CORRELATIONS OF ETHYLENIC PROTON COUPLING CONSTANTS WITH ELECTRONEGATIVITY

T. SCHAEFER

The Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received September 11, 1961

ABSTRACT

A strong correlation is found between the electronegativity, E_X, and the three proton coupling constant of the vinyl group in over a hundred compounds of the type $CH_2 = CHX$. This correlation extends over the range $E_X = 4$ to 1 and over the range $J_{gem}+J_{cis}+J_{trans} = 14$ to 50 c.p.s. Simple implications and some useful applications of this correlation are discussed.

A recent publication notes that for a number of vinyl compounds the sums of the three proton coupling constants in the vinyl radical fall into two groups, one of about 20 c.p.s. and one of about 30 c.p.s. (1). Vinyl fluoride is an exception, with a sum of 14.3 c.p.s. At present there are data available for about 140 vinyl compounds (2–10). The sums of the coupling constants, $J_{gem}+J_{cis}+J_{trans}$, are found to lie in the range 14.3 to 50.2 c.p.s. (see Table I). It appears that there is a regular progression from low to high values.

Banwell *et al.* (3) have recently plotted values of coupling constants for seven vinyl compounds against the electronegativities derived by Dailey and Shoolery from chemical-shift differences in ethyl halides (11). They find an inverse proportionality, E_X, for the compounds $CH_2 = CHX$ over the range $E_X = 2.5$ to 4.0. It is of interest to see whether this inverse proportionality extends to lower values of E_X.

In Table I the known coupling constants for a large number of vinyl compounds are collected. Opposite each group X is given the value of E_X used in Figs. 1 and 2. The apparent electronegativity of a group will be dominated by the atom at which the vinyl group is attached. With this in mind, the values of E_X are given for the atom to which the vinyl group is bonded. Thus we use the same values of E_X for aryl and alkyl ethers and so on. Two exceptions are to be noted. The value $E_X = 3.35$ has been taken for the nitro group and $E_X = 3.0$ for the vinyl sulphones. These values appear approximately correct from the work of Clifford (13).

In Fig. 1, the values of the coupling constants are plotted against E_X. There certainly is a strong correlation between the two parameters. Whether it is a linear relationship is perhaps questionable, but illustrative straight lines are drawn through the points. The values for bromine fall consistently far from the "straight line".

Inspection of the methods used for the analysis of the proton resonance spectra, which are all of the *ABC* type (15), shows that the sum of the coupling constants is a much more accurate experimental parameter than the individual values. This is so because this

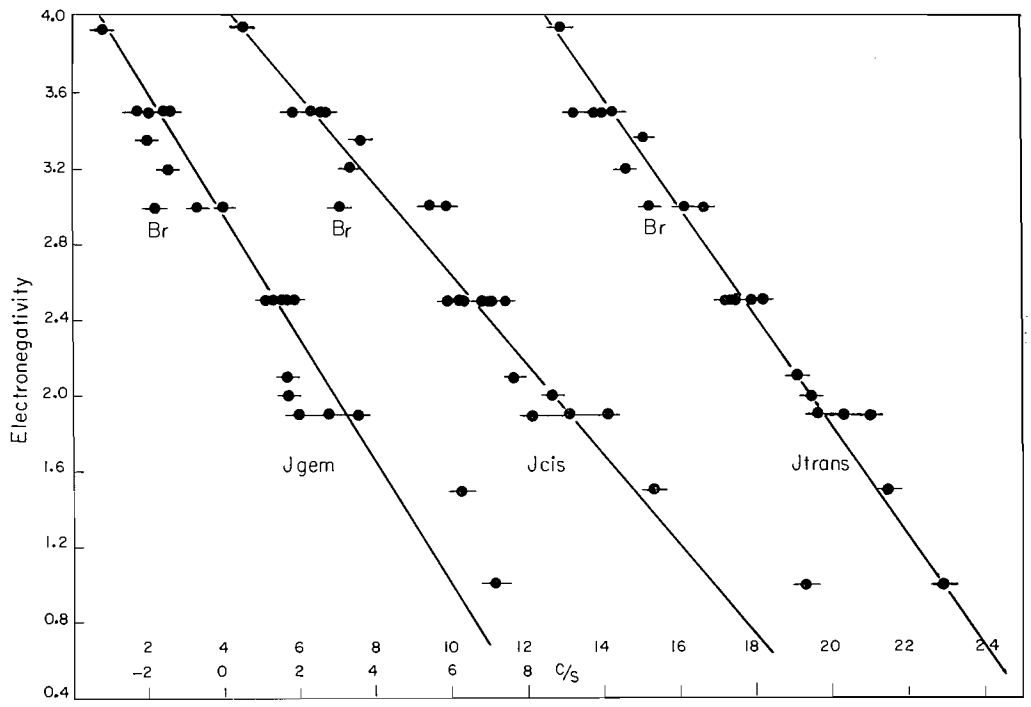

FIG. 1. The values of J_{gem}, J_{cis}, and J_{trans} in c.p.s. are plotted against the electronegativity E_X. Data are from Table I. Note that J_{cis} and J_{trans} are referred to the scale running from 0 to 24 c.p.s.

parameter can be gotten directly from the repeated line spacings in the spectrum (7), whereas the individual values must be extracted by a complete analysis involving the three chemical-shift parameters as well. The percentage error in J_{gem} is bound to be particularly large, since its magnitude is so small. Therefore it is gratifying that the best correlation between J and E_X is found for J_{trans}.

In Fig. 2, the sum of the coupling constants is plotted against E_X. Since in almost all

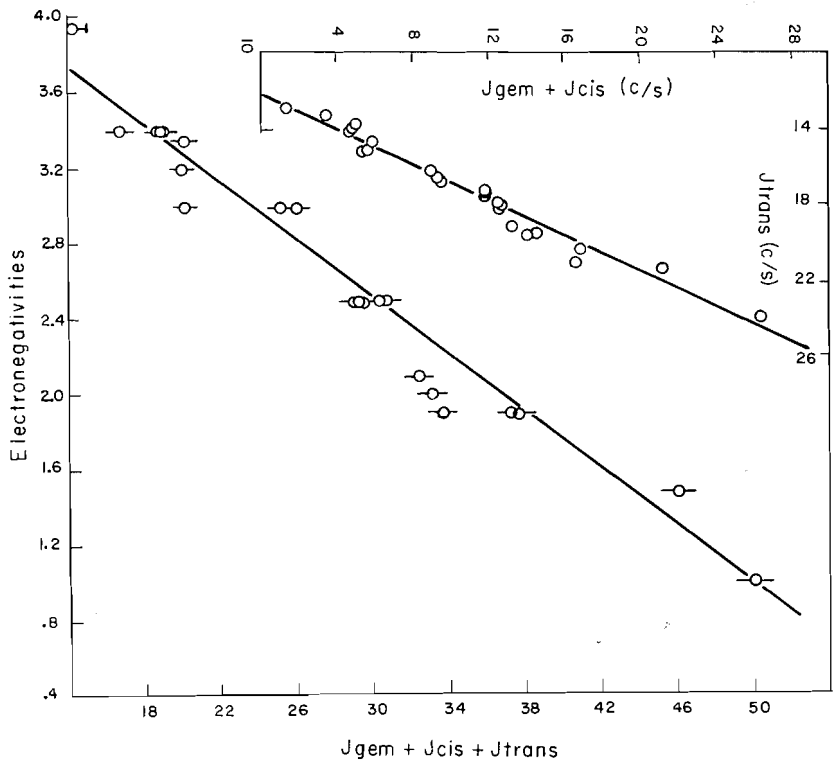

FIG. 2. The sum $J_{gem}+J_{cis}+J_{trans}$ in c.p.s. plotted against the electronegativity E_X; also sum $J_{gem}+J_{cis}$ plotted against J_{trans}, all in c.p.s. Data are from Table I.

the compounds this sum was accurately derived with a maximum error of about 0.5 c.p.s. (2), we can conclude from Fig. 2 that the scatter in most cases is due to factors other than that of large errors in the coupling constants. It would be surprising, I think, if there were a precise relationship between the two parameters. Extensive calculations suggest strongly that the value of J_{gem} should depend only on the angle between the two C—H bonds (5). In that case, Fig. 1 suggests that an approximate relationship exists between the bond angle and the electronegativity of the substituent on the β-carbon atom. In particular, the value of the CH_2 bond angle for metal vinyls should then lie between 110° and 120° (5).

It follows from Figs. 1 and 2 that there will be linear relationships between the coupling constants themselves. This has been found over a restricted range by Banwell and Shepherd (16). In order to minimize the relatively large errors in J_{gem}, Fig. 2 also shows a plot of $J_{gem}+J_{cis}$ against J_{trans}. The plot is linear, as expected.

An obvious practical application of the above correlations is in the analysis of the proton resonance spectra of other vinyl compounds. If the values found lie too far off

the lines in Fig. 1 they are probably incorrect. There are a number of examples in the literature. A striking one is tetravinylsilane (2). The coincidence of a large number of the 15 possible lines in the spectrum is probably the reason for the wrong assignment.

Another useful application is as a discriminant between two reasonable sets of parameters derived from a single spectrum. The iterative method for solving the ABC system does not always converge on the correct ones (7). The exact analysis of three spin spectra is now possible (7). In the exact analysis one always finds *all* the possible solutions, but the final choice is not always completely unambiguous; a consequence of the errors in peak-intensity measurements. An example is the ABC proton spectrum of acrylonitrile, the most reliable analysis of which is, no doubt, that of Castellano and Waugh (7). They find two sets of coupling constants, both of which would be accepted as reasonable if reached by the usual iterative method. They suggest that a final decision be made by running the spectrum in a magnetic field strength considerably different from the one they use. This has been done in these laboratories and, at the cost of considerable work, their preferred assignment has been substantiated. It is interesting to note that the reference to the plot of Fig. 1 would have resulted in the same conclusion.

THE RATE OF REACTION OF ACTIVE NITROGEN WITH AMMONIA AND ETHYLENE[1]

A. N. WRIGHT AND C. A. WINKLER
The Physical Chemistry Laboratory, McGill University, Montreal, Que.

Received August 14, 1961

ABSTRACT

The rate constants for the reactions of C_2H_4 and NH_3 are determined by termination of the reactions in the gas phase after different times of reaction. The average value for the rate constant of the N atom – C_2H_4 reaction at 150° C is 1.8×10^{10} cc mole^{-1} sec^{-1}, when the initial N-atom concentration is determined from the maximum production of HCN. The average value for the rate constant for the over-all reaction of NH_3 with excited nitrogen molecules, at 104° C in the "poisoned" system, and 83° C in the "unpoisoned" system, for low initial flow rates of NH_3, or short reaction time, is 2.2×10^{10} cc mole^{-1} sec^{-1}. The decrease in value of this rate constant at higher initial flow rates of NH_3 and longer reaction times in the "poisoned" system indicates that the species responsible for NH_3 decomposition is generated during the decay of N atoms in the presence of NH_3. The value for the NH_3 reaction is discussed in terms of energy transfer.

INTRODUCTION

Previous investigations (1) have indicated that the reaction of active nitrogen with C_2H_4 involves a direct attack of nitrogen atoms on the hydrocarbon, with production of HCN to the extent of about 96% of the nitrogen atoms destroyed. On the other hand, the corresponding reaction of NH_3 (2) appears to involve its destruction by excited nitrogen molecules. The maximum extent of NH_3 destruction, by active nitrogen, produced in a condensed discharge, is about one sixth the maximum production of HCN from C_2H_4 and other hydrocarbons. The reaction with NH_3 appears to be unaffected in extent by increase in reaction temperature, and to proceed at a quite rapid rate (2). With active nitrogen produced by a microwave discharge, Kistiakowsky and Volpi observed (3) that addition of NH_3 partially quenched the yellow nitrogen afterglow, without measurable destruction of NH_3, or decrease in N-atom concentration, as measured by a mass spectrometer. These authors estimated that the rate constant for a reaction between N atoms and NH_3 must be less than 10^8 cc mole^{-1} sec^{-1}. Since the reaction $N + NH_3 = NH + NH_2$ is endothermic to the extent of approximately 19 kcal, while the process $N + NH_3 = N_2 + H_2 + H$ conflicts with spin-conservation rules, they concluded that the efficient quenching of the afterglow was due to reaction between NH_3 and electronically excited nitrogen molecules. The concentration of the latter was estimated to be very low in the active nitrogen produced by the microwave discharge.

Further evidence that the destruction of NH_3 does not involve N atoms, in the rate-controlling step, is provided by the observation that addition of excess NH_3 to active nitrogen of microwave origin does not affect the ability of the active nitrogen to destroy nitric oxide (4). Moreover, it has recently been established (5) that its addition to active nitrogen produced by a condensed discharge, wherein appreciable destruction of NH_3 is observed, does not decrease either the ability of the active nitrogen to destroy NO, nor its capacity to produce HCN from C_2H_4. Hence, if the concentration of nitrogen atoms indicated by reaction of active nitrogen with NO is greater than that inferred from the

[1]*This work supported by the Geophysics Research Directorate, Air Force Cambridge Research Division, and by the Defence Research Board of Canada.*

maximum production of HCN from C_2H_4, as observed by Verbeke and Winkler (6), and this discrepancy is due to reactions of NO with excited nitrogen molecules, as these authors suggest, the excited molecules responsible for NH_3 decomposition might not be the same species as those responsible for reaction with NO.

Since NH_3 quenches the afterglow which originates in a transition between the B and A states of the nitrogen molecule, it seemed reasonable to assume (3) that $N_2(B^3\Pi_g)$ was probably responsible for the destruction of NH_3. However, recent work (7) has indicated that other precursors of the afterglow, such as the $^5\Sigma_g^+$ state, might also be involved. The destruction of NH_3 has also been attributed (8) to the $A^3\Sigma_u^+$ state of the nitrogen molecule, with a lifetime of at least 10^{-2} second (9, 10). This suggestion seems more plausible if it is assumed that the $A^3\Sigma_u^+$ molecules responsible for NH_3 decomposition have sufficient vibrational energy to permit crossover (7, 11) into the B state at vibrational levels high enough to give rise to at least part of the Lewis–Rayleigh nitrogen afterglow. Although vibrationally excited *ground-state* nitrogen molecules have a long lifetime (12, 13), and certain levels of this state could cause the decomposition of NH_3 (14), it is difficult to see how their removal by NH_3 would affect the afterglow (15).

The results of Kelly and Winkler (8) indicated that the excited nitrogen molecule responsible for NH_3 destruction is probably formed during homogeneous decay of nitrogen atoms. However, measurable amounts of NH_3 destruction have been observed only in active nitrogen produced by a condensed discharge, and it has been suggested (4) that the production of excited molecules might depend upon the mode of excitation of the nitrogen. In fact, recent studies of Beale and Broida (16), and Young and Clark (15), have indicated a large number of energetic species that *may* survive, at low concentrations, into the afterglow region. On the other hand, if the excited molecule is *formed* during homogeneous decay of ^4S nitrogen atoms, its concentration should be proportional to the square of the N-atom concentration, and, consequently, should be quite small in active nitrogen produced at low concentrations in a microwave system. It might be difficult, therefore, to detect destruction of NH_3 in such a system, even if the rate constant for the over-all reaction is relatively high.

The rate of reaction of active nitrogen with unsaturated hydrocarbons is quite fast (1). At the time this study was begun, no accurate determination of the rate constant for these reactions had been reported, although Greenblatt and Winkler (17) had obtained a rough estimate for the rate constant of the active nitrogen – ethylene reaction by a diffusion-flame technique. The average value, at a reaction temperature of about 52° C, was 4.0×10^{10} cc mole^{-1} sec^{-1}.

The purpose of the present work was to compare the rate constants, by a method involving variation in time of reaction, for the reactions of active nitrogen with C_2H_4 and NH_3. Active nitrogen was generated at relatively high concentrations in a condensed discharge (1), so that the ammonia reaction proceeded to an easily measurable extent. The reactions were terminated in the gas phase, after different times of reaction, by "flooding" the reaction mixture with another reactant. The reactions were studied only in an unheated reaction vessel, with temperatures in the reaction zones up to about 105° C with ammonia and 151° C with ethylene.

The rate constant for the NH_3 reaction presumably corresponds to the over-all reaction

$$N_2^* + NH_3 \rightarrow NH_3^* + N_2 \rightarrow \text{decomposition products} + N_2, \qquad [1]$$

where N_2^* and NH_3^* represent excited molecules. The previous studies of Freeman and Winkler (2) and Willey and Rideal (18) both indicated that the products of this reaction

are only N_2 and H_2. As in the photodecomposition of NH_3 (see, for example, reference 19), the excited NH_3 molecule probably breaks down to an hydrogen atom and the NH_2 radical, which is then followed by the reaction

$$2NH_2 \rightarrow N_2 + 2H_2. \qquad [2]$$

EXPERIMENTAL

The condensed discharge was operated for a "warm-up" period of at least 20 minutes prior to each experiment of 100-seconds duration. The reaction vessel was a straight, pyrex-glass tube of 25-mm i.d., with a fixed reactant jet 14.5 cm below the discharge and a *mobile reactant jet* (20) that could range from 0.1 to 45 cm below the fixed jet. Both jets contained six small holes placed symmetrically around their bulbous ends to produce an even flow of reactant into the active-nitrogen stream.

Because of the complicating reactions of hydrogen atoms with NH_3 at higher temperatures (2), the present experiments were made in an unheated reaction vessel. The pressure in the system was 3 mm of Hg, with a flow rate of molecular nitrogen of 378×10^{-6} mole sec^{-1}, corresponding to a linear flow rate of 478 cm sec^{-1}. The apparatus was "poisoned" against nitrogen-atom recombination by the introduction of less than 0.03×10^{-6} mole sec^{-1} of water vapor to the molecular nitrogen before the discharge. Such a small quantity of water vapor does not appear to affect the reactions of active nitrogen (21), but is an effective "poison" for wall recombination of atoms (22).

Nitrogen (Linde "bone-dry") was used without further purification, except during experiments in the "unpoisoned" system, when a liquid-air trap was used to ensure that no traces of moisture remained in the gas. Commercial NO (Matheson Co.) was freed from nitrogen by evacuation, while the NO was kept at liquid-nitrogen temperature; N_2O_3 was removed by three distillations of the NO from a bath held at $-78°$ C. Anhydrous ammonia (Canadian Industries Ltd.) and C. P. ethylene (Ohio Chemical Co.) were used after three bulb-to-bulb distillations during which only the middle fractions were retained. The reaction products were trapped at liquid-air temperature, and the production of HCN, or destruction of NH_3, was followed by the usual titration method.

The concentration of nitrogen atoms available for reaction at the fixed upper jet was estimated by the two methods in current use, i.e., by a gas-phase titration with NO (23, 24), and from the maximum production of HCN from C_2H_4 (1, 8).

RESULTS

After the 20-minute warm-up period, the temperature of the active-nitrogen stream, as measured with a glass-encased thermocouple 3 cm below the fixed jet, was found to be constant, for about 5 minutes, at 106° C in the "poisoned" system, and at 85° C in the "unpoisoned" system. The temperature measured during the C_2H_4 reaction, at flow rates of ethylene in the plateau region (see ref. 1), was 151° C in the "poisoned" system. The addition of excess NH_3 to the active nitrogen caused a *decrease* of 1° to 2° C in both the "poisoned" and "unpoisoned" systems. Possibly the reaction of NH_3 with N_2* removed a species from active nitrogen, which otherwise readily loses energy to the wall.

In the "poisoned" system, the maximum, or "plateau value", production of HCN from C_2H_4, when the reaction products were trapped 120 cm downstream from the fixed jet, was found to be independent of the reaction temperature in a cylindrical reaction vessel (5, 25) and indicated a flow rate of N atoms equal to 24.7×10^{-6} mole sec^{-1} at the fixed upper jet. The NO "titration" indicated a flow rate of N atoms equal to 45.0×10^{-6} mole sec^{-1} at the same point. The ratio NO/HCN of 1.8 is similar to that found by Verbeke and Winkler (6) at a pressure of 3 mm. This discrepancy between the two methods for estimating the N-atom concentration will be discussed elsewhere (5). Both values are used for calculating rate constants in the present study, to enable comparison with published values that are based on N-atom concentrations inferred from either method.

The experimentally observed quantities were measured as flow rates. These may be expressed as concentrations for calculations of rate constants by a multiplying factor equal to the ratio of molecular nitrogen concentration in the system, determined from the ideal gas law to be $1.43_3\times10^{-7}$ mole cc^{-1} at 3 mm and 25° C, to the molecular nitrogen flow

rate. The numerical value of this factor at 25° C was 3.79×10^{-4} sec cc^{-1}. The same value was used for other temperature conditions encountered in the study, since neither the pressure within the system, nor the linear flow rate of gas, showed appreciable variation with temperature between 25° C and 106° C, with the discharge off and on respectively. The flow rates mentioned above for the "poisoned" system corresponded to concentrations of N atoms at the fixed jet of $1.7_0\times10^{-8}$ and $0.93_6\times10^{-8}$ mole cc^{-1} for the NO and HCN methods respectively. In the "unpoisoned" system, the two methods indicated N-atom flow rates of 18.0×10^{-6} and 10.6×10^{-6} mole sec^{-1}, corresponding to N-atom concentrations of $0.68_1\times10^{-8}$ and $0.40_1\times10^{-8}$ mole cc^{-1} respectively.

The Reaction with Ethylene

The addition of an excess of NO (46.0×10^{-6} mole sec^{-1}) through the mobile jet, at different levels downstream from C_2H_4 introduced through the fixed upper jet, was found to decrease the HCN production from C_2H_4. The HCN production was reduced by only about 5% when NO was added at the 45- and 30-cm levels downstream, compared with the amount normally produced when the reaction was allowed to proceed to completion, i.e., for 120 cm, before the products were trapped. However, addition of NO at distances of 15, 10, 5, and 1.2 cm below the C_2H_4 inlet, corresponding to reaction times with C_2H_4 of 31.4, 20.9, 10.5, and 2.5 milliseconds respectively, decreased HCN production to a larger extent, as indicated by the results in Table I. The very rapid reaction of NO with nitrogen atoms (26) appeared to terminate the C_2H_4 reaction, by the rapid removal of any N atoms remaining in the gas stream.

TABLE I

Second-order rate constants for N+C_2H_4 at 150° C

Reaction time, milliseconds	Flow rate of C_2H_4, mole sec^{-1} ($\times10^6$)	HCN recovered, mole sec^{-1} ($\times10^6$)	k_{NO},* cc mole^{-1} sec^{-1} ($\times10^{-9}$)	k_{HCN},† cc mole^{-1} sec^{-1} ($\times10^{-9}$)
31.4	46.0	22.6	1.59	5.91
20.9	46.0	22.0	2.29	7.88
10.5	46.0	18.9 (23.0)	3.6 (4.9)	9.7 (19.5)
10.5	16.0	10.5 (13.3)	5.6 (8.2)	12.6 (18.9)
2.5	46.0	15.9 (18.1)	10.5 (13.9)	24.3 (36.2)

*k_{NO} is calculated for $[N]_0 = 1.7_0\times10^{-8}$ mole cc^{-1} (based on NO titration).
†k_{HCN} is calculated for $[N]_0 = 0.93_6\times10^{-8}$ mole cc^{-1} (based on maximum HCN production).

Rate constants were calculated from the integrated second-order rate equation, assuming that the initial N-atom attack on C_2H_4 is rate determining for HCN production, and that 1 molecule of C_2H_4 yields 1.5 molecules of HCN (1, 5) under the prevailing conditions. The equation then takes the form

$$k = \frac{1.5}{t}\frac{2.303}{a-1.5b}\log\frac{b(a-x)}{a\left(b-\frac{x}{1.5}\right)},$$

where x represents the concentration of HCN produced, and the other symbols have their usual significance.

When NO was added at distances of 5 cm or less from the C_2H_4 jet, considerable reaction of N atoms with NO occurred (the green NO_2 glow was observed), and condensation of ozone became a hazard. This was avoided by placing silver wire in the gas stream just before the trap, to remove oxygen atoms. However, the presence of silver oxide

decreased the amount of HCN recoverable by distillation from the product trap, and this decrease persisted even when the C_2H_4 reaction was allowed to go to completion, i.e., when no NO was added. The previously established HCN production for complete reaction at the particular initial flow rate of C_2H_4 used could be reproduced only after the product trap was cleaned with acid. This decrease in recoverable HCN was slightly variable, and a normalization factor for HCN loss was derived by making an experiment at the same C_2H_4 flow rate, but without added NO, immediately following each reaction that involved addition of NO at distances of 5 cm or less. The figures in parentheses in Table I are normalized in this way, to take into account the loss in HCN when silver oxide was present in the system. The normalization factor for a reaction time of 10.5 milliseconds, at a flow rate of 46.0×10^{-6} mole sec^{-1} of C_2H_4, was apparently a little too high, but the rate constant, based on an initial N-atom concentration inferred from the NO titration, lies somewhere between 3.6×10^{9} and 4.9×10^{9} cc $mole^{-1}$ sec^{-1}.

The values for the rate constant must be considered as minima, since the method assumes that neither NO, nor oxygen atoms, interferes with the *production* of HCN from the reaction of nitrogen atoms with ethylene. The averages (27) of the normalized values for the rate constant, based on the two methods for estimating the initial N-atom concentration, are $k_{NO} = 6.2\times10^{9}$ cc $mole^{-1}$ sec^{-1} and $k_{HCN} = 1.8\times10^{10}$ cc $mole^{-1}$ sec^{-1}. These are in fair agreement with the value previously obtained by observations on the length of the reaction flame (17).

The Reaction with Ammonia

Flooding the NH_3 – active nitrogen mixture with NO, to terminate the NH_3 reaction, would not be satisfactory because of the reaction of oxygen atoms with NH_3, and the reaction of NO with its decomposition products (19). However, it was found that the extent of NH_3 destruction was decreased by the addition of excess C_2H_4 (in the range 52×10^{-6} to 60×10^{-6} mole sec^{-1} in the "poisoned" system, and 46×10^{-6} mole sec^{-1} in the "unpoisoned" system) at the 45-, 30-, 15-, and 1.2-cm levels below the NH_3 inlet, corresponding to times for the NH_3 reaction of 94.3, 62.7, 31.4, and 2.5_1 milliseconds respectively. For a given flow rate of NH_3, the decrease became larger as the C_2H_4 was added closer to the NH_3 jet, and, at each level, became smaller as the flow rate of NH_3 was increased. The results are summarized in Table II.

It appeared that the excess of C_2H_4 quickly removed not only the N atoms remaining in the gas stream, but probably also removed (14) most of the excited nitrogen molecules remaining in the system. Experiments in which C_2H_4 was added at 15 and 30 cm above the point of introduction of NH_3 showed that the ability of active nitrogen to decompose NH_3 was completely destroyed. It should be noted that, even though C_2H_4 could deactivate many possible forms of N_2*, and became itself excited by a collision of the second kind, direct formation of HCN from this reaction is highly unlikely. Moreover, subsequent production of HCN from a possible breakdown product of the excited C_2H_4, such as C_2H_3 or CH_3, would still require consumption (14) of N atoms.

Experiments in the "poisoned" system, with a flow rate of NH_3 of $2.5_0\times10^{-6}$ mole sec^{-1}, represent those where the amount of NH_3 introduced is less than the maximum amount of NH_3 destroyed ($4.5_0\times10^{-6}$ mole sec^{-1}) at high flow rates of NH_3, when the reaction goes to completion. Under conditions of complete reaction, no NH_3 is recovered at an initial flow rate of $2.5_0\times10^{-6}$ mole sec^{-1}, and it appears, from the reaction for 94.3 milliseconds, that about 90% of the NH_3 introduced at that flow rate is destroyed at the 45-cm level. In all other experiments in the "poisoned" system, the initial flow rate of

TABLE II

*k_{obs} based on initial [active nitrogen] given by maximum amount of NH_3 destruction = $1.7_6\times10^{-9}$ mole cc^{-1}, "poisoned" system; = $0.55_6\times10^{-9}$ mole cc^{-1}, "unpoisoned" system.

NH_3 is greater than the maximum destruction of NH_3 when the reaction goes to completion. At an initial flow rate of NH_3 of 12.5×10^{-6} mole sec^{-1}, its destruction at the 45-cm level appears to be only 88% of the maximum destruction obtained at this flow rate when the reaction is not interrupted by the addition of C_2H_4. In the "unpoisoned" system, the initial NH_3 flow rates are slightly larger than the maximum destruction of NH_3 for complete reaction, $1.4_7\times10^{-6}$ mole sec^{-1}.

The selection of a value for the initial concentration of active nitrogen at the fixed jet, capable of reaction with NH_3, poses a problem. If one assumes that the reaction is due to excited molecules produced directly in the discharge, or formed by homogeneous recombination of N atoms between flashes within the discharge (8), the most obvious value to use for $[N_2^*]_{initial}$ would be the maximum destruction of NH_3 when the reaction goes to completion. When the reaction was allowed to proceed to the trap (120 cm from the fixed jet), the extent of NH_3 destruction in the "poisoned" system increased only by 0.2×10^{-6} mole sec^{-1} for an increase in NH_3 flow rates from $8.0_0\times10^{-6}$ to 13.0×10^{-6} mole sec^{-1}. In the "unpoisoned" system, the extent of NH_3 destruction after complete reaction ($1.4_7\times10^{-6}$ mole sec^{-1}) was quite independent of the initial flow rate of NH_3 between the same limits. These "plateau" values for NH_3 destruction indicated concentrations of active nitrogen capable of NH_3 destruction, at the fixed jet, of $1.7_0\times10^{-9}$ and $0.55_6\times10^{-9}$ mole cc^{-1}, in the "poisoned" and "unpoisoned" systems repectively.

Using these values for $[N_2^*]_{initial}$, second-order rate constants were calculated for the destruction of NH_3 by active nitrogen, on the assumption that excitation of NH_3, by a collision of the second kind, leads to its dissociation with an efficiency of 100% at the pressure of 3 mm used in the experiments. Precedent for the latter assumption is obtained from the observation that the photolytic decomposition of NH_3 proceeds with a primary quantum yield of unity (see ref. 19). The absence of collisional transfer of energy from

excited NH_3 to NO, added as a radical scavenger, at a pressure of 4 mm or less, has been explained (28) by a very short lifetime of the excited NH_3 molecule.

The calculated values of k_{obs} agreed well for initial flow rates of NH_3 of about $2.5_0 \times 10^{-6}$ mole sec^{-1}, at different reaction times, in both the "poisoned" and "unpoisoned" systems. However, consistently lower values were obtained for higher initial flow rates of NH_3, except for the shortest reaction time. The average value of k_{obs}, for all reaction times at the lowest flow rate of NH_3, and for the shortest reaction time for all flow rates, was found to be 2.2×10^{10} cc $mole^{-1}$ sec^{-1} (27). For the "poisoned" system, the experiments with higher initial flow rates of NH_3, and reaction times greater than 2.5_1 milliseconds, gave an average value of 0.52×10^{10} cc $mole^{-1}$ sec^{-1}.

DISCUSSION

The Reaction with Ethylene

The few experiments on this system indicated a minimum value for the second-order rate constant that compares well with two recently published values.

Herron (29) obtained an average value of 5.8×10^{10} cc $mole^{-1}$ sec^{-1} over the temperature range 200 to 330° C. The N-atom concentration was measured with a mass spectrometer after a fixed reaction time, with negligible decomposition of C_2H_4. The "absolute" value of the N-atom concentration was estimated by the NO titration.

Milton and Dunford (25) obtained a value for k of 9.63×10^{10} cc $mole^{-1}$ sec^{-1}, at 40° C, by a flame-diffusion technique. The initial N-atom concentration was inferred from the maximum production of HCN from ethylene. The method differed from that of Greenblatt and Winkler (17) in that the active nitrogen diffused into the hydrocarbon reactant. However, the flame technique must assume that the flame, emitted mostly by excited CN radicals (30), parallels the reaction of which the rate is presumably measured:

$$N + C_2H_4 \xrightarrow{k} HCN + CH_3\cdot \,. \qquad [3]$$

In fact, Bayes has recently presented evidence (31) that, for certain organic reactants at least, light emission in active-nitrogen reactions may be initiated by a second reactive species, possibly $A^3\Sigma_u^+$ metastable nitrogen molecules.

Although the minimum values, obtained by the present method, had to be normalized as outlined earlier, the method does involve variation of the fundamental reaction parameter, time, and an analysis for the products of the reaction of which the rate is presumably measured. With decrease of reaction time, the rate constant shows a trend toward higher values, and improved agreement with those obtained by the other methods (25, 29). Complicating factors probably became more significant at larger reaction times in this system, e.g., loss of N atoms by recombination at the wall, and disappearance of $CH_3\cdot$ radicals, produced in reaction [3], by reactions other than their rapid attack by N atoms to produce HCN (1).

The Reaction with Ammonia

The addition of excess C_2H_4 appeared to terminate the NH_3 reaction satisfactorily, since calculation of rate constants, at least for low flow rates of NH_3, in the "poisoned" system, gave reasonably constant values for k_{obs} after different reaction times. Moreover, the few experiments in the "unpoisoned" system, with its lower active-nitrogen concentration, gave values of k_{obs} similar to those obtained at low NH_3 flow rates, or at the shortest reaction time, in the "poisoned" system. Since addition of C_2H_4 always caused a decrease in the amount of NH_3 destroyed, reactions of NH_3 with C_2H_4, or its decomposition products, appeared to be insignificant at the temperature of reaction.

The variation in k_{obs} for the over-all reaction leading to NH_3 decomposition, based on an active-nitrogen concentration given by the maximum destruction of NH_3, would seem to give some information about the source of the reactive species in active nitrogen responsible for NH_3 destruction. The values for k_{obs} decrease only in the "poisoned" system, for reaction times greater than 2.5_1 milliseconds, and initial flow rates of NH_3 greater than $2.5_0\times10^{-6}$ mole sec^{-1}. This decrease indicates strongly that *part* of the N_2^* responsible for NH_3 destruction is formed, in the presence of NH_3, during the decay of N atoms down the reaction tube. The work of Kelly and Winkler (8) suggested that the N_2^* involved in destruction of NH_3 was formed during homogeneous recombination of N atoms prior to introduction of NH_3. Also, observations with a photomultiplier tube (32) have shown that a decrease in the intense active-nitrogen afterglow, produced in the present system, persists, upon addition of excess NH_3, for at least 45 cm in a "poisoned" reaction tube.

It is possible to estimate a concentration of N_2^* available for reaction with NH_3, in the "poisoned" system, at the fixed jet. Studies on the decrease of "plateau" values for HCN production from C_2H_4 have indicated (5) that a concentration of N_2^* equivalent to 1.5×10^{-6} mole sec^{-1} *may* be formed during homogeneous decay of N atoms between the fixed jet and the 45-cm level. The maximum destruction of NH_3 observed after a reaction time of 94.3 milliseconds shows that the maximum concentration of N_2^* formed between the 45-cm level and the trap is equivalent to a flow rate of $0.5_7\times10^{-6}$ mole sec^{-1}. The maximum concentration of N_2^* formed after the fixed jet is then equivalent to $\sim2.1\times10^{-6}$ mole sec^{-1}. An approximation to the concentration of N_2^* available at the fixed jet, deduced by subtracting this value from the maximum destruction of NH_3 for complete reaction, is equivalent to a flow rate of $\sim2.4\times10^{-6}$ mole sec^{-1}. The NH_3 destruction at a reaction time of 2.5_1 milliseconds, and a flow rate of 12.5×10^{-6} mole sec^{-1} of NH_3, gives direct evidence that a concentration of N_2^* equivalent to at least $1.4_5\times10^{-6}$ mole sec^{-1} is available at the fixed jet, since the formation of N_2^* from termolecular recombination of N atoms is negligible in this reaction time.

The k_{obs} values suggest that most of the reaction of NH_3, in the "poisoned" system, at least at low initial flow rates, occurs with a slowly decaying N_2^* formed prior to the fixed jet, at a concentration at least equivalent to $1.4_5\times10^{-6}$ mole sec^{-1}. Further reaction appears to occur at a slower over-all rate, which is governed by the rate of formation of excited nitrogen molecules during homogeneous decay of N atoms. At a flow rate of $2.5_0\times10^{-6}$ mole sec^{-1}, the maximum decomposition of NH_3 given in Table II is $2.2_3\times10^{-6}$ mole sec^{-1}, after a 94.3-milliseconds reaction time. Since the concentration of N_2^* required for this destruction of NH_3 is probably available at the fixed jet, the calculated values for k_{obs} at this flow rate do not vary appreciably with reaction time. At the shortest reaction time of 2.5_1 milliseconds, the concentration of N_2^* available at the fixed jet is sufficient to maintain the relation between extent of NH_3 destruction and reaction time, even at the higher flow rates of NH_3, and consequently the calculated values of k_{obs} do not show a decrease. (The experiment at a reaction time of 31.4 milliseconds, and an initial flow rate of NH_3 of $8.0_0\times10^{-6}$ mole sec^{-1}, indicates that the amount of N_2^* available at the fixed jet may be less than a flow rate of 1.9×10^{-6} mole sec^{-1}, since the calculated value for k_{obs} for this experiment falls into the low range of values.)

In the "unpoisoned" system, k_{obs} values are not "low" for initial flow rates of NH_3 somewhat greater than the concentration of active nitrogen indicated by maximum NH_3 destruction for complete reaction. However, in this system of low N-atom concentration,

formation of N_2^* beyond the fixed jet is probably insignificant, since recombination of N atoms occurs predominantly on the wall. Experiments on the present system have indicated (5) that homogeneous recombination in the "unpoisoned" system accounts for only one eighth of the total decay of N atoms between the fixed jet and the 45-cm level, whereas it accounts for about one half in the "poisoned" system.

From the previous discussion, the higher average value for $k_{obs} = 2.2\times10^{10}$ cc mole^{-1} sec^{-1} may be considered a more accurate measure of the over-all rate of reaction of active nitrogen with NH_3. This average value is probably a little low, since a rather large value is used for the initial concentration of active nitrogen, capable of NH_3 destruction, in the "poisoned" system. Nevertheless, this average value for k_{obs} is as high as that obtained for the fast reaction between N atoms and ethylene. It may be concluded, therefore, that failure to observe NH_3 destruction in active nitrogen, produced by a microwave discharge, is due to the low N-atom concentration, hence low N_2^* concentration, and is not due to a slow rate for over-all NH_3 destruction, nor to some unique characteristic of active nitrogen produced by a condensed discharge.

Since energy is not transferred from excited NH_3 during the photodecomposition of NH_3 (28), it may be assumed that its lifetime is probably very short at the pressure of 3 mm in the present system. Consequently, if the over-all reaction leading to NH_3 decomposition is represented by

$$N_2^* + NH_3 \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} NH_3^* + N_2 \qquad [4]$$

$$NH_3^* \xrightarrow{k_2} NH_2 + H, \qquad [5]$$

a steady-state approximation for the rate of change of $[NH_3^*]$ leads to the following expression for the over-all rate of the reaction:

$$-d[NH_3]/dt = k_2[NH_3^*] = k_1[N_2^*][NH_3]. \qquad [6]$$

This corresponds to the "low pressure" form of the rate expression for unimolecular decomposition. The values of k_{obs} may then be identified with k_1, the rate constant for a process involving a collision of the second kind.

If the exchange of energy occurred on every "kinetic" collision, the value of the rate constant would be approximated by the rate of binary collisions for molecules of moderate dimensions at room temperature, i.e., $10^{14.7}$ cc mole^{-1} sec^{-1} (33).

Terenin and Ermolaev (34) have shown that simultaneous transition, in which the *total spin* is conserved, can have a high probability of occurrence. Kistiakowsky and Volpi (3) suggested that decomposition of NH_3 by N_2^* in, say the $B^3\Pi_g$ state, could well occur as the result of an inelastic collision in which total spin is conserved, and in the course of which the nitrogen molecule undergoes a triplet–singlet transition to the $X^1\Sigma_g^+$ ground state, while the NH_3 molecule undergoes a singlet–triplet transition to an excited state capable of decomposition. However, these authors (3) were doubtful of the high efficiency of the transfer of energy to NH_3 molecules required in this mechanism. The present study indicates that the transfer of energy need not be particularly efficient, especially since it appears to occur with an excited state of the nitrogen molecule of rather long life.

Electronic energy transfer is probably greater for *molecules* when there is a large overlap of the emission spectrum of the donor and absorption spectrum of the acceptor, and when both radiative transitions have a high probability of occurrence (35). In the present

system, although the over-all reaction conserves spin, the transition in the N_2 molecule, for example, is not optically allowed, whether the N_2^* molecule be in the $B^3\Pi_g$ or $A^3\Sigma_u^+$ (the Vegard–Kaplan bands) states. Consequently, the mutual coupling would not be as strong as it would be (36) if the corresponding optical transitions in both molecules were allowed for electric-dipole radiation. The impact between electronically excited nitrogen molecules and NH_3 probably corresponds more closely to that involving triplet–singlet transition, with a value for the rate constant for energy transfer of 4.8×10^5 cc mole^{-1} sec^{-1} (34), than to the sensitization of the fluorescence of perylene by 1-chloroanthracene, which involves a singlet–singlet transition and gives a value of k_1 (corresponding to k_t of ref. 35) of the order of 10^{15} cc mole^{-1} sec^{-1} (37). If the N_2^* molecule capable of donating the energy to NH_3 is in the A state, the lower cross section, or probability of energy transfer, in the present system, may be compensated, as in the system studied by Terenin and Ermolaev (34), by the long lifetime of the donor molecule, the excited N_2 molecule in this case.

METAL OXIDE ALKOXIDE POLYMERS

PART III. THE HYDROLYSIS OF SECONDARY AND TERTIARY ALKOXIDES OF ZIRCONIUM[1]

D. C. BRADLEY[2] AND D. G. CARTER[3]

Received June 21, 1961

ABSTRACT

The hydrolysis of zirconium alkoxides with secondary or tertiary alkoxide groups $Zr(OR)_4$, where R = Pr^i, Bu^s, Bu^t, and Am^t, has been studied. The relatively low polymers formed by the metal oxide alkoxides have been interpreted on the basis of structural models involving octahedrally 6-co-ordinated zirconium.

INTRODUCTION

Previous work (1) on the hydrolysis of some primary alkoxides of zirconium showed that polymeric oxide alkoxides $[ZrO_x(OR)_{4-2x}]_n$ were formed. A satisfactory interpretation of the number-average degree of polymerization as a function of degree of hydrolysis was developed on the basis of three structural models involving 6-co-ordinated zirconium and identical with those originally proposed for titanium (2, 3). Model I was based on the unsolvated trimeric alkoxide $Zr_3(OR)_{12}$ and gave rise to a series of co-ordination – condensation polymers having the general formula $Zr_{3(x+1)}O_{4x}(OR)_{4(x+3)}$. The requirement of relatively low polymers by this structural model was a consequence of the highly compact structures which are made possible by the sharing of common faces of octahedra. Even lower polymers are predicted by the solvated species $Zr_2(OR)_8,(ROH)_2$ (model II) and $Zr(OR)_4,(ROH)_2$ (model III), where the zirconium achieves some or all (respectively) of its increase in co-ordination by bonding with alcohol molecules instead of by intermolecular bonding with alkoxide groups. The degrees of polymerization of zirconium secondary alkoxides (4) in benzene are lower than for the normal alkoxides, whilst the tertiary alkoxides (5) are monomeric. This behavior was ascribed to the powerful steric effects of secondary and, especially, tertiary alkoxide groups which prevent intermolecular co-ordination. The steric effect thus provides an entirely different process for the formation of low polymers and it was therefore important to study the polymeric nature of zirconium oxide alkoxides involving secondary and tertiary alkoxide groups. In this communication we report results on the hydrolysis of zirconium isopropoxide, *sec*-butoxide, *tert*-butoxide, and *tert*-amyloxide under carefully controlled conditions.

EXPERIMENTAL AND RESULTS

Zirconium Alkoxides

These were prepared and analyzed using previously described methods (4, 5). The *sec*- and *tert*-butoxides and the *tert*-amyloxide were redistilled *in vacuo* prior to each experiment. The tetraisopropoxide was distilled *in vacuo* and then crystallized from isopropanol as the solvate $Zr(OPr^i)_4,Pr^iOH$.

Ebulliometric Studies

The variation of number-average degree of polymerization with degree of hydrolysis for the zirconium oxide alkoxides in their respective boiling alcohols was determined by

[1]*For Part II, see ref. 6.*
[2]*Present address: The University of Western Ontario, London, Ontario.*
[3]*Present address: Norwood Technical College, London, England.*

the ebulliometric method which was described in detail in a previous paper (1). In the following tables we present the value for n (the number-average degree of polymerization) at each value of the degree of hydrolysis h (the ratio of water molecules added per metal atom).

(a) Zirconium Isopropoxide

TABLE I

(Initial concentration of zirconium isopropoxide = 0.382 g-mol./kg isopropanol)

h	0.000	0.115	0.269	0.462	0.761	1.043	1.329	1.612	1.905	2.19
n	1.91	2.17	2.52	2.99	3.84	5.48	9.49	12.8	16.0	20.3
n_{calc}	2.00	2.17	2.44	2.89	4.06	6.57	17.55	—	—	—

The solution remained clear up to $h = 2.19$ but the next addition of water (to $h = 2.47$) caused precipitation. Values of n_{calc} are derived from the theoretical equation $n = 6/(3-2h)$, which applies to the polymer series $Zr_{2(x+1)}O_{3x}(OR)_{2(x+4)},(ROH)_{2(x+1)}$ model II based on the solvated dimer $Zr_2(OPr^i)_8,(Pr^iOH)_2$.

(b) Zirconium sec-Butoxide

TABLE II

(Initial concentration of zirconium *sec*-butoxide = 0.101 g-mol./kg *sec*-butanol)

h	0.000	0.130	0.474	0.831	1.178	1.527	1.879
n	1.94	2.16	3.12	5.15	11.3	20.8	19.9
n_{calc}	2.00	2.19	2.92	4.48	9.31	—	—

The solution remained clear up to $h = 1.879$ but the next addition of water (to $h = 2.235$) resulted in unsteady readings on the differential water thermometer. The latter phenomenon was ascribed to the presence of "unreacted" water. Values of n_{calc} are derived from the theoretical equation $n = 6/(3-2h)$.

(c) Zirconium tert-Butoxide

When zirconium *tert*-butoxide was added to boiling *tert*-butanol in the ebulliometer the thermometer readings were unsteady and gave rise to an abnormally high value for the molecular weight of $Zr(OBu^t)_4$, which is known to be monomeric in benzene (3). However, it was shown that $Zr(OBu^t)_4$ was appreciably volatile in boiling *tert*-butanol and that the ebulliometric method was inapplicable.

(d) Zirconium tert-Amyloxide

Successive additions of $Zr(OAm^t)_4$ to boiling *tert*-amyl alcohol gave a linear increase of the elevation of boiling point (ΔT) with increase in concentration, and from the slope of this, the correct (monomeric) value for the molecular weight of $Zr(OAm^t)_4$ was calculated. Unfortunately the line did not pass through the origin but gave a negative intercept on the ΔT axis. It appeared that the first addition of $Zr(OAm^t)_4$ must be interacting with some impurity in the *tert*-amyl alcohol (possibly water), so that the elevation of the boiling point was less than it should be. This effect persisted in spite of various attempts to purify the alcohol and at present it defies explanation. In the determination of the molecular weight of $Zr(OAm^t)_4$ this effect could be ignored because several additions of alkoxide were made and the slope of the ΔT versus Δm line was used for the calculations. However, in the ebulliometric hydrolysis technique the molecular weight of each zirconium oxide *tert*-amyloxide is determined from the ΔT value for a single point and would be sensitive to errors in the absolute value of ΔT.

An empirical method was devised (7) for correcting the value of h to allow for this deviation but the results are probably less accurate than for the other alkoxides. Accordingly we show the results graphically in Fig. 1 but have not tabulated the data. The initial concentration of $Zr(OAm^t)_4$ was 0.0584 g-mol./kg *tert*-amyl alcohol.

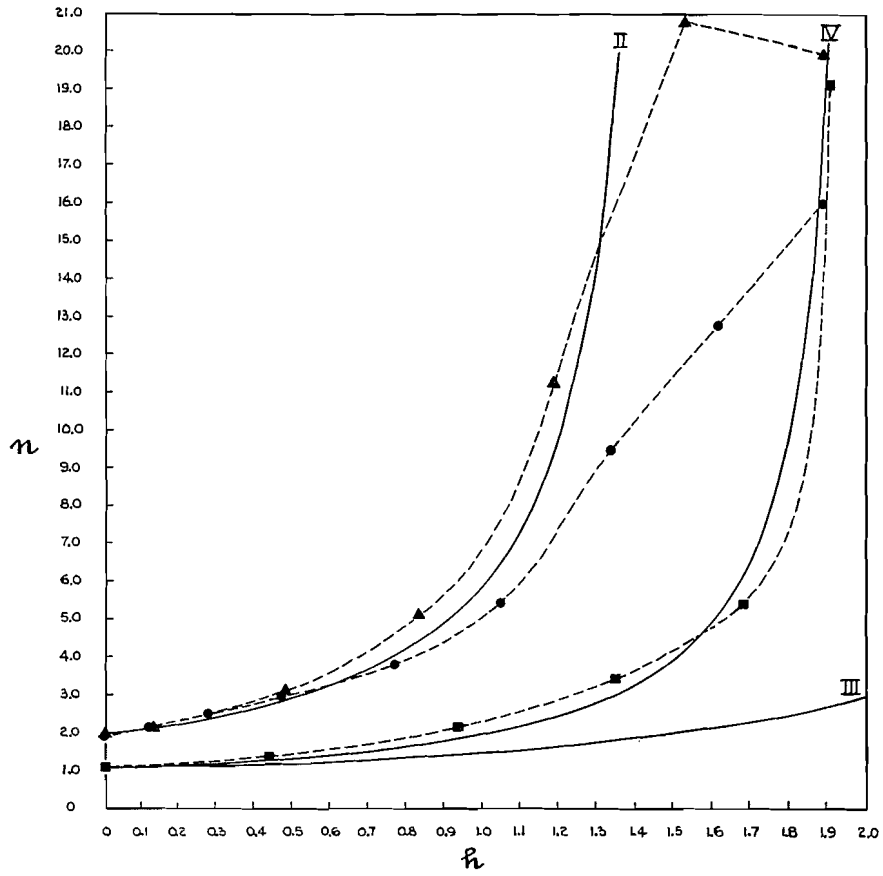

FIG. 1. The hydrolysis of $Zr(OPr^i)_4$, $Zr(OBu^s)_4$, and $Zr(OAm^t)_4$ in their alcohols: ●, $Zr(OPr^i)_4$; ▲, $Zr(OBu^s)_4$; ■, $Zr(OAm^t)_4$; II, $n = 6/(3-2h)$; III, $n = 3/(3-h)$; IV, $n = 2/(2-h)$.

Soluble Zirconium Oxide tert-Amyloxides

To establish the composition of zirconium oxide *tert*-amyloxides, samples (ca. 5 g) of $Zr(OAm^t)_4$ were hydrolyzed in boiling *tert*-amyl alcohol (ca. 25 cc) by the addition of measured amounts of aqueous *tert*-amyl alcohol (10% H_2O, w/w). The solution of the alkoxide was boiled under reflux and the lower, uncooled zone of the condenser was plugged with Fenske glass helices. The latter ensured that the added aqueous alcohol was rapidly mixed with the refluxing alcohol and thus diluted before entering the solution. Refluxing was continued for $\frac{1}{2}$ hour following the addition of water, and the solution was allowed to cool and then evaporated at room temperature under a pressure of 0.1 mm. When the product appeared to be free from alcohol the pumping was continued for another hour. The product was then analyzed for zirconium. The results are given in Table III. The calculated zirconium values are based on the formula $ZrO_h(OAm^t)_{4-2h}$

TABLE III

Ratio (h) of H_2O:$Zr(OAm^t)_4$	Nature of product	% Zr	
		Found	Calc.
0.211	Viscous liquid	22.3	22.4
0.360	Viscous liquid	23.6	23.8
0.597	Viscous liquid	26.8	26.4
0.780	Gum	28.2	28.8
0.982	Gum	30.2	32.1
1.007	Glass	31.3	32.5
1.340	Glass	38.2	40.1
1.691	Glass	42.4	53.0

and assume that hydroxyl groups are absent. Agreement between observed and calculated percentage of Zr is satisfactory up to $h = 0.780$ but for higher values the observed values are significantly lower than the calculated. However, these products were glassy and it is possible that some solvent was tenaciously bound in the product.

Insoluble Products

(a) An Insoluble Zirconium Oxide Isopropoxide

In the ebulliometric hydrolysis (Table I) of the isopropoxide no precipitation occurred up to $h = 2.19$ but the next addition of water ($h = 2.47$) caused the formation of a precipitate, which was dried and analyzed. Model II would give an infinite linear polymer $Zr_2O_3(OR)_2,2ROH$, which should be insoluble. The insoluble zirconium oxide isopropoxide was close in analysis to $Zr_2O_3(OPr^i)_2$ (found: Zr, 53.6; calc.: Zr, 52.4%).

(b) Insoluble Zirconium Oxide tert-Butoxides

A solution of $Zr(OBu^t)_4$ in *tert*-butanol was inadvertently exposed to the atmosphere for <1 minute and during the following 2 days it deposited some needle-shaped crystals (found: Zr, 27.0; $Zr(OBu^t)_4$ requires: Zr, 23.8; $Zr_2O(OBu^t)_6$ requires: Zr, 28.4; $Zr_2O_3(OBu^t)_2,(Bu^tOH)_4$ requires: Zr, 27.1%). A hydrolysis product ($h = 1.01$; found: Zr, 32.2; $ZrO_{1.01}(OBu^t)_{1.98}$ requires: Zr, 36.2%) was heated at 200° at 0.1 mm until the formation of volatile products appeared complete. The volatile products consisted of a small quantity of *tert*-butanol (sufficient to explain the low percentage of Zr of the original material) and $Zr(OBu^t)_4$. The insoluble, non-volatile residue was reasonably similar in composition to that of the infinite trilinear polymer of model I (found: Zr, 40.9; $Zr_3O_4(OBu^t)_4$ requires: Zr, 43.5%). A material balance was in reasonable agreement with the following disproportionation equation:

$$4/x[ZrO(OBu^t)_2]_x \rightarrow Zr_3O_4(OBu^t)_4 + Zr(OBu^t)_4.$$

DISCUSSION

Zirconium Oxide Isopropoxides

The variation of number-average degree of polymerization for zirconium oxide isopropoxides (Fig. 1) as a function of h is clearly in accordance with the predictions of the theory (1) for model II species between $h = 0$ and 0.76. This behavior is particularly significant because zirconium isopropoxide gives a relatively stable solvate which is dimeric $Zr_2(OPr^i)_8,(Pr^iOH)_2$ and lends strong support to the postulate of Bradley, Gaze, and Wardlaw (2) that such solvated species might exist in solution. The coefficient of variation for n (n_{calc} listed in Table I) for the region $h = 0$–0.76 is ±4%, which is of the order of probable experimental error. For $h > 0.76$ the experimental values of n deviate significantly from the $n = 6/(3-2h)$ equation with n less than n_{calc}. This suggests that as the

molar concentration of oxide isopropoxide decreases, solvation based on the monomer species $Zr(OPr^i)_4,(Pr^iOH)_2$ model III comes into play. It is interesting to note that although the polymer series based on model II should form infinite polymers at $h = 1.5$ and these would be expected to be insoluble, nevertheless, no precipitation occurred before $h > 2$. According to the calculations of Bradley and Holloway (6) based on the analogous structures for tantalum oxide ethoxides the failure to form insoluble products at $h > 1.5$ may be attributed to a disproportionation of h between the model II and model III series. However, this will not satisfactorily explain the present results because it would be necessary in making $h_{II} < 1.5$ to have $h_{III} > 2$ in view of the high proportion (83% at $h = 1.612$) of the model II polymers in the system. This suggests that at $h > 1.5$ the hydrolysis is incomplete, although there was no indication of "unreacted" water in the ebulliometer. On the other hand the absence of precipitation at $h = 2.19$ adds support to the suggestion that hydrolysis is incomplete as $h \rightarrow 2$. The situation is further complicated by the interesting fact that the solid $Zr_2O_3(OPr^i)_2$ which eventually precipitated at $h = 2.47$ had a degree of hydrolysis near that required by the infinite polymer of the model II series $Zr_2O_3(OPr^i)_2,(Pr^iOH)_2$, although it lacked the co-ordinated alcohol. Hence it appears that at $h > 1.5$, hydrolysis is incomplete, probably because of the presence of Zr—OH groups, and that the value of h_{II} for model II is less than h_{III} for model III. The material which precipitates is the model II infinite polymer, which loses its alcohol in the drying process.

Zirconium Oxide sec-Butoxides

The data in Fig. 1 show that the number-average degree of polymerization of a zirconium oxide *sec*-butoxide conforms reasonably well to the prediction of the theoretical equation $n = 6/(3-2h)$ based on the model II series over the range of hydrolysis $h = 0$–1.2. Thus the coefficient of variation for n (n_{calc} listed in Table II) for the first three points is ±4.5% and for the first five points it is ±12.5%. We have already pointed out (6) that n becomes rather sensitive to errors in h for $h > 1$ and the larger errors in the fourth and fifth points is understandable. For $h > 1.3$ it is clear that further solvation is setting in and that polymers from the model III series are present. The similarity of the n versus h curves for the zirconium oxide isopropoxides and the zirconium oxide *sec*-butoxides over the range $h = 0$–1.0 is quite striking. In fact zirconium *sec*-butoxide forms a crystalline solvate, $Zr_2(OBu^s)_8,(Bu^sOH)_2$, but it is less stable than the solvated isopropoxide and readily loses its alcohol of addition when dried *in vacuo*. Actually the similarity in hydrolytic behavior of these compounds is rather closer than might be expected. For example, in boiling benzene $Zr(OBu^s)_4$ is less polymeric than $Zr(OPr^i)_4$ (4) and this is believed to be due to a slightly greater steric effect of the *sec*-butoxide groups. Moreover, as *sec*-butanol has a higher boiling point than isopropanol and it is believed that an increase in temperature favors depolymerization and solvation of the alkoxide (3), we would have predicted that the degree of polymerization of $Zr(OBu^s)_4$ in boiling Bu^sOH should be significantly less than that of $Zr(OPr^i)_4$ in boiling Pr^iOH. Furthermore, we would have expected the zirconium oxide *sec*-butoxides to exhibit lower values of n than the corresponding oxide isopropoxides, whereas over a fair range in h (0.5–1.5) the opposite is true.

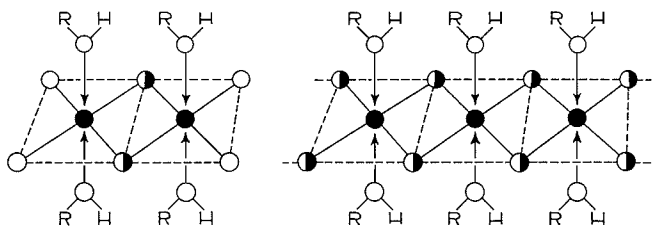
Zirconium Oxide tert-Butoxides

The high volatility of $Zr(OBu^t)_4$ in *tert*-butanol precluded the use of the ebulliometric method of studying its hydrolysis. However, some ebulliometric experiments were carried out with the view to determining at what value of h precipitation occurred. Values of $h > 2$ were required, in one case $h > 3.28$, and this behavior suggested that hydrolysis

was incomplete at the higher values of h, possibly due to the presence of ZrOH groups which were stable in the boiling solution. Two interesting insoluble products were isolated. A crystalline compound deposited when a solution of $Zr(OBu^t)_4$ in *tert*-butanol was inadvertently allowed to hydrolyze. The zirconium analysis corresponded to $Zr_2O_3(OBu)_2$, $(BuOH)_4$, which is the species for $h = 1.5$ in the solvated monomer model III series. Unfortunately there is ambiguity concerning this type of compound because of the alternative formulation involving say Zr(OH)(OR) in place of ZrO,ROH. Thus the above formula could be rearranged to $Zr_2(OH)_3(OBu)_5$,BuOH, which is also not very different from $Zr(OH)(OBu)_3$. The other insoluble product, obtained by the more extreme process of thermal disproportionation at 200°, had a zirconium content a little less than that for $Zr_3O_4(OBu^t)_4$, the infinite linear polymer for the unsolvated trimer model I series. Under the conditions of this experiment we should not expect Zr—OH groups to survive nor alcohol molecules to remain co-ordinated so it is not surprising that the product conforms to the model I series. The tendency towards model I would also be expected on the grounds that steric hindrance is alleviated by the small number of *tert*-butoxide groups per metal atom.

Zirconium Oxide tert-Amyloxides

The data presented in Table III show that for h values up to about 0.78 the hydrolysis of $Zr(OAm^t)_4$ produces unsolvated zirconium oxide *tert*-amyloxides. The intractable nature of the more highly hydrolyzed materials raises the doubt of whether or not they were completely dried free from alcohol. Alternatively, the low zirconium analyses may indicate the presence of solvated products or products containing ZrOH groups. Nevertheless it is clear that hydrolysis with the formation of zirconium oxide *tert*-amyloxides is substantially complete for h up to about 1.0. The ebulliometric data shown in Fig. 1 suggest that the polymeric species in solutions are initially close to the requirements of the solvated monomer model III (1) but tend towards the less solvated dimer model II as the hydrolysis is increased. This is the type of behavior to be expected if powerful steric effects are operating in the less-hydrolyzed species and thus preventing condensation polymerization. As the number of *tert*-amyloxide groups per zirconium atom decreases the molecules become capable of adopting the more compact structure of model II. An alternative possibility is that another structural model IV is adhered to by the zirconium oxide *tert*-amyloxides. This is based on the solvated monomer $Zr(OR)_4,(ROH)_2$ too but the oxide *tert*-amyloxide species involve condensation through ZrOZr groups sharing edges of the octahedra, as shown in Figs. 2 and 3. Structures in this model should conform



2 3

FIG. 2. The dimer $Zr_2O_2(OR)_4,(ROH)_4$: ●, Zr; ◑, oxygen in Zr·O·Zr; ○, oxygen in OR (R groups omitted).
FIG. 3. Section of the infinite polymer $[ZrO_2,(ROH)_2]_\infty$: ●, Zr; ◑, oxygen in Zr·O·Zr.

to the equation $n = 2/(2-h)$ and it is evident in Fig. 1 that the first five points in the hydrolysis of $Zr(OAm^t)_4$ are in reasonable agreement with the predicted curve IV.

CONCLUSIONS

1. The hydrolysis of zirconium alkoxides $Zr(OR)_4$, where R = Pr^i, Bu^s, Bu^t, and Am^t_2 leads to the formation of polymeric zirconium oxide alkoxides having low number-average degrees of polymerization.

2. No evidence of the formation of zirconyl compounds was obtained.

3. The variation of number-average degree of polymerization as a function of the degree of hydrolysis for zirconium isopropoxide and zirconium *sec*-butoxide conformed to the requirements of a structural model for the polymers based on octahedrally 6-co-ordinated zirconium.

4. At high degrees of hydrolysis it appears that highly solvated species are present and that hydrolysis may be incomplete in solution.

CONSTITUTION OF AN ALDOTETRAOURONIC ACID FORMED ON ENZYMIC HYDROLYSIS OF A 4-*O*-METHYLGLUCURONOXYLAN FROM THE WOOD OF WHITE BIRCH (BETULA PAPYRIFERA MARSH.)

T. E. TIMELL

The Pulp and Paper Research Institute of Canada and the Department of Chemistry, McGill University, Montreal, Que.

Received September 12, 1961

ABSTRACT

An aldotetraouronic acid has been isolated by enzymic hydrolysis of a 4-*O*-methylglucuronoxylan from the wood of white birch. It has been shown to be *O*-4-*O*-methyl-α-D-glucosyluronic acid-(1 → 2)-*O*-β-D-xylopyranosyl-(1 → 4)-*O*-β-D-xylosyl-(1 → 4)-D-xylose.

In a previous communication (1) an account was given of preliminary results obtained on treatment of a 4-*O*-methylglucuronoxylan from the wood of white birch with a commercial pectinase preparation. The enzymic hydrolysis was carried out inside a semipermeable membrane (2) and the oligosaccharides formed were allowed to diffuse rapidly through the latter, thus escaping further hydrolysis. Two series of oligosaccharides, one neutral and the other acidic, were obtained in high yields. The shortest acid oligomer formed was an aldotetraouronic acid. This paper is concerned with the structure of this new compound.

RESULTS AND DISCUSSION

The mixture of sugars obtained after the enzymic hydrolysis was resolved into an acidic and a neutral portion with an anion exchange resin. The sugar acids were separated either by gradient elution from a charcoal–Celite column or by preparative paper chromatography. The lowest acid was obtained as an amorphous powder, $[\alpha]_D^{20}$ +23°, in a yield of 11% of the original sugar mixture. Its rate of movement on the paper chromatogram was identical with that of an aldotetraouronic acid previously (3) isolated from a similar polysaccharide. The values for methoxyl, carboxyl, and reducing groups indicated the presence of an *O*-methylglucuronosyl xylotriose. Mild partial hydrolysis gave an aldotriouronic acid (4) and xylose, while an aldobiouronic acid was formed under more vigorous conditions. On oxidation with periodate, the compound consumed 5 moles of oxidant with concomitant formation of 2 moles of formic acid. From the structure of the parent polysaccharide (5), it appeared probable that the acid groups were attached to the 2-position of β-D-xylopyranose residues and that the latter were linked through their 1- and 4-positions. Consideration of the three possible structures of the aldotetraouronic acid showed that under these conditions only that alternative where the acid group was located at the non-reducing end was compatible with the above results.

A specimen of the aldotetraouronic acid which had been obtained from the charcoal–Celite column was methylated, first with dimethyl sulphate and alkali and subsequently according to Kuhn and co-workers (6). The fully methylated sugar acid was subjected to methanolysis, saponified, acidified, and resolved into an acidic and a neutral portion with an anion exchange resin. The acid fraction, a fully methylated aldobiouronic acid, was esterified and reduced with lithium aluminum hydride to give a partially methylated disaccharide, which could not be induced to crystallize. Hydrolysis yielded equimolar quantities of a di-*O*-methylxylose and a tri-*O*-methylglucose which were separated by gradient elution from charcoal–Celite. The first sugar was identified as 3,4-di-*O*-methyl-

D-xylose and the second as 2,3,4-tri-*O*-methyl-D-glucose. This shows that the methylated aldobiouronic acid was methyl 2-*O*-[methyl(2,3,4-tri-*O*-methyl-α-D-glucosyl)uronate]-3,4-di-*O*-methyl-D-xyloside. The neutral fraction contained only one compound, characterized as 2,3-di-*O*-methyl-D-xylose, 2 moles being obtained per mole of tri-*O*-methylglucose. A similar methylation of a specimen obtained by preparative paper chromatography gave the same results.

Of the three structures possible for the aldotetraouronic acid, only the alternative suggested by the periodate oxidation data would give 2 moles of 2,3-di-*O*-methyl-D-xylose in the neutral and 1 mole of 3,4-di-*O*-methyl-D-xylose in the acid fraction after methanolysis. The results obtained by the methylation technique are therefore unequivocal. The combined evidence shows that the acid isolated was *O*-4-*O*-methyl-α-D-glucosyluronic acid-(1 → 2)-*O*-β-D-xylopyranosyl-(1 → 4)-*O*-β-D-xylosyl-(1 → 4)-D-xylose. The aldotriouronic acid formed on mild partial hydrolysis was presumably *O*-4-*O*-methyl-α-D-glucosyluronic acid-(1 → 2)-β-D-xylopyranosyl-(1 → 4)-D-xylose, a compound which has previously been isolated from several xylans. The corresponding isomer with the acid group attached to the reducing xylose moiety of the triouronic acid does not seem to have been obtained so far, probably because of the much greater stability of the first isomer (3, 7, 8). This stability is also indicated by the fact that hardly any aldobiouronic acid was obtained on mild acid hydrolysis of the present aldotetraouronic acid.

The constitution of the other uronic acids, the physical characteristics of the neutral oligosaccharides, and the possible mechanism of the enzymic hydrolysis will be discussed elsewhere (9).

EXPERIMENTAL

All specific rotations were equilibrium values and were determined at 20° C. Melting points are corrected. Evaporations were carried out at 40–50° C *in vacuo*.

Paper Chromatography

Sugars were separated by the descending technique on Whatman No. 1 or, for preparative purposes, No. 3MM filter papers. Solvents (v/v) used were ethyl acetate – acetic acid – water in the proportions (A) (9:2:2), (B) (3:1:3), or (C) (18:7:8); butanone–water (D) (89:11); and ethanol–benzene–water (E) (47:200:15). Paper electrophoresis was carried out in 0.05 *M* borate solution with Whatman No. 3MM paper at 700 volts for 5 hours. *o*-Aminodiphenyl was used as a spray reagent (10).

Isolation and Preliminary Characterization of the Aldotetraouronic Acid

The enzymic hydrolysis and the isolation of the various oligosaccharides will be described in detail elsewhere (9). Two methods were used for obtaining a chromatographically pure aldotetraouronic acid, one involving gradient elution with aqueous ethanol from a charcoal–Celite column, the other separation on strips of filter paper with solvent C.

The aqueous solution of the aldotetraouronic acid was neutralized with sodium bicarbonate to pH 2.5 and concentrated to 250 ml. The solution was treated with Amberlite IR-120 (acid form) exchange resin, filtered, and evaporated to near dryness *in vacuo* at 25° C. Repeated evaporations from acetone gave a white, fluffy material (5–6 g by each method), $[\alpha]_D$ +23° (*c*, 3.0 in water). Anal. Calc. for $C_{22}H_{36}O_{19}$: OCH_3, 5.13%; equiv. wt. (acid), 604; equiv. wt. (reducing group), 604. Found: OCH_3, 5.18%; equiv. wt. (acid), 604; equiv. wt. (reducing group), 580 (11).

Partial hydrolysis at 100° C with 0.02 *N* hydrochloric acid for 2 hours gave an aldotriouronic acid and xylose, tentatively characterized from their rate of movement on the paper chromatogram with solvents A, B, and C. Hydrolysis at 100° C with *N* hydrochloric acid yielded an aldobiouronic acid and xylose.

Periodate Oxidation of the Aldotetraouronic Acid

Samples of aldotetraouronic acid (30–40 mg) were dissolved in 0.05 *M* aqueous sodium metaperiodate and the reaction was allowed to proceed in the dark at 30° C for various lengths of time. Remaining oxidant was determined by the excess arsenite method. The results, given as moles per mole tetraouronic acid, were as follows:

Time, hr	5	15	20	24	45	67
Periodate consumption	4.3	4.5	4.7	5.0	5.3	5.2

Samples of tetraouronic acid (30–40 mg) were dissolved in water (5–10 ml) and carefully neutralized with 0.01 *N* sodium hydroxide. Periodate solution (50 ml) was added and the oxidation was allowed to proceed in the dark. After the desired time, the reaction was interrupted by addition of excess ethylene glycol. After 30 minutes, formic acid was determined either by titration with 0.01 *N* sodium hydroxide or by the iodide–iodate method, the final titration being carried out with 0.01 *N* sodium thiosulphate in this case. The two procedures gave identical results throughout. The following moles of formic acid per mole of aldotetraouronic acid were produced:

Time, hr	24	48	72	96	240
Formic acid	1.8	1.9	2.0	2.1	2.5

Overoxidation with periodate was apparently very slow with the aldotetraouronic acid. In contrast, a sample of 2-*O*-(4-*O*-methyl-α-D-glucosyluronic acid)-D-xylopyranose, under the same conditions and within the first 15 hours, consumed 6.0 moles of periodate with concomitant formation of 4.3 moles of formic acid, the expected consumption of periodate being 2 moles with no formic acid produced.

The previously reported formation of 3 moles of formic acid on oxidation of the aldotetraouronic acid (1) was due to an experimental error.

Methylation of the Aldotetraouronic Acid

Aldotetraouronic acid (4.0 g) was dissolved in water (100 ml) containing sodium bicarbonate (5.0 g). Dimethyl sulphate (50 ml) and 40% (w/w) aqueous sodium hydroxide (50 ml) were added dropwise with stirring over a period of 4 hours at 10° C in a nitrogen atmosphere. Solid sodium hydroxide (30 g) was added, followed by dropwise addition of dimethyl sulphate (50 ml) over 1 day. The same amounts of reagents were then added once more. The reaction mixture was acidified to pH 2.0 with sulphuric acid and extracted three times with chloroform. The chloroform solution was dried over anhydrous sodium sulphate, filtered, evaporated to dryness, and dissolved in ethyl acetate. After filtration, the clear solution was evaporated to dryness and further dried *in vacuo* over calcium chloride to yield a crisp, white solid (4.4 g).

The partly methylated material was dissolved in dry dimethyl formamide (75 ml) (6), and silver oxide (30 g) and methyl iodide (30 ml) were added. After the mixture had been shaken in the dark at 30° C for 1 day, silver oxide (60 g), methyl iodide (75 ml), and some Drierite were added. The mixture was shaken for 3 days, after which the solid residue was washed with chloroform by filtration. The solution (1.5 liter) was concentrated to 250 ml and washed once with 10% aqueous potassium cyanide and then twice with water. The chloroform solution was dried with anhydrous sodium sulphate, filtered, and evaporated to dryness to give a sirup (3.1 g). Anal. Calc. for $C_{32}H_{56}O_{19}$: OCH_3, 45.8%. Found: OCH_3, 44.2%. The infrared diagram indicated the absence of hydroxyl groups.

Methanolysis of the Aldobiouronic Acid and Separation of Acidic and Neutral Sugars

A portion of the methylated aldotetraouronic acid (2.0 g) was boiled under reflux with 0.7 *N* methanolic hydrogen chloride in the presence of Drierite for 8 hours. After neutralization with silver carbonate and filtration through Celite, the sirup obtained (2.1 g) was heated at 60° C in 5% aqueous barium hydroxide (50 ml) for 2 hours. Barium hydroxide was removed by addition of solid carbon dioxide and filtration through Celite, and the solution was treated with Amberlite IR-120 exchange resin (acid form). After filtration and concentration to 100 ml, the solution was added to the top of a column (3.5×15 cm) containing Dowex 1-X4 anion exchange resin (acetate form). Neutral glycosides (765 mg) were removed by washing with water (2 liters), followed by elution with 30% aqueous acetic acid (2 liters) for recovery of acid glycosides (800 mg).

Characterization of Acid Fraction

The acid fraction was boiled under reflux with 0.7 *N* methanolic hydrogen chloride in the presence of Drierite, after which the methyl ester – methyl glycoside was dissolved in dry tetrahydrofuran (50 ml) and reduced in the usual way with lithium aluminum hydride (1.5 g). The partly methylated disaccharide obtained, which could not be induced to crystallize, was boiled under reflux with *N* sulphuric acid (100 ml) for 7 hours. After neutralization with barium carbonate, filtration through Celite, treatment with Amberlite IR-120 exchange resin (acid form), filtration, and evaporation, a sirup was obtained (780 mg). Paper chromatography (solvents D and E) suggested the presence of a di-*O*-methylxylose and a tri-*O*-methylglucose.

The sugar mixture was dissolved in water (25 ml) and added to the top of a column (3.5×55 cm) containing a 1:1 mixture of Darco G-60 charcoal and Celite. The sugars were separated by gradient elution with 3 liters each of 10% and 30% aqueous ethanol. Fractions, 25 ml each, were collected at an average rate of two per hour. Aliquots of 1 or 2 ml were withdrawn from every third test tube and examined by paper chromatography (solvent E). Di-*O*-methylxylose was collected from fractions 48–70, tri-*O*-methylglucose from fractions 140–210.

Identification of 3,4-Di-O-methyl-D-xylose

The colorless, clear sirup (275 mg) had $[\alpha]_D$ +21° (*c*, 2.0 in water). Anal. Calc. for $C_7H_{14}O_5$: OCH_3,

34.8%. Found: OCH_3, 34.0%. On paper electrophoresis and paper chromatography (solvent D), the compound had a rate of movement identical with that of an authentic sample of 3,4-di-*O*-methyl-D-xylose. A portion of the sirup (100 mg) was oxidized with bromine in the usual way (12). After removal of bromine and hydrobromic acid, the aqueous solution was treated with Amberlite IR-120 exchange resin (acid form) and evaporated to dryness. The remaining sirup was distilled at 150–200° C (bath temperature) and 0.05 mm Hg to give a clear sirup (50 mg) which crystallized spontaneously. After three recrystallizations from a 1:1 mixture of ethyl ether – petroleum ether (b.p. 30–60° C), the 3,4-di-*O*-methyl-D-xylono-δ-lactone had m.p. 66–67° C, $[\alpha]_D$ −22° (*c*, 1.0 in water). The 3,4-di-*O*-methyl-*N*-phenyl-D-xylosylamine, after one recrystallization from ethyl ether – petroleum ether, had m.p. 119–120° C (13).

Identification of 2,3,4-Tri-O-methyl-D-glucose

The colorless, clear sirup had $[\alpha]_D$ +71° (*c*, 3.5 in water). Anal. Calc. for $C_9H_{18}O_6$: OCH_3, 41.8%. Found: OCH_3, 40.0%. The 2,3,4-tri-*O*-methyl-*N*-phenyl-D-glucosylamine had m.p. and mixed m.p. 143–144° C (14).

Identification of the Neutral Fraction 2,3-Di-O-methyl-D-xylose

The neutral glycoside fraction was hydrolyzed in the usual way with *N* sulphuric acid to give a colorless, clear sirup (650 mg). Paper electrophoresis and paper chromatography (solvent D) indicated the presence of only 2,3-di-*O*-methylxylose. The sirup crystallized on standing, m.p. and mixed m.p. 93–94° C (15), $[\alpha]_D$ +22.4° (*c*, 1.0 in water). Anal. Calc. for $C_7H_{14}O_5$: OCH_3, 34.8%. Found: OCH_3, 34.5%. The dimorphic (16) 2,3-di-*O*-methyl-*N*-phenyl-D-xylopyranosylamine had m.p. 136.5–137.5° C, unchanged on further recrystallization from ethyl acetate, and $[\alpha]_D$ +148° (*c*, 1.7 in ethanol). Anal. Calc. for $C_{13}H_{19}O_4N$: OCH_3, 24.5%. Found: OCH_3, 24.5%.

Second Methylation of the Aldotetraouronic Acid

A sample of aldotetraouronic acid (3.0 g), obtained by preparative paper chromatography, was methylated as described above. The molar ratio between the 3,4-di-*O*-methylxylose, 2,3,4-tri-*O*-methylglucose, and 2,3-di-*O*-methylxylose obtained was 1:1:2.

Identification of Component Sugars

3,4-Di-O-methyl-D-xylose.—This sugar had $[\alpha]_D$ +20° (*c*, 1.0 in water). The corresponding δ-lactone had m.p. and mixed m.p. 65–66° C.

2,3,4-Tri-O-methyl-D-glucose.—This compound had $[\alpha]_D$ +70° (*c*, 1.0 in water). The aniline derivative had m.p. and mixed m.p. 143–144° C. Calc. for $C_{15}H_{23}O_5N$: OCH_3, 31.3%. Found: OCH_3, 30.0%.

2,3-Di-O-methyl-D-xylose.—The crystalline compound had m.p. and mixed m.p. 91–92° C and $[\alpha]_D$ +22° (*c*, 2.0 in water). Methoxyl content: 34.5%. The aniline derivative (16) had m.p. 142–143° C after three recrystallizations from ethyl acetate – petroleum ether and OCH_3, 24.3%.

ACKNOWLEDGMENTS

The author wishes to express his gratitude to Professor F. Smith, the University of Minnesota, for a specimen of an aldotriouronic acid. This investigation was supported in part by a United States Public Health Service Research Grant A-4258 from the National Institute of Arthritis and Metabolic Diseases, Public Health Service.

THERMOCHEMICAL STUDIES OF SOME ALCOHOL–ISOCYANATE REACTIONS

EDWARD G. LOVERING AND KEITH J. LAIDLER
The Department of Chemistry, University of Ottawa, Ottawa, Canada
Received September 13, 1961

ABSTRACT

The heats of reaction of normal-, iso-, and secondary-butyl alcohols reacting with phenyl isocyanate, the three tolyl isocyanates, and 2,4-tolylene diisocyanate were measured at 25° C, using a differential calorimeter of the Tian–Calvet type. The results are interpreted in terms of substituent effects.

From bond energy considerations the heats of formation of phenyl isocyanate and tolyl isocyanate have been estimated.

INTRODUCTION

Polyurethanes, formed by the reaction of a diisocyanate with a dihydroxy alcohol or polyol, are playing an increasingly important role in plastics technology. There is a lack of heat of reaction data for reactions of this type, and heats of formation for aryl isocyanates and urethanes do not appear to be available. In view of this situation it was decided to measure the heats of reaction of some simple alcohol–isocyanate reactions, since these are relevant to the more complicated reactions giving rise to polyurethanes. The reactions studied were those of normal-, iso-, and secondary-butyl alcohols with phenyl isocyanate, the three tolyl isocyanates, and 2,4-tolylene diisocyanate.

The only heats of formation available concerning isocyanates are those of Lemoult (1), who measured the heat of combustion of methyl and ethyl isocyanates. He reported the heat of combustion of liquid ethyl isocyanate to be 424.4 kcal mole^{-1}, but reported no analysis of the combustion products. Heats of formation do not appear to be available for any urethane of the type R—NH—COO—R′, although Kharasch (2) gives the heat of formation of urethane itself. The heat of formation of a few di-*N*-substituted urethanes are given by Schmidt (3). Recently Skinner and Snelson (4) have determined the heats of combustion of the four butyl alcohols at 25° C. The heats of formation of normal-, iso-, and secondary-butyl alcohols in the liquid state were given as -78.49 ± 0.20, -80.00 ± 0.20, and -81.88 ± 0.22 kcal mole^{-1} respectively.

EXPERIMENTAL

Purification and Preparation of Materials

The normal- and iso-butyl alcohols used were Fisher Certified Reagents. Secondary-butyl alcohol was a Fisher "Highest Purity" grade material. The alcohols were dried by refluxing over freshly ignited calcium oxide for 4 hours followed by fractionation through a 40-cm column packed with short lengths of 4-mm glass tubing. Only the middle fractions (collected at 117.7°, 108.4°, and 99.5° C for normal-, iso-, and secondary-butyl alcohols respectively) were retained. The alcohols were tested for dryness using the method suggested by Dyer, Taylor, Mason, and Samson (5). One or two drops of phenyl isocyanate were added to a sample of the alcohol; if no crystals of insoluble *sym*-diphenyl urea formed the alcohol was considered to be suitable for the experiments.

The phenyl and tolyl isocyanates used were manufactured by Eastman Organic Chemicals. They were purified by double vacuum distillation, the last distillation taking place immediately prior to use. Analysis of the distilled isocyanate using the Stagg technique (6) indicated that the isocyanates were between 99.5% and 100.5% pure. The boiling points and approximate boiling pressures for the isocyanates were phenyl: 46° C, 5 mm; *o*-tolyl: 57° C, 10 mm; *m*-tolyl: 62° C, 5 mm; *p*-tolyl: 66° C, 10 mm. The 2,4-tolylene diisocyanate was obtained from the Canadian Armaments Research and Development Establishment at Valcartier, Que. It was treated as were the other isocyanates; the boiling point was 165° C at approximately 50 mm.

Urethanes were prepared by causing isocyanate to react with a small excess of alcohol; in certain cases the reaction was catalyzed with ferric acetylacetonate. The urethanes were purified by recrystallization from petroleum ether. The urethanes of *m*-tolyl isocyanate are liquids at room temperature; they were purified by a double vacuum distillation, only the middle portion being retained in each case. In cases where the urethanes have been previously reported the melting point of the prepared material was compared with that given in the literature. In the cases of previously unreported urethanes a carbon and hydrogen analysis was carried out. For each urethane prepared, the melting or boiling point and, where appropriate, the literature melting point and the results of the elemental analysis are given in Table I.

TABLE I

Urethanes: melting points and analytical results

Urethane	M.p. (°C)	Literature m.p. (°C)	% carbon		% hydrogen	
			Exptl.	Theory	Exptl.	Theory

N,*N*′-2,4-Tolylene-di-*s*-butyl	90–91		63.57	63.40	7.95	8.14

Calorimetry

The heats of reaction were measured using a differential microcalorimeter of the Tian–Calvet (9) type. The instrument was fitted with electronic amplifier and integrator circuits as described by Attree, Cushing, Ladd, and Pieroni (10). It can be shown (9) that the area under the curve of amplified thermopile voltage vs. time is directly proportional to the amount of heat which produces the thermopile voltage. It was found experimentally that equal amounts of heat, liberated simultaneously in each cell of the calorimeter, gave rise to a net area of zero, indicating that the two opposing thermopiles are properly balanced.

The calorimeter was calibrated electrically; a curve of total area against heat was constructed by liberating various amounts of heat in the reaction cell of the calorimeter, and recording the resulting area. Because of a tendency for the electronic components of the system to drift, the calibration was checked after every measurement. This was done by duplicating, by electrical heating, the area due to the chemical reaction. The electrical calibration procedure was checked by measuring the heat of solution of anhydrous lithium sulphate crystals in water. The heat of solution for the process

$$Li_2SO_4\,(c.) + 220H_2O\,(l.) = Li_2SO_4.220\,(aq.)$$

was found to be -6.54 ± 0.10 kcal mole^{-1}. This is in good agreement with the value of -6.61 kcal mole^{-1} obtained from the N.B.S. tables (11).

In order to compensate for the heat evolved on mixing the alcohol and isocyanate reactants, an amount of urethane equivalent to the amount of isocyanate was dissolved in one cell of the calorimeter, while the reaction took place in the other cell. Since the calorimeter is a differential one, the net heat measured was that due to the heat of reaction.

The reaction cell assembly consists of a stainless steel capsule, with ends of aluminum foil, containing either the isocyanate or the urethane. It is suspended in a glass cylindrical cell which contains the alcohol. The reaction is initiated by piercing the ends of the cylinder with a length of wire held in place directly above the capsule. There is a calibrating resistor in the cell containing the isocyanate. The cells are stirred gently during the initial period of the reaction by a mechanical suction device; stirring was necessary to obtain reproducible results.

There is a tendency towards the formation of disubstituted ureas instead of urethanes during alcohol–isocyanate reactions. The tendency increases on going from normal to secondary to tertiary alcohols, and also as the temperature increases (5). Dyer *et al.* (5) report urea formation during the reaction between phenyl isocyanate and secondary-butyl alcohol at 25° C. None was observed under our reaction conditions. Because of the possibility of side reactions, however, the product of each reaction was examined

in the following way. The solution of the product in alcohol (the final state after reaction) was examined for the presence of crystals of the disubstituted urea (these ureas are insoluble in the butyl alcohols). The excess alcohol was removed under vacuum and an infrared spectrum of the solid product was taken. This was compared with the spectrum of the expected urethane, obtained from the previously prepared material. Only in the case of the reaction between *p*-tolyl isocyanate and secondary-butyl alcohol was there evidence of appreciable side reaction. Since only a few insoluble crystals were seen in the reaction vessel, the side reaction was estimated to involve less than 5% of the isocyanate. No correction to the observed heat was made; such a correction will be small since the reaction involving tertiary-butyl alcohol, which yields considerable urea, gives approximately the same heat of reaction as do the reactions which yield only urethane as product.

The calories used in this paper are defined calories, equal to 4.1840 joules.

EXPERIMENTAL RESULTS

The heats evolved per mole when normal-, iso-, and secondary-butyl alcohols react with phenyl isocyanates, the three tolyl isocyanates, and 2,4-tolylene diisocyanate, are given in Table II. In the table the weight of isocyanate used is given, as well as the heat measured experimentally. The measured heat is the heat evolved when the given weight of isocyanate is introduced into 10 ml of the given alcohol, less the heat evolved when a weight of urethane equivalent to the isocyanate is dissolved in 10 ml of the alcohol. The heat of reaction in kcal mole^{-1} calculated from the measured heat is also given in the table. The molecular weights of the isocyanates were taken to be for phenyl, 119.12; for tolyl, 133.14; and for 2,4-tolylene diisocyanate, 174.06.

In the case of certain reactions, a catalyst was used to shorten the reaction time and decrease the experimental error due to drift in the electronic components of the calorimeter over long periods of time. The heats of reaction measured in the presence of a catalyst are clearly marked in the table. In order to be certain that the added catalyst did not affect the heat of reaction, certain reactions were measured with and without a catalyst. As expected, the presence of catalyst does not affect the heat of reaction. The catalysts used were either ferric acetylacetonate or dimethylcetylamine.

Although the experimental deviation is usually less than $\frac{1}{2}$% for each reaction, we have attached a somewhat larger experimental error to our work because of our inability to detect side reactions, unless they are appreciable. The estimated error for each reaction is given in the table.

DISCUSSION

The heats of alcohol–isocyanate reactions do not appear to have been previously measured, and there are insufficient heat of formation data to permit their calculation. Consequently no comparison with previous measurements is possible. The heats of formation of the isocyanates can, however, be estimated using an empirical bond energy scheme. The scheme used is that devised by Laidler (12) together with certain modifications to it which are applicable to aromatic ring compounds.

Lemoult's value for the heat of combustion of ethyl isocyanate (424.4 kcal mole^{-1}) has been used without correction to calculate the heat of atomization of ethyl isocyanate as 976.3 kcal mole^{-1}. The bonds contributing to this value are

$$c_1+3p+2s+n = 976.3,$$

where, following Laidler, the carbon–carbon bond energy is c_1, primary carbon – hydrogen bonds are represented by p, and secondary carbon – hydrogen bonds by s. The contribution to the heat of atomization by the isocyanate group is denoted by n. Laidler gives values of 85.40, 98.96, and 98.23 kcal for the contributions to the heat of atomization of a compound in the liquid state for c_1, p, and s respectively. From these values

and the heat of atomization of ethyl isocyanate, the value of n, the bond energy of the isocyanate group, is calculated to be 397.6 kcal. Preliminary work on a bond energy scheme for aromatic compounds indicates that carbon–carbon bonds in an aromatic ring should have a special value, denoted by c_b, as should carbon–hydrogen bonds, denoted by t_b, when the carbon atom is part of the ring. Values of 124.29 and 97.55 kcal for c_b and t_b respectively have been used. The heat of atomization of phenyl isocyanate is given by $6c_b+5t_b+n$, yielding a value of 1631.01 kcal mole^{-1} for the heat of atomization of liquid phenyl isocyanate; from this, ΔH_f^0 (l., 25° C) = 3.5 kcal mole^{-1} is obtained. Similarly, for the tolyl isocyanates, ΔH_f^0 (l., 25°) is found to be -5.3 kcal mole^{-1}. There are insufficient data available to attempt to make allowance in ΔH_f^0 for the ring positions of the three tolyl isocyanate isomers. It is expected that two isocyanate groups on an aromatic ring would lead to considerable interaction; this would affect the heat of formation which, therefore, has not been calculated for 2,4-tolylene diisocyanate.

The heats of formation of the urethanes are readily approximated using the heats of formation of the alcohols, the estimated heats of formation of the isocyanates, and the appropriate heat of reaction.

The results of the heat of reaction measurements can be interpreted in terms of substituent effects. As far as the effect of changing the alcohol from normal- to iso- to secondary-butyl is concerned, a decrease in stability of the resulting urethane (the heat of reaction being a measure of the stability of the resulting urethane) would be expected on the grounds of steric hindrance. The inductive effect will act in the same direction, tending to put a partial negative charge on to the urethane group. This will decrease the resonance stabilization of the urethane group with the aromatic ring to which it is attached. It is observed in the case of every isocyanate that the heat of reaction decreases in the order normal > iso > secondary. Turning to the effects of a methyl group substituted into the aromatic ring of the urethane, it is expected that partial negative charges would appear ortho and para to the methyl group, due to the resonance effect. There will be, in addition, a small charge on the ring due to the inductive effect, which decreases in the order ortho > meta > para. Steric effects will also be of importance in cases of ortho substitution. From these considerations phenyl isocyanate should show the largest heat of reaction, *m*-tolyl isocyanate would be expected to yield a smaller value, followed by *p*-tolyl isocyanate. Because of the steric effect, the heat of formation of ortho urethanes should be considerably less than for the others. These predictions are substantiated by the experimental results; because of the difference in state the predicted behavior of *m*-tolyl isocyanate reactions cannot be verified.

KINETIC STUDIES OF SOME ALCOHOL–ISOCYANATE REACTIONS

EDWARD G. LOVERING AND KEITH J. LAIDLER
The Department of Chemistry, University of Ottawa, Ottawa, Canada
Received September 13, 1961

ABSTRACT

The kinetics of 12 alcohol–isocyanate reactions have been studied at a series of temperatures. The reactions were studied by a calorimetric technique, as well as the usual analytical method. The results are shown to be in agreement with a mechanism previously proposed by Baker. Certain objections to Baker's mechanism are discussed.

INTRODUCTION

The preceding paper described the measurement of the heats of reaction of normal-, iso-, and secondary-butyl alcohols with phenyl isocyanate, the three tolyl isocyanates, and 2,4-tolylene diisocyanate. During the course of these measurements it became apparent that kinetic rate constants could be deduced from the data obtained calorimetrically. In order to verify the rate constants so obtained the reactions were studied by the usual analytical technique of following the disappearance of one of the reactants with time. In addition, two mechanisms for the alcohol–isocyanate reactions have been suggested, and it was felt that the additional data would help to decide between them.

Kinetic rate constants were deduced from the calorimetric data using a method suggested by Baumgartner and Duhaut (1). In essence the method consists of obtaining the ratio of product concentration to initial reactant concentration at a given time, from the ratio of the heat evolved at that time, to the heat evolved at infinite time. The pseudo first-order rate constant can be readily calculated from this ratio.

The first kinetic study of an alcohol–isocyanate reaction appears to be that of Davies and Farnum (2), who measured relative rates by causing two alcohols to compete for a limited amount of isocyanate. Baker and Holdsworth (3), Baker and Gaunt (4), and Baker, Davies, and Gaunt (5) have carried out an extensive series of investigations of alcohol–isocyanate reactions. On the basis of their findings, they propose the following mechanism:

$$\phi\text{—N=C=O} + \text{ROH} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \phi\text{—N=C(—O}^-\text{)—ROH}^+ \qquad [1a]$$

$$\phi\text{—N=C(—O}^-\text{)—ROH}^+ + \text{ROH} \xrightarrow{k_3} \phi\text{—NH—C(=O)—OR} + \text{ROH}. \qquad [1b]$$

The alcohol is believed to function as a catalyst through its basic oxygen atom, as well as a reactant. Application of the steady-state treatment to this mechanism yields the following relationship:

$$\frac{[\text{ROH}]}{k_0} = \frac{k_2}{k_1 k_3} + \frac{[\text{ROH}]}{k_1}, \qquad [2]$$

where k_0 is the experimental second-order rate constant. Consideration was given to the possibility that a complex not containing isocyanate reacts with isocyanate; this,

however, was rejected, because such a mechanism would not fit equation [2], and because of evidence obtained in studies of the reaction in the presence of basic catalyst. This evidence clearly indicates that the isocyanate forms part of the initial complex. Baker and co-workers also report that the reaction is autocatalyzed by the urethane produced. The proposed mechanism has been tested by plotting $[ROH]/k_0$ vs. [ROH]. Such a plot should yield a straight line of slope $1/k_1$ and intercept k_2/k_1k_3. Baker and co-workers have studied reactions between phenyl isocyanate and methyl, ethyl, and isopropyl alcohols at 20° C and 30° C. In each case straight lines were obtained, except at very low alcohol concentrations.

The second-order rate constant was found to be dependent upon the ratio of alcohol to isocyanate. This effect is thought to be due to stabilization of the activated complex by polar alcohol molecules. The reported increase of rate in benzene solution, as compared with dibutyl ether solution, is thought to be due to the presence of monomeric alcohol molecules. The reactions were also studied in the presence of basic catalysts.

Dyer, Taylor, Mason, and Samson (6) have measured the reaction rates, at a series of temperatures, of phenyl isocyanate with *n*-butyl and *s*-butyl alcohols. They have interpreted their results in terms of Baker's mechanism.

The reaction between phenyl isocyanate and methyl alcohol has been studied at 20° C in a series of solvents by Ephraim, Woodward, and Mesrobian (7). They claim that the logarithm of the rate constant decreases as the dielectric constant of the solvent increases; a plot of their experimental data, however, shows that there is no significant correlation of this kind. These authors also find that deviations from second-order kinetics increase as the hydrogen bonding capability of the solvent increases. They propose the mechanism:

$$2ROH \overset{K_{1a}}{\rightleftharpoons} \text{complex 1}$$

$$ROH + \text{solvent} \overset{K_{1b}}{\rightleftharpoons} \text{complex 2}$$

$$ROH + \text{urethane} \overset{K_{1c}}{\rightleftharpoons} \text{complex 3}$$

$$\text{Complex 1} + RNCO \xrightarrow{k_{2a}} \text{urethane} + ROH$$

$$\text{Complex 2} + RNCO \xrightarrow{k_{2b}} \text{urethane} + \text{solvent}$$

$$\text{Complex 3} + RNCO \xrightarrow{k_{2c}} 2\text{urethane}.$$

No mention is made of Baker's argument that this type of mechanism is improbable.

Studies of amine-catalyzed alcohol–isocyanate reactions have been reported by Kogon (8), Burkus and Eckert (9), and Sato (10).

EXPERIMENTAL

The method used to purify the chemicals used in the experiments was completely described in the preceding paper.

Isocyanates were analyzed using a modification of Stagg's technique (11). The method consists of allowing the unknown isocyanate to react with an excess of a standard solution of dibutylamine in toluene, followed by back titration of the excess amine with standard hydrochloric acid to a bromphenol blue end point. Isopropyl alcohol is added to prevent the formation of a second phase during the titration.

The reaction was carried out in a round-bottomed flask with a ground-glass stopper. A weighed amount of alcohol was placed in the flask, which was put into the thermostat. When equilibrium was reached isocyanate was added by means of a hypodermic syringe. The weight of isocyanate was found by weighing the isocyanate container before and after addition of isocyanate to the reaction vessel. Five-milliliter samples of the reacting mixture were withdrawn by pipette at regular intervals; the reaction was stopped

by draining the pipette into a standard solution of dibutylamine. The time at which the pipette was half empty was recorded; the excess amine was back titrated with standard hydrochloric acid. The rate constant, k, was obtained from the integrated expression for a pseudo first-order reaction:

$$k = (1/tb) \ln (a/a-x),$$

where t is the time, b the concentration of alcohol, a the initial concentration of isocyanate, and x the concentration of product at time t. The experimental data were also treated by the differential method by plotting log rate vs. log concentration. The slope of the curve gives the order, and the intercept the rate constant.

The results of a typical calorimetric run are shown in Fig. 1. Figure 1(a) is a curve of electromotive

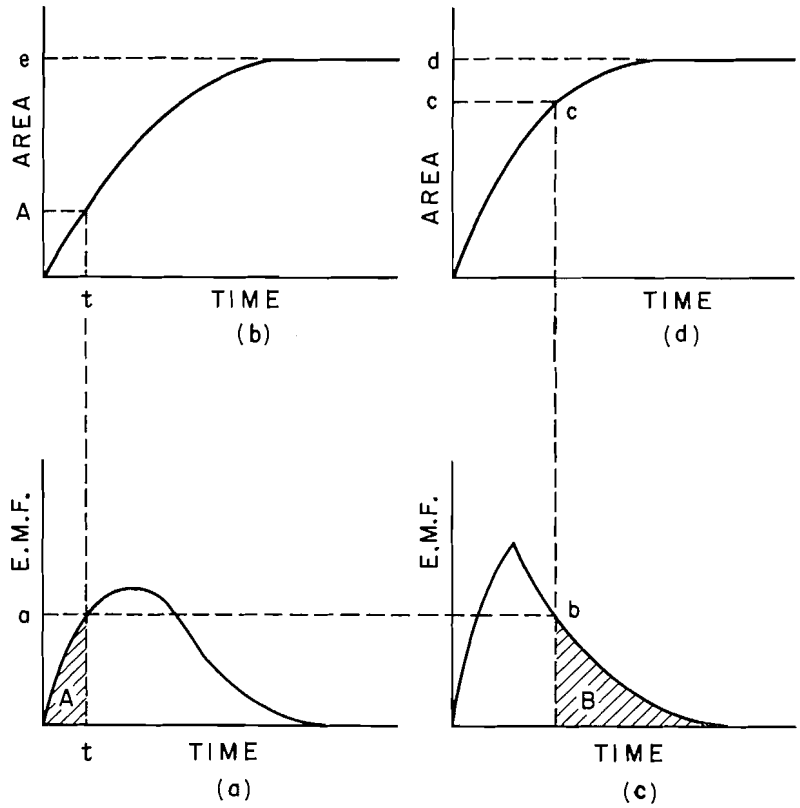

FIG. 1. Typical time–voltage curves: (a) chemical reaction, (b) integral of the chemical reaction, (c) electrical heating, (d) integral of the electrical heating.

force vs. time for a chemical reaction, and Fig. 1(b) shows the integral of this curve with time. The E.M.F.-vs.-time results for electrical heating are shown in Fig. 1(c); the integral of this curve appears in 1(d). It is desired to obtain values for the ratio a/x at a series of times. The heat evolved from the reaction cell from $t = 0$ to $t = t$ is the shaded area A in Fig. 1(a). The value of this area A is read directly from the plot of area vs. time in Fig. 1(b). The heat remaining in the reaction cell at time t is evolved in the same way that heat is evolved from the system after an electrical heating. Hence the area B under the electrical cooling curve from E.M.F. = b to E.M.F. = 0 is a measure of the unevolved heat in the reaction cell at time t. The sum of A+B gives the total heat produced by the reaction up to time t. Area B is obtained from Fig. 1(d) by subtracting c from d. The ratio of the heat produced at infinity to the heat produced at time t is a measure of a/x. This ratio is evaluated at a series of times, and the rate constant is calculated using the integrated pseudo first-order expression. The results for each run are averaged.

EXPERIMENTAL RESULTS

The rates of the reactions between normal-, iso-, and secondary-butyl alcohol and phenyl isocyanate and the three tolyl isocyanates have been measured at a series of

temperatures. The data were treated by the integral and differential method to obtain the second-order rate constant. The rate constant at a series of temperatures and the activation energy for each reaction is given in Table I. The rate constants at 25° C, deduced from the calorimetric measurements described in the preceding paper, are given in Table II, where they are compared to the rate constants determined analytically. The percentage difference between the two is also given.

DISCUSSION

It is seen from Table II that all the rate constants deduced calorimetrically are within 10% of those determined by chemical analysis. These results are satisfactory, as there are important sources of error present for which allowance could not be made. These are the increase in temperature as the reaction proceeds and the time lag between an event occurring in the reaction cell and its appearance as a signal on the recorder. Attempts to apply an empirical correction to the rate constant obtained in this way were unsuccessful. However, if steps were taken to ensure identical conditions of contact between the reaction cell and the calorimeter from one run to the next, we believe that an empirical time lag correction could be applied, with a considerable improvement in the accuracy of the rate constants so obtained.

The experimental results are in accord with the previously determined data for alcohol–isocyanate reactions and fit the mechanism suggested by Baker and his co-workers (3, 4, 5). Most of the reactions exhibit small deviations from pseudo first-order kinetics toward the end of the reaction. These deviations are probably due to autocatalysis.

The only previous work which is directly comparable to the results obtained here is that due to Dyer *et al.* (6), who measured rates and activation energies for reactions of phenyl isocyanate with normal- and secondary-butyl alcohols. They report activation energies of 8.1 and 9.9 kcal mole^{-1} for normal- and secondary-butyl alcohol reactions respectively; the values reported here are 11.5 and 12.5 kcal mole^{-1} respectively. This change in activation energy confirms the observations of Baker and his co-workers that the activation energy increases as the ratio of alcohol to isocyanate increases. The reactions reported here were carried out in a large excess of alcohol, while the work of Dyer *et al.* was in xylene solution.

For the reactions reported here it was found that the activation entropies are all in the region of −38 e.u. A large negative entropy of activation is an indication of an activated complex in which oppositely charged centers are separated from each other. The activated complex of Baker's mechanism is just such a species; it is doubtful if the formation of an alcohol–alcohol, an alcohol–solvent, or a urethane–alcohol complex, as suggested by Ephraim *et al.* (7), could account for this large negative entropy of activation.

It is of interest to note, at least for the reaction between *n*-butyl alcohol and phenyl isocyanate, that the free energy of reaction appears to be approximately independent of the reaction conditions, whereas the energy and entropy of activation are not. From the activation energy of 7.5 kcal mole^{-1} in xylene solution reported by Dyer, an activation entropy and free energy of −48 e.u. and 22.0 kcal mole^{-1} are calculated. For the same reaction in toluene catalyzed by triethylamine, Burkus and Eckert (9) report an activation entropy of −61 e.u. and a free energy of activation of 21.2 kcal mole^{-1}; the values reported here are −37 e.u. and 21.9 kcal mole^{-1}. The increase in activation energy as the alcohol concentration increases is probably an indication that more and more hydrogen bonds must be ruptured before the activated complex is formed. The increase in the entropy of activation probably indicates a decreasing amount of solvent

TABLE I

Isocyanate reactions: rate constants and activation energies

Alcohol	Rate constant (l. mole^{-1} sec^{-1}) 35° C	25° C	15° C	7° C	5° C	0° C	Activation energy (kcal mole^{-1})	Entropy of activation (cal mole^{-1} deg^{-1})

i-Butyl	*m*-Tolyl	1.57×10^{-4}	1.73×10^{-4}	10.0
s-Butyl	*m*-Tolyl	8.02×10^{-5}	7.94×10^{-5}	−0.7
i-Butyl	*p*-Tolyl	1.84×10^{-4}	1.65×10^{-4}	−10.4
s-Butyl	*p*-Tolyl	8.40×10^{-5}	7.64×10^{-5}	−9.0

rearrangement as the activated complex is formed. That is, the reactants are probably already well solvated with alcohol, and the formation requires mainly rearrangement of the solvent, and not addition of new solvent molecules. The lower entropy of activation for the amine-catalyzed reaction is probably an indication that the activated complex contains the amine molecule.

It would thus appear that all the experimental facts currently available support the mechanism proposed by Baker and his co-workers.

This work was supported by a grant from the Defence Research Board.

THE SYSTEM SILVER–INDIUM–GALLIUM

A. N. CAMPBELL AND W. F. REYNOLDS[1]
The Chemistry Department, University of Manitoba, Winnipeg, Manitoba
Received April 17, 1961

ABSTRACT

The system silver–indium–gallium has been investigated by the standard techniques of thermal analysis, photomicrography, X-ray photography, and hardness testing. The smallness of the heat effects made the determination of the liquid surface indefinite, at least in the low-temperature region where the pronounced tendency for metastable liquid phase to persist rendered all measurements indefinite, but the room-temperature isotherm was determined with more certainty. Owing to the complexity of the diagram there is still some uncertainty about some areas.

A one-phase area (α phase) exists in the silver-rich region of the ternary isotherm, representing the solid solubility of indium and gallium in silver. The silver-rich intermediate phase in the system silver–indium, δ, is shown to have a close-packed hexagonal structure and its lattice constants have been determined. The structure of γ, the corresponding phase in the system silver–gallium is more complex and was not determined. δ and γ phases do not form a continuous one-phase region.

Ternary peritectics exist at 623° C and 600° C (approximately). It is possible that two peritectics exist at the latter temperature, in close proximity.

The ternary eutectic lies at 14.5° C and has an approximate composition of 2% silver, 24% indium, and 74% gallium.

The system silver–indium–gallium has not been investigated previously; it is of interest because certain of the alloys can be used in transistors. In the present investigation, the liquidus surface and the location of the ternary peritectics and eutectics were investigated, as well as the room-temperature isotherm. Thermal analysis, X-ray and photomicrographic methods, as well as hardness testing, were used. A complete investigation of the system would involve the determination of the regions of stable existence of all phases at all temperatures and this would require quenching techniques. As two of the component binary systems are quite complicated the amount of work involved would be considerable. We did not undertake this, because the room-temperature condition is the most important.

The literature deals only with the component binary systems, as follows.

1. Gallium–indium: The first investigation was by de Boisbaudron (1), the discoverer of gallium. Other workers are French, Sidney, Saunders, and Ingle (2); Denny, Hamilton, and Lewis (3). The latest investigation is that of Svirbely and Selis (4), who investigated the system in its entirety from a study of the electrical resistivity of alloys over a range of temperature. All investigators agree that the system is of the eutectic type.

2. Silver–gallium: This system was studied in detail by Weibke, Meisel, and Weigels (5). Their results are shown in Fig. 1.

Investigations by Hume-Rothery and Andrews (6) indicated that β phase decomposes peritectically at 611° C and that β phase has a hexagonal close-packed structure. It transforms eutectoidally into α and γ phases at 378° C.

3. Silver–indium: Weibke and Eggers (7) carried out a systematic investigation of this system, using all the conventional techniques. Their results are shown in Fig. 2.

Frevel and Ott (8) report the following phases: a cubic phase rich in silver, a hexagonal phase, a pseudohexagonal phase, a face-centered cubic phase, and a tetragonal phase (in order of decreasing silver content). Presumably these correspond to α, δ, ϵ, and γ phases and solid solution of silver in indium.

[1]*Holder of N.R.C. Bursary, 1959–60.*

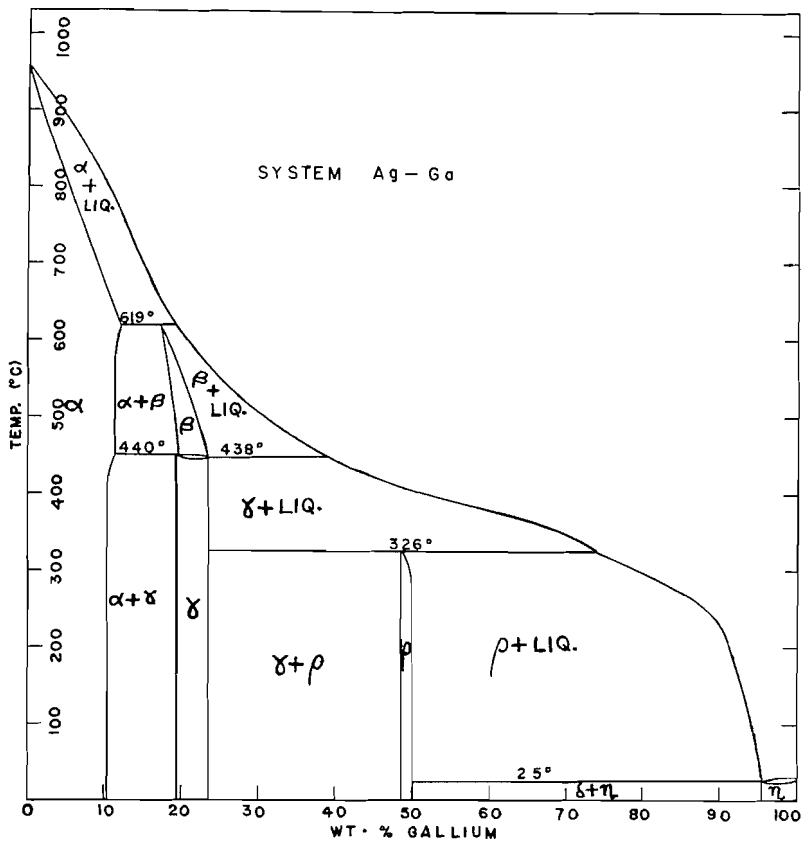

FIG. 1. Silver–gallium.

Hallner and Laues (9) report the following indium–silver phases (by X-ray methods): Ag_2In, cubic; $AgIn_2$, tetragonal; Ag_3In (hexagonal). Goldschmidt (10) reports that Ag_3In (δ) has a hexagonal close-packed structure, with cell dimensions $c = 4.76$ Å, $a = 2.95$ Å, $c/a = 1.626$. Hume-Rothery (11) and associates agree with Weibke and Eggers (7) about the solid solution of indium in silver.

EXPERIMENTAL

The individual metals were of the highest purity, as follows: (1) silver (Johnson, Matthey, Ltd.) 99.995%; (2) indium (Consolidated Mining and Smelting Company of Canada) 99.995%; (3) gallium (United Mineral and Chemical Corporation) 99.99%.

The alloys were prepared by fusion in an induction furnace at a temperature of approximately 1100° C. To prevent oxidation, the metals were sealed in evacuated pyrex tubes. This method was originated by Campbell, Wood, and Skinner (12), when studying the iron–tin system. The glass retains a complete vacuum, despite the fact that it softens at 600° C, if it is supported in the crucible so that it cannot run. The sealed tubes were heated in alundum crucibles packed with powdered alundum to provide the necessary support for the glass. In this way, the alloys could be melted and resolidified with formation of only a thin scum of oxide on the surface.

The alloys were allowed to cool in the furnace from 800° C to 100° C, over a period of about 30 hours. They were then further annealed in an oven at 100° C for 1 week, then left for a week at room temperature, before thermal analysis and preparation of polished sections were carried out.

Liquid was always present (to some extent, at least, metastably) in the lower-melting alloys, even after the above annealing treatment. Attempts were made to bring these alloys into true equilibrium by further

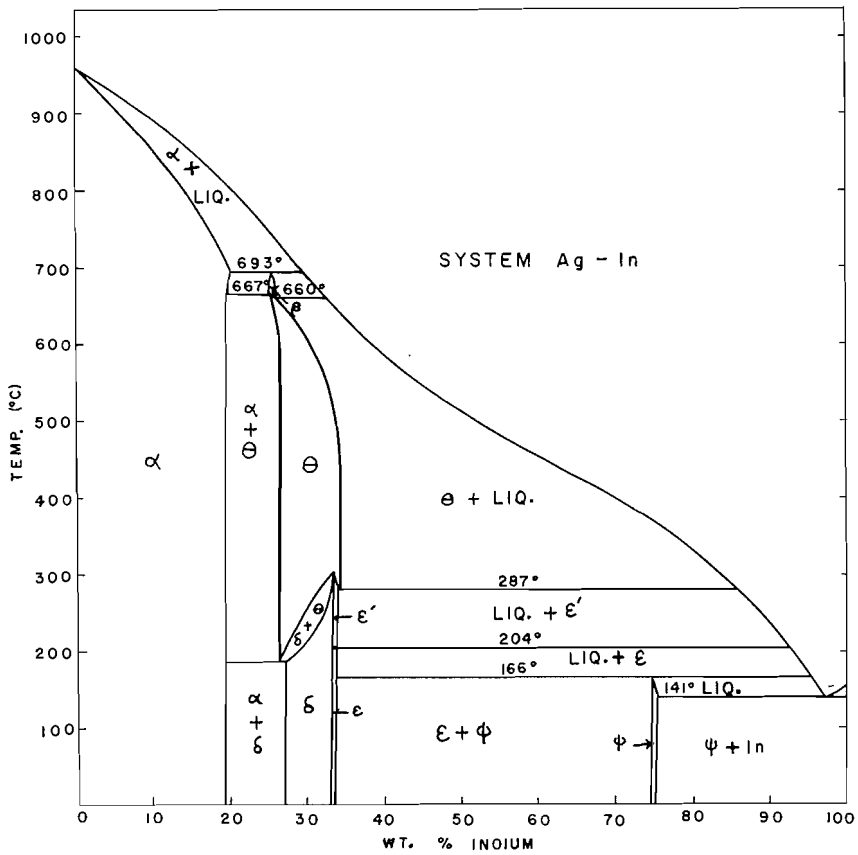

FIG. 2. Silver–indium.

annealing them at temperatures ranging between 50° C and 300° C, for periods of 3 weeks, but no decrease in the amount of liquid was ever noted.

The techniques used were those of thermal analysis, photomicrography, X-ray photography, and Rockwell hardness testing.

Those alloys which were completely solid at temperatures above 600° C were submitted to thermal analysis by the ordinary method of cooling, but the fact that gallium and gallium-rich alloys have a pronounced tendency to supercool makes this form of thermal analysis useless below 600° C. We therefore resorted to a controlled heating process, i.e., the temperature of the furnace was caused to rise as a straight-line function of the time. The furnace, consisting of a pyrex tube wrapped with asbestos paper and nichrome wire, was placed in a copper container packed with asbestos powder. This container was immersed in an ice–salt mixture to provide the necessary cold environment. The temperature was controlled by a "Variac", which was continuously adjusted by a geared-down electric motor. This gave a constant rate of voltage increase and a nearly constant rate of temperature increase (about 1° per minute).

The extreme hardness of gallium, despite its low melting point, renders polishing and etching of the metal difficult. The procedure adopted was as follows: The mounted specimen was polished on a series of successively finer sheets of emery paper, grades 2, 1, 0, and 00. Further polishing was done on a special polishing paper with a surface of alternate rows of fine abrasive and hollow spaces. The washed and dried specimen was then polished on a felt-covered wheel, using a paste of magnesium oxide as abrasive. When no scratches were visible to the naked eye, the polishing cloth was replaced by a velveteen cloth. Using levigated alumina as a fine polishing agent, the metal was polished until it had a mirror-like finish. The washed and dried specimen was examined under the microscope for scratches. If no scratches were visible, the alloy was etched with the following etchant: 98% H_2SO_4, 5 ml; $K_2Cr_2O_7$ (saturated solution), 100 ml; NaCl (saturated solution), 2 ml. This solution was diluted in the proportion of 1 part of etchant to 9 parts of water.

For the X-ray work a 57.3 mm Debye X-ray powder photography camera was used. Powder specimens were obtained in the following manner. The ingot was first cut and then a cleaned file was rubbed against one of the freshly cut surfaces. The second cut surface was then filed. Surface filings were discarded and only subsurface filings were kept as samples. An X-ray tube with copper anticathode and nickel filter was used. Measurements of "*d*" values gave a consistency of about 1% or better. Intensities were estimated visually.

Specimens for hardness testing were about 5 mm thick and had two parallel flat surfaces. A Rockwell hardness tester was used.

EXPERIMENTAL RESULTS

Table I reproduces all the experimental data, as obtained. A selection of the photomicrographs is given (Figs. 3–5). Figure 6 represents the room-temperature equilibrium diagram of the silver-rich region. The X-ray photographs are not reproduced, since most of them were used primarily for identification. In Table II, however, the interplanar distances and line intensities of alloys 5, 11, 14, and 15 are given, since these refer to pure, or almost pure phases, of, however, different compositions.

δ phase is shown to have close-packed hexagonal structure. For alloy 15, the lattice dimensions are $c = 4.725$ Å, $a = 2.942$ Å, and $c/a = 1.606$. This agrees with the theoretical $c/a = 1.633$ for hexagonal close-packed and with the results of Goldschmidt (10) for Ag_3In. Table III gives a summary of the results of photomicrography and (or) X-ray photography, together with hardness, of those alloys which were used for the definition of phase boundaries.

Hardness was used to delineate the regions of existence of δ and γ phases. Both phases showed nearly constant hardness throughout their regions of existence; there was no gradual transition in hardness from one phase to the other. The γ phase is quite hard, B-78 as compared with B-86 for mild steel. The hardness of the two phases is the more remarkable when one considers the relative softness of α phase.

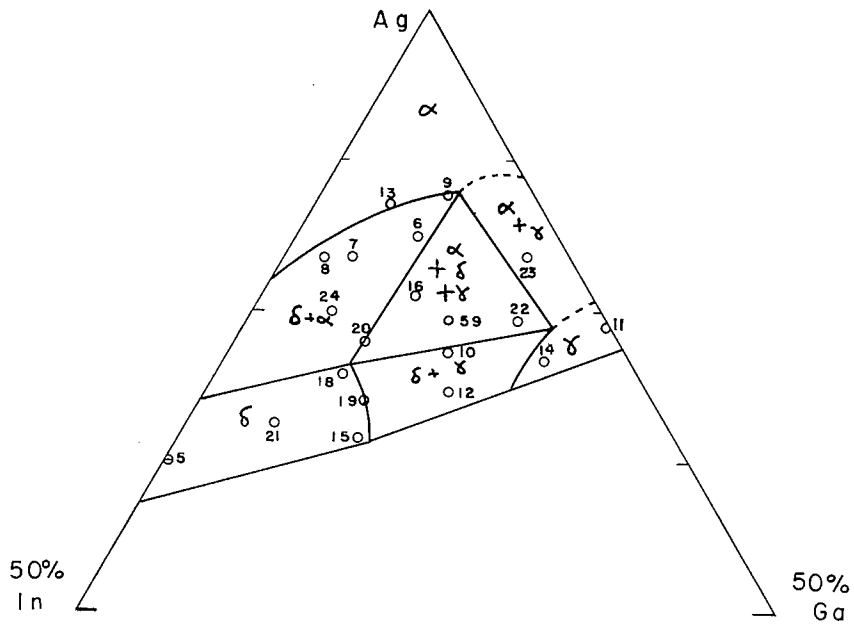

FIG. 6. Room temperature equilibrium diagram of the Ag-rich region.

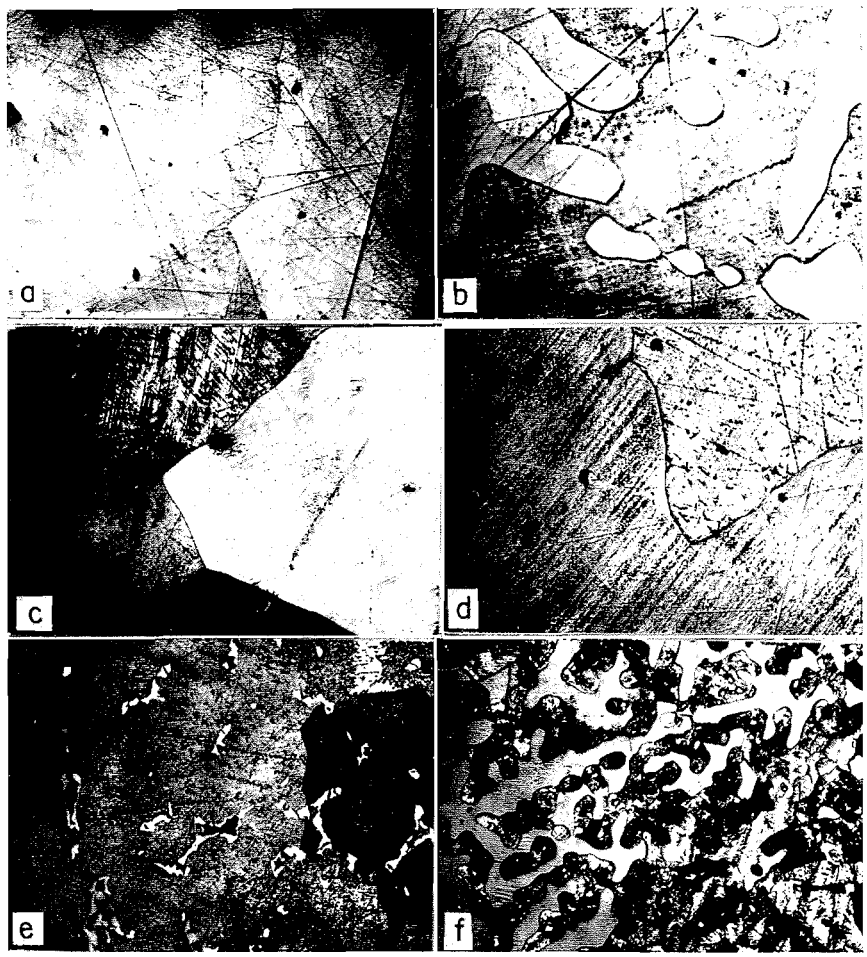

FIG. 3. (*a*) Alloy 1. This alloy is pure α phase. Note the existence of large grains of slightly different coloring due to oriented grain lustre.
(*b*) Alloy 3. This alloy contains α (dark) and δ (light) in approximately the same quantities.
(*c*) Alloy 4. This alloy is Ga-rich α phase. Again the grains show a variety of coloring.
(*d*) Alloy 5. This alloy is pure δ phase, in the Ag–In binary.
(*e*) Alloy 17. This alloy is ϵ phase with slight amounts of ψ phase. The ψ phase has a pitted appearance because it is much softer than ϵ phase and is worn away by polishing.
(*f*) Alloy 25. This alloy contains δ (light) and ϵ (mottled) phase.
NOTE: The magnification of Figs. 3, 4, and 5 is 120×.

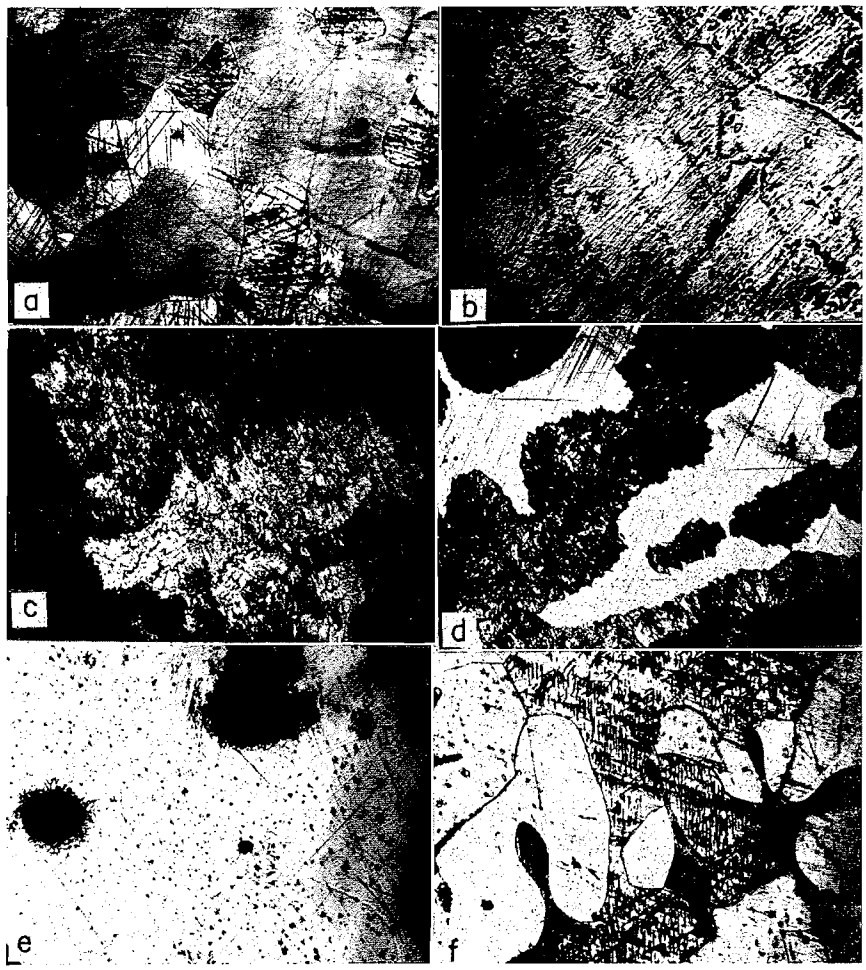

FIG. 4. (*a*) Alloy 6. This alloy contains α (dark) phase with a considerable amount of δ (light) phase.
(*b*) Alloy 21. This alloy contains only δ phase.
(*c*) Alloy 14. This alloy is pure γ phase. Its dark and mottled appearance indicates that is definitely not the same as δ phase.
(*d*) Alloy 12. This alloy contains approximately equal amounts of and δ and γ phases. This alloy definitely appears heterogeneous, indicating δ and γ are not the same phase.
(*e*) Alloy 19. This alloy contains δ phase with medium-sized inclusions of γ phase.
(*f*) Alloy 18. This alloy contains δ and α phases and possibly slight inclusions of γ phase (dark specks).

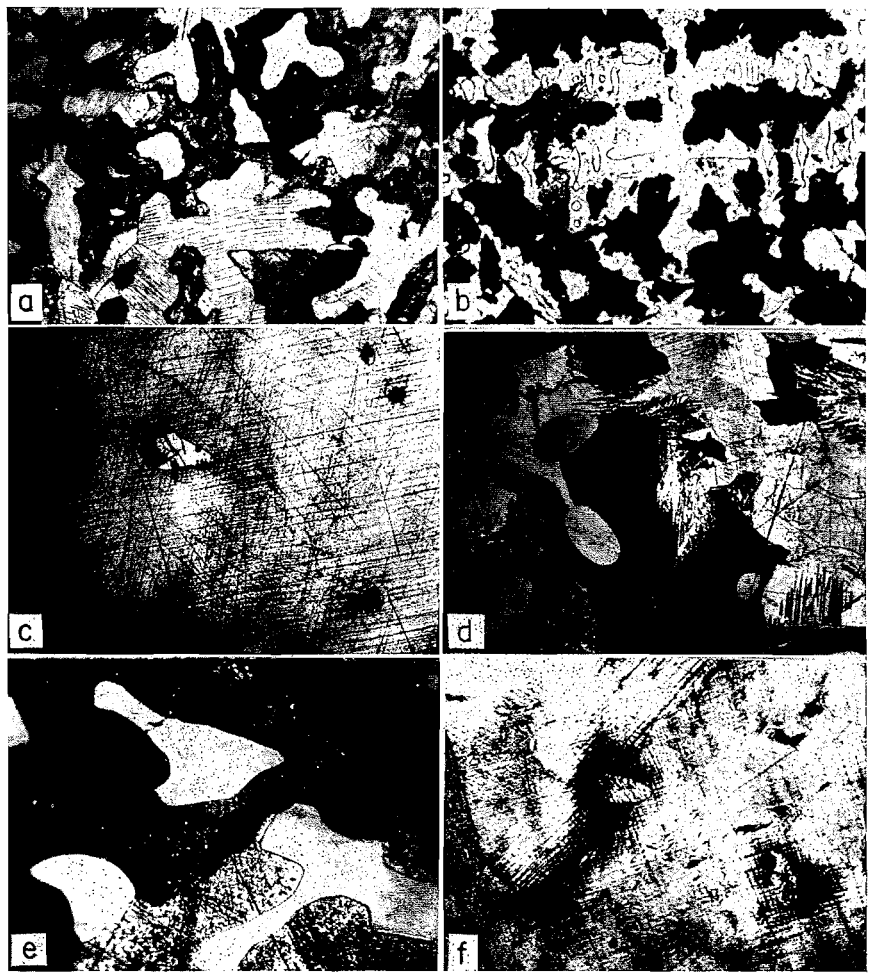

FIG. 5. (*a*) Alloy 22. This alloy contains γ and α phases with possible inclusions of δ phase. The similarity in appearance between α and δ phase makes it difficult to be certain.
(*b*) Alloy 59. This alloy definitely contains 3 phases: γ (mottled, dark), δ (light), and α (medium). This definitely establishes the existence of a ternary three-phase triangle.
(*c*) Alloy 8. This alloy contains α phase with slight inclusions of δ phase.
(*d*) Alloy 23. This alloy contains approximately equal amounts of α and γ phases.
(*e*) Alloy 28. This alloy apparently contains ϵ (mottled) and δ phases.
(*f*) Alloy 8. This shows a polished section from alloy 8 after lengthy annealing as described in the text. Notice the similarity to (*c*).

There are apparently three peritectic troughs and two ternary peritectics at 623±2° C and 600±4° C. The exact temperature of the second peritectic was indefinite, since decomposition appears to occur over a temperature range. Perhaps, there are two ternary peritectics in close proximity. Alloys on the indium-rich side of the composition triangle tend towards a peritectic or series of peritectics in the temperature region 100 to 118° C. Usually, during thermal analysis a long semihalt was observed over this temperature range, with an irregular series of breaks, alternating with halts. Alloys 52 and 53 gave halts at 118°, 110°, and 104° C. Alloys in the center and on the gallium-rich side gave the same results as for peritectics. This indicates the existence of a "hump" in the liquidus surface on the indium-rich side of the diagram. When heated, alloys in this region usually showed a halt corresponding to eutectic melting at 14.5° C, a change of slope in the region 22° to 30° C, and a halt at 30° to 32° C. The lack of success in thermal analysis is no doubt due to the smallness of the heat effects associated with the various ternary reactions.

The temperature data of Table I are plotted on Fig. 8 for the liquidus points as a function of silver concentration. Essentially this represents a projection of the liquidus surface upon the isopleth for equal gallium and indium concentration.

The cross-hatched line represents the outline of the liquidus in the system Ga–Ag, while the plain line gives the outline for the system Ag–In. Figure 9 shows isothermal lines on the liquidus surface. These two diagrams outline the shape of the liquid surface down to about 400° C (without giving the peritectic troughs in the surface).

Liquidus points below 400° C were not obtained with any degree of certainty and the

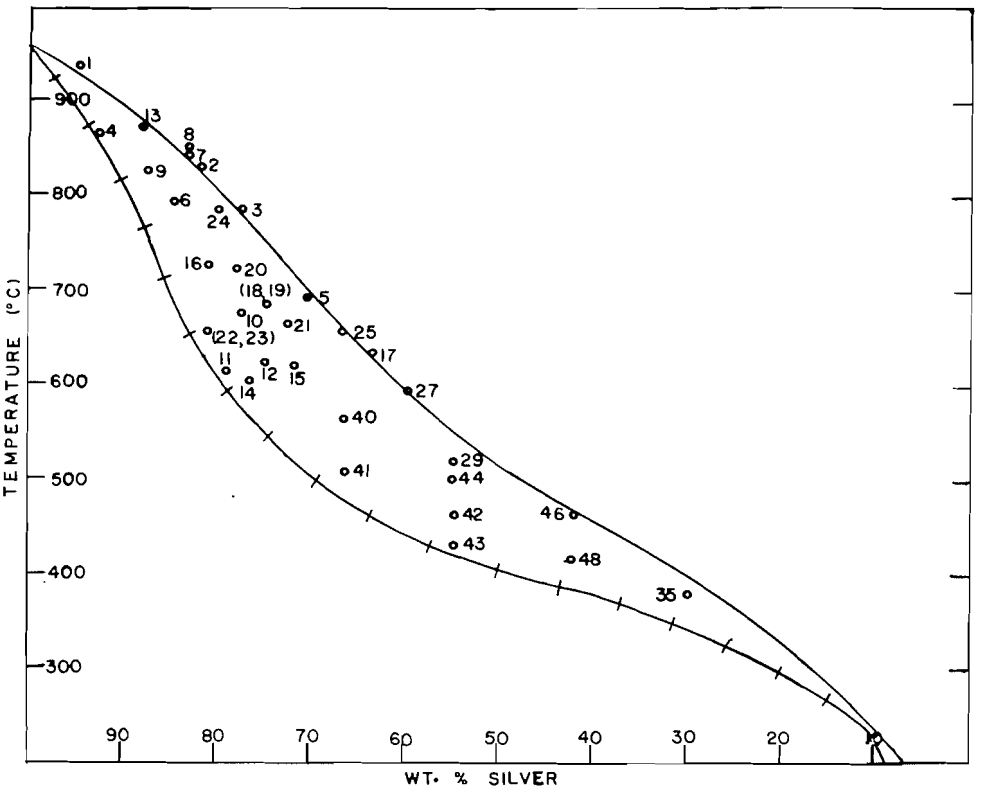

FIG. 8. Liquidus points as a function of silver concentration.

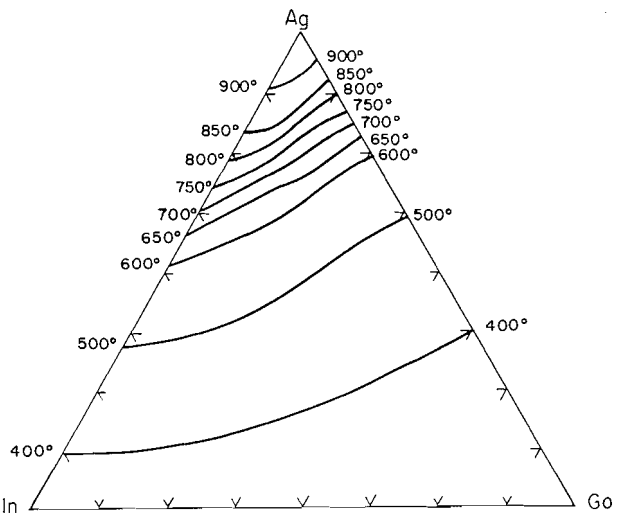

FIG. 9. Isothermal lines on liquidus surface.

peritectic troughs did not show up during thermal analysis. The temperatures of the ternary peritectic halts were obtained, but without a knowledge of the trough leading to the peritectic, it is not possible to specify the composition.

The ternary eutectic temperature is 14.5° C and the ternary eutectic alloy results when 2% silver is added to the binary eutectic indium–gallium.

More success was obtained with the low temperature (25°) isotherm. Our data show that the δ phase of the Ag–In system is different from the γ phase of the Ag–Ga system. Figure 6 represents the 25° isotherm of alloys containing more than 50% silver: each point on the figure is given a number which refers to Table III. There is no ambiguity about this part of the diagram. The diagram is drawn with a break in the line outlining the region of existence of α phase where the line touches the three-phase triangle. This break was not found experimentally, but theoretically it must occur. It is thermodynamically necessary that the extension of boundaries of solid solution must lie either both within the triangle or both within the adjoining two-phase regions (13). This means that of four possible combinations of phases within the three-phase triangle, two are thermodynamically impossible.

The δ phase has been shown to be hexagonal close-packed. The γ phase structure could not be characterized by X-ray powder techniques but it must be nearly hexagonal since well-formed crystals in the shape of a six-sided star were visible to the naked eye in alloys of pure γ phase.

REACTION OF IODOMETHANE WITH TERTIARY ARSINE MERCURIC IODIDE COMPLEXES

M. M. Baig, W. R. Cullen, and D. S. Dawson
The Chemistry Department, University of British Columbia, Vancouver, British Columbia
Received September 27, 1961

ABSTRACT

The reaction of 1:1 tertiary arsine mercuric iodide complexes with iodomethane gives arsonium derivatives of triiodomercury (II).

DISCUSSION AND RESULTS

The reaction of iodoarsines with alkyl iodides in the presence of mercury has been found to yield arsonium derivatives of triiodomercury (II) (1); for example:

$$R_2AsI + Hg + 2CH_3I \rightarrow R_2As(CH_3)_2HgI_3.$$

It has been suggested (1) that such reactions proceed through the formation of 1:1 tertiary arsine mercuric iodide complexes as intermediates which then react further with the alkyl iodide to give the arsonium derivative; for example:

$$R_2AsI + Hg + CH_3I \rightarrow R_2AsCH_3.HgI_2 \xrightarrow{CH_3I} R_2As(CH_3)_2HgI_3.$$

In the present investigation the plausibility of the second part of this reaction sequence has been investigated.

It has been found that the 1:1 mercuric iodide complexes of dimethylphenylarsine, methyldiphenylarsine, dimethyl-α-naphthylarsine react with excess iodomethane to give the corresponding arsonium triiodomercury (II) derivatives; for example:

$$(C_6H_5)_2AsCH_3.HgI_2 + CH_3I \rightarrow (C_6H_5)_2As(CH_3)_2HgI_3.$$

The reaction of the 1:1 complex of triethylarsine and mercuric iodide with iodomethane gives two products, triethylmethylarsonium triiodomercury (II) and bis(triethylmethylarsonium) tetraiodomercury (II). The 1:1 triethylarsine complex is unstable in solution with respect to the 2:3 complex $[(C_2H_5)_3As]_2[HgI_2]_3$ (2) and the tetraiodomercury (II) derivative is most probably formed from reaction of the 2:3 complex with iodomethane rather than from reaction of the 1:1 complex. Iodoethane and trifluoroiodomethane do not react with the 1:1 triethylarsine complex at 20°; however, at 100° some reaction with trifluoroiodomethane takes place producing diethyltrifluoromethylarsine in low yield. This compound is also produced by the reaction of triethylarsine with trifluoroiodomethane at 100° (3) and reaction in the case of the 1:1 complex may be due to dissociation or disproportionation of the complex to produce triethylarsine.

Coates and co-workers (4) have found that in acetone solution iodomethane reacts with some 2:1 tertiary arsine mercuric iodide complexes to give bisarsonium tetraiodomercury (II) derivatives, and in the present work it has been found that the 2:1 complex of triphenylarsine reacts similarly giving bis(methyltriphenylarsonium) tetraiodomercury (II). The triphenylarsine complex does not react with trifluoroiodomethane at 20° but does react slowly with iodoethane. Presumably the product from the latter reaction is the tetraiodomercury (II) derivative, though this was not established.

Similar reactions are known for tertiary phosphine mercuric iodide complexes (4, 5) and also for disubstituted sulphide mercuric iodide complexes (6). The mercuric iodide

complexes are labile and reactions of this sort most likely proceed through addition of the alkyl iodide to the complexing ligand produced by the dissociation of the complex; for example:

$$R_3As.HgI_2 \rightleftharpoons R_3As + HgI_2,$$
$$R_3As + CH_3I \rightarrow R_3AsCH_3I,$$
$$R_3AsCH_3I + HgI_2 \rightarrow R_3AsCH_3HgI_3.$$

Direct formation of the arsonium iodide from the tertiary arsine and iodomethane is known to occur at 20° for all the arsines involved in the above reactions, except triphenylarsine (7). However, the presence of mercuric iodide as an iodide ion acceptor could be expected to facilitate the formation of onium derivatives even when the onium iodides are not easily formed by direct reaction. An alternative mechanism involving "addition" of the alkyl iodide across the, say, As–Hg bond seems much less likely.

Two new 1:1 mercuric halide complexes of dimethyl-α-naphthylarsine were also prepared during this investigation. These are the compounds $C_{10}H_7As(CH_3)_2.HgX_2$ (X = Cl, m.p., 233–235°, X = I, m.p., 192–195°). Attempts to prepare the corresponding 2:1 adducts from hot alcoholic solutions of the components resulted only in the isolation of the 1:1 complexes. Anderson and Burrows (8) found similar difficulties in isolating the 2:1 mercuric halide complexes of dimethylphenylarsine. The 1:1 complex of dimethyl-α-naphthylarsine and mercuric iodide has a significantly low molecular weight when it is determined by the Rast method. This is probably due to dissociation. The corresponding mercuric chloride complex is insoluble in camphor so no measurement of its molecular weight was made.

EXPERIMENTAL

Except where otherwise indicated reactions were carried out at 20° and in sealed tubes in the absence of air and moisture. Volatile reactants and products were manipulated in a vacuum system.

Reaction of the 1:1 Complex of Methyldiphenylarsine and Mercuric Iodide with Iodomethane

Methyldiphenylarsine was prepared by the reaction of phenylmagnesium bromide on diiodomethylarsine (9). On mixing hot alcohol solutions of the arsine (1 mole) and mercuric iodide (1 mole) the 1:1 complex was obtained, m.p. 117° (lit. value 116° (8)). Acetone solutions of the complex (0.7 g) and iodomethane (0.8 g), on mixture in air, gave a yellow precipitate (0.8 g), m.p. 122°. The arsine complex (0.8 g) was soluble in iodomethane (14.5 g) but after 7 days a yellow precipitate had appeared. The unreacted iodomethane was removed under vacuum and the remaining yellow solid melted at 122°. The products from both these reactions when recrystallized from alcohol melted at 131° and were identified as dimethyldiphenylarsonium triiodomercury (II) (m.p. 131° (1)) on the basis of their melting points and mixed melting points with an authentic sample (undepressed), and their X-ray powder photographs.

Reaction of the 1:1 Complex of Dimethylphenylarsine and Mercuric Iodide with Iodomethane

The arsine was prepared from phenylmagnesium bromide and iododimethylarsine (9). The 1:1 arsine mercuric iodide complex was prepared by mixing hot alcohol solutions containing molar proportions of the arsine and mercuric iodide. The yellow precipitate which was obtained gave two fractions on fractional crystallization from alcohol: one, the major product, consisted of orange-yellow needles of the 1:1 complex, m.p. 144° (lit. value, 144° (8)), the other, small pale yellow needles, m.p. 89°. The 1:1 complex (5.4 g) was soluble in excess iodomethane but after 13 days a yellow precipitate had appeared. The excess iodomethane was removed under vacuum, leaving a yellow solid. This solid on recrystallization from acetone–alcohol was identified as trimethylphenylarsonium triiodomercury (II) on the basis of its melting point 128–129° (lit. value, 128° (1)) and the identity of its infrared spectrum and X-ray powder photograph with those of an authentic sample.

Reaction of the 1:1 Complex of Triethylarsine and Mercuric Iodide with Iodomethane

Triethylarsine was prepared from ethylmagnesium bromide and arsenic trichloride (10). The 1:1 arsine mercuric iodide complex was prepared using the procedure of Mann *et al.* (2). The complex so obtained melted at 89° (lit. value, 88–89°). The complex (3.19) was soluble in 22.3 g of iodomethane. The solution

slowly deposited a yellow oil and after 30 days the volatile contents of the tube were removed under vacuum. The residual oil (3.98) slowly solidified and the solid melted at 68°. On crystallization from acetone–alcohol two fractions were obtained. The less soluble pale yellow fraction (1.5 g) melted at 253°. The more soluble yellow fraction melted at 61° after further recrystallization (0.9 g). For the identification of these products reference compounds were prepared from triethylmethylarsonium iodide and mercuric iodide. Triethylmethylarsonium iodide was prepared by direct reaction between triethylarsine and iodomethane. The arsonium iodide was recrystallized from alcohol and melted at 273° (lit. value, 270°). *Triethylmethylarsonium triiodomercury (II)*, m.p. 64°, and *bis(triethylmethylarsonium) tetraiodomercury (II)*, m.p. 253°, were prepared by mixing hot alcohol solutions of the arsonium iodide and mercuric iodide in the calculated proportions (1:1 and 2:1 respectively); the products were recrystallized from alcohol. Anal. Found: C, 11.3; H, 2.39; Hg, 26.0%; mol. wt., 793. Calc. for $C_7H_{18}AsHgI_3$: C, 11.1; H, 2.37; Hg, 26.5%; mol. wt., 759. Found: C, 15.9; H, 3.34; Hg, 18.6%. Calc. for $C_{14}H_{36}As_2HgI_4$: C, 15.8; H, 3.38; Hg, 18.9%.

Comparison of the melting points and X-ray powder photographs of the products from the original reaction with those of the reference compounds showed that the least soluble fraction, m.p. 253°, was the arsonium tetraiodomercury (II) compound and the other fraction, m.p. 61°, was the arsonium triiodomercury (II) derivative.

Reaction of the 2:1 Complex of Triphenylarsine and Mercuric Iodide with Iodomethane

The 2:1 adduct was prepared by reacting together alcoholic solutions of triphenylarsine (2 moles) and mercuric iodide (1 mole). The product was purified by crystallization from alcohol. It melted at 198° (lit. value, 197° (2)). The complex (2.0 g) and iodomethane (9.7 g) were left for 7 days. The volatile contents of the tube were removed under vacuum and a yellow residue (2.1 g, m.p. 174°) was left in the tube. The product was expected to be *bis(triphenylmethylarsonium) tetraiodomercury (II)* so this compound, m.p. 175°, was prepared by reacting alcoholic solutions of commercial triphenylmethylarsonium iodide and mercuric iodide in correct proportion. The complex was recrystallized from alcohol. Anal. Found: C, 34.1; H, 2.64; Hg, 14.4%. Calc. for $C_{38}H_{36}As_2HgI_4$: C, 33.9; H, 2.67; Hg, 14.9%. Comparison of the infrared spectra and melting points of the reference compound and the product of the reaction suggested that they were identical. Confirmation was obtained from an undepressed mixed melting point.

Reactions of Tertiary Arsine Mercuric Iodide Complexes with Other Alkyl Halides and Trifluoroiodomethane

(a) The 1:1 complex of triethylarsine and mercuric iodide with iodoethane.—The complex (3.5 g) and iodoethane (6.4 g) were left for 28 days. The volatile contents of the tube were removed under vacuum, leaving a yellow solid, m.p. 50°. The X-ray powder photograph of this sample showed it to be mainly the starting material and showed the absence of detectable amounts of tetraethylarsonium triiodomercury (II) and bis(tetraethylarsonium) tetraiodomercury (II).

(b) The 1:1 complex of triethylarsine and mercuric iodide with trifluoroiodomethane.—The complex (3.6 g) was soluble in trifluoroiodomethane (16.595 g). After 40 days the volatile contents of the tube were taken into the vacuum system where trap-to-trap distillation showed that only trifluoroiodomethane (16.525 g) was present. The complex (7.3 g) and trifluoroiodomethane (16.3 g) after 48 hours at 100° gave diethyltrifluoromethylarsine (0.202 g) identified by its infrared spectrum (11), and unreacted trifluoroiodomethane (15.9 g).

(c) The 2:1 complex of triphenylarsine and mercuric iodide with iodoethane.—When the complex (2.7 g) and iodoethane (9.097 g) were left for 25 days 0.223 g of iodoethane was consumed. The solid product (2.8 g) melted in the range 89–97°. By recrystallization from alcohol, two products were obtained. The first consisted of 0.914 g of a colorless substance identified as the starting material by comparison of its infrared spectrum, X-ray powder photograph, and melting point (found, m.p., 202° (from acetone); lit. value, 197° (2)). The second product, after further recrystallization, melted at 88° and analysis indicated that it was still impure as the results do not correspond to any likely reaction product. Found: C, 29.5; H, 2.87; Hg, 20.3%; mol. wt., 751.

Reaction of the 1:1 Complex of Dimethyl-α-naphthylarsine and Mercuric Iodide with Iodomethane

Dimethyl-α-naphthylarsine was prepared from iododimethylarsine and α-naphthylmagnesium bromide (9). The product was purified by distillation in a nitrogen atmosphere; the colorless liquid boiled at 178–180° (24 mm). The arsine reacted directly with iodomethane at 20° to give trimethyl-α-naphthylarsonium iodide, m.p. 238° (lit. value, 230°). Anal. Found: C, 42.0; H, 4.35%. $C_{13}H_{16}AsI$ requires: C, 41.8; H, 4.31%. Mixing hot ethanolic solutions of the arsine (1 mole) and mercuric chloride (1 mole) gave the colorless 1:1 adduct, m.p. 233–235°. Anal. Found: C, 29.2; H, 2.89; As, 15.3; Cl, 14.5; Hg, 37.3%. Calc. for $C_{12}H_{13}AsCl_2Hg$: C, 28.7; H, 2.60; As, 14.9; Cl, 14.1; Hg, 39.9%. The same product was obtained on mixture of hot alcoholic solutions of the arsine (2 moles) and mercuric chloride (1 mole). The 1:1 arsine mercuric iodide complex was similarly obtained as a yellow solid, soluble in hot methanol, m.p. 192–195°. Anal. Found: C, 21.2; H, 1.88; Hg, 28.9%; mol. wt., 438. Calc. for $C_{12}H_{13}AsHgI_2$: C, 21.0; H, 1.91; Hg, 29.2%; mol. wt., 687. Attempts to prepare the 2:1 arsine mercuric iodide complex from hot alcoholic solutions gave only the 1:1 adduct. On mixing hot alcoholic solutions of trimethyl-α-naphthylarsonium iodide (1 mole) and mercuric iodide (1 mole) yellow crystals of trimethyl-α-naphthylarsonium triiodomercury (II) were obtained, m.p.

183–185°. Anal. Found: C, 19.0; H, 1.95; Hg, 24.4%; mol. wt., 829. Calc. for $C_{13}H_{16}AsHgI_3$: C, 18.8; H, 1.93; Hg, 24.2%; mol. wt., 850. The same compound was obtained when the 1:1 complex of dimethyl-α-naphthylarsonium iodide and mercuric iodide was left in contact with excess iodomethane in a stoppered flask (12 days). The product was identified by its melting point of 184–186° and its infrared spectrum.

THE STRUCTURE OF LICHENIN: SELECTIVE ENZYMOLYSIS STUDIES[1]

A. S. PERLIN AND S. SUZUKI[2]

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received September 13, 1961

ABSTRACT

Lichenin, the poly-β-D-glucan of *Cetraria islandica* (Iceland moss), is found by enzymic degradation to differ in fine structure from the poly-β-D-glucans of cereal grains. Enzymolysis has been carried out with a cellulase and a laminarinase preparation, the former yielding mainly *O*-β-D-glucopyranosyl-(1 → 3)-*O*-β-D-glucopyranosyl-(1 → 4)-α-D-glucose, and the latter mainly *O*-β-D-glucopyranosyl-(1 → 4)-*O*-β-D-glucopyranosyl-(1 → 3)-α-D-glucose. Di- and tetra-saccharides are produced in small proportions. Steric aspects of these enzymic degradations are discussed. The basis constitution of lichenin is represented by a tetrameric unit in which two adjacent (1 → 4) linkages alternate with an isolated (1 → 3) linkage; occasionally four consecutive monomers are linked by (1 → 4) bonds. The glucans of cereal origin differ mainly in possessing a higher proportion of the latter structural sequence. Despite their close chemical similarity to cellulose, all of these glucans are soluble, a property that appears to be related to the even distribution of β-(1 → 3) bonds along the chains, with a resulting disruption of linear orientation effects.

Lichenin, a major polysaccharide component of *Cetraria islandica* (Iceland moss) is composed of β-D-glucopyranose units linked in a linear manner by (1 → 4) and (1 → 3) glycosidic bonds (1, 2, 3). The only other known source of polysaccharides of this type is the Gramineae family (notably oats and barley). Careful chemical examination (3) has shown no distinct structural difference between these polymers isolated from such widely divergent botanical origins. In recent studies on the β-glucans of oats and barley (4) it was found that each of two enzymes—a cellulase and a laminarinase—degrades the β-glucans extensively in a highly selective fashion. Hence, it appeared that a study of the comparative behavior of the same enzymes on lichenin might indicate to what degree this polymer resembles the cereal β-glucans.*

The lichenin was isolated by the procedure of Peat, Whelan, and Roberts (3), and purified via the derived acetate. Based on periodate uptake the ratio of (1 → 4) to (1 → 3) linkages present in lichenin, as well as in the cereal glucans (2, 3, 4), is reported to be about 7 to 3. In the present study, overoxidation of the lichenin prevented an accurate measure of this ratio and, in parallel experiments, the oat and barley glucans were found to be overoxidized similarly. However, a comparison of the data (experimental section) indicated that lichenin consumes about 10% less of periodate, and that the incidence of (1 → 3) linkages in this polymer is perhaps 35%, whereas in the cereal polysaccharides it is closer to 25%.

When the lichenin was treated with a cellulase from *Streptomyces* sp. QM B814 (5) the products were found by paper chromatography to consist of a mixture of cellobiose together with tri- and tetra-saccharides. This mixture was readily fractionated by preparative paper chromatography. By far the major product was the trisaccharide *O*-β-D-glucopyranosyl-(1 → 3)-*O*-β-D-glucopyranosyl-(1 → 4)-D-glucopyranose (I), which accounted for about 60% of the polymer (Table I). Previously this trisaccharide had been characterized as the derived undecaacetate (3, 4) but the crystalline α-anomer of

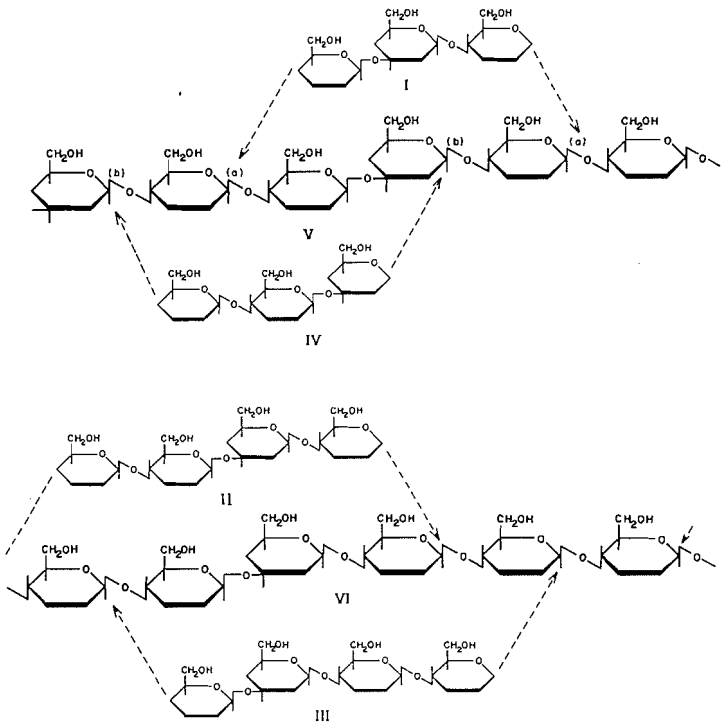
**This study was made possible through the kind co-operation of Dr. E. T. Reese, who provided the enzyme preparations.*

TABLE I

Products from the enzymolysis of polyglucans

	Initial polymer (mg)	Dimer (mg)	Trimer (mg)	Tetramer (mg)	Trimer / Tetramer
A. By cellulase					
Lichenin	24.4	2.2	14.2	3.6	4.0
Oat glucan	20.4	1.2	10.4	4.8	2.2
Barley glucan	23.0	1.5	11.7	4.8	2.4
B. By laminarinase					
Lichenin	24.4	3.4	13.4	3.7	3.6*
Oat glucan	21.5	2.6	10.2	6.8	1.5*
Barley glucan	21.1	3.4	10.2	5.5	1.8*

*These ratios are minimal values since the tetramer fractions, particularly that from lichenin, contained a substantial proportion of material travelling on the chromatograms at a slightly slower rate.



the free sugar has now been obtained. As found earlier with the cereal glucans, the tetrasaccharide fraction contained at least two components. These were not separable chromatographically but their presence was detected by selective degradation (4) to a mixture of two different triitols. One of the tetrasaccharides, which subsequently crystallized from the mixture, was found to be *O*-β-D-glucopyranosyl-(1 → 4)-*O*-β-D-glucopyranosyl-(1 → 3)-*O*-β-D-glucopyranosyl-(1 → 4)-D-glucopyranose (II), the structure of which had been determined previously with an amorphous sample derived from barley glucan (4). By seeding, the latter sample now has been crystallized also. A minor component of the mixture was *O*-β-D-glucopyranosyl-(1 → 3)-*O*-β-D-glucopyranosyl-(1 → 4)-*O*-β-D-glucopyranosyl-(1 → 4)-D-glucose (III) (4).

The main product formed from lichenin by the laminarinase of *Rhizopus arrhizus* QM 1032 (6) was also a trisaccharide, *O*-β-D-glucopyranosyl-(1 → 4)-*O*-β-D-glucopyranosyl-(1 → 3)-D-glucose (IV), accounting for about 55% of the polysaccharide (Table I). This trisaccharide has now been obtained as the crystalline α-anomer, being characterized previously as an undecaacetate.* Other products of the enzymic degradation, detected chromatographically, corresponded to laminaribiose, tetrasaccharide, and higher oligosaccharides, but all of these were minor products and pure fractions of them were not isolated. Cunningham and Manners have also found recently (private communication) that the degradation of lichenin by preparations of laminarinase yields mainly trisaccharide IV.

Peat, Whelan, and Roberts (3) concluded on the basis of data from partial acid hydrolysis that an important type of structural unit in lichenin is one in which four β-D-glucopyranosyl units are linked by a (1 → 3) bond and two consecutive (1 → 4) bonds, as in V. The present data clearly support their conclusion and show, in fact, that sequence V likely represents the major proportion of the lichenin molecule, just as found earlier with the cereal glucans (4). Such a structure is consistent with the formation in high yield of trisaccharide I (by cleavage at (*a*)) and of trisaccharide IV (by cleavage at (*b*)), taking into consideration the ratio of (1 → 4) to (1 → 3) linkages in the polymer, and the evidence available as to the specificity of the two enzymes (4, 9). Since I and IV each contains a (1 → 3) bond and hence accounts for a high percentage of such bonds present, liberation of these trisaccharides must involve mainly the scission of (1 → 4) linkages. Thus, attack at (*a*) by the cellulase appears to be related to a "(→ 4) (1 → 4)" bonding arrangement of the β-D-glucopyranosyl unit (to the left of (*a*) in V). The second unit engaged in forming linkage (*b*) is itself not 4-substituted, which presumably accounts for its lack of susceptibility to cellulase. However, this unit is 3-substituted, an arrangement consistent with the idea that the laminarinase action involves cleavage at (*b*) (4, 9).

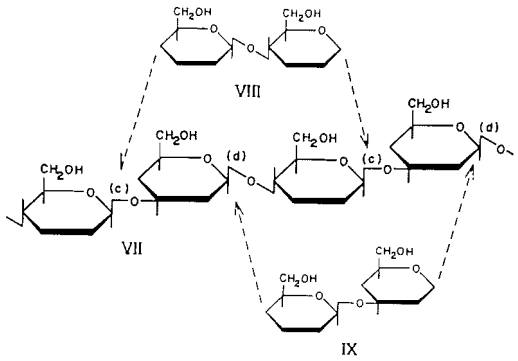
Formation of tetrasaccharides II and III by cellulase is indicative of the occurrence of structural units such as VI, in which a single (1 → 3) bond alternates with three consecutive (1 → 4) bonds, as noted with the cereal glucans (4). However, sequence V has relatively much greater prominence in the lichenin structure than in the cereal glucans, since the ratio of trisaccharide (representative of V) to tetrasaccharide (representative of VI) is much higher with lichenin (Table I), i.e., a value of 4 as against 2.3 (average) for the cereal glucans. This difference was detected also with laminarinase, which produced trimer and tetramer from lichenin in a ratio of 3.6 to 1, and from the oat and barley glucan in a ratio of 1.7 (average) to 1 (Table I). Consistent with these findings is the indication from periodate oxidation data that lichenin contains the higher proportion of (1 → 3) linkages. Other differences between these polysaccharides are reflected in the fact that cellulase produces more of tetrasaccharide II than of III from lichenin, whereas the reverse is true for the cereal glucans; also, 3′-*O*-cellotriosyl-D-glucose (4) is a major product of laminarinase action on the cereal glucans, whereas with lichenin much less tetramer (not identified) is produced and higher oligosaccharides are relatively more prominent.

Therefore, although lichenin closely resembles the cereal glucans it can readily be differentiated from them in terms of fine structure. The oat and barley polysaccharides, however, must be regarded, on the basis of the data available, as indistinguishable from each other.

**Two different sets of physical constants have been reported for the acetate of this trisaccharide (3, 4, 7). This complication has now been resolved by Moscatelli, Ham, and Rickes (8), who find that the different acetates represent two modifications, probably anomers, of the same parent trisaccharide.*

Apparently, the cereal glucans contain minor structural features which were not detected in the earlier enzymic study (4) nor by partial hydrolysis (3). With both these methods of examination the presence of only isolated (1 → 3) bonds was indicated, but other methods have shown the occurrence also of two and three consecutive (1 → 3) linkages (10, 11), although quantitative data are not yet available. The possibility that such sequences are present also in lichenin must await further examination.

In formulating structures such as V and VI no account has been taken of the fact that a small quantity of disaccharide (5–15%) is produced by each enzyme from lichenin as well as from the cereal glucans. For the present purposes of comparing the three polysaccharides these dimers are of little significance. From the standpoint of enzymic stereospecificity, however, it may be noted that the cellulase produces cellobiose whereas the laminarinase yields laminaribiose. This pattern of attack on the glucans is characteristic of enzymes of these classes isolated from a variety of sources (E. T. Reese, private communication), and is in agreement with recent suggestions about the specificity of polyglycosidases (9). According to this view, cellobiose is a product consistent with cellulase action since it is liberated by attack on alternate 4-substituted β-D-glucosyl units (which become reducing-end units), but the non-reducing end unit in the dimer is itself not substituted at position 4. In similar fashion, laminaribiose should be formed by attack on alternate β-D-glucose units linked through positions 1 and 3 to adjacent units, but should itself be stable because the non-reducing end unit is not 3-substituted. It is not inconceivable, therefore, that the polyglucans contain a small proportion of sequences such as



VII, and that cellobiose (VIII) is derived by attack at (*c*) (with actual cleavage of a (1 → 3) bond) whereas laminaribiose (IX) arises from attack at (*d*) (with actual cleavage of a (1 → 4) bond).

Lichenin and the cereal glucans are closely related in structure to cellulose in that they are composed primarily of (1 → 4)-linked β-D-glucopyranosyl units. As pointed out by Hirst (12), these polysaccharides provide a good illustration of how small variations in structure can markedly influence the physical characteristics of such polysaccharides. The insolubility of cellulose is attributed mainly to the high degree of linear orientation and strong intermolecular bonding possible with a molecule of this type (Fig. 1(*a*)). Replacement of a small percentage of the (1 → 4) bonds by (1 → 3) bonds "converts" this alkali-insoluble polymer into one readily soluble in water. This marked variation in solubility is perhaps understandable when the (1 → 3) bonds are seen to be distributed uniformly along the chains at intervals of three or four units, an arrangement (Fig. 1(*b*)) which should greatly minimize orientation effects such as are obtained in cellulose.

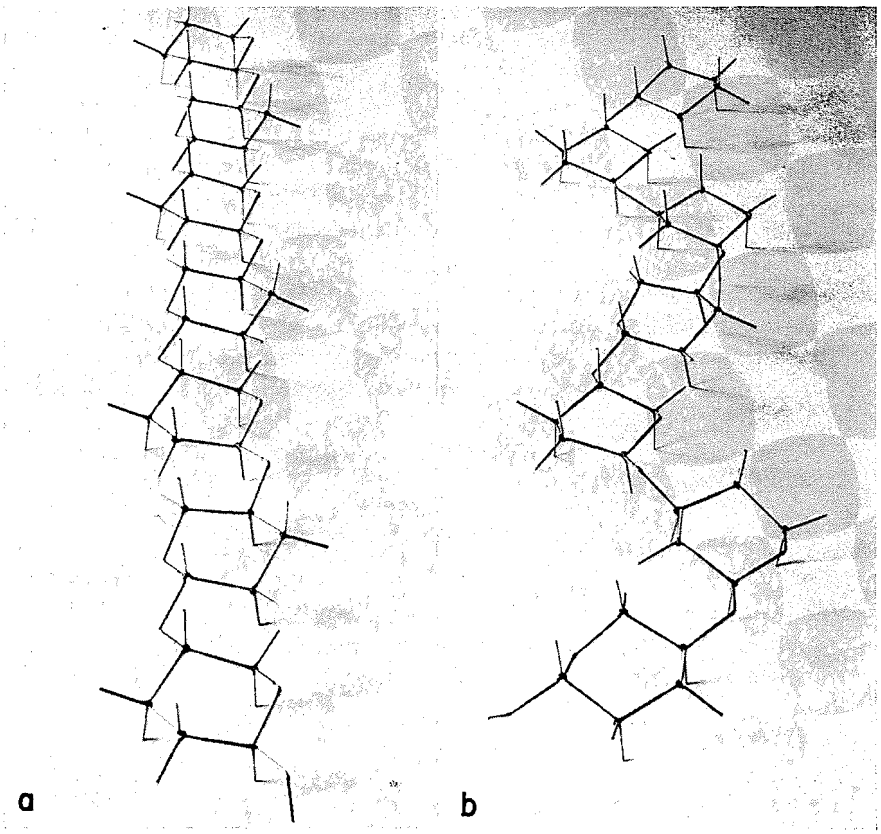


FIG. 1. Representation (Drieding models) of a molecule of (*a*) cellulose, (*b*) lichenin or the poly-β-D-glucans of oats and barley.

EXPERIMENTAL

The cellulase (obtained from *Streptomyces* QM B814) and laminarinase (obtained from *R. arrhizus* QM 1032) preparations were lyophylized powders, prepared by Dr. E. T. Reese.

Analytical and preparative paper chromatography was carried out using as solvents: (A) ethyl acetate – pyridine – water (10:4:3) and (B) ethyl acetate – acetic acid – water (9:2:2).

Evaporations were carried out at 40–45°. Optical rotations were measured at 25±2°. Melting points are corrected.

Isolation and Purification of Lichenin

The isolation procedure was essentially that described by Peat, Whelan, and Roberts (3). A commercial sample of powdered Iceland moss was extracted exhaustively with 2% potassium carbonate to remove tannins, and then twice with hot water. The water extract was frozen, then thawed, and the suspended gel collected by centrifugation. A vigorously stirred solution of the gel at 50° (pH 6.5) was treated with salivary amylase to degrade the isolichenin, and the polysaccharide remaining was precipitated out with ethanol and recovered. Yield, 101 g from 1 kg of moss.

Crude lichenin (20 g) was suspended in formamide (200 ml) with vigorous stirring, pyridine (200 ml) and acetic anhydride (100 ml) were added portionwise, and after 4 hours the reaction mixture was poured into ice water. The precipitated material was washed and dried, and reacetylated. Final yield, 24 g. The acetate (20 g) was extracted into acetone (600 ml) and fractional precipitation was carried out by gradual addition of light petroleum (b.p. 60–110°). Four fractions were obtained: (1) 6.0 g, $[\alpha]_D$ −36°; (2) 2.3 g, $[\alpha]_D$ −32°; (3) 1.4 g, $[\alpha]_D$ −31°; (4) 4.7 g, $[\alpha]_D$ −29° (specific rotations measured at 2% concentration in chloroform).

The acetates were deacetylated by dissolving them in acetone and adding excess 0.2 *N* potassium hydroxide, the free polysaccharide being recovered, after acidification with acetic acid, by precipitation with alcohol. Deacetylated fractions 2, 3, and 4 were white, fibrous materials, readily soluble in water at 40–45°. Compared on the basis of glucose content (each 92–95%), periodate uptake, degree of enzymolysis

by cellulase and laminarinase, and chromatographic examination of the enzymolysis products, these fractions appeared to be sufficiently similar to warrant their recombination for use in the experiments described below. Fraction 1 contained a higher percentage of impurities and was less soluble, and was not examined further.

Comparison of Some Properties of Lichenin with Those of Oat and Barley Glucans

(a) Periodate Oxidation

Lichenin was treated with two molar equivalents of sodium periodate at 19° in the dark. The periodate consumption (moles/mole (hours)) was 0.49 (16), 0.57 (40), 0.61 (88), 0.65 (160), 0.67 (208). At 208 hours the yield of formic acid was 0.019 moles/mole.

Oxidized under the same conditions, oat and barley glucans gave periodate uptake data (moles/mole (hours)) similar to those reported earlier (4): for oat glucan, 0.58 (40), 0.61 (88), 0.74 (160), 0.76 (208); for barley glucan, 0.59 (40), 0.66 (88), 0.77 (160), 0.79 (208).

(b) Enzymolysis

Each polysaccharide (20–25 mg) in water (2 ml) was treated at 45° with the enzyme preparation (cellulase or laminarinase, 5 mg). The copper-reducing power of the digest was essentially constant in each experiment within 5 hours' reaction time, the values (calculated as percentage of glucose) then being:

	Cellulase	Laminarinase
Lichenin	35.6	27.0
Oat glucan	37.6	26.9
Barley glucan	34.8	29.2

Each digest was heated on the steam bath for 10 minutes, concentrated, and chromatographed on Whatman No. 1 paper, using solvent A. The various components detected were eluted with water and estimated (Table I) with Nelson's reagent (13), using as standards cellobiose and trisaccharide I for the cellulase experiments, and laminaribiose and trisaccharide IV for the laminarinase experiments.

Degradation of Lichenin with Cellulase

Lichenin (1.0 g) in water (100 ml) was incubated at 44° with cellulase (0.12 g) for 5 hours. The digest was heated on the steam bath for 10 minutes, filtered, and the filtrate was concentrated and chromatographed on Whatman No. 3 MM paper sheets. The chromatogram was developed, first with solvent B and then with solvent A. The major products detected were eluted with water, and the eluates were purified by treatment with mixed-bed ion-exchange resins.

*O-β-*D*-Glucopyranosyl-(1 → 3)-O-β-*D*-glucopyranosyl-(1 → 4)-α-*D*-glucopyranose (I)*

The trisaccharide fraction (0.5 g) crystallized and was recrystallized from water–ethanol; m.p. 229–231°, $[\alpha]_D$ 18.7° → 13.0° (*c*, 1.4, H_2O). Calculated for $C_{18}H_{32}O_{16}$: C, 42.86%; H, 6.39%; molecular weight, 502. Found: C, 42.80%; H, 6.45%; molecular weight (vapor pressure osmometry (14), in water), 481.

On acetylation with acetic anhydride – sodium acetate at 95°, the compound afforded a derivative, m.p. 121–123°, undepressed by admixture with the β-undecaacetate of trisaccharide I.

An amorphous sample of I, obtained earlier from oat glucan (4), was induced to crystallize by seeding with the current crystalline material, and the identity of the two trisaccharide preparations was shown by a comparison of X-ray powder diagrams.

*O-β-*D*-Glucopyranosyl-(1 → 4)-O-β-*D*-glucopyranosyl-(1 → 3)-O-β-*D*-glucopyranosyl-(1 → 4)-*D*-glucopyranose (II)*

The tetrasaccharide fraction (0.15 g) was chromatographically homogeneous. However, degradation of a portion of this material by the procedure described previously (4)—involving lead tetraacetate oxidation, reduction, and partial hydrolysis—afforded two products, one corresponding chromatographically to 2-*O*-β-D-laminaribiosyl-D-erythritol (major component) and the other to 2-*O*-β-D-cellobiosyl-D-erythritol (minor component). This finding showed that at least two tetrasaccharides were present.

After prolonged storage in water–methanol the tetrasaccharide fraction afforded crystalline material (65 mg) which was recrystallized from the same solvent, m.p. 223–226°. This product served as seed for crystallization of an amorphous preparation of tetrasaccharide II ($[\alpha]_D$+19.8°), characterized earlier (4), the identity of the two products being shown by a comparison of X-ray powder diagrams. Calculated for $C_{24}H_{42}O_{21}.H_2O$: C, 42.10%; H, 6.48%. Found: C, 41.80%; H, 6.65%.

*O-β-*D*-Glucopyranosyl-(1 → 3)-O-β-*D*-glucopyranosyl-(1 →4) -O-β-*D*-glucopyranosyl-(1 → 4)-β-*D*-glucopyranose (III)*

The supernatant solution remaining after the isolation of II afforded a second product which, after three recrystallizations from water–methanol, had m.p. 187–188°; this product was found to be the dihydrate of III (4) by mixed melting point and from its X-ray powder diagram.

Degradation of Lichenin with Laminarinase

Lichenin (0.14 g) in water (15 ml) was incubated at 44° with laminarinase (25 mg) for 6 hours. The digest was heated at 95° for 10 minutes, concentrated, and chromatographed on Whatman No. 3 MM paper sheets using solvent A.

O-β-D-Glucopyranosyl-(1 → 4)-O-β-D-glucopyranosyl-(1 → 3)-α-D-glucose (IV)

The eluted trisaccharide fraction, after purification with mixed ion-exchange resins, crystallized and was recrystallized from water–ethanol; m.p. 236–239°, $[\alpha]_D$ 16.5° → 11.7° (*c*, 1.5, H_2O). Calculated for $C_{18}H_{32}O_{16}$: C, 42.86%; H, 6.39%; molecular weight, 502. Found: C, 42.81%; H, 6.47%; molecular weight (vapor pressure osmometry, in water), 480. The X-ray powder diagram was indistinguishable from that of trisaccharide IV, obtained previously as amorphous material from oat glucan (4) but which also has now been crystallized (m.p. 234–237°).

ACKNOWLEDGMENTS

The authors express their deep appreciation to Dr. E. T. Reese for his kindness in providing the enzyme preparations used. They also thank Mrs. J. Nuttall for able technical assistance. Microanalyses were performed by Mr. M. Mazurek. X-Ray powder diagrams were prepared by Miss I. Gaffney and Mr. W. Haid.

PHOTOCHEMICAL SYNTHESES

2. THE IRRADIATION OF ACENAPHTHENE WITH BENZIL

P. DE MAYO AND A. STOESSL[1]

The Department of Chemistry, University of Western Ontario, London, Ontario

Received September 15, 1961

ABSTRACT

The irradiation product of acenaphthene and benzil described by Oliveri-Mandalà, Giacalone, and Deleo has been shown to have the structure (III) and not that of the cyclobutane derivative (II, R = H) originally proposed. The main product obtained by the action of acetic anhydride and sulphuric acid on (III) is not the result of an acetylation process, but is the sultone (IV).

The irradiation of hydrocarbons, which are capable of giving stable radicals by hydrogen abstraction, in the presence of carbonyl compounds has been shown to give carbinols (2, 3). Cyclohexene and acetone, for instance, give cyclohexenyldimethylcarbinol (I). The reported irradiation (1), in sunlight, of such a hydrocarbon, acenaphthene, in the presence of a diketone was, therefore, of some interest. The product isolated had an analysis corresponding to 1:1 addition, and structure (II, R = H) was proposed on the basis of diacetate (II, R = Ac) formation on acetylation with acetic anhydride and sulphuric acid. Acetic anhydride and pyridine had no action. If correct, this scheme could well provide a new route to syntheses in the cyclobutane series.

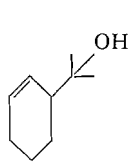
The formation of (II, R = H) was a priori not unreasonable since the expected initial product (III) might well cyclize, such an intramolecular reaction being unexceptional (4). However, the formation of a simple diacetate seemed surprising under conditions of such acidity. Such a strained molecule should provide ample opportunity for acid-catalyzed rearrangement and a number of mechanistically credible routes can be envisaged. Furthermore, the main product of the acetylation process was a substance for which no empirical formula was proposed and which was orange-red in color. Since no simple transformation product of (II, R = H) should be so colored the preparation of the irradiation product was repeated.

Irradiation of benzil and acenaphthene in benzene solution using, however, an ultraviolet lamp, gave the desired product with properties as previously described (1). The structure (II, R = H) was shown to be untenable since the infrared spectrum revealed bands in the carbonyl and hydroxyl region at 1669 and 3460 cm^{-1} compatible with those expected for a benzoin. The alternative structure (III) seemed, therefore, very probable and its correctness was established by the following experiments.

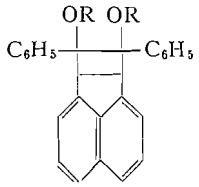
Reduction of (III) with sodium borohydride gave the corresponding diol showing no carbonyl absorption in the infrared. This was further characterized as a monoacetate. Cleavage of the diol with periodic acid then gave benzaldehyde (characterized as the 2,4-dinitrophenylhydrazone) and benzoylacenaphthene. The latter substance had the expected absorption in the infrared and ultraviolet. In addition the n.m.r. spectrum showed a typical ABX pattern for the three non-aromatic hydrogen atoms. (J_{AB} 17.2, J_{AX} 4.7, J_{BX} 7.9 c.p.s.; τ, 6.46, 6.12, and 4.62). However, since the literature (5) records a substance purporting to be 1-benzoylacenaphthene with a melting point differing from

[1]*Present address: Pesticide Research Institute, Canada Department of Agriculture, University Sub Post Office, London, Ontario.*

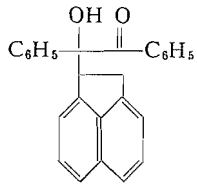
that of the degradation product by 60°, the ketone was converted to 1-benzylidine-acenaphthene identical with a specimen prepared by a Grignard synthesis from acenaphthenone. The structure of the hydrocarbon was confirmed by ozonolysis to benzaldehyde (isolated as the 2,4-dinitrophenylhydrazone) and by quantitative hydrogenation to the oily 1-benzylacenaphthene, which had the expected spectroscopic properties and yielded a crystalline picrate. In addition, heating the benzoylacenaphthene with sodium ethoxide at 180° in the presence of hydrazine resulted in bond cleavage and the formation, by dealdolization, of acenaphthene, together with benzoic acid presumably derived by a Canizzaro reaction from the first-formed benzaldehyde. The nature of the earlier substance, prepared by the irradiation of benzaldehyde and acenaphthene, remains in doubt. No analysis or properties other than the melting point were recorded.



(I)



(II)



(III)

Treatment of (III) with acetic anhydride and sulphuric acid gave the orange-red main product as described by the Italian workers (1). We were unable, however, to isolate any substance corresponding to the supposed "diacetate" even by chromatography. The original isolation involved hand picking of crystals and the recorded analysis for this substance (only carbon and hydrogen reported) lies midway between the starting material and the main product, as does, indeed, the melting point. It is therefore possible that it was a mixture.

The original carbon and hydrogen analysis for the orange-red substance was confirmed. No band attributable to a carbonyl group was visible in the infrared spectrum. The low value for hydrogen immediately suggested that some element other than carbon, hydrogen, or oxygen might be present. In fact, analysis for sulphur established the empirical formula $C_{26}H_{16}O_3S$. The condition of genesis of the substance suggested unsaturated sultone formation (6) and on mechanistic grounds the structure (IV) seemed probable. Its correctness was established in the following way.

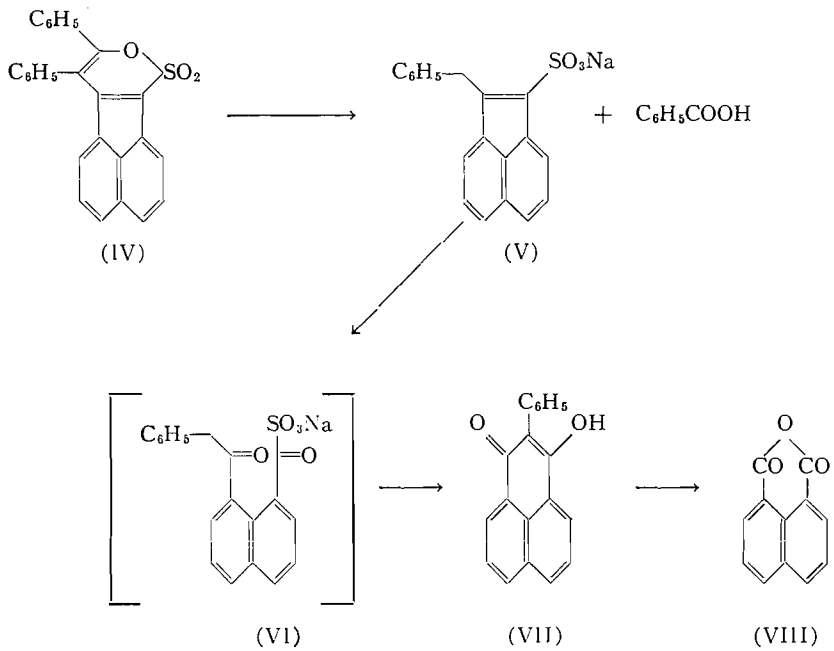
Hydrolysis of (IV) with aqueous alcoholic sodium hydroxide gave 1 molecule equivalent of benzoic acid together with the sodium salt of a yellow sulphonic acid formulated as (V). Its formation may be rationalized as a δ-addition of water to the unsaturated sultone followed by either cleavage of the δ-keto, α-β unsaturated acid, or dealdolization to the mixed anhydride followed by hydrolysis. Ozonolysis of (V) followed by treatment with base gave, by condensation of the intermediate 1,5-diketone (VI), the known hydroxyperinaphthenone (VII), which was identified by comparison with an authentic specimen (7) and by ozonolysis to naphthalic anhydride (VIII).

EXPERIMENTAL

Melting points were taken on the Kofler hot stage. Ultraviolet spectra were determined in 95% ethanol and infrared spectra as Nujol mulls.

Irradiation of Benzil and Acenaphthene

Benzil (15 g) and acenaphthene (11 g) in benzene (50 ml) were irradiated in a pyrex flask under nitrogen with an 85 w HC3 (Hanovia) lamp. After 2 days the precipitate was collected (1.28 g) and crystallized from ethyl acetate to give the adduct, m.p. 237–239° (lit. 234°). Calc. for $C_{26}H_{20}O_2$: C, 85.69; H, 5.53%. Found: C, 85.33; H, 5.35%. The substance showed λ_{max} 228 mμ (ϵ, 64,000) in the ultraviolet.



Reduction of the Adduct to the Diol

The adduct (102 mg) in dioxan (5 ml) was treated with a solution of sodium borohydride (21 mg) in methanol (5 ml) at 10°. After 1 hour, the mixture was poured onto ice water and the product isolated with chloroform containing methanol. The combined extracts were washed with water and dried (Na_2SO_4) and the solvent removed to give, after crystallization from methanol, the diol, m.p. 222–224°. Calc. for $C_{26}H_{22}O_2$: C, 85.21; H, 6.05%. Found: C, 85.12; H, 6.32%. The substance showed λ_{max} 230 mμ (ϵ, 64,000).

Acetylation (acetic anhydride – pyridine at 55° for 20 hours) of the diol (29 mg) gave the monoacetate, m.p. (from ethyl acetate) 264–266°. Calc. for $C_{28}H_{24}O_3$: C, 82.33; H, 5.92%. Found: C, 81.96; H, 6.13%.

Periodate Oxidation of the Diol

To the diol (25.4 mg) in ethyl acetate (3 ml) and methanol (6 ml) was added aqueous periodic acid (0.4 *N*; 2 ml) and the mixture allowed to stand overnight. The mixture was then steam distilled (after reduction of excess periodic acid with arsenite) and the distillate treated with 2,4-dinitrophenylhydrazine in hydrochloric acid. The precipitate (81% yield) was identified as benzaldehyde 2,4-dinitrophenylhydrazone (m.p. and mixed m.p. 236–240°) by comparison with an authentic specimen.

In a similar experiment on a larger scale (120 mg) the oxidizing mixture was allowed to stand 64 hours. After dilution with water the mixture was extracted with benzene and the isolated benzoyl acenaphthene crystallized from methanol and from ethyl acetate (charcoal), with m.p. 137–138.5°. Calc. for $C_{19}H_{14}O$: C, 88.34; H, 5.46%. Found: C, 88.56; H, 6.00%. The ketone (36 mg) when heated in a sealed tube at 180° in ethanol (1.25 ml) containing sodium (85 mg) and hydrazine (1 ml) (Wolff–Kishner conditions) gave, by isolation with benzene and sublimation, acenaphthene (12 mg), identified by melting point and mixed melting point, with an authentic specimen. Acidification of the aqueous phase and steam distillation gave, after extraction and crystallization from water, benzoic acid (7 mg), identified by m.p. and mixed m.p.

1-Benzylidine-acenaphthene

(a) From 1-Benzoylacenaphthene

The ketone (49 mg) was reduced with sodium borohydride as described above. The syrupy product was transferred to a Dean and Stark apparatus and refluxed overnight in toluene (100 ml) containing *p*-toluenesulphonic acid (200 mg). After it was washed with sodium hydroxide solution and water, the solution was evaporated under reduced pressure and the residue chromatographed on alumina (Brockmann Grade 1, 5 g). Light petroleum eluted a gummy fraction (15 mg) which, on hydrogenation, afforded 1-benzylacenaphthene (see below) identified by infrared spectrum and by m.p., mixed m.p., and infrared spectrum of picrate. Further elution of the column with benzene in light petroleum (1:9) furnished a crystalline compound (25 mg) which, after repeated recrystallization from acetone, was identical in all respects with a synthetic specimen of 1-benzylidineacenaphthene.

(b) From Acenaphthenone

Benzyl Grignard reagent was prepared from Mg (360 mg) essentially as described by Adkins and Zartmann (8). To the cooled ethereal solution was added acenaphthenone (9) (2.1 g) in cold dry benzene (18 ml) and the mixture was stirred at ice-temperature (10) for 2 hours, and for a further 1.5 hours while it was allowed to reach room temperature. The complex was decomposed with ice-cold hydrochloric acid (6 *N*; 100 ml) and the product isolated in the usual way as a syrup. A portion (950 mg) was intimately mixed with boric acid (925 mg) and heated at 160° for 30 minutes (11). The mixture was extracted with light petroleum and the extracts chromatographed on alumina (50 g).

Elution with light petroleum gave a yellow oil (473 mg) which was retained (fraction I). Elution with benzene – light petroleum (1:4) then gave an orange oil (fraction II) (92 mg) which crystallized slowly from ethyl acetate. Repeated crystallization from acetone gave a product having a melting point of 98.0–98.5°. In a similar experiment fraction II was sublimed *in vacuo* at 110° to give material which, on crystallization from acetone, was identical with that obtained by chromatography. Found: C, 93.66; H, 5.77%. Calc. for: $C_{19}H_{14}$: C, 94.18; H, 5.82%. The substance showed λ_{max} 246 mμ (ϵ, 27,000) in the ultraviolet.

1-Benzylacenaphthene

(*a*) 1-Benzylideneacenaphthene (m.p. 98–98.5°) (15.5 mg) in ethyl acetate (5 ml) was hydrogenated in the presence of palladized charcoal (5%; 15 mg) with the uptake of 0.94 molecule equivalent of hydrogen. The resultant oil was identical in every respect with that described under (*b*) below, and gave an identical picrate.

(*b*) Fraction I (473 mg) obtained from the boric acid treatment described above was hydrogenated in the presence of palladized charcoal with the uptake of 1 molecule equivalent of hydrogen. The oily product was converted, in ethanolic solution, to the picrate (618 mg) m.p. 81–82° unchanged by further crystallization from alcohol. Found: C, 63.42; H, 4.31; N, 8.90%. Calc. for $C_{25}H_{19}O_7N_3$: C, 63.42; H, 4.04; N, 8.88%. The picrate (320 mg) was filtered through a column of alumina (8 g) and the column washed with benzene. Isolation of the eluted hydrocarbon and sublimation gave benzylacenaphthene as an oil, λ_{max} 228 mμ (ϵ, 78,500), n_D^{25} 1.6409. Found: C, 93.20; H, 6.45%. Calc. for $C_{19}H_{16}$: C, 93.42; H, 6.60%.

Ozonolysis of 1-benzylideneacenaphthene

The crystalline hydrocarbon (20 mg) in ethyl acetate (2 ml) was treated with a stream of ozone at −10° for 10 minutes and the residue distilled from water containing a few drops of dilute sulphuric acid and a little Zn dust. The distillate was treated with 2,4-dinitrophenylhydrazine in dilute sulphuric acid and the precipitate (10 mg), purified by chromatography on bentonite–celite (1:1 by volume) and crystallization from benzene, was identified as the benzaldehyde derivative by melting point and mixed melting point.

Treatment of the Adduct (III) with Acetic Anhydride

The adduct (0.49 g) was suspended in acetic anhydride (3 ml) and sulphuric acid added dropwise with shaking until the solid had dissolved (about 10 drops). After 24 hours the precipitate (240 mg; m.p. 184–190°) was collected and crystallized from ethyl acetate to give the sultone, m.p. 190–191.5°. (Oliveri-Mandalà *et al.* (1) give 187–188°.) Calc. for $C_{26}H_{16}O_3S$: C, 76.45; H, 3.95; O, 11.75; S, 7.85%. Found: C, 75.87, 76.26; H, 3.72; 4.16; O, 12.30; S, 7.97%. The substance showed λ_{max} 450, 384, 366, 346, 289, 238 (inf) (ϵ, 6,200, 14,600, 15,100, 12,900, 11,700, and 14,000 respectively) in the ultraviolet.

Careful examination of the mother liquor in the manner previously described (1), and by chromatography failed to reveal any trace of the substance, m.p. 195–196°, reported by Oliveri-Mandalà *et al.* (1).

Hydrolysis of the Sultone (IV)

The sultone (999 mg) was refluxed in aqueous ethanol (80%; 800 ml) containing sodium hydroxide (32 g) until solution was complete (1 hour) and 1 hour further. After acidification the product was isolated by extraction with ethyl acetate. This was washed with saturated sodium sulphate solution and concentrated to 70 ml. The lower aqueous layer which separated was then further extracted with ethyl acetate and the organic phases dried over sodium sulphate,[2] evaporated to dryness, and added to a silica column (50 g) in benzene. Elution with chloroform gave benzoic acid (317 mg, 1.06 molecule equivalent) identified by melting point and mixed melting point and infrared spectrum with an authentic specimen.

Elution of the column with ethanol–chloroform (1:4) gave a crystalline mixture. This was extracted with boiling ethyl acetate and the residue crystallized from ethanol to give the sulphonic acid sodium salt (V), m.p. 280° (decomp.). Calc. for $C_{19}H_{13}O_3SNa.\frac{1}{2}H_2O$, C, 64.56; H, 3.99; S, 9.07; Na_2SO_4, 20.11%. Found: C, 64.16; H, 3.93; S, 8.92; ash (sulphated), 20.12%. The substance showed λ_{max} 350, 343, 328, 314, 264, 251, 233 mμ (ϵ 6,700, 6,700, 13,900, 9,200, 3,600, 2,800, 39,600 respectively) in the ultraviolet.

Ozonolysis of the Sulphonic Acid, Sodium Salt (V)

The sodium salt (49.5 mg) in ethanol (5 ml) was treated with a stream of ozone at −20° until the yellow color was discharged (about 10 minutes). Hydrogen peroxide (30%; 0.25 ml) was added, followed by sodium hydroxide solution (10%; 1 ml) and the mixture refluxed 30 minutes. After acidification the orange-yellow precipitate (18.4 mg, m.p. 218–221°) was recrystallized from ethyl acetate to give 3-hydroxy-2-phenylperinaphthenone, m.p. 219–221°, undepressed on admixture with an authentic specimen. The infrared spectra were superposable.

[2]*The sulphonic acid, being a strong acid, exchanged with the sodium sulphate, probably on drying.*

Ozonolysis of 3-Hydroxy-2-phenylperinaphthenone

The perinaphthenone, 18.4 mg, in alcohol (10 ml) was treated with ozonized oxygen at ca. −25° until just colorless. Water (100 ml) containing sodium hydroxide (80 mg) and hydrogen peroxide (30%; 0.2 ml) was added and the solution was concentrated on the steam bath to ca. 5 ml, cooled, and acidified. The precipitate was collected and crystallized from acetic acid containing a drop of acetic anhydride to furnish naphthalic anhydride (9.0 mg), m.p. and mixed m.p. 270–271°, further identified by the infrared spectrum.

The aqueous filtrate from which the naphthalic anhydride had separated was extracted with ether (3×10 ml). Evaporation of the extracts and sublimation of the residue followed by recrystallization from water gave benzoic acid (3.5 mg), m.p. and mixed m.p. 120–122°.

ACKNOWLEDGMENTS

We wish to thank Imperial Oil of Canada, Ltd., and the National Research Council of Canada for financial support. We are grateful to Dr. J. B. Stothers for the determination of the n.m.r. spectra.

METAL OXIDE ALKOXIDE POLYMERS

PART IV. THE HYDROLYSIS OF SOME TANTALUM ALKOXIDES[1]

D. C. BRADLEY[2] AND H. HOLLOWAY[3]
The Department of Chemistry, Birkbeck College, London, W.C.1, England
Received June 21, 1961

ABSTRACT

Ebulliometric studies on the hydrolysis of tantalum pentaalkoxides $Ta(OR)_5$, where R = Me, Pr^n, Bu^n, and Bu^s, have furnished important data on the polymeric nature of tantalum oxide alkoxides. It is shown from the variation of number-average degrees of polymerization as a function of degree of hydrolysis that the polymers conform to certain structural models. The structural models involve 6-co-ordinated tantalum.

INTRODUCTION

Recent work on the controlled hydrolysis of the tetraalkoxides of titanium (1, 2) and zirconium (3, 4) has revealed that the polymeric metal oxide alkoxides thus formed conform to certain structural models based on octahedral 6-co-ordination of the metal. These structural models give rise to unique equations describing the dependence of the number-average degree of polymerization on the degree of hydrolysis. A remarkable feature of these series of co-ordination – condensation polymers is that for a given degree of hydrolysis the number-average degree of polymerization is independent of the distribution of polymer sizes. The fundamental nature of these structural models was foreshadowed by our results on the products of hydrolysis of tantalum pentaethoxide in which the quinquevalent metal also appears to assume a co-ordination number of six. The introduction of a single parameter, namely the proportion of tantalum atoms conforming to one of the two appropriate structural models, was sufficient to define the number-average degree of polymerization as a function of degree of hydrolysis over a considerable range of hydrolysis. In order to test further the validity of the theory we have extended the work to include the hydrolysis of other tantalum pentaalkoxides which were amenable to study by the ebulliometric technique. We now report the results of the hydrolysis of the following alkoxides: $Ta(OR)_5$, where R = Me, Pr^n, Bu^n, and Bu^s.

EXPERIMENTAL AND RESULTS

Preparation of Tantalum Alkoxides

The pentaalkoxides were prepared using previously described procedures (6, 7) based on two methods: (i) the reaction involving $TaCl_5$ and the appropriate alcohol in the presence of excess of ammonia, (ii) alcoholysis of a lower alkoxide. We found that tantalum penta-*sec*-butoxide could be synthesized by the alcoholysis involving tantalum pentamethoxide and excess *sec*-butanol in benzene. Removal of the liberated methanol was achieved by fractional distillation of the minimum boiling binary azeotrope $MeOH/C_6H_6$. This result was of interest since Bradley *et al.* (8) have reported that tantalum pentaisopropoxide cannot be obtained by alcoholysis of the pentamethoxide because the reaction ceases with the formation of the stable mixed alkoxide $Ta(OMe)(OPr^i)_4$.

Drying of the Alcohols

Methanol

Absolute methanol was refluxed over magnesium methoxide for 4 hours and distilled. The distillate was kept in contact with "molecular sieve" granules in an all-glass apparatus and samples were withdrawn under an atmosphere of dry nitrogen.

Propanol

Commercially available *n*-propanol was dried and purified by "azeotropic drying" after the addition of benzene. The water was removed as the ternary minimum boiling azeotrope $Pr^nOH/C_6H_6/H_2O$, b.p. 69° C, and then the benzene as the binary azeotrope Pr^nOH/C_6H_6, b.p. 89° C. Fractionation was carried out at a very high reflux ratio in a Podbielniak column (150 cm long) with an efficiency of approximately 80 theoretical plates. The pure *n*-propanol was stored in contact with molecular sieve (Linde type 4A, previously dried at 210° C at 0.01 mm for 16 hours). The molecular-sieve drying apparatus consisted of a glass column (120 cm×2.5 cm diameter) surmounted by a reservoir (approx. 1 liter) and fitted with a grease-free ground-glass tap at the base of the column.

n-Butanol and sec-Butanol

Since these alcohols do not form ternary azeotropes with benzene and water the "azeotropic drying" was effected by the addition of ethanol, followed by fractional distillation to remove, in turn, the ternary azeotrope $EtOH/C_6H_6/H_2O$, b.p. 65° C; the binary azeotrope $EtOH/C_6H_6$, b.p. 68° C; and the remaining benzene, b.p. 80° C. Finally the butanol was distilled into a molecular-sieve column and dispensed under dry nitrogen.

The water content was shown in all cases to be less than 0.005% by the Karl Fischer method.

Ebulliometric Technique and Results

An all-glass ebulliometer using a differential water thermometer was used as described in Part II (5). The alkoxides were freshly distilled *in vacuo* immediately prior to the ebulliometric hydrolysis.

Tantalum Methoxide

Three separate experiments, each involving several additions of solute, were carried out on the determination of the molecular weight of tantalum pentamethoxide in boiling methanol. The elevation of the boiling point was a linear function of solute concentration within the probable experimental error over a wide concentration range (0.0195–0.330 g-mol./kg methanol). The three values for the number-average degree of polymerization, 1.78, 1.75, 1.74, gave an average of 1.76 ± 0.02. This value is significantly higher than that reported earlier (6).

The results of the ebulliometric hydrolysis of tantalum methoxide in two seperate experiments are reported in Table I, where n is the observed number-average degree of polymerization of the tantalum oxide methoxide of degree of hydrolysis h (number of g-mol. H_2O per g-atom Ta). No precipitation was observed in these experiments, which were terminated when the elevation of the boiling point became too low to be measured with reasonable accuracy.

Tantalum n-Propoxide

Two separate determinations of the molecular weight of tantalum penta-*n*-propoxide in *n*-propanol, each involving several additions of solute over a range of concentration (0.02–0.12 g-mol./kg), gave values of 1.62 and 1.57 for the number-average degree of polymerization for the alkoxide. The average value 1.59 ± 0.03 was taken. There was no evidence of concentration dependence of the molecular weight over the wide range of

when characteristic fluctuations in the thermometer reading indicated the presence of traces of water.

Tantalum sec-Butoxide

Two separate determinations of the molecular weight of $Ta(OBu^s)_5$ in boiling *sec*-butanol gave number-average degrees of polymerization of 1.08 and 1.06. The mean value of 1.07 ± 0.01 was taken for subsequent calculations. The measurements were made over a concentration range of approximately 0.0073–0.052 g-mol./kg and no evidence for a concentration dependence of molecular weight was detected. The results of two ebulliometric hydrolyses are recorded in Table III. No precipitation was observed but fluctuations of the thermometer reading at $h > 1.6$ indicated the presence of traces of water.

TABLE III

Initial concentration of $Ta(OBu^s)_5$ = 0.0982 g-mol/kg							
h	0.080	0.234	0.357	0.477	0.604	0.740	0.870
n	1.18	1.33	1.47	1.60	1.78	2.02	2.33

Initial concentration of $Ta(OBu^s)_5$ = 0.0861 g-mol./kg							
h	0.120	0.269	0.412	0.540	0.660	0.833	
n	1.22	1.39	1.54	1.70	1.90	2.26	
h	1.005	1.175	1.37	1.48	1.61		
n	2.79	3.59	5.37	7.22	10.1		

Tantalum n-Butoxide

Separate determinations of the molecular weight of $Ta(OBu^n)_5$ over the concentration range 0.00398–0.0308 g-mol./kg gave values of 1.34 and 1.37 for the number-average degree of polymerization, with no indication of concentration effects. The average value of 1.36 ± 0.02 was taken. In the ebulliometric hydrolysis of $Ta(OBu^n)_5$ it was found that the addition of aqueous *n*-butanol to the boiling solution of the tantalum compound caused an immediate *increase* in the elevation of the boiling point (ΔT). This was followed by a slow decrease in ΔT until a steady value was reached which was lower than the original value. This behavior was probably due to the partition of water between solution and vapor phases, coupled with a slow hydrolysis of $Ta(OBu^n)_5$. In the early stages of hydrolysis the time required to reach a steady value of ΔT after an increment $\Delta h \sim 0.2$ was about 45 minutes but in the later stages hydrolysis was slower and over 90 minutes was required to reach a steady ΔT. The ebulliometric measurements in boiling *n*-butanol were less accurate than in the other alcohols due to technical problems caused by the high boiling point of *n*-butanol. Elaborate precautions against heat loss by the thermometer were required. Also, the water thermometer was so sensitive at this temperature that random fluctuations in the temperatures of the two bulbs made accurate reading difficult. The results for two ebulliometric hydrolyses are recorded in Table IV. No

TABLE IV

Initial concentration of $Ta(OBu^n)_5$ = 0.0617 g-mol./kg								
h	0.300	0.659	0.838	1.26	1.46	1.71	1.95

n_{calc}	1.36	1.44	1.53	1.72	2.01	2.37		

precipitation was observed but at $h > 2$ addition of water produced an increase in ΔT which persisted for over 2 hours and indicated the presence of water.

DISCUSSION

Tantalum Oxide Methoxides

It is clear from the plot of n versus h in Fig. 1 that for h = 0–1.15, the tantalum oxide methoxides conform substantially to the bilinear polymer series based in structural model II, as was found for the tantalum oxide ethoxides (5). However, it is also evident from the lower number-average degree of polymerization for tantalum pentamethoxide compared with the pentaethoxide that a higher proportion of monomer species must be present in the tantalum oxide methoxide system. Following the procedure developed in Part II (5) we have taken all of the data from h = 0 to 1.15 inclusive and determined by the method of least squares the best fit for n^{-1} versus h. The equation $n^{-1} = 0.5721 - 0.3929h$ was thus derived and the coefficient of variation for the percentage error in n, $\sigma_n = \sqrt{[\Sigma\ (100\delta n/n)^2/(m-1)]}$ (where $\delta n = n_{calc} - n$, and m is the number of points), for the 19 points was $\pm 2.8\%$. There were 13 changes in sign in δn, showing that the linear equation was statistically valid. Values of n_{calc} from the least-squares equation are given in Table I. Examination of the errors ($\delta n = n_{calc} - n$) showed that the major contribution was caused by the last 3 points (h = 1.00, 1.13, and 1.15) and that the coefficient of variation for the first 16 points was $\pm 1.65\%$, which is close to the error ($\pm 1.2\%$) in determining the molecular weight of tantalum methoxide. Moreover, extrapolation of

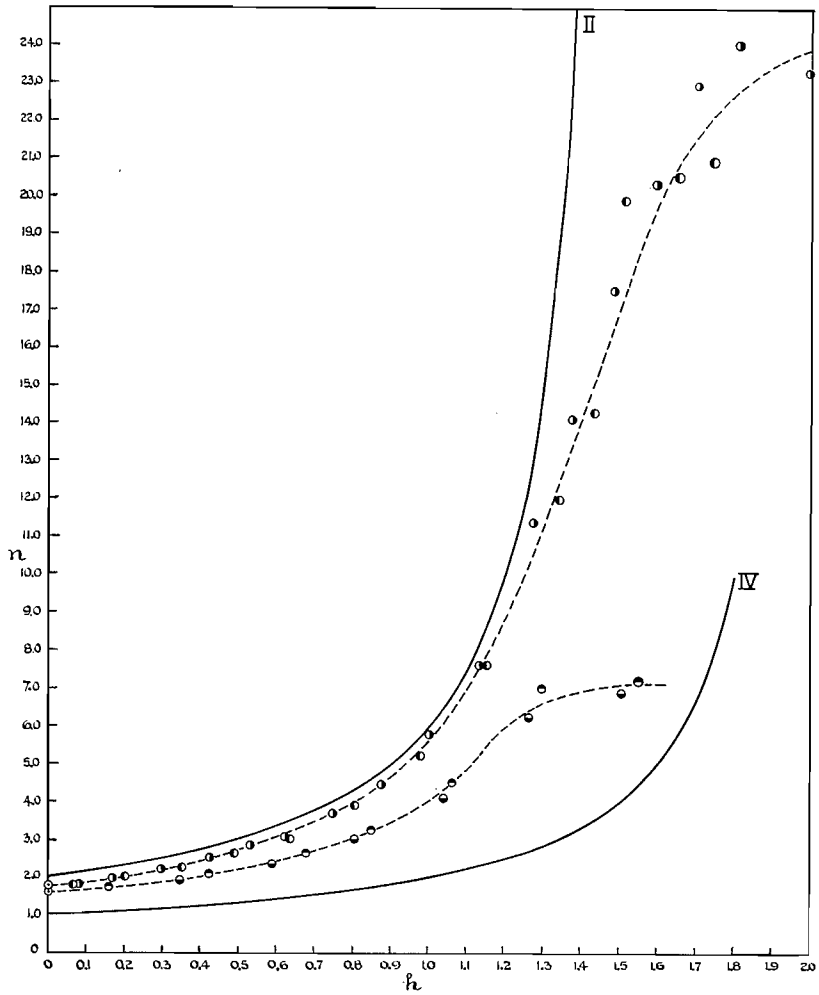

FIG. 1. The variation of n with h for tantalum oxide methoxides and oxide n-propoxides: ◐, tantalum oxide methoxides (Table I); ◑, tantalum oxide methoxides (Table II); ◓, tantalum oxide n-propoxides (Table III); ◒, tantalum oxide n-propoxides (Table IV); curve II, $n = 6/(3-2h)$; curve IV, $n = 2/(2-h)$.

the least-squares equation for the tantalum oxide methoxides to $h = 0$ leads to a value for n_0, the number-average degree of polymerization of tantalum methoxide, of 1.75, compared with the experimental value of 1.76 ± 0.02. Let us now consider the problem of which polymer series based on the solvated monomer $Ta(OMe)_5$,MeOH is present with model II. The intercept $n^{-1} = 0.5721$ ($h = 0$) shows that α_{II} (5), the proportion of metal atoms in the dimer series, is equal to 0.856 (cf. 0.908 for the tantalum oxide ethoxides) but this does not determine which monomer series is present. However, the slope $d(n^{-1})/dh$ is determined by which monomer species is present. Thus we showed for the tantalum oxide ethoxides (5) that for a system involving a mixture of the dimer series model II with the monomer series model III the predicted slope was -0.333_4, but for the mixture of model II and the monomer model IV the slope was $-(0.5000-0.166_7\alpha_{II})$. Substituting the value of α_{II} in the last expression gives a calculated slope of -0.357 to be compared with the slope -0.393 obtained for the least-squares equation. Clearly the

experimental slope favors the model II – model IV system for the tantalum oxide methoxides. For values of $h > 1.3$ it is evident from Fig. 1 that α_{II} is decreasing as solvation becomes more extensive and model IV is favored. This type of behavior has also been noted in the oxide alkoxides of titanium (1, 2) and zirconium (3, 4) and is believed to be due to the decrease in molar concentration which results from the formation of higher polymers. An interesting feature of the ebulliometric experiments on the hydrolysis of tantalum methoxide was the absence of precipitation even up to $h = 1.94$. Thus the model II polymer series predicts infinite polymers at $h = 1.5$ and these would presumably be insoluble. As in the case of the tantalum oxide ethoxides at $h > 1.5$ we suggest that disproportionation may be taking place, so that h for the species in model (h_{II}) is <1.5 (i.e. gives soluble species) while $h_{IV} > 1.5$. The limitation will be that h_{IV} must not reach 2.0 since this model gives an infinite polymer at $h_{IV} = 2$. It is noteworthy that the deviations of the experimental points from curve II become very marked at around $h = 1.6$ and it seems likely that for $h > 1.6$ the hydrolysis is incomplete due to the formation of Ta—OH bonds which are stable in solution. The presence of traces of water in this system would not cause the characteristic fluctuations of the thermometer readings noted in experiments involving the higher alcohols and would thus not be detectable.

Tantalum Oxide n-Propoxides

In Fig. 1 it can be seen that the number-average degrees of polymerization for tantalum oxide *n*-propoxides are between the values calculated for the dimer and monomer models from $h = 0$ to 1.06. However, the lower value of n_0 (1.59, cf. 1.76 for the methoxide) suggests that there should be a smaller proportion of model II species than was found in the oxide methoxides. This low value of n_0 is probably due to the higher boiling point of *n*-propanol compared with methanol since it has been suggested (1, 2, 3, 9) that a higher temperature causes depolymerization of the metal alkoxide co-ordination polymers and the metal is forced to maintain its higher co-ordination by the solvation mechanism. The experimental data for $n = 0$–1.06 were treated by the method of least squares to determine the best straight line for the variation of n^{-1} with h. The equation $n^{-1} = 0.6382 - 0.3838h$ was obtained and there were six changes of sign of δn when the 11 points were arranged in ascending order of h, showing that the straight line was statistically valid. The values of n_{calc} are given in Table II. The coefficient of variation for the percentage errors in n was $\pm 1.83\%$, which is near the probable experimental error. From the intercept at $h = 0$ a value for $n_0 = 1.57$ was obtained which is in good agreement with the value 1.59 ± 0.03 obtained from the measurements on tantalum penta-*n*-propoxide. The intercept also corresponds to $\alpha_{II} = 0.724$ for the proportion of model II species in the system. This value of α_{II} leads to a calculated value of -0.379 for the slope $d(n^{-1})/dh$, assuming that the structural model IV is present with model II, whereas for model III and model II the slope must be -0.333_4. The least-squares value of the slope is -0.384, in good agreement with that calculated for the participation of model IV. It appears from the data in Fig. 1 that for $h > 1.06$ increasing solvation (decrease in α_{II}) becomes quite marked and is greater than that found in the tantalum oxide methoxides. The behavior of the thermometer at $h = 1.6$ indicated the presence of traces of water and there seems little doubt that hydrolysis is incomplete at $h > 1.6$.

Tantalum Oxide sec-Butoxides

Tantalum *sec*-butoxide was of special interest because it is practically monomeric in both benzene ($n_0 = 1.06$) (7) and *sec*-butanol ($n_0 = 1.07$). Since benzene could hardly be regarded as a good donor solvent it is assumed that polymerization of the alkoxide

is prevented by the steric effect of the bulky alkoxide groups. Thus the tantalum penta-*sec*-butoxide has its tantalum predominantly in the 5-co-ordinated form in boiling benzene and this might still be true in boiling *sec*-butanol. However, in the latter solvent it is possible that the monomeric species is solvated as $Ta(OBu^s)_5,Bu^sOH$ and the tantalum is 6-co-ordinated because steric effects are smaller in the solvated monomer than in the dimer. This is evident from the drawings in Fig 2. For example, in the dimer the steric

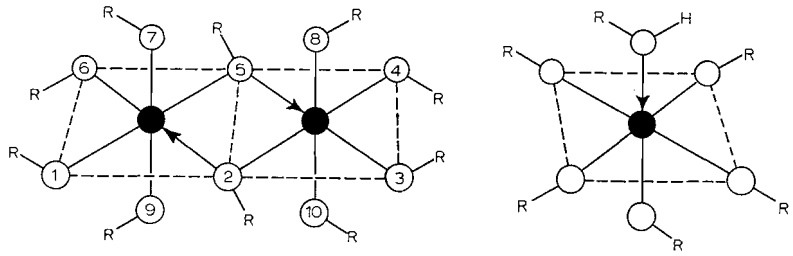

FIG. 2. $Ta_2(OR)_{10}$ and $Ta(OR)_5,ROH$: ●, Ta.

effects are strongest in the bridging alkoxide groups 2 and 5 since they are equidistant from six neighboring alkoxide groups. Next in steric effect are the four apical groups 7, 8, 9, and 10, which are each equidistant from five neighbors, while the least steric interaction is experienced by the four terminal groups 1, 3, 4, and 6, which have only four nearest neighbors. In the solvated monomer the steric interaction must be considerably less because each alkoxide group has only four nearest neighbors. However, as a result of hydrolysis and the formation of Ta.O.Ta groups (condensation polymerization) the alkoxide groups are progressively removed and the steric effects in the tantalum oxide *sec*-butoxides will be smaller than in the penta-*sec*-butoxide. In Fig. 3 we depict polymers

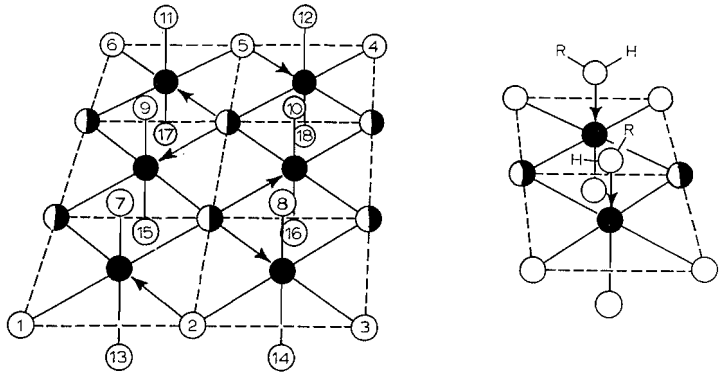

FIG. 3. $Ta_6O_6(OR)_{18}$ and $Ta_2O_2(OR)_6,(ROH)_2$: ●, Ta; ◑, oxygen attached to Ta only. R groups omitted from OR groups.

from the dimer series model II $Ta_6O_6(OR)_{18}$, and the monomer series model IV $Ta_2O_2(OR)_6,(ROH)_2$, both having the same value of h. Comparing first the model II polymer (Fig. 3) with the dimer (Fig. 2) we note that the proportion of highly hindered bridging alkoxide groups (2 and 5) is reduced from 1/5 in $Ta_2(OR)_{10}$ to 1/9 in $Ta_6O_6(OR)_{18}$. Moreover, the apical groups 7, 8, 11, 12, 13, 14, 17, and 18 have only four nearest-neighbor alkoxide groups and groups 9, 10, 15, and 16 have only three nearest neighbors compared with the apical groups in the dimer $Ta_2(OR)_{10}$, which have five. Also,

the terminal alkoxide groups 1, 3, 4, and 6 in $Ta_6O_6(OR)_{18}$ have only three nearest-neighbor akoxides whereas in $Ta_2(OR)_{10}$ the terminal groups have four nearest neighbors. Evidently the steric hindrance per alkoxide group to the formation of $Ta_6O_6(OR)_{18}$ will be considerably smaller than in $Ta_2(OR)_{10}$ and this release of steric strain is cumulative as the degree of hydrolysis increases. There is also a decrease in steric interaction on passing from $Ta(OR)_5$,ROH (all OR groups have four nearest neighbors) to the model IV polymer $Ta_2O_2(OR)_6$,$(ROH)_2$ (all OR groups have three nearest neighbors). It was clear from this analysis of steric factors that the polymeric nature of the tantalum oxide *sec*-butoxides might show some novel features.

The variation of n with h for these compounds is shown in Fig. 4 where it is clear

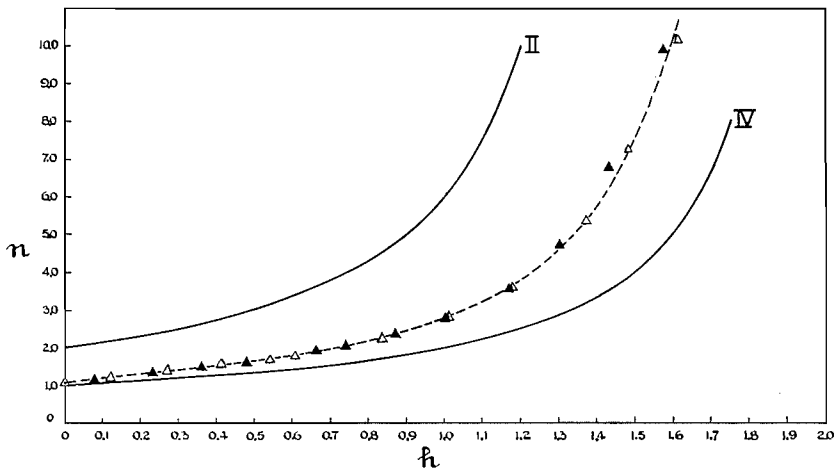

FIG. 4. The variation of n with h for tantalum oxide *sec*-butoxides: ▲, from Table V; △, from Table VI; curve II, $n = 6/(3-2h)$; curve IV, $n = 2/(2-h)$.

that experimental points deviate away from curve IV as h increases. A plot of n^{-1} against h showed curvature at the lowest and also at the highest values of h, with an intermediate region ($h = 0.3$ to 1.3) which was approximately linear.

Applying the method of least squares to the data between $h = 0.357$ and $h = 1.30$ inclusive gave the equation $n^{-1} = 0.857-0.494h$. Extrapolation to $h = 0$ for n_0 resulted in the value of $\alpha_{II} = 0.286$. Hence for a system consisting of models II and IV the calculated value of $d(n^{-1})/dh$ is -0.45 compared with the least-squares slope of -0.49 and the calculated slope of -0.33 for a system consisting of models II and III. Accordingly we conclude that over the range $h = 0.36$–1.3 the polymers conform to the structural models II and IV. Values for α_{II} were then calculated for each value of n from $h = 0$ to 1.61 and the results are shown graphically in Fig. 5. The rapid initial increase in α_{II} is quite striking and suggests strongly that the increase in the proportion of the model II polymers is due to the relief of steric hindrance as the branched alkoxides are removed in the hydrolysis. The continued steady rise in α_{II} over the rest of the range is not surprising, since our analysis of the steric interactions in the model II series of polymers showed that the steric hindrance becomes steadily less with increase in the degree of hydrolysis. However, it would be expected that as the bilinear polymer became large the steric factor would gradually become constant. Unfortunately our ebulliometric investigations were limited by the detection of water in the system at $h > 1.6$ presumably due to incomplete hydrolysis.

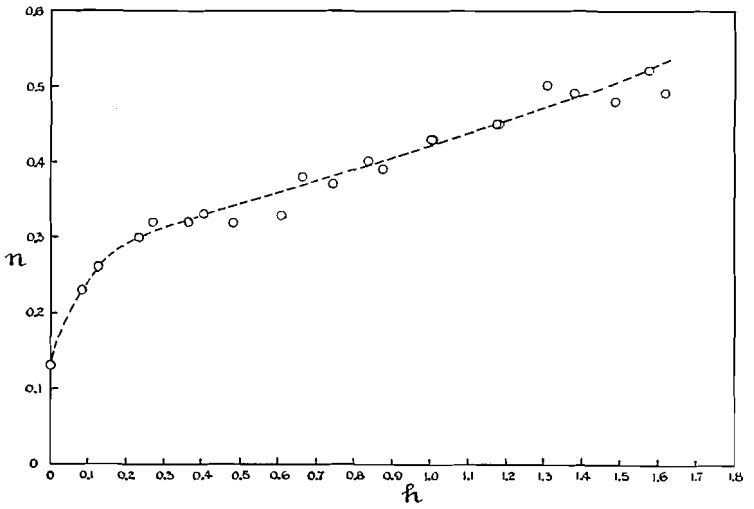

FIG. 5. The variation of α_{II} with h for tantalum oxide *sec*-butoxides.

Tantalum Oxide n-Butoxides

Tantalum penta-*n*-butoxide is dimeric in boiling benzene whereas in boiling *n*-butanol $n_0 = 1.36 \pm 0.02$. It seems reasonable to assume that the lower value in the alcohol is a result of solvation and that a considerable proportion of the monomer species is present. The results shown graphically in Fig. 6 indicate that the tantalum oxide

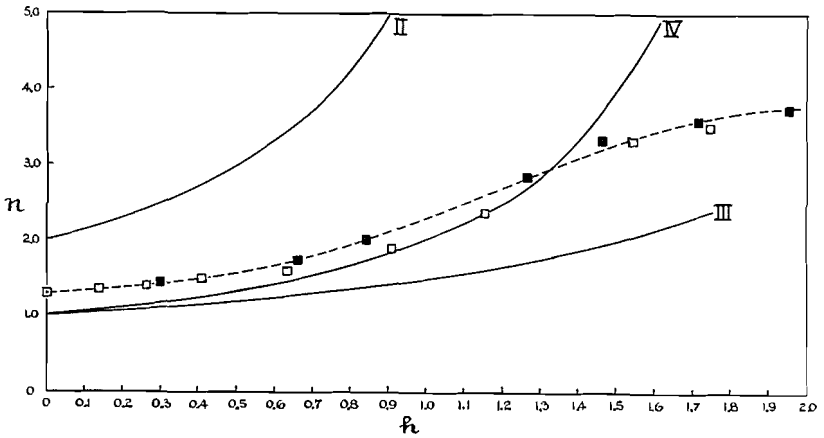

FIG. 6. The variation of n with h for tantalum oxide *n*-butoxides: ■, from Table VII; □, from Table VIII; curve II, $n = 6/(3-2h)$; curve III, $n = 3/(3-h)$; curve IV, $n = 2/(2-h)$.

n-butoxides contain a considerable proportion of polymers based on the model III or model IV series together with the model II polymers. However, a plot of n^{-1} versus h showed some unusual features. For example, there was pronounced curvature at both ends of the graph whilst in the middle section the scatter in the points was rather marked, with the values from one experiment following a slightly different path from that followed by the data from the second experiment. The curvature at high values of h is typical and is probably caused by incomplete hydrolysis but the curvature at low values of h

is perplexing since it is in the opposite sense to that observed in the hydrolysis of $Ta(OBu^s)_5$. Thus it appears that the degrees of polymerization of the tantalum oxide *n*-butoxides are abnormally low in the region $h = 0-0.2$ and two alternative possible explanations seem worthy of consideration. Firstly, there might be some specially preferred species with an abnormally low degree of polymerization which is formed in the early stages of hydrolysis. For example a stable metal–oxygen double bond might give rise to a 6-co-ordinated tantalum species such as $O{=}Ta(OR)_3,(ROH)_2$. Unfortunately this would require the presence of monomeric species at $h = 1.0$ and this is not found to be the case. The second possibility is that, for technical reasons, the hydrolysis may be incomplete in the very early stages of the experiment. This might well be the case due to the high boiling point of *n*-butanol (see the experimental section), which causes a considerable fraction of the added water to assume the vapor state and thus slows down the rate of hydrolysis. If the rate of hydrolysis is some function of the concentration of water in solution then the approach to the true degree of hydrolysis will obviously increase with increasing h. Since the hydrolysis is cumulative the error due to incomplete hydrolysis will become less as h becomes greater. This might also explain the scatter between the results of the two separate experiments. Nevertheless a least-squares fit of n^{-1} versus h for all the points from $h = 0$ to 1.26 gave the line $n^{-1} = 0.778-0.310h$, with a coefficient of variation $\sigma_n = \pm 5\%$. The calculated values of n are listed in Table IV. From the intercept n_0^{-1} ($h = 0$) a value of $\alpha_{II} = 0.44$ for the proportion of dimer species was obtained. Using this value of α_{II} leads to a calculated value of the slope $d(n^{-1})/dh$ of -0.426 for a mixture of model II and model IV polymers. However, the least-squares slope of -0.31 is clearly in much closer agreement with the predicted value of -0.33 required for a mixture of model II and model III polymer species.

CONCLUSIONS

1. The polymeric nature of the products of hydrolysis of tantalum pentaalkoxides can be rationalized in terms of structural models based on 6-co-ordinated tantalum.

2. The number-average degrees of polymerization of tantalum oxide *n*-alkoxides $TaO_x(OR)_{(5-2x)}$, where R = Me, Et, Pr^n, and Bu^n, are accurately described over a considerable range of degrees of hydrolysis by simple linear equations of the form $n^{-1} = a-bh$. From the numerical values of the constants a and b, deductions have been made concerning the participation of different structural models. When R = Me, Et, or Pr^n, the polymers are predominantly based on an unsolvated model II which is related to the dimeric alkoxide $Ta_2(OR)_{10}$ with smaller proportions of either models III or IV, which are related to the solvated monomer $Ta(OR)_5$,ROH. When R = Bu^n the polymers favor model III.

3. The tantalum oxide *sec*-butoxides show an interesting behavior which can be interpreted in terms of the changes in steric hindrance to polymerization as the degree of hydrolysis is increased.

4. The structural models which explain the polymeric nature of tantalum oxide alkoxides are directly related to the ones which were used to explain the behavior of the oxide alkoxides of titanium and zirconium. It appears, therefore, that these structures are of fundamental significance to metal oxide alkoxides in general.

THE SOLUBILITY OF BERYLLIUM OXIDE IN AQUEOUS BERYLLIUM SULPHATE SOLUTIONS

S. L. Bennett and W. J. Biermann
The Parker Chemistry Laboratory, University of Manitoba, Winnipeg, Manitoba
Received July 21, 1961

ABSTRACT

It is observed that ignited beryllium oxide was soluble in concentrated aqueous solutions of beryllium sulphate to the extent of 1 mole of oxide per 2 moles sulphate, saturation being virtually complete within 6 hours at 180° C. Since the molar solubility of aluminum oxide is much lower under similar conditions, it is suggested that partial resolution of oxide mixtures might be made on this basis.

INTRODUCTION

The majority of processes for the preparation of beryllium compounds from beryllium minerals employ a fusion of the mineral, with or without a flux, giving a mixture of oxides which can be taken into solution, usually with sulphuric acid (1, 2). Because beryllium oxide is more slowly dissolved by acids than are the oxides of aluminum, iron, and other accompanying metallic elements, standard procedures involve complete solution of all the metallic constituents, followed by addition of a succession of reagents to remove these until only beryllium compounds remain in solution, at which point beryllium is precipitated as an hydroxide. A solvent having a selective action on beryllium oxide would seem to have potential application by simplifying the chemical metallurgy of beryllium, provided, however, that its net cost were not so great as to wipe out any economies which might be brought about through its use.

Aqueous solutions of beryllium salts are known to dissolve considerable quantities of the carbonate and hydroxide. Some time ago, Sidgwick and Lewis (3) found that upon addition of beryllium carbonate to a concentrated solution of beryllium sulphate, followed by boiling of the mixture to remove carbon dioxide, there is an increase in the solubility of beryllium sulphate. A polynuclear species was postulated in accordance with the data that 1 molecule of salt dissolved for every 4 molecules of oxide added. This suggested to us the possibility that some equivalent compound could be formed between beryllium oxide and soluble beryllium salts. Such a reaction, should it be possible to be brought about, promised to be relatively specific with respect to attack of beryllium oxide in a mixture of metallic oxides, provided no highly basic oxide were present.

EXPERIMENTAL

Both the "nuclear grade" beryllium oxide, supplied by A. D. MacKay, Inc., and the beryllium sulphate tetrahydrate, supplied by Fisher Scientific Co., were analyzed by standard procedures (4, 5) to confirm the absence of any significant amount of foreign material. A solution of beryllium sulphate tetrahydrate, saturated at 22.5° C (0.002704 mole $BeSO_4$/g of saturated solution or 28.41 g $BeSO_4$/100 g saturated solution), was prepared and it was verified that the ratio of equivalents of beryllium and sulphate was unity. The beryllium oxide was ignited to 900° C to insure that no hydroxide would be present.

About 0.5 ml of beryllium sulphate solution and an amount of ignited beryllium oxide slightly in excess of the amount that, from preliminary work, was anticipated to dissolve, were weighed into a piece of heavy-walled Pyrex glass tubing about 1 × 10 cm O.D. and sealed on one end. The excess of solid phase in all runs was taken as an indication that supersaturation effects were unlikely. After a tube was filled the second end was sealed with a flame and the tube placed inside a short length of iron pipe, which was then closed by screwing on perforated caps. The pipe was, of course, intended for the protection of personnel. A

number of these assemblies were then placed in an air thermostat, whose regulation was about ±1° C and then withdrawn after an appropriate time interval.

After cooling, the tubes were broken and the contents washed onto a filter with the aid of distilled water. The undissolved beryllium oxide was collected on the filter, ignited to 900° C, and weighed. This mass, when used in conjunction with the masses of the liquid and solid reactants and the known analysis of the beryllium sulphate solution, permitted a calculation of the mole ratio of beryllium oxide dissolved per mole of beryllium sulphate in the original charge.

Studies were made to show (*a*) the effect of temperature on the amount of beryllium oxide dissolved, as summarized by the upper curve in Fig. 1, (*b*) the effect of time on the amount of beryllium oxide dissolved, as summarized by the upper curve in Fig. 2, and (*c*) the effect of the concentration of beryllium sulphate on the amount of beryllium oxide dissolved, as summarized in Fig. 3. The essential data on which these curves are based are tabulated in Tables I, II, and III.

Because aluminum and beryllium generally occur together in nature, and because of the general chemical similarity of this pair, ignited aluminum oxide was used as the solid reactant in a second series of determinations designed to give some indication of the amount of separation that could be expected. The lower curves of Figs. 1 and 2 summarize the effect of time and of temperature on the solubility of aluminum oxide in beryllium sulphate solutions. The numerical data on which these curves are based are contained in Tables I and II.

DISCUSSION

The data collected indicate that the optimum conditions for dissolving beryllium oxide in beryllium sulphate solutions are 180° C and a time of 6 hours; a high concentration of beryllium sulphate increased the rate of reaction considerably. Figures 1 and 2, and also some isolated runs not included here, indicate that some species with an empirical formula $2BeSO_4.BeO.xH_2O$, very stable in solution, is formed, the rate of formation being favored by high temperatures. The region of stability of this compound must be fairly extensive since highly diluted solutions obtained in washing the undissolved beryllium oxide onto a filter show no tendency to reprecipitate the dissolved beryllium oxide, even when allowed to stand for several months at room temperature. It seems unlikely that this apparent stability can be explained in terms of the inertness sometimes observed

with polynuclear species. Further studies of the chemical nature of this compound will be undertaken on the basis of inherent interest from a chemical, if not metallurgical, viewpoint.

The limited solubility of aluminum oxide is most likely due to its having a basicity similar to that of beryllium oxide and simply displacing some of the aquoberyllium ions from solution, the displaced beryllium then entering into polynuclear formation.

With the existence of a preferential solvent for beryllium oxide and suitable experimental conditions for its use established, this study will be continued by examining specific metallurgical situations in which it appears useful. One of the most obvious situations, of course, would be the partial resolution of the oxide mixture obtained when beryllium is fused and quenched.

ACKNOWLEDGMENT

The authors are much indebted to Sudbay Beryllium Mines, Ltd., for their generous support of our studies of the chemical metallurgy of beryllium.

THE ESTABLISHMENT OF CONFIGURATION IN DIELS–ALDER ADDUCTS BY N.M.R. SPECTROSCOPY[1]

ROBERT R. FRASER
The Department of Chemistry, University of Ottawa, Ottawa, Ontario
Received August 11, 1961

ABSTRACT

It has been shown that the magnetically anisotropic double bond in bicyclic Diels–Alder adducts exerts a paramagnetic effect on protons in an *exo* configuration and a diamagnetic effect on protons in an *endo* configuration. Thus the configuration of a proton or proton-bearing substituent can be ascertained by observing the change in its chemical shift when the double bond is removed by hydrogenation. However, caution must be used in applying the method to compounds in which the double bond bears a magnetically anisotropic substituent.

The Diels–Alder reaction between cyclic dienes and derivatives of ethylene may produce either of two diastereomeric adducts, the *endo* or the *exo* isomer. In most instances the *endo* isomer predominates in accordance with Alder's rule (1). However, exceptions to this rule have been observed (2, 3) so that each new adduct synthesized requires proof of its stereochemistry. Several chemical methods have been employed to establish the configuration of Diels–Alder adducts (4). Lactonization (5), iodolactonization (6), and titrimetric analysis (4) have been used for this purpose with carboxylic acid derivatives of bicyclo[2.2.1]hept-2-ene. The first two suffer the disadvantage that rearrangements do occur under the reaction conditions. Classical degradative procedures (7) are often unambiguous but exceedingly arduous.

The use of physical methods obviates both of these difficulties. Alder and co-workers (3) have employed infrared spectroscopy to assign configurations to the two 5-cyano-bicyclo[2.2.2]oct-2-enes formed from cyclohexadiene and acrylonitrile. Nuclear magnetic resonance has already proved itself capable of differentiating between diastereoisomers in cyclohexanes (8) and cyclopentanes (9) and between geometrical isomers in many olefin derivatives (10, 11). It therefore seemed worth while to investigate the ability of n.m.r. to be used in assigning structures to diastereomeric Diels–Alder adducts.

It has already been found that in the camphane-2,3-diols (12), in α and α' chloro-camphor (13), and in 3,8-cyclocamphor (14) the magnitude of the coupling of an *exo* proton with the adjacent bridgehead proton is larger (4–5 cycles/sec) than when the proton is *endo* (0–1 cycles/sec). Thus when such a proton is well separated from the rest of the absorption pattern, the size of its spin–spin interaction with the bridgehead proton will establish the configuration of the compound. A more general method would be possible if the chemical shift of a proton could be correlated with its *endo* or *exo* position. To explore this possibility we have examined the spectra of five derivatives of bicyclo[2.2.1]hept-2-ene whose configurations had been previously established (22). These are the two diastereomeric adducts of α-methacrylic acid and cyclopentadiene, the two adducts of *trans*-crotonic acid and cyclopentadiene, and the *exo* adduct of methyl methacrylate and cyclopentadiene. After removal of the double bond by hydrogenation, the spectra of the five dihydrocompounds were also measured.

[1]*This paper was presented at the 44th Annual Conference of the Chemical Institute of Canada, Montreal, Que., Aug. 3–5, 1961.*

The spectra of 5-*endo*-methylbicyclo[2.2.1]hept-2-ene-5-*exo*-carboxylic acid (I) and its dihydro derivative (II) are illustrated in Fig. 1. The assignments in A are as follows. The

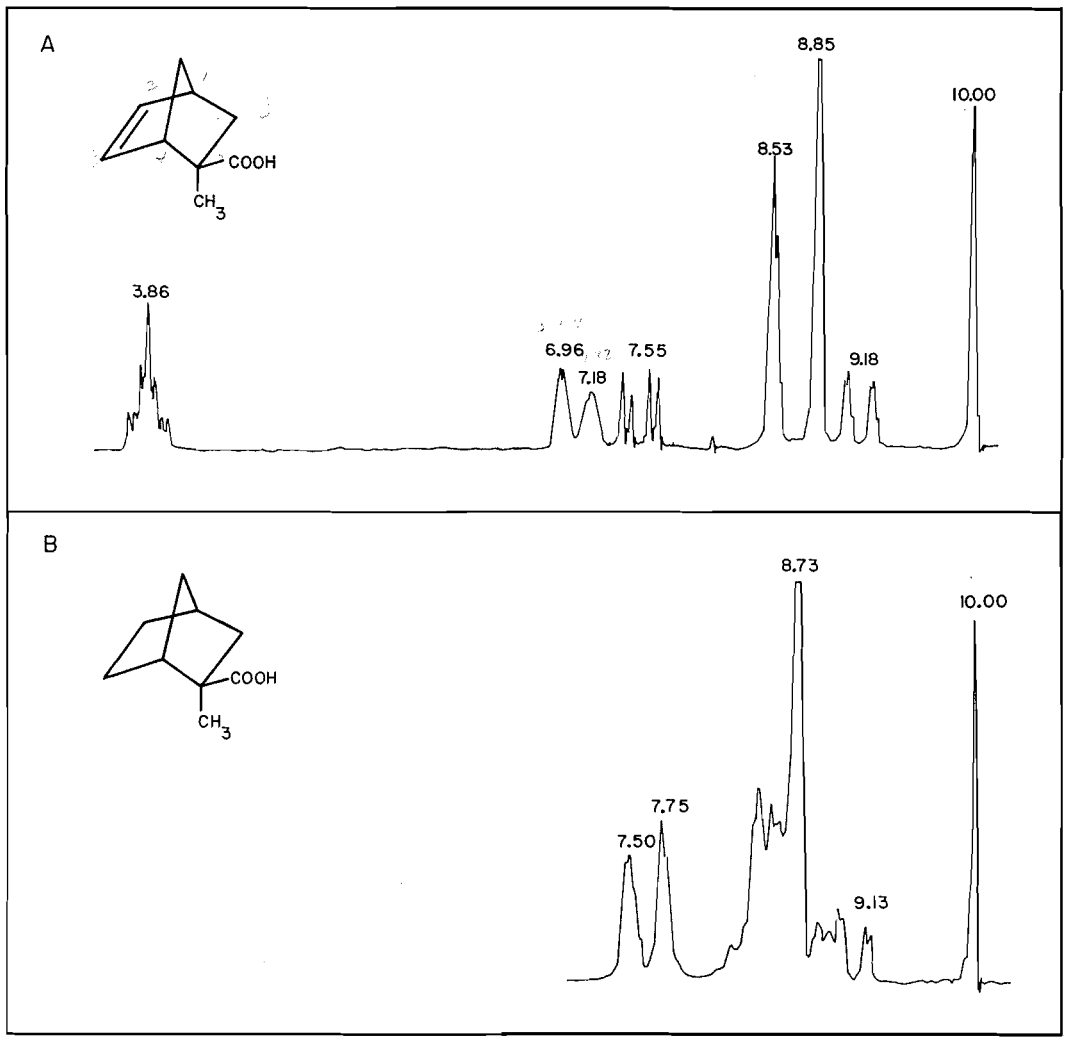

FIG. 1. (A) Spectrum of 5-*endo*-methylbicyclo[2.2.1]hept-2-ene-5-*exo*-carboxylic acid (I). (B) Spectrum of 5-*endo*-methylbicyclo[2.2.1]heptane-5-*exo*-carboxylic acid (II). The chemical shifts are given as τ values.

multiplet at low field has a τ value of 3.86, characteristic of protons attached to a carbon–carbon double bond (15). The two broad peaks at 6.96 and 7.18 τ are assigned to the two bridgehead protons at C_4 and C_1 (15), although the reverse assignment is not excluded. The quartet centered at 7.55 τ represents a proton coupled by 12.0 and 3.8 cycles/sec with two other protons. One of these must be the proton at 9.18 τ, which also possesses a 12.0 cycles/sec splitting. The second must be one of the bridgehead protons, as is indicated by the pronounced skewness of the two doublets at 7.55 τ. The peak at 7.55 τ is assigned to the proton in the *exo* C_6 position and the peak at 9.18 τ to the proton in the *endo* C_6 position. This accounts for the large 12.0 cycles/sec geminal coupling constant (16) and the *exo* bridgehead coupling constant of 3.8 cycles/sec. Under

very slow sweep each portion of the doublet at 9.18 τ appeared to be further split into a triplet of spacing 1.0 cycle/sec. This suggests that the *endo* C_6 proton is weakly coupled with a proton two carbons removed, in addition to being coupled slightly with the bridgehead proton. Similar long range coupling has been observed in this ring system previously (12). The remaining peaks at 8.53 and 8.85 τ are assigned, on the basis of their relative intensities, to the hydrogens at C_7 and the methyl group at C_5 respectively. The proton on the carboxyl group occurs at -2.45 and is not shown in the figure.

The spectrum of the hydrogenated adduct (II) shows fewer well-resolved peaks. The two peaks at 7.50 and 7.75 τ are assigned to the protons at the bridgehead positions. The *exo* proton absorption is likely obscured by one of these, presumably the more intense band at 7.75 τ. This assumption is supported by the spectrum of II in benzene, in which solvent a part of the *exo* multiplet is visible between the two bridgehead peaks. The only other identifiable bands are the methyl absorption at 8.73 τ and the band due to the *endo* C_6 proton at 9.13 τ. This is a pair of doublets of spacings 12.0 and 1.0 cycles/sec. The spectra of the other four adducts and their dihydroderivatives were examined and the assignments for individual protons were made in the same way. The chemical shifts of the protons in each of the compounds is given in Fig. 2. Blank spaces are present wherever the proton was not sufficiently separated to allow an unambiguous assignment.

Compound	Olefinic	Bridgehead	Hx	Hn	C_7-H_2	CH_3

FIG. 2. The chemical shifts of all identifiable protons in compounds I–X.

From the beginning it was recognized that the absolute τ value of a proton could not be used to assign its configuration. However, much is now known about the neighboring anisotropy effect from a study of aromatic rings (10, p. 176) and Jackman (17) has cited evidence indicating that a double bond also possesses an appreciable anisotropy. By this effect the absorption frequency of protons which lie above the plane of a double bond* are shifted upfield whereas a downfield frequency shift is experienced by protons which lie in the plane of the double bond (17). Figure 3 illustrates this diagrammatically. Therefore, because it is anisotropic, the double bond in any Diels–Alder adduct will provide

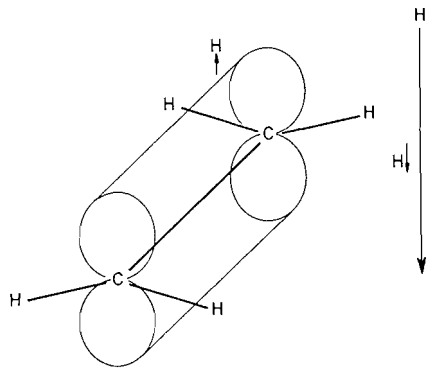

FIG. 3. A diagrammatic illustration of the magnetic anisotropy of the olefinic bond in ethylene. In the presence of a strong field *H*, the proton situated above the plane of the sp^2 bonds experiences a diamagnetic shielding. The proton at the right in the sp^2-bond plane is deshielded by the double bond.

a contribution to the total shielding of all neighboring protons, which will depend in magnitude and in sign upon the spatial position of the proton with respect to the double bond. In the bicyclo[2.2.1]hept-2-enes an *exo* proton is in a position approximately in the plane of the double bond and should therefore be shifted downfield by it. When the double bond is removed by hydrogenation the chemical shift of this *exo* proton should now be at higher field. In other words, if the τ value for the proton in the adduct is τ_1, and in the dihydro adduct is τ_2, then $\Delta\tau = \tau_2 - \tau_1$ represents the change in chemical shift upon hydrogenation and should be positive for an *exo* proton. Since the *endo* proton lies well above the plane of the double bond it should experience a negative $\Delta\tau$ upon hydrogenation. From the data in Fig. 2, all the $\Delta\tau$ values observable for protons in the *exo* and *endo* positions are compiled in Table I. It can be seen that when the proton or

TABLE I

Change in chemical shift ($\Delta\tau$) on hydrogenation

Compounds	H_{endo}	H_{exo}	$CH_{3\ endo}$	$CH_{3\ exo}$
I → II	−.05		−.12	
III → IV				+.18
V → VI		+.14		+.22
VII → VIII			−.12	
IX → X	−.03		−.13	+.05 (ester methyl)

proton-bearing methyl group is *exo* then $\Delta\tau$ is positive, when the proton or methyl group is *endo* then $\Delta\tau$ is negative.

**The "plane of the double bond" refers to the plane passing through the two carbon atoms of the double bond and the four atoms bonded to them.*

The theoretical relation of $\Delta\sigma$, the contribution of anisotropy to the total screening of the proton, with the distance R of the proton from the center of the double bond and the angle θ which the line joining the proton to the center of the double bond makes with the plane of the double bond can be written $\Delta\sigma = k(1/R^3)(1-3\cos^2\theta)$, where k is a constant proportional to the difference in the magnetic susceptibilities in the plane of and perpendicular to the double bond (10, p. 178). From Barton models θ_{exo} was estimated to be 25°, θ_{endo} 60°. The ratio R_{exo}/R_{endo} was measured and found to be 1.26. From these estimates $\Delta\sigma_{exo}/\Delta\sigma_{endo}$ is calculated from the above relationship to be -3.0. This is in reasonable agreement with the observed ratio of $\Delta\tau_{exo}/\Delta\tau_{endo}$, which was $0.14/-0.04 = -3.5$. This provides further justification for the reliability of our results.

We have used the method to establish the configuration of the nitro group in 5-nitronorbornene. This compound was prepared by the addition of nitroethylene to cyclopentadiene following the procedure of Roberts and co-workers (18). The spectra of 5-nitronorbornene and 5-nitronorbornane are reproduced in Fig. 4. In the 5-nitronorbornene spectrum the peaks at 3.87, 5.07, 6.47, and 7.01 τ are assigned to the olefinic protons, the proton on C_5, and the two bridgehead protons, in that order. The multiplet at higher field represents the remaining four protons. The proton at C_5 appears as a quintet of spacing 3.9 cycles/sec. Its structure is attributed to strong coupling (7.8 cycles/sec) with the *exo* proton at C_6 and weak coupling (3.9 cycles/sec) with both the *endo* proton at C_6 and the bridgehead proton at C_4. The magnitude of the C_4–C_5 proton–proton coupling constant indicates that the proton on C_5 is *exo* and that the nitro group is therefore *endo*. The fact that this quintet is shifted upfield upon hydrogenation by 12 cycles/sec ($\Delta\tau = +0.2$) corroborates this conclusion. Thus Robert's tentative assignment of the nitro group to the *endo* position (18) is confirmed.

It is interesting to note that the *endo* and *exo* adducts of benzyne to bicycloheptadiene show the same behavior in their n.m.r. spectra. Simmons (19) has recently published the spectra of both adducts and their hydrogenation products. His data shows that when the aromatic ring is *exo*, $\Delta\tau = +0.05$ for the aromatic protons, and when the ring is *endo* $\Delta\tau = -0.20$. The application of this method need not be confined to the bicyclo[2.2.1]heptane system. In fact we have observed the same behavior in the bicyclo-[2.2.2]octane system (20). The main limitation to its use will be the ability to observe and identify the desired protons in the spectra of both the adduct and its hydrogenation product. It should be noted that, if the double bond bears a substituent other than hydrogen, the method will not necessarily be applicable, especially if the substituent possesses an appreciable magnetic anisotropy. In this case the change in position of this substituent on hydrogenation could produce a greater effect than the removal of the double bond.

EXPERIMENTAL

All spectra were recorded on a Varian V-4302 high-resolution n.m.r. spectrometer operating at a radio frequency of 60 Mc/sec. All spectra were measured on 10% (w/v) solutions in carbon tetrachloride containing 1% of tetramethylsilane as an internal standard. Calibrations were performed by the side-band technique (10, p. 74). All τ values which were employed in calculating $\Delta\tau$'s are the average of six determinations and are accurate to ± 0.6 cycles/sec. The remaining τ values are the average of two determinations and are probably accurate to within 1 cycle/sec.

With the exception of the methyl esters described below, all the compounds were prepared by Alder's procedure (22). The nitroethylene used in the preparation of 5-nitronorbornene was prepared as previously described (21).

5-endo-Methyl-5-exo-carbomethoxybicyclo[2.2.1]hept-2-ene (IX)

To a solution of 1.3 g of 5-*endo*-methylbicyclo[2.2.1]hept-2-ene-5-*exo*-carboxylic acid in 5 ml of ether was added an ethereal solution of diazomethane until the yellow color of diazomethane persisted. The

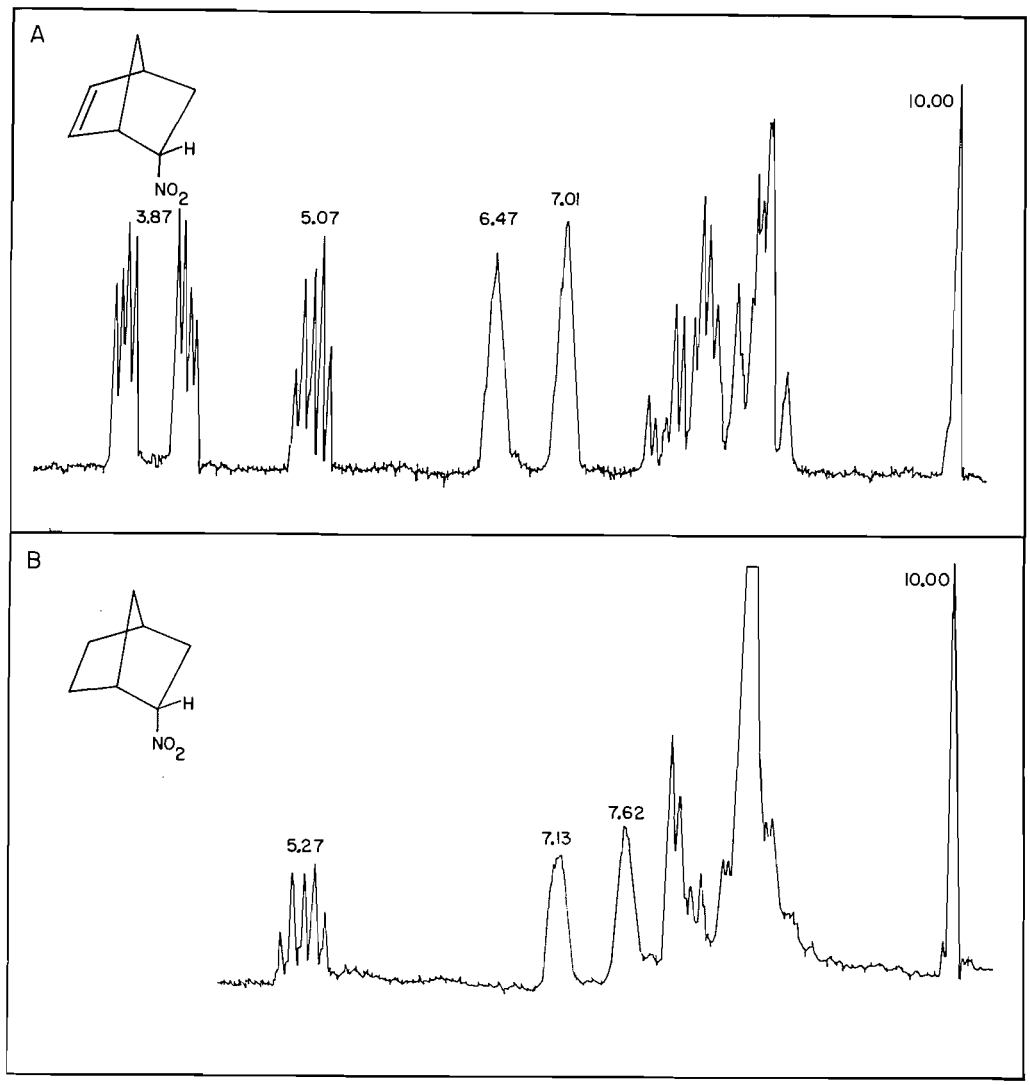

FIG. 4. (A) Spectrum of 5-nitronorbornene. (B) Spectrum of 5-nitronorbornane.

excess of diazomethane and ether was removed by distillation and the residue, 1.3 g, was distilled under reduced pressure to give 1.05 g of liquid, b.p. 62°, 5 mm. Both the infrared and n.m.r. spectra of this liquid showed no trace of an impurity and were completely consistent with the structure IX. Calc. for $C_{10}H_{14}O_2$: C, 73.2; H, 8.5. Found: C, 71.0, 70.8; H, 8.3, 8.1. Repeated analysis gave consistently low C and H values, which is attributed to the very high volatility of this compound.

5-endo-Methyl-5-exo-carbomethoxybicyclo[2.2.1]heptane (X)

A solution of 293 mg of IX in 7 ml of ethyl acetate was added to 7 ml of ethyl acetate containing 29.5 mg of prehydrogenated platinum dioxide in a hydrogenation apparatus. The mixture was stirred at room temperature until the uptake of hydrogen had ceased. The catalyst was removed by filtration through celite and the ethyl acetate was distilled off. The residue, 290 mg, was distilled in a capillary under a reduced pressure of 7 mm. The infrared spectrum of the distillate did not absorb above 3000 cm^{-1}. Calc. for $C_{10}H_{16}O_2$: C, 71.4; H, 9.6. Found: C, 71.8; H, 9.5.

ACKNOWLEDGMENTS

The author wishes to express his thanks to the Imperial Oil Company of Canada for a grant in aid of this research. The financial assistance of the National Research

Council of Canada is also acknowledged. The technical assistance of Mrs. L. Westland and Mrs. N. Stojanac was of great aid to this work. Microanalyses were determined by Miss E. Busk.

INFRARED ABSORPTION OF FORMALDEHYDE AT LOW TEMPERATURES

EVIDENCE FOR MULTIPLE TRAPPING SITES IN AN ARGON MATRIX

K. B. HARVEY AND J. F. OGILVIE[1]

The Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received September 22, 1961

ABSTRACT

The infrared absorption of formaldehyde in both the polycrystalline and the monomeric form has been measured at 4° K. In the latter case the molecules were suspended in an inert matrix of Ar or N_2. The fine structure of the matrix spectra is discussed from the point of view of rotation of the monomers but this interpretation is ruled out in favor of one based on multiple trapping sites in the matrix.

INTRODUCTION

In the past few years, the matrix isolation technique has become established as one of the principal aids in the investigation of free radicals and other chemically reactive species (1, 2, 3). More recently, however, interest has arisen in the physical aspects of the matrix environment particularly as related to the spectra of the trapped molecules. Milligan and his co-workers have published infrared evidence for the rotation of H_2O, D_2O, HDO (4), and NH_3 (5) in inert-gas matrices and were able in the latter case to assign the rotational transitions. Glasel (6) placed the same interpretation on fine structure observed in the O—H stretching region of H_2O in matrices of Xe and Ar. In the field of electronic spectroscopy, Robinson and McCarty have explained the spectrum of trapped NH_2 radicals in terms of rotation (7), and have achieved also considerable success in the theoretical interpretation of spectral shifts using a Lennard-Jones (6–12) potential function to represent the interaction between the trapped atoms or simple molecules and the matrix (8). The present high-resolution infrared study was undertaken with a view to providing further information on the interactions which take place between the matrix and trapped molecules. In particular, it provides optical spectroscopic evidence for multiple trapping sites, a feature which has also been investigated by electron spin resonance (9, 10).

EXPERIMENTAL

The low-temperature cell constructed for this work is basically of the Duerig–Mador type (11) equipped with optical windows of cesium iodide. The only major modification is a rotatable liquid helium chamber which makes it possible to spray the gaseous sample onto the trapping surface from the side rather than from below. A Au–Cu:Ag–Au thermocouple mounted directly below the cesium iodide trapping surface enables us to measure the approximate temperature of the sample during warmup.

Gaseous mixtures to be investigated were prepared in 5-liter bulbs in ratios determined by the partial pressures of the components. It is interesting that, even though the dilute component was introduced first, proper mixing of the components was not a trivial consideration. It was found necessary to heat parts of the bulb to produce convection currents to ensure effective mixing, and even then care had to be exercised to make certain that no pockets of pure formaldehyde were trapped in side arms etc. No attempt was made to measure absolute flow rates during the deposition of the sample, but reproducible conditions could be obtained through pressure measurements on the low-pressure side of the controlling needle valve.

The formaldehyde vapor was produced by heating paraformaldehyde (polyoxymethylene) until the required pressure of vapor was obtained in the bulb. Considerable care was taken to make certain that the paraformaldehyde contained a minimum of water, as indicated by its infrared spectrum. The purest material was that precipitated from a basic formalin solution (12) and then well dried under vacuum. Absorption in the O—H stretching region was very weak and since the O—H units terminate the chains, we were led to

[1]*Present address: Department of Physical Chemistry, University of Cambridge, Cambridge, England.*

the conclusion that the polymer units were quite large. This was further substantiated by the very weak intensity of the band attributable to the C—O stretching mode of the methoxyl group, also at the end of the chain. The matrix materials, Ar and N_2, were analyzed mass spectrometrically and contained less than 40 p.p.m. impurities. They were admitted directly from the gas cylinders, through an evacuated capillary, to the sample bulb to avoid the introduction of impurities through the use of a gas regulator.

Spectroscopic measurements were carried out on a Perkin–Elmer 112G spectrometer with a modified source unit. Calibration was effected through established grating spectra and the reported frequencies are estimated to be precise to ± 2 cm^{-1}. Spectral slit widths are indicated on the individual spectra.

RESULTS

In addition to the matrix isolation spectra, we examined the spectrum of polycrystalline formaldehyde at 4° K and 77° K. Figure 1 shows the more interesting spectra, and the

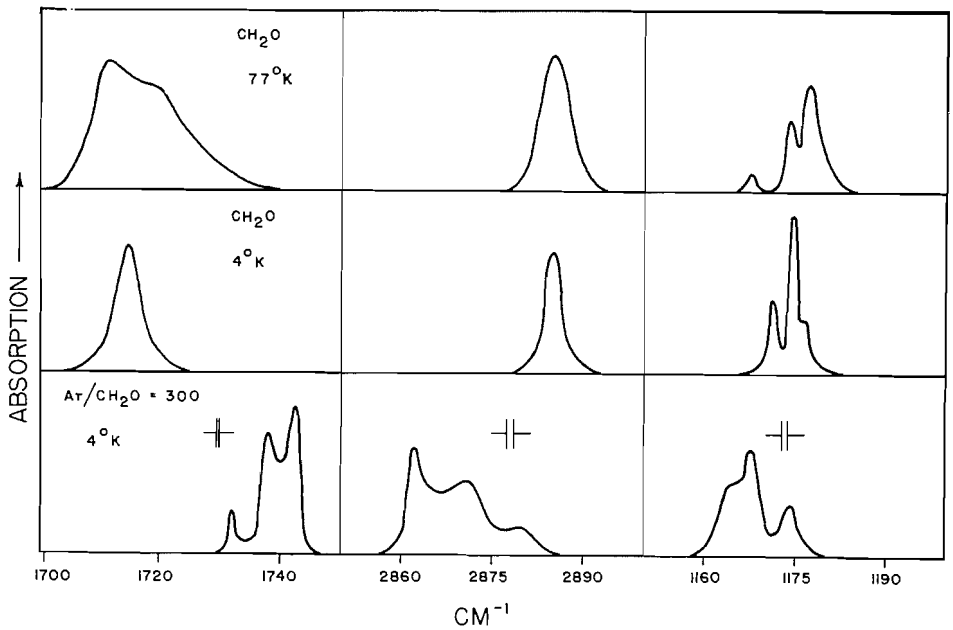

FIG. 1. The fundamentals ν_2, ν_4, and ν_6. Upper spectra are of normal associated CH_2O at 77° K and 4° K, lower spectrum is that of monomer dispersed in argon matrix at 4° K.

observed bands are summarized completely in Table I along with the gas phase measurements of Blau and Nielson (13) and previous low-temperature spectra of Schneider and Bernstein (14). Our results differ significantly from those of the latter authors in the fine structure observed in some of the bands, probably because of the higher resolution and lower temperatures used in our work. None of these lines coincide with those of the higher-temperature modification reported by Schneider and Bernstein, nor did we observe any effects to indicate the presence of two crystalline forms. On the other hand, our films were probably deposited much more slowly and we did not extensively investigate the effect of temperature on the spectrum. Our primary interest was in obtaining spectra of associated molecules at low temperatures for comparison with the matrix spectra.

With regard to the matrix spectra, our chief concern must be to estimate the degree of isolation attained. This can be done in a number of ways, all of which lead us to the conclusion that the matrix spectra are those of isolated monomers. That little or none of the normal associated species is present is confirmed by an inspection of the fundamentals ν_1 and ν_2. In these cases, the shifts from polycrystalline solid to matrix are quite

*The approximate relative intensities are quoted after the frequencies of absorption according to the following abbreviations: vs = very strong, s = strong, m = medium, w = weak, vw = very weak; sh = shoulder.

large and any associated species in the matrix would be readily detected. The presence of smaller polymer units (dimers, trimers, etc.) was investigated by varying the matrix ratio or rate of deposition, and by observing the spectrum of the deposit as it warmed. The mixture used in most cases was $Ar/CH_2O = 300$ but if this were reduced below 100 or so, then spectra of the type shown in Fig. 2 were observed. In the warmup spectra, it will be seen that the lines assigned to monomers disappear as the broadened bands due to absorption by polymers grow in intensity. We may, therefore, assume with reasonable certainty that the absorption of interest is due to monomers.

DISCUSSION

Polycrystalline Solid

There are several possible explanations for the fine structure observed in the spectrum of the crystalline solid. The fundamentals ν_2 and ν_3 both become considerably narrower as the temperature is lowered from 77° K to 4° K, suggesting a rotational envelope decreased in width by the depopulation of upper rotational levels. This interpretation is ruled out, however, by the n.m.r. spectrum at 77° K.* Alternatively, some of the weaker

**These spectra were very kindly run for us by Mr. D. Gilson on samples of formaldehyde specially prepared by double distillation. The observed doublet splitting was of the order of 7 gauss, much larger than the 3 gauss expected if the proton pair in CH_2O were rotating.*

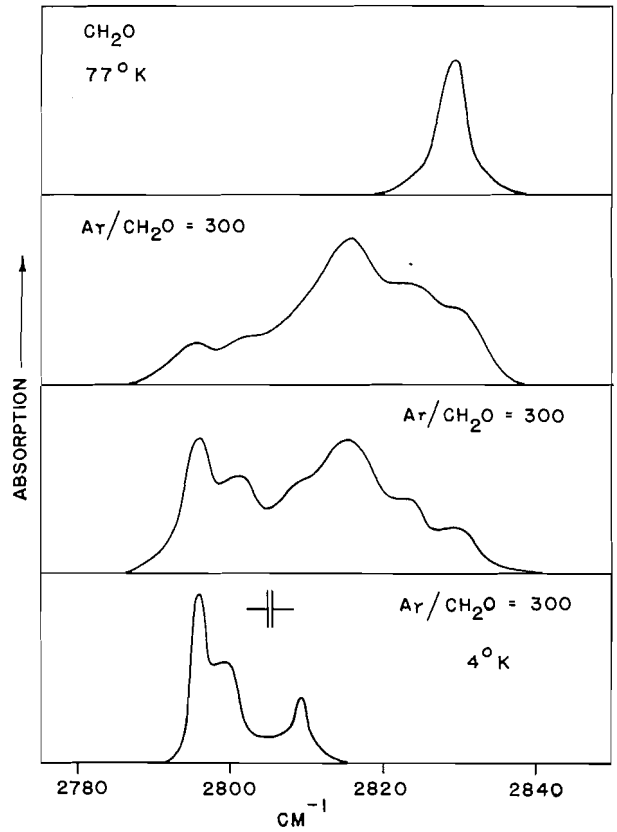

FIG. 2. Behavior of ν_1 fundamental during warmup of the deposit. Lowest spectrum is that of monomer at 4° K dispersed in argon and uppermost is that of normal associated CH_2O at 77° K. The middle two are matrix spectra at intermediate temperatures (about 35 and 50° K).

lines may be due to the presence of the isotopic species $C^{13}H_2O$, which has a natural abundance of about 1%. The expected shifts may be readily estimated for the two vibrations of species b_1 using the FG matrix method and introducing the appropriate symmetry co-ordinates. The calculated shifts were found to be -12 cm^{-1} and -9 cm^{-1} for ν_4 and ν_5 respectively. For the out-of-plane bending mode ν_6, the calculated shift was -12 cm^{-1}. It is possible then, that the weak lines at 1167.5 cm^{-1} and 1241 cm^{-1} are due to the presence of $C^{13}H_2O$. The lack of a corresponding line for ν_4 might be due to the low relative intensity of this mode. On the other hand, even if this assignment to isotopic species is correct, a number of lines remain unassigned. These are likely due to intermolecular effects, but since the crystal structure of formaldehyde is unknown, little can be done in the way of interpretation. They might arise, for example, from the existence of crystallographically non-equivalent molecules in the unit cell.

Matrix Spectra

Dealing with the argon matrix spectra first, it is noted that for four of the six fundamentals a triplet structure is observed. Only ν_3 and ν_5 lack this structure and in these two cases, the shift ν_{solid} to ν_{gas} is very small. Furthermore, the shapes of these bands are such as to suggest a closely spaced, unresolved fine structure. These observations alone tend to rule out rotation as the cause of the fine structure but this can be shown even more convincingly by considering the spectrum to be expected in the case of rotation.

Using the rotational constants of Lawrence and Strandberg (15), and treating the formaldehyde molecule as a prolate symmetric top (16), one may calculate the first few rotational energy levels. These are listed in Table II along with the appropriate Boltzmann

TABLE II
Rotational energy levels of formaldehyde

		Boltzmann factors	
$F(J,K)$	E (cm^{-1})	4° K (eq.)	4° K ($A \leftrightarrow B$)
(0,0)	0	1	1
(1,0)	2.44	0.42	0.42
(2,0)	7.32	0.07	0.07
(1,1)	10.63	0.01	1
(2,1)	15.51	0.01	0.17

factors. If thermal equilibrium obtains, then only the two lowest levels are significantly populated at 4° K so that the number of observable transitions is severely limited. For parallel bands (ν_1, ν_2, ν_3) the selection rules are: $\Delta K = 0$, $\Delta J = 0, \pm 1$ if $K \neq 0$ and $\Delta K = 0$, $\Delta J = \pm 1$ if $K = 0$; and three transitions $R(0,0)$, $R(1,0)$, and $P(1,0)$ are permitted. In the case of perpendicular bands (ν_4 and ν_5), $\Delta K = \pm 1$, $\Delta J = 0, \pm 1$ so that a Q branch is allowed and the transitions would be $Q(1,0)$, $R(0,0)$, and $R(1,0)$. The remaining vibration, ν_6, while of a different symmetry, may also be considered a perpendicular band in this approximation. Thus, if the trapped formaldehyde molecules were rotating, we might expect to see fine structure, as illustrated in Fig. 3.

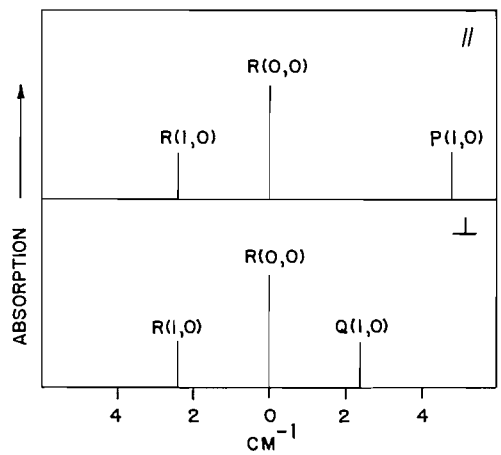

FIG. 3. Calculated rotational structure of parallel and perpendicular bands of CH_2O in thermal equilibrium at 4° K.

Comparison of the calculated fine structure with that observed reveals no agreement other than the fact that they are both triplets. Not only are the observed spacings far too large, but ν_1 and ν_2, which are of the same symmetry, do not exhibit the same band structure. A number of refinements might be considered in the theoretical treatment but these only serve to worsen the agreement. If, for example, the selection rule ortho $\leftrightarrow$ para were not violated during the freezing process, then a state of thermal non-equilibrium would be expected in which the (1,1) and (2,1) levels would also have a significant population. (These levels correlate with levels of species B in the more accurate asymmetric

rotor treatment while the (0,0) and (1,0) levels are of species A.) The main effect of this on the calculated spectra would be to introduce a Q branch into the parallel band and a P branch into the perpendicular band, giving more lines than observed. A similar situation would obtain if some of the selection rules were violated or if the rotational temperature were higher than 4° K. Alternatively, if the motion of the molecule were hindered in such a way that rotation about only one axis were allowed, the band structure would be like that of a linear or diatomic molecule. This would be a series of lines with a regular spacing of about 2.5 cm^{-1} or 18 cm^{-1} depending on the axis of rotation. Such an interpretation, like the others discussed, fails to account for the observed spectra so we must rule out rotation as the cause of the fine structure.

On the other hand, a strong argument can be presented for multiple trapping sites. In the three best-resolved bands, ν_1, ν_2, and ν_4, it is seen that the strongest lines are nearest to the gas phase absorption frequency while the weaker lines are shifted in the direction of the frequency of absorption in the polycrystalline solid. This suggests that the molecules are trapped in three types of holes of different sizes. The majority of the molecules occupy the largest type of hole and, being least perturbed, absorb at a frequency closest to that observed for the gas. A lesser number of molecules are present in somewhat smaller holes where the packing is more like that existing in the polycrystalline solid. From the small size of the gas-to-solid shifts for ν_3 and ν_5 it can be deduced that these vibrations are least perturbed by the close-packed environment of a solid. Hence the triplet splitting in the matrix spectrum should be small in these cases, in agreement with observation.

In speculating on the nature of the trapping sites, it is interesting to compare the present work with that of Foner *et al.*, who reported the trapping of hydrogen atoms on both substitutional and interstitial sites in inert-gas matrices. Specifically, they proposed that in these cubic close-packed structures, hydrogen atoms occupy substitutional sites and octahedral holes in both argon and xenon and possibly also tetrahedral holes in xenon. The sizes of these holes in argon are

$$r_{sub} = 1.88 \text{ Å}, r_{oct} = 0.77 \text{ Å}, r_{tet} = 0.43 \text{ Å},$$

so that a hydrogen atom may apparently squeeze into a hole considerably smaller than its own van der Waals radius (1.2 Å). The fact that the size of the tetrahedral hole in xenon is about the same as that of the octahedral hole in argon suggests that this is about the minimum size of hole which can accommodate a hydrogen atom. Taking into account the much larger size of the formaldehyde molecule it seems extremely unlikely that it could be accommodated in anything smaller than the environment of a substitutional site in argon. The distortion required to accommodate a formaldehyde molecule in an octahedral hole would likely be so large that the site would simply lose its identity as an octahedral hole and become a substitutional site. It is proposed, therefore, that the lines at 2809.5 cm^{-1}, 1732 cm^{-1}, and 2880 cm^{-1} in ν_1, ν_2, ν_4, respectively, be assigned to absorption by formaldehyde molecules replacing a single argon atom in the cubic close-packed structure. The remaining lines must be assigned to absorption by formaldehyde molecules occupying larger holes, presumably those in which two and three argon atoms are displaced. The environment of these sites would be such as to prevent rotation while still allowing greater freedom of vibration.

The spectrum exhibited by formaldehyde in a nitrogen matrix is less complex than that in argon. This was not unexpected since others have reported similar phenomena (4) and we have observed it ourselves for H_2O and D_2O. On the basis of the observed spectra,

it would appear that two types of sites are occupied but it is difficult to specify what these might be. In solid α nitrogen, which is the stable form below 35° K, the arrangement of the molecule centers is face-centered cubic with the axes of the molecules inclined at the tetrahedral angle to one another (17). The cylindrical substitutional site with a radius of about 1.5 Å and a length of approximately 4 Å, could probably accommodate a formaldehyde molecule with a small amount of distortion of the N_2 lattice. The other hole would have to be larger and likely corresponds to the case in which a formaldehyde molecule replaces two N_2 molecules.

ACKNOWLEDGMENTS

The authors are indebted to Mr. Rudolf Muelchen for his very capable assistance in the construction and maintenace of the apparatus. We wish also to thank Dr. R. Snider for many helpful discussions and Professor C. A. McDowell for criticizing the manuscript. The financial assistance of the National Research Council of Canada is gratefully acknowledged.

RÉSUMÉ

On a mesuré l'absorption infrarouge de formaldéhyde à 4° K dans l'état polycristallin et de forme monomérique. Dans le dernier cas, les molécules ont été suspendues dans une matrice inerte d'argon ou d'azote. Les fondamentales des monomères ont une structure qui suggère une rotation des molécules, mais cette interprétation est à écarter en faveur d'une explication basée sur l'existence de plusieurs emplacements différents dans la matrice.

THE DIELECTRIC BEHAVIOR AT LOW TEMPERATURES OF SEVERAL GASES ADSORBED UPON POROUS VYCOR GLASS

I. D. CHAPMAN AND R. MCINTOSH
The Department of Chemistry, University of Toronto, Toronto, Ontario
Received June 28, 1961

ABSTRACT

The complex dielectric constants of several systems comprising a gas adsorbed on Vycor glass have been measured at temperatures between 0° C and −180° C and frequencies between 3 kc/sec and 4 Mc/sec. The real and imaginary parts of the dielectric constant of the adsorbed phase have been computed. Loss maxima occurring at low temperatures are observed for some of the matter in the monolayer and are assumed to be due to complexes formed between the gas first admitted and hydroxyl groups which are covalently attached to the surface of the glass. The complexes may be considered either as dipoles having two equilibrium positions, or as highly damped oscillators. Ethyl chloride adsorbed in the first molecular layer and not bonded to OH behaves as an oscillatory system for which no loss is observed in the frequency and temperature ranges studied. Ethyl chloride adsorbed in the multilayers behaves similarly but shows a slightly greater temperature coefficient of ϵ'. Both these types of adsorbed ethyl chloride interact with the complexes and reduce the threshold temperature at which loss is observed in the complex. Methyl chloride interacts with OH groups in a similar fashion, but *n*-butane does not.

INTRODUCTION

The investigation of the dielectric properties of gases adsorbed upon solids can provide a useful means of investigating the modes of motion of molecules held upon the surface and in subsequent layers. In particular, the variation of the dielectric constant of the adsorbed phase with temperature and with frequency (especially in the dispersion region) can give useful information in the case of polar adsorbates. For such adsorbates the temperature coefficient of the dielectric constant will be negative if the molecule is free to rotate in three dimensions in an applied field (1) or, as McIntosh, Rideal, and Snelgrove (2) have shown, is free to rotate in a plane having random orientation in the field. Further, dipolar molecules in the liquid state and free to align themselves with the field, or dipoles in solids which may exhibit several orientations relative to the field, will reveal a characteristic dielectric dispersion, as Debye (1) and Fröhlich (3) have shown. The temperatures and frequencies at which dispersion occurs are dependent upon the nature of the molecules. The variation of dispersion with frequency or temperature will be different from that dispersion known as resonance absorption. Fröhlich (4) points out that resonance absorption is expected for rotational oscillators undergoing dispersion. Adsorbed oscillators should reveal a small temperature coefficient of the dielectric constant as Kurbatov (5) and Snelgrove and McIntosh (6) have demonstrated.

In this investigation the real and imaginary parts of the dielectric constant of systems consisting of gases adsorbed on porous Vycor glass have been measured over a wide range of temperature, from 0° C to −180° C, and of frequency, from 3 kc/sec to 4 Mc/sec. The real and imaginary parts of the dielectric constant of the adsorbate were calculated using the extended Böttcher treatment discussed by earlier workers (2, 7, 8). Allowance had to be made for the losses, both in the adsorbate and adsorbent, and, due to the complicated nature of the equations so obtained (see McCowan and McIntosh (9)), the results were computed on the IBM 650 computer. The value of the dielectric constant of the adsorbed ethyl chloride was approximately 7 for amounts less than monolayer coverage in the range of temperature where there were no losses. This value agrees

quite well with results of other workers (2, 7, 9) when one considers the very different temperatures and frequencies employed in the various assemblies. The major part of this work was undertaken using ethyl chloride. Methyl chloride and *n*-butane were also employed to test various hypotheses but were not investigated extensively.

The findings may be summarized as follows:

(1) A negative temperature coefficient of the dielectric constant was found for ethyl chloride in the monolayer. Its value was approximately one-sixth that of the bulk liquid. For matter adsorbed in the multilayers the coefficient was one-third that of the bulk liquid. These values were established for adsorbate at temperatures above $-130°$ C where the losses in the adsorbate were negligible.

(2) Broad loss maxima were obtained at temperatures below $-130°$ C for ethyl and methyl chlorides adsorbed in quantities less than the monolayer. A corresponding decrease in the real part of the dielectric constant was also observed. Over the narrow range of temperature within which loss maxima could be observed, it was found that the maxima of the loss curves did not change with change in temperature. The losses persisted in the region corresponding to capillary condensation but were not due to the quantities of gas adsorbed after the monolayer. It was possible to show further that the losses were due only to a part of the total gas adsorbed in the monolayer. Interaction between the material first adsorbed and that adsorbed at higher relative pressures was revealed by the fact that the temperature at which losses became observable was reduced with increasing amounts of adsorbate.

(3) No losses other than those already present for the glass alone were detected when a small quantity of *n*-butane was adsorbed. The computed values of ϵ' for *n*-butane were approximately constant over the entire range of temperature and agreed well with the values for liquid butane.

During the preparation of this paper an excellent study of the dielectric properties of small amounts of ammonia adsorbed upon a similar Vycor glass has been described by Fiat, Folman, and Garbatski (10). As the procedure employed by them to calculate molar polarization of the adsorbed matter differs from that employed here, some discussion of their paper will be given.

EXPERIMENTAL

The adsorbent used in this investigation was a tube of porous Vycor glass, Code No. 7930, obtained from the Corning Glass Works, Corning, New York. It weighed 8.751 g *in vacuo* and measured 10.00 cm in length, 1.50 cm O.D., and 1.19 cm I.D. The glass was cleaned by being boiled in a 30% nitric acid solution and heated in distilled water with repeated changes of water. The glass was then heated in the cell to 300° C and pumped to a pressure of 10^{-6} mm Hg. The adsorbates were obtained from the Ohio Chemical Co., and were purified by repeated trap-to-trap distillation under vacuum. Their purity was checked by vapor pressure measurements.

The test cell was made of Invar steel, of the same coefficient of expansion as the glass, and consisted of two coaxial cylinders which fitted around the glass tube and acted as the plates of a condenser. The inner or high-frequency voltage plate was insulated from the outer or ground plate by a glass spacer. The cell fitted into a thin-walled Monel tube which acted as a cell housing and was attached to the system as shown in Fig. 1. The cell could be heated to 350° C without leaks developing in the indium gasket at the top of the housing. The high-potential lead was brought into the housing through a metal–glass seal. The cell housing was further surrounded by a Monel jacket which could be evacuated to reduce heat transfer from the cell. This jacket was cooled with liquid air which enabled temperatures as low as $-180°$ C to be reached in the cell. Higher temperatures were obtained by means of a heating coil wound on the cell and regulated using a Variac. The temperature of the cell was measured with a calibrated copper–constantin thermocouple, and was controlled by a vapor pressure thermometer which operated a switch in the heating circuit.

The frequency range 3 kc/sec to 100 kc/sec was covered using a modified Schering bridge of standard design. Frequencies above 100 kc/sec to 4 Mc/sec were covered by a resonance system described in detail in other papers (7).

A correction of the capacitance readings due to the gap (estimated as 0.002 in.) between the glass tubes and the electrodes of the cell had to be made. This involved a consideration of the potentials across the two air gaps and the glass in the cell. The capacitance reading could then be directly related to the dielectric constant if the radii of the sections in the cell were known:

$$[1] \qquad 1/c = 2 \ln (b/a) + [2\epsilon']/[(\epsilon')^2 + (\epsilon'')^2] \ln (c'/b) + 2 \ln (d/c'),$$

where c is the capacitance per unit length, a, b, c', and d refer to the distances of glass, etc., from the center of the coaxial system. The magnitude of this correction was about 5%. Although the dimensional changes of the adsorbent due to a phase change of the adsorbate are not known, Hodgson and McIntosh (11) have observed expansion when adsorbed water freezes. From the magnitude of this expansion it may be estimated that the gap would not change by more than 4×10^{-5} in., that is, about 2%. Such a variation would be undetectable through the dielectric measurements. After each addition of gas, the system was investigated throughout the entire frequency and temperature range possible. Twenty-four hours elapsed between frequency measurements after a temperature change and no evidence of temperature hysteresis was ever found.

RESULTS

The dielectric constant of a system such as ethyl chloride and Vycor glass is a function of three variables—the volume adsorbed, temperature, and frequency. The variation of ϵ or cell capacitance with each one of these variables, the other two being kept constant, is used to summarize the data.

(i) If one plots the change in cell capacitance with volume of material adsorbed (Fig. 2)

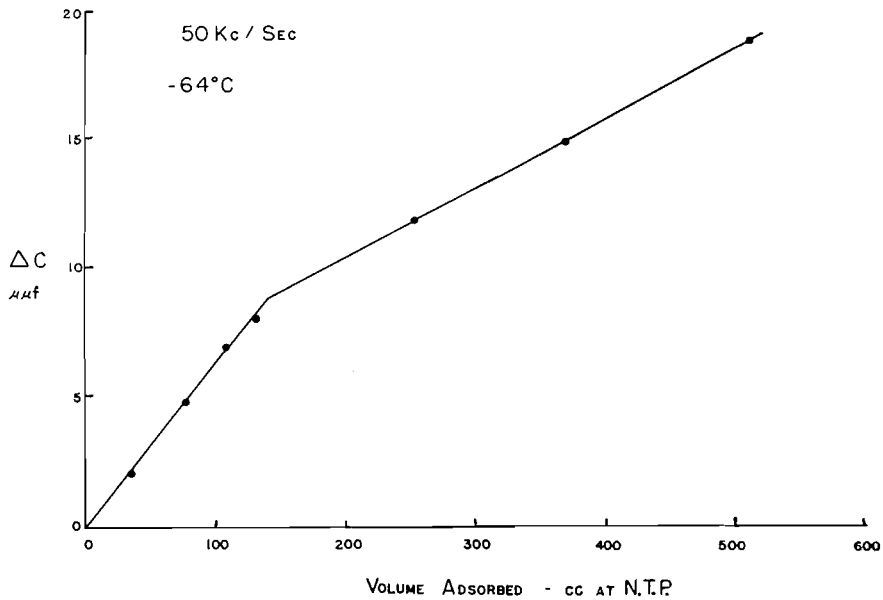

FIG. 2. Plot of change in cell capacitance against volume of gas adsorbed (cc at N.T.P.).

two linear sections result. The second has a lesser slope than the first, which confirms the observations of previous workers (2, 7, 9). To calculate the dielectric constant of the adsorbed phase the extended Böttcher formulae were used (2). The appropriate terms of equation [2] and the analogue of equation [4] were made complex in the program used in computing the results on the IBM 650 computer, and typical results are given in Table I both for the primary data for the composite material and the computed values for the adsorbed phase.

Values of the dielectric constant corresponding to points along the second section of Fig. 2 were, as expected, when computed in this way, lower than for points along the first section, and grew progressively smaller as more gas was adsorbed. This latter result was due to the method of using equation [2], where δ_3 is the volume fraction of free space, to

$$[2] \qquad \frac{\epsilon+2}{3}-\frac{3\epsilon\delta_3}{2\epsilon+1}=\frac{\epsilon_0-1}{4\pi C_1}+\frac{\epsilon-\epsilon_0}{4\pi C_2},$$

compute the results. The reason may be understood by considering an example using data which are not complex. In that event the term $(\epsilon_0-1)/(4\pi C_1)$ would be the intercept of the plot of the left-hand side of equation [2] against $\epsilon-\epsilon_0$. The plot would consist of two linear sections, and the slopes of these sections would yield the respective values of C_2 for the two regions of adsorption. If, however, the equation is solved analytically for

NOTE: true cell capacitance = 22.2 $\mu\mu$f; end capacitance = 2.0 $\mu\mu$f; frequency = 50 kc/sec.

each point along the second linear region, while retaining the value of the intercept $(\epsilon_0-1)/(4\pi C_1)$ as one point, and the value of the point on the second section as the other quantity defining the line, varying and progressively lesser values of C_2 would be obtained. This is essentially what is done in the procedure employed in using the computer. Previous workers had avoided this difficulty by using the values of the slopes of the two sections, and had thus obtained unique values of the dielectric constant for material corresponding to the first section (assumed to be monolayer) and the second section (assumed to be multilayer). In order to calculate the dielectric constant of the material in the region adsorbed in the multilayer (ϵ_{22}), the polarization/cc (C_2) calculated for the total adsorbed material was assumed to be made up of contributions from the monolayer (C_{21}) and the multilayer (C_{22}), which were further assumed to add on a volume fraction basis:

$$[3] \qquad C_2 = C_{21}\frac{V_1}{V_2+V_1} + C_{22}\frac{V_2}{V_2+V_1},$$

where V_1 represents the volume of material required to complete the monolayer and V_2 is the volume of material in the multilayer. Hence C_{22} can be evaluated and ϵ_{22} calculated from the equation

$$[4] \qquad \frac{\epsilon_{22}-1}{\epsilon_{22}+2} = \frac{4}{3}\pi C_{22}.$$

Some results for different temperatures, and amounts of gas adsorbed, are given in Table II and compared with results obtained graphically by plotting the left-hand side of equation [2] against $(\epsilon-\epsilon_0)$ and obtaining two straight lines of which the second slope gives C_{22} and hence ϵ_{22}. Results were not a function of frequency for temperatures above −130° C.

TABLE II

Dielectric constant of adsorbate from equation [3] and graphically

Volume adsorbed (cc at N.T.P.)	Temp. (°C)	Equation [3]	Temp. (°C)	Graphical method*

510.4	−85.3	3.74		
	−129.5	4.04		

NOTE: frequency = 10 kc/sec.
*Since the graphical method is based upon the slope of the second linear section of plots such as Fig. 2, the value of ϵ_2' is independent of amount adsorbed.

(ii) Figure 3 shows the variation of cell capacitance with temperature for glass and for various quantities of adsorbed ethyl chloride. It can be seen that there is a negative

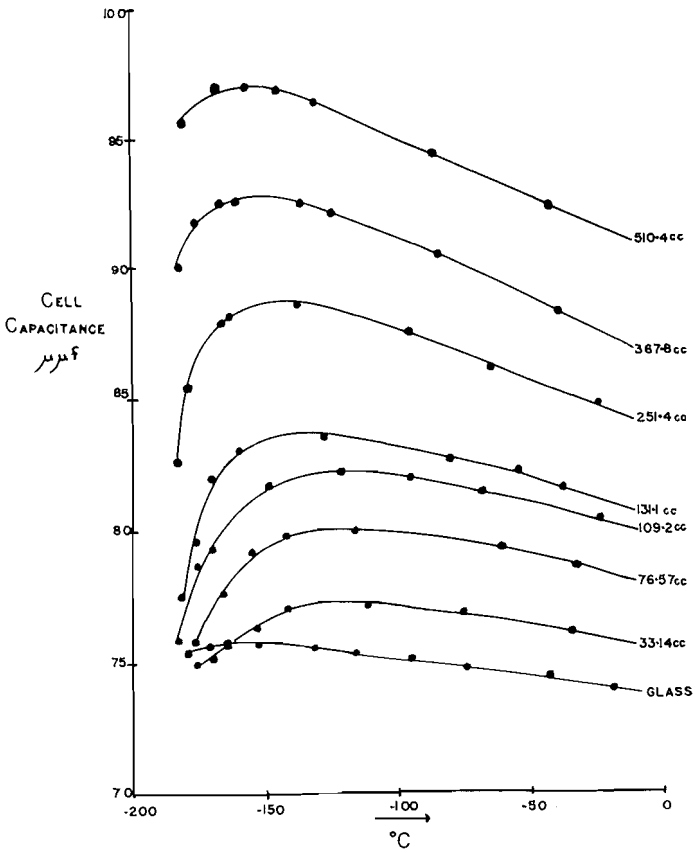

FIG. 3. Plot of cell capacitance against temperature with, and without, adsorbed ethyl chloride.

temperature coefficient for the glass alone, which was attributed to the presence of OH groups on the surface of the glass. Infrared studies by Folman and Yates (12) and Sidorov (13) have indicated the presence of these OH groups.

Treatment of the glass with a 3% aqueous solution of NH_4F, which reduced the concentration of the surface OH groups by replacing them with F (14), showed that the temperature coefficient was reduced. The effect of the OH groups on the dielectric constant can be estimated by extrapolating ϵ to high temperatures. When ethyl chloride is added, in quantities less than those that correspond to the monolayer, the curve virtually parallels that for glass alone down to $-130°$ C. Quantitative treatment of the data shows the temperature coefficient to have about one-sixth the magnitude expected for liquid ethyl chloride. However, as the low-temperature measurements and infrared studies (15) show, hydrogen bonding occurs between the surface OH groups and the ethyl chloride. We might, therefore, consider the OH—ClC_2H_5 complex as an entity and evaluate its variation of ϵ_2 with temperature using the baseline value of ϵ for the glass without OH groups. The temperature coefficient now increases to about one-half that of liquid ethyl chloride but more significantly the value of μ, the dipole moment, calculated using ϵ_2 of the complex and the Onsager (16) equation is still much lower than expected, namely, 1.66 D as compared with 2.0 D, which is the value of the dipole moment of ethyl chloride in the gaseous state. In the multilayer region, the temperature coefficient (from values of ϵ_{22} which were calculated by equations [3] and [4]) is about twice that in the monolayer.

Below $-130°$ C Fig. 3 indicates dispersion both for the glass and the complexed ethyl chloride. A plot for glass plus *n*-butane (not shown), however, parallels the curve for glass alone and therefore shows no dispersion and evidence of adsorbate–adsorbent interaction.

(iii) In the low-temperature region below $-130°$ C the real part of the dielectric constant ϵ' decreases and ϵ'' increases with increasing frequency for the glass and glass–chloride systems. Broad peaks are discernible for these latter systems and do not change in height as the temperature changes (see Fig. 4 and Table III). The behavior with either

TABLE III

†Temperature = $-183.9°$ C.

of the chlorides clearly shows the interaction of the adsorbate with the adsorbent, since in Fig. 3 the second curve crosses the first in the low-temperature region. This is due to the presence of the complex, which has a different dielectric dispersion behavior than do the OH groups alone on the glass. Methyl chloride, which is a lighter molecule than ethyl chloride, also showed the same effect, but because of its molecular weight, the inception of loss occurred at a lower temperature than for ethyl chloride. Beyond about one-quarter of the monolayer coverage (on the assumption that monolayer completion is revealed by the sudden change of dielectric constant with amount adsorbed), further addition of ethyl chloride does not increase the loss.

DISCUSSION

The loss peaks shown in Fig. 4 resemble Debye-type curves in that the amplitude and width appear constant over the narrow temperature range in which peaks could be defined.

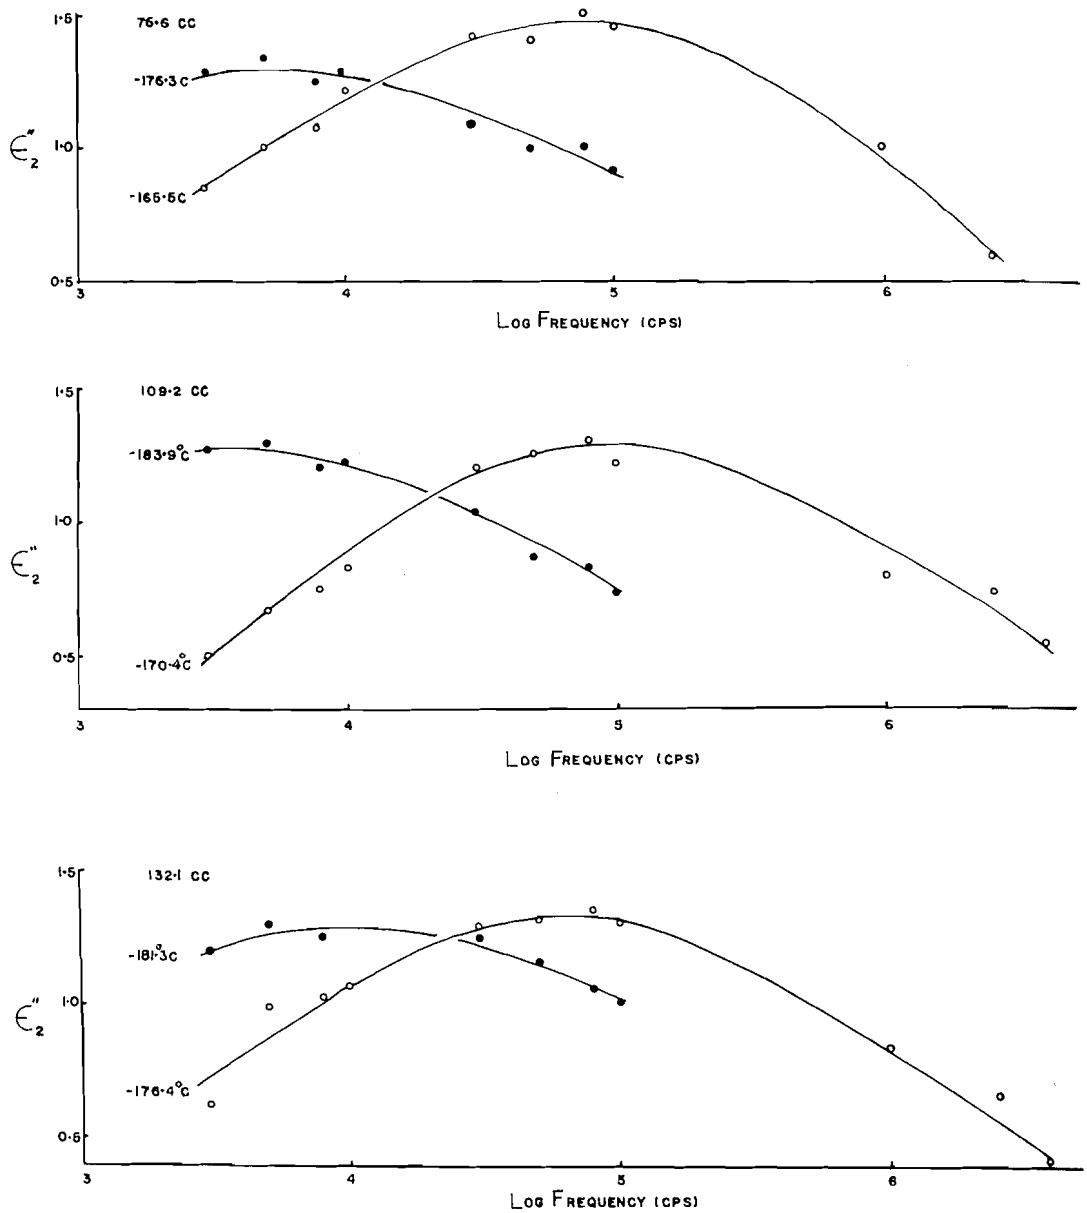

FIG. 4. Plot of ϵ_2'' for ethyl chloride against log frequency (c.p.s.).

However, it was not possible to obtain a typical Cole–Cole plot (17), which is usually taken as a criterion of Debye-type behavior. This failure could be due to the uncertain absolute values of ϵ_2'. As already stated, the temperature coefficient calculated for the

complexed ethyl chloride was smaller than expected. However, if one takes the form of the loss curves as a sufficient criterion of Debye-type behavior in the dielectric, a mechanism can be advanced based on a model having two positions between which the complex makes rotational transitions (1). As Fröhlich (3) points out, this leads, in the presence of a field, to an exponential approach to equilibrium and hence to the Debye equation. In particular, the well-known equation

$$\tau = \frac{1}{\omega_{max}} = \tau_0 e^{-H/RT}$$

may be applied if values of ω_{max} and τ are known. Table IV below gives values of τ_0 and H

TABLE IV

Volume adsorbed (cc at N.T.P.)	τ_0	H (kcal/mole)
76.6	6×10^{13}	4.47
109.2	1×10^{14}	4.30
132.1	5×10^{18}	6.72

calculated from Fig. 4. As can be seen the consistency between different doses of gas is moderately good, although the value of τ_0 is somewhat higher than expected; the small temperature range and the broad maxima of the peaks make the accuracy doubtful.

The two-position theory is the best available to explain Debye-type losses. A treatment based on an order–disorder theory as discussed by Fröhlich (18) cannot be valid in this case. One of the deductions of this latter theory is the decreasing value of the low-frequency value of ϵ_2' with decreasing temperature and no evidence of this was observed for adsorbed ethyl chloride. The fact that such a differentiation between theories is possible is due to a knowledge of ϵ_2', which can also provide a value of the temperature coefficient and dipole moment. This emphasizes the deficiencies in some of the work done on adsorbent–adsorbate systems, in which not only is no attempt made to calculate values of ϵ_2' and ϵ_2'' for the adsorbate itself, but values of ϵ' for the composite dielectric are sometimes not reported.

If the low value of temperature coefficient of the complexed ethyl chloride is considered too low for the Debye behavior discussed immediately above, the entity could be considered as an oscillator. This would require an explanation of the low frequency at which losses appear when the natural frequency (ω_0) would be close to 10^{12} oscillations/sec. The shape of the dispersion curves would also be anomalous if resonance absorption were advanced to explain the dielectric behavior. Von Hippel (19) gives the equation

$$[5] \qquad \hat{\epsilon} = A + \frac{B}{\omega_0^2 - \omega^2 + 2j\omega\alpha},$$

which results from the differential equation of motion

$$[6] \qquad \frac{d^2z}{dt^2} + 2\alpha\frac{dz}{dt} + \omega_0^2 z = \frac{e}{M}E',$$

where M is the mass of the oscillator, e the electronic charge, etc. In equation [5] A is the contribution of oscillators with natural frequencies very different from that of the species of natural frequency ω_0. The measuring frequency is ω and α is the damping coefficient. Since $\omega \ll \omega_0$, rationalization shows that ϵ' decreases continuously with ω, and ϵ'' goes through a maximum as a function of ω provided α is sufficiently large. Experimental finding may therefore be interpreted on the basis of the assumption of large α.

Although the following procedure does not provide an independent check of this interpretation, it was considered instructive to attempt to evaluate α from the known energy dissipation in the dielectric. The energy dissipation is given in ergs cm^{-3} sec^{-1} by $\omega E_0^2 \epsilon''/8\pi$, where E_0 is the applied field. The number of complexed ethyl chloride molecules has been estimated as 6×10^{21} per cc and ϵ'' may be taken as 0.5 at 10^5 cycles/sec. Thus, the ergs dissipated per molecule per second is 1×10^{-20}. One may relate α to this by means of the expression $[m\alpha(dz)/(dt)]\times[d/t]$, where m is the weight of one molecule and $(dz)/(dt)$ and d/t are the same quantity, namely, the distance moved by a molecule in 1 second. From the estimated size of the complex, namely 9×10^{-8} cm, one complete revolution would be about 5×10^{-7} cm. The distance turned by each molecule was evaluated on the assumption of a dielectric constant of about 12 in a field of about 10 volts cm^{-1}, giving a moment per cc of 0.03 e.s.u. Assuming a moment of 2.6 D for the complex, each molecule turns about 2×10^{-6} of a revolution each half cycle. Thus, in 1 second a distance of 10^{-7} cm is traversed by each molecule, so that $\alpha = 10^{-20}/(10^{-22}\times10^{-14}) = 10^{16}$ and $\omega\alpha = 10^{16}\times6\times10^5 \approx 10^{22}$. This is about the correct order of magnitude.

Thus it can be seen that a sufficiently large value of the damping coefficient will rationalize the shape of the absorption peak and also will predict a gradual decrease in the real part of the dielectric constant with frequency.

As already indicated, ethyl chloride, in greater quantity than about one quarter of the unimolecular layer capacity, does not enhance the losses. It is not only loss free but alters, towards lower temperatures, the condition for which loss is detected in the complexes which have formed. This situation is also recognized in the multilayer region. If the volume polarizability method of calculating the dielectric constant is extended to the region of loss, the added material in the multilayer appears to have a negative loss, which indicates that the condition for which loss was originally found in the monolayer has altered. There is, therefore, clear evidence of interaction between matter in the first and subsequent adsorbed layers.

The observation that an adsorbate may interact with the substrate yielding an unexpectedly low ϵ_2' could provide a second explanation for the phenomenon shown by Fig. 2. The lower dielectric constants in the multilayer region have previously been thought to be due to the location of the adsorbate in a region where the internal field is wrongly assessed by the Böttcher treatment. However, it could also be explained on the basis of interaction of the adsorbate and adsorbent through which the polarization of the substrate is reduced. However, in contrast with the matter adsorbed at the lowest relative pressures, the matter adsorbed in this range of pressure shows no dielectric loss, and there is, therefore, no positive evidence of interaction between adsorbate and adsorbent.

Since about three quarters of the ethyl chloride which enters the first molecular layer shows no loss and a low temperature coefficient, it would seem reasonable to consider the motion of this matter as oscillatory. Losses would presumably not be shown for such oscillators until much higher frequencies (20). Loss is also absent in matter going into the multilayer so that the behavior of these molecules does not resemble that of bulk liquid, on the presumption that bulk liquid would show losses at low temperatures and a frequency of 4 Mc/sec.

The recent paper by Fiat, Folman, and Garbatski (10), which deals with the adsorption of small amounts of ammonia on porous Vycor glass, should be discussed in relation to the present work. Fiat, Folman, and Garbatski calculate the molar polarization of the adsorbed ammonia by assuming that the heterogeneous dielectric may be considered as a solution, and the specific polarization of each constituent was added in proportion

to its volume fraction to yield the specific polarization of the composite dielectric. This polarization is related to the dielectric constant of the composite dielectric by the Onsager (15) equation. A somewhat similar solution treatment was given by Channen and McIntosh (8), but was not considered preferable by them. For example, ammonia adsorbed upon rutile showed a moment of 0.55 D, sulphur dioxide 0.0 D, ethyl chloride 0.55 D, in contrast with the gaseous moments of 1.47 D, 1.61 D, and 2.02 D, respectively. Miss Shimizu (21) employed the Onsager equation and the weight additivity of polarization in another attempt to treat these systems as solutions. Values obtained by Miss Shimizu were critized by Benson, Channen, and McIntosh (20). Nevertheless, in the present situation, when the evaluation of the property of the adsorbate must still be considered as somewhat empirical, the suitability of a given procedure must be judged, at least partly, by the apparent reasonableness of the values. On this basis Fiat, Folman, and Garbatski can report an excellent value for the dielectric constant of the glass alone. Differential molar polarizations of the adsorbed ammonia are considered satisfactory by them in view of the bonding with hydroxyl groups. Whether temperature variations of polarization are consistent with the calculated value of the moment is not demonstrated, however.

In general, the question remains as to whether an adsorbed molecule should show an increased or diminished value of the orientational polarization in comparison with bulk matter. This problem has been touched upon by Benson, Channen, and McIntosh (19). It was pointed out by them that a dipolar molecule which had created in it, by induction due to the surface field, an additional moment equivalent to one-half that of its moment in the gaseous state, would contribute no more than an additional 3% to the normal orientational polarization. Admittedly, the model discussed was one in which the dipole diminished with displacement from the position of minimum energy when no applied field was operating, but at the same time, the molecule was considered as free to rotate and the restoring force to the original position was ignored. Thus, an unrealistically large orientational polarization was calculated. In the present instance, Fiat, Folman, and Garbatski apparently calculated the moment on the basis of the molar polarization and the relation $P = 4/3\pi N[\alpha' + (\mu')^2/(3kT)]$, which implies a form of the orientational polarization which may well not be valid. As in the case of ethyl chloride bonded to hydroxyl, reported above, until a realistic model of the adsorbed entity can be analyzed, the deduction of values of dipole moments is open to serious doubt. In the experiments with ethyl chloride it has been shown that the increase of dielectric constant with quantity adsorbed is linear. Thus, the polarization of bonded ethyl chloride must be that of physically adsorbed ethyl chloride in the first layer. This latter material does not have a large contribution to the polarization from orientation if the value of the dielectric constant of 7 is accepted and the Onsager equation is used to calculate the dipole moment. The dipole moment (1.66 D) is less than that of the gaseous molecule. Such an assignment of a dipole moment is clearly unwarranted in view of the fact that no account has been taken of the mode of motion of the adsorbed molecule.

One further comment is indicated. A positive temperature coefficient of the polarization is observed at low coverages of ammonia by Fiat, Folman, and Garbatski. A similar result was found by McCowan and McIntosh (9) for very much higher measuring frequencies, and evidence of dispersion or loss was found associated with the positive temperature coefficient. One would expect losses for conditions in which the rotation of molecules is hindered, but the measurement of loss was not feasible with the device

and procedure employed by Fiat, Folman, and Garbatski. Interesting results should be obtained in the frequency and temperature ranges employed by them.

In summary, it appears that complexes form between the first quantities of adsorbed ethyl chloride and hydroxyl groups. To explain the losses of this species at low temperature the complexes may be considered either as dipoles having two equilibrium positions relative to the field, or as highly damped oscillators. Ethyl chloride adsorbed in the first molecular layer and not bonded to OH behaves as an oscillatory system for which no loss is observed in the frequency and temperature ranges studied. Multilayer ethyl chloride behaves similarly, but shows a slightly greater temperature coefficient of ϵ_2'. Both these types of adsorbed ethyl chloride interact with the complexes $OHClC_2H_5$ and reduce the temperature at which loss is observed.

STUDIES ON THE STRUCTURE OF CATALPOSIDE

W. H. LUNN,[1] DEIRDRE WALDRON EDWARD, AND J. T. EDWARD
The Department of Chemistry, McGill University, Montreal, Que.

Received September 25, 1961

ABSTRACT

Catalposide extracted from the unripe fruit of *Catalpa ovata* affords bisdesoxyaucubin on reduction with lithium in liquid ammonia. The reduction is accompanied by the shift of a double bond. From this and other evidence, two possible structures are proposed for the compound.

Claassen (1) in 1888 extracted a colorless crystalline compound from unripe fruit of *Catalpa bignonoides* Wal., and named it catalpin. The compound was renamed catalposide by Colin, Tanret, and Chollet (2) because it was hydrolyzed by emulsin and hence was probably a β-glucoside. This was recently confirmed by Bobbitt, Schmid, and Africa (3), who obtained glucose on acid hydrolysis and *p*-hydroxybenzoic acid on alkaline hydrolysis of catalposide. From the analytical data for the compound and for 12 crystalline derivatives, they calculated for it the formula $C_{22}H_{26}O_{12}$.

Our own investigations, started some time ago, have been carried out with catalposide isolated from the fruit of *Catalpa ovata*. This material after prolonged drying at 110° analyzed as $C_{22}H_{26}O_{12}$, but when dried at 64° analyzed as a monohydrate, $C_{22}H_{28}O_{13}$. Acid hydrolysis afforded glucose, identified by paper chromatography, and an insoluble black solid, while alkaline hydrolysis afforded *p*-hydroxybenzoic acid. The latter compound was also obtained in small yields by the pyrolysis of catalposide. It has previously been obtained by treatment of the fruit of *Catalpa bignonoides* with dilute acid (4).

The close similarity in the ultraviolet absorption spectra of catalposide and of ethyl *p*-hydroxybenzoate in neutral and alkaline solution (Fig.1) shows the phenolic hydroxyl

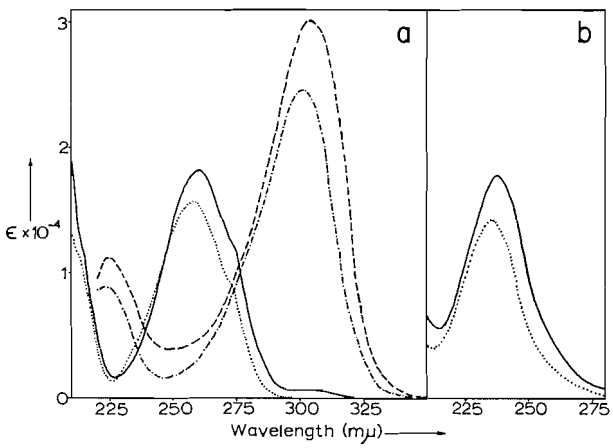

FIG. 1. Ultraviolet absorption of catalposide, ethyl *p*-hydroxybenzoate, heptaacetylcatalposide, and ethyl *p*-acetoxybenzoate.
(*a*) Catalposide: —— in 95% ethanol; — — in 0.01 *N* NaOH in 95% ethanol. Ethyl *p*-hydroxybenzoate: . . . in 95% ethanol; — · in 0.01 *N* NaOH in 95% ethanol.
(*b*) Heptaacetylcatalposide: —— in 95% ethanol. Ethyl *p*-acetoxybenzoate: . . . in 95% ethanol.

[1]*Holder of N.R.C. Studentships 1959–61.*

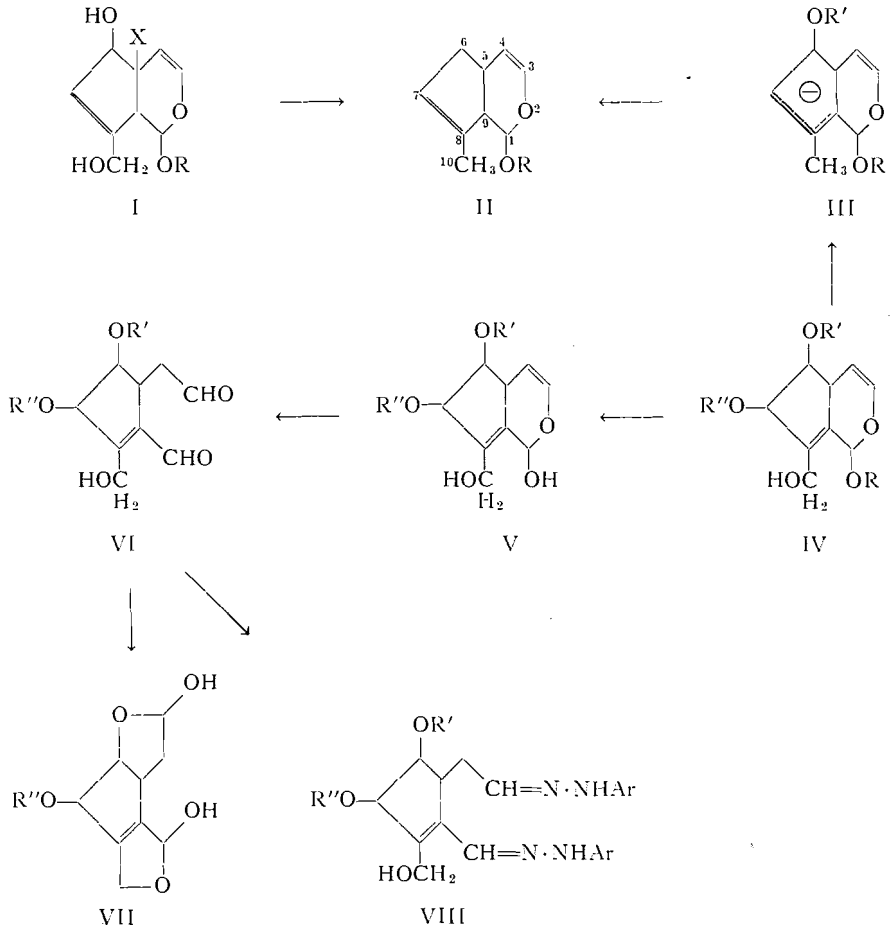
of the *p*-hydroxybenzoyl group to be free. Titration of the phenolic group in catalposide monohydrate with sodium hydroxide in 10% aqueous ethanol indicated a pK of 8.35, as compared with a pK of 8.45 for ethyl *p*-hydroxybenzoate, and an equivalent weight in good agreement with the formula $C_{22}H_{28}O_{13}$.

Acetylation of catalposide afforded a dimorphous compound which analyzed as a heptaacetate. Bobbitt *et al.* (3) reported obtaining a hexaacetate. The ultraviolet absorption of this compound was, as expected, very similar to that of ethyl *p*-acetoxybenzoate (Fig. 1).

Alkaline hydrolysis of catalposide yielded, besides *p*-hydroxybenzoic acid, a crystalline compound, *catalpol*, $C_{15}H_{22}O_{10}$. This compound also gave a heptaacetate. The analytical results suggested that catalpol might be a hydroxy derivative of aucubin, $C_{15}H_{22}O_9$ (I, R = β-glucosyl = $C_6H_7O(OH)_4$; X = H) (5, 6, 7, 8), a possibility supported by a close similarity in the infrared spectra of the compounds. A close relationship was shown by reducing catalposide with lithium in liquid ammonia, using various alcohols as proton donors, to give bisdesoxyaucubin (II, R = $C_6H_7O(OH)_4$), isolated in low yields as the tetraacetate. This compound had previously been obtained by Grimshaw and Juneja (6) by a similar reduction of aucubin.

In a preliminary communication (9) the structure I (R = $C_6H_7O(OH)_4$; X = $OCOC_6H_4OH$) was proposed for catalposide, on the basis of this evidence, on the assumption that the double bonds of catalposide have the same position as in bisdesoxyaucubin. However, this structure is excluded by a comparison of the nuclear magnetic resonance spectra of catalposide and several derivatives with those of aucubin and the corresponding derivatives. All compounds showed a highly characteristic quartet at low field (τ = 3.45 for aucubin, 3.39 for catalpol, both in D_2O; 3.83 for hexaacetylaucubin (8), 3.65 for heptaacetylcatalposide, 3.62 for heptaacetylcatalpol, all in $CDCl_3$) which must be due to the C-3 proton (8, 10), coupled strongly with the C-4 proton ($J_{34} \approx 5.9$ c.p.s.) and weakly with the C-5 proton ($J_{35} \approx 1.5$ c.p.s.). However, aucubin and hexaacetylaucubin showed complex peaks (τ = 3.93 and 4.20 respectively) due to the olefinic proton at the 7-position (8) which were absent from the spectra of catalposide and its derivatives. This indicates that the second double bond of the latter compounds must be at the Δ^8 position, as shown in formula IV, and that formation of bisdesoxyaucubin (II) in the Birch reduction of catalposide involves a $\Delta^8 \rightarrow \Delta^7$ double-bond shift via the mesomeric anion III (11). Further evidence for this position of the double bond comes from the peaks at highest field. Whereas hexaacetylaucubin has three complex peaks at 6.24, 6.81, and 7.16, which have been ascribed to the protons at C-5 and C-9 of the aglycone and C-5′ of glucose (8), heptaacetylcatalposide (τ = 6.18 and 7.27) and heptaacetylcatalpol (τ = 6.18 and 7.32) have only two peaks in this region, and hence must lack a proton at C-9.

The oxygen functions eliminated in the Birch reduction must be allylic to a Δ^7 or Δ^8 double bond (11), and can only be at the 6, 7, and 10 positions in view of the n.m.r. evidence for a proton at the 5-position; confirmation for the location of an oxygen at the 10-position comes from the failure to detect a C-methyl group in Kuhn–Roth oxidations. Catalpol is accordingly IV (R = $C_6H_7O(OH)_4$; R′ = R″ = H). The large shift in molecular rotation in going from catalpol ($[M]_D$ −443°) to catalposide ($[M]_D$ −841°) indicates that the *p*-hydroxybenzoyloxy group of the latter is probably attached to the 6- or 7-, rather than to the non-asymmetric 10-position, and that catalposide is either IV (R = $C_6H_7O(OH)_4$; R′ = COC_6H_4OH; R″ = H) or IV (R = $C_6H_7O(OH)_4$; R′ = H; R″ = COC_6H_4OH).



Confirmation of the Δ^8 position of a double bond comes from the properties of catalpogenin, the amorphous but chromatographically homogeneous aglycone given by hydrolysis with emulsion. This formed a crystalline bis-2,4-dinitrophenylhydrazone, $C_{27}H_{26}O_{14}N_8$, which had a broad, flat absorption peak centered at about 367 mμ (ϵ 43,300). A peak at this position and of this shape must be due to the merging of two sharper peaks due to 2,4-dinitrophenylhydrazone chromophores derived from a saturated aldehyde (λ_{max} 348–360 mμ (12)) and an α,β-unsaturated aldehyde (λ_{max} 366–387 mμ (12)). This is in accord with the expected structure VIII. However, the structure of catalpogenin itself is not given by the dialdehyde formula VI, because of the absence of aldehyde C—H stretching peaks in the 2700–2800 cm^{-1} region (13), nor by the formula V, because of the absence of a vinyl ether peak at about 1650 cm^{-1} (13). The formula VII (R″ = COC_6H_4OH) is one of several possible formulae, derived by cyclization from the dialdehyde VI, permitted by the infrared data. Catalpogenin formed an amorphous triacetate.

The treatment of catalposide in liquid ammonia with lithium and various alcohols gave, besides bisdesoxyaucubin, either catalpol or an isomer (isocatalpol), isolated as their heptaacetates. The formation of catalpol by attack of alkoxide ion on catalposide requires no comment; the formation of isocatalpol may possibly be explained by base-catalyzed epimerization at the 1-position. A similar base-catalyzed epimerization was

observed by Wolfrom and Husted (14), who found that the β-forms of the pentaacetates of gluco-, manno-, and galacto-pyranose could be converted to the α-forms by sodium hydroxide in anhydrous dioxane or ether. This formulation for isocatalpol is in accord with the infrared and n.m.r. spectra of its heptaacetate, which are very similar to those of heptaacetylcatalpol and indicate the same functional groups to be present in both compounds.

EXPERIMENTAL

Ultraviolet absorption spectra, except where otherwise noted, are for solutions in 95% ethanol. Nuclear magnetic resonance measurements were made at 60 Mc/sec and peak positions were measured relative to an internal tetramethylsilane reference. Microanalyses were carried out by A. Bernhardt (Mulheim, Germany) and C. Daesslé (Montreal).

Isolation of Catalposide

The procedure was modified slightly from that of Claassen (1). The green beans of *C. ovata* growing on the McGill campus were stripped of their outer coverings, covered with 95% ethanol, and simmered for 1 hour in the presence of a trace of calcium carbonate. The ethanol was poured off, the extraction repeated, and the combined extracts concentrated at reduced pressure to a small volume. The green solution was then washed with ether and left in the refrigerator for 1 week. The solid which separated was taken up in a small volume of ethanol and precipitated with chloroform. It was redissolved in ethanol and filtered through charcoal. The residue from evaporation of the solvent was recrystallized several times from water, giving fine white needles (0.26–0.30% yield). These when dried at 64° at 0.1 mm melted at about 160°, resolidified, and melted again at 209–211° (decomp.); λ_{max} 260 mμ, ϵ_{max} 18,200; in 0.01 *N* sodium hydroxide in ethanol, $\lambda\lambda_{max}$ 225, 305 mμ, $\epsilon\epsilon_{max}$ 11,000, 30,100; ν_{max}^{KBr}: 3540 s,sh, 3400 s, 2910 w, 1708 s, 1654 w, 1613 s, 1597 m, 1519 m, 1393 m, 1355 m, 1315 m, 1290 s, 1257 m, 1232 m, 1177 m, 1105 s, 1090 s, 1074 s, 1055 s, 1015 s, 994 s, 965 s, 921 w, 906 w, 886 w, 874 w, 855 m, 840 m, 813 w, 772 s, 735 w, 704 m, 689 w, and 665 w cm^{-1}. This material analyzed as a *monohydrate*: calc. for $C_{22}H_{28}O_{13}$: C 52.80, H 5.64%; found: C 52.93, H 5.65%. When dried at 110° at 0.1 mm catalposide melted at 209–211° (decomp.), $[\alpha]_D^{22}$ −174° (*c*, 2.11 in ethanol). Calc. for $C_{22}H_{26}O_{12}$: C 54.77, H 5.43, O 39.80%; found: C 54.74, H 5.38, O 39.10%.

Except where otherwise noted, the catalposide used in the experiments described below was dried at room temperature at 15 mm. Such material contained 4–5 molecules of water of crystallization per $C_{22}H_{26}O_{12}$, as shown by combustion analysis and titration, and melted unsharply at about 80°, resolidified, and melted again at about 211° (decomp.). The purity of the compound was checked by ascending chromatography on Whatman No. 1 filter paper with the butanol – acetic acid – water solvent system of Partridge (15). It gave rise to a well-defined black zone (R_f 0.80) when the dried chromatogram was sprayed with 50% aqueous sulphuric acid and warmed gently. It was shown to be essentially free from aucubin (R_f 0.27–0.30), which gave rise to a blue zone when the chromatogram was sprayed with a solution of *p*-dimethylaminobenzaldehyde in acidic ethanol (16); the sensitivity of this chromatographic method was such that less than 0.2% aucubin in catalposide could be detected.

Titration of Catalposide

Aliquots (1.00 ml) of a solution of catalposide monohydrate (132.0 mg) in ethanol (10.0 ml) were diluted to 10.0 ml with distilled water, and the solutions titrated with 0.196 *N* sodium hydroxide in a Radiometer (Copenhagen) continuous automatic titrator. A sigmoid titration curve was obtained; the p*K* of the compound was obtained from the pH value for the midpoint of the curve. Calc. for $C_{22}H_{28}O_{13}$: equivalent 500.5; found: 496, 496, 504.

Acid Hydrolysis of Catalposide

When heated to 100° for 2 hours, a solution of catalposide (220 mg) in 2 *N* sulphuric acid (3 ml) darkened and deposited as infusible black solid. The solution was neutralized with barium hydroxide, centrifuged, and the clear brown supernatant was concentrated to 2 ml. Analysis by paper chromatography, using the solvent systems butanol – acetic acid – water (15) and pyridine – amyl alcohol – water (17) and a developing spray of aniline acid phthalate (15), showed the presence of a substance developing the same brown color and having the same R_f values as glucose.

Alkaline Hydrolysis of Catalposide

Hydrolysis of air-dried catalposide (3 g) in 0.1 *N* barium hydroxide (50 ml) was followed by observing the change in absorption of aliquots diluted with 0.01 *N* sodium hydroxide. After 23 hours λ_{max} had changed from 305 mμ to 280 mμ, characteristic of *p*-hydroxybenzoic acid (18). The solution was slowly acidified with 5 *N* sulphuric acid with cooling and then extracted with ether. Removal of the ether from the dried (magnesium sulphate) extract left a residue (690 mg) which crystallized from acetone–hexane–benzene in needles, m.p. 213–214°, identified as *p*-hydroxybenzoic acid by mixed melting point.

The slightly acidic aqueous solution was neutralized with barium carbonate and filtered, and the water evaporated at reduced pressure at room temperature. A solution of the residue in a few drops of water was diluted gradually with acetone over a period of several days, yielding several gummy crops and finally a colorless crystalline solid. This was recrystallized several times from small volumes of water by addition of acetone, giving stout white needles of *catalpol* (321 mg); m.p. 207.5°–209° (decomp.); $[\alpha]_D^{25}$ −122° (*c*, 0.82 in 90% (v/v) aqueous ethanol); ν_{max}^{KBr}: 3360 s, 2925 m,sh, 2880 m, 1659 m, 1465 w,sh, 1435 w, 1386 m, 1340 w, 1313 m, 1281 w, 1260 w, 1238 m, 1150 m,sh, 1130 m,sh, 1104 s, 1084 s, 1055 s,sh, 1040 s, 1014 s, 989 s, 961 w,sh, 914 m, 900 m,sh, 887 w,sh, 861 w, 836 m, 762 m,sh, 754 m, and 736 m cm^{-1}. Calc. for $C_{15}H_{22}O_{10}$: C 49.71, H 6.12%; found: C 49.64, 49.92, H 6.27, 6.29%.

By ascending chromatography on Whatman No. 1 filter paper and spraying with 50% aqueous sulphuric acid, catalpol gave single, well-defined black zones with the following solvent systems: butanol – acetic acid – water (15), R_f 0.31; phenol saturated with water, R_f 0.77; pyridine – ethyl acetate – water (1:2:2 (vol.)), R_f 0.83. The R_f values of catalposide with these solvent systems were 0.80, 0.78, and 0.93 respectively.

Pyrolysis of Catalposide

A flask containing catalposide (1.5 g) under a pressure of 0.1 mm was heated by immersion in an oil bath, the temperature of which was raised from 170° to 260° C. At the higher temperature a green oil distilled over into a cold trap, and white crystals (70 mg) formed in the neck of the flask. The latter on crystallization from acetone–hexane–benzene had m.p. 213–214° C, undepressed by admixture with authentic *p*-hydroxybenzoic acid, and having an identical infrared spectrum.

Heptaacetylcatalposide

A solution of catalposide (2 g) in pyridine (6 ml) and acetic anhydride (5 ml), after standing overnight at room temperature, was diluted with a large volume of hexane. An oil precipitated which solidified on washing with hexane. The solid crystallized from aqueous isopropanol in white silky needles (2.08 g); m.p. 112.5°–113.5° C; λ_{max} 238 mμ, ϵ_{max} 17,700; ν_{max}^{KBr}: 2946 w, 2900 w,sh, 1750 s, 1720 s,sh, 1654 m, 1606 m, 1508 m, 1435 m, 1373 s, 1275 s,sh, 1247 s,sh, 1220 s, 1195 s,sh, 1164 s, 1100 s, 1065 s, 1040 s, 1015 s, 972 m, 932 s, 910 m, 870 w, 845 w, 762 w, and 700 w cm^{-1}. Calc. for $C_{36}H_{40}O_{19}$: C 55.66, H 5.19%. Found: C 55.77, H 5.29%.

Later preparations of this compound afforded needles, m.p. 142.5°–143.5° C, identical otherwise (ultraviolet and infrared spectra) with lower melting form; $[\alpha]_D$ −108° (*c*, 1.28 in chloroform).

Heptaacetylcatalpol

(a) From Catalpol

A solution of catalpol (127 mg) in pyridine (4 ml) and acetic anhydride (1 ml) was left overnight at room temperature, and then diluted with a large volume of hexane and left a further 24 hours. The precipitated solid was washed with hexane and crystallized from aqueous isopropanol to give large white needles (108 mg); m.p. 140.5°–141.5°; $[\alpha]_D^{23}$ −87° (*c*, 1.83 in chloroform); ν_{max}^{KBr}: 2950 m, 2900 w,sh, 1748 s, 1657 m, 1439 m, 1381 s, 1316 w,sh, 1248 s,sh, 1234 s, 1172 w, 1149 w, 1128 w, 1100 w,sh, 1072 s,sh, 1050 s,sh, 1042 s, 1019 s,sh, 984 m, 971 w,sh, 956 w,sh, 934 m, 921 m, 910 m, 882 w, 868 w, 840 w,sh, 768 m, 745 m, 699 w, 686 w,sh, and 670 w cm^{-1}. Calc. for $C_{29}H_{36}O_{17}$: C 53.04, H 5.53, CH_3CO 45.88%; found: C 53.27, 53.15, H 5.74, 5.71, CH_3CO 45.52, 45.37%.

(b) From Catalposide

Catalposide (2 g) in absolute ethanol (40 ml) was rapidly added dropwise with stirring to a mixture of lithium (2.5 g), liquid ammonia (600 ml), and ethanol (8 ml) cooled in an acetone – dry ice bath. After 20 minutes the cooling bath was removed and the solution left overnight to allow the ammonia to evaporate. Removal of volatile liquids was completed at reduced pressure, and then the residual brown solid was suspended in pyridine (250 ml) and treated with acetic anhydride (100 ml) with stirring and cooling. After standing overnight, the mixture was filtered to remove lithium acetate. The filtrate was concentrated at reduced pressure to 200 ml, diluted with water, and further concentrated to 25 ml. Dilution with water precipitated a viscous oil which was triturated with water, dried at room temperature at 0.1 mm, triturated with hexane, and then left under hexane overnight. The brown solid thus formed was dissolved in methanol, filtered through charcoal, recovered by evaporation at reduced pressure, and recrystallized from aqueous isopropanol. White needles of heptaacetylcatalpol were obtained, m.p. and mixed m.p. 139°–140.5° C, $[\alpha]_D^{20}$ −84° (*c*, 1.64 in chloroform), infrared spectrum identical with that of the compound described above.

Catalpogenin

Optical rotations of an aliquot of a solution of catalposide (3 g) and emulsin (300 mg) in water (1 l.), clarified by filtration through celite, decreased for 2 days and then became constant. The solution was concentrated to about 60 ml at reduced pressure and diluted with acetone to precipitate emulsin and some glucose. The mixture was filtered through celite, and the filtrate taken to dryness at reduced pressure. The yellow residue was dissolved in butanol saturated with water (30 ml) and passed through a column of Whatman cellulose powder (60 g) packed with the same solvent. Elution with water-saturated butanol (250 ml) removed the yellow color from the column. The eluate, taken to dryness at reduced pressure and

dried at 0.1 mm, gave a solid yellow foam (1.98 g). Paper chromatography of this solid, using butanol – acetic acid – water as irrigating solvent and an aniline hydrogen phthalate spray (15), revealed a single yellow spot of R_f 0.90 and no glucose. The solid could not be crystallized and so a portion of it (774 mg) in acetone solution was filtered through charcoal, recovered by evaporation, taken up in isopropanol, and deposited by rotary evaporation on celite (2.5 g). After drying at 0.1 mm, this solid was extracted with anhydrous ether in a Soxhlet apparatus for 3 days. *Catalpogenin* (365 mg) was obtained as a pale yellow amorphous solid on evaporation of the ether; λ_{max} 260 mμ, ϵ_{max} 14,400 (based on formula $C_{16}H_{10}O_7$); ν_{max}^{KBr}: 3440 s, 2950 s, 2886 m,sh, 1712 s, 1692 s, 1614 s, 1604 s, 1599 s,sh, 1519 m, 1468 m,sh, 1451 m, 1350 m, 1311 m, 1282 s, 1217 s,sh, 1170 s, 1112 s, 1068 s, 1030 s, 975 s,sh, 925 m,sh, 895 w, 852 m, 815 w, 773 m, 700 m cm^{-1}. All attempts to crystallize this solid failed, but on paper chromatography it gave rise to a single, well-defined spot.

Triacetylcatalpogenin

A solution of catalpogenin (180 mg) in pyridine (4 ml) and acetic anhydride (1 ml), after standing overnight, was diluted with a large volume of hexane. The brown gum which separated became solid after repeated trituration with hexane, and was taken up in methanol and filtered through charcoal. The colorless residue (60 mg) from the filtrate could not be crystallized, and so was dissolved in carbon tetrachloride, filtered through celite, and recovered by evaporation as an amorphous solid; ν_{max}^{KBr}: 3060 w, 2940 m, 1752 s, 1719 s, 1604 m, 1506 m, 1436 m, 1416 m, 1372 s, 1240 s,sh, 1217 s,sh, 1200 s, 1164 s, 1115 s, 1100 s,sh, 1041 s, 1016 s, 975 m,sh, 914 s, 862 m, 806 w, 764 m, 705 m, and 674 w cm^{-1}; $\nu_{max}^{CCl_4}$: 1757 s, and 1723 s cm^{-1}. Calc. for $C_{22}H_{22}O_{10}$: C 59.20, H 4.97%; found: C 58.64, H 5.45 %.

Catalpogenin bis-2,4-Dinitrophenylhydrazone

A warm solution of 2,4-dinitrophenylhydrazine (260 mg) in ethanol (5.3 ml) – sulphuric acid (1 ml) – water (1.7 ml) was added to a warm solution of catalpogenin (135 mg) in ethanol (3 ml). After 2 hours at room temperature, the mixture was diluted with water (20 ml) and kept for 4 hours in the refrigerator. The yellow-brown solid removed by filtration was washed with water until acid free and then taken up in a small volume of ethyl acetate. Dilution of this solution with boiling ethanol precipitated several crops of brown gum, which were removed by filtration through celite, and finally yellow needles of *catalpogenin bis-2,4-dinitrophenylhydrazone* (40 mg); m.p. 166.5°–167.5° C (decomp.); $[\alpha]_D^{23}$ −378° (*c*, 0.460 in ethyl acetate); $\lambda\lambda_{max}$ 258, 367 mμ, $\epsilon\epsilon_{max}$ 37,100, 43,300 (in ethyl acetate); ν_{max}^{KBr}: 3430 s,w, 3290 s, 3100 w, 1700 m, 1666 s, 1593 s,sh, 1516 s, 1426 m, 1334 s, 1310 s,sh, 1275 s, 1225 m, 1165 m, 1140 s, 1100 s, 1058 w,sh, 925 w, 852 w, 834 m, 772 w, 744 m, and 724 w cm^{-1}. Calc. for $C_{28}H_{24}O_{13}N_8$: C 49.42, H 3.56%; found: C 49.59, 49.40, H 3.90, 3.89%.

Reduction of Catalposide with Lithium in Liquid Ammonia

(a) With Ethanol as Proton Source

Catalposide (2.5 g) in warm absolute ethanol (45 ml) was added to liquid ammonia (320 ml), followed by lithium (10 g) in small pieces over a period of 15 minutes, giving a blue solution with a bronze phase. After 40 minutes, ethanol (25 ml) was added dropwise over a period of 20 minutes, during which the bronze phase disappeared; after another 40 minutes, the addition of more ethanol (20 ml) led to the disappearance of the blue color. The solution was worked up as described above for the preparation of heptaacetylcatalpol from catalposide, yielding a yellow gum (1.39 g) which was chromatographed on Woelm neutral alumina (42 g, activity II). Elution with hexane–benzene, 1:3, removed a solid (60 mg), which after crystallization from aqueous methanol melted at 132°–134.5° C, and was identified as tetraacetylbisdesoxyaucubin by melting point, mixed melting point, and infrared spectrum; $\nu_{max}^{CCl_4}$: 2920 w, 2865 w,sh, 1709 s, 1659 w, 1440 w, 1370 m, 1224 s, 1158 w, 1070 s,sh, 1056 s,sh, 1037 s, 996 w,sh, 965 m, 952 w,sh, 920 w,sh, 910 w, and 881 w cm^{-1}. (Authentic bisdesoxyaucubin was prepared by a similar reduction of aucubin, isolated by Mr. I. Puskas from *Aucuba japonica* leaves (16).)

Elution with benzene containing increasing amounts of ether removed a gum which crystallized from ether–hexane in white needles (53 mg) of *heptaacetylisocatalpol*; m.p. 127°–128° C; $[\alpha]_D^{25}$ −121°, −120° (*c*, 2.21, 2.09 in chloroform); $\nu_{max}^{CCl_4}$: 2950 w, 2883 w,sh, 1751 s, 1655 w, 1433 w, 1369 m, 1221 s, 1160 w, 1125 w, 1062 m, 1038 m, 1010 w,sh, 955 w, and 905 w cm^{-1}. Calc. for $C_{29}H_{36}O_{17}$: C 53.04, H 5.53, CH_3CO 45.88%; found: C 53.06, 53.06, H 5.79, 5.71, CH_3CO 44.51, 44.93%. Larger amounts of organic material were obtained as intractable gums on elution with ether containing 0–3% acetic acid.

(b) With Methanol as Proton Source

Catalposide (2.5 g) in anhydrous methanol (28 ml) was added to liquid ammonia (600 ml), followed by lithium (2 g) over a period of 2 hours. The blue color persisted while the mixture was agitated for a further 2 hours, but disappeared after the addition of methanol (22 ml) over another hour. Ammonium sulphate (70 g) was added, and the mixture left overnight. The solid residue was dissolved in water (150 ml) and the solution evaporated at reduced pressure to yield a near-white residue which was powdered and extracted several times with boiling anhydrous ether, followed by warm methanol. The methanol extract was filtered through charcoal, concentrated, and the residual gum dried and treated with pyridine (10 ml) and acetic anhydride (8 ml) overnight. Dilution of this solution with water precipitated a gum (1.86 g), which was

chromatographed on Woelm neutral alumina, activity grade II (60 g). Elution with hexane–benzene, 1:3 (v/v), removed tetraacetylbisdesoxyaucubin, which, after crystallization from aqueous methanol, melted at 134.7–137.0° (15 mg), $[\alpha]_D - 139°$ (*c*, 0.491 in chloroform), infrared spectrum identical with that of authentic material. Elution with benzene–ether, 9:1 (v/v), removed heptaacetylisocatalpol, which after crystallization from ether–hexane had m.p. and mixed m.p. 127–128° (225 mg).

(c) With Isopropanol as Proton Source

Lithium (3.6 g) and isopropanol (27 ml) were added to catalposide (0.8 g) in isopropanol (16 ml) – ammonia (200 ml) over 90 minutes. Ten minutes later the blue color disappeared and ammonium sulphate (35 g) was added. The reaction was worked up as in (*b*) above to give tetraacetylbisdesoxyaucubin (3 mg), m.p. 132–134°, followed by heptaacetylcatalpol (30 mg), m.p. 140–141°, and then heptaacetylisocatalpol (about 30 mg).

ACKNOWLEDGMENTS

We are grateful to Professor F. A. L. Anet for n.m.r. spectra and for help in their interpretation, to Professor A. J. Birch, for discussions and for suggesting reduction in liquid ammonia, to Mr. H. R. Juneja for details of the reduction of aucubin and for a sample of tetraacetylbisdesoxyaucubin, to Mr. I. Puskas for generous samples of aucubin, to Professor R. D. Gibbs for help and advice, and to the National Research Council for financial support.

THE INFRARED FREQUENCIES AND INTENSITIES OF THE HYDROXYL BAND OF ORTHO-ALKYL PHENOLS IN THE VAPOR PHASE[1]

K. U. INGOLD

The Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received September 27, 1961

ABSTRACT

The infrared frequencies and intensities of the fundamental stretching vibration of the hydroxyl group have been measured for a number of ortho-alkyl phenols in the vapor phase over a range of temperatures. Both quantities have been shown to depend on internal steric and environmental factors. The differences in enthalpy between the cis and trans isomers of several 2-tert-alkyl phenols have been measured, and it is concluded that the latter are not significantly stabilized relative to the former by solvation in non-polar solvents.

INTRODUCTION

The presence of two fundamental hydroxyl stretching bands in the infrared spectra of *o-t*-alkyl phenols has been reported recently by several workers (1, 2, 3, 4). The two bands are almost certainly due to geometrical isomerism of these phenols, i.e. to cis and trans structures in which the hydroxyl group—coplanar with the ring—points respectively towards and away from the alkyl substituent. In contrast to the related isomerism in which intramolecular hydrogen bonding occurs between the *o*-substituents and the hydroxyl group, the trans isomer predominates in *o-t*-alkyl phenols. We have recently measured the differences in free energy and enthalpy between the two isomers in carbon tetrachloride and hexachlorobutadiene for several different *t*-alkyl groups (1, 2). We suggested that these values might be appreciably higher than the values which would be obtained by measurements in the vapor phase, owing to the increased stabilization of the trans isomer as a result of its interaction with the solvent (5). The present work, in which the differences in enthalpy were measured in the vapor state, was therefore undertaken to estimate the stabilizing effect of the solvents used in the previous measurements. Moreover, enthalpy differences in the vapor are of greater theoretical importance from the point of view of non-bonding interactions in sterically hindered molecules. It was also hoped that the resolution of the two bands would be improved in the vapor, but this was found not to be the case, the resolution being about the same as in carbon tetrachloride at room temperature.

EXPERIMENTAL

The spectrometer and slit conditions have been described previously (1). A simple heated cell was constructed of quartz with a path length of 10.1 cm and a total volume of 207 cc. The temperature of the cell could be read and controlled to about ±2° C. To eliminate traces of air and moisture from the samples the following procedure was used. The cell was heated to 300° C and evacuated overnight, following which it was cooled to room temperature and filled with purified helium. It was then momentarily removed from the gas handling system and a previously weighed quantity of the phenol was dropped in. The cell was re-evacuated for 2 minutes and then sealed off under vacuum. The quantity of the phenol added was sufficient to give a concentration in the vapor of about 10^{-3} mole/liter.

At room temperature none of the phenols showed any absorption in the O—H region. As the temperature was raised the O—H band appeared and increased rapidly in intensity until the phenol was all in the vapor state, after which the maximum band height decreased rather slowly with increasing temperature. Measurements were made in this region at 20° C intervals. In three cases, only one measurement was made since the temperature had to be raised to about 300° C to get these phenols entirely into the vapor state. No measurements were recorded above 300° C since all the phenols examined above this temperature were apparently decomposing quite rapidly.

[1]*Issued as N.R.C. No. 6611.*

RESULTS

Although the main interest in this work was centered on relative band intensities it was found that, if these were obtained from the product of the apparent half-band width and the molecular extinction coefficient, they could differ by as much as 10% from the relative intensities obtained by graphical integration. For this reason, the intensities relative to phenol (A) recorded in Tables I and II were obtained by integration over the entire absorption band. They are probably correct to within ±5%. The integrated intensities are independent of temperature within the accuracy of the measurements, a decrease of about 1–2% every 10° C in the maximum band height, ($\log_{10} I_o/I_m$), being compensated by an increase in the apparent band width. This supports the view that the decrease in intensity with increasing temperature observed previously in solution (2) was due to expansion of the solvent. The primary effect of solvent expansion is to decrease the quantity of material in the cell. A secondary effect is that, as the solvent density decreases, phenol–solvent interaction is also decreased. The intensity therefore decreases, tending towards its smaller value in the vapor phase as the temperature is raised. Thus, the absolute intensity of the OH band of phenol obtained by integration, as far as the flat wings of the band using $\log_{10}(I_o/I)$ and not applying a wing correction, was found to be 0.18×10^4 mole^{-1} liter cm^{-2} in the vapor compared with $0.43_5\times10^4$ in carbon tetrachloride at room temperature (1).* The increase in frequency of the band maximum (ν_m) with increasing temperature in solution was also attributed to this secondary effect, which is confirmed by the fact that ν_m is independent of temperature in the vapor state. Values of A and ν_m, the latter accurate to about ±1 cm^{-1}, are recorded in Table I for those phenols which do not contain just one *o*-*t*-alkyl substituent. ν_m for phenol, which has a very pronounced flat top to the band, is actually the frequency of the band center (ν_c). In most cases ν_m does not differ from ν_c by more than 1 cm^{-1}, but in benzyl alcohol and 4-CHO phenol it is 2 cm^{-1} lower than ν_c and in 4-Me phenol and 2,6-$(Et_3C)_2$-4-Me phenol it is 2 cm^{-1} higher than ν_c. Benzyl alcohol, a fairly typical alcohol (6), is included in Table I and Fig. 1 for comparative purposes.

The band shapes of those phenols which are included in Table I show very marked differences in the vapor phase which are not apparent in solution. For example, $\log_{10}(I_o/I_m)$ increases and the band width decreases with increasing mass of the 4-substituent. Some typical band shapes are shown in Fig. 1. The bands have all been corrected to a concentration of 10^{-3} mole/liter and to a temperature of 250° C. The band shapes have also been indicated in Table I by including the apparent half-band widths ($\Delta\nu_{\frac{1}{2}}$), the ratio of the apparent one-quarter- to three-quarter-band widths ($\Delta\nu_{\frac{1}{4}}/\Delta\nu_{\frac{3}{4}}$), and $\log_{10}(I_o/I_m)$ under these conditions. These values were obtained by extrapolation when necessary, e.g. with 2-*sec*-dodecyl-4-Me phenol, 2,4,6-Am_3^n phenol and 2,6-Oct_2^{tt}-4-CHO phenol,† for all of which only a single high temperature measurement was made.

The bands of some of the substituted phenols show small irregularities which are perhaps due to the presence of overlapping hot bands. The contribution these irregularities make to the values of A obtained by integration over the whole band are probably not significant compared to the accuracy with which A can be measured. Therefore, no correction was applied for these irregularities. With 2,6-Bu_2^t-4-Cl phenol and 2,6-Bu_2^t-4-CHO phenol irregularities appeared on the low frequency side of the band at temperatures above 270° C. They were attributed to the partial decomposition of these phenols involving the loss of one of the *t*-butyl groups. 2,6-$(Et_3C)_2$-4-Me phenol showed a similar

**This value is incorrectly recorded as 4.35×10^4 in reference 1.*

†*The Oct^{tt} or t-t-octyl group is* $(CH_3)_3CCH_2(CH_3)_2C$—.

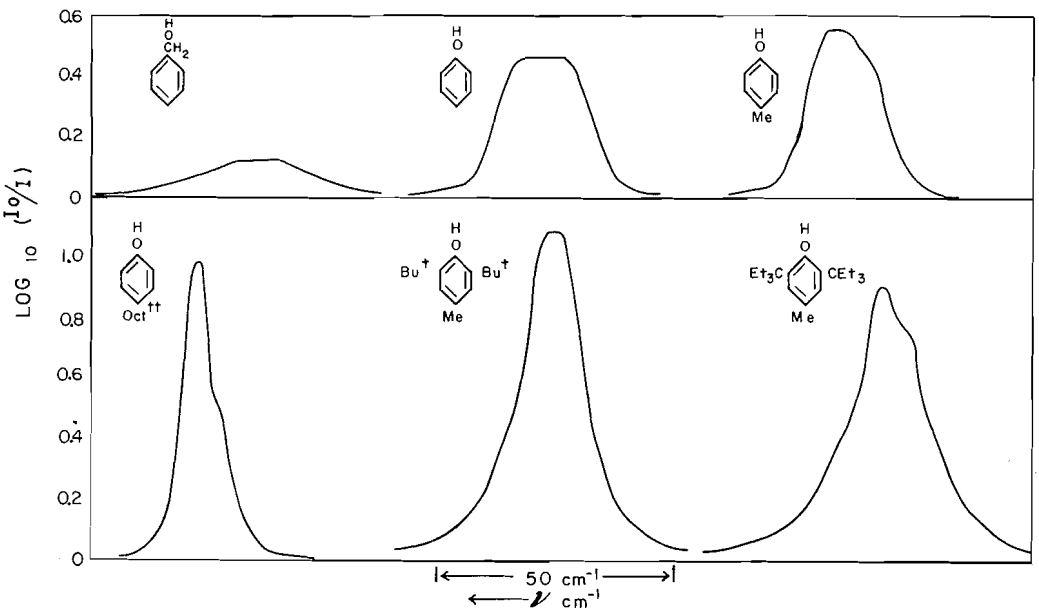

FIG. 1. The O—H vibration bands of benzyl alcohol and some phenols at 250° C and 10^{-3} mole/liter; path length = 10.1 cm.

irregularity even at the lowest experimental temperature (265° C) (Fig. 1). If this irregularity is also due to the partial loss of one of the ortho-alkyl groups the intensity recorded in Table I for this phenol is probably too low.

Phenols containing a single *o-t*-alkyl substituent show the expected double band, but the smaller of the two bands is relatively twice as large as it is in solution in CCl_4. The bands are shown in Fig. 2 at 10^{-3} mole/liter at the lowest temperatures at which they were measured so as to show the maximum resolution achieved. Values of total intensity, ν_m, $\Delta\nu_{\frac{1}{2}}$, etc. are given in Table II. With the exception of the total intensity, these values are not as accurate as those in Table I, owing to the problem of separating the two bands.

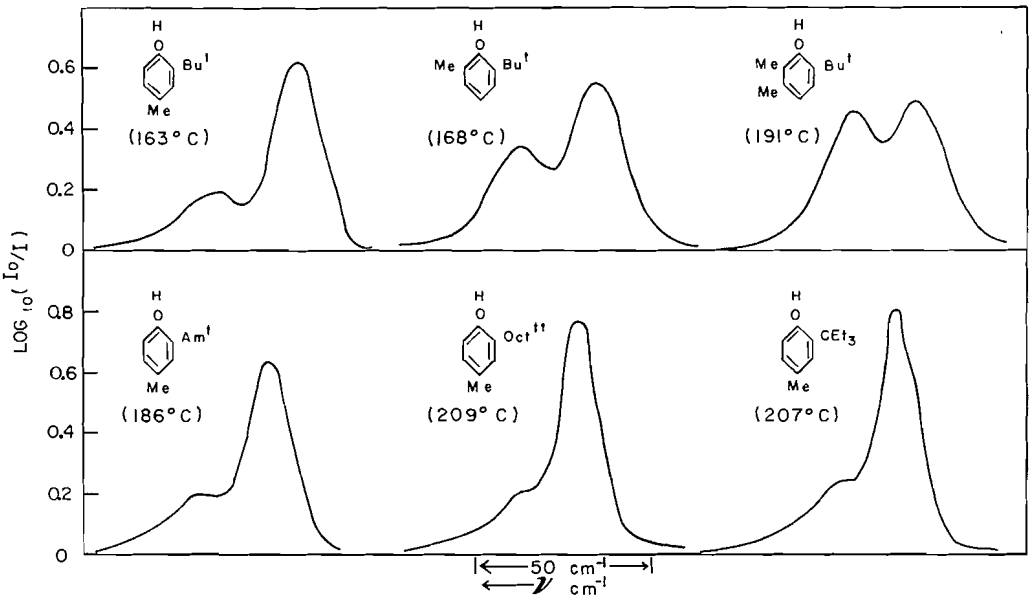

FIG. 2. The O—H vibration bands of ortho-*tert*-alkyl phenols at 10^{-3} mole/liter; path length = 10.1 cm.

DISCUSSION

(i) Phenols Not Containing a Single Ortho-t-alkyl Group

It has been shown previously (7) that ν_m, A, and $\Delta\nu_{\frac{1}{2}}$ for the fundamental O—H stretching mode of 4-substituted phenols and 4-substituted-2,6-di-*t*-butyl phenols can be correlated

in solution with the Hammett σ constants of the 4-substituents. Figure 3 shows the correlations which are obtained for ν_m and A in the vapor state, the σ constant of an ortho substituent being assumed equal to that of the same para substituent.* The error in this assumption (8) is negligible in view of the small σ-para constants of alkyl substituents. Because of their double hydroxyl band, phenols with a single *o*-*t*-alkyl substituent have not been included. For the phenols which do not have two ortho-*t*-alkyl groups, the points have been plotted against the total σ for all the substituents, i.e. $\sum\sigma$. The points for 2,6-di-*t*-butyl and 2,6-di-*t*-*t*-octyl phenols have been plotted against the σ constant of the 4-substituent only so as to make comparisons with the simple 4-substituted phenols easier.

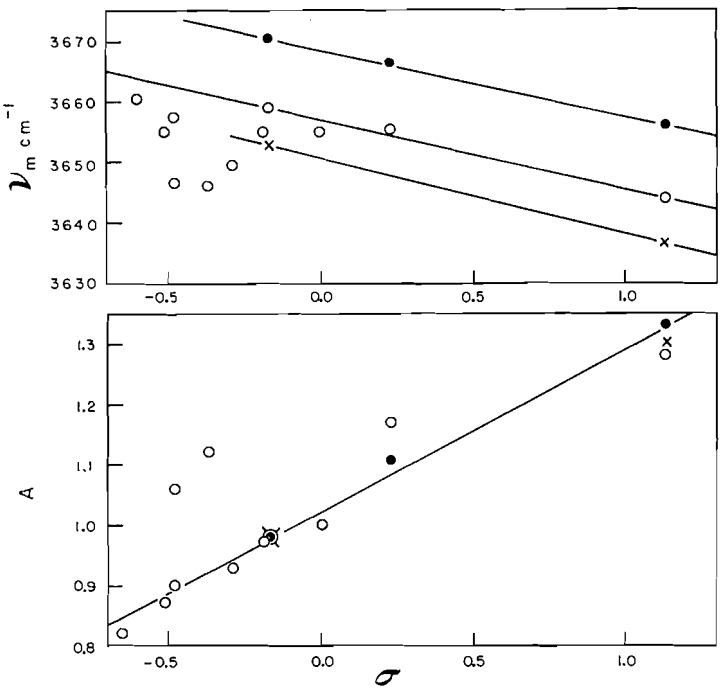

FIG. 3. Variation of A and ν_m with σ: phenols ○; 2,6-Bu_2^t phenols ●; 2,6-Oct_2^{tt} phenols ×.

In carbon tetrachloride and 1,2 dichlorethane a straight line was obtained by plotting A against σ for phenols and 2,6-di-*t*-butyl phenols with a slope $\rho = 0.37$ (7).† In a similar plot in Fig. 3 the intensities of 2,6-di-*t*-butyl and 2,6-di-*t*-*t*-octyl phenols have all been multiplied by 0.98/2.08 so that the A values of their 4-methyl derivatives coincide with

A figure showing the relation between $\Delta\nu_{\frac{1}{2}}$ and σ has not been included because, in the vapor state, the influence of a substituent on $\Delta\nu_{\frac{1}{2}}$ is primarily due to changes in the relative moments of inertia of the phenol and only secondarily due to the electronic effect of the substituent. With 4-substituted 2,6-Bu_2^t and 2,6-Oct_2^{tt} phenols, where changes in the moments of inertia can be neglected, $\Delta\nu_{\frac{1}{2}}$ decreases with an increase in σ, as was found in solution (7). $\Delta\nu_{\frac{1}{2}}$ for simple 4-substituted phenols also shows a decrease with increasing σ when allowance is made for the effect of changes in the moments of inertia. This trend is in the opposite direction to that observed in solution (7). A decrease in $\Delta\nu_{\frac{1}{2}}$ with an increase in σ is probably connected with an increase in the depth of the coplanar potential energy wells resulting from increased resonance of the hydroxyl group with electron-attracting 4-substituents. With non-hindered phenols in solution this effect is more than offset by increasing solvent interaction with the hydroxyl group.

†*It has recently been suggested (9) that $A^{\frac{1}{2}}$, rather than A, should be plotted against σ. The present results do not show any significant improvement when plotted against $A^{\frac{1}{2}}$ and have therefore been plotted against A to facilitate comparison with our previous work.*

4-Me phenol. The points for most 4-substituted phenols, methyl-substituted phenols, 2-*sec*-dodecyl-4-Me phenol, and 2,6-di-*t*-alkyl-4-substituted phenols fall close to a single straight line with a slope of 0.27.* This indicates that the orientation of the hydroxyl group is the same for all these phenols (7), i.e. if the hydroxyl is coplanar with the ring in phenol it is also coplanar in 2,6-di-*t*-alkyl phenols. This conclusion receives further confirmation from the parallel lines obtained with phenols and di-*t*-alkyl phenols in the ν_m versus σ plots. Moreover, the high intensities of all the di-*t*-alkyl phenols compared with a typical alcohol (benzyl alcohol) also suggest a coplanar hydroxyl, since the intensity would be expected to decrease to a value similar to that of an alcohol if the hydroxyl were twisted out of the plane by the alkyl groups.

In the plot of ν_m against σ three straight lines have been drawn to pass through the ν_m values obtained for the 4-Me and 4-CHO derivatives of phenol, 2,6-Bu_2^t phenol and 2,6-Oct_2^{tt} phenol. The lines are nearly parallel with slopes of -11.5, -11.5, and -12.5 cm^{-1} respectively, which are slightly lower than the slope of -13.7 cm^{-1} obtained with the first two phenols in CCl_4 (7). The lower slopes in the vapor are to be expected as a result of the elimination of solvent interaction with the hydroxyl group (7). The divergence of multi-alkyl substituted phenols from this line may be partly due to a saturation of electronic effects owing to the large number of electron-releasing groups attached to the ring. However, since Am_3^n, Bu_3^s, and 2-*sec*-dodecyl-4-Me phenols are further from the line than Me_5 phenol the divergence is probably mainly due to interaction of the hydroxyl with the alkyl groups. The results suggest that ν_m is more sensitive than A to such interactions.

In a previous publication (1) the differences between measured values of ν_m and A in CCl_4 for 2,6-dialkyl phenols and the values calculated from the Hammett equations were plotted against the difference in free energy between the cis and trans isomers of the corresponding *o*-alkyl phenols, i.e. $\Delta\nu_m$ and ΔA were plotted against ΔG. It was pointed out that although this procedure cannot be justified directly, the values of $\Delta\nu_m$ and ΔA for di-*o*-alkyl phenols must be related in some way to the steric interaction of the alkyl groups with the hydroxyl group and the magnitude of this interaction is some function of ΔG. The original plots are reproduced in Fig. 4 with the addition of the $\Delta\nu_m$ and ΔA values for the vapor state plotted against the slightly different values of ΔG found in the vapor (see below). The general shapes of the curves are similar in the vapor and in solution. The discontinuities between the methyl phenols and the *t*-alkyl phenols indicate that *o*-alkyl groups have two different effects on the hydroxyl; the relative magnitudes of the two effects varying with the size of the substituents. The solution curves were tentatively explained on the basis that mild steric interactions narrowed the potential energy well of the O—H stretching vibration, while stronger steric effects tended to polarize the hydroxyl bond (1). However, the present results suggest that changes in the environment around the OH group produced by alkyl substitution play an equally important role in determining $\Delta\nu_m$ and ΔA. The frequency of a "free" phenolic hydroxyl group (e.g. phenol) increases as the surrounding medium is changed from CCl_4 to a hydrocarbon to the vapor, and its intensity decreases (see Table I in reference 2). Alkyl substitution in both ortho positions changes the environment of the hydroxyl to one similar to that encountered by the OH group of phenol in a hydrocarbon. Provided the steric interaction between the OH and alkyl groups is small the environmental change produced

**The divergence of 4-chlorophenol from this plot may be due to the presence of some 2-chlorophenol since this was an unpurified commercial product. The divergence of Bu_3^s and Am_3^n phenols is probably due to the interaction of the ortho-alkyl groups with the hydroxyl. This interaction raises A towards its apparently limiting value of slightly more than 2.0, which is reached in di-o-t-alkyl phenols (Fig. 4).*

by alkyl substitution suggests that $\Delta\nu_m$ will be positive in CCl_4 and negative in the vapor while the reverse should be true of ΔA. The $\Delta\nu_m$ and ΔA values of 2,6-Me_2 and 2,3,5,6-Me_4 phenols show the expected changes in the vapor and in CCl_4, although the intensities do not seem to be as sensitive as the frequencies to environmental changes. The sudden increase in A to a virtually constant value on the substitution of two *o-t*-alkyl groups may be due to the complete enclosure of the hydrogen atom of the hydroxyl group by the alkyl substituents; that is, the OH is no longer "free" whatever the orientation of the alkyl substituents, and its environment should therefore be very similar to that encountered by the OH group of phenol in hexane. This environmental similarity is emphasized by comparing the absolute intensities of phenol in hexane with the absolute intensities of di-*t*-alkyl phenols in the vapor (Table III; the hexane values have been calculated from Table I, reference 2).* The positive values of ΔA observed with di-*t*-alkyl phenols in CCl_4 and hexane, and the small increase in ΔA on going from di-*t*-butyl to di-*t-t*-octyl phenol, are probably both connected mainly with steric effects. Specific solvent interactions may also play a part in these changes in ΔA, since the intensities of these phenols are virtually constant in carbon disulphide solution (2).

TABLE III

Comparison of ν_m and A in hexane and vapor

Substituents	ν_m (vapor) $-\nu_m$ (hexane), cm^{-1}	Absolute intensity, 10^4 $mole^{-1}$ liter cm^{-2}	
		Vapor	Hexane
None (phenol)	$32._5$	0.18	0.39
Me_5	23	0.15	0.24
2,6-Bu_2^t-4-Me	$14._5$	0.37	0.40
2,6-Am_2^t-4-Me	$14._5$	0.36	0.40
2,6-$(Et_3C)_2$-4-Me	15	0.36	0.51
2,6-Oct_2^{tt}-4-Me	14	0.37	0.47
2-Bu^t-4-Me	—	0.19_3	0.27_6
Trans	$26._5$	0.13 (250° C)	0.25 (25° C)
Cis	$18._5$	0.06_3 (250° C)	0.02_6 (25° C)

The increase in $\Delta\nu_m$ from 2,6-Me_2 phenol to 2,6-Bu_2^t phenol is probably connected with a narrowing of the O—H potential energy well because of the increased steric repulsion between the hydroxyl and alkyl groups. The decrease in $\Delta\nu_m$ above 2,6-Bu_2^t phenol is interesting in that it exactly parallels the decrease in the frequencies of these phenols in hexane (see Table III). The cause of the decrease must therefore be intramolecular in origin. A possible explanation would be that the C–$\widehat{O}$–H angle starts to increase as the *t*-alkyl group becomes larger than *t*-butyl, this would tend to decrease the O—H bond strength and hence ν_m.

Bu_3^s and Am_3^n phenols appear to provide a hydrocarbon type environment around the hydroxyl without the simultaneous introduction of large steric effects; that is, their steric effects are probably not much greater than those produced by two ortho-methyl groups, but their $\Delta\nu_m$ values are -15.5 cm^{-1} and -16 cm^{-1} respectively, and their ΔA values are 0.16 and greater than or equal to 0.20 respectively. There is no value of ΔG which will allow either of these phenols to be placed on both the $\Delta\nu_m$ and ΔA curves in Fig. 4. These phenols therefore provide additional evidence that both the frequencies and intensities of

**The calculated absolute intensity of all the 2,6-di-t-alkyl-4-methyl phenols in hexane (based on phenol and an assumed ρ value of 0.30 in hexane) is 0.33.*

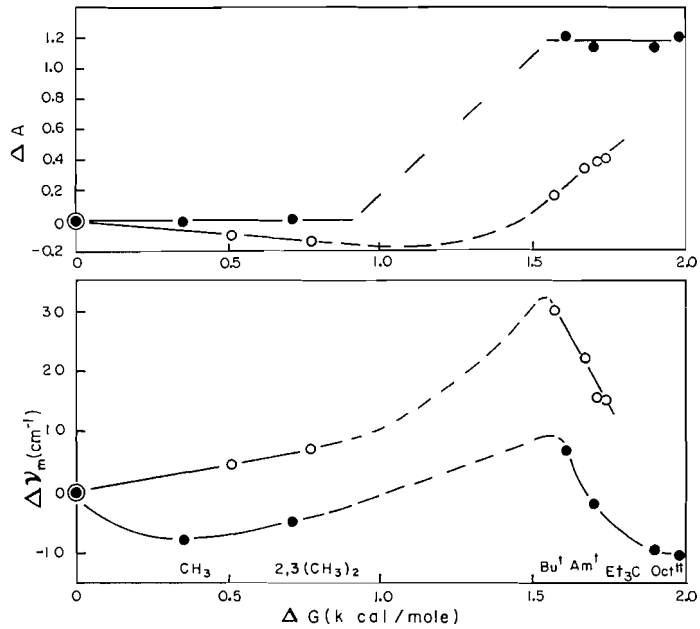

FIG. 4. Differences between measured and calculated frequencies, and intensities, of 2,6-dialkyl phenols plotted against ΔG: in CCl_4 solution ○; in vapor ●.

2,6-dialkyl phenols are determined by environmental as well as by steric factors. It is impossible on the basis of the present work to estimate how the relative importance of these two factors changes with changes in the structure of the alkyl substituents.

(ii) Phenols Containing a Single Ortho-t-alkyl Group

The double hydroxyl bands of *o-t*-alkyl phenols (Fig. 2) are similar to those found in solution (2), that is, the smaller band always occurs at the higher frequency. In solution the larger band was attributed to the trans (to *t*-alkyl) isomer and the smaller to the cis isomer because the frequencies of the two bands were quite close to the frequencies of phenol and the corresponding 2,6-di-*t*-alkyl phenol, respectively. It can be seen from the results in Table II for the measured values of ν_m and for the values calculated from the symmetrically substituted phenols by the Hammett equation that this is far from being the case in the vapor. In particular, the calculated ν_m's for the cis configuration of 2-Am^t-4-Me, 2-Et_2C-4-Me, and 2-Oct^{tt}-4-Me phenols are lower than the ν_m values calculated for the trans isomer (based on 4-Me phenol). This suggests that the identification of the smaller, high frequency, band with the cis isomer might be incorrect. However, the measured and calculated values of ν_m are in the expected order for 2-Bu^t-4-Me, 2-Bu^t-6-Me, and 2-Bu^t-5,6-Me_2 phenols, the calculated ν_m of the trans isomer being based on 4-Me, 2,4,6-Me_3, and 2,3,5,6-Me_4 phenols. Moreover, the measured total intensities of the double bands are in good agreement with the values calculated on the assumption that the smaller band corresponds to the cis isomer (Table II). The calculated intensities were obtained by adding the products of the theoretical intensities of the trans and cis isomers —calculated by the Hammett equation from the A values of the respective symmetrically substituted phenols—and the fraction of each isomer present in the mixture at a given temperature (see below). The agreement between measured and calculated A's would not be achieved if the opposite assignments were made, and therefore the smaller, high frequency, band will henceforth be attributed to the cis isomer.

The relative intensities of the two bands of *o*-*t*-alkyl phenols were estimated at each temperature by a graphical method for 2-*t*-alkyl-4-Me phenols and 2-Bu^t-6-Me phenol. The true ratio of the concentrations of the two isomers, i.e. [trans]/[cis], were obtained by multiplying these relative intensities by a factor which takes account of the intrinsic differences in the intensities of the two isomers. The derivation of this factor from the intensities of the corresponding symmetrically substituted phenols has been described previously (1). Since the A values of 2,6-di-*t*-alkyl-4-Me phenols are nearly constant, and since the A values of 2,4,6-Me_3 and 2,3,5,6-Me_4 phenols are very close to their calculated values (see Figs. 3 and 4), the factor is virtually the same for each phenol. An average correction factor of 2.32 was therefore used in each case. The graphical procedure could not be used to separate the two bands of 2-Bu^t-5,6-Me_2 phenol because they are of nearly equal height. This [trans]/[cis] ratio was therefore obtained by multiplying the ratio of the measured band heights by the correction factor.

The differences in enthalpy (ΔH) and entropy (ΔS) between the two isomers can, in principle, be obtained by plotting $\log_{10}$ [trans]/[cis] against $1/T$ (°K). These plots are shown in Fig. 5. In view of the difficulties involved in separating the two bands and the comparatively small temperature range that was covered the points are not sufficiently accurate to determine ΔS. The straight lines through the points have therefore been drawn to pass through the origin; that is, it was assumed that $\Delta S = 0$ and $\Delta H = \Delta G$, which means that the concentrations of the two isomers become equal as $T \rightarrow \infty$. The points measured at high temperatures for some phenols deviate appreciably from these lines, probably because some decomposition has occurred. The values obtained for ΔH in the vapor are given in Table IV together with the values of ΔG obtained previously at room temperature in CCl_4. ΔH for 2-Me and 2,3-Me_2 phenols was obtained by difference. The agreement between the two sets of data is surprisingly good in view of the expected stabilization of the trans isomer relative to the cis in CCl_4. If this stabilization was appreciable, ΔH in the vapor would be smaller than ΔG in solution. That such stabilization cannot be very large is indicated by the fact that the increases in ν_m for the cis and for the trans isomers on going from CCl_4 to the vapor never differ by more than 10 cm^{-1}. For example, the frequency increase with 2-Bu^t-4-Me phenol is 36 cm^{-1} for the trans and 27.5 cm^{-1} for the cis isomer, a difference of only 8.5 cm^{-1}. These differences are recorded for all the *o*-*t*-alkyl phenols under $\delta\nu_m$ in Table IV.

TABLE IV

Cis–trans isomers in *o*-*t*-alkyl phenols

Phenol substituent	$\delta\nu_m$, cm^{-1}	ΔH (vapor), kcal/mole	ΔG (CCl_4), kcal/mole
2-Bu^t-4-Me	8.5	1.61	1.57
2-Am^t-4-Me	9	1.70	1.67
2-Et_3C-4-Me	10	1.90	1.74
2-Oct^{tt}-4-Me	10.5	1.98	1.71
2-Bu^t-6-Me	3.5	1.26	1.06
2-Bu^t-5,6-Me_2	6	0.90	0.80
2-Me		0.35	0.51
2,3-Me_2		0.71	0.77

It is quite possible that the values of ΔH have been overestimated owing to an overestimation of the intrinsic intensity correction factor; that is, the data in Table II show that ν_m's for the trans isomers of 2-*t*-alkyl-4-Me phenols are about 15 cm^{-1} below the values calculated from 4-Me phenol. A similar, though smaller, effect was observed

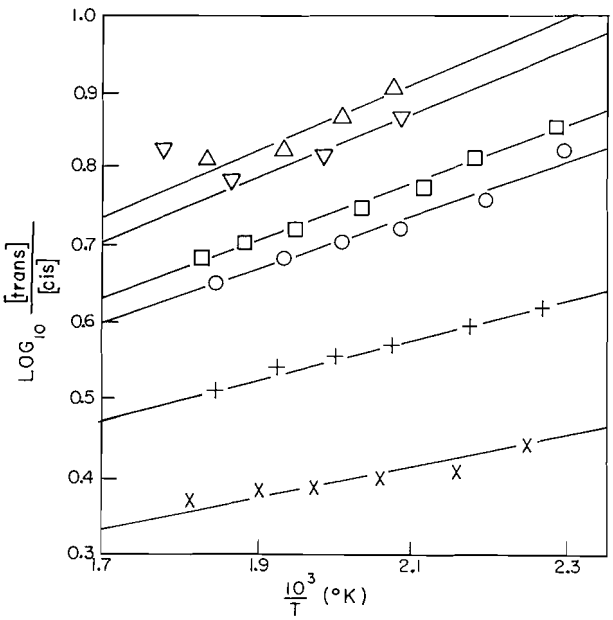

FIG. 5. Effect of temperature on $\log_{10}$ [trans]/[cis] for ortho-*tert*-alkyl phenols in vapor: 2-Bu^t-5,6-Me$_2$ ×; 2-Bu^t-6-Me +; 2-Bu^t-4-Me ○; 2-Am^t-4-Me □; 2-Et$_3$C-4-Me ▽; 2-Oct^{tt}-4-Me △.

previously in solution (1, 7). It was attributed either to van der Waals attraction of the lone pairs of electrons on the oxygen by the trans-*t*-alkyl group (1), or to a steric enhancement of resonance owing to the O—H group being held more rigidly in the plane by the trans-*t*-alkyl group (7). Since a similar effect will probably also be operative in decreasing the ν_m values of 2,6-di-*t*-alkyl phenols it may explain why the measured values of ν_m for the cis isomers of 2-*t*-alkyl phenols are larger than the values calculated from the di-*t*-alkyl phenols by a roughly equal amount (9–15 cm^{-1}). The directions in which the frequencies of the cis and trans isomers differ from their calculated values imply that the intrinsic intensity of the trans isomer will be larger than calculated and that of the cis isomer smaller than calculated. This means that the intrinsic intensity correction factor has probably been overestimated.* The values of ΔH recorded in Table IV are therefore maximum values. Since this source of error is larger in the vapor than in CCl_4, to judge by the differences in the measured and calculated values of ν_m in these two systems, the present results would not be inconsistent with a stabilization energy due to solvation by CCl_4 of a few tenths of a kilocalorie per mole for the trans isomer.

Carbon tetrachloride has been reported to stabilize the trans isomer of *o*-iodophenol ($\delta\nu_m$ = 23 cm^{-1}) by 1.4 kcal/mole with respect to the vapor (5). The present results suggest that this stabilization energy has been overestimated and that much of the observed decrease in the relative intensity of the trans isomer in the vapor is due to a decrease in its intrinsic intensity. If it is assumed that this decrease is of the same magnitude as the decrease observed with phenol in this work (i.e. 0.435/0.18 = 2.4) and that the

**If the measured ν_m values of the cis and trans isomers are used to derive σ constants for the two isomers from the ν_m versus σ plot, and if these σ values are then used to derive intrinsic intensities, the correction factors and ΔH's are reduced but the calculated total intensities are no longer in good agreement with the measured values (e.g. for 2-Bu^t-4-Me phenol the correction factor = 1.29, ΔH = 1.0 kcal/mole, but the total calculated A = 1.39). This again suggests that frequencies are influenced more than intensities by ortho substituents.*

intrinsic intensity of the cis isomer is unaffected by the medium, the stabilization energy only amounts to about 0.5 kcal/mole, which is in better agreement with the present results and with the small value $\delta\nu_m$.

On the basis of the measured steric repulsion of the hydroxyl group by an *o*-*t*-butyl group (~1.6 kcal/mole) and a dielectric measurement of the internal rotational barrier of the OH group in 2,4,6-Bu_3^t phenol (2.8 kcal/mole (10)) we have previously estimated the rotational barrier in phenol to be $\geqslant$4.4 kcal/mole (1). Evans (11) has recently calculated a barrier height of 3.37 from the complete infrared spectrum of phenol vapor. If all these values are assumed to be reasonably accurate, it implies that two *o*-*t*-butyl groups not only raise the coplanar potential minimum of the hydroxyl by 1.6 kcal/mole but also raise the barrier height by about 1.0 kcal, i.e., 4.4 kcal represents the barrier to rotation from the trans to the cis position of the hydroxyl group in 2-*t*-butyl phenol.

CONCLUSION

The frequency and intensity of the fundamental hydroxyl stretching band of a 2-alkyl or 2,6-dialkyl phenol are determined by internal steric and environmental factors in addition to the normal inductive and resonance effects described by the Hammett equation. 2-Alkyl phenols exist as cis and trans isomers both in the vapor and in solution. The trans isomers are not significantly stabilized relative to the cis by solvation in non-polar solvents such as carbon tetrachloride. A 2-*tert*-alkyl group (but probably not a 2-methyl group) can affect the hydroxyl even when the latter points away from it. This interaction may be due either to an attraction of the lone pairs of electrons on the oxygen by the alkyl substituent or to a steric enhancement of resonance between the hydroxyl group and the benzene ring.

ACID-CATALYZED REACTIONS OF VINYL COMPOUNDS

PART I. PRELIMINARY STUDIES ON VINYL ESTERS AND BENZENE[1]

J. M. PEPPER, B. P. ROBINSON, AND G. W. SCHWANBECK
The Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received July 26, 1961

ABSTRACT

A detailed study of the nature, and the mechanism of formation, of the products of the aluminum chloride catalyzed reaction of vinyl esters and benzene has been initiated. Using vinyl acetate the formation of the previously reported acetophenone, 1,1-diphenylethane, and 9,10-dimethylanthracene has been confirmed. By means of both column chromatography and thermal distillation, a similar carbonyl-containing fraction was obtained which, as a result of a gas chromatographic study, has been shown to be a mixture of six compounds. Of these, the two major components have been identified as acetophenone and *p*-ethylacetophenone, the latter previously unreported as a product of this reaction.

The reaction of vinyl formate and benzene has been studied for the first time. High yields of 9,10-dimethylanthracene were obtained but no carbonyl-containing compounds. A study of the effect of a variation in molar ratio of benzene to vinyl acetate indicated that a maximum yield of 9,10-dimethylanthracene was obtained using a 6:1 molar ratio.

The significance of these results is discussed.

A method has been devised for an improved synthesis of 9,10-dimethylanthracene. The generality of this procedure for the synthesis of other substituted polynuclear compounds is indicated.

Some years ago, Hopff, in a patent disclosure (1), indicated that the acid-catalyzed interaction of vinyl acetate and benzene gave rise to 2-phenylethyl acetate. The possibility thereby arose whereby this condensation followed by hydrolysis of the ester could provide a convenient method of synthesis of 2-phenylethanol, a perfume ingredient. Attempts to repeat the initial condensation were not successful, but the products that were obtained were of sufficient interest to warrant further study regarding their nature and mechanism of formation. In 1946, Korshak, Samplavskaya, and Gershanovich (2) reported the identification of acetophenone (I), 1,1-diphenylethane (II), and a compound believed to be 9,10-dimethyl-9,10-dihydroanthracene (III) in the reaction product of vinyl acetate and benzene in the presence of aluminum chloride. They proposed a mechanism involving the initial formation of I and acetaldehyde. Acetaldehyde then reacted further with benzene to produce II, two molecules of which subsequently gave rise to one molecule of III and two molecules of benzene. Some support for this theory was obtained by showing that acetaldehyde and benzene did react to yield these same compounds and also that II gave rise to III in the presence of aluminum chloride. It was also noted that the yield of III increased with increasing time of reaction. Evidence had been given much earlier for this mechanism. In 1895, Radziewanowski (3) showed that in the absence of benzene, aluminum chloride catalyzed the conversion of II to III, and in 1931, Bodendorf (4) reported that acetaldehyde, benzene, aluminum chloride, and hydrogen chloride at 0° gave rise to ethylbenzene, II, and III.

A review of the literature indicated that the acid-catalyzed interaction of vinyl compounds and benzene has been the subject of several reports since as early as 1884. The interaction with vinyl bromide was reported to yield 1-bromo-2-phenylethane and 1,4-di-(β-bromoethyl)benzene by Hanriot and Guilbert (5) in 1884; ethylbenzene, II, and III by Angeblis and Anschütz (6) in 1884. These latter workers suggested the addition of

[1]*Presented at the 44th Annual Conference, Chemical Institute of Canada, at Montreal, August 3–5, 1961.*

hydrogen bromide to vinyl bromide to give 1,1-dibromoethane, which reacted with benzene to give II and III. Later in 1886, Anschütz (7) reported the formation of some styrene, ethylbenzene, II, and III from a similar reaction.

Vinyl chloride and benzene in the presence of a catalyst made from mercuric chloride and aluminum gave rise to II and III according to Böeseken and Bastet (8) in 1913 and similar products plus ethylbenzene were reported by Davidson and Lowy (9) in 1929. The former workers first postulated the formation of styrene to which benzene added to give II. However, styrene as a reactant did not give the same products, so other mechanisms were suggested including that proposed earlier by Angeblis and Anschütz (6) and one involving the intial production of 1-chloro-1-phenylethane, which reacted with benzene to give II. However, no such intermediate was isolated. Schramm (10) had in 1893 reported that 1-chloro-1-phenylethane reacted with benzene to give ethylbenzene, II, and III. The latter investigators showed that styrene could not be an intermediate and also that the major product at 0–5° was II with only traces of III, whereas at 60–70° the yield of II decreased and that of III increased appreciably. In 1946, Korshak, Samplavskaya, and Gervanovich (2) also reported compounds II and III and showed that the yield of II decreases while that of III increases as the time of reaction is increased. These same two products along with some ethylbenzene and styrene were claimed by Malinovskii (11) in 1949 to be formed by the reaction of vinyl chloride and benzene. He claimed that III arises from 1-chloro-1-phenylethane in the presence of the aluminum chloride catalyst. The reaction of benzene with three other vinyl ethers has also been reported. Using vinyl-*n*-butyl ether, Korshak *et al.* (2) in 1946 reported small yields of *n*-butylbenzene and a polymer of the vinyl ether, whilst, in 1938, Hopff (1) claimed that vinyl ethyl ether and acrylic acid reacted with benzene in the presence of an acid catalyst to give β-phenylethyl ether and β-phenylpropionic acid respectively. The interaction of three substituted vinyl compounds with benzene in the presence of aluminum chloride has also been studied. In 1930, Gibson and Johnson (12) reacted $(CHCl{=}CH)_2AsCl$ to yield a compound $C_{16}H_{14}$ (yellow plates, m.p. 179–180°); in 1950 Kirk (13), in a patent, claimed that $C(CH_3)_2{=}CHY$ gave $C_6H_4(C(CH_3)_2CH_2Y)_2$ (Y = Ac or COOH); and in 1952, Hurd and Gershbein (14) reported that isopropenyl acetate gave rise to acetophenone (I).

The structure of the polynuclear product reported in these investigations as 9,10-dimethyl-9,10-dihydroanthracene (III) had been questioned and finally proved incorrect. As early as 1885, Friedel and Crafts (15) believed this product to be 9,10-dimethylanthracene (IV). Later in 1926, Barnett and Matthews (16) suggested that the product obtained by Anschutz (7) was really IV because it had a relatively high melting point, formed a picrate, and was identical with the product obtained by the reaction of methyl magnesium iodide and 9-methylanthrone. The relationship was finally proved when in 1941, Badger, Goulden, and Warren (17) effected a sulphur dehydrogenation of authentic 9,10-dimethyl-9,10-dihydroanthracene to produce a yellow, fully aromatic compound, m.p. 180–182°, identical with the compound III obtained as described above, and when, in 1950, Badger, Jones, and Pearce (18) performed a similar dehydrogenation with aluminum chloride. This last observation suggests the route by which 9,10-dimethylanthracene was formed in all the reactions described earlier.

It was decided, therefore, to reinvestigate the aluminum chloride catalyzed reaction of vinyl derivatives and benzenoid hydrocarbons in an attempt to establish more completely the nature of the products of the reaction and, if possible, to suggest a plausible

mechanism for their formation. In a series of exploratory experiments* I, II, and III were confirmed as the major components of the product of reaction of vinyl acetate, benzene, and aluminum chloride. Compound III was identified by comparison with an authentic sample.† Other acids, including zinc chloride, zirconium tetrachloride, sulphuric acid, boron trifluoride, hydrogen fluoride, and aluminum chloride sulphate, were investigated but only zirconium tetrachloride was found to be equivalent to aluminum chloride for this reaction. Both nitromethane and carbon disulphide were studied as diluents. In the former case, product yields were decreased but with the latter solvent higher yields and less resinous material were obtained than if it had been omitted. The presence of acetophenone (I) suggested a mechanism involving attack by the acetylium ion (CH_3CO^+). It was of interest therefore to investigate the products of reaction in which vinyl formate replaced vinyl acetate. In this case no acetophenone, no benzaldehyde, nor, indeed, any carbonyl-containing fragment was detected. However, good yields of 9,10-dimethylanthracene (III) were again obtained, indicating that the formation of this compound involved the vinyl part of the ester molecule. It was further shown that in reactions involving vinyl formate, carbon monoxide was eliminated as determined by the color tests described by Fiegl (19) using phosphomolybdic acid and palladium chloride.

Conflicting reports have been noted regarding the possible intermediary role of styrene in this reaction. It may be conceived that styrene could arise as a result of the attack by the vinylium ion, $CH_2{=}CH^+$, on benzene, the product of which then may dimerize to 9,10-dimethyl-9,10-dihydroanthracene, which, as has been shown experimentally, may be dehydrogenated by aluminum chloride to give the final product 9,10-dimethylanthracene. Under the conditions used, styrene, in the presence of benzene and aluminum chloride, gave rise only to a polymeric substance, indicating the inadequacy of this mechanism. Similarly β-phenylethyl acetate was tested as a possible intermediate but in this case no anthracene derivative was detected but, instead, appreciable yields of 1,2-diphenylethane were obtained.

These preliminary observations only emphasized the need for a more thorough study of the interaction of vinyl derivatives and aromatic hydrocarbons to clarify the relationship of reaction conditions to the nature of the products and to establish a mechanism for their formation. Furthermore the ease of synthesis of 9,10-dimethylanthracene suggested that the method may be capable of development as a general one for the preparation of 9,10-dialkyl-substituted polynuclear hydrocarbons and their derivatives, depending on the choice of the unsaturated and benzenoid substances. In particular, this method of synthesis of 9,10-dimethylanthracene is an improvement over that involving the aryllithium intermediate as reported by Mikhailov and Kozminskaya (20), either of those involving a Grignard reaction as described by Sandin and Kitchen (21) and Barnett and Matthews (16), and over that in which metallic sodium is used as described by Bachmann and Chemerda (22).

Initially the emphasis has been on the yield and nature of the products of reaction of vinylacetate and benzene in the presence of aluminum chloride. The reaction procedure was essentially that described by Korshak *et al.* (2) and gave a crude reaction product in the form of a brownish yellow paste. Chromatographic separation of this crude product on alumina effected a partial separation, as shown in Table I.

Carried out as an undergraduate thesis requirement by A. Francis (1955), H. Ford (1957), and A. Notation (1958) for the B.E. degree, and in part by A. Currie (1954) for the M.A. degree.

†*Authentic sample of 9,10-dimethylanthracene kindly supplied by Dr. R. Sandin, University of Alberta.*

TABLE I

Chromatographic separation of reaction product of vinyl acetate and benzene*

Eluent	Vol. of eluent (ml)	Nature of product	Remarks
Light petroleum	200	Colorless oil	
	100	Oil and solid	
	200	Pale yellow solid	
	100	Pale yellow solid	
	100	Yellow oil	Carbonyl-containing fraction (1.94 g) (36%)
Light petroleum: benzene (1:1)	1100	Yellow oil	
	600	Yellow solid	"Hydrocarbon fraction" (0.49 g) (9.1%)
Benzene	400	Yellow solid	
Benzene: Et_2O (1:1)	800	Viscous oil	
Methanol	2500	Dark residue	

*Crude reaction product (5.83 g); alumina (200 g).

The pale yellow crystals obtained in the light petroleum eluate were identified as 9,10-dimethylanthracene and a study of the yield of this product is reported later. The product designated as "hydrocarbon fraction" was crystallized from carbon tetrachloride, then methanol, to give white crystals, m.p. 190–210°, which have not been further investigated.

The carbonyl-containing fraction gave a negative aldehyde test but a strong haloform reaction. Attempts were made to separate further the components of this fraction by thermal distillation and rechromatography. In neither case were pure compounds obtained since subsequent gas chromatographic separation using a Beckman, 6-ft silicone column showed that all such fractions were mixtures. It was later found that an initial distillation under reduced pressure (90–140° at 12 mm) of the crude reaction product permitted of a separation of a fraction containing the same components and in the same relative abundance as the carbonyl-containing fraction obtained by column chromatography. Using gas chromatography, and by repeated injections and collections of the compound represented by its peak of the chromatogram, a sample of three of the compounds was obtained. Rechromatography, followed by distillation, gave analytically pure samples, the analytical data of which are given in Table II.

TABLE II

Gas chromatographic separation of carbonyl-containing products*

Compound	Retention time (min)	% of injected sample†	B.p. at 12 mm (°C)	Analyses	
				C (%)	H (%)

5	27	2.2	—	—	—
6	29.6	5.1	—	—	—

*Six-foot silicone column, Beckman No. 17,449; temperature 220°; helium gas 0.91 cc/min; each injection 100 μl.
†Total recovery 64.8%.
‡Calc. for acetophenone: C, 79.97; H, 6.71%.
§Calc. for *p*-ethylacetophenone: C, 81.04; H, 8.16%.
‖Calc. for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

Compound 3 was readily shown to be *p*-ethylacetophenone by its oxidation to terephthalic acid, and by formation of the oxime, semicarbazone, and 2,4-dinitrophenylhydrazone derivatives. The retention time of an authentic sample of *p*-ethylacetophenone

was also 13 minutes. This is the first report that this compound constitutes a major part (18.5%) of the products of the aluminum chloride catalyzed reaction of vinyl acetate and benzene. Compound 4 has an analysis corresponding to a diethyl acetophenone and its identification is under study.

At this stage it became evident that the reaction, as performed, led to a complex mixture of products. To facilitate a mechanistic study it would be desirable to modify the reaction conditions to minimize the initial number of products and later to determine the nature of any secondary reactions. To this end a study was made of the effect of variation in molar ratio of benzene to vinyl acetate under conditions of excess threefold molar ratio aluminum chloride to vinyl acetate. For comparison the following yields were determined: total product; 9,10-dimethylanthracene; a distillate, b.p. → 150° at 12 mm; a distillate, b.p. 150–175° at 0.17 mm; and the residue. It had been found that a simple washing of the crude reaction product with methanol permitted an effective separation of the slightly soluble anthracene derivative (0.1% soluble) from all other reaction products. The methanol was evaporated from the resulting solution and the residue distilled. The results of this series of experiments are given in Table III.

TABLE III

*Each run: vinyl acetate (8.6 g, 0.1 mole); aluminum chloride (40 g, 0.3 mole).
†Based on a calculated yield of addition of 2 moles benzene to 1 mole vinyl acetate.
‡Percentage of total product.

Some observations regarding the mechanism of this reaction may be made from these data. There is a parallel relationship to be found between the variation in yield of 9,10-dimethylanthracene and that of the higher-boiling distillate fraction, the former going through a maximum and the latter a minimum at a molar ratio of benzene to vinyl acetate of about 6:1. The relative constancy of the yield of the lower-boiling distillate, which has already been shown to be the carbonyl-containing fraction, suggests that the components of this fraction arise by a reaction involving the acetoxy part of the ester, whereas the higher-boiling fraction and the anthracene derivative are related by a reaction involving the vinyl part. The observation, too, that the yield of 9,10-dimethylanthracene decreases with dilution greater than a molar ratio of 6:1 supports the belief that this product results by a dimerization of two primary products, and not by a mechanism in which the final step involves reaction with benzene. On the other hand the increasing yield as the ratio varies from 2:1 to 6:1 is difficult to interpret at this time but may involve the availability of the aluminum chloride – vinyl acetate complex. Further identification of the reaction products will aid in the understanding of this reaction.

EXPERIMENTAL

Aluminum Chloride Catalyzed Reaction of Vinyl Formate and Benzene

Vinyl formate (7.2 g, 0.1 mole) (obtained from Monomer–Polymer Inc., Leominster, Mass.) was added slowly over a period of 1 hour to a well-stirred mixture of benzene (78 g, 1 mole) and sublimed anhydrous aluminum chloride (40 g, 0.3 mole) in a 200-ml 3-necked flask equipped with reflux condenser, dropping funnel, and mechanical stirrer. Both the condenser and dropping funnel were fitted with calcium chloride drying tubes. Throughout the addition, the flask was cooled in an ice bath and the color changed from colorless through yellow to orange. The reaction mixture was allowed to warm to room temperature, during which time the color deepened to a brown, and then refluxed for 3 hours, after which the mixture was red colored. Pouring this mixture into a mixture of concentrated hydrochloric acid (75 ml) and crushed ice (75 g) resulted in the formation of a pale yellow precipitate (4.9 g), m.p. 182–185°. A mixed melting point with an authentic sample of 9,10-dimethylanthracene showed no depression.

Aluminum Chloride Catalyzed Reaction of β-Phenylethyl Acetate and Benzene

In a manner similar to that described above, β-phenylethyl acetate (27 g, 0.16 mole) was added dropwise to a mixture of benzene (100 ml) and aluminum chloride (22 g, 0.16 mole) over a period of 0.5 hour. After hydrolysis, the benzene layer was separated and the aqueous layer extracted twice with benzene. The combined benzene extracts were evaporated to yield a pale yellow oil. When the oil was cooled, crystals separated which were removed by filtration and washed with ethanol; yield, 6 g, m.p. 45–46°. Recrystallization from ethanol gave white crystals, m.p. 50–51°. A mixed melting point with an authentic sample of dibenzyl, m.p. 50–51° (prepared by the Clemmensen reduction of benzoin (23)), showed no depression.

Aluminum Chloride Catalyzed Reaction of Vinyl Acetate and Benzene

A typical procedure involved the addition of vinyl acetate (8.6 g, 0.1 mole) to benzene (78 g, 1.0 mole) and sublimed, anhydrous aluminum chloride (40 g, 0.3 mole) followed by treatment as described above. A modification involved washing the benzene extract first with sodium hydroxide (10%), then with water, before drying it over anhydrous sodium sulphate. After removal of the solvent, a semisolid product remained (16.4 g). A portion (5.38 g) of this crude product was chromatographed through alumina (200 g) using successively, light petroleum, light petroleum – benzene (1:1), benzene, benzene – diethyl ether (1:1), and methanol, collecting 100-ml fractions.

In the series of runs involving varying ratios of benzene to vinyl acetate a similar procedure was used. In all cases except those involving the 100:1 and the 2:1 ratios the crude product solidified to a yellow-colored paste. The product was washed from the reaction flask using methanol (15 ml) and filtered. The resulting yellow solid, 9,10-dimethylanthracene, was washed again with methanol (5 ml). Two such samples of crude product melted at 176–181° and 180–184°; reported, 180–181° (21).

SYNTHESIS OF POTENTIALLY PHYSIOLOGICALLY ACTIVE β-PHENYLETHYLAMINES

PART I. 3,4,5-TRIMETHOXY-α-AMINOMETHYLBENZYL ALCOHOL AND 4-ACETOXY-3,5-DIMETHOXY-α-AMINOMETHYLBENZYL ALCOHOL DERIVATIVES[1]

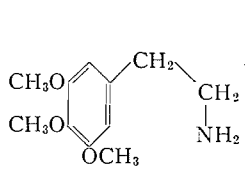
R. A. HEACOCK AND O. HUTZINGER
The Psychiatric Research Unit, University Hospital, Saskatoon, Saskatchewan

Received July 24, 1961

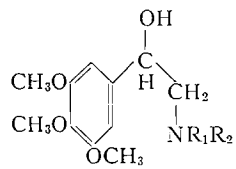
ABSTRACT

The preparation of several 3,4,5-trisubstituted-β-hydroxy-β-phenylethylamines related to mescaline, by the reduction or reductive alkylation of the corresponding nitroalcohols, is described.

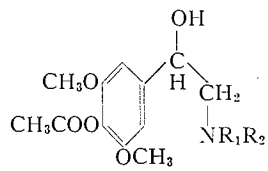
Mescaline (I) has been known for many years to produce marked psychological changes in human subjects (see ref. 1 for some of the more important references), and many chemically similar substances have been prepared and examined for psychopharmacological activity (cf. ref. 2). However, little attention, so far, seems to have been given to the preparation or physiological activity of mescaline-like compounds with a hydroxyl group in the side chain on the carbon atom adjacent to the aromatic ring (i.e. as in adrenaline). As yet, only two compounds of this type have been described, but as far as the authors are aware, there are no reports in the literature of studies on the psychological activity of either of these two substances.



I



II



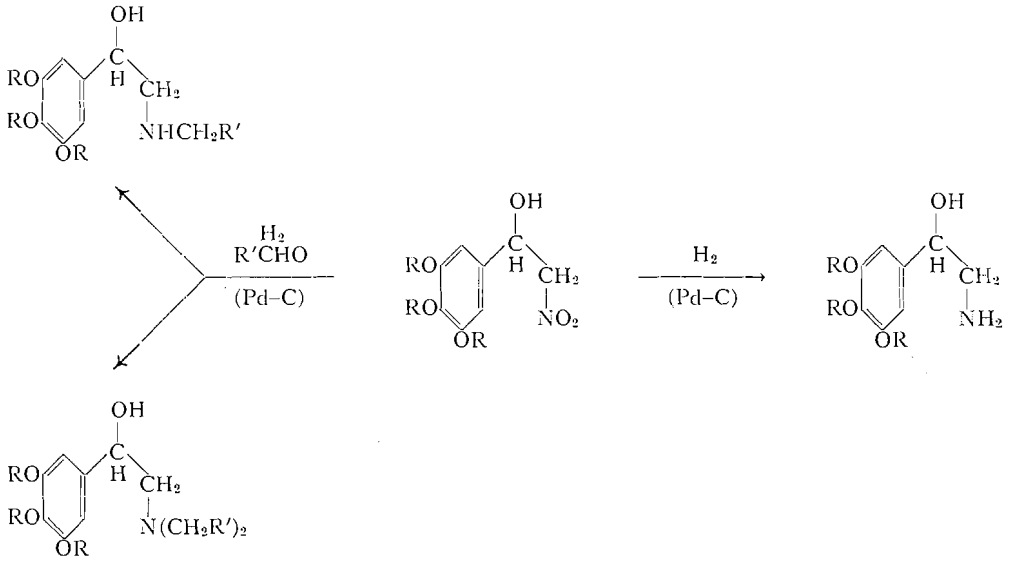
III

3,4,5-Trimethoxy-α-aminomethylbenzyl alcohol (II: $R_1 = R_2 = H$) was first prepared in 1931 by the catalytic reduction of 3,4,5-trimethoxybenzoyl cyanide (3). Twenty years later, it was shown that (II: $R_1 = R_2 = H$) could also be obtained by reduction of the corresponding aryl cyanohydrin (or aroyl cyanide) with lithium aluminum hydride (4, 5). The *N*-methyl analogue (II: $R_1 = CH_3$; $R_2 = H$) has been prepared by the catalytic hydrogenation of ω-(*N*-benzyl-*N*-methyl)-amino-3,4,5-trimethoxybenzophenone (6).

This communication describes a simple method for the synthesis of compounds of this nature by the reduction or reductive alkylation (cf. ref. 7) of suitable α-phenyl-β-nitroethanol derivatives. (These nitroalcohols are readily available by the method of Heacock, Hutzinger, and Nerenberg (8).)

The reduction of α-phenyl-β-nitroethanol derivatives with sodium amalgam and dilute acetic acid to the corresponding α-phenyl-β-aminoethanol was first described by Rosenmund (9). Later, Kanao obtained 3,4-diacetoxy-α-aminomethylbenzyl alcohol from the reduction of 3,4-diacetoxy-α-nitromethylbenzyl alcohol with zinc and dilute acetic acid

[1]*This investigation was supported by grants from the Government of Saskatchewan (Department of Public Health) and the Department of National Health and Welfare, Ottawa.*



(10). This author also reported several reductive alkylations of 3,4-diacetoxy-α-nitromethylbenzyl alcohol with zinc and dilute acetic acid in the presence of about one mole of a suitable aldehyde (10). Recently, Axelrod *et al.* prepared O^4-benzylnormetanephrine by the catalytic hydrogenation of 4-benzyloxy-3-methoxy-α-nitromethylbenzyl alcohol (11). O^4-Acetylnormetanephrine and O^4-acetylmetanephrine have recently been obtained from 4-acetoxy-3-methoxy-α-nitromethylbenzyl alcohol by catalytic reduction and reductive alkylation respectively (12).

3,4,5-Trimethoxy-α-aminomethylbenzyl alcohol (II: $R_1 = R_2 = H$) has been obtained in high yield (as the hydrochloride or oxalate salt) by catalytic hydrogenation of 3,4,5-trimethoxy-α-nitromethylbenzyl alcohol in aqueous suspension. If the hydrogenation was carried out in the presence of 1 equivalent of formaldehyde, reductive alkylation occurred with the formation of the monomethylamino derivative (i.e. 3,4,5-trimethoxy-α-methylaminomethylbenzyl alcohol; II: $R_1 = CH_3$; $R_2 = H$); reduction in the presence of 3 to 4 equivalents of formaldehyde lead to the formation of the dimethylamino derivative (i.e. 3,4,5-trimethoxy-α-dimethylaminomethylbenzyl alcohol; II: $R_1 = R_2 = CH_3$). 4-Acetoxy-3,5-dimethoxy-α-aminomethylbenzyl alcohol (III: $R_1 = R_2 = H$) and the corresponding *N*-methyl (III: $R_1 = CH_3$; $R_2 = H$) and *N*,*N*-dimethyl (III: $R_1 = R_2 = CH_3$) derivative could be obtained (as the oxalates) in an analogous manner from 4-acetoxy-3,5-dimethoxy-α-nitromethylbenzyl alcohol.

In view of the possibility of an intermolecular cyclization reaction of the Pictet–Spengler type (cf. ref. 13) occurring during the reductive alkylations which would have presumably led to the formation of tetrahydroisoquinoline derivatives, a sample of the product assumed to be 3,4,5-trimethoxy-α-dimethylaminomethylbenzyl alcohol (II: $R_1 = R_2 = CH_3$) was oxidized with aqueous alkaline potassium permanganate. 3,4,5-Trimethoxybenzoic acid was obtained, indicating that cyclization had not occurred, since a phthalic acid derivative would have been expected from the permanganate oxidation products of the tetrahydroisoquinoline ring system.

Further synthetic work in this field is underway and the physiological activity of this group of substances is under investigation. The results will be reported elsewhere in due course.

TABLE I

3,4,5-Trimethoxy-α-aminomethylbenzyl alcohol derivatives[a]

[e]It was not possible to prepare a pure sample of the hydrochloride salt of 4-acetoxy-3,5-dimethoxy-α-methylaminomethylbenzyl alcohol, either from attempts to prepare the salt directly by hydrogenation in the presence of hydrochloric acid or by treatment of the corresponding oxalate with calcium chloride. Two different substances, m.p.'s 207–209° and 150–151° respectively, were obtained, but in neither case could a completely satisfactory analysis for the desired product be obtained.
[f]MEK = methyl ethyl ketone.

EXPERIMENTAL

*General Procedure for Reduction and Reductive Alkylation**

A suspension of the nitroalcohol (prepared by the method of Heacock, Hutzinger, and Nerenberg (8)) containing one third of its weight of a palladium catalyst (5% on charcoal), an acid component, and formaldehyde (where applicable, see tables), was shaken in the presence of hydrogen at atmospheric pressure until the calculated amount was taken up. After filtration of the reaction mixture, the product was concentrated to dryness *in vacuo* (below 40°) and the residue was recrystallized from a suitable solvent.

Oxidation of 3,4,5-Trimethoxy-α-dimethylaminomethylbenzyl Alcohol Hydrochloride

A solution of 3,4,5-trimethoxy-α-dimethylaminomethylbenzyl alcohol hydrochloride† (0.2 g) in 1% aqueous sodium hydroxide (10 ml) was oxidized with potassium permanganate (0.6 g), the solution being maintained at 90° C for 2 hours. The reaction mixture was acidified with dilute sulphuric acid, after filtration, and the white solid which separated was recrystallized from aqueous ethanol. Colorless needles, m.p. 171–172°, were obtained, which were identical in all respects (no depression of melting point and identical infrared spectra) with an authentic sample of 3,4,5-trimethoxybenzoic acid.

†One example of a substance prepared by reductive alkylation of the nitroalcohol was chosen arbitrarily for oxidation. It was assumed that the other compounds prepared in this fashion would behave similarly on oxidation.

SYNTHESIS OF POTENTIALLY PHYSIOLOGICALLY ACTIVE β-PHENYLETHYLAMINES

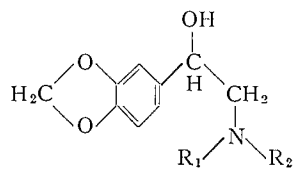
PART II. 3,4-METHYLENEDIOXY-α-AMINOMETHYLBENZYL ALCOHOL DERIVATIVES[1, 2]

R. A. HEACOCK, O. HUTZINGER, AND C. NERENBERG[3]
The Psychiatric Research Unit, University Hospital, Saskatoon, Saskatchewan
Received July 24, 1961

ABSTRACT

The preparation of 3,4-methylenedioxy-α-aminomethylbenzyl alcohol and a number of its *N*-alkyl and *N,N*-dialkyl derivatives by the reduction or reductive alkylation of 3,4-methylenedioxy-α-nitromethylbenzyl alcohol is described.

As a prerequisite for an examination of the physiological activity of several groups of compounds related to adrenaline, the preparation of a number of substituted α-aminomethylbenzyl alcohols has been undertaken. The methylenedioxyphenyl group is present in many naturally occurring physiologically important substances and a series of *N*-substituted derivatives of 3,4-methylenedioxy-α-aminomethylbenzyl alcohol has been prepared in order to study the effects of variation of the *N*-substituent on the physiological activity of this particular series of compounds.



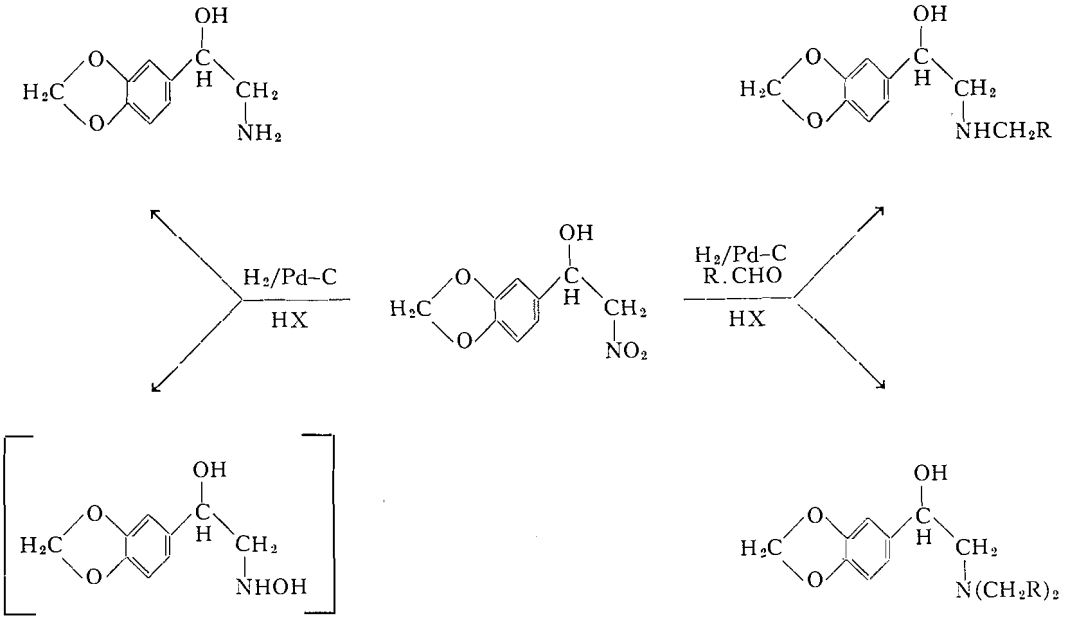
I

3,4-Methylenedioxy-α-methylaminomethylbenzyl alcohol (I: $R_1 = CH_3$; $R_2 = H$) was the first member of this series to be described (1) and was obtained by the action of methylamine on 3,4-methylenedioxy-α-bromomethylbenzyl alcohol. The dimethylamino analogue (I: $R_1 = R_2 = CH_3$) was obtained a few years later by a similar route (2). The analogous primary amino compound, 3,4-methylenedioxy-α-aminomethylbenzyl alcohol (I: $R_1 = R_2 = H$), was prepared, several years later, by the reduction of piperonal cyanohydrin with sodium amalgam in dilute acetic acid (3). Subsequently several authors have repeated and improved the afore-mentioned procedures (4, 5, 6, 7, 8). 3,4-Methylenedioxy-α-aminomethylbenzyl alcohol (I: $R_1 = R_2 = H$) has also been obtained by the catalytic reduction of (*a*) 3,4-methylenedioxybenzoyl cyanide (9) (reported to give better yields than reduction of the corresponding cyanohydrin), and of (*b*) ω-nitro-3,4-methylenedioxyacetophenone (10). Two further methods have been described for the preparation

[1]*This investigation was supported by grants from the Government of Saskatchewan (Department of Public Health) and the Department of National Health and Welfare, Ottawa.*
[2]*Part I. Can. J. Chem. This issue.*
[3]*Present address: Research Division, Columbus Psychiatric Institute and Hospital, Ohio State University Health Center, Columbus 10, Ohio, U.S.A.*

of compounds in this series. Firstly, by the decarboxylation of suitable 3,4-methylenedioxyphenylserine derivatives (11), which are readily available by the condensation of piperonal with an alkylglycine derivative (12), and secondly, 3,4-methylenedioxy-α-methylaminobenzyl alcohol (I: $R_1 = CH_3$; $R_2 = H$) has been obtained by the acid hydrolysis of 3-methyl-5-(3,4-methylenedioxyphenyl)-2-oxazolidone (13).

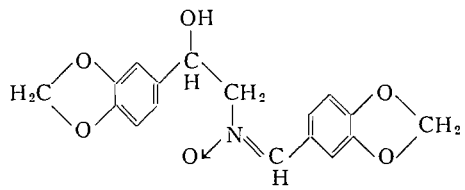
The preparation of α-aminomethylbenzyl alcohol derivatives by the reduction or reductive alkylation of the corresponding α-phenyl-β-nitroalcohol derivative has been discussed in Part I of this series (14) and these general procedures have been extended to the synthesis of 3,4-methylenedioxy-α-aminomethylbenzyl alcohol and a number of its *N*-alkyl and *N*,*N*-dialkyl derivatives.



3,4-Methylenedioxy-α-nitromethylbenzyl alcohol was reduced catalytically with hydrogen in aqueous suspension, at atmospheric pressure in the presence of 1 mole of oxalic acid; 3,4-methylenedioxy-α-aminomethylbenzyl alcohol was isolated as the "neutral" oxalate salt after the calculated quantity of hydrogen had been taken up. The presence of oxalic acid enabled the product to be isolated easily, as the oxalate salt crystallizes well. It should be noted that the neutral oxalate was invariably obtained irrespective of the amount of oxalic acid present. The hydrogen oxalate of 3,4-methylenedioxy-α-aminomethylbenzyl alcohol had previously been reported (7, 10) and it was claimed that it could be recrystallized from water (10). During the present investigation, however, it was only found possible to obtain the acid salt by treatment of the neutral oxalate with an excess of oxalic acid in absolute ethanol, followed by recrystallization of the product from a cold, saturated solution of oxalic acid in absolute ethanol. Attempted recrystallization of the acid oxalate from water always led, in our hands, to the formation of the neutral salt.

The catalytic hydrogenation of a number of similar α-phenyl-β-nitroalcohols using a

5% palladium-on-charcoal catalyst in the presence of oxalic acid had previously been reported to give the corresponding α-hydroxylaminomethylbenzyl alcohol derivatives (16). The formation of the hydroxylamino derivatives requires the uptake of 2 molecules of hydrogen as opposed to the 3 molecules required for the total reduction of the nitro group. We have found that with the 3,4-methylenedioxy-α-nitromethylbenzyl alcohol the reaction proceeded to completion easily. However, if the uptake of hydrogen was arrested after approximately 2 molecules of hydrogen had been absorbed, 3,4-methylenedioxy-α-hydroxylaminomethylbenzyl alcohol could be obtained (as the oxalate salt). All attempts to isolate 3,4-methylenedioxy-α-hydroxylaminomethylbenzyl alcohol as the free base from the oxalate salt were unsuccessful. This type of hydroxylamine derivative is known to be unstable in alkali and to rapidly form the corresponding *N*-(β-hydroxy-β-phenylethyl)-isobenzaldoxime (cf. ref. 16). It would thus appear that in the present case attempts to prepare the hydroxylamine derivative as the free base led to the formation of *N*-(β-hydroxy-β-(3,4-methylenedioxyphenyl)-ethyl)-3′,4′-methylenedioxyisobenzaldoxime (II).



II

Our earlier experiments were carried out with oxalic acid rather than a mineral acid to avoid the possibility of ω-nitrostyrene formation by dehydration of the nitroalcohol (cf. ref. 15) prior to its reduction. However, it was subsequently found that this did not occur readily and the hydrochloride salts could be prepared directly.

The reductive alkylations were carried out with 1 mole or 3–4 moles respectively of the desired carbonyl component, the products usually being the mono- or di-alkylamino derivatives respectively. In cases where steric hindrance could be a factor (e.g. when the carbonyl compound was a branched-chain aldehyde or a ketone, i.e. in the cases studied: acetone and isobutyraldehyde) even in the presence of a large excess of the carbonyl component, only the monoalkyl derivative was obtained.

When the reductive alkylation was carried out in the presence of 1 mole of oxalic acid, usually the mono- and di-alkyl derivatives were obtained as the hydrogen oxalate. In the only case studied (i.e. the *N*-monomethyl derivative) the neutral oxalate was obtained in the presence of a ½ mole of oxalic acid. The *N*-monoethyl derivative behaved anomalously, giving the neutral oxalate under all conditions investigated. The free bases could be obtained by treating the crude reduction mixtures with strong aqueous alkali followed by benzene extraction. In general, the monoalkyl derivatives were solids and the dialkyl derivatives oils at room temperature.

In most cases, the hydrochloride salts can be obtained directly (i.e. hydrogenation in the presence of hydrochloric acid) or by treatment of the free base with 1 equivalent of aqueous hydrochloric acid and removing the solvent *in vacuo* below 40°. Attempts to obtain the hydrochlorides by treating the base in dry ether (or dry benzene) with gaseous hydrogen chloride (or a saturated solution of hydrogen chloride in absolute

ethanol) sometimes led to anomalous results. (Microanalysis often suggested that the product contained two chlorine atoms.) The lability of the side-chain hydroxyl group in compounds of this nature is well known (cf. ref. 17), particularly when under the influence of the 3,4-dialkoxy substitution in the benzene ring. However, the exact nature of this phenomenon is still not fully understood and will be subject to further investigation. Unsuccessful attempts were made to effect reductive alkylation using 1,3-dihydroxyacetone, furfuraldehyde, and benzaldehyde as the carbonyl component. In all cases the unalkylated primary amino derivative was obtained. (Kanao (18) prepared the *N*-benzyl and *N*-furfuryl derivatives of 3,4-diacetoxy-α-aminomethylbenzyl alcohol by the reduction of 3,4-diacetoxy-α-nitromethylbenzyl alcohol with zinc and acetic acid in the presence of benzaldehyde and furfuraldehyde respectively.)

In view of the possibility of an intermolecular cyclization reaction of the Pictet–Spengler type (cf. ref. 19) occurring during the reductive alkylation, which would have presumably led to the formation of tetrahydroisoquinoline derivatives, a sample of the product assumed to be 3,4-methylenedioxy-α-*n*-propylaminomethylbenzyl alcohol* was oxidized with aqueous alkaline potassium permanganate; piperonylic acid was obtained, indicating that cyclization had not occurred, since a phthalic acid derivative would have been expected from the permanganate oxidation products of the tetrahydroisoquinoline ring system.

The physiological activity of these compounds will be the subject of a further study and the results will be reported elsewhere in due course.

EXPERIMENTAL

3,4-Methylenedioxy-α-nitromethylbenzyl Alcohol

3,4-Methylenedioxy-α-nitromethylbenzyl alcohol was prepared by the method of Heacock *et al.* (20).

Reduction and Reductive Alkylation of 3,4-Methylenedioxy-α-nitromethylbenzyl Alcohol

An aqueous suspension† of the above nitroalcohol, together with one third of its weight of a 5% palladium-on-charcoal catalyst, oxalic acid (or hydrochloric acid) (1 mole), and where applicable, 1 or 3–4 moles of the desired carbonyl compound, was shaken in hydrogen (atmospheric pressure; room temperature). After the hydrogen uptake was complete (4–6 hours), the reaction mixture was filtered and the filtrate was concentrated *in vacuo*, below 40°, and the residue recrystallized from a suitable solvent.

For the preparation of the free base, 40% aqueous sodium hydroxide was added to an aqueous solution of the oxalate or hydrochloride salt (or the filtrate from the crude reduction mixture), and the free base extracted with benzene. After concentration of the dried (Na_2SO_4) extract to dryness the crude product was purified either by distillation in high vacuum or by recrystallization from a suitable solvent. In some cases where difficulties were encountered in crystallizing the oxalates or hydrochlorides, the picrates were prepared for the accurate characterization of the bases. In the case of the *N*,*N*-divaleryl base, no crystalline salts could be obtained, but the free base had a satisfactory analysis.

Full details of the compounds prepared are given in Tables I, II, and III.

Oxidation of 3,4-Methylenedioxy-α-n-propylaminomethylbenzyl Alcohol Hydrochloride

A solution of 3,4-methylenedioxy-α-*n*-propylaminomethylbenzyl alcohol hydrochloride (0.2 g) in water (10 ml) and aqueous sodium hydroxide (2 *N*: 0.6 ml) was oxidized with potassium permanganate (0.6 g) at 90° for 2 hours. After filtration, the reaction mixture was acidified with dilute sulphuric acid and the white solid that was obtained recrystallized from aqueous ethanol. Small colorless needles of piperonylic acid, m.p. 230°, were obtained which were identical in all respects (i.e. no depression of melting point and identical infrared spectra) with a sample of authentic piperonylic acid.

**One compound, during the preparation of which a cyclization of this type could have occurred, was chosen arbitrarily for oxidation. It was considered justifiable to assume that other substances prepared in a similar manner would behave similarly on oxidation.*

†Water proved to be the most satisfactory solvent for the reductions and reductive alkylations. Several preliminary runs were made in methanol but the reaction was much slower, possibly due to the relatively low solubility of some of the oxalate salts in methanol. With methanol as a solvent a considerable amount of the product was adsorbed onto the catalyst and unless the catalyst was repeatedly extracted with hot water the yields obtained were very low.

NOTE: Footnotes to table on facing page.

[a]The properties of the compounds described here will be those of DL-mixtures of the two possible optical isomers.
[b]The quantities of reagents used and the yields obtained are for the reduction or reductive alkylation of 1 g of 3,4-methylenedioxy-α-nitromethylbenzyl alcohol.
[c]Oxalic acid dihydrate was used in all these preparations.
[d]The hydrogen oxalate was prepared from the neutral oxalate by treatment with an excess of oxalic acid in ethanolic solution.
[e]The hydrochloride was prepared from the free base and the calculated amount of aqueous hydrochloric acid, followed by concentration of the reaction mixture *in vacuo* below 40°.
[f]All attempts to prepare this hydrochloride directly by carrying out the reductive alkylation in the presence of hydrochloric acid were unsuccessful. Dialkylation invariably occurred and 3,4-methylenedioxy-α-dimethylaminomethylbenzyl alcohol hydrochloride was always obtained. 3,4-Methylenedioxy-α-methylaminomethylbenzyl alcohol hydrochloride (m.p. 136°) was prepared by treatment of the free base with 1 equivalent of hydrochloric acid in aqueous solution. A white crystalline solid (m.p. 156–157° with decomposition) was obtained from an attempt to prepare this hydrochloride by passage of dry hydrogen chloride gas into a solution of the free base in dry benzene. Analysis of this compound indicated that it probably contained two chlorine atoms per molecule (found: C, 49.03; H, 5.13; Cl, 27.60%). Adityachaudhury and Chatterjee report a melting point of 163–165° (with decomposition) for 3,4-methylenedioxy-α-methylaminomethylbenzyl alcohol hydrochloride, prepared by the action of hydrogen chloride gas on a solution of the free base in ether. In view of the proximity of this melting point to that obtained by the authors for the "chlorohydrochloride", it is possible that Adityachaudhury and Chatterjee did not, in fact, have the true hydrochloride, although they do report a satisfactory analysis for this salt (8).
[g]MEK = Methyl ethyl ketone.
[h]As in the case of the monomethylamino derivative, 3,4-methylenedioxy-α-dimethylaminomethylbenzyl alcohol hydrochloride (m.p. 175–176°) was prepared in aqueous solution. Attempts to prepare this salt by passage of dry hydrogen chloride gas into a solution of the free base in dry benzene (or dry ether) gave a white crystalline solid, m.p. 151–152° (with decomposition). Analysis of this compound indicated that it probably contained two chlorine atoms per molecule; probably the β-hydroxy group in the ethylamine side chain had been replaced by chlorine to give 3,4-methylenedioxy-α-dimethylaminomethylbenzyl chloride hydrochloride. Found: C, 49.88; H, 5.78; N, 5.37; Cl, 26.74. Calc. for $C_{11}H_{15}O_2NCl_2$: C, 50.02; H, 5.73; N, 5.31; Cl, 26.85%. The same substance was obtained by treating the free base with thionyl chloride in dry benzene (a reaction known to lead to the replacement of the side-chain hydroxyl group by chlorine (cf. 21)). It is interesting to note that Pyman reported the melting point of 3,4-methylenedioxy-α-dimethylaminomethylbenzyl alcohol hydrochloride as 151–153°, i.e., a melting point very close to that obtained in the current investigation for the anomalous hydrochloride; however, Pyman reported a satisfactory analysis for the true hydrochloride (2).
[i]An attempt to prepare this hydrochloride by treating a solution of the free base in benzene with saturated alcoholic hydrogen chloride gave a crystalline product, m.p. 156–157° (with decomposition), which probably contained two chlorine atoms per molecule (found: C, 50.46; H, 5.78; N, 5.34; Cl, 24.17%).
[j]It was not possible under any circumstances to obtain a crystalline oxalate of 3,4-methylenedioxy-α-diethylaminomethylbenzyl alcohol. However, the picrate of 3,4-methylenedioxy-α-diethylaminomethylbenzyl alcohol was prepared by addition of picric acid to the free base, both in benzene solution; yellow flat prisms from 95% ethanol, m.p. 148–150° (with decomposition). Found: C, 49.03; H, 4.81; N, 11.80. Calc. for $C_{19}H_{22}O_{10}N_4$: C, 48.93; H, 4.75; N, 12.01%.
[k]An attempt to prepare the hydrochloride by treating a solution of the free base in benzene with dry hydrogen chloride gas gave a substance, m.p. 139.5° (with decomposition), which probably contained two chlorine atoms per molecule (found: C, 58.19; H, 7.20; Cl, 24.89%).
[l]LP = light petroleum (boiling range 60–80°) (B.D.H. AnalaR grade).
[m]The picrate of 3,4-methylenedioxy-α-di-*n*-propylaminomethylbenzyl alcohol was prepared by addition of picric acid to the free base, both in benzene solution; yellow needles from ethanol, m.p. 144° (with decomposition). Found: C, 50.88; H, 5.45; N, 11.40. Calc. for $C_{21}H_{26}O_{10}N_4$: C, 51.01; H, 5.30; N, 11.33%.
[n]The picrate of 3,4-methylenedioxy-α-di-*n*-butylaminomethylbenzyl alcohol was prepared by addition of picric acid to the free base, both in benzene solution; yellow prisms from ethanol/benzene, m.p. 101° (with decomposition). Found: C, 53.04; H, 5.89; N, 10.52. Calc. for $C_{23}H_{30}O_{10}N_4$: C, 52.87; H, 5.78; N, 10.72%.
[o]No crystalline salts could be isolated but a satisfactory analysis was obtained for the free base prepared from this reaction mixture (see Table III).
[p]The picrate of 3,4-methylenedioxy-α-isopropylaminomethylbenzyl alcohol was prepared by addition of picric acid to the free base, both in benzene solution; yellow prisms from ethanol/benzene, m.p. 142–144° (with decomposition). Found: C, 47.88; H, 4.47; N, 12.41. Calc. for $C_{18}H_{20}O_{10}N_4$: C, 47.79; H, 4.46; N, 12.39%.

3,4-Methylenedioxy-α-hydroxylaminomethylbenzyl Alcohol Oxalate

Employing the procedure described by Allais for the preparation of similar compounds (16), an aqueous suspension of 3,4-methylenedioxy-α-nitromethylbenzyl alcohol (1 g), a palladium catalyst (0.3 g; 5% on charcoal), and oxalic acid dihydrate (0.3 g) was shaken in the presence of hydrogen at atmospheric pressure until the calculated quantity (i.e. 2 moles) had been taken up. The reaction mixture, after filtration, was concentrated to dryness *in vacuo*, below 40°, and the resulting white solid recrystallized extensively from water and aqueous ethanol, affording 3,4-methylenedioxy-α-hydroxylaminomethylbenzyl alcohol oxalate in colorless prisms, m.p. 173–174°. (Found: C, 51.06; H, 5.33; N, 6.00. Calc. for $C_{20}H_{24}N_2O_{11}$: C, 51.28; H, 5.15; N, 5.98%.)*

Attempted Preparation of 3,4-Methylenedioxy-α-hydroxylaminomethylbenzyl Alcohol as the Free Base

(*a*) An aqueous solution of the oxalate was made alkaline with 40% aqueous sodium hydroxide and the reaction mixture continuously extracted with benzene for 10 hours. After being dried (Na_2SO_4), the benzene extract was concentrated to small bulk; small colorless prisms (m.p. 175°) were obtained when the concentrated extract was cooled.

(*b*) The alkaline reaction mixture, prepared as described above, was repeatedly extracted with ethyl acetate; concentration of the dried (Na_2SO_4) extract gave a white solid, yielding small colorless prisms (m.p. 181–182°) on recrystallization from benzene.

(*c*) An aqueous solution of the oxalate was stirred, under nitrogen, for 3 hours with an excess of calcium carbonate, in the presence of ethyl acetate. The ethyl acetate layer was removed and the remaining aqueous suspension, after filtration, was further extracted with ethyl acetate. On concentration, the combined, dried (Na_2SO_4) extracts gave a white solid, affording small colorless prisms on recrystallization from benzene (m.p. 179°).

**Considerable difficulty was encountered in obtaining a satisfactory analysis for this compound. Several estimations on different samples for carbon, hydrogen, and nitrogen all reported a small amount of an incombustible residue, even when it was impossible to comprehend how the contamination with inorganic material could occur. The above figures are calculated after making allowance for the incombustible residue, it being assumed that complete combustion of this product is difficult to accomplish.*

[a]The free bases were prepared from the corresponding oxalate or hydrochloride salts or the crude reaction mixtures by treatment with strong alkali; extraction with benzene; and purification either by distillation in high vacuum or crystallization from a suitable solvent.
[b]LP = light petroleum (boiling range 60–80°) (B.D.H. AnalaR grade).

(*d*) 3,4-Methylenedioxy-α-nitromethylbenzyl alcohol (1 g) was dissolved in 95% ethanol (150 ml) and shaken with hydrogen in the presence of a palladium catalyst (0.3 g; 5% on charcoal) until 2 molecules of hydrogen had been absorbed. Concentration of the filtered reaction mixture gave a white solid, giving small colorless needles (m.p. 183–185°) on repeated recrystallization from ethanol.

Comparisons of infrared spectra and mixed melting point determinations showed the identical nature of the substances prepared by the four methods described above. This substance which appeared to crystallize from benzene in small colorless prisms and from ethanol in small colorless needles (m.p. 183–185°) is probably *N*-β-hydroxy-β-(3,4-methylenedioxyphenyl)-ethyl-3′,4′-methylenedioxyisobenzaldoxime (cf. Allais (16)). (Found: C, 62.10; H, 4.60; N, 4.25%; mol. wt., 329. Calc. for $C_{17}H_{15}O_6N$: C, 61.99; H, 4.59; N, 4.25%; mol. wt., 329.3.)

AMINO NITRILES

III. REACTION OF AMINO NITRILES WITH ISOTHIURONIUM SALTS[1]

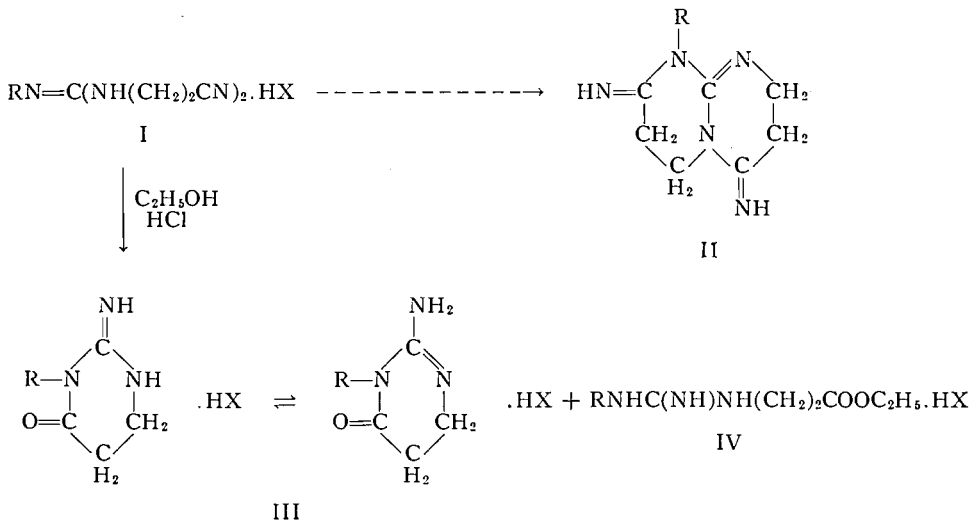
M.-E. KRELING AND A. F. MCKAY
The L. G. Ryan Research Laboratories of Monsanto Canada Limited, LaSalle, Que.

Received September 25, 1961

ABSTRACT

N-Substituted-N′,N″-di-(2-cyanoethyl)-guanidines have been cyclized with the elimination of acrylonitrile to 2-imino-3-substituted-4-keto-hexahydropyrimidines. These pyrimidine derivatives also were prepared by treating 1-substituted-3-(2-cyanoethyl)-S-methyl isothiuronium iodide salts with ammonia. 1-(3,4-Dichlorobenzyl)-3-(2-cyanoethyl)-urea was cyclized in the presence of absolute ethanolic hydrogen chloride to 2,4-diketo-3-(3,4-dichlorobenzyl)-hexahydropyrimidine.

A series of N-substituted-N′,N″-di-(2-cyanoethyl)-guanidines (I) (Table IA) was prepared from the corresponding thioureas (Table IB) in order to study their propensity for cyclization. The desired bicyclic derivatives (II) were not obtained. Under the reaction



conditions employed, the guanidine derivatives (I) lost 1 mole equivalent of acrylonitrile and the monocyclic 2-imino-3-substituted-4-keto-hexahydropyrimidines (III) were formed together with N-substituted-N′-(2-carbethoxyethyl)-guanidine (IV). When N-(3,4-dichlorobenzyl)-N′,N″-di-(2-cyanoethyl)-guanidine (I, R = 3,4-$Cl_2C_6H_3CH_2$) or its hydrochloride or hydroiodide salts were refluxed in absolute ethanol for 8 hours, the original compounds were recovered unchanged.

1-Phenyl-3-(2-cyanoethyl)-S-methyl-isothiuronium iodide (V, R = C_6H_5) on treatment with anhydrous ammonia in ethanol or anhydrous α-aminoisobutyronitrile gave 2,4-diimino-3-phenyl-hexahydropyrimidinium iodide (VI, R = C_6H_5). When aqueous

ammonia was employed in the same reaction, then the corresponding 2-imino-3-substituted-4-keto-hexahydropyrimidinium salts (III) were isolated. Treatment of 1-(3,4-dichlorobenzyl)-3-(2-cyanoethyl)-S-methyl-isothiuronium iodide (V, R = 3,4-$Cl_2C_6H_3CH_2$) with aqueous ammonia gave a mixture of 2-imino-3-(3,4-dichlorobenzyl)-4-keto-hexahydropyrimidinium iodide (III, R = 3,4-$Cl_2C_6H_3CH_2$) and N-(3,4-dichlorobenzyl)-N′-(2-cyanoethyl)-guanidinium iodide (VII, R = 3,4-$Cl_2C_6H_3CH_2$). When 1-methyl-3-(2-cyanoethyl)-S-methyl-isothiuronium iodide was heated under reflux in anhydrous ethanolic ammonia solution, it gave N-methyl-N′-(2-cyanoethyl)-guanidinium iodide instead of the expected 2,4-diimino-3-methyl-hexahydropyrimidinium iodide (VI, R = CH_3).

In order to obtain the 2,4-diimino-3-substituted hexahydropyrimidine salts (VI) strictly anhydrous conditions must be employed. The presence of moisture during reaction or during crystallization will convert these salts (VI) into the corresponding 2-imino-3-substituted-4-keto-hexahydropyrimidine salts (III). Also, crystallization of 1-(3,4-dichlorophenyl)-3-(2-cyanoethyl)-S-methyl-isothiuronium iodide (V, R = 3,4-$Cl_2C_6H_3$) from ethanol–ether solution gave some 2-keto-3-(3,4-dichlorophenyl)-4-imino-hexahydropyrimidinium iodide.

Attempts (1) to cyclize 1,3-di-(2-cyanoethyl)-urea and 1-(2-cyanoethyl)-3-(cyanomethyl)-urea by refluxing in ethanol solution were unsuccessful. Now 1-(2-cyanoethyl)-3-(3,4-dichlorobenzyl)-urea has been cyclized by heating with anhydrous ethanolic hydrogen chloride. In the presence of 9.5 mole equivalents of hydrogen chloride an 83% yield of 1-(3,4-dichlorobenzyl)-3-(2-carbethoxyethyl)-urea and an 11.9% yield of 2,4-diketo-3-(3,4-dichlorobenzyl)-hexahydropyrimidine were obtained. The latter compound was obtained in 65% yield when the hydrogen chloride was reduced to 1.2 mole equivalents.

Infrared Spectra

The pyrimidines which are reported here have been described as hexahydropyrimidine derivatives. Spectral evidence (2, 3) at present favors the ketonic structures for 2-hydroxy-, 4-hydroxy-, and 2,4-dihydroxy-pyrimidines. Moreover, the spectra given in Table II indicate that the 4-amino group in this series of 2,4-diamino- and 2-keto-4-amino-dihydropyrimidines exists in the imino form. The amino group in position 2 of the dihydropyrimidines probably exists in the amino form but no conclusion can be drawn from the present spectral data. In this investigation the infrared spectra were used mainly to confirm the formation of cyclic reaction products. A number of the band assignments in the 1500–1750 cm^{-1} region for pyrimidines are still regarded as tentative.

The C ≡ N stretching band between 2250 and 2265 cm^{-1} is a weak band and it disappears completely with some of the salts where the general absorption is high in this region.

TABLE II

EXPERIMENTAL[2]

1-Substituted-3-(2-cyanoethyl)-thioureas

All of the 1-substituted-3-(2-cyanoethyl)-thioureas which are listed in Table 1B were prepared by the following procedure for the preparation of 1-methyl-3-(2-cyanoethyl)-thiourea.

A solution of methyl isothiocyanate (5.4 g, 0.075 mole) in benzene (20 ml) was added slowly to a stirred solution of 3-aminopropionitrile (5.2 g, 0.075 mole) in benzene (15 ml) while the temperature was maintained at 20–30°. After addition was complete, the stirring was continued at room temperature for 1 hour. The thiourea was recovered by filtration and the product was purified by crystallizing from ethanol.

1-Phenyl-3-(2-cyanoethyl)-S-methyl-isothiuronium Iodide

Methyl iodide (7.4 g, 0.052 mole) was added over a period of 5 minutes to a refluxing solution of 1-phenyl-3-(2-cyanoethyl)-thiourea (9.73 g, 0.047 mole) in absolute methanol (75 ml). After the heating under reflux had been continued for 3 hours, the solution was evaporated to dryness *in vacuo*. The oily product crystallized on trituration with acetone (50 ml), yield 15.1 g (92.6%). Three crystallizations from absolute ethanol – ether (3:1) solution raised the melting point from 152–159° to 165–167°. Anal. calc. for $C_{11}H_{14}IN_3S$: C 38.04, H 4.06, I 36.55, N 12.10, S 9.23%; found: C 38.07, H 4.12, I 36.40, N 12.07, S 9.05%.

A picrate (m.p. 139–141°) was formed in 72% yield in the usual manner in aqueous solution. Anal. calc. for $C_{17}H_{16}N_6O_7S$: C 45.53, H 3.60, N 18.74%; found: C 45.83, H 3.87, N 18.51%.

1-Methyl-3-(2-cyanoethyl)-S-methyl-isothiuronium Iodide

1-Methyl-3-(2-cyanoethyl)-thiourea (9.3 g, 0.065 mole) was methylated by the procedure described above for the methylation of 1-phenyl-3-(2-cyanoethyl)-thiourea with the exception that the reflux period was 1 hour. After evaporation of the solvent *in vacuo*, the residual colorless oil was triturated with absolute ethanol. The crystals (m.p. 109–113°) were recovered by filtration, yield 4.3 g (30.2%). Three crystallizations from absolute ethanol raised the melting point to 116–117°. Anal. calc. for $C_6H_{12}IN_3S$: C 25.27, H 4.24, I 44.50, N 14.73, S 11.25%; found: C 25.16, H 4.39, I 44.34, N 14.61, S 11.25%.

1-(3,4-Dichlorophenyl)-3-(2-cyanoethyl)-S-methyl-isothiuronium Iodide

1-(3,4-Dichlorophenyl)-3-(2-cyanoethyl)-thiourea (10.95 g, 0.04 mole) and methyl iodide (6.25 g, 0.044 mole) in methanol (75 ml) were heated under reflux for 3 hours. Evaporation of the solvent *in vacuo* gave 16.5 g (99.5%) of a semicrystalline product. Since this product lost methyl mercaptan readily it was used without further purification for the next reaction.

An attempt to purify a sample (8.25 g) of the semicrystalline product by crystallizing from ethanol–ether (5:1) solution gave 2.1 g of a white crystalline product melting at 176–288°. This product did not contain sulphur and several crystallizations from ethanol raised the melting point to 301–301.5° decomp. (evac. cap.). Anal. calc. for $C_{10}H_{10}Cl_2IN_3O$: C 31.11, H 2.61, N 10.88, total halogen 51.25%; found: C 31.43, H 2.67, N 11.04, total halogen 50.74%. This product was identified by analyses and infrared spectrum as 2-keto-3-(3,4-dichlorophenyl)-4-imino-hexahydropyrimidine.

1-(3,4-Dichlorobenzyl)-3-(2-cyanoethyl)-S-methyl-isothiuronium Iodide

1-(3,4-Dichlorobenzyl)-3-(2-cyanoethyl)-thiourea (7.35 g, 0.025 mole) and methyl iodide (3.62 g, 0.025 mole) in absolute methanol were stirred at room temperature for 1 hour. The temperature was increased to 45° and the stirring was continued for 15 minutes. On the addition of ether to the cooled solution, crystals (m.p. 127–128°) separated, yield 6.3 g (57.5%). The melting point was not changed by recrystallization. Anal. calc. for $C_{12}H_{14}Cl_2IN_3S$: C 33.51, H 3.28, total halogen 46.00, N 9.77, S 7.45%; found: C 33.50, H 3.40, total halogen 45.56, N 10.06, S 7.38%.

A sample of the hydroiodide salt in methanol solution was converted into its picrate (m.p. 122.5–123.5°) in the usual manner. Anal. calc. for $C_{18}H_{16}Cl_2N_6O_7S$: C 40.69, H 3.04, Cl 13.35, N 15.82, S 6.03%; found: C 40.74, H 3.25, Cl 13.38, N 15.58, S 6.14%.

N-Substituted-N′,N″-di-(2-cyanoethyl)-guanidines

The N-substituted-N′,N″-di-(2-cyanoethyl)-guanidines listed in Table IA were all prepared by the following general procedure.

1-(3,4-Dichlorophenyl)-3-(2-cyanoethyl)-S-methyl-isothiuronium iodide (8.32 g, 0.02 mole) and 3-aminopropionitrile (1.4 g, 0.02 mole) were heated under reflux in absolute ethanol (50 ml) for 3 hours after which the evolution of methyl mercaptan had ceased. Evaporation of the solvent gave a crystalline residue which was purified by crystallizing from absolute ethanol.

A picrate (m.p. 218.5–219°) was prepared in 79.8% yield from aqueous solution in the usual manner. It was purified by crystallization from water.

Conversion of the guanidinium iodides into their corresponding hydrochlorides or free bases was accomplished by one of the following methods.

[2]*All melting points are uncorrected. Microanalyses were performed by Micro-Tech Laboratories, Skokie, Illinois.*

Method A. A solution of N-(3,4-dichlorophenyl)-N′,N″-di-(2-cyanoethyl)-guanidinium iodide (2 g, 0.0046 mole) in absolute ethanol (30 ml) was passed through a column of IRA 400 resin (25 ml in the chloride form). The resin was washed with methanol (50 ml) and the combined washings and eluate were taken to dryness *in vacuo*. The crystalline hydrochloride was obtained in 80% (1.26 g) yield. It was crystallized from ethanol–ether (3:2) solution.

Method B. A solution of N-(3,4-dichlorophenyl)-N′,N″-di-(2-cyanoethyl)-guanidinium iodide (0.32 g, 0.0007 mole) in absolute ethanol was treated with 1.5 mole equivalents of 4% aqueous sodium hydroxide solution at 0°. It was then held at room temperature for 15 minutes after which the solution was diluted with water. The aqueous solution was extracted with chloroform. After the combined chloroform extracts had been washed with water, the chloroform layer was treated with excess 1 *N* hydrochloric acid. An oil separated which crystallized immediately, yield 0.19 g (76.9%).

The free base was obtained by passage of a solution of the iodide salt (0.62 g) in absolute ethanol (45 ml) through a column of IRA 400 resin (in the hydroxyl form). The resin column was washed with ethanol (80 ml) and the washings and eluate were evaporated to dryness *in vacuo* under nitrogen. N-(3,4-Dichlorophenyl)-N′,N″-di-(2-cyanoethyl)-guanidine was obtained in 79.3% (0.44 g) yield. The free base was crystallized from absolute ethanol for analyses.

2,4-Diimino-3-phenyl-hexahydropyrimidinium Iodide

1-Phenyl-3-(2-cyanoethyl)-S-methyl-isothiuronium iodide (3.47 g, 0.01 mole) in absolute ethanol (25 ml) which had been saturated with anhydrous ammonia was heated under reflux for 12.5 hours. After evaporation of the solvent *in vacuo*, the semicrystalline product was crystallized from ethanol–ether solution. The crystals possessed a double melting point of 162–163° and 192°, yield 2.33 g (73.8%).

A sample of the hydroiodide salt in ethanol was converted into its picrate (m.p. 229–231°) in the usual manner. Anal. calc. for $C_{16}H_{15}N_7O_7$: C 46.05, H 3.62, N 23.50%; found: C 46.12, H 3.64, N 23.15%.

Reaction of 1-Phenyl-3-(2-cyanoethyl)-S-methyl-isothiuronium Iodide with 2-Aminoisobutyronitrile

A solution of 1-phenyl-3-(2-cyanoethyl)-S-methyl-isothiuronium iodide (1.87 g, 0.005 mole) and 2-aminoisobutyronitrile (0.45 g, 0.005 mole) in absolute ethanol (25 ml) was heated under reflux for 7 hours. Since a crystalline hydroiodide could not be isolated from the reaction, the crude hydroiodide in ethanol was passed through a column of IRA 400 resin (in the chloride form). The resin was washed with ethanol and the combined washings and eluate were taken to dryness *in vacuo*. The residual semicrystalline solid crystallized on trituration with absolute ethanol, yield 0.6 g (51.7%). Crystallization from ethanol–ether (1:2) solution raised the melting point from 85–216° to 217–218°. This compound gave the correct analyses for 2,4-diimino-3-phenyl-hexahydropyrimidinium chloride. Anal. calc. for $C_{10}H_{13}ClN_4$: C 53.45, H 5.83, Cl 15.78, N 24.93%; found: C 53.55, H 5.93, Cl 16.03, N 24.87%.

The picrate (m.p. 225–230°) was formed in the usual manner from the hydrochloride salt in aqueous medium. Two crystallizations from water raised the melting point to 229°. This picrate did not depress the melting point of 2,4-diimino-3-phenyl-hexahydropyrimidinium picrate (229–231°) formed from the reaction of anhydrous ammonia with 1-phenyl-3-(2-cyanoethyl)-S-methyl-isothiuronium iodide.

Reaction of 1-(3,4-Dichlorobenzyl)-3-(2-cyanoethyl)-S-methyl-isothiuronium Iodide with Ammonia

Concentrated aqueous ammonia solution (5 ml) was added to 1-(3,4-dichlorobenzyl)-3-(2-cyanoethyl)-S-methyl-isothiuronium iodide (1.83 g, 0.004 mole) in ethanol (4 ml). After the solution had been heated under reflux for 10 hours, the solvent was removed *in vacuo*. The residual oil partially crystallized on addition of a small amount of absolute ethanol. The crystals (m.p. 262–264°, decomp.) were removed by filtration, yield 0.12 g (8.6%). Two crystallizations from aqueous ethanol raised the melting point to 267.8–268.6°. The analytical results indicate that two molecules of 2-imino-3-(3,4-dichlorobenzyl)-4-keto-hexahydropyrimidine are associated with one molecule of hydrogen iodide. Anal. calc. for $C_{22}H_{23}Cl_4IN_6O_2$: C 39.31, H 3.45, total halogen 39.98, N 12.50%; found: C 39.40, H 3.84, total halogen 39.92, N 12.39%.

A sample of the crude product in aqueous solution gave a crystalline picrate (m.p. 205–207°) in 94.5% yield on treatment with aqueous picric acid. One crystallization from aqueous ethanol raised the melting point to 206–207°. Anal. calc. for $C_{17}H_{14}Cl_2N_6O_8$: C 40.74, H 2.82, Cl 14.15, N 16.77%; found: C 41.04, H 3.08, Cl 14.00, N 16.74%.

The mother liquor from the above crude hydroiodide gave a second crystalline iodide (m.p. 157–159°) on addition of ether, yield 0.18 g (10.6%). Crystallization from ethanol–ether raised the melting point to 163.2–163.8°. This product was identified as N-(3,4-dichlorobenzyl)-N′-(2-cyanoethyl)-guanidinium iodide by elemental and infrared analyses. Anal. calc. for $C_{11}H_{13}Cl_2IN_4$: C 33.10, H 3.28, total halogen 49.57, N 14.04%; found: C 32.90, H 3.32, total halogen 49.50, N 13.86%.

A picrate (m.p. 198–198.5°) was formed in 80% yield in the usual manner from aqueous solution. Anal. calc. for $C_{17}H_{15}Cl_2N_7O_7$: C 40.80, H 3.02, N 19.60%; found: C 40.95, H 2.97, N 19.74%.

Reaction of 1-(3,4-Dichlorobenzyl)-3-(2-cyanoethyl)-S-methyl-isothiuronium Iodide with 3-Aminopropionitrile

1-(3,4-Dichlorobenzyl)-3-(2-cyanoethyl)-S-methyl-isothiuronium iodide (6.89 g, 0.016 mole) and 3-aminopropionitrile (1.12 g, 0.016 mole) in absolute ethanol (40 ml) were heated under reflux for 4.5 hours. Evaporation of the solvent *in vacuo* gave 7 g of semicrystalline residue.

A portion (0.5 g) of the crude product was converted into a picrate (m.p. 60–65°) in the usual manner in water, yield 0.41 g (67%). Crystallization from aqueous acetone raised the melting point to 156–157°. The analyses are in agreement with those calculated for N-(3,4-dichlorobenzyl)-N′,N″-di-(2-cyanoethyl)-guanidine picrate. Anal. calc. for $C_{20}H_{18}Cl_2N_8O_7$: C 43.42, H 3.28, Cl 12.82, N 20.25%; found: C 43.70, H 3.42, Cl 12.82, N 20.21%.

The remainder of the original semicrystalline residue was dissolved in ethanol and passed through a column of IRA 400 resin (in the OH form). After the column was washed with ethanol, the washings and eluate were evaporated to dryness *in vacuo*. The oily product on solution in ethanol and acidification with concentrated hydrochloric acid gave a crystalline precipitate (m.p. 280–285°), yield 0.6 g (12%). One crystallization from ethanol raised the melting point to 288–290°. The analytical values for this compound agree with those calculated for 2-imino-3-(3,4-dichlorobenzyl)-4-keto-hexahydropyrimidinium chloride. Anal. calc. for $C_{11}H_{12}Cl_3N_3O$: C 42.80, H 3.92, Cl 34.46, N 13.62%; found: C 43.06, H 4.16, Cl 34.62, N 13.70%.

The picrate (m.p. 206–207°) was obtained in the usual manner from aqueous solution in 98% yield. A sample of this picrate on admixture with 2-imino-3-(3,4-dichlorobenzyl)-4-keto-hexahydropyrimidine picrate (m.p. 206–207°) from the reaction of ammonia with 1-(3,4-dichlorobenzyl)-3-(2-cyanoethyl)-S-methyl-isothiuronium iodide did not depress its melting point.

2-Imino-3-(3,4-dichlorophenyl)-4-keto-hexahydropyrimidine

Crude 1-(3,4-dichlorophenyl)-3-(2-cyanoethyl)-S-methyl-isothiuronium iodide (0.83 g, 0.002 mole) was dissolved in ethanol (4 ml) and treated with an excess of concentrated ammonia (5 ml). The solution was heated under reflux for 6.25 hours. Crystals (m.p. 247°) separated from the cooled solution in 60.6% yield. Crystallization from aqueous ethanol raised the melting point to 262–262.5°. Anal. calc. for $C_{10}H_9Cl_2N_3O$: C 46.52, H 3.52, Cl 27.47, N 16.28%; found: C 46.90, H 3.53, Cl 27.16, N 16.36%.

N-Methyl-N′-(2-cyanoethyl)-guanidinium Iodide

1-Methyl-3-(2-cyanoethyl)-S-methyl-isothiuronium iodide (2.3 g, 0.008 mole) in saturated absolute ethanolic ammonia solution (25 ml) was heated under reflux for 21 hours. Evaporation of the solution to dryness *in vacuo* gave 1.92 g (93.7%) of crystals (double melting point at 159–160° and 169–170°). Crystallization from ethanol–ether (2:1) solution gave a product with a double melting point. It melted at 160°, resolidified, and remelted at 173–173.8°. Anal. calc. for $C_5H_{11}IN_4$: C 23.63, H 4.36, I 49.95, N 22.05%; found: C 23.87, H 4.35, I 50.08, N 22.00%.

1-(3,4-Dichlorobenzyl)-3-(2-cyanoethyl)-urea

A solution of 3,4-dichlorobenzyl isocyanate (5.02 g, 0.025 mole) in ether (50 ml) was added to a cooled ethereal solution of 2-aminopropionitrile (1.75 g, 0.025 mole). The reaction mixture was held at room temperature for 2 hours after which the crystals (m.p. 125–127°) were recovered by filtration, yield 6.4 g (94.5%). The melting point was raised to 133.6–134.2° by crystallizing from aqueous ethanol. Anal. calc. for $C_{11}H_{11}Cl_2N_3O$: C 48.55, H 4.07, Cl 26.06, N 15.44%; found: C 48.58, H 4.21, Cl 26.06, N 15.47%.

1-(3,4-Dichlorobenzyl)-3-(2-carbethoxyethyl)-urea

A solution of 1-(3,4-dichlorobenzyl)-3-(2-cyanoethyl)-urea (2.16 g, 0.008 mole) in ethanolic hydrogen chloride (2.8 g, 0.077 mole of hydrogen chloride in absolute ethanol (20 ml)) was heated under reflux for 3.5 hours. When the solution was cooled, a small amount of ammonium chloride separated, yield 0.35 g. The filtrate was evaporated to dryness and the semicrystalline residue was triturated with ethanol (10 ml). The crystals (m.p. 183–185°) were removed by filtration, yield 0.26 g (11.9%). These crystals were identified as 2,4-diketo-3-(3,4-dichlorobenzyl)-hexahydropyrimidine by a mixed melting point determination.

The filtrate on evaporation yielded a solid which melted at 89–93°. Recrystallization from ethanol–ether solution raised the melting point to 110.5–111°. The yield of 1-(3,4-dichlorobenzyl)-3-(2-carbethoxyethyl)-urea was 2.1 g (83%). Anal. calc. for $C_{13}H_{16}Cl_2N_2O_3$: C 48.91, H 5.05, Cl 22.21, N 8.78%; found: C 48.96, H 5.17, Cl 22.20, N 8.90%.

2,4-Diketo-3-(3,4-dichlorobenzyl)-hexahydropyrimidine

1-(3,4-Dichlorobenzyl)-3-(2-cyanoethyl)-urea (0.68 g, 0.0025 mole) in ethanolic hydrogen chloride (0.1 g, 0.003 mole) in absolute ethanol (5 ml) was heated under reflux for 2.3 hours. The reaction mixture on cooling gave crystals (m.p. 180–183°) of 2,4-diketo-3-(3,4-dichlorobenzyl)-hexahydropyrimidine, yield 0.46 g (65%). One crystallization from absolute ethanol raised the melting point to 183.5–185°. Anal. calc. for $C_{11}H_{10}Cl_2N_2O_2$: C 48.37, H 3.69, Cl 25.96, N 10.26%; found: C 48.07, H 3.88, Cl 26.01, N 10.22%.

Attempted Cyclization of N-Substituted-N′,N″-di-(2-cyanoethyl)-guanidines

Method A. N-(3,4-Dichlorobenzyl)-N′,N″-di-(2-cyanoethyl)-guanidinium chloride (1 g) in absolute ethanol was refluxed for 8 hours. After concentration and cooling of the solution, the starting material was recovered unchanged in 81.5% yield. The recovered material was identified by a mixed melting point determination.

Under similar conditions both N-(3,4-dichlorobenzyl)-N′,N″-di-(2-cyanoethyl)-guanidine and its hydroiodide salt were recovered unchanged.

Method B. N-Phenyl-N′,N″-di-(2-cyanoethyl)-guanidinium chloride (0.97 g, 0.0035 mole) was heated under reflux for 2 hours in absolute ethanol (7.5 ml) containing hydrogen chloride (1 g, 0.028 mole). The reaction mixture was cooled and the crystals (m.p. 280–282°) were recovered by filtration, yield 0.43 g (54.8%). Two crystallizations from absolute ethanol raised the melting point to 292.4–292.8°. This product was identified as 2-imino-3-phenyl-4-keto-hexahydropyrimidinium chloride by elemental analyses and infrared spectrum. Anal. calc. for $C_{10}H_{12}ClN_3O$: C 53.21, H 5.36, Cl 15.71, N 18.62%; found: C 53.47, H 5.44, Cl 15.58, N 18.89%.

The picrate (m.p. 242–244°) was formed in 41% yield in the usual manner from aqueous ethanol. Anal. calc. for $C_{16}H_{14}N_6O_8$: C 45.94, H 3.37, N 20.09%; found: C 45.83, H 3.39, N 19.73%.

The mother liquor from the crystals was evaporated to dryness *in vacuo*. A mixture of oil and crystals was obtained, yield 1.14 g. A portion (0.23 g) of this mixture in absolute ethanol on treatment with aqueous picric acid gave a crystalline picrate (m.p. 133.2–133.8°), yield 0.15 g (38.7%). The melting point was raised to 134.4–134.8° by two crystallizations from aqueous ethanol. The analyses agree with those calculated for the picrate of 1-phenyl-3-(2-carbethoxyethyl)-guanidine. Anal. calc. for $C_{18}H_{20}N_6O_9$: C 46.54, H 4.34, N 18.10%; found: C 46.65, H 4.36, N 18.29%.

When N-phenyl-N′,N″-di-(2-cyanoethyl)-guanidinium chloride was treated under the same conditions as above using approximately 1 mole equivalent of hydrogen chloride instead of 8, the starting material was recovered in 44.3% yield and a 42% yield of 2-imino-3-phenyl-4-keto-hexahydropyrimidinium chloride was obtained.

ACKNOWLEDGMENT

The infrared spectra were determined by Dr. C. Sandorfy of the University of Montreal, Montreal, Quebec.

NOTES

THE ENZYMIC SYNTHESIS OF 3-*O*- AND 6-*O*-β-D-GALACTOPYRANOSYL-D-GALACTOSE*

A. M. STEPHEN, S. KIRKWOOD, AND F. SMITH

Chemical synthesis constitutes one approach to the proof of structure of disaccharides but, in general, only limited success has attended these procedures. The usual method, involving the combination of an acetohalogeno derivative (1) of the non-reducing moiety of the required disaccharide with a suitable blocked derivative of the aglycone residue leads, as a rule, to β-linked disaccharides (2). Those disaccharides having a biose linkage which engages C_6 of a hexose or C_5 of a pentose unit can be synthesized without too much difficulty because the necessary acceptor molecules are easily prepared and the reaction proceeds smoothly, giving reasonably good yields (3, 5). On the other hand, however, the synthesis of disaccharides whose biose linkage engages C_2, C_3, or C_4 of either a hexose (2, 3) or a pentose unit (4) is much more difficult because the required acceptor molecules are generally inaccessible and the yields of disaccharide are usually poor.

Certain disaccharides have been obtained as reversion products (6) by the action of acid on concentrated aqueous solutions of monosaccharides, and with the advent of chromatographic techniques for separating closely related isomeric substances, this approach has become useful and relatively simple for the preparation of some disaccharides (7).

Formerly the reversible effect of enzymes upon glycosidic bonds was put to good synthetic use, especially by Bourquelot, for the formation of the (at that time) inaccessible β-D-glucosides (8) and more recently Peat and his co-workers (9) have shown that almond emulsin can be used to transform D-glucose into the disaccharides gentiobiose, cellobiose, laminaribiose, sophorose, and β,β-trehalose. Bourquelot reported that such enzymes could be used to generate oligosaccharides. In particular it was found (10) that emulsin preparations would act on concentrated galactose solutions giving higher molecular weight oligosaccharides, and it has since been suggested (11), from a comparison of physical properties, that two of Bourquelot's crystalline products were probably identical with 3-*O*-β- and 6-*O*-β-D-galactopyranosyl-D-galactose. The widespread occurrence of β 1 → 3 and β 1 → 6 linked galactose units is of special interest in connection with our investigation of gums and mucilages, and it was therefore decided to re-examine the work of Bourquelot to ascertain the feasibility of using enzymes for synthesizing disaccharides and oligosaccharides that are relatively inaccessible by the usual chemical procedures.

In preliminary experiments the effect of a number of readily available enzymes on D-galactose was explored. Accordingly, certain enzyme preparations were incubated at pH 3.6, 4.6, and 6.9 with a 33% aqueous solution of D-galactose, the reaction products being examined chromatographically. As a result of these exploratory tests (12), it was decided to use a commercial β-D-glucosidase (emulsin) preparation at pH 7 (approx.) since this gave evidence of producing at least three oligosaccharides from D-galactose, two of which resembled 3-*O*- and 6-*O*-β-D-galactopyranosyl-D-galactose according to partition chromatographic and electrophoretic tests.

Paper No. 4543, Scientific Journal Series, Minnesota Agricultural Experiment Station.

Production of oligosaccharides from D-galactose with emulsin, the so-called β-D-glucosidase, appeared to reach a maximum after about 5 days at room temperature. The reaction was terminated by heating the digest to 100°, and separation of most of the unchanged D-galactose from the oligosaccharides was effected by passing the solution through charcoal. The oligosaccharides adsorbed by the charcoal were selectively displaced with gradually increasing concentrations of aqueous alcohol. The fraction eluted by 7.5 to 30% aqueous ethanol, which was richest in oligosaccharides, was further fractionated by chromatography on a cellulose column. The mixture of oligosaccharides proved to be quite complex; at least seven components moving faster than 6-*O*-β-D-galactopyranosyl-D-galactose were detected. The two components present in the greatest proportion readily crystallized and proved to be 3-*O*-β-D-galactopyranosyl-D-galactose and 6-*O*-β-D-galactopyranosyl-D-galactose, as suggested by Weinland (11). It is of interest to note that both galactose disaccharides have been previously synthesized chemically (13, 18) and the latter has been found among the products formed by the action of an enzyme from *Saccharomyces fragilis* on lactose (14).

It appears that the enzymatic method shows considerable promise since more suitable sources of β-D-galactosidase would most likely produce purer galactose di- and higher saccharides in better yields. The minor components from the emulsin reaction on D-galactose reported herein may represent disaccharides some of which, from their relatively high positive specific rotation, may be of the α-type. Clearly the use of an α-D-galactosidase would be invaluable for the synthesis of galactose oligosaccharides having α-linkages and it seems reasonable to believe that the enzymic method could be applied quite generally for the synthesis of oligosaccharides, many of which cannot readily be synthesized by chemical means.

EXPERIMENTAL

The Effect of Various Enzymes on Galactose

Solutions of D-galactose were prepared at a concentration of 33% in buffers of varying pH. The solutions were brought to the boiling point and cooled. To each of these solutions of galactose (5 ml) was added one of the enzyme preparations (20 mg), followed by a few drops of toluene to prevent mold growth. The containers were stoppered and the solutions kept at 37°. At intervals a paper chromatographic examination was made to ascertain the progress of oligosaccharide synthesis. The synthesis of oligosaccharides appeared to reach a maximum after about 5 days.

The results showed that the best pH was 6.9; at lower pH's less synthesis was noted. The enzymes, in order of decreasing efficiency, were as follows: "β-glucosidase" (Worthington Chemical Co.), emulsin (Nutritional Biochemicals Corp.), enzyme prepared from germinating alfalfa seeds by the procedure of Hill (12, 15, 16) (enzyme fractions were precipitated with 20% ammonium sulphate, 40% ammonium sulphate, and with saturated ammonium sulphate; the enzyme precipitates were dialyzed to remove ammonium sulphate and freeze-dried), and Cellulase 35 (Rohm and Haas Chem. Co.). Two other enzyme preparations, Lactase C and Cellulase 36, kindly supplied along with Cellulase 35 by the Rohm and Haas Chem. Co., Philadelphia, Pa., had little or no synthetic activity.

Enzymic Synthesis of D-Galactose Oligosaccharides

A solution of D-galactose (10 g) in hot water (30 ml) was cooled to room temperature and treated with a "β-glucosidase" preparation (70 mg, Worthington Biochemical Corp., Freehold, N.J.). The solution was covered with a layer of toluene to prevent growth of microorganisms. After 3 days, paper chromatography revealed the presence of two oligosaccharides whose R_F values corresponded to those of 3-*O*-β-D-galactopyranosyl-D-galactose and 6-*O*-β-D-galactopyranosyl-D-galactose isolated by the graded hydrolysis of *Virgilia oroboides* gum (17). Charcoal (3 g) was added in an attempt to adsorb the oligosaccharides and thus promote synthesis. After storage for 10 weeks (a shorter time, e.g. 1 week, would suffice) the reaction mixture was boiled, filtered through charcoal (60 g) contained in a Büchner funnel, and washed with water (the combined filtrate and washings amounted to 350 ml). The charcoal was then eluted successively with 3% ethanol (500 ml), 7.5% ethanol (500 ml), 10% ethanol (500 ml), 15% ethanol (500 ml), and 30% ethanol (500 ml). Chromatography, using ethyl acetate:pyridine:water (10:4:3), of the 7.5% eluate showed the presence of galactose and oligosaccharides. Galactose was also detected in the 15% eluate. The

fractions recovered were as follows: I (from aqueous filtrate and washings), 5.45 g; II (from 3% ethanol eluate), 2.19 g; and III (from 7.5 to 30% ethanol eluate), 0.65 g.

Separation of Oligosaccharides from Fraction III

Fraction III (0.65 g) obtained above, which was found to contain the two oligosaccharides having R_F values corresponding to 3-*O*-β-D-galactopyranosyl-D-galactose and 6-*O*-β-D-galactopyranosyl-D-galactose, was put on a cellulose column (4.5×60 cm packed dry) and eluted with ethyl acetate:pyridine:water (10:4:3), the eluate being collected automatically in 15-ml fractions every 30 minutes. The results are recorded in Table I.

§Composition of eluting solvent changed to ethyl acetate:pyridine:water (10:4:5).

Isolation of 3-O-β-D-Galactopyranosyl-D-galactose

The material from tubes 171 to 205 crystallized spontaneously and had m.p. 165° after washing with methanol and with diethyl ether, $[\alpha]_D^{24}$ +84° in water (*c*, 0.8) (15 minutes), +75° (35 minutes), +69° (1 hour), +64° (4 hours, const.). Lit. m.p. 163–170°, $[\alpha]_D$ +75° (5 minutes) → +60° (2 hours) in water (18). Paper chromatography (1-butanol:acetic acid:water) and paper electrophoresis (0.1 *M* borate buffer) showed that the disaccharide was quite different from 6-*O*-β-D-galactopyranosyl-D-galactose prepared from *V. oroboides* gum. The crystals were dissolved in the minimum volume of methanol containing a drop of water and were seeded with 3-*O*-β-D-galactopyranosyl-D-galactose (m.p. 200°) from *V. oroboides* gum (17). The crystalline material, which separated slowly, had m.p. 203° and showed no depression when mixed with the 3-*O*-β-D-galactopyranosyl-D-galactose used for nucleation. There was, however, a depression of the melting point when it was mixed with 4-*O*-β-D-galactosyl-D-galactose.

Isolation of 6-O-β-D-Galactopyranosyl-D-galactose

The crystalline material from tubes 240–261 was recrystallized from methanol, m.p. 136° with previous sintering at 106° (yield 40 mg). This disaccharide which appeared to crystallize with water and methanol of constitution gave no depression of the melting point when mixed with the 6-*O*-β-D-galactopyranosyl-D-galactose prepared from *V. oroboides* gum and crystallized from methanol (17). This enzymically synthesized disaccharide, which has the same chromatographic mobility (tested with two different solvent systems) as 6-*O*-β-D-galactopyranosyl-D-galactose, showed $[\alpha]_D^{18}$ +24° in water (*c*, 1) (5 minutes) changing in 5 hours to +32° (const. value). Lit. m.p. 114° (11), $[\alpha]_D$ +34° (water) (10, 11). Acid hydrolysis of this disaccharide gave only galactose and, when treated with crystalline β-D-galactosidase, only galactose was generated. When the crystalline disaccharide (20 mg) was treated with phenylhydrazine in the usual way, a phenylosazone was obtained, m.p. 206° (after two recrystallizations from aqueous ethanol). An identical phenylosazone (m.p. and mixed m.p.) was produced by the same procedure from the 6-*O*-β-D-galactopyranosyl-D-galactose obtained from *V. oroboides* gum. Lit. (13, 17) m.p. 207°.

ACKNOWLEDGMENTS

The authors thank Dr. Frank Reithel of the University of Oregon for a specimen of crystalline β-D-galactosidase, and one of us (A. M. S.) wishes to acknowledge the support of the International Cooperation Administration under the Visiting Research Scientists Program administered by the National Academy of Sciences of the United States of America.

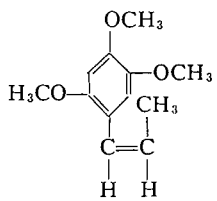
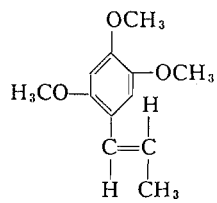
CIS–TRANS ISOMERS OF ASARONE, THEIR LIQUID–GAS CHROMATOGRAPHIC BEHAVIOR AND THAT OF CERTAIN OTHER PROPENYLPHENOLETHERS*

R. M. BAXTER, M. C. FAN, AND S. I. KANDEL

Previously the isolation of three compounds with hypnotic potentiating activity from the volatile oil of *Acorus calamus* L., Indian, had been reported (1). Two of these proved to be the cis–trans isomers of 1,2,4-trimethoxy-propenyl benzene, namely asarone (α-asarone) and β-asarone (II and I).



I



II

The cis–trans relationship of the asarones as well as other propenylbenzenephenolethers, many of which are constituents of volatile oils, has been well established (1, 2, 3). Although the Auwers–Skita rule is not strictly applicable in this series of compounds it has been utilized (3) in an attempt to elucidate the actual stereochemical configuration in this series (4). More recently Naves *et al.*, utilizing infrared spectroscopy, have shown that one of the isomer pair of each of isosafrole (5), anethol (6), isoeugenol, and isoeugenol-methylether (7) possesses a characteristic absorption band in a region at 963–967 cm^{-1}, which is in close proximity to the absorption band of *trans*-ethylenic compounds. The other isomer does not absorb in the same region. The present report is concerned with the

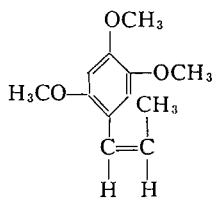
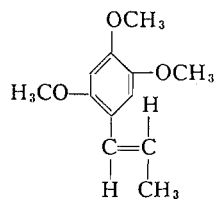
CIS–TRANS ISOMERS OF ASARONE, THEIR LIQUID–GAS CHROMATOGRAPHIC BEHAVIOR AND THAT OF CERTAIN OTHER PROPENYLPHENOLETHERS*

R. M. BAXTER, M. C. FAN, AND S. I. KANDEL

Previously the isolation of three compounds with hypnotic potentiating activity from the volatile oil of *Acorus calamus* L., Indian, had been reported (1). Two of these proved to be the cis–trans isomers of 1,2,4-trimethoxy-propenyl benzene, namely asarone (α-asarone) and β-asarone (II and I).



I



II

The cis–trans relationship of the asarones as well as other propenylbenzenephenolethers, many of which are constituents of volatile oils, has been well established (1, 2, 3). Although the Auwers–Skita rule is not strictly applicable in this series of compounds it has been utilized (3) in an attempt to elucidate the actual stereochemical configuration in this series (4). More recently Naves *et al.*, utilizing infrared spectroscopy, have shown that one of the isomer pair of each of isosafrole (5), anethol (6), isoeugenol, and isoeugenol-methylether (7) possesses a characteristic absorption band in a region at 963–967 cm^{-1}, which is in close proximity to the absorption band of *trans*-ethylenic compounds. The other isomer does not absorb in the same region. The present report is concerned with the

**This paper was presented at the 7th Canadian Conference on Pharmaceutical Research, August 1960.*

stereochemical configuration of asarone and β-asarone as determined by infrared spectroscopy and the chromatographic behavior of the asarones and other propenylphenolethers.

From Fig. 1 it may be seen that asarone absorbs at 964 cm^{-1} in a manner which is characteristic of *trans*-propenyl benzenes and that β-asarone exhibits no absorption in

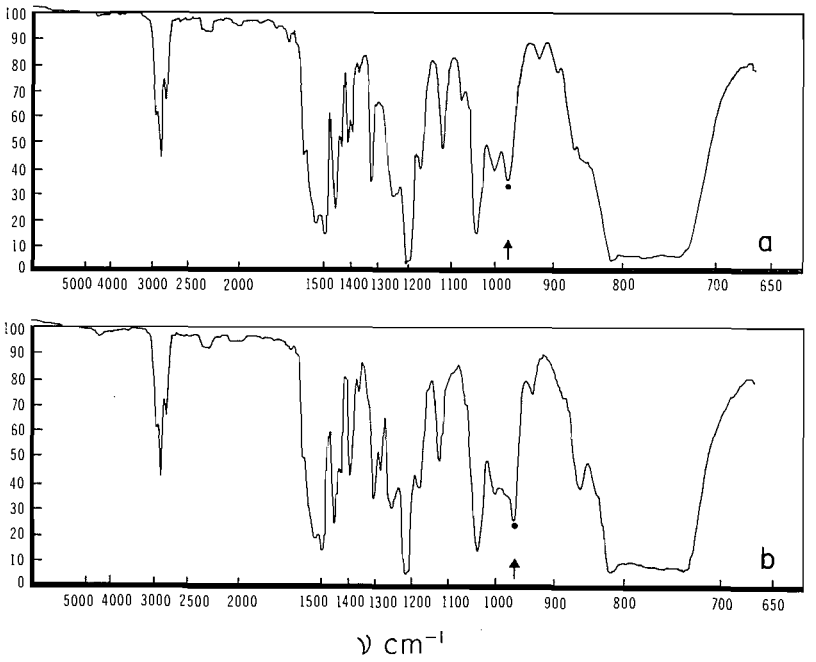


FIG. 1. The infrared spectra of (*a*) asarone and (*b*) β-asarone.

this region. It may therefore be concluded (5) that β-asarone (I) possesses a *cis*- and asarone (II) a *trans*-ethylenic side chain.

It was also found that the isomeric pairs of propenylphenolethers could be separated on each of the liquid–gas chromatographic columns used. The best separation can be achieved with a Ucon polar column where the mixture of *cis–trans*-isosafrole, *cis–trans*-isoeugenolmethylether, *cis–trans*-isoeugenol, and *cis–trans*-asarone (β-asarone and asarone) can be separated (Fig. 2). It will be observed that in each instance the cis

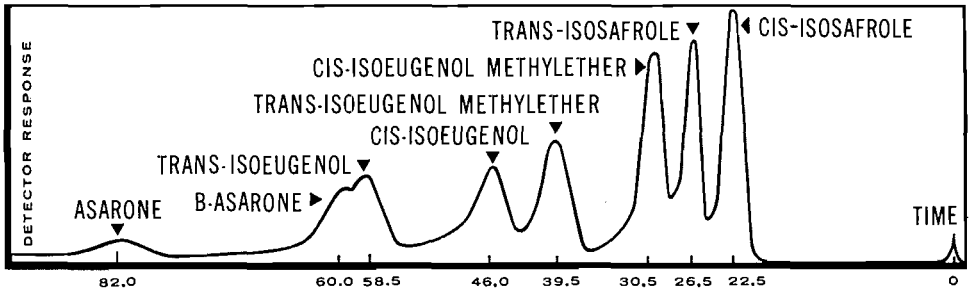

FIG. 2. Separation of certain propenylphenolethers by liquid-gas chromatography on Ucon polar column. Conditions as in Table I.

isomer had a lower retention time than the trans (Table I). There is at present no evidence to indicate that the higher retention times of the trans isomers were due directly to their

TABLE I

The retention time of certain propenylphenolethers as indicated by liquid–gas chromatography

Compounds	Retention times (min)		
	Ucon polar	Reoplex 400	Asphalt
cis-Isosafrole	22.5	13.0	15.0
trans-Isosafrole	26.5	17.0	19.0
cis-Isoeugenolmethylether	30.5	20.5	20.0
trans-Isoeugenolmethylether	39.5	24.5	25.5
cis-Isoeugenol	46.0	27.5	20.5
trans-Isoeugenol	58.5	34.5	26.0
β-Asarone	60.0	38.5	34.5
Asarone	82.0	57.0	50.5

NOTE: Column 10 ft × ¼ in. Liquid phases on chromosorb P (35–80 mesh) in a ratio 25/75 by weight. Temperature: 200° C ±2° C. Outlet flow: 70 ml of helium per minute.

configuration and not to their higher boiling points. It would appear, however, that in the propenylphenolethers studied, the trans isomers should exhibit longer retention times than the cis isomers. It is suggestive that this relationship would be applicable independent of the relative polarity of the chromatographic column. This method may allow for the simultaneous separation and the determination of the quantity and geometrical configuration of each individual cis, trans isomer in this series.

Subsequent to the presentation of this data, Stahl and Trennheuser (8) reported on the liquid–gas chromatographic separation of the same propenylphenolethers.

EXPERIMENTAL

Asarone and β-asarone were isolated from the volatile oil of Indian *Acorus calamus* L. (Fritzsche Bros. Inc.) by liquid–gas chromatography, using a "Ucon" polar column. The samples emerging from the column were collected in acetone and cooled in an acetone – dry ice bath. After the evaporation of the acetone, asarone and β-asarone were purified and identified as described earlier (1). *Cis*- and *trans*-isosafrole, *cis*- and *trans*-isoeugenol, *cis*- and *trans*-isoeugenolmethylether were generously provided by Dr. Y. R. Naves.

Infrared Spectra

The spectra of asarone and β-asarone (1.5% w/v in carbon tetrachloride) were obtained using a Beckman IR-4 recording spectrophotometer.

Liquid–Gas Chromatography

An Aerograph A 100-C liquid–gas chromatography unit was utilized. The column temperature was maintained at 200° C ±2° C. Dried helium was used as carrier gas with a flow rate of 70 ml per minute measured at the outlet of the apparatus. The sample (3–5 μl) was injected into a column with a 10-μl Hamilton fixed needle syringe. In the case of asarone the sample was dissolved in acetone.

The solid support used in the column was chromosorb P, 35–80 mesh. The liquid phase (6 g) was applied to the solid support in the ratio of 3 to 1 by weight dissolved in a solvent. In the case of Ucon polar (monoether of a random copolymer of ethylene oxide and propylene oxide, Wilkins Instrument & Research Inc.) and Reoplex 400 the solvent was acetone (100 ml) and in the case of asphalt the solvent was petroleum ether (100 ml, b.p. 60–80° C). The solution was added to the solid support (18 g) and shaken for 3 hours. The solvent was removed *in vacuo* at 30° C. After it was dried in a vacuum desiccator the material was packed into a 10 ft × ¼ in. (O.D.) copper column with constant tapping.

FLUORINE PERCHLORATE, INFRARED AND NUCLEAR MAGNETIC RESONANCE SPECTRA

H. AGAHIGIAN, A. P. GRAY, AND G. D. VICKERS

The preparation of $FClO_4$ has been reported (1, 2), but spectral data are not available. The infrared and fluorine nuclear magnetic resonance spectra of fluorine perchlorate are reported below.

Since the fluorine resonance appears to shift to low field with increasing electronegativity of an attached atom or group (3, 4*a* and *b*), the fluorine chemical shift of fluorine perchlorate was measured in order to determine the extent of the displacement of the fluorine resonance to low field.

The fluorine n.m.r. spectrum of neat perchloryl fluoride has been reported (3). A low-field fluorine chemical shift as well as fluorine–chlorine spin–spin coupling was observed in perchloryl fluoride (3).

Since the method (3) of measuring the chemical shift and the standard used were different from those used in this laboratory, a comparison among fluorine perchlorate, fluorine oxide, and perchloryl fluoride was made using $CFCl_3$ (5) as a standard and solvent.

The fluorine n.m.r. spectrum of fluorine perchlorate consisted of a single line, and a chemical shift of -225.9 p.p.m. relative to $CFCl_3$ was obtained. The chemical shift of fluorine perchlorate was not measured neat but as a 50% solution in Freon-11. Although the perchlorate will detonate in the pure form, in solution fluorine perchlorate appears to be stable and the data was obtained without incident.

A 50% solution of perchloryl fluoride in Freon-11 was studied in an effort to resolve the spectrum of the proposed quartets (3). However, the use of a solvent did little to help resolve the spectrum. The center of what appeared to be a broad doublet was -287.0 p.p.m. relative to $CFCl_3$. The splitting between the peaks was 460 cycles.

The fluorine chemical shift of fluorine oxide was measured as a gas under 5-atm pressure and relative to $CFCl_3$ in a sealed capillary. The chemical shift was -250.0 p.p.m.

The fluorine chemical shifts relative to $CFCl_3$ are shown below.

$FOClO_3$	-225.9 p.p.m.
FOF	-250.0 p.p.m.
$FClO_3$	-287.0 p.p.m.

The side-band technique (6) was used to measure the chemical shifts. Since different techniques were used, comparison of presented and published (3) data would be difficult, but the chemical shifts of the three compounds $FClO_4$, $FClO_3$, and OF_2, appear to be of the right order of magnitude, and are in the order predicted by theory (4).

The infrared spectrum of fluorine perchlorate was obtained in the sodium chloride region only. As the spectrum of fluorine perchlorate has not previously been reported,

FLUORINE PERCHLORATE, INFRARED AND NUCLEAR MAGNETIC RESONANCE SPECTRA

H. AGAHIGIAN, A. P. GRAY, AND G. D. VICKERS

The preparation of $FClO_4$ has been reported (1, 2), but spectral data are not available. The infrared and fluorine nuclear magnetic resonance spectra of fluorine perchlorate are reported below.

Since the fluorine resonance appears to shift to low field with increasing electronegativity of an attached atom or group (3, 4*a* and *b*), the fluorine chemical shift of fluorine perchlorate was measured in order to determine the extent of the displacement of the fluorine resonance to low field.

The fluorine n.m.r. spectrum of neat perchloryl fluoride has been reported (3). A low-field fluorine chemical shift as well as fluorine–chlorine spin–spin coupling was observed in perchloryl fluoride (3).

Since the method (3) of measuring the chemical shift and the standard used were different from those used in this laboratory, a comparison among fluorine perchlorate, fluorine oxide, and perchloryl fluoride was made using $CFCl_3$ (5) as a standard and solvent.

The fluorine n.m.r. spectrum of fluorine perchlorate consisted of a single line, and a chemical shift of -225.9 p.p.m. relative to $CFCl_3$ was obtained. The chemical shift of fluorine perchlorate was not measured neat but as a 50% solution in Freon-11. Although the perchlorate will detonate in the pure form, in solution fluorine perchlorate appears to be stable and the data was obtained without incident.

A 50% solution of perchloryl fluoride in Freon-11 was studied in an effort to resolve the spectrum of the proposed quartets (3). However, the use of a solvent did little to help resolve the spectrum. The center of what appeared to be a broad doublet was -287.0 p.p.m. relative to $CFCl_3$. The splitting between the peaks was 460 cycles.

The fluorine chemical shift of fluorine oxide was measured as a gas under 5-atm pressure and relative to $CFCl_3$ in a sealed capillary. The chemical shift was -250.0 p.p.m.

The fluorine chemical shifts relative to $CFCl_3$ are shown below.

$FOClO_3$	-225.9 p.p.m.
FOF	-250.0 p.p.m.
$FClO_3$	-287.0 p.p.m.

The side-band technique (6) was used to measure the chemical shifts. Since different techniques were used, comparison of presented and published (3) data would be difficult, but the chemical shifts of the three compounds $FClO_4$, $FClO_3$, and OF_2, appear to be of the right order of magnitude, and are in the order predicted by theory (4).

The infrared spectrum of fluorine perchlorate was obtained in the sodium chloride region only. As the spectrum of fluorine perchlorate has not previously been reported,

the four observed absorptions at 1298, 1049, 885, and 666 cm^{-1} will be briefly discussed. The two high-frequency bands are nearly coincident with those found in both anhydrous $HClO_4$ (7) and Cl_2O_7 (8) and are evidently associated with the covalent perchlorate group. In this case, the 1298 cm^{-1} band is assigned as the approximately degenerate antisymmetric ClO_3 stretches and 1049 cm^{-1} as the corresponding symmetric vibration. With NaCl prism resolution, the 1298 cm^{-1} band has no discernible structure, while a *P*,*R* contour is observed at 1049 cm^{-1}. The 666 cm^{-1} absorption has a similar contour and is consistent in position with the singly bonded Cl—O stretch. The symmetric Cl—O stretch in chlorine monoxide occurs at 688 cm^{-1} (9). The absorption at 885 cm^{-1} has a *PQR* structure and is assigned as the O—F stretch, corresponding to the symmetric vibration in fluorine monoxide at 928 cm^{-1} (10).

Inertially, ClO_3OF is expected to be similar to methanol, with singly bonded Cl—O being the axis of an approximate symmetric top. The 1049 and 666 cm^{-1} bands are therefore expected to have a *PQR* structure, whereas a *Q* branch is not observed. However, this is not considered sufficient reason for rejection of the above assignment, since even for truly symmetric tops, the *Q* branch in parallel bands is frequently unobserved, due to significant differences between upper- and lower-state inertial constants, resulting in non-superposition of the *Q*-branch subbands (11). The *PQR* structure of the O—F stretching at 885 cm^{-1} is that expected for a hybrid band of an approximate symmetric top.

EXPERIMENTAL

The n.m.r. spectrometer was a 56.4 Mc instrument, and the side-band technique (6) was used to measure the chemical shifts.

The fluorine oxide could not be measured in solution but was measured as a gas under pressure. A capillary was filled with $CFCl_3$ and sealed. This was inserted into the 5-mm pyrex tube and fluorine oxide was condensed into the n.m.r. tube and the tube was sealed. The chemical shift for fluorine oxide was uncorrected for bulk susceptibility.

The infrared spectra were obtained in the vapor phase using a 5-cm Monel cell with NaCl windows sealed vacuum tight with Fluorolube wax.

ACKNOWLEDGMENTS

PREPARATION OF SYNTHETIC GELS FOR CHROMATOGRAPHY OF MACROMOLECULES*

D. J. Lea† and A. H. Sehon

The introduction of the technique of column chromatography on cross-linked gels (1, 2) has provided a powerful new tool for the fractionation of complex mixtures of biological origin. These gels exhibit both adsorption and molecular sieve properties. Various polymers, such as dextran, starch, and polyvinyl alcohol, cross-linked in an undisclosed manner, have been used for the chromatographic separation of aqueous solutions of proteins, dextrans, and similar materials. So far gels which will permit the entry of materials with molecular weights up to 40,000 into the gel matrix have been prepared (1, 2). However, it has been found in this laboratory that certain compounds, such as pollen pigments, could not be readily desorbed from the dextran gel and that the gel had to be discarded after a single fractionation.

Two modifications of the method using dextran gel have recently been described (3): (i) Diethylaminoethyl-dextran gels, functioning by ion-exclusion, have been prepared, and (ii) the adsorption properties of dextran gels have been changed by using mixed solvent systems, such as acetic acid – pyridine – water, in place of the usual aqueous buffer solutions. A technique using agar gel, which is not cross-linked, has also been published recently (4).

Alternative methods for the preparation of different gels with a wide range of "pore" size and adsorption properties were explored in the present study. Polymerization of readily available charged and neutral monomers,‡ in the presence of cross-linking agents, in water or in mixed solvent systems, permitted the synthesis of gels suitable for the fractionation of mixtures of biological materials. The preparation of three different polymers, using N,N′-methylenebisacrylamide as the cross-linking agent, and the preliminary results of fractionation experiments are described below.

(1) Acrylamide, a water-soluble monomer, can be easily polymerized in aqueous solution to give hydrophilic gels (5). A suitable content of cross-linking agent gives gels which have sufficient mechanical stability to serve as packing materials for columns. Acrylamide§ (4.6 g) and N,N′-methylenebisacrylamide§ (0.4 g) were dissolved in boiled distilled water (98 ml). The initiators, dimethylaminopropionitrile (40 μl), followed by ammonium persulphate (40 mg) were added. The solution was stirred gently and covered by a layer of heavy paraffin oil to exclude oxygen. The appearance of milkiness indicated the beginning of polymerization. Several hours later, a firm white gel had formed, which was cut up into small pieces and washed exhaustively with running tap water to remove unreacted monomer. The pieces of gel were forced through a sieve (1-mm mesh) and the particles were again washed with water, alcohol, and acetone and finally with distilled water, until the ultraviolet-absorbing material ceased to elute from the solid. The finest particles were then removed by decantation or filtration through a sieve (U.S. 50 mesh).

‡It should be noted that samples of monomer may require fractional distillation before polymerization is possible.

§These materials were generously supplied by Cyanamid Co. of Canada, Ltd.

(2) A polymer of vinyl ethyl carbitol* (CH_2=$CH \cdot O \cdot CH_2 \cdot CH_2 \cdot O \cdot CH_2 \cdot CH_2 \cdot O \cdot C_2H_5$) was prepared using the same cross-linking agent and initiators.

Vinyl ethyl carbitol (12.75 g) was mixed with boiled distilled water (42.5 ml) and ethyl alcohol (42.5 ml). The solution was treated with Amberlite IR-120 (H^+ form) to remove the inhibitor, then sodium bicarbonate (1 g) and N,N′-methylenebisacrylamide (2.25 g) were added, giving a turbid solution. Dimethylaminopropionitrile (4 μl) and ammonium persulphate (4 mg) were added in turn, with gentle stirring, and the solution was covered with paraffin oil. In a few hours a firm, rather friable, white gel had formed, which was washed and broken up as before.

(3) Vinyl pyrrolidone† was also polymerized to a gel. Vinyl pyrrolidone (12.75 g) was dissolved in boiled distilled water (85 ml) and treated with ion exchange resin, as before, and N,N′-methylenebisacrylamide (2.25 g) was added. The catalyst system was concentrated ammonia solution (0.2 ml) and hydrogen peroxide (0.4 ml, 30%).

To evaluate the possible usefulness of these gels for column chromatography, some preliminary experiments were done with mixtures of materials readily available in this laboratory, such as human serum proteins, lysozyme, and the water-soluble components of ragweed pollen, which include proteins, polysaccharides, lipids, and pigments.

Serum (0.5 ml) containing haemoglobin was applied to a column (60 cm×2.5 cm I.D.) containing acrylamide gel. For elution, a solution of 0.9% saline and sodium phosphate buffer (17.25 g $Na_2HPO_4.7H_2O$ plus 1.417 g $NaH_2PO_4.H_2O$ per liter) was used, 5-ml fractions being collected. From optical density measurements and from immunochemical examination‡ of the eluates it was clear that a partial fractionation had been attained. The lipid present in the serum did not appear to be retained by the gel and appeared first in the eluate after the passage of about 60 ml, representing the dead volume of the column. Methaemoglobin and several serum proteins eluted immediately afterwards. These fractions were virtually free of albumin, which reached maximum concentration after collection of 90–100 ml of eluate. Lysozyme, when examined in the same way, reached maximum concentration at about 140–150 ml. Aqueous ragweed pollen extract on elution with water gave initial fractions containing lipid, followed by protein, and then by various pigments.

Polyvinyl ethyl carbitol under the same conditions gave results similar to those reported above with ragweed pollen preparations. However, polyvinyl pyrrolidone retained some of the pigments, which are derivatives of quercetin, so strongly that elution of these materials was quite difficult. These findings are in accordance with the known properties of polyvinyl pyrrolidone to complex with different compounds (6).

From these preliminary results, it appears that such polymer gels offer a new approach to adsorption chromatography. Obviously, this principle may be extended to the preparation of gels with ion exchange properties conferred by the incorporation of ionic groups, such as diethylaminoethyl, pyridine, and carboxyl groups.

REACTION OF GROUP V IODIDES WITH IODOMETHANE AND TRIFLUOROIODOMETHANE IN THE PRESENCE OF MERCURY

M. M. Baig and W. R. Cullen

The reaction of alkyl- or aryl-iodoarsines with alkyl iodides in the presence of mercury produces arsonium triiodomercury (II) derivatives (1). Under similar conditions using perfluoroalkyl iodides the products are trifluoromethylarsines (2, 3). It has now been found that arsenic triiodide does not react with trifluoroiodomethane in the presence of mercury to give trifluoromethylarsines and that similar results are obtained for phosphorus, antimony, and bismuth triiodides (see Table I). The reaction of iodomethane with these iodides in the presence of mercury produces tetramethylarsonium triiodomercurate (II) (1); tetramethylstibonium triiodomercurate (II), m.p. 167°; the 1:1 complex of trimethylphosphine and mercuric iodide, $(CH_3)_3P.HgI_2$, m.p. 197–200°; together with another unidentified minor product. In the case of bismuth triiodide a low yield of an unstable yellow solid is also produced.

The phosphine mercuric iodide adduct is a pale yellow solid. Its molecular weight in camphor indicates that it is present in solution largely as the monomer. Similar results have been obtained for other 1:1 tertiary phosphine mercuric iodide complexes (4). The reaction of iododimethylarsine with iodoethane in the presence of mercury similarly produces the 1:1 adduct of ethyldimethylarsine and mercuric iodide though all other reactions of this kind so far investigated produce onium derivatives of triiodomercury (II) if the reactant is an alkyl iodide (1).

Diiodophenylstibine in the presence of mercury does not react with trifluoroiodomethane, and with iodomethane the main product is methylmercury iodide. This compound is also formed as a by-product in similar reactions of iodophenylarsines (1). The reaction of diiodophenylstibine with iodomethane also produces a small amount of a yellow substance, possibly an onium complex, but the yield is not sufficient for easy isolation and identification. The absence of any significant reaction of the phenyliodostibine with both iodomethane and trifluoroiodomethane is surprising in view of the similar behavior of arsenic and antimony triiodides when reacted with iodomethane: both yield onium derivatives in moderately good yield.

It has been found that when the compounds R_nAsI_{3-n} (R = alkyl or aryl, n = 1 or 2) are reacted with trifluoroiodomethane in the presence of mercury the yield of trifluoromethylarsine decreases as the number of iodine atoms to be substituted increases (2, 3). Failure of arsenic triiodide to react with trifluoroiodomethane can thus be regarded as the limiting case.

EXPERIMENTAL

For these experiments commercial phosphorus and bismuth triiodides were used. Arsenic and antimony triiodides were prepared by the procedures given in *Inorganic syntheses* (5). Diiodophenylstibine, m.p. 69° (lit. value, 69°) (6), was prepared by reducing phenylstibonic acid with stannous chloride in the presence of sodium iodide. Phenylstibonic acid was prepared by the action of diazotized aniline on antimony trioxide (6). The reactions reported below were carried out in sealed tubes in the absence of air and light. The reaction temperature was 20° unless otherwise stated. Volatile reactants were manipulated in a vacuum system.

Reaction of Group V Iodides with Trifluoroiodomethane in the Presence of Mercury

Table I shows the results of these experiments. Mercury (ca. 200 g) was also present in the tubes in addition to the reactants listed. After shaking the tubes for the time shown the volatile contents were taken into the vacuum system. Trap-to-trap distillation and infrared examination of the fractions isolated failed in all cases to show that any volatile substance other than trifluoroiodomethane was present.

TABLE I

Reactants*	Time (days)	CF_3I recovered (g)
PI_3 (18.0), CF_3I (82.5)	50	83.0

*Weight, in grams, of reactants given in parentheses.
†No unreacted arsenic triiodide could be extracted from the solid residue with alcohol.

Reactions of Group V Iodides with Iodomethane in the Presence of Mercury

Phosphorus triiodide.—Phosphorus triiodide (18.5 g), mercury (215 g), and iodomethane (65 g) were shaken for 50 days. The contents of the tube were extracted with acetone and a slightly soluble, pale yellow solid was isolated. Fractional crystallization of this solid gave fractions melting in the range 148–162°. These were combined and recrystallization from a large volume of ethanol gave two fractions, one a pale yellow crystalline solid, m.p. 165–170° (6 g), and the other a small amount of a yellow waxy solid, m.p. 85–106°. Analysis of the first fraction (found: C 5.86, H 1.57, P 5.16, Hg 36.8, I 49.6%) (empirical formula $C_{2.9}H_{9.4}P_1Hg_{1.1}I_{2.4}$) suggested that the substance was mainly the 1:1 adduct of trimethylphosphine and mercuric iodide. A sample of the adduct was prepared by reacting trimethylphosphine (1.278 g, 1 mole) with mercuric iodide (1 mole) at 90° for 6 days. No volatile material was present in the tube after this time. The yellow solid which remained in the tube was only slightly soluble in hot ethanol or acetone but was eventually recrystallized using a large volume of a mixture of ethanol and acetone (2:1 by volume). The product melted at 197–200° and its infrared spectrum was identical with that of the product, m.p. 165–170°, from the reaction of phosphorus triiodide with mercury and iodomethane. The identity of the 1:1 adduct was confirmed by analysis. Found: C 6.90, H 1.65, P 5.75, Hg 37.5, I 47.7%, mol. wt. 565; calc. for $C_3H_9HgI_2P$: C 6.78, H 1.69, P 5.83, Hg 37.8, I 47.8%, mol. wt. 531. The reaction product melting at 85–106° was also analyzed but the results do not approximate to any reasonable compound.

Antimony triiodide.—The triiodide (13.9 g), mercury (219 g), and iodomethane (50.3 g) were shaken for 30 days. Extraction of the contents of the tube with acetone gave, after recrystallization, *tetramethylstibonium triiodomercurate* (II), m.p. 167° (41% yield). Anal.: found: C 6.81, H 1.59, Hg 25.6, I 48.8%; calc. for $C_4H_{12}HgI_3Sb$: C 6.3, H 1.57, Hg 26.3, I 50.0%.

Diiodophenylstibine.—The stibine (8.0 g), mercury (189 g), and iodomethane (31.4 g) were shaken for 40 days. Extraction of the contents of the tube with acetone gave a slightly colored (yellow) solid (15.6 g). This, on recrystallization from acetone, was colorless and was identified as methylmercury iodide. Anal.: found: C 2.98, H 0.74, Hg 57.6, I 37.4%, mol. wt. 316, m.p. 147–148°; CH_3HgI requires: C 3.50, H 0.87, Hg 58.7, I 37.0%, mol. wt. 343, m.p. 152° (7). The yellow impurity was not present in sufficient quantity to enable easy isolation and identification.

Bismuth triiodide.—The triiodide (22.2 g), mercury (300 g), and iodomethane (63.2 g) were shaken for 14 days. The acetone extract was yellow but on crystallization the product appeared to decompose with the liberation of mercuric iodide.

IMPROVED SYNTHESIS OF N-ALKYL-ASPARTIC ACIDS

R. Laliberté and L. Berlinguet

N-Alkyl-aspartic acids can now be prepared readily by nucleophilic addition of primary amines to the double bond of monomethyl maleate according to a technique first described by Zilkha and Bachi (1).

During the preparation of some N-alkyl-aspartic acids, we found that triethylamine could advantageously replace pyridine as solvent and catalyst. The yields are about 20% higher and the isolation of a much purer product is possible owing to the absence of colored secondary products.

We have extended this reaction to two more primary amines and we have obtained good yields of the following derivatives: N-ethyl-aspartic acid β-methyl ester (95%) and N-isopropyl-aspartic acid β-methyl ester (75%).

We also found that this method is quite general and that other types of amines can be used to give new N-alkyl-aspartic-acid β-methyl esters. Piperidine, ethanolamine, 2-propanolamine, and glycine methyl ester were condensed with monomethyl maleate to give the expected N-alkyl-aspartic acids β-methyl ester with yields of 76%, 75%, 82%, and 75% respectively.

When 2 equivalents of the amine were used, we obtained the corresponding N,N′-disubstituted asparagine: thus N,N′-dibutyl-asparagine and N,N′-dipiperidyl-asparagine were obtained.

Good yields of the N-alkyl-aspartic acids were obtained by hydrolysis of the corresponding methyl esters with cold barium hydroxide (1). All these amino acids were characterized as such except for N-(2-propanol)-aspartic acid, which is hygroscopic and was isolated as the copper salt.

EXPERIMENTAL

Preparation of N-Alkyl-aspartic Acids β-Methyl Esters

Maleic anhydride (56 g, 0.57 mole) was dissolved in 200 ml of methanol. After the mixture was refluxed on a water bath for 30 minutes, excess methanol was distilled off. One hundred milliliters of triethylamine was added to the residue, cooled in ice, very slowly and with stirring in order to avoid side reactions which could contaminate the product with colored by-products. One-half mole of the desired amine was then added in one portion. This mixture was stirred over a water bath for an hour. Usually the product started to crystallize in 20 minutes. The mixture was filtrated and washed twice with hot acetone or ethyl acetate. After these washings, the product is usually white and can be used without further purification (see Table I).

If necessary, the ester can be crystallized from a minimum volume of hot water by adding a large amount of acetone.

The addition of piperidine goes smoothly at room temperature and it is not necessary to heat the solution. However, in this reaction no solid crystallizes out, and the excess of triethylamine has to be evaporated, because the addition product remains in solution. The residue is taken in hot isopropanol and crystallized in the cold. A further crop of crystals is obtained after the addition of petroleum ether.

In the case of glycine methyl ester, 5 g (0.036 mole) of the hydrochloride were mixed with monomethyl maleate prepared from 5 g of maleic anhydride. To this mixture were added 30 ml of triethylamine and 5 ml of methanol. After heating on a water bath for an hour, the hydrochloride of triethylamine crystallized in the cold and was eliminated by filtration. The methanol and the excess of triethylamine were distilled off. The condensation product was dissolved in water and crystallized by the addition of isopropanol.

Preparation of N-Alkyl-aspartic Acids

The N-alkyl-aspartic acid methyl ester to be hydrolyzed (0.10 mole) was dissolved in 0.125 mole barium hydroxide solution and left for 2 hours at room temperature. The solution was heated for 10 minutes and

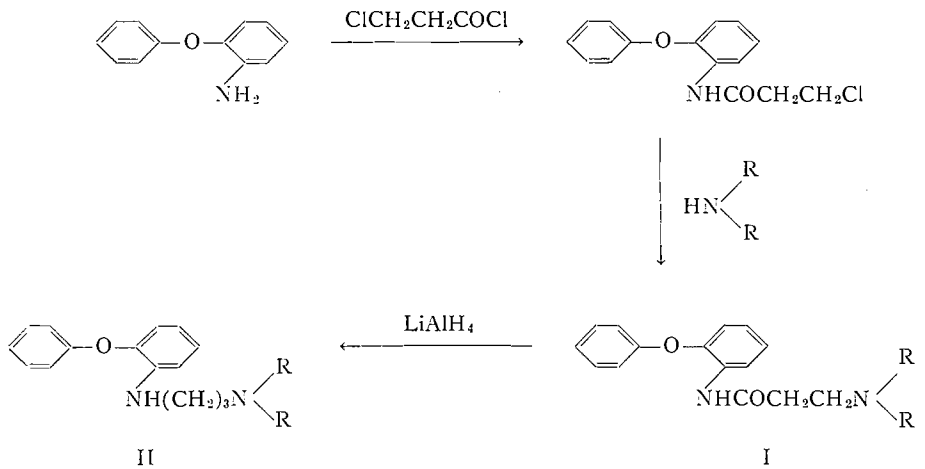
THE SYNTHESIS OF SOME BASIC DIPHENYL ETHERS

GERASSIMOS FRANGATOS, J. M. DODSWORTH, GEZA KOHAN, AND FRANCIS L. CHUBB

Recently several publications and patents (1–4) have appeared which described the synthesis and physiological activity (4) of 10-dialkylaminoalkylphenoxazines. In this communication we wish to describe the synthesis of some basic aromatic ethers, including two series of compounds, 2-(3-dialkylaminopropionamido)diphenyl ethers (I) (see Table I) and 2-(3-dialkylaminopropyl)diphenyl ethers (II) (see Table II), which may be regarded as open-chain analogues of the corresponding phenoxazine derivatives.

The basic ethers I and II were prepared from 2-aminodiphenyl ether according to the reaction scheme shown below.



In order to study further the relationship of structure to physiological activity in this series, some 4-(3-dialkylaminopropionamido)-2-nitrodiphenyl ethers (III) (see Table III) were synthesized in the same way as I, starting from 4-amino-2-nitrodiphenyl ether.

EXPERIMENTAL

Melting points are uncorrected. Microanalyses were performed by E. Thommen, Thannerstrasse 45, Basel, Switzerland.

2-(3-Chloropropionamido)diphenyl Ether

The procedure of Roberts and Turner (5) was adopted for the reduction of 2-nitrodiphenyl ether (6) to 2-aminodiphenyl ether.

A solution of 12.7 g (0.1 mole) of 3-chloropropionyl chloride in 50 ml of benzene was added dropwise to a cooled (ice bath) solution of 18.5 g (0.1 mole) of 2-aminodiphenyl ether and 10.1 g (0.1 mole) of triethylamine in 150 ml of benzene. After the addition was complete, the reaction mixture was allowed to stand overnight at room temperature, during which time crystals of triethylamine hydrochloride gradually separated. Water (300 ml) was added and the layers were separated. The aqueous layer was extracted with two 100-ml portions of benzene. After the combined benzene layers over sodium sulphate were dried, the benzene was distilled under reduced pressure. The residual oil which distilled at 207° under 1 mm pressure was recrystallized from benzene–hexane to yield 18.5 g (67.3%) of 2-(3-chloropropionamido)-diphenyl ether, m.p. 62°. Anal. calc. for $C_{15}H_{14}ClNO_2$: C 65.34, H 5.12, N 5.08; found: C 65.11, H 5.36, N 4.99.

2-(3-Morpholinopropionamido)diphenyl Ether

A mixture of 27.6 g (0.1 mole) of 2-(3-chloropropionamido)diphenyl ether, 300 ml of toluene, 8.71 g of morpholine, and 2.5 g of anhydrous potassium carbonate was stirred and refluxed for 5 hours. After the hot reaction mixture was filtered, the solid residue was washed with 150 ml of hot toluene. The combined toluene filtrates were dried over anhydrous sodium sulphate and the toluene was evaporated under reduced pressure. The oily residue crystallized on trituration with a minimum amount of ether. Recrystallization from ether yielded 25.6 g (78.5%) of 2-(3-morpholinopropionamido)diphenyl ether, m.p. 136°. Anal. calc. for $C_{19}H_{22}N_2O_3$: C 69.91, H 6.80, N 8.58; found: C 69.96, H 6.97, N 8.88.

The remainder of the ethers I and III, listed in Tables I and III respectively, were prepared as above.

2-(3-Morpholinopropylamino)diphenyl Ether

A solution of 16.3 g (0.05 mole) of 2-(3-morpholinopropionamido)diphenyl ether in 150 ml of absolute ether was added dropwise to a stirred solution of 8 g of lithium aluminum hydride in 200 ml of ether, at such a rate as to maintain gentle refluxing without external heating. After the addition was complete, the stirring and refluxing was continued for an additional 3 hours. The excess of lithium aluminum hydride was destroyed by the cautious addition of 10 ml of water. An additional 100 ml of water was added and the reaction mixture was filtered. After the solid residue was washed with 100 ml of ether, the combined ether layers were washed with water and dried over anhydrous sodium sulphate. Dry hydrogen chloride was passed into the solution and the dihydrochloride of 2-(3-morpholinopropylamino)diphenyl ether precipitated. Recrystallization from isoamyl alcohol – ethyl acetate yielded 16.8 g (87.2%), m.p. 184°. Anal. calc. for $C_{19}H_{20}Cl_2N_2O_4$: C 59.22, H 6.80, N 7.27; found: C 58.59, H 6.93, N 7.52.

The remaining members of the series (II) were prepared in a similar way and are listed in Table II.

4-(3-Chloropropionamido)-2-nitrodiphenyl Ether

The above compound was obtained from the reaction of 3-chloropropionyl chloride with 4-amino-2-nitrodiphenyl ether (7), using the procedure employed for the preparation of 2-(3-chloropropionamido)-diphenyl ether. The crude product was recrystallized from alcohol and 71.2% of material melting at 144° was obtained. Anal. calc. for $C_{15}H_{13}Cl_2N_2O_4$: C 56.17, H 4.08, N 8.74; found: C 56.71, H 4.27, N 8.65.

Received October 24, 1961

ABSTRACT

Various porphyrins and chlorophyll derivatives have been purified on a preparative scale by distribution between hydrochloric acid and ether on Celite columns. By this technique crude *Chlorobium* pheophorbide (650) was resolved into six components, which possessed almost identical visible absorption spectra, but slightly different acid distribution numbers. Chromic acid oxidation and subsequent gas–liquid partition chromatography of the neutral fractions indicate the presence of more than one *Chlorobium* chlorophyll (650) in the original pigment preparation.

The method most frequently used for resolving mixtures of porphyrins or chlorophyll derivatives is partition between aqueous hydrochloric acid and ether. The resolution obtained by this method depends on how much the compounds differ in basicity and solubility. An approximate quantitative expression of these properties is the "acid number", i.e. the percentage (w/w) of aqueous hydrochloric acid which extracts two thirds of a compound from an equal volume of ether (1). When the "acid numbers" of two pigments differ by several percentage units complete separation may be readily accomplished. However, when components possess almost equal "acid numbers" countercurrent distribution is usually necessary. This method has the disadvantages of requiring special, expensive apparatus and is not usually applicable to large quantities of material.

Liquid–liquid partition chromatography has been applied in a few instances to the resolution of mixtures of porphyrins (2, 3, 4). In particular, Falk (5) has quoted the use by Scott of Celite columns containing hydrochloric acid as the stationary phase and ether as the eluent. No experimental details have, to our knowledge, been published. We have developed such a procedure and have found that by choosing the appropriate strength of hydrochloric acid or by using solvents other than ether, many mixtures of porphyrins and chlorophyll derivatives of similar acid number can be resolved. Our experience fully confirms that of Lemieux *et al.* (6) concerning the ease of construction and extrusion of Celite columns, and of uniform and rapid flow through such columns.

[1]*Issued as N.R.C. No. 6616.*

[2]*National Research Council Postdoctorate Research Fellow, 1959–61. Present address: New Chemicals Group, National Chemical Lab., Teddington, Middlesex, England.*

The method did not resolve the isomers coproporphyrins 3 and 4 and was not applicable to acid-labile substances such as magnesium complexes and esters with high acid numbers. Esters with low acid numbers, e.g. methyl vinylphylloporphyrin (acid number: 1.4 (7)) and methyl phylloporphyrin (acid number: 0.9 (8)) were separated without hydrolysis when the column was developed rapidly (Fig. 1). A mixture of pyropheophorbide *a* and mesopyropheophorbide *a* (acid numbers: 12–13 and 12, respectively (9)) (Fig. 2) and

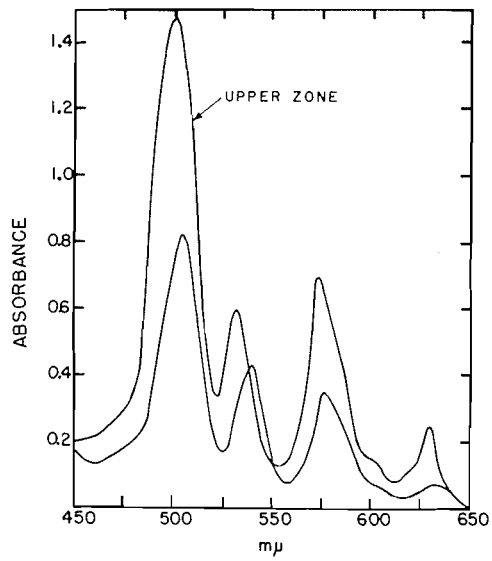

FIG. 1. Spectra of ether solutions of pigments separated on Celite column. Upper zone: methyl phylloporphyrin; lower zone: methyl vinylphylloporphyrin. Stationary phase: 1.5% (w/w) aqueous HCl saturated with ether; mobile phase: ether.

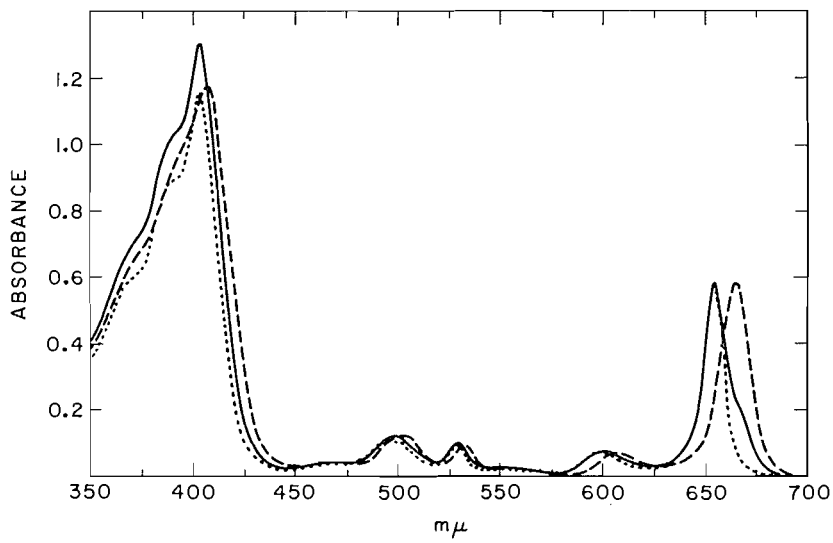

FIG. 2. Spectra of ether solutions of pyro- and mesopyro-pheophorbide *a* separated on Celite column: —— before partition; . . . upper zone (mesopyropheophorbide *a*); – – – lower zone (pyropheophorbide *a*). Stationary phase: 14% (w/w) aqueous HCl saturated with ether; mobile phase: ether.

a mixture of deuteroporphyrin 9 and mesoporphyrin 9 (acid numbers: 0.4 and 0.5, respectively (10)) were also resolved successfully. Neither partition using separatory funnels nor adsorption chromatography on sucrose followed by crystallization had previously given mesopyropheophorbide *a* completely free of pyropheophorbide *a*. Separation of deutero- and meso-porphyrin 9 was accomplished earlier by means of countercurrent distribution between hydrochloric acid and ether (11).

The column technique was applied to the further resolution of crude *Chlorobium* pheophorbide (650), which we have recently reported to be separable into two components by chromatography on sucrose (12). Eight zones were obtained and were designated as fractions 1 to 8 in the relative order of their position on the column, fraction 8 being uppermost. Fractions 7 and 8 were minor constituents and were discarded when they proved to have the same visible absorption spectra as *Chlorobium* pheophorbide (660) (13). The visible absorption spectra of the pigments in fractions 1 to 6 were, for practical purposes, almost identical, and the ratios of absorption at the indicated wavelengths are given in Table I. The percentage of each fraction extracted by two concentrations of

TABLE I

Ratios of absorbance (A) at wavelengths ($m\mu$) indicated for fractions of *Chlorobium* pheophorbide (650)

Fraction	$\frac{A_{531}}{A_{502}}$	$\frac{A_{403}}{A_{657}}$	Fraction	$\frac{A_{531}}{A_{502}}$	$\frac{A_{403}}{A_{657}}$
1	1.05	1.96	4	1.10	1.85
2	1.05	1.92	5	1.05	1.88
3	1.06	1.87	6	1.03	1.88

aqueous hydrochloric acid from ether solution is given in Table II. The latter results were to be expected from the order in which the fractions moved down the Celite column, i.e. fraction 1 was extracted the least and fraction 6 the most.

TABLE II

Percentage of fractions of *Chlorobium* pheophorbide (650) extracted from ether by two concentrations of aqueous hydrochloric acid

Fraction	12.3% HCl	14.0% HCl	Fraction	12.3% HCl	14.0% HCl
1	20	70	4	75	95
2	45	85	5	80	96
3	56	89	6	91	98

Countercurrent distribution of a sample of the same crude pheophorbide (650) between hydrochloric acid (14%) and ether gave partial resolution into four components after 620 transfers (see Fig. 3).

A sample from each of fractions 1 to 6 was oxidized by chromium trioxide in sulphuric acid. The products were resolved into neutral and acidic fractions and after the latter had been methylated each fraction was analyzed by gas–liquid partition chromatography (14). The retention times relative to that of quinoline of the components observed in the respective neutral fractions are given in Table III. Each pigment yielded chiefly one of three products, two of which had the same retention times as methylethylmaleimide and methyl-*n*-propylmaleimide. Fractions 3 and 6 gave evidence of contamination, which

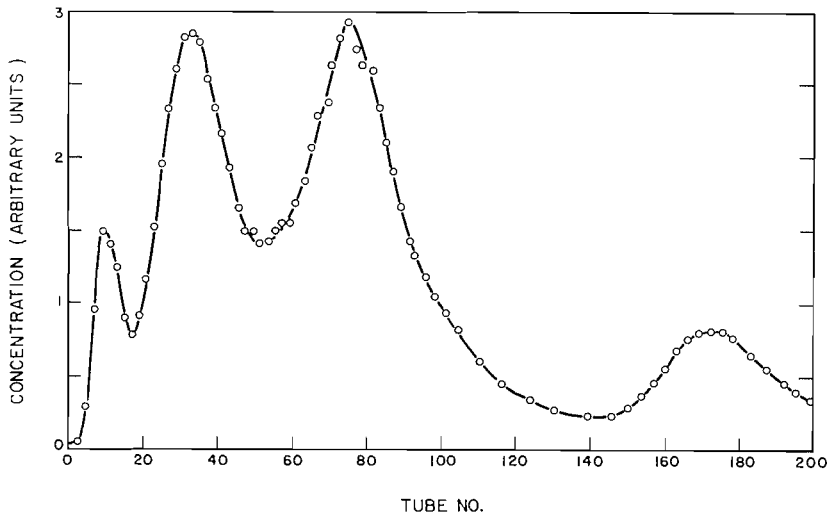

FIG. 3. Separation of components in crude *Chlorobium* pheophorbide (650) (40 mg) by countercurrent distribution between aqueous hydrochloric acid (14%, w/w) and ether.

TABLE III

Gas–liquid partition chromatography of the neutral products formed by oxidation of the fractions of *Chlorobium* pheophorbide (650)

Fraction	Retention time of neutral product relative to quinoline	Fraction	Retention time of neutral product relative to quinoline
1	1.58	5	1.33
2	1.33	6	0.93†
3	1.33*	Methylethylmaleimide	0.93
4	0.93	Methyl-*n*-propylmaleimide	1.33

*Contaminated by a small amount of material with a retention time of 1.58.
†Contaminated by a small amount of material with a retention time of 1.33.

presumably resulted from incomplete fractionation on the Celite column. The unknown product from fractions 1 and 3 has not been isolated in sufficient quantity to permit its identification. Each of the methylated acidic fractions contained one main component which had the same retention time as dihydrohematinic acid imide methyl ester. In addition, a complex mixture of products whose retention times were considerably lower was observed, but the nature of these has not been studied.

The above results show that the original *Chlorobium* chlorophyll (650) extracted from the cells contained more than one chlorophyll. It remains to be shown whether these arise from a mixed culture of different strains of *Chlorobium*, or whether the individual cells synthesize more than one chlorophyll.

EXPERIMENTAL[3]

I. Preparation and Use of Celite Columns

A glass column, plugged at its tapered end with glass wool, was tightly packed with dry, commercial Celite (Johns Manville 535 or 545) under suction and tamped. To protect the surface of the Celite the top was then covered with glass wool onto which the solutions were subsequently poured. Aqueous hydrochloric acid of chosen strength, saturated with ether, was first added to the column under slight suction. Iron

[3]*All visible absorption spectra were measured on a Cary Recording Spectrophotometer, Model 11M.*

impurity in the Celite was removed completely as ferric chloride, which travelled with the acid front. When low acid concentrations had to be used, the Celite was washed previously with concentrated acid. After the ferric chloride had been completely eluted, the "acid-saturated" ether solution was added to the column and allowed to percolate under gravity until separate aqueous and ether layers were observed in the receiver flask. The glass wool was removed, the column was allowed to run dry, retamped, and its upper surface was covered with a filter paper.

The pigment solutions to be partitioned were usually prepared by dissolving the pigment in pyridine and ether and then removing the pyridine with dilute hydrochloric acid. The pigment solution was absorbed at the top of the column and the chromatogram was developed with a continuous flow of ether under gravity or slight suction. The pigments were recovered from the individual bands either by elution or by first extruding the column, and then cutting out the individual bands and washing with acetone containing dilute aqueous hydrochloric acid.

For the resolution of porphyrins whose solubilities in ether were very low, e.g. meso- and deuteroporphyrins 9, alternative procedures of introducing the pigments onto the column were used (see below).

II. Resolution of Mixtures of Known Compounds

(a) Separation of Methyl Vinylphylloporphyrin and Methyl Phylloporphyrin

A mixture of the two porphyrins (ca. 2 mg) was chromatographed on a column (2×15 cm) using 2.5% (w/w) aqueous hydrochloric acid. Two zones, separated by 5 cm, were evident when the leading zone containing methyl vinylphylloporphyrin reached the bottom of the column.

(b) Separation of Deuteroporphyrin 9 and Mesoporphyrin 9

Deuteroporphyrin 9 (6 mg) and mesoporphyrin 9 (3 mg) were dissolved in a mixture of hydrochloric acid (12.5 ml, 0.75%) and tetrahydrofuran (5 ml) and mixed with Celite (25 g). The wet powder was packed on top of a column (5×30 cm) which had been prepared earlier using 0.75% hydrochloric acid. The column was developed for 4 hours, at the end of which time two discrete bands were observed. A more rapid and more satisfactory separation was obtained by using 2.5% hydrochloric acid and a mixture of chloroform and ether (2:1, v/v).

(c) Purification of Mesopyropheophorbide a

Impure mesopyropheophorbide *a* (15 mg), prepared from pyropheophorbide *a* (15, 16), was chromatographed on a column (4.5×30 cm) using 14% (w/w) hydrochloric acid and ether. Two bands were obtained. The products were recovered after the leading zone had moved 20 cm. The separation between the bands was then 6 cm.

(d) Attempted Resolution of Coproporphyrins 3 and 4

A mixture of the porphyrins (ca. 2 mg) was chromatographed on a column (2×48 cm) using hydrochloric acid (0.2%, w/w) and ether. No resolution was observed during 20 hours' development.

III. Growth of Chlorobium thiosulfatophilum (strain L) and Isolation of Chlorobium chlorophyll (650)

Chlorobium thiosulfatophilum (strain L) was cultured in mass in 1-gal bottles at 85–88° F for 7 to 9 days under Sylvania, 30W, Warm White fluoroscent lamps (light intensity: ca. 200 ft-c). Preliminary tests showed that strict asepsis was unnecessary and that maintenance of anaerobic conditions was sufficient to ensure good growth. Otherwise the procedures used were essentially those recommended by Larsen (17). The medium used is given below:

NH_4Cl	0.1%
KH_2PO_4	0.1%
$MgCl_2.6H_2O$	0.054%
NaCl	0.3%
$NaHCO_3$	0.2%
$Na_2S_2O_3.5H_2O$	0.158%
$Na_2S.9H_2O$	0.01%
$CaCl_2$	0.004%
Fe from $FeCl_3.6H_2O$	150 μg%
B from H_3BO_3	100 μg%
Zn from $ZnSO_4.7H_2O$	10 μg%
Co from $Co(NO_3)_2.6H_2O$	20 μg%
Cu from $Cu(SO_4).5H_2O$	10 μg%
Mn from $MnSO_4.H_2O$	1 μg%

The cells were harvested by filtration under suction through a 1-in. pad of Celite (545 and 505, 3 parts to 1) covered with filter paper (Whatman No. 1). The pigment was isolated as follows: the Celite pad and filter papers were blended in cold methanol containing tetrahydrofuran (10%, v/v) and the mixture filtered. The filtrate was poured into ether in a separatory funnel, water added, and the lower layer removed. Successive filtrates were added to the same ethereal solution until the discarded aqueous phase contained

significant amounts of pigment. Calcium chloride was used to break up any emulsion and to dry the solution, which was then filtered and evaporated. The mixture was dissolved in a minimum volume of tetrahydrofuran, and petroleum ether was added to precipitate the chlorophyll. The pigment was collected on Celite, redissolved, reprecipitated, dissolved once again, transferred into ethyl ether, and collected on water as described earlier (18). Material isolated by this procedure had no methoxyl content. It was stored at −25° C.

Crude *Chlorobium* pheophorbide (650) was prepared by adding chlorophyll (1 g in 25 ml of pyridine) to boiling methanolic potassium hydroxide (150 ml, 4%, w/v) under anaerobic conditions. After 20 minutes the mixture was poured into ether (3 l.), acidified with hydrochloric acid (2–3%), and shaken. The ether layer was washed twice with water and evaporated.

IV. Resolution of Chlorobium Pheophorbides (650)

An ether solution (500 ml) of crude pheophorbide, obtained from the chlorophyll (0.25 g), was shaken with 2–3% (w/w) aqueous hydrochloric acid and poured onto a column (9.5×44 cm) of Celite which had been previously prepared using hydrochloric acid (14%) and ether. The column was developed for 5 hours, and the pigments were recovered after extrusion of the Celite. Each fraction was rechromatographed once or twice more. The yields per gram of chlorophyll of fractions 1 to 6 were 39, 128, 55, 88, 42, and 29 mg, respectively.

V. Oxidative Degradation of Fractions 1 to 6 and Identification of the Products

Pigment (10 mg) in a test tube was dissolved in sulphuric acid (2.0 ml, 25%) and cooled to −10° C. Aqueous chromium trioxide (0.5 ml, 6.7%, w/v) was added, and the reaction mixture was stirred for 20 minutes. The pH was raised to 10 to 11 with aqueous sodium carbonate and the volume was adjusted to 10 ml. The solution was transferred to a separatory funnel and neutral products were extracted by 10 separate 25-ml volumes of ethyl acetate (19). Acidic products were removed similarly after the solution had been acidified. The solutions were dried ($MgSO_4$) and reduced to a small volume (ca. 0.1 ml). A Pye Argon Chromatograph was used to establish the identities of the oxidation products by comparing their chromatographic behavior with those of authentic samples of methylethylmaleimide, methyl-*n*-propylmaleimide, and dihydrohematinic acid imide methyl ester. The column (4 mm (I.D.)×117 cm) was packed with 15% (w/w) polyphenyl ether (*m*-bis(*m*-phenoxy-phenoxy)-benzene) on Celite. The flow rate was 100 ml per minute, and the temperatures 175 and 230° C for the neutral and acidic fractions, respectively.

ACKNOWLEDGMENTS

Samples of porphyrins were provided by Dr. S. F. MacDonald of the Division of Pure Chemistry, National Research Council. Gas–liquid partition chromatographic separations were done by Mr. F. Cooper. Cultures of *Chlorobium thiosulfatophilum* were kindly supplied by Drs. J. Lascalles and H. Larsen.

STUDIES IN THE PYRROLINE SERIES

I. THE PROTON MAGNETIC RESONANCE SPECTRA OF SOME PYRROLINES

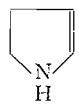
R. Bonnett and D. E. McGreer
The Chemistry Department, University of British Columbia, Vancouver 8, British Columbia
Received August 24, 1961

ABSTRACT

The proton magnetic resonance spectra of some pyrrolines and pyrroline oxides have been determined. The spectra accord with the Δ^1 formulation of the bases.

Interest in the 1-pyrrolines has been stimulated recently by the formulation (1) of the chromophore of vitamin B_{12} as a considerably reduced, ring-contracted porphyrin which can be regarded as being constituted of pyrroline rather than pyrrole nuclei. Up to this time the pyrrolines had attracted little sustained attention, and, except for the 3-pyrrolines, the position of unsaturation was in doubt, although the 2-pyrroline structure

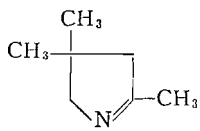
1-Pyrroline

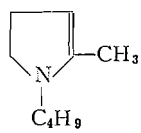


2-Pyrroline

was usually drawn. This question has been debated recently (2, 3, 4, 5, 6), and, in general, the conclusion has been drawn that these substances exist predominantly in the Δ^1 form.

Both chemical and physical evidence have been adduced to support this formulation. The Zerewitinoff determinations (6, 8) have probably been the most significant chemical evidence since they have shown that in the examples studied little or no active hydrogen was immediately available. Physical evidence has been based on some study of ultraviolet spectra (9), but the most significant results have come from infrared studies (2, 3, 4, 6). In general the pyrrolines have shown little or no absorption in the N—H stretching region, but a strong band, attributed to C=N absorption, is present in the 1620–1650 cm^{-1} region. The position of the C=N band, and the hypsochromic shift it undergoes on protonation of the base, are not definitive, however, as is indicated by the values given below.



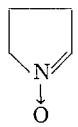


Base	1644 cm^{-1} (5)	1639 cm^{-1} (10)
Salt	1684 cm^{-1} (5)	1685 cm^{-1} (10)

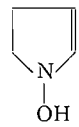
The strength of the C=N absorption band, and, especially, the absence of N—H absorption are, on the other hand, of considerable importance. In the latter area difficulties have arisen in certain instances. Thus Evans (3) reported that 2-methylpyrroline showed

a weak band at 3.02 μ, and Burckhalter and Short (4) considered a similar band at 3.05–3.10 μ in the spectrum of 2-benzylpyrroline to be anomalous since the compound did not contain active hydrogen. Other workers have considered that "the N—H region of the infrared absorption spectra of pyrrolidines and pyrrolines is difficult to interpret" (6, cf. ref. 7), and it is, of course, true that absorption in this region could be caused by species, notably traces of moisture or of dimer, other than the 2-pyrroline, which is presumed to be tautomeric with the Δ^1 form.

Proton magnetic resonance is particularly useful for studying the structures of compounds containing olefinic protons, and would be expected to distinguish clearly between the Δ^1 and Δ^2 forms of the pyrrolines, and also between the corresponding forms of the pyrroline-1-oxides:

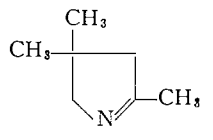


1-Pyrroline-1-oxide

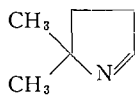


1-Hydroxy-2-pyrroline

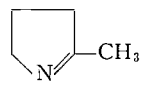
The proton magnetic spectra of five pyrrolines, I, II, III, IV, and V, and three pyrroline-1-oxides, VI, VII, and VIII, have therefore been determined for the pure liquids, and are reported in Table I.



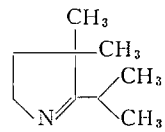
I



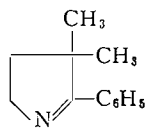
II



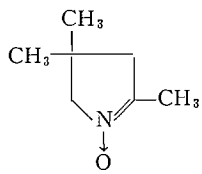
III



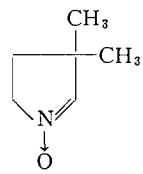
IV



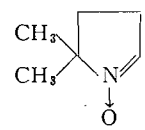
V



VI



VII



VIII

The spectra of 2-methylpyrroline (III), 2,4,4-trimethylpyrroline (I) and its N-oxide (VI) most clearly show the position of the double bond. The lack of signal in the olefinic proton region (2.0–5.5 τ) (11) is consistent with only that structure containing the double bond in the Δ^1 position (as shown) since all possible tautomers would have olefinic protons. As little as 5% of such tautomeric species would have been detected readily. The spectra of the other compounds studied are also consistent with the Δ^1 formulation. Thus the Δ^2 forms of II and VIII would be expected to show two olefinic proton signals, but area measurement clearly shows that only one proton is absorbing at low field. Again, the exo-Δ^2 form of IV would not be expected to show a septet, which is found here in the 7.8 τ region and which is characteristic of a tertiary proton coupled with six identical protons. Compounds V and VII cannot tautomerize to the Δ^2 form.

TABLE I

Proton magnetic resonance spectra of some pyrrolines and pyrroline-1-oxides

Compound	Proton position*					
	C_2	C_3	C_4	C_5	$(CH_3)_2$	Other
I	—	7.9	—	6.7	9.2	8.3 (CH_3 on C_2)
II†	3.1	7.8	8.8	—	9.1	—
III	—	8.0	8.5	6.7	—	8.4 (CH_3 on C_2)
IV	—	—	8.6	6.6	9.1	7.8 (3°H-septet)
						9.1 (CH_3 of *i*-Pr)
V	—	—	8.7	6.6	9.2	2.4 and 3.1 (Ph)
VI	—	7.4	—	6.5	8.9	8.2 (CH_3 on C_2)
VII‡	3.4	—	8.2	6.2	8.9	—
VIII§	3.4	7.6	8.0	—	8.8	—

*The protons on the saturated ring carbons of II, IV, V, and VII gave triplet signals with splittings of 7–7.5 c.p.s. In these cases and for other multiplets the center of the signal is recorded in units of τ.
†The area ratio of the signals for the H's on C_2 and C_3 was 1.0 to 2.0.
‡The area ratio of the signals for the H's on C_3, C_4, C_5, and the dimethyl group was 1.1:2.0:1.8:6.4 respectively.
§The area ratio of the signals for the H's on C_2 to those on C_3 plus C_4 was 0.9 to 4.0.

The assignment of signals to all other protons is straightforward since in at least one compound in each series the protons on each ring position are replaced by methyl groups. Thus examination of the spectra of the nitrones shows that the protons on ring positions 3, 4, and 5 give signals in the regions 7.5, 8.1, and 6.4 τ respectively. Similar signals for the pyrrolines are found in the regions 7.9, 8.7, and 6.7 τ respectively. These signals appear at higher field than those of the nitrones, presumably because the strong electron-withdrawing effect of the semipolar bond has been removed.

While it is possible that under certain conditions of substitution and environment the Δ^2 form may become detectable, or even isolable (cf. ref. 12), in the present simple but varied examples no evidence for the presence of a Δ^2 isomer has been forthcoming. The proton magnetic resonance spectra have strongly reinforced previous conclusions regarding the Δ^1 structures of these compounds.

EXPERIMENTAL

Pyrrolines

These were prepared by known methods: I and II (5); III (3); IV and V (13). The aliphatic pyrrolines were purified by distillation followed by preparative vapor phase chromatography on a 5-ft Uconpolar column at 85–120° (Aerograph A-100-C instrument) using helium as the carrier gas (cf. ref. 5). The aromatic compound V was purified by distillation.

Pyrroline-1-oxides

Compounds VI and VIII were prepared by known methods (14) and the preparation of VII will soon be reported. The nitrones were purified by distillation *in vacuo*.

Spectra

The proton magnetic resonance spectra were measured on a 40 Mc/s Varian spectrophotometer with field stabiliser VK 3506. Neat samples were used and calibrated to an external standard of hexamethyldisiloxane which had a chemical shift value of 10.3 τ as determined by reference to a solution of tetramethylsilane in carbon tetrachloride. A calibrated audio-frequency unit was used to determine chemical shifts by the side-band technique.

STUDIES IN THE PYRROLINE SERIES

II. OXYGEN TRANSFER FROM CYCLIC NITRONES TO TRIPHENYLPHOSPHINE

FRANCO AGOLINI AND R. BONNETT

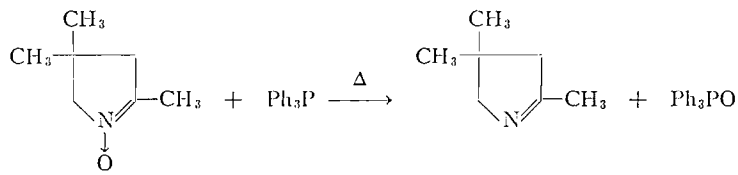
The Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received August 24, 1961

ABSTRACT

Triphenylphosphine, triphenylarsine, triphenylstibine, and triphenylbismuthine have been evaluated as acceptors in oxygen transfer reactions involving 1-pyrroline-1-oxides. The first reagent especially offers a useful route from the nitrones to the corresponding pyrrolines.

The direct reduction of 1-pyrroline-1-oxides to the corresponding pyrrolines has previously been carried out in two ways (1). 2,4,4-Trimethyl-1-pyrroline-1-oxide, I, for example, on treatment with zinc and acetic acid, gave a 66% yield of the corresponding pyrroline picrate, while a smaller yield was obtained when sulphur dioxide in chloroform was the reducing agent. A more convenient method has been sought which would avoid aqueous or acidic conditions and which, moreover, would give the product directly. Such a process is required in cases under examination (2) where the product of a preparative sequence is the 1-pyrroline-1-oxide from which it is then necessary to make the pyrroline; but it also offers a method of removing oxygen from certain of the products of syntheses involving the reactive nitrones.



I II

Oxygen transfer to compounds of other elements of group V suggested itself as a potential method, especially since triphenylphosphine has been used successfully to remove oxygen from pyridine oxides and other amine oxides (3, 4) and from oxazirans (5). The reduction of an aldonitrone has been noted (4), but no information appears to be available concerning the applicability of the reaction to purely aliphatic nitrones, including the 1-pyrroline-1-oxides. It was decided to examine as oxygen acceptors the complete range of compounds from triphenylphosphine to triphenylbismuthine, although it was expected that as this series was ascended the increasing instability of both the carbon–metal bond and the pentavalent state of the metal would intervene and at some stage make the reaction inconvenient or useless as a preparative method.

Trial experiments were carried out with 2,4,4-trimethyl-1-pyrroline-1-oxide, I, and triphenylphosphine. It was found that the reaction did not proceed to a useful degree in refluxing benzene or toluene. Reaction occurred speedily, however, when the substances were heated together with a free flame, and the product, 2,4,4-trimethyl-1-pyrroline, II, distilled directly out of the reaction mixture. A broadly similar result was obtained with triphenylarsine. With triphenylstibine and triphenylbismuthine, however,

extensive decomposition was evident, and in the latter case the main product in the distillate was benzene. These results are summarized, and some comparisons drawn, in Table I.

TABLE I

*Under the reaction conditions.
†One-gram portions of nitrone heated with an equimolar amount of the reagent (see Experimental).
‡Prepared in moist ether.
§Distillate extensively contaminated by decomposition products of the organometallic compound.

The triphenylphosphine reaction was examined further, and it was shown that triphenylphosphine oxide was isolable from the residue, thus confirming that the reaction involves oxygen transfer to phosphorus, rather than pyrolytic deoxygenation, a process which has been observed with certain amine oxides (8). The reaction was also applied to 5,5-dimethyl-1-pyrroline-1-oxide, a cyclic aldonitrone. In contrast to the cyclic ketonitrone, I, which is fairly stable to heat, 5,5-dimethyl-1-pyrroline-1-oxide is thermolabile. This decomposition is attended by the development in the infrared spectrum of a broad absorption band in the 1660 cm^{-1} region: this has led to the supposition that isomerization to the corresponding lactam may be one of the reactions involved. However, the oxygen transfer reaction evidently proceeds more rapidly than the decomposition, for the reaction gave a 65% yield of the crude 5,5-dimethyl-1-pyrroline (39% yield as the picrate), and triphenylphosphine oxide (57%) was isolated from the residue.

EXPERIMENTAL

The following equipment was used. Melting points: Fisher–Johns heated block. Infrared spectra: Perkin–Elmer Infracord or Model 21. Vapor phase chromatography: Aerograph model A-100-C with 5′ Uconpolar column.

2,4,4-Trimethyl-1-pyrroline from 2,4,4-Trimethyl-1-pyrroline-1-oxide

(*a*) The nitrone (1) (1 g) and triphenylphosphine (2.5 g) were heated (free flame) under a short Vigreux column. The volatile liquid which formed after a short time was refluxed gently for about 15 minutes and then distilled over at 110–130° (0.66 g, 75%). The infrared spectrum (film) of the basic liquid showed the presence of moisture (present in the hygroscopic starting material), together with a strong sharp band at 1650 cm^{-1} (lit. (9) 1644 cm^{-1}). No nitrone band was present. The picrate (1.52 g, 57%) was prepared in ether, and after recrystallization from ethanol had m.p. and mixed m.p. 195–196° (lit. (9) 195°). The infrared spectrum of the picrate (Nujol mull) was identical with that of an authentic sample.

The residue from the distillation was extracted with cyclohexane, and the solution treated with charcoal to give colorless needles (0.6 g, 23%) of triphenylphosphine oxide, m.p. 156–158°.

(*b*) In three trial experiments the reaction was repeated as above, except that the phosphine was replaced by equimolar amounts of triphenylarsine, triphenylstibine, and triphenylbismuthine. In the last two runs decomposition products (largely benzene) from the organometallic compound were present in the distillates. The results of these experiments are indicated in Table I.

Pyrolysis of 5,5-Dimethyl-1-pyrroline-1-oxide

A sample of 5,5-dimethyl-1-pyrroline-1-oxide was heated in a stoppered flask in an oil bath at 100° and the infrared spectrum of the liquid (film) was taken at intervals. During the course of 3 hours a peak at about 1660 cm^{-1}, very weak initially, increased slightly in intensity. After a further hour at 180° the sample became very dark. The new peak was now as strong as the nitrone peak at 1575 cm^{-1}, and the latter became weaker and less sharp as the experiment continued.

5,5-Dimethyl-1-pyrroline from the Corresponding Nitrone

5,5-Dimethyl-1-pyrroline-1-oxide (1) (1 g) was treated with triphenylphosphine (2.62 g) as before, and the volatile liquid boiling up to 104° was collected as crude 5,5-dimethyl-1-pyrroline (0.55 g, 65%), the infrared spectrum (film) of which showed a sharp peak at 1618 cm^{-1} (lit. (9) 1621 cm^{-1}). The yield was not improved by using a Wood's metal bath at 300° instead of a free flame. After purification by vapor phase chromatography the product had the same infrared spectrum as a similarly purified sample of the authentic base. The picrate, prepared in ether (1.13 g, 39%), was identical with an authentic sample.

Triphenylphosphine oxide (57%) was isolated from the dark residue after chromatography (3).

APPARENT DENSITIES AND INTERNAL SURFACE AREAS OF SELECTED CARBON BLACKS

P. L. WALKER, JR. AND W. V. KOTLENSKY*

The Fuel Technology Department, The Pennsylvania State University, University Park, Pennsylvania, U.S.A.

Received August 28, 1961

ABSTRACT

It is shown that the open pore volume within carbon blacks can be calculated from nitrogen adsorption isotherms (77° K) on the blacks. From this volume and a helium density, the apparent density of a black can be calculated. Other properties of the blacks which then can be calculated are free surface area, internal surface area, surface roughness factor, and the average pore diameter of the internal surface. These data are presented for five selected carbon blacks.

INTRODUCTION

Carbon blacks are more or less porous depending upon the perfection of their crystallite alignment and the extent of their oxidation during preparation (1). The amount of porosity can be of importance in affecting the behavior of carbon blacks in rubber, paints, and plastics; and yet little quantitative information is available on the nature of the porosity within blacks—such information as given by apparent densities and internal surface areas.

Kotlensky and Walker (2) used a mercury porosimeter to measure the apparent densities of some carbon blacks of large particle size. The volume of mercury forced between the particles was followed by the potential drop across a platinum–iridium wire looped and held taut inside a precision bore section of a dilatometer tube. Complete filling of the void volume between particles was taken as the point where a negligible change in potential drop first occurred with increase in pressure. From a knowledge of the weights of sample and mercury and the combined volume of the sample and mercury (with mercury filling the voids between particles), a particle density could be calculated. This technique appears to be satisfactory and convenient for carbon blacks of large particle size. However, for blacks of small particle size the pressure required to completely fill the voids between particles is high. For example, for Carbolac 1, a black having an arithmetic mean diameter of 106 Å (3), a pressure in excess of 20,000 p.s.i. would be required. At such pressures, crushing and distortion of the particles are of concern (4, 5). Therefore, it is of interest to explore another approach to determine apparent densities of carbon black particles. This approach and the information which can be derived therefrom are described in this paper.

EXPERIMENTAL

The carbon blacks studied were supplied by the Cabot Corp. with some of their properties listed by them (3). Some additional properties of interest are summarized by Kotlensky and Walker (2). Carbolac 1, Carbolac 2, Monarch 71, and Mogul A are channel blacks. Vulcan 3 is an oil furnace black.

Adsorption isotherms on the blacks were measured at 77° K using a standard gas adsorption apparatus (6) with nitrogen as the adsorbate. A description of the procedure used to measure helium densities (at 30±0.1° C) has been given previously (2).

RESULTS AND DISCUSSION

Adsorption isotherms for the blacks studied are given in Fig. 1. Typical calculations involved in using isotherm data to calculate apparent densities and other physical properties of the blacks can be demonstrated for Carbolac 1. As suggested by Pierce (7),

**Present address: Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, U.S.A.*

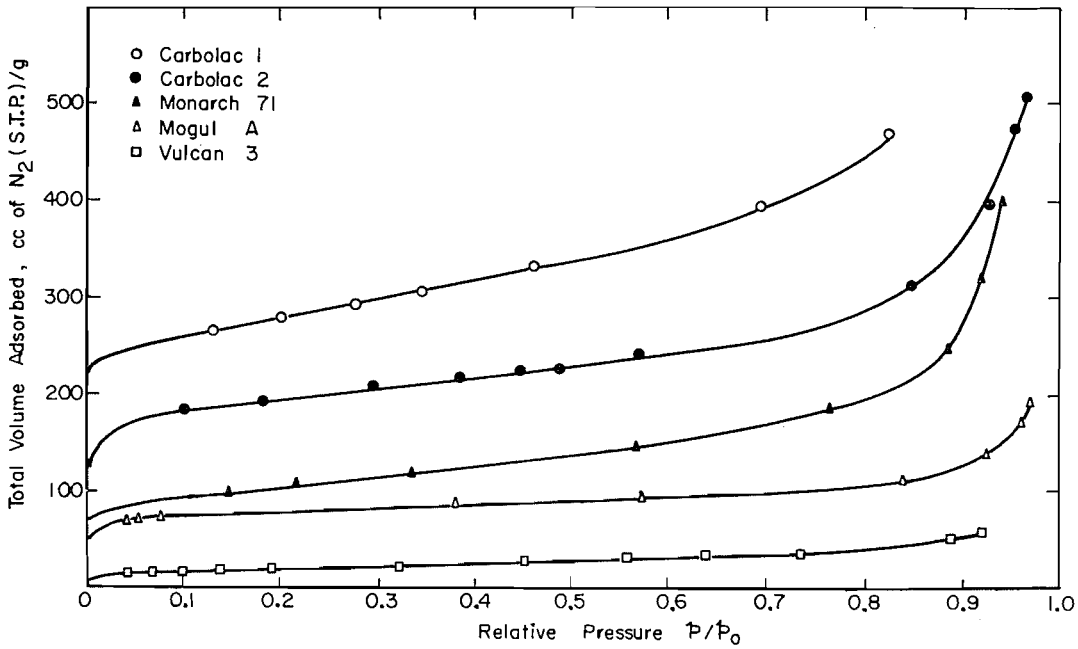

FIG. 1. Adsorption isotherms for nitrogen at 77° K on selected carbon blacks: ○ Carbolac 1, ● Carbolac 2, ▲ Monarch 71, △ Mogul A, □ Vulcan 3.

an isotherm for a porous solid can essentially be divided into three regions. In the middle region of the isotherm (region II), no capillary condensation occurs, but only multilayer adsorption on the free surface. In the lower region of the isotherm, monolayer and then multilayer adsorption is accompanied by the filling of the micropores within particles by capillary condensation. In the upper region of the isotherm, multilayer adsorption is accompanied by capillary condensation within the voids between particles.

In region II of the isotherm, it is possible to solve for the volume of adsorbate which completely fills the micropores (V_c) and the volume of adsorbate which covers the free surface with a monolayer (V_m'). That is, V_t, the total volume adsorbed at any relative pressure in region II, is given by

$$V_t = V_c + nV_m', \quad [1]$$

where n is the statistical number of layers of adsorbate at a particular relative pressure.

Or since V_c is constant in region II,

$$\Delta V_t = V_m' \Delta n. \quad [2]$$

Since n is known as a function of relative pressure for the adsorption of nitrogen on carbon at 77° K (8), ΔV_t can be plotted against Δn. From the slope of this plot, V_m' can be calculated. Figure 2 shows such a plot for Carbolac 1 over the relative pressure range 0.20 to 0.46, giving a value of V_m' of 135 cc N_2/g at S.T.P. From equation [1], then, V_c is calculated to equal 110 cc N_2/g at S.T.P.

As discussed by Pierce (8), if only multilayer adsorption is occurring, the ideal nitrogen isotherm is given by the Frenkel–Halsey–Hill equation

$$(V/V_m)^b = \frac{k}{\log (p_0/p)}, \quad [3]$$

where b equals about 2.75. Or for a porous solid, in region II, the Frenkel–Halsey–Hill isotherm can be re-expressed as

$$[4] \qquad (V_t - V_c)^b = \frac{k'}{\log (p_0/p)}.$$

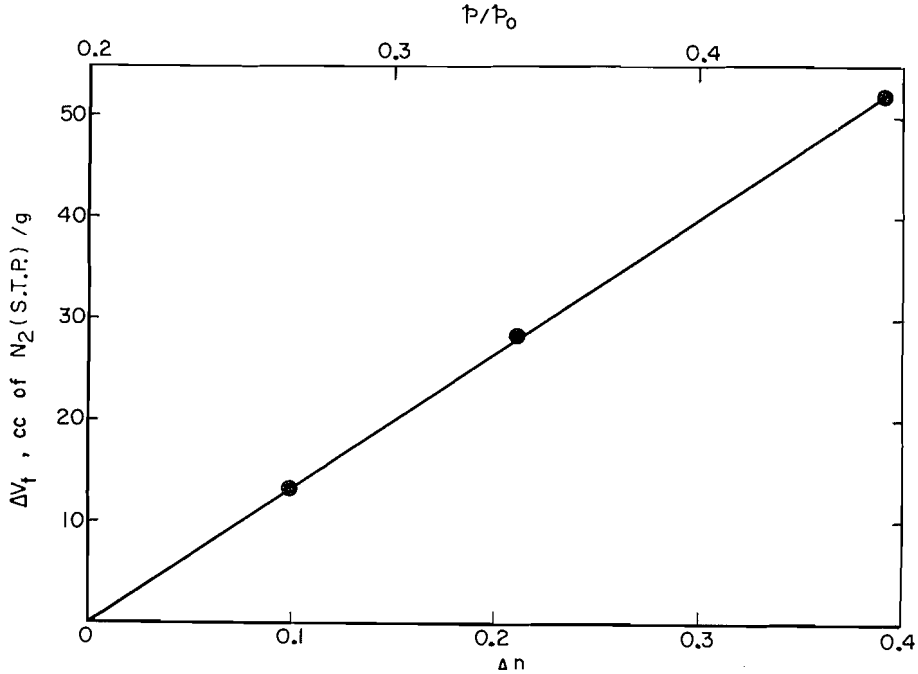

FIG. 2. Plot of ΔV_t versus Δn for Carbolac 1 over the relative pressure range 0.20 to 0.46.

For Carbolac 1, the Frenkel–Halsey–Hill isotherm is plotted between $p/p_0 = 0.20$ and 0.46, as shown in Fig. 3. A good straight line is obtained which has a slope of 2.77.

Taking the density of liquid nitrogen at 77° K as 0.81 g/cc (6), V_c for Carbolac 1 can be re-expressed as 0.170 cc of liquid N_2/g. The total volume of a Carbolac 1 particle equals the volume of solid, plus the volume of pores closed to helium at room temperature, plus the volume of pores open to N_2 at 77° K, plus the volume between the size of pore which helium can enter at room temperature (30 minutes equilibration) and the size of pore which nitrogen can enter at 77° K (30 minutes equilibration). Assuming the latter volume to be negligible,* the specific volume of Carbolac 1 is given by the reciprocal of its helium density plus V_c. For Carbolac 1 the helium density is 2.02 g/cc. Therefore, the specific volume of Carbolac 1 is 0.665 cc/g, or its apparent density is 1.50 g/cc.

From the total surface area, calculated from the simplified BET equation for the isotherm data in Fig. 1, and the free surface area, calculated from V_m', the internal surface area (A) of the blacks can be calculated. Then, assuming cylindrical pores, an approximation of their average diameter can be calculated from the relationship $\bar{d} = 4V_c/A$. Further, a surface roughness factor can be calculated as the ratio of the free surface area of the blacks to the geometric surface area. The geometric surface areas are reported by Cabot (3), from electron micrograph counts.

**From studies on zeolite molecular sieves (9), it appears that this volume is in pores between ca. 2.8 and 4.2 Å in diameter. As will be seen later, the average pore size in the internal pores of the carbon blacks studied is considerably greater than 4.2 Å. Therefore, this assumption appears reasonable.*

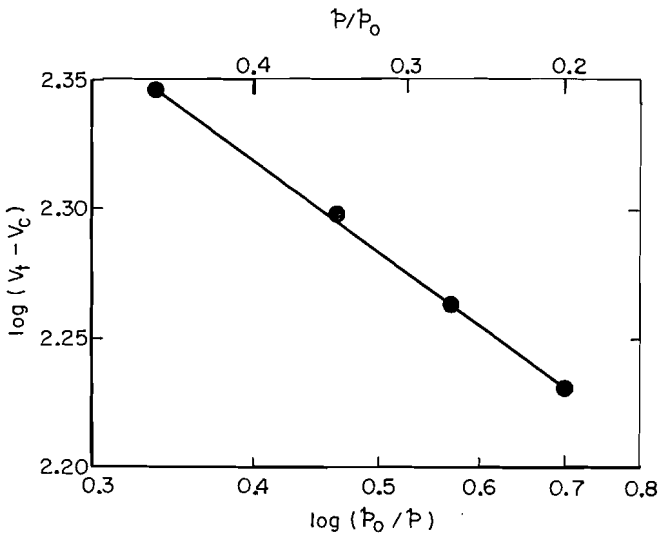

FIG. 3. Frenkel–Halsey–Hill isotherm for nitrogen on Carbolac 1 at 77° K.

Results for the five carbon blacks studied are summarized in Table I. For each black, a middle region of its isotherm was found over which the Frenkel–Halsey–Hill isotherm

TABLE I

for adsorption on the free surface was obeyed. The slope of the isotherms varied from 2.64 for Monarch 71 to 2.76 for Carbolac 2.

The results show that considerable variation exists in the extent of internal porosity within carbon blacks. The majority of the variation is thought to be due to differences in the extent of air after-treatment at elevated temperatures, which is a standard manufacturing step used to increase the volatile matter content of blacks (1). Carbolacs 1 and 2, with volatile matter contents of 17 and 12% respectively (3), have undergone considerable oxidation during after-treatment. Smith and Polley (10) have shown that such

oxidation can effectively open up porosity within carbon blacks. In addition, the presence of oxygen during carbon formation is known to inhibit crystallite growth and good crystallite alignment, probably because of crosslinking (11); this can result in higher porosity.

Voet (12) obtained nitrogen adsorption isotherms at 77° K on a series of carbon blacks. From these isotherms and the assumption that the amount of nitrogen filling the internal pores of the carbon blacks by capillary condensation is negligible, he calculated pore size distributions. For Carbolac 1, he reports a distribution in pore diameter between 16 and 48 Å, with the peak in the distribution occurring at ca. 20 Å. He further reports that the internal surface area of Carbolac 1 constitutes 55% of the total surface area. This can be compared with the data presented in this paper for Carbolac 1, where the average diameter of the internal pore system is 17 Å and the internal surface area constitutes 41% of the total surface area. The differences noted could possibly be due to the fact that different black samples were used in these two studies and/or to Voet's assumption of negligible capillary condensation within the internal pore system.

It is noted that the BET surface area for Vulcan 3 is less than the electron microscope surface area. This is relatively common for carbon blacks of low porosity (3, 13), and is probably due, in part, to uncertainty as to what value to use for the apparent density of the black. It does result in a surface roughness factor of less than 1 being calculated for Vulcan 3.

CHAIN TERMINATION IN THE PHOTOCHLORINATION OF METHYL CHLORIDE

K. G. Mathai and D. J. Le Roy
The Department of Chemistry, University of Toronto, Toronto, Ontario

Received July 28, 1961

ABSTRACT

The photochlorination of methyl chloride has been studied at 2.4°, 25.0°, and 50.1° C using absorbed light intensities of the order of 10^{-10} einstein cm^{-3} sec^{-1} and a wave length of 4358 Å. Chain termination was by chlorine atom removal but two mechanisms were operative. For the first, termolecular collisions, the evidence indicated somewhat different third-body efficiencies for methyl chloride, methylene chloride, and chlorine; the efficiency of SF_6 was lower than for these by a factor of 6 to 9; the efficiency of HCl was, relatively, too small to measure. The second mechanism involved "sticky" collisions. Methylene chloride was particularly efficient in this process, indicating an unusually stable CH_2Cl_2-Cl complex.

In most photohalogenation reactions in which a substance RH is converted to RX + HX the initial production of halogen atoms is followed by a Nernst chain:

$$X + RH \xrightarrow{k_a} R + HX,$$
$$R + X_2 \xrightarrow{k_b} RX + X.$$

In the steady state (X)/(R) will be approximately equal to $[k_b(X_2)]/[k_a(RH)]$, since the rates of the two reactions will be approximately equal. In the presence of roughly equal concentrations of the two reagents X_2 and RH the ratio (X)/(R) will be determined by the value of k_b/k_a. If X ≡ Br the latter ratio will be quite large and hence homogeneous chain termination will occur by the combination of two bromine atoms. If k_a should be comparable in magnitude to k_b, as, for example, in the *addition* of Cl to an olefin (1), homogeneous chain termination may also take place through the combination of a halogen atom with an R radical or through the combination of two R radicals. Because of the current interest attached to the rates of combination of atoms and the paucity of information on the rate of combination of atomic chlorine (2) we have undertaken the present investigation of the mechanism of the photochlorination of methyl chloride.

The choice of methyl chloride was particularly fortunate. Chain termination was found to occur exclusively by chlorine atom removal and evidence was obtained for both of the commonly assumed mechanisms of atom combination,

$$X + X + P = X_2 + P; \quad [I]$$
$$X + M = MX,$$
$$MX + X = X_2 + M. \quad [II]$$

We were also able to obtain some information about the relative efficiencies of various substances, both as third bodies, P, and as participants, M, in "sticky" collisions.

EXPERIMENTAL

The main features of the apparatus have already been described (3), but a few of the improvements are worthy of mention. The stability of the photoelectric photometer used in following chlorine consumption was greatly improved by replacing the Leeds and Northrup type 7673 electrometer with a Curtis Wright Dynamic Capacitor Electrometer (Model NA 100). This same instrument was used to activate a Honeywell recorder which plotted a function proportional to the decrease in chlorine concentration. For a fixed setting of the bridge the rate of change of chlorine concentration is inversely proportional to the apparent extinction

coefficient K_a (3) and directly proportional to the slope on the recorder chart. Since both the chart speed and the sensitivity of the electrometer could be controlled precisely, we were able to obtain values of $-d(Cl_2)/dt$ at any time by drawing tangents. For very slow reactions the off-balance voltage was simply read off the electrometer at regular intervals and plotted.

As in our previous work, the change in K_a during the course of a single experiment was insignificant. As a number of minor changes had been made in the optical system it was of interest to check the validity of our procedure for correcting for reflection, absorption, and scattering (4). As before, K_a was found to be a linear function of the square root of the apparent fraction of light transmitted. Although the slope differed from that found by Dignam and Le Roy for their apparatus, as might be expected, the value of the "true" extinction coefficient, K, for 4358 Å and 25° C was the same, namely 1.51×10^3 cm^2 mole^{-1}. The value of $K_{50.1°}/K_{25.0°}$ was 1.020, that of $K_{25.0°}/K_{2.4°}$ was 1.019, also in good agreement with our previous work.

Absolute light intensities were determined by the ferrioxalate actinometer using the recommended procedures (5) and correcting for reflections. To allow for gradual changes in the intensity of the light source, the intensity of 4358-Å light transmitted through the front window of the cell was related to the potential drop across the fixed resistance in series with the photocell which was exposed to the reference beam. For the "high" light intensity experiments the value of I_o was 1.118×10^{-8} einstein cm^{-2} min^{-1} volt^{-1}; for the "low" light intensity experiments this number was multiplied by 1/18.30, the transmission of the filter used to reduce the light intensity by a known amount. The voltage drop across the fixed resistor was measured accurately for each experiment; its average value was about 1.6 volts. The internal cross section of the cell was 13.07 cm^2, its length was 25.8 cm.

The main products of the reaction were, of course, hydrogen chloride and methylene chloride. A mass spectrographic analysis of the products of typical experiments showed that the amount of methylene chloride produced agreed with the amount of chlorine consumed within 6%. No evidence could be found for more highly chlorinated derivatives. The stoichiometry was, therefore, assumed to be $Cl_2 + CH_3Cl = CH_2Cl_2 + HCl$.

Experiments were performed at 2.4°, 25.0°, and 50.1° C using various concentrations of chlorine and methyl chloride. Hydrogen chloride, methylene chloride, and sulphur hexafluoride were added initially in certain instances. Each experiment consisted of two parts: the first was carried out at high light intensity, the second at low light intensity. The two values of $-d(Cl_2)/dt$ at the point of interruption, R' and R'', and their ratio, $r = R'/R''$, were determined. If λ is the ratio of the high to the low light intensity, 18.30 in the present case, then r would be equal to λ if the rate were proportional to the first power of the light intensity and to $\lambda^{1/2}$ if it were proportional to the square root of the light intensity.

RESULTS AND DISCUSSION

The experimental conditions and some of the results are shown in Table I. The significant features are as follows: (*a*) all values of r lay between λ and $\lambda^{1/2}$; (*b*) the addition of large amounts of hydrogen chloride (expts. 176–178) had no effect on the rate at high light intensity; (*c*) addition of methylene chloride caused a marked decrease in rate (expts. 215–217, 184–187); (*d*) the rate during a given experiment was found to decrease too rapidly to be accounted for by the loss of chlorine and methyl chloride; (*e*) the addition of sulphur hexafluoride caused a modest decrease in the rate (e.g. expts. 179–183); that this was not due to impurities was shown by subjecting the sulphur hexafluoride to an extensive "prephotochlorination" before addition of the methyl chloride; (*f*) addition of large amounts of hydrogen chloride and sulphur hexafluoride had very little effect on r.

Effect (*a*) is usually taken to indicate simultaneous first- and second-order chain termination. As pointed out previously (3), the rates of reactions for which $\lambda^{1/2} < r < \lambda$ can be expressed by the general equation

$$-d(Cl_2)/dt = A[(1+B\bar{I}_a)^{1/2}-1], \qquad [i]$$

in which A and B are combinations of rate constants and (or) concentrations. Substitution of the average rate of light absorption, $\bar{I}_a$, for the *local* rate of light absorption, I_a, was valid (3). Numerical values of B, and hence of A, were obtained for each experiment from a knowledge of r and λ; thus, if $\bar{I}_a''$ is the average rate of light absorption at the low light intensity,

$$B\bar{I}_a'' = 4r(r-1)(\lambda-r)(r^2-\lambda)^{-2}. \qquad [ii]$$

NOTE: All values apply to the time when the light intensity was reduced by the factor 18.30. Units used are moles, cm^3, and seconds.

The numerical evaluation of the two parameters made it possible to study the functional form of A and B and of combinations of the two.

If the values of r were greater than $\lambda^{1/2}$ because of a diffusion-controlled first-order chain termination process, then r would approach $\lambda^{1/2}$ as $\bar{I}_a$ is increased and also when the total pressure is increased by the addition of inert gas. It follows from [i] that the limiting rate expression at low light intensities would be

$$-d(Cl_2)/dt = \tfrac{1}{2}AB.\bar{I}_a. \qquad [iii]$$

For a diffusion-controlled first-order chain termination process the quantity AB would be inversely proportional to the diffusion coefficient of the species involved, and hence directly proportional to the total pressure under otherwise constant conditions. The results of expts. 179–183 show that this is not the case. We feel, therefore, that diffusion of chain carriers to the wall is not an important process.

The inhibiting effect of methylene chloride is difficult to explain on a chemical basis. Its reaction with Cl to form CH_2Cl and Cl_2 would be highly endothermic; its reaction with CH_2Cl would have no effect on the rate if a Cl atom were removed, and would result in the formation of appreciable amounts of higher chlorinated products if an H atom were removed, contrary to our mass spectrometric analysis.

Effect (*d*) could be accounted for if there were inhibition by either HCl or CH_2Cl_2, but effect (*b*) rules out inhibition by HCl. Effect (*e*) is easily accounted for if SF_6 acts as a third body for chain termination; this was shown to be the case.

Of the various attempts to formulate a mechanism in the light of the above considerations only the following was successful:

$$Cl_2 + h\nu = 2Cl \quad [1]$$

$$Cl + CH_3Cl = CH_2Cl + HCl \quad [2]$$

$$CH_2Cl + Cl_2 = CH_2Cl_2 + Cl \quad [3]$$

$$Cl + M = MCl \quad [4]$$

$$MCl = M + Cl \quad [5]$$

$$Cl + MCl = M + Cl_2 \quad [6]$$

$$2Cl + P = Cl_2 + P. \quad [7]$$

The substance or substances M and P are distinguished because of their different roles, but need not be specified further as yet. The group [4], [5], [6], on the one hand, and reaction [7], on the other, comprise the two general types that have been suggested for atom combination. In most cases it is not possible to distinguish between them, and the rates of atom combination reactions are simply expressed as third-order processes. In the present instance it appears to be possible to distinguish between them as a result of $k_5(MCl)$ being considerably smaller than $k_6(Cl)(MCl)$, i.e. M is very "sticky".

Before the results could be treated quantitatively it was necessary to consider the possibility of errors in A and B arising from deviations from isothermal conditions in the reaction vessel. Benson (6) has discussed the problem at some length and given correction terms applicable to spherical reaction vessels. Wilson (7) has derived relations for calculating the maximum temperature rise in cells of various shapes. More recently, Goldfinger *et al.* (8) have applied corrections to photochlorination reactions. In all treatments it was assumed that temperature gradients were controlled by thermal conductivity only, and no account was taken of convection or radiation; we have made the same assumption.

Treating the cell as an infinite cylinder, it is easy to show that if the rate, R, were independent of temperature the difference between the temperature at the central axis and at the wall would be given by the expression

$$\Delta T^0 = \frac{qRD^2}{16K}, \quad [iv]$$

in which q is the heat liberated per unit concentration change at constant volume, R is the corresponding rate, D is the diameter of the cell, and K is the coefficient of thermal conductivity.

Wilson (7) has shown that if the reaction has an activation energy E then the temperature rise at the center will be given, to a good approximation, by

$$\Delta T = \Delta T^0\left(1+\frac{3E\Delta T^0}{4\times 1.987T^2}\right), \quad [v]$$

provided the second term in the brackets is less than unity. In the present case this term is sufficiently small that we have felt justified in neglecting it, particularly since the value of ΔT calculated from [v] would be too large if convection were of any importance. The volume-average temperature rise calculated from [iv] is

$$\Delta\bar{T} = \frac{qRD^2}{32K}. \qquad [vi]$$

If R' is the rate at high light intensity that would obtain at the temperature T (of the cell wall), and $R'+dR'$ the observed rate, then,

$$dR'/R' = \frac{E\Delta\bar{T}}{1.987T^2} = \frac{EqR'D^2}{32\times 1.987T^2K}. \qquad [vii]$$

A similar expression will hold for R'', the rate at low light intensity. The fractional error in r will be given by the expression

$$dr/r = dR'/R' - dR''/R'' = (dR'/R')(1-1/r). \qquad [viii]$$

The fractional error in B is then,

$$d\ln B \equiv d\ln(B\bar{I}_a'') = (dR'/R')(1-1/r)\left(1+\frac{r}{r-1}-\frac{r}{\lambda-r}-\frac{r^2}{r^2-\lambda}\right). \qquad [ix]$$

The corrected values of A and B are given in Table I. The former were obtained from relation [i] using corrected values of R' and $B\bar{I}_a'$. The maximum value of $\Delta\bar{T}$ for any experiment was 1.5° C; the maximum correction to R' was 3.2%, to B, 7.8%. In making the corrections q was taken to be 23.5 kcal and E was assumed to be 3 kcal mole^{-1}. Values of K were calculated from the expression

$$K = \sum_i \frac{K_iN_i}{\sum_j a_{ij}N_j}, \qquad [x]$$

in which K_i is the thermal conductivity of a pure component and N_i and N_j are mole fractions; the coefficients a_{ij} were evaluated from the expression given by Reid and Sherwood (9).

It follows from [i] that the limiting rate equation at high light intensities is given by the expression

$$-d(Cl_2)/dt = AB^{1/2}\bar{I}_a^{1/2} = \frac{k_2}{k_7^{1/2}}\cdot\frac{(CH_3Cl)}{(P)^{1/2}}\cdot\bar{I}_a^{1/2}. \qquad [xi]$$

It is convenient to apply this relation in the form

$$\frac{(CH_3Cl)^2}{A^2B} = \frac{k_7}{k_2^2}(P). \qquad [xii]$$

It was evident from an examination of the values of $(CH_3Cl)^2/A^2B$ that the efficiencies of the various gases as third bodies were not the same; the efficiency of HCl appeared to be negligible in comparison with the other gases, and that of SF_6 considerably less than that of CH_3Cl, CH_2Cl_2, or Cl_2. Taking the efficiency of the latter three as unity, α, and β, and the efficiency of SF_6 as γ, [xii] may be written

$$\frac{(CH_3Cl)}{A^2B} = \frac{k_7}{k_2^2}\left(1+\alpha\frac{(CH_2Cl_2)}{(CH_3Cl)}+\beta\frac{(Cl_2)}{(CH_3Cl)}+\gamma\frac{(SF_6)}{(CH_3Cl)}\right). \qquad [xiii]$$

In Figs. 1 and 3 the left side of [xiii] is plotted for the experiments in which SF_6 was not used on the assumption that $\alpha = \beta = 1$; for these experiments the accuracy of the data did not justify doing otherwise. In Fig. 2(*a*) the corresponding data for 25° C are plotted using the same assumption. While the three curves provide ample justification for the mechanism and the values of $k_2/k_7^{1/2}$ derived from the slopes fit a satisfactory Arrhenius plot, as shown in Fig. 4, the activation energy difference $(E_2 - 1/2E_7) = 1.8$ kcal mole^{-1} must be accepted with reserve.

The sensitivity of the calculated values of $k_2/k_7^{1/2}$ to the assumed values of α and β is illustrated in Fig. 2(*b*). In this case a least-squares treatment gave $\alpha = 0.50$ and $\beta = 0.59$, and these values were used in plotting curve (*b*). While the fit is undoubtedly better than in Fig. 2(*a*), the value of $k_2/k_7^{1/2}$ has been increased by about 50%, from 0.087 to 0.127 sec$^{-1/2}$.

Assuming that $\alpha = \beta = 1$, the value of γ was determined by plotting the function $F = [(RH)^2/A^2B].[k_2^2/k_7].[\{1/[(RH)+(RCl)+(Cl_2)]\}-1]$ against $(SF_6)/[(RH)+(RCl)+(Cl_2)]$ as shown in Fig. 5, using the value of k_2^2/k_7 obtained from Fig. 2(*a*). The value obtained was 0.16. The alternative method, using $\alpha = 0.50$, $\beta = 0.59$, and the value of k_2^2/k_7 from Fig. 2(*b*) gave $\gamma = 0.11$. Average values of γ for 2.4° and 50.1° were 0.08 and 0.09, respectively.

The results obtained on the termolecular combination of chlorine atoms are not as satisfactory as one would wish. Among the reasons for this are (1) the occurrence of a second chain termination process (reactions [4], [5], and [6]) and the consequent necessity of determining two separate constants, A and B, in order to evaluate the quantity $(k_7/k_2^2)(P)$; (2) the impossibility of determining the absolute rate of reaction [7] from the equilibrium constant for the dissociation of chlorine and kinetic data for the thermal reaction in the same temperature range, as was done by Steiner for the case of bromine atoms (10). In spite of these difficulties it would appear, however, that the termolecular combination of chlorine atoms, like that of bromine and iodine (2), has rate constants characteristic of the particular third body involved. The relatively low efficiency of SF_6 is of particular interest.

According to the present mechanism the limiting rate expression at low light intensities given by [iii] takes the form

$$-d(Cl_2)/dt = \frac{AB}{2}\cdot \bar{I}_a = \frac{k_2}{k_4}\cdot\frac{(CH_3Cl)}{(M)}\cdot \bar{I}_a. \qquad [xiv]$$

Using the measured values of A and B, this relation was tested in the form

$$\frac{1}{AB} = \frac{k_4}{2k_2}\left(\frac{(CH_2Cl_2)}{(CH_3Cl)} + a\right), \qquad [xv]$$

in which a is the efficiency of CH_3Cl relative to that of CH_2Cl_2 as an "M". The quantity a was considerably less than unity, and the efficiencies of the other gases were negligibly small. The data are plotted in Figs. 6, 7, and 8. At 2.4° C a appeared to be zero within experimental error, the least-squares value of k_2/k_4 calculated on this basis was 6.5×10^2; at 25° C a was found to be 0.11, k_2/k_4 13.4×10^2; at 50.1° C a was found to be 0.06, k_2/k_4 18.4×10^2. The accuracy of the method is such that an efficiency of less than 10%, relative to that of methylene chloride, could not be readily detected in the case of methyl chloride or chlorine. It is clear, however, that the efficiencies of hydrogen chloride and sulphur hexafluoride as M's must be lower than this by at least another order of magnitude. Points derived from expts. 176, 177, and 178, in which an excess of HCl was used,

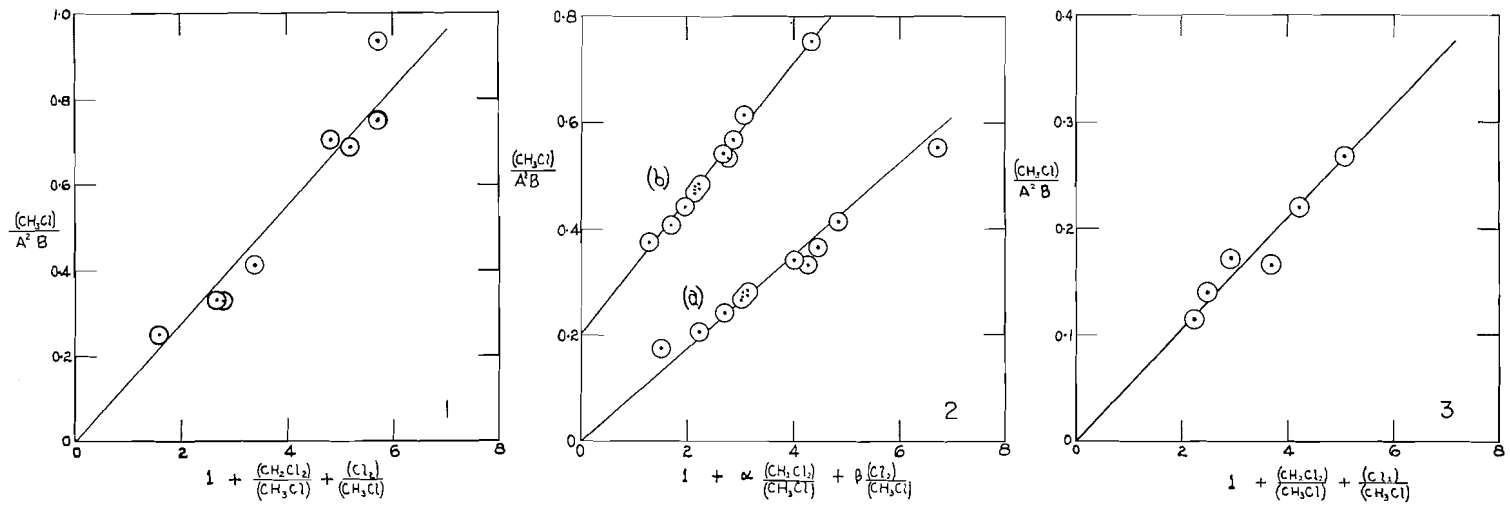

FIG. 1. Test of termolecular mechanism for chlorine atom combination at 2.4° C assuming $\alpha = \beta = 1$.

show no deviation from the curve of Fig. 7. The points derived from the experiments in which SF_6 was added are shaded in Figs. 6, 7, and 8; these show that SF_6 has no measurable efficiency as an M.

A theoretical interpretation of the combination process given by reactions [4], [5], [6] has been offered by Bunker and Davidson (11). These authors are inclined to the view that the "sticky" collision mechanism is quite general, and their theory accounts quite well for the negative activation energy found for the combination of iodine atoms. If k_5(MCl) were comparable in magnitude to k_6(Cl)(MCl) the "sticky" collision mechanism could not be distinguished kinetically from reaction [7]. On the other hand, the present measurements indicate that the bound state (11) of MCl is unusually stable when

FIG. 7. Test of "sticky" collision mechanism for chlorine atom combination at 25.0° C. Expts. 179–183, with added SF_6, indicated by shading; data from expts. 176–178, with added HCl, included among open circles.
FIG. 8. Test of "sticky" collision mechanism for chlorine atom combination at 50.1° C. Expts. 207 and 208, with added SF_6, indicated by shading.

$M = CH_2Cl_2$; rough calculations indicate a lifetime of the order of 1 second and a heat of formation of the order of 18 kcal mole^{-1}. This is to be compared to the heat of formation of 5.3 kcal mole^{-1} which Bunker and Davidson calculated for the bound state of the $I-I_2$ complex.

In deriving the value for the $Cl-CH_2Cl_2$ complex it was necessary to utilize the data obtained by Pritchard, Pyke, and Trotman-Dickenson (12), who measured k_2 relative to the corresponding value for the abstraction of an H atom from methane. The value for methane was, in turn, relative to that for the reaction $Cl + H_2 = HCl + H$, which had been determined by Ashmore and Chanmugam (13). The significant contribution of the latter authors is that they were able to measure the rate of hydrogen abstraction relative to the known equilibrium constant for the reaction $NO + Cl_2 = NOCl + Cl$ and did not have to rely on assumptions regarding the rate constant and activation energy for the combination of chlorine atoms. While such assumptions have been made in the past the present results indicate quite clearly that even at high light intensities, at which reaction [7] might predominate, errors will arise unless account can be taken of the efficiencies of all third bodies at the temperatures involved.

It should be pointed out that our results, and hence our mechanism, differ in various respects from those of Goldfinger *et al.* (14). They assume that the rate is proportional to $\bar{I}_a^{1/2}$. If this were so then all the values of r in Table I would be equal to $\lambda^{1/2}$, or 4.3, and hence independent of the concentration of methylene chloride. By using the rather large value of λ (18.30) we have been able to show, beyond any experimental error, that the rate is not directly proportional to $I_a^{1/2}$ in the range of light intensities used by us.

They give no evidence for a third-body effect on chain termination, shown clearly in our experiments with added SF_6, and according to their mechanism chain termination occurs by the combination of CH_2Cl with Cl and with CH_2Cl, but not by reaction [7]. If these were the chain termination reactions at high light intensities, at which the rate would be proportional to $I_a^{1/2}$, then the quantity $(Cl_2)^2/A^2B$ should be a linear function of $(Cl_2)/(CH_3Cl)$, with a positive intercept. When this function was plotted for each temperature, using our data, the points were quite scattered, but not about straight lines; furthermore, least-squares curves through the points gave negative intercepts. It does not seem possible, at present, to account for the discrepancies between the results obtained in the two laboratories.

ACKNOWLEDGMENTS

The authors are grateful to the National Research Council of Canada for a grant in aid of the research and to Professor A. G. Harrison for carrying out the mass spectrographic analyses.

A SYSTEM OF MOLECULAR THERMOCHEMISTRY FOR ORGANIC GASES AND LIQUIDS

PART III. EXTENSION TO AROMATIC AND CYCLIC COMPOUNDS

EDWARD G. LOVERING[1] AND OTHMAN BIN M. NOR
The Department of Chemistry, University of Ottawa, Ottawa, Ontario

Received September 21, 1961

ABSTRACT

The empirical bond energy scheme described in Part I has been modified and applied to saturated and aromatic ring compounds. The classes of compounds treated are the alkyl benzenes, alkyl cyclopentanes, and alkyl cyclohexanes. The scheme given permits values for the heats of atomization, formation, combustion, and vaporization to be calculated. Reasons for the failure of the scheme, when applied to aromatic nuclei containing a functional group, are discussed.

INTRODUCTION

In Part I (1) of this series a system of bond energy contributions to heats of formation, combustion, atomization, and vaporization for homologous series of organic compounds was described. Part II (2) described an extension of the scheme given in Part I to certain sulphur- and oxygen-containing compounds.

The scheme described in Part I, as applied to paraffins, contains four parameters; satisfactory agreement between calculated and experimental quantities is obtained, except in the case of compounds which exhibit considerable chain branching. This scheme is equivalent to one which considers only bond energies and interactions between adjacent bonds. Allen (3) has presented a scheme which, in addition, takes account of next-nearest-neighbor interactions, as well as steric effects which are present in certain compounds. A similar treatment has also been given by Skinner (4). This scheme, applied to paraffins, yields excellent agreement between calculated and observed heats of atomization. Recently, improved values of the constants have been calculated for Tatevskii's scheme by Skuratov and Shtekher (5).

A method for calculating thermodynamic properties of alkyl benzenes was also given in Part I. This was done by treating the aromatic nucleus as substituted cyclohexatriene; a resonance correction of 42.2 kcal was added to the calculated heats of atomization to obtain agreement between the calculated and experimental quantities. A somewhat different treatment of aromatic hydrocarbons is described in this paper;* all aromatic carbon–carbon bonds are considered to be identical and a new bond energy term is found for this type of bond. A related method has been applied to cyclohexanes and cyclopentanes.

Alkyl Benzenes

All carbon–carbon bonds, denoted by c_b, within an aromatic ring are considered to make the same bond energy contribution to the heat of atomization. Carbon–hydrogen bond strengths, where the carbon atom is part of an aromatic ring, are denoted by t_b. The strength of the carbon–carbon bond joining an alkyl side chain to the ring is denoted by c_s. As in Part I, the carbon–carbon bond strength of all other non-aromatic carbons is represented by c_1, primary carbon–hydrogen bond strengths by p, secondary carbon–hydrogen bond strengths by s, and tertiary carbon–hydrogen bond strengths by t. The

[1]*Present address: Inorganic Chemistry Laboratory, Oxford, England.*

**Another scheme for aromatic systems has just been published by Mackle and O'Hare, Trans. Faraday Soc., 57, 1521 (1961).*

values of p, s, t, and c_1 have been taken from Laidler (1). The values of c_s, c_b, and t_b were calculated from the heat of atomization data for several alkyl benzenes, which were selected to give the best agreement between experimental and calculated heats of atomization. The scheme also contains an ortho correction term, o_b, which is applied when two alkyl groups occupy adjacent positions on the aromatic nucleus. The value of this term was determined directly from the data for ortho-dialkyl benzenes. The bond energy values are given in Table I.

Comparisons between experimental and calculated heats of atomization are made in Table II. The heats of atomization were calculated using heats of atomization of graphite, hydrogen, and oxygen of 171.7, 52.09, and 59.16 kcal/mole respectively. Heat of formation data for the alkyl benzenes were taken from the A.P.I. tables (6).

Bond energy contributions to the heats of vaporization of alkyl benzenes have also been calculated. Bond contributions to the heats of vaporization are given in Table I. Again the experimental data were taken from the A.P.I. tables (6). Comparison between the calculated and experimental heats of vaporization is made in Table III.

Cyclohexanes

It was necessary to calculate six new parameters in order to obtain good agreement between experimental and calculated heats of atomization for alkyl-substituted cyclohexanes. Carbon–carbon bonds within the ring were considered to have the same strength as those in paraffins. New values were obtained for carbon–hydrogen bond strengths, where the carbon is part of the ring. These bonds can be secondary, denoted by s_6, or tertiary, denoted by t_6. In addition, carbon–hydrogen bonds, where the carbon is adjacent to the ring, can be primary, secondary, or tertiary; the strengths of these bonds are denoted by p_{r6}, s_{r6}, and t_{r6} respectively. Unfortunately, there are insufficient data for the calculation of t_{r6}.

The stable form of cyclohexane is the chair form. Side chains on a cyclohexane ring are either equatorial to the ring or axial to it; the equatorial position is the more stable. Thus there are six dimethyl-substituted cyclohexane isomers, of which three are cis and three are trans. The equatorial isomers are *trans*-1,2-, *cis*-1,3-, and *trans*-1,4-dimethylcyclohexane; the other three isomers are axial. In order to take into account the difference in stability of the axial and equatorial isomers an axial correction term, a_e, was introduced. There is, in addition, a steric correction, s_c, which is applied in the case of $n,n+1$ substituted cyclohexanes.

Values for the bond energy contributions to the heat of atomization, found in the usual way, are given in Table I. Calculated heats of atomization are compared to the experimental quantities in Table IV. Heats of atomization were calculated from data given in the A.P.I. tables (6).

Bond energy contributions to the heat of vaporization are given in Table I; experimental results are compared to calculated results in Table V.

Cyclopentanes

The treatment of the cyclopentanes is similar to that applied to the cyclohexanes. Carbon–hydrogen bonds, where the carbon is part of the ring, can be either secondary

or tertiary; the bond strengths are denoted by s_5 or t_5 respectively. Carbon–hydrogen bonds, when the carbon is adjacent to the ring, can be primary, secondary, or tertiary; these bond strengths are denoted by p_{r5}, s_{r5}, and t_{r5} respectively. There are again insufficient data available for the calculation of t_{r5}. There are five isomers of dimethylcyclopentane of which two are the less stable cis isomers. The correction terms for the cis isomers are different because of the large steric effect in the case of *cis*-1,2-dimethylcyclopentane. These correction terms are denoted by cis_{12} and cis_{13}.

Bond contributions to the heat of atomization are given in Table I. The calculated and experimental heats of atomization are compared in Table VI. Bond contributions to the heat of vaporization, and comparison of the experimental and calculated results are given in Table I and Table VII respectively. The experimental data were taken from the A.P.I. tables (6).

DISCUSSION

The agreement between the experimental and calculated heats of atomization for the benzenes and cycloalkanes is satisfactory. The method used to obtain the bond energy values for these classes of compounds does away with the necessity of adding an arbitrary term to the calculated heats of atomization to account for resonance stabilization or

ring strain, as the case may be. It has the disadvantage, however, that in the case of aromatic compounds it treats σ and π bonds together, instead of individually.

Recent data are also available for methyl-substituted phenols (7) and methyl-substituted pyridines (8). We attempted to treat the phenols in a manner similar to that applied to the methylbenzenes. We used the aromatic carbon–carbon bond strength, c_b, and the carbon–hydrogen bond strength, t_b, as calculated from the data for methylbenzenes. A value for the hydroxide group contribution to the heat of atomization was calculated from phenol. Values for the methyl group contributing in the three aromatic ring positions were obtained from the cresols. We then attempted to calculate the heat of atomization of the xylenols using these terms plus a correction term for ortho-methyl groups. The calculated heats of atomization so obtained were only a first approximation to the experimental values.

The additivity of the data available for methyl pyridines has been discussed by Cox (8), who gives an equation permitting heats of formation to be calculated for α- and γ-picoline, and for all the lutidines. The equation, which is equivalent to the scheme we attempted to apply to the phenols, cannot be applied to β-picoline, demonstrating that the data for methyl pyridines, like those for methyl phenols, are not additive in the sense described here.

From these results it seems reasonable to suppose that heat of formation data for aromatic compounds having a functional group within or attached to the aromatic

nucleus are not, in general, additive in the simple manner described here. The non-additivity of methyl pyridines is attributed (8) to hyperconjugation effects which stabilize α- and γ-picoline but not β-picoline. In the case of phenols we attribute the lack of additivity mainly to resonance and inductive effects which change considerably in going from cresols to xylenols.

The quantum mechanical approximation known as the linear combination of bond orbitals (LCBO) has been applied by Brown (9) to account for the additivity of heats of formation of paraffins. It would be useful if a similar treatment could be applied to aromatic compounds.

This work was supported by grant 1028–28 from the Defence Research Board.

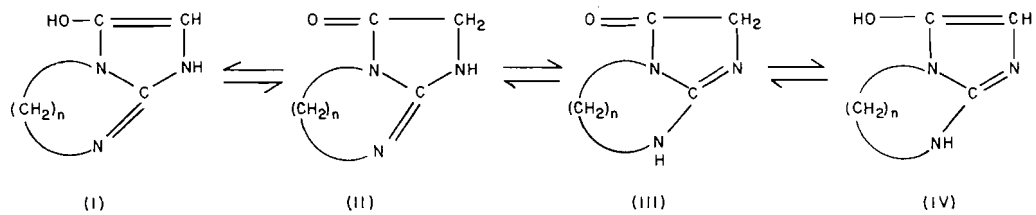
ABSTRACT

The preparation and properties of 3-keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-*a*)imidazole, 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-*a*)pyrimidine, and 4-keto-2,3,6,7,8,9-hexahydro-4(H)-pyrimido(1,2-*a*)pyrimidine are described. The first two bicyclic systems possess active methylene groups in position 2 and they are oxidized to indigo-type dyes.

INTRODUCTION

The bicyclic compounds 3-keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-*a*)imidazole* and 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-*a*)pyrimidine* were previously described (1). It has now been found that the original melting points given for these bicyclic compounds and their picrates are in error. Both of these compounds are readily oxidized and the presence of oxidation products in the original preparations is undoubtedly responsible for the high melting points previously reported. Both 3-keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-*a*)imidazole and 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo (1,2-*a*)pyrimidine may exist in the tautomeric forms I–IV. The presence of the pentad



(I) (II) (III) (IV)

n = 2 or 3

system —C=N—CH_2—C=O is responsible for the mobility of the hydrogens at C_2. Further proof of the presence of an active methylene group was obtained by condensing these bicyclic compounds (I, n = 2 and 3) with benzaldehydes to form the corresponding 2-benzylidene derivatives (V).

A comparison of the tautomeric structures I–IV with indoxyl tautomeric structures VI–VIII indicates that the bicyclic compounds (I–IV, n = 2 and 3) would be expected to oxidize to indigo-type dyes, and the residues from the sublimation of the crude preparations of these bicyclic compounds did have typical dye properties. The dark blue residue from 3-keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-*a*)imidazole gave a deep blue solution

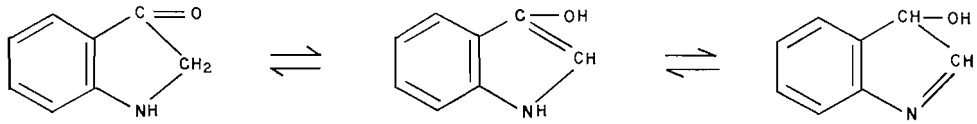
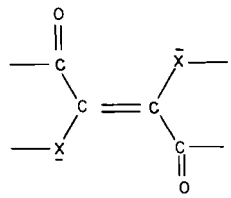
n = 2 or 3
X = H or Cl



(VI) (VII) (VIII)

on dissolving in concentrated hydrochloric acid while the residue from 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-*a*)pyrimidine gave a wine-red acid solution. These highly colored materials possess high melting points and are very insoluble in the common organic solvents.

Lüttke's (2) molecular orbital calculations and studies on indigo, selenoindigo, thioindigo, etc., have demonstrated that the benzene nucleus is not necessary for the development of indigoid characteristics such as light absorption. The ring-free chromophore IX

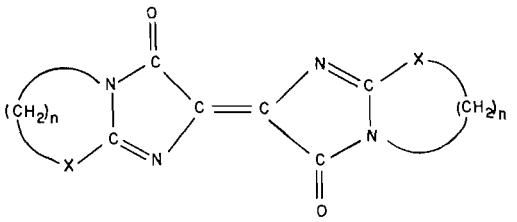


(IX)

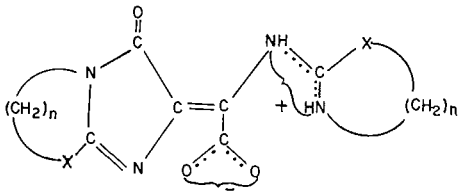
X = NH or S

with the double, crossed auxochrome–antiauxochrome groups on a common —C=C— group is considered to be the simplest system which will exhibit the characteristic properties of indigo-type dyes. Thus the formation of dyes from the above bicyclic systems II is understandable.

When 2-carboxymethylamino-Δ^2-dihydro-1,3-thiazine was prepared by refluxing glycine and 2-methylmercapto-Δ^2-dihydro-1,3-thiazine in aqueous methanol, a deep blue-black metallic dye was formed as a by-product. It might be expected that this dye as well as those from compounds II, $n = 2$, and II, $n = 3$, would possess a structure X similar to indigo. However, the analytical values agree with structure XI. This problem of structure is still under investigation.



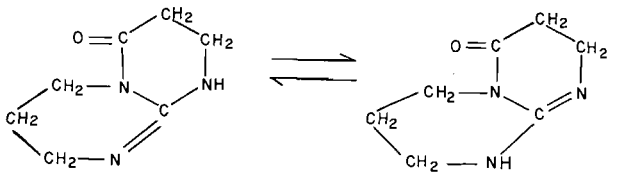
(X)



(XI)

DISCUSSION

The three bicyclic derivatives, 3-keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-*a*)imidazole (II, $n = 2$), 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-*a*)pyrimidine (II, $n = 3$), and 4-keto-2,3,6,7,8,9-hexahydro-4(H)-pyrimido(1,2-*a*)pyrimidine (XII), have been prepared by an improved procedure. These compounds were finally purified by sublimation *in vacuo* under nitrogen. Special care was required in the isolation of compound XII,

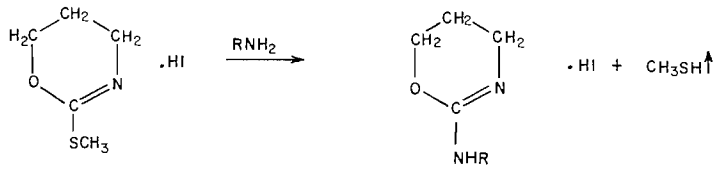


(XII)

which hydrolyzed extremely rapidly to the parent acid, 2-(2-carboxyethylamino)-Δ^2-tetrahydropyrimidine.

An attempt to prepare an analogous bicyclic compound from 2-methylmercapto-5,6-dihydro-4(H)-1,3-oxazine (XIII) and glycine was unsuccessful. This oxazine derivative was not very reactive in comparison with 2-methylmercapto-2-imidazolines (3) and 2-methylmercapto-2-thiazolines (4). After prolonged heating of compound XIII with benzylamine and α-naphthylmethylamine only small yields (10–13%) of the respective 2-benzylamino- (X, R = C_7H_7) and 2-α-naphthylmethylamino-5,6-dihydro-4(H)-1,3-oxazine (X, R = $C_{11}H_9$) were obtained.

Several methods were investigated for the preparation of 3,4,5,6-tetrahydro-2(H)-1,3-oxazine-2-thione. Two of these gave the desired compound in approximately 34% yield.



(XIII) (XIV)

On the other hand the procedure used by Fisher (5) for the preparation of 4,4,6-trimethyl-2-thio-tetrahydro-1,3-oxazine gave a 77% yield of 1,3-di-(3-hydroxypropyl)-thiourea and a 20.5% yield of potassium 3-hydroxypropyldithiocarbamate. 1,3-Di-(3-hydroxypropyl)-thiourea was also obtained when 3-amino-1-propanol was heated with carbon disulphide in ethanol for several hours.

3-Keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-*a*)imidazole (II, $n = 2$), on being heated under reflux with absolute ethanolic hydrogen chloride for 17 hours, gave a 66% yield of 2-carbethoxymethylamino-2-imidazoline. The other bicyclic compounds II, $n = 3$, and XII were much more stable towards ethanolic hydrogen chloride solution. After 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-*a*)pyrimidine was heated in this reagent for 6 days, 72.3% was recovered unchanged. Compound XII, on being heated with ethanolic hydrogen chloride for 7.5 days, gave 30% of 2-(2-carbethoxyethylamino)-Δ^2-tetrahydropyrimidine and 18% unchanged starting material.

2-(N-3,4-Dichlorobenzylcarbamyl)-methylamino-2-imidazoline was prepared by heating bicyclic compound II, $n = 2$, with ethanolic benzylamine solution.

EXPERIMENTAL*

2-Carboxymethylamino-2-imidazoline

2-Carboxymethylamino-2-imidazoline (m.p. 283° decomp.) was prepared in 86% yield as previously described (1) from 2-methylmercapto-2-imidazolinium iodide, aqueous sodium hydroxide solution, and glycine. The reported (1) melting point is 293° with decomposition.

3-Keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-a)imidazole

2-Carboxymethylamino-2-imidazoline (15 g, 0.105 mole) was heated under reflux with hydrogen chloride (11.5 g, 0.315 mole) in absolute ethanol (250 ml) for 3 hours. Benzene (50 ml) was added and the solution was heated for an additional hour. The benzene–water–ethanol azeotrope was distilled and the remaining ethanol solution was again treated with benzene. The removal of benzene–water–ethanol was repeated three times, after which the ethanolic solution was taken to dryness *in vacuo*.

The crude, oily ester hydrochloride in absolute methanol (400 ml) was passed through a column of IRA 400 resin (300 ml in hydroxyl form) which had been previously washed thoroughly with absolute methanol. The column was washed with methanol (300 ml) until the methanol washings were neutral and the combined eluate and washings were evaporated *in vacuo* to dryness. The yellowish crystalline solid melted at 165–170°, yield 9.5 g (72.6%). Crystallization from a minimum amount of ethanol in the presence of Norite gave colorless crystals melting at 168–170°, yield 5.56 g (42.4%). A sample was sublimed at 145–155° *in vacuo* (0.2 mm). The white crystalline sublimate melted at 169–170°. Anal. calc. for $C_5H_7N_3O$: C 48.00, H 5.64, N 33.59%; found: C 47.80, H 5.68, N 33.59%.

The picrate (m.p. 180–181°) was prepared in 86.2% yield in the usual manner with ethanolic picric acid solution. One crystallization from absolute ethanol raised the melting point to 180.5–181.5°. Anal. calc. for $C_{11}H_{10}N_6O_8$: C 37.30, H 2.85, N 23.73%; found: C 37.29, H 2.94, N 23.60%.

Opening One Ring of 3-Keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-a)imidazole

A. With Ethanolic Hydrogen Chloride

A solution of 3-keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-*a*)imidazole (0.2 g, 0.0016 mole) in ethanolic hydrogen chloride (0.063 g, 0.0017 mole) was refluxed for 17 hours. This solution on treatment with ethanolic picric acid solution gave a 66% yield of 2-carbethoxymethylamino-2-imidazoline picrate (m.p. 190.5–191.5°). The reported (1) melting point is 193–195°.

**All melting points are uncorrected. Microanalyses were determined by Micro-Tech Laboratories, Skokie, Ill.*

B. With 3,4-Dichlorobenzylamine

3,4-Dichlorobenzylamine (0.35 g, 0.002 mole) and 3-keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-*a*)-imidazole (0.25 g, 0.002 mole) in absolute ethanol (6 ml) was refluxed for 2 hours. The reaction mixture was evaporated to dryness and the solid product was crystallized from water in the presence of Norite, yield 0.26 g (43.3%). Two crystallizations from water raised the melting point of the 2-(N-(N'-3,4-dichlorobenzylcarbamylmethyl)amino)-2-imidazoline from 155° to 156–157°. Anal. calc. for $C_{12}H_{14}Cl_2N_4O$: C 47.84, H 4.69, Cl 23.54, N 18.60%; found: C 47.80, H 4.89, Cl 23.10, N 18.41%.

A sample in ethanol, on treatment with ethanolic picric acid, gave a 98% yield of a crystalline picrate (m.p. 195–196°). The melting point remained unchanged after crystallization from absolute ethanol. Anal. calc. for $C_{18}H_{17}Cl_2N_7O_8$: C 40.77, H 3.23, Cl 13.37, N 18.49%; found: C 40.60, H 3.48, Cl 13.47, N 18.11%.

2-Methylmercapto-Δ^2-tetrahydropyrimidine

2-Methylmercapto-Δ^2-tetrahydropyrimidinium iodide (6.45 g, 0.025 mole) in water (10 ml) at 0° was treated with an aqueous solution of potassium hydroxide (1.4 g, 0.025 mole in 5 ml water). This solution was extracted with ether (10×100 ml) and the combined ether extracts were dried over anhydrous sodium sulphate. Evaporation of the ether gave a 82.4% yield of the free base (m.p. 89–90°). The melting point of 2-methylmercapto-Δ^2-tetrahydropyrimidine was not changed by crystallization from acetone–hexane solution. Anal. calc. for $C_5H_{10}N_2S$: C 46.13, H 7.74, N 21.53, S 24.63%; found: C 46.35, H 7.74, N 21.94, S 24.78%.

The picrate (m.p. 179.5–180.5°) was formed in the usual manner from water, yield 94%. Anal. calc. for $C_{11}H_{13}N_5O_7S$: C 36.76, H 3.65%; found: C 36.88, H 3.81%.

2-Carboxymethylamino-Δ^2-tetrahydropyrimidine

The original procedure (1) for the preparation of 2-carboxymethylamino-Δ^2-tetrahydropyrimidine was modified because the product was difficult to isolate and purify.

An intimate mixture of 2-methylmercapto-Δ^2-tetrahydropyrimidine (19.53 g, 0.15 mole) and glycine (11.26 g, 0.15 mole) was heated in an oil bath at 90° for 50 minutes. After the mixture melted, white crystals began to form. The heating was continued for 35 minutes at 130°. After the crystalline product had cooled, *n*-amyl alcohol (20 ml) was added and the mixture was refluxed for 60 minutes. The crystalline solid (m.p. 212–214°) was removed by filtration, yield 71.6%. Two crystallizations from aqueous ethanol raised the melting point to 219–220° (reported (1) m.p. 211.5–212°).

2-Carbethoxymethylamino-Δ^2-tetrahydropyrimidine Hydrochloride

This compound was prepared in quantitative yield by the procedure given (1) for the esterification of 2-carboxymethylamino-2-imidazoline. The crude 2-carbethoxymethylamino-Δ^2-tetrahydropyrimidine hydrochloride (m.p. 162–168°) was used to prepare 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-*a*)-pyrimidine.

3-Keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-a)pyrimidine

A solution of 2-carbethoxymethylamino-Δ^2-tetrahydropyrimidine hydrochloride (18.6 g, 0.084 mole) in absolute methanol (370 ml) was passed through a column of IRA 400 resin (300 ml in hydroxyl form) which had been previously washed with methanol. The column was washed with absolute methanol (450 ml) and the eluate and washings were combined. The elution and washing procedures were carried out under nitrogen. The crude product from the evaporation of eluate and washings was dissolved in absolute ethanol (60 ml). A mixture of yellow, red, and white crystals separated from the solution on cooling to −10°, yield 5.85 g (50.2%). This crude mixture melted at 157–168°. Concentration of the mother liquors to a small volume gave an orange-colored microcrystalline powder (m.p. >350°), yield 0.15 g.

The first crop of mixed crystals (3.28 g) was sublimed *in vacuo* (0.2 mm) at a bath temperature of 150–160°. The white crystalline sublimate melted at 179.5–180° in an evacuated capillary tube, yield 2.92 g (89%). Resublimation did not change the melting point. Anal. calc. for $C_6H_9N_3O$: C 51.78, H 6.52, N 30.20%; found: C 51.73, H 6.51, N 30.18%.

The picrate (m.p. 193.8–194.8°) was prepared in 97.2% yield from ethanol solution. Anal. calc. for $C_{12}H_{12}N_6O_8$: C 39.14, H 3.29, N 22.82%; found: C 39.36, H 3.55, N 22.39%.

Treatment of 3-Keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-a)pyrimidine with Ethanolic Hydrogen Chloride

3-Keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-*a*)pyrimidine (0.35 g, 0.0025 mole) was heated under reflux in absolute ethanol containing hydrogen chloride (0.006 mole) for 6 days. Evaporation of the solvent left a semicrystalline hygroscopic mass (0.43 g). A portion (0.15 g) of the crude product in absolute ethanol was converted to its picrate (m.p. 189°) in the usual manner, yield 0.23 g (72.3%). This picrate did not depress the melting point of a known sample of 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-*a*)-pyrimidine picrate (m.p. 193°).

The original crude product was crystallized twice from ethanol–ether solution to give crystals (m.p. 209–210° (block), 214–215° (evac. cap.)) of the hydrochloride of the original bicyclic compound. Anal. calc. for $C_6H_{10}ClN_3O$: C 41.04, H 5.74, Cl 20.19, N 23.93%; found: C 40.87, H 5.68, Cl 20.28, N 23.80%.

2-(2-Carboxyethylamino)-Δ²-tetrahydropyrimidine

2-Methylmercapto-Δ²-tetrahydropyrimidine (28 g, 0.215 mole) and β-alanine (19.15 g, 0.215 mole) were mixed thoroughly and heated at 90° for 20 minutes. After the reaction mixture had melted, crystals began to sublime onto the cooler sides of the reaction flask. The temperature was raised to 105° and held at this temperature for 1 hour after which it was heated at 130° for 30 minutes. Ethanol (35 ml) was added to the solidified mass after it had cooled and the reaction mixture was refluxed for 4.6 hours. The white solid (m.p. 209.5–210°) was removed by filtration, yield 21.6 g (58.9%). This acid was very difficult to free from solvent and the melting point varied considerably on recrystallization from aqueous or anhydrous solvents. Thus the picrate (m.p. 164–165°) was formed in 60.6% yield in the usual manner from absolute ethanol. Crystallization from ethanol did not change the melting point. Anal. calc. for $C_{13}H_{16}N_6O_9$: C 39.00, H 4.03, N 21.00%; found: C 39.02, H 4.10, N 20.82%.

An attempt to purify a sample of 2-β-carboxyethylamino-Δ²-tetrahydropyrimidine by sublimation *in vacuo* at 170° gave a sublimate which melted at 120–123°. This sublimate in ethanol yielded a picrate in 39.1% yield melting at 212–213°. Two crystallizations from absolute ethanol raised the melting point to 214–215°. This picrate did not depress the melting point (214–215°) of 4-keto-2,3,6,7,8,9-hexahydro-4(H)-pyrimido(1,2-*a*)pyrimidine picrate (*vide infra*).

4-Keto-2,3,6,7,8,9-hexahydro-4(H)-pyrimido(1,2-a)pyrimidine

2-(2-Carboxyethylamino)-Δ²-tetrahydropyrimidine (10.01 g, 0.058 mole) was converted in quantitative yield into the hydrochloride salt of its ethyl ester by the procedure previously (1) described. A portion of the colorless oil in alcohol was converted into its picrate (m.p. 117°, resolidified and remelted at 128°) in 76.7% yield. Two crystallizations from absolute ethanol raised the melting point to 121° with resolidification and remelting at 136°. Anal. calc. for $C_{15}H_{20}N_6O_9$: C 42.06, H 4.71, N 19.62%; found: C 42.39, H 4.69, N 19.71%.

2-(2-Carbethoxyethylamino)-Δ²-tetrahydropyrimidine hydrochloride (13.8 g, 0.58 mole) in absolute methanol (250 ml) was passed through IRA 400 resin and the product was recovered. The procedure was the same as described above for the cyclization of 2-carbethoxymethylamino-Δ²-tetrahydropyrimidine hydrochloride to 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-*a*)pyrimidine. The crude product sintered at 110° and melted at 176–188°, yield 8.7 g.

The crude product was sublimed *in vacuo* (0.2 mm) at 120–130°, yield 3.34 g (38.4%). The sublimate of 4-keto-2,3,6,7,8,9-hexahydro-4(H)-pyrimido(1,2-*a*)pyrimidine melted at 127°. Two further sublimations did not change the melting point. This bicyclic compound hydrolyzed extremely rapidly and it was not possible to obtain an analytical sample free from traces of the parent acid, 2-(β-carboxyethylamino)-Δ²-tetrahydropyrimidine. Anal. calc. for $C_9H_{11}N_3O$: N 27.43%; found: N 26.60%. The sublimate in absolute ethanol gave a crystalline picrate (m.p. 214–215°) of 4-keto-2,3,6,7,8,9-hexahydro-4(H)-pyrimido(1,2-*a*)pyrimidine in 91.4% yield. Anal. calc. for $C_{13}H_{14}N_6O_8$: C 40.84, H 3.69, N 21.98%; found: C 40.73, H 3.70, N 22.08%.

Treatment of 4-Keto-2,3,6,7,8,9-hexahydro-4(H)-pyrimido(1,2-a)pyrimidine with Ethanolic Hydrogen Chloride

The bicyclic compound (0.17 g, 0.001 mole) in absolute ethanol containing hydrogen chloride (0.003 mole) was heated under reflux for 7.5 days. Evaporation of the solvent gave a viscous colorless oil which partially crystallized on standing in an evacuated desiccator for several days. A portion (0.09 g) of the product on treatment with ethanolic picric acid solution gave a crystalline picrate (m.p. 208–213°), yield 18.2%. One crystallization from ethanol raised the melting point to 214–215°. It did not depress the melting point of a known sample of 4-keto-2,3,6,7,8,9-hexahydro-4(H)-pyrimido(1,2-*a*)pyrimidine picrate (m.p. 214–215°) on admixture.

The mother liquor from the bicyclic picrate on concentration and cooling gave a second picrate (m.p. 121°, resolidification with remelting at 136–137°), yield 0.05 g (30.6%). This picrate was identified as the picrate of 2-(2-carbethoxyethylamino)-Δ²-tetrahydropyrimidine (m.p. 121° and 136–137°).

Benzylidene Derivative of 3-Keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-a)imidazole

3-Keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-*a*)imidazole (0.5 g, 0.004 mole), fused sodium acetate (0.58 g), and benzaldehyde (0.6 ml, 0.006 mole) in glacial acetic acid were heated in an oil bath at 140° for 75 minutes. The solution became dark orange in color and after 15 minutes yellow crystals separated. The mixture was allowed to cool to room temperature and the crystals (m.p. 266–274°) were collected by filtration, yield 0.45 g. A second crop (75 mg) of crystals was obtained from the mother liquors on further cooling, total yield 61.2%. Two crystallizations from absolute ethanol raised the melting point to 283.5–284.2°. Anal. calc. for $C_{12}H_{11}N_3O$: C 67.60, H 5.20, N 19.71%; found: C 67.33, H 5.37, N 20.17%. Ultraviolet absorption spectrum (in ethanol): λ_{max} 237 mμ, ε 11,350; λ_{max} 242 mμ (sh), ε 10,650; λ_{max} 347 mμ, ε 27,250.

The picrate (215–217° decomp.) was formed in the usual manner in ethanol solution, yield 38%. Two crystallizations from absolute ethanol raised the melting point to 217.4–218.2° decomp. Anal. calc. for $C_{18}H_{14}N_6O_8$: C 48.88, H 3.19, N 19.00%; found: C 48.94, H 3.33, N 18.51%.

Benzylidene Derivative of 3-Keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-a)pyrimidine

Freshly sublimed 3-keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-*a*)pyrimidine (0.51 g, 0.0037 mole), fused sodium acetate (0.61 g), and benzaldehyde (0.6 ml, 0.006 mole) in glacial acetic acid (4.5 ml) were refluxed for 75 minutes. After the solution was cooled in freezing mixture, crystals of sodium acetate separated, yield 0.27 g. The filtrate was taken to dryness *in vacuo* and the residue was extracted with water

to remove the remaining sodium acetate. The residue melted at 227–232°, yield 0.54 g (63.6%). Two crystallizations from absolute ethanol raised the melting point to 239.2–239.8°. Anal. calc. for $C_{13}H_{13}N_3O$: C 68.70, H 5.77, N 18.49%; found: C 68.21, H 5.83, N 18.50%. Ultraviolet absorption spectrum (in ethanol): λ_{max} 241 mμ, ε 13,600; λ_{max} 247 mμ (sh), ε 12,680; λ_{max} 365 mμ, ε 25,340.

The picrate (m.p. 217–219°) was prepared from ethanol solution in 90.6% yield. Two crystallizations from absolute ethanol raised the melting point to 223.4–224.2°. Anal. calc. for $C_{19}H_{16}N_6O_8$: C 49.99, H 3.53, N 18.42%; found: C 50.01, H 3.55, N 18.34%.

3,4-Dichlorobenzylidene Derivative of 3-Keto-1,2,6,7-tetrahydro-3(H),5(H)-imidazo(1,2-a)pyrimidine

This compound (m.p. 248–256° decomp.) was prepared in 91% yield by the procedure given above for the preparation of 2-benzylidene-3-keto-1,2,5,6-tetrahydro-3(H)-imidazo(1,2-*a*)imidazole. Two crystallizations from absolute ethanol raised the melting point to 265–266° decomp. Anal. calc. for $C_{13}H_{11}Cl_2N_3O$: C 52.73, H 3.74, Cl 23.94, N 14.19%; found: C 52.58, H 3.87, Cl 24.15, N 14.10%.

A crystalline picrate (m.p. 237–240° decomp.) was obtained in quantitative yield from ethanol solution. Two crystallizations from absolute ethanol raised the melting point to 246.2–246.6° decomp. Anal. calc. for $C_{19}H_{14}Cl_2N_6O_8$: C 43.44, H 2.69, Cl 13.50, N 16.00%; found: C 43.45, H 2.89, Cl 12.96, N 16.25%.

2-Carboxymethylamino-Δ^2-dihydro-1,3-thiazine

2-Methylmercapto-Δ^2-dihydro-1,3-thiazine (4) (17.68 g, 0.12 mole) and glycine (9.01 g, 0.12 mole) in methanol–water (1:1) solution (200 ml) were refluxed for 19 hours. The reaction mixture turned a deep blue color after the first few hours of heating. A dark blue crystalline solid (m.p. >360°) separated from the cooled solution, yield 3.53 g. This dye was virtually insoluble in all the common organic solvents. A dilute solution in hydrochloric acid was deep blue in color. Anal. calc. for $C_{12}H_{14}N_4O_3S_2$: C 44.25, H 4.33, N 16.67, S 19.65%; found: C 44.73, H 4.52, N 16.61, S 19.47%.

The filtrate, from which the dye had been removed, was evaporated to dryness. The residue was dissolved in hot methanol with the exception of a small amount (0.37 g) of blue dye. The filtrate from the blue dye, on cooling, gave a mixture of blue and white crystals (m.p. 170–173°), yield 6.49 g. The mother liquors yielded a second crop of crystals (m.p. 169–173°). The total yield of crude 2-carboxymethylamino-Δ^2-dihydro-1,3-thiazine was 9.87 g (46.8%). Two crystallizations from ethanol in the presence of Norite gave grey crystals melting at 174–175° (blue melt). Anal. calc. for $C_6H_{10}N_2O_2S.H_2O$: C 37.48, H 6.30, N 14.58, S 16.68%; found: C 37.29, H 6.41, N 14.82, S 16.42%.

The picrate (m.p. 159–160°, dark blue melt) was prepared in 82% yield in the usual manner from water. Anal. calc. for $C_{12}H_{13}N_5O_9S$: C 35.73, H 3.25, N 17.37, S 9.95%; found: C 36.01, H 3.33, N 17.28, S 7.72%.

3,4,5,6-Tetrahydro-2(H)-1,3-oxazine-2-thione

Method A

3,4,5,6-Tetrahydro-2(H)-1,3-oxazine-2-thione (m.p. 124–125°) was prepared in 34% yield by the method of Menard *et al.* (6).

Method B

A solution of carbon disulphide (31.2 g, 0.4 mole) in chloroform (80 ml) was added dropwise over a period of 40 minutes to a stirred solution of 3-amino-1-propanol (30 g, 0.4 mole) and triethylamine (40.4 g, 0.4 mole) in chloroform (80 ml) at 0°. This reaction mixture was stirred for 5 minutes at 25° and then cooled again to 0°. After ethyl chloroformate (43.2 g, 0.4 mole) was added over a period of 50 minutes, stirring was continued for 20 minutes. A solution of triethylamine (44.4 g, 0.44 mole) in chloroform (150 ml) was added during the next 50 minutes after which stirring was continued for 15 minutes. Then the chloroform solution was washed with 5% aqueous sodium hydroxide (2×150 ml), 5% hydrochloric acid (2×150 ml), and water (5×200 ml). After the chloroform solution was dried over anhydrous sodium sulphate and allowed to stand in the refrigerator for 15 minutes, it was evaporated to dryness. The crude yield of 3,4,5,6-tetrahydro-2(H)-1,3-oxazine-2-thione (m.p. 124–125°) was 15.6 g (33.3%). The structure of this compound was confirmed by its infrared spectrum, analyses, and molecular weight determination. The infrared spectrum of the compound dispersed in Nujol mull gave the following absorption bands: 3195 cm^{-1} (N—H stretching mode), 1573 cm^{-1} (N—H bending mode), and 1376 cm^{-1} (—N—C=S stretching mode (provisional assignment)). One crystallization from acetone raised the melting point to 126.5–127.5°. Anal. calc. for C_4H_7NOS: C 41.00, H 6.01, N 11.95, S 27.36%, mol. wt. 117.05; found: C 41.11, H 6.18, N 11.67, S 27.26%, mol. wt. (Rast) 119.

2-Methylmercapto-5,6-dihydro-4(H)-1,3-oxazine Hydroiodide

Methyl iodide (24.8 g, 0.17 mole) was added portionwise to a suspension of 3,4,5,6-tetrahydro-2(H)-1,3-oxazine-2-thione (15.8 g, 0.13 mole) in absolute ethanol (35 ml). The reaction mixture was heated under reflux for 45 minutes and then the clear solution was evaporated to dryness *in vacuo*. The crystalline residue was treated with cold absolute methanol (50 ml) and the insoluble residue was removed by filtration. Addition of water (20–25 ml) to the methanolic filtrate gave the crystalline product (m.p. 64.5–65.5°), yield 31.84 g (91.4%). Infrared spectrum of the compound in Nujol mull gave the following absorption bands: 3290 cm^{-1} (=N—H^+ stretching mode), 1638 cm^{-1} (C=NH^+ stretching mode), and 1536 cm^{-1} (=NH^+ bending mode). Anal. calc. for $C_5H_{10}INOS$: C 23.18, H 3.89, N 5.41, S 12.38%; found: C 23.15, H 3.78, N 5.08, S 11.94%.

2-Benzylamino-5,6-dihydro-4(H)-1,3-oxazine Picrate

2-Methylmercapto-5,6-dihydro-4(H)-1,3-oxazine hydroiodide (3.9 g, 0.015 mole) and benzylamine (1.6 g, 0.015 mole) in ethanol were refluxed for 17 hours. The solvent was removed *in vacuo* and the residual oil was dissolved in ethanol and treated with aqueous picric acid solution. The solvent was decanted from the oily picrate (yield 10.2%), which crystallized (m.p. 168–170°) on heating with fresh ethanol. Three crystallizations from ethanol raised the melting point to 172.5–173.5. Anal. calc. for $C_{17}H_{17}N_5O_8$: C 48.69, H 4.09, N 16.70%; found: C 48.33, H 4.13, N 16.73%.

A paper chromatogram of the residual oil from this reaction showed that very little reaction had taken place after the prolonged heating period.

2-(α-Naphthylmethylamino)-5,6-dihydro-4(H)-1,3-oxazine Picrate

A solution of α-naphthylmethylamine (2.3 g, 0.015 mole) and 2-methylmercapto-5,6-dihydro-4(H)-1,3-oxazine hydroiodide (3.9 g, 0.015 mole) in ethanol (12 ml) was heated under reflux for 26 hours. Evaporation of the solvent gave 5.53 g of a glasslike, solid mass. A sample (1.1 g) of this product in methanol was treated with aqueous picric acid solution. A mixture of oily and crystalline picrates formed. The crystals were collected by filtration and identified by a mixed melting point determination as α-naphthylmethylamine picrate (m.p. 226–228° decomp.). Treatment of the remaining oily picrate with boiling water (100 ml) and boiling methanol caused partial crystallization to occur. The crystals (m.p. 215–217°) were removed by filtration, yield 0.18 g (12.8%). Several crystallizations from methanol raised the melting point to 219–219.5°. Anal. calc. for $C_{21}H_{19}N_5O_8$: C 53.73, H 4.08, N 14.92%; found: C 53.80, H 4.34, N 14.85%.

1,3-Di-(2-hydroxypropyl)-thiourea

Method A

Carbon disulphide (22.84 g, 0.3 mole) in absolute ethanol (15 ml) was added to a cooled (5–10°) solution of 3-amino-1-propanol (22.53 g, 0.3 mole) in absolute ethanol (35 ml) over a period of 1 hour. The reaction mixture was heated at reflux for 7 hours and then the solvent was removed *in vacuo*. After the oily product had been heated at 110° for 8 hours, it was dissolved in absolute ethanol (50 ml) and heated under reflux for an additional 8 hours. The alcohol was removed *in vacuo* and the waxy solid (30 g, 85.5% yield) was crystallized from ethanol–ether solution. This crystalline product melted at 90.4–91°, yield 20.3 g. Anal. calc. for $C_7H_{16}N_2O_2S$: C 43.71, H 8.39, N 14.57, S 16.67%; found: C 43.58, H 8.33, N 14.19, S 16.68%.

Method B

3-Amino-1-propanol (62.7 g, 0.836 mole) was added to a solution of potassium hydroxide (16 g, 0.28 mole) in absolute ethanol (200 ml). Carbon disulphide (69.9 g, 0.92 mole) was added dropwise to this solution at 30° over a period of 1 hour. After standing at room temperature for 1.5 hours, the reaction mixture was heated under reflux (48°) for 3 hours. A small amount of unreacted carbon disulphide (6 ml) was removed by distillation and the residue was heated under reflux (72–76°) for 6 hours. The solution on standing at room temperature overnight deposited large prisms. The crystals (m.p. 148–152° decomp.) were recovered by filtration, yield 20.23 g. Evaporation of the ethanol filtrate *in vacuo* gave a yellow, mobile oil (95.5 g). Addition of acetone to this oil gave a second crop of the high-melting (150° decomp.) product. Careful fractional crystallization of the remainder with acetone and then hexane gave a total yield of 32.43 g (20.5% based on 3-amino-1-propanol) of the potassium salt of 3-hydroxypropyldithiocarbamic acid and 63.8 g (76.9%) of 1,3-di-(3-hydroxypropyl)-thiourea (m.p. 88–90°). The thiourea gave no depression in melting point on admixture with a sample of the 1,3-di-(3-hydroxypropyl)-thiourea (m.p. 90.4–91°) described above under Method A.

A portion of the crude potassium salt of 3-hydroxypropyldithiocarbamic acid was crystallized twice from warm ethanol–ether solution. The final melting point was 149.5–150.5° with decomposition. Anal. calc. for $C_4H_8KNOS_2$: C 25.37, H 4.26, N 7.40, S 33.87%; found: C 25.76, H 4.35, N 7.13, S 33.71%.

ACKNOWLEDGMENTS

The authors wish to thank Miss G. Schlauch for skillful technical assistance. The preparation of 2-carboxymethylamino-Δ^2-dihydro-1,3-thiazine was performed by Dr. D. J. Whittingham.

AROMATIC SUBSTITUTION

PART I. THE REACTION OF PHENYLLITHIUM WITH 3-ALKYLPYRIDINES. STERIC EFFECT AND QUANTITATIVE ANALYSIS OF ISOMER RATIOS[1]

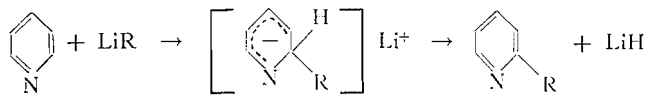
R. A. Abramovitch and Choo-Seng Giam
The Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received September 26, 1961

ABSTRACT

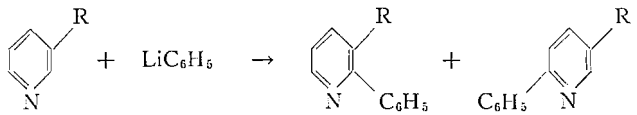
No 4-phenylpyridine is formed in the reaction of phenyllithium with pyridine. When phenyllithium reacts with a 3-alkylpyridine the main product is the 3-alkyl-2-phenylpyridine if the alkyl group is methyl, ethyl, or isopropyl, but it is the 5-alkyl-2-phenylpyridine when the substituent is *t*-butyl. Methods are described for the separation and quantitative analysis of mixtures of 3-alkyl- and 5-alkyl-2-phenylpyridines using vapor phase chromatography. The results are discussed briefly and possible explanations of the observed orientations are mentioned.

The well-known (1, 2) reaction of lithium alkyls and aryls with dry pyridine involves the formation of a dihydroderivative (I) which, on heating, eliminates lithium hydride to give the 2-substituted pyridine (3):



I

The formation of a 4-substituted pyridine has not been reported in such reactions except in those cases where the 2- and 6-positions of the pyridine ring are blocked, e.g. the case of acridine (4). It has now been verified that in the reaction of phenyllithium with pyridine no 4-phenylpyridine can be detected, even by vapor phase chromatography. Thus, the addition of an organo-lithium compound to a 3-substituted pyridine may lead to one isomer, or a mixture of two isomers:



II III IV

In two earlier papers (5, 6) the reaction of phenyllithium with a number of 3-substituted pyridines was examined. When 3-picoline (II; R = CH_3) was treated with phenyllithium the ratio of 2,3:2,5 isomers was found to be 19:1. With nicotine (II; R = 2-*N*-methylpyrrolidyl) the isomer ratio was approximately 1:1. Two further examples were studied: R = NH_2 and R = OCH_3. In both cases the only isomer detected was the 2,3-disubstituted pyridine. It was suggested (6) that in these last two cases the exclusive substitution at the 2-position might be explained by assuming some co-ordination of the lithium atom with a pair of electrons on the 3-substituent such that the phenyl group would be suitably oriented for attack at the 2-position.

[1]*This paper was presented as part of a lecture given at the Stereochemistry Symposium of the C.I.C. at Edmonton in September 1960.*

The preferential attack of the 2-position by the nucleophilic reagent in these and other reactions (for a brief summary of previous work on related reactions see ref. 5) was contrary to what would have been predicted a priori on the basis of a consideration of straightforward electronic and steric effects of the substituents studied. One would expect the 2-position to be somewhat more electron rich than the 6-position and also that attack at that site would be subject to the steric effect of the 3-substituent. That the 3-substituent does exert a steric effect is shown by a comparison of the isomer ratios for the reactions of 3-picoline and of nicotine. Appreciable steric hindrance by an ortho-methyl group in nucleophilic aromatic substitutions has also been observed in the reaction of 1-chloro-2,4-dinitro-6-methylbenzene with piperidine (7), though the geometry of the transition state is probably different from that in our reactions, which involve a more powerful nucleophilic reagent in a less polar solvent. It seems likely that with the more powerful nucleophilic reagent the transition state would resemble the reactants and that its formation would not lead to too much perturbation of the π-electron densities in the ground state (8, 9) (in which case hyperconjugation by the 3-alkyl group would probably be small).

It was clearly of interest to examine the effect of increasing the size of the 3-alkyl group systematically from methyl to *t*-butyl upon the ratio of III:IV obtained and this has now been done.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were measured with a Perkin–Elmer Model 21 instrument using sodium chloride optics; only the main peaks are reported. Vapor phase chromatography was carried out with a Beckman GC-2 unit fitted with a fraction collector and modified such that the heated sample inlet block permitted injection as close to the column as possible.

Preparation of 3-Alkylpyridines

3-Picoline was commercially available synthetic material (Reilly Tar and Chemical Corp.); this was dried (KOH) and distilled through a Podbielniak Mini-Cal Spinning Band Column, the fraction b.p. 138–140° at 720 mm being used.

3-Ethylpyridine was prepared by the alkylation of 3-picoline as described by Brown and Murphey (10). An average yield of 50.4% was obtained. However, even after several fractional distillations through a Podbielniak column, the 3-ethylpyridine could not be isolated in a completely pure state; it was always contaminated with small amounts of 3-picoline and 3-isopropylpyridine, as indicated by vapor phase chromatography. Since the 3-ethylpyridine required had to be essentially free of these contaminants it was prepared from 3-acetylpyridine using hydrazine hydrate and potassium hydroxide (11). A yield of 83.5% of pure product was thus obtained.

3-Isopropylpyridine was obtained initially as a by-product of the alkylation of 3-picoline (average yield 10%). When 3-ethylpyridine was the starting material the average yield was raised to 55%; the product, however, could not be freed from 3-ethylpyridine completely by fractional distillation. Pure 3-isopropylpyridine was, therefore, prepared from methyl nicotinate by treating the latter with methyl magnesium iodide (12), dehydrating the alcohol obtained with a mixture of concentrated sulphuric acid and acetic acid (10), and hydrogenating the resulting 3-isopropenylpyridine (in solution in a mixture of glacial acetic acid (1 part) and 95% ethanol (4 parts)) at 25 p.s.i. and room temperature in the presence of Adams' catalyst.

3-*t*-Butylpyridine was prepared by a modification (13) of the method for the alkylation of 3-isopropylpyridine. The time of addition of the methyl chloride was extended to 13 hours. In no case could a conversion of more than 10% be achieved, though Professor Brown informs us that he has obtained yields as high as 37%. Essery and Schofield (14) have recently also been unable to obtain such a high yield using potassium amide instead of sodamide in liquid ammonia. In spite of repeated and careful fractional distillations the product obtained was only 95% pure and had to be used as such in subsequent reactions with phenyllithium.

2-Phenylpyridine (2)

A solution of pyridine (0.93 g) in dry ether (2 ml) was added to a well-stirred, standardized ethereal solution of phenyllithium (6 ml, 0.007 mole) under nitrogen and worked up by the general procedure described below. The crude reaction product was subjected to vapor phase chromatography on a column 3 ft$\times\frac{1}{4}$ in. of "Apiezon N" on "Embacel" (May and Baker), the column temperature being 190° and the helium inlet pressure 50 p.s.i. The product had the same retention time as authentic 2-phenylpyridine (8 minutes, 10 seconds). No peak corresponding to 4-phenylpyridine (9 minutes, 30 seconds) was observed. It was verified that small amounts of 4-phenylpyridine would have been detected by this method by analyzing made-up mixture of authentic samples of 2- and 4-phenylpyridine. Purification of the crude reaction product gave 2-phenylpyridine (0.76 g; 69%).

Reaction of Phenyllithium with 3-Alkylpyridines

The procedure described below was adopted for all the reactions of phenyllithium with 3-picoline, 3-ethyl-, 3-isopropyl-, and 3-*t*-butyl-pyridine. The amounts of the reactants employed and the yields of products obtained are summarized in Table I.

TABLE I

Reaction of phenyllithium with 3-alkylpyridines

Expt. No.	3-Alkyl substituent	Wt. of lithium (g)	Wt. of bromobenzene (g)	Wt. of 3-alkylpyridine (g)	Total % yield of both isomers
1	CH_3	30.0	313.8	204	(*b*)
2	CH_3	0.15	1.05	1.02	41.6
3	CH_3	0.15	1.05	1.02	25.0
4	CH_3	(*a*)	(*a*)	(*a*)	41.6
5	C_2H_5	6.9	52.5	58.9	20.5
6	C_2H_5	0.15	1.05	1.10	22.9
7	C_2H_5	0.15	1.05	1.10	18.0
8	C_2H_5	(*a*)	(*a*)	(*a*)	39.4
9	iso-C_3H_7	0.28	2.1	2.66	(*b*)
10	iso-C_3H_7	3.8	28.8	33.2	15.0
11	iso-C_3H_7	(*a*)	(*a*)	(*a*)	25.2
12	*t*-C_4H_9	0.30	2.1	2.96	22.5
13	*t*-C_4H_9	1.89	13.1	18.7	25.0
14	*t*-C_4H_9	(*a*)	(*a*)	(*a*)	24.2

NOTE: (*a*) In these experiments, 0.007 mole of phenyllithium and 0.010 mole of 3-alkylpyridine were used. (*b*) Yields in these experiments were not determined.

Very finely cut lithium was suspended in anhydrous ether (approximately 300 ml for each mole of lithium) under dry nitrogen and to this was added dropwise a solution of bromobenzene in an equal volume of dry ether. Gentle reflux was continued for 3 hours after which a solution of the 3-alkylpyridine in dry ether was added dropwise so that boiling under gentle reflux was maintained. When the addition was completed the ether was distilled off and simultaneously replaced by an equal volume of dry toluene. The temperature of the reaction mixture was then raised to ca. 110° and kept there for 7½ hours. The mixture was cooled, treated cautiously with an excess of water, and exhaustively extracted with ether. The ether extract was dried (KOH) and the solvent removed by distillation. The residue was divided into two portions, the larger one being used for the isolation and identification of the reaction products and the smaller being used for the quantitative analyses of the isomeric alkylphenylpyridines.

Isolation of the 3-Alkylpyridines

The isomeric alkylphenylpyridines were separated and isolated by preparative vapor phase chromatography. In experiments (1) and (2) a copper tubing column 5½ ft × ¼ in. (I.D.) packed with "Apiezon N" on "Embacel" Kieselguhr (1:4 by weight) was used. In all the other experiments, four 10-in. columns (½ in. I.D.) connected in series and packed with "Apiezon N" on Celite 545 (1:4 by weight) were used.

Differentiation between 3-Alkyl- and 5-Alkyl-2-phenylpyridines by Infrared Spectroscopy

The isomeric alkylphenylpyridines could be characterized by using their infrared spectra as described by Abramovitch, Giam, and Notation (15). The 3-alkyl-2-phenylpyridines exhibited a characteristic absorption band in the range 1577–1589 cm^{-1}, and the 5-alkyl-2-phenylpyridines gave a band in the range 1592–1605 cm^{-1}. Assignment of orientation could also be made from a study of the range 900–750 cm^{-1} as discussed by Podall (16).

Some of the assignments were confirmed by oxidation of the isomers to known compounds and by the behavior on vapor phase chromatography (see below). In the case of the methylphenylpyridines n.m.r. spectroscopy has also been used (5).

3-Ethyl-2-phenylpyridine

B.p. 156–158° at 18 mm. Infrared spectrum (liquid film): 1583 (m), 1568 (m), 1435 (s), 1060 (m), 793 (s), 750 (s), 698 cm^{-1} (s). Calc. for $C_{13}H_{13}N$: C, 85.20; H, 7.15. Found: C, 85.26; H, 7.22. The product was identical with that obtained from authentic 3-methyl-2-phenylpyridine as described below. The picrate was recrystallized from benzene and had m.p. 104°. Calc. for $C_{13}H_{13}N,C_6H_3O_7N_3$: C, 55.34; H, 3.91. Found: C, 55.46; H, 3.96.

5-Ethyl-2-phenylpyridine

B.p. 179–180° at 22 mm. Infrared spectrum (liquid film): 1603 (m), 1567 (m), 1483 (s), 1440 (s), 842 (m), 793 (m), 742 (s), 695 cm^{-1} (s). Found: C, 84.81; H, 7.36. The picrate (from benzene) had m.p. 155–156°; found: C, 55.74; H, 4.04.

3-Isopropyl-2-phenylpyridine

B.p. 152–154° at 22 mm. Infrared spectrum (liquid film): 1580 (m), 1563 (m), 1436 (s), 1385 (m), 1367 (m), 793 (s), 750 (s), 698 cm^{-1} (s). Calc. for $C_{14}H_{15}N$: C, 85.23; H, 7.66. Found: C, 85.28; H, 7.61.

5-Isopropyl-2-phenylpyridine

White crystals, m.p. 53–53.5° (purified by sublimation after vapor phase chromatography). Infrared spectrum (Nujol mull): 1595 (m), 1561 (m), 842 (s), 787 (m), 737 (m), 693 cm^{-1} (s). Found: C, 85.17; H, 7.78.

3-t-Butyl-2-phenylpyridine

B.p. 140° at 18 mm. Infrared spectrum (liquid film): 1578 (w), 1561 (m), 1427 (s), 1395 (w), 1365 (m), 785 (s), 762 (s), 702 cm^{-1} (s). Calc. for $C_{15}H_{17}N$: C, 85.26; H, 8.11. Found: C, 84.90; H, 8.30.

5-t-Butyl-2-phenylpyridine

B.p. 130° at 0.72 mm. Infrared spectrum (liquid film): 1592 (m), 1535 (m), 1480 (s), 1377 (s), 1395 (w), 1365 (w), 845 (s), 750 (s), 730 (s), 690 cm^{-1} (s). Found: C, 85.32; H, 8.18.

A plot of the logarithm of the retention times against the number of carbon atoms in the side-chain alkyl groups in 3-alkyl-2-phenylpyridines gave a straight line as did the corresponding plot of the values for 5-alkyl-2-phenylpyridines. The slope of the latter line was greater than that of the former. This observed linearity in each case serves as confirmatory evidence for the orientation assigned to the various pairs of isomers.

Oxidation of 5-Ethyl-2-phenylpyridine

5-Ethyl-2-phenylpyridine was boiled under reflux with an aqueous solution of potassium permanganate for 8 hours and worked up as described for the oxidation of 3-methyl-2-phenylpyridine (5). 2-Phenylpyridine-5-carboxylic acid, m.p. 232°, was obtained. The melting point was undepressed on admixture with an authentic specimen of this acid (5).

Synthesis of 3-Ethyl-2-phenylpyridine

3-Methyl-2-phenylpyridine (6.9 g) was added to a suspension of sodamide in liquid ammonia (2.3 g of sodium in 80 ml of anhydrous ammonia and 0.03 g of ferric nitrate nonahydrate), followed by methyl chloride (5 g), the addition of the latter taking approximately 15 minutes. The mixture was allowed to stand overnight when the ammonia evaporated and the residue was cautiously treated with water and exhaustively extracted with ether. The ether extract was dried (KOH), the solvent evaporated, and the residue fractionally distilled under vacuum. The fraction b.p. 110–143° at 11 mm was subjected to vapor phase chromatography using a copper column, $5\frac{1}{2}$ ft$\times\frac{1}{4}$ in. (I.D.), packed with "Apiezon N" on "Embacel" (1:4 by weight), the column temperature being 220°. A compound having the same "emergence time" (the time taken for the compound to begin entering the detector cell) as the sample of 3-ethyl-2-phenylpyridine obtained from the reaction of phenyllithium with 3-ethylpyridine was isolated. This compound had an infrared spectrum identical with that of the compound which had been assigned the structure 3-ethyl-2-phenylpyridine on the basis of its infrared spectrum. Both samples formed picrates whose melting points (102–103°) were undepressed on admixture. In the alkylation reaction a 33% conversion of 3-methyl-2-phenylpyridine to 3-ethyl-2-phenylpyridine (2.2 g) was achieved.

Quantitative Analyses

Once the various isomeric alkylphenylpyridines had been isolated and characterized calibration curves were prepared for each individual isomer so that its concentration in a mixture could be estimated from the area under the curve of its vapor phase chromatogram. A linear plot of the areas of their chromatograms versus concentration was obtained for the individual isomers as well as for a number of made-up mixtures of known concentrations of isomeric pairs. The concentrations of the isomers formed during the phenylation reactions could then be read off from the calibration curves, provided the conditions established for the chromatographic analysis of each pair of isomers were kept constant. These conditions are summarized below:

Methylphenylpyridines: $5\frac{1}{2}$ ft$\times\frac{1}{4}$ in. (I.D.) copper tube packed with "Apiezon N" on "Embacel" (1:4 by weight); column temperature 220°; helium inlet pressure 30 p.s.i.

Ethylphenylpyridines: same conditions as for methylphenylpyridines.

Isopropylphenylpyridines: 2 ft$\times\frac{1}{4}$ in. (I.D.) copper tube packed with "Apiezon N" on Celite 545 (1:4 by weight); column temperature 220°; helium inlet pressure 40 p.s.i.

t-Butylphenylpyridines: 3 ft$\times\frac{1}{4}$ in. (I.D.) copper tube packed with "Apiezon N" on "Embacel" (1:4 by weight); column temperature 220°; helium inlet pressure 30 p.s.i.

The results of the quantitative analyses are summarized in Table II, which also contains the data for the reaction of nicotine with phenyllithium (5).

DISCUSSION OF RESULTS

The results given in Table II indicate that the 3-substituent exerts a slight steric effect which becomes quite large when the alkyl group is *t*-butyl. The sudden great increase in steric hindrance to attack at the 2-position on passing from 3-iso-C_3H_7 to 3-*t*-Bu is unexceptional

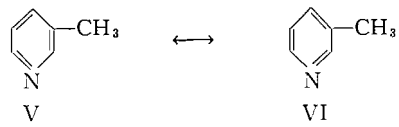
TABLE II
Ratio of III:IV in the reaction of C_6H_5Li with 3-RC_5H_4N

R	III:IV	No. of runs
CH_3	94.6:5.4 (±0.6)	4
C_2H_5	84.0:16.0 (±0.5)	4
iso-C_3H_7	70.0:30.0 (±4.0)	3
t-C_4H_9	4.5:95.5 (±0.5)	3
2-*N*-Methylpyrrolidyl (5)	49.6:50.4 (±0.2)	2

(17). The fact that the steric effect of the lower alkyl group is only relatively small seems to confirm the suggestion made above that in the transition state leading to the formation of the dihydroderivative the attacking phenyl group is almost perpendicular to the pyridine ring, whose ground-state configuration is only slightly distorted. The results also indicate quite strikingly that in spite of the greater deactivating influence of the +I effect of the alkyl group on the 2- than on the 6-position and some steric hindrance to attack at the 2-position, addition of the nucleophilic reagent takes place preferentially at that carbon atom. In fact, in the case of 3-picoline the ortho/para ratio (with respect to methyl) is as high as 19. This "ortho" effect is reminiscent of those encountered in electrophilic substitutions on compounds bearing substituents such as —NO_2, —CO_2H, —CN, and so on. Similar results to those reported above have been obtained by Brown and his group but using methyllithium instead of phenyllithium (13).

No decision can be made as to the correct explanation of the observed substitution pattern since too little is known about the detailed mechanism of this addition–elimination reaction and the effect of various substituents upon the rates and orientation in such nucleophilic substitutions. Both of these aspects are presently under investigation in these laboratories and the results of such studies should permit a clearer formulation to be made of the mechanisms involved. It is of interest though, to speculate a little about possible explanations of the orientation observed.

There is only one published molecular orbital calculation of the π-electron densities at the various nuclear carbon atoms in the ground state of 3-picoline, that due to Ploquin (18). Dr. K. L. McEwen has kindly repeated for us Ploquin's calculation for several different values of the nitrogen and methyl group inductive parameters. The results indicate that the 2-position would be slightly more favorable than position 6 for nucleophilic attack only if a negative inductive effect (−I) is attributed to the methyl group. With a positive inductive effect attack at the 6-position would be favored over attack at the 2-position. The introduction of methyl hyperconjugation into the ground-state calculations made little difference to the results. The nucleophilic localization energies at C_2 and C_6 were not calculated but if the postulate that the geometry of the transition state is more related to that of the ground state than to that of the intermediate is correct then these would not enter into the picture. A −I effect for methyl has been suggested by Murrell and McEwen to explain the observed shifts in the ultraviolet absorption spectra of some substituted benzenes (19). There is, however, a large body of chemical and physicochemical evidence which indicates that alkyl groups have a +I effect. Indeed, the n.m.r. spectrum of 3-picoline itself is consistent with the effect of the higher electron density in the ring due to the presence of the methyl substituent (20). Another possible explanation involves the contributions made by each of the two Kékulé structures V ↔ VI to the actual state of the 3-picoline molecule. If one assumes that the electrical effect of the 3-methyl substituent is such as to stabilize structure V with respect to VI, then V would have a larger coefficient than VI in the aromatic wave function, and



V VI

direction of a polar effect would be that which V would favor. If one then assumes that the phenyl anion (if such is the attacking species) will add at that end of the conjugated system whose other end is the N atom, then addition should take place preferentially at the 2-position.* It is not clear at the moment how an alkyl group would favor the stabilization of V with respect to VI. Yet another explanation possible would involve the hyperconjugation by the methyl group. Structure VIII, being *p*-quinonoïd in nature, might be more stable than VII so that the electron density at the 2-position would consequently

VII VIII

be less than at the 6-position. Similar arguments have been used to explain the high ortho/para ratios observed in the nitration of nitrobenzene and benzonitrile, for example ref. 21. Two further possibilities have to be taken seriously into account: one is that there may be some form of *steric acceleration* favoring substitution at the 2-position and not at the 6-position (the nitrogen atom in the picoline is obviously complexed in some way either with phenyllithium itself or with the lithium bromide present in solution and this would have the same steric effect as a substituent on the N atom). The other is some form of attractive interaction, perhaps of the nature of London dispersion forces, between the polarizable approaching nucleophile and the methyl substituent which would accelerate attack ortho to the methyl group rather than para to it. Dipolar field effects have been similarly suggested to explain the high ortho/para ratios in electrophilic substitutions mentioned above (22). This seems to be a very attractive possibility in the present case and is being investigated.

It should be pointed out that if the second stage in this reaction, the elimination of hydride ion, should be rate-determining, and if it is assumed that the addition step is rapidly reversible, a simple explanation is possible for the observed orientation. The transition state for such an elimination probably involves the abstraction by the lithium cation of the hydrogen atom with its bonding pair of electrons and the electron-repelling ortho-alkyl group should lower the energy of this transition state more than would a para-alkyl substituent.† At present, work is in progress to try to establish which step is the rate-determining one in this reaction, as well as to clarify the effect of alkyl substituents (activating or deactivating), the effect of the lithium bromide present in solution in this particular case, and the effect of quaternizing the ring nitrogen atom. There are some data in the literature on the last point. For example, in the reaction of 3,4-lutidine methiodide with benzyl magnesium chloride the only isomer formed was apparently the 1,2-dihydroderivative (23). Other examples of such reactions are known (24).

The authors would like to express their gratitude to Professor C. K. Ingold for a discussion of this point.

†*A referee has pointed out, however, that hydride expulsion from the ortho-substituted addition product should be less favorable on steric grounds than from the para-substituted addition product since in the former, formation of the transition state brings the alkyl and phenyl substituents closer together. We wish to thank the referee for bringing this to our attention.*

ACKNOWLEDGMENTS

The authors would like to thank Dr. K. L. McEwen for carrying out the molecular orbital calculations reported here and for many discussions, and Professor H. C. Brown for communicating some of the results of his investigations before their publication. Thanks are also offered to the University of Saskatchewan for the award of a Demonstratorship (to C.-S. G.) and to the National Research Council for financial support of this work.

ALIPHATIC CHEMISTRY OF FLUORENE

PART VIII. BENZYL 9-FLUORENYL SULPHOXIDE AND SOME 9-FLUORENYL SULPHIDES

P. M. G. BAVIN[1]

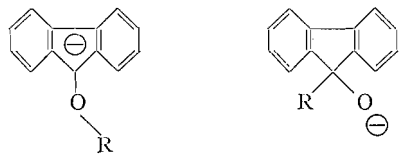
The Chemistry Department, the University, Hull, East Yorkshire, England

Received July 31, 1961

ABSTRACT

Allyl 9-fluorenyl sulphide, benzyl 9-fluorenyl sulphide, and di-9-fluorenyl sulphide are stable to boiling ethereal phenyl lithium, in marked contrast to the corresponding ethers. Benzyl 9-fluorenyl sulphoxide has been prepared and shown to be more weakly acidic than 9-fluorenyl sulphones.

Wittig and co-workers have reported (1) that the anions (I) derived from certain 9-fluorenyl ethers rearrange to the corresponding 9-substituted-9-fluorenyl alkoxides (II). Of particular interest to the present study were the anions of the allyl and benzyl ethers (I, R = $CH_2CH{=}CH_2$ and $C_6H_5CH_2$, respectively) which rearranged very rapidly at $-10°$. The anion of di-9-fluorenyl ether rearranged at room temperature but those of other alkyl and aryl ethers required elevated temperatures and longer reaction times.



I II

These reactions belong to a wider group known as the Stevens rearrangement (2, pp. 527–528; 3, pp. 282–283; 4). Most of the published work has been concerned with ethers (1, 5, 6, 7, 8) but Hauser and co-workers have examined some sulphides (4). Both benzyl methyl sulphide and dibenzyl sulphide underwent the Stevens rearrangement, more typical of the reactions of quaternary ammonium compounds. Similar rearrangements have been reported for some sulphonium compounds (4, 9). Although allylamine-N-oxides show allylic rearrangement from nitrogen to oxygen (10, 11), related allyl (12) and benzyl (4) sulphoxides and sulphones do not rearrange. Allyl phenyl sulphide and allyl *p*-tolyl sulphide possibly undergo the ortho Claisen rearrangement (13; cf. ref. 14) but more slowly than the corresponding ethers. Unlike the ether, *t*-butyl phenyl sulphide does not rearrange when distilled (15, 16).

We have now prepared by a general method (17) allyl 9-fluorenyl sulphide, benzyl 9-fluorenyl sulphide, and di-9-fluorenyl sulphide. All three sulphides dissolved in ethereal solutions of phenyl lithium with formation of the deep red color associated with fluorene anions of this type (1, 18) but the color was apparently unchanged after boiling under reflux for up to 24 hours. Hydrolysis with water regenerated the original sulphides. Thus the anions of the sulphides are more stable than those of the ethers, resembling the 9-fluorenyl-trialkylammonium compounds in not undergoing the ortho rearrangement (19).

[1]*I.C.I. Fellow, 1958–60. Present address: Smith Kline and French Laboratories Ltd., Mundells, Welwyn Garden City, Herts, England.*

The color of the anion derived from benzyl 9-fluorenyl sulphide was almost immediately discharged by the addition of methyl iodide. Oxidation of the tertiary sulphide gave benzyl 9-methyl-9-fluorenyl sulphone, isomeric with the product of benzylation of methyl 9-fluorenyl sulphone. The non-identity of the two sulphones confirmed that rearrangement of benzyl 9-fluorenyl sulphide anion had not occurred.

Allyl 9-fluorenyl sulphide was not obtained crystalline and decomposed on attempted distillation.* Like other allyl sulphides (22, 23) oxidation gave the sulphone without epoxidation of the double bond. Since allyl fluorene-9-carboxylate rearranges to 9-allylfluorene-9-carboxylic acid when heated with lithamide in toluene (24), the reaction of allyl 9-fluorenyl sulphone with sodamide has been examined. Extensive decomposition occurred, these results paralleling those reported by Cope (12) for other sulphones. The infrequency with which allyl and benzyl groups migrate from sulphur to carbon may be due to *d*-orbital resonance diminishing the charge on the potential migration terminus (cf. the effect of sulphur on the stability of anions (20, 21, 24)). Similar reasons have been put forward to account for the failure of thiophenol acetate to undergo the Fries rearrangement (26). A recent paper (27) has described the pyrolysis of some sulphones which resulted in the formation of rearranged hydrocarbons, but probably by a free radical mechanism.

The reaction between fluorene, thionyl chloride, and aluminum chloride has been reported (28) to yield di-9-fluorenyl sulphoxide, characterized by oxidation to di-9-fluorenyl sulphone (m.p. 199° with decomposition). Although one example of intramolecular acylation at the 9-fluorenyl position has been described (29), Friedel–Crafts and related reactions generally give 2-fluorenyl derivatives (30, p. 277). We have now prepared di-9-fluorenyl sulphone by oxidation of the sulphide and find it to have m.p. 242–244° with decomposition. Paucity of experimental details has prevented repetition of Courtot's preparation (28).

Allyl and benzyl 9-fluorenyl sulphides decomposed rapidly at 258–260° with formation of evil-smelling mixtures. The only product identified was di-9-fluorenyl (8–10%). Di-9-fluorenyl sulphide behaved similarly, giving difluorenyl (11%) accompanied by di-9-fluorenylidene (9%). These observations parallel those reported for the corresponding ethers (1).

In an earlier paper (17) the acidity of 9-fluorenyl sulphones was described. We have now prepared benzyl 9-fluorenyl sulphoxide and examined its reactions. (For a recent discussion of the formation of sulphoxides, see ref. 31.) It dissolves in methanol containing sodium methoxide without formation of the yellow color associated with 9-fluorenyl anions of this type (17, 32, 33). Further, the presence of the alkoxide does not significantly affect the ultraviolet spectrum. Addition to the solution of either methyl or allyl halides led to mixtures from which traces of hydrocarbons were isolated. The infrared spectra showed the presence of sulphones, and fluorenone could be isolated as the 2,4-dinitrophenylhydrazone. Failure to isolate alkylation products is probably due to the low acidity of the sulphoxide since, after 1 hour, dilution precipitated unchanged sulphoxide. Alkylation of the related sulphones is known to be rapid (17). Although disappointing, these results were not unexpected. Unlike the corresponding sulphones, sulphoxides are insoluble in aqueous sodium hydroxide solution (34), and dibutyl sulphoxide undergoes hydrogen exchange very slowly in alkaline media (35). It has been concluded from

**Allylic sulphides are readily isomerized to propenyl sulphides by strong bases (for examples, see refs. 20, 21). In view of the failure of benzyl 9-fluorenyl sulphide anion to undergo rearrangement, the structure of the allyl sulphide was confirmed only by its infrared spectrum (see Experimental).*

spectral and other studies (36) that the electron-accepting properties of the sulphoxide group are only slightly greater than those of the uncharged sulphides. Our results agree with this conclusion.

The infrared spectra of the sulphones reported in this and the earlier paper (17) have been discussed elsewhere (37).

EXPERIMENTAL

Benzyl 9-Fluorenyl Sulphide

Prepared from 9-bromofluorene and benzyl mercaptan in the usual way (17), it crystallized from acetone–methanol as colorless prisms and laths (87%), m.p. 66–67°. Found: C, 83.38; H, 5.80%. Calculated for $C_{20}H_{16}S$: C, 83.26; H, 5.59%.

Benzyl 9-Fluorenyl Sulphoxide

Following a series of trial experiments, the following was found to be reproducible:

The sulphide (2 g) in acetic acid (100 ml) and 50% hydrogen peroxide (15 ml) was heated on the steam bath for 15 minutes. The yellow solution was poured into water, precipitating the *sulphoxide* as a white solid. Crystallization from ethanol gave felted needles (1.45 g), m.p. 147–148° with decomposition to a red liquid. Found: C, 78.55; H, 5.40%. Calculated for $C_{20}H_{16}OS$: C, 78.91; H, 5.30%.

Benzyl 9-Fluorenyl Sulphone

The oxidation described above was continued for 2 hours, additional 50% hydrogen peroxide (10 ml) being added after 1 hour. The *sulphone* formed thick colorless needles from ethanol (82%), m.p. 169–170°. Found: C, 74.64; H, 4.85%. Calculated for $C_{20}H_{16}O_2S$: C, 74.97; H, 5.03%.

Benzyl 9-Methyl-9-fluorenyl Sulphide

Benzyl 9-fluorenyl sulphide (1 g) dissolved in ethereal phenyl lithium (from 2 g bromobenzene) with formation of a deep red color, which was not visibly altered after boiling of the solution under reflux for 24 hours. At the end of this period, methyl iodide (2 g) was added, the solution being almost immediately decolorized. After it was washed with ice water, the ether solution was dried (K_2CO_3), divided into two approximately equal parts, and each part evaporated to dryness.

The oil from one part was left under methanol for 4 weeks, crystallization slowly taking place. Recrystallization from methanol gave small colorless prisms (0.26 g), m.p. 59.5–61.0°. Found: C, 83.61; H, 6.29%. Calculated for $C_{21}H_{18}S$: C, 83.40; H, 6.00%.

The oil from the second part was oxidized in the usual way (17) with hydrogen peroxide. *Benzyl 9-methyl-9-fluorenyl sulphone* crystallized from methanol as colorless needles (0.4 g), m.p. 155–156°. Found: C, 75.66; H, 5.32%. Calculated for $C_{21}H_{18}O_2S$: C, 75.42; H, 5.42%. The same compound (m.p., mixed m.p., and identity of infrared spectra) was obtained by methylating benzyl 9-fluorenyl sulphone in the usual way (17).

Benzylation of 9-fluorenyl methyl sulphone (17) gave *9-benzyl-9-fluorenyl methyl sulphone*, crystallizing from acetone as lustrous plates (69%), m.p. 172–173°, depressed to 141–153° by addition of benzyl 9-methyl-9-fluorenyl sulphone. Found: C, 75.03; H, 5.32%. Calculated for $C_{21}H_{18}O_2S$: C, 75.42; H, 5.42%.

Di-9-fluorenyl Sulphone

9-Fluorenyl mercaptan (10 g) (38) and 9-bromofluorene (13 g) were dissolved in hot ethanol (500 ml). The addition of a solution of sodium methoxide (from 1.2 g sodium) in methanol (50 ml) brought about a vigorous reaction. The *sulphide* started to separate almost at once. Recrystallization from xylene gave colorless lustrous plates (16.5 g, 82%), m.p. 257–259° with decomposition to a red liquid.

Oxidation of the sulphide (1 g) in hot acetic acid (1500 ml) with 50% hydrogen peroxide (15 ml) gave the *sulphone*, which crystallized from xylene as almost colorless prisms (0.7 g), m.p. 242–244° with partial decomposition. Found: C, 78.85; H, 4.43%. Calculated for $C_{26}H_{18}O_2S$: C, 79.16; H, 4.60%.

Allyl 9-Fluorenyl Sulphone

The reaction between 9-bromofluorene (24.5 g), allyl mercaptan (10 g), and sodium methoxide (from 2.5 g sodium) in methanol (250 ml) gave the sulphide as an oil (18 g). It was not obtained crystalline but oxidation in the usual way (17) gave the sulphone (15.2 g) as prisms or plates from acetone–methanol, m.p. 120–121°. Found: C, 70.75; H, 5.23%. Calculated for $C_{16}H_{14}O_2S$: C, 71.08; H, 5.22%.

The sulphide was also obtained as an oil from the reaction between 9-fluorenyl mercaptan and allyl chloride.

9-Allyl-9-fluorenyl Methyl Sulphone

Prepared from 9-fluorenyl methyl sulphone in the usual way (17), it crystallized as elongated prisms from acetone, m.p. 168–169°. Found: C, 71.49; H, 5.33%. Calculated for $C_{17}H_{16}O_2S$: C, 71.80; H, 5.67%.

Pyrolysis of the Sulphides

Di-9-fluorenyl sulphide (2 g) was placed in a 100-ml Erlenmeyer flask, closed with a cotton plug, and maintained at 258–260° (oil bath) for 2 minutes. Crystallization from heptane gave colorless needles (0.2 g, 11%), m.p. 245–246° after two crystallizations. Comparison with an authentic specimen (39) showed the product to be di-9-fluorenyl. The mother liquors slowly formed a crust of red crystals, which were removed and crystallized from carbon tetrachloride – ethanol. The resulting red needles (0.16 g, 9%) had m.p. 185–186° and were identified as di-9-fluorenylidene by comparison with an authentic specimen (39).

The characteristic sulphone bands in the infrared spectra have been discussed elsewhere (37). The structure of allyl 9-fluorenyl sulphide was supported by strong bands at 989 and 912 cm^{-1}, indicative (40) of the vinyl group.

GLYCOSIDATION OF SUGARS

I. FORMATION OF METHYL-D-XYLOSIDES[1]

C. T. BISHOP AND F. P. COOPER
The Division of Applied Biology, National Research Council, Ottawa, Canada

Received October 2, 1961

ABSTRACT

The reactions of D-xylose, methyl α-D-xylofuranoside, and methyl β-D-xylopyranoside with methanolic hydrogen chloride under controlled conditions have been followed by gas–liquid partition chromatographic analysis of the products. Rate curves were established for each of the four methyl-D-xylosides and the results showed that the following sequence of reactions occurs in the formation of methyl xylosides: (1) xylose → furanosides, (2) anomerization of furanosides, (3) furanosides → pyranosides, (4) anomerization of pyranosides. The relative rates of these four reactions in order of decreasing velocity are 2, 1, 3, 4. Reaction 3 appears to proceed with retention of configuration at the anomeric center. Possible intermediates in these reactions are discussed. Substitution of positions 2 and 3 in the D-xylose molecule by *O*-methyl groups resulted in an increase in the furanoside content of the methanolysis products at equilibrium.

Reaction of sugars with methanolic hydrogen chloride to form methyl glycosides has been known since 1893 (1) and remains of considerable interest and importance in carbohydrate chemistry. The literature on this subject has been reviewed by Shafizadeh (2), who also presented postulated intermediates in the hydrolysis and formation of glycosides via a cyclic or an acyclic mechanism. It is noteworthy that much of the information contributing to those mechanisms was obtained by studies on the *hydrolysis* of glycosides; work on the *formation* of glycosides has been much less extensive and less definitive, probably because of difficulties in analyzing the products. Levene, Raymond, and Dillon (3) studied the methanolysis of nine monosaccharides (glucose, mannose, galactose, fructose, rhamnose, arabinose, lyxose, ribose, and xylose) and presented rate curves showing the changes in proportions of free sugar, furanoside, and pyranoside. Differences in rates of hydrolysis were used to distinguish between furanosides and pyranosides and the results showed that furanosides were formed early in the methanolysis and then decreased gradually with a concurrent increase in pyranosides. The validity of this conclusion has been recognized and substantiated by its general application to the preparation of glycoside mixtures enriched with respect to furanosides or pyranosides (4). However, more recent work has shown differences in rates of hydrolysis for individual furanosides and pyranosides (2) and it is apparent that neither the extent of initial furanoside formation nor the furanoside–pyranoside composition at equilibrium could be determined accurately by the procedure of Levene *et al.* (3). This was recognized by Mowery and Ferrante (5), who re-examined the methanolysis of galactose using modern chromatographic procedures for analyzing the products. These authors separated α- from β-anomers and then estimated the amounts of furanoside and pyranoside in the two fractions from optical rotations. The results showed that β-anomers were formed first and then change to α-anomers, this latter reaction being more "important" than the change of furanoside to pyranoside. Similar results were obtained when a cation exchange resin, rather than hydrogen chloride, was used as catalyst in the methanolysis (6).

[1]*Issued as N.R.C. No. 6628.*
Presented at the 140th Meeting of the American Chemical Society, Chicago, September 3–7, 1961.

Methanolysis of mannose was also investigated and it was found (7) that α-anomers predominate at all times and that furanosides gradually change to pyranosides.

The chromatographic procedures used by Mowery and Ferrante (5) and by Mowery (6, 7) provided more definitive information than the techniques available to Levene *et al.* (3). However, they are time consuming, require large samples, and therefore restrict the convenient analysis of products to relatively few intervals during the reaction. The use of gas–liquid partition chromatography for separating carbohydrate derivatives (8, 9, 10) provides a fast, accurate method for analyzing mixtures of glycosides and requires only small samples. By this means it is possible, with most monosaccharides, to obtain separate rate curves for each of the four methyl glycosides and to establish reliable quantitative data for the equilibrium compositions. The present paper reports the results obtained in the methanolysis of xylose, and the glycoside compositions at equilibrium of its 2-*O*-, 3-*O*-, and 2,3-di-*O*-methyl derivatives.

Reactions were carried out under carefully controlled conditions and products were analyzed by the following procedure. At various times samples were removed, neutralized by sodium methoxide to stop the reaction, and evaporated to dryness. The residue was then methylated by the Kuhn (11) procedure and the fully methylated methyl glycosides were analyzed by gas–liquid partition chromatography (8, 9, 10). Figure 1 shows a

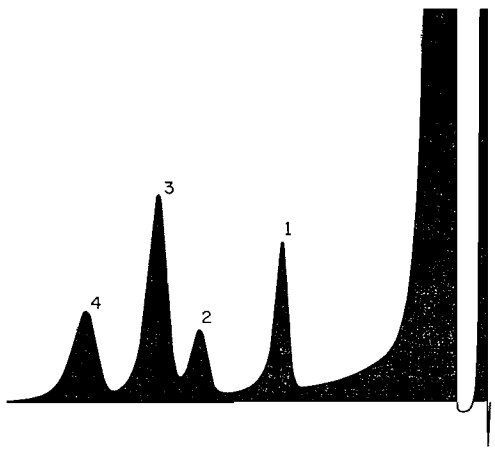

FIG. 1. Separation of fully methylated methyl-D-xylosides. Conditions: column (4 ft×4 mm)—Carbowax 6000 on acid-washed celite 545, 80–100 mesh, 1:9 w/w; temp.—125° C; flow rate—250 ml argon/minute. 1, methyl 2,3,4-tri-*O*-methyl-β-D-xyloside; 2, methyl 2,3,4-tri-*O*-methyl-α-D-xyloside; 3, methyl 2,3,5-tri-*O*-methyl-β-D-xyloside; 4, methyl 2,3,5-tri-*O*-methyl-α-D-xyloside.

typical separation of the four fully methylated methyl-D-xylosides. The components were identified by comparison with authentic samples of each of the four glycosides, and quantitative estimations were made by triangulation of the peaks. Disappearance of reducing sugar was followed by the hypoiodite method (12). Methylation of individual authentic methyl xylosides and gas–liquid partition chromatography of the products showed that no anomerizations or changes in the ring form occurred during these steps and also that complete methylation of each xyloside was achieved under the conditions used.

Figures 2 and 3 show the rate curves for the products from methanolysis of D-xylose at 25° C and 44° C respectively and reveal the general sequence of reactions. Thus, at 25° C (Fig. 2), the concentration of free sugar dropped very quickly to about 9% with concurrent production of furanosides, which then decreased as pyranosides were formed.

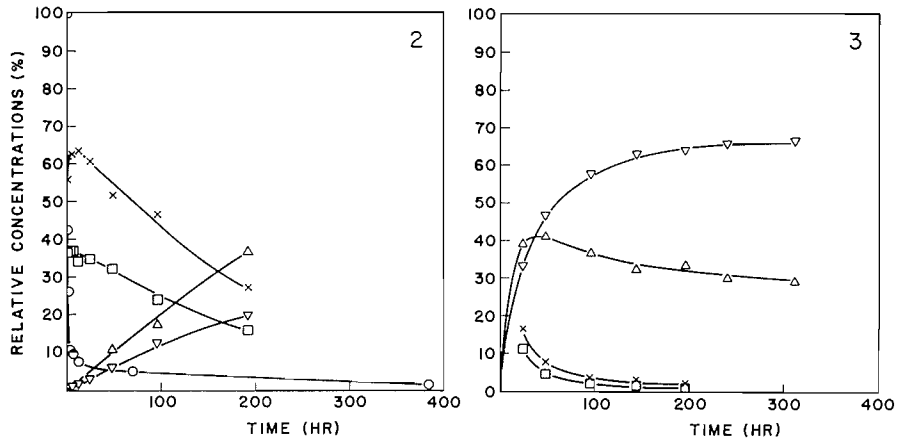

FIG. 2. Products from methanolysis of D-xylose (2% in 0.50% MeOH–HCl) at 25°±0.01° C. ○ D-Xylose, × methyl β-D-xylofuranoside, □ methyl α-D-xylofuranoside, ▽ methyl α-D-xylopyranoside, △ methyl β-D-xylopyranoside.

FIG. 3. Products from methanolysis of D-xylose (2% in 0.50% MeOH–HCl) at 44°±0.01° C. □ Methyl α-D-xylofuranoside, × methyl β-D-xylofuranoside, ▽ methyl α-D-xylopyranoside, △ methyl β-D-xylopyranoside.

The reaction was too slow at 25° C to be followed to equilibrium so it was repeated at 44° C when the rate curves (Fig. 3) showed that the sequence just described was followed by an anomerization of the pyranosides. It was not possible to obtain rate constants of sufficient accuracy to calculate activation energies for any of these reactions because the data did not fit first- or second-order rate kinetics ideally. This was probably caused by the simultaneous occurrence of competing reactions to a small but significant extent and, since the rates were shown to be dependent upon acid concentration, by reaction between methanol and hydrogen chloride. However, approximate *relative* rates could be determined by a comparison of first-order rate constants calculated from data over the same portion of each reaction. At 25° C the ratio of methyl-α-D-xylofuranoside to methyl-β-D-xylofuranoside was the same (1:1.72) throughout the reaction and must therefore be the equilibrium ratio for these two anomers. Any anomerization of furanosides must have occurred too rapidly to have been detected at that temperature. Accordingly, the rate for anomerization of furanosides was determined at 10° C using methyl α-D-xylofuranoside as the starting product and the same concentrations of reactants as used at the higher temperatures. The rate constants, relative to that of the slowest reaction, are given in Table I. The rate constants from which these values were calculated were obtained from the early portions of the reactions when the data fitted first-order

kinetics and when the occurrence of competing reactions would be expected to be at a minimum. It is apparent that reaction 2 was the fastest of the four, at both reaction temperatures, and was followed in order of decreasing velocity by reactions 1, 3, and 4. The results showed that it would be impossible to see if one of the anomeric furanosides is formed predominantly from a solution of D-xylose, in which the equilibrium composition of α and β forms is known, because the furanosides would be anomerized to their equilibrium mixture as soon as they were formed. However, the difference in the rates of reactions 3 and 4 permitted some information to be gained about these two reactions. During the conversion of furanosides to pyranosides the ratio of α- to β-anomers was the same in both ring forms and was constant until the concentrations of furanosides were relatively low. At that stage the anomerization of the pyranosides became the predominant reaction and the ratio of α- to β-anomers changed. These ratios, taken at various times, are shown in Table II. The results indicated that the conversion of

*Reaction of a 2% solution of D-xylose in 0.50% methanolic hydrogen chloride at 25° C.

D-xylofuranosides to D-xylopyranosides proceeds with retention of configuration at the anomeric center. This conclusion was supported by the rate curves, shown in Fig. 4, which were obtained by analysis of the products from the reaction of methyl α-D-xylofuranoside with hydrogen chloride in *p*-dioxane. It is readily apparent that the methyl

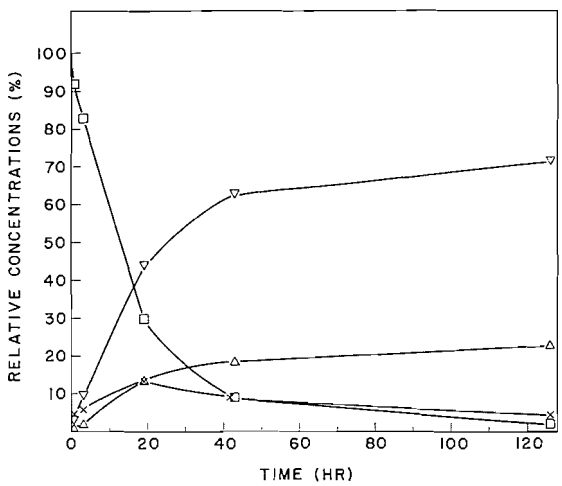

FIG. 4. Products from reaction of methyl α-D-xylofuranoside (2.0%) with hydrogen chloride (0.50%) in *p*-dioxane at 25°±0.01° C. □ Methyl α-D-xylofuranoside, × methyl β-D-xylofuranoside, ▽ methyl α-D-xylopyranoside, △ methyl β-D-xylopyranoside.

α-D-xylofuranoside yielded the methyl α-D-xylopyranoside predominantly. The smaller amounts of β-D-xylopyranoside could have arisen from minor competing reactions, e.g. (*a*) methyl α-furanoside → methyl β-furanoside → methyl β-pyranoside, (*b*) methyl α-pyranoside → methyl β-pyranoside. Very little anomerization of furanoside occurred in this system with *p*-dioxane being used as a solvent. This is in direct contrast to the results obtained with methanolic hydrogen chloride and showed that methanol was necessary for the rapid anomerization of furanosides described earlier.

Glycosidation with methanolic hydrogen chloride results in the formation of 1 mole of water from each mole of sugar. The water so formed could promote reverse reactions in the system. However, the results obtained on reaction of methyl α-D-xylofuranoside (Fig. 5) with methanolic hydrogen chloride were in complete agreement with those

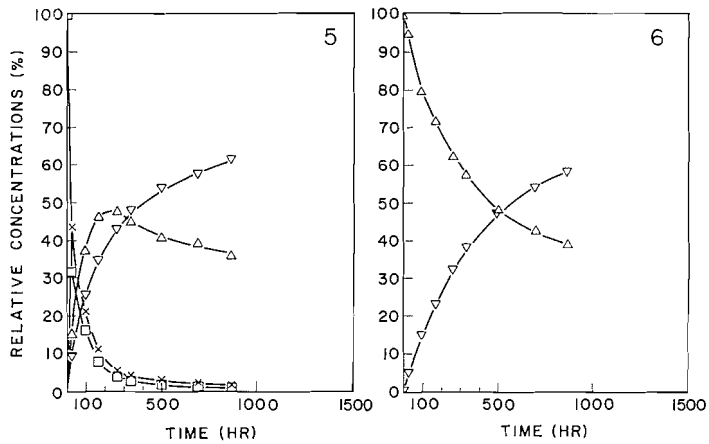

FIG. 5. Products from methanolysis of methyl α-D-xylofuranoside (2% in 0.50% MeOH–HCl) at 25°±0.01° C. □ Methyl α-D-xylofuranoside, × methyl β-D-xylofuranoside, ▽ methyl α-D-xylopyranoside, △ methyl β-D-xylopyranoside.

FIG. 6. Products from methanolysis of methyl β-D-xylopyranoside (2% in 0.50% MeOH–HCl) at 25°±0.01° C. △ Methyl β-D-xylopyranoside, ▽ methyl α-D-xylopyranoside.

given by D-xylose under the same conditions. This showed that, under the conditions used, the 1 mole of water produced from each mole of sugar had no demonstrable effect on the reaction.

The anomerization of methyl-β-D-xylopyranoside in methanolic hydrogen chloride is shown in Fig. 6. These results indicated that no furanoside ring forms were involved in the anomerization of methyl-D-xylopyranosides. Of course, as the reaction progressed, small amounts of furanosides (not shown) appeared due to the reverse reactions. However, the amounts of furanosides were those found at equilibrium (cf. Table III) and were consistent with the view that they arose entirely from the reverse reactions. The rates of all reactions were approximately 4 times faster when the acid concentration was quadrupled.

On the basis of the foregoing results some comments can be made about possible mechanisms for the methanolysis reactions of D-xylose. The sequence of reactions can be established definitely as (1) D-xylose → furanosides, (2) anomerization of furanosides, (3) furanosides → pyranosides, (4) anomerization of pyranosides. As mentioned before, little comment can be made about the first reaction because it was slower than reaction 2. However, from Table I it may be seen that the anomerization of furanosides is about

400 times faster than anomerization of pyranosides. If, by analogy, it may be assumed that the furanose and pyranose forms of D-xylose differ in reactivity in the same way and by the same order of magnitude, then the initial acetal formation would proceed primarily through the furanose form. Very little of the latter would need to be present in the equilibrium mixture given by D-xylose in methanol solution. Figure 7 shows a

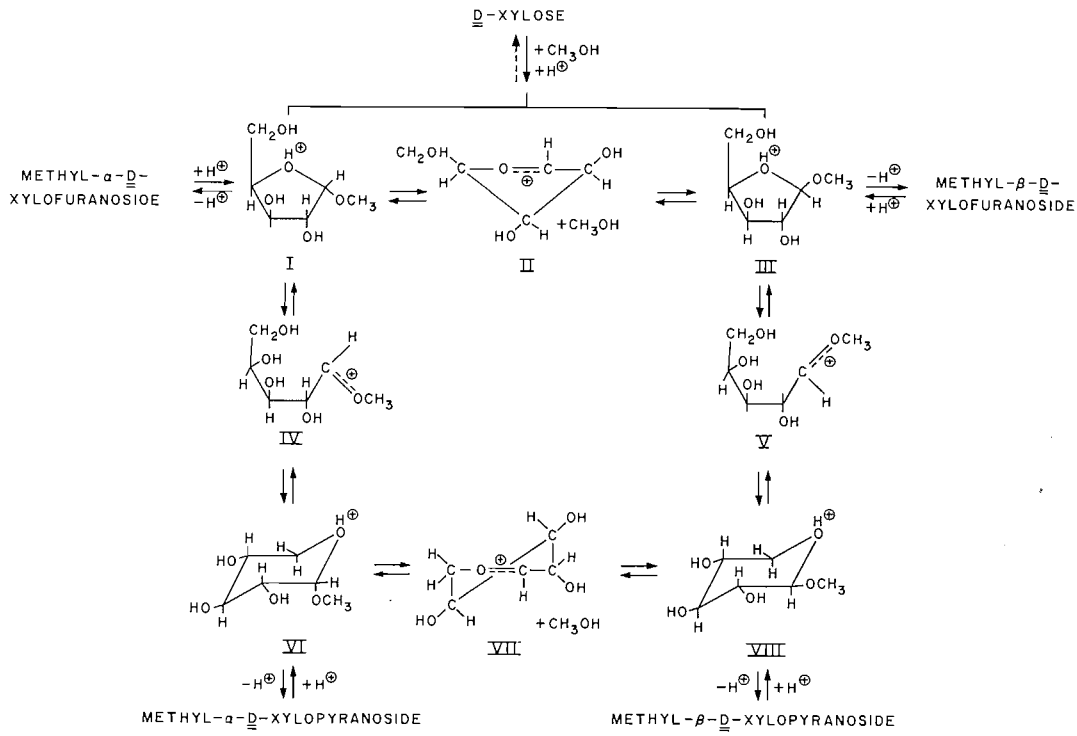

FIG. 7. Postulated mechanism in formation of methyl-D-xylosides.

postulated scheme for reactions 2, 3, and 4. In accordance with the accepted mechanisms for formation and hydrolysis of acetals (13) the proposed scheme is one of specific rather than general acid catalysis. Although probably correct, this requires confirmation by further kinetic studies. The differences in the observed rates of reactions are probably best explained by the postulation of cyclic carbonium ion intermediates (II and VII) for the anomerizations (reactions 2 and 4). Thus, the higher rate of reaction 2, relative to the other three reactions, may be explained by the ease of formation of the ion II from I and III. In the C_s conformation (14) the C_4, ring O, C_1, and C_2 atoms of the methyl-D-xylofuranosides (I and III) would be coplanar and practically no conformational change would be involved in the formation of II. Conversely, the production of ion VII in the half-chair conformation from the stable chair forms VI and VIII requires considerable change in conformation, and the energy demands make the reaction the slowest of the four. The reason for suppression of furanoside anomerization in the reaction of methyl α-D-xylofuranoside (I) with hydrogen chloride in *p*-dioxane is not clear but must be due to a solvent effect. It may be that carbonium ion II is stabilized by solvation with methanol but not with dioxane. This would lead to a shift in the equilibrium in favor of IV in the latter solvent to yield the pyranoside VI.

Retention of anomeric configuration during the furanoside → pyranoside reaction may be explained by considering the geometry of the acyclic ions IV and V. In these two ions, as they are formed from the protonated furanosides I and III, ring closure at C_5 to yield pyranosides requires a rotation about the C_3—C_4 bond of only some 10°. A simultaneous anomerization at C_1 would require a rotation about the C_1—C_2 bond of 180°. It might be expected, therefore, that the compound requiring the smaller change would predominate in the reaction products. For this to be true the ring closure in carbonium ions IV and V must be sufficiently rapid that the H, OCH_3, and C_2 are retained in their original tetrahedral configuration on C_1. Absence of the dimethyl acetal of D-xylose in any of these reactions provided negative evidence for such a rapid ring closure. Had the acyclic ions IV or V existed for any appreciable time it would be expected that a solvent attack at C_1 would yield the dimethyl acetal. Possible alternatives to the acyclic intermediates IV and V could be cyclic, "bridged" compounds involving partial bond formation from C_1 to both the C_4 and C_5 oxygens.

Glycoside compositions at equilibrium in the methanolysis reaction were determined for D-xylose and its 2-*O*-, 3-*O*-, and 2,3-di-*O*-methyl derivatives. Table III shows these

TABLE III

Methyl glycoside compositions at equilibrium in the methanolysis of D-xylose and its 2-*O*-, 3-*O*-, and 2,3-di-*O*-methyl derivatives*

Sugar	Methyl glycoside (%)			
	β-Pyranoside	α-Pyranoside	β-Furanoside	α-Furanoside
D-Xylose	32.0	60.0	6.5	1.4
3-*O*-Methyl-D-xylose	26.7	64.2	5.9	3.1
2-*O*-Methyl-D-xylose	29.2	58.0	9.5	3.3
2,3-di-*O*-Methyl-D-xylose	29.8	53.8	12.7	3.7

*Reaction of the sugar (0.06%) in 2% methanolic hydrogen chloride under reflux for 20 hours.

compositions and it is apparent that the methoxy groups on C_2 and C_3 result in an increase in the amounts of furanoside ring forms in the mixtures at equilibrium. This effect was probably caused by increased non-bonded interactions between the *trans* C_2 and C_3 substituents when hydroxyl groups were replaced by methanol. Since trans C_2 and C_3 substituents are closer together in the pyranoside than in the furanoside ring form, substitution at these positions should decrease the stability of pyranoside more than furanoside, leading to an increase in furanoside content at equilibrium.

EXPERIMENTAL

Reagents

D-Xylose was a purified product supplied by Fisher Scientific Co. Methanol was reagent grade and was distilled from magnesium–iodine immediately before use. Hydrogen chloride was obtained from a cylinder and was dried by passage through a calcium chloride tube. *p*-Dioxane was refluxed with *N* hydrochloric acid, treated with solid potassium hydroxide, and fractionally distilled from sodium; the fraction boiling at 101–102° C was used (15). *N*,*N*-Dimethyl formamide was distilled and stored over barium oxide.

Apparatus

Gas–liquid partition chromatography was carried out on an F and M Model 500 Chromatograph employing a thermal conductivity detector or on a Pye Argon Chromatograph using an ionization detector. On the former, separations of the fully methylated methyl-D-xylosides were made on an 8-ft column of coiled ¼-in. copper tubing packed with 20% w/w Carbowax 20M on Gas-Chrom A (120–140 mesh). Separations were carried out at 150° C with a flow rate of 60 ml of helium per minute. On the latter instrument separations were obtained on straight glass columns (4 ft×4 mm) packed with Carbowax 6000 on acid-washed Celite 545, 80–100 mesh, 1:9 w/w; temperature was 125° C and a flow rate of 250 ml Argon/minute was used.

Preparation of Methyl-D-Xylosides

These compounds were prepared by the method of Augestad and Berner (16). Each xyloside gave a single spot on paper chromatograms run in butanone–water azeotrope. Gas–liquid chromatography of each fully methylated (11) xyloside showed only one component clearly distinguishable (Fig. 1) from the other three xylosides. The methyl xylosides had the following physical constants:

	Our values		Reported values	
	M.p. (°C)	$[\alpha]_D$*	M.p. (°C)	$[\alpha]_D$
Methyl α-D-xylofuranoside	83–84	+181°	84	+182° (16)
Methyl β-D-xylofuranoside	Sirup	− 80°	45	− 89.5° (16)
Methyl α-D-xylopyranoside	89–91	+151°	91–92	+153.9° (17)
Methyl β-D-xylopyranoside	155.5–156.5	− 65°	156–157	− 65.5° (18)

*c, 1–2% in water, T = 25° C.

Glycosidations and Anomerizations

The reactions were carried out in screw-capped bottles fitted with silicone rubber septums and kept in a water bath at 10°, 25°, or 44° C (±0.01°). D-Xylose, methyl α-D-xylofuranoside, or methyl β-D-xylopyranoside (0.300 g) was dissolved in absolute methanol (10 ml) at the required temperature, and the solution was then made up to 15 ml by the addition of 1.50% methanolic hydrogen chloride. In one experiment, to determine the effect of acid concentration on the rate of reaction, 6.0% methanolic hydrogen chloride was added in the same proportions, giving a final acid concentration of 2%. In another experiment purified *p*-dioxane was used instead of methanol.

Analysis of Methyl-D-Xyloside Mixtures

Aliquots (0.5 ml) were withdrawn from the reaction bottles by a hypodermic syringe, neutralized immediately with sodium methoxide in 3-ml test tubes, and evaporated to dryness *in vacuo*. The dried samples were methylated (11) by addition of *N,N*-dimethyl formamide (0.1 ml), methyl iodide (0.1 ml), and silver oxide (0.1 g). The stoppered tubes, covered with foil paper, were shaken for at least 4 hours and sometimes up to 20 hours. The supernatant liquid was then analyzed directly by gas–liquid partition chromatography, the components being identified by comparison with authentic methyl-D-xylosides methylated in the same way. Amounts of individual xylosides were determined from the areas under the peaks.

Effect of Methylation Procedure on D-Xylose

A mixture of D-xylose (15.0 mg) and methyl β-L-arabinopyranoside (16.2 mg) was methylated as described above. Analysis of the products by gas–liquid partition chromatography gave the following results:

Compound	Units of area under peak	Percentage
Methyl 2,3,4-tri-*O*-methyl-β-D-xylopyranoside	1142	74.8
Methyl 2,3,4-tri-*O*-methyl-α-D-xylopyranoside	263	17.2
Methyl 2,3,5-tri-*O*-methyl-β-D-xylofuranoside	79	5.2
Methyl 2,3,5-tri-*O*-methyl-α-D-xylofuranoside	41	2.7
Total methyl tri-*O*-methyl-D-xylosides	1525	
Methyl tri-*O*-methyl-β-L-arabinopyranoside	1528	

This showed that D-xylose was quantitatively converted to fully methylated methyl xylosides by this procedure. Therefore, when D-xylose remained in samples taken for analysis a correction for products arising from the free sugar was made utilizing the percentages shown above.

Analysis for D-Xylose

This was carried out by the alkaline hypoiodite method (12). Reactions in which a methyl-D-xyloside was the starting product were also checked for the presence of free sugar but none was found at any time.

Glycosidation of Partially Methylated D-Xyloses

2-*O*-Methyl-D-xylose, m.p. 103–104° C; 3-*O*-methyl-D-xylose, m.p. 132–133° C; and 2,3-di-*O*-methyl-D-xylose, m.p. 78–79° C, had been characterized previously during work in this laboratory on the structural

investigation of polysaccharides. Samples (15 mg) of each were dissolved in 2% methanolic hydrogen chloride (25 ml) and refluxed for 20 hours. The products, recovered after neutralization with silver carbonate, filtration, and evaporation, were methylated and analyzed as described above.

SYNTHESIS OF 4-*O*-METHYL-L-ARABINOSE[1]

I. R. SIDDIQUI[2] AND C. T. BISHOP
The Division of Applied Biology, National Research Council, Ottawa, Canada

Received October 18, 1961

ABSTRACT

4-*O*-Methyl-L-arabinose has been synthesized from ethyl 2,3-di-*O*-benzyl-α-L-arabinofuranoside by successive methanolysis, methylation, debenzylation, and hydrolysis; a proof of structure is presented. Ethyl 2,3-di-*O*-benzyl-α-L-arabinofuranoside yielded 57% furanoside and 43% pyranoside at equilibrium in methanolic hydrogen chloride.

Among the mono-*O*-methyl derivatives of L-arabinose the 2-*O*- and 3-*O*-methyl isomers have been known for some time (1) and syntheses of the 5-*O*-methyl derivative have been reported more recently (2, 3). The present paper reports the synthesis and proof of structure of 4-*O*-methyl-L-arabinose, the only monomethyl ether of that sugar which has not been described.

The sequence of reactions in the synthesis was as follows:

Ethyl 2,3-di-*O*-benzyl-α-L-arabinofuranoside, prepared during the synthesis of 5-*O*-methyl-L-arabinose (3), was refluxed with methanolic hydrogen chloride to yield a mixture of the corresponding furanosides and pyranosides. This mixture was methylated, debenzylated, and hydrolyzed to yield 4-*O*- and 5-*O*-methyl-L-arabinose, which were separated by preparative paper chromatography.

The prolonged methanolysis (24 hours in 2% methanolic hydrogen chloride) of ethyl 2,3-di-*O*-benzyl-α-L-arabinofuranoside had been expected to convert the compound to a mixture in which the pyranoside-ring forms predominated (4, 5). However, subsequent analysis of the methyl mono-*O*-methyl-L-arabinosides by gas–liquid partition chromatography (6, 7) of their fully methylated derivatives gave a furanoside:pyranoside ratio of 1:0.75 (57% furanoside, 43% pyranoside). It has been reported (8) that *O*-methyl groups on C_2 and C_3 in the D-xylose molecule increase the ratio of furanoside forms at equilibrium in methanolic hydrogen chloride. The present results indicated that *O*-benzyl groups have a similar effect. In this connection it may be noted that 2,3-di-*O*-methyl-L-arabinose yields 75.4% furanosides at equilibrium in methanolic hydrogen chloride (9).

The 4-*O*-methyl-L-arabinose was a sirup having $[\alpha]_D +132° \pm 2°$ and giving only one spot on paper chromatograms. Complete methylation yielded methyl 2,3,4-tri-*O*-methyl-α,β-L-arabinoside and oxidation by bromine water yielded a δ-lactone. The *O*-methyl group therefore could not be on C_5. The mono-*O*-methyl-L-arabinose yielded a crystalline osazone without loss of methoxyl, showing that the C_2 hydroxyl was not substituted. On methanolysis the mono-*O*-methyl-L-arabinose yielded crystalline α- and β-methyl glycosides, which were separated by fractional crystallization. The configurations of the glycosides were assigned on the basis of Hudson's rules of isorotation (10). Periodate oxidation of a mixture of these two glycosides resulted in the consumption of 0.93 mole of oxidant per mole of glycoside and showed that the C_3 hydroxyl was not substituted. Direct proof that the *O*-methyl group was on C_4 was obtained by reduction and hydrolysis of the periodate-oxidized methyl glycosides (11) to yield 2-*O*-methyl glycerol, identified as its crystalline 1,3-di-*O*-trityl derivative.

EXPERIMENTAL

Methyl 2,3-Di-O-benzyl-α,β-L-arabinosides (Furanoside/Pyranoside)

Ethyl 2,3-di-*O*-benzyl-α-L-arabinofuranoside (3), 9.0 g, was refluxed for 24 hours in 2% methanolic hydrogen chloride (200 ml). The solution was neutralized with silver carbonate, filtered, and evaporated to a sirup (8.9 g); $[\alpha]_D^{25}$ +11.7°±2° (*c*, 2% in methanol); OCH_3, 7.09%, calc. OCH_3, 9.0%.

Methyl 2,3-Di-O-benzyl-4/5-O-methyl-L-arabinoside (Furanoside/Pyranoside)

The mixture (8.9 g) of methyl 2,3-di-*O*-benzyl-L-arabinosides obtained above was methylated twice by methyl iodide (75 ml) and silver oxide (10 g) (12). The product (7.2 g, 78.2%) showed no hydroxyl absorption in its infrared spectrum; $[\alpha]_D^{25}$ ±0° (*c*, 3.45% in methanol); OCH_3, 17.60%, calc. OCH_3, 17.30%.

Methyl 4/5-O-Methyl-L-arabinosides

The fully methylated di-*O*-benzyl derivative was debenzylated by reduction with sodium in alcohol (13) to yield a sirupy, water-soluble product (2.3 g, 88.4%); $[\alpha]_D^{26}$ −12.0°±1.5° (*c*, 1.3% in methanol).

A sample (5 mg) of this material was methylated by the Kuhn (14) procedure and the fully methylated derivatives were analyzed by gas–liquid partition chromatography (6, 7). Separations were carried out at 180° C on a 4-ft column of polyphenyl ether, 10% (w/w) on Celite 545 (80–100 mesh), with a flow rate of 75 ml argon per minute. Under these conditions the anomeric methyl glycosides of 2,3,5-tri-*O*-methyl-L-arabinose were resolved, those of 2,3,4-tri-*O*-methyl-L-arabinose ran as one component. Measurement of areas under the three peaks showed that the mixture contained 57% of the 2,3,5-tri-*O*-methyl and 43% of the 2,3,4-tri-*O*-methyl isomers.

4-O-Methyl-L-arabinose

The mixture of methyl 4/5-*O*-methyl-L-arabinosides (2.3 g) was hydrolyzed by 1.5 *N* sulphuric acid (50 ml) at 100° C for 8 hours. The solution was neutralized with barium carbonate, filtered, and evaporated to a sirup, $[\alpha]_D^{28}$ +35°±2° (*c*, 1.5% in water). Paper chromatography of the hydrolyzate in butanone saturated with 2% aqueous ammonium hydroxide revealed components, detected by *p*-anisidine hydrochloride spray reagent (15), with R_F values of 0.32 and 0.11. Authentic samples of 2-*O*-, 3-*O*-, and 5-*O*-methyl-L-arabinose had R_F values of 0.19, 0.14, and 0.32 respectively in the same solvent system. Very weak spots with R_F values of 0.56, 0.21, and 0.55 were also detected; these latter components were probably incompletely debenzylated products.

The component of R_F 0.11 was isolated by preparative paper chromatography using the same solvent system. Elution of the appropriate areas of the chromatograms and filtration and evaporation of the eluate yielded 4-*O*-methyl-L-arabinose as a straw-colored sirup (380 mg); $[\alpha]_D^{27}$ +132°±2° (*c*, 1.0% in water).

A sample (1 mg) of this product was methylated (14), and gas–liquid partition chromatography of the reaction mixture, using the conditions described previously, showed only one component which ran the same as methyl 2,3,4-tri-*O*-methyl-α,β-L-arabinoside.

4-O-Methyl-L-arabinolactone

4-*O*-methyl-L-arabinose (100 mg) in water (3 ml) was oxidized by bromine (0.5 ml) in the presence of barium carbonate (75 mg) for 60 hours. Bromine was removed by aeration and the mixture was adjusted to pH 1.0 by addition of *N* hydrochloric acid. The resulting solution was extracted continuously with ethyl acetate for 24 hours. The extract was dried (sodium sulphate) and evaporated to yield a sirup (95.3 mg) which was distilled, b.p. (bath temperature) 130–135° C at 0.02 mm. The distillate showed carbonyl absorption in its infrared spectrum at 1725 cm^{-1} indicative of a six-membered lactone ring (16).

The change in specific rotation of this lactone in aqueous solution, $[\alpha]_D^{27}$ +19.4° (7 minutes) → 0° (100 minutes and constant), was indicative of the rapid hydrolysis characteristic of six-membered sugar–acid lactones.

4-O-Methyl-L-arabinosazone

4-*O*-Methyl-L-arabinose (60 mg) in 20% aqueous acetic acid (3 ml) was heated on a boiling-water bath for 2 hours with sodium bisulphite (50 mg) and phenylhydrazine (0.5 ml). The solution was allowed to stand overnight at room temperature and the osazone that crystallized was removed by centrifugation. The product was recrystallized from ethanol–water to a constant melting point of 176–177.5° C, $[\alpha]_D^{29}$ ±0° (*c*, 0.7% in ethanol). Anal. Calc. for $C_{18}H_{23}O_3N_4$: C, 62.96%; H, 6.75%; N, 16.32%. Found: C, 62.94%; H, 6.55%; N, 16.35%.

Methyl Glycosides of 4-O-Methyl-L-arabinose

4-*O*-Methyl-L-arabinose (100 mg) was refluxed in 4% methanolic hydrogen chloride (15 ml) for 15 hours. Acid was neutralized by Amberlite IR-45 exchange resin and the neutral solution was evaporated to a brown sirup which crystallized spontaneously.

(a) Methyl 4-O-methyl-β-L-arabinoside.—Crystallization of the mixture from ethyl acetate containing a few drops of light petroleum (b.p. 30–60° C) yielded a crop of cubic crystals (36.7 mg) which were recrystallized to a constant melting point of 112–114° C, $[\alpha]_D^{28}$ +213°±2° C (*c*, 0.93% in methanol). Anal. Calc. for $C_7H_{14}O_5$: C, 47.18%; H, 7.92%. Found: C, 47.20%; H, 7.87%.

(b) Methyl 4-O-methyl-α-L-arabinoside.—All of the mother liquors from crystallization of the β-anomer were combined and evaporated to yield a mass of sticky crystals. Recrystallization from ethyl acetate containing a higher proportion (ca. 2:1) of light petroleum (b.p. 30–60° C) yielded crystals in the form of needles, which were recrystallized to a constant melting point of 83–84° C, $[\alpha]_D^{28}$ +58°±2° (*c*, 0.93% in methanol). Anal. Calc. for $C_7H_{14}O_5$: C, 47.18%; H, 7.92%. Found: C, 47.05%; H, 7.75%.

Periodate Oxidation of Methyl 4-O-methyl-α,β-L-arabinoside

Another sample of 4-*O*-methyl-L-arabinose was methanolysed as described above. The mixture of anomeric glycosides was dried to constant weight (178 mg, 1 mmole) and dissolved in 0.0143 *M* sodium metaperiodate (100 ml). The solution was kept at 35° C and the consumption of oxidant was followed spectrophotometrically (17). Consumption of periodate reached a constant value of 0.93 mole per mole of glycoside after 24 hours. The solution was neutralized with sodium bicarbonate, saturated with sodium sulphate, and extracted continuously with ether for 42 hours. The extract was dried (sodium sulphate) and evaporated to a sirup, which was hydrolyzed by 0.5 *N* sulphuric acid (5 ml) at 97° C for 2 hours. The hydrolyzate was neutralized with barium carbonate, filtered, and potassium borohydride (200 mg) was added to the filtrate. The solution was left at room temperature overnight and Amberlite-IR-120 exchange resin was then added until gas evolution ceased. The resin was filtered off, washed thoroughly with water and methanol, and the combined filtrate and washings were evaporated to dryness under reduced pressure at 35° C. Methanol was added to the residue and the solution was again evaporated. This procedure was repeated five times to assure complete removal of boric acid. The residue was then distilled *in vacuo* (b.p. up to 120° C at 0.02 mm). A solution of the distillate and triphenylchloromethane (61.8 mg) in pyridine (5 ml) was kept at room temperature overnight and then poured into water (50 ml). The insoluble, oily product was separated by centrifugation, dried *in vacuo*, and washed through an alumina column with benzene. The eluate was evaporated to a sirupy residue which crystallized from ethanol, m.p. 161–162° C unchanged on admixture with authentic 1,3-di-*O*-trityl-2-*O*-methyl glycerol; mixed melting point with triphenylcarbinol (m.p. 162–164° C) was 133–136° C. Anal. Calc. for $C_{42}H_{38}O_3$: C, 85.39%; H, 6.48%. Found: C, 84.95%; H, 6.24%.

Preparation of 1,3-Di-O-trityl-2-O-methyl Glycerol

1,3-Di-*O*-trityl glycerol (18), m.p. 174–176° C, was methylated by methyl iodide and silver oxide to yield the corresponding 2-*O*-methyl derivative, m.p. 162–163° C, reported (19) m.p. 158.5° C. The product showed no hydroxyl absorption in the infrared and a mixed melting point with triphenylcarbinol (m.p. 162–164° C) was 133–136° C.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the assistance of F. P. Cooper with the gas–liquid chromatography. Analyses were performed by A. E. Castagne, Microanalyst, Division of Applied Biology.

THE ALKALOIDS OF LYCOPODIUM ANNOTINUM

PART V. THE STRUCTURE AND STEREOCHEMISTRY OF LYCOFOLINE[1]

F. A. L. ANET, M. AHMAD, AND N. H. KHAN
The Department of Chemistry, University of Ottawa, Ottawa, Canada

Received October 26, 1961

ABSTRACT

Lycofoline forms a monoacetyl or a diacetyl derivative, depending on the reaction conditions. Hydrogenation of lycofoline yields dihydrolycofoline. Sodium borohydride reduction of acrifoline under non-epimerizing conditions gives the known acrifolinol, but reduction in the presence of sodium hydroxide gives both acrifolinol and lycofoline. From these reactions as well as the evidence of n.m.r. spectra, lycofoline is shown to have structure IV.

The alkaloid lycofoline, $C_{16}H_{25}O_2N$, m.p. 144–145°, $[\alpha]_D$ −75°, was isolated recently by Anet and Khan (1) from *Lycopodium annotinum* L. The infrared spectrum of lycofoline indicated the presence of a double bond and at least one hydroxyl group. A C-methyl group was found by Kuhn–Roth determination and the tertiary nature of the nitrogen atom was shown by the formation of a quaternary methiodide. The present paper deals with the elucidation of the structure and stereochemistry of lycofoline.[3]

The nature of the oxygen atoms in the alkaloid was first investigated. Acetylation with acetic anhydride in pyridine solution at room temperature gave a monoacetyl derivative, $C_{18}H_{27}O_3N$, m.p. 159–160°. This compound still had a hydroxyl group, as shown by a band at 3600 cm^{-1} in the infrared spectrum. Acetylation of the second hydroxyl group was much more difficult, being incomplete even after 7 hours at 80 to 90° with the acetic anhydride – pyridine reagent. The diacetyl derivative, $C_{20}H_{29}O_4N$, m.p. 113–118°, was, however, easily separated from the monoacetyl derivative by chromatography. Thus, there are two hydroxyl groups in lycofoline, and one hydroxyl group is quite strongly hindered.

Hydrogenation of lycofoline proceeded readily in the presence of Adams' catalyst to give dihydrolycofoline, $C_{16}H_{27}O_2N$, m.p. 146–147°. This compound was isomeric but not identical with dihydroacrifolinol (2), α-dihydroannofoline (3), or deacetylfawcettiine (4).

The proton nuclear magnetic resonance (n.m.r.) spectra (5) of lycofoline and its acetyl derivatives provided key information in the structure determination of the alkaloid.

The n.m.r. spectrum of lycofoline is shown in Fig. 1. The doublet (splitting, 6 c.p.s.) at 9.02 τ of intensity corresponding to three protons confirms the presence of a C-methyl group. The position of this band shows that the C-methyl group is attached to a saturated carbon atom, and the splitting of 6 c.p.s., that this carbon bears just one hydrogen atom. The triplet (splitting, 4 c.p.s.) of relative intensity 1:2:1 at 4.71 τ corresponds to one ethylenic proton. The magnitude of the splitting shows that the grouping involved

[1]*Taken in part from the Ph.D. thesis of N. H. Khan, University of Ottawa, 1959.*

[3]*After the preparation of this paper was complete, a preliminary communication (R. H. Burnell and D. R. Taylor, Chem. & Ind. (London), 1399 (1961)) appeared in which the same conclusions were reached, but based on different evidence.*

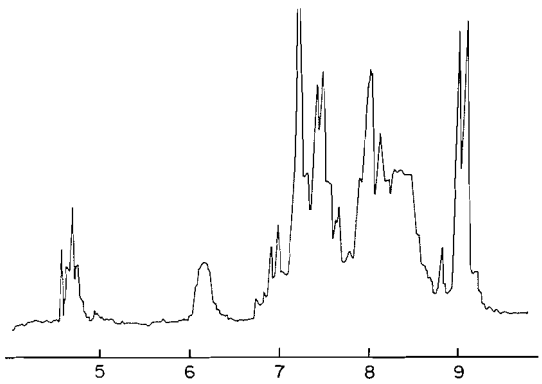

FIG. 1. Nuclear magnetic resonance spectrum of lycofoline in chloroform solution. The sharp band at lowest field is due to $C^{13}HCl_3$.

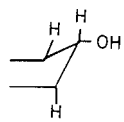
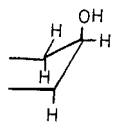
is $\begin{matrix} C \\ \diagdown \\ \quad C{=}CH{-}CH_2{-} \\ \diagup \\ C \end{matrix}$. Bands at 6.14 τ and 6.82 τ, each corresponding to one proton, can be assigned to $\diagdown CH{-}O{-}$ groups from their chemical shifts and from the effect of acetylation on the position of these bands. The protons of the hydroxyl groups corresponding to these bands probably give rise to the sharp band at 7.2 τ. No coupling is observed owing to fast exchange of the protons of hydroxyl groups caused by the basic nitrogen atom present in the alkaloid. The band at 6.82 τ is a quartet with spacings of 10.8 and 5.4 c.p.s., showing that there is coupling to two protons. The values of the coupling constants are consistent with the following arrangement about the hydroxyl group:



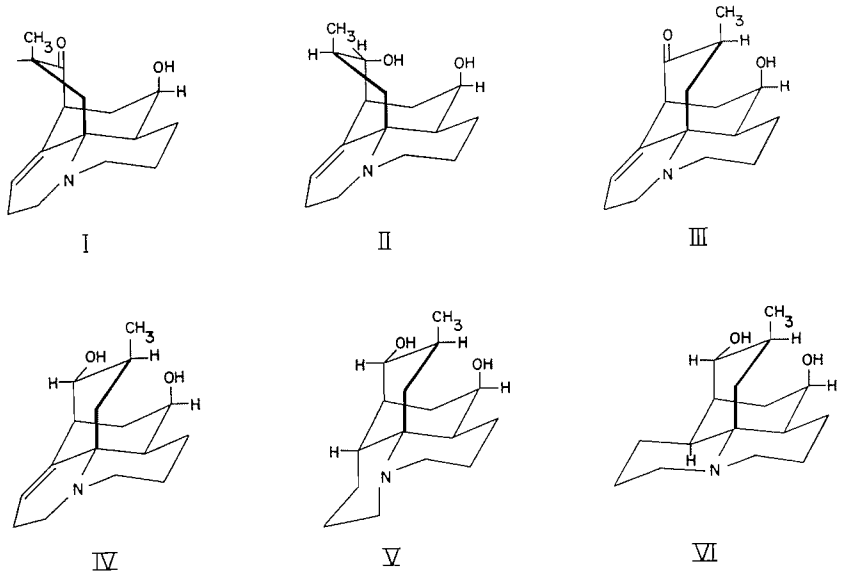
The band at 6.14 τ is quite broad, with a half-band width of 10 c.p.s., indicating coupling to three or four protons. The coupling constants cannot be very large and a structure of the following type is consistent with the evidence:



The n.m.r. spectrum of acetyllycofoline shows the same features as that of the parent alkaloid except that the quartet at 6.8 τ is shifted to 5.66 τ. This is consistent with the assignment already made that the proton responsible for this band is attached to a carbon atom bearing an equatorial, and therefore unhindered, hydroxyl group. In diacetyllycofoline, the n.m.r. spectrum is further modified by a shift on the band at 6.14 τ to 4.94 τ. In both acetylated derivatives the protons of the acetyl groups give rise to a sharp band at about 8.00 τ.

On the basis of the above evidence and of a probable structural relationship to other *Lycopodium* alkaloids the most likely structure for lycofoline was thought to be IV. In IV the axial secondary hydroxyl group is highly hindered, as required by the experimental evidence.

That lycofoline indeed has structure IV was proved in the following way. Reduction of acrifoline (I) with sodium borohydride in the presence of sodium hydroxide was



found to give a mixture of acrifolinol (2) and lycofoline. These reduction conditions have already been used to obtain deacetylfawcettiine from annofoline (4). The reaction of acrifoline with lithium aluminum hydride is known (2) to give acrifolinol. Although acrifoline is certainly unchanged by base (2, 6), it must isomerize to some slight extent to give an equilibrium amount of III. The ketone group in acrifoline, like that of annofoline, is highly hindered and therefore undergoes reduction with metal hydrides to give an axial alcohol, acrifolinol (II). This is also consistent with the fact that reduction of acrifoline with lithium and alcohol in liquid ammonia gives a different alcohol (6), in which the new hydroxyl group is presumably equatorial.

In III the carbonyl group is unhindered, and therefore hydride reduction should give the equatorial alcohol IV. In fact, this reduction product is identical with lycofoline.

Since dihydrolycofoline is not identical with deacetylfawcettiine (V), it must have structure VI. Acetyl derivatives of lycofoline occur in *L. fawcettii* (7), but have not been found as yet in *L. annotinum*.

EXPERIMENTAL

Infrared spectra were taken on a Perkin–Elmer Infracord instrument with carbon tetrachloride as the solvent and 1-mm-path-length cells. Paper chromatography was carried out on buffered paper with wet butanol as the developing agent. The n.m.r. spectra were measured on a Varian V-4302 high-resolution spectrometer at a frequency of 60 Mc/sec. Tetramethylsilane was used as an internal standard and chemical shifts are given on the τ scale of Tiers (5) (i.e. in p.p.m. with tetramethylsilane at 10.00). The chemical shifts obtained were not particularly accurate and may be in error by as much as 0.1 τ. The coupling constants should be accurate to 1 c.p.s.

Acetyllycofoline

A mixture of lycofoline (50 mg), pyridine (0.3 ml), and acetic anhydride (0.3 ml) was allowed to stand at room temperature for 5 hours. Methanol was added and the solution evaporated to dryness in a stream of nitrogen. Sublimation of the residue at 110–120° at 0.03 mm gave 45 mg of a compound giving a single spot on paper chromatography (pH 6.0) (R_f 0.66; R_f of lycofoline 0.25). The sublimate was crystallized from acetone–pentane to give 27 mg of acetyllycofoline, m.p. 159–160°, pK_a (50% aqueous ethanol) 8.7. (Found: C, 71.03; H, 8.86. Calc. for $C_{18}H_{27}O_3N$: C, 70.79; H, 8.91%.) In the infrared the compound had bands at 1740 and 3600 cm^{-1}.

Diacetyllycofoline

A mixture of lycofoline (103 mg), pyridine (1 ml), and acetic anhydride (1 ml) was heated at 80–90° for 7 hours. The reaction was worked up as described above to give an oily distillate (117 mg) which gave two spots on paper chromatography (pH 6.0) (R_f 0.61, 0.83; R_f acetyllycofoline 0.61). About two thirds of the product was the required diacetyl derivative. Chromatography of the product on alumina (25 g, deactivated with 5% water) resulted in the separation of diacetyllycofoline, which was eluted first with benzene, from acetyllycofoline, which was eluted with 4:1 benzene–chloroform. The diacetyllycofoline was sublimed at 110–120° at 0.03 mm and then recrystallized from ether and finally resublimed to give 12 mg of crystals, m.p. 113–118°. (Found: C, 68.85; H, 8.13. Calc. for $C_{20}H_{29}O_4N$: C, 69.13; H, 8.41%.) The infrared spectrum had a band at 1740 cm^{-1}, but no hydroxyl band.

Dihydrolycofoline

A mixture of lycofoline (35 mg), ethanol (6 ml), and Adams' catalyst (18 mg) was shaken in an atmosphere of hydrogen for 8 hours. The catalyst was removed and the solvent evaporated. Sublimation of the residue (130–140° at 0.03 mm) gave 30 mg of product which gave one main spot (R_f 0.37; R_f of lycofoline 0.60) on paper chromatography (pH 7.0). Traces of other compounds were also present (R_f 0.21, 0.77). The product was chromatographed on alumina (5 g, deactivated with 5% water). Elution with 2:3 benzene–chloroform gave a product which, after three sublimations, amounted to 12 mg, m.p. 146–147°. (Found: C, 72.12; H, 9.99. Calc. for $C_{16}H_{27}O_2N$: C, 72.41; H, 10.26%.)

Reduction of Acrifoline Hydrobromide with $NaBH_4$ in the Presence of Sodium Hydroxide

Acrifoline hydrobromide (205 mg), ethanolic sodium hydroxide solution (6.1 g in 150 ml), and sodium borohydride (0.712 g) were refluxed for 2 hours. Excess of sodium borohydride was decomposed with acetic acid and most of the ethanol was evaporated. The residue was dissolved in water, made basic with dilute sodium hydroxide solution, and extracted with chloroform. The chloroform extract was evaporated to give the crude reaction product. A paper chromatogram (pH 7.0) of this product gave two spots, R_f 0.50 (lycofoline, minor component) and 0.73 (acrifolinol, major component).

Since the two compounds present in the crude reaction product were well separated on the chromatogram, isolation of them was made by preparative paper chromatography on Whatman No. 3MM paper buffered to pH 7 and developed with butanol saturated with water.

The strip corresponding to the compound with the lower R_f value was cut from the rest of the paper and was eluted with 1% hydrochloric acid. The acid solution was well shaken with chloroform and the chloroform layer was rejected. The acid solution was then made basic with dilute sodium hydroxide solution and the alkaloidal contents were extracted with chloroform. The product obtained on removal of chloroform from the extract was sublimed at 105–115° under vacuum.

The sublimed product (25 mg, m.p. 140–144°) was crystallized from ether, m.p. 143–145°. A mixed melting point with an authentic sample of lycofoline did not show any depression. The infrared spectrum of the product in Nujol mull was identical with that of lycofoline. The product had $[\alpha]_D$ −74.5° (c, 2.0 in ethanol).

THE REACTION OF NITROGEN ATOMS WITH HYDROGEN ATOMS[1]

C. MAVROYANNIS[2] AND C. A. WINKLER
The Upper Atmosphere Chemistry Research Group, McGill University, Montreal, Que.

Received August 18, 1961

ABSTRACT

The reaction has been studied in a fast-flow system by the addition of atomic hydrogen to active nitrogen. Hydrogen atom concentrations were estimated from the maximum destruction of hydrogen bromide in the atomic hydrogen stream. The nitrogen atom consumption, in the reaction mixture, was determined by addition of nitric oxide at different positions along the reaction tube. A lower limit of $4.87 \pm 0.8 \times 10^{14}$ cc^{2}mole^{-2}sec^{-1} was derived for the rate constant of the reaction of nitrogen atoms with hydrogen atoms, over the pressure range 2.5 to 4.5 mm, in an unheated reaction tube, poisoned with phosphoric acid. No reaction between nitrogen atoms and molecular hydrogen was observed, even at 350° C.

INTRODUCTION

A good deal of recent work has provided evidence for the existence, in the gas phase, of radicals consisting of nitrogen and hydrogen, e.g., NH, NH_2, N_2H_2, N_2H_3. Most of these have been identified spectroscopically from studies on such substances as hydrazoic acid, hydrazine, and ammonia (1, 2, 3). The failure of many investigators (4, 5) to find NH radicals, by mass spectrometry, in the dissociation of hydrazoic acid, has been attributed to the ability of the NH radical to abstract hydrogen atoms from chemically stable molecules, without the need for any activation energy. On the other hand, the presence of atomic nitrogen and hydrogen in the reaction products has suggested that nitrogen atoms are more or less passive toward bound hydrogen (4). From chemical studies, Winkler and his co-workers (6, 7) have similarly concluded that nitrogen atoms do not abstract hydrogen atoms in their attack on hydrocarbons or ammonia.

An attempt has been made in the present investigation to establish the kinetics and mechanism of the reaction that occurs in a mixture of nitrogen and hydrogen atoms.

EXPERIMENTAL

The apparatus was a fast-flow system, similar to that used in other studies in this laboratory. Microwave generators (Raytheon 125-watt diathermy unit, operating at a frequency of 2400 Mc/sec) were used to produce atomic nitrogen in one, and atomic hydrogen in a second, quartz discharge tube, each of which was of 12-mm i.d., and 10 cm long. The reaction vessel was a pyrex tube of 20-mm i.d., and 30 cm long, poisoned with 20% phosphoric acid. Five small inlets were placed along the reaction tube at different distances.

Nitrogen and hydrogen, after passage through liquid air traps, were passed into their respective discharge tubes and the emerging gas streams, containing nitrogen and hydrogen atoms, were blended in the reaction vessel. The nitrogen atom consumption, in the reaction mixture, was determined by addition of pure nitric oxide at subsequent jet positions along the reaction tube.

Nitric oxide reacts with hydrogen atoms by the termolecular mechanism (8, 9)

$$NO + H + M \rightarrow HNO + M$$

followed by

$$HNO + H \rightarrow H_2 + NO.$$

Hence, destruction of nitric oxide should occur only as a result of attack by active nitrogen, which permits the nitric oxide titration (10, 11) to be used for estimation of the nitrogen atom flow rate in the presence of hydrogen atoms.

[2]*Holder of a "Cominco" Fellowship, 1959–60, and a National Research Council Studentship, 1960–61.*

Hydrogen atom concentrations at the point of mixing were determined, for the same pressure and flow conditions that prevailed during the reaction, but without the nitrogen discharge in operation, by introducing excess hydrogen bromide, and estimating the maximum amount of hydrogen bromide consumed by hydrogen atoms (12). Hydrogen bromide flow rates, and unreacted hydrogen bromide, were estimated by condensing it in a removable trap containing standard NaOH solution, and back titrating the excess alkali with standard acid.

All the experiments were made in an unheated reaction tube, with the one exception that the reaction of nitrogen atoms with molecular hydrogen was studied at temperatures up to 350° C.

RESULTS AND DISCUSSION

A series of experiments was first made in which molecular hydrogen was added to active nitrogen. No product was found from this reaction, and the afterglow intensity was unaffected (except for a possible dilution effect), even at high flow rates of molecular hydrogen, and at temperatures up to 350° C. This observation agrees with that from earlier studies by Kistiakowsky and Volpi (13) and Steiner (14), but is contrary to the results of Varney (15), who found small amounts of ammonia.

The reaction of nitrogen atoms with hydrogen atoms appeared to produce only small amounts of a basic substance, estimated by titration with standard acid. This product was assumed to be ammonia, since hydrazine, if formed, should react rapidly with either nitrogen or hydrogen atoms, which were present in excess in the gas stream (16). Moreover, earlier studies indicate that hydrazine is not a significant product of the reaction (1, 17). The data for ammonia production, in Table I, are in substantial agreement with earlier observations (1, 17).

TABLE I

Ammonia produced in the reaction of nitrogen atoms with hydrogen atoms
(Unheated reaction tube poisoned with phosphoric acid)

Nitrogen pressure, mm	Hydrogen pressure, mm	Total pressure, mm	Nitrogen atom flow rate, mole/sec×10⁶	Hydrogen atom flow rate, mole/sec×10⁶	Ammonia produced, mole/sec×10⁶
2.0	0.50	2.50	2.84	5.2	—
2.5	0.50	3.00	3.25	5.2	—
2.0	0.75	2.75	2.84	7.1	0.054
1.5	1.00	2.50	1.60	8.6	0.013
1.0	1.00	2.00	0.73	8.6	0.027
2.0	1.00	3.00	2.84	8.6	0.027
3.0	1.00	4.00	4.34	8.6	0.027
3.5	1.00	4.50	5.29	8.6	0.027

The following energetically favorable elementary reactions may be involved in a mixture of nitrogen atoms and hydrogen atoms:

	ΔH (kcal/mole)*	
$N + H + M \rightarrow NH + M$	− 85.0	[1]
$NH + N \rightarrow N_2 + H$	−140.0	[2]
$NH + NH \rightarrow N_2 + H_2$	−158.0	[3]
$NH + NH + M \rightarrow N_2H_2 + M$	−104.0±6.0	[4]
$NH + H \rightarrow H_2 + N$	− 18.0	[5]
$NH + H + M \rightarrow NH_2 + M$	− 88.0	[6]
$NH + H_2 + M \rightarrow NH_3 + M$	− 89.0	[7]
$NH_2 + H + M \rightarrow NH_3 + M$	−104.0	[8]
$NH_2 + H \rightarrow NH + H_2$	− 15.0	[9]

**The heats of reaction are approximate, based on the data D_{N-N} = 225 kcal, D_{H-H} = 103 kcal, D_{N-H} = 85 kcal (18), D_{H-NH} = 88 kcal (19), D_{H-NH_2} = 104 kcal (20), D_{HN-NH} = 104±6 kcal (4); but they do indicate the energetics of the reactions considered.*

$NH_2 + NH_2 \rightarrow N_2 + 2H_2$	-85.0	[10]
$NH_2 + N \rightarrow N_2 + H_2$	-155.0	[11]
$NH_2 + H_2 \rightarrow NH_3 + H$	-1.0	[12]
$NH_2 + NH_2 + M \rightarrow N_2H_4 + M$	-68.0	[13]
$N + N + M \rightarrow N_2 + M$	-225.0	[14]
$N + \text{wall} \rightarrow \frac{1}{2}N_2 + \text{wall}$		[15]
$H + H + M \rightarrow H_2 + M$	-103.0	[16]
$H + \text{wall} \rightarrow \frac{1}{2}H_2 + \text{wall}$		[17]

The NH_2 can be formed only by reaction [6] which, followed by reactions [8] and [12], would lead to the formation of ammonia. The very small amount of ammonia produced (Table I) indicates that NH_2 exists in the gaseous mixture only in small amounts, in accordance with its formation from ternary collisions (reaction [6]), and its destruction by the probable reactions [9], [10], [11], and [13]. For a kinetic treatment, reaction [6], and the other termolecular reactions [4], [7], and [8], may be neglected in comparison with the bimolecular reactions [2], [3], and [5]. Reactions [9] to [13], inclusive, may then also be neglected, since they depend upon reaction [6].

From reactions [1], [2], [5], [13], and [15],

$$-d(\mathrm{N})/dt = k_1(\mathrm{M})(\mathrm{H})(\mathrm{N}) + k_2(\mathrm{NH})(\mathrm{N}) - k_5(\mathrm{NH})(\mathrm{H}) + k_{14}(\mathrm{M})(\mathrm{N})^2 + k_{15}(\mathrm{N}). \quad [18]$$

Reaction [2], the attack of NH by N, is probably very fast, since it appears to be quite analogous to the reaction of NO with N, for which a rate constant between 10^{-10} and 10^{-11} cc molecule^{-1}sec^{-1} (21, 22) has been found in recent investigations. No similar basis seems to be available for estimating the rate of reaction [5]. It is quite conceivable that it, too, might be a fast reaction, but there is no reason to suppose that its rate would exceed that of reaction [2], under the conditions of the present experiments.

If it is assumed that the rates of reactions [2] and [5] are equal,

$$-d(\mathrm{N})/dt = k_1(\mathrm{M})(\mathrm{H})(\mathrm{N}) + k_{14}(\mathrm{M})(\mathrm{N})^2 + k_{15}(\mathrm{N}). \quad [19]$$

On the other hand, if it is assumed that reaction [5] may be neglected relative to reaction [2], application of the steady-state approximation to NH yields

$$d(\mathrm{NH})/dt = k_1(\mathrm{M})(\mathrm{H})(\mathrm{N}) - k_2(\mathrm{NH})(\mathrm{N}) - k_3(\mathrm{NH})^2 = 0.$$

Since the NH concentration is expected to be small (the half-life of NH is about 9×10^{-4} second (1), compared with a value of approximately 10^{-2} second for CH and CH_2), the term $k_3(\mathrm{NH})^2$ may be neglected. Then

$$k_1(\mathrm{M})(\mathrm{H})(\mathrm{N}) = k_2(\mathrm{NH})(\mathrm{N})$$

and

$$-d(\mathrm{N})/dt = 2k_1(\mathrm{M})(\mathrm{H})(\mathrm{N}) + k_{14}(\mathrm{M})(\mathrm{N})^2 + k_{15}(\mathrm{N}). \quad [20]$$

Calculation from equation [20] should therefore give a lower limit for the value of k_1, which, however, is not likely to be in error by more than a factor of two.

If the wall recombination of nitrogen atoms is neglected, since the reaction of nitrogen atoms with hydrogen atoms has been studied at pressures higher than 2.5 mm (23, 24, 25), the rate expression is given by

$$-d(\mathrm{N})/dt = 2k_1(\mathrm{M})(\mathrm{H})(\mathrm{N}) + k_{14}(\mathrm{M})(\mathrm{N})^2.$$

Upon integrating,

$$\ln \frac{(\mathrm{N})_0}{(\mathrm{N})_t} = 2k_1(\mathrm{M}) \int_0^t (\mathrm{H})dt + k_{14}(\mathrm{M}) \int_0^t (\mathrm{N})dt. \quad [21]$$

The rate expression for the decay of hydrogen atoms in reactions [16] and [17] is

$$-d(\mathrm{H})/dt = k_{16}(\mathrm{M})(\mathrm{H})^2+k_{17}(\mathrm{H}).$$

This integrates to

$$\ln \frac{(\mathrm{H})_0}{(\mathrm{H})_t}-\ln \frac{[k_{17}+k_{16}(\mathrm{M})(\mathrm{H})_0]}{[k_{17}+k_{16}(\mathrm{M})(\mathrm{H})_t]} = k_{17}t$$

or

$$(\mathrm{H})_t = \frac{k_{17}}{k_{16}(\mathrm{M})} \frac{1}{\left[1+\frac{k_{17}}{k_{16}(\mathrm{M})(\mathrm{H})_0}\right]e^{k_{17}t}-1}.$$

Hence,

$$\int_0^t (\mathrm{H})_t dt = \frac{1}{k_{16}(\mathrm{M})} \ln \left[1+\frac{k_{16}(\mathrm{M})(\mathrm{H})_0}{k_{17}}(1-e^{-k_{17}t})\right]. \qquad [22]$$

Similarly, the nitrogen atom concentration at time t (reaction [14]) is given by

$$(\mathrm{N})_t = \frac{(\mathrm{N})_0}{k_{14}(\mathrm{M})(\mathrm{N})_0 t+1}$$

or

$$(\mathrm{N})_t dt = \frac{(\mathrm{N})_0 dt}{k_{14}(\mathrm{M})(\mathrm{N})_0 t+1}.$$

Upon integrating,

$$\int_0^t (\mathrm{N})_t dt = \frac{1}{k_{14}(\mathrm{M})} \int_0^t \frac{d[k_{14}(\mathrm{M})(\mathrm{N})_0 t+1]}{k_{14}(\mathrm{M})(\mathrm{N})_0 t+1} = \frac{1}{k_{14}(\mathrm{M})} \ln [k_{14}(\mathrm{M})(\mathrm{N})_0 t+1]. \qquad [23]$$

Substitution of [22] and [23] in equation [21] yields the expression

$$k_1 = \frac{k_{16}}{2} \frac{\log \frac{(\mathrm{N})_0}{(\mathrm{N})_t}-\log [1+k_{14}(\mathrm{M})(\mathrm{N})_0 t]}{\log \left[1+\frac{k_{16}(\mathrm{M})(\mathrm{H})_0}{k_{17}}(1-e^{-k_{17}t})\right]}, \qquad [24]$$

where $(\mathrm{N})_0$ = initial nitrogen atom concentration, $(\mathrm{H})_0$ = initial hydrogen atom concentration, $(\mathrm{N})_t$ = nitrogen atom concentration at time t, t = reaction time. The rate constant of reaction [16] was taken as $k_{16} = 10^{16}$ cc^{2}mole^{-2}sec^{-1} (26, 27) with $\gamma = 2\times10^{-5}$ (28), which, for the conditions used, corresponds to $k_{17} = 2.5$ sec^{-1}. For the rate constant of reaction [14], the value of $k_{14} = 1.04\times10^{16}$ cc^{2}mole^{-2}sec^{-1} (25) was used.

Rate constants for the reaction of nitrogen atoms with hydrogen atoms under various conditions, derived from equation [24], on the assumption that atoms and molecules are equally effective as third bodies, are recorded in Table II. The average value of k_1 may be taken as

$$k_1 = 4.87\pm0.8\times10^{14} \text{ cc}^2\text{mole}^{-2}\text{sec}^{-1}$$

over the range of pressures from 2.5 to 4.5 mm, in an unheated reaction tube poisoned with phosphoric acid.

											Average $k_1 = 4.45$
											Average $k_1 = 4.87 \pm 0.8 \times 10^{14}$ $cc^2 mole^{-2} sec^{-1}$

The number of termolecular collisions may be calculated, using the collision model, and assuming the mechanism of the reaction to be

$$\begin{aligned} N + H &\rightleftarrows NH^* \\ NH^* + M &\rightarrow NH + M, \end{aligned}$$

as given by

$$Z_{ter} = Z_{NH} Z_{NH^*.M} \tau_{NH^*},$$

where Z_{NH} and $Z_{NH^*.M}$ are the binary collision frequencies between N and H and NH* and M respectively, and τ_{NH^*} is the mean life time of the complex NH*. For $T = 300°$ K; M = N_2; collision diameters $\sigma_N = 2.95$ Å, $\sigma_H = 2.4$ Å, $\sigma_{NH} = 2.68$ Å; and $\tau_{NH^*} = 10^{-13}$ second,

$$Z_{ter} = 1.2 \times 10^{16} \text{ cc}^2\text{mole}^{-2}\text{sec}^{-1},$$

and for M = H_2, and $\sigma_{H_2} = 2.7$ Å,

$$Z_{ter} = 9.2 \times 10^{15} \text{ cc}^2\text{mole}^{-2}\text{sec}^{-1}.$$

Thus, the reaction of nitrogen atoms with hydrogen atoms has a probability factor of 4×10^{-2} or 5×10^{-2} depending on whether nitrogen or hydrogen is considered as a third body.

The value of k_1 reported here for the three-body interaction of nitrogen and hydrogen atoms is lower than that found for many atom-combination reactions, but, within experimental error, it probably should be regarded as comparable with the value of 1.83×10^{15} cc^{2}mole^{-2}sec^{-1} found recently for the rate constant of the analogous reaction of nitrogen and oxygen atoms (25), and with the most recent value, 1.0×10^{15} cc^{2}mole^{-2} sec^{-1}, for the rate constant of the O + O + M reaction (29).

THE KINETICS OF THE DECOMPOSITION AND SYNTHESIS OF SOME DITHIOCARBAMATES[1]

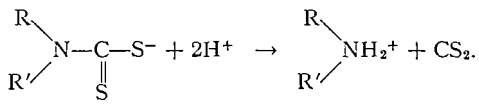
D. M. MILLER AND R. A. LATIMER[2]
The Pesticide Research Institute, Canada Department of Agriculture, London, Ontario
Received July 31, 1961

ABSTRACT

Rate constants, activation energies, and dissociation constants were determined in a kinetic study of the synthesis and decomposition of a number of *N*-substituted dithiocarbamates. These data combined with certain spectral evidence are evaluated and reaction mechanisms suggested.

INTRODUCTION

Studies on the acid-induced decomposition of a number of dithiocarbamates having the general structure I have been reported by Bode (1) and Zahradnik and Zuman (2). Bode made kinetic studies based on the assumption that decomposition occurs as the single reaction

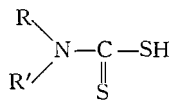


I

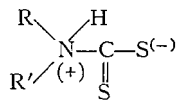
Zahradnik and Zuman, on the other hand, showed that the dithiocarbamate ion (A) first combines with a hydrogen ion, giving the protonated form HA, which then decomposes to CS_2 (C) and the corresponding amine (B) thus:

$$H^+ + A \rightleftharpoons HA \rightarrow C + B \overset{+H^+}{\rightleftharpoons} BH^+,$$

so that 2 moles of acid are consumed per mole of dithiocarbamate decomposing. They further suggest two possible structures (II and III) for the protonated form of which, they argue, III is the more likely. These conclusions are re-examined in the present work in the light of new information obtained through a study of a number of compounds, some of which have not been investigated previously.



II



III

EXPERIMENTAL

Materials

The *N*-[β-aminoethyl]-dithiocarbamate inner salt was synthesized by the method of McKay and Hatton (3), while standard methods were used in the synthesis of all other dithiocarbamates.* All these compounds were subjected to frequent recrystallizations while under study. The remaining chemicals used were reagent grade or of equivalent purity.

[1]*This paper constitutes part of a thesis submitted by R. A. Latimer in partial fulfillment of the Ph.D. degree (1959) from the University of Western Ontario, London, Ontario.*
[2]*Present address: John Labatt Ltd., Simcoe St., London, Ontario.*
**The authors wish to thank Dr. G. D. Thorn of this institute, who provided these compounds.*

Methods

(a) Decomposition Reaction

The dithiocarbamate in crystalline form was dropped into a well-stirred, deaerated 500-ml volume of distilled water, previously adjusted to the proper pH, in which it dissolved rapidly, initiating the reaction. The reaction vessel was sealed against the entry of air and a slow stream of nitrogen bubbled through the solution removed the CS_2 produced. A Radiometer titrator (available from Canadian Laboratory Supplies Ltd., Toronto, Ont.) was used to maintain the pH which otherwise would have risen due to the consumption of hydrogen ions. The titrator added standard HCl from a recording burette (4), which provided a record of the course of the reaction.

(b) Synthesis

The same apparatus was used in the study of the synthesis reactions with the following changes in procedure. Nitrogen saturated with CS_2 vapor was bubbled through distilled water at the proper pH and temperature until a saturated solution was attained. The reaction was started with the addition of a solution of the appropriate amine hydrochloride and the pH maintained by the titrator with the addition of standard NaOH solution. Samples of the solution were removed for CS_2 analysis (5) both at the beginning and end of the reaction to establish the concentration of CS_2.

All reactions were studied at a constant temperature (±0.05° C) and most measurements were made within the concentration range of 0.5–1.0 mM. In some cases, however, 10 times this value was used without noticeably altering the kinetics.

(c) Ultraviolet Spectra

Three ultraviolet spectra were obtained as follows using a Beckman D.K.1 recording spectrophotometer:

(1) The spectrum of the *N-methyldithiocarbamate* ion was obtained on a 6×10^{-5} M solution of the sodium salt in distilled water.

(2) The spectrum of the *protonated form* of the same ion was obtained by dissolving the salt in water to a concentration of 6×10^{-3} M and diluting with 100 volumes of 0.1 N HCl, being careful to exclude oxygen from all solutions. Other measurements were made in 1 and 6 N HCl, with no change in the shape of the spectrum.

(3) The *methyl ester* of N-methyldithiocarbamate was dissolved in alcohol to a concentration of 6×10^{-2} M and diluted with 1000 volumes of either water, 0.1 N HCl, or N HCl, giving similar spectra in all three solvents.

Following dilution by the appropriate solvent the solution in each case was introduced into the spectrometer as quickly as possible and the spectrum recorded. This was followed by further recordings at different time intervals to ascertain the rate of dissociation, if any. Only the acid solution of the salt decomposed, causing a drop in the height of the peaks with no change in the shape of the spectrum, provided oxygen was rigorously excluded. Plotting the optical density of the highest peak against time and extrapolating to zero time provided an estimate of the drop in absorption due to decomposition.

RESULTS AND CALCULATIONS

Decomposition of the Alkyldithiocarbamates

Figure 1 is a reproduction of an actual record of acid consumption against time resulting from the decomposition of sodium N-methyldithiocarbamate. Here Q_0 is the initial uptake required to satisfy the equilibrium

$$A + H^+ \rightleftharpoons HA, \qquad K_a = \frac{[H^+][A]}{[HA]}. \qquad [1]$$

For a first-order reaction,

$$dT/dt = k[HA]V, \qquad [2]$$

where V is the volume of solution, T is the total number of moles of dithiocarbamate present at any time t, and k is the first-order rate constant. Since $T/V = [A]+[HA]$ then [1] can be rearranged to give

$$[HA] = \frac{[H^+]}{K_a+[H^+]}\cdot\frac{T}{V} = \alpha\frac{T}{V}. \qquad [3]$$

Substitution of [3] into [2] followed by integration gives for the first-order rate constant,

$$k = \frac{2.303}{\alpha t}\cdot\log\frac{T_0}{T}, \qquad [4]$$

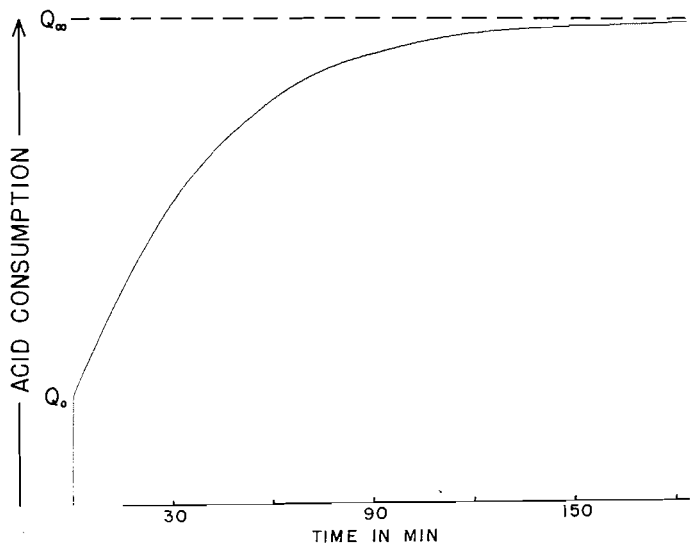


FIG. 1. Titration of sodium methyldithiocarbamate at pH 3.0 and 25° C.

where T_0 is the initial number of moles of dithiocarbamate. The amount of dithiocarbamate which has decomposed at time t will be T_0-T and the amount of acid consumed by this decomposition will be $2(T_0-T)$. Furthermore, some acid will have been consumed in the formation of the protonated form and since this equals $[HA]V$, the total acid consumption to time t will be

$$Q = 2(T_0-T)+[HA]V. \qquad [5]$$

During any given run, since the pH is a constant, α will be a constant. Thus the ratio $[HA]V/T$ at any time will be equal to α, and therefore to its original value $[HA]_0V/T_0$. The initial uptake of acid Q_0 results from the production of sufficient protonated form to satisfy [1] so that $Q_0 = [HA]_0V$. Furthermore, when the reaction is complete all the dithiocarbamate is decomposed, consuming 2 moles of acid per mole of dithiocarbamate initially present or $Q_\infty = 2T_0$. Thus we have $[HA]V = 2Q_0T/Q_\infty$ and $T_0 = Q_\infty/2$. These two expressions may be substituted into [5] to solve for T, which is then introduced into [4] to give [6], an equation for the rate constant in terms of the measurable values Q_0, Q, and Q_∞:

$$k = \frac{2.303}{\alpha t}\log\frac{Q_\infty-Q_0}{Q_\infty-Q}. \qquad [6]$$

To obtain the value of α it is necessary to determine K_a for each compound. This may be obtained directly from the graphs since

$$K_a = \frac{[H^+][A]_0}{[HA]_0} = \frac{Q_\infty-2Q_0}{2Q_0}\cdot[H^+]. \qquad [7]$$

These measurements were made at a number of pH's for each compound and the K_a values averaged. With this information, equation [6] could be applied to recordings of acid consumption at different pH's, allowing the rate constant to be determined at a

number of different time values. All these values were averaged for each compound and standard deviations calculated to provide the information listed in Table I. The activation energies were obtained in the usual way from measurements made at various temperatures.

TABLE I

Constants involved in the decomposition of some *N*-substituted derivatives of dithiocarbamic acid

Derivative	Dissociation constant K_a at 25° C (mole l^{-1})	Rate constant k at 25° C (min^{-1})	Activation energy (kcal)
Methyl	$(1.3\pm0.1)\times10^{-3}$	$(2.5\pm0.4)\times10^{-2}$	15±2
Ethyl	$(9.1\pm0.9)\times10^{-4}$	$(2.4\pm0.2)\times10^{-2}$	19±1
n-Propyl	$(7.9\pm0.8)\times10^{-4}$	$(2.0\pm0.2)\times10^{-2}$	16±3
Dimethyl	$(4.4\pm1.3)\times10^{-4}$	3.1±0.3	18±2
Diethyl	$(2.1\pm0.7)\times10^{-4}$	4.8±0.4	20±1
Di-*n*-propyl	$(1.9\pm0.3)\times10^{-4}$	3.1±0.3	19±3
β-Aminoethyl	$\sim10^{-1}$	$(k/K_a = 16\pm4)$	

Synthesis of the Alkyldithiocarbamates

The synthesis reactions which occur at high pH may be expressed as

$$BH^+ \rightleftharpoons B + H^+ \qquad [8a]$$

$$B + C \rightarrow HA \qquad [8b]$$

$$HA \rightleftharpoons A + H^+. \qquad [8c]$$

Equation [8*a*] is an equilibrium determined by the dissociation constant K_b of the amine and occurs virtually instantaneously as does [8*c*]. Thus we may shorten the over-all reaction to

$$B + C \rightarrow A + H^+. \qquad [9]$$

K_b for the various amines is available in the literature (6, 7). From them may be calculated the concentration of the free amine in each case as

$$[B] = \frac{[OH^-]}{K_b+[OH^-]}\cdot\frac{T_b}{V} = \alpha_b\frac{T_b}{V},$$

where T_b is the total amount of amine present. Reaction [9] is actually second order but since [C] is held constant it is reduced to first order and as in the previous section we may derive the expression

$$k_b = \frac{2.303}{\alpha_b[C]t}\log\frac{Q_\infty - Q_0}{Q_\infty - Q}, \qquad [10]$$

where Q_∞, Q_0, and Q now refer to quantities of base added.

As before, the rate constants were determined at a number of different time values from graphs recorded at a number of pH's and the values averaged to give those recorded in Table II.

Decomposition of β-Aminoethyldithiocarbamate and Disodium Ethylene Bisdithiocarbamate (Nabam)

The decomposition of Nabam ($NaS(S)CNHCH_2CH_2NHC(S)SNa$) is complicated by the fact that the two dithiocarbamate groups are present, resulting in the possible existence of two protonated forms (HA and H_2A) and in the formation of a monodithiocarbamate intermediate (the β-aminoethyl derivative) which itself has two forms (referred

TABLE II

Constants involved in the synthesis of some *N*-substituted derivatives of dithiocarbamic acid

Derivative	Rate constant k (l. mole^{-1}min^{-1})	Activation energy (kcal)
Methyl	14±3	19±6
Dimethyl	22±3	17±6
Diethyl	16±3	
Di-*n*-propyl	14±4	

to below as M and HM). Thus, before a reaction scheme for the decomposition of Nabam can be written the dissociation constants K_1 and K_2 for Nabam and K_3 for the β-aminoethyl compound must be determined, so that we may calculate the concentrations of the various forms from equations [11], [12], and [13].

$$[H_2A] = \alpha\frac{T}{V}, \text{ where } \alpha = \frac{[H^+]^2}{[H^+]^2+K_1[H^+]+K_1K_2}, \quad [11]$$

$$[HA] = \beta\frac{T}{V}, \text{ where } \beta = \frac{K_1[H^+]}{[H^+]^2+K_1[H^+]+K_1K_2}, \quad [12]$$

$$[HM] = \gamma\frac{T_M}{V}, \quad \text{where } \gamma = \frac{[H^+]}{[H^+]+K_3}, \quad [13]$$

where T (and later T_0) refer to the total amount of the various Nabam forms and T_M is the amount of intermediate (monodithiocarbamate) present.

From titration curves of Nabam at various pH's, Q_0 and Q_∞ were measured, and since

$$Q_0 = 2[H_2A]V+[HA]V = 2\alpha T+\beta T$$

and

$$T_0 = Q_\infty/4,$$

then by substitution we obtain

$$\frac{Q_0}{T_0} = \frac{4Q_0}{Q_\infty} = \frac{[H^+](2[H^+]+K_1)}{[H^+]^2+K_1[H^+]+K_1K_2}. \quad [14]$$

Using the values of $4Q_0/Q_\infty$ obtained as a function of $[H^+]$, K_1 and K_2 were obtained from [14] employing a modification of Hartley's statistical method as outlined by Williams (8).* These values are listed in Table III.

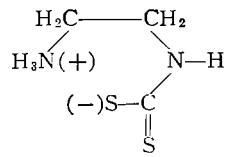
TABLE III

Constants involved in the decomposition of ethylenebisdithiocarbamic acid determined at 25° C

Dissociation constants (mole l^{-1})	Rate constants (min^{-1})
$K_1 = (5.0\pm1)\times10^{-3}$	$k_1 = (2.3\pm0.5)\times10^{-3}$
$K_2 = (2.5\pm0.5)\times10^{-4}$	$k_2 = (3.7\pm0.7)\times10^{-2}$

The authors are indebted to Mrs. P. M. Morse, Statistical Research Service, Canada Department of Agriculture, Ottawa, for assistance in these calculations.

The determination of K_3 was attempted using the methods previously described for the alkyl derivatives but it was found that even at pH 2, Q_0 was small, indicating a relatively large value for K_3, which could only be estimated as approximately 10^{-1} mole l^{-1}. This high value is probably due to stabilization of the ionized form as a cyclic inner salt (IV).

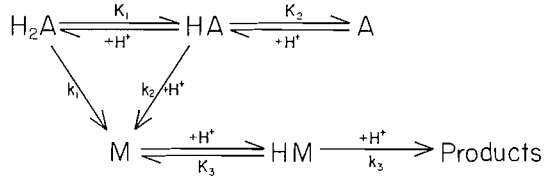


IV

Since K_3 is large relative to the range of $[H^+]$ used in this study (pH 2.5 to 4.0) we may let $\gamma = [H^+]/K_3$. Furthermore, since K_3 is not known accurately only the ratio $R = k_3/K_3$ (where k_3 is the decomposition rate constant) can be obtained employing instead of [6] expression [15] in which R is a constant independent of $[H^+]$. A value for R averaged from measurements made over a range of $[H^+]$ is given in Table I.

$$R = \frac{2.303}{[H^+]t} \log \frac{Q_\infty - Q_0}{Q_\infty - Q} \qquad [15]$$

Turning again to Nabam we may write for the over-all decomposition the following:



This may be simplified to

$$A \xrightarrow[+2H^+]{k} M \xrightarrow[+2H^+]{k'} \text{products}, \qquad [16]$$

where $k = \alpha k_1 + \beta k_2$ and $k' = \gamma k_3 = [H^+].R$.

The total acid consumption is given by $Q = Q_A + Q_M$, where Q_A is the acid consumed during the first decomposition step in [16] and Q_M acid consumption during the second. These in turn can be seen to be

$$Q_A = 2(T_0 - T) + [HA]V + 2[H_2A]V$$

and

$$Q_M = 2(T_0 - T) - 2T_M,$$

where T_M is the amount of unreacted intermediate, virtually all of which is in the dissociated form. Again, since $[HA]V + [H_2A]V$ is a constant fraction of T and $T_0 = Q_\infty/4$,

$$[HA]V + 2[H_2A] \cdot V = \frac{4Q_0}{Q_\infty} T$$

so that substitution in equation [4] provides the expression

$$k = \frac{2.303}{t} \log \frac{Q_\infty - Q_0}{Q_\infty - Q - 2T_M}. \qquad [17]$$

The amount of the intermediate may be found from the standard expression [18]. Obviously the substitution of [18] into [17] produces an equation much too complex for an easy solution of k, so that an approximation must be made. The first step is to obtain an estimate of k with $T_M = 0$. This value substituted into [18] gives a first approximation

$$T_M = \frac{k}{k'-k} T_0(e^{-kt} - e^{-k't}) \qquad [18]$$

for T_M which when introduced into [17] provides the second approximation for k. Further approximations of k and T_M are made until stabilized values are obtained. Since $k = \alpha k_1 + \beta k_2$ and, from [11] and [12], $\alpha = ([H^+]/K_1)\beta$, then

$$\frac{k}{\beta} = \frac{[H^+]}{K_1} k_1 + k_2$$

so that by plotting $[H^+]/K_1$ against k/β a straight line is obtained whose slope is k_1 and k/β intercept is k_2. Figure 2 represents such a plot from which the values listed in Table III were obtained.

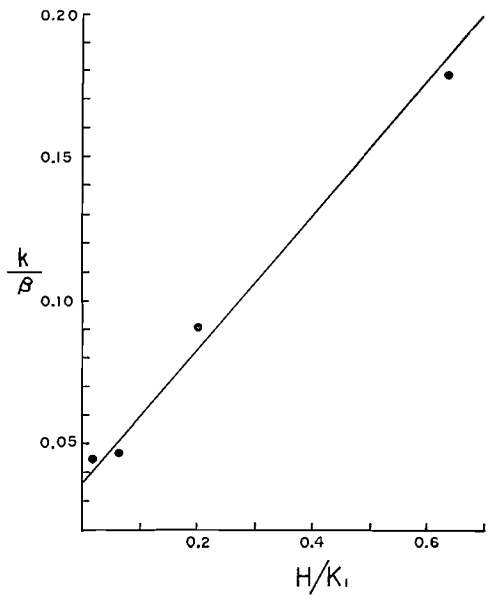


FIG. 2.

The Ultraviolet Spectra

The three spectra are reproduced in Fig. 3, the acid curve appearing twice to allow comparison between it and the others. The ester and salt concentration were 6.0×10^{-5} M while the acid form was estimated to be 5.4×10^{-5} M.

In the presence of oxygen the spectrum of the acid form slowly changed to one having a peak of 240 mμ and a shoulder at about 275 mμ. This later spectrum appeared to be stable with time and reverted to the ion form on neutralization.

DISCUSSION

The experimental results may be discussed most conveniently in three sections as follows:

(a) Spectral Evidence

Janssen (9) has made an extensive study of the ultraviolet spectra of some 70 thion compounds from which he concluded that the longer wavelength peak (shown in Fig. 3)

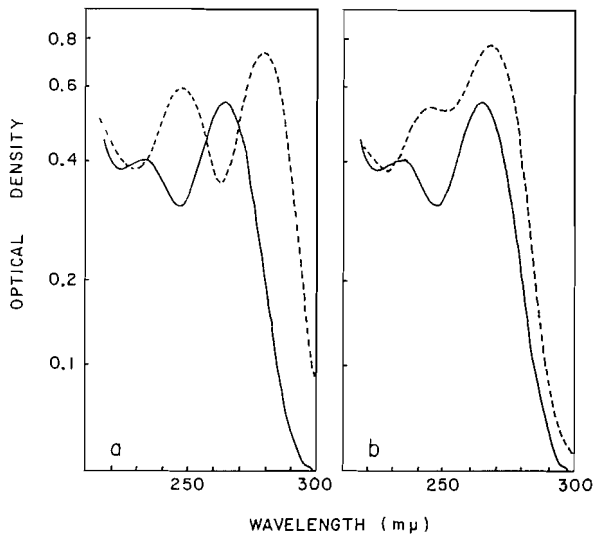

FIG. 3. (*a*) —— acid, – – – salt; (*b*) —— acid, – – – ester.

may be assigned to the structure —N—C(=S)— and the shorter wavelength peak to the structure —C(=S)—S—. This leads to the initial expectation that the addition of a proton to the ion would bring about a change in the shorter wavelength peak if structure II resulted and in the longer wavelength peak if structure III resulted. Actually *both* peaks are seen to shift to shorter wavelengths in Fig. 3. This is not surprising since the change in the ion either to a neutral molecule or a zwitter ion is bound to have profound effects on the entire structure. The *direction* of shift *is* significant, however, since a move to shorter wavelengths generally indicates a reduction in resonance. Structure II, having no free charges, has less resonance than the ion, and seems to be indicated here.

A comparison can also be made in Fig. 3 between the ester, which under the present conditions is not protonated and whose structure resembles that of II, and the acid form of the dithiocarbamate. The similarity between the longer wavelength peaks of these two compounds shows that the electronic configuration around the nitrogen is unchanged on esterification, thus ruling out structure III. The shift in the shorter wavelength peak probably occurs as a result of replacing a hydrogen by a methyl group on the CSS structure.

As there is no change in the spectrum of the acid form in solutions containing between 0.1 and 6 *N* HCl, it seems unlikely that the diprotonated form suggested by Zahradnik and Zuman (2) exists.

(b) The Acid Dissociation Constants

The ability of a compound to release protons depends on its electronegativity. Thus for any given acidic group, the acid dissociation constant K_a will decrease with increasing electron-donating power of the groups to which it is attached. This is the case with the dissociation constants of the alkyl-substituted compounds listed in Table I where the increasing size and number of the electron-donating alkyl groups causes a drop in K_a.

It is the case also for a change in substituent from an uncharged alkyl group to a group such as $^{-}S(S)C—NH—CH_2—CH_2—$ (K_2, Table III) whose negative charge provides it with a greater electron-donating power. Any increase in electron density about the nitrogen atom will be communicated to the sulphur, resulting in a similar dependence of the acidity of both structures II and III on substitution, so that neither is preferred as a result of these observations.

The β-aminoethyl derivative on the other hand, being anomalous, is more useful in regard to a selection of structure. That K_a for this compound should be higher than all the other compounds listed is not unexpected in view of the electrophilic nature of the positive charge on its substituent. However, an increase of at least 1000-fold is excessive and must result from other factors. In its ionized state, this compound is an inner salt in the form of a six-membered ring (IV), which is a very stable structure. The addition of a proton to the sulphur can only occur with the disruption of the salt bond. Thus if protonization is of this type its probability of occurrence is lower and its K_a higher than would be expected as a result of electronic effects alone. Such an argument would not apply if protonization is at the nitrogen since the ring structure would remain, so that once again structure II is preferred.

(c) Rate Constants

The results of the kinetic studies listed in Tables I, II, and III may be summarized as follows:

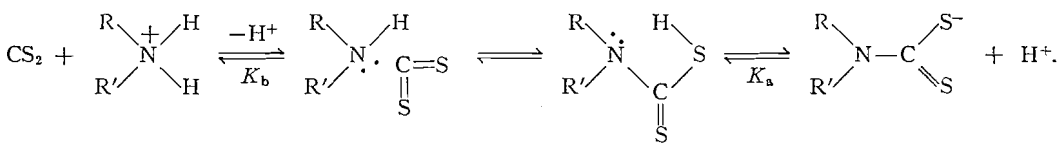
(1) With the exception of the β-aminoethyl derivative and diprotonated Nabam, the monosubstituted compounds all have decomposition rate constants of the same order. There is some indication that increased electron-donating power of the substituent groups results in a larger decomposition rate, since both increase in the substitution series $HSSCNHCH_2CH_2— <$ alkyl— $< {}^{-}SSCNHCH_2CH_2—$.

(2) The dialkyl decomposition rate constants also follow this rule, having values in excess of those of the monoalkyls. The almost 100-fold increase, however, appears to be too great to be due to electronic effects alone so that steric factors must make an added contribution.

(3) The β-aminoethyl derivative is again anomalous since it should certainly exhibit no greater steric hindrance than exists in Nabam, and furthermore it would be expected to show a reduced rate constant by virtue of the electron-withdrawing powers of the positive charge. In spite of this it was found to have a high rate constant ($\sim$2 min^{-1}) compared to other monosubstituted compounds.

(4) The rate of synthesis of the alkyl compounds is also revealing in that the dialkyls are synthesized at the same or greater rate than the monoalkyls, two of which (ethyl and *n*-propyl) were so slow in the pH range available to the method that they could not be measured. This fact appears to be in conflict with the conclusion reached in (2) since if steric factors aid in the decomposition by placing a strain on the C—N bond, it seems likely that they should hinder synthesis.

To reconcile these apparent contradictions the following reaction mechanism is offered:



V II

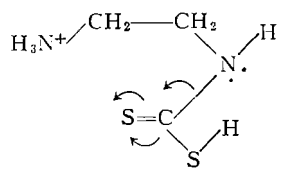
This scheme follows Zahradnik and Zuman's suggestion (2) that CS_2 acting as a Lewis

acid adds to the amine to form V. It also satisfies the overall observation that pH's near or less than the pK_a of the acid bring about decomposition while those near or in excess of the pK_b of the amine result in synthesis.

The crucial step in both synthesis and decomposition is the transfer of the hydrogen between the nitrogen and the sulphur, which occurs in the step between V and II. Groups adding to the electronegativity of the nitrogen should aid in transfer toward the nitrogen, increasing the rate of decomposition and decreasing the rate of synthesis.

The effect of steric factors on transfer is clearly indicated by models of V and II. In both compounds rotation about the N—C bond is virtually unrestricted if only one large group is attached to the nitrogen whereas disubstitution prevents free rotation and brings about important orientation effects. In V the S=C=S structure is forced into a plane at a right angle to that of the substituents so that the S—H distance is near optimal for the transfer. In II the HS group is forced into a position proximal to the free electron pair on the nitrogen, where transfer again should be facilitated. The net result of the addition of a second alkyl to the nitrogen then is that the electronic and steric effects are additive during decomposition, resulting in a large increase in rate, and opposed during synthesis, resulting in little change in rate, as is observed in Tables I and II.

With the β-aminoethyl compound, the hydrogen transfer is aided in another way. The protonated amino group exerts a strong inductive electron shift directly on the S=C bond, as in VI, reducing the electronegativity of the sulphide sulphur and weakening the C—N bond.



VI

This would promote the transfer step and lead to the unusually high decomposition rate observed.

Since hydrogen bond formation between the nitrogen and the sulphur is possible with structure II it is tempting to suggest that this does in fact occur, the hydrogen assuming a position intermediate to its position in II and III. Accepting this structure, however, leaves us without an explanation for the steric effects, and since such a compound would have some of the free charge characteristics of III, without an explanation of the downward shift in the spectrum of the protonated form. We are therefore forced to acceptance of structure II pending further evidence to the contrary.

ACKNOWLEDGMENTS

The authors wish to thank Mr. A. W. Tatham and Mr. H. J. Murphy for technical assistance in this work and Dr. G. D. Thorn and Dr. A. Stoessl for many helpful discussions.

ABSTRACT

The structures of two volatile alkaloids from the plant *Fabiana imbricata* have been elucidated. The occurrence in this plant of *p*-hydroxyacetophenone, large quantities of oleanolic acid, and a yellow pigment is reported.

An extract of the terminal branchlets of the South American plant *Fabiana imbricata* Ruiz and Pav. (common name pichi-pichi) has been used to treat kidney and bladder infections, liver flukes of goats and sheep, etc. (1). In early examinations of the plant Kunz-Krause (1) and Edwards and Rogerson (2) reported the presence of neutral and phenolic compounds and the latter indicated the presence of an alkaloid which gave an amorphous picrate, m.p. 125° (decomp.). In view of the reported physiological activity of the plant and its commercial availability we are undertaking a further examination of its constituents. This report will be mainly concerned with the alkaloids of the plant.

An alcohol extract of the ground plant material when concentrated yielded a large semicrystalline mass with a strong and pleasant odor. The crystals were collected and proved to be oleanolic acid.[4] The filtrate was concentrated and diluted with water and then dilute sulphuric acid was added. A mixture of oleanolic acid and a pale yellow phenolic pigment separated and was collected by filtration. The final filtrate was separated into neutral acidic and basic components. None of the fabiatrin, previously reported as occurring in the plant (2), has been isolated. The basic fraction contained fairly volatile liquid components, which were subjected to short-path distillation *in vacuo*. The most volatile base was relatively free from contamination. It was purified by conversion to its crystalline picrate (m.p. 114–116°) and regeneration. It was a fairly mobile, colorless liquid with negligible optical rotation. We have given this the name fabianine.

Fabianine analyzed for $C_{14}H_{21}NO$. Its infrared spectrum (liquid film) showed the presence of a hydroxyl group (ν_{max} 3280 cm^{-1}), and the bands at 1577 cm^{-1} and 1596 cm^{-1} resembled those of a pyridine ring (3). The presence of a pyridine ring was confirmed by its ultraviolet absorption maxima (Table I) and its low pK_a (5.25 in 50% ethanol). The position of the long-wave-length absorption maximum did not shift in acid solution, but the band increased in intensity, again characteristic of a pyridine, as distinct from an aniline or indoline type. The base failed to give a methiodide even when heated with methyl iodide in dimethyl formamide, behavior suggestive of a 2,6-disubstituted pyridine.

TABLE I

Base	$\lambda\lambda_{max}$	log ϵ	Reference
Fabianine	213, 273	3.9, 3.8	
5,6,7,8-Tetrahydroquinoline	215, 270	3.55, 3.65	4
6,7-Dihydro-5H-pyrindine	215, 275	3.7, 3.7	4

[1]*Issued as N.R.C. No. 6610.*

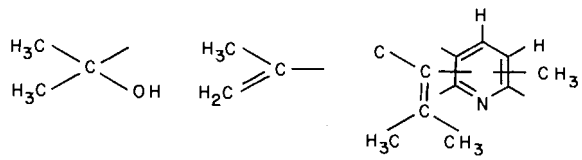
[4]*We are grateful to Dr. G. Just, who identified this component.*

The alkaloid proved inert to chromic acid in acetic acid, hence the hydroxyl was tertiary. It was dehydrated readily by a refluxing mixture of acetic acid and acetic anhydride containing *p*-toluene sulphonic acid or by thionyl chloride – pyridine combination. The double bond of this olefin (A) was terminal (ν_{max} 882, 1645 cm^{-1}). Olefin A was recovered unchanged after refluxing with formic acid for 4 hours, but in refluxing 6 *N* sulphuric acid, it was converted to the isomeric olefin (B) having its double bond in conjugation with the pyridine ring. Olefin B was obtained in a purer state by heating A with potassium hydroxide in ethylene glycol, thus making it very unlikely that B had a rearranged skeleton. Fabianine did not form a derivative with benzaldehyde when sodium hydroxide or acetic anhydride was used as catalyst, a fact which misled us to conclude that no α or γ methyl group was present on the pyridine ring.

The very informative nuclear magnetic resonance spectra[5] of fabianine and of olefins A and B (in CCl_4) are reproduced in Fig. 1. In the spectrum of the alkaloid the aromatic hydrogens appeared as pairs of doublets at 2.5 and 3.0 (J = 8.5), and hence were the γ and β hydrogens of the pyridine ring (6, 7). The hydroxyl group appeared at 2.74 and two 'benzylic' hydrogens were in an ill-defined peak at 7.2. The sharp signal at 7.5 was a methyl group directly attached to the aromatic ring, while three aliphatic methyl groups appeared at 9.1 (3 H) and 8.7 (6 H). The two groups responsible for the signal at 8.7 clearly had the oxygen on the adjacent carbon; hence most probably formed part of a dimethyl carbinol system (I).

The spectrum of olefin A contained bands at 5.25 and 5.8 (terminal methylene) and one methyl now resonated at 8.2. This is compatible with the presence of group II (in olefin A) derived from the dimethyl carbinol. The n.m.r. spectrum of conjugated olefin B (produced by acid-catalyzed rearrangement) showed it to be a mixture containing mainly a tetrasubstituted double bond but also some trisubstituted double bond, while that produced by the base-catalyzed rearrangement of A was almost pure tetrasubstituted



I II III

olefin. In addition to the aromatic methyl signal there were now two other methyls resonating at low field (7.5 and 8.15) which were hence attached to the double bond. It followed that olefin B had partial structure III.

The absence of conjugation other than that to be expected from one double bond and the pyridine ring in olefins A and B meant that to satisfy its empirical formula fabianine had to have two rings. In view of the limited number of carbons left to form it, the only structures compatible with the above evidence had this ring fused to the α and β positions of the pyridine ring.

The carbon in fabianine linking the side chain containing the dimethyl carbinol group to the pyridine ring must carry a tertiary 'benzylic' hydrogen. This left one 'benzylic' hydrogen to account for, from which it followed that the methyl group giving a doublet at 9.1 in the alkaloid had to be on the remaining carbon attached to the pyridine ring. Consideration of the above facts and a possible origin of the aliphatic portion in two

[5]*The n.m.r. data are reported in* τ *values throughout this paper (5).*

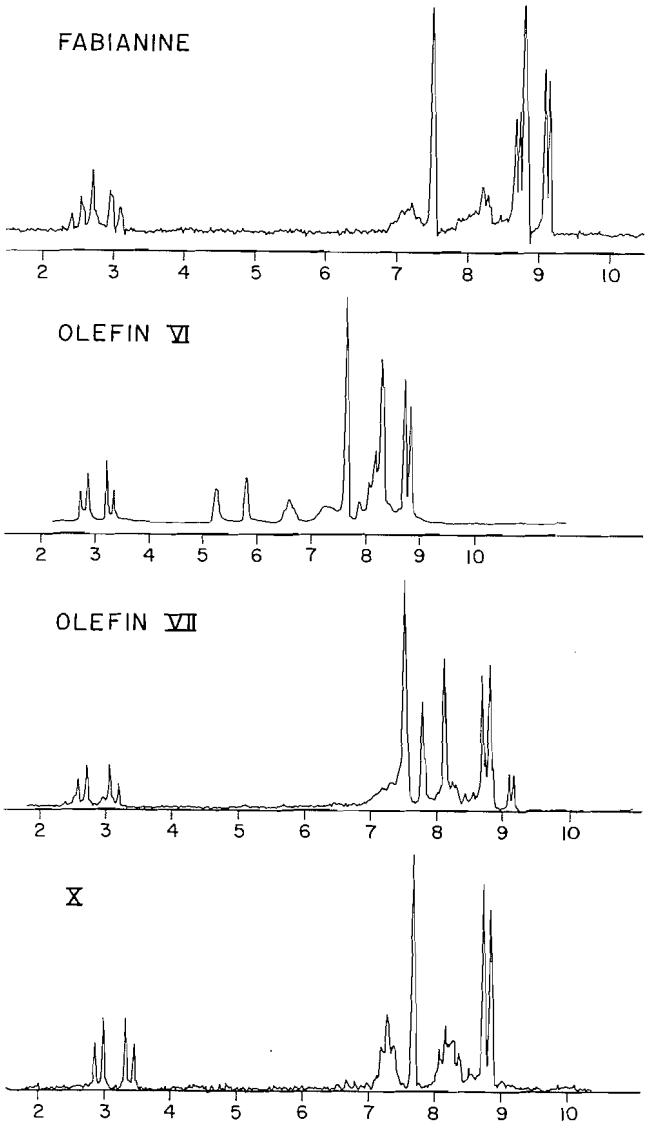


FIG. 1. The n.m.r. spectra (60 Mc, instrument) determined on 10% solutions in CCl_4 with $Si(CH_3)_4$ as internal standard.

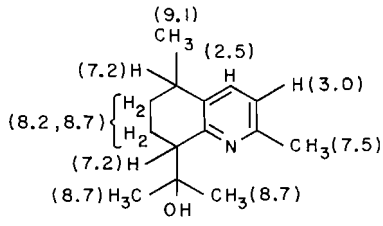
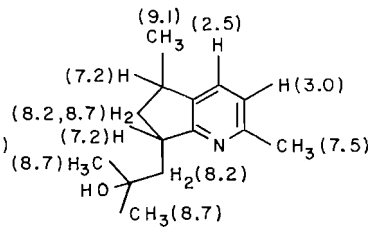
isoprene units (see below) led us to consider four expressions for fabianine, IV and (in the unlikely event that rearrangement had taken place in forming olefin B) V and the analogues with the substituents on ring A reversed. The latter possibilities were readily eliminated when it was found that dehydrogenation of both fabianine and olefin B with palladium–charcoal gave 2,5-dimethylquinoline.

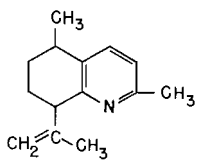
Structure IV accounted very neatly for the alkali-catalyzed isomerization of olefin A (VI) to olefin B (VII) via the α-picolyl anion VIII produced by base abstraction of the acidic 8-hydrogen. However, the conditions for the isomerization (180°) were severe enough that this fell short of proving IV to be correct. Similarly, the dehydrogenations



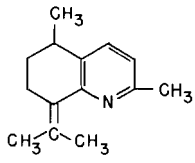
IV



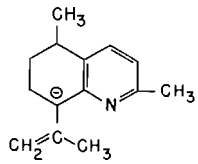
V



(VI)

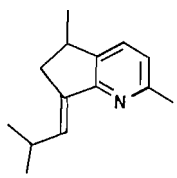


(VII)



(VIII)

could have involved expansion of a five-membered ring to give the quinoline. The n.m.r. spectrum of fabianine didn't enable us to distinguish between IV and V, although it seemed that it actually fitted V better[6] (see assignments on the formula). However, the n.m.r. spectrum of A fitted structure VI considerably better than that for the terminal olefin derived from V. As indicated earlier, it also appeared very unlikely that both acid- and alkali-catalyzed transformations of A into B would give the same product if a skeletal rearrangement were involved. The n.m.r. spectrum of B fitted formula VII as far as the methyl signals and the absence of olefinic hydrogen were concerned (see Fig. 1) and the spectrum was incompatible with the alternative IX derived from V, thus strongly

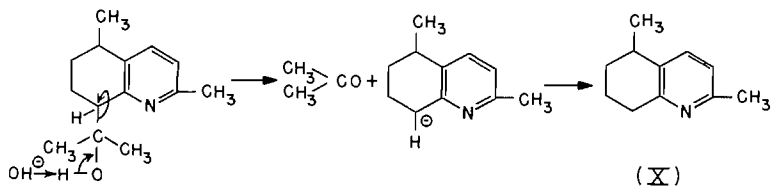


IX

favoring structure IV for the alkaloid. A decisive chemical distinction was sought to strengthen this conclusion.

Inspection of the two structures IV and V suggested that only the former would undergo base-catalyzed fission into acetone and 2,5-dimethyl-5,6,7,8-tetrahydroquinoline (X). When fabianine was heated with potassium hydroxide in ethylene glycol in a slow stream of nitrogen, acetone was formed and was trapped as its 2,4-dinitrophenylhydrazone. After prolonged heating to complete the fission the main fragment was isolated from the reaction mixture; its analysis and n.m.r. (Fig. 1) and infrared spectra were in

[6]*For structure IV the tertiary hydrogen on* C-*8 would be expected to resonate at considerably lower field than the tertiary hydrogen on* C-*5, while for V these should have very similar chemical shifts. Actually these protons were not very well resolved (Fig. 1). In addition the four hydrogens on* C-*6 and* C-*7 might be expected to have chemical shifts near 8.2. Actually, three hydrogens resonate near 8.2 but the fourth appears near 8.7.*



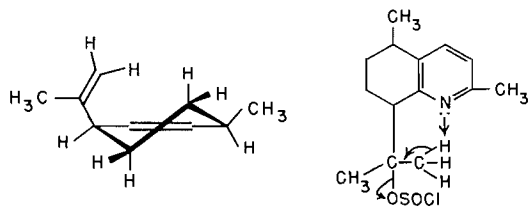
(X)

complete agreement with structure X. We thus consider structure IV for fabianine decisively proved.

It was hoped to deduce the relative stereochemistry of the alkaloid by observing whether or not hydrogenation of A and B produced the same product. Unfortunately similar but not identical mixtures were obtained from both,[7] indicating that double-bond migration had taken place before hydrogenation in the case of A at least.

However, two observations lead us to suggest a cis relation of the substituent at C-5 and C-8 in olefin A. Examination of models (Courtauld) leads us to conclude that the conformation illustrated in XI is the most favorable one for this configuration. This is consistent with the downfield shift of the methyl signal since the double bond and the methyl group are reasonably close, with the methyl in the plane of the double bond. This relative stereochemistry and conformation also account neatly for the large chemical shift difference (33 c.p.s.) between the two vinyl hydrogens since one of them is close to and above the pyridine ring, giving rise to its shielded character (τ = 5.8) (8). The cis relationship of these groups can also be deduced from the argument that only in fabianine is the 5-methyl quasi axial (and resonating at higher field) because the dimethyl carbinol group adopts the quasi-equatorial conformation (stabilized by hydrogen bonding to the nitrogen). When the 5-methyl is quasi equatorial in the two olefins and X, it is deshielded by being in the plane of the pyridine ring.

It is noteworthy that the dehydration of fabianine under two widely different conditions gives rise to the non-conjugated olefin VI instead of the conjugated olefin VII. There is considerable steric hindrance to attack at the 8-hydrogen in fabianine, as opposed to the ready accessibility of the methyl hydrogens and a sixfold multiplicity factor favoring removal of one of these. In addition, if the transition state for the dehydration to the conjugated olefin resembles the product then the serious interaction of the nitrogen and one of the methyl groups (Courtauld model) may impede its development and hence favor formation of the terminal olefin. The nitrogen atom undoubtedly influences the course of the dehydration and we suggest that in the *p*-toluene sulphonic acid catalyzed reaction the positive charge on the nitrogen in the pyridinium salt retards the formation of a proton in its vicinity so the proton is eliminated as far away from this center as



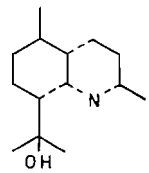
(XI) (XII)

[7]*We are indebted to Dr. H. J. Bernstein for help in analyzing the n.m.r. spectra of these mixtures.*

possible, yielding the terminal olefin. Again, with dehydration by thionyl chloride in pyridine one would expect abstraction of the acidic 8-hydrogen, but the fact that exclusively terminal olefin is produced indicates that an important factor is probably the internal base abstraction of the primary hydrogen in the cyclic process illustrated in XII.

The mother liquors from which fabianine picrate had crystallized yielded another liquid base which was very readily eluted from alumina. Its infrared and n.m.r. spectra were identical with those of 2,5-dimethyl-5,6,7,8-tetrahydroquinoline obtained by degradation of fabianine. Since it could have been formed by the action of the alumina used in regenerating the base from the picrate, a sample of fabianine was adsorbed on alkaline alumina and left for 5 hours. On elution only fabianine was recovered; hence this second tetrahydroquinoline must occur in the plant.

Fabianine is almost certainly constructed in nature from two isoprene units, linked head to tail, and a C_4N unit, probably derived from acetoacetate, as illustrated. The second base (X) could then be produced from it by an enzyme-catalyzed analogue of the retroaldol reaction described earlier.



It is interesting to note the recent assignment of structure to skytanthine (9, 10) and actinidine (11), where a monoterpene unit has been used to construct a piperidine and pyridine ring respectively.

EXPERIMENTAL

Ultraviolet spectra were determined in 95% ethanol (ϵ_{max} in parentheses). Unless otherwise stated, Woelm brand neutral alumina was used for chromatography, the cited activity being on the Brockmann scale (12). Distillations were over a short path in a chain of bulbs, the cited temperatures being that of the air bath.

The Extractives of Fabiana imbricata

A 22-kg quantity of twigs and terminal branchlets of *Fabiana imbricata* Ruiz and Pav. were obtained from the S. B. Penick Co. This was finely ground, then percolated exhaustively with ethanol. The resulting extract was concentrated to a thin syrup *in vacuo*. This deposited 180 g of fine crystalline solid which was collected by filtration. The filtrate was taken to a thick syrup on a rotating evaporator, then dilute sulphuric acid added. A further 335 g of solid which separated was removed by filtration, then the neutral and acidic material were extracted from the filtrate into methylene chloride. The organic layer was back extracted with dilute acid. The combined aqueous layers were adjusted to pH 8 using sodium carbonate, then the weak bases (51 g, crude) were extracted into methylene chloride. The aqueous solution was then adjusted to pH 11 using sodium hydroxide and the 'strong bases' (11 g) were extracted into methylene chloride.

The neutral and acidic fractions were separated by distribution between dilute sodium hydroxide solution and methylene chloride. A microcrystalline sodium salt, which separated, was filtered off (wt. 50 g). The neutral extract, with strong aroma, weighed 1900 g, while the acid fraction weighed 1200 g.

The Weak Bases

The crude weak-base fraction was repeatedly extracted with pure ether, leaving a large dark residue of neutral material. The ether extract was concentrated and the residue distilled under 10 mm pressure. The bulk of the base (16 g) distilled as a mobile liquid between 90 and 100°. This still contained considerable neutral material. A further 2.7 g of more viscous distillate was collected at bath temperatures up to 126°.

After a further passage through acid to remove neutral components, the volatile base was redistilled at 70°, 5×10^{-2} mm, giving 11 g of colorless oil. The 'strong-base' fraction proved to be mainly neutral, but a further 2 g of fabianine was recovered from it.

Fabianine

The 13 g of oil was converted to its picrate, which crystallized from concentrated ethanol solution. The salt was recrystallized from ethyl acetate, giving needles, m.p. 114–116°. Calc. for $C_{20}H_{24}N_4O_8$: C, 53.57;

H, 5.39. Found: C, 53.80, 53.76; H, 5.31, 5.50. The pure base was regenerated from the picrate by dissolving the salt in chloroform and passing this solution through a column of alkaline alumina. The eluted base distilled at 74°, 5×10^{-2} mm as a colorless oil with $[\alpha]_D$ less than 1°. Calc. for $C_{14}H_{21}NO$: C, 76.66; H, 9.65; N, 6.39. Found: C, 76.49; H, 9.51; N, 6.17. It had λ_{max} 213 (7440) and 273 (6765) mμ and ν_{max} (liq. film) at 3270 (OH), 1595, and 1575 cm^{-1} (pyridine ring).

Acetylation of Fabianine

Fabianine (120 mg) was dissolved in dry pyridine (5 cc) and acetic anhydride (5 cc) was added. After it was left to stand overnight at room temperature, the mixture was heated for 1 hour on the water bath and the base (117 mg) was isolated. Distillation at 70–75°, 10^{-2} mm gave an oil (62 mg) which was chromatographed on alumina (activity IV). The material eluted with hexane showed strong ester bands ($\nu_{max}^{CHCl_3}$ 1720 and 1280 cm^{-1}) but the substance repeatedly failed to analyze correctly.

Attempted Preparation of Benzylidene Derivative

(*a*) A solution of fabianine (80 mg) and benzaldehyde (80 mg) in 80% ethanol (2 cc) was treated with sodium hydroxide solution (0.2 cc) and left at room temperature for 60 hours. The organic base was isolated in the usual manner. Its infrared spectrum was identical with that of fabianine.

(*b*) Fabianine (100 mg) was dissolved in acetic anhydride (5 cc), and benzaldehyde (2 cc) was added. After 48 hours at room temperature the unchanged base was again recovered.

Attempted Preparation of the Methiodide

(*a*) Fabianine and excess methyl iodide in isopropyl ether were kept at room temperature for 24 hours. After removal of solvent the base was unchanged (infrared spectrum).

(*b*) The base was heated in a sealed tube with methyl iodide and dimethyl formamide for 10 hours at 125°. After tetramethyl ammonium iodide was removed by filtration the residue failed to crystallize.

Attempted Oxidation of Fabianine

(*a*) Fabianine (109 mg, 0.5 mmole) was dissolved in acetic acid (5 cc) and a solution of chromic oxide (50 mg, 0.5 mmole) in water (0.25 cc) was added. After 19 hours at room temperature the solution was still deep red. The base was recovered and its infrared spectrum showed retention of the strong OH band.

Dehydration of Fabianine to VI

(*a*) Fabianine (154 mg) and *p*-toluene sulphonic acid monohydrate (205 mg) were dissolved in acetic acid (10 cc) containing acetic anhydride (1 cc) and the solution was refluxed for 3 hours. After cooling, the solution was diluted to 50 cc with water, neutralized (Na_2CO_3), extracted with ether and the ether extract was dried over magnesium sulphate. Distillation gave a colorless oil (117 mg), b.p. 62–65°, 5×10^{-3} mm. λ_{max} 272 (3925) and 281 (3250) mμ; ν_{max} (liq. film) 882, 1645 cm^{-1} (—CH=CH_2), 1575, 1597 cm^{-1} (pyridine ring). Calc. for $C_{14}H_{19}N$: C, 83.53; H, 9.51; N, 6.96. Found: C, 83.71; H, 9.28; N, 7.05.

(*b*) Fabianine (165 mg) was dissolved in pyridine (2 cc), the flask was cooled in ice water, then thionyl chloride (0.25 cc) was added. The resulting red solution was left to reach room temperature during 2 hours. After hydrolysis with ice, sodium carbonate was added and the solution was extracted with ether. The ether extract was dried ($MgSO_4$), filtered, and evaporated on a rotating evaporator at 40°. The product distilled at 54–59°, 3×10^{-3} mm as a colorless oil (146 mg) whose infrared spectrum was identical with that of the product from the *p*-toluene sulphonic acid dehydration above.

Catalytic Reduction of the Olefin VI

The olefin VI (24 mg) in ethanol (4 cc) was hydrogenated over Pd(C) (20 mg, 10%). Uptake of hydrogen ceased after 90 minutes. The product was isolated in the usual manner and distilled at 52–55°, 10^{-3} mm, giving a colorless, mobile oil. Calc. for $C_{14}H_{21}N$: C, 82.70; H, 10.41. Found: C, 82.34; H, 10.37.

Treatment of Olefin VI with Formic Acid

The olefin (20 mg) in formic acid (10 cc, 98%) was refluxed for 4 hours. After cooling and neutralization (Na_2CO_3) the product was isolated. Its infrared spectrum was identical with that of the starting material.

Dehydrogenation of Fabianine

A bulb containing 190 mg of fabianine and 230 mg of 30% palladium–charcoal was immersed in a bath at 225°. While a slow stream of dry nitrogen was introduced into the bulb the bath temperature was raised during 80 minutes to 250°. This temperature was maintained for 5 hours. After cooling, the mixture was extracted several times with chloroform (total volume 20 cc) and the greenish-brown solution was filtered through a plug of cotton wool. The chloroform was evaporated and the residue on distillation gave 77 mg of a colorless liquid, b.p. 55–60°, 5×10^{-2}. The ultraviolet spectrum of the product had maxima at 234, 236, 282, 293, 306, and 319 mμ and minima at 222 and 249 mμ, corresponding in position and intensity to that of an alkylquinoline (13). The oil was treated with picric acid (100 mg), and ethanol (20 cc) was added. The solution was warmed but all of the solid would not dissolve; when it was cooled a mass of yellow crystals was obtained. The picrate (103 mg) was recrystallized once from ethanol to give yellow needles (71 mg), m.p. 212–216° raised to 217–220° after two crystallizations from methanol. A chloroform solution of the

picrate was filtered through a column of alumina (Fisher) and the base was distilled, giving a colorless oil, b.p. 47–50°, 10^{-3} mm. The n.m.r. spectrum of the base showed 5 aromatic protons and 2 aromatic methyl groups. Calc. for $C_{11}H_{11}N$: C, 84.04; H, 7.05. Found: C, 83.66; H, 6.95. λ_{max} 234 (50,730), 236 (50,360), 293 (4,520), 305 (4,035), and 319 (3,520) mμ.

The infrared spectrum of the base was identical with that of an authentic specimen of 2,5-dimethylquinoline (14).[8] The melting point of authentic 2,5-dimethylquinoline picrate was not depressed on admixture with a sample derived from the dehydrogenation product.

Rearrangement of Olefin VI to Olefin VII

(a) By Sulphuric Acid

The olefin VI (375 mg) was refluxed with sulphuric acid (6 *N*, 20 cc) during 4 hours. After cooling and neutralization (Na_2CO_3) the ether extract was dried ($MgSO_4$) and the product was distilled. Redistillation gave a colorless oil, b.p. 65–75°, 3×10^{-2} mm. λ_{max} 250 (9400) and 296 (7670) mμ; λ_{min} 271 (3455) mμ; ν_{max} (liq. film) 1630 cm^{-1} (tetrasubstituted double bond), 1575 cm^{-1} (pyridine ring). Calc. for $C_{14}H_{19}N$: C, 83.53; H, 9.51. Found: C, 83.28; H, 9.46.

(b) By Potassium Hydroxide

The olefin VI (650 mg) was refluxed for 24 hours with a solution of potassium hydroxide (2 g) in ethylene glycol (30 cc). After dilution with water the olefin was isolated and was dissolved in hexane and chromatographed on a short column of alumina (activity IV). The hexane eluate (60 cc) was evaporated to yield an oil (170 mg), which was distilled, and the fraction boiling at 60–65°, 6×10^{-3} mm was collected. It had λ_{max} 250 (8470) and 296 (6985) mμ; λ_{min} 271 (3760) mμ; ν_{max} (liq. film) 1630 cm^{-1} (double bond), 1570 cm^{-1} (pyridine ring). Calc. for $C_{14}H_{19}N$: C, 83.53; H, 9.51. Found: C, 83.66; H, 9.28.

Reduction of Olefin VII

(*a*) The olefin VII (143 mg) produced by alkaline rearrangement of olefin VI was hydrogenated over Pd(C) (10%) in ethanol at atmospheric temperature and pressure. The product was isolated in the normal manner and distilled at 58–63°, 8×10^{-3} mm as a colorless oil (95 mg).

The infrared spectrum of this reduction product was identical with that of the hydrogenated olefin VI but the n.m.r. spectra showed significant differences.

(*b*) A sample of olefin VII obtained by sulphuric acid rearrangement of olefin VI was reduced in the manner described in (*a*). The product had b.p. 50–54°, 7×10^{-3} mm and its infrared spectrum was almost superimposable upon that of the hydrogenated olefin VI.

Dehydrogenation of Olefin VII

Olefin VII (160 mg), obtained by acid-catalyzed rearrangement of olefin VI, was dehydrogenated by Pd(C) (160 mg, 30%) during 5 hours at 220° in a stream of dry nitrogen. The product (103 mg) was isolated as before and the ether-soluble material was filtered through a short column of alumina (activity IV). The eluted material was distilled up to 125°, 8×10^{-2} mm. The distillate was a pale yellow oil (66 mg) which exhibited a weak alkylquinoline-type ultraviolet spectrum. Picric acid (75 mg) was added to the oil in ethanol and the yellow needles obtained (45 mg) had m.p. 217–218° after recrystallization from methanol. The melting point was undepressed on admixture with a sample of 2,5-dimethylquinoline picrate. The base was regenerated in the usual manner and its infrared spectrum was identical with that of authentic 2,5-dimethylquinoline (14).

Retroaldol Reaction

Fabianine (250 mg) was placed in a two-necked flask connected to two tubes containing 2,4-dinitrophenylhydrazine sulphate in aqueous ethanol. A stream of dry nitrogen was passed through the apparatus. A solution of potassium hydroxide (1.85 g) in ethylene glycol (15 cc) and water (5 cc) was added to the base and the flask was heated slowly in an oil bath. After 4 hours the bath was at 130° and the contents began to boil. An orange solid appeared in the first trap and heating was discontinued after 100 minutes. The hydrazone (38 mg) was filtered and dried and had m.p. 113–119°. It was dissolved in benzene and chromatographed on alumina (Spence 'H'). The derivative was rapidly eluted and the solid obtained on evaporation of the benzene was crystallized three times from methanol and had m.p. 125.5–127°. When mixed with authentic acetone 2,4-dinitrophenyl hydrazone, the m.p. was 126.5–128.5°.

The reaction mixture was refluxed for a further 17 hours and the basic material was isolated in the usual manner. The infrared spectrum still showed some hydroxyl absorption so the oil was dissolved in hexane and filtered through alumina (activity IV). The product (125 mg) distilled as a colorless oil, b.p. 50–55°, 8×10^{-3} mm and was redistilled for analysis. λ_{max} 273 (4810) mμ; λ_{min} 245 (2150) mμ. Calc. for $C_{11}H_{15}N$: C, 81.93; H, 9.38. Found: C, 81.88; H, 9.47.

Isolation of 2,5-Dimethyl-5,6,7,8-tetrahydroquinoline

The mother liquors from the preparation of fabianine picrate were evaporated and the residual gum was dissolved in chloroform. The bases were regenerated from this solution by filtration through alkaline alumina.

[8]*We wish to thank Dr. Léo Marion for a sample of this base.*

Evaporation of the chloroform yielded a red oil which distilled at 85–95°, 5×10^{-2} mm to give a pale yellow oil (920 mg). The oil was dissolved in hexane (3 cc) and was chromatographed on neutral alumina (15 g, activity IV). The first 30 cc of eluate contained 478 mg of base which distilled at 68–73°, 4×10^{-2} mm as a colorless, mobile oil. The n.m.r. and infrared spectra of this oil were identical with those of compound X.

Isolation of p-Hydroxyacetophenone

A neutral component carried with the weak bases in one extraction proved readily separable from fabianine by chromatography on alumina. The more strongly adsorbed fractions yielded the crystalline substance. It crystallized from benzene as colorless needles, m.p. 109–110.5°. It was sublimed at 80°, 5×10^{-1} mm for analysis. Calc. for $C_8H_8O_2$: C, 70.57; H, 5.92. Found: C, 70.90; H, 5.94. A mixed melting point with *p*-hydroxyacetophenone was undepressed.

Isolation of Oleanolic Acid

The insoluble sodium salt described under the general isolation corresponded to the acid which was the main component of the crystalline material obtained directly from the concentrated alcohol extract. After recrystallization from methanol it melted at 299–305° and had $[\alpha]_D$ +76° (*c*, 0.67 in ethanol). It had ν_{max} (nujol mull) at 3400 cm^{-1} (OH) and 1688 cm^{-1} (carboxyl). Its methyl ester (CH_2N_2) melted at 199–201° and had $[\alpha]_D$ +69° (*c*, 0.95 in $CHCl_3$). The acetate was formed from the methyl ester using acetic anhydride–pyridine mixture. It melted at 218–220° and had $[\alpha]_D$ +66° (*c*, 1.65 in $CHCl_3$). Calc. for $C_{33}H_{52}O_4$: C, 77.30; H, 10.22. Found: C, 77.29; H, 10.22. The empirical formulae and physical properties correspond closely to those of oleanolic acid and its derivatives (15).

The Yellow Pigment

The 235 g of solid which precipitated from the concentrated alcohol extract on addition of dilute sulphuric acid was boiled with methanol. The bulk dissolved, leaving a small residue of oleanolic acid. When the solution was concentrated and diluted with water, several small crops of oleanolic acid crystallized, then finally the solution set to a solid mass of fine needles. After repeated recrystallization the compound separated from aqueous methanol as pale yellow needles, m.p. 188–189°. It was insoluble in acetone, chloroform, butanol, and cold water, but dissolved in alkali to give a deep yellow solution. It could be recrystallized from boiling water. It was dried at 100°, 0.1 mm for 4 hours for analysis. Found: C, 49.57; H, 5.93; N, absent. Its infrared spectrum had ν_{max} (nujol) 3405 cm^{-1} (OH), 1658, 1604 cm^{-1} and its ultraviolet spectrum had λ_{max} 258 mμ (E_1^1 = 42.6) and 360 mμ (E_1^1 = 32.1). It had no optical rotation. Further study is needed before an empirical formula can be assigned with confidence.

ACKNOWLEDGMENTS

We are indebted to Mr. A. Knoll for extraction and isolation of the plant constituents, Mr. M. Lesage for the characterization of fabianine, Mr. H. Seguin for the analyses, Mr. R. Lauzon for the infrared spectra, and Mr. J. Nicholson for the n.m.r. spectra.

ADSORPTION OF LIGNOSULPHONATES ON SOLIDS

J. BEECKMANS[1]
The Department of Chemistry, Ontario Research Foundation, Toronto, Ontario
Received July 25, 1961

ABSTRACT

The adsorption of various fractionated lignosulphonates on kaolin and on titanium dioxide was studied as a function of acidity and ionic strength. The quantity adsorbed at surface saturation was found to be remarkably dependent on the pH, and to some extent on ionic strength. The adsorption was irreversible with respect to dilution for all but the lowest molecular weight fractions, but desorption could be induced by changes in the pH. This fact was employed to fractionate some lignosulphonates and may be of general utility as a method for fractionating polyelectrolytes. The data are interpreted in terms of the contributions of the electrostatic and hydrogen-bonding forces to the adsorption energy.

INTRODUCTION

The adsorption of the lignosulphonate ion on solids is of interest because of the increasingly widespread use of waste sulphite liquor solids as dispersing agents, but the problem is also of more general interest because of the scantiness of our knowledge of the adsorption of polyelectrolytes. Only a few very limited studies on this subject have appeared in the literature to date, although the subject is potentially very rewarding because of the profound influence of even a very small amount of adsorbed polyion on the electrostatic potential of the surface. Thus polyelectrolytes have been found to act as dispersants in some cases (1) or as flocculating agents (2), or both, depending on the molecular weight. Previous studies with lignosulphonates have indicated that they act as dispersants in neutral solution only in a certain molecular weight range (3). A study on the adsorption of some synthetic polyelectrolytes on kaolin indicated that the pH plays a remarkable role in these systems (4).

Two adsorbents were chosen for this investigation, kaolin because the adsorption of lignosulphonate on clay is of commercial interest, and titanium dioxide, because its zeta potential can be either positive or negative, depending on the pH of the solution (5).

EXPERIMENTAL

Fractionation of Lignosulphonates by Selective Dissolution with Ethanol–Water

The starting material was a commercial paper grade waste sulphite liquor (70% balsam fir, 30% spruce, cooking time 6 hours, maximum cooking temperature 145° C, kindly supplied by Fraser Companies Ltd., Edmundston, New Brunswick). Sugars and other non-lignins were removed by a method described in reference 6. Four liters of waste sulphite liquor were de-ashed on Dowex 50 resin, extracted with 3 volumes of ether, and neutralized to pH 8.1 with calcium hydroxide to precipitate sulphuric and free sulphurous ions. The solution was filtered, de-ashed once more, and shaken with 3.5 liters of 1:4 benzene–butanol containing 10% by volume of tri-*n*-hexylamine. The lignosulphonates combined with the amine and went into the organic phase, and were later back-extracted with sodium bicarbonate solution. The original aqueous phase containing most of the non-lignins was washed with amine solution and discarded. Residual lignosulphonates in the extracted organic phase were stripped out by washing with dilute sodium hydroxide solution. These washings and the main lignosulphonate fraction previously extracted with bicarbonate were de-ashed, neutralized to pH 7, and freeze-dried. The analytical data are given in Table I.

The main-fraction lignosulphonates were separated into three fractions by elution on two grades of Sephadex controlled pore-size gels (Pharmacia, Uppsala, Sweden). Lignosulphonates sufficiently small to enter the grains of Sephadex G25 were labelled fraction 3, and those too large to enter were separated further on a column of Sephadex G50 to give fraction 2 (species sufficiently small to enter the grains) and

TABLE I

Separation of lignosulphonates from waste sulphite liquor

	Weight of solids (g)	Reducing value eq. glucose (g)	Glucose eq. as % of solids	ϵ_{281}* (l. cm^{-1} g^{-1})	Total neutr. eq. (meq.)
Starting material	396	103.2	26.1	10.30	1116
After treatment with $Ca(OH)_2$	435	102.4	23.6	8.38	1018
Main fraction	235.6	7.5	3.18	11.43	657
Washings	20.85	0.5	2.40	12.75	47.7
Sugar fraction	69.5	83.5	120.0	—	28.1

NOTE: some solids were lost in spillage.
*Extinction coefficient at 280 millimicrons.

fraction 1 (species too large to enter the grains). The columns were approximately 80 cm in height and 6 cm in diameter. Samples of the order of 1 g could be processed in one pass. Analytical data on this fractionation are presented in Table II.

TABLE II

Fractionation of purified lignosulphonates on Sephadex gels

Fraction	Weight %	ϵ_{281}	ϵ_{260}	$\epsilon_{231}/\epsilon_{260}$
1	30.1	13.94	10.51	1.327
2	45.3	11.13	7.93	1.405
3	24.6	7.27	4.70	1.547

Each fraction was split into subfractions by selective dissolution with enthanol–water mixtures from a column of Celite 535 (68 cm in height, 3 cm in diameter). The aqueous solution of each fraction was first mixed with a small portion of Celite and freeze-dried. The powdery mixture was then slurried in absolute ethanol and placed on top of the column, which was saturated with ethanol. Successive fractions were obtained by elution with 1-liter portions of ethanol–water followed by 1 liter of absolute ethanol. Results are presented in Table III. Optical absorbencies were measured on a Cary Recording Spectrophotometer Model 14 (Applied Physics Corporation). Equivalent weights were determined by titration with $N/10$ sodium hydroxide using a recording titrimeter. Diffusion coefficients were determined in double-ended cells in $N/20$ KCl, as described in reference 6. Molecular weights were calculated from diffusion coefficients by the equations of McCarthy *et al* (7).

Fractionation by Desorption from Titanium Dioxide

This method of fractionation is based on the observation, to be described below, that a mixture of lignosulphonates may be fractionated by adsorption at low pH followed by desorption induced by stepwise increases in the pH.

Two hundred and fifty milliliters of waste sulphite liquor (ammonia base, paper grade, 10.13% solids) was diluted to 7 liters with N HCl. Five pounds of titanium dioxide (Fisher reagent grade) was dispersed in the solution with vigorous stirring. The slurry was filtered and washed with 4 liters of N HCl, excess fluid being removed by suction. The filtrate and washings were discarded, and the solids were redispersed in 4 liters of 0.1 N sodium acetate – acetic acid buffer, to give a suspension of pH 3.2. The filtrate from this suspension, together with washings (using the same solvent), contained desorbed lignosulphonates which after removal of small anions by elution on Sephadex G25 and neutralization were labelled fraction T1. The procedure was repeated with buffer mixtures of higher pH to yield two more fractions, T2 at pH 4.7 and T3 at pH 6.0. Analytical data on these fractions are given in Table IV. They were not tested for reducing value because of lack of material, but in view of the method of preparation and of the relatively high absorbencies at 281 mμ it seems unlikely that they contained much sugar.

Adsorption Measurements

Adsorption measurements were made in cylindrical Pyrex cells 15 cm long and 2.8 cm in diameter consisting of a body with a 24/40 female ground-glass joint at one end with cap to fit. The insides of these cells and all ground surfaces were made water repellent by treatment with a 10% solution of Dow Corning 200 silicone fluid in toluene, followed by a 1-hour baking period at 265° C to polymerize the silicone into an insoluble film. This treatment practically eliminated any contact between the grease used to lubricate the joint and the contents of the cell. The cells were tumbled at 60 r.p.m. in a water thermostat during

equilibration. Isotherm points were determined in the usual manner by observing the decrease in concentration of a solution of adsorbate in contact with a known quantity of adsorbent. Twenty-five milliliters of solution consisting of lignosulphonate dissolved in buffer was added to a cell containing the adsorbent (usually 1±0.001 g). After a period of agitation (generally 8 hours) the suspension was allowed to settle for a few hours and then 10 ml of supernatant solution was withdrawn with a pipette. The solution was shaken with 1 ml of chloroform to reduce the size of the blank, and in addition, in some cases 0.1 ml of concentrated sulphuric acid was added to assist in clarification. These operations each resulted in a decrease of approximately 1% in the concentration of adsorbate and were allowed for in the calculations. They resulted in very considerable decreases in the blank readings. Finally the solutions were centrifuged at 2000 r.p.m. for 30 minutes and their optical absorbencies at 281 mμ were determined.

The titanium dioxide was obtained from Fisher Scientific Company, and was stated to be in the anastase form. Its specific surface as determined by argon adsorption was 4.65 m^2/g, and by adsorption of the dye crystal violet, 4.96 m^2/g (8).

The kaolin was supplied by the Merck Chemical Company, and its specific surface was 10.2 m^2/g by argon adsorption. Dispersion in water followed by drying at 110° C produced no change in the specific surface of either adsorbent.

RESULTS

Adsorption Isotherms

Adsorption was found to be rapid, irreversible, and independent of temperature in the range 25° to 35° C for most fractions, although some of the lowest molecular weight fractions showed partial reversibility. These findings are in agreement with those of Rezanowich *et al.* (3).

Three types of isotherms were obtained, which could be plotted as straight lines either according to the Langmuir equation or by a modification in which only extensive variables were used. Examples of these isotherms are given in Fig. 1. The modified Langmuir equation may be written as follows:

$$[1] \qquad \frac{Q-\Gamma}{\Gamma} = \frac{Q-\Gamma}{\Gamma_m} + k,$$

where Q is the total quantity of adsorbate added to the system, Γ the quantity adsorbed, Γ_m the quantity adsorbed at surface saturation, and k the intercept. This equation is independent of the volume of solution in the system, as required by the irreversibility of the adsorption process. Incomplete adsorption at less than maximum coverage in a system which adsorbs irreversibly implies fractionation of the adsorbate, and the isotherm provides some information on the heterogeneity of the sample. With a perfect fraction the adsorption is complete up to surface saturation and ceases at this point. Hence $(Q-\Gamma)$ must equal zero in equation [1] for Q less than Γ_m, with Γ equalling Γ_m for Q greater than Γ_m. This implies that the fixed term k equals zero, and the Langmuir plot becomes a straight line of slope Γ_m^{-1} passing through the origin, as the type A isotherm, Fig. 1.

Isotherms obtained with fractions which fractionate even at the limit of zero adsorption will have a positive intercept on the Langmuir plot. In the limit of zero Q and zero Γ,

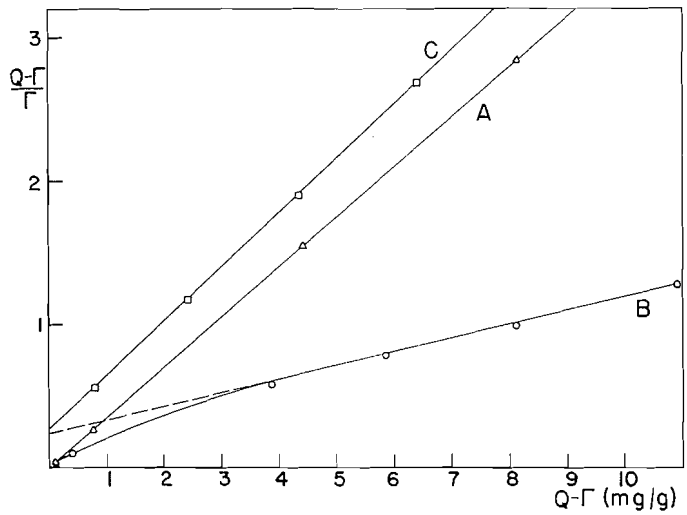

FIG. 1. Typical adsorption isotherms, illustrating three types obtained: A, adsorption of fraction Tl–2 on kaolin at pH 4.7; B, adsorption of fraction 2B on titanium dioxide at pH 1.1; C, adsorption of fraction 2B on kaolin at pH 4.7.

the ratio Γ/Q assumes a value α which equals the proportion of the adsorbate which adsorbs at the limit of zero adsorption. At this point equation [1] condenses to

$$\alpha = 1/(k+1). \qquad [2]$$

The parameter α, together with Γ_m, is used to characterize the results (Tables V and VI).

The partial fit of the data to the Langmuir equation must of course be purely fortuitous, since the considerations used in deriving that equation do not apply in this case. The type C isotherm is a limiting case applicable to an heterogeneous and poorly adsorbing adsorbate which only partially adsorbs at zero coverage. The type B isotherm was more common and represents an intermediate case in which initially the adsorption is total, with fractionation becoming very appreciable, well before completion of the monolayer.

Desorption Experiments

As may be seen in Table V the adsorbed lignosulphonates are much more densely packed on the surface at low pH values. It was found that adsorbed polyions which were attached irreversibly with respect to dilution of the 'equilibrium' solution at constant pH and supporting electrolyte concentration could nevertheless be desorbed by raising the pH, although, as was to be expected with such a system, there was some hysteresis. The saturation adsorption curves for a number of desorbing fractions were determined as follows. One gram of adsorbent was placed in a cell and dispersed with sufficient lignosulphonate dissolved in 0.1 *N* HCl to saturate the surface at that pH. After achievement of equilibrium and settling of the solids, 10 ml of the supernatant solution was withdrawn for analysis and replaced with 10 ml of 0.1 *N* buffer of a higher pH than the solution. The process was then repeated till the pH had reached a value of 11.7. The results are plotted in Figs. 2 and 3.

In the experiments described above, the surfaces of the adsorbents were saturated with adsorbent throughout the course of the run. Another experiment was made with one

system only, fraction 1A on titanium dioxide, at a number of unsaturated surface concentrations. The pH was raised from 1.1 to 4.7 in one step. The Langmuir constants of this run (at pH 4.7) were 3.98 for Γ_m and 0.612 for α. These figures may be compared with 3.17 and 0.394 for adsorption at pH 4.7.

DISCUSSION

The mechanism of the adsorption of a polyelectrolyte may be considered to be basically similar to that of the adsorption of a non-ionic polymer, but modified by the presence of electrostatic forces between the polyion and the solid surface, and by the intra- and inter-molecular forces between the charges on the polyions. The theoretical aspects of the adsorption of flexible non-ionic polymers have been treated in detail by Frish, Eirich, and Simha (9, 10, 11, 12). Their statistical mechanical analysis indicates that only a small number of randomly located segments of the flexible polymer chain are actually adsorbed

on the surface, the intervening segments forming bridges extending away from the surface into the solution. At low surface coverage the number of adsorbed segments per molecule and the heat of adsorption are approximately proportional to $t^{\frac{1}{2}}$, t being the number of segments per molecule. At higher coverage a second term proportional to t must be added. If the interaction potential between polymer and solid extends for a finite distance away from the surface and is large in relation to kT, the heat of adsorption and Γ_m become proportional to t, and the isotherm becomes very steep in the region of zero concentration. These conclusions have on the whole been substantiated by experimental results.

Jenckel and Rumbach (13) found that the quantity of polymer adsorbed was very large compared with that required for monolayer coverage for a number of polymers adsorbed on quartz, aluminum, glass wool, and carbon. Kolthoff, Gutmacher, and Kahn (14) and Kolthoff and Gutmacher (15), working with various rubber fractions adsorbed on carbon blacks, showed that the saturation adsorption on a given adsorbent depended on the solvent and on the pretreatment of the adsorbent. Kraus and Dugone (16), using similar systems, found good agreement of their results with the Frish–Eirich–Simha equation, but this must be to some extent fortuitous since the adsorption was partially irreversible. The high molecular weight species tended to displace lower molecular weight species from the surface in most of these investigations. It should, however, be mentioned that in at least one case the results seemed to indicate that the adsorbate lay flat on the surface (17).

More direct evidence in support of the Frish–Eirich–Simha theory is furnished by the work of Miller and Grahame (18) on the differential capacity of the interface between mercury and a solution containing polymethacrylic acid at low pH. A sharp peak in the differential capacity curve was interpreted as being due to rapid adsorption and desorption of polymer segments in phase with the 1000 cycle superimposed a-c. signal. Since entire polymer molecules would diffuse far too slowly to follow such rapid fluctuations the conclusion was reached that the bulk of the 'adsorbed' molecules lies in a surface phase parallel to but not touching the mercury, being held there by rather loose bonds between the mercury and a small number of segments in contact with it.

Finally, the paper by Heller and Pugh (19) on the protective action of polyethylene glycols of various molecular weights on gold sols may be cited in support of the view that large molecules are adsorbed in such a manner as to hinder the approach of sol particles to within a distance greater than the range of the attractive forces.

There appears to be even less data in the literature on the adsorption of polyelectrolytes than on the adsorption of non-ionic polymers. A systematic study of the effects of variables such as the molecular weight, the pH, and the ionic strength of the supporting electrolyte is still awaited, although some work has been done on the action of polyelectrolytes as flocculating or sensitizing agents. In general, polyions of opposite charge to that of the sol cause flocculation at low values of the surface coverage, and peptize at higher concentrations (20, 21). These facts are easily explicable in terms of an increase or a decrease in the effective surface charge due to adsorption of the polyion.

The adsorption of sodium polyacrylate and hydrolyzed sodium polyacrylamide on kaolin was studied by Michaels and Morelos (4), who found that the adsorption decreased sharply as the pH was raised, and became zero in the region of pH 8. These authors postulated hydrogen bonding between the unionized carboxyl groups and the oxygen atoms of the clay surface, which would favor increased adsorption at low pH.

The quantity of polymer adsorbed at surface saturation should be fairly independent of molecular weight, as the following reasoning will show. Let the polymer molecules of molecular weight M be represented by impenetrable spheres of radius R. If these spheres become attached at random to the surface a saturation value will ultimately be attained. Let θ be defined as the total projected area of the spheres per unit area of surface. The maximum value of θ is clearly $\Pi/4$, corresponding to close packing on a square lattice, but for random deposition θ will be less than this value. At saturation we have

$$[3] \qquad \frac{\Gamma_m}{A} = \frac{M\theta}{4R^2N_0},$$

N_0 being Avogadro's number, and A the specific surface of the adsorbent.

Strictly speaking R should be taken as the radius of the equivalent excluded volume sphere (22), but this is a refinement probably not justified when applied to a polyelectrolyte. As a useful approximation R will be taken as the root mean square distance of the polymer segments from the center of gravity of the molecule, $\overline{S^2}$. The ratio of M to $\overline{S^2}$ is constant for a non-ionic polymer homologous series, and was found to be constant (21.9×10^{16} g cm^{-2}mole^{-1}) for lignosulphonates in the molecular weight range 4,000–19,000 when checked by means of the intrinsic viscosity – number-average molecular weight data of Gardon and Mason (22) (for method of calculation of $\overline{S^2}$, see pp. 612 and 408 of reference 23). Substitution of $\overline{S^2}$ for R^2, 21.9×10^{16} for $M/\overline{S^2}$, and $\Pi/4$ for θ in equation [3] leads to the constant value 7.15×10^{-8} for Γ_m/A. Independence of the saturation adsorption from the molecular weight of the adsorbate has been found in most investigations (1, 15, 16) with non-ionic polymers.

Substitution of appropriate values for A yields the following values for Γ_m:

on titanium dioxide (A = 4.65 m^2/g)	3.33 mg/g,
on kaolin (A = 10.2 m^2/g)	7.30 mg/g.

These values are quite close to the observed saturation adsorptions in the vicinity of the isoelectric point of the adsorbents, approximately at pH 4 for titanium dioxide (5), and presumably at a low pH for kaolin.

The thermodynamic irreversibility of the adsorption process indicates a rather large molar heat of adsorption. On the other hand the ability to desorb on a rise in the pH of the medium points to the presence of strongly repulsive forces between solid and adsorbate or between adsorbate molecules. The forces favoring adsorption must be sufficiently large to overcome the opposing forces of desorption, and by a margin sufficiently great to render the adsorption irreversible. In other words, the net heat of adsorption must be large in relation to product of the absolute temperature and the entropy difference between adsorbed and unadsorbed polymer molecules. It appears unlikely that van der Waals forces alone could account for such an adsorption energy, even in the case of the higher molecular weight species, where the heat of adsorption would increase with molecular weight, since the opposing forces would also be rising functions of the molecular weight. Some kind of bonding, probably hydrogen bonding as suggested by Michaels and Morelos (4) or possibly an interaction with cations attached to ion-exchange site on the solid, appears to be required.

Repulsive forces may arise from electrostatic interactions between the ionized segments of the adsorbed molecules, which would tend to push the adsorbed molecules apart, and between the adsorbent and the charged ionized polymer segments, which would tend to

push the adsorbed molecules away from the surface. Qualitative electrophoretic measurements showed that the positively charged titanium dioxide sol in acid medium changes sign on adsorption of only a fraction of a monolayer of lignosulphonate. Hence even in an acid medium it would appear that the electrostatic surface forces are predominantly repulsive.

The effect of a decrease in the pH should, therefore, favor the adsorption process in three ways: firstly, by increasing the number of available unionized sulphonic acid groups in the polyelectrolyte capable of hydrogen bonding with oxygen atoms in the surface of the solid; secondly, by reducing the mutual repulsion between polyelectrolyte segments; and thirdly, by making the zeta potential of the adsorbent more positive. Similarly, an increase in the ionic strength should favor adsorption, because of reduced ionization and this was observed (Table VI). A more detailed analysis of these phenomena must be deferred until publication of a study of the adsorption of a synthetic polyelectrolyte of constant equivalent weight and constant composition.

The fractionation which occurs on desorption must be due to differences in the balance between attractive and repulsive forces with molecular weight, the larger species presumably having a greater net heat of adsorption at a given pH. This effect would be enhanced by the tendency to an increasing equivalent weight with increasing molecular weight. It may be remarked that a fractionation based on a pH-controlled adsorption–desorption method has theoretical advantages over conventional methods based on a partition between solvents. In the latter all species must be represented in both phases at equilibrium, and it may be shown (22) that a perfect fractionation can only be approached by means of an infinite phase volume ratio, a condition clearly impossible of attainment in practice. The pH-controlled desorption method on the other hand is a non-equilibrium system, and it should be possible to achieve excellent fractionation by very small changes in the pH. The method will shortly be tried with a synthetic polyelectrolyte, in which the complicating factor of variations in the equivalent weight will be absent.

THE CONFIGURATION OF GLYCOSIDIC LINKAGES IN OLIGOSACCHARIDES

X. KÖNIGS–KNORR REACTIONS OF 3,5-DI-*O*-BENZOYL-ARABINO- AND -RIBO-FURANOSYL BROMIDES AND THEIR 2-SUBSTITUTED DERIVATIVES[1]

P. A. J. GORIN

The National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received August 31, 1961

ABSTRACT

The reactions of 3,5-di-*O*-benzoyl-L-arabinofuranosyl and -D-ribofuranosyl bromides and their 2-substituted 1,2-trans-derivatives (2-acetates, 2-benzoates, 2-*p*-nitrobenzoates, and 2-nitrates) with methanol and 1,2,3,4-tetra-*O*-acetyl-β-D-glucose have been studied. The products of these reactions, the occurrence of retention or inversion of configuration or ortho-ester formation, and the suitability of bromo derivatives for stereospecific synthesis of glycosidic linkages were considered. In general, the syntheses of oligosaccharides are more stereospecific than the corresponding formation of methyl glycosides. As in the α-D-mannopyranosyl bromide series, the reactions with tetra-*O*-acetyl-glucose give products with retention of configuration about C-1, presumably via an intermediate cyclic carbonium ion when there is an ester at C-2, but retention can take place also even when there is no convenient ester group at C-2 of the bromide. The participation of the C-2 substituent is particularly noteworthy in the condensations of the 2-acetate and 2-benzoate derivatives of 3,5-di-*O*-benzoyl-β-D-ribofuranosyl bromide with 1,2,3,4-tetra-*O*-acetyl-β-D-glucose, which yield exclusively disaccharides of the orthoester type.

INTRODUCTION

In a previous paper (1) various derivatives of α-D-mannopyranosyl bromide were used in condensation reactions with hydroxyl compounds under Königs–Knorr conditions. In some cases the configuration of the product was different from that expected on the basis of earlier work (summarized in refs. 2 and 3). For instance, 3,4,6-tri-*O*-acetyl-α-D-mannopyranosyl bromide and its 2-*O*-benzyl derivative both gave disaccharides with an α-configuration on condensation with 1,2,3,4-tetra-*O*-acetyl-D-glucose. Previously, reactions examined in which a substituent in the 2-position could not participate by forming an intermediate cyclic carbonium ion (e.g. 2,3,4,6-tetra-*O*-acetyl-α-D-gluco- and -D-galactopyranosyl bromides) have given products with the configuration opposite to that of the starting material. A qualitative and semi-quantitative study has now been made using 1-bromo derivatives of L-arabino- and D-ribo-furanose benzoates in which the bromo groups are also mainly trans to the C-2 substituent. The nature of the grouping at C-2 was varied and the configuration and structure of the products studied in two series of experiments. These reactions were carried out in the presence of silver oxide (*a*) with pure methanol and (*b*) with an excess of tetra-*O*-acetyl-D-glucose in chloroform in the presence of Drierite.

The current interest in nucleosides and nucleotides has focussed attention on stereospecific Königs–Knorr syntheses of pentofuranosyl glycosidic linkages. β-D-Ribofuranosyl derivatives have been prepared from 2,3,5-tri-*O*-acetyl-α-D-ribofuranosyl chloride (4) and bromide (configuration unknown) (5) and 2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl bromide (6, 7) whereas α-D-ribofuranosides can be derived from 5-*O*-benzoyl-2,3,-*O*-carbonyl-D-ribofuranosyl bromide (8). In the arabinofuranosyl series the α-configuration is readily attainable and has been synthesized by Wright and Khorana, who used 2,3,5-tri-*O*-benzoyl-α-D- and -L-arabinofuranosyl bromides (9) and a 2,3,5-tri-*O*-acetyl-L-arabinofuranosyl bromide (9) of uncertain configuration. β-D-Arabinofuranosides are of interest

[1]*Issued as N.R.C. No. 6657.*

because of their natural occurrence in the nucleosides of sponges (10, 11). The Königs-Knorr synthesis of this type of linkage does not appear to have been carried out, although it has been formed by the inversion of the C-2 hydroxyl group of a D-ribofuranosyl uracil (12) and thymine (13, 14) derivatives. Although the conditions used above are different from those for disaccharide synthesis, it appeared that some of these bromides could be adapted for the preparation of α-L-arabinofuranosyl and β-D-ribofuranosyl disaccharides. Thus, the condensation of 2,3,5-tri-*O*-benzoyl-α-L-arabinofuranosyl bromide with 2,3,4-tri-*O*-acetyl-L-arabinose diethyl dithioacetal has now led to the synthesis of 5-*O*-α-L-arabinofuranosyl-L-arabinose, a structural component in sugar beet pentosan (15).

The use of substitutents on C-2 of a sugar bromide in order to control the configuration of the product has been demonstrated in the D-ribofuranose (8), the D-glucopyranose (16, 17, 18*a*), and the D-mannopyranose series (1), and use of this technique has now been utilized in the L-arabinofuranosyl and D-ribofuranosyl series. Convenient compounds for such starting materials in the preparation of 1-bromo derivatives of L-arabino- and D-ribo-furanose have been described by Fletcher and Ness (19, 20). These are 1,3,5-tri-*O*-benzoyl-β-L-arabinose and 1,3,5-tri-*O*-benzoyl-α-D-ribose, and from these compounds the 2-acetates (19, 21), 2-nitrates, and 2-*p*-nitrobenzoates can be prepared using conventional reactions. Treatment of these products with chloroform containing hydrogen bromide until constant rotation had been reached furnished the 1-bromo derivatives (Table I),

TABLE I

3,5-Di-*O*-benzoyl-L-arabino- and -D-ribo-furanosyl bromide derivatives and their reaction products with methanol and 1,2,3,4-tetra-*O*-acetyl-β-D-glucose

2-Substituted bromo derivatives	Specific rotations	Product from methanol	Product from 1,2,3,4-tetra-*O*-acetyl-β-D-glucose
3,5-Di-*O*-benzoyl-L-arabinofuranose			
α-2-Acetate	−112°	Mainly orthoacetate*	α-Disaccharide*
		α- and β-Glycoside	Trace of β
α-2-Benzoate		Orthobenzoate	α-Disaccharide
		α- and β-Glycoside (β > α)	Trace of β
α-2-*p*-Nitrobenzoate	−63°	Ortho-*p*-nitrobenzoate	α-Disaccharide
		α- and β-Glycoside (β > α)	Trace of β
α-2-Nitrate	−65°	β-Glycoside	β-Disaccharide
			Trace of α
α-2-Hydroxyl	−103°	β-Glycoside	α and β-Disaccharide (39:61)
3,5-Di-*O*-benzoyl-D-ribofuranose			
β-2-Acetate	−52°	Orthoacetate	Orthoester
		α- and β-Glycoside	
β-2-Benzoate	−11°	Orthobenzoate	Orthoester
		β-Glycoside	
β-2-*p*-Nitrobenzoate	+8°	Ortho-*p*-nitrobenzoate	β-Disaccharide
		α- and β-Glycoside	Orthoester
β-2-Nitrate	−39°	α-Glycoside	α- and β-Disaccharide (32:68)
		Trace of β	
α-2-Hydroxyl	+109°	α- and β-Glycoside	α- and β-Disaccharide (46:54)

*In all these reactions some free arabinose (or ribose) was obtained on de-esterification. However, the purpose of the paper is to compare orthoester and α- and β-glycoside formation.

which were used immediately because of possible instability. From the specific rotations of the bromides it was concluded that all the L-arabinofuranose derivatives were predominantly α and the D-ribofuranose compounds β, with the notable exception of 3,5-di-*O*-benzoyl-D-ribofuranosyl bromide (20), which appeared to be α because of its marked difference in specific rotation from the rest of the series (Table I).

When the 2-benzoates, 2-*p*-nitrobenzoates, and 2-acetates of 3,5-di-*O*-benzoyl-L-arabinofuranosyl bromide and 3,5-di-*O*-benzoyl-D-ribofuranosyl bromide were treated in one series of experiments with methanol and in the other with 1,2,3,4-tetra-*O*-acetyl-β-D-glucose (silver oxide being used in both cases as acid acceptor, with iodine present also in the arabinofuranosyl disaccharide syntheses) the course of reaction could be anticipated to some extent by taking into account participation, prior to glycoside formation, of the 2-substituted group via intermediate cyclic carbonium ions. In the L-arabinose series, methanol treatment of these bromides resulted in the formation of orthoester derivatives and methyl arabinofuranosides of which the β-anomer predominated. These results are essentially analogous to those obtained by Isbell and Frush when 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl bromide was treated with methanol in the presence of silver carbonate (22) except that in this instance some methyl α-L-arabinofuranoside was formed in addition to the β-anomer. Also analogous were the results from the use of excess 1,2,3,4-tetra-*O*-acetyl-D-glucose as the nucleophilic reagent (1). The disaccharide formed after deacetylation was 6-*O*-α-L-arabinofuranosyl-D-glucose (characterized as the free sugar and its heptaacetate) with little of the β-anomer. However, mixtures of α- and β-disaccharides (39:61) were formed from 3,5-di-*O*-benzoyl-α-L-arabinofuranosyl bromide, in contrast to the product formed from 3,4,6-tri-*O*-acetyl-α-D-mannopyranosyl bromide, which was mainly α in configuration (1). The possibility that the C-5 benzoyl group could participate in this reaction via a cyclic carbonium ion seems unlikely since on treatment with methanol the bromide yielded methyl β-L-arabinofuranoside and no 1,5-orthobenzoate.*

No orthoesters were obtained from the reaction of the arabinofuranosyl bromides with tetra-*O*-acetyl glucose, but their absence may have been due to the excess of acid which was found to be produced in early stages of the condensations. The Königs–Knorr condensations described in this paper were not carried out under optimum conditions in which the halide would be added slowly to an excess of the alcohol (23). Since some of the pentofuranosyl bromides were somewhat unstable, the mixture of alcohol and other components were added in one batch to a flask containing the bromide, immediately after its preparation. Such conditions were probably also responsible in all the condensations for a product in which gentiobiose and higher oligosaccharides could be detected after deacylation. In the case of the reaction using 3,5-di-*O*-benzoyl-α-L-arabinofuranosyl bromide, the disaccharide by-product was isolated and converted by de-esterification to gentiobiose. When 1,2,3,4-tetra-*O*-acetyl-β-D-glucose alone was treated with hydrogen bromide in chloroform, slow-moving spots corresponding to gentiobiose and higher oligosaccharides were noted on paper chromatograms after deacetylation. These results are similar to those described by Haq and Whelan (24), who produced 1,6-*O*-β-D-glucopyranose oligosaccharides by the self-condensation of 2,3,4-tri-*O*-acetyl-α-D-glucopyranosyl bromide. The yields of gentiobiose in the Königs–Knorr reactions in the L-arabinofuranose series appear to correspond to the reactivity of the starting halide towards alcohols. The 2-*p*-nitrobenzoyl and 2-*O*-nitro bromides gave little of the disaccharide by-product whereas the 2-benzoyl, 2-hydroxyl, and 2-acetyl bromides gave appreciable amounts.

Condensations using a 2-*O*-nitro halide have been reported by Wolfrom, Pittet, and Gillam (18), who prepared an α-disaccharide (contaminated with β) by the reaction of 3,4,6-tri-*O*-acetyl-2-*O*-nitro-β-D-glucopyranosyl chloride with 1,2,3,4-tetra-*O*-acetyl-β-D-glucose. From a preparative point of view, 3,5-di-*O*-benzoyl-2-*O*-nitro-α-L-arabino-

**Similarly, no 1,5-orthobenzoate was formed from 3,5-di-O-benzoyl-α-D-ribofuranosyl bromide.*

furanosyl bromide is similarly useful for synthesis of β-arabinofuranosides. Reaction of the 2-*O*-nitro bromide with methanol and 1,2,3,4-tetra-*O*-acetyl-β-D-glucose resulted in the formation of the methyl β-L-arabinofuranoside derivative and a β-disaccharide, respectively, and only traces of the α-anomers were formed. The latter result thus shows that the 2-nitrate group does not participate in the formation of an intermediate nitronium ion.

In the D-ribofuranosyl series the reactions with methanol and 1,2,3,4-tetra-*O*-acetyl-D-glucose gave mixtures of products (Table I), as would be expected on the basis of S_N1 mechanisms. Treatment of the bromides with tetra-*O*-acetyl-glucose gave mainly β-disaccharides, which were adulterated either with orthoester or α-disaccharide. In specific instances, such as the reaction of 3,5-di-*O*-benzoyl-2-*O*-nitro-β-D-ribofuranosyl bromide with methanol and 1,2,3,4-tetra-*O*-acetyl-β-D-glucose, some unexpected reactions took place. The methanol reaction gave complete inversion at C-1 whereas with tetra-*O*-acetyl-glucose there was much retention of configuration. This picture is similar to the condensation of 2-*O*-benzyl-3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl bromide with methanol and tetra-*O*-acetyl-β-D-glucose, which has been considered in a previous paper (1).

Under certain conditions trans-1-bromides of sugars can be converted to products of the same configuration without the chemical participation of an ester group at C-2. 3,4,6-Tri-*O*-acetyl-2-*O*-trichloroacetyl-β-D-glucosyl chloride yields mainly the α-glycoside and does not, in contrast to trans-2-acetate derivatives, give a 1,2-orthotrichloroacetate on reaction with methanol (25). This has been explained by the reduction of nucleophilic activity of the carbonyl oxygen by the three chloro groups so that a cyclic carbonium ion intermediate is not possible (3). A more limited reduction of carbonyl participation could explain the differing reactions of the 2-acetyl, 2-benzoyl, and 2-*p*-nitrobenzoyl derivatives of 3,5-di-*O*-benzoyl-β-D-ribofuranosyl bromides with 1,2,3,4-tetra-*O*-acetyl-β-D-glucose. The two former derivatives give orthoester products only whereas the 2-*p*-nitrobenzoate derivative gives rise to β-disaccharide also.

The reactions summarized in Table I can give rise to some overall generalizations. It appears that, in the five-membered ring, the ester group at C-2 can participate in the Königs–Knorr reaction by formation of cyclic carbonium ion intermediates to a greater extent than in the 6-membered series. The participation of C-2 is emphasized in the ribofuranosyl series since orthoester yield is very high in attempted ribofuranosyl disaccharide syntheses. This should not be surprising when the favorable stereochemistry of cis-carbon to oxygen bonds at C-1 and C-2 of the five-membered ring is considered. It can also be concluded that the reaction in disaccharide formation is more stereospecific than the corresponding methyl furanoside synthesis. This presumably is due to the size of the nucleophilic reagent, which could be a factor limiting the direction of approach of the tetra-*O*-acetyl glucose, in contrast to that of the smaller methanol molecule.

EXPERIMENTAL

Evaporations were carried out under reduced pressure at 50° C (bath temperature and optical rotations were measured at 23° C).

Preparation of 2-Substituted 1,3,5-Tri-O-benzoyl-β-L-arabinoses

(a) 2-p-Nitrobenzoate

1,3,5-Tri-*O*-benzoyl-β-L-arabinose (1.40 g) was heated at 80° C for 1 hour in pyridine (20 ml) containing *p*-nitrobenzoyl chloride (1.40 g). The mixture was then added to aqueous sodium bicarbonate, shaken for an hour, and the precipitate which formed was filtered off. Two recrystallizations from ethyl acetate – hexane gave the 2-*p*-nitrobenzoate with m.p. 170–171° C and $[\alpha]_D$ +114° (*c*, 1.0, $CHCl_3$). Calculated for $C_{33}H_{25}O_{11}N$: C, 64.8%; H, 4.1%. Found: C, 64.6%; H, 4.2%.

(b) 2-Nitrate

1,3,5-Tri-*O*-benzoyl-β-L-arabinose (1.38 g) dissolved in acetic anhydride (10 ml) was added slowly to a mixture of acetic anhydride (8 ml) and fuming nitric acid (2 ml), cooled in an ice bath. After 30 minutes at 0° C and 15 minutes at room temperature, ice-cold aqueous sodium bicarbonate solution was added to destroy the reagent. Extraction with chloroform and evaporation of the extract yielded a solid which, on two recrystallizations from ethanol, yielded the 2-nitrate (1.06 g) with m.p. 99–100° C and $[\alpha]_D$ +58° (*c*, 0.5, $CHCl_3$). Calculated for $C_{26}H_{21}O_{10}N$: C, 61.5%; H, 4.2%; N, 2.8%. Found: C, 61.3%; H, 4.2%; N, 2.1%.

Preparation of 2-Substituted 1,3,5-Tri-O-benzoyl-α-D-riboses

(a) 2-p-Nitrobenzoate

1,3,5-Tri-*O*-benzoyl-α-D-ribose was *p*-nitrobenzoylated by the above method. Two recrystallizations from ethyl acetate – hexane yielded the 2-*p*-nitrobenzoate with m.p. 112–115° C and $[\alpha]_D$ +100° (*c*, 1.0, $CHCl_3$). Calculated for $C_{33}H_{25}O_{11}N$: C, 64.8%; H, 4.1%; N, 2.3%. Found: C, 64.8%; H, 4.2%; N, 2.2%.

(b) 2-Nitrate

1,3,5-Tri-*O*-benzoyl-α-D-ribose was converted to its sirupy 2-nitrate derivative using the nitration procedure described above. It had $[\alpha]_D$ +69° (*c*, 0.7, H_2O). Calculated for $C_{26}H_{21}O_{10}N$: N, 2.8%. Found: N, 2.2%.

Bromination of 2-Substituted 1,3,5-Tri-O-benzoyl-β-L-arabinoses

To purify the chloroform, it was washed with water, dried with calcium chloride, and distilled, and hydrogen bromide was bubbled through it for 2 minutes to yield an approximately 0.3 *N* solution. A 1% solution of each benzoate derivative in this solvent was prepared and its specific rotation followed. The solution was then evaporated (bath temperature 0° C), and residual hydrogen bromide removed by evaporation three times of chloroform solutions. The specific rotations recorded are as follows, the initial reading being measured in chloroform separately, and the final reading being the constant value reached:

(*a*)	2-acetate	+60° → −112° (immediate),
(*b*)	2-*p*-nitrobenzoate	+114° → −63° (7 minutes),
(*c*)	2-nitrate	+58° → −65° (12 minutes),
(*d*)	2-hydroxyl	+4° → −103° (immediate).

Bromination of 2-Substituted 1,3,5-Tri-O-benzoyl-α-D-riboses

A similar bromination procedure was used, and the following specific rotations were measured:

(*a*)	2-acetate	+74° → −52° (6 minutes),
(*b*)	2-benzoate	+88° → −11° (9 minutes),
(*c*)	2-*p*-nitrobenzoate	+100° → +8° (16 minutes),
(*d*)	2-nitrate	+83° → −39° (2 hours),
(*e*)	2-hydroxyl	+87° → +109° (immediate).

Reactions of Pentofuranosyl Bromides with Methanol

The bromides prepared from the appropriate 1-benzoate derivative (0.50 g) were shaken for 1 hour in methanol (20 ml) containing an excess of silver oxide (2.5 g). The solutions were then filtered and evaporated. De-esterification, when necessary, was carried out in 30 hours using 0.1 *N* sodium methoxide in methanol (0.2 equivalents). Characterization of products was then carried out using paper chromatograms (sprays: *p*-anisidine hydrochloride (26) and ammoniacal silver nitrate (27); solvent: *n*-butanol–ethanol–water (40:11:19 v/v)). Orthoesters had R_F's ~0.8 and methyl α-L-arabinofuranoside was characterized since it moved faster than its β-anomer, both glycosides having R_F's ~0.4.

(a) L-Arabinofuranosyl Series

(i) 2-Acetate derivative.—The material appeared to be mainly the methyl orthoester. The reaction product had $[\alpha]_D$ +15° (*c*, 1.0, $CHCl_3$) and, after crystallization and two recrystallizations from hexane, had m.p. 120–121° C and $[\alpha]_D$ 0° (*c*, 2.3, $CHCl_3$). Calculated for $C_{22}H_{22}O_8$: C, 63.8%; H, 5.35%. Found: C, 63.9%; H, 5.4%. De-esterification did not give methyl arabinosides.

(ii) 2-Benzoate derivative.—The product had $[\alpha]_D$ −20° (*c*, 1.0, $CHCl_3$) and the de-esterified sample showed mainly orthoacetate, some methyl β-arabinoside, and only a small proportion of the α-anomer. Methyl 1,2-orthobenzoyl-L-arabinose was isolated by ethyl acetate extraction of an aqueous solution of the mixture which had been previously extracted with hexane to remove methyl benzoate. The product had no carbonyl absorption in the infrared and had $[\alpha]_D$ −5° (*c*, 2.1, H_2O). Treatment with 0.01 *N* sulphuric acid immediately changed this to +80° (*c*, 1.0) and the material (probably 2-*O*-benzoyl-L-arabinose) obtained after neutralization and evaporation had strong carbonyl absorption at 1710 cm^{-1}.

(iii) 2-p-Nitrobenzoate derivative.—The product had $[\alpha]_D$ +36° (*c*, 1.2, $CHCl_3$) and, on de-esterification, gave a similar picture on a paper chromatogram as the above 2-benzoate. 3,5-Di-*O*-benzoyl-1,2-methyl-ortho-*p*-nitrobenzoyl-L-arabinose crystallized, and two recrystallizations from ethyl acetate – hexane gave

material with m.p. 155–159° C and $[\alpha]_D$ +36° (*c*, 0.8, $CHCl_3$). Calculated for $C_{27}H_{23}O_{10}N$: C, 62.2%; H, 4.95%. Found: C, 61.8%; H, 4.8%. De-esterification gave material corresponding to a methyl ortho-*p* nitrobenzoate derivative on a paper chromatogram.

(iv) 2-Nitrate derivative.—The product, $[\alpha]_D$ +85° (*c*, 1.5, $CHCl_3$), crystallized, and two recrystallizations from hexane yielded methyl 3,5-di-*O*-benzoyl-2-*O*-nitro-β-L-arabinofuranoside with m.p. 98–99° C and $[\alpha]_D$ +85° (*c*, 0.8, $CHCl_3$). Calculated for $C_{20}H_{19}O_9N$: C, 57.55%; H, 4.6%; N, 3.4%. Found: C, 57.8%; H, 4.7%; N, 2.8%. The methyl glycoside (37 mg) was shaken in ethanol (10 cc) containing 5% palladium on charcoal (30 mg) under 2 atmospheres of hydrogen for 24 hours (28). After filtration and evaporation the product was de-esterified to yield methyl β-L-arabinofuranoside (identified on a paper chromatogram).

(v) Hydroxyl derivative.—The methyl glycoside derivative obtained appeared to be methyl 3,5-di-*O*-benzoyl-β-L-arabinofuranoside since only the β-L-glycoside was obtained on de-esterification.

(b) D-Ribofuranosyl Series

The products obtained in this series were sirupy and are summarized in Table I. The specific rotations of the products after treatment with methanol are as follows: 2-acetate +72° (*c*, 0.6, $CHCl_3$); 2-benzoate +90° (*c*, 0.9, $CHCl_3$); 2-*p*-nitrobenzoate +112° (*c*, 1.1, $CHCl_3$); 2-nitrate +69° (*c*, 0.7, $CHCl_3$); and 2-hydroxyl +39° (*c*, 0.8, $CHCl_3$). Methyl ribofuranosides were identified by their relative R_F values (29).

Reactions of L-Arabinofuranosyl Bromides with 1,2,3,4-Tetra-O-acetyl-β-D-glucose

In these experiments 1.0 g of the appropriate bromide was mixed with silver oxide (1.0 g), iodine (0.25 g), and Drierite (5.0 g). Then a solution of 1,2,3,4-tetra-*O*-acetyl-β-D-glucose (4.0 g) in dry chloroform (16 ml) was added, and the mixture was shaken overnight. After filtration and evaporation the sirup was de-esterified with 0.2 equivalents of 0.1 *N* sodium methoxide in methanol over 3 hours. The product was then examined on paper chromatograms in the ethyl acetate – pyridine – water (10:4:3 v/v) solvent using aniline oxalate (30) as spray. 6-*O*-α-L-Arabinofuranosyl-D-glucose had $R_{Galactose}$ 1.2 whereas the β-anomer had $R_{Galactose}$ 1.0. In each addition some gentiobiose and higher homologues were detected and the disaccharide was isolated in the case of the condensation with 2-hydroxyl derivative. The products were fractionated on a cellulose column. *n*-Butanol saturated with water gave a partial separation of the arabinosyl glucosides and *n*-butanol–ethanol–water (4:1:1 v/v) eluted gentiobiose.

(i) 2-O-Benzoyl derivative.—The product was mainly 6-*O*-α-L-arabinofuranosyl-α-D-glucose (0.30 g) with spots corresponding to 1,6-*O*-β-glucopyranosyl oligosaccharides. The former was recrystallized twice from ethanol and had m.p. 163–165° C and $[\alpha]_D$ −15° → −40° (*c*, 1.0, H_2O; constant value, 18 hours). Calculated for $C_{11}H_{20}O_{10}$: C, 42.3%; H, 6.5%. Found: C, 42.3%; H, 6.4%. The sugar was α rather than β since on oxidation in aqueous sodium periodate the specific rotation of the solution changed to −77° (*c*, 0.6, H_2O) (31). The crude disaccharide (0.24 g) was heated in acetic anhydride (2 ml) containing sodium acetate (0.20 g) at 100° C overnight. The anhydride was destroyed with ice water and the mixture extracted with benzene. The solution was evaporated and the residue crystallized from ethanol–hexane. Recrystallization from the same solvent gave hepta-*O*-acetyl-6-*O*-α-L-arabinofuranosyl-β-D-glucose (0.17 g) with m.p. 108–109° C and $[\alpha]_D$ −20° (*c*, 2.0, $CHCl_3$). Calculated for $C_{25}H_{34}O_{17}$: C, 49.5%; H, 5.7%. Found: C, 49.45%; H, 5.7%. The acetate appeared to be β since its mother liquor had a specific rotation of −10° (*c*, 2.0, $CHCl_3$).

(ii) 2-O-Acetyl derivative.—In addition to 6-*O*-α-L-arabinofuranosyl-D-glucose (310 mg) spots corresponding to 1,6-*O*-β-D-glucopyranosyl oligosaccharides were obtained. The arabinosyl glucose was converted to its hepta-*O*-acetate, m.p. and mixed m.p. 106.5–108° C.

(iii) 2-p-Nitrobenzoate derivative.—The product in this case contained only a trace of glucose containing oligosaccharides and in the arabinofuranosyl glucose fraction the α-anomer predominated. The isolated 6-*O*-α-L-arabinofuranosyl-D-glucose (252 mg) was converted to the hepta-*O*-acetate, m.p. and mixed m.p. 107.5–109.5° C.

(iv) 2-Nitrate derivative.—Here the reaction mixture was filtered and evaporated and half of the residue taken up in benzene, which was then washed three times to remove tetra-*O*-acetyl-glucose. On evaporation, the sirup crystallized and after two recrystallizations from ethanol yielded 0.22 g of 6-*O*-β-(3,5-di-*O*-benzoyl-2-*O*-nitryl-L-arabinofuranosyl)-(1,2,3,4-tetra-*O*-acetyl-β-D-glucose) with m.p. 152–153° C and $[\alpha]_D$ +83° (*c*, 1.1, $CHCl_3$). Calculated for $C_{33}H_{35}O_{18}N$: C, 54.0%; H, 4.8%. Found: C, 54.0%; H, 4.8%.

Of this material 0.11 g was denitrated by shaking in ethanol (25 ml) containing 5% palladium charcoal (0.20 g) under 2 atmospheres of hydrogen overnight. After filtration of the catalyst this process was repeated. Refiltration and evaporation gave a product (45 mg) which did not crystallize on seeding with the starting material. The product had $[\alpha]_D$ +49° (*c*, 1.1, $CHCl_3$), and de-esterification gave 6-*O*-β-L-arabinofuranosyl-D-glucose (20 mg) with $[\alpha]_D$ +73° (*c*, 0.6, H_2O).

Repetition of this process on the crude Königs–Knorr product showed that only a trace of the 6-*O*-α-L-arabinofuranosyl-D-glucose derivative was present.

(v) 2-Hydroxyl derivative.—The product consisted of 6-*O*-α- and 6-*O*-β-L-arabinofuranosyl-D-glucose. An attempt was made to fractionate these on a cellulose column and two fractions were obtained, one (373 mg) with $[\alpha]_D$ +34° (*c*, 1.5, H_2O) and the other (79 mg) with $[\alpha]_D$ +8° (*c*, 1.3, H_2O). Based on the known specific rotations of the α- and β-disaccharide, the mixture consisted of 39% of the α- and 61% of the β-anomer.

Gentiobiose (310 mg) was also separated from its higher oligomer and was converted to its β-octaacetate derivative (32). Two recrystallizations from ethanol gave crystals with m.p. 200–202° C and $[\alpha]_D$ −5° (*c*, 1.2, $CHCl_3$). Calculated for $C_{28}H_{38}O_{19}$: C, 49.6%; H, 5.6%. Found: C, 49.6%; H, 5.65%. X-Ray diffraction patterns of this and a specimen of authentic gentiobiose, β-octaacetate, were identical.

Action of Hydrogen Bromide in Chloroform on 1,2,3,4-Tetra-O-acetyl-β-D-glucose

1,2,3,4-Tetra-*O*-acetyl-β-D-glucose (0.48 mmole) was treated with hydrogen bromide (0.96 mmole) in chloroform (5.4 ml) and the specific rotation followed.

Time (minutes)	0	2	4	5	6	10
Specific rotation (in pure $CHCl_3$)	+11°	−26°	−32°	−39°	−43°	−46°

The solution after 10 minutes was washed with aqueous sodium bicarbonate, then water, and evaporated. Deacetylation gave mainly glucose with a small proportion of material corresponding to gentiobiose.

Reactions of D-*Ribofuranosyl Bromides with 1,2,3,4-Tetra-O-acetyl-β-D-glucose*

The conditions used in this series of experiments were identical with those used in the L-arabinofuranosyl series, except that the relative proportion of silver oxide was increased fivefold and no iodine was used.

(i) 2-O-Acetyl derivative.—The product, after deacetylation, gave a yellow spot with $R_{Galactose}$ 0.8 on paper chromatograms (solvent: *n*-butanol–ethanol–water (40:11:19 v/v); spray: *p*-anisidine hydrochloride) and this disappeared on acidification with acetic acid. No normal disaccharide was present.

(ii) 2-O-Benzoyl derivative.—When a similar procedure as for the above 2-acetyl derivative was used a spot with $R_{Galactose}$ 0.9 was obtained, also corresponding to orthoester. No ribofuranosyl-glucose was present.

(iii) 2-p-Nitrobenzoyl derivative.—The product on de-esterification appeared to be a mixture of orthoester and a normal disaccharide. The disaccharide fraction had $R_{Galactose}$ 0.95 (and a trace at 0.90) in the ethyl acetate – pyridine – water (10:4:3 v/v) solvent, and on isolation from a cellulose column it (35 mg) had $[\alpha]_D$ 0° (*c*, 1.0, H_2O). Oxidation with aqueous sodium periodate changed its specific rotation to −94° (*c*, 0.6, H_2O; constant value 5 minutes), indicating a β-linkage. Acetylation of the 6-*O*-β-D-ribofuranosyl-D-glucose by the hot acetic anhydride – sodium acetate method (see earlier in experimental reaction for method) yielded a substance which crystallized, and after two recrystallizations from ethanol–hexane the waxy hepta-*O*-acetate had m.p. 108–110° C and $[\alpha]_D$ +3° (*c*, 1.5, $CHCl_3$). Calculated for $C_{25}H_{34}O_{17}$: C, 49.5%; H, 5.65%. Found: C, 49.6%; H, 5.7%.

(iv) 2-Nitrate derivative.—After denitration (as for denitration of the 2-nitrate of the corresponding L-arabinofuranose derivative) followed by de-esterification the mixture was fractionated on a cellulose column. The product (41 mg) had $[\alpha]_D$ +34° (*c*, 0.9, H_2O), and on oxidation with sodium periodate a value of −48° (*c*, 0.5, H_2O; constant value 1 hour) was obtained. This corresponds to 68% of 6-*O*-β-D-ribofuranosyl-D-glucose and 32% of the α-anomer (31).

(v) 2-Hydroxyl derivative.—After de-esterification paper chromatography showed an almost equal mixture of the β- and α-anomers ($R_{Galactose}$ 0.95 and 0.90 respectively). Column chromatography yielded two fractions, one (16 mg) with $[\alpha]_D$ +77° (*c*, 1.0, H_2O) (after periodate oxidation +54° (*c*, 0.6, H_2O)) consisting mainly of 6-*O*-α-D-ribofuranosyl-D-glucose, and the other (14 mg) had $[\alpha]_D$ +12° (*c*, 0.6, H_2O) (after periodate oxidation −88° (*c*, 0.3, H_2O)) and was mainly β-anomer. The combined fractions thus appear to consist of 54% of β- and 46% of α-disaccharide.

Preparation of 5-O-α-L-Arabinofuranosyl-L-arabinose

5-O-α-L-Arabinofuranosyl-L-arabinose Diethyl Thioacetal

Using the same Königs–Knorr conditions as for the preparation of the other L-arabinofuranosyl disaccharides 2,3,4-tri-*O*-benzoyl-α-L-arabinofuranosyl bromide (1.0 g) was treated with 2,3,4-tri-*O*-acetyl-L-arabinose diethyl thioacetal. The product, after de-esterification, was fractionated on a cellulose column. Benzene–ethanol–water (1000:50:1 v/v) eluted unchanged thioacetal and the (500:50:1 v/v) mixture gave the disaccharide thioacetal (0.41 g). The mercaptal was crystallized twice from ethyl acetate – hexane and had m.p. 56° C and $[\alpha]_D$ −62° (*c*, 1.3, H_2O). Calculated for $C_{19}H_{28}O_8S_2$: C, 43.3%; H, 7.3%. Found: C, 42.9%; H, 7.3%. Oxidation with sodium periodate gave a product with $[\alpha]_D$ −91° (*c*, 0.6, H_2O), thus indicating an α-L-configuration for the disaccharide linkage.

5-O-α-L-Arabinofuranosyl-L-arabinose

The disaccharide thioacetal (100 mg) was acetylated by the hot acetic anhydride – sodium acetate method (see earlier in experimental section for method) to yield the hexa-*O*-acetate (158 mg). This was dissolved in acetone (3 ml) and water (1.5 ml). Mercuric oxide (2.0 g) was added, followed by mercuric chloride (0.40 g) in acetone (4 ml), to the stirred mixture. After 30 minutes the solution was refluxed for 10 minutes, and then filtered and evaporated. The sirup was dissolved in chloroform, which was washed twice with water, dried ($MgSO_4$), filtered, and evaporated. The product was deacetylated and the disaccharide obtained was fractionated on a cellulose column (*n*-butanol 3/4 saturated with water as solvent) to yield the purified material (55 mg) with $[\alpha]_D$ −94° (*c*, 1.4, H_2O). A sample of disaccharide prepared from

sugar beet araban had $[\alpha]_D$ −72° (15). On sodium periodate oxidation the $[\alpha]_D$ changed to −76° (210 minutes; *c*, 0.9, H_2O) (expected value: −79° to −88° (31)), thus indicating that the 5-*O*-α-L-arabinofuranosyl-L-arabinose was not entirely pure.

ACKNOWLEDGMENTS

The author wishes to thank Mrs. S. F. Hector for technical assistance, Mr. M. Mazurek for microanalytical determinations, and Miss I. Gaffney for measuring infrared spectra.

CHEMISTRY OF THE TRIFLUOROMETHYL GROUP

PART IV. DIPHENYLTRIFLUOROMETHYLPHOSPHINE AND COMPLEX FORMATION BY PHENYLTRIFLUOROMETHYLPHOSPHINES[1]

M. A. A. Beg and H. C. Clark

The Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received October 10, 1961

ABSTRACT

Three methods of preparing diphenyltrifluoromethylphosphine are described. The hydrolysis of the phosphine to diphenylphosphinic acid and fluoroform, and the formation of dibromo- and diiodo-phosphoranes from the phosphine are reported. The adducts $(C_6H_5)_3P.BF_3$ and $(C_6H_5)_2CF_3P.BF_3$ are described and the latter is found to be the less stable. With platinum (II) chloride, the complexes *trans*-$[(C_6H_5)_2PCF_3]_2PtCl_2$ and *trans*-$[C_6H_5P(CF_3)_2]_2PtCl_2$ are formed. The properties of the BF_3 adducts and $PtCl_2$ complexes are interpreted in terms of the electronegativity and size of the trifluoromethyl group.

INTRODUCTION

In the previous paper (1) of this series, the preparation and physical and chemical properties of phenylbistrifluoromethylphosphine were described. We now report the preparation of diphenyltrifluoromethylphosphine, and also the results of experiments designed to determine the abilities of both these phosphines to participate in complex formation.

DISCUSSION AND RESULTS

Three methods have been found successful in preparing diphenyltrifluoromethylphosphine. Since phenylbistrifluoromethylphosphine can be obtained by the addition of trifluoroiodomethane to the P—P bonds of tetraphenylcyclotetraphosphine, one obvious route to diphenyltrifluoromethylphosphine lay in the reaction of tetraphenyldiphosphine with trifluoroiodomethane:

$$(C_6H_5)_2P—P(C_6H_5)_2 + CF_3I \rightarrow (C_6H_5)_2PCF_3 + (C_6H_5)_2PI.$$

This and other reported additions (2, 3) to compounds of the type $R_2P—PR_2$ involve cleavage of the weak P—P bond. Its bond energy is only 50 kcal mole^{-1} (4), much less than that of the P—C bond (62 kcal mole^{-1}), so that the P—P bond will be the potential point of attack by a reactive species.

Tetraphenyldiphosphine is prepared by the reaction of diphenylphosphine and diphenylchlorophosphine (5, 6), preferably in a high-boiling solvent such as xylene. When tetraphenyldiphosphine is heated with excess trifluoroiodomethane at 185°, or when the two reactants are exposed to ultraviolet radiation, a mixture of diphenyltrifluoromethylphosphine and diphenyliodophosphine is produced, from which the former can be extracted with petroleum ether. Since the reaction will occur either thermally or on ultraviolet irradiation, a free-radical mechanism involving the attack of CF_3 radicals on the P—P bond seems probable.

The alternative methods of preparation require the reaction of either diphenylchlorophosphine or triphenylphosphine with trifluoroiodomethane at 185–200°. Although in both cases the yields are not high (approx. 20%), these methods are advantageous in

[1]*From part of the thesis submitted by M. A. A. Beg in partial fulfillment of the requirements for the Ph.D. degree.*

that the reactants are readily available and the preparation of the diphosphine is not required. A number of secondary products are obtained in each case so that the overall reactions can be represented as

$$(C_6H_5)_3P + CF_3I \rightarrow (C_6H_5)_2PCF_3 + (C_6H_5)_2PI + C_6H_5CF_3$$
$$(C_6H_5)_2PCl + CF_3I \rightarrow (C_6H_5)_2PCF_3 + (C_6H_5)_2PI + (C_6H_5)CF_3PCl + C_6H_5CF_3 + CF_3Cl.$$

The nature of the products strongly suggests that these reactions involve a radical mechanism, presumably the attack of CF_3 radicals on the P—C_6H_5 or P—Cl bonds.

Diphenyltrifluoromethylphosphine is a colorless, viscous liquid which boils at 255–257°. This is 28° lower than the boiling point of the methyl analogue, $(CH_3)_2PCF_3$, and 24° lower than that of the secondary phosphine, $(C_6H_5)_2PH$. Such low boiling points are common for the perfluoroalkyl derivatives of the group V elements and reflect the reduced molecular polarity and hence the weaker intermolecular interactions.

Diphenyltrifluoromethylphosphine is stable in air and is not decomposed easily on heating. After being heated to 300° for 24 hours, 85% of the phosphine is recovered. The phosphine is unaffected by water or by hydrochloric acid up to 150°. Only slight hydrolysis occurs with aqueous sodium hydroxide at 100°, in marked contrast to phenylbistrifluoromethylphosphine which is quantitatively hydrolyzed under these conditions. Diphenyltrifluoromethylphosphine can be hydrolyzed with alcoholic potassium hydroxide, although the reaction is only 78% complete after 96 hours at 80°. The hydrolysis products are fluoroform and diphenylphosphinic acid, $(C_6H_5)_2P(O)OH$.

It is of considerable interest that trifluoromethyl-metallic and -metalloidal derivatives are much more susceptible to hydrolytic attack than the analogous alkyl and aryl compounds. Exceptions among the phosphorus–trifluoromethyl compounds are trifluoromethylphosphonic acid (7) and compounds which also contain a phenyl group, e.g. diphenyltrifluoromethylphosphine. These show much greater resistance to hydrolysis, as do the comparable arsenic derivatives (8), this presumably being a consequence of electron delocalization involving the aromatic systems.

In general, however, the ready removal of the trifluoromethyl group on hydrolysis, usually to give fluoroform, can be understood in terms of its high electronegativity, and high electron-withdrawing effect, as shown by the value of the Taft polar substituent constant σ^*.

Group	σ^*	Electronegativity
CH_3	0.00 (9)	2.34 (11)
H	0.49 (9)	2.10 (11)
C_6H_5	0.60 (9)	2.70 (12)
OCH_3	1.46 (9)	2.92 (12)
Br	2.80 (9)	2.94 (12)
CCl_3	2.65 (10)	2.76 (11)
Cl	2.94 (9)	3.19 (12)
CF_3	2.81 (10)	3.3 (13)
F	3.08 (9)	3.93 (12)

These values indicate the high polarity of the M—CF_3 bond compared with M—CH_3 or M—C_6H_5, and suggest that the M—CF_3 bond will therefore be a very likely point of hydrolytic attack.

Bromine and iodine react readily with diphenyltrifluoromethylphosphine to form diphenyltrifluoromethyl-dibromophosphorane and -diiodophosphorane respectively. These

are stable oils which are unaffected by air or water and are stable to 200°. However, they are hydrolyzed quantitatively by aqueous sodium hydroxide to fluoroform, diphenylphosphinic acid, and sodium halide:

$$(C_6H_5)_2CF_3PX_2 + 2NaOH \rightarrow (C_6H_5)_2P(O)OH + CF_3H + 2NaX.$$

The fact that diphenyltrifluoromethyldiiodophosphorane can be prepared, whereas phenylbistrifluoromethyldiiodophosphorane could not be isolated (1), is interesting and must be due, at least in part, to the large steric effect of the CF_3 group. Thus, replacement of one CF_3 group in phenylbistrifluoromethylphosphine by a less bulky phenyl group gives a phosphine which is sterically capable of forming a diiodophosphorane. Similarly, triphenylphosphine in which steric effects are further reduced, also forms a stable diiodophosphorane (14). In its physical and chemical properties, therefore, diphenyltrifluoromethylphosphine is closely related to triphenylphosphine.

In an earlier paper (15), the ability of methyltrifluoromethylphosphines to take part in complex formation was examined, and one purpose of the present investigation has been the study of the corresponding properties of the phenyltrifluoromethylphosphines. Three types of reactions have been examined, namely the tendency of each phosphine to form (*a*) a phosphonium iodide with an alkyl iodide, (*b*) an addition compound with boron trifluoride, and (*c*) a planar complex with platinum (II) chloride.

As might be expected neither phenylbistrifluoromethylphosphine nor diphenyltrifluoromethylphosphine forms a phosphonium iodide with trifluoroiodomethane, nor is phenylbistrifluoromethylphosphine sufficiently basic to react with iodomethane. However, the more basic character of diphenyltrifluoromethylphosphine is shown by its reaction with iodomethane to form diphenylmethyltrifluoromethyl phosphonium iodide, $[(C_6H_5)_2CF_3CH_3P]I$. This yellow crystalline solid melts at 123–125° and is stable in dry air but it is very readily hydrolyzed by cold water to produce fluoroform, hydriodic acid, and methyldiphenylphosphine oxide:

$$(C_6H_5)_2CF_3CH_3PI + H_2O \rightarrow (C_6H_5)_2CH_3PO + CF_3H + HI.$$

Such ease of hydrolysis is consistent with other studies (16) of the decomposition of phosphonium hydroxides, which show that the most electron-withdrawing organic radical is always the one eliminated, the three less electron-withdrawing groups forming the phosphine oxide.

By examining the stability of phosphine – boron trifluoride adducts, information is obtained concerning the strength of the dative σ-bond between phosphorus and boron. Such studies for the phenyltrifluoromethylphosphines give results which parallel those obtained for the methyltrifluoromethylphosphines (15). Triphenylphosphine-boron trifluoride is a stable white solid of low volatility with a melting point of 128–130°. The boron trifluoride adduct of diphenyltrifluoromethylphosphine is an oil whose saturation pressure is greater than that of its triphenylphosphine analogue. Boron trifluoride adducts of phenylbistrifluoromethylphosphine and tristrifluoromethylphosphine could not be formed. In confirmation of our previous results (8), it is therefore clear that the introduction of one CF_3 group causes a very substantial reduction in the basicity of a phosphine, and the introduction of two such groups makes the phosphine such a weak base that a BF_3 adduct is not formed.

In complexes of phosphines with transition metal halides, such as platinum (II) chloride, the metal–phosphorus bonds contain both σ and π components. The way in which each of these components is influenced by the type of group attached to phosphorus

is reasonably well understood and was briefly outlined earlier (15). Bis(triphenylphosphine) dichloroplatinum (II) has been prepared by Jensen (17) as the cis isomer, but preparations of the corresponding complexes of diphenyltrifluoromethylphosphine and phenylbistrifluoromethylphosphine give only the trans isomers. This is shown by their zero dipole moments. Some caution must be used in interpreting these results in terms of the relative stabilities of cis and trans isomers, since the proportions of the two isomers obtained in such cases often varies somewhat according to the preparative method used. Although detailed studies of the cis–trans equilibria would be necessary to reach a conclusion regarding the stabilities of the two isomers, it is of interest that both the phenyltrifluoromethylphosphines seem to give chiefly the trans isomer. As in the methyltrifluoromethylphosphines, therefore, stepwise replacement of methyl by trifluoromethyl imposes steric restrictions on the phosphine which have the effect of stabilizing the trans isomer with respect to the cis. However, in the phenyl series, the introduction of only one CF_3 group seems to have a much greater effect, since methylbistrifluoromethylphosphine gives a very stable cis complex (15). The situation is parallel to that for tri-*n*-butylarsine and phenyldi-*n*-butylarsine, of which the former gives only the trans complex, but for the latter the cis–trans equilibrium is shifted in favor of the cis isomer (18).

Both bis(phenylbistrifluoromethylphosphine) dichloroplatinum (II) and bis(diphenyltrifluoromethylphosphine) dichloroplatinum (II) react with bromine and iodine to form the compounds $[C_6H_5P(CF_3)_2]_2PtCl_2X_2$ and $[(C_6H_5)_2PCF_3]_2PtCl_2X_2$, where X = Br or I. These are stable solids which are presumably Pt (IV) complexes of the type $[R_2R'P]_2PtX_2Cl_2$, although further investigation is required to establish such a formulation.

The above studies on complex formation emphasize the effect of the highly electronegative trifluoromethyl group in reducing the donor properties of phosphines, and they also reveal the importance of steric factors in the chemistry of the trifluoromethyl group.

EXPERIMENTAL

The general techniques used in the preparation, manipulation, and determination of physical and chemical properties of these compounds have been described previously (1).

Diphenylchlorophosphine was prepared by the method of Steube, LeSuer, and Norman (19). After aluminum chloride (222 g) had been added to a mixture of phosphorus pentasulphide (208 g) and benzene (224 g), the mixture was refluxed for 5 hours and after being cooled was poured onto crushed ice. The resultant dark green solution of diphenylphosphinodithiioc acid was diluted with an equal volume of benzene and chlorinated at 0° by a stream of chlorine. Diphenyltrichlorophosphorane crystallized out and, after separation, was heated with red phosphorus (15.5 g) to 180°. After the more volatile products had been removed, the residual mixture was vacuum distilled to give diphenylchlorophosphine (64 g, 63% yield), which boiled at 178° at 20 mm.

Diphenylphosphine was obtained by the reaction of diphenylchlorophosphine with lithium metal in ether solution, followed by hydrolysis (6).

Tetraphenyldiphosphine was prepared by refluxing an ethereal solution of diphenylchlorophosphine (11 g) and diphenylphosphine (9 g). The precipitated white solid was washed with ether and dried.

Preparation of Diphenyltrifluoromethylphosphine

(*a*) Tetraphenyldiphosphine (1.2 g) and excess trifluoroiodomethane (12.2 g) were heated in a sealed Pyrex tube at 185° for 12 hours. Removal of the volatile products, which were excess trifluoroiodomethane and a trace of fluoroform, left an involatile liquid (0.4 g). Analysis of a sample purified by vapor phase chromatography showed it to be diphenyltrifluoromethylphosphine. (Found: C, 60.86%; H, 4.25%; F, 22.69%; P, 11.79%. Calc. for $C_{13}H_{10}F_3P$: C, 61.41%; H, 3.94%; F, 22.45%; P, 12.21%.)

The same product was obtained when tetraphenyldiphosphine (10 g) and trifluoroiodomethane (10 g) were exposed to ultraviolet radiation for 7 days.

(*b*) Triphenylphosphine (2.5 g) was heated with excess trifluoroiodomethane (14.0 g) at 185° for 4 hours. Fractionation of the volatile products gave trifluoroiodomethane (10.6 g), fluoroform (0.46 g), and trifluoromethylbenzene (0.04 g). Vacuum distillation of the involatile residue gave diphenyltrifluoromethylphosphine (0.2 g), which was identified by its infrared spectrum. There remained a residue of diphenyliodophosphine. No reaction occurred between triphenylphosphine and trifluoroiodomethane at 110°, while heating at 214° gave only a resinous material which could not be identified.

(*c*) Diphenylchlorophosphine (5.6 g) and trifluoroiodomethane (17.0 g) were heated at 205° for 12 hours. The reactants were miscible and after being heated gave a reddish brown solution. The volatile products consisted of trace amounts of hexafluoroethane and fluoroform, unreacted trifluoroiodomethane (8.8 g), trifluorochloromethane (1.24 g), and trifluoromethylbenzene (0.04 g). The ethereal extract of the involatile materials was found to contain more trifluoromethylbenzene, phenyltrifluoromethylchlorophosphine, and diphenyltrifluoromethylphosphine. These were separated by distillation.

Diphenyltrifluoromethylphosphine is a colorless, oily liquid which boils at 255–257°. Its vapor pressure equation is $\log P_{mm} = 7.781 - (2598/T)$, whence the latent heat of vaporization is 11,850 kcal mole^{-1}, and Trouton's constant is 22.9. Diphenyltrifluoromethylphosphine is stable in air, and prolonged heating at 300° causes only 15% decomposition.

Hydrolysis Reactions

(*a*) Water: The phosphine (0.22 g) was sealed in a Pyrex tube with water (1.2 g) and heated at 120° for 48 hours. The compounds were immiscible and the phosphine was recovered quantitatively.

(*b*) Hydrochloric acid: Diphenyltrifluoromethylphosphine (0.34 g) was recovered unchanged after being heated with concentrated hydrochloric acid (2.4 g) at 150°.

(*c*) Aqueous sodium hydroxide: Diphenyltrifluoromethylphosphine (0.24 g) was unaffected by heating to 100° for 24 hours with 5 ml of 20% sodium hydroxide solution.

(*d*) Alcoholic potassium hydroxide: The phosphine (0.21 g) was heated to 70° with 5 ml of 20% alcoholic potassium hydroxide solution for 96 hours. The volatile product was fluoroform (0.046 g), corresponding to 78% hydrolysis of the phosphine. From the residual solution, diphenylphosphinic acid was recovered. This was identified by its infrared spectrum and its melting point of 193° (20).

Reactions with Halogens

(*a*) Iodine (0.18 g) reacted with diphenyltrifluoromethylphosphine (0.18 g) in carbon tetrachloride at 25°. After the mixture had stood for an hour, a brown oil separated, which was identified as diphenyltrifluoromethyldiiodophosphorane. (Found: I, 49.32%. Calc. for $C_{13}H_{10}F_3I_2F$: I, 50.0%.) When the phosphorane (0.123 g) was heated to 80° with aqueous sodium hydroxide solution, fluoroform (0.016 g) was evolved, representing 91.7% hydrolysis. The phosphorane was unaffected by water and only slight decomposition occurred after heating of the solution to 200° for 24 hours.

(*b*) Bromine (0.105 g) and diphenyltrifluoromethylphosphine (0.166 g) were reacted in carbon tetrachloride solution. The resulting orange oil was identified as diphenyltrifluoromethyldibromophosphorane. (Found: Br, 38.07%. Calc. for $C_{13}H_{10}F_3Br_2P$: Br, 38.64%.) Diphenyltrifluoromethyldibromophosphorane (0.272 g) was treated with aqueous sodium hydroxide solution at 80° to give fluoroform (0.044 g), representing 96.1% hydrolysis. Acidification of the remaining solution gave diphenylphosphinic acid, m.p. 194°.

Reaction with Trifluoroiodomethane

Diphenyltrifluoromethylphosphine (0.22 g) was quantitatively recovered after being heated with trifluoroiodomethane (0.86 g) at 100° for 24 hours.

Reaction with Iodomethane

Diphenyltrifluoromethylphosphine (0.234 g) was heated with iodomethane (0.269 g) to 100° for 12 hours. An orange oil separated from which the excess iodomethane was removed to give a yellow powder, identified as methyldiphenyltrifluoromethyl phosphonium iodide, m.p. 123–126°. (Found: C, 42.4%; H, 3.3%; F, 14.2%; P, 7.6%. Calc. for $C_{14}H_{13}F_3PI$: C, 42.6%; H, 3.3%; F, 14.3%; P, 7.9%.) Reaction of the phosphonium iodide (0.127 g) with water (3.5 g) gave fluoroform (0.022 g, 99.1%) and left an acidic solution. Evaporation of this solution and extraction of the residue with benzene gave a white solid identified as methyldiphenylphosphine oxide, m.p. 111–112°.

Reactions with Boron Trifluoride

(*a*) The passage of boron trifluoride through a petroleum ether solution of triphenylphosphine (0.368 g) precipitated a white solid which analyzed for triphenylphosphine-boron trifluoride. (Found: C, 65.5%; H, 5.02%. Calc. for $C_{18}H_{15}PBF_3$: C, 64.6%; H, 4.7%.) The adduct melted at 128–130°; it was stable in dry air but was decomposed rapidly by moisture and was insoluble in non-polar solvents. The saturation pressure is given by the equation $\log P_{mm} = 3.840 - (972/T)$ in the range 80–170°, whence the heat of sublimation is 4.43 kcal mole^{-1}.

(*b*) Diphenyltrifluoromethylphosphine (0.254 g) was mixed with boron trifluoride (0.136 g). No reaction occurred at room temperature but when the mixture was cooled to −78°, an oil formed from which excess boron trifluoride (0.063 g) was removed by pumping. This loss of BF_3 corresponds to the formation of a 1:1 compound. The adduct, which is an oil, has the same properties towards air, moisture, and non-polar solvents as the triphenylphosphine adduct. The saturation pressure in the range 40–110° C is given by the expression $\log P_{mm} = 6.609 - (1753/T)$, whence the heat of vaporization is 8.04 kcal mole^{-1}.

No reaction occurred between boron trifluoride and phenylbis(trifluoromethyl)phosphine either at 25° or at −78°.

Reactions with Platinum (II) Chloride

(*a*) Diphenyltrifluoromethylphosphine (0.254 g) in acetone was added to an aqueous solution of potassium chloroplatinite (0.21 g), and the mixture was heated for 30 minutes. Removal of the acetone gave a resinous mass which, after purification with animal charcoal and water, gave a pale yellow solid, bis(diphenyltrifluoromethylphosphine) dichloroplatinum (II). (Found: CF_3, 16.9%. Calc. for $C_{26}H_{20}F_6P_2PtCl_2$: CF_3, 17.8%.) Treatment with ether gave a small portion melting at 230°, while the bulk of the product was soluble in ether, and melted at 63–65°.

Reaction of the complex with a carbon tetrachloride solution of bromine or iodine gave a yellow and brown precipitate respectively. With bromine the product was bis(diphenyltrifluoromethylphosphine) dichlorodibromoplatinum (II). (Found: CF_3, 14.5%. Calc. for $C_{26}H_{20}F_6P_2PtCl_2Br_2$: CF_3, 14.7%.)

(*b*) Phenylbis(trifluoromethyl)phosphine (0.793 g) was heated with platinum (II) chloride (0.308 g) to 100° for 7 days. The product was recrystallized from acetone and was bis(phenylbistrifluoromethylphosphine) dichloroplatinum (II), m.p. 134–136°. (Found: C, 25.6%; H, 1.36%; F, 29.44%. Calc. for $C_{16}H_{10}F_{12}P_2PtCl_2$: C, 25.4%; H, 1.37%; F, 30.16%.) The same product was obtained by adding the phosphine to an aqueous solution of potassium chloroplatinite, although in this case, the product also contained a small amount of material which melted above 300°.

Treatment of the complex with a carbon tetrachloride solution of either bromine or iodine, as in (*a*) above, gave the dibromo or diiodo derivative. These were characterized by weight gain and by alkaline hydrolysis.

Dipole moments were measured as described previously (8); the platinum (II) complexes of both phenylbis(trifluoromethyl)phosphine and diphenyltrifluoromethylphosphine were found to have zero dipole moments.

ACKNOWLEDGMENTS

We gratefully acknowledge the support of the National Research Council, and one of us (M. A. A. B.) expresses thanks for a scholarship received from C.S.I.R. (Pakistan) under the auspices of the Colombo Plan.

MODIFICATION OF THE ILKOVIC EQUATION

R. S. SUBRAHMANYA
The Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore-12, South India

Received May 18, 1961

ABSTRACT

Taking into consideration the total amount of the depolarizer that reaches the surface of a flat stationary electrode, the following integral equation was obtained by Stackelberg:

$$\frac{2}{\pi D}.A.{}^{l}\delta_1 = \int_0^t \frac{A}{{}^{l}\delta_1}\,dt.$$

An equation of a similar form was also assumed to hold even in the case of the dropping mercury electrode. By this procedure he obtained the same expression for the flux $D[{}^*C/\sqrt{((3/7)\pi Dt)}]$ as obtained by Ilkovic. In the present work it has been shown that the same expression for the flux is obtained by introducing 'A' as a function of 't' in the basic integral and considering the effect which the moving surface will have on the thickness of the diffusion layer. The application of this new approach to the case of spherical diffusion to the dropping mercury electrode has lead to the following new polarographic equation:

$$i_d = 607\ nD^{1/2}{}^*Cm^{2/3}t^{1/6}(45.1\ D^{1/2}m^{-1/3}t^{1/6}+1).$$

INTRODUCTION

The Ilkovic equation in polarography derived by Ilkovic (1), MacGillavry and Rideal (2), and Stackelberg (3) represents the polarographic diffusion current. The current intensity at any time 't' is given by $i = nFAD(\partial C/\partial x)_{x=0}$. Each of the above authors determined the flux of the depolarizer at the electrode surface by different methods but they all obtained the same final result for the flux $D[{}^*C/\sqrt{((3/7)\pi Dt)}]$. Stackelberg (3, 4) derived the following integral equation taking into consideration the total amount of the depolarizer that reaches the surface of a flat stationary electrode:

$$\frac{2}{\pi D}\cdot A\cdot {}^{l}\delta_1 = \int_0^t \frac{A}{{}^{l}\delta_1}\,dt.$$

Since the area of the dropping electrode is $\propto t^{2/3}$, the following integral equation was assumed to be valid in the case of the dropping mercury electrode:

$$\frac{2}{\pi D}\cdot t^{2/3}\cdot {}^{d}\delta_1 = \int_0^t \frac{t^{2/3}}{{}^{d}\delta_1}\,dt.$$

In the present work it has been shown that the same final expression for ${}^{d}\delta_1$ is obtained when 'A' is introduced as a function of 't' in the basic integral and the effect which the moving surface will have on the thickness of the diffusion layer is considered. The method has also been used in the case of spherical diffusion to the dropping mercury electrode. This approach has led to a new polarographic equation.

NOTATIONS

n: number of electrons involved in the reduction process
A: area of the electrode
F: Faraday
${}^*C$: concentration of the depolarizer in the bulk in millimoles per liter

^0C: concentration of the depolarizer at the surface of the electrode; it becomes zero in the limiting diffusion current region

D: diffusion coefficient of the depolarizer in $cm^2\ sec^{-1}$

t: duration of electrolysis in seconds

$\left(\frac{\partial C}{\partial x}\right)_{x=0} = \frac{^*C - {}^0C}{\sqrt{(\pi Dt)}}$: gradient of the depolarizer at a stationary flat electrode surface

$D(\partial C/\partial x)_{x=0}$: flux of the depolarizer at the stationary flat electrode surface

$^l\delta_1 = \sqrt{(\pi Dt)}$: differential thickness of the diffusion layer at a stationary flat electrode surface

$^d\delta_1$, $^d\delta_s$: differential thickness of the diffusion layer at the dropping mercury electrode surface, for linear and spherical diffusion respectively

δ_s: differential thickness of the diffusion layer at the surface of stationary spherical electrode

$\left(\frac{\partial C}{\partial r}\right)_{r=r_2} = \left(\frac{1}{r_1} + \frac{1}{\sqrt{(\pi Dt)}}\right)\left(^*C - {}^0C\right)$: gradient of the depolarizer at a stationary spherical electrode

i: diffusion-controlled current in microamperes at any time 't'

$r_1 = \left(\frac{3m}{4\pi d}\right)^{1/3} t^{1/3} = a \cdot t^{1/3}$: radius of the mercury drop considered as a sphere at any time 't'. In the case of a stationary spherical electrode 'r_1' is the radius

m: rate of flow of mercury in mg per sec

d: specific gravity of mercury

$4\pi r_1^2 = 4\pi\left(\frac{3m}{4\pi d}\right)^{2/3} t^{2/3} = b \cdot t^{2/3}$: area of the mercury drop at any time 't'

THEORETICAL

Two cases are discussed: (i) linear diffusion to a growing spherical surface and (ii) spherical diffusion to a growing spherical surface.

Case (i). Linear Diffusion to a Growing Spherical Surface

When the surface is stationary the thickness of the diffusion layer is $^l\delta_1$. Let us suppose that when the surface is growing the thickness of the diffusion layer is changed by some factor 'x' so that the new thickness due to drop growing is $x\,^l\delta_1 = {}^d\delta_1$. The amount of the depolarizer reaching the electrode surface in time 'dt' as given by Fick's first law is

$$A \cdot D \frac{^*C - {}^0C}{x\,^l\delta_1}\, dt.$$

The total amount transferred to the electrode surface during the time interval $t = 0$ to $t = t$ is

$$\int_0^t D \cdot A \frac{^*C - {}^0C}{x\,^l\delta_1}\, dt = \int_0^t D \cdot b \cdot t^{2/3} \frac{^*C - {}^0C}{x\,^l\delta_1}\, dt$$

$$= \int_0^t D \cdot b \cdot t^{2/3} \frac{^*C - {}^0C}{x\sqrt{(\pi Dt)}}\, dt = \int_0^t D \cdot b \frac{^*C - {}^0C}{x\sqrt{(\pi D)}}\, t^{1/6} dt$$

$$= 2D \cdot b \cdot t^{2/3} \frac{{}^{*}C - {}^{0}C}{x\pi D} \cdot \frac{3}{7} \sqrt{(\pi Dt)} = 2D \cdot A \frac{{}^{*}C - {}^{0}C}{x^2 \pi D} \cdot \frac{3}{7} x \sqrt{(\pi Dt)}.$$

Hence for the dropping mercury electrode the following integral equation can be written

$$x^2 \int_0^t D \cdot A \frac{{}^{*}C - {}^{0}C}{{}^{d}\delta_1} dt = \frac{3}{7} 2D \cdot A \frac{{}^{*}C - {}^{0}C}{\pi D} {}^{d}\delta_1.$$

When the surface is stationary the following integral equation can be obtained (4):

$$\int_0^t D \cdot A \frac{{}^{*}C - {}^{0}C}{{}^{l}\delta_1} dt = \frac{2D \cdot A ({}^{*}C - {}^{0}C) {}^{l}\delta_1}{\pi D}.$$

Comparison of the integral equation obtained with the moving electrode with the integral equation obtained for the stationary electrode of the same area 'A' with diffusion layer thickness ${}^{l}\delta_1$ indicates that the value of 'x' is $\sqrt{(3/7)}$.

It can therefore be said that the effect of the growing of the mercury drop is to reduce the thickness of the diffusion layer from $\sqrt{(\pi Dt)}$ to $\sqrt{((3/7)\pi Dt)}$. This result is the same as that obtained by Stackelberg.

Case (ii). Spherical Diffusion to a Growing Spherical Electrode

The flux of the depolarizer at the surface of a stationary spherical electrode of radius 'r_1' is given by

$$D\left(\frac{\partial C}{\partial r}\right)_{r=r_1} = D\left(\frac{1}{r_1} + \frac{1}{\sqrt{(\pi Dt)}}\right)({}^{*}C - {}^{0}C).$$

The total amount of the depolarizer reaching the electrode surface during the time interval $t = 0$ to $t = t$ is

$$\int_0^t D \cdot A \left(\frac{1}{r_1} + \frac{1}{\sqrt{(\pi Dt)}}\right)({}^{*}C - {}^{0}C) dt$$

$$= \int_0^t D \cdot A ({}^{*}C - {}^{0}C) \frac{1}{r_1} dt + \int_0^t D \cdot A ({}^{*}C - {}^{0}C) \frac{1}{\sqrt{(\pi Dt)}} dt$$

I term II term

$$= D \cdot A ({}^{*}C - {}^{0}C) \frac{t}{r_1} + \frac{2D \cdot A ({}^{*}C - {}^{0}C)\sqrt{t}}{\sqrt{(\pi D)}}$$

$$= D \cdot 4\pi ({}^{*}C - {}^{0}C) r_1 t + \frac{2}{\pi D} D \cdot A ({}^{*}C - {}^{0}C) \sqrt{(\pi Dt)}.$$

It is clear that for spherical and linear diffusion to electrodes of equal area the reciprocal of the gradient differs by '$1/r_1$', where 'r_1' is the radius of the sphere. Consequently, the integral representing the total amount of the depolarizer can be split up into two portions. The II term is identical with the case of linear diffusion to a plane electrode of the same area. The difference between spherical diffusion and linear diffusion lies in the first term.

Since the thickness of the diffusion layer δ_s at a stationary spherical surface is given by the relation $1/\delta_s = 1/r_1 + 1/\sqrt{(\pi Dt)}$, one might consider the effect of growing surface on $1/\delta_s$ due to the effects on $1/r_1$ and $1/\sqrt{(\pi Dt)}$. Hence one can write $1/{}^{d}\delta_s = 1/yr_1 + 1/x\sqrt{(\pi Dt)}$, where '$y$' and '$x$' must be determined.

The total amount of the depolarizer that reaches the electrode surface in the case of the dropping mercury electrode would be

$$\int_0^t D \cdot A \left(\frac{1}{yr_1} + \frac{1}{x\sqrt{(\pi Dt)}} \right) (*C - {}^0C) dt.$$

This integral can be split up into the following two integrals:

$$\int_0^t D \cdot A \frac{*C - {}^0C}{yr_1} dt + \int_0^t D \cdot A \frac{*C - {}^0C}{x\sqrt{(\pi Dt)}} dt.$$

The two integrals can now be treated separately. Following the procedure that was followed in case (i) it can be shown that $x = \sqrt{(3/7)}$.

The value of 'y' can now be evaluated thus:

When the drop is growing 'A' and 'r_1' become functions of time. Hence

$$\int_0^t D \cdot A \frac{*C - {}^0C}{yr_1} dt = \int_0^t D \cdot 4\pi r_1 \frac{*C - {}^0C}{y} dt$$

$$= \int_0^t 4\pi D \frac{*C - {}^0C}{y} a \cdot t^{1/3} dt = 4\pi D \frac{*C - {}^0C}{y} a \cdot t^{4/3} \frac{3}{4}$$

$$= 4\pi D \frac{*C - {}^0C}{y} a \cdot t^{1/3} \cdot \frac{3}{4} t$$

$$= 4\pi D r_1 \frac{*C - {}^0C}{y} \cdot \frac{3}{4} t$$

$$= 4\pi D \frac{*C - {}^0C}{y^2} (yr_1) \frac{3}{4} t.$$

The following integral equation can be written:

$$y^2 \int_0^t D \cdot A \frac{*C - {}^0C}{(yr_1)} dt = 4\pi D (*C - {}^0C)(yr_1) \frac{3}{4} t.$$

We can now compare this equation with the following that has been obtained in the case of a stationary spherical electrode of area 'A' and radius 'r_1':

$$\int_0^t D \cdot A \frac{*C - {}^0C}{r_1} dt = 4\pi D (*C - {}^0C) r_1 t.$$

These equations are of the same form except that instead of 'r_1', 'yr_1' appears in the case of the dropping mercury electrode. Hence $y^2 = 3/4$ or $y = \sqrt{3}/2$.

The modified expression for the flux at the electrode surface can be written thus:

$$D\left(\frac{\partial C}{\partial r}\right)_{r=r_1} = D(*C - {}^0C)\left(\frac{1}{(\sqrt{3}/2)r_1} + \frac{1}{\sqrt{((3/7)\pi Dt)}}\right).$$

The current at any time 't' is

$$i_t = n.F.A.D.\left(\frac{\partial C}{\partial r}\right)_{r=r_1} = n.F.A.D.(*C - {}^0C)\left(\frac{1}{(\sqrt{3}/2)r_1} + \frac{1}{\sqrt{((3/7)\pi Dt)}}\right)$$

On expressing current in microamperes, 'A' and 'r_1' in terms of the amount of mercury flowing out per second, one gets

$$i_t = 706(*C - {}^0C) D^{1/2} n (51.6 D^{1/2} m^{1/3} t^{1/3} + m^{2/3} t^{1/6})$$

$$= 706(*C - {}^0C) D^{1/2} n m^{2/3} t^{1/6} (51.6 D^{1/2} m^{-1/3} t^{1/6} + 1).$$

The mean current is

$$\bar{i} = \frac{1}{t_{max}} \int_0^{t_{max}} i_t dt = 607\ nD^{1/2}(^*C - {}^0C)m^{2/3}t^{1/6}(45.1\ D^{1/2}m^{-1/3}t^{1/6}+1).$$

The following expression can be written for i_d, the limiting diffusion current:

$$i_d = 607\ nD^{1/2*}Cm^{2/3}t^{1/6}(45.1\ D^{1/2}m^{-1/3}t^{1/6}+1).$$

DETERMINATION OF 'K'

Several authors have treated the problem of the modification of the Ilkovic's equation. They have obtained an equation of the following form:

$$i_d = 607\ nD^{1/2*}Cm^{2/3}t^{1/6}(KD^{1/2}m^{-1/3}t^{1/6}+1),$$

the value of 'K' being 17 (5), 39 (4, 6), or 45.1 as in the present work. The equation derived by Koutecky (12) has the form

$$i_d = 607\ nD^{1/2*}Cm^{2/3}t^{1/6}(1+KD^{1/2}m^{-1/3}t^{1/6}+LDm^{-2/3}t^{1/3}+ \ldots),$$

the value of 'K' being 34. The equation derived in the present paper has only two terms inside the brackets corresponding in form to those derived by Stackelberg (5), Kambara, Suzuki, and Tachi (4), and Lingane and Loveridge (6) but differs from all other equations in that the value of 'K' is 45.1. It has to be pointed out that Kambara, Suzuki, and Tachi have employed the integral equation technique of Stackelberg for the case of diffusion to a growing spherical electrode. They have formulated the integral equation but in the subsequent mathematical operations the integration of $1/r_1$ is masked and hence they get a value of 39 for 'K'. In the present approach to the problem the effect of the growing drop is separately evaluated on each of the terms appearing in the expression for the thickness of the diffusion layer of the stationary spherical electrode leading to a value of 45.1 for 'K'. Lingane and Loveridge (6) obtained a value of 39.1 for 'K' for data for lead ions in 1 N potassium chloride. For the same data Strehlow and Stackelberg drew a least-square straight line and obtained a value of 17.4 for 'K' (7). The experimental determination of 'K' and the consequent verification of the theoretical equations derived by Strehlow and Stackelberg (5), Kambara, Suzuki, and Tachi (4), Lingane and Loveridge (6), and by the present author, are very difficult. Airey and Smales (8) have suggested that when a drop falls from the capillary it leaves a part of the depleted diffusion layer at the end of the capillary. Consequently the succeeding drop grows in a depleted region of the depolarizer solution. Hence the average current that is measured is smaller than the current one would expect from the 'first drop'. Ilkovic (9) has pointed out that the exhaustion effect may cause the diffusion current to decrease by as high as 15%. In order to verify the theoretical equations all experiments have to be conducted on the 'first drop'. In the alternative one has to use Smoler's horizontal capillary (10), where the drop dislodges at right angles to the tip of the capillary. With Smoler's technique there is mixing up of the solution and the impoverishment of the depolarizer does not exist at the tip of the capillary. Polarographers should also give careful thought to the suggestion of McKenzie (11) that one should measure the instantaneous current at the end of the drop life when the effect due to the impoverishment of the depolarizer is largely avoided. A detailed program of work employing Smoler's electrode has been planned in order to find out the exact value of 'K'.

ACKNOWLEDGMENTS

The author wishes to express his thanks to Professor M. R. A. Rao for helpful discussions. He is also thankful to Dr. S. K. Lakshmana Rao, Assistant Professor of Mathematics, Regional Engineering College, Warrangal, for his scrutiny of the mathematical aspects in this paper.

APPENDIX

(i) Constancy of 'x'

In the derivation presented in this paper 'x' has been introduced for the sake of convenience. In fact, it is not necessary to introduce 'x' nor assume anything regarding its dependence on 't'. In the case of linear diffusion to a growing mercury drop surface we have

$$\int_0^t D\cdot A\,\frac{{}^*C-{}^0C}{{}^l\delta_1}\,dt = \int_0^t D\cdot b\cdot t^{2/3}\,\frac{{}^*C-{}^0C}{\sqrt{(\pi Dt)}}\,dt = 2D\cdot A\,\frac{{}^*C-{}^0C}{\pi D}\cdot\frac{3}{7}\sqrt{(\pi Dt)}.$$

Adjustment of 3/7 with ${}^l\delta_1$ or $\sqrt{(\pi Dt)}$ puts the integral equation into the same form as that obtained in the case of stationary electrode. Hence in the case of the dropping mercury electrode it can be written

$$\int_0^t D\cdot A\,\frac{{}^*C-{}^0C}{\sqrt{(3/7)}\,{}^l\delta_1}\,dt = 2D\cdot A\,\frac{{}^*C-{}^0C}{\pi D}\sqrt{(3/7)}\,{}^l\delta_1,$$

where $\sqrt{(3/7)}\,{}^l\delta_1 = {}^d\delta_1$.

The basic technique employed in the present work is to evaluate the integrals of the time-dependent functions and then compare the final integral equation with that obtained in the case of a stationary electrode to obtain the thickness of the diffusion layer in the case of the growing surface. Since this means that the form of integral equations governing diffusion to the stationary and growing surface are the same, it can formally be shown that under these conditions 'x' must be a constant. In the general case let 'x' be equal to $f(t)$. The following integral equation can be written for the case of the growing surface since the relation in the case of a growing surface is identical in structure with that in the case of a stationary surface:

$$H\int_0^t \frac{t^{1/6}}{f(t)}\,dt = Jf(t)t^{7/6},$$

where

$$H = \frac{Db({}^*C-{}^0C)}{\sqrt{(\pi D)}} \quad \text{and} \quad J = 2Db\,\frac{{}^*C-{}^0C}{\sqrt{(\pi D)}}.$$

Differentiating with respect to 't', multiplying both sides of the equation by $t^{7/6}$, and rearranging, one gets

$$\frac{H}{J}\cdot t^{4/3} = f(t)\cdot t^{7/6}\frac{d}{dt}\left(f(t)\cdot t^{7/6}\right).$$

On integration it is found

$$\frac{H}{J}\cdot\frac{3}{7}t^{7/3} = \frac{1}{2}\left(f(t)\cdot t^{7/6}\right)^2 + \text{constant}.$$

The constant must be zero since when $t = 0$ both sides must be zero, which leads to

$$f(t) = \sqrt{(3/7)} = \text{constant}.$$

(ii) Constancy of 'y'

In a similar way it can be proved that 'y' also should be a constant.

A SIMPLE METHOD OF SOLVING ILKOVIC'S DIFFERENTIAL EQUATION FOR THE TRANSFER OF DEPOLARIZER TO THE DROPPING MERCURY ELECTRODE

R. S. SUBRAHMANYA

The Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore-12, South India

Received May 18, 1961

ABSTRACT

The method developed by Ilkovic for solving the differential equation

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} + \frac{2}{3}\cdot\frac{x}{t}\cdot\frac{\partial C}{\partial x}$$

which governs the diffusion of the depolarizer to the surface of the dropping mercury electrode is very difficult. In the present work a simple method is presented. The above equation is transformed into $\partial C/\partial T = \partial^2 C/\partial s^2$ by introducing the two new variables $s = xt^{2/3}/2.\sqrt{((3/7)D)}$ and $T = (1/4)t^{7/3}$. The boundary conditions for the transformed differential equation are formulated and the equation is solved by the Laplace transform method.

NOTATIONS

$C(x,t)$: concentration of the depolarizer at a distance 'x' from the electrode surface at time 't'.

$C(0,t)$: concentration of the depolarizer at the electrode surface at time 't' (^0C)

$^*C$: bulk concentration of the depolarizer

D: diffusion coefficient of the depolarizer in $cm^2\ sec^{-1}$

A: area of the electrode

p: variable in Laplace transformation

$L(C)$: Laplace transform of C

$L^{-1}u$: inverse transform of 'u'

$s = xt^{2/3}/2\sqrt{((3/7)D)}$: new variable

$T = (1/4)t^{7/3}$: new variable

INTRODUCTION

Several authors have treated the problem of diffusion of depolarizer to the dropping mercury electrode. A critical review of the various methods has been given by Markowitz and Elving (1). The methods employed fall into two classes. To the first class belong the differential methods wherein a differential equation is formulated and the equation solved using the appropriate boundary conditions. To the second class belong the integral methods where the problem is formulated as an integral equation. Ilkovic (2) treated the problem by assuming that the depolarizer reaches the surface of the dropping mercury electrode by linear diffusion. Since the thickness of the diffusion layer is much smaller than the radius of the mercury drop the curvature of the diffusion layer does not significantly differ from that of the mercury drop. In the formulation of the differential equation he also added an additional term to include the effect of the growing drop on the thickness of the diffusion layer. The following differential equation was formulated by him:

[1] $$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} + \frac{2}{3}\cdot\frac{x}{t}\cdot\frac{\partial C}{\partial x}.$$

This differential equation was solved by him by employing the Fourier integral method after introducing a new variable $u = xt^{2/3}$. MacGillavary and Rideal (3) treated the problem as three dimensional spherical diffusion, and formulated the following differential equation:

$$\frac{\partial C}{\partial t} = D\left(\frac{\partial^2 C}{\partial r^2}+\frac{2}{r}\cdot\frac{\partial C}{\partial r}\right)-\frac{a^3}{3r^2}\cdot\frac{\partial C}{\partial r},$$

where 'r' is the distance from the center of the mercury drop. Due to the simplifications introduced in the subsequent mathematical operations they obtained the same final equation as Ilkovic for the current. The following equation for the average diffusion current was obtained:

$$i_d = 607nD^{1/2}{}^*Cm^{2/3}t^{1/6}.$$

Ilkovic had noticed that the differential thickness of the diffusion layer in the case of linear diffusion to a stationary electrode was $\sqrt{(\pi Dt)}$ and in the case of linear diffusion to a growing drop $\sqrt{\{(3/7)\pi Dt\}}$. Lingane and Loveridge (4) argued that even in the case of spherical diffusion an equation for the diffusion current can be obtained provided a correction is applied to the gradient obtained in the problem of diffusion to a stationary spherical electrode. The gradient is written

$$^*C(1/r+1/\sqrt{((3/7)\pi Dt)}).$$

The following expression was obtained for the diffusion current:

$$i_d = 607nD^{1/2}{}^*Cm^{2/3}t^{1/6}(1+KD^{1/2}m^{-1/3}t^{1/6}).$$

The value of 'K' was 39.

Strehlow and Stackelberg (5) re-examined the derivation of MacGillavary and Rideal and modified the intermediate mathematical steps and obtained the same equation as above but in which 'K' has the value 17. Kambara and Tachi (6) applied Ilkovic's technique of the formulation of the differential equation to the case of spherical diffusion to a growing drop. They obtained the same differential equation as MacGillavary and Rideal. After introducing a new dependent variable φ $(= rC)$ and transferring the co-ordinates from the center to the surface of the drop they obtained the following differential equation:

$$\frac{\partial \varphi}{\partial t} = D\frac{\partial^2 \varphi}{\partial x^2}+\frac{2x}{3t}\cdot\frac{\partial \varphi}{\partial x}.$$

The above differential equation is of the same form as that obtained by Ilkovic in the case of linear diffusion (eq. [1]). The procedure employed for solving this differential equation is not clear. However, they get the same equation for the diffusion current as Lingane and Loveridge.

The above is only a short account of the differential methods used in solving the problem of diffusion of the depolarizer to the dropping mercury electrode. It is clear that in these problems one meets differential equations of the form of equation [1]. The published procedures for the solution of such equations are either very difficult or not clearly given. Hence work was undertaken in this laboratory to examine the possibilities of solving such equations by suitable mathematical techniques, i.e. conversion of these partial differential equations into standard forms by the technique of change of variables and then solution by the Laplace transform method. In the present paper the method of solving the Ilkovic differential equation is given.

THEORETICAL

(i) Transformation of Ilkovic's Differential Equation

In the differential equation

$$\frac{\partial C}{\partial t} = D\cdot\frac{\partial^2 C}{\partial x^2}+\frac{2}{3}\cdot\frac{x}{t}\cdot\frac{\partial C}{\partial x}$$

'x' and 't' are the independent variables. Let us now express the above differential equation in terms of the new independent variables 's' and 'T'. Employing the chain rule the following transformations can be written:

(*a*)
$$\frac{\partial C}{\partial t} = \frac{\partial C}{\partial T}\cdot\frac{\partial T}{\partial t}+\frac{\partial C}{\partial s}\cdot\frac{\partial s}{\partial t} = \frac{\partial C}{\partial T}\cdot\frac{1}{4}\cdot\frac{7}{3}t^{4/3}+\frac{\partial C}{\partial s}\cdot\frac{x}{2\sqrt{((3/7)D)}}\cdot\frac{2}{3}t^{-1/3}$$

$$= \frac{\partial C}{\partial T}\cdot\frac{1}{4}\cdot\frac{7}{3}t^{4/3}+\frac{\partial C}{\partial s}\cdot\frac{2}{3}\cdot\frac{xt^{2/3}}{2\sqrt{((3/7)D)}}\cdot\frac{1}{t}$$

$$= \frac{\partial C}{\partial T}\cdot\frac{1}{4}\cdot\frac{7}{3}t^{4/3}+\frac{\partial C}{\partial s}\cdot\frac{2}{3}\cdot\frac{s}{t}.$$

(*b*)
$$\frac{\partial C}{\partial x} = \frac{\partial C}{\partial T}\cdot\frac{\partial}{\partial x}\left(\frac{1}{4}t^{7/3}\right)+\frac{\partial C}{\partial s}\cdot\frac{\partial s}{\partial x} = \frac{\partial C}{\partial s}\cdot\frac{t^{2/3}}{2\sqrt{((3/7)D)}}.$$

$$\therefore\ \frac{2}{3}\cdot\frac{x}{t}\cdot\frac{\partial C}{\partial x} = \frac{2}{3}\cdot\frac{x}{t}\cdot\frac{t^{2/3}}{2\sqrt{((3/7)D)}}\cdot\frac{\partial C}{\partial s} = \frac{2}{3}\cdot\frac{s}{t}\cdot\frac{\partial C}{\partial s}.$$

(*c*)
$$\frac{\partial^2 C}{\partial x^2} = \frac{\partial}{\partial x}\cdot\frac{\partial C}{\partial x} = \frac{\partial}{\partial x}\left(\frac{\partial s}{\partial x}\cdot\frac{\partial C}{\partial s}\right).$$

Since

$$\frac{\partial C}{\partial x} = \frac{\partial s}{\partial x}\cdot\frac{\partial C}{\partial s},\quad \frac{\partial}{\partial x} = \frac{\partial s}{\partial x}\cdot\frac{\partial}{\partial s},$$

$$\frac{\partial}{\partial x}\left(\frac{\partial s}{\partial x}\cdot\frac{\partial C}{\partial s}\right) = \frac{\partial s}{\partial x}\cdot\frac{\partial}{\partial s}\left(\frac{\partial s}{\partial x}\cdot\frac{\partial C}{\partial s}\right)$$

$$= \frac{t^{2/3}}{2\sqrt{((3/7)D)}}\cdot\frac{\partial}{\partial s}\left\{\frac{t^{2/3}}{2\sqrt{((3/7)D)}}\cdot\frac{\partial C}{\partial s}\right\} = \frac{t^{4/3}}{\{2\sqrt{((3/7)D)}\}^2}\cdot\frac{\partial^2 C}{\partial s^2}.$$

$$\therefore\ D\frac{\partial^2 C}{\partial x^2} = D\frac{t^{4/3}}{\{2\sqrt{((3/7)D)}\}^2}\cdot\frac{\partial^2 C}{\partial s^2}.$$

On substituting for $\partial C/\partial t$, $D\partial^2 C/\partial x^2$, and $2/3(x/t)(\partial C/\partial x)$ in terms of the new variables 's' and 'T', in equation [1] one gets

[2]
$$\frac{\partial C}{\partial T} = \frac{\partial^2 C}{\partial s^2}$$

(ii) Boundary Conditions for the Equation $\partial C/\partial T = \partial^2 C/\partial s^2$

The boundary conditions for equation [1] can be written as follows:

$$C(x,0) = {}^*C;\ C(0,t) = {}^0C;\ C(x,t) = {}^*C \text{ as } 'x' \rightarrow \infty.$$

Ilkovic transformed equation [1] into $\partial C/\partial t = D(\partial^2 C/\partial u^2)t^{4/3}$ by introducing the new variable $u = xt^{2/3}$ and has given the following boundary conditions:

$$C(u,0) = {}^*C \text{ and } C(0,t) = {}^0C.$$

For equation [2] obtained in the present work the following boundary conditions can be given:

$$C(s,0) = {}^*C,\ C(0,T) = {}^0C, \text{ and } C(s,T) = {}^*C \text{ as } 's' \rightarrow \infty.$$

It is interesting to examine the significance of the boundary conditions that have been given above for equation [2]. The variable 'x' represents the distance of any point from the surface of the electrode and Ilkovic has restricted the range of 'x' such that 'Ax' is always a constant. The significance of this becomes clear if we consider the difference in volume between concentric spheres of radius r_1+x and r_1:

$$\Delta V = 4/3\pi\{(r_1+x)^3-r_1^3\} = 4/3\pi x(3r_1^2+3r_1x+x^2) \simeq 4\pi r_1^2 x$$

$$= 4\pi(3m/4\pi d)^{2/3}t^{2/3}x = Ax \text{ (when '}x\text{' is small as compared to '}r_1\text{')}.$$

It is interesting to find out the error that is introduced in neglecting $3r_1x$ and x^2 in comparison with $3r_1^2$. Let us take the case of a depolarizer with diffusion coefficient 10^{-5} cm^{2}sec^{-1} diffusing to the surface of a dropping mercury electrode with the following capillary characteristics: $m = 1.5$ mg per sec; $t = 5$ sec. At the maximum size of the drop the error introduced when the value of 'x' is equal to $\sqrt{\{(3/7)\pi Dt\}}$ (thickness of the diffusion layer in the case of the dropping mercury electrode) is about 16%. When the value of 'x' is about one eighth the thickness of the diffusion layer, 'Ax' is constant within about 2%. For smaller values of 'x' the error introduced becomes much smaller. It is therefore obvious that the condition put by Ilkovic that 'Ax' be a constant highly restricts the range of 'x'. Similar results are also obtained in calculations made at different times during the life time of a mercury drop.

Introduction of the variable 's', $xt^{2/3}/2\sqrt{((3/7)D)}$, suggests that we are considering the value of C at different concentric spheres from the surface of the electrode. Regarding 'T' it can be said that changes in 't' are similar to changes in 'T'.

(iii) Solution of the Equation $\partial C/\partial T = \partial^2 C/\partial s^2$

The boundary conditions are given by $C(s,0) = {}^*C$, $C(0,T) = {}^0C$, and $C(s,T) = {}^*C$ as 's' $\rightarrow \infty$. $\partial C/\partial T = \partial^2 C/\partial s^2$ is a partial differential equation with constant coefficients. Hence the Laplace transform method can be used for solving this equation.

We define the Laplace transform of $C(s,T)$ (abbreviated as $L\ C(s,T)$) as

$$u(s,p) = p\int_0^\infty e^{-pT}C(s,T)dT.$$

The equation $\partial C/\partial T = \partial^2 C/\partial s^2$ is transformed into

$$pu - p{}^*C = \frac{d^2u}{ds^2} \qquad [3]$$

since ${}^*C$ is the value of the function $C(s,T)$ when $T = 0$.
The solution of [3] is

$$u = u_c+u_p = A_1e^{+\sqrt{(p)}\cdot s}+A_2e^{-\sqrt{(p)}\cdot s}+\frac{-p{}^*C}{-p} = A_1e^{+\sqrt{(p)}\cdot s}+A_2e^{-\sqrt{(p)}\cdot s}+{}^*C.$$

Since the concentration of the depolarizer does not increase indefinitely with an increase in 's', $A_1 = 0$. $C(0,T) = {}^0C$ = constant. A Laplace transformation of a constant is the constant itself.

Therefore

$$L\,C(0,T) = u(0,p) = \text{constant} = {}^{0}C$$

$$A_2 = -(*C - {}^{0}C)$$

$$u = *C - (*C - {}^{0}C)e^{-\sqrt{(p)}.s}$$

$$C(s,T) = L^{-1}u(s,p) = L^{-1}*C - L^{-1}\,(*C - {}^{0}C)e^{-\sqrt{(p)}.s}$$

$$= *C - (*C - {}^{0}C)\left\{1 - \text{erf}\,\frac{s}{2\sqrt{T}}\right\}$$

[4] $$= {}^{0}C + (*C - {}^{0}C)\ \text{erf}\,\frac{s}{2\sqrt{T}}.$$

I n terms of the old co-ordinate system we have

[5] $$C(x,t) = {}^{0}C + (*C - {}^{0}C)\ \text{erf}\,\frac{x}{2\sqrt{((3/7)Dt)}}.$$

The value of $(\partial C/\partial x)_{x=0}$ can be obtained by differentiating with respect to 'x' under the integral sign either from [4] or [5]:

$$\left(\frac{\partial C}{\partial x}\right)_{x=0} = \frac{*C - {}^{0}C}{\sqrt{((3/7)\ \pi Dt)}}.$$

The current at any time 't' is given by

$$n.F.A.D\left(\frac{\partial C}{\partial x}\right)_{x=0} = n.F.A.D\,\frac{*C - {}^{0}C}{\sqrt{((3/7)\ \pi Dt)}}.$$

THE INFRARED ABSORPTION SPECTRA OF DEUTERATED ESTERS

III. METHYL LAURATE[1]

R. NORMAN JONES

The Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received October 17, 1961

ABSTRACT

The infrared absorption spectrum of methyl laurate in carbon tetrachloride and carbon disulphide solutions has been compared with the spectra of seven derivatives deuterated in the ω-methyl group, the α-methylene groups, the carbomethoxy group, and in binary and ternary combinations of these positions. The spectra of *n*-dodecanes deuterated in the terminal methyl groups and of methyl laurates chlorinated in the ω-methyl and α-methylene groups have also been measured.

From an analysis of these spectra, all the bands and inflections between 3100 and 700 cm^{-1} in the spectrum of methyl laurate can be assigned to localized group vibrations. The spectra of some related acid chlorides, alcohols, and bromides are also briefly noted.

INTRODUCTION

The molecular vibrations of open-chain polymethylene compounds have been investigated extensively. The earlier work was reviewed by Sheppard and Simpson (1) in 1953, and the more controversial aspects of recent work have been discussed by Sheppard (2), J. R. Nielsen, and Holland (3), and Krimm (4) among others. Most of these studies have dealt with the solid state in which the chain is extended in the all-trans form. In the liquid state, compounds containing short methylene chains exhibit more complex spectra because a limited number of non-linear conformational isomers are present in equilibrium with the all-trans form. As the chain lengthens the number of conformational isomers increases, but the spectral band envelope simplifies because only the predominating all-trans and a few of the cissoid infrared-active vibrations give rise to discrete resolved bands.

Earlier work from this laboratory (5, 6) has dealt with the effect of chain length on the infrared spectra of straight-chain fatty acids and their methyl esters. It was observed that the spectra of the acids and esters in the C_{14}–C_{21} range were very similar when measured in solution. Only small variations occurred in the relative band intensities and these could not be evaluated quantitatively by the experimental techniques then available. More recently we have studied quantitatively the effect of the chain length on the spectra of *n*-alkanes in solution, using an improved spectrophotometric technique (7). The absorption characteristic of the carbomethoxy group has also been examined by comparing the spectra of methyl and ethyl acetates with the spectra of derivatives in which the methyl and methylene groups have been selectively deuterated (8, 9).

These investigations showed that the carbomethoxy group vibrations of fatty acid methyl esters are "insulated" from the chain vibrations, and it is of interest to determine how precisely such spectra can be treated in terms of sets of independent absorption bands specific respectively to the chain and to the terminal groups. In the long-chain esters the vibrational modes of the α-methylene group are perturbed by the proximity of the carbonyl. Absorption specific to the ω-methyl group is also distinguished

[1]*Issued as N.R.C. No. 6650.*

Presented, in part, at the International Conference of the European Molecular Spectroscopy Group, Bologna, Italy, September 1959.

and the spectra of the long-chain esters can be most conveniently discussed in terms of the four vibrational "zones" (*a*)–(*d*) of structure I.

$$\underset{(a)}{CH_3}—\underset{(b)}{(CH_2)_n}—\underset{(c)}{CH_2}—\underset{(d)}{COOCH_3}$$

I

In order to investigate possible interaction effects among the vibrations assigned to these units of structure, a series of compounds has been prepared in which the ω-methyl group, the α-methylene group, and the carbomethoxy methyl group of a representative long-chain methyl ester have been selectively deuterated. Methyl laurate (II), with $n = 9$, was chosen for this purpose as this length of chain provides an optimum balance between the cumulative intensity of the weak chain methylene bands and the stronger absorption of the carbomethoxy group.

Seven selectively deuterated derivatives of methyl laurate were prepared (III–IX). These include III–V, deuterated respectively in the ω-methyl group, the α-methylene group, and the carbomethoxy group, VI–VIII deuterated at two of these positions, and IX deuterated at all three. The spectrum of *n*-dodecane (X) and its derivatives deuterated in one or both methyl groups (XI, XII) were also examined, as were two chlorinated analogues (XIII, XIV) and two acid chlorides (XV, XVI). Attempts to prepare a third chlorinated analogue (XVII) were not successful. The acetylenic ester XVIII and the alcohols and bromides XIX–XXIV were obtained as intermediates in the syntheses, and certain aspects of the spectra of XIX, XX, XXII, and XXIV will also be discussed.

EXPERIMENTAL

The deuterated and chlorinated esters were synthesized by Dr. L. C. Leitch and Miss M. E. Isabelle, and their preparation has already been described (10). The hydrocarbons XI and XII, also prepared by Leitch and Isabelle, were obtained from the esters II and III. These esters were reduced with $LiAlD_4$ to the alcohols XXI and XX, which were converted with bromine and phosphorus to XXIII and XXIV respectively. Dehalogenation of these bromides with zinc dust in deuterium oxide gave the hydrocarbons XI and XII. The deuterium content of several of these compounds was assayed by infrared analysis of the water formed on combustion (11) to give the following results, expressed as atoms of deuterium per molecule:

III (2.86, 2.93); VI (4.80); VIII (5.12, 5.09);
IX (8.09, 8.06); XI (2.89, 2.92); XII (5.81);
XX (5.10, 4.90); XXIV (4.91, 4.78).

The infrared spectra were measured on a Perkin–Elmer Model 112 single-beam double-pass spectrometer using LiF, CaF_2, and NaCl prisms. Carbon tetrachloride was used as solvent for the range 3200–1320 cm^{-1} and carbon disulphide below 1320 cm^{-1}.

Measurements were made at 1-mm path length. The spectrometer was calibrated with a ternary mixture of indene, camphor, and cyclohexanone (12) and the estimated precision of the band positions is ± 1 cm^{-1}

below 2000 cm^{-1}, diminishing to ± 3 cm^{-1} at the higher frequencies. A nominal spectral slit width of 2 cm^{-1} was used between 2000 and 650 cm^{-1}, increasing to 4 cm^{-1} at 3200 cm^{-1}. A separate solvent background spectrum was recorded on each chart, and the spectra were plotted as apparent molecular extinction coefficients (ϵ'_{ν}) against wavenumber. The reported intensities are the mean of at least two sets of measurements on separately prepared solutions; all peak intensities were measured at absorbances in the range 0.1–0.8. Between 890 cm^{-1} and 820 cm^{-1}, where carbon disulphide absorbs, the spectra of several of the compounds were also measured qualitatively on capillary films of the undiluted liquids, using a Perkin–Elmer Model 21 spectrophotometer with NaCl prism.

RESULTS

C—H Stretching Vibrations

The spectra of representative compounds in the C—H stretching region are shown in Fig. 1 and the complete data are summarized in Table I. Bands D and F are the

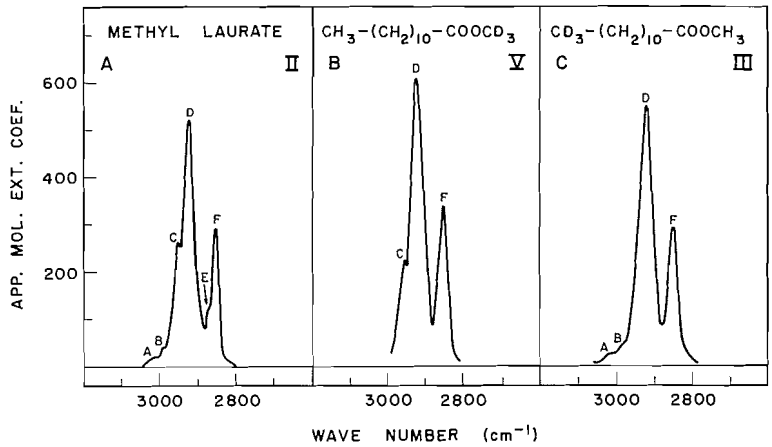

FIG. 1.

TABLE I

C—H stretching bands of methyl laurate and related compounds

Compound	Band[a] A	B	C	D	E	F
II	[3020] (16)	2995 (40)	2950 (260)	2922 (520)	[2870] (120)	2852 (290)
III	3015 (24)	[2990] (42)	—	2923 (550)	—	2851 (300)
IV[b]	3020 (25)	[2995] (40)	[2950] (250)	2923 (490)	[2870] (120)	2856 (270)
V	—	—	2952 (230)	2924 (610)	—	2852 (340)
VI[b]	[3020] (20)	2993 (33)	—	2928 (540)	—	2857 (295)

XVIII[d]	3020 (20)	2995 (35)	—	2926 (320)	—	2855 (165)
XX[b]	—	—	—	2926 (555)	—	2857 (305)

[a]The band maxima are in cm^{-1} followed by ϵ^{a}_{max} in parenthesis. The positions of points of inflection are indicated in square brackets.

[b]For spectra measured with a CaF_2 prism at a nominal spectral slit width of 10 cm^{-1}. The other spectra were obtained with a LiF prism at a nominal spectral slit width of 2 cm^{-1}. All measurements are for solutions in carbon tetrachloride at a concentration of approximately 0.01 *M*.

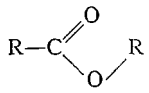
[c]Data obtained at higher resolution are reported in reference 7.

[d]The acetylenic ≡C—H stretching band is at 3310 cm^{-1} (ϵ^{a}_{max} 150) with shoulder at 3295 cm^{-1} (ϵ^{a}_{max} 20). The C≡C stretching band is at 2116 cm^{-1} (ϵ^{a}_{max} 15).

asymmetrical and symmetrical C—H stretching bands of the polymethylene chain. Band C and the inflection E at 2950 cm^{-1} and 2870 cm^{-1} are absent from the spectra of III, VI, VII, IX, XII, XVIII, and XX. These compounds lack the ω-CH_3 group and the bands are assigned to the asymmetrical and symmetrical stretching modes of this group. The spectra of XXII and XXIV were not measured in this region.

Absorption specific to the C—H stretching modes of the carbomethoxy group is less obvious. In the spectrum of $CH_3.COOCH_3$ there are weak bands at 3026, 2999, and 2957 cm^{-1}; these are absent from the spectrum of $CH_3.COOCD_3$ and have been assigned to the carbomethoxy methyl group (8). Similar bands near 3025 cm^{-1} and 3000 cm^{-1} are observed for III, VI, and XVIII but not for V, VII–XII, and XX, consistent with their assignment to the carbomethoxy group. The inflection at 3020 cm^{-1} (band A) and the maximum at 2995 cm^{-1} (band B) in the spectrum of methyl laurate can be assigned similarly. The third band near 2957 cm^{-1} is not observed for methyl laurate, but is presumed to be submerged beneath the stronger absorption of the other C—H bands (band α). Greek letters will be used in general to designate bands that are presumably present but are obscured by overlap in the methyl laurate spectrum.

Wilmshurst (13) has assigned both the 3026 cm^{-1} and the 2999 cm^{-1} bands of methyl acetate to asymmetrical C—H stretching modes of the methoxyl group, assuming that the molecule has the planar *s*-cis conformation XXV. The normally doubly degenerate mode is here split because of the presence of a plane of symmetry. The 3026 cm^{-1} band is attributed to the a' species, symmetrical with respect to the plane, and the 2999 cm^{-1} to the a'' antisymmetrical species. The presence of a similar doublet in the spectrum of methyl laurate indicates that the carbomethoxy group has the same *s*-cis configuration (XXVI). Wilmshurst's evidence for the *s*-cis configuration in methyl acetate is not conclusive, but it is based on analogy with methyl formate and fits the experimental data satisfactorily. Wilmshurst assigns the α band to the symmetrical mode.



XXV (R = —CH_3)
XXVI (R = —$C_{11}H_{23}$)

Absorption specific to the α-methylene group of methyl laurate should be most readily detected by comparisons among the spectra of VII, IX, and XII, but no significant differences are observed in the contours of these band envelopes.

C—D Stretching Vibrations

On deuteration of the ω-methyl group three bands appear at 2210, 2120, and 2075 cm^{-1} (Table II). These are observed in the spectra of III, XI, and XII, with the intensity for XII approximately twice that for XI. The more intense band is tentatively identified with the asymmetrical C—D stretching mode. The weaker doublet may involve a Fermi resonance of the symmetrical C—D stretching mode with an overtone or combination band.

Deuteration of the carbomethoxy group produces a more complex set of five bands at 2272, 2247, 2192, 2125, and 2080 cm^{-1}. On the basis of Wilmshurst's assignments for methyl acetate, three bands would be expected for the —$COOCD_3$ group.

Exchange of deuterium in the α-methylene group produces a very weak set of bands at 2312, 2220, and 2150 cm^{-1}. Here again the number of bands observed exceeds that anticipated for a pair of antisymmetrical and symmetrical C—D stretching vibrations.

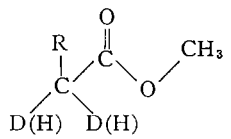
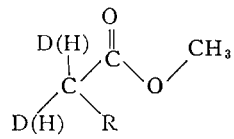
[a]The band maxima are in cm^{-1} followed by ϵ_{max} in parenthesis. The positions of points of inflection are indicated by square brackets. The spectra were measured at a nominal spectral slit width of 2 cm^{-1} in carbon tetrachloride solution at a concentration of approximately 0.1 *M*, except for IV, for which a concentration of 1.3 *M* was used.
[b]Broad band.

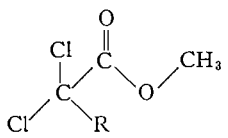
Apart from the obvious, but unproved, explanation in terms of Fermi resonance, the additional band could result from restricted rotation about the C—CO bond, leading to an equilibrium between XXVII and XXVIII or related non-eclipsed structures. Some anomalous C—D absorption could result from incomplete exchange of hydrogen, but the deuterium analyses indicate that the concentration of any —CHD— species must be small, and would be unlikely to give a C—D stretching band of significant intensity.



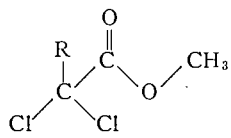
XXVII



XXVIII



XXIX



XXX

The spectra of esters deuterated at more than one center exhibit C—D bands that are consistent with the superposition of the spectra discussed above (Table II).

C=O Stretching Vibrations

The positions of the C=O stretching bands are listed in Table III. Deuteration of the carbomethoxy methyl shifts the band to lower frequency, as in methyl acetate. Deuteration in the ω-methyl or α-methylene has no effect. The insensitivity to α-methylene deuteration is notable, since deuteration of $CH_3.COOCH_3$ to $CD_3.COOCH_3$, which similarly involves deuterium replacement on the α-carbon, lowers the carbonyl frequency by 5 cm^{-1} (8, 9).

The spectrum of the α-chloro ester (XIV) has two maxima at 1768 and 1751 cm^{-1}, which probably result from restricted rotation about the C—CO bond (XXIX, XXX). By analogy with the doublet carbonyl maxima of chloroacetone (14, 15) and the ω-halogenated acetophenones (16), the 1768 cm^{-1} peak is attributed to the *s*-cis isomer (XXIX) and the 1751 cm^{-1} peak to the gauche form (XXX). Our sample of XIV had an additional

[a]The band maxima are in cm^{-1} followed by ϵ_{max} in parenthesis. The spectra were measured at a nominal spectral slit width of 2 cm^{-1} in carbon tetrachloride solution at a concentration of 0.01 *M*.

weak maximum at 1723 cm^{-1} which is difficult to explain in terms of conformational isomerism, nor is there any likely impurity that would absorb at this position. The acid chloride XV absorbs at 1803 cm^{-1} with secondary maxima at 1760 and 1711 cm^{-1} and the acid chloride XVI at 1810 and 1784 cm^{-1}. The satellite bands of XV may be due to impurity, but similar secondary absorption below the main C=O maximum is also observed in the spectrum of benzoyl chloride (17) and remains unexplained.

C—H Deformation Vibrations between 1500 and 1300 cm^{-1}

In this region of the spectrum the effects of selective deuteration are most specific. Methyl laurate exhibits eight peaks (bands H–N of Fig. 2A and band O of Fig. 7A). There is also indirect evidence that three bands (β–δ) contribute to the H/I system; an additional weak band (ϵ) is submerged beneath band J and two more weak bands (ζ, η) lie beneath bands L and M. Representative spectra are shown in Figs. 2–6 and the numerical data are summarized in Table IV.

Bands H and I (1467 and 1458 cm^{-1})

This doublet results from the overlapping of several bands. The principal components are the scissoring modes of the chain methylene groups, with secondary contributions from both methyl groups. The dominant methylene contribution (band β) is apparent from the spectra of IX and XII in Figs. 3D and 4C. The contribution from the asymmetrical C—H bending mode of the ω-methyl group (band γ) is indicated by the progressive diminution in the intensity of the H/I band envelope for X, XI, and XII in Fig. 4.

The short-chain *n*-alkanes exhibit a maximum at 1467 cm^{-1} with a satellite peak at 1457 cm^{-1}. With increasing chain length, an intermediate band appears at 1460 cm^{-1} which can be detected by graphical analysis for *n*-tridecane and is visually apparent for *n*-octacosane (7). The 1467 cm^{-1} and the 1460 cm^{-1} bands have been assigned to methylene scissoring vibrations and the 1457 cm^{-1} band to the asymmetrical C—H bend of the methyl groups. The contours and intensities of the H/I band group in Fig. 4 show that although the absorption at 1457 cm^{-1} weakens with deuteration of the methyl some absorption remains at 1457 cm^{-1}, and the 1467 cm^{-1} band of XII is highly asymmetrical on the low-frequency side. This suggests that methylene scissoring modes (probably from coiled or bent chains) are contributing to absorption in the 1460–1455 cm^{-1} region as well as the terminal methyl group vibration. The temperature dependence of these bands is currently under investigation.

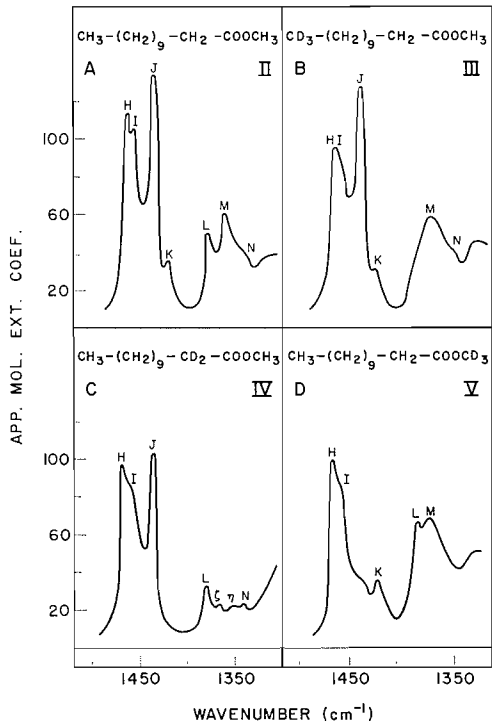

FIG. 2.

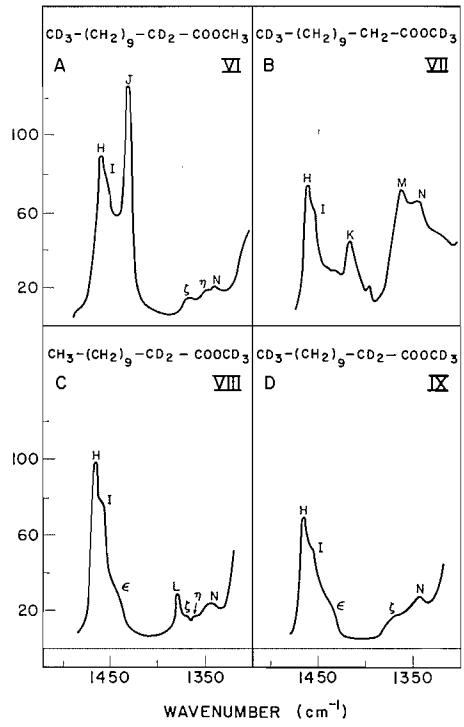

FIG. 3.

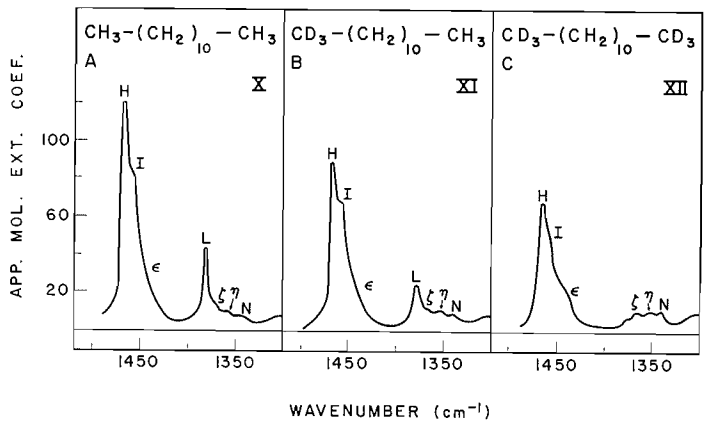

FIG. 4.

The carbomethoxy methyl group of methyl laurate also contributes to the absorption beneath the H/I envelope (band δ). The spectrum of $CD_3.COOCH_3$ has a band at 1456 cm^{-1} which has been attributed to the asymmetrical C—H bending mode (8). This is not distinguishable in the spectrum of methyl laurate, but its presence is suggested by the fall in the intensity of band I when the carbomethoxy group is deuterated (cf. Figs. 2A and 2D; 3A and 3D). If the carbomethoxy group is planar (XXVI) there should be two bands, and Wilmshurst has reported the second (weaker) band at 1469 cm^{-1} in methyl acetate (13).

TABLE IV

C—H deformation bands between 1500 and 1300 cm^{-1} of methyl laurate and related compounds

Compound	Band [a] H	I	ϵ	J	K
II	1467 (113)	1458 (107)	—	1436 (136)	1419 (36)

XXII[c]	1379 (26)	1373 (16)	—	1353 (12)	1341 (11)	[1298] (22)
XXIV	—	1368 (12)	—	1352 (13)	1343 (12)	1296 (20)

[a]The band maxima are in cm^{-1} followed by ϵ^{a}_{max} in parenthesis. The positions of points of inflection are indicated by square brackets. The spectra were measured at a nominal spectral slit width of 2 cm^{-1} in carbon tetrachloride solution at a concentration of approximately 0.05–0.10 *M* except for band O which was measured in carbon disulphide.
[b]Intensified by superposition on other absorption.
[c]Also a band at 1438 cm^{-1} (ϵ^{a}_{max} 42) assigned to C—H scissoring mode of $—CH_2Br$ group.

Band J (1436 cm^{-1}) (Band ϵ (1440 cm^{-1}))

The strong band J is absent from the spectra of esters containing the $—COOCD_3$ group (Figs. 2D, 3B, 3C, 3D). Its identification with a carbomethoxy methyl vibration is substantiated by its prominence in the spectrum of VI (Fig. 3A), and in the spectrum of $CD_3.COOCH_3$ (8). It is assigned to the symmetrical C—H bending mode. The position and intensity of this band make it particularly useful for distinguishing between methyl and other types of alkyl esters.

A considerably weaker broad band near 1440 cm^{-1} is observed as an inflection in the spectrum of *n*-dodecane and other compounds lacking the carbomethoxy group (VIII,

IX–XII, XX, XXI) (Figs. 3C, 3D, 4). This absorption (band ϵ) coincides with the strongly Raman-active methylene vibration of alkanes and probably derives from scissoring modes in which vicinal methylenes move in phase.

Dodecyl bromide (XXII) has a stronger band at 1438 cm^{-1} which is absent from the spectrum of XXIV (cf. Figs. 6C, 6D) and presumably involves a C—H scissoring

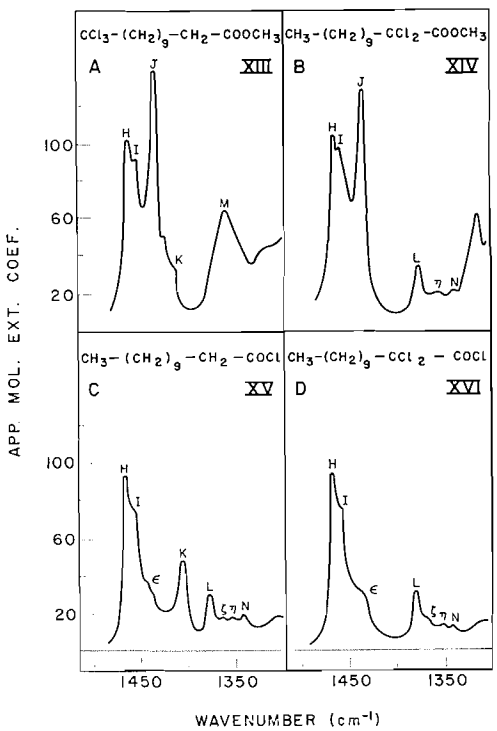

FIG. 5.

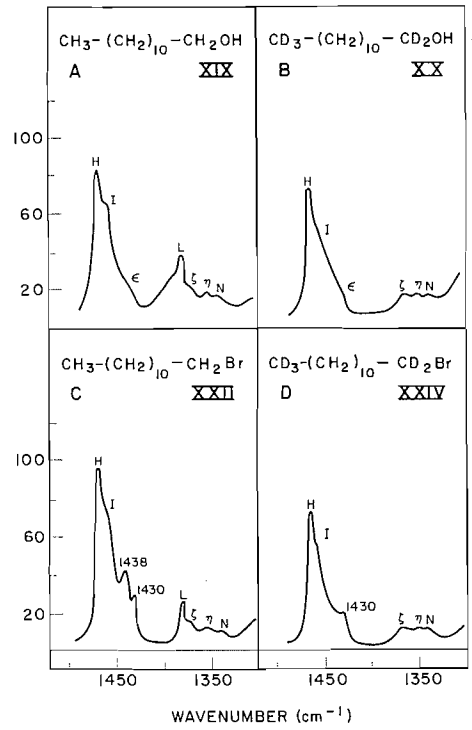

FIG. 6.

mode in the terminal —CH_2Br group. Brown and Sheppard assign a band at 1435 cm^{-1} in the spectrum of 1,2-dibromoethane to a similar vibration (18). Both XXII and XXIV also absorb weakly at 1430 cm^{-1}; possibly this is a scissoring mode of the methlyene α to the —CH_2Br or —CD_2Br group.

Band K (1419 cm^{-1})

The weak band *K* of methyl laurate is absent if the α-methylene is deuterated (Figs. 2C, 3A, 3C, 3D) or chlorinated (Fig. 5B); it is prominent in the spectrum of V (Fig. 2D), and is identified with the scissoring mode of the α-methylene group. In the acid chloride XV it is intensified and displaced to 1406 cm^{-1} (Fig. 5C) and it is absent from the spectrum of XVI (Fig. 5D).*

Band L (1378 cm^{-1})

This is the well-recognized symmetrical C—H bending band of the ω-methyl group. It is absent from the spectra of III, VI, VII, IX, XII, XIII, XVIII, XX, and XXIV and is prominent in the spectra of VIII and X (Figs. 3C and 4A).

**Isabelle and Leitch (10) noted that lauric acid also absorbs near 1419 cm^{-1} but the band does not disappear on α-methylene deuteration. Hadzi and Sheppard (19) have shown this is a skeletal vibration of the carboxylic acid dimer.*

Band M (1362 cm^{-1})

The presence or absence of this band runs parallel with that of band K and it is therefore due to α-methylene. A similar band is observed for diethyl ketone (20) and has been assigned to the wagging mode. Absorption between 1360 and 1320 cm^{-1} in the spectra of propionates and butyrates has been similarly assigned by Katritzky, Lagowski, and Beard (21).

Band N (1340 cm^{-1}) (Bands ζ (1368 cm^{-1}) and η (1353 cm^{-1}))

The weak band N inflection is part of a triplet of which the other two components at 1368 cm^{-1} and 1353 cm^{-1} (bands ζ and η) are overlapped in the methyl laurate spectrum by bands L and M. All three bands are seen in the spectra of IV, VI, X–XII, XIX, XX, XXII, and XXIV. They are most prominent for XII, XX, and XXIV (Figs. 4C, 6B, 6D) where they are free of overlap. Similar bands have been reported in the spectra of *n*-alkanes in the liquid state and are assigned by Sheppard and Simpson (1) to hydrogen deformation modes in non-linear configurations of the chain. Nielsen and Holland (3) assign the 1368 cm^{-1} component to the twisting mode in the all-trans configuration and the 1353 cm^{-1} band to the trans–gauche structure. Sheppard would place all twisting vibrations below 1300 cm^{-1} (2), in which case the 1368, 1353, and 1340 cm^{-1} bands would all be associated with wagging modes. Similar bands in amorphous polymethylene are also assigned to wagging modes by Krimm (4). This is a controversial problem to which the new data presented here makes no direct contribution, apart from emphasizing the association of all these bands with chain methylene groups.

Band O (1305 cm^{-1})

For technical reasons this band was measured in carbon disulphide solution and is illustrated in Figs. 7–10. It is broad and weak in the methyl laurate spectrum and partly obscured by stronger bands at lower frequency. It is seen more clearly in the *n*-alkane spectra (Fig. 10). Nielsen and Holland (3) assign it to a methylene twisting fundamental by analogy with the strongly Raman-active band at 1295 cm^{-1} as also does Krimm (4). The possibility of it being a wagging vibration has also to be considered.

"C—O Stretching" Vibrations between 1300 and 1150 cm^{-1}

Bands P, Q, and R (1248, 1196, and 1169 cm^{-1})

The spectrum of methyl laurate between 1300 and 1150 cm^{-1} is dominated by three bands, P, Q, and R (Fig. 7A). Strong absorption in this region is characteristic of carboxylic esters; the C—O linkages are clearly involved since analogous structure is missing from the spectra of the acid chlorides XV and XVI (Figs. 9B, 9C). Although these bands have been extensively discussed (22–24) no specific vibrational assignments have been made; it has been noted, however, that the spectra of methyl esters show unusual features, particularly near 1190 cm^{-1} (24).

The P, Q, and R bands are all perturbed by deuteration, but the effects are strikingly different for exchange in the α-methylene or carbomethoxy groups. On deuteration of the carbomethoxy group, band Q remains essentially unchanged, P is displaced slightly from 1245 cm^{-1} to 1256 cm^{-1}, but band R is replaced by a prominent narrow band at 1087 cm^{-1} (Fig. 7B). Deuteration in the α-methylene produces a more profound change. None of the P, Q, R band group is any longer recognizable and a new intense band appears at 1252 cm^{-1} (Fig. 8A). Chlorination of the α-methylene has a rather similar effect (Fig. 9A), two new peaks appearing at 1265 cm^{-1} and 1258 cm^{-1}; this doublet may be associated with an equilibrium between *s*-cis and *s*-trans conformations for which other evidence has been noted (band G). If the hydrogen in both the α-methylene and

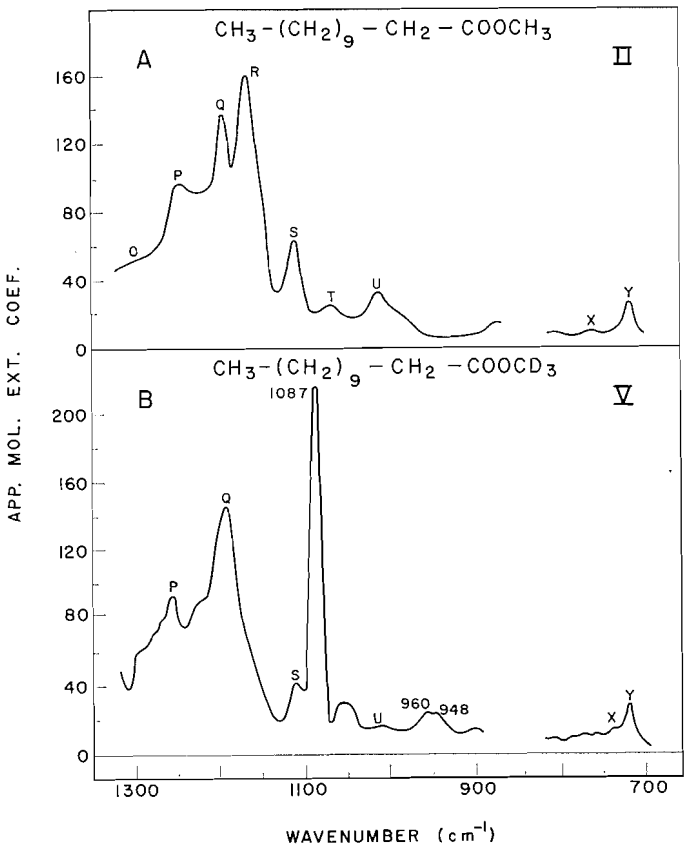

FIG. 7.

the carbomethoxy groups is exchanged (Fig. 8B) the effect on the methyl laurate spectrum approximates to a combination of the two separate exchange effects; the high-frequency band appears at 1275 cm^{-1} and the low-frequency band at 1088 cm^{-1}. As would be expected, deuteration of the ω-methyl group has no significant effect on this absorption (Table V).

In attempting to interpret these changes it is convenient to consider first the fully exchanged structure $R—CD_2—COOCD_3$, which has the simplest spectrum. The pair of strong bands near 1275 and 1088 cm^{-1} resemble structure seen in the spectra of many acetate esters, viz. $CH_3.COOCH_3$, $CH_3.COOCD_3$, $CD_3.COOCH_3$, $CD_3.COOCD_3$ (8); $CH_3.COOC_2H_5$, $CD_3.COOC_2H_5$ (9); $CH_3.COO.CH_2.CH_2.OOC.CH_3$, $CH_3.COO.CD_2.CD_2.OOC.CH_3$, $CH_3.COO.CH(CH_3)_2$, $CH_3.COO.CH_2.CH(CH_3)_2$ (25). The spectra of all the foregoing esters have a pair of strong bands in the ranges 1276–1217 cm^{-1} (ϵ^a_{max} 675–275) and 1106–1034 cm^{-1} (ϵ^a_{max} 395–130). For methyl acetate Wilmshurst assigns the upper band to the CO—O stretching mode and the lower band to the $O—CH_3$ stretching mode (13). It would seem probable that this pair of bands is the "normal" spectrum associated with the $R_1.CO.O.R_2$ structure, though in view of its manifest sensitivity to changes in the R_1 and R_2 groups Wilmshurst's assignments are oversimplified and it would be more realistic to regard both bands as involving skeletal stretching modes extending through the —CO.OC— group.

[a]The band maxima are in cm^{-1} followed by ϵ^{n}_{max} in parenthesis. The positions of points of inflection are indicated in square brackets. Bands listed in italics differ significantly in intensity from others in the same vertical column of Table VA; the associated vibrational modes are perturbed by vicinal structure and they are discussed in the text. The spectra were measured at a nominal spectral slit width of 2 cm^{-1} in carbon disulphide solution, except for the bands noted under the footnote *c*.

[b]Region not measured.
[c]Measured qualitatively on a capillary layer of the undiluted liquid.
[d]Attributed to CD_3— (see text).
[e]Attributed to C—Cl (see text).
[f]Attributed to —CO.Cl (see text).
[g]Intensity enhanced by overlap or interaction with —COCl absorption.
[h]Attributed to —OH group.
[i]Characteristic of the —$COOCD_3$ group (see text under *Bands P, Q, R*).
[j]Characteristic of the —CH_2.$COOCD_3$ group (see text under *Band U*).
[k]Characteristic of the —CD_2.$COOCD_3$ group (see text under *Band U*).
[l]Obscured by overlap with strong C—Cl band.
[m]Obscured by overlap with strong —COCl band.
[n]Attributed to α-CD_2—.
[o]See Fig. 10C.

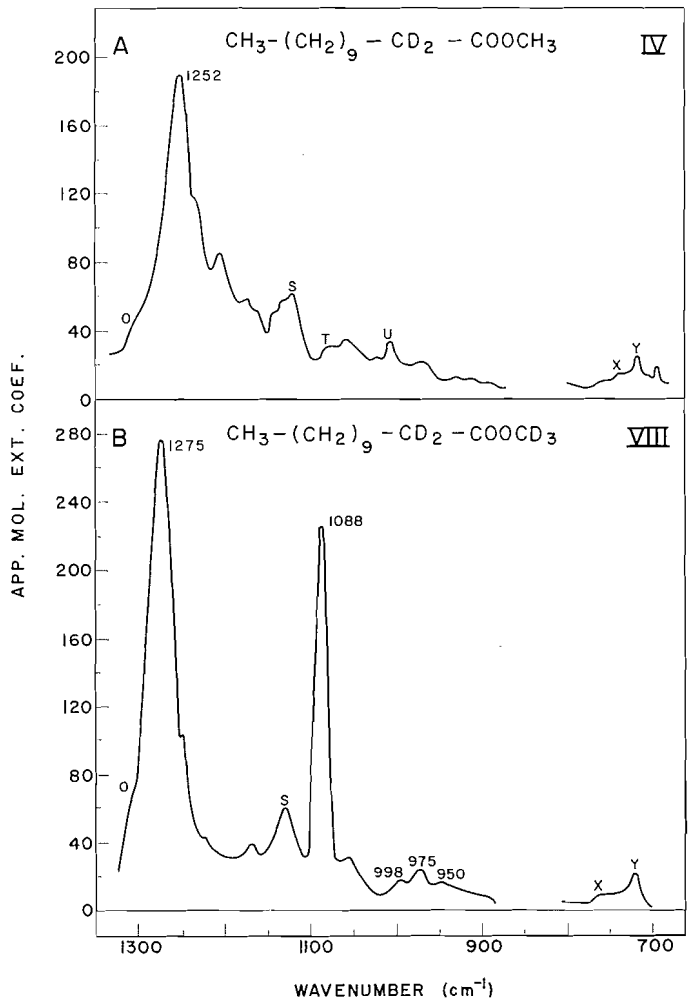

FIG. 8.

Since replacement of the α-methylene deuterium in $R.CD_2.COOCD_3$ by hydrogen strongly perturbs the 1275 cm^{-1} band and gives rise to the P and Q bands of the methyl laurate spectrum, it would appear that the P and Q bands involve strong coupling with a vibration of the α-CH_2 group. If band M is correctly assigned to the α-methylene wagging mode, the twisting mode may be concerned here.

The relation between the 1088 cm^{-1} band of $R.CD_2.COOCD_3$ and band R of the methyl laurate spectrum is more obscure. The 1088 cm^{-1} band is present in all the methyl laurate esters that contain —OCD_3 and is absent from those that do not. It could therefore be associated with an internal vibration of the —OCD_3 group, possibly the asymmetrical C—D bending mode (cf. band J). However, the 1088 cm^{-1} band is considerably more intense than band J, though this intensity might be gained by coupling with a skeletal mode. The band, however, does bear a close similarity to the band in the acetate spectra, noted above, where deuterium is not necessarily involved. A further difficulty is the seeming absence of both band R and the 1088 cm^{-1} band from the spectra

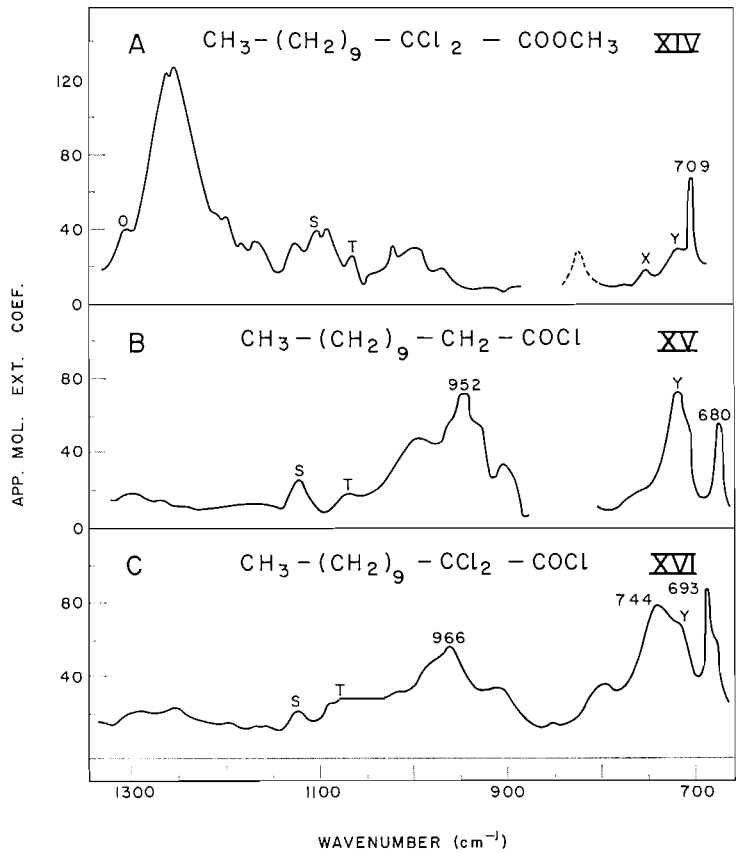

FIG. 9.

of $R.CD_2.COOCH_3$ and $R.CCl_2.COOCH_3$ (Fig. 8A, 9A), neither of which shows any intense absorption below 1200 cm^{-1} that can readily be attributed to the lower of the two postulated C—O stretching modes.

The complexity of these spectra recalls the confusion over attempts to interpret the "amide II" bands of secondary amides in terms of localized bond vibrations. The present studies indicate that the P, Q, and R bands of the methyl laurate spectrum involve vibrational modes that extend through the whole of the $—CH_2.CO.O.CH_3$ unit.

Vibrations below 1150 cm^{-1}

The spectrum of methyl laurate between 1150 and 650 cm^{-1} is weak and the bands are broad. There are well-resolved peaks at 1112, 1074, 1015, 875, 845, 755, and 720 cm^{-1} (bands S–Y). These bands are no doubt superimposed on much unresolved absorption associated with skeletal modes of various chain conformations. Considerable uncertainty still remains concerning the assignment of these bands even in the simplest case of the all-trans polymethylene chain (2, 4).

Band S (1112 cm^{-1})

This band is prominent in the spectra of II, III, V, VII, and XIII, which contain the structure $R.(CH_2)_9.CH_2.COOR$. For the esters IV, VI, VIII, and IX, containing

the group —CD_2.COOR, there is a band near 1130 cm^{-1}; the acid chlorides XV and XVI absorb near 1126 cm^{-1}, the alcohols and bromides XIX, XX, XXII, and XXIV absorb between 1120 and 1115 cm^{-1}, and the acetylenic ester XVIII at 1100 cm^{-1}. The intensities of these bands are variable over the range ϵ^a_{max} 14 to ϵ^a_{max} 100 and there is doubtful justification for assuming that they are necessarily associated with a common vibrational mode. If, however, this assumption is granted, a skeletal vibration of the —$(CH_2)_9$— chain perturbed slightly by the nature of the end groups would appear to be involved. For the homologous series of fatty acid methyl esters, the band shifts progressively from 1095 cm^{-1} to 1115 cm^{-1} with lengthening chain, and for a given chain length the position is the same for the methyl esters as for the free dimeric carboxylic acid (26). For *n*-alkanes Sheppard observes a band that shifts progressively from 965 cm^{-1} in *n*-butane to 1121 cm^{-1} in nonadecane (2, 27). This "1120 cm^{-1} series" has been tentatively assigned to a terminal methyl rocking mode and to a C—C skeletal mode (R_2 and Ψ in Sheppard's nomenclature). On chlorination of the ω-methyl group of methyl laurate this band is displaced by only 6 cm^{-1} from 1112 cm^{-1} (ϵ^a_{max} 62) for II to 1106 cm^{-1} (ϵ^a_{max} 68) for XIII. This would suggest that any coupling with the methyl rocking mode is small and that the vibration is predominantly C—C skeletal.

Band T (1074 cm^{-1})

A weak band between 1080 and 1070 cm^{-1} is observed in the spectra of II, IV, VI, X–XV. The assignment of this to a C—C skeletal mode is supported by the fact that a similar band is observed at 1080 cm^{-1} in the spectrum of XII, sandwiched between bands characteristic of the —CD_3 groups at 1115 cm^{-1} and 1055 cm^{-1}. Brown, Sheppard, and Simpson identify this band with the C—C skeletal mode α (the "1060 cm^{-1} series") as also does Krimm (4). In V and IX this band may be obscured or overlapped by the strong 1088 cm^{-1} band, but failure to observe it in the spectrum of III should be noted.

Band U (1016 cm^{-1})

This band appears prominently in the spectrum of II, III, XIII, and XVIII, all of which contain —CH_2.$COOCH_3$. A narrower band at 1008 cm^{-1} is associated with the —CD_2.$COOCH_3$ structure of IV and VI while a weaker doublet near 960 and 948 cm^{-1} characterizes the —CH_2.$COOCD_3$ group (Fig. 7B) and a triplet at 998, 975, and 950 cm^{-1} the —CD_2.$COOCD_3$ group (Fig. 8B).

Katritzky, Lagowski, and Beard (21) note the 1015 cm^{-1} band, which they locate in the range 1020–995 cm^{-1} in various saturated methyl esters, and assign tentatively to a skeletal mode or to an in-plane O—CH_3 rock of the carbomethoxy group. Wilmshurst (13), however, associates this mode with bands at 1230 cm^{-1} in methyl formate and 1248 cm^{-1} in methyl acetate. Comparison among the deuterated methyl laurates indicates that band U, like the P, Q, R triplet, involves the whole —CH_2.COOR structural unit.

Bands V and W (875, 845 cm^{-1})

The spectra of capillary films of II, III, IV, and V are shown in Fig. 10. Bands near 875 and 845 cm^{-1} are observed for II, III, and XIII, which contain —CH_2.$COOCH_3$. The —CD_2.$COOCH_3$ group of IV absorbs similarly at 855 and 815 cm^{-1} but the spectrum of V, containing the —CH_2.$COOCD_3$ group, shows no resolved absorption between 890 and 755 cm^{-1}. Bands V and W of methyl laurate therefore appear to be associated with the carbomethoxy methyl group and similar absorption is noted for various methyl esters by Katritzky and collaborators (21), who assign it to the methyl out-of-plane rocking mode. Wilmshurst (13) assigns a band at 844 cm^{-1} in the spectrum of methyl acetate to the CH_3.C— rocking mode, and if this is correct there can be no analogy with the methyl laurate spectrum in this respect.

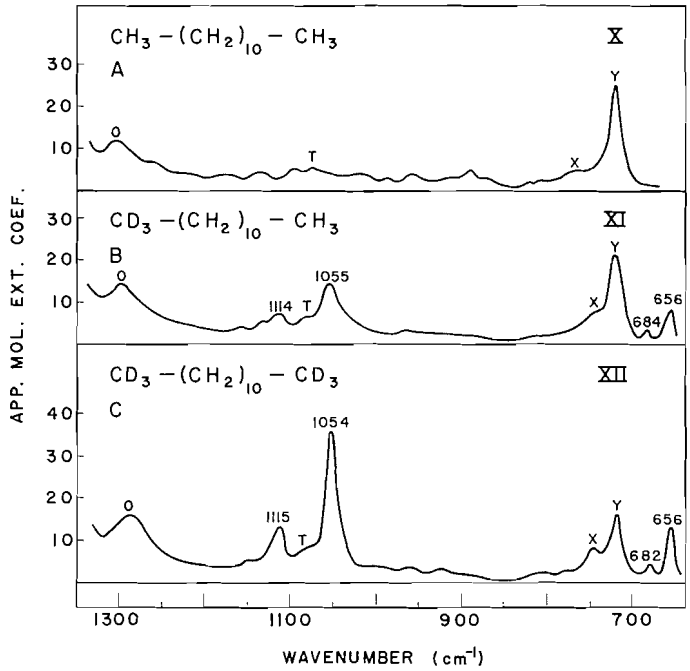

FIG. 10.

Bands X and Y (755, 721 cm^{-1})

Band Y is the well-recognized CH_2 rocking vibration of the polymethylene chain and its behavior is normal in all the compounds. The position of band X varies between 755 and 740 cm^{-1} and it is probably the second member of a progression of CH_2 rocking bands, the higher members of which are too weak for observation.

Other Absorption in the Substituted Compounds

Comparison of the spectra of the hydrocarbons X–XII (Fig. 11) indicates that on introduction of —CD_3 bands appear at 1115, 1054, 684, and 656 cm^{-1}. The two at

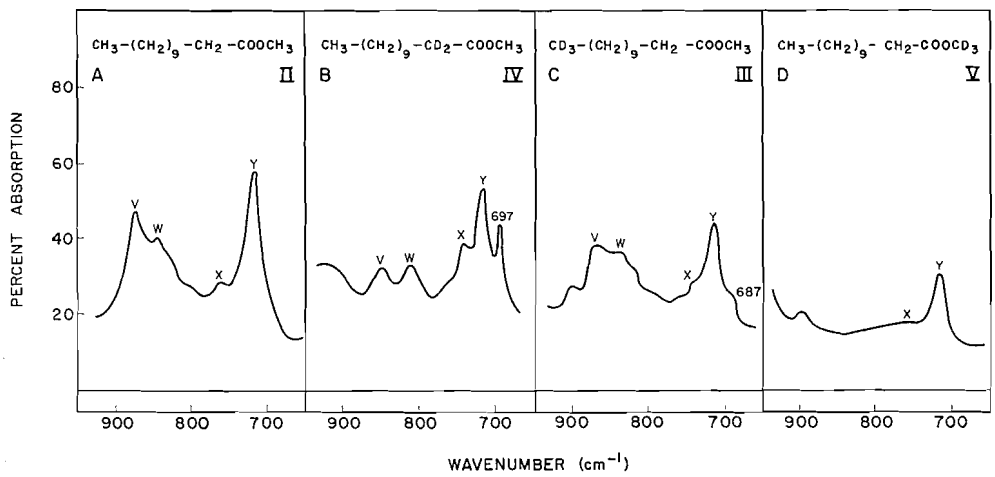

FIG. 11.

higher frequency are probably C—D bending modes and the others may be CD_3—C rocking modes. The 1054 cm^{-1} band is observed for the methyl trideuterolaurates (III, VI, VII, IX) and for the alcohol XX and the bromide XXIV (Table V), but the weaker band at 1115 cm^{-1} is obscured by band S in the ester spectra.

The methyl trichlorolaurate XIII exhibits prominent maxima at 777 and 694 cm^{-1} and the methyl α-dichlorolaurate XIV at 709 cm^{-1}. Presumably these bands involve C—Cl stretching modes. The acid chlorides XV and XVI show strong characteristic bands at 952, 722, 680 cm^{-1} and 966, 744, and 693 cm^{-1} respectively (Figs. 9B, 9C).

CONCLUSIONS

The complete spectrum of methyl laurate is shown in Fig. 12 plotted on a uniform ordinate scale, and the band assignments are summarized in Table VI. All peaks and

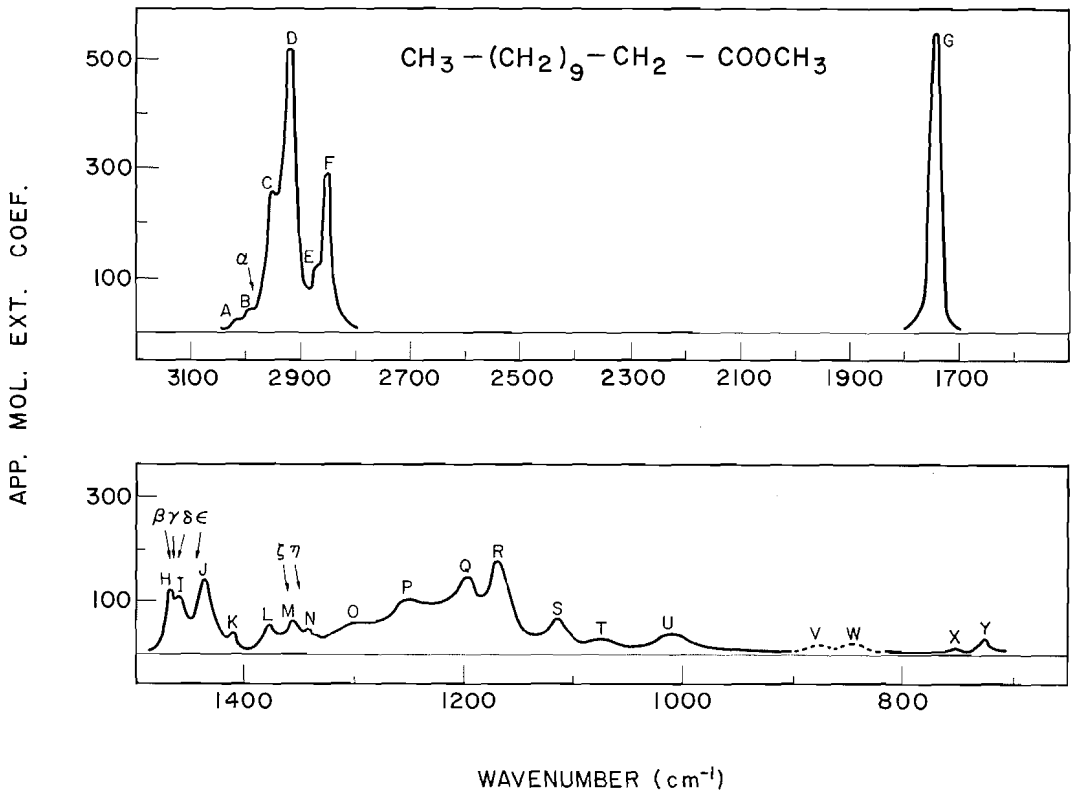

FIG. 12.

inflections in the spectrum can be assigned to the specific units of molecular structure (*a*)–(*d*) of I, except for bands P, Q, R, and U, which involve both the (*c*) and (*d*) units. The remaining uncertainty in the complete interpretation of the spectrum is due more to lack of knowledge concerning the nature of the vibrational modes within these structural units than to their mutual perturbation effects.

The use of the characteristic group frequency concept in analyzing the infrared spectra of complex molecules has been subject to some abuse, and has been used in different connotations by various spectroscopists. Theoretical spectroscopists, in particular, have

TABLE VI

Summary of band assignments for methyl laurate

Band[a]	ν_{max} (cm^{-1})	ϵ^{a}_{max}	Assignment	
			Group	Mode
A	[3020]	16	$-COOCH_3$	asym. C—H stretch (a')
B	2995	40	$-COOCH_3$	asym. C—H stretch (a'')

Q	1196	137	$-CH_2-COOCH_3$	C—O skeletal coupled with α-CH_2— deformation
R	1169	162	$-CH_2-COOCH_3$	C—O skeletal coupled with α-CH_2— deformation
S	1112	64	$-(CH_2)_9-$	C—C skeletal coupled with end groups
T	1074	25	$-(CH_2)_9-$	C—C skeletal
U	1016	30	$-CH_2-COOCH_3$	C—O skeletal coupled with α-CH_2— deformation
V	875	—	$-COOCH_3$	Methyl rock ?
W	845	—	$-COOCH_3$	Methyl rock ?
X	755	8	$-(CH_2)_9-$	C—H rock
Y	721	27	$-(CH_2)_9-$	C—H rock

[a]Points of inflection are designated by square brackets. Greek letters identify bands that are not observed in the methyl laurate spectrum but are presumed to be present from the analysis of the spectra of the deuterated derivatives.

been critical of its use for purely descriptive purposes, where there is often insufficient evidence from normal co-ordinate analysis to justify the localization of the vibration to the postulated restricted bond systems. It would be preferable to reserve this term for those situations where the vibration is in fact localized, in reasonable approximation, to motions of small groups of atoms, such as O—H stretching bands of non-hydrogen-bonded hydroxyl groups, and C=O stretching bands of ketones. In other cases, typified by the P, Q, R band system of methyl laurate, the group of three bands, taken as a whole, characterizes the $R.CH_2.COOCH_3$ structure, though the normal vibrations which are responsible for these bands within the group are not yet understood. In these circumstances we would prefer to use the expression "characteristic zone absorption" instead of "characteristic group frequency". The emphasis is here displaced from an individual band to a pattern of absorption that may extend over a wide wavenumber range, and that may characterize a unit of molecular structure consisting of a considerable number of atoms. The word "zone" identifies the region of molecular structure involved, and is consistent with the definition of a zone as "an area or region set off or characterized as distinct from adjoining parts" (28). The P, Q, R bands of methyl laurate provide a rather simple example of this zone concept, which is also being applied to the descriptive analysis of steroid spectra in the 1350–650 cm^{-1} range (29).

In a subsequent paper, the effects of varying the chain length on the fatty acid methyl ester spectra will be considered, and further discussion of the methyl laurate spectrum will be deferred in order that this additional data can also be discussed.

ACKNOWLEDGMENTS

We wish to thank Dr. L. C. Leitch and Miss M. E. Isabelle for synthesizing the deuterated and chlorinated compounds. Thanks are also due to Mr. R. Lauzon, Mr. A. Nadeau, and Mrs. M. A. MacKenzie for technical assistance with the measurement of the spectra. Mrs. MacKenzie was also responsible for the deuterium analyses.

THE EFFECTS OF CHAIN LENGTH ON THE INFRARED SPECTRA OF FATTY ACIDS AND METHYL ESTERS[1]

R. NORMAN JONES
The Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received October 17, 1961

ABSTRACT

The infrared spectra of straight-chain fatty acids and their methyl esters have been measured over the range 1500–650 cm^{-1} in carbon tetrachloride and carbon disulphide solution. The effects of the chain length on the peak intensities of the bands have been analyzed in relation to the group frequency assignments derived from comparative studies of deuterium-substituted methyl laurates.

INTRODUCTION

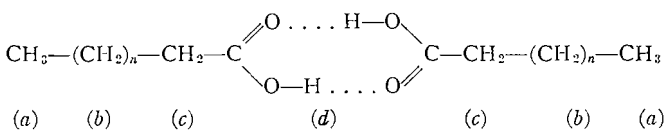
Comparison of the infrared spectrum of methyl laurate with the spectra of derivatives deuterated at specific sites (1) has shown that all of the 25 maxima and inflections between 3020 and 700 cm^{-1} in the methyl laurate spectrum can be attributed to localized group vibrations. Twenty-one of these bands can be assigned, in good approximation, to one of four "characteristic zones", (*a*)–(*d*) of structure I, while the remaining four bands involve coupled modes extending over zones (*c*) and (*d*).

$$\underset{(a)}{CH_3}\text{—}\underset{(b)}{(CH_2)_n}\text{—}\underset{(c)}{CH_2}\text{—}\underset{(d)}{COOCH_3}$$

I

If the group vibrations are strictly localized within the respective zones, it is easy to predict the effects of increasing the chain length. Bands associated with zones (*a*), (*c*), and (*d*) should be unaffected in position and intensity. For zone (*b*) the bands involving purely internal vibrations of each methylene group should intensify without wavenumber displacement, while for the modes that involve coupling between successive methylene groups, progressive wavenumber shifts may occur.

In order to examine these relationships, the spectra of the straight-chain methyl esters have been measured over the range $n = 0$ to $n = 15$ and the corresponding carboxylic acids (II) have been investigated between $n = 0$ and $n = 18$. The *n*-alkanes (CH_3—$(CH_2)_n$—CH_3) have been studied previously from $n = 4$ to $n = 34$ under the same experimental conditions (2).



II

EXPERIMENTAL

The acids and esters were obtained from commercial sources. The lower-boiling esters were distilled at atmospheric pressure through a Todd column. Five percent of the third quarter of the distillate was collected, and the homogeneity was checked by vapor-phase chromatography. Propionic and butyric

[1]*Issued as N.R.C. No. 6651.*

acids were dried with anhydrous sodium sulphate and distilled at atmospheric pressure in the presence of potassium permanganate.

The spectra were measured from 1500 to 1300 cm^{-1} in carbon tetrachloride solution and from 1300 to 700 cm^{-1} in carbon disulphide solution on a Perkin–Elmer Model 112 spectrometer under conditions described previously (1, 2).

RESULTS

In the preceding paper, the bands and inflections in the spectrum of methyl laurate were designated alphabetically in order of decreasing wavenumber, and the same identification system will be used here. Since these measurements do not extend above 1500 cm^{-1} only bands H–Y are considered. Bands H–M, P–U, and Y are clearly recognizable in the spectra of all the esters. Bands N, O, V, W, and X, though observed in most of the ester spectra, are unsuitable for quantitative consideration, because of weakness, or for other reasons. They are noted in the last column of Table I but will not otherwise be discussed. The carboxylic acids are predominantly in the dimeric form (II); in their spectra, bands H, I, L, S, T, and Y can be unequivocally identified with their counterparts in the ester spectra. Other bands, common to the acids but not present in the ester spectra, are distinguished by lower case letters (bands *a–f*).

The positions and peak heights of the methyl ester and acid bands are listed in Tables I and II respectively. The ester bands can be identified by reference to Fig. 12 of the preceding paper. The acid bands are shown in the representative spectrum of lauric acid in Fig. 1.

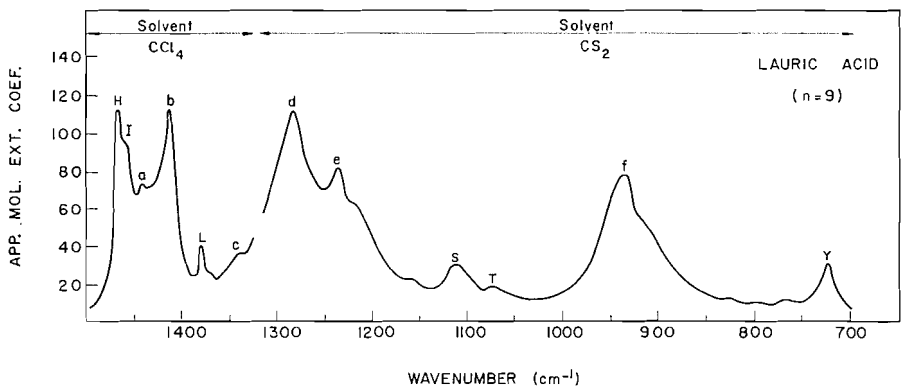


FIG. 1.

DISCUSSION

In an initial analysis of the ϵ^{a}_{max} versus chain length relationships, the band intensities were plotted against n, as was done previously for the n-alkane spectra (2). For most of the bands approximately linear relationships were observed, except in a few cases for low values of n. Representative plots for bands S and Y of both the esters and acids are shown in Figs. 2 and 3. The diagrams for the other bands are not reproduced, but the slopes (α) and the zero abscissal intercepts (β) for a linear least-square fit through the points are reported in Table III together with the standard deviation (S). For the majority of the bands the distribution about the least-square fit appears random, except in a few cases where abnormal departures from linearity are noted for the shorter-chain compounds. In these instances the short-chain homologues were omitted in fitting the data. This is indicated under the column headed n' in Table III. The more significant

[a]Bands H–M were measured in carbon tetrachloride solution and bands N–V in carbon disulphide. Unless otherwise indicated the band positions are listed in the column heading, and ϵ^n_{max} in the column.
[b]1456 cm^{-1}.
[c]Band H not observed.
[d]Note that band H is weaker than band I.
[e]1425 cm^{-1}.
[f]Tentatively identified with band V of methyl laurate.
[g]The band positions are given first followed by ϵ^n_{max} in parenthesis. Bands indicated in italics are superimposed on strong solvent absorption bands and their positions and intensities are less certain.
[h]Tentatively identified with band W of methyl laurate.
[i]Inflection.
[j]Tentatively identified with band X of methyl laurate.
[k]Tentatively identified with band O of methyl laurate.
[l]Tentatively identified with band T of methyl laurate.

[a]Values for α and β for the *n*-alkanes differ slightly from the values reported in Table 5 of reference 2. They are based on more accurate analysis of the same data.

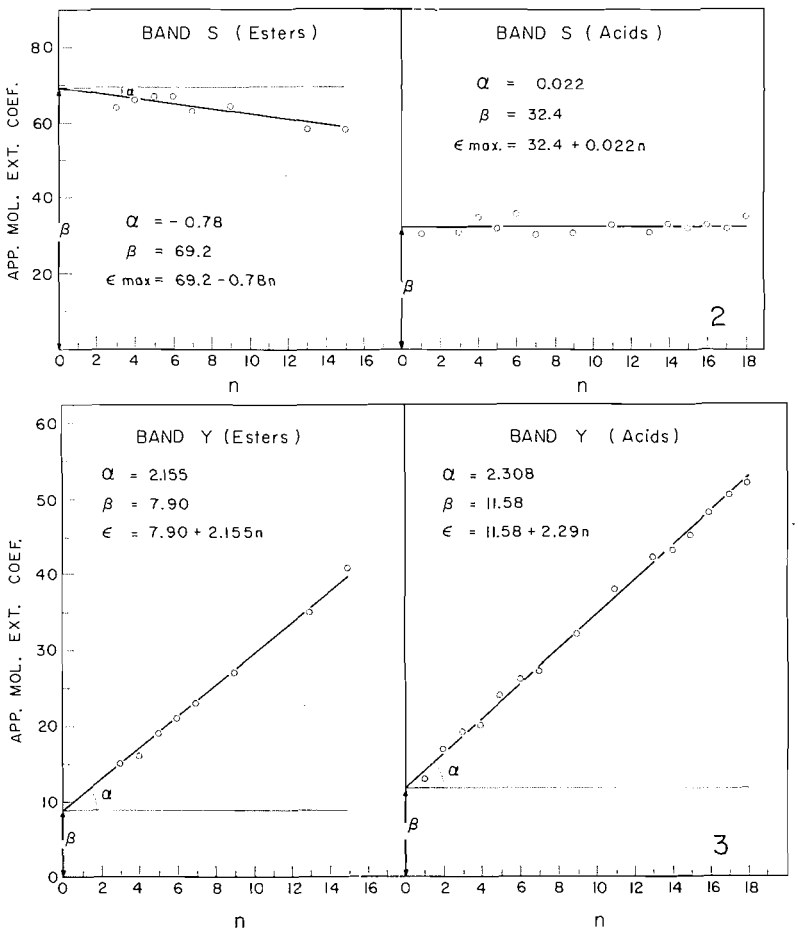
features of the ϵ^{a}_{max} versus n relationships for some of the individual bands will next be discussed, in relation to the zones with which they are associated.

Zone (a). The Terminal Methyl Group

Band L

Only band L near 1378 cm^{-1} is uniquely identified with the terminal methyl group, and its assignment to the symmetrical C—H deformation is well established. The intensity increases slightly with the lengthening chain; the increment per methylene (α) is about 0.5 for *n*-alkanes and acids and about twice as large for the esters.

This increase in intensity is probably due to weak underlying absorption from zone (*b*), principally band ζ, which is observed at 1368 cm^{-1} in the spectra of methyl laurates and *n*-dodecanes deuterated in the ω-methyl group. The effect of chain length on this



FIGS. 2 AND 3.

underlying absorption is difficult to evaluate quantitatively, but it is apparent from Figs. 4 and 5 of reference 2 that it intensifies considerably in passing from *n*-tridecane ($n = 11$) to *n*-octacosane ($n = 26$). The intercept β must be interpreted cautiously; values of 40.4, 35.8, and 39.5 were obtained for the *n*-alkanes, acids, and esters respectively. Since there are two ω-methyl groups in the *n*-alkanes, the intrinsic intensity per methyl is about 20. The higher value for the acids and esters is probably due to overlap from the shoulders of neighboring bands. In the ester spectra there is obvious enhancement from the shoulder of band M at 1362 cm^{-1}. In the acid spectra there may be contributions from the wings of the strong bands at 1413 and 1281 cm^{-1}. The similarity of the β values of the three classes of homologues therefore appears to be fortuitous and suggests that the transfer of peak-intensity measurements from one class of homologue to another must be treated circumspectly, though significance can probably be attached to the α values.

For the acids, the peak frequency of band L is displaced progressively from 1385 cm^{-1} to 1378 cm^{-1} as the chain lengthens (Table II). This could be a true displacement resulting

from weak coupling with a skeletal mode,* though it could result from a superpositional displacement effect of the underlying zone (*b*) band at 1368 cm^{-1}. Similar displacements are noted for band L in the short-chain methyl esters. They were not observed in the *n*-alkane spectra, where chain lengths below $n = 4$ were not investigated.

Zone (b). The Polymethylene Chain

Bands S, T, X, and Y have been assigned to the polymethylene chain of methyl laurate, also the β component of band H. Band X is too weak and uncertainly located for quantitative consideration and is noted only in Tables I and II. The complex H/I band system is discussed in a later section, and we shall be concerned here only with bands S, T, and Y.

Band Y

It is well established that band Y is associated with the CH_2 out-of-plane rocking mode. The intensity behavior is very similar for the esters, acids, and *n*-alkanes, the α values being 2.418, 2.308, and 2.155 respectively. For the *n*-alkanes β is small (0.8); it is much larger for the esters and acids, indicating that there is underlying unresolved absorption in the spectra of these compounds. In butyric acid ($n = 1$) the band Y maximum is at 748 cm^{-1} and it shifts progressively to 721 cm^{-1} in pelargonic acid ($n = 6$) and the higher homologues. The ester band behaves similarly. It is commonly stated that this band reaches its constant position for a chain of four methylenes. The additional displacements for the $—(CH_2)_5—$ and $—(CH_2)_6—$ systems only amount to 2–3 cm^{-1}, but they are believed to be significant.

Band S

The position of this peak in the ester spectra shifts progressively from 1086 cm^{-1} for $n = 0$ to 1115 cm^{-1} for $n \geqslant 13$. Band S is also observed in the spectra of the acids. For a given chain length it occurs at the same position in both the ester and acid spectra, but the intensity for the acids is only about one half of that for the esters. In neither series of homologues is the intensity much affected by chain length (Fig. 2). In the *n*-alkanes the intensity is lower by a factor of 10 and the band is not clearly recognizable in the solution-phase spectra. For the acids of shorter chain length there is some suggestion of an alteration in the intensity of band S for odd and even values of *n* (Fig. 2). This has not been observed on any other band and may be spurious. The wavenumber shifts with chain length are consistent with the assignment to a predominantly C—C skeletal mode. In several of the lower members of both the acid and ester series band S exhibits pronounced asymmetry on the high-frequency side and in some compounds a second band is resolved (e.g. methyl caproate (Fig. 4)).

Band T

This weaker band was identified in the methyl laurate spectrum with a skeletal mode that Sheppard designated "the 1060 series" (4). In the ester spectra it is only resolved over the narrow range of chain length from $n = 6$ to $n = 9$, and is most prominent for $n = 7$. It shifts progressively from 1050 cm^{-1} for $n = 6$ to merge into the low-frequency shoulder of band S for $n \geqslant 13$. In the spectra of the acids it can be distinguished

**Although the symmetrical* C—H *deformation mode of the methyl group is commonly regarded as an internal vibration, very simple calculations show that appreciable axial motion of the carbon atom is involved, and this must produce some perturbation at the next carbon atom. For the* XY_3 *molecule of* C_{3v} *symmetry Herzberg observes (3) that the motion of the* X *atom amounts to* $3m_Y/m_X.S_2.\sin\beta$, *where* m_X *and* m_Y *are the masses of the* X *and* Y *atoms,* β *is the angle between the* XY *bond and the symmetry axis, and* S_2 *the symmetry co-ordinate. From this it follows that the linear displacement of the carbon atom of the methyl group, in the absence of any coupling with the rest of the chain, would amount to about 8% of the displacement of each hydrogen atom.*

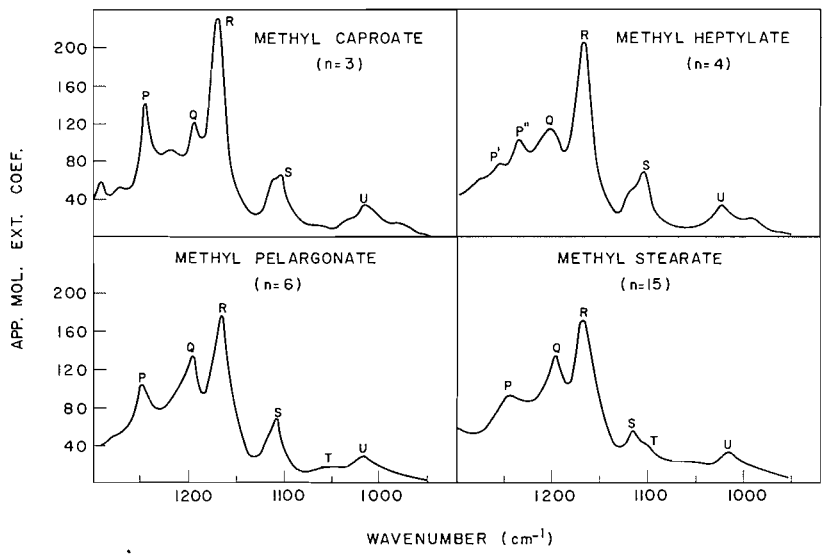


FIG. 4.

as an inflection for $n = 6$, 11, 15–18 and is resolved for $n = 7$, 9, 13, 14. Its position is similar for the esters and acids of the same chain length.

In both the acid and ester spectra there are other weaker inflections in the regions of bands S and T. Presumably these are derived from complex underlying absorption associated with skeletal modes of various subunits of the chain in trans–trans, trans–gauche, and gauche–gauche conformations. These show significant variation from compound to compound.

Zone (c). The α-Methylene Group

On the basis of the selective deuteration of methyl laurate, band K at 1419 cm^{-1} and band M at 1362 cm^{-1} have been assigned respectively to the scissoring and wagging modes of the α-methylene group.

Band K

In the ester spectra band K has an almost constant intensity ($\alpha = 0.2$); it lies on the shoulder of the strong band J, which is also insensitive to chain length. Band K has no obvious counterpart in the spectra of the acids.

Band M

For band M $\alpha = 1.17$ and it is therefore more affected by chain length than is band K. This is almost certainly due to its superposition on the methylene chain absorption (bands ζ, η) and indeed the intensification effect is very similar to that of the neighboring band L, for which $\alpha = 1.24$. The corresponding band in the spectra of the acids has not been positively identified. The acids do possess a band at 1336 cm^{-1} (band *c*) which might be associated with this mode.

Zone (d). The Carbomethoxy Group

Band J

This band, which has been assigned to the carbomethoxy group, shows a small intensity increment with chain length ($\alpha = 1.80$); this can be reasonably attributed to the overlap

effect of the wings of bands H, I, and ϵ. The general appearance of the band is similar in all the ester spectra and there is no significant wavenumber displacement.

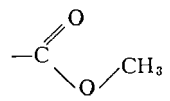
Bands Involving Multiple Zones

There are two types of bands involving more than one zone. One is typified by the H/I band system for which three components are recognized (bands β, γ, and δ), associated respectively with zones (*b*), (*a*), and (*d*). The deuterium-substitution studies on methyl laurate lead to the conclusion that the overlap is a simple additive one. The second type of multiple zone absorption is illustrated by the P, Q, R, and U bands of methyl laurate, where there can be no doubt that strongly coupled vibrations involving the participation of the atoms of both zones (*c*) and (*d*) are involved.

Bands H and I

In the H/I band system band H is dominant in the spectra of the long-chain homologues of the acids, esters, and *n*-alkanes. For all three classes of compound the ϵ^{a}_{max}/n plot for band H is linear with $\alpha = 8$ for esters and alkanes in which $n \geqslant 6$ and for acids in which $n \geqslant 4$. For all three homologous series the intercept β is $\sim$40.

For the short-chain compounds, the components of the H/I doublet are separately resolved. Band I becomes more prominent as the chain length diminishes, and the contour changes are qualitatively in accord with the postulated contributions from three component bands associated respectively with the scissoring mode of the chain methylene group (band β), the asymmetrical C—H bending mode of the ω-methyl group (band γ), and the asymmetrical C—H bending mode of the carbomethoxy group (band δ). Band β contributes predominantly to band H and bands γ and δ to band I, though the distinction is not a sharp one. If the carbomethoxy group has the planar conformation III there should be an additional band due to the a', a'' degeneracy



III

splitting of the asymmetrical C—H deformation mode. Wilmshurst (5) has assigned the a' vibration of methyl acetate to a weak band at 1469 cm^{-1} and the a'' vibration to a stronger band at 1450 cm^{-1}. There is no indication of this second band in the spectra considered here, but the a' band could be making an undetected contribution to band H. There is evidence from the C—H stretching region of the methyl laurate spectrum that the carbomethoxy group exists wholly or predominantly in conformation III and it is difficult to see why this should not hold also for the other homologues.

Bands P, Q, R, and U

These bands involve coupled vibrations extending through the (*c*) and (*d*) zones. They are observed with little change in position or intensity in the esters for which $n \geqslant 5$. For methyl heptylate ($n = 4$) band P is replaced by a doublet at 1255 and 1234 cm^{-1}, whereas for methyl caproate ($n = 3$) band P occurs at the normal position but with enhanced intensity. Band Q is "normal" at all chain lengths. The position of band R is unchanged at all chain lengths but it is significantly more intense for $n = 3$ and $n = 4$. The weaker band U is little affected. These bands are shown in Fig. 4. The spectrum of methyl propionate ($n = 0$) has bands at 1223, 1198, and 1175 cm^{-1} which may correspond with the P, Q, and R bands.

From the perturbations in the contours of the P, Q, and R bands of the lower homologues, it can be reasoned that zone (*b*) as well as zones (*c*) and (*d*) exercises some influence on these bands, particularly on band P. If this is so the perturbation effect of the polymethylene chain becomes constant when the number of methylene groups exceeds five. The effect could result from coupling with a skeletal mode of the chain, or it could be due to a steric effect influencing the conformation of the (*c*) and (*d*) zone structure. It would obviously be of interest to investigate the effect of temperature on these band contours for the short-chain esters. For methyl laurate temperature variation from 30° C to −70° C has no pronounced effect on the P, Q, R band contour.*

Other Bands Specific to the Carboxylic Acid Group

Bands *a–f* of the acids (Fig. 1) have no counterparts in the ester spectra.

Band a

This weak band appears as an inflection in the spectra of the short-chain acids and is resolved for $n \geqslant 9$. It might be identified with the scissoring vibration of the α-methylene group, since it is absent from the spectrum of $CH_3.(CH_2)_9.CD_2.COOD$.

Band b

This band, which occurs near 1416 cm^{-1}, exhibits an almost constant intensity. Sinclair, McKay, Myers, and Jones (6) assigned it erroneously to the α-methylene scissoring mode, but later Hadži and Sheppard (7) showed it to be associated with the carboxylic acid dimer group and assigned it to a mode in which C—O stretching vibrations are coupled with an O—H in plane deformation. In the acids substituted in the α-methylene group (e.g. isobutyric acid, α-bromostearic acid) it is displaced to 1430–1420 cm^{-1}.

Band c

This band appears as a weakly resolved peak or inflection near 1336 cm^{-1} and has been tentatively identified with the α-methylene wag (see section *Band M*).

Bands d and e

The prominent P, Q, R triplet of the ester spectra is replaced by the *d* and *e* doublet in the spectra of the acids. These are probably "C—O stretching" bands of the dimer ring system coupled with O—H in-plane deformations (cf. band *b*) (7). The intensity of band *d* is reasonably constant for all chain lengths except $n = 0$, but the position of the peak wanders between 1278 and 1288 cm^{-1} in an unsystematic fashion for the short-chain compounds; for $n \geqslant 9$ it remains steady at 1281 ± 1 cm^{-1}. The weaker band *e* is more variable in position, though it also becomes stabilized for $n \geqslant 9$. A distinct anomaly is observed for caproic acid ($n = 3$), where band *e* is replaced by a doublet at 1262 and 1242 cm^{-1}. Capric acid ($n = 7$) also shows a splitting of the absorption in the neighborhood of band *e*.

The shorter-chain acids show numerous other weakly resolved peaks and inflections in the region of the *d* and *e* bands. These are noted in the last column of Table II. They modulate the contour of the band envelope in a manner that is characteristic for each acid. This region of the acid spectra calls for more detailed examination under high resolution. In the solid phase these compounds exhibit well-defined progressions of equally spaced bands which are commonly attributed to coupled wagging or twisting vibrations of the methylene chain units. These vibrations may also be the cause of the fine structure in the liquid-phase spectra, though the uniform spacing is not apparent.

We wish to thank Dr. R. A. Ripley for making these measurements.

Band f

This characteristically broad band is well known in the spectra of carboxylic acids and has been assigned by Davies and Sutherland (8) to an out-of-plane deformation mode of the carboxylic acid dimer ring. The intensity is remarkably constant ($\alpha = 0.27$), consistent with its localization in zone (*d*). It exhibits a pronounced asymmetry on the low-frequency side.

CONCLUDING REMARKS

Over the range n' to n'', where linear correlations between ϵ^{a}_{max} and n appear to hold, the α values effectively distinguish the bands associated with the internal modes of the zone (*b*) bands, for which $\alpha = 2$–8, from the other types of bands which give much lower values of α. The zone (*b*) bands associated with skeletal modes also show low α values, but are distinguished by progressive frequency displacements. An exception must be made for the small frequency displacement of band L associated with zone (*a*). Most of the bands associated with zones (*a*), (*c*), and (*d*) do exhibit some intensification with increasing chain length, but this can be reasonably attributed to overlap effects from the shoulders of zone (*b*) bands. In the course of this intensity analysis no serious anomalies were observed that are inconsistent with the commonly accepted group frequency assignments for these bands, as reported in the earlier literature and substantiated by the measurements on the deuterium-substituted methyl laurates.

In column 7 of Table III the standard deviation (S) is reported, where

$$[1] \qquad S = \sqrt{\frac{\sum(\epsilon_{obs} - \epsilon_{calc})^2}{m}},$$

in which ϵ_{obs} is the experimentally observed absorption maximum, ϵ_{calc} the value obtained from the least-square fit, and m the number of compounds measured. Statistical considerations suggest that random errors in excess of $2S$ are improbable. The quantity $\alpha/2S$, shown in the final column of Table III, is therefore a convenient measure of the significance of the peak intensity as a criterion of chain length.

In the experimental section the absolute precision of the peak-intensity measurements was not discussed. In the present state of infrared spectrophotometry, it is not possible to evaluate quantitatively the experimental errors affecting absolute peak-intensity measurements. Since the measurements discussed here were made prior to the availability of commercial grating spectrometers, they do not represent the highest standards of photometric accuracy now obtainable with these new instruments. The spectral slit width employed was in the range 1–2 cm^{-1}, and although the majority of the bands are broad, we have preferred to express the intensities in "apparent" and not "absolute" units. Several laboratories are currently concerned with the determination of absolute standards for infrared band intensity measurements. When these data are available it will be of considerable interest to reinvestigate some of these acid and ester bands on a high-resolution grating spectrometer, accurately calibrated with respect to the absolute intensity. We would anticipate that the systematic errors associated with the finite slit function will principally affect the β values and that the increments per methylene will be less sensitive to this variable.

In this and the preceding paper we have dealt in considerable detail with the quantitative analysis of the infrared spectra of a family of compounds of a degree of complexity intermediate between the simple molecules susceptible to a rigid treatment by the methods of vibrational theory, on the one hand, and the large molecules of predominant

biological interest on the other. There are obvious difficulties in attempting to extend to such molecules the techniques of vibrational analysis applicable to small ones. While those concerned with the theory of molecular vibrations are well aware of this difficulty, organic chemists are naturally reluctant to accept the thesis that much of the absorption that they observed in the spectra of complex molecules must be dismissed as of empirical significance only. This creates a strong temptation to overextend the group frequency concept. The breakdown of the spectrum into sets of bands associated with more or less clearly differentiated subunits of molecular structure makes possible an analysis of complex spectra on a zonal basis without the necessity of invoking precise vibrational mechanisms.

In these solution-phase studies of homologous series we have been dealing with systems in which complex conformational equilibria are present, due to the flexibility of the polymethylene chain. The molecular spectroscopist can eliminate this by going to the crystalline state, and most of the literature dealing with the vibrational analysis of the polymethylene chain is restricted to solid-phase studies. The organic chemist seeking information about the contribution of polymethylene chain structure to the spectra of more complex molecules will not always be in a position to lay out the chain in a crystal of known *s*-trans chain configuration. Furthermore, if bulky cyclic groups are also present there can be no assurance that information derived from the analysis of the crystalline polymethylene chain system of simple hydrocarbons will be transferable to the very different packing system in more complex structures. Although the spectra of the liquid–phase polymethylene systems are less informative, the information they do convey is more widely applicable. This problem is currently being investigated with a series of long-chain steroid esters.

ACKNOWLEDGMENTS

We wish to thank Mrs. M. A. MacKenzie and Mr. A. Nadeau for technical assistance with the measurement of the spectra. We are also grateful to Dr. A. S. Hay, who purified the compounds and ran preliminary spectra.

ABSTRACT

The fit of polynomial series of varying degree to infrared absorption bands in the neighborhood of the maxima has been investigated, and, in the instances considered, an acceptable graduation was usually possible with a quartic equation. By differentiation of the polynomial an objective, and independently reproducible, numerical value can be obtained for the band maximum. The abscissal positions computed for the maximum converged as the degree of the polynomial was raised, provided the experimental points did not exhibit gross departures from a smooth distribution. The convergence of the roots of the quadratic, cubic, and quartic functions was employed to check the applicability of the technique in individual cases. A Lorentz curve can be fitted exactly by a parabola if the reciprocal of the absorbance is plotted as ordinate, but in practice no improvement in the fit of power series to real absorption bands was achieved by using the reciprocal ordinates.

Frequency shifts in the infrared spectra of benzene, acetone, and nitromethane on solution in carbon tetrachloride have been measured by this method. The finite displacements observed contradict a recent statement in the literature that the peak frequencies of the bands in the spectra of these and other substances are uninfluenced by solution in non-polar solvents.

INTRODUCTION

In a recent publication, de Maine, Daly, and de Maine (1) have claimed that, contrary to the observations of numerous other workers, the infrared absorption bands of a variety of organic compounds exhibit no frequency shifts between the spectrum of the pure compound in the liquid state and the spectrum in carbon tetrachloride solution over wide concentration ranges.

As part of a study of the factors determining infrared profiles, a technique has been developed in our laboratory by means of which objective and independently reproducible values can be obtained for the maxima of infrared absorption bands with a precision approaching that of the ordinate and abscissal data. The routine application of this technique is facilitated by the availability of a suitable program for the IBM 650 computer.

Several of the absorption bands of benzene, acetone, and nitromethane, which were investigated by de Maine and collaborators, have been remeasured on a high-dispersion grating spectrometer, and the peak positions evaluated by the new technique. This work was undertaken to test the general applicability of the computer program, and to check de Maine's measurements under more rigorous experimental conditions.

LOCATION OF INFRARED BAND MAXIMA

Experience with the evaluation of wavenumber data for the calibration of infrared spectrometers (2) has established that, over limited scanning ranges, an absolute accuracy within ± 0.1 cm^{-1} can be achieved. Our measurements were made with a

[1]*Issued as N.R.C. No. 6656.*
[2]*National Research Council Postdoctorate Fellow.*

Perkin–Elmer Model 112G grating spectrometer, with corrections applied for time-dependent calibration drift. Other investigators have also shown that accuracy of the same order can be achieved with other types of commercially available grating spectrometers (3). These instruments were calibrated from measurements of the rotational fine structure lines of vapor phase spectra, where precise location of the band maximum presents no serious problem.

For the broader bands of spectra measured in condensed phases, both the absolute accuracy and the reproducibility of the measured peak positions are limited by experimental uncertainty in locating the position of zero slope on the band envelope. In favorable cases this might be done with an accuracy approaching the absolute accuracy of the calibration data. Normally, however, the uncertainty in the measured peak position will be considerably greater, particularly if subjective visual methods are used.

In connection with the analysis of infrared band profiles from the truncated band moments (4) the need arose to determine the positions of the band maxima as precisely as possible and to eliminate any personal bias associated with subjective methods. The fit of polynomial power functions of various orders to limited regions of the band envelopes in the neighborhood of the maxima was therefore investigated.

If the equation of the absorption band envelope near the maximum can be approximated with sufficient accuracy by a power series of the form

$$[1] \qquad a_0+a_1x+a_2x^2 \ldots +a_nx^n = y$$

the position of the maximum will be adequately approximated by one of the roots of the first-derivative equation

$$[2] \qquad a_1+2a_2x+3a_3x^2 \ldots +na_nx^{n-1} = 0.$$

The graduation of the experimental points by such an nth degree polynomial equation, using the method of least squares, involves the solution of a series of $n+1$ equations of the form

$$[3] \qquad \begin{aligned} &a_0 \sum x_i^0+a_1 \sum x_i+a_2 \sum x_i^2+ \ldots a_n \sum x_i^n = \sum y_i \\ &a_0 \sum x_i+a_1 \sum x_i^2+a_2 \sum x_i^3+ \ldots a_n \sum x_i^{n+1} = \sum x_iy_i \\ &a_0 \sum x_i^n+a_1 \sum x_i^{n+1}+a_2 \sum x_i^{n+2}+ \ldots a_n \sum x_i^{2n} = \sum x_i^ny_i, \end{aligned}$$

where x_i, y_i are the measured co-ordinates.

On inverting the [X] matrix, these equations can be solved for the coefficients $a_0 \ldots a_n$, and the position of the maximum of the graduation can be obtained from equation [2].

Under idealized conditions, the infrared band profiles probably conform closely to the Lorentz contour

$$[4] \qquad f(x) = a/(b^2+x^2),$$

where $2b$ is the band width at half maximal intensity, a/b^2 is the peak height, and x the wavenumber displacement from the band center. In initial investigations, the fitting of power series of increasing order to the symmetrically disposed ordinates of the Lorentz curve was examined. The results of these computations are summarized in Table I; they show that a fit acceptable within the limits of the observational precision is obtained for a quadratic function over the range $-0.5j$ to $+0.5j$, where $j = x/b$. The Lorentz function has inflection points at $\pm 0.535j$, and the fit is likely to deteriorate if the interpolation is extended beyond $0.5j$ (i.e. beyond one half of the half-band width from the center).

TABLE I

Graduation of symmetrical Lorentz ordinates by polynomials of increasing degree
(ν_0 800 cm^{-1}; a/b^2 1; b 1.2 cm^{-1})

	$-0.25j$ to $+0.25j$		$-0.5j$ to $+0.5j$	
Degree of polynomial*	Discrepance† (cm^{-1})	R.M.S.E.‡ (cm^{-1})	Discrepance† (cm^{-1})	R.M.S.E.‡ (cm^{-1})
2	0.000001471	0.0012	0.0003408	0.0185
4	0.0000000156	0.0001	0.0000020	0.0014

*Because the curve is symmetrical, the values of the discrepance and the R.M.S.E. for 3rd and 5th power functions are the same as for the 2nd and 4th, respectively.
†The discrepance is given by $(y_{\text{Lorentz}}-y_{\text{polynominal}})^2/(\text{number of ordinates})$.
‡The root mean square error is the square root of the discrepance.

The envelopes of absorption bands will not generally conform to the Lorentz contour, and allowance must be made for perturbations that may include appreciable skewness. It was therefore anticipated that at least a quartic function would be needed to obtain an adequate fit for real absorption bands over the same abscissal range, and that an objective value for the maximum might be obtained by successively fitting power series of increasing order. For the technique to have practical value it would be required that above a certain degree the differences in successively computed maxima should fall below the limits of accuracy of the experimental observations (± 0.1 cm^{-1}).

In our experiments the spectra were determined on a single-beam spectrometer with which random errors may be encountered in both the background transmission curve and the experimental absorption curve. These errors involve both electronic noise of a comparatively high frequency, and longer-period perturbations due to variation in amplifier gain, electrical surges, and other uncontrolled factors disturbing the recorder. To avoid subjective influences on the data evaluation, no attempt was made to smooth these irregularities when transposing the chart measurements to absorbance, prior to processing for the calculation of the peak frequency. The magnitude of these random errors depends on the instrumental conditions, and the curves can be classified into three broad categories, as illustrated in Fig. 1. In case A, the band envelope appears smooth to the eye; in case B one or two clearly recognizable irregularities are present, which may reasonably be excluded as "catastrophic" errors affecting the particular ordinates. In case C, large and seemingly random departures from a smooth contour occur extensively through the spectrum. Excluding the exceptional situation where the true band shape is in fact modulated by fine structure, case C is indicative of gross random errors in the measurements, and under these conditions attempts to apply precision techniques for evaluating the center of the band envelope are inapplicable and meaningless.

Some examples of the fit obtained with polynomials of varying degree to real absorption bands are illustrated in Table II. In the majority of instances, as the degree of the polynomial was raised the experimental points were approximated more closely and the abscissal positions computed for the maxima either converged to a constant value or oscillated within the experimentally significant limits of ± 0.1 cm^{-1}. Exceptions were noted and these were usually for data conforming to type C bands (e.g. band IV of Table II).

With the increasing order of the polynomial, the number of roots of the differential equation increases proportionately, and the selection of the correct root may require computation of the ordinates in doubtful cases. This is rarely so for cubic or quartic

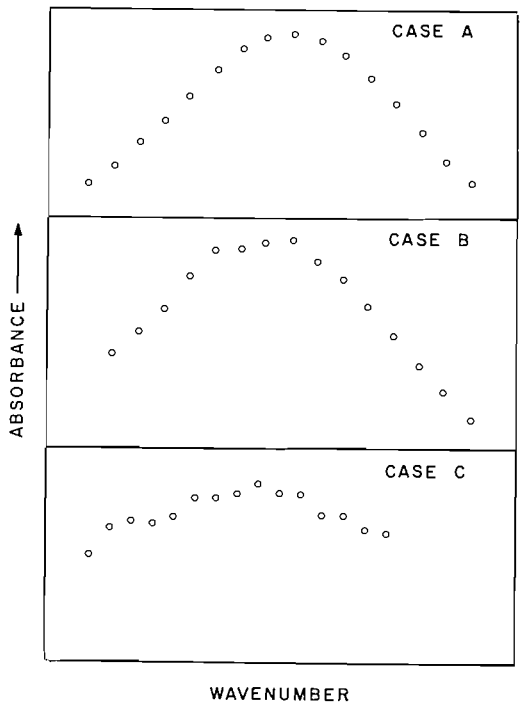

FIG. 1.

TABLE II

Approximation of real absorption bands by power series of increasing order

*Band I: perylene, 5.2×10^{-3} M in CS_2, visually estimated max. 812.7 cm^{-1}; band II, benzene, liquid, visually estimated max. 1036.1 cm^{-1}; band III: benzene, 3.33 M in CCl_4, visually estimated max. 1815.6 cm^{-1}; band IV: benzene, 3.33 M in CCl_4, visually estimated max. 1176.9 cm^{-1}.

The values in the y columns were computed for the absorbance ordinates and in the $1/y$ columns for the reciprocal absorbance ordinates.

Bands I and II were of type A, band III was of type B, and band IV of type C (see Fig. 1).

polynomials, for which the alternative roots are usually displaced by two or more cm^{-1} from the significant root, and the correct choice is seldom in doubt. On the basis of this survey it was concluded that no advantage will normally be gained by fitting polynomials above the fourth degree and that, provided the convergence or oscillation of the computed maxima for the quadratic, cubic, and quartic graduations meet the conditions noted in the preceding paragraph, the quartic value can routinely be accepted.

If the Lorentz function is inverted, the parabolic equation

$$f(x)^{-1} = (b^2+x^2)/a \qquad [5]$$

is obtained. It is therefore possible to fit a Lorentzian absorption band exactly by a quadratic equation if the reciprocal of the absorbance is plotted as ordinate. An extension of this argument would suggest that the perturbed Lorentzian envelopes of real absorption bands might also be graduated more precisely by power series if plotted in terms of the reciprocal absorbance.

The values for the maxima obtained by using the reciprocal absorbances are given in the "$1/y$" columns of Table II, and they show no significant differences from those computed directly. From this it is to be inferred that the perturbations from the Lorentz band profiles in the neighborhood of the maxima are sufficiently large to require significant third- and fourth-order terms in the graduating function of the reciprocal curve.

THE COMPUTER PROGRAM

In handling a problem of this kind with a desk calculator, it is convenient to choose the abscissal origin as close as possible to the band center, and to take equal numbers of points at equal abscissal intervals on either side of the origin. In this way the arithmetic is simplified as the odd powers of x vanish. For the computer program this simplification is not necessary, though it is still advantageous to choose the abscissal origin at the estimated band center. Since it is desirable to restrict the range of the graduation within one half of the half-band width on either side of the maximum, the half-band width with respect to the position of the estimated maximum must be estimated. The difference between this estimated width and the evaluated half-band width, is unlikely to significantly affect the interpolation range. Commonly the polynomials of the second, third, and fourth degree were evaluated, using, as data points, the estimated band center and two points on either side.

Our current program for the IBM 650 computer is based on one published by Spector (5) and consists of two parts. The first part inverts the [X] matrix and gives the coefficients of the graduating polynomial; control cards specify the degree of the polynomial and the number of data points. The second part, using these coefficients, evaluates (*a*) the calculated ordinates, (*b*) the differences between the experimental and calculated ordinates, (*c*) the squares of these differences, (*d*) the sums of the differences and of their squares. The last quantity provides a check on the fit of the graduation. At present the roots of the first-derivative equations are evaluated by a separate program on a Bendix computer, but it is our intention to combine these operations into a single program for the IBM 1620 computer. The technical details of this combined program will be published at a later date.

SOLVENT SHIFTS IN CARBON TETRACHLORIDE SOLUTION

In their investigations of frequency displacements in carbon tetrachloride solution, de Maine, Daly, and de Maine (1) examined several bands in the spectra of benzene, acetone, and nitromethane, as well as other compounds. The solute concentration ranges extended up to 11.25, 13.64, and 18.51 moles per liter respectively for these three substances, corresponding to the concentrations in the pure liquids at 20° C. The authors concluded from their measurements that no measurable frequency shifts were observed for any band in any solute – carbon tetrachloride pair studied, even for large changes in the electrical properties of the solutions. Since the reproducibility of their wavenumber measurements is given as "within 1 cm^{-1}" it is to be assumed that any solvent displacement in excess of 1 cm^{-1} should have been detected, and would have been regarded as significant.

Our measurements of the positions of five bands in the benzene spectrum, three in the acetone spectrum, and three in the nitromethane spectrum are reported together with other relevant information in Table III. These spectra were measured on a Perkin–Elmer 112G spectrometer, calibrated from the data in Tables 1–34 of the IUPAC calibration tables (2). Scanning speeds in the range 2–3 cm^{-1} per minute were used at chart speeds of 1 cm per minute corresponding to a chart spread of 3.3–5 mm per cm^{-1}. The calibration drift was checked by measurement of the rotational band at 3048.25 cm^{-1} in the spectrum of methane vapor, before and after each run, and did not exceed 0.005 cm^{-1} per minute. The solutes and the solvent were obtained from commercial sources and were distilled through a Todd column immediately before use; the middle 10% fraction was collected.

For the benzene band at 1036.0 cm^{-1} the measured displacement on solution in carbon tetrachloride is insignificantly small. The solvent effects on the benzene band at 1478.8 cm^{-1} and on the nitromethane band at 917.3_5 cm^{-1}, which only amount to about 1 cm^{-1}, could hardly have been detected using de Maine's technique. The nitromethane band at 656.5_5 cm^{-1} is also rather solvent insensitive, but was not accessible for measurement with the sodium chloride optics used in de Maine's experiments. The remaining bands, however, all show significantly large solvent shifts in the range 1.5–3.2 cm^{-1}.

Analysis of the 30 sets of duplicate values in Table III give a standard error of 0.31 cm^{-1} between pairs of measurements on identical bands. From this it may be concluded that the band positions can be reasonably reported to ± 0.3 cm^{-1} and that experimentally observed displacements in excess of 0.6 cm^{-1} are statistically suggestive of physical significance. The half widths of these bands vary considerably and a more precise analysis of the significance of the frequency differences between pairs of measurements should take this into consideration. It would be preferable to express the discrepancies in units of the fractional band width (j-units) instead of cm^{-1}. These considerations will be dealt with in more detail in connection with the discussion of band profiles in a later publication.

CONCLUDING REMARKS

We have to conclude that the general statement that solution in non-polar solvents has no effect on the position of the infrared band maximum is erroneous. In some cases, however, the displacement may be appreciably less than 1 cm^{-1} and will only be detected by refined methods of measurement. In other cases it can be quite large and well within the limits of measurements of simple instrumental techniques.

We do agree with de Maine and collaborators that the Kirkwood–Bauer–Magat equation, and the subsequent modifications that attempt to describe solvent shifts in terms of non-specific perturbing effects of the solvent cavity, are inadequate; the solvent–solute interaction is much more localized. Once this is conceded it is no longer possible to regard a molecule such as carbon tetrachloride as "non-polar", since it is the internal bond polarization and not the over-all dipole of the solvent molecule that is specifically involved. It is interesting in this connection to contrast the very small solvent effect of the nitromethane bands at 656.5_5 and 917.3_5 cm^{-1} with the large effect on the 1380.0 cm^{-1} band. These bands have been assigned (6) respectively to the symmetrical N—O deformation vibration, the C—N stretching vibration, and the symmetrical N—O stretching vibration. For the latter mode the motions of the oxygen atoms project more into the solvent cavity than for the two other modes where the C—N and N—O motions have more internal character. The greater solvent effect on the 1378.0 cm^{-1} band can be visualized in these terms, particularly if there exists some form of weak association between the oxygen atom of the nitromethane molecule and the chlorine atom of the solvent acting along the N—O . . . . . Cl—C bond direction.

ACKNOWLEDGMENT

We wish to thank Dr. S. D. Baxter and Mr. A. Croteau of the Mathematical Analysis Laboratory of the National Research Council for providing the computation facilities and for advice and assistance with the application of the computer program.

THE CHEMISTRY OF ALUMINUM–NITROGEN COMPOUNDS

II. REACTIONS OF TETRAMETHYLTETRAZENE WITH ALUMINUM HYDRIDE AND TRIALKYLALUMINUM COMPLEXES

NEIL R. FETTER AND BODO BARTOCHA*

The Chemistry Division, U.S. Naval Ordnance Laboratory, Corona, Calif., U.S.A.

ABSTRACT

The reaction of tetramethyltetrazene with $Me_3Al{:}NMe_3$, Et_3Al, and $H_3Al{:}NMe_3$ has led to a new method for the preparation of $(Me_2Al{-}NMe_2)_2$, $(Et_2Al{-}NMe_2)_2$, and $H_2Al{-}NMe_2$, respectively. The reaction of tetramethyltetrazene with Me_3Al has produced $Al(NMe_2)_3$, $MeAl(NMe_2)_2$, and $Me_2Al{-}NMe_2$, and with $Et_3Al{:}NMe_3$ has produced $Et_3Al{:}Me_2NN{=}NNMe_2$, $Et_2Al{-}NMe_2$, and the polymer $(-AlEtNEt-)_n$. In all but one case, the complexes are formed by the interaction of a dimethylamine radical, which results from the cleavage of $Me_2NN{=}NNMe_2$, with the aluminum moiety and the subsequent elimination of an alkane or hydrogen.

INTRODUCTION

Recently (1) we reported the reactions of several methylhydrazines with trimethylaluminum. As a continuation of this preparative survey on compounds with covalent aluminum–nitrogen bonds, we have found an interesting cleavage of tetramethyltetrazene (hereafter abbreviated as TMT) during its reaction with aluminum hydride trimethylamine, aluminum alkyls, and trialkylaluminum trimethylamine complexes.

The tetra-substituted tetrazenes exhibit thermal instability when heated in inert solvents, and they decompose to form tetra-substituted hydrazines and nitrogen (2):

$$R_2NN{=}NNR_2 \xrightarrow{\Delta} R_2N{-}NR_2 + N_2.$$

However, when TMT is treated with aluminum hydride trimethylamine, the dimethylamino groups do not combine, but react, with the aluminum–hydrogen bond to form $H_2Al{-}NMe_2$ plus hydrogen, nitrogen, and trimethylamine:

$$Me_2NN{=}NNMe_2 + 2H_3Al{:}NMe_3 \rightarrow 2H_2Al{-}NMe_2 + 2NMe_3 + N_2 + H_2.$$

The reactions of TMT with trimethylaluminum and triethylaluminum proceed in a similar manner. However, in several cases more than one alkyl group on aluminum was replaced by a dimethylamino group; thus, in the reaction of Me_3Al with TMT, we obtained $(Me_2Al{-}NMe_2)_2$, $MeAl(NMe_2)_2$, and $Al(NMe_2)_3$.

EXPERIMENTAL

Apparatus and Starting Materials

All the work described here was carried out with the aid of a conventional high-vacuum system. Infrared spectra were taken employing a Model IR-5 Beckman infrared spectrophotometer with sodium chloride optics. The spectra of gases were taken in a 10-cm cell equipped with NaCl windows, and the spectra of liquids were taken in a NaCl cell with a 0.001-inch lead spacer. Molecular weights were determined cryoscopically in an all-glass apparatus† which could be filled in an inert atmosphere chamber.‡ The solvent used was Fisher certified reagent grade cyclohexane.

Tetramethyltetrazene was supplied by the Chemistry Division, U.S. Naval Ordnance Test Station, China Lake, Calif. It was vacuum distilled from CaH_2 before use.

**Present address: U.S. Naval Propellant Plant, Indian Head, Maryland, U.S.A.*
†Bender & Hobein, G.m.b.H., Munich, Germany.
‡Model HE43/HE73, D. L. Herring Co., Inc., Sherman Oaks, Calif., U.S.A.

The trimethylaluminum was purchased from the Ethyl Corp., Baton Rouge, La., and the triethylaluminum, from Texas Alkyls, Inc., Houston, Texas. Both materials were used without further purification. The trimethylaluminum trimethylamine was prepared by a procedure described by Brown and Davidson (3). The compound was purified by vacuum sublimation at 60° C. Triethylaluminum trimethylamine was synthesized in this laboratory (4) and was used without further purification. The aluminum hydride trimethylamine was prepared by a procedure described first by Wiberg (5) and later improved and simplified in this laboratory (4).

The solvents used were reagent grade, and no further purification was required.

Analysis

The compounds obtained were analyzed by hydrolysis, and evolved gases were measured in the vacuum system by fractionating the mixtures through a series of traps into a calibrated volume and removing the non-condensable material with a Toepler pump. Elemental analyses were performed by the Schwarzkopf Microanalytical Laboratory, Woodside, New York.

Reaction of Tetramethyltetrazene with Aluminum Hydride Trimethylamine

By vacuum distillation, 2.40 g (0.0207 mole) of TMT was added to 1.95 g (0.0219 mole) of $H_3Al{:}NMe_3$. The mixture was allowed to warm from −196° C to room temperature and was then maintained at 65° C for 6 hours. During the reaction, 404.5 ml (STP) of a mixture of hydrogen and nitrogen (average molecular weight = 19.1) and 370.0 ml (0.0165 mole) of trimethylamine were evolved. The evolution of trimethylamine did not occur until heating at 65° C began.

The crude product was pumped at room temperature for 1 hour to remove any unreacted TMT. During this period the material changed from a liquid to a crystalline solid, which was then vacuum sublimed at 60° C (0.005 mm Hg) onto a −15° C cold finger. The yield of sublimate (m.p. 89–91° C) was approximately 90 mole%, based on the initial quantity of $H_3Al{:}NMe_3$. Anal. Calc. for C_2H_8NAl: C, 32.87; H, 11.03; N, 19.17; Al, 36.92. Found: C, 32.08; H, 10.72; N, 19.32; Al, 37.37. The melting point and the analytical data agree very well with those reported by Ruff and Hawthorne (6) for $H_2Al{-}NMe_2$ (89–90° C). As a confirmation, $H_2Al{:}NMe_2$ was prepared by the reaction

$$LiAlH_4 + Me_2HN{:}HCl \rightarrow H_2Al{-}NMe_2 + LiCl + 2H_2,$$

and a mixed melting point (90.0–93.0° C) was taken. The infrared spectra were also identical. The equation for the reaction of TMT with $H_3Al{:}NMe_3$ may then be written:

$$2H_3Al{:}NMe_3 + Me_2NN{=}NNMe_2 \rightarrow 2H_2Al{-}NMe_2 + N_2 + H_2 + 2NMe_3.$$

Reaction of Tetramethyltetrazene with Trimethylaluminum Trimethylamine

The TMT (1.54 g, 0.0133 mole) was distilled onto 1.78 g (0.0136 mole) of $Me_3Al{:}NMe_3$ at −196° C. The mixture was allowed to warm to room temperature and was then heated at 90° C for 10 hours. During the heating, the water-clear solution turned a deep red and 301.0 ml (0.0135 mole) of nitrogen, 57.1 ml (0.00255 mole) of methane, and 227.0 ml (0.0101 mole) of trimethylamine were evolved. The red solution was sublimed at 75° C (0.005 mm Hg) onto a −78° C cold finger. The deposit was a light yellow slush. This material was resublimed at room temperature onto a −15° C cold finger, and a white crystalline solid (m.p. 147–149° C) deposited. Resublimed again, the compound had a melting point of 151–153° C, which agrees quite well with that reported for $(Me_2Al{-}NMe_2)_2$ by Brown and Davidson (3) (m.p. 154–156° C). This conclusion was confirmed by elemental analysis and molecular weight determinations: Anal. Calc. for $C_4H_{12}NAl$: C, 47.50; H, 11.97; Al, 26.68. Found: C, 46.72; H, 11.59; Al, 25.79. Calc. for $(Me_2Al{-}NMe_2)_2$: molecular weight, 202.2. Found: molecular weight, 203.0 and 208.0. The reaction therefore proceeded as follows:

$$2Me_3Al{:}NMe_3 + Me_2NN{=}NNMe_2 \rightarrow (Me_2Al{-}NMe_2)_2 + N_2 + 2NMe_3 + 2CH_4.$$

The source of the hydrogen atoms, necessary for the formation of methane, is not known.

The yield of sublimed $(Me_2Al{-}NMe_2)_2$ was approximately 50 mole%, based on the quantity of $Me_3Al{:}NMe_3$.

Reaction of Tetramethyltetrazene with Trimethylaluminum

The TMT (2.82 g, 0.00243 mole) was vacuum distilled onto 1.60 g (0.0222 mole) of Me_3Al dissolved in 25 ml of pentane. The mixture was allowed to warm from −196° C to room temperature and then to remain at ambient temperature for 18 hours. At the end of this period the solution had a faint red color. The pentane and any excess TMT were removed by pumping, and the resulting colored liquid was sublimed at 55° C (0.005 mm Hg) onto a −15° C cold finger. A slushy deposit of white crystals formed on the cold finger, and the liquid in the bottom of the sublimation vessel turned a deep red color.

The solid material was heated in vacuum at 85° C for 1 hour. The mixture turned deep red, but no further gas evolution was observed. This mixture was sublimed at 50° C (0.005 mm Hg) onto a −15° C cold finger, and white crystals (m.p. 150.0–153.0° C) deposited on the cold finger. The melting point indicated that the sublimate was $(Me_2Al{-}NMe_2)_2$ and an elemental analysis confirmed this: Anal. Calc. for $C_4H_{12}NAl$: C, 47.50; H, 11.97; N, 13.85; Al, 26.68. Found: C, 46.94; H, 12.03; N, 13.55; Al, 26.73.

The red liquid from the sublimation vessel was vacuum distilled at 40° C (0.005 mm Hg), and approximately 1 ml of clear liquid was obtained. About 1 ml of deep red gum was left behind in the flask.

The clear distillate (m.p. −30° C) will slowly turn red in about 8 hours if heated to 50° C and will convert almost completely into the dark red gum in about 1 hour at 90° C. In fact, there is evidence that the clear liquid will change color very slowly at room temperature; hence, isolation has been difficult. However, elemental analysis gave results that agree with the empirical formula $C_6H_{18}N_3Al$: Anal. Calc.: C, 45.26; H, 11.39; N, 26.39; Al, 16.95. Found: C, 45.35; H, 11.50; N, 26.40; Al, 16.98. From these data, we propose the formula $Al(NMe_2)_3$ for this complex. Two molecular weight determinations showed the compound to be associated in cyclohexane: Calc. for $Al(NMe_2)_3$: 159.1. Found: 199 and 193.

Characterization of the red tar has been difficult because of purification problems. However, an elemental analysis of this material agrees with the empirical formula $C_5H_{15}N_2Al$. Anal. Calc. for $C_5H_{15}N_2Al$: C, 46.13; H, 11.62; N, 21.52; Al, 20.72. Found: C, 47.90; H, 10.88; N, 20.40; Al, 21.01.

A methanol hydrolysis of 0.1478 g (0.00114 mole) of the red fluid yielded 35.9 ml (0.00160 mole) of methane; hence we assigned the formula $MeAl(NMe_2)_2$ to this material.

The yields of $Me_2Al—NMe_2$ and $Al(NMe_2)_3$ were approximately 30 mole%, based on Me_3Al, and the remainder was the red residue.

The equation for the reaction is somewhat complex, but it appears that at least two routes are possible:

$$2Me_2Al + Me_2NN{=}NNMe_2 \rightarrow (Me_2Al{-}NMe_2)_2 + N_2 + 2CH_4 \quad [1]$$

$$2Me_3Al + 3Me_2NN{=}NNMe_2 \rightarrow 2Al(NMe_2)_3 + 3N_2 + 6CH_4 \quad [2]$$

$$\downarrow \Delta$$

red tar $(MeAl(NMe_2)_2)$

In another reaction, using 1.50 g of Me_3Al (0.0209 mole) and 1.20 g (0.0103 mole) of TMT, at room temperature, 325 ml (0.0145 mole) of nitrogen, but only 85.6 ml (0.00383 mole) of methane, were recovered.

Reaction of Tetramethyltetrazene with Triethylaluminum Trimethylamine

In the reactions discussed so far, the cleavage of TMT into nitrogen and $\cdot NMe_2$ radicals has occurred before products could be isolated. In this reaction, a complex has been isolated which appears to contain an uncleaved TMT molecule.

The TMT (0.982 g, 0.00845 mole) was distilled into 1.054 g (0.00646 mole) of $Et_3Al{:}NMe_3$ at −196° C. The mixture was allowed to warm to room temperature, and it was then heated and maintained at 60° C for 20 hours. During the heating period, 68.5 ml (0.00306 mole) of NMe_3 was evolved, but examination by infrared and mass spectrometry indicated that no ethane was present. The mixture was pumped at room temperature for 1 hour to remove any excess TMT and was then purified by vacuum transfer at 60–65° C (0.005 mm Hg). Approximately 0.5 ml of a clear liquid was obtained. Elemental analysis gave values which agreed with the empirical formula $C_{10}H_{27}N_4Al$: Anal. Calc. for $C_{10}H_{27}N_4Al$: C, 52.14; H, 11.82; N, 24.33; Al, 11.71. Found: C, 50.87; H, 12.01; N, 25.44; Al, 10.52. From these data we propose the formula $Et_3Al{:}Me_2NN{=}NNMe_2$ for the distillate.

Hydrolysis of 0.4416 g (0.00192 mole) of the above product with methanol produced 125.2 ml (0.00560 mole) of ethane. The molar ratio of ethane to $Et_3Al{:}Me_2NN{=}NNMe_2$ is 2.91, close to the calculated value of 3:1. The reaction may thus be written:

$$Et_3Al{:}NMe_3 + Me_2NN{=}NNMe_2 \xrightarrow{60^\circ\ C} Et_3Al{:}Me_2NN{=}NNMe_2 + NMe_3.$$

In another experiment, 0.586 g (0.00505 mole) of TMT was distilled onto 1.509 g (0.00919 mole) of $Et_3Al{:}NMe_3$ and was then heated at 85° C for 6 hours. A crack in the vacuum system prevented measurement of the evolved gases, but the crude product was recovered. It was purified by vacuum transfer at 65° C (0.005 mm Hg), and approximately 1 ml of clear liquid and a viscous orange residue were obtained. Elemental analysis of the liquid gave results which agree with the calculated empirical formula $C_6H_{16}NAl$: Anal. Calc. for $C_6H_{16}NAl$: C, 55.79; H, 12.49; N, 10.84; Al, 20.88. Found: C, 55.08; H, 12.53; N, 14.02; Al, 18.57.

Hydrolysis of 0.4050 g (0.00281 mole) of the distilled product with methanol gave 95.0 ml (0.00423 mole) of ethane. This corresponds to a ratio of 1:1.51 of compound to ethane. The infrared spectrum agreed closely with that obtained from $Et_2Al—NMe_2$ prepared from the reaction of Et_3Al and $HNMe_2$ (7). Based on these data, the formula $Et_2Al—NMe_2$ has been assigned to the complex.

Although the orange residue obtained above could not be distilled or otherwise purified, an elemental analysis gave results which agree with the empirical formula $C_4H_{10}NAl$: Anal. Calc. for $C_4H_{10}NAl$: C, 48.47; H, 10.17; N, 14.13; Al, 27.22. Found: C, 48.20; H, 10.99; N, 14.00; Al, 26.26.

This material is very viscous and appears to be polymeric; hence, we have assigned it the formula

$$\left[\begin{array}{c} Et \quad Et \\ | \quad | \\ -Al-N- \end{array}\right]_n.$$

In order that the evolved gases could be characterized and measured, the experiment was repeated, and 1.283 g (0.00743 mole) of $Et_3Al{:}NMe_3$ was reacted with 2.024 g (0.0174 mole) of TMT under the second set of conditions described above. From the mixture, 74.0 ml (0.00330 mole) of nitrogen, 201.0 ml (0.00895 mole) of trimethylamine, and a trace of TMT were recovered. No ethane or ethylene were detected in the infrared spectra of these gases.

Two molecular weight determinations of $Et_2Al{-}NMe_2$ in cyclohexane gave the values 241 and 235 (calc.: 288.3 for $(Et_2Al{-}NMe_2)_2$).

The reaction of TMT with $Et_3Al{:}NMe_3$ at 60° C appears to involve the formation of a complex in which TMT is exchanged with NMe_3; however, when the reaction is run at 80–85° C, the TMT cleaves:

$$2Et_3Al{:}NMe_3 + Me_2NN{=}NNMe_2 \xrightarrow{80^\circ\ C} Et_2Al{-}NMe_2 + 2NMe_3 + N_2 + C_2H_6(?).$$

Under these reaction conditions $Et_2Al{-}NMe_2$ also appears to lose two methyl groups to form the polymeric material:

$$n Et_2Al{-}NMe_2 \xrightarrow{80^\circ\ C} [{-}AlEtNEt{-}]_n + nC_2H_6.$$

The yields of the two complexes discussed above were approximately 50 mole% (based on $Et_3Al{:}NMe_3$), and the remainder in the second experiment was polymeric material.

Reaction of Tetramethyltetrazene with Triethylaluminum

With 25 ml of pentane as a solvent, 1.952 g (0.0168 mole) of TMT was vacuum distilled onto 1.945 g (0.0170 mole) of Et_3Al at −196° C. The mixture was warmed to room temperature and then heated at 55° C for 18 hours. The pentane was removed in vacuum, and the remaining brown fluid was purified by vacuum transfer at 90° C (0.005 mm Hg) (b.p. from reference 7 66° C at 0.15 mm Hg). A yield of approximately 75%, based on Et_3Al, was obtained. The experiment was repeated in nonane so that the condensable gases could be recovered more easily. Under the conditions described above, 1.422 g (0.0123 mole) of TMT was reacted with 2.330 g (0.0204 mole) of Et_3Al. From the reaction were recovered 252 ml (0.0112 mole) of nitrogen and 82.5 ml of a condensable (−196° C) gas which was estimated, by infrared analysis, to be a mixture consisting of 90% ethane and 10% ethylene. No trimethylamine or dimethylamine was observed.

Elemental analysis of the distillate gave values which agree with those calculated for $Et_2Al{-}NMe_2$: Anal. Calc. for $C_6H_{16}NAl$: C, 55.79; H, 12.49; N, 10.84; Al, 20.88. Found: C, 56.64; H, 12.73; N, 11.64; Al, 20.76. Methanol hydrolysis of 0.2872 g of the distillate (0.00222 mole $Et_2Al{-}NMe_2$) produced 83.4 ml (0.00372 mole) of ethane.

Although $Et_2Al{-}NMe_2$ is a liquid at room temperature, molecular weight data indicate that the complex is a dimer. Two determinations gave the values 285 and 283 (calc. for $(Et_2Al{-}NMe_2)_2$: 288.4).

The infrared spectrum of the complex was compared with that of a sample of $Et_2Al{-}NMe_2$ prepared (7) from the reaction of Et_3Al with $NHMe_2$ and found to be identical.

From these data, the equation for the reaction of Et_3Al and TMT is

$$2Et_3Al + Me_2NN{=}NNMe_2 \rightarrow (Et_2Al{-}NMe_2)_2 + N_2 + 2C_2H_6 + (C_2H_4).$$

No other products were isolated, and there appear to be no side reactions as is the case with $Et_3Al{:}NMe_3$ and TMT.

DISCUSSION

The reaction between $H_3Al{:}NMe_3$ and TMT appears to be straightforward, with the formation of $H_2Al{-}NMe_2$, H_2, N_2, and NMe_3.

However, the reaction between Me_3Al and TMT is more complex. If the latter reaction proceeded in the manner of the former, ethane and not methane should have been observed. The source of the hydrogen atom required to form methane must await further study of the mechanism of this reaction.

The referee of this paper proposed a reaction scheme which would eliminate the problem of the hydrogen atom in methane formation. The reaction would proceed as follows:

$$R_3Al + Me_2N{-}N{=}N{-}NMe_2 \rightarrow R_3Al{:}Me_2N{-}N{=}N{-}NMe_2 \quad [1]$$

$$R_3Al{:}Me_2N{-}N{=}N{-}NMe_2 \rightarrow R_2Al{-}NMe_2 + R{-}N{=}N{-}NMe_2 \quad [2]$$

$$R{-}N{=}N{-}NMe_2 + R_3Al \rightarrow R_2Al{-}NMe_2 + R{-}N{=}N{-}R, \quad [3]$$

where R = Me or Et.

An examination of the infrared spectra of the condensable gas from the reactions of this type showed, for the reaction of $Me_3Al{:}NMe_3$ with TMT, a strong absorption at 2100 cm^{-1} plus a weaker one at 2400 cm^{-1}. These peaks have been shown by Pierson, Fletcher, and Gantz (11) to be characteristic of diazomethane, but not azomethane; hence, a fourth reaction,

$$MeN{=}NMe \rightarrow CH_4 + CH_2N_2, \qquad [4]$$

must be added to the three written above. This mode of decomposition of azomethane does not follow the classical route at high temperature to ethane and nitrogen (12), but is necessary to account for the diazomethane and methane observed in the reaction gases.

An absorption at 2100 cm^{-1} is also present in the condensables from the reaction of Me_3Al with TMT, but it is much weaker than that observed for $Me_3Al{:}NMe_3$.

The infrared spectra of condensables from the reactions Et_3Al and $Et_3Al{:}NMe_3$ with TMT also have weak absorptions in the 2100 cm^{-1} region; hence, this mechanism appears to apply to all of the reactions involving the aluminum alkyls.

Another striking feature of the reaction of Me_3Al with TMT is the formation of a compound to which we have given the formula $Al(NMe_2)_3$. A complex of this composition was first reported by Wiberg and May (8), who prepared it by the reaction of aluminum hydride etherate and dimethylamine:

$$H_3Al.n\mathrm{Et_2O} + 3HNMe_2 \rightarrow Al(NMe_2)_3 + 3H_2 + n\mathrm{Et_2O}.$$

This compound has also been reported recently by Ruff (9) and by Longi, Mazzanti, and Bernardini (10). The former author employed two methods of preparation, namely:

$$H_3Al{:}NMe_3 + 3HNMe_2 \rightarrow Al(NMe_2)_3 + NMe_3 + 3H_2 \qquad [1]$$

$$LiAlH_4 + 4HNMe_2 \rightarrow LiAl(NMe_2)_4 + 4H_2 \qquad [2]$$

$$3LiAl(NMe_2)_4 + AlCl_3 \rightarrow 4Al(NMe_2)_3 + 3LiCl.$$

The latter authors employed the reaction of triisobutyl aluminum with dimethylamine at high temperature:

$$(i\text{-Bu})_3Al + 3HNMe_2 \xrightarrow[\text{heptane}]{195^\circ\,C} Al(NMe_2)_3 + 3i\text{-}C_4H_9.$$

They indicate that the product is a solid but do not report a melting point. The physical constants of the complex (Table I) we have prepared differ markedly from those described previously.

TABLE I

Physical constants of $Al(NMe_2)_3$

	M.p. (° C)	Mol. wt. (calc.: 159.1)
Authors	−30	199, 193* cryoscopically
Wiberg (8)	87–88	162† ebullioscopically
Ruff (9)	87–89	353‡ cryoscopically
Longi *et al.* (10)	Not reported	320‡ cryoscopically

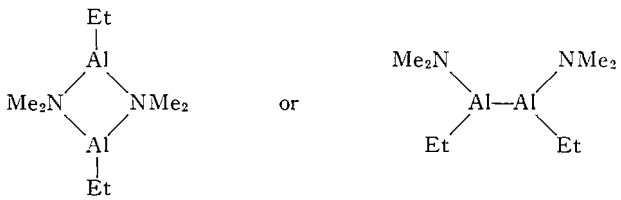
*In cyclohexane.
†In ether.
‡In benzene.

We have repeated the preparation of this complex, and the elemental analysis and other physical properties have been confirmed. It is hoped that instrumental studies being carried out in this laboratory will reveal the structure of this complex.

Finally, it should be noted that the data presented above indicate that it is possible to obtain from this reaction a complete series of dimethylamino substitutions on trimethylaluminum, namely $Me_2Al{-}NMe_2$, $MeAl(NMe_2)_2$, and $Al(NMe_2)_3$. However, there

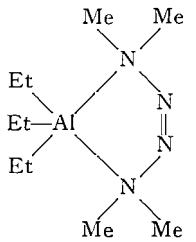
appears to be a discrepancy in the reaction sequence. Although one would assume that $Al(NMe_2)_3$ would be the most stable complex, heating the liquid $Al(NMe_2)_3$ produces the red fluid which analysis has established as $MeAl(NMe_2)_2$. Hence, this complex and $Me_2Al—NMe_2$ seem to be the most stable materials of this series.

Whether the complex $Et_3Al{:}NMe_2NN{=}NNMe_2$ is the precursor to $(Et_2Al—NMe_2)_2$ is not known, but it does appear that $(Et_2Al—NMe_2)_2$ undergoes an unusual rearrangement in which an ethyl group migrates to the nitrogen atom and two methyl groups are eliminated, presumably to form ethane. It should also be noted that the formula $(—AlEtNMe_2)$ also fits the elemental analysis to which the formula $(—AlEtNEt—)_n$ was assigned. The first formula above would require a structure of the type



to satisfy the valency of aluminum. In our experience, compounds of this type are rare, if non-existent; hence, for this reason and because of the polymeric character, we have chosen the latter formula.

The structure of $Et_3Al{:}Me_2NN{=}NNMe_2$ may be one of unusual character involving a cyclic ring with a pentavalent aluminum atom:



ACKNOWLEDGMENTS

The authors wish to thank Dr. Charles P. Haber and Dr. Frederick E. Brinckman, Jr. of the U.S. Naval Ordnance Laboratory, Corona, California, and Dr. William R. McBride of the U.S. Naval Test Station, China Lake, California, for their assistance and interest during the course of this work. This investigation was supported by funds from the Advanced Research Projects Agency through the U.S. Navy Department, Bureau of Naval Weapons.

THE STRUCTURAL ANALYSIS OF SOME ACIDIC XYLANS BY PERIODATE OXIDATION

G. G. S. DUTTON AND A. M. UNRAU
The Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received September 18, 1961

ABSTRACT

By determining the amount of formaldehyde produced on periodate oxidation of borohydride-reduced apple- and cherry-wood xylans the degree of polymerization was shown to be 155 and 100 respectively. Acid hydrolysis of the polyols obtained by periodate oxidation and borohydride reduction gave ethylene glycol in amounts indicating that these xylans have a small degree of branching. Mild acid hydrolysis of the polyols demonstrated that in these xylans D-glucuronic acid as well as 4-*O*-methyl-D-glucuronic acid was present and that some of the former occupied non-terminal positions.

The constitution of numerous hemicelluloses has been investigated by graded hydrolysis and characterization of the products and also by methylation followed by identification of the methylated monosaccharides produced on hydrolysis. These methods and the results obtained have been extensively reviewed (e.g. refs. 1, 2).

Recently a modified periodate degradative procedure has been described based on the mild acid hydrolysis of the polyalcohol obtained after borohydride reduction (2, 3). The conditions of hydrolysis are such that true acetal systems are cleaved whereas glycosidic bonds are stable. This method holds great promise as a convenient means of examining the fine structure of polysaccharides. It has so far been applied to oat glucan (3), brome grass hemicellulose (4), and oat hull hemicellulose (5). The present paper reports the application of this method to the 4-*O*-methyl-D-glucurono-xylans obtained from apple and cherry wood.

These two hemicelluloses have previously been examined by the methylation technique and were assumed to have essentially linear structures of D-xylose units joined by $\beta(1 \rightarrow 4)$ linkages. Each polysaccharide carried branches of 4-*O*-methyl-D-glucuronic acid with a xylose:acid ratio of about 6:1. From the quantity of 2,3,4-tri-*O*-methyl-D-xylose found, the chain length was estimated to be 120 for the applewood xylan (6) and 110 for the cherrywood xylan (7).

When the degree of polymerization (D.P.) of these polysaccharides was determined by measuring the formaldehyde produced upon periodate oxidation of the borohydride-reduced xylans (8) a value of 155 was obtained for the applewood xylan and 100 for the cherrywood xylan. These values are based on the assumption that the reducing end-group was not substituted at position 2. Complete acid hydrolysis of the polyalcohol obtained after reduction ($NaBH_4$) of the polyaldehyde from the applewood xylan gave ethylene glycol (1 mole, from terminal, non-reducing xylopyranose units), glycerol (40 moles, from internal $1 \rightarrow 4$-linked xylopyranose units), and xylose (7 moles, from xylose residues substituted at $C_{2\ (3)}$ and C_4, hence immune to periodate attack). The quantity of ethylene glycol found indicated that the xylan possessed a repeating unit consisting of about 50 sugar residues, which suggested that the xylan possessed two branch points other than those caused by the direct attachment of a single uronic acid residue to the main chain.

When the cherrywood xylan was subjected to the same sequence of reactions the ratio of ethylene glycol:glycerol:xylose was 1:42:10. These results suggested that this xylan had one such branch point.

Mild acid hydrolysis (3) of the polyalcohols derived from each xylan followed by adsorption of the acidic fragments of an anion exchange resin left a neutral residue which was composed of ethylene glycol, glycerol, and a non-reducing xyloside identified as 2′-*O*-glyceryl-β-D-xylopyranoside. The three compounds were converted to their crystalline *p*-nitrobenzoates. The xyloside was further characterized by periodate oxidation, reduction ($NaBH_4$), and hydrolysis, which gave a 1:1 ratio of ethylene glycol:glycerol, each characterized as their *p*-nitrobenzoates. The glycoside, 2′-*O*-glyceryl-β-D-xylopyranoside, mainly originated, as anticipated, from the xylose units substituted at $C_{2\ (3)}$ by uronic acid. This glycoside has been prepared previously by Perlin and his associates (9).

The acidic material adsorbed on an anion exchange resin was eluted with alkali, and the free acids were regenerated by passage through a cation resin. Evaporation of the eluate gave an acidic residue, chromatographically free of glycerol, which was subjected to heat under vacuum to effect lactonization. Reduction ($NaBH_4$) of the product (10) and chromatographic examination of the final residue in each case revealed three compounds, two in minor quantities corresponding to glycerol and erythritol and the major component corresponding to a synthetic sample of 2-*O*-methyl-D-erythritol. The molar ratio of erythritol:glycerol:2-*O*-methyl-D-erythritol was about 1:2.2:12 for the apple xylan and 1:1.6:9 for the cherry xylan. The three polyols were converted to their crystalline *p*-nitrobenzoates. The 2-*O*-methyl-D-erythritol arose, as expected, from periodate cleavage of the 4-*O*-methyl-D-glucuronic acid residues. Glycerol possibly arose from D-glucuronic acid residues while erythritol could only arise in this analysis sequence from a D-glucuronic acid residue substituted at C_4 with a residue other than methoxyl, presumably a xylopyranose unit. This structural feature would thus explain the formation of greater amounts of ethylene glycol than anticipated on the basis of the D.P. determinations, had the structures been strictly linear. Approximately equimolar quantities of acids and 2′-*O*-glyceryl-β-D-xyloside were obtained from both xylans. From the ratio of xylose to glycerol it may be deduced that in the apple xylan there is 1 uronic acid per 7 xylose units and that with the cherry xylan the ratio is 1:5.

These results show that both xylans possess similar structures and they largely confirm the earlier findings from the methylation studies (6, 7). The present periodate investigation has, however, revealed several points which were not observed in the earlier work (6, 7). When only small amounts of monomethyl pentoses are obtained in methylation studies it is difficult to ascertain whether these are of constitutional significance or are formed by demethylation. The isolation of ethylene glycol by periodate oxidation, reduction, and hydrolysis appears to be less subject to such uncertainties and indicates that these two xylans have a slightly branched structure.

From the analysis of the acidic fraction after periodate oxidation, reduction, and hydrolysis it is apparent that about 20% of the acid portion of the apple xylan is D-glucuronic acid, rather than its 4-*O*-methyl ether, and that of this about 30% (or 6% of the total acid) occupies non-terminal positions. In the case of the cherry xylan about 22% of the acid is D-glucuronic acid and of this 40% (or 8% of the total acid) occupies non-terminal positions.

In the earlier studies on these xylans chromatographic examination of the aldobiouronic acid fraction, produced on hydrolysis of the polysaccharides, showed in each case a component having an R_{xylose} 0.7. This component only showed faintly on the chromatograms and was assumed to be present in trivial amounts. The present work shows that this assumption was in error and that an unmethylated aldobiouronic acid is a significant

percentage of the acid component. This error in interpretation may well account for our inability to crystallize the methyl 2-*O*-(2,3,4-tri-*O*-methyl-D-glucosyl)-3-*O*-methyl-D-xylopyranoside obtained by reduction of the partly methylated acid fraction (6, 7).

It is thus apparent that the technique introduced by Smith (3) is a powerful tool in the elucidation of the structure of polysaccharides.

EXPERIMENTAL

Chromatographic studies were conducted by the descending technique using Whatman No. 1 filter paper. The solvent systems used were (*a*) 1-butanol:pyridine:water (6:4:3); (*b*) 1-butanol:ethanol:water (4:1:5) (upper phase); and (*c*) butanone–water azeotrope. Non-reducing sugar alcohols were detected with ammoniacal silver nitrate while reducing sugars were detected with *p*-anisidine trichloracetate spray. Whatman No. 3 MM paper was used for preparative separation of compounds.

The melting points reported are uncorrected and the specific rotations quoted are equilibrium values. Unless otherwise stated, all evaporations were carried out under reduced pressure at a bath temperature of 40° C.

Determination of D.P.

The D.P. of applewood xylan, using 62 mg of material, was estimated by a chemical procedure described elsewhere (8). After 72 hours of contact with periodate, the formaldehyde production from the reduced xylitol end-residues became constant. On the basis that 1 mole of formaldehyde was produced from each xylan molecule, the 0.084 mg CH_2O released corresponded to a D.P. of about 155. Similarly, 34.8 mg of cherrywood xylan yielded 0.074 mg CH_2O corresponding to a D.P. of about 100.

A. Applewood Xylan

Periodate Oxidation

Xylan (2.964 g) was dissolved in dilute alkali after which the solution was made slightly acidic and the volume adjusted to 200 ml, and after cooling to 5° C, 0.5 *M* periodic acid was added (50 ml). After 72 hours, 0.878 mole of periodate had been consumed per sugar residue and no change was observed thereafter. To the solution was added $BaCO_3$ to precipitate periodate and iodate, and to the clear filtrate was added $NaBH_4$ (945 mg) and the solution left overnight. The solution was neutralized, evaporated, and borate removed from the polyol by several treatments with methanolic hydrogen chloride.

Partial Hydrolysis of Polyol

The polyol was dissolved in 0.2 *M* hydrochloric acid and left at room temperature for 10 hours. The solution was passed through cation and anion exchange resins in that order and the neutral effluent evaporated to a syrup (1.795 g). Chromatographic examination of the syrup revealed the presence of glycerol, a slow-moving, non-reducing component believed to be a xylosyl glycerol, and a small amount of ethylene glycol. Part of the mixture was resolved using sheets of Whatman No. 3 MM paper and solvent C.

Component No. 1, ethylene glycol, 24 mg by weight, 20.2 mg (0.326 mmole) by chromotropic acid determination. The di-*p*-nitrobenzoate prepared in the usual manner had m.p. and mixed m.p. 139–141° C.

Component No. 2, glycerol, 995 mg by weight, 988 mg (10.7 mmoles) by chromotropic acid determination. An aliquot was treated with *p*-nitrobenzoyl chloride to give the tri-*p*-nitrobenzoate, m.p. and mixed m.p. 188–190° C.

Component No. 3, 2′-*O*-glyceryl-β-D-xylopyranoside, 530 mg by weight, 532 mg (2.38 mmoles) by the phenol – sulphuric acid (11) analysis. The compound in water had $[\alpha]_D^{22}$ −33° (*c*, 4.0), R_{xylose} in solvent *c* of 0.80, R_g was 1.45. Hydrolysis in 1 *N* H_2SO_4 of an aliquot (120 mg) of the compound gave glycerol and xylose in equimolar proportions. *Glycerol*, 43.2 mg (0.47 mmole), was converted to the tri-*p*-nitrobenzoate, m.p. and mixed m.p. 188–190° C. D-*Xylose*, 74.1 mg (0.49 mmole), $[\alpha]_D^{22}$ +18.1° in water (*c*, 1.5). The sugar crystallized from a mixture of acetonitrile, methanol, and petroleum ether, m.p. and mixed m.p. 143–145° C.

The glycoside was further characterized as follows:

(*a*) Preparation of *p*-nitrobenzoate: To the compound (40 mg) dissolved in pyridine (2 ml) was added a 10% molar excess of *p*-nitrobenzoyl chloride, and the solution was heated at 70° C for 40 minutes. After isolation and recrystallization from a petroleum ether – ethyl acetate mixture the penta-*p*-nitrobenzoate had m.p. 101–102° C, $[\alpha]_D^{22}$ −37.1° in ethyl acetate (*c*, 0.47). Calc. for $C_{43}H_{31}O_{22}N_5$: N, 7.23%. Found: N, 7.15%.

(*b*) Periodate oxidation: An aliquot (140 mg, 0.62 mmole) was treated with a 15% molar excess sodium periodate at 5° C. After 14, 24, and 48 hours, between 2.16 to 2.18 moles of periodate had been consumed per mole of compound, the theoretical value being 2.00 moles. The amount of formic acid produced was 0.66 milliequivalent, expected was 0.62 milliequivalent. No formaldehyde was formed. The dialdehyde (120 mg), $[\alpha]_D^{22}$ +11.3°, was reduced ($NaBH_4$); the product, freed from borate, had $[\alpha]_D^{22}$ −16.8° in methanol. The compound was cleaved with 1 *N* sulphuric acid on a steam bath for 10 hours to yield ethylene glycol and glycerol in equimolar quantities as expected. Ethylene glycol gave the corresponding di-*p*-nitrobenzoate, m.p. and mixed m.p. 138–140° C, while the tri-*p*-nitrobenzoate of glycerol had m.p. and mixed m.p. 188–190° C.

Quantitative analysis.—A portion of the syrup obtained by partial hydrolysis of the polyol was separated chromatographically using solvent *c* for 10 hours and the ratio of components 1, 2, and 3 was determined colorimetrically using a periodate – chromotropic acid procedure (8) for the alcohols and the phenol – sulphuric acid method (11) for the xyloside. To the figure for glycerol obtained by the former method was added 1 mole of glycerol for each mole of xylose found. The ratio thus obtained for ethylene glycol: glycerol (total): xylose was 1:40:7. The same ratio was obtained when the polyol (10 mg) was heated at 100° C with sulphuric acid (1 *N*, 15 ml) for 8 hours, thus hydrolyzing the glycoside. When this ratio was determined gravimetrically from the weights of the three components isolated the ratio was 1:38:6.5.

Isolation and characterization of acidic components.—The acidic material previously adsorbed onto the anion exchange resin was eluted with alkali followed by regeneration of the pure acid by passage through cation exchange resin. The acidic solution was evaporated and the residue treated several times with methanol to affect removal of HCl. The residue was transferred to a tube fitted with a cold finger packed with solid CO_2, and the material was heated at 80–90° C *in vacuo* for about 2 hours to affect lactonization. The residue was dissolved in water, $NaBH_4$ added (400 mg), and the solution left overnight. After evaporation, borate was removed as described previously and an aqueous solution of the residue deionized. The final product (285 mg) was examined chromatographically. A major component corresponding to a synthetic sample (12) of 2-*O*-methyl-D-erythritol was observed. Also present in minor quantities were compounds corresponding to glycerol and erythritol. The residue (220 mg) was resolved using Whatman No. 3 MM paper and solvent *c*. *Glycerol*, 20.2 mg (0.22 mmole), was converted to the tri-*p*-nitrobenzoate, m.p. and mixed m.p. 187–190° C. *Erythritol*, 12.0 mg (0.098 mmole) was treated with *p*-nitrobenzoyl chloride to give the tetra-*p*-nitrobenzoate, m.p. and mixed m.p. 248–250° C. *2-O-Methyl-D-erythritol*, 161.5 mg (1.19 mmoles), $[\alpha]_D^{22}$ +28° in methanol (*c*, 3.2), was converted to the tri-*p*-nitrobenzoate, m.p. and mixed m.p. 218–220° C, $[\alpha]_D^{22}$ −17.2° in pyridine (*c*, 1.5). The molar ratio of erythritol:glycerol:2-*O*-methyl-D-erythritol was 1:2.2:12. Using this ratio, the 285 mg of mixed alcohols obtained by reduction of the acidic components correspond to 2.31 mmoles and assuming that this reduction is essentially quantitative there must have been 2.31 mmoles of acidic components. This figure taken in conjunction with those previously determined gives the ratio for ethylene glycol:glycerol:xylose:acids as 1:40:7:7.

B. Cherrywood Xylan

Periodate Oxidation

A quantity (946 mg) of xylan was dissolved in alkali (about 0.2 *N* NaOH), the solution acidified with acetic acid, and the volume adjusted to 100 ml. To the cooled (5° C) solution was added 0.5 *M* periodic acid (20 ml) and the oxidation was allowed to proceed at 5° C in the dark. Periodate consumption was determined periodically, and after 4 days, 0.845 mole of periodate had been consumed per mole of sugar with no further change upon longer standing. The periodate and iodate ions were removed from the solution by precipitation ($BaCO_3$) and the solution was treated with $NaBH_4$ (1.5 g) overnight. The solution was neutralized, evaporated, and the residue treated several times with methanol containing about 1% HCl to remove borate. The residue was dissolved in 0.2 *N* hydrochloric acid, left overnight, and then passed through cation and anion exchange resin columns in that order, and the effluent evaporated.

Characterization of neutral components.—The neutral residue was chromatographed and found to contain ethylene glycol (minor amount), glycerol, and a slower-migrating, non-reducing compound believed to be a xylosyl glycerol. The components were resolved using sheets of Whatman No. 3 MM paper and solvent *c*.

Component No. 1, ethylene glycol, 4.3 mg by weight, 4.0 mg (0.064 mmole) by chromotropic acid determination, was converted to the di-*p*-nitrobenzoate, m.p. and mixed m.p. 138–140° C.

Component No. 2, glycerol, 183 mg by weight, 180 mg (1.96 mmoles) by chromotropic acid determination, was transformed to the tri-*p*-nitrobenzoate, m.p. and mixed m.p. 188–190° C.

Component No. 3, 2′-*O*-glyceryl-β-D-xylopyranoside, 140 mg (0.625 mmole), $[\alpha]_D^{22}$ −30° in water (*c*, 2.8). The compound had an R_g of 1.34 in solvent *a*, 1.45 in solvent *b*, and showed an R_{xylose} of 0.76 in solvent *c*. A portion of the glycoside was characterized as described previously and gave identical results. The compound was boiled in *N* H_2SO_4 for about 10 hours after which the observed rotation had changed to positive. Chromatography of the hydrolyzate showed the presence of xylose and glycerol in equal molar proportions. *Xylose*, 34 mg (0.23 mmole), $[\alpha]_D^{22}$ +18.2 in water (*c*, 1.3), was crystallized from hot acetonitrile after addition of a few drops of ether, m.p. and mixed m.p. 143–145° C. *Glycerol*, 21 mg (0.23 mmole), was converted to the tri-*p*-nitrobenzoate, m.p. and mixed m.p. 188–190° C.

Isolation and characterization of acidic components.—The material derived from the uronic acids and believed to be mainly 3-*O*-methyl-D-erythronic acid was eluted with alkali from the anion exchange column and the effluent passed through a column of cation exchange resin. The residue left after evaporation was transferred to a tube fitted with a cold finger packed with solid CO_2 and the contents heated for about 3 hours at 85–90° C *in vacuo* to effect lactonization. The residue was dissolved in water, $NaBH_4$ (0.3 g) was added, and the reduction mixture was left overnight. After evaporation of the solvent and removal of borate by several treatments with methanolic hydrogen chloride, chromatography of the residue (90 mg) revealed the presence of components presumed to be glycerol and erythritol in addition to the major component co-chromatographing with a sample of 2-*O*-methyl-D-erythritol prepared previously (12). The mixture was resolved using Whatman No. 3 MM paper and solvent *c* as irrigant. *Glycerol*, 9.0 mg by weight, 8.8 mg (0.096 mmole) by chromotropic acid, was converted to the corresponding tri-*p*-nitrobenzoate,

m.p. and mixed m.p. 188–190° C. *Erythritol*, 7.3 mg by weight, 7.1 mg (0.058 mmole) by chromotropic acid, was converted to the tetra-*p*-nitrobenzoate, m.p. and mixed m.p. 248–250° C. *2-O-Methyl-*D*-erythritol*, 73.5 mg by weight, 72.8 mg (0.535 mmole) by chromotropic acid, $[\alpha]_D^{22}$ +29° in methanol (*c*, 1.46), gave upon reaction with *p*-nitrobenzoyl chloride the corresponding tri-*p*-nitrobenzoate, m.p. and mixed m.p. 219–220° C, $[\alpha]_D^{22}$ −17.5° in pyridine (*c*, 1.2).

The molar ratio of alcohols derived from the acidic fraction to 2′-*O*-glyceryl-*β*-D-xylopyranoside was approximately 1:1. The molar ratio of erythritol:glycerol:2-*O*-methyl-D-erythritol was 1:1.6:9, and hence the molar ratio of ethylene glycol:glycerol (including the glycerol in the xylosyl glycerol component):xylose:acids was approximately 1:42:10:10.

ACKNOWLEDGMENTS

The continued financial support of the National Research Council is gratefully acknowledged, and we are indebted to Mrs. A. Aldridge for the nitrogen analyses.

SYNTHÈSES D'ACIDES AMINÉS CYCLIQUES À PARTIR DE DÉRIVÉS DE L'ACIDE ADIPIQUE[1]

LISE NICOLE ET LOUIS BERLINGUET
Département de Biochimie, Faculté de Médecine, Université Laval, Québec, Qué.

Reçu le 10 juillet 1961

ABSTRACT

The Dieckmann reaction has been reinvestigated in view of obtaining alkyl-substituted cyclopentanones. Control of the reaction during alkylation now permits either the opening of the cyclopentane ring to give, without the isolation of intermediates, substituted adipic esters in excellent yields or normal substitution on the ring.

Methyl- and allyl-substituted cyclopentanones were obtained from the corresponding Dieckmann esters or from the substituted adipic acids. These ketones were transformed by the Strecker method into their corresponding spirohydantoins. In both cases, two diastereoisomers were isolated and studied.

1-Amino-2-methyl-cyclopentanecarboxylic acid and 1-amino-2-allyl-cyclopentanecarboxylic acid were prepared in good yields from the spirohydantoins and characterized.

INTRODUCTION

L'acide amino-1 cyclopentane-carboxylique possède des propriétés chimiothérapeutiques contre certains types de cancer. Récemment, on a démontré que cet acide aminé non-naturel peut réduire le développement de l'hépatome de Novikoff (1) et du carcinosarcome Walker 256 chez le rat (2*a*, 2*b*) ainsi que le sarcome 180, le carcinome 755 et la leucémie L-1210 chez la souris (3).

Dans le but d'atténuer la toxicité de cette substance, tout en conservant son activité, nous avons pensé en modifier la structure moléculaire en introduisant sur le noyau, en position 2, une chaîne aliphatique.

Pour obtenir ces acides aminés cycliques, nous avons employé la méthode de synthèse de Strecker et Bucherer en partant de la cyclopentanone substituée en position 2. Ces cétones cycliques alkylées peuvent être obtenues par substitution directe au moyen d'halogènes ou d'halogénures d'alkyles en présence de sodium dans l'ammoniac liquide (4). Dans ce cas, il y a presque toujours formation de dérivés bi-substitués lesquels sont souvent difficiles à éliminer. Nos essais biologiques demandant des produits d'une très grande pureté, nous avons préféré utiliser une méthode où il ne peut y avoir de bi-substitution.

L'éther de Dieckmann (II) est un ester β-cétonique qui permet une alkylation simple. Par décarboxylation subséquente, on obtient une cétone cyclique mono-substituée (VII). Cette synthèse de cétones cycliques substituées par l'intermédiaire de l'éther de Dieckmann a été utilisée par plusieurs auteurs, lesquels mentionnent inévitablement que les rendements sont très variables (5–11). Sans raison apparente, on obtient, lors de l'alkylation, soit l'éther de Dieckmann substitué (V), soit le di-ester de l'acide adipique substitué (III).

Cornubert et Borrel en ont étudié les conditions expérimentales (12) et plusieurs auteurs (10, 11, 13) ont avancé des mécanismes de réaction. On admet aujourd'hui (14) que la température, la grosseur de la chaîne alkylée substituée et surtout la concentration en éthoxyde de sodium sont responsables de l'ouverture des éthers de Dieckmann substitués en esters adipiques correspondants.

[1]*Présenté au congrès annuel de l'Institut de Chimie du Canada, tenu à Ottawa en juin 1960.*

Nous avons repris ces travaux dans le but de préparer les cétones cycliques substituées avec le moins possible d'intermédiaires et de contrôler lorsqu'il y a lieu l'ouverture des éthers de Dieckmann.

Lorsqu'on effectue la cyclisation de l'adipate di-éthylique par un équivalent de sodium dans le toluène, il y a élimination d'une molécule d'éthanol, qui peut se combiner avec le sodium résiduel pour donner l'ion éthoxyde $C_2H_5O^-$, responsable de l'ouverture du cycle. En éliminant par distillation partielle l'alcool ainsi formé avant de faire l'alkylation, on parvient à éviter cette ouverture du cycle. Ainsi on obtient avec 88% de rendement la carboxyéthyl-2 méthyl-2 cyclopentanone-1, (V, R = $-CH_3$) par méthylation directe de l'éther de Dieckmann.

Si, au contraire, on veut obtenir le di-ester de l'acide adipique substitué en α, on ajoute, après alkylation, un excès d'éthanol. On obtient sans isoler d'intermédiaires et avec des rendements respectifs de 89% et de 80% les di-esters méthyl-2 adipate de diéthyle (III, R = $-CH_3$) et allyl-2 adipate de diéthyle (III, R = $-CH_2-CH=CH_2$). L'absence ou la présence d'éthanol lors de l'alkylation est donc en grande partie responsable de la stabilité ou de l'ouverture du cycle.

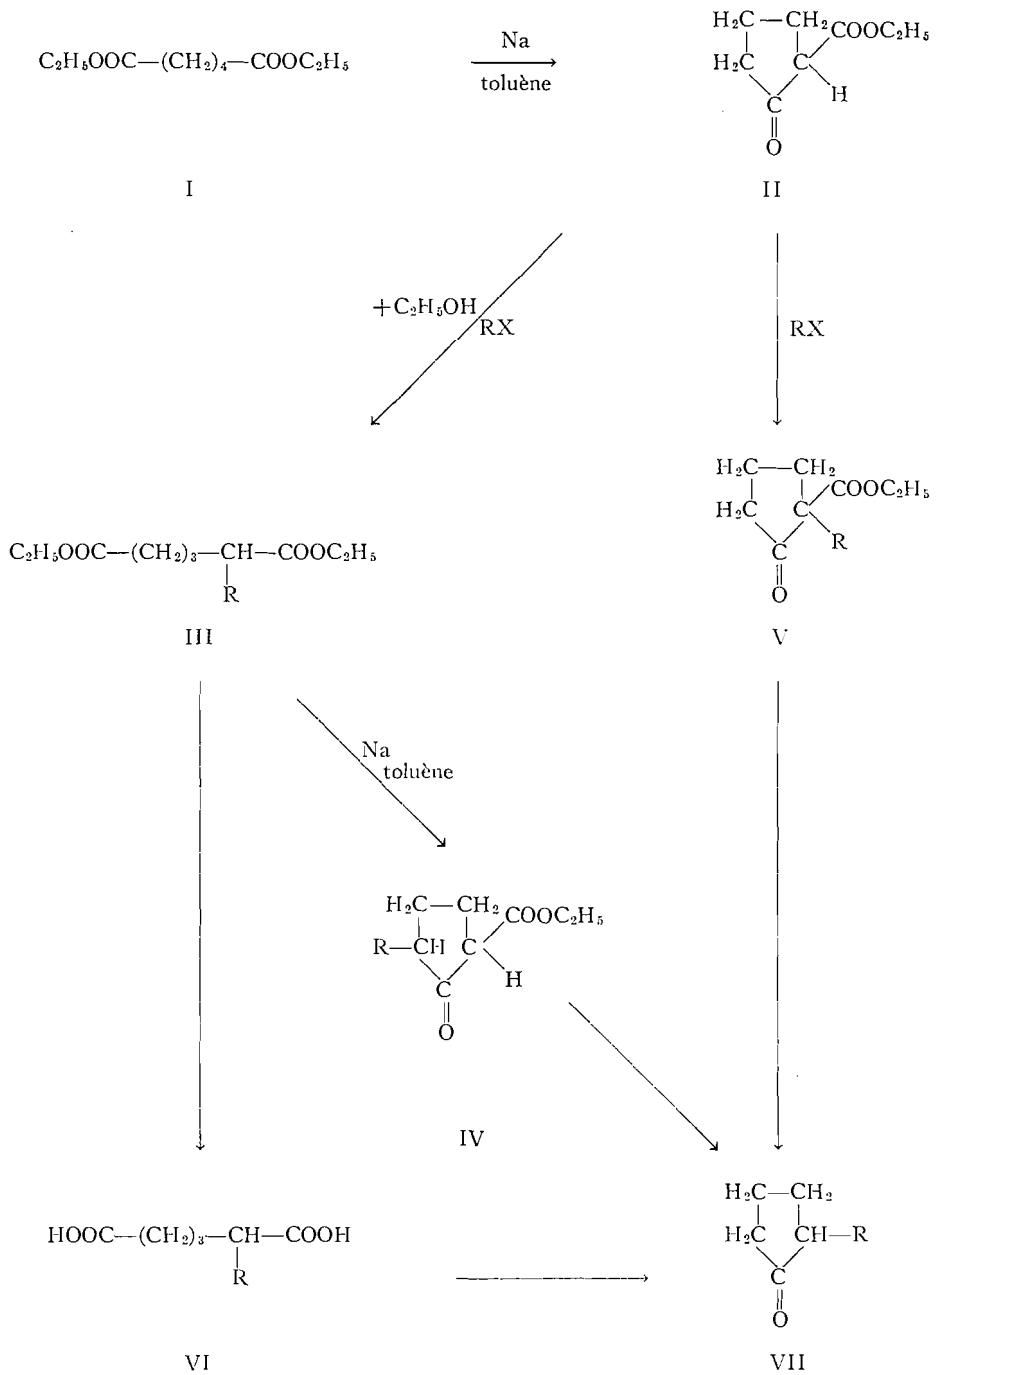
L'obtention des cétones substituées en α présente une autre difficulté. La décarboxylation de l'éther de Dieckmann alkylé en position 2 par ébullition en milieu acide ou en présence de baryte ne se fait bien qui si la chaîne alkylée est inférieure à trois atomes de carbone. Le traitement de l'allyl-2 carboxyéthyl-2 cyclopentanone-1 (V, R = $-CH_2-CH=CH_2$) par l'acide sulfurique à chaud pendant 6 heures, ne permet d'obtenir que 30% de l'allyl-2 cyclopentanone-1. On récupère, inchangé, le produit de départ. Ceci est dû de toute évidence à un empêchement stérique, puisque dans les mêmes conditions la décarboxylation de l'allyl-5 carboxyéthyl-2 cyclopentanone-1 (IV, R = $-CH_2-CH=CH_2$) donne un rendement presque quantitatif. Cope *et al.* (15) rapportent des difficultés analogues lors de la décarboxylation de l'allyl-2 carboxyéthyl-2 cyclopentanone-1, de même que Cornubert et Borrel (12) pour la méthyl-5 propyl-2 carboxyéthyl-2 cyclopentanone-1. Lorsque cet empêchement stérique existe, il y a évidemment avantage à effectuer la décarboxylation sur la carboxyéthyl-2 cyclopentanone-1 substituée en position 5, laquelle s'obtient par cyclisation de l'ester di-éthylique de l'acide adipique substitué. Dans ces conditions l'allyl-2 adipate di-éthylique (III, R = $-CH_2-CH=CH_2$) donne avec un rendement de 66% l'éther de Dieckmann substitué en position 5 (IV, R = $-CH_2-CH=CH_2$) lequel se décarboxyle avec facilité pour donner quantitativement l'allyl-2 cyclopentanone-1 (VII, R = $-CH_2-CH=CH_2$).

On peut aussi cycliser directement, par chauffage, en présence de baryte, suivant la méthode habituelle, un acide adipique substitué. Le rendement est excellent dans le cas de la méthyl-2 cyclopentanone-1.

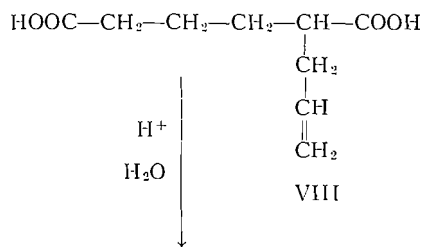
Dans les mêmes conditions, la cyclisation de l'acide allyl-2 adipique (VIII) donne de faibles rendements (18–50%) en allyl-2 cyclopentanone-1. Il se forme plutôt de la méthyl-4 (3-carboxypropyl)-2 butyrolactone (IX) qu'on obtient aussi avec un excellent rendement par chauffage de l'acide allyl-2 adipique en milieu chlorhydrique. Une lactonisation de même type a déjà été rapportée pour un produit analogue (16).

Par la méthode de Strecker, nous avons transformé les cyclopentanones substituées en spirohydantoïnes correspondantes. L'introduction d'un substituant sur le cycle cyclopentane crée deux centres asymétriques, donc deux paires de diastéréoisomères que nous avons réussi à séparer.

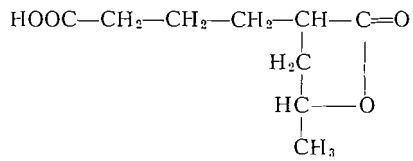
Il est curieux de constater que Granger et Techer (17) n'ont obtenu qu'un seul acétyl amino-1 cyano-1 méthyl-2 cyclopentane à partir de la méthyl-2 cyclopentanone-1.



Par cristallisation fractionnée, nous avons pu isoler les deux diastéréoisomères de la méthyl-6 diazaspiro-1,3(4-4) nonane dione-2,4 ayant des points de fusion de 197–199° et 136–138° et les deux diastéréoisomères de l'allyl-6 diazaspiro-1,3(4-4) nonane dione-2,4 dont les points de fusion sont de 170° et 140°.



VIII



IX

Quantitativement, il y a toujours un rapport de 2 à 1 entre les deux formes isomériques, celle qui a le point de fusion le plus élevé et qui est la moins soluble étant la forme prédominante. L'autre isomère plus soluble est moins stable. C'est ainsi que nous avons traité l'isomère de la (méthyl-2′) cyclopentyl hydantoïne-5 ayant un point de fusion de 136°–138° par une solution de soude à 10% pendant quelques heures. Le produit obtenu fond à 185°, soit le point de fusion du mélange. Dans ces conditions, l'isomère ayant un point de fusion de 197° est stable.

Peu de cas d'isomérie semblable ont été rapportés (18) et à notre connaissance aucun diastéréoisomère de spirohydantoïne n'a été isolé.

Nous avons donc étudié ces produits plus en détail. Les spectres à infrarouge ne permettent pas de mettre en évidence la structure différente des deux diastéréoisomères. Par ailleurs, les spectres obtenus par résonance nucléaire magnétique* suggèrent que les deux produits ayant des points de fusion de 138–140° et 197–199° et dont l'analyse correspond à la formule de la (méthyl-2′) cyclopentyl hydantoïne-5, sont en fait deux diastéréoisomères.

La chromatographie sur papier des deux spirohydantoïnes méthylées suivie de révélation au chlore et à l'iode suivant la technique de Rydon et Smith (19) n'a cependant pas permis de séparer les deux isomères puisque les valeurs R_f ont toujours été identiques dans plusieurs solvants.

L'hydrolyse par la baryte à 160° de ces spirohydantoïnes substituées donne les acides aminés correspondants avec d'excellents rendements. Il est probable que ce traitement alcalin à chaud a pour effet de changer la configuration des deux carbones asymétriques, de telle sorte que même en partant d'un diastéréoisomère de l'hydantoïne on doit s'attendre à obtenir un mélange des deux diastéréoisomères de l'acide aminé correspondant.

Nous n'avons pu isoler d'isomères stériques après hydrolyse alcaline de l'une ou l'autre des (méthyl-2′) cyclopentyl hydantoïne-5. Les produits obtenus ont toujours eu des R_f identiques tant en chromatographie sur colonne de Dowex-50 que par chromatographie sur papier en utilisant différents solvants et même par chromatographie sur papier imbibé de résines échangeuses d'ions.

Varian Associates, 611 Hansen Way, Palo Alto, California, U.S.A.

Par hydrolyse des deux isomères de la (méthyl-2′) cyclopentyl hydantoïne-5 au moyen de l'acide iodhydrique en présence de phosphore rouge, on obtient parallèlement deux produits ayant une solubilité quelque peu différente dans l'eau.

Les picrates de ces deux acides aminés ainsi que les dérivés phényl-uréidos des deux acides correspondants ont dans chacun des cas des points de fusion identiques. Les sels de cuivre ont par ailleurs une solubilité différente dans l'eau et peuvent servir à séparer les diastéréoisomères.

Les deux spirohydantoïnes ayant des points de fusion de 137° et 198° donnent par hydrolyse acide deux acides amino-1 méthyl-2 cyclopentane-carboxyliques. Par traitement avec KOCN, ces deux isomères donnent des acides hydantoïques dont les points de fusion sont différents.

Ces acides hydantoïques redonnent les deux spirohydantoïnes de départ par chauffage en milieu acide. Les acides aminés isolés sont donc bien des isomères qui conservent leur configuration lors de la transformation en hydantoïnes.

L'hydrolyse alcaline de l'(allyl-2′) cyclopentyl hydantoïne-5 donne un acide aminé dont l'analyse correspond à l'acide amino-1 allyl-2 cyclopentane-carboxylique mais qui en réalité doit être un mélange des formes allo et thréo.

Cette hydantoïne est par ailleurs peu stable en milieu acide et on obtient par chromatographie des solutions d'hydrolyse, deux taches d'acides aminés dont une correspond à l'acide amino-1 allyl-2 cyclopentane-carboxylique, l'autre étant probablement un produit d'addition sur la double liaison lequel produit d'addition peut se cycliser ou non.

Ces acides amino-1 cycloalkyl-carboxyliques substitués sont solubles dans l'eau et partiellement dans l'éthanol. Ils sont tout à fait insolubles dans l'acétone d'où ils précipitent sous forme de gels volumineux. Ils se volatilisent sur une plaque chaude pour donner une vapeur se solidifiant rapidement.

Des travaux biologiques avec ces acides aminés sont en cours et seront publiés sous peu.

PARTIE EXPÉRIMENTALE

Adipate de diéthyle (I)

On prépare l'adipate de diéthyle à partir de 400 g (2.74 mole) d'acide adipique, en présence d'acide sulfurique (120 ml), d'éthanol à 95% (600 ml) et de benzène (2000 ml) suivant la méthode de Van Ryssel-berghe (8). Rendement 477 g (86%). P.é. 130° à 15 mm, n_D^{20} 1.427 (lit. p.é. 138° à 20 mm, n_D^{20} 1.427) (8).

Carboxyéthyl-2 cyclopentanone-1 (éther de Dieckmann) (II)

On fait la cyclisation de l'adipate de diéthyle par le sodium dans le toluène suivant la méthode décrite par Cornubert et Borrel (12). À partir de 200 g (0.988 mole) d'adipate de diéthyle, on obtient 110 g d'éther de Dieckmann. Rendement 71%. P.é. 110–115° à 19 mm, n_D^{20} 1.454 (lit. p.é. 114° à 20 mm, n_D^{20} 1.452) (8).

Carboxyéthyl-2 méthyl-2 cyclopentanone-1 (V) (R = —CH_3)

(a) À partir de l'éther de Dieckmann

On fait la méthylation de l'éther de Dieckmann selon la méthode de Cornubert et Borrel (12) par condensation de l'iodure de méthyle avec le dérivé sodé de la carboxyéthyl-2 cyclopentanone-1. Tel que mentionné par Cornubert et Borrel, cette réaction doit être effectuée à très basse température et en présence d'une quantité rigoureusement exacte de sodium. Autrement, on s'expose à obtenir l'ester méthyl-2 adipate de diéthyle qui se forme par ouverture du cycle cyclopentanique.

Même en prenant toutes ces précautions, il arrive, comme l'ont mentionné plusieurs auteurs, que ce soit le di-ester substitué ouvert qu'on obtienne.

À partir de 60 g (0.384 mole) d'éther de Dieckmann, on obtient 57.5 g de carboxyéthyl-2 méthyl-2 cyclopentanone-1. Rendement 88%. P.é. 104° à 12 mm, n_D^{20} 1.440 (lit. p.é. 105° à 13 mm, n_D^{20} 1.4464) (5).

(b) Directement à partir de l'adipate de diéthyle

On chauffe dans un ballon muni d'un réfrigérant et d'un agitateur 14.0 g (0.61 mole) de sodium dans 725 ml de toluène dé-thiophéné. Lorsque le sodium est fondu, on agite vigoureusement pour fractionner le sodium en fines particules. On ajoute alors l'adipate de diéthyle (101 g, 0.50 mole) et on chauffe à reflux

pendant 2 heures. Le sel de sodium de la carboxyéthyl-2 cyclopentanone-1 se présente sous forme de masse spongieuse. On distille alors pour recueillir 125 ml de toluène et d'éthanol formé lors de la cyclisation. On ajoute 75 ml de toluène dé-thiophéné au mélange et on continue la distillation jusqu'à ce que le volume total du distillat atteigne 200 ml.

On refroidit alors dans la glace et on ajoute en une seule fraction 160 g (1.13 mole) d'iodure de méthyle. On chauffe à reflux pendant 16 heures. On ajoute alors de l'eau pour dissoudre l'iodure de sodium. On sépare le toluène, on le sèche et on recueille par distillation sous vide la carboxyéthyl-2 méthyl-2 cyclopentanone-1. Rendement total à partir de l'adipate de diéthyle 69.9 g (82.2%) passant à 100–105° sous 14 mm, n_D^{20} 1.444.

Carboxyéthyl-5 méthyl-2 cyclopentanone-1 (IV) (R = —CH_3)

On cyclise par la méthode de Cornubert et Borrel (12) le méthyl-2 adipate de diéthyle (137.0 g, 0.63 mole) par le sodium dans le toluène. Rendement en carboxyéthyl-5 méthyl-2 cyclopentanone-1 52.0 g (48.3%). P.é. 120–125° sous 25 mm, n_D^{20} 1.450 (lit. p.é. 123–124° sous 31 mm) (7).

Méthyl-2 adipate de diéthyle (III) (R = —CH_3)

En s'inspirant de la méthode de synthèse de l'éther de Dieckmann, décrite par Cornubert et Borrel (12), on place dans un ballon muni d'un réfrigérant et d'un agitateur 15.7 g de sodium dans 600 ml de toluène. Quand le toluène bout, on agite vigoureusement le ballon afin de diviser finement le sodium fondu. On ramène la température du toluène à 60° et on ajoute 112.2 g (0.55 mole) d'adipate de diéthyle. Aux environs de 80°, la réaction devient vive. Lorsqu'elle est entièrement terminée, on prolonge le chauffage encore 1 heure. On ajoute alors l'iodure de méthyle en excès (118.1 g, 0.82 mole). On laisse agiter à reflux, pendant 16 heures, après avoir ajouté 50 ml d'éthanol pour favoriser l'ouverture du cycle. On refroidit et on dissout l'iodure de sodium dans l'eau. On décante et on lave la partie aqueuse avec du toluène que l'on ajoute à la partie toluénique. On distille le toluène à la pression atmosphérique et on distille le résidu dans le vide. Rendement 105.8 g (89%). P.é. 140–145° à 33 mm, n_D^{20} 1.431 (lit. p.é. 141° à 26 mm) (7).

Acide méthyl-2 adipique (VI) (R = —CH_3)

(a) Par hydrolyse alcaline

On fait bouillir à reflux, pendant 16 heures, un mélange de méthyl-2 adipate de diéthyle (140.9 g, 0.65 mole) et d'hydroxyde de potassium (98.0 g, 1.47 mole) dans 1 litre d'éthanol à 95%. On dissout alors les sels par addition d'eau, et on évapore à sec. On reprend par de l'eau, on acidifie avec HCl concentré. On extrait la solution aqueuse plusieurs fois à l'éther qu'on sèche et qu'on évapore. Il reste 82.5 g (79.5%) d'une huile qui cristallise lentement.

(b) Par hydrolyse acide

On fait bouillir à reflux, pendant 16 heures, le méthyl-2 adipate de diéthyle (60 g, 0.278 mole) avec 100 ml d'acide chlorhydrique et 100 ml d'acide acétique glacial. On évapore alors à sec et on reprend le résidu par du benzène chaud. On cristallise l'acide par addition d'éther de pétrole et on porte au froid. Rendement 37.5 g (84.3%). P.f. 57°* (lit. 61°) (20).

Méthyle-2 cyclopentanone-1 (VII) (R = —CH_3)

(a) À partir de la carboxyéthyl-2 méthyl-2 cyclopentanone-1

On effectue la décarboxylation de la carboxyéthyl-2 méthyl-2 cyclopentanone-1 au moyen de l'acide chlorhydrique dilué dans les proportions 1:3, en chauffant à reflux durant 16 heures avec une bonne agitation. On extrait le produit à l'éther et on le distille. À partir de 56.7 g (0.333 mole) de carboxyéthyl-2 méthyl-2 cyclopentanone-1, on obtient 20.7 g de méthyl-2 cyclopentanone-1. Rendement 63%. P.é. 138–140° à 760 mm, n_D^{20} 1.433 (lit. p.é. 139° à 760 mm, n_D^{20} 1.4348) (21). La cétone donne des cristaux orangés avec la dinitro-2,4 phénylhydrazine, qui fondent après recristallisation du méthanol à 160°.

(b) À partir de la carboxyéthyl-5 méthyl-2 cyclopentanone-1

On chauffe avec une bonne agitation la carboxyéthyl-5 méthyl-2 cyclopentanone-1 (52.0 g, 0.30 mole) en présence de 100 ml d'acide sulfurique à 10%. Après 4 heures, on refroidit et on extrait plusieurs fois à l'éther. On fait une distillation de la solution éthérée. La méthyl-2 cyclopentanone-1 passe à 135–138° à 760 mm. Rendement 18.0 g (61.5%).

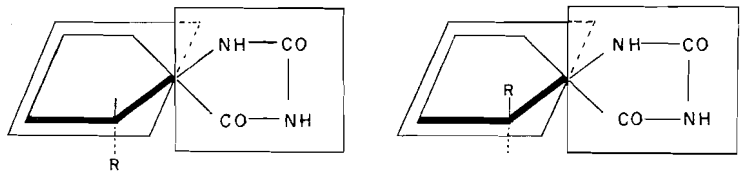
(c) À partir de l'acide méthyl-2 adipique

En utilisant la méthode décrite pour la cyclopentanone (22), on cyclise à 290° l'acide méthyl-2 adipique (33.5 g, 0.22 mole) en présence d'hydroxyde de baryum (2.0 g). On recueille 19.1 g de méthyl-2 cyclopentanone-1, n_D^{20} 1.435. Rendement 93%.

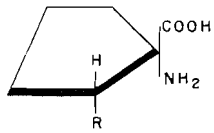
Méthyl-6 diazaspiro-1,3 (4-4) nonane dione-2,4 (X) (R = —CH_3) (méthyl-2') cyclopentyl hydantoïne-5

À la température de la chambre, on fait réagir la méthyl-2 cyclopentanone-1 (53.5 g, 0.546 mole) avec du cyanure de potassium (65.1 g, 1.0 mole) dissous dans un mélange contenant 150 ml de méthanol, 150 ml d'eau, du chlorure d'ammonium (53.4 g, 1.0 mole) et un peu de résine IR 4-B (23). On agite mécaniquement

**Les points de fusion ne sont pas corrigés.*



X



XI R = $-CH_3$

XII R = $-CH_2-CH=CH_2$

durant 3 heures. On ajoute alors au mélange un excès de carbonate d'ammonium et l'on chauffe durant 16 heures à 60° sur un bain-marie. On évapore la solution de moitié pour chasser l'alcool. On filtre la résine, on ajuste le pH à 5–6 et on refroidit. Une première précipitation donne 71.0 g de cristaux, p.f. 168°. En évaporant de nouveau, on obtient une seconde précipitation de cristaux, 11.0 g, p.f. 145°. Rendement brut total 82.0 g (89%).

Le premier précipité (71.0 g) est formé du mélange des deux diastéréoisomères. On peut les séparer par recristallisation fractionnée dans l'eau. Le plus insoluble cristallise facilement. Après filtration, on obtient 41.5 g d'un produit qui commence à sublimer à 130° et qui fond complètement à 197–199°. Anal. Calc. pour $C_8H_{12}N_2O_2$: N, 16.65%. Trouvé: N, 16.82%.

On recristallise de l'eau les 11.0 g de cristaux obtenus lors de la seconde précipitation. Si, à cette solution, on ajoute les eaux-mères du début, on obtient, par concentrations et filtrations successives, un total de 29.5 g du second diastéréoisomère fondant à 136–138°. Anal. Calc. pour $C_8H_{12}N_2O_2$: N, 16.65%. Trouvé: N, 16.82%.

Le rendement total des deux diastéréoisomères est 71.0 g (77%) dont 41.5 g ont un point de fusion de 197–199° et 29.5 g ont un point de fusion de 136–138°.

Les rendements habituels en hydantoïnes varient entre 70 et 85%, mais on a toujours la prédominance de l'isomère fondant à 197° sur l'isomère fondant à 138° dans les proportions de 2 à 1.

Propriétés des diastéréoisomères de la méthyl-6 diazaspiro-1,3 (4-4) nonane dione-2,4

Les deux diastéréoisomères des spirohydantoïnes sont insolubles dans l'éther, l'acétate d'éthyle et le benzène. Ils sont totalement solubles dans l'acétone et partiellement solubles à chaud dans l'eau et dans l'éthanol.

On peut les séparer soit par cristallisation fractionnée de l'eau soit en les dissolvant à chaud dans l'acétone et en ajoutant de l'éther de pétrole jusqu'à turbidité. Le diastéréoisomère le plus insoluble précipite le premier. Son point de fusion est 197–198°. Cet isomère est beaucoup plus stable que l'autre isomère fondant à 138°. Un chauffage de 2 ou 3 heures en présence de soude à 10% ou en tube scellé avec HBr 48% ne parvient pas à le transformer. Tout au plus peut-on déceler une trace de l'acide aminé correspondant par chromatographie sur papier, lequel provient de l'ouverture de l'anneau de l'hydantoïne. Par recristallisation de l'eau, on recueille l'hydantoïne inchangée ayant un point de fusion de 198°.

L'isomère fondant à 138° est par contre moins stable. On peut le transformer en l'autre diastéréoisomère par chauffage prolongé en milieu alcalin ou même en milieu très fortement acide. C'est ainsi que l'on dissout 2.92 g de l'hydantoïne fondant à 138° dans 6 ml de NaOH à 10% et 18 ml d'eau distillée. On laisse sur un bain-marie bouillant toute la nuit. Le lendemain, on acidifie avec HCl concentré et en portant au froid, l'hydantoïne cristallise en gros bâtonnets (1.42 g) qui commencent à sublimer vers 140° mais ne fondent complètement qu'à 182–188°.

Si on traite l'hydantoïne ayant un point de fusion de 138° en tube scellé pendant 2 ou 3 heures avec HBr 48%, on parvient à ouvrir partiellement l'anneau de l'hydantoïne et on peut déceler l'acide aminé correspondant par chromatographie sur papier. On recupère cependant une certaine quantité d'hydantoïne qui maintenant a un point de fusion de 185–190°.

Par ailleurs après une ébullition de 17 heures en présence d'acide chlorhydrique concentré, ou de quelques minutes en présence de soude à 10%, on récupère dans chaque cas les deux hydantoïnes inchangées.

Acide amino-1 méthyl-2 cyclopentane-carboxylique (XI) (R = —CH_3)

(a) Hydrolyse alcaline

Dans un autoclave, on hydrolyse 14.3 g (0.085 mole) de l'hydantoïne ayant un point de fusion de 197° avec 40 g (0.127 mole) d'hydroxyde de baryum dissous dans 120 ml d'eau bouillante. On porte la température à 165° durant une $\frac{1}{2}$ heure. On laisse le mélange refroidir, puis on ajoute 80 g (1.42 mole) de carbonate d'ammonium.

On concentre la solution par ébullition et on filtre le carbonate de baryum. Après avoir évaporé le filtrat sous pression réduite, on reprend le résidu par l'eau bouillante. Par cristallisations successives de l'eau, on obtient l'acide aminé, lequel cristallise avec une molécule d'eau. Anal. Calc. pour $C_7H_{13}NO_2.H_2O$: N, 8.70%. Trouvé: N, 8.79%. Rendement 10.9 g (90%). On sèche le produit à l'étuve à 110° pendant quelques heures. Le produit se décompose en brunissant vers 290°. Anal. Calc. pour $C_7H_{13}NO_2$: N, 9.78%. Trouvé: N, 9.94%.

On procède de la façon décrite plus haut pour hydrolyser l'autre isomère de l'hydantoïne ayant un point de fusion de 138°. En partant de 9.6 g (0.057 mole) d'hydantoïne, on obtient après séchage à l'étuve 5 g d'acide aminé. Rendement 61%. L'acide aminé n'a pas de point de fusion et commence à se décomposer à 290°. Anal. Calc. pour $C_7H_{13}NO_2$: N, 9.78%. Trouvé: N, 9.87%. Il cristallise aussi avec une molécule d'eau. Anal. Calc. pour $C_7H_{13}NO_2$: N, 8.70%. Trouvé: N, 8.62%.

(b) Hydrolyse acide

Dans un ballon muni d'un réfrigérant, on place 11.0 g (0.065 mole) de l'isomère fondant à 198° de la méthyl-6 diazaspiro-1,3(4-4) nonane dione-2,4, 125 ml d'acide iodhydrique 57% et 1 g de phosphore rouge amorphe. On chauffe à reflux pendant au moins 48 heures. En diminuant le temps d'hydrolyse on s'expose à retrouver des quantités importantes d'hydantoïne de départ. Après avoir refroidi la solution, on filtre le phosphore et on évapore à sec sous vide.

On dissout le résidu dans l'eau bouillante et on verse cette solution sur un excès de AgOH fraîchement préparé. Après avoir agité pendant $\frac{3}{4}$ heure, on chauffe à ébullition et on filtre les sels d'argent. On sature le filtrat de sulfure d'hydrogène. On filtre le sulfure d'argent et on rinse à l'eau chaude. Après avoir vérifié que le filtrat ne contient plus d'ions d'argent ou d'iode, on le décolore avec du noir animal et on évapore à sec sous vide. On reprend le résidu dans un minimum d'eau et on porte au froid. On évapore à sec et on reprend par un minimum d'eau bouillante. L'acide aminé précipite au froid. On concentre les eaux-mères pour obtenir d'autres cristaux. Par addition subséquente d'éthanol et d'acétone, on récupère les dernières traces de l'acide aminé. Rendement total en acide aminé 8.41 g (90%). L'acide aminé sublime à partir de 160° et se décompose en brunissant vers 290°. Anal. Calc. pour $C_7H_{13}NO_2$: N, 9.78%. Trouvé: N, 9.73%.

On procède de la façon décrite plus haut pour hydrolyser l'autre isomère de l'hydantoïne ayant un point de fusion de 138°. En partant de 18.2 g (0.109 mole) d'hydantoïne, on obtient 14.5 g d'acide aminé. Rendement 96%. L'acide aminé sublime vers 220° et se décompose à 297–299°. Anal. Calc. pour $C_7H_{13}NO_2$: N, 9.78%. Trouvé: N, 9.94%.

Propriétés de l'acide amino-1 méthyl-2 cyclopentane-carboxylique

L'acide aminé n'est presque pas soluble dans l'éthanol bouillant. Il est insoluble dans la plupart des solvants organiques. Il est plus soluble dans l'eau, à froid, et on peut le recristalliser assez facilement. Il est toutefois partiellement soluble dans un mélange eau–éthanol.

On peut le précipiter très facilement des solutions aqueuses ou alcooliques par addition d'acétone. Il se forme alors un volumineux gel qui se filtre très aisément.

Lorsque l'acide aminé solide est projeté sur une plaque chauffante, maintenue à 300°, il se volatilise en une sorte de sublimé qui se solidifie immédiatement au contact de l'air.

Picrates de l'acide amino-1 méthyl-2 cyclopentane-carboxylique

Les divers échantillons de l'acide aminé obtenus tant par hydrolyse acide que par hydrolyse alcaline des deux diastéréoisomères ont toujours donné des picrates dont le point de fusion est 215–216°. Ces picrates recristallisent de l'eau et ils sont assez solubles dans l'éther. Calculé pour $C_{13}H_{16}N_4O_9$: N, 15.07%. Trouvé: N, 14.84%.

Sels de cuivre de l'acide amino-1 méthyl-2 cyclopentane-carboxylique

On fait bouillir pendant 2 heures une solution aqueuse de l'acide amino-1 méthyl-2 cyclopentane-carboxylique avec un excès de carbonate de cuivre. On filtre à chaud et on recueille après avoir refroidi le sel de cuivre de l'acide aminé.

Les deux diastéréoisomères donnent des cristaux d'un bleu violet en forme d'aiguilles. Les deux sels de cuivre ont des solubilités différentes dans l'eau et par recristallisation fractionnée on peut séparer les deux diastéréoisomères. Ils sont aussi partiellement solubles dans l'éthanol et le méthanol à chaud.

Les sels de cuivre cristallisent avec une molécule d'eau. Calculé pour $C_{14}H_{24}O_4N_2Cu.H_2O$: N, 7.66%. Trouvé: N, 7.64%. Après séchage à l'étuve on obtient le sel anhydre. Calculé pour $C_{14}H_{24}O_4N_2Cu$: N, 8.06%. Trouvé: N, 7.98%.

Chlorhydrate de l'ester éthylique de l'acide amino-1 méthyl-2 cyclopentane-carboxylique

On suspend 2.80 g (0.019 mole) d'acide amino-1 méthyl-2 cyclopentane-carboxylique dans 100 ml d'éthanol bouillant dans lequel barbote HCl gazeux. Après 2 heures d'ébullition, on évapore à sec et on recristallise de l'éthanol par addition d'éther. Rendement 2.7 g (66%). P.f. 200°. Anal. Calc. pour $C_9H_{18}NO_2Cl$: N, 6.76%. Trouvé: N, 6.86%.

Acide uréido-1 méthyl-2 cyclopentane-carboxylique

On chauffe au bain-marie pendant 2 heures, une solution contenant 2.86 g (0.02 mole) d'acide amino-1 cyclopentane-carboxylique et 1.62 g (0.02 mole) de cyanate de potassium dans 40 ml d'eau. On refroidit dans la glace et on acidifie avec HCl concentré. On filtre les cristaux blancs et on les sèche. Rendement 2.86 g (77%). P.f. 205°. Anal. Calc. pour $C_8H_{14}N_2O_3$: N, 15.08%. Trouvé: N, 14.70%. Le poids moléculaire trouvé par neutralisation avec NaOH 0.1 *N* est 194. Calculé: 186. Les analyses ont été faites sur les cristaux séchés à l'étuve, le produit ayant tendance à cristalliser avec des molécules d'eau.

Les deux diastéréoisomères de l'acide amino-1 cyclopentane-carboxylique se comportent de la même façon et donnent avec le même rendement le produit décrit plus haut.

Cyclisation en spirohydantoïnes

On chauffe à reflux pendant 2 heures un mélange de 10 ml d'acide chlorhydrique concentré et 40 ml d'eau dans lequel est dissous 1.0 g d'acide uréido-1 méthyl-2 cyclopentane-carboxylique obtenu à partir de l'isomère le moins soluble de l'acide amino-1 méthyl-2 cyclopentane-carboxylique. On évapore à sec et on reprend le résidu dans l'acétone chaud. Par addition d'éther de pétrole, la méthyl-6 diazaspiro-1,3(4-4) nonane dione-2,4 cristallise. Rendement 0.70 g (79%). P.f. 195°.

Dans les mêmes conditions, l'acide uréido-1 méthyl-2 cyclopentane-carboxylique, obtenu à partir de l'isomère le plus soluble de l'acide amino-1 méthyl-2 cyclopentane-carboxylique, donne l'autre isomère de la spirohydantoïne dont le point de fusion est 140°.

Ces transformations indiquent bien que les deux diastéréoisomères de la spirohydantoïne donnent par hydrolyse acide les diastéréoisomères des acides aminés correspondants. Les acides aminés peuvent être transformés de nouveau par l'intermédiaire des acides uréido correspondants en diastéréoisomères de la spirohydantoïne de départ. Toutes ces transformations se font donc sans perte de configuration pour le deuxième carbone asymétrique.

Acide N-phényluréido-1 méthyl-2 cyclopentane-carboxylique

Dans une fiole conique, on dissout 2.86 g (0.02 mole) d'acide amino-1 méthyl-2 cyclopentane-carboxylique le plus insoluble dans un minimum d'eau. On ajoute ensuite de la soude (0.80 g, 0.02 mole) et on agite la solution. En une seule portion, on ajoute alors l'isocyanate de phényle (0.38 g, 0.02 mole). On agite vigoureusement pendant 15 minutes. Puis on filtre la diphényl urée qui a pu se former et on verse le filtrat sur la glace. L'addition d'acide chlorhydrique concentré précipite l'acide phényluréido-1 méthyl-2 cyclopentane-carboxylique. On filtre le précipité et on recristallise dans un mélange eau-éthanol. Rendement 3.45 g (66%). P.f. 145°. Anal. Calc. pour $C_{14}H_{18}N_2O_3$: N, 10.68%. Trouvé: N, 10.40%.

Méthyl-6 phényl-3 diazaspiro-1,3 (4-4) nonane dione-2,4

On cyclise par chauffage dans 50 ml d'acide chlorhydrique dilué pendant quelques heures, 1.0 g d'acide N-phényluréido-1 méthyl-2 cyclopentane-carboxylique obtenu plus haut (0.0038 mole). En refroidissant, les cristaux de la spirohydantoïne substituée apparaissent. On filtre et on sèche. Rendement 0.8 g (86%). On recristallise de l'eau et de l'éthanol. P.f. 148°. Anal. Calc. pour $C_{14}H_{16}N_2O_2$: N, 11.49%. Trouvé: N, 11.52%.

Essais de séparation des diastéréoisomères

Les acides amino-1 méthyl-2 cyclopentane-carboxyliques, obtenus à partir de l'une ou l'autre des deux formes isomériques des hydantoïnes soit par hydrolyse alcaline soit par hydrolyse acide, ont des propriétés chimiques très voisines. Par recristallisation fractionnée de l'eau, on parvient toutefois à isoler deux fractions dont les solubilités dans l'eau sont assez différentes.

Dans le but de mieux séparer ces diastéréoisomères, nous avons utilisé la chromatographie sur papier dans plusieurs systèmes de solvants. Tel que l'indique le Tableau I, les divers échantillons de l'acide amino-1 méthyl-2 cyclopentane-carboxylique migrent tous avec des valeurs R_f identiques.

N'ayant pu séparer les deux diastéréoisomères par chromatographie sur papier, nous avons utilisé des feuilles de cellulose imbibées de résines échangeuses d'ions.* Plusieurs auteurs ont utilisé avec profit ces feuilles de cellulose pour séparer des acides aminés dont les solubilités sont très voisines dans les solvants utilisés pour la chromatographie classique (24–27). Nous avons surtout utilisé le type WA-2, faiblement acide. Les autres types SA et SB, acide fort et base forte, donnent des mauvaises migrations. Comme l'indique le Tableau II, les diverses valeurs R_f des échantillons d'acide aminé sont très voisines, pour tous les solvants employés. Même dans ces conditions, il a été impossible de séparer les diastéréoisomères attendus.

Nous avons finalement essayé de faire la séparation par adsorption sur une colonne de résine Dowex-50 et élution subséquente avec diverses solutions. Les acides amino-1 méthyl-2 cyclopentane-carboxyliques

**Echantillons gracieusement fournis par Reeve Angel, 9 Bridewell Place, Clifton, N.J.*

TABLEAU I

Acide amino-1 méthyl-2 cyclopentane-carboxylique

Systèmes de solvants	Valeurs R_f (a)	(b)	(c)	(d)

sont fortement adsorbés sur la résine. Ils ne sont élués qu'à l'aide d'une solution d'ammoniaque à 10%. Nous n'avons pu, ici encore, mettre en évidence la présence des deux diastéréoisomères.

La migration de cet acide aminé cyclique lorsqu'on la compare à celle de d'autres acides aminés comme la lysine, la glycine et l'acide glutamique indique que l'acide amino-1 méthyl-2 cyclopentane-carboxylique est relativement basique. Le comportement de cet acide aminé sur la colonne de Dowex-50 confirme le même fait. Tel que démontré par Tillson et Noll (28) pour l'acide amino-1 cyclopentane-carboxylique, l'acide amino-1 méthyl-2 cyclopentane-carboxylique ne peut être titré par un alcali en présence de formol, suivant la méthode classique de Sörensen.

Spectres d'absorption dans l'infrarouge

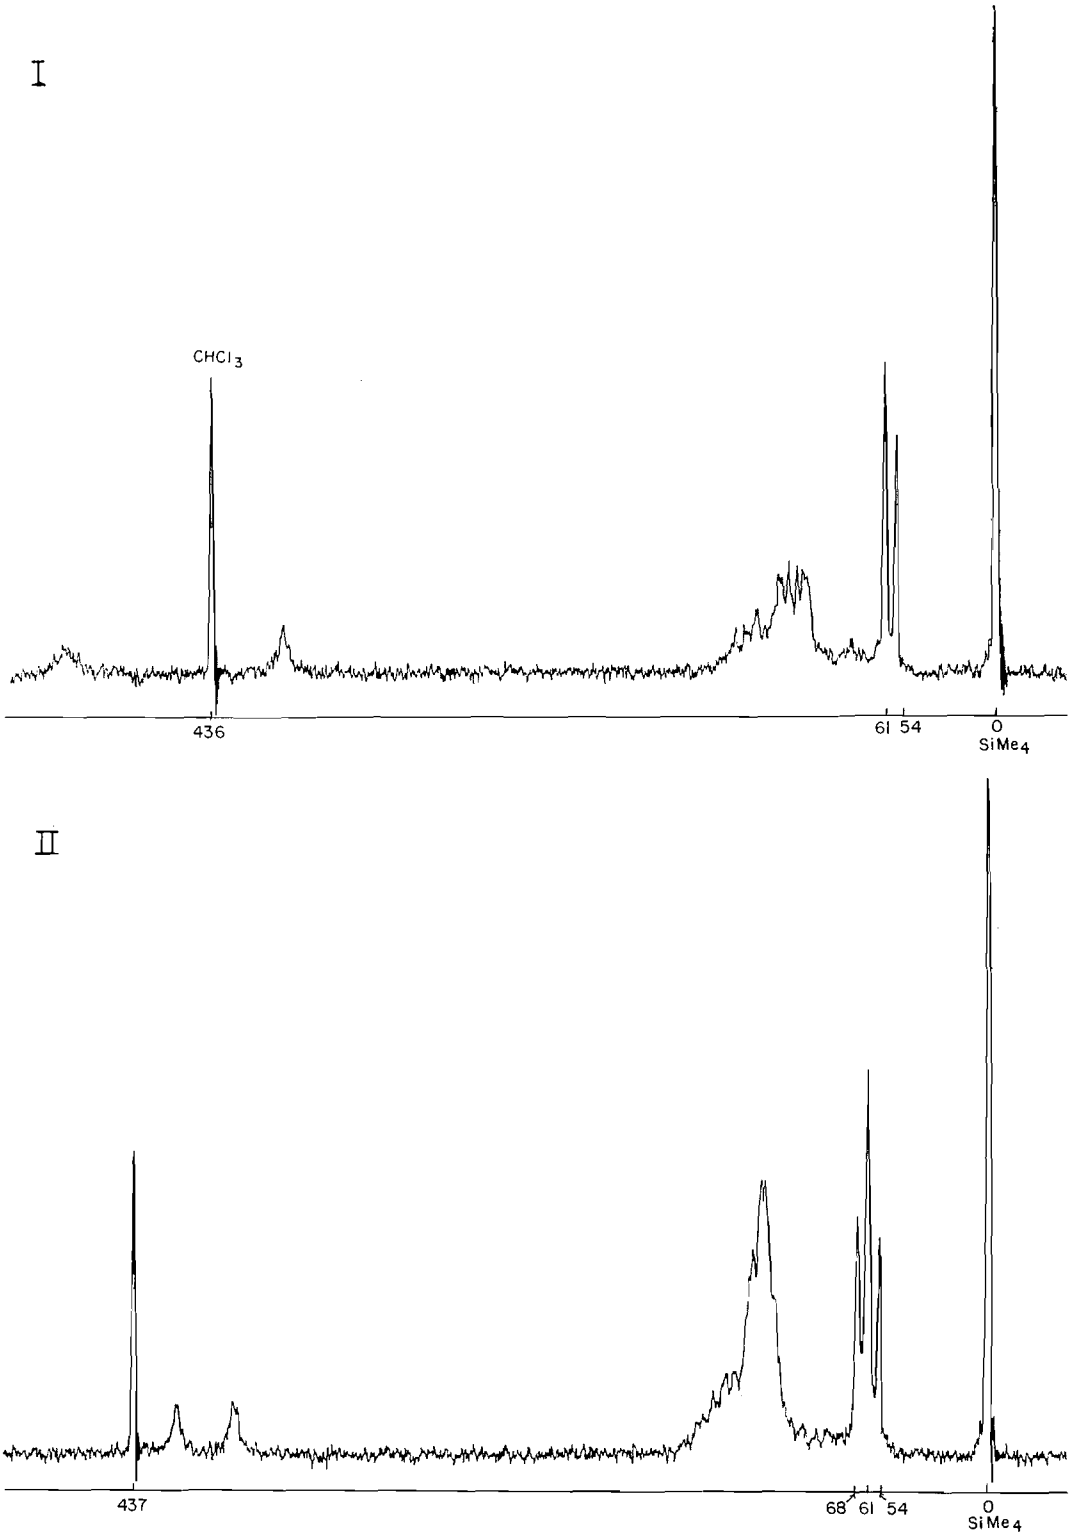
Les spectres d'absorption dans l'infrarouge ont été pris avec le spectrophotomètre Beckman, modèle IR-4. La comparaison entre les spectres des deux isomères, soit de la (méthyl-2′) cyclopentyl hydantoïne-5, soit de l'(allyl-2′) cyclopentyl hydantoïne-5, ne permet pas de conclure à la présence de deux diastéréoisomères. Les bandes d'absorption sont à toute fin pratique presque identiques.

Spectres magnétiques de résonance nucléaire

Les spectres des deux échantillons de la (méthyl-2′) cyclopentyl hydantoïne-5 ont été pris dans une solution de chloroforme deutéré avec une trace de tétraméthylsilane comme référence interne. La position des bandes est mesurée en cycles par seconde. On voit dans la Figure 1 que les deux bandes situées de chaque côté du spectre du chloroforme à 436 c.p.s. sont dues aux groupes NH. Le doublet que l'on observe à 54 c.p.s. est dû au radical méthyle. Cette bande est séparée en deux par suite de la vibration du proton voisin. Les autres bandes qui forment un complexe proviennent des sept protons du cycle à cinq carbones. Le spectre correspond donc à la structure proposée.

Le spectre de l'autre isomère montre lui aussi deux bandes dues aux groupes NH. Le triplet observé à 61 c.p.s. est en réalité un doublet dont la ligne gauche est superposée sur la ligne droite de l'autre. On retrouve ici aussi le complexe provenant des sept protons du cycle cyclopentanique.

FIG. 1. Spectre magnétique de résonance nucléaire des deux isomères de la méthyl-6 diazaspiro-1,3 (4-4) nonane dione-2,4. Échantillon I (p.f. 197°); échantillon II (p.f. 138°). Les spectres ont été pris dans une solution de chloroforme deutéré avec une trace de tétraméthylsilane comme référence interne. Le taux de balayage est X10-36/300 et la vitesse est de 3 pouces/minute. Le noyau est H′ et la fréquence 60 Mc.



Il semble aussi d'après les spectres que l'isomère dont le point de fusion est 138° ne soit pas pur et qu'il contienne un peu de l'autre isomère.

Toutefois la comparaison des deux spectres indique bien qu'il s'agit là de deux diastéréoisomères, ne différant que par l'orientation du radical méthyle par rapport au noyau hétérocyclique.

Allyl-2 adipate de diéthyle (III) (R = —CH_2—CH=CH_2)

On passe directement de l'adipate de diéthyle non substitué au di-ester substitué en alpha, sans isoler d'intermédiaires.

On chauffe à reflux avec une bonne agitation, l'adipate de diéthyle (303 g, 1.5 mole) dans 1500 ml de toluène sec, en présence de 42.0 g (1.83 mole) de sodium. Après 3 heures d'ébullition, le sel de sodium de l'éther de Dieckmann présente l'aspect d'une masse volumineuse et spongieuse. On ajoute alors 242 g (2.0 moles) de bromure d'allyle en une seule portion et on chauffe à reflux pendant 5 heures.

On ajoute un peu d'eau pour extraire les sels inorganiques et on ramène le pH à 7.0 avec quelques gouttes d'acide acétique. Après avoir séché la couche de toluène, on distille sous vide le toluène et l'ester adipique substitué. Rendement 290 g (80%). P.é. 150° à 14 mm, n_D^{20} 1.443.

Allyl-2 carboxyéthyl-2 cyclopentanone-1 (V) (R = —CH_2—CH=CH_2)

On utilise la méthode décrite par Vavon et Horeau (9) dans laquelle on ajoute lentement à une solution de carboxyéthyl-2 cyclopentanone-1 (40 g, 0.256 mole) et de bromure d'allyle (34 g, 0.281 mole) dans 100 ml d'éthanol, une solution d'hydroxyde de sodium (12 g, 0.300 mole) dans 50 ml d'eau. Rendement 30 g (60%). P.é. 125–127° à 13–15 mm, n_D^{20} 1.459 (lit. 129° à 16 mm) (9).

Allyl-5 carboxyéthyl-2 cyclopentanone-1 (IV) (R = —CH_2—CH=CH_2)

On effectue la cyclisation en ajoutant goutte à goutte l'allyl-2 adipate de diéthyle (121.6 g, 0.5 mole) à une suspension de fines particules de sodium (14.0 g, 0.61 mole) dans 800 ml de toluène sec et dé-thiophéné maintenu à 35–40°. On chauffe ensuite pendant 4 heures à 70°. On acidifie alors à 0° par H_2SO_4 dilué. On extrait au toluène qu'on lave au bicarbonate dilué et qu'on sèche et distille. Rendement 65.0 g (66%). P.é. 127–130° à 10 mm, n_D^{20} 1.462.

Allyl-2 cyclopentanone-1 (VII) (R = —CH_2—CH=CH_2)

(a) Par décarboxylation de l'allyl-2 carboxyéthyl-2 cyclopentanone-1

On place dans un ballon de 500 ml à trois cols, surmonté d'un réfrigérant, l'allyl-2 carboxyéthyl-2 cyclopentanone-1 (21.0 g, 0.107 mole) et 150 ml d'acide sulfurique 6 *N*. On agite fortement de façon à bien mettre en contact les deux couches et on chauffe au bain-marie pendant 6 heures. Après avoir refroidi, on extrait plusieurs fois à l'éther qu'on sèche et qu'on distille dans le vide. On obtient un résidu liquide qui donne après distillation fractionnée dans le vide, deux fractions. La première, l'allyl-2 cyclopentanone-1, pèse 4.0 g (30.7%) passant à 55–57° à 18 mm, n_D^{20} 1.458. La cétone donne avec la dinitro-2,4 phénylhydrazine des cristaux jaunes, recristallisés du méthanol et ayant un point de fusion de 130–132°.

L'autre fraction est surtout formée de l'allyl-2 carboxyéthyl-2 cyclopentanone-1 inchangé. On recueille ainsi 5.0 g (23.8% du produit initial) passant entre 75–125° à 18 mm, n_D^{20} 1.465.

En prolongeant le temps de chauffage, le rendement reste sensiblement le même.

Si l'on effectue la décarboxylation de l'allyl-2 carboxyéthyl-2 cyclopentanone-1 par chauffage en présence d'une solution d'hydroxyde de baryum (12) le rendement diminue sensiblement.

(b) Par décarboxylation de l'allyl-5 carboxyéthyl-2 cyclopentanone-1

Tel que décrit plus haut, on décarboxyle l'allyl-5 carboxyéthyl-2 cyclopentanone-1 (86.0 g, 0.439 mole) par chauffage pendant 4 heures sur un bain-marie bouillant en présence de 300 ml de H_2SO_4 4 *N*. Après extraction à l'éther, on obtient environ 50 g (92%) d'allyl-2 cyclopentanone-1 brute: n_D^{20} 1.458. Par distillation, on obtient 37.5 g (69%) de cétone pure, passant à 77–80° sous 23 mm, ou à 175–180° sous 758 mm, n_D^{20} 1.459.

On peut aussi effectuer la décarboxylation en chauffant à reflux l'allyl-5 carboxyéthyl-2 cyclopentanone-1 (20.0 g, 0.102 mole) pendant 4 heures en présence d'hydroxyde de baryum (20.0 g, 0.063 mole) dissous dans 100 ml d'eau (12). On filtre le carbonate de baryum formé et on extrait plusieurs fois à l'éther qu'on sèche et qu'on distille. On obtient: 11.0 g (88.7%) d'allyl-2 cyclopentanone-1 brute, n_D^{20} 1.459.

(c) Par chauffage de l'acide allyl-2 adipique

On place dans un ballon à trois cols, l'acide allyl-2 adipique (25.0 g, 0.135 mole) intimement mélangé avec de l'hydroxyde de baryum (2.0 g, 0.006 mole). On chauffe pour que la température du mélange se maintienne entre 290–300°, et on recueille le mélange d'eau et d'allyl-2 cyclopentanone-1 qui passe lentement par distillation. Après 6 heures de chauffage, on extrait à l'éther le distillat obtenu. Après avoir séché et évaporé l'éther, on obtient 9.0 g (54%) d'allyl-2 cyclopentanone-1 impure.

La formation de la cétone est fort lente. Si après quelques minutes de chauffage, on distille sous vide le mélange, on obtient plutôt la méthyl-4 (3-carboxypropyl)-2 butyrolactone.

Méthyl-4 (3-carboxypropyl)-2 butyrolactone (IX)

(a) Par traitement de l'acide allyl-2 adipique par l'hydroxyde de baryum

Ainsi par chauffage de l'acide allyl-2 adipique (37.2 g, 0.20 mole) avec de l'hydroxyde de baryum (3.0 g, 0.009 mole) à 290–300°, on obtient après 1 heure de chauffage, environ 7–8 ml d'un mélange azéotropique

d'eau et d'allyl-2 cyclopentanone-1. On fait alors le vide dans l'appareil et on recueille 21.5 g, d'un liquide passant à 210–215° à 17 mm. On reprend les deux distillats dans 50 ml d'eau et on ajoute suffisamment de soude pour avoir un pH alcalin. On extrait à l'éther plusieurs fois et après avoir séché et distillé l'éther, on recueille 4.5 g (18.3%) d'allyl-2 cyclopentanone-1 passant à 180° sous 760 mm.

On acidifie alors la fraction aqueuse avec H_2SO_4 dilué et on extrait au benzène l'huile qui se sépare. On sèche et on distille sous vide le benzène, ce qui laisse un résidu huileux pesant 18.5 g (50%) et qui ne tarde pas à cristalliser. Un échantillon de la méthyl-4 (3-carboxypropyl)-2 butyrolactone est recristallisé du benzène et de l'éther de pétrole. Les cristaux obtenus ont un point de fusion de 90–92°.

Le poids moléculaire trouvé par neutralisation avec NaOH en présence de phénolphtaléine est 187. Calculé pour $C_9H_{14}O_4$: 186.

La distillation sous vide d'un échantillon pesant 7.2 g, donne 5.0 g d'une huile ayant un point d'ébullition de 230° à 20 mm et qui cristallise rapidement en donnant des cristaux fondant à 90°.

(b) À partir de l'acide allyl-2 adipique par l'acide chlorhydrique

On chauffe à reflux pendant 7 heures 48.5 g (0.261 mole) d'acide allyl-2 adipique avec 150 ml d'acide chlorhydrique dilué 1:1. On évapore alors à sec dans le vide sur bain-marie et on obtient un résidu qu'on recristallise du benzène chaud auquel on ajoute de l'éther de pétrole. Rendement en méthyl-4 (3-carboxypropyl)-2 butyrolactone 42.0 g (86.6%). Poids moléculaire trouvé par neutralisation avec NaOH en présence de phénolphtaléine et en calculant une seule fonction acide: 184. Calculé pour $C_9H_{14}O_4$: 186.

(c) À partir de l'allyl-2 adipate de diéthyle

On chauffe à reflux pendant 7 heures l'allyl-2 adipate de diéthyle (81.7 g, 0.337 mole) avec 800 ml d'acide chlorhydrique dilué 1:1. On évapore à sec et on obtient un résidu qu'on distille dans le vide. On recueille 48.0 g (76.5%) de la lactone, passant à 210° sous 5 mm.

Acide allyl-2 adipique (VIII)

On fait bouillir à reflux pendant 17 heures un mélange d'allyl-2 adipate de diéthyle (62.0 g, 0.256 mole) et d'hydroxyde de potassium (35.0 g, 0.625 mole) dans 750 ml d'éthanol. On évapore ensuite l'éthanol dans le vide sur un bain-marie et on reprend le résidu dans l'eau. On extrait à l'éther l'allyl-2 adipate d'éthyle qui aurait pu résister à la saponification. En acidifiant la portion aqueuse avec H_2SO_4 dilué, une épaisse huile incolore vient flotter en surface. Après l'avoir extraite à l'éther, on sèche et on évapore l'éther. L'huile incolore résiduelle pèse 45.1 g (95%). Cette huile cristallise très lentement à température de la chambre pour donner un solide ayant un point de fusion de 55°. On peut recristalliser l'acide d'un mélange benzène – éther de pétrole ou éther – éther de pétrole. P.f. 57°. Poids moléculaire trouvé par neutralisation avec NaOH et en calculant deux fonctions acides: 189. Calculé pour $C_9H_{14}O_4$: 186.

L'acide allyl-2 adipique est relativement stable en milieu aqueux. Si l'on fait bouillir 2.0 g en présence de 150 ml d'eau pendant 5 heures et qu'on extrait le tout à l'éther, on retrouve une huile qui, recristallisée du benzène – éther de pétrole, redonne 1.5 g du produit initial, soit l'acide allyl-2 adipique. P.f. 56°. Poids moléculaire trouvé par neutralisation avec NaOH et en calculant deux fonctions acides: 185. Calculé pour $C_9H_{14}O_4$: 186.

Allyl-6 diazaspiro-1,3 (4-4) nonane dione-2,4 (XII), (allyl-2′) cyclopentyl hydantoïne-5

On ajoute l'allyl-2 cyclopentanone-1 (37.5 g, 0.30 mole) à un mélange de cyanure de potassium (65.1 g, 1.0 mole), de chlorure d'ammonium (53.4 g, 1.0 mole) et environ 5 g de résine IR A-400 (23) en suspension dans 100 ml de méthanol et 100 ml d'eau. On agite à la température de la chambre pendant 2 heures. On ajoute alors un excès de carbonate d'ammonium (2.0 moles) et on chauffe le tout à 60° pendant 15 heures. On filtre la résine insoluble, on évapore alors les trois-quarts du volume total pour chasser le méthanol et en portant au froid, l'hydantoïne cristallise de la solution saline. Rendement brut 49.0 g (83.3%). P.f. 148–155°.

L'(allyl-2′) cyclopentyl spirohydantoïne-5 est soluble à chaud dans l'éther, l'acétate d'éthyle, et partiellement dans l'eau. Elle est aussi soluble à froid dans l'acétone et l'éthanol et insoluble dans l'éther de pétrole.

On peut recristalliser l'hydantoïne brute soit de l'eau, soit de l'éther – éther de pétrole, soit de l'acétate d'éthyle – éther de pétrole.

On obtient ainsi une première précipitation de cristaux dont le point de fusion est 175–176°. Anal. Calc. pour $C_{10}H_{14}N_2O_2$: N, 14.44%. Trouvé: N, 14.41%.

Par cristallisation fractionnée, on obtient le deuxième isomère dont le point de fusion est 142–143°. Celui-ci beaucoup plus soluble que l'autre. Anal. Calc. pour $C_{10}H_{14}N_2O_2$: N, 14.44%. Trouvé: N, 14.43%.

Le point de fusion mixte des deux diastéréoisomères est 150–155°.

Acide amino-1 allyl-2 cyclopentane-carboxylique (XI) (R = —CH_2—CH=CH_2)

(a) Par hydrolyse alcaline

Dans un autoclave, on hydrolyse 37.0 g (0.19 mole) de l'allyl-6 diazaspiro-1,3 (4-4) nonane dione-2,4 avec 120 g (0.38 mole) d'hydroxyde de baryum dissous dans 500 ml d'eau bouillante. On porte la température à 165° durant ½ heure et on isole l'acide aminé tel que décrit pour l'acide amino-1 méthyl-2 cyclopentane-carboxylique. Par évaporations successives des eaux-mères, on isole 23.1 g (71.5%) de l'acide aminé. Dans le système de solvant pyridine–eau (80:20), l'acide aminé donne une tache violette avec la ninhydrine, dont le R_f est de 0.81. Anal. Calc. pour $C_9H_{15}NO_2$: N, 8.29%. Trouvé: N, 8.12%.

L'acide aminé est assez soluble dans l'eau, partiellement dans l'éthanol et il forme un gel volumineux par addition d'acétone à une solution aqueuse. Le picrate donne une huile qui ne cristallise pas de l'eau. Les sels de cuivre, préparés de façon habituelle, sont peu solubles dans l'eau et ils cristallisent en aiguilles soyeuses bleues. Anal. Calc. pour $C_{18}H_{28}N_2O_4Cu$: N, 7.03%. Trouvé: N, 6.60%.

Comme on doit s'y attendre, l'acide aminé n'est pas tellement stable à chaud en milieu chlorhydrique, puisqu'on retrouve après quelques heures d'ébullition deux taches par chromatographie sur papier. Une des taches correspond à l'acide allyl-2 amino-1 cyclopentane-carboxylique de départ. L'autre provient probablement d'un acide aminé bicyclique formé par addition d'eau sur la double liaison et cyclisation subséquente.

Acide N-phényluréido-1 allyl-2 cyclopentane-carboxylique

On agite violemment pendant 10 minutes un mélange formé de 0.845 g (0.005 mole) d'acide amino-1 allyl-2 cyclopentane-carboxylique, 0.20 g (0.005 mole) d'hydroxyde de sodium et 0.6 ml d'isocyanate de phényle (0.005 mole) dans 30 ml d'eau. On acidifie avec HCl concentré et on filtre le précipité obtenu, qu'on recristallise de l'eau et de l'éthanol. Rendement 1.0 g (69.5%). P.f. 138°. Anal. Calc. pour $C_{16}H_{20}N_2O_3$: N, 9.74%. Trouvé: N, 9.75%. Poids moléculaire trouvé par neutralisation avec NaOH: 294. Calculé pour $C_{16}H_{20}N_2O_3$: 288.

REMERCIEMENTS

Les auteurs remercient M. Bertin Girard pour sa précieuse aide technique.

Ils remercient l'Office des recherches scientifiques de la Province de Québec pour une bourse accordée à l'un d'eux (L. N.), ainsi que l'Institut National du Cancer du Canada pour son aide financière.

Ils remercient de plus le Dr. R. Deghenghi pour l'étude des spectres à l'infra-rouge et le Dr. J. N. Shoolery pour l'interprétation des spectres magnétiques de résonance nucléaire.

THERMODYNAMIC PROPERTIES AND GEOCHEMISTRY OF ISOTOPIC COMPOUNDS OF SELENIUM

H. R. KROUSE* AND H. G. THODE

The Departments of Chemistry and Physics, McMaster University, Hamilton, Ontario

Received August 10, 1961

ABSTRACT

Using "normal vibration equations" and statistical mechanics, the isotopic vibrational frequencies and the partition function ratios for various Se^{76}- and Se^{82}-containing compounds have been calculated. The equilibrium constants for selenium isotope exchange reactions derived from these partition function ratios indicate that noticeable fractionation of selenium isotopes can be expected in the laboratory and in naturally occurring processes.

The Se^{82}/Se^{76} ratios for 16 natural samples have been compared mass spectrometrically. Variations of up to 1.5% found in this ratio are discussed.

A kinetic isotope effect of 1.5% found in a chemical reduction of selenite ion to elemental selenium is also discussed.

INTRODUCTION

It is well known that isotopes of the lighter elements differ in their chemical properties to the extent that significant fractionation of these isotopes occurs in laboratory and natural processes. This is explained theoretically by the dependence of many thermodynamic properties of molecules upon their vibrational frequencies which, in turn, depend upon the masses of the atoms in the molecule. Earlier theoretical studies of possible chemical exchange processes involving the isotopes of many of the lighter elements were made by Urey and Rittenberg (1), Urey and Greiff (2), and Urey (3). Equilibrium constants for isotope exchange reactions were predicted to differ from unity and many of these have been confirmed experimentally.

Because of the large number of isotopes for many of the heavier elements, the percentage mass difference between the lightest and heaviest isotope is often considerable and, therefore, chemical differences are to be expected in these isotopes. With this in mind, investigations of the selenium isotopes were carried out. Selenium, element 34, has six stable isotopes, 74, 76, 77, 78, 80, and 82, with abundances of approximately 1.0, 9.0, 7.5, 23.5, 50.0, and 9.0%. Although the percentage mass difference between Se^{74} and Se^{82} is about 10%, Se^{76} and Se^{82}, in which case the percentage mass difference is greater than 7%, were examined because of the more favorable abundance of Se^{76} over that of Se^{74}.

The examination of the isotopes of selenium was also prompted by the results which had been obtained from studies on sulphur isotope abundances. The variations of up to 5% initially found in the natural S^{34}/S^{32} ratio by Thode *et al.* (4) in 1949 have been widened to 8% by subsequent investigations. Here the percentage mass difference is about 6% and a theoretical study by Tudge and Thode (5) in 1950 predicted equilibrium constants significantly different from unity for exchange of S^{32} and S^{34} between sulphur-containing compounds. The studies on sulphur isotope abundances have proved most interesting because of the wide distribution and the many chemical forms and valence states in which sulphur exists in nature.

Since selenium is, to some extent, chemically similar to sulphur, one might expect to find some analogous fractionations of the selenium isotopes in nature. On the other

**Present address: Department of Physics, University of Alberta, Edmonton, Alberta.*

hand, a study of the selenium isotopes might yield new and interesting information because of the physical differences between selenium and sulphur and their compounds. Therefore, the Se^{82}/Se^{76} ratio has been investigated both theoretically and experimentally to determine the extent to which it might be altered in natural and laboratory processes.

THEORY

Isotopic Equilibrium Exchange Reactions

Since the first application of statistical mechanics to the calculation of isotopic equilibrium exchange constants, Urey (3) and Bigeleisen and Mayer (6) have carried out further simplifications which make it possible to calculate these equilibrium constants, with the exception of the hydrogen isotopes, from a knowledge of the isotopic vibrational frequencies of the participating molecules.

A typical isotope exchange reaction can be written as

$$aA_1 + bB_2 \rightleftharpoons aA_2 + bB_1, \qquad [1]$$

where A and B are molecules containing the element being exchanged and the subscripts 1 and 2 refer to the light and heavy isotopes respectively of this element.

The equilibrium constant for this exchange is given by

$$K = \frac{[Q_{A_2}/Q_{A_1}]^a}{[Q_{B_2}/Q_{B_1}]^b}, \qquad [2]$$

where the Q's are the total partition functions of the molecules. Urey (3) and Bigeleisen and Mayer (6) showed that the equilibrium constant for isotopic exchange reactions could be expressed in terms of isotopic partition function ratios Q_2/Q_1 which depend only on the vibrational frequencies of the isotopic molecules. In the present work, the simplification of Bigeleisen and Mayer (6) was used in which the isotopic partition function ratio is given by

$$\frac{Q_2'}{Q_1'} = \frac{\sigma_1}{\sigma_2}\left[1 + \sum_i \left(\left(\frac{1}{2} - \frac{1}{u_{2_i}}\right) + \frac{1}{e^{u_{2_i}} - 1}\right)\Delta_{u_i}\right], \qquad [3]$$

where $u = hcw/kT$; "w" is the vibrational frequency in cm^{-1} units. The summation is over "i" fundamental vibrational frequencies of the molecule and an n-degenerate frequency is summed "n" times.

$\Delta_{ui} = u_{i1} - u_{2i}$ and is always positive. The σ's are the symmetry numbers of the molecule and σ_1/σ_2 is unity if the molecule contains only one atom of the element being exchanged or more than one atom occupying indistinguishable positions. The function $(1/2 - 1/u_2 + 1/(e^{u_2} - 1))$ has been termed the free energy function $G(u)$ by Bigeleisen and Mayer (6) and has been tabulated for values of u from 0 to 25.

Using this theory, the partition function ratios were calculated for Se^{82}- and Se^{76}-containing compounds. In the absence of specific spectroscopic data for these isotopic molecules, the experimental frequencies available were assumed to apply to the molecule containing the most abundant species Se^{80}, and the frequencies of the Se^{76} and Se^{82} molecular species were calculated by means of "known vibration equations". These equations relate the fundamental vibrational frequencies of molecules to "force constants" and atomic weights on the assumption of a particular model of the molecule in question.

Kinetic Isotope Effects

Since the discovery by Urey and Washburn (7) that partially electrolyzed water is enriched in deuterium because protium is evolved faster at the cathode, it has been shown

that isotopic molecules of other light elements have different rates of reaction and that, in general, the molecule containing the lighter isotope reacts faster.

The ratio of rate constants for competing isotopic reactions, in principle, can be calculated from formulae given by Eyring (8) and Bigeleisen (9). Making only the assumptions inherent in the "theory of absolute reaction rates" of Eyring (8) and Evans and Polanyi (10), Bigeleisen obtains the following expression for the ratio of the reaction rates:

$$\frac{k_1}{k_2} = \frac{K_1}{K_2} S \frac{\nu_{1L}}{\nu_{2L}} \left[1 + \sum_i^{3n-6} G(u_i)\Delta u_i - \sum_i^{3n-7} G(u_i)^{\ddagger}\Delta u_i^{\ddagger} \right], \qquad [4]$$

where, as before, $G(u)$ is the Bigeleisen and Mayer (6) free energy function, $\ddagger$ refers to the transition state of the absolute reaction rate theory, 1 and 2 refer to the light and heavy molecules respectively, S is a statistical factor and depends on the symmetry numbers of the molecules and, finally, ν_L is the imaginary frequency along the reaction co-ordinates in the transition state. The factor ν_{1L}/ν_{2L} gives the ratio of the number of light and heavy molecules in transition state which decompose in unit time. K_1/K_2, the ratio of the transmission coefficients for the isotopic reaction, has been shown by Hirschfelder and Wigner (11) to be nearly unity above room temperature.

According to the theorem of Slater (12), developed for unimolecular reactions, the frequency factor ν_{1L}/ν_{2L} of equation [4] may be replaced by $(\mu_2^{\ddagger}/\mu_1^{\ddagger})^{1/2}$, where μ is the reduced mass across the bond being ruptured. This is based on the premise that only the motions of the two atoms across the ruptured bond are involved.

Bigeleisen and Wolfsberg (13) have suggested a reaction co-ordinate which tears the two decomposition fragments apart. Such a co-ordinate would lead to

$$\nu_{1L}/\nu_{2L} = \left(\frac{\mu_2^{\ddagger}}{\mu_1^{\ddagger}}\right)^{\frac{1}{2}},$$

where μ, the reduced mass across the ruptured bond, is evaluated by using the masses of the two fragments rather than the masses of the two atoms. The choice of the co-ordinate to use, the Slater co-ordinate or the co-ordinate that tears the two fragments apart, will probably depend on the reactions under consideration and the relative bond strengths of the molecules. The usefulness of equation [4] is also limited because of the lack of knowledge concerning the "transition state" and the inability to calculate the last term of the equation $\sum_i G(u_i)^{\ddagger}\Delta u_i^{\ddagger}$. Because of these difficulties, simplifying assumptions must be made in the calculation of kinetic isotope effects.

Results of Theoretical Calculations

Table I summarizes the vibrational frequencies calculated for some Se^{76}- and Se^{82}-containing species. The spectroscopic data and the method of calculation used are found in Herzberg (14). Corrections for anharmonicity were taken into account.

Table II summarizes the fundamental vibrational frequencies that were calculated for Se^{82}- and Se^{76}-containing polyatomic molecules. References are given for the spectroscopic data and the normal vibrational force equations used in the calculations.

Table III summarizes the partition function ratios and the equilibrium constants for Se^{76}–Se^{82} exchange reactions. The method of tabulation is that used by Urey (15). The partition function ratios are listed in the first row under their respective compound at 0° C, 25° C, 100° C, and 250° C, while the equilibrium constants are contained in the main body of the table at the intersection of the pertaining row and column. An equilibrium constant greater than unity indicates that the heavier isotope will concentrate in the compound listed in the left column.

TABLE I

Diatomic molecular frequencies (cm^{-1})

	Molecule							
	PbSe	$Ge^{74}Se$	SnSe	$C^{12}Se$	$Si^{28}Se$	$SeSe^{80}$	Se_2	SeO^{16}

EXPERIMENTAL

The Se^{82}/Se^{76} ratios of various samples were compared using selenium hexafluoride gas in a mass spectrometer.

Preparation of Samples

Selenium was extracted in its elemental form from natural samples by the hydrobromic acid – bromine technique as outlined by Noyes and Bray (16). The adaptations of this method to natural samples by Robinson *et al.* (17) and Williams and Lakin (18) were generally followed. The extracted selenium was then fluorinated to SeF_6 in a monel fluorine line. The prepared SeF_6 was handled in monel sample tubes to avoid contaminations.

Reduction of Selenite Ion to Elemental Selenium (Kinetic Isotope Effect Study)

Hydroxylamine hydrochloride was used to reduce sodium selenite to elemental selenium in dilute solution according to the reaction

$$2H^+ + 2NH_2OH + SeO_3^{=} \rightarrow Se\downarrow + N_2O\uparrow + 4H_2O.$$

Five grams of sodium selenite were dissolved in 50 ml of water, and enough hydroxylamine hydrochloride (~0.04 g) in solution was added to slowly precipitate about 1% of the total selenium present. After 2 days, this precipitate was separated from the solution with a centrifuge. The remaining 99% of the selenium was then precipitated with excess hydroxylamine hydrochloride and separated. The Se^{82}/Se^{76} ratios for these two samples were then compared after fluorination to SeF_6.

Mass Spectrometry

In the normal electron bombardment of SeF_6, the most abundant ion species is SeF_5^+. Therefore, a 6-in. radius, 90° mass spectrometer was equipped with two collector slits for the simultaneous collection of $Se^{76}F_5^+$ and $Se^{82}F_5^+$ ions. The well-known null method of recording was used where a measured portion of the voltage produced by the one ion current is fed back inversely to cancel the voltage produced by the other ion current.

The sample handling system was of monel construction and entirely free of grease and mercury, which were found to produce contaminations. This system allowed two samples to be alternately introduced

into the mass spectrometer under identical conditions. Usually, 5 minutes were required to switch these samples and in this operation, parts of the line used in common by both samples were evacuated and flamed. No difficulties with memory effects were experienced. Up to three continuous recordings of each sample were made in an hour. With this method of comparison, measurements of the ratio in two samples, within a single run, could be obtained with a standard deviation of ± 0.0005. The same reproducibility could be obtained also for comparisons of the same samples on different days and for different chemical extractions from the same natural sample.

Experimental Results

Table IV and Fig. 1 summarize the selenium isotope abundance data obtained for a variety of natural samples.

In view of the remarkable uniformity in the S^{32}/S^{34} ratio in meteorites of all types (15, 19, 20) and the considerable evidence that this ratio represents the primordial ratio of sulphur isotopes in terrestrial sulphur, it seemed reasonable in the first instance to assume that the selenium extracted from troilite in the Canyon Diablo meteorite represents the primordial ratio of the selenium isotopes. The Canyon Diablo meteorite sample was therefore used as a primary standard and a sample of selenium from Noranda was used as a secondary standard because of the small amount of meteoritic selenium available.

In Table IV and Fig. 1, δ_{82} is the enrichment of Se^{82} in ‰ defined by

$$\delta_{82} = \frac{Se^{82}/Se^{76}\text{ sample} - Se^{82}/Se^{76}\text{ meteoritic}}{Se^{82}/Se^{76}\text{ meteoritic}} \times 1000.$$

TABLE IV

Variations of the Se^{82}/Se^{76} ratio in natural samples

Sample No.	Location	Alleged type of deposit	δ_{82} (‰)
1	Canyon Diablo meteorite	Selenium in troilite	0.000
2	Noranda, Quebec	Hypothermal or magmatic hydrothermal massive sulphide	+0.5±0.5
3	Murdochville, Quebec	Hypothermal or magmatic hydrothermal massive sulphide	+1.0±0.5
4	Flin Flon, Manitoba	Hypothermal or magmatic hydrothermal massive sulphide	+0.5±0.5
5	Sudbury, Ontario	Molten magma or igneous origin	+0.5±0.5
6	Mt. Lyell, Australia	Mesothermal	−1.0±1.0
7	Mt. Wingen, N.S.W.	Selenium precipitated below a pyrite bed	−1.0±1.0
8	Beaverlodge Lake, Saskatchewan	Umangite ($Cu_3SeCuSe$) in hydrothermal pitchblende bearing sulphide vein	0.0±0.5
9	Beaverlodge Lake, Saskatchewan	Chalcomenite ($CuSeO_3.2H_2O$) in association with No. 8	+0.5±0.5
10	Unknown	Refined selenium, Phelps Dodge Refining Corp., New York	+0.5±0.5
11	Unknown	Refined selenium, American Smelting and Refining Co.	+0.5±0.1
12	Unknown	Commercial SeF_6, Allied Chemical and Dye Corp., Baton Rouge, Louisiana; selenium was purchased from Company in No. 11.	+0.5±0.5
13	Southwestern U.S.A., exact location unknown	*Astragalus bisulcatus* plant containing selenite and complex organic selenium compounds	+2.0±0.5
14	Southwestern U.S.A., exact location unknown	*Astragalus pattersoni* plant containing selenite and complex organic selenium compounds	−11.0±1.0
15	County Meath, Ireland	Soil sample containing selenite and complex organic selenium compounds	+4.0±0.5
16	Mt. Shirane, Japan	Elemental selenium in volcanic sulphur	−2.0±1.0

Table V summarizes the results obtained on three reductions of Na_2SeO_3 to elemental selenium at 3° C.

TABLE V

Fractionation in reduction of sodium selenite to elemental selenium

Run	R
1	1.014
2	1.016
3	1.016
Average	1.015±0.001

The isotope effect which occurred in the 1% reaction is expressed by

$$R = \frac{Se^{76}/Se^{82} \text{ reduced Se (1\%)}}{Se^{76}/Se^{82} \text{ remainder of solution (99\%)}}.$$

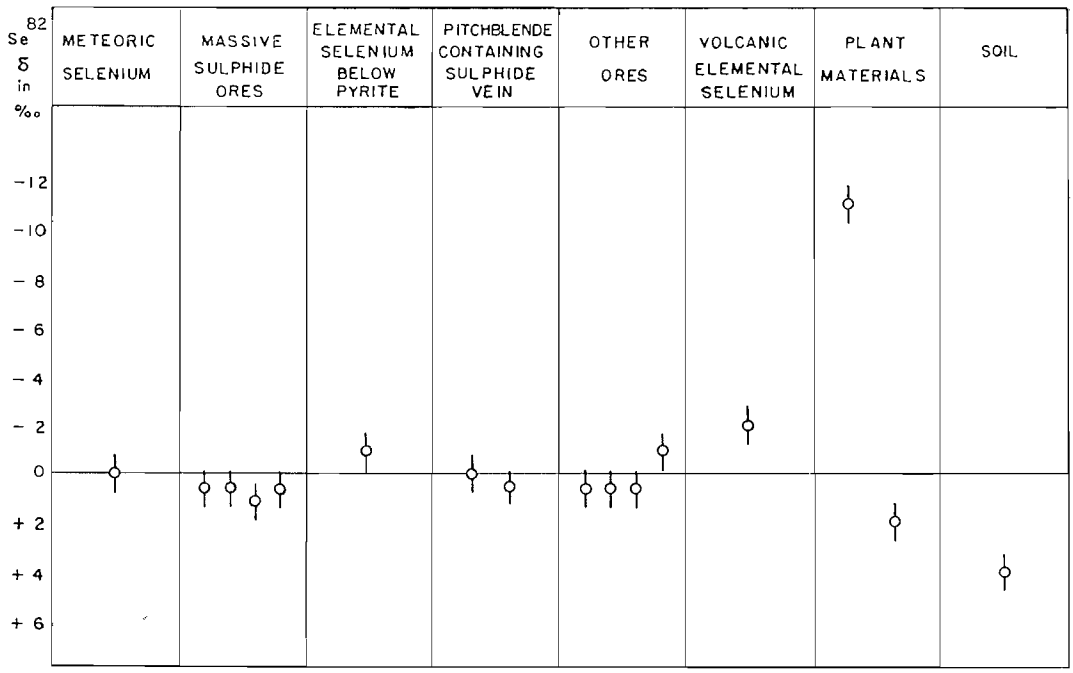

FIG. 1. Variations in the Se^{82}/Se^{76} ratio found for natural samples.

DISCUSSION AND CONCLUSIONS

Isotope Distribution in Nature

It is obvious from the theoretical study (Table III) that Se^{76} and Se^{82} differ in their chemical properties to the extent that isotope fractionations of up to 6% are predicted for Se^{76}–Se^{82} equilibrium exchange processes, provided that mechanisms are available for such exchanges.

Table IV and Fig. 1 show that the Se^{82}/Se^{76} ratio in the natural samples examined varied by 1.5%. The selenium samples from plant materials and soil show the largest variations to both sides of the meteoritic value, whereas selenium in massive sulphide ores shows little or no deviation from the meteoritic selenium value.

It is interesting to compare these selenium isotope results with similar results obtained in sulphur isotope studies.

There is an indication that the selenium extracted from massive sulphide ores is slightly enriched in the heavy isotope Se^{82} ($\delta_{82} = +0.5‰$). The effect in the case of sulphur is more pronounced. For example, samples of Sudbury igneous ore have been found enriched by 0.5 and 2.5‰ in Se^{82} and S^{34} respectively, the meteoritic values being taken as standard in each case (21).

The Se^{82}/Se^{76} ratio for volcanic elemental selenium from Mt. Shirane, Japan, is, of course, not indicative of the average value of the selenium in this volcano, since selenium is also present in other compounds. Since the theoretical study indicates that fractionation of selenium isotopes is possible between such compounds in volcanic gases, the depletion of Se^{82} ($\delta_{82} = -2‰$) found would indicate that such a fractionation occurred in this volcanic sample. Elemental sulphur from the same location is also depleted in the heavy isotope S^{34} ($\delta_{34} = -5‰$) (Sakai *et al.* 22).

The sample from Beaverlodge Lake, Saskatchewan, which contains umangite (Cu_2Se-CuSe) and chalcomenite ($CuSeO_3.2H_2O$) (samples 8 and 9, Table IV), is considered to

have been derived from primary sulphide ore as the selenide and subsequently partially oxidized (Robinson (23)). The results found show that little or no fractionation of the selenium isotopes occurred in this natural oxidation process.

The variations found in the Se^{82}/Se^{76} ratio for selenium extracted from plant material and soils indicate large isotope effects which have occurred probably in oxidation and reduction processes in biological systems. It is now fairly well established that the major portion of sulphur isotope fractionation in biological systems occurs in the bacterial reduction of sulphate (Thode *et al.* (24, 25)). In addition to reducing sulphates, anaerobic bacteria are known to reduce selenates and selenites as well, and these might provide a mechanism for fractionation of the selenium isotopes.

Equilibrium Isotope Effects

The fractionations in the Se^{82}/Se^{76} ratio is not expected to be as high as that found in the S^{34}/S^{32} ratio for two reasons:

(1) From statistical mechanics, the partition function ratios are lower, e.g., for $S^{34}O_4^{=}/S^{32}O_4^{=}$, $Q_2'/Q_1' = 1.088$ at 25° C; while for $Se^{82}O_4^{=}/Se^{76}O_4^{=}$, $Q_2'/Q_1' = 1.038$ at 25° C.

(2) The potential for oxidizing elemental selenium to the +6 valence state is quite high ($Se \rightarrow H_2SeO_4$ −1.89 volts) in comparison to that of sulphur ($S \rightarrow H_2SO_4$ −0.58 volts). For this reason, sulphates are abundant in nature, while selenates are rarely found. Since isotope effects are higher in equilibrium exchanges if a greater valence change is involved (See Table III), the above fact further lowers the natural isotope fractionation expected with selenium in comparison to sulphur.

Kinetic Isotope Effects

It has been found in studies of kinetic isotope effects in the bacterial reduction of sulphate that, while the fractionation varies with the metabolic rate, the maximum value obtained at low metabolic rates approaches that obtained in a direct chemical reduction (Harrison and Thode (25, 26)). For this reason, the isotope effect found in the reduction of selenite is of importance. The results (Table V) indicate a kinetic isotope effect of $(R-1)\times 100 = 1.5\%$ in the chemical reduction of selenite to elemental selenium.

The question may arise about whether this is a true kinetic effect in which case $R = k_1/k_2$ for

$$Se^{76}O_3^{=} \xrightarrow{k_1} Se^{76}$$

$$Se^{82}O_3^{=} \xrightarrow{k_2} Se^{82}$$

or whether some isotopic exchange of selenium has also occurred between the reactant and the product in the course of the experiment. Such an exchange would result in a gradual increase of $(R-1)$ since the equilibrium isotope constant for the exchange

$$Se^{76}O_3^{=} + Se^{82} \rightleftharpoons Se^{82}O_3^{=} + Se^{76}$$

would be considerably larger than 1.015. In this connection, Haissinsky and Pappas (27) observed with tracer experiments that amorphous selenium exchanges with its ions in a 5.5 *N* HCl solution 0.1 *M* with respect to SeO_2. The rate was found to increase with acid concentration approaching 40% in 1 hour at 10 *N* HCl. Since this exchange was found to take place only at high acid concentrations, it would seem that a true kinetic isotope effect was observed in the almost neutral dilute solutions of the present work.

The kinetic isotope effect for the reduction of selenite to elemental selenium could be calculated using the equation of Bigeleisen (9) if the isotopic vibrational frequencies were known for the selenite ion and the activated complex. The former is currently being

calculated, while the latter is unknown. The analogous reduction of sulphates indicated that the rate-controlling step is the initial S—O bond breakage. If the rate-controlling step in the reduction of selenites is assumed to be the initial Se—O bond breakage, a simple calculation can be made by considering a Se—O diatomic model whose bond is completely broken in the activated complex. With this model, k_1/k_2 from the Bigeleisen equation is found to be 1.015 and 1.014 at 0° C and 25° C respectively. In view of the simple model assumed, the close agreement with the experimental value indicates only that the result is of the order expected.

ACKNOWLEDGMENTS

We wish to thank the following people, who have supplied samples for this investigation: E. P. Henderson, Smithsonian Institution; O. A. Beath, University of Wyoming; G. A. Fleming, The Agricultural Institute, Ireland; S. C. Robinson, Geological Survey of Canada; M. Shima, McMaster University; W. C. Cooper, Canadian Copper Refineries, Montreal; Austin Smith, International Nickel Co.; H. Barkell, Phelps Dodge Refining Corp., N.Y.; H. M. Murray, Mount Lyell Mining and R. R. Co. Ltd., Australia; A. F. Evans, Electrolytic Refining and Smelting Co. of Australia.

Thanks are also due to Dr. R. H. Farquhar, who, several years ago, investigated sample preparation methods and made some preliminary calculations of selenium isotope exchange constants. Finally, we wish to acknowledge financial support from the National Research Council of Canada, without which this investigation would not have been possible.

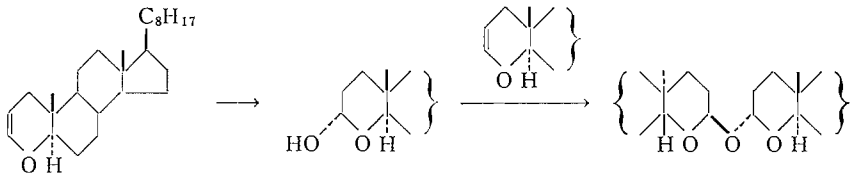
NOTES

DI-(4-OXA-5α-CHOLESTAN-3α-YL) ETHER

J. T. Edward and I. Puskas

Solutions in water-saturated ether of 4-oxa-5α-cholest-2-ene (I) (1), recovered from experiments carried out at different times, were stored in an unstoppered flask at room temperature. The gradual evaporation of the solvent caused the deposition of a solid which, after purification, melted at 205–208° and analyzed as $C_{52}H_{90}O_3$ (i.e. two molecules of I and H_2O). This compound must be di-(4-oxa-5α-cholestan-3α-yl) ether (III), formed



I II III

by hydration of the unsaturated ether (I) to give 4-oxa-5α-cholestan-3α-ol (II) (1), followed by reaction of the latter with a second molecule of I. This second reaction was employed (with a trace of acid as a catalyst) in a more deliberate synthesis of the compound.

Similar results have been obtained in the acid-catalyzed hydration of dihydropyran (2), analogues of II or III being obtained according to conditions.

On hydrolysis with aqueous acid in tetrahydrofuran solution the ether (III), m.p. 205–208°, yielded 4-oxa-5α-cholestan-3α-ol.

Arguments based on optical rotations indicate for the ether the 3α,3′α configuration shown in III. It seems likely (3, 4) that conversion of 4-oxa-5α-cholestan-3α-ol into a 3α- or 3β-alkoxy derivative is accompanied by shifts in molecular rotation of the same sign and of about the same magnitude as those accompanying the conversion of α-D-glucose into the corresponding alkyl α- or β-D-glucoside (1). The conversion of two molecules of α-D-glucose into a molecule of α,α′-trehalose is accompanied by a shift of +271° (both rotations measured in water (5)), fairly close to the difference (+386°, both measurements for chloroform solutions) between the molecular rotation of the ether (III) and of two molecules of 4-oxa-5α-cholestan-3α-ol. The formation of α,β′- and of β,β′-trehalose from two molecules of α-D-glucose involves shifts of −62° and −537° respectively (5).

EXPERIMENTAL

Di-(4-oxa-5α-cholestan-3α-yl) Ether

(a) From 4-Oxa-5α-cholest-2-ene

Ether solutions of 4-oxa-5α-cholest-2-ene were stored in an uncovered flask. The residue, after evaporation of the ether, was recrystallized several times from petroleum ether (b.p. 65–75°), giving *shining plates* melting at 205–208° (apparatus preheated to 190°; m.p. affected by rate of heating); $[\alpha]_D^{23}$ +116° (*c*, 1.30 in chloroform); $\nu_{max}^{CCl_4}$ in cm^{-1} (molar extinction coefficients in parentheses): 2930 (1120), 2860 (620), 1470 (300), 1449 (250), 1385 (235), 1370 (187), 1357 (156), 1339 (127), 1325 (108), 1161 (172), 1143 (313), 1123 (230), 1102 (245), 1092 (240), 1064 (425), 1052 (356), 1032 (520), 947 (236), 935 (233), 914 (104), 899 (142). Calc. for $C_{52}H_{90}O_3$: C, 81.82; H, 11.89%; mol. wt., 763. Found: C, 81.65; H, 11.67; mol. wt., 754 (Rast).

(b) From Reaction of 4-Oxa-5α-cholestan-3α-ol with 4-Oxa-5α-cholest-2-ene

A solution of 4-oxa-5α-cholestan-3α-ol (30 mg) and 4-oxa-5α-cholest-2-ene (30 mg) in anhydrous ether (5 ml) containing a trace of hydrogen chloride was allowed to evaporate at room temperature. The residue was recrystallized from ligroin, and the crystals were washed with ethyl acetate; the remaining solid (7 mg) was shown by melting point and infrared spectrum to be identical with the compound obtained above.

Hydrolysis of Di-(4-oxa-5α-cholestan-3α-yl) Ether

A solution of di-(4-oxa-5α-cholestan-3α-yl) ether (43 mg), water (20 drops), and concentrated aqueous hydrochloric acid (2 drops) in tetrahydrofuran (5 ml) was refluxed for 1 hour. The solvent was removed at reduced pressure, and the residue taken up in ether, washed with water, and dried over sodium sulphate. Evaporation of the ether left a crystalline solid (42 mg), m.p. 120–135°, shown to contain 4-oxa-5α-cholestan-3α-ol by its infrared spectrum. Recrystallization from methanol raised the melting point to 179–182° (28 mg), undepressed by admixture with authentic material.

ACKNOWLEDGMENTS

We are grateful to the National Research Council for a Studentship (to I. P.) and for financial support of the research, and to Miss D. J. Holder for a supply of 4-oxa-5α-cholest-2-ene.

STEROIDS

III. 12-METHYLENEPROGESTERONE

George Just and R. Nagarajan

We wish to report the synthesis of 12-methyleneprogesterone and an alternative route for the preparation of 12-hydroxy-12-methylpregnane derivatives (1, 2).

Partial succinylation of 3α,12α-dihydroxypregnane-20-one (I) at the 3-position (3, 4), and methylation of the hemisuccinate with diazomethane afforded the methyl succinate I*b*. Ketalization of the methyl succinate I*b* at the 20-position, followed by oxidation of the ketal II with chromium trioxide in pyridine (5) afforded 3α-hydroxypregnane-3,20-dione 20-ethylene ketal methyl succinate (III). This was a suitable intermediate for the introduction of a methyl group at C_{12}, and accordingly the 12-ketone III was reacted with an eightfold excess of methyl magnesium iodide. The Grignard reaction product was treated with *p*-toluene sulphonic acid and acetone, and then with methanolic potassium hydroxide to hydrolyze the ketal and methyl succinate groups respectively. The hydrolyzed product was oxidized with chromium trioxide and chromatographic separation of the oxidation product on alumina afforded the epimeric 12-methyl-12-hydroxypregnan-3,20-diones IV and V (1, 2). The yields of the 12α-alcohol IV and 12β-alcohol V were 25% and 12% respectively, for the reaction sequence III → IV + V. In accordance with our previously published results (1, 2), the 12α-alcohol IV was the major product.

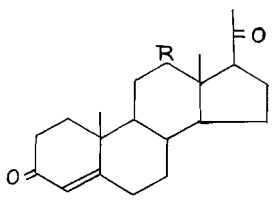
VII $R = =CH_2$

VIIa $R = =O$



VIII $R = \begin{matrix} OH \\ CH_3 \end{matrix}$

VIIIa $R = =CH_2$

VIIIb $R = \begin{matrix} OCOCH_3 \\ CH_3 \end{matrix}$

Dehydration of the epimeric hydroxy ketones IV and V with phosphorus oxychloride and thionyl chloride in pyridine (6, 7) was unsuccessful. However, treatment of the hydroxy ketone V with acetic acid, acetic anhydride, and *p*-toluene sulphonic acid gave a 53% yield of the 12-methylene compound VII. It had been observed that the epimeric hydroxy ketone IV under similar reaction conditions also affords a 53% yield of the exo olefin VII (2).

Since Δ''-dehydroprogesterone exhibits high progestational activity (8), the effect of the incorporation of a 12,12*a*-double bond by introduction of a methylene group at C_{12} to the parent hormone seemed a worth-while investigation. Consequently, the progesterone

analogue VIII (1) was dehydrated with acetic acid, acetic anhydride, and *p*-toluene sulphonic acid to 12-methyleneprogesterone, VIII*a*. A minor product was obtained as an oil and it was assigned the 12α-acetoxy-12β-methylprogesterone configuration VIII*b* since its infrared spectrum showed absorption bands characteristic of an acetate group, and also because the analogous reaction of 12α-hydroxy-12β-methylpregnane-3,20-dione (IV) with acetic acid, acetic anhydride, and *p*-toluene sulphonic acid gave the exo olefin VII and the 12α-acetate IV*a* (2).

Preliminary biological tests of the two progesterone analogues VIII*a* and VIII*b* did not exhibit any notable progestational, androgenic, diuretic, hypotensive, or anabolic properties.[1]

EXPERIMENTAL[2, 3, 4, 5]

3α,12α-Dihydroxypregnan-20-one 3-Methyl Succinate (Ib) (4)

To a solution of the diol I (12.2 g, m.p. 164–167°; crude product obtained by alkaline hydrolysis of 15.0 g of the diacetate I*a*) in pyridine (125 ml) was added succinic anhydride (32.5 g); the resulting solution was heated at 90° for 2 hours and left at room temperature for 12 hours. The reaction mixture was extracted with ether. The organic layer was washed with 2 *N* hydrochloric acid, water, and then dried over magnesium sulphate. The ethereal solution was methylated with diazomethane. Crystallization from acetone–hexane afforded 13.427 g of the methyl succinate I*b* (4), m.p. 125–127° (yield 84%).

3α,12α-Dihydroxy-20-pregnanone Ethylene Ketal 3-Methyl Succinate (II)

To a solution of 8.99 g of the methyl succinate I*b* in absolute benzene (200 ml) was added ethylene glycol (20 ml) and *p*-toluene sulphonic acid (100 mg), and the reaction mixture was heated at reflux temperature for 12 hours. The water that formed during the reaction was continuously removed. The reaction mixture was extracted with ether, the ethereal layer washed with sodium bicarbonate solution and then with water, until the washings were neutral, and dried over magnesium sulphate. Repeated crystallizations from ether–hexane afforded 3.92 g of broad needles of the ketal II, m.p. 181–184° (yield 40%).

Two crystallizations from ether–hexane raised the melting point of II to 182–184°, $[\alpha]_D^{27}$ 57° (*c* 1.01 in $CHCl_3$). Calc. for $C_{28}H_{44}O_7$: C 68.26, H 9.00; found: C 68.40, H 9.07.

3α-Hydroxy-12,20-pregnandione 20-Ethylene Ketal 3-Methyl Succinate (III)

A solution of 3.2 g of the ketal II in pyridine (36 ml) was added to a slurry of chromium trioxide (3.2 g) in pyridine (32 ml) with stirring and left at room temperature for 16 hours (5). The reaction mixture was poured into 500 ml of water and extracted with chloroform. The organic layer was washed with iced 2 *N* hydrochloric acid, 5% sodium bicarbonate solution, and water, until the washings were neutral. The chloroform solution was dried over magnesium sulphate and evaporated to about 40 ml. On addition of 20 ml of hexane, the ketone III crystallized as needles, 2.404 g, m.p. 239–240°. The mother liquors on crystallization from methylene chloride – hexane afforded 0.364 g, m.p. 237–239° (yield 98%).

Recrystallization of the ketone III for analysis did not raise the melting point, $[\alpha]_D^{27}$ 96° (*c* 0.78 in $CHCl_3$). Calc. for $C_{28}H_{42}O_7$: C 68.55, H 8.63; found: C 68.64, H 8.65.

Reaction of Methyl Magnesium Iodide with 3α-Hydroxy-12,20-pregnandione 20-Ethylene Ketal 3-Methyl Succinate (III)

To 300 ml of an ethereal solution of methyl magnesium iodide (from 700 mg of magnesium and 2.0 ml of methyl iodide) was added with stirring a solution of 1.0 g of the ketone III in benzene, and the resulting mixture was heated at reflux temperature for 18 hours. A solution of ammonium chloride (20 g) in water (500 ml) was added to the reaction mixture. The usual extraction procedure afforded 930 mg of an oil.

To a solution of the Grignard adduct (930 mg of oil) in 50 ml of acetone was added with stirring 75 mg of *p*-toluene sulphonic acid and the reaction mixture left at room temperature for 22 hours. Ether extraction afforded 884 mg of an oil. An infrared spectrum analysis of the oil showed a strong absorption band at 1707 cm^{-1} (C_{20}-ketone), and a weak absorption band at 1725 cm^{-1} (C_3-methyl succinate).

A solution of this oil in 25 ml of 5% methanolic potassium hydroxide was heated at reflux temperature for 45 minutes. The usual extraction procedure afforded 735 mg of foam. It was dissolved in 10 ml of acetic

[1]*Biological tests were carried out by Drs. C. I. Chappel and C. Revesz of Messrs. Ayerst, McKenna and Harrison Ltd., Montreal, Que.*

[2]*All melting points are corrected.*

[3]*Only the best yields obtained were reported.*

[4]*The commercially available aluminum oxide (Woelm) was used for chromatography.*

[5]*The microanalyses were carried out by Dr. A. Bernhardt, Mülheim, Germany, and Dr. C. Daessle, 5757 Decelles St., Montreal, Que.*

acid, and to it was added with stirring a solution of 250 mg of chromium trioxide in 3 ml of 90% acetic acid. The reaction mixture was left at room temperature for 12 hours. Ether extraction afforded 740 mg of oil, and it was chromatographed on 23 g of alumina (4.5% water).

The hexane–benzene (1:1) eluates on crystallization from acetone–hexane afforded 106 mg of the trione VII*a* (1, 9), m.p. 197–199°, identified by mixed melting point and comparison of infrared spectra with an authentic sample. Crystallization of mother liquors from acetone–hexane gave 21 mg, m.p. 192–197°.

The first half of the benzene fractions on crystallization from ether–hexane afforded 67 mg of the hydroxy ketone V, m.p. 123–124°.

The rest of the benzene eluates and the benzene–ether (9:1, 4:1) fractions on crystallization from acetone–hexane afforded 80 mg of the hydroxy ketone IV, m.p. 187–188°. Crystallization of mother liquors gave 29 mg, m.p. 184–187°.

The ether–methanol (9:1) eluates on crystallization from acetone–hexane afforded 34 mg of needles of 3α,12α-dihydroxy-12β-methylpregnan-20-one (VI), m.p. 225–259°. Recrystallization from acetone–hexane raised the melting point to 228–230°, $[\alpha]_D^{27}$ 106° (*c* 0.74 in $CHCl_3$). Calc. for $C_{22}H_{36}O_3$: C 75.80, H 10.41; found: C 75.96, H 10.07.

Chromium trioxide oxidation of the hydroxy ketone VI (10 mg) afforded 3 mg of the hydroxy ketone IV, m.p. 186–188°, identified by mixed melting point and comparison of infrared spectra with an authentic sample (1).

Taking into consideration the unreacted ketone III (isolated as the trione VII*a*), the yields of 12α-alcohol IV and 12β-alcohol V were 25% and 12% respectively.

12-Methylenepregnan-3,20-dione (VII) from 12α-Methyl-12β-hydroxypregnan-3,20-dione (V)

To a solution of 330 mg of the hydroxy ketone V in 25 ml of acetic acid were added 5 ml of acetic anhydride and 330 mg of *p*-toluene sulphonic acid monohydrate (10), and the suspension was stirred until the solid dissolved. The reaction mixture was left at room temperature for 4 hours, then poured into 500 ml of iced water. After 30 minutes, the usual extraction procedure afforded 390 mg of an oil which showed absorption bands in the infrared at 3080 cm^{-1}, 1645 cm^{-1}, 890 cm^{-1} ($>C=CH_2$) (11); 1755 cm^{-1}, 1218 cm^{-1} ($\Delta^{17(20)}$-enol acetate) (12); 1713 cm^{-1} (3-ketone). Under the above reaction conditions the $\Delta^{17(20)}$-enol acetate is known to be formed (2, 13). The enol acetate (390 mg of oil) was converted to the C_{20}-ketone by heating a solution of it in 30 ml of methanol and 700 mg of potassium carbonate in 10 ml of water at reflux temperature for 2 hours. Ether extraction afforded 360 mg of product showing no bands at 1750 cm^{-1} and 1218 cm^{-1} characteristic of enol acetates, and it was chromatographed on 10 g of alumina (4.5% water). The hexane–benzene (4:1, 1:1) eluates containing the olefin VII[6] crystallized from ether–hexane as needles, 134 mg, m.p. 89–90°. Crystallization of mother liquors afforded 33 mg, m.p. 89–90° (yield 53.4%).

A portion of the olefin VII was recrystallized from ether–hexane for analysis, m.p. 89–90°, $[\alpha]_D^{27}$ 133° (*c* 1.02 in $CHCl_3$), $\nu_{max}^{CS_2}$ 3075 cm^{-1}, 1645 cm^{-1}, 888 cm^{-1} ($>C=CH_2$); 1713 cm^{-1} (3,20-ketone). Calc. for $C_{22}H_{32}O_2$: C 80.41, H 9.82; found: C 80.18, H 9.84.

The benzene and benzene–ether eluates on crystallization from acetone–hexane afforded 56 mg of leaflets of IV*a* (1), m.p. 175–176° (yield 15.1%).

12-Methyleneprogesterone (VIIIa) and 12β-Methyl-12α-acetoxyprogesterone (VIIIb)

According to the procedure previously described by us (1), 900 mg of the hydroxy ketone IV was transformed to the progesterone analogue VIII. Crystallization from ether–hexane afforded 330 mg of VIII, m.p. 152–153°. The mother liquors (590 mg) were chromatographed on 17 g of alumina (4.5% water). The benzene and benzene–ether eluates on crystallization from ether–hexane afforded 160 mg of the progesterone analogue VIII, m.p. 152–153°. Crystallization of mother liquors afforded 51 mg, m.p. 135–142° (yield 61%).

In a solution of the progesterone analogue VIII (475 mg, m.p. 152–153°) in 25 ml of acetic acid and 5 ml of acetic anhydride was dissolved 475 mg of *p*-toluene sulphonic acid with stirring. The reaction mixture was left at room temperature for 2 hours. Ether extraction afforded 540 mg of an oil, and it was dissolved in 25 ml of methanol. To the methanol solution was added 750 mg of potassium carbonate dissolved in 10 ml of water and the reaction mixture was heated at reflux temperature for 2 hours. The usual extraction procedure afforded 520 mg of an oil, which was chromatographed on 15 g of alumina (4.5% water). The

[6]*In our previous publication it was concluded that the compound with m.p. 100–101° was the olefin VII and the compound with m.p. 73–74° contained mainly the exo olefin with probably traces of the endo olefin (2). It now seems that all the three forms melting at 73–74°, 89–90°, and 100–101° are different polymorphic forms of the olefin VII on the basis of the following evidence: A mixed melting point of the two forms of olefin VII melting at 73–74° and 89–90° on a Kofler block showed the form melting at 73–74° melted at the latter temperature, but crystallized on further raising the temperature, and the whole mass melted at 89–90°. The two forms of olefin melting at 89–90° and 100–101° were melted side by side, and the molten mass was seeded with a crystal of the form melting at 89–90°, and cooled. The whole mass melted at 89–90°. Furthermore, the infrared spectra and the rotations of the three forms were identical within experimental error.*

hexane–benzene (4:1, 1:1) and benzene eluates on crystallization from ether–hexane afforded 121 mg of cubic crystals of 12-methyleneprogesterone, VIII*a*,[7] m.p. 104–105° (yield 27%). Two recrystallizations from ether–hexane raised the melting point to 105–106°, $[\alpha]_D^{27}$ 189° (*c* 0.92 in $CHCl_3$), λ_{max}^{EtOH} 240 mμ (ε 18,500). $\nu_{max}^{CCl_4}$ 3070 cm^{-1}, 1643 cm^{-1}, 890 cm^{-1} (>CH=CH$_2$); 1707 cm^{-1} (20-ketone); 1675 cm^{-1}, 1617 cm^{-1} (Δ^4-3-ketone). Calc. for $C_{22}H_{30}O_2$: C 80.91, H 9.25; found: C 80.70, H 9.05.

The benzene–ether eluates afforded 210 mg of an oil which resisted crystallization. Its infrared spectrum showed absorption bands at 1727 cm^{-1} (12-acetate); 1705 cm^{-1} (20-ketone); 1675 cm^{-1}, 1617 cm^{-1} (Δ^4-3-ketone). It was tentatively assigned the 12β-methyl-12α-acetoxyprogesterone configuration VIII*b* on the basis of its infrared spectrum, and from the analogous reaction that 12β-methyl-12α-hydroxypregnan-3,20-dione with acetic acid, acetic anhydride, and *p*-toluene sulphonic acid gives 12β-methyl-12α-acetoxypregnan-3,20-dione as the minor product of the reaction (2).

PREPARATION OF ALUMINUM *tert*-ALKOXIDES

M. S. Bains*

The alcohol interchange method for the preparation of aluminum alkoxides has been mentioned by various workers (1, 2) and was used elegantly by Mehrotra (3, 4) in preparing pure primary and secondary aluminum alkoxides for studying their physical properties. It was claimed that repeated attempts to obtain aluminum *tert*-butoxide and aluminum *tert*-amyloxide from aluminum isopropoxide by the interchange method failed since the third isopropoxide group did not interchange. Steric hindrance was considered the main cause for this failure of complete interchange and consequently for steric reasons the dimeric nature of these mixed alkoxides was proposed through isopropoxide bridges as

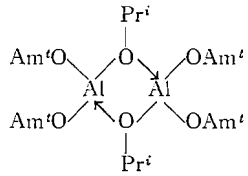
(I)

and



(II)

However, aluminum *tert*-butoxide could be prepared by direct action of *tert*-butanol on aluminum (5), but aluminum *tert*-amyloxide could not be obtained by this method.

Nevertheless, in the present research, attempts to prepare aluminum monoisopropoxide di-*tert*-butoxide, $Al(OPr^i)(OBu^t)_2$, by the interchange method resulted in the formation of aluminum tri-*tert*-butoxide and it was very difficult to prepare the pure mixed alkoxide in one operation. Found: Al, 10.91, 10.90%; $Al(OBu^t)_3$ requires: Al, 10.95%.

The interchange of aluminum isopropoxide with *tert*-amyl alcohol or diethylmethyl carbinol gave the hitherto unknown aluminum *tert*-amyloxide, $Al(OAm^t)_3$, or aluminum diethylmethylcarbinoloxide, $Al(OCMeEt_2)_3$, respectively. The former compound was sublimed at 130–135° C bath temperature under 0.02–0.03 mm pressure and the latter was sublimed at 155° C under the same pressure. The analysis for aluminum was as follows:

	Aluminum analysis		
Compound	Found		Calculated
$Al(OAm^t)_3$	9.3	9.35	9.37
$Al(OCMeEt_2)_3$	8.3	8.4	8.20

Since the higher tertiary alcohols are extremely sensitive to acids it is important that the reagents should be freed from acidic impurities. The apparatus should be washed with alkali and rinsed with distilled water before it is dried and used. The temperature of the heating bath for reflux purposes should be kept as low as possible and under no circumstances should a heating mantle be used since it may cause overheating.

A careful study of the literature (4, 6, 7) shows that in the preparation of aluminum *tert*-alkoxides by transesterification there is no evidence that the interchange of the third alkoxide group is hindered. Even Mehrotra's own results (4) show that in one of his interchange reactions, the ratio of Pr^iO:Al is 0.81 in the unsublimed material. Still he seems to draw a parallelism in his publications (4, 6) with previous work on zirconium alkoxides (9) and believes that the shielding effect of *tert*-alkoxide groups (I and II) hindered the co-ordination of *tert*-butanol for further interchange. In fact, it appears that, in his experiments, insufficient time was allowed for interchange to reach completion. Some preliminary experiments on alcohol interchange have further shown that even at a lower temperature (36° C) the interchange was approaching completion in the case of aluminum isopropoxide and *tert*-butyl alcohol.

Furthermore, the proton magnetic resonance spectrum (8) of the mixed alkoxide, $Al(OPr^i)(OBu^t)_2$, revealed resonances corresponding to two distinguishable isopropoxide groups and two *tert*-butoxide groups, quantitatively in accordance with the participation of both alkoxide groups in bridging. This indicates that the steric factors involved are not strong enough to prevent the *tert*-butoxide groups from bridging. Moreover, the fact that aluminum *tert*-butoxide is dimeric supports this conclusion since, in this compound, the bridging must of necessity involve the *tert*-butoxide groups.

The details of this work will be published in due course.

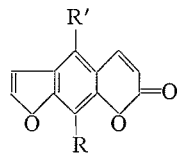
FURANOCOUMARINS OF PHELLOPTERUS LITTORALIS*

Chao-Hwa Yang† and Stewart A. Brown

Phellopterus littoralis Benth. has been reported by Noguchi and Kawanami (1) to contain the furanocoumarin pheleopterin (I*a*) in the fruit. Our interest in the biosynthesis of coumarins led us to initiate a preliminary extraction study of the coumarins in this species. This note reports the identification of bergapten (I*b*) and the tentative identification of imperatorin (I*c*) in extracts of greenhouse-grown plants, as well as the presence



Structure I

(*a*) R = $OCH_2CH{=}C(CH_3)_2$; R′ = OCH_3
(*b*) R = H; R′ = OCH_3
(*c*) R = $OCH_2CH{=}C(CH_3)_2$; R′ = H

of still-unidentified coumarins, but the failure to confirm the presence of phellopterin. The first two coumarins have not been found previously in this species. Evidence for the presence of imperatorin in *Phellopterus* plants up to the early fruiting stage was found, but when an attempt was made to confirm its presence in older plants imperatorin could not be detected, and instead the fruits, and probably the roots as well, contained bergapten. The Japanese authors gave no information about their source plants except the location of collection, but the present observations suggest that the stage of growth is an important factor controlling the nature of the coumarin pattern in this species.

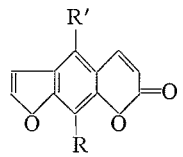
FURANOCOUMARINS OF PHELLOPTERUS LITTORALIS*

Chao-Hwa Yang† and Stewart A. Brown

Phellopterus littoralis Benth. has been reported by Noguchi and Kawanami (1) to contain the furanocoumarin pheleopterin (I*a*) in the fruit. Our interest in the biosynthesis of coumarins led us to initiate a preliminary extraction study of the coumarins in this species. This note reports the identification of bergapten (I*b*) and the tentative identification of imperatorin (I*c*) in extracts of greenhouse-grown plants, as well as the presence



Structure I

(*a*) R = $OCH_2CH{=}C(CH_3)_2$; R′ = OCH_3
(*b*) R = H; R′ = OCH_3
(*c*) R = $OCH_2CH{=}C(CH_3)_2$; R′ = H

of still-unidentified coumarins, but the failure to confirm the presence of phellopterin. The first two coumarins have not been found previously in this species. Evidence for the presence of imperatorin in *Phellopterus* plants up to the early fruiting stage was found, but when an attempt was made to confirm its presence in older plants imperatorin could not be detected, and instead the fruits, and probably the roots as well, contained bergapten. The Japanese authors gave no information about their source plants except the location of collection, but the present observations suggest that the stage of growth is an important factor controlling the nature of the coumarin pattern in this species.

The tentative identification of imperatorin is based on paper chromatographic behavior and on the fact that all absorption maxima of the unknown coumarin and authentic

imperatorin are identical over the range of 220–340 mμ. Insufficient material was available for rigorous purification, and as authentic phellopterin was not obtainable, the possibility that the unknown is phellopterin has not been strictly eliminated. Imperatorin and phellopterin both melt at 102°.

The demonstration of bergapten, and probably imperatorin, in this species is of interest from the biosynthetic point of view because of the structural similarities of both these coumarins to phellopterin. However, any attempt to suggest definite pathways of biosynthesis on the basis of existing data would be premature.

EXPERIMENTAL

Coumarins of Roots

In the late summer of 1959 young *Phellopterus* plants, grown from seed, were transplanted to coarse quartz sand which was irrigated at intervals from below with "California" nutrient medium (2). The temperature of the greenhouse was maintained at 25.5° during the day and 17° at night. Toward the end of January, 1960, three plants were harvested and dried under reduced pressure below 40° to give a total of ca. 20 g of powdered roots and 40 g of powdered shoots. After separate ether extractions of the root and shoot residues in Soxhlet extractors, a lactone fraction was prepared from each extract by the method of Baerheim Svendsen and Ottestad (3), which involved successive removal of acidic, phenolic, and unsaponifiable fractions from the ether extracts. Paper-chromatographic study of the lactone fractions indicated the absence of coumarins in the shoot extract, but the root extract contained small amounts of coumarin-like compounds. Several weeks later a second extraction representing 120 g of dried plant yielded an additional lactone fraction, but this was contaminated with oily material. The oil was largely distilled onto a cold finger by several hours' heating at 90° at a pressure below 1 mm Hg, and the residue was passed through an alumina column with benzene as the eluent. Coumarins moved off the column in two bands which fluoresced yellow when viewed under ultraviolet light (3660 Å), each band yielding a very small amount of a white solid upon solvent removal. Characterization was carried out by chromatographic comparison on paper with authentic samples of furanocoumarins. The material in the major band closely resembled imperatorin in its chromatographic behavior and its appearance under ultraviolet illumination after being sprayed with 1% alcoholic potassium hydroxide.

Coumarins of Fruits

At the end of March, 1960, fresh green fruits (160 g) were extracted by disintegration with a convenient volume of hot ethanol in a Waring blendor, and filtered. After two additional extractions of the residue with hot 80% ethanol, the combined extracts were concentrated *in vacuo* and the aqueous residue submitted to continuous ether extraction. The lactone fraction from the ether extract was isolated as described above. Chromatography of the coumarin fraction on alumina (Woelm, Grade II, non-alkaline) with benzene effected a separation of three major bands. The fastest gave 2 mg of crystals which were recrystallized from ether as long, colorless needles with an ultraviolet absorption spectrum in ethanol identical with that of authentic imperatorin (maxima at 249 and 300 mμ, shoulders at 243 and 264 mμ). The R_f values and other behavior of these two compounds checked very well when they were compared in 15% acetic acid and in isopropanol–water (1:4) on paper. The unknown had, however, a melting range of 90–95° (imperatorin melts at 102°), and as too little remained for further purification, the identification must be considered only tentative.

The compound from the second band gave 14 mg of colorless crystals after two recrystallizations from ether, m.p. 64–65°. In ethanol it gave a simple absorption spectrum with only two maxima, at 246 and 287 mμ. Its identity was not established, but its low melting point and simple spectrum suggest that it may be a furanocoumarin with a long aliphatic chain joined to the nucleus in an ether linkage. The last band from the column yielded only 3 mg of colorless solid, which was not purified.

In an attempt to obtain the additional material necessary for unequivocal identification, fresh fruits totalling 2 kg were collected over a 2-month period (May–July), and stored in the frozen state until used. The isolation procedure was modified to avoid heating *in vacuo*, which has been reported (4) to cause migration of the aliphatic chain of imperatorin to form an artifact, alloimperatorin. Oily material was removed from the lactone fraction by passage through a cellulose column in 20% isopropanol. The isopropanol in the eluate was removed by concentration *in vacuo*, and the coumarins in the aqueous residue were recovered by continuous ether extraction. The individual coumarins were separated in benzene solution on an alumina column (Woelm, Grade III, non-alkaline). Contrary to the assumption that it would be imperatorin, the material from the fast-moving band in this experiment gave colorless crystals which melted sharply at 185°. Its ultraviolet absorption spectrum closely resembled that of bergapten. When mixed with authentic bergapten, it caused no lowering of the melting point. The root coumarin fraction isolated at this growth stage also showed evidence of the presence of bergapten.

THE THERMOSIPHON AS A SIMPLE CIRCULATING PUMP FOR GASES*

D. VAN DER AUWERA† AND R. A. BACK

In gas kinetics and related fields, there is often a need for an efficient means of circulating gases in a closed system. Most pumps used in the past have been of either a piston-and-valve or a rotary-impeller type. While these pumps are reasonably satisfactory for most purposes, they suffer certain disadvantages, such as low flowrates (limited by displacement), intermittent action (piston pumps), mechanical failure, and an almost complete loss of efficiency at pressures below 1 mm Hg. For the past 2 years we have been using a thermosiphon as a circulating pump in this laboratory, and it appears to have some advantages in these respects. We thought it worth while to describe its characteristics, and to point out some of its advantages and limitations.

The thermosiphon consisted of two parallel Pyrex tubes, 25-mm i.d. and 2.1 m long, mounted vertically, and joined at the top in a smooth U-bend. One tube could be heated electrically, while the other was cooled by tap water passing through a jacket. The lower ends of the thermosiphon were joined to the components completing the circulation system, which in this case comprised two U-traps about 30 cm long and a cylindrical photolysis cell of about 200-cc capacity. The traps and all connecting tubing were of 20-mm i.d.

Flowrates were measured by injecting a small quantity of a second gas into the system and following its passage around the circuit by means of a thermistor mounted in the gas stream and linked through a suitable bridge to a chart recorder. The mixing of the added gas was slow enough so that from 10 to 20 complete passages around the circuit, each marked by a sharp deflection of the recorder pen, were easily observed, and the volume flowrate calculated.

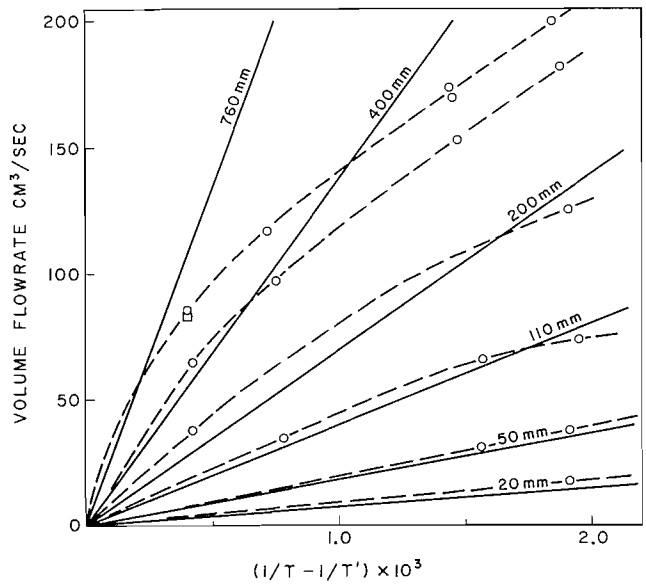

Fig. 1. Volume flowrates in thermosiphon. Solid lines are calculated, dashed curves are measured values. ○ = nitrogen, □ = methane.

Figure 1 shows measured flowrates of nitrogen and methane at various pressures, plotted against $(1/T-1/T')$, where T and T' are the absolute temperatures of the cold and hot arms of the thermosiphon respectively. It is interesting to compare these observed flowrates with those predicted by simple theory. The difference in density of the gas in the two arms introduces a force which drives the gas through the system at a volume flowrate (assuming simple viscous flow) given by

$$F = \frac{(\pi g/128R)(M/\eta)hP(1/T-1/T')}{r_I+r_E},$$

where g = gravitational acceleration, R = gas constant, M = molecular weight, η = coefficient of viscosity, h = height of thermosiphon, P = pressure, and r is a "flow resistance" defined as $\sum (L_i/d_i^4)$ where L_i and d_i are the length and diameter respectively of each component of the flow circuit. The term r_I is the "internal" flow resistance of the thermosiphon itself, while r_E is that of the "external" components of the system.

Flowrates calculated from this equation are shown as the solid lines in Fig. 1. At low pressures and flowrates, the measured values lie somewhat above the calculated ones, perhaps due to error in estimating r_I and r_E. The linear dependence of F upon P and upon $(1/T-1/T')$ is approximately confirmed by experiment at low pressures and flowrates, but F falls off rather badly at flowrates greater than 100 cc/sec. This is probably due to the failure of the gas to attain the temperature of the walls immediately upon entering each arm of the siphon. An increase in either pressure or flowrate enhances this effect and reduces the average temperature difference between the arms. This was, in fact, observed with a thermocouple mounted in the gas stream.

The relative flowrates obtained with nitrogen ($M/\eta = 1.57$) and methane ($M/\eta = 1.48$), shown in Fig. 1, are in approximate agreement with a linear dependence of F upon M/η.

Using experimentally practical values of h, P, T, and T', the absolute value of ΔP generated is very small, so that the flow resistance must be minimized in order to achieve

high flowrates. This is the most serious limitation of the thermosiphon, and makes it quite impractical as a means of forcing a gas through a constricted system. Furthermore, the need for large-bore tubing, since r varies as d^4, results in a rather large volume. Within these limitations, however, the thermosiphon is remarkably flexible, as the four parameters h, P, $(1/T-1/T')$, and r may be varied almost independently.* Thus, for example, if experimental conditions dictate certain values of P, T, and T', then h and r may be adjusted to give the desired flowrate, etc. In practice, T' is the most conveniently controlled parameter, permitting wide variation in F from 0 up to a maximum value dependent on the other parameters and upon the thermal stability of the gas.

The dependence of F upon d^4 permits, in theory, the achievement of very high flowrates where d is not limited by other factors. The observed fall-off in F (Fig. 1), probably due to the time lag in heating and cooling the gas in the two arms, could be at least partially eliminated by suitable preheating and precooling, and by increasing h. With its inability to operate against an appreciable pressure gradient or flow resistance, and its high flowrates, limited in theory only by d, the thermosiphon is seen to be the converse of the piston pump, in which the flowrate is fixed by the displacement, but which will operate against a large and variable pressure head.

The dependence of F upon pressure also deserves some comment. Although F decreases linearly with decreasing pressure, there should be no sudden loss of efficiency at low pressures, as observed with piston and impeller pumps, and in fact, F should increase somewhat as viscous flow gives way to molecular flow. Thus, if large enough values of h, T', and d can be used, the thermosiphon should operate well at pressures from 1 mm to 10^{-3} mm.

Finally, it should be noted that the thermosiphon has no moving parts or electronic components, and is thus completely reliable and trouble-free in operation.

proton resonance frequency with concentration of alcohol has also been associated with the hydrogen bonding between alcohol molecules (2). Davis, Pitzer, and Rao (2) have recently studied the proton magnetic resonance spectra of solutions of methanol, ethanol, *i*-propanol, and *t*-butanol in carbon tetrachloride and have calculated the apparent ΔH values. The trend in ΔH values was found to be methanol > ethanol > *i*-propanol > *t*-butanol. Although the uncertainties in the ΔH values are rather large, it is possible that the trend in ΔH with the structure of the alcohol may reflect either steric or electronegativity effects on the strength of the hydrogen bond. The monomer chemical shifts, δ_M, obtained by extrapolation to infinite dilution, also showed variation in the order methanol > ethanol > *i*-propanol $\cong$ *t*-butanol (3). In order to determine the importance of steric or (and) electrical effects in deciding the hydrogen bonding in alcohols, we have now studied the proton magnetic resonance spectra of trifluoroethanol and ethanol in benzene solution.

The proton magnetic resonance spectra of solutions of anhydrous ethanol and trifluoroethanol in benzene were recorded on a Varian high-resolution n.m.r. spectrometer operated at a fixed frequency of 40 Mc/sec. Sample tubes of 4.5-mm outer diameter were used and the measurements were made while the tubes were spinning. The chemical shifts of the hydroxyl proton have been calculated with respect to benzene signal. The error in the δ values varies between ± 0.3 and ± 1.7 cycles/sec. Each observation is an average of at least six independent measurements. All experiments were conducted at room temperature ($31 \pm 1°$ C).

The variation of δ with mole fraction of alcohol for trifluoroethanol and ethanol is shown in Fig. 1. It is clear from the figure that the δ at infinite dilution, δ_M, is lower for trifluoroethanol (246 cycles/sec, 6.015 p.p.m.) than for ethanol (292 cycles/sec, 7.03 p.p.m.). Further, the slope of the curve at low concentrations (<0.04 mole fraction) is greater for ethanol. It may be noted in this connection that the free O—H stretching frequency of trifluoroethanol has been found by earlier workers (4) to be slightly lower than that of ethanol. But the free O—H stretching band persists even in the pure liquid in trifluoroethanol, indicating appreciable concentration of monomeric species (4). Apparently, the equilibrium constant for dimer formation is lower for trifluoroethanol compared to ethanol. This probably explains the greater slope of the curve (Fig. 1) for ethanol. The lower δ_M for trifluoroethanol is understandable since a more electronegative group should lessen the shielding of the hydroxyl proton. The greater acidity of trifluoroethanol compared to ethanol should result in a decreased shielding of the hydroxyl proton. It would appear as though steric effects are important in view of the decrease in δ_M with the increase in the bulk of the alkyl group. There is no reason why steric effects should affect δ_M, while they may be important in determining the equilibrium constant and ΔH of dimerization. Apparently, a strict comparison of δ_M values is possible only if the alcohols are structurally very similar.

Our observation that trifluoroethanol is less associated than ethanol at low concentrations due to the electronegativity of the CF_3 group is further supported by the recent infrared (5) and n.m.r. (6) studies on chloroethanols. Chloroethanols also show greater concentration of monomeric species compared to ethanol. The δ_M of trichloroethanol has also been found to be about 40 cycles/sec lower than that of ethanol (7). It is interesting to note that decrease in δ_M in trichloroethanol and trifluoroethanol are of the same magnitude. The polarities of the CF_3 and CCl_3 groups are also very similar (8).

Recently it has been found that trifluoroethanol causes a much greater solvent blue-shift on the $n \rightarrow \pi^*$ transition of the carbonyl group than ethanol (9), indicating that trifluoroethanol is a better hydrogen-bond donor than ethanol. Thus, the $n \rightarrow \pi^*$ band

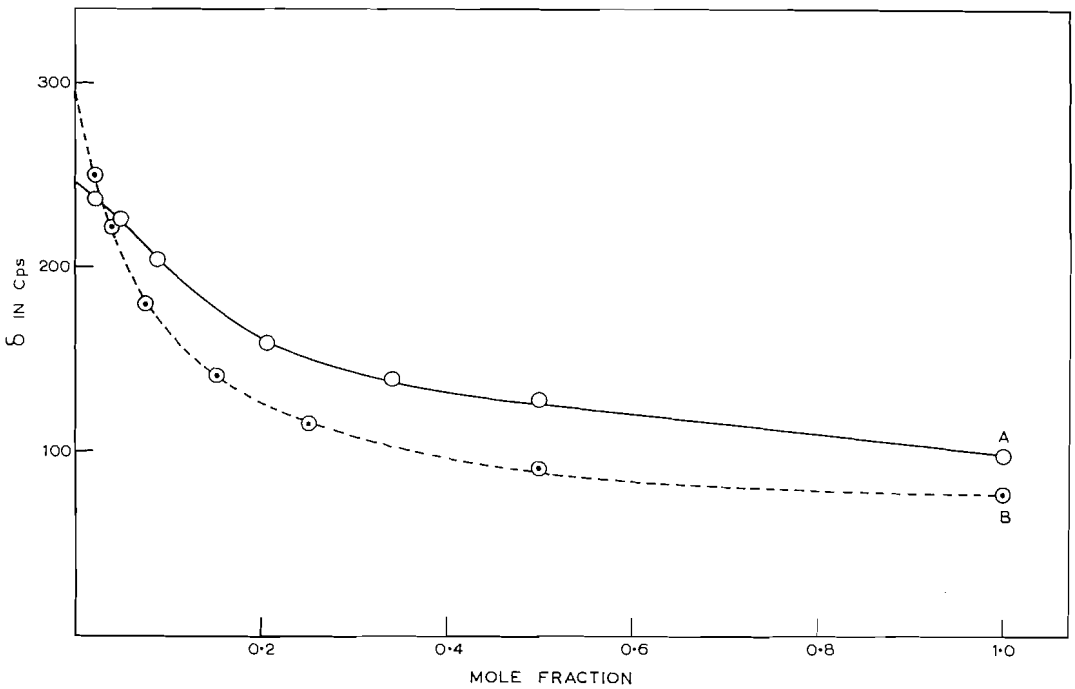

FIG. 1. Chemical shift of the OH proton resonance, δ in cycles/sec versus mole fraction of alcohol x: (A) trifluoroethanol, (B) ethanol.

maximum of acetone found at 277 mμ in heptane is shifted to 270 mμ and 265 mμ in ethanol and trifluoroethanol respectively. This may also be partly related to the higher concentration of monomeric species in trifluoroethanol. Mukherjee and Grunwald (10) have also concluded that trifluoroethanol is a better donor than ethanol, from their numerous physical measurements.

The authors are thankful to Professor M. R. A. Rao for his keen interest in the work and to Pennsalt Chemicals Corporation, Philadelphia, Pa., U.S.A., for a gift sample of trifluoroethanol.

IONIZATION POTENTIALS OF SOME PERFLUOROALKYL ARSINES[1]

W. R. CULLEN AND D. C. FROST

Measurements of the first ionization potentials of derivatives of the group V elements have been mainly confined to compounds of nitrogen (1), and little attempt has been made to study the effects of systematic substitution of the hydrogens of the parent hydrides by other groups. Derivatives of arsenic are especially suitable for such studies because of the availability of a large number of simple volatile compounds, and in this investigation the first ionization potentials of a number of arsines containing methyl, trifluoromethyl, and chloro groups have been measured.

EXPERIMENTAL

Compounds

The compounds shown in Table I were prepared by standard methods from the literature except for the arsenic trichloride where a commercial sample was used.

Apparatus and Method

The ionization potentials were obtained by electron impact mass spectrometry, and were derived by treating the relevant ionization efficiency curve and a standard (Xe^+ or Kr^+) with the Warren extrapolation method (2). The results, although reproducible to 0.1 ev, may well be slightly greater than the adiabatic values; however, this is not expected to unduly influence the trends shown within the groups of similar molecular species dealt with here.

Results

The new results are shown in Table I, together with some other values for comparison.

TABLE I

First ionization potentials

Compound	I.P. (ev)	Compound	I.P. (ev)
$(CF_3)_3As$	11.0	NH_3	10.15*
$(CF_3)_2AsCH_3$	10.5	CH_3NH_2	8.97*
$CF_3As(CH_3)_2$	9.2	$(CH_3)_2NH$	8.24*
$As(CH_3)_3$	8.3	$(CH_3)_3N$	7.82*

DISCUSSION

In the series of compounds containing CH_3, H, and As, a progressive decrease in ionization potential is found as the number of CH_3 groups is increased. This corresponds to a decrease of about 0.7 ev per CH_3 group substituted for a hydrogen in the parent arsine. In the case of ammonia a similar though less regular decrease is observed (Table I). It is generally felt that the parent ion of ammonia is formed by removal of an electron

[1]*Research supported by the National Research Council of Canada.*

from the lone pair on the nitrogen atom (3). It is not certain, however, that the parent ions of the methyl amines are also formed by the same process, though it is likely that this is so (4).

In the series $(CH_3)_xAsCl_{3-x}$ an irregular decrease in ionization potential occurs as the number of CH_3 groups is increased. This can be attributed to the inductive effect of the CH_3 groups and the electron-withdrawing effect of the chloro groups raising or lowering the energy of the arsenic lone pair. Similarly in the series $(CF_3)_xAsH_{3-x}$ and $(CF_3)_xAs(CH_3)_{3-x}$ an increase in ionization potential would be expected as the number of CF_3 groups is increased, owing to the strong electron-withdrawing power of this group. However, in the series $(CF_3)_xAsCl_{3-x}$ the substitution of CF_3 seems to result in a small but significant lowering of the ionization potential, a result which could indicate that to a first approximation the electron-withdrawing power of the CF_3 group is less than that of the chloro group. This conclusion is the reverse of that expressed by other workers (5).

Qualitatively the results of the present investigation for the series $(CF_3)_xAs(CH_3)_{3-x}$ can be compared with the ease of complex formation and ease of hydrolysis of these compounds. The ease of forming donor–acceptor complexes, e.g. with silver iodide, and onium complexes, e.g. with CH_3I, decreases as the number of CF_3 groups is increased (6). Haszeldine and West have attributed this effect to the ability of the CF_3 group to lower the energy of the lone-pair electrons to such an extent as to make complex formation difficult. The degree of difficulty would depend on the number of CF_3 groups present. The reverse tendency is found with respect to ease of solvolysis of these compounds to eliminate the CF_3 group as CF_3H. Thus, the rate of solvolysis increases as the number of CF_3 groups is increased. This has been interpreted (6) in terms of the solvolysis occurring by nucleophilic attack on the arsenic atom which, formally, becomes more positive as the number of electron-withdrawing CF_3 groups attached to it is increased. The ionization potential variation found for these compounds reflects the same trends.

Quantitative tests of these ionization potential values are more difficult to find, and only one source of such a test seems to be available. Certain of the electronic transitions of the aryl arsines have recently been assigned as being due to intramolecular charge transfer involving excitation of an electron from the non-bonding lone pair to an antibonding π-orbital of a phenyl group (7). The energy of such a transition is given to a first approximation by the expression (8) $I_D - E_A - C$, where I_D is the ionization potential of the donor (presumably the arsenic lone pair), E_A the electron affinity of the acceptor (the phenyl group), and C the mutual electrostatic energy of D^+ and A^- relative to that of D and A.

Therefore, for the compounds $C_6H_5As(CH_3)_2$ and $C_6H_5As(CH_3)(CF_3)$, assuming that the configuration around the arsenic is essentially the same in both cases, the energy difference in the charge-transfer bands should be approximately equal to the difference in ionization potential of the arsenic lone pair. From Table I it is seen that substitution of a CF_3 for a CH_3 should increase the energy of the transition by about 0.7 ev. The experimental difference is 0.34 ev, but this value is probably lower than it would otherwise be because of interaction between the CF_3 group and the C_6H_5 group (7). Unfortunately, interactions of this sort prohibit similar comparisons being made with the spectra of other arsines so far investigated.

If similar calculations are made for the phenyl amines then very much worse agreement is found; however, in this case there is probably less charge-transfer character in the excited state (8).

CHEMISTRY OF THE TRIFLUOROMETHYL GROUP

PART V. INFRARED SPECTRA OF SOME PHOSPHORUS COMPOUNDS CONTAINING CF_3

M. A. A. BEG* AND H. C. CLARK

The Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received November 20, 1961

ABSTRACT

The infrared spectra of several series of trifluoromethyl–phosphorus compounds are correlated, the compounds examined being the iodides CF_3PI_2 and $(CF_3)_2PI$, the methyl-trifluoromethyl-phosphines of the general formula $(CH_3)_nP(CF_3)_{3-n}$, where $n = 1$, 2, or 3, and the analogous phenyl-trifluoromethyl-phosphines. Satisfactory assignments are made for the majority of absorption bands in the 650–4000 cm^{-1} region. The infrared spectra of some phosphine – boron trifluoride adducts are also examined and assignments of the principal bands are made.

INTRODUCTION

Although in the past 12 years, a large number of perfluoroalkyl-metallic and -metalloidal compounds have been prepared, few attempts have been made to correlate their infrared spectra. This is surprising since the infrared technique has proved extremely valuable in the characterization of these compounds, largely because of the intense, characteristic C—F absorption in the 1000–1300 cm^{-1} region. However, it is only very recently that correlations have been formulated for such simple perfluoro compounds as the trifluoromethyl (1, 2) and pentafluoroethyl halides (3) and there is only one other detailed report dealing with the infrared spectra of perfluoro-organometallic compounds (4). In earlier papers of this series (5, 6) we have described the preparations of the phenyl-trifluoromethyl-phosphines and a number of their complex derivatives. Since the analogous methyl-trifluoromethyl compounds have been described previously (7–9), a wide range of trifluoromethyl–phosphorus derivatives is now available and it seemed useful to examine in some detail their infrared spectra.

EXPERIMENTAL

The preparations of the compounds have been described in detail elsewhere (5–9).

Infrared absorption spectra were recorded in the 650–4000 cm^{-1} range, using a Perkin–Elmer model 21 double-beam spectrophotometer fitted with NaCl optics, and operated at a slit program setting of 927. Gas spectra were recorded using a 9-cm gas cell fitted with NaCl plates, and were measured at a number of pressures so as to obtain complete resolution. The spectra of liquids were recorded using liquid films between NaCl plates. Most spectra were calibrated against known peaks of a polystyrene film, and frequencies are considered accurate to ±0.3%. Relative intensities and band characteristics are described in terms of the usual notation, as indicated by Stafford and Stone (4).

**Present address: Central Laboratories, Pakistan Council of Scientific & Industrial Research, Karachi, Pakistan.*

DISCUSSION

Before discussing the spectra of the trifluoromethyl–phosphorus compounds, some consideration should first be given to the CF_3 group itself, which gives rise to four fundamental vibrations. These are composed of two A_1 type vibrations, the symmetrical CF_3 stretching at about 1100 cm^{-1}, and the symmetrical CF_3 deformation at about 700 cm^{-1}; and two degenerate E type vibrations, the antisymmetrical CF_3 stretching at about 1180 cm^{-1} and the antisymmetrical CF_3 deformation at about 520 cm^{-1}. The atom or group bonded to the CF_3 group will give rise to two vibrations, symmetrical stretching of CF_3—X and the rocking of CF_3 against X. Edgell and May (10), from a study of CF_3—X vibrations, conclude that interaction between the CF_3 and CF_3—X vibrations is small and that the spectra are therefore best interpreted in terms of the behavior of the CF_3 group as a stiff or rigid group. This implies that the fundamental vibrations due to a CF_3 group should not differ greatly from molecule to molecule, although some small shifts in frequency may be expected as the electronegativity of X is changed (1).

Trifluoromethyliodophosphines

In considering the infrared spectra of trifluoromethyl–phosphorus compounds, it seems best to consider first the compounds CF_3PI_2 and $(CF_3)_2PI$ since the P—I stretching vibration lies outside the frequency range being studied. The observed frequencies and suggested assignments are listed in Table I, using the frequencies reported by earlier workers (11).

TABLE I

Vibrational frequencies in CF_3PI_2 and $(CF_3)_2PI$

CF_3PI_2	$(CF_3)_2PI$	Assignment
	2252 m	Comb. (2×1131?)
	2217 s	Comb. (2×1119?)
1272 m	1273 m	Comb. (2×P—C symm. stretch.?)
	1256 w	
	1203 s	Antisymm. and symm. CF_3 stretch.
	1183 m	
1157 s	1162 s	
1142 s	1131 s	
1111 s	1119 m	
1072 m		
	1029 m	
	951 w	
	854 w	
	798 m	
737 s	748 s	Symm. CF_3 deform.
	714 w	Antisymm. P—C stretch.

In CF_3PI_2, the absorption at 1111 cm^{-1} is assigned to the symmetrical CF_3 stretching corresponding to the 1073 cm^{-1} band in CF_3I (10), while those at 1142 and 1157 cm^{-1} arise from the doubly degenerate antisymmetrical CF_3 stretching, this being observed at 1185 cm^{-1} in CF_3I. The absorption at 737 cm^{-1} is probably the symmetrical CF_3 deformation frequency, found at 741 cm^{-1} in CF_3I. However, the P—C asymmetric stretching might also be expected about here, since it is observed at 717, 707 cm^{-1} in $P(CH_3)_3$ (12). This assignment of the 737 cm^{-1} is therefore only tentative.

When more than one CF_3 group is attached to the phosphorus atom, splitting of the characteristic C—F frequencies occurs, as would be expected from the presence of two

equivalent groups (14). Hence in the spectrum of $(CF_3)_2PI$ there are five resolved absorptions in 1100–1220 cm^{-1} region. These are actually observed as three main bands with submaxima at 1119 and 1183 cm^{-1}. When three CF_3 groups are attached to the same atom, as in $(CF_3)_3P$, four main absorption frequencies with submaxima are observed. The number of main absorption bands in this region is therefore sometimes taken as an indication of the number of CF_3 groups present; however, without detailed mathematical treatment no detailed assignments can be made. The symmetrical CF_3 deformation mode in $(CF_3)_2PI$ is observed at 748 cm^{-1} in support of the assignment of the 737 cm^{-1} band of CF_3PI_2. Possibly the 714 cm^{-1} absorption may be attributed to the P—C antisymmetrical stretching vibration, particularly since the splittings of the CF_3 deformation band are not likely to be greater than 15 to 20 cm^{-1}.

Methyl-trifluoromethyl-phosphines

It is now possible to make similar correlations of the spectra of $(CH_3)_3P$, $(CH_3)_2PCF_3$, $CH_3P(CF_3)_2$, and $P(CF_3)_3$. The vibrational frequencies of $(CH_3)_3P$ have recently been studied in detail (12) and while use is made below of these assignments, the present results also offer some confirmation of them. The observed absorption frequencies and their suggested assignments are given in Table II, which makes use of Halmann's (12)

*A number of weak absorptions are reported in the 1400–2200 cm^{-1} region.

assignments for $(CH_3)_3P$, and the reported frequencies of $P(CF_3)_3$ (11).

The assignments for C—F stretching and CF_3 deformation follow those discussed earlier. In $(CH_3)_2PCF_3$ the bands at 1175 and 1125 cm^{-1} are the antisymmetric stretching vibrations and that at 1118 cm^{-1}, the symmetric vibration, but detailed assignments cannot be made when more than one CF_3 group is present. Three points require further

comment. Firstly, there seems to be good agreement, in all cases, for vibrations involving the CH_3 group. There are two exceptions where expected bands are not observed for $CH_3P(CF_3)_2$ but this is probably due to their very low intensity. Secondly, for $(CH_3)_3P$, $(CH_3)_2PCF_3$, and $CH_3P(CF_3)_2$, there are marked similarities in band shapes in the 890–975 cm^{-1} region, these being quite different from the 966 and 923 cm^{-1} vibrations observed for $(CF_3)_3P$. For the former compounds, absorption in this region is attributed to CH_3 rocking. Thirdly, the moderately intense absorption observed for all compounds in the 700–730 cm^{-1} region is assigned to the antisymmetrical P—C stretching. If this is correct, it appears that this vibration is unaffected by the stepwise replacement of CF_3 for CH_3.

Phenyl-trifluoromethyl-phosphines

The infrared spectra of phosphorus compounds containing both phenyl and trifluoromethyl groups are much more complex than those already discussed, largely due to the numerous vibrations associated with the phenyl group. The observed frequencies for three such compounds are listed in Table III.

TABLE III

690 s	695 s	690 s	Out-of-plane C—H bend.

Although all frequencies cannot be assigned, the similarities in the three spectra are very striking. In phenyl compounds, the skeletal C—C vibrations usually occur at 1440–1625 cm^{-1}. In these phosphorus compounds, they are invariably found at 1440–45 cm^{-1} in the form of an intense sharp band, and accompanied by two other sharp absorptions of lesser intensity at 1490 and 1590 cm^{-1}. The ring vibration thought to be very sensitive to the substituent on the phenyl ring is said to occur at 1045–1185 cm^{-1} (15), and is observed at 1088 cm^{-1} for $(C_6H_5)_3P$. Since all the compounds of Table III show

a medium intensity band at 1070 cm^{-1}, it is assigned this vibration. Similarly, all three compounds show a well-resolved absorption at 1000 cm^{-1} which has been observed (13) in a large number of other compounds containing the phenyl—P grouping.

Other characteristic absorptions of the phenyl group are also observed. Thus the strong bands at 690 cm^{-1}, accompanied by another strong absorption at 745–750 cm^{-1}, and perhaps the weak absorption at 800–810 cm^{-1} are due to out-of-plane C—H bending vibrations and this particular combination of bands is characteristic of monosubstituted phenyl groups (16). The strong band at 750 cm^{-1} presumably overlaps the CF_3 deformation frequency observed in other CF_3 compounds. We again tentatively assign the weak 700–715 cm^{-1} band to the P—C antisymmetrical stretching vibration.

The C—F stretching vibrations are again observed in the 1100–1200 cm^{-1} regions; for $(C_6H_5)(CF_3)PI$ and $(C_6H_5)_2PCF_3$, only two such vibrations are observed in each case, those at 1150 cm^{-1} being due to the asymmetric mode, and those at 1115 cm^{-1} and 1105 cm^{-1} being assigned as symmetrical stretching. In $(C_6H_5)P(CF_3)_2$, coupling occurs between the CF_3 modes and an increased number of bands is observed.

Phosphine – Boron Trifluoride Adducts

As part of our studies of the donor properties of trifluoromethyl-phosphines, a number of their boron trifluoride adducts were prepared. In Table IV are listed the important maxima observed in their infrared spectra.

TABLE IV

Most of the frequencies found to be characteristic of the free phosphines are also observed in the spectra of their BF_3 adducts; however, the characteristic absorptions of boron trifluoride are not found. Instead of the intense B—F stretching vibrations at 1454 and 1505 cm^{-1} (18), there is a wide region of intense absorption at 1030–1180 cm^{-1}. Although the bands are broad and good resolution is impossible, it is clear from a consideration of the spectra of $(C_6H_5)_2PCF_3.BF_3$, $(C_6H_5)_2P.BF_3$, and $(C_6H_5)_3P.BF_3$ that absorption in this region is due to B—F vibrations (1030–1090 cm^{-1}) and also C—F

stretching vibrations (1125–1175 cm^{-1}). This shift in the B—F stretching vibrations to lower frequency results from the change of symmetry accompanying complex formation, and has been observed for other BF_3 adducts (19). Also, the spectra do not reveal any absorption due to water, so hydrolysis of the adducts to give BF_4^- cannot have occurred. A number of bands are observed in the 670–750 cm^{-1} region but it is impossible to make definite assignments. The P—C stretching vibrations should no longer be found in this region, but the phenyl C—H out-of-plane vibrations, the B—F bending vibrations, and the CF_3 deformation modes may cause absorption. In all four of the BF_3 adducts, a band is found at 770–790 cm^{-1}. The origin of this is uncertain, although a very weak band is observed here for fluoroborates (20) and has been assigned as the symmetrical breathing vibration of the B—F bonds. However, in the present instances, the intensities of these bands are much greater than observed in fluoroborates.

In conclusion, the examination of the infrared spectra of these trifluoromethyl–phosphorus compounds not only shows the usefulness of infrared spectroscopy in the characterization of organophosphorus compounds but also provides further information concerning C—F and P—C absorption in the infrared region of the spectrum. For a complete understanding of these absorptions, many other related compounds will have to be prepared and examined.

IONIZATION OF ORGANIC COMPOUNDS

II. THIOACETAMIDE IN AQUEOUS SODIUM HYDROXIDE. THE H_- ACIDITY FUNCTION[1]

J. T. EDWARD AND I. C. WANG

The Department of Chemistry, McGill University, Montreal, Que.

Received November 7, 1961

ABSTRACT

The ionization ratio of thioacetamide in aqueous sodium hydroxide, determined spectrophotometrically, is proportional to the concentration of hydroxide ion up to a concentration of about 1 M, and indicates a pK_{HA} of 13.4. For more concentrated solutions the ionizing power increases more rapidly than the hydroxide ion concentration; from the experimentally determined ionization ratios the values of the h_- acidity function for 1–6 M sodium hydroxide have been calculated. The relation of h_- values to the salting-out parameters and water activities of concentrated sodium hydroxide solutions is discussed.

INTRODUCTION

It has been customary to represent the ionization in aqueous alkaline solution of a weak uncharged acid HA by

$$HA + OH^- \rightleftarrows A^- + H_2O \qquad [1]$$

and its ionization ratio ($[A^-]/[HA]$) by

$$[A^-]/[HA] = K_{HA}[OH^-]f_{HA}f_{OH^-}/K_Wf_{A^-}, \qquad [2]$$

the quantities in square brackets representing molar concentrations, the f's molar activity coefficients, K_{HA} the ionization constant of the acid, and K_W the ionic product of water. It has been recognized that the various molecules and ions are hydrated to different extents, but for dilute enough solutions no explicit account needs to be taken of these effects; in such solutions the f terms approach unity, and equation [2] becomes

$$[A^-]/[HA] = K_{HA}[OH^-]/K_W. \qquad [3]$$

This equation holds as a reasonable approximation for the ionization of various weak organic acids in concentrations of up to about 0.5 M sodium or potassium hydroxide (1), changes in the activity coefficient terms with concentration cancelling out to a large extent. However, in more concentrated solutions of alkali the ionization ratio begins to increase much more rapidly than the hydroxide ion concentration. Accordingly, an acidity function, h_-, defined by

$$[A^-]/[HA] = K_{HA}/h_-, \qquad [4]$$

has been devised to measure the proton-abstracting power of strongly alkaline solutions (1, 2). By definition h_- approaches $[H^+]$ and H_- ($= -\log h_-$) approaches pH as a limit in dilute aqueous solution. This acidity function may be expected to prove useful in distinguishing between possible reaction mechanisms from kinetic results in strongly alkaline solution (3).

Schwarzenbach and Sulzberger (1) used substituted indigos as indicators, and obtained H_- values (which they preferred to term pH values) for aqueous sodium and potassium

[1]*The paper by H. J. Campbell and J. T. Edward, Can. J. Chem. 38, 2109 (1960), is to be considered as Part I of this retitled series.*

hydroxide solutions varying in strength from 0.1 M to saturated. They also tried variously substituted glutacondialdehyde dianils as indicators, and obtained ionization ratios (and hence H_- values) increasing more rapidly with hydroxide ion concentration than those obtained with substituted indigos. They rejected these H_- values and suggested that the glutacondialdehyde derivatives did not ionize by losing a proton according to equation [1], but instead added a hydroxide ion. No convincing reason was advanced for this mode of ionization, which in fact would not be expected to lead to the color changes observed with these indicators in strong alkali; an alternative explanation for the divergence of the two H_- scales is given later in this paper.

Both types of indicators were strongly salted out of the aqueous solutions by the concentrated alkali, so that an immiscible organic solvent was present as a second phase for reasons of solubility. Other investigators have avoided the salting out of indicators by using aqueous organic (4) or organic solvents (3), or by using bases such as hydrazine (5), ethylene diamine (6), or ethanolamine (7). However, small polar molecules are not salted out to the same extent as large dyestuff molecules, and in certain instances are salted in (8). In the present work we have studied the ionization in aqueous sodium hydroxide of the small, highly polar thioacetamide molecule.

EXPERIMENTAL

Thioacetamide was recrystallized from ether to a constant melting point of 112.6–113.9° C (reported m.p. 114° (9)) and dissolved in distilled water to give solutions of accurately known concentration, varying between about 0.2 M and 0.002 M, according to the region of the spectrum being investigated. Sodium hydroxide solutions were prepared by dilution of concentrated aqueous solutions from which sodium carbonate had settled, with the usual precautions to exclude carbon dioxide, were standardized by titration, and were shown to be substantially free from carbonate (10, 11). The solutions were brought to 25.0±0.1° C, and then 0.100 ml of thioacetamide solution was mixed quickly with 3.00 ml of sodium hydroxide solution in a stoppered quartz cell of 1-cm light path. The absorption of the solution was measured in a Beckmann DU spectrophotometer against a blank of the same hydroxide concentration, the cell compartment being maintained at 25.0±0.1° C by thermospacers. Hydrolysis of thioacetamide in the more alkaline solutions led to a progressive drop in absorption (cf. ref. 12); the absorption at the moment of mixing was obtained by measuring the absorption at different times after mixing and extrapolation. The reproducibility of measurements was found to be ±1%. The concentration of sodium hydroxide in the sample solution was determined by titration; it was shown that following the above procedure no significant amount of carbonate was formed.

RESULTS AND DISCUSSION

Effect of Ionization on Spectrum of Thioacetamide

The absorption spectra of thioacetamide in water (Fig. 1) and in buffer solutions of pH 9.71, 10.41, 10.73, and 11.87 are practically identical, and are evidently due to the unionized molecule (I). However, in solutions of more alkaline pH the spectrum changes, becoming finally constant again with concentrations of sodium hydroxide above about 4 M. The absorption curve for strongly alkaline solutions (Fig. 1) must represent the spectrum of the conjugate base (II); the fact that all curves go through an isobestic point at 250 mμ supports this interpretation of the spectral changes (13).[2]

[2]*A referee has suggested that the failure of the spectrum to change appreciably with increase of sodium hydroxide concentration above about 4 M may be explained by a levelling off of the basicity of the medium in the region 4 M–8 M, so that thioacetamide may be still incompletely ionized in 8.45 M hydroxide. While this is a theoretical possibility, we consider it most improbable in view of the strong increase in basicity with increase of hydroxide concentration from 4 M to 8 M found by Schwarzenbach and Sulzberger (1). (Admittedly, the* extent *of the increase is dependent on the choice of indicator, but it seems unlikely that thioacetamide should differ greatly from the substituted indigos.) Furthermore, the good agreement of spectral results in the more dilute hydroxide solutions with those expected from equations [3] and [5] indicates that the correct value of* ϵ_{A^-} *has been used in these equations; i.e., that ionization in 8.45 M hydroxide is essentially complete.*

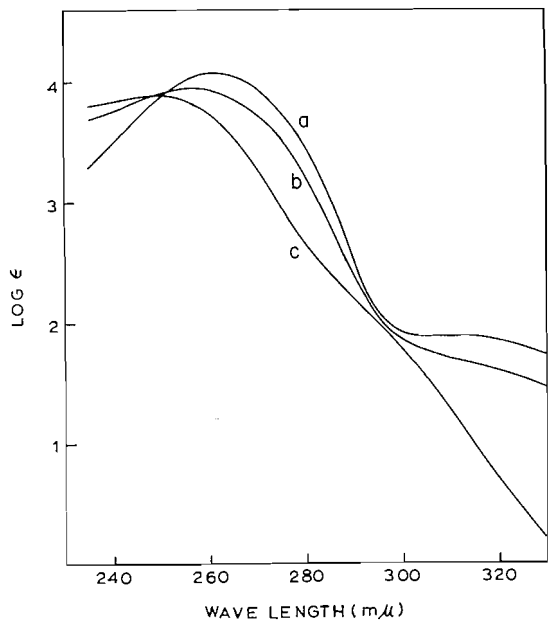

FIG. 1. Ultraviolet absorption of thioacetamide in (*a*) water; (*b*) 0.235 *N* sodium hydroxide; (*c*) 8.45 *N* sodium hydroxide.

Janssen (14) showed that thioacetamide in ethanol has a weak absorption peak at 327 mμ and a strong peak at 266 mμ, which he attributed to $n \rightarrow \pi^*$ and $n \rightarrow \sigma^*$ transitions respectively of the thiocarbonyl group. As expected for such transitions (15), both peaks undergo blue shifts when the solvent is changed from ethanol to water (Table I). The

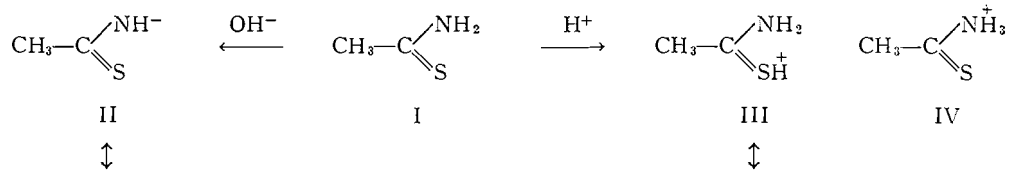
[b]Inflection at 290 mμ (cf. Fig 1).

further blue shifts in alkaline or acid solution (Table I), which cause the $n \rightarrow \pi^*$ peak to be submerged in the more intense $n \rightarrow \sigma^*$ peak, are in accord with the structures II and III for the conjugate base and acid respectively of thioacetamide; the ionic charge in both cases would be expected to oppose $n \rightarrow \pi^*$ or $n \rightarrow \sigma^*$ transitions, which involve the shift of an electron from sulphur towards carbon. As already pointed out by Janssen, the ultraviolet spectrum of the conjugate acid does not support the formulation IV advocated by Spinner (16).



Dissociation Constant of Thioacetamide

The ionization ratios of thioacetamide in various strengths of alkali were computed from the equation

$$[A^-]/[HA] = (\epsilon_{HA} - \epsilon)/(\epsilon - \epsilon_{A^-}), \qquad [5]$$

where ϵ_{HA}, ϵ_{A^-}, and ϵ are the molecular extinction coefficients at 310 or 260 mμ in water, in 8.45 *M* sodium hydroxide, and in the test solution respectively. A plot of log ([A$^-$]/[HA]) against log [OH$^-$] (Fig. 2) fits reasonably well a straight line of unit slope over the

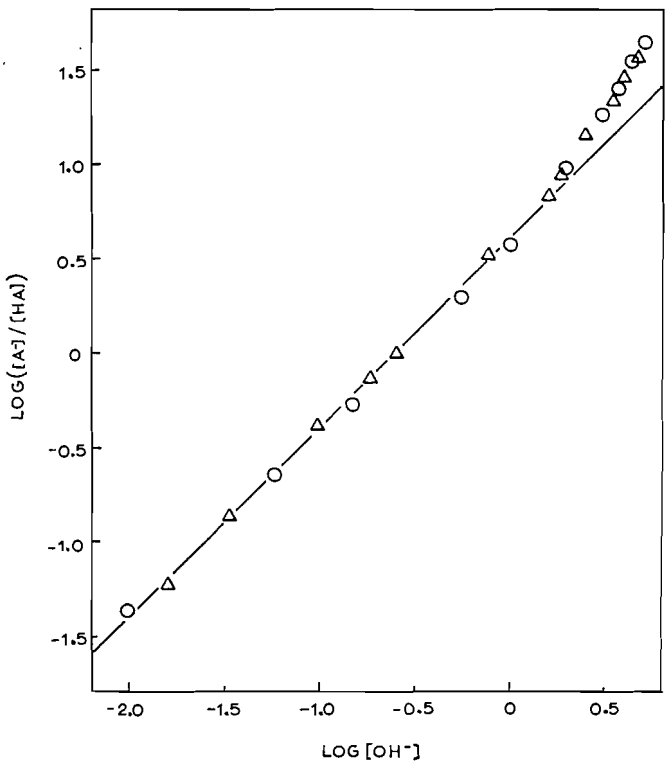


FIG. 2. Relation between hydroxide ion concentration and ionization ratio ([A$^-$]/[HA]) of thioacetamide, as determined by measurements of ultraviolet absorption at 260 mμ (○) and 310 mμ (△).

range 0.01–1 *M* sodium hydroxide (log [OH$^-$] of −2.0 to 0), as required by equation [3]. The intercept of this curve indicates $pK_{HA} = 13.4$ for thioacetamide, since $pK_W = 14.00$ at 25° (17, p. 481). Dissociation constants of about this order of magnitude have been reported for some amides (18, 19, 20), although acetamide shows no appreciable ionization

in 1 *M* sodium hydroxide (21). However, it seems likely that thioamides in general will prove more acidic than amides (cf. hydantoin and thiohydantoin (22)).

Experimental H_- Values of 1–6 M Sodium Hydroxide Solutions

The present work indicates that for the ionization of thioacetamide in 0.01–1 *M* sodium hydroxide, H_- is given by

$$H_- = pK_w + \log [OH^-]. \qquad [6]$$

(Previous work has shown the identity of H_- with pH for less alkaline aqueous solutions (5, 6).) However, for sodium hydroxide concentrations above 1 *M* the relationship given by equations [3] and [6] breaks down. The H_- values calculated for various concentrations of sodium hydroxide from the experimentally observed ionization ratios according to equations [4] and [5] are given in Table II, and shown as experimental points in Fig. 3.

TABLE II

H_- values for different molar concentrations of aqueous sodium hydroxide

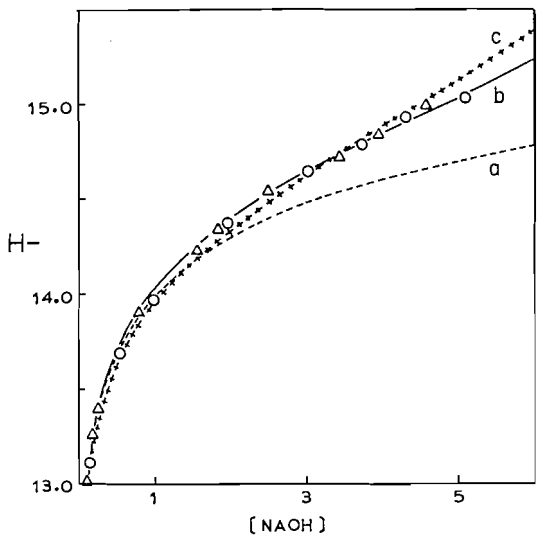

FIG. 3. Relation between molar concentration of sodium hydroxide and H_-. Points: experimental values calculated from ionization ratio of thioacetamide, determined from ultraviolet absorption at 260 mμ (○) and at 310 mμ (△). Curves: (*a*) theoretical for eq. [6]; (*b*) theoretical for eq. [13] with $v+y-p-1 = 3.2$; (*c*) Schwarzenbach and Sulzberger's experimental curve.

These values agree fairly well with those obtained by Schwarzenbach and Sulzberger (1) using substituted indigos as indicators, although the presentation by these authors of their results in graphical form only precludes a detailed comparison with our results.

Calculation of H_- Values for 1–6 M Sodium Hydroxide

The H_- values of 1–6 M solutions of sodium hydroxide may be calculated by a method developed essentially from that of Bascombe and Bell (23) for calculating H_0 values of solutions of mineral acids. We take account of the fact that the hydroxide ion, because of its small size and localized charge, is almost certainly more heavily hydrated than the usual organic conjugate base A^- with a charge dispersed by resonance. Consequently, equation [1] must be replaced by

$$HA + OH^- \rightleftarrows A^- + (p+1)H_2O, \qquad [7]$$

where HA, OH^-, and A^- represent the *hydrated* species, and p the difference in hydration numbers of (HA + OH^-) and of A^-. Equation [2] must then be replaced by

$$[A^-]/[HA] = K_{HA}[OH^-]f_{HA}f_{OH^-}/K_W a_W^{p+1} f_{A^-}, \qquad [8]$$

where a_W is the water activity of the sodium hydroxide solutions (24, p. 510). (For very dilute hydroxide solutions $a_W \rightarrow 1$ and equation [8] reduces to equation [2].) From the definition of H_- in terms of ionization ratios (equation [4]) we then obtain

$$H_- = pK_W + \log [OH^-] + \log f_{HA} + \log (f_{OH^-}/f_{A^-}) - (p+1) \log a_W. \qquad [9]$$

The possibility of using this equation to calculate the change in H_- with changing hydroxide ion concentration depends on whether or not some estimate of the change due to the activity coefficient terms can be made. Unfortunately, there is no satisfactory theoretical treatment for these changes in concentrated electrolyte solutions (8; 17, p. 379; 24, p. 223). However, it is known that for the salting out of neutral molecules $\log \gamma$ (where γ is the molal activity coefficient) is generally a linear function of the ionic strength of the electrolyte solution (8; 17, p. 379); while the ionic strength in turn is related to a_W. Consequently, it seems likely that as a first approximation

$$\log f_{HA} \approx v \log a_W. \qquad [10]$$

Such a relation is supported by the data shown in Fig. 4 for the molar activity coefficients f of the neutral molecules benzene (25), oxygen (26), and hydrogen (26) in aqueous sodium hydroxide, f being obtained from solubilities and defined as unity in pure water. Comparable data for thioacetamide are not available, but it would be expected that the slope (v) of a similar plot would be smaller than the slopes in Fig. 4, and possibly even of opposite sign, because of the polar character of the molecule (8). In such a case the deviation from linearity might be less serious than in the plots of Fig. 4.

It seems likely that the values of $\log f-$ for the anions of 1–1 electrolytes are also approximately linear functions of $\log a_W$ over the concentration range (1–6 M) being considered, so that

$$\log (f_{OH^-}/f_{A^-}) \approx y \log a_W. \qquad [11]$$

Starting with an infinitely dilute solution ($\log a_W = 0$), an increase in electrolyte concentration up to about 1 M (i.e. a decrease in $\log a_W$) leads to a decrease from unity (i.e. from $\log f\pm = 0$) in the molar mean activity coefficient $f\pm$, due to the interionic forces described in the Debye–Hückel treatment. However, further increase in concentration may lead to an increase in $f\pm$ because of the opposing effect of ion–solvent interactions

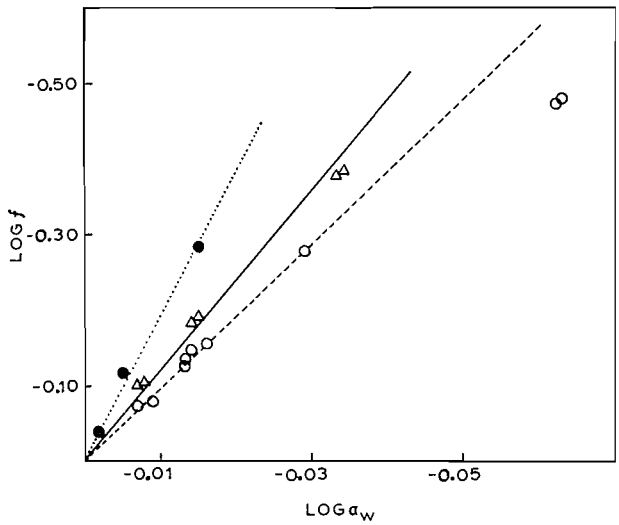

FIG. 4. Variation of molar activity coefficients (f) of hydrogen (○), oxygen (△), and benzene (●) in aqueous sodium hydroxide with the activity of the water (a_W).

(24, p. 223). This is shown in Fig. 5 for various concentrations (up to the highest for which data are available) of sodium chloride (up to 6 M), sodium hydroxide (up to 6 M),

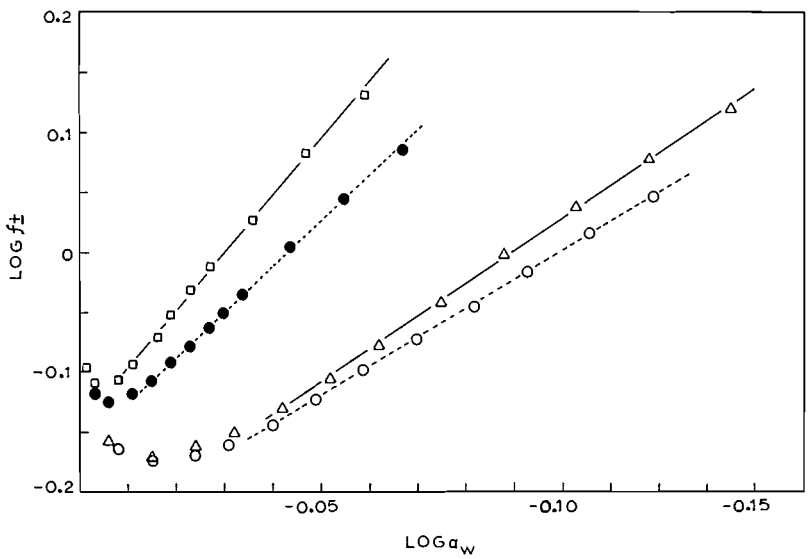

FIG. 5. Relation between molar mean activity coefficient ($f\pm$) and water activity (a_W) for aqueous solutions of sodium chloride (○), sodium hydroxide (△), sodium acetate (●), and sodium propionate (□).

sodium acetate (up to 3.5 M), and sodium propionate (up to 3 M). The $f\pm$ values for this figure were computed in the usual way (24, p. 32) from mean *molal* activity coefficients tabulated in the literature (24, p. 492) by taking account of the densities of the solutions (27). Water activities for various concentrations of sodium chloride (24, p. 476) and

sodium hydroxide (24, p. 510) are recorded, while those for various concentrations of sodium acetate and sodium propionate may be calculated from isopiestic data (28). It is evident from this figure that for concentrations of these electrolytes above about 1 M, $\log f\pm$ is an approximately linear function of $\log a_W$. Such a relationship is compatible with the relationship given in equation [11], if it is assumed that activity coefficients of both anions and cations are altering in the same way with increase in total electrolyte concentration.

Accepting equations [10] and [11], equations [8] and [9] may be transformed into

$$[A^-]/[HA] = K_{HA}[OH^-]a_W^{v+y-p-1}/K_W, \quad [12]$$

$$H_- = pK_W + \log [OH^-] + (v+y-p-1)\log a_W. \quad [13]$$

A plot of $\{\log ([A^-]/[HA]) - \log [OH^-]\}$ against $\log a_W$ for thioacetamide in sodium hydroxide gives an approximately straight-line curve (Fig. 6),[3] in accordance with

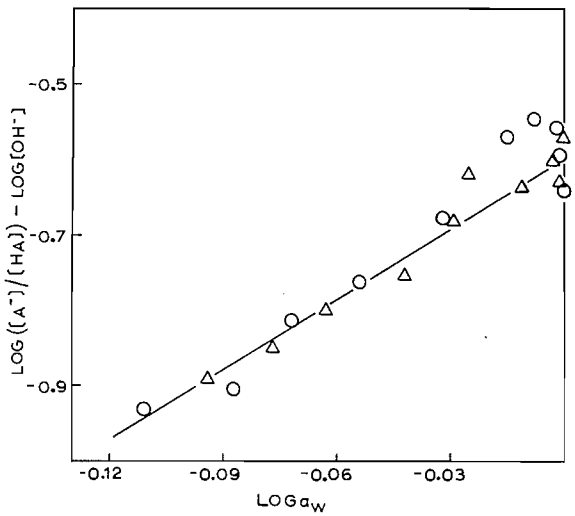

FIG. 6. Relation of ionization ratio ($[A^-]/[HA]$) and hydroxide ion concentration to the water activity of sodium hydroxide solutions. Experimental points: ionization ratio obtained from ultraviolet absorption at 260 mμ (○) and at 310 mμ (△).

equation [12]. The slope of the curve indicates $v+y-p-1 = 3.2$. Using this value, the H_- curve (6) shown in Fig. 3 has been calculated from equation [13]. The agreement with experimental values is reasonably satisfactory over the range of sodium hydroxide concentrations investigated.

Generality of H_- Scale for Sodium Hydroxide Solutions

The success of this treatment raises doubts as to whether any H_- scale for aqueous sodium hydroxide solutions is likely to have the generality of the H_0 scale for the common mineral acids. The success of the latter depends on the fact that the activity coefficients of different neutral molecules and their conjugate acids change only slightly with change of acid concentration (29). Consequently, the change of H_0 with acid concentration is

[3]*The scatter of points for the most dilute solutions, where* $\log a_W \to 0$, *is to be expected, since the points are based on the differences between small values, so that the effects of experimental error are magnified.*

determined chiefly by the differing degree of hydration of H_3O^+ and of the conjugate acids of the Brønsted bases being investigated (23); it seems likely that the failure of the ionization of a substance to follow H_0 can be ascribed to a degree of hydration of the conjugate acid differing from that of the conjugate acid of the Hammett indicator used to establish that portion of the H_0 scale (30). However, it is known that the activity coefficients of neutral molecules (and probably of ions) change very greatly, and in individual fashion, with change of concentration of sodium hydroxide, as shown by the strong but variable salting-out effects of this electrolyte (8). Additionally, it seems unlikely that different conjugate bases will be hydrated to the same extent. Hence it seems unlikely that $(v+y-p-1)$ of equation [13] should be the same for compounds of different type. This would explain the systematic differences observed by Schwarzenbach and Sulzberger (1) in the ionization of substituted indigos and of glutacondialdehyde dianils, while the similarity in the H_- scales established with thioacetamide and with substituted indigos would appear to be a chance coincidence. Obviously, a study of the ionization in sodium hydroxide of many widely varied indicators would be desirable. The success of the H_- scale in aqueous solutions of hydrazine (5) and organic bases (6, 7) with many different types of indicators may be ascribed to the weakly ionic nature of these bases, which causes them to have only minor salting-out effects.

ACKNOWLEDGMENTS

We are grateful to Professor R. Stewart for discussion, and to the National Research Council for financial assistance.

ON ELECTRODEPOSITED THALLIC OXIDE

WILLIAM T. FOLEY
The Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia
Received November 1, 1961

ABSTRACT

Thallium oxide, electrolytically deposited at the anode, has a defective oxide structure and the thallium (I) content is about 1% by weight. The conductivity of the oxide is $(1.54 \pm 0.04) \times 10^3$ ohm^{-1} cm^{-1} and the conductivity is of the *n*-type. The oxide contains variable amounts of water, which it retains very tenaciously.

The composition of thallium oxide formed on a platium anode by oxidation of aqueous thallium (I) solutions has been the subject of many research papers and a few names from an extensive literature will be mentioned. Gallo and Ceuni (1) reported the formation of Tl_2O_5 and Tzentnershver and Trebaczkiewicz (2) asserted that the oxide was Tl_2O_4. Skanavi-Grigor'eva and Starovera (3) found the oxide to contain substantial amounts of anions. This report deals with the composition and with some properties of the oxide.

Thallium oxide may be plated on the anode from a solution buffered to pH 9.5 by an NH_4NO_3–NH_4OH buffer and containing silver ion as a cathodic depolarizer. The electrochemical reactions occur with 100% current efficiencies (4) so that the weight of silver deposited affords a very precise measure of the electrochemical equivalent weight of the oxide. The equivalent weight based on the formula Tl_2O_3 is 114.2 but the experimental value varies from 116.1 to 116.8, with a mean value of about 116.3 for electrolysis conducted at room temperature and at a current density of 0.03 amp/cm^2. The deposit is jet-black and it is very adherent. The samples were dried for 20 minutes at 110° C; drying for prolonged periods of time yielded the same results as were obtained by drying for 20 minutes.

We have found that the oxide contains an appreciable quantity of thallium (I). The oxide dissolves readily in cold dilute solutions of hydrochloric acid by virtue of the high stability of the chloride complex of thallium (III). As the oxide dissolves, one may see on the electrode, traces of the bright yellow salt which one obtains on mixing solutions of thallium (I) chloride with thallium (III) chloride. The dissolved oxide may be analyzed for thallium (I) coulometrically with electrogenerated chlorine (5) and with the detection of the end point amperometrically. The possibility existed that the thallium (I) could have been formed in the process of solution by a redox reaction between thallium (III) and chloride. This point was checked by titrating with EDTA, at pH 5, with xylenol orange as indicator, the solution which had been used in the coulometric titration. The amount of thallium (III) calculated from the weight of silver and from the coulometric measurement checked beautifully with that calculated from the EDTA titration. Representative data are given in Table I.

The first column shows the weight of oxide and the second shows the number of microfaradays based on the weight of the cathode deposit. If we divide the number in the first column by the number of faradays we obtain the electrochemical equivalent. The fourth column indicates the volume of 0.1 *M* EDTA calculated from one-half of the total number of microfaradays.

TABLE I
Thallium (I) and (III) in oxide

Oxide (grams)	Silver (microfaradays)	From coulometer (microfaradays)	EDTA (ml)	
			Calc.	Meas.
0.5246	4499	52.6	22.76	22.74
0.5080	4341	65.4	22.03	22.04
0.6077	5203	69.7	26.36	26.32
0.3937	3373	45.9	17.10	17.10

The microfaradays for thallium (I) varied from run to run, but the average of 30 runs was 1.33% of the total number of microfaradays. There was a possibility that the thallium was present as thallium (II) rather than thallium (I) and that the latter was formed by dismutation of thallium (II) during the process of solution. A powdered sample was tested for paramagnetism by suspending in a magnetic field of 4.3 kilogauss, with a silk thread, a tiny capillary containing the oxide. The capillary lined up smartly at right angles to the field and thus displayed its diamagnetic character and showed the absence of thallium (II).

In an effort to show that the thallium (I) was not present in the compound as a result of adsorption, some electrolyses were performed at temperatures of 25°, 50°, and 75° C and also at current densities as low as 2×10^{-4} amp/cm^2. In all cases the thallium (I) content was independent of the current density and the temperature. At the highest temperature the weight of oxide based on the sum of the thallium (I) oxide and the thallium (III) oxide was much closer to the actual weight of the oxide than was true of an electrolysis carried out at room temperature. As will be shown later, this means that the water content of oxide samples prepared at 75° C and at low current densities was lower than the water content of oxide samples prepared at lower temperatures.

The conductivity of the oxide was next measured. A platinum anode 0.25 mm thick and 50 cm^2 in area was polished to a mirror finish and it was then plated with oxide at a current density of 6×10^{-4} amp/cm^2 until it was about 2.5 mm thick. The sample was dried for an hour at 110° C and, after cooling, it was given a heavy coating of collodian. The deposit was cut carefully with a razor blade near the perimeter of the electrode so that the main sheet of oxide could be removed readily from the platinum. The side which had been adjacent to the platinum had a metallic luster. Fairly large areas of the oxide would be free from cracks and such sections were removed and glued to glass slides with plastic cement. A block of this oxide was now cut to uniform size with a razor blade and was prepared for the conductivity measurement.

The four-terminal method was used to measure the conductivity. Since a pressure-laden contact would fracture the specimen, silver paint, such as is used to make printed circuits, was used to make the contacts. The current leads were made from No. 22 copper wire, whose ends were flattened by hammering, and they were painted to the ends of the oxide block with the silver paint. The potential leads were made from No. 44 copper wire, which was fastened to the oxide with silver paint that was applied through a narrow stencil. The current leads were connected to a regulated high-voltage supply through a 50,000-ohm resistor in order that a constant current would be had even though there might be minor changes in the contact resistances. In series also with these was a precision resistor across which was placed an L and N Type K2 potentiometer to provide a means of measuring the current. The potential leads were attached to a Keithly Model 610A

electrometer and, since no current was flowing, the contact resistance of the potential leads played no significant role. From the formula

$$\text{conductivity} = l/RA,$$

where l is the length, R the resistance in ohms, and A the cross-sectional area in cm^2, the conductivity of the oxide was found to be $(1.54 \pm 0.04) \times 10^3$ ohm^{-1} cm^{-1}. This order of magnitude is typical of a semiconductor.

The question of whether the defective oxide was a p or an n-type was answered by measurement of the sign of the Hall coefficient. A slab of oxide was prepared for such a measurement by attaching current leads as before and by spotting on it three Hall probes (two on one side and one on the opposite side) of No. 40 wire. The two probes on one side were centered electrically by means of a potentiometer while current was flowing. The specimen was placed in a magnetic field of 11.3 kilogauss. The magnetic field, acting on the current-bearing slab, gave rise to a transverse potential gradient, known as the Hall e.m.f. and a measurement of the sign of the Hall e.m.f. agreed with the conclusion that the conductivity was of the n-type. Apparently the oxide has a defective oxide lattice. The X-ray studies of Scatturin and Torrati (6) on the oxide of thallium prepared by oxidizing thallium sulphate with hydrogen peroxide suggested that their oxide had a defective oxide structure also.

A consideration of the data of Table I will show that the sum of the weights of thallium (III) oxide and thallium (I) oxide does not account for the electrochemical equivalent weight. Peltier and Duval (7) have found from a thermogravimetric study that the thallium oxide prepared by chemical means is distinctly different from that prepared by electrolytic means: the electrolytic oxide retains water very tenaciously and its pyrolysis curve beyond 677° C differs greatly from that of the other oxide.

In a study of the effect of temperature on the stability of thallium (III) oxide, samples of oxide were heated for a half hour at 190° under a pressure of 5 microns and these samples were sealed off and placed in a furnace at 300° C for several hours. When cooled, the ampules had droplets of water clinging to their inner walls. Samples of thallium oxide, which had been powdered and dried at 110° C, were heated in a tube furnace in a current of oxygen to minimize decomposition of the oxide–sesquioxide. In this way it has been possible to account quantitatively for the equivalent weight of the oxide. A typical result is given in Table II.

TABLE II

Analysis of thallium oxide

Equivalent weight of oxide	116.5_5
Wt. of Tl_2O_3 based on formula	114.22
Loss of water on heating to 340° C	0.81
Wt. of Tl_2O	1.48
Total	116.5_1

The oxide which had been dried for 1 hour at 340° C was analyzed for thallium (I) and it was found that, despite the atmosphere of oxygen, the thallium (I) content had increased to 1.95%. When this value of the thallium (I) oxide was added to 98.05%, the corrected value of the thallium (III) oxide, there was perfect accounting for everything in the moisture-free oxide. If the oxide is heated to 340° C in the air, the thallium (I) content is increased to a much higher value. The tendency of the oxide to decompose

when it is heated to render it anhydrous has been responsible for the confusion in the literature on the composition of the oxide.

How is the water retained by the oxide that is heated to constant weight at 110° C? The water seems to have its usual specific volume because the density of the electrodeposited oxide varies from 9.720 to 9.775 and these values have been determined by the buoyancy method and also by the pyonometer method. Thus the measured density of 9.730 for a sample of oxide whose equivalent weight was 116.2 agrees well with a value calculated on the assumption that the deposit is made up of thallium oxide with an X-ray density of 10.38 and of water present to the extent of 0.72%. An X-ray investigation of the oxide, using filtered copper radiation and large powder cameras, showed that the oxide dried at 110° C gave a pattern measured with a diffractometer identical with that of a sample which had been dried at 340° C in a current of oxygen. These findings do not invalidate the view that the water present in the oxide dried at 110° C is not in the crystal lattice. The powder pattern agreed almost perfectly with that reported by Swanson and Fuyat (8), who show that the crystal is cubic with space group $I2_13$, having 16 molecules to the unit cell. It might be mentioned here that a powder X-ray pattern was obtained for thallium oxide formed at the anode in the presence of ammonium fluoride and it showed that the lattice constants for this oxide, which contains fluoride, are distinctly different from those obtained for thallium oxide. The replacement of fluoride for oxygen in the lattice likely caused serious distortion of the crystal. Had the water been incorporated in the crystal it is likely that it would also have caused a change in the lattice constants.

If the water was mechanically trapped or occluded in the crystal lattice, one would expect to find traces of silver in the solution formed on dissolving the oxide: none was found. If the water was mechanically trapped, one would expect that freezing the sample would cause a change in the forces of attachment so that the water could then be removed readily on heating. A sample of oxide which had been dried at 110° C was immersed in liquid nitrogen for an hour. The electrode was then heated to 110° C for an hour and then was reweighed. There was no decrease in the weight of the oxide. This suggests that the water is not occluded.

It has been found in this laboratory that when the oxide is plated with the potential of the anode controlled by a potentiostat the plot of the logarithm of the current against the time did not give a straight line. According to Lingane (9) such a plot should yield a straight line when the electrode reaction occurs at 100% efficiency and when the rate of the reaction is controlled by the diffusion of the electroreactive species to the surface of the electrode. This suggests that the oxidation reaction is complex. Workers in kinetics of reactions, for example Vetter and Thiemke (10), have postulated the existence of Tl (II) as an intermediate in the oxidation of Tl (I). Perhaps the source of the defect structure of the oxide might be similarly explained.

ACKNOWLEDGMENTS

The author acknowledges with gratitude the technical assistance of Miss J. M. Osyany in making the conductivity measurements, and also the financial assistance of the Defence Research Board in making this work possible with Grant No. 9510-12.

ELECTRON PARAMAGNETIC RESONANCE STUDIES ON FREE RADICALS PRODUCED BY Tβ-PARTICLES IN FROZEN H_2O AND D_2O MEDIA AT LIQUID NITROGEN TEMPERATURE

J. KROH,[1] B. C. GREEN, and J. W. T. SPINKS

Received August 24, 1961

ABSTRACT

Samples of H_2O and D_2O and solutions of H_2O_2, $HClO_4$, HF, etc., in light and heavy water, were tritiated with T_2O to activities of from 0.1 to 1 c/ml.

The paramagnetic resonance spectra recorded at liquid nitrogen temperature and interpreted as representing H(D) atoms and OH(OD), $HO_2(DO_2)$ free radicals were compared with those induced under analogous conditions by Co^{60} γ-rays.

The lower radical yields observed in the present work have been ascribed to the difference in linear energy transfer between Tβ-particles and more penetrating radiations.

INTRODUCTION

As reported previously in several communications (1–3), the tritium technique of inducing electron paramagnetic resonance (EPR) spectra at low temperatures has several advantages. First of all, even for high doses of radiation (of the order of 10^{21} ev/ml) no spectral background due to irradiated glass or quartz (of the samples tubes) is produced. Secondly, the method may be used fairly universally in EPR studies of various systems, including organic materials not miscible with water (3). Lastly, the high density of ionization of Tβ particles allows one to examine the effects of linear energy transfer (LET) on the formation and trapping of free radicals.

The present work was undertaken to provide quantitative information on the production of radicals in tritiated H_2O and D_2O ice, as well as in some tritiated H_2O and D_2O solutions.

EXPERIMENTAL

Materials

Double-distilled H_2O, or D_2O (99.8% purity), was refluxed for several hours immediately before using, in a closed-circuit Pyrex apparatus, provided with a column 30 cm long and packed with glass Fenske helices. All materials present in the solutions ($HClO_4$, HF, H_2O_2, etc.) were of analytical grade and were used without further purification. A solution of T_2O, with an activity of 5 c/ml, provided by Merck and Co. Ltd., was used for tritiation of the samples.

Preparation of the Samples

The required activity of the sample was obtained by micropipetting and mixing the calculated volumes of T_2O solution and the experimental material directly in the sample tube. The tubes, Pyrex or quartz, were 4 mm in outside diameter and approximately 22 cm long. Some solutions were degassed by using the freeze–pump–thaw technique. This procedure was carried out in a small bulb, about 1 cm in diameter, blown onto the end of the sample tube.

Irradiation and Recording of the Spectra

The samples were kept in liquid nitrogen over the whole period of the experiment, in some cases up to 4×10^3 hours.

All electron spin resonance spectra were drawn with a Varian Associates V 4500 EPR spectrometer, equipped with an X band microwave bridge. The tip of a quartz Dewar flask containing the sample was inserted into the resonant cavity. A 6-inch Varian magnet system was used. The magnetic field modulation amplitude (frequency of 200 cycles/sec) was chosen for maximum signal strength at optimum resolution. The spectra are essentially "first derivative" curves.

[1]*Lodz, w. Zwirki 36, Politechnika, Poland.*

The magnetic field sweep in the region of $g = 2.00$ was calibrated by drawing spectra for the semi-quinone ion. Microcrystalline α,α-diphenyl-β-picrylhydrazyl (DPPH) was included with a sample when it was desired to mark the position of the DPPH peak on a spectrum.

Estimates of the quantity of spins in the samples were simplified by using the same size of tubing for all samples and by using sufficient material in the tubing to occupy fully the active region of the cavity. When the shape and width of spectra were identical, the heights of maxima on the curves were used for comparisons of relative numbers of spins. If shape and width differences were apparent, double integrations of the spectral curves were used when comparing relative concentrations. Estimates of absolute quantities of "spins" were obtained through indirect comparisons of the spectra of the samples and the spectra of freshly prepared solutions of DPPH, of known concentration, in benzene. Spectra which were compared for quantitative information were drawn under identical operating conditions and conditions for which power-saturation effects were absent. Indirect comparisons of the DPPH solutions and the samples were made through the use of the gamma-irradiated barium salt of dichloroacetic acid or a dispersion of charcoal in lactose. This technique was used because the DPPH solutions were found to be unstable, because the width of their spectra narrows greatly at liquid nitrogen temperatures, and because the homogeneity of the frozen "solution" is questionable.

The accuracies of estimates of relative "spin" concentrations are probably of the order of a few per cent. The estimates of absolute values of "spin" concentrations involve various uncertainties. The values obtained in this work appear to be reasonable and are considered to be well within 50% of the true values.

Warming Experiments

The thermal stability of the free radicals was examined in the following manner. The sample was placed in a hole 2 cm deep and 5.5 mm in diameter drilled along the axis in the upper end of a brass rod 30 cm long and 2.5 cm in diameter. The lower part of this rod was immersed in liquid nitrogen, and the temperature of the sample was regulated by the depth of the immersion. Two iron–constantin thermocouples, located near the sample, were used for recording the temperature. The measuring system was calibrated with several "freezing systems", and it allowed one to read the temperature to within 2 to 3 degrees.

The warming of the sample and recording of the spectrum, the latter always at liquid nitrogen temperature, were performed alternately. During the warming of a sample the temperature was raised from −196° C (liquid nitrogen temperature) to a required value in a period of about 8–10 minutes. This time was kept approximately constant by controlling the distance between the upper end of the brass rod and the level of the liquid nitrogen in which the lower end was immersed.

H_2 Analysis

The production of molecular hydrogen in the tritiated samples was examined by a gas chromatography method. After the samples were degassed and sealed up in the break-seal containers, they were kept in liquid nitrogen until the required dose of radiation was absorbed. Then, after the sample was thawed, the evolved gas was introduced, using helium as a carrier, into the gas chromatography system. The chromatograph was equipped with a silica gel column, and it operated at room temperature.

The system was calibrated with hydrogen produced in degassed water by Co^{60} γ-rays applied in doses varying from 4.8×10^{18} to 2×10^{19} ev/ml. In plotting the calibration curve (recorded signal vs. amount of H_2) the value of $G(H_2) = 0.45$ (4) for γ-irradiated water was used.

RESULTS

Irradiation of H_2O and D_2O Ice

The EPR spectra of degassed, tritiated H_2O, D_2O, and H_2O+D_2O ice are shown in Fig. 1A, 1B, and 1C, respectively. The location of spectra in the magnetic field is marked by a vertical line indicating the position of the center of the DPPH spectrum. In all diagrams, the magnetic field increases to the right.

The spectra in Fig. 1A and 1B have been interpreted (see discussion) as representing OH and OD radicals, respectively.

The spectrum of OH radicals (1A) consists of a doublet with a separation of about 40 gauss and $g = 2.01$. OD radicals (1B) are represented by a triplet with approximately the same g and separation of 6 gauss between neighboring lines.

The spectrum in Fig. 1C is that of the sample containing D_2O and H_2O in the volumetric ratio 4:1. The central OD triplet is located between two peaks ascribed to the OH doublet. The latter is just noticeable in the spectrum of Fig. 1B, since the amount of

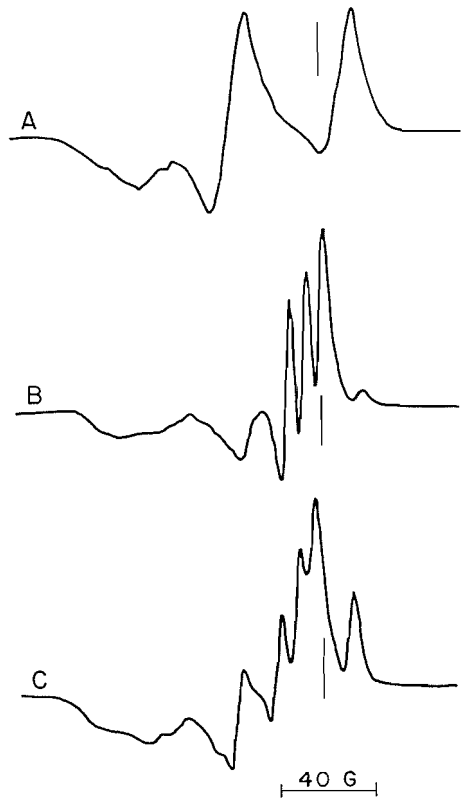

FIG. 1. EPR spectra of tritiated H_2O (A), D_2O (B), and H_2O+D_2O (C) ice.

H_2O unavoidably introduced into the sample with T_2O does not exceed, in this case, 2%.

The concentration of OH and OD radicals, as measured in the samples irradiated at a dose rate of 7.6×10^{17} ev/ml hr, are plotted against the total absorbed dose in Fig. 2.

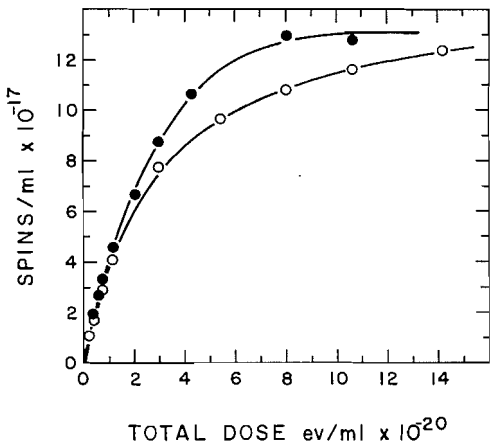

FIG. 2. Formation of OH (O) and OD (●) radicals in tritiated H_2O and D_2O ice.

Both types of radicals seem to reach their stationary concentrations at a level of about 1.3×10^{18} spins/ml.

To examine the dose-rate dependence at the initial radical yields, several samples were tritiated to lower activity and irradiated at a dose rate of 10^{17} ev/ml hr. The initial stage of the formation of OH radicals in one such sample is shown in Fig. 3, curve 1.

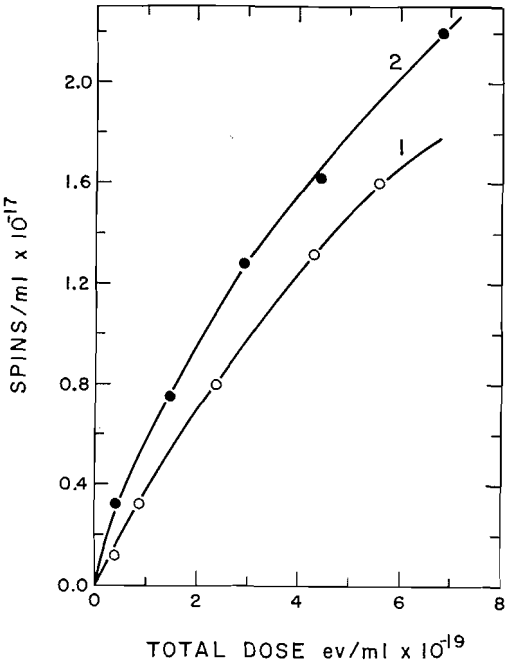

FIG. 3. Formation of OH radicals, as determined immediately after tritiation (1) and after melting and refreezing the sample (2).

Some of the samples were thawed, frozen in liquid nitrogen, irradiated, and examined again. It was found that such procedure results in increased radical yields. This may be seen in Fig. 3, where curve 2 represents the formation of OH radicals in the thawed and refrozen sample.

The yields of OH and OD radicals, as found under various experimental conditions, are as follows:

TABLE I

Radical yields in H_2O and D_2O Ice (G values)

	OH radical		OD radical	
Dose rate (ev/ml hr)	Immediately after tritiation	After second freezing	Immediately after tritiation	After second freezing
7.85×10^{16}	—	—	0.36	0.50
8.95×10^{16}	0.32	0.85	—	—
7.6×10^{17}	0.32	—	0.45	—

In the H_2O ice samples an interesting orientation effect was observed. Both the height of the OH doublet and its shape were found to depend on the position of the sample in the cavity. Turning the sample around its vertical axis changed the height of the OH

peaks. This passed through four successive maxima in a 360° rotation. Neighboring maxima were spaced approximately 90° apart. Moreover, of the two pairs of "opposite" maxima, spaced 180° apart, one was particularly pronounced. Effects on spectra of orientation with respect to the magnetic field for irradiated single ice crystals were reported by McMillan, Matheson, and Smaller (5) and by Livingston, Zeldes, and Taylor (6). It appears probable that a net crystallite alignment in our samples was responsible for the observed orientation effects. To ensure reproducibility, all OH spectra are recorded with the sample placed in its "maximum" position. A similar but less marked effect existed in the D_2O ice.

On warming of the sample, both OH and OD radicals seem to disappear in the same temperature range. As shown in Fig. 4, a rapid drop in the concentration of radicals

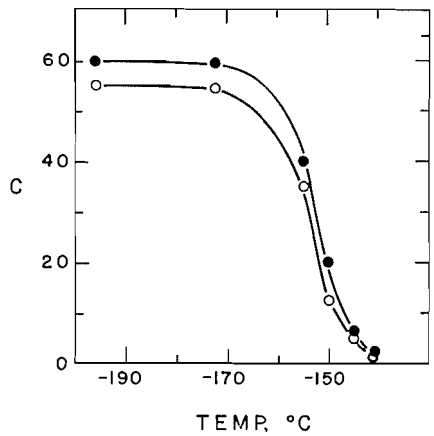

FIG. 4. Thermal decay curves of OH (○) and OD (●) radicals in H_2O and D_2O ice. The concentration (C) of free radicals is given in relative units.

occurs between −160 and −150° C. The weak EPR signal left after removal of OH radicals, i.e., at about −140° C, is shown in Fig. 5A. The concentration of the radical

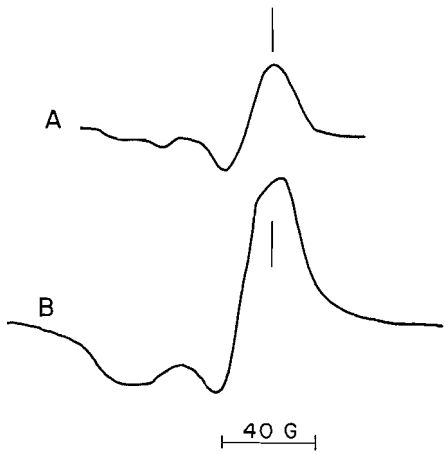

FIG. 5. EPR spectra of tritiated H_2O ice warmed from liquid nitrogen temperature to about −140° C (A) and tritiated H_2O_2 at −196° C (B).

represented by this spectrum for the sample with activity 1 c/ml irradiated with a total dose of 1.4×10^{21} ev/ml amounts to about 5% of the initial (before warming) concentration of OH radicals. The analogous spectrum recorded at $-140°$ C for D_2O ice was found to be much less intense.

In order to determine the nature of the radicals surviving in warmed H_2O ice, a 20% aqueous solution of H_2O_2 was tritiated to the activity 0.33 c/ml, degassed, and frozen in liquid nitrogen. The EPR spectrum of the radicals formed under these conditions is shown in Fig. 5B. The radical is formed with a very high yield, $G = 4$, and its concentration increases linearly with the time of irradiation up to doses of the order of 10^{21} ev/ml (see Discussion).

No H(D) atoms were found in tritiated $H_2O(D_2O)$ ice even in the samples subjected to large doses of the order of 10^{21} ev/ml.

Irradiation of Acidified and Alkaline H_2O and D_2O

Guided by the experiments of Livingston and Weinberger, several tritiated samples of $HClO_4+H_2O$ (I) and $HClO_4+H_2O+D_2O$ (II) mixtures were examined. In both types (I and II) of samples the activity was 0.5 c/ml, equivalent to the dose rate of 3.8×10^{17} ev/ml hr.

In samples I the molar ratio of $HClO_4$ was 1:7, whereas in samples II the molar ratio $HClO_4$:H_2O:D_2O was 1:3:4. Thus, in samples II the total numbers of H and D atoms were approximately equal. In all samples containing perchloric acid, H and D "atoms" were readily produced. The EPR spectra showed also the presence of other paramagnetic species, represented by absorption in the $g = 2$ region.

This "central" part of the spectrum could be almost completely eliminated by recording at the very low power necessary for the prevention of the saturation of the H and D lines. In contrast to this, by using high microwave power, the central spectrum was enhanced, whereas H and D signals were found to be strongly saturated and weakened.

The relative heights of the three deuterium lines changed extensively when the microwave power was altered at saturation levels. The "true" height of the center line is uncertain at higher-power levels, due to admixture with other absorption in the $g = 2.00$ region. It appears at these powers to be equal in height to or slightly shorter than the low-field deuterium line. The ratio of the peak height of the low-field line to the peak height of the high-field line changed from more than 5 to 1 as the microwave power was decreased. Jens, Foner, Cochran, and Bowers (8) reported the center line higher than *either* the low- or high-field line for condensed discharge products in deuterium at 4° K.

The low-field hydrogen line was *slightly* higher than the high-field line under power-saturation conditions. This difference reversed at lower microwave powers. The deuterium appears to show saturation effects more readily than the hydrogen.

The low-power spectrum of sample II is shown in Fig. 6. The spectrum consists of two hydrogen lines with separation of about 500 gauss and three D lines with separation of about 80 gauss.

Satellites were observed on both the H and D lines at microwave-power-saturation levels and in the earlier stages of the irradiations. They were not observed in the later stages. Zeldes, Livingston, and co-workers have reported satellites in similar systems (6, 9, 10).

Figure 7 shows the concentrations of H atoms in sample I (curve 1) and H and D atoms in sample II (curves 2 and 3) as plotted against the total dose of radiation.

FIG. 6. "Low-power" EPR spectrum of tritiated $HClO_4+H_2O+D_2O$ mixture at liquid nitrogen temperature. The spectrum consists of two H and three D lines.

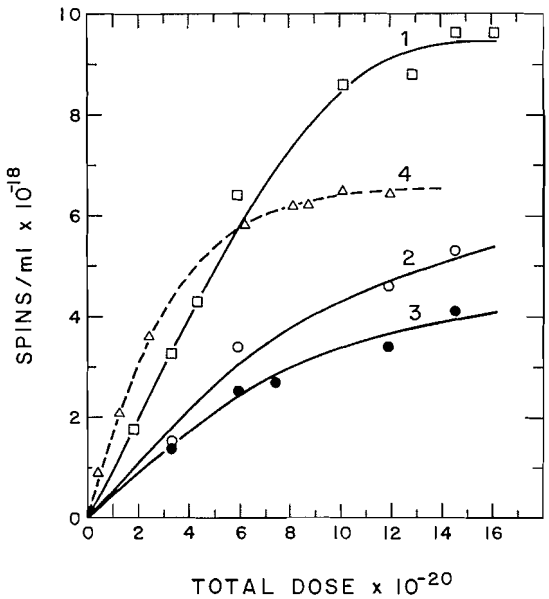

FIG. 7. Formation of stabilized atomic hydrogen and deuterium in $HClO_4$ solutions. Curve 1 shows hydrogen production in sample I ($HClO_4+H_2O$). Curve 2 shows the hydrogen production in sample II ($HClO_4+H_2O+D_2O$). Curve 3 shows the production of atomic deuterium in sample II. Curve 4 shows the formation of H atoms in sample I, as calculated on the basis of line height. The difference between the results of integration and determining line heights may be seen by comparing curve 1 and 4.

The initial yield rate of H radicals in sample I is $G(H) = 1$, and the saturation concentration of H atoms is of the order of 10^{19} spins/ml. In sample II the initial yield rates were $G(H) \approx G(D) = 0.5$, but the concentration of H atoms seems to increase faster than that of D atoms.

The width of the H and D lines increases noticeably with concentration, especially when the latter approaches the stationary level. This can be seen in Fig. 8, showing H lines corresponding to two different concentrations. Line-width changes with increased radiation dosage have been reported by Livingston and co-workers (6, 7). Thus, an estimate of H concentration based on the line height would be misleading. This is demonstrated in Fig. 7, in which the broken curve 4 represents the "concentrations" of H atoms in sample I, as calculated from the line heights.

The central "high-power" spectra of samples I and II are shown in Fig. 9A and 9B, respectively. The spectrum of the tritiated $HClO_4+H_2O+D_2O$ mixture (sample II)

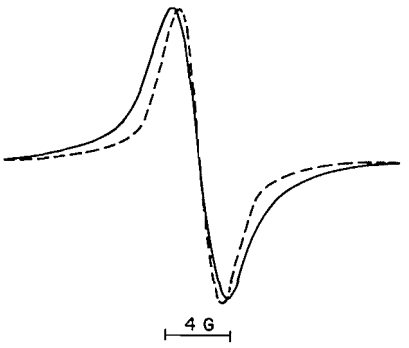

FIG. 8. Two hydrogen lines recorded for $HClO_4+H_2O$ sample after the dosage of 6×10^{20} ev/ml (broken) and 14.5×10^{20} ev/ml (continuous).

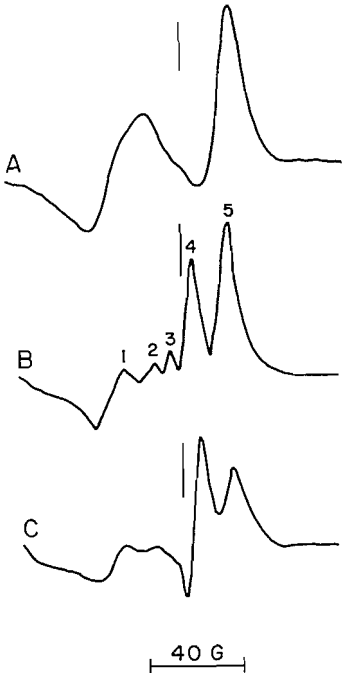

FIG. 9. "High-power" EPR spectra of $HClO_4+H_2O$ (A) and $HClO_4+H_2O+D_2O$ (B) samples. Spectrum (B) changes into (C) after subjecting the sample to large doses of radiation.

changes its shape in the course of irradiation. This can be seen by comparing spectra 9B and 9C, induced by low and high doses of radiation, respectively.

On warming sample II, the concentration of H and D atoms falls, as shown in Fig. 10. Curves denoted by "OH" and "OD+D" were determined by examining the decrease of the high-field peak in spectrum 9A and peak 4 in spectrum 9B, respectively.

At about $-150°$ C a new spectrum appears in both samples I and II. The broken curve in Fig. 10 represents the increase in intensity of this new, unidentified spectrum with temperature. Among the other members of this series, the simplest spectrum in the central, $g = 2$ region was obtained by irradiation of hydrofluoric acid (Fig. 11). On warming the acid, this spectrum disappears in a temperature range very close to that of the disappearance of "OH" radicals in $HClO_4$ samples (Fig. 10), but the deformation

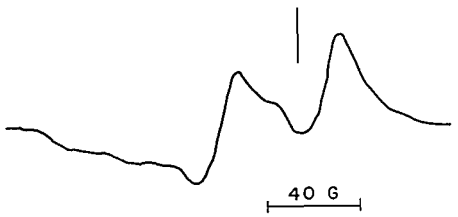

FIG. 11. High-power EPR spectrum of tritiated HF sample.

of the spectrum and the production of new species occurs to a much less extent than in perchloric acid. However, the formation of stable H atoms at −196° C is much lower in the HF medium than in $HClO_4$. In 16% HF, tritiated to 0.33 c/ml, the initial hydrogen yield was found to be 0.06. Moreover, the concentration of H atoms reaches the stationary state at about 2×10^{17} spins/ml, a much lower concentration than that found for $HClO_4$.

In other acidified and alkaline solutions which were examined, the concentration of atomic hydrogen was even lower. In 24% HCl solution, tritiated to 0.33 c/ml, H lines, though easily detectable, could not be used for any reliable quantitative measurements. In concentrated 10 *M* NaOH solution with the same activity, atomic hydrogen was produced with slightly higher yield, though still lower by one order of magnitude than in HF. Following the last observation, diluted (0.1 *M*) and concentrated (5 *M*) aqueous solutions of LiOH, NaOH, KOH, and $Ba(OH)_2$ were irradiated at liquid nitrogen temperature with Co^{60} γ-rays. In all concentrated solutions, small quantities of hydrogen were found. The most favorable conditions for the production of H atoms seem to exist in NaOH solutions.

Most of the tritiated materials became strongly colored in the course of irradiation. $HClO_4$ solutions acquired yellowish coloring; HCl, bright green; NaOH, dark blue.

Production of Molecular Hydrogen

Tritiated samples of water and 35% $HClO_4$, each 10 ml in volume, were degassed and frozen in liquid nitrogen. After they had absorbed the total dose of 2.55×10^{18} ev/ml at a dose rate of 1.52×10^{16} ev/ml hr, the samples were thawed and examined chromatographically. The whole analytical procedure was carried out under exactly the same conditions as in the calibration experiments, with γ-irradiated samples. The yields of molecular hydrogen in ice and frozen $HClO_4$ solution were found to have G values of 0.1 and 0.31, respectively.

In the identical H_2O and $HClO_4$ samples irradiated at room temperature to the total dose of 1.96×10^{19} ev/ml, the respective yields in water and perchloric acid had G values of 0.59 and 0.30.

DISCUSSION

The EPR spectra of tritiated H_2O and D_2O ice (Fig. I, A and B) have been assumed to represent OH and OD radicals, respectively. Such an interpretation seemed to be supported by recent reports of other authors. The EPR spectra found for Co^{60} γ-irradiated ice by Siegel (12) and his colleagues, and ascribed by them to OH and OD radicals, are identical with those reported here.* Very similar spectra were found by Piette *et al.* (13) for ice irradiated by fast electrons, and by McMillan *et al.* (5) for γ-irradiated single crystals of ice.

Results of ultraviolet irradiations of dilute H_2O_2 solutions at liquid nitrogen temperature, reported by us (11) recently, also support the above interpretation. The EPR spectrum recorded at liquid nitrogen temperature after prolonged ultraviolet irradiation of 10^{-3} to 10^{-2} M H_2O_2 becomes identical with that in Fig. 1, A. Photolysis of H_2O_2 most likely results only in OH formation, and in the dilute medium any secondary processes are of low probability.

The increase in radical yields after melting and refreezing (Table I and Fig. 3) is of considerable interest. Melting of the tritiated H_2O ice results in OH recombination and production of small quantities of H_2O_2. The concentration of the latter may be calculated from the specific activity of the sample and the duration of the experiment; in the case of the samples referred to in Table I as "after second freezing", this is of the order of 10^{-3} M. It is difficult to make any quantitative estimate of the probable effect of this amount of H_2O_2 on OH yield since, as indicated in ref. 11, the yield of OH on irradiation of H_2O_2 is strongly dependent on the H_2O_2 concentration. However, it has been pointed out (11) that the yield of HO_2 radicals in H_2O_2 is greater than that of OH radicals in ice by a factor of about 10, leading to G_{HO_2} in H_2O_2 of about 4. If HO_2 is formed by $OH + H_2O_2 \rightarrow HO_2 + H_2O$, it follows that the initial G_{OH} in H_2O_2 solutions must also be about 4. Thus, a small percentage of H_2O_2, say 1%, could give a 10% increase in OH yield, and it is therefore not unreasonable to attribute a good fraction of the observed 25% or so increase to H_2O_2 produced in the irradiation prior to thawing and refreezing.

The spectrum in Fig. 5A, left after warming H_2O ice to about $-140°$ C, is thought to represent the HO_2 radical. The spectrum is very similar to that obtained by irradiation

**Our attention has been drawn to a very recent paper by Flournoy and Siegel (given at the International Free Radical Symposium in Uppsala in June 1961) in which radical formation in tritium-enriched ice is reported. They give a curve for* OH *buildup similar to ours and then proceed to discuss the rate of disappearance of* OH *at 100° K.*

of concentrated H_2O_2, both with Tβ-particles (Fig. 5, B) and ultraviolet rays. In concentrated hydrogen peroxide most of the OH radicals are thought to be scavenged in the reaction $OH + H_2O_2 \rightarrow H_2O + HO_2$, resulting in the formation of HO_2 radicals. The thermal stability of the radical represented by spectrum 5A is the same as the stability of radicals produced in concentrated H_2O_2.

Of particular interest is the comparison of radical yields for various types of radiation. The corrected (14) value of $G(OH)$ reported by Siegel and colleagues (12) for γ-irradiated ice is about 0.6. The values for tritiated ice, given in the first column of Table I, are lower almost by half. An analogous situation occurs in the production of atomic hydrogen in $HClO_4$ solutions.

Several experiments were carried out in order to compare directly the yields of stabilized atomic hydrogen for Co^{60} γ-rays ($G(H)_\gamma$) and Tβ-particles ($G(H)_\beta$). Tritiated $HClO_4$ samples, used previously for the determination of $G(H)_\beta$ were melted, refrozen in liquid nitrogen, irradiated by Co^{60} γ-rays at a dose rate of 4.8×10^{18} ev/ml hr, and then immediately subjected to EPR examination. Under such conditions, atomic hydrogen was mainly produced by γ-radiolysis, the dose rate for γ-rays being more than one order of magnitude higher than that for Tβ-particles. However, the results $G(H)_{\gamma+\beta}$ were corrected by subtracting the small contribution of Tβ-particles. The value of $G(H)_\gamma$ in sample I was found to be very close to 2, in good agreement with the value of about 2.1 reported by Livingston and Weinberger for $HClO_4$ (0.125 mole fraction). Hence, by reference to Table II the ratio $G(H)_\gamma/G(H)_\beta$ may be assumed to be about 2.

The above differences between Tβ- and γ-radiolysis are most likely due to the higher LET of Tβ-particles, resulting in greater density of radicals and eventually in a larger fraction of radicals undergoing recombination.

The comparison of stationary concentrations of H and OH radicals in γ- and Tβ-irradiated samples is inconclusive. The stationary concentrations of H atoms in $HClO_4 + H_2O$ mixture (mole ratio 1:7) for γ-rays (5) and Tβ-particles are 2.9×10^{19} atoms/g and 10^{19} atoms/ml, respectively. However, for OH radicals produced in H_2O ice these values show a reversed order of magnitude and are 0.36×10^{18} * and 1.3×10^{18} spins/ml, respectively.

The spectra induced in $HClO_4$ and shown in Fig. 9 most likely represent some species produced by radiolysis of perchloric acid, superimposed on an OH doublet and OD triplet, respectively. This conclusion may be drawn by comparing the g values and separations of the spectra in Figs. 9 and 1. Neglecting the deformation of the spectrum by an unidentified component due to the presence of the acid, the spectrum in 9A may be treated as essentially representing an OH doublet, whereas in spectrum 9B, peaks 1 and 5 correspond to the OH doublet and peaks 2, 3, and 4 to the OD triplet. Moreover, peak 4 coincides with the central D line. Consequently, in the warming experiments (Fig. 10) the high-field peak in spectrum 9A and peak 4 in spectrum 9B are denoted as "OH" and "OD+D", respectively.

The difference in shape between the low-dose spectrum in 9B and the high dose spectrum in 9C may be explained by referring to Figs. 2 and 7, and assuming that the kinetics of OH(OD) formation, as determined for ice, remains approximately unchanged in $HClO_4$.

The above-mentioned figures show that the stationary concentration of OH and OD radicals in ice is approached at a much lower dosage than that of D atoms in $HClO_4$

**This value was estimated by applying to the stationary concentration reported by Siegel and colleagues (12) the same correction (14) given by the authors in reference to G values.*

(sample II, curve 3 in Fig. 7). Consequently, after prolonged irradiation, peak 5 in spectrum 9B reaches a constant height, whereas peak 4, representing OD radicals and D atoms, still increases.

The kinetics of formation and thermal stabilities of the H and OH and the D and OD radicals produced in H_2O and D_2O media are essentially the same. According to Fig. 2 and Table I, $G(OD) \geq G(OH)$, as in liquid water. However, in view of the limited accuracy of the quantitative results reported here, any theoretical discussion of the comparative mechanism of the H_2O and D_2O radiolysis would not be justified.

Some further conclusions, concerning the final fate of radicals disappearing on warming and to some extent in the course of irradiation, may be drawn on the basis of Table II.

TABLE II

Some radical and molecular yields (G values) of Tβ-radiolysis of H_2O and $HClO_4$

Product	Medium	
	$HClO_4$ (0.125 mole fraction)	H_2O
Stabilized H	1.0	0
Stabilized OH	—	0.32
H_2 After irradiating the sample at liq. N_2 temperature and melting	0.31	0.1
H_2 After irradiation at room temperature	0.30	0.59

According to Siegel *et al.* (12), OH radicals in γ-irradiated ice undergo mainly an H+OH reaction. Livingston and Weinberger (7) claim that the predominant process in the disappearance of H atoms in irradiated acids is H+H combination. Our results seem to be in agreement with both opinions.

The basic difference between conditions of radical recombination in H_2O and $HClO_4$ medium is that in the latter the concentration of stabilized H atoms is building up in the course of irradiation. Consequently, when the radicals are liberated by warming, the reaction H+H may successfully compete with other recombination processes. In ice at $-196°$ C, no stabilized atomic hydrogen is produced and most of the H atoms probably combine immediately after formation with OH radicals, the H+H process being negligible because of the very low concentration of hydrogen atoms.

The predominance of the H+H reaction in $HClO_4$ medium, and of the H+OH reaction in ice, may be seen by comparing $G(H_2)$ values in both media. The yield of molecular hydrogen in $HClO_4$ (Table II) is higher than in ice by a factor of 3 and accounts for almost two thirds of the hydrogen which could be theoretically produced by H+H combination. All samples prepared for gas analysis were irradiated with low doses so that during the irradiation, the concentration of radicals may be assumed to increase linearly with the dose. In this stage of irradiation the recombination of radicals is negligible.

The stationary concentrations of stabilized OH radicals in H_2O and $HClO_4$ matrix are hardly comparable. If, however, both values are of the same order, then, according to Figs. 2 and 7, the values of [H] would, after prolonged irradiation, reach a much higher level than the value [OH]. Thus, it is possible that as the irradiation progresses the conditions for H+H combination become even more favorable, as compared with the H+OH reaction.

The figures given in Table II show that the ratio $G(H_2)^{HClO_4}/G(H_2)^{H_2O}$ is about six times higher at liquid nitrogen temperature than at room temperature. This again seems to indicate that the accumulation of stabilized H atoms occurring only at liquid nitrogen temperature in $HClO_4$ is a main factor contributing to high H_2 yield in this medium.

Finally, comparison of Figs. 4 and 10 shows that OH radicals in ice disappear at about 10° lower temperature than OH radicals in $HClO_4$. Thus, the presence of stabilized atomic hydrogen does not facilitate the removal of OH radicals. On the contrary, the OH radicals are less mobile in $HClO_4$ matrix, possibly being more strongly hydrogen bonded or in complexes with the acid.

The yields of molecular hydrogen in $HClO_4$ (0.316 in 0.125 mole fraction solution) and in ice (0.1) given in Table II, are in very good agreement with those found by Livingston and Weinberger (7) for γ-irradiated acid and ice. However, the ratio $G(H_2)/G(H)$ is twice as high in tritiated acid as in γ-irradiated material. This may be, at least partly, accounted for by the different LET of these types of radiation.

It is worth mentioning that in $HClO_4$ medium, H atoms (and OH radicals) may also be removed by combining with some other species formed by irradiation of perchloric acid. This might explain the appearance of a new spectrum, when the sample is warmed, which is represented by a broken curve in Fig. 10, corresponding to the same temperature range in which H atoms rapidly disappear.

PERFLUOROALKYL ARSENICALS

PART IV. SOME REACTIONS OF TRIFLUOROIODOMETHANE WITH ALKYL ARSINES

W. R. CULLEN
The Chemistry Department, University of British Columbia, Vancouver, British Columbia
Received October 31, 1961

ABSTRACT

Trifluoroiodomethane reacts with triethyl- and tri-*n*-butylarsine, and tri-*n*-butylphosphine to give products of the type R_2MCF_3. Heptafluoroiodopropane reacts similarly with trimethylarsine. Trifluoroiodomethane also reacts with the compounds $(CH_3)_2AsX$ (X = C_6H_5, Cl, I) and CH_3AsI_2 to give $CH_3As(CF_3)_2$; and in most of these reactions the compound $CH_3As(CF_3)I$ is also formed, which is converted to the compound $CH_3As(CF_3)Cl$ by reaction with silver chloride.

DISCUSSION AND RESULTS

Alkyl-trifluoromethyl-arsines and -phosphines can best be obtained by exchange reactions using the compounds $(CF_3)_3M$ and $(CH_3)_3M$ (1, 2, 3):

$$(CF_3)_3M + CH_3I \rightarrow (CF_3)_2MCH_3 + CF_3I$$
$$2(CH_3)_3M + CF_3I \rightarrow (CH_3)_2MCF_3 + (CH_3)_4MI$$

or in the case of the arsines by the reaction of alkyl-iodo-arsines with trifluoroiodomethane in the presence of mercury (4), for example,

$$(CH_3)_2AsI + Hg + ICF_3 \rightarrow (CH_3)_2AsCF_3 + HgI_2.$$

However, it has recently been found (5) that the main products from the reactions of diethyl- and di-*n*-butyl-iodoarsine with trifluoroiodomethane in the presence of mercury are ethylbistrifluoromethylarsine and *n*-butylbistrifluoromethylarsine respectively. No di-*n*-butylbistrifluoromethylarsine was isolated from these reactions and only a little diethyltrifluoromethylarsine was found. These results suggest that an exchange reaction takes place between the initially formed dialkyltrifluoromethylarsine and trifluoroiodomethane, producing the alkylbistrifluoromethylarsine.

It has now been found that neither triethylarsine nor tri-*n*-butylarsine reacts with trifluoroiodomethane at 20°, and at 100° the major products (in good yield) of the reaction is the dialkyltrifluoromethylarsine. Only small yields of the corresponding alkylbistrifluoromethylarsines are obtained. Thus some other explanation must be sought for these apparently contradictory results. The reaction of trifluoroiodomethane with tri-*n*-butylphosphine occurs more readily than with the corresponding arsine. Thus at 20° di-*n*-butyltrifluoromethylphosphine is formed in low yield. When the reaction is carried out at 100° the yield is not much improved. There is no indication that further exchange to produce *n*-butylbistrifluoromethylphosphine takes place in this reaction. This result agrees with the findings of Haszeldine and West (3), who report that dimethyltrifluoromethylphosphine is stable to trifluoroiodomethane even at 240°, whereas the corresponding arsine at 240° is converted by trifluoroiodomethane to methylbistrifluoromethylarsine. Thus the result of the present investigation, that further reaction of dialkyl trifluoromethyl arsines takes place to a limited extent at 100° to give alkyl bistrifluoromethyl arsines, is not unexpected.

It is very difficult to recover the unreacted trifluoroiodomethane from reactions with tri-*n*-butylphosphine, suggesting that, on mixing, a moderately stable phosphonium

complex is formed. Mixtures of triphenylphosphine and trifluoroiodomethane behave similarly. Such a complex has been suggested as an intermediate for exchange reactions (2) and its stability in the case of the reaction of tri-*n*-butylphosphine could account for the low yield of the trifluoromethylphosphine.

Heptafluoroiodopropane has also been found to react in exchange reactions. Thus heptafluoropropyldimethylarsine is obtained in moderate yield from the reaction of trimethylarsine and heptafluoroiodopropane at 100°:

$$C_3F_7I + (CH_3)_3As \rightarrow C_3F_7As(CH_3)_2 + (CH_3)_4AsI.$$

The reaction in this case is slower than the one in which trifluoroiodomethane is used (2).

The effect of changing the basicity of the arsine in reactions of this sort has been investigated by reacting the compounds $(CH_3)_2AsX$ (X = C_6H_5, Cl, I) and CH_3AsI_2 with trifluoroiodomethane. In no case does reaction occur below 100°, a result which could be expected if the reaction proceeds through the formation of a quaternary iodide (2), since the basicity of these compounds must be considerably lower than that of trimethylarsine. However, reaction does occur at higher temperatures and a large number of products is obtained from a given reaction, for example,

$$(CH_3)_2AsI + CF_3I \rightarrow CF_3H + CH_3I + CH_3As(CF_3)_2 + CH_3As(CF_3)I + (CH_3)_4AsI_3 + ?$$

$$(CH_3)_2AsC_6H_5 + CF_3I \rightarrow CF_3H + CH_3I + C_6H_5CF_3 + CH_3As(CF_3)_2 + C_6H_5As(CF_3)CH_3 + C_6H_5As(CF_3)_2 + C_6H_5As(CH_3)_3I_3 + ?$$

Both methylbistrifluoromethylarsine and iodomethyltrifluoromethylarsine are amongst the products of the reaction of trifluoroiodomethane with chlorodimethylarsine and diiodomethylarsine. The reaction of triphenylphosphine and chlorodiphenylphosphine with trifluoroiodomethane has recently been found to give diphenyltrifluoromethylphosphine together with a number of other products (7). In all these reactions the nature and variety of the products suggest that a radical mechanism is involved. Such a mechanism has been suggested by many workers (e.g. ref. 8) for the reaction of arsenic metal (or arsenic triiodide) with trifluoroiodomethane, a reaction which yields the compounds $(CF_3)_nAsI_{3-n}$ (n = 1, 2, 3). On this basis a radical reaction could be expected to produce iodomethyltrifluoromethylarsine from the reaction of trifluoroiodomethane with the compounds $(CH_3)_2AsX$ (X = Cl, I) and CH_3AsI_2, though it would be difficult to account for the formation of this product using a mechanism based on an arsonium intermediate. However, in the reactions of the alkylarsines with trifluoroiodomethane there is no evidence for the formation of tristrifluoromethylarsine, a likely product from a radical reaction. The results of Haszeldine and West (3) suggest that in the presence of trifluoroiodomethane and iodomethane the most stable arsenic compound containing methyl and trifluoromethyl groups is methylbistrifluoromethylarsine, so the formation of this compound even in reactions with a free radical mechanism could be expected.

The new compound iodomethyltrifluoromethylarsine attacks mercury and has only been provisionally characterized on the basis of its infrared spectrum, which shows the presence of CH_3, and only one CF_3 group since there are only two strong bands in the C—F stretch region. This feature is present in the spectra of other reported trifluoromethyl-arsines and -phosphines (9, 10, 11), and in the spectra of the other new compounds prepared in this investigation, namely, di-*n*-butyltrifluoromethylphosphine, b.p. ca. 160° (760 mm), 115° (83 mm); di-*n*-butyltrifluoromethylarsine, b.p. 186° (760 mm), 110°

(60 mm); and chloromethyltrifluoromethylarsine, b.p. 76° (760 mm). The last compound is obtained by reacting the corresponding iodo-arsine with silver chloride, a result which confirms the identification of the iodo-arsine. The chloro-arsine has a boiling point midway between chlorobistrifluoromethylarsine (46° (12)) and chlorodimethylarsine (107° (13)), and other chemical and physical properties are expected to show the same trend. Further work is in progress on this interesting compound.

Dimethyltrifluoromethylarsine is sufficiently basic to form an arsonium iodide at 20° when reacted with iodomethane (2). However, diethyltrifluoromethylarsine does not react with iodomethane at 20° or with iodoethane at 100°; and at 150° reaction with iodoethane take place, producing fluoroform, trifluoroiodomethane, and tetraethylarsonium triiodide. The rate of hydrolysis of the ethyl-trifluoromethyl-arsines is faster than that of the corresponding methyl-trifluoromethyl-arsines (6), indicating that the ethyl compounds are less basic than the corresponding methyl compounds (2). Thus, formation of arsonium compounds by reaction with alkyl iodides would be expected to be less easy in the case of the ethyl-trifluoromethyl-arsines.

EXPERIMENTAL

The techniques used for this investigation were the same as have been described in previous papers in this series. Descriptions of the methods of preparation of starting materials are included only for those compounds not previously used in this series of investigations.

Reaction of Triethylarsine with Trifluoroiodomethane

Triethylarsine was prepared from arsenic trichloride and ethylmagnesium bromide (14). The arsine (14.0 g) and trifluoroiodomethane (99.0 g) in a sealed tube (100 ml) were left at 20° for 5 months. Only a small amount of white solid was produced and trap-to-trap distillation gave a quantitative recovery of trifluoroiodomethane (99.0 g). The white solid (<10 mg) was shown to be mainly tetraethylarsonium iodide by means of its infrared spectrum and X-ray powder photograph. When triethylarsine (6.563 g) and trifluoroiodomethane (10.760 g), in a sealed tube (50 ml), were left for 2 weeks at 20° no solid appeared, but after it was heated at 100° for 5 days a colorless solid was produced. Trap-to-trap distillation of the volatile contents of the tube gave two fractions. Infrared examination of the least volatile fraction showed it to be mainly diethyltrifluoromethylarsine together with a little ethylbistrifluoromethylarsine (5). The fraction was distilled in a nitrogen atmosphere (760 mm) and 3.2 g (78% yield) of diethyltrifluoromethylarsine was obtained, b.p. 110–114° (lit. value 111° (5)). The arsine was also identified by its infrared spectrum and gas phase molecular weight of 198 (calc. 204). The colorless solid remaining in the reaction tube was dissolved in ethanol (100 ml). The solution was filtered, and the solid was precipitated by the addition of a large excess of ether. This was repeated and the product was identified as tetraethylarsonium iodide (5.3 g, 82% yield) by means of its infrared spectrum and X-ray powder photograph. In another experiment triethylarsine (3.8 g) and trifluoroiodomethane (23.7 g) were heated to 100° for 18 days. The reaction mixture darkened in color but no solid was produced. Trap-to-trap distillation gave a less volatile fraction (2.5 g) which was found to contain a much greater proportion of ethylbistrifluoromethylarsine than was obtained from the reaction described above.

Reaction of Tri-n-butylarsine with Trifluoroiodomethane

Tri-*n*-butylarsine was prepared by the appropriate Grignard reaction (14). The arsine (7.8 g) and trifluoroiodomethane (17.7 g) were heated to 100° for 20 days. The mixture slowly darkened in color but no solid was deposited. Trap-to-trap distillation of the volatile contents of the tube gave 13.2 g of trifluoroiodomethane which contained some fluoroform, and a less volatile fraction (2.4 g) which when distilled in a nitrogen atmosphere at reduced pressure gave two fractions: one, b.p. 46–48° (50 mm), which was identified as *n*-butylbistrifluoromethylarsine (0.7 g) by its infrared spectrum (5); the other, b.p. 111° (60 mm), which was similarly identified as di-*n*-butyltrifluoromethylarsine (1.5 g) (q.v.). The residue in the reaction tube, a viscous red oil (5 g), was extracted with ether. Distillation of the ether extracts in a nitrogen atmosphere (760 mm) gave more *di-n-butyltrifluoromethylarsine* (1.0 g), b.p. 186°. Anal. Calc. for $C_9H_{18}AsF_3$: C, 41.8; H, 6.98; As, 29.1; F, 22.1%; mol. wt., 258. Found: C, 41.5; H, 7.10; As, 29.1; F, 22.4%; mol. wt., 250. The infrared spectrum showed the following absorption bands (liquid film): 2910 (s), 2885 (s), 2835 (m), 1460 (m), 1452 (m), 1411 (w), 1377 (m), 1340 (w), 1285 (w), 1251 (w), 1185 (m), 1133 (vs), 1092 (vs), 1035 (sh)(m), 885 (w), 765 (w), 710 (m). The ether-insoluble residue from the reaction tube was soluble in alcohol. Infrared examination of this oil showed that trifluoromethyl groups were absent. It decomposed on attempted distillation at 10^{-3} mm.

Reaction of Trimethylarsine with Heptafluoroiodopropane

Trimethylarsine was prepared by the Grignard method (15). There was no obvious sign of reaction at 20° between the arsine (3.3 g) and the heptafluoroiodopropane (20.3 g); however, at 100° immediate reaction occurred and after 3 days at this temperature a copious colorless precipitate had formed. The volatile contents of the tube were removed and distilled in a nitrogen atmosphere (760 mm) to give unreacted heptafluoroiodopropane and heptafluoropropyldimethylarsine (1.3 g), b.p. 89–90 (lit. value 93° (4)). The infrared spectrum of this sample was identical with that of the pure compound (4). The solid reaction product (2.4 g) was recrystallized from alcohol and was identified as tetramethylarsonium iodide by means of its infrared spectrum and X-ray powder photograph.

Reaction of Dimethylphenylarsine with Trifluoroiodomethane

Dimethylphenylarsine was prepared by the reaction of phenylmagnesium bromide on iododimethylarsine (16). The arsine (6.3 g) and trifluoroiodomethane (11.6 g) did not react after 3 weeks at 20° or after 4 days at 100°. The arsine (2.2 g) and trifluoroiodomethane (16.0 g) were heated to 170° for 12 hours. The reaction mixture became dark brown. Trap-to-trap distillation isolated the following volatile fractions (identified by their infrared spectra): 0.92 g of a mixture of fluoroform and trifluoroiodomethane; 12.9 g of trifluoroiodomethane; 1.05 g of a mixture containing iodomethane, methylbistrifluoromethylarsine, and benzotrifluoride; and 1.1 g of a mixture of phenylbistrifluoromethylarsine and methylphenyltrifluoromethylarsine. A reddish violet solid (0.8 g) was left in the reaction tube. The solid, after recrystallization from alcohol, melted at 93–98° and was probably impure phenyltrimethylarsonium triiodide (lit. value, m.p. 103° (17)).

Reaction of Tri-n-butylphosphine with Trifluoroiodomethane

Commercial tri-*n*-butylphosphine (7.2 g) and trifluoroiodomethane (11.7 g) were left at 20° for 3 days. After 1 day a considerable amount of pale yellow precipitate had formed. The tube was opened to the vacuum system and only trifluoroiodomethane (1.6 g) was recovered, with difficulty, from the viscous yellow oil remaining in the tube. The tube and contents were not warmed above room temperature. The oil was extracted with ether, leaving a pale yellow solid. The ether extract was distilled in a nitrogen atmosphere (760 mm) and gave 0.3 g of di-*n*-butyltrifluoromethylphosphine, b.p. ca. 160°, and an involatile gummy residue. The trifluoromethylphosphine was provisionally identified by its infrared spectrum, which showed the presence of *n*-butyl groups and only one trifluoromethyl group (only two strong C—F stretching vibrations). In a second experiment the phosphine (6.1 g) and trifluoroiodomethane (13.3 g) were heated to 100° for 2 days. Again the volatile contents of the tube were difficult to remove from the viscous residue; however, after the tube was heated to 60° for 3 hours, 7.6 g of impure trifluoroiodomethane and 0.7 g of di-*n*-butyltrifluoromethylphosphine were obtained. The trifluoromethylphosphine fractions from both experiments were combined and distilled in a nitrogen atmosphere at 83 mm, all the material boiled at 115°, and analysis confirmed the identification. Calc. for $C_9H_{18}F_3P$: C, 50.4; H, 8.34; F, 26.6; P, 14.5%; mol. wt., 214. Found: C, 50.7; H, 8.58; F, 26.4; P, 14.5%; mol. wt., 229. The infrared spectrum showed the following absorption bands (liquid film): 2980 (s), 2950 (s), 2885 (s), 2200 (vw), 1470 (s), 1420 (m), 1384 (s), 1348 (w), 1297 (w), 1274 (w), 1215 (m), 1162 (vs), 1103 (vs), 1051 (w), 1007 (w), 968 (s), 897 (w), 781 (w), 727 (sh)(m), 717 (s). In an attempt to improve the yield of the trifluoromethylphosphine, tri-*n*-butylphosphine (6.3 g) and trifluoroiodomethane (18.3 g) were heated to 100° for 2 weeks, but only 0.6 g of the trifluoromethylphosphine was isolated in the vacuum system.

Reaction of Iododimethylarsine with Trifluoroiodomethane

The iodo-arsine (4.8 g) and trifluoroiodomethane (11.8 g) did not react at 100° (2 days) since 11.8 g of trifluoroiodomethane were recovered. When the same reactants were heated to 170° for 1 day a dark solid formed. Trap-to-trap distillation gave 0.04 g of a mixture of fluoroform and trifluoroiodomethane, 9.3 g of trifluoroiodomethane, and 1.5 g of methylbistrifluoromethylarsine containing some iodomethane. These fractions were identified by their infrared spectra. A slightly volatile pale yellow liquid (0.37 g) was also obtained. This fraction reacted with mercury; its infrared spectrum showed the presence of methyl groups and only one trifluoromethyl group (only two strong bands in the C—F stretching region); and the fraction was provisionally identified as iodomethyltrifluoromethylarsine. The solid residue in the reaction tube (4.6 g) contained 0.4 g of an unidentified acetone-insoluble substance. The acetone-soluble solid consisted mainly of tetramethylarsonium triiodide on the evidence of its X-ray powder photograph.

Reaction of Diiodomethylarsine with Trifluoroiodomethane

Diiodomethylarsine (9.2 g) and trifluoroiodomethane (12.1 g) were immiscible at 20° and at 100°. No reaction took place after 20 hours at 100°. The same reactants after 18 hours at 170° had produced a dark solid. Trap-to-trap distillation of the volatile contents of the tube gave trifluoroiodomethane (10.4 g) containing a trace of fluoroform, methylbistrifluoromethylarsine (0.97 g) containing a little iodomethane, and 0.63 g of iodomethyltrifluoromethylarsine. The fractions were identified by their infrared spectra. The solid residue in the reaction tube (7.9 g) was identified as being mainly arsenic triiodide on the evidence of its X-ray powder photograph.

Reaction of Chlorodimethylarsine with Trifluoroiodomethane

There was no reaction between the arsine (11.3 g) and trifluoroiodomethane (11.5 g) after 1 day at 20°. Similarly the arsine (2.19 g) and trifluoroiodomethane (4.267 g) did not react when heated to 85° for 3 days. When the same reactants were heated to 240° for 10 hours an orange solid was formed. Trap-to-trap distillation gave fluoroform (0.88 g), a mixture of trifluoroiodomethane and chloromethane (1.911 g, mol. wt., 117), 1.091 g of a mixture of methylbistrifluoromethylarsine containing a little iodomethane, and 0.4 g of iodomethyltrifluoromethylarsine.

Preparation of Chloromethyltrifluoromethylarsine

The iodomethyltrifluoromethylarsine produced in the above reactions was condensed onto dry silver chloride and left for 1 week at 20°. Silver iodide was formed. The colorless product attacked mercury, contained only one trifluoromethyl group, and boiled at 76° in an atmosphere of nitrogen; it was identified as *chloromethyltrifluoromethylarsine*. Anal. Hydrolysis with 10% aqueous sodium hydroxide at 100° for 2 days gave fluoroform equivalent to a CF_3 content of 35.1%. The vapor phase molecular weight was 295. Calc. for $C_2H_3AsClF_3$: CF_3, 35.4%; mol. wt., 295. The infrared spectrum showed the following absorption bands (vapor phase): 3010 (w), 2930 (w), 2810 (vw), 2310 (w), 2260 (w), 2215 (w), 1880 (w), 1842 (w), 1420 (m), 1262 (m), 1205 (sh)(s), 1156 (vs), 1111 (vs), 1060 (m), 1049 (m), 1000 (vw), 900 (vw), (860 (sh), 855, 848, 844, 837) (s), 795 (vw), (735, 724, 720) (s).

Reaction of Diethyltrifluoromethylarsine with Iodoethane and Iodomethane

The arsine (0.5 g) and a large excess of iodoethane (5 ml) were left for 6 weeks at 20°. No solid product was formed. The same reactants were heated to 100° for 2 weeks; again no solid was formed, and trap-to-trap distillation showed that no fluoroform or trifluoroiodomethane had been produced. When the reactants were heated to 150° for 1 day, reaction occurred with the formation of a low-melting solid. The most volatile product of the reaction was found to be a mixture of fluoroform, ethylene, and trifluoroiodomethane (0.35 g, mol. wt., 64.0). The mixture was identified by its infrared spectrum. The violet solid was twice recrystallized from alcohol and the final product was identified as tetraethylarsonium triiodide, m.p. 56–57° (lit. value 54° (17)). The infrared spectrum of the crude solid showed the presence of ethyl groups and the absence of trifluoromethyl. Diethyltrifluoromethylarsine did not react with excess iodomethane after 1 month at 20°.

THE PROTON MAGNETIC RESONANCE SPECTRUM OF 1-FLUORO-2,4-DINITROBENZENE

T. SCHAEFER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received November 23, 1961

ABSTRACT

A reliable analysis of the proton resonance spectrum of 1-fluoro-2,4-dinitrobenzene is described. Solvent effects were used to obtain this analysis and a possible source of error in a previous analysis is indicated. Spectra parameters are also derived for 1,5-difluoro-2,4-dinitrobenzene. The spectrum of the latter compound confirms the assignment of peaks in the spectrum of the former.

INTRODUCTION

A recent publication presents the results of an analysis of the high-resolution nuclear magnetic resonance spectrum of 1-fluoro-2,4-dinitrobenzene (1). In the course of an as yet unpublished study in this laboratory of solvent effects on such spectra we have had occasion to measure the proton magnetic resonance spectrum of this compound in acetone and benzene. The results indicate a certain inaccuracy of the analysis in reference 1. By comparing the spectra in the two solvents a possible reason for this inaccuracy was found and a better set of coupling constants has been derived.

EXPERIMENTAL AND RESULTS

The proton magnetic resonance spectra were measured as 5 mole% solutions in acetone and benzene using a Varian spectrometer operating at 60 Mc/sec. The external reference was chloroform, and calibration of spectra was done by the sideband technique. Figures 1(*b*) and 2 show the spectra of 1-fluoro-2,4-dinitrobenzene in acetone and benzene, respectively. Figure 1(*a*) gives the spectrum of 1,5-difluoro-2,4-dinitrobenzene in acetone.

ANALYSIS OF SPECTRA

Proton Spectrum of 1-Fluoro-2,4-dinitrobenzene in Benzene

This spectrum can clearly be regarded as the *ABR* part of an *ABRX* spectrum, as indicated in the molecular diagram in Fig. 2 (2). The analysis of the *ABRX* case is straightforward and, in fact, the possible transitions and their intensities can be immediately written down in a concise manner in the notation developed by Pople and Schaefer (3). The calculated spectrum appears in Fig. 2 and it is clear that the spectrum is very nearly a first-order one.* Values of the parameters determined are given in Table I.

Proton Spectrum of 1-Fluoro-2,4-dinitrobenzene in Acetone

It is tempting to analyze the spectrum in acetone as the *ABR* part of an *ABRX* spectrum with the protons assigned as indicated in Fig. 1(*b*). However, the attempt soon results in the realization that the correct assignment would be that of an *ABC* part

**Perhaps it should be pointed out that in order to prevent some of the peaks from appearing high on the shoulder of the intense solvent line a very slight amount of u-mode was introduced into the signal input at the phase detector. This trick may have introduced some distortion of peak intensities near the solvent line. It is also true that coupling to C^{13} nuclei in the solvent results in weak, unwanted signals in the extreme regions of the recorded spectrum. These may have distorted some of the lines in those regions.*

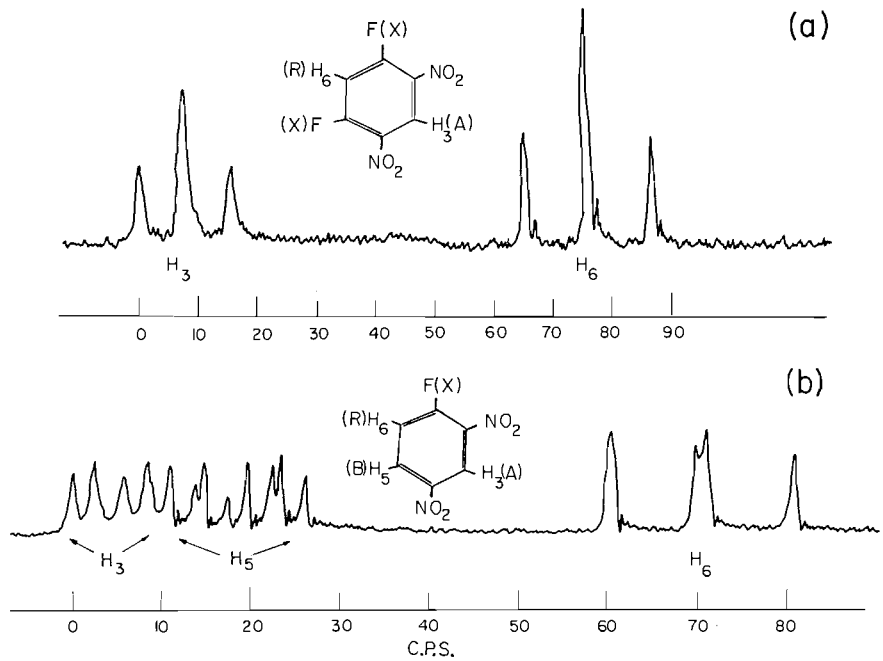

FIG. 1. (*a*) The proton resonance spectrum of 5 mole% 1,5-difluoro-2,4-dinitrobenzene in acetone at 60 Mc/sec. (*b*) The proton resonance spectrum of 5 mole% 1-fluoro-2,4-dinitrobenzene in acetone at 60 Mc/sec.

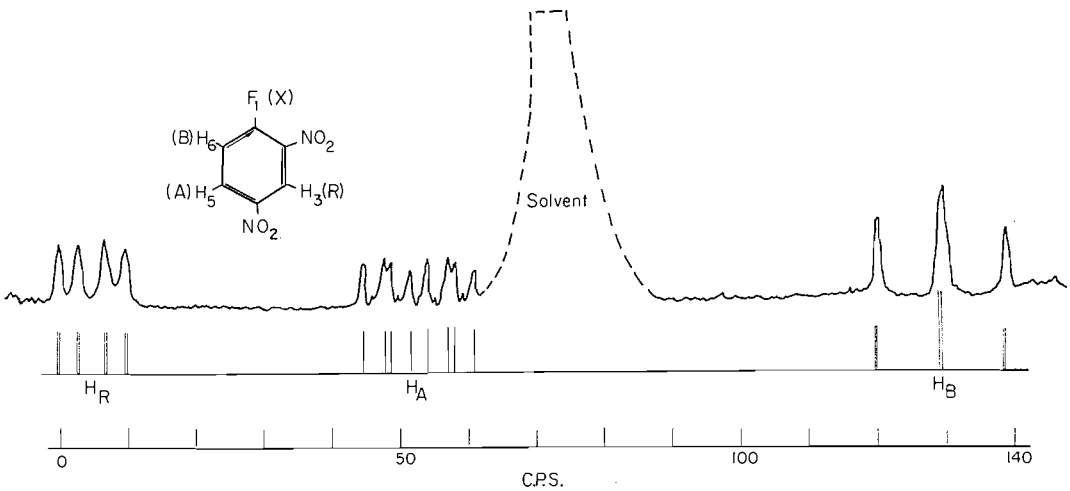

FIG. 2. The proton resonance spectrum of 5 mole% 1-fluoro-2,4-dinitrobenzene in benzene at 60 Mc/sec.

of an *ABCX* spectrum. The parameters obtained from an *ABRX* analysis are given in Table I. The large error in these values appears because of alternate choices for these values in an approximate analysis. From the chemical shift dependence of the relative positions in the high-field group of peaks it can be concluded that J_o^{HH} and J_o^{HF} have the same sign.

TABLE I

Parameters in c.p.s. obtained from the proton spectra of 1-fluoro-2,4-dinitrobenzene at 60 Mc/sec

	5 mole% in benzene	5 mole% in acetone*	Reference 1
J_o^{HH}	9.5±0.1	9.3±0.4	8.7±0.3
J_m^{HH}	3.0±0.1	3.0±0.1	2.9±0.2
J_p^{HH}	0.1±0.1	0.2±0.4	0.6±0.3
J_o^{HF}	9.5±0.1	10.1±0.4	10.4±0.2
J_m^{HF}†	6.4±0.1	6.7±0.1	6.5±0.3

†Proton situated between the nitro groups.
‡Proton situated next to one nitro group.
§External chloroform reference value corrected for bulk susceptibility.

Proton Spectrum of 1,5-Difluoro-2,4-dinitrobenzene in Acetone

The spectrum is the *AR* part of an ARX_2 spectrum and is therefore first order. This is clearly a consequence of the symmetry of the molecule and of the vanishingly small value of J_p^{HH}. The parameters obtained are $J_o^{HF} = 10.2\pm0.1$, $J_m^{HF} = 7.5\pm0.1$, $J_p^{HH} < 0.2$ cycles/sec, $\nu_6-\nu_3 = 67.9\pm0.2$ cycles/sec; $\nu_6-\nu_{CHCl_3\ ext} = -27.2\pm0.5$ cycles/sec, corrected for bulk susceptibility effects.

The peaks from proton 3 between the nitro groups are broadened by interactions depending on the quadrupole moment of the N^{14} nuclei in the nitro groups. This circumstance assures a correct assignment and also indicates the correct assignment in the spectra of 1-fluoro-2,4-dinitrobenzene, where the corresponding proton peaks are similarly broadened.

DISCUSSION

Since the proton spectrum of 1-fluoro-2,4-dinitrobenzene in benzene is very nearly first order its analysis yields the most reliable values of the parameters. The analysis of the spectrum of this compound in acetone illustrates the need for care in fixing probable errors of parameters obtained from an approximate analysis. Once again the spectra in different solutions indicate the great help solvent effects can give in spectra analysis. One assumption inherent in the use of different solvents is that the coupling constants in the solute do not change from solvent to solvent. In unpublished work we have found this assumption justified in the closely related molecule 1,5-difluoro-2,4-dinitrobenzene. If the molecule under investigation can exist in different conformations whose stability can be influenced by the polarity of the solvent the above assumption can be wrong (4).

Solvent effects in these compounds and related ones are very large. They reach 2 p.p.m. for some ring protons and will be reported later.

PHOTOLYSIS OF NITRATE ESTERS

PART I. PHOTONITRATION OF DIPHENYLAMINE

L. D. Hayward, R. A. Kitchen, and D. J. Livingstone
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received November 22, 1961

ABSTRACT

The photolysis of nitrate esters dissolved in benzene or ethanol or absorbed on filter paper occurred readily under illumination in the 265 mμ to 334 mμ spectral region. Equimolar amounts of 1,4;3,6-dianhydro-D-glucitol-2,5-dinitrate and diphenylamine dissolved in absolute ethanol or benzene did not react in the dark at 25°. Irradiation of the nitrogen-purged solutions for 2 hours at 15° with a mercury arc followed by chromatographic separation yielded 2-nitro-, 4-nitro-, N-nitroso-, and 4-nitroso-diphenylamine together with about 4% unreacted diphenylamine and an unidentified mixture of more polar compounds. In a partial fractionation of the aromatic photoproducts approximately 80% of the original diphenylamine was recovered in the form of the monosubstituted derivatives which contained about 37% of the original ester nitrogen as C-nitro groups and 2 to 3% as C- and N-nitroso groups.

Possible mechanisms of the photonitration are discussed.

INTRODUCTION

It was suggested by Gray and Williams in 1959 that photolysis of nitrate esters would be a useful method for the preparation of alkoxyl radicals provided that the nitrogen dioxide concurrently formed could be rapidly removed from the system (1). In this laboratory it was recently discovered that the photolysis of covalent nitrates in the presence of diphenylamine produced colored compounds useful for detecting the esters on paper chromatograms (2, 3). The yellow to orange photoproducts resembled those obtained by Coldwell and McLean (4, 5) by irradiation of nitrate ion and diphenylamine. These authors identified 2- and 4-nitrodiphenylamine as the major organic products and found no evidence for the formation of nitroso derivatives (5). In view of the well-known scavenging action of diphenylamine in both the solid state and in solution for nitrogen dioxide (6–9) it seemed probable that irradiation of nitrate esters in organic solvents containing diphenylamine would provide a system in which alkoxyl radical reactions might be conveniently studied.

We have been unable to find in the literature any detailed report of the products of photolysis of nitrate esters in solution. Photolysis of methyl and ethyl nitrates in the gas phase yielded hydrogen, nitromethane, formaldehyde, and acetaldehyde in addition to nitrogen, carbon, and their oxides (1, 10, 11). Bands attributed to ethoxyl radicals were detected in fluorescence when ethyl nitrate was irradiated in the Schumann region (12). The reactions postulated to account for the photoproducts paralleled those invoked for thermal decomposition where the initial, rate-determining step has been established as homolytic alkoxy–nitro bond fission (1, 13, 14). Photolysis of polynitrate esters in the condensed state also caused evolution of nitrogen and the oxides of carbon and nitrogen; the thermal stability of the explosive compounds was reduced and, for cellulose nitrate, depolymerization and oxidation occurred (15–21).

The present work was concerned with establishing the scope and conditions for the photoreaction of covalent nitrates with diphenylamine in solution and with the isolation and identification of the major aromatic products.

EXPERIMENTAL

Chromatography

Mixtures of nitrate esters, diphenylamine, and diphenylamine derivatives were separated by thin-layer chromatography (TLC) on glass plates coated with a mixture of silicic acid (Mallinckrodt, 100 mesh, for chromatography) and plaster of Paris (70:30 w/w) (22). Separation on a preparative scale was made on 1×1×18-in. chromatobars cast from the same mixture and developed by the ascending method (23). No separation of diphenylamine derivatives could be obtained with untreated or silicic-acid-impregnated paper (24); the hydrophobic compounds ran with the solvent front in each case.

Chromatograms were developed with mixtures of anhydrous solvents in the following volume ratios: S1: benzene – petroleum ether (1:1); S2: ether – petroleum ether (3:39); S3: ether–benzene (1:19). The purified petroleum ether fraction employed distilled over the range 85° to 110°.

Colorless compounds were detected with spray reagents as follows:

R1: A 5% solution of concentrated nitric acid in concentrated sulphuric acid (22). Diphenylamine and its derivatives gave characteristic colors at 25° and all organic components appeared as charred spots on heating the sprayed plates.

R2: A 1% solution of diphenylamine in 95% ethanol, followed by exposure to a shortwave ultraviolet lamp for 10 minutes. Nitrate esters appeared as yellow-green spots on a colorless background (3).

R3: A 5% solution of calcium nitrate in 95% ethanol, followed by ultraviolet irradiation. Diphenylamine produced yellow-green spots as for R2.

Materials

1,4;3,6-Dianhydro-D-glucitol-2,5-dinitrate (isosorbide dinitrate) was prepared by the method of Jackson and Hayward (14). The stable form of the compound was obtained (m.p. 69.2–70.0°), which showed the same elemental analyses, specific rotation, infrared spectrum, and chromatographic behavior as the labile form (m.p. 50.5–51.5°) (14). The ultraviolet spectrum of a 10^{-4} *M* solution of the dinitrate in absolute ethanol showed no absorption above 250 mμ and no inflection in the rapidly increasing absorption curve which commenced at an indefinite point around 250 mμ and continued beyond 210 mμ (Fig. 1). Similar

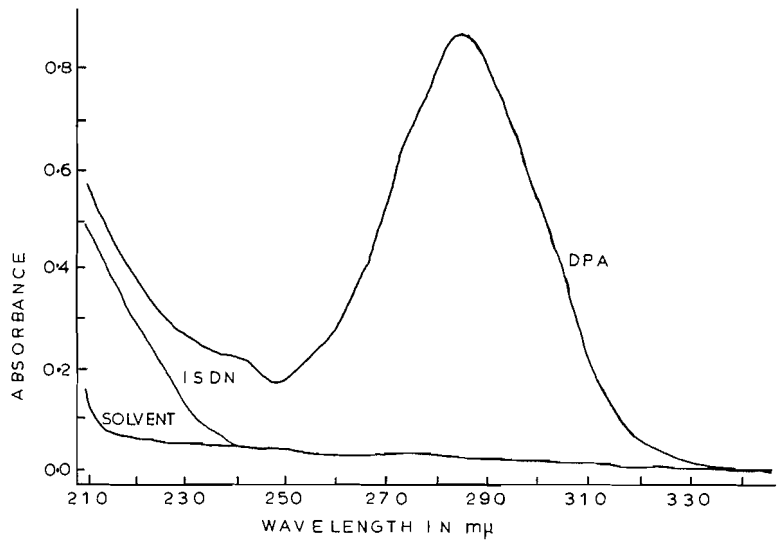

FIG. 1. Ultraviolet absorption spectra in absolute ethanol solution of 1,4;3,6-dianhydro-D-glucitol-2,5-dinitrate (ISDN, 10^{-4} *M*) and diphenylamine (DPA, 4×10^{-5} *M*).

curves were obtained at concentrations of 10^{-2} and 10^{-6} *M*. These spectra were distinctly different from those of open-chain, secondary aliphatic nitrate esters, which showed a characteristic inflection at 270 mμ (25), but agreed well with those of other polynitrate esters (31). The other nitrate esters employed have been described elsewhere (26–29, 34).

Diphenylamine, 2-nitrodiphenylamine, 4-nitrodiphenylamine, N-nitrosodiphenylamine, and 4-nitrosodiphenylamine were recrystallized to constant melting points (7) and then chromatographed on silicic acid until homogeneous. 4-Nitrosodiphenylamine required further purification by sublimation *in vacuo*. The corrected melting points and ultraviolet spectra of these compounds are shown in Table I, together with the reported values. The infrared spectra of 5% solutions of diphenylamine, 2-nitrodiphenylamine, and N-nitrosodiphenylamine in carbon tetrachloride closely matched the published spectra (30).

Irradiation of Solutions

Absolute ethanol or benzene solutions, 0.02 or 0.04 *M* in both isosorbide dinitrate and diphenylamine, were irradiated in quartz test tubes cooled to 15.0±0.5° by impinging streams of water. Nitrogen gas was introduced through thin glass capillaries for stirring and purging of air while the tubes were exposed at a distance of 20 cm to the unfiltered emission from a quartz capillary mercury arc lamp (Mineralite Model V43, Ultraviolet Products, Inc., Los Angeles). Aliquots of the solutions were removed from time to time for examination by TLC. The photoproducts were isolated on a preparative scale by concentration of the solutions in the dark followed by separation on chromatobars.

Photochemical Spot Tests

To determine the effective wavelength range for the photolysis, partially overlapped spots, 1 cm in diameter, of nitrate ester and diphenylamine (4) were deposited from ethanol solutions on 7-cm circles of Whatman No. 1 filter paper in a darkroom. A spotted and air-dried paper was exposed at 25° to each of the 10 major groups of lines between 250 mμ and 400 mμ in the medium-pressure mercury arc spectrum isolated by means of a 250-mm grating monochromator with quartz optics (Bausch and Lomb Optical Co., Rochester). The relative intensities of the lines were calculated from tables of emission spectra and transmission efficiencies of the monochromator and the irradiations were timed for intervals inversely proportional to these intensities. The colors developed in the overlapped and non-overlapped regions of the spots on the irradiated papers were compared visually in daylight with those of non-irradiated spots immediately after exposure and again after standing for several hours in the dark. Attempts to separate the photoproducts by irradiation of mixtures of nitrate ester and diphenylamine *in situ* as spots on chromatoplates or filter paper followed by direct chromatography were unsuccessful, probably because the penetration of the light into the solids was insufficient to produce detectable amounts of products.

RESULTS

A series of 25 crystalline nitrate esters containing from 1 to 8 nitrate groups per molecule produced greenish-yellow- to orange-colored products in the irradiation spot test with diphenylamine. No regular change in the color intensity of the developed spots with number of nitrate groups per molecule was apparent, although diastereoisomeric compounds such as the 1,2,4,5,6-pentanitrate derivatives of D-mannitol and D,L-glactitol (27, 28) differed in this respect. 1,4;3,6-Dianhydro-D-glucitol-2,5-dinitrate (isosorbide dinitrate) was selected for more detailed study as the simplest and most readily accessible crystalline aliphatic nitrate ester with known configuration and conformation. A difference in rate of reaction of the exo and endo nitrate ester groups in this optically active compound was demonstrated in an earlier research (14) and offered the possibility of detecting any stereospecificity in the photolysis.

Compounds containing oxy-nitrogen groups other than the nitrate ester group were also examined in the photochemical spot test with diphenylamine. Negative results were obtained with nitromethane, 2-nitropropane, 6-nitrosothymol, N-methyl-N-nitroso-

p-toluenesulphonamide, and the 1-oxides (32) of 5,5-dimethyl-Δ^1-pyrroline and 2,4,4-trimethyl-Δ^1-pyrroline. Isoamyl nitrite developed a pale yellow color which may have been caused by thermal rather than photolytic decomposition (33). Coldwell found (2) that aromatic C-nitro groups in 2,4-dinitrotoluene and 2,4,6-trinitrotoluene and N-nitro groups in trimethylenetrinitramine and 2,4,5-trinitrophenylmethylnitramide did not respond to the test.

Irradiation with light from the monochromator of isosorbide dinitrate and diphenylamine as partially overlapped spots established that the lines of the mercury arc spectrum lying between 265 mμ and 334 mμ produced a bright yellow color in the mixture. At shorter wavelengths the unmixed portions of the spots darkened, indicating more extensive photodecomposition of both diphenylamine and nitrate ester. At longer wavelengths no color appeared on the filter paper and this result was confirmed by absence of color in an alcohol solution of the reactants irradiated at 365 mμ.

Exposure to the unfiltered mercury arc spectrum of 0.04 *M* solutions of isosorbide dinitrate in absolute ethanol or benzene produced no apparent coloration. Examination of the solutions by TLC after irradiation for 3 hours indicated that, in addition to unchanged dinitrate, a highly polar product was present, which, like isosorbide, did not migrate on the chromatoplate with solvent S1. No other organic compounds could be detected on the developed plates with spray reagent R1. After irradiation for 21 hours the ethanol solution was evaporated to a colorless sirup which weighed 17.7% less than the original dinitrate and did not crystallize on seeding with isosorbide or its mono- and di-nitrate derivatives. The calculated weight loss for replacement of one NO_2 group by hydrogen in isosorbide dinitrate was 19.0%.

Solutions 0.02 *M* in both isosorbide dinitrate and diphenylamine in ethanol or benzene remained colorless on standing at room temperature for 24 hours in the dark; TLC showed only the original solutes to be present. After standing for a further 24 hours in closed Pyrex containers in the ordinary laboratory light, both solutions were very faintly yellow but the concentration of the photoproducts was too low to be detected by chromatography. When the nitrogen-purged solutions were exposed in quartz containers to the mercury arc at 15° they developed increasing intensity of yellow color with time of irradiation. After 20 minutes isosorbide dinitrate could no longer be detected in the ethanol solution by TLC, and spots corresponding to the colored reaction products began to appear. After irradiation for 2 hours six organic components of the reaction mixture were separated on the chromatoplates. Five of these products migrated with R_f values corresponding to unreacted diphenylamine, 2-nitrodiphenylamine, N-nitrosodiphenylamine, 4-nitrodiphenylamine, and 4-nitrosodiphenylamine in three different solvents (S1, S2, S3); the colorless sixth component did not move from the point of application on the plates. Similar patterns of spots were obtained from the photoreaction mixture and from a synthetic mixture of the nitro- and nitroso-diphenylamine compounds plus diphenylamine and isosorbide when chromatographed in the same solvents. When each of the diphenylamine derivatives in turn was added to an aliquot of the reaction mixture the developed chromatogram showed enrichment of a spot already present; the area and intensity of the original spot was increased in each case. The same pattern of spots was obtained also from the irradiated benzene solution and from ethanol solutions in which isosorbide dinitrate was replaced by D-mannitol hexanitrate (27) or meso-hydrobenzoin dinitrate (34).

The photoproduct from a 2-hour irradiation of an ethanol solution containing 170 mg of isosorbide dinitrate and 122 mg of diphenylamine was fractionated on a chromatobar and the central portion of each of the six separated zones was removed, powdered, and

eluted with acetone in subdued light. The weights of the six crude fractions obtained on evaporation of the acetone are shown in Table II. Fractions 2 and 4 were further purified

TABLE II

on chromatobars to yield 21.0 mg of pure 2-nitrodiphenylamine (m.p. 72.0–73.0°) and 6.95 mg of pure 4-nitrodiphenylamine (m.p. 132.5–133.2°) respectively. The identities of these compounds were confirmed by their ultraviolet spectra (Tables I and II), infrared spectra, and R_f values when compared with authentic samples.

Because of the small amounts of material available fractions 1, 3, 5, and 6 were rechromatographed from streaks applied to chromatoplates. The developed bands corresponding to the original fractions were scraped from the plates and worked up as before. The recovered fractions 1, 3, and 5 were not completely pure but the major components were identified from the R_f values and ultraviolet spectra (Tables I and II). Fraction 6 did not migrate and appeared to be a mixture.

DISCUSSION

The results showed clearly that an oxy-nitrogen group was transferred from nitrate esters to diphenylamine in the photolysis reaction in solution. Since the emphasis in working up the reaction mixture was primarily on isolation and identification of the aromatic products the fractionation results were only semiquantitative. The total weight of the separated fractions amounted to 49% of the weight of the original reactants. Based on the weights of the crude fractions (Table II), the identified products accounted for approximately 84% of the original diphenylamine, 80% in the form of the nitro and nitroso derivatives and the remainder in unchanged form. Thirty-seven percent of the original ester nitrogen was recovered as C-nitro groups in the diphenylamine derivatives and a further 2 to 3% could be accounted for as N- and C-nitroso groups. The apparent ortho to para ratio of 3 in the major products, 2- and 4-nitrodiphenylamine, could not be considered as significant, however, since the separations were not strictly quantitative.

The absence of a "dark reaction" between isosorbide dinitrate and diphenylamine at 25° and the slow reaction of the stronger base pyridine with the dinitrate at 115° (14) ruled out nucleophilic attack of unexcited diphenylamine on the ester from consideration in the mechanism of the photonitration. A comparison of the ultraviolet spectra of the reactants (Fig. 1) showed that diphenylamine absorbed far more of the incident light than the nitrate ester in the effective spectral region (265 to 334 mμ). This suggested

the possibility that the photoproducts resulted from attack on the ester by diphenylnitrogen radicals formed in a photodissociation of the diphenylamine. However, Tarutina has shown that irradiation of diphenylamine in benzene solution under similar conditions caused only slight decomposition of the N—H bonds unless an active radical was supplied simultaneously in the irradiated solution (35). This fact, taken together with the weight loss suffered by isosorbide dinitrate when irradiated alone in ethanol solution, indicated that a true photolytic cleavage of the nitrate ester group probably preceded the photonitration.

Among the seven other oxy-nitrogen functional groups which have been tested only the nitrite ester appeared to undergo a similar photolytic fission. Photolysis of nitrite esters with alkoxy–nitroso bond fission was reported recently by Barton and co-workers (36–38) as a preparative procedure. Yunker and Higuchi (33) showed that diphenylamine stabilized isoamyl nitrite by combining with the thermal decomposition products to form the same nitro derivatives of diphenylamine obtained in the well-known stabilization of nitrate ester explosives (6–9).

One pathway suggested by Coldwell and McLean (24) for the photonitration of diphenylamine was that the nitrodiphenylamine derivatives were formed by direct N-nitrosation of diphenylamine followed by rearrangement to the C-nitroso compound and subsequent oxidation. This mechanism appeared unlikely to predominate in the photoreaction in benzene solution in the present case. Molecular oxygen was continuously purged from the system during irradiation and the recent work of Kemula and Gabrowska on the photochemical reaction of benzene with oxygen (39) indicated that any atomic oxygen formed from nitrate ester would combine rapidly and irreversibly with the excited benzene solvent. The similarity of the products obtained in the two solvents would rule out this mechanism for the ethanol solutions also.

An alternative pathway for the photonitration, also suggested by Coldwell and McLean, was direct nitration of the phenyl rings. This seemed the more plausible, especially in the light of the recent work of Barnes and Hickinbottom on the thermal rearrangement of N-methyl-N-*p*-nitrophenylnitramine (40). These authors found that the migration of the nitro groups, brought about thermally, was not intramolecular but involved homolytic rupture of the N—NO_2 bond and the form of the nitro group thus created nitrated suitably activated phenyl rings. We believe a similar intermediate may be involved in the nitrate ester photolysis and further studies of the reaction are in progress.

ACKNOWLEDGMENTS

We thank Drs. C. Reid and P. Gray for helpful discussions and Dr. R. Bonnett for samples of pyrroline oxides. This work was supported by a research grant from the Defence Research Board of Canada.

ORGANIC PEROXIDES

III. REACTIONS OF DIALKYL PEROXIDES WITH ORGANOLITHIUM AND ORGANOMAGNESIUM COMPOUNDS[1]

G. A. Baramki, H. S. Chang, and J. T. Edward
Department of Chemistry, McGill University, Montreal, Que.

Received November 10, 1961

ABSTRACT

Optimum conditions for obtaining arylalkyl ethers from the reactions of aryl-lithium or -magnesium compounds with dialkyl peroxides have been investigated. The reactions are considered to take place by ionic or four-center mechanisms.

Gilman and Adams (1) found that, while di-(triphenylmethyl) peroxide is inert to phenylmagnesium bromide, diethyl peroxide reacts with it to give a 34% yield of phenetole. Di-*t*-butyl peroxide does not react with this Grignard reagent (2), even at 80° (3), but reacts at ordinary temperatures with the less-hindered Grignard reagents derived from primary and secondary bromides to give low yields of *t*-butyl ethers.

Because of the possible usefulness of this method for synthesizing certain otherwise inaccessible ethers, we have studied the reactions of four dialkyl peroxides with phenyllithium and the phenyl Grignard reagent (Table I), as well as the reaction of dimethyl peroxide with some other organo-lithium and -magnesium compounds (Table II). Best

TABLE I

Yields of ethers from reactions of dialkyl peroxides with phenyllithium and phenylmagnesium bromide

Peroxide	Reaction temp. (°C)	Yield (%) from PhLi	Yield (%) from PhMgBr
Dimethyl	15–20	80	77
Methyl *t*-butyl	15–20	63	20
Methyl *t*-butyl	35	72	38
Diethyl	15–20	38	30*
Di-*t*-butyl	0–5	3.3	—
Di-*t*-butyl	15–20	19	—
Di-*t*-butyl	35	39	0†
Di-*t*-butyl	80	38	0‡

*Gilman and Adams (1) report a 34% yield.
†Compare ref. 2.
‡Compare ref. 3.

TABLE II

Yields of methyl ethers (ROMe) from reactions of dimethyl peroxide with RLi and RMgBr at 15–20° C

R	Yield (%) with RLi	Yield (%) with RMgBr
p-Anisyl	45	47
p-Biphenylyl	65	53
β-Naphthyl	21	—

[1]*The papers by J. T. Edward, J. Chem. Soc, 1464 (1954), 222 (1956), are considered Parts I and II of this series.*

yields were obtained with dimethyl peroxide, which reacted equally well with both lithium and magnesium compounds. However, this peroxide is explosive and capricious, and the much safer methyl *t*-butyl peroxide gave with phenyllithium (but not with phenylmagnesium bromide) almost the same yields of anisole. No phenyl *t*-butyl ether was obtained from these reactions. With the more highly hindered di-*t*-butyl peroxide the superiority of phenyllithium was more marked (Table I), but even so the reaction was still incomplete after 12–14 hours at 15–20°, 45% of the peroxide being recovered. Reaction was complete in this time at 35°, but the yield was inferior to that obtained in the reaction of phenylmagnesium bromide with *t*-butyl perbenzoate, recently described by Lawesson and Yang (3). It would seem that the latter reaction will prove, in some instances, the method of choice for preparing *t*-butyl ethers, while the reaction of organolithium compounds with methyl *t*-butyl peroxide will prove perferable for preparing methyl ethers.

Gilman and Adams (1) isolated a 30% yield of biphenyl, along with phenetole, from the reaction of diethyl peroxide with phenylmagnesium bromide. We also obtained 10–30% yields of biaryls from the mixtures after reaction of the peroxides. However, it was shown in several cases (and seems likely for the others) that the biaryl was formed during the preparation of the organometallic compound.

Organometallic compounds sometimes react by free-radical mechanisms (4). However, while triphenylmethylsodium reacted with dimethyl peroxide to give a methyl ether, triphenylmethyl radical failed to react. Consequently, the reaction of triphenylmethylsodium is most plausibly explained by an ionic mechanism involving an S_N2 attack on oxygen:

$$Ph_3C^- \overset{R_1}{\curvearrowright} O\text{—}OR_2 \longrightarrow Ph_3C\text{—}OR_1 + {}^-OR_2.$$

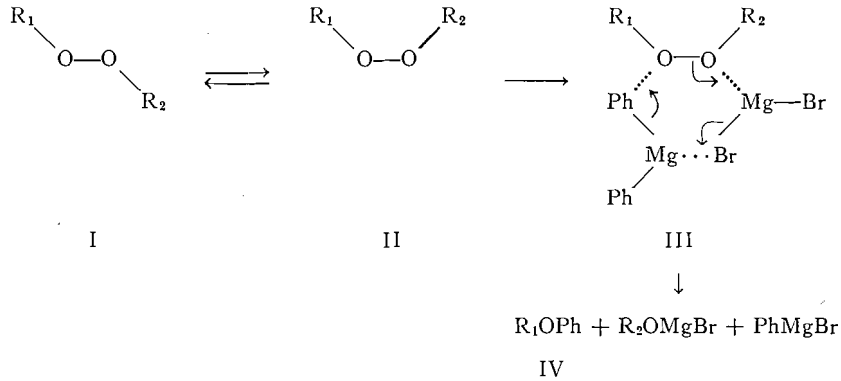
A similar mechanism appears likely for the reactions of phenyllithium. The decreased rate of reaction as R_1 is changed from methyl to *t*-butyl finds a parallel in the decreasing facility of S_N2 attacks on the carbon atom of alkyl halides as the neighboring alkyl group becomes more highly branched (5); the lesser effect of the nature of R_2 is also in harmony with this mechanism. On the other hand, the much greater sensitivity to steric effects, particularly to the nature of R_2, observed in the reactions of Grignard reagents, is best explained by a four-center mechanism of the type generally postulated for the reactions of these compounds (6). The recent work of Dessy (7) indicates the phenyl Grignard reagent to be a complex of Ph_2Mg and $MgBr_2$, with only a negligible amount of PhMgBr. A four-center reaction of this complex with the peroxide linkage would require a conformational change (I → II)[2] of the peroxide which becomes progressively more difficult as the bulk of *both* R_1 and R_2 increases. The effect of such conformational equilibria on reaction rates is now well established (10). Further, it would be expected that the more stable transition state (III) would be that one in which the R_1 was the less bulky of the two alkyl groups, because of bulk of the phenyl group. This accords with the exclusive formation of anisole (IV; R_1 = Me) from methyl *t*-butyl peroxide (I; R_1 = Me, R_2 = Bu^t).

EXPERIMENTAL

Materials

Dimethyl peroxide, prepared according to Rieche and Brumshagen (11), was not isolated as a pure liquid but was passed in a stream of nitrogen through a long column of Drierite and then into dry peroxide-free

[2]*It seems likely that neither I nor II are planar molecules (8, 9) but that attainment of the transition state (III) requires the movement of* R_1 *and* R_2 *towards each other.*



ether cooled to −70° (yield, about 70%). This ether solution was reasonably safe to handle and could be stored in the refrigerator without apparent deterioration; however, twice it exploded during addition to a solution of organometallic compound. It was analyzed for peroxide by a modification of Rieche and Brumshagen's method (11). Ten milliliters of the solution was mixed with standard aqueous stannous chloride solution (5 ml) in a tightly stoppered flask, and the mixture was stirred magnetically for 2 hours. The ether layer was then separated, washed quickly with two 10-ml portions of water, and the washings added to the stannous chloride solution. Excess standard iodine solution was added to this solution, which was then back-titrated with standard sodium thiosulphate solution.

Methyl *t*-butyl peroxide, b.p. 23° at 119 mm, d^{20} 0.811 g/ml, n_D^{24} 1.3770, was prepared by the procedure of Rust *et al.* (12), and diethyl peroxide, b.p. 22° at 90 mm, n_D^{22} 1.3862, by the method of Baeyer and Villiger (13) as modified by Harris and Egerton (14). Commercial grade di-*t*-butyl peroxide, b.p. 112° at 760 mm, n_D^{20} 1.3890, was used without purification.

General Procedure

Ether solutions of the Grignard reagent or aryllithium were prepared under nitrogen in the usual way, filtered, and the concentration of organometallic compound determined by addition of a 2-ml aliquot to an excess of standard hydrochloric acid and back-titration with standard sodium hydroxide. To aliquots of these solutions the dialkyl peroxide, diluted with an equal volume of anhydrous ether, was added under nitrogen over 1- to 2-hour periods with stirring at the temperatures indicated (Tables I and II). The reaction mixture was left overnight (12–14 hours) at this temperature, and then worked up in the usual manner, except that the ether solution was washed with aqueous sodium hydroxide to remove a trace of phenol formed by oxidation of the organometallic compound by molecular oxygen. The products, when liquid, were isolated by careful distillation through a Nester and Faust spinning-band column, and identified by boiling point, refractive index, and infrared spectrum. Solid products were identified by melting point, mixed melting point, and infrared spectrum. Yields are based on the quantity of peroxide, a 10–20% excess of organometallic compound being used.

Further details of some reactions are given below.

(a) Reaction of methyl t-butyl peroxide with phenyllithium.—*t*-Butanol, b.p. 79°, was isolated in 46% yield from the reaction carried out at 15–20° C.

(b) Reaction of methyl t-butyl peroxide with phenylmagnesium bromide.—The *t*-butanol (52% yield) isolated from this reaction carried out at 15–20° contained a small amount of unreacted peroxide, as shown by an additional strong band at 875 cm^{-1} (15, pp. 120–121) in its infrared spectrum.

(c) Reaction of di-t-butyl peroxide with phenyllithium.—From the reaction carried at 0–5° C, 89% of peroxide, b.p. 50–54° at 145 mm, was recovered; at 15–20°, 45%; at 35°, 0%.

(d) Reaction of dimethyl peroxide with p-anisylmagnesium bromide and p-anisyllithium.—The ether solution from reaction of the Grignard reagent was distilled through a short Vigreux column to give *p*-dimethoxybenzene, b.p. 88–96° at 6 mm, which solidified in the receiver. Similar treatment of the ether solution from reaction of phenyllithium gave an oil, b.p. 86–96° at 6 mm, which contained *p*-bromoanisole, and which partially crystallized only by chilling to 0°. *p*-Dimethoxybenzene was removed by repeated chilling and quick filtration.

(e) Reaction of dimethyl peroxide with 2-naphthyllithium.—After reaction, 2,2′-binaphthyl (30% yield) separated from the ether solution and was recrystallized from benzene as white flakes, m.p. 180° (reported m.p. 187° (16)). The residue from the ether solution was chromatographed on neutral alumina. Elution with petroleum ether (b.p. 67–69°) yielded naphthalene, while elution with benzene – petroleum ether, 40:60, yielded 2-methoxynaphthalene, m.p. 72°.

(f) Reaction of dimethyl peroxide with triphenylmethylsodium.—Dimethyl peroxide (0.08 mole) was added to triphenylmethylsodium (17) prepared from triphenylchloromethane (0.114 mole) and sodium amalgam (0.25 g-atom). After the addition (20 minutes), the triphenylmethylsodium had been largely consumed,

as shown by the change in color of the reaction mixture from red to yellow. The syrup remaining on evaporation of the ether, after dissolution in petroleum ether, afforded crystals of triphenylmethane, but only intractable gums were obtained on evaporation of the mother liquors. However, the presence of methoxytriphenylmethane in the gum was shown by an infrared peak of medium intensity at 2825 cm^{-1} characteristic of the methoxyl group (18) and found in an authentic specimen of methoxy-triphenylmethane prepared by the method of Straus and Hüssy (19). The gum also showed a peak at 2880 cm^{-1} corresponding to the C—H stretching vibration of triphenylmethane (20).

(g) Reaction of diethyl peroxide with triphenylmethylsodium.—This reaction also yielded an uncrystallizable gum, in which the presence of an ethyl ether was shown by a strong infrared peak at 1085 cm^{-1}, as well as by aliphatic C—H stretching frequencies at 2980 and 2940 cm^{-1} (medium intensity) (15, p. 13). A C—H stretching peak for triphenylmethane was observed at 2880 cm^{-1}.

Attempted Reaction of Dimethyl Peroxide with Triphenylmethyl Radical

Dimethyl peroxide (0.08 mole) in benzene solution was added with stirring under nitrogen to a solution of hexaphenylethane in benzene, prepared from triphenylchloromethane (0.066 mole) and zinc dust (0.63 g-atom) (21). After a further 30 minutes under nitrogen, air was bubbled through the reaction mixture to change any unreacted hexaphenylethane into the insoluble di-(triphenylmethyl) peroxide. The peroxide was removed by filtration and identified by melting point and infrared spectrum (peak at 895 cm^{-1} for peroxide linkage (15, pp. 120–121)). The benzene solution on evaporation gave a residue which had an infrared spectrum identical with that of triphenylchloromethane, and showed no absorption in the region 3000–2800 cm^{-1}, indicating the absence of any methoxytriphenylmethane. Recrystallization of the residue from benzene gave colorless plates, m.p. 108–110°, undepressed by admixture with authentic triphenylchloromethane.

ACKNOWLEDGMENTS

We are grateful to Dr. A. Taurins for assistance with infrared measurements, to the Ford Foundation for a special fellowship during 1957–1959 (to G. A. B.), and to the National Research Council for financial support.

THE INTERACTION OF FRIEDEL–CRAFTS CATALYSTS WITH ORGANIC MOLECULES

II. BORON TRIFLUORIDE WITH BENZOIC ANHYDRIDE[1]

DENYS COOK
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received November 24, 1961

ABSTRACT

The complex of boron trifluoride with benzoic anhydride has been prepared. One molecule of anhydride coordinates three molecules of boron trifluoride. The infrared spectrum shows that coordination takes place at the carbonyl groups, whose frequency is lowered some 200 cm^{-1}. There is no trace of the benzoylium cation, $C_6H_5CO^+$. Although the spectra are complex, tentative assignments are made.

INTRODUCTION

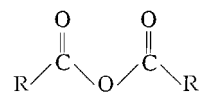
Recent work has shown the existence of the acetylium cation, CH_3CO^+, in mixtures of acid halides and strong Lewis acids (1, 2). This ion is thought to be an intermediate in the Friedel–Crafts ketone synthesis. There is strong evidence, however, that acid halides and Lewis acids can interact, giving stable complexes without ionization (2, 3). The complex formation is thought to be due to a donor–acceptor interaction between the carbonyl lone pair electrons and the vacant orbital of the Lewis acid. This complex presumably is also active in ketone synthesis.

Besides acid halides, acid anhydrides have been used in acylation reactions (4). Benzoic anhydride, for example, contains the structural elements of benzoylium benzoate, $C_6H_5CO^+OCOC_6H_5^-$, into which it could conceivably ionize under the influence of a strong Lewis acid. The purpose of the investigation was to see if any ionic species was present in the complex, thus identifying a possible common acylating agent in all Friedel–Crafts ketone syntheses, or, if not, to speculate on the constitution of the complex.

RESULTS AND DISCUSSION

Benzoic Acid – Boron Trifluoride Complex

The structure of anhydrides is probably as shown in I. Other structures derived from I



I

by rotation of the acyl group around the C—O bond are far more sterically hindered than I, even when R = CH_3. If R = C_6H_5 or any bulky alkyl groups, I is the only structure that can accommodate such groups without angular distortion. I is presumably planar, and therefore contains a plane of symmetry which bisects the C—O—C angle at right angles to the molecular plane.

The splitting of the carbonyl group frequency, observed in all anhydrides, has been ascribed to coupling of an in-phase and an out-of-phase motion of the two carbonyl

[1]*Contribution No. 57.*

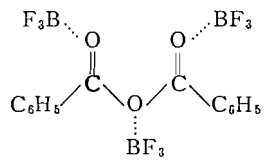
groups, resulting in a low- and high-frequency band (5, 6). This explanation has been tacitly accepted, but has been held with some reservations. Certainly both bands at 1799 cm^{-1} and 1738 cm^{-1} (doublets) are connected with the carbonyl group. (See Table I.)

TABLE I

Bands in spectrum of $(C_6H_5CO)_2O$ and the BF_3 complex

$(C_6H_5CO)_2O{:}3BF_3$, solid in nujol and fluorolube	1620m,sh, 1610s, 1601s, 1568s, 1561s, 1503m, 1463m,sh, 1458s, 1448s, 1434s, 1428m,sh, 1308w, 1272m, 1240s, 1208m, 1170s, 1153s, 1148s, 1065m,sh, 1044s,sh, 1032vs, 988s, 946w, 901w, 870m, 832vw, 810m, 770m, 721s, 695w, 681m
$(C_6H_5CO)_2O$, solution in CCl_4 and CS_2	1799vs, 1790vs, 1738s, 1733s, 1696w, 1603m, 1589m, 1494w, 1452s, 1402w, 1305w, 1270m, 1240m, 1203vs, 1168s, 1072m, 1034vs, 1012vs, 996vs, 935w, 872w, 780m, 702vs, 688m

In the complex both of these two bands have disappeared. To account for this it is suggested that each carbonyl group complexes with one BF_3 molecule as shown in II,



II

and a further BF_3 molecule coordinates at the bridge oxygen. This is in accord with the stoichiometry of the complex (see experimental section) requiring three BF_3 units per molecule of benzoic anhydride.

Having postulated BF_3 coordination at the carbonyl group, and with the knowledge that such coordination can lower carbonyl frequencies by a few hundred cm^{-1}, it is then proper to look for perturbed carbonyl frequencies in the region 1650 to 1450 cm^{-1}. There is, in fact, an abundance of bands, which makes the task somewhat difficult. Seven bands can be seen at 1610, 1601, 1568, 1503, 1458, 1448, and 1434 cm^{-1}. The last band would represent a shift of 366 cm^{-1} between anhydride and complex, and this seems rather a high value. Other fundamentals in this region would be ring modes of the aromatic nucleus, but the 1458 cm^{-1} band seems too intense for these. It is thought reasonable, therefore, to assign the 1601 cm^{-1} band to the perturbed high-frequency carbonyl vibration, and the 1458 cm^{-1} band to the low-frequency one. The 1610, 1568, 1503, and 1448 bands would then be assigned to ring modes or combinations. Their high intensity would be borrowed from the two carbonyl bands. The only other donor site in the benzoic anhydride molecule is the bridge oxygen which coordinates one BF_3 molecule. In the anhydride a very strong band is located at 1203 cm^{-1} and is generally thought to be associated with the C—O—C grouping. It has the character of an asymmetric C—O stretch. In acetic anhydride the band is at 1118 cm^{-1}. (It is doubtful if these frequencies can be designated as group frequencies, as, for example, carbonyl frequencies can. Variations in these frequencies do not have the significance that other group frequencies have.)

In the complex there are a number of bands in the 1000–1300 cm^{-1} region, but one of the bands near 1153 cm^{-1} could be approximately described as due to a C—O asymmetric stretching vibration. Vibrational interactions will be prevalent in the complex, and the free anhydride, in the C—C—O—C—C framework, so that it becomes difficult to

characterize each band as due to a specific vibration. However, the lower frequency in the complex compared with the anhydride is in keeping with known behavior of complex formation. This assignment seems a little arbitrary at the moment, but will be strengthened by subsequent assignment of other bands in the 1000–1300 cm^{-1} region to other vibrations.

In all boron trifluoride complexes the originally trigonally planar arrangement around the boron atom gives way to an approximately tetrahedral one. The three B—F bonds lengthen considerably and the donor atom makes the fourth bond at a distance closely approaching that of covalent organic compounds. Thus, in the complexes, one would expect two B—F stretching frequencies, one symmetric, the other asymmetric, in the region 900 to 1300 cm^{-1}. Furthermore, since boron has two isotopes of mass 10 and 11, in the natural ratio of 1:4, each of these B—F stretching frequencies should be doublets with a high-frequency component having about one fourth the intensity of the lower-frequency component. These doublets should be infrared active since it is only in the totally symmetric modes like ν_1 in BF_4^-, ν_1 in BF_3 that no isotope splitting occurs. It seems very unlikely that there would be no motion of the B atom in the B—F stretching modes in the complexes. The separation of the isotopic bands would be about 40 to 50 cm^{-1}.

Two bands which qualify extremely well for the asymmetric B—F stretch are located at 1272 and 1240 cm^{-1}. When rough corrections are made for band overlap these two bands have intensities in a ratio quite close to 1:4. For the symmetric B—F stretch the bands at 1065 and 1032 cm^{-1} seem very appropriate. They have the right frequency separation and intensity ratio.

One strong band is still unassigned in this region, at 988 cm^{-1}. This can be assigned to a B—O ligand bond. This is a good deal lower in frequency than a purely covalent B—O stretching vibration, as, for example, in methoxyboranes (7), 1250–1400 cm^{-1}, reflecting the weaker nature of the coordinate link. It is, however, consistent with other B—X stretching frequencies in various BF_3 complexes, for example, BF_3:pyridine, 1095 cm^{-1} (8).

While the complex nature of the spectra precludes a complete assignment at this stage, two very important incontrovertible facts are clear. First, there are no bands in the spectra near 2200 cm^{-1} associated with the ionic species ($C_6H_5CO^+SbF_6^-$, 2193 cm^{-1}) (9). Since these species give rise to intense bands it can be categorically stated that they are absent in gross amounts. Fractions of a percent could not be detected by present methods. Secondly, coordination of BF_3 occurs at both carbonyl groups and the bridge oxygen. It is clearly probable that whatever ability these complexes have in acylation does not come from any ionic species formed in the complex.

Acetic Anhydride – Boron Trifluoride Complex

Many similar features have been found in a complex of acetic anhydride with 2 moles of boron trifluoride. Total absence of absorption in the 2200–2300 cm^{-1} region indicates the absence of the acylium ion, CH_3CO^+. The absence of strong bands in the 1700–1800 cm^{-1} region also indicates an alteration in the C=O bond character. A structure similar to II is tentatively suggested, though some irreversible reaction cannot, at this stage, be ruled out. Further work is progressing with this material.

EXPERIMENTAL

The Spectra

A Perkin–Elmer 221 prism-grating spectrometer was used to record the spectra. Emulsions of the solid in nujol and fluorolube pressed between sodium chloride plates gave very good spectra. Since the compounds were somewhat sensitive to moisture the samples were prepared in a dry box.

The Compounds

Benzoic anhydride (Distillation Product Industries, white label grade), 22.6 g (0.1 mole), was dissolved in 450 g dry carbon tetrachloride, then saturated with BF_3, when a slowly developing white precipitate was observed. After filtration, and further treatment with BF_3, more solid was observed. No attempt was made to obtain a quantitative yield. The substance was slowly attacked by water, yielding benzoic acid and boric acid. A quantitative determination of the composition of the material by gravimetric methods showed that one anhydride molecule coordinated three BF_3 molecules.

ACKNOWLEDGMENT

The assistance of Miss C. D. Anderson in recording the spectra is gratefully acknowledged.

METALLO-ORGANIC COMPOUNDS CONTAINING METAL–NITROGEN BONDS

PART II. SOME DIALKYLAMINO DERIVATIVES OF Nb(V) AND Nb(IV)[1]

D. C. BRADLEY AND I. M. THOMAS[2]
Department of Chemistry, University of Western Ontario, London, Ontario

Received October 26, 1961

ABSTRACT

Reactions involving niobium pentachloride and lithium dialkylamides ($LiNR_2$, where R = Me, Et, Pr^n, Bu^n) led to considerable reduction of niobium to Nb(IV) as the length of the alkyl chains increased. $Nb(NMe_2)_5$ was isolated by sublimation but distillation of the other products gave tetrakis-(dialkylamino)-niobium(IV) compounds. Steric factors are apparently responsible for the low stability of pentakis-(dialkylamino)-niobium(V) compounds. The smaller steric effects of —$NMeBu^n$ and piperidino groups allowed the isolation of pentakis derivatives. The thermal decomposition of $Nb(NMeBu^n)_5$ gave mainly $Nb(NMeBu^n)_4$ with some $Bu^nN{=}Nb(NMeBu^n)_3$. Steric effects were also revealed in the replacement of —NMe_2 groups in $Nb(NMe_2)_5$ by —NEt_2 groups and in replacement of —NEt_2 groups in $Nb(NEt_2)_4$ by piperidino groups.

In a previous communication (1) we reported that tetrakis-dialkylamino derivatives $M(NR_2)_4$ of titanium and zirconium could be prepared by the action of the appropriate lithium dialkylamide and the metal tetrachloride. These new compounds were thermally stable insofar as they survived distillation under reduced pressure, although they were readily hydrolyzed or alcoholized. Aminolysis reactions revealed that very powerful steric effects came into play and it appeared in most cases that steric hindrance was sufficient to prevent polymerization through intermolecular metal–nitrogen coordinate bonds.

We now report some results obtained from the reactions involving lithium alkylamides with niobium pentachloride. When the lithium di-*n*-alkylamides, $LiNR_2$ (where R = Me, Et, Pr^n, and Bu^n), were used, reduction of the niobium to the quadrivalent state occurred to an extent which increased with the length of the *n*-alkyl chains in the amine, i.e. Me, 9%; Et, 69%; Pr^n, 85%; Bu^n, 91%. Only in the case of the dimethylamino derivative was it possible to isolate a pentakis compound, $Nb(NMe_2)_5$. This was obtained as a brown solid by sublimation at 100° at 0.1 mm. With the higher amines distillation of the reaction products led to the isolation of the tetrakis-dialkylamino-niobium(IV) compounds as red or brown liquids, as shown in Table I.

It is important to understand the factors which control the degree of reduction of the niobium in reactions involving lithium dialkylamides and niobium pentachloride. An obvious possibility is the opposition by steric factors to formation of stable pentakis compounds, and it is clear that the order of steric effects is: $Bu^n{}_2N > Pr^n{}_2N > Et_2N \gg Me_2N$. This order of steric effects is nicely in line with the observed order of degrees of reduction in the $LiNR_2$–$NbCl_5$ reactions. However, it is also possible that electronic factors may play an important part. Here we are on less certain ground but it seems reasonable to suppose that reduction involves the uncoupling of electrons in a metal–nitrogen bond, with the formation of an NR_2 radical. Assuming that the inductive effect (electron release) of the alkyl groups tends to stabilize the —NR_2 radical this would lead

‡Decomposes.

to the following ease of formation of radicals: $NBu^n_2 > NPr^n_2 > NEt_2 > NMe_2$, which is also in line with the observed degrees of reduction of the niobium. In an attempt to resolve this problem we have investigated some reactions of $NbCl_5$ with other lithium alkylamides. In the reaction involving the lithium derivative of N-methyl-*n*-butylamine, $MeBu^nNH$, no reduction occurred and the pentakis compound $Nb(NMeBu^n)_5$ was obtained. However, attempts to distill the compound led to extensive reduction of the niobium and the volatile product was substantially the tetrakis compound $Nb(NMeBu^n)_4$. We will defer discussion on the details of this interesting decomposition until later and point out at this stage that our success in obtaining $Nb(NMeBu^n)_5$ strongly supports the view that steric factors play a predominant role in the reduction of niobium alkylamides. This is because the relatively small N-methyl group will allow the bulky *n*-butyl group in Nb—$NMeBu^n$ groups to bend back and away from the center of intramolecular congestion. Further evidence in support of the stereochemical hypothesis resulted from the reaction involving lithium piperidide and $NbCl_5$. In this reaction only 15% reduction of niobium occurred. Moreover, by aminolysis of $Nb(NMe_2)_5$ with piperidine the pure pentakis-piperidino-niobium $Nb(NC_5H_{10})_5$ was obtained as a bright yellow crystalline compound. Since the piperidino-group has a steric effect very similar to that of the dimethylamino group but an inductive effect nearer to the diethylamino or di-*n*-propylamino group we conclude it must be steric effects which prevent the formation of stable pentakis-dialkylamino compounds of the higher di-*n*-alkylamino groups.

Some interesting results were obtained from the aminolysis reactions involving $Nb(NMe_2)_5$ and excess diethylamine under various conditions. In a reaction lasting 2 hours at the temperature of boiling diethylamine no reduction of niobium occurred and disubstitution was effected. However, attempts to distill the tris-(dimethylamino)-bis-(diethylamino)-niobium(V) $Nb(NMe_2)_3(NEt_2)_2$ so obtained led to decomposition. In another experiment, continued until it appeared that all of the dimethylamino groups had been replaced (9 days), reduction occurred (30%) and analysis showed that dimethylamino groups were still present. Distillation of the product gave a volatile quadrivalent niobium mixed alkylamide, $Nb(NMe_2)(NEt_2)_3$. From these experiments it is clear that steric effects are very powerful in preventing substitution of Me_2N groups by Et_2N groups. In addition, it appears that the niobium can accommodate three dimethylamino and two diethylamino groups but that the introduction of the third or fourth diethylamino group leads to instability.

The niobium(IV) compounds obtained in this research were similar in volatility to the tetrakis-dialkylamino-titanium compounds prepared before (1) and they should provide valuable starting materials for the synthesis of other Nb(IV) compounds. For example, we have prepared tetrakis-piperidino-niobium(IV) by aminolysis involving tetrakis-diethylamino-niobium(IV). Even in this system it was clear that steric hindrance was important because in a preliminary experiment conducted in boiling benzene for over 4 hours only disubstitution occurred. However, the $Nb(NEt_2)_2(NC_5H_{10})_2$ thus formed disproportionated when heated and a small amount of the volatile $Nb(NEt_2)_3(NC_5H_{10})$ was obtained. Complete replacement of diethylamino groups was effected by a reaction lasting 6 days, but the low volatility of $Nb(NC_5H_{10})_4$ precluded its purification by distillation. This feature of $Nb(NC_5H_{10})_4$ calls to mind the abnormally low volatility of $Ti(NC_5H_{10})_4$. From considerations of molecular size and organic content it would be expected that the tetrakis-piperidino derivatives would have volatilities intermediate between the tetrakis-diethylamino derivatives (Ti, 110° at 0.05 mm; Nb, 120° at 0.1 mm) and the tetrakis-di-*n*-propylamino derivatives (Ti, 150° at 0.1 mm; Nb, 155° at 0.1 mm). In fact they are considerably less volatile (Ti, 180° at 0.1 mm; Nb, decomposes at 170° at 0.1 mm). Since the piperidino groups will exert less steric hindrance than either NEt_2 or NPr^n_2 groups it was thought that the piperidino compounds might be polymeric in nature. Nevertheless, determination of the molecular weight of $Ti(NC_5H_{10})_4$ in boiling benzene showed that this compound was monomeric (1) and the reason for its abnormally low volatility is obscure.

Let us now return to the thermal decomposition of $Nb(NMeBu^n)_5$ mentioned earlier in the paper. About 90% of the niobium originally in the pentakis compound was recovered in the form of a deep red liquid which distilled at 150° at 0.1 mm. Analysis of the distillate showed that it was substantially tetrakis-(N-methyl-*n*-butylamino)-niobium(IV) but the N:Nb ratio of 4:1 and the average valency of 4.25 for the niobium showed that a quinquevalent niobium compound with N:Nb = 4:1 and a volatility similar to $Nb(NMeBu^n)_4$ must also be present. Our experience with tantalum compounds (2) suggested that the quinquevalent niobium compound might be $Bu^nN{=}Nb(NMeBu^n)_3$. This was confirmed by gas chromatography of the volatile products of alcoholysis by which means primary *n*-butylamine was identified in addition to N-methyl-*n*-butylamine. It appears that the thermal decomposition of $Nb(NMeBu^n)_5$ involves some novel reactions since besides practically quantitative recovery of niobium as $Nb(NMeBu^n)_4 + Bu^nN{=}Nb(NMeBu^n)_3$ there was obtained a more volatile product consisting of substantially N-methyl-*n*-butylamine. Further work on this interesting reaction is in progress. Special attention was paid to the possibility that compounds of the type $RN{=}Nb(NR_2)_3$ might also be formed in the thermal decomposition of the other $Nb(NR_2)_5$ compounds but no evidence for this was forthcoming.

EXPERIMENTAL

1. General

All reactions were carried out in carefully dried glass apparatus under an atmosphere of dry oxygen-free nitrogen.

Amines were stored over sodium wire and fractionally distilled over fresh sodium immediately prior to use. The purity of the amines was checked by gas chromatographic analysis.

The niobium analyses were obtained by weighing samples directly into weighed platinum crucibles, hydrolyzing cautiously with water, and igniting carefully to Nb_2O_5. The nitrogen content (as basic nitrogen) was determined by steam distillation and subsequent titration of the amine produced by hydrolysis in alkaline solution. The valency of the niobium was determined by the following chemical method. A sample of the compound was added to a 10-cc aliquot of a solution of anhydrous ferric chloride (15 g) and sulphuric acid (15 cc, conc.) in ethanol (150 cc). When a clear solution was obtained (usually within 10 seconds) the aliquot was added to dilute sulphuric acid and titrated against standard ceric sulphate solution. A blank determination was carried out on the ferric chloride – sulphuric acid – ethanol reagent.

2. Preparation of Lithium Dialkylamides

In order to remove lithium chloride by filtration from the products of the lithium dialkylamide – $NbCl_5$ reaction it was necessary to prepare a solution of $LiNR_2$ in pentane free from lithium halides. The following method proved to be satisfactory. Normal-butyl chloride (theoretical amount) in twice its volume of pentane was slowly added to a suspension of finely cut lithium ribbon in pentane. The rate of addition was adjusted to maintain the pentane at a moderate rate of reflux. The mixture was stirred until cool and then kept at room temperature for several hours. The clear solution of butyllithium was decanted from the insoluble lithium chloride and the concentration of butyllithium was determined by titration against standard acid. The dialkylamine (10% excess over theoretical) was then added dropwise to the stirred solution of butyllithium at a rate sufficient to maintain the pentane in a state of reflux. The lithium dialkylamide was precipitated and in all cases appeared to be practically insoluble. After completing the addition of the dialkylamine the system was stirred for a further 30 minutes and was then ready for use.

3. Reactions Involving $NbCl_5$ and Lithium Dialkylamides

(i) Lithium Dimethylamide

Niobium pentachloride (11.5 g) was added to a stirred suspension of lithium dimethylamide (0.215 g-equiv) in pentane. A slow reaction occurred with the development of an orange color. The mixture was kept stirred at room temperature for 20 hours and was then filtered to remove insoluble lithium salts. Evaporation of pentane from the filtrate left a light brown solid (13.8 g; calc. for $Nb(NMe_2)_5$, 13.3 g). Found: Nb, 27.4; NMe_2, 63.7; valency of Nb, 4.90, 4.93; Cl, trace; Li, trace; ratio N: Nb, 4.90:1. $Nb(NMe_2)_5$ requires: Nb, 29.7; NMe_2, 70.3%.

A sample of the foregoing product (11.0 g) was heated under 0.1 mm Hg pressure and sublimed at 100° C, giving a dark brown solid (6.33 g; 58% yield) which proved to be pentakis-(dimethylamino)-niobium(V). Found: Nb, 29.6; NMe_2, 70.0%; valency of Nb, 5.00, 4.98. The non-volatile residue (3.73 g) was also a brown solid. Found: Nb, 28.9; NMe_2, 38.8%; valency of Nb, 4.53, 4.54; ratio N: Nb, 2.83:1.

(ii) Lithium Diethylamide

Niobium pentachloride (10.1 g) and lithium diethylamide (0.195 g-equiv) were caused to react as in the previous experiment. The niobium product, isolated as before, was a red viscous liquid (16.4 g; calc. for $Nb(NEt_2)_4$, 14.29). Found: Nb, 20.4; NEt_2, 73.8; valency of Nb, 4.31, 4.32; Cl, trace; Li, absent; ratio N:Nb, 4.65:1. $Nb(NEt_2)_4$ requires: Nb, 24.4; NEt_2, 75.6%. Distillation of this product (13.7 g) gave tetrakis-(diethylamino)-niobium(IV) as a brown liquid product (9.0 g; 76% yield; b.p. 120° C at 0.1 mm). Found: Nb, 24.5; NEt_2, 76.3%; valency of Nb, 3.98.

(iii) Lithium Di-n-propylamide

Niobium pentachloride (13.2 g) was added to a stirred suspension of lithium di-*n*-propylamide (0.255 g-equiv) in pentane over a period of 30 minutes and a deep red color developed. After being stirred for 6 hours the mixture was filtered and the filtrate evaporated under reduced pressure, leaving a deep red liquid product (25.5 g; calc. for $Nb(NPr_2)_4$, 24.1 g). Found: Nb, 17.2; N, 10.9; valency of Nb, 4.16, 4.15; Cl, absent; Li, absent; ratio N:Nb, 4.22:1. $Nb(NPr_2)_4$ requires: Nb, 18.8; N, 11.36%. Distillation of this product afforded tetrakis-(di-*n*-propylamino)-niobium(IV) as a dark red liquid (17.9 g; 81% yield; b.p. 155° C at 0.1 mm). Found: Nb, 19.0; N, 11.4%; valency of Nb, 4.04, 4.07. A sample of this compound was allowed to react with *n*-butanol and the volatile products were subjected to gas chromatographic analysis. Only di-*n*-propylamine was identified as the volatile product of alcoholysis.

(iv) Lithium Di-n-butylamide

Niobium pentachloride (11.0 g) was added to a stirred suspension of lithium di-*n*-butylamide in pentane over a period of 45 minutes. The dark brown mixture was stirred at room temperature for 5 hours, then filtered, and the filtrate evaporated under reduced pressure. The product remaining after drying for 2 hours at 40° C at 0.1 mm was a dark red liquid (30.0 g; calc. for $Nb(NBu_2)_4$,Bu_2NH, 29.9 g). Found: Nb, 12.1; N, 9.53%; valency of Nb, 4.08, 4.10; Li, absent; Cl, trace; ratio N:Nb, 5.22:1. A sample (26.8 g) of this product was distilled under reduced pressure but due to the high temperature involved, decomposition was considerable. The product was redistilled and finally gave tetrakis-(di-*n*-butylamino)-niobium(IV) as a deep red liquid (4.05 g; b.p. 175° C at 0.1 mm). Found: Nb, 15.6; N, 9.17; valency of Nb, 4.25, 4.28; ratio N:Nb, 3.90:1. $Nb(NBu_2)_4$ requires: Nb, 15.3; N, 9.25%. The valency determination suggested that an appreciable proportion of a quinquevalent niobium compound was also present but the only reasonable possibility would be $Bu^nN{=}Nb(NBu^n)_3$ since this has the same N:Nb ratio as $Nb(NBu_2)_4$ and would have a similar volatility. Since $BuN{=}Nb(NBu_2)_3$ requires: Nb, 16.9; N, 10.2%, this would also explain the fact that the product was a slightly higher Nb% than $Nb(NBu_2)_4$ but it is not consistent with the lower N%. However, gas chromatographic analysis of the volatile products of *n*-butanolysis showed that di-*n*-butylamine was the only amine liberated, and this result rules out the possibility that the compound was contaminated with $Bu^nN{=}Nb(NBu^n_2)_3$.

(v) Lithium Piperidide

Niobium pentachloride (8.8 g) was added to a stirred suspension of lithium piperidide (0.165 g-equiv) in petrol (boiling range, 35–60° C). A slow reaction occurred and after the addition the brown mixture was refluxed for 6 hours and then left stirred at room temperature for a further 20 hours. The final product

obtained after filtration and evaporation of the solvent was a red viscous liquid (15.3 g; calc. for $Nb(NC_5H_{10})_5$, 16.4 g). Found: Nb, 15.6; NC_5H_{10}, 58.4; valency of Nb, 4.85; Cl, trace; Li, absent; ratio N:Nb, 4.14:1. $Nb(NC_5H_{10})_5$ requires: Nb, 18.1; NC_5H_{10}, 81.9%. Attempts to purify the crude product by means of crystallization from petrol or by distillation at 0.1 mm pressure were unsuccessful. At temperatures above 170° C, decomposition to a black solid (found: Nb, 27.2; NC_5H_{10}, 23.7%; valency of Nb, 4.16; ratio N:Nb, 0.96:1) occurred.

(vi) Lithium N-Methyl-n-butylamide

Niobium pentachloride (13.5 g) was added to a stirred suspension of lithium N-methyl-*n*-butylamide (0.252 g-equiv) in pentane over a period of 45 minutes and the mixture became orange. After being stirred for 6 hours at room temperature this mixture was filtered, and the filtrate evaporated under reduced pressure, leaving a dark brown liquid product (25.9 g; calc. for $Nb(NMeBu^n)_5$, 26.1 g). Found: Nb, 17.5; N, 12.7; valency of Nb, 4.96; ratio N:Nb, 4.82:1. $Nb(NMeBu^n)_5$ requires: Nb, 17.76; N, 13.4%. The pentakis-(N-methyl-*n*-butylamino)-niobium(V) (24.1 g) was heated under reduced pressure and a product was distilled over accompanied by considerable decomposition. Redistillation gave a deep red liquid distillate (17.0 g; yield 86%; b.p. 150° at 0.1 mm). Found: Nb, 21.5; N, 12.75; valency of Nb, 4.27, 4.24; ratio N:Nb, 3.94:1. $Nb(NMeBu)_4$ requires: Nb, 21.25; N, 12.82. $BuN{=}Nb(NMeBu)_3$ requires: Nb, 22.0; N, 13.26%. The analytical data on this substance suggested that it was a mixture of $Nb(NMeBu^n)_4$ and $Bu^nN{=}Nb(NMeBu^n)_3$. A sample (3.45 g) of the substance was treated with *n*-butanol (5.0 g) and refluxed until the solution became colorless (ca. 3 minutes). The volatile products and excess *n*-butanol were evaporated off under reduced pressure and the residue distilled under reduced pressure to give niobium pentabutoxide (3.37 g; 93% yield; b.p. 200° C at 0.1 mm). Found: Nb, 20.4; N, absent. $Nb(OBu)_5$ requires: Nb, 20.3%. Gas chromatographic analysis of the butanolic condensate revealed the presence of primary *n*-butylamine in addition to N-methyl-*n*-butylamine. The presence of $Bu^nN{=}Nb(NMeBu^n)_3$ in the original substance was thus confirmed. It is also interesting to note that oxidation of the niobium from quadrivalent to quinquevalent occurred during the butanolysis and it is clear that niobium tetraalkoxides are very unstable. In addition to the red substance produced by heating $Nb(NMeBu^n)_5$ there was obtained by condensation at ca. −78° C a volatile product (5.2 g) which was predominantly N-methyl-*n*-butylamine (about 90% as estimated by gas chromatography). Acidimetric titration gave an equivalent weight of 96 compared with the calculated 87 for $MeBu^nNH$ and this also suggested the presence of about 10% of non-basic component in the mixture.

4. Aminolysis of Dialkylamino-niobium Compounds

(i) Piperidine and $Nb(NMe_2)_5$

Piperidine (8 ml) was caused to react with $Nb(NMe_2)_5$ (3.19 g) in petrol (boiling range 35–60° C; 50 ml) at the boiling point. When no more dimethylamine appeared to be evolved (after 3 days) the solvent and excess piperidine were evaporated off under reduced pressure and a light brown solid was left. This was crystallized from petrol and gave the pentakis-(piperidino)-niobium(V) as a bright yellow solid (1.6 g; 31% yield). Found: Nb, 18.3; NC_5H_{10}, 81.0. $Nb(NC_5H_{10})_5$ requires: Nb, 18.1; NC_5H_{10}, 81.9%.

(ii) Piperidine and $Nb(NEt_2)_4$

Piperidine (10 ml) and $Nb(NEt_2)_4$ (3.93 g) were caused to react in boiling benzene (30 ml) in an apparatus fitted with a fractionation column in order to take off the diethylamine liberated. After 4 hours reaction the solvent and excess piperidine were evaporated off under reduced pressure and a dark brown viscous liquid (4.32 g) was left. Found: Nb, 22.8; N, 13.7; valency of Nb, 4.05; ratio N:Nb, 3.99:1. $Nb(NEt_2)_2(NC_5H_{10})_2$ requires: Nb, 22.9; N, 13.8%. A sample (2.8 g) of this product was distilled to give a brown liquid distillate (0.5 g; b.p. 170° C at 0.1 mm). Found: Nb, 23.6; N, 14.35; ratio N:Nb, 4.03. $Nb(NEt_2)_3(NC_5H_{10})$ requires: Nb, 23.6; N, 14.25%.

In an attempt to force the completion of the aminolysis another sample of $Nb(NEt_2)_4$ (2.58 g) was caused to react with piperidine (20 ml) in boiling benzene (70 ml) and the liberated diethylamine was fractionated off during 6 days. At this stage it appeared from gas chromatographic analysis of the distillate that the liberation of diethylamine was complete. After evaporating off the solvent and excess piperidine a dark brown liquid (3.1 g; calc. for $Nb(NC_5H_{10})_4$, 2.9 g) remained. Found: Nb, 20.1; NC_5H_{10}, 79.8; valency of Nb, 4.02, 4.05; N:Nb, 4.38:1. $Nb(NC_5H_{10})_4$ requires: Nb, 21.6; NC_5H_{10}, 78.4%. Gas chromatographic analysis of the volatile products of butanolysis showed that the only base present was piperidine. The analytical results suggested that some piperidine was coordinated to the tetrakis-(piperidino)-niobium(IV). Attempts to distill the compound under reduced pressure were unsuccessful since it decomposed at temperatures above 170° C.

(iii) Diethylamine and $Nb(NMe_2)_5$

Diethylamine (25 ml) was added to $Nb(NMe_2)_5$ (3.0 g) and refluxed for 2 hours during which time some dimethylamine was liberated. After evaporating off the excess diethylamine a light brown solid (3.33 g) remained. Found: Nb, 25.5; N, 18.8; valency of Nb, 4.95, 4.97; ratio N:Nb, 4.90:1. $Nb(NMe_2)_3(NEt_2)_2$ requires: Nb, 25.2; N, 19.0%. A sample of the tris-(dimethylamino)-bis-(diethylamino)-niobium(V) (2.6 g) was heated under 0.1 mm pressure, and at 110° C a red liquid distilled over (0.5 g). Found: Nb, 32.2; N, 13.6; valency of Nb, 4.39; ratio N:Nb, 2.80:1.

In another experiment $Nb(NMe_2)_5$ (3.92 g) was refluxed with diethylamine (50 cc) and the liberated dimethylamine fractionated off over a period of 9 days. At this stage it was apparent from gas chromatographic analysis of the distillate that liberation of dimethylamine had ceased. A red liquid product (3.86 g) remained after the evaporation of excess diethylamine. Found: Nb, 27.9; N, 14.7; valency of Nb, 4.70; ratio N:Nb, 3.5:1. That this product was a mixed alkylamide was shown by the gas chromatographic analysis of the volatile products of butanolysis, which revealed the presence of both diethylamine and dimethylamine. A sample (2.38 g) of the mixed alkylamide was heated to 120° C at 0.1 mm when a red liquid distilled over (1.0 g). Found: Nb, 26.0; N, 15.45; ratio N:Nb, 3.94:1. $Nb(NMe_2)(NEt_2)_3$ requires: Nb, 26.2; N, 15.9%.

ABSTRACT

The alkaloids tuberostemonine, oxotuberostemonine, and the new base tuberostemonine-A have been isolated from the rhizomes of *Stemona sessilifolia*. Tuberostemonine has been oxidized to oxotuberostemonine and tuberostemonine-A has been related to tuberostemonine through common oxidation products. Study of transformation products of tuberostemonine has enabled assignment of partial structure V to the alkaloid.

The work of Schild (1) and a group of Japanese chemists* has resulted in an array of transformation products of the alkaloid tuberostemonine. Their efforts have indicated the presence of an N-substituted pyrrolidine, a C-ethyl group, and two γ-lactones in the molecule. In the hope of obtaining other members of this interesting group of alkaloids for complementary investigation, we examined the bases from the rhizomes of *Stemona sessilifolia* Miq. (1). However, the main alkaloid proved to be tuberostemonine, the main alkaloid of *Stemona tuberosa*,† with a much smaller quantity of a new base and traces of oxotuberostemonine (4).

We hence commenced a thorough examination of the reactions of the nitrogen-containing ring of tuberostemonine. Oxidation of the sodium salt of partially hydrolyzed tuberostemonine with permanganate gave, as reported earlier (1), a lactam ($\nu_{max}^{CHCl_3}$ 1677 cm^{-1}) which still contained a γ-lactone ring ($\nu_{max}^{CHCl_3}$ 1770 cm^{-1}). This analyzed correctly for $C_{17}H_{25}NO_3$ and hence had lost a five-carbon group containing one lactone ring. Since no new oxygen function other than the lactam carbonyl appeared in the C_{17} compound, the C_5 unit must have been attached to one of the carbons α to the nitrogen. The formation of *l*-methylsuccinic acid was observed during an analogous oxidation (1, 2), suggesting that this represented the C_5 unit lost.

Further insight into the nature of the C_5 unit came from a dehydrogenation of the pyrrolidine ring. We were able to obtain an approximately 40% yield of the previously described bisdehydro compound by silver oxide oxidation of tuberostemonine (1, 5). The ultraviolet spectrum (λ_{max}^{EtOH} 236 mμ (ϵ 9200)), the positive Ehrlich test (1), and coupling with diazonium salts were all consistent with this being a pyrrole. We were able to confirm Schild's observation (1) that this underwent hydrogenolysis involving 1 mole of hydrogen, to give an acid. The latter was characterized for the first time. The hydrogenolysis and formation of the C_{17} lactam require that the pyrrole ring and one lactone have the relationship expressed in I.

Examination of the n.m.r. spectrum of the bisdehydro compound (Fig. 1) disclosed the presence of one vinyl hydrogen which, in view of the absence of evidence for the presence

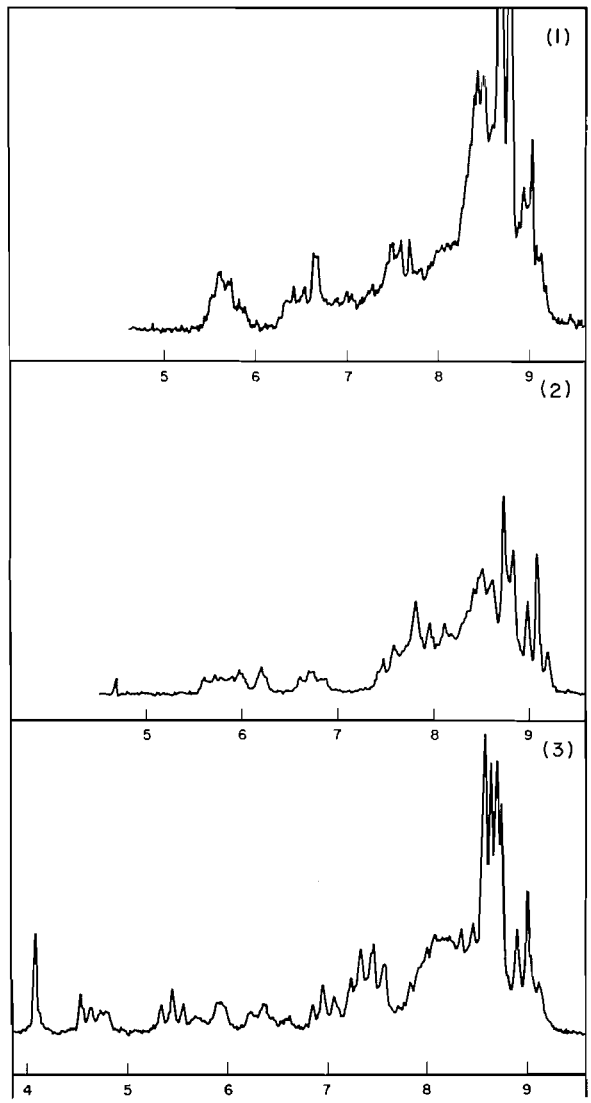

FIG. 1. The n.m.r. spectra of (1) tuberostemonine (V), (2) C_{17} lactam (III), and (3) bisdehydrotuberostemonine (II) in chloroform solution at 60 Mc/s with tetramethylsilane as an internal reference.

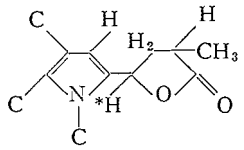
of a double bond in tuberostemonine, was probably on the pyrrole ring. This was confirmed by its smooth replacement with bromine on treatment with N-bromosuccinimide. The product had no vinyl hydrogen.

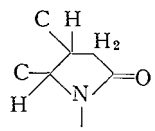
The pyrrole hydrogen had a chemical shift (τ 4.1)* which showed it to be on a β position on the ring (7). Finally, this hydrogen and the lactone side chain were proved to be vicinal by cyclization of the hydrogenolysis acid to give a ketone. The environment of the pyrrole ring in the bisdehydro compound could now be expanded to II, since the

**The chemical shifts are given in τ values following Tiers (6).*

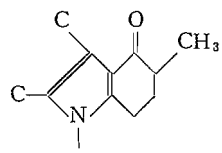
methyl group n.m.r. signal was still at low field (τ 8.5) in the above ketone (Fig. 1) and the signal for the starred hydrogen in the bisdehydro compound II (τ 4.7) showed



II



III

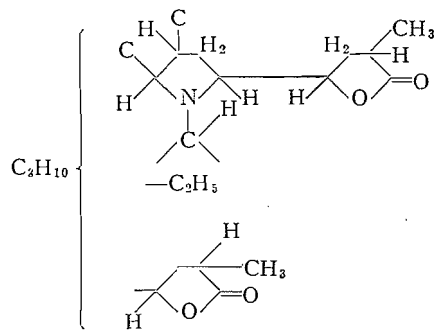


IV

complex coupling. The C_{17} lactam hence contained the structure III and the ketone structure IV.

The presence of a second C-methyl group was demonstrated by the doublet centered at τ 8.7 in the C_{17} lactam (Fig. 1) and a similar doublet at τ 8.8 in the ketone IV. From the chemical shift and relative constancy of position of this signal, the methyl group must be on the carbon α to the carbonyl, or on the one carrying the "ether" oxygen of the second γ-lactone ring. A clean triplet centered at τ 5.45 in the spectrum of the bisdehydro compound and near τ 5.2 in the spectrum of ketone IV must be due to a tertiary hydrogen on the carbon holding the "ether" oxygen of this lactone. The coupling pattern of this hydrogen and the methyl group precludes their being on the same carbon, hence the latter must be α to the lactone carbonyl. In addition the C-ethyl group observed by Kaneko (2) was discernible as an irregular triplet at τ 9.05 in the spectra of tuberostemonine and the transformation products (Fig. 1). Since its position is constant in these compounds it is not attached directly to the pyrrolidine ring in the alkaloid.

Attempts to find volatile aldehyde, acid, or ketone from mild permanganate oxidation of tuberostemonine, or volatile amine from hydrolysis of the bisdehydro compound failed. This is good but not decisive evidence that the nitrogen is common to two rings. Finally, the presence of only three hydrogen signals below τ 7.0 in the n.m.r spectrum of the C_{17} lactam requires that there is only one hydrogen on each of the carbons attached to the nitrogen. We can thus write the partial structure V for tuberostemonine. The empirical

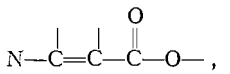


V

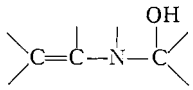
formula of tuberostemonine requires the presence of seven double bond equivalents, hence it contains two rings more than are present in formula V.

It seemed probable from the earlier observations (4) that oxotuberostemonine was a product of air oxidation of tuberostemonine. We have now shown that it can be produced in ca. 9% yield from tuberostemonine by mercuric acetate oxidation, thus establishing a definite connection between the two compounds. The empirical formula $C_{22}H_{31}NO_5$

showed the introduction of a double bond and an oxygen function. The infrared spectrum contained an OH stretching band (3540 cm^{-1}, $CHCl_3$) and the two lactone rings (ν_{max} 1742, 1780 cm^{-1}, mull; 1770 cm^{-1}, $CHCl_3$). It was a weak base (pK_a' 4.5 in 80% methanol), and in rough agreement with the spectrum described earlier (8), it had λ_{max}^{EtOH} 243 mμ (ϵ 8600). Its origin by mercuric acetate oxidation made it likely that it was a combined enamine and carbinolamine. The system shown,



was considered incompatible with the ultraviolet absorption (λ_{max} for N,N-dialkyl-β-aminoacrylic esters (9) is 274 mμ) and the unperturbed lactone frequencies in chloroform. We hence consider oxotuberostemonine to contain the system VI. The tetrasubstituted

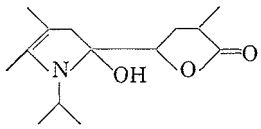


VI

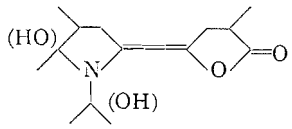
character of the double bond follows from the absence of vinyl hydrogens in its n.m.r. spectrum. Although oxotuberostemonine steadily consumes permanganate in slightly acidic acetone, much of it is recovered after reduction of the equivalent of 1.5 atoms of oxygen, and very little lactam is formed. From this, and the absence of a hydrogen signal below τ 6 in its n.m.r. spectrum, we conclude that the hydroxyl is on a fully substituted carbon, as illustrated in VI.

Oxotuberostemonine is not readily dehydrated, but after 0.5 hour in refluxing acetic anhydride only 20% was recovered unchanged (see also ref. 4). The balance was neutral, and gave a positive Ehrlich test. It would not crystallize however and had different ultraviolet absorption (λ_{max} 224 mμ) from the bisdehydro compound. This seems to eliminate from consideration the arrangement of functions shown in VII.

The product of hydrolysis of oxotuberostemonine using 2 moles of alkali gave an infrared spectrum showing the presence of a little residual γ-lactone but no ketone carbonyl. We hence also eliminate VIII as a possible partial structure. Insufficient evidence is available to distinguish between the remaining possibilities.

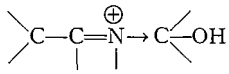


VII

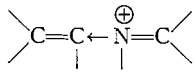


VIII

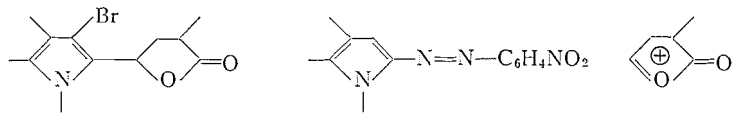
The weak basicity of oxotuberostemonine was not readily predictable on the basis of combined enamine and carbinolamine character. With no steric restriction to immonium salt formation either one alone is base strengthening (10, 11). We can only conclude that the inductive effect of one group is sufficient to destabilize the immonium salt formed from the other, i.e.,



or



The bromo derivative mentioned above must contain partial structure IX, but the diazonium coupling product had lost one lactone group, and we hence consider it to contain partial structure X. The displacement of alkyl groups and carboxyl groups from the



IX X XI

pyrrole ring by the diazonium ion has been reported (12). The lactone unit is probably displaced relatively easily because of a moderate stability of the oxonium ion XI.

It was found possible, after some experimentation, to produce what the Japanese workers designated as tuberostemonine (regenerated) (13) by prolonged exposure of tuberostemonine to hydrogen in the presence of platinum. This isomer of tuberostemonine gave very similar infrared and n.m.r. spectra to those of tuberostemonine, hence was probably a stereoisomer formed by a dehydrogenation–hydrogenation process. To test this we attempted to oxidize it with silver oxide in the hope that the same bisdehydro compound (II) would be obtained as from the original base. However, it proved inert to the reagent. Permanganate oxidation of the sodium salt gave a C_{17} lactam different from that described above.

From the mother liquors remaining from crystallization of tuberostemonine we were able to separate, by countercurrent distribution, oxotuberostemonine and an isomer of tuberostemonine which we have called tuberostemonine-A (m.p. 118°; $[\alpha]_D$ −65° (ethanol)). By silver oxide oxidation and action of permanganate on its sodium salt the latter gave the same bisdehydro compound and C_{17} lactam respectively as tuberostemonine. It is hence epimeric to tuberostemonine at the carbon on the pyrrolidine ring carrying the C_5 lactone unit. The new base showed a mixed melting point depression with a sample of isotuberostemonine (14) (which may be a third stereoisomer of tuberostemonine) kindly provided by Dr. T. Kaneko.

EXPERIMENTAL

Isolation of the Alkaloids

Freshly ground dried root of *Stemona sessilifolia* (44 lb), obtained from Mikuni and Co. Ltd., Tokyo, was percolated at room temperature with ethanol until little alkaloid was being extracted. The ethanol was removed under reduced pressure, leaving a thick syrup. This was diluted with water, made basic with sodium carbonate, and extracted with chloroform. The residue left after evaporation of the chloroform was dissolved in 10% sulphuric acid and the solution extracted with ether, which removed neutral material. The aqueous layer was made basic with sodium carbonate and the alkaloids extracted into benzene. The benzene was distilled, then the residue dissolved in the minimum quantity of methanol. On standing at 5° C the solution deposited crystalline tuberostemonine (137 g, 0.68%). The dark brown mother liquor was concentrated and acidified with hydrochloric acid. Fourteen grams of the hydrochloride of tuberostemonine-A, m.p. 136–140°, crystallized.

The final mother liquor was concentrated, made basic, and the alkaloids extracted into ether. The residue from evaporation of the ether would not crystallize. It was adsorbed from benzene onto 600 g of silica gel and separated into benzene-eluted and chloroform-eluted fractions. These were separately submitted to countercurrent distribution between benzene and buffer of pH 3.5 (upper phase moving). After 100 transfers the benzene eluate gave 500 mg of oxotuberostemonine (tubes 70–100) and 120 mg of tuberostemonine-A, m.p. 116–118° (tubes 60–70). The chloroform eluate gave 700 mg of oxotuberostemonine (tubes 70–100) and 1.5 g of tuberostemonine (tubes 25–40). The remaining tubes yielded nothing crystalline.

Tuberostemonine

This crystallized as needles from ethanol, m.p. 86–88°. After distillation at 150°, 1×10^{-4} mm it had ν_{max}^{film} 1770 cm^{-1}.

Oxotuberostemonine

Yield 1.2 g (0.006%). It crystallized as flat, shimmering needles from methanol, m.p. 217° undepressed when mixed with an authentic sample kindly provided by Dr. T. Kaneko. It had λ_{max}^{EtOH} 243 mμ (ε 8600) and $\nu_{max}^{CHCl_3}$ 3540 cm^{-1} (OH), 1770 cm^{-1} (γ-lactone), 1685 cm^{-1} (C=C).

Tuberostemonine-A

Yield 14 g (0.07%). The hydrochloride was recrystallized to a constant melting point of 140–141°. Found: C, 61.09; H, 8.59; N, 3.18. Calc. for $C_{22}H_{34}ClNO_4.H_2O$: C, 61.47; H, 8.38, N, 3.26. It had ν_{max}^{nujol} 2400, 1780 cm^{-1}. The salt was dissolved in water, the base liberated using ammonia, and then extracted into ether. It crystallized from methanol as needles, m.p. 118–120°, with pK_a' (5.45 in 80% methanol) and $[\alpha]_D$ −65° (*c*, 1.0). Found: C, 70.06; H, 8.79; N, 3.74; molecular weight by nonaqueous titration, 371. Calc. for $C_{22}H_{33}O_4N$: C, 70.36; H, 8.86; N, 3.73; molecular weight, 375. Its ultraviolet spectrum showed only end absorption. It had $\nu_{max}^{CHCl_3}$ 1765 cm^{-1} and an n.m.r. spectrum very similar to that of tuberostemonine. A mixture of the base with authentic isotuberostemonine showed a marked depression of melting point. No other crystalline salt of tuberostemonine-A was obtained.

Tuberostemonine-A (0.20 g) was oxidized in ethanol with silver oxide from 0.75 g of silver nitrate, as described for oxidation of tuberostemonine. A solution of the product in benzene was extracted twice with 10-ml portions of 2 *N* sulphuric acid, then with water. The material remaining in the benzene was adsorbed onto 2 g of neutral alumina, activity IV. The substance eluted with benzene crystallized from methanol, giving a 32% yield, m.p. 172–174°. Found: C, 71.58; H, 8.22. Calc. for $C_{22}H_{29}O_4N$: C, 71.13; H, 7.87. This did not depress the melting point of authentic bisdehydrotuberostemonine.

Tuberostemonine-A (0.5 g) was dissolved by being heated in 50 ml of 10% aqueous potassium hydroxide. The solution was cooled to −2° and carbon dioxide bubbled through it until the pH reached 8.5. After addition of 50 ml of methylene chloride 40 ml of 2% aqueous potassium permanganate was added during 1 hour to the stirred mixture. The neutral product was isolated as described for tuberostemonine oxidation, then adsorbed from benzene onto 150 mg of neutral alumina, activity III. Benzene, benzene–chloroform (1:1), and chloroform were used to elute the material. The last two solvents gave eluates which crystallized from acetone–heptane. Yield 25 mg, m.p. 127–130°. This did not depress the melting point of the C_{17} lactam from tuberostemonine.

Mild Permanganate Oxidation of Tuberostemonine

During a period of an hour, 75 ml of 4% aq. potassium permanganate was added to a stirred solution of 0.61 g of tuberostemonine in 20 ml of 5% aq. acetic acid. A gentle stream of nitrogen was passed through the mixture, and the effluent gas was passed through 2,4-dinitrophenylhydrazine reagent. There was no evidence of hydrazone formation.

No significant quantity of volatile acid was formed during an oxidation similar to the one described above in which phosphoric acid was used in place of acetic acid. (The pH was maintained at 5–7 during the course of the reaction.)

Oxidation of Tuberostemonine with Alkaline Potassium Permanganate

A mixture of 1.00 g of tuberostemonine (m.p. 82–84°) and 50 ml of 10% aq. potassium hydroxide was stirred and heated to reflux in an atmosphere of nitrogen until it was homogeneous. It was cooled in ice and a stream of carbon dioxide was passed through until the pH was between 9 and 10. Dichloromethane (50 ml) was added, the temperature was adjusted to −1°, and during a period of 45 minutes a total of 80 ml of 2% aq. potassium permanganate was added to the vigorously stirred mixture. The reaction mixture was made acid to Congo red by the careful addition of 10% aq. sulphuric acid, and sulphur dioxide was passed through until the manganese dioxide had dissolved. The organic layer was separated and the aqueous layer was extracted with dichloromethane (3×25 ml). The combined extracts were washed with water (2×25 ml), 2% aq. sodium carbonate (2×25 ml), and again with water (2×25 ml). They were filtered through anhyd. sodium sulphate and concentrated under reduced pressure. The residual viscous yellow oil (0.32 g) was chromatographed on neutral alumina, activity III. The fractions eluted with benzene–chloroform were crystallized from acetone–heptane, giving 0.165 g, m.p. 129–133°. This material seemed to be solvated; after it was distilled at 145° and 10^{-3} mm pressure, it melted at 139–141.5°; $[\alpha]_D$ −72° (*c*, 1.53 in $CHCl_3$); $\nu_{max}^{CHCl_3}$ 1770, 1677 cm^{-1}. Found: C, 70.05; H, 8.54; N, 4.87. Calc. for $C_{17}H_{25}NO_3$: C, 70.08; H, 8.65; N, 4.81.

Bisdehydrotuberostemonine

Freshly precipitated silver oxide from 7.5 g of silver nitrate was washed free of alkali and then washed with ethanol. Tuberostemonine (2 g) was dissolved in 100 ml of ethanol, then 20 ml of water was added. The silver oxide was added to this, and the suspension stirred in a nitrogen atmosphere for 12 hours. After filtration the solvent was removed under reduced pressure. The residue was dissolved in 100 ml of benzene, then the base extracted into two 20-ml portions of 3 *N* sulphuric acid. The benzene layer was washed with water, dried, and distilled, leaving 1.3 g of residue. This was adsorbed onto 6 g of alumina, activity IV. The material eluted with benzene was recrystallized from methanol three times, giving 0.8 g (40%) of bisdehydro compound, m.p. 172–174°. It had λ_{max}^{EtOH} 236 mμ (ε 9200).

Diazo Coupling of Bisdehydrotuberostemonine

A slight excess of *p*-nitrophenyldiazonium chloride was added dropwise to a stirred solution of 0.093 g of bisdehydrotuberostemonine in 10 ml of glacial acetic acid at 15° during 30 minutes. It was filtered and the filtrate was diluted with an equal volume of water. The resulting voluminous precipitate was collected by

filtration, washed well with water, and triturated with ethanol (2×5 ml). The amorphous brick red solid began to darken at 160° and decomposed at 166°. $\lambda_{max}^{CHCl_3}$ 471 mμ, ν_{max}^{nujol} 1757, 1602, 1588, 1517 cm^{-1}. Found: C, 64.95; H, 6.47; N, 13.19. Calc. for $C_{23}H_{26}N_4O_4$: C, 65.38; H, 6.20; N, 13.26.

Hydrogenation of Bisdehydrotuberostemonine

Bisdehydrotuberostemonine (0.131 g) was hydrogenated in ethanol over 30% palladium on charcoal at room temperature and atmospheric pressure. The uptake of hydrogen was 8.9 ml during 30 minutes. The catalyst was removed by filtration and the filtrate was concentrated under reduced pressure. The residue was a colorless, acidic glass; pK_a 5.7 (in 1:1 ethanol–water); λ_{max}^{EtOH} 224 mμ (ε 7600). It was analyzed as the methyl ester, which was prepared by treating it with an excess of ethereal diazomethane. The ester distilled at 170° at 10^{-3} mm; $[\alpha]_D$ +27.5° (*c*, 0.72 in $CHCl_3$); λ_{max}^{EtOH} 224 mμ (ε 7600); ν_{max}^{film} 1770, 1735 cm^{-1}. Found: C, 70.96; H, 8.34; N, 3.52. Calc. for $C_{23}H_{33}NO_4$: C, 71.29; H, 8.58; N, 3.61. The material gave a positive Ehrlich test.

Ketone IV

A solution of 0.222 g of the hydrogenated bisdehydrotuberostemonine in a mixture of 5 ml glacial acetic acid and 5 ml of acetic anhydride was allowed to stand at room temperature for 15 hours. Water (5 ml) was added, the solution was allowed to stand for an additional hour at room temperature and then was warmed on the steam bath for 5 minutes. It was diluted with 25 ml of water and extracted with benzene (4×10 ml). The benzene extracts were combined and washed with water (2×10 ml), 1% aq. sodium carbonate (until the washings were alkaline), and then again with water (2×10 ml). The benzene solution was filtered through anhyd. sodium sulphate and concentrated under reduced pressure. The tan-colored residue was recrystallized from ethanol, giving 0.135 g, m.p. 236–240°. After two additional recrystallizations from ethanol, white prisms melting at 245.5–248° were obtained; $[\alpha]_D$ +140° (*c*, 2.22 in $CHCl_3$); λ_{max}^{EtOH} 214 mμ (ε 13,500), 255 mμ (ε 10,200), 280 mμ (ε 5800); $\nu_{max}^{CHCl_3}$ 1644, 1757 cm^{-1}. Found: C, 74.18; H, 8.20; N, 4.08. Calc. for $C_{22}H_{29}NO_3$: C, 74.33; H, 8.22; N, 3.94.

Attempted Hydrolysis of Bisdehydrotuberostemonine

A mixture of 0.093 g of bisdehydrotuberostemonine, 0.084 g of anhyd. sodium bicarbonate, 0.105 g of hydroxylamine hydrochloride, and 2 ml of ethanol was heated in a sealed tube at 95° for 18 hours. The contents of the tube were cooled, made strongly alkaline with 10% aq. potassium hydroxide, and distilled to dryness. The distillate was titrated with hydrochloric acid and concentrated to dryness under reduced pressure. The infrared spectrum of the residue was identical with that of ammonium chloride.

Treatment of bisdehydrotuberostemonine with 25% ethanolic phosphoric acid in a sealed tube at 140° for 18 hours did not result in the formation of any volatile amine.

Bromination of Bisdehydrotuberostemonine

Two hundred milligrams of bisdehydrotuberostemonine was dissolved in 5 ml of dry chloroform. To this was added 100 mg of N-bromosuccinimide in 5 ml of dry chloroform. When the reagent had disappeared (starch–iodide test) the reaction mixture was washed with 2 *N* sodium hydroxide, then water. The product crystallized from methanol, giving 165 mg (64%), m.p. 120–125° (decomp.). Found: C, 58.70; H, 6.36; Br, 17.95. Calc. for $C_{22}H_{28}BrNO_4$: C, 58.53; H, 6.43; Br, 17.71. It had ν_{max}^{nujol} 1770 cm^{-1}.

Mercuric Acetate Oxidation of Tuberostemonine

Pure tuberostemonine (3 g), m.p. 86–88°, was dissolved in 20 ml of 10% acetic acid. A solution of 4 g of mercuric acetate in 40 ml of 10% acetic acid was added, then the solution warmed to 50° for ca. 5 minutes. Mercurous acetate which precipitated was collected by filtration. The residual mercuric ion was precipitated using hydrogen sulphide. After filtration the filtrate was extracted with ether but nothing was removed. The aqueous solution was made basic with ammonia and extracted with ether. The base recovered from the ether was dissolved in benzene and passed through a short column containing 4.5 g of alumina, activity IV. The benzene eluate crystallized from methanol, giving 250 mg (9%) of oxotuberostemonine, m.p. 217–218°. This did not depress the melting point of a sample of oxotuberostemonine kindly supplied by Dr. T. Kaneko. The more strongly adsorbed products did not crystallize.

Action of Acetic Anhydride on Oxotuberostemonine

A solution of 30 mg of oxotuberostemonine in 5 ml of acetic anhydride was refluxed for 0.5 hour. The solvent was removed under reduced pressure and the residue separated into neutral and basic products by distribution between benzene and 6 *N* hydrochloric acid. The 11 mg of neutral material was adsorbed from benzene on 40 mg of alumina, activity IV. Benzene eluted 7 mg of amorphous substance giving a positive Ehrlich test and having λ_{max} 224 mμ in ethanol. Its infrared spectrum ($CHCl_3$) contained only the γ-lactone band at 1760 cm^{-1} in the carbonyl region. The basic product gave 6 mg of unchanged oxotuberostemonine, m.p. 215–218°.

Oxidation of Tuberostemonine (Regenerated) with Alkaline Potassium Permanganate

The method described above for the preparation of the C_{17} lactam was used. The crude product was purified as follows. A benzene solution of the mixture was adsorbed onto a column of neutral alumina,

activity III. The fractions that were eluted with benzene–chloroform were crystallized twice from acetone–heptane and then distilled at 160° and 10^{-3} mm. The yield was 12% of the theoretical; m.p. 132–134.5°; $\nu_{max}^{CHCl_3}$ 1764, 1673 cm^{-1}. Found: C, 69.87; H, 8.39; N, 4.80. Calc. for $C_{17}H_{25}NO_3$: C, 70.08; H, 8.65; N, 4.81. A mixed melting point with the C_{17} lactam was depressed to 95–110°. The infrared spectra of the two compounds were quite different in the region between 900 and 1500 cm^{-1}.

ACKNOWLEDGMENTS

We wish to thank Mr. A. Knoll for the extractions and preliminary separations, Mr. H. Seguin for the analyses, Mr. J. Nicholson for the n.m.r. spectra, and Mr. R. Lauzon for the infrared spectra. We are grateful to Dr. T. Kaneko for reference samples.

ON THE MECHANISM OF DISSOLUTION OF MAGNESIUM IN AQUEOUS MAGNESIUM CHLORIDE SOLUTIONS

PART II[1]

E. J. CASEY, R. E. BERGERON,[2] AND G. D. NAGY[3]

The Defence Research Chemical Laboratories, Ottawa, Ontario

Received July 4, 1961

ABSTRACT

Measurements have been made of the effect of pressure on the rate of dissolution of Mg at pH 2.0 in two concentrations of aqueous $MgCl_2$. Over the pressure range 0.026–2.5 atmospheres, the rates in 0.3 and 3.0 molal solutions have, respectively, the pressure dependences

$$v \propto 1/P_{H_2}^{1/2} \text{ and } v \propto P_{H_2}.$$

The induction period of the reaction was studied in detail with a sensitive gas-measuring technique. Hydrogen enters the metal in the early stages, to about 1 cc per cc Mg at 27° C. Its rate of release after the specimen is dried is about five times higher than the rate at which it enters the magnesium.

X-Ray diffraction patterns of insoluble reaction products formed on the metal surface after prolonged reaction were examined. Magnesium and magnesium hydroxide are formed in both solutions, while a substantial amount of still unidentified extra solid material (not one of the hydrated hydroxy chlorides) is formed in the 3 molal solution.

A mechanism is proposed which describes the pressure measurements quantitatively and is consistent with the other known facts. It involves univalent magnesium as an essential intermediate, the rate being controlled by H_2 bubble growth through the gelatinous $Mg(OH)_2$ film, which remains on and protects the surface in 0.3 molal solution, and by bubble nucleation in 3 molal solution, in which the film is complexed away.

INTRODUCTION

In a paper a few years ago (1) we presented experimental results which showed that the corrosion of magnesium in aqueous magnesium chloride differed markedly from that in KCl and KNO_3. Although at low concentration (ionic strength <3) the initial rate of dissolution of the metal in these three salts is about the same, beyond ionic strength 3 of $MgCl_2$ the rate increases rapidly with increasing concentration and reaches a maximum value slightly before saturation. In this high-concentration region not only is the rate abnormally high but it is independent of pH and has an activation energy of 11.4 kcal, much higher than that found for dissolutions under transport control. Yet in the low concentrations the rate follows the solubility of MgO in the electrolyte, passing through a maximum value at 0.3 molal, the rates being just about the same as in KCl or KNO_3 at the same pH, and being proportional to hydrogen ion activity. The activation energy in acidic KCl was found to be 3 kcal/mole.

In both the high- and low-concentration regions the corrosion was found to be under cathodic control, the hydrogen electrode being polarized at least 1.8 volts and the magnesium about 0.4 volts.

The initial rates were measured as rates of gas evolution, and were confirmed by weight measurements in those cases in which no film was left on the surface. The measurements of volumes of H_2 evolved as a function of time all had a slight induction period, which, at the time, was ignored. The sensitivity of the measurements was about 0.1 cc.

Since the rate of dissolution of the metal in the early stages of the reaction is apparently controlled by the cathodic reactions of H_2 evolution, in the work now to be reported the

effect of pressure on rate was measured in both high and low concentrations. The induction period was then studied with a more sensitive (~0.005 cc) gas-measuring technique and the activation energy in 0.3 molal $MgCl_2$ (i.e. in the low concentration region) accurately measured. The results have led to a better understanding of the mechanism of the early stages of the dissolution process.

EXPERIMENTAL METHODS AND RESULTS

The magnesium specimens used for the experiments were short ($\frac{1}{4}$ in.) cylinders of $\frac{5}{8}$-in. diameter, turned from commercially pure, distilled magnesium ingot obtained from Dominion Magnesium Ltd. All but one flat face was covered with stop-off lacquer. The surface to be studied was prepared as described previously (1), by being filed, etched in 0.5 *N* HCl for 1 minute, washed in distilled water, and dried on an absorbent material (Webril) immediately before introduction into the reaction chamber.

The electrolytes were prepared from reagent grade $MgCl_2$. Since it is hygroscopic, it was first dried at 80° C, the solutions were made up approximately, and the pH was adjusted to 2.0 with HCl before analysis. The final concentrations were set to 0.30 and 3.0 molal, at pH = 2.0. Samples were saturated with H_2, with O_2, with N_2, and with air, but no differences were found either in the ultraviolet spectra or the rate of reaction. Apparently the reaction proceeds fast enough at pH = 2 that any foreign gas, even if it could have an effect, is displaced by H_2.

Effects of Pressure on Rate of Dissolution

Corrosion occurred in 20-ml portions of solution in a reaction chamber thermostated at 25° C. The remainder of the apparatus (see Fig. 1)—namely the filling device and

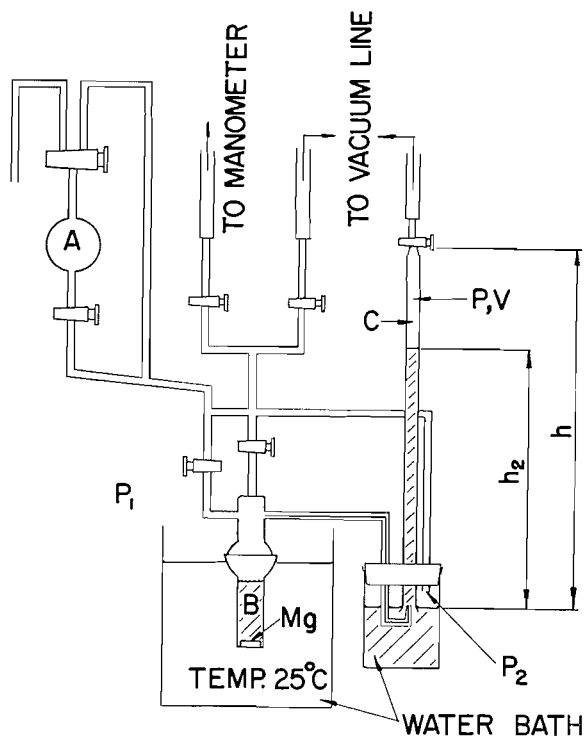

FIG. 1. Schematic diagram of apparatus used to measure rate as a function pressure. A = filling device, B = reaction chamber, C = gas collector, P_1 = atmospheric pressure.

the leads to the manifold, to the vacuum pump to the manometer, and to the gas-measuring unit—was not temperature controlled. However, the room temperature was about 25° C and since the longest test runs were not more than 2 hours, the problem of temperature deviation was not serious. In a typical run the electrolyte was added to the filling chamber A by first reducing the pressure in A and then allowing the air pressure to force liquid up and in through the tube at the left. With the stopcocks properly set, the air could be pumped from both the solution and the specimen, before the pressure at which reaction to occur was set, usually simply by admitting air. When reaction was to begin, the stopcocks under A were opened and the electrolyte flowed evenly down the delivery tube into the reaction chamber B. These cocks were then closed, the one to the manometer was closed, and collection of gas began in chamber C. The gas was collected in an inverted burette by the water displacement method, and the volume of gas collected was measured as a function of time of corrosion. The rate of gas production v'' was determined from the initial slope of the volume–time curve. In cases in which an induction period occurred, reasonably satisfactory initial rates could be obtained after the induction period was finished. The value of v'' determined by the slope of the volume–time curve at the same value of the volume for different runs was found to give reproducible results, and this method of analysis was adopted.

For the apparatus depicted in Fig. 1 a hydrostatics argument has been developed by which the rates of change of gas volume in the measuring burette ($dV^P/dt \equiv v''$) can be converted into rates ($dV^{760}/dt \equiv v'$) in terms of volume at 25° C and 1 atm pressure. Thus, it can be seen from Fig. 1 that since

$$P_2 = P + h_2/\rho$$

and

$$P = P^{\text{vap}} + P^{\text{H}_2},$$

then

$$\frac{V^{760}}{V^P} = \frac{P_2 - h_2/\rho - P^{\text{vap}}}{760}, \qquad [a]$$

where ρ is the density of mercury, and all pressures are in mm Hg, P^{vap} is the vapor pressure of water, P^{H_2} the pressure of the hydrogen gas in chamber C.

Differentiation with respect to time gives:

$$\frac{dV^{760}}{dt} = \frac{1}{760}\left[(P_2 - h_2/\rho - P^{\text{vap}})\frac{dV^P}{dt} + V^P(-dh_2/dt)/\rho\right]. \qquad [b]$$

Since

$$V^P = \pi r^2(h - h_2),$$

$$dh_2/dt = -(1/\pi r^2)dV^P/dt.$$

Letting v'' be dV^P/dt and v' be dV^{760}/dt, insertion of expressions for V^P and (dh_2/dt) into equation [b] gives

$$v' = (1/760)(P_2 - 2h_2/\rho - P^{\text{vap}} + h/\rho)v''. \qquad [c]$$

Conversions of the measured rates (v'') into the reduced rates (v') were made by means of this expression. Conversion of v' into rate v (in terms of weight of magnesium dissolved) was made assuming mole-for-mole reaction of Mg for H_2.

With the apparatus in this form (Fig. 1), it was possible to conduct experiments at atmospheric and at reduced pressures. For work at pressures greater than atmospheric it was necessary to seal off all leads from the reaction chamber, and as a result it became impossible to use the gas evolution method. Hence, at higher pressures only weight loss determinations could be obtained, and these could be relied upon only in cases where no insoluble products were accumulated on the surface over an extended period of time. For this reason measurements at higher pressures were made only in 3 molal $MgCl_2$.

The results of measurements in 0.3 molal $MgCl_2$ are contained in Table I, and the

results of measurements in 3.0 molal $MgCl_2$ are contained in Table II. In summary, the rate (converted to mg cm^{-2} sec^{-1}) in 0.3 molal $MgCl_2$ decreases with increasing pressure; in 3.0 molal $MgCl_2$ the rate increases slightly with increasing pressure. The latter dependence is linear (Fig. 2). By contrast, a plot of log rate vs. log P for the 0.3 molal results (Fig. 3) shows

$$v \propto P^{-0.5}.$$

Examination of the Induction Period

Corrosion experiments were carried out in 46 ml of 0.3 molal $MgCl_2$. The gas-measuring apparatus was simply a horizontal capillary tube of cross-sectional area 0.04 cm^2 with a 0.5-cm Hg bubble connected to the reaction vessel by about 16 in. of fine capillary tubing with short tygon connecting tubes. The measuring device was thermostated at 27.4°±0.1° C, while the reaction vessel was in a water–glycol bath which could be thermostated to ±0.03° from 0–45° (see Fig. 4). After the surface had been prepared, the Mg sample was dropped into the electrolyte in the reaction chamber, which had previously been allowed to come to thermal equilibrium with the bath, and the connections quickly made. The first reading was usually taken about 100 seconds after the sample

had hit the electrolyte. Since the mercury bubble sometimes stuck, the capillary was tapped sharply a few times before a reading until the equilibrium position was reached. Since the bubble position in the capillary could be read to ±0.02 cm, the sensitivity was about 0.001 cm, but being limited by temperature control, was found to be reliable to about ±0.005 cc.

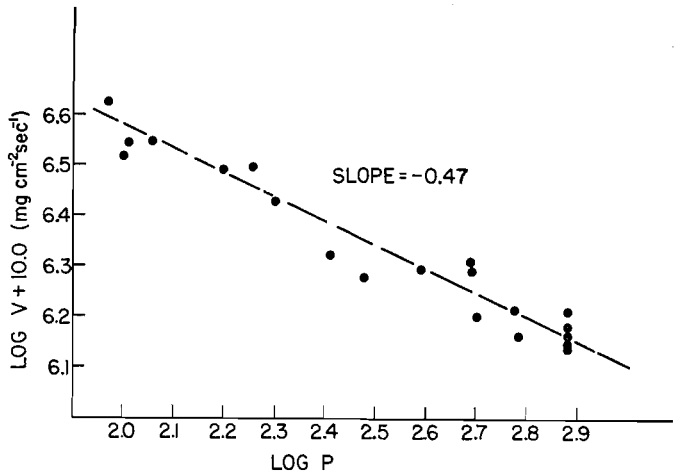

FIG. 3. Dependence of rate on pressure in 0.3 molal $MgCl_2$ (pH 2.0, 25° C).

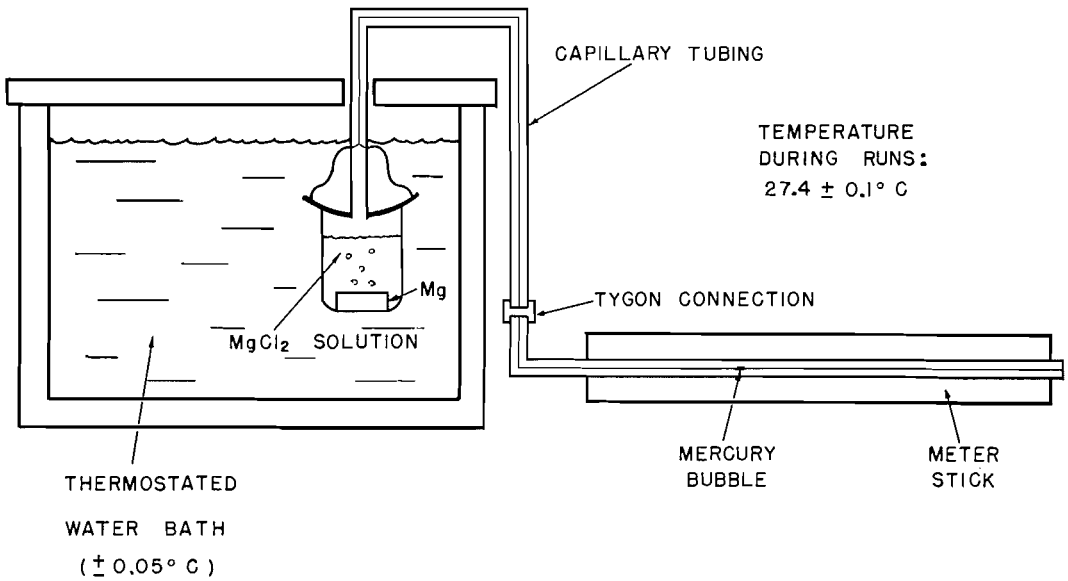

FIG. 4. Schematic diagram of capillary tube apparatus for studying induction period.

Figures 5 and 6 show typical results obtained at 0, 12, 18, 25, 30, 35, and 45°. Below 35° the "induction period" was usually, but not always, linear, and its slope (v_1) easily distinguished from the "true" rate (v). The break from v_1 to v occurs at a value of volume evolved which decreases with increasing temperature.

The rates at various temperatures are collected in Arrhenius plots in Figs. 7(*a*) and 7(*b*) (a duplicate set of experiments with fresh materials), from which the activation energy for both v_1 and v is seen to be 12.2 ± 0.6 kcal/mole. This fact is an indication that the rate-controlling step of the induction period is not different from that of the main corrosion period. In fact it was next shown that during the induction period hydrogen

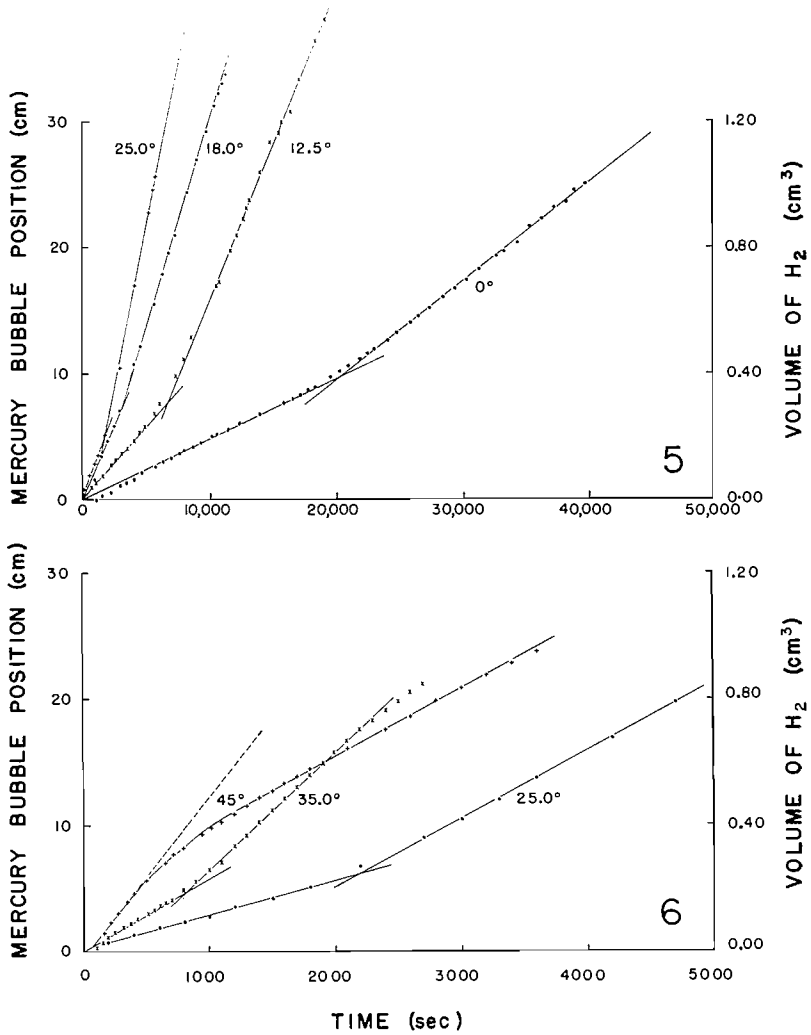

FIG. 5. Typical results of volume measured as function of time, at 0°, 12°, 18°, 25° C.
FIG. 6. Typical results of volume measured as function of time, at 25°, 35°, 45° C.

gas enters not only the electrolyte but also the metal itself to a rather astonishing amount, approximately 1 cc H_2 per cc Mg at 27°. The experimental procedures are described in the remainder of this section.

As a preliminary a *fresh* Mg specimen was allowed to react in *fresh* electrolyte to beyond the break from v_1 to v. Thus *used*, the specimen was then allowed to react in *fresh* electrolyte and the *used* electrolyte fitted with a *fresh* specimen of Mg. In the latter case the solution had been already saturated with H_2 from the preliminary part of the experiment. However, the results consistently showed the rate to be less than the final rate of the preliminary experiment (for example, see Fig. 8).

Optical stereomicroscopic examination of a used specimen, following rapid washing and dehydration in absolute alcohol and mounting under degassed mineral oil, disclosed the liberation of gas bubbles from the magnesium, rapidly at first and then more slowly,

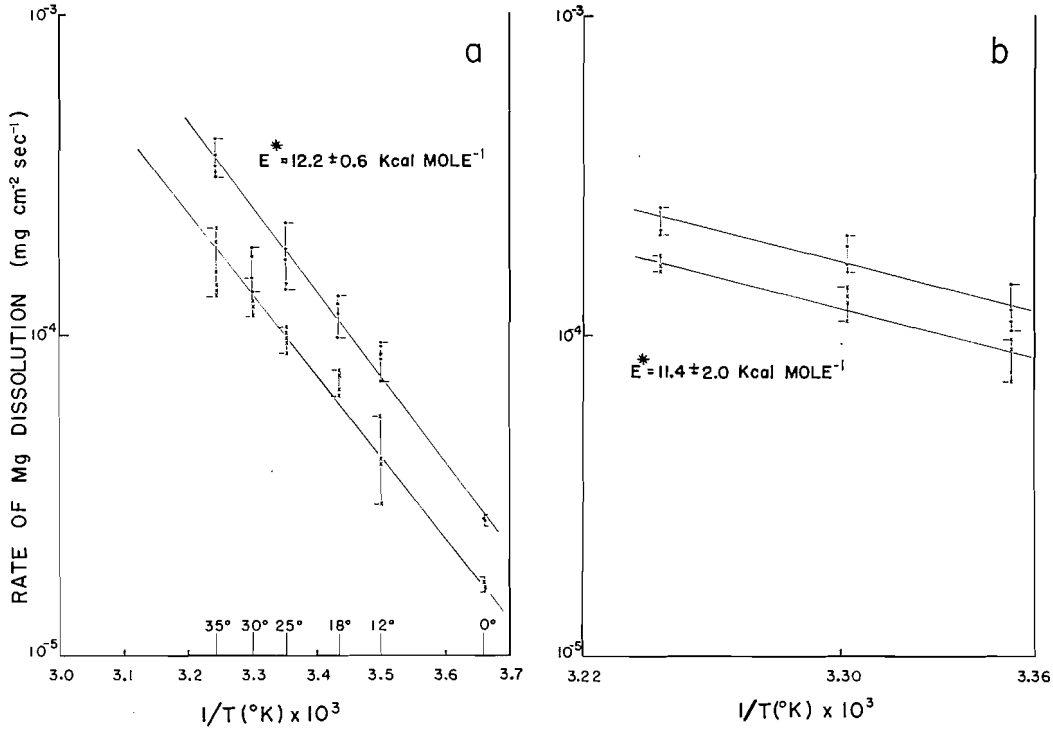

FIG. 7. Arrhenius plots for rate as function of temperature for 0.3 molal $MgCl_2$ solutions: (*a*) No. 1, (*b*) No. 2. Upper curve v; lower curve v_i; pH 2.0.

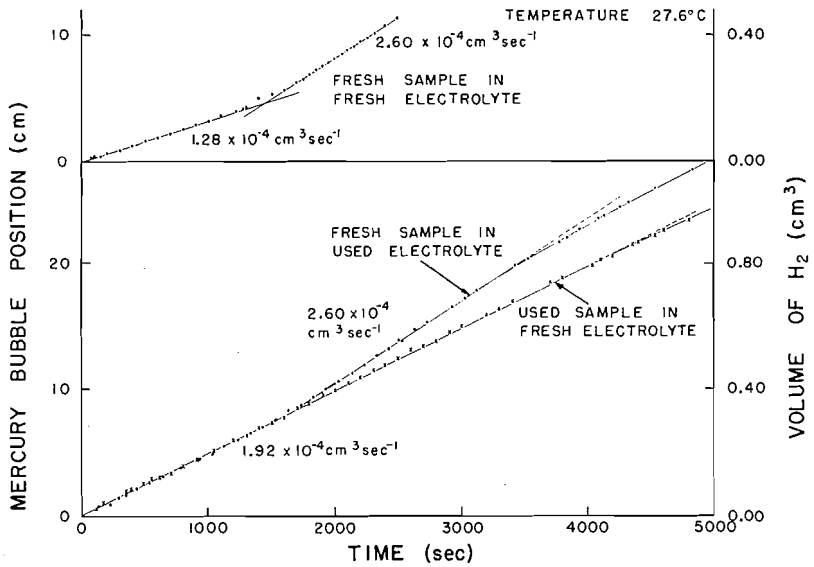

FIG. 8. Dissolution of freshly prepared magnesium in electrolyte already saturated with hydrogen; and dissolution of H_2-saturated magnesium in fresh electrolyte.

but continuing over several hours. At the same time, there was no indication that hydrogen had been stored in the plastic which coated the magnesium.

Figure 9 shows the results of measurement of the gas liberated at 27.6° C from a specimen corroded at the same temperature. Following the corrosion step, the specimen

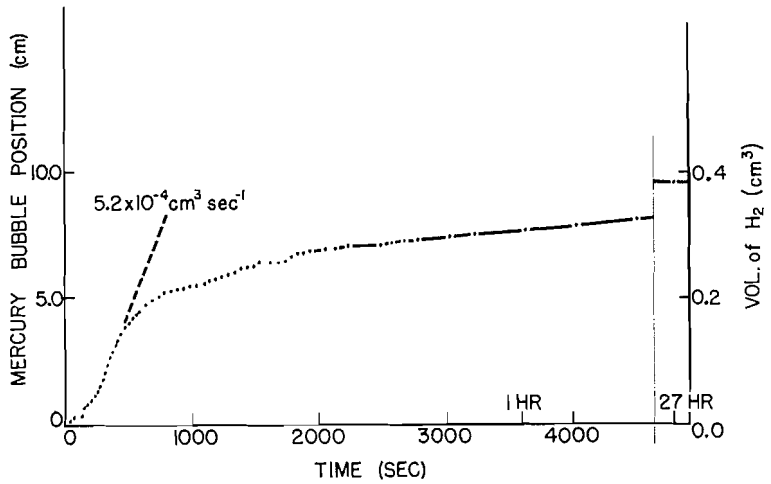

FIG. 9. Liberation of hydrogen stored in magnesium during corrosion in 0.3 molal $MgCl_2$. Volume vs. time after drying in cold absolute alcohol and mounting, under CCl_4, in small capillary measuring apparatus at 27.6° C.

(area 1.14 cm^2, 0.4 cm high) was washed with distilled water for 5 seconds at room temperature, then in cold (−20° C) absolute alcohol for 40 seconds before being mounted in the measuring chamber under 20 ml of CCl_4. Experience had shown that CCl_4 could be used to prevent O_2 from reaching the active surface, to float away any residual water contained in cracks and fissures, and yet to assist the release of gas bubbles as soon as they formed on the surface. Any side reaction adversely affects the measurement; for example, under absolute alcohol, a slow but detectable corrosion of Mg continued for hours and was measured superimposed on the stored H_2 which was being released. The possibility that some of this prolonged H_2 production is due to acid forced into cracks and fissures and not removed by the alcohol wash cannot be ruled out.

In the example considered in Fig. 9, v_i was 1.16×10^{-4} cm^3/sec and v was 2.38×10^{-4}. The break occurred at about 1500 seconds. If it is assumed that the difference is the rate at which H_2 penetrates the magnesium, it can be calculated that 0.18 cc is lost to the Mg sample in the induction period, and remains there during the steady state of the dissolution process. However, the measured value of the amount released was 0.38 cm^3. The difference is presently assumed to be that which entered during the preparation of the sample. (It will be recalled that the sample was etched for 1 minute in 0.5 *N* HCl prior to the dissolution experiment with a possible small contribution from acid left in the fissure.) The initial rate of escape of H_2, following a short induction period (which must exist because the Mg entered the chamber directly from alcohol at −20° C), was 5.2×10^{-4} cm^3/sec, nearly five times the rate at which it entered during corrosion in the aqueous $MgCl_2$.

Absorption and X-Ray Diffraction Spectra

The X-ray diffraction spectrum was taken of each of several samples of the product built up by extended reaction of Mg with $MgCl_2$ solutions. Spectra formed by precipitation reactions were taken for comparison. Table III lists lattice spacings obtained from reaction in 0.3 and in 3.0 molal $MgCl_2$.

TABLE III

*Two ASTM cards.

The product formed in 0.3 molal $MgCl_2$, after being scraped from the surface, washed, dried, and mounted on a quartz fiber under vaseline, had a spectrum which was attributable to $Mg(OH)_2$ plus a small amount of Mg metal.

The product formed in 3 molal $MgCl_2$ was more difficult to handle, being hygroscopic, but, after desiccation at 25° and mounting, gave a spectrum which contained at least two components. One was definitely $Mg(OH)_2$. None of the reported spectra of the hydrated magnesium hydroxy chlorides (2), either singly or superimposed, could account for the rest of the spectrum, although three of the five most prominent lines said* to be characteristic of Mg(OH)Cl appear, and this material may be a second part of the product. If so, a third part is still unidentified. The two prominent spacings of the remainder are at 11.6 and 4.17 Å, the former indicating a heavily hydrated, very basic hydroxy chloride.†

Before and after certain corrosion experiments ultraviolet absorption spectra were taken on solutions saturated with N_2 or O_2 or air. If oxygen was present, the characteristic absorption of OCl^- at 3800 Å was present, but its presence did not seem to have any effect on rate of H_2 evolution.

*ASTM cards. However, Bianco (Ann. de Chim. **3**, 370 (1958)) more recently ascribes this spectrum to be anhydrous $Mg_2(OH)_3Cl$.

†See Y. Bianco, Ann. de Chim. **3**, 370 (1958), for recent X-ray and chemical analyses of hydroxychlorides; and P. M. de Wolff and L. Walter-Lévy, Acta Cryst. **6**, 40 (1953), for spectrum and structural analysis of the most common hydrate, $Mg_2(OH)_3Cl.4H_2O$.

DISCUSSION

A Mechanism Which Describes Pressure Measurements

The simplest formulation which, in principle, describes the results obtained at low concentration is the following:

$$Mg + H^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Mg^+ + 1/2H_2, \qquad \text{fast} \qquad [1]$$

$$Mg^+ + H_2O \xrightarrow{k_2} Mg^{++} + 1/2H_2 + OH^-, \qquad \text{slow} \qquad [2]$$

for which a steady-state argument readily shows:

$$v = \frac{C_1[H^+]}{P_{H_2}^{1/2} + C_2},$$

where

$$C_1 = \frac{k_1 k_2}{k_{-1}}[H_2O][Mg] \text{ and } C_2 = \frac{k_2}{k_{-1}}[H_2O].$$

Further, if reaction [1] is in labile equilibrium, i.e. if $k_{-1} \gg k_2$,

$$v = C_1 \frac{[H^+]}{P_{H_2}^{1/2}}.$$

A more explicit mechanism, which is easy to envisage, and which does not differ in principle with the one above, is the hydrogen molecule–ion mechanism illustrated in Fig. 10 and described below:

$$Mg + H_2O = MgOH_{2\,ads} \qquad \text{fast} \qquad [1a]$$

$$MgOH_{2\,ads} + H^+_{ads} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} MgOH_{ads} + H_2^+{}_{ads} \qquad \text{fast} \qquad [1b]$$

$$MgOH_{ads} + H^+_{ads} \xrightarrow{k_3} MgOH^+ + 1/2H_2 \qquad \text{slow} \qquad [2]$$

or $MgOH_{soln}$

$$2H_2^+{}_{ads} \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} H_{2\,gas} + 2H^+_{ads}. \qquad [3]$$

From this it follows, as before, from a steady-state argument that

$$v = \frac{C_3[H^+]}{P_{H_2}^{1/2} + C_4},$$

where $C_3 = K_1(k_2/k_{-2})k_3K_4[Mg][H_2O]$; $C_4 = k_3(K_4/k_{-2})$; and $K_4 = k_4/k_{-4}$. Similar to the first case, if equilibrium obtains in reaction [2] (i.e. if $k_{-2} \gg k_3$), then:

$$v = \frac{C_3[H^+]}{P_{H_2}^{1/2}}.$$

Note that in this model the rate decreases with increasing P_{H_2} because of the increase in the number of adsorbed H_2^+ ions which react with and reduce the steady-state concentration of $MgOH_{ads}$. Thus the rate is controlled by the concentration of hydrogen molecule–ions adsorbed on the surface.

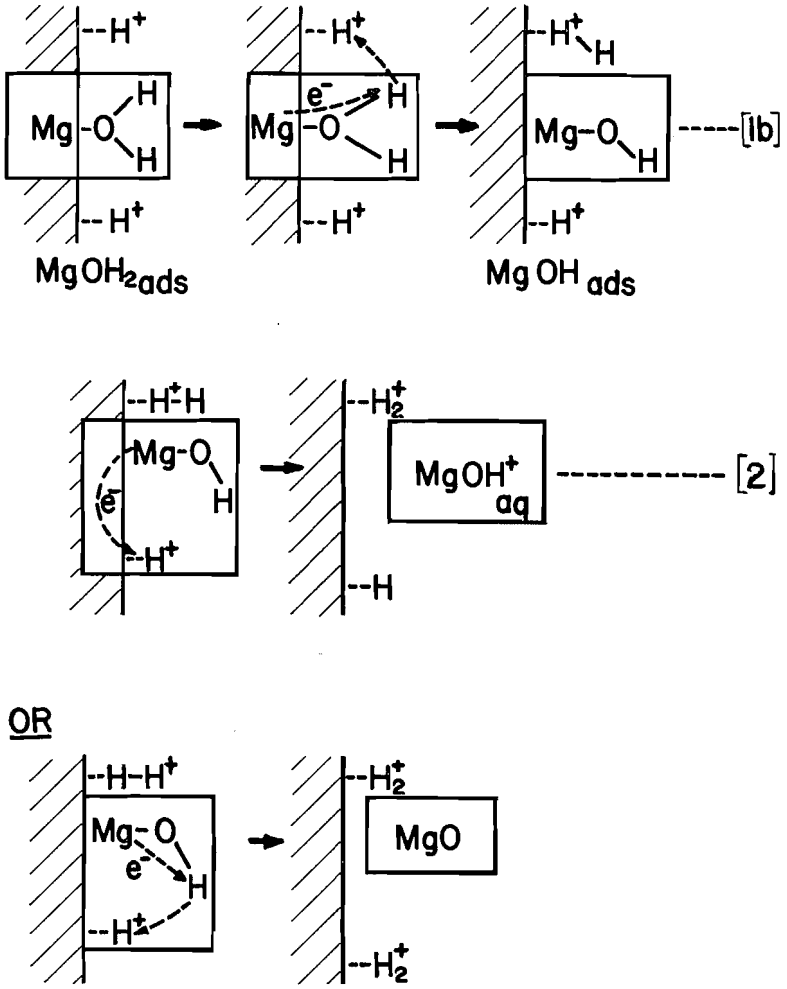

FIG. 10(*a*). Pictorial representation of reactions [1*b*] and [2].

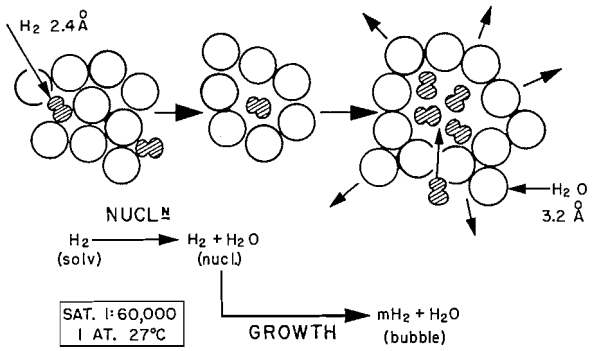

FIG. 10(*b*). Bubble formation.

Now consider the steps of reaction [3]:

$$2H^+_{2\,ads} = H_{2\,ads} + 2H^+ \qquad [3a]$$

$$H_{2\,ads} + nH_2O = H_{2\,aq} + S \text{ (S=surface site)} \qquad [3b]$$

$$S + H_{2\,aq} \underset{\text{collapse}}{\overset{\text{nucleation}}{\rightleftharpoons}} N + nH_2O \qquad [3c]$$

$$mN \underset{}{\overset{\text{growth}}{\rightleftharpoons}} \text{bubble} \qquad [3d]$$

$$\text{bubble} = H_2 \text{ gas.} \qquad [3e]$$

If the growth step, reaction [3*d*], is slow because of the high viscosity of the medium, say, then step [3*c*] is in equilibrium. Then reaction [3] is in equilibrium, and the derived rate $v \propto [H^+]/P_{H_2}^{1/2}$ applies. This is the observed fact in the dissolution of Mg in the low-concentration region (0.3 molal $MgCl_2$, pH = 2.0).

If, however, the growth step is rapid, step [3*d*] is not in equilibrium; and the rate is limited by the rate of nucleation [3*c*]. Then $v \propto P_{H_2}$, independent of $[H^+]$. This is the result obtained in the high-concentration region (3.0 molal $MgCl_2$, pH = 2.0).

Whether [3*d*] or [3*c*] is the slowest step in the hydrogen removal process, the elementary process—viz. H_2 molecule entering the elementary gas pocket—is the same; this is consistent with the fact that activation energy for the overall process is the same in both cases, about 12 kcal/mole.

A Further Test: Effects of X Irradiation on Rate

The subtle difference between equilibrium (0.3 molal) and lack of it (3 molal $MgCl_2$) in reaction [3*c*] has fostered the notion that any experimental variation which would disturb slightly the amount of adsorbed hydrogen molecule-ions in the steady state should affect the rate in the first case but not the second. Hence, corroding specimens in both solutions were subjected to 300 kv X rays and to a magnetic field of 15,000 gauss.

Ionizing radiation is now well known* to lead to increased adsorption of H atoms on noble metal surfaces provided they are at a potential positive to that of the hydrogen electrode. In the present case the potential is about 1.8 volts negative, and photodesorption would be anticipated. A result of photodesorption of H_2^+ ions would be (see reaction [1*b*]) increased concentration of $MgOH_{ads}$, and hence increased rate of dissolution for the case in which bubble growth is rate determining. Figure 11 is a composite of six experiments in which the specimen and reaction chamber were irradiated with X and gamma rays. The lower curve shows that the rate in 0.3 molal $MgCl_2$ is increased during irradiation by X rays and that the rate returns to the normal value after irradiation has ceased. The upper curves show not only that the irradiation must be very intense before the rate in 3 molal $MgCl_2$ is affected, but also the important fact that the rate remains enhanced after irradiation has ceased. After 3 Mev gamma irradiation, the solution gave strong visible and ultraviolet absorptions due to Cl_2 and OCl^- and perhaps some H_2 was produced by γ-ray absorption; but it is difficult to understand how either of these could enhance the rate after the radiation had ceased. It seems more probable that the absorbed radiation induced faults in the metal which enhanced subsequent nucleation of bubbles on the "activated" surface.

The effect of a 15,000 gauss magnetic field was explored for a slightly different reason. Since the postulated intermediates, Mg^+ and H atom, are both paramagnetic because of an unpaired electron, our analysis suggests that the rate might be altered in 0.3 molal $MgCl_2$, where rate $\propto [MgOH_{ads}]$, but not in 3 molal $MgCl_2$, where nucleation is rate determining.

After proper temperature control of the reaction chamber (when placed between the poles of the electromagnet) had been achieved, several experiments were done at both

*See I. Henderson, E. G. Lovering, R. L. Haines, and E. J. Casey, Can. J. Chem. **37**, 164 (1959); and F. S. Feates, Trans. Faraday Soc. **56**, 1671 (1960), for discussion and references to earlier work, particularly that of Veselovsky et al. in the period 1954–1956.*

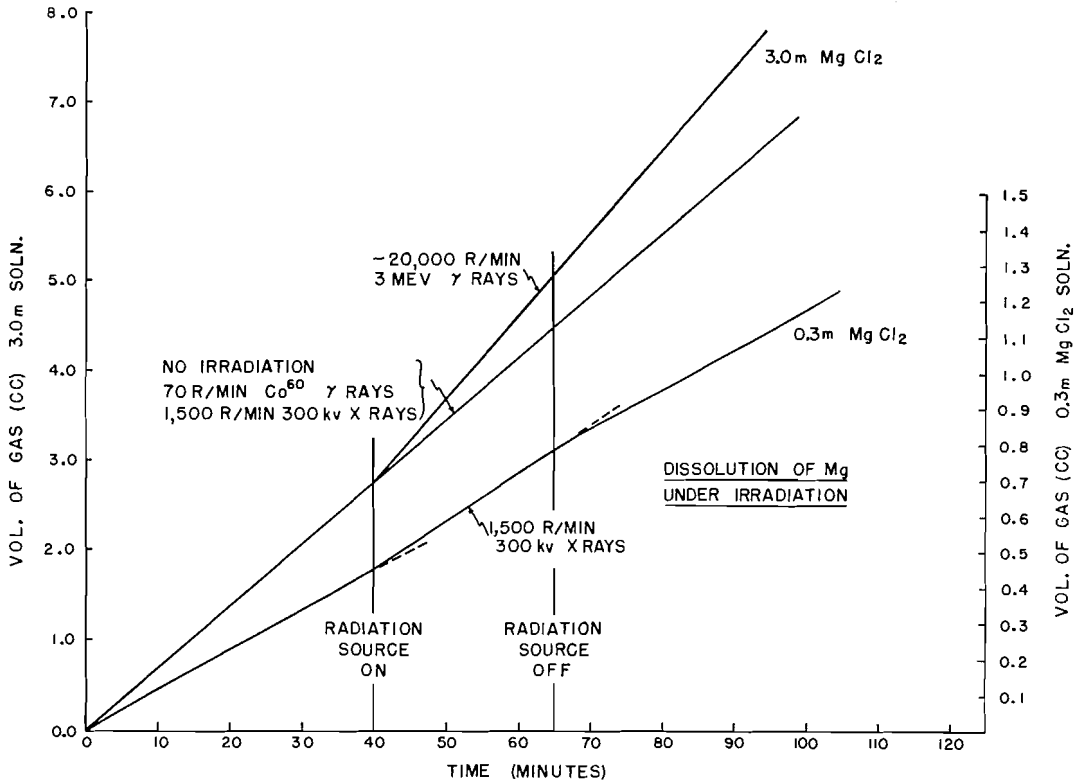

FIG. 11. Effect of X rays on rate of dissolution.

27° and at 1.5°. However, each experiment turned up a new difficulty, and sufficient sensitivity had not been achieved when the magnet had to be returned to its normal use. An indication of increased rate in 0.3 molal $MgCl_2$ was obtained, but the effect was not reliably demonstrated, and more work needs to be done.

Some Peculiarities of the Induction Period

If the rate following the induction period is the true initial rate of dissolution, then a fraction of the hydrogen liberated is not being measured in the early stages. The amount of H_2 needed to saturate 46 cc of distilled water at 27° is calculated, from the solubility, to be 0.6 cc. Because the gas is salted out by 0.3 molal $MgCl_2$, the solubility in the electrolyte would be much less, and can be estimated from the activity to be <0.1 cc. No pertinent solubility data could be found reported in the literature.

The induction period is not always linear, but is sometimes more or less sigmoid, as if it were an adsorption curve. Actually the induction probably is due to two processes: the sorption of gaseous hydrogen in small pores and crystal defects in the magnesium, and the "pouring" of two-dimensional liquid (i.e. adsorbed) hydrogen from the reaction surface into the larger cracks and fissures. It is currently assumed that "liquid pouring" predominates when the induction period is linear and that gas adsorption predominates when the induction period is sigmoid. The measured rate during the induction period v_i is the difference between the true rate v and the superimposed "storing" rates: (*a*) the "liquid" pouring rate, $v_{Mg}^{H_2\ liq}$; (*b*) the gas adsorption rate, $v_{Mg}^{H_2\ gas}$; and (*c*) the rate of solution of H_2 in the electrolyte, $v_{soln}^{H_2\ gas}$. Thus:

$$v_i = v - [v_{Mg}^{H_2\ liq} + v_{Mg}^{H_2\ gas}] - v_{soln}^{H_2\ gas}.$$

Figure 8 also shows (the result typical of triplicate experiments) that

$$v_{soln}^{H_2\ gas} \cong v_{Mg}^{H_2},$$

where

$$v_{Mg}^{H_2} = [v_{Mg}^{H_2\ liq} + v_{Mg}^{H_2\ gas}],$$

and discloses further the rather puzzling indication that a magnesium sample presaturated with H_2 corrodes in fresh electrolyte at a *constant* and significantly lower rate, as though the fresh electrolyte cannot receive hydrogen at any appreciable rate unless some of it at the same time penetrates the metal.

Other Comments on the Proposed Mechanism

The postulates concerning mechanism raise interesting questions about the nature of the activated complex in the gas liberation process. An analysis has been done which shows that the inverse half-power dependence of rate on pressure is mathematically consistent with a very large value (11.7 liters/mole, STP) for the volume of activation defined by absolute rate theory. This value seems intuitively to be of the right order of magnitude for a H_2 molecule divesting itself of water and pushing back water molecules as it forms the nucleus of a gas bubble. Yet, since the energy required to make a hole the size of a water molecule is approximately equal (4) to the latent heat of vaporization (10.4 cal/mole for pure water), and since the activation energy was found to be 12.2 cal/mole, the radius of the activated complex must be just a few angstroms. However, from the Kelvin equation derived in a form suitable to express surface energy as a function of radius of a bubble, and the volume of activation, the radius of the stable bubble nucleus can be estimated to be about 2×10^{-4} cm. This value can be compared with the estimate of Plesset *et al.* (3) of 10^{-3} cm obtained from a different approach; this riddle about the nature of the early stages of bubble formation has not been solved.

It is now well established (5) that the overvoltage for hydrogen evolution increases with decreasing hydrogen pressure. However, increased rate of hydrogen evolution with increased hydrogen pressure, as was found in the studies in high $MgCl_2$ concentration, is uncommon. The only other case of which we are aware is inferred to have existed in the experiments of Webb and Linford (6). They measured current efficiencies of electroplating of copper. The values of hydrogen evolution rate at different pressures are replotted in Fig. 12, and show that the rate increased with increased pressure. Common to their results and to ours are the conditions of very high overpotential ($\sim$1.8 volts in our case!) and continued renewal of surface.

Figure 10 depicts a mechanism by which Mg can leave the metal as either Mg^+ or Mg^{++}. Either is possible in our experiments, because the essential feature of the proposed mechanism is only that $v_{[1b]} \gg v_{[2]}$. However, in anodic dissolution in which external current flows, there is much controversial evidence* concerning whether the ion leaves the surface as Mg^+ or as Mg^{++}, or as both simultaneously: the number of coulombs passed to effect a given weight loss may vary by a factor of 2. The work described in this report throws no light on the anodic problem *per se*, although it does provide the following alternative mechanisms: the second electron from $MgOH_{ads}$ has the alternative of passing into the metal, leaving $MgOH^+$ (i.e. divalent magnesium) to desorb; or $MgOH_{ads}$ can itself desorb (i.e. as univalent magnesium) and reduce water by electron transfer out in the solution.

**For discussion of this question see reference 7.*

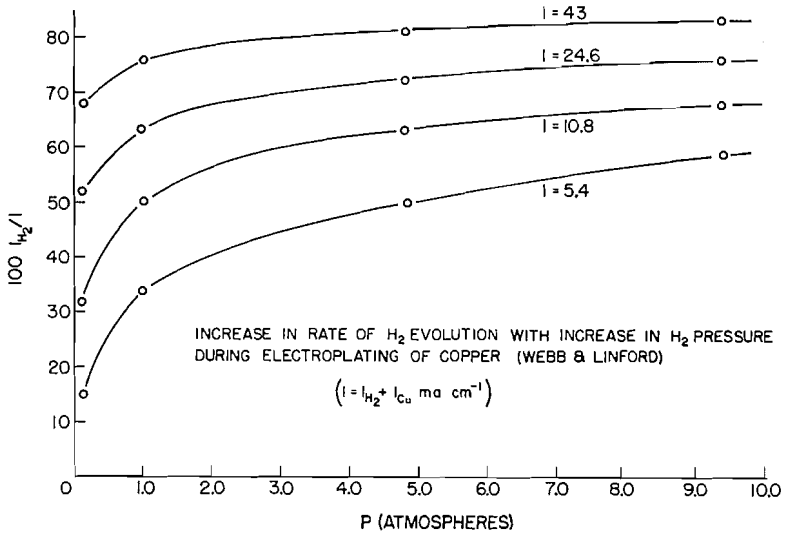

FIG. 12. Percent of total electroplating current which is due to hydrogen evolution.

Glicksman (8) has used our earlier (1) proposal, that the rate of dissolution is controlled by transport through gelatinous reaction product ($Mg(OH_2)$?), to explain why the hydrogen evolution reaction rate increases with increasing anodic current; thus higher anodic currents cause increased acid attack of the covering layer and therefore decrease the protection offered by it. The elaboration of the mechanism by the present work offers another simple explanation: more univalent magnesium is desorbed from the surface at higher currents. Since both the anodic and the dissolution reactions are highly exothermic, there probably exists at the metal–solution interface a high local temperature, which should favor the desorption of $MgOH_{ads}$.

SUMMARY

(1) The following table summarizes the facts, new and old, which are known about this reaction at pH = 2.

Concn. <1 molal $MgCl_2$	Concn. >1 molal $MgCl_2$
(*a*) v low, as in acidic KCl or KNO_3	v abnormally high
(*b*) $v \propto a_{H^+}^n$, where $n \simeq 1$	v independent of a_{H^+}
(*c*) $v \propto$ solubility of MgO in electrolyte	$v \propto$ solubility of Mg(OH)Cl?
(*d*) $E^* = 12.2 \pm 0.6$ kcal/mole	$E^* = 11.4 \pm 1.0$ kcal/mole
(*e*) Mg wet by Hg in electrolyte	Mg not wet by Hg in electrolyte
(*f*) Cathodic control	Cathodic control
(*g*) Dried reaction product: $Mg(OH)_2$ + Mg	Dried reaction product: $Mg(OH)_2$ + Mg(OH)Cl (possibly) + unidentified component
(*h*) $v \propto 1/P^{1/2}$ when $n = 1$	$v \propto P$
(*i*) $v_i = v - v_{Mg}^{H_2} - v_{soln}^{H_2\ gas}$ and $v_{Mg}^{H_2} \cong v_{soln}^{H_2\ gas}$	
(*j*) v increased by X rays, during irradiation only	v increased permanently by high-intensity radiation

(2) A kinetic analysis of the results indicates that bubble growth is rate determining in the low-concentration region, and that bubble nucleation is rate determining in the high-concentration region. The postulate of univalent magnesium ion (Mg^+) as an intermediate is essential to describing the results quantitatively.

(3) During the early stages of the reaction, hydrogen enters the magnesium metal to an amount ~1 cc per cc Mg at 27° C, decreasing with increasing temperature.

THE INTERACTION OF FRIEDEL–CRAFTS CATALYSTS WITH ORGANIC MOLECULES

III. THE $CH_3COCl:GaCl_3$ SYSTEM[1]

DENYS COOK
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received November 24, 1961

ABSTRACT

The equimolar complex of acetyl chloride and gallium trichloride has been prepared and its infrared spectrum, both in the pure state and in nitrobenzene solution, has been recorded. In the pure complex a strong band at 2300 cm^{-1}, hitherto attributed to the acetylium ion, has been observed. In solution in nitrobenzene, the 2300 cm^{-1} band is almost completely replaced by one at 2200 cm^{-1}, while undissociated CH_3COCl is present. Certain bands in this spectrum are consistent with the presence of the nitrobenzene – gallium chloride complex. A re-evaluation of the assignments of the acetylium ion suggests that a more complicated ionic species may be present in the solid state, possibly $[CH_3CO \ldots GaCl_3]^+Cl^-$.

INTRODUCTION

In the last 4 years many infrared spectroscopic investigations of acid halide – Lewis acid systems have been published by Susz and his colleagues (1)* in Geneva. Several communications from this laboratory have dealt with similar topics (2–4), while a brief comment on one system was made by Terenin and his collaborators (5).

There has been general agreement that a strong band at 2300 cm^{-1} in the spectra of acetyl halides with Lewis acids was due to the acetylium ion, CH_3CO^+, formed by the process [1]:

$$CH_3COX + MX_n = CH_3CO^+ + MX_{n+1}^- \qquad [1]$$

I

Similarly, aromatic acid halide complexes have given spectra containing a strong band at ~2200 cm^{-1}, indicating the presence of a (substituted) benzoylium cation, as in equation [2]:

$$R_xC_6H_{(5-x)}COX + MX_n = R_xC_6H_{(5-x)}CO^+ + MX_{n+1}^- \qquad [2]$$

II

The lower frequency of the benzoylium cation compared with the acetylium cation was attributed to conjugation of the CO group with the ring, a familiar situation in infrared spectroscopy.

In certain complexes two bands in the triple bond region have been observed for acetylium salts, viz. 2300 and 2200 cm^{-1} (2, 5), for which no adequate explanation has been offered. The present paper will examine possible causes of these two bands.

Greenwood and Wade showed the gallium chloride – acetyl chloride complex to be an excellent acetylating agent and an investigation of the liquid–solid phase diagram of the system revealed a dystectic point at 86° C (decomp.) with an equimolar ratio (6).

[1]*Contribution No. 58.*
**This paper is number XIII in the series and contains previous references.*

The investigation of the complex by infrared spectroscopy was therefore undertaken, in order to establish the active species in Friedel–Crafts ketone synthesis.

EXPERIMENTAL

Materials

Acetyl chloride (2.23 g, 0.0285 mole) was mixed with 5.0 g $GaCl_3$ (0.0285 mole) in a vacuum system similar to that described previously (2). All handling of the materials prior to mixing was done in a dry box. The $GaCl_3$ was supplied by the Eagle-Picher Co. and the acetyl chloride was from the J. T. Baker Co. The mixture was heated to about 80° C to allow complete interaction; it did not solidify on cooling to room temperature but remained as a light brown viscous liquid. This behavior has been observed previously by other workers (6). When allowed to react with excess benzene, acetophenone was found in good yield.

Spectra

A Perkin–Elmer 221G prism-grating spectrometer was used to record the spectra. The liquid spectrum was obtained as a film between BaF_2 plates (NaCl plates were attacked) and all preparative work was done in a dry box. The nitrobenzene solution was prepared by making a solution of 0.6 g complex in 1.5 g nitrobenzene. A sodium chloride sealed cell was used for this solution, and a variable path cell of similar thickness containing nitrobenzene was placed in the reference beam of the spectrometer. No damage was done to the sodium chloride sealed cell, as shown by the absence of window bands, or etching, after the run.

RESULTS AND DISCUSSION

Figure 1 shows a spectrum of the gallium trichloride – acetyl chloride complex as a liquid film. The bands from this spectrum are collected in Table I with those of the complex in nitrobenzene and compared with other spectra.

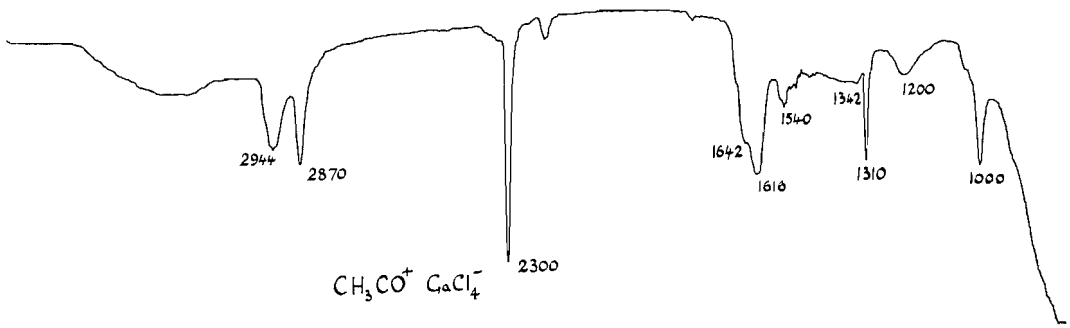

FIG. 1. Spectrum of the gallium trichloride – acetyl chloride complex as a liquid film.

The strong sharp band at 2300 cm^{-1} is typical of the acetylium ion: the weak band at 2199 cm^{-1} should also be noted. The two bands at 2944 and 2870 cm^{-1} are undoubtedly the asymmetric and symmetric CH stretching vibrations, and the expected deformation frequencies are present at 1342 and 1310 cm^{-1}. The 1000 cm^{-1} band has been regarded as a C—C stretching vibration. No vibration of the anion has been observed, since they are outside the range of a spectrometer using a sodium chloride prism-grating combination (7). The band of medium strength at 1616 cm^{-1} is associated with the presence of a small amount of the donor–acceptor complex (III). The spectrum of the complex in nitro-

$$CH_3COX + MX_n = CH_3—C(=O\ldots MX_n)X \qquad [3]$$

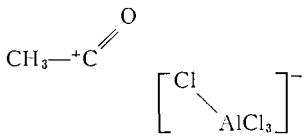
benzene shows some unusual features. The 2300 cm^{-1} band is reduced greatly in intensity and a new band is seen at 2195 cm^{-1}. The strong band at 1796 cm^{-1} obviously belongs to acetyl chloride. Two bands, one at about 1500 cm^{-1}, which is very broad and without structure, the other at 1244 cm^{-1}, which is fairly sharp, are to be identified with nitrobenzene complexed with gallium trichloride. Susz showed that the asymmetric NO_2 stretching vibration altered little on complex formation of nitrobenzene with $AlCl_3$, $AlBr_3$, and $TiCl_4$ (8). The symmetric NO_2 stretching vibration, however, decreased from about 1350 cm^{-1} in nitrobenzene to 1250–1260 cm^{-1} in the complexes. A shoulder on the high-frequency side of the 1550 cm^{-1} band, at about 1610 cm^{-1} recalls the 1616 cm^{-1} band in the primary complex.

On dissolution, therefore, of the primary complex in nitrobenzene, several different species are formed according to scheme [4]:

$$\text{primary complex} \rightarrow \begin{cases} CH_3COCl & 1796\ cm^{-1}, \\ CH_3C(Cl)=O \ldots GaCl_3 & 1610\ cm^{-1}, \\ C_6H_5N(=O)=O \ldots GaCl_3 & 1550 \text{ and } 1244\ cm^{-1}, \\ ? & 2200\ cm^{-1}. \end{cases} \quad [4]$$

It is proper, then, at this time, to consider more closely the nature of the species responsible for the absorption at 2200 cm^{-1} just discussed, and see what bearing this might have

on the structure of the primary complex. Originally (2) it was supposed that the 2200 cm^{-1} band in the $CH_3COCl:AlCl_3$ complex was due either to an ion pair of the type IV or a complex of the acetylium ion with $AlCl_3$ (V). Both of these explanations now seem



IV

$CH_3CO^+ \ldots AlCl_3 \equiv [CH_3CO \ldots AlCl_3]^+$

V

inadequate, the first since the central carbon atom is still trigonally hybridized, the second for a much more fundamental reason, which will now be considered.

The key to the problem will be stated first. Whenever a *linear* molecule such as CH_3CO^+ forms a complex with an electron deficient material the CO stretching frequency would be *raised* to a higher value than in the free ion. This viewpoint is diametrically opposed to that put forward earlier (2) and its justification is fundamental to the problem. The argument of a lowered CO frequency in the complex was made by analogy with the lowering of carbonyl frequencies when complexed with Lewis acids. Susz has recently summarized many experimental details (9) and in the $CH_3COCl:TiCl_4$ system which is of type III he found a decrease of some 3 md/Å in the force constant of the CO bond (10). The extrapolation to a linear model, however, is unjustified, since it does not take into account mechanical factors which become of great significance.

The rise in frequency when linear molecules form complexes with Lewis acids is best illustrated by a consideration of the vibrational spectra of some nitrile complexes, several of which are listed in Table II (11–14). The complex dimethylnitrilium hexachloroantimonate should be particularly noted (13). In every case, the complex has a higher CN stretching frequency than the free nitrile. Gerrard *et al.* (14), correctly discounting coupling or mass (of the ligand) effects, concluded that the bond order (and force constant, presumably) of the CN bond was higher in the complex than in the free nitrile. Such a conclusion is neither necessary nor realistic, for the correct explanation is implicit in the work of Overend and Scherer (15) on the vibrational frequencies and force constants of the carbonyl halides. The rather surprising result was established that, in COF_2, $COCl_2$, $COBr_2$, and several mixed halides, the force constant K_{CO} is virtually the same at about 12.7 md/Å, though there is about 100 cm^{-1} difference in the carbonyl frequencies. The

TABLE II

CN stretching frequencies in acetonitrile complexes

Compound	Frequency (cm^{-1})	$\Delta\nu$ (cm^{-1})
CH_3CN	2253*

$[CH_3CNCH_3]^+SbCl_6^-$	2416‡	163

*Ref. 11.
†Ref. 12.
‡Ref. 13.

explanation lies in the fact that in COF_2 only 84% of the potential energy of the CO vibration resides in the CO bond. Significant percentages come from the CX stretching mode and the XCX angular deformation. Alternatively, one can say that as the CO bond stretches it compresses the CX bond and deforms the XCX angle, and this resistance forces the vibrational frequency higher. The larger the force constant of the CX bond the larger will be this effect.

Naturally, as the XCX angle becomes smaller this effect becomes larger, which is the reason why small rings have elevated carbonyl frequencies (16). In the limit, therefore, a linear molecule results, such as the nitrile complexes or the acetylium ion complexes. Even a small force constant for the D—M bond in $CH_3C{\equiv}D{-}MX_n$ (D stands for donor) should produce a large rise in frequency for the CD stretching vibration in the complex compared with that in the free $CH_3C{\equiv}D$.

This effect is probably quite universal and seems to account for variations in acetylenic triple bond stretching frequencies, as shown in Table III. Although the changes in ν_{CC}

TABLE III

Triple bond stretching frequencies and force constants in some acetylenes*

		Force constant (md/Å)		
XC≡CY	Frequency (cm^{-1})	K_{XC}	K_{CC}	K_{CY}
HCCH	1974

CH_3CCI	2197		15.80	3.57
CH_3CCBr	2230		15.80	4.35
CH_3CCCl	2263		15.80	5.30
CH_3CCCH_3	2313	5.29	15.60	5.29

*A. G. Meister, J. Chem. Phys. **16**, 950 (1948).

from HCCH to CH_3CCH are probably due to a combination of mass and force constant effect, from CH_3CCI on it would seem to be due solely to the force constant effect, since ν_{CC} parallels K_{CY} and all the masses are greater than 15. This mass is probably close to the limiting value, as found by Halford (17) for carbonyl vibrations, and by Whiffen (18) for XCN molecules.

Returning now to the constitution of the complex, the foregoing arguments are quite in accord with the reversal of the assignments previously considered. The complex ion $(CH_3CO \ldots MX_n)^+$ would have a CO vibration at 2300 cm^{-1} and the uncomplexed acetylium ion, CH_3CO^+, a CO vibration at 2200 cm^{-1}. The reaction expressing the formation of the complex would then be [5]:

$$CH_3COX + MX_n = [CH_3CO \ldots MX_n]^+X^- \qquad [5]$$

V

It now remains to be seen whether the other bands in the spectra can be adequately assigned to the complex ion V. The CH_3 asymmetric and symmetric stretching and deformation frequencies fit the new structure reasonably well. In fact, the variations observed in these four frequencies in different complexes are easier to understand if the CH_3 group is in a slightly different environment in different complexes. That is to say, small differences in the MX_n portion of the complex might produce slight variations in the fundamentals. If the acetylium ion itself were subject to such variations one would have to invoke some kind of environmental interaction, which might be difficult to justify.

One of the difficulties with the assignments of the bands to the acetylium ion has been the lack of a suitable band for the methyl rocking vibration. A weak band at 1200 cm^{-1} in the $CH_3COCl:GaCl_3$ complex and at 1235 cm^{-1} in the $CH_3COF:SbF_5$ complex had been tentatively assigned to this vibration, but not even a weak band showed in the spectrum of $CH_3COF:BF_3$ (19), or $CH_3COCl:AlCl_3$ (20).

If now the assignments for the dimethylnitrilium ion (13) are kept in mind then the 1000 cm^{-1} band is more acceptably assigned to the CH_3 rocking vibration, and the medium to weak band at 716 cm^{-1} becomes the C—C stretching vibration. In several of the complexes with strong absorption bands near 700 cm^{-1}, due to metal–fluorine stretching vibrations, the C—C stretching vibration may be submerged. The M . . . O stretching vibration has not been observed, and it may be in the low-frequency region outside the range of NaCl optics. Many of the metal–halogen stretching vibrations, too, will lie outside this range.

The dissociation of the primary complex in solution now becomes quite understandable since the Lewis acid now just has to shift from a weak base, CH_3CO^+, to a stronger base, $C_6H_5NO_2$. This does then not involve the dissociation of a stable species MX_{n+1}^-, such as BF_4^-, $AlCl_4^-$, $GaCl_4^-$, etc., into $MX_n + X^-$, followed by recombination of the MX_n with nitrobenzene, and is therefore more plausible energetically.

ACKNOWLEDGMENTS

The assistance of Miss C. D. Anderson in recording the spectra is gratefully acknowledged, and Dr. S. J. Kuhn and Dr. G. A. Olah are warmly thanked for their preparation of the SbF_5 complex.

THE REACTION OF OXYGEN ATOMS WITH CARBON TETRACHLORIDE[1]

A. Y-M. UNG[2] AND H. I. SCHIFF
Upper Atmosphere Chemistry Group, McGill University, Montreal, Que.

Received November 22, 1961

ABSTRACT

The homogeneous reaction between O atoms and CCl_4 was studied in a flow system under conditions of complete consumption of atoms, in the presence and in the absence of molecular oxygen. The only products of the reaction are Cl_2, CO, CO_2, and $COCl_2$. No compounds containing more than one carbon atom were detected. The dependence of the products on CCl_4 concentration suggests that the primary reactions are

$$O + CCl_4 \rightarrow [O.CCl_4] \rightarrow COCl_2 + Cl_2$$
$$\rightarrow CO + 2Cl_2,$$

which are too slow to consume all the atoms. Carbon dioxide is produced by secondary reactions which are fast enough to consume all the atoms, the most important of which is

$$O + COCl_2 \rightarrow CO_2 + Cl_2.$$

However, the dependence of the ratio $(CO_2 + COCl_2)/CO$ on CCl_4 concentration in the presence of O_2 indicates other reactions also produce CO_2. The rapid disappearance of O atoms in the systems containing O_2 suggests a chain mechanism in which Cl_2 is mainly converted to the atomic form. Carbon dioxide can then be produced by the sequence

$$CO + Cl \rightleftharpoons COCl$$
$$COCl + O \rightarrow CO_2 + Cl$$
$$COCl + O_2 \rightarrow CO_2 + ClO.$$

The rate constant for the primary process was found to be independent of O, O_2, and CCl_4 concentration and could be represented by the equation

$$k = 3.3\times10^{-14} \exp(-4500/RT) \text{ cm}^3 \text{ molecule}^{-1} \text{ sec}^{-1}.$$

INTRODUCTION

The initial attack of an oxygen atom on a hydrocarbon molecule may occur in a variety of ways. Thus Avramenko *et al.* (1) have concluded that the atom may abstract one or two hydrogen atoms, rupture a C—C or a C=C bond, or insert itself into the C—H bond to form an alcohol. On the other hand, Cvetanović (2, 3) in a systematic investigation of the reaction of atomic oxygen with olefins finds that the atom first adds to the double bond to form a biradical. This biradical can then either undergo a triplet–singlet transition to form an epoxide, or rearrange to form a carbonyl compound.

The reaction of O atoms with CCl_4 was chosen for the present study, since none of these initial modes of attack is possible. The absolute rate constant for the initial reaction was also measured as a function of temperature, since only relative rate constants and activation energies are currently available for most oxygen atom reactions.

EXPERIMENTAL

Materials

A cylinder of oxygen was selected from a number supplied by the Imperial Oxygen Company, on the basis of its low nitrogen content, and used throughout the course of this work.

[1]*This work received financial assistance from the Defence Research Board of Canada and the U.S.A.F. Cambridge Research Laboratories.*

[2]*Present address: National Research Council, Ottawa, Canada.*

Reagent grade CCl_4, obtained from the Fisher Scientific Company, and Cl_2, $COCl_2$, CO, and CO_2, obtained from the Matheson Company, were further purified by trap-to-trap distillation.

Nitric oxide, a Matheson product, was freed from acidic impurities by passage through Ascarite. Nitrogen dioxide was prepared by oxidation of NO and distilled until the solid was colorless. It was stored with a small amount of O_2.

Apparatus

The reaction vessel and flow system were similar to those used previously in this laboratory (4). Atomic oxygen was formed by a microwave discharge operating at 2450 mc. This produced a few percent of atomic oxygen in a large excess of molecular oxygen. Alternately, O atoms could be produced in the absence of O_2 by the titration of N atoms with NO (5).

Flow rates of gases were controlled by fine needle valves and measured with calibrated flowmeters. The pressure was measured at both ends of the reaction vessel with McLeod gauges. Care was taken to exclude Hg vapor from the apparatus.

Procedure

In one set of experiments, the products of the reaction were studied as a function of the partial pressure of CCl_4 for several values of the total pressure, partial pressure of O atoms, and temperature. The CCl_4 flow rate was always a small fraction of the total gas flow to prevent its variation affecting the reaction time, but sufficiently large to consume all the atoms in the reaction tube. This condition was necessary to prevent O_3 formation in the traps. A metallic catalyst for recombining the atoms before the trap could not be used in the presence of CCl_4 without inducing heterogeneous reactions.

The initial atom concentration was determined by the NO_2 'clean-up' method (5). A relatively large excess of NO_2 was added through the inlet jet and the amount of NO produced by the rapid reaction $NO_2 + O \rightarrow NO + O_2$ determined. Carbon tetrachloride was then added through the jet and permitted to flow for at least half an hour to reach a steady condition before products were trapped. During this stabilization period the effluent gases were made to bypass the traps. Condensable products were then collected for a sufficient time to obtain analyzable samples. The products were identified mass spectrometrically and subsequently analyzed by conventional methods. Chlorine gas was absorbed by HgS; CO_2 and $COCl_2$ were separated with a Le Roy still and measured by a gas burrette. A mass spectrometric analysis of the non-condensable gas showed CO to be its only product component. Carbon monoxide was subsequently analyzed by conversion to CO_2 in a CuO-filled combustion column located downstream from the traps.

In the experiments designed to determine the rate constants for the initial reaction, O atom concentrations were measured as a function of time by the photometric method described by Elias and Schiff (4). The glow resulted from the small amount of NO produced in the discharge from the N_2 impurity in the oxygen. A small correction for these concentrations was made for the slight dilution caused by the introduction of the CCl_4.

Since the reaction is highly exothermic and also possesses an appreciable activation energy, the experiments were performed with low concentration of both reactants. Temperature measurements made with a thermocouple encased in a movable, thin-walled tube indicated that nowhere in the reaction vessel was the temperature more than 1° C above that of the walls.

RESULTS AND DISCUSSION

The reaction proceeded with no visible reaction flame. The products of the reaction were found to be $COCl_2$, CO, CO_2, and Cl_2 exclusively. A series of experiments designed to test the mass balance showed that, on the average, these products accounted for 98% of the CCl_4 reacted. No compounds containing more than one carbon atom were formed. Nor were there any liquid or solid deposits formed on the walls, a conclusion supported by the fact that the walls retained a constant catalytic activity towards atom recombination. This is in contrast to the deposits found by Sobering and Winkler (6) in the reaction of CCl_4 with N atoms. No solid deposits were formed even when CCl_4 was intentionally introduced in large excess or when the system was free of molecular oxygen.

Table I, and Figs. 1 to 3, show the products as a function of CCl_4 flow rate at three different temperatures and two different pressures. The total chlorine content in the products will be seen to be twice the total carbon within experimental error, which again indicates that no major product escaped detection. Chlorine gas shows initially a rapid and then a slower, approximately linear rise, as do CO and $COCl_2$. This behavior is consistent with these products being formed in the primary reaction, which is therefore

TABLE I

too slow to consume all the atoms under these conditions. On the other hand, CO_2 levels off after its initial rise, which suggests that it is not formed in the primary reaction. The secondary reactions must be sufficiently fast to consume all the atoms in the system.

Primary Reactions

The abstraction reaction

$$CCl_4 + O \rightarrow CCl_3 + ClO \qquad [1]$$

cannot be the sole primary reaction, since the CCl_3 radicals would react rapidly with the excess O_2 (7):

$$CCl_3 + O_2 \rightarrow COCl_2 + ClO, \qquad [2]$$

and there would be no reasonable way of forming CO. The same objection can be raised against the reaction

$$CCl_4 + O \rightarrow CCl_2 + Cl_2O, \qquad [3]$$

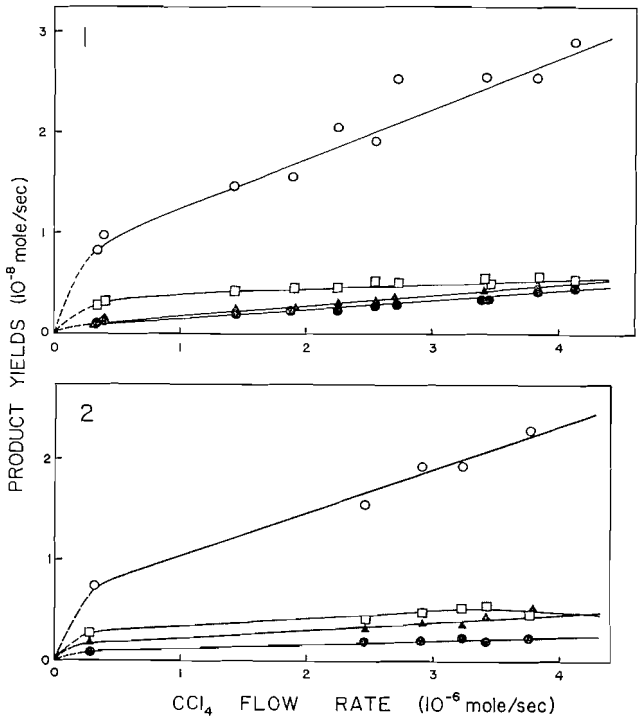

FIG. 1. Product yields as a function of CCl_4 flow rate: ○ Cl_2; ● $COCl_2$; ▲ CO; □ CO_2. $T = 4°$ C, $P = 2$ mm.

FIG. 2. Product yields as a function of CCl_4 flow rate: ○ Cl_2; ● $COCl_2$; ▲ CO; □ CO_2. $T = 10°$ C, $P = 4$ mm.

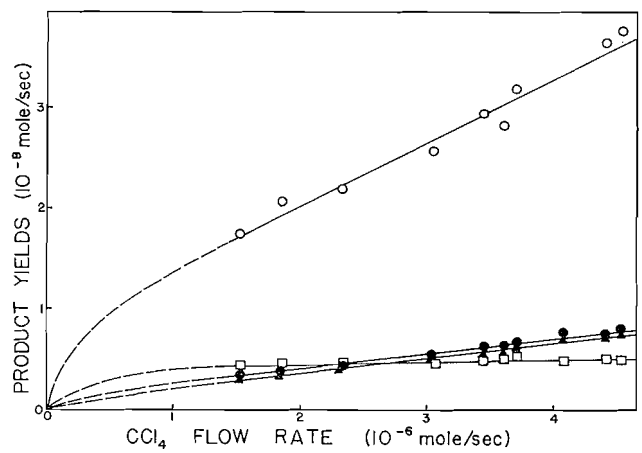

FIG. 3. Product yields as a function of CCl_4 flow rate: ○ Cl_2; ● $COCl_2$; ▲ CO; □ CO_2. $T = 100°$ C, $P = 2$ mm.

which would also be highly endothermic. Moreover, reactions [1] and [3] cannot even be significant primary processes since they should lead to radical recombination products (8) under conditions of large CCl_4 excess or in an O_2-free system.

It is actually unlikely that any free radical is formed in the primary process. Sato and Cvetanović (3) have shown that the presence of O_2 in atomic oxygen–olefin reactions has a marked effect on the products because of the reactions of free radicals with O_2,

most of which have appreciable activation energies. However, in the present studies, the products did not change appreciably when the O_2 content or the temperature was varied.

In view of the electrophylic nature of O atoms (2) and the electron density in CCl_4, it is likely that a reasonably stable collision complex is formed. The primary products could then be accounted for by two alternate decomposition modes of the complex:

$$O + CCl_4 \rightarrow [CCl_4.O] \rightarrow COCl_2 + Cl_2 \quad [4]$$

$$\rightarrow CO + 2Cl_2. \quad [5]$$

To account for the overall change in spin, one may suggest that the complex is initially formed in the triplet state. However, a considerable stereochemical rearrangement is required, which could be aided if the O atom inserts into the C—Cl bond. This would bring the two Cl atoms into proper bonding distance. Such insertion reactions have been suggested in explaining the formation of alcohols in atomic oxygen – paraffin reactions (1). Since reaction [4] is 97 kcal/mole exothermic, it might be suggested that the $COCl_2$ molecule is formed with excess internal energy and subsequently dissociates into $CO + Cl_2$. But if this occurred, the ratio $CO/COCl_2$ should decrease with pressure, while the converse was observed.

In the reaction of N atoms with CCl_4, Sobering and Winkler (6) postulated an atom attack on the complex

$$N + [CCl_4.N] \rightarrow N_2 + CCl_3 + Cl$$

to explain the formation of CCl_3 polymers in their system. The absence of such deposit in the present study mitigates against the analogous O-atom reaction.

Secondary Reactions

Some of the secondary reactions capable of producing CO_2 include:

$$CO + O + M \rightarrow CO_2 + M \quad [6]$$

$$CO + O \rightarrow CO_2^* \rightarrow CO_2 + h\nu \quad [7]$$

$$COCl_2 + O \rightarrow CO_2 + Cl_2. \quad [8]$$

The reaction of CO with O atoms has been found by several authors (9, 10) to be slow, and also, in the present study, to have a large temperature coefficient. Mahan (11) has recently reported that the reaction of O atoms with CO proceeds by [7] rather than [6], with a change in multiplicity and a rate constant of $1.5\times10^{-14}\exp(-4300/RT)$ $cm^3molecule^{-1}sec^{-1}$. It would therefore be far too slow to be important in the present investigation. Moreover, it would produce an increase in the CO_2/CO ratio with temperature, which is contrary to observation.

Reaction [8] probably does not proceed in a single step since it would be spin disallowed and would require the simultaneous rupture and formation of two bonds. Nevertheless, in separate experiments, O atoms were found to react rapidly with $COCl_2$ to form CO_2 and Cl_2, and reaction [8] can be used to represent this overall reaction. From these experiments the rate of this reaction can be estimated to be approximately 10^{-14} $cm^3molecule^{-1}sec^{-1}$, while the rate of the initial reaction was found to be 2×10^{-17} cm^3-$molecule^{-1}sec^{-1}$. The $COCl_2$ concentration should therefore be of the order of 10^{-3} times the CCl_4 concentration, in agreement with the results shown in Table I. The decrease in the $CO_2/COCl_2$ ratio with CCl_4 flow is explicable in terms of the corresponding decrease in the O atom concentration and the decreased rate of reaction [8]. However, this reaction cannot be the sole source of CO_2 in the system. If it were, the ratio $(CO_2 + COCl_2)/CO$ would be independent of CCl_4 concentration. This ratio is constant for the O_2-free system but decreases with CCl_4 flow rate in the systems containing molecular oxygen.

An explanation for this is suggested by an independent observation. It was possible to measure simultaneously the rate of CCl_4 consumption and the rate of O atom disappearance.[3] It was found that at 4° C and 2.1 mm, 40 oxygen atoms disappeared for each CCl_4 molecule consumed; this increased to 135 when the O_2 pressure was doubled, and decreased to 10 when the temperature was increased to 100° C. However, in the O_2-free system, only 2.5 oxygen atoms disappeared per CCl_4 molecule. The actual stoichiometry of the reaction corresponded to an average of 1.5 oxygen atoms appearing in the products per CCl_4 reacting.

Kaufman found (9) Cl_2 to be an extremely good catalyst for O atom recombination in the presence of O_2—some 10 oxygen atoms being recombined per Cl_2 molecule present. He proposed the following chain mechanism to account for his observations:

$$O + Cl_2 \rightarrow ClO + Cl \qquad [9]$$
$$O + ClO \rightarrow O_2 + Cl \qquad [10]$$
$$Cl + O_2 + M \rightarrow ClOO + M \qquad [11]$$
$$ClOO + O \rightarrow ClO + O_2. \qquad [12]$$

Such a chain might also occur in the present system and account for the catalyzed recombination of O atoms in the presence of molecular oxygen. The recombination would then be faster at higher O_2 pressure, and less important at higher temperature, since reactions [4] and [5] have a higher activation energy than reaction [9]. The excess consumption of atoms relative to stoichiometry in the O_2-free system could then be due to reactions [9] and [10], or to CCl_4 or the reaction products being more efficient third bodies in the normal atom recombination.

Such catalyzed atom recombination can also account for the shapes of the curves in Figs. 1–3. At low CCl_4 flow rates very little Cl_2 is present, the atom concentration will remain relatively high, and the rate of reactions [4] and [5] will be relatively fast. As the amount of Cl_2 produced increases, the atom concentration will decrease and the slope of the product curve will decrease. The increased O_2 pressure decreases the atom concentration and consequently the slope in Fig. 2. An increase in temperature increases the slope in Fig. 3 because $E_{4,5} > E_9$. The absence of such a chain in the O_2-free system means that the O atom concentration remains higher and this accounts for the large amount of CO_2 produced in the secondary reactions.

If reactions [9] to [12] are indeed operative in the present system, the fate of the new reactive species must be considered. Because of the relative rapidity of reactions [10] and [12], steady-state considerations show that the concentrations of ClO and ClOO are too small to be significant. On the other hand, this mechanism predicts that under the present experimental conditions more than half the chlorine will be present in atomic form.

The reaction of Cl atoms with CCl_4 and with $COCl_2$ are endothermic and have both been found to be slow at room temperature (12, 13). However, the following reactions may be significant in the present system:

$$Cl + CO \rightleftharpoons COCl \qquad [13]$$
$$COCl + Cl_2 \rightarrow COCl_2 + Cl \qquad [14]$$
$$COCl + O_2 \rightarrow CO_2 + ClO \qquad [15]$$
$$COCl + O \rightarrow CO_2 + Cl \qquad [16]$$
$$COCl + Cl \rightarrow CO + Cl_2. \qquad [17]$$

[3]*The rate of* O*-atom disappearance is corrected for the normal three-body recombination of the atoms in the absence of* CCl_4.

The equilibrium reaction [13] has been studied by Bodenstein and co-workers (15) and more recently by Burns and Dainton (16), who give for the equilibrium constant $\log K = -6310/4.571T+2.806$. Although objections may be raised against reaction [15] on steric grounds, Rollefson (17) claims that both [14] and [15] are required to explain the chlorine-catalyzed photooxidation of CO and gives $E_{14}-E_{15} = 3$ kcal and $A_{14}/A_{15} = 30\pm5$.

Reactions [13], [15], and [16] catalytically convert CO into CO_2, and provide an explanation for the change in the $(CO_2 + COCl_2)/CO$ with CCl_4 flow rate in the systems containing O_2. The decrease in the O atom concentration with CCl_4 flow rate results in a decrease in the Cl/Cl_2 ratio and consequently in the conversion of CO to CO_2. In the absence of O_2 the value of the ratio may still be augmented by the sequence of reactions [9], [10], [13], and [16]. But, since there is no chain mechanism for O atom recombination in this system, the value of the ratio will not vary with CCl_4 flow to the same degree as in the systems containing O_2. However, the fact that in all the systems the ratio tends assymptotically at high CCl_4 flows to a value slightly less than 2 suggests that the ratio k_4/k_5 is probably also close to this value.

Rate Constant of the Primary Reaction

Since CCl_4 is neither reformed nor consumed by any of the secondary reactions, the rate of its disappearance can be represented by the simple bimolecular equation

$$\frac{d[CCl_4]}{dt} = -k[O][CCl_4]$$

which, upon integration between times t_1 and t_2, becomes

$$\ln \frac{[CCl_4]_1}{[CCl_4]_2} = k\int_{t_1}^{t_2}[O]dt.$$

To determine the rate constant k, it is only necessary to know the CCl_4 concentration at two times and the O atom concentration as a function of time over this interval. Since all the atoms were consumed in the reaction tube, no explicit knowledge of t_2 was necessary; $[CCl_4]_1$ was then taken as the known initial concentration at the inlet jet, and $[CCl_4]_2$ the amount of unreacted reagent recovered in the trap. Since only a small percentage of the CCl_4 reacted, greater accuracy was obtained when $[CCl_4]_2$ was determined by subtraction of the product equivalents from the value of $[CCl_4]_1$. The time scale used in evaluating the integral was obtained from the calibrated flow rates and the diameter of the reaction tube. Axial and radial photometry measurements indicated that diffusion corrections in these directions are negligible and that streamlined flow conditions were closely approximated.

Rate constants were determined at several temperatures over a considerable range of reagent concentrations and are shown in Table II. The value of k at 19° C is seen to be constant within experimental error over a 13-fold change in CCl_4 concentration, which provides ample justification for the method. The small amount of NO produced in the discharge did not affect the value of k. This was proved by the experiments (marked with an asterisk in the table) in which additional NO was deliberately introduced. The presence of NO will increase the rate of O atom consumption but this is automatically accounted for in the evaluation of the integral. The independence of the rate constant on total pressure confirms that the reaction is homogeneous and agrees with Cvetanović's conclusion that the presence of molecular oxygen does not affect the rate of the initial reaction.

Figure 4 is an Arrhenius plot of the rate constant which can be represented by the equation

$$k = (3.3\pm1.5)\times10^{-14}\exp\left(\frac{-4500\pm300}{RT}\right)\ \text{cm}^3\ \text{molecule}^{-1}\ \text{sec}^{-1}.$$

The small pre-exponential factor indicates the difficulty of the O atom attack on the carbon atom of the molecule.

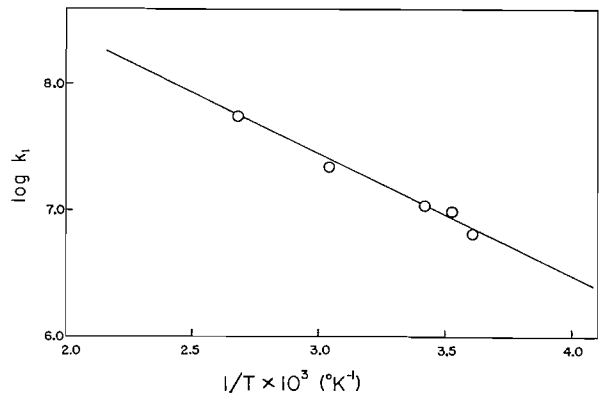

FIG. 4. Arrhenius plot of log k vs. $1/T$ (k in cm^3 mole^{-1} sec^{-1} units).

LE SPECTRE INFRAROUGE ET LA STRUCTURE MOLÉCULAIRE DE L'ACIDE PERCHLORIQUE ABSOLU

PAUL A. GIGUÈRE ET RODRIGUE SAVOIE[1]
Département de Chimie, Université Laval, Québec, Qué.

Reçu le 8 Novembre 1961

RÉSUMÉ

Les spectres d'absorption de l'acide perchlorique absolu dans les trois états physiques ainsi que ceux de l'acide deutéré $DClO_4$ solide et gazeux ont été étudiés en infrarouge de 5000 à 300 cm^{-1}. Toutes les bandes peuvent s'interpréter selon une structure quasi-tétraédrale de la molécule covalente de symétrie C_s. Les bandes OH dans le cristal révèlent des liaisons hydrogène sensiblement plus faibles que dans l'acide sulfurique (énergie moyenne, 3 kcal). Les fréquences mesurées conduisent indirectement aux longueurs de liaisons 1.70 Å pour Cl—OH et 1.45 Å pour Cl—O en bon accord avec les rayons covalents des atomes et la structure des perchlorates alcalins. La torsion interne dans la molécule libre est gênée par un seuil de potentiel de 1.6 kcal $mole^{-1}$. À partir de ces données on calcule les valeurs suivantes pour les fonctions d'état de la molécule $HClO_4$ à l'état standard à 25° C: $-(F^0-E^0)/T = 58.9$ et $S^0 = 70.7$ cal deg^{-1} $mole^{-1}$.

INTRODUCTION

On possède relativement peu de données sur la structure moléculaire de l'acide perchlorique anhydre $HClO_4$ contrairement au cas du monohydrate. En effet, ce dernier offre un intérêt particulier du fait de l'ion H_3O^+; aussi a-t-il été l'objet de nombreux travaux au moyen des méthodes spectroscopiques et de diffraction. (Voir référence 1 pour revue de la question.) Jusqu'ici l'acide absolu n'a été étudié qu'en effet Raman (2–6) où l'on a observé quelque neuf bandes (Tableau I) facilement identifiables avec

les vibrations normales de la molécule (5, 7). Pour l'infrarouge, le caractère corrosif et fortement oxydant de l'acide perchlorique pose des problèmes d'ordre technique. Un premier travail avec l'acide solide (p.f. −112° C) n'a pas permis de déchiffrer complètement le spectre à cause du chevauchement de certaines bandes. Heureusement l'acide

[1]*Boursier du Conseil national des Recherches.*

perchlorique est assez volatil et assez stable (en l'absence d'agents réducteurs) pour permettre d'observer sans trop de difficultés le spectre de la vapeur. Enfin, grâce à l'étude d'un échantillon d'acide fortement deutéré on a pu compléter l'identification des fréquences fondamentales.

PARTIE EXPÉRIMENTALE

L'acide pur a été obtenu par la méthode de Smith (8), i.e. en distillant sous pression réduite (environ 3 mm Hg) une solution aqueuse à 72% de $HClO_4$ commercial ("Reagent Grade", The Nichols Chemical Co.) additionnée d'oléum à 20% ("Technical Grade", Anachemia Chemicals Ltd.). L'appareil en Pyrex était assemblé au moyen de rodages non lubrifiés; pour assurer l'étanchéité ces derniers étaient enveloppés à l'extérieur de bandes de caoutchouc sous tension (Cenco "Para Rubber Tape"). La présence d'un excès d'oléum assurait un produit strictement anhydre; effectivement les spectres ne montraient aucune indication de la forte bande de l'ion ClO_4^- vers 940 cm^{-1} (9). L'acide deutéré a été préparé en distillant sous pression réduite à environ 65° C un mélange 1:5 de $KClO_4$ et de D_2SO_4 à 97% d'acide. Ce dernier provenait de la condensation ménagée de vapeurs de SO_3 (par évaporation d'un oléum à 30%) dans un petit volume d'eau lourde (à 99.7% de deutérium) refroidie dans un mélange réfrigérant approprié. Le produit ainsi obtenu était de nouveau distillé pour le débarrasser des traces d'impuretés, entre autre D_2SO_4 décelé par sa bande d'absorption caractéristique à 1360 cm^{-1} (10). Les deux acides sulfurique et perchlorique concentrés étant fortement hygroscopiques, il était presque impossible de prévenir toute contamination par l'humidité atmosphérique au cours des manipulations. D'après l'intensité relative des bandes OH dans les spectres de $DClO_4$ on peut évaluer le degré de contamination de ce dernier à quelque 15 ou 20%.

Autant que possible les échantillons étaient fraîchement préparés; autrement il fallait les garder à l'obscurité et dans la neige carbonique pour ralentir la décomposition. En effet, à température ordinaire l'acide anhydre se décompose pour donner des oxydes de chlore, dont Cl_2O_7, qui sont explosifs (8).

Pour le spectre de l'acide cristallin on pressait une goutte du liquide entre deux disques de chlorure d'argent fraîchement polis et montés ensuite dans une cellule à vide conventionnelle (11). En refroidissant avec l'azote liquide le film d'acide se solidifiait facilement. À en juger par l'allure des spectres les échantillons étaient surtout cristallins. Contrairement à son monohydrate (12) l'acide perchlorique absolu n'existe que sous une seule forme allotropique, du moins dans l'intervalle de température couvert ici. Pour le spectre de l'acide liquide les disques de chlorure d'argent portant l'échantillon étaient simplement entourés d'une mince bande de Teflon pour arrêter l'humidité atmosphérique. Comme le chlorure d'argent est opaque au-delà de 400 cm^{-1} il a fallu utiliser pour la région s'étendant jusqu'à 300 cm^{-1} des feuilles de polyéthylène d'environ 1 mm d'épaisseur. Des essais préliminaires ont révélé que ce matériau n'est que légèrement attaqué par l'acide perchlorique absolu pourvu qu'il soit d'abord refroidi suffisamment (en pratique à −70° C). De toute façon le spectre d'absorption des plaques de polyéthylène était enregistré par après pour fin de correction.

Enfin pour l'étude de la vapeur on a employé une cellule d'absorption de 12 cm d'épaisseur en Pyrex fermée par des fenêtres de chlorure d'argent ou de Téflon, selon la région, et maintenues contre le tube de verre par un dispositif à ressort. Un bouchon rodé et une tubulure latérale permettaient de remplir la cellule d'air sec et d'y introduire l'échantillon d'acide liquide. Malgré que cette dernière opération fut effectuée en atmosphère sèche il se formait toujours dans la cellule une légère fumée blanche qui se condensait finalement sur les parois et les fenêtres. Cependant il ne semblait pas en résulter d'absorption notable. Dans le cas des bandes les plus fortes les vapeurs d'acide étaient diluées avec de l'azote sec afin d'obtenir une absorption raisonnable.

Un spectrophotomètre de Beckman, modèle IR-4 à double faisceau, et un appareil de Perkin-Elmer, modèle 112-C, muni de prismes de chlorure de sodium ou de bromure de césium ont été utilisés. Avec ce dernier on a toujours enregistré le fond avec la cellule d'absorption sous vide et à la température de l'azote liquide, car la limite de transmission du chlorure d'argent est sensiblement déplacée vers les basses fréquences à basse température.

DISCUSSION DES RÉSULTATS

On sait qu'à l'état anhydre l'acide perchlorique existe essentiellement sous la forme covalente. En effet, bien que cet acide soit l'un des plus forts connus en milieu aqueux, ses propriétés physiques, et en particulier sa très basse conductivité électrique (4, 13), prouvent que l'autodissociation selon les schémas possibles

$$2HClO_4 \rightleftharpoons H_2ClO_4^+ + ClO_4^- \qquad [1]$$

et

$$2HClO_4 \rightleftharpoons HCl_2O_7^+ + OH^- \qquad [2]$$

est extrêmement faible, en sorte que le spectre moléculaire ne saurait montrer aucune indication d'espèces ioniques. Aussi bien toutes les fréquences observées tant en infrarouge qu'en Raman peuvent s'interpréter sans ambiguité selon la structure prévue pour la molécule covalente (5, 7). À noter que les quatre atomes situés dans le plan de symétrie C_s de la molécule peuvent se trouver dans la configuration *cis* ou *trans* ainsi:

A priori la première semble plus probable étant donné l'attraction entre l'atome d'hydrogène et l'un des atomes d'oxygène du groupe ClO_3. (Voir cependant le cas un peu analogue de HNO_2 (14, 15) où les deux formes coexistent même dans la vapeur.)

Des 12 vibrations fondamentales de $HClO_4$ 8 sont symétriques (a') et 4 asymétriques (a'') par rapport au plan C_s. L'identification des bandes observées (Tableau II) est relativement facile si on se refère au spectre déjà bien étudié (7) d'une molécule assez semblable spectroscopiquement, $FClO_3$. Les fréquences fondamentales de cette dernière devraient se retrouver dans $HClO_4$ à peu près inchangées, sauf que trois seront dédoublées. En outre on y observera les trois vibrations de l'atome d'hydrogène. La plus élevée de ces dernières, la vibration de valence O—H, apparaît dans la vapeur à 3560 cm^{-1} (Fig. 1).

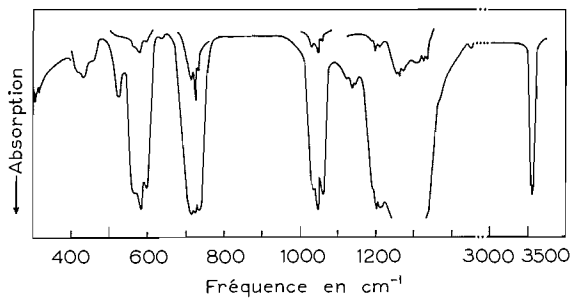

FIG. 1. Spectre infrarouge de $HClO_4$ à l'état gazeux.

Le décalage isotopique de cette fréquence dans $DClO_4$ (Fig. 2) est à peu près dans le rapport prévu, soit 1.36. Par ailleurs dans les phases condensées (Figs. 3 et 4) ces fréquences sont notablement abaissées du fait des liaisons hydrogène (Tableau II).

La fréquence de déformation OH est moins évidente car elle tombe dans la région des vibrations de valence du groupe ClO_3 vers 8 μ. La plus élevée de celles-ci à 1326 cm^{-1} appartient sans aucun doute à la vibration asymétrique ν_9 par analogie avec la vibration correspondante dans $FClO_3$ à 1315 cm^{-1} (Fig. 5). Des deux vibrations Cl—O symétriques l'une doit se trouver assez près de ν_9; on peut donc lui assigner avec certitude la forte bande à 1263 cm^{-1}. Quant à la seconde, ν_4, totalement symétrique par rapport à l'axe Cl—OH, on la trouve à 1050 cm^{-1} (comparé à 1061 cm^{-1} dans $FClO_3$). Effectivement ces trois fréquences demeurent presque identiques dans les spectres des phases condensées aussi bien que dans ceux de $DClO_4$. Il reste donc pour le mode de déformation OH la bande d'intensité moyenne à 1200 cm^{-1} dans la vapeur qui montre bien le décalage isotopique attendu (à 928 cm^{-1}) dans $DClO_4$. Cette fois les liaisons hydrogène causent

FIG. 4. Spectre d'absorption de $DClO_4$ solide en infrarouge.

une légère élévation de fréquence, soit à 1245 cm^{-1} dans $HClO_4$ et à 965 cm^{-1} dans $DClO_4$ à l'état solide. Il faut noter ici que la présence d'une forte bande exactement à 1200 cm^{-1} dans le spectre du cristal est une coïncidence. En effet, à cause du décalage vapeur–solide déjà mentionné, il faut attribuer cette bande non pas à la déformation OH mais plutôt à des harmoniques ou combinaisons de fondamentales.

Enfin la troisième fréquence OH dite de torsion doit naturellement être assez basse. Lide et Mann (7) ont suggéré de lui attribuer provisoirement la bande à 284 cm^{-1} dans le spectre Raman de l'acide liquide (Tableau I). Cette valeur conviendrait bien pour la molécule libre, mais elle est certainement trop basse pour l'acide liquide à cause des liaisons hydrogène. De toute façon il semble maintenant évident que la bande à 284 cm^{-1} n'appartient pas à $HClO_4$ mais bien plutôt à Cl_2O_7 (3, 16), un produit de la décomposition de l'acide anhydre, sans doute sous l'influence de la radiation excitatrice Raman. Nous croyons plus logique d'assigner au mode de torsion interne la large bande centrée autour

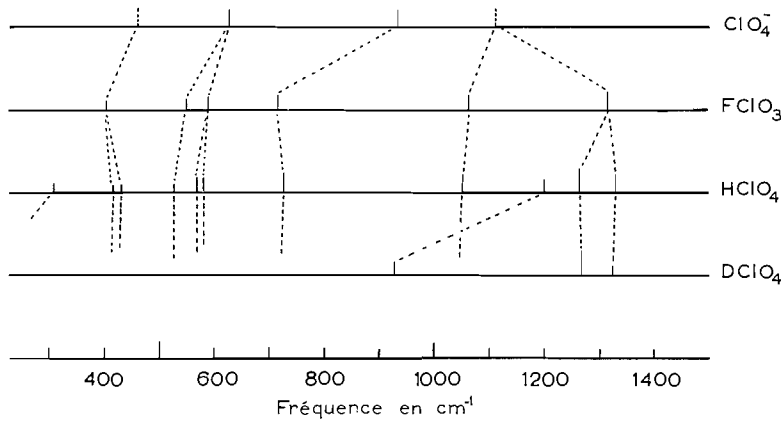

FIG. 5. Corrélation entre les fréquences normales de $HClO_4$ et autres molécules analogues.

de 310 cm^{-1} dans le spectre de la vapeur (Fig. 1) qu'on retrouve décalée à 480 cm^{-1} dans les phases condensées (Fig. 3). Pour $DClO_4$ dont seul le solide a été étudié dans cette région, la bande à 310 cm^{-1} est de fréquence appropriée pour le rapport isotopique, même si elle paraît un peu mince pour une vibration de ce genre.

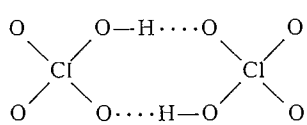
Il est intéressant de comparer les fréquences de valence OH dans l'acide perchlorique gazeux et solide avec les quantités correspondantes dans d'autres composés apparentés. (Tableau III). Il ressort clairement de ces données que les liaisons hydrogène dans

TABLEAU III

Vibrations de valence OH dans diverses molécules
(Fréquences en cm^{-1})

	ν_v	ν_s	Réf.		$\nu_v - \nu_s$	Réf.
$HClO_4$	3560	3260	—	$HClO_4$	300	—
HNO_3	3560	3226	17	H_2O_2	430	18
H_2SO_4	—	2970	10	CH_3OH	450	19
				H_2O	500	18

$HClO_4$ anhydre (aussi bien que dans HNO_3) sont nettement plus faibles que dans H_2SO_4 et même que dans H_2O, H_2O_2 et les alcools. Des corrélations empiriques (20) permettent d'évaluer l'énergie de ces liaisons dans $HClO_4$ à quelque 3 kcal et les distances interatomiques O—H et O—H . . . . O à environ 1.0 Å et 2.85 Å respectivement. La faiblesse relative des liaisons hydrogène dans cet acide est due en partie à la répulsion entre les groupes ClO_4 fortement électronégatifs. Ces observations rejoignent des conclusions antérieures sur le faible degré d'association moléculaire de l'acide perchlorique absolu basées, entre autre, sur la faible viscosité et la grande volatilité du liquide (6) et le point de fusion relativement bas (−112° C) du solide. Pour la même raison on doit écarter la suggestion faite autrefois (21) de molécules dimères



comme dans les acides gras.

La connaissance de toutes les fréquences normales de $HClO_4$ permet le calcul de ses fonctions d'état. Cependant, vu l'absence de détermination expérimentale directe des distances et des angles interatomiques, la contribution des niveaux de rotation ne peut être évaluée avec grande précision. Les paramètres utilisés à cette fin (Tableau IV) ont

TABLEAU IV

Données structurales et thermodynamiques de $HClO_4$

Distances (Å)	Angles	Moments d'inertie (g cm²)	Modes	$-\frac{(F^0-E^0)}{T}$ (cal deg^{-1} mole^{-1})	S^0 (cal deg^{-1} mole^{-1})
Cl—O = 1.45	$\widehat{OClO}$ = 114°	$I_A = I_B = 1.72\times10^{-38}$	Translation	34.76	39.73
Cl—OH = 1.70	$\widehat{OClOH}$ = 105°	$I_C = 1.59\times10^{-38}$	Rotation	22.37	25.36
O—H = 0.97	$\widehat{ClOH}$ = 105°	$I_{torsion} = 1.47\times10^{-40}$	Vibration	1.06	4.80
		Seuil, V_0 = 1.6 kcal	Torsion	0.71	1.81
			Total	58.9	70.7

été choisis comme suit: Les distances Cl—O dans l'acide doivent être à peu près les mêmes que dans l'ion ClO_4^-. Malheureusement les données existantes pour celles-ci dans les perchlorates alcalins (22) se situent entre des limites assez larges, soit de 1.42 à 1.49 Å. Par ailleurs la règle de Badger appliquée aux vibrations Cl—O ν_2 et ν_9 conduit à une valeur moyenne de 1.45 Å. Cette même règle donne, à partir de $\nu_5 = 725$ cm^{-1}, une longueur de 1.71 Å pour la liaison simple Cl—OH, soit à peu près la somme des rayons covalents simples des atomes Cl et O, 1.69 Å (23); d'où notre choix de la valeur intermédiaire, 1.70 Å. Pour la longueur et l'angle de la liaison OH des valeurs assez voisines de celles dans H_2O sont à prévoir. Quant aux angles dans le tétraèdre ClO_4, il est raisonnable de supposer que l'orbitale de l'unique liaison simple occupera moins d'espace que les orbitales des trois autres liaisons essentiellement doubles.

Mentionnons enfin que la contribution des degrés de liberté de translation a été calculée pour l'espèce isotopique $HCl^{35}OH$, et que la torsion, ou rotation interne, a été traitée par la méthode de Pitzer (24). De la fréquence $\nu_{12} = 307$ cm^{-1} dans la molécule libre on déduit pour le seuil de potentiel de symétrie $n = 3$ une valeur, 1.6 kcal, beaucoup plus faible que celle acceptée pour la molécule HNO_3, 7 kcal (25). La raison principale de cette différence tient sans doute à la plus grande distance entre les atomes H et O dans $HClO_4$, environ 2.3 Å, comparée à 1.7 Å dans HNO_3 (22).

REMERCIEMENT

Pour l'exécution de ce travail les auteurs ont bénéficié d'une généreuse subvention du Conseil national des Recherches du Canada.

SUMMARY

The infrared spectra of anhydrous $HClO_4$ and $DClO_4$ in the three physical states were measured between 300 and 5000 cm^{-1}. All the fundamental frequencies of the covalent molecule of C_s symmetry were obtained. The OH frequencies in the crystal indicate hydrogen bonds appreciably weaker (3 kcal) than those in sulphuric acid. From empirical correlations the following bond lengths are deduced: 1.70 Å for the Cl—OH and 1.45 Å for the Cl—O bonds. In the free $HClO_4$ molecule internal rotation is hindered by a threefold potential barrier of some 1.6 kcal. The measured vibrational frequencies were

used in conjunction with probable values of the structural parameters to calculate the following thermodynamic quantities for $HClO_4$ in the standard state at 25° C: $-(F^0 - E^0)/T = 58.9$ and $S^0 = 70.7$ cal deg^{-1} mole^{-1}.

THE SYNTHESIS OF ACETAMIDO-DEOXY KETOSES BY ACETOBACTER SUBOXYDANS

PART III

J. K. N. JONES, M. B. PERRY, AND J. C. TURNER
The Department of Organic Chemistry, Queen's University, Kingston, Ontario

Received November 14, 1961

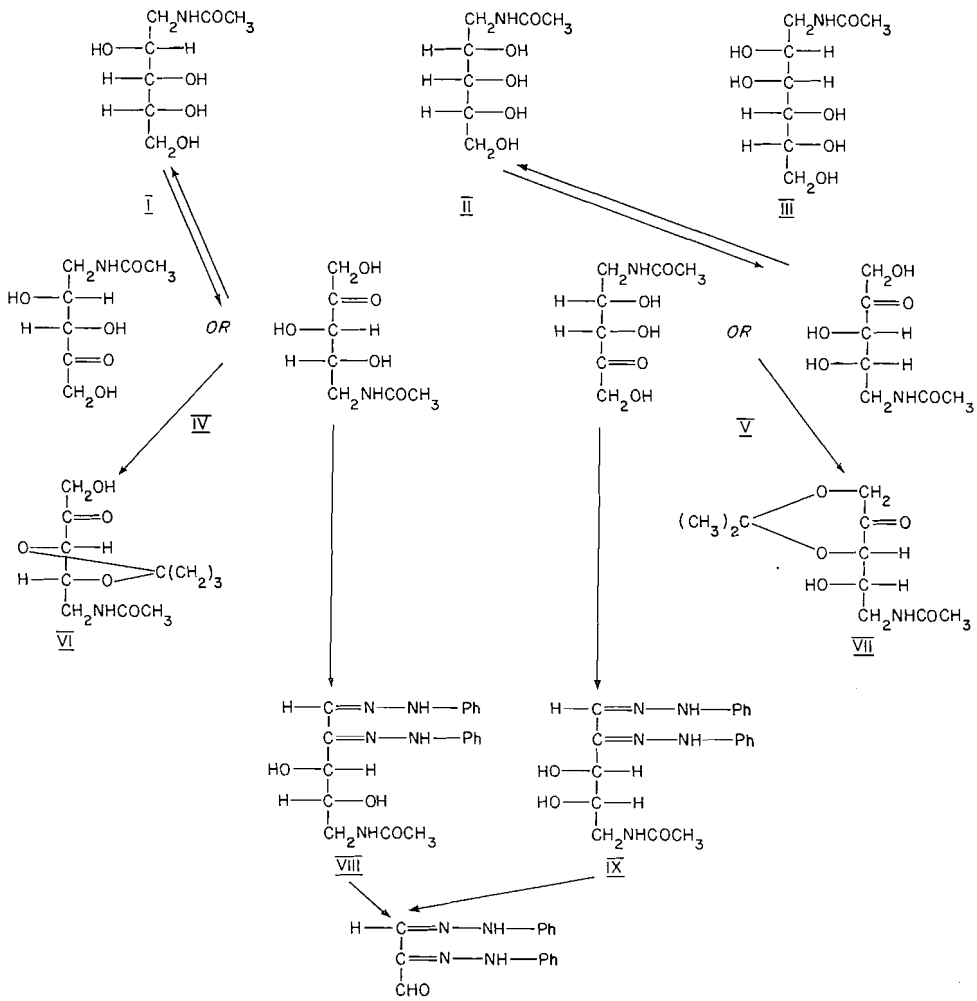
ABSTRACT

1-Acetamido-1-deoxy-D-arabinitol, 1-acetamido-1-deoxy-D-ribitol, and 1-acetamido-1-deoxy-D-mannitol were synthesized and characterized. Microbiological oxidation of 1-acetamido-1-deoxy-D-arabinitol and 1-acetamido-1-deoxy-D-ribitol gave the crystalline acyclic 2-pentuloses 5-acetamido-5-deoxy-D-*threo*-pentulose and 5-acetamido-5-deoxy-L-*erythro*-pentulose respectively.

RESULTS AND DISCUSSION

Crude 1-amino-1-deoxy-D-arabinitol, 1-amino-1-deoxy-D-ribitol, and 1-amino-1-deoxy-D-mannitol were prepared by the method of Holly *et al.* (1) and purified via the salicylidene Schiff's bases by the method of Kagan *et al.* (2). *N*-Acetylation of the pure amino-deoxy polyhydric alcohols with aqueous acetic anhydride (3) then gave 1-acetamido-1-deoxy-D-arabinitol (I), 1-acetamido-1-deoxy-D-ribitol (II), and 1-acetamido-1-deoxy-D-mannitol (III) respectively, which were characterized by periodate oxidation studies, elemental analyses, and infrared spectra.

The microbiological oxidation of acetamido-deoxy polyhydric alcohols by *Acetobacter suboxydans* has recently been investigated in this laboratory (4, 5). We now wish to report the microbiological oxidation of 1-acetamido-1-deoxy-D-arabinitol (I) to 5-acetamido-5-deoxy-D-*threo*-pentulose (IV) and of 1-acetamido-1-deoxy-D-ribitol (II) to 5-acetamido-5-deoxy-L-*erythro*-pentulose (V). Both oxidation products (IV, V) were obtained as strongly reducing crystalline solids which gave absorptions in the infrared corresponding to OH, NH, the amide linkage, and the saturated carbonyl group. Periodate oxidation studies yielded almost identical results in each case (periodate uptake 2.75 moles, formic acid 1.1 moles, formaldehyde 0.75 mole) and indicated that the compounds possessed a primary alcohol group. The results also indicate that approximately 0.2 mole glycollic acid was formed during the oxidation, which was then stable to further attack by periodate ion (6). It was concluded that the carbonyl group was located at carbon 2 in both cases and that cleavage by periodate ion was more rapid between carbons 1 and 2 than between carbons 2 and 3. Since both compounds were therefore probably 2-ketoses, the formation of furanose rings would be prohibited and the acyclic zigzag conformation would be adopted. The hydroxyl groups at carbons 3 and 4 of ketose IV would then be favorably situated for the formation of an isopropylidene derivative. Ketose IV, on reaction with acidified acetone, gave a strongly reducing syrupy isopropylidene derivative (VI) which gave absorptions in the infrared corresponding to OH, NH, the amide linkage, the saturated carbonyl group, and the isopropylidene group. The compound, on periodate oxidation, consumed 0.75 mole periodate, with the liberation of 0.63 mole titratable acid and 0.67 mole formaldehyde, indicating that carbons 1 and 2 were not involved in ketal formation and that the compound was the 3,4-*O*-isopropylidene derivative (VI). Ketose V under similar reaction conditions also gave a syrupy isopropylidene derivative (VII).



The infrared spectrum was similar to that of the 3,4-*O*-isopropylidene derivative (VI) except that the saturated carbonyl absorption was much stronger. However, the isopropylidene derivative VII was only weakly reducing and on periodate oxidation consumed 0.36 mole periodate, liberating 0.1 mole titratable acid and 0.1 mole formaldehyde, which suggested that hydrolysis to ketose V was occurring before oxidation. It was concluded that compound VII was probably the 1,3-*O*-isopropylidene derivative, which was possible since the carbonyl group distorted the carbon chain sufficiently to bring the primary alcohol group near carbon 3.

Ketose IV gave a crystalline phenylosazone (VIII) which, when oxidized with periodate by the method of Hough, Powell, and Woods (7), consumed 1.18 moles of periodate and released no formic acid or formaldehyde. A rapid formation of the 1,2-bisphenylhydrazone of mesoxalaldehyde (8) occurred. These results indicated that the phenylosazone (VIII) possessed free hydroxyl groups at carbons 3 and 4 and that the ketose (IV) from which it was derived was a 2-ketose. Ketose V also gave a crystalline phenylosazone (IX), which on periodate oxidation gave results closely similar to those

obtained from the oxidation of phenylosazone VIII, and the same conclusions were reached regarding the structure of phenylosazone IX and its parent ketose (V). In the case of IX, however, the precipitation of the 1,2-bisphenylhydrazone of mesoxalaldeh de occurred more slowly, which indicated that the free hydroxyl groups at carbons 3 and 4 of phenylosazone IX were less favorably situated for cleavage by periodate ion than those in the other phenylosazone (VIII), in agreement with the finding for the ketal formation of the free ketoses (IV and V).

Ketose IV on reduction with sodium borohydride gave crystalline 1-acetamido-1-deoxy-D-arabinitol (I), which indicated that the hydroxyl groups at carbons 3 and 4 of ketose IV were in the D-*threo* configuration, since the position of the carbonyl group had been fixed at carbon 2 by previous evidence. Ketose V on reduction with sodium borohydride gave a syrup which could not be satisfactorily crystallized, although paper chromatography and paper electrophoresis indicated the presence of a single compound. However, the syrup, when acetylated, gave a syrupy acetate which had infrared spectrum and retention time on gas–liquid chromatographic analysis identical with the syrupy acetate prepared from 1-acetamido-1-deoxy-D-ribitol (II), although the optical rotation was different. This indicated that some 1-acetamido-1-deoxy-D-ribitol (II) was present in the sodium borohydride reduction product and that the hydroxyl groups at carbons 3 and 4 of ketose V were in the L-*erythro* configuration, since the position of the carbonyl group had been fixed at carbon 2 by previous evidence.

The above evidence indicated that the biological oxidation product from 1-acetamido-1-deoxy-D-arabinitol (I) was the acyclic 2-pentulose 5-acetamido-5-deoxy-D-*threo*-pentulose (IV) and that the biological oxidation product from 1-acetamido-1-deoxy-D-ribitol (II) was the acyclic 2-pentulose 5-acetamido-5-deoxy-L-*erythro*-pentulose (V), in accordance with the Bertrand–Hudson rules for oxidation by *Acetobacter suboxydans* (9, 10).

Studies on the biological oxidation product from 1-acetamido-1-deoxy-D-mannitol (III) are in progress and will be the subject of a later communication.

EXPERIMENTAL

Solutions were concentrated under reduced pressure (ca. 15 mm) below 40° C. Melting points are uncorrected and optical rotations were measured at 23±3° C in water unless otherwise stated. Paper chromatography was carried out by the descending method (11) using Whatman No. 1 paper in the following solvent systems (v/v):

(A) butan-1-ol/ethanol/water, 9:3:3;
(B) ethyl acetate/acetic acid/formic acid/water, 18:3:1:4;
(C) butan-1-ol/pyridine/water, 5:3:2.

Rates of movements of compounds on paper chromatograms are given relative to that of rhamnose (R_{rh} value). Ketose sugars were detected on paper chromatograms with the orcinol – trichloroacetic acid spray reagent (12), other reducing compounds with the *p*-anisidine hydrochloride spray reagent (13), and non-reducing compounds with the alkaline silver nitrate spray reagent (14). Infrared spectra were measured in chloroform solution or as a dispersion in a potassium bromide pellet, using a Perkin–Elmer Model 21 spectrophotometer. Formaldehyde produced in periodate oxidations was determined by the chromotropic acid method (15).

Preparation of 1-Acetamido-1-deoxy Polyhydric Alcohols

1-Amino-1-deoxy polyhydric alcohols were prepared by the method of Kagan *et al.* (2) in which the free aldose sugar was dissolved in liquid ammonia and hydrogenated with Raney nickel catalyst at 2000 p.s.i. and 85° C for 2.5 hours. The 1-amino-1-deoxy polyhydric alcohols were isolated from the crude reaction mixture as the crystalline salicylidene Schiff's bases. Hydrolysis of the Schiff's bases with dilute hydrochloric acid then gave the corresponding 1-amino-1-deoxy polyhydric alcohol hydrochlorides which were deionized in aqueous solution on columns of Amberlite IRA 400 anion-exchange resin to yield the pure 1-amino-1-deoxy polyhydric alcohols. Physical constants of products and intermediates are listed in Table I.

TABLE I

SECTION A. STUDIES ON 5-ACETAMIDO-5-DEOXY-D-*threo*-PENTULOSE

5-Acetamido-5-deoxy-D-threo-*pentulose*

1-Acetamido-1-deoxy-D-arabinitol (10 g), sorbitol monohydrate (0.5 g), potassium dihydrogen phosphate (0.05 g), and yeast extract powder (0.5 g) were dissolved in tap water (100 ml), sterilized, and innoculated with *Acetobacter suboxydans* in the usual way (4). After 10 days, when Somogyi estimations (16) of the copper-reducing power of the medium indicated an 81% conversion to ketose sugar, the medium was poured into 2 volumes of ethanol, filtered, and the filtrate was deionized by rapid passage through small columns of Amberlite IR 120 (H^+) and Duolite A4 (OH^-) resins at 5° C and concentrated to dryness. The syrup obtained was fractionated on a cellulose column, butan-1-ol half-saturated with water being used as irrigant, and 5-acetamido-5-deoxy-D-*threo*-pentulose was obtained as a chromatographically pure syrup which crystallized after desiccation for 1 month. The ketose was recrystallized from ethanol/ether to give needles, m.p. 105–106° C, $[\alpha]_D$ +34°, which reduced Fehling's solution immediately at room temperature. Absorptions in the infrared were recorded at 3340 cm^{-1} (OH and NH), 1720 cm^{-1} (saturated carbonyl group), 1640 cm^{-1} (amide I), and 1580 cm^{-1} (amide II). The ketose had R_{rh} 0.94 (solvent A), 1.12 (solvent B), and 0.97 (solvent C), and gave an immediate intense spot with the alkaline silver nitrate spray reagent. Anal. Calc. for $C_7H_{13}O_5N$: C, 44.0%; H, 6.8%; N, 7.3%. Found: C, 43.8%; H, 6.9%; N, 7.5%.

Periodate Oxidation of 5-Acetamido-5-deoxy-D-threo-*pentulose*

The ketose was oxidized with an approximately twofold excess of sodium metaperiodate in unbuffered aqueous solution. The results are recorded in Table IV.

TABLE IV

Periodate oxidation of 5-acetamido-5-deoxy-D-*threo*-pentulose

Time (hours)	Periodate uptake (moles/mole)	Formic acid (moles/mole)	Formaldehyde (moles/mole)
0.08	2.20	1.09	0.73
2	2.74	1.11	0.73
3	2.75	1.11	—
4	2.75	1.11	0.73

5-Acetamido-5-deoxy-3,4-O-isopropylidene-D-threo-*pentulose*

5-Acetamido-5-deoxy-D-*threo*-pentulose (300 mg) was shaken at room temperature with dry acetone (150 ml) containing concentrated sulphuric acid (4 drops) for 18 hours. The solution was then neutralized with barium carbonate, filtered, and evaporated to dryness. The residual syrup was separated from a trace of unreacted ketose by chromatography on Whatman No. 3 MM paper in solvent A overnight, and obtained as a chromatographically pure syrup (180 mg), $[\alpha]_D$ +17° (*c*, 1.75 in ethanol), R_{rh} 2.3 (solvent A), 1.84 (solvent B), 1.54 (solvent C). The syrup reduced Fehling's solution rapidly at room temperature and gave the following infrared absorptions: 3460 cm^{-1} (OH), 3360 cm^{-1} (NH), 1725 cm^{-1} (saturated carbonyl group), 1665 cm^{-1} (amide I), 1525 cm^{-1} (amide II), 1390, 1380 cm^{-1} (CH of isopropylidene group).

Periodate Oxidation of 5-Acetamido-5-deoxy-3,4-O-isopropylidene-D-threo-*pentulose*

The isopropylidene ketose was oxidized in 50% aqueous ethanol solution (unbuffered) with a twofold excess of sodium metaperiodate. The results are recorded in Table V. (A fourfold excess of periodate was used for the estimation of formaldehyde.)

TABLE V

Periodate oxidation of 5-acetamido-5-deoxy-3,4-*O*-isopropylidene-D-*threo*-pentulose

Time (hours)	Periodate uptake (moles/mole)	Formic acid (moles/mole)	Formaldehyde (moles/mole)
0.08	0.14	0.07	0.19
1.17	0.29	0.29	0.40
5	0.42	0.38	0.51 (4 hours)
26	0.62	0.56	0.59 (22.5 hours)
52	0.75	0.63	0.67 (70 hours)

5-Acetamido-5-deoxy-D-threo-*pentose Phenylosazone*

The phenylosazone was prepared by the usual method, using freshly distilled phenylhydrazine and glacial acetic acid. Several recrystallizations from aqueous ethanol gave bright yellow needles, m.p. 197–199° C. The phenylosazone gave absorptions in the infrared at 3260 cm^{-1} (OH and NH), 3080 cm^{-1} (aromatic CH), 1660 cm^{-1} (amide I), 1640 cm^{-1} (amide II), and 1605, 1500, 745, 685 cm^{-1} (aromatic ring). Anal. Calc. for $C_{19}H_{23}O_3N_5.H_2O$: C, 58.9%; H, 6.5%; N, 18.1%. Found: C, 59.6%; H, 6.5%; N, 18.1%.

Periodate Oxidation of 5-Acetamido-5-deoxy-D-threo-*pentose Phenylosazone*

The phenylosazone was oxidized in 50% aqueous ethanol by the method of Hough, Powell, and Woods (7). The results of the oxidation are shown in Table VI. One minute after oxidation had started, yellow

TABLE VI

Periodate oxidation of 5-acetamido-5-deoxy-D-*threo*-pentose phenylosazone

1	1.16	0.00	0.00
2.5	1.15	0.00	—

needles separated from the solution. The crystals were centrifuged off and the supernatant was returned to the flask for oxidation studies. The crystals were recrystallized from aqueous ethanol and had m.p. 187–189° C. An authentic specimen of the 1,2-bisphenylhydrazone of mesoxalaldehyde had m.p. 194° C, and the mixed m.p. was 189–191° C. The infrared spectra of the authentic and derived specimens of the 1,2-bisphenylhydrazone of mesoxalaldehyde were identical over the range 4000–600 cm^{-1}.

Sodium Borohydride Reduction of 5-Acetamido-5-deoxy-D-threo-*pentulose*

5-Acetamido-5-deoxy-D-*threo*-pentulose (200 mg) was reduced with an equal weight of sodium borohydride in aqueous solution at 0° C for 3 hours. After removal of sodium borohydride and sodium borate the product was obtained as a clear syrup (200 mg). The syrup was dissolved in ethanol, cooled, and seeded with 1-acetamido-1-deoxy-D-arabinitol. Crystallization occurred and the crystals were filtered off, dried, and recrystallized from ethanol and had m.p. 145–147° C (47 mg). 1-Acetamido-1-deoxy-D-arabinitol had m.p. 146.5–147.5° C, and the mixed m.p. was 145–147° C. The infrared spectra of the authentic and derived specimens were identical over the range 4000–600 cm^{-1}. The derived specimen had $[\alpha]_D$ +22.6° and the authentic specimen had $[\alpha]_D$ +23°.

Section B. Studies on 5-Acetamido-5-deoxy-L-*erythro*-pentulose

5-Acetamido-5-deoxy-L-erythro-*pentulose*

1-Acetamido-1-deoxy-D-ribitol was oxidized by *Acetobacter suboxydans* using exactly the same procedure as that described for 1-acetamido-1-deoxy-D-arabinitol (Section A) to give an 83% conversion to ketose sugar after 10 days. After 21 days the medium was worked up in the usual way and the syrup obtained was fractionated on a cellulose column using butan-1-ol half-saturated with water as irrigant. 5-Acetamido-5-deoxy-L-*erythro*-pentulose was obtained as a chromatographically pure syrup which crystallized after desiccation for 1 week. The ketose was recrystallized from aqueous ethanol to give prisms, m.p. 160–164° C (decomp.), $[\alpha]_D$ +7°, which reduced Fehling's solution immediately at room temperature. Absorptions in the infrared were recorded at 3480 cm^{-1} (OH), 3310 cm^{-1} (NH), 1725 cm^{-1} (saturated carbonyl group), 1630 cm^{-1} (amide I), 1565 cm^{-1} (amide II). The ketose had R_{rh} 1.0 (solvent A), 1.15 (solvent B), 1.02 (solvent C), and gave an immediate intense spot with the alkaline silver nitrate spray reagent. Anal. Calc. for $C_7H_{13}O_5N$: C, 44.0%; H, 6.8%; N, 7.3%. Found: C, 43.8%; H, 6.9%; N, 7.5%.

Periodate Oxidation of 5-Acetamido-5-deoxy-L-erythro-*pentulose*

The ketose was oxidized with an approximately twofold excess of sodium metaperiodate in an unbuffered aqueous solution. The results are recorded in Table VII.

5-Acetamido-5-deoxy-1,3(?)-O-isopropylidene-L-erythro-*pentulose*

5-Acetamido-5-deoxy-L-*erythro*-pentulose (200 mg) was shaken with dry acetone (150 ml) containing concentrated sulphuric acid (4 drops), at room temperature, for 18 hours. The reaction mixture was neutralized with barium carbonate and filtered, the filtrate was evaporated to dryness, and the residue was examined on paper chromatograms. The orcinol – trichloroacetic acid spray reagent revealed three components, the major one having R_{rh} 2.74 (solvent A), 1.72 (solvent C), and this was separated by chromatography on Whatman No. 3 MM paper in solvent A. The material was obtained on elution as a

TABLE VII

Periodate oxidation of 5-acetamido-5-deoxy-L-*erythro*-pentulose

Time (hours)	Periodate uptake (moles/mole)	Formic acid (moles/mole)	Formaldehyde (moles/mole)
0.08	2.16	1.07	0.76
1.25	2.73	1.08	0.77
2.5	2.72	1.08	—
3.75	2.74	1.09	0.74

yellow syrup (83 mg). The optical rotation could not be measured due to the color of the solution. The syrup gave absorptions in the infrared at 3450 cm^{-1} (OH), 3350 cm^{-1} (NH), 1740 cm^{-1} (saturated carbonyl group), 1660 cm^{-1} (amide I), 1525 cm^{-1} (amide II), 1390, 1380 cm^{-1} (CH of the isopropylidene group). The syrup did not reduce Fehling's solution at room temperature but did so when heated; it gave a slow, weak reaction with the alkaline silver nitrate spray reagent.

*Periodate Oxidation of 5-Acetamido-5-deoxy-1,3(?)-O-isopropylidene-*L-erythro-*pentulose*

The isopropylidene ketose was oxidized in 50% aqueous ethanol solution (unbuffered) with a twofold excess of sodium metaperiodate. The results are recorded in Table VIII.

*5-Acetamido-5-deoxy-*L-erythro-*pentose Phenylosazone*

The phenylosazone was prepared by the usual method, using freshly distilled phenylhydrazine and glacial acetic acid. Several recrystallizations of the product from ethanol gave bright yellow needles, m.p. 180–182° C. The phenylosazone gave absorptions in the infrared at 3550 cm^{-1} (OH), 3310 cm^{-1} (NH), 3080 cm^{-1} (aromatic CH), 1650 cm^{-1} (amide I), 1630 cm^{-1} (amide II) and 1605, 1495, 745, 690 cm^{-1} (aromatic ring). Anal. Calc. for $C_{19}H_{23}O_3N_5$: C, 61.8%; H, 6.2%; N, 19.0%. Found: C, 61.2%, 61.7%; H, 6.5%, 7.0%; N, 19.7%, 19.4%. Good analyses were not obtained despite repeated recrystallizations.

*Periodate Oxidation of 5-Acetamido-5-deoxy-*L-erythro-*pentose Phenylosazone*

The phenylosazone was oxidized under the same conditions as those used for 5-acetamido-5-deoxy-D-*threo*-pentose phenylosazone (Section A). The results of the oxidation are shown in Table IX. Fifteen

TABLE IX

Periodate oxidation of 5-acetamido-5-deoxy-L-*erythro*-pentose phenylosazone

Time (hours)	Periodate uptake (moles/mole)	Formic acid (moles/mole)	Formaldehyde (moles/mole)
0.17	1.24	0.00	0.00
1.17	1.15	0.00	0.00
2.5	1.14	0.00	—
4	1.14	0.00	—

minutes after oxidation had commenced, a precipitate of the 1,2-bisphenylhydrazone of mesoxalaldehyde appeared and was isolated as described in Section A. It had m.p. 185–187° C and an authentic specimen had m.p. 192–193° C; mixed m.p. was 185–187° C. The infrared spectra of the authentic and derived specimens of the 1,2-bisphenylhydrazone of mesoxalaldehyde were identical over the range 4000–600 cm^{-1}.

Sodium Borohydride Reduction of 5-Acetamido-5-deoxy-L-erythro-*pentulose*

5-Acetamido-5-deoxy-L-*erythro*-pentulose (300 mg) was reduced with an equal weight of sodium borohydride in aqueous solution at 0° C for 4 hours. After removal of sodium borohydride and sodium borate the product was obtained as a pale yellow syrup (315 mg) which was dissolved in ethanol, seeded with 1-acetamido-1-deoxy-D-ribitol, and cooled. Crystallization occurred but on attempted filtration the crystals immediately liquefied, and repeated attempts to isolate the material failed. The syrup gave one spot on paper chromatograms R_{rh} 0.91 (solvent A), 1.0 (solvent B), 0.83 (solvent C). Paper electrophoresis in pH 9.2 sodium borate buffer at 500 volts for 5 hours gave one spot with a rate of movement slightly less than that of 1-acetamido-1-deoxy-D-ribitol. The syrup was acetylated with acetic anhydride in pyridine solution and gave a syrupy product (466 mg) which had $[\alpha]_D$ −15° (*c*, 3.78 in chloroform). Acetylation of 1-acetamido-1-deoxy-D-ribitol gave a syrupy acetate which had $[\alpha]_D$ +3° (*c*, 4.1 in chloroform). When subjected to gas–liquid chromatographic analysis (column packing D, reference 17) at a flow rate of 100 ml/minute and temperatures of 213° C or 225° C, the two acetates had identical retention times and a mixture of the two gave a single symmetrical peak. The two acetates had practically identical infrared spectra and gave absorptions at 3440 cm^{-1} (NH), 1740 cm^{-1} (carbonyl group of *O*-acetate), 1680 cm^{-1} (amide I), and 1520 cm^{-1} (amide II). It was concluded that the sodium borohydride reduction product from 5-acetamido-5-deoxy-L-*erythro*-pentulose contained mainly 1-acetamido-1-deoxy-D-ribitol and an isomeric 1-acetamido-1-deoxy pentitol.

ACKNOWLEDGMENTS

We wish to thank the National Research Council for financial assistance (N.R.C. 706 and T-39) and Queen's University for the award of a scholarship to one of us (J. C. T.). We would also like to thank Mr. J. Mackintosh for technical assistance, and the Royal Military College, Kingston, Ontario, for the use of a high-pressure hydrogenator.

THE SYNTHESIS OF MERCAPTOINDOLES

E. PIERS, V. B. HAARSTAD, R. J. CUSHLEY, AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received December 4, 1961

ABSTRACT

The 4-, 5-, 6-, and 7-mercaptoindoles have been prepared via the Reissert condensation of the isomeric benzylthio-*o*-nitrotoluenes. The latter were synthesized by diazotization of the corresponding 2-nitrotoluidines or by direct displacement of the halogen atom in monobrominated *o*-nitrotoluenes with the benzylmercapto group using dimethylformamide as solvent.

INTRODUCTION

Interest in the preparation of 4-mercaptoindole arose from the observation that the structurally analogous 6-mercaptopurine has been used successfully in the treatment of some forms of cancer (1, 2).

Apart from attempts to prepare 3-mercaptoindole, which oxidizes extremely easily to the diindolyl disulphide (3, 4), to our knowledge, no report exists in the literature concerning the remaining isomeric mercaptoindoles. Hence it was thought of interest to prepare the 4-, 5-, 6-, and 7-mercaptoindoles.

DISCUSSION

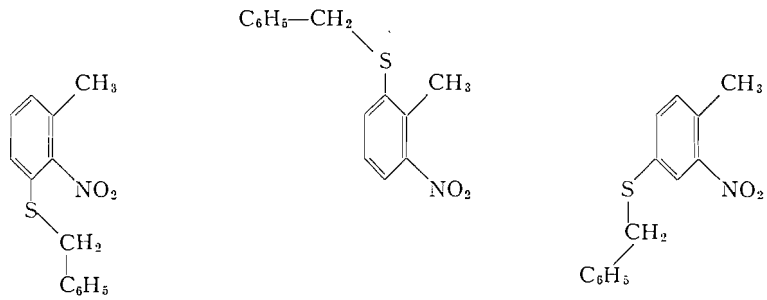
Attempts at direct replacement of nuclear bromine or chlorine in the benzene ring portion of indole by the mercapto group using potassium hydrogen sulphide or thiourea in various solvents met with failure, although similar procedures were successful when applied to 2-bromopyridine or to several chloropurines (5–7). Preparation of the mercaptophenylhydrazones which could be converted to the indole structure by Fischer's method (8) was quite unsatisfactory. However, since methoxy-*o*-nitrotoluenes and ethyl oxalate had been condensed and cyclized to methoxyindoles (9) via the Reissert procedure (10), the same approach was investigated in the present case and was found to be quite successful. Accordingly the isomeric 4-, 5-, 6-, and 7-benzylthio-2-nitrotoluenes were synthesized for this purpose.

The intermediate 4-benzylthio-2-nitrotoluene was prepared in 32% yield from 2-nitro-*p*-toluidine (11) by converting the latter to 4-mercapto-2-nitrotoluene via diazotization (12, 13) followed by treatment with base and benzyl chloride. The 5-benzylthio-2-nitrotoluene was obtained by nitration of aceto-*m*-toluidide according to the general method given by Fieser (14) and then conversion of the amine to the thioether as in the case of the 4-isomer.

The compound 6-nitro-*o*-toluidine required for the preparation of 2-benzylthio-6-nitrotoluene via the route indicated above could not be made satisfactorily by published procedures. Selective reduction of trinitrotoluene, reported to give 4-amino-2,6-dinitrotoluene (17), in our hands produced a substance which could be deaminated (18) only in very low yield. The crude 2,6-dinitrotoluene obtained from this reaction failed to reduce satisfactorily to 6-nitro-*o*-toluidine either with ammonium sulphide (19) or by electrolytic means (20). A more direct route to 6-benzylthio-2-nitrotoluene became available when it was found that the more nucleophylic potassium benzyl mercaptide displaced the halogen (21) in 2-bromo-6-nitrotoluene, especially if the reaction was carried out in dimethylformamide (22), yielding 26% of the thioether.

The fourth isomer, 3-benzylthio-2-nitrotoluene, necessary for the synthesis of 7-mercaptoindole, was obtained by two routes. The first involved the conversion of *m*-toluic acid to 2-nitro-*m*-toluic acid (23), which was then subjected to the Schmidt reaction (24), yielding 2-nitro-*m*-toluidine. This amine was converted to 3-benzylthio-2-nitrotoluene, in 19% yield, by the same method employed for the preparation of the 4- and 5-benzylthio-2-nitrotoluenes (12, 13). In the second route, the displacement of the halogen atom of 3-bromo-2-nitrotoluene (25) by treatment with potassium benzyl mercaptide in dimethylformamide gave the 3-benzylthio-2-nitrotoluene in 86% yield.

Although potassium ethoxide is a more effective base in the Reissert reaction of nitrotoluenes with ethyl oxalate (15), the cheaper sodium ethoxide was found to be quite satisfactory for the condensation of both 4- and 5-benzylthio-2-nitrotoluene with the ester. These conditions, when applied to the 3- and 6-benzylthio-2-nitrotoluenes, gave only small amounts of the pyruvate. However, use of potassium ethoxide as base and ether as solvent (15), along with extended reaction times of several days at room temperature, permitted the isolation of the potassium enolates of ethyl 3- and 6-benzylthio-2-nitrophenylpyruvate. The 6-benzylthio-2-nitrotoluene required, at the maximum, 6 days at room temperature to produce the enolate in 94% yield while the 3-benzylthio-2-nitrotoluene gave the condensation product in only 68% yield even after 16 days' reaction time. The greater difficulty which the 3- and 6-isomers find in undergoing the Reissert condensation might be attributed to the lower degree of activation which the methyl group experiences due to the ortho nitro group. If coplanarity of the nitro group with the ring is responsible, at least in part, for the activation of the methyl group and subsequent removal of a proton by base to form the carbanion, it is readily seen that the groups in the two positions ortho to the nitro substituent in 3-benzylthio-2-nitrotoluene (structure I) and the buttressing effect of the benzylthio group upon the methyl substituent in the 6-benzylthio-2-nitrotoluene (structure II) would indeed cause a marked restriction to the coplanarity of the nitro group with the ring as compared with that attainable in the 4- (and 5-) benzylthio-2-nitrotoluene (structure III). In support of this view it has been found that the position of the characteristic absorption bands in the infrared spectrum of the nitro group in these nitrotoluenes resemble those for the aliphatic nitro group in nitromethane to a progressively greater degree in the order 3-benzylthio-2-nitrotoluene > 6-benzylthio-2-nitrotoluene > 4-benzylthio-2-nitrotoluene (Table I). The order of the apparent ease of condensation of these toluenes with ethyl oxalate is 4-benzylthio-2-nitrotoluene > 6-benzylthio-2-nitrotoluene > 3-benzylthio-3-nitrotoluene.



I II III

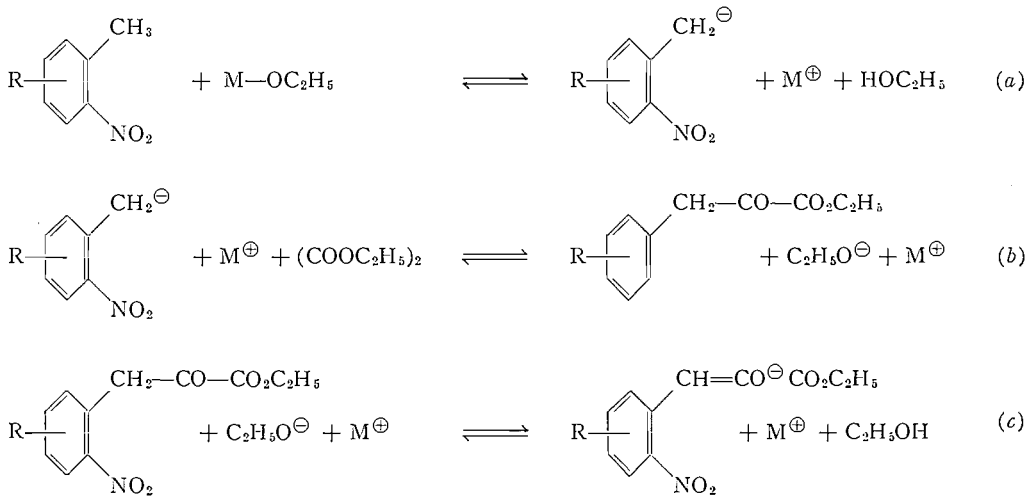
It is also possible that the greater difficulty in the formation of the pyruvate in the case of the 3- and 6-benzylthio-2-nitrotoluenes than for the 4- and 5-isomers may be due to an unfavorable shift in the equilibria indicated below.

TABLE I

Stretching bands of the nitro group in the infrared*
(Calibrated with polystyrene, 6.238 μ)

Compound	Stretching bands, μ	
	Asymmetric	Symmetric
o-Nitrotoluene	6.54	7.40
4-Benzylthio-2-nitrotoluene	6.53	7.40
6-Benzylthio-2-nitrotoluene	6.52	7.37
3-Benzylthio-2-nitrotoluene	6.50	7.29
Nitromethane	6.38	7.18

*Compare the data given for the infrared spectra of nitro compounds by R. N. Jones and C. Sandorfy in A. Weissburger's *Chemical applications of spectroscopy* (Interscience Publishers, Inc., New York. 1956. p. 540).



The requirement of a stronger base to shift the equilibrium to the right in equation (*c*) as well as solvent conditions which cause the precipitation of the enolate (step *c*) is therefore understandable. It has been found that in attempts at converting the potassium enolate of ethyl 6-benzylthio-2-nitrophenylpyruvate to the pyruvic acid by treatment with aqueous base some 6-benzylthio-2-nitrotoluene was obtained. Hence, for best results, the potassium enolate was used directly for the next step in the synthesis of the indole. In fact when pure 4-benzylthio-2-nitrophenylpyruvic acid was left in a solution of 95% ethanol (from which the acid could be crystallized) for a period of 4 weeks at room temperature, the bulk of the pyruvic acid reverted to 4-benzylthio-2-nitrotoluene. This clearly demonstrates the reversible nature of the Reissert reaction. The Reissert condensation appears to resemble the Claisen condensation in many respects (26). A detailed study of the Reissert reaction is at present under way in this laboratory.

The 4- and 5-benzylthio-2-nitrophenylpyruvic acids were reductively cyclized in the usual way with ferrous ammonium sulphate (9, 16). In the case of the potassium enolates of ethyl 3- (and 6-) benzylthio-2-nitrophenyl pyruvate, best results were obtained when a hot solution of the salt in dilute ammonium hydroxide was added to a boiling suspension of ferrous hydroxide. Following elimination of contaminating sulphate ion (16), decarboxylation of both 5- and 6-benzylthioindole-2-carboxylic acid was readily accomplished according to directions in the literature using a copper chromite catalyst (16). This

method, however, when applied to the 4- and 7-benzylthioindole-2-carboxylic acids gave low yields of products which were quite difficult to purify. In addition, considerable sulphur was lost as H_2S. A modified method of decarboxylation, recently described (27), using as catalyst a small amount of the copper salt of the respective indolecarboxylic acid, gave excellent yields of easily purified 4- and 7-benzylthioindoles.

Cleavage of the thioethers with sodium in liquid ammonia to the respective mercaptoindoles followed published directions with some slight modifications (28, 29).

EXPERIMENTAL

All melting points are uncorrected.

4-Benzylthio-2-nitrotoluene

Fifty-four grams (0.355 mole) of 2-nitro-*p*-toluidine, prepared by the method of Cohen and Dakin (11), was diazotized and converted to the xanthogenic ester according to Bennett and Berry (12, 13). The crude ester was hydrolyzed in a refluxing solution made from 20 g of sodium in 200 ml of ethanol to which 40 ml of water was added. An atmosphere of oxygen-free nitrogen was employed to minimize oxidation of the mercaptan to the disulphide. After 1 hour's reflux the solution was diluted with an equal volume of boiled distilled water (N_2) and poured into a separatory funnel previously flushed out with nitrogen. After the addition of 50 g of benzyl chloride, the mixture was shaken vigorously for 5 minutes. A further addition of 10 g of benzyl chloride was made and the mixture again shaken for 5 minutes. During this time enough 6 *N* sodium hydroxide was introduced periodically to maintain an alkaline condition. Combined ether extracts of the cooled solution were washed with water and dried (Na_2SO_4). Removal of the ether left an oil which was fractionally distilled under vacuum to yield 29 g (32%) of 4-benzylthio-2-nitrotoluene, b.p. 143° at 0.2 mm, m.p. 78°. The thioether crystallized well from 95% ethanol. Calc. for $C_{14}H_{13}O_2NS$: S, 12.37. Found: S, 12.23.

6-Nitro-m-toluidine

m-Toluidine was acetylated (ref. 14, p. 165) and the resulting *m*-acetotoluidide nitrated by the general method given by Fieser (ref. 14, p. 170). The crude product obtained proved to be a mixture of acetylated and unacetylated 6-nitro-*m*-toluidine. This material, without further purification, was hydrolyzed in 20-gram batches by refluxing with 1200 ml of a 1:1 mixture of concentrated hydrochloric acid and water containing enough ethanol to dissolve the solid when hot. Following a 1-hour reflux period, the solution was cooled and neutralized with solid sodium carbonate. The precipitate was removed and extracted with boiling dilute hydrochloric acid. (Any solid not soluble in the hot dilute acid was subjected to further hydrolysis as above.) The precipitate obtained from basification of the combined extracts was washed with water and air dried. The crude material melted at 129–130° (lit. 133–134° (30)) and was quite satisfactory for the next reaction.

5-Benzylthio-2-nitrotoluene

By the same method employed above 54 g of 6-nitro-*m*-toluidine was converted to 26.5 g (29%) of 5-benzylthio-2-nitrotoluene, m.p. 55.5–57°. Calc. for $C_{14}H_{13}O_2NS$: S, 12.37. Found: S, 12.28.

2-Bromo-6-nitrotoluene

o-Nitrotoluene was brominated by published procedures (32). The 2-bromo-6-nitrotoluene was separated from the 4-bromo-2-nitrotoluene by fractionation under reduced pressure with a meter-length column containing a stainless steel packing. The 2-bromo-6-nitrotoluene distilled over first and the product solidified in the receiver. The next fraction came over as an oil and proved to be a mixture of the two isomers. Recrystallization of the solid 2-bromo-6-nitrotoluene from ethanol containing a small amount of water gave a 26% yield of pure product. B.p. 108–110° at 3.3 mm; m.p. 41–42°, lit. 42° (19).

6-Benzylthio-2-nitrotoluene

Powdered potassium carbonate (38.8 g, 0.28 mole) was stirred into 50 ml of dimethylformamide containing 55 g (0.25 mole) of 2-bromo-6-nitrotoluene. To this was added 31.3 g (0.25 mole) of benzyl mercaptan (33) all at once. The stirred reaction mixture, kept under nitrogen, was heated for 4 hours at 50–55° and then stirred at room temperature for 14 hours. The addition of an equal volume of water, followed by cooling to 0°, produced a yellow solid which was triturated with dilute sodium hydroxide and then with water. Crystallization from ethanol gave 17.5 g (26%) of yellow needles, m.p. 102–103°. Calc. for $C_{14}H_{13}O_2NS$: C, 64.86; H, 5.02; N, 5.41; S, 12.35. Found: C, 64.72; H, 5.27; N, 5.38; S, 12.42.

3-Benzylthio-2-nitrotoluene

Following the same procedure outlined above, 17.0 g (0.079 mole) of 3-bromo-2-nitrotoluene (25) afforded 17.5 g (86%) of 3-benzylthio-2-nitrotoluene melting at 53–54°. Anal. Found: C, 64.56; H, 5.48; N, 5.27; S, 12.47.

4-Benzylthio-2-nitrophenylpyruvic Acid

To a solution of 6.9 g (0.30 mole) of sodium in 170 ml of anhydrous ethanol were added 44 g (0.30 mole) of diethyl oxalate and 77 g (0.30 mole) of 4-benzylthio-2-nitrotoluene. The reaction mixture, which rapidly became dark red, was refluxed for 1 hour, cooled, diluted with twice its volume of water, and then thrice extracted with ether. The aqueous layer was acidified to Congo red with concentrated hydrochloric acid. Air was blown through the solution to remove residual ether, whereupon crystallization occurred. The solid was separated, dissolved in dilute ammonium hydroxide, and again reprecipitated with hydrochloric acid. Crystallization from an alcohol–water mixture gave 66 g of 4-benzylthio-2-nitrophenylpyruvic acid which melted at 166–167° with decomposition. From the ethereal extract was recovered 9 g of unchanged 4-benzylthio-2-nitrotoluene. Yield, based upon the thioether consumed, 75%.

5-Benzylthio-2-nitrophenylpyruvic Acid

By the same method described above, 5-benzylthio-2-nitrotoluene afforded an oil which failed to solidify. It was therefore purified further by solution in cold dilute ammonium hydroxide followed by precipitation with concentrated hydrochloric acid. An ether extract of the oil was dried (Na_2SO_4), freed of solvent, and the residual oil subjected to the reductive cyclization step in the synthesis.

Potassium Enolate of Ethyl 3-Benzylthio-2-nitrophenylpyruvate

Potassium (4.7 g, 0.12 mole) was dissolved in 20 ml of anhydrous ethanol. To this solution, diluted with 150 ml of dry ether, was added 17.5 g (0.12 mole) of diethyl oxalate, followed 15 minutes later by an anhydrous ether solution of 3-benzylthio-2-nitrotoluene (26 g, 0.10 mole). A deep orange solution resulted which, when left at room temperature for 16 days, slowly deposited the potassium enolate as an orange precipitate. The solid, collected and washed thoroughly with anhydrous ether and then air dried, weighed 27.0 g (68% crude yield). This salt was used directly in the reductive cyclization step.

Potassium Enolate of Ethyl 6-Benzylthio-2-nitrophenylpyruvate

This salt was obtained in 94% yield from 6-benzylthio-2-nitrotoluene by the method described above. The reaction time required in this case was 6 days rather than 16.

6-Benzylthioindole-2-carboxylic Acid

The reductive cyclization of 4-benzylthio-2-nitrophenylpyruvic acid was accomplished according to published procedures (9). The resulting 6-benzylthioindole-2-carboxylic acid was freed from sulphate ion and purified according to Rydon and Tweddle (16). The solid acid obtained after removal of the ether was taken up in cold dilute ammonium hydroxide. Upon acidification (HCl) and cooling, the solution deposited a solid which was air dried. From 15 g of the pyruvic acid there was obtained 8 g (62%) of the indolecarboxylic acid, m.p. 215°. Calc. for $C_{16}H_{13}O_2NS$: S, 11.35. Found: S, 11.32.

5-Benzylthioindole-2-carboxylic Acid

The same method of reductive ring closure converted the crude, oily 5-benzylthio-2-nitrophenylpyruvic acid to 5-benzylthioindole-2-carboxylic acid, m.p. 210–211° (decomp.). Calc. for $C_{16}H_{13}O_2NS$: S, 11.35. Found: S, 11.40. Yield, based upon 45 g of 5-benzylthio-2-nitrotoluene used in the Reissert condensation reaction from which 19 g of the toluene was recovered unchanged, 15.2 g (54%).

7-Benzylthioindole-2-carboxylic Acid

For best results, the usual reductive cyclization (9, 16) was modified as follows. A solution of the potassium enolate of ethyl 3-benzylthio-2-nitrophenylpyruvate (10.0 g, 0.025 mole) in hot (80°) 4 *N* ammonium hydroxide (250 ml) was added slowly with stirring to a boiling suspension of ferrous hydroxide. (The latter was obtained by the addition of 25 ml of ammonium hydroxide, $d = 0.90$, to a boiling solution of ferrous sulphate heptahydrate, 45 g, 0.16 mole, in 300 ml of water.) The resulting mixture was boiled for 90 minutes and then filtered. The ferric oxide sludge was repeatedly extracted with boiling 2 *N* ammonium hydroxide until acidification of an aliquot of the extract failed to precipitate the indolecarboxylic acid. The combined extracts were cooled to 5°, filtered, and washed several times with ether. Upon acidification a solid appeared which when dried gave 2.2 g (31%) of 7-benzylthioindole-2-carboxylic acid melting at 165–166°. Calc. for $C_{16}H_{13}O_2NS$: C, 67.84; H, 4.59; N, 4.95; S, 11.31. Found: C, 67.59; H, 4.75; N, 5.05; S, 11.54.

4-Benzylthioindole-2-carboxylic Acid

This compound was prepared similarly in 56% yield from the potassium enolate of ethyl 6-benzylthio-2-nitrophenylpyruvate. Purification as above gave a brown solid melting at 185–186°. Anal. Found: C, 67.84; H, 4.63; N, 4.96; S, 11.22.

6-Benzylthioindole

Decarboxylation was carried out essentially according to published directions (16) using quinoline and copper chromite (31). Thirty-two grams of 6-benzylthioindole-2-carboxylic acid in 320 ml of distilled quinoline containing 5 g of copper chromite catalyst was heated 16 hours at 200°. The crude indole obtained from this reaction was dissolved in ethanol and clarified with charcoal. Three crops of product were obtained

by successive reductions in the volume of the solvent. The combined precipitates, crystallized from an alcohol–water mixture, afforded 18 g (67%) of 6-benzylthioindole, m.p. 106.5–107°. Calc. for $C_{15}H_{13}NS$: S, 13.41. Found: S, 13.32.

5-Benzylthioindole

5-Benzylthioindole-2-carboxylic acid (15 g) was similarly decarboxylated by heating for 11 hours at 200–210° and gave 6.6 g (52%) of 5-benzylthioindole melting sharply at 74–75°. Calc. for $C_{15}H_{13}NS$: S, 13.41. Found: S, 13.62.

7-Benzylthioindole

Since decarboxylation of 7-benzylthioindole-2-carboxylic acid by the usual procedure (16), employed successfully for the 5- and 6-isomers, proved to be quite unsatisfactory, giving poor yields even after extended times of reaction and also causing some loss of sulphur as H_2S, a modified procedure recently described (27) which avoids these difficulties was employed. From 2.83 g (0.01 mole) of the acid there was obtained 2.05 g (85%) of 7-benzylthioindole melting at 52–53° (from skellysolve B). Calc. for $C_{15}H_{13}NS$: C, 75.27; H, 5.47; N, 5.85; S, 13.40. Found: C, 75.36; H, 5.42; N, 5.93; S, 13.71.

4-Benzylthioindole

This compound was prepared in 80% yield from the corresponding indolecarboxylic acid as described above. It melted at 35–36° (from ethanol). Anal. Found: C, 75.49; H, 5.42; N, 5.98; S, 13.36.

6-Mercaptoindole

This compound was prepared by a modification of the procedure reported by du Vigneaud *et al.* (28, 29). Commercial anhydrous liquid ammonia (125 ml) was placed in a 50×150 mm test tube supported in a Dewar flask by means of a cork ring. To the ammonia was added 5 g (0.02 mole) of 6-benzylthioindole. Small pieces of freshly cut sodium metal were stirred into the ammonia until a blue color of 5–10 minutes' duration was obtained. Excess sodium was then destroyed by ammonium iodide, added until the blue color just disappeared. The reaction tube was then removed from the Dewar flask and the ammonia driven off under a blanket of purified nitrogen. Distilled water (125 ml), previously boiled and cooled, was added to the tube, along with sufficient 3 *N* hydrochloric acid to acidify the solution. The solid which appeared when the solution was cooled was removed and taken up in dilute sodium hydroxide and again precipitated with acid. When washed with water and dried in a desiccator over P_2O_5 (N_2) it melted sharply at 70–71°. Yield, 1.5 g (47%). Calc. for C_8H_7NS: S, 21.49. Found: S, 21.30.

5-Mercaptoindole

Debenzylation of 4 g of 5-benzylthioindole as above afforded 1.5 g (60%) of the mercaptan, which melted at 75–76°. Anal. Found: S, 21.48.

4-Mercaptoindole

Debenzylation of 3.57 g (0.15 mole) of 4-benzylthioindole followed the procedure described above but with the following changes. The ammonia was kept in an Erlenmeyer flask surrounded by dry ice. The flask was kept stoppered throughout the reaction as much as possible to minimize absorption of CO_2 by the liquid ammonia. Following the removal of ammonia, and addition of water to the ammonium salt of the mercaptan, the resulting aqueous solution was washed several times with ether to remove unreduced material. Acidification at 0° gave a solid which was dried in a desiccator under vacuum over dry calcium chloride. The substance was an oil at room temperature, but was readily crystallized from Skellysolve B at dry ice temperatures. Yield 1.5 g (68%). Calc. for C_8H_7NS: C, 64.39; H, 4.73; N, 9.39; S, 21.49. Found: C, 64.37; H, 4.93; N, 9.49; S, 21.08.

7-Mercaptoindole

Debenzylation of 3.3 g (0.014 mole) of 7-benzylthioindole by the same procedure as employed for the 4-benzylthioindole gave 1.8 g (87%) of the pure mercaptan melting at 57–58° (from Skellysolve B). Anal. Found: C, 64.25; H, 4.69; N, 9.31; S, 21.45.

ABSTRACT

The Stern–Grahame–Devanathan theory of the electrical double layer in aqueous systems is modified to include the so-called discreteness-of-charge effect of Esin and Shikov and Ershler. This provides an explanation of a number of phenomena which are at variance with the Stern theory. A simple method of incorporating the above effect into the Stern theory is suggested by the work of Grahame and is equivalent in principle to the discrete-ion approximation employed by the Russian authors. It is shown that the effect can be interpreted in terms of a 'self-atmosphere' potential at the counterions adsorbed in the Stern layer. This provides a new term in the energy of an adsorbed ion, which is very nearly proportional to the surface density of these ions and which had hitherto been included in the specific adsorption potential in the Stern adsorption isotherm. This energy is not small and accounts for the conclusion reached by Grahame that the adsorption potential varies strongly with the surface charge. Grahame found that the potential at the plane separating the compact and diffuse parts of the double layer in the solution phase (i.e. the outer Helmholtz plane) at the mercury – aqueous electrolyte interface displays a maximum as the potential across the interface is varied, and this property is reproduced by the theory. The effect of ion size on the adsorption isotherm is also considered.

1. INTRODUCTION

In the course of his extensive investigations of the properties of the electric double layer at the interface between mercury and aqueous electrolyte, Grahame (1) demonstrated a number of properties which are at variance with the Stern theory (2). One anomaly is that if the original Stern theory be accepted then the specific adsorption energy of an anion (e.g. chloride ion) adsorbed by the mercury surface is not constant, as had been previously assumed, but exhibits a marked increase as the surface charge becomes more positive. Grahame suggested that this variation of the specific adsorption energy is due to a covalent bond between the anion and the mercury surface, the strength of which increases as the mercury charge becomes more positive. Such a hypothesis seems inconsistent with the usual theory of chemical valency. The outer electron shell of the adsorbed anion is completed by the process of ionization, and although some electron sharing and anion polarization are likely, it is difficult to understand how such strong dependence of binding on surface charge can occur. In the present paper a simple explanation, based on distinguishing the mean electrostatic potential at any point in the plane of the centers of the adsorbed anions from the mean potential at the center of an adsorbed ion occupying this point will be developed. The difference between

[1]*Issued as N.R.C. No. 6696.*

these two potentials can be regarded as originating in the so-called discreteness-of-charge effect, which has been investigated by a number of Russian scientists (3–5) and by Grahame (6). The approach adopted here, first suggested by Grahame (6), is simpler but equivalent in principle.

In his modification of the original Stern picture of the region in the electrolyte solution adjacent to the mercury surface, Grahame (1) distinguished between the plane of centers of the layer of specifically adsorbed ions and the limit of the diffuse layer. These were designated as the inner Helmholtz plane (to be abbreviated to I.H.P.) and the outer Helmholtz plane (O.H.P.) respectively. In the Stern theory, the O.H.P. is identical with the I.H.P., and the mean potential at this common plane increases uniformly with the potential drop across the mercury–electrolyte interface. Assuming that the Gouy–Chapman theory applies to the diffuse layer, Grahame and Soderberg (7–9) were able to determine the variation with interfacial potential of the potential at the O.H.P. at a specified electrolyte concentration. They obtained the rather striking result that if specific adsorption takes place, the magnitude of the potential at the O.H.P. passes through a maximum. This behavior will be reproduced in the theory presented below. The discreteness-of-charge effect was originally proposed to explain the variation of mercury wall potential with electrolyte concentration at the electrocapillary maximum. This aspect has been treated by the Russian workers (3–5, 10, 11) and others (12), and will therefore not be discussed here.

Current interest in the region between the mercury wall and the O.H.P. is directed into two main channels, its dielectric and electrostrictive properties (13–15) and discrete-ion effects. The present paper is concerned with the second topic and for this purpose, any variation in the dielectric constant and thickness of this region with interfacial potential will be ignored, except for a brief discussion of certain aspects at the end of the paper. In this connection it is important to note that as well as the discreteness-of-charge effect there is another discrete-ion effect which is due to short range forces, i.e. to the size of each adsorbed ion. Such an ion will occupy at least one adsorption site and if it is large or if it retains part of its hydration shell it may occupy more than one. The occupied sites are not available to the other adsorbed ions and this affects the entropy of distribution and hence the chemical potential of the adsorbed ions. These ion-size effects have received inadequate attention up to now but they are incorporated in the present theory and it will be shown that they explain the large discrepancies between the results of two different methods used by Grahame (8) and Grahame and Parsons (9) to determine the ratio of the distances of the I.H.P. and the O.H.P. from the wall. As a result it seems likely that these distances vary much less with changes in the physical conditions of the system than these authors believed.

Since the discreteness-of-charge and ion-size effects are likely to be of importance in a number of colloidal phenomena, we shall not confine our attention to the mercury – aqueous electrolyte interface, but shall consider the more general case of a plane colloidal surface in contact with an aqueous electrolyte. Such a surface, for example, may be the wall of a plate-like particle immersed in a dispersion medium containing coagulating electrolytes. Recently the authors (16, 17) incorporated the discrete-charge effect into the theory of colloid stability of Derjaguin and Landau (18) and Verwey and Overbeek (19). This leads to an explanation of the dependence of coagulating electrolyte concentration on the surface potential of the particles, a property which had hitherto been inconsistent with the stability theory.

2. THE STERN–GRAHAME–DEVANATHAN MODEL OF THE DOUBLE LAYER

Employing the electric double layer model of Grahame (1) and Devanathan (20) for a single plate-like particle it is assumed that there is an 'inner region' of oriented water dipoles, of thickness d (~5 Å) and dielectric constant ϵ_1 (~10–20), lying between the plate wall and O.H.P. The volume density in the dispersion medium of the potential-determining ions, which constitute the original charge on the plate surface, is small compared with the corresponding density n (number of ions of either type per unit volume) of the coagulating electrolyte, which is a $z-z$ valency type. The centers of a layer of adsorbed counterions, of valency z_β, where z_β may be $+z$ or $-z$, are situated on the I.H.P. inside the inner region at a distance β from the plate wall. The I.H.P. thus divides the inner region into two parts, which will be called the inner and outer zones and which are of thicknesses β and $\gamma = d-\beta$ (Fig. 1). All the charge is assumed

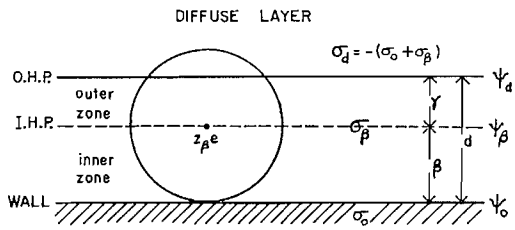

FIG. 1. Model of the electric double layer.

to be situated in the plane of the particle wall, in the I.H.P., or in the diffuse layer. Hence the two zones act as condensers of capacities dK/β and dK/γ per unit area, where $K = \epsilon_1/4\pi d$. The mean electrostatic potentials at the particle wall, the I.H.P., and the O.H.P. are denoted by ψ_0, ψ_β, and ψ_d respectively. Also, σ_0 and σ_β are the mean surface densities at the particle wall and I.H.P. and σ_d is the total charge contained in a column of the diffuse layer of unit cross section. Within each zone the potential distribution function satisfies Laplace's equation and therefore we have a linear variation in potential. Assuming the electric field in the particle interior to be zero, it follows from electrostatics that

$$\psi_0-\psi_\beta = \beta\sigma_0/dK \tag{2.1}$$

and

$$\psi_\beta-\psi_d = \gamma(\sigma_0+\sigma_\beta)/dK. \tag{2.2}$$

Applying the Gouy–Chapman theory to the diffuse layer,

$$\sigma_d = -\frac{\epsilon\kappa}{2\pi}\frac{kT}{ze}\sinh(ze\psi_d/2kT), \tag{2.3}$$

where k is Boltzmann's constant, T the absolute temperature, e the electronic charge, and κ the Debye–Huckel parameter defined by

$$\kappa^2 = 8\pi nz^2e^2/\epsilon kT. \tag{2.4}$$

Also, the condition of electrical neutrality reads

$$\sigma_0+\sigma_\beta+\sigma_d = 0. \tag{2.5}$$

For a given ψ_0 and n one more relation is required to determine the potential distribution, and this has the form of a modified Stern adsorption isotherm, which is obtained

by equating the chemical potential of an adsorbed ion, μ_β say, to that of an ion of the same type in the electrolyte interior. Let ν be the number of adsorbed ions per unit area and $g(\nu)$ the number of configurations per unit area available to these ions. Then the contribution to the chemical potential of an adsorbed ion from $g(\nu)$ is

$$\mu_\beta^c = -kTd \log_e g(\nu)/d\nu. \tag{2.6}$$

If each adsorbed counterion still retains a portion of its hydration shell and therefore occupies more than one adsorption site, say p sites, then a simple expression for $g(\nu)$ is obtained by adapting to surfaces the zero-order approximation to the entropy of mixing molecules of different sizes, which is provided by the volume fraction statistics of Flory (21) and Huggins (22). Suppose that N_s is the density of adsorption sites on the plate surface so that each occupied site spans an area $1/N_s$ and each ion an area p/N_s. Then the formula for $g(\nu)$ corresponding to Flory–Huggins' is

$$\log_e g(\nu) = -\nu \log_e (p\nu/N_s) - (N_s - p\nu) \log_e [(N_s - p\nu)/N_s]. \tag{2.7}$$

Differentiating with respect to ν and writing $\sigma_\beta = z_\beta e\nu$, (2.6) becomes

$$\mu_\beta^c = A + kT \log_e [\sigma_\beta (N_s z_\beta e)^{p-1}/(N_s z_\beta e - p\sigma_\beta)^p], \tag{2.8}$$

where A is a constant.

To determine the electrostatic contribution to μ_β, the Guntelberg–Muller (23) charging process in the theory of electrolytes is employed and it is imagined that the charge on a specified adsorbed ion is e', which is varied from 0 to its full value $z_\beta e$. Let Ψ_β be the mean potential at the center of the given adsorbed ion carrying the charge e', due to the Coulomb interaction of all the ions. Following Loeb (24) the potential is conveniently written as

$$\Psi_\beta = \psi_\beta + \phi_\beta, \tag{2.9}$$

where ψ_β is the mean potential at any point on the I.H.P. and ϕ_β is the "perturbation" potential due to the "self-atmosphere" of the adsorbed ion and its induced image in the plate wall. The electrostatic contribution to μ_β now reads

$$\mu_\beta^e = \int_0^{z_\beta e} \Psi_\beta de' = z_\beta e\psi_\beta + \int_0^{z_\beta e} \phi_\beta de', \tag{2.10}$$

noting that ψ_β may be assumed independent of e'. We may therefore write the chemical potential of an adsorbed ion as

$$\mu_\beta = \xi_\beta + kT \log_e [\sigma_\beta (N_s z_\beta e)^{p-1}/(N_s z_\beta e - p\sigma_\beta)^p] + z_\beta e\psi_\beta + \int_0^{z_\beta e} \phi_\beta de', \tag{2.11}$$

where ξ_β depends on temperature and pressure. There are other terms in μ_β which do not occur in ordinary electrolyte theory, in particular, the energy of polarization of the adsorbed ion in the electric field of the double layer. This will be considered briefly at the end of the paper.

The chemical potential of an ion in the electrolyte interior may be expressed as

$$\mu_0 = \xi_0 + kT \log_e nf/(2n + n_0), \tag{2.12}$$

where ξ_0 is a function of temperature and pressure only, n_0 is the number of water molecules per unit volume, and f is the activity coefficient. Equating the two chemical potentials (2.11) and (2.12) and assuming $n_0 \gg n$, it is easily seen that

$$\frac{\sigma_\beta}{nf} = \frac{(N_s z_\beta e - p\sigma_\beta)^p}{n_0 (N_s z_\beta e)^{p-1}} \exp [(\Phi_\beta + z_\beta e\psi_\beta)/kT], \tag{2.13}$$

where

$$\Phi_\beta = \xi_0 - \xi_\beta - \int_0^{z_\beta e} \phi_\beta de'. \tag{2.14}$$

The relation (2.13) becomes the Stern adsorption isotherm if $p = 1$, $f = 1$, and Φ_β is identified with the specific adsorption isotherm. It will be shown, however, that the last term on the right of (2.14) is a function of σ_β and this property is absent in the classical Stern theory.

3. SELF-ATMOSPHERE POTENTIAL AT AN ADSORBED ION

The mean potential ψ_β at a point on the I.H.P. is so defined that all ions are undergoing thermal motion, i.e. no ion is permanently located at this point. Thus ψ_β is the potential at any point in the I.H.P. when a uniform surface charge distribution σ_β is situated on the plane. Suppose now that the center of a specified adsorbed ion carrying the charge e', where $0 < |e'| < |z_\beta e|$, is situated at a point on the I.H.P. (Fig. 2). The

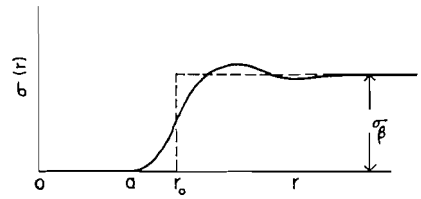

FIG. 2. Distribution of surface charge density in the inner Helmholtz plane surrounding an adsorbed ion.

mean charge distribution on the I.H.P. surrounding this charge will no longer be uniform but will be given by some function $\sigma(r)$, where r is the distance from the specified ion to an arbitrary point on the I.H.P. If $W(r)$ is the potential of the mean force acting between the specified ion e' and any other ion (charge $z_\beta e$) in the I.H.P. at distance r, then

$$\sigma(r) = \sigma_\beta f(r), \qquad f(r) = \exp\,[-W(r)/kT]. \tag{3.1}$$

At large r, the surface charge density should not be affected by the fixed ion at $r = 0$ and so $\sigma(r) \to \sigma_\beta$, which means $W(r) \to 0$, as $r \to \infty$; and if a is the nearest distance of approach between ion e' and a second adsorbed ion, $W(r) = \infty$ for $r < a$. The total charge on the I.H.P. defined by the charge distribution $\sigma(r)$ differs by an amount e' from that defined by the uniform distribution σ_β, since one ion of charge e' has been removed from the distribution. If the I.H.P. is assumed infinitely large, we obtain the relation

$$2\pi \int_0^\infty r[\sigma_\beta - \sigma(r)]dr = 2\pi\sigma_\beta \int_0^\infty r[1-f(r)]dr = e' \tag{3.2}$$

or, noting that $f(r) = 0$ for $r < a$,

$$2\pi\sigma_\beta \int_a^\infty r[1-f(r)]dr = e' - \pi a^2\sigma_\beta. \tag{3.3}$$

It is convenient to consider the following limiting case: (i) the dielectric constant is uniform right up to the plate surface and equal to ϵ, (ii) the electrolyte concentration

is vanishingly small, which means that the diffuse layer may be ignored. There will then be two terms in the perturbation potential of an adsorbed ion. One is the ordinary electrostatic image term in the wall of the colloidal plate, namely

$$\phi_\beta' = \left(\frac{\epsilon-\epsilon_p}{\epsilon+\epsilon_p}\right)\frac{e'}{2\beta\epsilon}, \tag{3.4}$$

where ϵ_p is the dielectric constant of the plate medium, which is assumed to be infinitely thick. The other term is due to the departure of the surface charge density on the I.H.P. from the uniform value and can therefore be expressed in terms of the difference in densities $\sigma_\beta - \sigma(r)$. It reads

$$\phi_\beta'' = -\frac{2\pi\sigma_\beta}{\epsilon}\int_0^\infty\left[\frac{1}{r}+\left(\frac{\epsilon-\epsilon_p}{\epsilon+\epsilon_p}\right)\frac{1}{(r^2+4\beta^2)^{\frac{1}{2}}}\right][1-f(r)]rdr, \tag{3.5}$$

where the second term in the square brackets is due to the corresponding image of the charge difference $\sigma_\beta - \sigma(r)$. An accurate determination of $\sigma(r)$ is difficult, but two approximations to it have been suggested. The first is the 'discrete-ion' model of Esin and Shikov (3) and Ershler (4), who consider the case of $\epsilon_p = \infty$. The distribution $\sigma(r)$ and its image in the plate wall* are replaced by an infinite hexagonal array of discrete ionic charges (each equal to $z_\beta e$) in the I.H.P. and a parallel array of opposite charges ($-z_\beta e$) at a distance 2β. The above authors make the further approximation of replacing each ion-image pair by an equivalent electric point dipole. If s is the distance between nearest-neighboring ions in the I.H.P. and $\epsilon_p = \infty$ then (3.5) becomes very nearly

$$\phi_\beta'' = -\frac{4\pi\sigma_\beta\beta}{\epsilon}+\frac{22\beta^2 z_\beta e}{\epsilon s^3} = -\frac{4\pi\sigma_\beta\beta}{\epsilon}\left(1-\frac{11\sqrt{3}}{4\pi}\frac{\beta}{s}\right) \tag{3.6}$$

since the area allotted to each ion in the hexagonal array is $(\sqrt{3}/2)s^2$ and the corresponding charge density is $\sigma_\beta = 2z_\beta e/\sqrt{3}s^2$. We shall employ a simpler method, which is equivalent in principle and may be termed the cutoff approximation. Each adsorbed ion is regarded as the center of a circular area in the I.H.P. from which the uniform charge density σ_β is removed. Thus

$$\sigma(r) = \begin{cases}0\\ \sigma_\beta\end{cases} \quad \text{or} \quad f(r) = \begin{cases}0, & r < r_0\\ 1, & > r\ r_0\end{cases} \tag{3.7}$$

where the radius r_0 of the area is determined by the condition (3.2) or (3.3) (Fig. 2). This yields

$$\pi r_0^2\sigma_\beta = e'. \tag{3.8}$$

Substitution of (3.7) into (3.5) yields

$$\phi_\beta'' = -\frac{2\pi\sigma_\beta}{\epsilon}\left[r_0+\left(\frac{\epsilon-\epsilon_p}{\epsilon+\epsilon_p}\right)\left\{(r_0^2+4\beta^2)^{\frac{1}{2}}-2\beta\right\}\right]. \tag{3.9}$$

When $r_0 \gg 2\beta$, this simplifies to

$$\phi_\beta'' = \frac{4\pi\sigma_\beta}{\epsilon}\left[\left(\frac{\epsilon-\epsilon_p}{\epsilon+\epsilon_p}\right)\beta-\frac{\epsilon r_0}{(\epsilon+\epsilon_p)}-\frac{\beta^2}{r_0}\left(\frac{\epsilon-\epsilon_p}{\epsilon+\epsilon_p}\right)+\ldots\right] \tag{3.10}$$

which, in the limiting case of $\epsilon_p = \infty$, reduces to

$$\phi_\beta'' = -\frac{4\pi\sigma_\beta\beta}{\epsilon}\left(1-\frac{\beta}{r_0}+\ldots\right). \tag{3.11}$$

**These authors actually put $\epsilon = \infty$ and introduced images in the O.H.P.*

On substituting $\pi r_0^2 = (\sqrt{3}/2)s^2$, the 'discrete-ion' approximation (3.6) reads

$$\phi_\beta'' = -\frac{4\pi\sigma_\beta\beta}{\epsilon}\left(1-0.80\frac{\beta}{r_0}+\ldots\right), \tag{3.12}$$

which does not differ much from the 'cutoff' approximation (3.11).

Suppose now that the adsorbed counterions are embedded in the inner region of thickness d and dielectric constant ϵ_1 at distance β from the plate wall. Then the self-atmosphere potential ϕ_β'' is conveniently written as

$$\phi_\beta'' = -\frac{4\pi\sigma_\beta\beta\gamma}{\epsilon_1 d}\,g = -\frac{\beta\gamma}{d^2K}\,\sigma_\beta g, \tag{3.13}$$

where g is a factor depending on r_0, γ, d, the dielectric constants, and the electrolyte concentration. The determination of g in the general case is difficult but certain limiting cases have been considered and these indicate the general behavior of g. Firstly suppose that the particle medium is conducting ($\epsilon_p = \infty$), $\epsilon \gg \epsilon_1$ so that effectively $\epsilon = \infty$, and $\beta = \gamma$. Then it is shown in the Appendix that

$$\phi_\beta'' = -\frac{\pi\sigma_\beta d}{\epsilon_1}\left[1-\frac{8\tau}{\pi}\sum_{m=1}^{\infty}\frac{1}{(2m-1)}K_1(\sqrt{2m-1}\;\pi\tau)\right], \tag{3.14}$$

where $\tau = r_0/d$ and K_1 is the Bessel function of the second kind with imaginary argument and of order 1. For $\tau > 1$ corresponding to $|\sigma_\beta| < 16$ μcoulombs/cm^2 when $z = 1$ and $d = 5$ Å, the first term only in the series need be considered and as shown in Table I, even this term is small. It is possible to extend the analysis to the case where the I.H.P. is no longer midway between the mercury wall and the O.H.P., and the corresponding leading term in ϕ_β'' becomes simply (3.13) with $g = 1$.

TABLE I

τ	1	2	3
$K_1(\pi\tau)$	0.34×10^{-2}	0.99×10^{-4}	0.34×10^{-5}

This is the limiting form for ϕ_β'' when $r_0 = \infty$ and $g = 1$ and it may be derived quite simply in the following way. Consider a sheet of charge of density $-\sigma_\beta$ situated at the I.H.P. between two equipotential planes A' and B' (the plate wall and O.H.P.) at zero potential and at distances β and γ. This sheet is imagined to have two sides with charge distributed as shown in Fig. 3. A and B are the image planes. The electric field between

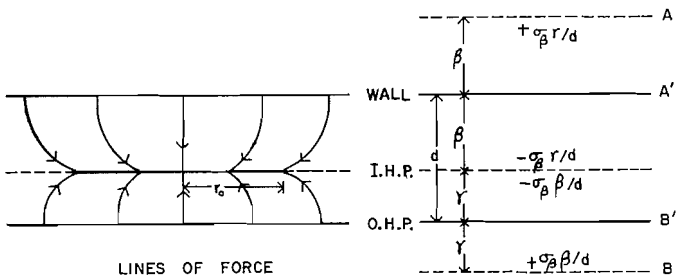

FIG. 3. Model of the inner region yielding the limiting expression (3.15) for the self-atmosphere potential when $r_0 = \infty$, $\epsilon = \infty$, and $\epsilon_p = \infty$ ($g = 1$).

A′ and the I.H.P. is $4\pi\sigma_\beta\gamma/d\epsilon_1$, and hence the potential drop from A′ to the I.H.P. is $4\pi\sigma_\beta\beta\gamma/d\epsilon_1$. This must also be the potential difference between the plane B′ and the I.H.P. Since A′ and B′ are at zero potential, the potential at the I.H.P. is

$$\phi_\beta'' = -\frac{4\pi\sigma_\beta\beta\gamma}{\epsilon_1 d}, \tag{3.15}$$

which is the required result. The higher terms in (3.14) and in the corresponding formula when $\beta \neq \gamma$ are small because the lines of force near the center of the circle of radius r_0 are practically normal to the I.H.P.; in other words, the edge effects are small for $r_0 > d$ ($\tau > 1$).

The drop in mean potential across the outer zone $\psi_\beta - \psi_d$ is designated the macropotential by Ershler (4). Also, if we exclude the self-image term ϕ_β' the true potential at the center of the adsorbed ion is

$$\psi_A = \psi_\beta + \phi_\beta'' = \psi_\beta - \beta\gamma\sigma_\beta g/d^2K \tag{3.16}$$

and Ershler refers to the difference $\psi_A - \psi_d$ as the macropotential. Putting $g = 1$ we readily derive from (2.1), (2.2), and (3.16),

$$\psi_A - \psi_d = \frac{\gamma}{(\gamma+\beta)}(\psi_0 - \psi_d). \tag{3.17}$$

This linear relation is already given by Grahame (6). In their rigorous mathematical treatment of a hexagonal array of discrete point charges situated on the I.H.P., with perfectly conducting colloidal wall and O.H.P., Levich, Kiryanov, and Filinovsky (5) also obtain (3.17) provided the coverage of adsorption sites by counterions does not exceed 25–30%. The Russian authors quite correctly maintain that the micropotential and not the macropotential should be introduced in the Stern adsorption isotherm. In our present notation, this means that in the exponential term on the right-hand side of (2.13) we should write

$$\Phi_\beta - z_\beta e\psi_\beta = \Phi_\beta' - z_\beta e\psi_A, \tag{3.18}$$

where

$$\Phi_\beta' = \xi_0 - \xi_\beta - \int_0^{z_\beta e} \phi_\beta' de', \tag{3.19}$$

which is independent of the charge densities σ_0 and σ_β and may be identified with the specific adsorption potential (apart from an additive constant). We note that ϕ_β'' is independent of e' and that the self-image term ϕ_β', which is proportional to e', is obtained in the usual manner by considering multiple image reflections in the O.H.P. and the plate wall, but we shall not require its explicit formula (5).

In the introduction we commented on Grahame's conclusion that the energy Φ_β exhibits a marked increase as the surface charge σ_0 becomes more positive in the case of chloride ion adsorbed at the mercury – aqueous electrolyte interface. Writing $\Phi_\beta = -eU_\beta$ ($z_\beta = -1$), Grahame (1) estimated that U_β increases by about 0.18 volts as σ_0 varies from -4 to 18 μcoulombs/cm^2 for 0.3 N NaCl solution. The corresponding variation of the charge density σ_β of adsorbed chloride ions is from -1 to about -28 μcoulombs/cm^2. In the present theory the variation in U_β is attributed to the term $-e\phi_\beta''$. An increase in the magnitude $|\Delta\sigma_\beta|$ of σ_β of 27 μcoulombs/cm^2 corresponds to an increase in U_β of

$$|\Delta U_\beta| = \frac{\beta\gamma}{d^2K}|\Delta\sigma_\beta| = 27\frac{\beta\gamma}{d^2K} \text{ volts},$$

where K is in μfarads/cm^2. According to Grahame and Parsons (9), $K \approx 30$ μfarads/cm^2 and $\gamma/d \approx \frac{1}{4}$, so that $|\Delta U_\beta| = 0.17$ volts, which is in excellent agreement with Grahame's estimate.

The dielectric constants ϵ_p of silver halide crystals are in the range 11–15 and are perhaps not very different from the dielectric constant ϵ_1 of the inner region. Thus for such colloidal media, a first approximation is obtained by putting $\epsilon_p = \epsilon_1$. If we assume $\epsilon = \infty$, then it follows from (3.11) that

$$\phi_\beta'' = -\frac{4\pi\sigma_\beta\gamma}{\epsilon_1}\left(1 - \frac{\gamma}{r_0} + \ldots\right). \tag{3.20}$$

When $\gamma/r_0 \ll 1$, this becomes identical with (3.13) provided $g = d/\beta$. For small coverages of the adsorption sites, g increases from 1 to d/β as ϵ_p decreases from ∞ to ϵ_1. In the limiting case of $r_0 = \infty$, it is easily shown that ϕ_β'' is given by the leading term in (3.20) for any (finite) value of the dielectric constant ϵ_p. As in the derivation of (3.15) we imagine a sheet of density $-\sigma_\beta$ situated at the I.H.P., but now the colloidal wall has a dielectric constant ϵ_p. The dielectric displacement within the colloidal medium may be assumed to vanish, since otherwise the I.H.P. would be at infinite potential with respect to the colloidal interior. This means that the dielectric displacement in the inner zone vanishes, differing from zero only in the outer zone. There is now one image plane at B (Fig. 4) and the electric field between the I.H.P. and B′ is $4\pi\sigma_\beta/\epsilon_1$. Since B′ is at zero

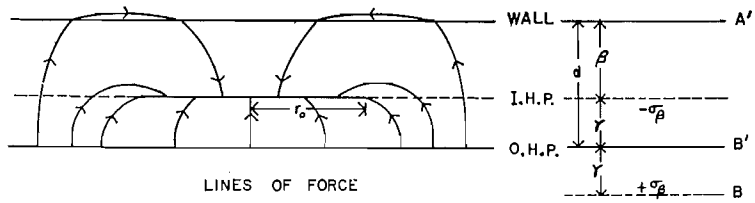

FIG. 4. Model of the inner region yielding the limiting expression $\phi_\beta'' = -4\pi\sigma_\beta\gamma/\epsilon_1$, for the self-atmosphere potential when $r_0 = \infty$, $\epsilon = \infty$, and $\epsilon_p < \infty$.

potential, the potential at the I.H.P. is given by the first term in (3.20). The plot of g as a function of r_0/d for various values of the ratio $f = (\epsilon_p - \epsilon_1)/(\epsilon_p + \epsilon_1)$ and for $\beta = \gamma$ and $\epsilon = \infty$, is shown in Fig. 5. (The mathematical details are omitted from the present

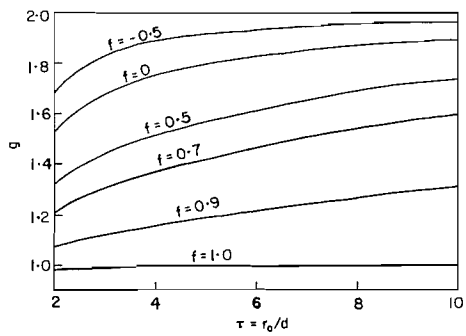

FIG. 5. Plot of g as a function of r_0/d for various values of the ratio $f = (\epsilon_p - \epsilon_1)/(\epsilon_p + \epsilon_1)$ and for $\beta = \gamma$ and $\epsilon = \infty$.

paper.) The convergence to the limiting value $g = 2$ at $r_0 = \infty$ is seen to be rather slow. This is due to the lack of symmetry on the two sides of the I.H.P., as illustrated in Fig. 4, leading to a much larger 'edge effect' than in the 'two-conductor' case of Fig. 3.

For fixed r_0/d and $\epsilon = \infty$, the magnitude of ϕ_β'' increases as the ratio ϵ_p/ϵ_1 diminishes. This behavior can be understood as follows. The potential ϕ_β'' at the center of a circular disk, situated on the I.H.P., is due to a uniform charge density $-\sigma_\beta$ on the disk and to the infinite set of induced images of this charge distribution in the two boundary planes of the inner region (Fig. 6). When these planes are perfectly conducting ($f = 1$),

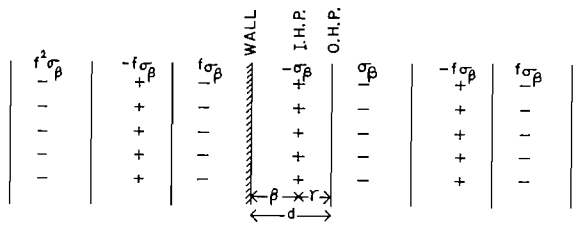

FIG. 6. Infinite set of images in the mercury wall and the outer Helmholtz plane; $f = (\epsilon_p - \epsilon_1)/(\epsilon_p + \epsilon_1)$, $\epsilon = \infty$.

the first-order image in each plane has a charge density σ_β and since these exert a greater influence than the higher-order images, the net effect of the images is to reduce the magnitude of ϕ_β''. If now the colloidal wall is a dielectric, the charge density in its first-order image drops to $f\sigma_\beta$ and the reduction in the magnitude of ϕ_β'' is correspondingly smaller. Thus ϕ_β'' increases in magnitude as f decreases.

Suppose now that the O.H.P. is no longer assumed to be an equipotential plane and that the electrolyte concentration is very small. The charge density of the first-order image in this plane will be $f'\sigma_\beta$ very nearly, where $f' = (\epsilon - \epsilon_1)/(\epsilon + \epsilon_1)$. For typical values of $\epsilon_1 = 16$ and $\epsilon = 80$, $f' = 0.80$, so that the reduction from the case of the perfect conductor is not large. The effect of the factor f' is again to increase the magnitude of ϕ_β''. However, with increase in electrolyte concentration, ϕ_β'' will approach the value corresponding to an equipotential O.H.P. Ershler (4) has given the following explanation for assuming an equipotential O.H.P. at large electrolyte concentrations. A single adsorbed ion in the I.H.P. induces an oppositely charged ionic cloud in the diffuse layer extending into this layer a distance comparable with $1/\kappa$, where κ is the Debye–Huckel parameter characteristic of the local ionic concentration. At large electrolyte concentrations or large values of ψ_d, the local value of $1/\kappa$ will be small and as first approximation we may assume that all the charge in the cloud lies in the O.H.P. The distribution of the charge in this plane must be such that the potential beyond the plane in the electrolyte solution is zero at every point. Such a distribution of potential is obtained when the solution side is a perfect conductor at zero potential.

The general conclusion is that g will not differ much from d/β when ϵ_p/ϵ_1 is of the order of 1, provided the coverage of adsorption sites is less than, say 10%. For smaller values of ϵ_p/ϵ_1 and at low coverage, g may exceed d/β.

The simple expression (3.13) for ϕ_β'', which applied at small σ_β, is a two-dimensional analogue of the Debye–Huckel self-atmosphere potential in the limit of small electrolyte concentrations. The two potentials differ in that ϕ_β'' is proportional to the surface concentration of adsorbed ions whereas the Debye–Huckel potential is proportional to the square root of the volume electrolyte concentration, and we shall demonstrate that

this different dependence on concentration is essential. It is well known that the self-atmosphere of an ion in the electrolyte interior should satisfy a certain condition of self-consistency (23) and it is readily shown that ϕ_β'' obeys a corresponding condition. The adsorbed layer of ions is treated as a separate phase, and an electrostatic free energy per unit area, which is associated with ϕ_β'', can be defined as follows. Introducing the Debye–Huckel charging process suppose that all the adsorbed ions carry a fraction λ of their normal charge and that a specified adsorbed ion is assigned a charge e′, which is varied independently. Then the self-atmosphere potential at this ion will depend on λ, e', and the density of adsorbed ions ν; thus we may write $\phi_\beta'' = \phi_\beta''(\lambda, \nu, e')$. The electrostatic free energy per unit area takes the form

$$f_{e1}(\nu) = \nu z_\beta e \int_0^1 \phi_\beta''(\lambda, \nu, z_\beta \lambda e) d\lambda, \tag{3.21}$$

where it is imagined that ν is held fixed during the charging from $\lambda = 0$ to 1. Then the condition of self-consistency that ϕ_β'' should satisfy takes the form

$$\int_0^{z_\beta e} \phi_\beta''(1, \nu, e') de' = \frac{df_{e1}(\nu)}{d\nu}. \tag{3.22}$$

From (3.13), the dependence of ϕ_β'' on the relevant parameters λ, ν, and e' takes the form $\phi_\beta'' = C\lambda\nu$, where C is a constant. It is seen that ϕ_β'' satisfies the condition (3.22) and we conclude that a linear dependence on σ_β requires that ϕ_β'' be independent of e'.

It is rather striking that the 'discrete-ion' and 'cutoff' approximations lead to the same linear relation (3.17) which is valid for perfectly conducting walls of the inner region and small coverage of adsorption sites. This must mean that the two methods of approximation give identical results under these conditions, but they may differ when ϵ_p is finite. The presence of a term in the adsorption energy which is proportional to the surface density of ions is not new in adsorption energy. It occurs in the theory of adsorption of gases on solids whenever the interaction of adsorbed molecules occupying adjacent sites on the solid surface is taken into account. An entirely different approach to the problem of the self-atmosphere effect and therefore to the determination of $\sigma(r)$ is suggested by the theory of adsorption of gases on solids, when dipole interactions between adsorbed molecules are considered. This involves the Bethe or some similar method designed to treat the immediate environment of a lattice site occupied by a molecule (see Miller (25)). Such an approach should help to decide which of the two approximations to $\sigma(r)$, the 'discrete-ion' or 'cutoff' model, provides a better estimate of ϕ_β'', but this will not be investigated here.

There is one inconsistency in the use of the cutoff approximation (3.7) which requires some explanation. Whereas the distances between the ions is fixed, independent of e' in the discrete-ion approximation, the radius r_0, defined by (3.8), is a function of e' in the cutoff approximation. In the Guntelberg process employed in (2.10), we imagine that the charge e' of an adsorbed ion varies from 0 to its full value $z_\beta e$, and by (3.8) the radius r_0 also increases from zero to its corresponding final value. However, it is easily shown that the cutoff model violates the formula (3.3) when $|e'| < \pi a^2 |\sigma_\beta|$. Suppose that z_β and therefore σ_β are positive. Since $\sigma(r)$ is either 0 or σ_β in the cutoff model, $\sigma_\beta - \sigma(r)$ and therefore the left-hand side of (3.3) cannot be negative, whereas for such small e', the right-hand side of (3.3) is negative. At small e', $\sigma(r)$ cannot be approximated by the cutoff formula (3.7); it is seen from (3.3) that $f(r) > 1$ (and thus $|\sigma(r)| > |\sigma_\beta|$) for some part of the range $r > a$. However, at small coverage the dominant term in ϕ_β'', which is independent of e', satisfies the condition of self-consistency (3.22) and is not affected by this correction to $\sigma(r)$ at small e'.

Instead of allowing r_0 to tend to zero, it would be more realistic to regard the 'exclusion diameter' a as the minimum value of r_0 and to suppose that $r_0 = a$ when $|e'| < \pi a^2|\sigma_\beta|$. For such small values of e', the relation (3.3) is satisfied if it is imagined that a ring of charge $\pi a^2\sigma_\beta - e'$, distributed uniformly round the circle of radius a, is superposed on the cutoff form (3.7). This is equivalent to assuming that when e' is so small that the charge in the area occupied by the ion on the I.H.P. is actually less than the average, then a compensating charge accumulates in the region immediately surrounding the ion (Fig. 2). For this crude but simple correction to the cutoff charge density (3.7), there will be a new term in the self-atmosphere potential of an adsorbed ion carrying the charge e'. It is sufficient to consider the simple case where $\epsilon_p = \epsilon_1$ and $\epsilon = \infty$. Then this new term reads

$$\phi_\beta''' = \frac{(\pi a^2\sigma_\beta - e')}{\epsilon_1}\left[\frac{1}{a} - \frac{1}{(a^2+4\gamma^2)^{\frac{1}{2}}}\right], \tag{3.23}$$

which contributes to the chemical potential μ_β of an adsorbed ion an amount

$$\int_0^{\pi a^2\sigma_\beta} \phi_\beta''' de' = \frac{(\pi a^2\sigma_\beta)^2}{2\epsilon_1}\left[\frac{1}{a} - \frac{1}{(a^2+4\gamma^2)^{\frac{1}{2}}}\right]. \tag{3.24}$$

This should be compared with the corresponding contribution from (3.20), which for $\gamma/r_0 \ll 1$ reads $-4\pi\sigma_\beta\gamma z_\beta e/\epsilon_1$. Choosing $a = 2\gamma$ and substituting $\pi r_0^2\sigma_\beta = z_\beta e$, the ratio of these two terms becomes $-0.073(a/r_0)^2$. This is small even for coverage of adsorption sites as high as 30% and we may conclude that the inconsistency in the cutoff approximation at small e' is unimportant.

In a paper dealing with the double layer free energy of soap micelles, Overbeek and Stigter (26) have suggested another method of correcting for the self-atmosphere of an adsorbed ion. It is imagined that the charge of an adsorbed ion is smeared out over a circular area of radius r_0, and the electrical work required to assemble this continuous charge distribution on the circle is determined. This is not equivalent to the corresponding energy of charging which is given by the integral in (2.10) and consequently the method of these authors cannot be correct.

4. VARIATION OF POTENTIAL AT O.H.P. WITH PLATE POTENTIAL

We proceed to investigate the effect of the self-atmosphere potential at an adsorbed ion on the double layer properties of a single plate. It is convenient to introduce the dimensionless quantities

$$\eta_0 = e\psi_0/kT, \qquad \eta_\beta = e\psi_\beta/kT, \qquad \eta_d = e\psi_d/kT \tag{4.1}$$

and also

$$Q = \frac{\epsilon_1 d}{4\pi\beta\gamma}\frac{kT}{e} = \frac{d^2K}{\beta\gamma}\frac{kT}{e}, \tag{4.2}$$

which has the dimensions of charge per unit area. Then (2.1) and (2.2) become respectively

$$\eta_0 - \eta_\beta = \frac{d}{\gamma}\frac{\sigma_0}{Q} \tag{4.3}$$

and

$$\eta_\beta - \eta_d = \frac{d}{\beta}\frac{(\sigma_0+\sigma_\beta)}{Q}. \tag{4.4}$$

Also, substituting (3.16) into (3.18), the equilibrium condition (2.13) can be expressed as

$$z_\beta\eta_\beta = \log_e \frac{nf}{n_0} + \log_e\left[\frac{(N_s z_\beta e - p\sigma_\beta)^p}{\sigma_\beta (N_s z_\beta e)^{p-1}}\right] + \frac{g z_\beta \sigma_\beta}{Q} + \frac{\Phi_\beta'}{kT}. \tag{4.5}$$

Eliminating σ_0 from (4.3) and (4.4),

$$\eta_d = \frac{d}{\beta}\eta_\beta - \frac{\gamma}{\beta}\eta_0 - \frac{d}{\beta}\frac{\sigma_\beta}{Q}, \tag{4.6}$$

and now eliminating η_β from (4.5) and (4.6),

$$\eta_d = \frac{d}{\beta}\left[\frac{1}{z_\beta}\log_e\frac{nf}{n_0} + \frac{1}{z_\beta}\log_e\left[\frac{(N_s z_\beta e - p\sigma_\beta)^p}{\sigma_\beta (N_s z_\beta e)^{p-1}}\right] - \frac{\gamma}{d}\eta_0 + \frac{(g-1)\sigma_\beta}{Q} + \frac{\Phi_\beta'}{kT}\right], \tag{4.7}$$

which expresses η_d in terms of σ_β and η_0. From (4.3) and (4.4) we can also eliminate η_β to obtain

$$\eta_0 = \eta_d + \frac{(\sigma_0+\sigma_\beta)}{Q}\frac{d^2}{\beta\gamma} - \frac{d}{\gamma}\frac{\sigma_\beta}{Q}. \tag{4.8}$$

It is convenient to introduce

$$\sigma_\beta^0 = Q/z_\beta g,\ x = \sigma_\beta/\sigma_\beta^0,\ b = \sigma_\beta^0/N_s z_\beta e. \tag{4.9}$$

Then, making use of (2.3), (2.4), (2.5), (4.1), and (4.2), the relation (4.8) can be written as

$$\eta_0 = \eta_d + \frac{\kappa\epsilon}{2\pi K z}\sinh\frac{1}{2}z\eta_d - \frac{dx}{\gamma g z_\beta} \tag{4.10}$$

and (4.7) as

$$x - \log_e x + p\log_e(1-pbx) = z_\beta\eta_d + \frac{z_\beta}{z}\frac{\kappa\epsilon}{2\pi K}\frac{\gamma}{d}\sinh\frac{1}{2}z\eta_d + C, \tag{4.11}$$

where

$$C = \alpha - \log_e nf. \tag{4.12}$$

Here α is a constant involving the specific adsorption potential Φ_β', the number of adsorption sites N_s, and the distances β and γ. The two relations (4.10) and (4.11) yield η_d as a function of η_0 in terms of the parameter x. We can also write (4.5) as

$$z_\beta\eta_\beta = x - \log_e x + p\log_e(1-pbx) - C, \tag{4.13}$$

thus expressing η_β in terms of x.

Suppose we vary the potential ψ_0 at the wall by changing the concentration of potential-determining ions in the dispersion medium, while the concentration n of the coagulating electrolyte is unaltered. It is assumed that K, β, and γ do not vary with ψ_0. For the mercury – aqueous electrolyte system, ψ_0 is the potential across the interface and this is varied externally. The density of adsorbed ions σ_β, and therefore the ratio x, will change with ψ_0. Differentiating (4.13) with respect to η_0, we find that

$$\frac{d\eta_\beta}{d\eta_0} = \frac{d\eta_\beta}{dx}\frac{dx}{d\eta_0} = 0 \tag{4.14}$$

when

$$1 - \frac{1}{x} - \frac{p^2 b}{1-pbx} = 0. \tag{4.15}$$

We shall find that $pb \ll 1$ and the root of the quadratic equation (4.15) in which we are interested is that in the neighborhood of $x = 1$; the discarded root is approximately $1/(pb)$. Differentiating (4.10) and (4.11) with respect to η_0,

$$\frac{dx}{d\eta_0} = \frac{\gamma g z_\beta}{d}\left[1-\left(1+\frac{\kappa\epsilon}{4\pi K}\cosh\frac{1}{2}z\eta_d\right)\frac{d\eta_d}{d\eta_0}\right] \tag{4.16}$$

$$\left[1-\frac{1}{x}-\frac{p^2b}{1-pbx}\right]\frac{dx}{d\eta_0} = z_\beta\left[1+\frac{\kappa\epsilon}{4\pi K}\frac{\gamma}{d}\cosh\frac{1}{2}z\eta_d\right]\frac{d\eta_d}{d\eta_0}. \tag{4.17}$$

It follows that at the value of x defined by (4.15)

$$dx/d\eta_0 = \gamma g z_\beta/d \tag{4.18}$$

and

$$d\eta_d/d\eta_0 = 0. \tag{4.19}$$

It is readily verified that the magnitudes of ψ_β and ψ_d have maxima at the root of (4.15). Thus differentiating (4.17) again and substituting (4.18),

$$\frac{d^2\eta_d}{d\eta_0^2} = \left(\frac{\gamma g}{d}\right)^2 z_\beta\left[\frac{1}{x}-\frac{p^3b^2}{(1-pbx)^2}\right]\Big/\left[1+\frac{\kappa\epsilon}{4\pi K}\frac{\gamma}{d}\cosh\frac{1}{2}z\eta_d\right], \tag{4.20}$$

evaluated at this root. When $z_\beta > 0$, the right-hand side of (4.20) is positive, so that we have a minimum in ψ_d. Assuming the plate wall to be negatively charged and ψ_d to be negative, this means that the magnitude of ψ_d has a maximum. When $z_\beta < 0$, we assume ψ_d is positive and again the magnitude of ψ_d has a maximum. Similar considerations apply to ψ_β.

The physical basis for the maxima can be understood on examining the potential ψ_A which is given by (3.16). The electrostatic work gained when an ion of valency z_β is adsorbed on the I.H.P. is not $z_\beta e\psi_\beta$ but $z_\beta e\psi_A$, and by (3.16) and (4.9),

$$z_\beta\eta_A = z_\beta\eta_\beta - x, \tag{4.21}$$

where $\eta_A = e\psi_A/kT$. It follows from (4.13) and (4.18) that at the maxima,

$$\frac{d(z_\beta\eta_A)}{d\eta_0} = -\frac{\gamma g z_\beta}{d}\left(\frac{1}{x}+\frac{p^2b}{1-pbx}\right), \tag{4.22}$$

which does not vanish. This implies that ψ_A increases steadily in magnitude with the plate potential. However, by (3.16),

$$\frac{d\psi_\beta}{d\psi_0} = \frac{d\psi_A}{d\psi_0} - \frac{d\phi_\beta''}{d\psi_0} \tag{4.23}$$

and the two terms on the right have opposite signs. At small coverages, $\psi_\beta \approx \psi_A$ and the first term dominates. At the value of x defined by (4.15), the two terms in (4.23) cancel one another and for larger coverages, the second (self-atmosphere) term is the larger. The classical Stern theory is obtained by putting $g = 0$ and $p = 1$ in equation (4.5). This means that the self-atmosphere term on the right of (4.23) is absent and therefore $d\psi_\beta/d\psi_0$ is always positive.

Making use of (4.2) and (4.9), it is readily verified that the self-atmosphere term (3.13) is given by

$$z_\beta e\phi_\beta''/kT = -x. \tag{4.24}$$

At the maximum in $|\psi_d|$, $x \approx 1$ and by (4.9) the fraction of sites occupied by adsorbed ions is conveniently obtained from values of Q. In Fig. 7, we have plotted Q in μcoulombs/cm^2 for various values of the relative position γ/d of the I.H.P. in the inner region and

of the dielectric constant ϵ_1, choosing $T = 25°$ C and $d = 5$ Å. These values are symmetrical about $\gamma/d = 0.5$. The fraction of adsorption sites occupied at the maximum is approximately $Q/|z_\beta|gN_s e$. For a density of adsorption sites $N_s = 5\times10^{14}$, $N_s e = 80$ μcoulombs/cm^2, and it is seen from Fig. 7 that for $|z_\beta| = 1$ and a typical range $g = 1$

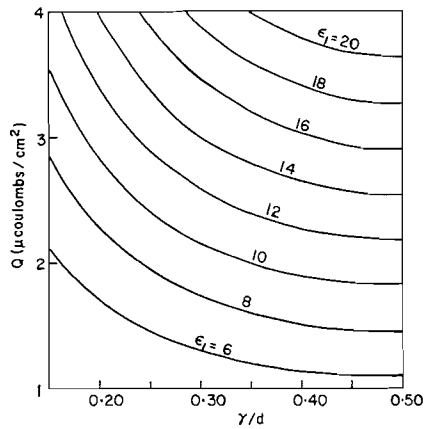

FIG. 7. Plot of Q against γ/d; $Q/z_\beta g$ equals approximately the charge density of adsorbed ions at the maximum in $|\psi_d|$.

to 2, the coverage of sites at the maximum is less than 5%. Furthermore, this coverage is reduced by the factor $1/|z_\beta|$, when $|z_\beta| > 1$.

From their measurements on the rate of change of differential capacity with the chemical potential of the electrolyte at the mercury – aqueous electrolyte interface, Grahame and Soderberg (7), Grahame (8), and recently Grahame and Parsons (9) determined the variation of ψ_d with ψ_0 and obtained a maximum in $|\psi_d|$ when univalent anions are adsorbed by the mercury surface. Comparison of the theory developed in this paper with the experimental results of Grahame (8) on the adsorption of iodide ions in the mercury – KI electrolyte system at 25° C will now be made. Since the plate wall is metallic, we shall assume $g = 1$. There is one difficulty encountered in the interpretation of these experiments which is relevant to our comparison and which concerns the value to be chosen for the ratio γ/d. Two methods of determining γ/d have been devised and it would appear that these disagree. In one method a relation which is obtained by adding (2.1) and (2.2) is employed, namely

$$\psi_0 - \psi_d = \frac{\sigma_0}{K} + \frac{\sigma_\beta}{K_2}, \tag{4.25}$$

where

$$K_2 = dK/\gamma \tag{4.26}$$

is the capacity of the outer zone. It is possible to determine all the quantities in (4.25) except K and K_2 and these can be calculated from the experimental data. We should mention that the experimentally determined potential at the mercury wall includes the so-called Lange χ-potential which may be regarded as originating in the dipole layers at the interface. Grahame (1) corrects for this by subtracting a potential difference of 0.488 volts, which is observed at the electrocapillary maximum (when $\sigma_0 = 0$) of an unadsorbed electrolyte and in this way obtains a value for the potential which can be

attributed to the true charge distributed and will be identified with the potential ψ_0 introduced in this paper. The relation (4.25) now yields $\gamma/d = 0.4$, which varies very little with σ_β.

The alternative method of calculating γ/d, which is simplified by Grahame and Parsons (9), involves the equation (4.5) for $g = 1$ and $z_\beta = -1$. Making use of (4.6), we may express (4.5) as

$$(4.27)\quad \log_e(|\sigma_\beta|/nf) - e\psi_d/kT - p\log_e(1 - p\sigma_\beta/N_s z_\beta e) = B + (\gamma/d)e(\psi_0 - \psi_d)/kT,$$

where B is a constant characteristic of the adsorbed ion and the adsorbing surface. The above authors omit the last term on the left-hand side of (4.27) and on examining the variation of $\psi_0 - \psi_d$ with the left-hand side of (4.27) at fixed σ_0 find that both B and γ/d depend on σ_0. For example, with KI, γ/d increases from 0.4 to 0.8 as σ_0 changes from -4 to 18 μcoulombs/cm^2. However, such a variation in γ/d is most unlikely since it would imply distances of the adsorbed I ion from the mercury surface smaller than its radius (2.18 Å). In Table II, we have substituted Grahame's data for electrolyte concentrations $c = 0.05$, 0.25 and 1.0 N KI into equation (4.27), assuming that γ/d has

the fixed value 0.4. The parameter p is determined by choosing the same value for B when $\sigma_0 = -4$ and 14 μcoulombs/cm^2 at $c = 0.05$ N KI. B^* is the value of B when the co-area term is omitted. The results in this table demonstrate that the insertion of the Flory–Huggins co-area term on the left of (4.27) largely removes the anomalies of strongly varying B and γ/d and so the two methods of determining γ/d are in reasonable agreement.

Most recently Mott and Watts-Tobin (15) arrived at the result (3.17) by arguing that for small concentrations of adsorbed counterions the lines of force are approximately normal to the mercury wall in the inner region. They also introduced an additional term in the adsorption energy of the counterion which is proportional to the 3/2th power of the surface density of adsorbed ions and which, in our notation, reads

$$\frac{2\pi z_\beta \sigma_\beta e \gamma^2}{\epsilon_1 r_0}.$$

This term is intended to serve the same purpose as our co-area term, namely to correct for varying B and γ/d. However, it resembles the second-order term in the expansion (3.11) and will therefore be practically eliminated when the multiple image reflections in the O.H.P. and mercury wall are properly introduced.

The equation (4.27) directly involves the co-area and discrete-ion effects but not the dielectric constant ϵ_1, of the inner region. However, the polarization energy of an absorbed ion has been omitted in the expression (2.11) for the chemical potential μ_β and therefore in (4.27). This energy is related to the dependence of ϵ_1 on the density ν of adsorbed ions and is usually regarded in colloid theory as the source of the apparent increase of specific adsorption potential with the polarizability of the ion, e.g. from F^- to I^-. A simple expression for this energy term can be obtained by assuming that the adsorbed ion is embedded in a homogeneous medium of dielectric constant ϵ_1. According to the linear relation (3.17), the electric field acting on the ion is equal to $(\psi_0-\psi_d)/d$ and hence its polarization energy is given approximately by (27)

$$\mu_\beta^{p} = -\frac{d}{8\pi}\left(\frac{\psi_0-\psi_d}{d}\right)^2\frac{\partial\epsilon_1}{\partial\nu} = -\left(\frac{kT}{e}\right)^2\frac{1}{8\pi d}(\eta_0-\eta_d)^2\frac{\partial\epsilon_1}{\partial\nu}, \tag{4.28}$$

making use of (2.1) and (2.2) and ignoring any 'natural' or 'residual' field when $\sigma_0 = \sigma_\beta = 0$. When μ_β^{p} is added to the expression (2.11) for μ_β, there is a corresponding new term on the right-hand side of (4.11) given by μ_β^{p}/kT and $\eta_0-\eta_d$ is expressed in terms of η_d and r by (4.10). This term should also be added to the left-hand side of equation (4.27). However, little is known about the magnitude of the derivative $\partial\epsilon_1/\partial\nu$. Grahame and Parsons (8, 9) have found that for KI and KCl electrolyte – mercury systems, K and therefore ϵ_1, depend only slightly on ν and this is consistent with the small variation in B demonstrated in Table II. The insertion of the polarization term in (4.27) should affect somewhat the value of p but since an independent estimate of $\partial\epsilon_1/\partial\nu$ is not known, we shall not pursue this further.

Let the experimental values of σ_0, σ_β, ψ_d, and ψ_0 at the maximum in $|\psi_d|$ be $\sigma_0^{(m)}$, $\sigma_\beta^{(m)}$, $\psi_d^{(m)}$, and $\psi_0^{(m)}$ respectively. Putting $z_\beta = -1$, and making use of (4.9), the relation (4.15) becomes

$$x = 1 - \frac{p^2\sigma_\beta^{(m)}/N_s e}{1+p\sigma_\beta^{(m)}/N_s e} = 1+h, \text{ say.} \tag{4.29}$$

Also, putting $g = 1$, $\gamma/d = 0.4$, $d = 5$ Å, and $p = 0$ and 2, we can determine $\sigma_\beta^0 = \sigma_\beta^{(m)}/x$ at the maximum and hence, from (4.2) and (4.9), the capacity K and the dielectric constant ϵ_1 of the inner region. Finally, the value of $\psi_0^{(m)}$ is calculated from (4.10) at a given electrolyte concentration c. Comparison with the experimental values for $\psi_0^{(m)}$ obtained by Grahame (8) for three electrolyte concentrations of KI are shown in Table III. Since the properties of the inner region are expressed in terms of the parameters γ/d and K only, ϵ_1 is proportional to the value chosen for d. The experimental values for K correspond to an empty inner region, i.e. $\sigma_\beta = 0$, and are assumed to depend on σ_0 only. We have also plotted (Fig. 8) the variation of ψ_0 with ψ_d in the case of 0.05 N KI for $p = 0$ and 2, $\gamma/d = 0.4$, and the fixed (theoretical) values of K given in Table III ($K = 25.2$ and 22.0 μfarads/cm^2 respectively). In the comparison with the experimental points of Grahame (8) it is convenient to choose the same value for $\psi_0^{(m)}$. When $p = 0$ and $g = 1$, it is possible to eliminate x from the equations (4.10) and (4.11) and so obtain a single equation relating η_0 and η_d. Putting $z_\beta = -1$, this reads

$$\eta_d + \frac{\kappa\epsilon}{2\pi Kz}\sinh\tfrac{1}{2}z\eta_d = \frac{\beta\eta_d+\gamma\eta_0}{d} - \exp\left[\frac{\beta\eta_d+\gamma\eta_0}{d} - C\right]. \tag{4.30}$$

We see from Table III that if K is assumed independent of ψ_0 at a given concentration c, its theoretical value at the maximum in $|\psi_d|$ is less than the experimental value for $\sigma_\beta = 0$ and the same σ_0. The dependence of K on ψ_0 at a given c is probably the

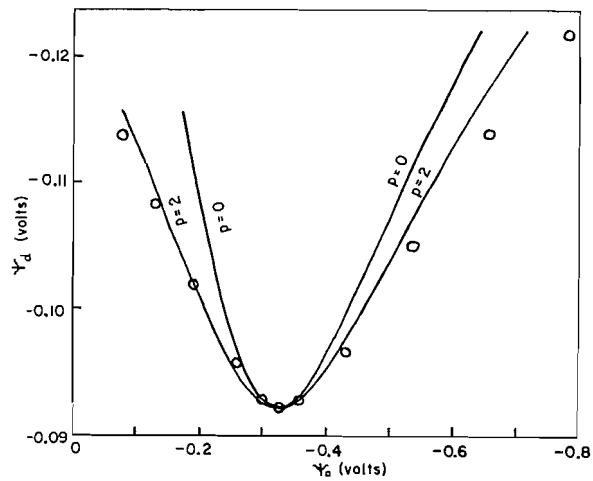

FIG. 8. Plot of ψ_d against ψ_0: O = experimental points. Mercury–electrolyte interface, 0.05 N KI.

main source of the difference, a secondary factor being the neglect of the polarization term (4.28). Introducing this dependence, the maximum in $|\psi_d|$ is no longer defined by (4.15), but, from (4.10) and (4.11), by

$$\left(\frac{1}{x} + \frac{p^2 b}{1-pbx}\right)\left(1 + \frac{\kappa\epsilon t}{2\pi K z}\sinh \tfrac{1}{2} z\eta_d\right) = 1 + \frac{dt}{\gamma g z_\beta}\frac{p^2 bx}{1-pbx}, \tag{4.31}$$

where $t = (1/K)(dK/d\eta_0)_c$. Putting $g = 1$ and $z_\beta = -1$, this may be written as

$$K = -\frac{\kappa\epsilon t}{2\pi z}\sinh \tfrac{1}{2} z\eta_d^{(m)} - \frac{1-(d/\gamma)ht}{1+h}\frac{e\beta\gamma}{kTd^2}\sigma_\beta^{(m)}, \tag{4.32}$$

where h is defined in (4.29) and $\eta_d^{(m)} = e\psi_d^{(m)}/kT$. The values of t can be estimated

from Grahame's data at $\sigma_\beta = 0$ if K is assumed independent of σ_β. It is seen from Table III that the theoretical values of K now exceed the experimental ones, although the agreement is somewhat closer for $p = 2$. The difference between the theoretical and experimental values of $\psi_0^{(m)}$ is greatly reduced at $c = 0.1$ and $p = 2$ but poorer agreement is obtained at $c = 0.025$ mole/l. Also, it readily follows from (4.11) that on the cathodic side of the maximum, where $x \approx 0$, the difference between the theoretical curves and the experimental points in Fig. 8 can be attributed to a drop in K with increase in $|\psi_0|$. However, the experimental decrease in K from 26.4 to 21 μfarads/cm^2 when σ_0 varies from -5 to -14 μcoulombs/cm^2 and $\sigma_\beta = 0$ is found to overcorrect for $p = 2$. A more detailed comparison seems unwarranted without the inclusion of the polarization energy and other factors, such as electrostriction, which have been ignored in the simple model of the inner region employed in this paper.

ACKNOWLEDGMENT

APPENDIX

Suppose that the inner region, of dielectric constant ϵ_1 and thickness d, is bounded by two perfectly conducting walls and that the I.H.P. coincides with the median plane, i.e. $\beta = \gamma = d/2$. In the cutoff approximation, ϕ_β'' is the potential at the center of a circular disk, situated in the I.H.P. and having radius r_0, due to a uniform charge density $-\sigma_\beta$ on this disk. We need to consider an infinite set of images associated with multiple reflections between two equipotential surfaces ($f = 1$) at separation d. (The array of images is illustrated in Fig. 6 in the more general case where $f \neq 1$ and $\gamma \neq \beta$.) The expression (3.5) is replaced by

$$\text{(A.1)} \qquad \phi_\beta'' = -\frac{2\pi\sigma_\beta}{\epsilon_1}\left[r_0 + 2\sum_{n=1}^{\infty}(-1)^n\{\sqrt{(r_0^2+n^2d^2)} - nd\}\right]$$

$$= -\frac{2\pi\sigma_\beta d}{\epsilon_1}\left[\tau + 2\sum_{n=1}^{\infty}(-1)^n\{\sqrt{(\tau^2+n^2)} - n\}\right].$$

When $\tau > 1$, it is possible to replace the series by a much more rapidly converging series by applying the Poisson summation formula in the following way.* Let $F(x)$ be a function which is integrable in the range $(-\infty, \infty)$ and is defined as $\frac{1}{2}\{F(x+0)+F(x-0)\}$ at points of discontinuity. Then, putting

$$\text{(A.2)} \qquad G(y) = \int_{-\infty}^{\infty} F(x)\exp(-2\pi i y x)dx,$$

the Poisson summation formula reads

$$\text{(A.3)} \qquad \sum_{x=-\infty}^{\infty} F(x) = \sum_{y=-\infty}^{\infty} G(y),$$

where the summation is taken over integral values of x and y only. If this is applied to the function

$$\text{(A.4)} \qquad F(x) = \begin{cases} \{\sqrt{(\tau^2+x^2)} - x\}\exp(\pi i x), & x > 0 \\ \frac{1}{2}\tau, & x = 0 \\ 0, & x < 0 \end{cases}$$

The authors are indebted to Professor G. E. H. Reuter of Durham University, for bringing this method to their attention.

then (A.1) becomes

$$\phi_\beta'' = -\frac{4\pi\sigma_\beta d}{\epsilon_1}\sum_{-\infty}^{\infty} F(x) = -\frac{4\pi\sigma_\beta d}{\epsilon_1}\sum_{-\infty}^{\infty} G(y). \tag{A.5}$$

Now

$$G(y) = \int_0^\infty \{\sqrt{(\tau^2+x^2)}-x\}\exp\{-2\pi i(y-\tfrac{1}{2})x\}dx \tag{A.6}$$

$$= \frac{\tau}{\pi i(2y-1)} + \frac{1}{\pi^2(2y-1)^2} - \frac{\tau^2}{\pi^2(2y-1)^2}\int_0^\infty \frac{\exp\{-2\pi i(y-\frac{1}{2})x\}}{(\tau^2+x^2)^{3/2}}dx,$$

integrating by parts twice. Noting that

$$\sum_{y=-\infty}^{\infty}\frac{1}{(2y-1)} = 0, \qquad \sum_{y=-\infty}^{\infty}\frac{1}{(2y-1)^2} = \frac{\pi^2}{4}$$

it follows that

$$\sum_{-\infty}^{\infty} G(y) = \frac{1}{4} - \sum_{-\infty}^{\infty} G_1(y) = \frac{1}{4} - \sum_{y=1}^{\infty}\{G_1(y)+G_1(1-y)\}, \tag{A.7}$$

where

$$G_1(y) = \frac{\tau^2}{\pi^2(2y-1)^2}\int_0^\infty \frac{\exp\{-2\pi i(y-\frac{1}{2})x\}}{(\tau^2+x^2)^{3/2}}dx$$

and so*

$$G_1(y)+G_1(1-y) = \frac{2\tau^2}{\pi^2(2y-1)^2}\int_0^\infty \frac{\cos(2y-1)\pi x}{(\tau^2+x^2)^{3/2}}dx = \frac{\pi(2y-1)}{\tau}K_1\{(2y-1)\pi\tau\}. \tag{A.8}$$

Thus, writing m instead of y, we obtain (3.14).

ELEMENTARY PROCESSES IN THE DECOMPOSITION OF OZONE

D. J. McKENNEY AND K. J. LAIDLER
The Department of Chemistry, University of Ottawa, Ottawa, Canada

Received June 2, 1961

ABSTRACT

Potential-energy surfaces are considered for the O_4 complex, treated as the three-body complex O . . . O . . . O_2. By means of these it is shown that $O(^3P)$ reacting with O_3 may give rise to a molecule of O_2 in its ground state and one in any of the states $^3\Sigma_g^-$ (ground), $^1\Delta_g$, and $^1\Sigma_g^+$; $^3\Sigma_u^+$ cannot be produced. Most of the oxygen molecules produced are expected to be in the ground electronic state, but will be vibrationally excited. Such molecules are readily deactivated and unlikely to lead to energy chains by the reaction

$$O_2^* + O_3 \rightarrow 2O_2 + O.$$

Such chains are therefore unlikely in the thermal decomposition and in that initiated by visible radiation. In ultraviolet light $O(^1D)$ atoms are produced and the potential-energy surfaces show that these give rise very efficiently to $O(^1D) + O_3 \rightarrow O_2 + O_2(^3\Sigma_u^-)$; the latter have 141 kcal in excess of the ground state. It is suggested that the subsequent radiative process

$$O_2(^3\Sigma_u^-) \rightarrow O_2(^3\Sigma_g^-) + h\nu$$

is responsible for sustaining the population of vibrationally excited oxygen molecules in the ground state and that these propagate energy chains, as postulated by McGrath and Norrish (1). The significance of these conclusions is discussed with reference to the experimental evidence.

INTRODUCTION

Recent papers (2, 3) have been concerned with the evidence for and against the existence of energy chains in the thermal and photochemical decomposition of ozone. There is general agreement that, in the thermal reaction and that brought about by visible (red) radiation, there is production of oxygen atoms in their ground (^3P) states, and that in ultraviolet light, excited (^1D) atoms are produced. An important question is whether these two types of atoms can give rise to energy chains by reacting with O_3 and producing excited oxygen molecules which can regenerate oxygen atoms by reaction with O_3. Benson (3) and McGrath and Norrish (1) have argued that the experimental evidence supports the conclusion that $O(^3P)$ atoms cannot give rise to chains, but that $O(^1D)$ atoms do; in other words, there are energy chains in the ultraviolet reaction, but not in the thermal reaction or in the reaction brought about by red light. These authors, however, have postulated quite different mechanisms for the reaction in the ultraviolet.

In the present paper we examine the question from the standpoint of potential-energy surfaces, and arrive at conclusions that are essentially the same as Benson's. It is suggested, however, that a modified McGrath and Norrish mechanism is probably correct for the ultraviolet reaction.

POTENTIAL-ENERGY SURFACES

The course of a reaction between oxygen atoms and ozone molecules may be considered with reference to the potential-energy surfaces for the O_4 system. Figure 1 shows that this requires six parameters for its complete description, but for convenience it may be considered as the three-body system O . . . O . . . O_2, and energy plotted as a function of the two distances r_1 and r_2. Such a potential-energy surface, shown as Fig. 2, may be regarded as a section through the complete seven-dimensional diagram required for a tetratomic complex, this section relating to a particular interatomic distance r' and to particular values for θ_1 and θ_2 and for the torsional angle ϕ.

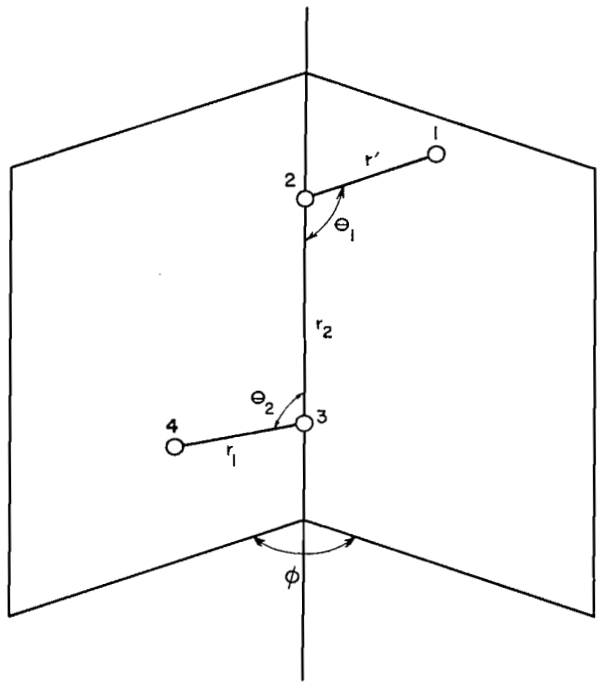

FIG. 1. The O_4 species.

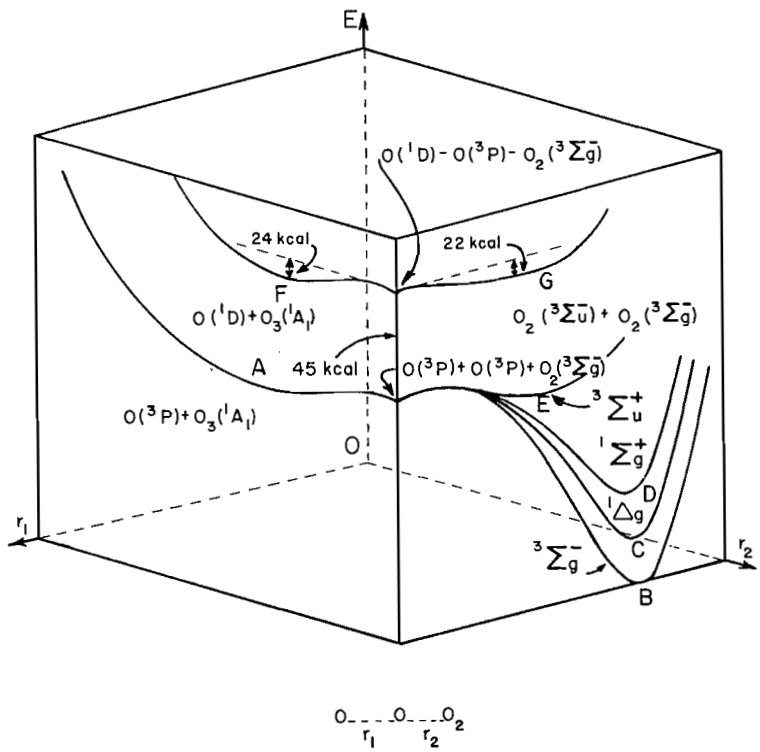

FIG. 2. Potential-energy surfaces for O_4, treated as the three-body system O . . . O . . . O_2.

Figure 2 shows two sets of curves, one for r_1 very large (i.e. for $O + O_3$) and the other for r_2 very large (for $O_2 + O_2$). These curves are connected by surfaces within the diagram, and reactions must involve motion along a potential-energy surface, possibly with a jump at a suitable crossing point.

The initial state of the reaction $O(^3P) + O_3$ is represented by point A in the diagram, and points B, C, and D represent the possible final states; experimentally (4) the activation energy is 6 kcal, so that the production of $O_2(^3\Sigma_g^-) + O_2(^3\Sigma_u^+)$ is excluded on energetic grounds since the final state E lies 8 kcal higher than the initial state. The reaction paths connecting A with B, C, and D are represented schematically in Fig. 3.

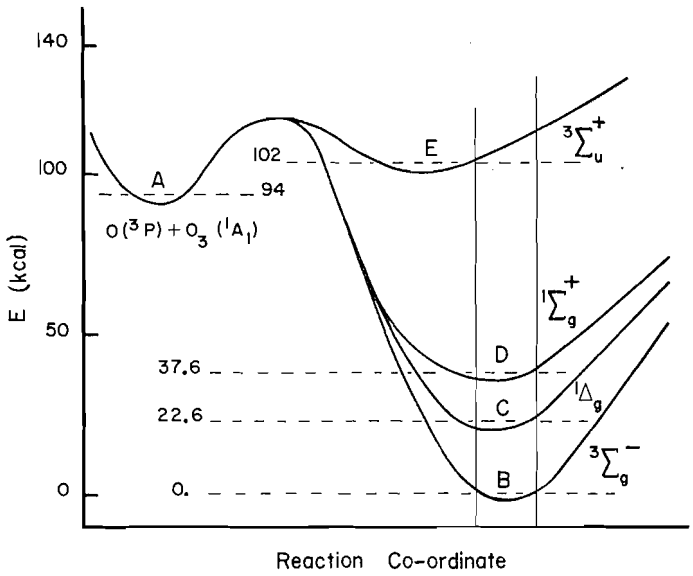

FIG. 3. Section through Fig. 2, showing the possible reaction paths.

If the splitting of the surfaces occurs after the activated state the probabilities of forming the $^3\Sigma_g^-$, $^1\Delta_g$, and $^1\Sigma_g^+$ states will be respectively 1/2, 1/3, and 1/6, corresponding to the multiplicities. (The $^1\Delta_g$ state is doubly degenerate.) It is also possible for the activated complex for the formation of $^1\Sigma_g^+$ to be higher than that for $^1\Delta_g$, which may be higher than that for $^3\Sigma_g^-$; in this case the probability of forming $O_2(^3\Sigma_g^-)$ is greater than 1/2. Most of the energy released in the reaction will therefore pass into non-electronic forms, and will be readily dissipated on collisions.

For energy chains to be set up the reaction

$$O_2^* + O_3 \rightarrow 2O_2 + O \qquad [1]$$

must occur. The ΔH for this reaction (5) is $25.7 - E_e$, where E_e is the excitation energy for the O_2 molecule, so that for the reaction to be exothermic E_e must be at least 25.7 kcal. This condition is only satisfied by the $^1\Sigma_g^+$ state or by the lower ($^1\Delta_g$ and $^3\Sigma_g^-$) states if they have sufficient vibrational energy. Since, however, the $^1\Sigma_g^+$ state is formed with, at the most, a probability of 1/6, and vibrational energy is readily dissipated, it is clear that the formation of oxygen atoms by reaction [1] will occur only with low efficiency. Energy chains cannot, therefore, be of any importance when $O(^3P)$ atoms are involved, i.e. in the thermal decomposition and in the photochemical decomposition induced by visible radiation.

Point F in Fig. 2 represents the system $O(^1D) + O_3$; it is connected by a surface to the curve passing through G and corresponding to the formation of $O_2(^3\Sigma_g^-) + O_2^*(^3\Sigma_u^-)$. The latter species has an energy of 141 kcal in excess of the ground state. Schumacher (2) has pointed out, as evident from Fig. 2 also, that this reaction is endothermic, the difference in energy between the initial and the final state being 2 kcal. One would expect, therefore, that this reaction should have an appreciable activation energy. Benson (3) has answered this objection by taking into account the fact that the O atoms can have excess translational energies, which are dissipated relatively slowly, and hence the production of $O_2^*(^3\Sigma_u^-)$ molecules can be quite fast at high O_3 concentrations. The nature of the surface does not permit the formation of the second molecule of oxygen in any lower excited state, except with very low probability. The highly excited $^3\Sigma_u^-$ molecules have a short life of 2.5×10^{-9} second (6) due to the radiative process $O_2(^3\Sigma_u^-) \rightarrow O_2(^3\Sigma_g^-) + h\nu$, which gives rise to the Schumann–Runge emission bands of O_2. The ground-state oxygen molecules produced by this process will, according to the Frank–Condon principle, give vibrationally excited O_2 molecules in exactly those levels observed in the ozone photolysis by McGrath and Norrish. This can be readily seen by reference to Fig. 4.

It is perhaps significant that these workers (8) observed a maximum value around $v'' = 13$ (53.5 kcal/mole) in the vibrational energy distribution. There is no explanation for this maximum given in their paper, and one would expect that if vibrationally excited O_2 molecules were produced solely by the endothermic process

$$O(^1D) + O_3(^1A) \rightarrow O_2^*(^3\Sigma_g^-) + O_2(^3\Sigma_g^-),$$

the population of these vibrational levels should be a maximum at the lower energy levels. The fact that there is a maximum at $v'' = 13$, however, strongly suggests that the population of these vibrational energy levels is a result of the process

$$O_2(^3\Sigma_u^-) \rightarrow O_2^*(^3\Sigma_g^-) + h\nu.$$

As can be seen from Fig. 4, the transition from the minimum of the $^3\Sigma_u^-$ state would produce O_2 molecules in the ground state ($^3\Sigma_g^-$) in roughly the 12th or 13th vibrational level. This should then be a maximum, as is the case. The radiation given off in the process is of very short wavelength (2000 Å) (2) and consequently would be absorbed by undecomposed ozone.

DISCUSSION

The above conclusions are consistent with the experimental results of the aforementioned authors. Some specific remarks about the decomposition mechanism may now be made.

McGrath and Norrish (1, 8) flash photolyzed, using ultraviolet radiation, a mixture of O_3, H_2O, and N_2 in the ratio 1:3:100, and obtained strong OH absorption. This is attributed to the occurrence of the exothermic reaction

$$O(^1D) + H_2O \rightarrow 2OH + 29.2 \text{ kcal.}$$

Hydroxyl radicals could not be obtained with $O(^3P)$ atoms, owing to the endothermicity of the reaction

$$O(^3P) + H_2O \rightarrow 2OH - 16.8 \text{ kcal.}$$

In agreement with this the addition of water has little or no effect on the thermal decomposition of ozone (3, 9).

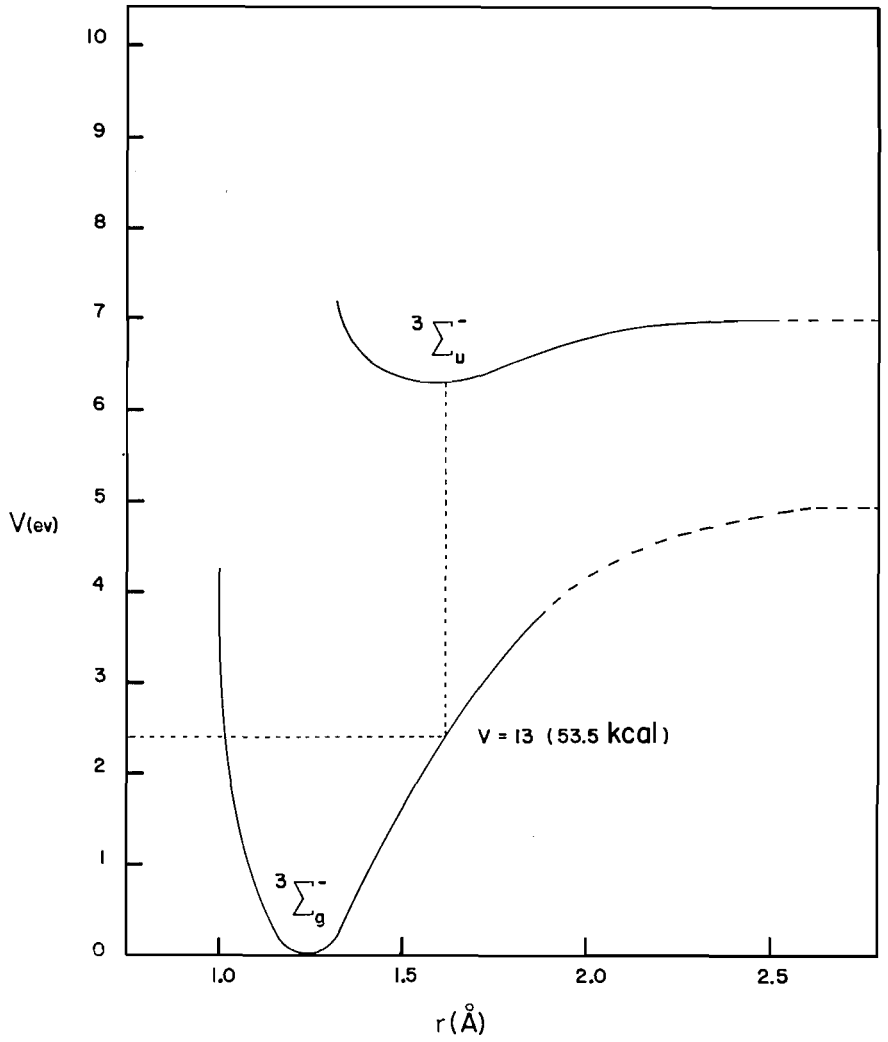

FIG. 4. Potential-energy curves (7) for the O_2 molecule, showing that a maximum in the vibrational energy distribution is expected for $v = 13$ for $^3\Sigma_u^- \rightarrow {}^3\Sigma_g^-$.

The most likely mechanism for the thermal decomposition of ozone (where only $O(^3P)$ atoms can be produced) is that of Benson and Axworthy (10), which is

$$O_3 + M \rightleftarrows O + O_2 + M \quad [2]$$

$$O + O_3 \rightarrow 2O_2. \quad [3]$$

At the ordinary pressures the first reaction will be in its second-order region (11). The probability of forming electronically excited $O_2(^1\Sigma_g^+)$ is very low, as was pointed out above, and therefore the possibility of energy chains in the thermal reaction is excluded. If, however, energy chains were involved, the following reactions would have to be added:

$$O + O_3 \rightarrow O_2 + O_2^* \quad [4]$$

$$O_2^* + O_3 \rightarrow 2O_2 + O, \quad [5]$$

but Benson and Axworthy (4, 10) showed that this led to a kinetic scheme which is inconsistent with experiment.

Similar comments apply to the work with visible radiation, which produces $O(^3P)$ atoms. The quantum yields are probably (3) always less than 2, so that there is no evidence for energy chains.

The most probable mechanism in ultraviolet light involves as the initiating step

$$O_3 + h\nu \rightarrow O_2 \text{ (singlet)} + O(^1D). \quad [6]$$

The oxygen molecules must be in a singlet state for spin conservation; it may be the $^1\Sigma_g^+$ state, which requires that the wavelength is less than 3100 Å. Reaction [6] will be followed by

$$O(^1D) + O_3 \rightarrow O_2(^3\Sigma_g^-) + O_2(^3\Sigma_u^-), \quad [7]$$

as discussed above, and this is followed by the rapid transition

$$O_2(^3\Sigma_u^-) \rightarrow O_2^*(^3\Sigma_g^-) + h\nu. \quad [8]$$

The propagation of the chain then takes place by the vibrationally excited $O_2^*(^3\Sigma_g^-)$ molecules of excitation energy > 69 kcal reacting with ozone, i.e.,

$$O_2^*(^3\Sigma_g^-) + O_3(^1A) \rightarrow 2O_2(^3\Sigma_g^-) + O(^1D). \quad [9]$$

The latter reaction is the essential feature in the McGrath and Norrish mechanism. The termination steps are probably

$$\begin{aligned} O + O + M &\rightarrow O_2 + M \\ O + O_2 + M &\rightarrow O_3 + M \\ O_2^* + M &\rightarrow O_2 + M, \end{aligned} \quad [10]$$

where M represents a molecule of oxygen, ozone, or an inert gas.

HIGH-PRECISION VOLUME TITRIMETRY

G. A. DEAN[1]
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia
Received July 31, 1961

ABSTRACT

Ways in which the ultimate limit of volume titrimetry may be reached are analyzed: the most suitable approach, based essentially upon the use of a bulb burette, allows, in theory, a mechanical precision better than that of the best weight techniques to be obtained, and the various factors influencing this precision are detailed. Several end-point systems potentially sensitive to considerably better than 1 part per million (p.p.m.) are discussed. An attempt at high precision with the iron(II)/dichromate titration, using refined equipment and an amperometric end point, is described: the observed precision was 0.7–1.1 p.p.m. for two experiments of about eight titrations each; the calculated precision, estimated from the resultant of the component precisions, was about 0.9 p.p.m. The ultimate limit of precision of any titrimetric operation, whether by weight or by volume, is shown to be about 0.1 p.p.m.

INTRODUCTION

Accounts of attempts to use titrimetric apparatus at the limit of their precision have appeared fairly frequently over the past 50 years. One of the most recent is that of Bishop (1), who has determined the attainable limits of weight titrimetry using refined apparatus and techniques: under the most favorable circumstances, and by working under "atomic weight" conditions, the highest precision obtained by him was ±13 parts per million (p.p.m.) for five titrations of arsenious oxide with potassium bromate. The overall mechanical precision was shown to be about ±2 p.p.m.; consequently, the greater part of the previous value would appear to be due to uncertainty in the location of the (graphical potentiometric) end point. This view is corroborated by reference to the work of Richards and Forbes (2), who, in their classic atomic-weight experiments involving the conversion of silver to silver nitrate, obtained a precision for the ratio $Ag:AgNO_3$ of ±2.7 p.p.m. in six determinations, or about the same as the estimated overall precision of the weighings. An interesting combination of techniques was used by Baxter and Hale for their determination of the atomic weight of iodine (3): weighed amounts of iodine pentoxide and sodium carbonate were allowed to react in solution and the neutralization completed volumetrically using bromothymol blue as indicator. The indicator exhibited a complete color change over the range 10 p.p.m., and an overall precision of ±13 p.p.m. for seven determinations was attained.

The attainable limits of volume titrimetry using conventional apparatus have been determined (4–7); minor changes in the apparatus allow improvements to be made, as exemplified by refs. 5 and 8; the present work discusses ways in which the ultimate limit may be reached and describes an attempt to reach this limit with refined equipment.

In the following account it is understood that the levels of precision being considered are often considerably better than the accuracy and consequently may be of diminished value. Aspects of accuracy have been fully discussed by Bishop (1) and will not be considered here.

PRECISION OF VOLUME TITRIMETRY

The ultimate precision of any titration is limited by the precision of the mechanical measurements and by the sensitivity of the end point. For the purpose of the present

[1]*National Research Council of Canada Postdoctorate Fellow, 1959–61. Present address: Soil Bureau, P.O. Box 8001, Wellington, New Zealand.*

work the system to be considered is that of a simple titration of one reagent with another. For maximum precision, 50 ml and 0.1 *N* are adopted as the nominal optimum volume and concentration, respectively, of each reagent. In the following account all values of precision are expressed as a standard deviation.

Mechanical Limit of Volumetric Measurements—Pipettes

A constant temperature is an inherent requirement of any precise volumetric operation. This means that, in practice, the volumetric apparatus has to be immersed in a liquid bath suitably thermostatted. Because of this immersion, and because the degree of temperature control required (see later) and the need for preventing evaporation prohibit the transfer of liquid in the usual manner, a conventional pipette is unsuitable and something akin to a burette must be used.

Mechanical Limit of Volumetric Measurements—Burettes

Other things being equal, the precision of a burette is a function of the tube diameter (5). Bulb or chamber burettes, in which the capacity is divided between a bulb and a finely divided graduated section, are often used to secure a moderate increase in precision at the expense of a restriction in range, and the carrying through of this principle to its logical conclusion allows the ultimate in precision to be obtained.*

The various factors influencing the precision of a burette have received detailed attention (5). Given adequate control of temperature and pressure, the mechanical precision of a bulb burette will be limited only by

(1) precision of the initial setting,
(2) precision of the volume of liquid remaining on the walls after delivery (the wall film),
(3) precision of the drainage,
(4) precision of the final setting.

To achieve maximum precision of the initial setting, the top of the bulb can be fitted either with a short graduated section, when similar considerations as for (4) would apply (see below), or with an "automatic zero". Of the various types of automatic zero currently in use, one similar to that shown in Fig. 1 is to be preferred. The internal diameter of the inner tip may be made as fine as required, since it is not subject to the same limitations as a graduated section (see below), and consequently the variability of the automatic zero may be rendered negligible. This factor, together with the automatic zero's positive, convenient, and unambiguous operation, renders it indispensable for precise work.

The variability of the wall film should not be a significant factor provided that the burette is not exposed to vibration (6). Unfortunately, the outflow rates for delivery from the bulb and from the graduated section, as determined by consideration of (2) and (3), see below, are not the same; hence provision must be made for changing the rate of outflow as the meniscus passes from the bulb to the graduated section. The decrease in the wall film owing to the decreased rate of delivery while setting to the mark, and the effect of this upon the overall precision, may be rendered negligible by an adequately long delivery time.

**Syringe burettes, in which the movement of a piston inside a precision-bore tube is controlled by a micrometer head, have found increasing use over the past few years (4, 9). However, apart from the difficulty of thermostatting such a burette, purely mechanical considerations preclude its use here. For example, the typical minimum division of a good micrometer head is 0.001 cm; assuming that 0.1 of this division is to be equivalent to, say, 0.00001 ml, then the maximum syringe diameter is about 0.3 cm, and would require a length of 5 m to contain a 50-ml volume. Conversely, a syringe 10 cm in length and 5 cm² in cross section would require a micrometer head sensitive to 20 mμ. Clearly, syringe burettes are impractical for high-precision work.*

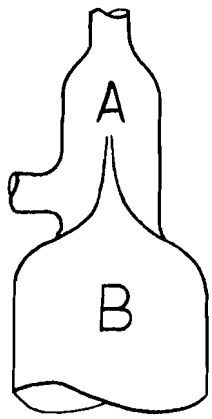

FIG. 1. Automatic zero. With B filled, the level in A is allowed to rise above the inner tip. The zero is then set by withdrawing liquid through the side arm until the level has fallen below that of the inner tip.

The influence of drainage over the time required for a titration may be prevented by an adequately long delivery time (6).

The variability of the final setting may, in theory, be made smaller indefinitely by reducing the internal diameter of the graduated section (5). In practice, however, there is a lower limit of between 0.5 and 1.0 mm, depending on the design of the burette, below which the outflow time becomes inconveniently long.

Consequently, of the four contributing precisions, the last is likely to set the overall limit. Using the results of Dean and Herringshaw (5), and the most accurate setting that can be expected with small tubes (i.e., between settings 1 and 2 of ref. 5), values of (4)

TABLE I

Calculated precision of the final setting

Bore of graduated section (mm)	Calculated precision of setting (ml)	Precision referred to 50 ml (p.p.m.)
1.25	0.00002	0.4
1.00	0.00001	0.2
0.75	0.000004	0.08
0.50	0.0000015	0.03

can be calculated, and are presented in Table I. By comparison, it is unlikely that a weight burette plus 50 g of liquid could be weighed *reliably* to better than ± 5 μg, or to about ± 0.1 p.p.m. (1).

Limiting Sensitivity of the End Point

Hitherto, the sensitivity of the end point has proved to be the limiting factor in the quest for high precision (see, e.g., ref. 1). As the sensitivity of the end point is largely subjective it is not possible to quote exact values; Table II summarizes some values for sensitive end points which have been reported in precise work. While even the best values of Table II are still approximately two orders of magnitude greater than the practical limit of mechanical precision, it is possible to achieve considerably better sensitivity by careful selection of the reagents and method. Two such methods are outlined in Table III

TABLE II

Observed sensitivity of some sensitive end points

Method of locating end point	Titration	Sensitivity* (p.p.m.)	Ref.
Visual	Oxalate/permanganate	100	10
	Fe(II)/dichromate/barium diphenylamine sulphonic acid	200	11
	Iodine/thiosulphate/starch	20	12
	Borax/hydrochloric acid	260	1
	Ferrocyanide/Ce(IV)/Victoria Green	240	7
	$As_2O_3/KBrO_3$	180	1
Photometric	Borax/hydrochloric acid	50	1
	Ferrocyanide/Ce(IV)/Victoria Green	80	7
	$As_2O_3/KBrO_3$	30	1
Graphical potentiometric	$As_2O_3/KBrO_3$	15	1
	$KBr/AgNO_3$	30	1
	$KI/KMnO_4$	50	13

*For titrations involving 50 ml of 0.1 *N* reagent, or equivalent, except for borax/hydrochloric acid (0.5 *N*).

TABLE III

Calculated sensitivity of two sensitive methods of detection

Method	Reagent	Minimum detectable change in concentration, $N \times 10^8$	Minimum detectable change in concentration, referred to 0.1 *N* (p.p.m.)
Spectrophotometric	$KMnO_4$	100*	10
	Ce(IV)	8*	0.8
	Iodine	4*	0.4
Amperometric ("dead-stop")	Fe(II)	0.1†	0.01
	Ce(IV)	~0.1‡	~0.01
	Iodine	~0.01‡	~0.001
	Bromine	0.5§	0.05

*The minimum detectable change in concentration, ΔN, was calculated from $\Delta N = \Delta d/\epsilon l$, where Δd = minimum detectable change in optical density = 0.002; l = path length ~ 4–5 cm; and ϵ = *normal* extinction coefficient = 450 at 520 mμ (14), 5,000 at 320 mμ (15), and 13,000 at 353 mμ (16) for $KMnO_4$, Ce(IV), and iodine, respectively.

†Experiments involving [Fe(II)] from 0.1 *N* to 0.0002 *N* in both macro- and micro-titrations, and with various amperometric pairs, have shown that in solutions *N* to sulphuric acid and 0.5 *M* to orthophosphoric acid the change in [Fe(II)] required to produce a change in current of 1 μa/cm² of electrode area (based on one electrode, both electrodes equal) under an applied potential difference of 300 mv is fairly constant at 2×10^{-6} *N*. The minimum detectable change in concentration was calculated by assuming electrodes each 1 cm² in area, a galvanometer of f.s.d. = 0.1 μa, and a minimum reliable change in deflection of 1% f.s.d., or about 0.001 μa. (Even this value can be exceeded by at least one order of magnitude by the sensitivity of some commercially available instruments (see, e.g., ref. 17).) Note that, for Fe(II), and under similar conditions of electrode area and galvanometer sensitivity, the method is more sensitive than the "sensitive end point procedure" of Cooke, Reilley, and Furman (18).

‡Estimated from the value for Fe(II) by comparison with the results of Stone and Scholten (19).

§From the results of Sease *et al.* (20) and corrected to the same conditions as for Fe(II).

and show that, in favorable cases, and provided that the conditions are carefully chosen to enable the full sensitivity to be realized, the limiting sensitivity of the end point can be made to equal or even exceed the limiting mechanical precision.

AN ATTEMPT AT HIGH PRECISION WITH THE IRON(II)/DICHROMATE TITRATION USING AN AMPEROMETRIC END POINT

The iron(II)/dichromate titration was chosen because the exceptionally low background and completeness of reaction at the end point allow the full sensitivity of the amperometric end point to be realized. The basis of the apparatus was a pair of 50-ml bulb burettes

with a 0.5-ml graduated section, designed in accordance with the previous considerations, and made of Kimble KG 33 borosilicate glass to special order by Ace Glass Inc., Vineland, New Jersey. The completed apparatus is shown diagrammatically in Fig. 2. It was situated in a basement laboratory, free from vibration and excessive variation in temperature.

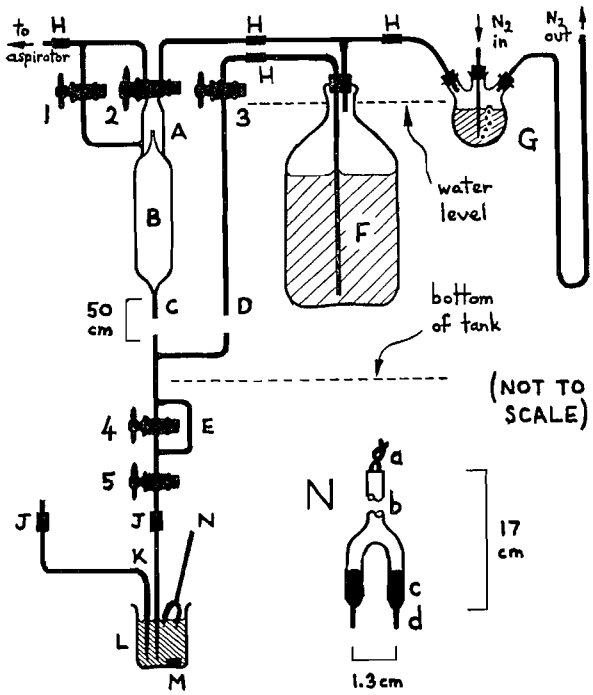

FIG. 2. Apparatus for high-precision volume titrimetry.

1–5 = Kimble stopcocks with Teflon plugs (For clarity, stopcocks 1–3, and E, have been turned through 90°; 4 and 5 through 180°, about the vertical; 4 and 5 are of 1-mm bore.)
A = automatic zero (see Fig. 1)
B = bulb, ~50 ml
C = graduated stem, 0.5 ml in 0.001-ml divisions, of precision-bore capillary tubing
D = side arm of 2-mm capillary tubing
E = capillary bypass: a slower rate of delivery is obtained by closing tap 4
F = 9-liter "serum" bottle of Pyrex glass
G = source of nitrogen at atmospheric pressure (used with the F-burette only) (The 250-ml 3-necked flask contains a solution of Fe(II) similar to that in F. The long U-tube of 7-mm tubing (capacity ~20 ml) guards against momentary overloads.)
H = silicone-rubber connections secured with tubing clamps (not shown)
J = 0.25-in. wall Tygon connections secured with tubing clamps (not shown)
K = 1-mm capillary tubing with finely drawn-out tip
L = 150-ml beaker
M = Teflon-sheathed stirring bar
N = amperometric pair: *a*, insulated solid copper wire; *b*, 7-mm soft-glass tubing; *c*, mercury; *d*, ~0.5-mm platinum wire.

(The D-burette etc. (not shown) are identical with the F-burette etc., except for the omission of G.)

EXPERIMENTAL

Temperature Control

A volume precision of 0.1 p.p.m. requires that a temperature constant to 0.0005° be maintained. To avoid the considerable difficulty of thermostatting to this level directly, a "tandem" arrangement was used: the whole apparatus was immersed in a large tank fitted with a Perspex window and filled with distilled water stirred slowly at constant speed, and this was immersed, in turn, in a larger tank also filled with distilled water and fitted with a similar window. Both tanks were equipped with covers.

The larger tank was thermostatted at 23° (about 1° higher than the maximum annual laboratory temperature) to ±0.005° (measured in the least favorable position between the Perspex windows) using a powerful

stirrer and a 500-watt immersion heater controlled by a "Red Top" mercurial thermoregulator via an electronic relay, with a minimum heating cycle of 1 minute. When a temperature difference of 1° was artificially maintained between the two tanks, the inner tank varied by about 0.03° per minute; consequently, the inner tank should be constant to $\pm 0.03 \times 0.005° = 0.00015°$. The total volume of water involved was just over 0.5 m^3, to which a few grams of thymol were added to prevent marine growths.

The lower burette taps protruded from the bottom of the tank: the exposed "dead space" was kept to a minimum (about 0.3 ml) to minimize the effect of any changes in room temperature. Owing to the difference in length between the two burette tips (Fig. 2) there was a difference in dead space of about 0.15 ml; during a titration, the observed change in temperature near the burette tips was never more than 0.2°, corresponding to a maximum difference of 0.000005 ml with respect to 0.15 ml. The difference in thermal expansion between the two reagents (see later), and referred to the remaining dead space, would tend to reduce this figure.

The burettes were viewed through the Perspex windows, and the upper taps manipulated by rods passing through seals in the windows. It was intended that the inner tank should be completely immersed, but owing to the failure of some of the seals the tanks could be filled only to the level shown in Fig. 2, and consequently the inner tank was not completely isolated from changes in room temperature. Fortunately, owing to the favorable location of the tank, room-temperature fluctuations were very small: short-term fluctuations in the inner tank could not be detected with an E-Mil GS 10300 Differential Thermometer (Beckmann type), minimum division 0.002°, and any temperature drift was never more than 0.001° per hour.

Stopcocks

Kimble stopcocks with Teflon plugs were used in preference to conventional stopcocks in order to avoid the use of grease. Taps 3 and 5 (Fig. 2), in particular, were required to be exceptionally leakproof, and those finally supplied* had to be very tight before a satisfactory performance was achieved: under these conditions their operation remained smooth, but the lockwashers were ineffective and the threads were in danger of stripping. However, by rotating the plug in one direction only, or by manipulating with both hands, a satisfactory performance was achieved. Under constant temperature conditions, the tendency to stick, which is often encountered with these stopcocks (due to the grossly dissimilar thermal expansion coefficients of glass and Teflon), was never observed. A small incision with a razor blade was made at right angles to the plug axis across the ends of the hole in the plug of tap 5; this allowed very fine control of the delivery.

Preparation of the Apparatus

The whole apparatus was cleaned with permanganic–sulphuric acid cleaning mixture (prepared by adding powdered potassium permanganate to concentrated sulphuric acid, with stirring, until the solution is deep green in color; the preparation and use of this solution is without hazard) followed by thorough rinsing with dilute acidified hydrogen peroxide to remove any traces of manganese dioxide, and then with water redistilled from dilute alkaline permanganate in an all-Pyrex-glass still fitted with splash guards; the bottles and connecting tubes were then steamed with steam evolved from boiling dilute alkaline permanganate. The rubber bungs and silicone–rubber connections were cleaned by immersion in boiling 3 *N* aqueous sodium hydroxide for two 1-hour periods followed by thorough rinsing in distilled water.

After conditioning the assembled apparatus for 1 month with the appropriate reagents, it was again thoroughly cleaned, as before. Finally, the bottles were filled with freshly redistilled water and the appropriate reagents added to approximately 0.1 *N* strength. After reassembly, the apparatus was allowed to condition itself for 8 weeks before the titrations of Table IV were performed.

Reagents

It was observed that solutions of reagent-grade potassium dichromate, of various manufacture, in redistilled water and contained in bottles treated as previously, had a strong tendency to become "greasy", as shown by incomplete wetting of the walls. On recrystallizing the dichromate four times from redistilled water according to the recommended procedure (21) it no longer showed this tendency, even on allowing the solution to stand for 3 months; consequently, such recrystallized dichromate was used.

Reagent-grade ferrous sulphate and sulphuric acid were found to be satisfactory with respect to "greasiness" and were used without further purification. However, the former (like most solid reagents) was found to contain minute quantities of dust and foreign matter, and a concentrated solution in dilute sulphuric acid was filtered through sintered glass and used for the preparation of the final solution. This final solution was deoxygenated by bubbling nitrogen through it for 7 days and was subsequently stored under nitrogen, as shown in Fig. 2.

"Titration acid" was prepared by adding 100 ml of reagent-grade concentrated sulphuric acid to 100 ml of reagent-grade orthophosphoric acid and 200 ml of redistilled water. Ten milliliters of titration acid per titration produced a better end point than 5 ml, while 20 ml produced little improvement over 10 ml; therefore 10 ml was used per titration, giving at the end point $[H_2SO_4] \sim 0.9$ *N* and $[H_3PO_4] \sim 0.45$ *M*.

**Messrs. Ace Glass Inc. reported having great difficulty in finding specimens of the required standard.*

Amperometric Apparatus

An amperometric "pair" (N, Fig. 2) was constructed of smooth platinum wire ~0.5 mm in diameter, sealed in soft glass, with ~0.7 cm or ~0.1 cm^2 exposed. The latter was deliberately small to avoid significant oxidation of iron(II) by the oxide film (22). A potential difference of 300 mv was applied across the pair by the circuit shown in Fig. 3. The pair was normally left exposed to the atmosphere (no improvement

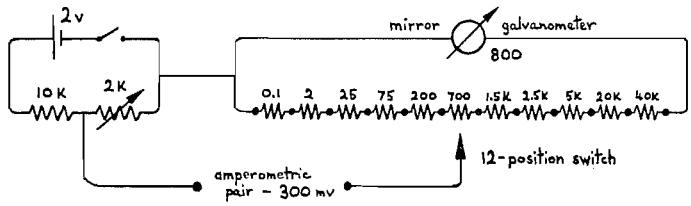

FIG. 3. Amperometric circuit. Resistances in ohms; total shunt resistance = 70 K = critical damping resistance of the Leeds and Northrup mirror-galvanometer type 2285f.

was noted on storing in water) except in between titrations, when the platinum was immersed in chromic–sulphuric acid cleaning mixture (prepared by grinding concentrated sulphuric acid with an excess of anhydrous chromium trioxide) in order to maintain a sensitive response.

A Leeds and Northrup mirror-galvanometer type 2285f (maximum sensitivity 0.025 μa for full-scale deflection (f.s.d.) = 50 cm) was used in conjunction with a special shunt (Fig. 3), similar in principle to that used by Cooke, Reilley, and Furman (15), constructed from high-stability resistors and which presented a constant resistance to the galvanometer independent of the sensitivity. The galvanometer was carefully checked for linearity by replacing the pair with a resistor and measuring the potential difference with a Beckmann model GS pH meter sensitive to 0.1% f.s.d.

At the fairly slow stirring rates required to avoid loss of solution through splashing, the limiting current (9) is not attained, and a constant rate of stirring is essential if steady currents are to be obtained. Ordinary variable-speed magnetic stirrers were found to exhibit random (and sometimes very pronounced) fluctuations in speed, and so a specially constructed synchronous magnetic stirrer was used together with a small Teflon-sheathed stirring bar.

Diffusion of reagent from the very fine, drawn-out capillary tips of the burettes could not be detected over the period required for the determination of the end point.

Reading the Burette

The graduated section was of Ace Glass "Trubore" precision-bore capillary tubing, about 0.12 cm in internal diameter (manufacturers tolerance ±0.002 cm), and 8 mm in external diameter. (Since the outcome of the experiments could not be anticipated, the higher potential precision afforded by the use of a smaller-diameter tube was sacrificed for the sake of a greater range in delivery.)

The minimum division was 0.001 ml and occupied ~1 mm. All graduations were deliberately confined to the front. To avoid parallax, a strip of "Vitrolite" (milk-white glass) carrying similar graduations was placed behind the tube at such a distance (~4 cm) that the situation depicted in Fig. 4A was obtained. In accurate work, the need for making all readings at a mark has been described (5). However, if the meniscus was inadvertently stopped between graduations, or if the setting was not exact, then an exact reading using an "optical-lever" vernier could be obtained: the eye was moved until the meniscus and the graduation were brought into the required relationship, when the correct position could be read off from the graduated backing, as illustrated in Fig. 4B. The method was sensitive to 0.01 of the minimum division, i.e., to 0.00001 ml, which corresponds well with the value previously calculated (Table I) despite the absence of a suitable background (which could not be provided owing to the immersion of the burettes).

Initial Adjustment of Concentration

Because of the restricted range of the burettes, the concentrations of the solutions had to be adjusted to suit: a solution could easily be concentrated without dismantling any part of the apparatus by blowing dry nitrogen through the solution via the tip of the burette. Minute bubbles of air or nitrogen that remained subsequently in the capillary network were easily removed by connecting an aspirator to the burette tip and manipulating the appropriate stopcocks. By this means a solution could be concentrated by up to 0.1% per hour. The final concentrations of reagents were: $K_2Cr_2O_7$, 0.101 *N*; $FeSO_4$, 0.100 *N* in 0.48 *N* H_2SO_4.

Titration Procedure

In the following account, the burette containing ferrous iron or dichromate is designated as the F-burette or D-burette, respectively.

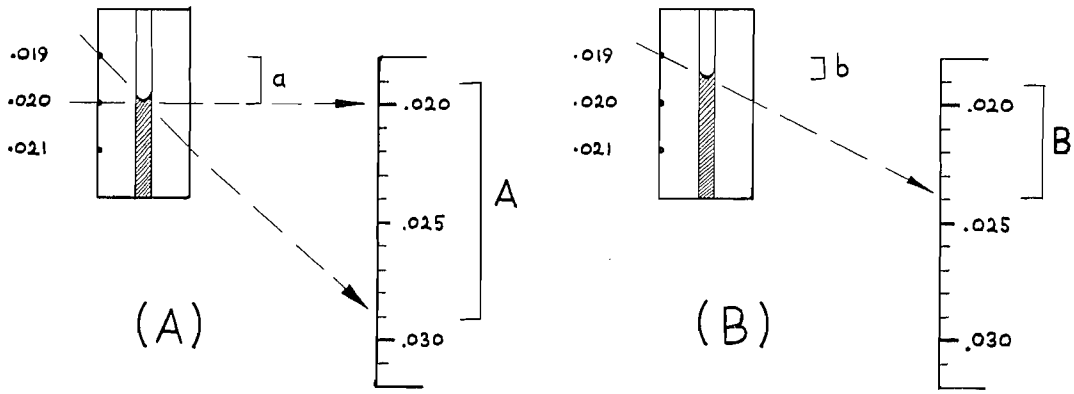

FIG. 4. Burette reading by "optical-lever" vernier.

(A) Correct relationship between burette scale and backing scale with the meniscus on a mark (the diagram is *not to scale*).

(B) Determination of reading when the meniscus is between marks. For the example shown, reading = 0.019 $+b$. Since $b/a = b/0.001 = B/A = (0.0238-0.019)/(0.029-0.019) = 0.0048/0.01$, or $b = 0.00048$, reading = 0.01948.

Both burettes were filled simultaneously, as follows: taps 1, 4, and 5 were closed, 3 was opened, 2 turned to connect A with the aspirator, and solution allowed to flow in until the inner tip of the automatic zero was covered. (A slow rate of filling was maintained to ensure that the heating due to kinetic effects (5) was negligible.) Tap 2 was then closed, 4 and 5 were opened, and a few milliliters of solution allowed to flow out, when 5 and 3 were closed and the outside of the tips rinsed with water. The beaker and stirring bar were placed in position and 2 turned to connect A with G. Tap 1 of the D-burette was manipulated until the level in the automatic zero had fallen well below that of the inner tip and was then closed. Finally, tap 5 of the D-burette was opened and the burette allowed to deliver.

After about three quarters of the volume had been delivered, as measured by a mark on the bulb, 10 ml of titration acid was added from a 10-ml graduated cylinder (the close timing involved did not permit a pipette to be used), and the stirrer started. The zero on the F-burette was adjusted, and the burette allowed to deliver as for the D-burette. When the meniscus in the D-burette reached a mark on the lower shoulder of the bulb, tap 4 was closed, and delivery allowed to continue at the slower rate until the meniscus entered the graduated section, when it was adjusted to the zero by manipulating tap 5. The amperometric pair was then thoroughly rinsed in running distilled water and placed in the solution. The F-burette was treated similarly to the D-burette, except that delivery was continued to the end point.

Very near the end point the reaction was somewhat slow, and at least 1 minute was allowed after each addition before the current was recorded. The maximum galvanometer sensitivity that could be used was $\sim$0.2 μa/f.s.d. or about one tenth of its maximum sensitivity. Some typical end points are given in Fig. 5.

RESULTS

Titrations without Temperature Control

To investigate the importance of temperature control, initial titrations were made *without* thermostatic control or water in the tanks. In two separate experiments of five and seven titrations each, in which the air temperature around the burettes increased by about 1° over 3 hours, the net titer increased by about 0.005 ± 0.001 ml/deg. (A decrease of a few seconds in the delivery time was also observed, but was too small to be significant here; the burettes were too similar for differences in volume to be significant: D-bulb, volume = 50.38 ml, F-bulb, volume = 50.25 ml.) Although the figure for this increase may be somewhat misleading, since the temperatures of the *solutions* were not determined, it compares fairly well with the value 0.003 ml/deg calculated on the basis of the difference in thermal expansion between water and 0.5 N sulphuric acid (23), and emphasizes the appreciable magnitude of this effect, which seldom receives consideration in volumetric work (24).

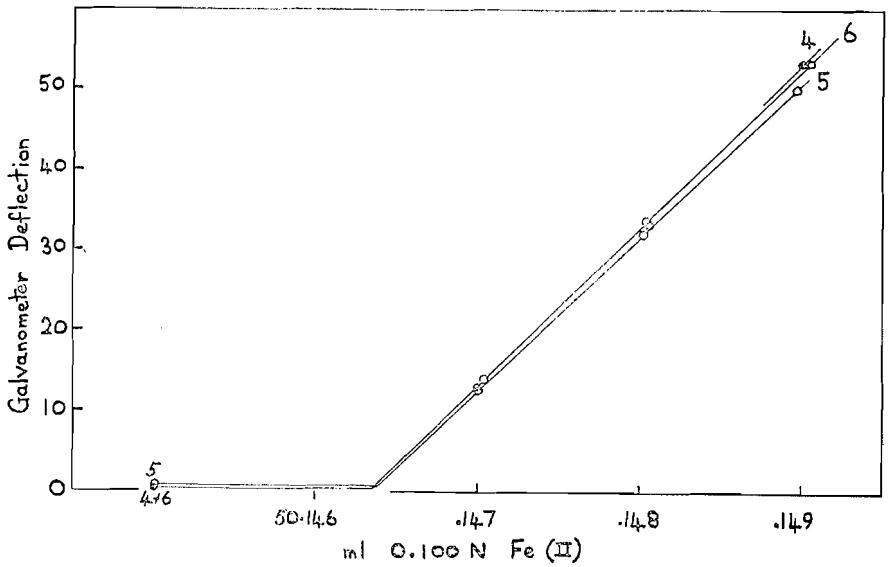

FIG. 5. Typical amperometric end points (titer uncorrected and f.s.d. = 0.18 μa). The values are taken from run II: 4, 50.14638 ml; 5, 50.14639 ml; 6, 50.14636 ml.

Air Oxidation of the Iron(II)

Owing to the presence of a few percent of oxygen in the nitrogen used (but which was not discovered until after the experiments had been completed), very gradual oxidation of the ferrous sulphate was observed. Over a period of 3 weeks, which included the titrations of Table IV, the rate of oxidation (calculated from the variation in titer from day to day) was constant and was equivalent to an increase in titer of 0.0000805 ±0.0000015 ml per hour, or about 0.0038% per day. (A value of 0.15% per day was observed without the use of nitrogen.)

As each titration occupied about 25 minutes, the overall change in titer over a series of titrations was significant; however, by recording the time at which each titration took place, and using the above value for the rate of oxidation, an accurate correction was easily made. This correction has been made for all titrations carried out in any one run. No correction has been made for the change in titer *between* runs.

Observed Precision

With the burettes properly thermostatted, and observing all precautions, the results given in Table IV were obtained. For some reason, possibly through evaporation within the body of the stopcock or at the silicone–rubber connections, the first few titrations were always considerably different (±20 p.p.m. average) from later ones, and consequently these have been omitted from Table IV. Three titrations with abnormal delivery times have also been omitted from Table IV. The results of Table IV show that a precision of about 1 p.p.m. for eight to nine titrations has been achieved, with a maximum precision of 0.7 p.p.m. for eight titrations (run II).

Calculated Precision

Some of the contributions to the overall precision have been evaluated previously. The remainder are detailed below, and the whole summarized in Table V.

TABLE IV

Observed precision of the iron(II)/dichromate titration using the apparatus of Fig. 2

	Run I (23.6.61)		Run II (30.6.61)		Run III (8.7.61)	
	Expt.	Titer	Expt.	Titer	Expt.	Titer
	4	50.13243	3	50.14676	4	50.16295
	5	41	4	71	5	86
	6	56	5	66	6	83
	7	55	6	61	8	92
			7	70	9	84
	(Without using "optical-lever" vernier)		8	69	10	80
			9	65	11	78
			11	62	13	89
			12	67	14	81
Mean		50.132488		50.146674		50.162853
Precision (ml)		0.000078		0.000047*		0.000057*
Precision (p.p.m.)		1.6		0.9		1.1
No. of titrations		4		9		9

*If the first result is omitted the precision is 0.000033 ml (0.7 p.p.m.) and 0.000047 ml (0.9 p.p.m.) for runs II and III, respectively.

TABLE V

Individual contributions to the overall precision

Source of error	Precision (ml)	Remarks
Imperfect graduation	0.00000	Assumed
Non-uniformity of bore	00	Assumed
Automatic zero (diameter of inner tip = 0.5 mm)	00	From Table I
Setting to mark, D-burette	01	From p. 551
Uncertainty in graphical location of end point	02	—
Titration-acid blank	015	From p. 555
Variability of wall film	~03	From p. 554
Fluctuations of temperature:		
inside tank	<01	<0.0005°
outside tank	<005	From p. 550
Leakage of taps	<01	Over 5 minutes
Air oxidation correction	<01	—
Total precision (ml)	~0.000045	
Total precision (p.p.m.)	~0.9	

NOTE: Owing to the compressibility of water, a change of only 1 mm in atmospheric pressure alters the volume by 0.06 p.p.m. (26). Fortunately, if the change is assumed to affect both solutions equally, the effect is self-cancelling.

Precision of the Wall Film

The precision of the wall film may be calculated from consideration of the delivery time (6). Observed values of the latter, together with the calculated wall-film precision, are given in Table VI.

Because of the significant personal error, the overall contribution to the total titration precision caused by variability of the wall film cannot be calculated accurately, but is estimated to be about 0.00003 ml, and is the same whether calculated directly from the results of Table VI or from the aspect of a variable error in the changeover position.

Titration-acid Blank

The titration acid was found to contain very small amounts of reducible impurities: the observed decrease in titer produced by a further addition of 10 ml of titration acid was: titration acid A, 0.0015 ml; titration acid B, 0.0017 ml (A and B were from different batches). Independent tests showed that about four fifths of this was due to impurities

TABLE VI

Observed delivery time (DT) and the calculated wall film

	D-burette	F-burette
DT, bulb, zero to mark (sec)	294	307
Precision (sec)	1.0	0.9
No. of determinations	(11+5+12)	(14+6)
Calculated wall film (ml)	0.0233	0.0229
Precision (ml)	0.000039	0.000034
DT, shoulder, mark to zero (sec)	170	64
Precision (sec)	3.0	2.5
No. of determinations	(4+9)	(16+18)
Estimated wall film (ml)	<0.0005	<0.0005
Precision (ml)	<0.000006	<0.000010
DT, graduated section, 0–0.1 ml (sec)	44	25
Calculated wall film, 0–0.1 ml (ml)	0.00066	0.00088

NOTE: The rate of meniscus descent at the mark was low, and a personal error of about 0.5 second was unavoidable; bulb deliveries timed to the zero of the graduated section showed a much better precision of about 0.2 second. No significant effect of small changes (0.5°) in room temperature upon the delivery time was observed.

in the orthophosphoric acid. These levels of impurities are equivalent to about 1 p.p.m. and 4 p.p.m. of SO_2 in the sulphuric and orthophosphoric acids, respectively, and are in good agreement with those found by Meites (25). The level of impurities was but little affected by boiling of the titration acid for an hour with a large excess of persulphate or peroxide, thus confirming the observations of Meites (25). Since the volume delivered by the 10-ml graduated cylinder was estimated to be precise to ± 0.1 ml, the variability caused by the titration acid was about ± 0.000015 ml.

Calculated Overall Precision of the Titration

The individual contributions to the total precision are summarized in Table V. As all these components are independent, the overall precision may be calculated in the usual manner, and the calculated precision for the titration is seen to be about 0.9 p.p.m., in good agreement with the observed precision of 0.7–1.1 p.p.m.

CONCLUSION

It has been shown that, with properly designed apparatus, a precision of 1 p.p.m. in volume titrimetry can be readily achieved. Further refinements are possible, and would lead to further improvements, but ± 0.1 p.p.m. is probably the maximum precision which can be achieved. The latter is of the same order as that of the best high-precision balances.

Consequently, the limiting precision of any titrimetric operation, whether by weight or by volume, is likely to be 0.1 p.p.m.; although even this is exceeded by the sensitivity of certain favorable end-point systems, it is still approximately three orders of magnitude better than the average accuracy of present atomic weights (27).

Although, from the aspect of accuracy, the volumetric technique described offers no advantage over weight techniques (a sensitive balance and calibrated weights are still required for calibration purposes and for the preparation of solutions), its convenience makes it an attractive proposition where purely comparative investigations are being made.

NOTES

OCCURRENCE OF LARGE NORMAL SECONDARY INTERMOLECULAR KINETIC ISOTOPE EFFECTS IN NON-EQUILIBRIUM SYSTEMS[1]

B. S. RABINOVITCH[2] AND J. H. CURRENT[3]

Recently it has been pointed out (1) that large *inverse* secondary isotope effects may occur in the low-pressure, non-equilibrium region of thermal unimolecular reactions. We wish to call attention to the existence also of large *normal* secondary kinetic isotope effects in non-equilibrium systems produced by non-thermal methods of activation.

Consider an equilibrium thermal unimolecular system in the RRKM formulation (1), then

$$k_\infty = \int_{\epsilon \geqslant \epsilon_0} k_\epsilon K(\epsilon) d\epsilon = \int_{\epsilon \geqslant \epsilon_0} \frac{I_r \sum_{\epsilon_v^+ \leqslant \epsilon^+} P^+_{\epsilon_v} N^*_\epsilon e^{-\epsilon/kT} d\epsilon}{hN^*_\epsilon} \frac{}{Q_v}, \qquad [1]$$

where $K(\epsilon)$ is a Boltzmann distribution factor, $P^+_{\epsilon_v}$ is the degeneracy of active energy states of the activated complex at the level ϵ_v^+, N^*_ϵ is the density of active energy states of the energized molecule at internal energy ϵ, Q_v is the corresponding partition function, and I_r is a residue of other partition functions for adiabatic degrees of freedom. It is evident that factors of N^*_ϵ cancel in equation [1]. For a non-thermal mode of excitation, e.g. light absorption, electron impact, radiolysis, chemical activation, etc., such cancellation need not occur and the average rate constant for activated molecules is

$$k = \int_{\epsilon \geqslant \epsilon_0} k_\epsilon f(\epsilon) d\epsilon,$$

where $f(\epsilon)$ is a non-equilibrium distribution of energized molecules. Then for two isotopically labelled species, say H and D,

$$k_H/k_D = \int k_{\epsilon H} f(\epsilon)_H d\epsilon \Big/ \int k_{\epsilon D} f(\epsilon)_D d\epsilon, \qquad [2]$$

where $f(\epsilon)_D$ may or may not equal $f(\epsilon)_H$, depending on the characteristics of the technique. In the special case that $f(\epsilon)_H = f(\epsilon)_D \sim \delta(\epsilon')$, we have

$$k \simeq k_{\epsilon'} = I_r \sum_{\epsilon_v^+ = 0}^{(\epsilon' - \epsilon_0)} P^+_{\epsilon_v}/hN^*_{\epsilon'}, \qquad [3]$$

and for the limiting case $\epsilon' \to \epsilon_0$, then

$$\sum P^+_{\epsilon_v H} \simeq \sum P^+_{\epsilon_v D} \simeq 1,$$

and

$$k_H/k_D \simeq \frac{I_{rH}N^*_{\epsilon'D}}{I_{rD}N^*_{\epsilon'H}}, \qquad [4]$$

where the I_r ratio is very close to unity but the density ratio may be a large number (2); for example, it has the approximate value 40 for C_3H_6 and C_3D_6 at 70 kcal mole^{-1} in the harmonic oscillator approximation (1, 2). Equation [4] gives the maximum effect; in general the $P^+_{\epsilon_v}$ ratio will not be unity and will partially compensate the density ratio. As seen further below, the $f(\epsilon)$ functions may also have compensatory character.

The correspondence between this case and the thermal, low-pressure, inverse secondary isotope effect is worth remarking on, and may be seen from the explanation previously given (1) for the latter. There, the collision probability replaces the specific decomposition probability k_ϵ, so

$$k_0 = \omega \int_{\epsilon \geqslant \epsilon_0} N^*_\epsilon e^{-\epsilon/kT} d\epsilon / Q_v,$$

and

$$k_{0H}/k_{0D} = \frac{\omega_H Q_{vD} R}{\omega_D Q_{vH}},$$

where the ω ratio is close to unity, and the integral ratio R is $\ll 1$, and no term in $\Delta\epsilon_0$ has been written for a purely secondary isotope effect. Since R strongly outweighs the Q_v ratio (which here has an effect similar to that of the $\sum P^+_{\epsilon_v}$ terms previously mentioned) a large inverse effect was found.[4]

The decomposition of chemically activated ethyl-d_x radicals provides an example of the new *normal* effect:

$$H_2C{=}CH_2 + D \rightarrow H_2\dot{C}{-}CH_2D^* \rightarrow H_2C{=}CHD + H, \qquad [d_1]$$

$$\textit{trans}\text{-}DHC{=}CHD + D \rightarrow DH\dot{C}{-}CHD_2^* \rightarrow DHC{=}CD_2 + H. \qquad [d_3]$$

The characteristics and energetics of a closely related system, *trans*-DHC=CHD + H → DHC—CH_2D^*, have been previously described (3). A large absolute effect is not to be expected in this case for several reasons: only two H atoms are replaced by D between the reacting species; also, $f(\epsilon)$ is by no means a delta function located just above ϵ_{0H}, since both radicals are produced by C—D bond formation and possess a minimum excess energy with respect to C—H rupture of ~1.8 kcal; finally, $f(E)$ for reaction $[d_3]$ is relatively broadened a little (4), which further tends to reduce the kinetic isotope ratio below the maximum limiting value.

The limiting observed average values per C—H bond for these systems studied at 195° and 300° K, and extrapolated to zero pressure,[5] is $(k_{d_1}/k_{d_3})_0 \simeq 2.2$. An expected small variation of the ratio, as between 195° and 300° K, was obscured by large experimental error. The accuracy of the determination is not high but the experimental effect is unequivocal.

A recent summary of secondary isotope effects for equilibrium thermal unimolecular systems gives an average value of 1.12 per D atom (5). The present quantum statistical effects are essentially unrelated to the mechanistic effects (6), which are of greatest

[4]*This effect has been explicitly confirmed for the* CH_3NC—CD_3NC *isomerization system by F. W. Schneider and B. S. Rabinovitch (unpublished results).*

[5]*This extrapolation gives* $\langle 1/k \rangle k^{-1}$ *(see reference 3).*

importance in the examples of the summary, and can be orders of magnitude larger than those that arise in such equilibrium unimolecular systems (7)—approaching as a limit in favorable cases, the ratio of the products of frequencies of the two species.

Investigation of other systems is continuing.

THE DECARBOXYLATION OF RING-SUBSTITUTED INDOLE-2(AND 3)-CARBOXYLIC ACIDS

E. PIERS AND R. K. BROWN

The synthesis of indoles by the Reissert method (1) or by Fischer cyclization (2) of pyruvic acid phenylhydrazone requires a final removal of carbon dioxide from the indole-2-carboxylic acid formed in these reactions.

Such decarboxylations have been accomplished in the case of 4-, 5-, 6-, and 7-fluoroindole-2-carboxylic acids in yields of 80, 52, 51, and 48% respectively by simply heating the substances above the melting point (3). The 4- and 6-chloroindole-2-carboxylic acids required more vigorous treatment but readily gave the decarboxylated product in 73 to 78% yield when they were heated with cuprous chloride in refluxing quinoline (4, 5). However, Barletrop and Taylor (6) were unsuccessful in their attempts to remove the carboxyl group from 4- or 6-bromoindole-2-carboxylic acid by heating these compounds in refluxing quinoline with or without catalysts such as cuprous bromide, cupric oxide, or copper powder.

The variable and frequently poor results obtained in decarboxylation of the benzene-ring-halogenated indole-2-carboxylic acids by Uhle's method (4, 5) was found by Rydon and Tweddle (7) to be due to contamination of the acid by sulphate ion stemming from the ferrous ammonium sulphate reductive cyclization step. These authors, by careful elimination of the sulphate ion as well as replacement of the usual cuprous chloride catalyst by copper chromite, were able to obtain consistently good yields of the 4-, 5-, 6-, and 7-chloroindoles.

Plieninger *et al.* (8) reported 60% yields of the 4- and 6-bromoindoles from the corresponding 2-carboxylic acids by mixing the acids with molten cuprous bromide followed by heating the fusion mixture in refluxing quinoline. Snyder and co-workers (9) obtained a 21–24% yield of 5-bromoindole by heating 5-bromoindole-2-carboxylic acid with a mixture of copper bronze and copper chromite, but only a very small yield of product

importance in the examples of the summary, and can be orders of magnitude larger than those that arise in such equilibrium unimolecular systems (7)—approaching as a limit in favorable cases, the ratio of the products of frequencies of the two species.

Investigation of other systems is continuing.

THE DECARBOXYLATION OF RING-SUBSTITUTED INDOLE-2(AND 3)-CARBOXYLIC ACIDS

E. PIERS AND R. K. BROWN

The synthesis of indoles by the Reissert method (1) or by Fischer cyclization (2) of pyruvic acid phenylhydrazone requires a final removal of carbon dioxide from the indole-2-carboxylic acid formed in these reactions.

Such decarboxylations have been accomplished in the case of 4-, 5-, 6-, and 7-fluoroindole-2-carboxylic acids in yields of 80, 52, 51, and 48% respectively by simply heating the substances above the melting point (3). The 4- and 6-chloroindole-2-carboxylic acids required more vigorous treatment but readily gave the decarboxylated product in 73 to 78% yield when they were heated with cuprous chloride in refluxing quinoline (4, 5). However, Barletrop and Taylor (6) were unsuccessful in their attempts to remove the carboxyl group from 4- or 6-bromoindole-2-carboxylic acid by heating these compounds in refluxing quinoline with or without catalysts such as cuprous bromide, cupric oxide, or copper powder.

The variable and frequently poor results obtained in decarboxylation of the benzene-ring-halogenated indole-2-carboxylic acids by Uhle's method (4, 5) was found by Rydon and Tweddle (7) to be due to contamination of the acid by sulphate ion stemming from the ferrous ammonium sulphate reductive cyclization step. These authors, by careful elimination of the sulphate ion as well as replacement of the usual cuprous chloride catalyst by copper chromite, were able to obtain consistently good yields of the 4-, 5-, 6-, and 7-chloroindoles.

Plieninger *et al.* (8) reported 60% yields of the 4- and 6-bromoindoles from the corresponding 2-carboxylic acids by mixing the acids with molten cuprous bromide followed by heating the fusion mixture in refluxing quinoline. Snyder and co-workers (9) obtained a 21–24% yield of 5-bromoindole by heating 5-bromoindole-2-carboxylic acid with a mixture of copper bronze and copper chromite, but only a very small yield of product

when they attempted to decarboxylate the ammonium salt of the acid in glycerol. Harvey later found that 5,6-dimethoxyindole-2-carboxylic acid heated in glycerol gave 97% yield of decarboxylated product (10).

The successful removal of carbon dioxide from 5-iodoindole-2-carboxylic acid (11) by the quinoline – copper chromite procedure of Rydon and Tweedle (7) indicates that to date this is the most generally satisfactory method reported in the literature for the decarboxylation of substituted indole-2-carboxylic acids.

In this laboratory a number of benzene-ring-substituted indoles were prepared from the corresponding 2-carboxylic acids. Plieninger's method (8) was found, in our hands, to be unsatisfactory as well as somewhat tedious, whereas the copper chromite – quinoline technique (7) gave quite unsatisfactory results in several instances (see Table I). Use

TABLE I

Indole compound	Method of decarboxylation	Temperature of decarboxylation	Time required (hours)	Yield of pure decarboxylated product (%)
5-Br; 2-CO_2H	*b*	Refluxing quinoline	36	22
	c	210–215°	4	63
6-Br; 2-CO_2H	*b*	Refluxing quinoline	36	25
	c	210–220°	5	74
7-Br; 2-CO_2H	*b*	Refluxing quinoline	48	48 (ref. 12)
	c	215–220°	5	61
4-$C_6H_5CH_2S$—; 2-CO_2H	*b*	Refluxing quinoline	24	Insignificant
	c	205–210°	2.5	80
7-$C_6H_5CH_2S$—; 2-CO_2H	*b*	Refluxing quinoline	24	15
	c	210–215°	5	85
6-NO_2; 3-CO_2H (ref. 14)	*a*	145–150°	3	90
	c	125–130°	1.5	86

(*a*) Method involved heated quinoline with no added catalyst.
(*b*) Method was that devised by Rydon and Tweddle (7) and modified as in ref. 12.
(*c*) Method is the present method involving hot quinoline, the acid, and catalytic amounts of its copper salt.

of this latter procedure on 7-bromoindole-2-carboxylic acid (12) required frequent additions of small amounts of copper chromite catalyst to the hot quinoline solution during the reaction for successful removal of carbon dioxide (48% yield). However, the 4- and 6-benzylmercaptoindole-2-carboxylic acids were decarboxylated in very poor yield with simultaneous loss of some of the sulphur as H_2S. Accordingly a route was sought which would provide not only improved yields but also avoid loss of substituent in the case of the more sensitive sulphur-containing compounds.

It has long been known that a carboxylic acid, heated with catalytic amounts of its copper salt, undergoes facile decarboxylation (13). When this method was applied to the decarboxylation of the substituted indole-2(and 3)-carboxylic acids in hot quinoline, a marked improvement in yield and quality of product was experienced. Generally, temperatures necessary to effect elimination of carbon dioxide were lower, and the times to complete the reaction were less, than those found for other methods employed. Furthermore, the thioethers did not lose sulphur during the decarboxylation. This procedure appears to be of wider applicability than those previously reported in the literature. The results are shown in Table I, in which the copper chromite and copper salt methods are compared.

Preparation of the Copper Salt

A stirred mixture of the acid (0.01 mole), sodium carbonate (0.005 mole), and water (100 ml) was heated until the acid dissolved. Upon the addition of a solution of cupric sulphate pentahydrate (0.005 mole) in 50 ml of water, the blue cupric salt of the indole-2-carboxylic acid precipitated. The solid was washed thoroughly with water, air-dried, and then given a final drying in a vacuum desiccator over calcium chloride.

The Procedure for Decarboxylation

A mixture of the indole-2-carboxylic acid (0.01 mole) and its copper salt (0.0004 mole) in 10 ml of synthetic quinoline was heated until carbon dioxide began to evolve. The mixture was kept at this temperature until gas evolution ceased (1.5–5 hours). The cooled solution was taken up in ether and the ether solution was washed several times with 1 *N* hydrochloric acid, once with water, twice with sodium carbonate solution, and finally with water. When the dried (Na_2SO_4) ether solution was freed from solvent a solid was obtained. This was further purified, if necessary, by passage through a short column of neutral alumina, using methylene dichloride as eluant.

N,N-BRIDGED DERIVATIVES OF ADENINE[1]

Sumner H. Burstein and H. J. Ringold

The reaction of 6-bis(2-hydroxyethyl)aminopurine (I*a*) with thionyl chloride was reported in 1957 by DiPaco and Tauro (1) to yield the adenine mustard derivative (II). Huber (2) in an earlier publication reported that the identical reaction gave an ionic halogen-containing product to which he assigned the dimeric piperazinium chloride structure (III). A 1960 United States patent of Lyttle and Petering (3) stated that the product derived from I*a* and thionyl chloride contained 1 equivalent of ionic halogen and

[1]*This work was aided by Grant No. T-185 from the American Cancer Society.*

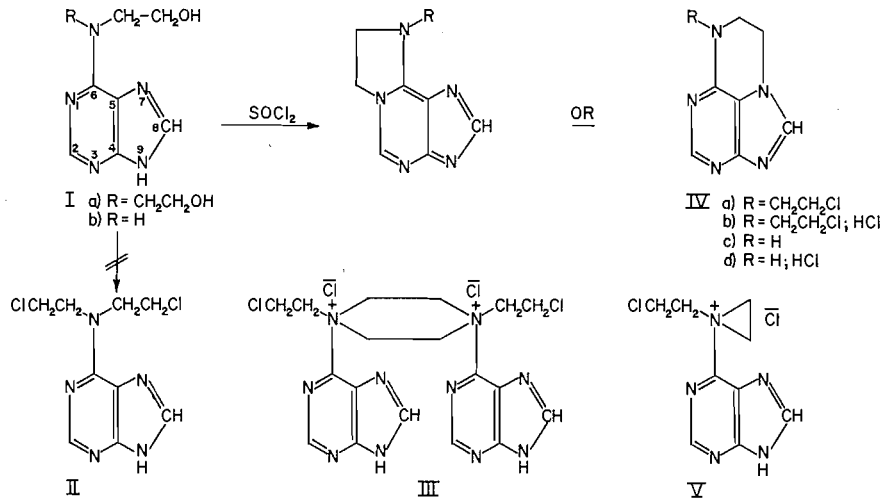
had probably undergone internal cyclization to the 1- or to the 7-nitrogen position. We have had occasion to prepare what appears to be the same product obtained by the three groups enumerated above and wish to record our observations and conclusions regarding its structure.



The reaction of 6-bis(2-hydroxyethyl)aminopurine (I*a*) with thionyl chloride, either at room temperature or under reflux, gave a product (IV*b*) of melting point 254–256° (decomp.) analyzing for $C_9H_{11}Cl_2N_5$. The compound, which was readily soluble in water, reacted instantaneously with excess silver nitrate, forming 1 equivalent of silver chloride. Titration with 0.1 *N* aqueous sodium hydroxide demonstrated a pK_a of 6.8 and when alkali was added to a pH of 12, followed by retitration with 0.1 *N* HCl, the titration curve did not show any major deviation. This behavior appeared to be indicative of a hydrochloride. When IV*b* was treated at room temperature with sodium acetate a product (IV*a*), which had lost a mole of hydrogen chloride, was isolated. The latter was readily reconverted to IV*b* by treatment with anhydrous hydrogen chloride in ethanol. This conclusively establishes that IV*b* is a hydrochloride and therefore eliminates the piperazinium structure (III), the conventional nitrogen mustard structure (II), as well as the quaternary aziridine structure (V). The latter could have been considered a structural possibility on the basis of ionic halogen content.

Thus it is evident that IV*b* is, in fact, a product that has undergone self-alkylation[2] on either the 1- or 7-nitrogen function and that IV*a* is simply the cyclized hydrogen-chloride-free product.

Before discussing the attempt to resolve the question of 1- or 7-cyclization, the behavior of the "one-armed" compound (I*b*) is pertinent at this point. When 6-(2-hydroxyethyl)-aminopurine (I*b*) (2, 4) (prepared by the reaction of 6-chloropurine with ethanolamine) was reacted with thionyl chloride a product, $C_7H_8ClN_5$ (IV*d*), was obtained. This compound exhibited an acidity parallel to IV*b*, the pK_a being 7.0. Further, the titration curve of IV*d* was very similar to that of IV*b* and neutralization with sodium acetate or alkali resulted in the loss of hydrogen chloride and formation of a halogen-free product (IV*c*). The latter was readily reconverted to the original hydrochloride. From these character-

[2]*W. T. Caldwell and S. Toukan, Temple University, have reached similar conclusions in an independent study (private communication from Professor Caldwell).*

istics as well as from the similar ultraviolet spectral curves of the two series of compounds, it may be concluded that the same type of cyclization has occurred with both the "one-armed" and "two-armed" substances. Further, the cyclization of I*b* establishes that a quaternary aziridine, V, is not an intermediate in the formation of IV*b*.

The n.m.r. of IV*a* in deuterochloroform solution showed adenine ring hydrogen peaks at $\tau = 1.79$ and 2.21, while N-benzyltriacanthine (5), a γ,γ-dimethylallyl 7-substituted adenine derivative, showed ring hydrogens at $\tau = 2.05$ and 2.23 (5). Assignment of the 2.21–2.23 position to the unperturbed 2-proton would be consistent with cyclization to the 7-position, the 8-proton being shifted various degrees by the different substituents attached to the 7-nitrogen.

The ultraviolet spectra of our products, however, are not in accord with that expected for a 7-substituted adenine. Triacanthine and 7-D-ribofuranosidoadenine (6) are reported to exhibit $\lambda_{max}^{neutral}$ 273 mμ, ϵ 13,000 and a $\lambda_{max}^{pH\ 1}$ for triacanthine of 277 mμ, ϵ 18,000. Compounds IV*a* and IV*c* respectively exhibit $\lambda_{max}^{H_2O}$ 264 mμ and 270 mμ and undergo a hypsochromic displacement of 2 mμ rather than a bathochromic shift in going from water to 0.1 *N* hydrochloric acid. It is possible that the presence of the third ring in IV is modifying the spectrum but at the present time neither the 1- nor 7-cyclized structure can be discarded. In this connection it should be noted that Ramage and Trappe (7) reported the cyclization of 2-chloro-4-methyl-5-amino-6(2-chloroethyl)aminopyrimidine to a five- rather than to a six-membered ring, while Chu, Harris, and Mautner (8) prepared 8-bis-(β-chloroethyl)-aminoadenine hydrochloride without internal cyclization having occurred, although self-alkylation to either the 7- or 9-position would have led to a new five-membered ring.

Compounds IV*a* and IV*c* were found to be non-toxic in the mouse at a daily dose of 500 mg/kg for a period of 1 week[3] and have not demonstrated any significant antitumor activity.[4]

EXPERIMENTAL

Melting points are uncorrected and ultraviolet spectral determinations were made with a Carey model 14 recording spectrophotometer. We are grateful to Mr. T. A. Wittstruck for the n.m.r. determination. Elementary analyses were performed by Midwest Microlab, Inc., 7838 Forest Lane, Indianapolis 20, Indiana.

6-Bis(2-hydroxyethyl)aminopurine (Ia)

A mixture of 6-chloropurine[5] (5.0 g), diethanolamine (10 ml), and absolute ethanol (50 ml) was heated for 8 hours under reflux and then cooled overnight at 0°, yielding 6.5 g of I*a*, m.p. 219–221° (reported 205° (1), 216–218° (2), 228–231° (3)); $\lambda_{max}^{H_2O}$ 213 and 276 mμ, ϵ 16,500 and 18,300; $\lambda_{max}^{0.1\ N\ HCl}$ 284 mμ, ϵ 16,400. The constants were unchanged after further crystallization from 95% ethanol. Anal. Calc. for $C_9H_{13}N_5O_2$: C, 48.42; H, 5.87; N, 31.37. Found: C, 48.28; H, 5.99; N, 31.23.

Reaction of Ia with Thionyl Chloride – Preparation of IVb

(a) With Heating

The bis-hydroxyethyl derivative (I*a*) (5.0 g) was heated for 16 hours, with stirring, in boiling, freshly distilled thionyl chloride (100 ml). The solvent was removed *in vacuo* and the residue stirred with absolute ethanol (50 ml). The product, 5.0 g, exhibited m.p. 250° (decomp.) while the analytical specimen from absolute ethanol melted at 254–256° (decomp.); $\lambda_{max}^{H_2O}$ 215 and 268 mμ, ϵ 18,500 and 13,100; $\lambda_{max}^{0.1N\ HCl}$ 215 and 268 mμ, ϵ 18,500 and 13,400. (Reported m.p. 245° (1), 243–247° (2), 253–255° (3).) Titration with 0.1 *N* sodium hydroxide gave pK_a 6.8. Anal. Calc. for $C_9H_{11}Cl_2N_5$: C, 41.56; H, 4.26; N, 26.93; Cl, 27.26. Found: C, 41.53; H, 4.34; N, 27.04; Cl, 27.29.

(b) Without Heating

A suspension of I*a* (480 mg) in thionyl chloride (15 ml) was stirred for 14 hours at room temperature. The precipitate was filtered through a sintered-glass funnel and washed with benzene and then absolute

[3]*Toxicity studies by Dr. R. I. Dorfman of this foundation.*
[4]*Antitumor assays by the Cancer Chemotherapy National Service Center.*
[5]*We wish to thank Burroughs Wellcome and Co. for a generous gift of material.*

ethanol, yielding 600 mg of IV*b*, m.p. 246–248°, whose ultraviolet and infrared spectra were identical with the product obtained in (*a*). Recrystallization from absolute ethanol gave 453 mg of product, m.p. 254° (decomp.), whose infrared spectrum was unchanged.

Reaction of IVb with Silver Nitrate

A solution of IV*b* (65 mg) in water (10 ml) was reacted with silver nitrate solution (2.0 equiv. in 5 ml of water) containing a drop of nitric acid, causing instantaneous formation of a precipitate. The silver chloride was rapidly filtered and then washed with ethanol–acetone and dried. Weight 32 mg (0.89 equiv.).

Neutralization of IVb – Preparation of IVa

Sodium acetate trihydrate (500 mg) was added to a solution of hydrochoride IV*b* (500 mg) in water (5 ml). The solvent was removed at room temperature *in vacuo* and the residue extracted with chloroform and crystallized several times from chloroform–hexane to yield an analytical specimen of IV*a*, m.p. 310–315°; $\lambda_{max}^{H_2O}$ 214 and 270 mμ, ε 18,300 and 12,700; $\lambda_{max}^{0.1N\,HCl}$ 215 and 268 mμ, ε 19,700 and 14,200; n.m.r. ($CDCl_3$) 1.79, 2.21, 5.50, 5.61, 5.71, 5.78, 5.97, and 6.06 τ. Anal. Calc. for $C_9H_{10}ClN_5$: C, 47.79; H, 4.69. Found: C, 47.92; H, 4.81.

Reconversion of IVa to IVb

Hydrogen chloride was bubbled for 30 minutes through a stirred suspension of IV*a* (50 mg) in absolute ethanol (5 ml). Ether was added and the precipitate was filtered, washed with ether, and recrystallized from methanol, yielding the hydrochloride IV*c*, m.p. 254° (decomp.), whose infrared spectrum was identical with the product described above.

6-(2-Hydroxyelhyl)aminopurine (Ib)

A mixture of 6-chloropurine (5.0 g) and 2-aminoethanol (10 ml) in absolute ethanol (50 ml) was heated for 3 hours under reflux and then cooled, yielding 5.14 g of I*b*, m.p. 250–252°. An analytical specimen obtained from ethanol exhibited m.p. 255–257° (reported 247–249° (2)); $\lambda_{max}^{H_2O}$ 267 mμ, ε 15,000, $\lambda_{max}^{0.1N\,HCl}$ 273 mμ, ε 14,500. Anal. Calc. for $C_7H_9N_5O$: C, 46.91; H, 5.06. Found: C, 46.73; H, 5.20.

Reaction of Ib with Thionyl Chloride – Preparation of IVd

A stirred suspension of I*b* (2.0 g) in freshly distilled thionyl chloride (50 ml) was boiled for 16 hours under anhydrous conditions. The thick paste was cooled, filtered, and the precipitate washed with benzene and then suspended in absolute ethanol and stirred for a few minutes. The collected precipitate of IV*d* weighed 1.7 g and exhibited m.p. 305–309° (decomp.). Crystallization from methanol gave an analytical sample, m.p. 306–310°, whose pK_a (titration with 0.1 *N* aqueous sodium hydroxide) was 7.0. Anal. Calc. for $C_7H_8ClN_5$: C, 42.54; H, 4.08; N, 35.45; Cl, 17.95. Found: C, 42.87; H, 4.08; N, 35.70; Cl, 17.93.

Reaction of IVd with Silver Nitrate

A solution of IV*d* (200 mg) in water (20 ml) was treated with silver nitrate (180 mg, 1.05 equiv.) in 5 ml of water. A few drops of dilute nitric acid were added and the precipitate, which had formed immediately after the silver nitrate addition, was removed by centrifugation, washed, and dried, yielding 137 mg (0.95 equiv.) of silver chloride.

Neutralization of IVd – Preparation of IVc

Solid sodium bicarbonate (200 mg) was added to a clear ice-cold solution of 200 mg of IV*d* in water (2 ml). Carbon dioxide was liberated and a crystalline product deposited. Collection of V*a* and recrystallization from methanol yielded 102 mg of pure product, m.p. 295–296°. When sodium acetate (400 mg) was substituted for bicarbonate the identical product was obtained. $\lambda_{max}^{H_2O}$ 212 and 264 mμ, ε 17,500 and 10,400. $\lambda_{max}^{0.1N\,HCl}$ 211 and 262 mμ, ε 18,900 and 11,600. Anal. Calc. for $C_7H_7N_5$: C, 52.16; H, 4.38; N, 43.46. Found: C, 51.94; H, 4.43; N, 43.27.

Reconversion of IVc to IVd

Treatment of IV*c* with hydrogen chloride exactly as described above for IV*a* to IV*b*, gave the hydrochloride, m.p. 305–309° (decomp.), identical with the original sample.

ADSORPTION OF CHROMIC ACID ON SILICA

H. P. DIBBS

INTRODUCTION

A chromic acid – sulphuric acid mixture is frequently used as a cleaning agent for glassware and silica ware and is widely recommended for this purpose in texts on quantitative analysis (1) and elsewhere (2). However, when precise measurements are involved, the use of this mixture is suspect, because of the possibility of etching the glass surface and the difficulty of removing final traces of chromium from the surface (3, 4). In order to investigate the amount of chromium left on fused quartz after chromic acid cleaning, a number of quartz rods, cleaned in this way, were irradiated with thermal neutrons and the amount of chromium remaining estimated with the aid of gamma-ray spectrometry.

EXPERIMENTAL DETAILS

The quartz used in this work was manufactured by the General Electric Company, Willoughby, Ohio, and had a specified purity of 99.97% SiO_2. It was in the form of 1-mm diameter rods which were cut into 3-cm lengths. Four batches, each containing 40 pieces, were prepared. Each batch was first cleaned in a detergent solution, with an ultrasonic generator, to remove superficial grease and dirt. After repeated rinsing in distilled water, the rods were dried at 110° C. One batch was then put aside to act as a standard. The remaining three groups were soaked overnight in a chromic acid – sulphuric acid mixture (35 ml of saturated sodium dichromate solution made up to 1 liter with concentrated sulphuric acid). Each batch of rods was then washed at least 20 times with distilled water and dried at 110° C. Two batches of these rods were taken and given further treatment. One group was placed in 10% hydrofluoric acid for 10 minutes and the other group in a 50/50 nitric acid – sulphuric acid mixture for 3 hours. After washing in distilled water they were dried as before.

For reactor irradiation, the four batches of rods were sealed into separate polythene bags, which in turn were wrapped in superpure aluminum foil. Fifty milligrams of potassium dichromate, sealed in a Vycor vial, was irradiated in the same irradiation can as the rods, to act as a chromium reference standard. Approximately 2 weeks after irradiation, the batches of rods were examined on a 100-channel gamma-ray spectrometer. Chromium was identified by half-life measurements and by the 0.32 Mev photo peak of chromium-51. The amount of chromium present was calculated by dissolving the potassium dichromate reference standard in water and counting a suitable aliquot of the solution in a position of geometry comparable to that of the quartz rods.

RESULTS

The amount of chromium found on the batches of rods is given in Table I.

TABLE I

Amounts of chromium detected

Batch	Treatment	Wt. of Cr/batch (μg)
S	None	0
1	Cleaned in chromic acid	7.7
2	Cleaned in chromic acid followed by HF	5.2
3	Cleaned in chromic acid followed by HNO_3/H_2SO_4	3.3

The geometrical surface area of the rods was approximately 40 cm^2. Therefore, for group 1, which had no treatment following the chromic acid – sulphuric acid cleaning, about 0.2 μg of chromium per apparent square centimeter of area remained after washing. Treatment with HF or the HNO_3/H_2SO_4 mixture, after the chromic acid – sulphuric acid cleaning (batches 2 and 3), resulted in a decrease in the amount of chromium on the quartz surface, but did not remove it all.

From these results it is apparent that a chromic acid – sulphuric acid cleaning mixture, although satisfactory for routine operations, should not be used in circumstances where minor traces of chromium are deleterious.

Adsorption behavior similar to that of quartz would be expected with laboratory glassware cleaned in a chromic acid – sulphuric acid mixture. However, most glassware now in common use is of the borosilicate type and it is not practical to use reactor irradiation to ascertain the amount of chromium remaining after cleaning because of the very high thermal neutron cross section of boron.

THE X-RAY ANALYSIS OF HETISINE HYDROBROMIDE*

MARIA PRZYBYLSKA

The crystals of hetisine hydrobromide, $C_{20}H_{27}O_3N.HBr$, were prepared and crystallized from absolute methanol by Dr. G. Feniak. They were found to belong to the space group $P2_1$. The unit cell dimensions are: $a = 9.75$, $b = 10.84$, $c = 9.46$ Å, $\beta = 114°40'$; $Z = 2$.

Three-dimensional data were collected from Weissenberg films, and the number of observed reflections, out of all those possible within the range given by the Cu radiation, amounted to 86%. The determination of space group was confirmed and the bromine atom was located at $x = 0.063$ and $z = 0.257$, by means of two Patterson syntheses, carried out with the $(h0l)$ and $(hk0)$ data. The y coordinate of bromine was taken as 0.250 and a three-dimensional Fourier synthesis, based on phases calculated only for the heavy atom, was computed for sections perpendicular to the b axis.

An examination of models of this synthesis led to the complete solution of the molecular structure of this compound. The choice of correct atomic positions and the elimination of their mirror image peaks was based solely on consideration of the interatomic distances and valency angles. In addition to mirror images, three spurious peaks were found along the b axis, directly above the bromine atom. Since the data were collected from levels normal to the b axis and the temperature factor is unusually low (2 Å^2), there was no doubt that they were diffraction effects caused by the termination of the Fourier series.

Issued as N.R.C. No. 6670.

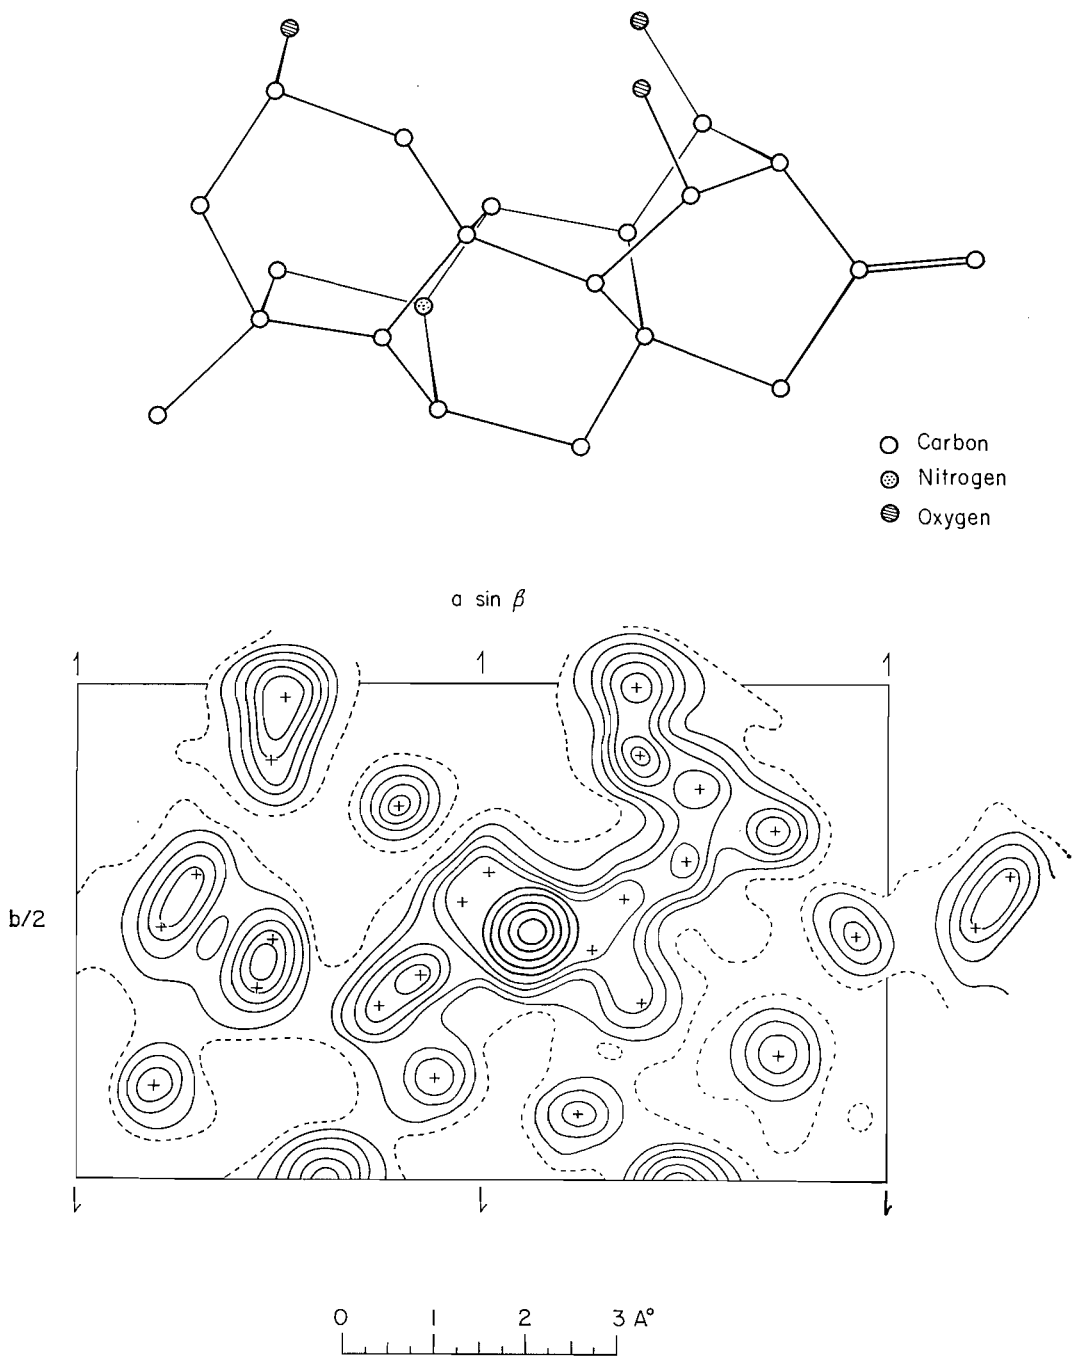

FIG. 1. A projection of the structure of hetisine hydrobromide along the c axis, with the corresponding diagram of the molecule. Light atom contours are at intervals of 2 e Å^{-2}, starting with a broken line at 2 e Å^{-2}. The bromine atom contours above 10 e Å^{-2} are at 10 e Å^{-2} and are drawn with heavier lines. The centers of all light atoms are marked by crosses.

This original molecular structure was later established as the correct one, but the first set of atomic coordinates consisted of only 21 atoms, all of which were treated as carbon atoms for the structure factor calculations. It is interesting that the $C{=}CH_2$ bond length was found even at this early stage of investigation to be 1.29 Å, and therefore in good agreement with the theoretical value. The ρ_o and $\rho_o - \rho_c$ maps for the three axial zones had confirmed the position of the additional three atoms and made possible the identification of the oxygen atoms. The nitrogen atom was identified by taking into account the chemical work on hetisine. Two structures have been postulated for hetisine (1) on the basis of limited chemical evidence. While the carbon–nitrogen skeleton proposed by Wiesner and Valenta (2) proves to be correct, the substituents were found to be located differently than in either of these structures.

The (001) Fourier projection of hetisine hydrobromide, together with the corresponding schematic drawing of the molecule, is given in Fig. 1.

A three-dimensional Fourier synthesis which was subsequently evaluated left no doubt as to the reliability of the structure, as all the false mirror image peaks had disappeared and the electron density values at the atomic centers were found to be in excellent agreement with the positions of the nitrogen and oxygen atoms.

The values of the discrepancy factor, R, omitting the unobserved reflections, are at present: 0.23, 0.18, and 0.14 for the $h0l$, $hk0$, and $0kl$ spectra, respectively. The overall R factor for the hkl data is 0.22. The refinement of atomic parameters is still in progress, and a detailed report of this work will be published later.

RING CONTRACTION IN THE MERCURY-PHOTOSENSITIZED DECOMPOSITION OF CYCLOPENTENE

W. A. Gibbons, W. F. Allen, and H. E. Gunning

Flowers and Frey (1) have recently reported that in the thermal isomerization of vinyl cyclopropane at 339–390° C, cyclopentene is the principal product (98%). In a current study of the mercury-photosensitized reactions of cyclopentene, we have found

vinyl cyclopropane to be a major product. In sharp contrast with early work on the thermal decomposition of cyclopentene (2, 3) where hydrogen and cyclopentadiene were the principal products, we found only small yields of hydrogen, no cyclopentadiene, a number of C_{10} products, and some liquid polymer, especially at low pressures. Typical quantum yields for a 10-minute run, at 27° C and 30 mm pressure of substrate, are: vinyl cyclopropane (0.24); H_2 (0.034); $C_{10}H_{14}$ (0.16); $C_{10}H_{16}$ (0.22); and $C_{10}H_{18}$ (0.05).

Preliminary results show that the quantum yields of all major products decrease gradually with increasing substrate pressure, and that the formation of C_{10} products is completely inhibited by 6% NO, whereas hydrogen and vinyl cyclopropane production remains unaffected.

Cyclopentene and vinyl cyclopropane have valence tautomeric structures, i.e. only carbon–carbon bond shifts are involved in isomerization. Similar valence tautomerism has been shown to occur with a number of cyclic dienes and trienes (4–7).

EXPERIMENTAL

Phillips Research grade cyclopentene, with a stated purity of 99.72%, was used. Gas chromatographic analysis with a silica gel column showed the presence of 0.15% cyclopentane and 0.05% cyclopentadiene. The nitric oxide was Matheson C.P. grade, distilled from a liquid-oxygen trap, the middle fraction being used. The propane for actinometry was Matheson "Instrument Grade" with a stated purity of 99.9%. After trap-to-trap distillation, the middle fraction was taken for the measurements.

A conventional high-vacuum apparatus was used, with 50-mm quartz cells. The lamp was an air-cooled, Hanovia 87A45 low-pressure mercury lamp (Vycor 7910 body).

The products condensable in liquid nitrogen were separated by gas–liquid chromatography, using silica gel columns to isolate a C_5 fraction and the three C_{10} products. The C_5 fraction was further partitioned into unreacted substrate, and the individual C_5 products on an oxydipropionitrile column. The non-condensable gas was shown to be hydrogen by mass spectrometry.

Parent peak analysis on a mass spectrometer indicated the principal products to be C_5H_8, $C_{10}H_{14}$, $C_{10}H_{16}$, and $C_{10}H_{18}$. The infrared spectrum of the C_5H_8 product showed that methyl groups were absent (i.e. no absorption at 1385 ± 10 cm^{-1}). In addition, the n.m.r. spectrum, using tetramethylsilane as an internal standard, revealed two bands, between 9.2 τ and 9.8 τ, which could be ascribed to a cyclopropyl group. The infrared spectrum was identical with that reported by Van Volkenburgh (8) for vinyl cyclopropane.

Selective absorption on a sulphuric acid:firebrick column (9) established that the $C_{10}H_{14}$ and $C_{10}H_{16}$ products were unsaturated while the $C_{10}H_{18}$ was not. The $C_{10}H_{18}$ had the same retention times as bicyclopentyl on two chromatographic columns. The products are believed to be a cyclopentenyl cyclopentene, a cyclopentyl cyclopentene, and bicyclopentyl.

A detailed study of the cyclopentene reaction will be submitted to this journal at a later date.

DIMETHYLPHENYLBENZYLAMMONIUM CHLORIDE AS A REAGENT FOR PLATINUM

D. E. RYAN

The use of dimethylphenylbenzylammonium chloride as a reagent for the gravimetric determination of platinum was recommended by Ryan (1). Westland and Westland (2), in a critical examination of the method, suggested a revised procedure to correct deficiencies they had found in the original method; unfortunately, their comments are based upon the use of impure reagent and are only valid in that instance. Their reagent was prepared by mixing commercial dimethylaniline and benzyl chloride with no intermediate purification of these materials; aqueous solutions of their reagent developed a blue coloration within 2 weeks. Dimethylphenylbenzylammonium chloride prepared from purified reactants is a white, stable compound; aqueous solutions, as stated in the original paper, may be kept for several months in a dark bottle with no signs of discoloration, and the platinum complex, under prolonged heating, shows no tendency to darken or tar.

H. M. Whitehead, in view of the Westland and Westland paper, recently prepared some dimethylphenylbenzylammonium chloride in this laboratory and reinvestigated the precipitation of platinum by this reagent. Determinations were carried out using both the original (1) and revised (2) procedures; no difference in results, as shown below, was evident.

	Pt recovered, mg	
Pt taken, mg	Original method	Modified method
21.08	21.08	21.07
13.72	13.73	13.72

The results show that washing with cyclohexane and dioxane are unnecessary when pure reagent is available. The losses in weight by the platinum precipitate, as recorded by Westland and Westland, are undoubtedly due to contamination by reagent impurities; washing by organic solvents gives good results by removal of these impurities. The thermal graphs given in the Westlands' paper confirm this rather than support the suggestion of decomposition of the platinum complex; 226.7 mg of complex decreased to 225.6 mg (by less than 0.5%) after 10 hours' heating.

A SYNTHESIS OF ISOASPARAGINE FROM β-BENZYL ASPARTATE

LEO BENOITON

In the course of the preparation of some aspartic acid peptides, ample supplies of β-benzyl aspartate and β-benzyl *N*-carbobenzoxyaspartate were required. The methods available for the synthesis of these compounds are lengthy. The latter is prepared by the

selective saponification of carbobenzoxyaspartic acid dibenzyl ester (1, 2), which in turn is decarbobenzoxylated with hydrogen bromide to provide the β-benzyl aspartate hydrobromide (3). We therefore sought a simplified synthesis for these intermediates.

β-Benzyl L-aspartate was prepared directly from aspartic acid by benzylation of the ω-carboxyl group in the manner used for glutamic acid (4). Subsequent carbobenzoxylation provided the β-benzyl *N*-carbobenzoxy-L-aspartate in good yield.

The ready accessibility of these intermediates permits a simple and unequivocal synthesis of isoasparagine, analogous to that already described for isoglutamine (5). β-Benzyl *N*-carbobenzoxy-L-aspartate was amidated using the mixed anhydride procedure (6), and the product, benzyl *N*-carbobenzoxy-L-isoasparagine,[1] was subsequently catalytically hydrogenated to give isoasparagine which is free of asparagine, the usual contaminating by-product in most isoasparagine syntheses.[2]

EXPERIMENTAL

β-Benzyl L-*Aspartate*

Sulphuric acid (10 ml) was added to anhydrous ether (100 ml) followed by benzyl alcohol (100 ml). The ether was removed under vacuum and finely ground L-aspartic acid (13.4 g) was added, in several portions, while the mixture was magnetically stirred. The ensuing solution was left at room temperature for 24 hours, 95% ethanol (200 ml) was added, followed by pyridine (50 ml), which was added dropwise while the solution was vigorously stirred. The mixture was cooled overnight, the deposit was filtered off and washed by trituration with ether. Recrystallization from water containing a few drops of pyridine afforded pure β-benzyl L-aspartate (8.9–9.9 g, 40–45%), m.p. 218–220° C, $[\alpha]_D^{25}$ +28.1° (*c*, 1; *N* HCl). (Found: C, 58.9; H, 5.7; N, 6.2. $C_{11}H_{13}NO_4$ requires: C, 59.2; H, 5.9; N, 6.3%.)

*β-Benzyl N-Carbobenzoxy-*L-*aspartate*

β-Benzyl L-aspartate (4.46 g, 20 mmoles) was dissolved in hot water (300 ml) and the solution was allowed to cool. When the temperature reached 60° C (the compound begins to crystallize at 55° C) sodium bicarbonate (3.5 g, 50 mmoles) and carbobenzoxy chloride (4.1 g, 24 mmoles) were added and the solution was stirred vigorously for 3 hours. The solution was then extracted twice with ether, and acidified to congo red with hydrochloric acid. The mixture was cooled for several hours (if the product is an oil it soon crystallizes), filtered, and the product was dried at 50° under vacuum. One recrystallization from benzene gave 5.3 g (75%), m.p. 107–108° C, $[\alpha]_D^{25}$ +11.9° (*c*, 10; acetic acid) (lit. m.p. 108°, $[\alpha]_D^{25}$ +12.1° (1)). (Found: N, 4.0. Calc. for $C_{19}H_{19}NO_6$: N, 3.9%.)

*Benzyl N-Carbobenzoxy-*L-*isoasparagine*

β-Benzyl *N*-carbobenzoxy-L-aspartate (1.79 g, 5 mmoles) was dissolved in purified dioxane (10 ml) containing tributylamine (1.2 ml, 5 mmoles). The solution was cooled to 10° and ethyl chloroformate (0.49 ml, 5 mmoles) was added. The solution was kept at 10° for 20 minutes after which anhydrous ammonia was bubbled through for 15 minutes. After an additional 15 minutes, the dioxane was removed under vacuum with a water-bath temperature under 45°. To the residue was added carbon tetrachloride (20 ml) and water (20 ml), and the mixture was shaken vigorously. The white product was filtered off, dried in a vacuum desiccator, and recrystallized from ethanol to give 1.1 g (62%), m.p. 103° C, $[\alpha]_D^{21}$ −12.8° (*c*, 2; dimethylformamide). (Found: C, 65.1; H, 5.5; N, 7.9. $C_{19}H_{20}N_2O_5$ requires: C, 64.0; H, 5.7; N, 7.9%.)

L-*Isoasparagine*

Benzyl *N*-carbobenzoxy-L-isoasparagine (0.89 g) was hydrogenated over palladized charcoal for 24 hours in 50% aqueous ethanol containing a few drops of acetic acid. The catalyst was filtered off, the solution was evaporated to dryness, the residue was dissolved in water, and three volumes of ethanol were added. After cooling, the product was recrystallized from water–ethanol to give needles (0.56 g, 75%), $[\alpha]_D^{25}$ +14.8° (*c*, 1.5; 0.1 *N* HCl) (lit. $[\alpha]_D^{20}$ +14.9° (8); $[\alpha]_D^{18}$ +15.5° (9)). (Found: C, 31.8; H, 6.6; N, 18.5. Calc. for $C_4H_8N_2O_3 \cdot H_2O$: C, 32.0; H, 6.7; N, 18.7%.) The material is free of asparagine, as evidenced by paper chromatography in *n*-butanol – acetic acid – water (12:3:5) (R_f isoasparagine 0.18; R_f asparagine 0.12).

FURFURALDEHYDE FROM THE ALDOBIURONIC ACID 2-*O*-(4-*O*-METHYL-α-D-GLUCOPYRANOSYL URONIC ACID)-D-XYLOPYRANOSE

S. K. SEN AND P. C. DAS GUPTA

It has been found by many workers (1) that uronic acids give 33–45% of the theoretical value of furfuraldehyde when distilled with 12% hydrochloric acid. Norris and Resch (2) have shown that glucuronic acid in combination gives 21.48% of its weight of furfuraldehyde. It has been suggested from time to time that the yield of furfuraldehyde for uronic acids be corrected before interpreting the results for pentosans. Wise and Ratliff (3) assumed that the uronic acids present in wood would evolve 35% of the theoretically possible amount of furfural and corrected their pentosan values accordingly. Hemicellulose from plant material generally contains 4-*O*-methyl-D-glucuronic acid as the major uronic acid component. The aldobiuronic acid 2-*O*-(4-*O*-methyl-α-D-glucopyranosyl uronic acid)-D-xylopyranose has been isolated from the partial hydrolysis product of many plant materials. It was thought that the yield of furfuraldehyde from this compound would correspond more closely with the yield to be expected from the acidic component of the parent polysaccharide.

The aldobiuronic acid used here was isolated by partial acid hydrolysis of the hemicellulose from Mesta fiber (*Hibiscus cannabinus*) (4) by column chromatography (5). Further purification by paper chromatography with the solvent system butanol–pyridine–water (10:3:3) removed small amounts of xylose. The aldobiuronic acid was extracted from the paper with water and the solution was treated with Amberlite resin IR-120(H), filtered, and concentrated to a syrup. The syrup was dried to a powder in a vacuum desiccator over P_2O_5. The aldobiuronic acid had $[\alpha]_D^{32}$ +96.6° (*c*, 1.07 in water) (found: OMe 9.25%, uronic anhydride 51.04%, equivalent weight 337.5; calc. for $C_{12}H_{20}O_{11}$: OMe 9.1%, uronic anhydride 51.76%, equivalent weight 340). The aldobiuronic acid was characterized as 2-*O*-(4-*O*-methyl-α-D-glucopyranosyl uronic acid)-D-xylopyranose by conversion to methyl 2-*O*-[methyl(2,3-di-*O*-acetyl-4-*O*-methyl-α-D-glucopyranosyl)uronate]-3,4-di-*O*-acetyl-D-xylopyranoside (6) having m.p. 201° C and $[\alpha]_D^{25}$ +99.6° (*c*, 0.6 in chloroform). Furfuraldehyde was estimated as phloroglucide according to the TAPPI method (7) and calculated from the weight of phloroglucide using Krober's table. In actual experiment 86.97 mg of aldobiuronic acid gave 50.7 mg furfural-phloroglucide. Thus after the xylose portion of the aldobiuronic acid is accounted for, it appears that 4-*O*-methyl-glucuronic acid residue evolves 15.04% of its weight of furfural. On glucuronic anhydride the yield is 16.24%, which is 29.77% of the theoretical value. The precipitate of furfural-phloroglucide did not contain any methoxyl group.

DIMETHYLPHENYLBENZYLAMMONIUM CHLORIDE AS A REAGENT FOR PLATINUM

D. E. RYAN

The use of dimethylphenylbenzylammonium chloride as a reagent for the gravimetric determination of platinum was recommended by Ryan (1). Westland and Westland (2), in a critical examination of the method, suggested a revised procedure to correct deficiencies they had found in the original method; unfortunately, their comments are based upon the use of impure reagent and are only valid in that instance. Their reagent was prepared by mixing commercial dimethylaniline and benzyl chloride with no intermediate purification of these materials; aqueous solutions of their reagent developed a blue coloration within 2 weeks. Dimethylphenylbenzylammonium chloride prepared from purified reactants is a white, stable compound; aqueous solutions, as stated in the original paper, may be kept for several months in a dark bottle with no signs of discoloration, and the platinum complex, under prolonged heating, shows no tendency to darken or tar.

H. M. Whitehead, in view of the Westland and Westland paper, recently prepared some dimethylphenylbenzylammonium chloride in this laboratory and reinvestigated the precipitation of platinum by this reagent. Determinations were carried out using both the original (1) and revised (2) procedures; no difference in results, as shown below, was evident.

	Pt recovered, mg	
Pt taken, mg	Original method	Modified method
21.08	21.08	21.07
13.72	13.73	13.72

The results show that washing with cyclohexane and dioxane are unnecessary when pure reagent is available. The losses in weight by the platinum precipitate, as recorded by Westland and Westland, are undoubtedly due to contamination by reagent impurities; washing by organic solvents gives good results by removal of these impurities. The thermal graphs given in the Westlands' paper confirm this rather than support the suggestion of decomposition of the platinum complex; 226.7 mg of complex decreased to 225.6 mg (by less than 0.5%) after 10 hours' heating.

FURFURALDEHYDE FROM THE ALDOBIURONIC ACID 2-*O*-(4-*O*-METHYL-α-D-GLUCOPYRANOSYL URONIC ACID)-D-XYLOPYRANOSE

S. K. SEN AND P. C. DAS GUPTA

It has been found by many workers (1) that uronic acids give 33–45% of the theoretical value of furfuraldehyde when distilled with 12% hydrochloric acid. Norris and Resch (2) have shown that glucuronic acid in combination gives 21.48% of its weight of furfuraldehyde. It has been suggested from time to time that the yield of furfuraldehyde for uronic acids be corrected before interpreting the results for pentosans. Wise and Ratliff (3) assumed that the uronic acids present in wood would evolve 35% of the theoretically possible amount of furfural and corrected their pentosan values accordingly. Hemicellulose from plant material generally contains 4-*O*-methyl-D-glucuronic acid as the major uronic acid component. The aldobiuronic acid 2-*O*-(4-*O*-methyl-α-D-glucopyranosyl uronic acid)-D-xylopyranose has been isolated from the partial hydrolysis product of many plant materials. It was thought that the yield of furfuraldehyde from this compound would correspond more closely with the yield to be expected from the acidic component of the parent polysaccharide.

The aldobiuronic acid used here was isolated by partial acid hydrolysis of the hemicellulose from Mesta fiber (*Hibiscus cannabinus*) (4) by column chromatography (5). Further purification by paper chromatography with the solvent system butanol–pyridine–water (10:3:3) removed small amounts of xylose. The aldobiuronic acid was extracted from the paper with water and the solution was treated with Amberlite resin IR-120(H), filtered, and concentrated to a syrup. PERFLUOROALKYL ARSENICALS

PART V. SOME SOLVOLYSIS STUDIES

W. R. CULLEN

Chemistry Department, University of British Columbia, Vancouver, British Columbia

Received November 17, 1961

ABSTRACT

The ammonolysis of tetrakistrifluoromethyldiarsine probably proceeds through solvolytic fission of the As—As bond. Solvolysis of the diarsine by sodium methoxide in methanol does not seem to proceed by this mechanism. Chlorobistrifluoromethylarsine is stable to ethanol and ethanethiol below 110° but reacts violently with solid sodium alcoholates to give only decomposition products. With solid sodium mercaptide chlorobistrifluoromethylarsine yields ethylmercaptobistrifluoromethylarsine. This mercapto-arsine is also obtained by reacting iodobistrifluoromethylarsine with mercuric mercaptide. Ammonolysis and hydrolysis studies of the compounds R_2AsCF_3 and $RAs(CF_3)_2$ ($R = C_2H_5$, C_4H_9) indicate that the mechanism of solvolysis could be S_N2.

DISCUSSION AND RESULTS

Alkaline hydrolysis of trifluoromethyl arsenicals to fluoroform is usually rapid and quantitative, though trifluoromethylarsine, bistrifluoromethylarsine, and tetrakistrifluoromethyldiarsine hydrolyze to fluoroform and fluoride (1, 2). The postulated mechanism for the hydrolysis of the diarsine involves hydrolytic fission of the As—As bond:

$$(CF_3)_2As—As(CF_3)_2 \xrightarrow{H_2O} (CF_3)_2AsH + (CF_3)_2AsOH.$$

Ammonolysis of trifluoromethyl arsenicals seems to parallel hydrolysis, though the diarsine and ammonia do not give fluoride (3). In this paper further solvolysis reactions of the diarsine and other trifluoromethyl arsenicals are described.

Ammonolysis of tetrakistrifluoromethyldiarsine gives 89% of the trifluoromethyl as fluoroform (3). Ammonolysis of bistrifluoromethylarsine under similar conditions gives 76% of the trifluoromethyl as fluoroform and no fluoride. Thus if the ammonolysis of the diarsine also proceeds through solvolylic fission of the As—As bond,

$$(CF_3)_2As—As(CF_3)_2 \xrightarrow{NH_3} (CF_3)_2AsNH_2 + HAs(CF_3)_2,$$

the yield of fluoroform would be expected to be 50% (from the $(CF_3)_2AsNH_2$ (3)) plus 76% of 50% (from the $(CF_3)_2AsH$): a total of 88%, in good agreement with the experimental result. Furthermore the experimental observations during the ammonolysis of the diarsine and bistrifluoromethylarsine correspond very well. The diarsine is stable to methanol at 20° (4 days) but is decomposed by methanolic sodium methoxide to give fluoroform (90%) but no fluoride. Bistrifluoromethylarsine under similar conditions gives

fluoroform (67%) and no fluoride. If the solvolysis of the diarsine occurred by fission of the As—As bond,

$$(CF_3)_2As—As(CF_3)_2 \xrightarrow{CH_3OH} (CF_3)_2AsOCH_3 + (CH_3)_2AsH,$$

then the expected yield of fluoroform would be 50% (from the $(CF_3)_2AsOCH_3$) plus 67% of 50% (from the $(CF_3)_2AsH$): a total of 83.5%, which is less than the experimental result. Methanolysis of $(CF_3)_2AsOCH_3$ would be expected to be complete since tris-trifluoromethylarsine, although slowly attacked by ethanol at 20°, is at least 98% solvolyzed to fluoroform by methanolic sodium methoxide. Methanolysis of both the diarsine and bistrifluoromethylarsine produces a green solution, but a water-insoluble product is obtained from methanolysis of the arsine. In view of this and the discrepancy between the expected and found yields of fluoroform it seems that methanolysis of the diarsine does not proceed through solvolytic fission of the As—As bond. The hydrolysis of tetrakistrifluoromethyldiphosphine is also believed to proceed through fission of the P—P bond, and part of the evidence offered for this is that bistrifluoromethylphosphine and fluoroform are produced by the reaction of the diphosphine with dilute hydrochloric acid at 100° (4). It has now been found that tetrakistrifluoromethyldiarsine is stable under the same conditions. The diphosphine is unstable to liquid ammonia and 48% of the trifluoromethyl is lost as fluoroform after 28 days. Thus the extent of ammonolysis of the diphosphine is less than that of the diarsine. Similar results have been found for tristrifluoromethyl-phosphine and -arsine (3).

Chlorobistrifluoromethylphosphine reacts with ethanol below 20° to give ethoxybistrifluoromethylphosphine (5), and when warmed with ethanethiol the corresponding mercapto-phosphine is obtained (6). Chlorobistrifluoromethylarsine is stable to ethanol below 120° and to ethanethiol below 110°. In an attempt to prepare alkoxybistrifluoromethylarsines chlorobistrifluoromethylarsine was reacted with sodium methoxide and ethoxide. A violent reaction takes place and only decomposition products can be isolated. In a more controlled reaction using sodium methoxide bistrifluoromethylarsine oxide was produced. The reaction of chlorobistrifluoromethylarsine with sodium mercaptide is less violent and ethylmercaptobistrifluoromethylarsine is obtained. The same product

$$(CF_3)_2AsCl + NaSC_2H_5 \rightarrow NaCl + (CF_3)_2AsSC_2H_5$$

$$(CF_3)_2AsI + Hg(SC_2H_5) \rightarrow C_2H_5HgI + (CF_3)_2AsSC_2H_5$$

is obtained from the reaction of mercury mercaptide with iodobistrifluoromethylarsine. The use of solid sodium and mercury mercaptides for reactions of this sort has not previously been reported, though the lead(II) derivatives have recently been used to prepare mercapto-silanes (7).

Chlorobistrifluoromethyl-arsine and -phosphine react readily with ammonia (3, 8), yet the phosphine does not react with sodamide (8). A similar result has now been found for the arsine. The arsine is also stable to formamide at 20°.

The rates of hydrolysis of the compounds $(CH_3)_xAs(CF_3)_{3-x}$ have been found to increase as the number of trifluoromethyl groups is increased (2, 9). A similar result has been found for the rates of hydrolysis and ammonolysis of the compounds $(C_3H_5)_xAs(CF_3)_{3-x}$ (10). It has now been found that the compounds $R_xAs(CF_3)_{3-x}$ (R = C_2H_5, n-C_4H_9) show this same trend with respect to ammonolysis and hydrolysis. Comparison of the details of these experiments with those of Haszeldine and West (9) suggests that for a particular number of trifluoromethyl groups the rate of hydrolysis decreases in the order $CH_3 > C_2H_5 > C_4H_9$. Ammonolysis of the ethyl compounds also seems to

be faster than ammonolysis of the corresponding *n*-butyl compounds. Heptafluoropropyldimethylarsine is also slowly attacked by ammonia, giving heptafluoropropane. These results are consistent with the idea that solvolysis involves nucleophylic attack at the arsenic atom (9), and suggest that mechanism could well be S_N2.

Tristrifluoromethylarsine is stable to liquid sulphur dioxide at 20°.

EXPERIMENTAL

The trifluoromethyl arsenicals were prepared by recorded methods. Techniques used were similar to those previously described. Most compounds solvolyzed to give fluoroform, the identity and purity of which was checked spectroscopically and, where possible, by molecular weight measurement.

Solvolysis of Chlorobistrifluoromethylarsine

Chlorobistrifluoromethylarsine (0.870 g) and dry ethanol (0.259 g) did not react after 3 days at 83° or 13 hours at 120°. Similarly no reaction occurred between the arsine (0.296 g) and ethanethiol (7.5 g) after 44 hours at 110°, or between the arsine (0.510 g) and formamide (0.34 g) after 3 days at 20°. Chlorobistrifluoromethylarsine (0.663 g) and excess sodium methoxide reacted violently on being warmed quickly from −196° to 20° to give fluoroform (0.142 g, 97% of the trifluoromethyl); methanol was identified in the remaining volatile fraction by its infrared spectrum. The water-insoluble solid product contained elemental arsenic, identified by its X-ray powder photograph. In a second experiment the chloro-arsine (1.457 g) and sodium methoxide (1.2 g) were allowed to warm up from −196° to 20° over 16 hours, a vigorous reaction took place at −10° and some charring occurred. The volatile products were fluoroform (0.331 g, 40%) and a fraction (0.434 g; molecular weight (M), 352) whose infrared spectrum was almost identical with that of a sample of bistrifluoromethylarsine oxide. Excess sodium ethoxide and chlorobistrifluoromethylarsine reacted violently, giving ethylene, fluoroform, ethanol, and arsenic metal, but no ethoxybistrifluoromethylarsine was formed. Chlorobistrifluoromethylarsine (1.325 g) and excess sodium mercaptide reacted vigorously on being warmed to 20° to give, amongst other unidentified products, ethylene and a slightly impure sample of *ethylmercaptobistrifluoromethylarsine* (1.107 g). Anal. Found: CF_3, 49.5%; M, 277. $C_4H_5AsF_6S$ requires: CF_3, 50.5%; M, 274. The infrared spectrum of this fraction was consistent with that expected for the mercapto-arsine. Found: liquid film: 2965 (m), 2925 (m), 2870 (w), 2220 (w), 1650 (vw), 1465 (m), 1434 (w), 1383 (w), 1264 (s), 1167 (vs), 1133 (vs), 1100 (vs), 1057 (m), 1043 (m), 966 (w), 758 (w), 726 (s). The same compound was produced in 90% yield from the reaction of iodobistrifluoromethylarsine with excess mercury mercaptide at 20° (4 days). Chlorobistrifluoromethylarsine (0.814 g) and sodamide (5 g) did not react at 20° (9 days) (93% recovery). Found: M, 250. Calc. for C_2AsClF_6: M, 249.

Solvolysis of Tristrifluoromethylarsine

Tristrifluoromethylarsine (0.924 g) and dry ethanol (1 g) at 20° (12 days) gave fluoroform (0.053 g, 7.7% of the trifluoromethyl). The arsine (0.765 g) and 5 ml of a 10% solution of sodium methoxide in methanol after 3 days at 20° gave fluoroform (0.548 g) equivalent to 98% of the trifluoromethyl. Tristrifluoromethylarsine (1.689 g) and sulphur dioxide (14.98 g) did not react after 7 days at 20°.

Solvolysis of Tetrakistrifluoromethyldiarsine

The diarsine (0.327 g) and dilute hydrochloric acid (10 ml) did not react after 24 hours at 100°. No reaction occurred between the diarsine (0.308 g) and dry methanol (10 ml) after 4 days at 20°. The diarsine (0.353 g) and 6 ml of a 5% solution of sodium methoxide in methanol gave, on being warmed to 20°, a green solution which slowly became colorless then brown after 12 hours. After 6 days fluoroform (0.209 g; 90% of the trifluoromethyl) was obtained. The solid remaining in the tube contained at least two phases and was completely soluble in water. This solution contained arsenite but no fluoride.

Solvolysis of Bistrifluoromethylarsine

Bistrifluoromethylarsine (0.306 g) and ammonia (4.40 g) gave a green solution and a white precipitate at low temperature. The color gradually faded from the solution as it was warmed to 20° and the solid became red-brown. After 28 days fluoroform (0.152 g; 76% of the trifluoromethyl) was obtained. Arsenite but no fluoride was produced. Bistrifluoromethylarsine (0.185 g) and 4 ml of a 5% solution of sodium methoxide in methanol gave a transient green solution on being warmed to 20°. After 12 hours a copious brown precipitate had formed. After 5 days fluoroform (0.081 g) equivalent to 67% of the available trifluoromethyl was isolated. The brown solid remaining in the reaction tube contained arsenite but no fluoride and was partly insoluble in water and acetone. The infrared spectrum of this solid indicated the presence of C—F groups.

Reaction of Tetrakistrifluoromethyldiphosphine with Ammonia

The diphosphine (0.264 g) and ammonia (1.79 g) gave a colorless solution at 20° which slowly deposited a white solid. After 14 hours the solid was red-brown. After 28 days fluoroform (0.105 g) equivalent to 48% of the trifluoromethyl was obtained. No fluoride was produced.

Solvolysis of Trifluoromethyl Arsenicals containing Ethyl and n-Butyl Groups

The results can be summarized as follows:

Compound	mmoles	Solvolysis reagent	Time	Temp. (°C)	Yield of fluoroform (%)
$C_2H_5As(CF_3)_2$	0.912	10% NaOH (10 ml)	4 days	100	100
	1.52	Liquid NH_3 (3.9 g)	10 days	20	36
$(C_2H_5)_2AsCF_3$	2.29	20% NaOH (10 ml)	3 days	20	1
	1.37	10% NaOH (10 ml)	12 hours	100	34
	1.67	Liquid NH_3 (6.9 g)	14 days	20	7
n-$C_4H_9As(CF_3)_2$	1.63	20% NaOH (10 ml)	5 days	20	2
	1.55	10% NaOH (10 ml)	11 hours	100	38
	1.83	Liquid NH_3 (6.3 g)	11 days	20	14
$(n$-$C_4H_9)_2AsCF_3$	1.43	10% NaOH (10 ml)	12 hours	100	10
	1.29	Liquid NH_3 (5.3 g)	13 days	20	<0.5
$(CH_3)_2AsC_3F_7$	0.722	Liquid NH_3 (1.2 g)	9 days	20	11 (C_3F_7H)*

*The excess ammonia was removed with hydrochloric acid.

DERIVATIVES OF MONOGERMANE

PART I. THE VIBRATION–ROTATION SPECTRA OF GERMYL FLUORIDE AND BROMIDE[1]

J. E. GRIFFITHS[2]
Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey, U.S.A.

AND

T. N. SRIVASTAVA[3] AND M. ONYSZCHUK
Inorganic Chemistry Laboratory, McGill University, Montreal, Que.

Received December 12, 1961

ABSTRACT

The vibration–rotation infrared absorption spectra of germyl fluoride and bromide have been observed. All of the fundamentals in GeH_3F were located, and the rotational structure of the *E*-type bands were resolved and analyzed. The low-frequency band, $\nu_3(a_1)$, in GeH_3Br was not observed but an estimate of its position was made from the frequencies of the combination band $\nu_3+\nu_6$ and of ν_6. The rotational constant A'' and the Coriolis constants ζ_4, ζ_5, and ζ_6 were calculated for both molecules, and agreement with microwave A'' values was satisfactory. Thermodynamic functions based upon a rigid-rotator, harmonic-oscillator model have been evaluated for germyl fluoride and bromide.

INTRODUCTION

The infrared vibrational spectra of only six compounds containing the germyl (GeH_3—) group have been reported. These are germane (1), monodeuterogermane (2), digermane (3), chlorogermane and chlorogermane-d_3 (4), and vinylgermane (5). The molecular structure of the fluoride (6), chloride (7), and bromide (8) have been determined by microwave spectroscopy, the results of which were subsequently confirmed in the case of the chloride by an analysis of the rotational structure of its perpendicular infrared absorption bands (4). In the course of an investigation of tetracovalent germanium compounds, in which the germyl derivatives were of particular interest, we prepared a series of GeH_3X compounds, where X is F, Cl, Br, I, CN, NCO, NCS, and CH_3, and measured their infrared vibrational spectra under medium dispersion. A detailed treatment of the vibration–rotation spectra of the fluoride and the bromide is presented here.

EXPERIMENTAL

All volatile compounds were manipulated in a glass high-vacuum apparatus in which the stopcocks were lubricated with a chlorofluorocarbon stopcock lubricant.

Germyl bromide was obtained by the reaction of germane with bromine, using a method similar to that described for the preparation of silyl bromide (9). Bromine (7.9 mmoles), in small portions, was condensed into a tube fitted with a stopcock in which a sample of germane (8.1 mmoles) had been cooled to −196° C. After each addition of bromine, the mixture was warmed slowly until the color of bromine had just disappeared. The products were separated from unconsumed germane by fractional condensation and vaporization in a trap cooled to −160° C before proceeding to the next addition of bromine. Germyl bromide was recovered from the product mixture by several distillations at −78° C (91% yield; found: molecular weight (M) 156.0, v.p. 25.7 mm at −23° C; calc. for GeH_3Br: M 155.5, v.p. 25.0 mm at −23° C (10)).

Germyl fluoride was prepared by the interaction of excess silver(I) fluoride with germyl bromide (11). The bromide (2.0 mmoles) was passed slowly through a sample of glass wool and powdered silver fluoride contained in a U-tube which was cooled to −22.9° C. The monofluoride (1.67 mmoles; found: M 94.7;

[1]*This work was presented in part at the Eighth Ottawa Symposium on Applied Spectroscopy, Ottawa, Ontario, September 18–20, 1961.*

calc. for GeH_3F: M 94.6) was separated from the difluoride (0.151 mmoles; found: M 112.8; calc. for GeH_2F_2: M 112.6) by passing a mixture of the two through a trap cooled to −95° C, at which temperature the difluoride is involatile. It is particularly important to ensure complete removal of the difluoride, since there are several very intense absorption bands in its infrared spectrum (12) which occur in the same spectral regions as absorptions due to the monofluoride.

Spectra were recorded in the range of 4000 to 625 cm^{-1} with a Perkin–Elmer Model 221-G spectrophotometer using a NaCl prism-grating optical system and with a Perkin–Elmer Model 21 instrument equipped with CaF_2 and NaCl prisms. These instruments were calibrated using CO_2, CO, and NH_3 so that an absolute accuracy of about 1 cm^{-1} is claimed. Small frequency differences, however, as encountered in the analysis of the rotational structure of the perpendicular bands, are expected to be accurate to about ±0.2 cm^{-1}. The ν_6 vibration in the spectrum of the bromide was observed with a Perkin–Elmer Infracord instrument equipped with a KBr prism. The resolution (ca. 4 cm^{-1}) was adequate to distinguish between successive peaks in this absorption band. This instrument was calibrated with polyethylene, and an accuracy of ±3 cm^{-1} was obtained. The measured separation of successive Q branches is expected to be accurate to about ±0.3 cm^{-1}.

Measurements were made on compounds in the gas phase contained in a 7.5-cm cell fitted with KBr windows at pressures of 5.5, 10.0, and 17.0 mm for the fluoride and 17.0 and 25.0 mm for the bromide.

RESULTS

The frequencies and assignments of the fundamental bands for germyl fluoride and bromide are listed in Table I and the vibrational spectra are shown in Figs. 1 and 2. The

individual fundamental bands, observed under higher resolution than that used to obtain Figs. 1 and 2, of the fluoride are shown in Figs. 3–7 and of the bromide in Figs. 8–11. Assignments of the subband peaks in the perpendicular absorption bands are listed in Table II for the fluoride, and in Table III for the bromide.

DISCUSSION

The rotational structure of the perpendicular-type bands and the band contours of the parallel-type bands confirm the microwave studies, which indicate that the fluoride and bromide are symmetric tops of C_{3v} symmetry. Monohalogermanes, GeH_3X, have three symmetric vibrations of species A_1 and three doubly degenerate perpendicular vibrations of species E. These, as well as all overtones and combinations, are infrared and Raman active.

Vibrational assignments for the A_1-type fundamentals were made on the basis of band contours which show a PQR structure, and for the E-type fundamentals on the basis of the s,w,w,s intensity alteration in the subband peaks arising from the nuclear spins of the protons and the C_{3v} symmetry of the molecule. Location of the centers of the P, Q, and R branches of the parallel bands was not always apparent because of the strong overlap with less intense perpendicular bands. Thus, vibrations ν_1 and ν_4, ν_2 and

ν_5, and ν_3 and ν_6 in the spectrum of the fluoride, and ν_1 and ν_4, and ν_2 and ν_5 in the spectrum of the bromide, overlapped. When it was not obvious, the structures of the parallel bands were estimated by subtracting the contributions of the perpendicular bands from the overall band contours as described by Lord and Steese (4). In this way, the frequencies of the P, Q, and R branches and the P–R separations were determined.

Non-degenerate (A_1) Vibrations

The fine structure in the parallel bands was not observed in the fluoride and bromide spectra because the resolution in our spectrometers was not high enough. The rotational constants, B_0, which are known from microwave investigations to be 0.335 cm^{-1} for the fluoride and 0.079 cm^{-1} for the bromide, determine the line spacings in the parallel bands. These values are so small that individual lines of separation $2B$ were not resolved. Parallel bands of the fluoride showed well-defined PQR triplet structure, since the ratio of rotational constants, B/A, is high and controls the relative intensity ratio of the Q to the P and R branches. This ratio is very small in the bromide so that the Q branch could not be resolved and only the P–R doublet structures were observed. The P–R spacings for germyl fluoride and bromide were calculated from the formulas of Gerhard and Dennison (13) and are compared with the observed values in Table IV. The agreement between observed and calculated spacings is considered to be reasonable in view of the overlapping parallel and perpendicular bands and the large number of germanium isotopes.

Degenerate (E) Vibrations

The rotational structure of the E-type bands was easily resolved since the rotational constants A and the ratios A/B are large in the fluoride and bromide. Analysis of the spectrum was facilitated by assigning appropriate K values to the ${}^RQ_K$ and ${}^PQ_K$ subbands of comparable intensity at high values of K, where there was negligible absorption

	Average	25.6	12.0
	Calculated	26.4	12.1

of the more intense overlapping parallel bands. The *s,w,w,s* intensity alteration of these subbands was helpful in this analysis, for the band centers lie between strong ${}^RQ_0$ and the weak ${}^PQ_1$ subbranches.

With the exception of ν_5 in the spectrum of GeH_3Br, the analysis of the rotational structure of the perpendicular bands was straightforward. The ${}^RQ_K$ subband peaks in ν_5 were strongly perturbed near $K = 4$, due to Fermi resonance with the combination band $\nu_3+\nu_6$. Thus, the ${}^RQ_4$ and the ${}^RQ_5$ subbands were each split into two lines, the separation of which should theoretically allow an evaluation of the constants of the perturbation. The details of these splittings, however, were rather poorly defined; therefore, the constants were not evaluated. Although ν_3 in GeH_3Br was not observed directly, it was possible to estimate its position from the difference $(\nu_3+\nu_6)-(\nu_6) = 319\ cm^{-1}$. Since the origin of the combination band is not known precisely and the effects of anharmonicity were ignored, the frequency of ν_3 is probably not accurate to better than $\pm 10\ cm^{-1}$. Because of the perturbation of ν_5 at small K and the overlapping of ν_5 by ν_2 at $K = 6$–9, the subband peaks were analyzed using only the frequencies of ${}^RQ_K$ subbands having $K > 10$. The general method used in the rotational analysis is as follows.

Subband frequencies may be represented (14) by the equation

$$[1]\quad \nu_i = \nu_0+[A_v'(1-2\zeta_i)-B_v']\pm 2[A_v'(1-\zeta_i)-B_v']K+[(A_v'-B_v')-(A_v''-B_v'')]K^2,$$

where ν_0 is the band origin, A (or B) $= h/8\pi^2 I_A$ (or $h/8\pi^2 I_B$), ζ is the Coriolis coupling coefficient, and the single and double primes refer to the upper and lower vibration states, respectively. Thus, the fundamental frequency of an E-type band occurs $(A_v'(1-2\zeta_i)-B_v')\ cm^{-1}$ below the strongest subband peak, ${}^RQ_0$. The coefficient of the K term was obtained by plotting $({}^RQ_K-{}^PQ_K)/2$ versus K, the slope being equal to the coefficient, while the slope and intercept of the straight line resulting from a plot of $({}^RQ_K+{}^PQ_K)/2$ against K^2 gave the coefficient of K^2 and the constant term, respectively. A least-squares treatment of the points gave the following equations for the subband frequencies of E-type bands in germyl fluoride and bromide.

For germyl fluoride,

$$[2]\quad \nu_4 = 2131.2\pm 4.85K-0.018K^2$$

$$[3]\quad \nu_5 = 877.0\pm 5.11K-0.004K^2$$

$$[4]\quad \nu_6 = 664.7\pm 3.32K-0.002K^2.$$

For germyl bromide,

$$[5]\quad \nu_4 = 2127.1\pm 5.29K-0.018K^2$$

[6] $$\nu_5 = 875.6 \pm 5.88K - 0.006K^2$$

[7] $$\nu_6 = 580.4 \pm 4.10K + 0.008K^2.$$

For XYZ_3 molecules, the ζ sum rule is

[8] $$\sum_{i=4}^{6} \Delta\nu_i = 6(A' - B') - 2A' \sum_{i=4}^{6} \zeta_i,$$

where

[9] $$\sum_{i=4}^{6} \zeta_i = B'/2A'$$

and

$$\Delta\nu_i = ({}^{R}Q_K - {}^{P}Q_K)/2K;$$

therefore,

[10] $$\sum_{i=4}^{6} \Delta\nu_i = 6A' - 7B'$$

if the variation of A' and B' with the vibrational state is neglected (see eq. [1]). Using the B_0 value from microwave studies for B', A' is readily obtained and represents an average $A' = (A_4' + A_5' + A_6')/3$. By assuming $B' = B''$ for ν_4, ν_5, and ν_6, the coefficients of K^2 in eqs. [2–7] allow an evaluation of A'' and of the various A_i', which then may be substituted in eq. [1] to yield values of ζ_i. The results are listed in Table V.

*Microwave results.

agree within experimental error with those determined by infrared methods, although the former tend to have somewhat higher values than the latter. This is not unexpected

since the microwave values were calculated for the ground state and the infrared constants were determined on the assumption that $B_v' = B_v''$ for all perpendicular vibrations.

ARSENIDES OF THE TRANSITION METALS

VI. ELECTRICAL AND MAGNETIC PROPERTIES OF THE TRIARSENIDES[1]

C. M. PLEASS[2] AND R. D. HEYDING

Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received November 29, 1961

ABSTRACT

Homogeneity limits at 750° C of the ternary DO_2 triarsenides $(Ni,Co)As_3$, $(Fe,Co)As_3$, and $(Fe,Ni)As_3$ have been established. The electrical and magnetic properties of these systems and the triarsenides of cobalt, rhodium, and iridium have been examined. The results are:

System	Limits	Magnetic properties	Electrical properties
$CoAs_3$	—	$\chi_g^{25°} = -0.158\times10^{-6}$	Semiconductor
$RhAs_3$	—	$\chi_g^{25°} = -0.219\times10^{-6}$	Semiconductor
$IrAs_3$	—	$\chi_g^{25°} = -0.253\times10^{-6}$	—
$Ni_xCo_{1-x}As_3$	$0 \leqslant x \leqslant 0.65$	$p_{eff} = 0.8$–$1.2\ \mu_B$/Ni	Ni donor atom
$Fe_xCo_{1-x}As_3$	$0 \leqslant x \leqslant 0.16$	$p_{eff} = 1.9$–$2.7\ \mu_B$/Fe	Fe donor atom
$Fe_xNi_{1-x}As_3$	$0.25 \leqslant x \leqslant 0.46$	Weak paramagnetism	Semi- to metallic

These data are discussed with reference to the bonding model proposed by Dudkin and Abrikosov. The model is satisfactory for the binary compounds and the Ni/Co system, but not for the Fe/Co and Fe/Ni systems.

INTRODUCTION

Skutterudite ($CoAs_3$, DO_2) type structures are found among the phosphides, arsenides, and antimonides of cobalt, rhodium, and iridium, as well as the phosphides of nickel and palladium (1). In this lattice each metal atom is surrounded octahedrally by six pnigogens,[3] while each of the latter is shared by two metal atoms and has two other pnigogens as nearest neighbors, forming a distorted tetrahedral environment. These compounds and the pyrite-type diarsenides $PtAs_2$ and $PdAs_2$ are the only transition metal pnictides in which the metal atoms are entirely surrounded by pnigogens, precluding direct metal–metal interaction.

Dudkin and Abrikosov (2–5) have proposed an electronic model for $CoSb_3$ which they have used with considerable success in describing the electrical properties of doped and undoped specimens. They have assumed that the bonds in these compounds are semiconducting bonds as defined by Mooser and Pearson (6, 7). In this model each antimony atom forms single covalent bonds with its two nearest antimony neighbors, and half bonds with the two metal neighbors, as indicated in Fig. 1. The antimony $5s$ and $5p$ orbitals are completely occupied, and are assumed to form sp^3 l.c.a.o. orbitals in accord with the distorted tetrahedral environment of the antimony atoms. Each metal atom in turn forms half bonds with the six pnigogen atoms which surround it, the three valence electrons required occupying octahedral d^2sp^3 hybrid orbitals. Although the metal bonding orbitals are only partially occupied they do not overlap other metal orbitals and metallic conduction would not be expected to occur.

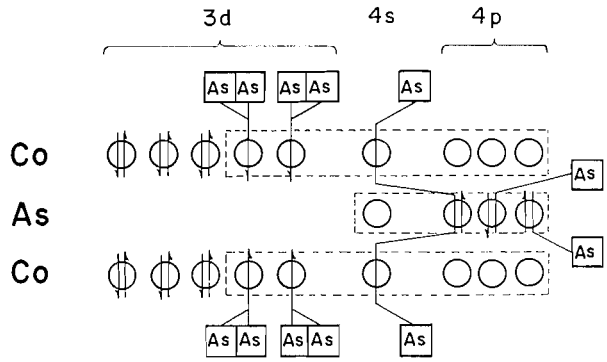

FIG. 1. Bonding model of $CoAs_3$ according to Dudkin and Abrikosov (5).

If this model is correct, certain predictions can be made concerning the magnetic and electrical properties of these compounds. The cobalt family of tripnictides, Co(Rh,Ir)P_3, Co(Rh,Ir)As_3, Co(Rh,Ir)Sb_3, should be diamagnetic and semiconducting. Indeed, both $CoSb_3$ (5) and $CoAs_3$ (8) are semiconductors, the latter having an energy gap of approximately 0.25 ev. Very recently Kjekshus and Pedersen have reported that $IrAs_3$ and $IrSb_3$ are diamagnetic (9). Similarly, the iron family analogues, with one less *d* electron, should be paramagnetic and semiconducting. In the nickel family analogues, the additional metal electron cannot be accepted by the *d* orbitals, which are completely occupied, and must be assumed to occupy a higher energy level, possibly within the conduction band; consequently these compounds should be weakly paramagnetic and metallic conductors.

With the exception of NiP_3 and PdP_3 (10), the iron and nickel analogues have not been prepared synthetically, nor do they exist in nature. However, cobalt is often partially replaced by nickel and iron in natural skutterudites (11), and Dudkin has established the substitutional solid solution limits of iron and nickel in $CoSb_3$ (2, 5). We have determined the substitution limits in the systems $Fe_xCo_{1-x}As_3$, $Ni_xCo_{1-x}As_3$, and $Fe_xNi_{1-x}As_3$ at 750° C in the presence of excess arsenic. Unit cell dimensions, magnetic susceptibilities, electrical conductances, and thermal e.m.f. polarities of these solid solutions and of the binary compounds $CoAs_3$, $RhAs_3$, and $IrAs_3$ have been determined for their intrinsic interest and as a measure of the validity of Dudkin's model.

EXPERIMENTAL

1. *Sample Preparation*

Alloys were prepared by the direct interaction of arsenic and metal powders in sealed, evacuated tubes. Iron, cobalt, and nickel sponges were supplied by Johnson, Matthey and Co., with the following spectroscopic analyses in p.p.m.:

	Mn	Fe	Co	Ni	Cu	Other
Fe	3	X	—	2	—	4
Co	—	—	X	1	2	5
Ni	—	2	2	X	—	8

Rhodium and iridium sponge supplied by Baker and Co. were found by spectroscopic analysis to contain slight traces of Ca, Cu, Si, and Fe and Sb, Si, and Ca, respectively. The sponge was reduced in purified hydrogen at 600° C prior to use.

Cominco high-purity arsenic, containing Ca, Cu, Pb, Mg, and S, each less than 0.1 p.p.m., and Si less than 0.2 p.p.m., was sublimed *in vacuo* at 450° C (i.e. converted to an amorphous form) to facilitate grinding, and stored *in vacuo*.

Specimens were prepared in 5- to 10-g quantities by weighing calculated quantities of metal and arsenic powders in air and sealing in pyrex tubes under high vacuum with 5–10% excess arsenic to suppress dissociation. After the specimen was heated for 24 hours at 400–450° C the product was removed, ground, and resealed in vycor or clear quartz for a series of 6- to 7-day annealing periods at 750° C. At the end of each annealing period the alloy was slow-cooled in the furnace, reground, and sampled for a Debye–Scherrer pattern. Annealing was repeated until all diffraction lines due to extraneous phases had been eliminated and consecutive photographs showed no change in lattice parameters. At temperatures below 750° C equilibrium was attained only slowly, and at higher temperatures most of the alloys suffered peritectic decomposition.

The excess arsenic was removed by maintaining a very small temperature gradient along the sample tube during annealing, thus causing the arsenic to crystallize in the void space away from the bulk of the sample.

Debye–Scherrer patterns were obtained in 11.46-cm Norelco cameras using Co K_α radiation.

Resistivity and Seebeck coefficient specimens were prepared by slow sintering at 750° C in the presence of excess arsenic. Finely ground partially reacted alloy was tamped firmly into 4-mm I.D. heavy wall vitreosil tubing, forming a rod 5–12 cm in length. Excess arsenic was added above the specimen, and the tube evacuated, sealed, and sintered for 6–7 days at 750° C. The rod was pushed from the capillary, sampled for diffraction pattern, and resealed in a standard annealing tube. Annealing then followed the course previously outlined.

2. Magnetic Susceptibilities

Susceptibilities were determined by the Curie method using Henry pole-caps and the experimental arrangement described in an earlier paper (10). The atmosphere in the temperature control system and balance was dry, purified nitrogen at 770 mm pressure. Powdered specimens of about 1 g were held in a quartz bucket for study in the temperature region 83° to 670° K. Under these experimental conditions the susceptibility of crystalline arsenic was determined with no tarnishing of the crystal faces or detectable loss in weight due to vaporization of As_2O_3 or arsenic itself. For higher temperatures the bucket was replaced by a sealed, flat-bottomed quartz ampoule of sufficient length that it could be opened and resealed in a region exposed to negligible field. The force on the specimen was determined at three magnet currents, the minimum field to which any part of the specimen was subjected being ca. 8000 gauss. The apparent susceptibilities were plotted against $1/(H_{max}+H_{min})$ for specimens showing field dependence, and the data extrapolated to infinite field strength to eliminate the effect of ferromagnetic impurities.

3. Electrical Properties

The resistivity of sintered specimens was determined in a simple d-c. circuit over the temperature range 80°–670° K. Current from a storage cell was passed through the specimen in series with a standard resistance, and the potential drop across a known length of sample measured using null-point probes. The direction of the current was reversed at each experimental point and the mean potential drop determined to eliminate stray contact and thermal voltages. Measurements were made with the specimen under vacuum above room temperature and under a small nitrogen pressure below room temperature.

The Seebeck coefficients of these compounds versus copper were determined for $CoAs_3$ specimens only. Calibrated copper/constantan thermocouples silver-soldered into pure copper hemispheres of ca. 0.35-mm D. made spring-loaded contact with the ends of the sintered specimen. The sample was held by a boron nitride sleeve which also served to support small differential heaters at each end of the specimen. The whole was sealed *in vacuo* and thermostated for measurements from 80° to 670° K. A minimum of 12 hours was allowed for the apparatus to come to equilibrium under any given set of conditions.

A very simple apparatus showing the polarity of the hot junction of the specimen/copper couple was used to determine the type of conduction occurring in the iron- and nickel-substituted semiconductors.

RESULTS AND DISCUSSION

1. Limits of Solid Solution Regions and Stoichiometry

The limits to which iron and nickel can be substituted for cobalt in $CoAs_3$, and iron for nickel in the hypothetical compound $NiAs_3$ at 750° C, as determined by Debye–Scherrer patterns, are given in Table I. In this table comparison is made with the limits and unit cell dimensions observed by Holmes in naturally occurring skutterudites (8). The unit cell dimensions of the solid solutions are, within experimental error, linear functions of the composition (Fig. 2).

TABLE I

Substitution limits at 750° C, and room-temperature lattice dimensions in iron- and nickel-substituted $CoAs_3$

System	Observed limits	Mineral limits (Holmes (11))	Specimen	Unit cell, obs. (Å)	Mineral (11)
$Fe_xCo_{1-x}As_3$	$0 \leqslant x \leqslant 0.16$	$0 \leqslant x \leqslant 0.25$	$CoAs_3$	8.206±2	8.187
$Ni_xCo_{1-x}As_3$	$0 \leqslant x \leqslant 0.65$	$0 \leqslant x \leqslant 0.50$	$Ni_{0.25}Co_{0.75}As_3$	8.236±2	8.207
$Fe_xNi_{1-x}As_3$	$0.25 \leqslant x \leqslant 0.46$	—	$Fe_{0.46}Ni_{0.54}As_3$	8.256±2	8.235

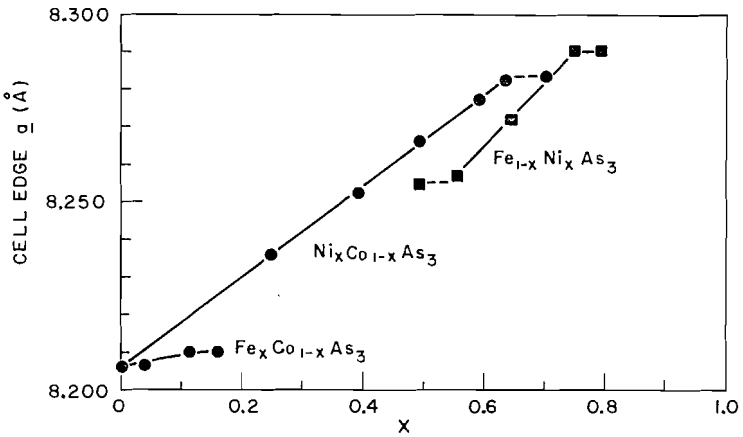

FIG. 2. Cubic unit cell dimensions of substituted triarsenides as a function of composition.

Throughout this study total analyses have indicated persistent deviations from stoichiometry. Indeed, specimens annealed at 750° C are more properly represented by the formula $(M_xM'_{1-x})As_{3-y}$, with $0 \leqslant y \leqslant 0.20$. The deviation from stoichiometry does not appear to be a function of the degree of substitution, nor is there any detectable variation in lattice dimensions with arsenic content. Analyses of some 40 alloys do indicate, however, that departure from ideality in the $(Fe,Co)As_3$ system is significantly greater than in the other three systems (Table II). In all systems the deviations are considerably less than have been observed in natural skutterudites (11).

TABLE II

Departure from stoichiometry

(Specimens annealed at 750° C in the presence of excess As)

System	$(3-y)_{min}$	$(3-y)_{max}$	$(3-y)_{mean}$
$CoAs_{3-y}$	2.946	2.962	2.955
$(Ni,Co)As_{3-y}$	2.91	2.99	2.95
$(Fe,Co)As_{3-y}$	2.66	2.94	2.87
$(Fe,Ni)As_{3-y}$	2.91	2.98	2.94

We were unable to devise a satisfactory technique for density determinations on these compounds; consequently it is not possible to say whether or not arsenic vacancies in the lattice are occupied by metal atoms.

Stoichiometric $CoAs_3$ can be prepared by prolonged annealing at 650° C in the presence of excess arsenic. The properties of stoichiometric $CoAs_3$ discussed below were obtained on specimens prepared at this lower temperature.

2. Magnetic and Electrical Properties

(a) $CoAs_3$, $RhAs_3$, and $IrAs_3$

The binary triarsenides are diamagnetic, as predicted by Dudkin's model. Room temperature (296° K) susceptibilities at infinite field strength are:

$$CoAs_3: \quad \chi_g^\infty = -0.158 \pm 0.002 \times 10^{-6} \text{ e.m.u./g};$$
$$RhAs_3: \quad \chi_g^\infty = -0.219 \pm 0.002 \times 10^{-6} \text{ e.m.u./g};$$
$$IrAs_3: \quad \chi_g^\infty = -0.253 \pm 0.002 \times 10^{-6} \text{ e.m.u./g}.$$

The susceptibilities of all three compounds are slightly temperature dependent, as shown in Fig. 3. The susceptibilities of $IrAs_3$ reported by Kjekshus and Pedersen (9) have

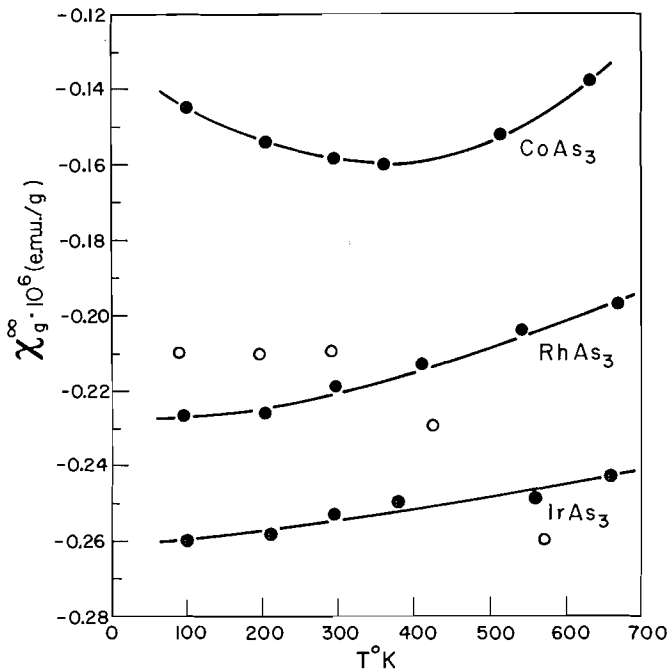

FIG. 3. Mass susceptibilities of $CoAs_3$, $RhAs_3$, and $IrAs_3$ at infinite field strength in c.g.s. e.m.u./g. Open points are the susceptibilities of $IrAs_3$ recorded by Kjekshus and Pedersen (9).

been included in this figure. Since the Gouy method was used by these authors and extrapolation of experimental susceptibilities to infinite field strength could not have been made, agreement with our values is not unsatisfactory.

Typical temperature/resistivity curves are shown in Fig. 4(*a*). The data represented were obtained on a stoichiometric specimen of $CoAs_3$, although deviations from stoichiometry did not affect the resistivity within experimental uncertainty. All three compounds were found to be *p*-type semiconductors. The thermal e.m.f. of $CoAs_3$ measured against copper increases from 10 μv/°C at 100° K to a maximum of 140 μv/°C at 320° K, and then decreases to 85 μv/°C at 600° K.

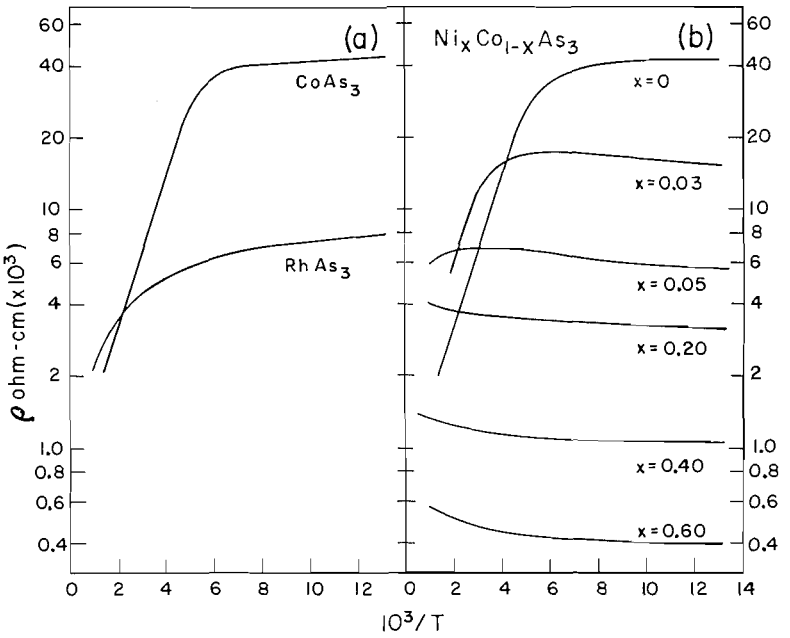

FIG. 4. (*a*) Resistivity of stoichiometric binary triarsenides as a function of temperature. (*b*) Resistivity of nickel-substituted cobalt triarsenide as a function of temperature and composition.

The decrease in diamagnetic susceptibilities observed at higher temperatures is consistent with the electrical behavior of these compounds. With increasing temperature, the number of electrons in the conduction band increases, and consequently the conductivity and the paramagnetic contribution due to the conduction electrons also increase.

(b) The System $Ni_xCo_{1-x}As_{3-y}$

The effect of nickel substitution on the electrical resistivity of $CoAs_3$ is illustrated in Fig. 4(*b*). In agreement with the model, nickel behaves as a donor impurity. At appreciable nickel concentrations semiconducting properties are lost and the system becomes metallic in character. Conduction becomes *n* type with 1% substitution of nickel for cobalt.

Susceptibilities of three specimens with 3, 20, and 40% substitution are given in Table III. At 3% substitution the triarsenide is weakly diamagnetic except at low temperatures; at higher concentrations the paramagnetic contribution of the conduction electrons is sufficient to make the overall susceptibility positive. Reciprocal susceptibilities are plotted as a function of temperature in Fig. 5. At 20% substitution the effective moment per nickel atom is 0.804 μ_B with a Weiss constant of $-290°$ K, while at 40% substitution $p_{eff} = 1.24\ \mu_B$, and $\theta_w = -1200°$ K.

(c) The System $Fe_xCo_{1-x}As_{3-y}$

Susceptibilities of three specimens in this system are given in Table IV. Observed susceptibilities are the sum of individual paramagnetic contributions due to conduction and unpaired electrons (if any), and diamagnetic contributions due to the arsenic, cobalt, and iron cores. At low iron concentrations the diamagnetic terms will be of the same order of magnitude as the paramagnetic terms, and to recognize the temperature

dependence of the paramagnetic terms some correction for diamagnetic susceptibility must be made. As a first approximation we have assumed the diamagnetic terms in $Fe_xCo_{1-x}As_3$ to equal the diamagnetic susceptibility of $CoAs_3$ itself. The corrected or paramagnetic susceptibilities, χ_p, given in Table IV were obtained by subtracting the mass susceptibilities of $CoAs_3$ at the appropriate temperatures (cf. Fig. 3).

TABLE IV

Mass susceptibilities of $Fe_xCo_{1-x}As_3$ (c.g.s. e.m.u./g)

						653	0.160	0.295

The reciprocals of these paramagnetic susceptibilities are plotted as a function of temperature in Fig. 6. Effective moments per iron atom obtained from this graph are given in Table V.

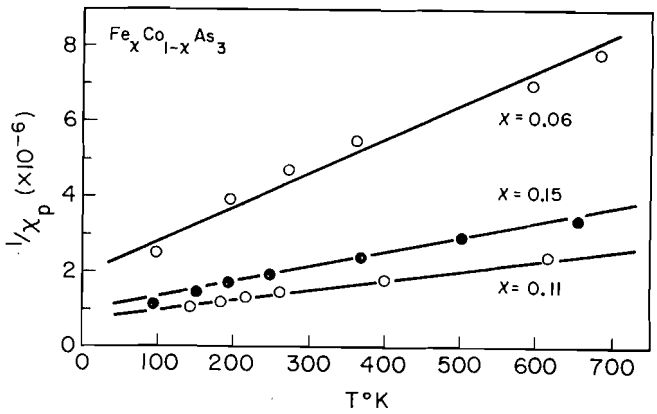

FIG. 6. Reciprocal of 'paramagnetic' susceptibility of iron-substituted cobalt triarsenides as a function of temperature and composition.

TABLE V

Effective moments per iron atom in $Fe_xCo_{1-x}As_{3-y}$

x	$3-y$	C	θ_w (°K)	p_{eff} (μ_B)
0.0592	2.915	0.542	−215	2.06
0.1070	2.890	0.935	−290	2.71
0.1508	2.890	0.480	−250	1.88

These data are consistent with an unpaired electron in Fe and an appreciable conduction electron contribution. This is in agreement with the model which requires an unpaired electron in a non-bonding d orbital. The model predicts that no appreciable change in semiconducting character should occur on the substitution of iron for cobalt. In fact, substitution of iron has a profound effect on the resistivity, as shown in Fig. 7(a). Metallic behavior results with the substitution of as little as 1% of the cobalt by iron, and additional substitution increases the resistivity. At 1% substitution conduction is p type, and at higher concentrations, n type.

Two possible explanations of this behavior can be considered. If the distribution of electrons in bonding and non-bonding levels is correct, conduction may occur via d band interaction. This implies that the Mooser–Pearson rules cannot be applied to these systems, and refutes the basic assumption in Dudkin's model. Alternatively, if d^3 hybrids rather than d^2sp^3 hybrids are the prominent bonding nodes about the iron atom, there will be two fully occupied non-bonding d orbitals, and the eighth electron may occupy the 4s level within the conduction band. One would expect the moment of this electron to be partially quenched and the effective moment to be less than has been observed; some decrease in effective moment with increasing iron concentration is indicated, but only after substitution of one iron atom in each unit cell has been made.

(d) The System $Fe_xNi_{1-x}As_{3-y}$

The model predicts that these compounds should be strongly paramagnetic due to the unpaired spin in Fe, and metallic in conduction due to the conduction electron in

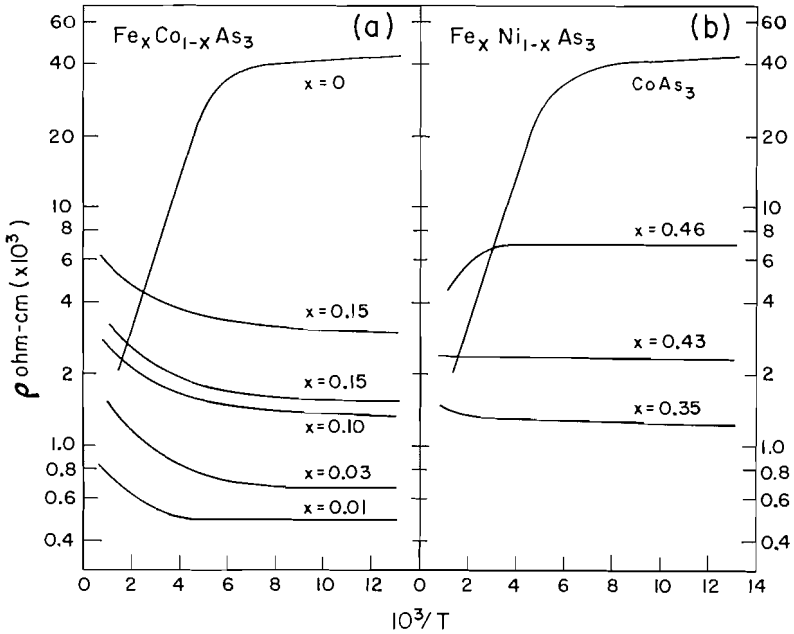

FIG. 7. (*a*) Resistivity of iron-substituted cobalt triarsenide as a function of temperature and composition; data for $x = 0.15$ were obtained with two separate alloys. (*b*) Resistivity of iron/nickel triarsenides as a function of composition and temperature.

Ni. Here again the model is not supported by experimental evidence. The compound with 46% Fe (i.e., at the iron-rich limit of the solid solution region) exhibits semiconducting character (cf. Fig. 7(*b*)). Conduction is *n* type. With increasing substitution of nickel for iron the resistivity decreases and the system becomes metallic.

The mass susceptibilities (Table VI) are small, and the moment per metal atom is much less than one might expect in comparison with the Fe/Co system. In Fig. 8 the

TABLE VI

Mass susceptibilities of $Fe_xNi_{1-x}As_3$ (c.g.s. e.m.u./g)

susceptibilities are compared with Ni/Co and Fe/Co alloys and with $CoAs_3$. The temperature dependence has the same form as that of $CoAs_3$ and the Ni/Co compounds; indeed, nickel and iron appear to form pairs which are equivalent in magnetic behavior

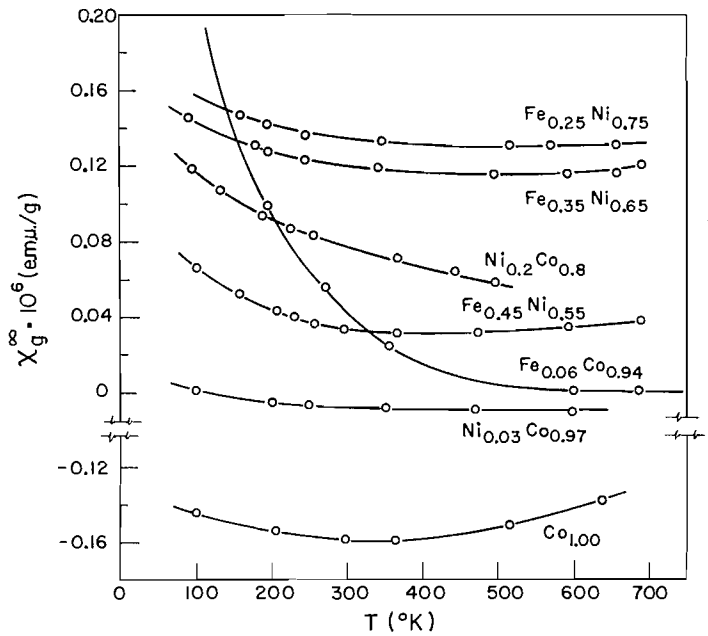

FIG. 8. Comparison of mass susceptibilities of $M_xM'_{1-x}As_3$ alloys as a function of temperature.

to cobalt in the nickel/cobalt system. Writing the general formula $Fe_xNi_{1-x}As_3$ in the form $Ni_{1-2x}(Fe,Ni)_{2x}As_3$, paramagnetic susceptibilities increase in the order $Ni_{0.03}Co_{0.97}$, $Ni_{0.1}(Fe,Ni)_{0.9}$, $Ni_{0.2}Co_{0.8}$, $Ni_{0.3}(Fe,Ni)_{0.7}$, with $(Fe,Ni)_{2x}$ roughly equivalent to Co_{2x}.

Even allowing that conductance measurements on sintered powders do not give reliable values of the resistivity, the same analogy can be drawn in the electrical properties of the Ni/Fe and Ni/Co alloys. There is a gradual transition from semiconducting to metallic behavior, and a decrease in resistivity, in the order $Ni_{0.03}Co_{0.97}$, $Ni_{0.05}Co_{0.95}$, $Ni_{0.08}(Fe,Ni)_{0.92}$, $Ni_{0.2}Co_{0.8}$, $Ni_{0.14}(Fe,Ni)_{0.86}$, $Ni_{0.3}(Fe,Ni)_{0.7}$, $Ni_{0.4}Co_{0.6}$ (cf. Figs. 4(*b*) and 7(*b*)).

It is tempting to propose that electron transfer occurs, and that (Fe^-Ni^+) pairs are formed. In terms of Dudkin's model, this simply requires that the conduction electron in Ni occupy the unpaired non-bonding *d* orbital in Fe. We feel that there is not sufficient evidence to support such a proposal. If it could be shown that an $Fe_{0.5}Ni_{0.5}$ tripnictide is diamagnetic, and that in an iron-rich region magnetic and electrical properties are analogous to those of an iron-substituted cobalt series, some form of electron transfer might be accepted as the basis of a model.

SUMMARY

1. The DO_2 triarsenides $CoAs_3$, $RhAs_3$, and $IrAs_3$ are diamagnetic semiconductors.

2. Substitution of Ni for Co in $CoAs_3$ causes a linear increase in unit cell dimensions. Nickel acts as a donor impurity. With nickel substitution greater than ca. 10%, conductance is metallic in nature. The effective moment per nickel atom is equivalent to less than one unpaired electron, and the Weiss constant in nickel-rich specimens is large and negative. In electrical and magnetic properties nickel behaves like cobalt with an additional electron in the conduction band.

3. Substitution of Fe for Co in $CoAs_3$ increases unit cell dimensions. Iron acts as a donor impurity, with less than 1% substitution leading to metallic character. The effective moment per iron atom is equivalent to between one and two unpaired electrons, and the Weiss constant is relatively small and negative. Iron in this system does not behave as cobalt with one less electron in a non-bonding orbital.

4. In the DO_2 $(Fe,Ni)As_3$ ternary system, iron appears to be in a different state than in the $(Fe,Co)As_3$ system. The effective moment per iron atom is less than one unpaired electron. The properties of this system are comparable to those of the $(Ni,Co)As_3$ system, implying that iron/nickel interaction results in behavior very similar to that exhibited by cobalt.

5. The model proposed by Dudkin describes adequately the electrical and magnetic properties of the binary triarsenides and the nickel/cobalt triarsenides. It is less satisfactory when applied to the iron/cobalt and iron/nickel triarsenides.

ACKNOWLEDGMENTS

We are indebted to Mr. G. J. G. Despault for assistance in preparing specimens, Miss M. McLellan for assistance in obtaining Debye–Scherrer patterns, and Mr. S. L. Bennett for much of the resistivity data.

THERMAL CONDUCTION IN A TIAN–CALVET MICROCALORIMETER[1]

L. BENJAMIN[2] AND G. C. BENSON
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received November 30, 1961

ABSTRACT

The transfer of heat in a Tian–Calvet microcalorimeter is treated theoretically. Although quantitative agreement between predicted behavior and experimental observation is not obtained, the qualitative features brought out by the considerations should be helpful in the design and use of this type of calorimeter.

INTRODUCTION

Several microcalorimeters of the Tian–Calvet type have been described in the literature and are being used to study small heat effects and reaction rates in both chemical and biological systems (for a survey and bibliography see Calvet and Prat (1) or Rossini (2)). Equations relating to the use of such instruments have been derived (3) on the basis of thermal conduction theory and applied to experiment (4, 5) by the empirical fitting of constants in the equations. A description is here given of a somewhat different approach to the same problem in which an attempt is made to calculate a priori the behavior of a microcalorimeter from the geometry and physical properties of the materials, using certain integrals tabulated recently (6). Although such a theory is necessarily approximate, the results should be helpful in the design of microcalorimeters with specified time constants and in the use of such instruments. Results of the theory are compared with experimental curves obtained with a microcalorimeter in operation in this laboratory.

CONDUCTIVITY THEORY

Detailed accounts of the construction of microcalorimeters of the Tian–Calvet type have been given elsewhere (1, 2, 7). For the purpose of the present treatment only brief reference will be made to the principal features of the calorimeter in this laboratory since the design of this equipment follows closely that described by Attree *et al.* (7). A Dural block with tapered holes to accommodate four thermopile units is held at a constant temperature inside five concentric cans contained in an air thermostat. Each thermopile is constructed between a silver thimble and a set of Dural rings separated by teflon spacers, the resulting unit fitting snugly into one of the holes in the block. The photograph (Fig. 1) shows one of these units, inverted, with 4 of the 12 rings in position; there are 12 rows of 6 junctions and an additional junction at the bottom of the thimble. Two such units are placed in diametrically opposite holes in the block and the thermopiles connected in opposition. The resulting e.m.f. and its integral with time are amplified and recorded as in reference 7.

For the purposes of the theory, heat effects of interest are considered to occur in one of the thimbles. In Fig. 2 the temperature of the thimble, $V(t)$, is assumed uniform, as would be the case with a well-stirred fluid content or if the thimble were a perfect conductor; a is the inner radius of the Dural rings and $v(r,t)$ is the temperature at a distance r

[1]*Issued as N.R.C. No. 6692.*

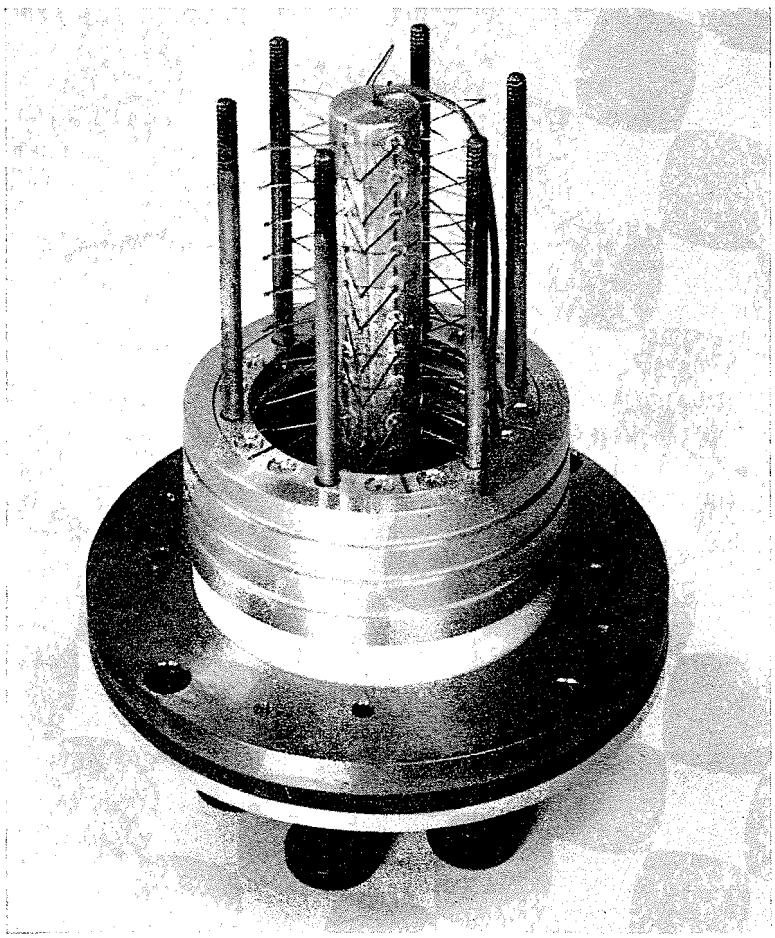

FIG. 1. Photograph of one of the partially assembled thermopiles.

from the center of the thimble at time t. The problem then reduces to that of predicting the following quantities:

(i) $V(t)-v_s(t)$, the temperature difference recorded by the thermopile, where $v_s(t) = v(a,t)$; this difference will be designated by E_t;

(ii) $\int_0^t [V(u)-v_s(u)]du$, which is proportional to the heat transferred to the block in time t and is referred to as I_t;

(iii) $v_s(t)$, the change in block surface temperature with time.

If the assumption is made that the block is infinite in both the axial and radial directions, then we can consider the calorimeter assembly as approximating to a region bounded internally by a circular cylinder of a perfect conductor (radius a) having a thermal resistance $1/H$ per unit area at the surface. This problem has been considered for certain heating conditions by Jaeger (8); in general, solutions are obtained by the Laplace transform method (9). Three dimensionless parameters are used to describe the thermal characteristics of the assembly:

$$h = K(aH)^{-1} \qquad [1]$$

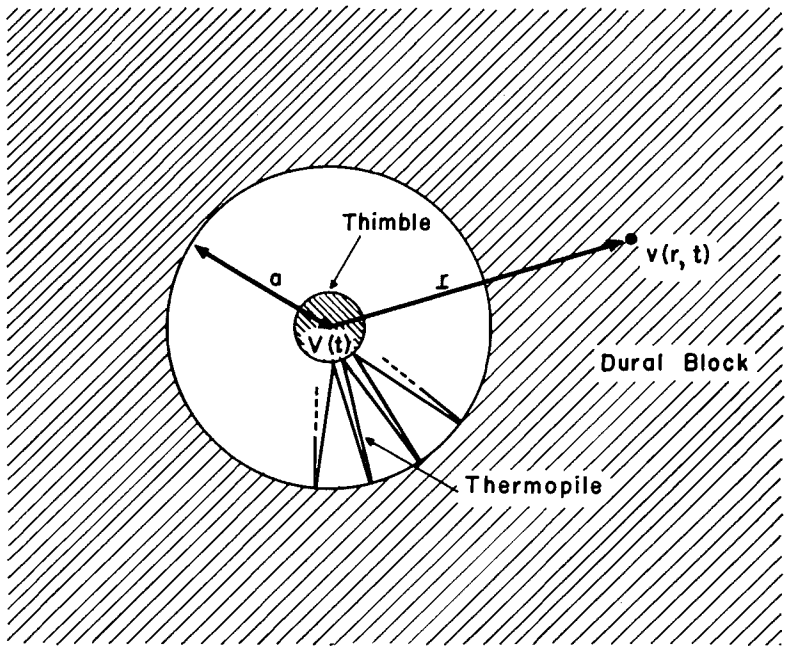

FIG. 2. Diagram of the cylindrically symmetric model used in calculating heat conduction in the microcalorimeter.

[2] $$\alpha = 2\pi a^2 \rho c S^{-1}$$

[3] $$\tau = \kappa t a^{-2},$$

where K, ρ, c, and κ are the thermal conductivity, density, specific heat, and diffusivity in the infinite region; S is the heat capacity of unit length of the internal cylinder; and t is the time. A heating condition frequently used in the microcalorimeter is as follows: at zero time the block and reaction thimble are at the same uniform temperature (taken to be zero) and heat is then supplied for a time t^* at a constant rate Q calories per second per unit length of the thimble. Using the method of the Laplace transformation it can be shown that for $t \leqslant t^*$,

[4a] $$V(t) = \frac{Q}{K} G(h,\alpha,\tau)$$

[5a] $$v_s(t) = \frac{Q}{K}\left[G(h,\alpha,\tau) - \frac{h}{2\pi}\{1-F(h,\alpha,\tau)\} \right]$$

[6a] $$V(t) - v_s(t) = \frac{Q}{K}\frac{h}{2\pi}[1-F(h,\alpha,\tau)]$$

[7a] $$\int_0^t [V(u)-v_s(u)]du = \frac{Q}{K}\frac{a^2 h}{\kappa}\left[\frac{\tau}{2\pi} - \frac{1}{\alpha} G(h,\alpha,\tau) \right]$$

and for $t \geqslant t^*$,

[4b] $$V(t) = \frac{Q}{K}[G(h,\alpha,\tau) - G(h,\alpha,\tau-\tau^*)]$$

$$[5b] \qquad v_s(t) = \frac{Q}{K}\left[G(h,\alpha,\tau)-G(h,\alpha,\tau-\tau^*) + \frac{h}{2\pi}\{F(h,\alpha,\tau)-F(h,\alpha,\tau-\tau^*)\}\right]$$

$$[6b] \qquad V(t)-v_s(t) = \frac{Q}{K}\frac{h}{2\pi}[F(h,\alpha,\tau-\tau^*)-F(h,\alpha,\tau)]$$

$$[7b] \qquad \int_0^t [V(u)-v_s(u)]du = \frac{Q}{K}\frac{a^2h}{\kappa}\left[\frac{\tau^*}{2\pi} - \frac{1}{\alpha}\{G(h,\alpha,\tau)-G(h,\alpha,\tau-\tau^*)\}\right].$$

In these equations the functions $F(h,\alpha,\tau)$ and $G(h,\alpha,\tau)$ are integrals which have been tabulated for certain values of h, α, and τ by Jaeger (8) and by Bullard (10). Values of $F(h,\alpha,\tau)$ and $G(h,\alpha,\tau)$ suitable for use in the present context have recently been computed (6), together with values of a third function, $E(h,\alpha,\tau)$, defined by the equation

$$[8] \qquad E(h,\alpha,\tau) = -\frac{\partial}{\partial\tau}F(h,\alpha,\tau).$$

This function can be used to determine the rate of change of $v_s(t)$ with time through differentiated forms of eqns. [5*a*] and [5*b*].

COMPARISON WITH EXPERIMENT

The theory as outlined above is approximate when applied to experiment in as much as the assumptions which have been made are not strictly valid for the following reasons:

(*a*) $V(t)$ is not uniform since very little stirring of the cell contents can take place in practise. However, $V(t)$ will not vary appreciably over the surface of the thimble because of the high thermal conductivity of silver and the uniform distribution of the thermocouple junctions over the surface. Within the cell a thermal gradient will be present but this radial variation should be small except for very low values of h.

(*b*) The calorimeter assembly does not have perfect cylindrical symmetry. The approximation introduced by neglecting the finite size of the block in directions normal to the axis of the thimble is probably quite good except for small h values. The presence of end effects associated with the finite length of the assembly may cause more serious errors in the use of the theory.

The total heat capacity calculated by summing the heat capacities of the thimble and its contents is about 20 cal (deg. C)$^{-1}$. This ignores contributions from the glass and plastic connections to the cell, which are difficult to estimate. A value near 35 cal (deg. C)$^{-1}$ is indicated by analysis of heating curves as described in reference 2 (see pp. 247–250). For the present calculations we have therefore used a value of $S = 3$ cal (deg. C)$^{-1}$, the length of the thimble being about 10.5 cm. The corresponding value of α is 9.39, which is taken as 9 for convenience.

The radiation constant H, defined as the heat transferred per second per unit temperature difference across unit area, will be made up mainly from conduction along the thermocouple wires H_{tc}, radiation from the thimble H_{rad}, and air convection (including air conduction) H_{air}.

H_{tc} is estimated to be 3.21×10^{-5} cal sec^{-1} cm^{-2} (deg. C)$^{-1}$. There must also be a considerable contribution to thermal conduction from connections to the cell and thimble, although these are made of poorly conducting materials where possible.

H_{rad} is less readily calculated since the emissivity of the silver thimble and thermocouple wires varies greatly, being 0.02 for polished silver and 0.2 for a dull surface. Using a value of 0.1, H_{rad} is found to be 0.6×10^{-5} cal sec^{-1} cm^{-2} (deg. C)$^{-1}$.

Both conduction and convection are possible in the air space separating the thimble and block. Convection in an enclosed vertical space is discussed by McAdams (11) and Jakob (12), who describe experimental results with air which show that no appreciable convection occurs between two surfaces as long as $x^3\Delta T < 11.4$ cm^3 deg. C, where x is the separation of the surfaces and ΔT the temperature difference between them. In the present case this corresponds to $V(t)-v_s(t)$ being less than 2° C, a condition which will be satisfied for heat inputs up to about 60 calories. Conduction in air leads to a value of 2.0×10^{-5} cal sec^{-1} cm^{-2} (deg. C)$^{-1}$ for H_{air}.

From the above considerations it appears that a minimum value of H is 6×10^{-5} cal sec^{-1} cm^{-2} (deg. C)$^{-1}$, corresponding to $h = 2200$, while larger values are to be expected due to conduction along cell connections.

The silver thimble containing a reaction cell is heated by means of an electrical heater wire and $E_t = V(t)-v_s(t)$ reaches a maximum value E_{t^*} at time t^*, decaying slowly to zero thereafter.[3] A convenient way of expressing this variation is by plotting the ratio E_t/E_{t^*} against time. This is done in Fig. 3 for curves calculated from theory and from

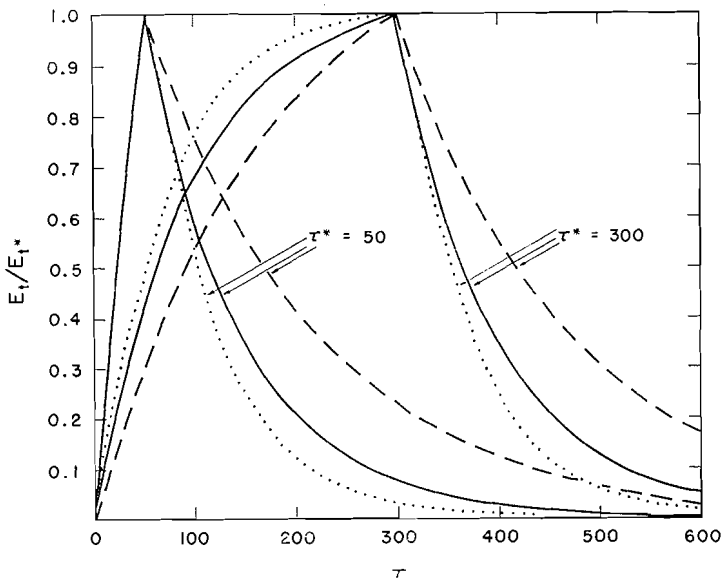

FIG. 3. Comparison of experimental and theoretical curves of the ratio E_t/E_{t^*}: · · · $\alpha = 9$, $h = 600$; — — $\alpha = 9$, $h = 1500$; —— experimental.

experimental observations and for two τ^* values (note $t = 0.202\tau$ minutes). The theoretical curves for two different values of h were obtained from eqns. [6a] and [6b] using the table in reference 6. It appears that using $\alpha = 9$ a value of h near 1000 would fit the experimental curves. The effect of variation of α can be judged from Fig. 4, where it may be seen that an increase in α leads to a lower time constant for the decay curve. A close fit of the experimental curve in Fig. 3 could therefore also be obtained with a somewhat higher α value (10–12) and a value of h more in keeping with that estimated (2200). This implies that a lower value of S should have been used in estimating α, as was indicated by a priori calculations.

[3]*In the absence of convection, heating and cooling result in reciprocal behavior and only heating will generally be referred to in this discussion.*

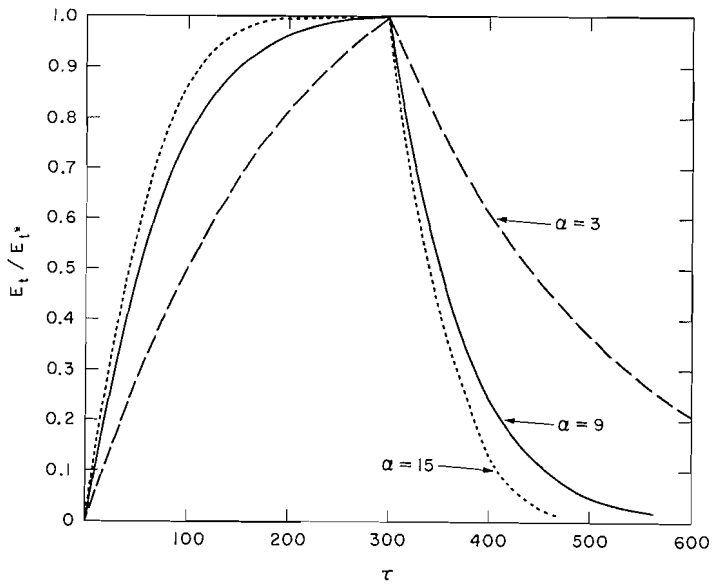

FIG. 4. Plots showing the effect on the ratio E_t/E_t^* of varying the parameter α ($\tau^* = 300$, $h = 600$).

The integrated temperature difference I_t is compared with theory in Fig. 5. The ordinates plotted in this graph are values of $1-I_t/I_\infty$, where I_∞ is the value I_t approaches in the limit as t goes to infinity.

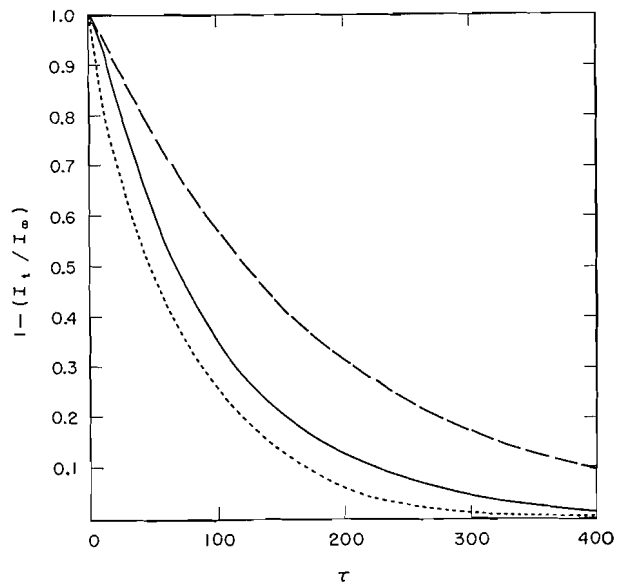

FIG. 5. Comparison of experimental and theoretical curves of $1-(I_t/I_\infty)$ ($\tau^* = 10$): - - - $\alpha = 9$, $h = 600$; — — $\alpha = 9$, $h = 1500$; —— experimental.

The block surface temperature $v_s(t)$ is found to have a maximum value near $t = t^*$ and decays to zero in a manner similar to $V(t)-v_s(t)$ but the curve is more drawn out.

This is illustrated in Fig. 6, where $v_s(t)$ is compared with the maximum temperature difference E_{t^*}. As τ^* increases, the variation during heating approaches a limiting curve

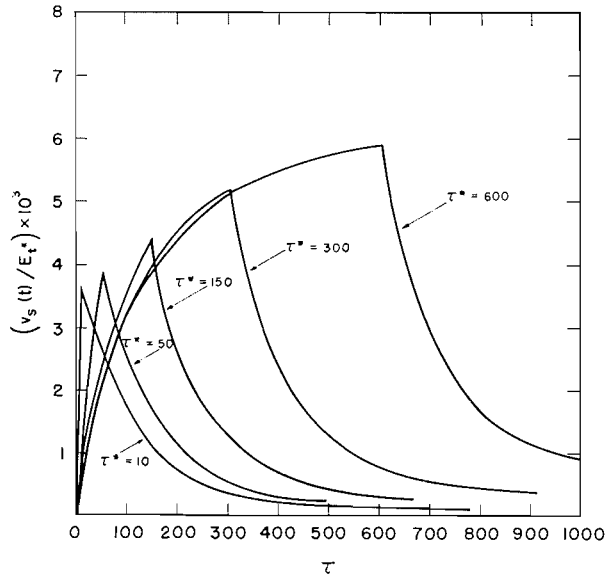

FIG. 6. Plots showing the effect on the ratio $v_s(t)/E_{t^*}$ of varying τ^* ($\alpha = 9$, $h = 600$).

which is not sensitive to changes in α but is more dependent on h. Increasing τ^* results in slower decay of the curves.

DISCUSSION

Prediction of the experimental behavior as outlined appears to be correct within a factor of two and is dependent on the values of the parameters h and α. Differences between experiment and theory are consistent with the probable errors in the estimated values of these parameters, requiring that smaller h and larger α be used.

Somewhat better agreement between the estimated value of α and that found by experiment might have been expected and the difference is no doubt due to neglect of contributions of the cell connections in calculating α. The method used to obtain α by experiment must take account of such contributions since it involves setting up a steady-state condition in which the heat loss from the cell equals the heat input and this will only be true when the temperature in all parts of the assembly is independent of time. Since there exists no large heat sink, similar to the metal block, in good thermal contact with the upper cell connections, considerable heating of the latter over a relatively large distance may pertain in the steady-state condition, resulting in a smaller value. Because of the time necessary to attain thermal equilibrium in these relatively poorly conducting components of the assembly, the value of the total heat capacity will lie between that calculated for the cell ($\sim$20 cal (deg. C)$^{-1}$) and that found for steady-state conditions ($\sim$35 cal (deg. C)$^{-1}$), depending on whether t^* is relatively small or very large. A value near 28 cal (deg. C)$^{-1}$ is indicated from the temperature rise found for t^* equal to 2 minutes; the corresponding α value would probably give better agreement of the theory with experiment. This variation of the heat capacity of the system is discussed by Calvet (1, 2), who, in a typical case, finds a 10% increase in heat capacity when t^* is increased

from 1 minute to 24 hours. An even larger increase is to be expected in the present calorimeter since it would appear to have a lower H value than that used by Calvet.[4]

In any heated cell which is not a perfect conductor, thermal disequilibrium will exist and may be characterized by a constant D for the particular cell together with its contents (2). This disequilibrium will also result in an increased apparent heat capacity but the effect is generally much smaller than that due to contributions of the cell connections.

In view of these considerations it is apparent that a straightforward estimate of the heat capacity neglecting cell connections may be in error by nearly 100% and the actual value depends on the time of heating, t^*. The 40% increase necessary to match this estimate with experimental values for small t^* in the present assembly may serve as an empirical guide to other applications of the theory described. An even greater increase would be necessary for very large t^* values.

Despite this variation in α (and also presumably small changes in h) with t^*, I_∞, the total area under the temperature difference – time curve, is found experimentally to be proportional to the heat input for t^* values of from 2 minutes to 1 hour and for heats up to 2–3 cal. At greater heat inputs, this proportionality, even for t^* values constant at 2 minutes, no longer holds, with I_∞ becoming increasingly lower than that expected as more heat is introduced during a heating period. Temperature rises in this region are not large (0.1–0.5° C) and any transfer of heat, other than by convection, should still be proportional to the temperature difference between the block and cell. As stated earlier, air convection would not be expected to be present in this range of temperature rise. Convection in the liquid contents of the cell may, however, become important at this stage and account for part of this non-linear variation of I_∞ with heat input. A further reason may be due to an increase in thermal disequilibrium in this range. The accuracy of the microcalorimeter for estimating heat effects in this region is less than in the range 0.05–2 cal, where optimum performance is found. This is to be expected if heat transfer is no longer linear, since I_∞ will then depend on the thermogenetic curve.

As can be seen in Fig. 6, v_s decays to zero very slowly and this has the effect of causing tailing of the temperature difference and I_t curves. Thus, accumulation of the last few percent of the heat effect may be somewhat prolonged and often it would be advantageous to stop a run at this point and reload the cells. This could be done by applying a correction to the I_t value at, say, 95% I_∞ on the basis of curves of the type shown in Fig. 5: little loss of accuracy should result in this way, particularly if a good fit of the experimental and theoretical curves is used.

ACKNOWLEDGMENTS

We are indebted to Dean P. R. Gendron, Professor K. J. Laidler, and Dr. H. M. Papée for supplying us with details of the calorimetric equipment at the University of Ottawa and to the late Dr. R. W. Attree and to Mr. L. Cushing for discussions of the calorimeter at A.E.C.L. Chalk River. The construction of our own calorimeter was undertaken in association with Dr. P. White and his collaboration in this phase of the work is gratefully acknowledged.

CYCLIZATION OF AROMATIC PHENYLHYDRAZONES WITH CARBON MONOXIDE TO YIELD SUBSTITUTED PHTHALIMIDINES*

ALEX ROSENTHAL AND MARY R. S. WEIR
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received December 5, 1961

ABSTRACT

The reaction of benzophenone phenylhydrazone with carbon monoxide at 230° and 3800 p.s.i. to give 3-phenylphthalimidine-*N*-carboxyanilide, and at lower temperatures (190–220°) to give a mixture of 3-phenylphthalimidine-*N*-carboxyanilide and 3-phenylphthalimidine has been studied. An independent synthesis of 3-phenylphthalimidine-*N*-carboxyanilide is described. 4-Methylbenzophenone phenylhydrazone reacted with carbon monoxide to give a mixture of two isomers, 3-phenyl-6-methylphthalimidine-*N*-carboxyanilide and 3-(*p*-tolyl)-phthalimidine-*N*-carboxyanilide, whose infrared spectra are described. An independent synthesis of 3-(*p*-tolyl)phthalimidine-*N*-carboxyanilide has also been carried out.

When aromatic nitrogen-containing compounds (having a $\rangle C{=}N-$ or a $-N{=}N-$ group) are treated with carbon monoxide in the presence of dicobalt octacarbonyl catalyst, ring-closure reactions have, in several instances (1–4), been observed. The present work deals with the reaction of carbon monoxide with benzophenone phenylhydrazone and 4-methylbenzophenone phenylhydrazone.

Benzophenone phenylhydrazone reacted with carbon monoxide at 3800 p.s.i. and at 230–240° in the presence of preformed dicobalt octacarbonyl catalyst to give 3-phenylphthalimidine-*N*-carboxyanilide (I) in about 70% yield. The structure determination of the latter was as follows: (I) was subjected to hydrolysis by 75% sulphuric acid and two products were isolated: aniline, identified as tribromoaniline, and a yellow solid of melting point 230° whose molecular formula was $C_{14}H_{10}O_2$. The latter was identical with the hydrolysis product of 3-phenylphthalimidine. Refluxing (I) in 99% deuterium oxide gave material whose infrared spectrum indicated the presence of an N—D grouping (see experimental section). These observations suggested that the carbonylation product contained the 3-phenylphthalimidine ring structure, an N—H group, and a group capable of yielding aniline on hydrolysis. Infrared and elemental analysis established the presence of two carbonyl groups. The work of Murahashi and Horiie (4) on azobenzene (see Chart II) suggested that the second carbonyl group (the first being incorporated into the 3-phenylphthalimidine ring) might well be situated between the two nitrogen atoms, forming an *N*-carboxyanilide side chain, which contains the required N—H group and which would give aniline an acid hydrolysis. The structure of (I) was then established by direct comparison (infrared analysis and mixed melting point) with an authentic sample of 3-phenylphthalimidine-*N*-carboxyanilide. The characteristic infrared absorption peaks of this carboxyanilide are listed in the experimental section.

When the reaction temperature was reduced to 210–220° the product was a mixture which separated on fractional crystallization from benzene into 3-phenylphthalimidine (II) (50%) and 3-phenylphthalimidine-*N*-carboxyanilide (12%). On further reduction of the temperature to 190–200° only 3-phenylphthalimidine (25%) was isolated. The structure of (II) was established by direct comparison with an authentic sample of 3-phenylphthalimidine, prepared by the method of Rose (8), and by the preparation of the monoacetyl derivative by treatment with sodium acetate and acetic anhydride (8).

**Presented at the 140th A.C.S. Meeting, Chicago, September 1961.*

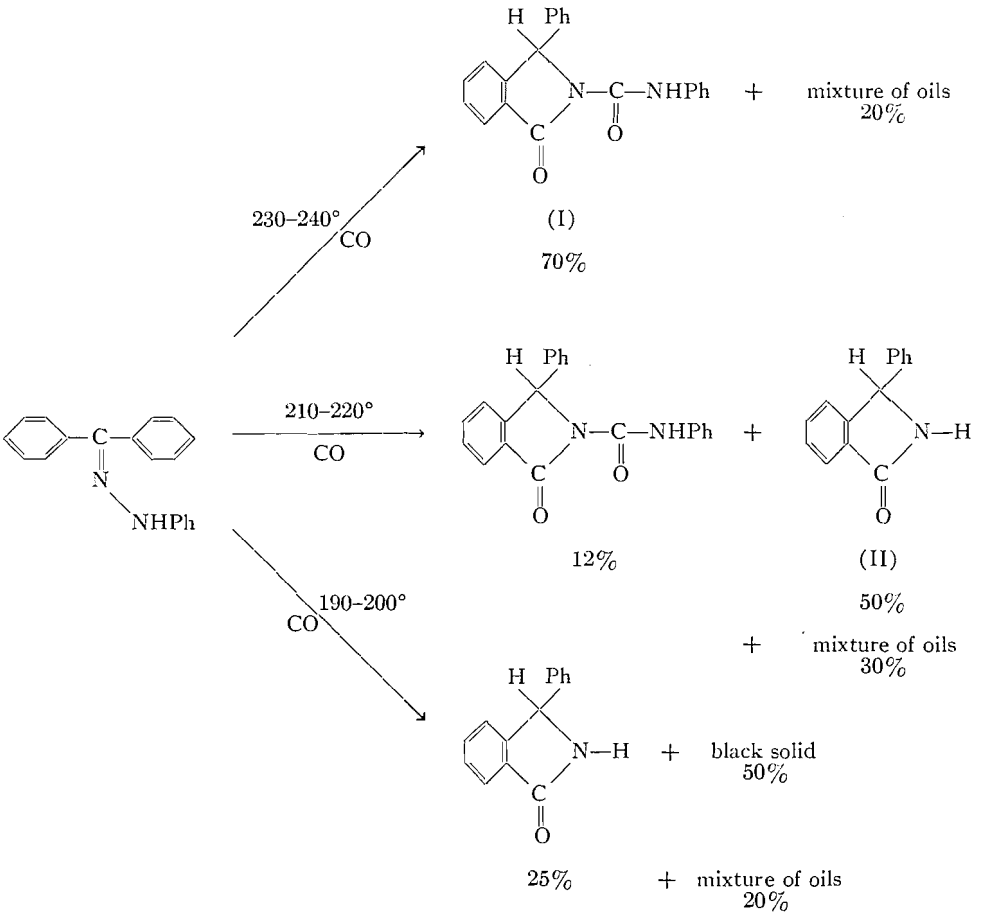

CHART I

The same temperature dependence of the number of carbon monoxide entities incorporated into the product was observed by Murahashi and Horiie (4), whose results are illustrated in Chart II.

When 4-methylbenzophenone phenylhydrazone was treated with carbon monoxide at 230° under the same conditions a mixture of two isomers, 3-(*p*-tolyl)phthalimidine-*N*-carboxyanilide (III) and 3-phenyl,6-methylphthalimidine-*N*-carboxyanilide (IV), of melting points 183–186° and 226–227° respectively, was obtained (Chart III). Both were present in about 20% yield, and were isolated from the reaction mixture in pure form by fractional crystallization from benzene. Structures (III) and (IV) are based on infrared analyses and elemental analyses, and, in the case of (III), on direct comparison with an authentic sample of 3-(*p*-tolyl)phthalimidine-*N*-carboxyanilide, prepared by the condensation (6) of 3-(*p*-tolyl)phthalimidine (7, 8) with phenyl isocyanate. The infrared spectra of (III) and (IV) differ only slightly from each other and from that of 3-phenylphthalimidine-*N*-carboxyanilide (I), the carbonyl peaks at 5.86 and 5.92 μ, and the other characteristic phthalimidine-*N*-carboxyanilide bands at 6.25, 6.42, 6.90, 7.40, and 8.10 μ, being present in the spectra of all three compounds. The strong band at 6.70 μ present in (I) and in (IV) is considerably weakened in (III), and a strong band at 8.54 μ in (IV) is absent in (I) and (III). Differences in the 11-, 12- ,and 13-μ regions of the spectra of these compounds were also observed.

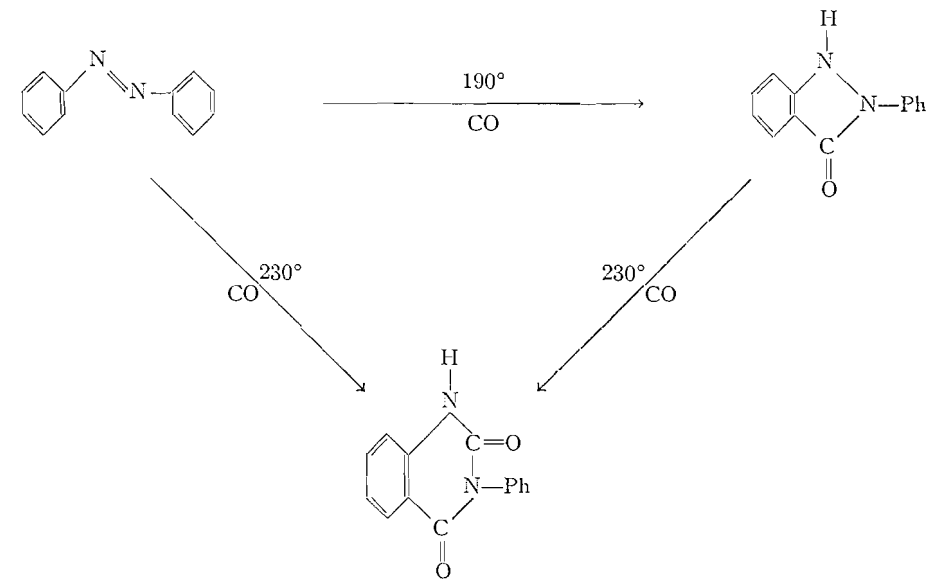

CHART II

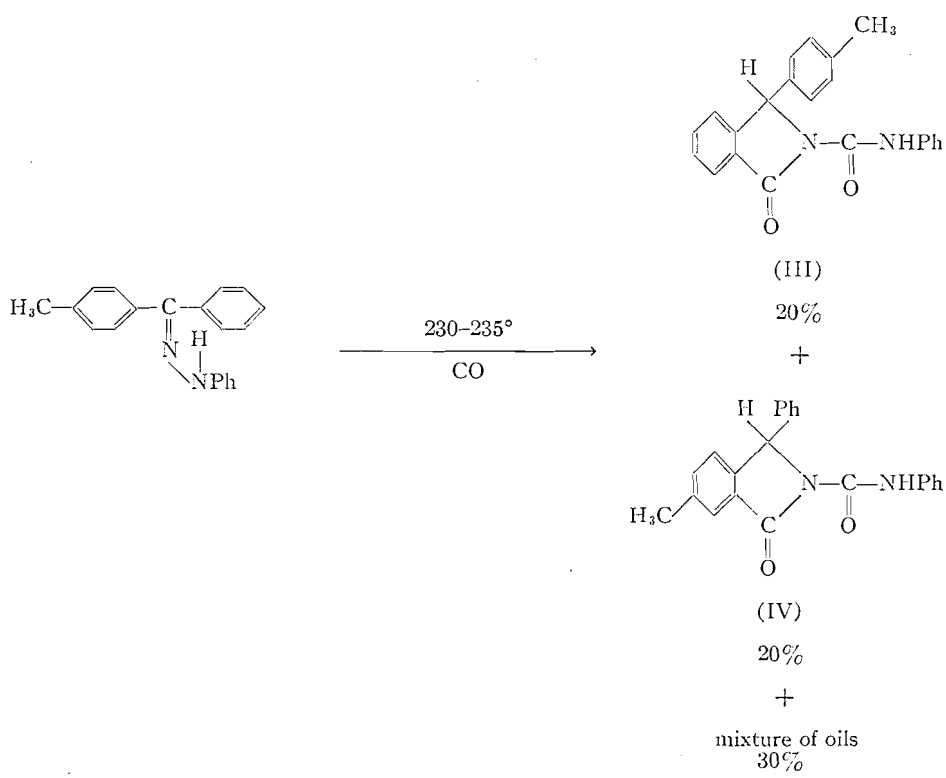

CHART III

Thus, having established by direct comparison structure (III), and it being apparent from infrared analysis that (III) and (IV) varied only slightly, it was concluded that (IV) must be 3-phenyl,6-methylphthalimidine-*N*-carboxyanilide.

This result differs from previous observations (4) on the effect of substituents on carbon monoxide ring-closure reactions in substituted azobenzenes; here the cyclization always occurred on the substituted ring.

EXPERIMENTAL

General Considerations

(*a*) The high-pressure equipment has been described previously (1).

(*b*) In every carbonylation run 2 g (0.006 mole) of dicobalt octacarbonyl catalyst was used, and carbon monoxide was added to an initial pressure of 2000 p.s.i. at room temperature.

(*c*) The reaction products listed include only those observed to be present in greater than 5%.

(*d*) The mixtures of oils obtained in all the runs after separation of the crystalline reaction products were shown by chromatography on alumina to be composed of at least five components. Further investigation of these mixtures was not pursued at this stage.

(*e*) The black solid (see Chart I) appeared to be an organo-cobalt complex which was insoluble in organic solvents.

Preparation of Benzophenone Phenylhydrazone

A mixture of 4 g (0.022 mole) of benzophenone, 4 g (0.034 mole) of freshly distilled phenylhydrazine, and 0.05 g of zinc chloride was heated to reflux, with stirring, for 30 minutes. On cooling of the mixture the material solidified to a pale yellow mass, which was washed with dilute acetic acid and then water, and was recrystallized from 95% ethanol; 4.7 g (78%) of white, needle crystals was obtained, m.p. 137–138° (5).

Preparation of 4-Methylbenzophenone Phenylhydrazone

To a solution of 6 g (0.033 mole) of 4-methylbenzophenone (prepared by a minor modification of the method of Bachmann (9)) in the minimum amount of glacial acetic acid was added 4.2 g (0.036 mole) of freshly distilled phenylhydrazine. The mixture was left overnight in the refrigerator and the brown oil thus obtained was washed free of acetic acid and dissolved in 95% ethanol. Allowing the ethanolic solution to stand at room temperature for 48 hours resulted in the formation of white crystals of m.p. 107–109° (yield, 63%) (10).

Carbonylation Reaction

A typical carbonylation run was as follows:

To a solution of 7 g (0.023 mole) of benzophenone phenylhydrazone in 50 ml of dry benzene was added 2 g (0.006 mole) of dicobalt octacarbonyl catalyst and 2000 p.s.i. of carbon monoxide (Matheson, C.P. gas). The mixture was heated to 230–240° with shaking for 190 minutes. The bomb was then cooled overnight and vented. The reaction product consisted of a dark brown liquid and 6 g (71%) of yellow solid. The solid was crystallized twice from 75% acetic acid, giving white needles of m.p. 211–214°. The infrared spectrum of this material in a KBr pellet showed strong carbonyl bands at 5.86 and 5.92 μ, and also strong bands at 6.25, 6.42, 6.70, 6.90, 7.40, 7.68, and 8.10 μ. Anal. Found: C, 76.51; H, 4.96; N, 8.41; O, 9.97; mol. wt. (Rast), 314. Calc. for $C_{21}H_{16}N_2O_2$: C, 76.80; H, 4.88; N, 8.50; O, 9.76; mol. wt., 328.

Sulphuric Acid (75%) Hydrolysis of 3-Phenylphthalimidine-N-carboxyanilide

3-Phenylphthalimidine-*N*-carboxyanilide (0.2 g) was dissolved in 40 ml of 75% sulphuric acid solution and refluxed for 4 hours. The mixture was then poured into 100 ml of water, the small amount of brown solid was filtered, and the remaining acidic solution was extracted with ether and dried over anhydrous sodium sulphate. Bromine water was added to 15 ml of the residual aqueous solution and a white precipitate was obtained of m.p. 120°; mixed m.p. with an authentic sample of 2,4,6-tribromoaniline, 121°. The infrared spectrum of the material was identical with that of 2,4,6-tribromoaniline.

Exchange Reaction of 3-Phenylphthalimidine-N-carboxyanilide with D_2O

3-Phenylphthalimidine-*N*-carboxyanilide (0.1 g) was refluxed for 6 hours in 10 ml of 99% D_2O containing 0.05 g of K_2CO_3. The solid was then filtered, washed with a small quantity of ethanol, and dried. The infrared spectrum showed a strong N—D band at 4.18 μ, and a weakening of the amide II band at 6.25 μ and the amide III band at 8.10 μ, these changes being in accord with those reported by Bellamy (11).

Synthesis of 3-Phenylphthalimidine-N-carboxyanilide (6)

A mixture of 0.3 g (0.0014 mole) of 3-phenylphthalimidine, 0.2 g (0.0017 mole) of phenyl isocyanate, and 20 ml of toluene (the latter dried over calcium chloride, filtered, and then stored over sodium) was refluxed for 24 hours. The solution was then cooled, and the resulting solid precipitate was filtered, washed with toluene, dried, and weighed; 0.45 g (95%), m.p. 212–215°, was obtained; mixed m.p. (with the product (1) of the carbonylation reaction) 213–215°. The infrared spectrum of this compound was identical with that of the carbonylation reaction product.

Carbonylation of Benzophenone Phenylhydrazone at 210–220°

The product obtained from the carbonylation of benzophenone phenylhydrazone at 210–220° consisted of 3.3 g of a greyish, granular solid and a brown benzene solution. On recrystallization from ethanol the solid had a m.p. of 211–214°. After purification by chromatography on alumina, using chloroform as eluent, the melting point was 223–225°, and the mixed melting point with an authentic sample of 3-phenylphthalimidine 223–226°. The brown benzene solution was boiled to destroy remaining catalyst and the solvent removed. This gave 1.6 g of a bluish solid, which, on washing with benzene and recrystallization from ethanol, gave white needles of m.p. 212–215°. The mixed melting point with an authentic sample of 3-phenylphthalimidine-*N*-carboxyanilide was 211–214°.

Carbonylation of 4-Methylbenzophenone Phenylhydrazone

The clear, brown benzene solution obtained from the carbonylation of 4-methylbenzophenone phenylhydrazone was boiled for 30 minutes to destroy any remaining catalyst, was filtered, and was concentrated to a volume of about 25–30 ml and then was left in the refrigerator overnight. This gave 1.9 g of white crystals, which on recrystallization from ethanol had m.p. 226–227°. (The purity of this material was checked by chromatography on both alumina and silicic acid columns, and no change in melting point was observed in the chromatographed material.) The residual benzene solution was reconcentrated to about 10 ml and was again cooled. A second 2-g fraction of white solid was thus obtained. Recrystallization from ethanol gave white crystals of m.p. 183–186°. Anal. Found: isomer of m.p. 226–227°: C, 76.93; H, 5.33; N, 8.20; isomer of m.p. 183–186°: C, 77.30; H, 5.20; N, 8.16. Calc. for $C_{22}H_{18}N_2O_2$: C, 77.20; H, 5.30; N, 8.19.

Preparation of 3-(p-Tolyl)phthalimidine

The method used here was an adaptation of that described by Rose (8) for the preparation of 3-phenylphthalimidine.

To a solution of 56 g (1.00 mole) of potassium hydroxide in 200 ml of water was added 24.5 g (0.10 mole) of *p*-toluyl-*o*-benzoic acid, prepared by the method of Fieser (7), and 16 g (0.19 mole) of hydroxylamine hydrochloride in concentrated aqueous solution. The reaction mixture was boiled for 20 minutes, with stirring, and was then allowed to stand for 12 hours at room temperature. The solution was cooled in ice, and the product anhydro-oxime was precipitated by the addition of concentrated hydrochloric acid, and was recrystallized from 95% ethanol. It was then dissolved in the minimum amount of glacial acetic acid, a large excess of zinc dust was added, and the mixture was heated with vigorous stirring for several hours. It was then cooled and poured into ice water, and the resulting white precipitate was filtered, and then recrystallized from 75% acetic acid, m.p. 216–219°. The infrared spectrum of this material was very similar to that of 3-phenylphthalimidine, with bands at 5.96, 6.22, 6.91, 7.38, 5.58, 7.70, and 8.80 μ. Anal. Found: C, 80.80; H, 5.91; N, 5.95. Calc. for $C_{15}H_{13}NO$: C, 80.80; H, 5.84; N, 6.28.

Preparation of 3-(p-Tolyl)phthalimidine-N-carboxyanilide (6)

A mixture of 0.7 g (0.0031 mole) of 3-(*p*-tolyl)phthalimidine and 1 g (0.0084 mole) of phenyl isocyanate in 40 ml of benzene was refluxed for 24 hours. The solution was then concentrated and cooled, and the resulting solid was crystallized from 95% ethanol, m.p. 187–188.5°; mixed m.p. of this compound with material (III) from the carbonylation reaction was 183–186°. Anal. Found: C, 77.37; H, 5.41; N, 8.05. Calc. for $C_{22}H_{18}N_2O_2$: C, 77.30; H, 5.27; N, 8.19.

THE INFRARED SPECTRA AND PHASE TRANSITIONS OF SOLID PIPERIDINIUM HALIDES

A. CABANA AND C. SANDORFY
Department of Chemistry, University of Montreal, Montreal, Que.
Received November 27, 1961

ABSTRACT

The infrared spectra of solid films of piperidinium halides were measured at both room temperature and low temperatures. The spectra of the chloride and the bromide are not appreciably affected by cooling, but the spectrum of the iodide exhibits spectacular changes. These changes are explained by assuming the occurrence of a phase transition at about −15° C. The possibility of a "chair" → "boat" interconversion is also discussed.

INTRODUCTION

Substituted ammonium halides often undergo crystalline phase changes at low temperatures. In this laboratory we have been investigating these phase changes by means of infrared spectra. Piperidinium halides exhibit some special features which are presented here. No attempt will be made to assign all the bands in the infrared spectra of the piperidinium halides; rather, the emphasis will be put on the comparison of room- and low-temperature spectra in order to investigate the occurrence and nature of changes in the crystal or molecular structure. The room-temperature spectra of piperidinium halides have already been discussed in the literature (1–4).

EXPERIMENTAL

Piperidinium chloride, bromide, and iodide were prepared and purified by standard methods; the spectra are those of solid films prepared by sublimation *in vacuo*. A Perkin–Elmer model 21 spectrometer was used, mounted with a sodium chloride prism. The spectra presented in this paper were measured at room temperature, 25° C, and at liquid-air temperature, −190° C. They were also measured at −72° C but these spectra are not given since, in all cases, they showed no significant differences from those measured at −190° C. The low-temperature cell was essentially a brass Dewar in which the sample was cooled by direct metallic conduction, dry ice plus alcohol and liquid air being the two refrigerants.

RESULTS

The NH_2^+ group does not have any degenerate vibrations. There is a group of strong bands between 3000 and 2800 cm^{-1} which contains the two NH_2^+ stretching bands and the two CH_2 stretching bands followed by a few combination bands. The complexity of the 2800 and 1400 cm^{-1} regions is probably partly due to the fact that CH_2 groups linked directly to the nitrogen have stretching and deformation frequencies slightly different from those of the other CH_2 groups. The NH_2^+ bending band lies near 1600 cm^{-1} and is split into two in the spectra of both the chloride and the bromide.

The differences between the room- and low-temperature spectra of the chloride and the bromide (Figs. 1 and 2) are slight, with the usual sharpening of the bands and resolution of some of the shoulders being evident at the low temperature: no indication of a change in the crystal structure can be discerned.

The iodide behaves differently. The spectrum measured at −190° C contains about twice as many bands as the one at 25° C (Fig. 3); and shows an appreciable increase in scattered light, a phenomenon often accompanying phase transitions. Some of the bands

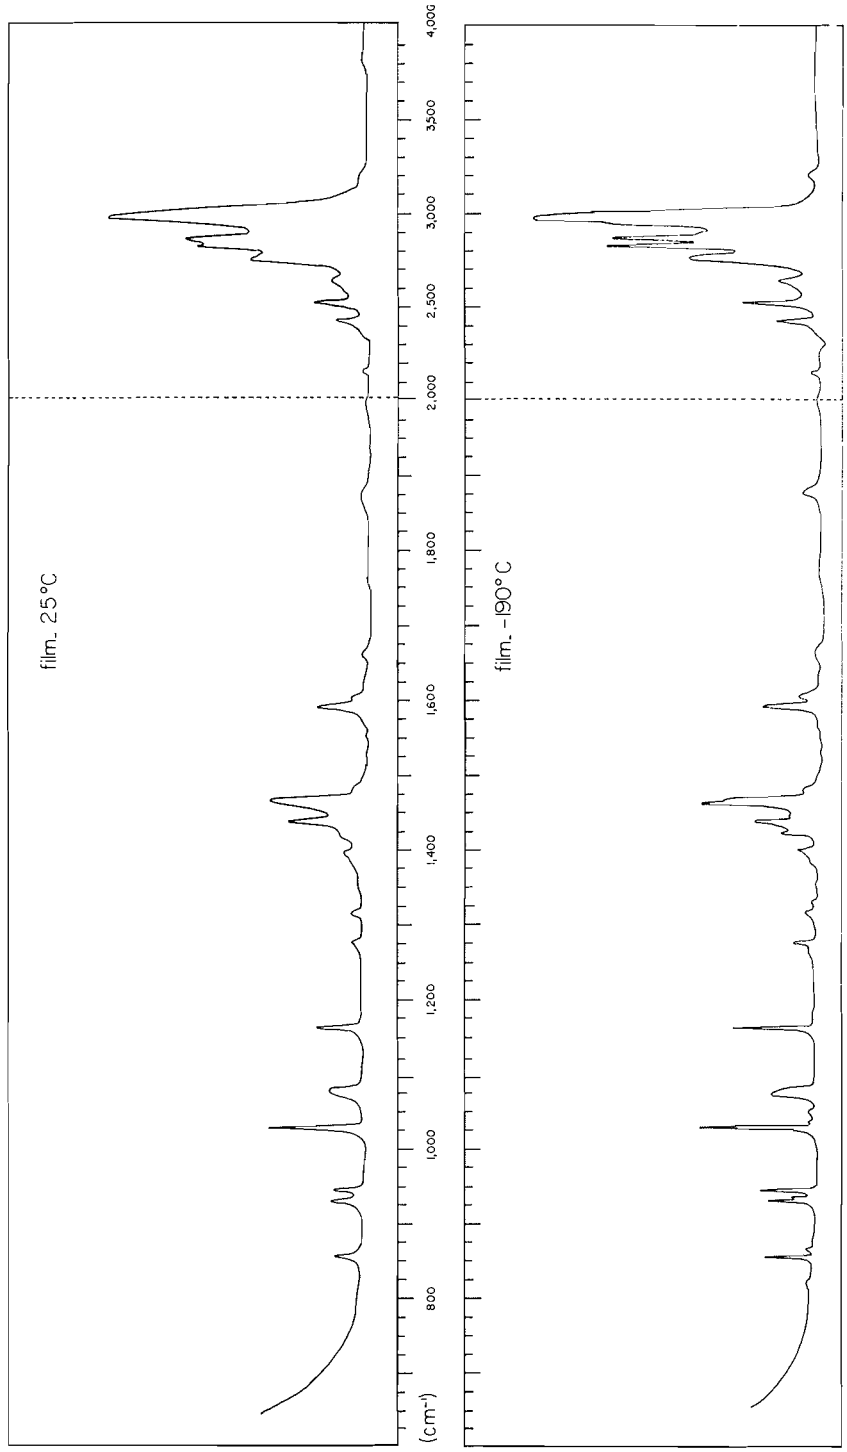

FIG. 2. The infrared spectra of piperidinium bromide at 25° C and −190° C. The ordinate is linear in % absorption.

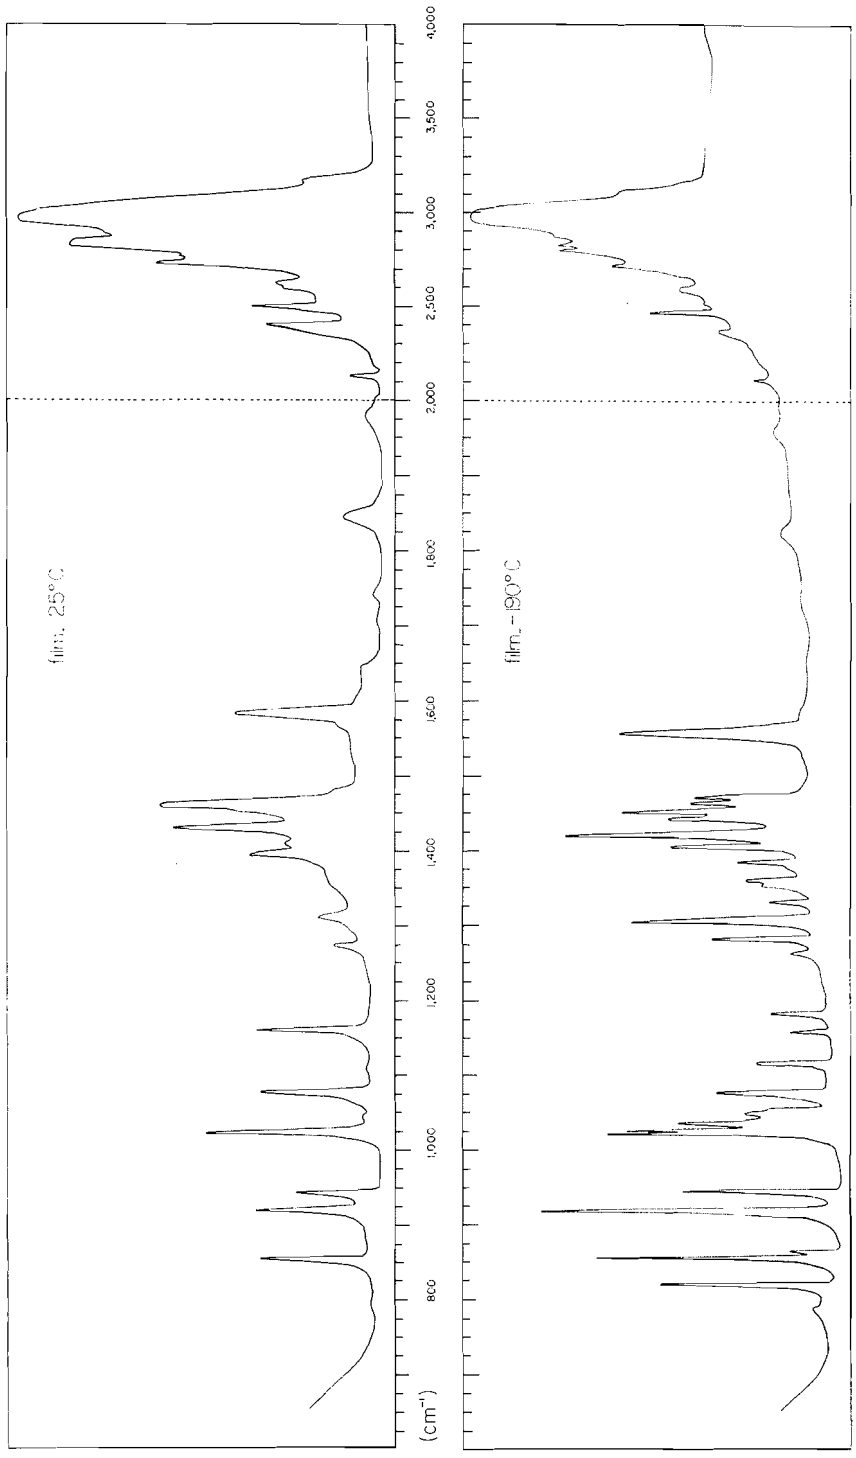

FIG. 3. The infrared spectra of piperidinium iodide at 25° C and −190° C. The ordinate is linear in % absorption.

in the low-temperature spectrum are obviously new, e.g. the bands near 817, 1046, 1114, 1180, and 1350 cm^{-1}. Some other bands are in almost exactly the same places in both the room- and low-temperature spectra, e.g. those at 854, 917, and 943 cm^{-1}. Some band splitting occurs at −190° C, e.g. at 1023 and 1455 cm^{-1}. The NH_2^+ stretching and bending vibrations do not yield new bands at −190° C, but they shift slightly.

DISCUSSION

Recently Rérat (5) examined the crystal structure of piperidinium chloride at room temperature using X-ray techniques. He found that the structure is orthorhombic (space group: D_{2h}^{11}—*Pcmb*) with four molecules per unit cell, and that the piperidinium ion has the "chair" form. From this alone we can conclude, on the basis of the close similarity between their spectra, that at room temperature all three halides have a similar crystal structure and the "chair" form. The same conclusion is valid at low temperature for the chloride and the bromide, but not the iodide, which must change its crystal structure and perhaps even its conformation.

The spectacular change in the spectrum of piperidinium iodide occurs suddenly at a temperature between −10° C and −20° C; further cooling does not radically change the spectrum. This seems to exclude the possibility of a mixture of "boat" and "chair" being present or in fact any other kind of mixture. Further evidence against the mixture contention is the fact that the NH_2^+ bending band shifts from 1580 cm^{-1} at 25° C to 1565 cm^{-1} at −190° C, remaining a single band throughout; if a mixture were present, two well-separated bands would be seen. The wealth of bands found in the low-temperature spectrum shows that a number of bands which are forbidden at room temperature become allowed at low temperature (the "new" bands). Some splitting of bands is also observed, e.g. at 1023 and 1455 cm^{-1}, and may be linked to coupling between molecules in the same unit cell or to removal of degeneracy.

The piperidinium ion is isoelectronic with cyclohexane. Therefore, assuming that the perturbation caused by the replacement of one carbon by a positively charged nitrogen is slight, the "chair" form must have approximately D_{3d} symmetry. Since in this symmetry group many bands are forbidden or degenerate, this explains the relatively low number of bands found in the room-temperature spectra. The problem is very similar to the one of cyclohexane which has been treated in detail by Ramsay and Sutherland (6). The low-temperature spectrum of the iodide can then be understood if we suppose that a phase transition has occurred, and that the symmetry of the crystalline environment has been decisively lowered around the piperidinium ion. This would explain, in a general way, the appearance of new bands and the observed splittings. The bands which are allowed anyway might not shift appreciably.

Table I compares the observed frequencies in the infrared and Raman spectra of cyclohexane, taken from Ramsay and Sutherland, and those in the infrared spectra of piperidinium iodide at 25° C and at −190° C. There is a close similarity between the spectra of the two compounds. It can be seen that at room temperature the piperidinium ion has an (approximate) center of symmetry in the crystal, and that at low temperature this is lost and the originally Raman-active or inactive (the one near 1110 cm^{-1}) fundamentals appear.

"Chair" → "boat" interconversion would explain the increase in the number of bands at the low temperature equally well, since the symmetry of the "boat" form is much lower than that of the "chair" form. It would be surprising, however, if the "chair" form were stable at higher temperatures and the "boat" form at lower temperatures,

although the replacement of one carbon atom by N^+ and the hydrogen bonds make the case somewhat different from that of cyclohexane. There is also a spectral argument against this interpretation. As we stated earlier, some bands are in almost exactly the same places in both the room- and low-temperature spectra. This is very unlikely to happen if "chair" → "boat" interconversion actually does occur, except for some highly localized CH_2 bands, which are certainly not the observed non-shifting bands below 1300 cm^{-1}.

The question arises as to why the chloride and the bromide do not exhibit the same phenomenon as the iodide. In this respect it may be pointed out that although there is a close similarity between the spectra of all three halides at 25° C, the spectra of the chloride and the bromide are much more nearly identical with each other than with the spectrum of the iodide. In particular, the positions of the NH_2^+ stretching and bending bands show that the hydrogen bonds are weaker in the latter compound.

CONCLUSION

The changes that occur in the spectrum of piperidinium iodide on cooling are probably due to a phase transition, the symmetry around the piperidinium ion being considerably lowered thereby. The interesting possibility of a "chair" → "boat" transformation seems to be unlikely.

The room-temperature spectra of the three halides, and the low-temperature spectra of the chloride and the bromide, are all well in accord with a "chair" configuration for the piperidinium ion and a relatively high crystal symmetry.

Further X-ray and Raman investigations would be expected to throw more light on these problems.

INFRARED SPECTRA AND PHASE CHANGES OF SOLID ANILINIUM HALIDES

A. CABANA AND C. SANDORFY
Department of Chemistry, University of Montreal, Montreal, Que.

Received November 27, 1961

ABSTRACT

The infrared spectra of anilinium chloride, bromide, and iodide, measured at 22° C and at −190° C, are presented. The spectrum of the chloride is essentially the same at both temperatures but the spectra of both the bromide and the iodide exhibit changes indicating a crystalline phase transition, in accordance with recent X-ray determinations of the crystal structures of these compounds.

INTRODUCTION

The crystal structure of methylammonium chloride was investigated by Hughes and Lipscomb (1), who found that at room temperature it is tetragonal, with the C—N axis coinciding with the fourfold crystallographic axis (space group: D_{4h}^{7}—$P4/nmm$), every nitrogen atom being surrounded by four chloride ions and there being two molecules per unit cell. The space group, along with the number of molecules per unit cell, indicates that the ions must be on sites of symmetry D_{2d} or C_{4v}. In order to reconcile the threefold symmetry of the ion with one of these site symmetries, the ion must randomize its orientation either by rotation or by orientational disorder. King and Lipscomb (2) have shown that *n*-propylammonium chloride and bromide have crystal structures similar to that of methylammonium chloride at room temperature (also space group D_{4h}^{7}—$P4/nmm$ with two molecules per unit cell). Again the NH_3^+ group must randomize its orientation. Taguchi (3) in a recent publication summarized our present knowledge of the crystal structures of primary amine hydrohalides, and divided them into two groups: In the first group he placed those with crystal structures similar to that of methylammonium chloride and having the aforementioned characteristics. In the second group the crystals are monoclinic or orthorhombic, every nitrogen atom is surrounded by three (not four) halogen ions, and there are four molecules per unit cell. Typical of the second group are cyclohexylammonium chloride and bromide, which were studied by Shimada, Okaya, and Nakamura (4), using X-ray techniques (space group: C_2^5—$Pca2_1$). The space group of the crystal along with the number of molecules per unit cell indicates that the molecules in the crystal lie on general positions. Therefore there is no longer any contradiction between the symmetries of the crystal and the NH_3^+ group: the atoms are in fixed positions. The crystals belonging to the first group undergo phase changes at lower temperatures. The resulting phases were studied by X-ray techniques by King and Lipscomb (5) for *n*-propylammonium chloride (space group: C_{2h}^3—$C2/m$), by infrared techniques by Waldron (6) for methylammonium chloride, and by the authors (7) for all four methylammonium halides. It turns out that the low-temperature phases of the halides belonging to the first group have crystal structures similar to those of the halides belonging to the second group,* which do not undergo phase changes at all (3).

Anilinium halides exhibit some unexpected features which have recently aroused renewed interest among crystallographers. They also constitute a good test of the usefulness of infrared spectra in detecting phase changes. We measured their spectra at different temperatures and we shall now discuss the cases of the three halides one by one.

**See, however, the δ-phases of methylammonium bromide and iodide (7).*

ANILINIUM CHLORIDE

Brown (8) determined the crystal structure of anilinium chloride at room temperature using X-ray techniques. It is monoclinic with three chlorine ions surrounding the NH_3^+ group and has four molecules per unit cell (space group: C_s^4—Cc). Thus, it is similar to the crystal structure of the amine hydrohalides of the second group. Accordingly it has never been reported to undergo phase changes at lower temperatures, and it has an infrared spectrum very similar to the spectrum of cyclohexylammonium chloride (Figs. 1 and 2).

The broad complex band centered at about 2810 cm^{-1} for anilinium chloride contains the NH_3^+ stretching vibrations overlapped and followed by a number of combination bands. The strong band at 2570 cm^{-1} has also been shown to be a combination band (9). The sharp band at about 2040 cm^{-1} has an appearance very similar to that of the band at 2062 cm^{-1} and 2080 cm^{-1} in the low-temperature phases (γ- and β-phases respectively) of methylammonium chloride. Waldron (6) assigned this band to the sum of the torsional oscillation frequency of the NH_3^+ group (ν_6) and its asymmetrical bending frequency (ν_9). It was shown by the authors (7) to be a good indicator of less than threefold symmetry around the NH_3^+ group; it is invariably also present in the spectra of solid primary amine hydrohalides whose crystal structure belongs to the second group—cyclohexylammonium chloride is a good example (Fig. 1). The asymmetrical and symmetrical bending vibrations of the NH_3^+ group give bands near 1600 cm^{-1} and 1500 cm^{-1} respectively, very close to the two well-known bands of the phenyl ring. The band at 1470 cm^{-1} is very probably the first overtone of the out-of-plane CH bending vibration near 740 cm^{-1}, its intensity being increased by Fermi resonance. The degenerate NH_3^+ rocking band is probably the one near 1100 cm^{-1} and the C—N stretching band the one at 1020 cm^{-1}. The comparatively lower frequency of the NH_3^+ stretching band in the spectra of anilinium chloride (2810 cm^{-1} compared to 2980 cm^{-1}) shows that the hydrogen bonds in anilinium chloride are stronger than in cyclohexylammonium chloride.

The main point to emphasize, as regards the present investigation, is that the spectrum of anilinium chloride is practically the same at 25° C as at −190° C. At the low temperature the normal sharpening of the bands in the spectra of crystals occurs to give a somewhat better resolution of overlapping bands, with a few shoulders becoming separate bands; but no differences indicating a change of phase are observable. This is in complete agreement with the crystallographic results.

ANILINIUM BROMIDE

While cyclohexylammonium bromide and iodide have spectra very similar to that of the chloride, anilinium bromide has a spectrum exhibiting significant differences from that of anilinium chloride (Fig. 3). At 25° C the NH_3^+ stretching region near 2860 cm^{-1} is very broad and structureless, as also are the NH_3^+ asymmetrical bending band near 1570 cm^{-1} and the NH_3^+ rocking band near 1110 cm^{-1}. They all belong to degenerate vibrations. At lower temperatures all these bands become much sharper, the extent of the sharpening being clearly much greater than in cases where no change of crystal structure occurs. The ($\nu_6+\nu_9$) band near 2040 cm^{-1} is absent from the spectra. These changes indicate a crystal structure at room temperature with a symmetry not very different from that of the α-phase of methylammonium chloride, and higher than that of cyclohexylammonium chloride or anilinium chloride.

This conclusion is in excellent agreement with the recent X-ray work of Taguchi (3). According to his measurements the higher-temperature phase is orthorhombic (space

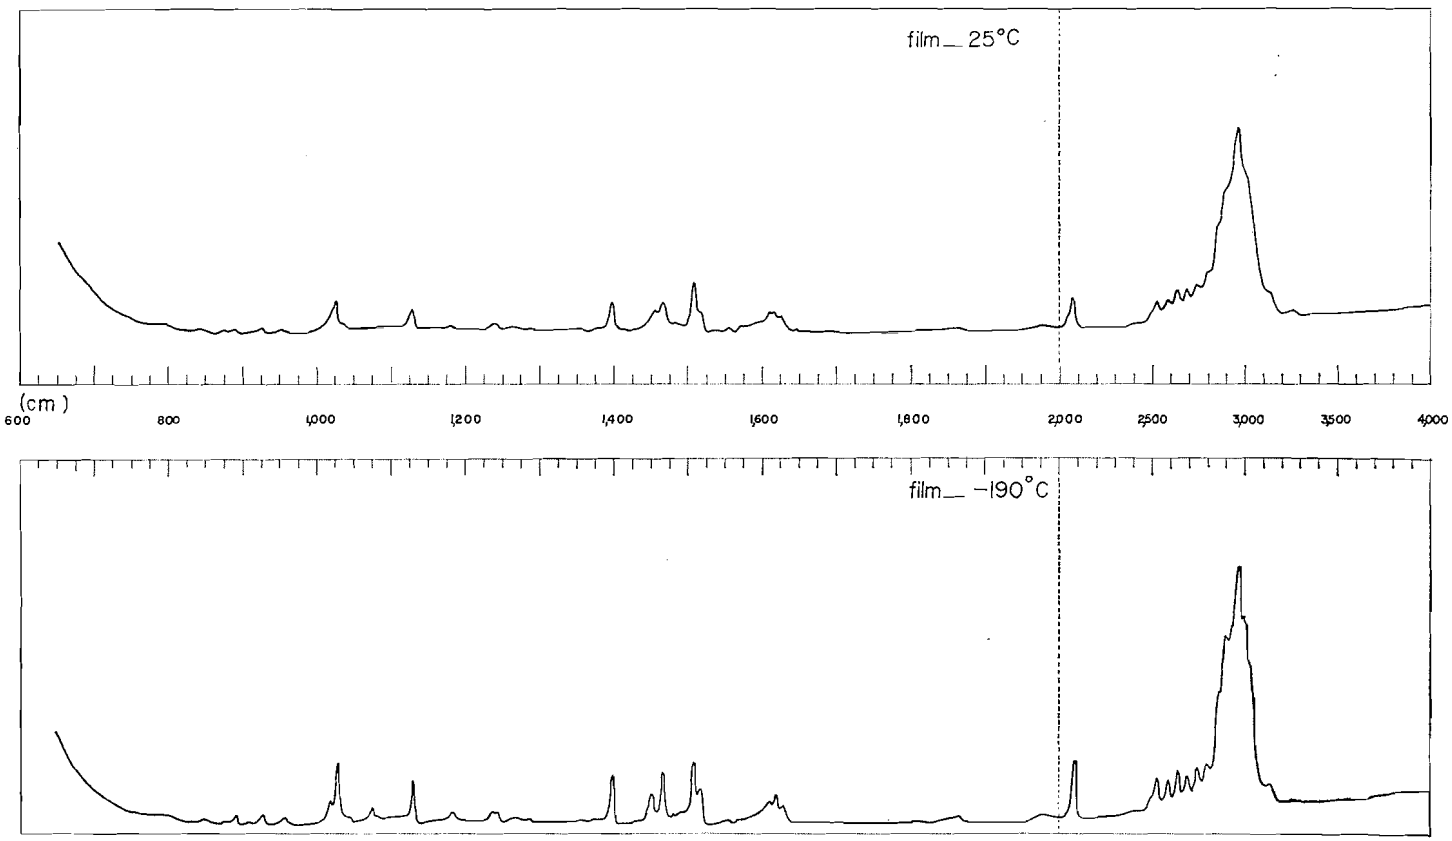

FIG. 1. The infrared spectrum of cyclohexylammonium chloride at 25° C (above) and −190° C (below). The ordinate is linear in percent absorption.

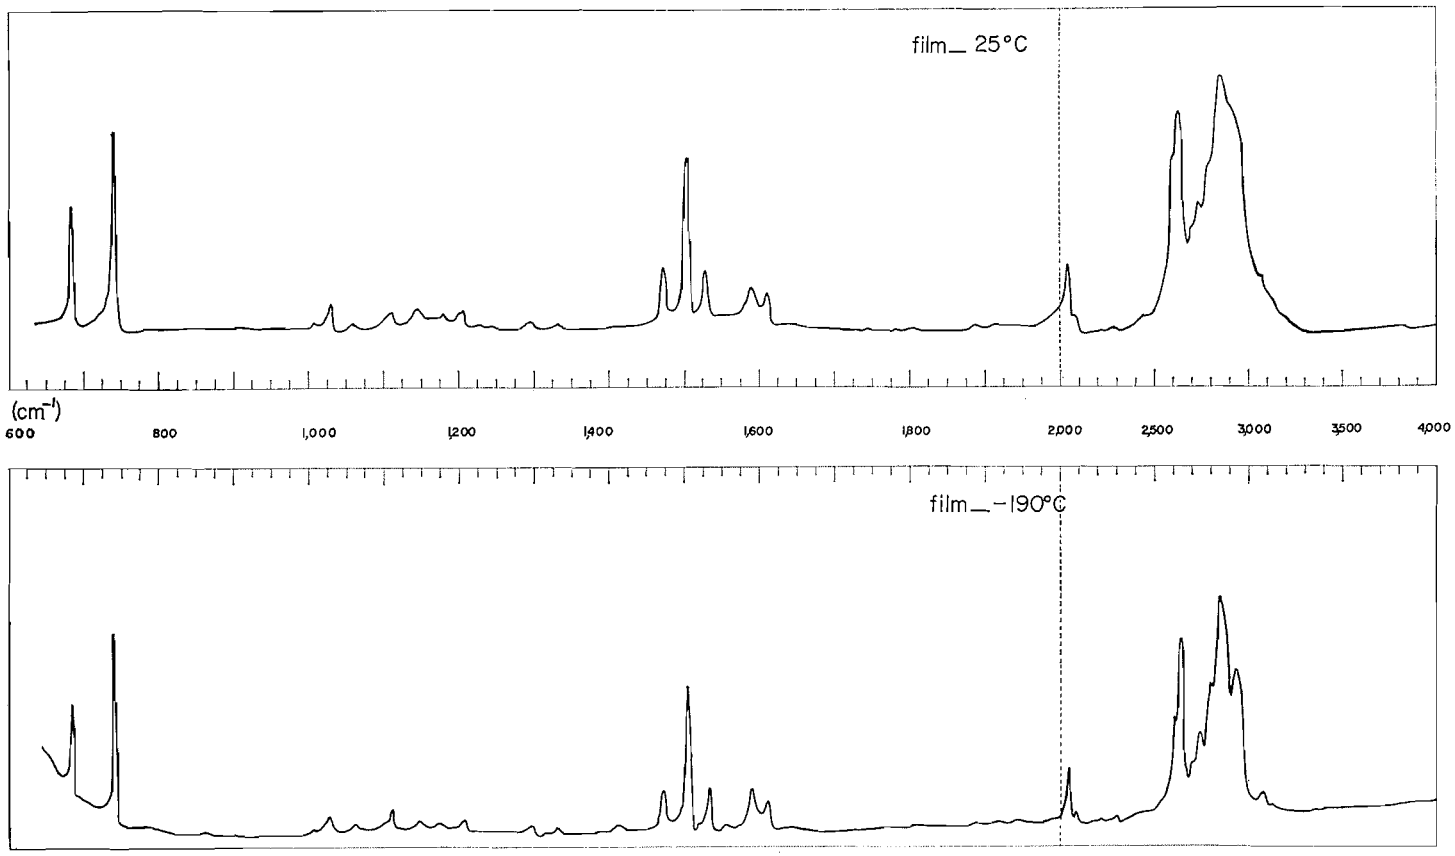

FIG. 2. The infrared spectrum of anilinium chloride at 25° C (above) and −190° C (below). The ordinate is linear in percent absorption.

group: D_{2h}^{10}—*Pnaa*) and the low-temperature phase monoclinic (space group: C_{2h}^{5}—$P2_1/a$), with both phases having four molecules per unit cell. The crystal symmetry of the higher-temperature phase requires that the N—C_1 – – – C_4 axis should lie on a digonal axis. Thus, the NH_3^+ group, which has threefold symmetry with respect to the same axis, must randomize its orientation with respect to this axis. According to Taguchi this is achieved by a disordering whereby the NH_3^+ group "assumes two (or a multiple of two) equally stable orientations with respect to the N—C_1 – – – C_4 axis, or may be flipping among different orientations". This ceases at lower temperatures since then the symmetry of the crystal is lower, the ions lie on general positions in the crystal, and the atoms can take up fixed positions. Suga (10), who has studied the thermal properties of anilinium bromide, has shown that the transition is a typical order–disorder transition with a critical temperature of 22° C. This well explains the broadness of the bands mentioned in the preceding paragraph.

A weak broad band appears in the low-temperature spectrum at 1850 cm^{-1} which may be due to a combination between the asymmetrical bending vibration and a lattice vibration at about 300 cm^{-1}. It may seem surprising that the ($\nu_6+\nu_9$) combination band, which was fairly prominent in the spectra of the chloride, does not appear in the low-temperature spectrum. This may indicate a lesser departure from threefold symmetry around the NH_3^+ group than in the chloride (cf. the δ-phase of methylammonium bromide (7)).

Concluding this section we can say that again there is excellent agreement between X-ray and infrared data.

ANILINIUM IODIDE

To the authors' knowledge the crystal structure of anilinium iodide has not been studied using X-ray techniques. Since, however, both room- and low-temperature spectra (Fig. 4) are very similar to the corresponding spectra of the bromide, it is probably safe to predict that the iodide has two phases with crystal structures similar to those of the corresponding phases of the bromide, and that a similar order–disorder transition must take place between them. Confirmation of this deduction by X-ray techniques or by a study of the thermal properties of the crystal would be most welcome.

EXPERIMENTAL

The salts were prepared and purified by standard methods. The spectra are those of solid films prepared by sublimation *in vacuo* under moderate heating. A Perkin–Elmer model 21 spectrometer was used mounted with a sodium chloride prism. The spectra given in Figs. 1–4 were measured at 25° C and −190° C. We also measured them at −70° C but in all cases they were similar to those measured at −190° C except for the greater degree of band sharpening at the lower temperature.

DISCUSSION

Infrared spectra are not an absolute means of discerning crystalline phase changes. There are normal changes which occur when the temperature is lowered: the bands become sharper, shoulders are often resolved as bands, and changing conditions for band overlap may alter the relative intensities of close-lying bands. If these are the only spectral differences observed, then the spectroscopist must conclude that no change in crystal structure has been detected. In the other extreme, spectacular changes in the spectrum, band splittings, and major changes in intensities and band positions accompany phase changes when these imply the loss of high-symmetry elements (such as threefold or higher axis), or a change in the number of molecules per unit cell. Such spectacular changes are observed in the case of the methylammonium halides.

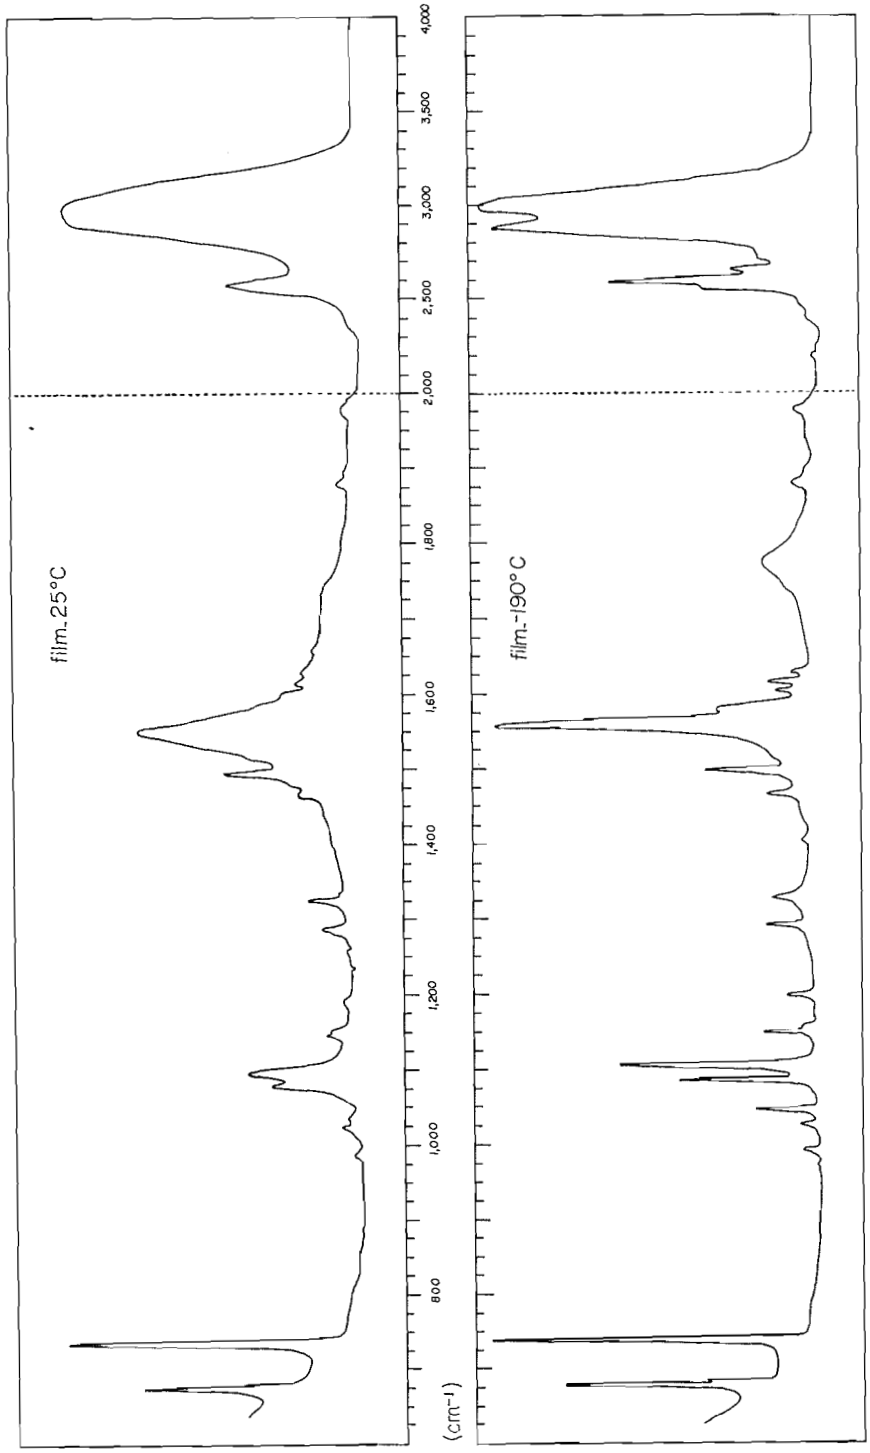

FIG. 4. The infrared spectrum of anilinium iodide at 25° C (above) and −190° C (below). The ordinate is linear in percent absorption.

Anilinium bromide and iodide appear to be intermediate cases: a moderate change in crystal symmetry is accompanied by an order–disorder transition. Correspondingly there are changes in the spectrum which are less spectacular but still significant—they concern the intensity and especially the broadness of the bands. This case constitutes a good illustration of the power of infrared spectra in the detection of phase transitions. Care should be taken not to discount relatively minor changes in the spectra when looking for phase transitions.

NITROGEN-FREE DERIVATIVES OF ATISINE: AN EXTREMELY HINDERED CARBOXYLIC ACID[1]

J. W. ApSimon,[2] O. E. Edwards, and R. Howe[2]
Division of Pure Chemistry, National Research Council, Ottawa, Canada

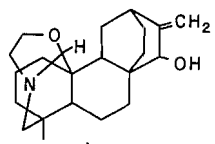
Received December 8, 1961

ABSTRACT

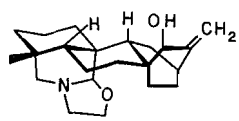
The action of nitrous acid on azomethines derived from the alkaloid atisine gave a good yield of nitrogen-free hemiacetal, thus providing the first means of removing the nitrogen from the diterpenoid alkaloids. Transformation products of the hemiacetal, including the most hindered carboxylic acid hitherto known, are described. The internal oxidation–reduction reactions encountered in this and related work are discussed.

The early work on the chemistry of atisine, the main alkaloid of *Aconitum heterophyllum*, was done by Jacobs and his colleagues (1). A structure for dihydroatisine was postulated by Wiesner and co-workers (2) and elaborated by addition of the oxazolidine ring to structure I for the alkaloid (3). The oxidation studies and selenium dehydrogenations at 340° which formed the basis for this assignment did not rigorously prove the structure, and left the stereochemistry unknown.

Recent work on atisine, however, has confirmed the presence of the bicyclo[2,2,2]octane system substituted as in I (4, 5); work on ajaconine has given strong support to the remaining features of the proposed skeleton (6(*a*)), and the Garrya alkaloids and atisine have been interrelated (7). Evidence has also been produced for the relative and absolute



I



II

stereochemistry illustrated in II (4–6, 8–10). In order to test these conclusions by interrelation of atisine with diterpenes of known structure and stereochemistry, a method was developed of removing the nitrogen from the alkaloid. We now amplify our preliminary report on this deamination (11).

Our early attempts to open the hetero ring centered on methods of raising both carbons flanking the nitrogen to aldehyde or carboxyl oxidation levels, when hydrolytic removal of the nitrogen should be possible. It seemed desirable to have C-16 and C-17 at different oxidation levels in the deamination product, so that C-17 could be selectively deoxygenated to the angular methyl while leaving a labelling function on C-16.

If immonium ions are intermediate in most oxidations of carbon attached to nitrogen (12), then it should not be possible to directly oxidize azomethine III to the lactam IV. Indeed, preliminary experiments using N-bromosuccinimide and potassium permanganate showed little promise.[3] An obvious way to surmount this difficulty was to oxidize the N-methyl carbinolamine V or its methyl ether in basic media. On the basis

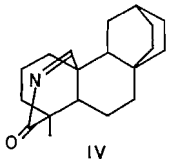
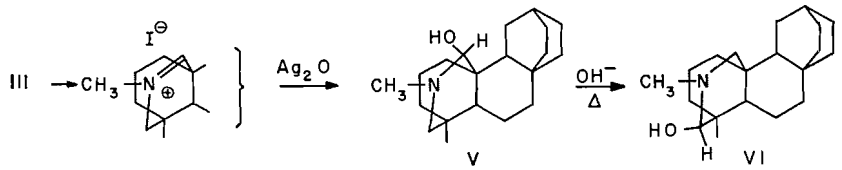
III



IV

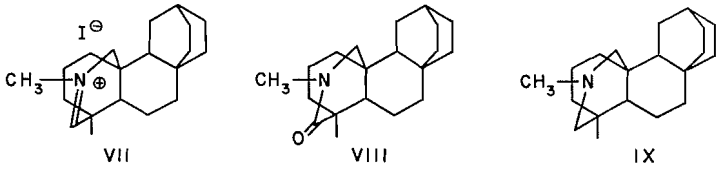
of the stereochemistry shown in V the 17-hydrogen is inaccessible to oxidizing agents; hence attack should be on the N-methyl or on C-16.

The carbinolamine V and the isocarbinolamine VI were prepared as illustrated. The



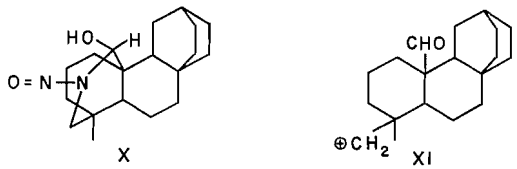
V VI

isocarbinolamine was characterized as its anhydronium iodide VII (the isomethiodide). Again, oxidation of V with alkaline ferricyanide, N-bromosuccinimide following by permanganate, and alkaline permanganate was not encouraging. The only crystalline neutral product isolated was the lactam VIII, which could also be prepared by chromium trioxide – pyridine oxidation of IX or permanganate oxidation of the isocarbinolamine VI. This implies a ready interchange of oxidation levels between C-16 and C-17, a point which will be discussed further in the sequel.



VII VIII IX

Two other possible methods of achieving the objective were attempted. One, the reaction of the azomethine with acetic anhydride, led to an unusual product[4] but little, if any, of the desired N-acetyl carbinolamine acetate. The second was the attractive possibility that the azomethine III was in slight but significant equilibrium with the hydrated form, the secondary aminocarbinolamine. If this could be trapped by nitrous acid, or if nitrous acid reacted directly with the azomethine, giving the N-nitroso carbinolamine X, we expected that an irreversible sequence would ensue, leading at least formally through the primary carbonium ion XI to products with the hetero ring open.

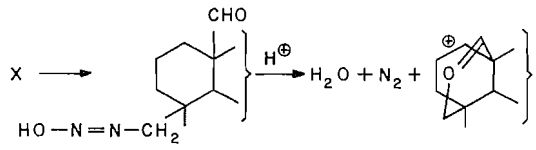


X XI

The reaction of III with nitrous acid was carried out in aqueous dioxane containing sodium acetate. The latter was added to provide a generous supply of nucleophilic anions, with the thought of trapping the primary carbonium ion before it could rearrange. However, a yield of up to 78% of hemiacetal was obtained from the reaction,

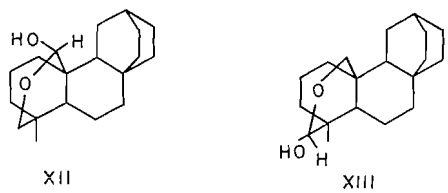
[4]*This work will be the subject of a separate communication.*

with no appreciable amount of aldehyde acetate. This indicated that the aldehyde oxygen was participating in the deamination as illustrated, forestalling any rearrangement, and that a cyclic oxonium ion was the primary product:

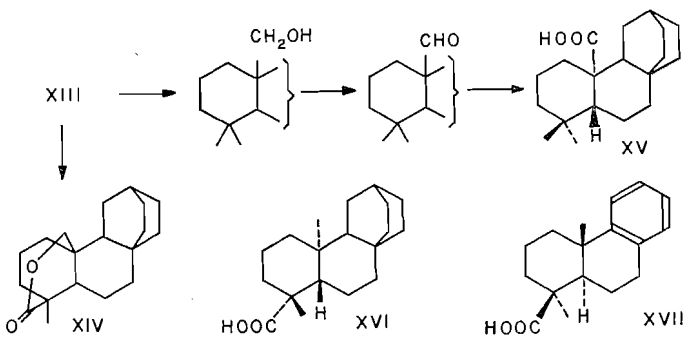


We at first believed the structure of the hemiacetal to be XII (11), but subsequent work provides convincing evidence that it is in fact XIII.[5] The evidence for this assignment will now be considered.

The hemiacetal analyzed correctly for $C_{19}H_{30}O_2$. Its infrared spectrum contained hydroxyl absorption at 3350 cm^{-1} and an ether band in the correct hemiacetal range (1050 cm^{-1}). It could be oxidized to a δ-lactone (XIV) (ν_{max} 1725 cm^{-1}) and reduced by lithium aluminum hydride to a diol. Wolff–Kishner reduction converted it to a primary alcohol. This could be oxidized with sodium dichromate to an aldehyde and the latter



converted to a carboxylic acid (XV) by Kiliani reagent (14). On the basis of XIII these changes can be formulated as shown:



Had the hemiacetal been XII the acid would have been XVI. The problem lay in distinguishing between these two possibilities.

The formation of the lactone would have favored XIII rather than XII if one could guarantee that the hemiacetal was oxidized as such, since as noted above, the 17-hydrogen of XII would have been inaccessible. However, since the hydroxy aldehyde could be the species being oxidized this argument is weak. The lactone, aldehyde, and acid had their C=O stretching vibrations at abnormally low frequencies (ν_{max} 1725, 1696, and

[5]*Djerassi and Vorbrüggen have recently carried out a parallel set of reactions in the Garrya series (9) and have obtained the hemiacetal analogous to XII. We are grateful to them for keeping us informed of the progress of their work. Recently also, Schaffner, Arigoni, and Jeger (13) have used an analogous deamination reaction in conessine chemistry.*

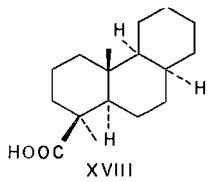
1690 cm^{-1} respectively), a phenomenon most probably associated with steric compression of the chromophore. Similarly the ultraviolet absorption of the acid (λ_{max} 222 mμ) occurred at longer wavelength than any known acid (Table I), an effect which can be

TABLE I

Ultraviolet data in 95% ethanol

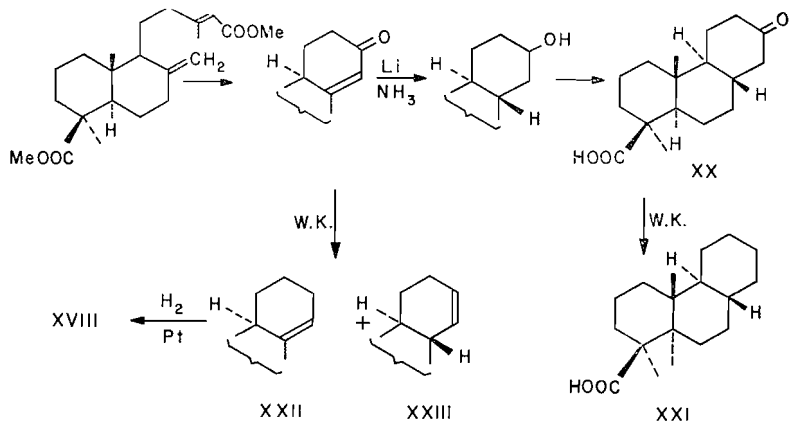
	λ_{max}	ϵ
Trans-anti-trans acid (XXI)	204.5	226
Trans-anti-cis acid (XVIII)	202	350
Tetrahydropimaric acid	203.5	135
Tetrahydroisopimaric acid	203.5	178
Unknown acid	222	80

correlated with the extent of alkyl substitution near a carboxyl (15).[6] However, the most unusual property of the acid was its very low acidity. In 70% ethanol its pK_a' was 9.6 and in 80% methyl cellosolve[7] its pK_a' was 9.2, compared to 7.1 and 7.8 for pimaric and isopimaric acid respectively in 75% ethanol. Our suspicion that the acid had structure XV rather than XVI was aroused when a sample of desoxypodocarpic acid XVII, kindly supplied by Professor E. Wenkert, was found to have a pK_a' of 8.25 (75% ethanol). This made it clear that the shielding of the axial carboxyl by the angular methyl was not sufficient to account for the weak acidity of the unknown. However, desoxypodocarpic acid is a poor model due to the flattened aromatic ring C. We hence decided to compare



XVIII

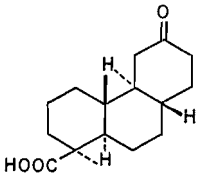
the unknown with acid XVIII, which we hoped could be produced from agathenedicarboxylic acid (17) as illustrated:



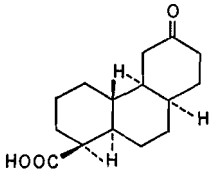
[6]*The values reported in our preliminary communication were determined on an old Beckman ultraviolet spectrophotometer. The new values, determined on a Carey Model 11 spectrophotometer with fused quartz optics, are more accurate. They cast doubt on the wavelengths of the maxima reported in reference 15.*

[7]*We are grateful to Dr. W. P. Arya, who determined this value. The calculated value (16) is 8.91.*

We were able to prepare the trans-anti-trans acid XXI in a pure state by the route shown. The optical rotatory dispersion curve[8] of XX was almost identical with that of cholestane-3-one (18), thus proving the configuration to be as illustrated. However, the Wolff–Kishner reduction of the α,β unsaturated ketone gave a mixture of olefins, presumably XXII and XXIII, from which, on hydrogenation, a mixture of XVIII and XXI resulted. A generous gift of ketones XXIV and XXV by Dr. R. H. Bible (derived from podocarpic acid (19)) enabled us to prepare XXI as a check on the assigned



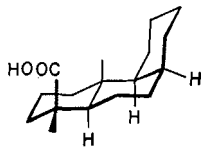
XXIV



XXV

structures,[9] and to prepare XVIII in a pure state.

The pK_a' (75% alcohol) of these acids was 8.2 and 8.4 respectively, again much stronger than the unknown. Since XVIII most probably has the conformation illustrated in XXVI ring C should simulate the branch of the bicyclooctane ring 'cis' to the carboxyl in the unknown acid. Thus it is an excellent model for XVI, making it unlikely that the unknown had this structure.



XXVI

Convincing evidence for structure XV for the unknown acid came from comparison of its n.m.r. spectrum with those of the model acids (Table II). Methyl groups attached

TABLE II

Chemical shifts of methyl groups in τ (CCl_4)

Acid	C-15	C-16	C-17
Tetrahydropimaric	—	8.84	9.26
XXI	8.78	—	9.27
XVIII	8.75	—	9.03
Unknown	9.20	9.10	—

to the same carbon as a carboxyl should resonate at considerably lower field than isolated methyls. However, trans-spatial deshielding of the angular methyl by an axial carboxyl on C-1 would introduce some ambiguity unless its magnitude were known.[10]

[8]*We are grateful to Dr. A. V. Robertson for determining this property.*

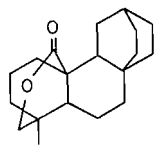
[9]*The identity of XXI from the two sources, incidentally, provides a direct steric correlation between podocarpic and agathenedicarboxylic acid (for correlation of podocarpic acid with abietic acid see ref. 20(a); for correlation of agathenedicarboxylic acid with abietic acid see ref. 20(b)).*

[10]*We are grateful to Dr. P. de Mayo, who suggested the use of this method of distinguishing between XV and XVI, and to Dr. F. A. L. Anet, who drew our attention to the trans-spatial factor. At that time (1959) good reference acids were not available.*

The chemical shift of C-17 in XXI is practically identical with that for the same carbon in the pimaric acids (Table II and ref. 21). However, in the case of XVIII C-17 resonates at considerably lower field[11] (9.03), indicative of steric pressure forcing it close to the axial carboxyl. This must represent close to the maximum possible transspatial deshielding for the system.

The effect of an equatorial carboxyl on the methyl attached to the same carbon in the resin acids results in a chemical shift for the group of around 8.84 (Table II and ref. 21). An axial carboxyl, however, gives a methyl on the same carbon a shift near 8.75. The chemical shift of the methyls in the unknown acid are incompatible with either of the above situations, but the signal at 9.10 corresponds well with that expected for a methyl in close proximity in space to a carboxyl. Hence of the two possible structures for the unknown acid, XV must be the correct one.

A further test of this assignment became possible when it was observed that oxidation by dichromate of the diol obtained by lithium aluminum hydride reduction of the hemiacetal XIII gave two lactones. The one produced in lesser amount proved to be identical with the lactone from bromine water or dichromate oxidation of the hemiacetal. The major lactone was isomeric with it, and should hence have structure XXVII. Comparison of the n.m.r. spectra of the two lactones showed that the lone methyl signal in the new lactone was at higher field (9.1) than that in the lactone from the hemiacetal (8.9), in agreement with the assigned structure.[12]



XXVII

In order to complete the comparison of physical properties attempts were made to prepare acid XVI. We were unable to open the lactone ring of XIV, hence a route to XVI via the hydroxy and aldehydo acids was closed.[13] It seemed possible that the lactones could be partially reduced to the hemiacetals, thus providing a method of going from XXVII via XII to acid XVI. In fact reduction with a limited amount of lithium aluminum hydride XIV was converted to XIII in good yield. However, comparable reductions of lactone XXVII gave mixtures of unchanged lactone, the diol, and hemiacetal XIII. Hence, once again, a possible promising route to acid XVI was not realized. We believe, however, that the above evidence is adequate to prove the deamination product to have structure XIII and the highly abnormal acid to be XV.

The acid XV could not be extracted from ether by dilute sodium hydroxide solution, a further indication of its abnormal character. All the unusual properties of this acid must be associated with shielding of the carboxyl by the angular methyl group and one branch of the dicyclooctane system. We attribute its very low acidity, the weakest hitherto reported (see also footnote 5), to steric hindrance of solvation of the anion derived from it.

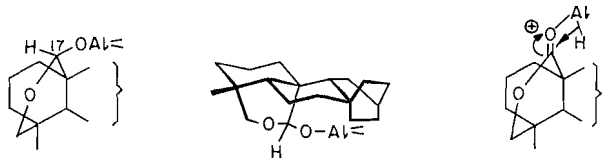
The slower $LiAlH_4$ reduction of lactone XXVII than of lactone XIV is not surprising, since normal reduction leading first to the alkoxide XXVIII is prohibited by the extreme

[11] *Chemical shifts are given in τ values (22).*

[12] *We are unable to account for the larger yield of XXVII, unless steric compression of the hydrogens on C-17 accelerates their elimination in the oxidation.*

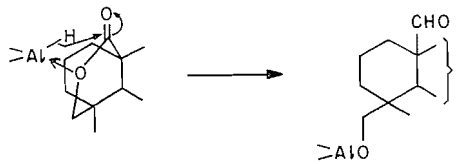
[13] *We thank Dr. A. Nicolson for some of these attempts.*

crowding of the side of C-17 facing the bicyclooctane ring (see XXIX). Internal hydride



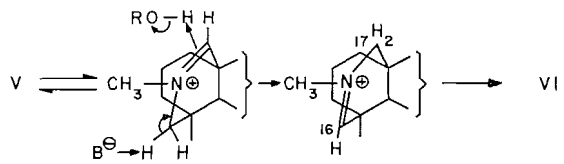
XXVIII XXIX XXX

transfer shown in XXX is possible but again subject to extreme hindrance. The most likely possibility is that the reaction proceeds mainly as shown:

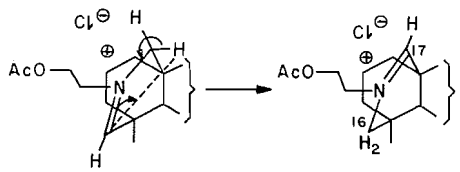


This relieves the serious interactions at once, and since the aldehyde would be rapidly reduced, accounts for the fact that little hemiacetal survives, in contrast to the reduction of the isomeric lactone (XIV).

In the above work three new instances were encountered in which an exchange of oxidation level between C-16 and C-17 took place: the original deamination, the oxidation of carbinolamine V, and the reduction of lactone XXVII. Three other phenomena of this type have been observed in the simpler diterpenoid alkaloids: (*a*) The atisine-to-isoatisine conversion exemplified in the present work by the rearrangement of V to VI. The mechanism of this strong base-catalyzed reaction is probably the following:



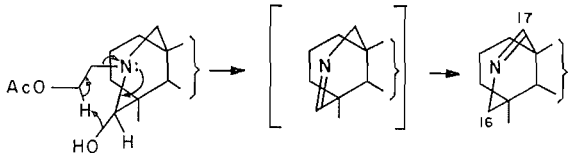
The driving force for the nearly complete conversion seems to be the 17-oxygen:5-hydrogen interaction (6(*a*)). (*b*) The thermal conversion of isoatisine salts to atisine salts in hot acetic anhydride (23), for which possible mechanism is a 1:3 hydrogen shift as illustrated:[14]



(*c*) The formation of the Δ^{17}-azomethine from isoatisine diacetate, when the Δ^{16}-azomethine was expected. This rearrangement took place in boiling carbon tetrachloride (24), i.e. in

[14]*A bimolecular process seems prohibited by the extremely crowded environment of the nitrogen.*

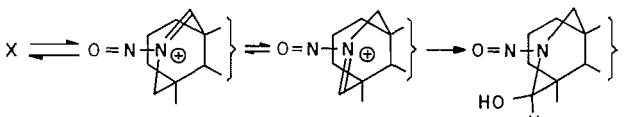
a relatively non-polar medium (but some water present) with possible base catalysis:



The driving force in the case of (*b*) and (*c*) appears to be the relief of 10:17:19 hydrogen interactions (6(*a*), 24).

The dismutation in (*c*) and in the three cases in the present work are remarkable for the mild conditions under which they take place. The species undergoing the dismutation in the deamination reaction could be the azomethine, the azomethine salt, the N-nitroso carbinolamine, or the hemiacetal. The reaction cited in (*c*) provides strong evidence that the azomethine double bond is mobile in the presence of organic base in hot carbon tetrachloride. It is tempting to think that the equilibrium is set up in the deamination, and that the Δ^{16} isomer reacts much faster with nitrous acid. However, the reaction takes place in acid medium, and despite the low pK_a' of the azomethine (6.0 in 80% alcohol) it must be largely in the form of its salt. Thus the base catalysis, which seems necessary for the isomerization, is absent and we consider it unlikely that any appreciable amount of the unstable azomethine is formed. Similarly the isomerization of immonium salts is negligible at 80° (24), hence even more so at room temperature. Even if equilibrium were set up, in each case almost exclusively on the Δ^{17} side, it seems very unlikely that the rate of reaction with nitrous acid would be sufficiently different to make the product arise exclusively from the Δ^{16} isomer.

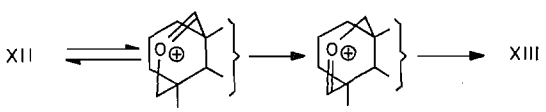
A more likely entity to equilibrate is the N-nitroso carbinolamine X. The 5-hydrogen: oxygen repulsion and 10:17:19 hydrogen interactions should force this into equilibrium with the immonium ion XXXI. This, however, would be a high-energy state because



XXXI XXXII XXXIII

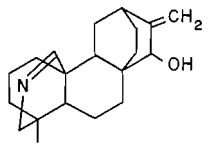
of the proximity of the positive nitrogen to the positive end of the N=O dipole. It thus might rearrange with greater facility than ordinary immonium salts by 1,3-hydride transfer or proton exchange with solvent to XXXII. The latter would hydrate nearly irreversibly to XXXIII, which would then give rise to hemiacetal XIII. However, if this were correct it is difficult to account for the fact that no product derived from X is isolated since opening of X to the N-nitroso aldehyde would also relieve the non-bonded interactions.

We are thus forced to the conclusion that part, if not all, of the dismutation takes place between the hemiacetals, XII going to XIII via the oxonium ions:

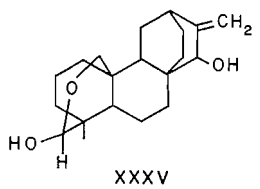


This also seems to be the best explanation of the formation of XIII on the reduction of lactone XXVII by lithium aluminum hydride. This would be acid catalyzed at least to the oxonium ion stage and also probably take place on the surface of alumina during chromatography. An attempt was made to generate a mixture of the two hemiacetals by the action of acid on XIII, but only unchanged XIII and amorphous products were obtained.

Finally, the deamination of the C_{20}-azomethine alcohol XXXIV (24) gave a good yield of a hemiacetal, presumably XXXV, characterized as the methyl acetal. This now had substituents on ring C, making possible conversion to known diterpenes. However, the conversion of ring C to a phenol in related work (4) proved very expensive, hence



XXXIV



XXXV

an interrelation with podocarpane derivatives by this route did not seem practical. Removal of the nitrogen from the Garrya alkaloids has recently enabled correlation with the diterpene kaurene and rotatory dispersion comparison with other members of the phyllocladene family (9, 10). This has provided confirmation of the absolute stereochemistry suggested for these and the atisine group of alkaloids (4, 6(*a*)).[15]

EXPERIMENTAL

Rotations of absolute ethanol solutions, ultraviolet spectra of 95% ethanol solutions, infrared spectra of nujol mulls, unless otherwise stated, were determined. The pK_a' values are the pH's at half titration in the indicated solvent mixture. Melting points were taken on a Kofler hot stage. Alumina activities are on the Brockmann scale (25).

Methiodide of C_{19}-Azomethine
