 5.0 c.p.s./sec. All compounds studied were commercial samples and were used as delivered with no further purification. Spectra were referenced from internal tetramethylsilane (TMS) and chemical shifts are expressed on the "tau" scale (3). Concentrations were maintained at 10% or lower in carbon tetrachloride where solubility permitted. In duplicate measurements, an average difference of 0.012 p.p.m. was observed.

RESULTS AND DISCUSSION

The data are presented in Tables I and II. The range of values obtained is remarkably narrow, considering the number of compounds included and the range of ring substituents. This is fortunate, since it enables one to pinpoint rather precisely the shift expected for alkoxy hydrogens in almost any conceivable environment. It should be noted that the present data were obtained with concentrations no greater than 10% by weight in an inert solvent. The resonance positions are strongly solvent dependent,

*All spectra were at a concentration of 10% in CCl_4. The chemical shifts of the ring hydrogens are given as ranges where spin-coupling patterns were not readily interpretable. Resonance positions are expressed on the "tau" scale (3).

and the use of concentrations greater than 10% leads to highly unreliable results. For example, the chemical shift of the methyl hydrogens in anisole varies from 3.34 τ for a 10% solution in CCl_4 to 3.63 τ for the neat liquid.

There seems to be a definite dependence of the resonance of the methoxy or ethoxy group on ring substitution. The data have been accumulated into a chemical shift chart (Fig. 1), although, with one exception, no effort has been made to show, on the chart,

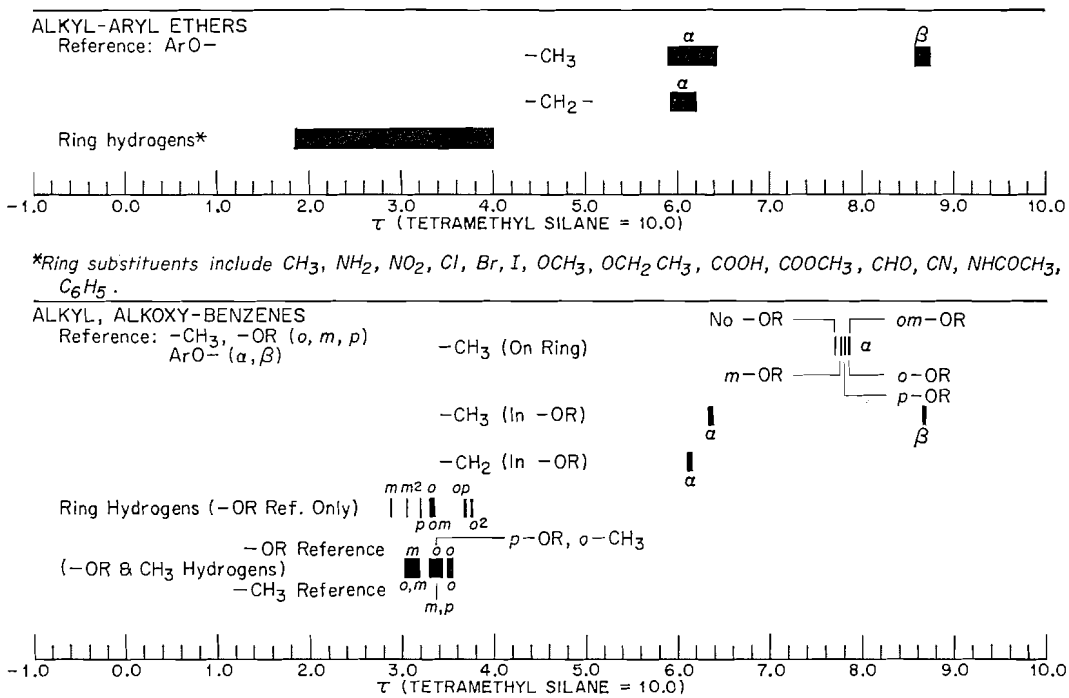

FIG. 1. Chemical shift chart for alkyl ethers of substituted phenols.

the fine distinctions caused by the ring substituents.[2] The one exception is in the alkyl, alkoxy benzenes. Because of the number of compounds studied in this category (14) and the regular trends observed, a separate part of the chart has been devoted to a summary of their chemical shifts.

The origin of the observed dependency of chemical shift on ring substituent is of interest. Figure 2 is a plot of the methyl resonances of meta- and para-substituted anisoles versus the corresponding Hammett σ functions. The Hammett functions are experimental parameters which provide a measure of the ability of a substituent to withdraw or donate charge through a combination of its inductive and resonance effects (4).

As is evident, the correlation is fairly good, although not perfect. The fact that a correlation exists is evidence that, at least to some extent, the dependence of the chemical shift of the alkoxy group on the nature of the ring substituent is due to the inductive and resonance effects of the substituent.

Several groups of workers have found analogous correlations in other systems. Taft (5) has found a precise correlation of the F^{19} resonance in meta- and para-substituted fluorobenzenes with the corresponding reactivity parameters. Bothner-By and Glick (6) noticed a relationship between the chemical shift of the para hydrogen in several mono-

[2]*See reference 1 for nomenclature of the chemical shift charts. The referencing nomenclature has been changed from the parts per 10 million from benzene scale originally proposed by Chamberlain to the "tau" scale in accordance with current usage.*

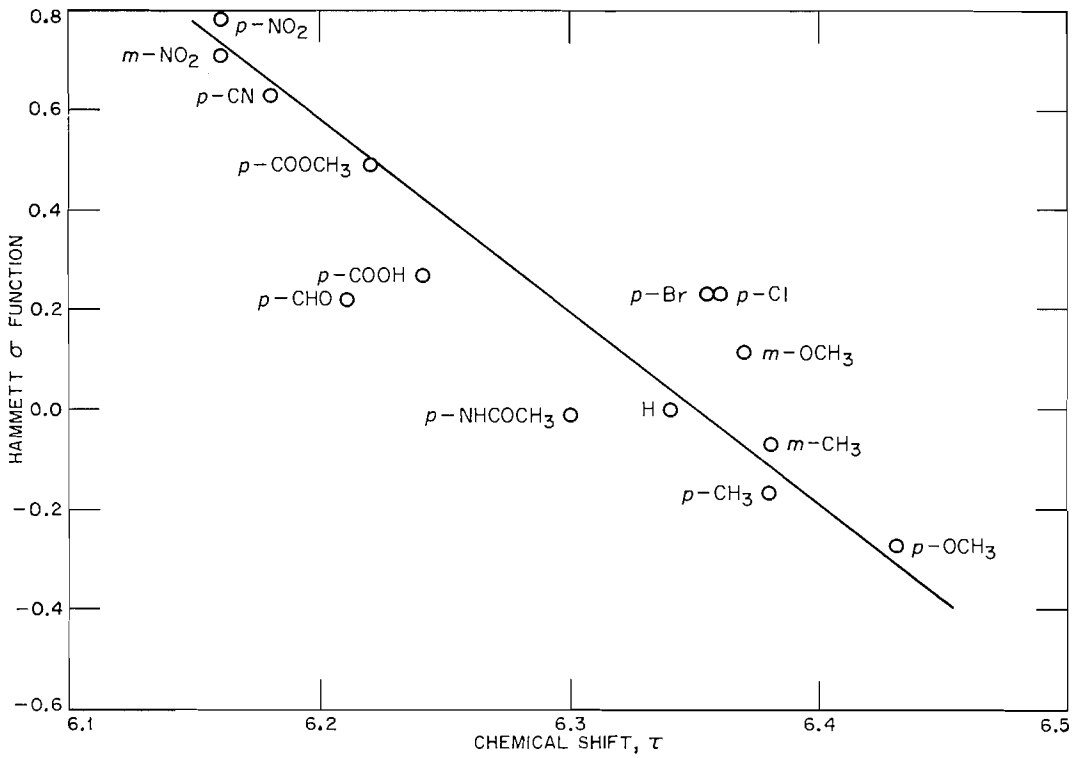

FIG. 2. Dependence of methoxy chemical shift on aromatic ring subtsituent.

substituted benzenes with the Hammett functions. More recently, Spiesecke and Schneider (7) were able to correlate the Hammett functions with the chemical shift of both C^{13} and H^1 in the para position of monosubstituted benzenes, although they failed to find a similar correlation in the meta position. Apparently, our work is the first example of a correlation between reactivity parameters and chemical shift of nuclei not a part of, or directly connected to, the ring. The fact that some of the points fall off the line of best fit simply indicates that these effects are not the only causes of the shifts observed. Also, the Hammett parameters are only accurate to $\pm 15\%$. In the case of substituents ortho to the alkoxy group, complexities are encountered. In this position, proximity effects must no doubt be taken into consideration.

As is mentioned above, the methyl resonance in anisole is highly solvent dependent. However, the ring hydrogen resonance is scarcely affected by dilution with CCl_4, as is shown in Fig. 3.

A similar behavior has been noticed by Hatton and Richards (8) with γ-picoline. These workers found that the resonances of the methyl and β-ring hydrogens shifted downfield upon dilution with CCl_4 while the α-ring hydrogens were not affected. They have proposed a structure for the neat liquid in which the molecules associate as dimers, with the methyl group of each molecule located roughly over the face of the ring of its partner molecule. Such an arrangement causes the methyl hydrogens and β-hydrogens to be shielded by the diamagnetic anisotropy of the adjacent aromatic ring, while the α-hydrogens are in approximately the right position for the net effect to be zero. Dilution with an inert solvent breaks up the association, with a resulting downfield shift for the hydrogens involved.

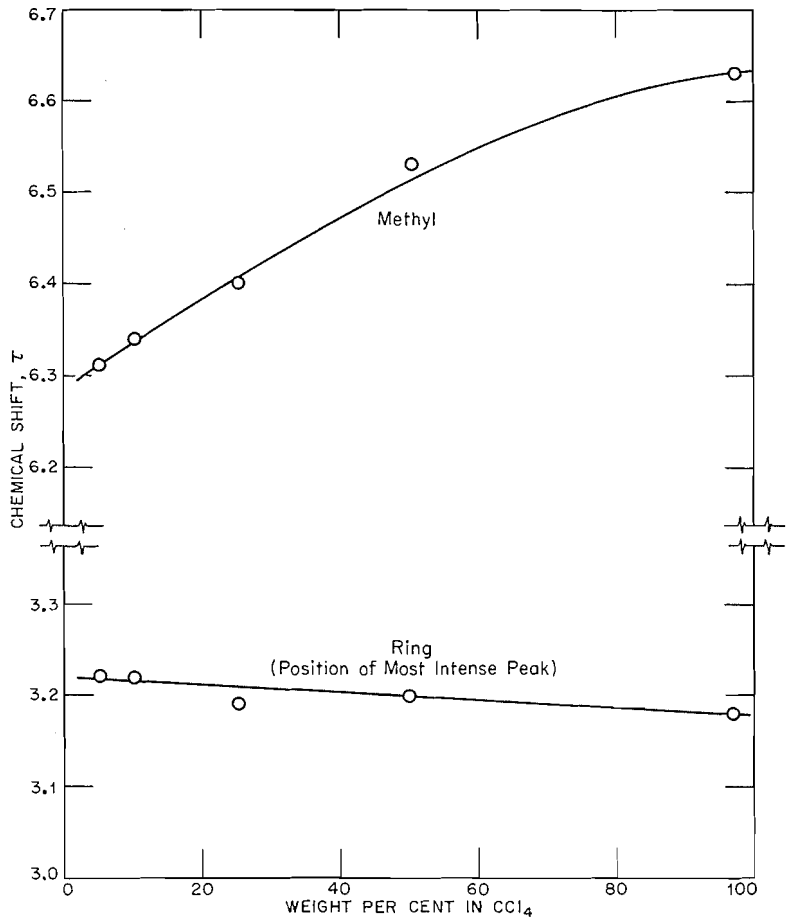

FIG. 3. Chemical shifts of anisole as a function of concentration.

An analogous arrangement seems to be indicated for anisole molecules. However, in the case of anisole, the inclusion of an oxygen between the aromatic ring and the methyl places all of the ring hydrogens in a region where the effect of the diamagnetic anisotropy of the partner molecule is negligible.

ACKNOWLEDGMENTS

The author wishes to thank N. F. Chamberlain and Dr. F. C. Stehling for many valuable discussions during the course of this work, and R. K. Saunders and T. J. Denson for obtaining some of the spectra used.

NUCLEAR MAGNETIC RESONANCE SPECTRA OF SIX-MEMBERED ALCYCLIC RING COMPOUNDS AT LOW TEMPERATURE

IV. PARTIALLY DEUTERATED 1,2-*trans*-CHLOROIODOCYCLOHEXANE

E. Premuzic and L. W. Reeves

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received March 16, 1962

ABSTRACT

A 50/50 mole% mixture of 1-iodo-2-chloro-1,3,3-trideutero-, and 1-chloro-2-iodo-1,3,3-trideutero-cyclohexane has been synthesized. At −93° C in a CS_2 solution iodochlorocyclohexane shows resolution into diaxial and diequatorial halogen forms. Analysis of the adjacent proton resonance signal intensities shows that this compound exists 68±3 mole% in the diaxial halogan form. This is quite similar to 1,2-dibromocyclohexane, which has 70 mole% in the diaxial form, and is in contrast to 1,2-dichlorocyclohexane, which has a more stable diequatorial form.

INTRODUCTION

In six-membered alcyclic ring compounds, axial and equatorial protons have been distinguished by chemical shift measurements (1). The indirect spin–spin coupling constants between the various protons have energies decreasing in the order $Je_1a_1 > Ja_1a_2 > Je_1a_2 \simeq Je_1e_2$ (17). In this notation, e_1 corresponds to a proton equatorial on carbon 1, a_1 axial on carbon 1, e_2 equatorial on carbon 2, and a_2 axial on carbon 2.

Several other techniques have been used to determine the configurations in the six-membered ring compounds. In particular, electron diffraction methods (2) give the bond lengths and bond angles in some cases. The technique is limited to the gas phase and the method is not sensitive enough to give accurate populations of two chair forms in equilibrium. Infrared measurements have been made on these types of compounds, and the separation of the skeletal carbon vibrations from the vibrations of the $\rangle$CH bonds have been made (3–5). The $\rangle$CH stretching region of the infrared spectrum of these molecules is too complex to interpret in terms of the configurations of the rings. Selective deuteration of the rings and observation of the $\rangle$CD stretching region have been carried out (15, 14). Axial and equatorial deuterium atoms in the rings have been distinguished by this means, but the method has not been accurate enough to determine an analysis of a compound with an unsymmetrical inverting ring system, chair to chair. The infrared method has also been used to distinguish axial and equatorial $\rangle$CX groups from the region of the spectrum appropriate to the $\rangle$CX stretching frequency (16, 13). Analysis of cyclohexyl chloride and cyclohexane thiol for axial and equatorial sulphur or halogen groups has been achieved by this technique.

Six-membered ring compounds which are not locked by the substitution of large groups around the ring into one configuration undergo chair-to-chair inversion. The rate of chair-to-chair inversion can be studied by proton resonance measurements. At room temperature these inverting ring compounds have a spectrum which is the weighted average of the equilibrium forms (18, 6, 12). Between room temperature and −150° C the two distinct forms in equilibrium become distinguishable in the n.m.r. spectrum so

that it is possible to analyze the percentage of each chair form by either measuring the intensities under respective proton resonance peaks at low temperature or by the techniques suggested in the paper of Gutowsky and Saika (18). Measurements of chemical shifts and coupling constants of the two distinguishable chair forms at low temperature may be combined with average chemical shift and coupling constant measurements at room temperature to give an analysis of the rapidly interconverting mixture at room temperature. The proton resonance technique has already been used to study halogenated cyclohexane (6, 12), *trans*-disubstituted cyclohexanes (7), N,N-dimethylpiperazine (8), bicyclic systems such as decalins (9), cyclohexane (10), and perfluorocyclohexane (11).

The difficulties of the proton resonance method as applied to these molecules are the complexities of the proton resonance spectrum, which increase as the symmetry of the molecule is lowered by substitution. In most cases the energy barrier for chair-to-chair inversion has been estimated from the so-called "coalescence temperature", assuming a frequency factor of 10^{13}. It is apparent that substitution of the cyclohexane ring or the introduction of a hetero atom into the ring of carbons may result in the mechanism of chair-to-chair inversions being changed. The assumption of a frequency factor 10^{13} is then not justified, since in these different inversion mechanisms the entropy of activation will not be the same. In simple monosubstituted cyclohexanes the proton resonance adjacent to the substituted group is in general chemically shifted to low field from the rest of the ring protons, and indirect spin–spin interaction with the α protons renders the proton resonance spectrum of this adjacent proton quite complex and in many cases up to 12 cycles in apparent half-width. At low temperatures the resolution of the two chair forms into distinct n.m.r. spectra sometimes results in overlap between the axial and equatorial proton peaks. In order to overcome some of the difficulties of the n.m.r. technique in the study of these molecules, this paper will describe a selective deuteration around the cyclohexane ring so as to simplify the complex spectrum and obtain more accurate populations of chair forms.

EXPERIMENTAL

The variable-temperature n.m.r. apparatus is part of a 40 Mc/s Varian high-resolution spectrometer and is described in previous work (1). The verification of the structure of intermediates was greatly aided by the use of an A60 Varian spectrometer.

Preparation of Cyclohexanone-2,6-D_4

Cyclohexanone was treated with D_2O from Stuart Oxygen Co. (99.8% deuterium). Twenty milliliters of cyclohexanone and a solution of 1–2 g of sodium carbonate in 10 ml D_2O were refluxed overnight. The D_2O layer was then frozen and separated. The cyclohexanone layer was dried over sodium sulphate. The exchange was repeated four times until the A60 spectra showed, from integrated intensity measurements, that only 2% of the α protons remained.

Reduction of 2,6-Tetradeuterocyclohexanone

A typical reduction was carried out with lithium aluminum hydride in the following manner. A saturated solution of lithium aluminum hydride in dry ether was placed into a two-necked, round-bottomed flask. The flask was cooled with ice and the reaction mixture stirred magnetically. A reflux was set up and cyclohexanone-D_4 was added dropwise from a separatory funnel. When the reduction was complete, excess of lithium aluminum hydride was destroyed with slow addition of moist ether. Ice-cold 10% sulphuric acid was then added gradually, until all of the precipitated aluminum hydroxide dissolved. The ether layer was then separated out and dried over anhydrous sodium sulphate. The ether was removed by distillation and the fraction boiling at 155–157° C collected. On a 10-g preparation, yield of cyclohexanol-D_4 (2,6-tetradeuterocyclohexanol) was **7.2 g**.

Dehydration of Cyclohexanol-D_4 to 1,3,3-Trideuterocyclohexene

The conventional dehydration of cyclohexanol with phosphoric acid was used. Phosphoric acid (85%) was added dropwise to 6.33 g of cyclohexanol-D_4 until a homogeneous mixture resulted (2.5 ml of phosphoric acid). The reaction mixture was then subjected to distillation using a small glass-bead column and the

fraction distilling at 82–83° C collected. A good yield of 3.4 g or 65.6% of pure deuterated cyclohexene was thus obtained.

Addition of Iodine–Chloride across the Double Bond of Cyclohexene-D_3

Cyclohexene-D_3 (1.23 g) was dissolved in 3 cc of ice-cold glacial acetic acid. Iodine–chloride (2.3 g) dissolved in 6 ml of glacial acetic acid was then added dropwise to this solution. The reaction mixture was cooled throughout. At the end of the reaction, the product containing a slight excess of iodine–chloride was transferred into a separatory funnel, and then shaken well with 5 ml of saturated sodium thiosulphate. The oily chloroiodocyclohexane was allowed to separate out, treated further with sodium bicarbonate, and dried over anhydrous sodium sulphate. The almost quantitative yield of the mixture of 1-iodo-2-chloro-1,3,3-trideuterocyclohexane and 1-chloro-2-iodo-1,3,3-trideutero cyclohexane was then subjected to n.m.r. studies.

RESULTS

Figure 1 shows 60 Mc/s spectra of 1-chloro-2-iodo-cyclohexane and the 50/50 mole%

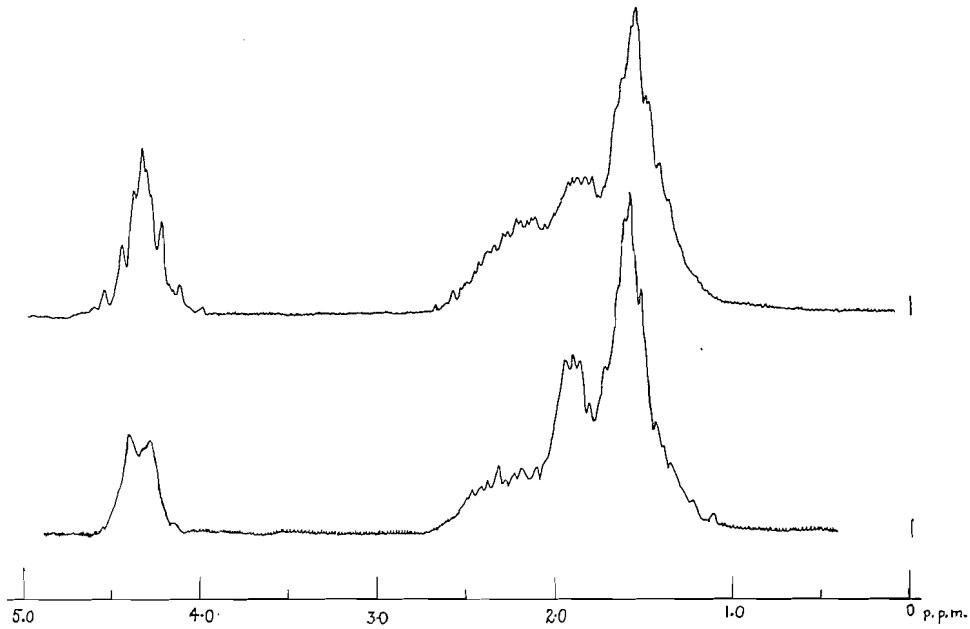

FIG. 1. Sixty-megacycle spectra of 1,2-*trans*-chloroiodocyclohexane (upper) and the 50/50 mixture of 1-iodo-2-chloro-1,3,3-trideuterocyclohexane and 1-chloro-2-iodo-1,3,3-trideuterocyclohexane. Both were diluted to 20 mole% in CS_2.

mixture of 1-iodo-2-chloro-1,3,3-trideutero cyclohexane and 1-chloro-2-iodo-1,3,3-trideuterocyclohexane. The chemical shift between the —CHI— proton and the —CHCl— is small and can be measured directly from the mixture of deuterated molecules (0.12 p.p.m. = 7.2 c.p.s.).

The peaks obtained for the —CHCl—CHI— group arise as follows. The two protons within this group comprise an AB spectrum requiring second-order theory in order to evaluate δ_{AB} and J_{AB}. The value for δ_{AB} is 7.2 c.p.s. (The —CH_2— groups adjacent to the —CHI—CHCl— group form a set of four inequivalent protons all of which are at least 120 c.p.s. removed to higher field.) There should be 16 lines in all, some of which may be coincident. Ten lines have been resolved in spectra taken under slower sweep conditions than those illustrated in Fig. 1. It has not been possible to satisfactorily assign these transitions to obtain coupling constant data.

Low-temperature Studies at 40 Mc/s

Figure 2 shows two spectra, at −44° C and −107° C, of the mixture of deuterated iodochlorocyclohexanes. There was no detectable change in the proton resonance spectra

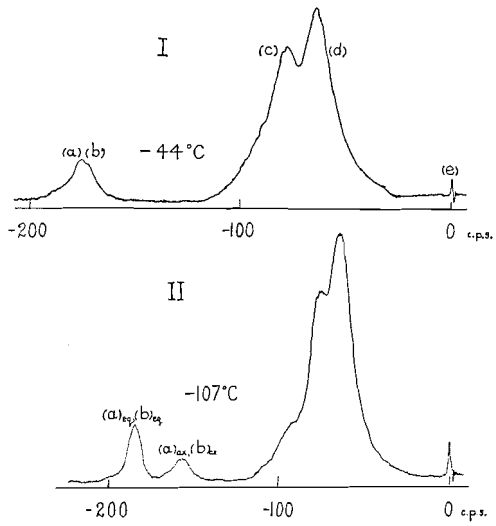

FIG. 2. Forty-megacycle spectra at −44° C and −107° C of the deuterated iodochlorocyclohexane at 40 mole% in CS_2.

between room temperature and −80° C so the spectrum at −44° C is typical of this temperature range. It can be related to the spectrum described in Fig. 1 at 60 Mc/s for the same sample. The low-field peak in spectrum I, Fig. 2, does not show complete resolution into the —CHI— and —CHCl— components. These are labelled (*a*) for the —CHI— proton resonance and (*b*) for the —CHCl— signal. Signals (*c*) and (*d*) marked in spectrum I, Fig. 2, correspond to the distinguishable peaks in the high-field spectra at 60 Mc/s in Fig. 1. The low-field tail of these peaks is barely distinguishable in the 40 Mc/s spectrum. The internal standard hexamethyldisiloxane appears in Fig. 2 marked as 0 c.p.s. The compound was dissolved in CS_2 at a concentration of 40 mole%.

The broadening of the low-field signals occurs below −80° C and they become clearly resolved into two peaks at −100° C. A single broad peak (the "coalescence temperature") is observed at −93° C. The two resolved low-field peaks are in fact composite so that at lowest field $(a)_{eq}(b)_{eq}$ are made up of equatorial proton signals geminal to chlorine in one half of the sample and to iodine in the rest. The corresponding axial proton resonances $(a)_{ax}(b)_{ax}$ are also designated in spectrum II of Fig. 2. The protons geminal to chlorine and iodine are not distinguishable at 40 Mc/s and so the spectra at low temperature can be analyzed into the percentage of the diaxial halogen chair form. Analysis of the spectra below −95° C shows that 68±3 mole% of this iodo–chloro compound exists in the diaxial halogen form. This result is based on the intensities obtained from 18 low-temperature spectra. The deviation from the mean is a maximum value. The mean chemical shift of $\rangle$CHI and $\rangle$CHCl protons at room temperature is −174.8 c.p.s. (−4.37 p.p.m.) from an internal hexamethyldisiloxane reference. At low temperature the mean of the two diaxial proton shifts adjacent to the halogens is −158.2 c.p.s. (−3.96 p.p.m.) and the

mean of the diequatorial protons is found at −185.2 c.p.s. (−4.66 p.p.m.). These values can be compared with earlier studies on dichloro- and dibromo-cyclohexane (7).

DISCUSSIONS

The difference in free energy, which is approximately the same as the energy content difference (6, 7) between diaxial and diequatorial halogen forms, is almost the same for iodochlorocyclohexane (+241 cal mole^{-1}) as for dibromocyclohexane (+305 cal mole^{-1}) (7). The repulsions of diequatorially substituted groups and the halogen with 3,5-diaxial hydrogens are almost exactly the same for iodochloro- as for dibromo-cyclohexane. The sum of the van der Waals radii of 1,2-*trans*-disubstituted groups appears to be the dominant effect in determining the stability of the configurations in the halogenated series of cyclohexanes.

NOTES

HIGH-FIELD KINETIC PROCESSES IN ANODIC OXIDE FILMS ON ALUMINUM

P. J. Ryan and M. J. Dignam

The electrode systems aluminum–alumina and tantalum–tantala afford a unique opportunity for the investigation of high-field ($\sim 10^6$ v/cm or higher) kinetic processes. A theory has been proposed by Bean, Fisher, and Vermilyea (1) to explain the complex transient behavior of these electrode systems. The qualitative predictions of this theory appear to be correct (2); however, critical analysis of data has indicated major discrepancies (3–5). This note presents some preliminary results which have bearing on the nature of these discrepancies and suggests a quantitative interpretation of them.

A full description of the model by Bean *et al.* can be found elsewhere (1–3, 5). Briefly, the ion current density, I, is assumed to depend on the electric field strength, E, and the concentration of interstitial cations, n, in accordance with Verwey's equation (6):

$$I = 2\,qa\nu n \exp\left[-(U-Eaq)/kT\right], \qquad [1]$$

where q is the charge on the ion, ν its vibrational frequency, U the activation energy for ion migration at zero field, and a the corresponding activation distance. Pairs of interstitial cations and cation vacancies (i.e. Frenkel defects) are assumed to be formed by the action of the field on lattice cations (N per unit volume), and to be destroyed by recombination, the collision cross-sectional area, πr^2, being assumed constant. The resulting equation is

$$dn/dt = N\nu \exp\left[-(W-E\lambda q)/kT\right] - I\pi r^2 n/q, \qquad [2]$$

where W is the zero-field activation energy and λ the activation distance for formation of a Frenkel defect. Equation [2] contains the assumption that the concentrations of interstitials and vacancies are essentially equal and are much smaller than N.

All measurements reported herein were performed by increasing the anodic overpotential, V, at a constant rate, $R = dV/dt$, the film thickness, δ, changing negligibly during a run. For these special conditions, elimination of n from equations [1] and [2] yields

$$\frac{d \ln I}{dV} = \frac{\pi r^2}{qR}\left[\frac{(\alpha \exp \beta E)^2}{I} - I\right] + \frac{qa}{kT\delta}, \qquad [3]$$

where α and β are constants occurring in the steady-state (i.e. $dn/dt = 0$) solution of equations [1] and [2]:

$$I = \alpha \exp \beta E, \qquad [4]$$

and are given by $\alpha = q\nu(2Na/\pi r^2)^{1/2} \exp\left[-(W+U)/2kT\right]$ and $\beta = q(\lambda+a)/2kT$. For R

sufficiently large, equation [3] predicts a linear relation between log I and V, the slope yielding the value of a. For smaller values of R, equation [3] can be rewritten as follows:

$$\ln Z = (2\beta/\delta)V + 2\ln\alpha, \qquad [5]$$

where

$$Z = I\left[\frac{qR}{\pi r^2}\left(\frac{d\ln I}{dV} - \frac{qa}{kT\delta}\right) + I\right].$$

Accordingly, for R sufficiently small, β (or $\lambda+a$) and α may be determined from a plot of log Z versus V, Z being calculated for various trial values for r, the value leading to the best linear plot being selected.

EXPERIMENTAL

Electropolished samples of superpurity aluminum were anodically oxidized at a constant current density, I_f, in a 30% solution of ammonium pentaborate in ethylene glycol (7) at room temperature. The instant the desired film thickness (100 → 500 Å) was achieved, the anodic overpotential was increased at a linear rate ranging from 10 to 2500 v/sec. The current during the rapid voltage sweep was recorded with an oscilloscope and camera. Details of the apparatus and procedure will be provided in a future publication.

RESULTS AND DISCUSSION

The results of our preliminary studies are summarized in Fig. 1 and Table I.

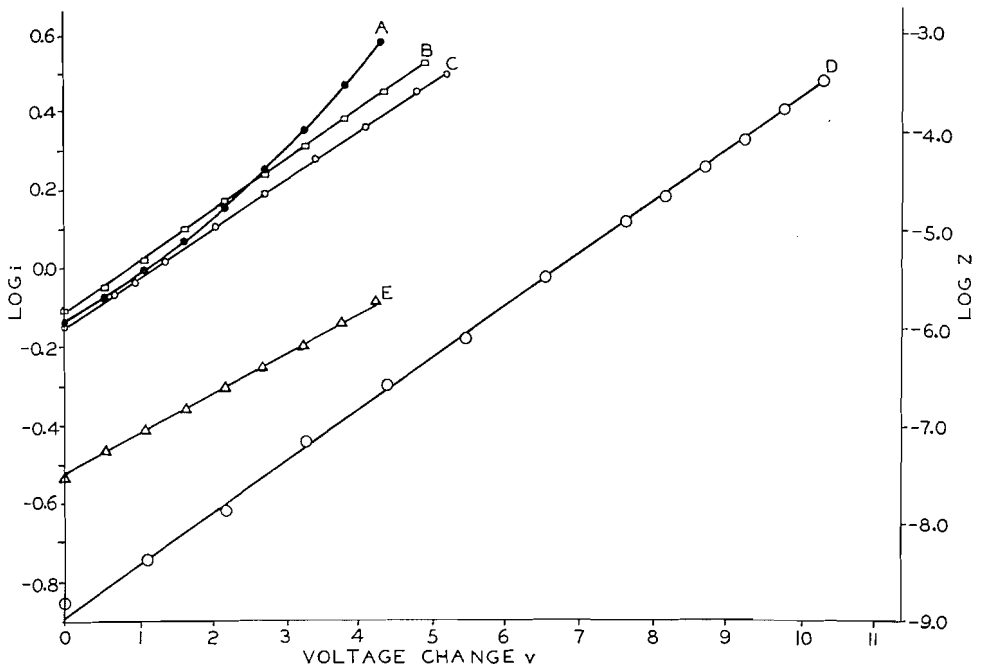

FIG. 1. Representation of transient conductivity measurements. Log i versus voltage change v: (A) $I_f \simeq 200$ μa/cm², $R = 107.6$ v/sec; (B) $I_f \simeq 200$ μa/cm², $R = 1076$ v/sec; (C) $I_f \simeq 200$ μa/cm², $R = 2703$ v/sec; (D) $I_f \simeq 20$ μa/cm², $R = 1076$ v/sec. Log Z versus voltage change v: (E) $I_f \simeq 200$ μa/cm², $R = 107.6$ v/sec. (Z in amp²/cm⁴, i in ma for an area $\simeq 3.4$ cm².)

TABLE I

Anodic oxidation parameters for the aluminum–alumina system

Reference	Method of measurement	$\lambda+a$ (Å)	a (Å)	r (Å)	α (amp/cm²)
Bernard and Cook (7)	Steady-state	8.2*			$\sim 10^{-22}$†
Present results	trans., $I_f = 2\times10^{-4}$	3.9	1.23	~4	$\sim 10^{-13}$
Present results	trans., $I_f = 2\times10^{-5}$	3.9	1.25	~4	$\sim 3\times10^{-1}$
Present results	trans., $I_f = 2\times10^{-6}$	4.0	~1.1	~4	$\sim 10^{-14}$

NOTE: trans. = transient; I_f in amp/cm².

*Steady-state values for $\lambda+a$ calculated from the literature from results obtained using aqueous electrolytes are: 7.1 to 8.1 Å (3), 7.3 Å (8), 7.2 Å (9), and 5.3 Å (10). All these results are ultimately interpreted as being $2(\lambda+a)$ rather than $\lambda+a$.

†Steady-state values for α for aqueous electrolytes are: 10^{-20} amp/cm² (8), 10^{-23} amp/cm² (9), and 10^{-18} amp/cm² (10). These results are ultimately interpreted as being α^2/I_f rather than α.

In accordance with the predictions, the logarithm of the current, i, is linear in the voltage change ($v = V(t) - V(t = 0)$) for $R \geqslant 1000$ v/sec. In addition, the resulting value of a (see equation [3]) is independent of R, within this limit, and also independent of the formation current density, I_f. Again, for runs in which $R \leqslant 100$ v/sec, log Z could be made linear in the voltage change, v, by a suitable choice for r, and $\lambda+a$ and α deduced from the slope and intercept. Within experimental error, r and $\lambda+a$ were also found to be independent of R and I_f. Neither r nor α could be determined with any degree of certainty. Values for the film thickness and sample area employed in the calculations were determined using the data of Bernard and Cook (7). Results of the calculations are presented in Table I.

The most interesting feature of these results is the disagreement, by a factor of 2, between $\lambda+a$ values calculated from steady-state and from transient data, and the corresponding discrepancy in the α values. The disagreement can be reconciled if it is assumed that N, the number of sites at which Frenkel defects may form, is not a constant equal to the number of lattice sites but is a function of the "amorphous" film structure, as proposed by Dignam (5). Quantitative agreement is obtained by setting N proportional to the rate of electrical energy dissipation per unit volume in the film for steady-state conditions, the rate of change of N with time being considered too slow to affect significantly the value of N during a transient measurement. Accordingly, setting $N = C'IE \simeq CI$ (since E varies by only a few percent for change of several powers of 10 in I) the steady-state solution of equations [1] and [2] becomes

$$I = \alpha' \exp 2\beta E, \qquad [6]$$

where $\alpha' = q^2\nu^2(2Ca/\pi r^2) \exp -(W+U)/kT$. Interpreting Bernard and Cook's steady-state data in terms of equation [6], $\lambda+a = 8.2/2 = 4.1$ Å, in agreement with the value of 3.9 Å obtained from the present transient measurements. Also, since $\alpha^2/\alpha' = I_f$, we have I_f equal to $(10^{-13})^2/10^{-22}$, $(3\times10^{-14})^2/10^{-22}$, and $(10^{-14})^2/10^{-22}$, which compare favorably with the measured values of 2×10^{-4}, 2×10^{-5}, and 2×10^{-6} amp/cm² respectively.

An extensive investigation of this system using techniques outlined herein is at present under way.

STEREOCHEMISTRY OF ARSENIC
V. CRYSTAL DATA FOR TRIARYLARSINES

J. TROTTER

Crystal structure studies of the halogenodiphenylarsines (1) have shown that, as a result of steric interactions, the phenyl groups are rotated from the positions that they might be expected to occupy in an "ideal" structure with maximum interaction between the arsenic lone pair and the aromatic π-electrons. The deviations are not, however, symmetrical, one ring being rotated approximately 90° and the other only about 30° from the orientation with maximum interaction.

Similar steric effects are to be expected in triarylarsines, except that the deviations are probably symmetrical; the analyses of the crystal and molecular structures of a few molecules of this type have been undertaken to determine the molecular configurations. The unit cell dimensions and space groups of crystals of triphenylarsine, tri-*p*-tolylarsine, and tri-*p*-xylylarsine were determined from single crystal rotation, oscillation, Weissenberg (all with Cu K_α radiation, $\lambda = 1.542$ Å), and precession films (Mo K_α, $\lambda = 0.7107$ Å). These data and other relevant information are given in Table I.

Crystal data for the triphenyl derivative have been reported previously by Wetzel (2), and these dimensions (with the cell reoriented by taking [101] as the new a axis) agree well with the present measurements (Table I). This compound has obviously a rather complex crystal structure, and no further work on it is proposed. We hope, however, to carry out detailed analysis of the *p*-tolyl and *p*-xylyl derivatives. A comparison of the configurations of these molecules will be of some interest, since tri-*p*-xylylarsine has a methyl group ortho to the arsenic, while the *p*-tolyl compound has no ortho substituent.

The author thanks Dr. W. R. Cullen for the crystal samples and helpful discussion, and the National Research Council for financial support.

FORMATION OF KETENEIMINE LINKS IN ACRYLONITRILE POLYMERIZED UNDER FREE RADICAL CONDITIONS*

J. C. Crosthwaite, J. J. McLeskey, III,† and P. Smith‡

Recently it has been shown (1) that polyacrylonitrile prepared by X-ray irradiation of pure liquid acrylonitrile at −78° C contains keteneimine links. On the other hand, acrylonitrile polymerized in bulk at 50° C using benzoyl peroxide as initiator has been reported to give polymer not possessing keteneimine links (2). The object of the present work was to determine whether the formation of keteneimine structures was peculiar to X-ray-initiated polymer by testing whether polyacrylonitrile made using conventional free radical initiation at dry ice – ethanol temperatures could give rise to these structures. The results obtained gave positive evidence for keteneimine link production. Consequently, the tests were extended to higher temperatures, with similar success.

In the case of polymethacrylonitrile formed under free radical conditions, Grassie and McNeill (3) have shown that keteneimine links form mainly via the chain termination step. If this were the case for polyacrylonitrile, these structures would be more readily detected for short-chain polymer. Hence, the experimental conditions of this work were aimed at producing short-chain polymer. Also, because it was thought that the keteneimine link formed by coupling of polyacrylonitrile free radicals in this system

might be unstable towards water, special efforts were made to exclude water from reaction mixtures. As the investigation progressed, it was shown that this precaution was perhaps unimportant.

‡To whom all correspondence should be addressed.

Initial attempts to polymerize acrylonitrile at dry ice – ethanol temperatures ($-72\pm 2°$ C) by ultraviolet irradiation of undiluted monomer were unsuccessful. The polymerization rate was too slow and insufficient polymer was obtained. With either benzoyl or *t*-butyl peroxide initiators added, the rate was increased sufficiently and the polymer was found in every case to possess the characteristic absorption of keteneimine structures at 4.93 μ (1–6).

In a like fashion, the bulk polymerization of acrylonitrile at $12\pm 2°$ C was carried out using ultraviolet irradiation both alone and with each of the two peroxide initiators mentioned above. No keteneimine links could be detected in the infrared absorption spectra of these polymers. This was attributed to their long chain length. Consequently, the polymerization was repeated with *t*-butyl peroxide as initiator under conditions similar to those above except that the monomer was made 1 *M* by dilution, in one case, with *n*-heptane and, in another, with methanol containing ca. 6–7% v/v water. In both experiments the polymer again showed an absorption at 4.93 μ.

Finally, to test the formation of keteneimine links at still higher temperatures, a 0.2 *M* solution of the monomer in absolute methanol with *t*-butyl peroxide as initiator was irradiated at $50\pm 2°$ C. Again, the polymer produced was found to possess the characteristic keteneimine absorption at 4.93 μ. A summary of all polymerizations may be found in Table I.

TABLE I

Summary of polymerization runs*

Run	[Monomer], *M*	Solvent	Initiator†	[Init.] $\times 10^2$, M	Temp., °C	Irrad. time,‡ hr
1	Bulk	None	None	—	−72	16
2	Bulk	None	A	0.5	−72	6
3	Bulk	None	A	3	−72	7
4	Bulk	None	B	9	−72	11
5§	Bulk	None	None	—‖	12	0.5
6	Bulk	None	A	0.6	12	0.4
7	Bulk	None	B	7	12	0.4
8	1.0	*n*-Heptane	B	7	12	0.3
9	1.0	Methanol¶	B	7	12	0.3
10	0.2	Methanol	B	14	50	1.0

*The polymers containing keteneimine links were tinted yellow when first formed and the color deepened on standing in air. All others appeared white.
†A and B refer to benzoyl peroxide and *t*-butyl peroxide, respectively.
‡The irradiation times correspond to ca. 1–2% conversion, except for run 1, where no polymer was isolated.
§Runs 5, 6, and 7 gave no infrared absorption at 4.93 μ; the others, except run 1 (see ‡), had an absorption peak at this wavelength.
‖The polymer from the prepolymerization runs at room temperature ($25\pm 2°$ C) showed no absorption peak at 4.93 μ.
¶Containing ca. 6–7% v/v water.

The usual tests (3) were run to confirm the presence of keteneimine structures. For details of these, see Experimental. As expected, the results of the tests further confirmed the presence of keteneimine structures in the polymers.

Recent work by Tsuda (7) indicates that a free radical mechanism predominates in the X-ray-induced bulk polymerization of pure liquid acrylonitrile at −78° C, while an anionic mechanism tends to be more important when the polymerization is carried out with dilute solutions of the monomer. The present results suggest that the keteneimine structures formed at −78° C with X-ray initiation may arise via a free radical mechanism, in harmony with the conclusions of Tsuda. Electrical discharges through acrylonitrile monomer also produce keteneimine structures (8). Details of this work are not complete

enough to allow much comment here. Nevertheless, it seems possible that some of the keteneimine structures formed by electrical discharge may also be free radical derived.

This investigation is being continued.

EXPERIMENTAL

The acrylonitrile was Monsanto 200 X grade,* purified by three fractionations from reagent grade P_2O_5, through a 20-plate column, under a nitrogen atmosphere, the middle 80% fraction being collected each time. (This method of collection applied to all fractionations and bulb-to-bulb distillations *in vacuo*.) The monomer from the last fractionation was collected over P_2O_5 and given two simple bulb-to-bulb distillations *in vacuo*. After each distillation, the monomer was prepolymerized to ca. 1% conversion by ultraviolet irradiation at room temperature, n_D^{25} 1.388_6. Benzoyl peroxide, Eastman White Label, was twice recrystallized from chloroform by precipitation with methanol (9). *t*-Butyl peroxide, Wallace and Tierman, Inc., Lucidol Div., 97% min., was given a simple bulb-to-bulb distillation *in vacuo*. *n*-Heptane, Eastman White Label, was washed with C.P. concentrated H_2SO_4, then water, dried over Drierite, fractionated, and finally dried with Linde Molecular Sieves, n_D^{25} 1.326_7. Deionized water (Amberlite MB-3) was used for the aqueous polymerization. Dimethylformamide, Eastman White Label, was given three fractionations from P_2O_5, n_D^{25} 1.427_0. Merck reagent grade chloroform was twice fractionated from P_2O_5. Merck reagent grade ethanol was used without further purification.

All reactions were carried out in cylindrical pyrex tubes, 25-cm length, 2.5-cm o.d., and 1-mm wall thickness, with ca. 30 ml of reaction mixture. For the irradiations at $-72\pm2°$ C the reaction vessel was immersed in a dry ice – ethanol mixture in an unsilvered pyrex dewar surrounded by a pyrex water jacket containing tap water. The ultraviolet radiation was provided by two B.T.H. Mazda Type ME/D 250-watt mercury vapor compact sources of the rectangular-box variety set side by side and aimed at the reaction mixture 10 ± 1 cm away. They were run with the supplied glass windows removed. However, there was still approximately 6 mm of pyrex in the light path. For the polymerizations at 12 and 50° C, the reaction vessel was placed in the water jacket alone and located 3.5 ± 0.5 cm from the lamps. Because the dewar was omitted, a total of only ca. 4 mm of pyrex remained in the light path. The prepolymerization runs described above were carried out following a procedure similar to that used for those at 12 and 50° C.

Since the effect of solvents on the anticipated keteneimine structures was not known, the first infrared spectra were obtained from polymers which had been freed of excess monomer by evacuation on a high-vacuum line. Later it was found that washing with methanol did not destroy keteneimine structures, but did dissolve some of the short-chain polymer. Consequently, all polymers were dried *in vacuo* and left unwashed. The infrared spectra were obtained in KBr disks on a Perkin–Elmer Model 21 double-beam spectrophotometer with sodium chloride optics.

The existence of keteneimine structures in the polymer was further investigated by the following tests. Heating *in vacuo* for 3 hours at $103\pm3°$ C caused a significant reduction in the infrared absorption at 4.93 μ. After 18 hours, the peak had completely disappeared. Treatment with methanol, water, or dilute aqueous HCl caused no detectable change in the 4.93-μ peak. This is not surprising since the polymer is insoluble in these reagents. However, when dissolved in dimethylformamide made 0.1 *M* in HCl by the addition of sufficient 6 *M* aqueous HCl, and heated *in vacuo* for 5 hours at $100\pm2°$ C, infrared absorption showed no indication of keteneimine structures. The action of chlorine on a dimethylformamide solution of the polymer again destroyed the absorption at 4.93 μ. The results of these tests are in agreement with those obtained for keteneimine structures in polymethacrylonitrile (3).

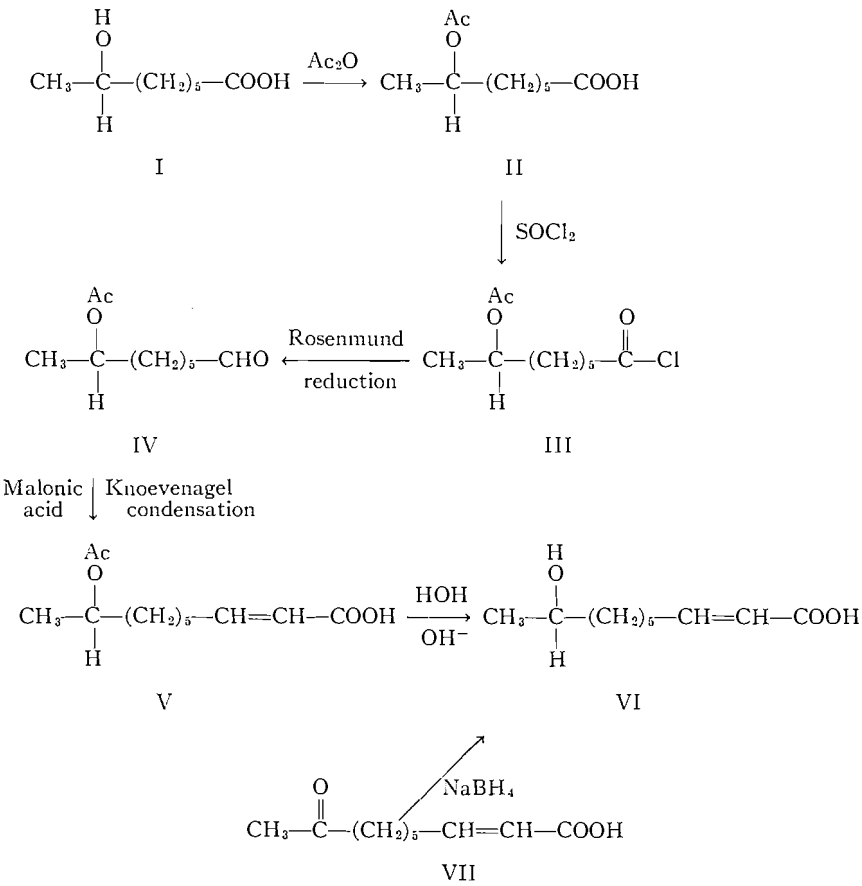
SYNTHESIS AND PHYSIOLOGICAL PROPERTIES OF 9-HYDROXY-2-DECENOIC ACID

Wm. H. Brown,[1] Ethel E. Felauer,[1] and M. V. Smith[2]

It has been recently reported by Brown and Felauer (1) that small amounts of 9-hydroxy-2-decenoic acid (VI) are present in the mixture of carboxylic acids isolated from royal jelly by the procedure described by Brown and Freure (2). It was of interest to synthesize the acid and determine its physiological properties since it is closely related to 9-keto-2-decenoic acid (VII). The latter acid is known as "queen substance" and has interesting effects on the behavior of worker bees (3). Several methods of synthesis for VII have been reported, the most recent by Kennedy *et al.* (4).

Our method of synthesis of (VI) is shown in the following scheme:



The 7-hydroxyoctanoic acid (I) was prepared by the method of Lease and McElvain (5). Since both 9-acetoxy-2-decenoic acid (V) and 9-hydroxy-2-decenoic acid (VI) are liquids which do not crystallize, a solid derivative, the *p*-bromophenacyl ester of VI, was

[1]*Department of Chemistry, Ontario Agricultural College.*
[2]*Department of Apiculture, Ontario Agricultural College.*

prepared. The latter was shown to be identical with the same derivative of authentic VI prepared by sodium borohydride reduction of 9-keto-2-decenoic acid (VII). The iodoform test is given readily by VI, which is contrary to the findings of Barbier and Hügel (6).

EXPERIMENTAL

Melting points are corrected. Infrared data were determined on a Beckman IR5 instrument and ultraviolet data on a Bausch and Lomb Spectronic 505.

9-Hydroxy-2-decenoic Acid (VI) and p-Bromophenacyl Ester

Saponification of 0.3 g of 9-acetoxy-2-decenoic acid (V) with 10% aqueous sodium hydroxide solution gave 0.2 g of crude VI, a liquid which did not crystallize. After chromatography on Whatman seed test paper using propanol-1 – ammonia (70:30) as the developing solvent (R_f 0.73 at 25°) the compound still failed to crystallize. The ultraviolet spectrum showed that the compound is unsaturated. The infrared spectrum showed bands for unsaturation and free hydroxyl group. The iodoform test was positive.

Treatment of VI with *p*-bromophenacyl bromide by the usual procedure gave the ester, white needles from hexane (150 ml/g), m.p. 73–74°. Anal. Calc. for $C_{18}H_{23}BrO_4$ (383.28): C, 56.4; H, 6.05; Br, 20.8. Found: C, 56.4; H, 6.08; Br, 21.0.

Physiological Activity

The bioassay method described by Butler and Gibbons (7) was used. The acid (VI) was supplied to 10 cages of test bees by dissolving 10 mg of the compound in 2 ml of acetone and dipping the dead bodies of worker bees in this solution. Two bee bodies, so treated, were placed in each cage. The 10 control cages all built queen cells but results with the acid were extremely variable, i.e., in some cages queen cells were constructed while in others they were not. Repeated tests and doubling of the amount of acid presented to the bees gave no clear-cut differences.

Presentation of the acid on filter paper to cages of young bees according to the method of Pain (8) gave no indication that it has any attractiveness to the bees.

Results of the evaluation of the antitumor activity of 9-hydroxy-2-decenoic acid (VI) will be reported in the series "Studies on the in vitro antitumor activity of fatty acids", of which the fourth paper appeared recently (9).

ACKNOWLEDGMENTS

The studies herein described were carried out in connection with projects supported by the National Cancer Institute of Canada, whose financial assistance is gratefully acknowledged.

We are indebted to Dr. R. K. Callow of the National Institute for Medical Research, London, England, for providing a sample of authentic 9-keto-2-decenoic acid. DuPont of Canada Limited supplied a generous amount of adipic acid.

THE ELECTRON SPIN RESONANCE OF NON-ALTERNANT AROMATIC HYDROCARBON – IODINE COMPLEXES[1]

S. S. DANYLUK[2] AND W. G. SCHNEIDER

The electron spin resonance (e.s.r.) spectra have been reported recently for a number of molecular complexes of iodine with a variety of electron donors (1–3). Matsunaga (1) and Kommandeur and Singer (3) have observed e.s.r. in polycyclic alternant aromatic hydrocarbon – iodine complexes and Kommandeur and co-workers (3, 4) have shown a correlation between electron spin concentration and charge carrier concentration in electronic conduction for these complexes. Recently Kommandeur (5) reported hyperfine structure in the e.s.r. spectrum for a dilute solution of perylene in molten iodine. In this note we report the e.s.r. measurements for iodine complexes formed with the non-alternant aromatic hydrocarbons azulene, guaiazulene, and acepleiadylene.

The complexes were prepared by refluxing equimolar amounts of the hydrocarbon and iodine in oxygen-free benzene under an inert atmosphere for several hours. A deep blue-black precipitate was formed in each case, and after treatment with excess benzene to remove unreacted material the solids were analyzed for iodine composition. The analyses confirmed a 1:1 stoichiometry for each complex: azulene–iodine, calc. for $C_{10}H_8.I_2$: 66.3%, found: 66.1%; guaiazulene–iodine, calc. for $C_{15}H_{18}.I_2$: 56.1%, found: 54.8%; acepleiadylene–iodine, calc. for $C_{16}H_{10}.I_2$: 55.7%, found: 55.2%.

An X-ray examination[3] of the complexes showed the azulene.I_2 complex to be mainly amorphous while the acepleiadylene.I_2 complex was crystalline. All of the complexes decomposed when heated above 120° C in sealed tubes.

The e.s.r. spectra were measured with a Varian 4500 spectrometer equipped with 100 kc/s modulation. Polycrystalline samples of the complexes were examined in sealed quartz tubes. The line widths and g values were determined by calibration of the spectra with signals from diphenylpicrylhydrazyl and a single crystal of MgO doped with Cr^{+3} (6). Electron spin concentrations were measured by comparison of the integrated signals for the complex with the signal for a known standard D.P.P.H. sample. The results for these measurements are listed in Table I. Preliminary measurements of the spin concentration for the azulene.I_2 at low temperatures showed no appreciable change from the room temperature value.

TABLE I

E.S.R. spectra of non-alternant hydrocarbon–iodine molecular complexes

Complex	Number of spins per gram	g value	Line width (gauss)
Azulene.I_2 (1:1)	2.2×10^{19}	2.0039 ± 0.0002	13.9 ± 0.3
Acepleiadylene.I_2 (1:1)	1.3×10^{19}	2.0034 ± 0.0002	4.9 ± 0.2
Guaiazulene.I_2 (1:1)	2.5×10^{17}	2.0030 ± 0.0002	10.3 ± 0.3

A single relatively broad e.s.r. signal with a g value close to the free electron value was noted for each complex, confirming the presence of unpaired electron spins in these

[1]*Issued as N.R.C. No. 7008.*

[3]*We are indebted to Dr. A. Hansen for carrying out these examinations.*

systems. No hyperfine splitting was resolvable for the solids under the present conditions. The paramagnetic species present in these complexes are very probably aromatic radical ions, Ar^+, formed by electron transfer from the hydrocarbon to iodine in a charge-transfer reaction:

$$Ar + I_2 \rightarrow Ar^+I_2^-.$$

Evidence supporting the existence of aromatic radical ions in related systems has been reported recently (5). A marked similarity was noted between the e.s.r. spectra for perylene in molten iodine and sulphuric acid, indicating the presence of monopositive ions in the former solution.

Comparison of the line widths in Table I shows that the line width of the acepleiadylene. I_2 complex is considerably narrower than the line widths for the azulene complexes, and is close to the value observed for the isomeric pyrene–iodine complexes (3). No correlation between line widths and spin concentrations is apparent at room temperature and accordingly the line broadening is not primarily attributable to pure dipolar broadening. It is likely that an electron-exchange process between the radical ions and neutral molecules, similar to that proposed for the perylene–iodine complex (5), is the predominant cause of line broadening in the non-alternant complexes.

The spin concentrations for the azulene– and acepleiadylene–iodine complexes are of the same order of magnitude as observed in alternant hydrocarbon–iodine systems. However, a 100-fold decrease in spin concentration is noted for the guaiazulene complex. The lower spin concentration in this case could result from steric hindrance of the alkyl groups on the five- and seven-membered rings to complex formation with iodine.

THE DE-*O*-ACETYLATION OF ACETYLATED AMINO SUGARS*

D. R. Whitaker, M. E. Tate,† and C. T. Bishop

In the course of attempts to prepare oligosaccharides of *N*-acetyl-D-glucosamine (2-deoxy-2-acetamido-D-glucose) by acetolysis of chitin, substantial amounts of products with R_f values greater than *N*-acetyl-D-glucosamine were found on chromatograms of the de-*O*-acetylated products. A similar experience has been reported by Barker *et al.* (1). As it seemed likely that these products would interfere with the isolation, in pure form, of the oligosaccharides of *N*-acetyl-D-glucosamine, the nature and source of these products was investigated to determine whether their occurrence could be prevented.

THE DE-*O*-ACETYLATION OF ACETYLATED AMINO SUGARS*

D. R. Whitaker, M. E. Tate,† and C. T. Bishop

In the course of attempts to prepare oligosaccharides of *N*-acetyl-D-glucosamine (2-deoxy-2-acetamido-D-glucose) by acetolysis of chitin, substantial amounts of products with R_f values greater than *N*-acetyl-D-glucosamine were found on chromatograms of the de-*O*-acetylated products. A similar experience has been reported by Barker *et al.* (1). As it seemed likely that these products would interfere with the isolation, in pure form, of the oligosaccharides of *N*-acetyl-D-glucosamine, the nature and source of these products was investigated to determine whether their occurrence could be prevented.

Issued as N.R.C. No. 6921.
†*National Research Council Postdoctorate Fellow 1960–1962.*

Reaction of *N*-acetyl-D-glucosamine or of α-D-glucosamine pentaacetate with 0.5 *N* sodium methoxide in methanol yielded substantial amounts of the unknown products. Hence these products were artifacts produced during the de-*O*-acetylation rather than during the acetolysis.

The major artifact had chromatographic mobility relative to *N*-acetyl-D-glucosamine (R_{NAG}) of 1.85; minor components of R_{NAG} 2.81 and 3.22 were found under some conditions of de-*O*-acetylation. Barker *et al.* (1) report R_{NAG} 1.87 for the major artifact found in their experiments. The component with R_{NAG} 1.85 gave a positive reaction with silver nitrate – alkali sprays (2) and negative reactions with *p*-anisidine hydrochloride

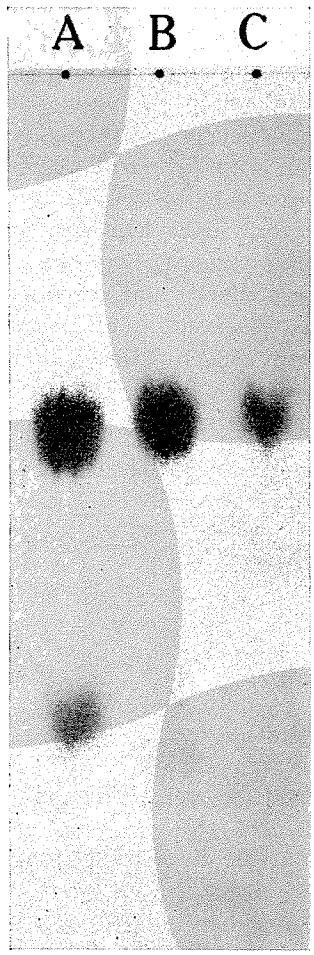

FIG. 1. Paper chromatogram of (A) de-*O*-acetylation of α-D-glucosamine pentaacetate by sodium methoxide; (B) de-*O*-acetylation of α-D-glucosamine pentaacetate by magnesium methoxide; (C) *N*-acetyl-D-glucosamine.

(3) and ferric hydroxamate (4) spray reagents. These results showed that the compound was polyhydroxylated, contained no aldehyde or hemiacetal groups, and was devoid of *O*-acetyl groups. The major artifact gave an immediate, intense, positive reaction when sprayed with an acidic solution of *p*-dimethylaminobenzaldehyde (Ehrlich reagent (5)) without prior spraying with alkali; under the same conditions *N*-acetyl-D-glucosamine gave no reaction. This result indicated that the artifact was the chromogenic

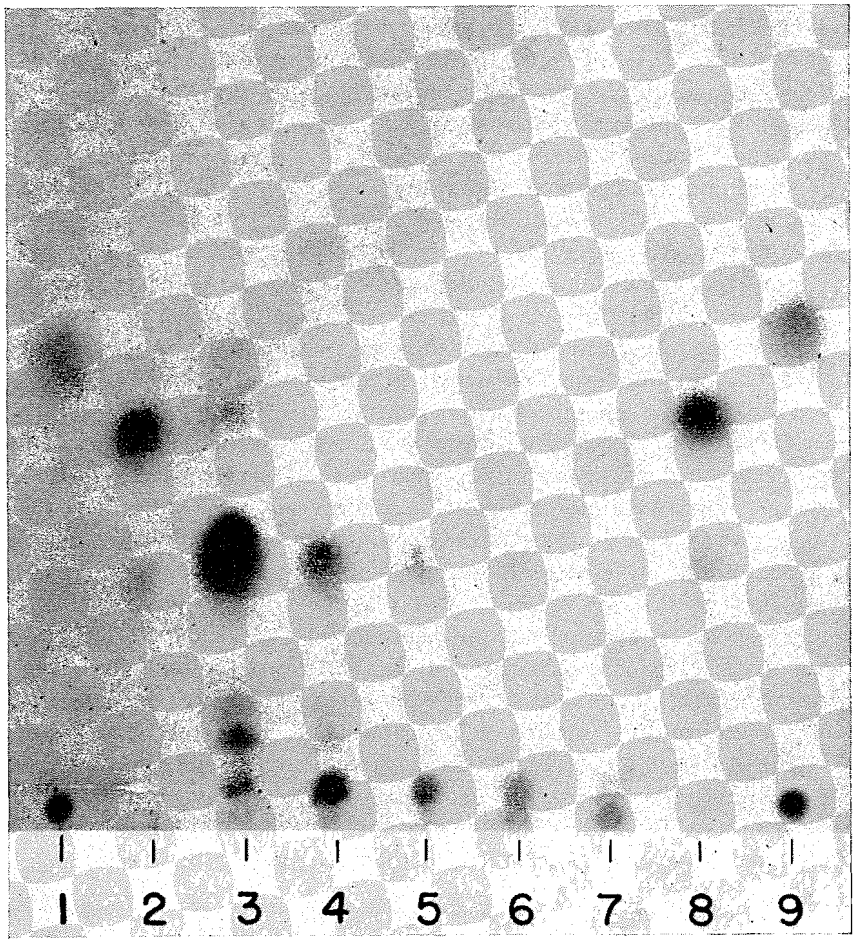

FIG. 2. Thin-layer chromatogram of de-*O*-acetylation of α-D-glucosamine pentaacetate by 1% magnesium methoxide at 0° C. (3) 1 minute; (4) 5 minutes; (5) 10 minutes; (6) 30 minutes; (7) 60 minutes; (1 and 9) marker dyes; (2 and 8) α-D-glucosamine pentaacetate.

material which is formed during the alkaline treatment of *N*-acetylhexosamines in the Morgan–Elson test (6). Three Ehrlich-positive chromogens can be obtained from *N*-acetyl-D-glucosamine depending on the conditions of alkaline treatment (7). The only one of these to be characterized, 3-acetamido-5-(1,2-dihydroxyethyl)furan, is formed at high temperatures (100° C) (8). The artifact in the present work was produced during de-*O*-acetylation of hexosamine acetates, which was carried out at room temperature (25° C) or lower, and therefore was probably one of the chromogens which has not yet been characterized. The minor artifacts of R_{NAG} 2.81 and 3.22 gave positive tests with both acidic *p*-dimethylaminobenzaldehyde and ferric hydroxamate sprays, indicating that they were probably *O*-acetyl derivatives of the major artifact.

Conditions were sought for de-*O*-acetylation which would minimize or prevent the formation of these artifacts. Reaction of α-D-glucosamine pentaacetate or of *N*-acetyl-D-glucosamine with the following reagents in methanol gave substantial yields of the major artifact under a variety of conditions of concentration, temperature, and time (see Experimental): sodium methoxide, barium methoxide, potassium hydroxide, and dry ammonia. A typical result is shown in Fig. 1,A.

The formation of artifact was least when magnesium methoxide in methanol was employed as a de-*O*-acetylating agent. Investigation of conditions showed that a high concentration of magnesium methoxide in methanol at low temperatures and for a short reaction time gave a smooth de-*O*-acetylation of α-D-glucosamine pentaacetate with practically no production of artifact; this is shown in Fig. 1,B. Apparently, the Ehrlich-positive chromogen is produced from acetylated hexosamines by only the slightest trace of hydroxyl ion. It is very difficult to keep the de-*O*-acetylation reactions absolutely anhydrous and any water in the system would yield hydroxyl ion with most de-*O*-acetylating agents. However, magnesium methoxide would tend to maintain anhydrous conditions and any hydroxyl ion formed would be removed from the reaction as insoluble magnesium hydroxide. Magnesium methoxide in methanol is therefore the preferred reagent for de-*O*-acetylation of alkali-sensitive compounds.

The de-*O*-acetylation of α-D-glucosamine pentaacetate by 1% magnesium methoxide in methanol at 0° C was followed by thin-layer chromatography (9). The results, Fig. 2, showed that the reaction was very rapid; most of the pentaacetate was converted into a tetraacetate in 1 minute and no pentaacetate was present after 5 minutes. The amounts of *O*-acetyl derivatives then decreased gradually until, at the end of 1 hour, only traces of ferric-hydroxamate-positive material were present. Figure 1,B shows the paper chromatogram of this de-*O*-acetylation reaction after 1 hour.

The reference spots of α-D-glucosamine pentaacetate, 2 and 8, Fig. 2, showed small amounts of a material which corresponded to the major product from the 1-minute de-*O*-acetylation (3, Fig. 2). These samples of α-D-glucosamine pentaacetate had been dissolved in magnesium-dried methanol for application to the chromatographic plates. The lability of the acetate groups together with the subsequent rearrangements of the glucosamine molecule emphasizes the need for care in the purification of hydroxylic solvents. Basic impurities such as magnesium methoxide or amines can be removed from alcohols by distillation from 2,4,6-trinitrobenzoic acid (10, p. 168).

EXPERIMENTAL

Materials

N-Acetyl-D-glucosamine (2-deoxy-2-acetamido-D-glucose) was a commercial product obtained from the California Corporation for Biochemical Research. α-D-Glucosamine pentaacetate, m.p. 133–134° C, $[\alpha]_D^{25}$ +84.3±2° (*c*, 1.21% in chloroform), was isolated from an acetylation of D-glucosamine hydrochloride with acetic anhydride and sodium acetate (11) by repeated recrystallization from ether. Methanol was refluxed with magnesium and distilled through a 2-ft column (10, p. 169). Paper chromatograms were run by the descending method using a solvent system of butan-1-ol:ethanol:concentrated ammonium hydroxide:water —40:10:1:49 (v/v, upper phase). Thin-layer chromatograms were run on silica gel G and were developed twice in an ascending direction with benzene:methanol (9:1, v/v).

De-O-acetylations

To solutions (2%) of *N*-acetyl-D-glucosamine and of α-D-glucosamine pentaacetate were added the de-*O*-acetylating reagents under conditions of temperature and reagent concentration given below. At the times indicated samples were removed for examination by paper chromatography (silver nitrate – alkali spray reagent). All samples showed varying but substantial amounts of the major artifact (R_{NAG} 1.85) and

Reagent	Concentration (*N*)	Temperature (°C)	Time (hr)
Sodium methoxide	0.24	0	1
	0.01	25	2, 5, 22
	0.0007	25	20
Barium methoxide	0.25	25	1, 5, 24
	0.01	5	20
Potassium hydroxide	0.25	25	20
Ammonia	2	25	2, 5, 16

the chromatogram shown in Fig. 1A was typical. The minor artifacts of R_{NAG} 2.81 and 3.22 were more pronounced in the samples taken at early times. No differences were found when the samples were acidified with acetic acid, diluted with water, and deionized by Amberlites IR-120 and IR-45 exchange resins before chromatography.

Magnesium methoxide was added to a 2% solution of α-D-glucosamine pentaacetate in dry methanol under the following conditions: (1) 1% at 0° C; (2) 0.01% at 0° C; (3) 1% at 28° C; (4) 0.01% at 28° C. At 1, 5, and 24 hours samples were removed from each of these solutions for examination by paper chromatography. The major artifact (R_{NAG} 1.85) was present under conditions 2, 3, and 4 but in smaller amounts than in the previous de-*O*-acetylations. Under the first condition (1% magnesium methoxide at 0° C) there was only a trace of the major artifact after 1 hour (Fig. 1B), the amount increasing in the samples taken at 5 and 24 hours. It was apparent that the optimum conditions for de-*O*-acetylation of acetylated hexosamines were a high concentration of magnesium methoxide at low temperatures for a short time.

De-*O*-acetylation of α-D-glucosamine pentaacetate under condition 1, given above, was followed by thin-layer chromatography (Fig. 2); the results showed the reaction to be complete in 1 hour.

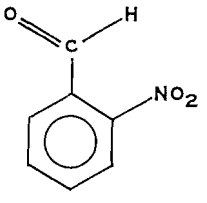
ABSTRACT

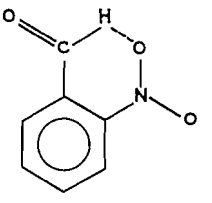
Certain unusual features in the infrared spectra of *o*-nitrobenzaldehyde have been interpreted either in terms of an intramolecular hydrogen bond or in terms of steric interactions. As an extension of these studies we have investigated the ultraviolet, infrared, and n.m.r. spectra of *o*-nitrobenzaldehyde and of suitable reference compounds and have re-examined the available other evidence. It is concluded that the observed spectral changes can best be explained in terms of steric interactions rather than in terms of intramolecular hydrogen bonding.

INTRODUCTION

In 1955 Pinchas proposed that the increased infrared frequency of the aldehyde C—H stretching band in *o*-nitrobenzaldehyde (I) and related compounds may be explained by the formation of an intramolecular hydrogen bond as shown in I*a* (1, 2). West and



I



Ia

Whatley (3) criticized this interpretation because the infrared N—O stretching frequency is similar for the three isomeric nitrobenzaldehydes (i.e., the frequency is not appreciably lowered in the *o*-isomer), and they proposed instead that the effect results from steric interactions. That is, they supposed that the presence of bulky *o*-substituents forces the aldehyde group out of the preferred configuration coplanar with the aromatic ring. Pinchas (4) has criticized this steric interpretation because he maintains that the arguments against the formation of an intramolecular hydrogen bond are not convincing, and he, moreover, puts forward a number of arguments against the steric hypothesis.

[1]*Part VI: Can. J. Chem.* **38**, *1852 (1960).*
[2]*Present address: Chemistry Department, University of Waterloo, Waterloo, Ontario.*

Since ultraviolet and n.m.r. spectra can also provide information concerning intramolecular hydrogen bonding, we have determined the relevant spectra. We have also redetermined the infrared spectra of the nitrobenzaldehydes together with the infrared spectra of a number of reference compounds. The purpose of the present paper is to rediscuss the intramolecular interactions in *o*-nitrobenzaldehyde in the light of this additional information.*

EXPERIMENTAL

The infrared spectra were determined on a Beckman Model IR 7 spectrophotometer, calibrated against a polystyrene film, using a NaCl prism and a diffraction grating. The frequency accuracy in the 1700-cm^{-1} region is believed to be ± 2.0 cm^{-1} and the frequency reproducibility ± 0.5 cm^{-1}. Solutions were examined in 0.5- or 0.2-mm cells equipped with sodium chloride windows. The solute concentration was ca. 10^{-3} mole/l. Infrared data are shown in Tables I, II, and III and in Fig. 1.

The ultraviolet spectra were determined by standard methods in matched 1-cm silica quartz cells using both a Beckman DK 2 spectrophotometer and a Unicam SP 500 spectrophotometer calibrated against a didymium filter and solutions of potassium chromate and potassium nitrate. Wavelength readings obtained on the two instruments were found to be within 1 $m\mu$ of each other. The accuracy of λ_{max} values is estimated to be ± 1 $m\mu$, and the precision of molar absorptivities $\pm 5\%$ or better. Most molar absorptivity values were reproducible to $\pm 2\%$. Data are given in Table IV and Fig. 2.

Nuclear magnetic resonance data were determined by means of a 33-Mc spectrometer equipped with a Varian magnetic flux superstabilizer. Measurements were carried out in carbon tetrachloride solutions using tetramethylsilane as an internal indicator. Shift measurements were usually reproducible to within ± 1 cycle/sec.

The compounds examined were commercial samples purified by recrystallization until their melting points indicated that the samples were pure. Sample purity was also sometimes confirmed by vapor phase chromatography. The solvents used were commercially available spectroanalyzed solvents (Fisher).

THE SPECTRA OF *o*-NITROBENZALDEHYDE AND RELATED COMPOUNDS

A. Infrared Spectra

The infrared carbonyl band of *o*-nitrobenzaldehyde in carbon tetrachloride is structureless and does not show a doublet or shoulder such as might be expected if the molecule were to exist in two conformations with the NO_2 and C=O groups being either cis or trans with respect to each other (cf. ref. 5). The infrared carbonyl bands of *o*-nitrobenzaldehyde and reference compounds are listed in Fig. 1 and Table I. Although the carbonyl band doublet shown in Fig. 1 and Table I for *m*-nitrobenzaldehyde may be caused by factors other than *s*-cis, *s*-trans isomerism, the *absence* of fine structure in the carbonyl band of *o*-nitrobenzaldehyde indicates that *o*-nitrobenzaldehyde exists predominantly in only *one* form; this is probably a structure like I, in which the C=O and NO_2 groups are approximately trans with respect to each other, or more precisely a gauche form in which the substituent groups are twisted out of the plane of the benzene ring.

Next, the N—O stretching frequencies, as noted by West and Whatley (3), are not lowered in the *o*-isomer compared with the same band in the *p*-isomer. The relevant data are listed in Table II. West and Whatley deduce from the symmetrical stretching band data that no hydrogen bonding to the nitro group occurs in *o*-nitrobenzaldehyde. However, as Pinchas (4) correctly points out, the N—O stretching frequencies sometimes remain approximately constant, even if the nitro group is involved in an intramolecular hydrogen bond (cf. also ref. 6). Our more complete data for the nitrobenzaldehydes and the nitrophenols show that a displacement to lower frequency is observed in the

**Since this paper was submitted for publication, a referee has drawn our attention to the work of P. Coppens (to be published), who has shown, using X-ray crystallographic methods, that (1) the aldehyde group is forced out of the plane of the ring and (2) the oxygen atom of the nitro group is much too distant from the aldehyde hydrogen for hydrogen bonding to take place.*

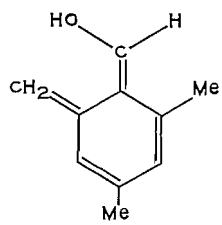
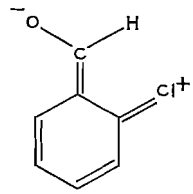
Pinchas in his later paper (4) also associates frequency displacements (to higher frequency) with quinonoid forms of type II and hence this may provide a third cause



II



III

for the observed frequency displacement to higher frequency. However, a number of other *p*-substituted benzaldehydes, such as *p*-hydroxy- or *p*-nitro-benzaldehyde (1, 8), do not afford this displacement (although appropriate quinonoid forms can be written) and this points against the hypothesis that such displacements are caused by classical quinonoid forms.* On the other hand, it is possible that a displacement to higher frequency is caused by electrostatic interactions, which can be crudely represented by structures of type III and which are favored by a coplanar arrangement.

One argument against a steric explanation of the spectral displacements (4) is that one would anticipate, when comparing *o*-chloro- and *o*-bromo-benzaldehyde, that an *o*-bromo substituent should cause a greater frequency displacement relative to the C—H bands in benzaldehyde; in fact, *o*-chlorobenzaldehyde affords the greater displacement. However, compounds like *o*-substituted benzaldehydes may exist in *a number of conformations* in which the angle between the plane of the benzene ring and the plane of the formyl group assumes various values because of torsional vibrations across the C—C bond linking the two planar entities. Moreover, infrared data indicate that *o*-chloro- and *o*-bromo-acetophenone exist in both *s*-cis and *s*-trans forms (5) and the infrared carbonyl band of *o*-chlorobenzaldehyde affords a doublet which may indicate an equilibrium of *s*-cis and *s*-trans forms (unpublished information). It follows that other explanations may account for the relatively greater displacement to high frequency observed in *o*-chlorobenzaldehyde. For example, *o*-chlorobenzaldehyde may still be sufficiently coplanar for contributions of type III to be important, while for *o*-bromobenzaldehyde steric interactions

The author is grateful to a referee for drawing his attention to this result.

†These runs were carried out not using high-resolution techniques and the frequency accuracy is therefore believed to be only ca. ±5.0 cm^{-1}.
‡The principal C—H absorption bands of the *m*- and *p*-isomers for most of the substances listed in the table are close to the value given for benzaldehyde.
§Pinchas (2).
‖This band shows some fine structure.
¶Structures of type III and related structures (see text) may also contribute to this displacement since 2,4-dihydroxybenzaldehyde also absorbs at higher frequency (2765 cm^{-1} (2)). An explanation for this latter displacement in terms of a dimeric hydrogen bond seems unlikely since no subsiduary maximal frequencies are evident in the relevant carbonyl band.

may inhibit these contributions and in this way a smaller frequency displacement may be observed for the principal C—H bands. Consequently a steric interpretation of the C—H band data cannot be rejected. Finally, in this discussion of the C—H bands near 2750 and 2850 cm^{-1}, it should be noted that the maximal frequency of infrared stretching bands is *normally lowered* if the relevant band is involved in a hydrogen bond, whereas the frequencies of the above C—H stretching bands are *raised* for the *o*-substituted benzaldehydes under discussion. Therefore such a displacement to higher frequency is inherently more readily interpreted in terms of steric interactions rather than in terms of intramolecular hydrogen bonding, since the latter explanation requires an additional hypothesis (cf. ref. 2).

B. Ultraviolet Spectra

Ultraviolet spectra, on the basis of previously noted generalizations, may contribute in two ways to the problem. First, intensity decreases are generally known to be indicative of steric interactions, and second, solvent changes, on determining ultraviolet spectra in different solvents, are sometimes decreased in the presence of intramolecular hydrogen bonding (see, for example, ref. 7).

Figure 2 shows the ultraviolet spectra of *o*- and *m*-nitrobenzaldehyde in constant-boiling ethanol. The spectral data in a number of solvents are also listed in Table IV. These data show that in both solvents the main absorption bands (indicative of conjugation) are considerably decreased in the *o*-isomer relative to the *m*-isomer, consistent with the explanation that the aldehyde and nitro groups are displaced from the plane of the benzene ring. Further, in intramolecularly hydrogen bonded nitrobenzenes—such as *o*-nitrophenol—the ultraviolet nitrobenzene band is displaced to *longer* wavelength relative to the similar absorption band in the *m*-isomer or other reference compound (7).

However, the ultraviolet absorption data for the nitrobenzaldehydes show (see Table IV) that the *o*-isomer absorbs at *shorter* wavelength than the *m*-isomer, which then again

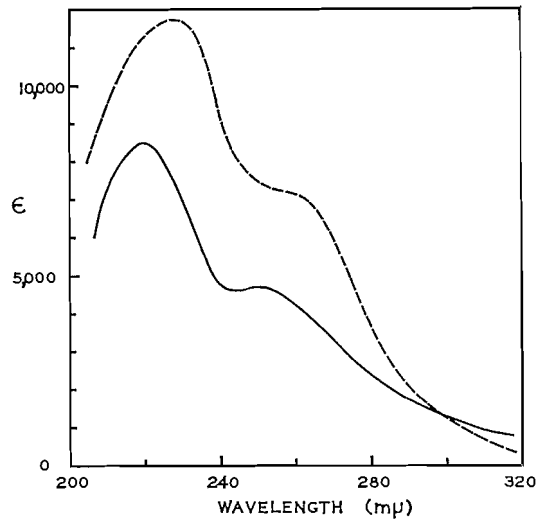

FIG. 2. The ultraviolet absorption spectra of *o*-nitrobenzaldehyde (——) and of *m*-nitrobenzaldehyde (– –) in constant-boiling ethanol (9).

TABLE IV

Main ultraviolet absorption bands of *o*- and *m*-nitrobenzaldehyde in various solvents

		Absorption band associated with benzaldehyde chromophore		Absorption band associated with nitrobenzene chromophore

m-Nitrobenzaldehyde	Cyclohexane	227	30,000	ca. *245* ca. *260*	*10,500* *6,000*
	Ether	226.5	26,000	ca. *260*	*6,000*
	Chloroform	242	13,500	ca. *262*	*6,500*
	Ethanol	227	11,000	258.5	7,500
	Water	233	22,000	ca. *266*	*7,000*

indicates steric interactions. Steric interactions between the *C—H* part of the aldehyde group and the ortho substituent are also suggested in compounds like *o*-chlorobenzaldehyde (λ_{max} 246 mμ, ϵ = 11,000; λ_{max} 252 mμ, ϵ = 8,500 (10)), *o*-bromobenzaldehyde (λ_{max} 245.5 mμ, ϵ = 12,500 (11)), *o*-tolualdehyde (λ_{max} 251 mμ, ϵ = 13,000), and 2,6-dimethylbenzaldehyde (λ_{max} 251 mμ, ϵ = 12,500 (12)), by the relatively low ϵ_{max} values of these compounds compared with the ϵ_{max} values of benzaldehyde (ϵ = 14,000 at 241 mμ and ϵ = 12,000 at 247 mμ (11)). (The ϵ_{max} of *o*-chlorobenzaldehyde is less than that of *o*-bromobenzaldehyde but, as previously noted in the discussion of the infrared spectra, a number of explanations can account for this.) Although these absorptivity decreases are

not directly related to steric interactions (since, for example, compounds like *m*-chlorobenzaldehyde in which steric interactions are small also show an absorptivity decrease relative to benzaldehyde), the general lowering of absorptivity observed in the above-mentioned *o*-substituted benzaldehydes, compared with the absorptivity of a number of reference compounds, strongly suggests the presence of some steric interactions. The absence of a direct, quantitative relationship between steric interactions and either ultraviolet absorptivities or infrared C—H frequency shifts is also indicated by the examples of *o*-tolualdehyde and mesitylaldehyde. Both compounds show similar ultraviolet spectra, indicative of steric interactions, but only mesitylaldehyde affords the C—H frequency increase which is also associated qualitatively with steric, though not necessarily with identical steric, interactions.

The data in Table IV also show that *o*-nitrobenzaldehyde does not afford a similar spectrum in various solvents in the same way as has been observed for intramolecularly hydrogen bonded nitrobenzenes such as nitrophenol (7). This then again tends to point against the existence of a strong intramolecular hydrogen bond except that the similarity of the spectra of the *o*-isomer in cyclohexane and ether solution may indicate some interactions between the formyl and nitro groups. Recent ultraviolet data obtained by Lutskii and Alekseeva for different solvents have similarly been interpreted to show the absence of intramolecular hydrogen bonding in *o*-nitrobenzaldehyde (13).

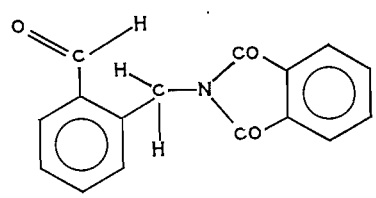
C. N.M.R. Spectra

The n.m.r. spectra of *o*- and *m*-nitrobenzaldehydes showed that in the *o*-isomer the proton signal of the formyl group is displaced by ca. 0.4 ± 0.1 p.p.m. to lower field with respect to this signal in the *m*-isomer. Since in intramolecularly hydrogen bonded compounds this displacement is usually much larger (14), the n.m.r. data also point against the existence of a strong intramolecular hydrogen bond in *o*-nitrobenzaldehyde in carbon tetrachloride solution.

CONCLUDING REMARKS

The spectral data discussed in the previous section favor the explanation that no intramolecular hydrogen bond exists in *o*-nitrobenzaldehyde and that the anomalous spectral effects are caused by steric interactions. It remains to discuss the evidence available from other physical data.

The most important of these is, as mentioned in the Introduction, that recent X-ray crystallographic evidence has in fact established the presence of appreciable steric interactions and the absence of intramolecular hydrogen bonding in *o*-nitrobenzaldehyde. Next, it may be noted that α-phthalimido-*o*-tolualdehyde (IV) is able to assume con-



IV

formations which, as judged from molecular models, have a similar effect on the planarity of the benzaldehyde part of the molecule as has the *o*-methyl group in *o*-tolualdehyde.

Hence the similar *C—H* frequencies of α-phthalimido-*o*-tolualdehyde (IV) and *o*-tolualdehyde are not surprising on the basis of a steric interpretation of the spectral changes (cf. ref. 4). Further, the inhibited interaction of *o*-nitrobenzaldehyde with rhodamine B may be caused by the proximity of the nitro group preventing another molecule approaching the hydrogen atom of the aldehyde group. It does not necessarily imply the presence of an intramolecular hydrogen bond in *o*-nitrobenzaldehyde, as suggested by Lundgren and Binkley (15, cf. also 4).

It is concluded therefore that none of the data reported so far conclusively show the existence of an intramolecular hydrogen bond in *o*-nitrobenzaldehyde. On the other hand, many of the data can be explained satisfactorily in terms of a proximity effect between the formyl group and the nitro group, an effect to which a secondary steric interaction (that is, a steric effect involving a twisting of the formyl and nitro groups away from the plane of the benzene ring) makes a significant contribution. The spectral data therefore substantiate the X-ray data on *o*-nitrobenzaldehyde.

ACKNOWLEDGMENTS

Thanks are due to Mr. G. W. West for determining the n.m.r. spectra, to Mr. A. A. Sioumis for determining the infrared spectra, and to Miss V. R. Jellett for determining the ultraviolet spectra.

METHYLATION OF SUGAR DITHIOACETALS

IV. D-XYLOSE DIETHYL DITHIOACETAL

G. G. S. DUTTON AND Y. TANAKA[1]

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received June 21, 1962

ABSTRACT

Partial methylation of D-xylose diethyl dithioacetal in tetrahydrofuran with methyl iodide and silver oxide yielded 2-, 3-, and 5-*O*-methyl-D-xyloses in the ratio of 20:10:1. The poly-*O*-methylated components were not examined. The 2-*O*-methyl-D-xylose was identified as the crystalline sugar and the 3-*O*-methyl ether as the phenylosazone and *p*-bromophenylosazone. An alternative preparation of the dithioacetal in tetrahydrofuran solution is described.

It has been reported in the preceding papers of this series (1, 2) that D-glucose and L-arabinose dithioacetals were predominantly methylated at their 2-hydroxyl groups with methyl iodide and silver oxide in tetrahydrofuran, and from the latter dithioacetal a small amount of 5-*O*-methyl-L-arabinose was also detected. The case of D-galactose diethyl dithioacetal was rather different in that positions 2, 3, and 6 were of approximately equal reactivity (3). The present paper is the fourth in a series on the relative reactivities of hydroxyl groups in sugar dithioacetals and describes the partial methylation of D-xylose diethyl dithioacetal.

D-Xylose diethyl dithioacetal was first prepared as a sirup by Fischer (4) in 1894 and was not crystallized until 1931 when it was obtained by the deacetylation of its crystalline tetraacetate (5). More recently the crystalline dithioacetal has been obtained directly by Zinner (6) using Fischer's method followed by neutralization of the reaction mixture with an ion-exchange resin. Repetition of Zinner's procedure failed to give us a crystalline product and we therefore carried out the preparation in tetrahydrofuran followed by neutralization with barium carbonate. This method also yielded a sirup but it was later found that dilution of the sirup with a small amount of 2-propanol caused rapid crystallization. Similar dilution of the sirups obtained by either Fischer's or Zinner's procedures gave crystalline material. The results discussed in this section are those obtained with the crystalline dithioacetal but essentially the same results were obtained starting from the sirupy compound as shown in the experimental part.

Since D-xylose diethyl dithioacetal was soluble in methyl iodide the methylation was first attempted in the absence of tetrahydrofuran. The methylation reaction was exothermic and the product gave, on hydrolysis, a mixture of poly-*O*-methylated D-xyloses. When the methylation was performed at 0° C in methyl iodide, no appreciable methylation was observed. Methylation to yield a reasonable amount of mono-*O*-methyl-D-xyloses was possible in a mixture of methyl iodide and tetrahydrofuran (1:1 by volume) at room temperature. The methylation product thus obtained was hydrolyzed with acid and a strong spot of mono-*O*-methyl ethers as well as spots of poly-*O*-methylated D-xyloses together with free D-xylose were detected by paper chromatography. The methylated mixture was chromatographed for 7 hours on Whatman No. 3MM filter papers using butanone–water azeotrope as a developing solvent, and the mono-*O*-methyl ethers were extracted from the appropriate area of the sheets. The area which corresponded to the di-*O*-methyl ethers was also extracted from the same chromatograms. It was necessary

[1]*Present address: Department of Chemistry, Queen's University, Kingston, Ontario.*

to examine this part of the chromatogram because in general monomethylfuranose sugars travel as fast as the corresponding dimethylpyranoses (7). The two groups may be readily differentiated by the high electrophoretic mobility of the former, e.g. 5-*O*-methyl-D-xylose, M_g 1.00. It was assumed that any di-*O*-methyl sugar would be substituted at C_2 and thus have a low mobility (8).

The mixture of mono-*O*-methyl-D-xyloses gave two spots, M_g 0.49 (strong) and 0.92 (weak), by paper electrophoresis, which corresponded to 2- and 3-*O*-methyl-D-xyloses, respectively. The mixture was also shown to contain 2- and 3-*O*-methyl-D-xyloses by paper chromatography (20 hours) in butanone–water azeotrope (R_{xylose} 3.16 (strong) and 3.65 (weak) respectively). Separation of these two spots was much clearer when one drop of concentrated ammonia was added to the developing solvent. The mixture of di-*O*-methyl-D-xyloses was examined by electrophoresis and showed three components, M_g 1.00 (weak), 0.37 (very weak), and 0.00 (strong). The component of M_g 1.00 was electrophoretically identical with a synthetic sample of 5-*O*-methyl-D-xylose but was obtained in too small an amount to be characterized.

The sirup of mono-*O*-methyl-D-xyloses was dissolved in absolute ethanol and 2-*O*-methyl-D-xylose crystallized on dilution with petroleum ether and seeding with an authentic sample. The mother liquor still showed a strong spot of the same compound as well as one of 3-*O*-methyl-D-xylose. The mother liquor was therefore rechromatographed and the 3-*O*-methyl-D-xylose converted into 3-*O*-methyl-D-xylose phenylosazone.

The phenol – sulphuric acid method (9) was used to estimate the ratio of 2- and 3-*O*-methyl-D-xyloses and of 5-*O*-methyl- and di-*O*-methyl-D-xyloses, and the combination of these results with the weights of the fast- and slow-running components isolated from the paper chromatograms gave approximately 20:10:1 for the ratio of 2-, 3-, and 5-*O*-methyl-D-xyloses. In experiments starting with sirupy dithioacetal the trace of the 5-*O*-methyl ether was not observed.

In the course of this work authentic samples of 3- and 5-*O*-methyl-D-xyloses were needed and these compounds were synthesized according to the procedure of Levene and Raymond (10). In this paper the melting points and rotations for the two *p*-bromophenylosazones have been transposed (11).

The results of this methylation study again demonstrate the superior reactivity at C_2 and differ from those for L-arabinose diethyl dithioacetal in that there is appreciable reactivity at C_3.

EXPERIMENTAL

Preparation of D-*Xylose Diethyl Dithioacetal*

Method I

D-Xylose (15.0 g) was suspended in dry tetrahydrofuran (100 ml) which had been saturated with hydrogen chloride at 0° C. The suspension was cooled in an ice-water bath, and ethanethiol (10 g) was added portionwise with vigorous shaking and occasional cooling in ice water. After all the thiol was added (ca. 10 minutes), the mixture was shaken for another 20 minutes, during which time all the D-xylose dissolved to give a homogeneous solution. The reaction mixture was diluted with dry tetrahydrofuran (100 ml), neutralized with excess barium carbonate, and filtered. The filtrate was dried with calcium chloride, the solvent was removed, and the residue was extracted with dry tetrahydrofuran (50 ml). Evaporation of the extract gave a product (20.3 g, 79%) which remained as a sirup for many weeks but which crystallized almost immediately on dilution with a small amount of 2-propanol. The crude product was recrystallized from 2-propanol – petroleum ether. Yield 15.8 g, m.p. 63–64° C, lit. (5) 63–65° C.

Method II

D-Xylose (4.5 g), ethanethiol (4.5 g), and concentrated hydrochloric acid (4.5 g) were shaken for 30 minutes with occasional cooling in an ice-water bath. To the clear reaction mixture was added ice water (50 ml), then sufficient Duolite A-4 resin to neutralize the acid. (An additional amount (50 ml) of water was needed to facilitate stirring.) The filtrate was evaporated to a sirup, which was diluted with isopropyl

alcohol (10 ml). Petroleum ether (3–4 ml) was added to the solution, and after several hours' storage of the solution at 5° C a crystalline mass was obtained. The crude crystals were recrystallized from isopropyl alcohol – petroleum ether. Yield 3.2 g (42%), m.p. 62–63° C. No depression of the melting point was observed when mixed with the sample prepared by the method I.

Methylation of Sirupy D-*Xylose Diethyl Dithioacetal*

Methylation I

D-Xylose diethyl dithioacetal (3.00 g, sirup) was dissolved in a mixture of methyl iodide (35.0 ml) and dry tetrahydrofuran (35.0 ml). Silver oxide (7.0 g) and drierite (7 g) were added to the solution, and the mixture was shaken at room temperature for 3 hours. The reaction mixture was filtered in order to remove the inorganic substances, which were washed with tetrahydrofuran (10 ml). The filtrate and washing were evaporated and the residue was redissolved in chloroform (10 ml). Evaporation of the filtered chloroform solution yielded a light brown sirup (2.49 g).

The sirup (2.49 g) was refluxed for 5 hours in a mixture of ethanol (20 ml), water (1.5 ml), and concentrated hydrochloric acid (1.5 ml). The hydrolyzate was neutralized with Duolite A-4 resin, and after treatment with charcoal, evaporation of the neutral solution gave a light yellow sirup (1.42 g). The sirup showed the following R_f values in butanone–water azeotrope: 0.94, 0.87, 0.79, 0.62, 0.54, 0.46, 0.18, and 0.05. The spot of R_f 0.18 was strong in intensity and the others were all weak.

Methylation II

Using the same quantities of reactants under the same conditions, a sirup (3.12 g) of the methylated mercaptals was obtained. Hydrolysis of this sirup under the same conditions provided a sirupy mixture (1.97 g) of the methylated D-xyloses which showed two strong spots (R_f 0.20 and 0.06) and a few very weak spots with higher R_f values in butanone–water azeotrope.

*Isolation and Examination of Mono-O-methyl-*D-*xylopyranoses*

The sirup (1.42 g) of the methylation I was chromatographed on twelve 15-cm-wide Whatman No. 3MM sheets for 7 hours, and the mono-*O*-methyl-D-xyloses, located by means of guide strips, were extracted with cold water (200 ml×3). Evaporation of the extracts gave a sirup, which was redissolved in methanol (ca. 5 ml), and a mixture (96.7 mg) of mono-*O*-methyl-D-xylopyranoses was obtained by evaporation of the filtered methanolic solution.

In a similar manner a sirup (118.6 mg) of mono-*O*-methyl-D-xylopyranoses was isolated from the hydrolyzate (1.97 g) of methylation II.

The mixtures were chromatographed for 20 hours and two spots (R_{xylose} 3.16 (strong) and 3.65 (weak)) were shown to be 2- and 3-*O*-methyl-D-xyloses, respectively. Separation of these spots was clearer when one drop of concentrated ammonia was added to the solvent.

Electrophoretic examination (900–1000 v, 20–90 ma, 90 minutes in 0.05 *M* sodium borate solution) of the mixtures also showed that they consisted of 2-*O*-methyl-D-xylose (M_g 0.49 (strong)) and 3-*O*-methyl-D-xylose (M_g 0.92 (weak)).

Isolation and Electrophoresis of the Fast-moving Components

From the same chromatograms used for the isolation of mono-*O*-methyl-D-xylopyranoses in methylation mixture I, the area which corresponded to the di-*O*-methyl ethers (R_f 0.54 and 0.46) was extracted with cold water (200 ml×3). A sirup (21.1 mg) was obtained by evaporation of the extracts, followed by the removal of methanol-insoluble impurities. The sirup gave only one spot of M_g 0.00.

Identification of the Component R_{xylose} *3.16 as 2-O-Methyl-*D-*xylose*

The mixture of mono-*O*-methyl-D-xylopyranoses isolated from methylation I was dissolved in warm absolute ethanol, and after cooling, petroleum ether was added to turbidity. Colorless crystals, m.p. 133° C, lit. (12) 132–133° C, precipitated from the solution on seeding. Admixture with an authentic sample gave no depression of the melting point.

Identification of the Component R_{xylose} *3.65 as 3-O-Methyl-*D-*xylose*

After 2-*O*-methyl-D-xylose crystallized, the mother liquor was decanted and evaporated to a sirup which still showed a strong spot for 2-*O*-methyl-D-xylose. The sirup (52.1 mg) was combined with that (118.6 mg) obtained from methylation II, and the combined sirup was chromatographed for 20 hours on three 15-cm-wide Whatman No. 3MM sheets using butanone–water azeotrope to which one drop of concentrated ammonia was added. The areas corresponding to 3-*O*-methyl-D-xylose were extracted with cold water (50 ml×3), and evaporation of the extracts gave a sirup (28.5 mg) which was electrophoretically homogeneous.

The sirup (28.5 mg) was dissolved in water (3 ml), and phenylhydrazine (56.2 mg) in ethanol (0.31 ml) and a small amount of sodium metabisulphite were added. The mixture was heated for 5 hours in boiling water and yellow crystals precipitated on cooling. The crystals (21.6 mg) were recrystallized from ethanol–water, m.p. 171–172° C, lit. (13) 172° C. No depression of the melting point was observed when mixed with synthetic 3-*O*-methyl-D-xylose phenylosazone.

Methylation Study on Crystalline D-*Xylose Diethyl Dithioacetal*

(1) Methylation

Crystalline D-xylose diethyl dithioacetal (1.00 g) was dissolved in a mixture of methyl iodide (12.0 ml) and tetrahydrofuran (12.0 ml). Silver oxide (2.40 g) and drierite (5 g) were added to the solution and the mixture was shaken for 3 hours at room temperature. The methylation product was treated as described above and the sirup (991 mg) thus obtained was hydrolyzed in a similar manner to yield a light yellow sirup (582 mg) which showed the following R_f values in butanone–water azeotrope: 0.91, 0.85, 0.73, 0.60, 0.51, 0.40, 0.20, and 0.07. Only the spot of R_f 0.20 was strong in its intensity; the others were weak.

*(2) Isolation and Electrophoresis of Mono-O-methyl-*D-*xyloses and Di-O-methyl-*D-*xyloses*

The sirup (583 mg) of the methylated D-xyloses was chromatographed for 7 hours on six 15-cm-wide Whatman No. 3MM sheets using butanone–water azeotrope as developing solvent, and the areas of R_f 0.20 and of 0.51 plus 0.40 were separately extracted with cold water (100 ml×3 each). A sirup (41.9 mg) was obtained from the extracts of the R_f 0.20 component, and a sirup (16.3 mg) from the components of R_f 0.51 and 0.40.

By electrophoresis in 0.05 *M* sodium borate solution, the component of R_f 0.20 showed two spots (M_g 0.45 (strong), 2-*O*-methyl-D-xylose; and 0.91 (weak), 3-*O*-methyl-D-xylose; 950–1100 v, 25 ma, 60 minutes), whereas the components of R_f 0.51 and 0.40 showed three spots (M_g 1.00 (weak) (5-*O*-methyl-D-xylose), 0.37 (very weak), and 0.00 (strong); 950–1100 v, 25–35 ma, 70 minutes).

The components of R_f 0.20 were separated by paper electrophoresis and analysis by the phenol – sulphuric acid method (9) gave a ratio of 2:1 for 2- and 3-*O*-methyl-D-xyloses. Similarly the components of R_f 0.51 and 0.40 gave a ratio of 1:10 for 5-*O*-methyl-D-xylose and poly-*O*-methyl-D-xyloses.

Combination of these results with the weights of these two sirups gives approximately 20:10:1 for the ratio of 2-*O*-methyl-D-xylose to 3- and 5-*O*-methyl isomers, respectively.

*Synthesis of 3-O-Methyl-*D-*xylose*

This compound was synthesized by the published method (10) from crude 1,2-*O*-isopylidene-D-xylofuranose (2.97 g) via the 5-*O*-trityl derivative. The yield of chromatographically and electrophoretically homogeneous product was 758 mg.

The sirup (238 mg) was treated in water (5 ml) with phenylhydrazine hydrochloride (650 mg) and anhydrous sodium acetate (400 mg), and 3-*O*-methyl-D-xylose phenylosazone, m.p. 179–181° C, lit (13) 172° C was obtained.

The sirup (351 mg) was heated for 3 hours in water (5 ml) with *p*-bromophenylhydrazine hydrochloride (1.5 g) and anhydrous sodium acetate (0.7 g). The osazone was recrystallized from ethanol–water, m.p. 168–170°, lit. (11) 174–175°.

*Synthesis of 5-O-Methyl-*D-*xylose*

Crystalline 1,2-*O*-isopropylidene-5-*O*-tosyl-D-xylose (6.25 g), m.p. 135–136° C, lit (10) 133–134° C, was obtained by the published procedure (10) from crude 1,2-*O*-isopropylidene-D-xylose (5.12 g). The tosylated compound (2.70 g) provided crystalline 1,2-*O*-isopropylidene-5-*O*-methyl-D-xylose (1.23 g), m.p. 85° C, lit. (10) 80.5–81.5° C, by treatment with sodium methoxide in a sealed tube. Chromatographically pure 5-*O*-methyl-D-xylose (593 mg) was obtained by chromatographic purification of the hydrolyzate of 1,2-*O*-isopropylidene-5-*O*-methyl-D-xylose.

The sirup (293 mg) of 5-*O*-methyl-D-xylose was treated for 3 hours in boiling water with *p*-bromophenylhydrazine hydrochloride (1.20 g) and anhydrous sodium acetate (0.5 g), and the precipitated *p*-bromophenylosazone was recrystallized from ethanol–water, m.p. 152–154° C with softening about 140–144° C, lit. (11) 153–155° C.

ISOTOPE EFFECTS IN NEUTRAL H_2O–D_2O IRRADIATED SOLUTIONS AND THE NATURE OF THE REDUCING RADICAL

CHAVA LIFSHITZ[1]

Department of Physical Chemistry, The Hebrew University of Jerusalem, Israel

Received June 4, 1962

ABSTRACT

Neutral solutions of sodium formate in H_2O–D_2O mixtures were irradiated by 200-kv X rays. The atomic deuterium isotope effect (α_A) and its dependence on deuterium concentration were determined. In a 1×10^{-1} *M* HCOONa, 96% D_2O solution, G(hydrogen) = 1.14 and $\alpha_A = 4.3$. It is concluded that the hydrogen atom cannot be formed from a *single* water molecule. Possible mechanisms of hydrogen atom formation are discussed. The alternative possibilities for the atoms to react as H or H_2O^- are viewed in the light of the proposed mechanisms.

INTRODUCTION

The nature of the reducing radical produced in the radiolysis of aqueous solutions is the subject of several recent studies. It has been shown that two forms of hydrogen atoms are involved—basic and acidic (1–3)—and that these are the solvated electron H_2O^- and the hydrogen atom H, respectively (4). It has further been shown that the transition from H_2O^- to H is brought about in acid solution by H_3O^+.

The relative contribution of the two species to reactions with the solute at neutral pH's is still debated. Czapski and Allen (5), while studying H_2O_2–O_2 solutions, found that the total yield of the reducing species, $G = 2.85$ (where G is the number of radicals formed for 100 ev absorbed), is in the form of solvated electrons. Allan and Scholes (3) and Rabani (6), when studying aqueous solutions of organic solutes, found, on the other hand, that part of the yield of reducing species reacts in neutral solutions in the acid H form, with a yield of $G(H) \simeq 0.6$ (to be termed "residual" yield). This part of reducing species was attributed to hydrogen atoms having excited water molecules as their precursors (3).

All of these studies employed the use of competitive kinetics, the difference between them being the choice of solutes. The use of a different method to investigate the problem of the nature of the reducing radical and the mechanism by which it is formed in neutral solutions seems important. The present study employs the use of the deuterium isotope effect.

When a mixture of H_2O and D_2O is irradiated, the deuterium content of the reducing radicals is lower than that of the irradiated water (7–10). The isotope effect $\alpha_A = (H/D)_{atoms}/(H/D)_{water}$ was found experimentally to depend on the deuterium concentration of the solution, both in acid (8) and in neutral (10) solutions.

Statistical arguments show that if $\alpha_A > 2$ at $\sim$100% D, then more than one water molecule is involved in the reaction producing hydrogen atoms (9).

In the present study further attention is given to the determination of α_A in neutral solutions and its dependence on deuterium concentration, with special emphasis on the "residual" yield. The aim is to determine the value of α_A of these atoms, at high deuterium concentrations, specifically, whether α_A is smaller or bigger than 2. This will enable one to decide whether one or more water molecules are involved in the reaction producing these atoms.

[1]*Present address: Department of Chemistry, Cornell University, Ithaca, New York.*

α_A is determined by studying the isotopic composition of the hydrogen gas evolved from H_2O–D_2O solutions of sodium formate. Formate was chosen as solute, because only the "residual" hydrogen atoms react with it to form molecular hydrogen. It was found by Rabani (6) that, in fact, the relative rate constants of the reaction of formate and ferricyanide ions with hydrogen atoms are the same in acid and neutral solutions. This is explained if the formate reacts, at all the pH values studied, with the same hydrogen atom species (6).

The mechanism by which the "residual" atoms are formed will be discussed, as well as the alternative possibilities that these atoms react with the solute as H or H_2O^-.

EXPERIMENTAL

Mixtures of light and heavy water containing different solutes were irradiated. The yield and isotopic composition of the hydrogen gas were determined.

Irradiations were carried out with an X-ray machine operated at 200 kv and 15 ma. The vessels were cylindrical Pyrex tubes with about 200 cc free volume above the 10 cc liquid phase. Dose rates were approximately 6500 r/min, as measured by the Fricke dosimeter, taking $G(Fe^{+3}) = 15.5$ (11). Total doses given varied from 1×10^{22} to 3×10^{22} ev/l.

Solutions were prepared from triply distilled water. Heavy water (99.8% deuterium) was from Norsk Hydro-Elektrisk. The materials used were of "Analar" grade purity. α_A was determined from experiments on HCOONa solutions, with or without phosphate buffer. Auxiliary experiments were carried out on KBr, KNO_2, and $K_4Fe(CN)_6$ solutions.

The solutions were degassed to an ultimate air pressure of less than 10^{-4} mm Hg. After irradiation the evolved gas was pumped by a Toepler, through a liquid air trap, into a known volume and its pressure was measured by a McLeod gauge. In view of the possibility, that the gas contains oxygen, the hydrogen yields were determined in some auxiliary experiments, where the isotopic composition of the gas was not determined, by burning the gas on a Pt filament.

Mass spectrometric analysis of H_2, HD, and D_2 was carried out on a Consolidated 21-401 instrument.[2] The peak heights were determined in the order of m/e: 2, 3, 4, 3, 2, in order to take into account pressure changes in the mass spectrometer. From the mean peak height of each isotopic species and the total hydrogen yield, the individual HD, H_2, and D_2 yields could be calculated. Contribution to mass 2 by D^+ was taken into account, at high deuterium concentrations, while the isotopic concentrations at low deuterium content were checked by Zn-decomposed water mixtures.

RESULTS

Table I shows the results from experiments on HCOONa. The D_2O percentage is

rounded off to the nearest half percent, while the value $(D/H)_{water}$ is the exact value of free exchangeable D atoms to exchangeable H atoms in the irradiated solution. The

[2]*The author wishes to thank the Isotope Department of the Weizman Institute, Rehovoth, for performing these analyses.*

hydrogen atoms of sodium formate are not taken into account, in the calculation of $(D/H)_{water}$, because they do not exchange (12). G(hydrogen) means the total hydrogen yield, light and heavy, as measured by the McLeod and is expressed in molecules formed per 100 ev absorbed radiation. The yields of the different isotopic species were calculated as explained in the previous section. In some experiments the isotopic composition of the gas is expressed by the ratio $(D/H)_{gas}$ and not by the individual H_2, HD, and D_2 yields.

For α_A to be calculated from the isotopic composition of the gas, the composition of the "molecular" product formed by the primary radiation–chemical act has to be known (8). The auxiliary experiments, given in Table II, were carried out for this reason. The

hydrogen gas obtained in these experiments is the "molecular" product alone and α_M has its usual meaning (7, 8), namely: $\alpha_M = (H/D)_{gas}/(H/D)_{water}$. α_A is calculated from the formate results at high deuterium concentrations, by the procedure of Baxendale and Hughes (8). The experiments 9 and 10 in Table I show that this procedure is applicable, as part of the gas—$G(D_2)$—is the "molecular" yield, having the isotopic composition of the water (100% D), and the other part of the gas—G(HD)—is the atomic abstraction yield. This procedure is, however, inapplicable at low deuterium concentrations, since the solute contains light hydrogen atoms. The expression

$$G(\text{hydrogen})(D/H+D)_{gas} = \tfrac{1}{2}G(H)(D/H+D)_A+G_{H_2}(D/H+D)_M$$

is instead used, in order to calculate the isotopic composition of the atoms—$(D/H+D)_A$. In this expression G(H) and G_{H_2} are the "atomic" and "molecular" yields, respectively (light and heavy) and $(D/H+D)_M$ is the isotopic composition of the "molecular" product. $(D/H+D)_M$ and G_{H_2} are known from the independent experiments of Table II, while $G(H) = G(\text{hydrogen}) - G_{H_2}$. The experiments in Table II show that α_M is independent of the solute and, to a certain extent, of solute concentration, provided the gas yield and deuterium concentration remain the same.

In order to calculate α_A at low deuterium concentrations, the following values were taken: $G_{H_2} = 0.65$ and $\alpha_M = 1.75$.[3] α_M adopted at high concentrations was 3.9. These values are averages from experiments in Table II, where the scavenger concentrations and molecular yields are similar to the ones expected in the formate experiments. In experiments 9 and 10 of Table I, the $G(D_2)$ values are the "molecular" yields. A comparison of these yields with the yields of Table II at ~100% D shows that the "molecular" yield in formate is intermediate between the KBr and KNO_2 yields. The value of $G_{H_2} = 0.65$ was chosen at low deuterium concentrations, by analogy to the ~100% D experiments, as it is intermediate between the KBr and KNO_2 values.

[3] *For example, the isotopic composition of the atoms was calculated in experiment 1 from the following:* $1.44[6.8\times10^{-3}/(1+6.8\times10^{-3})] = \tfrac{1}{2}(1.44-0.65)(D/H+D)_A+0.65[(1.98\times10^{-2}/1.75)/(1+1.98\times10^{-2}/1.75)]$.

The results obtained for α_A are given in the last column of Table I. The values of α_A at low deuterium concentrations are less certain than those at high ones, because of some arbitrariness in the choice of G_{H_2}. The "molecular" yields, calculated for experiments 5, 6, and 8 from $\alpha_M = 3.9$ and from the experimental G_{D_2}'s (8), in these experiments, are close to the experimental G_{D_2} values for 100% D (experiments 9 and 10). This relates further confidence to the choice of α_M from the auxiliary experiments. Furthermore, even if a considerably different α_M is used, α_A is only slightly affected, in experiments 5, 6, and 8.

DISCUSSION

Fiquet-Fayard (9) has shown that if a single excited water molecule decomposes, independently of all other molecules, without prior energy transfer, then α_A should be lowered by high deuterium concentrations of the solution and α_A cannot be higher than 2 at $\%D \simeq 100$. At high deuterium concentrations the only isotopic water molecule species virtually present are HDO and D_2O. If the composition of the water is one HDO molecule for every n molecules of D_2O and if excitation is random, then there will also be one excited HDO for every n excited D_2O molecules. In the limit of an infinitely high isotope effect in favor of light hydrogen, HDO decomposes to give H only. But if every excited molecule decomposes independently of all others, there will be one H atom for every n D atoms formed. As the original *atom* concentration in the water is one H atom for every $2n$ D atoms, it is evident that the maximum isotope effect is 2. This statistical argument, developed by Fiquet-Fayard (9), holds for any process by which a *single* water molecule decomposes by itself; for instance, it holds also if

$$H_2O^- \rightarrow H + OH^- \qquad [1]$$

or if H_2O^- reacts with the solute, according to

$$H_2O^- + RH \rightarrow H_2 + R + OH^-. \qquad [2]$$

If the excitation energy or the electron is shared among several water molecules so that out of several D_2O and HDO molecules there is a bigger chance than the statistical one for HDO to decompose, although a D_2O molecule was originally excited, then α_A may be bigger than 2 at ~100% D (9).

The results in Table I show that α_A is higher at high deuterium concentrations than at low ones and that it is bigger than 2. A similar behavior was noted for acid solutions (8, 9) and was attributed to reaction (9)

$$H_3O^+ + e \rightarrow H + H_2O \qquad [3]$$

being the one responsible for hydrogen atom production, since H_3O^+ is formed by the interaction of more than one water molecule.

In the formate experiments, where low yields are obtained (Table I, except for experiments 3 and 7) one deals with the "residual" yield (3), after the majority of the electrons have been scavenged, without yielding hydrogen gas. It is apparent from α_A that this yield cannot be due to either [1], [2], or

$$H_2O^* \rightarrow H + OH. \qquad [4]$$

Reaction [4] has been proposed to account for this yield (3), because it could explain why, under certain conditions, electron scavengers do not affect this yield. If excited water molecules (as in [4]), and not solvated electrons, are the precursors of the hydrogen

atoms, electron scavengers would not be able to affect the "residual" yield (3). On the other hand, our isotopic results are incompatible with reaction [4].

If reaction [1] were fast enough, it could explain why, under some conditions, the "residual" yield is scavenged as H, while under others, it is scavenged as H_2O^-. But, as has already been said, this reaction would lead to a similar dependence of α_A on deuterium concentration, as reaction [4], if only one molecule is bound to the electron, in H_2O^-.

The *only* possible explanations for the "residual" yield which are compatible with the observed isotope effect are those reactions in which more than one water molecule is involved. Reaction [3] or sharing of excitation energy (or of the electron) among several water molecules belongs to that category.

Reaction [3] is very likely to occur, since H_3O^+ is formed in the track of the ionizing electron, by the sequence (9)

$$H_2O \rightarrow H_2O^+ + e \qquad [5]$$

and

$$H_2O^+ + H_2O \rightarrow H_3O^+ + OH. \qquad [6]$$

It is significant to note that the "residual" yield is suppressed by those solutes which are efficient electron scavengers, like H_2O_2, O_2 (5), and CO_2 (13). These could compete with reaction [3]. Reaction [3] thus accounts best for all the results.

It is seen that the addition of phosphate to the formate changes the yield, as well as the isotopic composition of the gas. The isotope effect, when full hydrogen yields are obtained in neutral solutions, was previously determined. It was shown by tracer exchange reactions that HDO decomposes independently of the medium (H_2O or D_2O) (10); moreover, a calculation of the numerical exchange results, according to our notation, gives $\alpha_A = 1.6$ at $\sim$100% D. These studies were done at low concentrations of the scavenger (hydrogen molecules) and at a complete absence of efficient electron scavengers. Under these conditions, reaction [1] followed by reaction of H with a hydrogen molecule, or reaction [2], where RH is H_2, can occur. α_A obtained by us in experiments 3 and 7 is not equal to that from the hydrogen experiments (10), either because of a different scavenger concentration—a factor which has not yet been studied—or because of the interaction of the $H_2PO_4^-$ ion with the electrons, to give hydrogen atoms.

The dependence of hydrogen yield on phosphate concentration will be given in a forthcoming publication (14), where the influence of buffers will be further discussed.

CONCLUSIONS

A mechanism for the production of the "residual" yield, compatible with the deuterium isotope effect, is one in which more than one water molecule is involved. A track reaction between H_3O^+ and an electron accounts best for isotopic, as well as scavenger, results.

ACKNOWLEDGMENTS

This research was sponsored by the Israel Atomic Energy Commission. The author wishes to thank Professors G. Stein and E. D. Bergmann for their continuous interest in this work. The author also thanks Professor M. Anbar for his help with the isotopic analyses.

ABSTRACT

Interaction of potassium 1-phenylcyclopentanecarboxylate and 2-diethylaminoethyl chloride in absolute ethanol proved the most satisfactory of four methods examined for the preparation of 2-diethylaminoethyl 1-phenylcyclopentanecarboxylate hydrochloride (Parpanit). This procedure was used to obtain 2-(ethyl-2′-fluoroethylamino)ethyl (I), 2-(ethylisopropylamino)-ethyl (II), 2-diisopropylaminoethyl (III), 2-pyrrolidinoethyl (IV), and 2-piperidinoethyl (V) 1-phenylcyclopentanecarboxylate hydrochlorides. 2-Diethylaminoethyl 1-(*p*-nitrophenyl)-cyclopentanecarboxylate hydrochloride (VI) was also prepared in this way but was obtained more conveniently by direct nitration of 2-diethylaminoethyl 1-phenylcyclopentanecarboxylate. The preparation of intermediates required in these syntheses is described.

Preliminary results are given on the potency of these compounds as substitutes for atropine sulphate in the usual oxime and atropine sulphate treatment of mice which have been poisoned with Sarin.

In connection with extension of our studies on the usefulness of substitutes for atropine in the treatment of Sarin poisoning (1, 2) it became necessary to prepare certain analogues of 2-diethylaminoethyl 1-phenylcyclopentanecarboxylate hydrochloride, which is known commercially as Parpanit, Panparnit, Caramiphen hydrochloride, or Pentaphen. Many compounds of this type have been synthesized previously and the method most frequently employed has been interaction of the acid chloride with the requisite aminoalcohol in an aromatic solvent (3–8) (method 1). Other procedures which have been utilized less frequently include transesterification of ethyl 1-phenylcyclopentanecarboxylate with an aminoalcohol and sodium in xylene (8–11) (method 2); interaction of an alkali metal salt of the acid and an aminoalkyl halide in a hydrocarbon solvent (5, 7, 12–14) (method 3); treatment of the acid chloride with an aminoalcohol hydrochloride in a hydrocarbon solvent (5) (method 4); and heating the acid with an aminoalkyl chloride hydrochloride in an alcohol (5) (method 5). Method 2 was considered unsuitable for preparation of the compounds required because it sometimes furnishes very poor yields (11). It was not clear, however, which of the other four procedures referred to above would be most satisfactory. Accordingly, the merits of methods 1, 3, 4, and 5 were briefly examined with respect to yield and manipulative convenience for preparation of 2-diethylaminoethyl 1-phenylcyclopentanecarboxylate hydrochloride (3).

Interaction of equimolar quantities of 1-phenylcyclopentanecarboxylic acid chloride and 2-diethylaminoethanol in anhydrous benzene under reflux for 2 hours furnished the ester hydrochloride in 65% yield. Prolonging the period of reflux did not improve the yield (method 1).

When potassium 1-phenylcyclopentanecarboxylate was heated under reflux in absolute ethanol for 18 hours with a 20 mole% excess of 2-diethylaminoethyl chloride, followed by treatment with hydrogen chloride, an 80% yield of 2-diethylaminoethyl 1-phenylcyclopentanecarboxylate hydrochloride was obtained. Lengthening the period of reflux did not improve the yield but the latter decreased to ca. 60% when heating periods shorter than 12 hours were employed (method 3).

[1]*Issued as D.R.C.L. Report No. 374.*

Interaction of equimolar quantities of 1-phenylcyclopentanecarboxylic acid chloride and 2-diethylaminoethanol hydrochloride in dry benzene at reflux temperature for 48 hours gave a 51% yield of the desired material. The yield decreased sharply when shorter reflux periods were used (method 4).

When equimolar quantities of 1-phenylcyclopentanecarboxylic acid and 2-diethylaminoethyl chloride hydrochloride were heated under reflux in absolute ethanol for 48 hours only a 29% yield of the desired ester hydrochloride was obtained (method 5).

From the foregoing results it is evident that method 3 is superior to the others examined on the basis of yield. It is also best from the standpoint of manipulative convenience, since the other methods either required much longer periods of heating under reflux and/or furnished products of inferior quality, which necessitated multiple recrystallizations to provide material equivalent to that obtained by method 3. This method was therefore adopted for preparation of the esters shown in Table II and was satisfactory in all cases.

1-Phenylcyclopentanecarbonitrile was prepared by interaction of phenylacetonitrile and tetramethylene dibromide with sodamide in liquid ammonia, following the general method of Case (15) as modified by Tilford and co-workers (9). The nitrile was hydrolyzed to the acid in 93% yield by the action of 48% hydrobromic acid, by modification of the method used by Weston (5) for preparation of 1-phenylcyclohexanecarboxylic acid. Interaction of the acid and thionyl chloride in dry benzene furnished the acid chloride in 79% yield. Potassium 1-phenylcyclopentanecarboxylate was obtained in 97% yield by neutralization of an alcoholic solution of the acid with 10% alcoholic potassium hydroxide. 1-(*p*-Nitrophenyl)cyclopentanecarboxylic acid was prepared in 80% yield by nitration of 1-phenylcyclopentanecarboxylic acid. The nitro group was concluded to be para to the phenylcyclopentanecarboxylic acid group on the basis of the infrared absorption pattern of the compound in the 1650- to 2000-cm^{-1} region (16). The potassium salt of this acid was readily obtained by the method employed for preparation of potassium 1-phenylcyclopentanecarboxylate.

2-(Ethyl-2′-fluoroethylamino)ethanol was prepared in 78% yield from 2-ethylaminoethanol and 2-fluoroethyl bromide (17), which were caused to react in dry benzene in the presence of anhydrous potassium carbonate. 2-(Ethylisopropylamino)ethanol was obtained similarly and in 41% yield from isopropylaminoethanol and ethyl bromide and was characterized as the halogen acid salts shown in Table I. Isopropylaminoethanol was prepared from isopropylamine and ethylene oxide following Biel's method (18) and characterized as the hydrochloride.

2-Diethylaminoethanol, N-(2-hydroxyethyl)pyrrolidine, N-(2-hydroxyethyl)piperidine, 2-(ethyl-2′-fluoroethylamino)ethanol, 2-(ethylisopropylamino)ethanol, and 2-diisopropylaminoethanol were converted to the corresponding chloride hydrochlorides in the yields given in Table I by treating them with thionyl chloride in dry chloroform (cf. Bartlett *et al.* (19)). These salts were treated with 20% aqueous sodium hydroxide and the free bases were recovered by ether extraction. The latter compounds were not analyzed but were kept at 4° until required in the esterifications.

Finally, 2-diethylaminoethyl 1-(*p*-nitrophenyl)cyclopentanecarboxylate hydrochloride (VI), which had been obtained by esterification of potassium 1-(*p*-nitrophenyl)cyclopentanecarboxylate with 2-diethylaminoethyl chloride, was prepared in 65% yield by direct nitration of 2-diethylaminoethyl 1-phenylcyclopentanecarboxylate. The identity of the two samples was established by comparison of melting points and infrared spectra.

The effectiveness of Parpanit analogues I–VI (Table II) as substitutes for atropine

identical with that described previously (1). Compounds III and IV are the only members of the group which exhibit greater protective ability than atropine sulphate. The marked improvement in protective effectiveness displayed by the diisopropyl analogue III relative to Parpanit suggests that further improvement in atropine substitute activity in the Parpanit molecule may result by placing suitable bulky electron-donating substituents on the nitrogen atom.

EXPERIMENTAL[2,3]

1-Phenylcyclopentanecarbonitrile

This compound was prepared in 64% yield (b.p. 144–148° at 12 mm pressure; n_D^{25} 1.5323) using the procedure of Tilford and co-workers (9), who report b.p. 148–153° at 20 mm pressure.

1-Phenylcyclopentanecarboxylic Acid

1-Phenylcyclopentanecarbonitrile (34.2 g, 0.020 mole) was heated under reflux with 48% hydrobromic acid (140 ml) for 3 days. The precipitated acid was collected by filtration, washed with water, and dissolved in ether (500 ml). The ether solution was extracted with 10% sodium hydroxide (2×150 ml) and the alkaline extract was acidified with 10% hydrochloric acid. The resultant precipitate was recrystallized from aqueous alcohol, yielding 35.5 g (93.4%) of light fawn plates, m.p. 159–160°. Case (15) reports m.p. 158–159°.

1-Phenylcyclopentanecarboxylic Acid Chloride

Thionyl chloride (11.9 g, 0.10 mole) was added dropwise to a mechanically stirred solution of 1-phenylcyclopentanecarboxylic acid (9.5 g, 0.05 mole) in anhydrous benzene (100 ml). Stirring was continued for 2 hours at room temperature, after which the solution was heated under reflux for 2 hours. Distillation *in vacuo* furnished 8.20 g (78.5%) of pale yellow oil, b.p. 114–115° at 4 mm pressure; n_D^{25} 1.5418. Levshina and Sergievskaya (13) report b.p. 149–150° at 20–23 mm pressure.

Potassium 1-Phenylcyclopentanecarboxylate

A solution of 1-phenylcyclopentanecarboxylic acid (3.80 g, 0.020 mole) in absolute ethanol (100 ml) was titrated with 10% ethanolic potassium hydroxide using phenolphthalein as external indicator. Removal of the solvent *in vacuo* followed by two recrystallizations from ethanol–ether gave 4.42 g (97.0%) of fine colorless needles which did not melt below 350°. Calc. for $C_{12}H_{13}O_2K$: C, 61.07; H, 5.74; K, 17.13%. Found: C, 61.18; H, 5.74; K, 17.08%.

1-(p-Nitrophenyl)cyclopentanecarboxylic Acid

1-Phenylcyclopentanecarboxylic acid (5.00 g, 0.0263 mole) was added portionwise with stirring to fuming nitric acid (75 ml) kept at −10°. Stirring was continued for a further hour at 0°, after which the reaction mixture was poured onto crushed ice (300 g). The resultant precipitate was collected by filtration and recrystallized from methanol, yielding 4.93 g (80.0%) of colorless to light tan platelets, m.p. 179–182°. Calc. for $C_{12}H_{13}NO_4$: C, 61.27; H, 5.57; N, 5.96%. Found: C, 60.94; H, 5.52; N, 5.98%. This procedure is based on that used by Rubin and Wishinsky (20) for preparation of 1-(*p*-nitrophenyl)cyclohexanecarboxylic acid.

[2]*All melting points and boiling points are uncorrected.*

[3]*Microanalyses were performed by J. G. Helie of these laboratories.*

Potassium 1-(p-Nitrophenyl)cyclopentanecarboxylate

This compound was prepared in 96% yield from the corresponding acid, using the method described for potassium 1-phenylcyclopentanecarboxylate and was obtained as fawn needles, m.p. 225°, after recrystallization from methanol–ether. Calc. for $C_{12}H_{12}NO_4K$: C, 50.56; H, 4.43; N, 5.12; K, 14.31%. Found: C, 50.81; H, 4.57; N, 4.93; K, 14.38%.

2-(Ethyl-2′-fluoroethylamino)ethanol

A mixture of 2-ethylaminoethanol (Eastman, 67.0 g, 0.750 mole), 2-fluoroethyl bromide (120 g, 0.940 mole) (17), anhydrous potassium carbonate (103 g, 0.750 mole), and dry benzene (475 ml) was heated under reflux with stirring for 40 hours. The solid which separated from the cooled solution was collected by filtration and washed with benzene. The benzene was removed by distillation and the residue fractionated *in vacuo*, yielding 79.0 g (78.0%) of 2-(ethyl-2′-fluoroethylamino)ethanol as a colorless liquid, b.p. 71–72° at 8 mm pressure; n_D^{25} 1.4330. Equivalent weight: Calc. for $C_6H_{14}NOF$: 135. Found: 134.

2-Isopropylaminoethanol

2-Isopropylaminoethanol, b.p. 169–170°, n_D^{25} 1.4388, was prepared in 78% yield by the method of Biel (18), who reported b.p. 169–171°. This compound was characterized as the hydrochoride, m.p. 69–70° (see Table I).

2-(Ethylisopropylamino)ethanol

A mixture of 2-isopropylaminoethanol (28.8 g, 0.280 mole), anhydrous potassium carbonate (38.7 g, 0.280 mole), ethyl bromide (30.5 g, 0.280 mole), and anhydrous benzene (50 ml) was heated under reflux with stirring for 5 hours. The solid was removed by filtration and discarded. The filtrate was dried over anhydrous magnesium sulphate, then distilled *in vacuo*, yielding 15.2 g (39.4%) of colorless oil, b.p. 95° at 57 mm; n_D^{25} 1.4380. Brill (21) reports b.p. 175°. This compound was further characterized as the hydrochloride, m.p. 85–86°, and hydrobromide, m.p. 71–72°, which were prepared by conventional methods (see Table I). The hydriodide was prepared directly as follows. A mixture of 2-isopropylaminoethanol (11.3 g, 0.11 mole), ethyl iodide (15.6 g, 0.10 mole), and 90% ethanol (50 ml) was heated under reflux for 24 hours, then kept at room temperature for 3 days. Volatiles were removed *in vacuo*; the oily residue was dissolved in water (100 ml) and extracted with ether (6×15 ml). The aqueous layer was concentrated and dried at 0.001 mm pressure, yielding an oil which crystallized on standing. Three recrystallizations from ethanol–ether gave 9.88 g (39.7%) of 2-(ethylisopropylamino)ethanol hydriodide as colorless needles, m.p. 76–77° (see Table I).

Dialkylaminoethyl Chloride Hydrochlorides

These compounds were all prepared in the same manner, by interaction of thionyl chloride with the dialkylaminoethanol in anhydrous chloroform. The preparation of 2-diisopropylaminoethyl chloride hydrochloride is typical.

A solution of thionyl chloride (5 ml, 8.3 g, 0.07 mole) in dry chloroform (5 ml) was added dropwise to a stirred solution of 2-diisopropylaminoethanol (7.26 g, 0.05 mole) in dry chloroform (50 ml) kept at −10°. The mixture was heated under reflux for 6 hours, and methanol (5 ml) was added. Removal of solvents, first at water pump pressure, then at 0.001 mm, followed by recrystallization of the solid residue from acetone–ether, gave 7.25 g (72.5%) of 2-diisopropylaminoethyl chloride hydrochloride as colorless needles, m.p. 130–131°. The dialkylaminoethyl chloride hydrochlorides prepared are shown in Table I.

Dialkylaminoethyl Chlorides

These compounds were prepared from the corresponding hydrochlorides according to the method used by Breslow and co-workers for the preparation of 2-diethylaminoethyl chloride (22). The preparation of 2-(ethylisopropylamino)ethyl chloride is typical.

A mixture of 2-(ethylisopropylamino)ethyl chloride hydrochloride (4.65 g, 0.025 mole), ice-cold 20% aqueous sodium hydroxide (5 ml), crushed ice (10 g), and ice-cold ether (25 ml) was stirred vigorously for 5 minutes. The ether layer was decanted and the aqueous layer extracted with ice-cold ether (2×15 ml). The combined extracts were dried for 3 hours at 4° over anhydrous magnesium sulphate. The drying agent was removed by filtration and the ether was removed *in vacuo*, yielding 2.85 g (76.0%) of colorless oil. No attempt was made to characterize the product and it was used immediately in the esterification conducted according to method 3. The dialkylaminoethyl chlorides are unstable on storage at room temperature but may be kept at 4° for periods up to 2 weeks without separation of solid, which is considered to be the cyclic dimer (cf. Breslow *et al.* (22) and Wright *et al.* (24)). The following dialkylaminoethyl chlorides were prepared by this method and yields are given in parentheses: 2-(ethylisopropylamino)ethyl (76), 2-(ethyl-2′-fluoroethylamino)ethyl (87), 2-diisopropylaminoethyl (89), 2-pyrrolidinoethyl (82), 2-piperidinoethyl (83).

Dialkylaminoethyl 1-Phenyl- and 1-(p-Nitrophenyl)-cyclopentanecarboxylate Hydrochlorides

(a) Method 1.—Freshly distilled diethylaminoethanol (Eastman, 5.85 g, 0.050 mole) dissolved in dry benzene (25 ml) was added dropwise with stirring to a solution of freshly prepared 1-phenylcyclopentanecarboxylic acid chloride (10.4 g, 0.050 mole) in dry benzene (100 ml) at 25°. The solution was heated under reflux with stirring for 2 hours, during which time a precipitate separated. The mixture was cooled to room

temperature and anhydrous ether (400 ml) was added to complete precipitation. The precipitate was recrystallized three times from acetone, yielding 10.9 g (69.0%) of 2-diethylaminoethyl 1-phenylcyclopentanecarboxylate hydrochloride as colorless needles, m.p. 142–143°. Swiss Patent 234,452 (3) reports m.p. 145–146° for this compound.

(b) Method 3.—Potassium 1-phenylcyclopentanecarboxylate (2.28 g, 0.01 mole) dissolved in absolute ethanol (25 ml) was added in one portion to freshly prepared 2-diethylaminoethyl chloride (1.62 g, 0.012 mole) dissolved in absolute ethanol (10 ml). The solution immediately became turbid and a precipitate began to separate. The mixture was heated under reflux for 18 hours and, after cooling to 0°, the precipitated inorganic salt was collected and discarded. The filtrate was evaporated to dryness *in vacuo* and the oily residue was extracted with anhydrous ether (4×25 ml). The ether solution on saturation with dry hydrogen chloride gave a precipitate which was recrystallized once from acetone, yielding 2.61 g (80.0%) of colorless needles, m.p. 145–147°.

(c) Method 4.—A mixture of 1-phenylcyclopentanecarboxylic acid chloride (4.18 g, 0.02 mole), 2-diethylaminoethanol hydrochloride (Eastman, 3.07 g, 0.02 mole), and dry benzene (50 ml) was heated under reflux for 2 days. The precipitate which separated on cooling was collected and the filtrate was evaporated to dryness *in vacuo*. The combined residue and precipitate were recrystallized from acetone, yielding 3.32 g (51.0%) of colorless needles, m.p. 140–141.5°.

(d) Method 5.—A mixture of 1-phenylcyclopentanecarboxylic acid (1.90 g, 0.01 mole) and 2-diethylaminoethyl chloride hydrochloride (1.72 g, 0.01 mole) in absolute ethanol (50 ml) was heated under reflux for 2 days. The dark precipitate was collected, discarded, and the filtrate was evaporated to dryness *in vacuo*. The residue was recrystallized three times from acetone, yielding 0.96 g (28.6%) of colorless needles, m.p. 144–146°.

The products from the four methods were shown to be identical with an authentic sample of Parpanit (2-diethylaminoethyl 1-phenylcyclopentanecarboxylate hydrochloride), kindly provided by Geigy Pharmaceuticals, Montreal, by comparison of melting points and infrared spectra.

The other esters of 1-phenylcyclopentanecarboxylic acid and 1-(*p*-nitrophenyl)cyclopentanecarboxylic acid shown in Table II were prepared by method 3.

2-Diethylaminoethyl 1-(p-Nitrophenyl)cyclopentanecarboxylate Hydrochloride (VI) by Nitration of 2-Diethylaminoethyl 1-Phenylcyclopentanecarboxylate

2-Diethylaminoethyl 1-phenylcyclopentanecarboxylate (5.00 g, 0.0153 mole) was added portionwise with stirring during a period of 1 hour to fuming nitric acid (75 ml) kept at −15°. The reaction mixture was stirred at 0° for an additional hour then poured onto crushed ice (200 g). The resultant mixture was neutralized with ice-cold 10% sodium hydroxide and extracted with ether (4×50 ml). The extract was dried over anhydrous magnesium sulphate, filtered to remove the desiccant, and saturated with hydrogen chloride. The precipitated solid was recrystallized twice from ethanol–ether, yielding 3.63 g (65.2%) of colorless crystals, m.p. 182–182.5° alone and in admixture with an authentic sample of 2-diethylaminoethyl 1-(*p*-nitrophenyl)cyclopentanecarboxylate hydrochloride (VI). The infrared spectra of the two samples were also identical.

ACKNOWLEDGMENT

We are indebted to Mr. J. R. Blanchfield for preparation of some of the 1-phenylcyclopentanecarboxylic acids used in this work and for providing the 2-diisopropylaminoethanol.

ORGANOPHOSPHORUS COMPOUNDS

IX. DIARYL PHOSPHOROFLUORIDATES AND DIARYL PHOSPHOROFLUORIDOTHIOATES[1, 2]

GEORGE A. OLAH AND ALEXIS A. OSWALD[3]
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received April 18, 1962

ABSTRACT

Diaryl phosphorofluoridates and diaryl phosphorofluoridothioates were prepared and their properties investigated.

INTRODUCTION

Of the diaryl phosphorofluoridates, diphenyl phosphorofluoridate was alone prepared by Saunders and co-workers (2) from phosphorus oxydichlorofluoride and phenol in the presence of dimethyl aniline, with 60% yield:

$$POCl_2F + 2C_6H_5OH + 2C_6H_5N(CH_3)_2 \rightarrow (C_6H_5O)_2POF + 2C_6H_5N(CH_3)_2HCl.$$

Gottlieb (3) claimed to have prepared this compound previously in 7% yield by the action of potassium fluoride on the corresponding diphenyl phosphorochloridate. The obtained compound was rapidly decomposed by water whereas diphenyl phosphorofluoridate is quite stable against water. As no fluorine analysis data were given by Gottlieb, it is doubtful that he had obtained the pure compound.

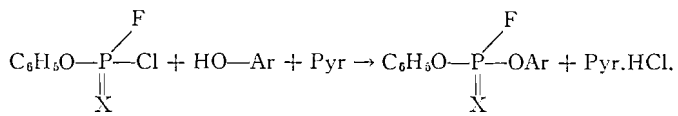
RESULTS AND DISCUSSION

No aryl phosphorofluoridothioates were reported in the literature although the preparation of diaryl phosphorochloridothioates from phosphorus thiotrichloride and anhydrous sodium phenolates is known (4–6):

$$PSCl_3 + 2ArONa \rightarrow (ArO)_2PSCl + 2NaCl.$$

In continuation of previous work on the biologically active phosphorofluoridates (7) it was of some interest to prepare diaryl phosphorofluoridates and diaryl phosphorofluoridothioates and investigate some of their properties.

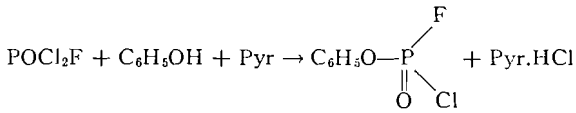
O,O′-Phenyl,aryl phosphorofluoridates and O,O′-phenyl,aryl phosphorofluoridothioates were conveniently prepared from phenyl phosphorochlorido-fluoridate or -fluoridothioate and the corresponding phenol in the presence of pyridine or dimethylaniline as acid binding agent:

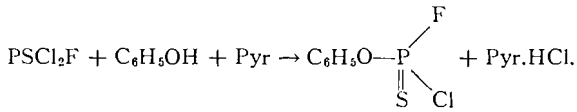


X = O, S

[1] *Contribution No. 67.*
[2] *For Part VIII, see reference 1.*
[3] *Present address: Esso Research and Engineering Company, Linden, New Jersey.*

Phenyl phosphorochlorido-fluoridate and -fluoridothioate were obtained from phosphorus oxydichloridefluoride or thiophosphoryl dichloridefluoride and phenol:





Diaryl phosphorofluoridates and fluoridothioates can also be obtained in one step from phosphorus oxydichloridefluoride or thiophosphoryl dichloridefluoride and 2 mole equiv of phenols:

$$POCl_2F + 2ArOH + 2Pyr \rightarrow (ArO)_2POF + 2Pyr.HCl$$
$$PSCl_2F + 2ArOH + 2Pyr \rightarrow (ArO)_2PSF + 2Pyr.HCl.$$

The one-step procedure, however, does not allow the preparation of "mixed" diaryl derivatives.

The prepared diaryl phosphorofluoridates and fluoridothioates, together with some of their properties and analytical data, are listed in Table I.

Both the diaryl phosphorofluoridates and fluoridothioates are quite stable against aqueous hydrolysis. They show practically no myotic effect. Although they show insecticide properties, they are considerably less toxic than their aliphatic analogues.

EXPERIMENTAL

Phenyl phosphorochloridofluoridothioate was prepared according to Olah and Oswald (J. Org. Chem. **25**, 603 (1960)).

Phenyl Phosphorochloridofluoridate

To a solution of 170 g (1.1 mole) phosphorus oxydichloridefluoride in 250 ml of toluene a solution of 1 mole of phenol in 300 ml toluene was added. To the resulting mixture 80 g (1 mole) of pyridine was added, diluted with 200 ml of toluene. (All operations were carried out with efficient stirring and external cooling, allowing the mixture to warm up from −50° slowly to room temperature.) The mixture was stirred for 2 hours at room temperature and another half hour at 40° to complete the reaction. The precipitated pyridine hydrochloride was filtered and the product fractionated in vacuum. Yield 87%, b.p. 66–70 at 5 mm. $C_6H_5OPOClF$: calc.: P 15.9, Cl 18.25, F 9.76; found: P 15.8, Cl 18.1, F 9.7%.

O-Phenyl,O'-Aryl Phosphorofluoridothioates

To a stirred solution of 0.1 mole of phenyl phosphorochloridofluoridothioate and 0.1 mole of the appropriate phenol in 150 ml of benzene, 7.9 g (0.1 mole) of anhydrous pyridine was added slowly, while the reaction mixture was cooled with ice water. After about half an hour the cooling was discontinued and the reaction mixture was heated for 15 minutes on a water bath and then was allowed to cool to room temperature. The pyridine hydrochloride crystals were removed by filtration and washed with benzene. The combined benzene filtrate was washed with water, 5% aqueous sodium carbonate solution, and again with water and dried over sodium sulphate.

Fractional distillation of the benzene solution *in vacuo* yielded the corresponding O,O'-phenyl,aryl phosphorofluoridothioate as a high-boiling colorless liquid fraction. Physical properties and analytical data of the products are shown in Table I.

O,O'-Diaryl phosphorofluoridothioates can also be prepared with a similar method in ether solvent. When using ether as solvent, a 3-day standing of the reaction mixture at room temperature was required to complete the reaction. Instead of pyridine, tertiary amines, e.g. triethylamine, are suitable to bind the hydrochloric acid formed during the reaction.

O,O'-Diphenyl Phosphorofluoridothioate

To a stirred solution of 0.1 mole of thiophosphoryl dichloridefluoride and 0.2 mole of phenol in 150 ml of toluene 16 g (0.2 mole) of anhydrous pyridine was added slowly, while the reaction mixture was cooled with ice water. The reaction was thereafter carried out and the product isolated as previously described for the preparation of O-phenyl,O'-aryl phosphorofluoridothioates.

O-Phenyl,O'-Aryl Phosphorofluoridates

To a stirred solution of 0.1 mole phenyl phosphorochloridofluoridate and 0.1 mole of the appropriate phenol in 150 ml of benzene, 12 g (0.1 mole) of dimethylaniline was added, while the reaction mixture was cooled with ice water. The reactions were then further carried out and the products isolated similarly as described previously for the preparation of O-phenyl,O-aryl phosphorofluoridothioates using pyridine instead of dimethylaniline as acid binding agent.

NITRATION AND REDUCTION OF SUBSTITUTED AZOBENZENES AND AZOXYBENZENES[1]

JOGINDER SINGH,[2] PRITAM SINGH, JEAN L. BOIVIN, AND PAUL E. GAGNON
Department of Chemistry, Laval University, Quebec, Que.

Received May 4, 1962

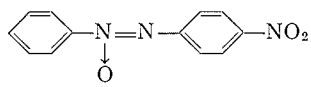
ABSTRACT

The nitration of some symmetrically tetrasubstituted azo- and azoxy-benzenes in various nitrating media was found to yield the 4-nitro derivatives in some cases, while more drastic conditions gave the 4,4′-dinitro compounds. Some nitroazobenzenes were transformed to the 4-nitroazo and 4,4′-dinitroazoxy derivatives.

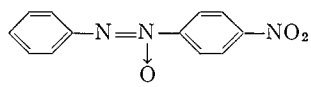
Reduction of the mononitroazo-, dinitroazo-, and azoxy-benzenes gave the monoaminoazo, diaminoazo, and azoxy derivatives under mild conditions while strong reducing agents converted the whole molecule to 1,4-diaminobenzene. One exception was found with 2,2′,5,5′-tetramethyl-4,4′-dinitroazobenzene, which was reduced to 2,2′,5,5′-tetramethyl-4,4′-dinitrohydrazobenzene.

INTRODUCTION

The nitration and bromination of the α- and β-isomers of *p*-nitroazoxybenzenes have been reported (1, 2) to take place at the para position with the β-isomers only, the α-isomer being unaffected due to the protective action of the oxygen atom on the adjacent ring:



α-isomer



β-isomer

However, recently it has been reported (3) that, using a nitrating mixture of fuming nitric acid in phosphoric acid, nitration takes place in both rings. It was thought of interest to investigate the nitration and reduction of some symmetrically substituted azo- and azoxy-benzenes.

DISCUSSION OF RESULTS

Nitration

During the nitration of azo compounds, both mononitro and dinitro derivatives were obtained. 2,2′-Dimethyl-5,5′-dichloro- and 2,2′-dimethyl-3,3′-dichloro-azobenzenes, when treated with concentrated HNO_3 and glacial acetic acid produced mononitro derivatives, while 2,2′-dimethyl-5,5′-dichloro- and 2,2′,5,5′-tetramethyl-azobenzenes gave the dinitro compounds with fuming HNO_3. The ortho- and para-directing influence of azo groups was confirmed by the introduction of nitro groups in the para position. While in the above cases only nitration took place, 2,2′-dimethyl-3,3′-dichloroazobenzene treated with a mixture of fuming HNO_3 and glacial acetic acid gave both the oxidation and nitration derivative 2,2′-dimethyl-3,3′-dichloro-4,4′-dinitroazoxybenzene.

[1]*This paper constitutes part of a thesis submitted to the Graduate School, Laval University, by Joginder Singh, in partial fulfillment of the requirements for the degree of Doctor of Science.*

This work was supported in part by a grant from the Defence Research Board of Canada (1959).

[2]*Graduate Student, holder of scholarships from Canadian Industries Limited (1960) and Shell Oil Company of Canada (1961).*

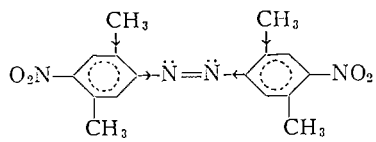
The nitration of 2,2′-5,5′-tetrachloro-, 2,2′-dimethyl-5,5′-dichloro-3,3′,4,4′-tetrachloro-, and 2,2′-dimethoxy-5,5′-dichloro-azoxybenzenes gives rise to α-isomers only, in agreement with the work of Angeli (4).

Reduction

For the purpose of determining the constitution of substituted azo- and azoxy-benzenes, many reducing agents have been used, such as zinc in acetic acid, zinc in caustic soda (5), and tin in hydrochloric acid. When 2,2′-dimethyl-5,5′-dichloroazoxybenzene was treated with zinc and acetic acid, the corresponding hydrazo compound was obtained in good yield, but using alkaline reduction with zinc dust in caustic soda, the yield was low. The alkali decomposes the hydrazo derivative readily. 2,2′-Dimethyl-4,4′-dinitro-5,5′-dichloroazobenzene when reacted with sodium sulphide in methanol gave a diamino compound. The reduction of both nitro groups can easily be explained by considering the electromeric effect of adjacent chlorine atoms and the electron-donating nature of the azo group itself. These two effects increase electron density at the nitro groups and by doing so facilitate its reduction rather than that of the azo group (6).

Reduction of 2,2′-dimethyl-3,3′-dichloro-4,4′-dinitroazoxybenzene by excess hydrazine hydrate in ethanol gave the corresponding 4,4′-diaminoazoxy compound. In this case, the nitro groups rather than the azoxy groups are reduced; this is because the two electron-donating chlorine substituents are in positions ortho to the two electron-sink nitro groups. The reduction seems to stop after the nitro groups are reduced. When this compound was reduced with excess sodium sulphide in aqueous methanol, it gave the 4,4′-diaminoazobenzene.

Similar results were observed with the reduction of the 4,4′-dinitroazo derivatives. For instance, 2,2′,5,5′-tetramethyl-4,4′-dinitroazobenzene was reduced by sodium sulphide in ethanol to the 4,4′-diamino compound. The reduction of 2,2′,5,5′-tetramethyl-4,4′-dinitroazobenzene with ammonium sulphide in alcoholic solution gave a yellow crystalline compound which the analysis indicated to be the dinitrohydrazo compound. The attack in this case on the azo group rather than on the more vulnerable nitro groups is very surprising. A possible explanation for this is that methyl groups, due to their positive inductive effect, prevent the electromeric shift of electrons from the azo to nitro group, as shown below, thus keeping the electron density at the azo group sufficient to be attacked by ammonium sulphide.



EXPERIMENTAL

General Procedure

(*a*) *Nitrations*

The azo- and azoxy-benzenes were nitrated in a mixture of nitric acid (*d*: 1.5) or fuming nitric acid in glacial acetic acid at temperatures of 60–90° C for a few hours. When the reaction was over the mixture was poured into crushed ice and the product which separated out was filtered and crystallized from suitable solvents. The conditions of nitration, yields, and physical properties of the nitro derivatives are recorded in Table I together with their analyses.

(*b*) *Reductions*
