NO Destruction Experiments

To determine the total amount of undecomposed NO, present in the trapped products as NO and $NO_2 + N_2O_4$, a new method was developed. The trapped products of the NO reaction were transferred to a known volume V_1 and the pressure P_1 (< 10 mm Hg) was measured at room temperature, from which X, the number of moles in V_1, was calculated. The gas was then expanded into a second known volume, V_2, which included V_1 and was approximately $4V_1$. The pressure was now P_2 and Y moles of gas were present. From these data and the equilibrium constant $K_p = (P_{NO_2})^2/P_{N_2O_4}$, the amount of undecomposed NO was calculated in the following manner.[d] If a is the number of moles of NO and b the number of moles of $NO_2 + N_2O_4$, counted as NO_2, per mole of NO, then $a(1 + b)$ is the equivalent amount of undecomposed NO. Defining further α_1 and α_2 as the fraction of N_2O_4 dissociated in volume V_1 and V_2 respectively, and

$$Q \equiv \frac{4P_1}{K_p} \frac{Y - X}{X}$$

we obtain

$$[A] \qquad a(1 + b) = \frac{(1 - \alpha_1)Y + (1 - \alpha_2)X}{\alpha_2 - \alpha_1},$$

in which

$$[B] \qquad \alpha_2 = \alpha_1\{1 + [\alpha_1/(1 - \alpha_1)]Q\}$$

[d]*The equilibrium data of ref. 12 together with* $\Delta H(2NO_2 \rightarrow N_2O_4) = -13.9$ *kcal mole*$^{-1}$ *were used.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

and

$$[C] \qquad \frac{\alpha_1}{1-\alpha_1} = \frac{-1 + \{[V_2/(V_1Q)][Q + (V_2/V_1) - 1]\}^{1/2}}{Q + (V_2/V_1)}.$$

The method was checked by introducing known amounts of NO into the system followed by partial oxidation of the NO and agreement was found to be within 2%. The developed method involves, admittedly, considerable calculation but has the advantage of being experimentally faster than the conventional method of total oxidation of the trapped sample, followed by PV determination of the equivalent amount of NO as $NO_2 + N_2O_4$. For one experiment the equivalent amount of NO was determined both ways. The agreement was again better than 1% which also showed that less than 1 mole % of the condensables could have been substances other than NO and NO_2. The absence of N_2O in the reaction products is in agreement with the results of earlier workers (13, 14). The PV measurements also yield directly the amount of nonoxidized NO in the sample since

$$[D] \qquad a = \frac{(1+\alpha_2)X - (1+\alpha_1)Y}{\alpha_2 - \alpha_1},$$

which makes this method also applicable to the NO_2 titration of O atoms by the cleanup method (15).

NH_3 Experiments

The amount of undestroyed NH_3 was analyzed either by PV measurement or by dissolving into excess 0.1 N H_2SO_4 followed by back titration with 0.1 N KOH. Both methods agreed to within 2%. Hydrazine was analyzed by the method of Freier and Resch (16). Its production did not exceed 0.005% of the amount of NH_3 destroyed. These results confirm those of previous workers who showed that N_2 and H_2 were the only major reaction products (17, 18),

Ethylene Experiments

The trapped reaction products of the ethylene reaction were distilled at temperatures equal to or lower than 250 °K (the melting point of solid CCl_4, with which the traps were covered during the distillation) into a removable analysis flask containing about 25 cc of frozen 1 N KOH solution. This solution was next partially melted by submerging the bottom part of the flask in hot water and the still solid HCN was then dissolved in it.[e] In this way polymerization of HCN was prevented. The resulting KCN solution was then titrated by the Liebig–Deniges method (19) using standard 0.1 N $AgNO_3$.

RESULTS AND DISCUSSION

NO Light Titration and NO Decomposition

The results of the NO experiments are shown in Fig. 3, based on the data given in Table I. The NO light titration end-point, corresponding to complete consumption of the N atoms (20, 21)[f,g] by

$$[1] \qquad N + NO \rightarrow N_2 + O,$$

was seen as a series of blue and whitish-green flashes following each other in rapid succession through the full length of the probe. At NO flow rates slightly lower or higher (about ±1–2%) than that at the light titration end-point the blue or the whitish-green glow respectively, filled the probe. These glows were readily visible in a darkened room. Earlier work (5, 24) had shown that at the light titration end-point all the NO added is decomposed. It seems allowable therefore to include the results of the titration experiments in the NO destruction plot as corresponding to 100% destruction. As shown in Fig. 3 they fall on a straight line with the other NO destruction values below the destruction plateau but above the titration end-point, which in itself also indicates complete NO destruction at this point. The data show a limiting amount of NO destruction, i.e. a

[e] *This method was described to us by Dr. A. N. Wright of Dr. Winkler's laboratory at McGill University.*

[f] *See below for a discussion of the merits of the titration technique as a quantitative measure of N-atom flow.*

[g] *The long-lived metastables $N(^2P)$ and $N(^2D)$ like $N(^2S)$ may react with NO in a spin-allowed reaction and may be expected to have been consumed completely at the titration end-point. These atoms, located 2.38 and 3.58 eV, respectively, above the ^4S state, have been observed in active nitrogen (22, 23). Their relative concentration should, however, be small in pure nitrogen discharges (22).*

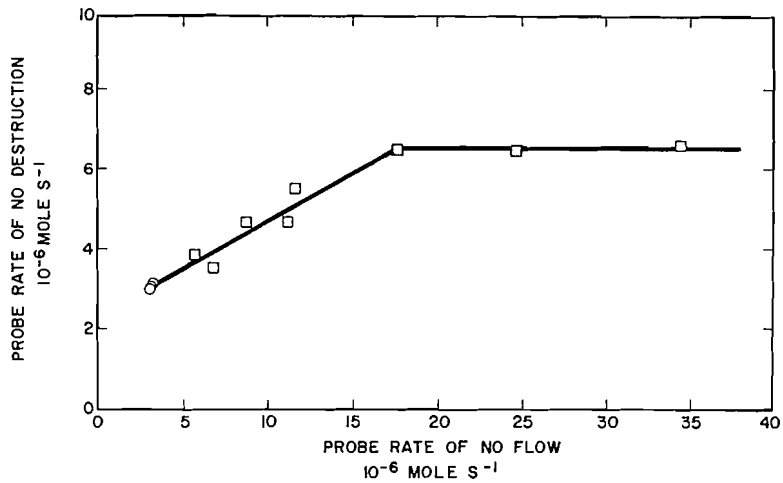

FIG. 3. NO experiments. Probe rate of N_2 flow: 2.6×10^{-4} mole s^{-1}; ○, NO light titration □, NO destruction.

plateau 2.1 times as high as the NO light titration end-point flow.[h] To explain this difference we postulate the presence of an excited molecule, N_2^*, which causes a reaction of the type

[2] $$NO + N_2^* \rightarrow \text{NO disappearance.}$$

Reaction [2] could result simply in the dissociation of NO followed by reaction [1], or be more complicated,[i] but in either case two NO molecules would ultimately disappear because of reaction [2]. From these scavenger probe data the N_2^* flow is thus 0.55 times the N-atom flow, as inferred from the NO light titration.

Reaction [2] has to be slow compared to [1] since $[N_2^*]$ is comparable to [N] and the reaction takes place with NO flows in excess of that at the titration end-point.[j] Had reaction [2] been of a rate comparable to that of [1] it would merely have increased the NO flow needed to obtain the titration end-point. It has been suggested (4, 13) that (i) large differences (factors of 1.4–2.4) observed in previous work between the NO titration end-point flow and the HCN formation plateau from ethylene are due to a reaction between excited molecules and NO and that (ii) the HCN formation plateau is a quantitative measure of the N-atom flow. Although further indirect evidence (27) in favor of this idea has been obtained, there are rather strong arguments[k] against it. However, even if the HCN production were a true measure of the N-atom flow, then to falsify the NO light titration appreciably an excited state of N_2 other than N_2^* must be involved, i.e. an N_2^{**} which reacts with NO much faster than N_2^*, the latter being responsible for the NO destruction beyond the light titration end-point.

[h] *In only one other case (4) has it been reported that under certain discharge conditions the limiting amount of* NO *destruction exceeded the light titration end-point flow. In that work the observed ratio was, at most, 1.25.*

[i] *Reactions of this nature have been discussed (25, 26). Although a reaction such as suggested by Wright and Winkler (25) or simple* NO *dissociation could not falsify the* NO *light titration (26), such reactions could be responsible for the destruction of* NO *added in excess of the light titration end-point flow with which the present discussion is concerned.*

[j] *Only at most a few percent of the* NO *added beyond the titration end-point is consumed (40) by* $O + NO + M \rightarrow NO_2 + M$ *since this reaction is followed by the much faster reaction* $O + NO_2 \rightarrow NO + O_2$.

[k] *For arguments against the* NO *titration indicating too high an atom concentration see refs. 1, 26, 28, 29.*

*Nature and Origin of N_2**

To obtain an idea of the nature of the N_2* postulated above the following residence and collision time calculations have to be considered. It took a given portion of the gas about 10^{-5} s to travel from the exit of the electrical discharge region (the nozzle throat) to the shock front, 10^{-4} s to pass from there through the probe entrance orifice during which time some initial reaction occurred, and 3×10^{-2} s from there to the 90° bend in the probe. An excited molecule would suffer, respectively, about 10^2, 10^4, and 3×10^6 collisions with N_2 during these periods. Mixing was judged complete within the probe head, since in the work with ethylene, discussed below, the characteristic blue reaction zone luminescence from the reaction $N + C_2H_4$, which is two to three orders of magnitude slower (e.g. ref. 30) than reaction [1] (28, 29, 31), did not extend beyond the 90° bend. The time required for most of the N_2* to react implies that it be a relatively long-lived, i.e. a metastable, molecule if it was formed inside the discharge region. The amount of N_2 formed by atom recombination between the nozzle throat and before complete atom consumption by reaction [1] was calculated [l] to be less than 10% of the initial atom concentration, and the heterogeneous recombination was estimated to be even smaller.[m] Both mechanisms are quite inadequate to explain the large N_2* concentration observed. It may thus be concluded that N_2* is predominantly or exclusively a metastable molecule (or a mixture of metastable molecules) formed in the electrical discharge region. No conclusion regarding the relative importance of possible mechanisms of N_2* formation in the discharge region (e.g. excitation by electron bombardment or atom recombination) can be made on the basis of the present results.

Several authors have recently discussed the various metastable states of nitrogen that could contribute to the chemical reactivity of active nitrogen (e.g. refs. 4 and 6). Our results do not make it possible to state definitely which excited state or states are involved in reaction [2] and such states as the $A^3\sum_u^+$, $^3\Delta_u$, and $a'^1\sum_u^-$ all have to be considered, as does $a^1\Pi_g$ state. The latter is too short-lived to have been of importance in previous conventional subsonic flow system studies (6)—where the average gas molecule typically was transported from the discharge to the reaction zone in times of the order of 10^{-2} s—but it may well cause considerable reaction in the present system. Such an assumption is not contradictory to reaction [2] being slow compared to [1] since the latter only requires about 10 collisions to occur. The high relative concentration of N_2* in the present system may be peculiar to the type of electrical discharge used—and the conditions under which it is operated—or to the faster delivery of discharge products to the reaction zone. For vibrationally excited $N_2(X^1\sum_g^+)$ to be involved in reaction [2], $v \geqslant 27$ would be required. It appears somewhat unlikely that many such highly vibrationally excited molecules would be present in the reaction zone but this possibility cannot be excluded entirely. Finally, it should be remarked that ion-initiated reactions, although highly energetic, can be discounted as major sources of NO destruction, since previous work (38, 39) at this laboratory had shown that the ion concentration in the free jet is less than 1% of the atom concentration.

[l] *A value for k in the expression* $-d[N]/dt = k[N]^2[M]$ *of* 3×10^{-32} *cc*^{2} *molecule*$^{-2}$ *s*$^{-1}$ *was used, which represents a reasonable upper limit. See, e.g., refs. 6, 32, 33, 34, 35.*

[m] *A wall recombination coefficient* $\gamma = 3 \times 10^{-4}$, *which represents an upper limit (33, 36, 37), was used in this calculation. In fact wall losses should have been considerably smaller than those calculated since, over most of the probe head, the regions near the probe walls were apt to be much richer in scavenger gas and helium than the central region of the flow. Reaction with the scavenger gas would thus have prevented most of the surviving* N *atoms from reaching the wall, since the rate of reaction [1] is* 10^3 *to* 10^4 *times the corresponding rate for wall reactions in the probe head.*

NH_3 Experiments

The addition of NH_3 did not extinguish the afterglow in the probe but diminished its intensity. The NH_3 reaction does not appear to involve N atoms (6, 17, 41). From Table I it may be seen that the amount of NH_3 reaction was much higher than that of any of the other reactants investigated and no destruction plateau could be observed for the NH_3 inlet flow rates used. Based on N_2^* concentrations estimated from the NO experiments, at least about 11 NH_3 molecules are destroyed for every N_2^* present. No reasonable chain mechanism seems to be capable of explaining these results on the basis of an N_2^* reaction alone, and it is therefore quite possible that an excited molecule $N_2^{\ddagger}$ incapable of NO destruction is responsible for most of the NH_3 decomposition observed. The same arguments as were given for N_2^* imply that $N_2^{\ddagger}$ molecules would be predominately metastables formed in the electrical discharge zone. Another explanation of these observations, suggested to us by the referee, is photodecomposition of NH_3 by light emitted from the discharge. Although this would clarify the apparent absence of a destruction plateau, there is no good precedent for it. A more definitive explanation of the ammonia destruction results must await further work.

HCN Formation

The results of Table I show that an ethylene flow – independent HCN production plateau is obtained. The observed flow rate ratio (NO light titration end-point)/(HCN production plateau) may be seen to be 3.2. This value should be compared to a ratio of 2.4 obtained in conventional flow system work at 16 mm Hg (13). The present result must be regarded as preliminary however, since it has been observed in conventional flow system studies that the height of the HCN production plateau can, depending upon flow conditions (4), increase with temperature up to about 520 °K (13). We have not established whether the observed HCN plateau was temperature-independent. In the absence of such data and because of the unresolved controversy between the HCN production plateau and the NO light titration technique as a measure for the atom concentration, the scavenger probe results reported here may be taken to indicate a mole fraction of nitrogen atoms in the sampled portion of the jet of from 0.37 to 1.18%, the higher value (inferred from the NO light titration) being the more likely one.

Absence of Diffusional Separation Effects

Two possible errors arising from the partial spillage of helium – scavenger gas mixture in the probe inlet region have to be considered in some detail. While the procedure used for calculating scavenger gas destruction was explicitly chosen because it allows for the possibility of such spillage, a basic assumption made here is that the helium/scavenger gas composition ratio in the reaction zone is negligibly different from the corresponding mixture ratio in the secondary gas supply system. This would not be the case if diffusional separation occurred in the probe inlet region because of the increased mobility of helium atoms through active nitrogen. Secondly, it has been assumed that the N_2^*/N ratio inferred from the nitric oxide experiments is negligibly different from that actually existing in the probe inlet region in the absence of scavenger gas flow and is not the result of preferential loss of N atoms from the system due to their higher mobility.

With regard to the first of these possibilities, the very fact that the nitric oxide data plotted in Fig. 3 exhibit a horizontal plateau constitutes experimental proof that helium – scavenger gas diffusional separation was negligible (10); i.e. if the concentration ratio in the reaction zone differed from that in the supply system in a manner consistent with the relative diffusion coefficients, then a horizontal plateau could never be observed. As

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

corollaries, it also follows that the difference between the NO titration end-point and NO peak destruction flow rates could not be the result of such a process; nor could the observed lack of an apparent NH_3 destruction plateau be the result of this process.

While the experimental data cannot be used directly to rule out a diffusional enrichment of the N_2^*/N ratio by a Fick mechanism, introduction of reasonable values for the fluid dynamic and transport parameters associated with the flow field in the inlet region of the probe revealed that the concentrations of either N atoms or N_2^* in the reaction zone could not possibly differ from their respective values behind the shock wave by more than a few parts per hundred (10). Order of magnitude estimates also led to the conclusion that N/N_2 separation by thermal and pressure diffusion was negligible under the experimental conditions investigated—thereby ruling out the sampling error recently discussed by Reis and Fenn (42), which can become significant for detached shock microprobes in supersonic streams.

CONCLUDING REMARKS

Our results show that the maximum rate of NO destruction by active nitrogen can be considerably larger than the NO flow rate at the light titration end-point. This is attributed to the presence of excited molecules, N_2^*, which react with NO too slowly to alter the light titration end-point measurably. It thus appears that the electrical discharge–supersonic nozzle source used in this work delivers active nitrogen to the reaction zone with a higher N_2^*/N ratio than observed in conventional subsonic discharge flow systems. The chemical scavenger probe method developed here is useful for quantitative studies of local concentrations of active species in nonequilibrium gas streams (43) and may also be employed to distinguish between various excited states of the same molecule.

THE PHOTOLYSIS OF FORMALDEHYDE, FORMALDEHYDE-d_2, AND THEIR MIXTURES[1,2]

M. VENUGOPALAN[3] AND K. O. KUTSCHKE
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received June 29, 1964

ABSTRACT

It has been verified that H atoms are formed when formaldehyde vapor at 300 °C is illuminated by the 3 655 Å group of the mercury arc. Isolation of the group of lines was achieved by a combination of glass and solution filters. This observation gives further support to the "high" value of D(H—CO).

It was found that D_2CO also is predissociated following absorption at this wavelength. This observation is not in agreement with predictions based on purely spectroscopic studies of these molecules.

INTRODUCTION

The technique used by Klein and Schoen (1) to locate the long wavelength limit for the predissociation of formaldehyde involved the photolysis at 300 °C of mixtures ($\sim$ 300 mm total pressure) of H_2CO and D_2CO at various wavelengths in the near ultraviolet. The detection of HD among the products at some wavelength indicated the formation of atoms in the primary process which then initiated the long chain reaction known (2) to occur for these conditions of temperature and concentration. It was found that the ratio $r = [HD]^2/[H_2][D_2]$ was near the equilibrium value of four and was independent of exciting wavelength in the region 3 100 to 3 700 Å. It was concluded that the quantum at 3 650 Å provided sufficient energy ($\sim$ 78 kcal/mole) to break the first C—H bond in H_2CO. This, together with the thermochemical datum (3), $H_2CO \rightarrow 2H + CO$, ΔH = 105.5 kcal/mole, provided a minimum value for D(H—CO) near 27 kcal/mole. The value of D(H—CO) has been in dispute for some time (1, 4–8).

The evidence of the predissociation limit has been questioned (4–6) on the basis that light of shorter wavelength might have been present in the output of the monochromator used (1). An attempt was made several years ago (9) to verify the existence of predissociation following absorption of the 3 655 Å group of the mercury arc spectrum; solution filters were used to isolate the 3 130 Å or 3 655 Å groups from the light source. Indeed, HD was observed in experiments similar to those described below when excitation was by the 3 655 Å group, but the value of r was near 1 at this wavelength and near 6 at 3 130 Å. Values of $r > 4$ are not compatible with the usual chain mechanism. It was thought that the low total pressures used in that work (9) (near 10 mm) favored unknown surface effects which led to the inconsistent value of r. Consequently the interpretation to be applied to that work is not straightforward and the present work was undertaken to obtain data at higher pressures where surface effects would be less favored.

EXPERIMENTAL

Monomeric formaldehyde was generated by the method of Spence and Wild (10) from well dried paraformaldehyde. Fully deuterated paraformaldehyde (Merck, Sharpe and Dohme, Montreal) was treated similarly. The individual species were stored at −80 °C, except when samples were taken for experiments;

[1]*Issued as N.R.C. No. 8116.*

[3]*National Research Council Postdoctoral Fellow, 1961–1962. Present address: Department of Chemistry, Royal Military College, Kingston, Ontario.*

after storage for a few weeks, it was necessary to warm the storage ampoule above room temperature to generate sufficient vapor.

Those parts of the vacuum apparatus with which aldehyde made contact were maintained at ~ 115 °C. An air thermostat at that temperature contained a glass diaphragm pressure gauge, used as a null device, a glass impeller to circulate the mixed aldehydes through the reaction vessel, the quartz reaction vessel (10 cm long, 5 cm diameter) which was provided with additional heating to maintain it near 300 °C, and several metal valves (Hoke type 411 or 413). The mixture of carbon monoxide and the isotopes of hydrogen were separated at −196 °C, measured in a gas burette, and analyzed by mass spectrometry or gas chromatography (11).

The light source was a medium pressure mercury arc (Hanovia S-500) whose output was rendered nearly parallel. The 3 130 Å group was isolated with the combination recommended by Hunt and Davis (12) and the 3 655 Å group with the combination described by Kasha (13). Both in this work and that attempted earlier (9) the concentration of the "cn" dye in the Kasha filter (sometimes used as the perchlorate rather than the iodide) was increased to 1 g/l in order to decrease the transmission at 3 340 Å to values unobservable with a Cary recording spectrophotometer. An attempt was made to photolyze acetone (67 mm) with the light passed by the 3 655 Å filter. No absorption could be detected and the amount (~ 0.3 μmole) of noncondensable gases found after an exposure for 96 h at 141 °C was no larger than that produced by degassing from the walls of the vacuum system for a similar time.

Fractional absorptions were measured with an RCA 935 phototube coupled to a Keithley Electrometer (Model 210). Fractional absorptions less than 5% are subject to an instrumental error approaching 100% of the measured value. The output of the phototube was calibrated in absolute units of intensity by the photolysis of azomethane at 125 °C; Φ_{N_2} was taken as unity at both wavelengths (14). Photolysis of acetone at 125 °C provided an additional check at 3 130 Å; it agreed within 10%.

In most experiments with pure H_2CO, neutral density filters were used to adjust the incident intensity to values such that I_a was similar at 3 130 Å and 3 655 Å. Experiments with the mixtures also employed a similar adjustment but this was not done in experiments with pure D_2CO.

It was demonstrated that synthetic mixtures of H_2 and D_2 were unchanged after storage for several hours in the reaction system, that no equilibration of HD could be detected after similar treatment, and that mixtures of H_2 and CO could be recovered quantitatively.

RESULTS AND DISCUSSION

Data from several experiments are given in Tables I and II. The ratio of carbon monoxide to hydrogen is greater than unity as was also observed earlier with this system (1, 9). The cause of the deviation from unity is not known but, in view of the long chains involved for these conditions (2), it is not likely to be the result of the occurrence of another primary process which produces carbon monoxide but not hydrogen. The data on the photolysis of the mixtures at low pressure and on the thermal reaction demonstrate the difficulties encountered in attempts to reproduce and to interpret the data taken earlier (9).

The scatter in the observed fractional absorption of H_2CO at 3 655 Å presumably originates in instrumental error. Quantum yields calculated from these measurements are subject to similar uncertainties. An extinction coefficient near 0.1 $(\text{mole/l})^{-1}$ cm^{-1} (decadic logarithms) can be calculated; this is in reasonable agreement with 0.07 $(\text{mole/l})^{-1}$ cm^{-1} reported by Norrish and Kirkbride (15) at 100 °C. A somewhat larger value is expected at the higher temperature of this investigation since absorption at 3 655 Å is in the temperature-sensitive α-band of formaldehyde (16).

The much larger fractional absorption of D_2CO at 3 655 Å could be measured more precisely and presumably is a consequence of the near coincidence of the α-band of D_2CO, located by Brand (17) at 3 653 Å, with one of the components of the 3 655 Å group of the mercury arc. Moreover, the ν_4 and ν_6 frequencies in the $^1A_1$ ground state of D_2CO are lower than are the analogous frequencies of H_2CO (16). Enhancement of the absorption by the latter effect alone is insufficient to account for difference observed in the fractional absorption of the two species. It might also be noted that a band of the $^3A_1 \leftarrow {}^1A_1$ system of D_2CO lies nearby, 3 641 Å (8), but the absorption due to this transition is

*Two analyses are given for each experiment. The first analysis is that obtained by mass spectrometry in which the amount of each component could be estimated from the mass spectrum and measured sensitivities of each of the components. The second analysis was done by gas adsorption chromatography (11) which yielded only values for the amounts of the isotopes of hydrogen present in the mixture. For many of the experiments the results quoted are the average of two or more analyses by each of the two analytical methods. A value of Φ was calculated from the results of each kind of analysis.

† Φ represents the quantum yield for the formation of H_2 or D_2, as applicable.

so weak that it probably would not be detected by the present apparatus, nor is any such absorption likely to have given rise to a significant fraction of the photodecomposition.

The fractional absorption of the mixtures (Table II) is close to that expected from the amounts of the two components present.

The interpretation of the fractional absorption, and thus also of the quantum yields determined from them, is made more uncertain by the fact that the three somewhat broadened lines of the 3 655 Å group are absorbed in the relatively sharp rotational lines of the α-band. At lower temperature and pressure, these are resolvable at least to 0.1 cm^{-1} (8, 18, 19) and possibly show only Doppler broadening (0.03 cm^{-1} for H_2CO at 300 °C); of course, some further broadening is expected for the present experimental conditions. In calculating quantum yields, it has been assumed that none of the rotational lines show complete absorption. If complete, or very high, absorption is present in any of the lines, calculation of an effective reaction volume would be very difficult and consideration of the effect of longitudinal diffusion would be required.

See footnote of Table I. Values of r and of Φ were calculated from the results of each kind of analysis.
† $r = [HD]^2/[H_2][D_2]$.
‡ Φ represents the sum of the quantum yields for the formation of the isotopes of hydrogen.

Values of Φ in the tables refer to quantum yield for the formation of H_2, D_2, or $H_2 + HD + D_2$ from the photolyses of H_2CO, D_2CO, or the mixtures, respectively. Since all the Φ exceed unity at 3 655 Å a chain reaction must have occurred so that atoms were produced by excitation at this wavelength. Because Φ_{3130} exceeds Φ_{3655}, some inefficiency is present at the longer wavelength which does not occur at 3 130 Å. Fluorescence has been observed (20, 21) at lower temperature and pressure but no observations have been reported for the conditions employed here. A molecular process leading to carbon monoxide and hydrogen has been reported (1, 2) and another, giving rise to methanol and carbon monoxide, has been detected both in the photolysis at 3 130 Å and in the pyrolysis (1, 2, 22). However, it is not possible to present a quantitative description of the primary process at either wavelength.

It might be noted that Φ tends to decrease as I_a is increased in the photolysis of H_2CO at 3 130 Å. The present data at the lower intensities agree reasonably well with those from the experiments at the highest intensity reported by Calvert and Steacie (2). This observation suggests that the predominant termination process is changing in this region of I_a from one which is of the first order to a process which is of the second order in chain carriers. The data on the photolysis of D_2CO at both wavelengths are too limited in number and that on the photolysis of H_2CO at 3 655 Å too imprecise to permit any conclusion on this point for those systems.

HD was observed in the products of the photolyses of the mixtures at 3 655 Å. The value of r obtained, for which reasonable consistency was achieved by both analytical methods, is some 30% less than that obtained by Klein and Schoen (1); no explanation

For personal use only.

can be offered for this discrepancy. The fractional absorptions of the components of the mixture suggest that most of the initiation occurred via the photodecomposition of D_2CO. Nevertheless, the quantum yield data discussed above supports the conclusion reached in earlier investigations (23, 24), in which scavengers were used, that H_2CO is predissociated at 3 655 Å. Absorption by H_2CO in this region is based on the ν_4(3.3 kcal/mole) or ν_6(3.6 kcal/mole) vibrations of the ground state (16). Thus D(H—CHO) $\leqslant$ 78.2 + 3.3(3.6) = 81.5 (81.8) kcal/mole and D(H—CO) $\geqslant \sim 24$ kcal/mole.

The absence of emission from the 1^+ level of the $^1A_2$ excited state of H_2CO has led to the conclusion that this level is predissociated (8, 17, 19); the 1^+ level lies 82.1 kcal/mole above the zero-point level of the ground state. This excellent agreement in the energetics might be purely fortuitous, however; the same type of spectroscopic evidence (19) suggests that no known levels of the $^1A_2$ state of D_2CO are predissociated. Values of Φ greater than unity in the photolysis of D_2CO at 3 655 Å obviously are at variance with this prediction.

ACKNOWLEDGMENT

The authors wish to thank Mr. R. J. Pilon for the mass spectrometric analyses. They also are grateful to Dr. D. A. Ramsay of these laboratories for most valuable discussions of the spectroscopy of formaldehyde.

LYCOPODIUM ALKALOIDS

XV. STRUCTURE AND MASS SPECTRA OF SOME MINOR ALKALOIDS OF L. FLABELLIFORME

S. N. ALAM, K. A. H. ADAMS, AND D. B. MACLEAN
Department of Chemistry, McMaster University, Hamilton, Ontario

Received July 7, 1964

ABSTRACT

Hydroxy-des-*N*-methyl-α-obscurine, $C_{16}H_{24}O_2N_2$, has been isolated from *L. flabelliforme* and a structure assigned to it on the basis of physical evidence. A structure is assigned to *Lycopodium* alkaloid L.5, which we have named flabellidine, on the basis of physical evidence and its chemical derivation from lycodine. The mass spectra of hydroxy-des-*N*-methyl-α-obscurine, flabellidine, and flabelline are discussed.

The alkaloids of *L. flabelliforme* were first investigated by Manske and Marion (1), who isolated lycopodine (the major alkaloid), nicotine, and six bases, which they designated by number only. Alkaloid L.1 is now known to be dihydrolycopodine (2), L.2 to be acetyldihydrolycopodine (3), and L.6 to be a mixture of α- and β-obscurine (4). The structures of lycopodine and its derivatives (2) and of α- and β-obscurine (5) are now known. The structure of alkaloid L.5, to which we have assigned the trivial name flabellidine, is discussed in this paper, leaving alkaloids L.3 and L.4 of the original six still uninvestigated.

By using chromatographic and countercurrent distribution methods, an additional seven alkaloids have been isolated from *L. flabelliforme* in this laboratory. Thus Young (6) has reported the isolation of two new alkaloids, flabelliformine and flabelline, to each of which a structure has been assigned (7, 8). Alam (9) has found four alkaloids of known structure (clavolonine, lycodine, annotinine, and des-*N*-methyl-α-obscurine) and a new base hydroxy-des-*N*-methyl-α-obscurine, the structure of which is discussed in this paper.

The structure assigned to hydroxy-des-*N*-methyl-α-obscurine I rests on physical evidence as insufficient material was available to investigate its chemistry.

The presence of a hydroxyl group in I is inferred from its infrared spectrum, which, in Nujol and in chloroform, shows a peak at 3510 cm^{-1}. The position of this peak in chloroform solution is not shifted upon dilution, thereby indicating that the hydroxyl group is intramolecularly hydrogen bonded. Aside from the peak in the hydroxyl region, the spectrum of this compound is remarkably similar to that of α-obscurine (II) and des-*N*-methyl-α-obscurine (III). The spectra of the three are reproduced in Fig. 1 for the region 3600–1500 cm^{-1}.

The ultraviolet spectrum of I ($\lambda_{max}^{CH_3OH}$ 255 mμ, log ε = 3.78) is almost identical with that of II ($\lambda_{max}^{CH_3OH}$ 255 mμ, log ε = 3.75) and III ($\lambda_{max}^{CH_3OH}$ 255 mμ, log ε = 3.81). From the spectral evidence it appears that I must have the same chromophoric system as II and III.

The mass spectrum of the hydroxy compound shows a molecular weight of 276, corresponding to the molecular formula $C_{16}H_{24}O_2N_2$. This formula differs in composition from III ($C_{16}H_{24}ON_2$) by one oxygen atom, suggesting that the new base may be a simple hydroxy derivative of the latter. The fragmentation pattern of I, discussed later, is in agreement with this proposition.

The nuclear magnetic resonance (n.m.r.) spectrum of I shows a three proton doublet

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

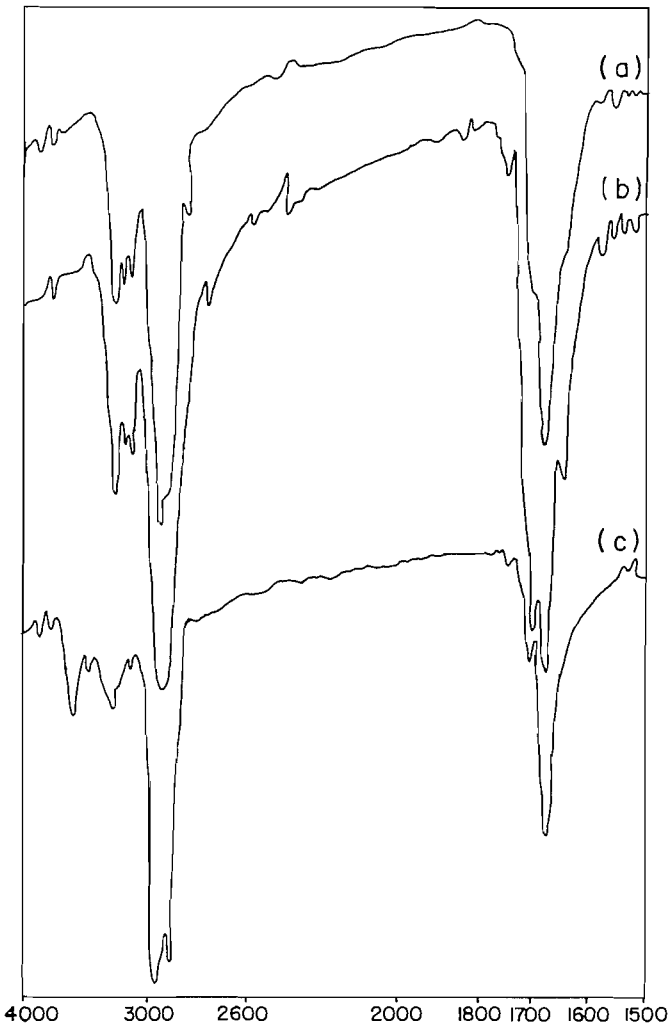

FIG. 1. Infrared spectra of (*a*) α-obscurine, (*b*) des-*N*-methyl-α-obscurine, and (*c*) hydroxy-des-*N*-methyl-α-obscurine.

at $\tau = 9.18$ corresponding to the presence of a $\diagup$CH—CH$_3$ group. In the low-field region the spectrum shows a signal at $\tau = 2.7$, which may be attributed to the hydrogen on the amide nitrogen atom, and a weak broad signal at $\tau = 2.3$, which may be due to the secondary amino proton. No signal corresponding to a $\diagup$N—CH$_3$ group is found in the spectrum, indicating that if the alkaloid conforms to the obscurine structure the second nitrogen atom is secondary in nature. Since there is no other signal in the low field region below $\tau = 6.5$, it may be concluded that the double bond is tetrasubstituted, as in II and III.

The data presented to this point suggest that I may be a hydroxy derivative of III. To locate the hydroxyl group within this framework, it is necessary to reexamine the n.m.r. and infrared data. The absence of a signal in the n.m.r. spectrum between $\tau = 2.7$ and

τ = 6.5 indicates that the hydroxyl group may be attached to a tertiary carbon atom. This observation, coupled with the fact that the hydroxyl group is intramolecularly hydrogen bonded, makes it possible to reduce the number of possible sites of attachment of the hydroxyl group in III. Attachment at C_{14} may be excluded on the basis of the n.m.r. spectrum, which shows a split peak at τ = 9.18 corresponding to a $\diagup\!\!\diagdown$CH—CH_3 group, and attachment at C_5 may be ruled out because intramolecular hydrogen bonding is forbidden on steric grounds. Thus it appears that the most likely position for the hydroxyl group is at C_4. The hydrogen bonding will then involve the lone pair of electrons of the amino nitrogen and is similar to that reported for the alkaloid lycodoline (10), which has the hydroxyl group in the same position—relative to the nitrogen atom. The location of the hydroxyl group at C_4 is further borne out by an examination of the fragmentation pattern of hydroxy-des-*N*-methyl-α-obscurine upon electron impact.

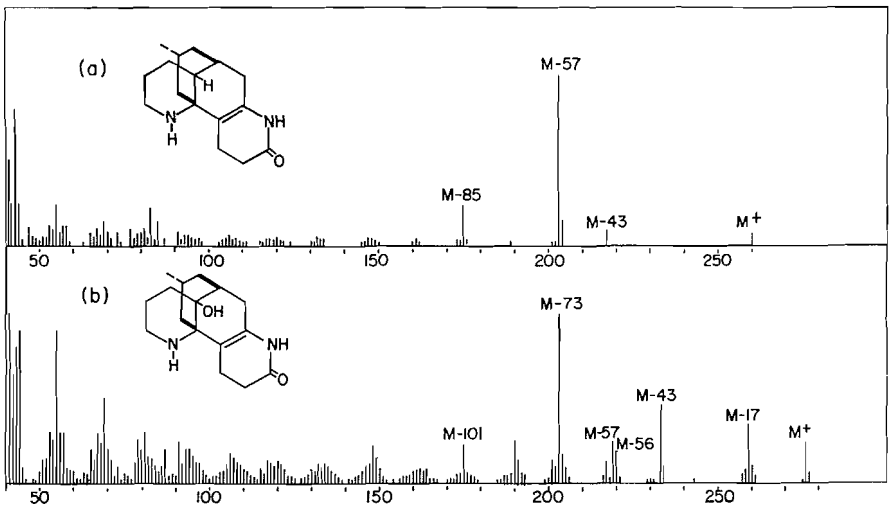

FIG. 2. Mass spectra of (*a*) des-*N*-methyl-α-obscurine and (*b*) hydroxy-des-*N*-methyl-α-obscurine.

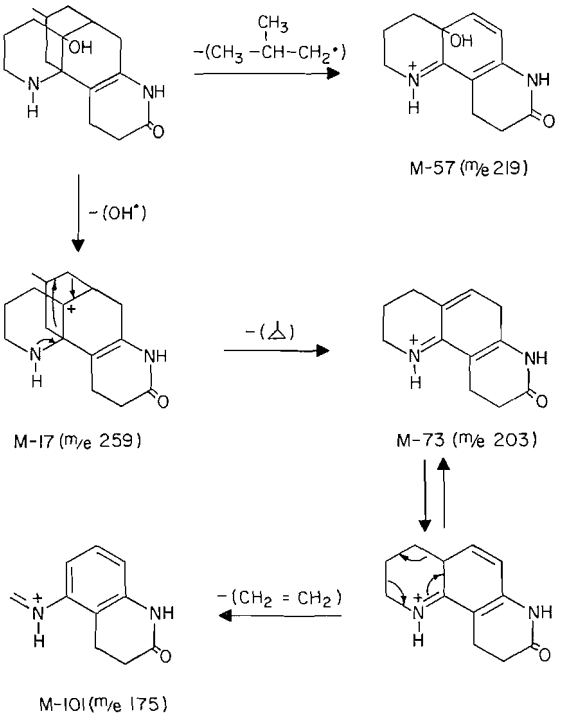
In Fig. 2 the mass spectra of des-*N*-methyl-α-obscurine and hydroxy-des-*N*-methyl-α-obscurine are shown. The mass spectrum of des-*N*-methyl-α-obscurine (2*a*) is relatively simple with peaks appearing at M-43, M-57, and M-85, as in the case of lycopodine and of α-obscurine (11). A fragmentation mechanism compatible with the observed peaks in the mass spectrum of des-*N*-methyl-α-obscurine has been proposed previously (11). As in the case of many *Lycopodium* alkaloids, the loss of the bridge plus hydrogen (M-57) is the dominant feature in the spectrum.

The mass spectrum of hydroxy-des-*N*-methyl-α-obscurine (2*b*) shows a more complex pattern with more peaks in the high mass region. The M-73 peak (*m/e* 203) is now the most intense in the spectrum, while the M-57 peak (*m/e* 219), which is the most intense peak in the spectrum of des-*N*-methyl-α-obscurine, is now less intense than several other peaks. The spectrum also has intense peaks at M-17 (*m/e* 259), M-43 (*m/e* 233), and M-101 (*m/e* 175). A mechanism consistent with the formation of some of these ions is shown in Scheme I. The peak at M-43 is present in the spectrum of most *Lycopodium* alkaloids, although it is usually of low intensity, and it has been suggested that it arises by loss of three of the bridge carbon atoms and a hydrogen atom. It appears as a peak of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

relatively high intensity only in those compounds which are substituted at C_4 (e.g. lycodoline and acrifoline) (11). The intensity of the molecular ion peak is also greatly increased relative to those of alkaloids unsubstituted at C_4.



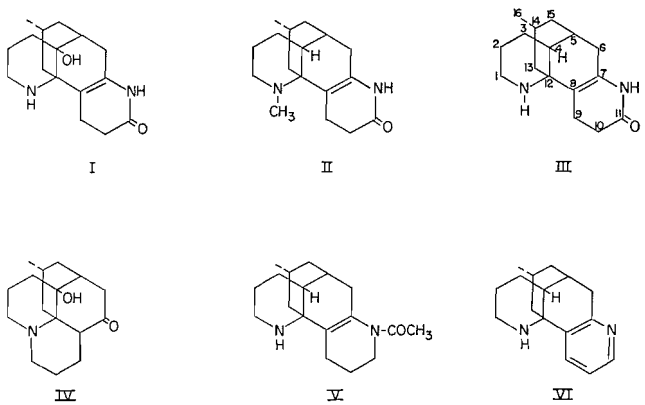
The spectrum of lycodoline IV, which carries a hydroxy group at C_4 differs from that of lycopodine (2) in much the same way as the spectrum of hydroxy-des-*N*-methyl-α-obscurine differs from that of des-*N*-methyl-α-obscurine. The spectrum of lycodoline has been discussed in detail elsewhere (11) and it is only necessary to indicate the points of similarity with the spectrum of hydroxy-des-*N*-methyl-α-obscurine. It has, for example, an intense M-17 peak and an intense M-73 peak. Its M^+ peak is more intense than that in lycopodine, just as the M^+ peak in I is more intense than in III, indicating that the hydroxylated molecules are less prone to fragment in each case. In both spectra the peak at M-57 is no longer the most intense peak in the spectrum and the M-56 peak is much stronger than a normal isotope peak. Furthermore, both spectra show relatively intense peaks at M-43.

The similarity in the spectra of hydroxy-des-*N*-methyl-α-obscurine and of lycodoline suggests that the hydroxyl group is situated in the same relative position in the two molecules. It was pointed out in an earlier paper that hydroxyl substitution at other sites in the lycopodine nucleus does not have such a profound effect on the fragmentation pattern (11). It is proposed, therefore, on the basis of the infrared, ultraviolet, n.m.r., and mass spectrometric examination, that hydroxy-des-*N*-methyl-α-obscurine has structure I.

The stereochemistry assigned is based solely on analogy with other *Lycopodium* alkaloids of known structure and stereochemistry. The properties of hydroxy-des-*N*-methyl-α-obscurine are very similar to those reported for base I, isolated by Burnell

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

et al. from *L. fawcettii* (12). It is possible that the two alkaloids may be identical but a direct comparison has not been made.



I II III IV V VI

The alkaloid, flabellidine V, was isolated as its perchlorate salt. The analysis of the perchlorate indicated that the alkaloid has the molecular formula $C_{18}H_{28}ON_2$. The melting point of flabellidine perchlorate (280–282°) is the same as that of alkaloid L.5 perchlorate (280–282°) and a comparison of flabellidine perchlorate with an authentic sample of L.5 perchlorate obtained from Dr. L. Marion showed that the two samples were identical. Although Manske and Marion (1) assigned the formula $C_{18}H_{28}O_2N_2$ to alkaloid L.5, the elemental composition reported by them can be better accommodated by the formula $C_{18}H_{28}ON_2$. The latter formula is consistent with the molecular weight of 288 found by mass spectrometry.

The presence of a secondary amino group in flabellidine is inferred from its infrared spectrum, which shows an absorption band at 3280 cm^{-1} (Nujol). This band may be assigned to a hydrogen-bonded N—H stretching absorption (13). In the infrared spectrum of flabellidine perchlorate, this band is very weak and, in addition, a series of bands between 2700–2625 cm^{-1} appear. This weakening of the normal N—H stretching band on salt formation and appearance of a complex series of absorption bands in the region 2700–2600 cm^{-1} ($\overset{+}{N}H_2$ stretching vibrations) has been shown (13) to be characteristic of the secondary amino group. The formation of an acetyl derivative of flabellidine, described later, substantiates the secondary nature of the basic nitrogen.

The infrared spectrum also shows bands at 1640 cm^{-1} (s) and 1680 cm^{-1} (m), which may be attributed to an amide carbonyl group and a carbon–carbon double bond respectively (13). The absence of amide II and III bands suggests that the amide function may be tertiary. This is further supported by the fact that the perchlorate salt of flabellidine does not show amide N—H stretching absorption. It has been found in the case of flabelline (8), which contains both a basic nitrogen and a secondary amide group, that the perchlorate salt has a medium intensity band in the N—H stretching region in the infrared spectrum.

The n.m.r. spectrum of flabellidine shows a split peak at $\tau = 9.12$ (3 protons) which indicates the presence of a $\rangle CHCH_3$ group, and a singlet at $\tau = 7.9$ (3 protons) which may be assigned to a $\rangle NCOCH_3$ group. In the low-field region, the spectrum has only a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

very weak broad signal at $\tau = 2.84$ which may be due to the proton on the secondary nitrogen atom. Since there is no signal below $\tau = 6.10$ in the low-field region, other than that at $\tau = 2.84$, the double bond must be tetrasubstituted. The molecular weight 288 and the molecular formula $C_{18}H_{28}ON_2$, combined with the spectral evidence, indicate that flabellidine is tetracyclic.

The structural features deduced from the infrared and n.m.r. spectra of flabellidine may be accommodated within the framework of the known ring systems of the *Lycopodium* alkaloids in structure V for flabellidine. This structure is also compatible with the ultraviolet spectrum and the mass spectrum discussed below.

The ultraviolet spectrum of flabellidine shows an absorption at λ_{max}^{MeOH} 237 mμ (perchlorate, λ_{max}^{MeOH} 237, log $\epsilon = 3.84$). In contrast, flabelline (8), which is isomeric with flabellidine, shows no absorption above 220 mμ, while α-obscurine shows a band at λ_{max} 255 mμ (log $\epsilon = 3.75$). All three alkaloids have the chromophoric system $\diagdown$C=C—NCO—.
$\diagup$ R

In flabelline, only the double bond is incorporated in a ring system; in flabellidine, both the double bond and the nitrogen atom are incorporated in the ring system; while in α-obscurine, the double bond, nitrogen, and carbonyl are all present in a six-membered ring. One may explain the shift in the absorption maximum by the greater degree of planarity enforced upon the chromophoric system as one moves from flabelline to α-obscurine.

Confirmation of structure V for flabellidine was obtained by the conversion of lycodine VI into *N*-acetylflabellidine. Lycodine contains all the ring carbon atoms of the structure proposed by flabellidine. We considered that high pressure reduction of lycodine in the presence of acetic anhydride would lead to the formation of *N*-acetylflabellidine. It is known, for example, that a 7,8 double bond in the lycopodine system is highly resistant to saturation. Thus, anhydrodihydrolycopodine is not affected by hydrogen at 1050 p.s.i.g. and 110 °C (2). Similarly, it is known (8) that flabelline is formed upon high pressure reduction of lycopodine oxime in the presence of acetic anhydride. In the obscurine series it is found (5) that β-obscurine is converted to α-obscurine with lithium in ammonia, thereby showing that the 7,8 double bond is resistant to reduction. It seemed likely that the reduction of lycodine in the presence of acetic anhydride, hydrogen, and Raney nickel would stop at the tetrahydro stage and that the two nitrogen atoms would undergo acylation under the conditions employed.

Accordingly, lycodine was treated with acetic anhydride over Raney nickel and hydrogen at high pressure (1160 p.s.i.g.) and temperature (110°). The acidic reaction mixture, after decomposing with water, was extracted with chloroform, leaving basic material behind. The chloroform extract yielded a neutral crystalline compound melting at 150–152°.

The acetyl derivative of flabellidine was prepared by heating flabel dine with acetic anhydride and purifying the product by column chromatography. The crystalline compound obtained melted at 150–152°. The melting point of a mixture of this compound with the synthetic acetylflabellidine was undepressed. The infrared and ultraviolet spectra of the two, as well as the mass spectra (which are discussed in the next section), were identical.

Since the structure and the stereochemistry of lycodine is known (14), structure V is an adequate representation of the structure and stereochemistry of flabellidine.

The fragmentation pattern observed upon electron impact is consistent with the

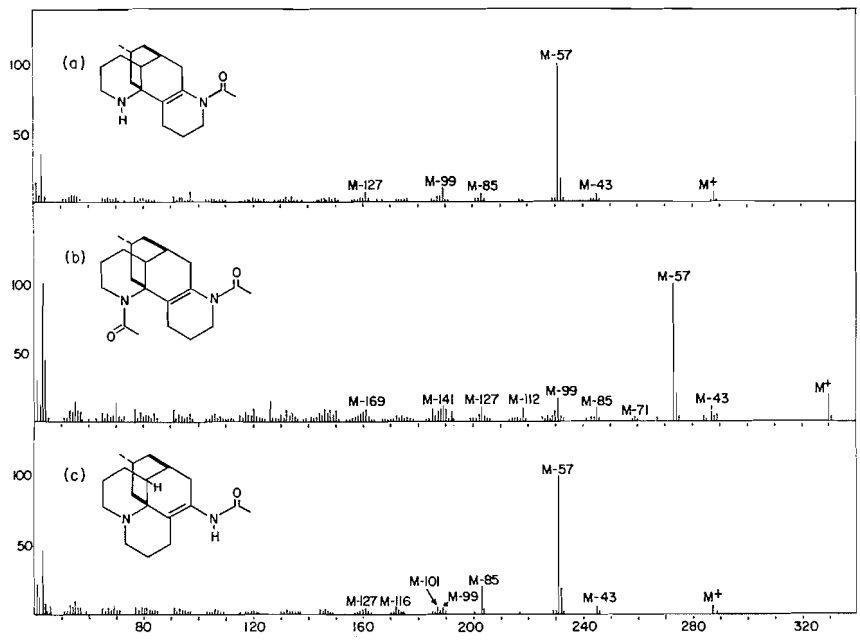

FIG. 3. Mass spectra of (*a*) flabellidine, (*b*) acetyl flabellidine, and (*c*) flabelline.

structure V for flabellidine. The mass spectrum of flabellidine (Fig. 3*a*) shows peaks in the high mass region at M-43, M-57, M-85, M-99, and M-127. The M-57 peak is by far the most intense peak in the spectrum. The origin of this peak is undoubtedly due to the loss of bridge plus hydrogen, a process common to *Lycopodium* alkaloids of the lycodine and lycopodine group. The M-85 peak, which may arise by the loss of 28 mass units from the M-57 fragment ion, and the M-43 peak are also common to alkaloids of both ring systems. The peaks characteristic of this alkaloid are at M-99 and M-127 and arise because of the presence of the *N*-acetyl group. It has been shown by Djerassi *et al.* (15) that amides readily lose ketene (CH_2=C=O) upon electron impact. The ions of M-99 and M-127 may arise by loss of ketene from the ions of M-57 and M-85 respectively. A mechanism consistent with the formation of these fragment ions is shown in Scheme II.

The mass spectrum of acetylflabellidine (Fig. 3*b*) and the mass spectrum of the acetylated product obtained from reduction of lycodine are identical. The fragmentation pattern is similar to that of flabellidine. Additional peaks are present, however, because of the presence of the second acetyl group. The peaks observed are at M-43, M-57, M-71, M-85, M-99, M-112, M-127, M-141, and M-169 mass units. The most intense peak in the spectrum is again the M-57 peak. Loss of 28 mass units from the fragment ion *m/e* 273 will give the peak at M-85 (*m/e* 245) mass units. On the other hand loss of 42 mass units (CH_2=C=O) from the fragment ion *m/e* 273 will give the M-99 peak (*m/e* 231). Loss of another ketene molecule from the ion of *m/e* 231 will result in the formation of the fragment ion *m/e* 189 (M-141), which then may lose another 28 mass units (CH_2=CH_2) forming the fragment ion *m/e* 161 (M-169). The peak at M-127 (*m/e* 203) may arise by the loss of 28 mass units from the fragment ion *m/e* 231 (M-99), which may lose 42 mass units giving rise to the M-169 peak (*m/e* 161).

The fragmentation pattern of flabellidine and acetylflabellidine upon electron impact

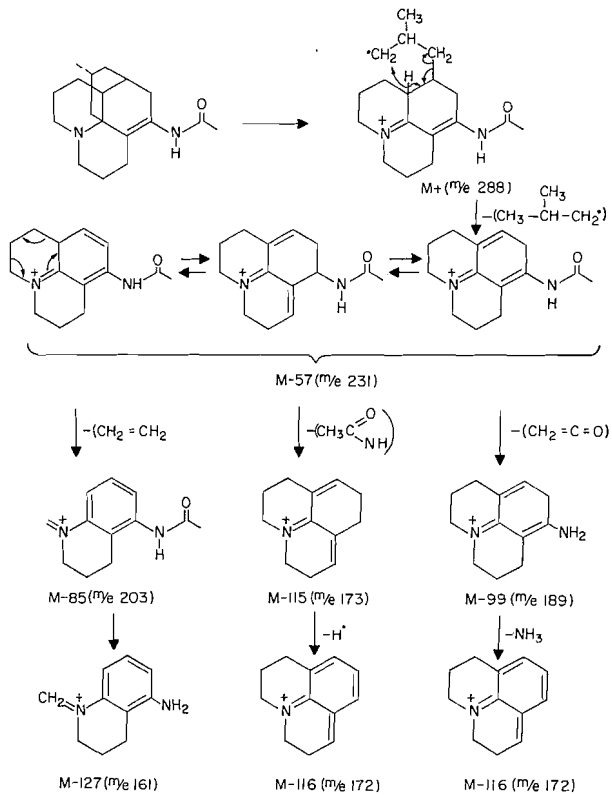
are in agreement with the proposed structure V and with the fragmentation patterns of other *Lycopodium* alkaloids.

A comparison of the mass spectrum of flabellidine with that of its isomer flabelline is made below. Flabellidine is a member of the lycodine group of *Lycopodium* alkaloids, while flabelline conforms in structural type to lycopodine (11). Flabelline is unique among the lycopodine group, however, inasmuch as it carries a nitrogenous substituent. It is of interest, therefore, to ascertain if the two structural types may be differentiated by the mass spectrometric method.

Although the mass spectra of flabelline and flabellidine are similar, a comparison shows that the presence of a secondary amide substituent in flabelline results in additional characteristic peaks in its spectrum. The spectrum (Fig. 3*c*) has peaks in the high mass region appearing at M-43, M-57, M-85, M-99, M-101, M-116, and M-127. The M-43, M-57, and M-85 peaks are again common to all *Lycopodium* alkaloids of the lycopodine and lycodine types. The peaks at M-99 and M-127 are present in the spectrum of both flabelline and flabellidine, confirming the assumption that they arise because of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

presence of an *N*-acetyl group. The peak at M-116 is absent in the spectrum of flabellidine and hence is characteristic of flabelline, although of relatively low intensity. A fragmentation mechanism accounting for the formation of these ions is postulated in scheme III.



The peak at *m/e* 172 (M-116) corresponds to the loss of acetamide from the fragment of *m/e* 231 (M-57), and it appears that acetamide may be lost in more than one manner. In one stepwise process it is proposed that ketene is first eliminated to yield the ion of *m/e* 189 (M-99), which then loses ammonia. In support of this process there is a strong metastable peak in the spectrum at *m/e* 157.8, corresponding to loss of 17 mass units from the fragment of *m/e* 189 [$m^*(189 \rightarrow 172) = 156.8$]. Another stepwise process, the loss of $CH_3C(=O)NH$ followed by the loss of H, is suggested by the presence of metastable peaks at *m/e* 129.8 and 171.5, corresponding respectively to the transformations *m/e* 231 → 173 (m^* calcd. = 129.5) and *m/e* 173 → 172 (m^* calcd. = 171). A final possibility, the concerted elimination of acetamide, cannot be ruled out from the evidence at hand. To accommodate the formation of the fragments of *m/e* 203, 189, and 172, it is necessary to postulate that the double bonds and the hydrogen atoms in the fragment ions are mobile.

In the fragmentation of flabelline, the loss of one nitrogen atom in the transformation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

m/e 189 → 172 is observed. The loss of one nitrogen atom as an ammonia molecule or as an amine fragment is less likely from a heterocylic system, and is not a discernible transformation in the spectra of lycodine or α-obscurine reported by MacLean (11) or that of flabellidine discussed above. It appears that the mass spectrometric method will differentiate between alkaloids with the lycopodine skeletal structure carrying a nitrogenous substituent and alkaloids with a lycodine skeleton where both nitrogens are incorporated into the ring system.

EXPERIMENTAL

Apparatus, Methods, Materials

Melting points were recorded on a Kofler micro hot stage melting point apparatus and are uncorrected.

The infrared spectra were recorded on a Beckman Model IR-5 recording spectrophotometer in Nujol mull, unless otherwise stated.

Ultraviolet spectra were measured in methanol on a Perkin–Elmer Model 4000 spectracord.

The mass spectra were determined on a C.E.C.-103 mass spectrometer at an ionizing potential of 70 eV and an ionizing current of 50 μA. Samples were introduced through a heated inlet system maintained at 140 °C. The samples were run through the courtesy of Professor K. Biemann, Massachusetts Institute of Technology, Cambridge, Massachusetts. All mass spectra are plotted in terms of relative abundance, with the most intense peak ("base peak") being taken as 100%.

The n.m.r. spectra were measured in deuterochloroform solutions, with tetramethylsilane as an internal standard, on a Varian V-4300 B high resolution spectrometer at a frequency of 60 Mc/s.

Isolation of Hydroxy-des-N-methyl-α-obscurine

The crude alkaloid from *L. flabelliforme* was worked up in the manner described by Young and MacLean (8). The fraction eluted by them with 2% methanol in chloroform was rechromatographed and the column eluted successively with chloroform, 1%, 1.5%, 2%, and 5% methanol in chloroform. The fraction eluted with 1.5% methanol in chloroform was subjected to a six funnel distribution between chloroform and citrate–phosphate buffer of pH 6. The base recovered from buffer fractions 1 and 2 crystallized from a methanol–acetone mixture. After recrystallization from the same solvent mixture, a compound melting at 237–238° was recovered. This compound was identified as clavolonine (16) by comparison with an authentic sample obtained from Dr. R. H. Burnell. The mother liquors from the original crystallization were taken to dryness and dissolved in chloroform. From the chloroform solution, 0.035 g of a crystalline base separated which, after recrystallization from methanol–acetone, melted at 300–305° with decomposition. The hydroxy-des-*N*-methyl-α-obscurine so obtained showed a molecular weight of 276 by mass spectrometry. Its ultraviolet, infrared, and n.m.r. spectra were discussed in the previous section.

Flabellidine (Alkaloid L.5)

This alkaloid was isolated as its perchlorate salt from *L. flabelliforme* by the procedure described by Alam (9). The perchlorate was purified by recrystallization from acetone and melted at 281–282°. A comparison of the ultraviolet and infrared spectrum of this compound with that of an authentic sample of L.5 perchlorate established the identity of the two.

Calcd. for $C_{18}H_{28}ON_2 \cdot HClO_4$: C, 55.52; H, 7.50; N, 7.20. Found: C, 55.49; H, 7.65; N, 7.37.

Preparation of Acetylflabellidine

Flabellidine (37 mg), regenerated from the perchlorate salt, was heated under reflux for 1¼ h with acetic anhydride (15 ml). The reaction mixture was cooled and poured on crushed ice (50 g) and the aqueous mixture was extracted with chloroform. The chloroform extract was washed with 10% aqueous sodium carbonate solution and water, and dried over anhydrous sodium sulphate. Removal of the solvent yielded a gummy substance which did not show a peak corresponding to flabellidine upon vapor phase chromatography but instead showed a new peak with higher retention time. The crude product was adsorbed on a non-basic alumina (Woelm) column and was eluted successively with petroleum ether, benzene, and chloroform. Most of the material was eluted with benzene. The residue from the benzene fraction, after removal of the solvent, crystallized from ether. After recrystallization from acetone–ether it melted at 150–152°. The ultraviolet spectrum of this compound showed an absorption at $\lambda_{max}^{CH_3OH}$ 237 mμ, log ε = 3.84. The infrared spectrum in chloroform solution showed an absorption peak at 1620 cm^{-1}, but no absorption in the N—H region. The mass spectrum showed a molecular weight of 330 for this compound.

Calcd. for $C_{20}H_{30}O_2N_2$: C, 72.70; H, 9.10; N, 8.48. Found: C, 72.25; H, 9.11; N, 8.06.

High Pressure Hydrogenation and Acetylation of Lycodine

Lycodine (0.095 g) was dissolved in freshly distilled acetic anhydride (30 ml) and Raney nickel (200–300 mg) added. The mixture was shaken with hydrogen (at 1160 p.s.i.g.) at 110 °C for 16 h. After removal of most of the acetic anhydride under reduced pressure, the reaction mixture was poured on crushed ice

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and the aqueous mixture extracted with chloroform. The chloroform extract was washed with water, dried over anhydrous sodium sulphate, and the solvent removed. The residue crystallized from acetone–ether, and on recrystallization from the same solvent melted at 150–152°. A mixed melting point with acetylflabellidine was undepressed. The ultraviolet spectrum and the infrared spectrum were superimposable on those of acetylflabellidine. The mass spectrum (Fig. 3*b*) showed a molecular weight of 330 and was identical with that of acetyl flabellidine.

ACKNOWLEDGMENT

Financial assistance to S. N. Alam from the Canadian Commonwealth Scholarship Committee during the period 1960–1963 is gratefully acknowledged. This work was supported by a grant from the National Research Council of Canada.

Also, we wish to thank Dr. R. H. Burnell, who supplied an authentic sample of clavolonine.

MECHANISM OF THERMAL DECOMPOSITION OF AMMONIUM METAVANADATE

M. TANIGUCHI[1] AND T. R. INGRAHAM[2]

Extraction Metallurgy Division, Mines Branch, Department of Mines and Technical Surveys, Ottawa, Canada

Received June 24, 1964

ABSTRACT

When ammonium metavanadate is roasted at 225 °C, ammonia and water are eliminated in the ratio 2:1 and an intermediate compound identified by weight loss and chemical analysis as $(NH_4)_2 \cdot O \cdot V_2O_5 \cdot$ is formed. An X-ray diffraction pattern for this material is reported. Transpiration experiments have been used to establish the free energy of this reaction. The second stage of the decomposition involves an endothermic and an exothermic process, both of which occur with the production of a gaseous product. The liberation of ammonia is not quantitative, and its oxidation on the vanadium pentoxide, in the last stage of decomposition, is suggested as a possible source of the exothermic heat.

INTRODUCTION

Ammonium metavanadate, which may be recovered from the hydrometallurgical treatment of some ores containing vanadium, is one of the major starting materials in the preparation of vanadium chemicals. Most vanadium pentoxide, for example, is produced by the roasting of ammonium metavanadate

[1] $$2NH_4VO_3 \rightleftharpoons V_2O_5 + 2NH_3 + H_2O.$$

Although there have been a number of investigations of the process of roasting ammonium metavanadate (1–5), there is no general agreement on the course of the reaction. It is agreed that a stable intermediate is formed, but it has not been positively identified. In Table I, some of the suggested intermediates are listed.

TABLE I

Weight losses accompanying formation of proposed intermediates

Proposed intermediate	% weight loss	Ratio NH_3:H_2O released
$(NH_4)_2 \cdot O \cdot (V_2O_5)_3$ (1, 2)	14.84	2:1
HVO_3*(3)	14.56	1:0
$NH_3 \cdot H_2O \cdot (V_2O_5)_2$ (4)	14.77	3:1

*Accepted by most current textbooks.

It will be apparent from Table I that since the weight losses involved in the production of the intermediate are almost identical, any technique based entirely on thermogravimetric methods would be likely to produce inconclusive results. When balanced chemical equations are written for the formation of each of these intermediates, it is evident from the wide variation in the ratio of ammonia to water, as shown in the third column of Table I, that analysis of the gaseous decomposition products should be helpful in resolving the reactions involved.

In this work chemical analyses have been made of the gaseous products of reaction.

[1]*National Research Council of Canada Postdoctoral Fellow. Present address: Department of Synthetic Chemistry, Tokyo Institute of Technology, Tokyo, Japan.*

[2]*Head, Research Section, Extraction Metallurgy Division, Mines Branch, Department of Mines and Technical Surveys, Ottawa.*

This information has been combined with the weight loss and chemical analysis to determine the composition of the intermediate. The transpiration method was used to estimate the free-energy change for the reaction to form the intermediate. Differential thermal analysis was used to detect the temperatures at which the most vigorous reaction was obtained, and to assess the complexity of the decomposition reactions.

EXPERIMENTAL METHODS AND RESULTS

Material

The ammonium metavanadate used in the experiments was "purified ammonium metavanadate" (14.56% NH_3, 44.48% V) supplied by Fisher Scientific Co. A few experiments were done using British Drug House reagent grade material, but, from the development of a yellow color on roasting, it was evident that the material was contaminated with a potassium salt.

Analytical Methods

Ammonia and Water

Two methods were used for the determination of ammonia. When only ammonia was required, it was absorbed from the gaseous decomposition products in 0.1 *N* H_2SO_4 and the excess back-titrated with standard alkali.

When both ammonia and water were required for determining the ratio in which they were produced during the decomposition, the products were passed through a known weight of concentrated sulphuric acid. The increase in weight was equivalent to the absorption of both water and ammonia. The amount of ammonia in the acid was determined by the Kjeldahl method.

Vanadium

Vanadium was determined by a redox titration, using *N*/30 $KMnO_4$, *N*/30 $Fe(NH_4)_2(SO_4)_2$, and a diphenylamine phosphoric acid indicator.

Differential Thermal Analysis and Effluent Gas Analysis Experiments

The first group of experiments on the thermal decomposition of ammonium metavanadate was done using a Robert L. Stone Co. differential thermal analysis apparatus equipped with a thermal conductivity cell for analyzing the effluent gas stream. During a run, a carrier gas was flushed through the powdered sample at the rate of 50 cc per min as the sample was heated at a rate of 3 °C per min. The carrier gases were nitrogen, oxygen, ammonia, and steam. The results of the thermal analysis and gas analysis were plotted simultaneously on a strip chart. Tracings of two typical charts are shown in Fig. 1.

It is evident, from the lines for a nitrogen carrier gas experiment shown at the bottom of Fig. 1, that the decomposition reaction is complex, involving several stages. The first stage of the reaction, which occurs in the temperature range 210–215 °C, may take place in two steps. A gaseous product is evolved, but the gas analysis trace does not differentiate the gas from each step. At the completion of the first stage of reaction, an intermediate product is formed that is stable up to a temperature of 260 °C. The material then undergoes an endothermic reaction, evolving a gaseous product at maximum rate at about 325 °C. The product from this second stage then undergoes additional reaction; an exotherm is developed at 375 °C and a gaseous product is evolved. The final product of this decomposition reaction in nitrogen was a dark-colored vanadium oxide in which the average vanadium valence was slightly less than 5.

When the same experiment was repeated using oxygen as a carrier gas, as shown at the top of Fig. 1, there was better differentiation of the doublet developed in the first

For personal use only.

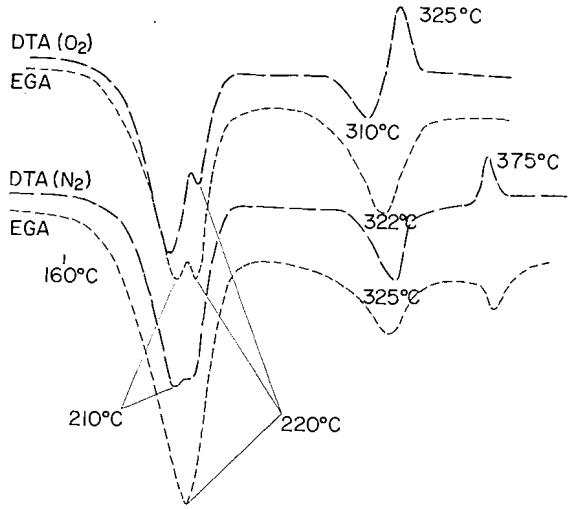

FIG. 1. Differential thermal analysis and effluent gas analysis traces of the reactions involved in the conversion of ammonium metavanadate to vanadium pentoxide, with oxygen and nitrogen sweep respectively.

stage of reaction. It was shown by both the thermal- and gas-analysis tracings. The first part of the second stage of decomposition was identical with that observed in nitrogen. However, because of the increased area under the gas analysis tracing and the occurrence of the exotherm at a temperature 50 deg less than that in the nitrogen experiment, it seems likely that both of the gases evolved in the second stage of the decomposition were released simultaneously. It also seems reasonable to expect that in an oxygen atmosphere, the intermediate is oxidized at a lower temperature than when vanadium pentoxide is the source of oxygen.

When the experiments were repeated using steam and ammonia as carrier gases, the effluent gas analysis tracings were erratic. In both instances, however, a single clearly defined peak was generated by the first stage of the reaction. The peak occurred at 225 °C in steam and at 240 °C in ammonia. The sharpness of the peaks indicated that some suppression of the reaction may have occurred.

Determination of the Composition of the Intermediate

In this group, three types of experiments were done. The first type consisted of heating a sample of ammonium metavanadate in an American Instrument Company recording thermogravimetric balance. The heating was done at a constant rate of 3 °C per min in a 50 cc per min stream of nitrogen gas. A tracing of the instrument-drawn chart is shown in Fig. 2, from which it is evident that the decomposition reaction takes place in two stages that are sufficiently well defined to warrant attempts to isolate the intermediate.

Isolation of the intermediate was done by heating 2 g samples of ammonium metavanadate in an open boat within a tube furnace in a slow stream of dry oxygen. Oxygen was used because the experiments shown in Fig. 1 indicated that the steps in the decomposition occur more sharply in it than in nitrogen. At a selected temperature, the boat was heated and then periodically cooled and weighed. It was found that at 225 °C a constant weight was attained after 2.5 h. The weight loss was 14.85%. At a temperature of 200 °C, equilibrium was not obtained after 4 h. At a temperature of 245 °C, there was no observable plateau in the weight loss curve.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

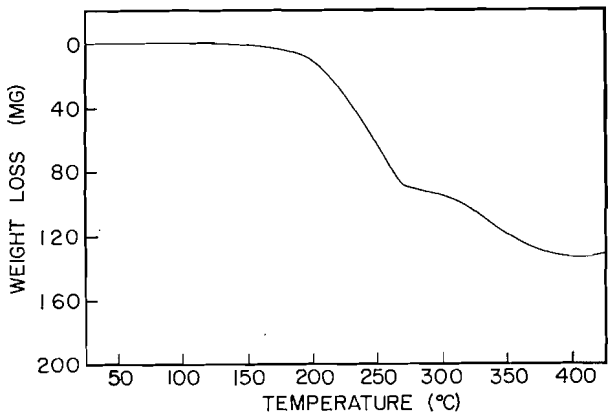

FIG. 2. Thermogravimetric analysis curve of the conversion of ammonium metavanadate to vanadium pentoxide – oxygen sweep at 3 deg per min increase in temperature.

When the conditions for achieving a constant composition had been established, the experiment was repeated and the product gases analyzed for ammonia and water. It was found that the weight loss was entirely accounted for by the combined loss of ammonia and water, and it was established that they are released in the ratio of 2.00 ± 0.02 ammonia to 1.00 water. Chemical analyses were done on the intermediate. The results are shown in Table II.

TABLE II

Percentage composition of intermediate

	NH_3	H_2O	V	O*	NH_3/V
Found	5.69	2.97	52.19	39.15	0.109
Calc'd.†	5.69	3.01	51.10	40.20	0.111

*By difference.
†Calculation was made on the assumption that the intermediate is of formula $(NH_4)_2 \cdot O \cdot (V_2O_5)_3$.

The weight loss, gas composition, and chemical analysis are in agreement with the following equation representing the first stage in the thermal decomposition of ammonium metavanadate:

[2] $$6NH_4VO_3 \rightleftharpoons (NH_4)_2 \cdot O \cdot (V_2O_5)_3 + 4NH_3 + 2H_2O.$$

X-ray powder diffraction patterns were made of the intermediate compound, and the results shown in Table III were obtained.

Transpiration Experiments

The object of the transpiration experiments (6) was to established the free-energy function for the formation of the intermediate compound from ammonium metavanadate. These experiments were done using the pyrex vessel shown schematically in Fig. 3. Preheated oxygen at a known flow rate was passed through a loosely fitted plug of pyrex glass wool into the saturation zone. This zone was about 7 cm in length in a 2.5 cm diameter pyrex glass tube. The ammonium metavanadate powder was piled in ridges to a depth of about 1 cm. The product-saturated oxygen stream was discharged through another plug of pyrex wool and a 2 cm length of 0.05 cm capillary. The exit gases were passed to

absorbers for analysis. The gas saturation vessel was arranged in a fixed position and a movable 12 × 1 in. cylindrical tube furnace was used to heat the vessel. The temperature of the furnace was controlled to ±2 °C with a Kelvin and Hughes controller. Sample temperature was determined by a chromel–alumel thermocouple fitted in the central thermocouple well shown in Fig. 3.

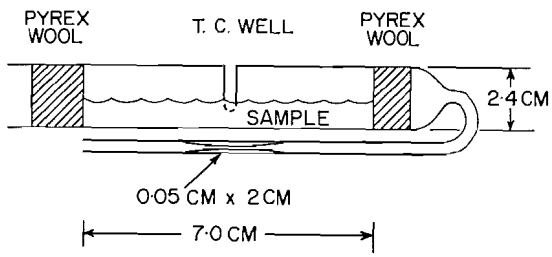

FIG. 3. Pyrex sample vessel used in transpiration experiments.

At a given temperature, experiments were done at a variety of flow rates with the object of establishing a gas composition over the sample such that the composition would be independent of changes in the gas flow rate and in which the partial pressures of ammonia and water would be identical with the decomposition pressures that the two gases would establish over the sample in an evacuated vessel at the same temperature. The results of this series of experiments are shown graphically in Fig. 4, from which it will be apparent that, for at least three of the experimental temperatures, there is a relatively wide range of gas flows for which the sample is in equilibrium with the gas flow.

From a chemical analysis of the ammonia in the oxygen stream, the partial pressure of ammonia in the equilibrium gas was calculated for each of the experimental temperatures. The calculations are shown in Table IV.

Regression analysis of the results in Table IV and Fig. 5 yielded the following equation for 1 mole of ammonium metavanadate

$$\text{Log } K = 10.148 - 5.052 \times 10^3/T$$

or

$$\Delta G^0 = 23\,115 - 46.4T.$$

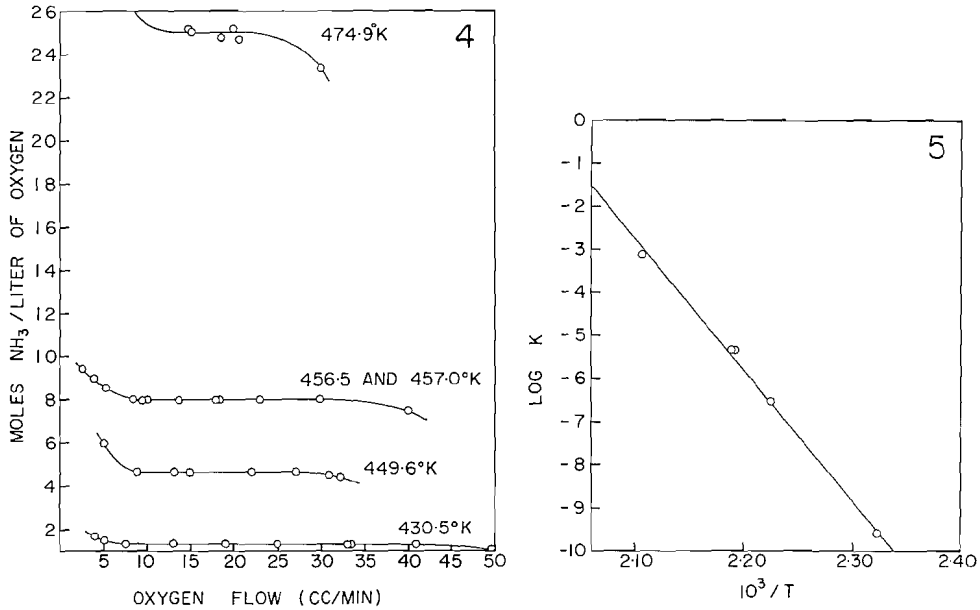

FIG. 4. Graph used to establish equilibrium ammonia pressure in transpiration experiments at 430.5, 449.6, 456.5, 457.0, and 474.9 °K.

FIG. 5. Log equilibrium constant vs. reciprocal temperature relation for the reaction to form $(NH_4)_2 \cdot O \cdot (V_2O_5)_3$ from NH_4VO_3.

TABLE IV

Decomposition pressures over ammonium metavanadate, calculated from a dynamic experiment ($p_{NH_3} + p_{H_2O} = 1.5\ p_{NH_3}$)

T (°K)	$10^3/T$	Moles NH_3 per l O_2 at 25 °C	$p^4_{NH_3}$	$p^4_{NH_3} \cdot p^2_{H_2O}$	Log K
430.5	2.323	13.18×10^{-4}	9.512×10^{-7}	2.319×10^{-10}	−9.634
449.6	2.225	4.66×10^{-3}	1.095×10^{-4}	2.865×10^{-7}	−6.543
456.5	2.191	8.02×10^{-3}	7.216×10^{-4}	4.846×10^{-6}	−5.315
457.0	2.188	7.77×10^{-3}	6.871×10^{-4}	4.503×10^{-6}	−5.346
474.9	2.106	25.1×10^{-3}	2.092×10^{-2}	7.564×10^{-4}	−3.121

Because a linear equation was used to fit the results in Table IV, the assumed ΔC_p for the reaction is 0; hence, $\Delta H^0_{298} = 23.1$ kcal/mole and $\Delta S^0_{298} = 46.4$ entropy units (e.u.). Because the heat of formation of ammonium netavanadate is not known, it is not possible to estimate the heat of formation of the intermediate compound. It is possible, however, to check the reasonableness of the entropy change. The principal change in entropy in reaction [2] is the evolution of 4 moles of ammonia and 2 moles of water for each 6 moles of ammonium metavanadate. Since the entropy of formation per mole of water at 298 °K is 45.11 e.u. and the entropy of formation of ammonia is 45.96 e.u., the combined entropy change per mole of ammonium metavanadate would be 45.7 e.u., which is in reasonable agreement with the experimental value of 46.4 e.u.

When both the transpiration technique and the analysis of the gas stream for the ratio of ammonia to water were applied to the reaction for the formation of vanadium pentoxide from the intermediate, the results were inconclusive. The ratio of ammonia to water in the decomposition gases was erratic, but always indicated that some of the ammonia was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

being decomposed. In the experiments using a nitrogen carrier gas, the vanadium oxide product showed evidence of reduction. The vanadium oxide was its normal color only when oxygen was used. From these observations and from the evidence of differential thermal analysis and effluent gas analysis, it seems likely that the final stage of the decomposition reaction consists of the catalytic decomposition of ammonia on the surface of freshly formed vanadium pentoxide.

CONCLUSIONS

The production of vanadium pentoxide from ammonium metavanadate involves a series of chemical reactions. The first stage of the reaction is the almost simultaneous elimination of ammonia and water, in the molar ratio of 2:1, to produce an intermediate compound having the chemical composition $(NH_4)_2 \cdot O \cdot (V_2O_5)_3$. The second stage of the decomposition involves both an exothermic and an endothermic reaction. The endothermic reaction may be the liberation of water, and the exothermic reaction is consistent with the degradation of ammonia on the vanadium pentoxide surface.

ACKNOWLEDGMENT

The authors wish to express their thanks to P. Marier for the differential thermal analysis and effluent gas analysis experiments and to S. Kaiman for X-ray analyses.

THE SIGNIFICANCE OF HALIDE IN GRIGNARD REAGENTS

WARREN FRENCH AND GEORGE F WRIGHT
Department of Chemistry, University of Toronto, Toronto, Ontario
Received May 27, 1964

ABSTRACT

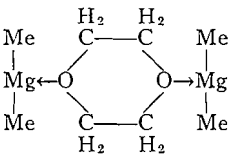
The optical activity of 1-phenylethanol from benzaldehyde and methyl chloride Grignard reagent coordinated with (+)2,3-dimethoxybutane is about one fourth of that found for the same product when bis-methylmagnesium is the reagent. The difference has been attributed to the relative coordinating power of magnesium chloride versus the optically active ether.

Grignard reagents usually contain bound halogen because they are commonly prepared by corrosion of magnesium by means of an organic halide. Indeed, this process historically defines the reagent. However, these reagents may be rendered halogen free by the dioxane precipitation technique of the Schlenks (1) and the resultant solution of bis-organomagnesium also has been considered to be a Grignard reagent. We adhere to this extended definition largely because the amount of magnesium halide in a Grignard reagent is dependent on the type of halide and upon the method of reagent preparation. Thus a reagent series may exist with bis-organomagnesium at one extreme and Grignard reagent saturated with magnesium halide at the other. Such a series would be important only if there is a difference in reactivity in time or type between the extremes. Interest in these differences has increased during recent years (2, 3, 4). In this report the difference in coordination of the organometallic compound with an ether has been investigated.

The method we used is the induction of optical activity in a product of Grignard reagent addition (5, 6, 7) by use of (+)2,3-dimethoxybutane to effect an asymmetric synthesis. We synthesized 1-phenylethanol from methyl Grignard reagent and benzaldehyde and compared yields and optical rotation when either bis-methylmagnesium or methyl chloride Grignard reagent is used.

For the comparison to be meaningful it is important that the first of these reagents be quite free from halide. Mosher (4) found it difficult to attain this condition. By contrast, our precipitate initially contains not only the halide *in toto* but also some of the halogen-free complex. To obtain a reasonable yield of bis-methylmagnesium we must wash the precipitate thoroughly. Subsequently a small amount of white precipitate tends to appear in the solution, presumably because of temperature variations. However, both the solution and the slight precipitate are halogen free by silver halide test. The difference between our results and those of Mosher may be due to our specific reagent or else to the dioxane–Grignard ratio or to our use of heat during the precipitation.

The halide-free solution contains bis-methylmagnesium dioxanate or dioxanate–etherate, so these ethers must be removed to ensure that the optically active ether will be fully effective. Most of the diethyl ether is removed easily at 50 °C under 1 atm of nitrogen, leaving a solid residue. Comparison of the weight of this residue with the basic magnesium equivalence, according to titration (8), indicates a composition of one-half dioxane per mole of bis-methylmagnesium.



The removal of dioxane occurs under a pressure of 0.001 mm of mercury, slowly at 25 °C as is shown by the upper curve of Fig. 1 and more rapidly at 50 °C (lower curves). The weight loss does not reach the level of bis-methylmagnesium even when the final temperature is raised to 140°. This apparent retention of some dioxane even after 4 h is probably an analytical error caused by the necessity of releasing the systems to atmospheric pressure by means of nitrogen to make the intermediate weighings. An alternative possibility, splitting of the ether at elevated temperature, is unlikely because in preparative experiments involving only an initial and final weight (3), the loss conformed with complete removal of ether. Moreover, the amount of dioxane condensed in a dry ice trap during the experiments shown in Fig. 1 is exactly 0.5 mole.

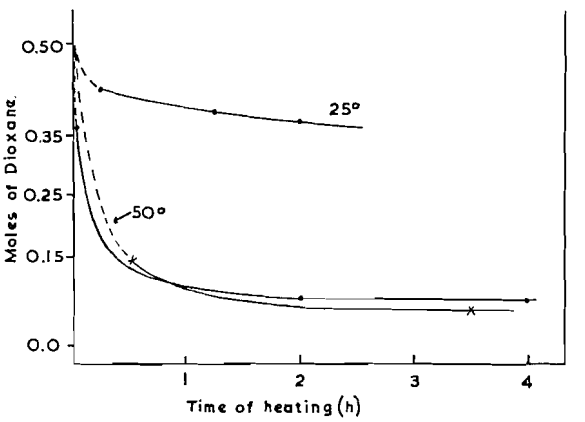


FIG. 1. Removal of ether from MeMg at < 0.001 mm pressure.

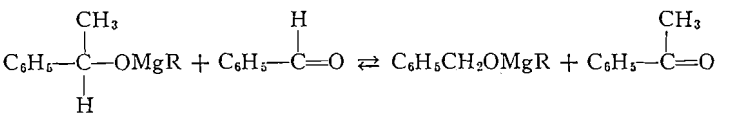
Ether-free bis-methylmagnesium is insoluble in benzene but the addition of a molar equivalent of (+)2,3-dimethoxybenzene to the benzene suspension causes immediate solution with heat evolution that is large in consideration of the ease with which dioxane removal is effected. Doubtless the strong coordinating power of the optically active ether is responsible for the ease with which methyl chloride reacts smoothly with magnesium in a solution of 1 molar equivalent of this ether in an equal volume of benzene to give the halide-containing Grignard reagent for our comparative reactions.

There are certain disadvantages in the reaction that we have chosen for demonstration. The chief disadvantage is a concomitant oxidation–reduction of the Meerwein type (9), because the benzyl alcohol so produced is difficult to separate from 1-phenylethanol by distillation or absorption chromatography on alumina. Moreover the by-product formation



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

is greater in the system containing bis-methylmagnesium than in the halide-containing reagent, so the optical purity may appear to be lower than is warranted by its actual enantiomer content. Nor can it be purified by crystallization for closer evaluation because the racemic compound separates preferentially upon cooling. Against these disadvantages is the reliable knowledge of the specific rotation, +13.02°, of optically pure 1-phenylethanol (10, 11).

The two reactions were carried out with the same ratio of magnesium to carbonyl in order that only one C—Mg linkage would be involved in the comparative reactions. The results are shown in Table I where the halide-containing reagent is nominally described as "MeMgCl".

TABLE I

Asymmetric synthesis of 1-phenylethanol

Expt. No.	Grignard reagent	Yield of product (%)	n_D^{20}	$[\alpha]_D^{25}$ (neat)	Optical purity (%)
1	MeMgCl	74	1.5256	−0.72±0.02	5.5
2	MeMgCl	82	1.5251	−0.59±0.01	4.5
3	Me_2Mg	61	1.5283	−2.40±0.01	18.5+
4	Me_2Mg	67	1.5256	−2.61±0.01	20.0+

It may be seen from these experimental values that the extent of asymmetric synthesis is almost four times higher in absence of halide than in its presence. Actually the difference must be greater, because the product of expt. 3 when it was analyzed by gas–liquid chromatography was found to contain 10–15% of benzyl alcohol and acetophenone and therefore only 85% of the active alcohol, whereas the active alcohol of expt. 1 was essentially pure. Only traces of acetophenone and benzyl alcohol were found in the latter sample.

Thus it is the experimental fact that asymmetry is induced by an optically active ether much more when magnesium halide is absent than when it is present in the reaction between methyl Grignard reagent and benzaldehyde. Unfortunately, interpretation of this phenomenon depends upon a knowledge of the manner in which magnesium halide participates in Grignard system and this knowledge is largely lacking. For example there is still much controversy (ref. 2, p. 99), after 60 years, about the relative importance of the several constituent forms in the so-called Schlenk equilibrium.

$$2RMgX \rightleftarrows R_2Mg + MgX_2 \rightleftarrows R_2Mg \cdot MgX_2$$

However, none of the conclusions is entirely definitive. The demonstration by X-ray diffraction (12) that bromobenzene Grignard reagent yields crystals of structure $RMgX \cdot 2ET_2O$ tells nothing about the composition in solution, as is evident in the fact that diphenylmagnesium may be isolated in good yield from such a solution after the halide in the system is precipitated by dioxane. Actually these observations lead only to the conclusion that Grignard reagent systems are labile.

Morever there is evidence that any one system may be altered by the environment and perhaps by the temperature. Ashby and Becker (13) have shown that the state of complexity is dependent on the ether that is involved with the reagent. In tetrahydrofuran their ebullioscopic studies are interpreted to show that ethyl chloride and ethyl bromide Grignard reagents actually exist as RMgX, whereas the boiling point elevation in other ether media (14, 15) have indicated that RMgX is not predominant.

Actually even greater complexity is possible. After Jolibois (ref. 2, p. 109) showed that

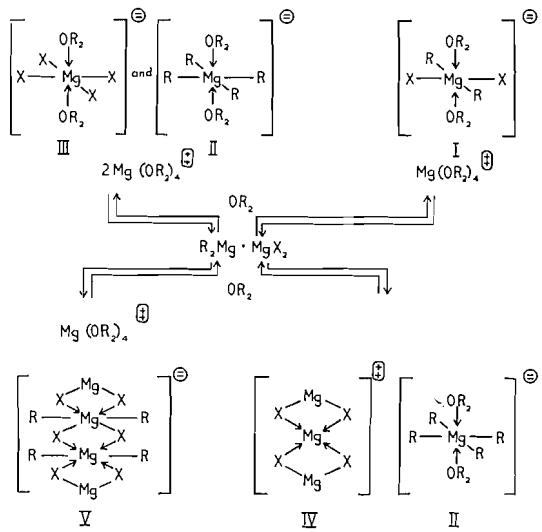
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Grignard reagents are electrically conducting it was found by electrolytic transport studies (16–19) that they show ionic properties where magnesium is both in the cation and the anion. In this circumstance ebullioscopic evidence for the monomeric form, RMgX, may also be interpreted in terms of an ionized dimer.

$$2RMgX \rightleftarrows R_2Mg_2X_2 \rightleftarrows Mg^{++} \text{ and } (MgR_2X_2^{--})$$

At the present time one cannot say whether monomer, dimer, ion pair, or ions predominate. Probably the predominance depends upon the specific reagent as well as the reaction medium. Each will serve for description, but the ionic formulation seems to be convenient to illustrate the effect of magnesium halide on our asymmetric synthesis.

An explanation is needed for the fact that although halogen-free Grignard reagents ordinarily are less reactive than those in which halide is present (20, 21) the presence of magnesium halide in the present reaction tends to reduce the extent of asymmetric induction due to an optically active solvent. The anomaly is resolved if magnesium halide is considered to be alternative to the ether as a coordinating agent. To the extent that it displaces (+)2,3-dimethoxybutane the tendency for enantiomeric preference cannot occur.



The deleterious effect of magnesium halide is not apparent in the ion pair I nor in ion pairs II and III because III would not enter into product formation with adducts like benzaldehyde. Likewise the asymmetry-inducing ether in the ion pair IV–II ought to be free to exert its influence on the entering adduct because the magnesium halide (even in excess over the composition $R_2Mg \cdot MgX_2$) is relegated to the cation. However, in the ion pair V the ether would be ineffective because it has been excluded from coordination by magnesium halide which occupies its place in the anion. Although the ether might (or might not) solvate the cation its effectiveness at this distance ought to be minimal, especially if the pair is dissociating in the medium. The existence of a complex species like V in significant amount cannot be excluded. Indeed it may be noted that its composition is such that it could be the source of the Et_2Mg plus $EtMg_2Cl_3 \cdot THF$ which was separated from solution by Ashby and Becker if, as seems likely, their R_2Mg was solvated.

Obviously there may be many variations of these five typical ions pairs, and it is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

apparent that complexity and not necessarily charge separation is the significant factor. No matter how the Grignard reagent is described the effect of magnesium halide is best explained as a displacement at the reaction site of the asymmetry-inducing ether. No doubt the explanation is incomplete because the geometry of the complex must also be a factor. But this geometry is an additional attribute which will be discussed in a forthcoming extension of the present work.

EXPERIMENTAL

Methyl Chloride Grignard Reagent

Into a dry, nitrogen-filled flask fitted with a dry ice cold-finger condenser, mercury-sealed stirrer, and gas inlet tube leading near the bottom of the flask were placed 9.7 g (0.40 g-atom) of distilled magnesium and 30 ml of diethyl ether. Approximately 2 g of methyl chloride was introduced, and the mixture stirred until reaction started (ca. 10 min). When the reaction ceased the mixture was diluted with 200 ml of diethyl ether, and the rest of the methyl chloride (initially 15.7 g, 0.31 mole) was introduced during 15 h with occasional cooling of the mixture to control the rate of reaction. The reaction was accompanied by the formation of a thick, gray precipitate. The mixture was stirred 4 h longer at 25°, then poured under nitrogen into a centrifuge bottle. The clear colorless supernatant layer obtained by centrifuging at 1 500 r.p.m. for 20 min was transferred by syringe to a second three-necked flask, and the precipitate washed with four 30 ml portions of ether (Gilman test, negative). Titration of an aliquot of the ether solution indicated 0.272 equivalents (88%) of basic magnesium.

Solvent-Free Dimethylmagnesium

To the rapidly stirred methyl chloride Grignard reagent, described above, was added 27.3 g (0.31 mole) of dioxane during 15 min. The mixture was heated under gentle reflux with stirring for 30 min longer, then was poured under nitrogen into a centrifuge bottle. The supernatant layer formed on centrifugation was found to contain 0.118 equivalents (38%) of magnesium. Six washings of the precipitate with 25 ml portions of ether raised the yield to 0.130 equivalents (42%). A test of an aliquot was made in acidified silver nitrate. The chlorine-free ethereal solution of dimethylmagnesium slowly deposited a white solid on standing.

In order to obtain solvent-free dimethylmagnesium, the ether content of the dimethylmagnesium was determined at various temperatures in the following way.

Into a weighed nitrogen-filled 50 ml distilling flask, connected through an interchangeable joint to a liquid nitrogen trap and thence to a vacuum system, was placed 10 ml of a stock solution of dimethylmagnesium in ether (0.169 mmole/ml by titration, or gravimetrically as the oxinate). The ether was removed by distillation with an external bath at 50° leaving a white solid. The flask was then cooled in dry ice and evacuated to < 0.001 mm pressure. The dry ice was removed and the flask temperature returned to 25° during 20 min. At suitable intervals (ca. 1 h), the flask was filled with nitrogen, removed from the vacuum line, and weighed. The above procedure was repeated at various temperatures so that plots of weight vs. time were obtained. No magnesium was lost from the flask at high temperatures since the magnesium content of the residue was the same after heating as before. The magnesium content was determined by first dissolving the residue in dry ether, hydrolyzing with 15 ml of 0.5 *N* HCl, and precipitating the magnesium as the oxinate (22).

In another experiment, the solvent was removed from an ether solution containing 0.0514 mole (2.79 g) of dimethylmagnesium. Evaporation of the ether with an external bath at 50° left 5.36 g (corresponding to $Me_2Mg \cdot 0.57$ dioxane) of white solid. The flask was cooled in dry ice and evacuated to < 0.001 mm pressure, then warmed to 25° during 20 min. After 10 min at 25° (0.001 mm), the residue weighted 4.79 g (corresponding to $Me_2Mg \cdot 0.44$ dioxane). The cold trap between the sample and the vacuum system was cleaned and the apparatus reassembled. After evacuating the system to < 0.001 mm again, the dimethylmagnesium was heated to 75°. At the end of 4 h, the residue weighed 3.072 g (corresponding to $Me_2Mg \cdot 0.07$ dioxane). This weight is 10% higher than expected from the analysis of the starting solution by titration, but the preceding experiment (Fig. 1) also shows that a 10% weight excess exists even when the ether is removed at a higher temperature. The volatile material collected in the cold trap was distilled *in vacuo* into a weighed tube. The colorless liquid weighed 1.720 g (100%) and melted at 8.5–9.5°. A mixture melting point with dioxane was not lowered.

1-Phenylethanol

(a) From Dimethylmagnesium

To solvent-free dimethylmagnesium (0.0514 mole, 2.79 g) was added 50 ml of benzene, then 6.0 g (0.051 mole) of dextro-2,3-dimethoxybutane (5). Although the solid was insoluble in benzene, dissolution was rapid on addition of the ether and the system became very warm. The ether solution was cooled in an ice bath; then a solution of 6.05 g (0.057 mole) of freshly distilled benzaldehyde in 15 ml of benzene was added to it during 20 min. Fifty min after the addition was complete, the pale yellow solution was hydrolyzed with 50 ml of cold 15% aqueous ammonium chloride. The organic layer was separated, washed with water,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and dried over anhydrous potassium carbonate. The solvents were removed under reduced pressure and the pale yellow residual oil distilled at 12 mm pressure. The main fraction boiling at 85–86° (12 mm) weighed 4.20 g (67%). The before- and after-fractions, boiling two degrees on either side of this range, amounted to 0.76 g. The oil boiling at 85–86° (12 mm) had a melting range of 5.0–7.5°, $n_D^{20} = 1.5283$, and showed $[\alpha]_D^{25} = -2.43 \pm 0.04°$ in 95% ethanol ($c = 10.03$), $[\alpha]_D^{25} = -3.06 \pm 0.08°$ in chloroform ($c = 5.95$), and $[\alpha]_D^{25} = -2.40 \pm 0.01$ (neat). A portion (1%) of the product was analyzed by gas–liquid chromatography. It contained 15–20% of benzyl alcohol and acetophenone. The rest of the oil was dissolved in 15 ml of petroleum ether and cooled to −12°. The solid which separated was crystallized twice more by the same method to give 0.90 g of material melting at 15–17°. A small amount of material melting at 20.0–20.5° was obtained by further crystallization. The specific rotation of the material melting at 15–17° was −1.0° (neat), $n_D^{20} = 1.5233$. The material in the filtrate from the above purification procedure showed $[\alpha]_D^{25} = -2.75 \pm 0\ 01°$ (neat).

(b) From Methyl Chloride Grignard Reagent

To 2.43 g (0.10 g-atom) of sublimed magnesium under nitrogen was added 7.0 g (0.06 mole) of dextro-2,3-dimethoxybutane (5) in 25 ml of benzene. Methyl chloride was then slowly added to the stirred mixture through a gas inlet tube leading beneath the surface of the organic liquid (the reaction started within 10 min). The reaction mixture was stirred a further 1.5 h at 25° after the addition of methyl chloride (3.0 g, 0.06 mole) was complete, then was diluted with 25 ml of benzene. Titration of an aliquot of the clear, colorless supernatant layer (unchanged magnesium removed) indicated 0.047 equivalents (78%) of basic magnesium.

The stirred ice-cold Grignard solution was treated with 2.66 g (0.025 mole) of freshly purified and distilled benzaldehyde in 15 ml of benzene over a period of 15 min. A colorless oil separated from the reaction medium during the addition. Stirring was continued 20 min longer, then the mixture was hydrolyzed with 50 ml of cold 15% ammonium chloride solution. The organic layer was separated, washed with water, and dried over anhydrous sodium sulphate. Removal of the organic solvents by distillation left a colorless oil that was distilled under reduced pressure. The main fraction distilled at 79–80° (9 mm), weighed 2.5 g (82%), n_D^{20} 1.5251, and had a specific rotation of $[\alpha]_D^{25} = -0.59 + 0.01°$ (neat).

KINETICS OF THE REACTION $H + D_2 = HD + D$

W. R. SCHULZ AND D. J. LE ROY
Department of Chemistry, University of Toronto, Toronto, Ontario
Received July 6, 1964

ABSTRACT

The authors have measured the rate constant for the reaction $H + D_2 = HD + D$ in the temperature range 368–468° K. This was found to be given by the relation:
$k_4 = 4.3_7 \times 10^{12} \exp(-7.3_0 \times 10^3/RT)$ cm^3 mole^{-1} s^{-1}.
A comparison is made with previous experimental and theoretical work on the reaction.

During the past 30 years much attention has been directed to the possibility of calculating the kinetic parameters for chemical reactions from quantum mechanical principles. In this connection the major proving ground has been the experimental and theoretical study of the following reactions:

[1] $H + H_2 = H_2 + H$
[2] $D + D_2 = D_2 + D$
[3] $D + H_2 = DH + H$
[4] $H + D_2 = HD + D$
[5] $H + HD = H_2 + D$
[6] $D + DH = D_2 + H$
[7] $H + DH = HD + H$
[8] $D + HD = DH + D.$

On the theoretical side, the use of high-speed computers has made possible the calculation, with a considerable degree of sophistication, of the potential energy surfaces of the intermediate complexes (1–4). On the other hand, the available experimental data are far from adequate in providing a test for any theory. Indeed, many of the "experimental" data (e.g. ref. 5) are not experimental in the true sense. The present status of the experimental work has been critically reviewed by Shavitt (3) and need not be treated in detail here. It should be pointed out, however, that the high-temperature experiments (720–1 000 °K) consisted primarily in the determination of the kinetics of the overall reactions,

$$H_{2(p)} = H_{2(o)}$$
$$D_{2(o)} = D_{2(p)}$$
$$H_2 + D_2 = 2HD.$$

In addition to the purely experimental problems associated with the determination of the orders and rate constants for these overall reactions, the subsequent calculation of the rate constants for reactions [1]–[6] from these data (reactions [7] and [8] are unobservable even in this sense) involved a number of assumptions which can be questioned (3). The low-temperature experiments (283–373 °K) involved only a study of reaction [1]. In these experiments the atomic hydrogen was produced by an electrical discharge and its concentration measured with a Wrede gauge. While in principle the method was a good one, the experimental arrangement was such as to lead to uncertainties in the rate constant of a factor varying from 1.5 to 3.7.

Recent improvements in the method of Tollefson and Le Roy (6), and further refinements described here, have encouraged us to reinvestigate the kinetics of these reactions. In this paper we report the results of our investigation of reaction [4]. Because of the

importance of these results we will describe the experimental approach in reasonable detail.

EXPERIMENTAL

The reaction vessel consisted of a pyrex tube 2.54 cm internal diameter and 37 cm long. This was surrounded by a pyrex jacket through which fluid from a thermostat was circulated. The jacket was itself surrounded with glass wool insulation. The temperature of the reactor was maintained within ±0.01 °C; specially constructed tungsten resistance thermometers placed at the entrance and exit of the jacket were used to measure the temperature, subsequently defined as T_w, and the temperature gradient along the reactor. At the highest temperature used the gradient was 0.05 deg in the 37 cm tube.

To the top of the reactor was connected the dissociator chamber in which the atomic hydrogen was formed. This was approximately 30 cm long and 4.5 cm in internal diameter, except at the lower end where it tapered to the internal diameter of the reactor. The dissociator was surrounded by a jacket which was kept at 23 °C with the aid of an external thermostat and circulating system. The top of the dissociator was closed by a pyrex flange with an O-ring seal to which the lead-in wires and the H_2 inlet were attached. The hydrogen was partially dissociated by passage over an electrically heated tungsten spiral which extended over most of the length of the chamber. In the present experiments the concentration of atomic hydrogen produced in this way was varied from 2.5% to 3.5%. The dissociator filament was heated by direct current from a power supply with remote sensing leads which maintained the applied voltage constant to within ±0.025%.

The deuterium, mixed with the reference gas helium, entered the reactor through a capillary tube which passed through the wall of the tube joining the dissociator and reactor and then down the axis of the latter to a distance about 2.5 cm below the level of the jacket. The internal walls of the dissociator and reactor were coated with orthophosphoric acid applied in aqueous solution and subsequently baked under a stream of dry nitrogen.

The H-atom concentration in the reactor was measured with a detector, consisting of a flat spiral of 0.0125 in. diameter platinum wire which reached within about 1 mm of the wall of the reactor; it had a resistance of the order of 0.6 Ω under operating conditions. Two current and two potential leads were connected to the platinum and passed through glass-to-metal seals into a hollow ¼ in. stainless steel shaft. This shaft could be raised or lowered manually to determine the H-atom concentration throughout the reactor.

The bottom of the reactor was connected, through a flange and O ring, to a stainless steel block. This had a cylindrical hole coaxial with the reactor and of somewhat larger diameter which terminated in a flat surface containing a hole just large enough to permit the shaft of the detector to pass through. A Teflon gasket, in the shape of a hollow cone, at this point, and a similar one at the bottom of the block, permitted axial motion of the shaft. Compression of the gaskets was provided by adjustable metal washers. The space between the two gaskets was enlarged and connected to a separate pump to reduce the possibility of air leaking into the reactor, although no leak could be detected across either gasket with a pressure differential of 1 atm. The reaction products were removed through a ⅜ in. diameter hole leading into the side of the block immediately above the upper gasket.

The detector current was supplied by d-c. power supplies stable to ±0.01%. The actual current was measured in terms of the potential drop across a standard 1 Ω resistor in series; the potentials across this and the detector itself were measured with a Leeds and Northrup type K-2 potentiometer.

As in our previous work, the number of H atoms combining on the detector in unit time was measured in terms of W_H, the rate of heat liberation by H-atom combination, expressed as a wattage. Previously we determined W_H from the expression,

[i] $$W_H = R(I_0^2 - I^2),$$

in which I_0 is the current required to keep the detector at a constant temperature, corresponding to the resistance R, in the absence of H atoms, and I is the corresponding value when H atoms are present. The detector therefore acted as an isothermal calorimeter. This method had a number of disadvantages: very careful adjustment of I had to be made to maintain R constant (R was measured in a Wheatstone bridge type circuit); allowance had to be made for the lead resistance and its variation with temperature and with the position of the detector; a great deal of time was required to make the necessary measurements.

In this work the isothermal calorimeter method was given up in favor of determining W_H from the temperature rise (increase in R) brought about by H-atom combination. It was assumed that the rate of loss of energy from the detector was directly proportional to the difference in temperature between the detector and the wall.

[ii] $$W = \alpha(T_d - T_w).$$

It was also assumed that in the temperature range concerned in any particular measurement of W_H the resistance of the detector was a linear function of its temperature

[iii] $$R = R_0(1 + \beta T_d).$$

For any fixed position of the detector three measurements were made. (*a*) With the dissociator off, the resistance of the detector was measured using a current of 0.02 A. This current, while large enough to obtain four-figure accuracy in the determination of the resistance, was small enough to avoid heating the detector as much as 0.01 deg above its surroundings. This resistance was, therefore, defined as R_w, the resistance corresponding to the wall temperature. (*b*) With the same current, but with the dissociator on, the resistance of the detector was again determined and defined as R_H. (*c*) A calibration was then done by turning the dissociator off and measuring the resistance of the detector with a current of the order of 0.6–0.8 A flowing through it; this was defined as R_c, the corresponding wattage as W_c.

If [ii] and [iii] are valid, it follows that

$$[iv] \qquad W_H = W_c(R_H - R_w)/(R_c - R_w).$$

Equation [ii] was found to hold for any of the pressures and flow rates used in the present work. An example is shown in Fig. 1. The detector was placed in a fixed position and the value of T_w was varied while keeping

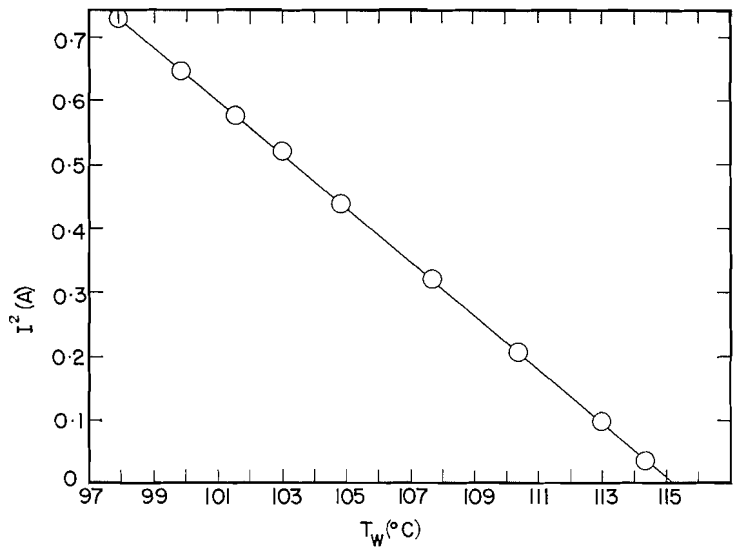

FIG. 1. Test of the relation $W = \alpha(T_d - T_w)$. I is the current required to maintain T_d at 115.2 °C.

the resistance of the detector, and hence its temperature T_d, constant by controlling the current. The wall temperature T_w was measured using the calibrated tungsten thermometers referred to previously. The strict linearity of Fig. 1 justifies the use of [ii]. Equation [iii] would be expected to hold if the temperature range were not too large; it was verified experimentally over the temperature range 90–195 °C.

A further check on the validity of [iv] was made in the presence of atomic hydrogen by measuring W_H by the original bridge method as well as by the new temperature-rise method. The average deviation from unity of the values of W_H determined by the two methods was ±3%. The new method is to be preferred because of its precision and speed.

The reagents were commercial electrolytic hydrogen, and deuterium and helium supplied by Matheson. The hydrogen was purified by passing it through a Deoxo catalytic unit, a trap at liquid nitrogen temperature, a water-cooled cylindrical vessel containing an electrically heated tungsten spiral, and a second trap cooled with liquid nitrogen. Its flow rate was determined in terms of the pressure drop across a calibrated capillary tube, as measured by a sensitive differential manometer. Slip and end corrections were applied to Poiseuille's equation. Immediately before entering the dissociator chamber the hydrogen pressure was reduced to the working value of ca. 3 mm by means of a needle valve.

The deuterium and helium were purified by passage over a hot tungsten filament and through a trap cooled with liquid nitrogen. The mixed gases were stored in a 10 l vessel at approximately 1 atm pressure. During an experiment they were admitted to the reactor through a fine uncalibrated capillary tube after having passed through a buffer volume. The pressure in this volume was kept within ±0.1 mm of a prearranged value in the range of 200 mm by means of an automatic device which controlled the rate of admission to the buffer volume from the storage vessel. The actual flow rate of the deuterium–helium mixture into the reactor could be measured by isolating the buffer volume from the storage vessel and measuring the time required for a calibrated portion of the buffer volume to be filled with mercury; the

For personal use only.

rate of admission of the mercury was automatically controlled to maintain the same fixed pressure in the buffer volume.

The pressure in the reactor was measured with a McLeod gauge calibrated for use in the linear way. Most of the gas leaving from the bottom of the reactor was pumped off with a 40 c.f.m. Stokes Microvac pump. Fluctuations in pressure in the reactor were avoided by providing for sonic flow through a valve placed immediately before the pump. The remaining portion of the gas was removed upstream from this valve and compressed to 1 atm pressure by a Cenco Hyvac 2 pump. Sonic flow through the valve leading to this pump was also arranged. The compressed gas was allowed to flow continuously through a 25 cm^3 volume attached to the sampling valve of the gas chromatograph.

Preliminary experiments showed that under operating conditions there was no change in W_H when the deuterium–helium stream was turned on. Deuterium was therefore conserved by making the β_1 measurements in the absence of deuterium, setting the detector at the final value of x_0 to be used in the deuterium consumption measurements, and then turning on the deuterium–helium flow.

Separate experiments showed that no exchange took place in the sampling system. Hydrogen was used as the carrier gas in the gas chromatographic analysis, so the H_2 peak did not appear, except as indicated below. The column consisted of a 6 ft length of $\frac{1}{4}$ in. copper tubing filled with 80–100 mesh activated alumina; the separation was effected at the temperature of liquid nitrogen. The detector was of the two-thermistor bridge type and was specially constructed to be kept in an ice–water bath. A trace of an original chromatogram is shown in Fig. 2. It is evident that the column not only separates D_2, HD, and He but

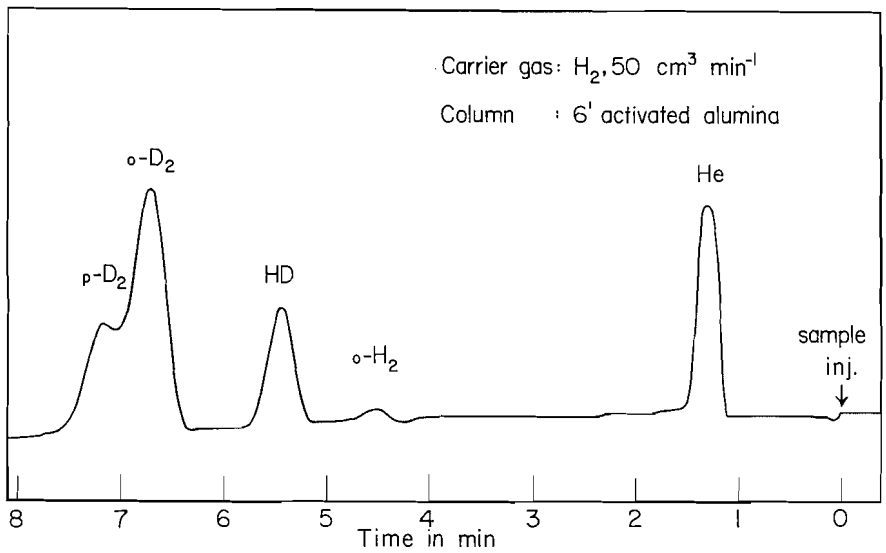

FIG. 2. Gas chromatographic analysis of D_2, HD, and He in the presence of H_2.

also achieves a partial separation of ortho and para deuterium. It also detects the excess ortho hydrogen in the sample; this arises because the ortho hydrogen content of the hydrogen in the sample is nearer to the high temperature equilibrium value of 75% than that of the carrier gas as the result of its passage through the dissociator chamber.

The ratio $[D_2]_0/[D_2]_{x_0}$ required in the calculation of k_4 was obtained from the relation,

$$[v] \qquad [D_2]_0/[D_2]_{x_0} = (A_{D_2}/A_{He})_0/(A_{D_2}/A_{He})_{x_0},$$

in which the A's are chromatographic peak areas (accurate to at least 1%) and the subscripts 0 and x_0 refer to the initial unreacted gas and to the gas leaving the reactor when the detector is at a distance x_0 from the deuterium inlet.

RESULTS AND DISCUSSION

The value of k_4 was obtained from the relation:

$$[vi] \qquad \ln \frac{[D_2]_0}{[D_2]_{x_0}} = \frac{k_4}{f} \int_0^{x_0} [H]\, dx = \frac{k_4 W_H}{4.184 \Delta HDAf(\beta_1 + \beta_2)} \left[\frac{e^{\beta_1 x_0}}{\beta_1} - \frac{1 - e^{-\beta_2 x_0}}{\beta_2} \right],$$

in which ΔH is the molar enthalpy of formation of atomic hydrogen at the temperature of the detector, D is the diffusion coefficient of atomic hydrogen, A is the cross-sectional area of the reactor, f is the linear flow rate in cm s^{-1}, $\beta_1 = (f/2D)[(1 + 4kD/f)^{1/2} - 1]$, and $\beta_2 = \beta_1 + f/D$; k is the first-order rate constant for the consumption of atomic hydrogen in the reactor.

Equation [vi] is based on the relation between [H] and W_H developed and confirmed experimentally by Schulz and Le Roy (6) and subsequently applied to the reaction between atomic hydrogen and propane (7). It takes into account the influence of the detector on the H-atom concentration in the reactor on the assumption that all H atoms reaching the level of the detector are combined thereon, and that H-atom consumption is first order in [H].

The values of β_1 were determined from plots of $-\ln W_H$ vs. x_0. These all showed some curvature as predicted (6). A smooth curve was drawn through the experimental points and the slope evaluated at a particular value of x_0. Assuming that the initial H-atom concentration is independent of x_0, the slope is equal to $\beta_1 + (\beta_1 + \beta_2)/(e^{(\beta_1+\beta_2)x_0} - 1)$. By setting β_1 equal to the slope in the first approximation, its actual value was obtained by successive approximations. A check on the validity of the values of β_1 obtained in this way was made in several instances by comparing the experimental values of $-\ln W_H$ with those predicted by the relation (6),

[vii] $$W_H = 4.184\Delta HDA[H]_0(\beta_1 + \beta_2)\, e^{-\beta_1 x_0}/(1 - e^{-(\beta_1+\beta_2)x_0}).$$

The value of $[H]_0$, the H-atom concentration at the inlet, was eliminated by arbitrarily making the curve pass through one of the experimental points, the one corresponding to the largest value of x_0. The experimental points fitted the theoretical curve quite well except at small values of x_0 where it was evident that the close proximity of the detector was reducing the value of $[H]_0$ at the inlet. A small error in β_1 could be tolerated, for a sample calculation showed that a change in β_1 of 18% led to a change in k_4 of only 3%.

It was necessary also to consider the effect of an error in D. Values calculated from Amdur's work (8) were used previously (6) and have also been used in the present work. However, if Schulz and Le Roy had taken the value of D at, for example, 1 mm pressure as the quantity to be determined their results (6) would indicate that the accepted value may be low by about 13%. To examine the influence of a possible error in D on the present results we evaluated k_4 using values of D 20% larger than those used in Table I. The effect was to decrease the Arrhenius activation energy by 0.08 kcal $mole^{-1}$ and the A factor by 3%, changes which are within the standard deviations of the present results.

In using eq. [vi] it is assumed that the heat liberated on the detector arises exclusively from the combination of H atoms, i.e. that the number of D atoms reaching the detector is negligible, even though they are produced in reaction [4]. We believe that this assumption can be justified as follows. Since wall recombination is a small effect in this work (β_1 is small), most of the D atoms formed in (4) would either have to undergo reaction (3) or combine on the detector. For a given H-atom concentration the rate of [3] relative to that of [4] will increase as the ratio $[D_2]/[H_2]$ is lowered, so that the correct value of k_4 could be obtained by plotting the experimental values against % D_2 and extrapolating to 0%. In a series of tests in which the bridge method was used to evaluate W_H the values of k_4 at a particular temperature were found to be in the ratio 1:1.04:0.96 for deuterium percentages of 1.81, 1.30, and 0.79, respectively. This would indicate that for these low percentages of D_2 the error is negligible. Actually, in the experiments reported in Table I the percentages of D_2 used were less than 0.5% in all cases. These experiments

support the generally accepted, but as yet experimentally unconfirmed assumption (3) that k_3 is considerably greater than k_4 in the temperature range of the present work.

The final results are given in Table I and are shown in the form of an Arrhenius plot in Fig. 3. A least-squares treatment yielded the relation:

$$k_4 = 4.3_7 \times 10^{12} \exp(-7.3_0 \times 10^3/RT)\ cm^3\ mole^{-1}\ s^{-1}.$$

The standard deviation of E_a was 0.1 kcal $mole^{-1}$, that of $\log_{10} A$ was 0.05.

The results obtained in the present experiments are not *directly* comparable with any of the previous experimental values. The temperature range used in the present experiments is well below that used in the high-temperature measurements on the rate of $H_2 + D_2$ made by Farkas, by Boato *et al.*, and by van Meersche, and which have been discussed by Shavitt (3). It is probably quite justifiable to extrapolate our results down to 300 °K and up to 500 °K; it may be less justifiable to extrapolate our results to the range 600 – 1 000 °K as the Arrhenius activation energy may increase with temperature (3). However, in Table II we have shown our own rounded and extrapolated results

together with the other available experimental values and the calculated values of Shavitt (3). It should be realized that the latter are semi-empirical since Shavitt *assumed* a value of E_c, the classical activation energy without zero-point corrections (8.350 kcal $mole^{-1}$ in calculation I, 8.150 in calculation II). He had reason to believe that the imaginary force constant A_u used in calculation I (-7.32×10^4 dyn cm^{-1}) might be in error by as much as a factor of two, and in calculation II he used the value -3.58×10^4. Rapp and Weston (9) have pointed out that symmetry considerations require that Shavitt's values be multiplied by a factor of two.

In recent calculations on the H_3 system the values obtained for the potential energy barrier, e.g. 9.1 (4) and 9.7 kcal $mole^{-1}$ (10), have been closer to what one might guess the correct value to be than the value of 15.35 obtained by Boys and Shavitt (2). However, these values appear to be extremely sensitive to the triplet repulsions between the end atoms in the complex (10). In a recent interesting deviation from the usual statistical mechanical methods of deriving rate data from the properties of the activated complex, Karplus, Porter, and Sharma (11) have combined their interaction potential (4) with appropriate equations of motion to obtain reaction cross-sections as a function of the relative velocities of the reagents. An Arrhenius plot of the rate constants so obtained gave an activation energy of 7.49 kcal $mole^{-1}$, remarkably close to our value for reaction [4]. Their value of k_3 at 1 000 °K was greater than our extrapolated value of k_4 by a factor of 10.

KINETIC STUDIES OF THE AgO/Ag_2O ELECTRODE IN ALKALINE SOLUTIONS

R. G. BARRADAS AND G. H. FRASER[1]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received May 25, 1964

ABSTRACT

The anodic oxidation of Ag_2O to AgO in normal aqueous potassium hydroxide solution was investigated quantitatively under both galvanostatic and potentiostatic conditions at 25 °C. A few results for similar experiments in $N/40$ KOH are also reported. Tafel slopes and other parameters were determined. The experimental results show the dependence of current density as a hyperbolic function of overpotential, i.e. $i = 2i_0 \sinh(\lambda F\eta/2RT)$. The electron number λ was found to be 2 and the symmetry factor β was confirmed to be 1/2. It is proposed that the rate-determining step for the formation of AgO from Ag_2O occurs at the Ag_2O/AgO interface and involves the transfer of O^{-2} ions.

INTRODUCTION

Studies of anodic polarization of silver in aqueous alkaline solutions were extensively examined for many years and comprehensive reviews of this field have been carried out (1, 2). One of the most significant early works was that of Luther and Pokorny (3), who reported the conditions for formation of argentous and argentic oxides (Ag_2O and AgO respectively) when the silver electrode was polarized in normal sodium hydroxide solutions.

The increasing utility and importance of the silver–silver oxide electrodes in lightweight alkaline storage batteries capable of high discharge rates have been a strong incentive for considerable fundamental research activity (4–9). Despite the proliferation in the published literature, there appears to be disagreement concerning the actual thermodynamic and experimental values of potential for the AgO/Ag_2O and Ag_2O/Ag couples. In addition, considerable confusion exists about the kinetics of the reactions taking place on these electrodes. The anodic charging curve indicates that Ag_2O formation ceases in an abrupt manner in the transition region to the higher valent AgO. There does not appear to be any consistent explanation for this phenomenon. Furthermore, there is no agreement about whether the oxidation of silver proceeds via the penetration of the silver lattice by oxide ions (10) or by silver migrating through the oxide layer (11, 12).

The contradictory circumstances are not surprising in view of the inherent complexity of the system and of its associated experimental difficulties. Surface conditions of the electrode must be reproducible in order to obtain reliable current–potential relations, since it is well established that overpotential measurements vary with time as a result of changing surface characteristics.

Hitherto, the mechanisms proposed for the overall reactions,

$$[1] \qquad 2Ag + 2OH^- = Ag_2O + H_2O + 2e$$

$$[2] \qquad Ag_2O + 2OH^- = 2AgO + H_2O + 2e,$$

for the silver–silver oxide electrodes have been somewhat qualitative and speculative in nature owing in part to an absence of reliable kinetic data for diagnostic interpretations.

EXPERIMENTAL

(a) Electrode Preparation

The anode and reference electrodes were constructed from commercially available silver plate (99.99% Ag and 0.03 in. supplied by Johnson, Matthey and Mallory, Ltd.). The silver was cleaned by washing in dilute nitric acid followed by distilled water. It was then subjected to either (i) mechanical polishing by successively finer grades of emery paper (final grade of 4/0), washed with acetone, and lastly with copious amounts of conductivity water or (ii) to electropolishing based on a modified* cyclic technique (13, 14) in a conventional cyanide bath, followed by repeated washing with liberal amounts of conductivity water. The latter method of polishing silver is slightly more satisfactory but there does not appear to be any significant difference on the course of experimental results obtained for the AgO/Ag_2O electrode. It may be possible, however, that polarization and kinetic studies of the Ag_2O/Ag electrode could depend more critically on the initial surface properties of the silver metal.

The counter and reference electrodes were composed of the Ag_2O/Ag couple and constructed in the same manner, but their thermodynamic properties were remarkably stable. Silver plate of suitable size was anodized at 1 mA/cm^2 until the potential began to rise from the first plateau in the oxidation curve. The electrode was partially reduced and then reoxidized. This procedure was repeated three times and resulted in a stable and satisfactory reference electrode. The potential of the Ag_2O/Ag reference electrode measured against a standard HgO/Hg couple was found to be 0.245 ± 0.002 V, which compares favorably with the value of 0.244 ± 0.005 V reported by Janz and Ives (15). Our experimental value corresponds to 0.343 ± 0.002 V, when calculated with respect to a standard hydrogen electrode as reported by other workers (16, 17, 18).

(b) Reagents and Solutions

The electrolyte was 1 *M* aqueous potassium hydroxide, and this solution was ascertained analytically in every run to contain less than 0.013 molar quantities of potassium carbonate. For some runs the electrolyte was diluted fortyfold. Conductivity water (1.0×10^{-6} mho/cm) was used throughout all the experiments and it was prepared by passing distilled water through an Illco-way research model deionizer or by redistillation in a tin-lined Barnstead Redistiller Model E.P.R. 1/2. The electropolishing bath contained 35 g silver cyanide, 37 g potassium cyanide, and 38 g potassium carbonate per liter.

(c) Electrolytic Cell

Standard two-compartment cells were used for all the experiments. These were constructed from pyrex glass and were capped with closed ground glass joints which had appropriate openings through the top for the insertion of the anode, cathode, and pre-electrolysis electrodes. The reference electrode was used in conjunction with a Luggin capillary probe. The ground glass joints were employed with close-fitting plastic sleeves and partly insulated with silicone grease to prevent "freezing" of the joints.

(d) Electrical Measurements

The galvanostatic and potentiostatic measurements were carried out at room temperature and corrected to 25 °C on a simple apparatus constructed in our laboratory, comprised of an electromechanical potentiostat and a constant current source. Details of this instrument will be published elsewhere.

(i) Galvanostatic Measurements

The anode was oxidized at a chosen constant current and after a predetermined amount of charge had passed, the driving applied potential was decreased. The new constant current was noted and the corresponding change in electrode potentials recorded. The potentials were recorded at each different constant current for periods of approximately 5 to 15 s. More rapid changes of constant current would lead to undesired voltage transients. On the other hand, any excessive polarization times would result in drastic changes of electrode surface conditions, giving kinetic data which would be almost impossible to resolve. The choice of intermediate time intervals of approximately 10 s duration tends to give reproducible Tafel behavior within reasonable limits of experimental error. On this basis one could assume that surface conditions of the electrode are moderately stable.

(ii) Potentiostatic Measurements

The electrode was polarized at several constant potentials for a few minutes at a time and the corresponding currents were determined. The polarization times were much longer than those used in the

**The cyclic technique means the attainment of oscillatory fluctuations in current during the electrolytic polishing process. Successful electropolishing depends on many factors, such as the composition of the bath, electrolytic cell geometry, history of the electrode, temperature, electrode separation and configuration, amount of applied current, cell voltage, and rate of stirring of the electrolyte. Quantitative changes of these and other parameters affect the nature of the finished surface. The cycling phenomenon results from repeated formation and destruction of the oxide films. Bright and smooth surfaces depend primarily on the achievement of cycling and at a rate of approximately 5–10 cycles per second under d-c. electrolysis. We have observed that the superimposition of an a-c. on the d-c. signal did not appreciably increase the rate of cycling, but it has led in several instances to an improved polish when viewed under a microscope. Further work in this area is presently being carried out and will be reported in detail elsewhere.*

galvanostatic studies reported above, but at considerably lower apparent current densities, which does not alter the surface conditions significantly.

RESULTS

(i) Galvanostatic Runs

Potential measurements were obtained at constant currents and plotted in a conventional Tafel manner (see Fig. 1). Average Tafel slopes ($2.3\ RT/\lambda\beta F$) for sets of runs

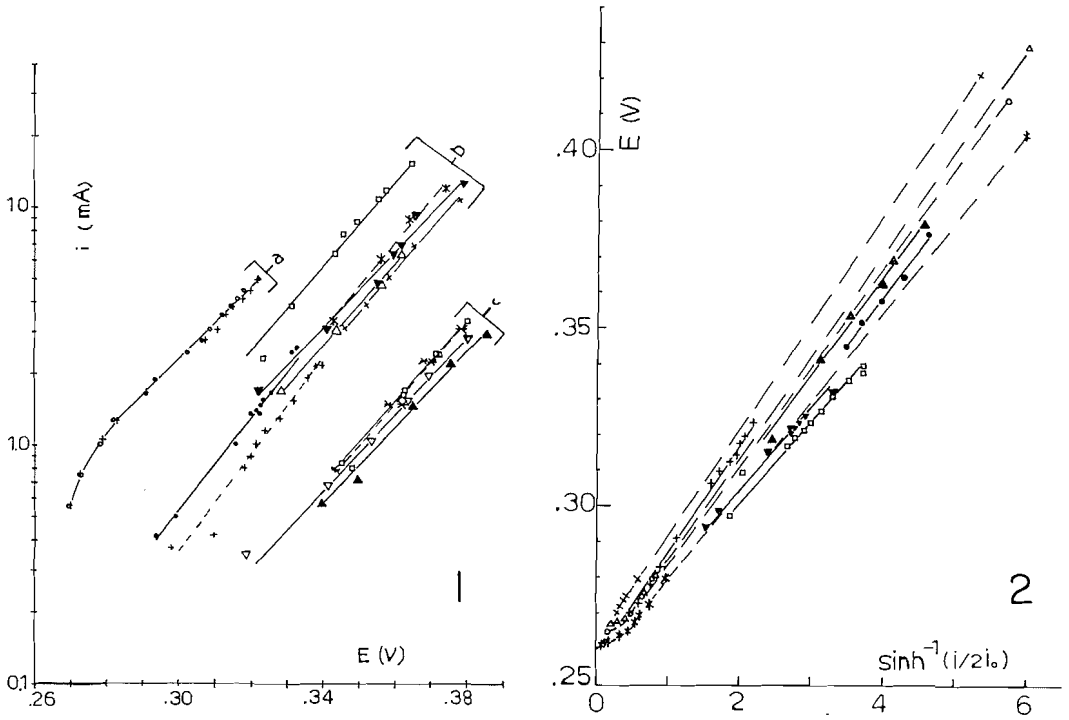

FIG. 1. Tafel plots for galvanostatic runs. Set *a*: two runs with mechanically polished electrodes in 1 *N* KOH. Set *b*: seven runs with electropolished electrodes in 1 *N* KOH. Set *c*: four runs with electropolished electrodes in *N*/40 KOH.

FIG. 2. Typical dependence of potential as hyperbolic function of current. Broken lines, potentiostatic data; solid lines, galvanostatic data.

marked *a*, *b*, and *c* were 0.0658 ± 0.0002, 0.0567 ± 0.0032, and 0.0595 ± 0.0007 respectively. They lead to respective calculated values of 0.90, 1.04 ± 0.06, and 0.99 ± 0.01 for the product $\lambda\beta$; λ, the stoichiometric number, is a small integer indicating the amount of charged passed in the rate-determining step and β is the usual symmetry factor. It is evident that if β is assumed to be 1/2 then we would obtain a value of approximately 2 for λ. For convenience the detailed information relating to Fig. 1 is summarized in Table I. Better reproducibility of potential measurements was obtained in the dilute electrolyte (*N*/40).

(ii) Potentiostatic Runs

In the low overpotential region (below 0.280 V) linear relations between current and potential have been obtained under potentiostatic conditions for mechanically polished electrodes. From these linear plots we have obtained values of $i_0\lambda$, according to the following equation:

$$i = i_0\lambda(F\eta/RT). \qquad [3]$$

DISCUSSION

The general equation for an activation-controlled anodic process can be written as

$$i = i_0 \exp(\beta\lambda F\eta/RT) - i_0 \exp[-(1-\beta)\lambda F\eta/RT]. \quad [4]$$

If the symmetry factor is equal to 1/2, one could write (19, 20)

$$i = 2i_0 \sinh(\lambda F\eta/2RT). \quad [5]$$

At high overpotentials eq. [4] reduces to the familiar Tafel relation

$$\eta = a + b \ln i. \quad 6]$$

However, at low overpotentials eq. [4] reduces to eq. [3], namely

$$i = i_0\lambda F\eta/RT. \quad [3]$$

Equation [5] can be written in the following form:

$$E/b = \sinh^{-1}(i/2i_0) + E_R/b, \quad [7]$$

where $E = \eta + E_R$ (E_R is the reversible potential of the AgO/Ag$_2$O couple) and

$$b = RT/\lambda F\beta \text{ or } 2RT/\lambda F. \quad [8]$$

From the Tafel plots (Fig. 1) for the galvanostatic results, i_0 values were obtained for each run by extrapolating the E vs. log i plot to the reversible potential of AgO/Ag$_2$O. Using these i_0 values in eq. [7] we obtain "b" values for the sets of runs a, b, and c of 0.0302 ± 0.0001, 0.0230 ± 0.0005, and 0.0262 ± 0.0002 respectively (listed in Table II), which are consistent with those derived from eq. [6] of 0.0286 ± 0.0001, 0.0246 ± 0.0014, and 0.0258 ± 0.0002. This treatment of the galvanostatic results was done to make comparison with the type of results obtained in the potentiostatic runs at lower fields. The overall results imply that the slope "b" remains relatively unchanged over the entire

*The observed reversible potential of the AgO/Ag$_2$O electrode vs. the Ag$_2$O/Ag electrode is in agreement with the value of 0.262 V reported by Bonk and Garrett (21).

range of overpotentials studied and also that the assumption of $\beta = 1/2$ is reasonably correct, otherwise eq. [7] would not be valid.

In the potentiostatic runs reported above, potential and current were in general linearly related but deviations were observed at very low overpotentials. The deviations from linearity may be due to either new kinetic processes or changes in surface conditions owing to the extended time of polarization. The latter explanation seems more acceptable when one considers that the potentials were decreased by manual control over a long period of time. One also notices that on reversing the procedure of measurement, i.e. from lower to higher potentials, somewhat smaller currents were observed. This gives in part some substance to the speculation that surface conditions may change, which may account for the variations in exchange currents experienced from run to run.

Since we have derived values of λi_0 from the potentiostatic runs, we can now choose suitable integral values of λ to calculate i_0. The computed values of i_0 were used to replot the results of each respective potentiostatic run according to eq. [7] (see Fig. 2). A hyperbolic relation between current and potential at conditions of low overpotentials (ca. 20 mV) is in itself not entirely significant, since eq. [7] readily reduces to eq. [3]. However, we have made corresponding measurements (i.e. within closely related time intervals and therefore similar electrode conditions) under galvanostatic control at considerably higher overpotentials (in excess of 140 mV). The latter results are linearly aligned with the plots obtained from eq. [7] at low overpotentials (see Fig. 2).

To derive "b" values from the potentiostatic data we had to make arbitrary choices for λ. The values of "b" were found to be relatively insensitive to choices of λ, e.g. when λ was changed from 2 to 4, the average value of "b" was decreased by only 8%. The choice of $\lambda = 2$ is justified from the observed slope of eq. [7].

The values of "b" and the corresponding values of $\lambda\beta$ for both galvanostatic and potentiostatic runs are summarized in Table II. Fairly good agreement within the limits of experimental error is reported. All the results are consistent with the conclusion that $\lambda = 2$ and $\beta = 1/2$, and hence the experimental Tafel slope for the formation of AgO from Ag_2O is $2.3RT/F$.

Recent stereochemical neutron diffraction studies (22) have confirmed that there are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

two types of silver atoms in the AgO unit cell with bond lengths corresponding to the covalent bonding properties of $Ag^+(4\ d^{10})$ and $Ag^{3+}(4\ d^8)$. The two types of silver contained in the lattice explain the diamagnetic properties of AgO and exclude the presence in the lattice of $Ag^{2+}(4\ d^9)$. Hence one can write $2\ AgO \equiv Ag(I) - Ag(III)O_2$ and conversely one could write $Ag_2O \equiv Ag(I)_2O$.

We may consider the possibilities of a rate-determining reaction occurring at any of the three interfaces, i.e. the metal/Ag_2O, Ag_2O/AgO, and AgO/electrolyte (see Fig. 3). It

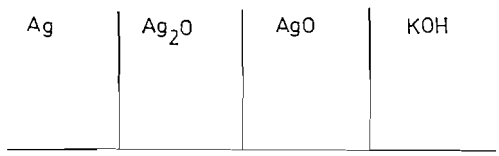

FIG. 3. Interfacial regions of the silver/silver oxide electrode in aqueous alkaline solution.

would be reasonable to eliminate reactions at the metal/Ag_2O interface, since only electron transfer could occur at this junction. For the other two interfaces one can propose mechanisms of the following type which would be consistent with the structural evidence cited above.

At the oxide/electrolyte interface we may write

[9] $$(OH^-)_{aq} = (OH^-)_s$$

followed by either [10], [11], or [12]

[10] $$(OH^-)_s + (OH^-)_{aq} = H_2O + (O^{-2})_s$$

[11] $$2(OH^-)_s = H_2O + (O^{-2})_s$$

[12] $$\begin{cases} (OH^-)_s = (H^+)_{aq} + (O^{-2})_s \\ \text{and} \\ (H^+)_{aq} + (OH^-)_{aq} = H_2O. \end{cases}$$

Reaction [12] represents a disproportionation of the adsorbed hydroxyl ion. The subscripts "s" and "aq" refer to the solid surface and the aqueous phases respectively.

At the Ag_2O/AgO interface we postulate the following reaction:

[13] $$Ag^+ = Ag^{3+} + 2e.$$

For reaction [13] we can write the following equations. For $\beta = 1/2$,

[14] $$v_1 = k_1[Ag^+] \exp(2\beta\eta F/RT) = k_1' \exp(\eta F/RT)$$

[15] $$v_{-1} = k_{-1}[Ag^{3+}] \exp(-2(1-\beta)\eta F/RT) = k_{-1}' \exp(-\eta F/RT);$$

$[Ag^+]$ and $[Ag^{3+}]$ may be assumed to be constant since both are solid-state concentration terms.

When $\eta = 0$,

[16] $$i_0 = i_1 = 2Fk_1[Ag^+] = i_{-1} = 2Fk_{-1}[Ag^{3+}].$$

From [14], [15], and [16] we obtain

[17] $$i = i_1 - i_{-1} = 2i_0 \sinh(\eta F/RT).$$

Hence $b = RT/F$.

We suggest that the rate-determining step may be given by eq. [13] and that the actual

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

mechanism of formation of AgO from Ag_2O involves [13] in conjunction with [9] and either [10], [11], or [12]. In essence we propose that O^{-2} ions can migrate by ionic conduction through the AgO layer to the mixed oxide interface where the slow step may take place. The migration process cannot be a rate-controlling step since there has been no dependence of the observed Tafel slope on the extent of conversion of Ag_2O to AgO, i.e. on the thickness of the AgO film. The two electrons shown in [13] may be presumed to enter the Ag_2O layer. Since Ag_2O has been suggested as a metal-deficit oxide (cf. Cu_2O) with cation vacancies (i.e. a p-type semiconductor (23)), the electrons may be expected to fill positive holes. Creation of new positive holes in the Ag_2O layer may occur by charge transfer across the Ag/Ag_2O interface.

There is also the possibility that the rate-controlling step could be the transfer of O^{-2} ions across the Ag_2O/AgO interface. If we consider that O^{-2} ions move over a symmetrical energy barrier, we would obtain a set of results comparable to that derived from [14], [15], and [16], namely forward and reverse slopes of RT/F and $-RT/F$ respectively. This mechanism, although equivalent in result to [13], is somewhat more attractive because there is no certainty that reaction [13] should lead to a one-step 2-electron liberation. One can allow for the possibility of two 1-electron steps. Furthermore, it is a simpler physical picture to visualize a mechanism involving the transfer of O^{-2}, followed by the coalescence of 2 p-holes and one Ag^+ ion in the Ag_2O layer to form the Ag^{3+} species.

Our theoretical analysis leads to results in good agreement with experimental evidence. This supports our contention that the rate-determining step for the formation of AgO from Ag_2O is probably the reaction involving the transfer of O^{-2} ions, which occurs at the mixed oxide interface. The small deviations in galvanostatic and potentiostatic measurements mentioned earlier in the experimental section may be adduced as additional evidence that this statement is correct. The Ag/Ag_2O and the AgO/electrolyte interfaces can conceivably be fairly stable in surface conditions. However, the suggested fluctuations of surface conditions referred to previously must be due to internal disruptions which originate at the Ag_2O/AgO interface. This must result in a departure from the idealized smooth "sandwich layers" of the two oxides as depicted in Fig. 3.

We have examined various other mechanisms involving the adsorption of *ionic* intermediates at the AgO/electrolyte interface and calculated the Tafel slopes using modifications of the theories proposed by Conway and his co-workers (24, 25). These predicted slopes were not in agreement with our experimental results for the silver oxide electrode. Our modified calculations and reaction schemes, showing dependence on Langmuir and Temkin conditions of surface coverage, which may be applicable to semiconductor oxide/solution interfaces other than AgO, will be presented in a future communication (26).

ACKNOWLEDGMENTS

The authors are indebted to the late Professor F. E. W. Wetmore, who initiated this project. Some experimental aspects described here are contained in an M.A. thesis by one of us (G. H. F.), who worked under his direction. After his untimely death in January 1963 the authors continued the work which led to the eventual conclusions reported in this paper. We are grateful to Professor M. J. Dignam for reading the manuscript and offering helpful discussions, and also to Mr. R. E. Barry for his assistance with the galvanostatic experiments performed on the mechanically polished electrodes. We wish to thank the National Research Council of Canada and the University of Toronto for generous financial support.

CHARACTERISTIC VIBRATIONAL FREQUENCIES OF COMPOUNDS CONTAINING Si—O—Si, P—O—P, S—O—S, AND Cl—O—Cl BRIDGING GROUPS

FORCE CONSTANTS AND BOND ORDERS FOR THE BRIDGE BONDS

R. J. GILLESPIE
Department of Chemistry, McMaster University, Hamilton, Ontario
AND
E. A. ROBINSON
Department of Chemistry, University of Toronto, Toronto, Ontario

Received May 22, 1964

ABSTRACT

The assignment of characteristic frequencies for the X—O—X group in compounds containing Si—O—Si, P—O—P, S—O—S, and Cl—O—Cl bonds is discussed with reference to the vibrational spectra of disiloxanes, diphosphoryl, and disulphuryl compounds and dichlorine heptoxide. The stretching force constants of the X—O—X bridging bonds have been obtained by treating the molecules as simple triatomic species X_2O. X—O bond orders and bond lengths have been calculated from the stretching force constants and the calculated and observed bond lengths are compared. The variation in the observed X—O—X angles is related to the bond orders and is discussed in terms of the electron-pair repulsion theory. It is shown that bond orders in the isoelectronic series $Si_2O_7^{6-}$, $P_2O_7^{4-}$, $S_2O_7^{2-}$, and Cl_2O_7 may be simply deduced from the empirical rule that the valency shell of a second-row element tends to be occupied by twelve electrons (the duodecet rule).

INTRODUCTION

We have recently proposed assignments for the characteristic vibrational frequencies of the S—O—S group in molecules such as the disulphuryl halides and SF_5OSF_5 (1). In this paper we discuss the characteristic vibrational frequencies of compounds containing the Si—O—Si group (e.g. the disiloxanes), the P—O—P group (e.g. diphosphoryl compounds), and the Cl—O—Cl group. From the frequencies and calculated force constants, information is obtained concerning the nature of Si—O—Si, P—O—P, S—O—S, and Cl—O—Cl bonds.

RESULTS

Compounds Containing the Si—O—Si Group

The occurrence of the asymmetric Si—O—Si stretch, ν_a, at approximately 1 050 cm^{-1} is well recognized and has been used previously as a diagnostic frequency for compounds containing Si—O—Si bonds (2), but the occurrence of the symmetric stretching frequency, ν_s, in the region 400–600 cm^{-1} has only recently been firmly established by Kriegsmann (3, 4, 5) although it had been recognized earlier by Lord and co-workers (6) as having frequencies of 606 and 555 cm^{-1} in the vibrational spectra of disiloxane and disiloxane-d_6 respectively. Table I shows the Si—O—Si frequencies (ν_s, ν_a, and ν_b, the bending mode) for a number of disiloxanes. Some of the data are taken from the work of Kriegsmann (3, 4, 5); in other cases we have reassigned the spectra observed by other workers. Lord and co-workers (6) find a frequency of 68 cm^{-1} for the bending vibrations of $[H_3Si]_2O$ and $[D_3Si]_2O$. They suggest that the Si—O—Si group is quasi-linear because of the large value of the Si—O—Si bond angle and that the Si—O—Si bending vibration may be highly anharmonic. For this particular molecule, therefore, the simple valence – force field

type of calculation of force constants is probably unreliable. Nevertheless we find that, in general, force constants obtained in this way are consistent with observed bond lengths. We have arbitrarily assigned ν_b, in compounds where no complete vibrational assignment is available, as the lowest frequency observable in the Raman spectrum. In the light of the results of Lord and co-workers (6) these arbitrarily assigned frequencies may all be too high, but we show later that this could give only a small error in the calculated values of the stretching force constants.

It is interesting to note that there appears to be a linear correlation between ν_s and $M^{\frac{1}{2}}$, where M is the mass of the group attached to silicon, as has been observed previously for the SOS group (Fig. 1). In this connection it is useful to examine the nature of $\nu_s(\nu_1)$ and

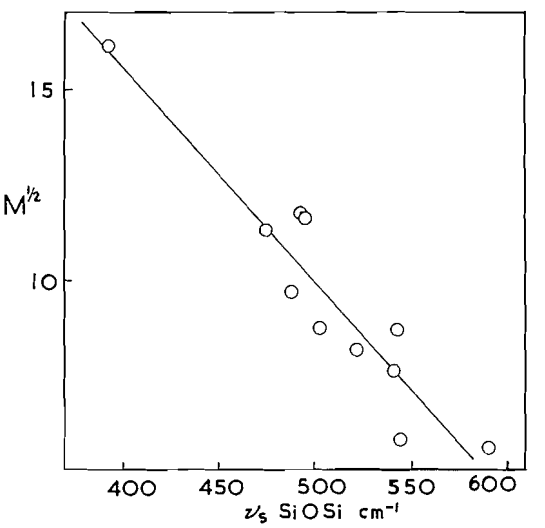

FIG. 1. Correlation between $\nu_{Si-O-Si}$ (sym.) and $M^{\frac{1}{2}}$.

$\nu_a(\nu_3)$ in a simple triatomic molecule YX_2. We assume that we can regard the compounds under discussion as triatomic molecules OX_2 where X is a group with a relatively large mass compared to that of oxygen. Herzberg (7) gives the vibrational frequencies and amplitudes of vibration for H_2O, F_2O, and Cl_2O, and as the mass of X becomes greater the asymmetric stretch (ν_3) can be reasonably described as a vibration in which only the oxygen atom moves. This is consistent with the observation that ν_a, in e.g. compounds containing the Si—O—Si group, occurs at a relatively constant frequency which is determined mainly by the character of the Si—O bonds and not by the mass of the group X. However, as the mass of X increases the symmetric stretch (ν_1) which in the case of H_2O involves essentially the motion of the H atoms only and has a frequency close to that of the asymmetric stretch, takes on much of the character of a bend involving movement of both the heavy X groups and the oxygen atom. It thus seems reasonable that the symmetric stretch becomes widely separated from the asymmetric stretch, and occurs at a much lower frequency as the mass of X increases.

Compounds Containing the P—O—P Group

Unfortunately there has been much less accurate work on compounds containing a P—O—P bridging group than on Si—O—Si or S—O—S compounds. The P—O—P asymmetric stretch is relatively well established at approximately 950 cm^{-1} (2, 8), but the frequencies of the P—O—P symmetric stretch and bend are less well known. Table II shows collected values of ν_s and ν_a for most of the diphosphoryl compounds that have been investigated. The only Raman or low-frequency infrared measurements that are available are those for the pyrophosphate ion (9, 10), the dihydrogen pyrophosphate ion (10), diphosphoryl tetrachloride (11, 12), and diphosphoryl tetrafluoride (13).

Compounds Containing the S—O—S Group

Assignments of the characteristic frequencies of the S—O—S bridging group have been discussed previously and are shown in Table III (1). Recently Walrafen, Irish, and Young (14) have discussed the vibrational spectra of S_2O_7 groups in the $S_2O_7^{2-}$ and $HS_2O_7^-$ ions and $H_2S_2O_7$. Without giving any detailed justification, they assign the symmetric stretching vibration of the S—O—S group of $S_2O_7^{2-}$, $HS_2O_7^-$, and $H_2S_2O_7$ at 730–738, 702–735, and 732–735 cm^{-1}, respectively and the asymmetric stretching vibrations at 790, 799, and 805–806 cm^{-1}, respectively. They assign the bending vibrations at 320–335, 316–325, and 325–326 cm^{-1}, respectively.

These assignments are in line with those of earlier workers, which we criticized previously (1).

Compounds Containing the Cl—O—Cl Group

The only known compound, apart from triatomic Cl_2O, which contains a Cl—O—Cl bridge is dichlorine heptoxide, Cl_2O_7. The vibrational spectrum has been investigated by Fonteyne (15) and recently by Savoie and Giguère (16). The latter authors assign lines in their spectra at 695, 429, and 280 cm^{-1} to ν_a, ν_s, and ν_b, respectively. They report all three lines to be polarized in the Raman spectrum. Although the line appears to be polarized in the Raman spectrum, the frequency of 695 cm^{-1} seems appropriate for the asymmetric stretch; moreover, there is no other line in the reported spectrum which could be reasonably assigned to this vibrational mode. In the light of the previous discussion of the characteristic frequencies of Si—O—Si, P—O—P, and S—O—S bonds a frequency of 429 cm^{-1} seems too high for ν_s in Cl_2O_7. The values of ν_a for Si—O—Si, P—O—P, S—O—S, and Cl—O—Cl bonds are approximately 1 050, 950, 800, and 695 cm^{-1}, respectively, and we have assigned

the symmetric stretches at approximately 500, 450, and 325 cm^{-1} for Si—O—Si, P—O—P, and S—O—S bonds, respectively. Thus the polarized line in the Raman spectrum of Cl_2O_7 at 280 cm^{-1} would seem more appropriate for the symmetric Cl—O—Cl stretching frequency since it fits an apparent trend in the values of ν_s for Si—O—Si, P—O—P, S—O—S, and Cl—O—Cl bonds which is similar to that for the asymmetric stretching frequency. No lines were reported in this spectrum below 280 cm^{-1} and it is likely that the bending mode occurs at a frequency below the limit of Savoie and Giguère's measurement.

DISCUSSION

We previously calculated (1) the stretching force constant k_{SO} and the bending force constant d_{SO} for the S—O—S bridge bonds in polysulphuryl compounds by treating the molecules as simple triatomic species X_2O and using a simple valency force field. The same method of calculation is used here for the force constants k and d of Si—O, P—O, and Cl—O bridge bonds. In these calculations the mass of the group X attached to the bridging oxygen atom has been used without modification. We have previously shown (1) that modification of the mass X, as e.g. Goubeau has suggested (17), makes very little difference to the value obtained for the force constant. Values for the stretching and bending force constants, k_1 and d, are given in Table IV. In the case of compounds containing Si—O—Si

*Calculated from force constants.
†The values in parenthesis have been calculated assuming $\nu_b = 0$.

bonds, values of the stretching force constant k_1 have been calculated from the vibrational frequencies given in Table I and also from the values of the symmetric and asymmetric stretches given in that table, assuming that the bending vibration has a very low frequency (approaching zero for relatively heavy groups X) as Lord and co-workers have suggested. Both sets of calculations give very comparable values and so it appears that even if the values of ν_b are unreliable the stretching force constants are close to the correct values.

We have recently obtained linear correlations between bond orders and stretching force constants of Si—O, P—O, S—O, and Cl—O bonds and also relations between their bond orders and bond lengths (18, 19). It is thus possible to calculate both the bond orders and bond lengths for the bridge bonds from the force constants, as is shown in Table IV. Experimental data for bond lengths are available for only a few species; these are also given in Table IV. The agreement between the observed and calculated values is reasonably good. Bond orders calculated from the observed bond lengths for these species and

§Calculated from bond lengths.

for species containing X—O—X bridges in longer chains and rings are given in Table V. In each case the bond orders are greater than unity, confirming earlier suggestions (4, 20–23) that these bridge bonds have a certain amount of double-bond character and we see that the bond order increases in the series Cl—O—Cl, S—O—S, P—O—P, Si—O—Si. The general increase in the bond angle in this series indicates an increasing repulsion between the bonds and this is consistent with the increasing bond order.

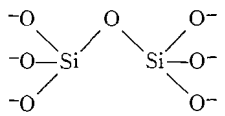
Kriegsmann (4) gives values of $k_{Si-O} = 4.65 \times 10^5$ and $d_{Si-O} = 0.10 \times 10^5$ dyn cm^{-1} for the bridge bonds in hexamethyl disiloxane for which he estimates an Si—O bond order of approximately 1.25. An Si—O bond order of this magnitude would imply an Si—O bond length of about 1.72 Å, whereas the observed distance is 1.63 Å (Table V). The present treatment leads to a much greater bond order of 1.6, which is consistent with the observed bond length.

Cruickshank (21) has attributed the increasing bond angles in the series Cl—O—Cl, S—O—S, P—O—P, Si—O—Si to the increasing electrostatic repulsion between the two ends of the molecules and he considers that the amount of double-bond character is determined by the angle. Although this explanation could conceivably be correct in the series $Si_2O_7^{6-}$, $P_2O_7^{4-}$, $S_2O_7^{2-}$, and Cl_2O_7, it should be noted that very large bond angles are also found in uncharged molecules, such as $[(CH_3)_3Si]_2O$ and $[(CH_3)_2SiO]_4$, and electrostatic repulsion between the groups at the ends of the oxygen bridge hardly seems feasible in such cases. Our view is that there is delocalization of electrons onto the atom of the second-row element from the bridging oxygen atom. This occurs because there is space

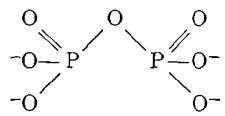
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(orbitals) available around the atom of the second-row element to accommodate the electrons which are delocalized because of strong repulsions between the electron pairs in the filled shell of oxygen (22). We consider that the resultant double bonding and the large repulsions between the double bonds leads to the large X—O—X bond angle rather than the double bonding being the consequence of a large bond angle caused by electrostatic repulsion between the ends of the molecule. For the isoelectronic series $Si_2O_7^{6-}$, $P_2O_7^{4-}$, $S_2O_7^{2-}$, and Cl_2O_7 the decreasing tendency of oxygen to delocalize its lone electron pairs into vacant orbitals on the adjacent second-row element (22) can perhaps be understood in the following manner.

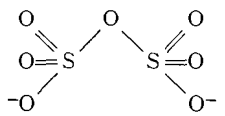
If possible double bonding by the bridging oxygen is first ignored and if it is assumed that the most stable valence-bond structure will be that which has a minimum number of formal charges and in which any formal negative charges are localized on the most electronegative (oxygen) atoms, I, II, III, and IV will be the most stable structures:



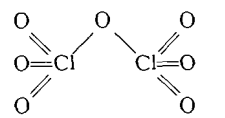
I



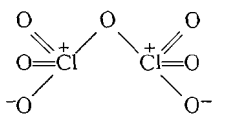
II



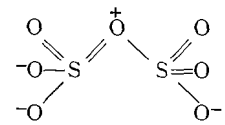
III



IV



V



VI

If we also use a very useful empirical rule (the duodecet rule) (19), namely, that there is a tendency for the valency shell of a second-row element to contain twelve electrons (i.e. six pairs), which has been previously shown (18, 19) to be a realistic basis for describing the bonding in species such as e.g. SiO_4^{4-}, PO_4^{3-}, SO_4^{2-}, and ClO_4^-, and other molecules and ions containing highly electronegative ligands attached to Si, P, S, or Cl, then V rather than IV is a better representation of the bonding in Cl_2O_7. If the duodecet rule holds for all these compounds, there will be little tendency for delocalization of unshared electron pairs from the oxygen bridge atom into vacant orbitals on the second-row atom for Cl_2O_7 and $S_2O_7^{2-}$, but there will be an increasing tendency for this to occur in passing to $P_2O_7^{4-}$ and $Si_2O_7^{6-}$, because in II and I there are, respectively, only five and four electron pairs in the valency shell of the second-row atom. Because structures such as VI are expected to make a small contribution, some delocalization of the bridge oxygen lone pairs is to be expected even in the case of $S_2O_7^{2-}$ and the amount of double bonding by the bridging oxygen atom would therefore be expected to increase in the order Cl—O—Cl, S—O—S, P—O—P, Si—O—Si.

The sum of the experimental bond orders for the bonds formed by the second-row element in $Si_2O_7^{6-}$, $P_2O_7^{4-}$, $S_2O_7^{2-}$, and Cl_2O_7, as shown in Table VI, confirms the validity of the application of the duodecet rule in these cases. This rule also works well for species such as $(SiO_3^{2-})_n$, $(SiO_2)_n$(α-quartz), P_4O_{10}, $P_4O_{12}^{4-}$, $(P_2O_5)_\infty$, $(PO_3^-)_\infty$, $P_3O_{10}^{5-}$, $HS_2O_7^-$, $(SO_3)_n$, S_3O_9, and $S_3O_{10}^{2-}$ (Table VI), although the evidence comes from bond lengths alone, since the evaluation of force constants is not easily accomplished in these cases.

THE PRESENCE OF EXCITED MOLECULES IN ACTIVE NITROGEN[1]

H. B. DUNFORD, E. R. V. MILTON,[2] AND D. L. WHALEN
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 17, 1964

ABSTRACT

Spectra of active nitrogen have been photographed under conditions comparable to those used for most studies of reactions of active nitrogen with other molecules. Bands observed were identified as the first positive system of nitrogen and the β- and γ-bands of nitric oxide. No trace of Vegard–Kaplan emission was observed. The 2 537 line of mercury was detected under certain conditions.

The results are used to rationalize the large discrepancy which exists between estimates of the lifetime of $N_2(A^3\sum_u^+)$ by optical spectroscopy and reaction kinetics. In the former method, the measurements are performed in an oxygen-free system and are clearly related to a radiative lifetime. In the latter method, the measurements are performed in the presence of traces of oxygen and are believed to indicate a collisional lifetime. The reaction kinetic measurements are shown to be in complete agreement, both with regard to decay kinetics and lifetime, with electron spin resonance measurements on active nitrogen produced under near-identical conditions.

INTRODUCTION

Recent reviews have all agreed that the major reactive component in active nitrogen is $N(^4S)$ ground-state atoms (1–3). However, the possible concentrations of other species capable of causing chemical reaction remains a topic of controversy. In 1956, Evans and Winkler (1) postulated that $A^3\sum_u^+$ nitrogen molecules were spilling into highly excited metastable vibrational levels of the electronic ground-state, $X^1\sum_g^+$. It has since been shown that vibrationally excited nitrogen is indeed present, but only excited to the first vibrational level of the ground state, and this only in active nitrogen produced in a microwave discharge (4–7). A condensed discharge produces negligible concentrations of vibrationally excited ground-state nitrogen* (8, 9). Thus with both types of discharge, appreciable chemical reactions of highly vibrationally excited ground-state nitrogen appear to be ruled out.

Since 1956 Lichten's molecular-beam work (11) combined with the absorption spectroscopy experiments of Wilkinson and Mulliken (12) indicated that the lifetime of $A^3\sum_u^+$ molecules was 0.026 s. Oldenberg, Bills, and Carleton (13) actually detected the $B^3\pi_g \leftarrow A^3\sum_u^+$ system (first positive bands or Lewis–Rayleigh afterglow) in absorption in a discharge through nitrogen, a feat which had eluded many other competent spectroscopists. This provided the most direct proof that $A^3\sum_u^+$ molecules are present in detectable amounts in discharged nitrogen. Their work was extended to deduce that the radiative lifetime of the $A^3\sum_u^+$ state is 2 s for the $v = 0$ level (14, 15).

It seems well established that nitrogen atoms do not react with ammonia (16–19) and it has been suggested that the destruction of ammonia observed with active nitrogen produced in a condensed discharge is due to reaction with triplet A-state molecules (20, 21). In two recent studies an attempt was made to elucidate the kinetics of $A^3\sum_u^+$ molecule formation and decay from the reaction of active nitrogen with ammonia (8, 22). In the earlier work, by Wright, Nelson, and Winkler, it was assumed that $d[N_2^*]/dt = \frac{1}{2}ak_2[N]^2P$

[1]*Presented at the 47th Canadian Chemical Conference, Kingston, Ontario, June, 1964.*

**Excitation by low-energy electrons through transient negative-ion formation (10), which would be favored in the microwave discharge, seems a likely explanation of these observations.*

$+ \frac{1}{2}bk_1[N] - k_3[N_2^*]$, where N_2^* represents $N_2(A^3\sum_u^+)$. The first term on the right represents formation of N_2^* by homogeneous atom combination, the second by heterogeneous combination, and the third term, decay of N_2^*. If it was assumed that $a = b = 1$, in other words that N_2^* is formed from all atom combinations, then a half-life of 0.08 s for N_2^* was obtained. If it was assumed that $a = 1$, $b = 0$, then a half-life of 0.07 s resulted. The assignment of unity to either a or b appears questionable. Recent theoretical work (23) indicates that atoms prefer to combine into the electronic ground-state of a molecule. The above equation is also incompatible with the plateaus observed in ammonia destruction in the presence of atomic nitrogen. If the equation were valid, then the plateau in ammonia destruction could only occur when all atoms are removed from the system. Values of k_3 are rather insensitive to the presence of the first two right-hand terms, however. In the later work, conducted in our laboratory, N_2^* was shown to decay by first-order kinetics, which indicates that its appreciable formation occurs in the discharge tube only. A half-life of 0.08 s was deduced from this study. In the present work, attempts are made to obtain more information on the properties of $N_2(A^3\sum_u^+)$.

EXPERIMENTAL

Active nitrogen was produced either by using a 4 μF condensed discharge or a Baird Atomic Hg 198 Microwave Exciter of 250 W output which was connected to a cylindrical cavity obtained from the Ophthos Instrument Company, Rockville, Maryland. The nitrogen of prepurified grade, obtained from the Canadian Liquid Air Company, Hamilton, was passed through a liquid nitrogen trap directly into the flow system, which was kept at a pressure of ~ 3 mm Hg. Flow rates of nitrogen were nearly identical with those of the earlier work conducted at 2.5 mm. The distance from discharge to viewing tube was 40 cm. A McLeod gauge was connected to the flow system but was kept isolated except for occasional pressure measurements. The viewing tube was made of Pyrex, 1 m long and 27 mm inside diameter. A quartz plate was attached to one end of the tube with sealing wax. The viewing tube was poisoned with water vapor and perhaps oxygen present in the atmosphere and then pumped down to a pressure of 10^{-4} mm before a series of experiments. Photographs of the spectrum were taken using a quartz medium Hilger instrument and either Kodak 1-O or 1-F plates. Exposure times ranged from 5 to 30 min. A low-pressure mercury arc was used to check the calibration scale of the Hilger instrument.

RESULTS

Band spectra were identified by comparison with plates published in Pearse and Gaydon (24) and Jevons (25). Bands identified were the β- and γ-systems of nitric oxide and the first positive system of nitrogen. In all cases a direct correlation was noted between the intensities of the nitric oxide bands and the nitrogen afterglow. In the first exposures obtained after pumping down the system, the NO and N_2 bands would appear brightly after 5 min exposure; these would then fade gradually and would become very weak when the discharge had been left running for many hours. Band intensities tended to be weaker for active nitrogen produced by the microwave method. When the condensed discharge was used and a trace of mercury was present, the 2 537 line was clearly apparent. In no cases were the 0-5 and 0-6 bands of the Vegard–Kaplan system present, although they would have been readily discernible despite the presence of the NO emission.

DISCUSSION

The estimate of a lifetime of 1 s or greater for $N_2(A^3\sum_u^+)$ (14, 15) has been supported by Noxon's study of active nitrogen at high pressure (26) and the recent work of Zipf (27). On the other hand, a great deal of evidence, much of it admittedly negative, points to the $A^3\sum_u^+$ state of nitrogen as the predominant species which reacts with ammonia, and studies of this reaction indicate that A-state molecules have a half-life of about 0.08 s, i.e. a lifetime of 0.12 s. If this conclusion is correct, it poses two serious problems. First,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

there is a discrepancy in the spectroscopic and reaction kinetic estimates of the lifetime of $A^3\sum_u^+$ nitrogen, both of which appear to be well established, at least as to orders of magnitude. Second, estimates of the population of the $A^3\sum_u^+$ state by the two methods are also in disagreement. In the work of Carleton *et al.* (13–15, 28) the maximum estimate which they obtained was a population of 10^{11} A-state molecules per cc and this was right in the discharge tube, whereas in the work in this laboratory for example (22), a concentration of 4.5×10^{14} A-state molecules per cc is reported at a considerable distance from the discharge. Furthermore, these two discrepancies are operating in the wrong direction. Since for a given set of conditions the intensity of the Vegard–Kaplan emission is directly proportional to the population of the A state and inversely proportional to the lifetime of this state, then the greater the population, the longer the observed lifetime should be. Yet we have reported the greater population, the shorter lifetime, and furthermore observe no Vegard–Kaplan bands. It is the purpose of the following discussion to offer a rationalization of the above apparent conflict of evidence.

Conditions for observation of the Vegard–Kaplan bands are clearly established. The nitrogen must be exceptionally pure with particular care taken to remove the last traces of oxygen from the system. On the other hand, chemists, who are interested in studying atomic nitrogen reactions, find it necessary to operate under conditions where traces of oxygen, oxygen-containing materials, or other substances capable of performing the same role (29) are present. Although the ratio of the Lewis–Rayleigh afterglow intensity to the square of the nitrogen atom concentration is independent of oxygen concentration, the concentration of atomic nitrogen decreases with decreasing oxygen content (30). Furthermore, if the system is flamed out and carefully degassed, the afterglow intensity goes to zero (31). Our experiments have been conducted under conditions where a strong Lewis–Rayleigh afterglow is observed and so the absence of the Vegard–Kaplan bands might be expected.

The nitric oxide band emission is dependent upon the production of atomic oxygen, which could be formed by

[1] $$N_2(^3\Sigma) + O_2(^3\Sigma) \rightarrow N_2(^1\Sigma) + O_2(^5\Sigma)$$

[2] $$O_2(^5\Sigma) \rightarrow 2O(^3P).$$

The quintet state of molecular oxygen has not been observed but is postulated on grounds of spin conservation. It is equivalent to the case where there are no bonding electrons and hence would be a repulsive state. Rapid destruction of the nitric oxide, formed by atom combination, by atomic nitrogen reforms the atomic oxygen, so that only a trace of oxygen gives rise to strong nitric oxide emission. Although a precise kinetic study of the effect of traces of oxygen on Vegard–Kaplan emission remains to be carried out, it is difficult to envisage reaction [1] as the prime mechanism of quenching of the Vegard–Kaplan emission, since the trace of oxygen present would spend most of its time in its atomic state. The reaction

$$2O(^3P) + M \rightarrow O_2(^3\Sigma) + M$$

would not be able to compete with the reaction between atomic nitrogen and atomic oxygen because of the large excess of atomic nitrogen present. Whether oxygen plays a primary or secondary role, it would appear clear that the lifetime which we have measured, if it is indeed of the $A^3\sum_u^+$ state, is a collisional lifetime, whereas the work of Carleton *et al.* is definitely concerned with a radiative lifetime. In our work the A-state molecules are quenched before they have time to radiate and so the apparent discrepancy between the two lifetimes is removed.

In this connection, it is interesting to note that the magnetic resonance spectrum of active nitrogen produced in an electrode discharge in the presence of traces of oxygen has been studied by Anderson and Barry (32). They observed the presence of a species which was neither atomic nitrogen nor free electrons, and which decayed homogeneously by first-order kinetics with a half-life of 0.07 s at 4.4 mm pressure. The most logical candidate for such a paramagnetic substance would appear to be the $A^3\sum_u^+$ state of molecular nitrogen. If this assignment is correct, their work provides the first example of the detection of a diatomic free radical in the gas phase by conventional electron spin resonance (e.s.r.). Other radicals which have been detected have obeyed electric dipole rather than magnetic dipole selection rules (33, 34).

With regard to the apparent discrepancy in populations of the $A^3\sum_u^+$ state, if ammonia does indeed react with triplet-state nitrogen molecules, then the concentration of A-state molecules which it indicates should be correct. This could mean that (*a*) under our operating conditions, it is possible to produce a much higher population of A-state molecules than that obtained by Carleton *et al.*; (*b*) the latter workers actually produced a much higher concentration of A-state molecules than they at first believed. The latter statement if true would mean that the radiative lifetime of A-state molecules is considerably longer than 2 s and (or) one or more of the calculated quantities or experimental data which they had to use in order to deduce the population of the A state is in error (35, 36).

In summary, the reaction of ammonia with a non-atomic species, present to an appreciable extent in active nitrogen prepared in a condensed discharge, indicates that this species decays by first-order kinetics and that is has a half-life of 0.07–0.08 s. These observations are in complete agreement with results obtained by e.s.r. measurements on active nitrogen produced under near identical conditions, indicating that the non-atomic species is paramagnetic. A wide variety of evidence points to molecular nitrogen in its triplet A-state as the identity of this species. The absence of Vegard–Kaplan emission indicates that in the ammonia and e.s.r. work, the A-state molecules are being collisionally deactivated, which removes any necessary discrepancy with the much longer radiative lifetime which has been measured.

A UNIFIED TREATMENT OF INTEGRALS FOR ONE-ELECTRON OPERATORS[1]

SERAFIN FRAGA
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received June 4, 1964

ABSTRACT

A general formula has been developed to express, in terms of *C*-functions, the integrals appearing in the evaluation (when using Slater-type orbitals) of the expectation values of the most important one-electron operators.

INTRODUCTION

One of the goals of quantum-mechanical calculations is the theoretical evaluation of the physical and chemical properties of atomic and molecular systems. Since the introduction of high-speed, digital computers in recent years, the calculation of such quantities has received new emphasis.

The corresponding calculations could be simplified if one had a unified treatment for the integrals which are needed. It appears that the development of such a formulation should be based on the so-called *C*-functions (1, 2, 3), used in the evaluation of integrals required for the energy calculations.

The aim of this paper is the development of a simple formula which would enable one to express in terms of *C*-functions all the two-center integrals, using Slater-type orbitals (STO's), which appear (4, 5) when evaluating the expectation values of the one-electron operators corresponding to those properties.

GENERAL THEORY

In the present paper normalized STO's (in complex form), defined by

$$[1] \qquad \chi_{nlm}(r, \theta, \varphi) = (2\zeta)^{n+\frac{1}{2}}[(2n)!]^{-\frac{1}{2}} r^{n-1} e^{-\zeta r} Y_{lm}(\theta, \phi),$$

are used. In this equation r, θ, and ϕ are the polar coordinates; n, l, and m are the three quantum numbers; ζ is the orbital exponent, and $Y_{lm}(\theta, \phi)$ are the normalized spherical harmonics defined by

$$[2] \qquad Y_{lm}(\theta, \varphi) = \left[\frac{(l - |m|)!}{(l + |m|)!}\frac{2l + 1}{4\pi}\right]^{\frac{1}{2}} P_l^m(\cos\theta)\, e^{im\phi},$$

where $P_l^m(\cos\theta)$ is a Legendre function of the first kind. Expansion of eq. [2] leads to

$$[3] \qquad Y_{lm}(\theta, \phi) = \frac{1}{2^l \cdot l!}\frac{(2l)!}{(l - |m|)!}\left[\frac{(l - |m|)!}{(l + |m|)!}\frac{2l + 1}{4\pi}\right] (\sin\theta)^{|m|} e^{im\phi} \left\{(\cos\theta)^{l-|m|} - \frac{(l - |m|)(l - |m| - 1)}{2 \cdot (2l - 1)} (\cos\theta)^{l-|m|-2} + \frac{(l - |m|)(l - |m| - 1)(l - |m| - 2)(l - |m| - 3)}{2 \cdot 4 \cdot (2l - 1)(2l - 3)} (\cos\theta)^{l-|m|-4} - - - - -\right\},$$

which is the expression which will be used here.

The two centers are designated by the subscripts a and b; their mutual distance by R. The Cartesian coordinates at the centers a and b are chosen so that the z-axes lie along the internuclear axis, pointing toward each other.

Prolate spheroidal coordinates will be used. They are defined by

$$\xi = (r_a + r_b)/R,\ \eta = (r_a - r_b)/R,\ \phi = \phi_a = \phi_b;$$

the volume element is $(R^3/8)(\xi^2 - \eta^2)\,d\xi\,d\eta\,d\phi$, and the integration limits are 0 and 2π for ϕ, -1 and 1 for η, and 1 and ∞ for ξ. In the preceding expressions r is the distance of the electron to nucleus a or b.

Let us assume that the one-electron operator to be considered introduces a factor of the form

$$[4] \qquad P = (R/2)^{\omega}(\xi + \eta)^{\alpha'}(\xi - \eta)^{\beta'}(1 + \xi\eta)^{\gamma'}(1 - \xi\eta)^{\delta'}(\xi^2 - 1)^{\epsilon'}(1 - \eta^2)^{\epsilon'} f(\phi),$$

with

$$[5] \qquad \omega = \alpha' + \beta' + \gamma' + \delta' + 2\epsilon',$$

and where α', β', γ', and δ' are integers and ϵ' is integer or half-integer. For any two STO's, centered on nuclei a and b respectively, it can then be written

$$[6] \qquad \langle \chi_a | P | \chi_b \rangle \equiv \int \bar{\chi}_a P \chi_b \, d\tau$$

$$= k_a k_b (R/2)^{n_a + n_b + 1 + \omega} \zeta_a^{\,n_a + \frac{1}{2}} \zeta_b^{\,n_b + \frac{1}{2}} \pi^{-1} \left\{ \int_0^{2\pi} f(\phi)\, e^{-i(m_a - m_b)\phi}\, d\phi \right\}$$

$$\sum_p \sum_q c_{ap} c_{bq} \left\{ \int_1^{\infty} d\xi \int_{-1}^{1} e^{-(R/2)[(\xi+\eta)\zeta_a + (\xi-\eta)\zeta_b]} \right.$$

$$(\xi + \eta)^{n_a - l_a + 2p + \alpha'} (\xi - \eta)^{n_b - l_b + 2q + \beta'} (1 + \xi\eta)^{l_a - |m_a| - 2p + \gamma'} (1 - \xi\eta)^{l_b - |m_b| - 2q + \delta'}$$

$$\left. [(\xi^2 - 1)(1 - \eta^2)]^{\frac{1}{2}(|m_a| + |m_b|) + \epsilon'}\, d\eta \right\},$$

where

$$[7a] \qquad k = 2^{n - l - \frac{1}{2}} [(2n)!]^{-\frac{1}{2}} (l!)^{-1} (2l)! (2l + 1)^{\frac{1}{2}} [(l + |m|)!(l - |m|)!]^{-\frac{1}{2}},$$

$$[7b] \qquad c_0 = 1,$$

$$[7c] \qquad c_{\substack{p \\ (p>0)}} = (-1)^p \frac{(l - |m|)(l - |m| - 1) \ldots (l - |m| - 2p + 1)}{(2 \ldots 2^p)(2l - 1)(2l - 3) \ldots (2l - 2p + 1)}.$$

Making use of the C-functions,* defined by

$$[8] \qquad C\{\alpha, \beta, \gamma, \delta, \epsilon; \rho, \tau\} = (-1)^{\beta + \delta + \epsilon} (\rho_b/2)^{\alpha + \beta + \gamma + \delta + 2\epsilon + 1} \int_1^{\infty} d\xi$$

$$\int_{-1}^{1} e^{-\rho\xi - \tau\rho\eta} (\xi + \eta)^{\alpha} (\xi - \eta)^{\beta} (1 + \xi\eta)^{\gamma} (1 - \xi\eta)^{\delta} (\xi^2 - 1)^{\epsilon} (1 - \eta^2)^{\epsilon}\, d\eta,$$

with

$$[9a] \qquad \rho = \tfrac{1}{2}(\rho_a + \rho_b) = \tfrac{1}{2}(\zeta_a + \zeta_b)R,$$

$$[9b] \qquad \tau = (\rho_a - \rho_b)/(\rho_a + \rho_b) = (\zeta_a - \zeta_b)/(\zeta_a + \zeta_b),$$

**The definition used here for the C-functions is the one given in the technical report (see ref. 1); it differs from the one given in the published version of that report by the factor $(-1)^{\beta+\delta+\epsilon}$. In order to simplify the notation hereafter, the convention $C\{\alpha, \beta, \gamma, \delta, \epsilon; \rho, \tau\} = C_{\alpha\beta}{}^{\gamma\delta\epsilon}(\rho, \tau)$ will be adopted.*

eq. [6] yields

$$[10]\quad \langle\chi_a|P|\chi_b\rangle = (-1)^{-n_b-\frac{1}{2}(|m_a|-|m_b|)-\sigma} k_a k_b F(\phi) \zeta_a^{\,n_a+\frac{1}{2}} \zeta_b^{\,-(n_a+\frac{1}{2}+\omega)} \sum_p \sum_q c_{ap} c_{bq} C\{n_a - l_a + 2p + \alpha', n_b - l_b + 2q + \beta', l_a - |m_a| - 2p + \gamma', l_b - |m_b| - 2q + \delta', \tfrac{1}{2}(|m_a| + |m_b|) + \epsilon'; \rho, \tau\},$$

with

$$[11]\quad \sigma = \beta' + \delta' + \epsilon',$$

$$[12]\quad F(\phi) = \pi^{-1} \int_0^{2\pi} f(\phi)\, e^{-i(m_a - m_b)\phi}\, d\phi.$$

Equation [10] is completely general, subject only to the restrictions governing the C-functions, namely (1, 2, 3): (a) β, γ, δ, and ϵ are non-negative numbers; (b) the negative values of α are limited by the condition $\alpha + \gamma + 2\epsilon + 1 \geqslant 0$; ($c$) $\alpha + \beta + \gamma + \delta + 2\epsilon \geqslant 0$, if the C-function is to have a finite limit for $\rho \to 0$.

SUMMARY OF FORMULAE

In the following expressions the two STO's involved are designed by χ_i and χ_j, respectively. The operator P is supposed to be of the form

$$[13a]\quad P_a = (R/2)^{\omega}(\xi + \eta)^{\alpha'}(\xi - \eta)^{\beta'}(1 + \xi\eta)^{\gamma'}(1 - \xi\eta)^{\delta'}(\xi^2 - 1)^{\epsilon'}(1 - \eta^2)^{\epsilon'} f(\phi),$$

$$[13b]\quad P_b = (R/2)^{\omega}(\xi + \eta)^{\beta'}(\xi - \eta)^{\alpha'}(1 + \xi\eta)^{\delta'}(1 - \xi\eta)^{\gamma'}(\xi^2 - 1)^{\epsilon'}(1 - \eta^2)^{\epsilon'} f(\phi),$$

depending on whether it is referred to center a or b.

The integrals are then given by the following formulae:

$$[14]\quad \left.\begin{matrix}\langle\chi_{ia}|P_a|\chi_{jb}\rangle \\ \langle\chi_{ib}|P_b|\chi_{ja}\rangle\end{matrix}\right\} = (-1)^{-n_j-\frac{1}{2}(|m_i|-|m_j|)-\sigma} k_i k_j F(\phi) \left\{\begin{matrix}\zeta_i^{\,n_i+\frac{1}{2}} \zeta_j^{\,-n_i-\frac{1}{2}-\omega} \\ \zeta_j^{\,n_j+\frac{1}{2}} \zeta_i^{\,-n_j-\frac{1}{2}-\omega}\end{matrix}\right\}$$
$$\sum_p \sum_q c_{ip} c_{jq} C\{n_i - l_i + 2p + \alpha', n_j - l_j + 2q + \beta', l_i - |m_i| - 2p + \gamma', l_j - |m_j| - 2q + \delta', \tfrac{1}{2}(|m_i| + |m_j|) + \epsilon'; \rho, \tau\},$$

$$[15]\quad \left.\begin{matrix}\langle\chi_{ia}|P_b|\chi_{jb}\rangle \\ \langle\chi_{ib}|P_a|\chi_{ja}\rangle\end{matrix}\right\} = (-1)^{-n_j-\frac{1}{2}(|m_i|-|m_j|)-\sigma'} k_i k_j F(\phi) \left\{\begin{matrix}\zeta^{\,n_i+\frac{1}{2}} \zeta_j^{\,-n_i-\frac{1}{2}-\omega} \\ \zeta_j^{\,n_j+\frac{1}{2}} \zeta_i^{\,-n_j-\frac{1}{2}-\omega}\end{matrix}\right\}$$
$$\sum_p \sum_q c_{ip} c_{jq} C\{n_i - l_i + 2p + \beta', n_j - l_j + 2q + \alpha', l_i - |m_i| - 2p + \delta', l_j - |m_j| - 2q + \gamma', \tfrac{1}{2}(|m_i| + |m_j|) + \epsilon'; \rho, \tau\},$$

where ρ and τ are defined by eqs. [9a] and [9b], respectively, and with

$$[16]\quad \sigma' = \alpha' + \gamma' + \epsilon'.$$

Inspection of eqs. [14] and [15] shows that the relations

$$[17]\quad \langle\chi_{ib}|P_b|\chi_{ja}\rangle = (\zeta_j/\zeta_i)^{n_i+n_j+\omega+1} \langle\chi_{ia}|P_a|\chi_{jb}\rangle,$$

$$[18]\quad \langle\chi_{ib}\rangle P_a|\chi_{ja}\rangle = (\zeta_j/\zeta_i)^{n_i+n_j+\omega+1} \langle\chi_{ia}|P_b|\chi_{jb}\rangle$$

hold, assuming that the proper orbital exponents are used and taking into account that the C-functions which appear in the expression of the integral on the right-hand side are defined in terms of a τ with opposite sign to the one obtained when applying eq. [9b].

For the limiting cases the expressions of the integrals* are determined by the relations

$$[19] \qquad \langle \chi_{ib}|P_b|\chi_{jb}\rangle \equiv \langle \chi_{ia}|P_a|\chi_{ja}\rangle = \lim_{\rho\to 0}\langle \chi_{ia}|P_a|\chi_{jb}\rangle,$$

with

$$[20] \qquad \tau = (\zeta_i - \zeta_j)/(\zeta_i + \zeta_j)$$

(the limit is applied to the C-functions involved; there is a change of sign if $\chi_{jb} \to -\chi_{ja}$ when $\rho \to 0$), and

$$[21] \qquad \left.\begin{matrix}\langle \chi_{ib}|P_a|\chi_{jb}\rangle \\ \langle \chi_{ia}|P_b|\chi_{ja}\rangle\end{matrix}\right\} = (-1)^{1-(n_i+n_j)+\frac{1}{2}(|m_i|+|m_j|)-\sigma} k_i k_j F(\phi)\zeta_i^{n_i+\frac{1}{2}}\zeta_j^{n_j+\frac{1}{2}}(\zeta_i+\zeta_j)^{-(n_i+n_j+1+\omega)}$$

$$\sum_p \sum_q c_{ip}c_{jq} C\{1+\alpha', (n_i+n_j)-(l_i+l_j)+2(p+q)-1+\beta', \gamma',$$

$$(l_i+l_j)-(|m_i|+|m_j|)-2(p+q)+\delta', \tfrac{1}{2}(|m_i|+|m_j|)+\epsilon'; \rho, \tau\},$$

with

$$[22a] \qquad \rho = \tfrac{1}{2}(\zeta_i+\zeta_j)R,$$

$$[22b] \qquad \tau = -1.$$

In the case of the dipole-velocity operator† it can be written

$$[23] \qquad \left.\begin{matrix}\langle \chi_{ia}|\partial/\partial x|\chi_{jb}\rangle \\ \langle \chi_{ib}|\partial/\partial x|\chi_{ja}\rangle\end{matrix}\right\} = (-1)^{-n_j-\frac{1}{2}(|m_i|-|m_j|)} k_i k_j \left\{\begin{matrix}\zeta_i^{n_i+\frac{1}{2}}\zeta_j^{-n_i+\frac{1}{2}} \\ \zeta_j^{n_j+\frac{1}{2}}\zeta_i^{-n_j+\frac{1}{2}}\end{matrix}\right\} \Bigg(F(\cos\phi)\sum_p\sum_q c_{ip}c_{jq}$$

$$\Bigg[(-1)^{\frac{3}{2}}(n_j - l_j + 2q - 1)C\{n_i - l_i + 2p, n_j - l_j + 2q - 2,$$

$$l_i - |m_i| - 2p, l_j - |m_j| - 2q, \tfrac{1}{2}(|m_i|+|m_j|)+\tfrac{1}{2}; \rho, \tau\}$$

$$+ (-1)^{\frac{1}{2}}|m_j| C\{n_i - l_i + 2p, n_j - l_j + 2q, l_i - |m_i| - 2p, l_j - |m_j| - 2q,$$

$$\tfrac{1}{2}(|m_i|+|m_j|) - \tfrac{1}{2}; \rho, \tau\}$$

$$- (-1)^{\frac{1}{2}} \left\{\begin{matrix}1 \\ (\zeta_j/\zeta_i)\end{matrix}\right\} C\{n_i - l_i + 2p, n_j - l_j + 2q - 1, l_i - |m_i| - 2p,$$

$$l_j - |m_j| - 2q, \tfrac{1}{2}(|m_i|+|m_j|)+\tfrac{1}{2}; \rho, \tau\}\Bigg]$$

$$+ F(\sin\phi)\sum_p\sum_q c_{ip}c_{jq} C\{n_i - l_i + 2p, n_j - l_j + 2q, l_i - |m_i| - 2p,$$

$$l_j - |m_j| - 2q, \tfrac{1}{2}(|m_i|+|m_j|) - \tfrac{1}{2}; \rho, \tau\}\Bigg)$$

(a similar expression holds for $\partial/\partial y$, with $F(\cos\phi)$ and $F(\sin\phi)$ replaced with $F(\sin\phi)$ and $-F(\cos\phi)$, respectively; $F(\cos\phi)$ and $F(\sin\phi)$ are defined by eq. [12], with $f(\phi)$ being $\cos\phi$ or $\sin\phi$, respectively) and

$$[24] \qquad \left.\begin{matrix}\langle \chi_{ia}|\partial/\partial z|\chi_{jb}\rangle \\ \langle \chi_{ib}|\partial/\partial z|\chi_{ja}\rangle\end{matrix}\right\} = (-1)^{-n_j-\frac{1}{2}(|m_i|-|m_j|)} k_i k_j F(\phi) \left\{\begin{matrix}\zeta_i^{n_i+\frac{1}{2}}\zeta_j^{-n_i+\frac{1}{2}} \\ \zeta_j^{n_j+\frac{1}{2}}\zeta_i^{-n_j+\frac{1}{2}}\end{matrix}\right\} \sum_p\sum_q c_{ip}c_{jq}$$

$$[(n_j - l_j + 2q - 1)C\{n_i - l_i + 2p, n_j - l_j + 2q - 2, l_i - |m_i| - 2p,$$

$$l_j - |m_j| - 2q + 1, \tfrac{1}{2}(|m_i|+|m_j|); \rho, \tau\}$$

*The numerical values depend, of course, on the values of the orbital exponents of the orbitals involved.

†For this operator the Cartesian coordinate x, y and z are chosen in such a way that $\partial/\partial z = \partial/\partial z_a = -\partial/\partial z_b$; $\partial/\partial x = \partial/\partial x_a = \partial/\partial x_b$; $\partial/\partial y = \partial/\partial y_a = \partial/\partial y_b$.

$$+ (l_j - |m_j| - 2q)C\{n_i - l_i + 2p, n_j - l_j + 2q, l_i - |m_i| - 2p, l_j - |m_j| - 2q - 1, \tfrac{1}{2}(|m_i| + |m_j|); \rho, \tau\}$$

$$+ \begin{Bmatrix} 1 \\ (\zeta_j/\zeta_i) \end{Bmatrix} C\{n_i - l_i + 2p, n_j - l_j + 2q - 1, l_i - |m_i| - 2p, l_j - |m_j| - 2q + 1, \tfrac{1}{2}(|m_i| + |m_j|); \rho, \tau\}]$$

(where $F(\phi)$ is determined for $f(\phi) = 1$).

For the limiting cases the analytical expressions of the integrals are determined by the relations*

[25a] $$\langle \chi_{ib}|\partial/\partial x_b|\chi_{jb}\rangle = \langle \chi_{ia}|\partial/\partial x_a|\chi_{ja}\rangle = \lim_{\rho\to 0}\langle \chi_{ia}|\partial/\partial x|\chi_{jb}\rangle,$$

[25b] $$-\langle \chi_{ib}|\partial/\partial z_b|\chi_{jb}\rangle = \langle \chi_{ia}|\partial/\partial z_a|\chi_{ja}\rangle = \lim_{\rho\to 0}\langle \chi_{ia}|\partial/\partial z_a|\chi_{jb}\rangle$$

[in both cases the limit is taken for the C-functions involved; there is a change of sign if $\chi_{jb} \to -\chi_{ja}$ when $\rho \to 0$; $\tau = (\zeta_i - \zeta_j)/(\zeta_i + \zeta_j)$] and (5)

[26a] $$\langle \chi_{ib}|\partial/\partial x_a|\chi_{jb}\rangle = \langle \chi_{ia}|\partial/\partial x_a|\chi_{ja}\rangle,$$

[26b] $$\langle \chi_{ib}|\partial/\partial z_a|\chi_{jb}\rangle = \langle \chi_{ia}|\partial/\partial z_a|\chi_{ja}\rangle.$$

CONCLUSION

The preceding treatment has been applied to several one-electron operators: electronic charge cloud; electric potential, electric field, and electric field gradient produced by an electron at one of the nuclei; electric dipole (length, velocity, and acceleration) and quadrupole moments; electric polarizability; magnetic susceptibility; and nuclear magnetic shielding.

Tables† have been prepared (up to $n = 3$) for the basic operators involved in all those cases, using STO's.

LYCOPODIUM ALKALOIDS

VII.[1] LYCODOLINE (ALKALOID L.8)[2,3]

W. A. AYER AND G. G. IVERACH
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received July 15, 1964

ABSTRACT

Lycodoline (alkaloid L.8) is shown to have the structure and stereochemistry depicted in II. The transformation of lycodoline into lycopodine is described. The use of infrared spectroscopy in assigning the configuration at C-12 and the nitrogen in these and related alkaloids is described. The effect of the configuration at C-12 on the optical rotatory dispersion spectra and on the mass spectra of lycopodine (I) and 12-epilycopodine (X) is discussesd.

Lycopodium alkaloid L.8, for which we have chosen the name lycodoline, was first isolated by Manske and Marion in 1943 from *L. annotinum* Linn. (1). This substance is of particular interest since it is one of the most widely distributed of the minor alkaloids of the Lycopodiaceae, having also been isolated from *L. annotinum* var. *acrifolium* (2) (the substance as isolated from this species was originally designated alkaloid L.30, but it was later shown (3) that L.30 is identical with L.8), *L. selago* (4), *L. fawcettii* (5), *L. lucidulum* (6), *L. clavatum* (7, 8), and *L. prostratum* (9). The lycodoline used in this investigation was isolated from *L. annotinum* and was identical with an authentic sample of alkaloid L.8 provided by R. H. Manske.

Earlier workers had established that lycodoline has the molecular formula $C_{16}H_{25}O_2N$ (1, 2, 4, 5, 10), that the oxygens are present as a ketonic carbonyl group and a hydroxyl group (10), and that the nitrogen is tertiary (5, 10). Our analytical and spectroscopic data confirmed these conclusions and, in addition, revealed the presence of a secondary C–methyl group (0.68 mole of volatile acid on Kuhn–Roth oxidation, doublet at 9.14 τ in the nuclear magnetic resonance (n.m.r.) spectrum). Lack of olefinic absorption in the n.m.r. spectrum, coupled with the fact that lycodoline is recovered unchanged on attempted catalytic hydrogenation, leads to the conclusion that there are no carbon–carbon double bonds and that the molecule is tetracyclic.

The environment of the carbonyl group in lycodoline was defined in the following manner. The infrared spectrum, measured in CCl_4, showed absorption at 1703 cm^{-1}, accompanied by a band at 1410 cm^{-1}, indicative of the grouping —CO—CH_2— (11). Neither of these absorption bands was present in dihydrolycodoline ($C_{16}H_{27}O_2N$), the product obtained by lithium aluminum hydride reduction of the carbonyl group. Dehydration of dihydrolycodoline with thionyl chloride in methylene chloride at room temperature yielded anhydrodihydrolycodoline ($C_{16}H_{25}ON$), which showed a single olefinic proton at 4.56 τ (mult.) in its n.m.r. spectrum. Since it will be shown that the hydroxyl group lost in the dehydration is that one produced in the reduction of the keto group, then, provided that no rearrangement has occurred during the dehydration, the grouping —CH—CO—CH_2— must be present in lycodoline.

Concerning the environment of the nitrogen and hydroxyl group, it was found that

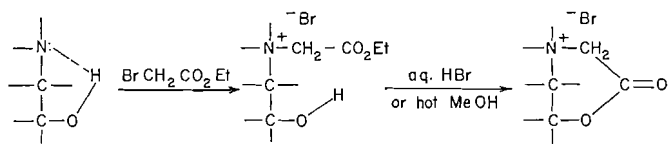
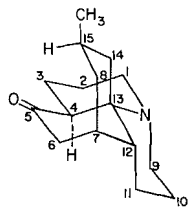
lycodoline was resistant to both acetylation and mild oxidation (CrO_3–pyridine, CrO_3–acetic acid), suggesting that the hydroxyl as well as the nitrogen was tertiary. The position of the —OH stretching vibration in the infrared spectra of lycodoline and its derivations was especially informative. The infrared spectrum of lycodoline, measured in dilute carbon tetrachloride, showed a concentration-independent band at 3545 cm^{-1}. It is known (12) that intramolecular hydrogen bonding causes a concentration-independent shift of the —OH stretching vibration from the non-bonded 3615–3635 cm^{-1} region to lower frequency. In this case, we attribute the shift to intramolecular hydrogen bonding between the hydroxyl group and the tertiary nitrogen. The alternate possibility, that the association is between the hydroxyl group and the ketonic carbonyl group, was ruled out by the observation that dihydrodeoxylycodoline (in which the carbonyl group has been converted to a methylene group by Wolff–Kishner reduction) also shows H-bonded hydroxyl absorption (3545 cm^{-1}). Dihydrolycodoline showed —OH stretching vibrations at 3625 cm^{-1} (non-bonded) and 3550 cm^{-1} (H-bonded), while its dehydration product, anhydrodihydrolycodoline, displayed only the H-bonded absorption (3565 cm^{-1}), showing that it is the original hydroxyl group of lycodoline which is retained in the dehydration product. These studies indicate that the hydroxyl group and the nitrogen are in close proximity to one another. The fact that they are vicinal was shown in the following manner: reaction of lycodoline with ethyl bromoacetate gave a salt (A) which showed absorption in the infrared (Nujol) at 3240, 1753, and 1717 cm^{-1}, attributable to hydroxyl, ester carbonyl, and ketonic carbonyl stretching vibrations, respectively. Hydrolysis of the ester salt (A) with aqueous hydrobromic acid gave a lactone salt (B), which showed no hydroxyl absorption in the infrared, but showed carbonyl bands at 1756 (lactone) and 1705 (ketone) cm^{-1}. The lactone salt also formed to some extent when the ester was recrystallized from hot methanol. The ease of formation of the lactone, coupled with the fact that the lactonic carbonyl absorbs at essentially the same frequency as the ester carbonyl, strongly suggests that the lactone is six-membered. An analogous pair of salts was prepared from dihydrodeoxylycodoline. In this case the ester absorbed at 1747 cm^{-1} and the lactone at 1754 cm^{-1}, confirming the assignments made above.

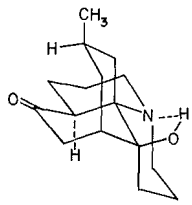


With these structural features established, it seemed possible that lycodoline might be very simply related to lycopodine (I), the most commonly occurring *Lycopodium* alkaloid. Replacement of the C-12 hydrogen in lycopodine by hydroxyl leads to a structure (II) which incorporates all of the features of lycodoline defined to this point. Structure III, the C-12 epimer of II, would also fit the evidence presented so far. The optical rotatory dispersion curve for lycodoline was positive and very similar to that of lycopodine (13). Since, however, the Octant Rule (14) states that substituents at C-4 of the carbonyl-containing ring have little or no effect on the dispersion curve, it was not possible to exclude structure III on this basis.

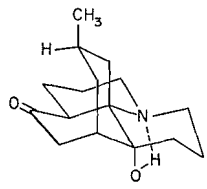
Evidence that lycodoline does indeed have the carbon–nitrogen skeleton shown in II and III was obtained in the following manner. Dihydrodeoxylycodoline, the product of



I.

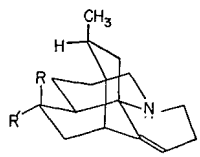


II.

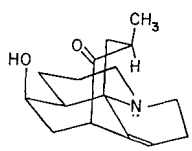


III.

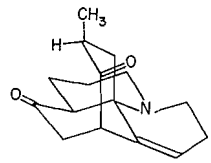
Wolff–Kishner reduction of lycodoline, was dehydrated with phosphorus pentoxide in refluxing toluene. The product, anhydrodihydrodeoxylycodoline (IV), could not be obtained in crystalline form, but was conveniently isolated and characterized in the form of its hydrochloride. The free base showed no hydroxyl absorption in the infrared and a single olefinic proton at 4.64 τ (poorly resolved triplet) in its n.m.r. spectrum. Oppenauer oxidation of acrifoline (V) (15) gave the diketone VI, which was assigned the stereochemistry shown, since the transformation of C-5 from tetrahedral to trigonal should remove the non-bonded interaction which forces ring D into a boat conformation (16) and since the equilibrating conditions of the reaction should then favor the equatorial conformation for the methyl group. Wolff–Kishner reduction of the diketone VI yielded anhydrodihydrodeoxylycodoline (IV), confirming the proposed skeleton. Since the Wolff–Kishner reduction does not necessarily lead to the most stable of two possible epimers (17), this result does not establish the configuration at C-15.



IV. R = R′ = H
IX. R = R′ = O



V.

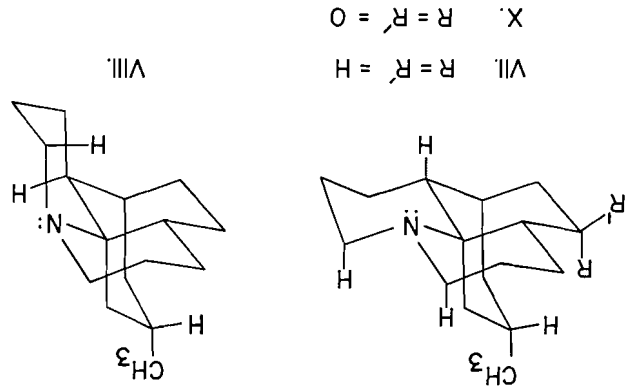


VI.

Catalytic hydrogenation of the olefin IV gave a mixture of the saturated amines VII (major product) and VIII, which was separable by chromatography. Compound VIII, in the form of its methiodide, was identical with dihydrodeoxylycopodine (13), the product of Wolff–Kishner reduction of lycopodine, thus rigorously establishing the carbon–nitrogen skeleton as well as the configuration at C-15. Compound VII, the major product of the reduction formed by addition of hydrogen from the less hindered side of the olefin IV, was also prepared from dihydroacrifoline (15, 16) by Oppenauer oxidation, followed by Wolff–Kishner reduction of the previously reported (16, 18) diketone.

The amines VII and VIII showed significant differences in their infrared spectra in the C—H stretching region. Bohlmann has pointed out (19, 20) that a series of absorption bands between 2700 and 2850 cm^{-1} are prominent in the infrared spectra of quinolizidine derivatives, in which at least two hydrogens *alpha* to the nitrogen are oriented *trans* diaxial to the electron pair on the nitrogen. In agreement with this generalization, amine VII shows well-developed bands in this region (Fig. 1) while the amine VIII does not. This observation provides us with a method for distinguishing between compounds which are epimeric at C-12 (and hence at the nitrogen), and thus between structures II and III for lycodoline. As shown in Fig. 2, lycodoline does not display these prominent bands and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



thus must possess structure II. Compounds with a double bond in the 11,12-position are free to take up either conformation about the nitrogen. Acrifoline (V) (Fig. 2), the olefin IV, and the diketone VI show prominent bands in the 2700–2850 cm^{-1} region, and hence must exist largely in the conformation shown. The formation of the epimers VII and VIII in the hydrogenation of anhydrodihydrodeoxylycodoline (IV) provides further evidence for the location of the double bond in IV, and thus the hydroxyl group in lycodoline.

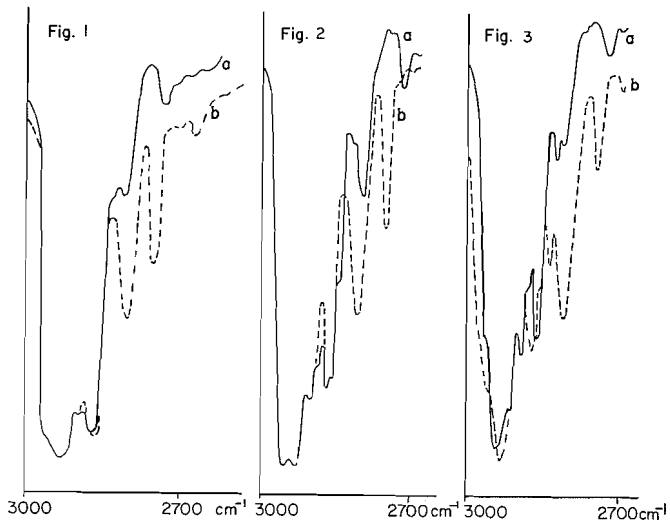


FIG. 1. Infrared spectrum of (*a*) the amine VIII, (*b*) the amine VII.
FIG. 2. Infrared spectrum of (*a*) lycodoline, (*b*) acrifoline.
FIG. 3. Infrared spectrum of (*a*) lycopodine, (*b*) 12-epilycopodine.

In order that we might more firmly establish the position of the carbonyl group in lycodoline, we now sought to transform lycodoline (II) directly into lycopodine (I). Dehydration of lycodoline with phenylphosphoric dichloride–pyridine gave anhydrolycodoline (IX) in 90% yield. Anhydrolycodoline was an unstable oil that was characterized by means of its mass spectrum (Fig. 4*a*). The n.m.r. spectrum showed a single olefinic proton at 4.44 τ (triplet, J = 3.5 c.p.s.) and the infrared spectrum (CCl_4) showed carbonyl absorption at 1698 cm^{-1} and C=C absorption at 1650 cm^{-1}. Catalytic hydrogenation of the perchlorate of IX, followed by liberation of the bases and chromatography over

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

alumina, gave a mixture of lycopodine (isolated in 10% yield) and 12-epilycopodine (isolated in 65% yield). 12-Epilycopodine (X) displayed well-developed bands in the 2700–2850 cm^{-1} region (see Fig. 3) as expected for the *trans*-quinolizidine system. The infrared spectrum of lycopodine is shown in Fig. 3 for comparison.

Unexpectedly, the optical rotatory dispersion curve for compound X showed a negative Cotton effect (extrema at 306 and 265 mμ, amplitude $-5100°$). Since the absolute configuration of lycopodine has been ascertained (6, 21), the cause of this anomoly is not readily apparent, but the fact that lycodoline shows a positive curve similar to that of lycopodine, whereas the C-12,N epimer X shows a negative Cotton curve, serves further to exclude structure III as a possibility for lycodoline.

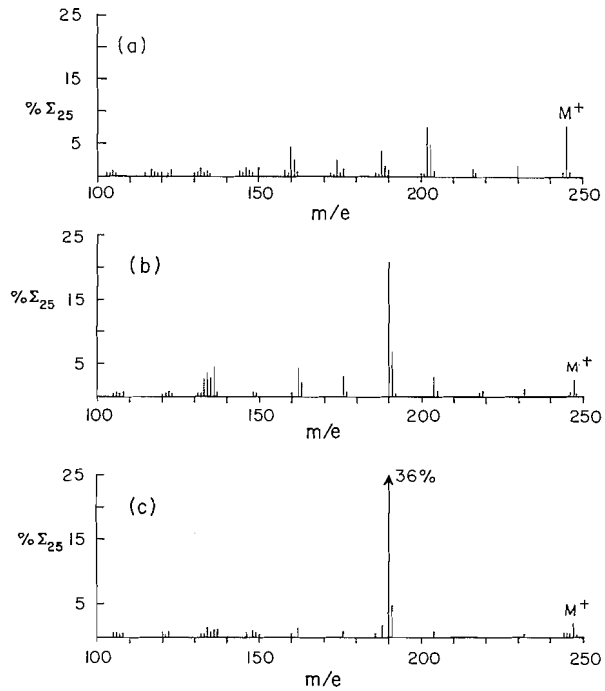

FIG. 4. Mass spectrum of (*a*) anhydrolycodoline, (*b*) 12-epilycopodine, (*c*) lycopodine.

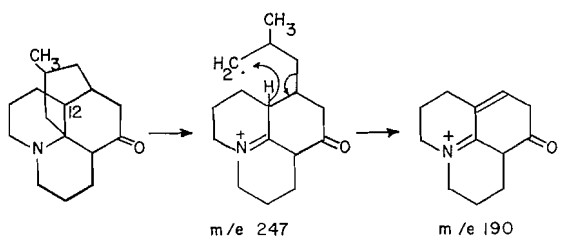
The mass spectrum of 12-epilycopodine (X) (Fig. 4*b*) is worthy of comment. MacLean has suggested (22) that loss of ring D in lycopodine and related alkaloids, upon electron impact, may occur as shown in the following manner.



The base peak in the mass spectrum of 12-epilycopodine (Fig. 4*b*), like that of lycopodine (Fig. 4*c*), occurs at *m/e* 190. However, in the case of the epi compound X, the 190 peak

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

accounts for only 21% of $\sum_{25}$ (sum of the relative intensities of all peaks from mass 25 to the molecular weight (23)), whereas in lycopodine it accounts for 36%. This indicates that if a cyclic mechanism, such as that shown above, is operative, a *cis* arrangement of the C-12 hydrogen and the bridged ring facilitates, but is not necessary for, loss of the bridge. The mass spectrum of anhydrolycodoline (IX, Fig. 4*a*) again emphasizes the necessity of a hydrogen at C-12 for easy loss of the bridge (22), since in this case the parent peak is now the most intense peak in the spectrum, and the 188 peak (corresponding to loss of the bridge plus a hydrogen) is only 4% of $\sum_{25}$. In lycodoline (II), the mass spectrum of which has already been discussed (22), the parent peak is again the most intense peak in the spectrum.

EXPERIMENTAL

Ultraviolet spectra were measured in 95% ethanol and, unless otherwise specified, infrared spectra in carbon tetrachloride. For hydrogen-bonding studies, spectra were determined on 0.1, 0.05, and 0.01 *M* solutions in CCl_4 using a Perkin–Elmer Model 221 or 441 spectrophotometer. Nuclear magnetic resonance spectra were measured on ca. 5–10% w/v solutions in chloroform or deuterochloroform using a Varian Associates Model A-60 spectrometer. Internal tetramethylsilane was used as standard. Some of the optical rotatory dispersion curves were obtained by Dr. M. M. Marsh, Eli Lilly, Indianapolis; the others were determined by Mr. R. N. Swindlehurst of these laboratories using a Rudolph Automatic Recording Spectropolarimeter. The mass spectra were determined on an AEI MS2-H mass spectrometer. Samples were introduced through a heated inlet system maintained at 200°. Melting points were determined on a hot stage and are uncorrected. The alumina used for column chromatography, unless otherwise specified, was basic alumina of activity III–IV. Thin-layer chromatograms were carried out on 0.25 mm layers of Alumina G (Research Specialties Co., Richmond, California) and were developed with Dragendorff's reagent (24). Skellysolve B refers to Skelly Oil Company light petroleum, b.p. 62–70°. Microanalyses are by Pascher Mikroanalytisches Laboratorium, Bonn, West Germany, and C. Daessle, Montreal, Quebec.

Isolation of Lycodoline

Lycopodium annotinum L. was extracted as previously described (1) and most of the annotinine removed by crystallization (1). The resulting "annotinine-free" alkaloids were chromatographed over alumina. Lycodoline was eluted with ether and with ether – methylene chloride. Lycodoline has a characteristic sharp band at 960 cm^{-1} in the infrared which facilitates its detection. Suitable combination of fractions and crystallization from acetone gave lycodoline, m.p. 180–181°, identical with an authentic sample of alkaloid L.8 kindly furnished by R. H. Manske.

Infrared spectrum: ν_{max} 3545, 1703 cm^{-1}. Rotatory dispersion in methanol (*c*, 0.15): $[\alpha]_{308}$ +2660° (peak), $[\alpha]_{265}$ −6950° (trough).

Lithium Aluminum Hydride Reduction of Lycodoline

Lycodoline (148 mg) in ether (100 ml) was added to a slurry of $LiAlH_4$ (180 mg) in ether (75 ml) and the mixture refluxed for 18 h. Excess hydride was destroyed with wet ether and the solution extracted with dilute hydrochloric acid. The aqueous layer was made basic with aqueous ammonia and extracted with chloroform. Evaporation of the solvent and crystallization from acetone yielded dihydrolycodoline (0.10 g), m.p. 186–187°.

Calcd. for $C_{16}H_{27}O_2N$: C, 72.41; H, 10.26. Found: C, 72.16; H, 10.14.

Infrared spectrum: ν_{max} 3625, 3550 cm^{-1} (concentration independent).

Anhydrodihydrolycodoline

A solution of dihydrolycodoline (91 mg), methylene chloride (20 ml), and thionyl chloride (1.5 ml) was kept at room temperature for 2½ h. Then the solvents were removed at the pump. The oily residue was dissolved in dilute hydrochloric acid, washed with ether, and made basic with aqueous ammonia. Extraction with chloroform yielded a pale yellow oil (68 mg) which was chromatographed over alumina (2 g). Ether elution gave a colorless oil (62 mg) which was transformed to the hydrobromide in acetone solution. Recrystallization from acetone gave the analytical sample, m.p. 293–295°.

Calcd. for $C_{16}H_{25}ON \cdot HBr$: C, 58.55; H, 7.99. Found: C, 58.62; H, 8.11.

A sample of the free base was recovered from the hydrobromide and distilled at 130° at 0.5 mm. Infrared spectrum: ν_{max} 3565 (concentration independent), 1650 cm^{-1} (very weak). Nuclear magnetic resonance spectrum: 4.56 τ (1H, mult.), 9.08 τ (3H, poorly defined doublet).

Attempts to hydrogenate this olefin were not successful.

Dihydrodeoxylycodoline

Anhydrous hydrazine was added to a solution of sodium (0.5 g) in diethylene glycol (25 ml) until the solution refluxed at 190°. The solution was then cooled to 50° and lycodoline (200 mg) added, then the resulting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

solution refluxed for 17½ h. The cooled reaction mixture was diluted with water, acidified with hydrochloric acid, continuously extracted with ether for 18 h (to remove diethylene glycol), made basic with aqueous ammonia, and extracted six times with chloroform. Evaporation of the chloroform left a solid which was recrystallized from acetone to give dihydrodeoxylycodoline (175 mg), m.p. 122.5–123.5°.

Calcd. for $C_{16}H_{27}ON$: C, 77.05; H, 10.91; O, 6.42; N, 5.62. Found: C, 76.51, 76.84; H, 10.65, 10.74; O, 6.82; N, 5.57.

Infrared spectrum: ν_{max} 3545 (concentration independent).

The perchlorate, recrystallized from acetone–ethyl acetate, melted at 273–275°.

Calcd. for $C_{16}H_{27}ON \cdot HClO_4$: C, 54.95; H, 8.07; N, 4.01. Found: C, 54.95; H, 8.07; N, 4.14.

Ester Salt (A) from Lycodoline

A solution of lycodoline (45 mg), ethyl bromoacetate (1.5 ml), and benzene (4 ml) was refluxed for 2 h. Filtration of the cooled reaction mixture gave the quaternary bromide (40 mg), m.p. above 340°, which was recrystallized from methanol–ether.

Calcd. for $C_{20}H_{32}O_4NBr$: C, 55.81; H, 7.50. Found: C, 55.51; H, 7.46.

Infrared spectrum: ν_{max}^{Nujol} 3240 (hydroxyl), 1753 (ester), 1717 cm^{-1} (ketone).

Ester Salt (A) from Dihydrodeoxylycodoline

The salt, prepared as above, melted at 212–213°.

Calcd. for $C_{20}H_{34}O_3NBr$: C, 57.69; H, 8.23; Br, 19.78. Found: C, 58.74; H, 8.53; Br, 19.78.

Infrared spectrum: ν_{max}^{Nujol} 3248 (hydroxyl), 1748 cm^{-1} (ester).

Lactone Salt (B) from Lycodoline

The ester salt from lycodoline (140 mg) was refluxed with 4 *N* HBr (10 ml) for 24 h. Then the solvent was evaporated and the residue recrystallized from methanol to give the lactone salt, m.p. above 340°.

Calcd. for $C_{18}H_{26}O_3NBr$: C, 56.26; H, 6.82; Br, 20.80. Found: C, 55.85; H, 6.64; Br, 21.50.

Infrared spectrum: ν_{max}^{Nujol} 1757 (lactone), 1710 cm^{-1} (ketone).

Lactone Salt (B) from Dihydrodeoxylycodoline

The lactone salt was prepared as described above for lycodoline and, after recrystallization from methanol–ether, melted at 325–326°.

Calcd. for $C_{18}H_{28}O_2NBr$: C, 58.38; H, 7.62. Found: C, 57.85; H, 7.35.

Infrared spectrum: ν_{max}^{Nujol} 1754 cm^{-1} (lactone).

Anhydrodihydrodeoxylycodoline (IV)

(A) From Dihydrodeoxylycodoline

A mixture of dihydrodeoxylycodoline (143 mg), phosphorus pentoxide (1 g), and toluene (100 ml) was heated under reflux for 3 h. Then the excess phosphorus pentoxide was decomposed with ice. The resulting two phase system was separated and the organic layer washed thoroughly with dilute hydrochloric acid. The combined acid solutions were washed with ether, made basic with aqueous ammonia, and extracted with chloroform. Evaporation of the chloroform left an oily residue (139 mg) which showed no hydroxyl absorption in its infrared spectrum. This product was dissolved in dilute hydrochloric acid and the hydrochloride extracted into chloroform. The hydrochloride hemihydrate obtained was recrystallized from acetone–ether, m.p. 232–233.5°.

Calcd. for $C_{16}H_{25}N \cdot HCl \cdot \frac{1}{2}H_2O$: C, 69.40; H, 9.83; Cl, 12.80. Found: C, 69.21, 69.60; H, 9.52, 9.65; Cl, 12.93.

The n.m.r. spectrum of the free base liberated from the purified hydrochloride showed signals at 4.64 τ (1H, poorly resolved triplet, J = 3 c.p.s.), and at 9.16 τ (3H, doublet, J = 5.5 c.p.s.).

(B) From Dehydroacrifoline (VI)

Dehydroacrifoline hydrobromide (210 mg, see below) was added to a solution of sodium, diethylene glycol, and hydrazine, made up as described for the preparation of dihydrodeoxylycodoline. The solution was refluxed for 14 h at 190°, then allowed to distil until the reflux temperature reached 215–220°. The solution was kept at this temperature for 11 h. Then the cooled solution was diluted with dilute hydrochloride acid and continuously extracted with ether for 1 day. The aqueous solution was made basic and extracted with chloroform to give a yellow oil, which was dissolved in dilute hydrochloric acid and the hydrochloride extracted into chloroform. Evaporation of the chloroform left a crystalline residue, which was recrystallized from acetone–ether to give anhydrodihydrodeoxylycodoline (IV) hydrochloride hemihydrate identical in melting point, mixed melting point, infrared spectrum ($CHCl_3$), and optical rotation ($[\alpha]_D^{23°}$ −28° (*c*, 1.9, ethanol)) with that prepared from lycodoline.

Hydrogenation of Anhydrodihydrodeoxylycodoline (IV)

The hydrochloride of IV (0.60 g) was shaken in methanol (100 ml) in the presence of platinum (from 300 mg of Adams' catalyst) and hydrogen (3 atm) for 3 h. Evaporation of the filtered reaction mixture left a crystalline residue (0.59 g) which was chromatographed on alumina (10 g). Elution with benzene (250 ml) removed the major component (0.50 g) (as evidenced by thin-layer chromatography of the fractions), and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

elution with ether (200 ml) yielded the minor component (80 mg). The major component was dissolved in acetone and neutralized with 70% aqueous perchloric acid. Dilution of this solution with ethyl acetate yielded the crystalline perchlorate of the amine VII, which melted, after several recrystallizations from acetone – ethyl acetate, at 240–241°.

Calcd. for $C_{16}H_{27}N \cdot HClO_4$: C, 57.55; H, 8.45; N, 4.20. Found: C, 57.18; H, 8.51; N, 4.41.

The infrared spectrum of the free base showed prominent bands in the 2700–2850 cm^{-1} region (Fig. 1).

The minor component was shown to be dihydrodeoxylycopodine (VIII) in the following way. A portion (32 mg) of the material eluted with ether was dissolved in acetone (5 ml) and methyl iodide (1 ml) added. After 12 h at room temperature, the solvents were removed and the residue was recrystallized several times from acetone to give dihydrodeoxylycopodine methiodide, m.p. 290–291°, identical (mixed melting point, infrared spectrum) with an authentic sample (13).

Dehydroacrifoline (VI)

Acrifoline (V, 0.73 g) was dissolved in a solution of aluminum isopropoxide (0.8 g) in toluene (40 ml) and cyclohexanone (6 ml) added. The solution was refluxed for 3 h, diluted with benzene, and extracted with 1 *N* hydrochloric acid. The extract was washed with ether, made basic with aqueous ammonia, and extracted with chloroform to give a pale yellow oil (0.68 g) which was chromatographed over alumina (12 g). Elution with benzene (500 ml) gave an oily material (0.37 g) which was transformed to the hydrobromide in ethanol. Further elution with ether and chloroform gave unreacted acrifoline.

The ethanol solution of the hydrobromide was diluted with ethyl acetate. The resultant crystalline material was filtered off and recrystallized from ethanol – ethyl acetate to give dehydroacrifoline hydrobromide, m.p. 309–310° (sealed tube).

Calcd. for $C_{16}H_{21}O_2N \cdot HBr$: C, 56.56; H, 6.52; N, 4.12. Found: C, 56.21; H, 6.67; N, 3.76.

The infrared spectrum of the hydrobromide showed carbonyl absorption at 1728 and 1714 cm^{-1}, while the free base absorbed at 1712 and 1708 cm^{-1}.

Anhydrolycodoline (IX)

Lycodoline (II, 215 mg) was dissolved in a solution of phenylphosphonic dichloride (10 ml) and pyridine (10 ml) and the reaction mixture kept at 60–70° for 13 h. The excess phenylphosphonic dichloride was carefully decomposed with water. The resulting aqueous solution was made basic with 5% sodium hydroxide and extracted with chloroform to give, after evaporation of the chloroform, a deep red oil (0.20 g) which was chromatographed over alumina (6 g). Elution with benzene afforded a colorless oil (0.18 g) which showed a single spot on thin-layer chromatography but which rapidly colorized on standing. A portion was distilled (120° at 0.5 mm) and its mass spectrum recorded (see Fig. 4*a*). The infrared spectrum showed prominent bands in the 2700–2850 cm^{-1} region, no hydroxyl absorption, carbonyl absorption at 1698 cm^{-1}, and a weak band at 1655 cm^{-1} (C=C). Nuclear magnetic resonance spectrum: 4.44 τ (1H, triplet, J = 3.5 c.p.s.), 9.17 τ (3H, doublet, J = 5.5 c.p.s.). Rotatory dispersion in methanol (*c*, 0.08): $[\alpha]_{308}$ +1140° (peak), $[\alpha]_{264}$ −3900° (trough).

Hydrogenation of Anhydrolycodoline (IX)

A solution of anhydrolycodoline (170 mg) in methanol was acidified with perchloric acid and shaken with platinum (from 200 mg of Adams' catalyst) under hydrogen (3 atm). The catalyst was removed by filtration and the filtrate evaporated to a crystalline residue, which was dissolved in water, made basic with aqueous ammonia, and extracted with chloroform. The colorless oil (0.17 g), obtained when the chloroform was evaporated, showed two spots on thin-layer chromatography and was chromatographed over alumina (6 g), using pentane–ether, (400:1 to 9:1) as the eluant. Forty fractions (each 20 ml) were collected and each fraction was examined by thin-layer chromatography. Fractions 30–32 (17 mg) were homogeneous and showed an R_f identical with that of lycopodine. Crystallization from pentane–ether gave lycopodine, identical in melting point, mixed melting point, infrared spectrum, and optical rotation with an authentic sample.

Fractions 33–39 (0.15 g) were combined and rechromatographed over alumina (5 g). Elution with pentane (200 ml) removed only traces of material, while elution with benzene (50 ml) gave a crystalline fraction (0.11 g), which was recrystallized from pentane to give 12-epilycopodine (X), m.p. 89–90°.

Calcd. for $C_{16}H_{25}ON$: C, 77.67, H, 10.19; N, 5.66; molecular weight, 247. Found: C, 77.78; H, 9.99; N, 5.41; molecular weight, 247 (by mass spectrometry, see Fig. 4*b*).

Infrared spectrum: ν_{max} 2700–2850 cm^{-1} (see Fig. 3), 1698 cm^{-1}. Rotatory dispersion in methanol (*c*, 0.09): $[\alpha]_{306}$ −930° (trough), $[\alpha]_{265}$ +1130° (peak).

ACKNOWLEDGMENTS

We thank Dr. R. H. Manske for a sample of alkaloid L.8, Dr. P. Kebarle and Mr. A. N. Hogg for determining the mass spectra and for helpful discussion, Mr. R. N. Swindlehurst and Mrs. Gail Conway for determining the infrared and n.m.r. spectra, and Dr. M. M. Marsh for determining some of the optical rotatory dispersion curves. This research was

REGULARITIES IN THE INFRARED SPECTRA OF 4-PICOLINE COMPLEXES[1]

DENYS COOK
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received July 6, 1964

ABSTRACT

Complexes of 4-picoline with Lewis acids have been prepared and their infrared spectra from 4 000 to 650 cm^{-1} recorded. Regular trends in certain absorption bands in the aromatic molecule, particularly those due to vibrations of the CC and CN bonds, are similar to those in pyridine complexes.

INTRODUCTION

Complex formation of electron-deficient species with pyridine has been thoroughly investigated (1–12). The main result of infrared spectroscopic studies on such complexes has been the fact that fairly marked changes occur in the spectrum of the complex compared with the free base but that the complex spectra are quite similar. The fine details of the spectra reveal small trends in certain bands depending on the acceptor strength of the electron-deficient species.

While pyridine complexes have been studied exhaustively, very few other substituted pyridine complexes have been described (4). The present work was initiated to see if the behavior with pyridine was general.

RESULTS AND DISCUSSION

The absorption bands in the spectra are listed in Table I, and Fig. 1 shows schematically the trends in certain bands depending on the acceptor strength. To facilitate comparison,

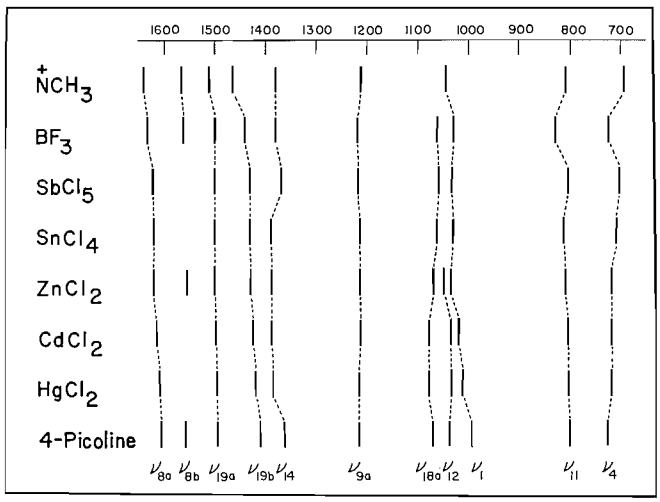

FIG. 1. Schematic representation of bands in 4-picoline complexes.

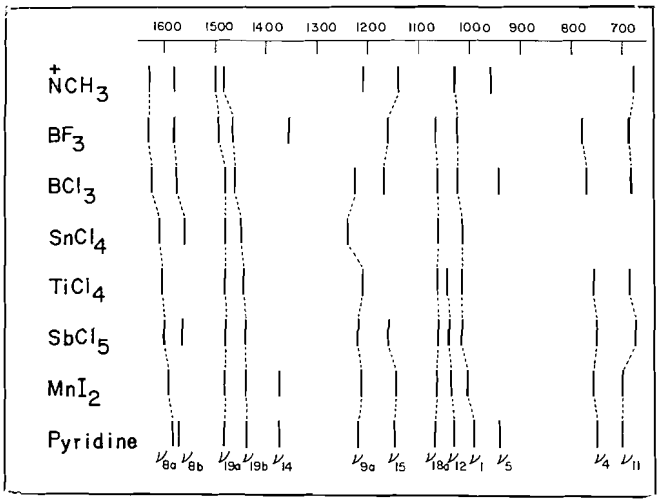

FIG. 2. Schematic representation of bands in pyridine complexes.

TABLE II

Trends* in certain bands in 4-picoline and pyridine complexes

	CC and CN vibrations†						
Compound	8*a* (A_1)	8*b* (B_1)	19*a* (A_1)	19*b* (B_1)	14 (B_1)	12 (A_1)	1 (A_1)
4-Picoline	T	C	t	t	C	C‡	T
Pyridine	T	C	t	T	C	C‡	T

	CH vibrations†					
Compound	9*a* (A_1)	15 (B_1)	18*a* (A_1)	10*b* (B_2)	4 (B_2)	11 (B_2)
4-Picoline	C	§‖	−t‖	C	C	§‖
Pyridine	C	C	C	§	C	C

*The sequence in the trends is base → base : weak complex → base : strong complex.
†Abbreviations: T, large trend; t, small trend; C, approximately constant.
‡Lack of information in the stronger complexes prevents an unequivocal decision (see text).
§No entry signifies insufficient data to make a choice.
‖Minus sign indicates a trend to lower frequency.

a similar diagram has been prepared for pyridine complexes in Fig. 2. Table II summarizes the activity of bands in the two series of complexes.

The assignments in 4-picoline have been considered by Spinner (13) on the basis of the infrared and Raman spectra of the pure liquid, and by Long and George (14) who also studied its vapor spectrum, and the infrared and Raman spectrum of the fully deuterated compound, 4-picoline-d_7. These results have been helpful in making the assignments in the complexes.

In considering the changes brought about by complex formation and the accompanying trends because of differences in acceptor properties, we will find it convenient to consider, in what follows, the sequence: base → base : weak acceptor → base : strong acceptor. A typical weak acceptor is $HgCl_2$, while the boron halides are examples of a strong acceptor.

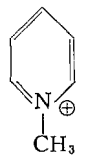
Apart from bands due to the Lewis acid portion of the complexes, the spectra of all the complexes are rather similar. The differences between the spectra of the complexes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

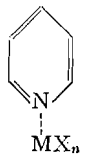
and the free base are smaller than in the pyridine series. Shifts in the individual band assignments and the trends in these bands will be considered in turn, beginning with CC (CN) vibrations.

Vibration ν_{8a}

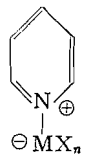
In both the pyridine and 4-picoline series ν_{8a} shows an increase of 7–9 cm^{-1} on formation of a complex with a weak acceptor and a further 21–28 cm^{-1} increase in the strong complexes. At the head of the series with the largest shift is the quaternary compound 1,4-dimethylpyridinium iodide (I). The unique place occupied by this compound is due to the unit formal positive charge which exists on the nitrogen atom. This is thus similar to one of the limiting structural forms of the complexes where complete charge separation takes place. (See II and III.)



I



II



III

Vibration ν_{8b}

The assignments to this vibration must be viewed with reserve since the band is rather weak. Spinner (13) and Long and George (14) agree on the 1 561 cm^{-1} assignment to this vibration in the pure base, though neither comment on the shoulder at 1 600 cm^{-1}. This is probably the first overtone of the very strong 800 cm^{-1} band. The 1 561 cm^{-1} band is very difficult to follow in the complexes, and in some cases is not observed. In all of them the 1 600 cm^{-1} shoulder is present but may still be explained as above. In the pyridine series similar difficulties were experienced. If, in the BCl_3 complex, the Greenwood and Wade (5) assignment is preferred to that of Katritzky (4), then a fairly consistent set of figures between 1 565 and 1 585 cm^{-1} results with little trend. This would result in a similar situation in both the pyridine and 4-picoline series. If, on the other hand, a reversal of this preference is made, then a trend in ν_{8b} from 1 570 to 1 610 cm^{-1} would result, but without parallel in the 4-picoline series. Some Raman shifts of the 4-picoline complexes would be helpful to clear up this point.

Vibration ν_{19a}

The 1 495 cm^{-1} band assigned to this vibration shows no trend at all. This is almost the same behavior as in the pyridine series where the 1 482 cm^{-1} band is observed near 1 485 cm^{-1} with a scatter of a few reciprocal centimeters throughout the complexes.

Vibration ν_{19b}

The band assigned to this vibration in the free base is at 1 417 cm^{-1}. It moves about 3–4 cm^{-1} to higher frequency on complex formation, and as the acceptor becomes stronger a further rise of about 11–17 cm^{-1} is observed. Movements of the same size are seen in the pyridine series.

Vibration ν_{14}

Apart from an initial shift from 1 365 to 1 386 cm^{-1} on weak complex formation there is a random variation of no more than a few reciprocal centimeters in this absorption band. This situation cannot be compared to that in the pyridine series, since with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

exception of the weak complexes studied by Gill *et al.* (8), who quote a value near 1 375 cm^{-1} with no trend, the assignments to this vibration are quite sparse. From the available data a constant value of $\sim$ 1 375 cm^{-1} is indicated.

Vibration ν_{12}

The unsymmetrical ring breathing mode, ν_{12}, gives rise to an absorption band near 1 040 cm^{-1}, which is of variable, but chiefly weak, intensity. Assignments are therefore not complete, so that although it appears to be constant in position, the bands in the stronger complexes, where a trend would be most pronounced, are missing. A very similar situation exists in the pyridine series. The difficulty in discerning trends is compounded by the possibility of transposing assignments when three bands, ν_{18a}, ν_{12}, and ν_1, are close together.

Vibration ν_1

The totally symmetric ring breathing mode, giving an intense Raman line, and a moderately strong infrared absorption band, near 1 000 cm^{-1}, has been well characterized in the pyridine series. The band moves progressively to higher frequency in stronger complexes, as pointed out by Terenin *et al.* (2, 11) and Greenwood and Wade (5). 4-Picoline complexes show a similar trend of about 50 cm^{-1} magnitude, with no ambiguity in assignment. In both cases the quaternary salts give the largest shifts.

CH Vibrations

In most cases no systematic variations have been found for absorption bands due to CH vibrations. These are listed in Table II, the designation C meaning constant position. One band in the 4-picoline series, ν_{18a}, appears to shift to lower frequency in the stronger complexes by about 15 cm^{-1}, though comparable behavior in the pyridine series does not seem to be observed. No other regular trend to *lower* frequency has been found in any absorption band.

From the results presented it seems that the 4-picoline complexes duplicate rather closely the pyridine complexes in both the position of certain bands and their systematic variation with acceptor strength. This behavior is to be expected from such similar molecules.

The systematic variations are found only in bands due to vibrations involving CC and CN bonds, not in any bands due to CH vibrations. (There are some nonsystematic variations in γ_{CH}, the out-of-plane hydrogen-deformation vibrations, which will be taken up later.) This again seems reasonable since the primary effect on complex formation is at the nitrogen lone-pair electrons. These electrons in the complex are in the modified form of a coordinate bond which can be expected to have an influence on the other ring bonds. Nor would it be realistic to limit the modifications solely to σ-bonds, since some degree of interaction between the nitrogen sp^2 and $p\pi$ electron distribution must take place.

Such effects, being small in themselves, are either not transmitted to the CH bonds, or are so weakly transmitted that the methods of vibrational spectroscopy are too insensitive to detect them. Smith and Schneider (15) have suggested that protonation of pyridine results in large changes in the proton shielding in the α-, β-, and γ-sites, from the free base, and it may be that this more sensitive probe would reveal changes in the CH bonds in the 4-picoline complexes. This problem is being taken up.

Attempts have been made without success to relate a systematic variation in a band to the species, or symmetry type, of the vibration causing it. Table II clearly denies such a link. The mass of the acceptor molecule also plays little part in the vibrational behavior,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

provided the molecular weight of the coordinated species is greater than about 15. Long and George (14), after calculating the frequencies of four-substituted pyridines with R = H, D, mass 15, and mass 99, concluded that little change in frequency in any of the bands listed in Table II occurred above mass 15, though large ones occurred below mass 15. Partly for this reason it has been deemed not a fair comparison to include the protonated bases or their N-deuterated analogues in these series.

Gill *et al.* (8), following a suggestion of Nyholm (16), believe that back-bonding of the metal d-electrons with the aromatic molecule is responsible for the similarity of the spectra of the compounds studied even though variations in ν_{16a} and ν_{16b} were related to the ionic radius of the metal. The acceptor strength of the inorganic molecules in the series was generally low, and the trends with ligands incapable of such back-bonding, such as BX_3, $\overset{+}{N}CH_3$, show that though this effect may be present, it is not the primary cause for the systematic variations.

It is believed that the systematic shifts are due primarily to the electron deficiency of the acceptor (2, 5, 11) for which relative orders have been proposed from spectroscopic evidence (17, 18). Superimposed on this effect is that of back-bonding which tends to counteract the effect of the Lewis acid. Thus the order in Fig. 1 which shows $SbCl_5$, believed to be a stronger Lewis acid than BF_3, in a position lower than BF_3, can be explained by the absence of back-bonding in the boron halide complexes. Similar anomalies are revealed in Fig. 2 and can be explained similarly. The anomalous position of $TiCl_4$ and $SbCl_5$ in Fig. 2 cannot be explained in the same way, and no satisfactory answer seems possible.*

A nonsystematic variation in the out-of-plane hydrogen deformation, ν_{11}, can perhaps best be accounted for by perturbations due to external forces rather than internal changes in the electronic structure of the base. Thus weak interactions of the C—H group with neighboring anions may slightly affect their out-of-plane vibrational characteristics.

EXPERIMENTAL

Spectra

Emulsions of the finely ground solid in Fluorolube or Nujol between sodium chloride plates were examined on a Perkin–Elmer model 221 prism-grating spectrometer between 4 000 and 650 cm^{-1}.

Complexes

$HgCl_2$.—Addition of 2.72 g $HgCl_2$ in 10 ml acetone to 0.93 g 4-picoline in 5 ml acetone gave an immediate white solid; m.p. 169–170°.

Anal. Calcd. for $C_6H_7N.HgCl_2$: N, 3.84. Found: N, 4.05.

$CdCl_2$.—On mixing 1.13 g 4-picoline in 10 ml ethanol with 2.22 g $CdCl_2$ in 125 ml hot ethanol a white precipitate; m.p. > 290°, was obtained.

Anal. Calcd. for $C_6H_7N.CdCl_2$: N, 5.07. Found: N, 5.08.

$CuCl_2$.—Slight warming of 1.70 g $CuCl_2$ and 1.86 g 4-picoline gave a blue solid. This was identical with the material prepared by boiling anhydrous $CuCl_2$ with excess 4-picoline; m.p. 163–164°.

Anal. Calcd. for $(C_6H_7N)_4.CuCl_2$: N, 11.05. Found: N, 10.73.

$ZnCl_2$.—Addition of 1.07 g 4-picoline to 1.57 g $ZnCl_2$ in 20 ml acetone gave a white solid on removal of the solvent; m.p. 152–154°.

Anal. Calcd. for $(C_6H_7N)_2.ZnCl_2$: N, 8.68. Found: N, 8.22.

$SnCl_4$.—On treating a CCl_4 solution of the base with $SnCl_4$ a pale yellow precipitate resulted; m.p. > 295°. This complex and those described below were handled in a dry box after preparation because of their very hygroscopic nature. For the same reason no analytical figures were obtained.

$SbCl_5$.—A Freon 113 solution of the base gave a light yellow solid when treated with $SbCl_5$; m.p. 103–105°.

**It may be mentioned here that these results for the pyridine complexes are from widely different sources and instrumental capability. Variations of a few cm^{-1} could displace a compound quite a few places in the overall order.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

BF_3.—The gas was passed into a solution of 4-picoline in Freon 113 giving a white solid; m.p. 65–68°.

1,4-Dimethylpyridinium iodide.—Excess methyl iodide was added to the free base with the usual exothermic reaction yielding the quaternary salt; m.p. 150–151°.

Anal. Calcd. for $C_7H_{10}NI$: N, 5.96. Found: N, 6.16.

ACKNOWLEDGMENTS

The assistance of Mrs. R. H. Veach (Miss C. D. Anderson) in preparing most of the compounds, and recording their spectra, is gratefully acknowledged. Mr. L. E. Swim and his associates (The Dow Chemical Company, Midland, Michigan, U.S.A.) are thanked for the microanalytical determinations.

^{19}F N.M.R. SPECTRA OF HEPTAVALENT FLUORIDES AND OXIDE PENTAFLUORIDES

N. BARTLETT,* S. BEATON, L. W. REEVES, AND E. J. WELLS
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received June 8, 1964

ABSTRACT

The ^{19}F n.m.r. spectra of IF_7, ReF_7, IOF_5, $ReOF_5$, and $OsOF_5$ have been recorded. IF_7 gives rise to a broad symmetric doublet with a splitting of 4 100 ± 300 c.p.s. interpreted as partially collapsed and unresolved ^{19}F—^{127}I coupling. ReF_7 gives a single line of width 65 c.p.s. at low field. These spectra give no information about the molecular structure other than that there is a fast intramolecular process causing magnetic equivalence. IOF_5 and $ReOF_5$ both exhibit a quintet/doublet spectrum indicative of locked C_{4v} symmetry. The multiplet splittings in IOF_5 are not resolved in pure IOF_5 or in IOF_5/IF_7 mixtures, but can be seen for IOF_5 in solution in IF_5. The doublet lies to higher field than the quintet in IOF_5, but the reverse occurs in $ReOF_5$. In the paramagnetic molecule $OsOF_5$ only the resonance of the unique axial fluorine is observed, indicative of localization of the non-bonding d-electron in the equitorial plane of the molecule.

INTRODUCTION

The recent controversy (1, 2) over the molecular structure of IF_7 and the demonstration in these laboratories by infrared studies (3) that much of the earlier work on IF_7 was carried out on samples contaminated with IOF_5 have made a reinvestigation of the structure of these and related compounds desirable. We set out to characterize these molecules by their ^{19}F (n.m.r.) spectra. At the onset of our investigation of the heptafluoride the only previously reported n.m.r. study was from the early work of Gutowsky and Hoffman (4), who, using material of uncertain purity, reported a multiple ^{19}F spectrum which they ascribed to nonequivalent fluorine nuclei.

EXPERIMENTAL

Preparation of the Compounds

The fluorides or oxyfluorides were prepared in all-welded monel cans provided with Hoke A431 valves joined to them by monel solder tube fittings. The cans were joined to the fluorine line and the metal vacuum line by way of monel Swagelock fittings provided with Teflon front ferrules and nylon back ferrules.

Iodine pentafluoride was made by fluorinating iodine, the reaction being moderated by immersion of the can in cold water. The more volatile fluorides were removed by vacuum distillation.

Iodine heptafluoride was best made by fluorinating the distilled pentafluoride with a twofold excess of fluorine at 200° for an hour or so. Excess fluorine was removed under vacuum with the can held at −196°. Heptafluoride prepared in this way was shown by infrared spectroscopy to be oxyfluoride free.

Iodine oxide pentafluoride was most conveniently prepared by the addition of a quantity of water, calculated to satisfy the eq. $IF_7 + H_2O \rightarrow IOF_5 + 2HF$, to the heptafluoride which was measured out tensimetrically, then condensed in a KelF tube. This tube was joined to the vacuum system by a flare fitting. Hydrogen fluoride was removed by keeping the products of the reaction over sodium fluoride in a monel can. Indeed, hydrogen fluoride was conveniently removed from all of the fluorides in this way.

Rhenium oxide pentafluoride was prepared by the fluorination of rhenium dioxide as previously described (5), the reaction being done, however, in a monel can.

Rhenium heptafluoride was prepared according to the directions given by Malm and Selig (6).

Osmium oxide pentafluoride was prepared by the fluorination, at 200°, of osmium dioxide, the more volatile hexafluoride being removed by vacuum distillation at −20°. The purity of the material was checked by infrared spectroscopy.

Tungsten hexafluoride (high purity grade) was used as supplied by Allied Chemical Co.

**E. W. R. Steacie Memorial Fellow and Alfred P. Sloan Fellow.*

Preparation of the Samples

The sample tubes were generally of quartz or pyrex glass. Consequently the fluorides had to be hydrogen fluoride free to prevent the hydrolytic cycle: $4HF + SiO_2 \rightarrow SiF_4 + 2H_2O$, $H_2O + MF_x \rightarrow MOF_{x-2} + 2HF$, etc. The tubes of 3 mm internal diameter were joined by way of Swagelock compression fittings, with Teflon and nylon ferrules, to a monel vacuum system. This was provided with Hoke A431 valves and KelF traps. The system, including the sample tubes, was evacuated to better than 10^{-3} mm Hg and the tubes and lines heated. When all had been thoroughly dried the fluorides were separately distilled into the tubes and cooled in liquid nitrogen. The filled tubes were then drawn off under vacuum. Teflon containers were used for two samples of iodine heptafluoride. The cells each consisted of a flanged Teflon tube made by drilling and turning a rod. This was connected to a brass valve by compressing the Teflon flange against a brass counterpart on the valve. A brass collar in the throat of the tube and an external collar, which served as the connecting nut for the union, ensured a leak-tight joint.

Since rhenium and osmium oxide pentafluorides (m.p. 40.8 and 59.8° respectively) and rhenium heptafluoride (m.p. 48.3°) were considered to be too corrosive at their melting points to be kept in quartz, it was decided that solutions only would be examined. The convenient liquid range (m.p. 2.0°, b.p. 17.1°) (7) of tungsten hexafluoride, and its similarity to the materials in question, recommended it as a solvent. The simple n.m.r. spectrum, associated with the O_h symmetry, was an added advantage.

Nuclear Magnetic Resonance Spectra

The fluorine spectra were obtained at 40 or 56.4 Mc/s using a Varian HR machine. Chemical shifts and spin coupling constants were evaluated by standard techniques, either from sideband-calibrated charts, or in the case of sharp resonances, by superposition of the sidebands as observed visually on the oscilloscope. The sidebands were generated by a Hewlett-Packard audio oscillator and monitored by a Hewlett-Packard 522B frequency counter. Where possible, the sharp line of silicon tetrafluoride was used as an internal reference.

RESULTS

The data obtained are summarized in Table I. All of the compounds were studied in the liquid phase, either as pure liquids or as solutions in one another, or in IF_5 or WF_6.

The 40 Mc/s ^{19}F spectrum of IF_7 at 27 °C in a Teflon cell is reproduced in Fig. 1*a* and that of a fresh pure sample in flamed quartz is given in Fig. 1*b*. Comparison of the two spectra indicate rapid reaction of the IF_7 with the Teflon cell, yielding IF_5 as one of the reaction products. This product was identified by the shifts and splittings of the doublet and quintet impurity peaks which were found to correspond quite closely to those we have measured for pure IF_5 in pyrex at room temperature, against added silicon tetrafluoride as standard. These measurements are also quoted in Table I and correspond roughly to those given previously for this compound by Muetterties and Phillips (8). Figure 1*a* shows two other impurity peaks which evidently arise from the reaction of IF_7 and Teflon; one broad and centered in the IF_7 doublet, and the other sharp at +40 p.p.m. from SiF_4. It is suggested that these may be due to a reaction product $IF_6 \cdot CF_3$. On prolonged exposure of IF_7 to Teflon at room temperature extensive attack occurs (and rapidly at higher temperatures) with eventual perforation of the cell.

The course of the reaction of IF_7 in a silica cell is shown in Fig. 1*b*–1*e*, where the appearance of two broad peaks to high field of the IF_7 doublet, together with the reinforcement of the SiF_4 standard peak, is obvious. The assignment of the product giving rise to the broad doublet as IOF_5 follows from the data obtained for pure samples of this compound and displayed in Table I, and from infrared studies (3). We are evidently seeing here the net reaction:

$$2IF_7 + SiO_2 \rightarrow 2IOF_5 + SiF_4.$$

These results are in agreement with recent measurements of Muetterties (9), Alexakos, Cornwell, and Pierce (10),* and Gillespie and Quail (11).

**We thank both Dr. E. L. Muetterties and Dr. C. D. Cornwell for their courtesy in communicating their results in advance of publication.*

TABLE I

Compound	State (molar ratio given for solutions)	Chemical shifts (p.p.m. from SiF_4)		Coupling (c.p.s.)	Line width (c.p.s.)	
		Equatorial	Axial		Equatorial	Axial
IF_7	Pure liquid	-334 ± 3			4 100±300	
ReF_7	1:4 in WF_6	-510 ± 1			65±2	
IOF_5	Pure liquid	-236 ± 1	-272 ± 1		930±100	1 050±50
IOF_5	2:1 in IF_7	-236 ± 2	-271 ± 2		950±100	1 200±100
IOF_5	2:1 in IF_5	-234.5 ± 1	-272 ± 1	$J_{FF} = 280$	170±30	
$ReOF_5$	1:4 in WF_6	-361.9 ± 0.5	-159.6 ± 0.5	$J_{FF} = 68.6\pm1$	12±2	
$OsOF_5$	1:3 in WF_6	Not seen	-215 ± 2			1 100±200
IF_5	Pure liquid	-173.6 ± 0.5	-222.2 ± 0.5	$J_{FF}=85.0\pm0.8$	5±2	
WF_6	4:1 in ReF_7	-330.5 ± 0.5		$J_{^{183}W-F} = 43.8\pm0.5$		

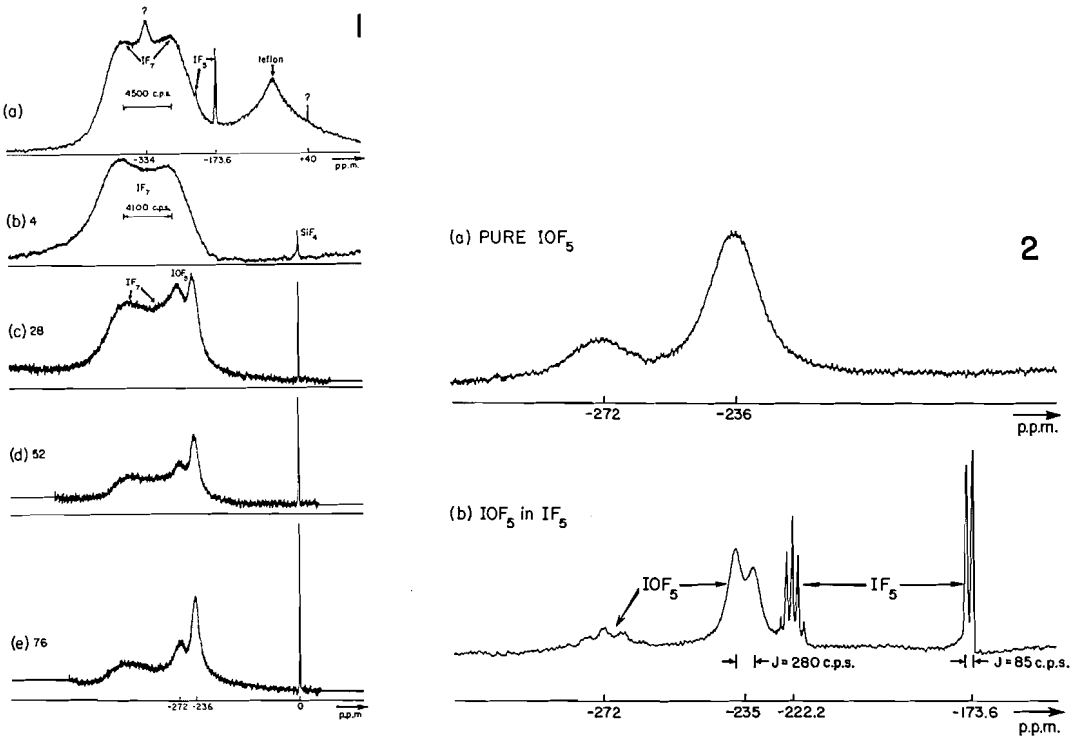

FIG. 1. ^{19}F spectra of IF_7 at 40 Mc/s. (*a*) In Teflon cell, showing the solid Teflon signal and reaction products of IF_7 with Teflon; (*b–e*) in flamed silica cell, showing the decomposition of IF_7 to IOF_5 and SiF_4 by prolonged reaction with silica.

FIG. 2. ^{19}F spectra of IOF_5 at 56.4 Mc/s. (*a*) Pure liquid; (*b*) 2:1 solution in IF_5, showing resolution into J_{F-F} multiplets, chemical shifts are relative to SiF_4 internal reference.

We have observed the two components of the IF_7 doublet to sharpen noticeably at elevated temperatures up to 70 °C. The IF_7 resonance at 28 °C for a 1:1 solution in IF_5 shows a doublet structure in a more complete stage of collapse, with a splitting of only 3 600 c.p.s. The IF_7 signal collapses to a single broad line on cooling this solution.

Solutions of rhenium heptafluoride in tungsten hexafluoride were used to obtain the room temperature ^{19}F spectrum of the heptafluoride. It is a single line of width 65 c.p.s., at −510 p.p.m. from internal silicon tetrafluoride. Its position and width in the liquid appear to be temperature independent. We have searched for a chemically shifted resonance without success.

The ^{19}F spectrum of pure iodine oxide pentafluoride at 56.4 Mc/s is given in Fig. 2*a* and is seen to consist of two broad resonances of intensity ratio near 1:4 and each of width at half-height of approximately 1 kc/s. This spectrum is to be compared with the 40 Mc/s ^{19}F resonance for IOF_5 in IF_7 shown in Fig. 1*b–1e*. The line widths are unchanged by the presence of sodium fluoride, which would remove hydrogen fluoride. Interestingly, when the IOF_5 is dissolved in IF_5 the absorption sharpens, as shown in Fig 2*b*, and a typical AB_4 type spectrum is seen with some second-order perturbation of intensities. The spin coupling here resolved is evidently fluorine–fluorine coupling between structurally non-equivalent nuclei, and is measured as 280 c.p.s. The spectrum indicates C_{4v} symmetry for the fluorine nuclei and thus a pseudo-octahedral structure for the molecule. These

results are in accord with very recent measurements on IOF_5 by Cornwell and his co-workers (10) and by Gillespie and Quail (11). The former authors note the resolution of the broad resonances into a doublet and quintet in the gas phase and the latter noted similar behavior in IF_5 solution.

Rhenium oxide pentafluoride in tungsten hexafluoride solution displays a sharp doublet and quintet with a shift large enough to produce a simple first-order spectrum. However, for this molecule the quintet from the apical fluorine nucleus occurs to much higher field than the doublet, which is the reverse situation observed for iodine oxide pentafluoride.

We have carried out a preliminary study of the ^{19}F resonance in the related paramagnetic species $OsOF_5$* also in WF_6. A single broad low-intensity peak was observed which, in the basis of its chemical shift at -215 p.p.m. from internal SiF_4 and its low intensity, is ascribed to the unresolved quintet of the axial fluorine. However, the anticipated stronger equatorial resonance was not observed.

DISCUSSION

The Heptafluorides

The ^{19}F spectrum of ReF_7 is a single sharp line and that of IF_7 a broad symmetrical doublet the splitting of which is field independent. These observations are most satisfactorily explained by a time-average magnetic equivalence of the seven fluorine nuclei in each molecule. Furthermore the experimental evidence indicates that the equivalence is due to a fast intramolecular rearrangement.

The central magnetic nuclei ^{127}I, ^{185}Re, and ^{187}Re all have spin 5/2, and for a spherically symmetric field gradient tensor at the central atom we should expect six equally spaced lines of equal intensity but not of equal half width for the resonance of the ^{19}F nuclei attached to the central quadrupolar nucleus, the sextet splitting being a measure of the X—F spin coupling. Appropriate patterns corresponding to this limiting case have been observed for species of O_h and T_d symmetry as in the $I = 9/2$ cases of $^{93}Nb\ F_6^-$ (12) and $^{73}Ge\ F_4$ (13), and for the $I = 3/2$ case of $^{11}BF_4^-$ (14, 15), $^{75}AsF_6^-$ (14), and SF_6 (16). However, when the field gradient symmetry at the quadrupolar nucleus is of low symmetry, as in the case of singly coordinated quadrupolar atoms, rapid relaxation of the quadrupolar nucleus occurs which results in a single sharp resonance absorption. If the heptafluoride molecules have the anticipated ligand close packing associated with the D_{5h} (2) model, the C_{2v} model (1), or other derivatives of an octahedral molecule, the field gradient symmetry will not deviate greatly from that in octahedral molecules. The heptafluorides are therefore expected to show an intermediate stage of collapse. The line shapes in the intermediate region have been calculated for spin 1 (17), spin 3/2 (15), and spin 9/2 (12) and have been estimated for spin 5/2 by Muetterties (9), who judges the ^{127}I—^{19}F coupling in IF_7 to be ~ 1 kc/s.†

**The electron spin resonance spectrum of this compound in tungsten hexafluoride solution has been recorded here by Dr. J. B. Farmer, who notes a signal centered approximately on the free electron value and some 200 gauss wide. No fine structure has been observed.*

†This value has recently been questioned by Gillespie and Quail, who have advised us, in advance of publication, that they disagree with the details of Muetterties and Packer's calculation, and prefer the value 2 100 c.p.s. for $J(^{127}I—^{19}F)$. They also point out that the fluoride ligands in IF_7 need not be equivalent but that small differences of no more than 2 p.p.m. in chemical shift would be detectable in the ^{19}F spectrum of IF_7. With such a small permitted chemical shift difference however, the fluorine ligands are still at least approximately equivalent. One would expect the ^{19}F chemical shifts difference for two sets of fluorine ligands as given by Burbank (1) for IF_7 in the crystal, with two I—F bonds at 1.97 Å and five at ~ 1.83 Å, to be of the order of 20–100 p.p.m. Thus our overall argument is not affected. However, Gillespie and Quail's value for $J(^{127}I—^{19}F)$ moves the point for IF_7 on Fig. 4 up to $(J/\gamma_X\gamma_F)^{\frac{1}{2}} = 19.2$, which is more in keeping with what we should expect for a group VII fluoride.

Interpretation of the spectra of IF_7 and ReF_7 in terms of very fast intramolecular averaging of the 7F nuclei together with unresolved spin coupling from the central nucleus to the surrounding fluorines is consistent with the following.

(*a*) The quadrupole moments of ^{185}Re, ^{187}Re (2.8, 2.6) are some four times larger than that of ^{127}I (0.75) and the Re—F coupling is expected to be an order of magnitude smaller than the I—F coupling (see later). It has been shown (15) that the inverse lifetime $\frac{1}{\tau}$ of a Zeeman level of a quadrupolar nucleus depends on the square of its quadrupole moment, and that the line shape is a function of $(J\tau)^2$, being a sharp multiplet for $J\tau$ large, and a collapsed single line for $J\tau$ small. Thus both above effects cause the ^{19}F signal in ReF_7 to show a much greater state of collapse than in IF_7, as is observed.

(*b*) The IF_7 doublet sharpens somewhat at high temperatures, and collapses at low, as required by the quadrupolar mechanism, and in contrast to the reverse behavior expected for an intermolecular exchange process. The IF_7 line width is independent of added NaF, which would abstract HF impurity. Intermolecular exchange via labile F atoms might be expected to be enhanced by hydrogen fluoride.

(*c*) Our picture of the quadrupolar mechanism means that the observed splitting of the IF_7 doublet is related to the I—F spin coupling, and leads to an estimated J of ~ 1 kc/s (9). This infers that all fluorine nuclei have a lifetime on a given ^{127}I nucleus of more than 1.5×10^{-4} s, and points to an *intra*-molecular averaging. A lower limit on the rate of this process is set by the absence of F—F coupling in the sharp ReF_7 signal. Assuming this to have a similar value to J_{F-F} in $ReOF_5$ (68 c.p.s.) sets the maximum lifetime of a given configuration of IF_7 or ReF_7 at $\sim 2.5 \times 10^{-3}$ s.

Bonding in the Oxide Pentafluorides

The ^{19}F n.m.r. spectra of IOF_5 and $ReOF_5$ are in accord with C_{4v} symmetry; a strong doublet, arising from four equivalent equatorial nuclei, and a weaker quintet from an axial nucleus is observed in each case. There is, however, marked difference in the two spectra. In $ReOF_5$ the quintet is greatly shifted to high field from the doublet, whereas in IOF_5 the quintet lies slightly to low field of the doublet.

In general the ^{19}F chemical shielding in the volatile transition metal fluorides is less than for nontransition element fluorides of related stoichiometry. For the fluorides under consideration the ^{19}F chemical shielding is also reduced when the oxidation state of the central atom increases, e.g. IF_7 resonates to lower field than IF_5, and ReF_7 to lower field than WF_6. Since oxygen does not have the electron-withdrawing power of fluorine, it is anticipated that the replacement of two fluorine ligands by one oxygen will reduce the positive charge on the central atom. Higher field ^{19}F resonance is therefore expected for the oxide pentafluorides than is observed in the heptafluorides. The equatorial ^{19}F resonance in $ReOF_5$ is to high field of ReF_7 and lower than WF_6, and the related resonance in IOF_5 is to high field of IF_7 but lower than the equatorial ^{19}F resonance in IF_5 (see Fig. 3). However, the axial fluorine in $ReOF_5$ is significantly affected by the *trans* oxygen ligand, since the ^{19}F resonance for this nucleus is far removed to high field from the ReF_7 or WF_6 resonances. Such is not the case in IOF_5, where axial and equatorial resonances are not widely separated.

These effects can be correlated with the availability of d-orbitals on the central atom for π-bonding with p-orbitals on the ligands. It may be supposed that in ReF_7 and WF_6, where vacant 5d-orbitals are available, the σ-bonding of the ligands is supplemented by $p\pi$–$d\pi$ bonding and that in the iodine fluorides there will be no such supplementation. The π-bonding will reduce the polarity of the fluorine-central atom bond and cause the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

^{19}F resonance to be moved to lower field. Conversely if bonding is slight, or absent, a more polar bond will result and the ^{19}F resonance will appear at higher field.

Since an oxygen ligand is a better electron donor than a fluorine ligand the oxygen–rhenium $p\pi$–$d\pi$ bonds will be the strongest in $ReOF_5$ molecule. The oxygen will have two p-orbitals disposed for interaction with two d-orbitals of the rhenium. If the Re—O axis is taken as the z-axis, the latter orbitals will be d_{zy} and d_{zx}. Those are also the only d-orbitals which the axial fluorine ligand can use in bonding. The equatorial fluorine ligands, however, can interact with the d_{xy}-orbital, which is not available to the oxygen. Multiple bonding by the oxygen will therefore considerably diminish the possibility of $p\pi$–$d\pi$ bonding by the axial fluorine. The axial fluorine rhenium bond should, in consequence, be more polar than the equatorial bonds and the axial ^{19}F resonance should, therefore, be to high field of the equatorial resonance.

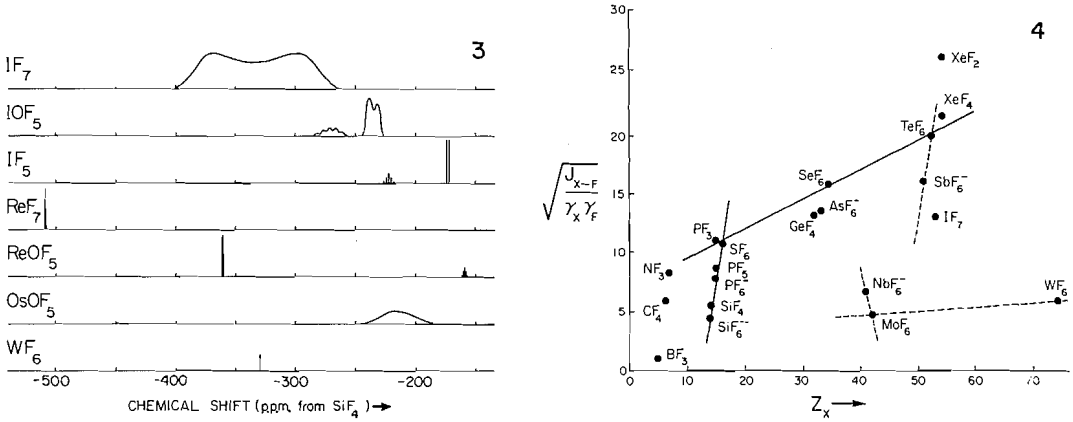

FIG. 3. Schematic diagram of 56.4 Mc/s ^{19}F spectra of heptavalent fluorides and oxide pentafluorides.
FIG. 4. Correlation plot of the reduced coupling constant $(J_{XF}/\gamma_X\gamma_F)^{\frac{1}{2}}$ against Z_x in a number of binary fluorides.

Since $OsOF_5$, which is paramagnetic (d^1), shows a single broad resonance to high field and in the region where, by analogy with $ReOF_5$, the quintet of the axial ^{19}F resonance should be observed (Fig. 3), it is presumed that this is a smeared quintet. If so, this is consistent with the model used to account for the $ReOF_5$ spectrum. Again assuming that the oxygen dominates as a π-bond donor and hence monopolizes the d_{zx}-orbitals and d_{zy}-orbitals, the non-bonding unpaired electron will be constrained to reside in the d_{xy}-orbital. Since this orbital can interact with the four equatorial fluorine ligands but not with the axial fluorine, the unpaired electron spin obscures only the equatorial fluorine resonance.

In IOF_5, where π-bonding is presumed to be absent, the σ-bonded O^- ligand will, as a consequence of its smaller nuclear charge, be larger than the isoelectronic σ-bonded F ligands. Because of the higher charge on the oxygen it will be the most strongly attracted ligand to the positive iodine but will have the most strongly repelling effect on the other ligands. The I—O bond will therefore be short, but the oxygen, equatorial-fluorine distances will be long. The length of each fluorine–iodine bond will be determined by the balance of the fluorine–iodine attraction and the fluorine – other ligand repulsion. The latter will be greater for the equatorial-fluorine ligands since the four ligands in close contact include the larger oxygen with its lower nuclear charge. The axial fluorine being

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

furthest from the oxygen will suffer less repulsion and experience the same attractive interaction as the other fluorines. Consequently the axial-fluorine – iodine bond should be slightly shorter (more covalent) than the equatorial.

Although the pattern of the ^{19}F resonance in IOF_5 is similar to that of IF_5, with the quintet slightly downfield of the doublet, the IOF_5 line widths are much greater than in IF_5. This indicates that the environment of the quadupolar iodine nucleus in IOF_5 cannot deviate too far from an O_h symmetry case, since the broadness of the lines must be attributed to unresolved I—F coupling.

It is reasonable to suppose the bonding in iodine fluorides to be analogous to that in the xenon fluorides, for which there are two distinct bonding schemes. One, which employs the molecular orbital approach, has been discussed by Pitzer (19, 20, 21) and Rundle (18). It utilizes only Xe 5p-orbitals and F 2p-orbitals for three center molecular orbitals of which the bonding and non-bonding are filled. The bonds represented by this model are semi-ionic in nature. The alternative valence bond approach supposes electron promotion to higher orbitals, followed by hybridization and the formation of normal, covalent, electron-pair bonds (22, 23). The high field ^{19}F shifts in XeF_2 and XeF_4 (20) and the small quadrupole splittings in ICl_2^- and ICl_4^- (24) favor the semi-ionic bonding model at least for the lower halides of iodine and xenon. However, the large values of $\{J_{XF}/\gamma_X\gamma_F\}^{\frac{1}{2}}$ in XeF_2 and XeF_4 (see Fig. 4 and later) indicate much more s-character in the XeF bonds than the molecular orbital model would suggest. The valence bond model may be a better approximation for the higher fluorides of iodine and xenon. Thus the molecular orbital model predicts an octahedral structure for XeF_6, whereas the valence bond model anticipates a distorted octahedron, all of the valence shell electrons being sterically active, as in IF_7. Some support for this expectation is given by the involvement of all eight valence electrons in xenon trioxide (25), the perxenates (26), and xenon tetroxide (27). It is interesting to note that if XeF_6 is distorted or undergoes intramolecular exchange as discovered in IF_7, then the ^{129}Xe—^{19}F coupling will appear sharply in the n.m.r. spectrum, whereas the ^{131}Xe—^{19}F coupling will show quadrupolar collapse. In octahedral XeF_6 both couplings will be sharp. Of all the bonding schemes so far advanced to describe the xenon fluorides, none has yet included the Xe 4f-orbitals which lie below the 5d-levels which are included. The energy considerations used by some authors to neglect even the 5d-contributions in XeF_6 do not appear valid, for such considerations should apply a fortiori to SF_6, long regarded as a normal sp^3d^2 octahedron.

IF_5 as a Solvent

Comparison of spectra of pure IF_7 and IOF_5 in the liquid and in the gas with those obtained in solution in IF_5 shows that IF_5 has the ability to raise the solute correlation time for molecular reorientation and thus yields spectra intermediate between the pure liquid solute spectrum and the pure solute in the gas. IF_5 is polar with a lone electron pair and the process could occur either through weak solute–solvent interaction via this lone pair, or perhaps through a solvent cage effect, by isolating a solute molecule from similar molecules for an appreciably longer time than a normal solvent.

Spin–Spin Coupling Constants

It was recently shown that proton spin–spin coupling constants correlate linearly with the atomic number of the conjugate nucleus in a series of compounds of similar hybridization (28, 29), and this correlation was interpreted in terms of the Fermi contact interaction of the nuclei and thus of the s-character of the bonds joining the nuclei. More recently fluorine couplings have been demonstrated to follow the same law (13), indicating

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

a similar coupling mechanism. We can now discuss the I—F coupling estimated in IF_7 (9) and the Xe—F coupling measured in XeF_2 and XeF_4 (20), along with many other X—F couplings previously reported (30, 12), for binary fluorides. An approximate parallelogram relation for $\{J_{XF}/\gamma_X\gamma_F\}^{\frac{1}{2}}$ vs. Z_X for octahedral nontransition metal species XF_6 is shown in Fig. 4. Deviations from the true parallelogram are probably due to variations in ionicity of the X—F bonds (31). A glance at the figure shows the transition metal fluorides MF_6 to have remarkably small couplings, presumably reflecting the use of outer s-bonding rather than inner s-bonding orbitals.

That fluorine couplings are transmitted through the s-electrons may be seen from the points for PF_3, PF_5, and PF_6^- in Fig. 4, for which the s-character of the P—F bond should be in the ratio 25%:20%:16.6%, and thus $J^{\frac{1}{2}}$ in the ratio 1.25:1.1:1. The measured ratio is 1.4:1.1:1.

The estimated value of 1 000 c.p.s. for J_{I-F} in IF_7 leads to the point shown in Fig. 4. The s-character of the I—F bonds in this molecule is probably smaller than in the XF_6 species, but the point lies within the region expected for nontransition metal fluorides. The large values of the reduced Xe—F couplings in XeF_2 and XeF_4 must then reflect high s-character bonding.

At the present time there appears to be no regularity in J_{F-X-F} couplings, apart from the fact that such couplings are small (< 100 c.p.s.) if X is a transition metal.

CONCLUSION

The ^{19}F n.m.r. spectra of IF_7 and ReF_7 indicate that both molecules are undergoing rapid intramolecular exchange causing magnetic equivalence of the seven F nuclei. The spectrum of IF_7 is complicated by quadrupolar broadened ^{127}I—^{19}F coupling, but there is no doubt that a single sharp ^{19}F signal analogous to that observed in ReF_7 would appear if the ^{127}I nuclei could be decoupled by double irradiation. The absence of F—F coupling in these molecules sets a minimum rate constant of about 4×10^2 s^{-1} on the intramolecular process. It is probably much faster.

A growing body of evidence points to rapid internal rearrangement of the ligands to be common in five and seven coordinate species. In $Fe(CO)_5$ all ^{13}C nuclei are equivalent down to -63 °C (32). Similarly PF_5 (33), RPF_4, and AsF_5 (30) and SOF_4 (34) all show equivalent ^{19}F nuclei in their n.m.r. spectra. The mechanism of this internal process may be thought of as an ammonia-like inversion or 'pseudo-rotation' occurring through a distorting vibration (35). In principle it should be possible to observe directly the tunnelling frequency in the radio or microwave region. However such an electric-dipole transition may be expected to be extremely weak owing to the combined effects of the near spherical symmetry, and low transition energy.

π-ELECTRON DENSITIES IN THE PYRIDINIUM CATION

THE EFFECT OF THE COUNTERION ON THE PROTON MAGNETIC RESONANCE SPECTRUM

G. KOTOWYCZ,* T. SCHAEFER, AND E. BOCK
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received June 30, 1964

ABSTRACT

Proton shifts relative to internal benzene of pyridine hydrochloride, hydrobromide, and hydriodide in methylene chloride, acetonitrile, nitromethane, and formic acid are reported. A model involving a hydrogen-bonded ion pair between the pyridinium cation and the counterion is discussed. It is assumed that the counterion reduces considerably the π-electron polarization in the pyridinium ion calculated for the isolated ion by the V.E.S.C.F. method. If the electric fields arising from the π-electrons, the counterion, and the positive charge in the N—H^+ sigma bond are taken into consideration, the observed order of the C—H proton shifts is predicted. The N—H^+ proton shifts are sensitive to the counterion, the solvent, and traces of water. In formic acid the N—H^+ proton shifts of the hydrochloride and hydrobromide are characteristic of the solvent only. In these two cases the N—H^+ proton does not exchange rapidly and an ^{14}N—H^+ coupling constant of 67.6 $\pm$ 0.5 c/s is found.

INTRODUCTION

The use of proton magnetic resonance shifts relative to benzene in the determination of π-electron densities of aromatic molecules and ions is by now well known (1–8). The presence of a heteroatom in the aromatic nucleus complicates the derivation of an electron density from the proton shift relative to benzene. For instance, in the case of pyridine, a low energy n–π^* transition causes a large low-field shift of the nitrogen resonance (9) as well as of the ortho proton resonance. Gil and Murrell (10) have very recently had considerable success in calculating the magnitude of these low-field shifts. In addition, they take into account the magnetic anisotropy contribution from the nitrogen to the proton shifts. They also estimate the effect on the proton shifts of the electric field from the lone pair on the nitrogen. The net result of these corrections is reasonable agreement of the corrected shifts with π-electron densities calculated by the V.E.S.C.F. method (11).

In the case of an ion, the simple linear relation (3) between the excess charge Δq on the carbon and the shift relative to benzene of the bonded proton $\Delta\sigma$, $\Delta\sigma = k\Delta q$, is perhaps a poor approximation (4, 7, 10, 12). In such a case, it is probably preferable to take into account the field from neighboring charges and to include a term in the square of the field arising from these charges (7, 12). Gil and Murrell (10) remark that this procedure results in poor agreement of the calculated π-densities (11) with experimental shifts (5) for the pyridinium cation. They surmise that the counterion is involved.

We shall present experimental evidence that this is indeed the case. Calculations based on various models involving the counterion suggest that the counterion is very important in determining the measured proton shifts. In this way we can understand why the shifts predicted by the π-densities calculated for an isolated pyridinium cation (11) do not fall in the same order as the experimental ones (5). The presence of the counterion appears to reduce the polarization of the π-cloud considerably, as might be expected.

EXPERIMENTAL

(a) Preparation and Measurements

Pyridine hydrochloride, hydrobromide, and hydriodide were prepared by standard methods (13, 14). Because they are very hygroscopic they were kept in a desiccator. Their solubility in nonpolar solvents is very low and therefore proton magnetic resonance spectra were taken on 3 mole % solutions, whenever possible, in methylene chloride, acetonitrile, nitromethane, and formic acid. In some cases (see Table I)

TABLE I

Proton shifts in p.p.m. to low field from internal benzene for pyridine hydrohalides in four solvents

Salt	Concentration (Mole %)	Solvent	$\epsilon(25°)$*	$\Delta\sigma_{N—H^+}$	$\Delta\sigma_o$	$\Delta\sigma_m$	$\Delta\sigma_p$

the solubility was considerably less than 3 mole %, in which case saturated solutions were used. The spectra were taken on a Varian DP-60 spectrometer and were calibrated relative to internal benzene.

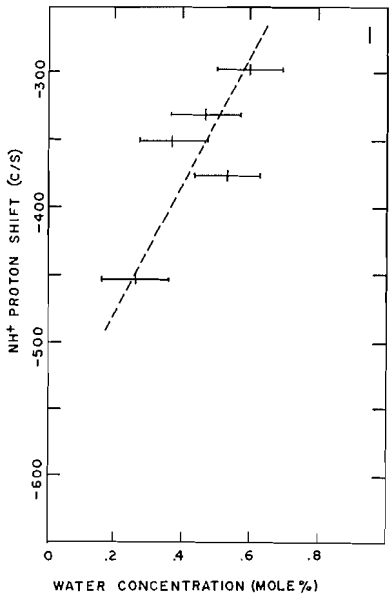
The solvents were spectro grade and only formic acid was further purified. It was purified very thoroughly (15), and its dielectric constant was 65 as compared to $\approx$ 80 for the unpurified formic acid which contains some water. However, the proton spectra, including the $N—H^+$ proton spectrum, did not differ noticeably in the two cases.

(b) Determination of Shifts from Spectra

A proper analysis of the C—H proton spectra implies an A_2B_2C approach (16), not really feasible in our case. However, the shift between protons ortho to one another was not less than 0.5 p.p.m. An ortho coupling constant of about 8 c/s and much smaller meta and para constants (17) would therefore mean a reasonable approach to a first-order spectrum. We therefore determined the centers of gravity of the multiplets arising from the three types of protons and took these to be the shifts. In Fig. 2 a typical spectrum is shown and estimated shifts are indicated. We think that in this way the error in the shifts was reduced to 1 or perhaps 2 c/s. It is almost certain that the error introduced by this method of analysis is less than 0.03 p.p.m. For our purposes this is quite sufficient.

(c) The Effect of Water in Solvents

Experiments were done to determine the effect of water on the proton spectrum of the hydrochloride in methylene chloride. The C—H proton shifts were not much affected but the $N—H^+$ proton shifts were strongly shifted (the solubility of water in CH_2Cl_2 at room temperature is roughly 0.6 mole %, as determined by comparing the ^{13}C sideband intensities from the solvent with that of the water peak). In Fig. 1 a plot of the $N—H^+$ proton shift relative to internal benzene is given as a function of water concentration. Rapid exchange with water no doubt causes these shifts. Although we tried a number of techniques, we found none of them reliable in the determination of a really good value for the $N—H^+$ proton shift in the absence of water. This problem is not insoluble, of course. However, because the $N—H^+$ proton shift depends strongly on the counterion (see results) and because of ion-pair formation by hydrogen bonding (see discussion), we do not pursue this aspect further here. We are chiefly interested here in the C—H proton shifts, which are *not* sensitive to small amounts of water.



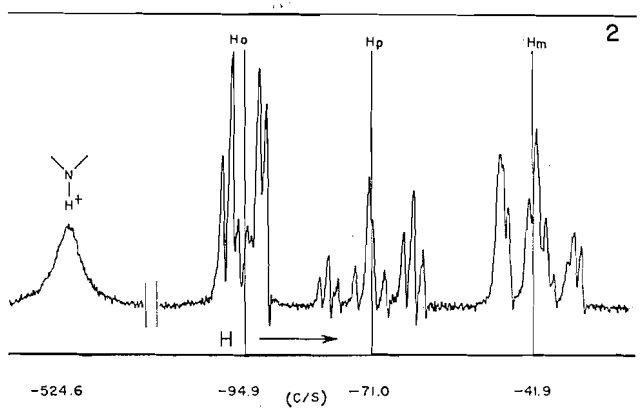


FIG. 1. A plot of the N—H+ proton shift relative to internal benzene of pyridine hydrochloride in methylene chloride as a function of water concentration, c/s at 60 Mc/s. Note the large uncertainty in the water concentration.

FIG. 2. The proton resonance spectrum of a saturated solution (< 3 mole %) of pyridine hydrochloride in methylene chloride. The calibration is in c/s at 60 Mc/s to low field of internal benzene. The vertical lines indicate the estimated shifts of the C—H protons.

RESULTS

In Table I the proton shifts of the ring protons are given relative to internal benzene. The average of all the C—H proton shifts is $\Delta\sigma_o = -1.53 \pm 0.13$, $\Delta\sigma_m = -0.78 \pm 0.13$, $\Delta\sigma_p = -1.30 \pm 0.13$, all in p.p.m. The value 0.13 p.p.m. is the maximum observed deviation for any salt in any solvent. In any individual case the order is $\Delta\sigma_o < \Delta\sigma_p < \Delta\sigma_m$. We found no rational trend in shift with respect to salt or solvent. Why this might be so is discussed below.

The N—H+ proton shifts are lowest for the hydrochloride and highest for the iodide in solvents other than formic acid. The broad single peaks (see Fig. 2) in these solvents indicate exchange, probably with small amounts of water. In formic acid (pure or impure) the N—H+ resonances for both the hydrochloride and the hydrobromide are triplets with the same shifts relative to benzene. The ^{14}N—H coupling constant is 67.6 ± 0.5 c/s. No N—H+ proton peaks were observed for the hydriodide or for pyridine dissolved in formic acid.

DISCUSSION

Before discussing the detailed calculations involving the counterion, we consider secondary contributions to the C—H proton shifts. The N—H+ proton shifts are discussed last.

(A) Secondary Contributions to the C—H Shifts

Since we measure our shifts relative to benzene, the replacement of a C—H by the N—H+ entity introduces a magnetic anisotropy contribution to the shifts. According to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Gil and Murrell (10) this amounts to not more than +0.03 p.p.m. at any position, small enough to be within our experimental error.

The low energy transition from the lone-pair orbital to the lowest vacant π-antibonding orbital lies at about 4.5 eV (18). It is no longer present in the protonated ion and this accounts for the small, low-field shift of the ortho proton signal on protonation relative to that of the meta and para protons (10). We will therefore ignore any contributions from this source, since the new $\sigma-\pi^*$ transition will be close to that for benzene and probably not lower than about 8 eV.

The proton shifts in Table I show no clear trend with dielectric constant of the solvent. Thus acetonitrile and nitromethane have the same dielectric constant and according to the reaction field theory (19, 20) the shifts should be the same in the two solvents (at least for the same salt). A plot of the shifts versus the dielectric function given by Buckingham (20) shows that some other effect masks the expected behavior.* It appears that the main function of the solvent, from our viewpoint, is as solvating agent for the counterion. If it forms a bulky solvated complex either with the counterion or with the pyridinium ion, thus removing the counterion sufficiently far from the cation, the effect on the proton shifts will be much larger than any reaction field shifts. The latter would not be expected to be larger than about 10% of the observed shifts. We will not consider them further.

(B) Ion-Pair Formation: Evidence from Other Work

Lord and Merrifield (21) found a shift of many hundreds of cm^{-1} in the N—H stretching frequency of solid pyridinium hydrochloride. This shift persists in solution and the stretching frequency itself is highly anharmonic. They attribute this to a very strong hydrogen bond interaction, perhaps even of a covalent character, of the $N—H^+$ entity with the counterion. For us it is important that the large shift is present also in solution, indicating ion-pair formation. Somewhat similar conclusions are reached by Chenon and Sandorfy (13) and by Spinner (22). Cook's infrared studies (22*a*) on the solid hydrohalides indicate a strong interaction between the $N—H^+$ hydrogen and the anion. The interaction is somewhat less for the hydriodide than for the hydrochloride but still very strong compared to the free state.

Rérat (23) has determined the crystal structure of the salt. The N—Cl distance is 2.95 Å, considerably less than the sum of the van der Waals' radii of 3.3 Å. The chloride ion lies 0.14 Å out of the plane of the ring. Together with the infrared data it seems probable that a solution model involving a counterion situated in the plane of the ring along the $N—H^+$ direction is reasonable.

The proton resonance measurements of Fraenkel (24) on solutions of anilinium salts strongly suggest ion-pair formation with, however, rapid exchange of counterions between pairs. If the time taken for transfer is very small on an n.m.r. time scale, as is usually assumed in rate studies (25), then the model mentioned above is still a good one. Reynolds and Schaefer (26) found that a similar ion-pair model predicted shifts of the ring protons of the anilinium ion in trifluoroacetic acid in reasonable agreement with experiment. We take these results as additional evidence in favor of ion-pair formation in our solutions.

There is evidence from electron spin resonance (e.s.r.) of aromatic ions in favor of ion-pair formation (27, 28).† Even at concentrations as low as 10^{-4} *M*, hydrocarbon anions form ion-pairs with alkali metal cations in solvents like acetonitrile or dimethoxyethane (28). Small cations like Li^+ or Na^+ are, however, highly solvated so that the effective

Also, for reasons of solubility, we could not use a solvent of very low dielectric constant, so that the range of values of the dielectric function is very small.

†*Reference 28 gives a good discussion of this evidence.*

For personal use only.

counterion is a "bulky solvent complex which perturbs the state of the anion less strongly than the more weakly solvated larger cations like K^+" (28).† This conclusion does not apply to radical anions with functional groups, such as nitrobenzene anions, which appear to form stable complexes with the smaller counterions at the site of the functional group (29). In view of our much higher concentrations, the e.s.r. data support the assumption of ion-pair formation at the site of the N—H^+ group in our solutions.

Conductivity and ultraviolet spectra of solutions of aromatic hydrocarbon anions indicate one-to-one ion pairs between anion and alkali metal cation in ether solvents (30). The larger the radius of the counterion the smaller is the stability of the ion pair.

(C) The Counterion Models

a. The Various Models

We have considered a number of somewhat different models involving the counterion. The results of the calculations are given in Table II.

TABLE II

Average observed shifts (in p.p.m. to low field from internal benzene) and calculated shifts for the C—H proton in solutions of pyridine hydrohalides

*The shifts are calculated for the different models described in the text.

(1) This model uses the average of the four sets of π-electron densities calculated by the V.E.S.C.F. method (11) which are $\Delta q_o = -0.051$, $\Delta q_m = -0.097$, $\Delta q_p = -0.176$, and $\Delta q_N = 0.473$. The effect of the polar N—H^+ sigma bond is ignored. The counterion, approximated by a point charge of $\Delta q = 1.00$, is placed at various distances along the N—H^+ direction in the plane of the ring.

(2) This model differs from the first only in that it takes the N—H^+ bond into account by considering the additional contribution from a single positive charge of one electron unit placed (*a*) at the N—H^+ proton and (*b*) 0.34 Å along this bond from the proton.

(3) This model assumes that the π-electron density is unity on all the ring atoms. Otherwise it is the same as the second but the positive charge is placed (*a*) at the N—H^+ proton and (*b*) 0.515 Å (halfway) along the N—H^+ bond.

(4) Here we assume much smaller charges on the ring carbons arising from polarization of the π-electrons. These are $\Delta q_o = -0.01$, $\Delta q_m = -0.02$, $\Delta q_p = -0.05$, and $\Delta q_N = 0.11$.

†*It is probably for this reason that the proton shifts in the cyclopentadienyl, fluorenyl, indenyl, and other ions gave good agreement with the calculated π-electron densities in ref. 3. The counterions were* Li^+ *or* Na^+.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

They run in the same order as those calculated for the isolated cation (11). It seems probable that the counterion will affect such a reduction in polarization. The positive charge is placed (*a*) at the N—H^+ proton and (*b*) 0.515 Å along the bond.

b. The Electric Field Calculations

We include the fields from the charges on all the atoms including the counterion on the shift of a particular C—H proton. We use the equation

$$\Delta\sigma \text{ (p.p.m.)} = 12.5 \times 10^{-6} \sum_i [(\Delta q_i \cos\theta_i)/R_i^2] - 17.0 \times 10^{-6}(\sum_i \Delta q_i/R_i^2)^2,$$

where Δq_i is the excess electron density at atom i, R_i is the distance in Å from that atom to the proton in question, and θ_i is the angle of the field vector with respect to the C—H bond axis. This equation was used by Schweizer *et al.* (7) and is obtained from the usual expression (20) for field calculations, $\Delta\sigma = -aE_z - bE^2$. The value of a is 2.60×10^{-12}, between the values of 2.0×10^{-12} suggested by Buckingham (20) and 2.9×10^{-12} found by Musher (12). Musher's value for b, as calculated by Marshall and Pople (31), was used.

The geometry of the pyridinium ion was taken as a regular hexagon with bond lengths of 1.39 Å and a C—H bond length of 1.08 Å. The N—H^+ bond length was taken as 1.03 Å, the same as in the ammonium ion (32, 33). The crystal structure data (23) indicate a distorted hexagon but their use would result in relatively small changes in calculated shifts, well within the approximations inherent in our models.

No doubt the interaction of the halide ion with the cation varies from ion to ion and from solvent to solvent. Our simple models cannot take this variation into account, except as a variation of the N—H^+. . .X^- distance. To a first approximation we therefore consider only the averages of the observed shifts. The calculated shifts are given in Table II.

c. Comparison of Observed and Calculated Shifts

From Table II it is clear that no model which assumes the V.E.S.C.F. π-densities of the free cation reproduces correctly the order of the observed shifts for the ortho, meta, and para protons (models 1, 2*a*, 2*b*). This is true also for the models (3*a*, 3*b*) which assume unit π-densities on the ring atoms. The models (4*a*, 4*b*) which assume a much lower polarization of the π-electrons do reproduce the observed order of the shifts. Only a slight adjustment of the π-electron densities, of the order of 0.01 units, together with a small shift of the positive charge along the N—H^+ bond would clearly produce complete agreement with observation for any counterion distance. Although the observed order is also predicted in the absence of the counterion, it would be hard to account for the reduced polarization of the π-electrons in that case. The agreement also depends on the positive charge in the N—H^+ sigma bond. Our model takes it into account in an admittedly naive way. Together with the other evidence discussed above, we feel that we have a fairly reasonable case for ion-pair formation in our solutions. We do not think that a refinement of our crude model would be very useful at present in accounting for the details of the shifts of individual salts in different solvents

(D) The N—H^+ Proton Shifts

We can make no definite statement about the isolated N—H^+ proton shift, of course, since it is affected by the field from the counterion and also by traces of water. Furthermore, the inclusion of a point positive charge very close to this proton in our models make them useless in calculating its shift. In the solvents other than formic acid the order of shifts (Table I) can be rationalized if one assumes incipient bond formation between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the proton and the halide ion. Thus HI has the highest proton shielding of the hydrogen halides due to magnetic anisotropy (34). The hydrochloride was the most hygroscopic of the three and if the shift had been completely determined by exchange with traces of water, the opposite order of N—H^+ shifts would have been expected.

In formic acid it appears that the shift is characteristic of the solvent, i.e. N—H^+. . .O instead of N—H^+. . X^-, where X^- is a halide ion. Chenon and Sandorfy (13) reached a similar conclusion from their infrared studies of these salts in water. The very similar shifts of the C—H protons for the three salts and pyridine in formic acid support this suggestion. However, we do not know why there is no proton exchange in the hydrochloride and hydrobromide, while for the hydriodide and pyridine no signal was observed at all. These matters merit further study.

CONCLUSIONS

Solutions of pyridine hydrohalides in methylene chloride, acetonitrile, and nitromethane contain hydrogen-bonded ion pairs. The presence of the counterion reduces considerably the π-electron polarization calculated for the isolated pyridinium ion. Models which take into account the effect of the counterion, the positive charge in the N—H^+ sigma bond, as well as the π-densities account for the observed order of the C—H proton shifts. In formic acid the shifts appear to be characteristic of a complex involving the solvent rather than the halide ion. The N—H^+ proton shifts are very sensitive to the solvent, counterion, and traces of water. In formic acid the N—H^+ protons do not exchange in the case of the hydrochloride and hydrobromide and the ^{14}N—H^+ coupling constant is 67.6 ± 0.5 c/s.

ACKNOWLEDGMENTS

We are grateful to B. Blackburn for a sample of pyridine hydrobromide. J. M. T. M. Gieskes kindly determined some dielectric constants. The financial support of the National Research Council is deeply appreciated.

THE PRINCIPAL CONFORMATIONS OF SOME ORTHO-SUBSTITUTED DIPHENYL ETHERS[1]

W. D. CHANDLER, W. MACFARLANE SMITH, AND R. Y. MOIR
Department of Chemistry, Queen's University, Kingston, Ontario

Received July 13, 1964

ABSTRACT

A study of the nuclear magnetic resonance, infrared, and ultraviolet spectra showed that some doubly and triply ortho-substituted diphenyl ethers adopt, principally but not exclusively, the "H-inside" conformation, while the quadruply ortho-substituted 7-(4′-carbomethoxy-2′,6′-dinitrophenoxy)metameconine (V) adopts the "methoxy-inside" conformation. Interconversion of conformational isomers is extremely fast. Reduction of methyl 4-methoxy-3-nitrobenzoate with tin and hydrochloric acid gave methyl 3-amino-2-chloro-4-methoxybenzoate.

It has been well established[2] that the principal conformations of diphenyl ethers, in solution or in the gas phase, are asymmetric (Fig. 1),[3] one ring being in the C—O—C plane and able to accommodate the ethereal oxygen's p-electrons, the other ring lying in a plane approximately perpendicular to the first so that resonance with the ethereal oxygen is small or negligible.

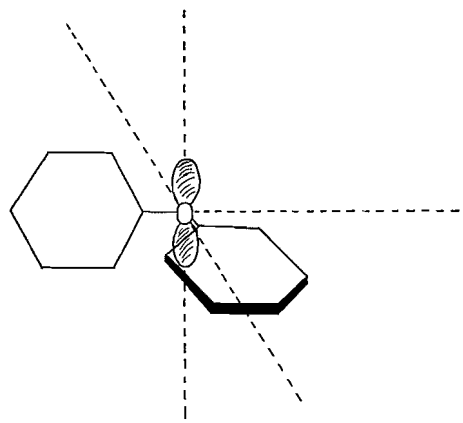

FIG. 1. Asymmetric diphenyl ether conformation.

Allen and Moir (17) pointed out that eight such conformations exist for a diphenyl ether bearing four different ortho-substituents, and that these conformations can be divided into two classes of four each. The members of each class are interconvertible by synchronous rotations which do not require ortho-groups to be forced past each other,

[1]*Most of the material of this paper was presented at the national meeting of the Chemical Institute of Canada, Toronto, June 8, 1963.*

[2]*The asymmetry of ethers of low steric hindrance has been shown by ultraviolet spectroscopy (1–3), dipole moments (4–7), electron and X-ray diffraction (8–10), microwave absorption, and relaxation times (11–14), and from theoretical calculations of ultraviolet spectra (15). For highly hindered diphenyl ethers, the fact has been assumed from a study of models (2, 16–18).*

[3]*For convenience and clarity, an unshared pair is represented as essentially in a p-orbital, the planes of the rings at right angles, and the* C—O—C *valence angle as near 90°. It will be understood that these are intended only as rough approximations suitable to the present qualitative discussion. Because the figure does not display the easy increase in the oxygen valence angle, some of the conclusions of the paper seem more obvious, a priori, than is justified.*

but a member of one class can be converted to a member of the other only by surmounting this barrier. (The same idea of synchronous rotation had been developed in considerable detail for diphenyl ether itself by Calderwood and Smyth (11), who used it to explain the abnormally low relaxation time of diphenyl ether in the absorption of microwaves.) It is the object of this paper to show which of the eight conformations are occupied preferentially. Since the eight conformations are divided into pairs of mirror images, and since in a symmetrical environment mirror-image conformations will be equally occupied (18), it is enough to distinguish among the four conformations[4] of a single class.

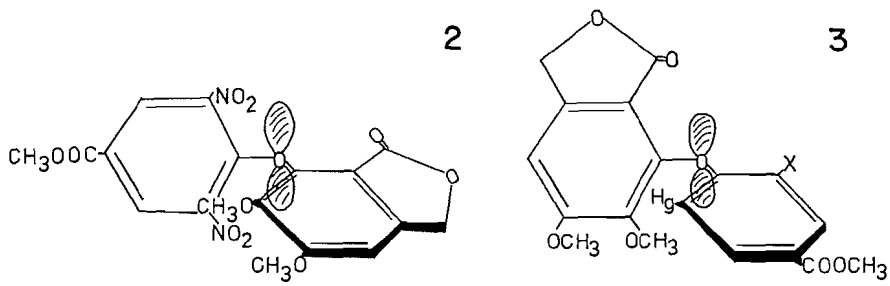

FIG. 2. "Methoxy-inside" conformation (V as example).
FIG. 3. "Hydrogen-inside" conformation (typical of I–IV).

The problem could be broken into two parts: to show (*i*) which ring lies in the C—O—C plane, and (*ii*) which ortho-substituent of this ring occupies the "inside" position (Figs. 1, 2, 3). Mangini and Passerini (1) were able to solve the first problem for some diphenyl sulphides by ultraviolet spectroscopy; the substances gave spectra typical of two almost independent chromophores, and the ring which included the sulphur in its chromophore must have been in the C—S—C plane. It will be shown later that this method can lead to erroneous conclusions if not carefully handled. The second problem does not seem to have been attempted previously. Our method is the straightforward one of comparing the proton magnetic resonance (n.m.r.), infrared, and ultraviolet spectra of a series of highly hindered diphenyl ethers with each other and with the spectra of the corresponding anisoles formed by replacing one or other of the phenyl groups with a methyl group.

Evidence from the N.M.R. Spectra

Although several factors determine the chemical shifts of aromatic protons, the relative shifts of H_a in a series such as I–VII depend mainly on inductive and resonance effects. Thus the electron-donating methoxy group would be expected to cause H_a to be more shielded in VI than in VII. The replacement of the 7-methoxy group in VI by aryloxy groups could have two opposite effects. (1) There would be a deshielding of H_a (relative to its environment in VI) by an increased inductive withdrawal of electrons which would become greater as the groups X and Y (in I–V) became more electronegative. The effect would be especially large if the lower ring were approximately in the plane of the C—O—C bonds. (2) A mesomeric electron donation, which would tend to offset the deshielding noted in (1), would occur if the upper ring were in the plane of the C—O—C bonds. The observed effects are noted in the second column of Table I. The shielding induced by the presence of methoxy at position-7 (VI), the lesser shielding by aryloxy groups in that

[4]*Each conformation is conveniently named by the ortho-group which occupies the "inside" position in that conformation (e.g. methoxy in Fig. 2, hydrogen in Fig. 3).*

position (I–IV), and the uniformly declining shielding of H_a as the electronegativity of the groups X and Y increases, all are exactly as expected in the sequences I–IV and VI–VIII. However, there is a sharply increased shielding of H_a in going from IV to V, in

[5]*The assignment of the methoxy peaks was based on (a) their expected relative positions, and (b) the expected effects of changes in the group at position-7 and position-4, an ortho-methoxy being affected much more than a meta-methoxy. To some extent the conclusions have been checked with ethoxy analogues of substituted metameconines (7-ethoxymetameconine, 7-chloro-6-ethoxy-5-methoxyphthalide).*

[6]*These splittings of the phthalide hydrogens by a hydrogen ortho to them formed part of the evidence for the assignment of the configuration to the phthalide–isoquinoline alkaloids (19).*

spite of the much greater electron withdrawal of the groups in the latter. This can only mean that in V the two conformations corresponding to Fig. 2 are much more important than they are in I–IV or in VIII. In all these others, the two conformations corresponding to Fig. 3 must be more important than in V. It is most striking that the (inductively) electron-withdrawing aryloxy group produces almost the same shielding of H_a as does the methoxy group of VI.[7]

This argument cannot decide between the "methoxy-inside" conformation of Fig. 2 and the "carbonyl-inside" conformation for compound V. That the conformation of Fig. 2 is at least very important, and probably dominant,[7] is shown by an examination of the last column of Table I, where it is seen that the methoxy hydrogens H_d are much more shielded in V than in the other compounds, even though V possesses the most electron-withdrawing groups. Such shielding can only be due to the incursion of the methoxy into the shielding region of the other benzene ring (19–21). Since the effect is large,[7] the occupancy of the conformation of Fig. 2 must also be large in compound V, relative to that for the other compounds.[7]

A consideration of the chemical shifts of the hydrogens on the lower ring confirms and extends the previous conclusions. Examination of Figs. 4–9[8] shows that, except for compound I*a*, assignment of lines can be made by inspection, the ortho-coupling constants being much larger than the meta-coupling constants, and the para-coupling constants being unresolved. It will be seen that the signal for H_g in the triply ortho-substituted diphenyl ethers I, III, IV, and VIII lies at higher field by 16–23 c.p.s. than in the corresponding anisoles (I*a*, III*a*, IV*a*, and VIII*a*, respectively), the signal for H_f at higher field by 8–11 c.p.s., and the signal for H_e at lower field by 4–12 c.p.s. This variation for H_g and H_f is in a direction opposite to that actually observed for H_e (or for H_a in a similar situation in the upper ring). The increase in shielding of H_g and H_f can only be due to shielding by the other ring and the conformation of Fig. 3 must be important for these compounds.

The climax of our argument comes with the examination of the spectra of II and II*a* (Fig. 8). In the first place, the simple A_2B_2 pattern from II shows that the two "H-inside" conformations are exchanged at such a rate as to give each an average lifetime much shorter than the average lifetime of the proton spin states. In the second place, H_k is slightly less shielded in II than in the corresponding anisole II*a*; shielding by the other ring is not quite sufficient to compensate for inductive withdrawal, even though this is less than in III, IV, and VIII. Since the two "H-inside" states must be equally populated in II, the extra shielding of H_g in I, III, IV, and VIII shows that the "H_g-inside" conformation must be occupied much more than the "nitro-inside" conformation, and must be the dominant conformation.

The equivalence of the hydrogens H_e and H_f in V is less illuminating, since it could be due either to a predominantly "methoxy-inside" conformation (Fig. 2) or to a rapid averaging of the two "nitro-inside" conformations.

[7]*The fact that compounds I–IV, and VIII, have* H_a *either more shielded than, or about as shielded as, in metameconine (VII), and the fact that* H_d *is more shielded in them than in methoxymetameconine (VI), in spite of the electrical character of the lower rings, presumably mean that in them the conformation corresponding to Fig. 2 also must be occupied an appreciable part of the time, though much less than in V. In principle, the relative occupancies are calculable from both effects. This is now being attempted with more favorable examples.*

[8]*In all the spectra, except that for Ia, the lines reproduce the center and the approximate amplitude of the observed peaks. The spectrum for Ia is the result of an ABX calculation which agreed very closely indeed with the observed spectrum. ABX calculations were done for a few other compounds as well, but except for Ia, the changes incurred in band positions with respect to simple inspection were negligible.*

Evidence from Infrared Spectra

A plot of the stretching frequency of the phthalide carbonyl vs. the sum of the Hammett parameters σ_m for the ortho-groups of the lower ring of I, II, III, IV, and V (Fig. 10) shows a linear[10] variation for the first four ethers, but a sharp variation from the line for the fifth. The latter has a frequency lower than IV although it contains an extra nitro group. This evidence strongly indicates that the principal conformation of V must be that of Fig. 2, where the inductive effect is strongly opposed by electron donation from the ether oxygen to the carbonyl. Similarly, the high value of the asymmetric nitro stretching frequency (Table III), both for the quadruply ortho-substituted diphenyl ether V and the corresponding anisole V*a*, shows that in neither compound is the (lower) benzene ring coplanar with the C—O—C bond under study (Fig. 2). The lower values for IV and IV*a* are in agreement with the greater opportunities for resonance in the conformation similar to that of Fig. 3. The values for VIII and VIII*a*, though presumably they refer to the para-nitro group, also correspond to considerable resonance between the lower ring and the oxygen under study (Fig. 3).

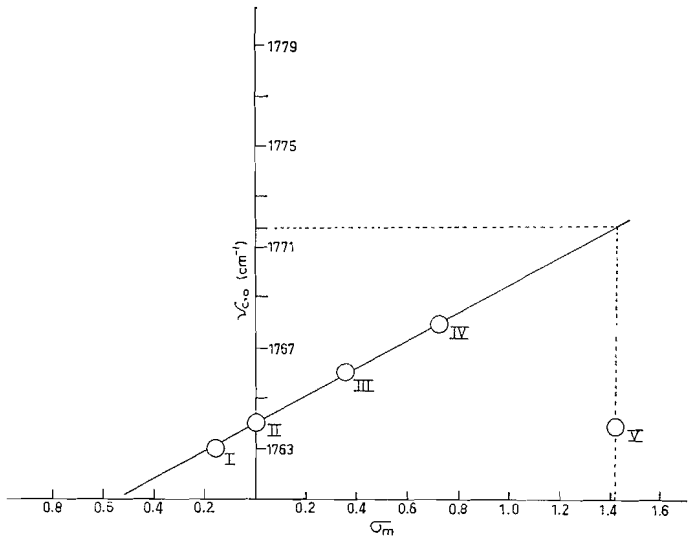

FIG. 10. Lactone carbonyl absorption vs. σ_m of ortho-substituent on other ring.

TABLE III

Asymmetric nitro absorption frequencies

Compound*	Frequency (cm^{-1})
V	1551
V*a*	1550
IV	1541
IV*a*	1539
VIII	1540†
VIII*a*	1531†

*In chloroform solution.
†With shoulder on the high-frequency side.

[10]*The linear variation is good evidence that the steric effects are the same in the four ethers concerned. The conformation of Fig. 3 also is strongly suggested, since otherwise the varying sizes of the ortho-groups would have a noticeable effect. However, it can be shown that the choice of σ_m, rather than some other, is not significant.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

The single sharp peak for the asymmetric nitro stretching vibration of V is noteworthy inasmuch as it is to be expected for the "methoxy-inside" conformation (Fig. 2), but would be surprising in the "nitro-inside" conformation because of the extremely short average lifetimes of vibration states. Conclusions from the ester carbonyl stretching frequency merely confirmed those made from the n.m.r. frequencies of the ester methyl.

Relation to the Ultraviolet Spectra

According to the method used by Mangini and Passerini (1) for diphenyl sulphides, the configuration of Fig. 2 (V) might be expected to show ultraviolet absorption approximately the same as the sum of the absorptions of methoxymetameconine (VI) and methyl 3,5-dinitrobenzoate, whereas the configuration of Fig. 3 should absorb the same as the sum of the absorptions of metameconine (VII) and the anisole corresponding to the other ring. In Figs. 11–16 are shown the absorption of several diphenyl ethers, together with the

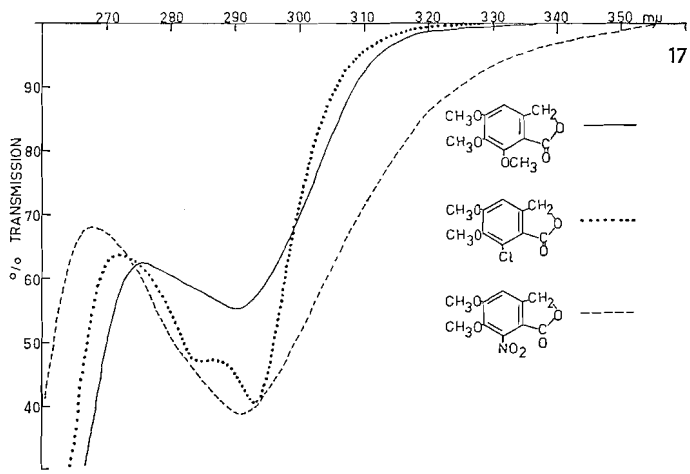

FIGS. 11–17. Ultraviolet spectra of diphenyl ethers and of corresponding anisoles. Concentrations are 1.00×10^{-4} *M* in CCl_4.

spectrum of a solution of a mixture of the two anisoles corresponding to the parts of the diphenyl ethers; each anisole is at the same molarity as its related diphenyl ether. It is at once evident that caution must be used in interpreting the curves. The absorption of each diphenyl ether is similar to, but greater than, the sum of the absorption of its two related anisoles, and therefore much greater than the absorption of the related anisole plus phenyl derivative considered by Mangini and Passerini. A first (naive) conclusion would be that the central ethereal oxygen is capable of resonance with both rings at once. The corrective to this conclusion is supplied by Fig. 17, where it is seen that an increasingly electron-withdrawing group at position-7 of metameconine results in an increasingly intense absorption. Therefore, the diphenyl ethers I–IV, and VIII, probably are acting simply as the summation spectra of the corresponding anisoles (I*a*–IV*a*, and VIII*a*, respectively) plus a metameconine substituted at position-7 with a group rather more electron-withdrawing than the methoxy group. In fact, the summation curve of IV*a* and either 7-nitrometameconine or 7-acetaminometameconine was found to be very close to that of the diphenyl ether IV. These results are therefore in agreement with the conformation of Fig. 3. We have not managed to obtain suitable monomers for comparison with V (expected to have the other configuration of Fig. 2), but at least it does differ empirically from all the other diphenyl ethers studied in the enormous difference in the long-wave absorption between the diphenyl ether (V) and its two related anisoles (VI and V*a*).

The practical utility of the determination of the principal conformations of diphenyl ethers was made apparent almost immediately by its use in the discovery of a new rearrangement reaction in the diphenyl ether series, and by the application of the method, based on the present work, to the determination of conformation and configuration in the phthalide–isoquinoline alkaloids (19). The present work is continuing in attempts to relate quantitatively the temperature, solvent, and the size and nature of the substituents to the principal variables of the system: the magnitude and area of the shielding current loops, the magnitude of the oxygen valence angle, and the percentage occupancy of each major conformation.

EXPERIMENTAL

Melting points below 215° were determined in a precision capillary apparatus; higher melting points were determined on a Kofler micro hot stage, and are uncorrected.

Solvents of spectral or analytical grade were used for ultraviolet and infrared spectroscopy. Ultraviolet spectra were determined on a Beckman model DK-1 recording spectrophotometer; calibration of the instrument with benzene (A.C.S. grade, 0.00788 *M* in heptane) showed that the corrections required were negligible (22). All spectra were obtained on solutions 1.00×10^{-4} *M* in carbon tetrachloride.

Infrared spectra were determined on a Perkin–Elmer model 21 spectrophotometer repeatedly calibrated with a polystyrene standard (23). With care, results were reproducible within 1 cm^{-1}. Spectra were determined on solutions in chloroform containing 6% of the substance investigated (w/v).

The n.m.r. spectra were determined on the Varian A-60 spectrometer at 60 Mc.p.s. At the end of the work, the same sweep width used to determine the reported frequencies was calibrated by a sideband method; the largest error was about 2 c.p.s. and was exceptional. The reproducibility of spectra taken several weeks apart ensured the stability of the calibration. Spectra for I*a*–VIII*a*, VI, and VII were determined on 75 mg of sample in 0.5 ml of chloroform or deuterochloroform. Minor variations in concentration were unimportant, as shown; IV*a* gave identical spectra in concentrations of 75 mg/0.5 ml and 30 mg/0.5 ml. The spectra of compounds II–V and VIII were determined using a concentration of 50 mg/0.5 ml chloroform or deuterochloroform. However, I, because of its low solubility, would dissolve only at a concentration of 20 mg/0.5 ml.

A few substances, mentioned in the introduction but not in the sections below, were available as analytical samples from previous work (16–18, 24).

The following substances were made by treatment of the appropriate phenol with ethereal diazomethane (the melting point after purification is also given): methyl 4-methoxybenzoate (II*a*) (25), 47.7–48.5°; methyl 4-methoxy-3-nitrobenzoate (IV*a*) (26), 109.1–109.4°; methyl 3,5-dinitro-4-methoxybenzoate (V*a*) (27, 28), 53.6–54.2°; 2,4-dinitroanisole (VIII*a*) (29), 87.2–88.1°.

Methyl 3-Amino-4-methoxybenzoate (Ia)

Methyl 4-methoxy-3-nitrobenzoate (IV*a*) (3.0 g, m.p. 107.5–108.5°) was covered with ethanol (95%, 150 ml) and water (100 ml) and stirred while amalgamated aluminium foil (10 pieces, 2 × 1 in.) was added. After 5–6 h, the heavy sludge was removed, the filtrate concentrated by evaporation, and then diluted with water to give needles, m.p. 69.3–69.6°, in a yield of 1.29 g. The needles were purified by solution in dilute hydrochloric acid and by reprecipitation with ammonia, and then by four recrystallizations from ligroin, to give the analytical sample, m.p. 70.1–70.8°, slightly yellow needles. The infrared spectrum showed the presence of N—H stretching bands and the absence of nitro-group stretching bands. The melting point differed considerably from the literature value of 85–86° (26).

Calcd. for $C_9H_{11}O_3N$: C, 59.66; H, 6.12; N, 7.73. Found: C, 59.71, 59.77; H, 6.06, 6.05; N, 7.66, 7.67.

Attempts to reduce the nitro ester with iron and acetic acid failed, though this reduction system worked well for the corresponding diphenyl ether (IV). Reduction of 4-hydroxy-3-nitrobenzoic acid with aluminium amalgam also failed. The course of reduction of IV*a* with tin and hydrochloric acid was unusual, as shown in the next section.

Methyl 3-Amino-2-chloro-4-methoxybenzoate

Methyl 4-methoxy-3-nitrobenzoate (IV*a*) (2.0 g, m.p. 107.5–108.5°) was stirred with concentrated hydrochloric acid (25 ml) and aqueous ethanol (5 ml) while mossy tin (six pieces the size of a pea) was added. Heat was applied until a green solution resulted. The solution was cooled, neutralized with aqueous sodium hydroxide (30%), and the heavy white precipitate (0.66 g) was collected. Two crystallizations from ligroin (the material insoluble in hot ligroin being discarded) gave the analytical sample, obtained as white plates, m.p. 91.7–92.2°. (Recrystallization from dilute ethanol gave needles.) The infrared spectrum showed two bands of medium intensity in the N—H stretching region, and the orientation of the compound followed from the n.m.r. spectrum, which showed an aromatic AB pattern with a coupling constant (8.4 c.p.s.) characteristic of ortho-protons.

Calcd. for $C_9H_{10}O_3NCl$: C, 50.13; H, 4.67; N, 6.50. Found: C, 50.30, 50.38; H, 4.84, 4.74; N, 6.32, 6.26.

Methyl 3-Iodo-4-methoxybenzoate (IIIa)

This compound was difficult to obtain. The iodination of methyl 4-hydroxybenzoate in aqueous potassium hydroxide and potassium iodide gave only the free acid corresponding to the starting material. Iodination of 4-hydroxybenzoic acid in ethanol with mercuric oxide and iodine by the method of Brenans and Prost (30) failed to give a recognizable product. Reduction of 3,5-diiodo-4-hydroxybenzoic acid with triphenylphosphine in boiling xylene (31), or with iron and acetic acid, gave only starting material. Small yields of 4-hydroxy-3-iodobenzoic acid were obtained by the reduction of the 3,5-diiodo-acid with zinc and aqueous sodium hydroxide.

Moderate yields of the desired acid were obtained by the method of Sanromá (32). Methyl 4-hydroxybenzoate (6.0 g) was dissolved in aqueous sodium hydroxide (2.85 g in 25 ml of water). Iodine (10.0 g) and sodium peroxide (1.8 g) were added in alternate portions over the course of 4 h, and the mixture kept a further 18 h. The product was then fractionally precipitated with hydrochloric acid, seven fractions being

obtained. The first six were united and recrystallized from a dilute aqueous solution of sodium bisulphite. The material insoluble in the hot solution was mainly the diido acid, while the cooled filtrate deposited crude 4-hydroxy-3-iodobenzoic acid, m.p. 160–175° (uncorrected), which gave a typical aromatic ABC pattern in the n.m.r. spectrum. (The seventh fraction seemed to be mainly 4-hydroxybenzoic acid.) The crude monoiodo acid was methylated with ethereal diazomethane and the product recrystallized once from ligroin, once from methanol, and once from absolute ethanol to give a fluffy white product, m.p. 94.6–95.2°. The lit. value (33) is 94–95°. Its aromatic spectrum showed a typical aromatic ABC pattern and two methoxy resonances; the infrared spectrum showed no bands due to hydroxyl or carboxyl.

7-(4′-Carbomethoxy-2′-nitrophenoxy)metameconine (IV) (16, 17), m.p. 155.6–156.6°, 7-(2′-amino-4′-carbomethoxyphenoxy)metameconine (I) (18), m.p. 197.1–197.8° (with slight softening at 195°), and 7-(4′-carbomethoxy-2′-iodophenoxy)metameconine (III) (18), m.p. 204.2–205.0°, were made as previously described.

4-Carbomethoxy-2-nitrophenyl Toluene-p-sulphonate

This compound, needed in the above syntheses, was made by a method giving a much purer product in better yield than obtained previously (16, 17). Methyl 4-hydroxy-3-nitrobenzoate (15 g) and *p*-toluenesulphonyl chloride (15 g tech.) were shaken with dry pyridine (25 ml) until the mass became almost solid (10–15 min). The solid was washed with water into a beaker containing dilute hydrochloric acid (500 ml) and ice, and the resulting lumps were thoroughly crushed under the acid solution. White crystals were recovered, washed, and dried, and without further purification had a m.p. of 93.4–94.2°, yield 26.65 g (100%).

7-(4′-Carbomethoxyphenoxy)-metameconine (II)

Sodium nitrite (0.124 g) was dissolved with slight heating in concentrated sulphuric acid (2.5 ml); the solution was cooled to 0° and treated with glacial acetic acid (2.5 ml). A second solution was prepared from 7-(2′-amino-4′-carbomethoxyphenoxy)-metameconine (I) (18) (0.5 g) in concentrated sulphuric acid (1.0 ml) and glacial acetic acid (2.5 ml). The second solution was slowly added to the first over a period of 0.5 h, the reaction temperature being kept slightly below 0°. A few milliliters of concentrated sulphuric acid were then added to make the mixture more fluid, and after a further 1.75 h, the mixture was poured onto ice (100 g) to which had been added a small amount of cupric sulphate. Hypophosphorous acid (12 ml, 50%) was added dropwise with stirring. The mixture was kept 42 h in the refrigerator, and the granular precipitate (0.45 g) recovered. Two recrystallizations from dilute ethanol gave yellowish-white crystals, m.p. 195.2–196.1°, more easily purified than those obtained by the previous method (18). The n.m.r. spectrum of the present sample was identical with that of the sample made in the previous work (18).

ACKNOWLEDGMENTS

The work was supported by the National Research Council with a grant and with a Scholarship awarded to one of us. The large amounts of vanillin needed were donated by Dr. G. H. Tomlinson, Howard Smith Paper Company, Cornwall, Ontario.

Received May 26, 1964

ABSTRACT

The discovery that the (benzylthio)carbonyl group is stable in concentrated hydrochloric acid has permitted the removal in that medium of isopropylidene blocking groups from 3-*O*-[(benzylthio)carbonyl]-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose to furnish crystalline 3-*O*-[(benzylthio)carbonyl]-β-D-glucopyranose. Benzoylation of the latter provided a derivative which has made possible the synthesis of methyl 2,4,6-tri-*O*-benzoyl-α and β-D-glucopyranosides.

INTRODUCTION

Two of the four possible anomeric pairs of the tribenzoate derivatives of the methyl glucopyranosides have been known for many years. The use of the specific triphenylmethyl ether group to block the primary (C-6) hydroxyl group permits the syntheses of methyl 2,3,4-tri-*O*-benzoyl-α and β-D-glucopyranosides (1). The 2,3-di-*O*-benzoate of each methyl glucopyranoside, prepared with the aid of the 4,6-*O*-benzylidene blocking group, was specifically benzoylated at C-6 to furnish the 2,3,6-tri-*O*-benzoyl derivatives (2). A recent paper (3) described the synthesis of methyl 2-*O*-[(benzylthio)carbonyl]-α-D-glucopyranoside, which served as a precursor to methyl 3,4,6-tri-*O*-benzoyl-α-D-glucopyranoside, by a specific substitution of the (benzylthio)carbonyl group at C-2 in methyl 4,6-*O*-benzylidene-α-D-glucopyranoside. The thiocarbonate ester, $C_6H_5—CH_2—S—CO—O—$, serves as a useful blocking group for the synthesis of partial esters of carbohydrates due to the ease with which it can be removed without cleavage of other ester groupings (4).

Attempts to duplicate this specific substitution reaction at C-2 with methyl 4,6-*O*-benzylidene-β-D-glucopyranoside resulted in the recovery of disproportionately high yields of the disubstituted product. This method does not serve, therefore, as a practical route to methyl 3,4,6-tri-*O*-benzoyl-β-D-glucopyranoside.

The synthesis of 3-*O*-[(benzylthio)carbonyl]-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose has been described (4). Attempts to remove selectively the isopropylidene groups from this compound by treatment with acid under refluxing conditions resulted also in the hydrolysis of the (benzylthio)carbonyl group. A method of removing the isopropylidene groups has now been found which provides crystalline 3-*O*-[(benzylthio)carbonyl]-β-D-glucopyranose and, ultimately, methyl 2,4,6-tri-*O*-benzoyl-α and β-D-glucopyranosides. Thus, all of the isomeric tribenzoate derivatives of methyl-α-D-glucopyranoside have now been characterized and, in the β-series, only the 3,4,6-isomer remains unknown.

RESULTS AND DISCUSSION

When methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (I) is treated with 1.1 moles of (benzylthio)carbonyl chloride (II) in pyridine solution, a 58% yield of the pure 2-*O*-

[1]*To whom inquiries should be directed. Present address: Textile Research Institute, Princeton, New Jersey, U.S.A.*
[2]*Present address: Chemistry Department, The University, Edgbaston, Birmingham 15, England.*

[(benzylthio)carbonyl] derivative of I is obtained, together with 10% of the 2,3-di-*O*-[(benzylthio)carbonyl] derivative (3). Repeated attempts to duplicate this experiment using methyl 4,6-*O*-benzylidene-β-D-glucopyranoside (III) and 1 mole of II resulted in the recovery of 40% of the disubstituted derivative (IV), previously described (4). From the remaining products, consisting necessarily of 40% of unreacted III, a monosubstituted product could be isolated only in very low yield.

It can be calculated[3] from considerations of chemical kinetics that 33.3% of the disubstituted product would be formed if it is assumed that the hydroxyl groups have equal reactivities which are not changed after substitution at the other position (see appendix). Substitution of the (benzylthio)carbonyl group at one of the hydroxyl groups would be expected to activate the remaining hydroxyl group (5). This activation can account for the high proportion (40%) of disubstituted product formed when the substitution is carried out on the β-glucoside. One explanation for the low yield (10%) of disubstituted product in the case of substitution in the α-glucoside is that the reactivity at C-2 is considerably greater than that at C-3 and substitution at C-2 does not increase the reactivity at C-3 sufficiently to enable it to compete with the more reactive C-2. This explanation is consistent with the observation (3) that all of the monosubstituted product isolatable in the case of the α-glucoside is that substituted at C-2. The radical difference in behavior of the α- and β-methyl glucosides encountered in these experiments was not expected.

Because of the low yield of mono-(benzylthio)carbonyl derivatives of III obtained, the synthesis of methyl 3,4,6-tri-*O*-benzoyl-β-D-glucopyranoside by this route is not practical. Another possible route to this compound was discarded, since repeated attempts to saponify preferentially one of the (benzylthio)carbonyl groups from the disubstituted product IV under mild conditions again resulted in the recovery of proportionately high yields of disubstituted and unsubstituted products.

Diethylmercaptal derivatives can be prepared directly from 1,2-*O*-isopropylidene derivatives by treatment with a mixture of concentrated hydrochloric acid and ethyl mercaptan (6). The behavior of 3-*O*-[(benzylthio)carbonyl]-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (V) in concentrated hydrochloric acid therefore was investigated. The optical rotation of a solution of V in concentrated hydrochloric acid at room temperature increased slightly and essentially was constant after 20 h. Evaporation of the acid *in vacuo* yielded a crystalline reducing product (VI) which was homogeneous, and readily distinguishable from D-glucose, on paper chromatograms. The pure product showed a mutarotation of $-4.3° \rightarrow +60.2°$ (in acetone), indicative of a β-configuration. Its elemental analysis agreed with that calculated for a mono-(benzylthio)carbonyl derivative of glucose.

The crystalline (benzylthio)carbonyl-D-glucose derivative VI was shown to have the β-pyranose configuration by the sequence of reactions shown in Fig. 1. Benzoylation in pyridine gave a tetrabenzoyl derivative (VII). Levene and Meyer (7) found that β-D-glucopyranose, under similar conditions, yielded the pentabenzoate derivative without any accompanying change in the configuration of the ring. Oxidative removal of the (benzylthio)carbonyl group from VII, followed by benzoylation of the regenerated hydroxyl group, gave a product (IX) having a melting point and optical rotation identical with those reported (7) for 1,2,3,4,6-penta-*O*-benzoyl-β-D-glucopyranose. The higher-melting crystalline form of this compound reported by Ness, Fletcher, and Hudson (8) was not encountered in this work. Migration of the (benzylthio)carbonate ester grouping

[3]*The authors would like to acknowledge the assistance of Dr. D. Prevorsek and Dr. S. Winchester, Textile Research Institute, in performing these calculations.*

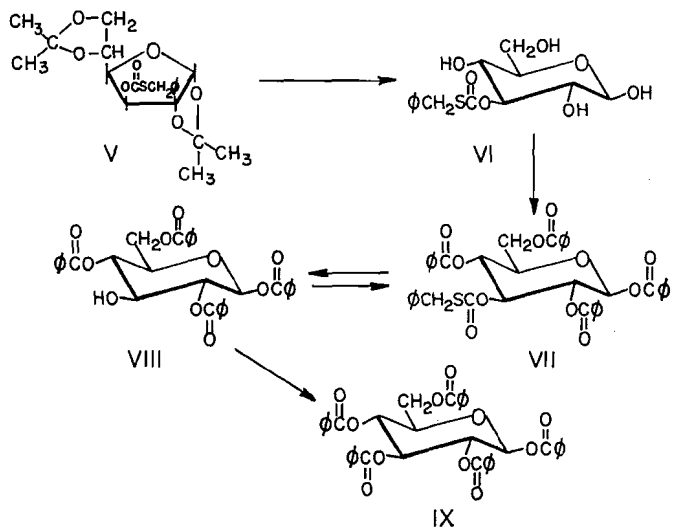

FIG. 1.

from C-3 under the acidic conditions used to remove the isopropylidene grouping is unlikely. The assignment of the (benzylthio)carbonate grouping to C-3 is confirmed by comparison of the physical properties of methyl 2,4,6-tri-*O*-benzoyl-α-D-glucopyranoside (XV) and its derivatives, subsequently synthesized, with those of the known 2,3,4-, 2,3,6-, and 3,4,6-derivatives.

When treated with (benzylthio)carbonyl chloride, VII was resynthesized from VIII, proving the absence of benzoyl migration during the removal of the (benzylthio)carbonyl group. The 3-*O*-acetyl and 3-*O*-(*p*-tolylsulphonyl) derivatives of VIII were prepared.

The 3-*O*-[(benzylthio)carbonyl]-tetra-*O*-benzoyl derivative (VII) was then used to synthesize methyl 2,4,6-tri-*O*-benzoyl-α and β-D-glucopyranosides, as shown in Fig. 2. Peracetylated hexoses are converted to the acetochlorohexose on treatment with titanium tetrachloride in chloroform (9). This method has been shown, more recently, to be applicable to perbenzoylated glucose derivatives (8, 10). The presence of the (benzylthio)-carbonyl group did not cause any anomalous behavior during the use of this reagent. The α-chloro derivative (X) was converted smoothly to methyl 2,4,6-tri-*O*-benzoyl-3-*O*-[(benzylthio)carbonyl]-β-D-glucopyranoside (XI) when treated with silver carbonate in boiling methanol. Oxidative removal of the (benzylthio)carbonyl group gave methyl 2,4,6-tri-*O*-benzoyl-β-D-glucopyranoside (XII), which on benzoylation gave the known (8, 11) methyl 2,3,4,6-tetra-*O*-benzoyl-β-D-glucopyranoside. The 3-*O*-(*p*-tolylsulphonyl) (XIII) and 3-*O*-acetyl derivatives of XII also were synthesized.

Anomerization of the β-glycosidic group in XI by a standard procedure (9) gave a sirupy product (XIV). Oxidative removal of the (benzylthio)carbonyl group gave a crystalline product, methyl 2,4,6-tri-*O*-benzoyl-α-D-glucopyranoside (XV), which on benzoylation gave the known (1, 8) methyl 2,3,4,6-tetra-*O*-benzoyl-α-D-glucopyranoside; its 3-*O*-(*p*-tolyl-sulphonyl) derivative (XVI) was prepared in the usual manner.

The structures of methyl 2,4,6-tri-*O*-benzoyl-α and β-D-glucopyranoside (XII and XV) were related unequivocally to that of 1,2,4,6-tetra-*O*-benzoyl-β-D-glucopyranose (VIII) by

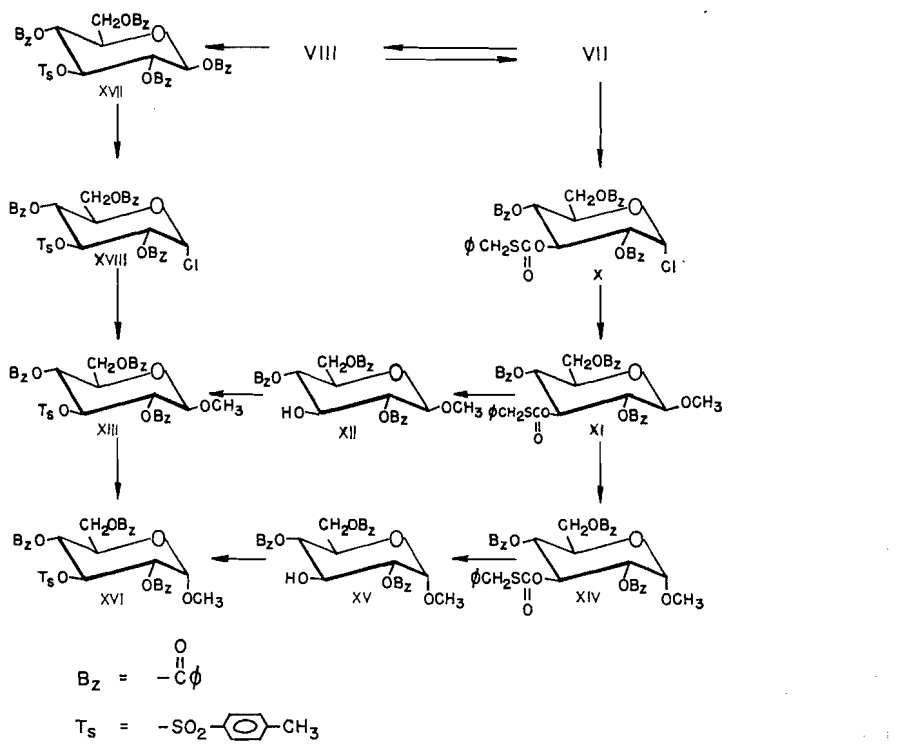

FIG. 2.

taking the *p*-tolylsulphonyl derivative (XVII) through the reaction sequence (XVII → XVIII → XIII → XVI) shown in Fig. 2. The *p*-tolylsulphonates (XIII and XVI) thus obtained were indistinguishable from those derivatives prepared from methyl 2,4,6-tri-*O*-benzoyl-α and β-D-glucopyranosides, respectively.

APPENDIX

The reaction of the methyl 4,6-*O*-benzylidene-α and β-D-glucopyranosides (I), containing two reactive hydroxyl groups, with 1 mole of (benzylthio)carbonyl chloride (II) falls into the class of competitive, consecutive (series) second-order reactions treated by Frost and Schwemer (11). The reactions are represented by:

$$A + B \xrightarrow{k_1} C,$$

and

$$A + C \xrightarrow{k_2} D,$$

where A, B, C, and D represent the molar concentrations of II, I, monosubstituted glucoside, and disubstituted glucoside, respectively. To apply the above reaction scheme, two assumptions must be made: (1) the two hydroxyl groups in the unsubstituted state have equal reactivities, and (2) substitution in one hydroxyl group produces the same change in reactivity as substitution in the other. The above authors solved the rate equations

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$$[1] \qquad dA/dt = -k_1AB - k_2AC$$

$$[2] \qquad dB/dt = -k_1AB$$

$$[3] \qquad dC/dt = k_1AB - k_2AC$$

$$[4] \qquad dD/dt = k_2AC$$

for the case where initial concentrations were set at $A_0 = 2B_0$.

In the present study it was necessary to solve the above rate equations for the case where $A_0 = B_0$. From a material balance, summing eq. [1] $-$ 2 $\times$ eq. [2] $-$ eq. [3] and integrating gave

$$[5] \qquad A - 2B - C = A_0 - 2B_0.$$

Since $A_0 = B_0$,

$$[6] \qquad C = -2B + A + B_0,$$

and substituting in eq. [1],

$$[7] \qquad dA/dt = (2k_1 - k_2)AB - k_2A^2 - k_2AB_0.$$

If one chooses as dimensionless quantities:

$$[8] \qquad \alpha = A/A_0; \beta = B/B_0; \tau = B_0k_1t; \kappa = k_2/k_1,$$

then eqs. [2] and [7] can be solved to produce

$$[9] \qquad d\alpha/d\beta = (1 - 2\kappa) + \kappa(\alpha/\beta).$$

Integration of eq. [9] gives

$$[10] \qquad \alpha = \left(\frac{1 - 2\kappa}{1 - \kappa}\right)\beta + \left(\frac{1}{1 - \kappa}\right)\beta^\kappa - 1,$$

the constant of integration being determined at $\alpha = \beta = 1$.

Solutions of eq. [10] for β as a function of α at different κ values are shown plotted in Fig. 3. The case of particular interest in the present study is that in which the reactivities of the hydroxyl groups are not changed after substitution, that is, $k_1 = k_2$ or $\kappa = 1$. The solution was obtained for $\kappa = 0.99$, as an approximation for $\kappa = 1$ which is not readily solvable. At $\alpha = 0$, it is seen that $\beta = 0.333$; that is, at the end of the reaction one-third of the initial I remains unsubstituted. Another one-third of the initial I must therefore be disubstituted, since the unsubstituted and disubstituted products must be equal at the end of the reaction. By difference, the remaining one-third of the initial I would be present as monosubstituted product.

To obtain the 40% of disubstituted product in the present work with the β-glucoside, it can be calculated that $k_2 = 2.5k_1$. The 10% yield of disubstituted product obtained with the α-glucoside can be interpreted to mean that $k_1 = 13k_2$.

EXPERIMENTAL

3-O-[(Benzylthio)carbonyl]-β-D-glucopyranose (VI)

3-*O*-[(Benzylthio)carbonyl]-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (V) was synthesized as previously described (4). The pure form (recrystallized from ethanol–water) had m.p. 75–77° and $[\alpha]_D^{20}$ −24.6° (*c*,2, $CHCl_3$).

One gram of V was ground in a mortar and dissolved in 3 ml of concentrated (37%) hydrochloric acid. After standing at room temperature for 18 h, the solution was evaporated *in vacuo* with a bath temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

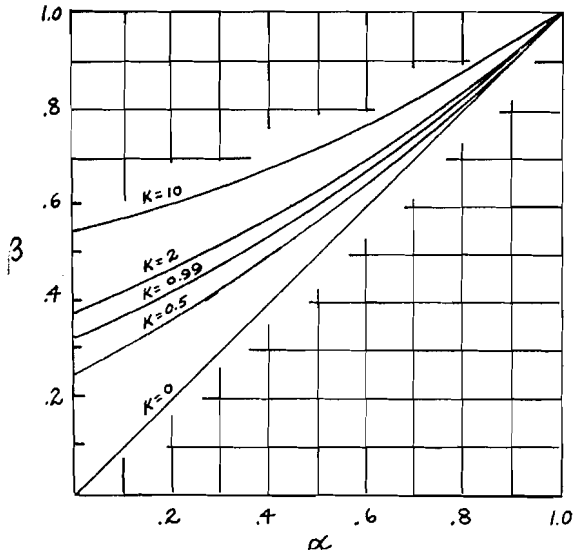

FIG. 3.

of 35–40°. The solid residue was washed with ice water until the washings were neutral and then dried *in vacuo* overnight over potassium hydroxide and phosphorus pentoxide. The product (0.78 g, 97%) reduced Fehling's solution and a paper chromatogram irrigated with butanol–ethanol–water (5:1:4, top layer) showed only one spot with R_f 0.87 (glucose R_f 0.17) when developed with alkaline silver nitrate. After recrystallization from boiling water, the product had m.p. 170–173° (decomp.), $[\alpha]_D^{21}$ −4.3° → +60.2° (*c*,1, acetone). The rotation reached a constant value after 26 h; it is seen that the acetone contained sufficient water to permit mutarotation.

Anal. Calcd. for $C_{14}H_{18}O_7S$: C, 50.91; H, 5.46; S, 9.70. Found: C, 50.64; H, 5.67; S, 9.59.

1,2,4,6-Tetra-O-benzoyl-3-O-[(benzylthio)carbonyl]-β-D-glucopyranose (VII)

To 2.0 g of VI in anhydrous pyridine (30 ml) was added benzoyl chloride (5.0 ml) with cooling in an ice bath. After standing overnight at room temperature, the solution was poured into ice water. The solid deposited was recovered by filtration and washed thoroughly with water. After drying, recrystallization from a mixture of acetone and ethanol gave the product (4.4 g, 98%) having m.p. 199–201°. Two further recrystallizations afforded the pure product having m.p. 200–202°, $[\alpha]_D^{24}$ −16.55° (*c*,1, $CHCl_3$).

Anal. Calcd. for $C_{42}H_{34}O_{11}S$: C, 67.57; H, 4.56; S, 4.28. Found: C, 67.46; H, 4.62; S, 4.11.

In a separate experiment, the solid product VI (50 g, m.p. 157–163°), obtained by evaporation of the hydrochloric acid but omitting the crystallization from water, was benzoylated in the same fashion and gave, after 1 crystallization, 100 g (89%) of VII, m.p. 190–194°. The pure product VII was obtained in 75% yield after 1 recrystallization.

1,2,4,6-Tetra-O-benzoyl-β-D-glucopyranose (VIII)

To a solution of VII (8.0 g) dissolved in chloroform (450 ml) and glacial acetic acid (550 ml) was added potassium acetate (2.0 g) and 30% hydrogen peroxide (150 ml). After standing for 7 days at room temperature, the solution was concentrated *in vacuo* (air-leak) to 150 ml, and water (30 ml) was added to turbidity. Cooling the mixture at 5° gave 6.3 g (98%) of product in 2 crops of crystals, m.p. 176–179°. Two recrystallizations from acetone–petroleum ether gave 5.6 g (89%) having m.p. 179–180° and $[\alpha]_D^{21}$ +8.7° (*c*,1, $CHCl_3$).

Anal. Calcd. for $C_{34}H_{28}O_{10}$: C, 68.46; H, 4.70. Found: C, 68.02; H, 4.82.

Derivatives of VIII

Derivatives of VIII were prepared from 0.5 g samples in pyridine solution by standard procedures. After 48 h reaction time at room temperature, each product was obtained as a solid by pouring the reaction mixture into ice water; filtration and recrystallization (twice) from acetone–petroleum ether afforded the pure compound.

1,2,3,4,6-Penta-O-benzoyl-β-D-glucopyranose (IX).—Yield: 0.45 g (77%); m.p. 156–158°; $[\alpha]_D^{19}$ +23.4° (*c*,1, $CHCl_3$). Reported (6): m.p. 157°; $[\alpha]_D$ +24° (*c*,3, $CHCl_3$).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

3-O-Acetyl-1,2,4,6-tetra-O-benzoyl-β-D-glucopyranose.—Yield: 0.39 g (73%); m.p. 224–226°; $[\alpha]_D^{20}$ +9.4° (*c*,1, $CHCl_3$).

Anal. Calcd. for $C_{36}H_{30}O_{11}S$: C, 67.71; H, 4.70. Found: C, 67.39; H, 4.65.

1,2,4,6-Tetra-O-benzoyl-3-O-(p-tolysulphonyl)-β-D-glucopyranose (XVII).—Yield: 0.31 g (48%); m.p. 193° (decomp.); $[\alpha]_D^{20}$ +11.7° (*c*,1, $CHCl_3$). Another reaction using 4 days reaction time gave this product in 69% yield.

Anal. Calcd. for $C_{41}H_{34}O_{12}S$: C, 65.60; H, 4.54; S, 4.27. Found: C, 65.61; H, 4.59; S, 4.49.

2,4,6-Tri-O-benzoyl-3-O-[(benzylthio)carbonyl]-α-D-glucopyranosyl Chloride (X)

To a solution of VII (50 g) in pure, dry chloroform (1 500 ml) was added titanium tetrachloride (14.7 ml) and the solution was refluxed for 5 h with the exclusion of moisture. The product was isolated by pouring the solution on to ice pieces and by washing the separated chloroform layer with aqueous potassium bicarbonate and then 3 times with water. The dried ($MgSO_4$) chloroform solution was evaporated to dryness and the solid residue was recrystallized, first from acetone–ether and then from ethanol, to give the product (35 g, 78%), m.p. 139–141°. In purest form the product had m.p. 140.5–141° and $[\alpha]_D^{21}$ +122.8° (*c*,1, $CHCl_3$).

Anal. Calcd. for $C_{35}H_{29}O_9ClS$: C, 63.59; H, 4.39; Cl, 5.38; S, 4.84. Found: C, 63.33; H, 4.29; Cl, 6.14;[4] S, 4.97.

Methyl 2,4,6-Tri-O-benzoyl-3-O-[(benzylthio)carbonyl]-β-D-glucopyranoside (XI)

To a solution of X (6.3 g) in anhydrous methanol (600 ml) was added 15 g of freshly precipitated, dried silver carbonate and the mixture was refluxed (drying tube) for 5 h. The silver salts were removed by filtration of the reaction mixture prior to cooling. The product, which crystallized from the solution on addition of 50 ml of water, was dissolved in acetone and filtered through carbon to remove the last traces of silver salts. The acetone was evaporated and the residue recrystallized twice from ethanol to give the product (3.3 g, 53%), having m.p. 165–166° and $[\alpha]_D^{23}$ +24.9° (*c*,1, $CHCl_3$).

Anal. Calcd. for $C_{36}H_{32}O_{10}S$: C, 65.85; H, 4.88; S, 4.88. Found: C, 65.79; H, 5.08; S, 5.24.

Additional amounts of product could be obtained by further treatment with silver carbonate in methanol of the low-melting material obtained as final crops in the alcohol recrystallizations.

Methyl 2,4,6-Tri-O-benzoyl-β-D-glucopyranoside (XII)

The (benzylthio)carbonyl group was removed oxidatively from XI in the manner herein described for the synthesis of VIII. After 2 crystallizations from ethanol–water, the product (90%) had m.p. 152–154° and $[\alpha]_D^{21}$ +16.5° (*c*,1, $CHCl_3$).

Anal. Calcd. for $C_{28}H_{26}O_9$: C, 66.40; H, 5.14. Found: C, 66.16; H, 5.26.

Derivatives of XII

The following derivatives were prepared by standard procedures and were recrystallized twice from ethanol.

Methyl 3-O-Acetyl-2,4,6-tri-O-benzoyl-β-D-glucopyranoside.—Yield: 80%; m.p. 160–162°; $[\alpha]_D^{23}$ +28.4° (*c*,1, $CHCl_3$).

Anal. Calcd. for $C_{30}H_{28}O_{10}$: C, 65.69; H, 5.11. Found: C, 65.80; H, 5.26.

Methyl 2,4,6-Tri-O-benzoyl-3-O-(p-tolylsulphonyl)-β-D-glucopyranoside (XIII).—Yield: 78%; m.p. 191° (decomp.); $[\alpha]_D^{17}$ +33.9° (*c*,1, $CHCl_3$).

Anal. Calcd. for $C_{35}H_{32}O_{11}S$: C, 63.63; H, 4.85; S, 4.85. Found: C, 63.60; H, 4.94; S, 5.10.

Methyl 2,3,4,6-Tetra-O-benzoyl-β-D-glucopyranoside.—Yield: 66%; m.p. 158–160°; $[\alpha]_D^{19}$ +27.6° (*c*,1, $CHCl_3$). Reported (12): m.p. 160–162°; $[\alpha]_D$ +31° ($CHCl_3$).

Methyl 2,4,6-Tri-O-benzoyl-3-O-[(benzylthio)carbonyl]-α-D-glucopyranoside (XIV)

To a solution of XI (3.3 g) in pure, dry chloroform (300 ml) was added titanium tetrachloride (2.0 ml) and the solution was refluxed for 5 h. The product, isolated as described previously, could not be induced to crystallize and showed $[\alpha]_D^{21}$ +95.45° (*c*,2, $CHCl_3$).

Methyl 2,4,6-Tri-O-benzoyl-α-D-glucopyranoside (XV)

The product (XIV) from the foregoing experiment was treated in glacial acetic acid (100 ml) with potassium acetate (0.98 g) and 30% hydrogen peroxide (8.2 ml). The change in optical rotation was followed and attained a constant value after 9 days. The solution then was poured into 1 500 ml ice water and the solid product was recovered by filtration and was washed thoroughly. After drying, the product was crystallized twice from petroleum ether to give 1.82 g (72%), m.p. 74–76°, and $[\alpha]_D^{18}$ +94.9° (*c*,1, $CHCl_3$).

Anal. Calcd. for $C_{28}H_{26}O_9$: C, 66.40; H, 5.14. Found: C, 66.05; H, 5.02.

Derivatives of XV

Methyl 2,4,6-Tri-O-benzoyl-3-O-(p-tolylsulphonyl)-α-D-glucopyranoside (XVI).—This compound, prepared by the procedure previously described for XVII, had m.p. 163–165° and $[\alpha]_D^{18}$ +101.6° (*c*,0.8, $CHCl_3$).

[4]*The high value found in chlorine analysis can probably be attributed to interference from the sulphur present in the substance.*

Anal. Calcd. for $C_{35}H_{32}O_{11}$: C, 63.63; H, 4.85; S, 4.85. Found: C, 63.38; H, 4.75; S, 4.87.

Methyl 2,3,4,6-Tetra-O-benzoyl-α-D-glucopyranoside.—This compound, prepared as previously described, had m.p. 104–106° and $[\alpha]_D^{20}$ +84.2° (*c*,0.5, $CHCl_3$). Reported (7): m.p. 105–108° and $[\alpha]_D$ +84° (*c*,0.95, $CHCl_3$).

Synthesis of XIII and XVI from VIII. 2,4,6-Tri-O-benzoyl-3-O-(p-tolylsulphonyl)-α-D-glucopyranosyl Chloride (XVIII)

Compound XVII was treated in a manner identical with that for VII in the preparation of X. The product XVIII was crystallized twice from ethanol (yield 82%) and had m.p. 154–156°, $[\alpha]_D^{22}$ +123.8° (*c*,1, $CHCl_3$).

Anal. Calcd. for $C_{34}H_{29}O_{10}ClS$: C, 61.40; H, 4.36; Cl, 5.34; S, 4.82. Found: C, 61.45; H, 4.41; Cl, 6.36;[4] S, 5.04.

Compound XVIII was converted to XIII as described herein in the synthesis of XI from X. The product had m.p. 192° (decomp.) and $[\alpha]_D^{17}$ +32.8° (*c*,0.5, $CHCl_3$). A mixed melting point with XIII synthesized from XII was not depressed.

Anomerization of this product (XIII) to XVI, as described for the synthesis of XIV from XI, gave a product with m.p. 163–165° and $[\alpha]_D^{19}$ +102.4° (*c*,1, $CHCl_3$). Admixture with XVI, synthesized from XV, did not depress the melting point.

Resynthesis of VII from VIII

Compound VIII (0.15 g) was treated overnight in 2 ml pyridine with 0.15 g (benzylthio)carbonyl chloride and the solid obtained on pouring the reaction mixture into ice water was filtered off and recrystallized from acetone. The product (0.17 g), after 2 recrystallizations from ethanol, had m.p. 199–201° and did not depress the melting point of VII, obtained by benzoylation of VI.

ACKNOWLEDGMENTS

THE REACTIVITY OF THE CYCLIC POLYENES TOWARDS FREE RADICALS

I. COPOLYMERIZATION WITH ACRYLONITRILE

E. S. Ferdinandi, W. P. Garby, and D. G. L. James
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received June 1, 1964

ABSTRACT

Cyclohexadiene-1,3 and bicyclo[2.2.1]heptadiene-2,5 each (B) copolymerize with acrylonitrile (A) in bulk at 60 °C in the presence of 0.01 *M* benzoyl peroxide. The copolymerization parameters for cyclohexadiene-1,3 are $r_A = 0.026 \pm 0.014$, $r_B = 0.20 \pm 0.01$, $Q_B = 1.76$, $e_B = -1.18$; for bicycloheptadiene the parameters are $r_A = 0.65 \pm 0.02$, $r_B = 0.47 \pm 0.08$, $Q_B = 0.27$, $e_B = 0.03$; limits of error are given at the 10% probability level. Cycloheptatriene and cyclooctatetraene inhibit the polymerization of acrylonitrile under similar conditions over a wide range of concentration. These results are discussed in terms of the general reactivity of the cyclic polyenes and of the behavior of structurally related monomers in polymerization, and a consistent pattern of reactivity emerges.

INTRODUCTION

The monocyclic polyenes have received little attention from investigators of free radical copolymerization and are not mentioned in Young's recent comprehensive review of copolymerization parameters (1). This neglect is surprising as the reactivity of the monocyclic polyenes toward the addition of free radicals is often of a high order. Table I includes some results from a recent kinetic study of the addition of the ethyl radical to various polyenes (2); both the rate constant at 60 °C, k_a, and the energy of activation, E_a, are given. In both respects each of the monocyclic polyenes is decidedly more reactive than the familiar monomer vinyl acetate (4).

TABLE I

Indices of reactivity among monomers

Monomer (B)	k_a at 60° (l mole^{-1} s^{-1})	Q_B	E_a (kcal/mole)	$1/r_A$	k_a/k_m at 60°
Cyclohexadiene-1,3	40 000	1.76	5.2±0.3	40.	4.7
Cycloheptatriene	15 000	—	6.4±0.2	—	4.2
Cyclooctatetraene	13 000	—	5.6±0.6	—	21.3
Bicycloheptadiene	5 200	0.27	7.0±0.1	1.5	>10.
Vinyl acetate	1 900	0.026	6.9±0.5	0.25	>10.

Constants k_a and k_m are respectively the rate constants for addition and metathesis of the ethyl radical with the monomers, and E_a the energy of activation for addition (2, 3); r_A is the reactivity ratio for copolymerization of the monomer (B) with acrylonitrile (A), and Q_B is the intrinsic reactivity of monomer B (this work and ref. 1), based upon the value $Q = 1.00$ for styrene.

Moreover the values of k_a are all greater than the propagation constants of typical vinyl monomers (5), which for vinyl acetate and acrylonitrile are 3 700 and 1 960 l mole^{-1} s^{-1} respectively at 60 °C. We suggest that the value of k_a provides an approximate index of the intrinsic reactivity of the monomer; certainly in Table I, k_a and Q are monotonically related.

It must be admitted that our present knowledge of the free radical polymerization of the monocyclic polyenes does not encourage us to regard these substances as reactive comonomers. Although cyclohexadiene-1,3, cycloheptatriene, and cyclooctatetraene all

homopolymerize under free radical conditions, the yields are generally poor and the reaction conditions severe. Cyclohexadiene-1,3 will polymerize thermally (6) in the range 100–155 °C but the yield of high polymer does not exceed 34%; azoisobutyronitrile seems to have almost no sensitizing action, and the degree of polymerization (7) does not exceed 15. The nature of the mechanism appears to be in dispute (8, 9). Cycloheptatriene requires rather severe conditions (10); a polymerization carried out in bulk with di-*tert*-butyl peroxide at 6 000 atm yielded only 3.6% of polymer in 6 h at 130 °C. Cyclooctatetraene can be polymerized by diluting the vapor heavily with steam, heating for a brief period above 500 °C, and quenching at a cool surface. A transparent film of polymer is deposited which does not soften at 250 °C and is resistant to solvents (11). Benzene is even more intractible; an attempt to copolymerize it with ethylene in the presence of di-*tert*-butyl peroxide under a pressure of 20 000 p.s.i. at 130 °C did indeed yield a copolymer containing a small proportion of benzene units, but it was established that these were incorporated entirely by a chain transfer process (12). As the polyethylene radical is probably the most reactive of the polymer radicals, it is likely that the free radical copolymerization of benzene by an addition mechanism is impossible.

Bicyclo[2.2.1]heptadiene-2,5 appears to stand in sharp contrast to the monocyclic polyenes in its reactivity towards free radical polymerization. Both the homopolymerization (13) and the copolymerization (14) of this monomer have been described, and neither requires other than mild conditions.

One purpose of this series is to question the apparent lack of reactivity of the monocyclic polyenes as monomers, and of this paper to demonstrate the reactivity of cyclohexadiene-1,3. Certainly cyclohexadiene-1,3, cycloheptatriene, and cyclooctatetraene are all reactive towards the addition of the ethyl radical. Relevant values of the rate constant, k_a, and the energy of activation, E_a, are given in Table I; in both respects each of the monocyclic polyenes is more reactive than bicycloheptadiene. However, in this study we are attempting to add the polyacrylonitrile radical to the polyene molecule and we must first establish whether values of k_a have any relevance. Certainly the ethyl radical should simulate the polyethylene radical quite well, accepting the usual assumption that the reactivity of a polymer radical is determined by the nature of the terminal unit. Denoting acrylonitrile by A and the polyene by B and the corresponding polymer radicals by A· and B· respectively we define the rate constants:

$$CH_3CH_2\cdot + B \rightarrow CH_3CH_2B\cdot \qquad (k_a)$$

$$2CH_3CH_2\cdot \rightarrow C_4H_{10} \qquad (k_c)$$

$$A\cdot + A \rightarrow A\cdot \qquad (k_{AA})$$

$$A\cdot + B \rightarrow B\cdot \qquad (k_{AB}) \qquad r_A = \frac{k_{AA}}{k_{AB}}$$

To discover whether the copropagation constant k_{AB} is simply related to k_a we have plotted log $(1/r_A)$ against 13 + log $(k_a/k_c^{\frac{1}{2}})$ for a series of monomers in Fig. 1. The values of r_A for the monomers named are taken from Young's tables (1); values of $k_a/k_c^{\frac{1}{2}}$ are given for the same or a closely related monomer (2, 4, 15, 16, 17), thus isoprene is represented by 2,3-dimethyl butadiene-1,3. A straight line of unit gradient has been drawn for reference. Correlation between k_{AB} and k_a is fairly good for the hydrocarbons, vinyl acetate and allyl alcohol; for those monomers polar effects are small and of similar magnitude for the two radicals. Wide deviations are observed for the two monomers with a nitrile substituent; electrostatic repulsion between the nitrile groups in the polyacrylonitrile radical and in the monomer molecule depresses $1/r_A$ in a manner not possible for

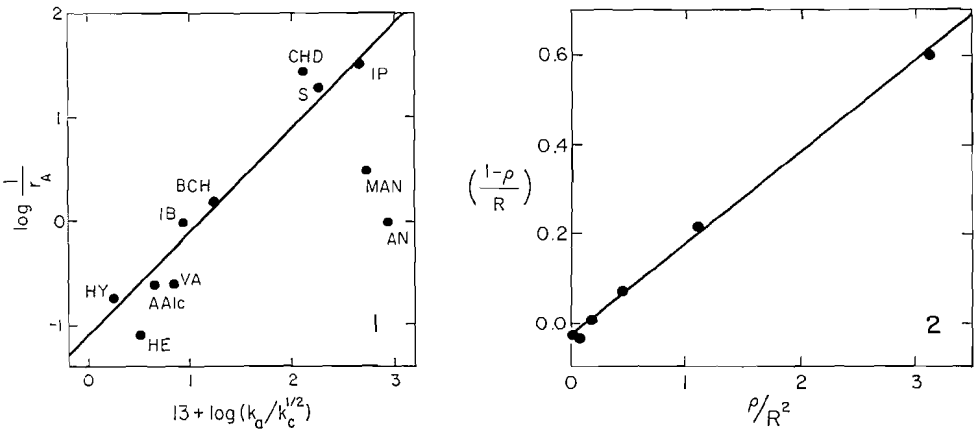

FIG. 1. Addition of the polyacrylonitrile radical (A·) and the ethyl radical to various monomers (B) at 60 °C; the reference line has unit gradient. Abbreviations: HY, hexyne-1; HE, hexene-1; AAlc, allyl alcohol; VA, vinyl acetate; IB, isobutene; BCH, bicycloheptadiene; CHD, cyclohexadiene-1,3; S, styrene; IP, isoprene; MAN, methacrylonitrile; AN, acrylonitrile.

FIG. 2. Fineman–Ross plot of $(1 - \rho)/R = r_B\rho/R^2 - r_A$ for acrylonitrile (A) and cyclohexadiene-1,3 (B) at 60°, yielding $r_A = 0.026 \pm 0.014$, $r_B = 0.20 \pm 0.01$.

the other monomers. Such deviations are to be expected from the difference in the electrostatic character of the two radicals, expressed by the values of e: acrylonitrile, 1.11 (18); ethylene, −0.21 (1), and should be observed with all monomers having a strongly electrophilic substituent in the vinyl group.

EXPERIMENTAL SECTION

All the monomers were commercial materials of the highest grade commonly obtainable. Each monomer was distilled through an efficient fractionating column in a stream of nitrogen; cyclooctatetraene was distilled at reduced pressure. The purity of fractions was tested by vapor phase chromatography; the monomers used were free from contaminants. Benzoyl peroxide, the White Label grade from the Eastman Co., was purified by three cycles of solution in chloroform and precipitation with methanol. The chloroform and methanol were of reagent grade.

All copolymerizations were attempted in the presence of 0.01 M benzoyl peroxide at 60.0 ± 0.5 °C (except where otherwise stated). The reaction vessels were pyrex tubes constricted for sealing off under vacuum. The sensitizer was introduced as an appropriate volume of 0.01 M benzoyl peroxide in chloroform, and the solvent removed under vacuum. The purified monomers were measured by using 5 ml graduated pipettes, and the mixture deaerated by five cycles of freezing, evacuating under vacuum, isolating, and melting. The reaction vessel was then sealed under vacuum, exposed to the reaction conditions for the required period, and quenched at −78 °C. The detailed procedure varied with the nature of the system, and will be described under the heading of the polyene, acrylonitrile being the comonomer unless explicitly stated.

Cyclohexadiene-1,3

The curvature of the copolymer composition line (Fig. 3) persuaded us to limit the yield of polymer to 1.5%; at this point the polymer usually began to precipitate. After the reaction the polymer was precipitated by methanol and proved to be almost insoluble in carbon tetrachloride, acetone, toluene, and petroleum ether. The only effective solvent found was N,N-dimethyl formamide, but this was unsuitable for purification as the copolymer composition was to be determined by nitrogen analysis. The polymer was washed exhaustively with methanol on a sintered glass filter crucible and dried for 3 days under vacuum over a 4-A molecular sieve. The composition of the polymer was determined with a Coleman Model 29 nitrogen analyzer. A 4% solution of the polymer in camphor ($K_f = 40$ deg kg/mole) did not depress the freezing point of camphor detectably; this and the general insolubility of the polymers indicate a fairly high degree of polymerization.

Bicycloheptadiene

The copolymer composition curve does not deviate much from the diagonal (Fig. 6), and conversions up to 5% were allowed; at this point the polymer usually began to precipitate. After the reaction, precipitation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was completed with methanol; the polymer was purified by solution in chloroform and reprecipitation with methanol, dried for 3 days under vacuum over a 4-A molecular sieve, and analyzed for nitrogen as above.

Cycloheptatriene and Cyclooctatetraene

Each of these polyenes inhibits the radical polymerization of acrylonitrile, and the details are more conveniently considered under the appropriate headings in the next section.

RESULTS AND DISCUSSION

The kinetics of the copolymerization of acrylonitrile (A) with the cyclic polyene (B) may be represented by four propagation steps and two reactivity ratios (19):

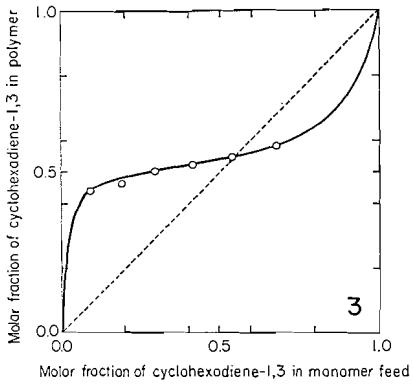
$$\begin{aligned} A\cdot + A &\rightarrow A\cdot \quad (k_{AA}) \qquad r_A = \frac{k_{AA}}{k_{AB}} \\ A\cdot + B &\rightarrow B\cdot \quad (k_{AB}) \\ B\cdot + B &\rightarrow B\cdot \quad (k_{BB}) \qquad r_B = \frac{k_{BB}}{k_{BA}} \\ B\cdot + A &\rightarrow A\cdot \quad (k_{BA}) \end{aligned}$$

The polymer radical is characterized by its terminal unit. Values of the reactivity ratios may be found from either of the conjugate plots of Fineman and Ross (20);

$$[1] \qquad (1 - \rho)/R = r_B\rho/R^2 - r_A$$

$$[2] \qquad R(\rho - 1)/\rho = r_A R^2/\rho - r_B,$$

where R is the molar ratio (A:B) of monomers in the feed and ρ is the molar ratio in the polymer. Such plots are shown in Figs. 2, 4, and 5. Alternatively, eqs. [1] and [2] may be



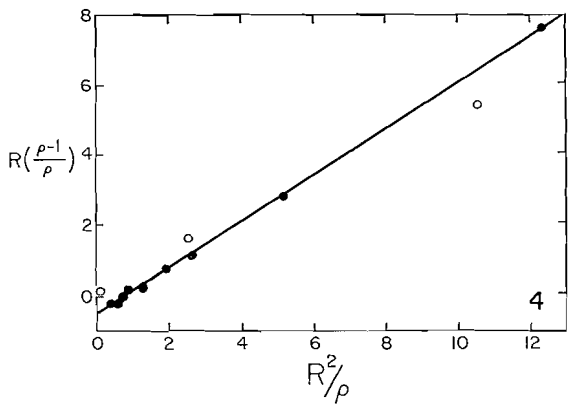


FIG. 3. Copolymer composition curve for acrylonitrile (A) and cyclohexadiene-1,3 (B) at 60°, drawn for $r_A = 0.026$, $r_B = 0.20$.

FIG. 4. Fineman–Ross plot of $R(\rho - 1)/\rho = r_A R^2/\rho - r_B$ for acrylonitrile (A) and bicycloheptadiene (B) at 60°, yielding $r_A = 0.65 \pm 0.02$, $r_B = 0.47 \pm 0.08$; ● this work, ○ ref. 14.

adapted to the method of Mayo and Lewis (21); concordant results were obtained in each case by the two methods. As each of the polyenes possesses a peculiar feature of interest, they will be discussed under separate headings.

Cyclohexadiene-1,3

Figure 2 shows the Fineman–Ross plot for the copolymerization of acrylonitrile (A) with cyclohexadiene-1,3 (B). The straight line drawn by the method of least squares yields the reactivity ratios:

$$r_A = 0.026 \pm 0.014; r_B = 0.205 \pm 0.011$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(limits of error are given at the 10% probability level). The product $r_A r_B = 0.0053 \pm 0.0025$ indicates a considerable degree of alternation in this system. The parameters $Q_B = 1.76$ and $e_B = -1.18$ were calculated from $Q_A = 0.58$ and $e_A = 1.11$ for acrylonitrile (18). The value $r_A = 0.026$ reveals the high reactivity of cyclohexadiene-1,3 as a monomer in this system; this reactivity arises from the favorable conjunction of high values of Q_B and of $e_A - e_B$ (2.29). The positive deviation of the point for cyclohexadiene-1,3 from the reference line of Fig. 1 may be a natural result of the latter factor.

Cyclohexadiene-1,3 can homopolymerize by a radical mechanism (6–9) and this capacity is implicit in the value $r_B = 0.20$. Figure 3 gives the copolymer composition curve for this system; the experimental points fit the theoretical line drawn for $r_A = 0.026$, $r_B = 0.20$ quite well.

Barb (22) and Ham (23) have shown that in certain copolymerizations the reactivity of the polymer radical may be determined in part by nonterminal monomer units and that this phenomenon may be treated by characterizing a polymer radical by its terminal and its penultimate unit. This gives eight propagations steps and four reactivity ratios:

$$\begin{aligned}
&AA\cdot + A \rightarrow AA\cdot \quad (k_{AAA}) \qquad r_{AA} = \frac{k_{AAA}}{k_{AAB}}\\
&AA\cdot + B \rightarrow AB\cdot \quad (k_{AAB})\\
&BA\cdot + A \rightarrow AA\cdot \quad (k_{BAA}) \qquad r_{BA} = \frac{k_{BAA}}{k_{BAB}}\\
&BA\cdot + B \rightarrow AB\cdot \quad (k_{BAB})\\
&BB\cdot + B \rightarrow BB\cdot \quad (k_{BBB}) \qquad r_{BB} = \frac{k_{BBB}}{k_{BBA}}\\
&BB\cdot + A \rightarrow BA\cdot \quad (k_{BBA})\\
&AB\cdot + B \rightarrow BB\cdot \quad (k_{ABB}) \qquad r_{AB} = \frac{k_{ABB}}{k_{ABA}}\\
&AB\cdot + A \rightarrow BA\cdot \quad (k_{ABA})
\end{aligned}$$

This penultimate unit effect was observed (23) in the copolymerization of acrylonitrile (A) with styrene (B). Electrostatic repulsion between an acrylonitrile monomer molecule and an acrylonitrile unit in the penultimate position in the polymer radical is expected to make $r_{BA} > r_{AA}$ and $r_{AB} > r_{BB}$. Only the former of these inequalities will be detectable in a system for which the Fineman–Ross plot gives $r_B \gg r_A$; a good approximation is obtained by placing $r_{AB} = r_{BB} = r_B$. Moreover if r_A is very small it is reasonable to take r_{AA} as zero; then we obtain the relation:

$$[3] \qquad \rho = (1 + (1 + 1/r_{BA}R)^{-1})/(1 + r_B R).$$

To find whether a penultimate unit effect can be detected in the copolymerization of acrylonitrile with cyclohexadiene-1,3 we have compared the closeness of fit to the experimental points obtained from eq. [3] and a rearranged form of eq. [1]:

$$[1] \qquad \rho = (1 + r_A R)R/(r_B + R)$$

The values $r_A = 0.026$ and $r_B = 0.20$ were retained, and various values of r_{BA} tried. Crowding of the data was avoided by using axes of $(1/R, 1/\rho)$ and $(\log R, \log \rho)$. The curve drawn for the penultimate unit effect with $r_{BA} = 0.030$ (and $r_{AA} = 0$) gave the best fit; it was as good, but no better than, the fit obtained using eq. [1]. We conclude that there is no unequivocal evidence for a penultimate unit effect in this system.

Cycloheptatriene

Cycloheptatriene inhibited the radical polymerization of acrylonitrile, and thus stands

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in complete contrast to cyclohexadiene-1,3. This is the more striking, since these two polyenes react very similarly towards the ethyl radical (k_a/k_m = 4.7 and 4.2 respectively at 60 °C) and should also possess similar values of *e*. The polymerization of acrylonitrile in the presence of 0.01 *M* benzoyl peroxide may be sensitized thermally at 60 °C, or photochemically at 0 °C; inhibition was observed in all such systems to which cycloheptatriene had been added, that is for the range from 2.3 to 74 mole % for the thermal sensitization, and from 2.3 to 22 mole % for the photochemical sensitization. Such systems did not become appreciably more viscous even after 24 h of reaction; this indicates a very efficient mode of inhibition able to prevent even the development of short chains. Evaporation yielded only a trace of white solid, which was identified as the sensitizer.

This evidence suggests rapid degradative chain transfer between the chain centers and cycloheptatriene. The mode of chain transfer must not form involatile materials, and so abstraction of a hydrogen atom from the cycloheptatriene molecule by the polyacrylonitrile radical or the benzoyloxy radical is indicated. Both radicals have a high electron affinity and the cycloheptatrienyl radical has the low ionization potential of 6.6 ± 0.1 eV (24); this conjunction should cause polar contributions to the transition state in metathesis to be particularly important and the transfer to be abnormally rapid. The low ionization potential of the cycloheptatrienyl radical is closely connected with the stability of the derived tropylium cation ($C_7H_7^+$) with its sextet of non-localized π-electrons; indeed both $C_7H_7^+ClO_4^-$ and $C_7H_7^+BF_4^-$ have been prepared in acetic acid solution by the action of oxygen on cycloheptatriene in the presence of the appropriate acid (25). The cyclohexadienyl radical does not yield a cation of comparable stability on ionization, and so there is no reason to suppose that cyclohexadiene-1,3 should share the peculiar reactivity of cycloheptatriene toward metathesis with the polyacrylonitrile or benzoyloxy radical.

Cyclooctatetraene

Cyclooctatetraene was found to inhibit the bulk polymerization of both acrylonitrile and 4-vinyl pyridine, sensitized by 0.02 *M* benzoyl peroxide at 60 °C. The induction period for acrylonitrile exceeded 45 h, whether cyclooctatetraene was present at a concentration of 14, 3.2, or 1.6 mole %, and during this period the color of the system changed gradually to deep amber. However, the induction period for 4-vinyl pyridine was only about 4 h in the presence of 4.5 or 2.2 mole % cyclooctatetraene; a similar but much more intense coloration developed, and the end of the induction period was marked by a sudden increase in viscosity. After a total period of 5 h polymer could be precipitated from this system with water, which, on drying, yielded a white, fibrous powder soluble in methanol. Analysis showed that all the cyclooctatetraene had been incorporated in this polymer.

Cyclooctatetraene has been shown to retard the γ-ray initiated polymerization (26) of vinyl acetate and of vinylpyrrolidone in bulk at 20 °C; even 0.1 mole % cyclooctatetraene lowered the yield of polymer very considerably. Similar retardation was observed with styrene and vinyl ethyl ether. The remarkable power of cyclooctatetraene to retard radiation-induced reactions parallels but exceeds that of benzene. Ellinger has suggested (26) that this power arises from the high electron affinity of the cyclooctatetraene molecule, which also governs the ease with which this substance captures thermal electrons in the vapor phase (27), undergoes reduction at the dropping mercury electrode (Table II and ref. 28), and polymerizes in the presence of sodium (29). Polar effects may well be expected to dominate the radical copolymerization of cyclooctatetraene.

Inhibition of the polymerization of acrylonitrile by cyclooctatetraene may proceed by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the addition of polyacrylonitrile radicals to cyclooctatetraene to form a radical which is unable to add to either acrylonitrile or cyclooctatetraene and which is terminated by mutual interaction. Certainly the structurally related α-cyanoisopropyl radical will add to cyclooctatetraene in bulk at 60 °C, and 1,4-radical addition then occurs to the exclusion of polymerization (30). A polymer radical terminated by a cyclooctatetraene unit would be highly electrophilic and would add extremely slowly to acrylonitrile ($e = 1.11$) but more rapidly to 4-vinyl pyridine ($e = -0.20$). Thus it is possible that some regeneration of chain centers occurs in the latter system, involving the incorporation of cyclooctatetraene units by a copropagation sequence and leading to a relatively short period of highly retarded polymerization rather than full induction.

The development of color during the induction period recalls the orange coloration observed when cyclooctatetraene is illuminated with 2 537 Å radiation, both in the vapor phase (31) and in solution in ether (32). The colored substance was provisionally identified as bicyclo[4.2.0]octatriene-2,4,7 (32), and appears to be the precursor of polycyclooctatetraene in the vapor-phase experiments (31). However the α-cyanoisopropyl radical adds to cyclooctatetraene yielding initially 5,8-bis-(α-cyanoisopropyl)-cyclooctatriene-1,3,6 without producing coloration, ring contraction, or polymerization (30). Possibly a substituted bicyclooctatriene is formed in our systems by a disproportionation reaction involving a polymer radical with a terminal cyclooctatetraene unit.

Bicyclo[2.2.1]heptadiene-2,5

Figures 4 and 5 are conjugate Fineman–Ross plots for the copolymerization of acrylonitrile (A) with bicycloheptadiene (B). Straight lines drawn by the method of least squares yield the reactivity ratios:

$$r_A = 0.65 \pm 0.02 \qquad r_B = 0.47 \pm 0.08 \qquad \text{(Fig. 4)}$$

$$r_A = 0.63 \pm 0.10 \qquad r_B = 0.44 \pm 0.08 \qquad \text{(Fig. 5)}$$

(limits of error are given at the 10% probability level).

From the first set we obtain $r_A r_B = 0.31 \pm 0.06$, which indicates only mild alternation in this system. The parameters $Q_B = 0.27$ and $e_B = 0.03$ were calculated from $Q_A = 0.58$ and $e_A = 1.11$ for acrylonitrile (18). Figure 6 gives the copolymer composition curve for this system; the experimental points fit the theoretical line drawn for $r_A = 0.65$, $r_B = 0.47$ quite well.

Our results are in partial agreement with those obtained at 50 °C by Zutty (14), from which he derived the ratios $r_A = 0.67$ and $r_B = 0.08$. His points are shown as open circles in Figs. 4, 5, and 6. From Fig. 6 it is apparent that only one of his analyses is in serious conflict with ours. Figures 4 and 5 show that Zutty's results complement our own, and therefore we prefer the values $r_A = 0.65$ and $r_B = 0.47$ obtained from Fig. 4.

CONCLUSIONS

The high intrinsic reactivity of cyclohexadiene-1,3 as a monomer is clear from the value $Q_B = 1.76$. However the labile nature of the α-methylenic hydrogen atoms leads to extensive chain transfer in the thermal homopolymerization (8, 9). A favorable polar effect is required to raise the ratio of propagation to transfer to produce high polymer in good yield and this is achieved in the system [acrylonitrile + cyclohexadiene-1,3] for which $e_A - e_B = 2.29$.

Cycloheptatriene and cyclooctatetraene also possess considerable intrinsic reactivity.

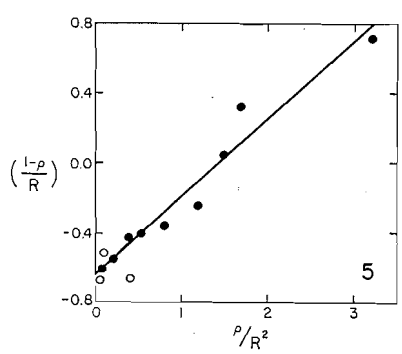

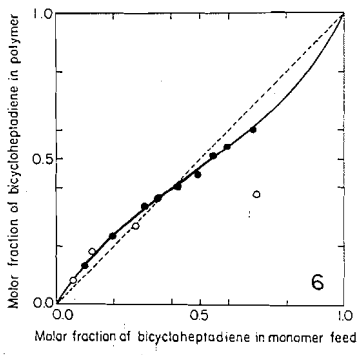

FIG. 5. Fineman–Ross plot of $(1 - \rho)/R = r_B\rho/R^2 - r_A$ for acrylonitrile (A) and bicycloheptadiene (B) at 60°, yielding $r_A = 0.63 \pm 0.10$, $r_B = 0.44 \pm 0.08$; ● this work, ○ ref. 14.

FIG. 6. Copolymer composition curve for acrylonitrile (A) and bicycloheptadiene (B) at 60°, drawn for $r_A = 0.65$, $r_B = 0.47$; ● this work, ○ ref. 14.

This is clear from the corresponding values of k_a and E_a in Table I, which are nearly as favorable as those for cyclohexadiene-1,3 and more favorable than those for bicycloheptadiene, a monomer which easily copolymerizes with acrylonitrile. The apparently anomalous behavior of cycloheptatriene and cyclooctatetraene towards acrylonitrile is due to the operation of an unfavorable polar effect in two distinct ways. This effect promotes degradative chain transfer in the case of cycloheptatriene and depresses the rates of the copropagation steps in the case of cyclooctatetraene. The slow copolymerization of cyclooctatetraene with 4-vinyl pyridine ($e = -0.20$) suggests the possibility of copolymerizing these polyenes with a monomer of high intrinsic reactivity and a low value of e, such as 2,3-dimethyl butadiene-1,3 ($Q = 5.86$, $e = -1.81$), and this is being pursued.

The values $Q = 1.76$, $e = -1.18$ for cyclohexadiene-1,3 seem reasonable when they are compared with the values $Q = 2.39$, $e = -1.05$ for butadiene-1,3 (Table II). The conjugated systems are closely similar, and the lack of terminal vinyl groups in cyclohexadiene-1,3 is likely to depress its intrinsic reactivity below that of butadiene-1,3. The values of e are consistent with the ready homopolymerization of both monomers with cationic initiators; indeed the homopolymerization of cyclohexadiene-1,3 is far more successful with boron trifluoride than with a radical sensitizer (33).

The values $Q = 0.27$, $e = 0.03$ for bicycloheptadiene are most appropriately compared with $Q = 0.019$, $e = -0.28$ for hexene-1. The enhanced intrinsic reactivity of bicycloheptadiene may arise from partial conjugation of the double bonds imposed by the geometry of the molecule.

TABLE II

Copolymerization parameters and some related characteristics

Monomer	Q	e	Half-wave potential (V)*	Most successful initiation
Cyclohexadiene-1,3	1.76	−1.18	No wave	Cationic
Cycloheptatriene	—	—	−1.96	?
Cyclooctatetraene	—	—	−1.28	Anionic
Bicycloheptadiene	0.27	+0.03	No wave	Radical
2,3-Dimethyl butadiene-1,3	5.86	−1.81	ca. −2.3	Cationic
Styrene	1.00	−0.80	−1.98	Cationic
Acrylonitrile	0.58	+1.11	−1.67	Anionic

*At 25 °C for 1 mM monomer in acetonitrile containing 0.1 M tetrabutyl ammonium iodide (2).

RAMAN SPECTRA AND VIBRATIONAL ASSIGNMENTS FOR TWO FORMS OF TETRAPHENYL CYCLOTETRAPHOSPHINE

R. L. AMSTER, W. A. HENDERSON, AND N. B. COLTHUP
Central Research Laboratories, American Cyanamid Company, Stamford, Connecticut
Received Aug. 23, 1963

ABSTRACT

Raman spectra have been obtained and vibrational assignments made for two isomeric compounds of tetraphenyl cyclotetraphosphine. The asymmetric P_4 ring stretch has been identified near 500 cm^{-1} while the symmetric ring-breathing vibration most probably mixes with other low-frequency motions and is not explicitly assigned.

There are reported in the literature two solid phosphorus compounds of the empirical formula C_6H_5P (1). Cryoscopic, mass spectrometric, and nuclear magnetic resonance (n.m.r.) data (1) have shown both compounds to be stereoisomeric forms of tetraphenyl cyclotetraphosphine, $(C_6H_5P)_4$. As part of an overall study of the vibrational frequencies of cyclotetraphosphines, Raman spectra of both compounds in the solid state were obtained and vibrational assignments made.

EXPERIMENTAL

Both compounds studied in this investigation were prepared as described by Henderson, Epstein, and Seichter (1). Compound A has a melting point of 153–155 °C while compound B melts at 195–199 °C. Each of the two crystalline compounds, approximately 1 g in quantity, was placed into a Raman tube which was then sealed under an atmosphere of dry nitrogen to prevent oxide formation.

Raman spectra, excited by Hg 4 358 Å were obtained using the instrument previously described (2). Spectra were recorded on Kodak IIa-O plates with exposure times ranging from 2 to 4 h. Tracings of the photographed spectra were made using a Leeds and Northrup microphotometer. Frequency values were obtained using helium calibration.

The observed frequencies for compounds A and B are listed in Table I along with relative intensities and vibrational assignments. Measured Raman shifts are estimated to be accurate within 5 cm^{-1}.

DISCUSSION

There is no literature available concerning the molecular symmetry of tetraphenyl cyclotetraphosphine. However, it is assumed in this study, as it was in the discussion of tetraalkyl cyclotetraphosphines (3), that the P_4 ring is puckered and by itself possesses D_{2d} symmetry. Addition of the four phenyl groups to the P_4 ring can yield a molecule of D_{2d} or lower symmetry depending upon the relative orientation of phenyl groups, and since several orientations appear reasonable, one might expect the existence of more than one form of tetraphenyl cyclotetraphosphine.

Interaction of the four phenyl groups attached to the P_4 ring can lead to the appearance of more than one Raman band corresponding to each vibration of a single monosubstituted phenyl group. However, since such band multiplicity does not occur for the alkyl vibrations in the tetraalkyl tetraphosphines (3) it is not expected to occur in the related phenyl compound. In addition to the often characterized modes of a monosubstituted benzene ring (4), there are in ϕ_4P_4 six vibrations corresponding to internal motions of the P_4 ring, and additional modes associated with deformations of the C—P—P angles. With respect to the six P_4 ring vibrations, the assumption of D_{2d} symmetry leads to a distribution of the motions as follows: a ring stretch and a ring deformation in class A_1, a class B_1 ring stretch and class B_2 ring deformation, a doubly degenerate ring deformation lying in

*The description of the phenyl modes follows the notation of Whiffen (4).

class *E*. As mentioned previously, the overall molecular symmetry of ϕ_4P_4 may be lower than D_{2d}, thus necessitating a reclassification of these P_4 ring vibrations.

Reference to vibrational assignments for tetraalkyl cyclotetraphosphines (3) and ϕPH_2 (5) leads us to expect four substituent-sensitive phenyl vibrations and all P_4 ring vibrations to fall below 550 cm^{-1}; this region will also contain the low frequency C—P—P deformations (3). One would thus predict some mixing of the substituent-sensitive phenyl, P_4 ring, and C—P—P deformation vibrations in the low frequency normal modes. A simple characterization of most modes in this frequency range, therefore, cannot be made.

VIBRATIONAL ASSIGNMENTS

In the observed spectra, we have not been able to detect any splitting of vibrational bands as a result of crystal symmetry. Therefore, assignments for the crystalline state have been made on the basis of the normal vibrations of the isolated molecule. In the discussion below, the assignments are given together in the order A, B.

The substituent-insensitive phenyl modes are readily assigned for both A and B by comparison with vibrational assignments to ϕPH_2 (5) and other monosubstituted

benzenes (4). Raman bands at 1 087 and 1 095 cm^{-1} and 687 and 693 cm^{-1} are assigned, by comparison with ϕPH_2, to the substituent-sensitive phenyl modes *q* and *r*. The similarity in frequencies for *q* and *r* in ϕ_4P_4, *A* and *B*, and ϕPH_2 indicates that in the cyclotetraphosphines these normal modes receive little contribution from P_4 ring vibration. Furthermore, absence of more than one Raman band corresponding to each of these substituent-sensitive and substituent-insensitive vibrations points up a lack of significant interaction among phenyl groups.

Four bands are observed between 390 cm^{-1} and 505 cm^{-1}. In the tetraalkyl cyclotetraphosphines (2) the asymmetric P_4 ring stretch lies between 465 cm^{-1} and 490 cm^{-1} and the symmetric P_4 stretch lies between 390 cm^{-1} and 410 cm^{-1}. Furthermore, the substituent-sensitive modes *y* and *t* are observed in ϕPH_2 at 445 cm^{-1} and 392 cm^{-1}, respectively. The ϕ_4P_4 band at 488 and 501 cm^{-1} is, thus, most reasonably assigned to the asymmetric P_4 stretch. However, some mixing is expected to occur between the simple symmetric P_4 stretch and *y* and *t* vibrations. In addition, these modes most probably mix with the lower frequency P_4 ring and C—P—P deformations. Hence, it would be unrealistic to make an assignment to each of three bands between 390 cm^{-1} and 445 cm^{-1} in terms of a simple vibration. They are, therefore, ascribed as a group to the ν^s P—P, *t* and *y* vibrational modes. One might describe the (444, 440 cm^{-1}) band, the most intense of the group, as predominantly ν^s P—P since the P—P stretching vibrations give rise to the most intense bands in the 300–600 cm^{-1} region in the tetraalkyl cyclotetraphosphines.

The remaining bands below 400 cm^{-1} are assigned as a group to normal modes described as combinations of the simple substituent-sensitive phenyl vibrations and P_4 and C—P—P bending modes.

The similarity between the Raman spectra of compounds A and B, and their resemblance to the low-frequency Raman spectra of the tetraalkyl cyclotetraphosphines (3) support previous conclusions that both compounds are tetraphenyl cyclotetraphosphines.

ULTRAVIOLET ABSORPTION OF SUBSTITUTED PHENYL AND POLYCYCLIC ARYL CHALCONES

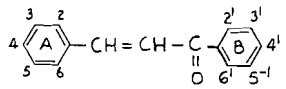
OWEN H. WHEELER, PETER H. GORE, MARCELINA SANTIAGO, AND ROSITA BAEZ
Department of Chemistry and Puerto Rico Nuclear Center, University of Puerto Rico, Mayaguez, Puerto Rico
Department of Chemistry, Brunel College, London

Received February 14, 1964

ABSTRACT

The ultraviolet and near-visible light absorption of a number of substituted *trans*-chalcones are reported.

Chalcones (I) possess a complex conjugate system since the carbonyl group is interposed between phenyl and styryl groups. *trans*-Chalcones generally show two main regions of selective ultraviolet absorption, one near 230 mμ (band II), the other beyond 300 mμ (band I) (see Table I). These two maxima were formerly attributed (1) to the partial benzoyl (PhCO—) and cinnamoyl (PhCH=CHCO—) chromophores, respectively, but the long wavelength band (band I) is now believed to involve the whole conjugate system (2). A third band, at 205 mμ, has been observed (3) and may be attributed to a modified E-band of the phenyl groups (cf. benzene λ_{max} 205 mμ, ε 6 300 (4)).



I

A so-called "middle" band, near 250 mμ, is shown by *cis*-chalcones (5) and by certain *trans*-chalcones (cf. compounds 5, 7, and 21, Table I) and this probably results from the partial (5) benzoyl (cf. PhCHO—, λ_{max} 248 mμ, ε 12 700 (6)) or benzoyl–vinyl (PhCOCH=CH—) chromophores (cf. PhCH=CHCOCH$_3$, λ_{max} 286 mμ, ε 25 000 (7)).

Szmant and Basso (2) have discussed the effect of para- and meta-substituents on the long wavelength band and have noted that a substituent produces a larger bathochromic displacement when it is located on ring A rather than on ring B (cf. Table II). In the case of band II, examination of the present data (Table I) and those reported in the literature (2, 3, 7–9) proved unsuccessful in arriving at general conclusions. The situation is complex since the singlet $\pi \rightarrow \pi^*$ transitions (K-bands) of most simple substituted aryl groups (contributing here as partial chromophores) fall within the region of absorption of band II (cf. styrene, λ_{max} 249 mμ, ε 10 000 (10); phenol, λ_{max} 270 mμ, ε 1 450 (11)).

ortho-Substituents are known to cause large hypsochromic effects in certain chalcones (2). Thus, negative values were shown for 2-chlorochalcones (8, 12) and for certain ortho-nitro (7) and mesityl derivatives (1*b*, 7). Similarly, 2-chloro-4′-methoxychalcone (compound 18) exhibits a $\Delta\lambda = -22$ mμ, compared to the calculated absorption (2). While one ortho-substituent in ring B may give a bathochromic displacement (e.g. 2′-hydroxychalcone, $\Delta\lambda = +17$ mμ), the introduction of a further ortho-substituent may give an overall hypsochromic effect (e.g. 2′-hydroxy-6′-methoxychalcone, $\Delta\lambda = -16$ mμ (9*b*)). A splitting of the K-band, with reduction of the intensity of absorption, has been observed in 2-methoxychalcone which exhibited λ_{max} 297 and 348 mμ, ε 15 400 and 14 800,

respectively (8). A similar effect is noticed in 2-methoxy-4′-bromochalcone (compound 19) where three long wavelength bands are observed. Data recently obtained by Noyce and Jorgenson (8) on corresponding 2- and 4-substituted chalcones allow the calculation of the hypothetical angle of deformation, which may be responsible for the lowered intensity of the K-band of the 2-isomer. Assuming that the molar extinction of the K-band for the 2-isomer would be that of the 4-isomer (ϵ_0) in the absence of an angular deformation of one phenyl chromophore relative to the other, then the deformation angle (θ) in the 2-isomer may be calculated from the equation (13) $\cos^2\theta = \epsilon_a/\epsilon_0$, where ϵ_a is the value for the 2-isomer. The values so obtained are nearly equal for methyl-(35°), chloro-(36°), or methoxy-(39°) substituents, and are similar to those observed for 2,2′-disubstituted azoxybenzenes (14).

Polycyclic Chalcones

The K-bands of a series of chalcone derivatives with one of its aryl groups a naphthyl or phenanthryl residue are given in Table III. Substitution for phenyl in ring A results

TABLE III

Absorption of polycyclic aryl chalcones

Ar_1	Ar_2	Solvent	K-band	$\Delta\lambda$
Phenyl	Phenyl	EtOH	310(27 000)	—
1-Naphthyl	Phenyl	EtOH	352(14 700)	+42
2-Naphthyl	Phenyl	EtOH	328(24 300)	+18
1-Phenanthryl	Phenyl	EtOH	317[a](7 100)	+7

in bathochromic shifts of the K-band maxima in increasing order of conjugating powers, phenyl < 1-phenanthryl < 2-naphthyl < 1-naphthyl < 9-phenanthryl, and in ring B, phenyl < 2-naphthyl < 2-phenanthryl < 3-phenanthryl. Significantly the effect is more pronounced in ring A than in ring B. Certain anthryl chalcones were also examined, but their K-bands correspond in wavelength with, and are submerged in, the absorption of the anthracene moiety.

EXPERIMENTAL

Chalcones

These were prepared by condensation of the appropriate acetophenones and benzaldehydes (15) and were recrystallized before use. Compounds 3, 13, 17, and 21 (Table I) were also purified by chromatography on alumina from benzene and hexane. Their melting points are recorded in Table I. The preparations of the polycyclic chalcones (Table III) will be published in connection with other work.

Spectra

The ultraviolet and near visible spectra were determined, unless otherwise stated, using solutions in 95% ethanol, which had been purified by refluxing with zinc dust and sodium hydroxide. The dioxan was purified by refluxing with, and distilling from, sodium, using only the center fraction. Chloroform was analytical grade. Measurements were made with a Bausch and Lomb spectronic 505 spectrophotometer with 1.0 cm cells. Concentrations were such as to give optical densities of 0.5–0.8. Several spectra were rechecked on a Beckman DU spectrophotometer.

LYCOPODIUM ALKALOIDS

XVI. ANNOTINE

W. A. Szarek, K. A. H. Adams, M. Curcumelli-Rodostamo, and D. B. MacLean
Department of Chemistry, McMaster University, Hamilton, Ontario

Received July 13, 1964

ABSTRACT

Annotine, $C_{16}H_{21}O_3N$, is shown to be pentacyclic and to contain a tertiary hydroxyl group, a lactone function, a tertiary nitrogen atom, and a dialkylated double bond. The position of the double bond and the tertiary hydroxyl group relative to the nitrogen atom has been established by Emde degradation of annotine methiodide. The presence of a lactone function is inferred from the reduction of annotine to dihydroannotinol, a hemiacetal, which reacts with 1 mole of ethyl mercaptan. The reduction of the lactone to a diol in an annotine derivative has been carried out. The chemical studies and the examination of annotine and its derivatives by modern instrumental methods allow the assignment of a plausible structure to the alkaloid.

Annotine, $C_{16}H_{21}O_3N$ (I), was first isolated from *L. annotinum* of Canadian origin by Manske and Marion and designated alkaloid L.11 (1). It was subsequently found in European plant material by Bertho and Stoll (2), who assigned the name annotine to it, and by Achmatowicz and Rodewald (3). An examination of the functional groups of annotine was carried out by Perry and MacLean (4), who concluded that the alkaloid contained a tertiary nitrogen atom, a double bond, a hydroxyl group, a ketonic carbonyl group, and a third inert oxygen function, which they ascribed to an ether linkage other than an epoxide.

In this communication we wish to report further studies on annotine by chemical and modern instrumental methods. These studies have shown that annotine is a lactone and have thereby established the nature of the third inert oxygen function. They have also allowed an assignment of the position of the double bond and the hydroxyl group in the molecule relative to the nitrogen atom and have led to the development of a plausible structure for the molecule.

Nuclear magnetic resonance (n.m.r.) spectroscopy has been used extensively in this study and has provided useful information about the functional groups and their environment in annotine and its derivatives. The n.m.r. spectrum of annotine has a quartet centered at $\tau = 4.04$ ($J = 10$ c.p.s.) with an intensity corresponding to two protons. This band indicates the presence of the grouping $\begin{matrix} H \\ \diagdown \\ \quad C{=}C \\ \diagup \\ \quad \end{matrix}\!\!\begin{matrix} \quad \\ \diagup \\ H \\ \diagdown \\ \quad \end{matrix}$ and is an example of an intermediate case of an AB spectrum in which the chemical shift between the two nuclei is comparable to the coupling constant between them (5). It was possible to resolve each component of the quartet into a triplet in each of which the splitting was the same. These data indicate the presence of a methylene group adjacent to the double bond, as in the grouping $\begin{matrix} \quad \\ \diagup \\ C \\ \diagdown \\ \quad \end{matrix}\!\!-CH{=}CH-CH_2-$.

A singlet occurring at $\tau = 8.57$ with an intensity corresponding to three protons points to the presence of a methyl group attached to a quaternary carbon. The low τ value of the C—methyl group in this system can possibly be explained by the deshielding effect of a carbonyl group beta to the methyl protons. It has been postulated that the deshielding effect in such a system is due to the anisotropy of the carbonyl group and that the deshielding effect will be greatest if the methyl group lies in the plane of the carbonyl group (5).

The n.m.r. spectrum also shows a band at $\tau = 5.83$, corresponding in intensity to two protons. This band in more concentrated solution appears as two overlapping peaks, which are tentatively assigned to the groupings $>CH-O-C(=O)<$ and $>C-OH$. It should be pointed out at this stage that the hydroxyl group in annotine is believed to be tertiary, since the substance is recovered unchanged after treatment with chromic acid or by the Oppenauer method. Other peaks in the spectrum are more difficult to assign, but one might suggest that the peak at $\tau = 6.63$, corresponding to two protons, may be attributed to a methylene group sandwiched between the double bond and the nitrogen atom, while the peak at 7.32 is due to a second methylene group adjacent to nitrogen but attached to a saturated center.

In an effort to check the assignments above, we examined the n.m.r. spectrum of dihydroannotine (II). We found that the preparatory procedure reported previously (4) gave a product of uncertain composition, but that catalytic hydrogenation over platinum in the presence of a trace of hydrochloric acid gave a pure dihydroannotine in high yield. Its n.m.r. spectrum lacks the ethylenic absorption of annotine but retains the $>C-CH_3$ absorption at $\tau = 8.56$. The proton of the hydroxyl group probably gives rise to the sharp band observed in the spectrum at $\tau = 6.82$. A band of intensity equal to one proton at $\tau = 5.74$ has been assigned again to the grouping $>CH-O-C(=O)<$. The half-band width of 9.9 c.p.s. for this band indicates coupling to three or four protons.

The above n.m.r. data establish that the double bond is dialkylated and joined to a methylene group on one side and probably to a quaternary center on the other side. They show that the methyl group is attached to a quaternary carbon center and that it may be beta to a carbonyl function. The presence of the peak centered at 5.83 in annotine and 5.74 in the dihydro compound implies the presence of a hydrogen attached to a carbon carrying an ester function. This observation provided the first clue that annotine might be a lactone. The following structural sequences are suggested from the n.m.r. data:

$$>C-CH=CH-CH_2-N< \quad \text{and} \quad \begin{array}{l} \\ HC-O-C(=O)-C-CH_3 \\ \\ \end{array}$$

The experiments reported below support both of these structural assignments.

The sequence $>C-CH=CH-CH_2-N<$ suggested by the n.m.r. spectra of annotine and dihydroannotine has been confirmed and extended by degradation of annotine methiodide. Annotine readily forms a methiodide, and attempts were made to degrade it by several methods. An attempted elimination with potassium tertiary butoxide yielded an oil which resisted all attempts at crystallization. Attempts to prepare crystalline salts were also unsuccessful. Attention was therefore turned to the Emde degradation. Although annotine methiodide did not react with sodium amalgam, it readily reacted with hydrogen over Adams' catalyst to form a crystalline saturated compound III, $C_{17}H_{27}O_3N$.

The infrared spectrum of III shows absorption at 3485 cm^{-1} in the hydroxyl region and strong absorption at 1712 cm^{-1} in the carbonyl region. The n.m.r. spectrum of III shows that no ethylenic protons are present. It does indicate, however, the presence of two C—methyl groups in the compound with absorptions at $\tau = 8.55$ and $\tau = 8.98$. The signal at $\tau = 8.55$ is a single sharp peak and corresponds to the original $>C-CH_3$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

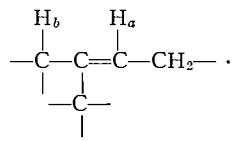
group in the alkaloid. The band at $\tau = 8.98$ is quite broad, indicating coupling with neighboring protons. This band is assigned to a methyl group at the end of an alkyl chain formed by cleavage of a C—N bond in the hydrogenolysis reaction. A single sharp peak occurring at $\tau = 7.47$ with an intensity corresponding to three protons is assigned to the N—CH_3 group in the compound. A broad band at $\tau = 5.73$ is also present in the n.m.r. spectrum of compound III.

Significantly, dihydroannotine methiodide did not undergo an Emde degradation when treated with hydrogen over Adams' catalyst. The driving force for the Emde degradation of annotine must be the presence of the double bond, in a position β,γ to the nitrogen. In support of the latter hypothesis it should be noted that the pK_a values of annotine and dihydroannotine were found to be 7.5 and 8.61 respectively (4). These results substantiate the n.m.r. assignment.

The presence and the nature of an alkyl side chain in the Emde degradation product III were established by a modified Kuhn–Roth oxidation (6). The volatile carboxylic acids produced were separated and identified by gas chromatography of their methyl esters. Oxidation of the Emde degradation product III yielded acetic and propionic acids, a result that established the presence of an ethyl group in the compound. When the same oxidation procedure was applied to annotine itself, there was no carboxylic acid detected by gas chromatography. Considering the evidence for a $>C—CH_3$ group in the alkaloid, one would have expected acetic acid to have been produced by the oxidation—even if in low yield—because of the quaternary character of the $>C—CH_3$ group.

Detailed information on the structure of the ring opened in the Emde degradation was obtained from a study of the anhydro derivative of degradation product III. Attempts to dehydrate III with thionyl chloride or phosphoric acid were unsuccessful. It was dehydrated cleanly to compound IV, $C_{17}H_{23}O_2N$, by *p*-toluenesulphonic acid or 47% hydriodic acid. The infrared spectrum of compound IV shows carbonyl absorption at 1730 cm^{-1} but it does not show any hydroxyl absorption. The ultraviolet spectrum shows no absorption characteristic of an α,β-unsaturated carbonyl system.

Nuclear magnetic resonance spectroscopy provided key information about the anhydro compound IV. In the n.m.r. spectrum the $>N—CH_3$ group gives rise to a single sharp peak of intensity corresponding to three protons at $\tau = 7.79$, and a $>C—CH_3$ group appears as a singlet at $\tau = 8.76$. The band at $\tau = 8.96$, representing the methyl group at the end of the alkyl chain, appears as a distinct triplet, a result which establishes that the terminal methyl group is adjacent to a $—CH_2—$ group. This conclusion had been reached previously from the results of the modified Kuhn–Roth oxidation of the Emde product III. The n.m.r. spectrum also shows the ubiquitous broad band at $\tau = 5.63$. Of prime importance, however, is the triplet (splitting, 6.1 c.p.s.) of relative intensity 1:2:1 at $\tau = 4.77$ corresponding to one ethylenic proton. This band is assigned to the grouping $>C=CH—CH_2—$. Each component of the triplet could be resolved into a doublet (splitting, 0.9 c.p.s.). A grouping of the following type is compatible with this observation:

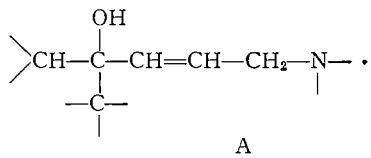


Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The doublet can be considered to arise from spin–spin coupling between H_a and H_b with coupling constant $J_{ab} = 0.9$ c.p.s. Usually, coupling only occurs across one, two, or three bonds, although it can and does extend further in systems with double bonds.

Catalytic reduction of the anhydro compound IV led to the formation of a non-crystalline compound V, $C_{17}H_{27}O_2N$. A modified Kuhn–Roth oxidation of compound IV yielded acetic and propionic acids, whereas the saturated compound V yielded butyric acid as well as propionic and acetic acids.

The results of the Kuhn–Roth oxidations in conjunction with information gleaned from the n.m.r. spectra of compounds derived from the Emde degradation indicate the presence of the system A in annotine:



A

The results obtained by a study of the Emde degradation of annotine are summarized in Scheme I.

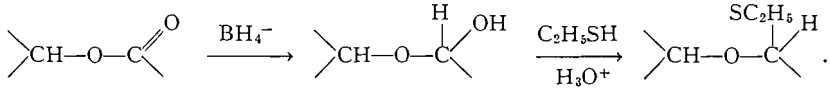
It was intimated that annotine is a lactone and not a ketone, as Perry and MacLean believed (4). Their evidence for the ketonic character of the carbonyl group was based on two reactions. One of these was the treatment of annotine with sodium borohydride yielding annotinol, $C_{16}H_{23}O_3N$, which differs in composition from the starting compound by two hydrogens. Annotinol no longer had carbonyl absorption in its infrared spectrum and was converted to annotine by oxidation. The second reaction, with phenyl lithium, gave phenylannotine, $C_{22}H_{27}O_3N$. The analysis showed that a single phenyl group was incorporated and the compound showed no carbonyl absorption in its infrared spectrum. We have reexamined these two processes and have confirmed Perry and MacLean's observations. In addition, we independently established the molecular weight of phenylannotine by recording its mass spectrum, and have also examined its ultraviolet spectrum (which displayed only benzenoid absorption). There seemed little reason to doubt the presence of a ketonic carbonyl group.

There are a number of observations, however, at variance with their assignment. The n.m.r. spectra of annotine, dihydroannotine, and the products of Emde degradation all contain a peak at $\tau = 5.7 \pm 0.1$ of an intensity of one proton. This peak is lower than might be expected of a hydrogen in a cyclic ether, $\rangle CH—O—R$, but lies more in the region expected of a lactone or ester, $\rangle CH—O—C(=O)\langle$ (5). Secondly, we found that annotine was unreactive toward common carbonyl reagents. Thirdly, upon attempted Wolff–Kishner reduction, only a very small amount of annotine was recovered by chloroform extraction of the basic reaction mixture. It appears that annotine forms a water-soluble salt when it is heated at high temperatures with potassium hydroxide. In confirmation of this postulate, we found that annotine shows the same behavior when it is treated under conditions identical with those employed in the Wolff–Kishner reduction, but in the absence of hydrazine. Finally, a deuterium exchange study showed that there were no hydrogens in annotine that take part in enolate ion formation. At least one enolic hydrogen might be expected of a ketonic substance based on the structural framework common to the *Lycopodium* alkaloids of known structure. All the evidence noted above militates against the presence of a ketonic carbonyl group in annotine, but it does not directly support the presence of a lactone function.

There are two experiments which lend direct support to the lactone formulation for annotine. We found that dihydroannotinol, $C_{16}H_{25}O_3N$ (VI), formed by borohydride reduction of dihydroannotine, reacted with ethyl mercaptan in acid medium to form the substance $C_{18}H_{29}O_2NS$ (VII) in which a thioethyl group has apparently replaced a hydroxyl group of VI. A reaction of this nature can be readily interpreted on the basis of a lactone structure for annotine but not for a ketonic structure. Thus, the borohydride reduction of dihydroannotine would proceed to the hemiacetal, which, with ethyl mercaptan in the presence of acid, yields the product VII, as depicted by the partial formulae below:



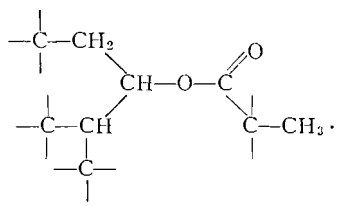
Dihydroannotinol reverted to dihydroannotine upon Oppenauer oxidation, indicating that the reaction was a simple reduction production.

In the n.m.r. spectrum of VII there is now a singlet at $\tau = 5.17$, presumably due to the hydrogen situated on the carbon carrying the thioethyl group. It is significant that the

peak present in other spectra at 5.7 ± 0.1 and assigned to the $>CH-OC<^{O}$ proton is no longer present; instead a broad peak corresponding to one proton is observed at $\tau = 6.19$. The methyl and methylene protons of the thioethyl group appear as a triplet at $\tau = 8.73$ and as a quartet centered at 7.35, respectively, but both underlie other absorption. The original C—methyl group has not altered appreciably in position, appearing at $\tau = 8.66$. Apparently the two electron-attracting groups attached to the beta carbon, —SR and —OR, have a deshielding effect equivalent to a carbonyl group in the beta position. The fact that two thioethyl groups were not introduced is another indication of the stability of this cyclic system. Other examples of its unreactivity toward ring opening are the resistance of the lactone to hydrolysis and the absence of carbonyl absorption in the infrared spectra of the hemiacetal, dihydroannotinol, and the hemiketal, phenylannotine.

In the second experiment, the lactone ring was successfully reduced to a diol with lithium aluminium hydride. Perry and MacLean reported that annotine was recovered unchanged upon treatment with $LiAlH_4$ in tetrahydrofuran and we have confirmed their findings. The failure of this reaction may be due to the formation, by interaction of $LiAlH_4$ with the hydroxyl group, of an insoluble salt which separates from the medium. Accordingly, we carried out the reaction on a derivative of annotine which no longer had the hydroxyl group. Compound IV was chosen because of its relative ease of preparation. Reaction of IV with $LiAlH_4$ yielded diol VIII, $C_{17}H_{29}O_2N$. The uptake of four hydrogen atoms in the conversion IV → VIII shows that the function which underwent reduction is a lactone rather than a ketone.

If the deductions regarding the position of the C—methyl group relative to the carbonyl carbon are correct, we may summarize these findings in expression B.



B

This formulation is compatible with the chemical and spectroscopic data presented before. Since the infrared absorption of the carbonyl group of annotine and its derivatives never appears above 1740 cm^{-1}, one must assume that the lactone is six-membered or larger.

All *Lycopodium* alkaloids of established structure with a single nitrogen atom conform in structure to lycopodine (6), with the exception of annotinine (7) and lyconnotine (8). The three alkaloids are closely related, having in common a hydrojulolidine system. In lyconnotine the hydrojulolidine system is not bridged as it is in annotinine and lycopodine. Since annotine occurs in the same plant as these alkaloids and since it may be deduced from its composition that it contains a combination of four carbocyclic and (or) heterocyclic rings other than its lactone ring, it seemed likely that it might conform in skeletal structure to either lycopodine or annotinine. However, attempted incorporation of expressions A or B into the skeletal framework of either alkaloid proved impossible. Other formulations based upon the hydrojulolidine framework were therefore considered, and

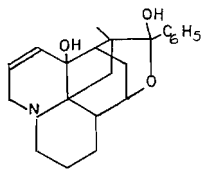
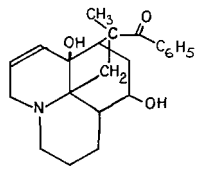
Lyconnotine X



IX (a)



IX (b)

The placement of the bridge in C, D, and E follows from analogy to other alkaloids of this family. This placement is supported by the n.m.r. spectrum of IV which was discussed previously. The conclusions with respect to the structure of ring D are corroborated by investigation of the pyrolysis of phenylannotine. This compound, represented by structure IX*a* and IX*b*, was heated at 300° in the presence of zinc dust. The distillate collected during the pyrolysis was examined by gas–liquid partition chromatography. It was found to consist of two substances which, from their ultraviolet spectra, appeared to be phenones. The identity of the two compounds was established by comparison of their retention times with known phenones. They proved to be propiophenone and α-methylacrylophenone. In structure IX*b* the carbon atoms participating in the formation of α-methylacrylophenone are designated.

It is appropriate to consider here whether any of the structures C, D, or E proposed for annotine is favored over the others. The conclusion, discussed previously, that dihydroannotinol and phenylannotine exist in the hemiacetal and hemiketal forms, respectively, is evidence against structure E. Examination of molecular models, based on E, of dihydroannotinol and phenylannotine reveal that considerable strain is released by opening the hemiacetal and hemiketal rings, respectively. Thus if structure E were correct, one would expect dihydroannotinol to be a hydroxyaldehyde rather than a hemiacetal and phenylannotine to exist as the hydroxyketone, provided that reduction had ceased at this stage.

Structure C is favored over D and E on the basis of the following considerations. In all *Lycopodium* alkaloids of established structure there is a methylene group present at C_{13}. There is no recorded case of substitution at this site. Recently, structure X has been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

proposed for lyconnotine, a new alkaloid isolated from *L. annotinum* (8). This structure bears a strikingly close relation to C. The carbon skeleton of annotine (as in C) is formally derived from X by formation of a bond between C_5 and C_{14}. Thus it may be that X and annotine are formed in the plant from a common precursor, or one may be the precursor of the other. The conversion of annotine to the carbon skeleton of X in vitro is readily visualized. Transformation of annotine to the hydroxymethyl ester (oxidation of the C_7 hydroxyl to the ketone followed by a β-elimination) leads to the carbon skeleton of X.

The configuration suggested for annotine in structure C is based upon the following considerations. Neither annotine itself nor dihydroannotine show the Bohlmann bands (9) characteristic of the *trans*-fused quinolizidine system in the 2900 cm^{-1} region of their infrared spectra. Anhydrotetrahydroannotine, obtained by dehydration of dihydroannotine over *p*-toluenesulfonic acid in xylene followed by reduction with hydrogen, does exhibit the Bohlmann bands. Reduction of the $\Delta^{3,4}$ double band would be expected to proceed from the least hindered side and to lead to the inverted configuration of C_4 and the *trans*-fused quinolizidine system. Unfortunately, neither the dehydration product nor the anhydrotetrahydroannotine were crystalline compounds and fully characterized, so that these conclusions must be accepted with some reservation. Furthermore, the hydroxyl group in dihydroannotine is intramolecularly hydrogen bonded, showing the hydroxyl absorption at 3545 cm^{-1} (which is not shifted upon dilution). This result is also compatible with the *cis*-fused quinolizidine system and is analogous to lycodoline (10), which carries a hydroxyl group in the same relative position in the hydrojulolidine system. The configuration at C_7 and C_8 follows from the stability of the lactone to hydrolysis and the stability of the hemiacetal and hemiketal forms of dihydroannotinol and phenylannotine, respectively.

EXPERIMENTAL

Apparatus and Methods

Melting points were recorded on a Kofler micro hot stage melting point apparatus and are uncorrected.

The infrared spectra were recorded on a Beckman Model IR-5 recording spectrophotometer in Nujol mull, unless otherwise stated.

Ultraviolet spectra were measured in methanol on a Perkin–Elmer Model 4000 spectracord.

The mass spectra were determined on a C.E.C.-103 mass spectrometer at an ionizing potential of 70 eV and an ionizing current of 50 μA. Samples were introduced through a heated inlet system maintained at 140 °C. The samples were run through the courtesy of Professor K. Biemann, Massachusetts Institute of Technology, Cambridge, Massachusetts.

The n.m.r. spectra were measured in deuterochloroform solutions with tetramethylsilane as an internal standard on a Varian V-4300 B high-resolution spectrometer at a frequency of 60 Mc/s.

Annotine (I)

Annotine was obtained from annotoxine which had crystallized from the mother liquors remaining after the separation of annotinine from the mixed alkaloids of *L. annotinum*. Annotoxine was readily separated into acrifoline and annotine by fractional crystallization of the hydrobromide salts.

Annotine was purified through the nitrate salt. The crude alkaloid was dissolved in the minimum volume of 2 *M* acetic acid and treated with a concentrated solution of sodium nitrate. The crystals of annotine nitrate were separated and dissolved in water, and the solution was basified with ammonia. Immediately after basification, the base precipitated in snowflake-like clusters. The base was separated by filtration and recrystallized from acetone, yielding rectangular plates which melted at 174.6–176 °C.

Calcd. for $C_{16}H_{21}O_3N$: C, 69.79; H, 7.69; N, 5.09. Found: C, 69.78; H, 7.83; N, 5.05.

The infrared spectrum in Nujol showed weak absorption at 3300 cm^{-1} in the hydroxyl region and a split peak at 1728 cm^{-1} and 1739 cm^{-1} in the carbonyl region. In chloroform solution there was absorption at 3500 cm^{-1} attributable to an intramolecularly bonded hydroxyl group, strong absorption at 1720–1730 cm^{-1} in the carbonyl region, and absorption at 1644 cm^{-1} which is assigned to unsaturation. There was also absorption at 1374 cm^{-1} attributable to a C—methyl group.

Preparation of Dihydroannotine (II)

A solution of annotine (0.050 g) in 30 ml of redistilled methanol containing 5 drops of concentrated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

hydrochloric acid and 0.040 g of Adams' catalyst was subjected to a hydrogen pressure of 50 p.s.i.g. for 5 h. The solution was filtered free of catalyst and the organic solvent removed under reduced pressure. Water was added to the residue, and the resulting solution was basified with ammonia and extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure to yield 0.050 g of product which crystallized immediately on contact with ether. Recrystallization from acetone–petroleum ether gave colorless crystals melting at 203–204 °C.

Calcd. for $C_{16}H_{23}O_3N$: C, 69.28; H, 8.36; N, 5.05; active H, 0.36 (1). Found: C, 69.55; H, 8.71; N, 5.23; active H, 0.37.

The infrared spectrum of this material in Nujol had hydroxyl absorption at 3510 cm^{-1}, carbonyl absorption at 1728 cm^{-1}, and strong absorption at 1118 cm^{-1}. In carbon disulphide solution there was hydroxyl absorption at 3545 cm^{-1} and carbonyl absorption at 1740 cm^{-1}.

Preparation of Annotine Methiodide

A solution of annotine (0.100 g) in 5 ml of acetone and 1 ml of methyl iodide was heated under reflux and within 5 min a crystalline methiodide began to separate. The mixture was heated under reflux for 15 min longer, cooled, and allowed to stand at room temperature for 1 h. Filtration gave 0.125 g (81%) of product melting at 235.5–237 °C (with decomposition). An additional 0.021 g (13%) of product was obtained from the filtrate on further treatment with methyl iodide in acetone. The methiodide was recrystallized first from methanol–acetone and then from water to yield colorless crystals melting at 236–237 °C (with darkening).

Calcd. for $C_{16}H_{21}O_3N \cdot CH_3I \cdot H_2O$: C, 46.90; H, 5.97; N, 3.22. Found: C, 47.24; H, 6.10; N, 3.74.

Achmatowicz and Rodewald (3) report a melting point of 317° (violent explosion) and Bertho and Stoll (2) a melting point of 236–237° for annotine methiodide.

Treatment of Annotine Methiodide with Hydrogen

A solution of annotine methiodide (0.200 g) in 50 ml of distilled water containing 0.200 g of Adams' catalyst was subjected to a hydrogen pressure of 50 p.s.i.g. for 5 h. The solution was filtered free of catalyst, basified with ammonia, and extracted several times with chloroform. The combined chloroform extract was dried over sodium sulphate and evaporated under reduced pressure to yield 0.111 g (79%) of product which crystallized on standing. Recrystallization from acetone–ether yielded rectangular plates melting at 221–222 °C.

Calcd. for $C_{17}H_{27}O_3N$: C, 69.59; H, 9.28; N, 4.77. Found: C, 69.10, 69.12; H, 9.24, 9.33; N, 4.77, 4.97.

The infrared spectrum of compound III showed absorption at 3485 cm^{-1} in the hydroxyl region and strong absorption at 1712 cm^{-1} in the carbonyl region.

Modified Kuhn–Roth Oxidation of Annotine

The oxidation procedure and analytical method described by Harrison *et al.* (6) were used. Oxidation of 0.057 g (0.21 mmole) of annotine did not yield any carboxylic acid detectable by vapor phase chromatography.

Modified Kuhn–Roth Oxidation of the Emde Degradation Product III

Oxidation of 0.018 g (0.062 mmole) of the Emde degradation product III yielded 0.079 meq (64%) of volatile carboxylic acids. Vapor phase chromatography of their methyl esters revealed the presence of methyl acetate and methyl propionate in the molar ratio of 78:22 respectively.

Dehydration of III

(a) With p-Toluenesulphonic Acid

Compound III (0.146 g) was heated under reflux with *p*-toluenesulphonic acid in *o*-xylene overnight. The reaction mixture was cooled, water added, and the *o*-xylene separated and washed with dilute acid. The combined aqueous layer and acid washings were washed with ether, basified with ammonia, and extracted several times with chloroform. The chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure to yield a crystalline material (0.121 g). Recrystallization from acetone–petroleum ether gave crystals melting at 164 °C. The compound was purified for analysis by sublimation at 80° and 0.01 mm Hg, m.p. 164 °C.

Calcd. for $C_{17}H_{25}O_2N$: C, 74.14; H, 9.15. Found: C, 73.61; H, 9.12.

The infrared spectrum of compound IV showed carbonyl absorption at 1730 cm^{-1}, but no hydroxyl absorption. The ultraviolet spectrum showed no absorption characteristic of an α,β-unsaturated carbonyl system.

(b) With Hydriodic Acid

A solution of III (0.050 g) in 5 ml of 47% hydriodic acid was heated under reflux for 6 h. The reaction mixture was cooled and poured on ice. The aqueous solution was made alkaline with ammonia and extracted several times with chloroform. The combined chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure to yield 0.040 g of a crystalline material whose infrared absorption spectrum was identical with that of the compound obtained from the treatment of compound III with *p*-toluenesulphonic acid.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Hydrogenation of IV

A solution of compound IV (0.110 g) in 40 ml of redistilled methanol containing 0.080 g of Adams' catalyst was subjected to a hydrogen pressure of 50 p.s.i.g. for 5 h. The solution was filtered free of catalyst and evaporated to dryness to yield a pale yellow oil which could not be induced to crystallize. This material was sublimed at 80 °C and 0.01 mm Hg to give a white amorphous solid.

Calcd. for $C_{17}H_{27}O_2N$: C, 73.60; H, 9.81; N, 5.05. Found: C, 73.45; H, 9.36; N, 5.22.

The infrared spectrum of compound V showed strong carbonyl absorption at 1730 cm^{-1}, but no hydroxyl absorption.

Modified Kuhn–Roth Oxidation of IV

Oxidation of 0.065 g (0.236 mmole) of IV yielded 0.40 meq (85%) of volatile carboxylic acids. Vapor phase chromatography of their methyl esters revealed the presence of methyl acetate and methyl propionate in the molar ratio of 66:34 respectively.

Modified Kuhn–Roth Oxidation of V

Oxidation of 0.060 g (0.216 mmole) of compound V yielded 0.31 meq (72%) of volatile carboxylic acids. Vapor phase chromatography of their methyl esters revealed the presence of methyl acetate, methyl propionate, and methyl butyrate in the molar ratio of 63:34:3 respectively.

Dihydroannotinol (VI)

A mixture of 0.060 g of sodium borohydride in 10 ml of ethanol and 0.200 g of dihydroannotine (II) in 10 ml of ethanol was refluxed for 4 h, cooled, and the excess borohydride destroyed by the addition of acetic acid. Most of the alcohol was removed by distillation, 50 ml of water was added, and the solution was basified with ammonia and extracted several times with chloroform. The combined chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure to yield 0.190 g of a colorless oil which crystallized on standing. Recrystallization from chloroform gave crystals melting at 186–187 °C. The infrared spectrum of this compound (dihydroannotinol) showed hydroxyl absorption at 3526 cm^{-1}, but no carbonyl absorption. The mass spectrum showed a molecular ion peak at 279.

Calcd. for $C_{16}H_{25}O_3N$: active H, 0.72 (2). Found: active H, 0.74.

Oppenauer Oxidation of Dihydroannotinol

A solution of dihydroannotinol (0.050 g) and aluminium tertiary butoxide (0.300 g) in 5 ml of toluene and 1 ml of cyclohexanone was heated under reflux for 6 h, then poured into cold dilute hydrochloric acid, and the organic layer extracted several times with dilute acid. The aqueous extract was made alkaline with 10% sodium hydroxide solution and extracted several times with chloroform. The chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure, leaving a white solid whose infrared spectrum was the same as that of dihydroannotine.

Treatment of Dihydroannotinol with Ethyl Mercaptan

Dihydroannotinol (0.030 g) in 1 ml of concentrated hydrochloric acid (density 1.19) was treated, at 0 °C and under mechanical stirring, with ethyl mercaptan (1 ml) for 10 h. The solution was poured on a mixture of sodium hydroxide solution (40%; 2 ml) and cracked ice. The basic solution was extracted several times with chloroform. The chloroform extract was dried over anhydrous sodium sulphate and evaporated under reduced pressure to yield a colorless oil (0.021 g) which crystallized on standing. This substance was recrystallized from acetone to yield rectangular plates melting at 130 °C.

Calcd. for $C_{18}H_{29}O_2NS$: C, 66.82; H, 9.03; S, 9.91. Found: C, 66.93; H, 9.09; S, 10.25.

The infrared spectrum of compound VII showed hydroxyl absorption at 3410 cm^{-1}, but no carbonyl absorption. Its molecular weight was found to be 323 by mass spectrometry.

Reduction of IV with Lithium Aluminium Hydride

Compound IV (190 mg) in dry ether was added dropwise to a suspension of excess lithium aluminium hydride in dry ether. The reaction mixture was stirred at room temperature overnight and the excess hydride decomposed with moist ether. The ether solution was decanted and evaporated to yield 160 mg of viscous oil. The oil was converted to its hydrobromide salt and the latter recrystallized from methanol–acetone. It melted at 301–305°. The infrared spectrum showed hydroxyl absorption, but no carbonyl absorption. The mass spectrum of the base liberated from the hydrobromide showed a molecular ion peak at 279 corresponding to the molecular formula $C_{17}H_{29}O_2N$.

Phenylannotine

This compound was prepared by the method of Perry and MacLean (4). It was recrystallized from acetone and melted at 215–217°. The mass spectrum showed a molecular ion peak at 353. The infrared spectrum has an intense band in the hydroxyl region at 3470 cm^{-1} and a weak band at 1640 cm^{-1} attributable to non-benzenoid unsaturation. There was no absorption in the carbonyl region. In the ultraviolet spectrum there was only benzenoid absorption.

Pyrolysis of Phenylannotine

A mixture of phenylannotine (0.02 g) and zinc dust (1 g) was placed in a pyrex tube and covered with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

more zinc dust (1 g). The empty end of the tube was drawn to a capillary; the tube was then evacuated and the capillary sealed. The part of the tube carrying the mixture was placed in an oven and heated at about 300° for 1 h. The material which distilled in the capillary was studied by vapor phase chromatography. The following two columns were used: 5% SE-30 on Chromosorb W, 80–100 mesh, and 5% Carbowax 1500 on Chromosorb P, 60–80 mesh. The pyrolysis product consisted of two major components which had retention times identical with those of propiophenone and α-methacrylophenone, prepared by the method of Burckhalter and Fuson (11), on both columns.

The two components of the pyrolysis product mentioned above were collected together in methanol as they left the column and were thus separated from other minor constituents present in the pyrolysis mixture. The ultraviolet spectrum of the mixture of the two substances shows bands at 240 and 280 mμ.

ACKNOWLEDGMENTS

We are indebted to Dr. W. A. Ayer for a generous sample of annotine. The award of a National Research Council Bursary (1960–61) and Studentship (1961–62) to W. A. Szarek is gratefully acknowledged. This work was supported by the National Research Council of Canada.

SOME CONSIDERATIONS ON THE STRUCTURE AND RADIATION CHEMISTRY OF WATER

ROBERT SCHILLER AND ISTVÁN KISS
Central Research Institute for Physics, Budapest, Hungary
Received March 31, 1964

ABSTRACT

The variation in the yields of products from the radiolysis of water at high solute concentrations and with increasing temperature are as yet unexplained by the diffusion theory. It is shown that by considering some structural features of water, both the temperature dependence of the yields and the concentration dependence of H_2 production in the entire range of solute concentration can be interpreted. The results predicted from the relations thus established agree within an order of magnitude with the measured temperature coefficients of the yields.

INTRODUCTION

The diffusion theory of aqueous radiation chemistry fails to account for some of the experimental observations. Thus, for example, the effect of temperature can be explained only by choosing values of parameters not fully justified by the physical conceptions of the theory. Similarly, the dependence of molecular H_2 yield on solute concentration is not satisfactorily explained. In the diffusion theory, liquid water is assumed to consist of disordered molecules without any preferential orientation or even any short-range order. Actually, however, water exhibits some definite structural properties which cannot be left out of consideration in establishing the mechanism of radiolytic processes. An attempt is made, using a semi-empirical treatment of the diffusion model, to consider the role played by the physical structure of water in its radiation chemistry.

Effect of the Structural Features of Water on Yields

Theories (e.g. refs. 1, 2) of the structure of water can be divided into two groups, namely the single state and the multistate models. In the former, the hydrogen bonds between the water molecules are assumed to extend over the whole system, and the partial disorder characterizing the liquid phase is assumed to be due to local distortions or ruptures of individual bonds. In the latter group, an almost ideal order is assumed within clusters consisting of a few or a few tens of water molecules. These clusters, held together by hydrogen bonds, are imbedded among water molecules interacting with one another and with the clusters by means of dipole forces. For simplicity, the multistate model will be used in present considerations.

Multistate models have been proposed recently by Wada (3), who assumed two states on the basis of phenomenological thermodynamics, and by Némethy and Scheraga (2), who proposed a five-state model derived by statistical mechanical methods. The former suggested only a "disordered" and an "ice-like" structure, while the latter distinguished between molecules in disordered arrangements and molecular species with from one to four hydrogen bonds. The hydrogen-bonded molecules are in rather large molecular clusters comprising 90 molecules at 0 °C and 20 molecules at 100 °C on the average. Without having precisely the structure of ice, they are ice-like in that the bonds are not distorted and contain the maximum possible number of molecules having coordination number four. The average lifetime of a cluster being about 10^{-10} s (4), there is a continuous interchange between clusters and disordered structures. The mole fraction of the hydrogen-bonded molecules monotonously decreases with increasing temperature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Assuming two-state water, let us consider first the formation of radical spurs, which are known to form in close proximity to primary ionization acts. The ionization probability of a molecule bound in an "ice-like" cluster is equal to the mole fraction γ of water molecules in the "ice-state". Most radical reactions occur within about 10^{-10} s (the mean lifetime of a cluster (5)) after the primary act. Thus a cluster may be considered as stable with respect to the physicochemical steps of the radiolytic process which, in fact, determine the primary yields.

The substantial difference between the yields from ice and water (6) and, moreover, between the yields from crystalline and glassy ice (7), seems to indicate that the spur formation is not insensitive to the ordered or disordered structure of the water domain. It follows that at least two *average* spur types are expected in water, namely "ice-like" and "disordered" spurs. The radical yields should thus be considered as the weighted means of two yields, the weighting factor being the mole fraction of the water molecules having "ice-like" structure. Thus,

$$G_R = \gamma g_R^* + (1 - \gamma) g_R, \qquad [1]$$

where the contributions of the "ice-like" and "disordered" spurs to the measured average radiation chemical yield are g_R^* and g_R, respectively.

The combination of radicals results either in the formation of H_2 and H_2O_2 or in the re-formation of H_2O. Let us write the molecular yield G_M as the fraction $\sum$ of the combined radical yield G_c in the form

$$G_M = \Sigma G_c = \Sigma (G_p - G_R), \qquad [2]$$

where G_p is the yield of initially dissociated water molecules. Similarly, the molecular yields in "ice-like" and "disordered" domains are

$$g_M^* = \sigma^* g_c^* = \sigma^*(G_p - g_R^*)$$

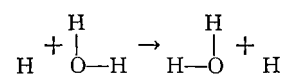
$$g_M = \sigma g_c = \sigma(G_p - g_R)$$

respectively. The coefficient Σ is in fact again a weighted mean of the form

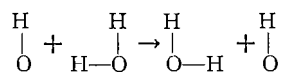
$$\Sigma = \gamma\sigma^* + (1 - \gamma)\sigma \qquad [3]$$

and G_c leads by definition to an expression similar to eq. [1], since G_p is taken to be the same for both structures.

From the measurements on crystalline ice, g_H^* and $g_{H_2}^*$ seem to be less than G_H and G_{H_2} respectively, i.e. $\sigma^* < \sigma$, $g_H^* < g_H$. If G_p is indeed independent of the structure, the only explanation of these facts is an increased probability of the H + OH reaction. In fact, primary recombination probability must be higher in the crystalline state because of the increased rigidity of the cage. Moreover, the diffusion is thought to proceed, at least in ordered structures, by a "valence transfer" mechanism as suggested by Semenoff (8) and represented for water molecules by the scheme



and



Thus diffusion paths are traced out by water molecules. Considering the structure of ice, the probability of geminate recombination is increased by "valence transfer diffusion" relative to that for "random diffusion", even after the radicals have traversed several water molecules.

If the presence of H_3O^+ ions is taken into consideration, the formulae for the yields become somewhat more complicated. In earlier papers (9, 10) the primary yields have been related to pH through the formula

$$\bar{G} = xG' + (1 - x)G, \qquad [4]$$

where x is the electron capture probability for H_3O^+ ions which increases from 0 to 1 with decreasing pH. G and G' are the yields in neutral and strongly acidic solutions, respectively. If the structure of water is also taken into account, G and G' each can be given by an equation of type [1]. Since the factor x is a function of spur structure, eqs. [1] and [4] combine to

$$\bar{G}_R = \gamma[x^* g_R^{*\prime} + (1 - x^*)g_R^*] + (1 - \gamma)[xg_R' + (1 - x)g_R], \qquad [5]$$

where the asterisks refer to "ice-like" spurs and the primed values to the strongly acidic system.

For the pH dependence of the molecular yields, one must take into consideration the dependence of both Σ and G_c, writing all the yields that contribute to Σ and G_c in the form of eq. [4]. Thus for strongly acidic solutions, where $x = x^* = 1$, the radical and molecular yields are

$$G_R' = \gamma g_R^{*\prime} + (1 - \gamma)g_R' \qquad [1']$$

$$G_M' = [\gamma\sigma^{*\prime} + (1 - \gamma)\sigma'][\gamma g_c^{*\prime} + (1 - \gamma)g_c'] \qquad [2', 3']$$

respectively.

Concentration Dependence of Molecular H_2 Yield

In a plot of $G(H_2)$ versus cube-root solute activity which is initially linear, Mahlman (11) observed a relatively abrupt break followed by a second linear portion with decreased slope. This second portion, when extrapolated to zero scavenger concentration, intersected the $G(H_2)$ axis at the value of $G(H_2)$ for crystalline ice. Only a simple linear cube-root dependence is expected from the diffusion model (12, 13). In the Ganguly–Magee (14) formulation used in these calculations (12, 13), however, the concentration never appears independently, but as a factor in the product $k_s t_0 c_s$ where k_s is the rate constant for reaction between radical and solute, c_s is the concentration and t_0 is a time characteristic of spur size. The numerical results calculated from the theory can be expressed in the form

$$G(H_2) = G_{H_2} - b(k_s t_0 c_s)^{1/3}. \qquad [6]$$

Thus if $G(H_2)$ is plotted against $c_s^{1/3}$, a straight line having a slope proportional to $(k_s t_0)^{1/3}$ will be obtained. The two different types of spur with different average radical concentrations appear in this formulation as two different values of k_s. Thus, $G(H_2)$ has to be expressed as the sum of two equations of the form [6] to take account of the two average spur types. Graphically, this can be done by superposition of two straight lines with different slopes. Numerical values could be obtained only by computing the differential equations of the diffusion theory with appropriate initial concentrations. Moreover, it follows from eq. [3], that for $\gamma = 1$, $G_{H_2} = g_{H_2}^*$, i.e. in a completely ordered structure like crystalline ice the total hydrogen yield is of the same magnitude as the contribution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of the "ice-like" spurs to the hydrogen yield in real water. Both results are in full agreement with Mahlman's observation.

The Temperature Effect

With increasing temperature the molecular yields of radiolysis are observed to decrease while the radical yields increase. The simple diffusion model predicts no such temperature effect since an increase in the diffusion constant with temperature is exactly balanced by an increase in the recombination rate constant (15). In solutions of moderate concentration the value of γ is independent of concentration and depends only on temperature. Values of g^* and g, on the other hand, as stated previously, are insensitive to temperature. The partial derivative with respect to temperature of the measured radical yield for neutral water is given by

$$[7] \qquad \left(\frac{\partial G_R}{\partial T}\right)_{c_s} = (g_R^* - g_R)\frac{d\gamma}{dT}$$

and that of the molecular yield by

$$[8] \qquad \left(\frac{\partial G_M}{\partial T}\right)_{c_s} = [(\sigma^* - \sigma)G_c + (g_c^* - g_c)\Sigma]\frac{d\gamma}{dT}.$$

For strongly acidic solutions the forms of eqs. [7] and [8] do not change, but the corresponding yields measured in acid systems are substituted.

The Dependence of Radical and Molecular Yields on Temperature

The validity of the present concept may be further checked by comparison of the temperature dependence of primary yields determined experimentally by Hochanadel and Ghormley (15) with relations [7] and [8]. In the present calculations it is assumed that (*a*) the radiation-chemical behavior of crystalline ice is similar to that of ice-like clusters in liquid water and (*b*) the stabilization process of radicals in the ice matrix competes as efficiently with recombination as ion-scavenging does in liquid water.

The terms on the right-hand sides of eqs. [7] and [8] are obtained as follows. The mole fraction of the "ice-like" water molecules is computed by means of a two-state water model. The value of γ is determined by Wada's theory at 1 deg intervals up to 10 °C and at 5 deg intervals from 10 to 20 °C. At higher temperatures the values given by Némethy and Scheraga (2) at 10 deg intervals in the range from 0 to 100 °C are used. Among the five species of the latter model the water molecules of coordination number three and four are regarded as bound in "ice-like" clusters. The combined use of the two approaches is thought to be justified by the agreement (to about 1%) between the temperature coefficients computed from the two models in the range from 0 to 20 °C. The absolute γ values determined from the two theories are much more different.

The characteristic paramagnetic resonance spectra of H atoms and OH radicals were measured in irradiated ice at 4.2 °K. In neutral ice the formation rate of the two radicals was found to be about the same, i.e., $g_H^* \cong g_{OH}^*$ (6). Above 4.2 °K the H atoms cease to be stable in neutral ice; in frozen acidic solutions however, they could be detected even at 77 °K. The H_2 yield from irradiated ice was also measured, after melting the sample (7). Since, to our knowledge, no measurements have yet been reported on frozen acidic solutions at 4.2 °K, in which the H atoms should be stable, no experimental data on $g^{*\prime}$ are available. The increase in $g^{*\prime}$ as compared with g^* is, however, attributed to the broader spatial distribution of H atoms in acidic solutions. The computations of Dyne and Kennedy

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(5) show the yields to vary almost linearly with the distribution radius of the H atoms. Therefore, to a good approximation,

$$[9] \qquad g_R^{*\prime} = g_R^* + g_R' - g_R$$

and combining this equation with eqs. [1] and [1′] or with [2] and [2′] two simple sets of equations in three unknowns are obtained, one of them yielding $g_R^{*\prime}$, the other $g_M^{*\prime}$. The derivatives in eqs. [7] and [8] are approximated by the average rate of change in the temperature interval under investigation.

In Table I the data used in the present calculations are summarized, and in Table II the measured and calculated temperature coefficients of the yields are listed. A value of six was taken for G_p, the only quantity not measured (5).

Measured and calculated temperature coefficients of the radical yields

	Calculated 2–20°	Measured (15) 2–23°	Calculated 20–60°	Measured (15) 23–65°
$\frac{\Delta G_{OH}'}{\Delta T} \times 10^3$	8.86	5.23	5.93	5.25
$\frac{\Delta G_H'}{\Delta T} \times 10^3$	11.2	3.82	7.50	3.58
$\frac{\Delta G_{H_2}'}{\Delta T} \times 10^3$	$\sim\pm0.2$	−0.52	$\sim\pm0.2$	−0.24

DISCUSSION

The agreement between the calculated and measured temperature coefficients is seen to be within an order of magnitude. A simple error-propagation law shows the error in the calculated values for radicals be about 20%, taking the relative error in g_R^* as high as 50% and neglecting that of other quantities. Considering the 30% error in the measured temperature coefficients, the agreement is fairly good for OH radicals. However, the difference between measured and calculated values for H atoms is considerably greater than the error limit. This may be due to the reducing agent appearing in two different forms, the H atom and the hydrated electron, the ratio of which may be sensitive to the temperature and the structural features of water.

For personal use only.

The error in the calculated temperature dependence of the H_2 yield as determined as above is at least about 100%; moreover the error in g_{H_2}* (not reported) must be considerable. This and the 50% error of the measured value make it impossible to determine even the sign of the effect. The whole calculation involves, in addition to these factors, the uncertainty of γ values which depend strongly on the water model adopted.

SPECTRES ÉLECTRONIQUES DU FLUORANTHÈNE ET DE L'ACÉNAPHTYLÈNE EN SOLUTION A BASSE TEMPÉRATURE

L. PESTEIL, P. PESTEIL ET F. LAURENT
Laboratoire de Physique P.C.B.1; Faculté des Sciences de Marseille, Marseille, France
Reçu le 28 mai 1964

RÉSUMÉ

L'analyse de la structure vibrationnelle des spectres d'absorption et de fluorescence permet de déterminer les fréquences de vibrations actives; les résultats obtenus sont en accord avec les prévisions de la théorie des groupes; la structure de la bande 0–0 du fluoranthène obéit à une loi de forme quasi hydrogénoïde.

Ce mémoire a pour but d'appliquer aux molécules de fluoranthène $C_{16}H_{10}$ et d'acénaphtylène $C_{12}H_8$ la méthode d'analyse déjà décrite dans de nombreux articles (1–5). Nous rappellerons donc seulement le principe de ces recherches.

La molécule à étudier est mise en solution diluée dans le pentane *n*; la solution est refroidie à 20 °K, température d'ébullition de l'hydrogène. La fluorescence, excitée avec une lampe à vapeur de mercure et des filtres convenables, permet d'obtenir avec précision les vibrations de l'état fondamental qui interviennent dans la transition électronique; l'absorption, pour laquelle on utilise le spectre continu d'une lampe à xénon de 500 W, permet de connaitre les vibrations correspondantes de l'état excité. La fluorescence ne donne donc pas de résultats nouveaux, puisque les mêmes renseignements peuvent également être obtenus par diffusion Raman ou par absorption infrarouge; elle permet cependant de confirmer le cas échéant certains résultats. L'absorption, au contraire, qui permet d'atteindre l'état excité, ne peut être suppléée par aucune autre méthode.

Mais il y a encore un intérêt à ces recherches: la transition électronique pure (niveau non vibrationnel) est généralement séparée en de nombreux niveaux; il y a donc lieu d'étudier également la structure du niveau 0–0 du fluoranthène et de l'acénaphtylène, tant en absorption qu'en fluorescence, et de vérifier sur ces nouveaux exemples les résultats déjà obtenus pour d'autres molécules en solution (6, 7).

Les deux molécules dont il sera question dans le présent article ont déjà fait l'objet de recherches théoriques et expérimentales à la température ordinaire (8). Les auteurs ne recherchaient que la position de la transition électronique; l'élargissement des bandes ne leur permettant pas d'accéder aux structures vibrationnelle et électronique.

Les montages expérimentaux ne présentent rien d'exceptionnel; ils ont d'ailleurs été décrits dans des articles antérieurs (3, 4); nous n'en parlerons pas ici.

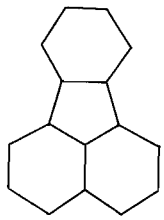
Dans l'exposé qui suit, nous observerons le plan suivant:

Aprés avoir effectué le dénombrement des vibrations prévisibles dans le cas des deux molécules, nous donnerons les résultats expérimentaux concernant la structure vibrationnelle; pour terminer, nous étudierons la structure de la bande 0–0 elle-même.

DÉNOMBREMENT DES VIBRATIONS

1. Fluoranthène (symétrie C_{2v})

Il y a 7 familles (*sets of equivalent atoms*) de carbones dans le plan *xz* et 2 familles sur l'axe *z*; il y a également 5 familles d'hydrogènes dans le plan *xz*. Les 26 atomes ont 78° de liberté qui donnent lieu à 72 vibrations internes. L'application simple de la théorie des



groupes permet de répartir les 72 vibrations de la façon suivante entre les divers types de symétrie:

25 vibrations A_1 (totalement symétriques),
11 vibrations A_2,
24 vibrations B_1,
12 vibrations B_2.

Il est bien évident que si les 72 vibrations apparaissaient dans les spectres de fluorescence et d'absorption, la structure, encore compliquée par l'éclatement de la transition électronique pure, serait inextricable. On admet généralement que, sauf cas exceptionnel, les seules vibrations actives sont celles qui sont totalement symétriques (ici les vibrations A_1); cela nous fait donc 25 vibrations à trouver.

On peut aussi, pour aider au dénombrement et à son interprétation, considérer la molécule de fluoranthène comme composée de deux groupes (un benzène et un naphtalène) liés par deux liaisons. La théorie justifie d'ailleurs cette hypothèse puisqu'elle indique des indices de liaison faibles (0.398) entre naphtalène et benzène (8). Nous essayerons donc, en première approximation, de considérer que les vibrations actives du fluoranthène sont la somme de vibrations du benzène et de vibrations du naphtalène qui deviennent totalement symétriques quand la symétrie diminue à C_{2v}; ces deux dernières molécules étant d'ailleurs substituées ont une symétrie différente de celle qui est la leur à l'état libre.

Il est alors facile de trouver les vibrations du benzène que l'on risque de voir dans les spectres du fluoranthène; ce sont les vibrations suivantes (9):

2 vibrations A_{1g}: 992 et 3062 cm^{-1},
4 vibrations E_g^+: 606, 1178, 1600 et 3060,
3 vibrations E_u^-: 1037, 1485 et 3080,
2 vibrations B_{2u}: 1110 et 1648.

Si l'on fait de même le dénombrement des vibrations actives du naphtalène, on peut s'attendre à trouver également les vibrations suivantes (4, 5):

9 vibrations A_{1g}: 512, 770, 941, 1026, 1237; 1390, 1638, 3028 et 3063,
8 vibrations B_{2u}: 362, 620, 1125, 1265, 1389, 1601; 2945 et 3014.

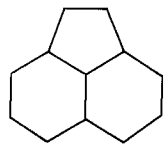
Il va sans dire que, tant pour le napthtalène que pour le benzène, l'alourdissement de la molécule conduit à une variation importante de ces fréquences dans le fluoranthène.

Les harmoniques et les combinaisons rendent la structure vibrationnelle extrèmement complexe vers les grandes fréquences; pour cette raison, nous avons arrété notre analyse vers 1700 cm^{-1}. Nous avons donc à trouver dans les spectres du fluoranthène 21 vibrations (sur 28) des deux molécules.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

2. Acénaphtylène (symétrie C_{2v})

Il y a 5 familles de carbones et 4 familles d'hydrogènes dans le plan xz et 2 familles de



carbones sur l'axe z; les 20 atomes ont 54° de liberté de vibrations internes répartis de la manière suivante entre les 4 types de symétrie:

19 vibrations A_1,
8 vibrations A_2,
18 vibrations B_1,
9 vibrations B_2.

Comme pour le cas du fluoranthène, on peut aussi supposer que l'acénaphtylène dérive du naphtalène; on doit donc s'attendre à retrouver, dans ses spectres, les vibrations correspondant aux 17 oscillations du naphtalène considérées précédemment. Parmi ces vibrations, 4 sont de fréquences nettement supérieures à 1700 cm^{-1}; elles ne figureront donc pas dans nos résultats expérimentaux; par contre, on devra tenir compte de certaines vibrations du radical —CH=CH— (5 des vibrations des molécules $X_2Y_2Z_2$ sont de symétrie convenable).

RESULTATS EXPÉRIMENTAUX

1. Structures vibrationnelles

Nous avons réuni nos résultats dans deux figures; le premier est relatif à la fluorescence; le second à l'absorption.

A. Fluorescence

Nous n'avons pas obtenu le spectre de fluorescence de l'acénaphtylène qui est probablement trop faible pour impressionner la plaque photographique.

Nous avons réuni dans le Fig. 1 les fréquences de vibrations du fluoranthène, de l'acénaphtène (2, 4) et celles du benzène et du naphtalène. Nous avons bien trouvé les 21 vibrations prévues précédemment et nous avons essayé d'établir une correspondance entre les vibrations des diverses molécules; cette correspondance est indiquée par des flèches.

B. Absorption

Dans le Fig. 2, on trouvera, disposés de la même manière que dans le Fig. 1, les résultats relatifs aux structures vibrationnelles des spectres d'absorption correspondant à la même transition que les spectres de fluorescence. De plus, nous avons indiqué entre parenthèses les fréquences de vibrations correspondantes de l'état fondamental tirées du Fig. 1. Les points d'interrogation qui figurent sur la ligne du naphtalène indiquent des vibrations de symétrie B_{2u} dont on ignore la fréquence à l'état excité.

2. Structure des transitions électroniques

L'analyse vibrationnelle est toujours compliquée par la présence de nombreuses composantes de la bande électronique 0–0 qui sert d'origine. Récemment, il a été montré que les diverses raies sont liées entre elles par une loi en $1/n^2$ qui implique l'existence d'une quasi particule appelée *transféron* (10, 11).

Nous sommes parvenus à classer les raies 0–0 du fluoranthène et nous proposons la formule suivante:

$$\nu'(cm^{-1}) = 24\,857 - 3065/n^2.$$

Aprés les naphtalènes H_8 et D_8 (10) et les phénanthrènes H_{10} et D_{10} (11), c'est la cinquième molécule dont les spectres en solution présentent ce phénomène.

Dans le cas présent, nous avons trouvé (en absorption et en fluorescence) les niveaux $n = 3, 4, 5, 6, 7$ et 8; le niveau 7 est le plus intense à la concentration choisie (10^{-3} mole/l).

Nous n'avons pas trouvé le transféron de l'acénaphtylène; ce qui ne veut évidemment pas dire qu'il n'existe pas. Les principales raies qui servent d'origines au spectre de l'acénaphtylène sont les suivantes: 21 283, 21 301 et 21 322 cm^{-1}.

For personal use only.

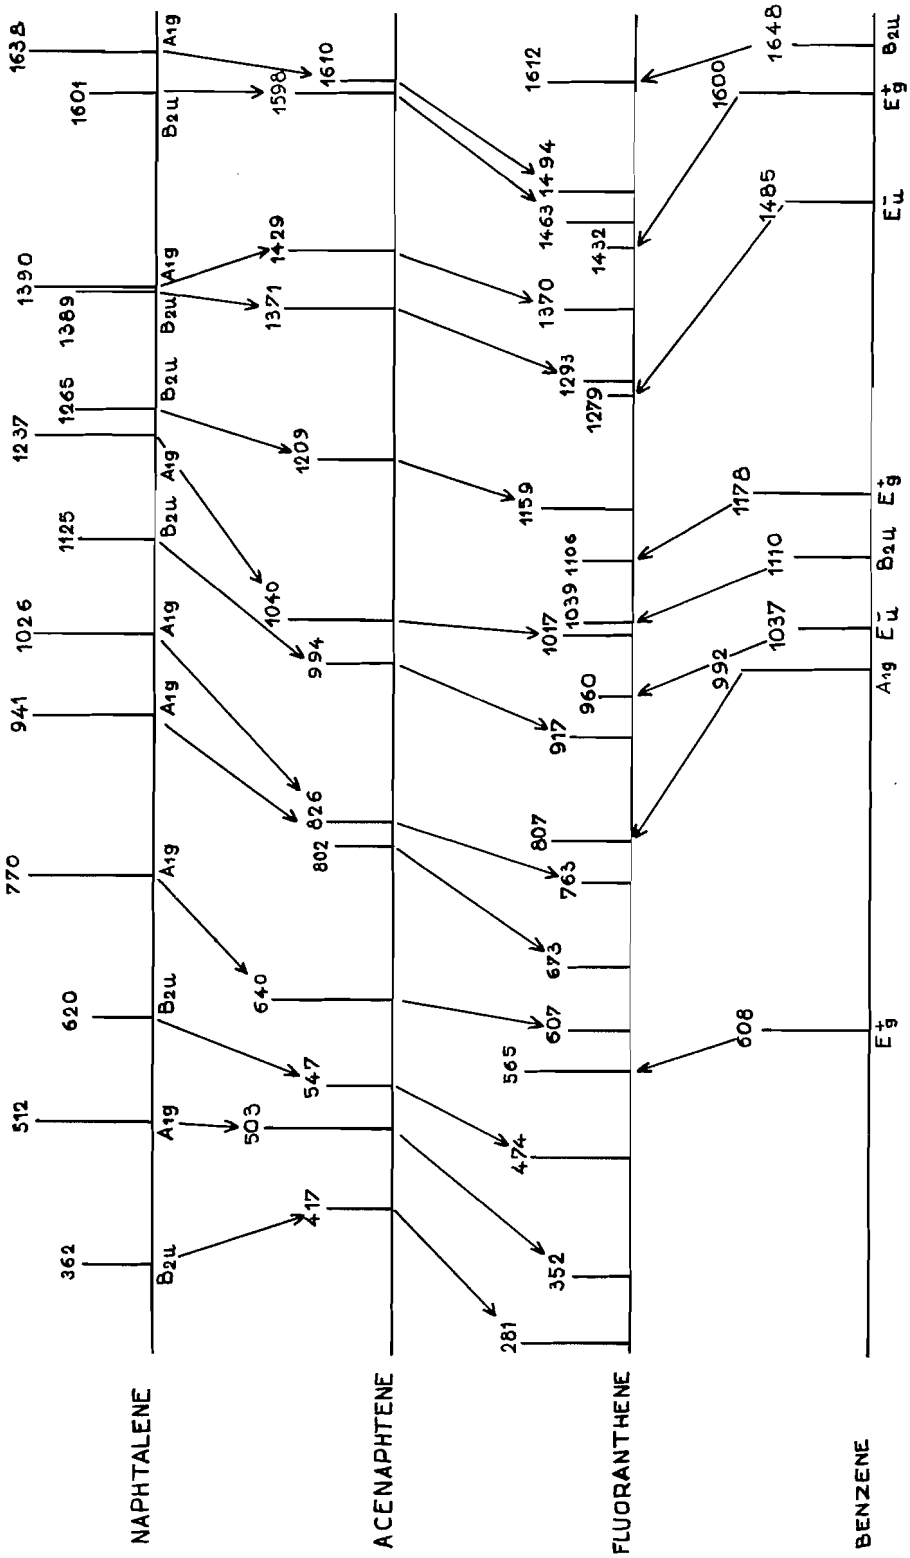

FIG. 2. Vibrations de l'état fondamental.

CONCLUSION

L'analyse vibrationnelle des spectres d'absorption et de fluorescence des deux molécules étudiées permet de retrouver d'une façon qui nous satisfait les prévisions théoriques concernant le nombre d'oscillations actives dans les transitions électroniques; les correspondances avec les molécules composantes (naphtalène et benzène) ne sont proposées qu'à titre indicatif.

La structure de la bande 0–0 du fluoranthène établit une fois de plus expérimentalement l'existence d'une loi de classement des raies de forme quasi hydrogénoïde.

TRACER DIFFUSION OF THALLIUM IN THALLIUM AMALGAMS

WILLIAM T. FOLEY AND MICHAEL T. H. LIU
Department of Chemistry, St. Francis Xavier University, Antigonish, Nova Scotia
Received June 19, 1964

ABSTRACT

The tracer diffusion coefficient of thallium in thallium amalgams was measured at 25 °C by the capillary-reservoir technique. The values of 10^5D in $cm^2\ s^{-1}$ at 0.0075, 0.0713, 0.1610, 0.2004, 0.2858, 0.3460, 0.3868, 0.4158 mole fraction thallium were 0.98, 0.85, 0.71, 0.62, 0.47, 0.41, 0.38, 0.39 with an average standard deviation of $0.016 \times 10^{-5}\ cm^2\ s^{-1}$. The compound Tl_2Hg_5 plays a significant role in the tracer diffusion.

INTRODUCTION

This is a report on measurements, by the capillary method of Anderson and Saddington (1), of the tracer diffusion coefficient of thallium in thallium amalgams at 25 °C over the concentration range 0.76 to 42.04 weight % thallium. In the composition range studied, the amalgams are liquid at room temperature and, because of the presence of the compound Tl_2Hg_5, the two metals form a solution which is far from regular. Because the alloy is liquid over such a large concentration range and because of its nonideality, this liquid metal system constitutes an excellent system for diffusion studies.

Fick's second law of diffusion for a one-dimensional system states that

$$\frac{\partial C}{\partial t} = D\,\partial^2 C/\partial x^2, \qquad [1]$$

where C is the concentration of the diffusing species, t is the time, and D is the diffusion coefficient with dimensions of area per unit of time. Consider a capillary of length l with one end closed, having an initial concentration of C_i uniform throughout. Let the capillary be immersed in so large a volume of solution of composition C_∞ that at infinite time, when diffusion is complete and the composition within the capillary and outside the capillary is the same, the composition is still C_∞. The solution of eq. [1] for time t under these conditions is

$$\frac{C_{av} - C_\infty}{C_i - C_\infty} = \frac{8}{\pi^2} \sum_{n=0}^{n=\infty} \frac{1}{(2n+1)^2} \exp -\left(\frac{2n+1}{2l}\right)^2 \pi^2 Dt, \qquad [2]$$

where C_{av} is the average composition in the capillary at time t. The series on the right side of eq. [2] is rapidly convergent. Under the conditions of the experiment described here, the value of C_∞ is zero, so that a measurement of C_i, C_{av}, l, and t enable one to calculate D.

EXPERIMENTAL

Mercury was purified by making it the anode in an electrolysis cell using a platinum cathode and 1 N sulphuric acid as an electrolyte. The electrolysis was conducted at a current density of $5 \times 10^{-4}\ A/cm^2$ and the electrolysis was stopped when a film of mercurous sulphate appeared on the anode. The mercury was further purified by covering it with dilute nitric acid and then drawing air through the liquids. Finally the mercury was doubly distilled under reduced pressure.

The preparation of thallium amalgams, the apparatus, and the procedure for diffusion measurements were similar to those used by Foley and Reid (2) in the study of the interdiffusion of thallium in thallium amalgams. The apparatus consisted of a diffusion chamber, at the base of which a three-way stopcock was connected by spherical joints to two storage reservoirs holding amalgams of identical composition except that one of them contained ^{204}Tl. The two samples of the amalgam were made by an approximately

equal division of about 900 g of stock alloy, whose concentration had already been determined. The tagged amalgam was prepared under oxygen-free conditions by an exchange reaction between a solution of radioactive thallium nitrate and the thallium amalgam. The danger of thallium dissolving into the aqueous solution during the exchange was minimized by keeping the pH high by the addition of sodium acetate. After the exchange reaction had taken place, the metal was transferred to the reservoir. The activity of the amalgam corresponded to about three counts per min per mg.

In a run, the capillaries, which were 3 cm long by 1 mm in diameter, were first filled with radioactive amalgam and, after the diffusion chamber was emptied, the nonradioactive amalgam was run into the diffusion chamber until the capillaries were covered. The method of transferring the alloy was the same as that used in the above-mentioned work on the interdiffusion of thallium. The diffusion cell was left in the constant temperature bath, maintained at 25 °C, until it was judged that the concentration of radioactive thallium in the capillary had fallen to about 50% of its initial value. The radioactive amalgam was then transferred from the diffusion chamber and returned to the storage vessel. The duration of the diffusion run was recorded. The amalgam was withdrawn from the capillary and the activity of the amalgam was measured.

The concentration of ^{204}Tl could not be determined by direct measurement of the activity of the amalgam because of the rapidity with which thallium is oxidized by oxygen of the air. The procedure of Foley and Osyany (3) was used to separate the thallium in the form of the sulphate from the mercury. To this thallium sulphate sufficient inert thallium sulphate was added to bring the total weight of thallium sulphate to 400 mg. The thallium was precipitated as the chromate, dried, and counted.

RESULTS

The results are shown in Table I. The values of the diffusion coefficient are also plotted in curve *A* of Fig. 1.

TABLE I

Tracer diffusion of thallium at 25 °C

Mole fraction Tl	$D \times 10^5$ ($cm^2\ s^{-1}$)	Standard deviation $\times 10^5$ ($cm^2\ s^{-1}$)	Number of runs
0.0075	0.98	0.012	8
0.0713	0.85	0.021	6
0.1610	0.71	0.009	8
0.2004	0.62	0.020	9
0.2858	0.47	0.020	8
0.3460	0.41	—	2
0.3868	0.38	0.013	8
0.4158	0.39	0.013	8

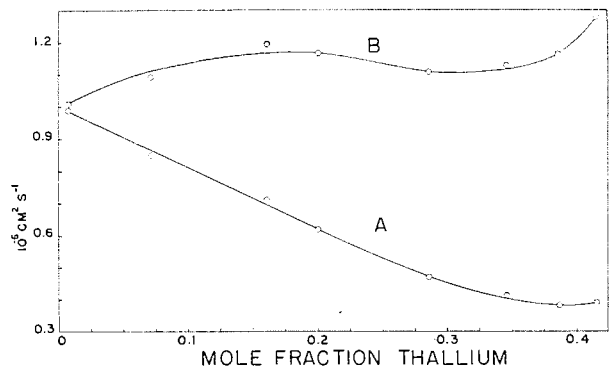

FIG. 1. Curve *A*, variation of tracer diffusion coefficient *D* with concentration; curve *B*, variation of $D\eta/\eta_{Hg}$ with concentration.

DISCUSSION

The results show that the diffusion coefficient suffers a steady decrease with increasing mole fraction of thallium until at mole fraction 0.2857, which corresponds to the com-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

position of Tl_2Hg_5, there is a change in slope amounting almost to a halt. At the composition corresponding to the compound the forces of attraction between the constituents in the solution are at a maximum and as a result the tracer diffusion coefficient would be low. It is known (2) that the compound Tl_2Hg_5 exists in the liquid amalgam. At concentrations of thallium greater than that corresponding to the compound ($X_{Tl} = 0.2858$) the forces of attraction between the constituents of the liquid become smaller. Opposing this latter tendency for an increase in the tracer diffusion coefficient as X_{Tl} exceeds 0.2858 is the steady increase in viscosity with increase of thallium content. At about $X_{Tl} = 0.40$ a minimum occurs in D, and at this composition the opposing tendencies are equal. Curve B shows a plot of the product of the tracer diffusion coefficient and ratio of the viscosity (4) of the amalgam to the viscosity of mercury. Bearman (5) has shown that for regular solutions the value of the product of the tracer diffusion coefficient and the viscosity should be independent of the composition. Curve B confirms that the amalgam solutions are not regular.

ACKNOWLEDGMENT

Grateful acknowledgment is made by one of us, W. T. F., for a grant-in-aid of research from the National Research Council of Canada.

ESSENTIAL OILS AND THEIR CONSTITUENTS[1]

XXII. DETECTION OF NEW TRACE COMPONENTS IN OIL OF GINGER

M. C. NIGAM,[2] ISHWAR C. NIGAM, AND LEO LEVI
Pharmaceutical Chemistry Division, Food and Drug Directorate, Ottawa, Canada
AND
K. L. HANDA
Regional Research Laboratory, Jammu-Tawi, India

Received June 22, 1964

ABSTRACT

Oil of ginger was found to contain the following, as yet unreported, constituents—cumene, β-pinene, myrcene, *p*-cymene, γ-selinene, β-elemene, 2-heptanol, 2-nonanol, and bornyl acetate. The presence of 2 alcohols, for which gas chromatographic and infrared criteria of identity were determined, was also demonstrated. These data are important for establishing the authenticity of the essential oil.

INTRODUCTION

Oil of ginger derived from *Zingiber officinale* Roscoe is an important raw material of the food, drug, and cosmetic industry. Its composition has been the subject of a number of studies reported since the beginning of this century. These established the presence of the following constituents—camphene, α-pinene, β-phellandrene, limonene, zingiberene, farnesene, *ar*-curcumene, bisabolene, *n*-decylaldehyde, *n*-nonyl aldehyde, citral, methyl heptenone, cineole, linalool, borneol, geraniol, and zingiberol (1–4). Specifications for ginger flavor, extract, and essence are given in the Canadian Food and Drugs Act. Ginger is, moreover, an official pharmacopoeial product used widely for masking objectionable tastes of medicinals. It is the purpose of this paper to describe the identification of some hitherto unreported compounds of this spice, achieved by detailed investigation of its essential oil. The data reported should prove of value for the recognition of genuine preparations and the detection of subtle product sophistication.

EXPERIMENTAL

Analytical Sample

The essential oil used in this study was made available by S. Kelkar and Co., Bombay, India. It was obtained by hydrodistillation of ginger roots grown in the state of Kerala (product yield 2.0%).

Physicochemical constants—d_{20}^{20} 0.9081; n_D^{20} 1.4950; $[\alpha]_D^{20}$ −46.40°; saponification value 1.8, after acetylation 46.9; carbonyl content ($C_{10}H_{16}O$) by oximation 2.7%.

Rectification of the Essential Oil

The oil was subjected to fractional distillation under reduced pressure through a Towers column. Four fractions were isolated, as shown in Table I.

TABLE I

Fractional distillation of oil of ginger

Fraction	Weight (g)	Pressure (mm)	Temp. (°C)	n_D^{20}	$[\alpha]_D^{20}$	% (w/w)
L	41.7	15	60–95	1.468	+34°	4.4
M	630.5	10	115–127	1.494	−55°	66.3
H	101.5	7	120–135	1.498	—	10.7
Residue	158.5	—	—	—	—	16.7

[1]*Paper XXI. J. Org. Chem. In press.*
[2]*National Research Council of Canada Postdoctoral Fellow, 1964.*

Refractionation of Fraction L

The isolate was rectified at atmospheric pressure and 10 subfractions (L-1 to L-10) weighing 3–3.5 g each were collected. They possessed the following physical characteristics—b.p. 156–178 °C; d_{20}^{20} 0.8660–0.8885; n_D^{20} 1.467–1.468; $[\alpha]_D^{20}$ +50.2 to +19.6°.

Refractionation of Fraction M

Rectification of this fraction was carried out at 15 mm pressure in a Towers column operated at a reflux ratio of 20:1. Twenty-three cuts were collected; b.p. 130–167 °C at 15 mm; d_{20}^{20} 0.895–0.874; n_D^{20} 1.479–1.497; $[\alpha]_D^{20}$ −20.6 to −49.0°.

Isolation of Carbonyls from Fraction M-1 to M-4

Infrared examination showed these fractions (71 g; 7.6% of the essential oil) to be rich in oxygenated compounds. They were combined and found to contain 36.0% of carbonyl constituents (oximation method). Treatment of a 36 g aliquot with Girard T reagent (5, 6) yielded 12.5 g carbonyl and 23.1 g non-carbonyl compounds.

Isolation of Total Hydrocarbons from the Essential Oil

The essential oil (2.0 g) was chromatographed over 50 g of basic grade 1 alumina and eluted with petroleum ether (b.p. 40–60 °C). Evaporation of the first 50 ml of effluent yielded 1.5 g of hydrocarbons.

Gas Chromatography of the Essential Oil and Isolated Fractions

Apparatus and general procedures have been described (7). Two stationary phases Reoplex 400 (20%) and Silicone Nitrile XE-60 (10%) deposited on acid washed Chromosorb W (60–80 mesh) were used. Columns and operating conditions are shown in Table II.

TABLE II

Experimental conditions for gas chromatographic analyses

Sample	Column	Temp. (°C)	Gas flow (ml/min)
Oil of ginger	Reoplex 400	170	75
Fraction L and subfractions	Reoplex 400	110	60
Fraction M and subfractions	Reoplex 400	170	75
Sesquiterpenes of fractions M and H	Silicone Nitrile	150	75

Identification and Determination of Constituents

Constituents were identified by the serial dilution technique and by comparison of infrared spectra of effluents—collected in carbon tetrachloride and purified by rechromatography under optimal conditions of temperature and carrier gas flow rate—with those of authenticated reference standards or published data (8). Percentages were calculated by the sigma method (9, 10).

RESULTS AND DISCUSSIONS

The gas chromatogram of the essential oil is reproduced in Fig. 1-A. In addition to its major constituents, sesquiterpenes, the presence of small amounts of a number of lower boiling compounds was also observed. Special attention was given to the characterization of minor and trace components detected. A quantity of 950 g of the oil was used in this investigation to obtain sufficient amounts of fractions which were enriched with these compounds. Preliminary rectification (Table I), which separated the distillate into low (L), middle (M), and high boiling (H) fractions, was halted when the sesquiterpene hydrocarbons appeared to have been distilled over completely.

Identification of Low-Boiling Constituents

All subfractions of fraction L were subjected to gas chromatographic analysis. The chromatogram of subfraction L-1 is reproduced in Fig. 1-B. The following constituents were identified by the techniques described.

Cumene.—The presence of trace amounts of this compound was detected in fraction L-1.

α-Pinene, β-pinene, camphene, and myrcene.—These constituents were readily detected in fractions L-1 to L-5 and trace amounts found to be present in later fractions also.

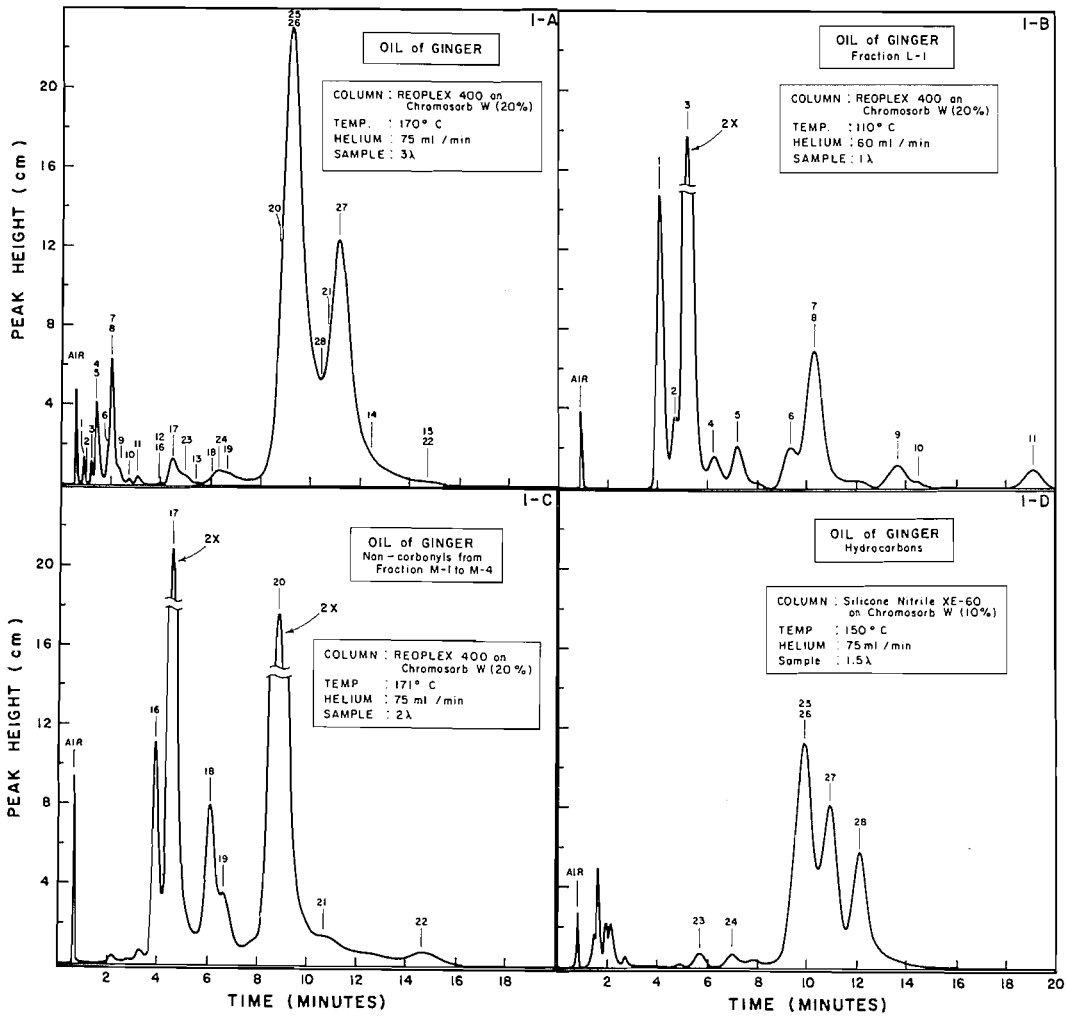

FIG. 1. Gas chromatographic examination of oil of ginger and its fractions.

Limonene.—This terpene was chiefly concentrated in fractions L-8 to L-10 but variable amounts were also found to occur in earlier fractions.

Cineole and β-phellandrene.—These two constituents formed a single peak when chromatographed on the Reoplex column. The presence of cineole in the oil was confirmed by isolation via its resorcinol complex, m.p. 81–82 °C (11). β-Phellandrene was identified in fraction L-9, which had been freed from cineole. Infrared analysis of g.l.c. effluent showed that the terpene obtained was almost free from admixture with cineole.

p-Cymene.—Small quantities of this compound were identified in fractions L-7 to L-9, and trace amounts found to be present in earlier fractions also.

2-Heptanol.—This alcohol appeared as a minor peak in the chromatograms of fractions L-1 to L-3 just before emergence of *p*-cymene.

Methyl heptenone.—A small peak appearing in the chromatograms of fractions L-8 to L-10 was found to be generated by this ketone.

Constituents of Fraction M

The first four of the 23 subfractions collected were rich in alcohols, esters, and carbonyls (infrared bands at 3 430, 1 730, 1 715, and 1 670 cm^{-1}), whereas succeeding ones (M-5 to M-23) were largely composed of sesquiterpene hydrocarbons.

Fractions M-1 to M-4 were combined, treated with Girard T reagent, and analyzed for carbonyl and non-carbonyl constituents.

Nonyl aldehyde, decyl aldehyde, and citral.—The presence of these constituents was confirmed in the isolate. Traces of methyl heptenone were also detected.

Linalool and borneol.—These alcohols were found to be the major constituents of the non-carbonyl fraction (30.1 and 51.8% respectively, see Fig. 1-C).

2-Nonanol, bornyl acetate, and geraniol.—These compounds gave rise to minor peaks in the chromatogram of the non-carbonyl fraction and were identified by infrared examination of effluents collected after repeated sample injections.

Alcohol A.—This constituent, emerging between linalool and bornyl acetate, was of semisolid consistency and had a musty odor. Its infrared spectrum displayed characteristic bands at 3 600, 3 400, 1 125, and 1 100 cm^{-1} (OH group) and at 3 020, 1 660, and 838 cm^{-1} (—C=CH— group). Additional absorptions were observed at 1 465, 1 445, 1 435, 1 375, 1 365, 1 312, 1 270, 1 213, 1 202, 1 170, 1 065, 1 037, 1 010, 988, 965, 950, 907, and 885 cm^{-1}. On catalytic hydrogenation, the alcohol yielded a product (m.p. 84–85 °C) showing absorptions at 3 600, 3 440, 2 950, 2 920, 2 870, 1 463, 1 455, 1 377, 1 370, 1 343, 1 307, 1 232, 1 207, 1 166, 1 142, 1 113, 1 088, 1 042, 1 030, 996, 963, 940, 930, 900, 870, and 853 cm^{-1}.

Alcohol B.—One of the peaks observed in Fig. 1-C was found to be generated by an aromatic hydroxy compound exhibiting distinct bands at 3 600, 3 480, and 1 095 cm^{-1} (OH group), 1 625 and 1 507 cm^{-1} (phenyl ring), and 1 645 and 900 cm^{-1} (—C(=CH_2)— group).

Sesquiterpene Hydrocarbons

Curcumene and Farnesene

Infrared and gas chromatographic analyses proved that fractions M-5 to M-23 were rich in sesquiterpene hydrocarbons which formed the bulk of fraction H. They were combined and separated by gas chromatography into three well-resolved fractions. Infrared examination identified the second and third of these isolates as curcumene and farnesene, respectively.

α- and β-Zingiberene and β-Bisabolene

The first of the three gas chromatographic fractions, which on the basis of its infrared analysis appeared to be a mixture of α- and β-zingiberene, was rechromatographed. Ascending and descending portions of the peak were collected separately and again purified by repeated gas chromatography at reduced temperature and flow rate (130 °C; 60 ml/min). The ascending portion was found to be composed of α-zingiberene and the descending portion further resolved into β-zingiberene and β-bisabolene.

γ-Selinene and β-Elemene

Gas chromatographic analysis of the hydrocarbon fraction isolated by column chromatography of the essential oil over alumina showed the presence of some minor constituents in the oil which emerged, following the elution of the monoterpenes and preceding the

elution of sesquiterpenes. Two of these constituents were identified as γ-selinene and β-elemene respectively (see Fig. 1-D).

High Boiling Sesquiterpene Alcohols

Infrared examination of the high-boiling residue obtained after fractional distillation of the oil showed that it consisted largely of hydroxy compounds. Gas chromatography could not be applied successfully, however, to the analysis of this isolate. Marked decomposition of some of the constituents to sesquiterpenes occurred at 250 °C. Thin-layer chromatography revealed a high degree of compositional complexity of the product and the presence of a number of alcohols.

Composition of Essential Oil

The composition of the oil as deduced from correlation of the distillation and gas chromatographic data is shown in Table III.

THE THERMAL REVERSIBILITY OF THE MICHAEL REACTION

IV. THIOL ADDUCTS

C. F. H. ALLEN

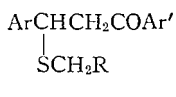
ABSTRACT

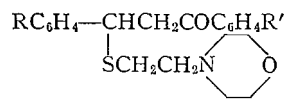
The hydrochlorides of 27 Michael adducts, formed from alkylthiols and chalcones monosubstituted successively in each ring by nitro, chloro, and methoxy groups, were thermally cleaved by hot water. The amount of cleavage was readily determined iodimetrically.

A systematic study of the thermal reversibility of Michael adducts, formed by the addition of mercaptans to the conjugated system of double bonds present in ketones, esters, and the like, is believed to be new. The only instances on record are those described in one of our previous papers (1). The current account is limited to adducts which are formed from chalcones and which have β-alkylmercapto substituents. They comprise a new class that can be used for a study of thermal cleavage. A following paper will contain an account of similar adducts derived from unsaturated esters, nitriles, ketones with fewer substituents, and the like. It has been found that they are not sufficiently active to reverse thermally.

The extent of thermal cleavage is susceptible to quantitative estimation, since the mercapto addends regenerated can be titrated against standard iodine solutions. This operation is much more convenient than the use of gas chromatography, as previously employed (1). Since these adducts can give only normal cleavage, it makes possible an examination of the effect, if any, of substituents in different positions of both benzene rings on the extent of the reversal. The extent of cleavage of all the adducts is summarized in Table I.



I



II

The adducts investigated were mainly those (II) formed from β-morpholinoethanethiol, because of its availability (2), because the hydrochloride salts are easily crystallized solids, because of their increased solubility, and because they give good cleavage rates. A few preliminary experiments showed that other thiols could be so used (Table I, Nos. 1, 2, 3, 7, 8), that the reversal was general, and that it was not confined to β-mercaptoethylamines. Three kinds of ring substituents were employed—nitro (strong electron-withdrawing), chloro (weak electron-withdrawing), and methoxy (electron-donating). These groups, one at a time, were located in ortho-, meta-, and para-positions in both rings.

The process may depend upon (*a*) the activity of the α-hydrogen atom of the adduct, (*b*) the resonance stabilization of the structure —C=C—C=O formed by cleavage, and

$C_6H_5CHCH_2COC_6H_5$ $SCH_2CH_2N(C_2H_5)_2$·HCl	69.2

The adducts (as their salts) were cleaved at 100 °C by a simple rapid procedure. The titration results suggest that the activity of the α-hydrogen atom of the adducts influences the extent of release of mercaptan.

Cleavage of adducts of chalcones to form a conjugated system, that is, a product having greater resonance, may be a predominant factor in heat-induced reversal. The adduct of methyl vinyl ketone with β-morpholinoethanethiol is incompletely reversed by alkali and only slightly affected by heat. However, the adduct of benzalacetone with this mercaptan is almost completely cleaved by alkali, as will be described in a forthcoming paper. All of the corresponding adducts of substituted chalcones are rapidly cleaved nearly quantitatively by alkali and, in addition, are reversed by heat.

The Conjugate Addition

Addition of β-morpholinoethanethiol to chalcones occurs rapidly in refluxing alcohol. The salts were formed by replacement of the solvent by ether and the addition of hydrogen chloride.

Addition of mercaptoethanol or mercaptoacetic acid by refluxing in acetic acid for 15 min forms adducts in 80–99% yield.

Sodium methoxide catalyzed addition of mercaptoacetic acid in alcohol produced the adduct in only a 17% yield (4). The data are included in Table I.

EXPERIMENTAL

Preparation of Starting Materials

3′-Methoxyacetophenone (5), b.p. 131° at 19 mm, n_D^{25} 1.5391; 2′-chloroacetophenone (6), b.p. 100° at 10 mm, n_D^{25} 1.5409; 3′-chloroacetophenone (7), b.p. 52–54° at 0.25 mm, n_D^{25} 1.5472; and β-morpholinoethanethiol, b.p. 97–98° at 15 mm, n_D^{25} 1.5020 (2) were prepared as described in the literature. All the chalcones were known: NO_2 and Cl (8), *o*-OCH_3 (9), *m*-OCH_3 (10), *p*-OCH_3 (11), *o*′-OCH_3 (12), *m*′-OCH_3 (13), *p*′-OCH_3 (14), *p*′-OH (15), *p*-CH_3 (16), and *p*′-C_6H_5 (17). The melting points agreed with the reported values except for the *o*′-chloro (9), which did not crystallize.

Anal. Calcd. for $C_{15}H_{11}ClO$: C, 74.2; H, 4.6; Cl, 14.6. Found: C, 74.5; H, 4.5; Cl, 14.4.

Preparation of Adducts

(a) From Chalcones and β-Morpholinoethanethiol or N,N-Diethylaminoethanethiol (2)

Equimolar amounts of the chalcone and the thiol were refluxed in absolute ethanol for 1 h and evaporated to dryness *in vacuo*. In some instances, the oils crystallized and the adduct was purified as the free base. The free base, oil or solid, was dissolved in ether and converted to the hydrochloride with hydrogen chloride. Perchlorates were prepared by treating the hydrochlorides with aqueous sodium perchlorate.

(b) From Chalcones and β-Mercaptoethanol or Mercaptoacetic Acid

A solution containing 1 mole of the chalcone and 1.5 moles of the mercaptan in glacial acetic acid was boiled for 15 min and allowed to cool. On addition of water an oil separated. The water was decanted and the oil rinsed with water two or three times, after which the oil crystallized. The products were recrystallized from ether–petroleum ether, b.p. 35–60°. The analyses are included in Table I.

Cleavage of Adduct and Titration of the Thiol

Approximately 1 meq of the adduct in a small aluminium foil "boat" was weighed exactly. The boat and the sample were then immersed for exactly 2 min in 100 ml of vigorously boiling water (in a 500-ml Erlenmeyer flask), at which time solution generally occurred, followed by formation of solids. Then 100 g of ice and water was added, the flask was set in an ice bath, and 50 ml of glacial acetic acid was added. These additions took 5–6 s. Ten milliliters of 0.25% starch indicator was then added and the mixture was titrated with a standard 0.1 *N* iodine solution to a blue end point.

NOTES

RADIOLYSIS OF AQUEOUS BROMAL HYDRATE SOLUTIONS; DETECTION OF OXALIC AND GLYOXYLIC ACIDS

R. L. EAGER, R. W. O'DONNELL, AND L. J. TUSZ

Various workers have investigated the products from the irradiation of aqueous solutions of bromal hydrate with beta particles and gamma rays (1–5). All of these workers reported the formation of hydrobromic acid together with relatively small amounts of some additional acid. Woods and Spinks (1) also detected dibromoacetaldehyde and dibromoacetic acid. Heusinger, Woods, and Spinks (2) detected a small yield of carbon dioxide and carboxylic acids. Norris (3) detected dibromoacetaldehyde, tribromoacetic acid, and carbon dioxide. Norris' results indicated that various side reactions occur which yield very small quantities of products, thus making their identification by straightforward chemical means very difficult. Bricknell (4) made a tentative proposal of a mechanism for the radiolysis of aqueous bromal hydrate solutions. This mechanism predicts the formation of one molecule of oxalic acid for every three molecules of hydrobromic acid produced. The oxalic acid was postulated to be formed in the following reaction, which is one step of a chain reaction:

$$Br_2\dot{C}\cdot CH(OH)_2 + O_2 \rightarrow HBr + (COOH)_2 + Br\cdot$$

The present authors decided to look for oxalic acid in aqueous bromal hydrate solutions which had been irradiated with ^{60}Co gamma rays. Since it was possible that glyoxylic acid, CHO·COOH, might be an intermediate in the formation of oxalic acid we decided to look for it also.

EXPERIMENTAL

Samples of aqueous bromal hydrate solutions (0.05 *M* and 0.1085 *M*) were irradiated with ^{60}Co gamma rays. The temperature of the solutions was approximately 22 °C. During the radiolyses oxygen was bubbled through the solutions. To increase the sensitivity of detection of the two compounds, bromal hydrate labelled with ^{14}C in the aldehyde position was used.

Oxalic acid was determined as follows. A solution of inactive sodium oxalate, to serve as a carrier, was added to the irradiated solution. The solution was extracted with ether to remove bromal hydrate. An excess of calcium chloride, followed by sufficient ammonia water to bring the pH to a value of approximately 5.4, was added. Preliminary experiments had indicated that at this pH bromal hydrate did not tend to precipitate, and yet the recovery of calcium oxalate was good. The calcium oxalate precipitate was washed with cold water. A weighed sample of the precipitate was converted to carbon dioxide using the Van Slyke method. The radioactivity of the carbon dioxide was determined with a Dynacon vibrating-reed electrometer (supplied by Nuclear-Chicago Corporation). In control experiments, in which bromal hydrate solutions which had not been irradiated were treated in a similar fashion, the amount of radioactivity carried through to the counting step was found to be negligible.

From the specific activity of the calcium oxalate, the weight of carrier added, the specific activity of the bromal hydrate, and the dose absorbed by the sample, it is possible to calculate the *G* value for the production of oxalic acid. The results are summarized in Table I.

Glyoxylic acid was determined in the irradiated solutions by first adding inactive glyoxylic acid as carrier. Sodium bicarbonate was used to adjust the pH of the solution to the bromophenol blue end-point. The solution was extracted 10 times with chloroform. The aqueous layer was used to form the 2,4-dinitrophenylhydrazine derivative. The precipitate was washed with 5 *N* H_2SO_4 followed by a distilled water wash. The derivative was recrystallized twice from methanol. A weighed sample of the 2,4-dinitrophenylhydrazine derivative was converted to carbon dioxide and counted in a manner similar to that used for the calcium

TABLE I

Formation of oxalic acid

Dose rate (rads min^{-1})	Conc. (M)	Dose $\times 10^{-3}$ (rads)	G (oxalic acid)	Average G
1320	0.0534	256	0.14	
1320	0.0534	716	0.14	0.14
1320	0.0534	1030	0.14	
260	0.0534	371	0.14	
260	0.0534	609	0.14	0.14
260	0.0534	1810	0.14	
1140	0.1085	427	0.09	
1140	0.1085	755	0.13	0.11
1140	0.1085	1390	0.12	

oxalate precipitates. In control experiments the amount of radioactivity carried through to the counting step was found to be negligible. The G values for the production of glyoxylic acid were calculated and are given in Table II.

TABLE II

Formation of glyoxylic acid: dose rate 1140 rads min^{-1}

Conc. (M)	Dose $\times 10^{-3}$ (rads)	G (glyoxylic acid)
0.1085	1360	0.64
0.055	1500	2.6
0.055	1040	0.72

DISCUSSION

The results indicate that both oxalic acid and glyoxylic acid are formed when bromal hydrate solutions are irradiated with ^{60}Co gamma rays. For the dose rates and concentrations of bromal hydrate used in the present work the G value for the production of hydrobromic acid would be in the neighborhood of 100 (5).

The results presented in Table I should not be taken to indicate necessarily that the G value for the appearance of oxalic acid is independent of the dose rate. Over the range of dose rates investigated in the present work the effect of dose rate on the G value for the appearance of hydrobromic acid is also not very significant (5). The effect of concentration on the G value is similar to that for the appearance of hydrobromic acid (5), i.e. it is smaller for higher concentrations.

The much smaller G values found for the appearance of oxalic acid, compared to those for the appearance of hydrobromic acid, would indicate that it is not formed in the reactions by which most of the hydrobromic acid is produced. It is possible that the G value for the production of oxalic acid is actually higher than found in the present work because of radiolysis of oxalic acid itself. If the radiolysis of oxalic acid had been significant, the G values for its appearance would have been expected to decrease with an increase in the absorbed dose. Since the G values were constant over a wide range of absorbed doses it would appear that radiolysis of oxalic acid was not very singificant. Hence, the G values for the production of oxalic acid are probably close to the values reported here for the appearance of oxalic acid.

The results for glyoxylic acid production indicate that it, too, is not formed in the reactions by which most of the hydrobromic acid is produced in the radiolysis of bromal

hydrate solutions. From Table II it may be seen that there is some doubt about the *G* value for the appearance of glyoxylic acid. The value of 2.6 may, however, be in error since the amount of radioactivity being worked with was very small and hence, even a small amount of contamination would result in higher apparent *G* values. Thus, *G* values of 0.6 to 0.7 may be more nearly correct for the appearance of glyoxylic acid. It would appear that glyoxylic acid is not an intermediate in the formation of oxalic acid since, if it were, the *G* value for the appearance of oxalic acid might be expected to increase with increased absorbed dose.

SOME BASICALLY SUBSTITUTED CAMPHANES

Ling Wei and Edgar A. Steck[1]

There have been numerous indications (*inter alia*, refs. 1–6) that morpholine derivatives may exhibit valuable levels of pharmacological activity. For this reason, synthesis of I was undertaken. The route chosen for the preparation of the perhydro-5,8-methano-2*H*-1,4-benzoxazine type is indicated as II–IV to I. It was hoped that 3-bromo-*d*-camphor and ethanolamine would provide facile access to such a type. It was anticipated that these compounds would produce 3-(2-hydroxyethlyamino)camphor, III, however, *N*-(2-hydroxyethyl)camphanimine, V, was formed. This compound was obviously produced by a reductive debromination at the 3-position in I, followed by formation of the Schiff base. Such a fundamental reaction is well known (and not unexpected for such reducing agents) to occur when II is acted on by hydroxylamine (7–10) or phenylhydrazine (11). The structure assigned V was supported by infrared spectra, and also by synthesis from *d*-camphor and ethanolamine. Attempts were made to convert V to an oxazine type, but without success. These approaches included dehydration of V; conversion of V to VI, and dehydration of VI; transformation of V to VII, and of VI to VIII, followed by elimination of hydrogen chloride. No useful activity was uncovered when compounds V–VIII were subjected to broad pharmacological screening in rodents. All products were tested for effects on the central nervous system, and compounds VII and VIII were evaluated for possible actions on the autonomic nervous system. Neither antibacterial nor antifungal testing in vitro gave evidence of significant activity in this series.

EXPERIMENTAL[2]

N-(2-Hydroxyethyl)camphanimine, V

(a) From 3-Bromo-d-camphor and Ethanolamine

A mixture of 23.1 g (0.1 mole) of 3-bromo-*d*-camphor, 30.5 g (0.5 mole) of ethanolamine, and 0.2 g of copper powder[3] was heated on the steam bath with vigorous stirring for 18 h. The cooled material was quenched on ice, filtered, and the solid was air-dried before dissolving in anhydrous ether, then filtered. Addition of dry hydrogen chloride to the ether solution gave a white precipitate of *N*-(2-hydroxyethyl)-camphanimine hydrochloride. It was crystallized from ethanol to obtain 14.5 g (61%) of prismatic needles which melted at 206° with decomposition; ν_{max} 3.10, 3.40, 3.65, 5.19, 5.86, 6.75, 6.90, 7.06, 9.26, 10.30 μ. The compound had a dull, somewhat camphoraceous odor.

Anal. Calcd. for $C_{12}H_{21}NO \cdot HCl$: C, 62.17; H, 9.57; N, 6.04. Found: C, 62.16; H, 9.58; N, 6.03.

A sample of the hydrochloride (5.0 g) was converted to the base with aqueous ammonia and crystallized

[2]*All melting points are uncorrected. Infrared spectra were determined with 2% potassium chloride pellets in a Perkin–Elmer Model 21 spectrophotometer. Messrs. J. Weinberger and P. D. Carp, of these laboratories, carried out the analytical determinations and spectral studies.*

[3]*The copper could be eliminated with no appreciable effect in yield of product.*

For personal use only.

from ethanol. The creamy prisms (3.8 g) melted at 71–71.5°; ν_{max} 3.19, 3.42, 3.48 (shoulder), 5.94, 6.86, 7.56, 9.31, 11.04 μ. It had a musty, camphoraceous odor.

Anal. Calcd. for $C_{12}H_{21}NO$: C, 73.79; H, 10.83; N, 7.17. Found: C, 73.44; H, 10.82; N, 7.62.

(b) From d-Camphor and Ethanolamine

Interaction of *d*-camphor with an excess of ethanolamine was carried out on the steam bath with and without copper catalyst (cf. ref. 12). In all cases, *N*-(2-hydroxyethyl)camphanimine was formed, and was identified as V by comparison of infrared spectra and melting points of the base and hydrochloride with those produced in (*a*).

2-(2-Hydroxyethylamino)camphane VI

(a) Catalytic Hydrogenation of V

A solution of 19.5 g (0.1 mole) fo 2-(2-hydroxyethylimino)camphane in 50 ml of ethanol was reduced at 39 kg/cm^2 hydrogen pressure in the presence of 5 g of Raney nickel. The reaction required 3 h for completion, and then the filtered solution was treated with hydrogen chloride. A 96.1% yield (22.5 g) of hydrochloride resulted after crystallization of the crude product from ethanol. The microcrystalline solid, which melted at 271–272°, had a slight camphor-like odor; ν_{max} 3.10, 3.42, 6.51, 6.88, 6.95, 7.08, 9.30 μ.

Anal. Calcd. for $C_{12}H_{23}NO \cdot HCl$: C, 61.65; H, 10.35; N, 5.99. Found: C, 61.83; H, 10.56; N, 5.48.

(b) Sodium Borohydride Reduction of V

A solution of 9.8 g (0.05 mole) of *N*-(2-hydroxyethyl)camphanimine in 50 ml of ethanol was cooled to 0° and a solution of 2.0 g (0.05 mole) of sodium hydroxide in 10 ml of water was added. It was then treated with 4.7 g (0.125 mole) of sodium borohydride, portionwise, during 0.5 h. Then the mixture was stirred at room temperature for 1 h before heating on the steam bath for an hour. It was cooled and extracted with ether. The extracts were washed with water and then dried (sodium sulphate). The filtered extracts were treated with hydrogen chloride, and the precipitated salt collected, washed (acetone), and crystallized from methanol–ether. The product (9.5 g, 81% yield) melted at 271–272° and exhibited spectral characteristics identical with the compound prdouced by catalytic hydrogenation.

Anal. Calcd. for $C_{12}H_{23}NO \cdot HCl$: C, 61.65; H, 10.35. Found: C, 61.90; H, 10.30.

N-(2-Chloroethyl)camphanimine, VII

N-(2-Hydroxyethyl)camphanimine hydrochloride (11.6 g, 0.05 mole) was slowly treated, with stirring, with 22.8 g (0.2 mole) of thionyl chloride. The mixture was stirred at room temperature for 1 h, collected, and washed with acetone. It separated from benzene (12.0 g, 96% yield) in the form of platelets m.p. 226–227°, which had an odor resembling that of eucalyptol; ν_{max} 3.40, 3.84, 5.83, 6.80, 6.92, 7.08, 7.17, 8.28, 9.29 μ.

Anal. Calcd. for $C_{12}H_{20}ClN \cdot HCl$: C, 57.20; H, 8.46; N, 5.59. Found: C, 57.37; H, 8.58; N, 5.45.

2-(2-Chloroethylamino)camphane, VIII

This compound was prepared from VI in the manner employed for VII. It was obtained (92% yield; crystallized from benzene) as a cryptocrystalline solid which had a slight, dull, camphoraceous odor, m.p. 273° with decomposition; ν_{max} 3.40, 3.69, 6.25, 6.80, 6.88 (bifurcation), 7.02, 7.15 μ.

Anal. Calcd. for $C_{12}H_{22}ClN \cdot HCl$: C, 57.14; H, 9.15; N, 5.55. Found: C, 57.19; H, 9.30; N, 5.44.

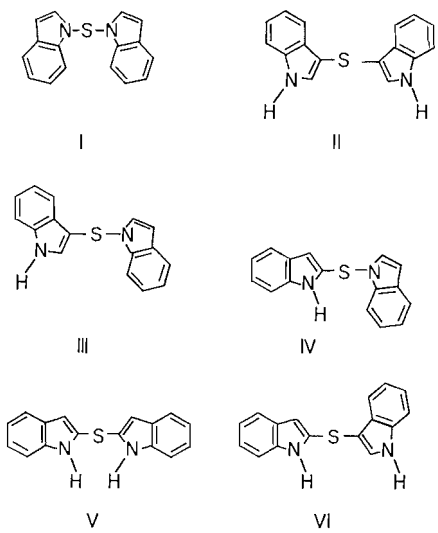
CORROBORATION THAT 3,3′-DIINDOLYL SULPHIDE IS THE COMPOUND OBTAINED FROM THE REACTION OF INDOLE MAGNESIUM BROMIDE WITH SULPHUR

R. V. Jardine and R. K. Brown

In an attempt to prepare 3-mercaptoindole by the reaction of indole magnesium bromide with sulphur, Madelung and Tencer obtained a compound which analyzed for a diindolyl sulphide (1). They found that this compound was unusually inert, being stable to oxidation by potassium permanganate, to boiling potassium hydroxide solution, and to acetic anhydride or nitrous acid. On this basis they suggested structure I as a possibility for this substance. Nevertheless, structure II (3,3′-diindolyl sulphide) was accepted, presumably because of the preference of indole magnesium bromide to react at the β-position (1–3).



While seeking routes for the synthesis of 3-alkylthioindoles, we have obtained as one of the products from the reaction of indole magnesium bromide with ethanesulphenyl chloride a compound analyzing correctly for diindolyl sulphide and showing an infrared spectrum identical with that of the compound prepared according to Madelung and Tencer's procedure (1). We felt that the structure of this compound should be placed on a firmer basis before elucidation of the route to its formation could be investigated.

A clear choice of the appropriate structure from among I–VI could be made by the following infrared and nuclear magnetic resonance (n.m.r.) spectral examinations. Because of the general poor solubility of the diindolyl sulphide in suitable solvents, the infrared spectrum was obtained in a Nujol mull. A sharp doublet at 3395 cm^{-1} and 3410 cm^{-1}, in the region expected for indole N—H stretching (4), eliminated structure I and agreed with structures II–VI. Replacement of hydrogen on the nitrogen atom by deuterium, a reaction very easily accomplished for this compound by the usual procedure of repeated treatment of the sulphide with D_2O in pyridine or acetone, eliminated this doublet as well as doublets at 1405 and 1410 cm^{-1} and 1085 and 1095 cm^{-1} and also bands at 1105 cm^{-1} and 1118 cm^{-1}. A new band appeared at 2535 cm^{-1}, accompanied by a lesser band at 2522 cm^{-1} along with a new doublet at 910 and 915 cm^{-1}. This shift in

absorption of 3395 cm^{-1} to 2535 cm^{-1}, upon replacement of the hydrogen on nitrogen by deuterium, is approximately that predicted by Hooke's law (5).

The appearance of the doublets in the infrared spectrum indicated the possibility of structure VI, containing two slightly different N—H groups. However, n.m.r. evidence supported structure II. It has been shown (6) that in $CDCl_3$ solution, the C_2 and C_3 protons of indole absorb at $\tau = 3.32$ and 3.62 respectively (referred to tetramethylsilane). Because of the solubility limitations of the diindolyl sulphide, acetone was chosen as the solvent for n.m.r. analysis. In this solvent, the C_2 (or C_3) proton was shifted farther downfield because of the combined inductive effect of the sulphur and nitrogen atoms and appeared as a sharp doublet at $\tau = 2.43$ ($J = 2$ c.p.s.). The integrated area for this doublet corresponded to *two* protons. This assignment was made because replacement of the N—H by N—D caused the doublet to collapse to a sharp singlet, whose integrated area was equal to two protons. The disappearance of splitting provides evidence of coupling between the N—H and the C_2 (or C_3) proton and indicates that the protons (C_2 or C_3) are equivalent, thus eliminating structures III, IV, and VI and supporting structures II and V.

A decision between II and V could be made by determining the extent of the change in chemical shift of the signals for the C_2 (or C_3) proton of the indole structure as one changes from one solvent to another. It is known that the signal position of the C_2 proton of indoles is markedly affected by solvent, while that of the C_3 proton of indoles remains practically unchanged in various solvents (7). The poor solubility of the diindolyl sulphide limited the application of this technique but it was sufficiently useful to permit clear distinction between II and V.

The signals for the C_3 protons of indole, ethyl indole-2-carboxylate, and indole-2-carboxylic acid have been found to be nearly at the same positions in the three solvents dioxane, dimethyl sulphoxide, and acetone. However, the positions of the C_2 proton signals of the compounds indole, ethyl indole-3-carboxylate, and indole-3-carboxylic acid were found to vary considerably in these solvents (7). In any pair of the solvents used there was never more than a difference of 0.08 τ found for the C_3 proton signal position, but that of the C_2 proton changed as much as 0.18 to 0.24 τ.

The signal positions of the C_2 (or C_3) protons of the diindolyl sulphide are shown in Table I.

TABLE I

Signal positions of the C_2 (or C_3) proton of diindolyl sulphide

Solvent	Dioxane	Dimethyl sulphoxide	Acetone
Signal (doublet centered at)	2.66	2.40	2.43
J (c.p.s.)	2	2	2

Since the difference in the signal position in dioxane and dimethyl sulphoxide is 0.26 τ, this is strong evidence for the adoption of structure II rather than structure V.

The likelihood that the substance is a mixture of II and V is ruled out by the n.m.r. spectrum, which would show two doublets which are reduced upon deuteration to two singlets, one of which would shift in position more than the other upon solvent change. This has not been observed.

The doublet observed for the N—H stretching in the infrared spectrum of 3,3′-diindolyl sulphide (II) may be due to the interaction between neighboring molecules in the crystalline state (4, pp. 28 and 380). Hence, observation of multiplicity of N—H peaks in Nujol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

can not be taken as evidence for the existence of *two different* N—H groups since each of the compounds II to VI could show this phenomenon. Therefore the appearance of absorption in this region indicates unequivocally only the *presence* of the N—H group.

Such band duplication disappears upon solvation of the substance, and, in fact, a solution of the sulphide in dioxane gave a single though somewhat broadened band whose maximum is at 3300 cm^{-1}. In methylene chloride, the infrared spectrum of II, measured at high resolution, showed a single peak at 3460 cm^{-1}.

EXPERIMENTAL

Infrared spectra were recorded on Perkin–Elmer Instruments models 21, 221G, and 421. Nuclear magnetic resonance spectra were recorded on a Varian Associates model A-60 instrument. Further details and spectra are available in the thesis of R. V. Jardine.*

Deuteration of 3,3'-Diindolyl Sulphide

About 120 mg of 3,3'-diindolyl sulphide (1) was dissolved in 8 ml of reagent acetone and then 2 ml of D_2O (99.7%) was added. The solution was stirred for 10 min and then freed of solvent in a rotary evaporator under vacuum. This treatment was repeated two or three more times. Final drying of the compound was carried out over P_2O_5 in a desiccator. Care was taken to protect all solutions from direct light.

The extent of deuteration was determined by infrared spectroscopy. Disappearance of the N—H peak between 3100 and 3500 cm^{-1} in the infrared and the appearance of a new peak due to N—D at a frequency of about 0.75 of the N—H stretching frequency gave a measure of the amount of deuterium exchange.

UNIT CELL DIMENSIONS AND SPACE GROUPS OF SYM-DIPHENYL THIOUREA AND SYM-DIPHENYL UREA

Roy Kari and N. R. Kunchur

A preliminary X-ray examination of *sym*-diphenyl urea and *sym*-diphenyl thiourea has been carried out as part of the program to study the crystal and molecular structures of the derivatives of urea and thiourea. These two derivatives are formed by a symmetrical substitution of one hydrogen by a benzene ring on each of the two nitrogen atoms of urea and thiourea. From the examination of the ultraviolet absorption spectra of the substituted ureas, Picard and McKay (2) pointed out that some double bond character

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

exists between nitrogen of urea or thiourea and the phenyl group. Since urea and thiourea are known to have planar structures (2, 3), one can predict that their substituted compounds should have a similar configuration having a molecular symmetry identical with that of the parent molecules. The results of the preliminary work on *sym*-diphenyl thiourea shows that this compound has the same molecular symmetry as thiourea.

sym-Diphenyl Thiourea ($C_{13}H_{12}N_2S$)

Molecular weight 228.31. The crystals obtained by recrystallization from benzene are thin plates on (001) outlined by (100) and (010). The unit cell dimensions and space group were determined from various oscillation and Weissenberg photographs with Cu K_α radiation.

Crystal Data

Orthorhombic; $a = 8.15 \pm 0.03$ Å, $b = 26.17 \pm 0.05$ Å, $c = 5.63 \pm 0.02$ Å.

Volume of the unit cell is 1 200.8 Å^3.

Absorption coefficient for X rays; $\lambda = 1.542$ Å, $\mu = 21.8$ cm^{-1}.

Total number of electrons per unit cell $F(000) = 480$. The density, 1.25 g cm^{-1}, calculated on the assumption that the unit cell contains four molecules, agrees with the measured value (flotation method) of 1.24 g cm^{-3}. The systematic absences—$hk0$ for h odd and $0kl$ for $k + l$ odd—correspond to the space groups $Pnma$ and $Pn2_1a$. The ambiguity regarding the space group determination was resolved by doing the Wilson's statistical test which is consistent with the centrosymmetric space group $Pnma$. Since the symmetry of the general positions of this space group is eightfold and there are four molecules per unit cell, it follows that the molecule should occupy one of the special four-position 4*a*, 4*b*, or 4*c*. From chemical considerations, the molecule has a mirror plane of symmetry and so can be located at 4*c*, which also has a mirror plane point symmetry. The positions 4*a* and 4*b* can be ruled out since they require the molecule to posses a center of symmetry which it cannot have. A three-dimensional crystal structure analysis of this compound is in progress.

sym-Diphenyl Urea ($C_{13}H_{12}N_2O$)

Molecular weight 212.24. The crystals formed from ethanol are flat plates parallel to the '*b*' axis. The crystal data was obtained in a similar manner as described for the previous compound.

Crystal Data

Orthorhombic; $a = 9.07 \pm 0.03$ Å, $b = 11.70 \pm 0.03$ Å, $c = 10.60 \pm 0.03$ Å.

Volume of the unit cell is 1 124.8 Å^3.

Absorption coefficient for X rays; $\lambda = 1.542$ Å, $\mu = 7.5$ cm^{-1}.

Total number of electrons $F(000) = 448$.

The density 1.25 g cm^{-1} calculated on the assumption of four molecules in the unit cell, agrees with the experimental value (flotation method) of 1.24 g cm^{-3}. The systematic absences—$hk0$ for h odd and $0kl$ for $k + l$ odd—correspond to the space groups $Pnma$ and $Pn2_1a$.

No further work on this compound is planned.

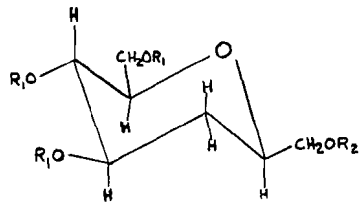
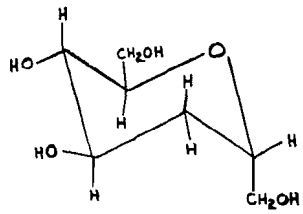
THE STRUCTURES AND ABSOLUTE CONFIGURATIONS OF ANHYDRODEOXYHEPTITOLS

A. CAMERMAN, H. J. KOCH, A. ROSENTHAL, AND J. TROTTER

Hydroformylation in the presence of dicobalt octacarbonyl (1) of tri-O-acetyl-D-glucal yielded two isomeric products, which then were deacetylated and the parent polyols separated by paper chromatography. The fast running fraction had m.p. 137–138°, $[\alpha]_D = 1°$ (*c*, 3.5, water), and the other isomer had m.p. 156°, $[\alpha]_D = +60°$ (*c*, 1.4, water). Proton magnetic resonance (p.m.r.) spectra of the individual deacetylated polyols indicated that the carbon skeletons were linear. Hence the compounds are isomeric anhydrodeoxyheptitols. Rotation rules (2) then suggested that the lower melting isomer is 2,6-anhydro-3-deoxy-D-*gluco*heptitol (I, $R_1 = R_2 = H$), and the higher melting isomer is 2,6-anhydro-3-deoxy-D-*manno*heptitol (II). However, since these rules are not of universal



I



II

application and have not been applied to heptitols, further definite evidence for the structures was sought. The p.m.r. spectra of the polyols obtained by using deuterium in the hydroformylation gave further support to the tentative assignment of structure, but an X-ray investigation was undertaken to establish the structure conclusively.

For X-ray analysis the *p*-bromobenzenesulphonyl triacetyl derivative of the lower melting polyol was prepared by treatment of the mixture of triacetylanhydrodeoxyheptitols with *p*-bromobenzenesulphonyl chloride. The required derivative preferentially crystallized out of the reaction mixture, and subsequently was deacetylated and debrosylated by standard methods to yield a pure sample of the lower melting polyol. Crystals of the derivative (m.p. 104°, $[\alpha]_D = -10°$ (*c*, 3, chloroform)) are orthorhombic with four molecules in a unit cell of dimensions $a = 13.71$, $b = 29.37$, $c = 5.79$ Å, space group $P2_12_12$. The intensities of the reflexions were measured with a scintillation counter and Cu K_α radiation. The bromine and sulphur positions were determined from the three-dimensional Patterson function, the coordinates of the carbon and oxygen atoms were obtained from successive three-dimensional electron-density distributions, and all the parameters were refined by differential syntheses and the method of least squares; the final *R* factor was 0.09. A perspective drawing of the molecule is shown in Fig. 1 (the atom numbering is for convenience in the crystallographic investigation).

The structure is I($R_1 = CH_3 \cdot CO-$, $R_2 = Br \cdot C_6H_4 \cdot SO_2-$), in agreement with the indirect evidence. The ring has the chair form, and all the substituents are equatorial.

EFFECTS OF pH IN THE γ-RADIOLYSIS OF AQUEOUS SOLUTIONS OF CYSTEINE AND METHYL MERCAPTAN

D. A. ARMSTRONG AND V. G. WILKENING

Packer (1) has recently shown that the yield of peroxide, which accumulates in irradiated air-free acid solutions of cysteine, is consistent with the accepted molecular yield, $G_{H_2O_2}{}^M$. This observation confirms the earlier results of Whitcher, Rotheram, and Todd (2), and we may conclude that the molecular peroxide formed in acidified solutions does

not react with cysteine or affect its decomposition (provided the peroxide concentration never rises to such a level that it begins to compete for radical intermediates). Similar considerations should obviously apply for the molecular hydrogen.

It has generally been assumed (1, 3) that hydroxyl radicals will abstract hydrogen atoms from the thiol group,

[1] $$OH + RSH \rightarrow H_2O + RS,$$

and that in air-free solutions the resulting thiol radicals will dimerize,

[2] $$2RS \rightarrow RSSR.$$

These rather straightforward assumptions appear entirely reasonable to us. In contrast there is evidence that the reactions of the reducing radicals, e_{aq}^- and H, with cysteine are highly complex. Littman, Carr, and Brady (4) examined the products of reaction between hydrogen atoms from an electrical discharge and cysteine in aqueous solution. At pH's in the range 0–6 cystine was the major product, but smaller quantities of H_2S were also formed. These authors suggested that reaction [3],

[3] $$H + RSH \rightarrow RS + H_2,$$

predominated over [4],

[4] $$H + RSH \rightarrow R + H_2S,$$

and was followed by [2]. As the pH was increased above 7 the relative proportions of the two products began to be reversed until at a pH of 11 H_2S was by far the major product. This reversal was attributed to the ionization of the thiol group,

[5] $$RSH \rightleftharpoons RS^- + H^+$$

(pK = 8.36 (5)), and the replacement of reactions [3] and [4] by [6]:

[6] $$H + RS^- \rightarrow R + SH^-.$$

Earlier work by Dale and Davies (6) had shown that H_2S was an important product of the X-radiolysis of dilute aqueous cysteine solutions. The yield was appreciable in the region of pH 3 and passed through a maximum at pH 7. At pH's above 8, where Littman *et al.* had observed an enhancement of the H_2S yield from hydrogen-atom attack on cysteine, the radiolytic H_2S yield declined. The production of H_2S with a G value of the order of 3 from cysteine solutions at pH's lower than 7 was subsequently confirmed by Whitcher, Rotheram, and Todd (2) and by Markakis and Tappel (3). The results of these two groups are presented in Table I together with our own. The values of $G(H_2S)$ in parentheses were calculated from the data of the present study using the expression:

[i] $$G(H_2S) = \left\{G_H + G_e \frac{k_8[H^+]}{k_8[H^+] + k_7[RSH]}\right\} \frac{k_4}{k_3 + k_4} + G_e \frac{k_7[RSH]}{k_8[H^+] + k_7[RSH]}.$$

The rate constants in this expression are identified below and the values of G_H and G_e were taken from the current literature.

Clearly, if the work of Littman, Carr, and Brady is correct, it is rather difficult to reconcile the pH dependence of the radiolytic H_2S yields with hydrogen-atom attack on cysteine. It is necessary, therefore, to consider the possibility that reaction [7] produces H_2S,

[7] $$e_{aq}^- + RSH \rightarrow R + SH^-,$$

and competes with reaction [8],

[8] $$e_{aq}^- + RSH \rightarrow R + SH^-,$$

which in acid solution converts e_{aq}^- to H. If k_7/k_8 is sufficiently large, the appearance of H_2S at pH's below those at which the thiol group is significantly ionized can then be explained. Such a competition for e_{aq}^- would be analogous to that already observed with the chloroacetic acids (7), and should manifest itself in drastic changes in the hydrogen and H_2S yields over the pH range in which [7] and [8] are competing.

Table I shows values of $G(H_2)$ and $G(H_2S)$ from experiments with air-free 10^{-3} M cysteine solutions in sulphuric acid at several different pH's between 0–8. Absorbed doses of ^{60}Co radiation were in the range 0.4–5 $\times$ 10^{18} eV/gm. The yields of H_2S in these solutions were measured by the molybdate method (8). Their downward trend over the pH range corresponding to the increase in the hydrogen yields provides strong support for a competition between reactions [7] and [8]. The hydrogen yields from 0.05 M methyl mercaptan solutions* showed a similar pH dependence with those obtained from cysteine, and the formation of H_2S in appreciable quantities at the higher pH's was confirmed colorimetrically.

For methyl mercaptan the R radical formed in reactions [4] and [7] would be a methyl radical. This should abstract a hydrogen atom from another thiol molecule to form methane, viz.

$$R + RSH \rightarrow RH + RS. \qquad [9]$$

In all the mercaptan experiments a second noncondensable gas remained after diffusion of the hydrogen through a palladium thimble. This was confirmed by mass spectrometric analysis to be methane. As shown in Fig. 1, $G(CH_4)$ followed the expected downward trend as the pH was decreased. In the case of cysteine, reaction [9] would yield alanine, and, in support of the proposed mechanism, we find $G(H_2S) \simeq G$(alanine) $\simeq 2.9$ from the data of Markakis and Tappel at pH 1.6 and a dose of 10^6 r. (Beyond this dose

These were prepared by admitting a known quantity of mercaptan to 5 ml of degassed acidic solvent in a cell of known total volume. After the contents of the cell were melted, the mercaptan was equilibrated at room temperature between the vapor and solution phases. Its concentration in solution was calculated using an experimentally measured solubility coefficient (3.8×10^{-3} moles per l per cm pressure of mercaptan).

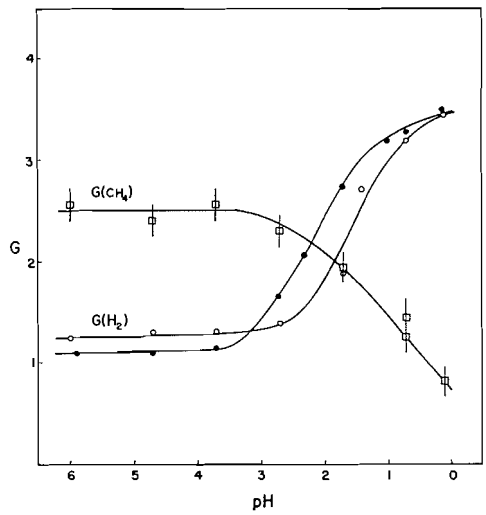

FIG. 1. Dependence of $G(CH_4)$ and $G(H_2)$ from γ-irradiated methyl mercaptan solutions on pH; (○) $G(H_2)$ from 0.04 to 0.06 M MeSH solutions, (□) $G(CH_4)$ from 0.04 to 0.06 M MeSH solutions, (●) $G(H_2)$ from 0.005 to 0.008 M MeSH solutions.

secondary reactions of the products become important.) If [1], [3] or [4], and [7] are the only important reactions of OH, H, and e_{aq} the total number of RS radicals from all sources would be equal to $G_{OH} + G_H + G_e$ (= 3.65 + 2.95, taken from ref. 9*a* for acid solutions; 3.65 = total $G_{reducing}$). Hence G(cystine) should be 3.30. Markakis and Tappel observed 3.7, in reasonable agreement.

Assuming $G_{H_2}^M = 0.3$ in 5×10^{-2} M mercaptan solutions, one may obtain $G_{reducing} = G(CH_4) + G(H_2) - G_{H_2}^M = 3.8$ at pH 0.72. This is consistent with other work (9) for acid solutions. Furthermore, since at this pH almost all e_{aq}^- appear to react via [8], k_3/k_4 should be equal to $(G(H_2) - G_{H_2}^M)/G(CH_4) = 6.4$. At pH's between 4 and 7 the data indicate values of $G_{reducing}$ and G_H slightly larger than those observed with most other scavengers. These results will be discussed in detail elsewhere. Similar calculations may be made for cysteine, for which k_3/k_4 has a value of about 1.5.

Application of the steady-state approximation leads to the expression:

$$[ii] \qquad \frac{1}{\Delta G(H_2)} = \frac{(k_3 + k_4)}{k_4 G_e}\left(1 + \frac{k_7[RSH]}{k_8[H^+]}\right),$$

in which $\Delta G(H_2)$ is the increase in hydrogen yield over that observed at higher pH's. Plots of $1/\Delta G(H_2)$ vs. $[RSH]/H^+]$ in accordance with [ii] gave $k_7/k_8 = 0.5 \pm 0.2$ and 0.8 ± 0.3 for cysteine and methyl mercaptan respectively. Since k_8 is known (10) it is possible to obtain $k_7 = 1.1 \pm 0.4 \times 10^{10}$ l mole^{-1}s^{-1} for cysteine. This large rate-constant means that careful consideration must be given to the possible importance of reaction [7] in radiation biological mechanisms. Also of significance is the fact that cysteine and other thiols will be able to compete with oxygen* at comparable concentrations for e_{aq}^-.

It must be remembered that, as well as influencing the rate of reaction [8], changes in pH and ionic strength will also alter the degree of ionization of the three acid groups of cysteine (5) and its conformation in solution. In this connection it is noteworthy that the

*$k_c + O_2 = 1.88 \times 10^{10}$ *l mole*$^{-1}$*s*$^{-1}$ *(10),* cf. *the appreciable formation of* H_2S *in the oxygenated solutions of Markakis and Tappel (Table I).*

decline in the radiolytic yield of H_2S observed by Dale and Davies (6) in the pH range 7–11 may be attributed to ionization of the thiol group* and the consequent replacement of reaction [7] by some other process which does not produce H_2S. Since the pK for the NH_3^+ group is slightly higher (pK of $NH_3^+ = 10.5$ (5)) than that for the SH group, reaction [10] is one such alternative process (ref. 11):

[10] $$e_{aq}^- + CH_2(S^-)—CH(NH_3^+)—C(=O)O^- \rightarrow CH_2(S^-)—\dot{C}H—C(=O)O^- + NH_3$$

in the pH range 10–11. It is clear, however, from the earlier work (3, 6) that ammonia is not an important product in the pH range 0–7.

STABILITY CONSTANT OF THE BORON–DIAMINOCHRYSAZIN COMPLEX

R. S. Brown

One of the methods for the determination of boron in microgram amounts uses hydroxyanthraquinones (1) or substituted hydroxyanthraquinones (2, 3) as reagent and concentrated sulphuric acid as solvent. In some cases a formula for the complex has been suggested. For the formula the ratio of boron to reagent has been obtained from the continuous-variation method (4, 5) or the mole ratio method (6). A survey of the literature has shown that only in the case of 1,1′-dianthrimide has the stability constant of the boron

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

complex been calculated (7). In the present investigation the reagent used was diaminochrysazin, and the stability constant of the boron complex has been determined spectrophotometrically.

METHODS

By analogy with metal–ligand complexes, it is assumed that boron is the central group and hydroxyanthraquinone is the ligand. The hydroxyanthraquinones are all highly colored in concentrated sulphuric acid, and in many cases the maximum absorbance of the boron complex is at a wavelength where the reagent has an appreciable absorbance. With a colored ligand the application of any method for calculation of a stability constant is limited to the small range of wavelengths where there is a sizeable difference between the absorbance of the complex and that of the ligand.

1. Continuous Variation

The method of continuous variation was originally proposed by Job (4) and extended by Vosburgh and Cooper (5). For the determination of compound formation, the continuous-variation method is least ambiguous when only one compound is formed. Application of the method at several wavelengths spread over the visible spectrum, all of which give a peak in the y function at the same mole fraction, can be taken as an indication that only one compound is formed. The use of several different total concentrations of boron plus reagent to give the same peak in y may be taken as additional evidence. To calculate the stability constant from the continuous-variation data it is necessary to know the molar absorbance of the complex. Since boron has no absorbance in the visible region, a large excess of boron may be added to the reagent. Under these conditions all the reagent should be in the form of the complex. The Beer–Lambert law may be checked and the molar absorbance of the complex obtained.

When the only complex formed is 1:1, the equation for the equilibrium is

$$B + Q \rightleftarrows BQ$$

and the equilibrium constant expression for the reaction is

$$K = \frac{C_C}{(C_B - C_C)(C_Q - C_C)},$$

where C_C is the concentration of the complex at equilibrium, C_B is the initial concentration of the boron, and C_Q is the initial concentration of the hydroxyanthraquinone.

Since only the complex and the reagent absorb in the visible range, then in the equilibrium system

$$A = (C_Q - C_C)\epsilon_Q + C_C\epsilon_C,$$

where A is the measured absorbance and the ϵ's are molar absorbancies. Thus, on rearranging,

$$C_C = \frac{A - C_Q\epsilon_Q}{\epsilon_C - \epsilon_Q},$$

where $A - C_Q\epsilon_Q$ is the y function of the method of continuous variation. From the y value, the stability constant, K, may be calculated at a series of concentrations used in the continuous-variation determination. For a 1:1 complex the value of K should be reproducible at any concentration and at any wavelength, provided it does not depend on a small difference between large numbers.

For personal use only.

2. Corresponding Solutions

The method of corresponding solutions, originally formulated by Bjerrum (8), has been extensively used for the determination of stepwise formation constants. Woldbye (9) stated that the method is preferable to the continuous-variation method even when only one compound is formed. In the present work the method of corresponding solutions as outlined by Rossotti and Rossotti (10) has been used. The data obtained are a (free ligand concentration at equilibrium) and $\bar{n}$ (average number of ligands bound to a central group). When the only complex formed is 1:1, the stability constant can be obtained from the expression

$$K = \frac{\bar{n}}{(1 - \bar{n})a}.$$

The value of K obtained should be the same at any wavelength. However, since the calculations to obtain a and $\bar{n}$ depend on $A - C_Q\epsilon_Q$, the limitations are similar to those for the continuous-variation method with a ligand that absorbs in the same range as the complex.

3. Method of Rose and Drago

Rose and Drago (11) calculated the formation constant and the molar absorbance of molecular addition compounds of iodine. The molecular addition compound of iodine with benzene in carbon tetrachloride as solvent is a 1:1 complex. Their method assumes that ϵ_C is not known; by assigning a series of values to ϵ_C and by the use of the equation

$$K^{-1} = \frac{A - C_Q\epsilon_Q}{\epsilon_C - \epsilon_Q} - C_Q - C_B + \frac{C_Q C_B(\epsilon_C - \epsilon_Q)}{A - C_Q\epsilon_Q},$$

the corresponding values of K^{-1} are obtained. When K^{-1} values are plotted against ϵ_C, a straight line is obtained. Using a series of concentrations, all lines should intersect at the values of K^{-1} and ϵ_C. By this method it is possible to confirm the value of ϵ_C obtained by using a large excess of boron and also to check the value of K.

EXPERIMENTAL

The sulphuric acid used was commercial reagent grade and all solutions were made up in this solvent. The particular lot of acid used was analyzed 95.7% sulphuric acid by alkimetric titration.

Three samples of diaminochrysazin (trade name "boran") were purchased at different dates from the Lamotte Chemical Products Co. None of these samples had a lot number. The spectrum of each corresponded to that reported by Cogbill and Yoe (2) but the first sample obtained had a molar absorbance which was 20% below the other two. The second and third samples had identical melting points and were used without further purification. Before use, the samples were dried *in vacuo* at 60 °C overnight. A stock solution (2.22×10^{-3} M) was prepared by dissolving 600 mg in 1 l of concentrated sulphuric acid. The stock solution was stored in the dark. Solutions stored on open shelves showed some darkening after a few weeks, with a general increase in the absorbance above 450 mμ. Solutions ranging in concentration from (0.5 to 11.1) $\times 10^{-4}$ M were obtained by dilution of the stock solution.

Boric acid of reagent grade was dried *in vacuo* at 60 °C overnight. A stock solution (1 mg boron/ml) was prepared, and solutions in the range (1.0–40.0) $\times 10^{-4}$ M were prepared by dilution.

Absorption measurements were made in 1 cm matched Corex cells with a Beckman model DU spectrophotometer. For the higher concentrations, silica blocks 0.9 cm thickness were inserted in the 1 cm cells to give a light path of 0.1 cm of solution. The cell compartment was flanked by thermospacers through which water, maintained thermostatically at 25 °C, was circulated. When spectra over a wide range of wavelengths were desired, these were measured by a Bausch and Lomb model 505 spectrophotometer. Absorbances measured on the two instruments agreed with each other within 1%.

All glassware employed for volumetric purposes was of the "soft-glass" type (Kimble brand). For storage and ordinary handling of acid solutions, Corning alkali-resistant ("boron-free") glass No. 7280 was used.

RESULTS AND DISCUSSION

Results of the continuous-variation method at concentrations 1.11×10^{-4}, 2.22×10^{-4}, 5.55×10^{-4}, and 22.2×10^{-4} M and at wavelengths 372, 400, 440, 496, and 526 mμ all gave a maximum in the y function at a mole fraction of 0.5. The curves for the y function vs. mole fraction were similar to those given by Cogbill and Yoe (2). The continuous-variation method indicated that only the 1:1 complex is formed.

In an attempt to find the molar absorbance of the complex by adding an excess of boron, it was found that up to a 10-fold excess of boron gave consistent ϵ_C values which obey the Beer–Lambert law. When there was a 100-fold excess of boron, however, the ϵ_C value of the peaks at 496 and 526 mμ had decreased. The solution had changed color and a new peak had developed at 605 mμ. The molar absorbancies are listed in Table I. When a

TABLE I

Molar absorbancies $\times 10^{-3}$

372	2.61	1.65	2.20	
400	4.32	2.14	1.84	
440	6.73	4.12	3.00	3.95
496	1.03	11.75	8.20	11.28
526	0.025	11.28	9.02	
605	0.012	0.46	8.76	

TABLE II

Stability constant of the boron–diaminochrysazin complex at 25 °C

Wavelength, mμ	Method 1 No. of points	Method 1 $K \times 10^{-3}$	Method 2 No. of points	Method 2 $K \times 10^{-3}$	Method 3 No. of points	Method 3 $K \times 10^{-3}$
400			9	3.52±0.28		
440	24	4.11±1.28	7	3.25±0.24		
496	24	3.50±0.36	13	3.47±0.15	43	3.70±0.22
526	24	3.51±0.37	15	3.63±0.15		

solution containing a 100-fold excess of boron was reduced to a 10-fold excess by addition of reagent and dilution, the peak at 605 mμ disappeared and the ϵ_C values at 496 and 526 mμ returned to the higher figures. Sillen *et al.* (12) have studied borates in water solution and have reported that above a concentration of 0.025 M there is polymerization of the borate. In the present work the new peak at 605 mμ was obtained with a reagent concentration of 1.0×10^{-3} M and a boron concentration ranging from 0.084 to 0.84 M. If there is comparable polymerization of borate in sulphuric acid solvent, this phenomenon would explain the decrease in molar absorbance at 496 and 526 mμ and would suggest that the peak at 605 mμ is due to some complex between the polymer and the reagent. Table II lists average values of the stability constant calculated by method 1 from ϵ_C values for a 10-fold boron excess.

The data a and $\bar{n}$ obtained by the corresponding solutions method are plotted in Fig. 1. The curve obtained for the four wavelengths is the same within the experimental error for each set. The stability constant has been calculated for each point and the average values are given in Table II.

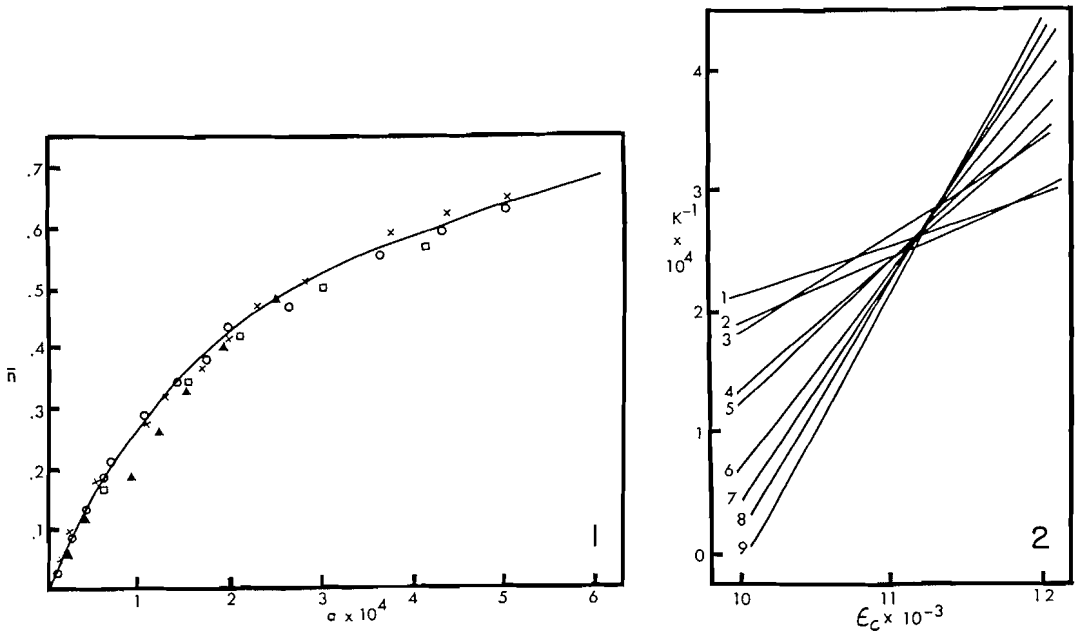

FIG. 1. Plot of n vs. a for the boron–diaminochrysazin complex: □ 400 mμ, ▲ 440 mμ, ○ 496 mμ, × 526 mμ.

FIG. 2. Plot of K^{-1} vs. ϵ_C for method 3.

Line	Molar concentration × 10^4 Diaminochrysazin	Boron
1	1.25	1.25
2	2.75	2.5
3	4.4	5.5
4	5.5	11.0
5	2.75	11.0
6	8.5	20.0
7	4.4	20.0
8	2.75	20.0
9	0.50	20.0

To check the above methods by that of Rose and Drago (11), 10 of the measured absorbancies at 496 mμ have been used to plot the K^{-1} vs. ϵ_C lines. The data chosen range from a solution 1.25B/1.25Q to 20B/8.5Q. A plot of these lines is given in Fig. 2. The 10 lines give 43 points of crossing, and the values of ϵ_C and K^{-1} were determined for each point. The value of K obtained by this method is given in Table II and that of ϵ_C in Table I.

If a 1:1 complex is assumed, each of the methods gives a comparable value for the stability constant. A possible structure for the complex is that outlined by Cogbill and Yoe (2).

VOLUME 42 DECEMBER 1964 NUMBER 12

A STUDY OF PROTON EXCHANGE REACTIONS OF SUBSTITUTED ANILINES IN TRIFLUOROACETIC ACID

W. F. REYNOLDS* AND T. SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received May 29, 1964

ABSTRACT

The acid proton exchange rates of solutions of some halo-substituted anilines in trifluoroacetic acid have been determined by measuring the acid proton signal width. In addition, the proton exchange rate of protonated N,N-dimethylaniline in trifluoroacetic acid is discussed. It is suggested that proton exchange occurs via the following reaction:

$$\phi NH_3^+ + A^- \rightleftharpoons (\phi NH_3^+ \ldots A^-) \rightleftharpoons \phi NH_2 + HA.$$

The reaction is believed to occur in two steps: the oppositely charged ions form ion pairs which then transfer protons internally. Experimental evidence indicates that the ion-pair dissociation constant is less than, or equal to, one.

The activation energies range from 10 to 24 kcal/mole. The rate constants at 25 °C for a possible bi-ionic reaction are calculated. Ionic activity coefficients are estimated by the Debye–Hückel equation. Another set of rate constants is calculated, assuming that the ions exist partly or completely as ion pairs.

The free energies, enthalpies, and entropies of activation are calculated for an ion-pair reaction and for an overall bi-ionic reaction. The free energies of activation range from 10 to 17 kcal/mole and for haloanilines are less than that of aniline. In the ortho- and para-substituted anilines, $\Delta F^{\ddagger}$, in general, decreases with decreasing halogen electronegativity. $\Delta F^{\ddagger}$ values for metasubstituted anilines decrease with increasing substituent electronegativity. $\Delta F^{\ddagger}$ values are largest for parahaloanilines and smallest for orthohaloanilines. The $\Delta F^{\ddagger}$ values for haloanilines can be rationalized by reasonable combinations of inductive and mesomeric effects. The values of entropies of activation are determined largely by the positions of the substituents. $\Delta S^{\ddagger}$ values range from 35 to −10 entropy units (e.u.) with aniline and para-substituted anilines having the largest positive values and orthosubstituted anilines having negative values. The value of $\Delta F^{\ddagger}$ for protonated N,N-dimethylaniline is larger than that for protonated aniline, as would be expected. $\Delta S^{\ddagger}$ is quite small. This is attributed to steric hindrance of solvation of the dimethylanilinium ion.

INTRODUCTION

The effect of chemical exchange upon nuclear magnetic resonance (n.m.r.) spectra was established several years ago (1–5). Since then, proton magnetic resonance (p.m.r.) spectroscopy has been used by various workers to study exchange reactions in aqueous and alcoholic solutions (6–23).

During the investigation of protonated anilines in trifluoroacetic acid (TFA) it was noted that the observed H^+—N—CH_3 coupling constant of protonated N,N-dimethylaniline was temperature dependent (24). The apparent temperature dependence of this coupling constant was measured, and the exchange rate and thermodynamic properties of exchange were calculated. It was originally intended to investigate the exchange reactions of a number of ring-substituted N-alkylanilines. This investigation would have

**Holder of a N.R.C. Studentship, 1962–1963.*

provided information about the effects of substituents upon exchange rates and thermodynamic variables. However, because of experimental difficulties in the measurements of small coupling constants, it was decided to try an alternative method. The TFA proton signal width depended upon the exchange rate of the protonated aniline in solution. The acid proton peak was intense and its width could be measured with minimum experimental difficulty. Therefore, the acid proton signal widths of a series of dilute solutions of haloanilines in TFA were measured at different temperatures. The haloanilines were chosen for study because there seemed to be some confusion about the nature of halogen substituent effects (25, 26).

The acid proton exchange rates of such solutions were measured, rate constants calculated from them for the postulated exchange reaction, and thermodynamic data estimated. Possible errors in the measurement of exchange rates are discussed.

EXPERIMENTAL

1. Materials and Preparation of Solutions

Most of the anilines used in this study were obtained from Distillation Products Ind. and were Eastman White Label grade. The *p*-fluoroaniline was Eastman Practical grade. *m*-Chloroaniline was obtained from K and K Laboratories, Inc. *m*-Fluoroaniline was obtained from Matheson, Coleman and Bell. *m*-Iodoaniline was obtained from Aldrich Chemicals. Solid anilines were used without purification. Liquid anilines were distilled under reduced pressure and small constant temperature fractions were collected for use in exchange studies. TFA was an Eastman White Label grade chemical. The aliquots of acid used in preparing the solutions were first treated with one or two drops of trifluoroacetic anhydride per aliquot to remove any water in the acid. TFA was not further purified. Cyclohexane was a Fisher Spectro-Analyzed reagent and was used without purification.

The TFA solutions were prepared by weighing. The solutions contained 3 mole % of cyclohexane and from 1 to 3 mole % of substituted aniline. Cyclohexane was chosen as an internal reference because it did not react with TFA or aniline and because it gave an intense signal, even when present in low molar concentration. Whenever possible, the aniline concentration was adjusted so that exchange-broadening of the acid proton signal occurred at temperatures just above room temperature. Solutions were placed in thick-walled 5 mm outside diameter sample tubes. The solutions were degassed and then the sample tubes were evacuated and sealed.

Originally, aniline concentrations of from 4 to 8 mole % were used. However, the plots of log (acid proton line width) vs. (absolute temperature)$^{-1}$ were always curved in the low-temperature regions (0–30 °C). In two extreme cases, the slope of the line actually changed sign. It was found that if aniline concentrations of from 1 to 3 mole % were used, the plots for all but one of the aniline solutions (*p*-fluoroaniline) were essentially linear in the region of slow exchange.

2. Acid Proton Line Width Measurements

Spectra were measured on a Varian DP-60 spectrometer. Experiments at different temperatures were carried out with the aid of an N.R.C. manufactured temperature device. The spinning air was heated by a nichrome wire heater. Temperature control was attained by variation of the air flow rate and by variation of the power supplied to the heater. Temperatures from 10 °C to room temperature were obtained by passing the spinning air through a copper coil immersed in an ice–salt mixture before it passed through the temperature device. To obtain lower temperatures it was necessary to use precooled nitrogen gas to spin the sample. The nitrogen gas was cooled by a dry ice – acetone mixture. Because the precooled nitrogen had to be heated approximately 80 deg and also because it was difficult to keep the nitrogen flow rate constant, it was impossible to maintain constant temperature in the temperature region below 10 °C. Therefore, line widths could not be accurately measured in this region. The exchange reactions of *o*-iodoaniline in TFA could not be studied, because rapid proton exchange occurred below 10 °C. One measurement of the line width of a *m*-chloroaniline solution was made at 0 °C. Since the line width was nearly constant at that temperature, temperature control was not very important.

Temperatures were measured with a copper–constantan thermocouple attached to a Varian G-11 recording potentiometer. The potentiometer was regularly recalibrated to insure that there was no error in the recorder readings. The temperature was usually changed by about 2–3 deg between runs. Solutions were allowed to equilibrate for at least 2 h at each temperature before the spectra were obtained. Usually solutions were heated slightly above the desired temperature and then allowed to cool to that temperature. It is estimated that temperature readings were accurate to within 0.5 °C.

The ammonio proton signals were broad and weak. Line widths of these signals could not be measured. However, the acid proton signal widths were easily measured. Because there were large concentrations

For personal use only.

of acid protons in the solutions studied, low radiofrequency power could be used, even when the protons were exchanging rapidly. Therefore, signal saturation was not a problem. Signal widths between 1 and 15 c/s could be measured accurately. The possible error in measuring line widths of less than 1 c/s was quite large. If the signal was broader than 15 c/s, it was necessary to use high radiofrequency power and the signal sometimes appeared to be partially saturated.

The resolution was carefully controlled while acid proton signal widths were measured. Before each pair of measurements of the acid proton signal, the width of the cyclohexane signal was measured twice (forward and reverse) by placing sidebands of the signal 5 c/s on both sides of itself. The sideband frequency was measured with a Hewlett–Packard 521C electronic counter with an accuracy of 0.1 c/s. The sweep rate was approximately 10 c/s min. The width of the acid proton signal was then measured twice (forward and reverse). Sideband frequencies of 5–20 c/s were used for signals of different widths. The width of the cyclohexane signal was then remeasured. This procedure was repeated until 10 measurements of the acid proton line width were obtained. If the resolution changed appreciably while a pair of measurements of the acid proton line width were being made, those measurements were discarded. Occasionally, the acid proton line width at room temperature was remeasured at the finish of a series of measurements at higher temperatures to determine if chemical reaction or decomposition had altered the line width. In all cases, the two sets of measurements at room temperature agreed within experimental error.

Line widths were measured directly with a ruler calibrated in tenths of millimeters. In each spectrum the region to low field of the TFA proton signal was scanned because there were no peaks in that region and an accurate measurement of the base-line position could be obtained. The "half-height" of the peak was then determined and the width of the signal was measured at that point. This was compared to the peak-to-peak separation of the sidebands in order to calculate the line width in c/s.

3. Other Experiments

A number of specific experiments were carried out to determine points of interest. The line width of the acid proton signal of a solution containing only 2 mole % cyclohexane in TFA was measured at two temperatures. The width of the acid proton signal of a similar solution which contained 0.9 mole % of water was also measured.

The line width of the acid proton was also measured as a function of aniline concentration. Five solutions with aniline concentrations from 1 to 5 mole % were used. The samples were not degassed because it was felt that some of the TFA might evaporate. The cyclohexane line width was not larger than in other solutions. These experiments were carried out at 50 °C because viscosity effects seemed unimportant at this temperature and also because the 1 mole % solution did not exchange appreciably below this temperature. The chemical shifts of the acid and phenyl protons of the aniline solutions were measured relative to cyclohexane at different temperatures.

Trifluoroacetic anhydride was added to a series of solutions of aniline in TFA. The effect of changing anhydride concentration upon acid proton line widths at room temperature was investigated.

The ultraviolet spectrum of a 1 mole % solution of aniline in TFA was obtained to determine the amount of free aniline in solution. For purposes of comparison, a 20 mole % solution of aniline in TFA was prepared and diluted approximately 1:100 and 1:1000 in acetonitrile. A Beckmann DK spectrophotometer was used to obtain these spectra.

4. Calculation of Acid Proton Line Widths

For slow exchange between uncoupled protons in nonequivalent sites it can be shown (4) that the line width $\Delta\nu$ in c/s for a given proton site is $\pi\Delta\nu = 1/\tau + 1/T_2$. The line width is characterized by $1/T_2$ in the absence of exchange, and τ is the average lifetime in the site. For our solutions it was assumed that the line width of the cyclohexane peak, determined by field inhomogeneity, was equal to $1/\pi T_2$. The corrected line widths of the acid protons and their exchange rates (s^{-1}) were thus obtained.

RESULTS AND DISCUSSION

1. Line Widths in the Absence of Anilines; Effect of Water

The line widths of TFA and cyclohexane protons of two solutions of cyclohexane in TFA are given below. All results are the average of 10–12 measurements. The error limits are root mean square deviations. Since line widths are constant, T_2 must be the same for the protons of cyclohexane and TFA in the absence of aniline. T_2 for both types of protons appears to be independent of temperature in this range and is no doubt determined by the inhomogeneity of the magnetic field. Water apparently has little effect upon the acid proton line width. Luz and Meiboom have recently found that proton exchange between the carboxyl group of acetic acid and water is too rapid for direct measurement by our methods (30).

2. Line Widths of the Aniline Solutions

The corrected widths of the acid proton signals and acid proton exchange rates of various aniline solutions are given in Table I. The quoted error limits are the root mean square deviations. A least-squares plot of log (line width) vs. $1/T$ is given for a 4 mole % solution of aniline in Fig. 3. Figure 4 illustrates the unwanted behavior obtained for a *p*-fluoroaniline solution and will be discussed later. Figure 5 shows a typical plot of log (line width) vs. $1/T$ over the region from slow exchange to fast exchange.

The corrected acid proton line widths of a series of aniline solutions of different concentrations are given in Table II. It was not possible to obtain the same temperature for each solution. The exchange rates have all been corrected to the expected rate at 50.2 °C from the measured activation energy for proton exchange of aniline in TFA (see below).

The chemical shifts of the acid protons and phenyl protons of the various solutions are given in Table III. The acid protons shift to high field with increasing temperature. The shifts seem to be nearly independent of aniline concentration. The phenyl proton shift is independent of aniline concentration and temperature in these solutions.

The corrected line widths of solutions of aniline in TFA and trifluoroacetic anhydride are given in Table IV. The decrease in acid proton line width appears to be closely related to the ratio of aniline to trifluoroacetic anhydride.

TABLE IV

Acid proton line width of solutions of aniline and trifluoroacetic anhydride in TFA at 25 °C

Concentration (mole %)				Acid proton line width (c/s)	Change in line width when anhydride added	
ϕNH_2	C_6H_{12}	TFA anhydride	TFA		Anhydride / ϕNH_2	Original line width

7.0	2.2	2.1	88.7	4.29±0.14	0.3	0.3

3. The Ultraviolet Spectra

The ultraviolet spectra are given in Fig. 1 (aniline in TFA) and Fig. 2 (aniline and TFA in acetonitrile). There should be a secondary peak due to aniline at ≈ 280 mμ and one due to anilinium ions at ≈ 254 mμ. These values are for the two substances in water and may be slightly different in other solvents. The extinction coefficients are respectively 1 430 and 160. Consequently, the aniline peak should be relatively more intense. It can be seen in Fig. 1 that there is a large peak in the region of 270 mμ which partly overlaps with the solvent peak, starting at 252 mμ. The peak has a "tail" in the region 320–270 mμ which may or may not be due to aniline. In Fig. 2 there is a large peak at approximately 285 mμ which must be due to free aniline. The peak due to anilinium ions, if present, is obscured by the TFA peak. The aniline peak is quite broad and occurs in the same region as the "tail" of the anilinium ion in Fig. 1. Therefore, the tail probably represents a peak due to free aniline which partly overlaps with the anilinium ion peak. The ratio $[\phi NH_2]/[\phi NH_3^+]$ must be very small to give a spectrum of this type.

4. Activation Energies and Enthalpies of Activation

The experimental activation energies of acid proton exchange are given in Table V. The activation energies have been calculated from the least-squares plots of log (corrected acid proton line width) vs. $1/T$ by using the logarithmic form of the Arrhenius equation. The error limits are 95% confidence limits. There appears to be a general correlation with the position of ring substitution. The activation energy is greatest for parasubstituted anilines and least for orthosubstituted anilines. There is no specific correlation between types of substituents and activation energies, although the activation energies of the metasubstituted anilines do seem to be crudely related to substituent electronegativity. Enthalpies of activation at 25 °C are also given in Table V.

5. Calculation of Rate Constants for the Aniline Solutions at Various Concentrations at 50 °C

We consider that the acid proton exchange reactions are catalyzed by the anilinium ions. Of the many possible reactions which involve changes in the magnetic environments

N,N-Di-Me	18.8±1.1	18.2±1.1

of protons, we assume the following to be predominant in determining the acid proton line width

$$[1] \qquad \phi NH_3^+ + A^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \phi NH_2 + HA.$$

The large excess of TFA alters equilibrium concentrations in favor of the ions. This is also indicated by the ultraviolet spectra discussed above.

The total acid proton exchange rate is $1/\tau[HA]$ and therefore

$$1/\tau = k_1[\phi NH_3^+]\,[A^-]/[HA] = k_{-1}[\phi NH_2],$$

where concentrations are in moles/l and the k's are apparent rate constants. We can also write the rate of reaction [1] in terms of the activities of the ions and the "true" second-order rate constant k_0,

$$1/\tau[HA] = k_0[\phi NH_3^+]\,[A^-]F = k_0[\phi NH_2^+]^2F,$$

where F is the activity coefficient term. Using the Debye–Hückel theory to estimate the activity coefficients (27, 28), we arrive at

$$\log k_0 = \log k_1 + [2.5\sqrt{\mu}/(1 + 0.89\sqrt{\mu})]$$

at 50 °C. We have taken the dielectric constant of TFA to be 39.5 and the parameter* a as 2 Å; μ is the ionic strength.

We have applied these equations to the exchange rates of the aniline solutions of various concentrations at 50 °C (Table II). First we plotted $[\phi NH_3^+]^n/[HA]$ vs. the lifetime of the acid protons and obtained the best fit for $n = 1.2$ (Fig. 6), although reasonable fits can be had with $n = 1.0$–1.4. In the first part of Table II*b* can be found the apparent rate constants, using experimental values of exchange rates and also "smoothed" values from Fig. 6. In the second part of Table II*b* are the corresponding "true" second-order rate constants, k_0. They do not vary as much as the apparent rate constants. In view of our crude model the values must be looked upon as a first approximation.

**a is often considered to be the distance of closest approach of charge centers in the extended Debye–Hückel theory. Other, perhaps more reasonable, values might be as high as 6 Å but the approximations involved in our case do not make this value critical.*

6. Effect of Ion-Pair Formation

We assume that the variation of the "true" second-order rate constants in Table II may be partly due to the formation of ion pairs.* In that case the activities of the ions in solution will be reduced. If a value of the ion-pair dissociation constant is known or assumed, the free-ion concentrations and their activity coefficients can be calculated. This results in a new set of rate constants. Thus, in the final column of Table II, the rate constants for an ion-pair dissociation constant of 1 are found to be nearly equal for the 1 and 5 mole % aniline solutions. Because the Debye–Hückel correction terms are probably too large, the actual dissociation constant is probably less than 1.

This crude approach allows us to rationalize the plot in Fig. 6. The exchange rate can be expressed in terms of the concentration of the ion pairs in solution. If the molar ion-pair dissociation constant (uncorrected for ionic activities) is

$$K_D = [\phi NH_3^+]\,[A^-]/[\phi NH_3^+ \ldots A^-],$$

we can write

$$1/\tau[HA] = k_1[\phi NH_3^+]\,[A^-] = k_1K_D[\phi NH_3^+ \ldots A^-].$$

Consider 0.25 M and 0.50 M solutions of aniline in TFA. Compare the ratios of $[\phi NH_3^+ \ldots A^-]$ and of [total ϕNH_3^+] for the two solutions. If $K_D = 10^{-1}$, we have

$$[\phi NH_3^+ \ldots A^-]_{0.5}/[\phi NH_3^+ \ldots A^-]_{0.25} = \{[\text{total } \phi NH_3^+]_{0.5}/[\text{total } \phi NH_3^+]_{0.25}\}^{n=1.3};$$

while if $K_D = 10^{-2}$ the exponent $n = 1.1$. Therefore, the plot of acid proton exchange rate vs. anilinium ion concentration in Fig. 6 is reasonable if the reaction is bi-ionic and the apparent molar ion-pair dissociation constant lies between 10^{-1} and 10^{-2}. Our results are too crude to justify any definite conclusions but an ion-pair dissociation constant of from 10^0 to 10^{-2} does appear reasonable from other work (27).

It seems to us that in terms of our (oversimplified) approach, the formation of an ion pair occurs as an intermediate step in the reaction, since ions must come together before they can react. At present we have no evidence concerning more sophisticated reaction mechanisms in our solutions, such as transfer of protons from cation to anion via intervening solvent molecules.

7. Calculation of Rate Constants, Free Energies, and Entropies of Activation at 25 °C

According to the theory of activated complexes (29) we have

$$k_{rate} = \kappa kTh^{-1} \exp(-\Delta F^{\ddagger}/RT).$$

We take κ, the transmission coefficient, as equal to 1. The specific rate constant, k_{rate}, must be expressed in terms of the activities of the reactants. We consider (*a*) an activated "bi-ionic" complex and (*b*) an activated "ion-pair" complex. (*a*) The free energy of activation, $\Delta F^{\ddagger}$, of an ionic reaction is the free energy change which occurs when the two ions are brought together plus the free energy required to activate the ion pair; (*b*) $\Delta F^{\ddagger}$ for a reaction of ion pairs does not include the free energy change which occurs when the ion pair is formed.

On this basis the specific rate constants for the two cases are to be obtained. The apparent rate constants for the bi-ionic reaction can be corrected by use of the Debye–Hückel term, as discussed before. For the ion-pair reaction we assume that the ion pair is a neutral group unaffected by the ionic strength of the solution. This approximation

**At the concentrations we are working this would seem to be a reasonable assumption (27).*

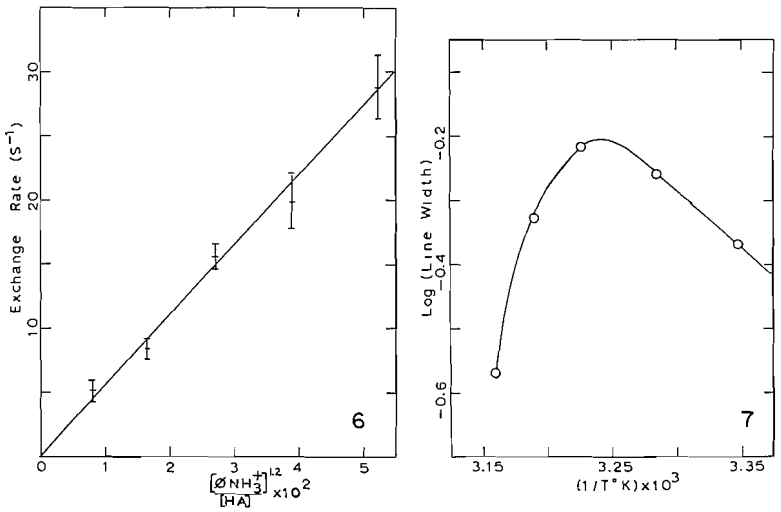

FIG. 6. Plot of TFA proton exchange rate vs. $([\phi NH_3^+]^{1.2}/[HA] \times 10^2)$. Concentrations are expressed in moles/l. It is assumed that the aniline is completely protonated.

FIG. 7. Plot of log (additional acid proton line width) vs. $1/T$ for a 1 mole % solution of *p*-fluoroaniline in TFA. The additional acid proton line width has been determined by extrapolating log (acid proton line width) in the high-temperature region to the low-temperature region (Fig. 4).

may not introduce drastic errors since the ion pair and the activated complex are both polar in character. From the last equation above it is clear that even if the activity coefficients differ by a factor of two the error will be only about 0.4 kcal/mole in the calculated free energies. The error should be similar for the different anilines.

Four different sets of rate constants have been calculated for the exchange reactions between substituted anilines and TFA at 25 °C. They are given in Table VI. The first set are the corrected second-order rate constants for the bi-ionic reaction, assuming that no ion pairs exist in solution. In column 3 the calculated rate constants for ion-pair reactions are given. These two sets of rate constants represent the limiting situations of our model. In addition, we have assumed $K_D = 1$. In this case the *apparent* rate constants of the bi-ionic reaction and the ion-pair reaction are the same because $[\phi NH_3^+][A^-]$

8. Discussion of $\Delta F^{\ddagger}$ and $\Delta S^{\ddagger}$ Values

The $\Delta F^{\ddagger}$ values are in general lowest for the orthosubstituted anilines and highest for parasubstituted anilines and always less than $\Delta F^{\ddagger}$ for aniline itself. The pattern is reasonable if the inductive effect of the halogens increases in the order I < Br < Cl < F and the mesomeric effect increases in the same order. In no case is an error larger than 0.3 kcal/mole necessary to fit the $\Delta F^{\ddagger}$ values into the postulated pattern. The results

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in column 3 fit the pattern best. The overall consistency of $\Delta F^{\ddagger}$ values and their correlation with the inductive and mesomeric properties of the halogens suggests that our approach has at least some merit.

The $\Delta S^{\ddagger}$ values are too inaccurate to allow any reliable interpretations of the relative effects of the halogens upon entropies of activation.* However, there does seem to be a definite trend to lower $\Delta S^{\ddagger}$ as the substituent moves closer to the reaction center. This may be a result of a decrease in solvation of the substituent and the reaction center due to steric and electrostatic effects.

9. N,N-Dimethylaniline

For ring-substituted anilines, the rate constants were calculated from the acid proton exchange rates. The proton exchange rates of protonated N,N-dimethylaniline were measured directly (24). Perhaps, then, additional reactions were involved which do not affect the acid proton lifetimes. For example, the reaction

$$\phi N(CH_3)_2 + H^+(CH_3)_2N\phi \rightarrow \phi N(CH_3)_2H^+ + (CH_3)_2N\phi$$

would cause collapse of the methyl proton doublet but would not affect the acid proton line width.

The thermodynamic data in Tables V–VIII were obtained in the way discussed for the other anilines. Collapse of the methyl doublet was assumed to occur only as a result of reactions in which ammonio protons were replaced by protons which had spins opposite to that of the original protons. The proton exchange rate was assumed to be twice as large as the calculated spin exchange rate.

The activation parameters are consistent with those found for other anilines. This encourages us to think that the same reaction is involved when one measures the lifetime of acid protons as when one measures the lifetime of ammonio protons. The activation energy for proton transfer in N,N-dimethylanilinium ion is much lower than that of protonated aniline. $\Delta F^{\ddagger}$ is much larger, however, as would be expected since the former is a stronger base. The lower $\Delta S^{\ddagger}$ results in the smaller value of E_A for N,N-dimethylaniline. We suggest that steric hindrance to solvation by the methyl groups is involved.

10. Errors in Calculated Rate Constants and Parameters of Activation

These errors are in addition to those resulting from experimental uncertainties. They include the approximations in the correction factors for ionic activities. It is perhaps doubtful whether we are justified in using these correction factors for solutions as concentrated as ours. Furthermore, our estimates of ion-pair dissociation constants are at best approximate. They are presumably different for different compounds and change with temperature.

In this connection one may well ask what activation energy is being measured in our models. There is an activation energy for the overall bi-ionic reaction as well as for proton transfer by ion pairs. If ΔH^0 of dissociation of the ion pairs is zero, the ratio of free ions and ion pairs is independent of temperature and the experimental value of E_A is equal to the values of the activation energy for the overall reaction *and* for the ion-pair reaction. If ΔH^0 is positive, the concentration of ion pairs decreases with increase of temperature and thus the measured activation energy is smaller than the true activation energy for proton transfer by ion pairs. If ΔH^0 is negative, the measured activation energy

**The largest errors occur for the orthosubstituted anilines. A referee has suggested that this is because we used line width values very near the region of maximum line width. But the same objection could be used against some of the other anilines. We did have fewer points for the orthoanilines and, therefore, the 95% confidence units on the activation energies and, hence, enthalpies and entropies are relatively large.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

is larger than the activation energy of the overall bi-ionic reaction because the concentration of free ions decreases as the temperature increases. If anilines in solution exist almost entirely as ion pairs, then E_A is about equal to the activation energy for the reaction of ion pairs. If the anilines exist almost entirely as ions, then E_A is almost equal to the activation energy for the complete bi-ionic reaction. The difference in activation energies is equal to ΔH^0, which is usually less than 3 kcal/mole in magnitude (27). If this magnitude is less than 2 kcal/mole, our E_A will usually agree, within experimental error, with both values of the activation energies.

11. Effect of Impurities on the Experimental Line Widths

There probably were some impurities present in the compounds used to prepare the solutions. Only for the solution containing *p*-fluoroaniline was there any evidence that exchange was occurring between TFA and impurities. The plot of log (acid proton line width) vs. $1/T$ (Fig. 4) is nearly linear in the high-temperature region. If the straight line is extrapolated to lower temperatures (dotted line), then deviations from expected behavior can be plotted against $1/T$ (Fig. 7). The additional exchange rate increases, then decreases with increasing temperature. This is exactly the behavior expected for exchange between acid and an impurity. Distillation apparently concentrated the impurity since there were larger deviations from expected behavior in the solution containing redistilled *p*-fluoroaniline. Whatever the impurity was, it must have been present in appreciable quantities ($\simeq$ 10% of the total aniline concentration) since it broadened the acid proton peak by as much as 0.6 c/s. Since the exchange took place near room temperature, the impurity was quite probably some other substituted aniline.

The absence of proton exchange between TFA and impurities in other solutions is understandable, even though some impurities may have been present. Impurities will appreciably affect acid proton line widths only if they fulfill the following three conditions: (1) they must contain exchangeable protons or be able to accept protons, (2) they must be present in significant amounts, (3) they must exchange with acid at an intermediate rate at the same temperature at which the protonated aniline exchanges with TFA or else they must catalyze the anilinium ion exchange reaction. These three points can be dealt with in order. Firstly, any impurity which does not exchange protons with TFA will have no effect upon the acid proton line width since it will not alter the proton lifetime. Secondly, the maximum width of the acid proton signal depends upon the concentration of the substance with which it exchanges. For example, 3 mole % solutions of substituted anilines broadened the acid proton signal by as much as 15 c/s while the maximum line width of acid proton signals in 1 mole % solutions was about 6 c/s. If there is only a very low concentration of impurity in solution, then its relative exchange rate will be so much greater than that of the acid that the two signals will coalesce before the acid proton signal is appreciably broadened. Thirdly, there will normally be little broadening of the acid proton signal if the exchange rate of the reaction between the impurity and TFA is either very slow or very fast in the region of interest. However, this is not necessarily true if the impurity catalyzes the exchange reaction between anilinium ions and trifluoroacetate ions. For example, consider the effect of water in solution. It has been shown that water has little effect upon the acid proton line width. This probably indicates that water is rapidly exchanging protons with TFA (30). It is conceivable that unprotonated water molecules could accept protons from anilinium ions and donate them to trifluoroacetate ions. Such a transfer would introduce a proton with a different Larmor precession frequency into the system of acid and water molecules

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and cause a broadening of the coalesced acid–water peak. There are three reasons why it is considered unlikely that catalysis reactions of this type occurred in the solutions studied. Firstly, it has been shown that the exchange reaction between ammonium ions and water has an activation energy of 12.2 kcal/mole (13). Since aniline is a weaker base, the corresponding exchange reaction between anilinium ions and water should have a lower activation energy. The experimental activation energy of proton transfer of the solution of aniline in TFA is 23.8 kcal/mole. Secondly, any water in the TFA was presumably almost completely protonated. Consequently, the concentration of free water molecules which could exchange with anilinium ions must have been small. Thirdly, if the measured exchange reactions had been catalyzed by water or other impurities, then there should have been no correlation between exchange rate and structure because the exchange rate would have depended upon the catalyst concentration.

Swarts showed that the reaction between aniline and TFA to form trifluoroacetanilide occurred after the reactants had been heated for 8 h at 120 °C (31). Therefore, it is unlikely that any appreciable reaction between aniline and TFA occurred at the temperatures used in this study. However, the decrease in acid proton line width observed when trifluoroacetic anhydride was added to solutions of aniline in TFA was probably due to formation of trifluoroacetanilide. This would explain the observed relation between the concentration ratio of aniline and trifluoroacetic anhydride and the acid proton line width. Less than 0.01 g of trifluoroacetic anhydride was added to each sample of TFA used to prepare a solution for exchange studies. It was added to the acid several minutes before the acid was added to the aniline. It possibly reacted with any water in the acid before the acid was added to the aniline. Because of the time interval and because only a very small amount of anhydride was added, it is considered unlikely that any appreciable reaction occurred between the anhydride and aniline.

12. Acid Proton Line Widths in the Collapsed Region

The line widths of the acid proton signals of 1 mole % solutions of anilines in TFA (Fig. 5) reach maximum values and then decrease with increasing temperature. The decreases must occur when the exchange rates are fast enough to coalesce the acid and ammonio proton signals. The acid proton exchange rate which causes this collapse depends upon the relative populations of acid and ammonio protons and upon the chemical shift between the two types of protons in the absence of exchange.

The slope and, therefore, E_A is higher in the collapsed region. The difference amounts to about 8 kcal/mole in all cases. Since the ammonio protons are present in much smaller concentrations than the acid protons, it is unlikely that incomplete collapse of the ammonio triplet or reactions which affect only the ammonio proton lifetimes are the reason. A probable explanation is suggested by the data in Table III. The acid proton resonance high-field shifts with temperature are large and nearly independent of aniline concentration. It is probable that the high-field shift results from a decrease in acid molecule hydrogen bonding. This would account for the increased slope of the line width plot in the collapsed region. The larger E_A is somehow related to the hydrogen bond breaking. There are possibilities here which merit further exploration.

LOW-TEMPERATURE PYROLYSIS

I. THE PYROLYSIS OF HYDROGEN PHTHALATE ESTERS OF SOME TERTIARY ALCOHOLS

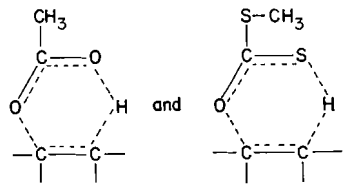
K. G. Rutherford and D. P. C. Fung
Department of Chemistry, University of Windsor, Windsor, Ontario
Received January 7, 1964

ABSTRACT

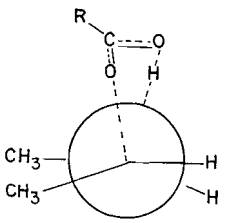
Some hydrogen phthalate esters of tertiary alcohols have been subjected to liquid phase pyrolysis. Olefinic mixtures and phthalic acid are the only products of the reaction. A study of the olefin distribution for each of the compounds pyrolyzed was made. Evidence of ionic character in liquid phase pyrolysis is presented.

INTRODUCTION

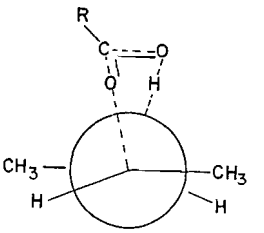
The vapor phase pyrolysis of esters of aliphatic and alicyclic alcohols has been the subject of intensive study by numerous investigators who were interested in olefin-producing reactions. In general, olefin-producing reactions fall into two classes: those which yield predominantly the most highly alkylated isomer (Saytzeff product) and those which yield predominantly the least alkylated isomer (Hofmann product). The vapor phase pyrolysis of esters (acetates and xanthates, etc.) of primary alcohols has been found by several workers to yield exclusively the Hofmann product while that of esters of secondary and tertiary alcohols yields a mixture of Hofmann and Saytzeff products (1). The mechanism of pyrolysis of acetate and xanthate esters has been well established in both cases and is known to involve a cyclic transition state of the nature



respectively. The appearance of both Hofmann and Saytzeff products in the vapor phase pyrolysis of acetates and xanthates of secondary and tertiary alcohols has been explained on the basis of statistical, steric, and thermodynamic effects. The high-temperature pyrolysis of *sec*-butyl acetate exemplifies the operation of statistical effects. The formation of 1-butene is favored statistically over 2-butenes by a factor of 3:2. The experimental values are in excellent agreement (57% 1-butene and 43% 2-butenes). Similar agreement between statistical and experimental results is obtained in the vapor phase pyrolysis of *tert*-amyl acetate. Steric effect appears to govern the proportion of the *cis*- and *trans*-2-butenes in the pyrolysis of *sec*-butyl acetate. Statistically they should be formed in equal amounts. However, the *trans* olefin predominates over the *cis* isomer by a factor of 2. De Puy and co-workers (2) suggest that the methyl–methyl repulsion in the transition state leading to the *cis* olefin is absent in the transition state leading to the *trans* olefin.



cis Olefin transition state



trans Olefin transition state

Hence, as a general rule, steric effects will favor the formation of primary and *trans* olefins and will hinder the formation of internal and *cis* olefins.

Thermodynamic considerations should favor the more stable isomer in pyrolytic elimination reactions. Voge and May (3) reported that at equilibrium at 500°, the butenes exist in the ratio 28% 1-butene, 41% *trans*-2-butene, and 31% *cis*-2-butene. However, the contact time in vapor phase pyrolysis is usually so small that thermodynamic effects should not be noticeable. Again, thermodynamic effects should be almost nonexistent in low-temperature pyrolysis in which the contact time is of the order of only a few seconds.

The pyrolysis of xanthates (Chugaev Reaction) can be carried out at much lower temperatures than required for corresponding acetates. While both pyrolytic reactions have been carried out with the same system, the product ratios have been found to compare favorably despite the great differences in temperature and conditions. For example, the acetate of 1-methylcyclohexanol yields, on pyrolysis at temperatures greater than 450°, 74% 1-methylcyclohexene and 26% methylenecyclohexane (2, 4). The xanthate yields, on pyrolysis at 200°, 79% of the former and 21% of the latter isomer (5). It is interesting to note, however, that liquid phase pyrolysis of the acetate of 1-methylcyclohexanol at 220° yields 83% 1-methylcyclohexene and 17% methylenecyclohexane. Bailey (4) concluded that liquid phase pyrolysis would be more apt to follow the Saytzeff rule than would vapor phase pyrolysis. Barton (6) had previously suggested, mostly on the basis of liquid phase pyrolyses, that the Saytzeff rule was followed quite generally. This involves two possibilities: the stability of the olefin may be a controlling factor or the mechanism of the elimination is shifting from a cyclic intermediate to one involving an ionic intermediate. Indeed Bailey has suggested both possibilities.

In the past six years some interesting cases of pyrolytic elimination reactions have appeared in the literature. Thus, Bordwell and Landis (7) have reported that *cis*-2-*p*-tolylsulfonylcyclohexyl-*s*-methyl xanthate (I) decomposes on heating to yield almost exclusively 1-*p*-tolylsulfonyl-1-cyclohexene (II) rather than the expected 3-cyclohexene isomer. This is interpreted mechanistically as a stepwise intramolecular "*trans*" elimination promoted by the high acidity of the beta hydrogen atom which undergoes elimination (Fig.1).

The same authors (8) also reported that pyrolytic decomposition of *cis*-2-*p*-tolylsulfonylcyclohexyl methyl sulfite yielded 1-*p*-tolylsulfonyl-1-cyclohexene, instead of the expected 3-cyclohexene derivative. Again the acidity of the beta hydrogen atom lost on pyrolysis presumably leads to a dipolar ion analogous to Fig. 1, thus accounting for the "*trans*" elimination product.

Kingsbury and Cram (9) reported that although the diastereomeric 1,2-diphenyl-1-propyl phenyl sulfoxides decomposed in a stereospecific manner at 80°, stereospecificity

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

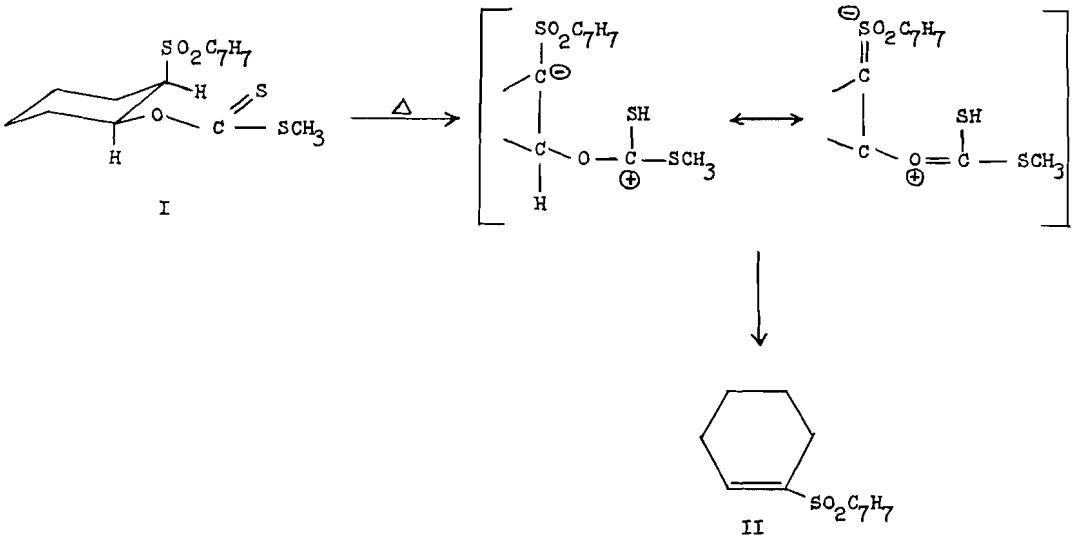

FIG. 1. Pyrolysis of *cis*-2-*p*-tolylsulfonylcyclohexyl-*s*-methyl xanthate.

was lost on decomposition at 120°. These authors proposed the formation of a radical pair to account for the loss of stereospecificity (Fig. 2).

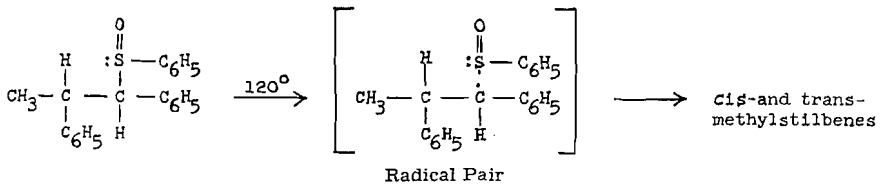

FIG. 2. Pyrolysis of diastereomeric 1,2-diphenyl-1-propyl phenyl sulfoxides at 120°.

Botteron and Shulman (10) found that the 2-methylcyclohexyl-*s*-methyl xanthates of *cis*- and *trans*-2-methylcyclohexanol did not decompose in a stereospecific manner. These authors suggest that the Chugaev reaction is not as stereospecific as once thought.

More recently Sixma and co-workers (11) have investigated the thermal decomposition of 27 aliphatic acetates. It was found that the rate of elimination was enhanced markedly as the degree of alkylation on the alpha carbon atom was increased. A tentative mechanism was proposed which was based on the reversible formation of an ion pair.

Our interest in low-temperature pyrolysis stemmed from a paper of Zeiss (12) who reported that the hydrogen phthalate derivative of 2-phenyl-2-butanol decomposed at its melting point (111°). Although no study was made of the decomposition products, it seemed reasonable to assume that an ordinary ester pyrolysis had occurred and at a very low temperature. The procedure for the preparation of the hydrogen phthalate derivative involved the conversion of the tertiary alcohol to its potassium salt in boiling benzene followed by the addition of phthalic anhydride. A more convenient procedure was developed in this laboratory for the preparation of hydrogen phthalate derivatives of tertiary alcohols and was reported in a previous paper (13). This procedure involves conversion of a tertiary alcohol to its sodium salt by means of the strong base triphenylmethyl sodium in ether solution, with subsequent addition of phthalic anhydride. Several

For personal use only.

hydrogen phthalate esters of tertiary alcohols were characterized and reported. It is interesting to note that all the hydrogen phthalate esters prepared from the tertiary aliphatic and alicyclic alcohols are well-defined, sharp-melting solids and have decomposition points between 130–155°. The only products of decomposition are olefins and phthalic acid. It was logical, then, to study in detail the products of pyrolysis of a number of these esters since the low decomposition points suggest that a different mechanism may be operative in the decomposition of such internally strained systems.

The general procedure of pyrolysis consisted of heating an oil bath to the desired temperature and introducing into the bath a flask which contained the solid hydrogen phthalate ester. The flask was fitted with a Claisen head, thermometer, condenser, and receiving tube which was placed in a dry ice – acetone bath. Depending upon the boiling points of the olefins obtained, the system was subjected to reduced pressure. This eliminated excess contact of the olefinic mixtures with the phthalic acid generated and thus minimized possible isomerization. Later it was shown that the possibility of phthalic acid catalyzed isomerization of the olefinic mixtures was remote under the conditions employed.

RESULTS AND DISCUSSION

Table I summarizes the hydrogen phthalate esters under investigation in this work and indicates melting points, decomposition temperatures, and product distribution. Table II summarizes results of vapor phase pyrolysis of corresponding acetates. Wherever possible, low-temperature (liquid phase) pyrolysis results are given for comparison. It is to be noted that all the acetate esters are liquids.

In the low-temperature pyrolysis of both the acetate and hydrogen phthalate esters of tert-amyl alcohol, the Saytzeff product predominates. This is in sharp contrast to high-temperature (400°) acetate ester pyrolysis which yields 70% Hofmann isomer (2-methyl-1-butene). Low-temperature pyrolysis (155–160°) of the hydrogen phthalate and acetate esters of 1-methylcyclohexanol shows the same trend, with the hydrogen phthalate ester yielding 5% more Saytzeff product than the acetate ester. Pyrolysis of the hydrogen phthalate ester of 1-methylcyclopentanol at 150–160° yields an almost quantitative amount (97%) of the Saytzeff product in contrast to 84% obtained from high-temperature pyrolysis (450°) of the corresponding acetate. It is interesting to note that De Puy (2) claimed that no Hofmann product (methylenecyclopentane) could be obtained from the pyrolysis of the acetate of 1-methylcyclopentanol at 450°. However, the separation of methylenecyclopentane and 1-methylcyclopentene is extremely difficult. Bailey (14) separated the isomers effectively using a column containing silver nitrate in diethylene glycol absorbed on Johns–Manville Chromasorb (10–30 mesh, acid washed) in a "special" vapor phase chromatographic column. We were unsuccessful with this column packing in a 6 ft copper column (1/4 in. diameter) but managed to separate the isomers using a Golay "R" column (175 ft). The presence of the exo isomer could be detected by means of a small band at 11.2 μ in the infrared. This band disappeared when the olefinic mixture was boiled with *p*-toluenesulfonic acid for 3 h.

Of particular interest in this investigation are the products obtained from the pyrolysis of the hydrogen phthalate ester of *trans*-1,2-dimethylcyclohexanol, especially the appearance of 19% 1,2-dimethylcyclohexene. De Puy (2) had previously reported that this compound was not obtained on the pyrolysis of the corresponding acetate at 450° although a 28% yield was obtained from the *cis* isomer (Table II). The pyrolysis of the acetate of *trans*-1,2-dimethylcyclopentanol at 450° was reported to have yielded small amounts

Pyrolysis of acetate esters of tertiary alcohols

Acetate ester	Decomposition temperature	Product distribution	
		Saytzeff	Hofmann
tert-Amyl	225° (4) 400°	2-Methyl-2-butene (58%) [30%]	2-Methyl-1-butene (42%) [70%]
1-Methylcyclopentyl	450° (9)	1-Methylcyclopentene (84%)	Methylenecyclopentane (16%)
1-Methylcyclohexyl	220° (4) 450°	1-Methylcyclohexene (83%) [74%]	Methylenecyclohexane (26%)
1-Methylcycloheptyl	440° (9)	1-Methylcycloheptene (76%)	Methylenecycloheptane (24%)
trans-1,2-Dimethylcyclohexyl	450° (2)	2,3-Dimethylcyclohexene (45%) 1,2-Dimethylcyclohexene (0)	2-Methylmethylenecyclohexane (55%)
cis-1,2-Dimethylcyclohexyl	450° (2)	2,3-Dimethylcyclohexene (26%) 1,2-Dimethylcyclohexene (28%)	2-Methylmethylenecyclohexane (46%)

(5–10%) of 1,2-dimethylcyclopentene as well as the other expected isomers but it was established that the olefin products isomerized under the conditions of pyrolysis. We find, however, in the case of the olefin mixture obtained from the cyclohexyl phthalate analogue that the olefin distribution obtained on pyrolysis does not change when redistilled from phthalic acid even at 180°. Thus it is inconceivable that isomerization occurs under the conditions employed. We suggest that carbonium-ion character is evident in the transition state in the pyrolysis of this hydrogen phthalate ester and that this elimination is kinetically controlled. This may well be extrapolated to the low-temperature pyrolysis of esters of the other tertiary systems studied. The fact that more of the 1,2-dimethylcyclohexene was not obtained may well be attributed to the "*cis* effect" which would be exhibited in the transition state of elimination. It is suggested then that in olefin formation involving initial ionization of the hydrogen phthalate ester, the amount of Saytzeff product is controlled by steric effects in the transition state as well as by statistical considerations. The possible elimination transition states for the 1,2-dimethylcyclohexyl carbonium ion are illustrated in Fig. 3. The steric effect of the *cis* methyl groups in transition state "A" would hinder the initial formation of 1,2-dimethylcyclohexene, the most stable isomer from hyperconjugative considerations. Pertinent to this, it has been observed (15) that iodine dehydration (an equilibrium process) of *trans*-1,2-dimethylcyclohexanol yields 73% 1,2-dimethylcyclohexene, 24% 2,3-dimethylcyclohexene, and 3% methylene-2-methylcyclohexene.

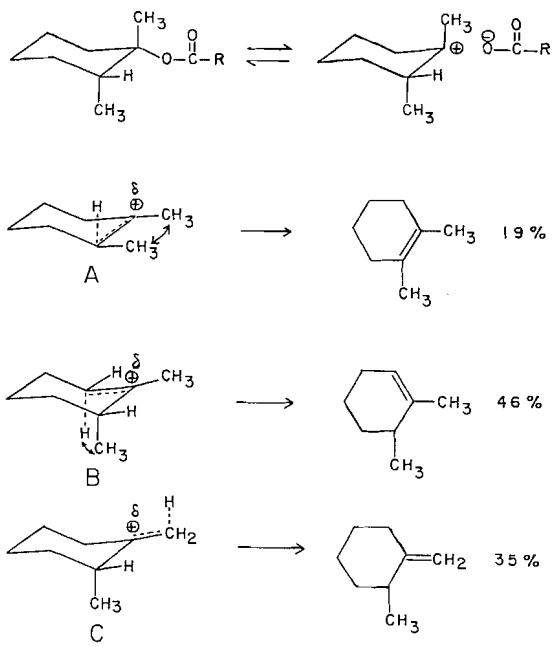

FIG. 3. Possible elimination transition states for 1,2-dimethylcyclohexyl carbonium ion.

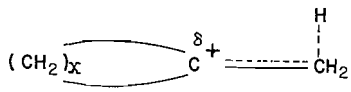
There is much less "*cis* effect" in transition states "B" and "C". The former, however, would be more favorable from hyperconjugative influences. The abnormal amount of methylene-2-methylcyclohexane (35%) is indeed surprising when compared with the amount of methylenecyclohexane (12%) obtained from the low-temperature pyrolysis

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of the hydrogen phthalate ester of 1-methylcyclohexanol. Again, this large amount of exo isomer would preclude the possibility of any isomerization reaction occurring during pyrolysis. It is possible that in transition state "B", 1,3-hydrogen – methyl interaction presents an adverse effect.

That the elimination reaction may in part occur by the usual cyclic mechanism cannot be completely excluded. Dreiding models show that the preferred orientation of the ring substituents is such that the methyl groups are axial and that if the ester carbonyl group occupies a position in the vicinity of the methyl hydrogen atoms on the same ring carbon atom then a maximum of free rotation of the benzene ring and the ortho carboxylic acid substituent is realized.

It is interesting to note that in the case of low-temperature pyrolysis of the hydrogen phthalate esters of methylcyclopentanol, methylcyclohexanol, and methylcycloheptanol, the amount of exo isomer (Hofmann product) increases markedly with increasing ring size (3%, 12%, and 28% respectively). One may conclude that the larger the ring size, the more favorable the ionic transition state since the ring bond angle can expand towards 120°.



It is very difficult to draw a comparison with liquid phase pyrolysis of tertiary hydrogen phthalate esters and corresponding acetates. The former, because of much greater internal strain, may well lend themselves more readily to an ionic-type breakdown and thus decompose at much lower temperatures. Indeed, we have found that all aliphatic hydrogen phthalate esters of tertiary alcohols which contain one or two phenyl groups on the carbonyl carbon atom decompose at their melting points. Thus the hydrogen phthalate ester of 2-phenyl-2-propanol decomposes at 109–110° in mineral oil to yield on subsequent steam distillation 95% alpha-methylstyrene. Similarly, the hydrogen phthalate ester of 1,1-diphenylethanol yields 1,1-diphenylethylene at 110°. The presence of the phenyl grouping along with the low decomposition temperatures suggests added stability of the carbonium ion as well as increasing the internal strain of the molecule, thus enabling ion formation at even lower temperatures. With the limited amount of low-temperature experiments carried out with tertiary acetates, indications are that an increase in the ionic character of the elimination transition state is realized with a decrease in decomposition temperature.

The effect of benzenoid substituents which would increase or decrease carbonium-ion character in both acetate and hydrogen phthalate ester pyrolysis is presently under investigation.

EXPERIMENTAL

Melting points were taken on the Fisher–Johns melting point apparatus.

Preparation of Alcohols

1-Methylcyclopentanol, 1-methylcyclohexanol, and 1-methylcycloheptanol were prepared according to the procedure of Bailey and Hale (4). *trans*-1,2-Dimethylcyclohexanol was prepared according to the procedure of Hammond (16). Tertiary amyl alcohol was obtained commercially. The physical constants of all the alcohols agreed closely with reported values.

Hydrogen Phthalate Esters

All hydrogen phthalate esters were prepared according to the procedure developed in this laboratory

and reported in a previous paper (13). The esters of *t*-amyl alcohol, 1-methylcyclopentanol, and 1-methylcyclohexanol have been recorded in this previous work. The hydrogen phthalate esters of 1-methylcycloheptanol and *trans*-1,2-dimethylcyclohexanol were well-defined solids, m.p. 90–91° and 124–125° respectively, and were prepared in yields ranging from 85 to 90%.

Anal. Calcd. for $C_{16}H_{20}O_4$: C, 69.54; H, 7.30; neutralizing equivalent, 276.3. Found: C, 69.80; H, 7.56; neutralizing equivalent, 276.5.

Anal. Calcd. for $C_{16}H_{20}O_4$: C, 69.54; H, 7.30; neutralizing equivalent, 276.3. Found: C, 69.40; H, 7.43; neutralizing equivalent, 279.6.

Pyrolysis Studies

All the pyrolysis reactions were carried out essentially under the same conditions. An oil bath was preheated to desired temperature (see Table 1). A round-bottomed flask (100 ml) containing 10–15 g of hydrogen phthalate esters was fitted with a Claisen head, thermometer, Liebig condenser, and receiving tube and was immersed in the bath. The receiving tube was cooled in a dry ice – acetone bath. The olefins produced on pyrolysis of the esters of *t*-amyl alcohol and 1-methylcyclohexanol were collected at atmospheric pressure. The remaining pyrolyses were carried out under reduced pressure as indicated in Table I. In all cases the hydrogen phthalate esters melted sharply and then decomposed rapidly as the critical temperature was reached. The distillate was collected between 10 and 15 min, after which only traces of olefins distilled. As decomposition takes place, a deposit of phthalic acid accumulates rapidly in the reaction flask. This was found to trap some olefins, thus decreasing olefinic yields. Total olefinic yields obtained from the *t*-amyl, methylcyclopentyl, methylcyclohexyl, methylcycloheptyl, and *trans*-1,2-dimethylcyclohexyl systems were 70, 67, 67, 88, and 67% respectively. The olefinic mixtures obtained were subjected immediately to gas phase chromatographic analysis although no difference in isomer distribution was observed with any of the mixtures allowed to stand in the refrigerator for long periods of time. Separations of the olefinic mixtures from the *t*-amyl, methylcyclohexyl, and *trans*-1,2-dimethylcyclohexyl systems were effected with a Perkin–Elmer model 154 instrument using Column "A". Separations of the olefins obtained from the methylcyclopentyl and methylcycloheptyl systems were effected with a Perkin–Elmer model 800 using a Golay "R" column (175 ft).

Authentic samples of 2-methyl-1-butene, 2-methyl-2-butene, and 3-methyl-1-butene were obtained from the Phillips Petroleum Co., Bartlesville, Oklahoma. A mixture of 1-methylcyclopentene and methylenecyclopentane was obtained by the known iodine dehydration of 1-methylcyclopentanol (14). Similarly a mixture of 1-methylcyclohexene and methylene cyclohexane was obtained by the known iodine dehydration of 1-methylcyclohexanol (2). The thermal dehydration (14) of 1-methylcycloheptanol provided a mixture of 1-methylcycloheptene and methylenecycloheptane. Iodine dehydration (15) of *trans*-1,2-dimethylcyclohexanol provided 73% 1,2-dimethylcyclohexene, 24% 2,3-dimethylcyclohexene, and 3% methylene-2-methylcyclohexane. Retention times of all olefins obtained from low-temperature pyrolysis reactions were coincident with the known olefins. Authentic samples of 1-methylcyclopentene and 1-methylcycloheptene were obtained from the Aldrich Chemical Company.

ACKNOWLEDGMENTS

The authors would like to thank Dr. S. J. W. Price and Messrs. M. Jacko, M. Krech, and J. Kominar for able assistance with the gas phase chromatographic analysis and the National Research Council for financial support.

REACTIONS WITH DIAZOALKANES

III. 1,4-NAPHTHAQUINONE AND DIAZOALKANES*

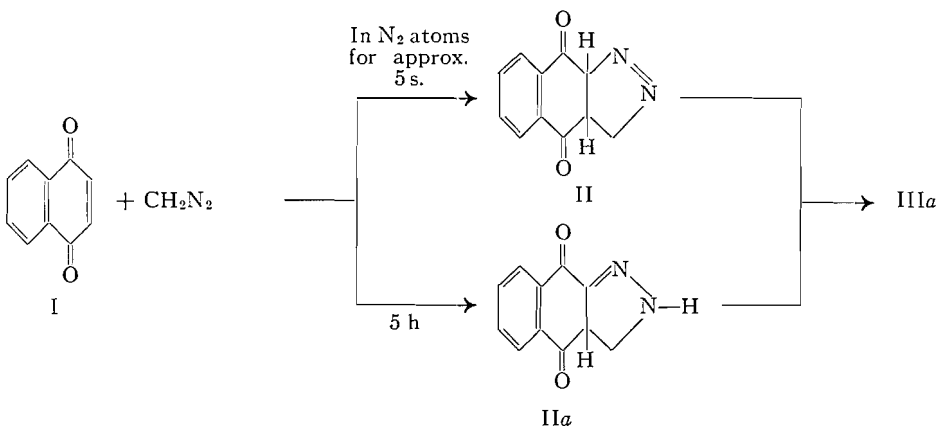
WILLIAM IBRAHIM AWAD AND ALFRED BOULOS
Faculty of Science, A'in Shams University, Abbassia, Cairo, Egypt, U.A.R.

Received May 25, 1964

ABSTRACT

The addition of diazomethane to 1,4-naphthaquinone has been reexamined. Two products are isolated from this reaction, one of them (III*a*) has been previously reported. Similarly, diazoethane gives two products. The constitution of these products is discussed, particularly in the light of their ultraviolet and infrared spectra. The thermal stability of diazoalkane adducts to I is discussed.

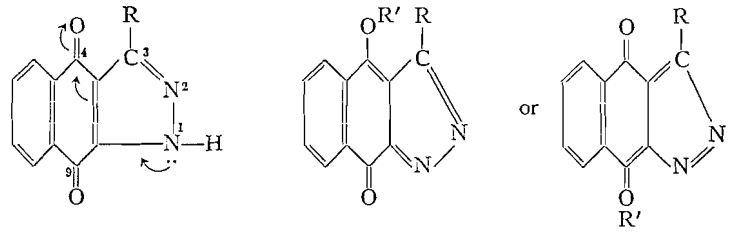
A recent publication by Dean and Jones (1), which describes *inter alia* compounds derived from diazomethane and 1,4-naphthaquinone, prompts us to publish our related work on this topic. Dean *et al.* (1) suggested the following mechanism:



The elucidation of the structure of the immediately formed compound as 3*a*,4,9,9*a*-tetrahydro-3*H*-benz[*f*]indazole (II) may be uncertain. The band described for the azo linkage at 1548 cm^{-1} is unreliable, as similar bands appear in the case of III*a* at 1538 cm^{-1}. The lack of absorption close to 1620 cm^{-1}, from which it was concluded that the 2,3-double bond of the naphthaquinone nucleus has been removed, is actually a negative proof. In reality, this band is also absent in other compounds where it is expected, e.g. III*a*, III*b*, and VII.

It was found, however, in the present investigation that the reaction of diazomethane with I yields two products, one having a high melting point (345°) (III*a*) and the other a low melting point (172°) (IV*a*). These products are at a higher oxidation level than those described by Dean *et al.* (1). The latter compound has not been described either by early investigators (2, 3) or by recent ones (1). The fact that a mixture of compounds results from such a reaction may throw some doubt on the purity of the uncrystallized product used by Dean (1) for the analysis of the supposed II*a* (which, however, was at a lower level of oxidation than the compounds isolated in our work).

**Part II. W.I. Awad, S.M.A.R. Omran, and M. Sobhy, J. Chem. U.A.R. In press.*



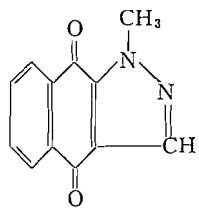
III

IV

III*a*; R = H
III*b*; R = CH_3

IV*a*; R = H, R′ = CH_3
IV*b*; R = CH_3, R′ = C_2H_5

The structure of IV*a* is based upon (i) absence of N—H stretching frequency near 3333 cm^{-1}, (ii) analytical data, (iii) presence of C=O stretching frequency of 1666 cm^{-1}, (iv) presence of a strong band at 1250 cm^{-1} (absent in IIIa and V) which is characteristic of enol–ether linkage (4), and (v) the fact that methylation of III*a* with dimethyl sulphate in alkaline medium gives two products—(*a*) a high melting compound (310°), which was previously isolated (1, 2, 3) and assigned the N–CH_3 structure (1) (V), and (*b*) a low melting compound (172°). The latter compound was identical with IV*a* isolated from the diazomethane experiment, as shown by mixed melting point determinations and infrared spectra.



V

The ultraviolet spectra of III*a*, IV*a*, and V (Fig. 1) indicate that III*a* and V are of similar structure and that IV*a* is quite different. The action of diazomethane on III*a* gave mainly IV*a* together with a small quantity of V. Comparison of the ultraviolet spectra of III*a* in alcohol and in alkaline solution (Fig. 2) indicates that, in alkaline solution, there is only a slight bathochromic shift and a hyperchromic effect, and that the hybrid anion is fundamentally similar to III*a* (cf. curved arrows in III*a*).

Diazoethane has also been allowed to react with I. Two products have been isolated—a high melting compound to which structure III*b* is assigned and a low melting compound to which structure IV*b* is assigned. The structure III*b* is confirmed by (i) analytical data, (ii) infrared spectrum that shows N—H stretching frequency at 3333 cm^{-1} and a carbonyl stretching frequency at 1666 cm^{-1}, (iii) solubility in alkali, and (iv) its ultraviolet spectrum (Fig. 3), which shows its clear resemblance to that of III*a*. The structure of IV*b* is based upon (i) analytical data, (ii) the absence of a N—H stretching frequency near 3333 cm^{-1}, the presence of a carbonyl stretching frequency at 1665 cm^{-1} and the presence of a enol–ether stretching frequency at 1250 cm^{-1}, (iii) insolubility in alkali, and (iv) its ultraviolet spectrum (Fig. 3), which shows its resemblance to that of IV*a*.

The pyrolysis of diazoalkane derivatives from naphthaquinone is of interest. It is known (2, 5) that VI decomposes on pyrolysis with loss of nitrogen, that VII is stable

EXPERIMENTAL

Melting points are uncorrected. Analyses were carried out by Alfred Bernhardt, Max-Plank Institute, Mulheim, Germany. Infrared spectra were measured on a Perkin–Elmer Infracord Model 137 spectrophotometer, using the KBr Wafer technique. Ultraviolet spectra were measured on a Perkin–Elmer Spectracord Model 4000A spectrophotometer with ethyl alcohol solutions, except in case of III*a* (Fig. 2—the dotted curve) where it is carried out in 5% sodium hydroxide solution.

4,9-Dihydro-4,9-dioxo-1H-benz[f]indazol (IIIa) and its O-Methyl Derivative (IVa)

Naphthaquinone (1.0 g) and diazomethane (from nitrosomethyl urea, 4.0 g) were left for a couple of hours in ice-cooled ether (ca. 100 ml). The reaction began at once with the separation of a brownish precipitate. This precipitate was filtered off (0.65 g) and III*a* was crystallized from acetic acid as colorless crystals, m.p. ≈ 345°.

Calcd. for $C_{11}H_6O_2N_2$: C, 66.65; H, 3.05; N, 14.1. Found: C, 66.4; H, 3.3; N, 13.9.

III*a* sublimed unchanged *in vacuo*. The ethereal mother liquor was concentrated and cooled, at which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

time IV*a* separated out (0.2 g). It was crystallized from light petroleum (80–100°) as colorless crystals, m.p. 172°. IV*a* was insoluble in alkali.

Calcd. for $C_{12}H_8O_2N_2$: C, 67.9; H, 3.8; N, 13.2. Found: C, 67.9; H, 3.7; N, 13.1.

Action of Dimethyl Sulphate on IIIa

Methyl sulphate (0.1 ml) was added to a filtered solution of III*a* (0.2 g) in 2 ml 5% NaOH. The mixture was shaken well and the precipitate formed was filtered off. The precipitate was boiled with light petroleum (80–100°). The fraction, which was soluble in light petroleum, crystallized out as colorless crystals (0.05 g), m.p. 172° (undepressed on admixture with IV*a* obtained previously). The insoluble fraction, 4,9-dihydro-1-methyl-4,9-dioxobenz[*f*]indazole, was crystallized from alcohol (0.05 g), m.p. 310° (2, 3, 4).

Action of Diazomethane on IIIa

An ice-cooled ethereal diazomethane solution (from methyl nitroso urea, 4 g) was added to III*a* (0.5 g) and left overnight. The insoluble part (0.1 g), which crystallized from EtOH, was proved to be V by means of mixed melting point determinations. The ethereal solution was concentrated to give IV*a* (0.40 g), crystallized from light petroleum (80–100°), and identified by melting points and mixed melting points.

4,9-Dihydro-4,9-dioxo-1H,3-methyl-benz[f]indazol (IIIb) and its O-Ethyl Derivative (IVb)

Naphthaquinone (7.00 g) and diazoethane (from ethyl nitroso urea, 20 g) were left in ice-cooled ether (ca. 350 ml) for a couple of hours. The reaction was similar to that described for diazomethane. The ether-insoluble product (4.0 g) was filtered off. III*b* was crystallized from ethyl alcohol as colorless crystals, m.p. 292°. Calcd. for $C_{12}H_8O_2N_2$: C, 67.9; H, 3.8; N, 13.8. Found: C, 68.1; H, 4.1; N, 13.6.

This product was soluble in 5% NaOH solution and sublimed unchanged *in vacuo*. The ethereal mother liquor was concentrated to give IV*b* (0.70 g), which was crystallized from light petroleum (80–100°) as colorless crystals, m.p. 119°. It was insoluble in alkali (cf. Fig. 3 for ultraviolet spectra).

Calcd. for $C_{14}H_{12}O_2N_2$: C, 69.99; H, 5.03; N, 11.66. Found: C, 70.5; H, 5.1; N, 11.5.

Action of Heat on VII and VIII

Both compounds (3) were heated under vacuum (2 mm/Hg), where they sublimed unchanged, as shown by melting points and mixed melting points.

THE ^{19}F N.M.R. SPECTRUM OF IF_7

R. J. GILLESPIE AND J. W. QUAIL[1]
Department of Chemistry, McMaster University, Hamilton, Ontario
Received July 8, 1964

ABSTRACT

It is shown that the line shape calculated for the n.m.r. spectrum of a magnetic nucleus attached to a nucleus of spin 5/2 undergoing quadrupole relaxation agrees well with the observed spectrum of iodine heptafluoride. The iodine–fluorine coupling constant was found to be $J_{IF} \simeq 2\,100$ c/s. The apparent magnetic equivalence of the fluorine atoms in IF_7 is discussed.

The ^{19}F nuclear magnetic resonance (n.m.r.) spectrum of IF_7 at room temperature is an extremely broad doublet (Fig. 1A). Our spectrum agrees closely with that reported previously (1–4). Muetterties and Packer (3) have suggested that the observed spectrum is a partially collapsed sextet arising from the coupling of seven spectroscopically equivalent fluorines to the iodine which is undergoing quadrupole relaxation. They did not, however, calculate the expected spectrum.

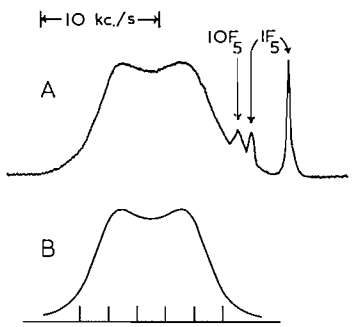

FIG. 1. (A) ^{19}F n.m.r. spectrum of IF_7 containing small amounts of IF_5 and IOF_5 and (B) theoretical line shape for the spectrum of a nucleus of spin 5/2 according to Suzuki and Kubo for a value of $\alpha = 55$. The vertical lines indicate the positions of the sextet in the absence of quadrupole relaxation.

Recently, Suzuki and Kubo (5) have given a general method for calculating multiplet line contours for the resonance of nuclei coupled to a high-spin nucleus which is undergoing quadrupole relaxation. Previous calculations of line shapes for nuclei coupled to nuclei having $I = 1$ (6, 7) and $I = 3/2$ (8) may be considered as limited applications of this more general theory. It has been pointed out that the theory involves some approximations (5, 6) but the agreement between calculated and experimental line shapes for $I = 3/2$ (8) indicates that the approximations do not lead to any serious error. Suzuki and Kubo calculate spectral shapes as a function of a parameter

$$\alpha = \left(\frac{e^2qQ}{\hbar}\right)^2 \frac{\tau_c}{2\pi J},$$

where e = the charge on an electron, eq = the electric field gradient at the nucleus, eQ = the quadrupole moment of the nucleus, τ_c = the correlation time for molecular

[1]*Present address: Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan.*

reorientation, and J = the coupling constant in c/s; $(e^2qQ/\hbar)$ = the quadrupole coupling constant in rad/s. For $I = 5/2$,

$$\alpha = \frac{1\,000}{24}\left(\frac{1}{T_1}\right)\frac{1}{2\pi J},$$

where T_1 = the relaxation time of the nucleus undergoing quadrupole relaxation.

We had already calculated line shapes for $I = 5/2$ by essentially the same method as that used by Suzuki and Kubo when their paper appeared. With these line shapes we are able to interpret the ^{19}F spectrum of IF_7.

The splitting between the peaks in the IF_7 spectrum (Fig. 1A) is $\sim 4\,000$ c/s, in agreement with the observation of Alexakos, Cornwell, and Pierce (2). Muetterties and Packer (3) report a value of 4 400 c/s for this splitting. The small discrepancy between the two values could be due to a higher viscosity in our sample and the sample of Alexakos *et al.* and thus a longer correlation time for the iodine nuclei. This higher viscosity could be the result of either the impurities in the samples or a lower sample temperature. The longer correlation time would result in more relaxation of the iodine nuclei and thus a more collapsed spectrum. Because of the extreme broadness of the lines the disagreement might, however, simply be due to the difficulty of determining the peak positions.

There are two peaks in our spectrum due to IF_5 (9) and a third peak due to IOF_5 (2, 10, 11). The other part of the IOF_5 spectrum is of too low an intensity to be observed. This absorption, which is one quarter as large as the observed IOF_5 line, is spread out on top of the high-field half of the IF_7 doublet (compare the spectrum in ref. 2).

A very good fit with the experimental spectrum is obtained for $\alpha \sim 55$ (Fig. 1B). This allows us to extract a coupling constant, $J_{IF} \sim 2\,100$ c/s, for this compound. An estimate of the relaxation time for the iodine nucleus can also be made ($T_1 \sim 5.7 \times 10^{-5}$ s). There is no reliable criterion of accuracy but errors in line-matching would introduce an error of less than 10%.

The discussion of the collapse of the spectrum arising from coupling to an $I = 5/2$ nucleus, given by Muetterties and Packer (3), is somewhat misleading. The description of the system as made up of six absorption signals, which are drawn together by transitions between the spin states of the $I = 5/2$ nucleus, is valid only for the very initial stages of the multiplet collapse (12). The theory shows that the spectral lines will merge, but they certainly cannot cross as supposed by Muetterties and Packer (3). Furthermore, by the time any appreciable movement of the absorption lines occurs, dispersion components have become appreciable in all of the lines, and thus the concept of individual absorption components loses its physical significance as the lines merge.

The relaxation of the iodine nucleus results from an interaction of the quadrupole moment of the iodine nucleus with the field gradient at the site of the nucleus through molecular reorientations characterized by the correlation time τ_c. In agreement with Muetterties and Packer we observed that the doublet sharpened at higher temperatures. The correlation time would then be shorter, resulting in a spectrum corresponding to a smaller value of α.

The field gradient at the iodine in IF_7 arises from the fact that although all the ligands are identical, no arrangement of seven ligands can have cubic symmetry. The structure of IF_7 is uncertain. Although the X-ray and spectroscopic data have generally been considered to indicate a pentagonal bipyramid structure, Burbank considered that the X-ray data in fact support a structure with C_{2v} symmetry which may be regarded as being derived from the 8-coordinated dodecahedral structure by merging two adjacent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

positions (13). In any case there should be at least two groups of nonequivalent fluorines and therefore at least two peaks should be observed in the fluorine n.m.r. spectrum. To explain the apparent equivalence of the seven fluorine atoms Muetterties and Packer have proposed that intramolecular fluorine exchange provides a mechanism for time-averaging of the ligand environments. The same explanation has been proposed to explain the apparent magnetic equivalence of the fluorine atoms in PF_5 and other trigonal bipyramid molecules (14, 15). It should be noted, however, that in the case of IF_7 a chemical shift of 2 p.p.m. or less between nonequivalent fluorines and a variation in the coupling constant J_{IF} of as much as 10% would not appreciably affect the observed spectrum because of the extreme broadness of the lines. Such a small chemical shift is not unreasonable. For example, the chemical shift between the basal and equatorial fluorines in SF_5X compounds varies from over 80 p.p.m. in SF_5Br to nearly 0 p.p.m. in SF_5OOSF_5 (0.6 p.p.m.) and CF_3OOSF_5 (2 p.p.m.) and to negative values for other compounds such as CF_3SF_5 (~ -23 p.p.m.) (18). Thus, it cannot be concluded with certainty that there is a time-averaging of nonequivalent fluorines, although this seems very plausible.* We may note that there are at least four 7-coordinate structures of rather similar energies (13, 16, 17) and all except one of these could provide the close-lying vibronically excited states which it has been suggested (3) provide a mechanism for intramolecular fluorine exchange.

EXPERIMENTAL

Calculated spectra were obtained numerically using an IBM 7 040 computer. The ^{19}F n.m.r. spectrum of IF_7 was obtained using a Varian HR-56.4 n.m.r. system with a 15 mm insert and a 12 mm (outside diameter) sample tube. The oscilloscope trace of the spectrum was recorded photographically. IF_7 was prepared by the fluorination of iodine pentafluoride in a monel reaction tube at 250 °C. Purification was effected by trap-to-trap distillation.

THE STUDY OF HYDROGEN BONDING AND RELATED PHENOMENA BY SPECTROSCOPIC METHODS

PART VIII. THE ULTRAVIOLET AND INFRARED SPECTRA OF SOME 2,4-DINITRODIPHENYLAMINES[1]

A. Balasubramanian, J. B. Capindale, and W. F. Forbes
Chemistry Department, University of Waterloo, Waterloo, Ontario

Received April 14, 1964

ABSTRACT

The ultraviolet spectra of a number of 2,4-dinitrodiphenylamines suggest that these compounds are generally non-planar in a number of different solvents. The infrared and ultraviolet spectral data in different solvents also suggest that an intramolecular hydrogen bond is present in these molecules, at least in inert solvents. There is evidence that a *p*-nitro substituent is necessary to increase the positive charge on the amino group sufficiently to permit it to form this fairly strong type of hydrogen bond.

INTRODUCTION

2,4-Dinitrodiphenylamine (I) is of interest because compounds of this type are readily converted on irradiation to species containing unpaired electrons (unpublished information and cf. ref. 1). This suggests that such compounds may prove suitable as protective agents against various forms of radiation (cf. ref. 2). A series of substituted 2,4-dinitrodiphenylamines was prepared and their properties are being investigated. As part of these investigations, and since the geometry of substituted diphenylamines has not been investigated previously (cf. ref. 3), the ultraviolet and infrared spectra of these compounds have been determined.

EXPERIMENTAL

Ultraviolet Spectra

The ultraviolet spectra were determined by standard methods in matched 1 cm quartz cells, using both a Cary Model 14 spectrophotometer and a Beckman Model DU spectrophotometer, calibrated against a standard solution of potassium chromate. Wavelength readings obtained on the two instruments were found to be within 0.5 mμ of each other. The accuracy of λ_{max} values is estimated to be $\pm$ 1 mμ, and the precision of molar absorptivities $\pm 5\%$ or better. For each spectrum, at least two independent sets of observations were made and absorptivity values were generally found to be reproducible to $\pm 2\%$. Solute concentrations were usually between 1.5×10^{-5} and 7×10^{-5} molar, except that several spectra of more concentrated solutions were determined as previously described (4). 2′-Methyl-2,4-dinitrodiphenylamine, examined in this way, did not show any concentration dependence in the range 1.8×10^{-5} to 4.4×10^{-4} molar. The ultraviolet spectra of some of the reference compounds, but not of the substituted 2,4-dinitrodiphenylamines, have previously been determined by other workers. Our results are in good agreement with earlier data.

Infrared Spectra

The infrared spectra were determined on a Beckman Model IR9 spectrophotometer, calibrated against a polystyrene film using a KBr prism and diffraction gratings. The frequency accuracy in the 3400 cm^{-1} and 1400 cm^{-1} regions is believed to be ± 0.6 cm^{-1} and 0.4 cm^{-1} respectively and the frequency repeatability ± 0.1 cm^{-1}. Solutions were examined in matched 1 cm quartz cells (3400 cm^{-1} region) or in 0.5 mm, 0.2 mm, or variable path cells equipped with sodium chloride windows (1400 cm^{-1} region). The solute concentration was ca. 5×10^{-3} molar. The integrated absorption intensities (A_{RJ}) were calculated from the equation

$$A_{RJ} = K(1/cl) \log (T_0/T)_{max} \Delta\nu_{\frac{1}{2}} \times 2.303 \times 10^{-4},$$

where c is molar concentration, l the cell length in cm, $\log (T_0/T)_{max}$ the absorbance at the absorption maximum, and $\Delta\nu_{\frac{1}{2}}$ the band width in cm^{-1} at half maximum intensity (cf. ref. 5). K was determined from

[1]*Part VII. Can. J. Chem. 40, 1891 (1962).*

Ramsay's Tables (6). The intensities were also expressed in the new units, A_{IUPAC} (7). The accuracy of the A values are estimated to be ±5%. Two independent sets of observations were also carried out for the infrared data.

The solvents used, except the ethanol, were commercially available spectroanalyzed solvents (Fisher). The ethanol was best grade undenatured absolute ethanol (Consolidated Alcohol, Toronto).

The diphenylamines were prepared by heating together on the steam bath equimolar quantities of 2,4-dinitrochlorobenzene and the appropriate aniline until the mixture solidified. The solid was dissolved in hot benzene, the resulting solution was filtered, and the solid was reprecipitated by the addition of petroleum ether. The diphenylamines were recrystallized until the melting point indicated that the samples were pure. Most of the diphenylamines have been described in the literature with the exception of the following. 2,4-Dinitro-2′,6′-dimethyldiphenylamine, which crystallized from acetone–water in yellow prisms, m.p. 163.5–164.5 °C. (Calcd. for $C_{14}H_{13}N_3O_4$: C, 58.6; H, 4.55; N, 14.6. Found: C, 58.6; H, 4.65; N, 14.7.) 2,4-Dinitro-2′-fluorodiphenylamine, which crystallized from benzene – petroleum ether as orange needles, m.p. 132–134 °C. (Calcd. for $C_{12}H_8N_3O_4F$: C, 52.0; H, 2.9; N, 15.2; F, 6.9. Found: C, 52.1; H, 3.0; N, 15.0; F, 7.05.)

The remaining compounds were prepared by standard methods as described in the literature.

RESULTS AND DISCUSSION

Ultraviolet Spectra

The main ultraviolet absorption maxima of the diphenylamines and of suitable reference compounds are listed in Table I.

TABLE I

Main ultraviolet absorption maxima of 2,4-dinitrodiphenylamines and of suitable reference compounds in cyclohexane solution*

Compound	Long wavelength band		Short wavelength band

Planarity of 2,4-Dinitrodiphenylamines

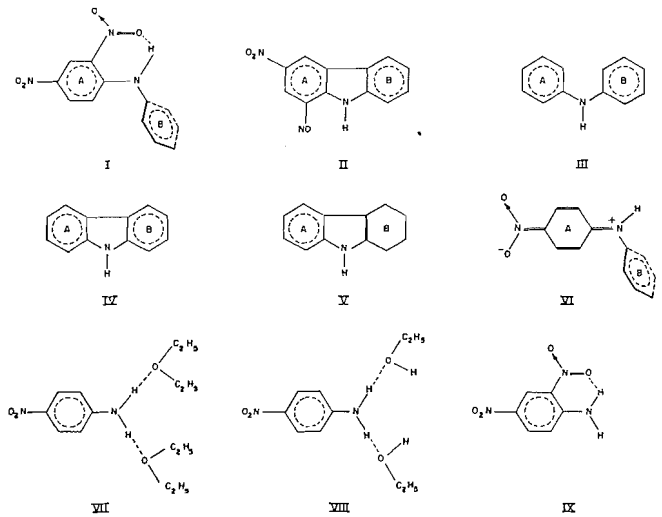
The existence of two separate band envelopes suggests absorption by two chromophores. This, in conjunction with the long wavelength band data, is consistent with the assumption that the 2,4-dinitrodiphenylamines in solution have a molecular conformation in which the two aromatic rings are as shown in structure I. Specifically, the following may be noted.

(*i*) All the 2,4-dinitrodiphenylamines listed in Table I absorb maximally at 338 ± 10 mμ whereas ring-substituted anilines show a wider variation in the location of the long

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

wavelength band as the substituent is altered. For example, in inert solvents 4-nitroaniline and aniline absorb at 321 mμ and 234 mμ respectively. Since the wavelength displacement between 2,4,4′-trinitrodiphenylamine and 2,4-dinitrodiphenylamine (I) is smaller, this indicates that the 4′-nitro substituent does not contribute as much to the long-wavelength band in the 2,4,4′-compound as in 4-nitroaniline.

(*ii*) Comparison of the spectra of 2,4-dinitro-2′,6′-dimethyldiphenylamine and 2,4-dinitro-4′-methyldiphenylamine shows that the two compounds have similar molar absorptivity values (see Table I). However, two ortho-methyl groups will almost certainly increase the non-planarity of a planar or nearly planar system, and such non-planarity would be expected to give rise to a pronounced hypochromic effect. Since no such effect is observed, it is probable that the 4′-methyl compound is already non-planar (as shown in structure I) and that for this reason the anticipated hypochromic effect is not observed in the di-ortho substituted diphenylamine.



(*iii*) The main absorption maximum of aniline occurs at 234 mμ, whereas diphenylamine (III), in which both rings may be assumed to be perpendicular or nearly perpendicular to their C—N bond – unshared pair planes, absorbs maximally at 282 mμ. Hence introduction of a second benzene ring into the aniline system apparently affords a wavelength displacement of ca. 47.5 mμ, which corresponds to a frequency displacement of 7200 cm^{-1}. On the other hand, the wavelength displacement between 2,4-dinitroaniline and 2,4-dinitrodiphenylamine (I) in carbon tetrachloride solution is only 342.5 − 316 = ca. 26.5 mμ or 2450 cm^{-1}. This suggests that the main absorption maximum of I corresponds predominantly to the 2,4-dinitroaniline part of the molecule, which in turn can be rationalized by assuming that ring B is not coplanar with the unshared electron pair of the central nitrogen atom (structure I).

(*iv*) The 2,4-dinitrocarbazole (II), prepared by the method of Stárková *et al.* (8), absorbed at appreciably longer wavelength then 2,4-dinitrodiphenylamine (I). This again suggests that the rings in compound II are more nearly coplanar than in compound I (Table I). In contrast, the carbazole (IV) absorbs maximally at only slightly longer wavelength and with slightly greater absorption intensity than diphenylamine (III). This indicates that the effective length of the conjugated system which gives rise to the absorption band is greater for the carbazole (IV) than for the diphenylamine (III).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Appreciable conjugation must occur between the two benzene rings in diphenylamine (III), since the main absorption maximum of III occurs at longer wavelength than that of the tetrahydrocarbazole (V) (see Fig. 1 and Table I).

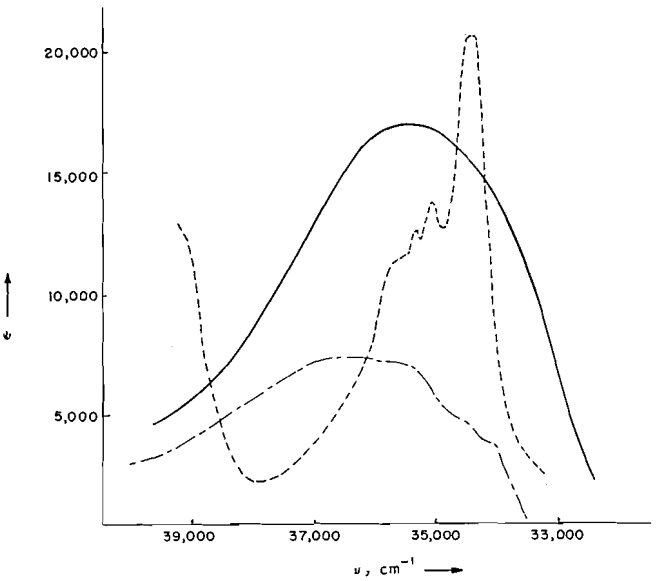


FIG. 1. Main ultraviolet absorption bands in cyclohexane solution of diphenylamine (III, —), carbazole (IV, - - -), and tetrahydrocarbazole (V, — - — -).

We therefore conclude that diphenylamine (III) is nearly planar, whereas 2,4-dinitrodiphenylamine is appreciably non-planar. This non-planarity may be caused by two factors. First, the *o*-substituents of ring A may displace the ring B as shown in structure I. Even in the absence of a large *o*-substituent, as in compounds like 4-nitrodiphenylamine, increased conjugation, which may be crudely represented by resonance forms of type VI, tends to change the bond configuration around the nitrogen atom from a tetrahedral configuration towards a trigonal structure. This would also decrease the N—C bond length because of the increased double bond character of the bond. This in turn may increase the steric interactions between the ortho groups and thus cause the B ring to be no longer perpendicular to the C—N bond – unshared pair plane. Such an explanation can account for the relatively small displacement observed between 4-nitroaniline and 4-nitrodiphenylamine (see Table I; cf. the wavelength displacement of ca. 48 mμ (7270 cm^{-1}) observed between aniline and diphenylamine).

Solvent Effects and Hydrogen Bonding in 2,4-Dinitrodiphenylamines

Table II lists the main absorption maxima of some of these compounds in different solvents. Comparison of the results in Table I and Table II shows that changing the solvent from cyclohexane to carbon tetrachloride gives rise to small spectral changes. For each compound the absorption maximum is displaced slightly to longer wavelength in carbon tetrachloride solution. This change may be associated partly with the red shift which increases approximately in proportion to the refractive index of the solvent, and with increased solute dipole – induced solvent dipole interactions (cf. refs. 9 and 10).

On changing the solvent from carbon tetrachloride to chloroform, slightly larger displacements are observed for 2,4-dinitro-*N*-methyldiphenylamine than for the other

2,4-dinitrodiphenylamines. Since other data (particularly the infrared N—H band data) suggest the presence of an intramolecular hydrogen bond, this difference may tentatively be associated with an intramolecular hydrogen bond. This implies that in carbon tetrachloride solution 2,4-dinitrodiphenylamines would absorb at slightly shorter wavelength in the absence of an intramolecular hydrogen bond. This bond may thus be responsible for a displacement of, approximately, 100 cm^{-1}. This is illustrated schematically in Fig. 2, which also indicates that the displacement ascribed to intramolecular hydrogen bonding is much smaller than that ascribed, partly, to intermolecular hydrogen bonding. The greater importance of intermolecular hydrogen bonding is not surprising since, for example, the non-intramolecularly bonded 4-nitro group can also interact with $CHCl_3$ molecules. The above rationalization is clearly not strong evidence for intramolecular hydrogen bonding in 2,4-dinitro substituted diphenylamines. However, it shows that the similar frequency displacements for 2,4-dinitro-*N*-methyldiphenylamine and other 2,4-dinitrodiphenylamines, observed on changing the solvent from cyclohexane or carbon tetrachloride to chloroform, are not inconsistent with the existence of an intramolecular hydrogen bond in the latter compounds.

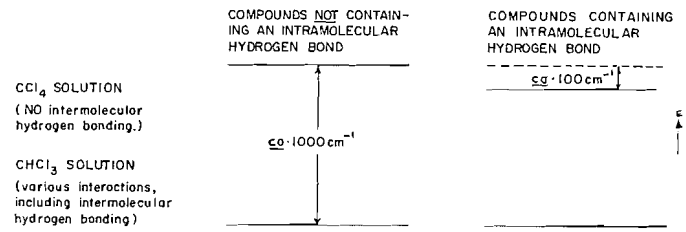

FIG. 2. Schematic representation of energy levels for compounds in the presence and in the absence of an intramolecular hydrogen bond.

In ether solution, the largest displacement is observed for 4-nitroaniline (see Table III), which may be associated with structures of type VII (cf. ref. 11). Strong intermolecular hydrogen bonding may be favored in this compound because of the presence of a *p*-nitro substituent and because of the absence of competitive intramolecular hydrogen bonding.

The spectral changes occurring on alteration of the solvent from chloroform to ethanol can also be rationalized in terms of available active hydrogen atoms. That is, for 4-nitroaniline the displacement of 1790 cm^{-1} (see Table II) may be associated with a number of interactions, including interactions of type VIII. For the 2,4-dinitro compounds this wavelength displacement is drastically reduced, presumably because in structures of type IX the nitrogen-bonded hydrogen atom is not as readily available for intermolecular (solvent–solute) hydrogen bonding.

Infrared Spectra

The discussion of the ultraviolet spectra in inert solution indicates that these spectra can be rationalized by assuming that the 2,4-dinitrodiphenylamines contain an intramolecular hydrogen bond (structure IX). If such bonding occurs, this should involve both the N—H and N—O vibrations. The observed infrared spectra of the N—H and N—O vibrational stretching frequencies are listed in Tables IV and V respectively.

The results in Table IV show that the N—H band in *o*-nitro-substituted diphenylamines, compared with the N—H band in diphenylamine, shows a pronounced frequency displacement of about 100 cm^{-1} to lower frequency (3). This displacement is much larger than is observed in the absence of intramolecular hydrogen bonding. For example, a

frequency displacement of -4 cm^{-1} is observed between the N—H bands of diphenylamine and 4-nitrodiphenylamine and frequency displacements of 13 and 8 cm^{-1} are observed between the N—H bands of *p*-nitro- and *m*-nitro-*N*-methylanilines and *N*-methylaniline (12). Steric effects do not afford frequency displacements of such magnitude. For example, *p*-phenylaniline absorbs at 3483 and 3398 cm^{-1}, whereas *o*-phenylaniline absorbs at 3481 and 3393 cm^{-1}; 2,4,6-trichloroaniline absorbs at 3503 and 3404 cm^{-1} and 2,4,6-tribromoaniline absorbs at 3492 and 3394 cm^{-1}, whereas aniline absorbs at 3479 and 3396 cm^{-1} (12). The small frequency displacement of 5 cm^{-1} observed between 2,4-dinitro- and 2,4-dinitro-2′,6′-dimethyldiphenylamine may also be noted in this connection.

However, intramolecular hydrogen bonding does give rise to larger spectral displacements of the same order as are observed in *o*-nitro-substituted diphenylamines. For example, methyl-*N*-methylanthranilate absorbs at 3382 cm^{-1}, a frequency 71 cm^{-1} lower than does the methyl ester of *p*-aminobenzoic acid, and *o*-nitro-*N*-methylaniline absorbs at 3401 cm^{-1} compared with 3456 cm^{-1} for *p*-nitro-*N*-methylaniline (13). Incidentally, analogous observations may be made for the infrared carbonyl band data of compounds like acetophenones or benzophenones where again only hydrogen bonding causes pronounced displacements to lower frequency (cf. refs. 5, 14, 15). It is concluded that the explanation of the spectral change is to associate it with a strong intramolecular N—H - - - O—N hydrogen bond. It may further be noted from the data in Table IV that substituents in the second benzene ring (the B ring of structures I and VI) do not affect appreciably the ν_{max} or ϵ_{max} values of the N—H vibrational frequency. This suggests that the intramolecular hydrogen bond is not appreciably affected by that kind of substitution. This is consistent with structure I (see discussion of the ultraviolet spectra).

Three main bands might be expected to occur in the 1200–1550 cm^{-1} region. Actually, a more intense band, associated with the N—O symmetrical stretching band, is observed near 1340 cm^{-1} and a considerably weaker band occurs near 1315 cm^{-1} (see Table V). The displacement is of the order of 25 cm^{-1}, which is qualitatively similar to the displacement which has previously been noted for intermolecular hydrogen bonding (11). However, the aromatic C—N stretching band also occurs near 1310 cm^{-1}. Unfortunately, the N—O unsymmetrical stretching band could not be detected unequivocally because this band occurs at a similar frequency as the aromatic vibrations in that region.

THE CHEMICAL FATE OF RECOIL IODINE ATOMS IN IODINE–METHYL IODIDE SOLUTIONS[1]

N. V. KLASSEN[2] AND A. P. BAERG
Division of Applied Physics, National Research Council, Ottawa, Canada

Received March 6, 1964

ABSTRACT

The organic yield of recoil ^{126}I, produced by the 14 MeV neutron irradiation of iodine–methyl iodide solutions, was examined over iodine concentrations from 0.34 mole fraction iodine to "pure" methyl iodide. By correcting for exchange between I_2 and methyl iodide, the initial organic yield at very low iodine concentrations was found to be 57%. The time for one-half of the I_2 to exchange with CH_3I was found to decrease with decreasing iodine concentration. At all iodine concentrations the organic products containing ^{126}I consisted mainly of CH_3I and CH_2I_2. The formation of products is discussed in terms of thermal reactions, diffusion-controlled reactions in the spurs, and hot reactions.

INTRODUCTION

Naturally occurring, monoisotopic ^{127}I can be converted into radioactive iodine by (n,γ), (n,2n), (d,p), and (γ,n) reactions. The radioactive iodine atoms are probably formed positively charged. Their average recoil energies are much greater than bond energies but are characteristic of the nuclear reaction involved. Most of these "hot" iodine atoms leave their parent compound and produce a track of ions and free radicals as they are slowed to thermal energies before entering into chemical combination. In methyl iodide and iodine – methyl iodide solutions the organic yield[3] is nearly independent of the nuclear reaction utilized despite large differences in the average recoil energies (1). However, the organic yield is strongly influenced by small quantities of molecular iodine which act as a scavenger for iodine atoms.

Conflicting results have been reported for the organic yield of the $^{127}I(n,\gamma)^{128}I$ reaction in pure methyl iodide. Levey and Willard (2) obtained a value of 56%. Brustad and Baarli (3) favored this result although they always obtained experimental values greater than 93%. Alimarin and Svoboda (4) found a value of 100%. A plausible explanation for such varied results has been provided by Behrens and Maddock (5, 6). They studied the iodine exchange reaction in dilute solutions of $^{131}I_2$ in methyl iodide to elucidate the scavenging effect of iodine and a time dependence of this effect found by others (7). The time for one-half of the I_2 to exchange was found to decrease with decreasing I_2 concentration. This suggested that the order of the exchange reaction is less than unity with respect to I_2. Thus, in very pure methyl iodide where the I_2 concentration is extremely low, the radioactive iodine present as I_2 should be rapidly and completely transferred to the methyl iodide, resulting in an apparent organic yield of 100%.

Svoboda (8, 9) has already recognized the influence of exchange reactions between separable inorganic iodine and the parent methyl iodide in the Szillard–Chalmers process. He suggested that an exchange of psuedo-monomolecular mechanism was responsible for raising organic yields. Recently (10) he has further reported organic yields of 50% for

[1]*Issued as N.R.C. No. 8148.*
[2]*National Research Council Postdoctoral Fellow 1961–1963. Present address: Radiation Research Laboratories, Mellon Institute, 4400 Fifth Avenue, Pittsburgh, Pa.*
[3]*The organic yield is defined as the fraction (expressed as a percentage) of the radioactive iodine which is not extractable by aqueous solutions of reducing agents such as sodium thiosulfate.*

methyl iodide stirred with sodium sulfite solutions during neutron irradiations and 100% organic yields for irradiations without simultaneous sodium sulfite extraction.

The present study was undertaken to investigate the exchange reaction directly in irradiated solutions, using 14 MeV neutrons which produce ^{126}I by the (n,2n) reaction. This was done to permit a further investigation of the distribution of radioactive organic products and the dependence on I_2 concentration, taking exchange effects into account.

EXPERIMENTAL

Purification of Materials

The alkyl iodides were obtained from Eastman Organic Chemicals. For most experiments methyl iodide was distilled slowly through a 130 cm column packed with glass beads. The middle fractions of methyl iodide were used to make up solutions with low iodine concentrations. Distillate, shown by gas chromatography to be less pure, was sometimes used to prepare concentrated iodine solutions after it was shown that this had no effect on the final product distribution. For some experiments the methyl iodide was dried overnight with phorphorus pentoxide and then carefully distilled at reduced pressures, the operation being carried out in a closed system. The purification of methyl iodide was carried out in semidarkness to reduce the possibility of photolytic formation of iodine.

Other alkyl iodides, used as carriers in the fractionation of the irradiation products, were not purified except when it was deemed advisable to remove the small amounts of iodine sometimes present by extraction with aqueous sodium thiosulfate. Analar brand iodine was used without purification.

Neutron Irradiations

Shortly before most irradiations the methyl iodide solutions were de-aerated by repeated evacuation of the frozen samples in a cyclic freezing–melting procedure. The solutions were then sealed in pyrex tubes. The irradiations were carried out in darkness at 25 °C. The neutrons, with an average energy of 14.6 MeV, were obtained from the T(d,n)^{4}He reaction using about 1 mA of 120 keV deuterons incident on a thick, tritium-loaded, titanium target.[4] The total flux of neutrons produced was about 10^{10} n s^{-1} and the samples were irradiated at a distance of 5 cm in front of the tritium target. A rough estimate of the maximum energy deposited in the methyl iodide by neutron scattering is 8×10^{15} eV per gram of methyl iodide per hour. Assuming that 100 eV produces 1.5 molecules of I_2 (11), the maximum rate of I_2 formation was 3×10^{-6} mole fraction per hour. The duration of the irradiations (3 min to 2 h) was chosen to avoid excessive alteration to the initial product distribution by exchange. A flux of slow neutrons sufficient to produce a useful ^{128}I activity could be achieved by surrounding the solutions and target with paraffin to moderate the neutrons.

Counting Radioactivity

The radioactivity of liquid samples was measured by counting their gamma activity with a 3 in. × 3 in. sodium iodide detector. The gamma spectrum and decay rate of irradiated methyl iodide indicated that the only radioactivity present was due to 25 min ^{128}I and 13 d ^{126}I. The two species were easily distinguished by decay curve analysis. In most instances 5 ml samples were counted. In activity measurements, differences in the self-absorption were found to be insignificant for methyl iodide, ethyl iodide, propyl iodide, and diiodomethane. The standard deviation in the activity measurements was usually less than 0.5%. However, for samples of lower activity such as those which contained only radioactive C_2H_5I, the standard deviation was about 2%.

Separation of Radioactive Products

The radioactive inorganic products (I_2 and HI) were extracted from the irradiated methyl iodide solutions into an aqueous solution of sodium thiosulfate and potassium iodide. The organic yield was determined by measuring the radioactivity of a solution before and after extraction. In some cases the inorganic activity was also measured to confirm that the techniques accounted for all of the activity. Before counting the inorganic activity, the aqueous solution into which it had been extracted was washed with inactive methyl iodide. Then the iodide ions were oxidized to I_2 with nitric acid and sodium nitrite, and the I_2 was extracted into methyl iodide for counting.

After the removal of inorganic products, the methyl iodide solutions were diluted with the carriers C_2H_5I, n-C_3H_7I, n-C_4H_9I, CH_2I_2, and CHI_3. Then a separation of some of the organic products was carried out by distillation. The specific activity of the distilled CH_3I, C_2H_5I, and CH_2I_2 each remained constant throughout its take-off interval. The removal, by distillation, of radioactive CH_3I was followed by the addition of inactive CH_3I to the residue to prevent radioactive contamination of the later, less active, fractions. The purity of each distillate fraction, except that of CH_2I_2, was checked by gas chromatography to permit small corrections due to impurities to be made to the observed specific activity. Most distillations were made at reduced pressures to prevent thermal decomposition. For example, CH_2I_2 was distilled at a pressure

[4] *A 150 kV Texas Nuclear Corporation neutron generator was used.*

For personal use only.

of 8 mm Hg where its boiling temperature was 57 °C. Small amounts of I_2 accumulated in the residue during distillation, but the radioactivity present as I_2 was found to be insignificant.

Exchange Experiments

The exchange transfer of radioactive iodine from inorganic to organic products was measured after irradiation. The methyl iodide solution to be irradiated was divided and sealed, under vacuum, into several pyrex tubes. These tubes were kept in darkness during the irradiation and until they were opened, in semi-darkness, to extract the inorganic activity with aqueous sodium thiosulfate. The transfer of activity, by exchange, was followed by extraction of the samples in the separate tubes at various intervals of time. Exchange of ^{131}I (as I_2) with inactive methyl iodide was also examined. All exchange experiments were carried out at 25 °C.

RESULTS AND DISCUSSION

Most of the present results were obtained using ^{126}I (13 d half-life) from the (n,2n) reaction of 14.6 MeV neutrons. Some experiments were performed using the ^{128}I (25 min half-life) which could be formed simultaneously in the solution by the (n,γ) reaction of thermal neutrons. The longer half-life of ^{126}I permitted more time-consuming separations to be made and also permitted exchange to be studied over a wide range of I_2 concentrations. Unless otherwise specified, the radioactive isotope referred to is ^{126}I.

Exchange

It is important for the interpretation of observed product distributions to know whether the initial distribution was altered by exchange prior to separation. Behrens and Maddock (5, 6, 12) examined exchange in methyl iodide containing dilute $^{131}I_2$ and concluded that the transfer of ^{131}I from I_2 to CH_3I follows the usual unimolecular progress in time (i.e., the logarithm of the I_2 activity decreases linearly with time). Moreover, they found that the half-time for exchange decreases with decreasing I_2 concentration.

In the studies reported here the exchange of ^{126}I was examined, after irradiation, over I_2 concentrations from 7×10^{-5} mole fraction to "pure" methyl iodide (i.e., methyl iodide containing no added iodine but in which minute, unknown, amounts may have been present). Up to I_2 concentrations of 3.5×10^{-5} mole fraction the exchange could be followed essentially to equilibrium when the activity was all found to be in organic combination. In methyl iodide very rapid exchange is expected to take place between I_2 and HI (13), the most likely forms of inorganic iodine. The loss of inorganic activity due to exchange should then follow a simple exponential progress in time. The individual points in any one experiment at a given I_2 concentration were obtained by the analysis of separate samples irradiated simultaneously. The majority of the data in a single experiment were usually well represented in the simple exponential form. However, the reproducibility was poor and with a given experiment some individual samples showed large deviations from the average rate of exchange. In Fig. 1 the exchange half-times are shown as a function of I_2 concentration. The values in Fig. 1 are those graphically assessed to best fit the data, while the error bars indicate the maximum variations among all the samples of a given experiment.

There was no indication that the results were affected by the dim light to which the solutions were exposed during extraction of the inorganic products. The reasons for the poor reproducibility of the exchange experiments are not completely understood at present (cf. ref. 6), but heterogeneous effects have been suggested (12). Clearly, the samples in each experiment were not identical and, evidently, minute impurities can profoundly affect the exchange rate. Traces of water might lead to more rapid exchange. This contention seems to be supported by the relatively long half-times (cf. values 1 in Fig. 1) observed for the exchange in the methyl iodide which had been well dried over phosphorus

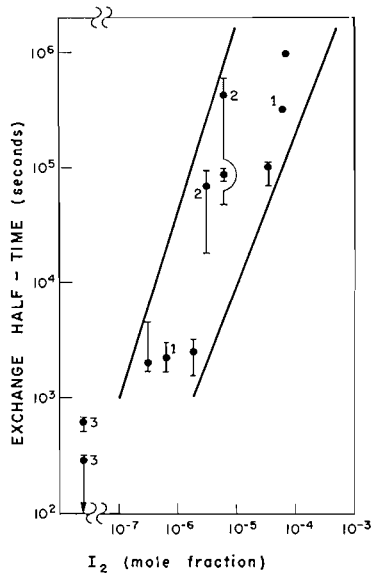

FIG. 1. The dependence of the I_2 – methyl iodide exchange half-time on I_2 concentration: (1) not done by irradiation but by adding $^{131}I_2$ to methyl iodide; (2) the methyl iodide was dried with phosphorus pentoxide; (3) "pure" methyl iodide, no I_2 added.

pentoxide. The larger degree of scatter of the data in these anhydrous solutions can reasonably be attributed to the greater role which traces of water would assume.

In Fig. 1 two lines have been drawn to form a band representing the range of observed exchange half-times. Included are the results of two experiments in which $^{131}I_2$ was used. The half-times observed here are in general agreement with those of Behrens and Maddock (6) for $^{131}I_2$ – methyl iodide exchange. The present results also support their contention that the apparent organic yield in dry, de-aerated, iodine-free methyl iodide must approach 100% due to rapid exchange. This can account for the high organic yield (3, 4) reported for the $^{127}I(n,\gamma)^{128}I$ reaction when irradiations were performed with little concomitant radiation damage. The value of 56% reported by Levey and Willard (2) suggests that irradiation may have produced sufficient iodine in their solutions to significantly increase the exchange half-times.

Organic Yield

The initial organic yield[5] of ^{126}I was determined in methyl iodide solutions containing from 3×10^{-7} to 0.34 mole fraction I_2. These results are given in Table 1 and illustrated in Fig. 2A. To determine the initial organic yields at the lower I_2 concentrations, it was necessary to follow the change in organic yield with time and to correct for exchange which had occurred during the irradiation and before analysis of the first sample. Between 3×10^{-5} and 3×10^{-7} mole fraction I_2 the initial organic yield remained essentially constant at 57%, even when the I_2 – methyl iodide solution, while being irradiated, was shaken with aqueous KI (see Table I, footnote *c*) in an attempt to convert the thermal, radioactive I atoms into the iodide form. This is in good agreement with the value of 56% reported by Levey and Willard (2) for the organic yield of ^{128}I in pure methyl iodide which may have acquired iodine during the irradiation (see preceding paragraph). The

[5]*The initial organic yield is that value which would have been observed if no exchange had occurred.*

[a]These values are the experimental determinations of the initial yields and have not been normalized.
[b]The yield of polyiodomethanes was calculated by subtracting the other organic products from the organic yield as described in the text.
[c]This solution was irradiated while shaking it with aqueous 0.01 *M* KI.
[d]This value of the organic yield was assumed to equal that marked [f].
[e]The activity in the *n*-C_3H_7I plus *n*-C_4H_9I distillate was 0.2%.
[f]See footnote [d].

decrease in organic yield which occurs as the mole fraction of I_2 is increased above 3×10^{-5} presumably arises from the very efficient scavenging of recoil atoms and free radicals by I_2.

Radioactive Organic Products

The analyses for some of the organic products of recoil ^{126}I in iodine – methyl iodide solutions are given in Table I. Obviously, the production of organic compounds must approach zero as the mole fraction of I_2 approaches unity. However, to a first approximation, the experimental yields of organic products can be corrected for that part of the decrease which is due solely to the dilution of methyl iodide by I_2 by simply dividing the yields by the mole fraction of methyl iodide. Results corrected in this manner will be designated as normalized yields, in the manner of Harris (14).

Methyl Iodide

In agreement with previous investigators (2, 3, 15) the most abundant organic product of ^{126}I was found to be $CH_3{}^{126}I$. In Fig. 2C the normalized yield of $CH_3{}^{126}I$ is plotted against the iodine concentration. Extrapolation of the curve suggests that the normalized yield of $CH_3{}^{126}I$ approaches 21% as the mole fraction of I_2 approaches unity.

Ethyl Iodide

The radioactivity which distilled with the ethyl iodide carrier probably represented only $C_2H_5{}^{126}I$ because no other unsaturated alkyl iodides boil within 16 °C of the boiling

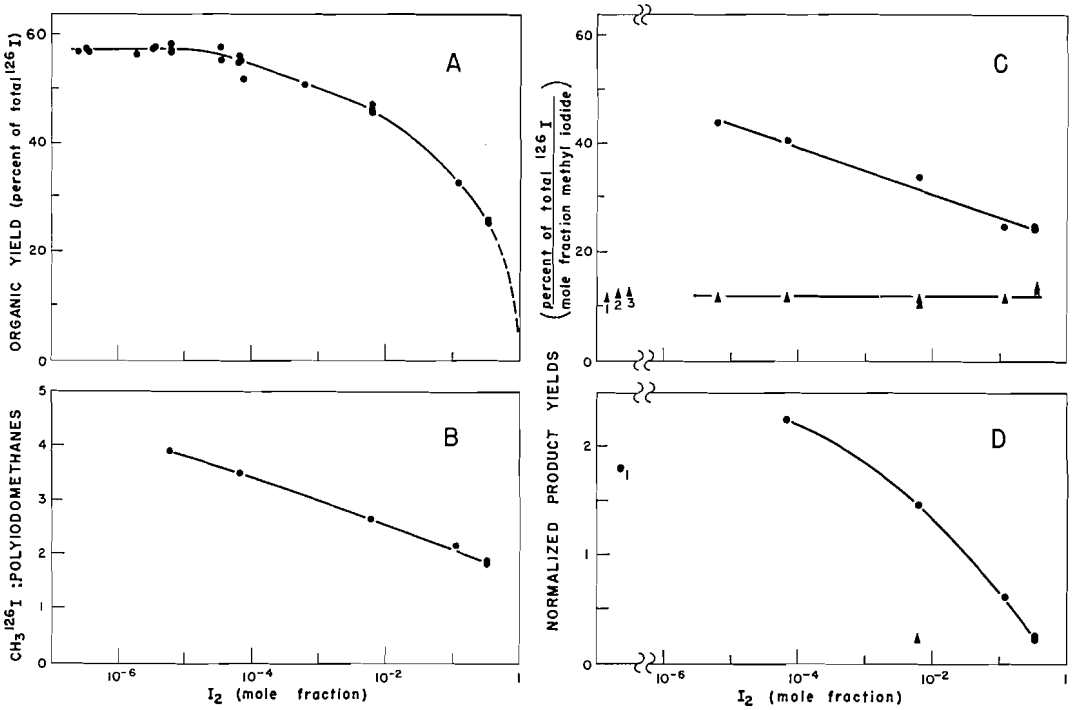

FIG. 2. The relation of products containing ^{126}I to the iodine concentration of the methyl iodide solution. In Fig. 2C ● $CH_3{}^{126}I$; ▲ ^{126}I in polyiodomethanes (in 1, 2, and 3 considerable exchange had occurred prior to analysis) (1) "pure" methyl iodide irradiated in the presence of solid potassium iodide, (2) 8×10^{-8} mole fraction I_2, (3) "pure" methyl iodide. In Fig. 2D ● $C_2H_5{}^{126}I$, (1) "pure" methyl iodide irradiated in the presence of solid potassium iodide; ▲ the activity which distilled with *n*-propyl iodide and *n*-butyl iodide.

point for ethyl iodide and because the specific activity of the distillate remained constant throughout its take-off interval. The normalized yield of $C_2H_5{}^{126}I$ (see Fig. 2D) approaches zero as the mole fraction of I_2 approaches unity. In one experiment in which "pure" methyl iodide was irradiated, the yield of $C_2H_5{}^{126}I$ was 1.8%. Thus, it appears that below 10^{-4} mole fraction I_2 the production of $C_2H_5{}^{126}I$ is about 2%.

Propyl and Butyl Iodide Fraction

A small amount of activity was found in the *n*-propyl iodide and *n*-butyl iodide distillate (see Fig. 2D). This activity, which could have been due to a number of products, represents less than 0.3% of the total activity. It appears that the fraction of ^{126}I in compounds containing more than two carbon atoms is very small indeed.

Polyiodomethanes

After distillation of *n*-butyl iodide from the organic products the undistilled residue still contained a significant fraction of the organic activity. This is believed to represent the higher boiling compounds $CH_2{}^{126}I_2$, $CH^{126}I_3$, and $C^{126}I_4$. This undistilled fraction will be referred to as the "polyiodomethanes". The production of polyiodomethanes bears a striking resemblance to the production of polybromomethanes by recoil Br atoms in bromine – methyl bromide, a system which has been examined in considerable detail by Harris (14). The activity of polyiodomethanes was not measured directly but was deduced by subtracting the activity of the $CH_3{}^{126}I$, the $C_2H_5{}^{126}I$, and the propyl butyl iodide fractions from the organic yield. In experiments where the relatively small contributions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of $C_2H_5{}^{126}I$ and of the propyl and butyl iodide fraction were not determined experimentally they were estimated from Fig. 2D. Three of the polyiodomethane estimates represent solutions in which considerable exchange had occurred prior to extraction of the inorganic products, and yet the normalized values of the polyiodomethane yields, as shown in Fig. 2C, remained constant at about 12% regardless of the iodine concentration or any exchange which may have occurred.

In an experiment with 0.34 mole fraction I_2 the polyiodomethane fraction was partially separated by distilling some of the diiodomethane. The experimental yield of $CH_2{}^{126}I_2$ was 6.3% and the activity due to undistilled, higher-boiling compounds was roughly 2.2% giving 8.5% as the total activity in the polyiodomethane fraction. By the subtraction method described above the total polyiodomethane activity was estimated to be 9.0%, a discrepancy which could be due to partial decomposition of $CH^{126}I_3$ and $C^{126}I_4$ during the distillation.

The Ratio $CH_3{}^{126}I$: Polyiodomethanes

The ratio $CH_3{}^{126}I$ activity : polyiodomethane activity vs. the mole fraction I_2 is shown in Fig. 2B for experiments in which no significant exchange occurred. The ratio appears to approach the value 1.6 as the mole fraction of I_2 approaches unity. The consistency of the data suggests that, independent of the organic yield, the experimental yields of $CH_3{}^{126}I$ and polyiodomethanes are quite accurate relative to one another.

Product Distribution at Low I_2 Concentrations

Below 10^{-5} mole fraction I_2, the $C_2H_5{}^{126}I$ and polyiodomethane yields remained essentially constant even in solutions which had experienced significant exchange. Since the initial organic yield was also constant at these concentrations it is evident that the initial yield of $CH_3{}^{126}I$ must also have been essentially constant.

The Exchange Reaction

In Fig. 3 the yield of $CH_3{}^{126}I$ is plotted against the observed organic yield. Organic yields above 57% represent experiments in which exchange occurred. By extrapolation it is seen that if exchange had been allowed to raise the organic yield to 100%, the apparent yield of $CH_3{}^{126}I$ would have been 85% leaving the other products essentially unaffected, at 12% polyiodomethanes, 2% $C_2H_5{}^{126}I$, and 1% other products. Therefore, within experimental error, exchange at low iodine concentrations serves only to increase the yield of $CH_3{}^{126}I$ and does not detectably affect the other organic products which are present in extremely low concentrations. These results may be compared with those of Behrens and Maddock (6) who found that 91% of the thermal exchange between $^{131}I_2$ and methyl iodide produced $CH_3{}^{131}I$. Badger, Chmiel, and Schuler (16) studied the exchange of $^{131}I_2$ with ethyl, *n*-propyl, and isopropyl iodides and found that $>98\%$ of the exchange transferred ^{131}I to the alkyl iodide comprising the solvent.

Reactions of Recoil Iodine Atoms

The thermal neutron (n,γ) reaction forms ^{128}I, with an estimated average recoil energy of the order of 100 eV (17) and with an average positive charge due to conversion and Auger electron emission. When gaseous ethyl iodide containing a little iodine is irradiated with thermal neutrons, the organic yield of ^{128}I is only 1% (18) indicating that almost every ^{128}I atom leaves the carbon atom which was the original partner. Formation of ^{126}I by the (n,2n) reaction gives ^{126}I atoms an estimated average recoil energy of 10^5 eV (17). The dissociation energy of the I—I bond in iodine is 1.5 eV and that of the C—I bond in methyl iodide is 2.4 eV. It may thus be safely assumed that an overwhelming

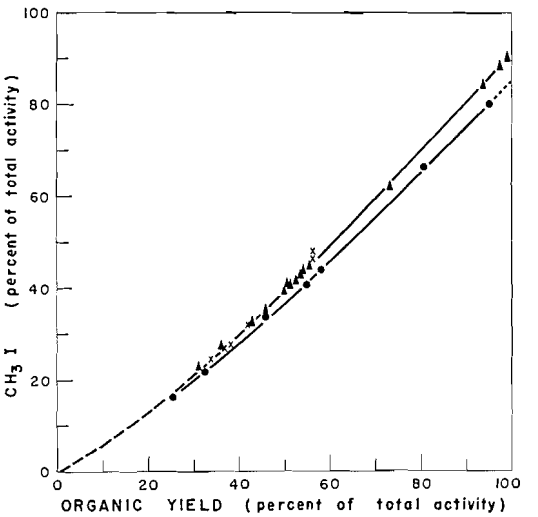

FIG. 3. The yield of radioactive CH_3I vs. the organic yield. × $CH_3{}^{128}I$ by Levey and Willard (2); ▲ $CH_3{}^{128}I$ by Brustad and Baarli (3); ● $CH_3{}^{126}I$ in present work.

proportion of the ^{126}I atoms formed will leave the atoms to which they were originally bound. If, as is likely, primary recombination is infrequent, then the reactions of all ^{126}I atoms, whether originating from I_2 or CH_3I, can be treated in the same manner.

It seems reasonable to attribute the products of ^{126}I in iodine – methyl iodide solutions to the three classes of reactions to which Harris (14) ascribed the products of recoil Br in the bromine – methyl bromide system. These are the reactions of thermalized recoil atoms, hot recoil atoms, and the diffusion-controlled reactions of recoil atoms in the spurs. The collisions which finally reduce the recoil atom to thermal energies leave it in a spur which contains a high local concentration of atoms and radicals. If the ^{126}I atom escapes combination with these atoms and radicals, it will diffuse freely in the solution. Its subsequent reactions are described as thermal. An iodine atom diffusing in the relatively unreactive solvent methyl iodide (19) will be very susceptible to scavenging by an exchange reaction with even minute concentrations of the extremely reactive iodine molecule (20). However, before escape from the spur can occur, the thermal ^{126}I atoms may undergo diffusion-controlled reactions with the reactive species in the spur. Only when the I_2 concentration is high enough to compete with, and for, these reactive species can I_2 significantly affect this class of diffusion-controlled reactions. On the other hand, reactions which are not influenced even by high concentrations of I_2, except to the extent of a simple dilution effect, are described as hot reactions. For example, the product of a hot reaction could be formed after a complete collisional transfer of energy from an energetic ^{126}I atom to a bound I atom if the thermalized ^{126}I atom, before diffusing, reacted with the fragments left by the departing I atom.

For each of the three classifications of reactions just described it is possible to predict the effect of allowing the mole fraction of I_2 to approach unity (as done by Harris (14) for the bromine – methyl bromide system). The normalized yields of organic products due solely to thermal reactions or diffusion-controlled reactions in the spurs must approach zero. The normalized yields of organic products due solely to hot reactions will, by definition, be unaffected by the I_2 concentration. If only a fraction of a product is formed by hot reactions, then its normalized yield will decrease with increasing I_2 concentration

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and approach a finite value (equal to the extent of its formation by hot reactions) as the mole fraction of I_2 approaches unity. The unvarying value of the normalized yield of polyiodomethanes (Fig. 2C) indicates that normalization to the mole fraction of methyl iodide provides a satisfactory correction for the dilution effect up to at least 0.34 mole fraction I_2. However, it is possible that at still higher I_2 concentrations a more complicated normalization factor might be required. For example, in a solution comprised mainly of iodine, with which an I atom can be thermalized in a single collision, the energy distribution (and hence the reactions) of ^{126}I might be radically different from that in a solution of lower iodine content.

The preceding paragraph describes how it is possible to assess fairly unambiguously that fraction of a product which is formed by hot reactions. For thermal reactions and diffusion-controlled reactions in the spurs the assignment is less certain. It has been reported (21) that the rate constant for the exchange of I atoms with liquid methyl iodide is 20 ml $mole^{-1}$ s^{-1} at 25 °C, whereas that for the exchange of I atoms with I_2 in hexane (20) is 8×10^{10} ml $mole^{-1}$ s^{-1}. Hence, for all experiments in which the initial organic yields were determined, the I_2 concentrations were sufficient to insure that essentially all the thermal, freely-diffusing I atoms were scavenged by I_2; so even between 3×10^{-5} and 3×10^{-7} mole fraction I_2, where the organic yield is constant, all organic products result solely from hot reactions or diffusion-controlled reactions in the spurs. Roy, Williams, and Hamill (22) report that at low I_2 concentrations 5% of the inorganic yield is due to hot reactions. It is of interest that, if the remainder of the inorganic products resulted from freely-diffusing I atoms, the probability that recoil I atoms escape their spurs would be very similar to the 40–60% of I atoms, produced by the photolysis of I_2 in hexane at 25 °C (23), which excape recombination with their initial partners. The decrease of normalized organic yield with increasing I_2 concentration, above 3×10^{-5} mole fraction I_2, is believed to result solely from the scavenging by I_2 of thermalized I atoms in the spurs.

The value of the initial organic yield in absolutely pure methyl iodide would be difficult to determine. As the I_2 content of the liquid is decreased, the exchange reaction reaches equilibrium with increasing rapidity. Moreover, irradiations would have to be terminated before a significant amount of I_2 had been formed. The most enlightening approach seems to be to determine the extent to which organic and inorganic products are formed by hot reactions, by thermal reactions, and by diffusion-controlled reactions in the spurs.

The maximum observed yield of the predominant organic product, $CH_3{}^{126}I$, was 43%. The normalized yield of $CH_3{}^{126}I$ approaches 21% as the mole fraction of I_2 approaches unity. On the basis of the suggested model, 21% of the ^{126}I forms $CH_3{}^{126}I$ by hot reactions whereas a maximum of 22% forms $CH_3{}^{126}I$ by diffusion-controlled reactions in the spurs. The normalized yield of polyiodomethanes remains constant over the entire range of I_2 concentrations studied. Hence, polyiodomethanes must be produced predominantly by hot reactions. At present, it is difficult to suggest mechanisms to account for the quite significant formation of $CH_2{}^{126}I_2$ and $CH_2{}^{128}I_2$ in neutron-irradiated methyl iodide. However, it has been shown that ^{128}I formed in the presence of CH_4 can form $CH_3{}^{128}I$ by a hot reaction with the direct displacement of a hydrogen atom (18, 24). The normalized yield of $C_2H_5{}^{126}I$ approaches zero as the mole fraction of I_2 approaches unity. Probably $C_2H_5{}^{126}I$ is formed through diffusion-controlled reactions of two 1-carbon fragments within the spurs. If so, it is not surprising that products containing more than two carbon atoms are formed to an even lesser extent than $C_2H_5{}^{126}I$.

The particular reactions by which the products are formed are still largely speculative. The recoiling atom probably generates active species such as I, CH_3, CH_2, CH, etc. To

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

account for the relative insensitivity of product distribution to recoil energy, Willard (17) has suggested that charge neutralization near the end of the recoil track is an important factor in determining the course of reactions. Since charge neutralization is likely to be very rapid, the final reactions probably involve mainly neutral I atoms. More recently, Geissler and Willard (25) have proposed that a major portion of the organic yield in alkyl iodides is due to combination with radicals formed by the conversion and Auger electrons emitted by the atom itself. This hypothesis derives from their observation that high yields of the parent alkyl iodide occur even in dilute pentane solutions.

The mechanism by which methyl iodide and I_2 exchange in the absence of light is not yet understood. Estimates of exchange via I atoms which are present in thermal equilibrium with I_2 (19, 26) indicate exchange half-times many orders of magnitude longer than those observed. A mechanism involving a complex between I_2 and CH_3I (13) does not appear consistent with the observed decrease of exchange half-time with decreasing I_2 concentration. The possibility of heterogeneous effects has already been noted (12). Minute quantities of impurities appear to exert a profound influence on the observed exchange, and these may well obscure the exchange for the perfectly pure system.

Influence of Recoil Energy

The average recoil energy of ^{126}I produced by 14 MeV neutrons is about 10^5 eV compared to about 100 eV for ^{128}I from thermal neutrons. The effect of recoil energy on the fate of I atoms has been studied a number of times (1, 27–29). In alkyl iodides the organic yields of ^{126}I were almost identical to those of ^{128}I. This was confirmed in the present experiments where it was possible to produce ^{126}I and ^{128}I simultaneously in methyl iodide solutions with about 90% of the ^{128}I resulting from slow neutrons. At 6×10^{-5} mole fraction I_2 the organic yield of ^{126}I was 55.9% and of ^{128}I was 54.6% (an absolute difference of $2.4 \pm 1.6\%$). At 6×10^{-3} mole fraction I_2 the organic yield of ^{126}I was 46.1% and of ^{128}I was 45.5% (an absolute difference of $1.3 \pm 1.6\%$); whereas the yields of total organic products other than CH_3I (hence predominantly the "hot" polyiodomethanes) were 12.4% for ^{126}I and 11.2% for ^{128}I (an absolute difference of $10 \pm 4\%$). These results suggest that the yields of products which are formed predominantly by hot or by thermal reactions will be more sensitive than the total organic yield to differences in recoil energy. This arises because the yields of the products may be affected in opposing ways, resulting in a partial cancellation of the effect. In Fig. 3, $CH_3{}^{128}I$ yields determined by others (2, 3) are shown for comparison with the present $CH_3{}^{126}I$ yields.

STEROIDS

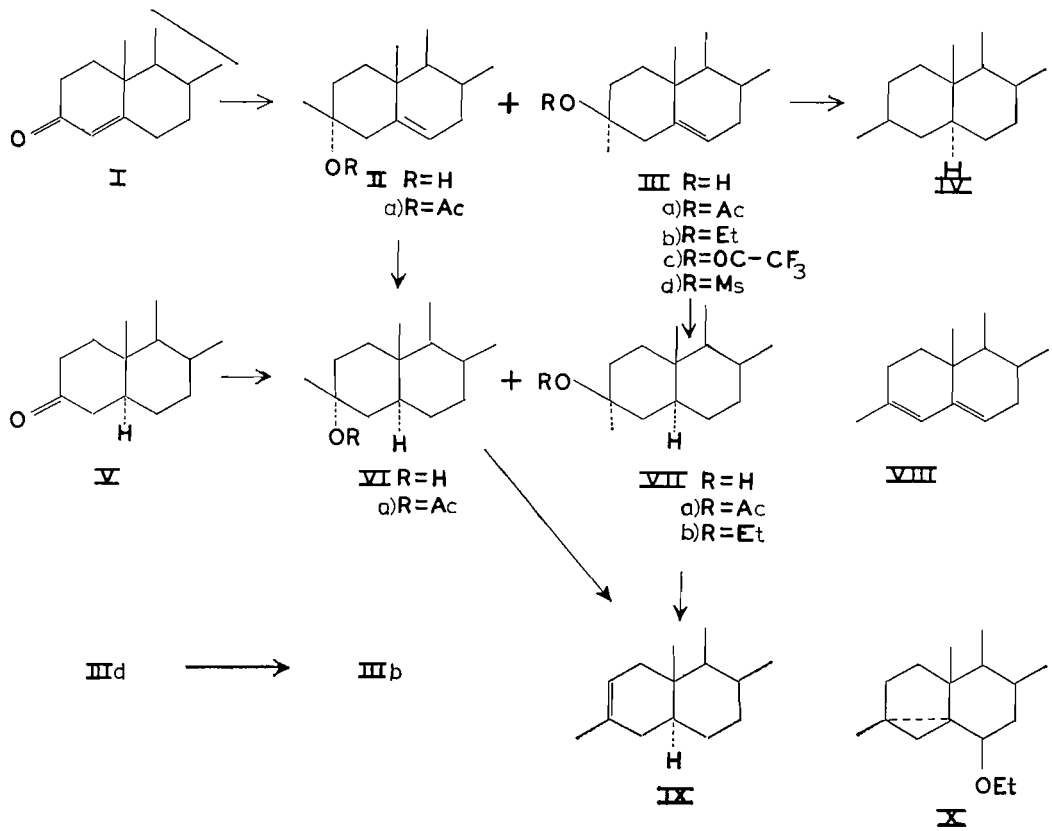
VIII. SOME REACTIONS OF THE 3-METHYLCHOLEST-5-EN-3-OLS AND THEIR DERIVATIVES[1]

G. JUST AND V. DI TULLIO[2,3]
Department of Chemistry, McGill University, Montreal, Quebec
Received December 27, 1963

ABSTRACT

The preparation and ethanolysis of 3-methylcholesteryl derivatives is described. It was noticed that Δ^5-3-methyl-3-oxygenated steroids undergo hydrogenolysis, which can be suppressed by addition of sodium nitrite.

During the work described in the preceding paper (3), we required samples of the epimeric 3-methylcholest-5-en-3-ols II and III and their reduction products VI and VII, as well as their respective acetates and ethyl ethers.



[1]*Part VII. See ref. 2.*
[2]*This work was supported by the National Research Council of Canada.*

Cholest-5-en-3-one (I) (4) was treated with methyl magnesium iodide. Chromatographic separation of the reaction product on alumina gave 3β-methylcholest-5-en-3α-ol (II), cholest-4-en-3-one, and 3α-methylcholest-5-en-3β-ol (III) in that order. The stereochemical assignments of the epimeric alcohols II and III were based on their relative ease of elution and the reactions described below. The possibility of the product being 4-en-3-ols can be excluded, since such allylic alcohols would have been dehydrated under the experimental conditions employed (5, 6).

The infrared spectrum of the 3α-alcohol II showed an absorption peak at 3 580 cm^{-1} (7). This band is shifted towards a lower frequency probably because of hydrogen bonding with the Δ^5-double bond, itself characterized by a nuclear magnetic resonance (n.m.r.) signal centered at 5.4 p.p.m. Attempted acetylation of alcohol II with acetic anhydride in pyridine at room temperature gave starting material. Treatment of the lithium salt of alcohol II with acetyl chloride (8) gave a good yield of acetate II*a*, ν 1 728, 1 274, and 1 239 cm^{-1}. Catalytic reduction of II in acetic acid, using Adam's catalyst, gave 3-methylcholestane (IV) (9). However, when sodium nitrite was added to the reducing mixture the hydrogenolysis reaction was suppressed (1) and a quantitative yield of the expected alcohol VI (8) was obtained.

3α-Methylcholest-5-en-3β-ol (III) showed, in the infrared, an unsymmetrical absorption band at 3 608 cm^{-1} and, in the n.m.r., a signal for a single proton centered at 5.45 p.p.m., which can be assigned to the C_6-olefinic hydrogen. Treatment of alcohol III with acetic anhydride in pyridine at room temperature gave starting material. At reflux temperature, a mixture of 3-methylcholesta-3,5-diene (VIII) and 3α-methylcholesteryl acetate (III*a*) was obtained. However, treatment of the lithium salt of III (8) with acetyl chloride gave a good yield of III*a*. Catalytic reduction of III resulted in the formation of 3-methylcholestane (IV) (9) and 3α-methylcholestan-3β-ol (VII) (8) in approximately 20 and 80% yield respectively. The hydrogenolysis could be eliminated by addition of sodium nitrite to the reducing mixture (1).

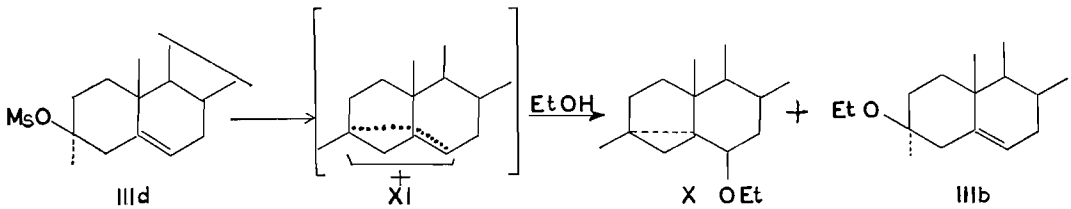
Since hydrogenolysis of homoallylic alcohols is somewhat unusual, we investigated this reaction to exclude the possibility of dehydration under the reaction conditions. 3β-Methylcholest-5-en-3α-ol (II), which had given hydrogenolysis products exclusively, was used as a model substance for more detailed work. A sample, dissolved in acetic acid containing prereduced platinum, was kept overnight under 60 p.s.i. of nitrogen at 40°. Only starting material was recovered. A similar reaction carried out at 100° and atmospheric pressure for 16 h, converted 19% of alcohol II to 3-methylcholesta-3,5-diene (VIII). These experiments prove that hydrogenolysis could have occurred by a dehydration–hydrogenation sequence to a small extent only, if at all.

The reaction of cholestan-3-one (V) with methyl magnesium iodide, described by Barton and co-workers (8), gave a 1:1 mixture of the epimeric 3-methylcholestanols VI and VII. In the reaction on cholest-5-en-3-one (I), we obtained the two alcohols II and III in 4 and 63% yield respectively. We proposed recently (10) that the ratio of axial to equatorial alcohols obtained in Grignard reactions depended on the degree of steric hindrance due mainly to 1,3-diaxial interactions. Removal of a hydrogen at the 5-position by introduction of a Δ^5-double bond should decrease the hindrance at C_3 and result in the formation of a large amount of 3β-alcohol. The yields of the alcohols obtained support the hypothesis. An electronic effect of the Δ^5-bond can be excluded since participation of the double bond during Grignard reaction would have favored the other epimer.

When alcohols VI and VII were treated with acetic anhydride or acetyl chloride in

pyridine at room temperature, only starting materials were recovered. When acetic anhydride, acetic acid, and *p*-toluene sulfonic acid (11) were used as an acetylating medium, 3-methylcholest-2-ene (IX), which appeared to be identical with IX described by Barton (8), was obtained in approximately 60% yield from either alcohol VI or VII. When the lithium salts of alcohols VI and VII (8) were treated with acetyl chloride, good yields of the acetate VI*a*, ν 1 730, 1 273, and 1 239 cm^{-1}, and VII*a*, ν 1 730 and 1 245 cm^{-1}, were obtained.

Attempts to form an ethyl ether of alcohol VII either by treatment of a lithium or sodium salt of VII with an ethyl halide (8, 12) or by reduction of acetate VII*a* with sodium borohydride and boron trifluoride etherate (13) failed. Hence it appeared necessary to find another reaction to transform a tertiary alcohol to its ethyl ether. Ethanolysis of a suitable derivative of 3α-methylcholesterol (III) should proceed through the homoallylic ion XI and give ethers III*b* and X. The methyl group at C_3 should stabilize a positive charge at the 3-position, and 3β-ethoxy-3α-methylcholest-5-ene (III*b*) should be formed as a major product.



3α-Methylcholest-5-en-3β-ol (III) was converted to its trifluoroacetate III*c* by trifluoroacetic anhydride in pyridine at 0° (14). The trifluoroacetate III*c* was heated under reflux overnight in ethanol containing either potassium ethoxide or potassium acetate. Only starting alcohol III was obtained. Attempts to form the tosylate of the 3β-alcohol III failed. When 3α-methylcholest-5-en-3β-ol was reacted with methanesulfonyl chloride in pyridine at −5° overnight, 3-methylcholesta-3,5-diene (VIII) and starting material were isolated in 54 and 15% yields respectively. However, if the mesylation reaction was quenched with ethanol as soon as crystals of pyridine hydrochloride started to form and the mixture evaporated, there was obtained after chromatography on silica gel, 3-methylcholesta-3,5-diene (VIII) and 3β-ethoxy-3α-methylcholest-5-ene (III*b*), in 22 and 48% yields respectively. No trace of 6β-ethoxy-3β-methyl-3α,5-cyclo-5α-cholestane (X) could be detected. The ether III*b* was identical with 3β-ethoxy-3α-methylcholest-5-ene, obtained in the photolysis of 3-methylcholesta-3,5-diene (3).

EXPERIMENTAL[4]

Preparation of 3α-Methylcholesterol (III) and 3β-Methylcholest-5-en-3α-ol (II)

The alcohols II and III were prepared by adding 5 g of solid cholest-5-en-3-one (4) to 250 ml of an ethereal solution of an excess of methyl magnesium iodide. The solution was heated under reflux overnight. The excess reagent was destroyed by slowly adding 5 g of ammonium chloride in 25 ml of water. The ether layer was washed with water until neutral, dried over magnesium sulfate, and evaporated at 40° under reduced pressure. The oily residue was chromatographed on alumina (activity II–III, 150 g). Elution with benzene–ether (99:1) gave 3β-methylcholest-5-en-3α-ol (II) (214 mg, 4%), m.p. 112–115°. Three crystallizations from acetone raised the m.p. to 119–120°, $[\alpha]_D$ −28.6° (*c* 1.3), 3 580 cm^{-1}, δ 5.4 p.p.m. (1H, broadened singlet, C=C_6—H).

Anal. Calcd. for $C_{28}H_{48}O$: C, 83.93; H, 12.08. Found: C, 84.02; H, 12.00.

For personal use only.

Further elution with benzene–ether (9:1) gave cholest-4-en-3-one (1.2 g), identified by melting point, mixed melting point, and ultraviolet (λ_{max}^{EtOH} 239 mμ, $\lambda_{max}^{cyclohexane}$ 232 mμ).

Ether eluted 3α-methylcholesterol (III) (3.275 g, 63%), m.p. 161°. Three crystallizations from chloroform–ether raised the m.p. to 169–170°, $[\alpha]_D$ −27° (*c* 1.8), ν 3 608 cm^{-1}, δ 5.45 p.p.m. (1H, singlet, C=C_6—H).

Anal. Calcd. for $C_{28}H_{48}O$: C, 83.93; H, 12.08. Found: C, 83.77; H, 12.06.

3β-Methylcholestan-3α-ol (VI) and 3α-Methylcholestan-3β-ol (VII)

Using the condition described (8), 3β-methylcholestan-3α-ol (VI), m.p. 129° (lit. 126–127°), ν 3 610 cm^{-1}, and 3α-methylcholestan-3β-ol (VII), m.p. 150–151° (lit. 147–149°), ν 3 608 cm^{-1} were obtained in 51 and 45.5% yield respectively.

The Acetates of the 3-Methylcholest-5-ene-3-ols (IIa, IIIa) and 3-Methylcholestan-3-ols (VIa, VIIa)

1. An anhydrous ether solution (10 ml) of 3β-methylcholest-5-en-3α-ol (237 mg) was added to phenyl lithium (prepared from 261 mg of phenyl bromide and 190 mg of lithium in 50 ml of anhydrous ether) and stirred 4 h at room temperature (8). Acetyl chloride (2 ml) was added to the solution and the mixture stirred overnight. Methanol was added to the reaction mixture, which was then diluted with water. The ether extract was washed neutral, dried over magnesium sulfate, and evaporated under vacuum at 40°. The oily residue was chromatographed on alumina (activity II–III, 20 g). Elution with hexane gave 183 mg of 3β-methylcholest-5-en-3α-yl acetate (IIa) (70%), m.p. 70–71°. Recrystallization from acetone raised the m.p. to 75–76°, $[\alpha]_D$ −19.1° (*c* 1.3), ν 1 728, 1 274, and 1 239 cm^{-1}.

Anal. Calcd. for $C_{30}H_{50}O_2$: C, 81.39; H, 11.38. Found: C, 81.35; H, 11.67.

2. Similarly, alcohol III was transformed to 3α-methylcholesteryl acetate (IIIa) (61%), recrystallized from acetone, m.p. 129–130°. $[\alpha]_D$ −26.3° (*c* 1.2), ν 1 734 and 1 247 cm^{-1}.

Anal. Calcd. for $C_{30}H_{50}O_2$: C, 81.39; H, 11.38. Found: C, 81.73; H, 10.95.

3. Alcohol VI was transformed to its acetate VIa (85%), m.p. 87–89°, using the same conditions described above. Recrystallization from acetone raised the m.p. to 89–90°, $[\alpha]_D$ 26.4° (*c* 1.6), ν 1 730, 1 273, and 1 239 cm^{-1}.

Anal. Calcd. for $C_{30}H_{52}O_2$: C, 81.02; H, 11.79. Found: C, 81.21; H, 11.60.

4. Alcohol VII was also transformed to its acetate VIIa (67%), m.p. 110–114°. Recrystallization from acetone raised the m.p. to 114–115°, $[\alpha]_D$ 24.9° (*c* 0.9), ν 1 730 and 1 245 cm^{-1}.

Anal. Calcd. for $C_{30}H_{52}O_2$: C, 81.02; H, 11.79. Found: C, 81.19; H, 11.55.

3α-Methylcholest-5-en-3β-yl Trifluoroacetate (IIIc)

Alcohol III (105 mg, 0.21 mmole) was dissolved in 8 ml of pyridine (0 °C) followed by the addition of 3 ml of trifluoroacetic anhydride at −8° (14). The solution was kept at 0° for 5 min. As 25 ml of ice-cold water was added to the mixture, crystals began to form. The trifluoroacetate IIIc (107 mg), m.p. 132°, was washed free of trifluoroacetic acid and then crystallized from ether–methanol, m.p. 134–135°, $[\alpha]_D$ −22.6° (*c* 1.0), ν 1 780, 1 220, 1 168, and 1 095 cm^{-1}.

Anal. Calcd. for $C_{30}H_{47}O_2F_3$: C, 72.59; H, 9.46; F, 11.50. Found: C, 72.24; H, 9.59; F, 11.33.

Hydrogenation of 3-Methylcholest-5-en-3-ols (II, III) in the Presence and Absence of Sodium Nitrite

1. Platinum oxide (201 mg) and 255 mg of 3β-methylcholest-5-en-3α-ol (II) were added to 50 ml of acetic acid and hydrogenated in a Parr apparatus at 70° and 60 p.s.i. for 10 h. The platinum was filtered off and the filtrate diluted with 50 ml of concentrated aqueous sodium carbonate and ether. The ether layer was washed neutral, dried over magnesium sulfate, and evaporated under vacuum. The crystalline residue, m.p. 99°, was chromatographed on alumina (activity II–III, 10 g). The only crystalline compound eluted (by hexane) was 177 mg of 3-methyl-cholestane (IV), m.p. 99–100°. It was identified by mixed melting point and comparison of the infrared spectra with an authentic sample prepared below.

2. Under similar reaction conditions, 125 mg of 3α-ol II, dissolved in 25 ml of acetic acid, was hydrogenated in the presence of 95 mg of platinum oxide and 18 mg of sodium nitrite. The oily residue (138 mg) was chromatographed on alumina (activity II–III, 10 g). Elution with benzene gave 114 mg of 3β-methylcholestan-3α-ol (VI), m.p. 129°, identified by mixed melting point and comparison of its infrared spectrum with that of an authentic sample prepared above.

3. 3α-Methylcholesterol (III) (320 mg) in 30 ml of acetic acid was hydrogenated at room temperature and 60 p.s.i. in the presence of 200 mg of platinum oxide. The oily residue was chromatographed on alumina (activity II–III, 10 g). Elution with hexane gave 68 mg of 3-methylcholestane, m.p. 99°. Further elution with benzene gave 258 mg of 3α-methylcholestan-3β-ol (VII), m.p. 151°. The two compounds were identified by comparison with authentic samples (melting point, mixed melting point, and infrared) prepared above and below.

4. Alcohol III (230 mg) in 25 ml of acetic acid was hydrogenated in the presence of 210 mg of platinum oxide and 27 mg of sodium nitrite, using the same conditions described above. The crystalline residue, m.p. 120–122°, was chromatographed on alumina (activity II–III, 10 g). Benzene eluted 204 mg of 3α-methylcholestan-3β-ol (VII), m.p. 151–152°, identified by mixed melting point and comparison of its infrared spectrum with that of an authentic sample.

3-Methylcholestane (IV)

3-Methylcholesta-3,5-diene (VIII) (105 mg) in acetic acid was hydrogenated overnight in the presence of 140 mg of platinum oxide at 40° and 60 p.s.i. The crystalline reaction product, m.p. 93–95°, was recrystallized from hexane–acetone to give 81 mg of hydrocarbon IV, m.p. 99–100° (lit. 96–97° (6*b*)), $[\alpha]_D$ 23.3° (*c* 0.99).

Anal. Calcd. for $C_{28}H_{50}$: C, 86.97; H, 13.03. Found: C, 87.01; H, 13.11.

Treatment of 3β-Methylcholest-5-en-3α-ol (II) with Acetic Acid and Platinum

1. When alcohol II (83 mg) and 84 mg of platinum in 25 ml of acetic acid were heated at 40° in a 60 p.s.i. nitrogen atmosphere overnight, only starting material was recovered.

2. Repetition of the reaction using the recovered platinum (75 mg) from above along with 103 mg of alcohol II in 15 ml of acetic acid at 100° and atmospheric pressure for 16 h gave 96 mg of an oily residue. Chromatography on alumina (activity II–III, 8 g) and elution with hexane gave 19 mg of 3-methylcholesta-3,5-diene (VIII), m.p. 79°. Further elution with benzene gave 72 mg of starting material, m.p. 129°. Both samples were identified by comparison of their infrared spectra and by mixed melting point with authentic samples.

3-Methylcholest-2-ene (IX)

1. 3β-Methylcholestan-3α-ol (VI) (216 mg) was treated with an acetic anhydride – acetic acid – *p*-toluenesulfonic acid mixture as described by Turner (11) and 207 mg of crystalline 3-methylcholest-2-ene (IX), m.p. 82°, was obtained. The infrared spectrum showed no hydroxyl or carbonyl bands. Crystallization from ether–methanol raised the m.p. to 84–85°, $[\alpha]_D$ 71.6° (*c* 1.8), δ 1.63 p.p.m. (3H, singlet, C=C—CH_3), 5.27 p.p.m. (1H, poorly resolved doublet, C=CH—CH_2).

Anal. Calcd. for $C_{28}H_{48}$: C, 87.42; H, 12.58. Found: C, 87.51; H, 12.39.

2. When alcohol VII (107 mg) was treated under the same conditions, 100 mg of olefin IX, m.p. 84–85°, was obtained. There was no depression in melting point upon admixture of 3-methylcholest-2-ene (IX) obtained above.

3. 3α-Methylcholestan-3β-ol (VII) (141 mg) was heated under reflux overnight with 207 mg of sodium hydride and 5 ml of ethyl iodide in 20 ml of toluene (12). Work-up of the reaction mixture gave 114 mg of crystalline olefin IX, m.p. 78°. Recrystallization from ether–methanol raised the m.p. to 84–85°, which was not depressed upon admixture of 3-methylcholest-2-ene (IX).

Preparation and Ethanolysis of 3α-Methylcholest-5-en-3β-ol Mesylate (IIId)

To 3α-methylcholesterol (III) (169 mg) dissolved in 20 ml of pyridine at −5 °C, was added 10 ml of cold (−8°) methanesulfonyl chloride. The solution was kept at −5° for 1 h and then poured into 500 ml of absolute ethanol. The ethanol was evaporated. The oily residue was taken up in ether, washed neutral with water and then saturated sodium chloride solution, and evaporated. The oily residue (143 mg) was chromatographed on silica gel (10 g). Elution with hexane gave 36 mg of 3-methylcholesta-3,5-diene (VIII), m.p. 79–80°, λ_{max}^{EtOH} 232, 239, and 248 mμ (log ε 4.26, 4.29, and 4.16). Further elution gave 87 mg of 3β-ethoxy-3α-methylcholest-5-ene (III*b*), m.p. 124–125°. Recrystallization from acetone raised the m.p. to 125–126°. Ether III*b* was identified by comparison (mixed melting point and infrared and n.m.r. spectra) with a sample obtained elsewhere (3).

ACKNOWLEDGMENTS

We wish to thank Dr. C. Stammer of these laboratories for taking the n.m.r. spectra.

THE STRUCTURE OF INDACONITINE[1]

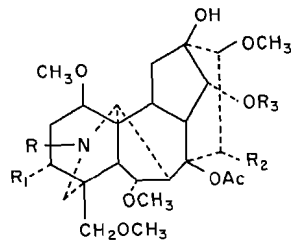
ROBERT E. GILMAN[2] AND LÉO MARION
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received August 14, 1964

ABSTRACT

The alkaloid indaconitine has been converted into delphinine by replacement of a secondary hydroxyl by hydrogen and substitution of an imino-methyl for the imino-ethyl group originally present. This correlation rigorously establishes the structure of indaconitine and its absolute configuration. The product of the saponification of indaconitine, pseudaconine, is identical with the product of the saponification of pseudaconitine, and this last alkaloid has been correlated previously with aconitine. It follows that the secondary hydroxyl which was removed in the conversion of indaconitine to delphinine has the same configuration as in aconitine.

Indaconitine ($C_{34}H_{47}O_{10}N$) has been isolated from *Aconitum chasmanthum* Stapf by Dunstan and Andrews (1) nearly sixty years ago. According to these authors, it melts at 202–203°, has $[\alpha]_D$ +18.3° (EtOH), and forms crystalline salts. Further, on acid hydrolysis it yields acetic acid and benzoylpseudaconine, while on alkaline hydrolysis it produces acetic acid, benzoic acid, and pseudaconine ($C_{25}H_{41}O_8N$) which still contains the four methoxyl groups present in indaconitine. The alkamine, pseudaconine, is identical with that produced in the alkaline hydrolysis of pseudaconitine ($C_{36}H_{51}O_{12}N$). When heated above its melting point, indaconitine loses one mole of acetic acid and gives rise to pyroindaconitine ($C_{32}H_{43}O_8N$). It has also been established that indaconitine contains an imino-ethyl group (2).

In its behavior on hydrolysis and on pyrolysis indaconitine resembles aconitine I (R = Et; $R_1 = R_2 = OH$; $R_3 = C_6H_5CO$) and delphinine I (R = Me; $R_1 = R_2 = H$; $R_3 = C_6H_5CO$).

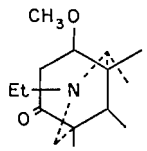


I

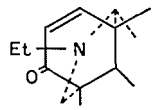
Since the empirical formula of indaconitine differs from that of aconitine only in containing one oxygen less, it has been assumed as a working hypothesis that indaconitine possessed the same carbon–nitrogen skeleton as aconitine (3, 4) and that it lacked one of the three hydroxyls present in the latter. The first step in the investigation, which has been the subject of a preliminary communication (5), was to determine which of the hydroxyls present in aconitine was absent in indaconitine.

[1]*Issued as N.R.C. No. 8140.*
[2]*National Research Council of Canada Postdoctoral Fellow.*

Aconitine is known to be oxidized by chromic oxide to the ketone, aconitinone (partial formula II), which readily loses the elements of methanol to form the $\alpha\beta$-unsaturated



II

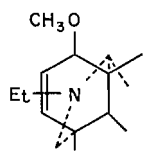


III

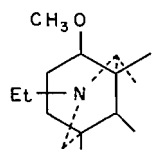
ketone, aconitoline III (6). Indaconitine has been found to undergo a similar oxidation with the formation of indaconitoline ($C_{33}H_{45}O_9N$), which is an $\alpha\beta$-unsaturated six-membered cyclic ketone as suggested by an absorption band at 1 675 cm^{-1} (CO) in its infrared spectrum and one at 710 cm^{-1} indicative of a double bond. Hence, like aconitine, indaconitine seems to contain a secondary hydroxyl group at R_1.

In the pyrolysis of aconitine (in which R_2 = OH) the acetoxy group is eliminated with a neighboring hydrogen, and there results the formation of an enol that tautomerizes to a ketone (7). On the other hand, in the pyrolysis of delphinine (in which R_2 = H) a similar elimination takes place resulting in the formation of an olefinic bond (8, 9). Pyroindaconitine, the product of the pyrolysis of indaconitine, was transesterified to pyropseudaconine, which showed no carbonyl absorption in the infrared but did show an absorption band at 1 620 cm^{-1} indicative of a double bond. It has been shown previously (10) that the double bond in pyropseudaconine can be isomerized and can be hydrogenated just like the double bond in pyrodelphonine. It can thus be concluded that it is the R_2 hydroxyl of aconitine that is absent in indaconitine, and that the structure of the latter must be represented by I (R = Et; R_1 = OH; R_2 = H; R_3 = C_6H_5CO). In order to prove or disprove this conclusion an attempt was made to convert indaconitine into delphinine by removal of the R_1 hydroxyl and replacement of the *N*-ethyl group by an *N*-methyl group.

Indaconitine when refluxed with thionyl chloride lost the elements of water and was converted into anhydroindaconitine, $C_{34}H_{45}O_9N$ (IV), which was purified as its perchlorate. Catalytic hydrogenation of anhydroindaconitine in absolute ethanol over platinic oxide gave rise to deoxyindaconitine (V) which, when refluxed in 3% acetic acid with



IV



V

mercuric acetate, lost the imino-ethyl group. The amorphous secondary base, *N*-desethyl-deoxyindaconitine, thus produced had an n.m.r. spectrum that contained no ethyl group signal. That no other change had taken place in the course of the last reaction than the removal of the imino-ethyl group was ascertained by conversion of a small quantity of the product to deoxyindaconitine via the action of ethyl iodide.

Refluxing *N*-desethyl-deoxyindaconitine for 1 h with methyl iodide gave *N*-methyl-*N*-desethyl-deoxyindaconitine, m.p. 188–192°, $[\alpha]_D^{27}$ +26° (EtOH). The recorded physical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

constants of delphinine are $[\alpha]_D^{25}$ +25° (EtOH) and m.p. 198–200°. The melting point was not altered by mixture of the product with an authentic sample of delphinine. The behavior of the product on a chromatoplate was identical with that of delphinine, and a mixture of the two gave only one spot. The infrared absorption spectra of both were superimposable, and the X-ray powder patterns were identical.

The conversion of indaconitine into delphinine confirms the correctness of the assumed structure of indaconitine I (R = Et; R_1 = OH; R_2 = H; R_3 = C_6H_5CO). Since the reactions involved in the conversion do not disturb the asymmetric centers of the molecule except for the removal of the R_1 hydroxyl, the stereochemical arrangement present in delphinine must also be present in indaconitine. Furthermore, since pseudaconitine has been correlated with aconitine (10), and the hydrolytic alkamine derived from indaconitine is identical with that derived from pseudaconitine, it follows that the stereochemistry of the R_1 hydroxyl of indaconitine is the same as that of the R_1 hydroxyl of aconitine.

Consequently, the conversion of indaconitine into delphinine not only proves the structure of indaconitine, but also establishes its absolute configuration to be the same as that of aconitine and delphinine. The relative positions and the configurations of the two ester groups in indaconitine which are derived from the correlation are also confirmed by the n.m.r. characteristics of the alkaloid (cf. ref. 11).

EXPERIMENTAL

In all column chromatographic separations, Woelm neutral alumina was used. Melting points were determined on a Kofler hot stage. The n.m.r. spectra were obtained on a Varian A-60 instrument.

Indaconitine

The indaconitine used in this investigation was isolated from the root of *Aconitum chasmanthum* Stapf.[3] It was purified by chromatography in ether solution over grade III alumina, and eluted with benzene–chloroform (4:1). The base recovered from the second fraction of the eluate was crystallized several times from ether, from which it separated as colorless hexagonal plates, m.p. 193–195° (decomp.), $[\alpha]_D^{25}$ +19.2° (*c*, 0.78 in EtOH).

Anal. Calcd. for $C_{34}H_{47}O_{10}N$: C, 64.86; H, 7.47. Found: C, 64.63; H, 7.40%.

The n.m.r. spectrum indicates the presence of four methoxyl groups, one *O*-acetyl, and one imino-ethyl.

Indaconitoline

Indaconitine (208 mg) was dissolved in acetone (10 ml). The solution was cooled to 5° and added to a solution of chromic oxide (210 mg) in acetone (10 ml) also previously cooled to 5°. The reaction mixture was set aside at room temperature for 2 d, by which time it had formed a bulky brown deposit. The mixture was evaporated to dryness, water was added to the residue, and a stream of sulfur dioxide was bubbled through until a clear solution was obtained (15 min). The solution was made basic (pH 8) with solid potassium carbonate and repeatedly extracted with chloroform. The combined extract was washed with water, dried over sodium sulfate, and evaporated to dryness. A residual colorless glass was left which was dissolved in ether; the solution was filtered and evaporated to dryness. The ether-soluble residue was dissolved in a 1:1 benzene–hexane mixture and chromatographed on grade III alumina. The chromatogram was eluted first with 1:1 benzene–hexane, then with benzene, and finally with chloroform. The chloroform eluate yielded the bulk of the material which was further purified by large scale thin-layer chromatography on silica gel, with benzene–cyclohexane–ethylamine (4.5:4.5:1) as developing solvent. The top main band was scraped off and extracted with chloroform, and the product left after evaporation of the chloroform was crystallized from ether – petroleum ether. The colorless indaconitoline (at a slow rate of heating) melted at 208–211° (decomp.).

Anal. Calcd. for $C_{33}H_{41}O_9N$: C, 66.54; H, 6.94; N, 2.35. Found: C, 66.41; H, 6.88; N, 2.43%.

Infrared spectrum analysis: ν, 1 725 cm^{-1} (ester carbonyl), 1 675 cm^{-1} ($\alpha\beta$-unsaturated six-membered cyclic ketone), 1 225 cm^{-1} (acetyl ester), 710 cm^{-1} (C=C).

Pyroindaconitine

Indaconitine (710 mg) was introduced into a distillation bulb which was then evacuated to 5 mm and heated in an air bath at 200–205° for 4 min. Evolution of gas took place. After cooling, the residue in the bulb was dissolved in ether, chromatographed in grade IV alumina, and eluted with ether. The residue (465 mg)

[3]*Obtained through the courtesy of Mr. K. L. Handa, Regional Research Laboratory, Jammu, India, to whom we express our gratitude.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

from the ether eluate was a colorless gum that could not be induced to crystallize. In the n.m.r. the acetyl protons signal was no longer present.

Pyroindaconitine (465 mg) was dissolved in absolute ethanol (30 ml) and a few mg of sodium was added to the solution which was left at room temperature for 2.5 h. The solution was evaporated to dryness, and the residue was dissolved in water and extracted with petroleum ether to remove the ethyl benzoate. The aqueous liquor was then extracted with chloroform, the extract was evaporated to dryness, and the residue was crystallized from ether. This product partially melted at 89–90°, resolidified, and melted at 157–167° (decomp.). In admixture with an authentic sample of pyropseudaconine (12), the behavior on melting was identical. The infrared spectrum contained a band at 1 620 cm^{-1} indicative of a double bond, but contained no carbonyl absorption. Pyropseudaconine readily forms a perchlorate which crystallizes from acetone–ether as colorless clusters, m.p. 215–225° (decomp.).

Anhydroindaconitine

Indaconitine (500 mg) was dissolved in thionyl chloride (previously distilled from quinoline) (5 ml), and the solution was refluxed for 4 h. The thionyl chloride was distilled off *in vacuo* and the residue (470 mg) was dissolved in methanol. The methanolic solution was evaporated to dryness, and the residue was dissolved in water, made basic (pH 8) with sodium carbonate, and extracted with three portions of chloroform. The combined extract was washed with water, dried over sodium sulfate, and evaporated to dryness. The residue from the extract was dissolved in benzene–chloroform (2:1), chromatographed over grade III alumina, and eluted with the same solvent. Fractions of 50 ml were collected. Fractions 2 to 11 were combined and the residue left after evaporation was crystallized from chloroform. The crystalline base was converted to the perchlorate, which crystallized from methanol–ether as colorless prisms, m.p. 190–203° (decomp.), $[\alpha]_D^{27}$ +31° (*c*, 0.5 in EtOH).

Anal. Calcd. for $C_{34}H_{45}O_9N \cdot HClO_4$: C, 57.45; H, 6.53. Found: C, 57.32; H, 6.51%.

Deoxyindaconitine

Anhydroindaconitine (720 mg) recovered from the perchlorate was dissolved in 95% ethanol and hydrogenated catalytically over platinum oxide. The product, worked up as usual, was dissolved in methylene chloride, chromatographed on grade III alumina, and eluted with methylene chloride. The eluate yielded 520 mg of benzene-soluble substance which was crystallized from hexane, m.p. 175–180° (decomp.), $[\alpha]_D^{27}$ +14° (*c*, 0.6 in EtOH).

Anal. Calcd. for $C_{34}H_{47}O_9N$: C, 66.54; H, 7.72; N, 2.28. Found: C, 66.69; H, 7.55; N, 2.40%.

The perchlorate of the base, which separated from methanol–ether as large colorless crystals, decomposed at 177–183°.

Anal. Calcd. for $C_{34}H_{47}O_9N \cdot HClO_4$: C, 57.18; H, 6.77. Found: C, 56.89; H, 6.52%.

N-Desethyl-deoxyindaconitine

Deoxyindaconitine (95 mg) was dissolved in 3% acetic acid (25 ml) and the solution warmed on the steam bath. Mercuric acetate (500 mg) was added, and the solution was kept on the steam bath for 8 h and allowed to stand overnight at room temperature. The reaction mixture was filtered and the filtrate extracted with three portions of chloroform. The combined extract was washed with aqueous sodium bicarbonate and with water, dried, and evaporated to dryness. The residue (56 mg) was dissolved in benzene–hexane (1:1) and chromatographed on grade III alumina. The column was eluted first with benzene–hexane, then in succession with benzene, 10% methylene chloride in benzene, 1:1 methylene chloride – benzene, and methylene chloride. The last fraction eluted with methylene chloride yielded only a trace of product, which no longer contained starting material. The elution was then continued with chloroform, which yielded 32 mg of product. This product, which could not be induced to crystallize, showed no signal indicative of the *N*-ethyl group in the n.m.r. A sample of *N*-desethyl-deoxyindaconitine, by treatment with ethyl iodide in methanol, was converted back to deoxyindaconitine, identical with the starting material.

N-Methyl-N-desethyl-deoxyindaconitine

N-Desethyl-deoxyindaconitine (50 mg) was dissolved in ether (5 ml) and a few drops of methyl iodide were added to the solution. A white precipitate formed immediately and more methyl iodide (3 ml) was added until the precipitate had dissolved. The solution was then refluxed on the steam bath for 1 h and subsequently evaporated to dryness. It left a residue which was dissolved in hot water. The filtered solution was cooled in ice, made alkaline with sodium carbonate, and extracted with three portions of chloroform. The combined extract was washed with water, dried over sodium sulfate, and evaporated to dryness *in vacuo*. The residue (50 mg) was dissolved in benzene–*n*-hexane (1:1) and chromatographed on grade III alumina. The column was eluted first with the same solvent, then with benzene, and finally with methylene chloride, and the eluate was collected in 30 ml fractions. The benzene eluate (fractions 5–7) yielded a crystalline product (14 mg) which after crystallization from *n*-hexane started to sinter at 180° and melted at 188–192°; $[\alpha]_D^{27}$ +26° (*c*, 0.6 in EtOH).

Anal. Calcd. for $C_{33}H_{45}O_9N$: C, 66.09; H, 7.56. Found: C, 66.30; H, 7.66%.

In admixture with an authentic sample of delphinine, it sintered at 184° and melted at 188–191°. The infrared spectra of the product and of delphinine were superimposable, and the X-ray powder patterns of the two bases were identical.

FURTHER ALKALOIDS RELATED TO ASPIDOALBINE AND LIMASPERMINE[1]

C. FERRARI[2] AND LÉO MARION
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received July 30, 1964

ABSTRACT

The stem bark of *Aspidosperma album* (Vahl) R. Ben. is shown to contain at least eight more alkaloids than had been reported previously. The new alkaloids have been separated from the extract by a combination of countercurrent distribution and preparative scale thin-layer chromatography. Of these eight alkaloids, five have been definitely characterized and their structure determined. They are the previously known aspidolimidine, together with N-propionyl-N-deacetylaspidolimidine, N-acetyl-N-depropionyllimaspermine, N-acetyl-N-depropionylaspidoalbinol, and aspidolimidinol. The natural occurrence of the last four alkaloids had not been reported previously.

The stem bark of *Aspidosperma album* (Vahl) R. Ben. already has been reported (1, 2) to contain the alkaloids aspidoalbine ($C_{24}H_{32}O_5N_2$), its N-acetyl-N-depropionyl homologue ($C_{23}H_{30}O_5N_2$), aspidocarpine ($C_{22}H_{30}O_3N_2$), and O-demethylaspidocarpine ($C_{21}H_{28}O_3N_2$). We now wish to report the isolation from this plant of eight more alkaloids which were separated through countercurrent distribution of the basic fraction of the crude plant extract and preparative scale thin-layer chromatography. Of these, three have not yet been identified and of the remaining five, one proved to be a known alkaloid and four were new.

From the countercurrent distribution four main fractions were obtained. Although all fractions contained more than one base, a different component was predominant in each of the first three. Fraction I contained mainly aspidoalbine; fraction II, mainly N-acetyl-N-depropionylaspidoalbine and alkaloid B; fraction III, mainly alkaloid A; while fraction IV yielded alkaloids C, D, and E.

Alkaloid A was obtained easily as colorless crystals, m.p. 192–195°, $[\alpha]_D$ +245° ($CHCl_3$). For aspidolimidine I, the literature (3) gives m.p. 196–199°, $[\alpha]_D$ +239° ($CHCl_3$). The infrared and nuclear magnetic resonance (n.m.r.) spectra of the base also suggested its identity with aspidolimidine, and a direct comparison with an authentic sample[3] confirmed the identity. The melting point of a mixture of the two bases was the same as that of alkaloid A. The X-ray powder patterns were identical and the behavior of alkaloid A in thin-layer chromatography was the same as that of authentic aspidolimidine.

Alkaloids B, C, D, and E failed to crystallize, but all formed crystalline salts. Alkaloid B gave a perchlorate that analyzed correctly for $C_{23}H_{30}O_4N_2.HClO_4$. The behavior of the free alkaloid B in countercurrent distribution and in thin-layer chromatography indicated that it might be N-propionyl-N-deacetylaspidolimidine II. Its n.m.r. spectrum was the same as that of aspidolimidine, except that it contained a triplet ($\delta \sim 1.26$) and a quartet($\delta \sim 2.57$) corresponding to an N-propionyl group instead of the N-acetyl signal ($\delta \sim 2.32$) present in the latter. Alkaloid B was hydrolyzed in the usual manner (2) to remove the imino-propionyl group and subsequently acetylated.

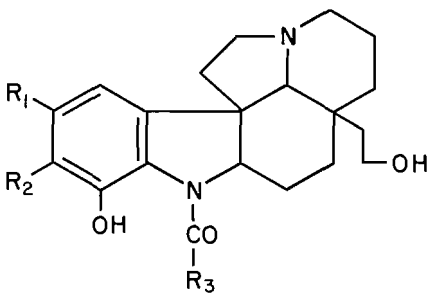
I ($R_1 = H$; $R_2 = CH_3$)
II ($R_1 = H$; $R_2 = C_2H_5$)
VI ($R_1 = CH_3O$; $R_2 = CH_3$)



III ($R_1 = R_2 = H$; $R_3 = CH_3$)
IV ($R_1 = R_2 = CH_3O$; $R_3 = CH_3$)
V ($R_1 = H$; $R_2 = CH_3O$; $R_3 = CH_3$)

The N-acetyl-N-depropionyl alkaloid B thus produced was identical in every respect with aspidolimidine, thus confirming the structure (II) of the alkaloid.

After this work had been completed, Burnell, Medina, and Ayer in a short communication (4) reported the occurrence in *Aspidosperma fendleri* Woodson of fendlerine to which this same structure II has been assigned. Fendlerine is reported to melt at 179–181°, while alkaloid B could not be induced to crystallize. Since, however, fendlerine has been converted to aspidolimidine by the same method that we have used, it is highly probable that alkaloid B is identical with fendlerine.

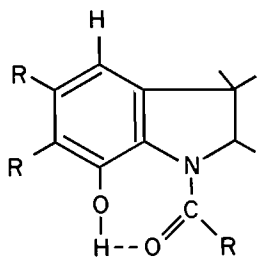
The tubes 42–65 of the countercurrent distribution with pH 4 buffer (see experimental part) contained two main fractions that were separated by preparative scale thin-layer chromatography. The fraction with the higher R_f (alkaloid C) formed a crystalline perchlorate, m.p. 278–281°, $C_{21}H_{28}O_4N_2 . HClO_4$. The n.m.r. spectrum of the oily alkaloid C liberated from the perchlorate showed three aromatic protons, the typical hydrogen-bonded hydroxyl (δ 10.95), one acetyl group (δ 2.30), a triplet centered at δ 3.54 ($J = 7$ c.p.s.) indicative of —CH_2—CH_2OH, a multiplet at δ 4.09 corresponding to a C-2 hydrogen, and finally the peaks between δ 2.9–3.3 that have been considered characteristic of the aspidospermine carbon skeleton (3). No methoxyl or C-methyl signals were present. The infrared absorption spectrum showed a strongly hydrogen-bonded hydroxyl and contained the characteristic displaced and split carbonyl peak corresponding to the hydrogen-bonded amide (5). All this spectral evidence points to structure III for alkaloid C which would therefore be N-acetyl-N-depropionyllimaspermine. Comparison of the n.m.r. spectrum of the base with that published for limaspermine (6) revealed that the only difference between them was attributable to the different N-acyl groups. Replacement of the N-acetyl group in alkaloid C by an N-propionyl group via the usual procedure yielded a product that proved to be identical in every respect (melting point that of the mixture, X-ray patterns) with an authentic sample of limaspermine,[4] thus confirming structure III for alkaloid C.

The second main fraction obtained by preparative scale thin-layer chromatography of the contents of tubes 42–65 of the countercurrent distribution with pH 4 buffer—the fraction of lower R_f value—was a basic oil. In thin-layer chromatography it gave only one spot and seemed to be homogeneous, but it failed to crystallize or to form crystalline salts with either perchloric acid or picric acid. The n.m.r. spectrum of the basic oil, however, suggested that it probably consisted of a mixture of two alkaloids. It contained

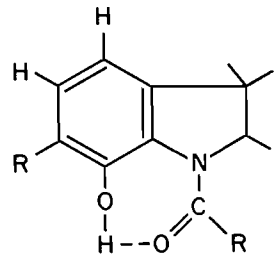
[4]*Kindly sent by Dr. M. Pinar, Instituto de Quimica 'Alonso Barba', Madrid, Spain.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

two peaks of different intensities at low field (δ 10.96 and 11.36) corresponding to hydrogen-bonded aromatic hydroxyls and two peaks in the aromatic region (δ 6.32 and 6.58), also of different intensities. Since one peak in each region corresponded to less than one proton these peaks must be attributed to another alkaloid present in smaller quantity, so that the basic oil must be a mixture of two alkaloids which will be designated D and E. The larger peaks in each region (δ 11.36 and 6.32) were in a 1:1 relation suggesting partial structure (*a*). The two smaller peaks (δ 10.96 and 6.58) were in a 2:1 relation suggesting partial structure (*b*). The n.m.r. spectrum also contained a triplet at δ 3.56 (J = 7 c.p.s.) indicating the probable presence of a $-CH_2-CH_2OH$ group, together with signals attributable to methoxyl and N-acetyl groups. No C-methyl could be detected. All this evidence pointed to structures IV and V respectively for alkaloids D and E present in the mixture.



(a)



(b)

If these deductions be correct, then alkaloid D (structure IV) should be derivable from N-acetyl-N-depropionylaspidoalbine VI by reductive cleavage of its cyclic ether, and alkaloid E (structure V) should be derivable similarly from aspidolimidine I. Both N-acetyl-N-depropionylaspidoalbine VI and aspidolimidine were independently reduced with sodium borohydride. In thin-layer chromatography both products had the same R_f value as the mixture of alkaloids and the n.m.r. spectra of the products showed the correctness of the assignments previously made. It was found that synthetic N-acetyl-N-depropionylaspidoalbinol (IV) could be crystallized as its hydrochloride, while synthetic aspidolimidinol (V) formed a sparingly soluble crystalline hydrobromide. By making use of these properties it was possible to separate the mixture of alkaloids D and E into a hydrochloride and a hydrobromide that proved identical respectively with synthetic N-acetyl-N-depropionylaspidoalbinol hydrochloride and aspidolimidinol hydrobromide.

The alkaloids found and identified so far in *A. album* belong to three characteristic structures. They are the aspidospermine structure in which a C-ethyl side chain is present (aspidocarpine, O-demethylaspidocarpine), the limaspermine structure which contains a C-hydroxyethyl side chain (N-acetyl-N-depropionyllimaspermine, N-acetyl-N-depropionylaspidoalbinol, aspidolimidinol), and the aspidoalbine structure in which the side chain is involved in a cyclic ether (aspidoalbine, N-acetyl-N-depropionylaspidoalbine, aspidolimidine, N-propionyl-N-deacetylaspidolimidine).

EXPERIMENTAL

Unless otherwise specified, melting points were taken on a Kofler hot stage, and the analytical samples were dried at 100° *in vacuo* over phosphoric oxide. The n.m.r. spectra were obtained on a Varian A-60 instrument.

Separation of the Alkaloids

The basic fraction of the crude extract of *A. album* (1) was further separated into fractions containing one, two, or three main alkaloids by countercurrent distribution using chloroform as stationary phase and pH 3 buffer (citric acid – phosphate) as moving phase. After 100 transfers the main alkaloids were distributed as follows: fraction I (tubes 4–25) contained aspidoalbine; fraction II (tubes 30–50), N-acetyl-N-depropionylaspidoalbine and alkaloid B; fraction III (tubes 55–75), alkaloid A and two other components; fraction IV (tubes 76–99), mixture of several alkaloids. The fourth fraction was again subjected to countercurrent distribution, this time using pH 4 buffer; it yielded alkaloids C, D, and E.

Aspidolimidine (Alkaloid A)

Alkaloid A was obtained readily by direct crystallization from fraction III. It crystallized from methanol as colorless prisms, m.p. 192–195°, $(\alpha)_D$ +245° (*c*, 1.26 in $CHCl_3$). The literature (2) gives m.p. 196–199°, $[\alpha]_D$ +239° ($CHCl_3$) for aspidolimidine. In admixture with an authentic sample of aspidolimidine (m.p. 192–195°) obtained through the courtesy of Dr. B. Gilbert, alkaloid A melted at 191–195°. The X-ray powder patterns of the authentic sample and of alkaloid A were identical, and in thin-layer chromatography the behavior of both was the same.

N-Propionyl-N-deacetylaspidolimidine (Alkaloid B)

From the second fraction of the countercurrent distribution separation, alkaloid B was obtained by means of preparative scale thin-layer chromatography. The appropriate band was scraped off and extracted with ether. The extract was evaporated to dryness, the residue dissolved in methanol, and the solution adjusted to pH 4 by the addition of perchloric acid. Colorless crystals separated which were recrystallized from aqueous methanol, m.p. 209–211°.

Anal. Calcd. for $C_{23}H_{30}O_4N_2.HClO_4$: C, 55.35; H, 6.26; N, 5.61. Found: C, 55.51; H, 6.10; N, 5.79.

The free base liberated from the perchlorate failed to crystallize. After distillation *in vacuo*, it consisted of a colorless glass, $[\alpha]_D$ +226° (*c*, 1.08 in $CHCl_3$). The base was hydrolyzed and subsequently acetylated according to the usual procedure (1). This gave a product which after two crystallizations from methanol melted at 192–194° and, in admixture with an authentic sample of aspidolimidine,[3] at 190–195°. $[\alpha]_D$ +240° (*c*, 1.22 in $CHCl_3$). The infrared spectrum of the product was superimposable on that of aspidolimidine, and the behavior of the two bases in thin-layer chromatography was identical.

N-Acetyl-N-depropionyllimaspermine (Alkaloid C)

The fourth fraction obtained from the countercurrent distribution with pH 3 buffer as a moving phase was subjected to another countercurrent distribution, using pH 4 buffer. Tubes 42–65 collected in this second distribution contained two main components that could be separated either by preparative scale thin-layer chromatography or by chromatography on a grade III alumina column and elution with chloroform. The band with the higher R_f value was scraped off and extracted with ether. The extract yielded a base that formed a crystalline perchlorate, m.p. 278–281°, $[\alpha]_D$ +50° (*c*, 0.84 in 50% aqueous methanol).

Anal. Calcd. for $C_{21}H_{28}O_3N_2.HClO_4$: C, 55.21; H, 6.39; N, 6.13. Found (sample dried at 120°): C, 55.12; H, 6.39; N, 6.26.

The base (alkaloid C) liberated from the salt could not be induced to crystallize. After distillation *in vacuo*, it consisted of a colorless glass, $[\alpha]_D$ +127° (*c*, 0.52 in $CHCl_3$). According to its infrared absorption spectrum, alkaloid C contained an N-acetyl group. This group was hydrolyzed off and replaced by an N-propionyl group by the usual method (1). This substitution gave a product which, after two crystallizations from methanol, melted at 174–174.5°, $[\alpha]_D$ +113° (*c*, 0.54 in $CHCl_3$). For limaspermine the literature (4) reports m.p. 175–175.5° and $[\alpha]_D$ +108° ($CHCl_3$). In admixture with an authentic sample of limaspermine[4] (m.p. 172–174°) the product melted at 171–173°. The X-ray powder patterns of the two bases were different and the infrared spectra also showed some differences. Since these differences could be due to a difference in crystalline form, Dr. Pinar's sample was recrystallized from methanol. It then melted at 175–175.5° and in admixture with the product at 173–173.5°. The recrystallized sample had an infrared absorption spectrum superimposable on that of the product, and the X-ray powder patterns of the two were identical.

N-Acetyl-N-depropionylaspidoalbinol Hydrochloride

A sample of N-acetyl-N-depropionylaspidoalbine was reduced with sodium borohydride in the usual way. This cleaved the cyclic ether present in the alkaloid and gave rise to the primary alcohol, N-acetyl-N-depropionylaspidoalbinol. The product was purified by preparative scale thin-layer chromatography. It was subsequently dissolved in methanol and converted to the hydrochloride by the addition of methanolic hydrogen chloride. The solution was evaporated to dryness and the residue dissolved in a small volume of methanol. After the addition of ethyl acetate the salt crystallized out. The hydrochloride recrystallized once from methanol – ethyl acetate, melted at 267–269° (in a sealed evacuated capillary). For analysis it was dried at 120°.

Anal. Calcd. for $C_{23}H_{32}O_5N_2.HCl$: C, 60.98; H, 7.34; N, 6.18; Cl, 7.83. Found: C, 60.70; H, 7.50; N, 6,02; Cl, 7.85.

Aspidolimidinol

A sample of aspidolimidine was reduced with sodium borohydride by the usual procedure. The product was purified by preparative scale thin-layer chromatography, dissolved in methanol, and converted to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the hydrobromide by the addition of hydrobromic acid in methanol. The solution was evaporated to dryness and a few drops of methanol were added to the residue which immediately crystallized. The hydrobromide, after recrystallization from aqueous methanol, melted at 197–199°.

Anal. Calcd. for $C_{22}H_{30}O_4N_2.HBr$: C, 56.55; H, 6.70; N, 6.00; Br, 17.10. Found: C, 56.69; H, 6.82; N, 5.94; Br, 17.26.

Alkaloid E Hydrobromide

The mixture of alkaloids D and E was dissolved in methanol and the solution adjusted to pH 4 by the addition of hydrobromic acid diluted with methanol. The solution was evaporated to dryness and methanol was added to the residue. The hydrobromide crystallized immediately; it was recrystallized from aqueous methanol, m.p. 194–197°. After a second recrystallization from the same solvent, m.p. 197–200°, either alone or in admixture with aspidolimidinol hydrobromide, $[\alpha]_D$, +70° (*c*, 0.66 in H_2O). The infrared absorption spectra of the two salts were identical.

Alkaloid D Hydrochloride

The mother liquor from the initial crystallization of alkaloid E (aspidolimidinol) hydrobromide was diluted with water, and the solution neutralized with sodium bicarbonate. The liberated base was extracted with methylene chloride and the extract evaporated to dryness. The residue was dissolved in methanol and the solution adjusted to pH 4 by the cautious addition of methanolic hydrogen chloride. The acid solution was evaporated to dryness, the residue dissolved in a small volume of hot methanol, and ethyl acetate was added. This solution, on cooling, deposited the crystalline hydrochloride of alkaloid D. After two recrystallizations from methanol – ethyl acetate, m.p. (in sealed evacuated capillary) 267–269°, either alone or in admixture with N-acetyl-N-depropionylaspidoalbinol hydrochloride. The infrared absorption spectra of the hydrochloride of the product and of the synthetic N-acetyl-N-depropionylaspidoalbinol hydrochloride were superimposable. $[\alpha]_D$ +64° (*c*, 0.70 in CH_3OH).

ACKNOWLEDGMENTS

We acknowledge our indebtedness to Mr. M. Lesage for the n.m.r. spectra, to Mr. H. Séguin for the microanalyses, and to Mrs. Christine Mackey for the X-ray powder patterns. We also express our cordial thanks to Dr. B. Gilbert and to Dr. M. Pinar for the samples that they have so kindly supplied.

REACTION OF LOWER OLEFINS AND IODINE IN A LIQUID PHASE

NOVEL PREPARATION OF ALKENE IODOHYDRINS

GENE SUMRELL,[1] BERT M. WYMAN, RONALD G. HOWELL, AND MACK C. HARVEY
Research Department, El Paso Natural Gas Products Company, El Paso, Texas

Received June 29, 1964

ABSTRACT

A simplified procedure for preparing alkene iodohydrins has been developed utilizing olefin diiodide, aqueous acetone, and hydrogen peroxide. It was learned in this work that, contrary to general information in the literature, lower alkenes and iodine react quickly and essentially completely in a liquid phase at room temperature to give the diiodide.

Alkene iodohydrins are conventionally prepared either by the reaction of hydriodic acid with the appropriate epoxide (1) or by preparation of the appropriate chlorohydrin or bromohydrin followed by exchange of the halogen using sodium iodide and acetone (2). During an investigation in this laboratory involving the conversion of lower olefins to other materials of potentially greater economic value, attempts were made to develop a one-step procedure for converting these materials to their respective iodohydrins by carrying out the reaction of the olefin with iodine in a mixture of water and acetone or a variety of other water-miscible organic materials. For convenience the work was initiated with 1-pentene, since it is a liquid at room temperature. We quickly learned that in the presence of a liquid phase iodine rapidly undergoes a mildly exothermic reaction with 1-pentene at room temperature to go essentially completely to the right in the following equation:

$$CH_3CH_2CH_2CH{=}CH_2 + I_2 \rightleftarrows CH_3CH_2CH_2CHICH_2I.$$

This result is contrary to information commonly found in the literature (3, 4).[2] The pentene diiodide described above could not be prepared completely free of the olefin because of slow decomposition to iodine and 1-pentene even at room temperature and more rapidly at higher temperatures. The ratio of 1-pentene and diiodide could be readily determined by the use of nuclear magnetic resonance. When 1 mole of 1-pentene and a 0.5 mole of iodine were stirred together for a few minutes, the ratio of olefin to diiodide was 1:1. A trace of iodine remained as detected by its color, but the solution was transparent and titration with sodium thiosulfate indicated a negligible amount of free iodine present. The free iodine could be completely removed by stirring the mixture with aqueous sodium hydroxide. The decomposition was not hastened by the presence of aqueous caustic, however, and the major part of the diiodide was still present after many hours of stirring with 20% sodium hydroxide. No hydrolysis to iodohydrin or glycol occurred under these conditions.

When aqueous acetone was added to a mixture of 1-pentene and its diiodide, moderately rapid decomposition of the diiodide occurred, and within a few hours a layer composed

For personal use only.

mainly of 1-pentene and acetone had separated to the top. Some diiodide remained in the bottom aqueous acetone layer, and a large amount of iodoacetone was present. Slow hydrolysis of the diiodide occurred, and after three days of stirring at ambient temperature a 15% yield of pentene iodohydrin was present. The presence of hydrogen peroxide was found to increase the yield of the iodohydrin to 84% under the same conditions. The procedure is described in the experimental section.

The rapid reaction of iodine with propylene and 1- and 2-butene was confirmed by bubbling these gases into a slurry of iodine and water. In the case of propylene, the reaction was also carried out in numerous organic liquids (including carbon tetrachloride) and in all cases proceeded rapidly and essentially to completion, though enough free iodine always remained to color the solution. The recovery of the propylene and reuse of the iodine was investigated as a possible means of purifying propylene from small amounts of inert gases such as propane. Though the propylene could be recovered essentially quantitatively by heating the diiodide solution somewhat above 100°, after many recycles substantial amounts of isopropyl iodide began appearing in the off-gas and small amounts of iodine-containing tar became apparent in the pot, rendering the process uneconomical.

Propylene iodohydrin was prepared from the diiodide in 70% yield by the method described for pentene iodohydrin. The role of the hydrogen peroxide in these preparations is obscure, since, in the absence of acetone, no iodohydrin was detected even when stirring was carried out with hydrogen peroxide present.

EXPERIMENTAL

Boiling ranges are uncorrected. Fractionations were carried out using a 60 cm Podbielniak-type column with heated jacket and partial reflux head similar to that described by Cason and Rapoport (5). Gas chromatographic studies were done with an F & M Model 720 chromatograph using a 6 ft column packed with 20% Dow 9N9 nonionic surfactant on Chromasorb P of 30–60 mesh. The column was maintained at 200°, and helium used as the carrier. The n.m.r. spectra were obtained on a Varian A-60 spectrometer. Carbon tetrachloride was used as the solvent, and the chemical shift values are with respect to internal tetramethylsilane at 0 p.p.m.

Reaction of Iodine with 1-Pentene

When 1 mole of 1-pentene and 0.5 mole of iodine were stirred together at room temperature, the iodine dissolved within a few minutes, the temperature of the reaction mixture increased to the boiling point and 1-pentene refluxed (dry ice – acetone condenser) mildly for a time. After 1 h of stirring, the mixture was studied by gas chromatography and n.m.r. spectroscopy. The diiodide was not sufficiently stable to pass through the chromatographic column, decomposing to iodine and 1-pentene, and the latter passed through the column. The n.m.r. study revealed that the three vinyl hydrogens of 1-pentene give a series of lines from 4.8 to 6.2 p.p.m., while the three hydrogens on the first and second carbons of 1,2-diiodopentane give a series of sharp lines from 3.1 to 4.6 p.p.m. The chemical shifts and splitting of these latter lines are as would be expected for 1,2-diiodopentane, and this part of the spectrum is very similar to that shown for 1,2-dichloropropane (6). Assuming all the area under the lines at 3.1–4.6 p.p.m. as due to the three hydrogens on the first and second carbons of the diiodide and all the area under the lines at 4.8–6.2 p.p.m. as due to the three vinyl hydrogens of the olefin allowed determination of the mole ratio of these two materials in the mixture. The areas in these two parts of the n.m.r. spectrum of the reaction mixture described above were equal, indicating 50 mole % of 1-pentene and 50 mole % of 1,2-diiodopentane to be present. This mixture was colored with iodine, but titration for free iodine with sodium thiosulfate gave a negligible value. Similar results were obtained with another reaction mixture prepared using 1 mole of 1-pentene and 0.25 mole of iodine. For this mixture, the area under the lines at 4.8–6.2 p.p.m. and at 3.1–4.6 p.p.m. were in a ratio of 3:1, indicating the mixture to be composed of 75 mole % olefin and 25 mole % of the diiodide.

A number of attempts were made to bring about a chemical reaction with one or both iodines in the diiodide. The mixture composed of 50 mole % each of diiodide and 1-pentene was completely miscible with glacial acetic acid, but showed no reaction with it. When a similar mixture of the diiodide and 1-pentene was stirred with 20% aqueous sodium hydroxide, no reaction was observed except that the iodine color disappeared. The mole ratio of these components after stirring overnight was 45:55, indicating only a slow removal of iodine as the equilibrium shifted. The mixture was then warmed in the hope of speeding hydrolysis to form either the iodohydrin or glycol, but vigorous decomposition ensued, resulting in complete removal

of the iodine and formation of a colorless upper layer which gave a peak only for 1-pentene when passed through the chromatographic column.

Preparation of 1-Iodo-2-hydroxypentane

A 1 l, three-necked flask was fitted with a stirrer, thermometer, dropping funnel, and dry ice – acetone condenser, and a mixture of water (100 ml), iodine (0.5 mole), and 1-pentene (1 mole) was added to the flask. The mixture was stirred for 0.5 h to allow the diiodide to form, then was cooled to 10°. Acetone (250 ml) was added, followed by 30% hydrogen peroxide (56 ml, 0.55 mole). The cooling bath was removed and stirring continued for 3 days at ambient temperature. The mixture separated into two nearly equal phases (both somewhat discolored with iodine) when stirring was stopped. The lower phase contained most of the iodine-containing organic materials, while the upper phase consisted mainly of acetone and water. The two phases were separated and analyzed separately by gas chromatography. The data indicated the presence of 90.6 g (84.6% based on 0.5 mole of iodine) of the iodohydrin, 20.6 g (22.4%) of iodoacetone (*caution*: this material is extremely lachrymatory and is far more potent than chloroacetone), and 2.0 g (2%) of mixed iodopentanes. These various products were trapped by gas chromatography and identified by infrared and n.m.r. spectroscopy. Three iodopentanes were present, with the 2-isomer predominating. There was substantially less of the 3-isomer and a very small amount of 1-iodopentane. A portion of the organic phase was fractionally distilled, yielding a nearly colorless liquid at 68° (3 mm), n_D^{25} 1.5215.

Anal. Calcd. for $C_5H_{11}IO$: C, 28.07; H, 5.15; I, 59.31. Found: C, 28.30; H, 5.30; I, 59.40.

The above sample gave one peak when passed through the gas chromatographic column. Its n.m.r. spectrum was consistent for 1-iodo-2-hydroxypentane. A sextet centered at 3.55 p.p.m. (J = 6 c.p.s.) was assigned to the proton on the second carbon; a doublet centered at 3.25 p.p.m. (J = 6 c.p.s.) was assigned to the two protons on the first carbon; a singlet at 3.4 p.p.m. (which shifted upfield on dilution) was assigned to the hydroxy group; a mixture of a 5- and 7-line pattern centered at 1.4 p.p.m. was assigned to the four protons on the methylene groups of carbons 3 and 4; and a triplet centered at 0.95 p.p.m. (J = 7 c.p.s.) was assigned to the methyl group.

Another similar run was converted to the epoxide by the following procedure: The acetone was removed at water-pump pressure, and the residue was cooled to 0° and treated with 1 mole of 20% sodium hydroxide. The cooling bath was removed and stirring continued for 2 h as the mixture warmed to room temperature. The organic phase (31 g) was separated, and the aqueous layer extracted twice with 100 ml portions of diethyl ether. The extracts were added to the organic phase and the mixture was dried and fractionated, yielding 30.5 g (71% based on 0.5 mole of iodine) of 1,2-epoxypentane at 79–81° (665 mm), n_D^{25} 1.3930 (lit. (7) b.p. 89–90° (750 mm), n_D^{20} 1.3963).

Preparation of 1-Iodo-2-hydroxypropane

Propylene diiodide was prepared in a similar manner to that described for pentene diiodide except that propylene gas was bubbled into the iodine–water mixture until the gas was no longer absorbed (15–20 min). The reaction was mildly exothermic and the propylene was taken up quantitatively initially. Hydrogen peroxide was then added and the run carried out as described for pentene diiodide. Fractionation gave 65 g (70%) of the iodohydrin at 58–62° (9 mm), n_D^{25} 1.5340 (lit. (2) b.p. 59–63° (9 mm), n_D^{30} 1.5365).

THE REACTIONS OF FREE RADICALS WITH NITROUS OXIDE[1]

T. N. BELL[2] AND K. O. KUTSCHKE
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received June 19, 1964

ABSTRACT

A study of the reactions of methyl, ethyl, and trifluoromethyl radicals with nitrous oxide has shown that each radical causes the formation of nitrogen at temperatures below 400°. It is believed that the oxygen abstraction reaction occurs.

$$R + N_2O \rightarrow RO + N_2.$$

A semiquantitative study of the reaction of trifluoromethyl with nitrous oxide has been made, and difficulties in studying this type of reaction quantitatively are discussed.

The interaction of free radicals with nitrous oxide is considered to be important, either as a chain transfer process in the oxidation of thermally stable molecules, such as methane (1), or as the initiation process in the oxidation of molecules which readily decompose into free radicals, such as ethane (2).

To elucidate fully the oxidation of ethane by nitrous oxide, Kenright, Robinson, and Trenwith (2) studied the reactions of ethyl and methyl radicals with nitrous oxide. They concluded that ethyl radicals produced during the pyrolysis of propionaldehyde and diethyl ether at 560° reacted with nitrous oxide to form ethoxy radicals and nitrogen. The results of similar experiments with methyl radicals from the pyrolysis of acetaldehyde gave no indication of a similar abstraction of oxygen atoms by the methyl radical.

Castellion and Noyes (3) studied the photochemical reaction between nitrous oxide and ethane at temperatures up to 105°. They concluded that ethyl radicals formed in the system do not undergo reaction with nitrous oxide at these temperatures.

Mandelcorn (4) photolyzed acetone in the presence of nitrous oxide at 360° and obtained no evidence for the formation of nitrogen in the products. He concluded that methyl radicals produced during the photolysis do not abstract oxygen.

Hydrogen atoms are produced in the ethane system through the decomposition of the ethyl radical. As a result of product analyses, Kenright, Robinson, and Trenwith concluded that in this system the hydrogen atom did not abstract oxygen. On the other hand, Melville (5) has demonstrated that the chain oxidation of hydrogen can be induced photochemically at 294°. One of the chain-propagating steps is undoubtedly

$$H + N_2O \rightarrow OH + N_2.$$

Kenright and Trenwith (6) measured the rate constant for the abstraction of oxygen from nitrous oxide by comparing the rate of formation of nitrogen to the rate of formation of ethylene in the nitrous oxide – ethane system. On the assumption that the ethylene results solely from the decomposition of the ethyl radical, the data leads to an evaluation of the rate constant for oxygen transfer by the ethyl radical compared with the rate constant for ethyl decomposition, as measured by Bywater and Steacie (7). The velocity constant for oxygen abstraction determined in this way gave $k = 10^{17} \exp -31\,000/RT$, cc mole^{-1} s^{-1}.

[1]*Issued as N.R.C. No. 8141.*
[2]*National Research Council of Canada Postdoctoral Fellow, 1963–1964. Permanent address: Department of Physical and Inorganic Chemistry, University of Adelaide, Adelaide, South Australia.*

In summarizing this previous work, we found that anomalies appear to exist and that an unusual marked difference in reactivity between the ethyl and methyl radical is apparent. To clarify this situation it seemed worthwhile to investigate the reactions of a number of free radicals with nitrous oxide.

Moreover, the very unusual A factor for oxygen abstraction by the ethyl radical would warrant a further quantitative study of the reaction,

$$R + N_2O \rightarrow RO + N_2.$$

The results obtained in this present study clearly show that methyl, ethyl, and trifluoromethyl radicals are capable of abstracting the oxygen atom from nitrous oxide at temperatures below 400°. It is considered that the earlier failure to observe this reaction of methyl radicals was due to the competing reactions which this radical could undergo under the conditions chosen in those experiments.

The photolysis of hexafluoroacetone is reasonably well understood (8) and is a convenient source of trifluoromethyl radicals. This system in the presence of nitrous oxide appeared to be ideally suited for an unambiguous quantitative study of the reaction,

$$CF_3 + N_2O \rightarrow CF_3O + N_2,$$

in comparison with the recombination step,

$$CF_3 + CF_3 \rightarrow C_2F_6.$$

In fact, the complexities of this system are such as to preclude an accurate determination of the rate constant. The present results cast some doubt on Kenright and Trenwith's value for the rate of the ethyl reaction.

EXPERIMENTAL

The source of methyl and ethyl radicals used was the pyrolysis of the corresponding mercury dialkyls, while the photolysis of hexafluoroacetone was used as the source of trifluoromethyl radicals.

The dialkyls, diethyl mercury from Eastman Kodak and dimethyl mercury from Chemical Procurement Laboratories, were thoroughly degassed before use, while the hexafluoroacetone from Allied Chemical Co. was fractionated and degassed thoroughly at −140° before use. This latter served to remove traces of fluoroform. The ketone was stored in a blackened bulb and kept at liquid nitrogen temperature.

The pyrolysis experiments were carried out in a silica reaction vessel (volume 156 ml). Known quantities of the reactants were condensed into a sidearm of the vessel and the vessel sealed from the storage system. The vessel was brought to temperature in a tubular furnace and the reaction initiated by rapid volatilization of the reactants from the external sidearm. After reaction, the noncondensable products were transferred via a break-seal on the reaction vessel to a gas burette, then to sample tubes for mass spectrometric and gas chromatographic analyses.

The latter employed a 3 ft column of 40/60 mesh activated charcoal at room temperature; hydrogen was used as a carrier gas at a flow rate of 72 ml/min. A Gow-Mac hot-wire detector was used as the sensing element.

Photolysis experiments were carried out in a quartz reaction vessel (volume 176 ml) fitted with plane parallel windows. This was suspended in the center of a tubular furnace in the path of a light beam from a Hanovia S-500 mercury lamp. The light beam was filtered with Corning filters, color specification 754 and 953, giving radiation in the range 2 600 – 4 000 Å. The single filter No. 754 transmitted sufficient radiation of low wavelength to cause decomposition of the nitrous oxide. The lamp was manually controlled and monitored with an R.C.A. 935 photocell in conjunction with a Keithley electrometer.

Temperature measurement was through chromel–alumel thermocouples taped to the cell walls.

The reaction vessel was connected directly through metal valves, Hoke 413, to the storage and analytical systems, the latter consisting of cold traps and a combined gas burette sampling system. Pressure measurements were made using a Pyrex spiral gauge as a null-point instrument.

In operation each reactant was admitted separately to the reaction vessel; the mixture was frozen into a small appendage protruding through the furnace and then pumped on for several minutes. After warming, mixing was allowed to occur for 55 min, in certain cases for 20 min.

Analysis of the noncondensable products was done using either a 40/60 mesh activated charcoal column (length 3 ft) at room temperature (helium carrier gas flow rate 50 ml/min) or a 30/60 mesh molecular

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

sieve, Linde 5A, column (length 18 in.) at room temperature (helium carrier gas flow rate 46 ml/min). The latter column was used only when checks for molecular oxygen were being made among the noncondensable products. In all cases these proved negative.

Analysis of the condensable products for hexafluoroethane from the hexafluoroacetone – nitrous oxide system proved troublesome because of the large excess of nitrous oxide; in general, the quantities involved were of the order: C_2F_6, 1 μmole; N_2O, 1 600 μmole. Conventional Ward Still separations proved impossible because of the similarity of the boiling points (N_2O −88°; C_2F_6 −78°).

Analysis by mass spectrometric means was attempted. The total condensable sample was scrubbed with water to remove hexafluoroacetone and other possible products by hydrate formation, followed by fractionation at −130°. To the volatile fraction was added a known amount of xenon (approximately 1 μmole) to act as an internal standard. The swamping effect of the large excess of nitrous oxide was too great to yield, even at the highest permissible input pressures, quantitatively measurable peaks at mass 69 and 132.

The infrared method (9) seemed possible and a spectrum of the volatile fraction after water scrubbing was recorded. Excellent C—F absorption bands were observed and this method gave indication of promise. Eventually the method described below was developed and used.

The analytical technique finally adopted involved "double gas chromatography". Here the total condensable sample including unreacted ketone, approximate volume 40 ml, was condensed into a U trap (volume 50 ml) through a sidearm, which was then sealed off; the vertical limbs of the U were fitted with break-seals. A bypass connected the limbs exterior to the break-seals.

One limb of the trap was connected to a helium carrier gas supply, the other to a 2 ft 6 in. column of molecular sieve, Linde 5A, mesh 40/60. The output from the column was sealed to a collecting U tube which was packed with glass wool and had a chromatographic sampling tube connected to it. The whole assemblage could be evacuated or opened to the atmosphere from a point after the collecting trap. No taps or valves were incorporated at any point between the sample trap and collecting trap.

In operation the whole assemblage was evacuated for several hours; the helium carrier was introduced and a flow rate of 30 ml/min was established with the collecting trap cooled in liquid nitrogen. The bypass connecting the limbs of the break-seal trap was sealed off, and the break-seals crushed. In this way the whole sample was swept onto the molecular sieve column, and any condensable effluent from the column collected for a period of 6 min. Periods of less than 6 min resulted in some of the hexafluoroethane being retained on the column.

After collection, the arm of the collecting trap adjacent to the column was sealed off and the trap then evacuated, followed by final sealing of the trap from the pump. Transfer of the sample collected to the chromatographic sample tube was achieved by condensation into this appendage and sealing off. The final sample contained all of the hexafluoroethane together with a small amount of nitrous oxide.

This sample, now in small bulk and highly enriched in hexafluoroethane, was analyzed on the 18 in. molecular sieve column described earlier. The peaks for nitrous oxide and hexafluoroethane were well separated.

RESULTS AND DISCUSSION

(a) Qualitative Results

N_2O–$(CH_3)_2Hg$ System

In a typical experiment, dimethyl mercury (90 μmole) and nitrous oxide (2 170 μmole), mole ratio 1/24, were heated for 75 min at 386°; the estimated total pressure in the reaction vessel was 560 mm. The noncondensable products (37 μmole) contained essentially equal amounts of nitrogen and carbon monoxide, ascertained from gas chromatography. Mass spectrometric analysis yielded N_2 + CO, 8%; CH_4, 91%; H_2, 1%.

N_2O–$(C_2H_5)_2Hg$ System

In a typical experiment, diethyl mercury (36 μmole) and nitrous oxide (882 μmole), mole ratio 1/24, were heated for 75 min at 390°; the estimated total pressure in the reaction vessel was 247 mm. The noncondensable products (6.7 μmole) contained similar amounts of carbon monoxide and nitrogen as determined by gas chromatography. Mass spectrometric analysis yielded N_2 + CO, 38%; CH_4, 58%; H_2, 4%. Blank experiments showed the absence of carbon monoxide and nitrogen from the reactants, when heated separately under conditions similar to those above.

N_2O–$(CF_3)_2CO$ System

A large number of experiments in which hexafluoroacetone – nitrous oxide mixtures were photolyzed were carried out between 193 and 375°. In all cases the noncondensable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

products contained nitrogen and carbon monoxide; no oxygen was detected (vapor-phase chromatography and mass spectrometry). The amount of nitrogen formed increased with increasing temperature. Data is presented below where attempts to obtain quantitative information are discussed.

(b) Discussion of Qualitative Results

In all these experiments nitrogen is obtained in the presence of a free radical, and this is most simply explained by the occurrence of reaction [1].

[1] $$R + N_2O \rightarrow RO + N_2.$$

Strong competition to [1] will be encountered through reactions [2] in the case of methyl and through [3] and [4] in the corresponding ethyl case.

[2] $$CH_3 + (CH_3)_2Hg \rightarrow CH_4 + \text{other products.}$$

[3] $$C_2H_3 + (C_2H_5)_2Hg \rightarrow C_2H_6 + \text{other products.}$$

[4] $$C_2H_5 \rightarrow C_2H_4 + H.$$

The yield of nitrogen is thus governed by the competition among these reactions for the various radicals.

The alkoxy radical produced in [1] would be expected to react further, and the additional noncondensable products formed in the mercury dialkyl system lends support to the suggestion that the alkoxy radical is indeed formed. Decomposition of the alkoxy radical will in both cases lead to formaldehyde; carbon monoxide may be expected to arise by radical attack on the formaldehyde. In this sequence of reactions hydrogen will undoubtedly be formed. The methane produced in the ethyl – nitrous oxide system could well be produced through formation of the methyl radical from reaction [5].

[5] $$C_2H_5O \rightarrow CH_3 + CH_2O.$$

The photolysis of hexafluoroacetone under the experimental conditions is adequately described by the sequence,

[6] $$(CF_3)_2CO \xrightarrow{h\nu} 2CF_3 + CO,$$

[7] $$2CF_3 \rightarrow C_2F_6,$$

and in the presence of nitrous oxide the additional step [8] may be considered to occur.

[8] $$CF_3 + N_2O \rightarrow CF_3O + N_2.$$

If [8] is the only source of nitrogen and [7] the only source of hexafluoroethane, then

$$\frac{R_{N_2}}{R_{C_2F_6}^{1/2}[N_2O]} = \frac{k_8}{k_7^{1/2}}.$$

At first sight it would appear that the trifluoromethyl system would be an ideal one to determine the rate constant for the abstraction process by measuring the nitrogen and hexafluoroethane produced. Side reactions would be expected to be small compared with the ordinary alkyl systems, and a clean reference reaction is available. Experimentally this was not found to be so.

(c) Quantitative Results ($CF_3)_2CO$–N_2O System

A series of controlled experiments in which nitrous oxide (340 mm) and hexafluoroacetone (12 mm) were photolyzed for 60 min at temperatures between 316 and 375° were carried out. A constant mixing time was allowed in each case. The noncondensable products were analyzed for nitrogen and carbon monoxide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In two separate experiments the hexafluoroethane was measured by the method outlined above to establish the material balance relation between the nitrogen, carbon monoxide, and hexafluoroethane formed.

375° CO 1.54 μmole, N_2 0.231 μmole, C_2F_6 1.45 μmole.

297° CO 1.57 μmole, N_2 0.055 μmole, C_2F_6 1.54 μmole.

Thus it appears that, to a first approximation, the stoichiometric relation holds.

$$CO = C_2F_6 + \tfrac{1}{2}N_2.$$

Because of the difficulty in measuring the hexafluoroethane formed each time, the relation $CO - \frac{1}{2}N_2$ was applied as a measure of the hexafluoroethane.

TABLE I

The results of a series of quantitative runs are given in Table I, and an Arrhenius plot of the $k_8/k_7^{1/2}$ values are shown in Fig. 1. A least-squares evaluation of the data yields

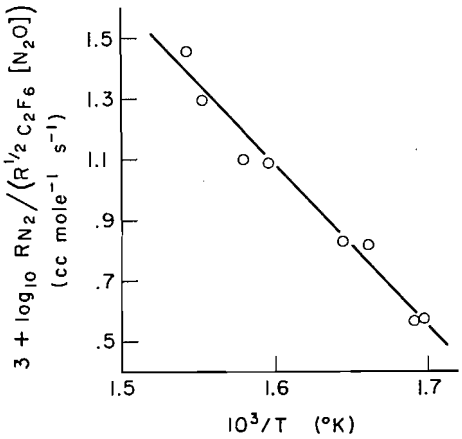

FIG. 1. Arrhenius plot of log $R_{N_2}/(R_{C_2F_6}^{1/2}[N_2O])$ against $1/T$.

$E_8 - \frac{1}{2}E_7 = 24 \pm 1$ kcal. If we use the value derived by Ayscough (10) for the recombination constant $k_7 = 2.3 \times 10^{13}$ cm^3 mole^{-1} s^{-1} and take $E_7 = 0$, k_8 may be derived. $k_8 = 1.4 \times 10^{13} \exp -24\,000/RT$ cc mole^{-1} s^{-1}. If we assume a collision diameter of 5 Å for CF_3 and N_2O species, the collision number for CF_3–N_2O collisions is 3×10^{14} cm^3 s^{-1} in concentration units appropriate to the rate constant above. Thus a steric factor of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

10^{-1} is operative for the oxygen transfer process. This is comparable with a steric factor of 10^{-3} for hydrogen transfer processes involving similar radicals. In consideration of the more easily polarizable p-electrons on the oxygen atom and the strong polarizing power of the trifluoromethyl radical, longer range interactions would seem in order here.

Complicating Features

Hexafluoroacetone itself decomposes thermally under the experimental conditions; thus at 360° the carbon monoxide formed in the dark reaction is approximately 5% of that formed during the photolysis. However, this makes only a minor correction to the rates. Initially no thermal or photolytic decomposition of nitrous oxide was apparent; however, after a considerable number of runs it was noticed that a dark decomposition of nitrous oxide had intervened. Analysis of the noncondensable products showed only nitrogen to be formed. Nitrous oxide is thermally stable under the experimental conditions, and it must be concluded that the dark decomposition is caused by a heterogeneous process. Evidence that this is indeed the case arises through the fact that the extent of nitrous oxide decomposition is considerably reduced by baking the reaction vessel in oxygen at 550° for several hours. Thus at 360° it was found that the dark nitrogen contribution could be reduced by 75% after three such bakings.

The behavior observed is typical of carbon (11), which readily reduces nitrous oxide at these temperatures; alternatively, a fluorocarbon polymeric deposit on the walls of the reaction vessel could be responsible for the dark reaction involving nitrous oxide. Presumably this surface reaction arises through deposition from the thermal decomposition of hexafluoroacetone.

$$(CF_3)_2CO \xrightarrow{\Delta} CO + C \text{ or polymer.}$$

This would explain why initially the dark reaction was not detectable. Interestingly, mixtures of nitrous oxide and hexafluoroacetone gave the same amounts of nitrogen and carbon monoxide when heated together as each did separately. Thus a bimolecular reaction between the two reactants can be discounted.

The dark nitrous oxide decomposition was not noticed until a considerable number of runs had been made. Hence an unknown amount of heterogeneous nitrogen must be considered to be included in the quantitative data, and therefore the derived rate constants must be considered uncertain. It is, however, felt worthwhile to report these results in that the Arrhenius plot is reasonably consistent, and it is felt that if a large heterogeneous contribution were apparent, the nature of the reaction would be such as to destroy this consistency. Moreover the value derived for k_8 is not considered unreasonable for this type of reaction.

(d) Quantitative Discussion

A few comments are in order here with regard to previous findings.

Kenright, Robinson, and Trenwith failed to detect nitrogen in the system CH_3CHO–N_2O at 550° and concluded that methyl radicals did not undergo reaction [1]. In these experiments competition for methyl radicals is created by reaction [9].

[9] $$CH_3 + CH_3CHO \rightarrow CH_4 + CH_3CO$$

where $k_9 = 10^{12} \exp -7\,500/RT$ cc mole^{-1} s^{-1} (12*a*). In their system also the mole ratio $N_2O/CH_3CHO = 1$. Using the derived value for k_8 as a reasonable approximation to the truth, and assuming k_8 is, in value, similar to the general rate constant k_1, we have

$$\text{rate [9]/rate [1]} = 1\,700.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

It is therefore not surprising that in this system the small quantity of nitrogen formed would not be detectable in the presence of the large amount of methane and carbon monoxide produced.

The same type of competition accounts for an early failure of Mandelcorn to detect nitrogen in the photolysis of acetone at 360° in the presence of equimolar amounts of nitrous oxide. In that system hydrogen abstraction by methyl [10] occurs some 1 600 times faster than oxygen abstraction.

[10] $$CH_3 + (CH_3)_2CO \rightarrow CH_4 + CH_2COCH_3.$$

In the system dimethyl mercury – nitrous oxide the strongest competition to oxygen abstraction is through [2] where k_2 is near $5 \times 10^{11} \exp -10\,800/RT$ cc mole^{-1} s^{-1} (12*b*). A similar calculation to that above allows the ratio, rate [2]/rate [1], to be determined. $R_{[2]}/R_{[1]} = 21$. Hence in this system reaction [1] proceeds at a measurable rate.

Similarly for the diethyl mercury – nitrous oxide system, rate [3]/rate [1] may be calculated taking $k_3 = 1.6 \times 10^{10} \exp -6\,200/RT$ cc mole^{-1} s^{-1} (12*c*). Here under the experimental conditions $R_{[3]}/R_{[1]} = 50$. Hence, as was indeed observed, nitrogen should be detectable in this system.

The only other quantitative measurement on reaction [1] is where R = ethyl (see introduction) (6). The value obtained for the velocity constant is vastly different from that obtained for trifluoromethyl in the present work. The A factor obtained is certainly abnormal; so much so that it appears impossible to account for except in terms of extremely improbable long range interactions between the ethyl radical and nitrous oxide, or that the parameters measured do not correspond exactly to reactions [1] and [11].

[11] $$C_2H_5 \rightarrow C_2H_4 + H$$

Some uncertainty is introduced into the calculated value of A_1 by the fact that A_{11} is not precisely determinable; Trotman-Dickenson (12*d*) discusses this point. The error involved, however, will not account for the large abnormality observed.

Other possible complicating factors include a contribution to the nitrogen formation through interaction of H atoms and CH_3 radicals with nitrous oxide. However the strong competition for these species through hydrogen abstraction from the ethane molecule might well be considered to make their contribution to nitrogen formation negligible. Thus the proposed overall mechanism for oxidation is not contravened by the present work.

If we note the complexities observed in the much simpler N_2O–$(CF_3)_2CO$ system, it appears probable that a heterogeneous contribution to nitrogen formation might be important in the N_2O–C_2H_6 system. The amounts of ethane present are much larger than the hexafluoroacetone used here, and at a temperature of 560° carbonation might well be expected to occur. Under these conditions, a heterogeneous contribution might well be large enough to account for the abnormalities in the observed rate constant.

In summation, it appears that the reaction between a free radical and nitrous oxide results in oxygen abstraction at temperatures below 400°; thus the reaction,

$$R + N_2O \rightarrow RO + N_2,$$

is quite general. The rate of this reaction, as measured by the nitrogen formed, is difficult to evaluate accurately owing to the existence of other reactions involving nitrogen formation.

PROTONATED CARBONYL GROUPS

IV. N,N-DIMETHYLACETAMIDE SALTS[1]

DENYS COOK
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received July 3, 1964

ABSTRACT

The infrared spectra of N,N-dimethylacetamide salts have been recorded and are consistent with protonation at the oxygen atom. ν_{OH} is between 2 095 and 3 360 cm^{-1} depending on the anion. The average value of the two components of the OH in-plane hydrogen-bending mode, δ_{OH}, is 1 253 cm^{-1} (splitting of about 147 cm^{-1} due to correlation field effects). The out-of-plane hydrogen-deformation mode occurs at 928 to 761 cm^{-1} depending on the salt. The 1 680 and 1 400 cm^{-1} bands which are present in all the salts are associated chiefly with stretching the CN and CO bonds respectively, in the OCN group, though it is likely that the vibrations are somewhat mixed.

Some salts of complex acids are of the 2 base : 1 acid variety with very strong broad absorption centered near 900 cm^{-1}, containing sharp transmission windows.

INTRODUCTION

Evidence now overwhelmingly favors the oxygen atom as the protonation site in the salts of carboxylic acid amides. The subject has recently been reviewed (1). Nuclear magnetic resonance (n.m.r.) spectroscopic results were instrumental in deciding this point, but infrared methods are becoming equally unequivocal (2). The central argument in the latter case is based on a fundamentally different absorption in the deformation mode between $\rangle N^+—H$ and $=O^+H$, the first corresponding to N protonation, the second to O protonation. Average frequencies for these modes are 1 420 and 1 265 cm^{-1} respectively (2).

The spectrum of N,N-dimethylacetamide.HCl has been examined once and several assignments were made (3). Unfortunately, only the HCl salt was described; had other salts been studied, the implausibility of some assignments would have been immediately apparent.

RESULTS AND DISCUSSION

The bands from the spectra have been collected in Table I. Bands due to the protonating H atom (and D atom) are summarized in Table II.

A comparison of the spectra of the HCl, HBr, and HI salts shows immediately that the band at 1 785 cm^{-1} in the HCl salt is not associated with an internal mode of the organic ion, but with the hydrogen bond, as it is not present in the other salts. This band is almost certainly some overtone or combination tone* and has been previously observed in salts of N,N-dicyclohexylacetamide (2*a*). A band similar to this is often present in salts of organic bases and, in some cases, can be more intense than the $X^+—H\cdots Y^-$ stretching fundamental, when the hydrogen bond is very strong. While the origin of the high intensity is not well understood, it is probable that the great breadth and rich structure of the X—H stretching vibration and this high intensity are related. Neither of these phenomena are observed in other systems with weaker hydrogen bonds, $X—H\cdots PF_6^-$, for example (2). It is also probable that other combination tones with low-lying lattice modes may be present in these salts with strong hydrogen bonds. Such salts may be expected to have the

strongest coupling constants for vibrations involving any of the participants in the hydrogen bond and may give rise to stronger combinations and overtones than those with weak hydrogen bonds. In the sense that these bands unnecessarily complicate the vibrational spectrum, it is thought advisable to study salts with large complex anions or at least one other hydrogen halide as well as the HCl salt. Often, as is the present case, some of the salts of complex acids have a different stoichiometry than the 1:1 salts, for example 2 base : 1 acid (2*c*, 4). These are generally quite unsuited to a study of the protonated base, as they involve strong, possibly symmetrical, hydrogen bonds, which have totally different properties from those in the 1:1 salts.

X—H In-Plane Hydrogen-Deformation Modes

In the HCl salt two medium intensity bands near 1 352 and 1 188 cm^{-1} have been assigned to the in-plane hydrogen-deformation mode, δ_{OH}. These bands are not present in the deuterated salt but are replaced by two at 1 050 and 976 cm^{-1}. The ratio δ_{OH}/δ_{OD} for these two bands is 1.29 and 1.22 for the high-frequency and low-frequency pair respectively. The position of this bending mode is sufficient to exclude the possibility of N protonation, for as observed previously (2) a protonated sp^3-nitrogen atom has its deformation mode in the 1 420 cm^{-1} region.

Some difficulty was experienced in assigning the two components of the in-plane hydrogen-bending mode because of a complicating band at 1 250 cm^{-1}. This band diminishes markedly in intensity in the deuterated salt, but it is impossible to find three new bands in the deuterated salts. Its loss of intensity on deuteration may be simply because it is a shoulder of the 1 190 cm^{-1} band which does move on deuteration. This explanation receives some support from a consideration of the spectra of complexes of N,N-dimethylacetamide and Lewis acids (BCl_3 and BBr_3 (5), $HgCl_2$, $CdCl_2$, BF_3, $SbCl_5$, and BBr_3 (6)). In such complexes both the 1 350 and 1 190 cm^{-1} bands are absent (as are the bands due to ν_{OH} and γ_{OH}, of course), but the 1 250 cm^{-1} band is still present, though in a slightly shifted position, at 1 232 cm^{-1}.

The splitting of the bending mode is most plausibly explained by correlation field effects. These have been previously observed in many carbonyl compounds (2) and, in some cases, a knowledge of the crystal structure of the solid (2*b*) has permitted confirmation that the selection rules for the solid state demand such coupling. The splitting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

in the present salts is the largest (147 cm^{-1}) that has been observed. From the theory underlying correlation field coupling in the unit cell (8) it results that the coupling constant is proportional to the splitting observed. Although lack of knowledge of the crystal structure of N,N-dimethylacetamide salts makes accurate calculation impossible, it seems reasonable to assume that those organic bases which give solid salts capable of forming the strongest hydrogen bonds should have the largest splitting. In this connection the available data show a rough parabolic relation between $\Delta\delta_{OH}$, the splitting, and ν_{OH} in various salts having a common anion, the largest splitting being associated with the lowest ν_{OH}. If it is assumed that ν_{OH} reflects the strength of the hydrogen bond (for the same base) then these data satisfy the assumption made above. This relation does not mean that those salts with strong hydrogen bonds *will* have large correlation field splittings. It means only that when the selection rules permit splitting, it should be large when the $X^+—H\cdots Y^-$ bond is strong.

A generalization seems to exist that stronger hydrogen bonds have lower X—H stretching frequencies and higher deformation frequencies (9). In compounds containing protonated carbonyl groups a very rough correlation between ν_{OH} and δ_{OH} exists, but the scatter is large (2). The rise in δ_{OH} associated with strengthening hydrogen bonds occurs chiefly in the HCl and HBr salts with little further movement in salts with more complex anions, even though there may still be a large shift in the stretching frequency. Table II shows a parallel behavior in the salts of N,N-dimethylacetamide in that those with the two smaller halide anions have δ_{OH} markedly higher than the other halide and the $SbCl_6^-$ salt, while a difference of over 600 cm^{-1} exists in the stretching frequency of the last two salts.

Further support for this generalization comes from an inspection of the infrared spectrum of the hydrate of the $HSbCl_6$ salt. This compound has bands at 3 590 and 3 523 cm^{-1} which are the asymmetric and symmetric OH stretching frequencies respectively of the water molecule. A deformation mode near 1 590 cm^{-1} is also observed. From these values it can be concluded that the OH groups form very weak hydrogen bonds. The other feature in the spectrum at 2 515 cm^{-1} is very broad and is assigned to the $O^+—H$ stretching vibration in the hydrogen bond $CO^+—H\cdots OH_2$. Its low frequency, compared with the anhydrous salt (3 360 cm^{-1}), arises from the much greater basicity of the water molecule than the $SbCl_6^-$ ion. The important fact about the hydrate is that since the $O^+—H\cdots OH_2$ bond has become stronger than the $O^+—H\cdots Cl_6Sb^-$ hydrogen bond in the anhydrous salt, the in-plane hydrogen-deformation mode now gives rise to the two split bands at a higher frequency, namely, 1 360 and 1 188 cm^{-1}.

X—H Out-of-Plane Hydrogen-Deformation Modes

Bands in the spectra at 928, 839, and 761 cm^{-1} are to be identified with the out-of-plane hydrogen-deformation (torsional) mode of the OH group in the HCl, HBr, and HI salts respectively. This band was not observed for the $HSbCl_6$ salt and is presumably below 650 cm^{-1}. These bands shift on deuteration but only in one case, that of the DCl salt, has it been possible to observe the torsional mode at 662 cm^{-1}. The ratio γ_{OH}/γ_{OD} is 1.40, indicating little interaction between this mode and others.

In contrast to the in-plane hydrogen-deformation mode, the out-of-plane hydrogen-deformation does show a marked dependence on the anion. A difference of over 150 cm^{-1} exists between the HCl and HI salts. Equally large variations have been observed in other amide and γ-pyridone salts, which, together with certain regularities in their position, will be reported elsewhere.

The calculated values of the first overtones of these out-of-plane deformation frequencies are at 1 856, 1 678, and 1 522 cm^{-1} (Table II) for the HCl, HBr, and HI salts respectively. Allowing for the effects of anharmonicity, these values are close to those of the Σ band discussed earlier, at 1 785 and 1 646 cm^{-1} in the HCl and HBr salts respectively. On this basis the HI salt would be expected to have a band near 1 480 cm^{-1} but, if present, it is not very pronounced. Nor could any band be found near 1 200 cm^{-1} in the $HSbCl_6$ salt which would be the first overtone of the torsional mode assumed to be near 620 cm^{-1}. The 1 155 cm^{-1} band is, however, broad and could be a doubled band. Information from the lower frequency region would be useful to solve this problem.

The intensity of the Σ bands varies rather markedly, that of the HCl salt being the greatest. It is in the HCl salt that the band comes closest to the OH stretching vibration at 2 095 cm^{-1}, and this proximity may be partly responsible for the high intensity. In salts of other bases this Σ band has been observed with greater intensity than the fundamental X—H stretching absorption. It is only in the more strongly hydrogen-bonded salts, however, that this occurs.

Vibrations Involving the Amide Skeleton

The reversal of the CN and CO stretching frequencies between the free base and the salts noted previously (2*a*) also occurs in the salts presently considered. Thus the 1 670 cm^{-1} band may be due chiefly to stretching the CN bond which now has acquired a larger bond order than in the free base and the 1 402 cm^{-1} band to the protonated carbonyl group stretching vibration. It is quite probable that some mixing of these two vibrational modes occurs as it does in the free amides (10). This idea is encouraged by comparison with values of ν_{CO} in other protonated heterocyclic carbonyl compounds where vibrational interaction seems less likely. These compounds show a fairly strong absorption near 1 500 cm^{-1} (2*b*, 2*c*, 2*d*).

Evidence derived from the infrared spectra of complexes of N,N-dimethylacetamide can also help in determining some of these assignments. In complexes of Lewis acids with compounds containing carbonyl groups, the decrease in ν_{CO} has been used frequently as a measure of the strength of the interaction (7). As the figures in Table III show, there is no

TABLE III

Bands in spectra of amide complexes

Lewis acid			
$HgCl_2$	1 591	1 409	1 264
$CdCl_2$	1 610	1 400	1 265
BF_3	1 630	1 404	1 260
$SbCl_5$	1 618	1 388	1 236
BBr_3	1 635	1 386	1 248

decrease in the 1 600 cm^{-1} band in the amide complex as the Lewis acid strength increases down the column, but rather an increase. The band at 1 400 cm^{-1} shows a small decrease down the column, but there is no correlation between the 1 600 and 1 250 cm^{-1} bands. These facts tend to confirm that the 1 600 cm^{-1} band should not be assigned to the carbonyl stretching mode, but, equally, the smallness of the shift to lower frequency in the 1 400 cm^{-1} band can only indicate that coupling exists between the CO and CN stretching modes. These assignments are different from those advanced previously (5). Other tentative assignments are indicated in Table I.

2 Base : 1 Acid Salts

Salts prepared from complex acids such as $HAsF_6$ are of the type 2 base : 1 acid, of which many examples are now known (2*c*, 4, 11–15). The spectrum of the $(C_4H_9NO)_2.HAsF_6$ salt shows the usual features associated with materials containing strong, possibly symmetrical hydrogen bonds, namely, strong, very broad absorption starting in the 1 500 cm^{-1} region reaching a maximum near 900 cm^{-1}. The characteristic transmission windows are also observed. These experimental findings are completely analogous to those described by Evans and Wright (16).

EXPERIMENTAL

Spectra

The spectra were determined under conditions described previously (2).

Materials

N,N-Dimethylacetamide was purchased from Distillation Products Industries and distilled before use. A fraction boiling at 164° and 760 mm Hg was used.

The HCl salt was prepared by saturating an ethereal solution of the amide with anhydrous HCl gas. The precipitated salt was handled in a dry box because of its hygroscopic nature; m.p. 121–2 °C.

Anal. Calcd. for $C_4H_9NO.HCl$: HCl, 29.5. Found: HCl, 29.4.

The DCl salt was prepared by exchange with a 100 fold excess of D_2O followed by removal of excess D_2O *in vacuo*.

The HBr salt precipitated when a Freon 113 solution of the amide was treated with anhydrous HBr gas. It was also handled in a dry box. m.p. 167–168 °C.

Anal. Calcd. for $C_4H_9NO.HBr$: HBr, 48.1. Found: HBr, 47.9.

The DBr salt was made by exchange with D_2O and by using DBr, both materials having identical spectra.

The HI salt was made by adding the stoichiometric amount of aqueous (57%) HI to the amide which gave the hydrate. The anhydrous salt was made by heating the hydrate *in vacuo*. m.p. 140–143° (decomp.).

Anal. Calcd. for $C_4H_9NO.HI$:HI, 59.4. Found: HI, 59.0.

Exchange with D_2O in a vacuum system gave the DI salt.

The $HSbCl_6$ salt was prepared by the method described by Klages and Zange (17); m.p. 158–161°. On exposure to atmospheric moisture it became hydrated; m.p. 104° (decomp.).

Anal. Calcd. for $C_4H_9NO.HSbCl_6.H_2O$: C, 10.90; H, 2.74; N, 3.18. Found: C, 10.86; H, 2.60; N, 3.24.

The deuterated analog was made by exchange with liquid DCl in a vacuum system. Signs of a 2:1 salt were evident, but this was not investigated further.

The HPF_6 salt crystallized about 24 h after mixing 4.03 g aqueous ($\sim$ 60%) HPF_6 and 1.56 g amide in a polyethylene vessel. The crystals were washed with methanol; m.p. 99–101°.

Anal. Calcd. for $(C_4H_9NO)_2.HPF_6$: C, 30.00; H, 5.98; N, 8.75. Found: C, 30.15; H, 6.22; N, 8.99.

Infrared (Nujol and fluorolube mull): 2 954 w, 1 658 m, 1 494 m, 1 452 m, 1 416 m, 1 378 m, 1 250 m, 1 195 m, 1 060 s, 835 vs (PF_6^-). The maximum in the very broad absorption seems to be near 900 cm^{-1}.

The $HAsF_6$ salt was made by adding 2.15 g aqueous ($\sim$ 60%) $HAsF_6$ to 0.67 g amide and allowing the water to evaporate. After about 24 h crystals of the 2:1 salt appeared; m.p. 121–122°.

Anal. Calcd. for $(C_4H_9NO)_2.HAsF_6$: C, 26.38; H, 5.26; N, 7.69. Found: C, 26.35; H, 5.22; N, 7.60.

Infrared (Nujol and fluorolube mull): 2 995 w, 2 951 m, 2 660 m, 1 503 m,sh, 1 496 m, 1 450 m, 1 418 m, 1 379 m, 1 254 m, 1 198 m, 1 062 s, 688 vs (AsF_6^-). The maximum in the broad absorption appears to be between 800 and 900 cm^{-1}.

ACKNOWLEDGMENTS

The author is indebted to Dr. J. C. Evans (The Dow Chemical Company, Midland, Michigan, U.S.A.) for discussion on the anomalous transmission in the 2:1 salts. The assistance of Mrs. R. H. Veach (Miss C. D. Anderson) in preparing some of the compounds and recording their spectra is gratefully acknowledged. Dr. L. E. Swim and his associates (The Dow Chemical Company, Midland, Michigan, U.S.A.) are thanked for the microanalyses.

ELECTROINITIATED POLYMERIZATION OF STYRENE

I. ELECTROLYSIS OF ALKALI METAL NITRATES IN DIMETHYLFORMAMIDE CONTAINING STYRENE MONOMER[1]

B. LIONEL FUNT AND SHARON WALKER LAURENT
Parker Chemistry Laboratory, University of Manitoba, Winnipeg, Manitoba

Received June 18, 1964

ABSTRACT

Electrolysis of alkali metal salts in dimethylformamide containing styrene monomer produced polymerization. The rate of reaction increased with increase in current and monomer concentration and varied dramatically with choice of initiating salt. The alkali metal nitrates from sodium to cesium produced polymer but lithium was ineffective. KNO_3 was the most efficient of the alkali metal salts tested.

The effects of inhibitors on the rates of polymerization together with analysis of copolymer composition established that polymerization proceeded by an anionic mechanism.

A detailed study with KNO_3 solution showed that relatively high electrical efficiencies were attained and that the number-average molecular weights ranged between 2 000 and 5 000.

Although there are now a number of reports of polymerization induced by electrolysis of solutions of monomer, most investigations have been confined to the polymerization of methyl methacrylate. Only fragmentary references to the polymerization of styrene have been made.

In 1952 Goldschmidt and Stockl (1) obtained polystyrene by electrolysis of solutions of monomer in anhydrous fatty acids containing the corresponding fatty acid salts. The major part of the product of the reaction consisted of dimer and trimer, and only 0.09 g of a "semi-colloid" of molecular weight 3 200 was obtained from the electrolysis of a solution containing 20 g of styrene. Das and Palit (2) reported a trace of polymer formed under similar conditions in propylene glycol.

A brief note by Yang, McEwen, and Kleinberg (3) reported on the initiation of styrene polymerization at a cathode. These workers electrolyzed a pyridine solution of NaI and monomer. An unstated quantity of polymer was obtained with molecular weight of 1 800. In the light of present knowledge it is probable that this was the first electrically initiated anionic polymerization. Kolthoff and Ferstandig were not successful in obtaining polystyrene with their redox systems, although acrylonitrile was polymerized with great efficiency. Failure to obtain polystyrene was also reported by Friedlander, Swann, and Marvel (4), and the field has recently been reviewed in excellent detail (5, 6, 7).

Exploratory experiments were conducted in our laboratories with the salt and solvent systems which we used for the anionic polymerization of acrylonitrile (8) and the free radical polymerization of methyl methacrylate (9). It became apparent that polystyrene can be formed by the electrolysis of anhydrous solutions in dimethylformamide if a suitable salt is employed. The present report represents an attempt to discover the effects of various parameters on the yield and configuration of the polymer formed by this method.

EXPERIMENTAL

The procedures and apparatus were based on those previously described by us.

Materials

Dimethylformamide (DMF), A.R. grade, was purified by mixing with 10% benzene previously dried

[1]*Presented at the Twelfth Canadian High Polymer Forum. Ste. Marguerite, Quebec. May 1964.*

over CaH_2. After standing 24 h the mixture was fractionally distilled, and the fraction boiling at 150–152 °C was collected over BaO, allowed to stand 24 h, and redistilled at reduced pressure (10).

Styrene monomer was passed through chromatographic alumina and then distilled at reduced pressure.

Salts were A.R. grade and were dried for 48 h before use.

Polymerizations

Electrically regulated constant current power supplies were employed. For voltages up to 40 V and currents to 100 mA the Power Designs type 4005 units were used. For high voltages and low currents to a maximum of 15 mA specially designed units from Mr. W. G. Hoyle of N.R.C. were employed. For some experiments manual adjustment of large dropping resistors powered by a 250 V d-c. regulated line proved satisfactory. In such instances the output was continually monitored by a pen recorder.

The polymerization cells were of a basic test tube type. Two platinum electrodes each of dimensions 1 in. × 1 in. and spaced 1 cm apart were sealed into a 34/45 inner joint and fitted into an outer joint test tube with a sidearm. The cells were purged with N_2 and sealed. A magnetic stirring bar agitated the solutions during electrolysis. A bank of four such cells was operated simultaneously in a constant temperature bath. One geared motor rotated a series of magnets which provided uniform, constant stirring for all cells. Samples were withdrawn with a hypodermic syringe through a serum cap fitted over the sidearm of each cell.

For kinetic analysis samples were precipitated in cold methanol, filtered, vacuum dried for 24 h, and weighed.

With all experimental runs blank experiments were performed, in which sample cells were allowed to stand for the full reaction time without passage of current. Precipitation of the contents showed that there was no detectable polymer formation in the absence of current.

Coloring of the reaction mixture during electrolysis of nitrate salts was noted previously and also occurred in this work. The characteristic color of the "living" styryl anion was not observed, and color formation is not attributed to this source.

RESULTS

With all parameters held constant except the nature of the salt, the maximum amount of polymer was formed in solutions saturated with KNO_3. The data are given in Table I together with the solubilities of salts in the system.

TABLE I

Relative yields of polystyrene with various salts at a current of 100 mA for 47 h

Salt	Solubility of salt, g/100 ml		% conversion of monomer
	In DMF	In solution	
$LiNO_3$	20		0
$NaNO_3$	16.4		0
KNO_3	1.05	0.28	33.4
$RbNO_3$	0.48	0.28	10.3
$CsNO_3$	0.48	0.15	10.2

The favored position of KNO_3 is puzzling. It is not the most soluble salt on either a molar basis or a weight basis, but its superiority to the other nitrates has been confirmed in a large number of experiments. On the other hand, all potassium salts will not give uniform polymer production at the cathode. This aspect of the polymerization mechanism deserves further investigation. Our attempts with polarographic measurements have not produced unequivocal results.

To determine the propagation mechanism, polymerizations were conducted in the presence of the free radical inhibitors *t*-butylcatechol and *p*-benzoquinone. Very high concentrations of inhibitor were used to insure that electrolytic destruction of the inhibitor would not invalidate the results. Even with 2.4% by weight of *t*-butylcatechol the degree of conversion was reduced only modestly in comparison with the uninhibited solution. The data are presented in Table II and indicate that the reaction occurs primarily by a non-radical mechanism.

TABLE II

The effect of inhibitors on the yield of polystyrene

Inhibitor	Concentration of inhibitor, %	Electrolysis time, h	Current, mA	Initial monomer concentration, %	% conversion
t-Butylcatechol	0	20	50	30	23.0
"	2.4	20	50	30	31.9
"	0	20	50	40	20.5
"	2.4	20	50	40	32.3
Benzoquinone	0	21	100	40	19
"	4.0	21	100	40	35
"	0	28	100	40	28
"	4.0	28	100	40	36.1

In an equimolar mixture of styrene and methyl methacrylate it is well known that the initial copolymer formed is approximately 50% polymethylmethacrylate in a radical copolymerization, but only 1% styrene in an anionic reaction (11).

A study of this point was made using ^{14}C-tagged monomer for ease of analysis. The data presented in Table III show that the free radical contribution is apparently confined to the first few % of polymerization, whereas at later stages the reaction is anionic. This is consistent with the inhibitor studies and may reflect some hydrogen atom initiation of the free radical reaction in the early stages.

TABLE III

The copolymerization of a mole-to-mole mixture of styrene and methyl methacrylate in a KNO_3–DMF system

Reaction time, h	% conversion	Activity of styrene monomer, counts/g min	Activity of copolymer, counts/g min	% free radical reaction
3	6.2	285 000	73 800	52.0
3	6.2	285 000	88 500	63.3
6	8.2	218 300	8 250	7.6
10	13.7	218 000	8 300	7.6
10	13.7	218 300	8 200	7.5

A systematic study was performed of the production of polymer at currents of 25, 50, and 100 mA for initial concentrations of 20, 30, and 40 volume % of monomer in dimethylformamide solutions saturated with KNO_3. The results are shown in Figs. 1 and 2 for the 30 and 40% systems.

Although the data show conclusively a dependence of polymerization rate on current and initial monomer concentration, it was not possible to assign a simple order dependence of the rate on these parameters. When the data are expressed in terms of the degree of conversion of the monomer initially present in the reaction mixture, they show an asymptotic approach to a maximum at about 50% conversion. This apparently reflects a wastage of some of the monomer in the formation of low molecular weight products which are not separated by our precipitation techniques. Hence the rate of monomer disappearance and the rate of polymer production are not equivalent in the present situation, and this fact results in a further complication in the kinetic analysis.

The molecular weights were measured on an absolute number-average basis with a Mechrolab vapor pressure instrument. The data in Table IV show no pronounced influence of the conditions of polymerization on the length of the polymer chain. The molecular weight is apparently increased by increase in monomer concentration and in temperature.

FIG. 2. Formation of polymer for a 30 volume % solution of styrene in dimethylformamide containing KNO_3 as electrolyte.

However, changes in the initiating salt or the presence of free radical inhibitors exerted only a minor influence on the molecular weight.

*With benzoquinone as inhibitor.
†With *t*-butylcatechol as inhibitor.

The absolute electrical efficiency can be determined from Faraday's Laws, in terms of moles of polymer per faraday. The data are given in Table V and indicate a high electrical efficiency of approximately 20% of the theoretical maximum during the early stages of the reaction, although this percentage falls with time as the monomer becomes depleted.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

TABLE V

The efficiency of electrolytic initiation in a 30 volume % solution

Current, mA	Electrolysis time, h	Molecular weight of polymer, g/mole	% efficiency
100	4.0	2 500	19.2
100	22.5	2 500	9.6
50	5.5	4 000	15.3
50	20.5	4 000	8.8
25	5.0	3 100	21.8
25	21.5	3 100	16.2

Infrared spectra were taken of samples of the electrically produced polymer. The data confirmed that the polymer thus produced was identical to that formed by conventional free radical polymerization.

It is evident that the KNO_3–dimethylformamide system represents the best medium thus far reported for the polymerization of styrene. Although the electrical efficiency is high, the system is not amenable to the type of kinetic analysis applied to our previous work on anionic polymerization of acrylonitrile (8). Nevertheless, we believe that the formation of a radical ion and its subsequent polymerization most probably represents the reaction path.

ELECTROINITIATED POLYMERIZATION OF STYRENE

II. KINETICS IN SOLUTIONS OF TETRAMETHYLAMMONIUM SALTS[1]

B. Lionel Funt and Suraj N. Bhadani
Parker Chemistry Laboratory, University of Manitoba, Winnipeg, Manitoba
Received June 18, 1964

ABSTRACT

The kinetics were studied of the electrically initiated polymerization of styrene in solutions of tetramethylammonium salts. The reaction was confined to the cathode and was found to proceed via an anionic mechanism. Free radical inhibitors had little influence on the yield of polymer, but the reaction was quenched by the addition of methanol.

The polymerization was investigated at six currents between 10 and 100 mA and at eight initial concentrations of monomer. Kinetic analysis of the data indicated a dependence on the first power of monomer concentration and of current.

The high electrical efficiencies and molecular weights of 15 000 to 50 000 contrast sharply with previous fruitless attempts to electroinitiate styrene polymerization. Some features of the mechanism are discussed.

Previous attempts to polymerize styrene by electrolytic means have not met with pronounced success. The work has been reviewed in an accompanying paper (1) in which the successful electroinitiated polymerization of this monomer in solutions of alkali metal nitrates was reported.

The possibility arose that the polymerization was merely a side effect due to the interaction of a deposit of the alkali metal with the monomer. Although this eventuality was eliminated by other observations, we nevertheless sought conclusive confirmation of our views. Therefore, we investigated the electrolysis of solutions of tetraalkylammonium salts. Breitenbach reported that with different anions these salts can result in either anionic or cationic polymerization (2). In these systems there is no possibility of depositing an active metal, and we found that satisfactory yields of polymer were obtained.

Further investigation proved that these systems were amenable to simple kinetic analysis, and a systematic study was undertaken of the rate of polymer formation as a function of monomer concentration, current, solvent, and salt.

EXPERIMENTAL

The experimental techniques and apparatus were similar to those described in an accompanying paper (1).

Tetramethylammonium chloride, 1.5 g, was added to 100 ml of monomer solution in dimethylformamide. This furnished a saturated solution with some excess salt present. During the course of the reaction samples were withdrawn periodically, and their polymer content was determined.

RESULTS AND DISCUSSION

Rates of Polymerization

The reaction profile as a function of current and time for a 40 volume % solution of styrene in dimethylformamide is shown in Fig. 1. A systematic increase of polymer formation with time and with impressed current is evident. Furthermore, there is no inhibition period for currents above 25 mA, and only a very small inhibition is noted for lower currents. With the small samples employed here, a correction of the volume change due to sample withdrawal did not appreciably alter the data (3) and is not presented here.

[1]*Presented at the Twelfth Canadian High Polymer Forum. Ste. Marguerite, Quebec. May 1964.*

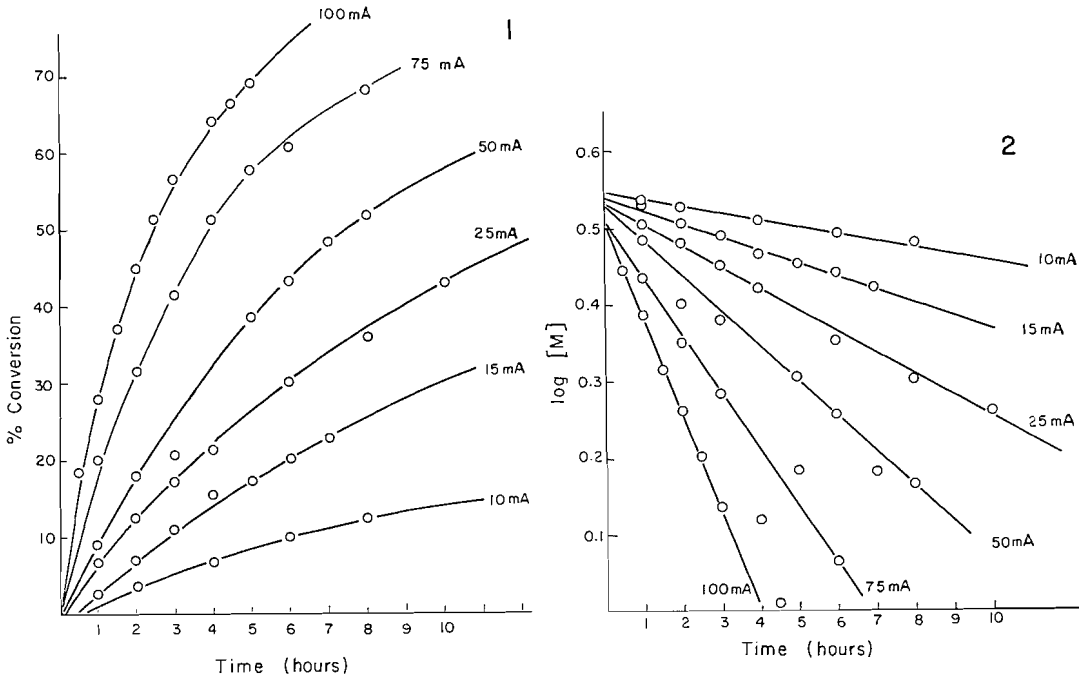

FIG. 1. Formation of polymer as a function of inscribed current and time for a 40 volume % solution of styrene in dimethylformamide containing 1.5 g of tetramethylammonium chloride.
FIG. 2. Logarithmic dependence of monomer concentration on time for a 40 volume % solution at the inscribed currents.

The results strongly suggested a first order dependence on monomer concentration. The data were expressed in terms of the logarithmic dependence of monomer concentration with time and are plotted in Fig. 2. Good linearity is observed. Similar data for 30% styrene are given in Table I.

For personal use only.

The variation of yield of polymer with time at a constant current of 15 mA but with initial monomer concentrations of 20 to 70% by volume was investigated, and the data are shown in Fig. 3. A logarithmic dependence on time should be evidenced in a family of curves of the same slope and of differing intercepts, which correspond to the initial monomer concentration. The data are consistent with this point of view and are shown in Fig. 4. The slopes of the lines in Fig. 2 were determined. For a first-order reaction these would be proportional to the rate constants. In the present instance the slopes are dependent on current, and a plot of the slope against the impressed current was found to be linear.

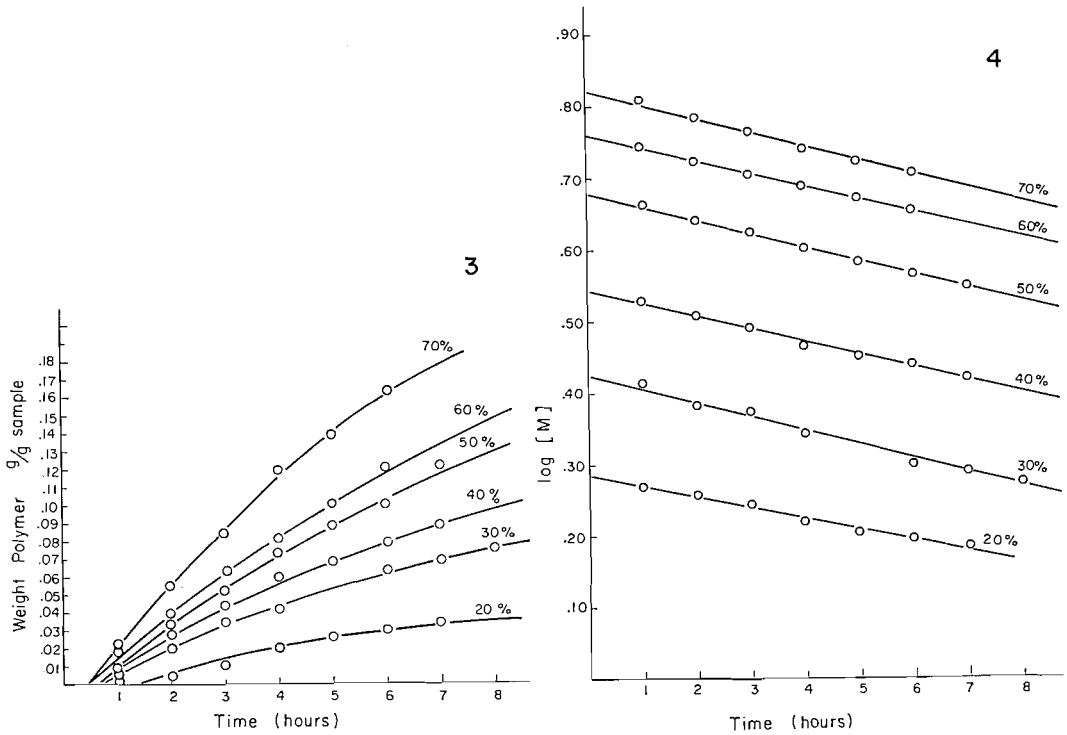

FIG. 3. Polymer formation at inscribed initial monomer concentrations with a current of 15 mA.
FIG. 4. Logarithmic dependence of polymer formation on time at the inscribed initial concentrations.

This suggested the possibility that all the data for different concentrations could be contained in a single unified expression. If the rate constant is a linear function of the impressed current, then

$$\ln (M/M_0) = - kIt,$$

where M and M_0 are instantaneous and initial monomer concentrations, I is the current, and t is the elapsed time. A plot of log $(M_0/M)/I$ versus t for all our data is shown in Fig. 5. A gratifying agreement is evident.

Locus of Polymerization

The locus of polymerization was determined to be the cathode. In an experiment with a divided cell in which the anode and cathode compartments were separated by a fritted disk, 1.29 g of polymer formed at the cathode during the first hour, but no polymer was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

formed at the anode. Although polymer can be isolated from the anode compartment at later stages in the reaction, it is believed that this results from diffusion into rather than formation in this region. The same conclusion was reached for polymerizations with other anions. The data are given in Table II.

TABLE II

Polymer formation at anode and cathode compartments of a divided cell with 20 volume % of styrene in dimethylformamide and current of 15 mA

Salt	Electrolysis time, min	Wt. of cathodic polymer, g	Wt. of anodic polymer, g
$(CH_3)_4NCl$	30	0.503	<.002
$(CH_3)_4NCl$	58	1.293	<.002
$(CH_3)_4NCl$	90	1.300	.224
$(CH_3)_4NClO_4$	60	0.765	<.002
$(CH_3)_4NNO_3$	60	0.808	<.002

In this system there is little dependence of the yield of polymer or the electrical efficiency upon the anion employed. There is apparently some correlation between the yield of polymer and the solubility of the salt in the system. However, the data are too limited in range to consider this point established. This type of correlation was not found in the alkali metal systems (3).

Electrical Efficiency

The electrical efficiency, expressed in moles of monomer polymerized per faraday, increased with increase in monomer concentration to very high concentrations. In solutions of over 60 volume % of styrene, the conductance decreased to such an extent that lower currents had to be employed. The data are presented in Table III. Only at the very highest concentration of 80 volume % is there a notable decrease in electrical efficiency.

TABLE III

Yield and electrical efficiency at various initial monomer concentrations

Styrene concentration, volume %	Time of Electrolysis, h	Current, mA	Wt. polymer, g	Moles styrene polymerized per faraday
10	7	35	2.65	2.79
20	7	35	6.22	6.54
30	7	35	11.8	12.4
40	7	35	13.2	13.9
50	7	35	20.7	21.7
60	7.5	25	22.8	31.3
70	23	8	25.5	35.7
80	21	2	23.0	14.1

Molecular Weights

The molecular weights were determined on the basis of intrinsic viscosity measurements with values of $K = 1.12 \times 10^{-4}$ and $\alpha = 0.73$ (4). No notable change in molecular weight was found with variation of any of the controlled parameters. The data in Table IV show maximum possible changes from 14 000 to 19 000 molecular weight between 10 and 100 mA, but the scatter in the data indicates that this is the limit of variation. No intensive work was done with systems at low temperature, but an indication was obtained that the molecular weight increased for runs performed at 0 °C and −8 °C.

TABLE IV

Molecular weights of polymers formed at various currents and temperatures

Current, mA	Temperature, °C	Limiting viscosity number	Molecular weight
10	25	0.12	14 000
15	25	0.16	21 000
35	25	0.15	19 000
50	25	0.13	16 000
75	25	0.13	16 000
100	25	0.15	19 000
15	45	0.16	21 000
15	0	0.22	32 000
15	−8	0.29	47 000

Inhibitors

The kinetics were investigated in the presence of free radical inhibitors, *t*-butylcatechol and *p*-benzoquinone, and with methanol as a chain-stopping agent for anionic reactions. Approximately 0.4 to 0.5 weight % were used in each case, which corresponded to .036 *M* *p*-benzoquinone, 0.249 *M* *t*-butylcatechol, and 0.123 *M* methanol. The data are shown in Fig. 6. Little overall effect on the rate is exhibited by the free radical inhibitors. However, with 0.49 *M* methanol there is no sensible rate of reaction. The data strongly support the concept of anionic propagation as the dominant step in chain addition.

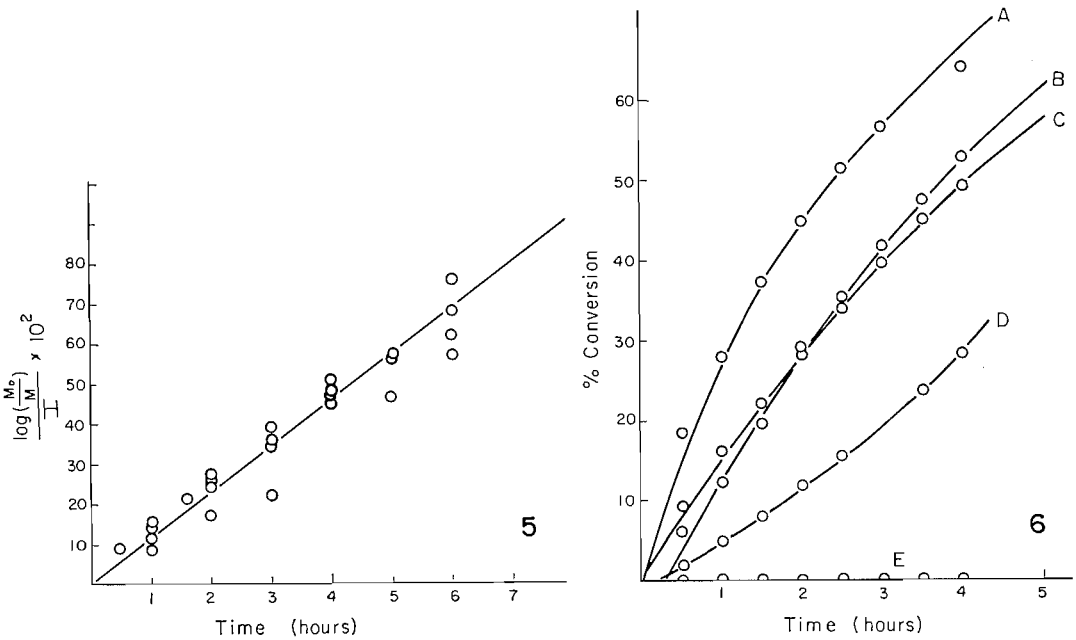

FIG. 5. Dependence of all the data on the proposed relationship with time and current.

FIG. 6. Effect of various free radical and ionic inhibitors of the rate of polymer formation at a current of 100 mA and an initial concentration of 40 volume % styrene. A, no inhibitor; B, 0.036 *M* *p*-benzoquinone; C, 0.0249 *M* *t*-butylcatechol; D, 0.123 *M* methanol; E, 0.493 *M* methanol.

Copolymerization

The propagation mechanism in electroinitiated polymerization has been determined from data on copolymerization. Thus from an equimolar mixture of styrene and methyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

methacrylate the initial polymer should be approximately 1% styrene for anionic polymerization but 50% styrene for free radical propagation. In replicate tracer experiments with ^{14}C-tagged styrene it was determined that the initial polymer contained 36% styrene. This result was confirmed by experiments at different currents. The experiments were repeated with tagged methyl methacrylate in order to eliminate any systematic error in analysis, but the data showed 64% by weight of methyl methacrylate, thus substantiating the previous results.

The bulk of the evidence is against these findings which are equivocal in the present instance. There is no other evidence to suggest a free radical contribution to the reaction. The formation of polymer solely at one electrode, the inhibitor studies, the smooth rate curves, and the constancy of molecular weight all point to an ionic mechanism and tend to eliminate a free radical mechanism. It is possible that the electrolysis is affecting the course of the copolymerization, but this, if it exists, must be considered a new effect.

The general kinetic features of the mechanism are similar to those exhibited in the acrylonitrile system which we investigated previously (3). One major difference in the present work is the smaller role of chain transfer to monomer. The lower electrical efficiency indicates a smaller degree of chain transfer than would be expected with styrene in contrast to acrylonitrile. However, the assumption, which we employed previously, that the rate-determining step is the dimerization of radical ions to form di-anions will explain the experimentally determined dependence of rate on current and on monomer concentration.

THE ALUMINIUM – ALUMINIUM BROMIDE AND ALUMINIUM – ALUMINIUM IODIDE SYSTEMS

JOMAR THONSTAD
Department of Metallurgical Engineering, University of Toronto, Toronto, Ontario
Received July 20, 1964

ABSTRACT

The Al–Al_2Br_6 and Al–Al_2I_6 binary systems have been investigated by cryoscopy and solubility measurements. Pure Al_2Br_6 melts at 98.01 ± 0.02 °C; the eutectic is found at 97.91 ± 0.02 °C and 0.017 wt. % Al; at 254 °C the solubility of aluminium increases to 0.0195 wt. %. Pure Al_2I_6 melts at 188.32 ± 0.02 °C; the eutectic is found at 188.17 ± 0.02 °C and 0.018 wt. % Al; at 320 °C the solubility increases to 0.021 wt. % Al. From the results it is concluded that dissolved aluminium is present in the melt either as Al_2^0 dimer species or as associated molecules of Al_4Br_6 and Al_4I_6.

INTRODUCTION

Aluminium bromide and aluminium iodide are white crystalline compounds that melt into colorless liquids. The melting points are given as 97.1 °C (1) to 97.5 °C (2) for the bromide and 191 °C (2) for the iodide. The boiling points are 255 and 381 °C (3) respectively.

The structure of aluminium bromide has been found (4) to consist of bromine in closest hexagonal packing, with the aluminium in adjacent tetrahedral holes. This corresponds to Al_2Br_6 molecules where aluminium is tetrehedrally surrounded by four bromine atoms, the two tetrehedra sharing an edge. A corresponding but somewhat distorted bimolecular structure is found (5) in the vapor phase of both bromide and iodide, although a certain dissociation takes place at high temperatures. Raman spectra (6) show that the bimolecular configuration is also maintained in the liquid phase for the bromide and the iodide. The covalent molecular state of the melts has been confirmed by measurements of specific conductivities (2) which were found to be extremely low.

The solubility of aluminium in aluminium iodide has been measured (7) and was found to be 0.6 mole % (Al in Al_2I_6) at 423 °C and 0.0 mole % at 380 °C. Apart from these measurements the solubilities of metals in metal halides of covalent molecular structure have not been studied. In view of this fact it was found to be of interest to investigate the solubility of aluminium in Al_2Br_6 and Al_2I_6 in some detail.

EXPERIMENTAL

Aluminium bromide and iodide were made by direct reaction of the component elements. The aluminium was of 99.998% purity (Refined ALCAN aluminium). The bromine and iodine were "Baker Analysed" reagents with the following analyses: bromine 99.8% Br, 0.01% non-volatile matter, 0.15% Cl, 0.05% I, 0.001% S0, .001% heavy metals; iodine 0.002% non-volatile matter, 0.001% Cl + Br.

Both compounds were extremely hyroscopic and had to be synthesized in evacuated pyrex tubes. The reactants were transferred to the reaction tubes in a dry-box under an inert nitrogen atmosphere.

The rates of reaction between the aluminium and the halide vapors were kept under control by maintaining the tubes at temperatures well below the boiling points of bromine and iodine respectively. The resulting compounds were distilled twice and could then be used directly for the solubility measurements. For the melting point determinations further purification was needed, as will be described subsequently.

Solubility Measurements

The distilled product was allowed to equilibrate with aluminium metal for 24 h in a furnace kept at constant temperature. At the end of this period the tube was tilted to separate the metal from the melt and was quenched in air. The quenched sample had a grayish tinge, probably because of its metal content.

The sample was then transferred to an analysis apparatus where it was dissolved in alcohol and water. To prevent the initially occurring violent reaction of the anhydrous salt with water, alcohol was added first. The excess metal content reacted with alcohol or water with the evolution of hydrogen

$$(\text{e.g. } Al + 3H_2O \rightarrow Al(OH)_3 + 3/2\,H_2),$$

which was determined by a combustion technique. To this purpose the evolved hydrogen, mixed with nitrogen as a carrier gas, was led through a liquid air trap to a heated tube containing CuO at 300 °C. The water vapor produced was absorbed in an absorption tube and weighed. The method was tested with blank runs and by using samples of different weights. The blanks gave no weight increase of the absorption tube, while the runs with samples of different weights showed a precision as given for the results.

Melting Point Determinations

The compounds were kept in capillary tubes immersed in a thermostatically heated oil bath. The temperature was measured with a Beckmann thermometer calibrated against an ERTCO precision thermometer, calibrated according to ASTM standards.

By manual control the temperature of the oil bath could easily be kept within ±0.005 °C. The melting points were determined by increasing the temperature in steps of 0.01 °C at intervals of 1–2 h, until the crystals in the capillary had melted.

The distilled samples did not melt at a definite temperature but over a range of 0.2–0.3 °C, either because of the influence of impurities or because of an excess of halogen or metal. For further purification the samples were kept within the observed solidus–liquidus range at gradually increasing temperatures, the molten phase being discarded each time. An alternative procedure was to let the compound crystallize out from the molten samples by keeping them within the corresponding liquidus–solidus range. The presence of seed crystals was necessary in this case because the melt had a strong tendency to undercooling. Undercooling was generally about 8 °C for Al_2Br_6 and about 12 °C for Al_2I_6.

Pure samples which melted completely at one definite temperature were finally obtained. Samples saturated with metal were made by equilibrating the pure samples with metal for 24 h before being transferred to the capillary. Intermediate compositions were obtained by adding the pure compound to the saturated mixtures. The samples were finally analyzed for their metal content.

Melting points could be determined with a precision better than ±0.01 °C. Thus freezing point depressions could be determined with a precision better than ±0.02 °C. Because of possible errors in the calibration of the thermometer, the accuracy of the melting points presented herein is given as ±0.02 °C.

RESULTS

From the combined results of the melting point and the solubility measurements, the liquidus curve for solutions of aluminium in aluminium bromide and aluminium iodide melts was determined.

The results for the Al–Al_2Br_6 system are given in Table I.

TABLE I

Melting points and solubilities in the Al–Al_2Br_6 system

	Temperature, °C	Composition, wt. % Al
From melting point determinations	98.01±0.02	0
	97.96±0.02	0.0084
	97.91±0.02	0.017
	105	0.017
From solubility measurements	145	0.018
	198	0.018
	241	0.019
	254	0.0195

The observed melting point for pure aluminium bromide is 98.01 ± 0.02 °C, which is 0.5–0.9 °C higher than the values given in the literature (1, 2). The results indicate a eutectic at 97.91 ± 0.02 °C and 0.017 wt. % Al. On a molar scale (atom % Al in Al_2Br_6) this composition corresponds to 0.34 mole % Al. Within the precision of the measurements, the freezing point depression of the eutectic is 0.10 ± 0.02 °C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Five solubility determinations at 198 °C gave results between 0.0177 wt. % and 0.0188 wt. % Al. At higher temperatures the precision apparently was not so good.

The results for the Al–Al_2I_6 system are given in Table II.

TABLE II
Melting points and solubilities in the Al–Al_2I_6 system

	Temperature, °C	Composition, wt. % Al
From melting point determinations	188.32±0.02	0
	188.17±0.02	0.018
	190	0.018
From solubility measurements	202	0.0185
	265	0.020
	320	0.021

The observed melting point for pure aluminium iodide is 188.32 ± 0.02 °C, which is about 2.7 °C lower than the value given in the literature (2). The results indicate a eutectic at 188.17 ± 0.02 °C and 0.018 wt. % Al, corresponding to 0.54 mole % Al. The freezing point depression of the eutectic is 0.15 ± 0.02 °C. The precision of the solubility measurements was not as good as in the bromide system.

DISCUSSION

The measured melting points and the solubility data give the liquidus curves of the phase diagrams of the two systems, as shown in Figs. 1 and 2. The shape of the curves is similar to those available for some metal–salt systems (8), but the solubilities are in this case unusually low. This is probably due to the covalent molecular structure of the melts.

Extrapolation of the liquidus curve in Fig. 2 to 423 °C indicates that the solubility at that temperature is ~0.023 wt. % or ~0.7 mole % Al in Al_2I_6. This is in fair agreement with the measurement by Corbett and Winbush (7) giving a solublity of 0.6 mole % at 423 °C. The other measurement by these authors, indicating no solubility at 380 °C, is apparently in error.

From cryoscopic calculations some information can be obtained about the species that are present in the melt. Assuming ideal behavior and the absence of solid solubility, the simplified equation is:

$$\log N = -\frac{H_f}{R\,T_f^2}\,\Delta T,$$

where N, H_f, and T_f are the mole fraction, the heat of fusion, and the melting point respectively of the solvent (aluminium bromide or iodide), and ΔT is the corresponding freezing point depression.

The heats of fusion of the compounds are (9) 5.4 kcal/mole Al_2Br_6 and 7.6 kcal/mole Al_2I_6 respectively. The uncertainty of the data is estimated (9) to be ±0.4–0.6 kcal/mole.

Assuming different schemes of solution, corresponding values for N and ΔT can be calculated and the latter can be compared to the measured values. The following schemes are considered (X stands for Br or I, n is the number of moles).

1*a*. Free aluminium atoms:

$$Al \rightarrow Al^0$$

$$N_{Al_2X_6} = \frac{n_{Al_2X_6}}{n_{Al_2X_6} + n_{Al}}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

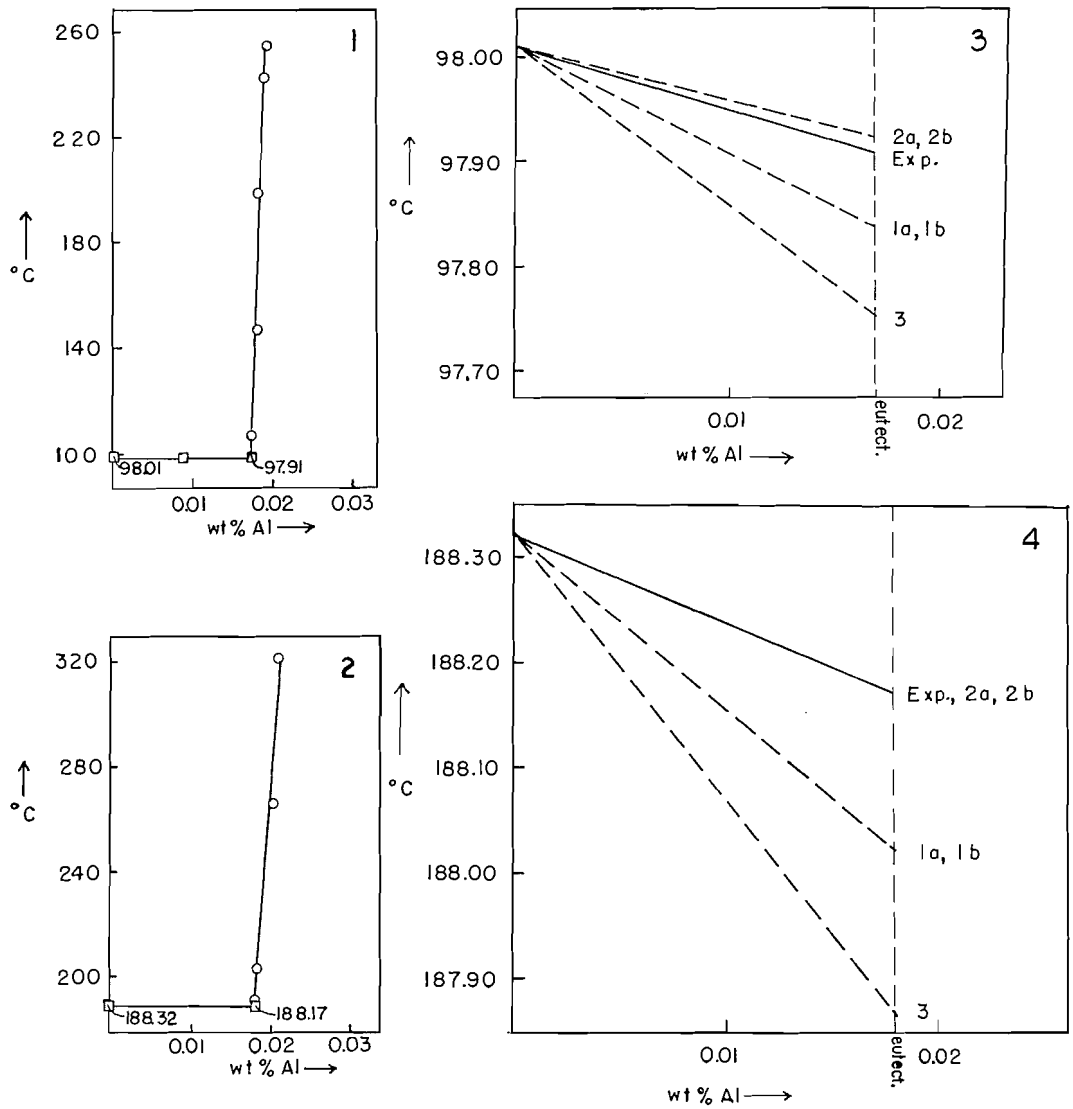

FIG. 1. Liquidus curve of the Al_2Br_6–Al system. □, From melting point determinations; ○, from solubility measurements.

FIG. 2. Liquidus curve of the Al_2I_6–Al system. □, From melting point determinations; ○, from solubility measurements.

FIG. 3. Measured and calculated freezing point depressions in the Al_2Br_6–Al system.

FIG. 4. Measured and calculated freezing point depressions in the Al_2I_6–Al system.

1*b*. Associated Al atoms:

$$Al + Al_2X_6 \rightarrow Al_3X_6$$

$$N_{Al_2X_6} = \frac{n_{Al_2X_6} - n_{Al}}{n_{Al_2X_6}}.$$

2*a*. Dimer aluminium atoms:

$$2Al \rightarrow Al_2^0$$

$$N_{Al_2X_6} = \frac{n_{Al_2X_6}}{n_{Al_2X_6} + \frac{1}{2}n_{Al}}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

2*b*. Associated dimers:

$$2Al + Al_2X_6 \rightarrow Al_4X_6$$

$$N_{Al_2X_6} = \frac{n_{Al_2X_6} - \frac{1}{2}n_{Al}}{n_{Al_2X_6}}.$$

3. Monovalent aluminium:

$$4Al + Al_2X_6 \rightarrow 6AlX$$

$$N_{Al_2X_6} = \frac{n_{Al_2X_6} - \frac{1}{4}n_{Al}}{n_{Al_2X_6} + \frac{5}{4}n_{Al}}.$$

The resulting liquidus curves calculated for the eutectic points are given in Figs. 3 and 4. Schemes 2*a* and 2*b* give almost identical results, and it may be seen that either scheme is in good agreement with the experimentally measured depressions of the freezing points. For the bromide system the calculated depression for the eutectic composition is 0.085 ± 0.006 °C as against the measured 0.10 ± 0.02 °C. For the iodide system the calculated depression is 0.15 ± 0.01 °C and the measured is 0.15 ± 0.02 °C. It should be noted that the same results are obtained if the bromides and iodides are taken as monomolecular ($AlBr_3$ and AlI_3). Testing of schemes other than those listed here confirms that 2*a* and 2*b* are the only conceivable models that agree with the experimental data.

From the preceding treatment it appears that the Al_2Br_6–Al and Al_2I_6–Al systems contain either neutral diatomic groups of aluminium or associated dimers like Al_4Br_6 and Al_4I_6.

ACKNOWLEDGMENT

The author wishes to thank Professor S. N. Flengas, University of Toronto, for helpful suggestions and for critically reading the manuscript.

RÉACTIONS AVEC LE DIFLUOROAMINO-PENTAFLUOROSULFURE[1]

JEAN L. BOIVIN
Centre Canadien de Recherches et de Perfectionnement des Armes, Département de Défense Nationale, Valcartier, Québec

Reçu le 29 mai 1964

ABSTRACT

Difluoroamino-sulphur pentafluoride was prepared in quantitative yield by heating tetrafluorohydrazine and disulphur decafluoride at 150° for a period of 12 h under autogenous pressure conditions. The reactions of the product with potassium iodide, oxygen, water, hydrogen chloride, sulphur dioxide, acetone, ethyl bromide, methyl iodide, ethyl nitrite, cyanogen bromide, and acetonitrile are reported.

INTRODUCTION

Le difluoroamino-pentafluorosulfure (DPS) a été synthétisé et utilisé dans ce laboratoire depuis quelques années (1), mais plusieurs méthodes de préparation ont été décrites dans la littérature par différents chercheurs (2, 3, 4).

Le produit a été préparé en faisant réagir la tétrafluorohydrazine sur le tétrafluorure de soufre, le pentafluoro-chlorosulfure ou le soufre avec des rendements n'excédant pas 30% (2). Une autre méthode consiste à faire réagir la tétrafluorohydrazine et le décafluorobisulfure; on a obtenu des rendements de 60% (3) et de 12% (4). La méthode que nous décrivons ici donne des rendements quantitatifs en difluoroamino-pentafluorosulfure.

Nous l'avons obtenu en chauffant la tétrafluorohydrazine et le décafluorobisulfure à une température de 150° durant 5 à 12 h sous pression autogène. Si l'on opère à des températures plus basses, on obtient aussi des rendements quantitatifs mais seulement après un temps de chauffage excessif. De plus, on ne peut chauffer le mélange à des températures dépassant 150°; le décafluorobisulfure commence à se décomposer d'une façon appréciable pour donner du tétrafluorure de soufre et de l'hexafluorure de soufre (5). Si l'on emploie un léger ou grand excès de décafluorobisulfure, on obtient un rendement quantitatif en DPS à partir de la tétrafluorohydrazine. Cependant, nous préférons employer le rapport stoichiométrique parce que le décafluorobisulfure est laborieux à préparer. Avec un excès de tétrafluorohydrazine, on a tendance à produire beaucoup d'hexafluorure de soufre grâce à l'oxydation de S_2F_{10} par l'action de N_2F_4.

Propriétés chimiques du difluoroamino-pentafluorosulfure

Quand on chauffe le DPS à des températures de 100 à 150°, on constate qu'il se décompose lentement suivant l'équation suivante:

$$2\ F_2N{-}SF_5 \rightarrow F_2N{-}NF_2 + F_5S{-}SF_5.$$

Lors de la détermination de la température critique du DPS, on a identifié du décafluorobisulfure dans les produits de décomposition. Cependant, à des températures supérieures (150–200°), on observe une décomposition importante du DPS en N_2F_4, SF_6 et SF_4 (2, 3, 4) suivant l'équation:

$$2\ F_2N{-}SF_5 \rightarrow F_2N{-}NF_2 + F_5S{-}SF_5 \downarrow SF_4 + SF_6.$$

[1]*Publié comme Mémoire Technique No. 436 et travail exécuté sous le numéro de projet: D46-10-28-34.*

A 200° et au-dessus, la décomposition de N_2F_4 continue jusqu'à NF_3 et N_2 (2, 3, 4).

Avec une solution aqueuse d'iodure de potassium, le DPS libère de l'iode, démontrant ainsi son pouvoir oxydant. Mais la réaction semble se produire en deux étapes; en premier lieu, le fluor de la partie NF_2 est libéré à température ordinaire, puis en chauffant la solution, il y a plus d'iode libéré lequel semble provenir de la partie SF_5.

Avec l'oxygène, le DPS se décompose en NO, N_2, NOF, SF_6 et SOF_2. La présence de NOF a été démontrée à partir de son spectre de masse et de son temps de rétention (6.2 min). Les pics de son spectre de masse se présentent à *m/e* 30 et 33 seulement, indiquant les groupements NO et NF. L'ion NF ne peut provinir de NF_3 ou N_2F_4 puisqu'ils n'ont pas le même temps de rétention dans le chromatogramme.

La réaction du DPS avec l'eau en léger excès donne naissance à N_2, NO, SF_6, SO_2 et HF comme produits principaux, démontrant ainsi que l'eau seule ne peut libérer complètement le fluor de la molécule.

Avec le chlorure d'hydrogène, le DPS donne N_2, SF_6, SF_4 et $ClSF_5$. Le produit principal de la réaction avec HCl dans des conditions optimum aurait été $ClSF_5$. Il serait formé suivant la réaction:

$$F_2N—SF_5 + HCl \rightarrow F_2NH + ClSF_5.$$

La difluoramine formée se décomposerait rapidement dans les conditions utilisées (150° pendant 10 h). La forte proportion de SF_6 obtenue indique que le fluor de la difluoramine a réagi avec les groupements SF_5.

La réaction du DPS avec l'acétone à une température de 100° donne plusieurs produits dont N_2, SF_6, SOF_2 et SO_2, tandis qu'à des températures plus élevées (150°) on obtient HF, SOF_2 et du carbone. Cela indique que le DPS enlève l'oxygène de la molécule d'acétone pour conduire à des produits du soufre et du fluor plus stables.

L'action du DPS sur le bromure d'éthyle produit du fluorure d'éthyle et du brome; avec l'iodure de méthyle, on obtient du fluorure de méthyle et de l'iode, et en plus SF_6 et SF_4. Le DPS décompose le nitrite d'éthyle en C_2H_5F, N_2O et SOF_2.

Le bromure de cyanogène et le DPS réagissent pour donner du cyanogène, du trifluorométhylimino-difluorosulfure, du trifluorosulfure d'azote et du brome. L'acétonitrile est décomposé par le DPS en tétrafluorométhane.

L'action de l'anhydride sulfureux sur le DPS donne naissance au difluoroamino-fluorure de sulfuryle (6) d'après l'équation suivante:

$$F_2N—SF_5 + SO_2 \rightarrow F_2N—SO_2F + SF_4.$$

PARTIE EXPERIMENTALE

Produits de départ

On a obtenu la tétrafluorohydrazine de Du Pont. Le produit était 95% pur et contenait des traces de NF_3, NO et de fluorocarbures. Le décafluorobisulfure nous a été donné par Defence Research Chemical Laboratories, Ottawa, et fut utilisé sans autre purification. Ce produit est très toxique.

Procédé général

La plupart de toutes les réactions ont été faites sous pression dans des autoclaves de 110 et 330 millilitres de capacité. Les liquides ou les gaz ont été distillés sous vide dans les autoclaves refroidis à −196°, −78° ou 0°, dépendant des propriétés des composés. Le mélange réactionnel a été chauffé par contrôle à distance dans un compartiment bien protégé contre les explosions. La réaction terminée, les gaz ont été analysés par chromatographie et spectrométrie de masse.

Pour l'identification et l'analyse des mélanges gazeux, on s'est servi d'un chromatographe en phase gazeuse accouplé à un spectrographe de masse à temps d'envol. Le chromatographe était un Perkin–Elmer modèle 154D dont la colonne mesurait 30 pieds. Elle consistait d'une longueur de 20 pieds faite de tube de cuivre de $\frac{1}{4}$ pouce de diamètre lequel avait été chargé de "Chromosorb P" contenant 33% d'huile Kel-F No. 10; l'autre partie, longue de 10 pieds, était chargée aussi de "Chromosorb P" contenant 10% de didodécyl

For personal use only.

phtalate. Dans tous les cas, la colonne était maintenue à 35° et balayée par un courant d'hélium passant à un débit de 17 ml/min. Un intégrateur donnait le pourcentage de produit d'après l'aire relative occupée par les pics.

Une portion du gaz effluent du chromatographe était détournée pour alimenter un spectrographe de masse à temps d'envol Bendix. L'ionisation était maintenue constante à 50 V. Le spectre de masse était enregistré au moyen d'un Visicorder ou photographié sur l'écran d'un oscilloscope.

Difluoroamino-pentafluorosulfure

On a ajouté du décafluorobisulfure (20 g, 0.08 mole) dans un autoclave de 330 ml préalablement refroidi à la température de l'azote liquide et on a fait le vide sur le système jusqu'à 1 mm de Hg. Ensuite, on y a distillé sous vide de la tétrafluorohydrazine (8.3 g, 0.08 mole). On a chauffé le mélange sous pression autogène à 150° pour une période de 5 h et on l'a laissé refroidir à température ordinaire. Les produits gazeux de la réaction furent condensés dans un récipient refroidi dans l'azote liquide pour donner 28.0 g de produit brut. On a ensuite laissé le récipient à −30° pour se débarrasser de la tétrafluorohydrazine qui n'a pas réagi, de l'hexafluorure de soufre et du tétrafluorure de soufre. Lorsqu'on a laissé le mélange résiduel se réchauffer à température ordinaire, on a condensé le difluoroamino-pentafluorosulfure brut à −78° pour obtenir 23.0 g de produit, à peu près pur, p.e. −25° à −15°. En refractionnant ce produit, on a obtenu 22.5 g de DPS bouillant à −16.5° sous 750 mm de Hg. Rendement: 88%. On récupéra 2.5 g de S_2F_6. Le rendement est donc quantitatif si on le calcule à partir du S_2F_{10} utilisé dans la réaction.

Si l'on emploie un excès de décafluorobisulfure de 50% par rapport à la tétrafluorohydrazine et que l'on effectue la réaction dans les mêmes conditions que ci-haut, on obtient un rendement quantitatif de DPS à partir de N_2F_4.

La même réaction en présence d'un excès de 100% de tétrafluorohydrazine par rapport au décalfluorobisulfure conduit à un rendement faible en DPS. L'excès de N_2F_4 se décompose pour fluorer S_2F_{10} en SF_6.

Le DPS a donné un spectre de masse et infrarouge identiques aux données de la littérature (2, 3, 4).

La température critique du DPS fut déterminée par la méthode de Cailletet et Colardeau (7) comme étant 1 702° avec une pression critique d'environ 33 atm. La pression critique n'a pas pu être déterminée avec certitude parce que le DPS se décompose lentement à cette température.

On a mesuré aussi la pression de vapeur à 8, 21, 30 et 45° comme étant 48, 59, 72 et 100 lb/pouce^2 respectivement.

Le DPS avait un point d'ébullition de −16.5°, un point de fusion d'environ −110° et une densité à −78° de 2.0. On a déterminé le poids moléculaire par la méthode d'effusion des gaz et on a trouvé 174 au lieu de 179. Toutes ces constantes physiques concordent avec celles données dans la littérature (2, 3, 4).

Stabilité du DPS à température élevée

Dans un autoclave de 110 ml préalablement refroidi à la température de l'azote liquide et évacué à 1 mm de Hg, on a distillé du DPS pur (5.0 g, 0.028 mole) et on a chauffé le produit à 200° pendant 2 h. Après refroidissement de l'autoclave à température ordinaire, on a analysé les gaz par chromatographie et spectrométrie de masse pour obtenir les pics de temps de rétention suivants: 6.0 min, N_2 (0.1%); 7.2 min, SF_6 (4.0%); 7.6 min, N_2F_4 (3.8%); 10.2 min, SF_4 (24.7%); 12.8 min, DPS (67.4%).

Quand on a chauffé le même mélange pendant une période additionnelle de 10 h à 200°, on a obtenu les résultats suivants: 6.0 min, N_2 et NF_3 (traces); 7.2 min, SF_6 (13.0%); 7.6 min, N_2F_4 (10.6%); 10.2 min, SF_4 (46.7%); 12.8 min, DPS (29.7%).

On chauffa une autre quantité de DPS dans les mêmes conditions à 125° pendant 10 h. On obtint les résultats suivants: 7.2 min, SF_6 (traces); 7.6 min, N_2F_4 (5.0%); 12.8 min, DPS (90.0%); 28.7 min, S_2F_{10} (5.0%).

Comportement du DPS vis-à-vis l'iodure de potassium en solution aqueuse

En passant quelques millilitres de DPS à travers une solution aqueuse d'iodure de potassium, on obtint une libération instantanée d'iode. En chauffant légèrement la solution, une quantité plus grande d'iode est dégagée.

Réactions du DPS

1. Avec l'oxygène

Dans un autoclave de 110 ml refroidi à −196°, on a distillé du DPS (5.0 g, 0.028 mole) et de l'oxygène (1.0 g, 0.032 mole) sous un vide de 1 mm de Hg. Après chauffage d'une heure à 125°, l'analyse chromatographique des gaz donna les temps de rétention suivants: 6.0 min, N_2 et NO (10.5%); 6.2 min, NOF (2.4%); 7.2. min, SF_6 (5.0%); 7.6 min, N_2F_4 (0.7%); 8.8 min, SO_2F_2 (2.9%); 10.2 min, SOF_2 (10.1%); 12.8 min, DPS (68.4%). L'oxygène a complètement réagi.

La même réaction a été effectuée avec un grand excès d'oxygène (5.0 g) pour ne laisser aucune quantité de DPS n'ayant pas réagi, pendant que les autres produits étaient les mêmes que précédemment.

2. Avec l'eau

Dans un autoclave évacué à 1 mm de Hg, on a introduit de l'eau (2.0 g, 0.11 mole), puis on a refroidi l'autoclave à −196° pour condenser du DPS (5.0 g, 0.028 mole). On a chauffé le mélange à 125° pendant une

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

heure. L'analyse des gaz par chromatographie donna: 6.0 min, N_2 et NO (16.7%); 7.2 min, SF_6 (67.6%); 8.8 min, SO_2F_2 (10.8%); 19.2 min, SO_2 (5.9%). Le poids total des gaz étaient de 4.5 g. HF était aussi présent en grande quantité. L'analyse révèle que SF_6 est un des produits majeurs obtenus à partir de l'eau et du DPS.

3. Avec le chlorure d'hydrogène

Dans un autoclave de 110 ml refroidi à −196°, on a distillé du DPS (6.0 g, 0.033 mole) et HCl (1.0 g, 0.027 mole) sous un vide de 1 mm de Hg et on a chauffé le mélange à 100° pendant une heure. Il n'y eut aucune réaction. On le chauffa ensuite à 150° pour une période additionnelle de 10 h. On a obtenu le mélange de gaz suivants: 6.0 min, N_2 (14.8%); 7.2 min, SF_6 (22.8%); 7.6 min, N_2F_4 (0.1%); 10.2 min, SF_2 (52.1%); 12.8 min, DPS (8.4%); 14.8 min, $ClSF_5$ (1.8%).

4. Avec l'acétone

En employant la même méthode que précédemment, on a fait réagir de l'acétone (0.5 g, 0.008 mole) et du DPS (3. 0 g, 0.016 mole) à 125° durant 12 h. On a obtenu les pics chromatographiques suivants: 6.0 min, N_2 (32.5%); 7.2 min, SF_6 (3.9%); 8.8 min, SO_2F_2 (8.0%); 10.2 min, SOF_2 (7.3%); 19.2 min, SO_2 (48.3%).

Quand on a effectué la réaction à 150° pendant 10 h, le mélange se carbonisa et on obtint de l'acide fluorhydrique et du fluorure de thionyle.

5. Avec le bromure d'éthyle

On chargea l'autoclave de la façon habituelle avec du bromure d'éthyle (10.9 g, 0.1 mole) et du DPS (5.4 g, 0.03 mole) et on chauffa le mélange à 100° pendant 12 h, puis ensuite pour des périodes additionnelles identiques à 125° et à 150°. On obtint les résultats suivants: 6.0 min, N_2 (1.2%); 7.2 min, SF_6 (33.5%); 10.2 min, SF_4 (33.8%); 12.2 min, C_2H_5F (31.5%). L'autoclave contenait aussi du carbone et du brome (7.0 g, 0.043 mole).

6. Avec l'iodure de méthyle

La réaction fut faite de la façon habituelle avec l'iodure de méthyle (7.0 g, 0.05 mole) et le DPS (8.0 g, 0.044 mole). Le mélange fut chauffé à 125° pour une période de 5 h suivie d'une autre période de 5 h à 150°. La fraction gazeuse a donné les pics suivants: 6.0 min, N_2 (19.2%); 7.2 min, SF_6 (0.1%); 8.0 min, CH_3F (29.0%); 10.2 min, SF_4 (51.7%). Les autres produits qui restaient dans la bombe étaient du carbone et de l'iode (6.0 g, 0.024 mole).

7. Avec le nitrite d'éthyle

De la même façon, on a fait réagir du nitrite d'éthyle (7.5 g, 0.1 mole) et du DPS (4.5 g, 0.025 mole) en chauffant le mélange à 75° pendant 5 h, suivi d'une autre période de chauffage de 5 h à 100°. On obtint les pics chromatographiques suivants: 6.0 min, N_2 (40.9%); 7.2 min, SF_6 (0.2%); 7.8 min, N_2O (18.5%); 10.2 min, SOF_2 (34.4%); 12.2 min, C_5H_2F (3.0%); 19.2 min, SO_2 (traces). Il y avait aussi un liquide dans l'autoclave qui fut identifié comme du nitrite d'éthyle.

8. Avec le bromure de cyanogène

De la même façon que ci-haut, on a fait réagir du bromure de cyanogène (6.0 g, 0.056 mole) et du DPS (5.0 g, 0.028 mole) en chauffant le mélange pendant des périodes consécutives de 5 h à 75°, 100° et 125°. On a obtenu les résultats chromatographiques suivants: 6.0 min, N_2 (12.9%); 7.2–7.6 min, SF_6 et CO_2 et N_2F_4 (16.6% ensemble); 8.8 min, SiF_4 (1.3%); 10.2 min, SF_4 (3.6%); 13.3 min, $(CN)_2$ (12.0%); 14.0 min, NSF_3 (12.0%); 19.5 min, CF_3NSF_2 (8.7%); 28.7 min, S_2F_{10} (32.9%). Le décafluorobisulfure était présent dans le produit de départ comme impureté dans le DPS. Dans l'autoclave, il y avait du brome libre (3.5 g, 0.022 mole).

9. Avec l'acétonitrile

D'une façon semblable, on a fait réagir de l'acétonitrile (5.0 g, 0.12 mole) et du DPS (5.0 g, 0.028 mole) en chauffant le mélange pour des périodes consécutives de 5 h à 100° et 125°. Les produits suivants furent obtenus: 6.0 min, N_2 et CF_4 (17.7%); 7.2 min, SF_6 (13.9%); 10.2 min, SF_4 (7.9%); 12.8 min, DPS (52.0%); 14.0 min, NSF_3 (8.5%).

10. Avec l'anhydride sulfureux

Dans un autoclave de 110 ml refroidi à −78°, on a introduit de l'anhydride sulfureux (6.4 g, 0.1 mole) et du DPS (5.0 g, 0.028 mole). On a chauffé le mélange à 75° pendant 90 h et l'on obtint seulement des traces d'un produit qui correspondait, d'après le spectre de masse, au difluoroamino-fluorure de sulfuryle, $F_2N—SO_4F$. On chauffa alors le mélange de façon consécutive par périodes de 5 h à 100°, 125° et 150°. Après cette longue période de chauffage, tout le DPS avait été consumé. La fraction gazeuse consistait en gaz suivants: 6.0 min, N_2 (5.9%); 7.6 min, N_2F_4 (2.3%); 8.8 min, SiF_4 (traces); 8.8 min, SO_2F_2 (1.1%); 10.2 min, SF_4 (23.5%); 15.4 min, $F_2N—SO_2F$ (20.2%); 19.2 min, SO_2 (47.0%).

En chauffant le même mélange pendant 5 h à 150°, on a obtenu les résultats suivants: 6.0 min, N_2 (8.5%); 7.6 min, SF_6 (3.3%); 8.8 min, SO_2F_2 (1.4%); 10.2 min, SOF. (28.9%); 15.4 min, $F_2N—SO_2F$ (17.2%); 19.2 min, SO. (40.7%).

Le difluoroamino-fluorure de sulfuryle donna un spectre de masse dont les pics furent assignés aux ions positifs suivants: 102 (NFSOF), 97 (NSO_2F), 83 (SO_2F), 67 (SOF), 64 (SO_2), 52 (NF_2), 51 (SF), 48 (SO), 33 (NF). Ce spectre de masse est identique à celui rapporté dans la littérature (6).

RÉSUMÉ

Le difluoroamino-pentafluorosulfure a été préparé à partir de la tétrafluorohydrazine et du décafluorobisulfure avec un rendement quantitatif, en chauffant le mélange à une température de 150° durant une période de 12 h sous pression autogène. On a étudié le comportement du difluoroamino-pentafluorosulfure avec l'iodure de potassium, l'oxygène, l'eau, le chlorure d'hydrogène, l'anhydride sulfureux, l'acétone, le bromure d'éthyle, l'iodure de méthyle, le nitrite d'éthyle, le bromure de cyanogène et l'acétonitrile.

DENSITY AND VISCOSITY OF THALLIUM AMALGAMS

WILLIAM T. FOLEY, ARUN K. BASAK, AND JOHN R. DELOREY
Chemistry Department, Saint Francis Xavier University, Antigonish, Nova Scotia

Received June 29, 1964

ABSTRACT

The densities of thallium amalgams were measured at 25, 50, 70, 90, 105, 125, and 160 °C over the concentration range 0 to 42% thallium by weight and the results were fitted to equations of the form $d = a + bx + cx^2$, where d is the density in grams per ml, a, b, and c are constants and x is weight % thallium in the amalgam. The coefficient of expansion was calculated for the temperature range 25 to 90 °C. Viscosities relative to mercury were also determined over the same range of composition and at the same temperatures as were used in the density measurements. Equations were presented which show the variation of viscosity with composition and also the variation of viscosity with temperature.

INTRODUCTION

This is a report on the densities and viscosities of thallium amalgams over the concentration range of 0 to 42% thallium by weight and over a temperature range extending from 25 to 160 °C. T. W. Richards and J. H. Wilson (1) measured at 20 °C the densities of amalgams containing 0.793, 1.14, and 1.85% thallium by weight. T. W. Richards and F. Daniels (2) determined the densities at 20 and 30 °C of amalgams whose composition varied from 4.93 to 42.86% thallium by weight. Olsen and Johnson (3) reported the densities of amalgams at 25 °C over the range 0 to 42 weight % thallium. Feniger (4) reported the viscosity of 0.3, 0.5, and 0.8 weight % thallium amalgams at 18 °C.

EXPERIMENTAL

The pycnometer used in the present investigation was a modification of the type proposed by Robertson (5). It was constructed by sealing two micropipets to a pyrex bulb of 5 ml volume in such a manner that the bulb was in one arm of a U tube. The two micropipets, graduated to 0.001 ml, formed the upper limbs of the U tube and these two limbs were sealed to a glass tee. The pycnometer was calibrated with mercury which had been purified by a procedure to be described later. The calibration was such that the volume of the pycnometer was known at all readings of the graduated scales and at all temperatures selected.

The mercury was purified by electrolyzing it anodically in dilute sulfuric acid at a current density of 5×10^{-4} A/sq. cm until a precipitate of mercurous sulfate formed, and then the mercury was washed with dilute nitric acid while drawing air through it. The metal was distilled under reduced pressure three times. The source of thallium metal was thallium sulfate of 99.9% purity. The metal was plated into a mercury cathode from an electrolyte of thallium sulfate dissolved in 1 *N* sodium hydroxide. Hydrazine was used as an anodic depolarizer and the cathode potential was maintained at −0.50 V with respect to the normal hydrogen electrode. At this potential, lead, should it have been present, could not have been plated into the amalgam. The content of thallium in the amalgam was determined by the procedure of Foley and Osyany (6).

In an actual density determination the pycnometer was filled with metal under reduced pressure and then an atmosphere of nitrogen was admitted. The volume of the metal in the pycnometer was recorded at each temperature. For temperatures above 60° the liquid for the constant-temperature bath was Dow Corning 200 silicone fluid.

The modified Ostwald viscometer is shown in Fig. 1. The measuring bulb had an average diameter of 5 cm and the volume between fiducial marks was 35 ml. The capillary was 12 cm long and the diameter was 0.5 mm. The viscometer was maintained at 130° C under high vacuum for an hour before use and then it was cooled and filled through tube F with liquid metal under an atmosphere of purified nitrogen. The metal was transferred from the receiving bulb to the measuring bulb by closing the stopcock at the top of the viscometer and then lowering the pressure on the measuring-bulb side of the viscometer with the aid of a special pump attached at E. To make a measurement, the pressure in the two arms was equalized by opening the stopcock and then the time of transpiration was noted. The viscometer was held in the constant-temperature bath by a holder that ensured the same position of the viscometer every time it was used so that errors due to misalignment were avoided.

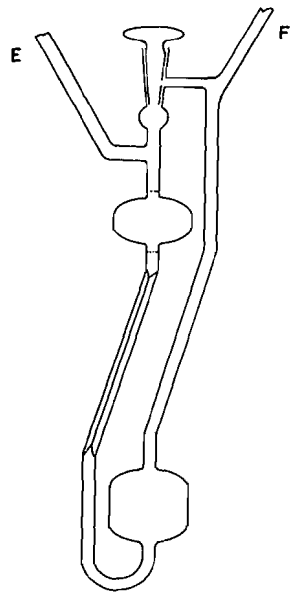

FIG. 1. Modified Ostwald viscometer.

For a viscometer used for relative measurements of viscosity, the equation which describes streamline flow is as follows

$$\eta = Apt - \frac{Bd}{t}, \qquad [1]$$

where η is the absolute viscosity, p is the average effective pressure, d is the density, t is the time, and A and B are constants for the viscometer (7). Mercury was used to calibrate the viscometer and the values of the viscosity coefficients used were those recommended by Erk (8). A calculation of Reynold's numbers showed that all flow rates were well below the turbulent region. Since the first portion of metal runs through the viscometer more rapidly than the last portion, the average pressure is not the mean of the initial and final pressure. To obtain the mean effective head, the difference in heights of the two mercury levels were observed with a cathethometer for successive positions of the menisci between the two extremes, together with the time required for each position to be reached as the liquid moved down under its own head. The values of the experimental pressures at various positions were plotted as ordinates against time as abscissae. The average pressure was determined by graphical integration. The viscometer was calibrated at eight temperatures between 5 and 95 °C. The values of the constants A and B were determined to be 4.209×10^{-10} and 1.272×10^{-1}, respectively, by the method of least squares. The values of the viscosity of mercury as calculated using these constants agreed with the values calculated from Erk's formula with an average deviation of 0.15% and a maximum deviation of 0.25%.

RESULTS AND DISCUSSION

Density

Densities were determined at 25, 50, 70, and 90 °C for amalgams having the following weight % thallium: 0.59, 4.98, 7.77, 14.09, 19.48, 24.89, 29.19, 33.54, 37.50, and 43.66. By the method of least squares, equations of the form,

$$d = a + bX + cX^2, \qquad [2]$$

were constructed, where d, is the density in grams per ml, X is the weight % thallium, and a, b, and c are the constants. The results are displayed in Table I. The last column

TABLE I

Constants for density–composition equations

T (°C)	a	$b \times 10^2$	$C \times 10^5$	Average deviation
25	13.532	−2.144	2.197	0.0038
50	13.470	−2.088	2.332	0.0048
70	13.422	−2.079	2.355	0.0046
90	13.375	−2.069	2.661	0.0037

in the table gives the average deviation of the experimental value for the density from the density calculated from the equation. There were also calculated for the temperature range 25 to 90 °C the volume coefficients for expansion, that is, the ratio of the change in volume per degree to unit volume at 25 °C and the results are shown in Table II. Density

TABLE II

Volume coefficient of expansion for 25 to 90 °C

Weight % Tl	5.00	10.00	15.00	20.00	25.00	30.00	35.00	40.00	43.66
Coefficient of expansion	179.3	177.7	175.6	173.4	170.8	167.7	164.5	160.7	157.9

measurements were also made at 105, 125, and 160 °C for amalgams having the following weight % thallium: 10.18, 19.06, 30.34, and 42.01. These densities were plotted against composition and the values given in Table III were read off from the curves.

TABLE III

Densities at 105, 125, and 160 °C

	Weight % Tl			
T (°C)	10.00	19.00	30.35	42.00
105	13.136	12.961	12.739	12.523
125	13.090	12.916	12.697	12.484
160	13.008	12.839	12.625	12.414

The estimated precision of the experimental values of the densities is 0.003 g per ml.

Viscosity

Viscosities of the amalgams were determined at 25, 50, 70, 90, 105, 125, and 160 °C. Equations of the form,

$$\eta = a + bx + cx^2, \quad [3]$$

where η is the viscosity in centipoise, a, b, and c are constants, and x is weight % thallium were obtained by the method of least squares. The constants for the temperatures chosen are given in Table IV. The last column in the table shows the average deviation of the measured viscosities from the viscosities calculated from eq. [3]. The plot of viscosity against temperature shows that as the temperature rises the viscosity–concentration curve tends to become a straight line. In fact, the curve for 160° is virtually a straight line. Because of the poorness of fit of eq. [3] at 25 and 50 °C the original data are offered in Table V.

TABLE V

Viscosity in cP of thallium amalgams at 25 and 50 °C

Weight % Tl	8.29	10.73	16.05	21.01	22.00	28.38	35.70	42.19
25 °C	2.024	—	2.543	—	3.005	3.545	4.270	5.048
50 °C	1.829	1.951	2.233	2.533	2.588	2.998	3.518	4.055

Many workers have expressed the variation of viscosity with temperature in degrees Kelvin by means of the following equation:

[4] $$\eta = A\, e^{E_v/RT}.$$

The constants A and E_v are reported in Table VI. The last column in the table shows the

TABLE VI

Constants for eq. [4]

Weight % Tl	A	E_v (kcal/mole)	Average deviation (cP)
5	1.815	0.704	0.0007
10	1.835	0.802	0.0016
15	1.896	0.909	0.0025
20	1.988	1.022	0.0052
25	2.102	1.136	0.0090
30	2.233	1.249	0.0130
35	2.378	1.361	0.0187
40	2.534	1.469	0.0250

average deviation of the experimental viscosities from the viscosities calculated from eq. [4].

Viscosity measurements made on different samples of the same stock of amalgam agreed among themselves to better than 0.20% and measurements made on different stocks of amalgam having the same composition agreed to within 0.35%. If it is assumed that the viscosity of mercury is known to an accuracy of 0.3%, then it is estimated that the experimental results reported here have an accuracy of ±0.5%.

THE INDUCED DECOMPOSITION OF *tert*-BUTYL HYDROPEROXIDE

R. HIATT,[1] JOHN CLIPSHAM, AND TEUNIS VISSER
Lash Miller Memorial Laboratory, University of Toronto, Toronto, Ontario

Received August 5, 1964

ABSTRACT

In a study of the "induced" decomposition of hydroperoxides by alkoxy radicals, *tert*-butyl hydroperoxide has been decomposed by the action of di-*tert*-butyl peroxyoxalate at 45°. The homolytic cleavage of peroxalate to *tert*-butoxy was unaffected by the presence of hydroperoxide and 7 to 10 molecules of hydroperoxide were destroyed for each radical thus produced. The kinetics have been analyzed and a mechanism developed which has significance for any system containing peroxy radicals.

INTRODUCTION

The thermal decomposition of hydroperoxides, while proceeding partially by unimolecular homolysis of the oxygen–oxygen bond, is usually complicated by a side reaction called "induced" decomposition arising from attack of radicals produced by the hydroperoxide on itself. This combination of unimolecular and induced decomposition may be analyzed by the method of Nozaki and Bartlett (1) devised for use in similar reactions of the diacyl peroxides. That hydroperoxides may be destroyed by a large variety of reagents, for example, acids, bases, phenols, and catalytic amounts of various metal ions (2) is well known. It has, however, remained to demonstrate the destruction of hydroperoxides by the radicals they themselves produce under conditions where the thermal decomposition is negligible. This we have done.

In an unreactive solvent *tert*-butyl hydroperoxide is suggested to decompose thermally according to the following scheme (3, 4):

[1] $$t\text{-BuOOH} \rightarrow t\text{-BuO}\cdot + \cdot\text{OH}, \qquad k_1.$$

[2] $$t\text{-BuO}\cdot + t\text{-BuOOH} \rightarrow t\text{-BuOH} + t\text{-BuOO}\cdot, \qquad k_2.$$

[3] $$2t\text{-BuOO}\cdot \rightarrow \text{O}_2 + 2t\text{-BuO}\cdot, \qquad k_3.$$

The hydroxy radical will presumably account for a molecule of hydroperoxide, but this is insignificant compared to the destruction caused by the regenerated alkoxy radical.

Di-*tert*-butyl peroxyoxalate decomposes thermally at low temperatures to *tert*-butoxy radicals and carbon dioxide (5). At 45 °C, where *tert*-butyl hydroperoxide is indefinitely stable, the peroxalate has a half-life of about 45 min. In the presence of the peroxalate at this temperature *tert*-butyl hydroperoxide could be subjected to attack by *tert*-butoxy radicals, the number and rate of production of which was subject to ready computation. The following is an account of the results of such experiments.

EXPERIMENTAL

tert-Butyl hydroperoxide was purchased from Lucidol Corporation, freed from gross amounts of water using a Dean-Stark apparatus, and distilled at reduced pressure to give material titrating iodometrically 99+%.

Di-tert-butyl peroxyoxalate was prepared by the method of Bartlett, Benzing, and Pincock (5).

Benzene was Fisher Reagent Grade used without further purification.

Kinetic runs involved dissolving weighed amounts of hydroperoxide and peroxalate in benzene, degassing the solution, decanting it into ampoules and sealing these off under vacuum. The ampoules were heated in a constant temperature bath, withdrawn at intervals, and the contents determined by iodometric titration. Since both the hydroperoxide and peroxalate liberate iodine, this gave a total peroxide concentration.

[1]*Present address: Stanford Research Institute, Menlo Park, California.*

To 1.00 ml of solution was added 15 ml of 20% acetic acid in isopropyl alcohol and approximately 300 mg of sodium iodide. After the mixture was refluxed for 20 min, the liberated iodine was titrated with aqueous sodium thiosulfate. This procedure gave quantitative results for *tert*-butyl hydroperoxide; it did not for the peroxalate, nor does any iodometric method. It did, however, give consistently a titer of 54 to 60% of theoretical depending on the concentration of the peroxalate in the benzene solution. Since the concentration of peroxalate could be calculated at any time from a knowledge of its rate of decomposition, the amount of iodine that would be liberated could be calculated and this subtracted from the total to give that corresponding to the *tert*-butyl hydroperoxide concentration.

Alternately di-*tert*-butyl peroxyoxalate was determined by its absorption at 1 783 cm^{-1} and *tert*-butyl hydroperoxide by its absorption at 1 327 cm^{-1}. This too had difficulties as *tert*-butyl alcohol, a product of the reaction, absorbs at 1 327 cm^{-1}, and it was necessary to assume a linear relation between hydroperoxide reacted and alcohol produced.

Both methods of analysis gave values of hydroperoxide concentration (subject to some uncertainty) relative to time of reaction that were consistent with each other and which were subjected to kinetic analysis.

Products in completely reacted solutions, containing no more titratable peroxides, were determined by gas-liquid chromatography (g.l.c.). The evolved noncondensable gas was measured quantitatively in a vacuum line and its constitution determined by mass spectrograph.

RESULTS AND DISCUSSION

Solutions in benzene of *tert*-butyl hydroperoxide, 0.05–0.8 *M*, and di-*tert*-butyl peroxyoxalate, 0.005–0.05 *M*, were heated at 45° *in vacuo*[2] and the rate of disappearance of hydroperoxide measured. The decomposition of the peroxalate was found to be unaffected by the presence of hydroperoxide. Rates measured with and without its addition were identical and compared well with those determined by Bartlett and co-workers (5).

The decomposition of one molecule of peroxalate was sufficient to destroy 12–20 molecules of hydroperoxide (or 6–10 molecules per *tert*-butoxy radical). This kinetic chain length was within experimental error, independent of initial concentration of either hydroperoxide or peroxalate (Table I) and did not vary much during the course of any run.

TABLE I

Decomposition of *tert*-butyl hydroperoxide by di-*tert*-butyl peroxyoxalate in benzene at 45 °C

$[ROOH]_0$	$[P]_0$	$\Delta[ROOH]/\Delta[P]$*
0.123	0.0059	12.5
0.145	0.0102	15.0
0.152	0.0194	12.3
0.140	0.050	12.6
0.156	0.0106	15.0
0.292	0.0087	13.9
0.502	0.0130	19.4
0.821	0.0071	14.6

*Average over 1 000 to 6 000 s depending on how far the run was carried.

Heating 2.034 mmoles of hydroperoxide and 0.207 mmoles of peroxalate, (in 20 ml of benzene for 12 h) gave 93 ± 5 mmoles oxygen, 2.046 mmoles of *tert*-butyl alcohol, 0.127 mmoles of di-*tert*-butyl peroxide, and 0.04 mmoles of acetone, thus accounting for 96.2% of the *tert*-butyl groups and almost all of the oxygen. Carbon dioxide was also produced from the peroxalate but was not measured quantitatively.

The rate of disappearance of *tert*-butyl hydroperoxide was not subject to ready analysis. The reaction is a chain one, depending on the regeneration of *tert*-butoxy radicals from

[2]*Since oxygen was produced almost quantitatively from the hydroperoxide, this might be regarded as a senseless precaution. However, it enabled comparison of initial rates of reaction where effects of oxygen would be minimal.*

For personal use only.

tert-butyl peroxy radicals, and its kinetic form is dependent on a choice of radical formation. The amount of di-*tert*-butyl peroxide in the products suggests that this is the major termination product, and the reaction might be written

[4] $$2t\text{-BuO}\cdot \rightarrow t\text{-BuOO-}t\text{-Bu}, \qquad k_4.$$

Bartlett and Traylor, however, suggest that this is not a very probable reaction for tertiary alkoxy radicals (4). Alternately

[5] $$2t\text{-BuOO}\cdot \rightarrow t\text{-BuOO-}t\text{-Bu} + O_2, \qquad k_5.$$

Ignoring this mode of termination, using only eqs. [2]–[4] plus the initiation,

[6] $$t\text{-BuOO}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{C}}\!\!-\!\!\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{C}}\text{-OO-}t\text{-Bu} \rightarrow 2t\text{-BuO}\cdot + 2CO_2, \qquad k_6,$$

and assuming steady states in oxy and peroxy radicals, the rate expression is

[7] $$-\frac{\partial[\text{ROOH}]}{\partial t} = k[\text{P}]^{1/2}[\text{ROOH}] \qquad \text{(where P = peroxalate).}$$

It was possible to fit some of the rate data to this expression but, at the extreme concentration ranges, the reaction seemed less responsive to hydroperoxide concentration and more to peroxalate concentration than predicted. Furthermore this expression predicts a chain length inversely proportional to $[\text{P}]^{\frac{1}{2}}$, which was contrary to the results.

The effect of discounting [4] and substituting [5] was not immediately obvious. However, setting up the steady state expressions:

[8] $$\frac{\partial[\text{RO}\cdot]}{\partial t} = 2k_6[\text{P}] - k_2[\text{RO}\cdot][\text{ROOH}] + 2k_3[\text{RO}_2\cdot]^2 = 0,$$

[9] $$\frac{\partial[\text{RO}_2\cdot]}{\partial t} = k_2[\text{RO}\cdot][\text{ROOH}] - 2(k_3 + k_5)[\text{RO}_2\cdot]^2 = 0.$$

Adding [9] to [8],

[10] $$k_6[\text{P}] = k_5[\text{RO}_2\cdot]^2.$$

If the chain length is reasonably long, the loss of RO· by attack on ROOH must be equalled by its regeneration from $\text{RO}_2\cdot$.

[11] $$k_2[\text{RO}\cdot][\text{ROOH}] = 2k_3[\text{RO}_2\cdot^2]$$

and

[12] $$[\text{RO}\cdot] = \frac{2k_6k_3[\text{P}]}{k_2k_5[\text{ROOH}]}.$$

Then since

[13] $$-\frac{\partial[\text{ROOH}]}{\partial t} = k_2[\text{RO}\cdot][\text{ROOH}],$$

[14] $$-\frac{\partial[\text{ROOH}]}{\partial t} = \frac{2k_3k_6[\text{P}]}{k_5}.$$

The invariance of chain length then results,

[15] $$+\frac{\partial[\text{ROOH}]}{\partial[\text{P}]} = \frac{2\,k_3}{k_5}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Equation [14] can be integrated

$$-\frac{\partial[\mathrm{ROOH}]}{\partial t} = \frac{2k_3k_6}{k_5}[\mathrm{P}]_0\, e^{-k_6 t},$$

$$[\mathrm{ROOH}] = \frac{2k_3}{k_5}[\mathrm{P}]_0\, e^{-k_6 t} + [\mathrm{ROOH}]_0.$$

Using the published value of k_6 (6), plotting [ROOH] vs. $e^{-k_6 t}$ gives straight lines for all of the runs (Fig. 1) and the slopes are proportional to $[P]_0$, the initial concentration of peroxalate (Fig. 2).

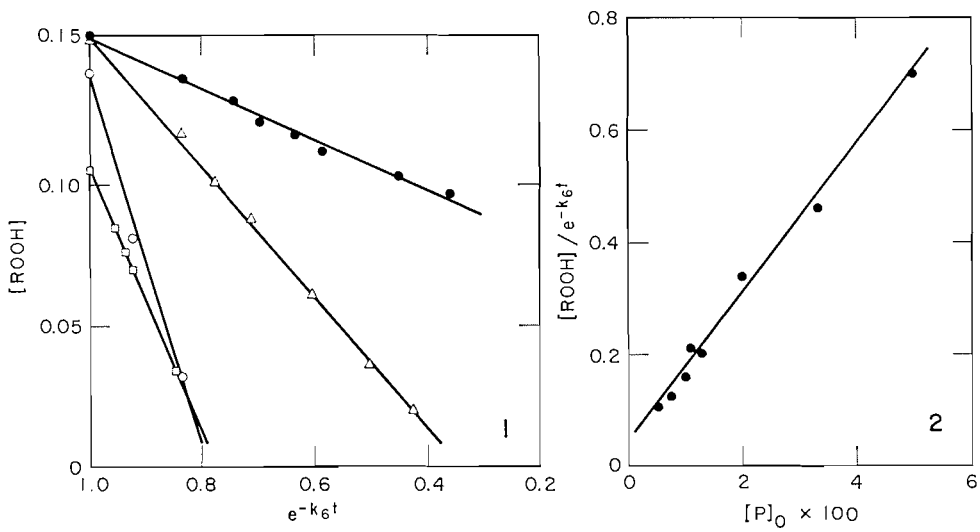

FIG. 1. [ROOH] vs. $e^{-k_6 t}$ at 45 °C in benzene.

FIG. 2. Slope of [ROOH] vs. $e^{-k_6 t}$ against $[P]_0$.

It was expected that this research would give some information regarding k_2, the rate constant for the induced decomposition. It seems to have been lost, however, in the steady state. The results do, on the other hand, offer confirmation of the general mechanism and constitute a proof of the probable termination reaction of alkoxy and peroxy radicals.

ACKNOWLEDGMENTS

We wish to thank Prof. A. Harrison for the mass spectrographic analyses, and the National Research Council of Canada for a grant under which this research was pursued.

THE CRYSTAL STRUCTURE OF K_2TeBr_6

I. D. BROWN
Department of Physics, Hamilton College, McMaster University, Hamilton, Ontario
Received May 27, 1964

ABSTRACT

Crystals of K_2TeBr_6 are monoclinic, space group $P2_1/n(C_{2h}^5)$ with $a = 7.521$, $b = 7.574$, and $c = 10.730$ Å; $\beta = 89° 40'$. Atomic positions have been found by three dimensional X-ray diffraction analysis (least squares $R = 0.12$). The crystals possess a K_2PtCl_6 structure which is distorted to allow a more efficient packing of the comparatively large anions than is possible with the undistorted cubic form. The stereochemistry of the octahedral $TeBr_6^=$ ion (Te—Br = 2.71 Å) is discussed.

INTRODUCTION

A few years ago, Gillespie and Nyholm (1) predicted that hexa-coordinated complexes of Te(IV) and Se(IV) should not possess a regular octahedral structure but rather one based on seven coordination with a lone pair of electrons occupying the seventh position. However, all structures so far reported, for example Cs_2TeCl_6 (2) and $(C_5H_5NH)_2TeCl_6$ (3), indicate that such complexes are in fact regular octahedra. A recent nuclear magnetic resonance (n.m.r.) and X-ray study by Nakamura *et al.* (4) indicated that K_2TeBr_6, while possessing a structure close to that of the cubic K_2PtCl_6, where the $PtCl_6^=$ ion is a regular octahedron, is distorted to orthorhombic or lower symmetry. The present work was undertaken to discover if the lower symmetry was caused by a deviation of the $TeBr_6^=$ ion from a regular octahedron.

EXPERIMENTAL

Bright red crystals of K_2TeBr_6 were prepared by the method described in Inorganic Syntheses (5). When rotated under a polarizing microscope, the crystals show the extinction pattern typical of non-cubic crystals, which indicates that they do not possess the regular cubic K_2PtCl_6 structure. Such an examination was used to select an untwinned crystal for X-ray measurements, but since twinning can be induced by a small uneven pressure on the crystal, particular care had to be taken in mounting it. The crystal which was finally chosen for the measurement of three-dimensional intensity data was an irregularly shaped plate, about 0.3 mm across and 0.05 mm thick, which was mounted on a precession camera with the plane $(10\bar{1})$ of the plate perpendicular to the X-ray beam. All X-ray diffraction measurements were made from precession photographs taken with Mo K_α radiation. The crystal data are summarized in Table I.

TABLE I
Crystal data for K_2TeBr_6

System	Monoclinic

β	89°40′±4′

Number of formula units (K_2TeBr_6) per unit cell is 2.
Calculated density 3.72 g/ml.
Measured density 3.68 g/ml.
Systematic absences $\begin{cases} hOl & h + l = 2n + 1. \\ OkO & k = 2n + 1. \end{cases}$
Absorption coefficient for Mo K_α 96 cm^{-1}.
Relation between the axes chosen above and the axes of the cubic K_2PtCl_6 pseudo isomorph:
a is along the cubic $[1\bar{1}0]$ direction,
b is along the cubic [110] direction,
c is along the cubic [001] direction.

Intensity data were measured visually from films of the $hk0$, $h0l$, and h, k, $h + n$ layers, where n runs from 0 to 6 inclusive, and were corrected for Lorentz and polarization effects but not for absorption. The structure was initially refined on the assumption that it was a distortion of the K_2PtCl_6 structure belonging to the space group Pn and that the $TeBr_6^=$ ion was irregular and did not possess a center of symmetry. It soon became apparent that the true space group was $P2_1/n$ as indicated by the systematic absences. Difference electron density projections down [001] and [010] were used in the initial stages, and a full matrix least-squares refinement, using a Fortran program based on that of Busing, Martin, and Levy (6), was used later with three-dimensional data to produce a structure that gave a weighted agreement index $[(\sum\omega(|F_o| - |F_c|)^2/\sum\omega|F_o|^2)^{\frac{1}{2}}]$ of 0.122. The scattering factors used were taken from International Tables for X-ray Crystallography (7). The observed structure factors are given in Table II,* along with the final set of structure amplitudes calculated from the atomic parameters given in Table III.

DESCRIPTION OF THE STRUCTURE

Although it was assumed initially that the $TeBr_6^=$ ion was not a regular octahedron, it soon became clear that this assumption was wrong. The final parameters show that there is no significant difference in the three non-equivalent Te—Br distances and that the angles between them do not vary significantly from 90° (Table IV). The mean length of the Te—Br bond is 2.692 ± 0.006 Å before correction for the thermal motion of the atoms (8). The temperature factors (see Table V) of the bromine atoms show a marked anisotropy, indicating that their root-mean-square displacement perpendicular to the Te—Br bonds is about one and a half times as large as that (0.14 Å) along the bonds. A rigid $TeBr_6^=$ ion librating about the tellurium atom would give rise to an anisotropy of this sort and, if this were the case, the Te—Br bond length corrected for temperature effects would be 2.706 Å. However, it is possible that there is no correlation between the motions of the tellurium and bromine atoms, and that the anisotropy arises from the fact that the bending modes of vibration of the Te—Br bond have a larger amplitude than the stretching modes. If such were the case, the true Te—Br distance would be 2.724 Å. It is not possible to distinguish between these two cases, and the true situation probably lies somewhere between the two extremes.

The positions of the $TeBr_6^=$ ions in the crystal are the same as those of the $PtCl_6^=$ ions in the K_2PtCl_6 structure (Fig. 1*a*) to which K_2TeBr_6 is closely related. The large octahedral ions lie on a face-centered cubic lattice, with the alkali metal ions occupying the tetrahedral cavities between them. In K_2PtCl_6 the $PtCl_6^=$ ions are all equivalent and are arranged with the Pt—Cl bonds pointing along the directions of the three principal axes of the cubic cell. The K_2TeBr_6 structure is obtained from this by a reorientation of the $TeBr_6^=$ octahedra (Fig. 1*c*). Alternate octahedra, as viewed down the *c*-axis, which is the same in both the cubic K_2PtCl_6 and the monoclinic K_2TeBr_6 structures, are first twisted about the *c*-axis in opposite directions by 12°. They are then twisted about the monoclinic *b*-axis (cubic (110)) by 9°. Finally, the potassium atoms are displaced in the *b*-direction, and the axial lengths and angles are changed to accommodate these distortions.

Alternatively, the K_2PtCl_6 structure may be described as an approximately close-packed array of chlorine and potassium atoms with platinum atoms occupying octahedral holes. The chlorine and potassium atoms are arranged within the array so that every potassium atom has twelve chlorine nearest neighbors, and every chlorine atom is surrounded by four potassium atoms, four chlorine atoms belonging to its own $PtCl_6^=$ ion, and four chlorine atoms belonging to different $PtCl_6^=$ ions. In the K_2TeBr_6 structure the environment of the halogen atoms is only slightly altered but the environment of the potassium atom is markedly different (see Table IV and Fig. 2). It is still possible to pick out the twelve

*The standard errors in bond distances indicated by the least-squares residual are: Te—Br, 0.006 Å; Br—Br, 0.01 Å; K—Br, 0.02 Å.

†The atoms defining the $TeBr_6^=$ ion have the coordinates listed in Table III. Those marked with a double dagger are related to these by inversion through the origin. The correction for thermal motion is made assuming that the $TeBr_6^=$ ion is librating.

nearest neighbors which are arranged symmetrically with respect to a mirror plane perpendicular to *c*, but they are no longer equally distant. There are four bromine atoms arranged almost tetrahedrally at a distance of 3.43 ± 0.04 Å. The next four are at a distance of 3.66 ± 0.04 Å, then there are two at a distance of 4.13 ± 0.03 Å and two at a distance of 4.53 ± 0.02 Å. These are arranged between the three non-equivalent bromine atoms in such a way that the mean distance between any one bromine atom and the four potassium atoms with which it is associated is 3.81 Å. The correction which should be applied to these lengths for thermal motion is about +0.03 Å if it is assumed that there is no correlation between the motions of the potassium and bromine atoms.

The van der Waals contacts between bromine atoms in different $TeBr_6^=$ ions are grouped into six short contacts of 3.83 Å and six long contacts of 3.93 Å, with an average contact of 3.88 Å between any one bromine and its four neighbors. These distances should be increased by about 0.025 Å if the thermal motions of the bromine atoms are uncorrelated.

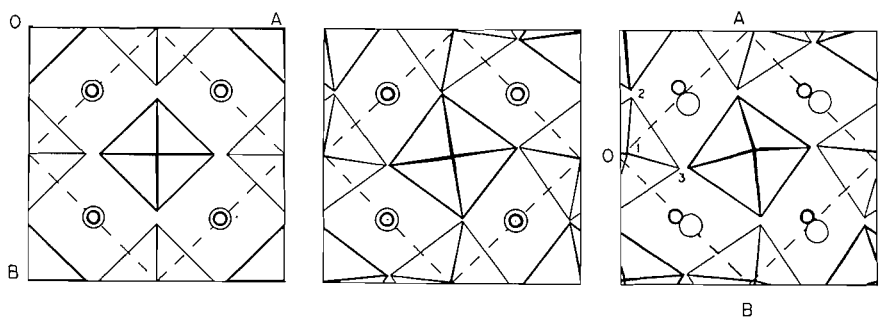

FIG. 1. The arrangement of cations (open circles) and anions (octahedra) in (*a*) K_2PtCl_6, (*b*) K_2SnBr_6, and (*c*) K_2TeBr_6 as viewed down the *c*-axis.

DISCUSSION OF THE $TeBr_6^=$ ION

The fact that the $TeBr_6^=$ ion has the configuration of a regular octahedron needs an explanation.

In four-coordinated complexes of Te (IV) the four ligands and the lone pair of electrons lie approximately at the apices of a trigonal bipyramid (for example $(C_6H_5)_2TeBr_2$ (9), $TeCl_4$ (11), and $(CH_3)_2TeCl_2$ (12)). Similarly, five-coordinated complexes have the five ligands and the lone pair at the apices of an octahedron (for example $CON_2H_5TeCl_5$ (3)). It has been suggested by Gillespie and Nyholm (1) that six-coordinated Te (IV) should have the six ligands and the lone pair arranged at the apices of a pentagonal bipyramid. However, in all the complexes of this sort which have so far been studied the ligands are arranged in a regular octahedron with the distance between the central atom and the ligands considerably longer than the covalent radius sums (2, 3, 10). It has been suggested by Beach (14) that in these complexes the lone pair occupies the s-orbital in the valence shell, leaving the p^3d^2s-orbitals for octahedral bonding. The reason why the lone pair

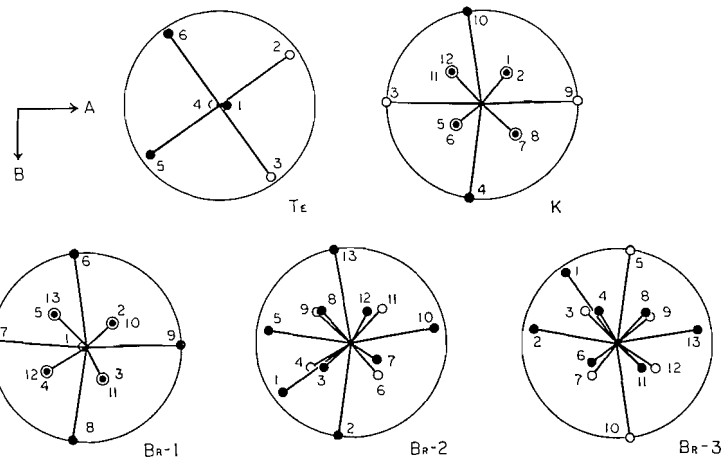

FIG. 2. Stereographic projections of the environment of atoms in K_2TeBr_6. The *c*-axis is the axis of projection. The numbering corresponds to that used in Table IV.

appears in the coordinating sphere when there are four or five ligands but not when there are six can be understood by considering the mutual repulsions between the ligands. If the distance between the ligands is greater than the van der Waals separation, the repulsion will be coulombic and relatively weak, but as the distance becomes shorter than the van der Waals separation, the stronger Pauli forces will dominate until a point is reached where further compression of the ligands can only be achieved at the expense of considerable energy. A $TeBr_6^=$ ion in the form of a seven coordinate pentagonal bipyramid with normal bonds would bring some of the bromine atoms to within 2.96 Å of each other, a distance which is only three-quarters of the normal van der Waals distance. An octahedral $TeBr_6^=$ ion with longer bonds, on the other hand, would have a Br—Br separation (3.82 Å) which is quite close to the van der Waals distance. The repulsions between the bromine atoms will thus tend to favor the octahedral form. In a tetrahedrally coordinated tellurium bromide ion, where the Br—Br distances will be greater than 4.0 Å, Pauli repulsion is absent and is only weak in ions with trigonal bipyramidal and octahedral coordination (Br—Br separation greater than 3.56 Å). Thus complexes with few ligands can accommodate the lone pair in the coordination sphere more conveniently than can those with many ligands. Similarly, complexes with a large central atom and small ligands will be able to accommodate the lone pair in the coordination sphere more easily than those with a small central atom and large ligands. Sevenfold coordination would be difficult for bromine atoms around tellurium, but several seven-coordinated fluoride complexes are known (15) and in these the fluorine–fluorine distances are, in general, not much shorter than the van der Waals distance.

DISCUSSION OF THE DISTORTION

The distortion of K_2TeBr_6 from the cubic K_2PtCl_6 structure is thus not related to a distortion of the $TeBr_6^=$ ion. It is rather the result of packing large anions with small cations. The anions form a face-centered array and are oriented in such a way that each halogen atom is in contact with four halogens on neighboring anions. This leaves cavities in the structure into which the cations fit. Each cavity is formed by twelve halogen atoms, three from each of the four anions which surround the cavity. Since the cations are usually

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

much smaller than the halogen atoms, the size of the cavity will be determined by the halogen–halogen contacts between anions, rather than the halogen–cation contacts. If the cation is very much smaller than the cavity into which it fits, it will be free to rattle inside the cavity unless the anions reorient themselves in such a way as to reduce the effective size of the cavity and thus lock the cation into place. Distortions which are probably due to this effect are found among many crystals with the K_2PtCl_6 structure where the quadrivalent metal is large (e.g. tellurium and tin) and in most of the iodide complexes in which the cation is potassium or ammonium. Some of these are listed in Table VI. An obvious criterion for deciding whether such a distortion will occur is the ratio of the

TABLE VI

Some crystals with the distorted K_2PtCl_6 structure

Compound	Radius ratio*	Structure	Reference
K_2TeI_6		Triclinic at 293 °K	†
K_2TeBr_6	0.83	Monoclinic at 293 °K	13
K_2PtI_6		Orthorhombic (?) at 293 °K	17

K_2PtBr_6		Transforms to cubic between 63 and 200 °K	24, 17
K_2ReCl_6		Cubic above 111 °K	25, 26
K_2PtCl_6	0.98	Remains cubic below 4 °K	2, 27

*See Appendix.

†These crystals have been found in this laboratory to be triclinic with $a = 11.51$, $b = 11.51$, $c = 11.60$ Å, $\alpha = 90.0°$, $\beta = 90.5°$, $\gamma = 91.0°$.

size of the cation to the size of the cavity into which it must fit. The univalent ionic radii given by Pauling (16) are a suitable measure of the size of the cation, but a realistic measure of the size of the cavity is more difficult to obtain, since it involves a knowledge of the van der Waals radius of the halogen atom, and this is not as well defined as the ionic radius. Effective radii for the cavities in various complexes can be found empirically as described in the appendix, but these radii are not as reliable as could be desired. They have been used to calculate the cation–cavity radius ratios which are listed in Table VI, but because of their empirical nature, they may be in error by as much as 2%. However, even with this error certain trends are clear. Crystals with a radius ratio of less than about 0.89 are distorted at room temperature. Those crystals with radius ratios between about 0.89 and 0.98 are cubic at room temperature but distort at lower temperatures, while those with still larger radius ratios would not be expected to distort at any temperature. Unfortunately, the data for the low-temperature structures is far from complete, and it is not certain that all the phase transformations listed in Table VI correspond to a distortion of the kind discussed here. The only other crystal whose distortion has been studied in detail is K_2SnBr_6 (18) which has tetragonal symmetry (Fig. 1*b*). With a radius ratio of 0.86, this structure falls about midway between that of K_2TeBr_6 (radius ratio = 0.83) and an undistorted K_2PtCl_6 structure (radius ratio greater than 0.89). The distortion in the case of K_2SnBr_6 is of the same type as that in K_2TeBr_6 but is only about half as great. The rotation about the *c*-axis is only 7° and there is no rotation about the cubic [110] direction. It would be interesting to have more information about the distortions in other

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

crystals and in particular about the nature of the various phase transformations which have been reported.

ACKNOWLEDGMENTS

I wish to thank Dr. R. J. Gillespie for suggesting this problem and for helpful discussions, Mr. J. Vekris for preparing the crystals, Mr. R. C. Davidson for taking some of the X-ray photographs, and the National Research Council of Canada for financial support.

APPENDIX

Calculation of the Ratios of the Cation Radii to the Cavity Radii in K_2PtCl_6 Type Crystals

The cavity in which the cation in the K_2PtCl_6 structure fits is formed by 12 close-packed halogen atoms whose centers lie on a sphere with a radius (A) equal to the halogen–halogen contact distance. A section through this sphere is shown in Fig. 3. The space available to the cation is a smaller concentric sphere whose radius (B) is given by

$$B = A - C,$$

where C is the ionic radius of the halogen atom.

The radius ratio (R) is then given by

$$R = D/B = D/(A - C),$$

where D is the ionic radius of the cation.

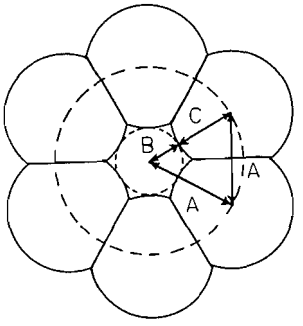

FIG. 3. A section through the environment of the cation site in a crystal with the K_2PtCl_6 structure.

The ionic radii, C and D, are conveniently chosen as the univalent ionic radii of Pauling (16), corrected for twelvefold coordination.

IONIC RADII	(Å)
K^+	1.45
NH_4^+	1.56
Rb^+	1.60
Cl^-	1.98
Br^-	2.10
I^-	2.30

The ionic radius given for NH_4^+ is an empirical one chosen to be consistent with the other radii.

The choice of the halogen–halogen distance (A) is a little more difficult, since the distance between halogen atoms in the same $MX_6^=$ ion and the distance between halogen atoms in different ions will in general not be the same. The former distance is influenced by the size

of the central atom of the anion, while the latter ought to depend only on the van der Waals radius of the halogen atom. Some of the observed values for these two quantities are given in Table VII. The value that has been chosen for A for any one anion is the mean of several observations of the intraionic and inter-ionic X—X distances. It is apparent from the observations quoted in Table VII that the inter-ionic X—X distances representing van der Waals contacts, show a systematic increase with the cation size. For this reason the inter-ionic Cl—Cl distances observed in the caesium compounds were not used in the calculation of A. It was assumed in this case that the large caesium ion is affecting the size of the cavity, and that the observed Cl—Cl distances do not represent true van der Waals contacts. Because of the large standard error which is apparent in the observed value of the interhalogen distances, the estimates of the cavity radii will only be accurate to about 0.03 Å. This will result in the radius ratios (R) being accurate to about 2%.

THE SYNTHESIS AND REACTIONS OF DIVINYL CARBONIUM IONS[1]

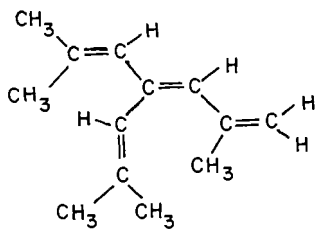
T. S. SORENSEN
Department of Chemistry, University of Alberta, Calgary, Alberta
Received July 7, 1964

ABSTRACT

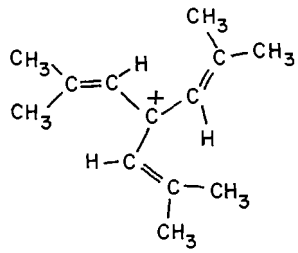
A number of alkyl-substituted trienes have been protonated. In some cases, the existence of divinyl carbonium ions can be shown, while in others, a cyclization reaction leading to, cyclopentenyl carbonium ions takes place so rapidly that the presumed initially formed divinyl carbonium is never observed. Steric arguments are invoked to explain these differences. Complete n.m.r. and ultraviolet spectral data are presented in support of the assigned carbonium-ion structures. Some evidence has been obtained regarding the mechanism of the cyclization reaction. Finally, one of the cyclic carbonium ions is decomposed and the cyclic dienes which are produced are isolated and characterized.

INTRODUCTION

Recently, a number of stable carbonium ions have been prepared and characterized (1). In particular, the tricyclopropyl carbonium ion has been prepared (2) and found to be unusually stable. Our initial object was to prepare a trivinyl carbonium ion and to determine the stability and properties of this ion. The tetraene I was synthesized (3) and, by addition of a proton, might have been expected to yield the trivinyl carbonium ion II. The proton magnetic resonance (n.m.r.) spectrum of this ion would have been exceedingly



I



II

simple, one or perhaps two closely spaced peaks for the 18 methyl protons and a single broad peak for the 3 alkene protons. The spectrum which was obtained was much more complicated, however, suggesting that a rearrangement, probably a cyclization reaction, had occurred. To sort out this complex spectrum, we undertook the preparation of some divinyl carbonium ions. The cyclization products from these, if any, would be much simpler.

The only known analogs of divinyl carbonium ions* are protonated benzenoid compounds, of which a number have recently been reported (4). One might expect these two

[1]*Presented at the 47th Canadian Chemical Conference, Kingston, Ontario. Abstract of Paper, p. 34 of the Abstracts publication.*

**While this manuscript was in preparation, a communication appeared (14) describing the preparation of several divinyl carbonium ions including two of the systems which we describe in this paper. Our method of preparation is different, however, and we have made many added observations.*

systems to have similar ultraviolet spectra (taking appropriate account of the ring structure in the one case) and similar chemical shift positions, for similar types of protons in their n.m.r. spectra.

Interestingly, some of the carbonium ions reported in this work may have been previously prepared but not recognized as such. A Russian paper (5) has appeared describing compounds called "halochromic" alcohols, meaning that yellow and red colors are produced when these are dissolved in strong acids. Among the alcohols which they studied were several divinylcarbinols.

The carbonium ions discussed in this paper have been prepared by the protonation of conjugated trienes by 96% sulfuric acid. The problem, really, is getting the triene into the sulfuric acid in a very dilute form, so that polymerization is minimized or avoided. Deno *et al.* (6) have discussed this problem and were able to prepare reasonably pure cyclopentenyl cations by adding the organic compound through a capillary to the sulfuric acid, kept at 0 °C. Trienes, however, seem to be even more reactive and another method was necessary. We have added the trienes, in the gas phase at about 0.01 mm, to a sulfuric acid solution spread out over the bottom of a conical flask (Fig. 9) and vigorously stirred with a large magnetic stirring bar. Very clean n.m.r. spectra are obtained and this method has the advantage that the sulfuric acid can be kept at any particular temperature from −30 °C upwards, using a cooling bath. We have also used 87.5% sulfuric acid in the same procedure. Unless one is studying rates or the protonation equilibria involved, there is no advantage in using less than 96% acid.

RESULTS AND DISCUSSION

The first system studied was the hypothetical methyl divinyl carbonium ion (III). This should be obtained from the protonation of *cis-* or *trans*-2,4,6-trimethyl-1,3,5-heptatriene or 4-methylene-2,6-dimethyl-2,5-heptatriene. All of these compounds were available and each one was protonated. There was no detectable difference in the product of the protonation from each of these trienes, even though the carbonium ion, which was formed, was not III. The n.m.r. spectrum of these trienes in concentrated sulfuric acid is shown in Fig. 1. When the addition of the trienes to the sulfuric acid was carried out at 25 °C, a small peak was found at 2.32 τ which disappeared fairly rapidly giving the spectrum in Fig. 1B. Attempts to prepare the ion III by working at −30 °C resulted in a solution whose spectrum is shown in Fig. 1A; the peaks were considerably broadened by the viscosity of the acid. We were aided very much in the assignment of the peaks in our carbonium-ion spectra by the recent paper of Deno and co-workers (6) on cyclopentenyl and cyclohexenyl carbonium ions. In fact, the peaks in Fig. 1B agree perfectly with the spectrum Deno has published for the carbonium ion IV (our numbering system will be as shown in IV). The principal carbonium ion at −30 °C is V (about 65%) along with about 35% of IV. The rearrangement of V to IV has also been observed by Deno (7).

The second system studied was the divinyl carbonium ion VI. This should be obtained from the protonation of *trans*-2,6-dimethyl-1,3,5-heptatriene. The spectrum of the protonation product is shown in Fig. 2A. The position of the peaks are 7.33 and 7.38 τ, CH_3 on a carbonium-ion center; 2.79 and 3.01 τ, alkene protons at C3 and C5 split by a single proton at C4; 0.75, 0.96, and 1.18 τ, the proton at C4, is uniquely satisfied by the cation structure VI. The relative areas are 12:2.05:1; theory, 12:2:1. The magnitude of the coupling constant (J = 13.2 c.p.s.) between the protons at C3 and C5 and C4 can best be explained by assuming an s-*trans* conformation (about the 4,5 and 3,4 "single" bonds). At 25 °C, the carbonium ion VI has a half-life of about 3 days; at 76 °C, less than

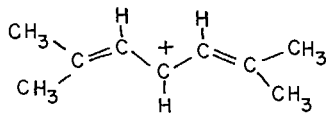
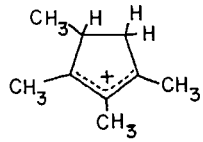
V



VI



VII

10 min. This crude rate study indicates that this reaction rate is remarkably temperature dependent. The spectrum in Fig. 2C is that of the rearranged product and the spectrum in Fig. 2B shows that, in intermediate stages, only a mixture of the two carbonium ions of Figs. 2A and 2C is observed. The carbonium ion responsible for the spectrum in Fig. 2C can unambiguously be assigned the structure VII. Peaks at 8.53 and 8.66 τ, CH_3 not on a carbonium-ion center split by a single adjacent proton (J = 7.8 c.p.s.); 7.16 τ, CH_3 at C1 and C3; 6.46 and 6.75 τ, protons at C4 and C5. The relative areas are 3.1:3.3:6.3:2.7; theory, 3:3:6:3 (the methylene and methyl protons may overlap to some extent).

The triene, alloöcimene (VIII), was also protonated. Fig. 3A shows the n.m.r. spectrum of the resulting ion. A comparison with the ion VI, making allowance for an ethyl in place of a methyl group, indicates unambiguously that a divinyl carbonium-ion structure (IX) has been formed. Like VI, this ion also rearranges to a cyclic product. The spectrum of the rearrangement product is shown in Fig. 3B. One can see that, within experimental measurement, the ethyl group has ended up in, at most, only *three* of the four possible positions, viz. ions X, XI, and XII but not XIII. If ion XIII had been formed, one should have observed a quartet of peaks for the methylene protons in the 7–8 τ region. The cyclization reaction of IX proceeds at nearly the same rate as the ion VI.

The radically different behavior of the hypothetical carbonium ion III and the observed ion VI was rather baffling since it was assumed that, the more heavily alkyl-substituted (inductive, hyperconjugative effects) the carbonium ion, the more stable it would be. We considered that this conflicting behavior could be rationalized if one considered an argument based on steric effects. Studies of molecular models of the ion XIV indicated that the double bonds, needed for resonance delocalization of the positive charge, would have difficulty achieving coplanarity (carbons 2, 3, 4, 5, and 6 of XIV). Ion VI, on the other hand, is minus the worst offender, the methyl group at C4. Further support for a steric explanation is provided by an examination of the ultraviolet spectra of the trienes corresponding to these carbonium ions. The geometry of the trienes and their ions is not exactly the same but the analogy is fairly close. An analysis (7*a*) of this ultraviolet spectral data

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

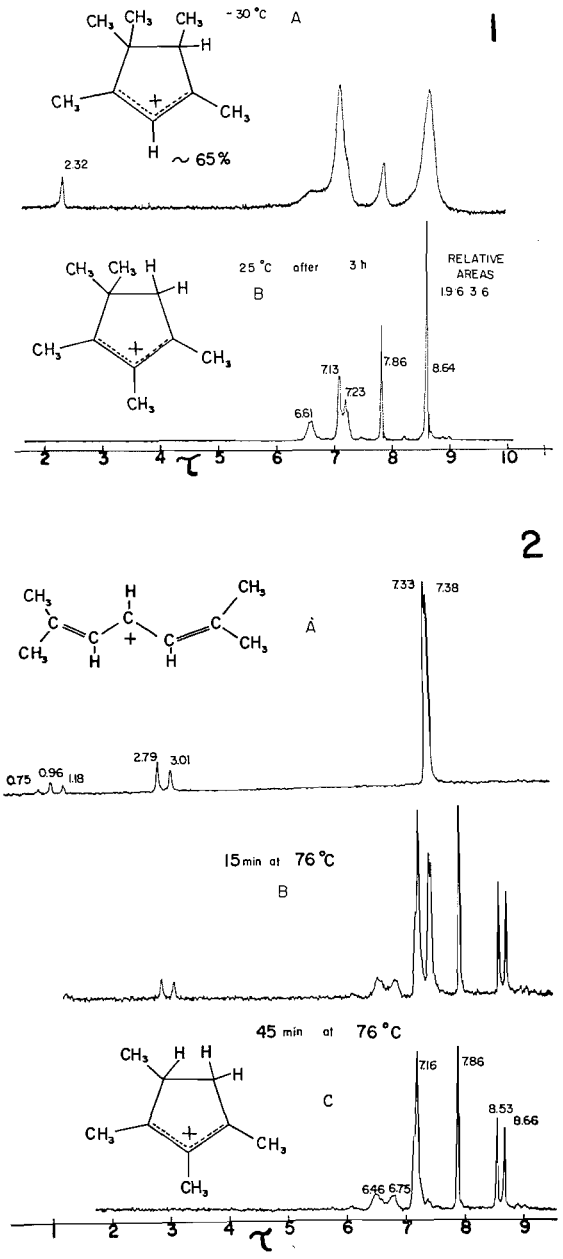

FIG. 1. Nuclear magnetic resonance spectra of IV and V.
FIG. 2. Nuclear magnetic resonance spectra of VI and VII.

has resulted in the conclusion that the trienes leading on protonation to XIV are not planar, while those leading to VI are planar. The stability of these divinyl carbonium ions is probably very much dependent upon the ability of the system to delocalize the positive charge. One would expect that progressive deviations from planarity, due to steric interactions, would be manifest in a steeply rising curve representing an energy loss of the

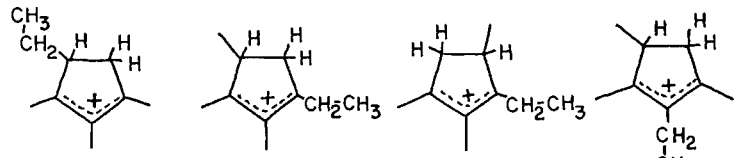
VIII IX



X XI XII XIII

ground state of the molecule. This could then result in a smaller activation energy for the conversion of III to IV as compared with VI to VII, other things being equal.

To test this hypothesis, we have studied systems where methyl groups are systematically removed from the ion XIV. Protonation of *trans*-4,6-dimethyl-1,3,5-heptatriene, which, if only normal protonation occurred, would correspond to the removal of one methyl group from the end position of XIV, gives a solution whose n.m.r. spectrum is shown in Fig. 4. This spectrum can be interpreted unambiguously in terms of the carbonium-ion structure XV. Peaks at 8.59 τ, CH_3 at C4; 7.03 and 7.13 τ, CH_3 at C1 and C3; 6.58 τ, CH_2; 2.50 τ, H at C2. The relative areas are 5.8:6.3:1.9:1; theory, 6:6:2:1. At −30 °C, the same spectrum was observed. We have previously shown that the triene used to make this carbonium ion exhibits ultraviolet spectral features rationalized as "steric hindrance to coplanarity" so it is perhaps not unexpected that a cyclization reaction also occurs in this system.

Attempts to prepare the carbonium ion resulting from the removal of two methyl groups from XIV, one at either end, viz. protonation of 4-methyl-1,3,5-heptatriene, result in a solution whose n.m.r. spectrum is shown in Fig. 5. This spectrum can be interpreted unambiguously in terms of the carbonium-ion structure XVI. Peaks at 8.50 and 8.62 τ, CH_3 on C4 split by a proton at C4 (J = 7.2 c.p.s.); 7.05 τ, CH_3 at C1 and C3; 6.40 and 6.58 τ, a complex pattern, protons at C4 and C5; and 2.43 τ, proton at C2. The relative areas are 3.0:6.2:2.7:1; theory, 3:6:3:1. When attempts were made to prepare this ion at −30 °C, polymerization took place to such an extent that the sulfuric acid became a solid mass. At 10 °C, however, little if any polymerization occurred. This behavior is unusual since these carbonium ions are normally more stable the lower the temperature. We suspect that the carbonium ion XVII may be formed at low temperatures and, being a very reactive species, polymerizes. Why this polymerization should disappear when the temperature is raised, we are not quite certain, since a large number of factors are involved (rates of the polymerization and the rearrangement reactions, diffusion rates of the ions formed on the surface of the acid, rate of addition of the trienes to the acid, etc.). Polymerization appeared to take place on the surface of the sulfuric acid, since each time the stirring bar exposed a new surface, a scum would immediately form over it.

This behavior points out the problem involved in attempting to substantiate our "steric interactions" argument discussed previously. Removing methyl groups from the ion XIV undoubtedly decreases the steric interactions but as the same time substantially decreases the stability of these ions by removing groups capable of providing inductive

XIV

and hyperconjugative stability. This is shown very clearly in Fig. 6 where we present the spectrum of the solution obtained from the protonation of 2-methyl-1,3,5-heptatriene. If the normal carbonium ion were formed, it would correspond to the removal of one methyl group from the carbonium ion VI, previously shown be to relatively stable. At −30 °C, a spectrum, Fig. 6A, is obtained which can be readily assigned the carbonium-ion structure XVIII (compare with ion VI). Peaks at 7.27 τ, CH_3 on a carbonium-ion center; 2.59 and

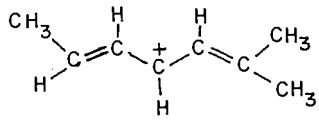
XVII



XVIII

2.81 τ, protons at C3 and C5; an unresolved peak about 1.70 τ, probably the proton at C6; a triplet of peaks 0.97, 1.17, and 1.37 τ, probably the proton C4. At −10 °C, a cyclization reaction begins and eventually results in an ion whose spectrum is shown in Fig. 6B. This spectrum can be readily assigned to the carbonium-ion structure XIX. Peaks at 8.55 τ, CH_3 group at C4, not connected to a carbonium-ion center; 6.91 τ, CH_3 at C3; 6.51 τ, protons at C5; 2.13 and 2.21 τ, proton at C2; −0.03 and 0.04 τ, proton at C1. The coupling constant of protons at C1 and C2 is 4.5 c.p.s. This ion is not very stable and after 1 h at 25° C, the spectrum shown in Fig. 6C is obtained. This spectrum is nondescript and probably represents a mixture of products, including polymers.

Attempts to prepare the carbonium ion resulting from the removal of two methyl groups from VI, one from each end, viz. addition of hepta-3,5-dien-2-ol to sulfuric acid at −10 °C, result in a solution whose spectrum is shown in Fig. 7. This spectrum can readily be interpreted in terms of the carbonium ion XX. Peaks at 7.72 τ, CH_3 at C2; 6.90 τ, CH_3 at C1; 6.23 and 6.50 τ, protons at C4 and C5; 0.23 τ, proton at C3. The relative areas are 3:2.9:3.7:1; theory, 3:3:4:1. This carbonium ion decomposes rapidly at 25 °C. Attempts to prepare this ion using 1,3,5-heptatriene resulted in extensive polymerization during the addition. The alcohol however is less volatile, thereby decreasing the gas-phase concentration (i.e. a more dilute addition), and is probably less reactive than the triene.

These final two systems demonstrate very clearly the decreased stability associated with the removal of methyl groups from the end positions of divinyl carbonium ions. We are therefore forced to conclude that we have neither proved nor disproved the original argument based on steric effects.

Ultraviolet Spectra

The ultraviolet spectral data for all of the carbonium ions which have been prepared in this work are shown in Table I. There seems to be a natural break in the absorption maxima for the cyclopentenyl cations depending upon whether a methyl group or a hydrogen is present as R_4. The positions of the observed absorption maxima are in good agreement with the results reported by Deno *et al.* (8) for similar cyclopentenyl ions; however, in the one case of duplication, our ϵ_{max} is somewhat higher. As expected, the divinyl carbonium ions absorb at much longer wavelengths than the allylic ions. The position of the maximum is similar to that found for protonated benzenes (9) but the intensities are higher, reflecting the open structure of the divinyl carbonium-ion system.

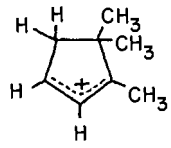
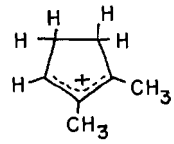
Recovery Experiments

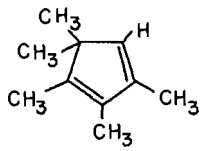
Using the high-dilution procedure employed by Deno *et al.* (6) (see experimental), we have recovered the dienes from the carbonium ion IV in 80% yield. These were separated by vapor-phase chromatography (g.l.c.) into the pure components: the low-retention product ca. 40% of the mixture, the middle one ca. 40%, and the highest-retention product ca. 20%. The low-retention product has an ultraviolet absorption maximum (in cyclohexane) at 258 mμ, ϵ_{max} = 3 600 and an n.m.r. spectrum (10% in carbon tetrachloride) as shown in Fig. 8A. The ultraviolet absorption (long wavelength, low intensity) is quite characteristic of cyclopentadienes and this assignment is backed by the n.m.r. spectral result which shows no methylene proton peaks and, on integration, only 1 alkene proton versus 15 methyl protons. On this basis, the structure of the low-retention product is 1,2,3,5,5-pentamethylcyclopentadiene, XXI. The presence of two sharp unequal peaks in the methyl region at 9.04 and 9.10 τ is an anomaly we are unable to explain. Analysis of this liquid on two different g.l.c. columns has failed to show the presence of significant amounts of impurity. The middle-retention product has an ultraviolet maximum (in cyclohexane) at 240.5 mμ, ϵ_{max} = 20 500; the high-retention product, 242 mμ, ϵ_{max} = 18 700. The n.m.r. spectra of these two dienes are shown in Figs. 8B and 8C. The other two



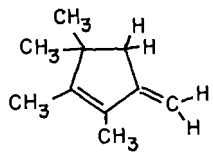
XIX



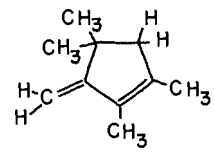
XX



XXI



XXII



XXIII

possible products, besides XXI, from the de-protonation of the carbonium ion IV are dienes XXII and XXIII, for which the ultraviolet data (above) are in excellent accord (estimated from Woodward's rules, 242 mμ). The gross features shown in the n.m.r. spectra, two alkene protons, two methylene protons, two methyl groups on a double bond, and two not on a double bond, are also in excellent accord. In spite of their similarity in structure, their n.m.r. spectra are considerably different in detail. We have assigned to the high-retention product (n.m.r. in Fig. 8B) the structure XXII, based almost entirely on what appears to be coupling between the methylene group and the vinyl protons, such as appears possible only in XXII.

In addition to these monomers, about 10% of a product having a v.p.c. retention time of the right order of magnitude for a dimer was also recovered.

The triene, 2,6-dimethyl-1,3,5-heptatriene, has been recovered in over 80% yield using the same technique (as above). Attempts to recover monomers from the carbonium ion XX were less successful. Most of the recovered material appeared to be dimeric or trimeric (g.l.c. retention times).

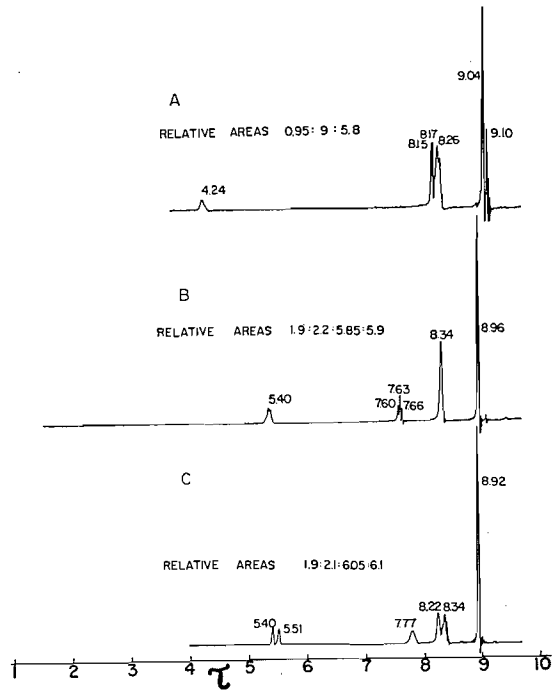


FIG. 8. A. Nuclear magnetic resonance spectrum of the low-retention product from the decomposition of IV. B. Nuclear magnetic resonance spectrum of the high-retention product from the decomposition of IV. C. Nuclear magnetic resonance spectrum of the middle-retention product from the decomposition of IV.

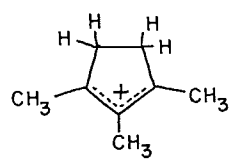
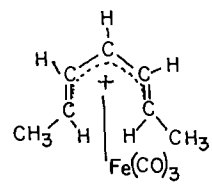
Mechanism

From the isomeric C_9H_{14} trienes, 4,6- and 2,6-dimethyl-1,3,5-heptatriene, one obtains finally the cyclopentenyl ions VII and XV. These are not interconverted one to the other under the same conditions under which these ions were formed originally. Thus there must be no common intermediate in these two rearrangement reactions. A postulated mechanism which accounts for the end products and the absence of a common intermediate is shown below. Note that concerted double methyl shifts are necessary if one is to proceed from one allylic system to another. In some cases this double shift is not possible; for example, the ion XIX is very unstable but, in spite of the fact that there is a stable isomeric ion, 1,2,3-trimethylcyclopentenyl cation (6) XXIV, the conversion of XIX to XXIV is not observed (or only in small amounts). All of the other products can also be explained using double methyl shifts and allylic proton rearrangements.



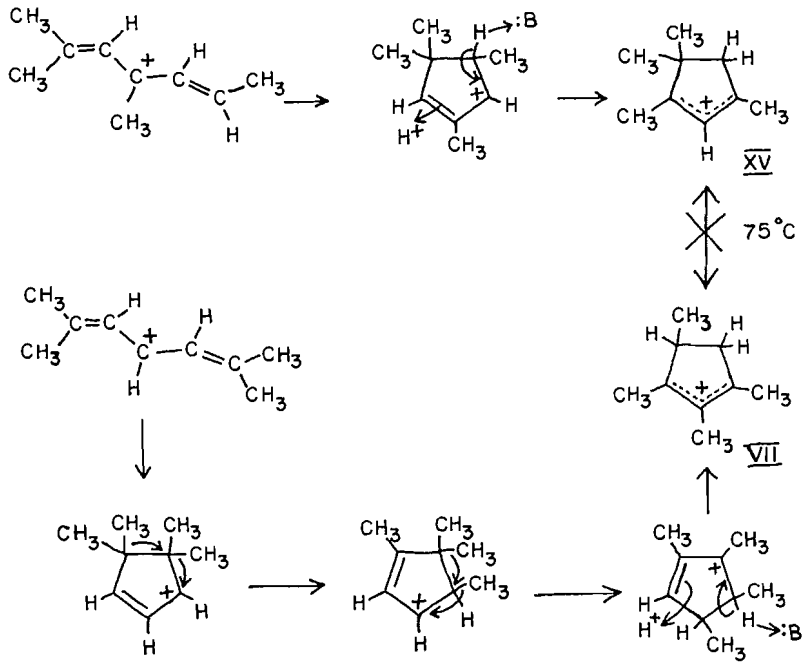
XXIV



XXV

It is interesting to compare the stability of the divinyl carbonium ion – iron carbonyl complexes prepared by Mahler and Pettit (10) with those prepared in this work. The ion XXV is completely stable at ambient temperatures while the corresponding ion without

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



the iron carbonyl function undergoes a cyclization reaction very rapidly and has not been observed. The position of the n.m.r. proton signals of XXV also shows the increased electron density at all positions when compared with VI as a reference.

An interesting rate study could be made on S_N1 or S_N1' reactions leading to the transition states corresponding to III and VI. Would the former be significantly slower, due to a less stable carbonium ion being formed, or are the transition states in S_N1 reactions unrelated in structures to these "stable" carbonium ions?

EXPERIMENTAL

The preparation of all of the trienes used in this work has been described in a separate paper (7*a*), with the exception of alloöcimene and 1,3,5-heptatriene. Alloöcimene was kindly provided by the Hercules Powder Co. of Wilmington, Del. and was distilled before use, $n_D^{23} = 1.5421$, reported (11) $n_D^{20} = 1.5446$. Analysis by g.l.c. shows alloöcimene to be composed of two isomers in about equal amounts. This has previously been deduced (11) by spectral means although questioned in a later publication (12). Both isomers should (and do) protonate to give the same carbonium ion. A 96% yield of 3,5-heptadien-2-ol was obtained by the addition of methyl magnesium bromide to sorbaldehyde, b.p. 61.5–62 °C at 6 mm, $n_D^{20} = 1.4920$, reported (13) $n_D^{20} = 1.4882$. Heptatriene was prepared (13) by the dehydration of this alcohol.

The apparatus which was used to prepare these carbonium ions is shown in Fig. 9. The system was evacuated, with the flask containing the trienes cooled in liquid nitrogen. The system was then isolated by closing the stopcock and the flask containing the trienes allowed to warm up. Generally, about 200 mg of the triene was added to 2–3 ml of concentrated sulfuric acid, resulting in 4–5% carbonium-ion solutions. The addition of the trienes took anywhere from 10 min to an hour depending upon the pressure and the temperature differential between the acid and the trienes. The sulfuric acid could be kept at any temperature from 25 °C to −30 °C during the addition, in spite of the fact that the freezing point of the acid is − 15°C. It fortunately supercools quite easily. A number of the carbonium ions are stable for several weeks at 25 °C but many begin to darken noticeably after a few hours.

The n.m.r. spectra were obtained on a Varian Assoc. A-60 spectrophotometer equipped with a variable temperature probe. Tetramethylammonium cation was used as an internal reference for the sulfuric acid solutions (6) (set at 6.90 τ). Other compounds were measured as 10% solutions in carbon tetrachloride using tetramethylsilane (TMS) as the internal reference. Ultraviolet measurements were made using a Beckman DK-1 spectrophotometer with a variable temperature cell compartment.

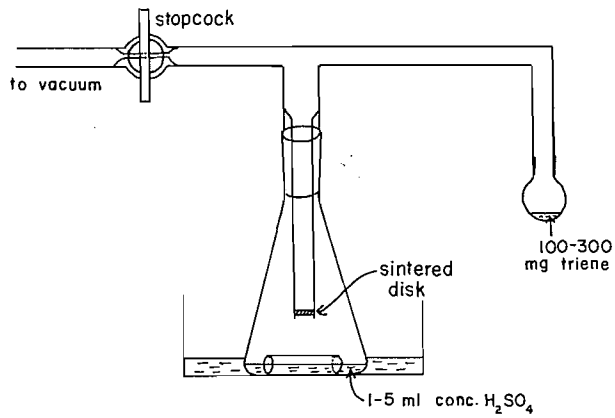

FIG. 9. Apparatus for preparing the carbonium ions.

Recovery of the dienes from the carbonium ion IV was accomplished by adding the sulfuric acid solution (from 2.75 g of triene and 30 ml concentrated sulfuric acid), from a 2 ml hypodermic syringe, to a vigorously stirred mixture of ice, dilute sodium hydroxide solution, and 50 ml of ether. The ether layer was separated and the aqueous solution extracted with two more 100 ml portions of ether. The combined ether extracts were dried over potassium carbonate. The ether was then carefully distilled off at atmospheric pressure. The residual dienes were then distilled at low pressure into a dry-ice cooled trap, 1.8 g (80% recovery). A small viscous residue remains in the distillation flask, 0.3 g (10% recovery). The volatile diene fraction consists of three components (analytical v.p.c.). These can be separated by preparative g.l.c. into the pure individual components (Aerograph "Autoprep", 12 ft. × ⅜ in. column of 30% carbowax 20 M on 60/80 Chromsorb W, HMDS treated, helium flow, 200 ml/min, column temperature, 90 °C, sample size, ca. 0.1 ml). The retention times and percentages of the total are low-retention product, 9.4 min, 40%, middle-retention product, 11.2 min, 40%, and high-retention product, 13.3 min, 20%.

Low-Retention Product, 1,2,3,5,5-Pentamethylcyclopentadiene(XXI)
Anal. Calcd. for C_9H_{16}: C, 88.16; H, 11.84. Found: C, 88.01; H, 12.12. n_D^{21} = 1.4610.

Middle-Retention Product, 1-Methylene-2,3,5,5-tetramethyl-2-cyclopentene(XXIII)
Anal. Calcd. for C_9H_{16}: C, 88.16; H, 11.84. Found: C, 87.74; H, 11.85. n_D^{21} = 1.4783.

High-Retention Product, 1-Methylene-2,3,4,4-tetramethyl-2-cyclopentene(XXII)
Anal. Calcd. for C_9H_{16}: C, 88.16; H, 11.84. Found: C, 88.10; H, 11.95. n_D^{25} = 1.4806.

The same procedure was used to recover the hydrocarbons from several other carbonium ions. A curious green-colored compound (azulenes?) was formed in some cases when the carbonium-ion solutions were decomposed (by adding water to them).

THE PREPARATION AND PROPERTIES OF SOME METHYL-SUBSTITUTED HEPTATRIENES

T. S. SORENSEN
Department of Chemistry, University of Alberta, Calgary, Alberta
Received July 7, 1964

ABSTRACT

The synthesis and assignment of the geometry of a number of previously unknown methyl-substituted 1,3,5-heptatriens are described. A table of the ultraviolet spectral maxima of these and other trienes is included. Anomalies in the ultraviolet spectral curves of certain trienes are attributed to steric interactions affecting the coplanarity of the chromophore system.

INTRODUCTION

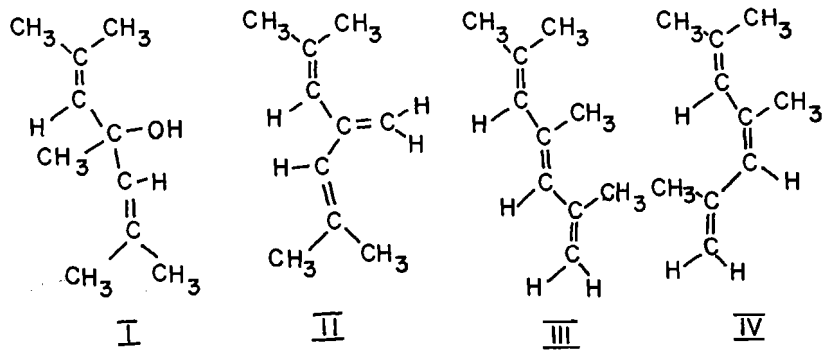
In connection with our studies of divinyl carbonium ions (1), we have had occasion to synthesize a number of aliphatic trienes. In particular, we were anxious to have pure geometric isomers available for this study. The assignment of the geometry to these isomers, however, is not always straightforward (2). We have used both proton magnetic resonance spectroscopy (n.m.r.) and ultraviolet spectroscopy and believe that the assigned structures are reasonably consistent with the facts. A table of the ultraviolet spectra of a large number of trienes is included, particularly to show that "steric hindrance to planarity" becomes serious in some highly substituted derivatives. This fact will be important in the related discussion of the carbonium ions.

The general synthetic method for preparing these trienes involves the addition of Grignard reagents to appropriate aldehydes and ketones, giving a diene-alcohol which is then dehydrated. Three of these triene systems have been prepared from an α,β-unsaturated carbonyl compound and an allylic Grignard reagent. The simultaneous addition (the allyl chloride and carbonyl compound) method of Nazarov (3) gave excellent yields of the unsaturated alcohols with no sign of products resulting from conjugate addition (4).

RESULTS AND DISCUSSION

2,4,6-Trimethyl-1,3,5-heptatriene

Dehydration of the alcohol I, obtained in good yield from the addition of methyl magnesium bromide to phorone (5), has been reported (6) to yield 4-methylene-2,6-dimethyl-2,5-heptadiene (II).



I II III IV

Using a catalytic amount of *p*-toluenesulfonic acid in benzene and removing the water formed in the dehydration by azeotropic distillation, we obtained three compounds, accounting for > 99% of the volatile dehydration products. This mixture of compounds was separated by preparative vapor-phase chromatography (g.l.c.) into the pure components. Their n.m.r. spectra show the absence of saturated methylene proton peaks in each case, so each isomer must be fully conjugated. There are only three possible conjugated products, viz. trienes II, III, and IV. Braude and co-workers (7) in a series of papers, have described the very facile allylic rearrangement of divinyl alcohols, including I, so the occurrence of trienes III and IV might be expected. The middle-retention product (24% of the total) can safely be assigned the structure II, on the basis of the exceedingly simple n.m.r. spectrum observed (and expected) for this symmetrical structure. The natural tendency might be to assign to the lowest-retention product the *cis*

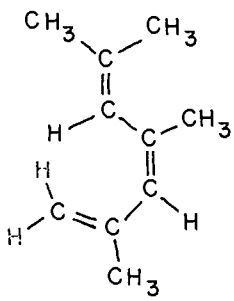
*This datum was taken from ref. 10. However, these authors' assignment of the geometry of the two isomers may be open to question.

†This datum was taken from ref. 2.

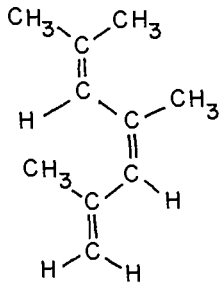
‡Kindly provided by the Hercules Powder Co., Wilmington, Delaware. The g.l.c. analysis shows the presence of two isomers in nearly equal amounts. We thank a referee for pointing out the recent work of C. Cappas (Ph.D. Thesis, University of Florida, Gainesville, Florida. 1962. Dissertation Abstr. 23, 846 (1962)) in which these two isomers are separated and the ultraviolet absorption reported for the pure isomers. The two isomers are identified as 4,5-*trans*-6,7-*trans* and 4,5-*trans*-6,7-*cis*.

structure IV (41% of the total) and to the highest-retention product the *trans* structure III (35%). There seems to be no general justification for this, however (cf. the work of Hwa, de Benneville, and Sims (2) on hexatrienes).

The n.m.r. spectra of these two trienes are reasonably dissimilar and are shown in Fig. 1. The ultraviolet spectra are also dissimilar; the lower-retention product has a λ_{max} 239.5 and 209 mμ, ϵ_{max} 11 300 and 8 800, while the absorption of the high-retention product is λ_{max} 258.5 mμ, ϵ_{max} 9 900. A comparison of these with the complete ultraviolet spectral data in Table I for a number of trienes shows that both the intensity and the wavelength of the maxima are much smaller than would be expected. Similar effects have often been observed (8) in cases where steric repulsions prevent molecules from being completely planar. For each isomer there are four possible conformers, corresponding to rotation about the two single bonds of the backbone. For the *cis* isomer, two of these, the s-*cis-cis* and the s-*trans-cis*, are clearly very strained (repulsion by methyl groups at C2 and C6); the remaining two, IVA and IVB, are shown below.

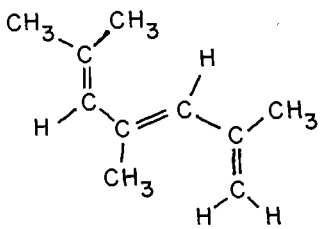


IV A

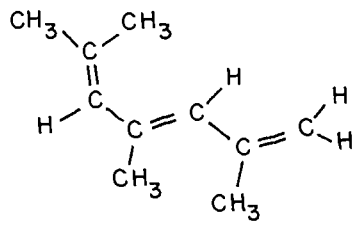


IV B

For the *trans* isomer, none of the four conformers is impossible; however, the s-*trans-trans* and the s-*cis-trans* appear to be the more impossible because of the accumulated repulsion of methyl groups on the one side of the backbone of the triene framework; the remaining two, IIIA and IIIB, are shown below.



III A



III B

The molecular models (Fisher–Hirschfelder–Taylor) of both the *cis* and *trans* isomer in all of the possible rotational states are never planar; however, the *trans* isomer in conformations IIIA or IIIB attains the greater coplanarity of the three double bonds. We, therefore, assign to the *trans* isomer the longer wavelength absorption maximum; this isomer also happens to be the higher g.l.c. retention product.

For personal use only.

The interpretation of the n.m.r. spectra is fairly arbitrary. There is an abnormally shielded methyl group peak at 8.40 τ in the low-retention product. This same feature is also present in the n.m.r. spectrum of the low-retention product described below (Fig. 2),

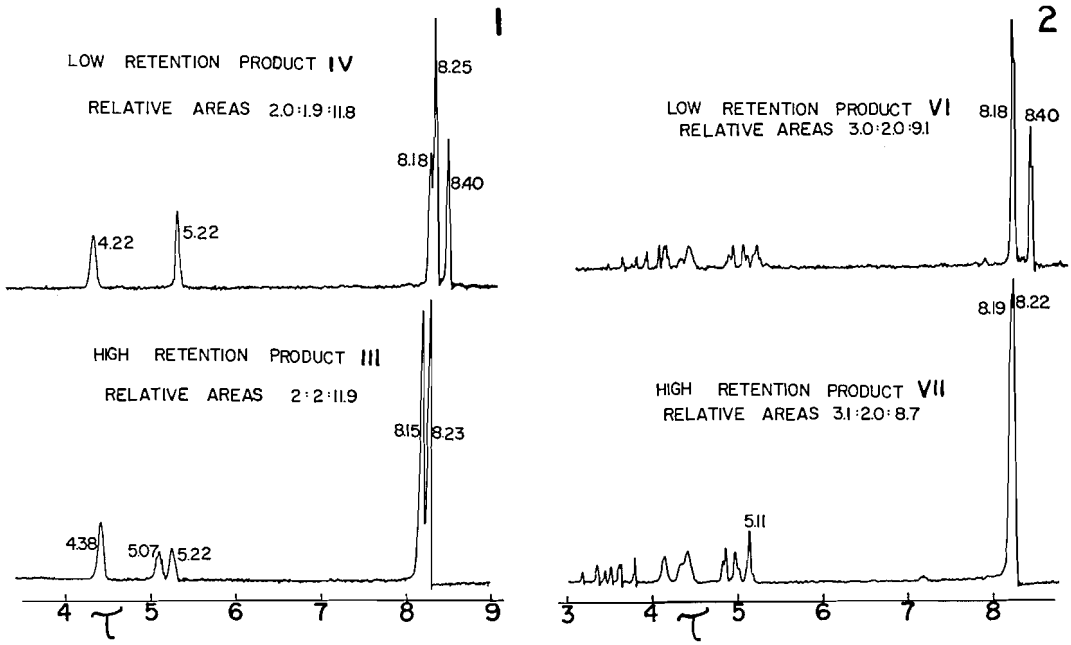

FIG. 1. Nuclear magnetic resonance spectra of *cis*- and *trans*-2,4,6-trimethyl-1,3,5-heptatriene.
FIG. 2. Nuclear magnetic resonance spectra of *cis*- and *trans*-4,6-dimethyl-1,3,5-heptatriene.

also assigned a *cis* geometry and having the same partial structure for carbon atoms 3 to 7. Methyl groups orientated near or in the π-electron cloud of double bonds have been observed to be abnormally shielded (9). This same situation can arise in both of the *cis* isomers referred to above, if one assumes (as the molecular models would indicate) that the 5,6-double bond is twisted about 90° from the plane of the remaining 1,2-3,4-planar diene system. This results in one of the terminal methyl groups being orientated above the diene π-electron system. We have no satisfactory explanation for the two peaks observed for the exocyclic methylene protons in the *trans* isomer as against the sharp single peak for this same structure in the *cis* compound. In a number of other compounds containing this partial structure, only one sharp peak has been observed.

4,6-Dimethyl-1,3,5-heptatriene

The reaction of allyl magnesium chloride and mesityl oxide produces the alcohol V, in excellent yield.

Dehydration (as above) yielded at least eight compounds, resolved or partially resolved by g.l.c. The two largest fractions, the lower-retention product about 25% of the total dehydration product and the higher about 35%, were separated by preparative g.l.c. and were identified as VI and VII respectively. The other compounds likely correspond to products formed from dehydration into the methyl group at C4 and from allylic rearrangement. The assignment of the structures of VI and VII was based upon (1) the absence of saturated methylene proton peaks in their n.m.r. spectra (Fig. 2), indicating completely

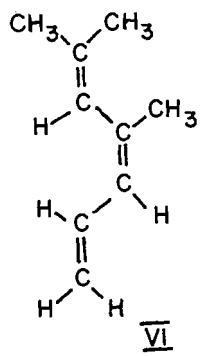
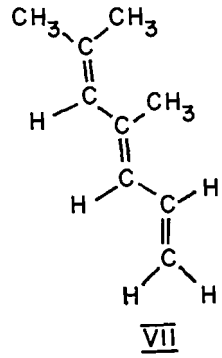
V



VI



VII

conjugated compounds, and (2) absence of the partial structure in their n.m.r. spectra, indicating that these compounds are not of the isomeric 2,4-dimethyl-1,3,5-heptatriene system. The ultraviolet results (Table I) again show that the higher-retention product has the longest wavelength absorption. Molecular model studies again show that the *trans* isomer can attain better coplanarity of the chromophore system than the *cis* isomer and an analogous assignment to that previously discussed is made for the structures VI and VII. The decreased intensity of the ultraviolet absorption is again indicative of interference to the coplanarity of the system in both isomers.

2,6-Dimethyl-1,3,5-heptatriene

This compound was prepared by the reduction of phorone with lithium aluminium hydride (7). It shows a single peak when subjected to vapor-phase chromatography and although there are two possible geometric isomers, this one is in all likelihood the *trans* compound, in view of its relatively high melting point and normal ultraviolet spectrum. Molecular model studies of the two isomers indicate that the *cis* one would have serious steric interference to coplanarity of the double bonds, caused by the methyl group at C2 (or a hydrogen at C1) and the hydrogen at C5.

2-Methyl-1,3,5-heptatriene

The reaction of crotonaldehyde with methallyl magnesium chloride yields the alcohol VIII. This was dehydrated by adding it dropwise to powdered potassium acid sulfate at 150–160 °C. The crude mixture is resolved or partially resolved into nine peaks on g.l.c.; five of these (85% of the total mixture) come off the column with retention times expected for C_8 compounds. The two largest fractions were separated (pure) by preparative g.l.c.;

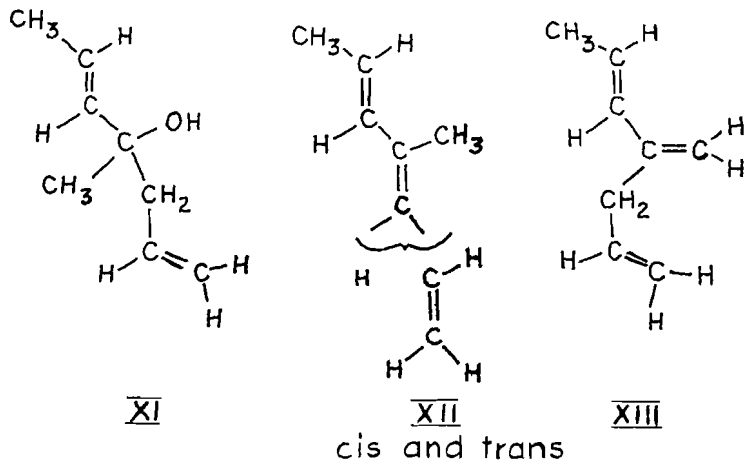
the higher retention product (30% of the total trienes) shows no saturated methylene proton peaks in its n.m.r. spectrum and is therefore conjugated. The partial structure  is still intact (n.m.r.), so this compound is not the isomeric 6-methyl-1,3,5-heptatriene. The steric arguments concerning this triene are very similar to those just discussed for 2-methyl-1,3,5-heptatriene. The *trans* isomer (the 3,4-double bond) can take up a planar structure, while the *cis* isomer has the same steric repulsions as previously discussed. In view of its normal ultraviolet absorption, we would assign to this compound the *trans-trans* structure. The geometry of the 5,6-double bond is *trans* in crotonaldehyde and presumably also in the dienol VIII. There would be no reason to expect that the major conjugated triene product would be the rearranged *cis*-5,6-triene. Some of the smaller peaks in the g.l.c. results may represent the *cis* isomers but the other major product collected (43% of the total trienes) shows saturated methylene proton peaks in its n.m.r. spectrum and must be the dehydration product X, corresponding to allylic rearrangement.

4-Methyl-1,3,5-heptatriene

The reaction of allyl magnesium chloride and 3-penten-2-one produced the alcohol XI, in excellent yield.



Dehydration again yielded a complex mixture of five or more compounds from which the two present in largest amounts were isolated by preparative g.l.c. The high-retention product, which was collected (70% of the mixture), is actually composed of two compounds with very close retention times, in the ratio of about 1:2. The n.m.r. spectrum of this mixture shows no saturated methylene proton peaks, so the trienes are fully conjugated. There are four geometric isomers of the title compound, however; it seems unlikely that the geometry of the 5,6-double bond will change from the expected *trans* position in the pentenone and the dienol XI, at least not to the extent that the major products have this geometry. These two compounds would then be the *cis* and *trans* isomers XII involving the 3,4-double bond. Molecular model studies show that neither of these isomers have significant steric interactions to distort the planarity of the chromophore system and, in agreement with this, normal ultraviolet absorption is observed for this triene-pair mixture. The lower-retention product (20% of the trienes)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

shows saturated methylene proton peaks in its n.m.r. spectrum and presumably corresponds to a triene, XIII, resulting from dehydration into the 4-methyl group, since the partial structure $\begin{matrix} CH_3 \\ \diagdown \\ H \diagup \end{matrix}\!\!>C=$ is still present.

Ultraviolet Spectra

The significant feature of unhindered trienes is a triplet of peaks, the middle one being the highest, separated by about 10 mμ. The ultraviolet data in Table I also verify the bathochromic shift of the maxima expected when methyl groups are substituted on the basic triene system (except when steric effects become dominant).

EXPERIMENTAL

All melting points and boiling points are uncorrected. Ultraviolet spectra were measured in isoöctane or cyclohexane solution with a Beckman DK-1 spectrophotometer and are for the most part listed in Table I. Infrared spectra of all of the compounds described in this work were recorded by a Perkin–Elmer model 337 spectrophotometer and are available upon request. The n.m.r. spectra were obtained on a Varian Associates A-60 spectrophotometer using ca. 10% solutions in carbon tetrachloride and internal tetramethylsilane (TMS) as a reference. The n.m.r. results are often most useful in the negative sense that certain characteristic proton signals are not observed. No analysis of complex splitting patterns was attempted beyond ascertaining that this behavior was not unexpected; in addition, methyl group positions are reported as single peaks even in cases where they are actually doublets or multiplets with very small coupling constants (interaction with protons across a double bond). Gas chromatography separations were made using the Aerograph "Autoprep" model A-700. Analytical g.l.c. results were obtained with the above machine and an Aerograph "Hy-Fi", model 600. The purity of all of the compounds described here, whether separated in preparative amounts by g.l.c. or not, was finally checked by analytical g.l.c. and in most cases was 98% or better apparent homogeneity. All conjugated trienes are sensitive to air and subject to polymerization and were kept under nitrogen in a freezing compartment.

2,4,6-Trimethyl-hepta-2,5-dien-4-ol (I)

Phorone, recrystallized from diethyl ether, (40 g, 0.29 moles) in 200 ml of ether was added dropwise to a stirred solution of methyl magnesium bromide (ca. 0.36 moles) held at 0 °C. The solution was stirred an additional hour and then poured into ice and ammonium chloride. The ether layer was separated and the aqueous layer extracted with a further 100 ml of ether. The combined ether layers were dried over potassium carbonate. The ether was removed under vacuum to leave an oily solid. This was recrystallized from pentane to yield 25 g of the alcohol I (56%), m.p. 57 °C, reported (5) 57.5 °C. Peaks were observed in the n.m.r. spectrum at 8.69 τ, $O-\overset{|}{\underset{|}{C}}-CH_3$; 8.32 τ, CH_3; 8.12 τ, O—H; and a complex peak centered at 4.58 τ, $=CH$. The relative areas of the peaks were 3:12:1:2; theory 3:12:1:2.

Dehydration of I

A solution of 15 g I (0.097 moles) and 0.05 g of *p*-toluenesulfonic acid in 60 ml of dry benzene was heated to reflux, using a Dean-Stark trap to remove the water by azeotropic distillation. Ether was added to the remaining benzene and the resulting solution was washed with 5% sodium hydroxide solution and several times with water before drying over potassium carbonate. The solvent was removed by distillation and the residue distilled at 9 mm pressure to yield a fraction, b.p. 45–47 °C, n_D^{25} = 1.480, and another fraction b.p. 47–51 °C. Total yield of product, 10.7 g (81%). Analysis (g.l.c.) showed that neither fraction was a single compound and in subsequent runs only one triene fraction was collected. Analysis (g.l.c.) on the distilled and undistilled trienes yields the same number of peaks in the same relative area; low-retention product, 41% of the total, middle-retention product, 24%, and the high-retention product, 41%. The trienes were separated in preparative amounts using a 12 ft × 3/8 in. column of 30% carbowax 20 M on 60/80 Chromosorb W, HMDS treated. The column temperature was 110 °C, helium flow 150 ml/min, sample size ca. 0.1 ml, and the retention times 9, 11.25, and 12.75 min respectively.

Low-Retention Product, cis-2,4,6-Trimethyl-1,3,5-heptatriene (IV)

Nuclear magnetic resonance spectrum shown in Fig. 1, n_D^{23} = 1.4791.

Anal. Calcd. for $C_{10}H_{16}$: C, 88.16; H, 11.84. Found: C, 87.78; H, 11.93.

Middle-Retention Product, 4-Methylene-2,6-dimethyl-2,5-heptadiene (II)

Nuclear magnetic resonance peaks at 8.25 τ, CH_3; 5.14 τ, $=CH_2$, and 4.28 τ, $=CH$. The relative areas were 12.3:2.0:2.1; theory 12:2:2. n_D^{23} = 1.4799.

Anal. Calcd. for $C_{10}H_{16}$: C, 88.16; H, 11.84. Found: C, 87.75; H, 11.91.

Anal. Calcd. for $C_{10}H_{16}$: C, 88.16; H, 11.84. Found: C, 87.85; H, 12.13.

4,6-Dimethyl-hepta-1,5-dien-4-ol (V)
To a 1 l 3-necked flask equipped with a condenser and mechanical stirrer was added 100 ml of ether, 24.3 g (1.0 moles) of magnesium turnings, and a small crystal of iodine. A solution of 10 g of allyl chloride in 100 ml of ether was added to this stirred suspension; a small amount initially to start the reaction and the rest at such a rate that gentle refluxing was maintained. Then, a solution of 54 g (0.55 moles) of mesityl oxide and 66 g (0.87 moles) of allyl chloride in 300 ml of ether was added dropwise with stirring (maintaining moderate reflux) over a 2.5 h period, during which time magnesium chloride precipitates. This makes the solution very viscous but otherwise does not affect the reaction. The solution was allowed to stand at room temperature for 3 h and then decomposed by pouring it into 600 ml of ice – ammonium chloride solution. The ether layer was separated and the aqueous layer extracted with a further 150 ml portion of ether. The combined ether fractions were dried over anhydrous potassium carbonate. Removal of the ether by careful distillation at atmospheric pressure yielded an almost colorless liquid residue. This was distilled through a 1 m "Nester" spinning band column to yield essentially one fraction, b.p. 55–57 °C at 6–7 mm, $n_D^{26} = 1.4569$, reported (3) 1.462. Yield 70.0 g (90%).
Anal. Calcd. for $C_9H_{16}O$: C, 77.09; H, 11.50. Found: C, 77.28; H, 11.47.
Nuclear magnetic resonance peaks were found at 8.75 τ, O—C(—CH_3)—; 8.51 τ, O—H; 8.14 and 8.30 τ, two different CH_3 groups; 7.68 and 7.81 τ, $—CH_2—$ split by a single proton; and a very complex pattern of peaks from 4–5 τ, $=CH_2$ and $=C(—H)—$. The relative areas were 2.6:1:5.5:2:4; theory 3:1:6:2:4.

Dehydration of V
A solution of 32 g (0.23 moles) of the alcohol V and 0.1 g of *p*-toluenesulfonic acid in 200 ml of dry benzene was heated to reflux, using a Dean-Stark trap to remove the water. The benzene solution was then cooled, washed with 5% sodium hydroxide solution, and washed several times with water before being dried over potassium carbonate. The benzene was distilled at about 100 mm to leave a crude triene fraction. This was fractionated using a spinning band column; however, the individual fractions which were collected were each shown to be complex mixtures. In subsequent runs, only one fraction, b.p. 22–36 °C at 5–6 mm, was collected. Yield 20 g (70%), residue 3 g. The vapor-phase chromatogram of this triene mixture is shown in Fig. 3. The two largest peaks were collected using the preparative column previously described (sample size ca. 0.1 ml, helium flow 200 ml/min, column temperature 120 °C). The lower peak represents about 25% of the total trienes and the higher about 35%.

Low-Retention Product, cis-4,6-Dimethyl-1,3,5-heptatriene (VI)
Nuclear magnetic resonance spectrum, Fig. 2. $n_D^{26} = 1.4838$.
Anal. Calcd. for C_9H_{14}: C, 88.45; H, 11.55. Found: C, 88.08; H, 11.68.

High-Retention Product, trans-4,6-Dimethyl-1,3,5-heptatriene (VII)
Nuclear Magnetic resonance spectrum, Fig. 2, $n_D^{26} = 1.5128$.
Anal. Calcd. for C_9H_{14}: C, 88.45; H, 11.55. Found: C, 88.52; H, 11.53.

2,6-Dimethyl-1,3,5-heptatriene
This triene was prepared in 25% yield by the published procedure, b.p. 44.5–45.5 °C at 8–9 mm, $n_D^{21} = 1.5303$, reported (7) 1.5130–1.5190. The compound appeared to be completely homogenous (g.l.c.) and has a melting point of about −20 °C. Nuclear magnetic resonance peaks were found at 8.13 τ, CH_3; 8.21 τ, $2CH_3$ groups; 5.12 τ, $=CH_2$; and a complex series of peaks 3.4–4.3 τ, =C—H. The relative areas were 9.2:2.0:1.1:2.0; theory 9:2:1:2.
Anal. Calcd. for C_9H_{14}: C, 88.45; H, 11.55. Found: C, 87.94; H, 11.74.

4-Methyl-hepta-1,5-dien-4-ol (XI)
Using a procedure similar to that described for the preparation of V and starting with 7 g of allyl chloride in 75 ml of ether and 17.0 g (0.7 moles) of magnesium in 50 ml of ether and then adding a solution of 46.2 g (0.61 moles) of allyl chloride and 30.0 g (0.36 moles) of 3-penten-2-one (11) in 300 ml of ether, we obtained after removal of the ether, by careful distillation at atmospheric pressure, a liquid residue which was distilled through a spinning band column. Fractions, b.p. 44–46 °C at 5–6 mm, were collected and combined. Yield 28.3 g (78%), $n_D^{23} = 1.4528–1.4536$. Nuclear magnetic resonance peaks were found at 8.80 τ, O—C(—CH_3)—; 8.27 and 8.35 τ, $—CH_3$; 8.04 τ, O—H; 7.73 and 7.84 τ, $—CH_2—$ split by a single proton; and a complex

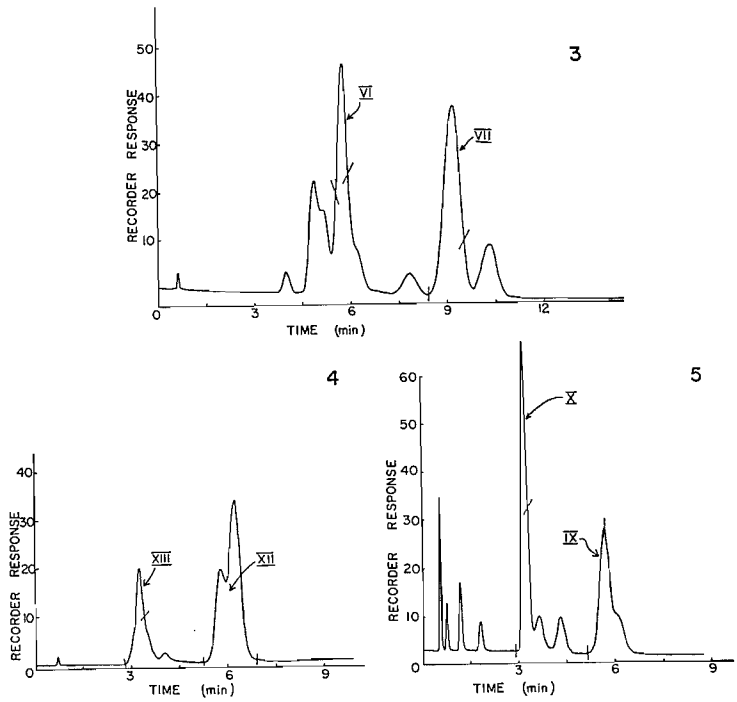

FIG. 3. Gas–liquid chromatography trace of dehydration products from V.
FIG. 4. Gas–liquid chromatography trace of dehydration products from XI.
FIG. 5. Gas–liquid chromatography trace of dehydration products from VIII.

Dehydration of XI

Dehydration of 20 g (0.16 moles) of the alcohol XI in a manner similar to that described for V gave, after distillation, a crude triene fraction, b.p. 25–35 °C at 35 mm. Yield 12 g (69%). The vapor-phase chromatogram of this triene mixture is shown in Fig. 4. The two largest peaks, the lower-retention product about 20% of the total trienes and the higher 70%, were collected using the same preparative column as previously (sample size ca. 0.1 ml, helium flow 200 ml/min, column temperature 120 °C). As can be seen from Fig. 4, the high-retention product which was collected is actually a mixture of two compounds in the ratio of about 1:2.

Low-Retention Product, 4-Methylene-1,5-heptadiene XIII

This compound was obtained in only about 90% purity (g.l.c.).

Nuclear magnetic resonance peaks for XIII were found at 8.19 and 8.28 τ, CH_3, split by a single proton; 7.08 and 7.17 τ, $—CH_2—$ split by a single proton; and a complex series of peaks 3.4–5.2 τ, $=CH_2$ and $=C\begin{smallmatrix}H\\ \diagup\\ \diagdown\end{smallmatrix}$. The relative areas were 3.2:1.7:7; theory 3:2:7.

High-Retention Products, cis-trans- and trans-trans-4-Methyl-1,3,5-heptatriene (XII)

Peaks in the n.m.r. spectrum were found at 8.26 τ, CH_3 split by a single proton and 8.18 τ, the other half of the split CH_3 and an unsplit CH_3, and a complex series of peaks from 2.9–5.2 τ, $=CH_2$ and $=C\begin{smallmatrix}H\\ \diagup\\ \diagdown\end{smallmatrix}$. The relative areas were 6:6; theory 6:6. $n_D^{25} = 1.5318$.

Preparation of 2-Methyl-hepta-1,5-dien-4-ol (VIII)

Using a procedure similar to that described for the preparation of V and starting with 8 g of methallyl chloride in 50 ml of ether and 13.4 g (0.55 moles) of magnesium in 25 ml of ether and then adding a solution of 22 g (0.31 moles) of crotonaldehyde and 44 g (0.48 moles) of methallyl chloride in 300 ml of ether, we

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

obtained, after distillation through a spinning band column, essentially one fraction, 37.4 g (96%) of VIII, b.p. 56–57.5 °C at 6 mm, n_D^{25} = 1.4559.

Anal. Calcd. for $C_8H_{14}O$: C, 76.08; H, 11.17. Found: C, 76.14; H, 11.05.

Peaks were found in the n.m.r. spectrum at 8.35 τ, $-CH_3$ split by a proton and 8.27 τ, unsplit $-CH_3$ and the other half of the split peak; 8.11 τ, O—H; 7.80 and 7.91 τ, $-CH_2-$ split by a single proton; a complex band centered at 5.95 τ, H—C—O; 5.24 τ, $=CH_2$; and a complex pattern with the main peaks at 4.41, 4.48, and 4.55 τ, $=C\begin{smallmatrix}H\\ \diagup\\ \diagdown\end{smallmatrix}$. The relative areas were 6:1.2:2.4:1:2:2; theory 6:1:2:1:2:2.

Dehydration of VIII

The alcohol VIII, 5 g (0.04 moles), was added dropwise to 5 g of powdered potassium acid sulfate, contained in a 50 ml 2-necked round bottom flask immersed in an oil bath at 150–160 °C. The other outlet of the flask was connected to a condenser head, condenser, and a dry ice cooled receiver. As much of the round-bottomed flask as possible was immersed in the oil bath to decrease the amount of holdup. About 2 g (46%) of a hydrocarbon fraction and 0.3–0.4 ml of water were collected in the receiver. The hydrocarbon layer was separated from the lower water layer with a medicine dropper and dried over a small amount of anhydrous potassium carbonate. The vapor-phase chromatogram of this crude fraction is shown in Fig. 5. The two largest peaks, the lower-retention product about 43% of the total trienes and the higher 30%, were separated in gram quantities using the preparative column described previously (sample size 0.1–0.15 ml, helium flow 200 ml/min, column temperature 125 °C, retention times as shown in Fig. 5).

Low-Retention Product, 2-Methyl-1,4,6-heptatriene (X)

n_D^{25} = 1.4645, showing an ultraviolet maximum in cyclohexane at 226.5 mμ, ϵ_{max} 27 200, in reasonable agreement for a monosubstituted diene. Peaks were found in the n.m.r. spectrum at 8.45 τ, $-CH_3$; 7.35 and 7.45 τ, $-CH_2-$ split by a single proton; and a complex series of peaks 3.5–5.5 τ, $=CH_2$ and $=C\begin{smallmatrix}H\\ \diagup\\ \diagdown\end{smallmatrix}$. The relative areas were 3.1:2.0:7.2; theory 3:2:7.

Anal. Calcd. for C_8H_{12}: C, 88.82; H, 11.18. Found: C, 88.60; H, 11.13.

High-Retention Product, trans-trans-2-Methyl-1,3,5-heptatriene (IX)

n_D^{25} = 1.5232. Peaks were found in the n.m.r. spectrum at 8.33 τ, $-CH_3$ split by a proton and 8.24 τ, the second peak of this split CH_3 and an unsplit CH_3; 5.17 τ, $=CH_2$; and a complex series of peaks 3.6–4.7 τ. $=C\begin{smallmatrix}H\\ \diagup\\ \diagdown\end{smallmatrix}$. The relative areas were 6.1:2.1:4; theory 6:2:4.

Anal. Calcd. for C_8H_{12}: C, 88.82; H, 11.18. Found: C, 88.58; H, 11.54.

SELF-CONDENSATION OF *p*-CHLOROPHENACYL CHLORIDE IN THE PRESENCE OF GRIGNARD REAGENT

MARSHALL KULKA
Research Laboratories, Dominion Rubber Co. Ltd., Guelph, Ontario
Received May 12, 1964

ABSTRACT

A crystalline by-product, formed in the reaction of *p*-chlorophenacyl chloride (I) with ethylmagnesium chloride, has been identified as 1,3-dichloro-2,4-bis(*p*-chlorophenyl)-2,4-hexanediol (IV). Its formation has been attributed to aldolization of I followed by reaction with Grignard reagent at the carbonyl function. The dehydrochlorination of IV yielded one of two possible compounds to which the diepoxide structure VI was assigned on the basis of n.m.r. spectra. The dehydrochlorinated product (VI) was synthesized from 1-chloro-2,3-epoxy-2,4-bis(*p*-chlorophenyl)-4-butanone (VIII) by treatment with ethylmagnesium chloride followed by reaction of the resulting epoxy alcohol IX with alcoholic alkali. It is suggested that the epoxy alcohol IX did not dehydrochlorinate directly to the 3,4-epoxytetrahydrofuran derivative V but instead rearranged first by epoxide alcohol transposition to X and then dehydrochlorinated to 1,2,3,4-diepoxy-2,4-bis(*p*-chlorophenyl)hexane (VI).

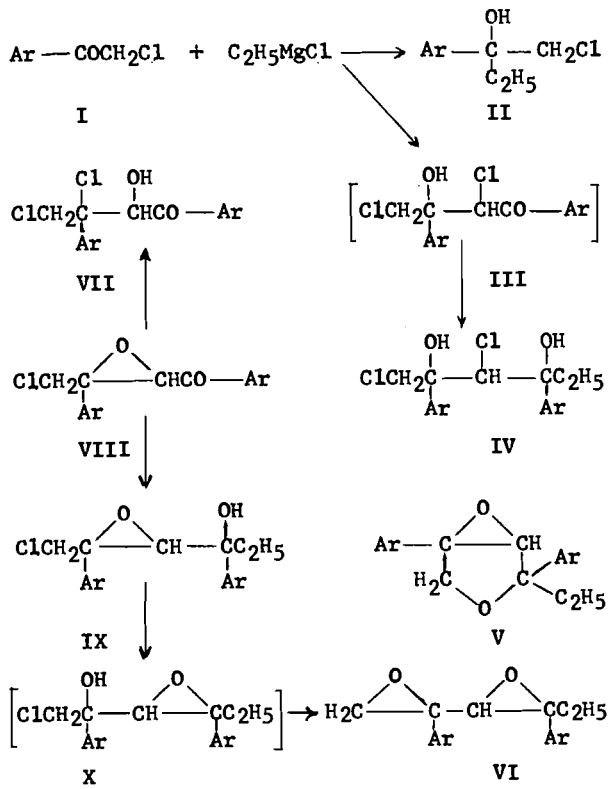
The condensation of *p*-chlorophenacyl chloride (I) with ethylmagnesium chloride produced the normal compound, 1-chloro-2-*p*-chlorophenyl-2-butanol (II) (1) as well as a crystalline by-product. The latter was formed in higher yield when the order of addition was reversed and the Grignard reagent was added to I. This investigation describes the properties and identification of this crystalline by-product and provides evidence for the mechanism of its formation.

The infrared spectrum of this compound showed the presence of hydroxyl groups and the absence of carbonyl groups. The OH band appeared at 3.0 μ (3 333 cm^{-1}), a shift from the normal which indicated hydrogen bonding. The reluctance of the compound to react with phenyl isocyanate or with acetic anhydride suggested the presence of tertiary hydroxyl groups. Of the possible modes of formation of the hydroxyl group from the carbonyl group, aldolization appeared to be the most likely. Analysis of the unknown compound provided the formula $(C_9H_9Cl_2O)_n$ with half the chlorine not removable and the other half easily removable by dehydrochlorination with cold methanolic or ethanolic potassium hydroxide. The dehydrochlorination was accompanied by loss of the hydroxyl groups, as evidenced by infrared spectra, and this indicated epoxide formation from a chlorohydrin.

The molecular weight of the unknown compound could not be determined by the Rast method because it liberated hydrogen chloride on heating. The dehydrochlorinated compound, on the other hand, though sensitive to acids and bases, was more stable to heat and could be distilled *in vacuo*. Analysis and molecular weight determinations of the dehydrochlorinated compound gave the empirical formula $(C_9H_8ClO)_2$ from which the formula $(C_9H_9Cl_2O)_2$ could be deduced for the chlorohydrin. On the basis of the above evidence the structure IV was assigned to the by-product of the Grignard reaction and the structure V or VI to the dehydrochlorinated product. Degradation studies showed that IV could be cleaved by phosphorus pentoxide in boiling benzene to *p*-chlorophenacyl chloride (I) in 80% yield. This cleavage was attributed to retrograde aldolization.

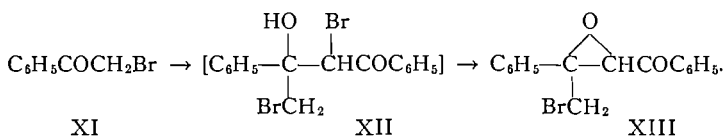
The formation of 1,3-dichloro-2,4-bis(*p*-chlorophenyl)-2,4-hexanediol (IV) in the Grignard reaction can be explained by aldolization of two molecules of *p*-chlorophenacyl chloride (I) followed by attack of the intermediate hydroxyketone III by ethylmagnesium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



Ar = p-chlorophenyl

chloride at the carbonyl function. A similar aldolization occurs in the Darzens reaction but the intermediate halohydrin cannot survive the strong alkaline conditions and is converted into an epoxide by intramolecular displacement. The Darzens reaction (2, 3, 4) is illustrated by the self-condensation of phenacyl bromide (XI), catalyzed by alcoholic sodium alkoxides, to form the two geometrical isomers of 4-bromo-1,3-diphenyl-2,3-epoxy-1-butanone (XIII) (5–8).



The intermediate bromohydrin XII has never been isolated. However there is one report (3) of the isolation of a fluorohydrin. In this investigation the isolation of the chlorohydrin IV was made possible through the stabilization of the aldolization product III by reaction with ethylmagnesium chloride.

The structure of 1,3-dichloro-2,4-bis(*p*-chlorophenyl)-2,4-hexanediol (IV) was confirmed by synthesis of its dehydrochlorination product. The starting material was 4-chloro-2,3-epoxy-1,3-bis(*p*-chlorophenyl)-1-butanone (VIII) which was obtained from *p*-chlorophenacyl chloride (I) by the Darzens method using sodium ethylate as catalyst. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

recent confirmation (5, 6) of the structure of the epoxyketone XIII obtained from phenacyl bromide under similar conditions validates the structure VIII. The first approach to IV failed because in the presence of hydrogen chloride the oxirane ring of VIII opened in the undesired direction to form 3,4-dichloro-2-hydroxy-1,3-bis(*p*-chlorophenyl)-1-butanone (VII) and not the required isomer III. That epoxyketone VIII yielded the secondary alcohol VII was established by infrared spectra and by the analogous behavior of 2,3-epoxy-1,3-diphenyl-1-butanone which yielded 3-chloro-2-hydroxy-1,3-diphenyl-1-butanone under similar conditions (9).

The second approach to IV consisted of the reaction of 4-chloro-2,3-epoxy-1,3-bis(*p*-chlorophenyl)-1-butanone (VIII) with ethylmagnesium bromide. In previously studied reactions of α,β-epoxyketones with Grignard reagents it had been observed that epoxyalcoholates are formed which undergo cleavage easily unless stabilized by very low temperatures or by introduction of an alpha substituent (10, 11). When the epoxyketone VIII was treated with ethylmagnesium bromide at $-10°$ followed by decomposition with dilute acid, the epoxyalcohol IX was formed. Since epoxyalcohols are labile compounds (12) no attempt to purify IX was made. Instead, the crude IX was treated with methanolic potassium hydroxide to form a crystalline compound which proved to be identical in all respects with the dehydrochlorinated product V or VI obtained from the unknown compound IV by a similar treatment.

The structure of the compound IV was thus established as 1,3-dichloro-2,4-bis(*p*-chlorophenyl-2,4-hexanediol by the deductive reasoning based on the fact that IV dehydrochlorinated to V or VI, the compound which also resulted from the reaction sequence VIII → IX → V or VI. There remained the task of assigning a structure to the product of dehydrochlorination, V or VI. A casual examination of the reaction sequence VIII → IX → V or VI would favor the assignment of the structure V. Such a structure would not be unreasonable because the 3,4-epoxytetrahydrofuran system is not very strained and has been prepared in the unsubstituted form (14, 15) as well as in the sugar series (16, 17). However, it is necessary to consider the remarkable ease of rearrangement of α,β-epoxyalcohols analogous to IX by transposition of hydroxyl and epoxide (β-oxanol rearrangement) (13). Thus 2,3-epoxy-1-chloro-2,4-bis(*p*-chlorophenyl)-4-hexanol (IX) on treatment with alcoholic alkali could first rearrange by alcohol epoxide transposition to 3,4-epoxy-1-chloro-2,4-bis(*p*-chlorophenyl)-2-hexanol (X) and then dehydrochlorinate to 1,2,3,4-diepoxy-2,4-bis(*p*-chlorophenyl)hexane (VI). Nuclear magnetic resonance (n.m.r.) spectra studies favor the assignment of structure VI to the dehydrochlorinated product of IV and this supports the suggestion that the rearrangement of IX to X does occur before the dehydrochlorination to VI.

The n.m.r. spectra of VI (or V) and of two model compounds are shown in Fig. 1. The peaks for the protons of epoxide methylenes in the spectra of VI (or V) and 2-*p*-chlorophenyl-2-ethyloxirane (XV) are upfield of where one would normally expect to find such resonances. This upfield shift is quite typical of strained three-membered systems which are pseudoaromatic because of some delocalization of electrons. The methylene proton peaks as shown in the spectra of the tetrahydrofuran model compound XIV (14, 15) are downfield and are more typical of protons on carbons directly bonded to oxygen. The geminal methylene protons of the epoxide VI (5.5 c.p.s.) as well as those of the model epoxide compound XV (5.5 c.p.s.) show small coupling constants as compared to those of the tetrahydrofuran model compound XIV (11 c.p.s.). On the basis of this evidence the diepoxide structure VI and not the epoxytetrahydrofuran structure (V) is assigned to the dehydrochlorinated product of IV.

EXPERIMENTAL

1,3-Dichloro-2,4-bis(p-chlorophenyl)-2,4-hexanediol (IV) and 1-Chloro-2-p-chlorophenyl-2-butanol (II)

A Grignard solution was prepared from magnesium turnings (30 g), dry ether (600 ml), and ethyl chloride (100 g) and decanted from the excess magnesium. Three quarters of this solution was added dropwise over 6 h to a cooled and stirred solution of *p*-chlorophenacyl chloride (I) (150 g) in dry benzene (850 ml). The temperature was kept at 10° by cooling on an ice bath. The reaction mixture was allowed to stand overnight and then treated at 10–15° with the other quarter of the Grignard solution. The resulting solution was decomposed with a cold solution of concentrated hydrochloric acid (120 ml) in water (200 ml) at 10–15°. The organic layer was separated, washed with water, concentrated *in vacuo* to about 200 ml, and allowed to cool. The white precipitate was removed by filtration, washed, and dried. The yield of IV from two crops was 46 g (28%), m.p. 180–182° with decomposition. Crystallization from benzene yielded white prisms melting at 185–186° with decomposition.

Anal. Calcd. for $C_{18}H_{18}Cl_4O_2$: C, 52.94; H, 4.41; Cl, 34.80. Found: C, 52.51, 52.82; H, 4.47, 4.63; Cl, 35.89.

The infrared spectrum of this compound showed the OH band at 3.0 μ (3 333 cm^{-1}). This is a shift from the free hydroxyl range and indicates hydrogen bonding.

The mother liquors from the above crystallizations were combined, taken to dryness *in vacuo*, and the residue distilled. The distillate of 1-chloro-2-*p*-chlorophenyl-2-butanol (II) (1) was a colorless liquid boiling at 92–95° (0.5 mm); n_D^{27} = 1.5465. The yield of II was 53 g or 30%.

Anal. Calcd. for $C_{10}H_{12}Cl_2O$: C, 54.80; H, 5.48. Found: C, 54.81, 55.00; H, 5.29, 5.40.

1,2,3,4-Diepoxy-2,4-bis(p-chlorophenyl)hexane (VI)

(a) From 1,3-Dichloro-2,4-bis(p-chlorophenyl)-2,4-hexanediol (IV)

To a solution of 1,3-dichloro-2,4-bis(*p*-chlorophenyl)-2,4-hexanediol (IV) (25 g) in methanol (500 ml) at 30° was added a solution of potassium hydroxide (10 g) in methanol (100 ml). Precipitation soon began.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

After allowing the reaction mixture to stand for 3 h the precipitate was removed by filtration, washed well with water to wash out the potassium chloride, and dried, yielding 15 g of white crystals. The methanol filtrate on concentration gave a second crop weighing 2.5 g. The total yield of VI was 17.5 g or 85%, melting at 132–134°. Crystallization from methanol yielded sparkling white prisms melting at 133–134°.

Anal. Calcd. for $C_{18}H_{16}Cl_2O_2$: C, 64.48; H, 4.77; Cl, 21.19. Found: C, 64.70, 65.04; H, 4.86, 4.83; Cl, 21.27, 21.75.

(b) From 1-Chloro-2,3-epoxy-2,4-bis(p-chlorophenyl)-4-hexanol (IX)

To a solution of 1-chloro-2,3-epoxy-2,4-bis(*p*-chlorophenyl)-4-hexanol (IX) (see below) (2 g) in methanol (25 ml) was added a solution of potassium hydroxide (0.5 g) in methanol (5 ml). The resulting solution was allowed to stand overnight. The white crystals (1.2 g or 75%) were removed by filtration, washed with water and with methanol, and dried, m.p. 132–134°. Crystallization from methanol yielded white prisms melting at 132–134° alone or in admixture with the compound obtained in (*a*). The infrared spectra of the compounds obtained in (*a*) and (*b*) were identical. This compound could be easily distilled at 0.5 mm pressure at a bath temperature of 180°.

Anal. Calcd. for $C_{18}H_{16}Cl_2O_2$: C, 64.48; H, 4.77. Found: C, 64.83, 65.03; H, 4.63, 4.67.

1-Chloro-2,3-epoxy-2,4-bis(p-chlorophenyl)-4-butanone (VIII)

To a stirred solution of *p*-chlorophenacyl chloride (I) (40 g) in methanol (1 400 ml) cooled at 5 to 10° was added dropwise a solution of sodium (3 g) in methanol (150 ml) over 0.5 h. The resulting yellow solution was stirred at 10° for 2 h and then allowed to stand overnight. It was concentrated *in vacuo* to 500 ml and then poured into water. The sticky solid was extracted with benzene, washed with water, and the solvent removed. The residue on crystallization from methanol yielded white prisms (15 g or 42%), melting at 134–136°.

Anal. Calcd. for $C_{16}H_{11}Cl_3O_2$: C, 56.22; H, 3.22. Found: C, 56.62, 56.57; H, 3.21, 3.49.

The infrared spectrum of this compound showed a strong carbonyl band at 5.9 μ.

1-Chloro-2,3-epoxy-2,4-bis(p-chlorophenyl)-4-hexanol (IX)

A Grignard solution prepared from magnesium turnings (2 g), dry ether (100 ml), and ethyl chloride (6 g) was added dropwise over 0.5 h to a cooled and stirred solution of 2,4-bis(*p*-chlorophenyl)-1-chloro-2,3-epoxy-4-butanone (VIII) (4 g) in dry ether (100 ml). The temperature was kept at −8 to −10° by cooling on an ice–salt bath. The reaction mixture was stirred at −10° for 0.5 h and then decomposed at −10° first with wet ether and then with 1 *N* hydrochloric acid. The ether layer was washed with water and then the solvent was removed, the last traces *in vacuo*. The residual viscous liquid (4 g or 93%) would not crystallize.

Anal. Calcd. for $C_{18}H_{17}Cl_3O_2$: C, 58.14; H, 4.58. Found: C, 58.39, 58.44; H, 4.97, 4.82.

The infrared spectrum of this compound showed a strong band at 2.8 μ.

1,2,3,4-Diepoxy-2,4-bis(p-chlorophenyl)pentane

This was prepared in 1% yield by the condensation of *p*-chlorophenacyl chloride (I) with methylmagnesium bromide followed by treatment of the crude oily product with methanolic potassium hydroxide, following the method used for the preparation of 1,2,3,4-diepoxy-2,4-bis(*p*-chlorophenyl)hexane (VI) above. The intermediate 1,3-dichloro-2,4-bis(*p*-chlorophenyl)-2,4-pentanediol could not be isolated in pure form. The crude 1,2,3,4-diepoxy-2,4-bis(*p*-chlorophenyl)pentane distilled at 160–200° (0.5 mm) and the distillate when crystallized from methanol–benzene yielded white prisms melting at 153–154°.

Anal. Calcd. for $C_{17}H_{14}Cl_2O_2$: C, 63.55; H, 4.36; Cl, 22.1. Found: C, 63.46; H, 4.07; Cl, 23.82.

Degradation of 1,3-Dichloro-2,4-bis(p-chlorophenyl)-2,4-hexanediol (IV) to p-Chlorophenacyl Chloride (I)

To a stirred solution of 1,3-dichloro-2,4-bis(*p*-chlorophenyl)2,4-hexanediol (IV) (10 g) in dry benzene (500 ml) was added phosphorus pentoxide (25 g) and the resulting mixture was stirred and heated under reflux for 2 h. The benzene solution was decanted from the dark residue, washed with cold water, and the solvent removed. The residual semisolid was crystallized from carbon tetrachloride – petroleum ether (30–60°), yielding white prisms (3.5 g or 80%) melting at 99–100° alone or in admixture with *p*-chlorophenacyl chloride.

1,2-Dichloro-2,4-bis(p-chlorophenyl)-3-hydroxy-4-butanone (VII)

Into a solution of 1-chloro-2,3-epoxy-2,4-bis(*p*-chlorophenyl)-4-butanone (VIII) (10 g) in glacial acetic acid (150 ml) at 30° was passed hydrogen chloride until saturated and the solution was allowed to stand overnight. The solvent was removed *in vacuo* below 40° and the residue was crystallized from benzene – petroleum ether (30–60°). The white prisms (6.0 g or 55%) melted at 133–134° with decomposition. One recrystallization from the same solvent raised the melting point to 136–137° with decomposition.

Anal. Calcd. for $C_{16}H_{12}Cl_4O_2$: C, 50.79; H, 3.17. Found: C, 50.96, 50.68; H, 3.46, 3.29.

The infrared spectrum of this compound showed the ketone band at 5.95 μ and the secondary hydroxyl bands at 7.85 and 9.1 μ. This compound when treated with phosphorus pentoxide in benzene did not yield *p*-chlorophenacyl chloride. Also it did not react with ethyl magnesium bromide at 5°; at room temperature it reacted to give an intractable product.

2-*p*-CHLOROPHENYLALKANOLS

MARSHALL KULKA
Research Laboratories, Dominion Rubber Co. Ltd., Guelph, Ontario
Received May 12, 1964

ABSTRACT

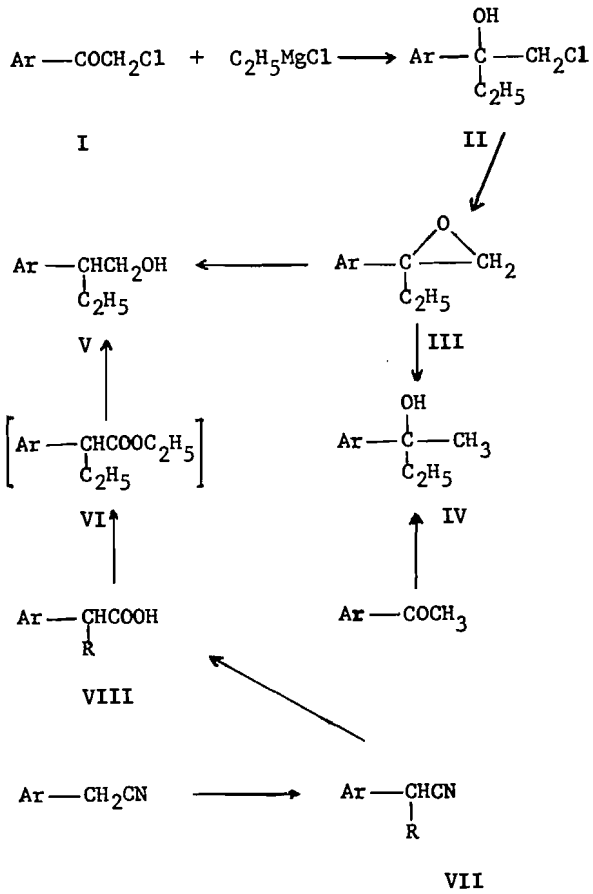
2-*p*-Chlorophenyl-1-butanol (V) has been synthesized by the condensation of *p*-chlorophenacyl chloride (I) with ethylmagnesium chloride and dehydrochlorination of the resulting 1-chloro-2-*p*-chlorophenyl-2-butanol (II) to 2-ethyl-2-*p*-chlorophenyloxirane (III), followed by reduction. It has been discovered that reduction of III with lithium aluminium hydride yielded the tertiary alcohol, 2-*p*-chlorophenyl-2-butanol (IV), while reduction of III with aluminium hydride yielded the primary alcohol V. The two alcohols IV and V were also prepared by unambiguous methods. Attempts to synthesize the higher homologues of the alcohol V were not very successful.

This paper describes the synthesis of some 2-*p*-chlorophenylalkanols which were required for evaluation as agricultural chemicals. The method devised for the synthesis of 2-*p*-chlorophenyl-1-butanol (V) comprised the condensation of *p*-chlorophenacyl chloride (I) with ethylmagnesium chloride, dehydrochlorination of the resulting 1-chloro-2-*p*-chlorophenyl-2-butanol (II) to 2-ethyl-2-*p*-chlorophenyl oxirane (III), and reduction of the oxirane (III) to V. In the condensation of ethylmagnesium chloride with I the order of addition was important. Best results were obtained when *p*-chlorophenacyl chloride (I) was added to the Grignard reagent. The reverse addition produced considerable amounts of a second component, a study of which is reported in another communication (1).

Theoretically the hydrogenation of the oxirane III could follow two reaction paths, one leading to the tertiary alcohol, 2-*p*-chlorophenyl-2-butanol (IV) and the other to the primary alcohol, 2-*p*-chlorophenyl-1-butanol (V). Actually it was found that catalytic hydrogenation of the oxirane III in the presence of Raney nickel catalyst gave a complex mixture from which the primary alcohol V was isolated in 30% yield. On the other hand, reduction with lithium aluminium hydride produced the tertiary alcohol IV in 80% yield. Finally reduction with a mixture of lithium aluminium hydride and aluminium chloride (3 to 1 ratio) which is in fact aluminium hydride gave the primary alcohol V in 80% yield. These results are in accord with those of Eliel and co-workers (2, 3) who have shown that reduction of 2,2,3-triphenyloxirane with lithium aluminium hydride alone led to diphenylbenzylcarbinol by attack at the least substituted carbon of the epoxide, whereas reduction with aluminium hydride produced phenylbenzhydrylcarbinol through ring opening and attack of hydride at the tertiary carbon atom.

The two reference compounds required in this investigation were synthesized by unambiguous methods. The tertiary alcohol IV was obtained through the condensation of *p*-chloroacetophenone with ethylmagnesium bromide. The primary alcohol, 2-*p*-chlorophenyl-1-butanol (V) was synthesized from *p*-chlorobenzyl cyanide by a number of steps which included ethylation with ethyl bromide in the presence of quaternary ammonium base, hydrolysis of the resulting 2-*p*-chlorophenylbutyronitrile (VII, R = ethyl) (4) to the acid VIII (R = ethyl), and reduction of the ester VI to V.

Attempts to prepare higher homologues of 2-*p*-chlorophenyl-1-butanol (V) by the Grignard method were not successful because alkylmagnesium halides higher than ethyl



Ar = p-chlorophenyl

reacted with I to form complex mixtures. The abnormal behavior of long- or branched-chain alkylmagnesium halides in reactions with ketones has been observed by other workers (5–7). The cyanide method also found limitation because long chain substituted *p*-chlorobenzyl cyanides (VII, R = *n*-dodecyl and hexadecyl) could not be hydrolyzed to the corresponding acids even on prolonged heating with aqueous–alcoholic alkali. However 2-*p*-chlorophenylhexanoic acid (VIII, R = *n*-butyl) was obtained from the cyanide VII, (R = *n*-butyl) by prolonged hydrolysis. The reduction of its ester yielded 2-*p*-chlorophenyl hexanol.

EXPERIMENTAL

1-Chloro-2-p-chlorophenyl-2-butanol (II)

To a Grignard solution prepared from magnesium (10 g), dry ether (250 ml), and ethyl chloride (30 g) was added dropwise with stirring a solution of *p*-chlorophenacyl chloride (I) (50 g) in dry benzene (300 ml) over about 0.5 h. The temperature was kept at 10–15° by cooling. The reaction mixture was stirred for 5 h and then decomposed with dilute hydrochloric acid. The organic layer was separated, washed with water, and the solvent removed. The residue distilled at 92–95° (0.5 mm); n_D^{23} = 1.5472. The yield was 50 g or 86%.

Anal. Calcd. for $C_{10}H_{12}Cl_2O$: C, 54.80; H, 5.48. Found: C, 54.81, 55.00; H, 5.29, 5.40.

In another experiment when the Grignard reagent was added to the *p*-chlorophenacyl chloride the yield of II dropped and 1,3-dichloro-2,4-bis(*p*-chlorophenyl)-2,4-hexanediol formed (1).

For personal use only.

1-Chloro-2-p-chlorophenyl-2-propanol

This was prepared in 30% yield as above from *p*-chlorophenacyl chloride (I) and methylmagnesium bromide. It boiled at 92–95° (1 mm); $n_D^{22} = 1.5576$.

Anal. Calcd. for $C_9H_{10}Cl_2O$: C, 52.68; H, 4.88; Cl, 34.61. Found: C, 52.85, 52.96; H, 4.82, 4.87; Cl, 34.35, 34.64.

2-Ethyl-2-p-chlorophenyloxirane (III)

To a stirred solution of 1-chloro-2-*p*-chlorophenyl-2-butanol (II) (62 g) in methanol (300 ml) was added dropwise at 15° a solution of potassium hydroxide (21 g) in methanol (150 ml). The reaction mixture was stirred 1 h at 15° and 1 h at room temperature. The solution was decanted from the precipitated potassium chloride, the solvent was removed, and the residue combined with the potassium chloride was treated with water. The precipitated oil was extracted with benzene, the extract washed with water, and the solvent removed. The residue distilled at 110–112° (11 mm) yielding 44 g or 88% of a colorless liquid; $n_D^{20} = 1.5315$.

Anal. Calcd. for $C_{10}H_{11}ClO$: C, 65.74; H, 6.03. Found: C, 65.94, 66.10; H, 5.93, 6.11.

2-Methyl-2-p-chlorophenyloxirane

This was prepared in 85% yield by the dehydrochlorination of 1-chloro-2-*p*-chlorophenyl-2-propanol as above, b.p. (11 mm) 106–108°; $n_D^{22} = 1.5390$.

Anal. Calcd. for C_9H_9ClO: C, 64.09; H, 5.34; Cl, 21.04. Found: C, 63.72, 64.06; H, 5.37, 5.47; Cl, 21.04, 21.18.

2-p-Chlorophenyl-1-butanol (V)

(a) By Catalytic Reduction of 2-p-Chlorophenyl-2-ethyloxirane

A mixture of 2-*p*-chlorophenyl-2-ethyloxirane (III) (30 g), methanol (100 ml), anhydrous sodium carbonate (0.5 g), and Raney nickel catalyst (ca. 0.5 g) was shaken under 50 lb of hydrogen pressure until there was a drop in pressure of 12 lb (ca. 5 h). The catalyst was filtered off and the filtrate distilled. The fraction distilling at 134–137° (11 mm) weighed 10 g (30%); $n_D^{21} = 1.5372$. This was identical with 2-*p*-chlorophenyl-1-butanol (V) obtained by an unambiguous method (see (*c*)).

Anal. Calcd. for $C_{10}H_{13}ClO$: C, 65.04; H, 7.05. Found: C, 64.87, 64.80; H, 7.02, 7.12.

(b) By reduction of 2-p-Chlorophenyl-2-ethyloxirane (III) with Aluminium Hydride

To a stirred suspension of pulverized lithium aluminium hydride (5 g) in dry ether (100 ml) was added, with cooling, aluminium chloride (7 g). This reaction mixture was stirred for about 15 min and then a solution of 2-*p*-chlorophenyl-2-ethyloxirane (III) (15 g) in dry ether (50 ml) was added dropwise with cooling on a water bath. After heating under reflux for 0.5 h the reaction mixture was cooled, and decomposed first with wet ether and then with dilute acid. The ether layer was washed, the solvent removed, and the residue distilled. The main fraction boiled at 140–142° (13 mm) yielding a colorless liquid (12 g or 80%): $n_D^{25} = 1.5350$, which gave an infrared spectrum identical with that given by the product of catalytic hydrogenation (*a*).

(c) By Reduction of Ethyl 2-p-Chlorophenylbutyrate (VI) with Lithium Aluminium Hydride

To a stirred suspension of pulverized lithium aluminium hydride (3 g) in dry ether (100 ml) was added dropwise a solution of ethyl 2-*p*-chlorophenylbutyrate (VI) (prepared from the nitrile VII (R = ethyl) by alkaline hydrolysis followed by esterification (4)) (12 g) in dry ether over about 15 min. The reaction mixture was heated under reflux for 30 min, cooled, and decomposed by addition of wet ether followed by dilute hydrochloric acid. The ether solution was washed with water, the solvent removed, and the residue distilled, b.p. 140–141° (13 mm); $n_D^{23} = 1.5342$. The yield of colorless liquid was 9.5 g or 85%. The infrared spectrum of this alcohol was identical with that of the alcohol obtained in (*a*).

2-p-Chlorophenyl-2-butanol (IV)

(a) By reduction of 2-p-Chlorophenyl-2-ethyloxirane (III)

To a suspension of powdered lithium aluminium hydride (6 g) in dry ether (150 ml) was added dropwise with stirring a solution of 2-*p*-chlorophenyl-2-ethyloxirane (III) (15 g) in dry ether (50 ml). After heating under reflux for 1 h the reaction mixture was decomposed in the usual manner and the product distilled. It boiled at 120–121° (10 mm) and weighed 12 g (80%); $n_D^{25} = 1.5330$. That this was the tertiary alcohol IV and not the primary alcohol V was shown by comparison of its properties and infrared spectra with those of IV prepared unambiguously (see (*b*) below).

(b) By the Reaction of Ethylmagnesium Bromide with p-Chloroacetophenone

To a Grignard solution prepared from magnesium (16 g), ethyl bromide (25 g), and dry ether (200 ml) was added dropwise with stirring and cooling a solution of *p*-chloroacetophenone (30 g) in dry ether (50 ml). The reaction mixture was decomposed with dilute sulfuric acid, the ether layer washed with water, and the solvent removed. The residue distilled at 120–121° (10 mm); $n_D^{25} = 1.5318$. The yield was 31 g or 80%.

Anal. Calcd. for $C_{10}H_{13}ClO$: C, 65.04; H, 7.05. Found: C, 64.90, 65.08; H, 7.30, 7.08.

2-p-Chlorophenylcapronitrile (VII, R = n-Butyl)

To a stirred solution of potassium hydroxide (100 g) in water (60 ml) was added benzyl triethylammonium chloride (5 g) followed by *p*-chlorobenzyl cyanide (100 g). This was cooled to 10° and *n*-butyl chloride (90 g) was added. The resulting reaction mixture was stirred at 12 to 15° for 24 h, diluted with water, and extracted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with benzene. The benzene extract was washed with water, the solvent removed, and the residue distilled. The distillate which boiled at 142–170° (11 mm) was dissolved in a solution of sodium (7 g) in methanol (200 ml) and treated with benzaldehyde (40 ml). After standing overnight the reaction mixture was filtered to separate the precipitated α-*p*-chlorophenyl-β-phenylacrylonitrile. The filtrate was diluted with water and extracted with benzene; the benzene solution was washed with water, with aqueous sodium bisulfite, and with water. The solvent was removed and the residue distilled yielding 42 g (32%) of nitrile boiling at 158–164° (12 mm); $n_D^{22} = 1.5192$.

Anal. Calcd. for $C_{12}H_{14}NCl$: C, 69.40; H, 6.75. Found: C, 69.03, 69.32; H, 6.92, 6.78.

The known compounds 2-phenylbutyronitrile (8, 9) (54%), 2-*p*-chlorophenylbutyronitrile (4) (60%), and 2-phenylcapronitrile (10) (41%) were prepared in the same manner as was VII (R = *n*-butyl).

α-n-Dodecyl-p-chlorobenzyl Cyanide (VII, R = n-Dodecyl)

This was prepared in 56% yield by the alkylation of *p*-chlorobenzyl cyanide with *n*-dodecyl bromid as above. The crude product distilled at 180–185° (0.5 mm); $n_D^{27} = 1.4959$.

Anal. Calcd. for $C_{20}H_{30}ClN$: C, 75.12; H, 9.39. Found: C, 75.30, 74.94; H, 9.09, 9.17.

The residue from the distillation of the above product was crystallized from benzene–methanol to yield (15%) white prisms of α,α-di-*n*-dodecyl-*p*-chlorobenzyl cyanide melting at 56–58°.

Anal. Calcd. for $C_{32}H_{54}ClN$: C, 78.77; H, 11.08. Found: C, 78.20, 78.79; H, 10.79, 10.99.

α-n-Hexadecyl-p-chlorobenzyl Cyanide (VII, R = n-Hexadecyl)

This was prepared in 49% yield by the alkylation of *p*-chlorobenzyl cyanide with *n*-hexadecyl bromide as above. It distilled at 211–215° (0.5 mm) and the distillate on crystallization from petroleum ether (30–60°) melted at 38–40°.

Anal. Calcd. for $C_{24}H_{38}ClN$: C, 76.70; H, 10.12. Found: C, 76.53, 76.45; H, 9.91, 9.90.

The residue from the above distillation on crystallization from methanol–benzene yielded (12%) almost white prisms of α,α-di-*n*-hexadecyl-*p*-chlorobenzyl cyanide melting at 56–58°.

Anal. Calcd. for $C_{40}H_{70}ClN$: C, 80.07; H, 11.68. Found: C, 79.63, 80.19; H, 11.54, 11.42.

2-p-Chlorophenylcaproic Acid (VIII, R = n-Butyl)

To a solution of sodium hydroxide (20 g) in water (200 ml) and ethanol (15 ml) was added 2-*p*-chlorophenylcapronitrile (VII, R = *n*-butyl) (30 g), and the reaction mixture was heated under reflux for 5 days. The resulting solution was acidified and extracted with benzene; the benzene solution was washed with water and the solvent removed. The residue distilled at 135–137° (0.5 mm) as a colorless liquid (29 g or 90%) which soon solidified; $n_D^{25} = 1.5215$. A small portion when crystallized from petroleum ether (30–60°) yielded white prisms which melted at 63–65°.

Anal. Calcd. for $C_{12}H_{15}ClO_2$: C, 63.72; H, 6.64. Found: C, 63.80, 63.95; H, 6.94, 6.69.

2-p-Chlorophenylmyristic Acid Amide

When α-*n*-dodecyl-*p*-chlorobenzyl cyanide (VII, R = *n*-dodecyl) was subjected to alkaline hydrolysis as above, no acid was obtained. Instead the amide was formed. It crystallized from methanol as white prisms melting at 90–92°.

Anal. Calcd. for $C_{20}H_{32}NClO$: C, 71.11; H, 9.48. Found: C, 71.31, 71.37; H, 9.31, 9.25.

2-Phenyl-1-hexanol

The ethyl ester of 2-phenylcaproic acid (prepared from 2-phenylcapronitrile, but not purified) (10, 11) was reduced with lithium aluminium hydride to form a colorless liquid boiling at 134–135° (11 mm); $n_D^{26} = 1.5085$. The yield was 90%.

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.90; H, 10.11. Found: C, 80.23, 80.36; H, 9.68, 9.67.

2-p-Chlorophenyl-1-hexanol

This was prepared in 80% yield by the reduction of ethyl 2-*p*-chlorophenylcaproate with lithium aluminium hydride. It boiled at 158–160° (11 mm); $n_D^{22} = 1.5235$.

Anal. Calcd. for $C_{12}H_{17}ClO$: C, 67.76; H, 8.00. Found: C, 68.01, 68.13; H, 7.98, 8.00.

PHOTOCHEMICAL TRANSFORMATIONS OF DIENES

IV. THE STEREOCHEMISTRY OF THE PHOTO-INDUCED ETHANOL ADDITION TO 3-METHOXYCHOLESTA-3,5-DIENE

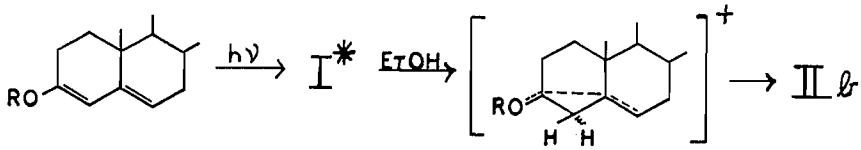
CLIFFORD C. LEZNOFF[1,2] AND GEORGE JUST
Department of Chemistry, McGill University, Montreal, Quebec

Received May 15, 1964

ABSTRACT

The photolysis of 3-methoxycholesta-3,5-diene in ethanol-*d* resulted in a 1:1 mixture of 4α- and 4β-deuterio-3β-ethoxy-3α-methoxycholest-5-ene (II, II*a*). A stereospecific synthesis of 4β-deuterio-3α,5-cyclo-5α-cholestan-6β-ol is described.

Recently we have shown that the photo-induced addition of alcohols to 3-alkoxycholesta-3,5-dienes gave in reasonably good yield 3,3-dialkoxycholest-5-enes (1) (e.g. I $\rightarrow$ II). The addition of the alkoxy moiety seemed to be quite stereospecific (3β) (1). In this paper we wish to report on the stereochemistry of protonation of the diene system, and to propose a reaction scheme accounting for the products of these and related reactions (2, 3).



I A

The geminal protons at C-4 are clearly shifted away from most signals in the nuclear magnetic resonance (n.m.r.) spectrum of 3,3-dialkoxycholest-5-enes (1), but seem to be equivalent and hence give rise to a single two-proton peak. In order to determine the stereochemistry of the proton addition at C-4, it was necessary to devise a means of making the two protons at C-4 non-equivalent. In principle, this could be achieved by incorporating them into a cyclopropane ring. The C-4 deuterated product could then be compared by n.m.r. to 4β-deuterio-3α,5-cyclocholestan-6β-ol (VIII), stereospecifically synthesized by an independent route.

Cholest-4-en-3β-yl acetate (4) was treated with monoperphthalic acid (5) in ether and the resulting 4α,5α-epoxycholestan-3β-yl acetate (V) (6) reduced with lithium aluminium deuteride to give 4β-deuteriocholestan-3β,5α-diol (VI). These reductions are known to result in a *trans* diaxial opening of oxide rings (6, 7, 8). Monoacetylation and dehydration with thionyl chloride gave 4β-deuteriocholesteryl acetate (VII*a*), which, after hydrolysis, was transformed into 4β-deuteriocholesteryl tosylate (VII*b*). The n.m.r. spectrum of VII*b* in benzene showed a one-proton signal at 2.45 p.p.m. (doublet, J = 4.5 c.p.s.) corresponding to the C-4 α proton. Pure cholesterol tosylate shows a two-proton signal at

[1]*From a thesis to be presented to the Graduate Faculty, McGill University in partial fulfillment of the requirements for the Ph.D. degree.*

2.45 p.p.m. (doublet, J = 8.8 c.p.s.) due to the C-4 protons. Solvolysis of VII*b* yielded 4β-deuterio-3α,5-cyclocholestan-6β-ol (VIII) (9). Whereas 3α,5-cyclocholestan-6β-ol shows complex signals between 0.2 and 0.7 p.p.m. due to the cyclopropane protons, its 4β-deutero analogue showed in the high field region a one-proton doublet at 0.23 p.p.m. (J = 8.5 c.p.s.) only. The 4α-hydrogen is coupled with the hydrogen at C-3 and the coupling constant is that expected for *cis*-hydrogens on a cyclopropane ring (10, 11).

Whereas the photolysis of 3-alkoxycholesta-3,5-dienes in methanol or ethanol proceeded without any difficulty, this was not the case for the corresponding reaction in deuterioethanol, prepared by decomposition of diethyl sulfite in heavy water (12). It seemed that in spite of all precautions taken in its preparation, a small amount of acidic material was present in the deuterated solvent. The reaction was hence carried out in deuterioethanol containing a small amount of pyridine. Mono-4-deuterio-3β-ethoxy-3α-methoxycholest-5-ene (II, II*a*) (1) was isolated in approximately 50% yield by chromatography. Its n.m.r. spectrum showed a one-proton peak at 2.56 p.p.m. (benzene), indicating that one deuterium atom had been taken up per molecule of diene. The ketal was hydrolyzed with malonic acid in acetone to 4-deuteriocholest-5-en-3-one (III, III*a*), which showed a signal at 2.80 p.p.m. (benzene) due to one proton at C-4. No exchange with solvent could have taken place to any large extent at this stage, since any resulting non-deuterated cholest-5-en-3-one would have given (*vide infra*) non-deuterated 3α,5-cyclocholestan-6β-ol (9), which has a very characteristic n.m.r. spectrum in the 0.2–0.7 p.p.m. region. Lithium aluminium hydride reduction of III and treatment of the resulting alcohol with *p*-toluenesulfonyl chloride in pyridine overnight yielded 4-deuteriocholesteryl tosylate (IV*b*, IV*c*).

Solvolysis of (IV*b*, IV*c*) in buffered aqueous acetone gave 4-deuterio-3α,5-cyclocholestan-6β-ol (VIII, VIII*a*). Its n.m.r. spectrum showed two signals (approximately 0.5 protons each) in the region characteristic of cyclopropane protons. The signal at 0.23 p.p.m. (doublet, J = 8.5 c.p.s.) was identical to that of 4β-deuterio-3α,5-cyclocholestan-6β-ol. The low-field signal, centered at 0.48 p.p.m., showed up as a triplet. There is little doubt that this signal can be assigned to the 4β-hydrogen, and that this proton is spin–spin coupled with the hydrogen at C_3. In addition, some long range coupling similar to that observed in 3α-methyl-3β,5-cyclocholestane (2) must also be present. The results can only be interpreted by assuming that the deuteration at C-4 was non-specific and that an approximately 1:1 mixture of 4α- and 4β-deuterio-3β-ethoxy-3α-methoxycholest-5-ene (II, II*a*) was obtained in the photo-induced reactions. This is in contrast with the stereochemistry of protonation of the 3β,5-cyclosteroids obtained in the photolysis of cholestadiene and its 3-methyl homologue, in which one deuterium atom was introduced stereospecifically at C-4β (2, 3). It seems therefore quite likely that no bicyclobutane intermediate was formed as a primary photoproduct, since a 3-ethoxybicyclobutane intermediate should be protonated by ethanol as specifically as the analogous 3-methyl and 3-unsubstituted bicyclobutanes.

In order to gain further insight into the reaction, the photolysis of 3-ethoxycholesta-3,5-diene was carried out in the presence of oxygen, which is known to react as a rule rapidly with triplets (13, 14, 15), although exceptions are known (16). The yield of 3,3-diethoxycholest-5-ene was identical to that obtained in the absence of oxygen.

Since benzophenone is known to induce photoreactions to go through the triplet state (17, 18), 3-ethoxycholesta-3,5-diene was photolyzed in the presence of benzophenone, using a "pyrex" tube to filter out wavelengths below 330 mμ. This reaction led to a rapid disappearance of the chromophore. No ketal, however, was formed under these reaction conditions.[3]

The photolyses of cholesta-3,5-diene and 3-alkoxycholesta-3,5-dienes can be summarized as follows: the former is sensitive to oxygen (3), proceeds through a bicyclobutane which can be isolated (19), and the intermediate bicyclobutane is protonated stereospecifically by deuterioethanol (2, 3) to give 4β-deuterio-6β-ethoxy-3β,5-cyclo-5β-cholestane. The products of photolysis in ethanol are identical to those obtained when the photolysis is carried out in pentane, and the intermediate bicyclobutane (19) reacted with ethanol. In contrast, the photolysis of 3-alkoxycholestadienes is insensitive to oxygen. No intermediate bicyclobutane can be isolated, when the enol ether is photolyzed in pentane, and reaction of that photoproduct with ethanol does not give ketals (1). The protonation at C-4 is not stereospecific. Based on the evidence presented, it is not unreasonable to assume that these two reactions proceed through different pathways, in particular since the photolysis of 3-methylcholesta-3,5-diene cannot be explained in terms of only one reaction path (2).

Too little information is available at the present time to give a more detailed interpretation of reaction course of these photolyses.[4]

EXPERIMENTAL[5]

4β-Deuteriocholestan-3β,5α-diol-3β-acetate (VIa)

To 0.300 g of lithium aluminium deuteride in 20 ml of anhydrous ether was added 2.0 g of solid V (6). Anhydrous ether (20 ml) was then added and the mixture stirred for 2 h. After careful addition of water, the

[3]*The same reaction, in the absence of benzophenone, resulted in the recovery of most of the starting material.*
[4]*See, however, ref. 21.*
[5]*General procedures and instrumentation as in ref. 1.*

solution was washed neutral, dried over sodium sulfate, and evaporated to dryness to give 1.9 g of crystals, m.p. 198–218°. Recrystallization from ethyl acetate gave 1.2 g of 4β-deuteriocholestan-3β,5α-diol (VI), m.p. 221° (lit. m.p. 224.5–225.5° (22)).

About 1.2 g of VI in 40 ml pyridine and 15 ml of acetic anhydride were left standing overnight at room temperature. After the usual work-up, recrystallization from acetone–methanol gave 1.2 g of 4β-deuteriocholestan-3β,5α-diol-3β-acetate (VI*a*), m.p. 184–185° (lit. 184.6–185.6° (23)).

4β-Deuteriocholesteryl Acetate (VII)

To a solution of 1.15 g of VI*a* in 20 ml of pyridine at 0 °C, 3 ml of thionyl chloride was added and the solution stirred for 20 min. Ice water was added and after the usual work-up, the oily crystals were crystallized twice from acetone–methanol to give 500 mg of VII, m.p. 105–109°.

4β-Deuterio-3α,5-cyclocholestan-6β-ol (VIII) (9)

About 425 mg of VII was hydrolyzed (6) and 300 mg of 4β-deuteriocholesterol (VII*a*), m.p. 146–148°, was obtained after crystallization from acetone–methanol.

Tosylation of 260 mg of VII*a* gave 290 mg of 4β-deuteriocholesteryl tosylate (VII*b*), m.p. 131–132° (9).

A solution of VII*b* (238 mg) in 12 ml of acetone and 3 ml of water was refluxed with 200 mg of sodium acetate for 15 h. Ether extraction, and chromatography of the resulting oil on 4 g of alumina, gave 60 mg of crystals, eluted by hexane–benzene mixtures. Recrystallization from acetone afforded 50 mg of VIII, m.p. 61–63° (identified by melting point and mixed melting point with an authentic sample (9)).

Irradiation of 3-Methoxycholesta-3,5-diene (I) in Ethanol-d

A solution of 2.1 g of I in 475 ml of dry pentane, 55 ml of ethanol-*d* (C_2H_5OD), and 0.25 ml pyridine was irradiated (Hanovia lamp, 450 W) for 3.5 h until little absorption could be detected in the ultraviolet After evaporation, the crude photolysis product was chromatographed on alumina. Elution with hexane gave 1.1 g of oily 4-deuterio-3β-ethoxy-3α-methoxycholest-5-ene (II, II*a*). Crystallization from ethanol gave 500 mg of (II, II*a*), m.p. 92–93° (1).

4-Deuteriocholest-5-en-3-one (III, IIIa)

A solution of 500 mg of 4-deuterio-3β-ethoxy-3α-methoxycholest-5-ene (II, II*a*) in 30 ml acetone and 3 ml of water containing 100 mg malonic acid was allowed to evaporate slowly at room temperature. After 66 h, 350 mg of 4-deuteriocholest-5-en-3-one (III, III*a*), m.p. 127–128°, was obtained by filtration. Its m.p. was not depressed upon admixture of cholest-5-en-3-one (24*a*).

4-Deuterio-3α,5-cyclocholestan-6β-ol (VIII, VIIIa)

To 350 mg of lithium aluminium hydride in 25 ml ether was added 350 mg of the 3-ketone (III, III*a*) obtained above. After stirring for 2 h, the reaction mixture was worked up and 355 mg of crystals were obtained. Recrystallization from acetone–methanol gave 210 mg of 4-deuteriocholesterol (IV, IV*a*), m.p. 138–140°. Its m.p. was not depressed upon admixture of cholesterol.

Tosylation of 4β-deuteriocholesterol obtained above gave 230 mg of 4-deuteriocholesteryl tosylate (IV*b*, IV*c*). The n.m.r. spectra of compounds (IV, IV*a*) and (IV*b*, IV*c*) were consistent with the structures assigned.

Solvolysis of 230 mg (see above) (9) of the tosylate gave 130 mg of (VIII, VIII*a*). Crystallization from acetone yielded 38 mg of (VIII, VIII*a*), m.p. 64–66°. Its melting point was not depressed upon admixture of an authentic sample (lit. m.p. 63–65° (9)).

Irradiation of 3-Ethoxycholesta-3,5-diene (IX) in Ethanol Saturated with Oxygen

A solution of 0.8 g of IX in 565 ml ethanol, through which oxygen had been bubbling for 40 min, was irradiated until the absorption maximum of IX had decreased to 2% of its original intensity (1 h). Chromatography on alumina gave, in the hexane fractions, 525 mg of 3,3-diethoxycholest-5-ene, m.p. 48–49°. Its melting point and infrared spectrum were identical to those of an authentic sample (1). Elution with ether yielded 75 mg of cholest-4-en-3-on-6β-ol, m.p. 182–183°, identified by mixed melting point with an authentic sample (24*b*). Both products had been formed in similar yields when oxygen had been excluded from the photolysis reaction (1).

Irradiation of 3-Ethoxycholesta-3,5-diene (IX) in Ethanol Using Benzophenone as a Photosensitizer

Irradiation (utilizing a pyrex sleeve to eliminate radiation below 330 mμ) of 0.5 g of IX in ethanol (525 ml), containing 0.5 g of benzophenone, for 2.5 h resulted in a decrease of the absorption maximum to less than 20% of the original absorbance. Evaporation of the solvent gave 0.2 g of benzpinacol as crystals. The remaining oil (0.6 g) was chromatographed on alumina. Elution with hexane gave 90 mg of IX. Further elution with hexane–benzene mixtures gave fractions which seemed to contain benzophenone, benzpinacol, and cholest-4-en-3-one. Elution with ether gave 190 mg crude cholest-4-en-3-on-6β-ol (X), from which 60 mg of X, m.p. 186–187°, was obtained by crystallization from hexane.

LITHIUM CHLORIDE CATALYZED DECARBOXYLATION OF OXALACETIC ACID IN ETHANOL

G. W. Kosicki, S. N. Lipovac, and R. G. Annett
Department of Chemistry, University of Windsor, Windsor, Ontario
Received July 20, 1964

ABSTRACT

The monovalent metal salt lithium chloride promotes the decarboxylation of oxalacetic acid in ethanol. The absorption peak which appears at 230 mμ during the reaction is interpreted to be the enol form of pyruvic acid. Hydrogen chloride has a similar effect on the decarboxylation.

INTRODUCTION

Oxalacetic acid (OAA) decarboxylates spontaneously to pyruvic acid and CO_2 in water (1, 2, 3), and nonaqueous solvents (4). This reaction has been shown to be promoted by metal ions, but only by the di- and tri-valent metal salts (1, 5–10). The rates are dependent on the solvent, pH, and ionic strength (11, 12, 13). The addition of the di- and trivalent metal salts to ethanolic OAA solution causes a shift of the absorption maximum to higher wavelengths and an increase in the integral absorption, indicating formation of a chelate (14). The keto form of the acid has been shown to be the decarboxylating species (15) by using the α,α-dimethyl substituted oxalacetic acid, in which only the keto form can exist.

In this paper, using an ethanolic system, we present evidence for the decarboxylation of OAA promoted by the monovalent metal salt, lithium chloride. Ethanolic hydrogen chloride has a similar behavior on the promotion of decarboxylation. Addition of lithium chloride to ethanolic OAA does not show the characteristic absorption shift to higher wavelengths of the polyvalent metal salts.

EXPERIMENTAL

The following materials were commercial preparations: oxalacetic acid (Sigma Chemical Co.), lithium chloride (Fisher Reagent). Absolute ethanol was used as the solvent.

Absorption spectra were measured with a Bausch and Lomb Spectronic 505 Spectrophotometer. The rate of CO_2 production was followed with a Warburg Respirometer, using a modified flask enabling introduction of the solid acid into the CO_2 saturated ethanol system. Readings were taken at constant pressure, measuring increase of volume. The bath temperature was maintained at 25.0 ± 0.1 °C.

Kinetic experiments were performed spectrophotometrically using a Beckman monochromator and a Gilford Instrument Model 2000 Absorbance Recorder. One centimeter light path cuvettes of 3 ml volume were used. The temperature of the system was maintained at 25.0 ± 0.2 °C by means of a thermostated water circulation system. All solutions were prepared by quantitative volumetric dilution of a weighed OAA sample, followed by appropriate addition of a stock solution of ethanolic lithium chloride. The observed rate constants were calculated from the slopes of first-order rate plots.

RESULTS

(1) Spectral Changes

Oxalacetic acid in ethanol has a maximum of absorption at 260 mμ attributed to the enol form of the acid. Addition of LiCl to the ethanolic OAA increases the absorption in the region of 230 mμ as shown in Fig. 1. On the other hand, the addition of polyvalent cations increases the absorption with a shift of the maximum to 280–300 mμ, indicative of chelate formation (14). In ethanol freshly distilled pyruvic acid, probably all in the keto

form, has a negligible absorption (Fig. 1). Addition of LiCl and HCl to the pyruvic acid system increases the absorption in the region of 230–280 mμ.

(2) Rate of Reaction

The spectral pattern observed with LiCl and OAA in ethanol changes with time (Fig. 2). The absorption decreases at 260 mμ but at 230 mμ it initially increases then decreases, a behavior which is indicative of a consecutive reaction. Increasing the concentration of LiCl and consequently the LiCl/OAA ratio, increased the rate of absorption decrease when followed at 260 mμ, but a saturating ratio could only be approached (Fig. 3) because of the limited solubility of LiCl in ethanol. The rate constants used for the graph were calculated from the slopes of first-order plots of the absorption changes at 260 mμ. At the lower ratios of LiCl/OAA two phases appeared, where only the second phase of the

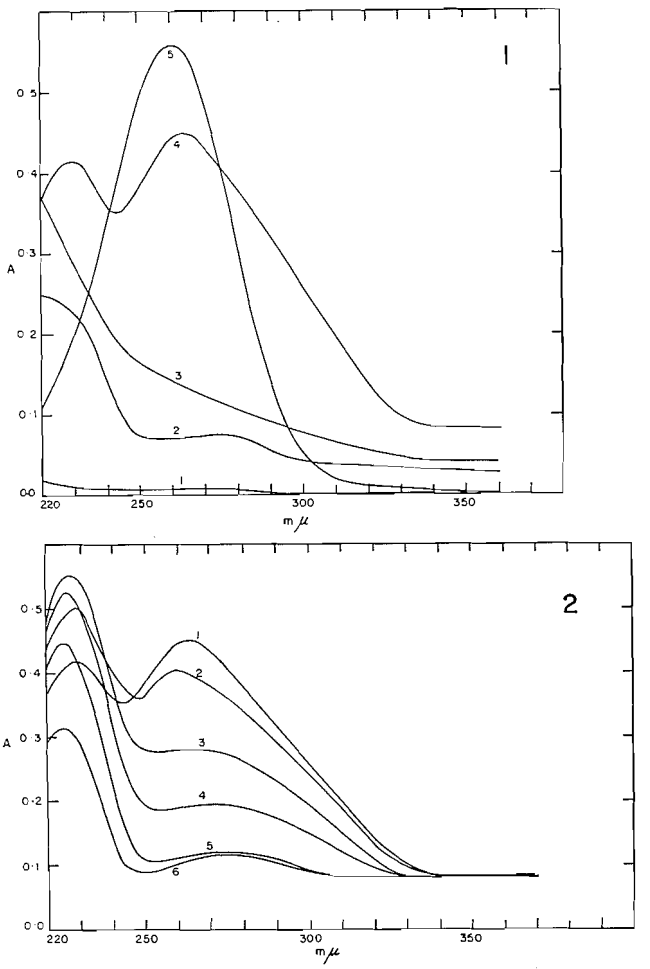

FIG. 1. The effect of LiCl on the spectra of OAA and pyruvic acid in ethanol. All samples were dissolved in absolute ethanol and measured in a 1 cm light path cell. The cuvettes contained (1) 1.0×10^{-4} *M* freshly distilled pyruvic acid, (2) 1.0×10^{-4} *M* pyruvic acid and 0.618 *M* LiCl, (3) 1.0×10^{-4} *M* pyruvic acid and 2.16 *M* HCl, (4) 1.0×10^{-4} *M* OAA and 0.618 *M* LiCl, and (5) 1.0×10^{-4} *M* OAA.

FIG. 2. Absorption spectra for OAA–LiCl–ethanol system as a function of time. The cuvette (1.0 cm light path) contained 1.0×10^{-4} *M* OAA and 0.618 *M* LiCl. The curves represent the change in the absorption of the acid at the following times after mixing; (1) 4 min, (2) 10 min, (3) 20 min, (4) 30 min, (5) 40 min, (6) 99 min, and (7) the same as curve six at 135 min.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

reaction was linear. At higher concentrations of LiCl, those approaching saturation, the linearity of the second phase of the curve increased to over 85% of the reaction.

In Fig. 4 the absorption changes as a function of time are compared at three wavelengths (230 mμ, 243 mμ, and 260 mμ) for the spontaneous reaction and for the LiCl and HCl promoted reactions. These wavelengths were chosen because the difference in their behavior indicated that different species were being followed. At 243 mμ in the spontaneous system an isosbestic point was approached where there was no change in absorption during the first phase of the reaction, since the decrease of the absorption of the reactant was cancelled by the increase of the absorption of the product.

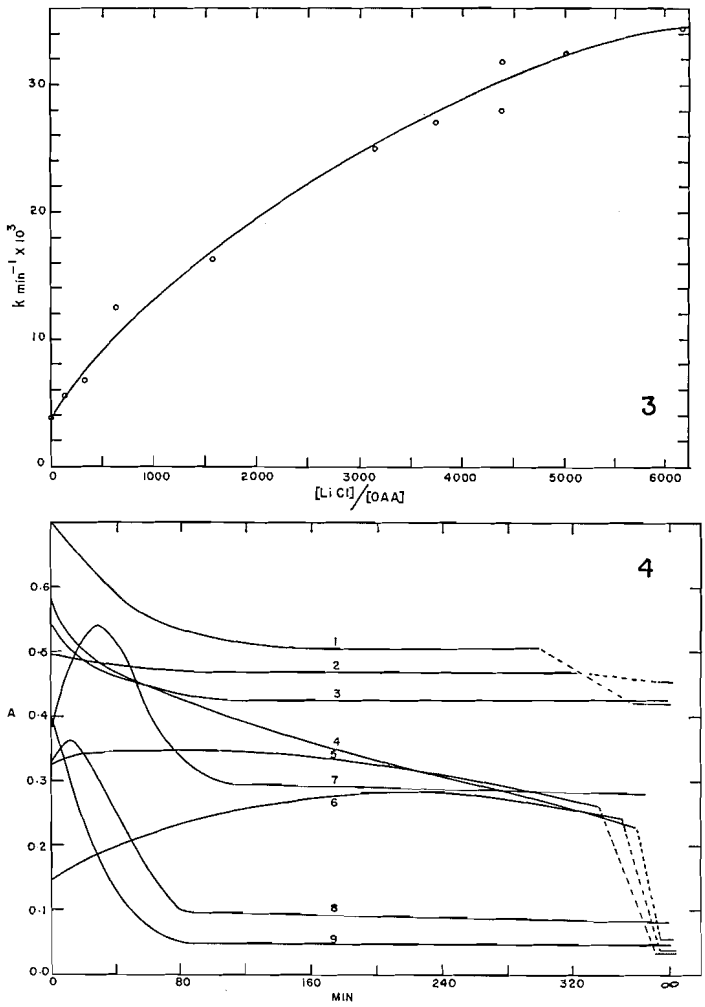

FIG. 3. Observed first-order rate constants as a function of the [LiCl]/[OAA] (260 mμ). Each cuvette contained 1.0×10^{-4} *M* OAA and LiCl of the appropriate concentration to give the indicated molar ratios.

FIG. 4. The rate of reaction for the catalyzed and the uncatalyzed decarboxylation of OAA in ethanol. The changes of absorption with time are shown for the uncatalyzed system, for the LiCl catalyzed system where the molar ratio of LiCl/OAA is 6 180, and for the HCl catalyzed system where the molar ratio is 21 600, at each of the wavelengths indicated. The OAA concentration is 1.0×10^{-4} *M*. The curves represent the system: (1) HCl catalyzed at 260 mμ, (2) HCl catalyzed at 230 mμ, (3) HCl catalyzed at 243 mμ, (4) uncatalyzed at 260 mμ, (5) uncatalyzed at 243 mμ, (6) uncatalyzed at 230 mμ, (7) LiCl catalyzed at 230 mμ, (8) LiCl catalyzed at 243 mμ, (9) LiCl catalyzed at 260 mμ.

TABLE I

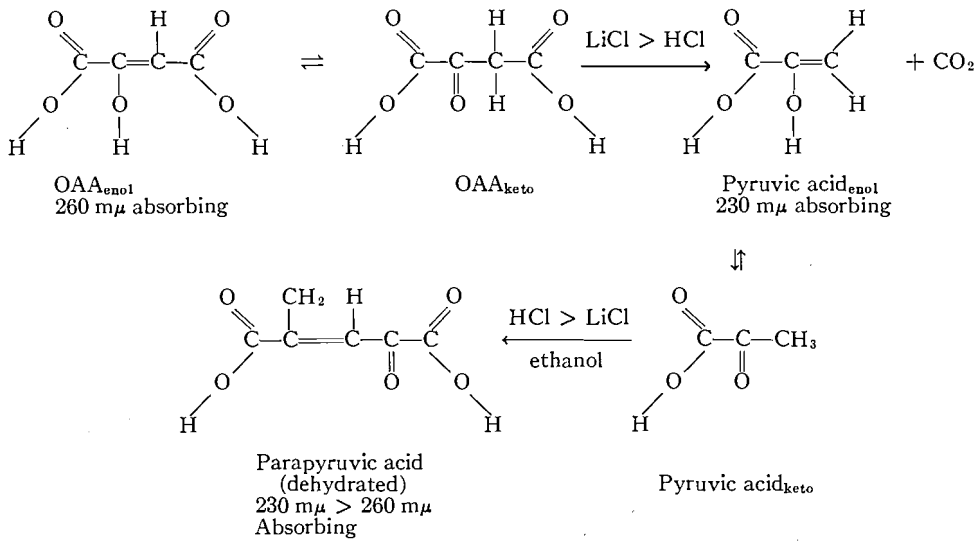
The observed first-order rate constants

	260 mμ absorption decrease (1.0×10^{-4} *M* OAA)	CO_2 production (3.0×10^{-2} *M* OAA)
	$10^3 \times k_{obs}$ (min^{-1})	$10^3 \times k_{obs}$ (min^{-1})
OAA in ethanol	3.80	0.42
OAA + 2.16 *M* HCl	9.44	
OAA + 0.618 *M* HCl	5.98	
OAA + 0.618 *M* LiCl	34.6	
OAA + 0.625 *M* HCl		0.97
OAA + 0.625 *M* LiCl		2.52

Evolution of gas was measured during the reaction of OAA in ethanol in the presence and absence of KOH to confirm that CO_2 was one of the expected products. The observed first-order rate constant in the case of the spontaneous system (Table I) is lower than that measured spectrophotometrically at 260 mμ, probably because of the lower degree of dissociation of OAA in the manometric system. This situation arises because a much higher concentration (300×) of OAA is needed to follow the reaction. Pyruvic acid was confirmed to be the other expected product by assay with lactic dehydrogenase and reduced nicotinamide-adenine dinucleotide (16). The additions of LiCl (and HCl) increased the spontaneous rate of decarboxylation (Table I), but the high ratios of LiCl/OAA needed for saturation of the rate could not be reached in the manometric system because of the higher concentrations of OAA needed to observe the decarboxylation.

DISCUSSION

Oxalacetic acid undergoes a decarboxylation in ethanol. The reaction is promoted by the presence of lithium chloride and HCl. From the nature of the absorption changes at 260 mμ and 230 mμ an equilibrium system can be used to describe the reaction where each of the steps are catalyzed by LiCl and HCl.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The active species that decarboxylates in ethanol is postulated to be the keto form of OAA, as in the aqueous system. The presence of LiCl (and HCl) which partially dissociated in ethanol to Li^+ would favor decarboxylation by coordination with the negative end of the polarized β-carbonyl group. The presence of LiCl and HCl would also catalyze the keto–enol tautomerization (17).

The successive appearance of the various species with their major contributions to the observed absorptions at the indicated wavelengths can account for the consecutive reactions observed in the uncatalyzed and LiCl catalyzed systems. The reaction begins with the rapid ketonization of OAA as the solid enol dissolves in ethanol, a rapid reaction too fast to measure at 25 °C in our system (4, 18, 19). As the keto form of OAA decarboxylates, the concentration of the intermediate enol of pyruvic acid increases as observed by the increase of absorption at 230 mμ. The principal assumption is that the enol form of pyruvic acid absorbs at 230 mμ in ethanol, an assumption that is supported by the approach to an isosbestic behavior at 243 mμ for the uncatalyzed system, at which wavelength the enol forms of OAA and pyruvic acid have approximately the same absorbancy index (cf. Fig. 4). The catalyzed formation of the dimer parapyruvic acid (20) causes a further increase in the absorption as shown in Fig. 1 so that the equilibrium absorption is greater than in the uncatalyzed reaction. The parapyruvic acid could dehydrate in the ethanolic system to form a conjugated acid with this greater absorption. The lack of an observed consecutive reaction at 230 mμ in the HCl–OAA system may be accounted for by the masking of the absorption with the fast formation of parapyruvic acid or its conjugated derivative.

The monovalent metal salt lithium chloride does promote decarboxylation of OAA in ethanol (Table I) but a high molar ratio of LiCl/OAA is required to reach a saturating rate effect. The effects of NaCl and KCl could not be compared in this system because of the insolubility of these salts in ethanol. Comparison of the effects in ethanol–water mixtures also presents difficulties arising from change in the degree of dissociation of both the OAA and the metal salts.

STRUCTURE OF MAGNESIUM ALUMINIOSILICATE LIQUIDS AT 1 700 °C[1]

E. F. RIEBLING

Research and Development Laboratory, Corning Glass Works, Corning, New York

Received August 6, 1964

ABSTRACT

An improved counterbalanced sphere viscometer–densitometer was used to obtain precise viscosity and density data for melts on (*a*) the silica·cordierite ($2MgO \cdot 2Al_2O_3 \cdot 5SiO_2$)·spinel ($MgO \cdot Al_2O_3$) join and (*b*) the 50 mole % SiO_2 line at temperatures between 1 500 and 1 720 °C. The viscosity, activation energy for viscous flow, and expansion data are indicative of a general tightening of melt flow parameters and structure as either the silica or the alumina content is increased.

The density-derived data have been interpreted in terms of a model that involves no significant change of the partial molar volume of SiO_2 (V_{SiO_2}). Crystalline coordination number information was used to develop a liquid molar volume model that agrees rather closely with the experimental information. This model involves AlO_4 tetrahedra as the major aluminium (III) species for all melts studied with Al_2O_3/MgO ratios equal to or less than unity. The gradual formation of MgO_6 octahedra from MgO_4 tetrahedra appears to accompany the substitution of MgO for Al_2O_3 in melts containing 50 mole % SiO_2.

It has been demonstrated that a reasonable correlation can exist between the coordination number of a given cation in the crystalline state and in high-temperature liquids of similar composition.

I. INTRODUCTION

The $MgO \cdot Al_2O_3 \cdot SiO_2$ ternary system is of current scientific and technological importance. Magnesium aluminiosilicate slags are encountered in steel manufacturing (1, 2, 3). Compounds such as forsterite ($2MgO \cdot SiO_2$), mullite ($3Al_2O_3 \cdot 2SiO_2$), periclase (MgO), spinel ($MgO \cdot Al_2O_3$), and corundum (Al_2O_3) make useful ceramic bodies. Corning Code 9606 glass–ceramic material contains crystals of cordierite ($2MgO \cdot 2Al_2O_3 \cdot 5SiO_2$).

This system is also of geophysical significance. It has been suggested that the structural state of natural cordierites can be used as a qualitative geologic timer for the crystallization history of the enclosing rock (4).

Schreyer and Shairer (4) have also shown that a series of metastable β-quartz solid solutions can be formed along the silica–spinel join. The Al^{+3} substitution for Si^{+4} is accompanied by Mg^{+2} "stuffing" or buttressing of the β-quartz structure. One Mg^{+2}, located in a β-quartz interstitial vacancy, and two Al^{+3} can substitute for two Si^{+4} species. Some low-temperature phases can possess the open high-temperature β-quartz structure because of this lattice buttressing.

It would be expected that the Si—O—Si bond angles and lengths for the low-temperature phases would be similar to those reported for pure SiO_2 at higher temperatures. The basic SiO_2 structure should be preserved, even for relatively large equimolar substitutions of MgO and Al_2O_3 for SiO_2. The present study is an attempt to relate the structure of specific high-temperature magnesium aluminiosilicate liquids to their low-temperature crystalline and glass analogues, some of which possess the open β-quartz structure.

The answers to two specific questions were sought:

1. Does molten SiO_2 in the presence of Al_2O_3 and MgO behave as it does in the presence of just MgO?

2. What coordination number changes occur and how are they related to the variation of composition?

[1]*Presented before a Symposium on High-Temperature Inorganic Chemistry, sponsored by The Chemical Institute of Canada, at Carleton University, Ottawa, Ontario, on September 2–4, 1964.*

Of additional interest was the effect of one network-forming species on another network-forming species. This is of importance with respect to the formation and structure of glasses, since more than one network-forming species is usually included in a given batch formulation.

An improved counterbalanced sphere viscometer–densitometer (5) was used to obtain precise viscosity and density data for melts on the silica·cordierite·spinel join and the 50 mole % SiO_2 system at temperatures between 1 500 and 1 720 °C. The structure of these ternary melts will be compared with those that have been postulated for binary alkaline earth silicate melts (6, 7).

II. EXPERIMENTAL

The MgO and Al_2O_3 powders used to prepare the glass samples were Baker reagent grade analyzed materials. The SiO_2 was 200 mesh Pennsylvania Glass Sand Company ceramic grade sand. Spectrographic analysis of the sand indicated 0.05 to 0.5 wt. % Al_2O_3, 0.01 to 0.1 % CaO, 0.005 to 0.05 % MgO and TiO_2, 0.001 to 0.01 % B_2O_3, Fe_2O_3, ZrO_2, and K_2O, 0.0005 to 0.005 % BaO and Na_2O, and lesser amounts of other oxides.

The powders were mixed and air-dried overnight at 800 °C. The 50 cc sample slugs were individually prepared to ensure close adherence to the desired compositions. The 600 to 1 200 g batches were melted for 6 to 8 h at 1 650 °C in Pt·20% Rh crucibles to allow time for complete reaction and fining. The more viscous liquids were mechanically stirred. Rapid cooling of the 50 cc samples, which were poured directly into the Pt·40% Rh crucibles, gave clear glasses. The samples were stored in dessicators.

The Al_2O_3 contents of the glasses were determined complexometrically with ethylenediaminetetraacetic acid (EDTA). After heating the solutions (at pH 4.6) to ensure complete reaction of the aluminium(III) and EDTA, the excess EDTA was backtitrated with standard zinc solution.

Silica was determined in these glasses by a procedure developed in this laboratory (8). The method is based on the precipitation of the silicomolybdate complex with 8-quinolinol. Excess standard 8-quinolinol solution is added to a solution of the silicomolybdate complex. The excess 8-quinolinol is backtitrated with coulometrically generated bromine.

The chemical analyses were generally within 1% of the attempted batch formulations. Therefore, it was assumed that the MgO contents could be determined by difference.

The improved high-temperature counterbalanced sphere viscometer–densitometer and its operation have been described previously (5, 9). No changes in design or operating procedure were instituted for the present study.

Portions of the ternary phase diagram for the $MgO·Al_2O_3·SiO_2$ system have been recently redetermined (4). One of the binary systems was the silica·spinel join. This information and the available viscosity data were used to decide the best composition and temperature range to be studied. All of the viscosity and density data were obtained at temperatures between 1 500 and 1 720 °C at viscosities that were under 10^3 P. This viscosity range allows a high sensitivity for density determinations with the counterbalanced sphere viscometer–densitometer instrument.

III. RESULTS

The experimental mole % compositions are depicted on the ternary diagram in Fig. 1.

The least squares viscosity and density equations, calculated from the experimental data, are presented in Tables I and II. The analyzed SiO_2 and Al_2O_3 contents are expressed in terms of mole %. Viscosity isotherms for the two systems are shown in Figs. 2 and 3 while the corresponding activation energy vs. composition plots are depicted in Figs. 4 and 5.

Machin and Yee (10) reported some viscosity results for seven high-silica melts in this ternary system. However, they were primarily interested in the quaternary system $CaO·MgO·Al_2O_3·SiO_2$. Bobkova (1) subsequently examined the viscosity of 45 melts, all but 5 of which contained additions of CaO, FeO, and Cr_2O_3. Shilo (2) also examined the viscosity of melts in this ternary system. The compositions corresponded to those of slags encountered in the production of silicochromium alloys. Liutikov and Tsylev recently studied the viscosity and electrical conductance of 50 melts (3) in the same general composition area that was covered by Shilo.

A comparison of the above studies with the present viscosity data for the 50 mole % SiO_2 system reveals absolute differences for individual points. However, the general trends with composition are similar. For example, the present 1 700 °C viscosity isotherm for the 50 mole % series (Fig. 3) falls between the values given by Shilo and those given by Liutikov and Tsylev. In some cases, the literature compositions do not exactly match each other or the ones presented herein. In addition, the purity of the literature samples apparently differed. Thus, Shilo cited previous experimental errors while Liutikov and Tsylev criticized Shilo's use of graphite crucibles. A complete quantitative comparison of the present viscosity data with the literature values is therefore difficult to justify.

Molar volume isotherms for 1 700 °C are presented in Figs. 6 and 7 while the corresponding molar volume expansion coefficients $(\Delta V/\Delta T)_P$ are given as functions of composition in Figs. 8 and 9. No previous literature values for these ternary melts are available for comparison. However, the binary magnesium silicate results of Bockris *et al.* (11) have been presented in Figs. 7 and 9.

IV. DISCUSSION

A. Viscosity

The viscosity isotherm presented in Fig. 2 shows that most of the structural alteration that occurs with the addition of equimolar amounts of MgO and Al_2O_3 requires less than 25 mole % SiO_2 substitution. The viscosity at 1 700 °C drops by a factor of about 10^4 in this composition region. Substitution of an additional 25 mole % SiO_2 only decreases the viscosity by a factor of 30. Figure 4 shows that the flow mechanism undergoes a similar transition. The activation energy for viscous flow decreases from the 120–160 kcal level to about 75 kcal with the substitution of the first 25 mole % SiO_2. The activation energy change for the substitution of an additional 25 mole % SiO_2 amounts to only about 25 kcal. It appears that not all of these equimolar magnesium aluminate liquids completely retain the rigid three dimensional SiO_2 array.

The experimental results are in general agreement with the discrete anion theory developed by Bockris and co-workers for binary silicate melts (6). The absence of ΔE_η^* maxima in the 75 to 50 mole % SiO_2 region supports the formation of anionic aggregates that are smaller than either infinitely long chains (at 50 mole % SiO_2) or infinite two dimensional sheets (at 67 mole % SiO_2).

A degree of inflexibility accompanies the substitution of Al_2O_3 for MgO in the 50 mole % SiO_2 melts (Figs. 3 and 5). The substitution of Al_2O_3 for 50% of the MgO in a binary 50 mole % magnesium silicate melt causes a fourfold viscosity increase (from about 2 to 8 P) that is accompanied by a 50% increase (about 16 kcal) in the activation energy for viscous flow. The binary data is that of Bockris *et al.* (12). It would appear that the aluminium(III) is entering into "network formation" in the form of AlO_4 tetrahedra.

If AlO_4 tetrahedra can take the place of SiO_4 tetrahedra in the discrete anions postulated for these 50 mole % SiO_2 melts, then one could regard a 25 mole % MgO·25 mole % Al_2O_3 melt as having general structure and flow properties similar to those postulated for a binary 25 mole % MgO silicate melt. Indeed, if the lower curve of Fig. 4 is extrapolated to 25 mole % MgO, the resultant ΔE_η^* is close to the value for the 50 mole % SiO_2 melt of the ternary system.

The recent viscosity studies of Rossin, Bersan, and Urbain (13) and also of Kozakevitch (14) in the binary aluminiosilicate system are of related interest. Their results for an equimolar binary aluminiosilicate melt composition are included in Figs. 3 and 5. The viscosity and activation energy increases reported herein are continuous and gradual with

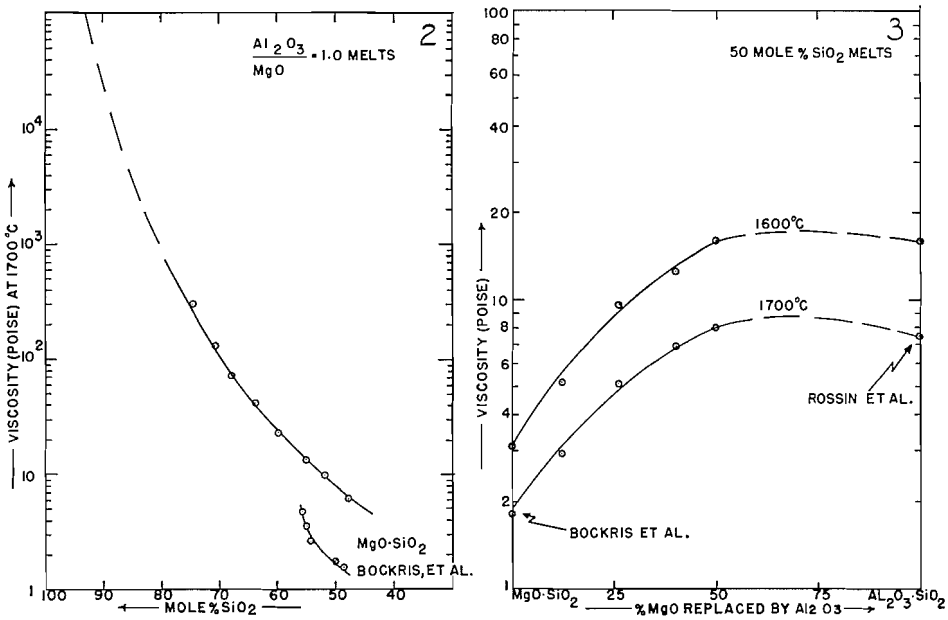

FIG. 2. Viscosity of melts studied on the silica–spinel join. Binary data of Bockris *et al.* shown for comparison.

FIG. 3. Viscosity of melts studied on the 50 mole % SiO_2 line. Binary data of Bockris *et al.* and Rossin *et al.* shown for comparison.

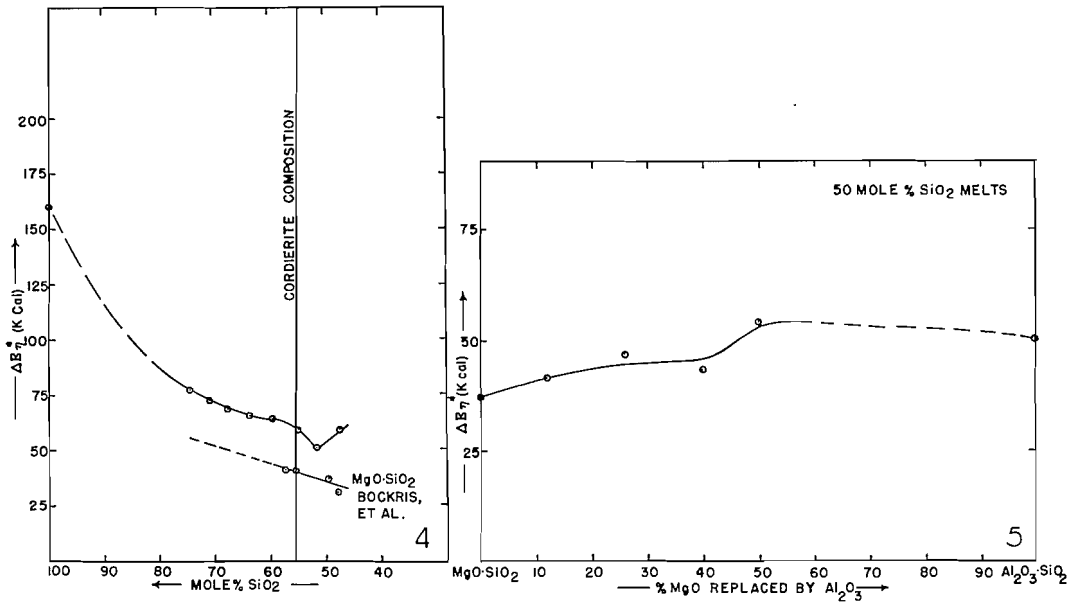

FIG. 4. Activation energy for viscous flow as a function of composition for the silica–spinel join.

FIG. 5. Activation energy for viscous flow as a function of composition for the 50 mole % SiO_2 melts.

the substitution of Al_2O_3 for MgO. Both functions appear to level off for Al_2O_3 substitutions of more than 50% (actual ternary compositions containing less than 25 mole % MgO). Thus, the presence of AlO_4 groups in the predominantly SiO_4 containing discrete anions does not significantly alter the flow mechanism in these 50 mole % SiO_2 liquids.

A change from octahedral to tetrahedral coordination for the Mg^{+2} ions could also influence the viscosity properties as the Al_2O_3 content was increased. Although the oxygen packing is less efficient in the tetrahedral configuration, the Mg—O distances would be slightly less than in the octahedral configuration. Thus, a more tightly bound liquid structure could occur.

It would appear that AlO_6 octahedra (which could form when $Al_2O_3/MgO > 1.0$)[2] do not radically alter the flow properties of these 50 mole % SiO_2 liquids. As pointed out by Rossin *et al.* (13) the low ΔE_η^* ($\sim$27 kcal) of molten Al_2O_3 is characteristic of other octahedral oxides such as CaO, FeO, etc. The addition of 50 mole % SiO_2 to molten Al_2O_3 only increases the ΔE_η^* to about 50 kcal. There must be a fair number of AlO_6 octahedra at the 50 mole % SiO_2 binary composition because most of the ΔE_η^* increase occurs with the addition of more SiO_2 in the form of SiO_4 tetrahedra. A similar behavior has been observed for binary borogermanate and borosilicate liquids (15).

The ΔE_η^* vs. composition trend observed for the 50 mole % SiO_2 melts (Fig. 5) is generally similar to the sequence reported by Kozakevitch (13) for melts in the $CaO \cdot Al_2O_3 \cdot SiO_2$ ternary system. He observed a steady increase of ΔE_η^* for melts with an O/Si ratio of 7/2. These compositions fall between the $CaO \cdot SiO_2$ binary (40 mole % SiO_2) and the Al_2O_3/CaO = unity line. The activation energy remained relatively constant between the Al_2O_3/CaO = unity line and the $Al_2O_3 \cdot SiO_2$ binary (67 mole % SiO_2). Kozakevitch postulated the formation of AlO_6 octahedra for $Al_2O_3/CaO >$ unity.

B. Density-Derived Information

1. Molar Volumes

An advantage of binary systems is that established procedures can be used to obtain partial molar quantities. The graphical method of intercepts (16) and a mirror technique (17), applied to a plot of ΔV (the deviation from ideality) vs. composition, allow a complete exploitation of the Gibbs–Duhem equation (18). This equation explains the interrelationships between the partial molar quantities for the components in a binary system.

The above advantage can be lost in a ternary system. However, it is possible to calculate partial molar quantities such as V_n in a ternary system if V_1 is known as a function of composition for a series of constant values of M_2/M_3 (where M_2 and M_3 are mole fractions) (19). This is usually a rather stringent requirement for the elevated temperatures encountered in molten oxide research.

Bockris *et al.* (20, 11) found that V_{SiO_2} differed very little from $V^0_{SiO_2}$ for alkali and alkaline earth contents of 0 to 50 mole %. This was especially true of the magnesium silicate melts where the difference was rather small. Riebling (21) has recently found that assumption of a constant V_{SiO_2} (equal to $V^0_{SiO_2}$) allowed the formulation of a reasonable model for melts in the system

$$0.25Na_2O \cdot (0.75 - x)GeO_2 \cdot xSiO_2.$$

[2]*D. E. Day and G. E. Rindone have recently obtained evidence for the formation of* AlO_6 *octahedra in alkali aluminiosilicate glasses when* $Al_2O_3/Na_2O > 1.0$. *Refractive index, density, and infrared results (J. Am. Ceram. Soc. 45, 489 (1962)), internal friction results (J. Am. Ceram. Soc. 45, 496 (1962)), and X-ray fluorescence data (J. Am. Ceram. Soc. 45, 579 (1962)) were cited. E. D. Lacy (Phys. Chem. Glasses 4, 234 (1963)) favors the formation of* AlO_4 *triclusters for similar compositions.*

For personal use only.

Finally, a plot of ΔV vs. mole % SiO_2 for melts in the SiO_2–spinel join indicated that V_{SiO_2} was close (0.0–0.5 cc difference) to $V^0_{SiO_2}$ (27.22 cc). It was concluded that a constant value of 27.22 cc could be assumed for V_{SiO_2} for all melts on the SiO_2–spinel join as well as the 50 mole % SiO_2 series.

With V_{SiO_2} fixed, the number of unknowns in eq. 1 is reduced to two (V_{MgO} and $V_{Al_2O_3}$):

$$[1] \qquad V_{obs} = M_{MgO} \cdot V_{MgO} + M_{Al_2O_3} \cdot V_{Al_2O_3} + M_{SiO_2} \cdot V_{SiO_2}.$$

At 1 700 °C V_{MgO} is known for melts in the 40 to 55 mole % MgO region of the $MgO \cdot SiO_2$ system. Bockris *et al.* (11) give a value of 12.5 cc for V_{MgO} at 50 mole % SiO_2 in the binary system. This is relatively close to the molar volume of crystalline periclase (MgO) at 1 700 °C, the value of which is 12.20 cc as calculated from density (22) and expansion coefficient information (23). It would appear that magnesium(II) remains in octahedral coordination with the addition of SiO_2 to form the molten protoenstatite composition.

The coordination of magnesium(II) in spinel ($MgO \cdot Al_2O_3$) is known to be tetrahedral while the coordination of aluminium(III) is octahedral (24). The molar volume of the crystalline material at 1 700 °C, as calculated from density (25) and expansion coefficient information (23), is 41.57 cc.

The molar volume of corundum (Al_2O_3 with the aluminium(III) octahedrally coordinated) is 26.88 cc at 1 700 °C. This was also calculated from density (26) and expansion coefficient information (23). When this volume is combined with the molar volume of MgO (with MgO_6 octahedra (27)), a combined ideal volume of 39.08 cc is obtained for spinel. This ideal high-temperature molar volume for spinel is 2.49 cc less than the observed value (previous paragraph). It has been assumed that this difference of 2.49 cc is primarily due to the greater volume occupied by magnesium(II) in tetrahedral coordination. The molar volume of MgO has therefore been taken as 12.5 + 2.5 = 15.0 cc at 1 700 °C for the tetrahedral packing of oxygens around magnesium(II).

An additional problem concerns the volume increase accompanying the octahedral to tetrahedral coordination change for the aluminium(III) species. The low-temperature form of cordierite ($Al_3Mg_2(Si_5Al)O_{18}$) has a beryl ($Be_3Al_2Si_6O_{18}$) structure with cyclic $(SiO_3)_n^{-2n}$ ions (28). All of the Mg^{+2} ions occupy octahedral holes compared to only 75% of the Al^{+3} ions. Schreyer and Schairer (4) have stated that the X-ray derived density of cordierite is less than that observed for a glass of the same composition at room temperature (2.51 vs. 2.62 g/cc). However, they thought that the low thermal expansion of cordierite raised doubt as to whether the anomalous density behavior held at liquidus temperatures.[3] Thus, the evidence is not clear-cut in favor of three AlO_6 per AlO_4 in a liquid of the cordierite composition.

The feldspars (1–1–6 compounds) are known to possess the three dimensional network structure of SiO_2 with all of the aluminium(III) in the form of AlO_4 tetrahedra (29). They generally contain the larger cations such as Na^+, K^+, and Ca^{+2}. Although one crystalline modification of the $2MgO \cdot 2Al_2O_3 \cdot 5SiO_2$ composition (which is close to a typical feldspar composition) will tolerate only 25% of the aluminium(III) in the form of AlO_4 tetrahedra, the less restrictive liquid state could contain most of the aluminium(III) in the form of AlO_4 tetrahedra. There follows an attempt to determine (*a*) the volume occupied by Al_2O_3 in these liquids, (*b*) the molar volume associated with AlO_4 tetrahedra, and (*c*) the coordination numbers of the aluminium(III) and magnesium(II) species.

[3]*The thermal expansion of cordierite is only about one-half of the value for a 1–1–4 glass over the range 25–700 °C.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(*a*) For a 50 mole % SiO_2 melt on the Al_2O_3/MgO = unity join, with MgO_4 tetrahedra assumed,

$$[2] \qquad V_{obs} = 25.35 = 0.50(27.22) + 0.25(15.0) + 0.25(V_{Al_2O_3}).$$

The calculated value of $V_{Al_2O_3}$ at 1 700 °C is 31.44 cc. This is 4.5 cc greater than the value previously calculated for pure corundum at the same temperature. It amounts to a 17% volume increase at 1 700 °C and compares favorably to the percentage increase observed at elevated temperatures for the same coordination change in GeO_2 (5.5 cc and 20%) (9). Similar values have been observed for SiO_2 (~6 cc and 32% for the stishovite to coesite change) (30) and MgO (2.5 cc and 20% as calculated above).[4] It would appear that the above 4.5 cc difference is associated with the octahedral to tetrahedral transformation for aluminium(III) in these magnesium aluminiosilicate liquids.

(*b*) It is possible to qualitatively check the previous conclusion for aluminium(III) by examining a compound in which AlO_4 tetrahedra are known to occur. $AlPO_4$ possesses a low cristobalite structure (AlO_4 and PO_4 tetrahedra) with an $\diagdown O \diagup$ angle of 145° (31). The molar volume of this compound is 47.53 cc at room temperature (32). If $AlPO_4$ consists of one-half mole of Al_2O_3 and one-half mole of P_2O_5, the calculated molar volume is 12.84 cc (one half V_M of corundum, with AlO_6 octahedra) plus 29.72 cc (one-half V_M of P_2O_5; P_4O_{10} consists of PO_4 tetrahedra) (33). This value of 42.56 cc is 4.97 cc less than the observed value at room temperature. The difference can be ascribed to the use of an Al_2O_3 volume that is associated with AlO_6 octahedra. The 4.97 cc difference agrees fairly well with the previous value of 4.5 cc that was calculated in an independent fashion.

(*c*) Figure 6 depicts the experimentally observed molar volume isotherm for 1 700 °C as a function of melt composition in the silica–spinel join. The lowest line represents the isotherm obtained if the assumed structural model for these melts consists of AlO_6 and MgO_6 octahedra. The line just below the experimental isotherm corresponds to a model that involves AlO_4 and MgO_4 tetrahedra. The second model gives much better agreement with experiment (to within 0.3–0.4 cc). This strengthens the concept that liquids on this join contain silica-like anionic species. It can be concluded that the aluminium(III) species are AlO_4 tetrahedra and that they occur within the silica-like anion aggregates rather than as individual ions. The main effect of adding 45% or more SiO_2 to spinel is apparently to create AlO_4 tetrahedra from AlO_6 octahedra, while retaining tetrahedrally coordinated Mg^{+2} ions.

Figure 7 depicts the experimentally observed molar volume isotherm for 1 700 °C as a function of composition for the 50 mole % SiO_2 system. The lowest line represents the isotherm obtained if the assumed structural model consists of AlO_4 tetrahedra and MgO_6 octahedra.[5] The line just below the experimental isotherm corresponds to a model that involves AlO_4 tetrahedra with the gradual formation of MgO_6 octahedra from MgO_4 tetrahedra as the MgO content is increased. The second model gives slightly better agreement with experiment. This strengthens the previously postulated occurrence of MgO_4 tetrahedra in melts on the silica–spinel join.[6] It would also appear that the AlO_4 tetrahedra are the major aluminium(III) species for melts with Al_2O_3/MgO ratios equal to or less than unity.

[4]*The smaller absolute difference for the coordination change in* MgO *is probably associated with the larger size of the* Mg^{+2} *ion as well as the stoichiometry involved. The octahedral configuration does not represent as efficient a method of packing, with respect to the tetrahedral configuration, for* Mg^{+2} *as it does for the smaller* Al^{+3} *and* Ge^{+4} *ions. Also, there are twice as many oxygens per metal atom in* GeO_2 *and* SiO_2 *and one and one-half as many oxygens per metal atom in* Al_2O_3 *as there are in* MgO.

[5]*Any model involving* AlO_6 *octahedra would give worse agreement.*

[6]*A distorted* MgO_6 *octahedra would be another possibility.*

For personal use only.

A significant aspect of the complete liquid model is that within the composition limits studied in the silica–cordierite–protoenstate sub-ternary system, the Mg^{+2} ions, not the Al^{+3} ions, appear to be the cations involved in a coordination change.

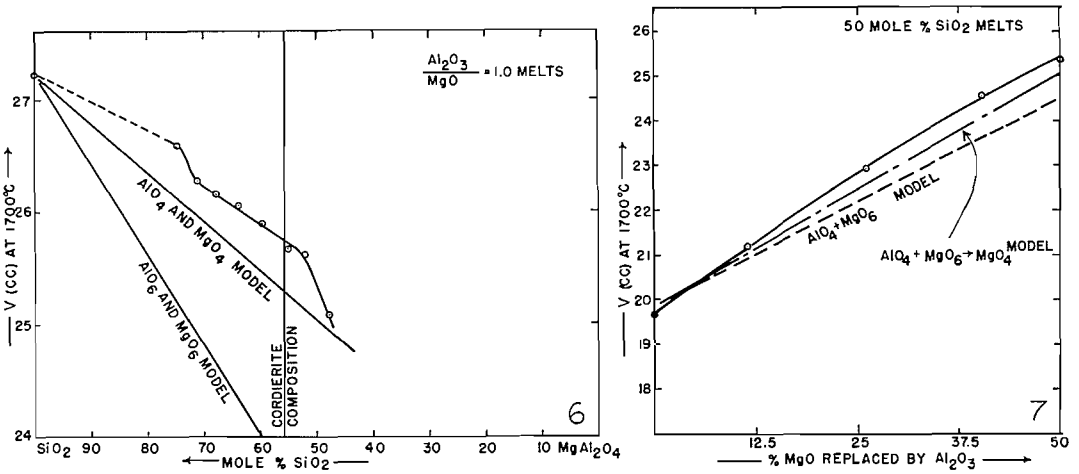

FIG. 6. Experimental molar volume isotherm compared to model isotherms for melts on the silica–spinel join.

FIG. 7. Experimental molar volume isotherm compared to model isotherms for melts on the 50 mole % SiO_2 line.

2. Expansion Coefficients

The absolute values of the expansion coefficients and their variations with composition can be relatively small for melts in the $MgO \cdot Al_2O_3 \cdot SiO_2$ ternary system. The addition of equimolar amounts of MgO and Al_2O_3 to molten silica at 1 700 °C produces no significant increase of $(\Delta V/\Delta T)_P$ until the amount of SiO_2 decreases below 65% (Fig. 8). This represents an MgO content of more than 18 mole %. Subsequent additions of MgO and Al_2O_3 only increase $(\Delta V/\Delta T)_P$ from zero to the 7×10^{-4} level. These results generally agree with the available information and model for melts in the binary alkaline earth silicate systems (11).

It would appear that the presence of Al_2O_3 serves to increase the amount of MgO required to break up the "disturbed SiO_2 network" postulated by Bockris *et al.* (11). About 18 mole % MgO is required to reach the same structural point in the ternary system that only 12 mole % MgO took in the binary system.

Figure 9 shows the marked effect of substituting 50% of the MgO with Al_2O_3 at a constant SiO_2 content of 50 mole %. The net result of the substitution of two Al^{+3} ions for one of two Mg^{+2} ions is to reduce the melt expansion coefficient by a factor of one-half. However, most of this change occurs for low Al_2O_3 contents. The higher field strength of Al^{+3}, compared to Mg^{+2}, is probably responsible for most of this reduction.

V. CONCLUSIONS

A synthetic liquid model had been previously shown to fit the experimental data for a portion of the $Na_2O \cdot GeO_2 \cdot SiO_2$ ternary system (21). This paper takes an additional step. The available crystalline information has been extensively used, in conjunction with a limited amount of previously known information on molar volumes of molten silicates, to construct a liquid model that agrees with the present experimental results. It is concluded

For personal use only.

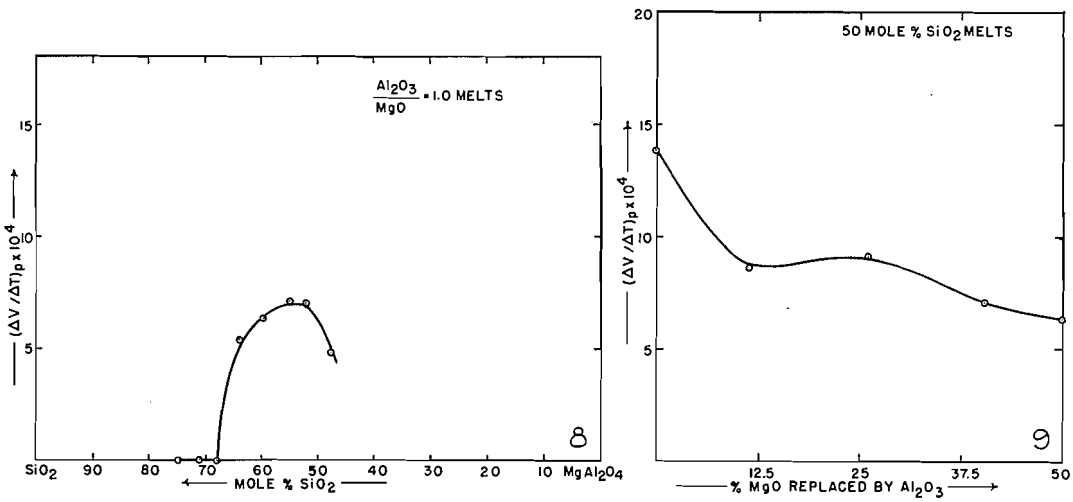

FIG. 8. Expansion coefficient as a function of composition for melts studied on the silica–spinel line.
FIG. 9. Expansion coefficient as a function of composition for melts on the 50 mole % SiO_2 line.

that crystalline information concerning oxide structure changes can be used to interpret the observed high-temperature density data for the corresponding ternary liquids.

It has been demonstrated that a reasonable correlation can exist between the coordination number of a given cation in the crystalline state and in high-temperature ternary liquids of similar composition. This could represent a useful concept for understanding and predicting the structure of more complex high-temperature oxide liquids. The extension of these concepts from liquids to their corresponding glasses awaits further attention.

ACKNOWLEDGMENTS

The author would like to thank Dr. S. D. Stookey for his interest, Dr. D. E. Campbell for his cooperation with the chemical analyses, and Dr. G. H. Beall for discussions concerning this system. I would also like to acknowledge the cooperation of Dr. A. A. Erickson who provided the melting facilities for sample preparation. Mr. P. C. Logel and Mr. P. E. Blaszyk assisted with the experimental work.

PHOTOCHEMICAL SYNTHESES

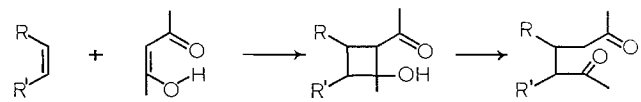
9. THE CONVERSION OF DIBENZOYLMETHANE TO TRIBENZOYLETHANE

G. KORNIS AND P. DE MAYO
Department of Chemistry, University of Western Ontario, London, Ontario
Received July 13, 1964

ABSTRACT

Irradiation of dibenzoylmethane in benzene gives tribenzoylethane. In more concentrated solution a solid dimer (II) separates which, on solution, is converted by dealdolization into an isomer. This isomer (I, R = H) on irradiation, gives tribenzoylethane in a photolytic reaction which has been shown to have some generality. The overall conversion of dibenzoylmethane to tribenzoylethane therefore involves two photochemical and one chemical reactions.

Some time ago, as part of our studies on photochemical cyclo-addition, we reported the reaction between acetylacetone and a number of alkenes and cycloalkenes (1). The main products derived from the process are indicated below.



To ascertain whether the process was general for all enolized β-diketones, we studied the reaction between dibenzoylmethane and cyclohexene. This diketone is largely enolized in hydrocarbon solvents and the reaction could be conveniently followed by observing the formation of the non-enolized benzoyl grouping in the carbonyl region.

The products proved difficult to crystallize and the first substance obtained in crystalline form, from a study of its spectra, evidently did not contain a cyclohexyl residue. This conclusion was confirmed when it was found that the yield was greatly increased (to 37%) by irradiation of dibenzoylmethane in benzene solution.*

The substance showed only benzoyl carbonyl in the infrared spectrum, and the ultraviolet absorption was typical of acetophenones. The nuclear magnetic resonance (n.m.r.) spectrum showed the presence of only three protons other than aromatic hydrogen. These were a doublet (two protons) at τ 6.23 and a triplet (one hydrogen) at τ 3.85. These protons were coupled with $J = 7$ c.p.s. The two protons of the doublet were evidently identical. This required the part structure $-CH_2-CH\langle$.

Alkaline hydrolysis of the substance under mild condition gave diphenacyl and benzoic acid (1 mole) as the only isolable products. The substance was therefore identified as tribenzoylethane. The remarkably low-field position of the methine proton is noteworthy.

The mode of genesis of the tribenzoylethane was not immediately obvious, but since two molecules of dibenzoylmethane, at least, were required to participate in its formation the possibility of dimerization at some stage appeared reasonable. Accordingly, the irradiation was performed with a higher concentration of dibenzoylmethane.

Under these conditions the reaction proceeded differently. Although the infrared spectrum of the *solution* appeared to be showing the expected changes, a white crystalline solid separated during the irradiation. This material was separated by filtration and

**We are indebted to Mr. R. W. Yip for this observation.*

For personal use only.

although it initially appeared insoluble in chloroform, it dissolved in a large volume of this solvent from which, after considerable concentration, it could be crystallized on the addition of light petroleum.

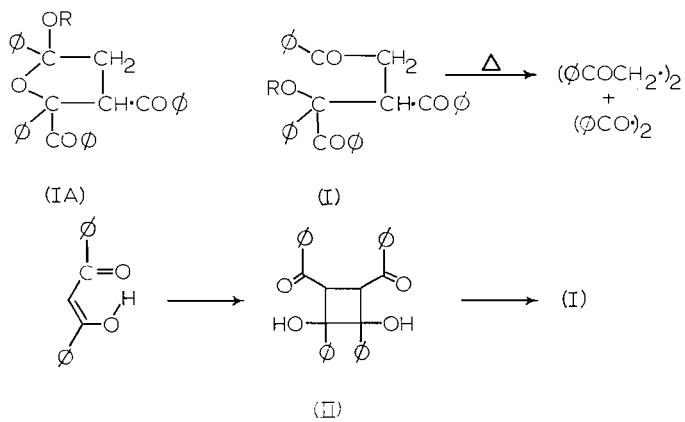
This substance was not tribenzoylethane, but a new substance. Again, the ultraviolet spectrum indicated essentially acetophenone-type absorption. The infrared spectrum showed absorption at 3 400 (hydroxyl), 1 680, and 1 645 cm^{-1}. From this it seemed probable that the absorption at 1 645 cm^{-1} was due to benzoyl carbonyl lowered by hydrogen bonding with the hydroxyl group. The n.m.r. spectrum showed the presence of three protons attached to carbon. These were present as three quartets centered at τ 6.29, 6.17, and 4.57. All three protons were therefore coupled together. This again suggested the $-CH_2-CH\langle$ system, where now the methylene protons were not identical.

The n.m.r. spectrum further indicated that the ratio of the ortho hydrogens to meta and para hydrogens (near τ 2.0 and 2.5 respectively) was not that (2:3) expected of benzoyl groups. It appeared to be rather greater than 1:2 which suggested that an isolated phenyl group might be present. Combination of these facts led to the consideration of (I, R = H) as a structure for this new substance.

Chemical attempts to confirm this by dealdolization to benzil and diphenacyl were unsuccessful. The desired object was achieved by heating at 195°, when both these substances sublimed away and were obtained in high yield.

In an earlier attempt to dehydrate (I) or to induce dealdolization, the substance was allowed to stand at room temperature in methanol in the presence of a small amount of sulfuric acid. A crystalline product separated which now lacked the hydroxyl group in the infrared spectrum, but which still showed only acetophenone absorption in the ultraviolet.

Six protons attached to carbon, other than aromatic protons, were visible in the n.m.r. spectrum. Of these one appeared near τ 4.0 as an apparent triplet and two in the τ 7.0–6.3 region as two quartets centered at τ 7.20 and 7.29. In addition a singlet (three protons) appeared at τ 7.62. No acetyl group or vinyl methyl was possible, and a methoxyl group, despite the impressively high position, seemed inevitable. This was confirmed by the analysis which revealed the presence of one methoxyl group. The structure (I, R = Me) or an alternative, cyclic, structure (IA, R = Me) is possible (and the equivalent IA, R = H may contribute to I) for this molecule; the latter formulation is supported by the ultraviolet extinction.*



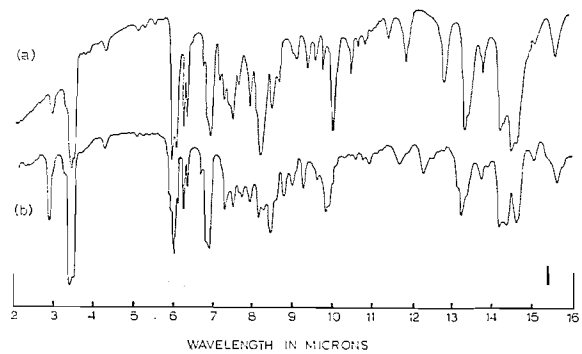
We are grateful to Dr. R. E. Lutz for informing us of his own relevant observations in similar systems and stressing the likelihood of the cyclic structure.

The structure (I, R = H) could be reasonably derived from a dimer (II) by dealdolization accelerated by relief of strain from the opening cyclobutane ring. At this point the original crystalline precipitate from the irradiation was subjected to closer scrutiny.

As originally obtained it was completely different from (I) in solubility in all solvents. However, once having been dissolved only (I) could be recovered. Hence the wish to examine its properties appeared necessarily subject to a degree of frustration. Its infrared spectrum in Nujol was significantly different from that of (I, R = H) (Fig. 1) and is at least compatible with the formulation (II).

The final step in the sequence was the required conversion of (I, R = H) into tribenzoylethane. In fact, irradiation of (I, R = H) in benzene gave the triketone in 48% yield. The formation of tribenzoylethane from dibenzoylmethane can thus be rationalized.

The photolysis of (I, R = H) was of general interest and was investigated briefly. Since the dibenzoylethyl group attached to the carbon bearing the hydroxyl group should be without special significance, similar cleavage could be expected when this grouping was replaced by some other function.



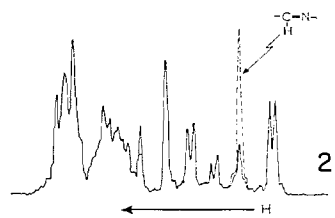


FIG. 1. Infrared spectrum (Nujol mull) of (*a*) alcohol (I) and (*b*) diol (II).
FIG. 2. Nuclear magnetic resonance spectrum of aromatic protons and azomethine proton in benzaldehyde 2,4-dinitrophenylhydrazone and the partially deuterated derivative. Solvent: dimethyl sulfoxide at 103°.

The substituted benzoin (III), itself having been prepared photochemically, was available in these laboratories from other studies (2). Irradiation of this in benzene solution gave benzoylacenaphthene (IV) (2), though in poor yield, and no benzaldehyde. Similar irradiation of benzoin (V, R = H) itself gave benzaldehyde. Irradiation of deuteriobenzoin (V, R = D) gave a mixture of benzaldehyde and (VI) deuteriobenzaldehyde. The location of the aldehydic deuteron was accomplished by a determination of the n.m.r. spectrum (in dimethylsulfoxide at 103°) of the 2,4-dinitrophenylhydrazone when, in the deuterated compound, the azomethine proton (see Fig. 2) was reduced by about 50%. This was confirmed by deuterium analysis. That the deuterium was not lost by exchange through hydrogen abstraction prior to photolysis was shown by brief irradiation, with partial conversion of the deuteriobenzoin. No methine proton was detected in the recovered benzoin.

The presence of the hydroxyl proton is necessary for benzaldehyde formation, but its absence, as in the phenyl ether (3), does not significantly affect the rate of destruction of the benzoin as measured by the disappearance of the methine proton. Hence, assuming the photolytic step is the same in both cases, it is not preceded by hydrogen abstraction

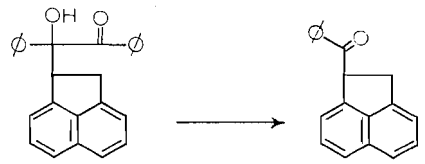
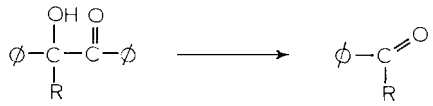
For personal use only.



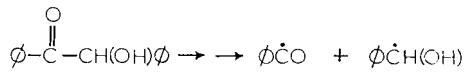
(III) (IV)



(V) (VI)

of the hydroxyl proton. Abstraction of the methine proton is unlikely since this proton is not present in the substituted benzoins already discussed. Furthermore the methine proton, as indicated by deuteration, appears in the same position in the resultant benzaldehyde.

No benzaldehyde in appreciable amount is produced in the substituted benzoins, so it seems likely that after photolysis, the benzyl radicals, by hydrogen transfer, act as



the only source of benzaldehyde. Such exchange as does occur probably occurs after the initial photolysis.

EXPERIMENTAL

Melting points were determined on the Kofler hot stage and are uncorrected. The term 'petrol' refers to petroleum ether of b.p. 60–80°. The benzene used (thiophene free) was percolated through a column of alumina before use. Infrared spectra were determined in chloroform solution and n.m.r. spectra in deuteriochloroform, unless otherwise stated.

Irradiations were conducted in a water-cooled vycor immersion apparatus of capacity ca. 250 ml under oxygen-free nitrogen, and with magnetic stirring. The light source was a Hanovia 450 W mercury arc and was encased in a pyrex cylinder.

Irradiation of Dibenzoylmethane

(a) A solution of dibenzoylmethane (5 g) in benzene (250 ml) was irradiated for 75 h (until the carbonyl absorption near 6 μ did not appear to be increasing). After evaporation of the solvent the residue was extracted with petrol until the extract was colorless. Evaporation of the petrol extract gave an oil which was dissolved in ethanol, and a solution (0.25 *M*) of 2,4-dinitrophenylhydrazine added until no more precipitate formed. Crystallization from ethyl acetate – petrol gave the 2,4-dinitrophenylhydrazone of benzaldehyde (36 mg, 11%) identical in every respect with an authentic specimen.

The residue remaining after petrol extraction was crystallized from ethyl alcohol to give tribenzoylethane (1.4 g, 37%), m.p. 153–155°, raised to 154–156° on recrystallization. (Lit. (4) 156–157°.) λ_{max} 248 mμ (log ϵ 4.7).

Anal. Calcd. for $C_{23}H_{18}O_3$: C, 80.68; H, 5.30. Found: C, 80.81; H, 5.72.

A solution of tribenzoylethane (0.21 g) in aqueous sodium hydroxide (0.1 *N*, 50 ml) and ethanol (100 ml) was allowed to stand at room temperature for 17 h. Concentration of the solution gave a precipitate of diphenacyl which on crystallization from methanol (0.11 g, 76%) had m.p. 145–146°. (Lit. (5) 145°, λ_{max} 244 mμ (log ϵ 4.42).)

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.64; H, 6.92. Found: C, 80.59; H, 5.78.

Acidification of the aqueous filtrate gave, after isolation with ether and crystallization from water, benzoic acid, m.p. 120–122°, identical in every respect with an authentic specimen.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In a separate experiment titration of the hydrolyzed tribenzoylethane showed the generation of 1 equivalent of acid.

(b) A solution of dibenzoylmethane (30 g) in benzene (250 ml) was irradiated. After 45 h a heavy precipitate (6.3 g) was collected. Irradiation for 24 h more gave a further 4.9 g and prolonged irradiation (67 h) produced 0.9 g. The combined precipitates were washed with petrol and dried *in vacuo* to give a total of 12.1 g (40%), of (II), m.p. 140–141°.

Anal. Calcd. for $C_{30}H_{24}O_4$: C, 80.33; H, 5.39. Found: C, 79.57; H, 5.44.

1-Phenyl-1,2,3-tribenzoylpropan-1-ol (I, R = H)

A solution of (II) (12.1 g) in chloroform (500 ml) was heated under reflux for 1 h. Evaporation to dryness and crystallization from petrol gave the alcohol (I, R = H) (3.6 g), m.p. 138–140°. Admixture with (II) gave a depression of 20°. λ_{max} 250 mμ (log ϵ 4.46).

Anal. Calcd. for $C_{30}H_{24}O_4$: C, 80.33; H, 5.39. Found: C, 80.64; H, 5.10.

A solution of the alcohol (I, R = H) (45 mg) in acetone (5 ml) and 0.1 *N* sodium hydroxide (20 ml) was heated under reflux for 30 min. Concentration, collection of the precipitate, and crystallization from methanol gave diphenacyl (13 mg, 55%) identical in every respect with the material described above.

Sublimation of the alcohol (I, R = H) (40 mg) at 195° and 1.5 mm gave a yellow oil. Separation by thin-layer chromatography using silicic acid and eluting with chloroform gave diphenacyl (20 mg, 95%), m.p. 145–146°, and benzil (17 mg, 90%), melting point and mixed melting point 93–95°.

1-Methoxy-1-phenyl-1,2,3-tribenzoylpropane (I, R = Me or IA, R = Me)

To a solution of the alcohol (I, R = H) (0.1 g) in methanol (10 ml) concentrated sulfuric acid (2 drops) was added and the mixture allowed to stand. Crystallization occurred within 5 min, but the solution was left for 14 h. Collection of the crystalline precipitate and recrystallization from methanol gave the ether (I, R = Me) (48 mg, 47%), m.p. 189–191°, λ_{max} 252 mμ (log ϵ 4.32).

Anal. Calcd. for $C_{31}H_{26}O_4$: C, 80.56; H, 5.67; OMe (1), 6.7. Found: C, 80.88; H, 5.84; OMe, 6.21.

Irradiation of 1-Phenyl-1,2,3-tribenzoylpropan-1-ol (I, R = H)

The alcohol (0.114 g) in benzene (250 ml) was irradiated for 12 min. Evaporation of the solution and crystallization from ethanol gave tribenzoylethane (42 mg, 48%), m.p. 153–155°.

Irradiation of α-1-Acenaphthenylbenzoin (III)

A solution of (III) (0.2 g) in benzene (250 ml) was irradiated for 1 h. After evaporation of the solvent the brown residual oil was crystallized twice from methanol (charcoal) to give 1-benzoylacenaphthene (IV) (20 mg, 14%), m.p. 133–135°, identical in every respect with an authentic specimen.

Irradiation of Benzoin

A solution of benzoin (0.5 g) in benzene (250 ml) was irradiated for 70 min. The solvent was evaporated and the residue extracted with petrol. Conversion of the material extracted by the petrol to the 2,4-dinitrophenylhydrazone in the usual way gave the derivative of benzaldehyde (0.13 g, 20%) identical with an authentic specimen in every respect. The residue from the extraction contained material with the same retention time as benzyl alcohol on a 20% Carbowax 20M 6 ft × ¼ in. column at 150°. Calibration of response indicated that it was present to the extent of 4%.

Similar irradiation of α-deuteriobenzoin (0.53 g) gave the 2,4-dinitrophenylhydrazone containing 5.94% excess deuterium.

α-Deuteriobenzoin

Sodium (0.1 g) was added to a mixture of D_2O (99.6%, 3 ml) and dioxan (50 ml), followed by benzoin (2.2 g). The mixture was heated under reflux for 1 h under nitrogen, the solvent evaporated, and the residue redissolved in dioxan (50 ml) and D_2O (3 ml) and again refluxed for 1 h. The cycle of operation was repeated twice more, the mixture being protected from outside moisture throughout. After the final evaporation D_2O (8 ml) was added and the mixture acidified with *N* hydrochloric acid. The benzoin was collected and crystallized from benzene–petrol, m.p. 134–136°. No methine proton could be detected in the n.m.r. spectrum.

Irradiation of α-Deuteriobenzoin

The deuterated benzoin (0.13 g) was irradiated in benzene (250 ml) for 5 min. Evaporation of the solvent and crystallization from petrol gave recovered deuteriobenzoin (0.05 g, 39%). Irradiation of benzoin phenyl ether and benzoin in comparable concentrations (100 mg, 250 ml) in benzene showed approximately the same rate of disappearance of the methine hydrogen, as followed by n.m.r. Disappearance was complete in about 30 min.

ACKNOWLEDGMENTS

The authors are indebted to the A.F.O.S.R. for support of this research under grant AF-AFOSR-61-6. They thank Mr. R. E. Klinck and Mr. D. Ross for the n.m.r. spectra.

PHOTOCHEMICAL SYNTHESES

10. ADDITION OF MALEIC ESTER TO CYCLOALKENES: THE PRODUCTS

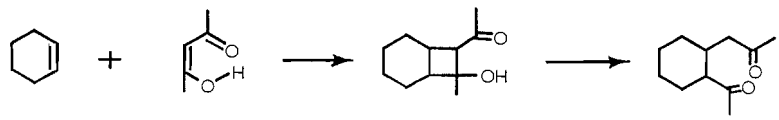
P. DE MAYO, S. T. REID, AND R. W. YIP
Department of Chemistry, University of Western Ontario, London, Ontario
Received July 13, 1964

ABSTRACT

The intermolecular photochemical cycloaddition of maleic ester to cyclopentene and to cyclohexene has been observed. The saturated products were diesters of the (3:2:0) and (4:2:0) bicycloheptane and octane series, respectively. The stereochemistry of these products was studied and, in the latter series, derivatives of the *trans*-fused (4:2:0) bicyclooctane system identified.

In addition to the saturated esters, cyclohex-2-enyl succinic ester and cyclopent-2-enyl succinic ester, produced by addition of the cycloalkenyl radical to maleic ester, also were formed.

At the outset of these investigations* only one example of intermolecular photochemically induced cycloaddition to an isolated ethylenic linkage had been reported (2, 3). In that instance (the addition of the enol of acetylacetone to cyclohexene), the intermediate cyclo-addition product (I) was not isolated because of its facile conversion, by dealdolization, to the pentane dione (II). It was, therefore, desirable to investigate a system in which



(I) (II)

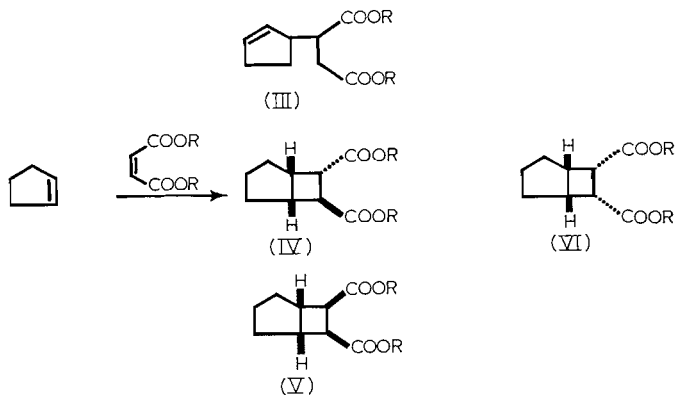
the cyclobutane ring would be retained intact. As a result of an earlier observation made in these laboratories we noted that diethyl maleate added to cyclohexene. The present paper reports the structure and stereochemistry of the products—discussion of the mechanism will be deferred until a following paper in this series, wherein a more detailed study of the irradiation is reported.

While this work was in progress Eaton reported (4) the addition of cyclopentenone to cyclopentene. Simultaneously with our first publication (1),† Corey (5, 6) reported the addition of cyclohexenone to isobutene, and very shortly thereafter Barltrop (7) reported the addition of cyclohexene to maleic anhydride and maleic ester.

Irradiation of dimethyl maleate‡ in cyclopentene, followed by distillation, gave a mixture of esters which was separated by gas–liquid chromatography to give the unsaturated ester (III, R = Me), which was then hydrolyzed to the corresponding dicarboxylic acid, m.p. 127–129°.

Although no maximum in the ultraviolet spectrum was observed, the absorption at 200 mμ (ϵ, 4 870) clearly indicated unsaturation. Further, the n.m.r. spectrum of the ester showed a multiplet, centered at τ 4.33, of two protons, indicating the presence of two vinyl protons. In addition, another multiplet (two protons) was centered at about τ 8.33, there being no protons other than these above $\sim \tau$ 7.9. These protons are the only ones

Part of the material here presented formed a preliminary communication (1).
†*These results were first presented at the C.I.C. Organic Symposium, Hamilton, August, 1962.*
‡*Under the conditions of the reaction very little fumarate is produced. This will be discussed in a following paper.*



in the molecule not moved from the normal cycloalkyl methylene position by substitution. These two facts are sufficient to exclude the cyclopent-1- (one vinyl proton) and cyclopent-3-enyl (four high field protons) isomers. The nature of the carbon skeleton itself follows from mechanistic considerations and from analogy with the cyclohexene system to be described. Photochemically induced radical addition to maleic ester has been recorded, for instance, by Pitts (8) and by Schenck (9).

To facilitate the separation of the saturated products (effected by g.l.c. on Carbowax 20M) the unsaturated products were first destroyed by ozonolysis. Although three saturated esters were obtained, corresponding to the three possible *cis*-fused products, on hydrolysis one of the esters (VI, R = Me), obtained in very minor amount, was converted, by epimerization under the hydrolytic conditions, into the same decarboxylic acid (IV, R = H) that was obtained by hydrolysis of the largest saturated fraction. The remaining fraction, on hydrolysis, gave a new acid (V) m.p. 178–179.5°. By calibration, the percentage composition of the ester mixture was obtained.

Both acids were transparent in the ultraviolet, both showed absorption in the τ 7.0–7.3 region (2H) expected for the protons at the ring junction, and both showed complex multiplets (6H) in the τ 8.35 region for the cyclopentane protons. This evidence for the structure is persuasive and, when coupled with the more strictly defined analogy with the cyclohexene series, may be regarded as compelling.

By heating with acetic anhydride, the acid (V, R = H) was converted into an anhydride (showing bands in the infrared spectrum at 1 775 and 1 850 cm^{-1}) which was hydrolyzed by warming with water to regenerate the selfsame acid. In contrast, on similar treatment the acid (IV, R = H) was converted into acid (V, R = H). On this basis it must be concluded that in (IV) the carboxyls are *trans* and that in (V) they are *cis*. The minor ester, which is converted into (IV, R = H), must be that of the acid (VI, R = H) in which there are significant non-bonded interactions.

The allocated stereochemistry of the carboxyl groups was supported by pK measurements. Although the specific values for the pK's are without immediate significance, the difference in the pK_1 and pK_2 would be expected to be so. Thus, for instance, *cis*-caronic acid has ΔpK 5.7 and *trans*-caronic acid has ΔpK 1.5. (For a succinct summary, see ref. 10.) In agreement with our expectations, the *trans* diacid showed a smaller ΔpK (1.3) than the *cis* diacid (ΔpK, 2.3).

The irradiation of maleic ester with cyclohexene gave a mixture of products which was, however, more complex than that obtained from the use of cyclopentene as substrate.

In this instance the unsaturated hydrocarbon, bicyclohexenyl (XIV), was isolated from the lower boiling material. By g.l.c. chromatographic separation of the ester mixture, the ester corresponding to VII was isolated and hydrolyzed to give the free dicarboxylic acid, m.p. 141–143°. The presence of unsaturation was shown by the extinction (3 500) at 200 mμ and by the presence of a multiplet near τ 4.4 for two protons in the n.m.r. spectrum. This, by analogy with the cyclopentene equivalent, places the ethylenic linkage. The carbon skeleton was established by hydrogenation to give cyclohexylsuccinic acid which was compared with an authentic specimen.

Ozonolysis of the ester mixture, followed by distillation, removed the unsaturated material. The remaining saturated esters were separated by g.l.c. on Carbowax 20M. After hydrolysis the separated acids were further purified, where necessary, by chromatography on silica gel. This was necessary since the preparative separation was not as efficient as the analytical procedure. Four acids were obtained: VIII, m.p. 181–182°; IX, m.p. 201–202°; X, m.p. 199–200°;* XI, m.p. 174–176°.

By treatment with acetic anhydride and hydrolysis the acid (VIII) was converted into XII, m.p. 153–155°; a similar observation was made for the diacid (IX). On the other hand acid (X) was converted into acid (XI). As expected, therefore, XI was recovered when subjected to this treatment.

All four acids were optically transparent down to 200 mμ, and all showed four protons in the τ 6.5–7.5 region for the methine protons adjacent to the ester functions and for the bridgehead methines. It seemed very likely, therefore, that all these acids, together with acid (XII), were bicyclo(4:2:0)octane derivatives. Further, because two acids (VIII and IX) could be converted into the same, necessarily *cis*-, dicarboxylic acid (XII) and were probably, therefore, both *trans*-dicarboxylic acids, the presence of a *trans*-fused bicyclo (4:2:0)octane system was most likely for this set. Only in the *trans*-fused system can there be two *trans*-dicarboxylic acids.

**This acid has also been reported by Barltrop (7).*

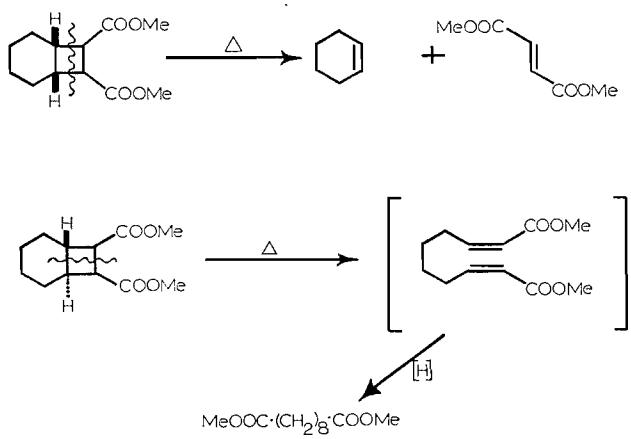
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

On this basis acids (X) and (XI) most probably belonged to the *cis*-fused bicyclooctane system. The gross structure of X was demonstrated by pyrolysis at 405–410°, when dimethyl fumarate was obtained. Dimethyl succinate was also formed (and at higher temperatures became the only C_4 acid derivative) and, in a separate experiment, it was shown that dimethyl fumarate is converted into succinate by heating at 410–415° with an equimolar amount of cyclohexene. Traces of cyclohexene were also detected.

Confirmation that the fusion of the ring system was *cis* in X was obtained by the oxidation of this substance with potassium permanganate. *cis*-Cyclohexane-1,2-dicarboxylic acid was obtained (isolated by g.l.c. as the ester) with no trace of the more stable *trans* acid. Less than one-fifth of 1% of the amount of *cis* acid actually obtained could have been detected of the *trans* acid, had it been formed. Accordingly, the stereochemistry indicated is assigned to acids X and XI. The all-*cis* alternative for XI—compound XIII—is not considered probable because of the more severe non-bonding interaction as compared with XI. The configurational assignments were supported by the pK measurements, ΔpK for X being smaller (1.7) than that for XI (2.3).

Confirmation of the gross structure of the *trans*-fused group of acids was sought in the pyrolysis of VIII (as the dimethyl ester). After hydrogenation of the pyrolyzate, over palladized charcoal in ethyl acetate, material having the same retention time and infrared spectrum as dimethyl sebacate was isolated, by chromatography, and characterized by conversion to sebacic acid. It appears that, in the *trans*-fused series, the additional strain induces preferential cleavage in the opposite sense to that of the *cis* series. The additional strain was reflected, also, in the fact that pyrolysis could be effected at as low a temperature as 340–350°. No trace of dimethyl fumarate or succinate could be detected.

Scheme



With the exception of the distinction between VIII and IX, the structure and stereochemistry of all the cycloaddition products is thus defined.

The reactions described provide a *direct* synthesis of the *trans*-fused (4:2:0) bicyclooctane system, which previously had been obtained only by ring contraction (11, 12).

EXPERIMENTAL

Materials

Cyclohexene (supplied by Matheson, Coleman, and Bell) and cyclopentene (Phillips Petroleum) gave single peaks on chromatography on Carbowax 20M (20 ft × 1/4 in.; 10% on 80–100M Chromosorb P at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

63°, helium flow 120 ml/min). Cyclohexene was shaken repeatedly with saturated ferrous sulphate solution, washed, dried, and distilled. Cyclopentene was refluxed over zinc dust and distilled. Immediately prior to use the cycloalkenes were filtered through a column of alumina. Dimethyl maleate was prepared according to the method of Clemo and Graham (13). It gave a single peak on the above column (at 180°) under conditions adequate to resolve a mixture of maleate and fumarate.

Apparatus

(*a*) An apparatus previously described (14) was used, modified by replacing the nitrogen bubbler with a magnetic stirrer. An inlet for oxygen-free nitrogen was provided. An 80 W Hanovia CH-3 medium pressure arc was the source, the capacity of the container being about 200 ml. The immersion well was quartz.

(*b*) A similar apparatus was used in which the light source was a 450 W Hanovia medium pressure arc in a water-cooled Vycor immersion well (Engelhard Hanovia Inc.).

Nuclear magnetic resonance spectra were recorded on a Varian D.P.60. Melting points are uncorrected and were determined on a Kofler block.

Irradiation of Cyclopentene and Dimethyl Maleate

A solution of dimethyl maleate (25 ml) in cyclopentene (155 ml) was irradiated in apparatus (*a*) for 30 h. The adducts (b.p. 100–120° at 2 mm; 18 g) were separated from unreacted maleate, fumarate, and polymer by simple distillation. A portion of the mixture was chromatographed (20% Carbowax 20M at 205°, column 10 ft × 1/4 in., He flow 25 ml/min, retention time 43 min) to obtain the unsaturated isomer.

The mixture (23 g) in methylene chloride (100 ml) was ozonized at −70° until excess ozone was present. After removal of the solvent the residue was digested for 3 h with 15% hydrogen peroxide at 80°. The neutral material then was isolated in the usual way and distilled to give a mixture of saturated adducts (5.9 g). These were separated by repeated gas–liquid chromatography on 30% Carbowax 20M at 200°.

The estimated percentages of products (by calibration and integration) in the mixture are as follows (retention times in parentheses): (1) 64–65% (40 min); (2) 29–34% (45 min); (3) 2–5% (55 min); (4) 0.1–0.7% (59.5 min).

Hydrolysis and Characterization of the Cyclopentene Adducts

The unsaturated diacid (III) was obtained by refluxing the corresponding ester (I) (119 mg) in 5% aqueous KOH (1.5 ml) for 1 h 20 min. The hydrolysate was acidified with concentrated HCl and repeatedly extracted with chloroform. Evaporation of the dried solution gave 100 mg of crude acid. The residue was recrystallized 3 times from ethyl acetate – petrol giving material melting at 127–129°.

Calcd. for $C_9H_{12}O_4$: C, 58.69; H, 6.57. Found: C, 58.99; H, 6.59.

The diacid had no absorption maximum in the quartz ultraviolet, ϵ_{200}^{EtOH}, 4 870. The n.m.r. spectrum of the dimethyl ester (5% in CCl_4) showed the following bands: τ 8.32 (multiplet), τ 7.61 (multiplet), τ 7.15 (multiplet), τ 6.38 (singlet), and τ 4.33 (multiplet).

Diacid (IV) was obtained by heating the corresponding ester (2) (2.10 g) in 3 *N* NaOH (15 ml) under reflux for approximately 1 h. Acidification of the hydrolysate with concentrated HCl, followed by repeated extractions (approximately 20 times) with chloroform, yielded, after 1 recrystallization, an acid, m.p. 174.5–177° (1.26 g), which was raised to 175–177° on further recrystallization. Reesterification (diazomethane) gave an ester with identical retention time with the starting material, indicating that no inversion had taken place on hydrolysis.

Found: C, 59.16; H, 6.70.

The acid had no absorption maximum in the quartz ultraviolet, ϵ_{200}^{EtOH}, 140. The n.m.r. spectrum of the dimethyl ester (5% in CCl_4) showed the following bands: τ 8.35 (multiplet), τ 7.10 (multiplet), and τ 6.38 (singlet). Titration in carbon dioxide free water with *N*/10 sodium hydroxide gave pK_1 4.4, pK_2 5.7.

Diacid (V) was obtained by heating the corresponding ester (3) (357 mg) in aqueous 3 *N* NaOH (3.5 ml) under reflux for approximately 1 h. The hydrolysate was treated as previously and an acid (194 mg), m.p. 178–179.5°, was obtained after several recrystallizations.

Found: C, 58.80; H, 6.73.

The acid had no absorption maximum in the quartz ultraviolet (ϵ_{200}^{EtOH}, 167). The n.m.r. spectrum of the dimethyl ester (5% in CCl_4) showed the following bands: τ 8.35 (multiplet), τ 7.25 (multiplet), τ 7.01 (multiplet), and τ 6.44 (singlet). Titration in carbon dioxide free water with *N*/10 sodium hydroxide gave pK_1 4.6, pK_2 6.9.

Diacid (IV) also was obtained by heating the ester (4) (18 mg) in aqueous 3 *N* NaOH (0.5 ml) under reflux for 3 h. The hydrolysate was treated as previously and an acid (13 mg), m.p. 173–175°, was obtained after 4 recrystallizations from ethyl acetate – petrol. It was undepressed on admixture with the acid obtained from the hydrolysis of ester (2).

Treatment of Diacids IV and V with Acetic Anhydride

Diacid V (8.5 mg) was heated in redistilled acetic anhydride at 140° for 1 h in an 8 mm diameter pyrex tube equipped with a drying tube filled with anhydrous calcium chloride. Excess anhydride was removed under 1 to 4 mm pressure and the residue distilled for 1/2 h under water suction (cold trap, drying tube).

The white, crystalline distillate, m.p. 122.0–122.5°, possessed bands in the infrared (CCl_4) at 1 775 and 1 850 cm^{-1}. Hydrolysis of the anhydride by heating with a few drops of water yielded, after 1 recrystallization, a diacid (3.8 mg) with m.p. 174–176°, undepressed when mixed with V.

Diacid IV (9.6 mg), similarly treated with acetic anhydride, gave an anhydride with an infrared spectrum identical with that possessed by the anhydride from diacid V. Hydrolysis gave a diacid (2.9 mg), m.p. 172–174°, undepressed when mixed with compound V but depressed when mixed with diacid IV.

Irradiation of Cyclohexene and Diethyl Maleate

Diethyl maleate (25 ml) and cyclohexene (175 ml) were irradiated in apparatus (*b*) for 9 h. Cyclohexene was removed under reduced pressure and the residue distilled. The fraction boiling at 110–111° at 0.4 mm (12 g) was collected. The liquid was chromatographed on a 10 ft × 1/2 in., 20% diethylene glycol succinate (DEGS) column at 175° (He, 300 ml/min) and the following fractions were collected (retention times in parentheses): (1) (59 min); (2) (82 min); (3) (89 min); (4) (97 min).

In another experiment the fraction with b.p. 100–105° at 0.8 mm was collected and the fraction with retention time 21 min (15 ft × 3/8 in., 30% DEGS at 170°) was identified as bicyclohexenyl (n_D^{24} 1.5045). It had an infrared spectrum identical with that of an authentic specimen.

The unsaturated diacid (VII) was obtained by refluxing the ester (88 mg) corresponding to fraction 3 on the g.l.c. in 5% aqueous KOH (1 ml) for 4 h. The hydrolysate was acidified with concentrated HCl and extracted 10 times with chloroform. Evaporation of the dried chloroform extract yielded an acid (46 mg), m.p. 141–143° after 4 recrystallizations.

Calcd. for $C_{10}H_{14}O_4$: C, 60.59; H, 7.12. Found: C, 61.41; H, 7.01.

The acid had no absorption maximum in the quartz ultraviolet, ϵ_{200}^{EtOH}, 3 500. The n.m.r. of the diethyl ester (10% in CCl_4) showed bands at τ 8.75 (triplet), τ 8.4 (broad multiplet), τ 7.5 (multiplet), τ 5.88 (2 quartets), and τ 4.40 (multiplet).

Hydrogenation of the diacid (VII) (18 mg) over 10% PtO_2 (63 mg) in glacial acetic acid (5 ml) for 35 min (uptake of 1.06 moles H_2) gave cyclohexylsuccinic acid (13 mg), m.p. 143–145.5° after 1 recrystallization. The melting point was undepressed on admixture with an authentic specimen of m.p. 143–144° (15).

Irradiation of Cyclohexene and Dimethyl Maleate

Dimethyl maleate (n_D^{25} 1.4409) (25 ml) and cyclohexene (190 ml) were irradiated in apparatus (*b*) for 34 h. Cyclohexene was removed under reduced pressure and the residue distilled. The fraction boiling at 100–130° at 0.7 mm (16 g) was dissolved in CH_2Cl_2 (75 ml), and the solution ozonized at −70° (dry ice–acetone temperature) until a blue color due to excess ozone appeared and a negative test to tetranitromethane was obtained. The solvent was removed *in vacuo* and the residue was heated in a water bath at 90° in 15% aqueous H_2O_2 for 10 min. Extraction with $CHCl_3$, followed by distillation, gave 8 g of oil b.p. 106–118° at 0.7–0.8 mm. The n.m.r. spectrum of the oil (18% in CCl_4) showed no signal at τ 4.40. The adducts were separated preparatively by repeated g.l.c. (8 ft × 3/8 in., 30% Carbowax 20M and 10 ft × 3/8 in., 17% DEGS).

The estimated percentages of products and their retention times in parentheses are: (1) 14%, (63 min); (2) 5%, (66.5 min); (3) 70%, (77 min); (4) 10%, (85 min).

Hydrolysis of the Dimethyl Esters from Irradiation of Cyclohexene and Dimethyl Maleate

Diacid (VIII) was obtained by hydrolysis of a mixture of esters in fractions (1) and (2). Preparative g.l.c. poorly resolved the esters. By collecting only the first portion of the peak due the ester of acid VIII, a mixture, which was shown by analytical g.l.c. to contain 90% of the ester of VIII and 10% of the ester of IX, was obtained. The mixture (420 mg) was stirred overnight with 3 *N* NaOH (5 ml) at 35°. The hydrolysate was acidified with concentrated HCl and extracted repeatedly with chloroform. Evaporation of the dried chloroform extract and 2 recrystallizations from ethyl acetate–petrol yielded 174 mg of acid, m.p. 177–181°, raised to 181–182° on further crystallization.

Calcd. for $C_{10}H_{14}O_4$: C, 60.59; H, 7.12. Found: C, 60.93; H, 6.96.

The acid had no absorption maximum in the quartz ultraviolet, ϵ_{200}^{EtOH}, 154. The n.m.r. of the dimethyl ester (5% in CCl_4), showed bands at τ 8.35 (broad multiplet), τ 7.03 (broad multiplet), and τ 6.34 (singlet). Titration in carbon dioxide free water with 0.1 *N* NaOH gave pK_1 3.9, pK_2 5.8.

Diacid (IX) was obtained by chromatographing a mixture comprising acids VIII and IX over BDH silica gel. A mixture of the esters of acids VIII and IX (fractions (1) and (2)) was collected as a single peak on a DEGS column. The mixture (192 mg) was refluxed with 3 *N* aqueous NaOH (1.5 ml) for 1 h. Acidification of the hydrolysate, followed by the usual procedural steps, gave 130 mg of crude acid. The crude acid was chromatographed on 1 g of BDH silica gel. Elution with 85 ml benzene and 20 ml 2% ether–benzene gave, after 1 recrystallization from EtOAc–petrol, acid IX (14 mg), m.p. 198–201°, which was raised to 201–202° on further crystallization.

Found: C, 61.03, 7.14.

Diacid IX had no absorption maximum in the quartz ultraviolet, ϵ_{200}^{EtOH}, 280. Titration in carbon dioxide free water with 0.1 *N* NaOH gave pK_1 4.4, pK_2 5.9.

Diacid (X) was obtained by hydrolysis of the corresponding ester (fraction 3). The ester (580 mg) was

refluxed with 10% KOH for 2 h. Acidification of the hydrolysate, followed by the usual procedural steps, gave, after 2 recrystallizations, 164 mg of acid, m.p. 199–200°.

Found: C, 60.86; H, 7.41.

The melting point was depressed on admixture with acid IX. It had no absorption maximum in the quartz ultraviolet, ϵ_{200}^{EtOH}, 340. Titration in carbon dioxide free water with 0.1 *N* NaOH gave pK_1 3.6, pK_2 5.3. The n.m.r. of the dimethyl ester (5% in CCl_4) showed bands at τ 8.48 (multiplet), τ 7.53 (multiplet), τ 6.72 (approximate doublet), and τ 6.38 (singlet).

Diacid (XI) was obtained by refluxing the ester (200 mg) (fraction 4) with 3 *N* aqueous NaOH for 1 h. The usual procedure, followed by two recrystallizations, gave 84 mg of acid, m.p. 174–176°.

Found: C, 60.90; H, 7.10.

It had no absorption maximum in the quartz ultraviolet, ϵ_{200}^{EtOH}, 330. The n.m.r. showed bands at τ 8.57 (multiplet), τ 7.30 (multiplet), τ 7.04 (multiplet), and τ 6.40 (singlet). Titration in carbon dioxide free water with 0.1 *N* NaOH gave pK_1 4.7, pK_2 7.0.

Treatment of Diacids (VIII), (IX), (X), and (XI) with Acetic Anhydride

Diacid (VIII) (5.6 mg) was heated in redistilled acetic anhydride (0.3 ml) at 140° for 1 h in an 8 mm diameter tube equipped with a drying tube. Excess anhydride was removed under about 1 to 4 mm pressure and the residue distilled for 1/2 h under water suction (cold trap, drying tube). Hydrolysis of the oil (infrared bands at 1 775, 1 850 cm^{-1}) by heating with a few drops of water yielded after 2 recrystallizations, a diacid (XII), m.p. 150–155° (4.0 mg), whose m.p. was depressed when mixed with VIII. XII had end-absorption only in the quartz ultraviolet, ϵ_{200}^{EtOH}, 360. Titration in carbon dioxide free water with 0.1 *N* NaOH gave pK_1 4.2, pK_2 6.7.

Diacid (IX) (4.8 mg), similarly treated with acetic anhydride (0.3 ml), gave an anhydride with an infrared spectrum identical with that of the anhydride from diacid (VIII). Hydrolysis followed by 2 recrystallizations gave a diacid (1.0 mg), m.p. 153–155°. Its melting point was undepressed when mixed with XII, but was depressed when mixed with VIII and IX.

Diacid (X) (28 mg) on treatment with acetic anhydride (0.5 ml) gave an oil with infrared bands at 1 775 and 1 855 cm^{-1}. Hydrolysis of the oil, followed by 3 recrystallizations of the solid, yielded material melting at 172–173° (3.7 mg). The melting point was undepressed when mixed with XI but was depressed when mixed with X, the starting acid.

Diacid (XI) (6.5 mg) and acetic anhydride (0.3 ml) gave an anhydride with an infrared spectrum identical with that of the anhydride from X. Hydrolysis followed by 1 recrystallization afforded a diacid with m.p. 174–175°, identical with the melting point of XI, the starting acid.

Pyrolysis of the Dimethyl Esters of X and VIII

The dimethyl ester of X (22 mg), prepared by diazomethane esterification of the purified diacid, was sealed in a 10 mm diameter pyrex tube under a reduced pressure of between 1 to 4 mm. The sealed tube was heated in a sand bath at 400–410° for 10 min, cooled, and centrifuged. The products were estimated by g.l.c. (on 18 ft × 1/4 in., 10% DEGS column) and by the calibration of the response of the chromatographic apparatus with the following authentic compounds: dimethyl succinate (0.1 mg), dimethyl fumarate (0.1 mg), unchanged dimethyl ester of X (8.3 mg). Cyclohexene also was detected and identified by retention time (g.l.c.) and infrared spectrum. In a separate experiment starting with 68 mg of the dimethyl ester of X, dimethyl fumarate and succinate were isolated by g.l.c. and identified by comparison of their infrared spectra with authentic specimens. At higher temperatures 410–420° (17 min) of pyrolysis, only succinate is observed and no fumarate was detected.

Cyclohexene (24 mg) and dimethyl fumarate (31 mg) were heated in a sealed tube at 410–415° for 10 min, the tube having been sealed at −70° *in vacuo*. Chromatography of the product (25 ft × 1/4 in., 10% DEGS at 167°, He, 40 p.s.i.) permitted the isolation of dimethyl fumarate and dimethyl succinate (identified by retention time and infrared spectra).

The dimethyl ester of VIII (51 mg), prepared by repeated g.l.c. (8 ft × 3/8 in., 30% Carbowax 20M at 200°), was sealed in a 10 mm diameter pyrex tubing under a reduced pressure of between 1 to 4 mm. The sealed tube was heated at 400–410° for 10 min. The pyrolysis was repeated using 53 mg of ester. The combined pyrolyzates were distilled at 0.1 mm to separate the liquid pyrolyzates from tar. The distillate (62 mg) was hydrogenated overnight in ethyl acetate using 5% palladium on charcoal (32 mg) as catalyst. A liquid (3 mg) having the same retention time (35 min on 5 ft × 1/4 in., 20% Ucon Polar, 200°, He flow 67 ml per min) and infrared spectrum as that of dimethyl sebacate was isolated by g.l.c. The refluxing of the ester with 12% aqueous NaOH (0.4 ml) for 1 h, followed by repeated extraction with chloroform, the drying of the chloroform layer, and the evaporation of the solvent afforded, after 2 recrystallizations from ethyl acetate – benzene – petrol, a diacid (1.5 mg, m.p. 129–132°) whose melting point was undepressed when mixed with sebacic acid. Pyrolysis of the dimethyl ester of VIII was observed to occur as low as 340–350°.

Permanganate Oxidation of X

X (726 mg) was stirred overnight at room temperature with $KMnO_4$ (1.5 g), water (4 ml), and acetone (4 ml) in a flask equipped with a reflux condenser to prevent evaporation of solvent. Solvent was removed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

under reduced pressures and the residue esterified with diazomethane. Chromatography of the esterified residue (on 18 ft × 1/4 in., 10% DEGS at 200°) revealed a peak which corresponded to *cis*-cyclohexane-1,2-dicarboxylate and revealed no trace of the *trans* isomer which preceded, and was clearly resolved from, the *cis* isomer. The peak corresponding to the *cis* isomer was isolated by g.l.c. and possessed an infrared spectrum indentical with that of an authentic specimen of the ester. Hydrolysis of the oil (3.5 mg) in 5% KOH (0.2 ml) at room temperature overnight, followed by the usual procedure, yielded a small quantity of crystals melting at 189–189.5°. The melting point was undepressed when mixed with an authentic sample of *cis*-1,2-cyclohexane dicarboxylic acid. The products were analyzed by g.l.c. by calibrating the response with each ester: dimethyl ester of X (204 mg), dimethyl *cis*-cyclohexane-1,2-dicarboxylate (3.5 mg), dimethyl adipate (approximately 10 mg), dimethyl glutarate (4 mg), and dimethyl succinate (4 mg). As little as 0.005 mg of the *trans* ester would have been detectable.

CONTRIBUTION A L'ÉTUDE STRUCTURALE DU CÉDRÉLANOL (δ-CADINOL), ALCOOL SESQUITERPÉNIQUE $C_{15}H_{26}O$ DE L'HUILE ESSENTIELLE CEDRELA ODORATA BRASILIENSIS

R. R. SMOLDERS

Service de Chimie Organique Générale et Analytique, Institut des Industries de Fermentation, Institut Meurice Chimie (CERIA), Bruxelles, Belgique

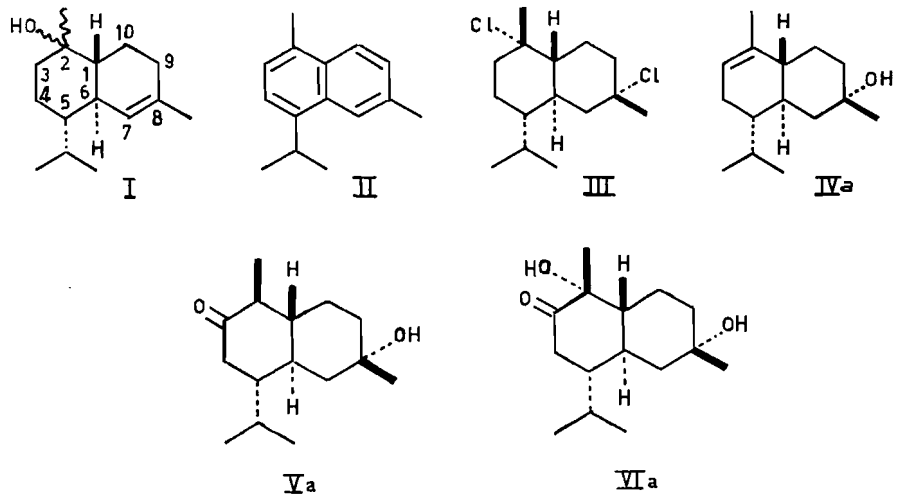
Reçu le 16 juin 1964

RÉSUMÉ

Le cédrélanol, alcool sesquiterpénique $C_{15}H_{26}O$ de l'huile essentielle *Cedrela odorata brasiliensis*, est identique aux (−)-δ-cadinol, pilgérol, albicaulol et alga cadinol. Il est, en outre, l'antipode optique du (+)-δ-cadinol, du sesquigoyol et du torreyol. Dans le présent travail, la structure proposée pour l'albicaulol par Dauben, Weinstein, Lim et Anderson, celle du Δ³-2,8-diméthyl-5-isopropyl-bicyclo-[0,4,4]-décèn-8-ol, est confirmée, mais la configuration de l'hydroxyle s'avère équatoriale plutôt qu'axiale. Dès lors, la configuration absolue du cédrélanol est celle indiquée par IV*b*.

Le cédrélanol, alcool sesquiterpénique $C_{15}H_{26}O$, p.f. 139–140°, $[\alpha]_D^{23}$ −106 ($CHCl_3$), a été isolé de l'huile essentielle *Cedrela odorata brasiliensis* et décrit depuis 1961 (1). Il est identique aux (−)-δ-cadinol, pilgérol, albicaulol et alga cadinol (1–4). D'autre part, (+)-δ-cadinol, torreyol et sesquigoyol sont trois noms désignant l'antipode optique du précédent (4, 5, 6).

La structure I du cédrélanol fut proposée sur la base d'une étude hâtive en résonance magnétique nucléaire (7) et de la conversion du composé (1) en cadalène II et en (−)-dichlorhydrate du cadinène dont la configuration absolue III est désormais connue (8).

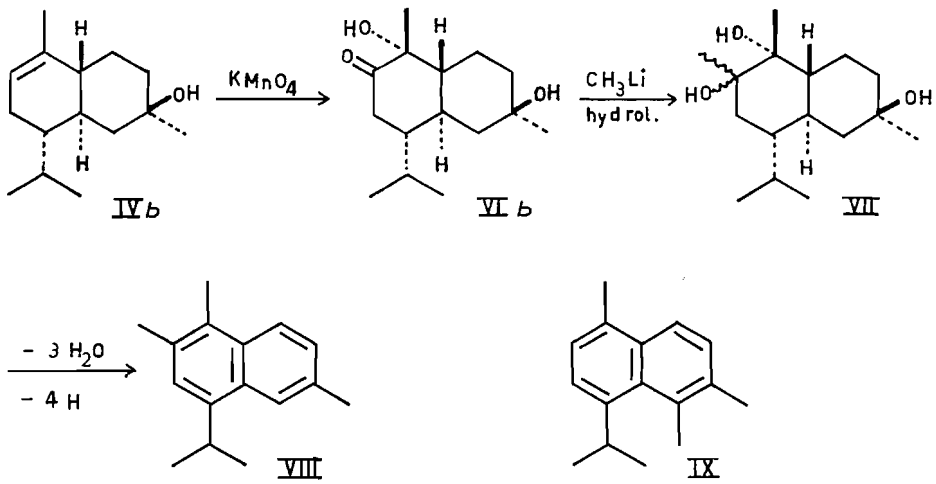


Dauben, Weinstein, Lim et Anderson (3) formulèrent IV*a* pour l'albicaulol au travers d'une étude attentive du spectre de résonance magnétique nucléaire du cadinol et de l'attribution, par dispersion rotatoire, des structures V*a* et VI*a* aux cétones dérivant du produit naturel par la transformation adéquate de la double liaison. Dans les formules IV*a*, V*a* et VI*a*, la configuration axiale de l'hydroxyle en C_8 était déduite de la résistance de IV*a* à l'estérification, tout comme l'avaient suggéré les chercheurs tchèques (2).

Quelques transformations chimiques du cédrélanol confirment la localisation de la double liaison en Δ^2 et, partant, celle de la fonction alcool en C_8 mais infirment le caractère axial de l'hydroxyle.

Une tentative de méthylation du carbone tertiaire de la double liaison du cédrélanol (désormais IV*b*), par action de l'iodure de méthylmagnésium sur l'époxycédrélanol, ayant échoué (9), nous nous sommes tourné vers la dihydroxycétone VI*b*, p.f. 140–141° (VI*a*, p.f. 143–144° selon (3)), $\nu_{C=O}$ 1 689 cm^{-1}. Il est surprenant d'observer, d'une part, que le spectre infrarouge de VI*b* est dépourvu de la bande d'absorption caractéristique des méthylènes voisins du carbonyle (10) dans la région sise entre 1 435 et 1 405 cm^{-1} et, d'autre part, que ce cétodiol présente un test de Zimmermann (11, 12) (cétone méthylénique, *m*-dinitrobenzène, alcali) négatif, encore que des exceptions notoires à ce test coloré soient connues, les 6-, 7- et 12-oxostéroides notamment (cf. (12) et les références y citées). Ces faits eussent plaidé en faveur de la structure I du cédrélanol.

L'action du méthyllithium sur VI*b*, suivie d'hydrolyse, conduit au méthylcédrélanetriol VII $C_{16}H_{30}O_3$, p.f. 180°, qui, déshydraté par le couple d'acides acétique et perchlorique, puis déshydrogéné par le soufre, fournit le méthylcadalène VIII (picrate, p.f. 140°; lit. p.f. 142.5–143° (13), 140–140.5°, 143–144° (14)).



Un dérivé de référence du picrate de VIII ne nous a malheureusement pas été accessible pour effectuer l'épreuve de mélange. L'ensemble de ces résultats permet cependant de localiser, sans ambiguité, la double liaison en Δ^2 puisque I, au cours de la transformation effectuée, aurait conduit à l'aromatique IX dont le picrate (p.f. 102.5–103.5° (15), 103–104° (16)) est nettement distinct de celui de VIII.

D'autres expériences montrent le caractère équatorial de l'hydroxyle en C_8 et sont en accord avec IV*b*.

Le dihydrocédrélanol X (mélange des épimères en C_2), p.f. 65–68.5° $[\alpha]_D^{23}$ −38.1 (pyridine), est déshydraté ($SOCl_2$) en l'oléfine méthénique XI $C_{15}H_{26}$, $[\alpha]_D^{23}$ −14.3 (*n*-hexane), infrarouge 890, 1 646 et 3 080 cm^{-1}. Sachant qu'un tel comportement est l'apanage des 1-méthylcyclanols tertiaires dont l'hydroxyle est équatorial (17), la configuration absolue du cédrélanol est celle indiquée par IV*b*.

XI, après osmylation et traitement à l'hydrogène sulfuré, fournit le diol XII $C_{15}H_{26}O_2$, p.f. 110–120°, qui, via l'oxydation periodique, conduit à la cétone liquide XIII $C_{14}H_{24}O$,

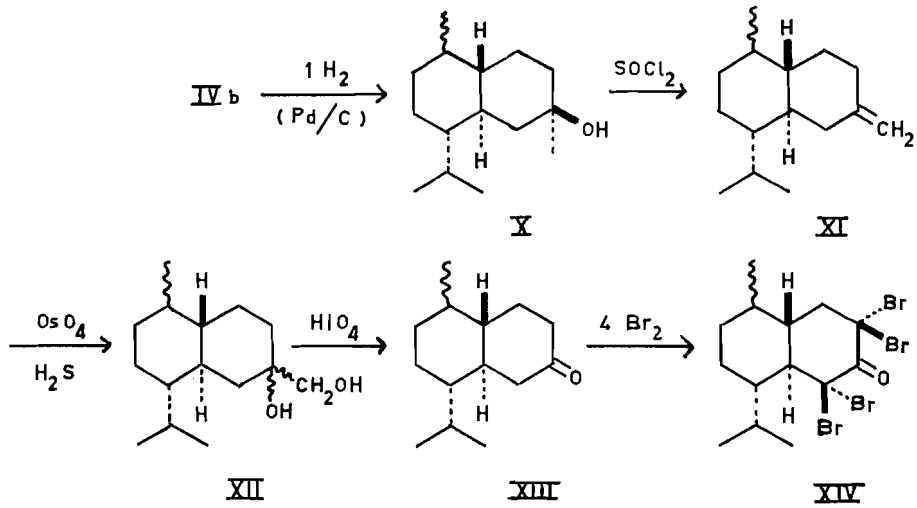
$[\alpha]_D^{22}$ −29.6 (éther isopropylique), infrarouge $\nu_{C=O}$ 1 715 cm^{-1}. Cette cétone renferme quatre hydrogènes en α et α' du carbonyle comme le montre l'expérience de bromuration comparative suivante.



On a mis à réagir, séparément et à l'obscurité, la cétone XIII, la cyclohexanone, la cycloheptanone et la 2-méthylcyclohexanone à raison de 3.6×10^{-2} mole/l, dans un mélange de brome (4.5×10^{-1} mole/l) et d'une solution quasi-saturée d'acide trichloracétique dans le tétrachlorure de carbone. La bromuration, initiée à 40°, a été poursuivie à 50°. Le brome non consommé a été dosé, blanc à l'appui, à des intervalles de temps appropriés. La consommation de 4 équivalents de brome par mole de cétone est compatible avec la structure XIV et permet, une fois de plus, le rejet formel de I. Le déroulement de la bromuration est résumé dans le Tableau I. Une confirmation de la structure XIII par la conversion de cette cétone en 1-méthyl-4-isopropylnaphtalène sera rapportée ultérieurement.

TABLEAU I

Bromuration des carbones voisins du carbonyle

	Equivalents de brome consommés, par mole de cétone, au cours du temps:			
Cétone mise en oeuvre	20 h à 40°	70 h à 40°	70 h à 40° + 65 h à 50°	70 h à 40° +130 h à 50°
Cyclohexanone	3.59	3.61	3.81	3.91
XIII	2.22	2.78	3.49	3.82
Cycloheptanone	3.16	3.29	3.47	3.83
2-méthyl cyclohexanone	2.78	2.82	2.90	2.93

PARTIE EXPÉRIMENTALE

L'huile essentielle *Cedrela odorata brasiliensis* utilisée dans le présent travail provient de la Dierberger Oleos Essencias, Sao-Paulo, Brésil.

Les températures de fusion (F) ne sont pas corrigées.

Les spectres infrarouges de la quasi-totalité des produits manipulés ont été relevés en film mince pour les liquides et en pastille de bromure de potassium pour les solides, à l'aide d'un spectrographe Hilger H800 et (ou) d'un infracord Perkin–Elmer à double réseau, modèle 237B. Dans tous les cas, les valeurs des fréquences observées étaient en accord avec celles tabulées en (10) et (18).

Isolement du cédrélanol

L'huile brute (1 310 g) est tout d'abord débarassée de ses acides par la voie habituelle puis, par la distillation, démunie de ses matières les plus volatiles. Le résidu (171 g), à point d'ébullition supérieur à 70° sous 0.05 mm Hg, est une huile visqueuse et brunâtre que l'on chromatographie sur alumine neutre d'activité II (2 700 g). Après l'élution préliminaire à la ligroine et au tétrachlorure de carbone, le trichloréthylène, le benzène et l'éther, purs ou en mélange, ont désorbé une série de fractions cristallines qui, recristallisées dans l'isooctane ou, mieux, dans l'acétonitrile, fournissent le cédrélanol pur (5.5 g), aisément sublimable sous dépression; pf.. 139–140°, $[\alpha]_D^{23}$ −106 ($CHCl_3$).

Anal. Calc. pour $C_{15}H_{26}O$: C, 81.04; H, 11.73. Trouvé: C, 80.84; H, 11.68.

Méthylcédrélanetriol VII à partir de la dihydroxycétone VIb

Sous atmosphère d'azote, on met en présence le lithium (200 mg), coupé en parcelles menues, et l'éther éthylique anhydre (20 ml). A −10°, on y fait barboter du bromure de méthyle sec entraîné par un courant d'azote. Après 1 h de ce traitement, le lithium disparait et fait place à une suspension laiteuse à laquelle on ajoute, toujours sous refroidissement, une solution de VI*b* (525 mg) dans l'éther éthylique anhydre (20 ml). Successivement, on abandonne la préparation à la température ambiante durant 4 h 30 min, chauffe à reflux d'éther durant 2 h 30 min puis laisse séjourner le milieu réactionnel à la température ordinaire pendant 9 h. On additionne ensuite de l'éther saturé d'eau, de la glace puis de l'acide chlorhydrique dilué à 5% et glacé. La phase organique, séchée sur carbonate de potasse anhydre, est filtrée, portée à l'ébullition en présence d'une pincée de charbon actif et filtrée une seconde fois. Le filtrat, après évaporation, fournit le triol VII (551 mg), p.f. 180°, dépourvu d'absorption du carbonyle dans l'infrarouge.

Anal. Calc. pour $C_{16}H_{30}O_3$: C, 71.06; H, 11.18; O, 17.75. Trouvé: C, 71.05; H, 11.16; O, 17.79.

Déshydratation du triol VII et déshydrogénation subséquente

Le triol VII (535 mg) est dissout dans l'acide acétique glacial (6.2 ml) puis additionné de 5 gouttes d'acide perchlorique à 70%. La solution est chauffée au bain-marie bouillant durant 2 h 30 min, refroidie, diluée par l'eau (80 ml) et extraite par l'éther. La phase éthérée est lavée au bicarbonate dilué, séchée sur carbonate de potassium anhydre, filtrée et évaporée Il reste alors une huile jaune (423 mg) dont l'infrarouge montre la nature hydrocarbonée. Ce matériau brut est déshydrogéné durant 6 h 30 min entre 240 et 250°, par le soufre (143 mg). Le produit de réaction, mélangé à de l'alumine standard (1 g), est chromatographié sur le même adsorbant (8 g). En éluant par le *n*-hexane, on obtient 3 fractions: f(i) 16 mg (40 ml); f(ii) 14.5 mg (42 ml); f(iii) 3.2 mg (47 ml). Le picrate brut de f(ii) (EtOH, 1 ml; acide picrique 15 mg) fond entre 134 et 137°. Une recristallisation dans l'alcool absolu amène ce dérivé (16.5 mg) à fondre à 139°. Une deuxième recristallisation identique laisse un magma d'aiguilles oranges (12 mg) fondant à 140°.

Oléfine méthénique XI à partir du dihydrocédrélanol X

Le dihydrocédrélanol (3.20 g), p.f. 65–68.5°, $[\alpha]_D^{22}$ −38.1 (pyridine), est dissout dans la pyridine anhydre (26 ml) et refroidi à −15°. Une solution de chlorure de thionyle (4.2 ml) dans la pyridine anhydre (16 ml), refroidie à −10°, lui est ajoutée, par portions, de façon à maintenir le milieu entre −10 et −15°. L'ensemble maintenu d'abord durant 50 min dans cette zone de température, est progressivement réchauffé à 0° (50 min) avant d'être versé sur la glace et extrait par l'éther. La solution organique, lavée plusieurs fois à l'acide tartrique dilué (6%), est séchée sur du sulfate de magnésium anhydre et évaporée. Le résidu, chromatographié sur de l'alumine neutre d'activité II (60 g), fournit, par élution au *n*-hexane, l'oléfine liquide XI (2.94 g) $C_{15}H_{26}$, $[\alpha]_D^{23}$ −14.3 (*n*-hexane).

Anal. Calc. pour $C_{15}H_{26}$: C, 87.30; H, 12.70. Trouvé: C, 87.0; H, 13.0.

Diol XII à partir de l'oléfine XI (inspiré de (19))

A une solution de XI (2.80 g) dans le dioxanne sec (5 ml), on ajoute de la pyridine anhydre (0.5 ml) et une solution de tétroxyde d'osmium (5.20 g) dans le même éther (75 ml). Le milieu réactionnel séjourne 75 h à l'obscurité puis est traité par l'hydrogène sulfuré, filtré et évaporé. Les cristaux bruts obtenus (3.37 g) sont recristallisés, par deux fois, dans l'acétonitrile. Il reste alors 1.67 g de diol XII, p.f. 110–120°.

Anal. Calc. pour $C_{15}H_{26}O_2$: C, 74.95; H, 11.74; O, 13.31. Trouvé: C, 75.18; H, 11.60; O, 13.16.

Cétone XIII à partir du glycol XII (inspiré de (19))

A XII (0.254 g), dissout dans le dioxanne (21.5 ml), on additionne une solution aqueuse (5.2 ml) d'acide paraperiodique (0.648 g). Après un contact de 20 h, une large part du solvant est éliminé à 0°, sous dépression. Le reliquat, dilué par l'eau, est extrait à l'éther. L'extrait est séché au sulfate de magnésium anhydre, filtré puis évaporé. Le résidu, repris dans le *n*-pentane (4 ml), est chromatographié sur alumine standard (5.4 g) et livre, par élution au même solvant (70 ml), la cétone XIII (0.158 g), $[\alpha]_D^{23}$ −29.6 (éther isopropylique).

Anal. Calc. pour $C_{14}H_{24}O$: C, 80.71; H, 11.61; O, 7.68. Trouvé: C, 80.10; H, 12.10; O, 7.73.

Bromuration comparative de la cétone XIII

On dilue, jusqu'à 100 ml, 7.5 g de brome par une solution quasi-saturée d'acide trichloroacétique dans le tétrachlorure de carbone. A l'aide de ce mélange, on porte à 10 ml les quatre cétones suivantes: XIII (74.37 mg), cyclohexanone (35.32 mg), cycloheptanone (40.40 mg) et 2-méthylcyclohexanone (40.37 mg).

For personal use only.

En plus d'un blanc, on chauffe ces échantillons, à l'obscurité, durant 70 h à 40° et 130 h à 50°. A des intervalles de temps appropriés, on effectue, au sein de prises de 1 ml, le dosage iodométrique du brome non consommé. Les résultats observés ont été consignés dans le Tableau I.

REMERCIEMENTS

L'auteur est heureux d'exprimer sa profonde gratitude à Messieurs G. Chiltz et J. M. Piérard, Directeur et Sous-Directeur de l'Institut des Industries de Fermentation – Institut Meurice Chimie, des larges facilités de recherches qu'ils n'ont cessé de lui accorder tout au long de ce travail.

Il remercie également le Docteur A. Toussaint des discussions fructueuses échangées durant le présent mémoire.

SUBSTITUTED METHANES

PART XXXVI. CALCULATED WAVE NUMBERS, ASSIGNMENTS, AND THERMODYNAMIC PROPERTIES FOR CH_2DI AND CD_2HI, AND CALCULATED ROTATIONAL DISTORTION CONSTANTS AND MEAN AMPLITUDES FOR CH_3I AND CD_3I[1]

EARLE F. DITZEL,[2] ARNOLD G. MEISTER,[3] EDWARD A. PIOTROWSKI, FORREST F. CLEVELAND, Y. ANANTARAMA SARMA, AND S. SUNDARAM

Spectroscopy Laboratory,[4] Department of Physics, Illinois Institute of Technology, Chicago, Illinois

Received July 13, 1964

ABSTRACT

A set of potential energy constants has been obtained for CH_3I and CD_3I from their vibrational spectral data. From these constants, the rotational distortion constants and the mean amplitudes have been calculated for these two molecules. The rotational distortion constants D_J, D_{JK}, and D_K were, respectively, CH_3I, 6.34, 59.36, and 3 542.30; CD_3I, 3.90, 33.08, and 866.43 kc/s. The principal mean amplitudes of vibration in pm (pm = picometer = 10^{-12} meter = 10^{-2} Å) at 298.16 °K are CH_3I, 5.25 (C—I), 7.71 (C—H), 12.37 (H · · · H), and 12.00 (H · · · I); CD_3I, 5.14 (C—I), 6.63 (C—D), 10.85 (D · · · D), and 10.65 (D · · · I). The potential energy constants were used to obtain the wave numbers of CH_2DI and CD_2HI. A complete assignment of the observed wave numbers for the molecules CH_2DI and CD_2HI has been made. The fundamental wave numbers for the gaseous state of CH_2DI are a', 2 980, 2 235, 1 418, 1 170, 723, and 519; a'', 3 091, 1 266, and 871 cycles/cm. For CD_2HI, the corresponding values are a', 3 017, 2 174, 1 185, 1 009, 757, and 508; a'', 2 273, 1 279, and 676. With these wave numbers, the thermodynamic functions have been calculated for the two molecules for 12 temperatures from 100 to 1 000 °K for 1 atm pressure. The values of $(H^0 - E_0^0)/T$, $-(F^0 - E_0^0)/T$, S^0, and C_p^0 at 298.16 °K are, respectively, CH_2DI, 8.82, 54.66, 63.48, and 10.98; CD_2HI, 9.00, 55.20, 64.19, and 11.53 cal deg^{-1} mole^{-1}.

INTRODUCTION

Fenlon *et al.* (1) determined the potential energy constants of CH_3I from observed vibrational spectral data. The set of F's thus obtained when transferred to the isotopic molecule CD_3I gives an agreement between the observed and calculated wave numbers to within 2.24%. Transferability of the potential energy constants to isotopic molecules is one of the most important criteria for establishing the validity of the potential energy constants. Therefore it was necessary to redetermine the potential energy constants for CH_3I to satisfy the above criterion better than in the previous study (1).

The purpose of the present investigation is to obtain a set of potential energy constants for CH_3I and CD_3I which will not only reproduce the observed wave numbers, but also yield rotational distortion constants and mean amplitudes of vibration that agree with experimental values for these quantities. This is a better procedure, since the set of F's thus obtained would then have satisfied these additional criteria also.

Courtoy (2) and De Hemptinne and Doehaerd (3) have obtained the spectra for CH_2DI and CD_2HI, the other isotopic molecules in this series of iodomethanes. It was therefore the other main aim of this study to calculate the f's from the F's for CH_3I and CD_3I by the systematic procedure of Gold *et al.* (4) and to use these f's to calculate the wave numbers of the isotopic molecules CH_2DI and CD_2HI to facilitate the assignments of their spectral data (2, 3). This procedure made possible not only a complete analysis of

[1] *For previous papers in this series, see Spectroscopia Mol. 13, 56 (1964).*
[2] *Present address: Naval Research Laboratory, Code 5210, Washington 25, D.C.*
[3] *Present address: Physics Department, Arizona State University, Tempe, Arizona.*
[4] *Publication No. 183.*

the spectral data for CH_2DI and CD_2HI but also the establishment of the fundamentals and hence of the numerical values of the thermodynamic properties for these two molecules.

MOLECULAR CONSTANTS FOR CH_3I AND CD_3I

Using the previously tabulated values of the observed wave numbers (1), and the Wilson **FG** matrix method, the symmetrized F's were redetermined for CH_3I and CD_3I. The maximum difference between the calculated and observed wave numbers is 0.97% for CH_3I and 1.40% for CD_3I. The internuclear distances used in the calculations are 109.3 pm (1.093 Å) for C—H and C—D and 213.9 pm for C—I.

The set of F's thus obtained were then used to calculate the rotational distortion constants D_J, D_{JK}, and D_K by the method given by Dowling *et al.* (5). Previously, Chang (6) had calculated the constants D_J and D_{JK} for CH_3I, and observed values had been obtained by several investigators (7–9) for CH_3I and by Simmons (10) for CD_3I. The calculated and observed values are compared in Table I.

TABLE I

Rotational distortion constants for CH_3I and CD_3I*†

	CH_3I					CD_3I	
	Calculated		Observed			Calculated	Observed
D	P	C	J	SA	O-T	P	S
D_J	6.34	6.39	7.95	7.95	6.28	3.90	3.57
D_{JK}	59.36	88.70	99.40	99.40	98.50	33.08	48.30
D_K	3 542.30	—	—	—	—	866.43	—

*D = rotational distortion constant; P = present results; C = Chang, ref. 6; J = Johnson *et al.*, ref. 8; SA = Simmons and Anderson, ref. 7; O-T = Orville-Thomas *et al.*, ref. 9; and S = Simmons, ref. 10.
†All of the rotational distortion constants are in kc/s.

While the calculated values of D_J are in reasonable agreement with the observed values, the values of D_{JK} are somewhat smaller than the observed values. These differences may perhaps be due to the neglect of the anharmonicity, which would be rather large for these molecules and which would be different for the two molecules. Since the F's were adjusted to give the best agreement between the observed and calculated wave numbers of both molecules, the effect of differing anharmonicities could have produced some deviation of the calculated distortion constants from the observed values for each of the molecules. Further, the magnitudes of these quantities are such that maximum accuracy is not possible in evaluating them from experimental measurements.

The F's were then used to determine the mean square amplitudes of vibration for CH_3I and CD_3I. In terms of the potential energy matrix **F**, the mean square amplitude matrix **Σ** is given by (11)

$$|\mathbf{\Sigma F} - \mathbf{E\Delta\lambda}| = 0,$$

where **E** is the unit matrix and **Δ** and **λ** are related to the wave number σ by the expressions

$$\Delta_i = (h/8\pi^2 c\sigma_i) \coth (hc\sigma_i/2kT)$$

and

$$\lambda_i = 4\pi^2 c^2 \sigma_i^2,$$

where Δ_i and λ_i are the matrix elements corresponding to the ith fundamental vibrational mode, h is Planck's constant, k is Boltzmann's constant, and T is the temperature in degrees Kelvin.

By means of the potential energy constants, the matrix elements $\sum_{ij}$ and therefore the principal mean amplitude quantities for the various internuclear distances were computed for CH_3I and CD_3I. The calculations were made for 298.16 °K and the results are summarized in Table II. There are at present no experimental values for comparison. However, the values reported here should be useful in the analysis of future electron diffraction investigations on these molecules.

TABLE II

Mean amplitudes of vibrations in pm*

CH_3I		CD_3I	
C—H	7.71	C—D	6.63
C—I	5.25	C—I	5.14
H · · · H	12.37	D · · · D	10.85
H · · · I	12.00	D · · · I	10.65

*These calculated values correspond to 298.16 °K; pm = picometer = 10^{-12} meter = 10^{-2} Å.

A consistent set of f's was then obtained from the relation $\mathbf{f} = \tilde{\mathbf{U}}\mathbf{F}\mathbf{U}$ (4) and the values are listed in Table III, and the observed and calculated wave numbers for CH_3I and CD_3I are given in Table IV.

TABLE III

Potential energy constants for CH_3I, CH_2DI, CD_2HI, and CD_3I*

md/Å		md/rad		md Å/rad²	
f_i	2.27665†	f_i^{hh}	−0.06464	f_{hh}	0.45151
f_h	5.07113	f_i^{hi}	0.06464	f_{hi}	0.45672
f_h^h	−0.05060	f_h^{hh}	0.03792	f_{hh}^{hi}	−0.07609
f_h^i	0.06351	$f_h^{hh'}$	−0.28414	$f_{hh}^{h'i}$	−0.09076
		f_h^{hi}	0.21563	$f_{hh}^{hh'}$	−0.10429
		$f_h^{h'i}$	−0.00367	$f_{hi}^{h'i}$	−0.10689

*The potential energy constants are expressed in the descriptive notation of Davis, Cleveland, and Meister (J. Chem. Phys. 20, 454 (1952)): i = C—I, h = C—H or C—D, hh = H—C—H or D—C—D or H—C—D, hi = H—C—I or D—C—I, and h and h' represent different C—H or C—D bonds; md = millidyne; rad = radian.

†This number of significant figures is not justifiable by the accuracy of the experimental data but is needed to obtain the best reproduction of the observed wave numbers and to secure internal consistency in calculations.

THE INHIBITION OF AUTOXIDATION BY 2,4,6-TRI-*tert*-BUTYL SUBSTITUTED PHENOL, ANILINE, AND THIOPHENOL[1]

D. V. GARDNER,[2] J. A. HOWARD, AND K. U. INGOLD
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received August 11, 1964

ABSTRACT

The reactions of peroxy radicals with 2,4,6-tri-*t*-butyl substituted phenol, aniline, and thiophenol have been examined by a kinetic method. The primary process involves abstraction of the hydrogen atom attached to the functional group, since all three compounds show fairly large isotope effects when this hydrogen is replaced by deuterium. The phenol and aniline react with about two peroxy radicals per molecule. In contrast, the thiophenol reacts with only a single peroxy radical.

The present work was undertaken because of the absence of reliable data on the rates and mechanism of the reaction of peroxy radicals with anilines and thiophenols. The reaction of phenols with peroxy radicals, i.e.,

[6]* $$RO_2\cdot + AH \rightarrow ROOH + A\cdot$$

[7] $$RO_2\cdot + A\cdot \rightarrow ROOA,$$

is now fairly well understood (1, 2, 3), but there is no comparable information regarding anilines and thiophenols. In particular, there is still disagreement in the literature as to whether or not amine-inhibited oxidations show any deuterium isotope effect when the amino hydrogen is replaced by deuterium. That is, there is disagreement as to whether or not the rate-controlling step for inhibition by amines involves reaction [6] (see refs. 1 and 4 for a discussion of the literature on amine inhibition). The reaction of thiophenols with peroxy radicals has not been studied previously.

The 2,4,6-tri-*t*-butyl derivatives of phenol, aniline, and thiophenol were chosen for study with the hope that steric protection of the reaction center would prevent chain transfer reactions between the inhibitor radical (A·) and the substrate,

[8] $$A\cdot + RH \rightarrow AH + R\cdot$$

or its oxidation product,

[−6] $$A\cdot + ROOH \rightarrow AH + RO_2\cdot.$$

Suppression of these reactions when A· is a phenoxy radical by a suitable choice of substrate (1, 2) or by steric protection of the hydroxyl group (3) greatly simplifies the kinetics of the inhibition process (3). Unfortunately, it was found that oxidations inhibited by the hindered amine and thiophenol did not follow the same simple kinetics as oxidations inhibited by the phenol.

The experimental technique has been described previously (1, 2, 3). α,α' Azo-bis-isobutyronitrile (AIBN) was used as the initiator, with styrene, tetralin, and cumene as the oxidizable substrates. The 2,4,6-tri-*t*-butylaniline was a gift from the E. I. du Pont Company and the 2,4,6-tri-*t*-butylthiophenol was prepared by the method of Rundel (5). Deuterium isotope effects were obtained from the ratio of the inhibited rates in the presence

of H_2O and D_2O (1, 2, 3). In no case did the added H_2O have any significant effect on the inhibited rate. All the work reported here was done at 65 °C.

The inhibited rates under standard conditions are given in Table I. These rates were not affected by a change in the oxygen pressure from 760 to 400 mm.

TABLE I

Oxidation rates at 65 °C in mole/l s $\times 10^7$ with 4.9×10^{-4} mole/l [AIBN]

Inhibitor	Styrene	Tetralin
None	135	44
Tri-*t*-butylphenol (1×10^{-4} mole/l)	62	2.2
Tri-*t*-butylaniline (1×10^{-3} mole/l)	46	14.5
Tri-*t*-butylthiophenol (1×10^{-4} mole/l)	145	6.2

Styrene

The kinetics for the inhibition of styrene autoxidation by 2,4,6-tri-*t*-butylphenol have been described previously (2). Over a wide range of reactant concentrations, the rate of the inhibited oxidation can be represented by (2)

$$[1] \qquad P\alpha \frac{[RH][I_2]}{[AH]},$$

where RH represents the styrene, I_2 the initiator, and AH the phenol. The inhibited rates in the presence of H_2O and D_2O gave a deuterium isotope effect $P_{D_2O}/P_{H_2O} = 10.5$, i.e., $(k_6)_{AH}/(k_6)_{AD} = 10.5$.

The rate for inhibition by the hindered aniline can be represented by

$$P\alpha \frac{[RH]^{1.28}[I_2]^{0.59}}{[AH]^{0.64}}$$

over a concentration range for I_2 of 10^{-4} to 10^{-2} mole/l and for AH of 10^{-3} to 2×10^{-2} mole/l. The kinetic order in styrene was determined by its dilution from 50% to 10% by volume with *o*-dichlorobenzene. Although the oxygen absorption curves do show a very slight auto-acceleration, the rate under the standard conditions was unaffected by the addition of 6×10^{-2} mole/l of styrene polyperoxide. Within the limits of experimental error, the above expression is equivalent to

$$P\alpha \frac{[RH]^{1.5}[I_2]^{0.5}}{[AH]^{0.5}},$$

which is the simplified kinetic relation describing inhibition with extensive chain transfer to the substrate (reaction [8] (3, 6)). Unfortunately, the relative rates of hydrogen-atom abstraction from the aniline and the phenol (i.e. the k_6's) cannot be compared because of the different kinetics exhibited by these two compounds. The measured deuterium isotope effect was 117/38 = 3.08 (see Fig. 1). Assuming that P is proportional to [aniline]$^{-1/2}$ then $(k_6)_{AH}/(k_6)_{AD} = (3.08)^2 = 9.5$ (3). The magnitude of the isotope effect for reaction [6] has almost certainly been overestimated since the measured order in [AH] was actually -0.64. Using this order rather than -0.5, we obtain $(k_6)_{AH}/(k_6)_{AD} = 5.8$.

The hindered thiophenol catalyzes the oxidation of styrene both in the presence and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

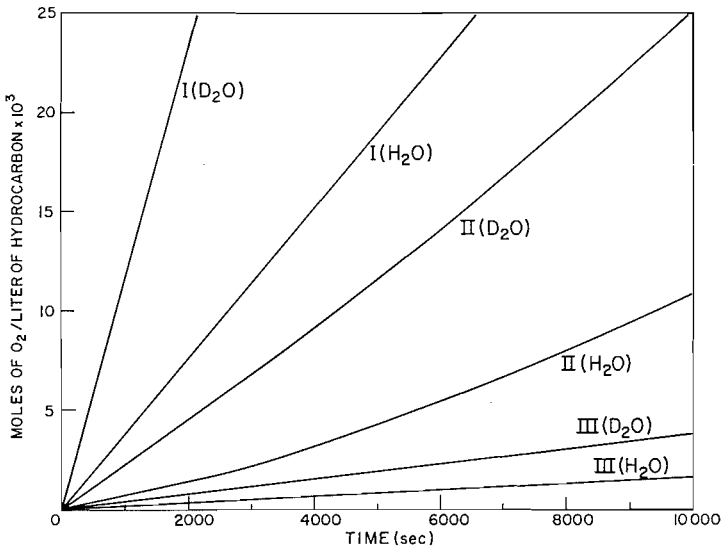

FIG. 1. Oxygen absorption curves at 65 °C. Key: (I) styrene with 4.9×10^{-3} mole/l [AIBN] and 1.4×10^{-2} mole/l [tri-*t*-butylaniline]; (II) tetralin with 9.8×10^{-4} mole/l [AIBN] and 8.2×10^{-3} mole/l [tri-*t*-butylaniline]; (III) tetralin with 4.9×10^{-4} mole/l [AIBN] and 5.6×10^{-4} mole/l [tri-*t*-butylthiophenol].

absence of AIBN. It has roughly half the efficiency of AIBN as an initiator. This behavior is similar to that reported for equimolar mixtures of styrene and 4-methoxythiophenol in heptane at room temperature (7). However, in the present case oxidation did not cease after the absorption of less than 1 molar equivalent of oxygen based on the amount of thiophenol (7). Instead, the rate showed no decrease until more than 10 equivalents of oxygen had been absorbed. This difference may be due either to the higher temperatures or to the lower concentrations of thiophenol relative to styrene which were employed in this work. It is also possible that the steric protection of the SH group by the adjacent *t*-butyl groups influenced the amount of oxygen absorbed. Since the thiophenol inhibits the oxidation of cumene and tetralin (see below), its catalysis of the oxidation of styrene can probably be best represented by

$$[1'] \qquad AH \xrightarrow{RH} A\cdot$$

$$[2'] \qquad A\cdot + RH \rightarrow AR\cdot H$$

$$[3] \qquad AR\cdot H + O_2 \rightarrow \text{normal chain propagation}$$

$$[5] \qquad RO_2\cdot + RO_2\cdot \rightarrow \text{non-radical products}$$

$$[6] \qquad AH + RO_2\cdot \rightarrow A\cdot + ROOH,$$

where reaction [1′] is slow and reaction [2′] is very fast (cf. ref. 8). Reaction [6] does not lead to chain termination since the A· radical is consumed in reaction [2′].

Tetralin

Equation [1] describes the kinetics of the tri-*t*-butylphenol inhibited oxidation. The rate was not affected by the addition of tetralin hydroperoxide, i.e., reaction [−6] does not occur. The measured deuterium isotope effect, $(k_6)_{AH}/(k_6)_{AD}$, was 10.0.

The oxygen absorption curves with the aniline show a strong autocatalysis. This is due to the hydroperoxide formed during the reaction, since the initial rate increases linearly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with the square root of the initial hydroperoxide concentration (3, 9). In this respect and in the overall kinetics, this compound shows a behavior which is very similar to that of phenol itself in tetralin (3). The sensitivity of the initial inhibited rate to added hydroperoxide is only slightly less than that of phenol itself. Reaction [−6] is therefore fairly rapid in spite of the hindering action of the two ortho-*t*-butyl groups. In the presence of an effective hydroperoxide concentration of about 2×10^{-3} mole/l,* the rate could be represented by

$$P\alpha \frac{[RH]^{1.0}[I_2]^{0.5}}{[AH]^{0.5}}$$

over a range of [RH] from 2% to 10% by volume in *o*-dichlorobenzene, a range of $[I_2]$ from 5×10^{-5} to 5×10^{-3} mole/l, and a range of [AH] from 2×10^{-4} to 10^{-2} mole/l. This expression describes the kinetics for inhibition when reaction [−6] is fast (3, 9). Reducing the effective initial hydroperoxide concentration to about 1×10^{-4} mole/l by increasing the reactant volume gave

$$P\alpha \frac{[RH]^{1.03}[I_2]^{0.71}}{[AH]^{0.66}}$$

over the same range in reactant concentrations. The fact that the order in [RH] did not increase significantly whereas the orders in $[I_2]$ and [AH] both did increase indicates that chain transfer with the tetralin (reaction [8]) is relatively unimportant in this system (3, 6). The deuterium isotope effect, measured at an oxygen absorption of 2×10^{-3} mole/l, was 23/7.5 = 3.0 (Fig. 1). This gives a maximum possible isotope effect for $(k_6)_{AH}/(k_6)_{AD}$ of 9.0.

The oxygen absorption curves with the hindered thiophenol were only very slightly autocatalytic and the inhibited rate was not significantly affected by the addition of 4×10^{-2} mole/l of hydroperoxide. These results indicate that reaction [−6] is relatively unimportant. The kinetics are described by

$$P\alpha \frac{[RH]^{1.06}[I_2]^{0.70}}{[AH]^{0.78}}$$

over a range in $[I_2]$ from 2×10^{-4} to 2×10^{-3} mole/l and in [AH] from 4×10^{-5} to 10^{-3} mole/l. The order in tetralin was obtained by its dilution to 20% by volume with *o*-dichlorobenzene. These kinetics can probably be most readily accounted for by the complex expression which describes inhibition with chain transfer by reaction [8] when this reaction is relatively slow (3). The fact that the thiophenoxy radicals disappear by dimerization (see below) suggests that at sufficiently high concentrations the thiophenol should show the same unusual kinetics that are exhibited by 4-methoxyphenol. That is, the rate should become independent of the thiophenol concentration when this is very large (3). This was not observed up to 3×10^{-2} mole/l [thiophenol]. That is, with 2×10^{-3} mole/l $[I_2]$, the order in [thiophenol] was found to have decreased only to −0.5 in the concentration range of 1×10^{-3} to 3×10^{-2} mole/l. Reaction [8] is therefore probably quite slow (cf. 4-methoxyphenol in tetralin (3)). The deuterium isotope effect was 3.8/1.65 = 2.3 (see Fig. 1). The measured order of −0.78 in thiophenol gives $(k_6)_{AH}/(k_6)_{AD}$ = 2.9.

**This was the average amount of hydroperoxide formed in the oxidation of a 5 ml sample at the point where the rate was measured.*

Cumene

This substrate was used only to determine the average number of radicals, n, trapped by the three inhibitors. The induction periods produced by these compounds were compared under the same experimental conditions with the induction period produced by 2,6-di-*t*-butyl-4-methylphenol, an inhibitor which is known to stop two oxidation chains per molecule (10). Cumene is an excellent substrate for induction period determinations because even weak inhibitors produce quite sharp breaks in the oxygen absorption curves. With 2.8×10^{-2} mole/l [AIBN] and 1.3×10^{-3} mole/l [AH] only tri-*t*-butylaniline had a significant initial rate (3.0×10^{-6} mole/l s). Under these conditions the induction periods were 4 200 s for 2,6-di-*t*-butyl-4-methylphenol* and 3 800 s for tri-*t*-butylphenol and tri-*t*-butylaniline ($n = 1.8$). In each case the final rate equalled the rate in the absence of inhibitor (i.e., 2.37×10^{-5} mole/l s). With tri-*t*-butylthiophenol, on the other hand, the induction period was only 2 000 s ($n = 0.95$) and the rate at the end of this induction period was only about one-third of the uninhibited rate. This rate very slowly increased and reached the uninhibited value after about 9 000 s. This suggests that the thiophenol reacts rapidly with only one peroxy radical per molecule (reaction [6]) and that the thiophenoxy radicals disappear by dimerization (presumably to the disulfide (5, 11) which must itself be a very weak inhibitor) rather than by reaction with a peroxy radical (reaction [7]).

In conclusion, the deuterium isotope effects observed in this work indicate that inhibition by these three compounds involves abstraction of the active hydrogen atom by a peroxy radical in the slow rate-determining step. The anilino and thiophenoxy radicals formed in this process undergo secondary reactions which complicate the kinetics and prevent a comparison of the rates of hydrogen atom abstraction from the phenol, aniline, and thiophenol.

AGENTS AFFECTING LIPID METABOLISM

XIII. THE SYNTHESIS OF 1,4-DISUBSTITUTED BICYCLO[2.2.2]OCTANE DERIVATIVES[1]

L. G. HUMBER, G. MYERS, L. HAWKINS, C. SCHMIDT, AND M. BOULERICE
Ayerst Research Laboratories, Montreal, Quebec

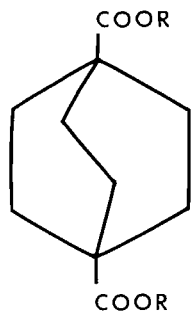
Received March 25, 1964

ABSTRACT

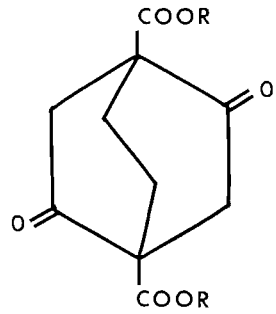
Several routes to the synthesis of 1,4-disubstituted bicyclo[2.2.2]octanes have been explored and the syntheses of several such derivatives are reported. The 1,4-disubstituted bicyclo[2.2.2]-octane nucleus could not be prepared through an elimination reaction on a corresponding 2,5-disubstituted derivative or by the Diels–Alder reaction of various dienophiles with dimethyl 1,3-cyclohexadiene-1,4-dicarboxylate.

Unusual products are obtained from the reaction of tetracyanoethylene with dimethyl terephthalate and with 1,3-cyclohexadienes containing electron-attracting groups in the 1,4-positions. Some spectral properties of these compounds are described.

In connection with the synthesis of potential cholesterol-lowering agents related to *trans*-1,4-bis-(2-chlorobenzylaminomethyl)-cyclohexane (AY-9944) (1), it was of interest to obtain, as an intermediate, bicyclo[2.2.2]octane-1,4-dicarboxylic acid or a corresponding diester (I).



I (a) R= H
(b) R= C_2H_5
(c) R= CH_3



II (a) R= H
(b) R= C_2H_5

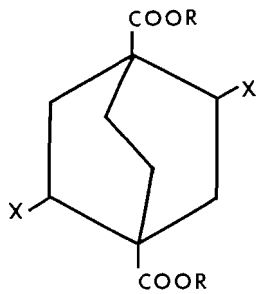
We have prepared I*b* in high yield by desulphurization of the bis-ethylenethioketal derivative of the diketo–diester II*b*, as described by Roberts *et al.* (2). II*b*, in turn, has been previously prepared (2, 3) by bridging diethyl 2,5-diketocyclohexane-1,4-dicarboxylate with ethylene dibromide, using a sodium alkoxide as the base. This bridging procedure gave low yields of impure material. We found that the bridging can be executed in consistently high yield (80–85%) by using sodium hydride as base and 1,2-dimethoxyethane as solvent.

A route was available, therefore, for the synthesis of the desired bicyclooctane derivatives I, but it required the use of large quantities of ethanedithiol and of Raney nickel.

[1]*For Part XII of this series, see ref. 1b.*

Thus we investigated alternate procedures not requiring the use of these reagents. The Clemmensen reduction of II*b* using anhydrous conditions (4) gave low yields of I*b*, and attempted desulphurization of the bis-ethylenethioketal derivative of II*b* with sodium and liquid ammonia (5) or with hydrazine and potassium hydroxide (6) was unsuccessful.

We next envisaged a bis-elimination on a suitable 2,5-disubstituted bicyclo[2.2.2]-octane-1,4-dicarboxylate (III) to yield a 2,5-bicyclooctadiene, which then would be reduced to the desired bicyclooctane I. The configurations of the 2,5-substituents in III are unknown. However, whether one or both of these substituents are exo or *endo* to the ring to which they are both attached, they will have identical environments with respect to the hydrogens in the alpha-positions, in that each substituent is eclipsed by one of these hydrogens. Elimination reactions resulting in bicyclooctene derivatives have been observed previously in such systems (7). Thus, the diketo–diester II*b* and the diketo–diacid II*a* (3) were reduced, in high yields, with ruthenium dioxide catalyst at high pressure in ethanol and water respectively, to give diethyl 2,5-dihydroxybicyclo[2.2.2]octane-1,4-dicarboxylate (III*a*) and the corresponding diacid, III*b*, which was characterized as its dimethyl ester.



III

(a) R= C_2H_5 X= OH
(b) R= H X= OH
(c) R= C_2H_5 X= SO_3CH_3
(d) R= C_2H_5 X= p-$CH_3C_6H_4SO_3$
(e) R= C_2H_5 X= $OCOCH_3$
(f) R= C_2H_5 X= Br

The dihydroxy–diester (III*a*) was converted to a number of derivatives, viz. dimethanesulphonate (III*c*), di-(*p*-toluene)sulphonate (III*d*), diacetate (III*e*), and dibromide (III*f*).[2] When the dimethanesulphonate–diethyl ester (III*c*) was refluxed for 5 h with alcoholic sodium hydroxide, only the corresponding diacid was obtained; when the reflux period was extended to 30 h, terephthalic acid was obtained in 70% yield, as indicated by the ultraviolet spectrum. When the diacetoxy–diethyl ester (III*e*) was pyrolyzed at 350–400° for 30 min, a mixture of 20% diethyl terephthalate and starting material was obtained. When the dibromo–diester (III*f*) was refluxed in toluene with potassium *tert*-butoxide, a quantitative yield of diethyl terephthalate was obtained. The recovery of only starting materials or terephthalic acid derivatives in the above elimination experiments must be due to the instability of the initially formed 1,4-disubstituted bicyclo[2.2.2]-2,5-octadiene, which contains two electron-attracting groups in the 1,4-positions and probably undergoes a reverse Diels–Alder reaction with ease. Bicyclo[2.2.2]-2,5-octadiene itself (8) is reported to undergo a reverse Diels–Alder reaction on pyrolysis to yield benzene.

We have investigated also the susceptibility of diethyl 2,5-disubstituted bicyclo[2.2.2]-octane-1,4-dicarboxylates to substitution reactions. The dimethanesulphonate (III*c*), the di-(*p*-toluene)sulphonate (III*d*), and the dibromide (III*f*) were treated with sodium cyanide, with lithium fluoride, and with sodium iodide (in acetone solutions). In all cases only starting materials were recovered. Because of the symmetrical nature of the

[2]*This dibromo derivative was characterized as the corresponding diacid (see experimental).*

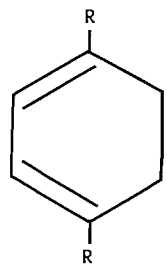
bicyclo[2.2.2]octane system, the accessibility of substituents, in the 2,5-positions, to rear end attack by a nucleophilic agent is identical, if the substituents are di-exo or di-*endo* with respect to the ring to which they are both attached. If they are exo–*endo*, then the exo-substituent would be expected to be subject to additional rear end shielding by the *endo*-substituent. However, the exo-substituent should react as readily as those in the di-exo and di-*endo* derivatives. Thus, the failure of the above displacement reactions with SN_2-type reagents is interpreted as indicating that, in a bicyclo[2.2.2]octane system, the non-bridgehead positions are inaccessible to rear end attack, as are the bridgehead positions. On the other hand, the dibromide (III*f*) readily undergoes acetolysis on treatment with silver acetate in acetic acid, yielding the diacetoxy derivative (III*e*).

The diketo–diacid (II*a*) was converted to the corresponding 1,4-dibromo derivative by a Hunsdiecker reaction on the silver salt. Bromination of this product yielded a compound $C_8H_6Br_4O_2$, $\nu_{max}^{CHCl_3}$ 1 768 cm^{-1} (probably 1,3,4,5-tetrabromo-2,5-diketobicyclo[2.2.2]-octane). Bromination of the diketo–diester (II*b*), gave a compound $C_{14}H_{16}Br_2O_6$, $\nu_{max}^{CHCl_3}$ 1 750 cm^{-1} (most likely the 3,6-dibromo derivative).

We next turned our attention to preparing the desired bicyclo[2.2.2]octane-1,4-dicarboxylate (I*c*) by a Diels–Alder reaction of dimethyl 1,3-cyclohexadiene-1,4-dicarboxylate (IV) and a suitable dienophile.



IV R= $COOCH_3$

V R= $CONH_2$

VI R= CN

VII R= CONH-CYCLOHEXYL

VIII R= $CONHCH_2$-CYCLOHEXYL

IX R= COCl

The diene–diester (IV) was prepared from cyclohexane-1,4-dicarboxylic acid in 70% overall yield, as described previously (8). IV has been described before by Baeyer (10) and by Burnell and Taylor (11), the latter authors reporting λ_{max} 309 mμ (ϵ = 27 300). In our hands a carefully purified sample had λ_{max} 309 mμ (ϵ = 13 100) and the nuclear magnetic resonance spectrum exhibited three sharp peaks at 2.91 (2 vinyl hydrogens), 6.20 (6 carbomethoxy hydrogens), and 7.44 τ(4 allylic hydrogens).

The Diels–Alder reaction between the diene–diester (IV) and the following dienophiles was investigated: ethylene, *cis*-dichloroethylene, vinyl chloride, maleic anhydride, and tetracyanoethylene (TCNE). Only starting materials were recovered with the first three dienophiles.

With maleic anhydride, 1,4-dicarbomethoxybicyclo[2.2.2]oct-2-ene-*endo*-5,6-dicarboxylic anhydride (X), m.p. 183–185°, was obtained in high yield. After this work was completed, this compound was reported by Smith *et al.* (12) and by Kauer (13) to have m.p.'s 191.5° and 188–188.6° respectively. Catalytic hydrogenation, followed by hydrolysis of the anhydride function of X, yielded the corresponding saturated diacid.

Attempts to convert this to a 1,4-disubstituted bicyclooctene (related to I*c*) by oxidative bis-decarboxylation (14) under various conditions were unsuccessful. The inability to effect this bis-decarboxylation has also been reported by Smith *et al.* (12).

The Diels–Alder reaction between TCNE and IV in tetrahydrofuran solution yielded a bright yellow crystalline compound, $C_{16}H_{12}N_4O_2$, m.p. 112–114° (XI), which did not exhibit the spectral properties expected for a Diels–Alder adduct. Smith *et al.* (12) have apparently obtained the same compound from this reaction. They report m.p. 120–140° and consider it to be a π-complex. Initially, we also had considered that XI was a stable molecular π-complex of the type proposed as an intermediate in Diels–Alder reactions with TCNE (15), and that it might be convertible to a normal Diels–Alder adduct; however, prolonged refluxing in benzene or toluene led only to recovery of XI. The appearance of the report of Smith *et al.* (12) prompted us to investigate further the spectroscopic properties of XI. π-Complexes between TCNE and various aromatic compounds have been described previously (16); they exhibit characteristic absorption bands in the visible or near ultraviolet. We have examined XI spectroscopically in these regions, both in tetrahydrofuran and in methylene chloride solutions, and, in contrast to the findings of Smith *et al.* (12), we are unable to detect any π-complex absorption, the spectra corresponding essentially to a summation of those of TCNE and the diene–diester IV (see Table I, *a* and *b*). Similar complexes with TCNE have been obtained with the diene–dinitrile VI and with dimethyl terephthalate, and they show spectral properties, in solution, analogous to those of XI.

TABLE I

Comparison of optical densities of the TCNE-adduct XI and components thereof*

(*a*) Diene–diester IV, TCNE, and their adduct in CH_2Cl_2 (concentration = 10^{-4} *M*)

λ	265 mμ	276 mμ	283 mμ	310 mμ
IV	0.22	0.46	0.65	1.34
TCNE	1.44	1.30	0.65	0.0
Total	1.66	1.76	1.30	1.34
TCNE–IV(XI)	1.77	1.82	1.27	1.34

(*b*) Diene–diester IV, TCNE, and their adduct in tetrahydrofuran (concentration = 10^{-4} *M*)

λ	262 mμ	270 mμ	310 mμ
IV	0.20	0.33	1.21
TCNE	0.74	0.67	0.15
Total	0.94	1.00	1.36
TCNE–IV(XI)	0.95	0.97	1.13

*In all cases, the adduct shows maxima at the same wavelengths as those of the components and no other maxima or inflections are discernible.

We considered that it might be possible to demonstrate π-complex character with XI in the solid state; however, examination of the visible and near ultraviolet spectra of XI and of its components in potassium bromide pellets does not show any characteristic π-complex absorption. When XI is dissolved in glacial acid, a pink color is observed and a visible spectrum of this solution (10^{-2} *M*) immediately after its preparation shows a weak absorption maximum at 525 mμ, which gradually reduces in intensity and is absent after 20 min. A spectrophotofluorimetric determination on this freshly prepared solution shows an activation wavelength at 395 mμ, and a fluorescence wavelength at 460 mμ.* Neither of these properties of XI in acetic acid are shown by either TCNE of the diene–diester IV at equivalent concentrations in the same solvent. Thus, it appears that XI is a weak

**Measured on an Aminco–Bowman spectrophotofluorimeter.*

molecular π-complex, whose existence can be demonstrated not by an examination of the absorption spectrum, but by a study of the fluorescence spectrum.

The failure of the dienes IV and VI to form Diels–Alder adducts with TCNE, whereas 1,3-cyclohexadiene itself forms such an adduct (15) and IV forms an adduct with maleic anhydride in high yield, can be attributed to the high electron-demand of TCNE, which is not met by the dienes IV and VI due to the strong electron-attracting groups attached to the ends of the diene system. Similarly, with dimethyl terephthalate, the presence of such groups attached to the benzene ring prevents the formation of a strong π-complex with TCNE, similar to the type formed with other benzene derivatives (16*a*, 16*c*).

A number of derivatives of 1,3-cyclohexadiene-1,4-dicarboxylic acid were prepared. The diacid chloride IX was converted to the substituted diamides VII and VIII by reaction with cyclohexylamine and cyclohexylmethylamine respectively. These diamides, as well as the dinitrile VI and the unsubstituted diamide V, could not be reduced to diamines with lithium aluminium hydride.

The reactions summarized in Chart I were carried out to obtain compounds XII–XVII for testing as cholesterol-lowering agents. Compounds XII–XIV were obtained by the condensation of 1,4-bisaminomethylbicyclo[2.2.2]octane with the appropriate aldehyde or ketone, followed by reduction of the resultant Schiff base with sodium borohydride. Compounds XV and XVI were obtained by lithium aluminium hydride reduction of the diamides obtained from condensation of bicyclo[2.2.2]octane-1,4-dicarboxyl chloride with the appropriate amines. Compound XVII was prepared from 2-chlorobenzaldehyde and 1,4-diaminobicyclo[2.2.2]octane, which was obtained in high yield by a Hofmann reaction on the corresponding diamide followed by hydrolysis of the intermediate dicarbamate.

EXPERIMENTAL[3]

Diethyl 2,5-Dioxobicyclo[2.2.2]octane-1,4-dicarboxylate (IIb)

A 49% dispersion of sodium hydride in mineral oil (60.0 g, 1.18 mole) and diethyl succinylsuccinate (17) (111.1 g, 0.394 mole) were added, alternately in 10.0 g portions, to 1,2-dimethoxyethane (400 ml) over 15 min with stirring to yield the disodium salt as a pink suspension. The mixture was distilled until 200 ml of 1,2-dimethoxyethane were removed. Ethylene dibromide (666 g) was added and the distillation was continued until an additional 150 ml of 1,2-dimethoxyethane had been removed. The mixture then was stirred and heated at 110–120° until the pink color had disappeared (ca. 20 h). The mixture was filtered while still hot and the solids washed with 3 × 25 ml of chloroform. Hexane (300 ml) was added to the filtrate and, on cooling, 70 g of product was obtained, m.p. 109–111°. The filtrate from the first crop was evaporated to dryness *in vacuo*. Trituration with methanol, filtration, and washing with hexane yielded an additional 23 g of product, m.p. 108–111°. Total yield: 83.7%. Lit. m.p. 108–110.5° (2).

The above diketo–diester (2.8 g) was dissolved in carbon tetrachloride (50 ml) and allowed to stand overnight at room temperature with bromine (3.5 g). Evaporation of the solvent and crystallization from an ether–hexane mixture yielded the dibromo derivative (2.6 g), m.p. 142–145°, $\nu_{max}^{CHCl_3}$ 1 750 cm^{-1}.

Anal. Calcd. for $C_{14}H_{16}Br_2O_6$: Br, 36.33. Found: Br, 36.31.

Bisethylenethioketal of Diethyl 2,5-Dioxobicyclo[2.2.2]octane-1,4-dicarboxylate

A solution of diethyl 2,5-dioxobicyclo[2.2.2]octane-1,4-dicarboxylate (II*b*) (70 g, 0.248 mole), boron trifluoride etherate (70 ml, 0.55 mole), and ethanedithiol (71.0 g, 0.75 mole) in glacial acetic acid (300 ml) was kept at room temperature for 17 h. Chloroform (200 ml) was added and the mixture washed with water (3 × 50 ml), 5% aqueous sodium hydroxide (2 × 200 ml), and water (2 × 100 ml), followed by drying and concentration *in vacuo*. Crystallization from methanol yielded the product (95.5 g, 88.9%), m.p. 82–85°. Lit. m.p. 91.8–92.7° (2).

Clemmensen Reduction of Diethyl 2,5-Dioxobicyclo[2.2.2]octane-1,4-dicarboxylate

Amalgamated zinc (prepared from mossy zinc (190 g)), mercuric chloride (9.5 g), and concentrated hydrochloric acid (45 ml)) was washed with absolute ethanol (4 × 100 ml). Then absolute ethanol (500 ml) was added, followed by diethyl 2,5-dioxobicyclo[2.2.2]octane-1,4-dicarboxylate (II*b*) (9.65 g). The mixture was refluxed for 60 h, during which it was saturated with hydrogen chloride 4 times. The ethanol solution was

[3]*All melting points are corrected and were recorded on a Thomas–Hoover apparatus.*

XV R= CH$_2$-CYCLOHEXYL

XVI R= 1-INDANYL

decanted from the zinc, the ethanol removed *in vacuo*, and the residue distributed between ether and water. The ether phase was washed with water and dilute sodium bicarbonate solution, and then dried and fractionated to yield diethyl bicyclo[2.2.2]octane-1,4-dicarboxylate (I*b*) (3.5 g, 40%), b.p. 118–126° at 0.3 mm, n_D^{26} 1.4683. Roberts *et al.* (2) report b.p. 113–115° at 0.3 mm and n_D^{25} 1.4660.

Dimethyl 2,5-Dihydroxybicyclo[2.2.2]octane-1,4-dicarboxylate

To 2,5-dioxobicyclo[2.2.2]octane-1,4-dicarboxylic acid (3) (100 g), dissolved in water (500 ml), was added 5% ruthenium dioxide on Norite (5 g). The mixture was hydrogenated at 170 kg/cm² for 10 h at 150°, during which time the theoretical hydrogen uptake was observed. After removal of the catalyst, the solution was evaporated to dryness *in vacuo* to yield the diacid, which did not crystallize readily. It was converted to the dimethyl ester with diazomethane in methanol–ether solution. The diester was crystallized from benzene–ether to yield 97 g of product (95%), m.p. 129–130°, $\nu_{max}^{CHCl_3}$ 3 560, 1 706 cm^{-1}.

2,5-Dibromobicyclo[2.2.2]octane-1,4-dicarboxylic acid

Diethyl 2,5-dihydroxybicyclo[2.2.2]octane-1,4-dicarboxylate, m.p. 91°, (143 g, 0.5 mole) was treated with triphenylphosphite (310 g, 1.0 mole) and hydrogen bromide at 20° (18) for 80 min. The mixture was poured onto cracked ice and extracted with ether. The ether solution was washed with dilute sodium hydroxide solution, dried, and fractionated to yield an oil (90 g), b.p. 175–180° at 1 mm. It was freed of traces of phosphorus by passing it through a column of alumina (2 700 g), using benzene as eluant. Fractionation yielded the diethyl ester of the title compound (III*f*), 70 g, b.p. 145–150° at 0.5 mm, $\nu_{max}^{CHCl_3}$, 1 710 cm^{-1}. Hydrolysis of the diethyl ester with glacial acetic acid and 47% hydrobromic acid yielded the diacid, which was obtained as a dihydrate on crystallization from ethanol–water (1:1), m.p. 285°.

Anal. Calcd. for $C_{10}H_{12}Br_2O_4 \cdot 2H_2O$: Br, 40.80; H_2O, 9.19. Found: Br, 40.75; H_2O, 9.1.

Elimination Reactions on Dibromo, Dimesyloxy, and Acetoxy Derivatives

(*a*) Diethyl 2,5-dibromobicyclo[2.2.2]octane-1,4-dicarboxylate (III*f*) (412 mg), dissolved in toluene (3 ml), was refluxed with potassium *t*-butoxide (448 mg) for 2 h. The mixture was poured into ice water. Acidification of the aqueous phase yielded terephthalic acid (100 mg), m.p. > 300°, λ_{max}^{EtOH} 240 mμ (ϵ = 20 000).

(*b*) Diethyl 2,5-dimesyloxybicyclo[2.2.2]octane-1,4-dicarboxylate (III*c*) (2 g), dissolved in ethanol (8 ml) and water (2 ml), was refluxed with sodium hydroxide (2.0 g) for 5 h. Removal of the alcohol *in vacuo*, dilution with water, and acidification yielded 2,5-dimesyloxybicyclo[2.2.2]octane-1,4-dicarboxylic acid (1.0 g), m.p. 202° (ethanol).

Anal. Calcd. for $C_{12}H_{18}O_{10}S_2$: C, 37.20; H, 4.71; S, 16.55. Found: C, 37.54; H, 4.87; S, 16.58.

When the above mixture was refluxed for 30 h, terephthalic acid was isolated in 70% yield.

(*c*) Diethyl 2,5-diacetoxybicyclo[2.2.2]octane-1,4-dicarboxylate (III*e*) (25 g) was pyrolyzed at 350–400° for 0.5 h. Only slight charring occurred. The mixture was distilled to yield diethyl terephthalate (5 g), b.p. 120° at 1 mm, m.p. 44°, λ_{max}^{EtOH} 240 mμ (ϵ = 20 450). The residue was identified as starting material.

1,4-Dibromo-2,5-dioxobicyclo[2.2.2]octane

The silver salt of 2,5-dioxobicyclo[2.2.2]octane-1,4-dicarboxylic acid (38.45 g, 0.087 mole), prepared by treatment of the corresponding diacid in potassium hydroxide solution with silver nitrate, was refluxed in carbon tetrachloride (200 ml) with bromine (27.9 g, 0.17 mole) for 8 h. Filtration of the mixture and evaporation of the filtrate yielded a residue which, on crystallization from chloroform, yielded the product (4.8 g, 18.5%), m.p. 169–170°, $\nu_{max}^{CHCl_3}$ 1 748 cm^{-1}.

Anal. Calcd. for $C_8H_8Br_2O_2$: Br, 54.02, C, 32.43, H, 2.72. Found: Br, 53.96, C, 32.09, H, 2.48.

The above 1,4-dibromo-2,5-dioxobicyclo[2.2.2]octane (2.96 g, 0.01 mole) was dissolved in 30 ml of acetic acid and 3.4 g of bromine and refluxed for 2 h. The solvents were removed, the residue dissolved in chloroform, and the resulting solution washed with dilute sodium bicarbonate solution. The chloroform was removed *in vacuo* and the residue crystallized from a chloroform–ether mixture. It had m.p. 210–211° and $\nu_{max}^{CHCl_3}$ 1 768 cm^{-1}.

Anal. Calcd. for $C_8H_6Br_4O_2$: Br, 70.1. Found: Br, 70.9.

Dimethyl 1,3-Cyclohexadiene-1,4-dicarboxylate (IV)

The title compound was prepared from dimethyl 1,4-dibromo-cyclohexane-1,4-dicarboxylate as described by Guha and Hazra (9). It was crystallized from a chloroform–hexane mixture and had m.p. 83–84.5°, λ_{max}^{EtOH} 309 mμ (ϵ = 13 100), $\nu_{max}^{CHCl_3}$ 1 640 and 1700 cm^{-1}, τ_{max} 2.91, 6.20, 7.44.[4]

Anal. Calcd. for $C_{10}H_{12}O_4$: C, 61.21; H, 6.17. Found: C, 61.31; H, 6.27; 6.31.

A tetracyanoethylene adduct was prepared by refluxing the diene–diester (0.68 g, 0.003 mole) with tetracyanoethylene (0.44 g, 0.003 mole) in tetrahydrofuran (20 ml) for 30 min. The solution was evaporated to dryness *in vacuo* and the residue crystallized from an ether–hexane (2:1) mixture to yield the adduct (0.87 g, 89.4%) as yellow crystals, m.p. 112–114°.

Anal. Calcd. for $C_{16}H_{12}N_4O_4$: C, 59.25; H, 3.73; N, 17.28. Found: C, 59.14; H, 3.78; N, 17.58, 17.68.

1,3-Cyclohexadiene-1,4-dicarbonylchloride (IX)

1,3-Cyclohexadiene-1,4-dicarboxylic acid (9), λ_{max} 309 mμ (ϵ = 13 000), (84 g, 0.5 mole) and thionyl chloride (500 ml) were refluxed for 3 h in the presence of a catalytic amount of dimethylformamide (19) (0.5 ml). The excess of thionyl chloride was removed *in vacuo* and the residue crystallized from an ether–hexane mixture to yield the product (85.6 g, 83%), m.p. 54–56°. A sample sublimed in high vacuum had m.p. 56–58°, λ_{max}^{ether} 329 mμ (ϵ = 16 500), $\nu_{max}^{CHCl_3}$ 1 740 and 1 630 cm^{-1}.

Anal. Calcd. for $C_8H_8Cl_2O_2$: Cl, 34.59. Found: Cl: 34.39, 34.44.

1,3-Cyclohexadiene-1,4-dicarboxamide (V)

The diacid chloride (20.5 g) was added in portions to concentrated aqueous ammonia (200 ml) at 0°. The mixture was warmed at 80° for 60 min. Filtration yielded the product, m.p. 300–310° (decomp.) (13.0 g, 78.4%). A sample, crystallized twice from methanol, had m.p. 312–314° (decomp.), ν_{max}^{Nujol} 3 160, 3 360, and 1 650 cm^{-1}, λ_{max}^{EtOH} 305 mμ (ε = 11 830).

Anal. Calcd. for $C_8H_{10}N_2O_2$: C, 57.81; H, 6.07; N, 16.86. Found: C, 57.22; H, 6.35; N, 16.74.

1,3-Cyclohexadiene-1,4-dicarbonitrile (VI)

The diamide (5.0 g) was refluxed in thionyl chloride (30 ml) for 18 h in a nitrogen atmosphere. The excess thionyl chloride was removed *in vacuo* and the residue was triturated with petroleum ether to yield the product, m.p. 163–165° (3.5 g, 89.8%). A sample was crystallized twice from a benzene – petroleum ether mixture. It had m.p. 170–172°, λ_{max}^{EtOH} 295 mμ (ε = 11 600) and 311 mμ (ε = 10 700).

Anal. Calcd. for $C_8H_6N_2$: C, 73.83; H, 4.65; N, 21.53. Found: C, 73.84; H, 4.68; N, 21.40.

A tetracyanoethylene adduct was prepared as described above. It had m.p. 127–130° (ether–hexane); $\lambda_{max}^{CH_2Cl_2}$ 247 mμ (ε = 14 700), 266 mμ (ε = 17 600), 277 mμ (ε = 18 700), 295 mμ (ε = 11 600), 307 mμ (ε = 11 400), 320 mμ (ε = 6 600).

Anal. Calcd. for $C_{14}H_6N_6$: C, 65.1; H, 2.39; N, 32.55. Found: C, 65.42; H, 2.78; N, 32.66.

TCNE Adduct with Dimethyl Terephthalate

The adduct was prepared from equimolar quantities of TCNE and dimethyl terephthalate and had m.p. 138–140°; $\lambda_{max}^{CH_2Cl_2}$ 242 mμ (ε = 30 200), 266 mμ (ε = 17 200), 276 mμ (ε = 14 600), 295 mμ (ε = 2 000).

Anal. Calcd. for $C_{16}H_{10}N_4O$: C, 59.63; H, 3.13. Found: C, 59.30; H, 3.12.

1,4-Dicarbomethoxybicyclo[2.2.2]oct-2-ene-endo-5,6-dicarboxylic Anhydride (X)

Dimethyl 1,3-cyclohexadiene-1,4-dicarboxylate (42.6 g, 0.22 mole) and maleic anhydride (23 g, 0.23 mole) were mixed together and heated at 90–100° under a nitrogen atmosphere in a sealed tube for 17 h. The reaction mixture was triturated with hot hexane and the residue was crystallized from chloroform to yield the product (36.5 g). The mother liquors were retreated with maleic anhydride (as described above) to yield an additional 12.5 g of product. The total yield was 49 g, 76.8%. It had m.p. 183–185°, $\nu_{max}^{CHCl_3}$ 1 735 and 1 780 cm^{-1}.

Anal. Calcd. for $C_{14}H_{14}O_7$: C, 57.16; H, 4.80. Found: C, 56.94; H, 4.81.

1,4-Dicarbomethoxybicyclo[2.2.2]octane-5,6-dicarboxylic Anhydride

The unsaturated anhydride (36.5 g) was hydrogenated in tetrahydrofuran (500 ml) in the presence of platinum oxide (0.5 g) at 50° and at a slight positive hydrogen pressure. Hydrogen uptake was complete in 1 h, and the product was isolated in the conventional manner. It had m.p. 163–165° ($CHCl_3$ – petroleum ether), (32.5 g, 88.4%).

Anal. Calcd. for $C_{14}H_{16}O_7$: C, 56.75; H, 5.44. Found: C, 57.07; H, 5.54.

1,4-Dicarbomethoxybicyclo[2.2.2]octane-5,6-dicarboxylic Acid

The saturated anhydride (11.9 g) was refluxed with water (150 ml) for 3 h. The solution was evaporated to dryness *in vacuo* and the residue crystallized from an ether–hexane mixture to yield the product (10.3 g), m.p. 190–192°.

Anal. Calcd. for $C_{14}H_{18}O_8$: C, 53.50; H, 5.77. Found: C, 53.58; H, 5.78.

N,N'-Dicyclohexyl-1,3-cyclohexadiene-1,4-dicarboxamide (VII)

The diacid chloride (1.03 g, 0.005 mole) and cyclohexylamine (1.98 g, 0.02 mole) were refluxed in benzene for 20 min. The solvent was removed, the residue was washed with water, and the solid was crystallized then from methanol to yield the product (1.0 g, 60.1%), m.p. > 310°, λ_{max}^{EtOH} 308 mμ (ε = 14 000), ν_{max}^{Nujol} 1 625 cm^{-1}.

Anal. Calcd. for $C_{20}H_{30}N_2O_2$: C, 72.68; H, 9.15; N, 8.48. Found: C, 72.41; H, 8.98; N, 8.34.

N,N'-Di-(cyclohexylmethyl)-1,3-cyclohexadiene-1,4-dicarboxamide (VIII)

The diacid chloride (4.1 g, 0.02 mole) and cyclohexylmethylamine (9.06 g, 0.08 mole) were reacted in benzene, as described above, to yield the title product (5.8 g, 81%), m.p. > 310° (methanol), λ_{max}^{EtOH} 307 mμ (ε = 14 700), ν_{max}^{Nujol} 1 625 cm^{-1}.

Anal. Calcd. for $C_{22}H_{34}N_2O_2$: C, 73.70; H, 9.56. Found: C, 73.70; H, 9.56.

1,4-Bisaminomethylbicyclo[2.2.2]octane

(*a*) Bicyclo[2.2.2]octane-1,4-dicarboxamide (20) (6.2 g) was refluxed in tetrahydrofuran (200 ml) with lithium aluminium hydride (5.0 g) for 30 h. The reaction was treated in the conventional manner to yield the product (4.4 g, 83%), b.p. 90° at 0.02 mm. The dihydrochloride salt had m.p. > 360°.

Anal. Calcd. for $C_{10}H_{22}Cl_2N_2$: N, 11.61; Cl, 29.3. Found: N, 11.63; Cl, 28.7.

(*b*) Reduction of bicyclo[2.2.2]octane-1,4-dicarbonitrile (20), using conditions similar to those described above for the diamide, gave a 90% yield of the bisaminomethyl derivative.

1,4-Bis-(2-chlorobenzylaminomethyl)-bicyclo[2.2.2]octane

1,4-Bisaminomethylbicyclo[2.2.2]octane (4.4 g, 0.026 mole) and 2-chlorobenzaldehyde (7.3 g, 0.052 mole) were refluxed in benzene (80 ml) for 6 h with removal of water through a Dean-Starke trap. The resultant Schiff base, $\nu_{max}^{CHCl_3}$ 1 640 cm^{-1}, λ_{max}^{EtOH} 250 mμ (ϵ = 28 000), a semisolid (10.7 g), was refluxed in methanol (100 ml) with sodium borohydride (1.9 g) for 10 h. The methanol was removed *in vacuo* and the residue distributed between water and benzene. The benzene phase yielded the product (8.0 g), m.p. 82–84° (ether–petroleum ether), λ_{max}^{EtOH} 263 mμ (ϵ = 468). The dihydrochloride salt had m.p. 289–290° (ethanol).

Anal. Calcd. for $C_{24}H_{32}Cl_4N_2$: N, 5.71; Cl, 28.92. Found: N, 5.71; Cl, 28.73.

1,4-Bis-(2-trifluoromethylbenzylaminomethyl)-bicyclo[2.2.2]octane

2-Trifluoromethylbenzaldehyde (1.74 g, 0.01 mole), b.p. 28–38° at 0.3–0.6 mm, prepared by lithium tri-(*t*-butoxy)-hydride reduction (21) of the corresponding acid chloride, and 1,4-bisaminomethylbicyclo-[2.2.2]octane (0.84 g, 0.005 mole) were converted to the Schiff base as described above. It was reduced with sodium borohydride (4.0 g) in methanol to yield the product as an oil, λ_{max}^{EtOH} 265 mμ (ϵ = 2 030), 272 mμ (ϵ = 1 710). The dihydrochloride salt had m.p. 284–286.5° (methanol–ether) (1.4 g, 50%).

Anal. Calcd. for $C_{26}H_{32}Cl_2F_6N_2$: Cl, 12.72; N, 5.03. Found: Cl, 12.65; N, 4.90, 5.28.

1,4-Bis-(cyclohexylaminomethyl)-bicyclo[2.2.2]octane

1,4-Bisaminomethylbicyclo[2.2.2]octane (1.54 g) and cyclohexanone (1.8 g) were converted to the Schiff base as described above. It had $\nu_{max}^{CHCl_3}$ 1 643 cm^{-1} and was reduced with sodium borohydride (4 g) in methanol to yield the title product as an oil. The dihydrochloride salt (2.3 g, 62%) had m.p. > 310° (methanol–ether).

Anal. Calcd. for $C_{22}H_{42}Cl_2N_2$: Cl, 17.49; N, 6.91. Found: Cl, 17.17; N, 6.94, 7.18.

N,N'-Dicyclohexylmethylbicyclo[2.2.2]octane-1,4-dicarboxamide

Bicyclo[2.2.2]octane-1,4-dicarbonyl chloride (7.05 g) was added to a benzene solution (100 ml) of cyclohexylmethylamine (13.5 g) (prepared by catalytic hydrogenation of benzylamine). The mixture was refluxed for 20 min and then the solvent was removed *in vacuo*. The residue was washed well with water and crystallized from methanol. It had m.p. 248–250°.

Anal. Calcd. for $C_{24}H_{40}N_2O_2$: C, 74.17; H, 10.38; N, 7.21. Found: C, 73.81; H, 10.64; N, 7.12, 7.16.

N,N'-Di-(d,l-1-indanyl)-bicyclo[2.2.2]octane-1,4-dicarboxamide

Bicyclo[2.2.2]octane-1,4-dicarbonyl chloride (3.5 g) and *d,l*-1-aminoindane (8 g) were reacted together as described above to yield the title diamide, m.p. 250–252° (methanol).

Anal. Calcd. for $C_{28}H_{32}N_2O_2$: C, 78.46; H, 7.53; N, 6.54. Found: C, 77.98; H, 7.80; N, 6.63.

1,4-Bis-(cyclohexylmethylaminomethyl)-bicyclo[2.2.2]octane

N,N'-Dicyclohexylmethylbicyclo[2.2.2]octane-1,4-dicarboxamide (9.8 g) and lithium aluminium hydride (10 g) were refluxed in tetrahydrofuran (500 ml) for 24 h. The reaction was treated in the conventional manner to yield the title product as an oil. The dihydrochloride salt had m.p. > 310° (ethanol).

Anal. Calcd. for $C_{24}H_{46}Cl_2N_2$: Cl, 16.35; N, 6.46. Found: Cl, 16.10; 16.34; N, 6.50.

1,4-Bis-(d,l-1-indanylaminomethyl)-bicyclo[2.2.2]octane

N,N'-Di-(*d,l*-1-indanyl)-bicyclo[2.2.2]octane-1,4-dicarboxamide (6.1 g) was reduced with lithium aluminium hydride (10 g), as described above, to yield the title compound as a semisolid. The dihydrochloride salt had m.p. 308–310° (ethanol–ether).

Anal. Calcd. for $C_{28}H_{38}Cl_2N_2$: Cl, 14.97; N, 5.92. Found: Cl, 14.44; N, 5.87.

Dimethyl Bicyclo[2.2.2.]octane-1,4-dicarbamate

A solution of sodium methoxide in methanol (600 ml), prepared from 22.5 g of sodium (0.97 mole), and bromine (30 ml, 0.58 mole) were added alternately, in small portions, to a refluxing mixture of bicyclo[2.2.2]-octane-1,4-dicarboxamide (10 g, 0.05 mole) in methanol (100 ml). The addition took 3 h. Then the hot reaction mixture was filtered and evaporated to dryness *in vacuo* and the residue triturated with water. The remaining solid was crystallized from methanol to yield the product (8.5 g, 65%), m.p. 166–168°,

Anal. Calcd. for $C_{12}H_{20}N_2O_4$: C, 56.33; H, 7.87; N, 10.93. Found: C, 56.74; H, 7.65; N, 10.88.

1,4-Bis-(2-chlorobenzylamino)-bicyclo[2.2.2]octane

The above dicarbamate (8.5 g) was refluxed with concentrated hydrochloric acid (100 ml) for 17 h. The acid was removed *in vacuo* and the residue crystallized from a methanol–ether mixture to yield the dihydrochloride of 1,4-diaminobicyclo[2.2.2]octane, m.p. > 310°.

Anal. Calcd. for $C_8H_{18}Cl_2N_2$: N, 13.15. Found: N, 12.76.

The free base obtained from the dihydrochloride salt (2.5 g, m.p. 83–85°) and 2-chlorobenzaldehyde (5.0 g) were converted to the bis-Schiff base by refluxing in benzene (100 ml) for 2 h. It was obtained in a crystalline form from a benzene–hexane mixture and had m.p. 170–175° (5.1 g). The Schiff base was reduced with sodium borohydride (8.0 g) in methanol (50 ml) to yield the product as a solid, m.p. 95–97°. The dihydrochloride salt (4.6 g) had m.p. > 310° (MeOH–ether).

Anal. Calcd. for $C_{22}H_{28}Cl_4N_2$: Cl, 30.68; N, 6.06. Found: Cl, 30.82; N, 6.07.

THE WATER-SOLUBLE POLYSACCHARIDES OF DERMATOPHYTES

III. A GALACTOMANNAN FROM TRICHOPHYTON INTERDIGITALE[1,2]

ABSTRACT

The water-soluble polysaccharide preparation from *Trichophyton interdigitale* was fractionated to give two distinct galactomannans and a glucan. A galactomannan isolated via its insoluble copper complex had $[\alpha]_D$ +75° (water) and was composed of D-galactose (12%) and D-mannose (88%). On periodate oxidation, the galactomannan consumed 1.73 mole periodate and released 0.67 mole formic acid and 0.12 mole formaldehyde per anhydrohexose unit. Hydrolysis of the methylated galactomannan gave 2,3,5,6-tetra-*O*-methyl-D-galactose (1 part), 2,3,4,6-tetra-*O*-methyl-D-mannose (1 part), 2,3,4-tri-*O*-methyl-D-mannose (4 parts), and 3,4-di-*O*-methyl-D-mannose (2 parts). Mild acid hydrolysis of the galactomannan removed all the galactose residues, leaving a mannan having $[\alpha]_D$ +84° (water) whose structure was analyzed by periodate oxidation and methylation techniques.

Previous papers in this series have described the structural features of polysaccharides isolated from *Trichophyton granulosum* (1) and *Microsporum quinckeanum* (2). The water-soluble polysaccharides of dermatophytes form a part of the antigenic materials of these organisms (3) and as part of a program directed towards a study of the immunological properties of a group of related dermatophytes, the water-soluble polysaccharides isolated from *Trichophyton interdigitale* Priestly, 1917, have now been investigated. This paper records the structural analysis of a galactomannan isolated via its insoluble copper complex from the crude polysaccharide preparation obtained on extraction of *T. interdigitale* with 3% sodium hydroxide solution.

The polysaccharides were extracted in about 6% yield from the powdered cells of *T. interdigitale* in the way described previously for *T. granulosum* (1). The product was a light-brown powder containing 0.6% nitrogen and 5.1% ash and on hydrolysis gave mannose, glucose, and galactose in the approximate ratio of 5:1:1. Moving boundary electrophoresis of the polysaccharides in 0.05 *M* sodium tetraborate solution showed it to be composed of at least three components having the mobilities 8.43×10^{-5}, 8.19×10^{-5}, and 3.83×10^{-5} cm²/V s. The preparation was fractionated according to the scheme outlined in Fig. 1.

The polysaccharide obtained via its insoluble copper complex (galactomannan I) on moving boundary electrophoresis in 0.05 *M* sodium tetraborate gave a single sharp symmetrical peak (Fig. 2) having the same mobility as the fastest moving component in the original polysaccharide mixture. The non-copper complexing polysaccharides were recovered by ethanol precipitation from the deionized Fehling solution and were then resolved by chromatography on diethylaminoethyl (DEAE) cellulose (4). A glucan, which had $[\alpha]_D^{21}$ −16° (water) and on moving boundary electrophoresis in 0.05 *M* sodium

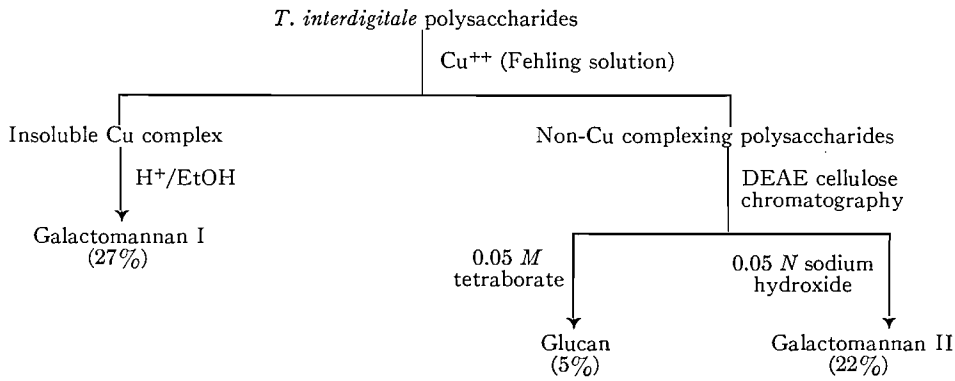

FIG. 1.

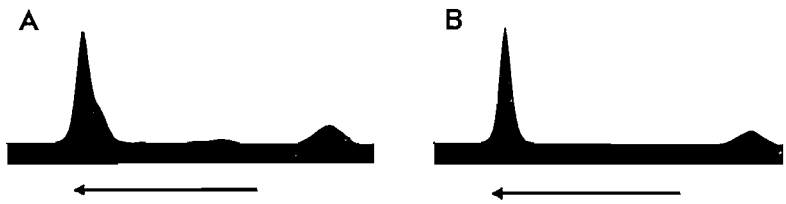

FIG. 2. Moving boundary electrophoresis of polysaccharides from *T. interdigitale*. (A) Crude polysaccharide mixture, (B) purified galactomannan I. Buffer, 0.05 *M* sodium tetraborate.

tetraborate had the same mobility as the slowest component of the original polysaccharide mixture, was eluted from the DEAE cellulose column by 0.05 *M* sodium tetraborate solution. A second galactomannan (galactomannan II) eluted from the column by 0.05 *N* sodium hydroxide solution had $[\alpha]_D^{20}$ +20.6° (water) and a mobility on moving boundary electrophoresis almost identical with that of the component in the original mixture which moved slightly slower than galactomannan I. The structures of the glucan and galactomannan II will be discussed in a future communication.

Galactomannan I was a white powder having $[\alpha]_D^{20}$ +75° (water), was readily soluble in water, and did not give a color with iodine or reduce Fehling solution. Acid hydrolysis of the polysaccharide followed by paper chromatographic examination of the hydrolysate showed it to be composed only of galactose and mannose. The component glycoses were separated chromatographically and were identified as D-galactose and D-mannose. Quantitative determinations of the component glycoses by the gas–liquid partition chromatographic (g.l.p.c.) method (5) and by the colorimetric phenol – sulfuric acid method (6) showed D-galactose and D-mannose to be present in a ratio 1:8.2. The change in the specific optical rotation of the polysaccharide on hydrolysis from +75° to +20.8° (constant value) is that expected of a glycan having the above composition.

Hydrolysis of galactomannan I with 0.02 *N* sulfuric acid at 100° was found to release all the galactose residues from the polysaccharide, leaving a polymer (mannan I) which had $[\alpha]_D$ +84° (water) and gave only mannose on hydrolysis. The above conditions have been shown (7) to effect the selective hydrolysis of galactofuranose residues without affecting the considerably more stable mannopyranose residues. It is considered that the mannan I retains the main structural features of galactomannan I.

Methylated galactomannan I was hydrolyzed, the mixture of products was analyzed by paper chromatography, and the individual components identified after isolation by

For personal use only.

cellulose column chromatography (9). In addition, the methyl glycosides of the sugar ethers, prepared from a portion of the hydrolysate, were analyzed by gas–liquid partition chromatography (8). The overall data obtained by fragmentation analysis of the methylated polysaccharide are given in Table I.

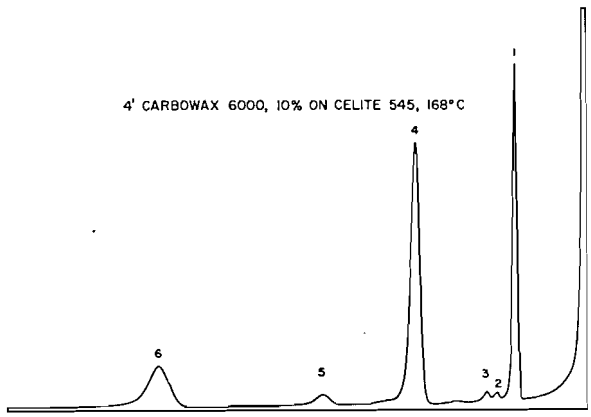

FIG. 3. Gas–liquid chromatogram of methyl *O*-methyl glycosides from the methylated galactomannan I of *T. interdigitale*. (1) Methyl 2,3,5,6-tetra-*O*-methyl-α-D-galactoside and methyl 2,3,4,6-tetra-*O*-methyl-α-D-mannoside (T_G 1.01), (2) methyl 2,3,5,6-tetra-*O*-methyl-β-D-galactoside (T_G 1.26), (3) methyl 2,3,4,6-tetra-*O*-methyl-β-D-mannoside (T_G 1.40), (4) methyl 2,3,4-tri-*O*-methyl-α-D-mannoside (T_G 2.37), (5) methyl 2,3,4-tri-*O*-methyl-β-D-mannoside (T_G 3.68), (6) methyl 3,4-di-*O*-methyl-α-D-mannoside (T_G 5.95).

Since the presence of even minor amounts of a particular type of glycosidic linkage in a polysaccharide is revealed in the immunological and serological properties of the material (10, 11), the tri-*O*-methyl and di-*O*-methyl glycose fractions were carefully examined to establish the absence of glycoses other than the identified components. The tri-*O*-methyl fraction gave only mannose on demethylation (12) and g.l.p.c. of the methanolysis product gave two peaks corresponding to methyl 2,3,4-tri-*O*-methyl-α- and 2,3,4-tri-*O*-methyl-β-D-mannoside (peaks 4 and 5, Fig. 3). All the other possible tri-*O*-methylmannopyranose derivatives, with the exception of 3,4,6-tri-*O*-methylmannose, give methyl glycosides having higher relative retention times. The absence of 3,4,6-tri-*O*-methylmannose was shown by the fact that paper electrophoresis of the fraction in borate buffer (13) did not reveal a mobile component. The purity of the fraction was further established by the fact that periodate oxidation of the glycitol produced by borohydride reduction of a portion of the fraction consumed 1 mole periodate and released 1.01 mole formaldehyde per mole of glycitol and the oxidation product contained only 2,3,4-tri-*O*-methylarabinose which was identified by paper chromatography and g.l.p.c. analysis; the only tri-*O*-methylmannose derivative which could give this result is 2,3,4-tri-*O*-methylmannose.

The di-*O*-methyl fraction gave only mannose on demethylation, and g.l.p.c. analysis of the product obtained on methanolysis of the fraction gave a single peak having the same relative retention time as authentic methyl 3,4-di-*O*-methyl-α-D-mannopyranoside. Thin-layer chromatography of the di-*O*-methyl fraction indicated the presence of trace amounts of a derivative having the chromatographic properties corresponding to 3,5-di-*O*-methyl-D-mannose.

The molecular ratios of the *O*-methyl glycoses were determined by quantitative paper chromatography, phenol – sulfuric acid being used for their colorimetric assay (6), and by quantitative analysis of the g.l.p. chromatogram. The results are in good agreement with those from the yields obtained in the cellulose column separation (Table I).

TABLE I

Molecular ratios of the methylated glycoses obtained from methylated galactomannan I

	2,3,5,6-Tetra-*O*-methyl-D-galactose	2,3,4,6-Tetra-*O*-methyl-D-mannose	2,3,4-Tri-*O*-methyl-D-mannose	3,4-Di-*O*-methyl-D-mannose
Quantitative paper chromatography	1	1.12	4.02	1.97
Gas–liquid partition chromatographic analysis of methyl glycosides	← 2 →		3.90	1.80
Cellulose column (weight of fraction)	1	1.02	4.22	2.13

The fission of methylated mannan I gave 2,3,4,6-tetra-*O*-methyl-D-mannose, 2,3,4-tri-*O*-methyl-D-mannose, and 3,4-di-*O*-methyl-D-mannose. The absence of any other glycoses in the tri-*O*- and di-*O*-methyl fractions isolated by preparative paper chromatography was established in the same way as that described above in the analysis of the methylated galactomannan I. Quantitative g.l.p.c. of the methyl glycosides prepared from the hydrolysate of the methylated mannan showed the tetra-*O*-, tri-*O*-, and di-*O*-methyl glycoses to be present in the molecular ratios 1:5:1.

The galactomannan I was oxidized with metaperiodate under unbuffered conditions. Extrapolation of the 'overoxidation' part of the periodate curve to zero time gave a value for the periodate uptake corresponding to 1.73 mole of periodate per anhydrohexose unit and a release of 0.67 mole of formic acid per anhydrohexose unit. Periodate oxidation of the polysaccharide also released 0.12 mole of formaldehyde (50 min constant value) per anhydrohexose unit, which probably all arises from the cleavage of the C_5-C_6 glycol system in the galactofuranose residues. Hydrolysis of the reduced, periodate-oxidized galactomannan I gave glycerol and no detectable amounts of tetritols or aldohexoses, which is the result expected from the polysaccharide having the proposed structure (II).

Periodate oxidation of the mannan I showed an uptake of 1.86 mole of periodate and a release of 0.76 mole of formic acid per anhydromannose unit. Hydrolysis of the reduced, periodate-oxidized mannan I, gave only glycerol and no mannose.

The methylation and periodate oxidation results are in agreement with a structure such as I for mannan I, although several other types of arrangement are clearly possible. As a means of limiting these possibilities, selective oxidation (14) of the side units to D-mannuronic acid residues has been attempted. So far this oxidation step has not been carried out successfully, but the formation of such residues should clearly permit aldobiuronic acids to be isolated from the oxidized polysaccharide and the type of linkage binding the end units to be established directly.

$$-\left[-(\text{D-Man}p)-(1\rightarrow 2 \text{ or } 6)-(\text{D-Man}p)-[-(1\rightarrow 6)-(\text{D-Man}p)]_4-\right]_n-.$$
$$\begin{array}{c} \\ \\ \\ 2 \text{ or } 6 \\ \uparrow \\ 1 \\ \text{D-Man}p \end{array}$$

(I)

The fact that the tri-*O*-methyl fraction obtained from the hydrolysate of the methylated mannan I contained only 2,3,4-tri-*O*-methyl-D-mannose and no 3,4,6-tri-*O*-methyl-D-mannose and the hydrolysate of the methylated galactomannan I contained 3,4-di-*O*-methyl-D-mannose as the di-*O*-methyl glycose leads to the conclusion that the D-galactofuranose residues in the original polysaccharide are linked $1\rightarrow 2$ to mannose units. One of the several possible structures for the galactomannan I, consistent with the methylation and periodate oxidation data, is given below (II). The indicated presence of a small

$$-\left[-(1\rightarrow 6)-(\text{D-Man}p)-(1\rightarrow 6)-[(\text{D-Man}p)-(1\rightarrow 6)]_2-(\text{D-Man}p)-(1\rightarrow 6)-[\text{D-Man}p)-(1\rightarrow 6)]_2-\right]_n-$$
$$\begin{array}{cc} 2 & 2 \\ \uparrow & \uparrow \\ 1 & 1 \\ \text{D-Gal}f & \text{D-Man}p \end{array}$$

(II)

proportion of 3,5-di-*O*-methyl-D-mannose in the di-*O*-methyl fraction obtained from the fission products of the methylated galactomannan I suggests the presence of 2-*O*- and 6-*O*-substituted D-mannofuranose residues in the original polysaccharide; this unusual possibility has not been unequivocally proved at this time. In view of the high positive specific optical rotation of the polysaccharide it is probable that most of the linkages have the α-D-configuration.

It appears that the galactomannan I from *T. interdigitale* bears a remarkable similarity in many of its structural features to the galactomannan from *T. granulosum* (1), which, to our knowledge, was the first galactomannan to be isolated from a microorganism. Both galactomannans are unusual in having all of the galactose units present as terminal nonreducing furanoside residues.

EXPERIMENTAL

Paper chromatography was performed by the descending method (15) on Whatman No. 1 filter paper using the following solvent systems: (A) pyridine : ethyl acetate : water (2:5:5 v/v, upper phase) and (B) butanone saturated with water. Paper electrophoreses were done on Whatman 3MM paper in 0.1 *M* sodium tetraborate at 700 V (potential gradient ca. 25 V/cm) and 25–35 mA for 2–3 h. The glycoses were detected on the paper chromatograms and electrophoretograms by (*a*) spraying with a solution of 2% (w/v) *p*-anisidine hydrochloride in butan-1-ol (16) or (*b*) with a solution of 2% (w/v) silver nitrate in acetone followed by 3% (w/v) ethanolic sodium hydroxide solution (17). The rates of movement of the glycoses on the paper chromatograms are quoted relative to that of D-galactose (R_{Gal}) or 2,3,4,6-tetra-*O*-methyl-D-glucose (R_G), and relative to D-glucose (M_G) on the paper electrophoretograms.

Gas–liquid partition chromatography was done with a Pye Argon Chromatograph fitted with an ionization detector (^{90}Sr, 80 μcuries) using straight glass columns (120 × 0.5 cm inside diameter) which were packed with 10% (w/w) Carbowax 6 000 on 80–100 mesh acid-washed Chromosorb W (Johns-Manville). The retention times of the glycoses are quoted relative to methyl 2,3,4,6-tetra-*O*-methyl-α-D-glucoside (T_G).

Solutions were concentrated under reduced pressure below 35°. Melting points were determined on a Fisher-Johns Apparatus and are corrected.

Preparation of Water-Soluble Polysaccharides

Trichophyton interdigitale was grown in 500 ml Erlenmeyer flasks containing 250–300 ml each of an agar medium containing the following nutrients: 4% (w/v) unpurified glucose (cerelose), 1% (w/v) neopeptone "Difco", 0.05% (w/v) yeast extract "Difco", 0.001% (w/v) thiamine, 0.005% (w/v) inositol, made up in tap water. The polysaccharides were extracted from the autoclaved, washed, freeze-dried, and milled mycelium as described previously for *T. granulosum* (1). The polysaccharides were obtained as a light-brown powder which contained 0.6% N and 5.1% ash and amounted to 5.9% of the dry mycelium. A sample of the preparation (10 mg) after hydrolysis with 2 *N* sulfuric acid for 5 h at 100 °C was found by paper chromatography (solvent A) to give spots corresponding to galactose, glucose, and mannose in the visual ratio 1:1:5. Moving boundary electrophoresis showed that at least three components were present.

Isolation of Galactomannan I

The polysaccharide preparation from *T. interdigitale* (50 g) was dissolved in water (350 ml) and Fehling solution A (500 ml). Fehling solution B (500 ml) was added dropwise over a 30 min interval to the vigorously stirred solution and after a further 30 min the precipitated complex was collected by centrifugation. The complex was washed twice with water (500 ml) by gentle mixing in a Waring Blendor and the product was then suspended in ice water (60 ml) and decomposed by the addition of just sufficient dilute acetic acid to bring the material into solution. The clear-blue solution was poured into 10 volumes of absolute ethanol and the precipitated polysaccharide was collected by centrifugation, deionized by passing its aqueous solution (70 ml) through columns of Amberlite IR120(H^+) and Amberlite IR45(OH^-) ion-exchange resins, and the neutral effluent and washings, after concentration to about 100 ml, was poured into absolute ethanol (1.2 l). The precipitated polysaccharide was collected by centrifugation, washed with ethanol, and dried under vacuum. The yield of polysaccharide (galactomannan I) was 13.5 g (27%). The non-copper complexing polysaccharides were recovered from the solution containing the excess Fehling solution by precipitation with ethanol.

Properties of Galactomannan I

Galactomannan I was a white powder, readily soluble in water, and had $[\alpha]_D^{22}$ +75° (*c*, 2 water).

Anal. Calcd. for hexosan $(C_6H_{10}O_5)_n$: C, 44.44; H, 6.22. Found: C, 44.0; H, 6.40; N, nil; ash, 0.03. The polysaccharide was neutral, gave no color with iodine, and did not reduce Fehling solution.

Moving boundary electrophoresis of galactomannan I in 0.05 *M* sodium tetraborate showed a single

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

sharp symmetrical peak having the mobility of the fastest component in the original polysaccharide preparation ($\mu = 8.43 \times 10^{-5}$ cm²/V s).

Component Glycoses of Galactomannan I

Galactomannan I (0.4 g) was hydrolyzed by 2 *N* sulfuric acid (50 ml) at 100° for 5 h, and, after neutralization ($BaCO_3$) and filtration, the filtrate was concentrated to a syrup. The syrup was fractionated on sheets of Whatman 3MM paper using solvent system A. Sections of the paper containing the glycoses were extracted with water. The solutions were deionized by passage through mixed Amberlite IR120(H^+) and Amberlite IR45(OH^-) ion-exchange resins and concentrated to dryness. The glycoses were identified as (A) D-galactose (the syrup (34 mg) had $[\alpha]_D^{22}$ +80° (*c*, 1 water) and gave a 1-methyl-1-phenylhydrazone derivative having m.p. and mixed m.p. 163°) and (B) D-mannose (the syrup (310 mg) had $[\alpha]_D^{20}$ +14° (*c*, 2 water) and gave a phenylhydrazone derivative having m.p. and mixed m.p. 186–187°).

Quantitative Estimation of the Component Glycoses of Galactomannan I

Samples of the galactomannan I (40–50 mg) were hydrolyzed for 6 h with 2 *N* sulfuric acid at 100°. The neutralized ($BaCO_3$) hydrolysates were concentrated and, after paper chromatographic fractionation with solvent A, the glycoses were estimated colorimetrically by the phenol – sulfuric acid method (6). The results indicate that the D-galactose and D-mannose are present in the ratio 1:8.6.

Found: D-galactose: 11.3, 12.1, 11.7. D-Mannose: 88.7, 87.9, 88.3%.

Quantitative analysis of reduced acetylated products of samples of the hydrolyzed galactomannan I (c. 5–6 mg) by gas–liquid partition chromatography using the procedure described by Gunner *et al.* (5) indicated the D-galactose : D-mannose ratio to be 1:7.4. On hydrolysis of a sample of the galactomannan I with 2 *N* hydrochloric acid at 100° the specific optical rotation of the solution was found to change from $[\alpha]_D^{20}$ +74° (*c*, 2) to $[\alpha]_D^{20}$ +20.8° (*c*, 1.2).

Partial Hydrolysis of Galactomannan I to Give Mannan I

Galactomannan I (1.5 g) was heated with 0.02 *N* sulfuric acid (100 ml) at 100 °C for 4 h and then deionized by passage through a column of Amberlite IR45(OH^-) ion-exchange resin. The neutral effluent was concentrated to about 12 ml and the solution was poured into absolute alcohol (200 ml). The precipitated polysaccharide (mannan I) was collected, washed with ethanol, and dried *in vacuo* (1.14 g, 76%). The polysaccharide had $[\alpha]_D^{20}$ +84° (*c*, 2 water). Paper chromatographic examination in solvent system A of a sample (5 mg) of the polysaccharide hydrolyzed for 6 h with 2 *N* sulphuric acid (3 ml) at 100° showed only mannose to be present. The ethanol solution was concentrated and on paper chromatographic analysis (solvent A) it showed a single spot, corresponding to galactose.

Methylation of Galactomannan I

To the galactomannan I (5 g) in water (50 ml) were added simultaneously and dropwise with stirring, 30% (w/v) sodium hydroxide solution (150 ml) and dimethyl sulfate (64 ml), at a rate such that the mixture remained slightly alkaline throughout. After 6 h, 30% (w/v) sodium hydroxide solution (160 ml) and dimethyl sulfate (50 ml) were added dropwise during 8 h and stirring was continued for 20 h. The mixture was then heated on a boiling water bath for 30 min to destroy any excess dimethyl sulfate and the cooled solution was very carefully neutralized in the cold with 2 *N* sulfuric acid. The partially methylated product was extracted with chloroform (6 × 100 ml) and the dried (Na_2SO_4) extract was concentrated to a syrup (5.42 g). The syrup (5.2 g) was further methylated (18) by treating its vigorously stirred solution in dimethylformamide (60 ml) and methyl iodide (50 ml) with finely powdered barium oxide (60 g). Water (0.2 ml) was added to the mixture and after 2 h the pasty reaction mixture was diluted with chloroform (300 ml). The reaction mixture was filtered and the filtrate was extracted with water (5 × 150 ml). The dried (Na_2SO_4) chloroform solution was concentrated to yield a syrup (5.1 g). The syrup, dissolved in ethanol (10 ml), was poured into light petroleum (b.p. 30–60°) (300 ml) and the precipitated methylated polysaccharide was collected (4.51 g). The final product was a cream-colored powder having $[\alpha]_D^{21}$ +80° (*c*, 2.1 chloroform) and OMe 44.5% (calcd. OMe 45.6%) which could not be raised by re-methylation.

Fission of Methylated Galactomannan I

The methylated galactomannan I (3.5 g) was dissolved in cold 72% (v/v) sulfuric acid (20 ml). After 30 min at room temperature, the solution was diluted with water (140 ml) and the hydrolysis was continued by heating the mixture on a boiling water bath for 5 h. The cooled solution was neutralized by passage down a column of Amberlite IR45(OH^-) ion-exchange resin and the effluent washings were evaporated in a stream of dry air to a syrup (3.7 g). Paper chromatographic examination of samples of the hydrolysate using solvent system A showed three spots having R_G 0.99, 0.87, and 0.72, respectively; four components having R_G 1.05, 0.98, 0.72, and 0.39 were detected, using solvent system B. A portion of the hydrolysate (60 mg) was heated in a sealed tube at 95° with 2% methanolic hydrogen chloride solution (5 ml) for 5 h. The cooled solution was neutralized (Ag_2CO_3), filtered, and the filtrate was concentrated to a thin syrup in a stream of dry air. The methyl glycosides were examined by gas–liquid partition chromatography to give the separation shown in Fig. 3.

The *O*-methyl glycoses (2.1 g) were separated chromatographically on a column of powdered cellulose (3 × 58 cm), using solvent system B, to yield the following fractions.

Fraction 1, 2,3,5,6-Tetra-O-methyl-D-galactose

Fraction 1 (141 mg) on paper chromatography gave a single spot having R_G 1.02 (solvent B) corresponding to authentic 2,3,5,6-tetra-*O*-methyl-D-galactose. Oxidation of a portion of the fraction (60 mg) with bromine gave a lactone which was converted to its amide (32 mg) which had $[\alpha]_D$ +8° (*c*, 2 water) and m.p. 158° which was undepressed on admixture with 2,3,5,6-tetra-*O*-methyl-D-galactonamide.

Fraction 2, 2,3,5,6-Tetra-O-methyl-D-galactose and 2,3,4,6-Tetra-O-methyl-D-mannose

The syrup (208 mg) contained two components with R_G 1.02 and 0.97 (solvent B) corresponding to 2,3,5,6-tetra-*O*-methylgalactose and 2,3,4,6-tetra-*O*-methylmannose respectively. Further fractionation of the syrup by filter paper chromatography gave pure 2,3,5,6-tetra-*O*-methyl-D-galactose (107 mg) and 2,3,4,6-tetra-*O*-methyl-D-mannose. The latter compound was combined with fraction 3.

Fraction 3, 2,3,4,6-Tetra-O-methyl-D-mannose

Fraction 3 (253 mg) was chromatographically pure giving a single spot corresponding to 2,3,4,6-tetra-*O*-methylmannose. It had $[\alpha]_D$ +3° (*c*, 1 water) and a portion of the syrup (60 mg) after heating under reflux with aniline (32 mg) in ethanol (2 ml) gave crystalline 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-mannosylamine, which on recrystallization from ethanol had m.p. and mixed m.p. 142° and $[\alpha]_D$ −75° to −7° (*c*, 0.04 MeOH).

Fraction 4, 2,3,4-Tri-O-methyl-D-mannose

The fraction (982 mg) was shown by paper chromatography and electrophoresis to consist of one component. Bromine oxidation converted the material to a lactone from which 2,3,4-tri-*O*-methyl-D-mannanamide was prepared; when recrystallized from ethyl acetate, the amide had m.p. 142–143°, undepressed; $[\alpha]_D$ +5 (*c*, 1 water).

A portion of fraction 4 (60 mg) was reduced with excess of sodium borohydride. The derived glycitol consumed 1.0 moles of periodate and released 1.0 moles of formaldehyde per mole. The sugar formed in this oxidation, as shown by paper chromatography and by g.l.p.c. analysis of its methyl glycoside, appeared to consist entirely of 2,3,4-tri-*O*-methyl-L-arabinose.

Fraction 5, 3,4-Di-O-methyl-D-mannose

The fraction (465 mg) having R_G 0.72 (solvent A) and 0.72 (solvent B) and M_G 0.34 showed $[\alpha]_D^{22}$ +35.7° (*c*, 1.6 methanol) and corresponded in the above properties to 3,4-di-*O*-methyl-D-mannose. On standing, the fraction crystallized and the material after recrystallization from ethyl acetate solution had m.p. and mixed m.p. 78–79° and $[\alpha]_D^{20}$ +5.5° (*c*, 2 water). A sample of the original fraction, before crystallization, was refluxed with 2% (w/v) methanolic hydrogen chloride (4 ml) for 6 h and the product on g.l.p.c. examination was found to give a single peak corresponding to methyl 3,4-di-*O*-methyl-α-D-mannoside. Demethylation with BCl_3 of a portion of the fraction and paper chromatographic examination of the product showed only one spot corresponding to mannose. A portion of the di-*O*-methyl fraction examined by thin-layer chromatography on a silica gel G using benzene : acetone (1:1) as the developing solvent revealed a major component having the same mobility as 3,4-di-*O*-methyl-D-mannose and a minor component (ca. 4%) having a slightly greater mobility. The minor component isolated by preparative thin-layer chromatography had M_G 0.56 and R_G 0.67 (solvent A) and was indistinguishable chromatographically from 3,5-di-*O*-methyl-D-mannose.

Periodate Oxidation of Galactomannan I

The galactomannan I (0.210 g) was dissolved in water (200 ml), 0.3 *M* sodium metaperiodate solution (25 ml) was added, and the total volume adjusted to 250 ml with water. A blank solution containing no polysaccharide was prepared at the same time. Oxidation was allowed to proceed in the dark at 22°. At intervals, the periodate uptake was determined by transferring samples (10 ml) from the oxidation mixture and the blank to a fresh mixture of *M*/15 sodium phosphate buffer (pH 6.99) (100 ml) and 20% (w/v) potassium iodide solution (10 ml), and the liberated iodine was titrated with 0.025 *N* sodium thiosulfate solution, using starch as an indicator. Formic acid liberation was followed by titration of samples (10 ml) of the oxidation mixture, treated for 5 min with ethylene glycol to destroy the excess periodate, with 0.01 *N* sodium hydroxide solution using methyl red screened with methylene blue as the indicator. The results are recorded below (Table II).

The formaldehyde released from the galactomannan I on periodate oxidation was determined by treating the polysaccharide (32.8 mg) in water (20 ml) containing 0.05% *p*-hydroxybenzaldehyde with 0.3 *M*

TABLE II

Periodate oxidation of galactomannan I

Time of oxidation (h)	18	42	66	89	116	140	171
Mole of IO_4 consumed per 162 g galactomannan	1.60	1.85	1.92	1.97	2.07	2.12	2.20
Mole HCO_2H released per 162 g galactomannan	0.55	0.75	0.82	0.91	0.93	1.06	1.17

sodium metaperiodate solution (3 ml). The total volume of the reaction mixture was adjusted to 25 ml with water and the oxidation was allowed to proceed in the dark at 22°. Samples (1 ml) were withdrawn from the mixture at intervals and were neutralized with 20% (w/v) lead dithionate solution (1 ml) and, after removal of the precipitated lead salts by centrifugation, the formaldehyde contents of the clear supernatant liquids were determined by the chromotropic acid method (19). The moles of formaldehyde released per anhydrohexose unit were found to be 0.074 (3 min), 0.088 (10 min), 0.119 (25 min), 0.120 (50 min, constant value).

A sample of the galactomannan I (50 mg) in water (10 ml) was oxidized by the addition of 0.3 *M* sodium metaperiodate solution (5 ml) and after the reaction had been allowed to proceed in the dark at 22° for 50 h, the mixture was deionized by passage through a bed of mixed Amberlite IR120(H^+) and Duolite A4(OH^-) ion-exchange resins. The neutral solution was reduced by the addition of sodium borohydride (50 mg) and after 5 h the solution was treated with Amberlite IR120(H^+) ion-exchange resin to destroy the excess borohydride and remove sodium ions. The solution was filtered and the concentrated filtrate was hydrolyzed with 2 *N* sulfuric acid (4 ml) at 100° for 4 h. The neutralized solution ($BaCO_3$) was filtered and the filtrate was concentrated in a stream of dry air. Paper chromatographic examination of the residue using solvent system A showed a single spot whose chromatographic behavior was identical with glycerol, and no spots corresponding to tetritols or hexoses were observed.

Methylation of Mannan I

Mannan I (0.5 g) was methylated in the same way as that described for galactomannan I to give a product (0.38 g) having $[\alpha]_D^{20}$ +90° (*c*, 1 chloroform) and OMe 44.2%, which could not be raised by further methylation using silver oxide and methyl iodide.

Fission of Methylated Mannan I

Methylated mannan I (0.3 g) was dissolved in cold 75% sulfuric acid (3.6 ml) and after the addition of water (22 ml) the solution was heated on a boiling water bath for 7 h. The cooled reaction mixture was neutralized by passage down a column of Amberlite IR45(OH^-) ion-exchange resin and the solution containing the *O*-methyl glycoses was concentrated to a syrup by evaporation in a stream of dry air. Paper chromatography of the concentrate in solvent system A indicated the presence of 2,3,4,6-tetra-*O*-methylmannose, 2,3,4-tri-*O*-methylmannose, and 3,4-di-*O*-methylmannose having R_G 0.99, 0.86, and 0.71, respectively. A portion (30 mg) of the *O*-methyl glycoses was heated in a sealed tube with 2% methanolic hydrogen chloride (5 ml) for 7 h and after neutralization (Ag_2CO_3) and concentration of the solution, the methyl glycosides were examined by g.l.p.c. The gas–liquid partition chromatogram showed the same peaks as those obtained on methanolysis of the products obtained from the methylated galactomannan I. Quantitative analysis of the g.l.p.c. chromatogram indicated the glycoses to be present in the tetra-*O*- : tri-*O*- : di-*O*-methyl glycose ratios of 1 : 4.8 : 0.97.

The *O*-methyl glycoses were fractionated (solvent A) on two large sheets of Whatman 3MM filter paper to give (A) 2,3,4,6-tetra-*O*-methyl-D-mannose (32 mg), which gave a derivative 2,3,4,6-tetra-*O*-methyl-*N*-phenyl-D-mannosamine having m.p. and mixed m.p. 141°, (B) 2,3,4-tri-*O*-methyl-D-mannose (170 mg), which gave an amide having m.p. 141–143°, undepressed on admixture with authentic 2,3,4-tri-*O*-methyl-D-mannonamide, and (C) 3,4-di-*O*-methyl-D-mannose (28 mg), which had m.p. and mixed m.p. 78–79°. An examination of the tri-*O*-methyl fraction by paper electrophoresis in borate buffer showed only a single spot having M_G 0.00, and periodate oxidation of a portion of the reduced fraction gave a single product, identified by paper chromatography, and by g.l.p.c. analysis of its methyl glycoside preparation, as 2,3,4-tri-*O*-methylarabinose.

Periodate Oxidation of Mannan I

Mannan I (125 mg) was dissolved in water (200 ml) and after the addition of 0.3 *M* sodium metaperiodate the volume of the solution was adjusted to 250 ml. A blank solution containing no polysaccharide was prepared at the same time. Oxidation was allowed to proceed in the dark at 22° and at intervals samples were withdrawn for the determination of periodate uptake and formic acid release. The results are recorded below (Table III).

A sample of mannan I (60 mg) was dissolved in water (50 ml) and was oxidized by the addition of 0.3 *M* sodium metaperiodate. After oxidation had been allowed to proceed at 20° for 78 h, the reaction mixture was deionized by passing it through a bed of mixed Amberlite IR120(H^+) and Amberlite IR45(OH^-)

TABLE III

Periodate oxidation of mannan I

Time of oxidation (h)	20	26	45	72	96	118	150
Mole of IO_4 consumed per 162 g mannan I	1.78	1.87	1.98	2.01	2.07	2.14	2.20
Mole of HCO_2H released per 162 g mannan I	0.61	0.69	0.81	0.87	0.90	0.93	1.00

ion-exchange resins, and sodium borohydride (100 mg) was added. After 12 h the excess borohydride was destroyed with IR120(H^+) resin and the solution was evaporated to dryness. The residue was hydrolyzed with 2 *N* sulfuric acid (4 ml) at 100° for 4 h, neutralized ($BaCO_3$), and the filtered solution was evaporated to dryness. Paper chromatographic examination (solvent A) of the hydrolysate showed a single spot corresponding to glycerol. No mannose could be detected, even on heavily spotted chromatograms.

ENERGY TRANSFER IN THE RADIOLYSIS OF CYCLOPENTANE–CYCLOHEXANE MIXTURES[1]

J. A. STONE
Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario

Received July 20, 1964

ABSTRACT

Energy transfer in the radiolysis of cyclopentane–cyclohexane mixtures has been studied by observing the yields of HD and D_2 obtained when small amounts of cyclohexane-d_{12} are added. Energy migration occurs from cyclopentane to cyclohexane but this transfer can be prevented by the addition of carbon tetrachloride or iodine. The relative yields of the dimers $(C_6H_{11})_2$, $C_5H_9C_6H_{11}$, and $(C_5H_9)_2$ show that the $\cdot C_6H_{11}$ and $\cdot C_5H_9$ radicals, which are the precursors of the dimers, can abstract hydrogen atoms from the solvent and may thus change their identity. Added iodine or carbon tetrachloride removes the diffusing radicals, and the residual dimer yield, which is unaffected by solute, has a composition determined solely by the composition of the mixtures. The yields of cyclohexene and cyclopentene show evidence of both energy transfer and radical change of identity.

INTRODUCTION

The lowering of the yields of hydrogen from the radiolysis of binary mixtures of hydrocarbons below those expected from a simple mixing of the two species has been interpreted in terms of energy transfer processes. This latter term includes any process, e.g. charge transfer, excitation transfer, or electron capture, which can be described as a physical process as opposed to chemical processes represented by, for example, radical scavenging. Most examples of energy transfer have resulted from studies on mixtures of a saturated and an aromatic hydrocarbon (1–4). Departures from ideality in the radiolysis of binary mixtures of saturated hydrocarbons are not so pronounced and hence not so readily observable. Fewer examples have been recorded.

Dyne and Denhartog (5) using isotopically labelled hydrocarbons have shown that different alkane solvents can influence the yield of hydrogen from a given hydrocarbon solute to widely differing extents. From a study of the products formed in the radiolysis of dilute solutions of cyclohexane in cyclopentane, they showed that an increase in cyclohexene yield above that expected from the electron fraction of the parent hydrocarbon occurred, but that the yield of dimers containing cyclohexyl groupings was reduced (6). The increased olefin yield was attributed to a transfer of energy initially absorbed in the cyclopentane to the cyclohexane. The decreased yield of dimeric products containing cyclohexyl groups was in agreement with earlier work of Muccini and Schuler (7). These authors found over the whole range of cyclohexane–cyclopentane mixtures a greater proportion of dimeric products containing cyclopentyl groupings than would be expected from the electron fraction of the parent hydrocarbon. This was explained in terms of a change in identity of the radicals which, they assumed, were formed initially according to the electron fraction of the parent hydrocarbons.

[1] $$\cdot C_5H_9 + C_6H_{12} \rightarrow \cdot C_6H_{11} + C_5H_{10}$$

[2] $$\cdot C_6H_{11} + C_5H_{10} \rightarrow \cdot C_5H_9 + C_6H_{12}$$

If the rate of reaction [2] is greater than that of [1], then the steady-state concentration of cyclopentyl radicals will be increased at the expense of the cyclohexyl radicals. The

saturated dimeric products (bicyclohexyl, bicyclopentyl, and cyclopentylcyclohexane) formed by radical dimerization should therefore show a bias towards cyclopentyl groups.

Previous work with cyclohexane – carbon tetrachloride mixtures (8) has shown that, at the lowest carbon tetrachloride concentration that it is practical to work with ($\sim 0.04\ M$), all cyclohexyl radicals are scavenged. However, although at this concentration the yield of the dimeric product bicyclohexyl has been reduced to a very low limiting value, the cyclohexene yield is still high and is not reduced to its limiting value until much higher solute concentrations. This demonstrates that cyclohexene is formed in at least two ways, one of which involves disproportionation of cyclohexyl radicals. The same conclusion will probably apply to the formation of cyclopentene from cyclopentane.

The present work was undertaken to study the cyclopentane–cyclohexane system in detail, and in particular the energy transfer process and its relationship to the yields of the major products.

EXPERIMENTAL PROCEDURES

Materials

Cyclopentane (Phillips Research Grade) was shaken with sulfuric acid to remove cyclopentene and was then fractionally distilled. Cyclohexane (Fisher Spectrograde), iodine (Anachemia), carbon tetrachloride (Fisher Certified Reagent), and cyclohexane-d_{12} (Merck) were used as received. As the cyclohexane was free of cyclohexene it was not further purified.

Sample Preparation and Irradiation

All samples were of 2 ml volume contained in pyrex tubes fitted with break seals. Samples were made up individually and were then degassed by the freeze-thaw-pump technique. ^{60}Co-γ-irradiations were carried out at dose rates of 1.66×10^{22} eV/l h and 1.43×10^{21} eV/l h to total doses of $\sim 3.3 \times 10^{22}$ eV/l.

Product Analysis

The measurement of the hydrogen yield has been described previously (9). The isotopic composition of the hydrogen was determined on a C.E.C. 21-610 mass spectrometer.

Liquid products, olefins and dimers, were determined by gas–liquid chromatography using the following columns and column conditions: for cyclohexene, 1/4 in. × 10 ft, 30% 1,2,3-tris(2-cyanoethoxy)propane at 65 °C; for cyclopentene, 1/4 in. × 12 ft, 10% squalane at 80 °C; for bicyclohexyl, either a 1/4 in. × 12 ft, 20% Xe-60 (General Electric) column at 170 °C or a 1/8 in. × 9 ft, 12% OS-124 (Monsanto) column at 145 °C. Identical results were obtained with the last two columns. Bicyclopentyl and cyclopentylcyclohexane were determined by temperature programming the OS-124 column from 60 to 160 °C. Standard solutions were run alternately with the irradiated samples. No standards were available for the dimers containing cyclopentyl groups and so these were determined from a comparison of the chromatographic peak areas with those of standard bicyclohexyl solutions, corrections being applied for the different carbon numbers since a hydrogen flame detector was used.

RESULTS AND DISCUSSION

A major advantage in choosing cyclohexane and cyclopentane for a study of the radiolysis of a binary hydrocarbon mixture lies in their relatively small range of major products. In the case of the pure compounds the major gaseous product is hydrogen whilst the main liquid products are the olefins, cyclohexene and cyclopentene, of the same carbon number as the parent hydrocarbon and the dimers bicyclohexyl and bicyclopentyl. In mixtures of the two hydrocarbons the only other major product is the mixed dimer cyclopentylcyclohexane.

(a) Hydrogen

For a total dose of 3.3×10^{22} eV/l, $G(H_2)$ for pure cyclohexane was 5.37 while that for pure cyclopentane was 4.97. Within experimental error $G(H_2)$ from mixtures of the two was a linear function of composition. It does not follow, however, that energy transfer does not occur. Hardwick (10) has shown that departures from ideal behavior do occur

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in the hydrogen yield from binary mixtures of saturated hydrocarbons. Such deviations were, however, readily observable only in mixtures of hydrocarbons having markedly different $G(H_2)$ values, i.e. mixtures of normal and highly branched hydrocarbons. In the case of cyclohexane–cyclopentane mixtures the $G(H_2)$ values of the individual compounds are very similar. An energy exchange would therefore result in a decrease in $G(H_2)$ for one compound which might well be balanced by an almost equal increase in $G(H_2)$ for the other. A deviation from ideality in the hydrogen yield would not therefore be observed.

Deviations from ideal behavior can be readily observed in systems containing small quantities (2–5%) of a deuterated hydrocarbon (5). Figure 1 shows the yields of H_2, HD, and D_2 obtained from various mixtures of cyclohexane and cyclopentane each containing 5% by volume of cyclohexane-d_{12}. Although $G(H_2)$ is linear with composition,

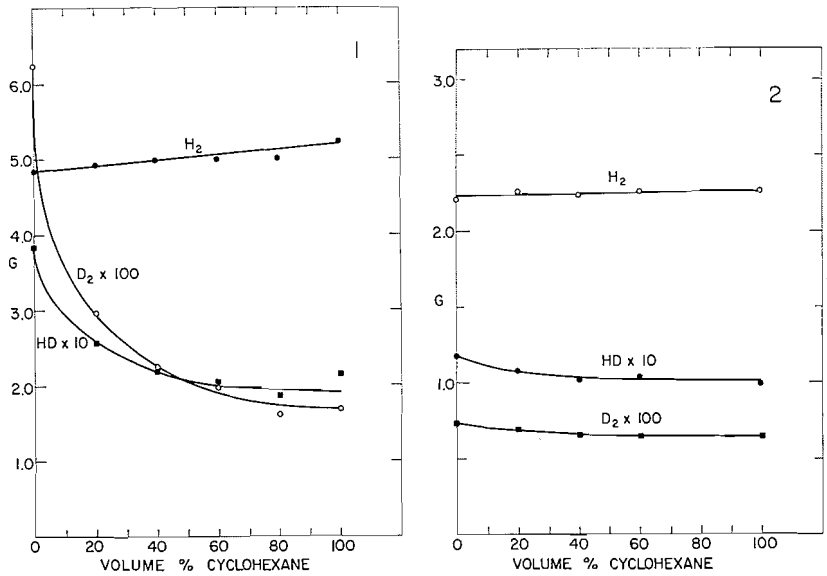

FIG. 1. The yields of H_2, HD, and D_2 from cyclopentane–cyclohexane mixtures each containing 5% by volume of cyclohexane-d_{12}.

FIG. 2. The yields of H_2, HD, and D_2 from cyclopentane–cyclohexane mixtures each containing 5% by volume of cyclohexane-d_{12} and 2% by volume of carbon tetrachloride.

both $G(HD)$ and $G(D_2)$ depart markedly from the behavior expected for a constant electron fraction of cyclohexane-d_{12}. The departure from ideality is not a linear function of solvent composition, but shows a rapid variation at low cyclohexane concentrations. The yields of HD and D_2 depend strongly on environment. The relative contributions to the total hydrogen yield from cyclohexane and cyclopentane must also be dependent on mixture composition. The same effect has been demonstrated in *n*-hexane – cyclohexane mixtures (11).

The value of $G(D_2) + G(HD)$ from 99.6% isotopically pure cyclohexane-d_{12} is 4.1 (12) so that it would be expected that the hydrogen evolved from mixtures of hydrocarbons containing 5% of this compound would be ~ 4 atom % in deuterium. This is not the case. As shown in Table I for cyclohexane we find 2.3 atom %, while for cyclopentane it is 5.1 atom %. Much of the deuterium is present as HD with about 20% present as D_2. This large difference in deuterium content cannot be attributed to a kinetic isotope effect on HD formation since (i) this would require too great a difference in the C—H bond

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

TABLE I

The deuterium content (HD + D_2) of the hydrogen evolved from cyclohexane and cyclopentane containing 5% by volume of cyclohexane-d_{12}

	Atom % deuterium	
Solvent	No solute	2% CCl_4
Cyclopentane	5.1	2.8
Cyclohexane	2.3	2.4

dissociation energy between cyclohexane and cyclopentane and (ii) the yield of D_2, which is formed in a unimolecular decomposition (13), shows a similar variation in going from one solvent to the other. The effect must be attributed to a migration of energy, presumably initially partitioned according to electron fraction, amongst the components.

Certain solutes in low concentration reduce the yields of hydrogen from saturated hydrocarbons to less than 50% of their initial values (14). Further addition of solute has little effect. Figure 2 shows the effect of the addition of 2.5% by volume of carbon tetrachloride on $G(H_2)$, $G(HD)$, and $G(D_2)$ for mixtures of cyclohexane and cyclopentane containing 5% by volume of cyclohexane-d_{12}. Similar results were obtained using iodine instead of carbon tetrachloride. Once again $G(H_2)$ is a linear function of mixture composition. However, $G(HD)$ and $G(D_2)$ do not now show the marked solvent effect, i.e. the yields are practically independent of whether cyclopentane or cyclohexane forms the environment of the cyclohexane-d_{12} molecules. The hydrogen evolved from pure cyclohexane containing 5% cyclohexane-d_{12} is 2.4 atom % in deuterium (Table I), while for cyclopentane the corresponding figure is 2.8 atom %. Carbon tetrachloride or iodine have no effect on the deuterium content in the case of cyclohexane but cause a large decrease in the case of cyclopentane. While there is considerable energy transfer in cyclohexane-d_{12}–cyclopentane mixtures which can be suppressed by the addition of solute little or no energy transfer occurs in cyclohexane–cyclohexane-d_{12} mixtures.

The direction of the energy migration is consistent with the charge transfer reaction suggested by Hardwick (10) which takes place whilst the molecules are in the ionized state, i.e. between the time of ionization and that of charge neutralization.

[3] $$C_5H_{10} \rightsquigarrow C_5H_{10}^+ + e$$

[4] $$C_5H_{10}^+ + C_6D_{12} \rightarrow C_5H_{10} + C_6D_{12}^+$$

[5] $$C_6D_{12}^+ + e \rightarrow C_6D_{12}^* \rightarrow D_2, HD \ldots$$

The first ionization potentials of cyclohexane and cyclopentane are different in the correct direction by about 0.5 eV, but since this is an effect observed so far with only one indicator molecule, cyclohexane-d_{12}, judgment must be reserved.

From a study of the effect of iodine and benzene on the H_2, HD, and D_2 yields from cyclohexane containing small amounts of cyclohexane-d_{12}, Dyne and Jenkinson (15) showed that no sharp distinction could be drawn between the residual hydrogen yield and the inhibitable hydrogen yield. Table I shows that although the addition of solute prevents energy transfer, the deuterium content (D_2 + HD) of the hydrogen evolved from pure cyclohexane containing 5% cyclohexane-d_{12} does not change. In particular, the yield of HD is still high, signifying that bimolecular hydrogen formation still occurs. This would be the case if the residual yield were due to reactions occurring in spurs.

If no energy transfer occurs in cyclohexane–cyclohexane-d_{12} mixtures, then the low deuterium content (D_2 + HD) of the hydrogen evolved is due to an isotope effect. Most

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of the deuterium is present as HD which must be formed in a second-order process. We can therefore postulate two intermediate species, X_H and X_D, which are formed from cyclohexane and cyclohexane-d_{12} respectively and which react in second-order processes to yield H_2, HD, and D_2.

[6] $$X_H + C_6H_{12} \rightarrow H_2 + \ldots$$

[7] $$X_H + C_6D_{12} \rightarrow HD + \ldots$$

[8] $$X_D + C_6H_{12} \rightarrow HD + \ldots$$

[9] $$X_D + C_6D_{12} \rightarrow D_2 + \ldots$$

The species X could be atoms, excited molecules, or ions, the only qualification being that they take part in a bimolecular reaction to yield H_2, HD, or D_2. At the low concentrations of cyclohexane-d_{12} used, reaction [9] can be neglected. Every X_D formed must therefore react as in [8], i.e. HD will be formed in reaction [8] in proportion to the electron fraction of cyclohexane-d_{12} present in the mixture. The formation of HD via X_D will therefore not be susceptible to an isotope effect. HD can also be formed via [7] which is competing with [6]. An isotope effect will favor [6] over [7] resulting in HD yields lower than expected from the mixture composition. The low HD yield observed in cyclopentane–cyclohexane-d_{12} containing small amounts of carbon tetrachloride is similarly explained.

(b) Dimeric Products

Figure 3 shows the yields of the three main dimers, bicyclohexyl, bicyclopentyl, and cyclopentylcyclohexane, at a dose rate of 1.66×10^{22} eV/l h. In agreement with Muccini

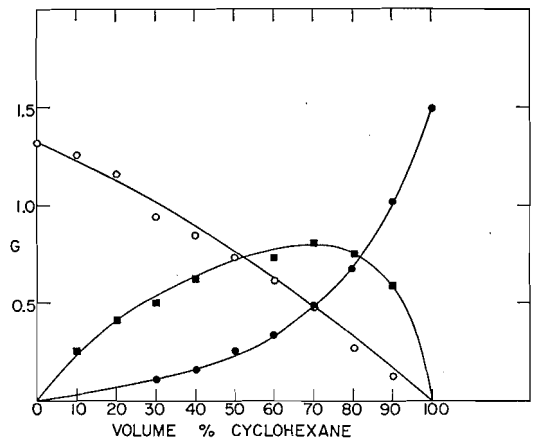

FIG. 3. The yields of bicyclohexyl, ●, bicyclopentyl, ○, and cyclopentylcyclohexane, ■, in cyclopentane–cyclohexane mixtures.

and Schuler (7) the yields are not as expected from the composition of the mixtures. More cyclopentyl groups are present than would be expected if the dimers were formed by a statistical mixing of radicals produced in the ratio of the electron fractions of the parent hydrocarbons. If radicals are produced according to the hydrocarbon electron fractions then the results are qualitatively in agreement with the radical transfer mechanism of reactions [1] and [2]. If [2] has a slightly greater rate constant than [1], then over the course of many such reactions before dimerization the concentration of cyclopentyl radicals will build up at the expense of the cyclohexyl radicals. If no radical transfer occurred, the yield of the mixed dimer, cyclopentylcyclohexane, would show a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

maximum yield at very nearly equimolar hydrocarbon concentrations. In fact the maximum occurs in a mixture containing $\sim 70\%$ cyclohexane. This radical transfer mechanism is supported by dimer yields determined at the lower dose rate (1.43×10^{21} eV/l h). The cyclopentyl content of the dimer increases still further while the cyclohexyl content is correspondingly depleted. The maximum yield of the mixed dimer moves to even higher cyclohexane concentrations. A lowering of dose rate increases the time between formation of radicals and final dimerization, i.e. affords a greater time for change-of-identity reactions to occur.

The addition of iodine or carbon tetrachloride reduces the yield of dimers. In a previous paper we showed that at the solute concentrations used this reduction was probably due to a reaction with some precursor of the radicals rather than with the radicals themselves (8). The residual yields are of interest here. Figure 4 shows the measured dimer yields

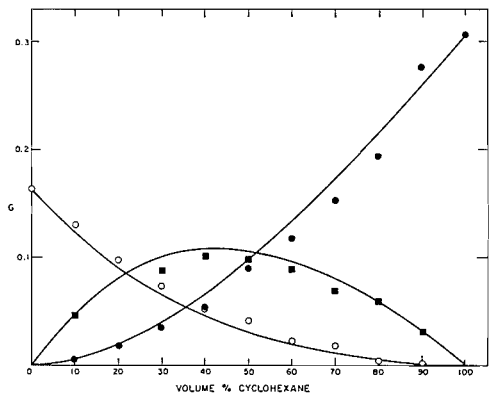

FIG. 4. The yields of bicyclohexyl, ●, bicyclopentyl, ○, and cyclopentylcyclohexane, ■, in cyclopentane–cyclohexane mixtures 0.0038 *M* in iodine. The solid lines are the "expected" values.

(points) together with the yields calculated by assuming a statistical combination of radicals (curves). These residual yields were obtained in the presence of 0.004 *M* iodine. The concentrations of the cyclohexyl and cyclopentyl radicals were calculated by assuming that they were proportional to the electron fractions of the parent hydrocarbons multiplied by the respective residual dimer yield in the pure hydrocarbons. The agreement between experiment and calculation is good. The mixed dimer yield in particular shows no evidence of radical transfer reactions. The residual yields are therefore formed according to the relative electron fractions (which are much the same as the relative mole fractions in this particular case) of the two hydrocarbons. The residual yields need not be formed by radical dimerization, but they cannot be due to freely diffusing species susceptible to solute attack. As in the case of the residual hydrogen yields the results are consistent with reactions occurring in spurs.

(c) Olefins

The precise mechanism of olefin formation in irradiated cyclohexane is not known. Evidence has been presented to show that there are at least two different processes, one which involves the disproportionation of cyclohexyl radicals (8) and one which involves the molecular detachment of hydrogen (13). The relative contributions of these two processes are not known, and other mechanisms of olefin formation may also be important. Cyclopentene would similarly be expected to be formed in more than one process. The

olefin yields in mixtures of these two hydrocarbons cannot therefore be expected to show a simple behavior. Such is the case as shown in Fig. 5 for cyclohexene and in Fig. 6 for cyclopentene. The broken lines show the yields expected if the system behaved

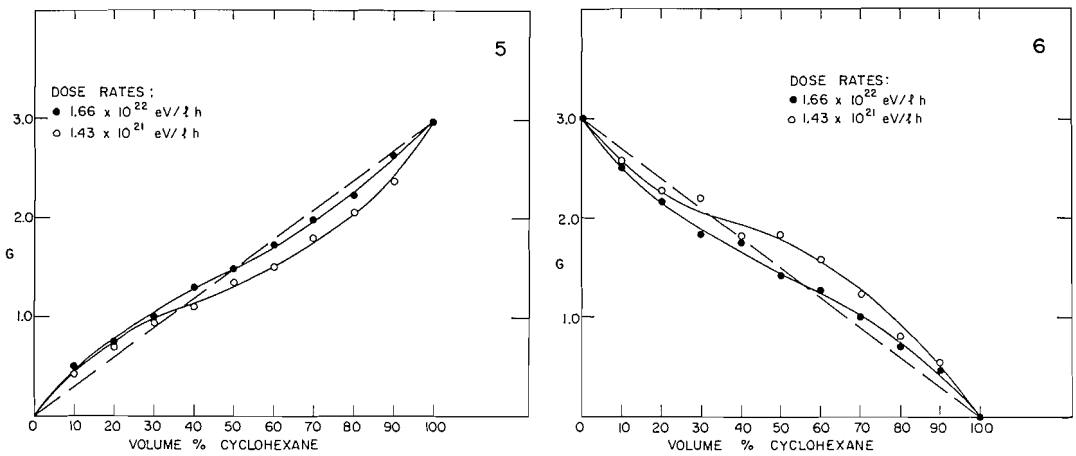

FIG. 5. The yields of cyclohexene in cyclopentane–cyclohexane mixtures.
FIG. 6. The yields of cyclopentene in cyclopentane–cyclohexane mixtures.

ideally. The cyclohexene yields are reduced at high cyclohexane concentrations but increased at low concentrations. The reverse is the case for cyclopentene.

The reduced cyclohexene yields and the increased cyclopentene yields at high cyclohexane concentrations are explicable in terms of the radical transfer reactions [1] and [2]. Since part of the olefin yield results from radical disproportionation, formation of cyclopentene will be favored at the expense of cyclohexene. With a decrease in dose rate an even greater deviation from the expected yields is found in accordance with this theory.

The enhanced yield of cyclohexene at low cyclohexane concentrations shows only a small dose-rate effect. Since the yield of cyclopentene is depressed in this region below the expected value, a mechanism other than one involving radical transfer must be responsible. Preferential formation of cyclohexene in disproportionation reactions cannot account for the effect since it would be dose-rate dependent. The effect can be correlated with the energy transfer process which accounted for the increased HD and D_2 yields described earlier. The energy which can be transferred must therefore result in cyclopentene or cyclohexene production without the prior formation of freely diffusing radicals.

ACKNOWLEDGMENTS

It is a pleasure to acknowledge the helpful advice and comments received from Dr. P. J. Dyne throughout this work and the critical comments of Dr. R. H. Betts on the contents of this paper.

THE REACTION OF METHOXIDE ION WITH PERFLUOROCYCLOPENTENE

RICHARD F. STOCKEL, MICHAEL T. BEACHEM, AND FREDERIC H. MEGSON
American Cyanamid Co., Bound Brook, New Jersey

Received June 16, 1964

ABSTRACT

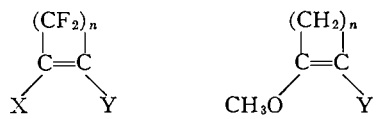
The reaction of methoxide ion with perfluorocyclopentene gave two major components. These have been identified as 1-fluoro-2-methoxyhexafluorocyclopentene (II*f*) and 1,2-dimethoxyhexafluorocyclopentene (II*e*).

A third component (3-methoxy-2,4,4,5,5-pentafluoro-2-cyclopenten-1-one (VII)) was isolated and a structure is proposed based on n.m.r. evidence.

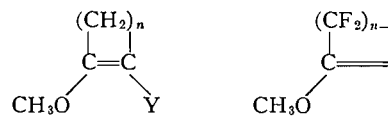
A list of carbon–carbon double bond stretch frequencies is given for a number of 1,2-disubstituted perfluorocyclopentenes which follow the electronegativities of the atoms adjacent to the double bond.

INTRODUCTION

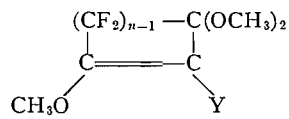
While the four- (1) and five-membered (2) 1,2-dichlorofluorocycloalkenes (I*a*, I*b*) gave the mono- (II*a*, II*b*) and tri-substituted (III*a*, III*b*) unsaturated ethers on treatment with methoxide ion, perfluorocyclobutene (3) (I*c*) yielded unexpectedly the 1,2-dimethoxy (II*d*) and the mono derivative (II*c*). For the latter procedure no trimethoxy compound was detected. Recently, a low yield of the dimethoxy derivative (4) (IV*a*) was obtained by



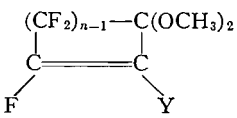
I*a*. $n = 2$, X = Y = Cl
I*b*. $n = 3$, X = Y = Cl
I*c*. $n = 2$, X = Y = F
I*d*. $n = 3$, X = Y = F



II*a*. $n = 2$, Y = Cl
II*b*. $n = 3$, Y = Cl
II*c*. $n = 2$, Y = F
II*d*. $n = 2$, Y = OCH_3
II*e*. $n = 3$, Y = OCH_3
II*f*. $n = 3$, Y = F



III*a*. $n = 2$, Y = Cl
III*b*. $n = 3$, Y = Cl
III*c*. $n = 3$, Y = F



IV*a*. $n = 3$, Y = Cl

treating 1,2-dichlorohexafluorocyclopentene-1 (I*b*) with methoxide ion. This was found to be an extremely reactive intermediate because of the vinyl fluoride structure and it was easily converted to the more stable trimethoxy compound (III*b*).

DISCUSSION

To determine whether perfluorocyclobutene (I*c*) behaved anomalously with methoxide ion in comparison with the 1,2-dichlorofluorocycloalkenes, the reaction was studied with perfluorocyclopentene (I*d*) as the substrate. By the consecutive addition of two equivalents of methoxide ion to one equivalent of olefin at low temperature, a mono- and a di-alkoxide derivative were found to be the major components. These were (II*f*) and (II*e*), respectively, determined by analysis and infrared spectroscopy.

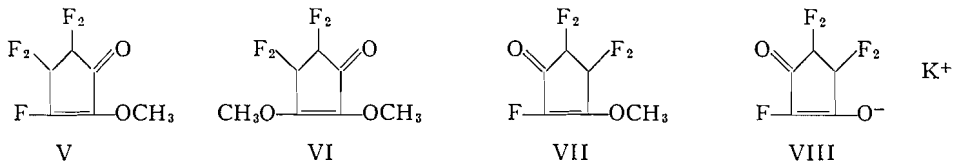
Thus both the perfluoro and 1,2-dichloro alicyclic olefins undergo a similar S_N2 for the first step by what is believed to be an addition–elimination mechanism (1, 5). The second methoxide ion must go via another addition–elimination with the perfluorocyclic olefin, while it is known that the 1,2-dichloro derivative undergoes an S_N2' (6) as the second step. The difference is that a vinyl fluoride is much more reactive towards nucleophilic dis-

placement than a vinyl chloride (5). Another factor is steric hindrance. Chlorine is much more bulky than fluorine, and this also contributes to the difference in mechanism.

From the experimental data it is obvious that the 1,2-dialkoxy derivative is stable towards further nucleophilic displacement under these conditions because the theoretical amount of base is not completely consumed.

From the second fraction a minor component ($\cong 4\%$) was obtained by a vapor-phase chromatographic (v.p.c.) Autoprep.* While analysis was inconclusive, both the infrared and n.m.r. spectra† were obtained and a structure was rationalized.

From the physical data three structures were possible, V, VI, or VII. The infrared



spectrum showed 3 H—C stretch bands at 3.35, 3.42, and 3.55 μ; a C—O—C stretch at 8.82–8.93 μ; a $\rangle C{=}O$ at 5.68 μ; and a $\rangle C{=}C\langle$ stretch at 5.98 μ. This information can fit any of the above structures; however, the fluorine n.m.r. of this component led to a more concrete decision. The spectrum showed a doublet (splitting $\cong$ 13.8 c.p.s.) at 121.0 ϕ, a doublet (splitting $\cong$ 5.4 c.p.s.) at 127.2 ϕ, and a complex band at 140.6 ϕ. Intensity ratio was 2:2:1. Therefore, VI was ruled out. A decision between V and VII was difficult, but it was significant that the average of the two F to F_2 couplings was about the same as that for compound VIII.‡ On this basis structure VII was favored. It should be noted that very little coupling occurred between the two F_2's and that the single F coupled appreciably to the OCH_3.

It is proposed that during the reaction, work-up, or distillation the allylic fluorines were hydrolyzed to a carbonyl group by the presence of water, which was not rigorously excluded. Alternately, structure VII could have come from the hydrolysis of the tri-substituted unsaturated ether (III*c*). This is the same type of product observed with the reaction of methoxide ion with the 1,2-dichlorofluorocycloalkenes (I*a*, I*b*). This would mean that two separate reaction paths are operating at the same time, with the latter resulting in the minor product. More studies are contemplated on this point in subsequent work.

Finally, a list of double bond absorptions for symmetrical and unsymmetrical 1,2-disubstituted hexafluorocyclopentene-1 is given. It is apparent from Table I that the 1,2-dimethoxy derivative is intermediate in relation to the 1,2-dichloro and 1,2-difluoro double bond position. The frequency of the double bond absorption follows the electronegativity (7) of the adjacent atoms, i.e., the order of increasing frequency is F > O > Cl. The magnitude of $\Delta\nu$ is also in this order. It is interesting to note that the 1,2-dichloro compound has approximately the same carbon–carbon double bond stretch as found in cyclopentene (10), so that the double bond order is not reduced to any degree by resonance effects involving chlorine.

*A value of 6.13 was reported by C. O. Parker, J. Am. Chem. Soc. 81, 2183 (1950). However, a value of 6.19 μ was consistently obtained on a Perkin-Elmer Model 317 spectrophotometer. All spectra were run as films (neat).

EXPERIMENTAL

Reaction of Methoxide Ion and Perfluorocyclopentene

To 100 ml of methanol was added 4.6 g (0.2 mole) sodium with stirring. When all of the sodium reacted, the solution was cooled with dry ice. Then 42.4 g (0.2 mole) of olefin was added over a 10 min period. After stirring for 1 h at approximately −40°, another equivalent of methoxide ion, 4.6 g (0.2 mole) sodium in 50 ml of methanol, was added. The solution was then allowed to stir for 5 h. The solution was then poured into water (≅ 400 ml) and the organic layer (lower) was isolated and washed twice with 50 ml water and dried over magnesium sulfate. The crude weight was 40.5 g, excluding volatile starting material.

Distillation, at atmospheric pressure, of the crude in a microapparatus gave two fractions: (1) 99–102°, (2) 144–151°. Neither fraction was found to be homogeneous by an F&M Model 500 VPC equipped with an automatic integrator. On a 10 ft 10% Silicon Gum Rubber on Chromosorb P column run as an isotherm at 125°, a total of three peaks was obtained in both fractions with the following retention times in minutes, II*f*, 2.04; VII, 2.48; II*e*, 2.70. The combined integrated peak areas of both fractions were 34.36, 4.14, 61.50%, respectively.

The two major components were easily separated by redistillation of their respective fractions. From fraction one, II*f* was obtained in analytical purity. It was identified as 1-methoxyheptafluorocyclopentene-1 by analysis and infrared spectroscopy. Its boiling point was 100–101° (uncorrected). η_D^{27} = 1.3323. The infrared spectrum gave the following bands: three C—H stretches at 3.30, 3.36, and 3.48 μ; C=C stretch at 5.80 μ; C—O—C stretch, broad 8.70–8.80 μ with other bands at 6.83, 7.30, 7.50, 7.71, 8.29, 9.63, 10.15, 10.74, and 11.44 μ.

Anal. Calcd. for $C_6H_3F_7O$: C, 32.15; H, 1.34. Found: C, 31.76; H, 1.75.

Component II*e* was similarly identified by redistillation of the second fraction. Its boiling point was 148–149° (uncorrected). η_D^{27} = 1.3658. The infrared spectrum gave the following bands: three C—H stretches at 3.30, 3.35, and 3.49 μ; C=C stretch 5.90 μ; C—O—C stretch, broad 8.80–8.90 μ with other bands at 6.80, 7.40, 7.51, 7.73, 8.27, 8.34, 9.50, 10.00, 10.65, and 11.52 μ.

Anal. Calcd. for $C_7H_6F_6O_2$: C, 35.60; H, 2.56. Found: C, 35.70; H, 2.73.

ACKNOWLEDGMENTS

We are obliged to Dr. J. E. Lancaster for running and interpreting the n.m.r. fluorine spectrum and Dr. Richard A. Parent for the isolation of the minor component.

ANIONIC POLYMERIZATION OF ISOPRENE[1]

D. J. WORSFOLD AND S. BYWATER
Applied Chemistry Division, National Research Council, Ottawa, Canada
Received April 8, 1964

ABSTRACT

The polymerization of isoprene with butyllithium in cyclohexane has been studied. The initiation reaction was found to be complex; plots of conversion of butyllithium against time are sigmoidal. The order with respect to the initiator was found to be between one-half and one. The order of the isolated propagation reaction in polyisoprenyllithium was found to be one-quarter and was correlated with a fourfold association of active chain ends determined by dilute solution light-scattering measurements.

The major effect of tetrahydrofuran on the reaction was the great increase of the initiation rate. The kinetic order changes slowly with the addition of small amounts of tetrahydrofuran, suggesting that the aggregates are broken down with difficulty. The microstructure of the polymer has been determined by n.m.r. measurements and shows a steady transition from a largely 1:4 to a largely 3:4 structure as the polarity of the solvent is increased by the addition of tetrahydrofuran.

Very little attention has been paid to the initiation reaction in the polymerization of isoprene by *n*-butyllithium. Most studies of this system have been concerned with the structure of the polymer formed (1, 2) or with the kinetics of the propagation reaction (3, 4, 5) and the effect on both of additives. The reaction of *n*-butyllithium with both styrene (6) and 1,1-diphenylethylene (7) has been investigated in aromatic hydrocarbon solvents. It is found that when the solvent is cyclohexane, the kinetic behavior is considerably different for isoprene and also for styrene and butadiene (8).

The several published investigations of the propagation reaction have mostly acknowledged the difficulty of ascertaining whether the slow initiation reaction has gone to completion. By use of spectrophotometric measurements it is possible to determine more certainly when chain initiation is complete and hence to ensure that a true propagation rate can be measured. It is possible, also, to see the effect of only partial initiation on the propagation rate.

The microstructure of polyisoprene has been investigated, in the past, by infrared spectroscopy (9, 10) but the method is not always satisfactory, especially with anionic polymers. It is now possible to determine these structures by nuclear magnetic resonance n.m.r. (11) and, although this method still has some shortcomings, it supplements the infrared method. From these measurements, it seems necessary to modify previous ideas on these structures.

EXPERIMENTAL

The methods used to measure the reaction rates of *n*-butyllithium with isoprene were similar to those used in the past for other systems (6). The absorption band of polyisoprenyllithium in cyclohexane has a maximum at 270 mμ, ϵ 6 900, but to measure its concentration a wavelength of 275 mμ was used to avoid as far as possible the absorption of isoprene. Beers law was tested over the range 10^{-4}–10^{-2} *M*, the results showed a random scatter of ±5%. The isoprene concentration was measured at suitable lower wavelengths.

Cyclohexane was clarified by two passages through silica gel columns and stored in vacuum over calcium hydride. Before use it was transferred on the vacuum system to a flask containing butyllithium and from there to the reaction vessel.

[1]*Issued as N.R.C. No. 8135.*

Isoprene was fractionally distilled under nitrogen. Then, after it was degassed, it was distilled in the vacuum system onto butyllithium and allowed to stand for 15 min at room temperature. This was repeated three times. Distillation into a storage flask containing calcium hydride followed.

The *n*-butyllithium was supplied as a 15% hexane solution by the Foote Mineral Company.

Infrared spectra were measured on polymer films with a Perkin–Elmer model 21 spectrometer. The n.m.r. spectra were measured on a Varian Associates spectrometer at 56.4 mc/s with the polymer dissolved in either carbon tetrachloride or benzene.

The light-scattering measurements were made partly in a Brice-Phoenix instrument, and partly in a Sofica instrument in which angular scattering was also measured. The polymer concentrations were in the 0.1–0.6% range, and the carbanion concentration in the 10^{-5}–10^{-4} M range.

All reactions were made at 30 °C, and all reaction rates are in units of liters, moles, and minutes.

RESULTS AND DISCUSSION

Initiation

The increase of optical density at 275 mμ when isoprene and butyllithium are mixed together in cyclohexane can be used to measure the rate of formation of polyisoprenyllithium, as this has an absorption maximum at 270 mμ. It was found that the increase in optical density is not linear with time at the start of the reaction, but the rate of formation of the carbanion seems at first to gradually increase (Fig. 1). This initial stage is followed by a period where the concentration–time curve is linear. This could be artificial and may be caused by compensation of the apparent increase in active butyllithium by a decrease in isoprene concentration. Finally the rate decreases because of a decrease in butyllithium and isoprene concentrations. The curve is in fact sigmoidal.

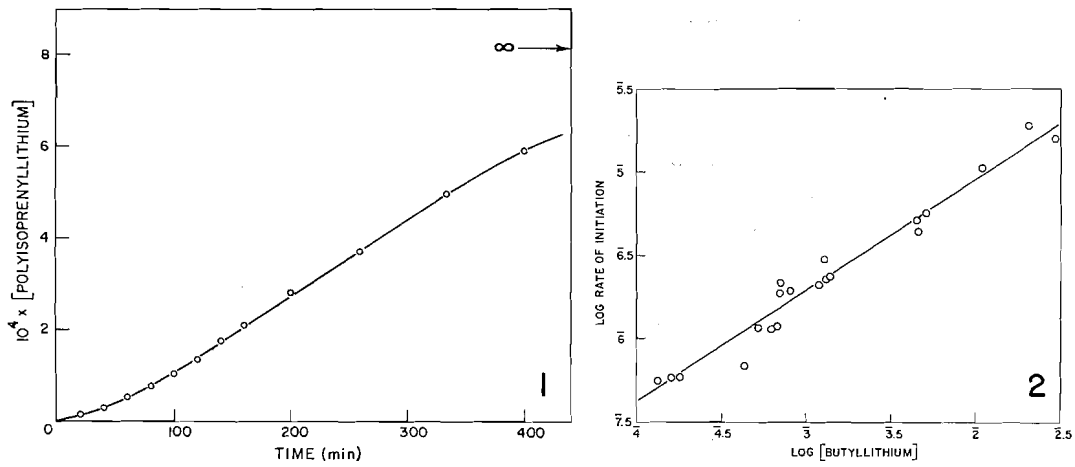

FIG. 1. Typical initiation reaction curve. [Butyllithium] = 1.18×10^{-3} M; [isoprene] = 0.60 M, at 30°. At ∞ not all the butyllithium had been consumed; a further addition of isoprene increased the polyisoprenyllithium concentration.

FIG. 2. Dependence of the linear part of the initiation reaction on the butyllithium concentration, at 30°.

Attempts were made to reduce this induction period by adopting even more rigorous techniques. For example, distilling the solvent and remaining monomer, from an already polymerizing mixture, onto fresh butyllithium in another part of the reaction vessel. But such methods did not remove the initial slow reaction. It was found that the slow reaction could be eliminated by breaking a bulb of air in the reaction vessel at the start of the reaction, sufficient oxygen being released to react with half the butyllithium. It is supposed that the lithium butoxide formed acts as a catalyst, the reaction in the absence of salts being very slow. The polyisoprenyllithium formed could itself act as a catalyst.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The reaction would then be autocatalytic and thus account for the initial increasing rate. It does, however, appear that the induction period is not caused by impurities and is a characteristic of initiation in cyclohexane.

If the apparently linear portion of the reaction curve is taken to be the rate of initiation, it is found that the reaction is close to first order in monomer and about 0.7 order in butyllithium (Fig. 2). There is considerable scatter in the points, and presumably the reaction is very sensitive to quite small amounts of adventitious salt-like impurities. In view of the complex nature of the reaction curve, these kinetic orders have no simple significance and give no clue to the mechanism of the reaction. The reaction is likely to be first order in monomer, but the order in butyllithium is unexpected.*

For the corresponding reaction in benzene solution of styrene and butyllithium the order in butyllithium is about one-sixth and can be correlated with the sixfold association of *n*-alkyllithiums in hydrocarbon solvents (12, 13, 14). With styrene in benzene no induction period in the initiation reaction is observable and the reaction must be less complex. In cyclohexane, however, styrene also exhibits an induction period similar to that for isoprene in the initiation. The apparent order in butyllithium, as determined by the apparently linear portion of the reaction curve, is also similar. Moreover, even the maximum rate is nearly two powers of ten lower than in benzene solution, indicating the reluctance of the reaction to take place in such a poor solvent for ionic species. Thus the presence of added salts or the increasing concentration of the polymer – lithium salt could well be thought of as providing centers of sufficient polarity to promote the conversion of the less polar butyllithium to the ionic polymer – lithium salt.

Propagation

The kinetics of the propagation reaction are far simpler. After all the butyllithium has reacted, the optical density at 275 mμ remains constant and it is then possible to follow the isolated propagation reaction by the decrease in the ultraviolet absorption of the residual isoprene or of a further addition of isoprene. It is found that the consumption of isoprene follows a first-order plot over at least three half-life times (Fig. 3).*

The order with respect to the initial concentration of butyllithium and, hence, the concentration of active chain ends is close to one-fourth. The rates are considerably more reproducible than those of the initiation reaction. The literature on this subject contains several values for this reaction order, which vary from one-half to one-sixth. A number of propagation rate constants from several authors have been plotted in Fig. 4 together with those from this work. The values of Sinn (4) were calculated from his 20° figures using his activation energy. Similarly the figures of Morton (15) were corrected to 30°. Only rates whose numerical values were given are used; both Sinn and Spirin *et al.* (3) have diagrams containing far more points which concur with the quoted values. There is a remarkable concordance among the various sets of results, particularly as the solvents differ, although all are hydrocarbons. The same kinetic behavior could be expected in different aliphatic hydrocarbons, but in toluene the rate might be expected to differ appreciably. The rates found by Morton are about 25% lower than the others, with the exception of one point. But this is not unexpected because reactions involving ions are very sensitive to solvents. The range of concentrations taken by Morton, however, really does not seem wide enough to allow us to say that the reaction order is appreciably different in hexane from that in the other solvents.

**The detailed rate data have been placed in the Unpublished Data Depository. Photocopies may be obtained upon request to Depository of Unpublished Data, National Science Library, National Research Council, Ottawa, Canada.*

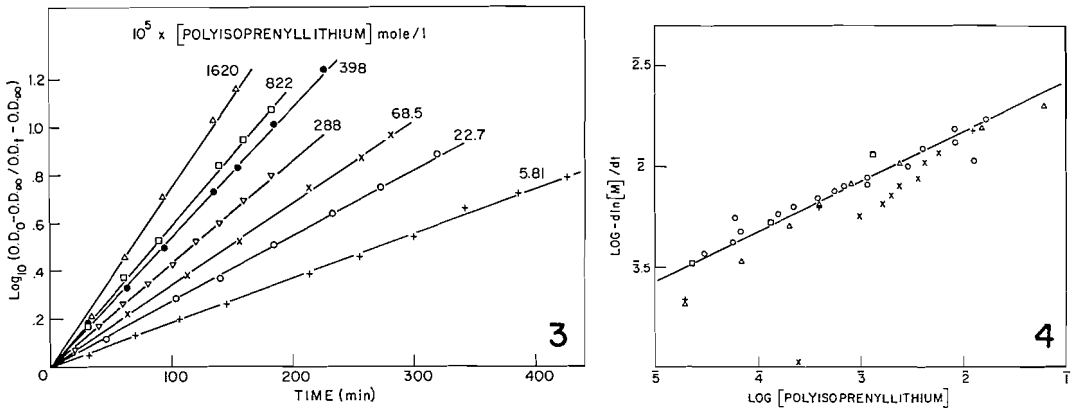

FIG. 3. First-order plots of the propagation reaction at various polyisoprenyllithium concentrations, at 30°.

FIG. 4. Dependence of the propagation rate on the polyisoprenyllithium concentration, at 30°. (△) Sinn *et al.* (4), in heptane solution; (×) Morton *et al.* (15), in hexane solution; (+) Spirin *et al.* (3), in heptane solution; (□) Spirin *et al.* (3), in toluene solution; (○) this work, in cyclohexane solution.

It was found that in the presence of an excess of butyllithium the propagation rate was depressed by appreciable amounts. When half the butyllithium was converted to polyisoprenyllithium, the propagation rate was half that expected from that concentration of polyisoprenyllithium. This suggests that there is some cross association of the butyllithium and the isoprenyllithium, which would also add to the complications in the initiation reaction. Morton has noted this cross association before (16) and V. Sinn has made a quantitative study of its effect on the propagation rate (17).

From the ratio of the rates of propagation and initiation, a several hundredfold excess of monomer would be required to complete initiation. The criterion for complete initiation of satisfactory first-order rate curves is of little value when the order in chain ends is so low, unless the reaction is followed for several half-life times. It is probably true to say that all reaction rates measured when the butyllithium concentration is greater than 10^{-2} M are suspect in the present work and that of others. Sinn (18) has also commented on this fact.

In all these studies the fractional order in polyisoprenyllithium has been attributed to polymer association caused by interaction of the ion-pair chain ends. Morton has made viscosity measurements on the 'living' and 'dead' polymerization solutions and from an extension of the bulk viscosity relation showed that the apparent degree of association was twofold (5), in agreement with his stated kinetic order. Unfortunately, this method can only give a ratio of weight average molecular weights, not the number averages which are really required, although the ratio of the two was probably quite close to one in Morton's work.

It is possible to use other methods of molecular weight determination to find the degree of association. Light-scattering measurements were made on several diluted polymerization solutions before and after the addition of methanol. The dilutions were effected by distillation of the solvent from one part of a complex all glass light-scattering cell to another. The whole process was carried out under vacuum with the apparatus first washed out by butyllithium solutions and rinsed as described for the vessels for the kinetic experiments. The results are shown in Table I. The calculated molecular weight is that derived from the monomer–catalyst ratio. In the second and third examples it was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

checked against the polyisoprenyllithium concentration as measured spectrophotometrically. In the first experiment the conditions were such that chain initiation was incomplete. The observed molecular weights are much too high for this reason. Even in the last two experiments the molecular weight found for the terminated polymer is still somewhat higher than that calculated. Even under the most favorable conditions, which were chosen, chain initiation is barely completed before the monomer is consumed. This will lead to an $\bar{M}_W/\bar{M}_N$ ratio of about 1.3 in the polymer produced, which largely explains the results.

TABLE I

Molecular weights of 'living' and 'dead' polyisoprenes found by light scattering

Molecular weights		
Calculated	Killed	Living
27 000	89 000	142 000
48 000	77 000	188 000
58 000	70 000	257 000

The experiments show that the degree of association based on the calculated molecular weight of unassociated polymer is about four even at 10^{-5} M polyisoprenyllithium concentrations. This should be close to a ratio of number average molecular weights as the $\bar{M}_W/\bar{M}_N$ ratio will be less than 1.3 in the fourfold associated form. It is also clear from the first experiment that if chain initiation was incomplete, the polymer solution would show a low degree of association if based on measured molecular weights, presumably because butyllithium has taken the place of some polymer molecules in the associated species.

Effect of Tetrahydrofuran

The presence of ethers has been found to have a marked effect on the microstructure of the polymer produced with lithium based initiation. Also the polymerization rate has been reported greatly increased. The great increases in rate reported are undoubtedly due to the increased initiation rate, as is also suggested by the work of Kropacheva *et al.* (19). Normally initiation in cyclohexane at 30° will take hours but in the presence of ten molecules of tetrahydrofuran for every one of butyllithium, initiation is essentially complete in 15 min with 0.3 M monomer. At this level, however, tetrahydrofuran has only increased the propagation rate by 25%, at a 10^{-3} M concentration of chain ends, and a hundredfold excess is necessary to double the rate. This is the same order of magnitude as found by Morton (5) in hexane solution. It is found that at a tetrahydrofuran concentration of 7×10^{-3} M the kinetic order in chain ends is still low, about one-third or less, and even at 0.1 M tetrahydrofuran the order is still less than one, and averages about one-half over the range covered here (Table II). This indicates that the aggregates are not separated completely into ion-pairs until even greater concentrations are used. Thus it appears that the energy from ion-pair aggregation is very much greater than the solvation energy obtained from tetrahydrofuran.

Because of the small changes in rate it is not possible to carry out a full kinetic analysis of this system, as was done for the similar polymerization of styrene in benzene solution (24). Also the large amount of tetrahydrofuran necessary to complete the breakdown of aggregates would cause too large a change in the dielectric constant to be ignored. What

15.8	1 000	21.2
110	1 000	61.0
127	1 000	53.2

evidence there is, however, does support Morton's contention that only a monoetherate is formed (5).

It has been shown (20) that in the presence of tetrahydrofuran the polyisoprenyl carbanion undergoes an isomerization. This takes about a day to complete when 1% tetrahydrofuran is present. Under these circumstances, measurements of the degree of association of reaction mixtures left to go to completion have little value when compared with kinetic studies.

Polymer Microstructure

The structure of the polymer formed from isoprene in hydrocarbon solvents by lithium based anionic initiators has been reported several times. Although the reported structures have always been high in *cis* 1:4 content and low in 3:4, the amount of *trans* 1:4 structures reported has varied. The normal method of determining structure has been by infrared analysis, but this presents considerable difficulties, both theoretical and practical, when determining a small amount of *trans* 1:4 structures in a predominantly *cis* 1:4 polymer, or any 1:4 in a highly 3:4 polymer. This is because the shape of the absorption peak is likely to be a function of the block length. Chen has shown (11) how n.m.r. measurements may be used to determine polyisoprene structures, and this method appears to be far more suitable for determining 1:4 structures. A complete analysis of the polymer structure may, in theory, be carried out but in practice this presents some difficulties with present equipment and a combination of infrared and n.m.r. studies is probably best. Nevertheless it still would be unrealistic to claim any great accuracy for the methods. All methods of analysis will fail to some extent for polymers made by some catalyst systems because of the presence of extraneous structures not included in the normal 1:4, 1:2, and 3:4 structures expected. This is particularly true for sodium and potassium initiated polymers (9, 20).

The structures found for variously prepared polyisoprenes are shown in Table III, using primarily the n.m.r. methods of Chen and supplementing them with infrared measurements. Several of the spectra are shown in Figs. 5 and 6. When the polymer had a low 3:4 content this was measured from the infrared spectrum and the ratio of the 1:4

structures estimated from the n.m.r. spectrum in benzene solution (Fig. 5). The peak assignments and numbers are those used by Chen (11). Peak 5 is resolved in benzene solution into 5*a* and 5*b* corresponding to the methyl group in *cis* 1:4 and the combined methyl groups of the *trans* 1:4 and 3:4 structures respectively. The polymers with low 1:4 content or mixed structures were analyzed entirely by the n.m.r. method. The peaks are seldom completely resolved, and sometimes considerable judgment is required to estimate the desired peak area. Nevertheless, where large differences from the infrared analyses occur the evidence for these differences is strong.

TABLE III

Polyisoprene microstructures

*Butyllithium concentration ca. 3×10^{-4} *M*.

The amount of *trans* 1:4 structures in the polymer formed in cyclohexane by butyllithium is rather higher than that usually found by infrared methods, which are weak at this point. The amount of 3:4 structures is in good agreement with that normally found. The effect of small amounts of tetrahydrofuran on the structure is seen to be less marked than normally found, the 3:4 content increasing less rapidly than found by Tobolsky and Rogers (2). This is partly because the more dilute solutions used in this investigation would cause less of the etherate to form. Also, in pure tetrahydrofuran it is seen that n.m.r. measurements show no 1:4 structures, although previous infrared studies have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

shown considerable amounts. But infrared measurements are again unreliable in determining the low absorbance of the 1:4 bands compared with the strong 3:4 band. Chen also found very little 1:4 structure in a polymer formed in ether solution, so the absence of it in the even more polar tetrahydrofuran is not unexpected.

The sodium initiated polymer in tetrahydrofuran is even higher in 3:4 content than usually reported. This polymer is more stereospecific than is the Li/hydrocarbon polyisoprene, although it is the latter which is normally considered stereospecific because of its desirable structure. The polymer formed by sodium in cyclohexane shows a far more mixed *cis–trans* 1:4 structure than previously reported by infrared methods, but undoubtedly in this polymer extraneous structures are formed which interfere with the infrared measurements.

The structure found for the emulsion polymer was similar to that reported by other authors. The small amount of 1:2 structure probably present is not shown by the n.m.r. method.

From the structures found here, it is seen that the transition of structure from one anionic system to another, although large, is far less abrupt than previously thought. The Li/hydrocarbon polyisoprene is not overwhelmingly stereospecific and this initiator system with the addition of small amounts of tetrahydrofuran gives a more mixed structure, similar to the polymers formed in cyclohexane by sodium. The further transition to a solvent that is richer in tetrahydrofuran causes the polymer to become progressively enriched in 3:4 structures for both lithium and sodium initiation until the extreme ones formed in pure tetrahydrofuran have no 1:4 structures. Tobolsky has, however, reported before that little change in microstructure occurred after the abrupt change caused by the first small addition of tetrahydrofuran. The smoother change above is more in accord with the finding from ultraviolet studies of the polyisoprenyl carbanion formed in these systems (20). There appears to be very little change in the ionic nature of the carbon metal bond as the solvent and the alkali metal are changed, and little reason to expect abrupt changes in microstructure.

Why certain initiator systems should give certain structures is still not clear. Suggesting that the lithium/hydrocarbon system gives an intermediate of specific structure to explain the high *cis* 1:4 content, while the others do not, does not seem too satisfactory. It would appear that the equally high 3:4 content in the sodium/tetrahydrofuran system would deserve the formulation of a similar specific intermediate structure. The in-between ranges would then also need their intermediates, since their polymer microstructures are also quite well defined.

Both butadiene and isoprene give, with lithium-based initiators, polymers which are composed largely of 1:4 structures. Both monomers, when the solvent is made more polar, give polymers richer in pendant vinyl groups to the point where the polymers formed in tetrahydrofuran are almost entirely these structures. Similarly a change from lithium to sodium decreases the 1:4 structures. The effect must be caused by the increase in the effective cation size, because of solvation and the change from lithium to sodium. The high *cis* content in the largely 1:4 polyisoprene formed in hydrocarbon solvents by lithium-based reagents must be a function of the presence of the methyl group which distinguishes it from butadiene. The methyl group will modify the configuration of either the anion or the approaching monomer molecule.

Of interest is the effect of the presence of lithium compounds on the microstructure of the polymer formed by butyllithium in cyclohexane, as shown in Table III. A similar effect has been shown before for both butadiene and isoprene (21, 22). This suggests that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

a complex of the polyisoprenyllithium and the lithium compound is an active polymerization agent in much the same way as the etherate is. But it also raises the question whether the free ion pair does in fact normally carry all the polymerization. Sinn has suggested, from very low-concentration studies (23), that the reaction is in fact more complex at least in that concentration range. But at such considerable dilutions as 10^{-7} M, the concentration of adventitious salts inevitably becomes significant and must affect the reaction.

ACKNOWLEDGMENTS

The authors wish to acknowledge the assistance of Dr. S. Brownstein in the interpretation of the n.m.r. spectra, and also for measuring these spectra.

CARBONYL AND THIOCARBONYL COMPOUNDS

VIII.[1] SYNTHESIS OF FLUORENE ETHERS BY THE ACTION OF TETRAHALO-*o*-BENZOQUINONES

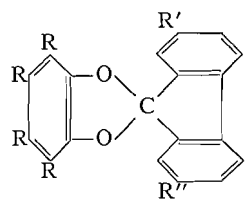
N. LATIF AND N. MISHRIKY
National Research Centre, Dokki, Cairo, U.A.R.

Received February 7, 1964

ABSTRACT

The halogenated fluorene ethers I*c*–I*f* are directly produced by the action of tetrachloro- and tetrabromo-*o*-benzoquinone on the corresponding halofluorene in boiling dry benzene. The preparation of the fluorene ethers by the action of tetrahalo-*o*-benzoquinones on 2-chloro- and 2,7-dichloro-fluorenone hydrazone is described. The ketohydrazones are readily oxidized by mercuric oxide to the corresponding 9-diazofluorenes which react readily with the haloquinones yielding the methylene ethers.

Cyclic ethers have become important commercial materials for use both as synthetic intermediates and as solvents and this has directed the attention of various authors to study the chemistry of this group of compounds in more detail. The chemistry of halogenated cyclic ethers was the object of various investigators in this laboratory. It has been shown (1) that the fluorene ethers, I*a* and I*b*, can be directly synthesized by the action of tetrachloro- and tetrabromo-*o*-benzoquinone, respectively, on fluorene. In an attempt to generalize this reaction which provides a new and simple method for the direct synthesis of fluorenylidene cyclic ethers, the action of tetrahalo-*o*-benzoquinones on 2-chloro- and 2,7-dichloro-fluorene was investigated. It was found that the methylene ethers I*c* and I*e* are readily produced when tetrachloro-*o*-benzoquinone is allowed to react with the corresponding halofluorene in boiling dry benzene. The bromo analogues, I*d* and I*f*, are obtained similarly when using tetrabromo-*o*-benzoquinone. The constitution of the fluorene ethers is based on their lack of color, on analytical data, and on their



I*a*. R = Cl, R′ = R″ = H.

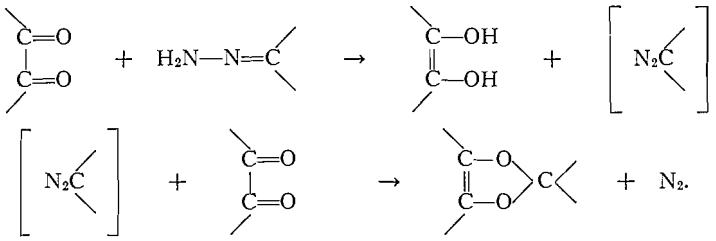
II*a*. R = Cl, R′ = H.
II*b*. R = R′ = Cl.

formation from either the halofluorene itself or its corresponding 9-diazo derivative. Thus, I*c*–I*f* are produced in excellent yield by the action of 2-chloro- (II*a*) and 2,7-dichloro-9-diazofluorene (II*b*) on the corresponding tetrahalo-*o*-benzoquinone. The formation of methylene ethers by the action of diazoalkanes on tetrahalo-*o*-benzoquinones is well established (2). The 9-diazofluorenes are readily produced by oxidizing the corresponding

[1]*For Part VII of this series see N. Latif and I. Fathy, J. Org. Chem. 27, 1633 (1962).*

fluorenone hydrazone with yellow mercuric oxide. The hydrazones are prepared by the action of hydrazine hydrate on the corresponding fluorenone in *n*-butanol. The 2-chlorofluorenone hydrazone obtained is different from the product, described by Warren (3), which was obtained when the reaction was carried out in ethanol. However, both compounds give the same diazofluorene upon oxidation. It has been shown (3) that some 2-substituted fluorenones, such as 2-iodo- and 2-cyano-fluorenone, yield two different hydrazones when they are allowed to react with hydrazine hydrate in ethanol. In each case, both hydrazones yielded the same diazofluorene upon oxidation.

In a previous report (4) it has been shown that methylene ethers are directly produced by the action of tetrahalo-*o*-benzoquinones on ketohydrazones. In the present investigation it is found that 2-chloro- and 2,7-dichloro-fluorenone hydrazone react readily with tetrachloro- and tetrabromo-*o*-benzoquinone to give directly I*c*–I*f*, respectively, according to the scheme below. The production of the corresponding tetrahalocatechol in this reaction together with evolution of gas supports the suggested mechanism.



EXPERIMENTAL

Melting points were not corrected. Microanalyses were performed by A. Bernhardt, Germany, and by the microanalysis unit, National Research Centre, Cairo.

Preparation of 2-Chlorofluorenone Hydrazone

A solution of hydrazine hydrate (98–99%, 1.5 ml) and 2-chlorofluorenone (5) (2 g) in the least amount of *n*-butanol, was refluxed for 3 h, filtered while hot, concentrated, and left to cool. The product obtained was filtered off, washed with a few milliliters of methanol, and recrystallized from the same solvent to give 2-chlorofluorenone hydrazone (1.7 g) as yellow crystals, m.p. 145–146 °C.

Anal. Calcd. for $C_{13}H_9N_2Cl$: C, 68.42; H, 3.94; N, 12.28; Cl, 15.35. Found: C, 68.48; H, 4.11; N, 12.92; Cl, 14.53.

Preparation of 2,7-Dichlorofluorenone Hydrazone

This was obtained from 2,7-dichlorofluorenone (6) as yellow crystals, m.p. 175–176 °C.

Anal. Calcd. for $C_{13}H_8N_2Cl_2$: C, 59.31; H, 3.04; N, 10.64; Cl, 26.99. Found: C, 59.75; H, 3.26; N, 10.05; Cl, 26.06.

Preparation of 2-Chloro-9-diazofluorene (IIa)

2-Chlorofluorenone hydrazone (2 g) was oxidized with yellow mercuric oxide in the presence of ethanolic potassium hydroxide, according to the method described by Schönberg *et al.* (7). The diazo compound was obtained (1.6 g) as red crystals (from ether) which melted with vigorous decomposition at about 120 °C. The diazo compound is identical with that obtained by Warren (3).

Preparation of 2-Chloro-9-(tetrachloro-o-phenylenedioxy)fluorene (Ic)

Tetrachloro-*o*-benzoquinone (8) (1.2 g) was added in portions to a solution of 2-chloro-9-diazofluorene (1.1 g) in dry benzene (15 ml). A vigorous reaction with evolution of gas occurred after each addition. When all the quinone had been added, a solid crystalline product separated after a few minutes. This was filtered off, washed with acetone, and recrystallized from the same solvent to give I*c* (1.5 g) as colorless crystals, m.p. 281–282 °C.

Anal. Calcd. for $C_{19}H_7O_2Cl_5$: C, 51.35; H, 1.57; Cl, 39.98. Found: C, 51.83; H, 1.81; Cl, 38.87.

Preparation of 2-Chloro-9-(tetrabromo-o-phenylenedioxy)fluorene (Id)

Tetrabromo-*o*-benzoquinone (9) (2.1 g) was added to an ethereal solution of 2-chloro-9-diazofluorene (1.11 g) as above. The separated product was washed with acetone and crystallized from benzene to give I*d* as colorless crystals, m.p. 325-326 °C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Anal. Calcd. for $C_{19}H_7O_2ClBr_4$: C, 36.65; H, 1.12; Cl, 5.62; Br, 51.44. Found: C, 37.38; H, 1.18; Cl, 5.66; Br, 51.29.

Reaction of Tetrachloro-o-benzoquinone with 2-Chlorofluorene

A solution of the quinone (2.4 g) and 2-chlorofluorene (10) (2.1 g) in dry benzene (30 ml) was refluxed (protected from moisture) for 6 h. The benzene was then evaporated to dryness under reduced pressure and a few ml of ether was added to the oily residue. The solid which separated was washed with acetone and crystallized from the same solvent to give I*c* (1.1 g). The infrared spectrum of the substance is identical with that obtained by the action of 2-chloro-9-diazofluorene on the quinone.

The bromo analogue I*d* was obtained in a similar manner by the action of tetrabromo-*o*-benzoquinone.

Reaction of Tetrachloro-o-benzoquinone with 2-Chlorofluorenone Hydrazone

The hydrazone (1.2 g) was added in small portions to a solution of the quinone (2.4 g) in dry ether (20 ml). When all the quinone had been added, the reaction mixture was refluxed for 10 min. The solid which separated (0.8 g) was crystallized from acetone and proved to be I*c*.

When tetrabromo-*o*-benzoquinone was used instead of the chloroquinone, I*d* was similarly obtained.

Preparation of 2,7-Dichloro-9-diazofluorene (IIb)

This was prepared as usual by oxidizing 2,7-dichlorofluorenone hydrazone with yellow mercuric oxide in benzene. It was obtained as light-red crystals (from ether) which melted with decomposition at about 160 °C.

Anal. Calcd. for $C_{13}H_6N_2Cl_2$: C, 59.77; H, 2.29; N, 10.72; Cl, 27.20. Found: C, 60.35; H, 2.62; N, 11.03; Cl, 26.02.

Preparation of 2,7-Dichloro-9-(tetrachloro-o-phenylenedioxy)fluorene (Ie)

Tetrachloro-*o*-benzoquinone (1.2 g) was added to a solution of II*b* (1.3 g) in dry benzene (15 ml), as in the case of the monochloro derivative. The reaction mixture was then warmed on a water bath for 15 min. The crystalline solid which separated on cooling was recrystallized from acetone to give I*e* (1.7 g) as colorless crystals which melted above 360 °C.

Anal. Calcd. for $C_{19}H_6O_2Cl_6$: C, 47.59; H, 1.25; Cl, 44.46. Found: C, 47.94; H, 1.53; Cl, 43.68.

Preparation of 2,7-Dichloro-9-(tetrabromo-o-phenylenedioxy)fluorene (If)

This was prepared from tetrabromo-*o*-benzoquinone (2.1 g) and II*b* (1.3 g), as in the case of I*e*. It was obtained as colorless crystals (2.4 g) from benzene, m.p. 355–357 °C.

Anal. Calcd. for $C_{19}H_6O_2Cl_2Br_4$: C, 34.7; H, 0.91; total halogen, 59.50. Found: C, 35.29; H, 1.09; total halogen, 58.42.

Reaction of Tetrachloro-o-benzoquinone with 2,7-Dichlorofluorene

A solution of the quinone (2.4 g) and the fluorene (11) (2.3 g) in dry benzene (30 ml) was refluxed for 6 h and worked up, as in the case of monochlorofluorene. The product which separated was crystallized from acetone to give I*e* (1.3 g). The infrared spectrum of the product is identical with that of the product obtained by the action of II*b* on the quinone.

When using tetrabromo-*o*-benzoquinone instead of the chloro derivative, the bromo analogue I*f* was obtained.

Reaction of Tetrachloro-o-benzoquinone with 2,7-Dichlorofluorenone Hydrazone

The quinone (2.4 g) and the hydrazone (1.3 g) were allowed to react together, as described in the case of the monochloro derivative. The product (0.85 g) was crystallized from acetone and proved to be I*e*.

When tetrabromo-*o*-benzoquinone was used in this experiment, the bromo analogue I*f* was similarly produced.

A STUDY OF THE HYPOCHLORINATION OF STYRENE

PREPARATION OF CHLOROHYDRINS IN AQUEOUS ACETONE

GENE SUMRELL,[1] BERT M. WYMAN, RONALD G. HOWELL, AND MACK C. HARVEY

Received June 29, 1964

ABSTRACT

A study has been made of the hypochlorination of styrene and of the by-products which accompany the formation of styrene chlorohydrin. A process was developed utilizing hypochlorination in aqueous acetone which gave a yield of 72% of the chlorohydrin. Application of this procedure was extended to several other olefins with good results.

Because of a need for substantial quantities of styrene chlorohydrin for use as an intermediate in other work, we have investigated in some detail its preparation from styrene. Frisch (1) claims the production of approximately equal quantities of the chlorohydrin and dichloride of styrene by the passage of chlorine into an aqueous suspension of styrene in the presence of sodium bicarbonate. The yield of chlorohydrin was determined indirectly by conversion to styrene oxide and fractionation to separate the oxide from accompanying styrene dichloride. Since the dichloride and chlorohydrin of styrene are readily separable by fractionation (1) and since the former may, in turn, be hydrolyzed to the chlorohydrin, the simple method of Frisch for converting styrene to the chlorohydrin was attractive to us and served as a starting point in our work.

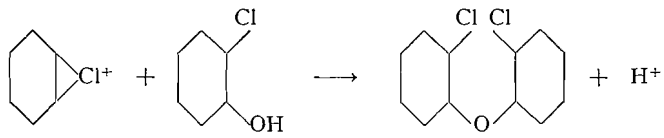
We were disappointed to learn early in this work that a large percentage of the material reported as styrene oxide by Frisch was actually β-chlorostyrene, which distills at essentially the same temperature as styrene oxide, and that the yield of chlorohydrin was far less than reported by Frisch. A typical run gave the following yields of products: β-chlorostyrene, 20%; styrene dichloride, 59%; and styrene chlorohydrin, 6%.

The possibility occurred to us that better results in hypochlorinating styrene by directly adding chlorine in the presence of water might be achieved if we also had present an inert water-miscible organic material which would keep the styrene and water in one phase or, at least, greatly increase the amount of water present in the same phase with the styrene. A number of such solvents were investigated and all gave improved yields of styrene chlorohydrin. However, acetone proved to be far superior to the others. The yields of products from a typical run, described in the experimental section, were styrene chlorohydrin, 72%; styrene dichloride, 13%; and β-chlorostyrene, 7%.

Similar work with cyclohexene gave a yield of 69% (isolated as the epoxide) of the chlorohydrin and 15% of the dichloride. Application of the aqueous acetone method to 1-pentene resulted in a yield of 66% of the mixed chlorohydrins (isolated as the epoxide) and 27% of the dichloride.

Investigation of the higher boiling residue from the cyclohexene chlorohydrin preparation showed it to be composed primarily of bis(2-chlorocyclohexyl) ether (II). This material undoubtedly results from the reaction of chlorohydrin already present with the chloronium intermediate, I, resulting from the initial reaction of olefin and chlorine (3) to give the ether, instead of the normal reaction with water to give the the chlorohydrin.

[1]*To whom inquiries should be directed. Present address: Southern Regional Research Laboratory, P.O. Box 19687, New Orleans, Louisiana, 70119.*



I II

Attempts were not made in our work to isolate ethers analogous to II from the higher boiling residues obtained with 1-pentene and styrene. However, cursory investigation by infrared spectroscopy indicated the presence of ether linkages, suggesting that analogs of II were in all likelihood present.

A cursory investigation was made of the conversion of gaseous olefins to their chlorohydrins by the aqueous acetone technique described in this paper. Such chlorohydrins are conventionally prepared from the olefin and chlorine in sufficient water to give a 5% solution of the resulting chlorohydrin, with yields of 60–70% for the C_4-alkenes and 80% for propylene. We found that in the presence of acetone the volume of water could be greatly reduced without sacrifice of yield. For example, an 80% yield of the chlorohydrin was obtained when 1 mole each of propylene and chlorine were passed into a mixture of 200 ml of water and 300 ml of acetone, a combined volume of only a quarter that required for a similar yield of chlorohydrin with water alone.

During our work with styrene, we learned that the styrene chlorohydrin, produced either by direct chlorination of styrene in the presence of water (1) or by hypochlorination using an alkali hypochlorite (4, 5), usually analyzed high in chlorine. We were able to isolate varying amounts of (1,2,2-trichloroethyl)-benzene from such material by treatment of the mixture with aqueous caustic which converted the chlorohydrin to the oxide while leaving the trichloroethylbenzene unchanged. These products were then easily separated by fractionation. The trichlorinated compound and styrene chlorohydrin distill at essentially the same temperature and cannot be separated by fractionation, which explains the fact that previous investigators have failed to observe the presence of (1,2,2-trichloroethyl)-benzene in their product. This material undoubtedly arises from addition of chlorine to the double bond of β-chlorostyrene. The latter appears to be invariably formed in varying amounts in preparations of styrene chlorohydrin. We found the ratio of styrene dichloride to β-chlorostyrene formed on a variety of preparations of styrene chlorohydrin to be of the order of 3:1 on a weight basis. This is the same ratio of dichloride and β-chlorostyrene as was reported by Emerson and Agnew (6) on the addition of chlorine to styrene in carbon tetrachloride solution at 40–50°. We also investigated the preparation of styrene dichloride by chlorinating styrene at 0–10° in a variety of solvents and at varying concentrations without greatly changing the ratio of addition to substitution from that reported by Emerson and Agnew.

EXPERIMENTAL

Melting and boiling ranges are uncorrected. Fractionations were carried out using a 60 cm Podbielniak-type column with heated jacket and partial reflux head similar to that described by Cason and Rapoport (7). Gas chromatographic studies were done with an F & M Model 720 chromatograph using a 6 ft column packed with 20% Dow 9N9 nonionic surfactant on Chromasorb P of 30–60 mesh.

Hypochlorination of Styrene in Aqueous Acetone

A mixture of styrene (1.25 moles), sodium carbonate (0.5 mole), acetone (1 000 ml), and water (250 ml) was placed in a 2 l, three-necked flask which was fitted with a mechanical stirrer, thermometer, and inlet

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

tube for chlorine gas. One mole of chlorine was allowed to vaporize during approximately 4 h from a cold trap and pass into the mixture. No cooling or heating was resorted to, and the temperature of the reaction mixture rose to 41° during this time. The mixture was present as one phase initially (with the carbonate out of the solution), but a lower aqueous phase separated soon after the chlorine addition was started. The aqueous layer grew in size during the addition and, at the end, contained most of the water in the reaction mixture as a nearly saturated sodium chloride solution. The latter was separated and acetone was removed from the organic layer by distillation. Fractionation of the residue gave a recovery of 24 g of styrene, followed by 9.8 g (7% based on the styrene consumed) of β-chlorostyrene at 69–70° (5 mm), n_D^{25} 1.5744 (lit. (8) b.p. 89–90° (15 mm), n_D^{13} 1.5781), 23 g (13%) of styrene dichloride at 93–95° (4 mm), n_D^{25} 1.5492 (lit. (2) b.p. 90° (4 mm), n_D^{15} 1.5544); and 113 g (72%) of styrene chlorohydrin at 108–109° (4 mm), n_D^{25} 1.5506 (lit. (4, 9) b.p. 110–111° (6 mm), n_D^{20} 1.5525).

Chlorination of Styrene in Aqueous Suspension

Chlorine (1 mole) was added as described in the preceding paragraph to an agitated mixture of water (500 ml), styrene (1 mole), and sodium bicarbonate (1 mole) with cooling to maintain the reaction mixture at approximately 10°. The heavy oil layer was separated, dried, and fractionated, yielding 28 g (20%) of β-chlorostyrene at 68–70° (5 mm), 103 g (59%) of styrene dichloride at 93–95° (4 mm), and 10 g (6%) of impure styrene chlorohydrin at 105–110° (4 mm), n_D^{25} 1.5520. The polymeric residue amounted to 19 g.

Separation of (1,2,2-Trichloroethyl)-benzene from the Styrene Chlorohydrin Runs

A sample of 150 g of impure styrene chlorohydrin was accumulated from a number of runs similar to that described in the preceding paragraph. This material was carefully fractionated and a cut of 109 g taken at 107–109° (3.5 mm), n_D^{25} 1.5522. The latter material analyzed 27.20% chlorine (theory for styrene chlorohydrin, 22.64%). A sample of 100 g of this cut was treated with 20% aqueous sodium hydroxide (0.6 mole), with stirring at room temperature, and then maintained at 50° for 1 h. The organic phase was separated, dried, and fractionated. After a very small forerun, 57 g of styrene oxide was taken at 67° (5 mm), n_D^{25} 1.5329 (lit. (2) b.p. 70° (5 mm)). After an intermediate cut of 3.5 g of material, n_D^{25} 1.5526, there was obtained 10 g of (1,2,2-trichloroethyl)-benzene at 108–110° (3 mm), n_D^{25} 1.5592 (lit. (8) b.p. 130° (17 mm)).

Anal. Calcd. for $C_8H_7Cl_3$: C, 45.86; H, 3.37; Cl, 50.77. Found: C, 45.70; H, 3.30; Cl, 50.50.

Chlorination of Styrene in Solution

Chlorine (1 mole) was added during 4 h to a solution of styrene (1 mole) in carbon tetrachloride (1 035 ml), with cooling to maintain the temperature at 0–10°. The mixture was stirred for 1 h after the addition was complete. Then the solvent was flashed off under a column and the residue was fractionated, yielding 39 g (28%) of β-chlorostyrene at 68–70° (5 mm), 119 g (68%) of styrene dichloride at 93–95° (4 mm), and 4.2 g (2%) of (1,2,2-trichloroethyl)-benzene at 107–110° (3 mm).

Cyclohexene Oxide

A mixture of acetone (250 ml), water (125 ml), and sodium carbonate (0.5 mole) was placed in a 1 l, three-necked flask which was fitted with a mechanical stirrer, dry ice – acetone condenser, dropping funnel, thermometer, and gas inlet tube extending below the surface. Chlorine (1 mole) was added through the inlet tube during 3 h while cyclohexene (1 mole) was concurrently added through the dropping funnel. Cooling was used to maintain the reaction mixture at 40–45°. After the additions were complete, the reaction mixture was filtered to remove precipitated salt. Then the acetone was removed at water-pump pressure under the column, and the two-phase residue was stirred for 1 h at room temperature with 20% aqueous sodium hydroxide (1 mole). The two phases were separated, and the organic phase was dried over sodium sulfate. Fractionation gave 68 g (69%) of cyclohexene oxide at 54–55° (50 mm), n_D^{25} 1.4492 (lit. (10) b.p. 54–55° (50 mm), n_D^{30} 1.4462), and 23 g (15%) of *trans*-1,2-dichlorocyclohexane at 52–53° (5 mm), n_D^{25} 1.4875 (lit. (11), b.p. 88–89° (30 mm), n_D^{20} 1.4904). After removal of an intermediate cut of 10 g of material at 53–137° (5–3.5 mm), n_D^{25} 1.5050, without any indication of a stable boiling point, there followed 9 g (7%) of bis(2-chlorocyclohexyl) ether at 137–139° (3.5 mm), n_D^{25} 1.5019. This material crystallized on standing and after recrystallization from acetone melted at 71–72° (lit. (12) m.p. 70–71°).

1,2-Epoxypentane

1-Pentene was converted to the epoxide in the same manner described above for cyclohexene, with the exception that the sodium carbonate was added portionwise to the reaction mixture after the additions of chlorine and olefin were complete.[2] Fractionation gave 57 g (66%) of 1,2-epoxypentane at 80–81° (665 mm), n_D^{25} 1.3932 (lit. (13) b.p. 89–90° (750 mm), n_D^{20} 1.3963). After a small intermediate fraction, 38 g (27%) of 1,2-dichloropentane was obtained at 55–57° (30 mm), n_D^{25} 1.4439 (lit. (14) b.p. 146° (739 mm), n_D^{25} 1.4448), leaving 9 g of higher boiling residue.

[2]*This procedure was used to avoid loss of the more volatile 1-pentene in the evolving carbon dioxide. In the case of cyclohexene it was found that the yields of products were essentially identical whether the sodium carbonate was present initially or added to the acidic mixture after the chlorination. Under acidic conditions, however, there was some slight attack on the acetone by chlorine, yielding chloroacetone and a slightly lachrymatory reaction mixture.*

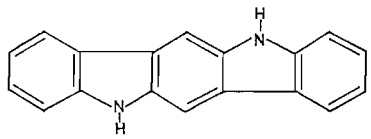
NOTES

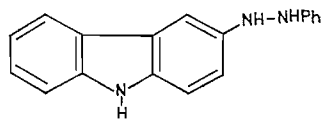
THE NON-CATALYTIC FISCHER INDOLIZATION OF HEXANE-2,5-DIONE BISPHENYLHYDRAZONE

B. ROBINSON

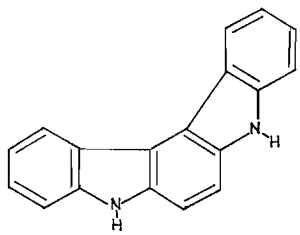
It has recently been found that Fischer indolization of cyclohexane-1,4-dione bisphenylhydrazone leads to the formation of indolo (3′,2′;2,3) carbazole, I (1, 2), 3-phenylhydrazinocarbazole, II (1), and 1,2,3,4-tetrahydro-3-oxocarbazole (2), no formation of indolo (2′,3′;3,4) carbazole, III, being detected.



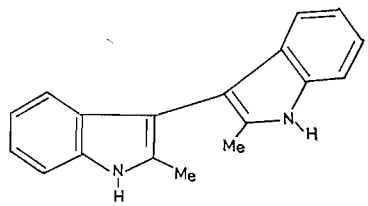
I



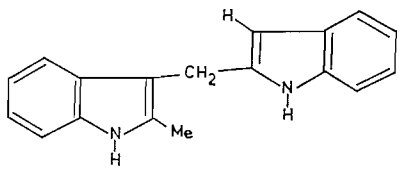
II



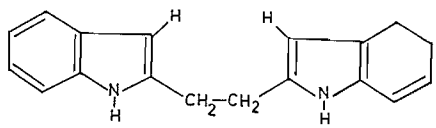
III



IV



V



VI

The Fischer indolization of the acyclic analog of cyclohexane-1,4-dione bisphenylhydrazone, hexane-2,5-dione bisphenylhydrazone (3), has now been investigated. Since it has previously been shown (4) that hexane-2,5-dione bisphenylhydrazone under acidic conditions is converted into 1-anilino-2,5-dimethylpyrrole, the Fischer indolization was effected by the non-catalytic technique using refluxing monoethylene glycol (5) to prevent (or lessen) formation of the undesired pyrrole. The indolization could theoretically lead

to one or more of three compounds having structures IV, V, and VI. However, only one indolic product of molecular formula $C_{18}H_{16}N_2$ has been obtained from the reaction [although proton magnetic resonance data suggested the formation of traces of a further indolic product(s), possibly V and (or) VI (see experimental section)]. This product has been distinguished from V and VI and shown to have structure IV from the following evidence.

(i) The infrared spectrum (in Nujol) shows a single N—H stretching band at 3 350 ± 10 cm^{-1} [cf. the single N—H stretching band of 3,3′-diindole (prepared by the method of Gabriel, Gerhard, and Wolter (6)) (in Nujol) at 3 360 ± 10 cm^{-1}]. (Compound V might be expected to show two N—H stretching bands in its infrared spectrum since it contains two N—H groups in different environments.)

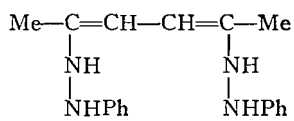
(ii) The compound was recovered unchanged after boiling under reflux for 24 h with acetic anhydride (compounds V and VI under these conditions would be expected to give mono- and di-acetyl derivatives respectively, since indoles having unsubstituted 2- and (or) 3-positions are known (7) to be acetylated at these positions in refluxing acetic anhydride).

(iii) The proton magnetic resonance spectrum (in pyridine and in dimethylsulfoxide) had no absorption band between 3.3 and 4.5 τ, and therefore indolic 3-protons (present in structures V and VI) are absent (8). The spectrum in pyridine, however, did have a strong singlet at 7.60 τ, indicative of the two equivalent methyl groups substituted at the 2- and 2′-positions of IV.

(iv) The mass spectrum shows, apart from a strong molecular ion peak at m/e = 260, only minor fragmentation with a weak peak at m/e = 130 (cf. the mass spectrum of 3,3′-diindole (6) which shows an abundant molecular ion peak with little fragmentation to an ion at m/e = 116 and a slightly more abundant ion at m/e = 115). This eliminates structure VI which would be expected to give an intense peak in its mass spectrum at m/e = 130.

(v) The ultraviolet spectrum was almost identical to that of 3,3′-diindole (6) (see experimental section).

Preferential or exclusive formation of IV in the above indolization may be explained by consideration of the direction of bisenehydrazine formation (the first stage in the mechanism of the indolization (9) and the one which ultimately controls the direction of cyclization), for whereas the bisenehydrazine intermediate which leads to compound IV is the fully conjugated bisenehydrazine system VII, the analogous intermediates which



VII

would lead to structures V and VI would consist of two nonconjugated monoene-hydrazines and would therefore be less favorable (similar reasoning can be applied if one of the phenylhydrazone moieties indolizes before the other undergoes hydrazone–ene-hydrazine tautomerization). However, since one of the indolization products from cyclohexane-1,4-dione bisphenylhydrazone is the indolocarbazole I (1, 2), it is likely that bisenehydrazine formation in hexane-2,5-dione bisphenylhydrazone does not occur exclusively in favor of the fully conjugated system VII and the above discussion would not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

therefore explain the sole formation of IV, although it could explain its formation as the major indolic product. It is known (10), however, that indolization of methyl alkyl ketone phenylhydrazones yields only the corresponding 2-methylindoles (with one exception) and therefore, by analogy, compound IV would be expected as the only indolic product in the indolization of hexane-2,5-dione bisphenylhydrazone.

EXPERIMENTAL

Infrared spectra were recorded on a Unicam SP 200 spectrophotometer, ultraviolet spectra were measured on a Beckmann DB spectrophotometer, and proton magnetic resonance spectra were recorded on a Varian A 60 spectrometer using tetramethylsilane as internal standard.

The Non-Catalytic Fischer Indolization of Hexane-2,5-dione Bisphenylhydrazone

Hexane-2,5-dione bisphenylhydrazone (3) (20 g) was added to redistilled monoethylene glycol (200 ml). The mixture was warmed to effect solution and then gently refluxed (a copious evolution of ammonia began after about 5 min) for 6 h, after which time the ammonia evolution had ceased and the initially pale-yellow solution had become dark brown. The reaction mixture was cooled to room temperature and water (1 l) was added, followed by extraction of the liberated oil with ether (8 × 150 ml). The combined ether extracts were washed with water (2 × 250 ml), extracted with 3 *N* hydrochloric acid (3 × 150 ml), washed with water (250 ml), and dried (magnesium sulfate) and the ether removed under reduced pressure (11 mm) to leave a dark-brown gum (A) (4.18 g) which, on cooling to 5° and trituration with ether, partially crystallized. After filtration and washing with a little ether, a white crystalline solid (1.17 g, 6.5%) was obtained which was sublimed [200–210° (bath temperature) at 0.4 mm] to give pure 2,2′-dimethyl-3,3′-diindole, IV, as a pale-yellow crystalline solid (0.90 g, 5%). Recrystallization from aqueous ethanol afforded white needles, m.p. 226–228° (uncorrected).

Anal. Calcd. for $C_{18}H_{16}N_2$: C, 83.04; H, 6.20; N, 10.76. mol. wt. 260. Found: C, 83.33; H, 6.31; N, 10.67; mol. wt. (mass spectrum) 260. λ_{max}^{EtOH} 232 mμ, log ε 4.64; 283 mμ, log ε 4.10; 291 mμ, log ε 4.08. λ_{min}^{EtOH} 260 mμ, log ε 3.79; 288 mμ, log ε 4.07. (Confer 3,3′-diindole (6). λ_{max}^{EtOH} 233 mμ, log ε 4.60; 282 mμ, log ε 3.91; 291 mμ, log ε 3.92. λ_{min}^{EtOH} 264 mμ, log ε 3.76; 286 mμ, log ε 3.90.)

The proton magnetic resonance spectrum (in dimethylsulfoxide) of the mother liquors remaining after the removal of compound IV from (A) shows a weak signal at 3.70 τ, suggesting the possible presence of traces of a 3-unsubstituted indole(s) (8) (i.e. V and (or) VI), but attempts to isolate such compounds or any other crystalline product(s) failed.

The combined dark-brown acidic extracts from above were carefully basified with sodium hydroxide pellets (with cooling by the addition of ice) and the liberated oil was extracted with ether (3 × 250 ml). The combined ether extracts, after drying (magnesium sulfate) and evaporation of the solvent, afforded a dark-brown oil (4.33 g) which could not be induced to crystallize or made to form a picrate with picric acid in ethanol or in benzene and was therefore not examined further.

ACKNOWLEDGMENT

I wish to thank Drs. G. Spiteller and H. Eggers of the University of Vienna for determination of the mass spectra of 3,3′-diindole and compound IV.

PRÉPARATION D'ESTERS ORTHOTHIOBORIQUES A PARTIR DU SULFURE DE BORE

J. BRAULT ET J. M. LALANCETTE

La première mention d'un ester orthothioborique $B(SR)_3$ est due à Goubeau et Wittmeier qui rapportent la préparation de l'homologue méthylé à partir du sel d'argent du méthanethiol et du tribromure de bore (1). Plus récemment, Brotherton et Petterson ont breveté une méthode de préparation de certains orthothioborates faisant appel à l'action d'un mercaptan sur un aminoborane en milieu acide (2) et Mikhailov a obtenu ces esters à partir du trichlorure de bore ou du diborane et des mercaptans (3).

Une nouvelle méthode permettant d'accéder à cette classe de composés a été mise au point en étudiant l'action des mercaptans sur le sulfure de bore. En effet nous avons noté que ce sulfure donne avec des mercaptans une réaction modérée, s'accompagnant d'un dégagement de H_2S et conduisant à l'ester orthothioborique correspondant avec de bons rendements.

$$6RSH + B_2S_3 \rightarrow 2B(SR)_3 + 3H_2S.$$

La réaction semble générale pour tous les mercaptans (voir le Tableau I) et offre un accès facile aux orthothioborates.

*Déterminé sous forme de H_3BO_3 par une lente hydrolyse en présence d'air humide.

PARTIE EXPÉRIMENTALE

Préparation d'esters orthothioboriques

A une suspension de 23.0 g (0.20 mole) de sulfure de bore (4) dans l'éther de pétrole sec, p.éb. 40–50°, on ajoute 74.0 g (1.2 mole) d'éthanethiol Eastman Kodak, White Label. Suit un reflux de 36 h, sous bonne agitation. Au terme de cette période, le dégagement de H_2S a cessé et la filtration de la masse réactionnelle donne un filtrat que l'on concentre à pression atmosphérique et fractionne sous vide. Ces opérations, exécutées en milieu rigoureusement anhydre et sous atmosphère d'azote, conduisent à 57 g (0.29 mole) d'un liquide incolore, p.éb. 88° à 0.70 mm.

Anal. Calc. pour $BC_6H_{15}S_3$: C, 37.11; H, 7.78; S, 49.53; B, 5.57. Trouvé: C, 36.81; H, 7.60; S, 49.17; B, 5.60.

Le spectre infrarouge montre de nouvelles bandes dans la région de 900 cm^{-1} attribuables vraisemblablement à la liaison B—S.*

Un mode opératoire similaire permet d'accéder aux orthothioborates homologues supérieurs (voir le Tableau I). Avec le méthanethiol, les espèces sont mises en contact à froid (0 °C) et une pression de 0.3 atm est établie à l'intérieur du système. On porte alors le diluant à la température de reflux et procède selon le mode décrit plus haut.

**Les spectres infrarouges d'une série d'esters orthothioboriques feront l'objet d'une prochaine communication.*

Analyses élémentaires des esters orthothioboriques

Les orthothioborates s'avèrent des substances extrêmement hygroscopiques, la réaction des premiers termes avec l'eau étant quasi explosive. Cette sensibilité a rendu les analyses C—H—S très difficiles et n'ont été effectuées que pour le dérivé éthyle. Les déterminations de bore ont été effectuées en utilisant la méthode spectrométrique à flamme décrite par Yoshizaki (5). Les solutions standards d'acide borique servant à établir une courbe de calibration renfermait de l'éthanethiol dans le rapport molaire H_3BO_3/EtSH = 1/3. Des échantillons des esters orthothioboriques (≈1.0 g) ont été pesés exactement dans des ballons jaugés de 100 ml et hydrolysés par simple addition d'eau. Les mesures ont été effectuées à l'aide d'un spectromètre Beckman DU avec une flamme d'hydrogène, à une longueur d'onde de 519 mμ.

Avec l'orthothioborate de méthyle, un échantillon (1.0028 g) de l'ester a été placé dans un dessicateur contenant une solution à 20% de NaOH. Après 48 h sous un léger vide, l'ester est transformé en un solide dont le poids demeure constant; l'acide borique, 0.4162 g, p.f. 178°; soit 7.26% de bore dans l'ester initial.

Anal. Calc. pour $B(SCH_3)_3$: 7.11.

THE SYNTHESIS OF 5-MERCAPTOTRYPTAMINE, THE THIOL ANALOG OF SEROTONIN

J. Kenneth Horner and W. A. Skinner

The antimetabolite concept of drug development is, of course, well known and widely utilized. Wooley (1) has discussed the use of antimetabolites of serotonin in the treatment of hypertension and certain other diseases. Serotonin (5-hydroxytryptamine) was first isolated from beef serum and its structure proved in 1948 (2). We report the synthesis of the thiol analog of serotonin, 5-mercaptotryptamine (V).[1]

The route to V was via 2,3-piperidione-3-(4′-benzylthio)phenylhydrazone (I). Compound I was prepared in 35% yield by a Japp-Klingemann reaction (3) from 4-benzylthiobenzene diazonium chloride and potassium 2-oxopiperidine-3-carboxylate at 0° by a general, published procedure (4, 5). The hydrazone I was cyclized smoothly with hydrogen chloride in glacial acetic acid (6) to 6-benzylthio-1,2,3,4-tetrahydro-1-oxo-β-carboline (II) in 73% yield. Recent experiments in the same field have shown that refluxing hydrazone I in 90% formic acid for 1 h also gave good yields of II. The β-carboline II was cleaved with aqueous-ethanolic potassium hydroxide (4) by refluxing overnight to afford 3-(2′-aminoethyl)-5-benzylthio-2-indole carboxylic acid (III) in quantitative

[1]*C. J. Peake, F. L. Benton, and C. E. Brambel, Abstracts of Papers, 140th A.C.S. Meeting, Chicago, September, 1961, p. 6-O, reported the synthesis of V in 1961. The meeting abstracts give no physical properties nor experimental details and no further reference to this compound is found in the later literature.*

yield. The decarboxylation of III was achieved with a mixture of 2 *N* hydrochloric acid and acetic acid (3:2, v/v) giving 5-benzylthiotryptamine (IV) in 70% yield. This facile decarboxylation during overnight refluxing was somewhat unexpected because of the published report (4) that 3-(2′-aminoethyl)-5-benzyloxy-2-indole carboxylic acid could not be decarboxylated under a variety of conditions. The thio ether IV was debenzylated with sodium in liquid ammonia under a nitrogen atmosphere and 5-mercaptotryptamine (V) was isolated as the picrate in 67% yield. The thiol V in dilute ammonia gave the characteristic aromatic thiol test with nitroprusside. Quantitative determination of the SH function of thiol V hydrochloride by ultraviolet spectrophotometry according to the method of Ellman (7) showed the absence of appreciable disulfide.

EXPERIMENTAL[2]

2,3-Piperidione-3-(4′-benzylthio)phenylhydrazone (I)

Ethyl 2-oxopiperidine-3-carboxylate (23.3 g, 0.136 mole) was dissolved in 60 ml of warm ethyl alcohol, cooled to 0° and diluted with a solution of 9.29 g (0.139 mole) of potassium hydroxide in 50 ml of water. This clear solution was cooled overnight, diluted with 500 g of ice water, and stirred while adding a suspension of 4-benzylthiobenzene diazonium chloride (prepared from 0.13 mole of 4-benzylthioaniline and 0.13 mole of sodium nitrite in 100 ml of 4 *N* hydrochloric acid). Immediately after the addition was complete, 20 g of sodium acetate was added. The tan mixture was stirred at 0° for 5 h then left at 25° overnight. The solid product was collected, washed with water, and recrystallized from dilute ethyl alcohol or methyl ethyl ketone to give 14.8 g deep-yellow rosettas, m.p. 203–205°. The analytical sample prepared by further recrystallizations from the same solvents melted at 207–208°. $\lambda_{max(\mu)}^{Nujol}$ 3.10, 3.15 (NH); 6.00 (amide C=O); 6.23 (aryl); 6.44 (amide II); 12.1 (1,4-disubstituted benzene).

Anal. Calcd. for $C_{18}H_{19}N_3OS$: C, 66.4; H, 5.89; N, 12.9. Found: C, 66.2; H, 5.99; N, 13.0.

[2]*All melting points are uncorrected and were taken with a Fisher–Johns melting block.*

6-Benzylthio-1,2,3,4-tetrahydro-1-oxo-β-carboline (II)

Dry hydrogen chloride was passed into a solution of 6.2 g (0.019 mole) of 2,3-piperidione-3-(4′-benzylthio)phenyl hydrazone (I) in 120 ml of warm acetic acid for 15 min. The resulting suspension was refluxed 15 min, reduced to half volume *in vacuo*, and poured over cracked ice. The resulting grey solid was collected and recrystallized from isopropyl alcohol to give 4.3 g of β-carboline II, m.p. 194–195°. Additional purification by recrystallization gave m.p. 197–198° $\lambda_{max(\mu)}^{CHCl_3}$ 2.89, 3.07 (NH); 5.97 (amide C=O); absence of 1,4-disubstituted benzene band at 12.1.

Anal. Calcd. for $C_{18}H_{16}N_2OS$: C, 70.1; H, 5.23; N, 9.09. Found: C, 70.3; H, 5.45; N, 9.26.

3-(2′-Aminoethyl)-5-benzylthio-2-indole Carboxylic Acid (III)

6–Benzylthio-1,2,3,4-tetrahydro-1-oxo-β-carboline (II) (4.0 g, 0.013 mole) was refluxed overnight with a solution of 8.6 g (0.13 mole) of potassium hydroxide, 48 ml of ethyl alcohol, and 32 ml of water. The red solution was concentrated to half volume and adjusted to pH 5 with acetic acid. The white solid was collected, washed with water, and dried to give a quantitative yield of product III, m.p. 224–227°. The analytical sample (dilute ethyl alcohol) decomposed at 237°. $\lambda_{max(\mu)}^{Nujol}$ 2.94 (NH); 3.10 (NH, OH); 5.90 (acid C=O); 6.20 (aryl); 13.0, 14.3 (monosubstituted benzene).

Anal. Calcd. for $C_{18}H_{18}N_2O_2S$: C, 66.2; H, 5.56; N, 8.58. Found: C, 66.0; H, 5.57; N, 8.70.

5-Benzylthiotryptamine (IV)

A solution of 3.0 g (0.009 mole) of 3-(2′-aminoethyl)-5-benzylthio-2-indole carboxylic acid (III) in 45 ml of 2 *N* hydrochloric acid and 30 ml of acetic acid was refluxed overnight. The clear, red solution was concentrated to half volume and cooled to yield 2.0 g of 5-benzylthiotryptamine hydrochloride, m.p. 207–210°. Recrystallization from isopropyl alcohol – ether produced the analytical sample, m.p. 213–214°. $\lambda_{max(\mu)}^{Nujol}$ 3.00 (indole NH); absence of acid C=O at 5.90; 6.20, 6.25 (NH_2, aryl); 12.9, 14.2 (monosubstituted benzene).

Anal. Calcd. for $C_{18}H_{18}N_2O_2S$: C, 64.0; H, 6.01; N, 8.79. Found: C, 63.9; H, 6.02; N, 8.90.

5-Mercaptotryptamine (V)

Dry 5-benzylthiotryptamine hydrochloride (0.5 g, 1.58 mmoles) in a dried 50 ml flask was finely powdered and covered with 15 ml of anhydrous ammonia. The reaction was immersed in a dry ice – acetone bath and protected from moisture with a drying tube packed with dried cotton. The mixture was stirred magnetically and 0.2 g of sodium in small pieces was added in one portion. The blue reaction mixture was stirred for 0.5 h. Then 0.002 mole of ammonium iodide was added and the ammonia removed at 25° under a dense stream of dry nitrogen. A prepared solution of 0.002 mole of hydroquinone, 0.002 mole of acetic acid, and 0.002 mole of picric acid in 33 ml water and 2 ml ethyl alcohol was quickly added. The solution was adjusted to pH 5 with 5 ml of acetic acid and the orange precipitate was stirred under nitrogen for 0.5 h, then left at 25° overnight. The picrate was collected and washed with water and dried to give 0.45 g, m.p. 220° (decomp.). The picrate (150 mg) was recrystallized from ethyl alcohol – water.

Anal. Calcd. for $C_{10}H_{12}N_2S \cdot C_6H_3N_3O_7$: C, 45.6; H, 3.59; N, 16.6. Found: C, 45.7; H, 3.55; N, 16.7.

5-Mercaptotryptamine picrate (0.4 g) was suspended in 50 ml of boiled ethyl alcohol and stirred under nitrogen overnight with 5 g of Dowex chloride resin. The mixture was filtered and the filtrate concentrated to give 5-mercaptotryptamine hydrochloride as an oil which was stored in a cold, dark place under nitrogen. $\lambda_{max(\mu)}^{film}$ 2.95, 3.05 (NH); 6.18 (aryl); absence of benzene monosubstitution bands at 12.9, 14.2. A solution of mercuric chloride was added to 0.043 mmoles of the thiol V hydrochloride in water to give 21.6 mg of the salt; theoretical weight for RSHgCl·HCl is 21.4 mg.

HYDROGEN SORPTION BY CADMIUM OXIDE

M. J. D. Low and A. M. Kamel

In general, little is known of the surface properties of CdO and the knowledge of the interaction of CdO with hydrogen seems to be limited to reports that the reduction of CdO begins at 95° (1) or at 221° (2). Because of the possibility of comparison with the plentiful data on hydrogen sorption by ZnO, an attempt was made to study the surface properties of CdO. The simultaneous effects of surface "activation" and of changes in surface areas by thermal sintering and hydrogen reduction precluded quantitative study, but permitted quantitative observations to be made.

EXPERIMENTAL DETAILS

A conventional high-vacuum apparatus (3) suitable for the determination of nitrogen B.E.T. surface areas (4) and also for the measurement of hydrogen take up was used. Hydrogen was purified by diffusion through hot palladium. Nitrogen and helium were purified by passage through glass wool filled traps at the temperature of liquid nitrogen. Baker A. R. or Coleman C. P. CdO of equivalent purity and identical surface areas was used. The initial hydrogen pressure for all sorption experiments was 1.83 cm Hg.

EXPERIMENTS, RESULTS, AND DISCUSSION

The plots of Fig. 1 show that a rapid decline in surface areas of CdO occurred even at relatively low temperatures. The first point of each curve was obtained after heating at the various temperatures for 3 min. At 400 and 500° a cadmium mirror formed on the cool portion of the tubing leading from the sample chamber to the pumping system and the samples lost weight. Because of this the specific surface area was calculated on the basis of the final sample weight for the points shown as filled circles in Fig. 1. The single datum indicated by a filled triangle at zero time represents the surface area of the unsintered material after degassing at 22° for 12 h. That point is considerably lower than the 3 min points that mark the beginning of each sintering curve except that at 200°. However, it seems unlikely that the development of a new surface was involved by the mild heat treatment. A more reasonable explanation is that the solid had a network of pores that was made accessible to N_2 molecules after the 3 min degassing.

Numerous measurements of the uptake of hydrogen by CdO were made in an attempt to establish the conditions that would permit reproducible measurements to be made. In general, these experiments showed the surfaces to be unstable. Figures 2 and 3 illustrate such "activation" effects, which may plausibly be ascribed to a change in stoichiometry of the surface. Figure 4 illustrates the type of data obtained with arbitrarily selected "standard" degassing conditions. The characteristics of the sorption at 22° and 100° are like those generally observed for a chemisorption process. At the higher temperatures, however, the uptake process was not "normal." At the points R the decline in pressure ceased and the pressure within the adsorption system increased. Such increases were generally found at 200° and above and occasionally at 150°. On one occasion, a sample degassed for 12 h at 100° was exposed to hydrogen at 100°. The pressure initially decreased as hydrogen was taken up, but increased after about 15 min. When the temperature was raised to 200°, water condensed on the cold portions of tubing. In some cases, the surface area of the CdO was measured before and after exposure to hydrogen. The surface area of a CdO sample was 8.8 m^2/g after 30 min degassing at 200°. The hydrogen was then removed and after pumping for 15 min at room temperature, the surface area was again

For personal use only.

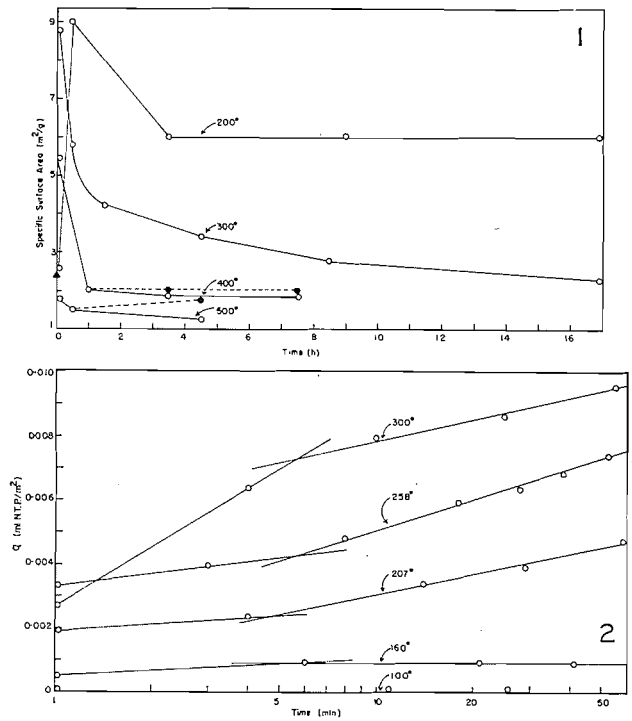

FIG. 1. Sintering of CdO in vacuum. A fresh CdO powder sample was used at each temperature. The sample was heated *in vacuo* for a predetermined time and the quenched and the B.E.T. surface area was measured. Heating then continued.

FIG. 2. Effect of degassing temperature on hydrogen sorption at 22°. A separate CdO sample was used for each experiment and was degassed by pumping at about 10^{-6} mm Hg for 12 h at each temperature indicated.

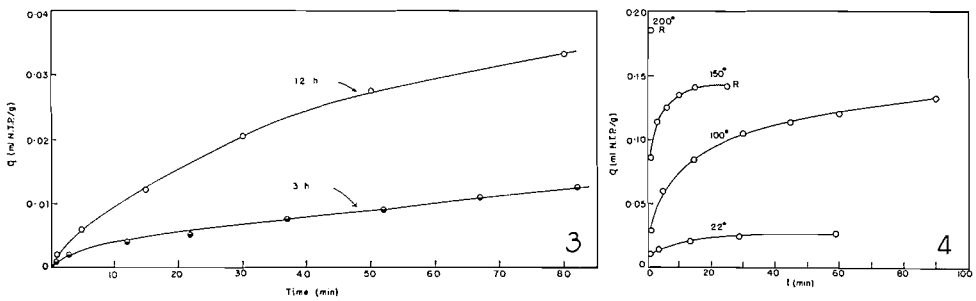

FIG. 3. Effect of degassing time on hydrogen sorption at 100°. Individual CdO samples were degassed at 150° for 3 or 12 h.

FIG. 4. Effect of temperature on hydrogen sorption. A fresh CdO sample was degassed at 200° for 12 h before each sorption experiment.

8.8 m²/g. The same sample was then re-exposed to hydrogen for 3 h at 200°. An increase of pressure within the system occurred. It was found that the surface area had declined to 2.5 m²/g. After a further degassing at 200° for 1 h, the surface area was 2.5 m²/g.

The various effects suggest that reduction of CdO occurred at and above about 100°. The observed pressure increases and the decrease in surface area with hydrogen treatment lend some support to the suggestion that some reduction occurred even below 100° and

For personal use only.

that some or all of the water that was formed was retained by the surface. Desorption of appreciable amounts of water then would not occur until the surface had become fully covered with adsorbed water, the attainment of that saturated state being helped by the decline of the surface by the reduction process.

SUBSTITUTED HYDANTOINS AND OROTIC ACIDS

R. U. LEMIEUX AND I. PUSKAS

The structure of 5-(carbethoxymethylidene)-hydantoin (1) was established by Mitchell and Nyc (2, 3), who showed that treatment of the compound with aqueous base produced first the salt of 5-(carboxymethylidene)-hydantoin which was subsequently isomerized to the salt of orotic acid. That the rearrangement occurred before acidification was demonstrated by following the change in the ultraviolet spectrum of the basic solution (3). Direct evidence that the ring of the orotic acid was in fact established in the alkaline medium was obtained in the present investigation through the observation that potassium orotate precipitated directly from the reaction mixture.

Clerk-Bory and Mentzer (4) extended the method to the preparation of mono- and di-substituted orotic acids. The hydantoin acid could not be isolated as an intermediate when there was present a substituent at the 3-position of the starting material. We also failed to isolate the hydantoin-acid intermediate expected on the treatment of 3-methyl-5-(carbethoxybenzylidene)-hydantoin with base. The acid, was however, obtained by acid-catalyzed hydrolysis of the ethyl ester.

The main purpose of this communication is to report the hydantoin derivatives listed in Tables I and II and the substituted orotic acids shown in Table III. The methods used were virtually the same as those previously reported (2–4). Except for 3-phenyl-5-(carboxymethylidene)-hydantoin, as previously shown (4), the ultraviolet absorption maxima using 95% aqueous ethanolic solutions for the hydantoin derivatives, 296–309 mμ (ϵ_{max} = 10 000 – 14 500), were to higher wavelength than those for the substituted orotic acids, 280–283 mμ (ϵ_{max} = 7 000 – 9 500). For the 3-phenyl compound, the maximum absorption was at 280 mμ (ϵ_{max} = 14 500).

The infrared absorption frequencies observed in the carbonyl region are reported in Tables I–III. As seen, the hydantoin derivatives, as Nujol mulls, showed characteristic absorption in the region 1 758 – 1 803 cm^{-1}. The multiple strong absorptions in the carbonyl region displayed by substituted orotic acids are also present in the spectrum of

that some or all of the water that was formed was retained by the surface. Desorption of appreciable amounts of water then would not occur until the surface had become fully covered with adsorbed water, the attainment of that saturated state being helped by the decline of the surface by the reduction process.

SUBSTITUTED HYDANTOINS AND OROTIC ACIDS

R. U. LEMIEUX AND I. PUSKAS

The structure of 5-(carbethoxymethylidene)-hydantoin (1) was established by Mitchell and Nyc (2, 3), who showed that treatment of the compound with aqueous base produced first the salt of 5-(carboxymethylidene)-hydantoin which was subsequently isomerized to the salt of orotic acid. That the rearrangement occurred before acidification was demonstrated by following the change in the ultraviolet spectrum of the basic solution (3). Direct evidence that the ring of the orotic acid was in fact established in the alkaline medium was obtained in the present investigation through the observation that potassium orotate precipitated directly from the reaction mixture.

Clerk-Bory and Mentzer (4) extended the method to the preparation of mono- and di-substituted orotic acids. The hydantoin acid could not be isolated as an intermediate when there was present a substituent at the 3-position of the starting material. We also failed to isolate the hydantoin-acid intermediate expected on the treatment of 3-methyl-5-(carbethoxybenzylidene)-hydantoin with base. The acid, was however, obtained by acid-catalyzed hydrolysis of the ethyl ester.

The main purpose of this communication is to report the hydantoin derivatives listed in Tables I and II and the substituted orotic acids shown in Table III. The methods used were virtually the same as those previously reported (2–4). Except for 3-phenyl-5-(carboxymethylidene)-hydantoin, as previously shown (4), the ultraviolet absorption maxima using 95% aqueous ethanolic solutions for the hydantoin derivatives, 296–309 mμ (ϵ_{max} = 10 000 – 14 500), were to higher wavelength than those for the substituted orotic acids, 280–283 mμ (ϵ_{max} = 7 000 – 9 500). For the 3-phenyl compound, the maximum absorption was at 280 mμ (ϵ_{max} = 14 500).

The infrared absorption frequencies observed in the carbonyl region are reported in Tables I–III. As seen, the hydantoin derivatives, as Nujol mulls, showed characteristic absorption in the region 1 758 – 1 803 cm^{-1}. orotic acid [1 695 (s), 1 645 (s), and 1 605 (w) cm^{-1}] and seem to require that these compounds exist in the keto forms rather than in the pyrimidine form sometimes inferred (5, 6) for orotic acid. The proton magnetic resonance spectra of the compounds and the neutral equivalents of the acids were in agreement with those expected for the structures indicated. Several of the compounds listed, especially the orotic acids, showed crystalline transitions in the course of the melting-point determinations.

EXPERIMENTAL

Substituted Hydantoins Esters (Table I)

Diethyl ketosuccinate or the appropriately 3-substituted diethyl ketosuccinate was condensed with either urea or the monosubstituted area following the directions reported by Clerk-Bory and Mentzer (4). When the product did not crystallize directly from the reaction mixture, it was isolated by solvent removal *in vacuo* for crystallization.

Substituted Hydantoin Acids (Table II)

Mild alkaline hydrolysis followed by acidification and recrystallization of the precipitate from aqueous ethanol (4) provided the desired acid except for 3-methyl-5-(carboxybenzylidene)-hydantoin. This compound was obtained by refluxing a solution of the ester (12 g) in 400 ml of a 1:1 mixture of ethanol and 1% aqueous perchloric acid for 9 days. The acid was isolated from the incompletely hydrolyzed product in the usual manner and purified by recrystallization from ethanol–benzene.

Substituted Orotic Acids (Table III)

Except as described below, the ethyl esters reported in Table I were heated for about 4 h in refluxing 2 *N* aqueous potassium hydroxide (4). In order to achieve homogeneous conditions, ethanol was added at the beginning of the heating period until solution was complete. The ethanol was then removed during the course of the reaction. In each case, when the reaction was stopped, the ultraviolet absorption spectrum of the solution no longer showed the maximum absorption above 290 mμ originally present for the hydantoin derivative. In the preparation of the 3-methyl- and 3-phenyl-orotic acids, the reaction mixture was stirred at 50° and the ethanol was not removed.

EXPERIMENTAL

Reagent grade potassium peroxydisulfate which was further purified by recrystallization from water was used. The recrystallization step was found effective for removing traces of sulfate ions present in the reagent grade material.

The irradiation source was a Gamma Cell 220 ^{60}Co Irradiation Unit manufactured by Atomic Energy of Canada Ltd. Ferrous sulfate dosimetry was used, and the difference in the electron densities of the sample and the dosimeter was considered in calculating the absorbed dose. The samples were irradiated in 9 ml glass vials, each of which was closed with a plastic cap fitted with an aluminium foil washer.

The yield of acid was determined by microtitration with standard base using methyl red as an indicator. It was found necessary to add the indicator as close as possible to the end point to prevent it from being destroyed by the potassium peroxydisulfate before the end point was reached. With this technique very satisfactory end points were obtained.

The yield of sulfate ions was determined by a nephelometric method (1) using a Fisher Nefluoro-Photometer. The amount of sulfite ions present was determined by adding hydrogen peroxide to the solution before addition of $BaCl_2$.

Oxygen was determined by gas chromatography using a column packed with Linde 5A molecular sieve. The sample was dissolved in oxygen-free water kept under an atmosphere of helium. After solution of the sample was complete, the gas phase above the solution was pushed, by helium pressure, into the helium stream flowing through the column. For complete recovery of the oxygen it was necessary that all of the oxygen should diffuse from the solution into the helium stream in a short interval of time. Failure for this to occur may have been responsible, in part at least, for the low results obtained.

RESULTS AND DISCUSSION

Analysis of the aqueous solutions showed the presence of acid and of sulfate ions. Oxygen was detected by the use of gas chromatography. Figure 1 shows the variation of the yields of sulfate ions and of acid with the absorbed dose. The dose rate was 1 450 rads min^{-1}. The yield of acid was linear with respect to absorbed dose over the entire range of doses investigated, namely up to 78×10^6 rads. At this point approximately 4% of the peroxydisulfate ions had been decomposed, based on the yield of acid. From the slope of the line for the yield of acid vs. dose, it was calculated that $G_{acid} = 3.41$. Up to a dose of approximately 13×10^6 rads the yield of sulfate ions was also linear with respect to dose and is, within experimental error, equal to the yield of acid. This latter fact is in agreement with the equation:

$$[1] \qquad S_2O_8^{=} + H_2O \rightarrow 2SO_4^{=} + 2H^+ + \tfrac{1}{2}O_2.$$

At doses higher than 13×10^6 rads the yields of sulfate ions become increasingly lower than those of acid. That sulfite ions are also present is indicated by the increased amount of $BaSO_4$ formed when hydrogen peroxide is added to the solution before addition of $BaCl_2$. From the curves in Fig. 1 and the yield of sulfite ions for a dose of 47.9×10^6 rads, it follows that at this dose the yield of sulfate ions is 22% lower than the yield of acid, whereas the yield of sulfate ions plus sulfite ions is only 10% lower than the yield of acid.

Preliminary determinations of the yield of oxygen indicated that the yield may be in agreement with eq. [1]. The results were somewhat scattered and, based on the yields of acid, the observed yields of oxygen were somewhat lower than those predicted by eq. [1]. The low yields observed for oxygen may have been due to incomplete recovery of the oxygen liberated in the solution of the sample. The yields of oxygen became less as the particle size of the potassium peroxydisulfate was decreased. This may indicate that some of the oxygen was being lost from the sample before analysis either by diffusion from the solid or by reaction of the radiolysis products with adsorbed water.

Atkins *et al.* (2) have obtained the electron spin resonance (e.s.r.) spectra of alkali metal peroxydisulfates which had been irradiated either with γ-rays or with ultraviolet radiation. They reached the conclusion that γ-ray irradiation produces at least three

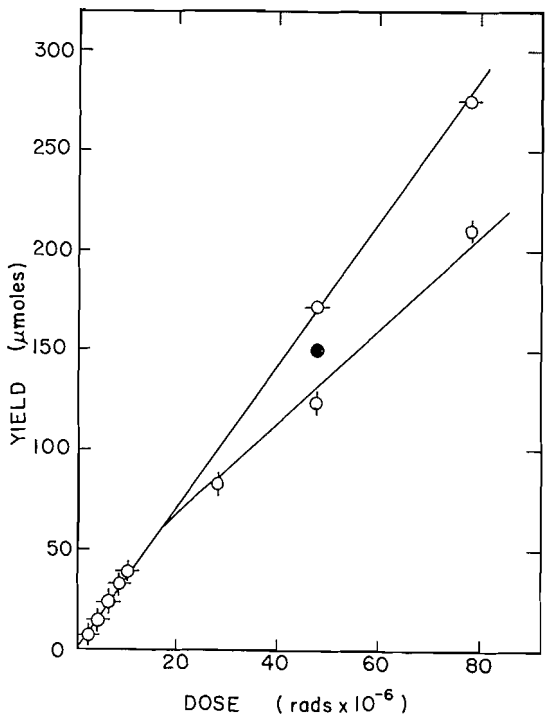

FIG. 1. Yield of products as a function of absorbed dose for γ-irradiated potassium peroxydisulfate; -O- acid; ○ sulfate ions; ● sulfate plus sulfite ions.

different radicals. Two of these were tentatively identified as SO_4^- and $S_2O_8^-$, the authors' types 2 and 1, respectively. It might be expected that SO_4^- radicals would react with water in an overall reaction as follows

[2] $$2SO_4^- + H_2O \rightarrow 2SO_4^{=} + 2H^+ + O$$

If it is assumed that the SO_4^- radicals were formed by a breaking of the peroxide bond in the peroxydisulfate ion,

[3] $$S_2O_8^{=} \rightsquigarrow 2SO_4^-,$$

then the stoichiometry suggested by eq. [1] would hold. A possible mechanism involving the $S_2O_8^-$ radical is given below.

[4] $$S_2O_8^{=} \rightsquigarrow e + S_2O_8^-.$$

Upon solution of the sample in water

[5] $$e + H_2O \rightarrow H + OH^-$$

[6] $$S_2O_8^- + H_2O + H \rightarrow SO_4^{=} + SO_3^{=} + O_2 + 3H^+.$$

The sum of eqs. [4], [5], and [6] is

[7] $$S_2O_8^{=} + H_2O \rightarrow SO_4^{=} + SO_3^{=} + O_2 + 2H^+.$$

Equation [7] together with eq. [1] predicts that the sum of the yields of sulfate and sulfite should be equal to the yield of acid, whereas the yield of oxygen should be higher than that given by eq. [1]. Since the sum of the yields of sulfate and sulfite has been found to be smaller than the yield of acid, the presence of some other sulfur containing species is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

suggested. Since the yield of sulfite ions was smaller than the yield of sulfate ions, then, on the basis of the above mechanism, the number of SO_4^- radicals present in the irradiated salt must be several times larger than the number of $S_2O_8^-$ radicals. Using the smoothed curve in Fig. 1 for the yield of sulfate, we calculated, on the basis of the above mechanisms, for a dose of 47.9×10^6 rads, that the number of SO_4^- radicals is approximately seven times the number of $S_2O_8^-$ radicals. Atkins *et al.* give no estimate of the relative number of the two radicals, nor of the doses received by their samples. However, it would appear on the basis of their Fig. 1 that the number of SO_4^- radicals is several times larger than the number of $S_2O_8^-$ radicals.

MANIFESTATIONS OF CHANGES WITH AGE IN SILICA HYDROGELS[1]

A. F. SIRIANNI, F. W. MEADUS, AND I. E. PUDDINGTON

INTRODUCTION

Hydrocarbon oil dispersions of finely divided silica that has been prepared from aqueous solutions of sodium silicate by electrodialysis exhibit well-defined maximum yield values and sedimentation rates when the aquagels from which the silica was separated were prepared at about pH 5.5. A minimal electrophoretic mobility of the silica dispersed in oil and a pronounced minimum in the gelation time of the aquasols are also observed here (1). These maximal and minimal effects are presumably associated with the isoelectric point of the silica which is observed to be in the vicinity of pH 5 (2, 3). It was found by Plank and Drake (4) that the surface area of silica gels increased as the aquagels from which they were prepared were aged in a closed system. It was therefore of interest to look for changes in other properties of silica that might depend on the age of their aquagels. In particular, properties that depend on interaction between suspended silica particles have been examined.

EXPERIMENTAL

Solutions containing about 760 g of N grade sodium silicate produced by Philadelphia Quartz Co. dissolved in 5 l of distilled water were electrodialyzed to pH values ranging from 4.9 to about 6.0. A 6-l capacity lucite cell fitted with a screen platinum anode and a perforated copper cathode was used. A tightly woven cotton fabric which was resistant to alkali was found to be a very satisfactory membrane. The cathode compartment

suggested. Since the yield of sulfite ions was smaller than the yield of sulfate ions, then, on the basis of the above mechanism, the number of SO_4^- radicals present in the irradiated salt must be several times larger than the number of $S_2O_8^-$ radicals. Using the smoothed curve in Fig. 1 for the yield of sulfate, we calculated, on the basis of the above mechanisms, for a dose of 47.9×10^6 rads, that the number of SO_4^- radicals is approximately seven times the number of $S_2O_8^-$ radicals. Atkins *et al.* give no estimate of the relative number of the two radicals, nor of the doses received by their samples. However, it would appear on the basis of their Fig. 1 that the number of SO_4^- radicals is several times larger than the number of $S_2O_8^-$ radicals.

MANIFESTATIONS OF CHANGES WITH AGE IN SILICA HYDROGELS[1]

A. F. SIRIANNI, F. W. MEADUS, AND I. E. PUDDINGTON

INTRODUCTION

Hydrocarbon oil dispersions of finely divided silica that has been prepared from aqueous solutions of sodium silicate by electrodialysis exhibit well-defined maximum yield values and sedimentation rates when the aquagels from which the silica was separated were prepared at about pH 5.5. A minimal electrophoretic mobility of the silica dispersed in oil and a pronounced minimum in the gelation time of the aquasols are also observed here (1). These maximal and minimal effects are presumably associated with the isoelectric point of the silica which is observed to be in the vicinity of pH 5 (2, 3). It was found by Plank and Drake (4) that the surface area of silica gels increased as the aquagels from which they were prepared were aged in a closed system. It was therefore of interest to look for changes in other properties of silica that might depend on the age of their aquagels. In particular, properties that depend on interaction between suspended silica particles have been examined.

was kept short to reduce the electrical resistance of the cell and to allow the alkali produced in this compartment to be removed easily with a continuous stream of water. When a desired pH was obtained, measured with a Beckman pH meter, the sols were drained into clean 4 l pyrex beakers before shutting off the power and were tightly covered with saran wrap. These sols, which set with time to aquagels, were aged up to a period of about 2 years.

Dispersions of the silica aquagels in 1 P viscosity hydrocarbon oil and in stanolax ca. 0.4 P in viscosity contained 5% silica by weight. The removal of water from the suspensions by azeotropic distillation with *n*-propyl alcohol, homogenization of the pastes, and viscosity measurements were as previously described (1).

RESULTS AND DISCUSSION

The flow properties of the silica suspensions in the two hydrocarbon oils are indicated by Fig. 1 and Fig. 2. These show the change in yield value (Bingham yield value in arbitrary units) of the pastes as a function of the pH at which the silica sols were prepared.

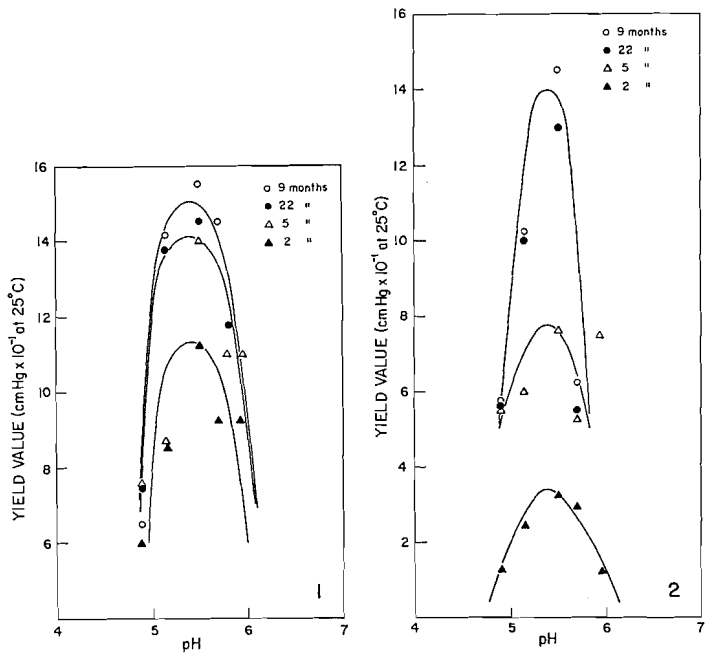

FIG. 1. Flow properties of silica suspensions in hydrocarbon oil ca. 1 P in viscosity.
FIG. 2. Flow properties of silica suspensions in Stanolax ca. 0.4 P in viscosity.

The maximum yield value at about pH 5.5 remained virtually constant over the aging period in both oils. The magnitude of the yield values increased with aging time reaching a maximum value after about 9 months.

Although the pastes made with stanolax using silica aged for short periods were considerably softer than the corresponding dispersions in the lubricating oil the differences disappeared with prolonged aging of the aquagels. No aging effects were detected after the water of the aquagels was replaced with oil. The pastes of maximum yield value prepared in stanolax were diluted to 1% silica by weight with reagent grade toluene. These suspensions were held in 1.5 cm diameter pyrex tubes filled to a height of 16 cm. After equilibrating for about 3 days, the sealed suspensions were homogenized by ultrasonic irradiation for about 5 min using a 40 kc Circo Ultrasonic Generator and their settling behavior is indicated by Fig. 3. The settling rates of the dispersions decreased and the sediment volume increased regularly as the yield value of the pastes increased.

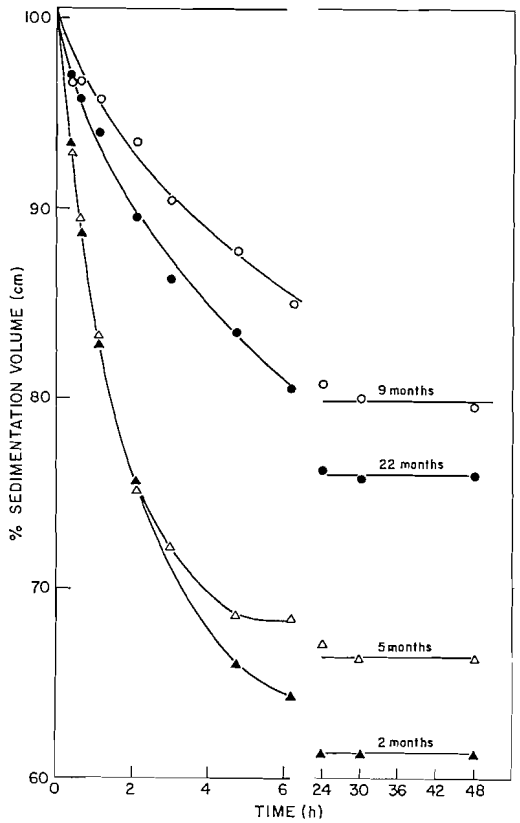

FIG. 3. The settling behavior of silica suspensions in toluene.

These observations suggest that the freshly prepared aquagels contain clusters of hydrous silica particles that are bonded sufficiently strongly to resist dispersion under the conditions of shear imposed during the preparation of the oil pastes. It is probable that the area of the junctions at the points of contact between the primary particles is an appreciable fraction of the area of the spheres. This fraction becomes larger with more dense forms of the packing on the clusters. Reinforcement of these junctions by the polymerization of added silica sol following initial gelation has been described by Iler (5) and it is possible that a similar phenomenon takes place to a degree during normal gelation. This form of aggregation is consistent with the relatively lower observed yield values of the pastes, the higher rates of settling, and the lower sedimentation volumes of the toluene-diluted pastes prepared from the fresher silica aquagel. To explain the subsequent behavior, the aging process would have to involve the reduction of the sizes and strengths of the contacting areas to a significant degree. This might come about through a ripening process that involved the preferential depolymerization of polysilicic acid at the junctions and its migration and deposition elsewhere. The repolymerization could take place either on new nuclei to form new primary particles or on established surfaces of different curvature. Changes of this kind would lead to an increased specific surface area of the separated gel following aging as reported by Plank and Drake (4). They would also explain the observations in the present work, since the bonds forming the clusters would be weakened

For personal use only.

to the point where they would be broken by the shearing action applied during the preparation of the pastes. The increased number of separate primary particles would flocculate to less efficiently packed clusters giving higher equilibrium sedimentations volumes and lower sedimentation rates than the more densely packed material. The increased number of junctions would also lead to the higher observed yield values of the pastes made with fresh silica, and oils of two different viscosities may well reflect different amounts of shearing force transmitted to clusters during the preparation of the pastes. Since the oil viscosities differ by a factor of 2.5, this implies a rather critical shear strength of the bonds between the primary particles that was barely exceeded during the milling operation when the lower viscosity oil was used as the suspending medium. This seems a more attractive explanation, however, than the differences being ascribed to different surface activities of the two oils. The aging process can possibly be facilitated at an elevated temperature. A portion of freshly prepared gel pH 5.4 was aged at room temperature and a similar amount at 90 °C for 7 days and an additional 10 days at about 35 °C in tightly sealed pyrex beakers. Pastes in Stanolax "medium" and suspensions in toluene were prepared as described. A stiffer paste was obtained with the heated gel. The sedimentation volumes were of the order of 93.5 and 84.5% for the heated and the unheated aquagels respectively, after standing 48 h at room temperature. This is in good qualitative agreement with the behavior observed with the aquagels aged at room temperature for a long time. X-ray examination of the pastes revealed no differences in the silica particles from the fresh and from the aged aquagels. Both patterns consisted of equally broad halos of the type expected from the particles of this size range.

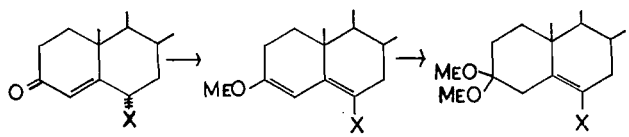
irradiated for 0.5 h. 3,3-Dimethoxy-6-methylcholest-5-ene (III*a*) was obtained in 75% yield by direct crystallization. Its n.m.r. spectrum showed the presence of two methoxy groups at 3.12_5 and 3.23 p.p.m. and a methyl group attached to a double bond (1.66 p.p.m.). The infrared spectrum of III*a* showed strong absorption in the ether region that was practically identical with that of 3,3-dimethoxy-cholest-5-ene (III), obtained in the photolysis of 3-methoxycholesta-3,5-diene (II) in methanol (1). Evaporation of the filtrate from the photolysis reaction product III*a* gave an oil, whose infrared spectrum showed the presence of III*a*, 6-methylcholest-5-en-3-one, and 6-methylcholest-4-en-3-one. Hydrolysis of III*a* with malonic acid in aqueous acetone for 3 days gave a mixture of 6-methylcholest-5-en-3-one (ν 1 720 cm^{-1}) and 6-methylcholest-4-en-3-one (I*a*) (ν 1 685 cm^{-1}).



I	X = H	II	X = H	III	X = H
I*a*	X = CH_3	II*a*	X = CH_3	III*a*	X = CH_3
I*b*	X = F	II*b*	X = F	III*b*	X = F
I*c*	X = NO_2	II*c*	X = NO_2		

Similarly, 6-fluoro-3-methoxycholesta-3,5-diene (II*b*) was irradiated in methanol for 0.33 h and 3,3-dimethoxy-6-fluorocholest-5-ene (III*b*) was obtained in 85% yield, by direct crystallization. Its n.m.r. spectrum shows signals at 3.07 and 3.16 p.p.m. corresponding to the two methoxy groups. The infrared spectrum of III*b* showed strong absorption between 1 000 and 1 200 cm^{-1} due to the C—O and C—F stretching frequencies (3). Evaporating a solution of III*b* in carbon tetrachloride on the steam bath (1) resulted in hydrolysis of III*b*. The infrared spectrum of the oil showed the presence of an α,β-unsaturated ketone (ν 1 695 cm^{-1}) and a saturated ketone (ν 1 725 cm^{-1}). These peaks no doubt arise from the hydrolysis products of III*b*, i.e. 6-fluorocholest-4-en-3-one (I*b*) and 6-fluorocholest-5-en-3-one.

In the two photolysis reactions described, hydrolysis accounted for approximately 10% of the total reaction products, compared to 40% for 3-methoxycholesta-3,5-diene (II) (1).

When a solution of 3-methoxy-6-nitrocholesta-3,5-diene (II*c*) was irradiated in methanol, an oil was obtained from which no crystalline material could be isolated.

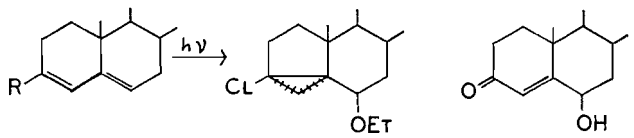
2. 3-Substituted Cholesta-3,5-dienes

A 0.2% ethanolic solution of 3-chlorocholesta-3,5-diene (IV) (5, 6) was irradiated until the absorption maximum of the solution had decreased to less than 5% of the original absorption (4 h). When the solvent was evaporated and a n.m.r. spectrum of the crude photolysis mixture taken, the presence of cyclopropyl protons was detected at 0.25 p.p.m. and at 0.5 p.p.m. Chromatography on silica gel or aluminium oxide gave in the hexane fraction about 50% of oily crystals from which was obtained by successive crystallizations 3–4% of impure V, m.p. 111–113°. Since no pure product could be obtained by a combination of column chromatography and crystallizations, the crude photolysate was purified by thin-layer chromatography (t.l.c.). Thin-layer chromatography revealed the presence of 18 products, 7 of them in trace amounts.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Fraction 9 (designated according to decreasing R_f values) yielded a saturated chloroether V, m.p. 131–133°. Its n.m.r. spectrum showed signals at 0.25 p.p.m. (one proton, $J = 4.0$ c.p.s.) and 0.5 p.p.m. (shoulder) characteristic of geminal protons attached to a cyclopropane ring (7, 8), and a complex, poorly resolved signal between 3.20 and 3.80 p.p.m. due to the three protons alpha to the oxygen function. The latter absorption was virtually identical to that observed for 6β-ethoxy-3β, 5-cyclocholestane (9, 10) and its 3-methyl analogue (2) and provides further evidence for the formulation of V as 3-chloro-6β-ethoxy-3β, 5-cyclocholestane. The infrared spectra of fractions 15–18 indicated that they were mixtures of saturated ketones, α,β-unsaturated ketones, and hydroxy ketones.

Photolysis of IV in spectrograde pentane yielded an inseparable mixture.



IV R = Cl
IV*a* R = OAc
IV*b* R = Ph
IV*c* R = p-OEtPh
IV*d* R = SEt
IV*e* R-N(CH$_2$)$_4$

V VI

When a 0.2% solution of 3-acetoxycholesta-3,5-diene (IV*a*) (II) was photolyzed in ethanol, methanol, or pentane, the absorption maximum at 234 mμ decreased rapidly (1 h). The only product which could be isolated from the complex reaction mixture in approximately 10% yield was cholest-4-en-3-on-6β-ol (VI), identified by comparison with an authentic sample (12*a*).

Irradiation of IV*b*, IV*c*, IV*d*, and IV*e* in various solvents gave intractable mixtures.

3. Chemical Shifts of the C-4 and C-6 Protons of Cholesta-3,5-dienes

In the course of studying these photolyses, it was observed that the chemical shifts of the C-4 proton of the cholesta-3,5-dienes varied by as much as 2 p.p.m. In order to compare them, it was necessary to provide a standard. The n.m.r. spectrum of cholesta-3,5-diene exhibits unresolved peaks between 5.20 and 5.90 p.p.m. By introducing deuterium at C-3, it was hoped to simplify the n.m.r. spectrum of this compound.

Cholest-4-en-3-one was reacted with lithium aluminium deuteride, and the resulting 3-deuteriocholest-4-en-3-ol was dehydrated directly by refluxing with hydrochloric acid in ethanol to give 3-deuteriocholesta-3,5-diene. The 3-deuteriocholesta-3,5-diene showed signals at 5.79 and 5.22 p.p.m. due to the C-4 and C-6 protons respectively.[4]

The chemical shifts of the C-4 and C-6 protons of the dienes are recorded in Table I.

Deshielding due to a negative inductive effect cannot be important except perhaps for 3-chlorocholesta-3,5-diene (14) in which the C-4 proton is deshielded compared to cholesta-3,5-diene by 0.28 p.p.m. The deshielding of the C-4 protons in 3-phenyl and 3-(*p*-ethoxyphenyl) cholesta-3,5-dienes is due to the paramagnetic effect of the benzene rings, which are probably coplanar with the diene system (13*b*).

When an oxygen or nitrogen atom is attached at C-3, the C-4 proton is strongly shielded.

[4]*The C-4 proton appears in all 3-substituted cholesta-3,5-dienes as a singlet, and the C-6 proton as a broad signal due to coupling with the C-7 protons.*

Solvents in which irradiations were carried out: [a]pentane, [b]methanol–pentane, [c]ethanol, [d]ethanol and 0.25 ml pyridine, [e]acetic acid – pentane. [f]Time required for nearly complete disappearance of chromophore. [g]Doublet, J = 10 c.p.s. (13*a*).

This shielding must be due to the effect of the π-electrons of the oxygen or nitrogen atom (15, 16, 17).

The large deshielding effect of the 6-nitro group (1.13 p.p.m.) is not unusual (18) and overrides the shielding effect of the methoxy group in 3-methoxy-6-nitrocholesta-3,5-diene.

The chemical shifts of the C-6 protons of cholesta-3,5-dienes are only slightly affected by the substituent at C-3.

EXPERIMENTAL[5]

3-Methoxy-6-methylcholesta-3,5-diene (IIa)

To 0.55 g of 6α-methylcholest-4-en-3-one (I*a*) (19, 20) in 5 ml of dioxane and 0.5 ml of trimethylorthoformate was added one drop of concentrated sulfuric acid in 0.5 ml of dioxane and the solution was refluxed for 2 min. Pyridine (0.25 ml) was added and the solvent evaporated *in vacuo*. The resulting oil was covered with methanol and allowed to crystallize overnight. Recrystallization from methanol gave 0.47 g of II*a*, m.p. 89.5–91°, λ_{max}^{EtOH} 247 mμ (ε 24 800), (21), $[\alpha]_D$ −127° (*c*, 1.0 in pyridine). Calcd. for $C_{29}H_{48}O$: C, 84.40; H, 11.72. Found: C, 84.24; H, 11.73.

Irradiation of 3-Methoxy-6-methylcholesta-3,5-diene (IIa) in Methanol

Irradiation of 0.4 g of II*a* in 70 ml of pentane and 450 ml of methanol for 30 min gave directly by concentration of the solution and filtration about 0.32 g of 3,3-dimethoxy-6-methylcholest-5-ene (III*a*), m.p. 118–119°. Recrystallization from ether–methanol gave III*a*, m.p. 119–121°, $[\alpha]_D$ −43.5° (*c*, 1.14 in chloroform). Calcd. for $C_{30}H_{52}O_2$: C, 81.02; H, 11.79. Found: C, 81.55; H, 11.82.

Evaporation of the mother liquors left 110 mg of an oil whose infrared spectrum indicated the presence of ketal III*a*, an α,β-unsaturated ketone (ν 1 685 cm^{-1}), and a saturated ketone (ν 1 720 cm^{-1}).

A solution of 125 mg of III*a*, 50 mg of malonic acid, 10 ml of acetone, and 1 ml of water was allowed to stand for 4 days at room temperature. An infrared spectrum of the product, obtained after the usual work-up, showed that complete hydrolysis had occurred to give an α,β-unsaturated ketone (ν 1 685 cm^{-1}), and a saturated ketone (ν 1 720 cm^{-1}).

6-Fluoro-3-methoxycholesta-3,5-diene (IIb)

To a solution of 0.375 g of 6-fluorocholest-4-en-3-one (I*b*) (22) in 5 ml of dioxane and 0.5 ml of trimethylorthoformate was added one drop of concentrated sulfuric acid in 0.5 ml of dioxane and the solution was

[5]*See (1) for general procedures.*

For personal use only.

refluxed for 2 min. Pyridine (0.25 ml) was added and the solvent was evaporated *in vacuo*. The oil obtained was covered with methanol to induce crystallization. Recrystallization from ether–methanol (containing one drop of pyridine) afforded 0.30 g of II*b*, m.p. 90.5–91.5°, $[\alpha]_D$ −107.5° (*c*, 0.93 in pyridine), λ_{max}^{EtOH} 239 mμ (ε 22 600). Calcd. for $C_{28}H_{45}OF$: C, 80.71; H, 10.89; F, 4.56. Found: C, 80.18; H, 10.26; F, 4.65.

Irradiation of 6-Fluoro-3-methoxycholesta-3,5-diene (IIb) in Methanol

Irradiation of 0.20 g of II*b* in 50 ml of pentane and 475 ml of methanol for 20 min gave directly by concentration of the solution and filtration 0.172 g of 3,3-dimethoxy-6-fluorocholest-5-ene (III*b*). Recrystallization from ether–methanol gave III*b*, m.p. 104–104.5°, $[\alpha]_D$ −31.4° (*c* 1.0 in chloroform). Calcd. for $C_{29}H_{49}O_2F$: C, 77.63; H, 11.01; F, 4.23. Found: C, 77.29; H, 10.28; F, 4.67.

Evaporation of the mother liquors gave 35 mg of oil whose infrared spectrum indicated the presence of ketal III*b*, an α,β-unsaturated ketone (ν 1 695 cm^{-1}), and a saturated ketone (ν 1 730 cm^{-1}).

A solution of 25 mg of III*b* in 5 ml of carbon tetrachloride was evaporated on the steam bath (1). The resulting oil showed absorption in the infrared spectrum at 1 730 cm^{-1} and 1 695 cm^{-1} indicating the formation of saturated and α,β-unsaturated ketones respectively.

6β-Nitrocholest-4-en-3β-ol (VII)

A solution of 5.0 g of 3β-acetoxy-6-nitrocholest-5-ene (4, 23) in 300 ml of methanol, containing 3.0 g of potassium hydroxide, was heated under reflux for 1.5 h. Acidification with acetic acid, addition of water, and filtration gave a product which was crystallized from aqueous methanol to yield 1.83 g of 6β-nitrocholest-4-en-3β-ol. Recrystallization from methanol gave VII, m.p. 141–142°, $[\alpha]_D$ −98.9° (*c* 0.89 in chloroform). Calcd. for $C_{27}H_{45}O_3N$: C, 75.13; H, 10.51; N, 3.25. Found: C, 75.01; H, 10.74; N, 3.70.

Its n.m.r. spectrum showed signals at 5.72_5, 4.50, 4.04, and 3.31 p.p.m. due to the C-4 olefinic, C-6α, C-3α, and hydroxy protons respectively. The position of the hydroxy proton was proved by exchange with heavy water.

6β-Nitrocholest-4-en-3-one (VIII)

To a solution of 1.0 g of VII in 60 ml of acetone at 0° was added an excess of Jones reagent (24, 25, 26) and the solution was stirred for 2 min. Addition of water and filtration of the resulting precipitate gave 1.0 g of VIII. Recrystallization from ether–methanol gave 0.8 g of VIII, m.p. 118–119°, $[\alpha]_D$ −98.8° (*c* 0.87 in chloroform), λ_{max}^{EtOH} 233 mμ (ε 12 600). Calcd. for $C_{27}H_{43}O_3N$: C, 75.48; H, 10.09; N, 3.26. Found: C, 75.44; H, 10.47 N, 3.29.

Its n.m.r. spectrum showed absorption bands at 6.02 p.p.m. and 4.83 p.p.m. corresponding to the C-4 olefinic and the C-6α protons respectively. The infrared spectrum of VIII showed the presence of a nitro group at 1 540 cm^{-1} and an α,β-unsaturated ketone at 1 670 cm^{-1}.

6α-Nitrocholest-4-en-3-one (Ic)

A solution of 0.6 g of VIII in 5 ml of methanol, containing 25 mg of potassium hydroxide was kept at room temperature for 2 min. After acidification with acetic acid, addition of water gave 0.6 g of I*c*. Recrystallization from methanol gave pure I*c*, m.p. 136–137°, $[\alpha]_D$ +78.0° (*c* 0.91 in chloroform), λ_{max}^{EtOH} 232 mμ (ε 15 800). Calcd. for $C_{27}H_{43}O_3N$: C, 75.48; H, 10.09; N, 3.26. Found: C, 75.55; H, 9.99; N, 2.47.

Its n.m.r. spectrum showed signals at 5.28 p.p.m. (doublet, J = 1.8 c.p.s.) and at 5.14 p.p.m. (multiplet) corresponding to the C-4 olefinic and C-6β protons respectively. The C-4 proton which appears as a doublet is apparently coupled with the C-6 hydrogen (27). The infrared spectrum of I*c* showed the typical nitro absorption at 1 543 cm^{-1} and an α,β-unsaturated ketone peak at 1 672 cm^{-1}.

3-Methoxy-6-nitrocholesta-3,5-diene (IIc)

To a solution of 0.35 g of I*c* in 5 ml of dioxane and 0.5 ml of trimethylorthoformate was added one drop of concentrated sulfuric acid in 0.5 ml of dioxane and the solution was refluxed for 2 min. Pyridine (0.25 ml) was added and the solvent removed *in vacuo* at 80°. The oil was covered with methanol and after standing in the cold overnight, 0.25 g of II*c*, m.p. 135–136°, was obtained. Recrystallization from ether–methanol (containing one drop of pyridine) decreased the m.p. of I*c* to 129–136°, $[\alpha]_D$ −8.3 (*c* 1.27 in pyridine), λ_{max}^{EtOH} 233 mμ (ε 14 000). Calcd. for $C_{28}H_{45}O_3N$: C, 75.80; H, 10.22; N, 3.16. Found: C, 76.01; H, 10.20; N, 2.58.

Irradiation of 3-Methoxy-6-nitrocholesta-3,5-diene (Ic) in Methanol

Irradiation of 0.2 g of I*c* in 10 ml of pentane and 515 ml of methanol for 10 min gave upon evaporation of the solvent 0.23 g of oil. Its n.m.r. spectrum showed broad absorption peaks indicative of a complex mixture of compounds.

Irradiation of 3-Chlorocholesta-3,5-diene (IV) in Ethanol

A solution of 1.8 g of IV (5, 6), λ_{max}^{EtO} 242 (ε 22 400), 250 (ε 20 400), and 230 (ε 15 300) mμ in 450 ml ethanol and 50 ml of pentane was irradiated until no ultraviolet absorption could be detected (4 h). After evaporation of the solvent, the photolysis mixture was separated by t.l.c. (silica gel). Using hexane as solvent, two fast (A and B) and two slow moving bands (C and C) were evident. Desorption of bands A and B with ether gave 200 mg of oil, which on rechromatography gave six fractions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Desorption of band C with ether and rechromatography (t.l.c., hexane–benzene 4:1) yielded fractions 7–14. Fraction 9 gave 53 mg of crystals, m.p. 125–129°. Recrystallization from hexane gave 16 mg of pure 3-chloro-6β-ethoxy-3β,5-cyclocholestane (V), m.p. 131–133°, $[\alpha]_D$ +6.8 (*c* 1.5 in chloroform). Calcd. for $C_{29}H_{49}OCl$: C, 77.56; H, 11.00; Cl, 7.90. Found: C, 77.54; H, 10.57; Cl, 8.01.

Fractions 7, 8, 10, 11, 12, 13, and 14 could not be sufficiently purified for structural studies.

Band D, after extraction with ether, was rechromatographed (t.l.c., benzene–ether 19:1). Fractions 15–18, accounting for 65% of the photolysis products, were obtained but could not be characterized.

Irradiation of 3-Acetoxycholesta-3,5-diene (IVa)

A solution of 1.1 g of IV*a* (11), λ_{max}^{EtOH} 234 mμ (ε 16 000) in 1 700 ml of ethanol, methanol, or methanol containing a few drops of pyridine was irradiated until the absorption maximum had decreased to less than 5% of the original absorption (1 h). Chromatography on alumina yielded in the ether fractions 100 mg of cholest-4-en-6β-ol-3-one (VI), m.p. 160–165°. Recrystallization from hexane gave VI, m.p. 181–184° (mixed melting point with an authentic sample; 181–184°).

Irradiation of IV*a* in pentane yielded intractable mixtures.

3-(p-Ethoxyphenyl)cholesta-3,5-diene (IVc)

p-Bromophenetole (9 ml) in 40 ml of anhydrous ether was added slowly to 2.75 g of magnesium, activated by a few crystals of iodine. After completion of the reaction (3 h), 10 g of cholest-4-en-3-one was added to the Grignard reagent and the reaction mixture was stirred under reflux overnight. A 20% solution of hydrochloric acid in ethanol was added slowly to the reaction mixture to destroy excess Grignard reagent and the mixture was refluxed for 4 h to ensure dehydration of the reaction product.

About 8.0 g of IV*c*, m.p. 120–121°, λ_{max}^{EtOH} 288 mμ (ε 25 900), 227 (10 300), 234 (shoulder), was obtained. Calcd. for $C_{35}H_{52}O$: C, 86.00; H, 10.72. Found: C, 86.00; H, 10.38.

The n.m.r. spectrum of IV*c* showed signals at 6.84 p.p.m. (quartet, corresponding to the four aromatic protons), 6.10 p.p.m. (sharp singlet, C-4 proton), 5.35 p.p.m. (broad peak, C-6 proton), and 3.84 p.p.m. (a quartet, CH_3—CH_2—O protons).

Irradiation of 3-(p-Ethoxyphenyl)cholesta-3,5-diene (IVc)

Irradiation of 1.3 g of IV*c* in 1 800 ml of ethanol for 4 h gave some starting material and 0.74 g of oil. Chromatography on alumina did not result in isolation of pure product.

Irradiation of 1.3 g of IV*c* in 1 370 ml of pentane and 230 ml of acetic acid for 7 h yielded 1.45 g of product. Thin-layer chromatography of 1.45 g on silica gel revealed at least 12 major and over 20 minor bands.

Irradiation of 3-Phenylcholesta-3,5-diene (IVb) (28) in Ethanol

Irradiation of 1.2 g of IV*b* in 1 300 ml of ethanol and 400 ml of pentane for 24 h gave 2.8 g of product. Chromatography on alumina gave a total of 1.6 g of oily fractions. The n.m.r. spectrum of the major fraction indicated mixtures.

Irradiation of 3-Ethylthiocholesta-3,5-diene (IVd) (29) in Ethanol

Irradiation of 0.37 g of IV*d* in 425 ml of ethanol, 100 ml of pentane, and 0.25 ml of pyridine for 0.5 h yielded 0.5 g of a brown, smelly oil. Chromatography on alumina did not result in isolation of pure material.

Irradiation of 3-N-Pyrrolidinylcholesta-3,5-diene (IVe) (30, 31) in Pentane

Irradiation of 0.5 g of IV*e* in 525 ml of pentane for 1 h gave, upon evaporation of the pentane *in vacuo* at room temperature, 0.5 g of a clear oil. The n.m.r. spectrum of the oil showed very broad absorption characteristic of a mixture. Despite considerable effort to purify the material, no homogeneous fractions were obtained.

3-Deuteriocholesta-3,5-diene

To a solution of 0.2 g of lithium aluminium deuteride in 20 ml of ether was added as a solid 0.5 g of cholest-4-en-3-one and the solution was stirred for 1 h. A solution of 2 ml of concentrated hydrochloric acid in 10 ml of ethanol was added and the reaction mixture allowed to reflux for 1 h. After the usual work-up, 0.3 g of pure 3-deuteriocholesta-3,5-diene, m.p. 81°, was obtained. Its melting point was not depressed on admixture of authentic cholesta-3,5-diene (12*b*).

ACKNOWLEDGMENT

We should like to thank Dr. C. Stammer for taking the n.m.r. spectra.

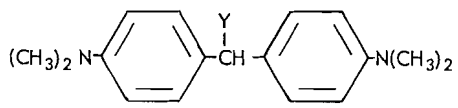
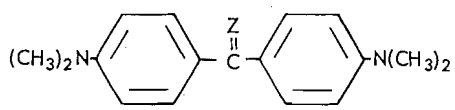
COMPLEX METAL HYDRIDE REDUCTION OF A KETIMINE AND A THIOKETONE

M. R. V. SAHYUN

During a current investigation, 4,4′-bis(dimethylamino)benzhydrylamine (I*a*) and the corresponding thiol (I*b*) were desired. Both these compounds are well known and thoroughly characterized (1, 2). The reported routes for their synthesis are, however, relatively inconvenient, and more recent advances in organic synthesis commend other approaches.



I(a, Y = NH_2; b, Y = SH; c, Y = OH)



II(a, Z = NH; b, Z = S; c, Z = O)

The available starting materials were the ketimine (II*a*), commonly called "auramine," and the thioketone (II*b*), "Michler's" thioketone, respectively. Lithium aluminium hydride was expected to reduce II*a*, as the reduction of N-substituted aldimines to the secondary amines is known (3). The literature apparently contains no specific precedent for the lithium aluminium hydride reduction of ketimines which bear no substituent on the imino nitrogen atom. Sodium borohydride also reduces N-substituted aldimines (4).

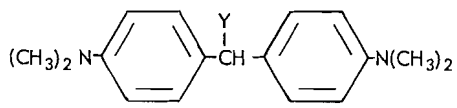
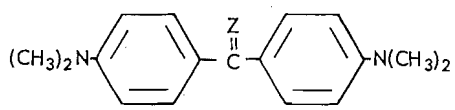
COMPLEX METAL HYDRIDE REDUCTION OF A KETIMINE AND A THIOKETONE

M. R. V. SAHYUN

During a current investigation, 4,4′-bis(dimethylamino)benzhydrylamine (I*a*) and the corresponding thiol (I*b*) were desired. Both these compounds are well known and thoroughly characterized (1, 2). The reported routes for their synthesis are, however, relatively inconvenient, and more recent advances in organic synthesis commend other approaches.



I(a, Y = NH_2; b, Y = SH; c, Y = OH)



II(a, Z = NH; b, Z = S; c, Z = O)

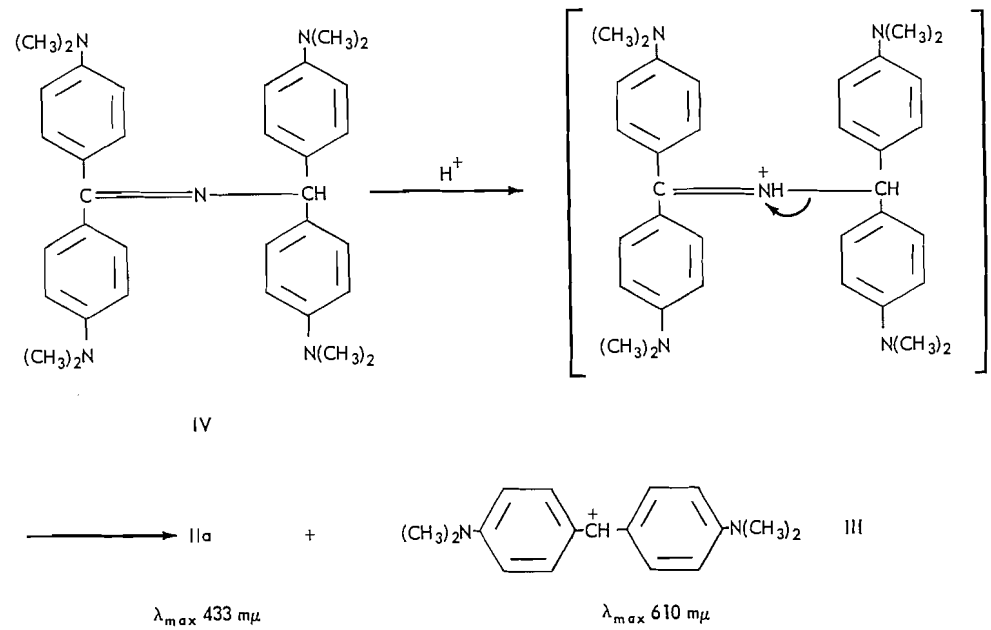
The available starting materials were the ketimine (II*a*), commonly called "auramine," and the thioketone (II*b*), "Michler's" thioketone, respectively. Lithium aluminium hydride was expected to reduce II*a*, as the reduction of N-substituted aldimines to the secondary amines is known (3). The literature apparently contains no specific precedent for the lithium aluminium hydride reduction of ketimines which bear no substituent on the imino nitrogen atom. Sodium borohydride also reduces N-substituted aldimines (4).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Until now, the reduction of thioketones with sodium borohydride appears to be unknown.

Conover and Tarbell (5) found that aromatic amines with a carbonyl group para to the amino group underwent hydrogenolysis with lithium aluminium hydride, converting the carbonyl group into a methylene linkage. Mustafa and Hilmy (6) extended this observation to the thioketone (II*b*). Gaylord (7) interprets the above results by considering the compounds studied to be "vinylogs" of amides. As sodium borohydride does not ordinarily reduce amides (8), II*b* might thus be inert towards this reagent. The mechanism advanced for the hydrogenolysis of the carbonyl compounds studied by Conover and Tarbell (5) involves essentially an S_N1 nucleophilic displacement of the hydroxy group of the initially formed carbinol, e.g. I*c* from II*c*, by hydride ion. The ionization of the carbon–oxygen bond required by this mechanism is driven by the stabilization of the resulting carbonium-ion intermediate by the electron-releasing amino group (5, 7). The analogous ionization step would not, however, be expected with the amine (I*a*) under the reduction conditions. Hence, II*a* should not undergo hydrogenolysis with lithium aluminium hydride.

The reduction of II*a* with lithium aluminium hydride was tried first in tetrahydrofuran. It yielded 82% of the theoretical quantity of I*a*. The product formed the reported (1) blue color in glacial acetic acid (λ_{max} 610 mμ, log ϵ 5.11); this absorption is characteristic of the carbonium ion (III) (9). The spectral data further agree with the reported data for the carbonium ion generated by spontaneous ionization of the corresponding carbinol (I*c*) in nitromethane (λ_{max} 610 mμ, log ϵ 5.12)(9). A satisfactory analysis for I*a* was obtained. When the lithium aluminium hydride reduction was carried out in dimethoxyethane, the crystalline product differed from I*a* in melting point. In glacial acetic acid solution this product showed the absorption maximum at 610 mμ (log ϵ 5.14) and one at 433 mμ (log ϵ 4.35), suggestive of the starting material (II*a*) (λ_{max} 433 mμ, log ϵ 4.48). The compound analyzed for $C_{34}H_{41}N_5$; therefore, structure IV adequately represents this product. The visible spectrum in glacial acetic acid arises as follows.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Sodium borohydride in 2-propanol also reduced II*a* smoothly and gave an optimal yield of 43% of the theoretical quantity of I*a*. As lithium aluminium hydride is unsatisfactory for the reduction of II*b* to I*b* (6), sodium borohydride was the only reducing agent used with II*b*. In 2-propanol, no reaction occurred below reflux temperature. After 20 min of refluxing, the only product isolated exhibited the characteristic absorption maximum at 610 mμ (log ϵ 5.38; two carbonium ions per molecule) in glacial acetic acid. The melting point was close to that reported for the sulfide (V), which reportedly also absorbs at 610 mμ in acetic acid (2).

V 
A strong odor of hydrogen sulfide had been noticed as soon as the reaction was quenched and indicated that V arose during the course of the reaction and not from I*b* in the process of isolating the product. Clearly compounds II*a* and II*b* cannot be considered analogous to amides in terms of their behavior with sodium borohydride (*vide supra*).

EXPERIMENTAL

Melting points (corrected) were determined on a Fisher-Johns melting point apparatus. The visible spectra were determined in glacial acetic acid with a Cary model 11 spectrophotometer. All the compounds obeyed Beer's law. All reactions were carried out under Seaford grade dry nitrogen.

*Reduction of 4,4′-bis(Dimethylamino)benzophenone Imine (II*a*)*

Tetrahydrofuran was redistilled from lithium aluminium hydride. In 100 ml of this dry solvent was placed 3.8 g (0.1 mole) of lithium aluminium hydride. In another 100 ml portion was dissolved 4.6 g (0.017 mole) of dry 4,4′-bis(dimethylamino)benzophenone imine (II*a*), obtained from the commercially available* hydrochloride. After the mixture of the above two solutions was refluxed 0.5 h the yellow color of the imine had disappeared. The excess lithium aluminium hydride was decomposed with water. The reaction mixture was then partitioned between methylene chloride and water. The organic phase was dried over magnesium sulfate and filtered. The solvent was removed under reduced pressure at room temperature. The solid residue was recrystallized from ethanol to give 3.7 g (0.014 mole) of the primary amine (I*a*) (82% yield), m.p. 130.5–131.5°, close to the published value of 135° (1). Analysis confirmed the formula $C_{17}H_{23}N_3$.

Anal. Calcd.: C, 75.78; H, 8.63; N, 15.59. Found: C, 75.84, H, 8.56, N, 15.30.

An undried sample (2.5 g, 8.7 mmole) of the imine (assumed to be the monohydrate) was dissolved in approximately 200 ml of 2-propanol which had been redistilled from sodium borohydride. To this solution was added 1.0 g (26 mmole) of sodium borohydride. After this solution was heated at reflux for 20 min, the solution became colorless. The resulting mixture was treated analogously to the lithium aluminium hydride reaction mixture to yield 1.0 g (3.9 mmole, 43% yield) of I*a*, m.p. 129–131°.

The reduction with lithium aluminium hydride in dimethoxyethane was conducted in the same manner as those described above. The only crystalline product isolated was that to which structure IV has been assigned (7% yield), m.p. 167–168°. The compound analyzed for $C_{34}H_{41}N_5$.

Anal. Calcd.: C, 78.57; H, 7.94; N, 13.49; molecular weight, 519. Found: C, 78.73; H, 8.16; N, 13.30; molecular weight, 520.

**"Auramine O" (IIa hydrochloride) was manufactured by Chroma Gesellschaft, Germany, and supplied by Roboz Surgical Instrument Co., Inc., 818 18th Street, N.W., Washington 6, D.C.*

Reduction of 4,4'-bis(Dimethylamino)thiobenzophenone (IIb)

In 500 ml of redistilled 2-propanol, 3.8 g (0.1 mole) of sodium borohydride and 2.8 g (9.8 mmole) of the commercially available* thioketone (II*b*) were dissolved. After the solution was refluxed for 20 min, the red color of the thioketone had disappeared. The product was isolated in the same manner as the amine above. After recrystallization from ethanol, the product weighed 1.7 g, m.p. 169–171°. The analysis suggested $C_{34}H_{42}N_4S$.

Anal. Calcd.: C, 75.77; H, 7.86; N, 10.40; S, 5.97; molecular weight, 538. Found: C, 76.05; H, 7.57; N, 10.34; S, 5.94; molecular weight, 520.

These data indicated that the compound was bis[4,4'-bis(dimethylamino)benzhydryl] sulfide (V), reported m.p. 172° (2).

PHOTOMETRIC OBSERVATIONS ON THE REACTIONS OF ACTIVE NITROGEN WITH CHLORINE AND BROMINE

K. S. RAXWORTHY AND L. F. PHILLIPS

In an earlier publication (1) evidence was presented for the formation of metastable $A(^3\Sigma_u^+)$ nitrogen molecules during the reaction of iodine with active nitrogen. Previous work on the reactions of active nitrogen with chlorine and bromine would probably not have revealed the production of metastable species and these reactions have therefore been reinvestigated with this possibility in mind.

Our observations with chlorine and bromine have substantially confirmed those of previous workers (2–6). The chlorine reaction gave rise to almost no emission other than the weakened nitrogen afterglow, while the main feature of the bromine reaction was bright orange NBr emission from a layer on or very close to the walls of the reaction vessel. (This was particularly apparent during the present experiments because the reaction vessel was of square cross section.) Emission from excited halogen molecules was in both cases extremely weak and decayed with time in a manner which paralleled the decay of the nitrogen afterglow. There was usually a net decrease in the intensity of radiation at the

For personal use only.

wavelength of the halogen emission bands when halogen was added, but this decrease was appreciably less than that shown by the nitrogen afterglow at other wavelengths.

These results are in marked contrast to those for iodine, where intense emission in the blue and ultraviolet from excited I_2 is the most prominent feature of the reaction. Since the iodine emission is believed to be mainly due to energy transfer from A-state nitrogen molecules, the lack of similar emission with chlorine and bromine suggests either that A-state molecules are not produced or that the energy is not readily transferred. When bromine was added to the flow system at a point upstream from a jet through which iodine vapor was being introduced into active nitrogen, the blue iodine emission was quenched simultaneously with the nitrogen afterglow. This shows that the bromine reaction does not produce appreciable quantities of metastable species.

The essential steps of the mechanism which has been proposed (1, 6) for the reaction of a halogen with active nitrogen are

$$N(^4S) + X_2(^1\Sigma) \rightarrow NX(^3\Sigma) + X(^2P) \quad [1]$$

$$N(^4S) + NX(^3\Sigma) \rightarrow N_2 + X(^2P), \quad [2]$$

where the nitrogen molecule produced by reaction [2] is in the ground state unless X is iodine. There are actually two long-lived states of N_2 which could be produced in the iodine case, namely $A(^3\Sigma_u^+)$ and the predicted $^3\Delta_u$ state (7). There would probably not be sufficient energy available to produce the $^3\Delta_u$ state from NBr or NCl, since the dissociation energy of NBr is 58 kcal/mole (6), which leaves only 167 kcal/mole to be taken up by N_2, and the dissociation energy of NCl is likely to be still higher. The available evidence suggests that the energy of the $^3\Delta_u$ state is nearer to 175 kcal/mole (8). This would provide an explanation for the lack of metastable species from the bromine and chlorine reactions. No such explanation is available if it is the A-state that is involved. Experiments to decide between these two possibilities are in progress.

Halogen atoms are able to recombine very efficiently on the walls of the reaction vessel (9) so that halogens are expected to be present almost entirely as undissociated molecules. Graphs of log(afterglow intensity) vs. time have been found to be linear in the presence of halogens, and from the slopes of the lines and the partial pressures of the halogens the rate constants for reaction [1] at 20 °C have been calculated on the assumption that this reaction leads to the immediate removal of two nitrogen atoms. The results (in cm^3 $molecule^{-1}$ s^{-1}) are $k_1 = 2 \times 10^{-15}$ for chlorine and $k_1 = 2 \times 10^{-14}$ for bromine. The main source of error in these values is likely to be the neglect of the possibility of destruction of NBr and NCl at the walls, which could cause the values to be too low by up to a factor of two. In view of the apparent stability of NBr on the walls and the large volume-to-surface ratio of the reaction tube this neglect appears to be justified. The estimated error arising from the measurements is $\pm 30\%$ in each case.

EXPERIMENTAL

The apparatus was similar to that described previously (1) except that the reaction vessel consisted of a 38 cm length of square cross section quartz tubing, 3.5 cm wide, through which the gases were pumped at velocities of between 1 and 2 m/s at pressures between 1 and 4 torr. Analytical reagent grade bromine and fractionally distilled chlorine were carried to a spherical inlet jet by a stream of argon from saturators immersed in an ice bath and a solid CO_2/acetone bath respectively. Saturator temperatures were monitored with thermocouples. Halogen flows were calculated from the vapor pressure (10, 11), the measured argon flow, and the measured pressure drop across the saturator. Nitrogen, nitric oxide, and iodine were as described previously (1). Light intensities were measured with a 1P28 photomultiplier in combination with various filters. Spectrolab type P interference filters of 16 Å half-width at 6 250 Å and 5 590 Å were used for the nitrogen afterglow and the bromine emission respectively (12). For the chlorine emission a Baird-Atomic type A11 interference filter of 100 Å half-width at 2 600 Å was used (2).

THE DENSITIES AND SURFACE TENSIONS OF LIQUID ETHANE AND NITROUS OXIDE

A. J. LEADBETTER, D. J. TAYLOR, AND B. VINCENT

The densities and surface tensions of ethane and nitrous oxide have been measured in the normal liquid ranges, using experimental techniques which have been fully described elsewhere (1). The ethane used was of 99.9% purity, as supplied by the National Chemical Laboratory. The nitrous oxide was medicinal grade (99.96%) supplied by the British Oxygen Company Limited.

The density was determined by condensing a known mass of gas into a volume-calibrated glass capillary tube. The mass of gas was determined by measuring its pressure, volume, and temperature and using, for ethane, the second virial coefficients of Michels *et al.* (2), and, for nitrous oxide, the data quoted by Blue and Giauque (3). The surface tension was measured by the method of capillary rise, using three interconnected capillaries. These were Veridia precision bore tubing, with nominal bores 0.2, 0.4, and 2.0 mm.

The cryostat consisted of a dewar vessel containing CF_2Cl_2 (Arcton 12, I.C.I. Limited). The temperature was controlled by a vapor pressure thermometer, containing nitrous oxide or ethane, which was used to regulate the flow of cold nitrogen through a cooling coil. The temperature was derived from the measured vapor pressures, using the data given in the A.P.I. tables for ethane (4) and that of Blue and Giauque (3) for nitrous oxide. In all cases, the overall uncertainty in the temperature was less than 0.1 °K.

RESULTS

A detailed discussion of the accuracy of the present experimental methods has been given previously (1). The probable error in the densities is estimated to be about $\pm 0.1\%$. The surface tension values calculated from the differences in height of the menisci in the three tubes were internally consistent to better than 0.5%. The results given below are

THE DENSITIES AND SURFACE TENSIONS OF LIQUID ETHANE AND NITROUS OXIDE

A. J. LEADBETTER, D. J. TAYLOR, AND B. VINCENT

The densities and surface tensions of ethane and nitrous oxide have been measured in the normal liquid ranges, using experimental techniques which have been fully described elsewhere (1). The ethane used was of 99.9% purity, as supplied by the National Chemical Laboratory. The nitrous oxide was medicinal grade (99.96%) supplied by the British Oxygen Company Limited.

The density was determined by condensing a known mass of gas into a volume-calibrated glass capillary tube. The mass of gas was determined by measuring its pressure, volume, and temperature and using, for ethane, the second virial coefficients of Michels *et al.* (2), and, for nitrous oxide, the data quoted by Blue and Giauque (3). The surface tension was measured by the method of capillary rise, using three interconnected capillaries. These were Veridia precision bore tubing, with nominal bores 0.2, 0.4, and 2.0 mm.

The cryostat consisted of a dewar vessel containing CF_2Cl_2 (Arcton 12, I.C.I. Limited). The temperature was controlled by a vapor pressure thermometer, containing nitrous oxide or ethane, which was used to regulate the flow of cold nitrogen through a cooling coil. The temperature was derived from the measured vapor pressures, using the data given in the A.P.I. tables for ethane (4) and that of Blue and Giauque (3) for nitrous oxide. In all cases, the overall uncertainty in the temperature was less than 0.1 °K.

RESULTS

A detailed discussion of the accuracy of the present experimental methods has been given previously (1). The probable error in the densities is estimated to be about $\pm 0.1\%$. The surface tension values calculated from the differences in height of the menisci in the three tubes were internally consistent to better than 0.5%. The results given below are

weighted averages of the individual values, and are probably accurate to ±0.5%. The contact angle was assumed to be zero for both ethane and nitrous oxide.

Ethane

TABLE I

The density and surface tension of ethane

T (°K)	ρ (g cm^{-3})	T (°K)	γ (dyn cm^{-1})
126.9	0.6081	129.2	25.00
133.3	0.6017	133.2	24.54
135.0	0.5997	137.1	23.72
138.8	0.5951	149.1	21.75
141.6	0.5934	150.6	21.68
143.9	0.5906	155.9	20.71
148.1	0.5860	157.5	20.46
149.9	0.5831	161.3	19.86
157.6	0.5752	164.4	19.28
164.8	0.5677	170.3	18.31
167.2	0.5651	180.6	16.63
169.1	0.5630		
171.9	0.5599		
174.6	0.5572		
176.4	0.5551		
178.1	0.5527		
179.2	0.5516		
183.4	0.5478		

The present results for the density agree within experimental error over the whole temperature range with those of Barkelew *et al.* (5) and of Tester (6). The older results of Maass and co-workers (7, 8) in the temperature range 165–200 °K are about 1% higher. The surface tension of ethane has previously been measured by Maass and Wright (8) in the range 165–185 °K using the method of capillary rise. Their results, calculated using their own density data, are 0.5% higher than the present values.

Nitrous Oxide

TABLE II

The density and surface tension of nitrous oxide

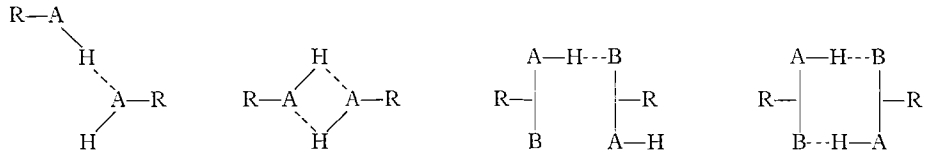
THE DETERMINATION OF MONOMER–DIMER SELF-ASSOCIATION EQUILIBRIUM CONSTANTS IN DILUTE SOLUTIONS

S. N. VINOGRADOV[1]

A compound containing an A—H group or an A—H and a B group (A, B = O, N, S etc.) is capable of self-association through hydrogen bonding (1) to open (linear) and (or) closed (cyclic) polymers, as shown below for the simplest case, that of a dimer.



I*a* I*b* II*a* II*b*

The variation in intensity of a monomer absorption band as a function of concentration can be calculated from infrared spectroscopic data. From these data it is relatively simple to evaluate the mode of self-association for dilute solutions in inert solvents when only closed polymers are present. Methods for calculating the stepwise self-association equilibrium constants have been proposed (2).

Evidence has been accumulating that the contribution of "end" A—H groups from open polymers (as in I*a* and II*a*) to the absorption of "free" A—H groups must be taken into consideration (3). Coexistence of open and closed dimers was indicated in the cases of caprolactam (4) and cyclohexanol (5) in CCl_4, and the predominance of linear self-association has been established in the cases of imidazole, 1,2,4-triazole, benzotriazole, and 1,2,3-triazole (6, 7) in CCl_4 and C_6H_6. No treatment of infrared absorption intensity data has been proposed for any case of coexistence of open and closed polymers. Masschelein has used an empirical method in the specific case of the monomer – open dimer and monomer – closed dimer self-association of cyclohexanol (5), and several methods have been used in the determination of the overall monomer–dimer equilibrium constant (8, 9).

The concentration of the "free" A—H groups obtained from infrared absorption measurements is the sum of the "monomer" and "end" A—H group concentrations if the

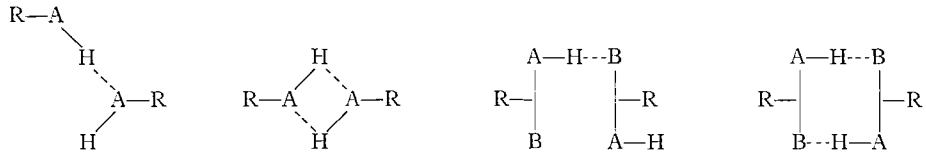
THE DETERMINATION OF MONOMER–DIMER SELF-ASSOCIATION EQUILIBRIUM CONSTANTS IN DILUTE SOLUTIONS

S. N. VINOGRADOV[1]

A compound containing an A—H group or an A—H and a B group (A, B = O, N, S etc.) is capable of self-association through hydrogen bonding (1) to open (linear) and (or) closed (cyclic) polymers, as shown below for the simplest case, that of a dimer.



I*a* I*b* II*a* II*b*

The variation in intensity of a monomer absorption band as a function of concentration can be calculated from infrared spectroscopic data. From these data it is relatively simple to evaluate the mode of self-association for dilute solutions in inert solvents when only closed polymers are present. Methods for calculating the stepwise self-association equilibrium constants have been proposed (2).

Evidence has been accumulating that the contribution of "end" A—H groups from open polymers (as in I*a* and II*a*) to the absorption of "free" A—H groups must be taken into consideration (3). Coexistence of open and closed dimers was indicated in the cases of caprolactam (4) and cyclohexanol (5) in CCl_4, and the predominance of linear self-association has been established in the cases of imidazole, 1,2,4-triazole, benzotriazole, and 1,2,3-triazole (6, 7) in CCl_4 and C_6H_6. No treatment of infrared absorption intensity data has been proposed for any case of coexistence of open and closed polymers. Masschelein has used an empirical method in the specific case of the monomer – open dimer and monomer – closed dimer self-association of cyclohexanol (5), and several methods have been used in the determination of the overall monomer–dimer equilibrium constant (8, 9).

The concentration of the "free" A—H groups obtained from infrared absorption measurements is the sum of the "monomer" and "end" A—H group concentrations if the

[1]*Present address: Department of Biochemistry, Yale University, New Haven, Connecticut.*

self-association is partly or wholly linear and if the frequencies of the two types of A—H groups overlap. Thus the sum of the "free" A—H group concentrations, E, obtained from infrared absorption measurements is

$$E = \epsilon B/\epsilon_1^{m} = b_1 + \sum_{2}^{Q} \gamma\beta_{q0}{}^{o} b_1{}^{q},$$

where B is the stoichiometric concentration, ϵB is the total measured absorbance at the monomer peak, b_1 is the monomer concentration, $\beta_{q0}{}^{o}$ are the stepwise monomer – open Q-mer association equilibrium constants, and γ is the ratio $\epsilon_1{}^{e}/\epsilon_1{}^{m}$ of the absorptivities of the "end" and "monomer" A—H groups.

The simultaneous determination of the monomer – open dimer and monomer – closed dimer equilibrium constants from infrared absorption data is possible, based on the following assumptions: only the monomer–dimer equilibria exist in the solution, the dilute solution is ideal, Beer's law applies, and the absorptivity of the "monomer" A—H group is the absorptivity of the monomer peak at infinite dilution. Let $\beta_{20}{}^{c}$ and $\beta_{20}{}^{o}$ be the monomer – closed dimer and monomer – open dimer association equilibrium constants, respectively; assuming that $\epsilon_1{}^{m} = \epsilon_1{}^{e}$, the "free" A—H group concentration will be

$$E = b_1 + \beta_{20}{}^{o} b_1{}^{2}. \qquad [1]$$

Substitution of the relation,

$$B - E = (\beta_{20}{}^{o} + 2\beta_{20}{}^{c}) b_1{}^{2}, \qquad [2]$$

into the appropriate expression for B and into [1] yields

$$B/(B - E)^{1/2} = 1/[\beta_{20}{}^{o} + 2\beta_{20}{}^{c}]^{1/2} + (2(\beta_{20}{}^{o} + \beta_{20}{}^{c})/[\beta_{20}{}^{o} + 2\beta_{20}{}^{c}])(B - E)^{1/2} \qquad [3]$$

and a similar relation for $E/(B - E)^{1/2}$. Plots of $B/(B - E)^{1/2}$ and $E/(B - E)^{1/2}$ versus $(B - E)^{1/2}$ must be straight lines with a common intercept A and slopes A_1 and A_2 respectively ($A_1 = A_2 + 1$); either of the two equations can be solved for $\beta_{20}{}^{c}$ and $\beta_{20}{}^{o}$.

The plots for the self-association of caprolactam in CCl_4 (4) are shown in Fig. 1A. The results of the least-squares treatment of the data with standard deviations obtained in the usual manner (10) are: $A = 0.0693 \pm 0.0016$, $A_1 = 1.0679 \pm 0.0063$, $A_2 = 0.0677 \pm 0.0063$, giving $\beta_{20}{}^{o} = 14.2 \pm 2.1$ moles^{-1} l and $\beta_{20}{}^{c} = 97.3 \pm 5.4$ moles^{-1} l; the latter figure can be compared with the published value, which is calculated on the assumption that only closed dimers exist and which varies from 95 to 115 moles^{-1} l depending on the concentration range (4). Thus the magnitude of $\beta_{20}{}^{o}$, while only about a tenth of $\beta_{20}{}^{c}$, seems to be real. An investigation of the self-association of valerolactam (11) used a band assigned to the dimer, while closed-dimer association was assumed in a more recent study of caprolactam in various solvents (12).

The self-associations of *N*-methylmethanesulfonamide (13) and *N*-phenylmethanesulfonamide (14) in CCl_4, shown in Fig. 1B, illustrate the case of the coexistence of monomers and closed dimers only: $A_1 = 1$, $A = \beta_{20}{}^{o} = 0$, within the experimental error of the data.

The self-association of cyclohexanol in CCl_4 (5) shown in Fig. 1C, where the E function has a negative slope, is a case where one or more of the underlying assumptions probably do not hold, in agreement with the conclusions of Masschelein who found that $\epsilon_1{}^{m} \neq \epsilon_1{}^{e}$ and that $\beta_{20}{}^{c}$ and $\beta_{20}{}^{o}$ were not constants. Similar plots were obtained with the available data on the self-association of oximes in CCl_4 (15), which also is not simple (16).

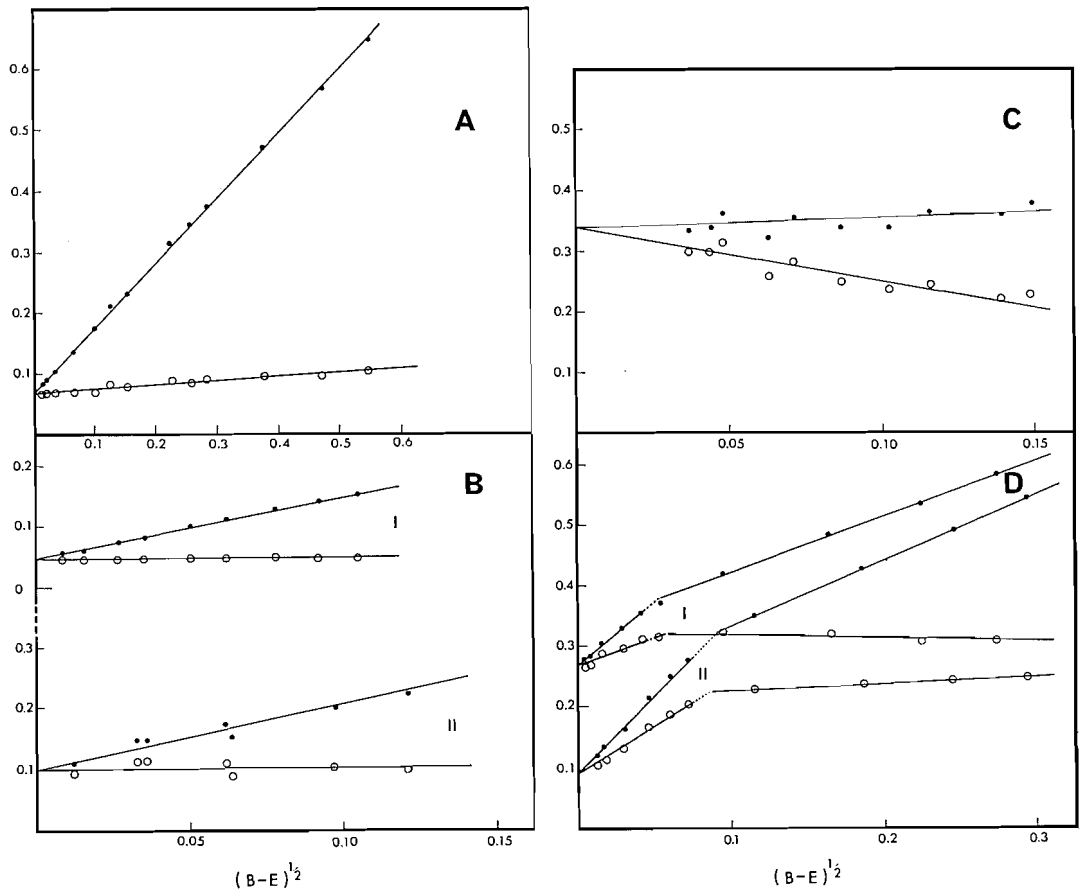

FIG. 1. Plots of $B/(B-E)^{1/2}$ (●) and $E/(B-E)^{1/2}$ (○) versus $(B-E)^{1/2}$: A, caprolactam in CCl_4 (4); B, I, *N*-methylmethanesulfonamide (13) and II, *N*-phenylmethanesulfonamide (14) in CCl_4; C, cyclohexanol in CCl_4 (5); D, *N*-phenylmethanesulfonamide in $CHCl_3$ (I, $\epsilon_1^m = 112$; II, $\epsilon_1^m = 130$) (14).

The plots for *N*-phenylmethanesulfonamide in $CHCl_3$ ($\epsilon_1^m = 130$ and $\epsilon_1^m = 112$) (14) shown in Fig. 1D illustrate the following important points which are strongly pertinent to any infrared spectroscopic investigation of self-association: ϵ_1^m must be known accurately, preferably measured directly, not obtained by extrapolation; a sufficient number of experimental points must be available over a given concentration range in order to avoid ambiguity in the determination of the mode of self-association; the possibility always exists that in some cases the mode of self-association may change with concentration.

In general it seems likely that in self-association of type I*a*, such as perhaps in the case of alcohols, and also in that of type II*a* where the groups A and B are adjacent, as in oximes, $\epsilon_1^m \neq \epsilon_1^e$. If $\epsilon_1^m \gg \epsilon_1^e$ then the usual discussion of the equilibria will be satisfactory, but in cases of possible coexistence of open and closed polymers it would be better to start with a treatment that does not neglect ϵ_1^e, the absorptivity of the "end" A—H groups.

An interesting relation for ϵ_1^e can be derived from $d\epsilon/dB$ at $B = 0$. Let $X = 1 - (\epsilon/\epsilon_1^m)$, then eq. [2] can be rewritten as $BX = b_1^2/A^2$, from which

$$B = A(BX)^{1/2} + A_1BX. \qquad [4]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Manipulation of [4] yields

$$B = A^2X(1 - A_1X)^2. \quad [5]$$

Differentiation and application of the condition $(X = 0)_{B=0}$ to [5] gives

$$(d\epsilon/dB)_{B=0} = -\epsilon_1{}^m/A^2 \quad [6]$$

whence

$$\epsilon_1{}^e = (1/\beta_{20}{}^o)(d\epsilon/dB)_{B=0} + (2\epsilon_1{}^m/\beta_{20}{}^o)(\beta_{20}{}^o + \beta_{20}{}^c). \quad [7]$$

Also, eq. [3] is transformed into

$$B/(B - E)^{1/2} = 1/[(2 - \gamma)\beta_{20}{}^o + 2\beta_{20}{}^c]^{1/2} + (2(\beta_{20}{}^o + \beta_{20}{}^c)/[(2 - \gamma)\beta_{20}{}^o + 2\beta_{20}{}^c])(B - E)^{1/2}. \quad [8]$$

If the plots of $B/(B - E)^{1/2}$ and $E/(B - E)^{1/2}$ as a function of $(B - E)^{1/2}$ are linear and have positive slopes A_1 and A_2 respectively, then

$$\gamma\beta_{20}{}^o = A_2/A^2 \quad \text{and} \quad \beta_{20}{}^o + \beta_{20}{}^c = A_1/2A^2 = -(A_1/2\epsilon_1{}^m)(d\epsilon/dB)_{B=0}. \quad [9]$$

Equations [6] and [8] are related and hence no unique set of values for γ, $\beta_{20}{}^o$, and $\beta_{20}{}^c$ can be calculated a priori. A physically valid set of values can perhaps be selected from the possible solutions in a specific case. No sufficiently precise set of measurements is available in the literature for a case of coexistence of open and closed polymers which could be used in a trial calculation.

Cases where the E function has a negative slope merit further attention and careful investigation using more than one physical method, particularly in the region of low concentrations.

ACKNOWLEDGMENTS

The data on the self-association of caprolactam was very kindly provided by Mr. T. J. Porro of the Perkin–Elmer Corporation.

BIOSYNTHESIS OF ERGOT ALKALOIDS. THE ORIGIN OF THE N-METHYL GROUP[1]

ROSS M. BAXTER, S. I. KANDEL, A. OKANY, AND R. G. PYKE

The origin of the N-methyl group of alkaloids has been the subject of a number of investigations (1). Two general types of mechanism could account for the N-methylation: (*a*) direct methylation by an active one carbon fragment such as formate, and (*b*) transmethylation by the transfer of the intact methyl group of methionine. In this work the origin of the N-methyl group of the ergot alkaloids has been investigated to ascertain via which of the two general mechanisms the N-methyl group arises. The following compounds were administered separately to growing cultures of *Claviceps purpurea*, ^{14}C-formate, L-methionine-methyl-^{14}C, and L-methionine-methyl-^{14}C,^{3}H.

TABLE I

Incorporation of methionine and formate into festuclavine and pyroclavine

Substance added	Total alkaloid, mg	Mixture of festuclavine and pyroclavine		
		Specific activity		Specific incorporation, %
		c.p.m.*/mmole	μc*/mmole	
Na-formate-^{14}C: 5.5 μc (0.224 mg) s.a. = 1.67 mc/mmole	2.4	8.72×10^{6}	6.18	0.37
L-Methionine-methyl-^{14}C: 5.6 μc (0.526 mg) s.a. = 1.099 mc/mmole	5.3	20.82×10^{6}	14.78	1.35

*Abbreviations: counts/min = c.p.m.; μcurie = μc.

It will be observed from Table I that although the specific activity (s.a.) (1.670 millicurie (mc)/mmole) of the added formate is higher than the specific activity (1.099 mc/mmole) of the added methionine, the specific percentage incorporation [(s.a. product/s.a. precursor) $\times$ 100] of the ^{14}C-labelled methionine is more than three times that of the ^{14}C-labelled formate. These data indicate that transmethylation is the preferred mechanism. The direct comparison of the percentage incorporation of the two supposed precursors assumes, however, that the rate of alkaloid formation before administration of the label is the same in all the experimental cultures. The variations in the alkaloid concentration (2) indicate that this assumption cannot be made. These difficulties were circumvented by the subsequent use of L-methionine-methyl-^{14}C,^{3}H as a substrate. The results in Table II show that the ^{3}H to ^{14}C ratio in methionine and in the total and individual alkaloids, purified by paper chromatography and crystallization, are essentially the same, indicating that the S-methyl of methionine is transferred as a unit into the alkaloids. Any significant incorporation of radioactivity as a result of direct methylation from formate would result in the drastic change in the ^{3}H to ^{14}C ratio in the alkaloids as compared to that of methionine. The finding that all of the incorporated radioactivity from ^{14}C formate and L-methionine-methyl-^{14}C resides in the N-methyl group of festuclavine-^{14}C rules out the earlier postulated role of formate (3, 4).

[1]*A preliminary report of part of this work appeared in Chem. Ind. 1453 (1961).*

*Abbreviation: disintegrations/min = d.p.m.

EXPERIMENTAL

Separation, Identification, and Estimation of the Alkaloids

The total alkaloids were obtained from a clavine-producing strain of *Claviceps purpurea* by utilizing the procedure as previously published (5). The purified and dried ether extract (total alkaloids) was chromatographed at room temperature on formamide-impregnated Whatman No. 1 paper with the solvent system composed of methylene chloride saturated with formamide (6). The following alkaloids were separated in order of increasing R_f. Chanoclavine, unknown I (M_I), unknown II (M_2), festuclavine, pyroclavine, agroclavine, and setoclavine. The identification of the individual spots is based on the comparison of their R_f values with that of the reference alkaloids, as compared under ultraviolet light and on development of the chromatograms with van Urk's reagent (1% paradimethylaminobenzaldehyde in 10% hydrochloric acid). The radioactive festuclavine and chanoclavine were also identified by co-crystallization of the eluted alkaloids with the respective authentic reference carrier alkaloids.

The concentration of the alkaloids was determined by the method of Allport and Cocking (7), at 590 mμ, using agroclavine as a standard.

Isolation of the Alkaloids

Chanoclavine, festuclavine, and the mixture of festuclavine and pyroclavine were eluted from the dried paper with ammoniacal peroxide-free ether (2 × 10 ml each spot). An aliquot of the eluate of the above-mentioned alkaloids was transferred into the counting vial, evaporated to dryness by a stream of nitrogen, and dissolved in 10 ml of anhydrous methanol. A volume of 2–5 ml of this methanolic solution was utilized for the quantitative estimation; the residue was evaporated and counted (Tables I and II).

An aliquot of the ether solution of chanoclavine (derived from L-methionine-methyl-^{14}C,^3H) was evaporated and unlabelled chanoclavine (30 mg) was added. The chanoclavine was dissolved in 2 ml of acetone, filtered, and evaporated. Aliquots of the ether solutions of the two festuclavines (derived from ^{14}C-formate, and L-methionine-methyl-^{14}C respectively) were treated similarly, except that unlabelled festuclavine (50 mg) prepared from agroclavine by catalytic hydrogenation, m.p. 239–242 (8), was added in each case. Chanoclavine was recrystallized from methanol and festuclavine from acetone. The specific activities of the crystalline samples remained constant after three recrystallizations. The two festuclavine samples so obtained were used for the degradation (Table III) and the chanoclavine sample for the determination of the ratio of ^3H to ^{14}C (Table II).

TABLE III

Radioactivities of festuclavine and its degradation product (s.a. d.p.m./mmole × 10^{-6})

Tracer	Festuclavine	Triethylmethyl-ammonium iodide	Recovery, %
Formate-^{14}C: 225 μc s.a. = 9.5 mc/mmole	2.29	2.27	99
L-Methionine-methyl-^{14}C: 7.5 μc s.a. = 4.96 mc/mmole	1.47	1.47	100

Preparation of Samples and Counting Procedures

Festuclavine from ^{14}C-labelled methionine and ^{14}C-labelled formate was degraded by the Herzig and Meyer technique, as modified by Brown and Byerrum (9), to obtain a crystalline derivative of the N-methyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

group of festuclavine. The slightly yellowish, crystalline trimethylammonium iodide so obtained was purified by recrystallization from dry acetone and petroleum ether (b.p. 60–80°). Yield 36–40%.

Crystalline samples of the ^{14}C-labelled compounds were combusted by the method of Van Slyke *et al.* (10). The carbon dioxide was collected in an ionization chamber and assayed with a Dynacon electrometer (Nuclear Chicago Corp.). Other ^{14}C-containing and all of the ^{3}H-containing samples and samples containing both ^{3}H and ^{14}C were counted with a Packard liquid scintillation spectrometer (Model 314E). The samples of the alkaloids were dissolved in 1 ml of anhydrous ethanol and the methionine samples in 1 ml of a 1 *M* solution of hyamine hydroxide 10-X in methanol (11) before addition of the fluor. The effect of quenching was determined in each sample by the use of an internal standard.

ACKNOWLEDGMENTS

This work was supported by a grant A-686 from the National Research Council of Canada. We wish to express our appreciation to Dr. A. Hofmann, Sandoz Ltd., Basel, and to Dr. M. Abe, Takeda Pharmaceutical Company, Osaka, Japan, for the samples of pure alkaloids and the sclerotia of the clavine-alkaloid-producing strain of *C. purpurea*, respectively.
