THE REACTION OF HYDROGEN ATOMS WITH KETENE[1]

NICK DEMCHUK[2] AND H. GESSER
Parker Chemical Laboratory, University of Manitoba, Winnipeg, Manitoba

Received July 22, 1963

ABSTRACT

The gas-phase reaction of atomic hydrogen with ketene has been investigated over a temperature range of −130° to 232° C using a low-pressure, fast-flow system. In most cases methane, carbon monoxide, and ethane were the major products, but trace amounts of glyoxal were also detected. Above −96° C. considerable evidence exists for the occurrence of a chain reaction carried by HCO radicals. The surface reaction at −196° C produced methane and glyoxal predominantly with only a minor amount of carbon monoxide.

INTRODUCTION

Photochemical studies of ketene by a number of investigators (1–9) have revealed that the most probable primary step over a wide range of wavelengths was the rupture of the C—C bond with the formation of methylene radicals and carbon monoxide. The methylene radicals, either in the $^3\Sigma^-_g$ state or in the $^1A_1$ state, reacted rapidly with the excess ketene molecules and with any other appropriate species that happened to be present in the system.

Gesser and Steacie (10) made a thorough investigation of the photolysis of ketene in the presence of hydrogen over the temperature range of −40° to 207° C at a wavelength of 2700 Å. The major products were carbon monoxide, ethylene, and ethane, but at higher temperatures traces of methyl ethyl ketone were detected and a considerable amount of methane was also formed. The mechanism most consistent with their results was:

$$CH_2CO + h\nu \rightarrow CH_2 + CO \quad [1]$$

$$CH_2 + CH_2CO \rightarrow C_2H_4 + CO \quad [2]$$

$$CH_2 + H_2 \rightarrow CH_3 + H \quad [3]$$

$$H + CH_2CO \rightarrow CH_3 + CO \quad [4]$$

$$CH_3 + CH_3 \rightarrow C_2H_6 \quad [5]$$

$$CH_3 + H_2 \rightarrow CH_4 + H \quad [6]$$

From an Arrhenius plot the value of E_6 was calculated to be 10.2±0.5 kcal/mole, a result in good agreement with previous work.

The reactions in the above scheme had been well established previously except reaction [4], which was first suggested by Knox, Norrish, and Porter (11). If this reaction was part of the actual mechanism then, in a flow-system study of the reactions of hydrogen atoms with ketene, at high ketene flow rates all hydrogen atoms would be scavenged to form carbon monoxide and methyl radicals. The latter may recombine to form ethane and the amount of carbon monoxide produced would be a good measure of the hydrogen atom concentration in the system. At high temperatures methane should also appear due to reaction [6] and there would be a good possibility that a chain mechanism might occur with hydrogen atoms as chain carriers. The present investigation was undertaken in an attempt to check the validity of the above arguments.

Reaction [3] has been thoroughly investigated recently by Bell and Kistiakowsky (20) and is postulated to pass through an intermediate excited state as follows:

$$CH_2 + H_2 \rightarrow CH_4^* \qquad [3a]$$

$$CH_4^* + W \rightarrow CH_4 + W \qquad [3b]$$

$$CH_4^* \rightarrow CH_3 + H, \qquad [3c]$$

where W is a third body. However, under the low pressure conditions of the following experiments the pressure quenching of the excited state would be expected to be very small and the overall reaction could be represented by [3].

EXPERIMENTAL

Apparatus and Methods

The apparatus consisted of a conventional fast-flow, low-pressure system. Hydrogen from a high pressure cylinder was passed through a reducing valve into a copper furnace maintained at 410° C. It was then further purified by passage through a trap cooled to −196° C. An Edward's high vacuum needle valve (type OSIC) was used to maintain the flow of hydrogen to the discharge tube at the rate of 1530 μmoles/min where it was partially dissociated into atoms by microwaves which were generated by a Raytheon Manufacturing Company Microtherm (Model CMD 7) unit. The discharge tube consisted of a 20-cm length of 19 mm (O.D.) quartz tubing which was internally cooled by means of a water condenser.

A 500-cc spherical bulb served as the reaction vessel in most high temperature experiments. For low temperature work the reaction vessel consisted of a U-shaped cylindrical tube as shown in Fig. 1. Its diameter was 30 mm (O.D.) and it was 18 cm long. The reaction temperature was determined by a sheathed thermocouple projecting into the reaction zone and the pressure was measured by a McLeod gauge. For experiments above room temperature the reaction vessel was surrounded by an appropriately shaped furnace. Low-temperature experiments were conducted in the cylindrical vessel only because it was designed for easy insertion into a Dewar flask containing the coolant at the required temperature. In some cases, the reaction vessel walls were poisoned with $Na_2HPO_4.10H_2O$.

All condensable reaction products were frozen out in a large trap maintained at −196° C with liquid nitrogen. Non-condensable gases, other than H_2, were trapped and collected as previously described (12).

In all cases the hydrogen pressure in the reaction vessel was maintained at 1.05 mm Hg. Under these conditions the hydrogen atom flow rate was found to be 47 μmoles/min as estimated by using CCl_4 as a scavenger (14). This value was kept approximately constant during each series of experiments by adjusting the power output of the microwave generator.

Condensable reaction products were separated in the conventional manner by means of a Le Roy still. The "pure" components were pumped into a gas burette where they were quantitatively measured from P.V.T. measurements. The identity of all components was established by vapor pressure data and infrared analysis. Ethylene in the C_2 fraction was determined by hydrogenation over a nickel–kieselguhr catalyst maintained at 100±1° C (13).

Non-condensable reaction products were desorbed from the silica gel trap at 170° C and were pumped into the gas burette. The amount of CO in the CH_4 was determined by oxidation in a CuO furnace at 210° C (13).

Materials

Commercial grade hydrogen was obtained from the Linde Company and was claimed to be 99.5% pure with oxygen, water vapor, and oil being the main impurities. Spectrograde carbon tetrachloride was purchased from the Eastman-Kodak Company. It was degassed three times by bulb-to-bulb distillation and

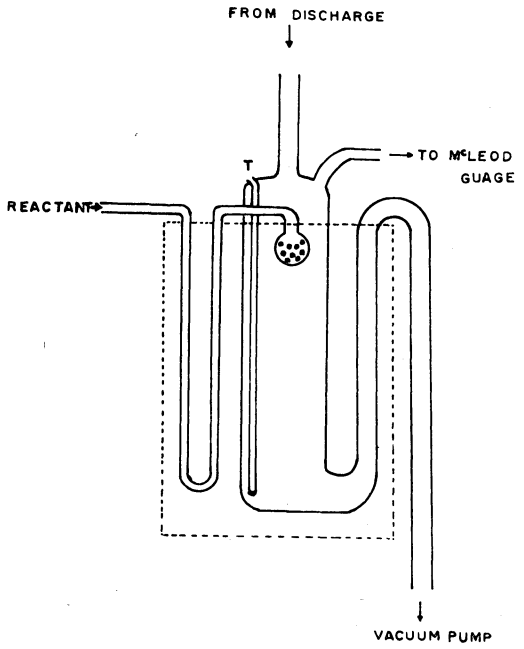

FIG. 1. Diagram of reaction vessel.

was used without any further purification. Ketene was prepared by the pyrolysis of commercial acetic anhydride at 500° C (15). It was degassed at the temperature of liquid oxygen, and distilled from a trap maintained at −125° C into a conical bulb where it was stored in liquid nitrogen.

RESULTS

The reaction of hydrogen atoms with ketene was examined over the temperature range of −196° to 232° C in two different reaction vessels. In the experiments conducted at −196° C the ketene was frozen onto the sides of a poisoned cylindrical reaction vessel and hydrogen atoms were then passed over it. In this case CH_4 and glyoxal were the main products but some CO was also produced (see Table I). The glyoxal was qualitatively

identified by its infrared absorption spectrum but its quantitative determination was difficult owing to its low vapor pressure at room temperature. Only in one case was a quantitative estimate made. At all other temperatures only trace amounts of it were found. At −196° C twice the yield of glyoxal added to the CO produced was approximately equal to the yield of CH_4 and thus there was some indication of a material balance.

At −130±5° C it was possible to study the gas-phase reaction between hydrogen

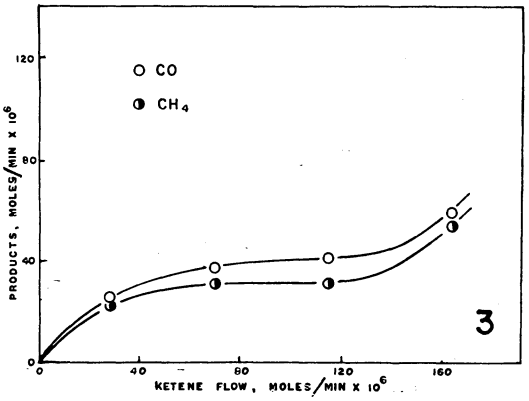
atoms and ketene because at this temperature the ketene vapor pressure is less than 1.0 mm Hg. A number of experiments were performed to determine the variation of the rates of formation of products with the flow rate of ketene and the results are listed in Table II. The main products were CO and CH_4 in this case along with a small amount of ethane. Figure 2 shows that the CO production levels off at the hydrogen atom concentration in the system (47 μmoles/min) while the methane production also levels off but at a smaller value. Only trace amounts of glyoxal were found.

Results obtained at $-96\pm2°$ C have been plotted in Fig. 3. Examination of this figure shows that at low ketene flow rates the behavior is about identical with that obtained in the previous set of experiments. However, at higher ketene flow rates a chain reaction is obviously initiated and a greater amount of ketene reacts than is possible if hydrogen atoms produced in the discharge were the only reactive species. This effect is even more pronounced at $-78°$ C (Fig. 4) where at high ketene flow rates all the ketene that is



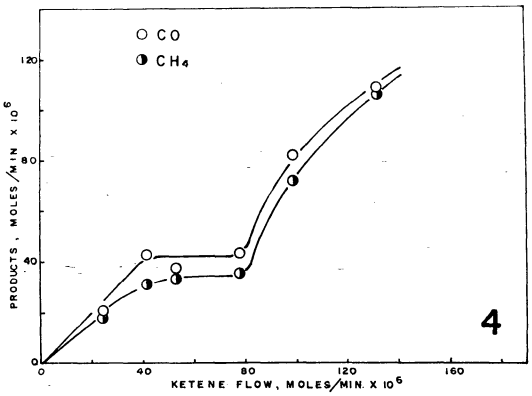


FIG. 3. Yields of products versus ketene flow rate in the reaction of hydrogen atoms with ketene at $-96\pm2°$ C in a cylindrical, poisoned reaction vessel.
FIG. 4. Yields of products versus ketene flow rate in the reaction of hydrogen atoms with ketene at $-78\pm2°$ C in a cylindrical, poisoned reaction vessel.

introduced into the reaction vessel is completely reacted. In both of these cases, only small amounts of ethane and glyoxal were detected.

The results for the same reaction at $72\pm2°$ C in an unpoisoned spherical reaction vessel are plotted in Fig. 5. At this temperature the most significant change is the appearance of considerable amounts of ethane, expecially at high ketene flow rates. Also, it is quite evident that a chain reaction is occurring. The ratio $(2C_2H_6+CH_4)/CO$, an indication of material balance, is in most cases approximately equal to one. The fact that this ratio is less than unity in some instances was probably due to the formation of a trace amount of free carbon which was deposited on the sides of the reaction vessel during the reaction. The formation of trace amounts of glyoxal can possibly account for the fact that the ratio exceeds unity at other times. This behavior is quite similar to that observed at $232\pm2°$ C.

Figure 6, in comparison to Fig. 5, shows the effect of poisoning the reaction vessel with $Na_2HPO_4.10H_2O$. The methane production is decreased considerably and seems to level off while the ethane yield increases. This seems to indicate that methane is in part formed by a heterogeneous surface reaction which is competitive with a reaction by which ethane is produced. The same behavior was obtained in a poisoned cylindrical reaction vessel indicating that the shape of the reaction vessel has very little effect on the reaction.

In blank experiments at 232° C in which hydrogen atoms were not generated, no thermal decomposition of the ketene was observed. Also, at 232° C and at −196° C the reaction of hydrogen atoms with carbon monoxide did not produce detectable amounts of glyoxal in a time comparable to that used in the above experiments.

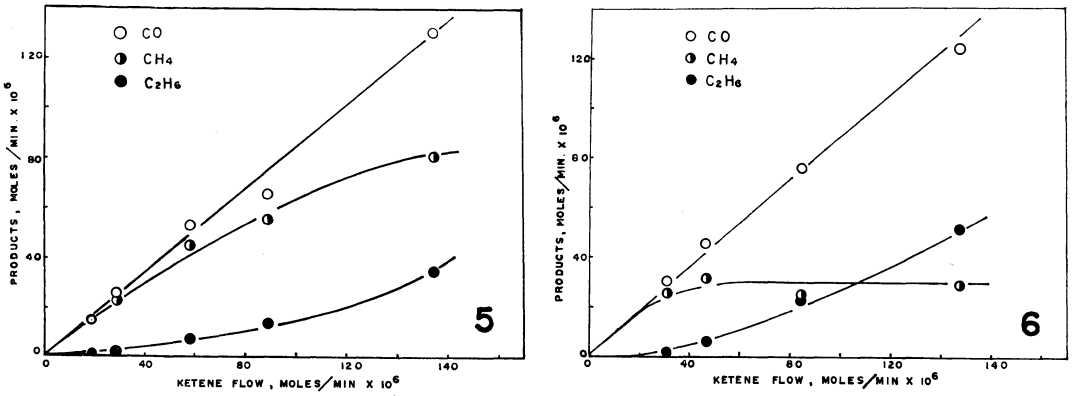

FIG. 5. Yields of products versus ketene flow rate in the reaction of hydrogen atoms with ketene at 72±2° C in a spherical, unpoisoned reaction vessel.
FIG. 6. Yields of products versus ketene flow rate in the reaction of hydrogen atoms with ketene at 232±2° C in a spherical, poisoned reaction vessel.

Finally, a few experiments were performed using hydrogen gas diluted with helium to see whether molecular hydrogen really entered into the reaction scheme. In such experiments, the flowing gas contained only about 18.5% hydrogen. Upon passage through a discharge this system gave a hydrogen atom flow rate of 13 μmoles/min, although it was difficult to keep this value constant. Introduction of ketene into such a system at 232±2° C resulted in the production of carbon monoxide as the main product with the yield varying from 11 to 25 μmoles/min. This shows that the chain reaction had been quenched

and that hydrogen was indeed participating in the chain (see Table III). No methane was found and only a small amount of ethane was produced along with trace amounts of glyoxal. In a similar manner one experiment was conducted at −196° C using the H_2–He

mixture in the flow system. Here again methane was completely eliminated and carbon monoxide became the main product along with a trace of glyoxal. This series of experiments has thus shown that molecular hydrogen is necessary for the formation of methane and for the propagation of chain processes, which were observed in the pure hydrogen system.

DISCUSSION

A list of some of the most probable reactions occurring during the reaction of hydrogen atoms with ketene is as follows:

$$H + CH_2CO \rightarrow CH_2—CHO^* \quad [7]$$

or

$$H + CH_2CO \rightarrow CH_3—CO^* \quad [8]$$

$$H + CH_2—CHO^* \rightarrow CH_3 + HCO \quad [9]$$

or

$$H + CH_3—CO^* \rightarrow CH_4 + CO \quad [10]$$

$$\left.\begin{matrix} CH_2—CHO^* + H_2 \\ CH_3—CO^* + H_2 \end{matrix}\right] \rightarrow CH_4 + HCO \quad [11]$$

$$2HCO \rightarrow (HCO)_2 \quad [12]$$

or

$$2HCO \rightarrow H_2 + 2CO \quad [13]$$

$$HCO + CH_2CO \rightarrow CH_2—CHO^* + CO \quad [14]$$

or

$$HCO + CH_2CO \rightarrow CH_3—CO^* + CO \quad [15]$$

$$2CH_3CO^* \rightarrow C_2H_6 + 2CO \quad [16]$$

$$2CH_2CHO^* \rightarrow C_2H_4 + (HCO)_2 \quad [17]$$

$$CH_3—CO^* \rightarrow CH_3 + CO \quad [18]$$

$$CH_2—CHO^* \rightarrow CH_2 + HCO \quad [19]$$

$$HCO \rightarrow H + CO \quad [20]$$

$$CH_2 + H_2 \rightarrow CH_3 + H \quad [21]$$

$$CH_3 + H + W \rightarrow CH_4 + W \quad [22]$$

$$CH_3 + HCO + W \rightarrow CH_4 + CO + W \quad [23]$$

$$CH_3 + H_2 \rightarrow CH_4 + H \quad [24]$$

$$CH_3 + CH_3 \rightarrow C_2H_6 \quad [25]$$

At all temperatures the most probable primary step is an addition of the hydrogen atom to the olefinic double bond of ketene with the production of an excited radical. However, this addition could take place on either carbon. The rupture of one of the double bonds requires about 65 kcal/mole of energy but the formation of a C—H bond is exothermic by approximately 80 kcal/mole and as a result either radical will have at least 15 kcal/mole of excess energy. Since there was no evidence of any C_2 fraction at $-196°$ C, reactions [9], [16], and [17] must be eliminated as possible secondary steps. However, glyoxal formation seems to point to the presence of HCO radicals. Consequently, reaction [11]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

is favored over [9] and [10] as the secondary step. This is followed by [12] in which two HCO radicals recombine on a surface to form glyoxal. Reaction [13] is postulated to occur to explain the small amount of CO at this low temperature. Also, reaction [11] is favored over [9] and [10] by the observation that dilution of the molecular hydrogen stream with helium reduces methane production to nil.

At $-130\pm5°$ C the same scheme could be postulated except that now reaction [13] predominates over [12] because there are fewer third body collisions in the gas phase. The fact that CO production levels off at the hydrogen atom concentration is another factor favoring the elimination of reactions [9] and [10] since these would require two hydrogen atoms for every molecule of CO produced. The trace amounts of ethane observed at this temperature may be due to reaction [16]. Such a mechanism for ethane formation is favored over that involving reactions [18] and [25] because reaction [18] is endothermic and would not be expected to occur at such low temperatures. This is also true for reaction [19].

A chain reaction must be postulated to explain the results at $-96°$ C at very high ketene flow rates. This can best be done by assuming that the HCO radicals act as the chain carriers, owing to the fact that the temperature is now high enough for reaction [14] to occur. This is supported by the fact that HCO radicals have been postulated as chain carriers in the photolysis of formaldehyde (16) and acetaldehyde (17). This effect is even more predominant at $-78°$ C with the chain reaction now being initiated at even lower ketene pressures.

The appearance of considerable quantities of ethane at higher temperatures (72°, 232° C) necessitates the presence of methyl radicals in the system. These could be most readily formed by the decomposition of the CH_3—CO* radical at these temperatures as postulated by Trost, Darwent, and Steacie (18) in their study of the reaction of hydrogen atoms with acetaldehyde. However, the production of such large quantities of ethane as have been observed in our experiments at high ketene flow rates would require that most of these radicals decompose and hence the chain reaction resulting from step [11] would cease. This would cause a leveling off in the CO production at high ketene flow rates. No such effect is observed in any of the high temperature plots. Also, hydrogen atoms produced by reaction [24] could not serve as the major chain carriers in the reaction sequence [8], [18], [24] because in such a case CH_4 and CO would be produced in approximately equal amounts with very little C_2H_6. Consequently, it must be assumed that even at high temperatures the HCO radical produced by reaction [11] is still responsible for the chain except that at these temperatures it is very probable that it does decompose according to reaction [20] and initiates a chain "carried" by hydrogen atoms. Also it must be postulated that methyl radicals are formed by an entirely different process, namely, the dissociation of the CH_2—CHO radical (reaction [19]) followed by the reaction of methylene radicals with the excess hydrogen in the system as postulated by Rosenblum (6), and Gesser and Steacie (10). In this way the chain reaction could still be propagated by HCO radicals. It is this fact that favors reaction [7] over reaction [8] as the primary step. The formation of methane could be accounted for by surface reactions such as [22] and [23] in agreement with the fact that a poisoned surface decreases the methane production and reaction [25] probably becomes more prominent.

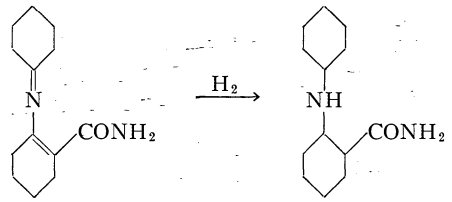
CONDENSATION OF ALICYCLIC KETONES WITH UREA AND THIOUREA

A. F. McKay, C. Podesva,[1] E. J. Tarlton, and J.-M. Billy[2]
L. G. Ryan Research Laboratories of Monsanto Canada Limited, LaSalle, Quebec[3]
Received August 2, 1963

ABSTRACT

The previous assignment of a cis conformation to cyclohexyl 2-carbamylcyclohexylamine, which was prepared by the condensation of urea with cyclohexanone, has been confirmed by equilibration in the presence of potassium *t*-butoxide. The failure of 4-*t*-butylcyclohexyl 2-carbamyl-4-*t*-butylcyclohexylamine to equilibrate under the same conditions is discussed in relation to its structure. 1,2,3,4,5,6,7,8-Octahydroacridine was prepared by the condensation of 2,2′-methylene-bis-cyclohexanone with urea.

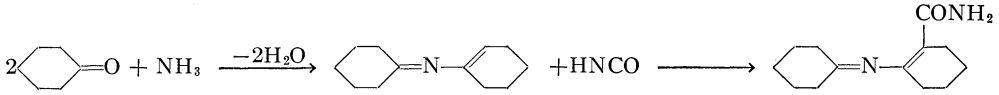
The product from the condensation of cyclohexanone with urea in alkaline medium was assigned (1) structure I on the basis of its analysis, infrared spectrum, and hydrogenation to cyclohexyl 2-carbamylcyclohexylamine (II). Later Scarborough and Gould



I II

(2) reported an improved procedure for the preparation of compound I. During the present investigation a new process (cf. Experimental) was developed which gives high yields of this condensation product. The latter procedure was used in the preparation of the compounds listed in Table I. Cyclohexylidene 2-thiocarbamylcyclohex-1-enylamine was prepared from the condensation of cyclohexanone with thiourea. The infrared and ultraviolet absorption bands listed in Tables II and III respectively show that these condensation products have the same general structure. If the imino nitrogen in structure I is assumed to be equivalent to carbon for calculating the ultraviolet absorption maximum then the calculated (3) value of 308 mμ is in good agreement with the observed value of 305 mμ (Table III).

Cyclohexylidene 2-carbamylcyclohex-1-enylamine (I) was considered (1) to be formed by the carbamylation of an enamine intermediate and the reaction sequence may be represented as follows:



The previous (1) scheme showed the addition of HNCO to 1-aminocyclohexene instead of cyclohexylidene cyclohex-1-enylamine. Isocyanic acid would be expected to add more readily to the latter compound because of its closer structural relationship to typical

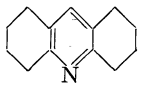
*The ultraviolet spectra were determined on ethanolic solutions of the compounds with a Beckman DK–1 recording spectrophotometer.

enamines. Some evidence in support of the prior condensation of two more equivalents of cyclohexanone with ammonia is provided by the following observation.

An attempt to form a carbamyl derivative of 2,2′-methylene-bis-cyclohexanone under the conditions used for the preparation of cyclohexylidene 2-carbamylcyclohex-1-enylamine gave the known (4, 5) 1,2,3,4,5,6,7,8-octahydroacridine (III). This new method



III

of producing *sym*-octahydroacridine involves condensation with ammonia and then oxidative aromatization.

The previous assignment (1) of a cis configuration to cyclohexyl 2-carbamylcyclohexylamine (IV*a* $\rightleftharpoons$ IV*b*) was confirmed by its equilibration in the presence of potassium tertiary butoxide. The equilibration product containing the trans epimer (V*a* $\rightleftharpoons$ V*b*) melted at 95° and on nitrosation gave a nitrosamine melting at 158°. The nitrosamine from the cis epimer (IV*a* $\rightleftharpoons$ IV*b*) melted at 167°. Infrared spectra of the epimeric cyclohexyl 2-carbamylcyclohexylamines and their N-nitroso derivatives also show distinct differences (see Table II).

Several attempts to equilibrate 4-*t*-butylcyclohexyl 2-carbamyl-4-*t*-butylcyclohexylamine were unsuccessful. The original compound was recovered in good yields in each experiment. Thus 4-*t*-butylcyclohexyl 2-carbamyl-4-*t*-butylcyclohexylamine must possess conformation VI*a* (cis 1*a*, 2*e*/cis 2*e*, 4*e*) or VI*b* (trans 1*e*, 2*e*/cis 2*e*, 4*e*). This conformation VI*a* would be formed by cis addition of hydrogen at the less hindered approach to the double bond. This conformation with the carbamyl group equatorial is stabilized by the 4-*t*-butyl group which prevents the ring from flipping over into the conformation with the carbamyl group axial and the amino substituent equatorial. Conformation VI*b* with all substituents equatorial could account also for the stability of the 4-*t*-butyl compound. Formation of conformation VI*b* can be explained by the migration of a double bond prior to hydrogenation. Actually the hydrogenation of cyclohexylidene 2-carbamylcyclohex-1-enylamine proceeded at a much more rapid rate than the hydrogenation of its 4-*t*-butyl derivative. The former compound absorbed two mole equivalents of hydrogen in 2 hours while 4-*t*-butylcyclohexylidene 2-carbamyl-4-*t*-butylcyclohex-1-enylamine absorbed one mole equivalent of hydrogen in 1 hour and then required an additional 20 hours to absorb a further 0.6 mole equivalents.

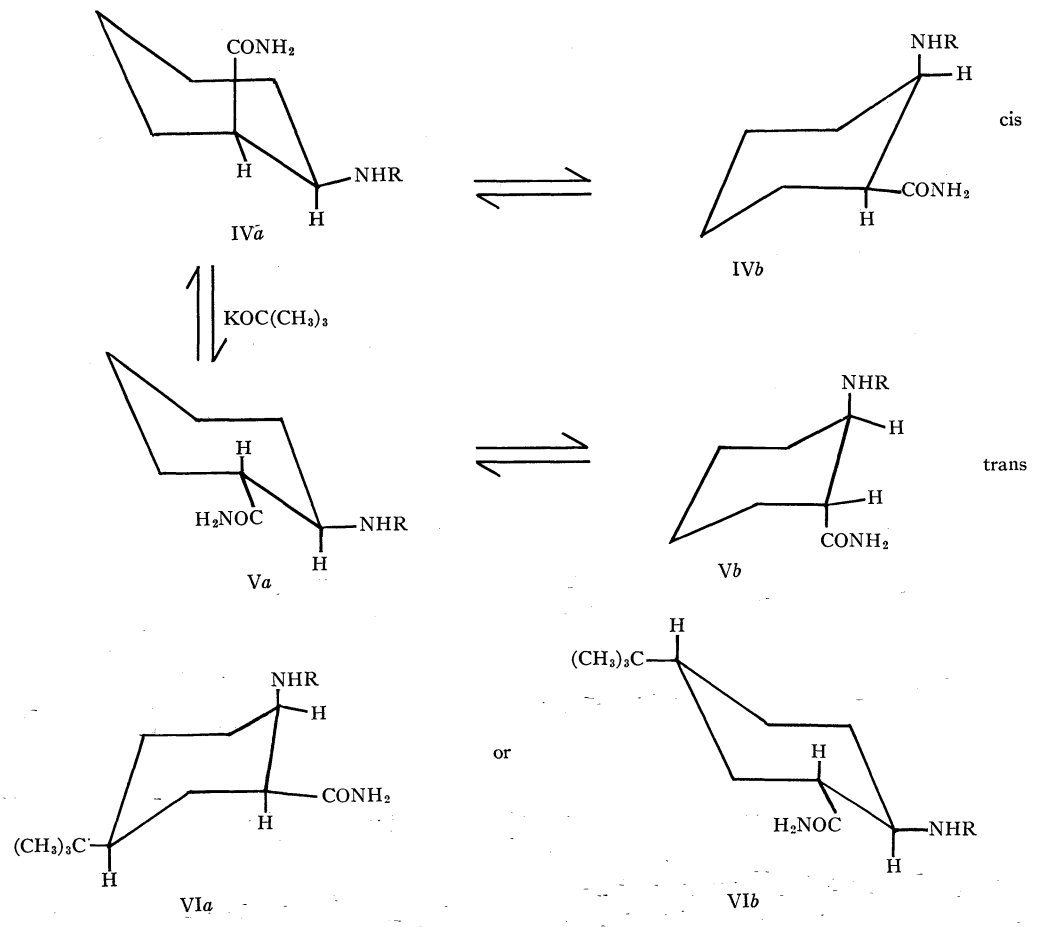
For personal use only.



R = cyclohexyl or 4-*t*-butylcyclohexyl.

Cyclopentyl 2-carboxylcyclopentylamine was prepared by hydrolysis of the hydrogenation product from cyclopentylidene 2-carbamylcyclopent-1-enylamine. Attempts to prepare cyclopentyl 2-carboxylcyclopentylamine by other routes were unsuccessful. After heating cyanocyclopent-1-ene and cyclopentylamine in glacial acetic acid at 113° for 19 hours, the reagents were recovered unchanged. Heating an aqueous solution of cyclopentylamine and cyclopent-1-enylcarboxylic acid in a sealed tube at 155° for 48 hours gave mainly N-cyclopentyl cyclopent-1-enylcarboxamide (m.p. 141.5°).

EXPERIMENTAL*

4-t-Butylcyclohexanone

4-*t*-Butylcyclohexanone (m.p. 42°) was prepared in 75% yield from 4-*t*-butylcyclohexanol by the procedure described (6) for the conversion of menthol to menthone. The product was purified by distillation at 95–97° at 3 mm; m.p. 47°; oxime m.p. 137° (lit. (7) 137.5–138.5°).

Reaction of Alicyclic Ketones with Urea and Thiourea

The compounds listed in Table I were prepared by one of the following procedures.

**All melting points are uncorrected. Microanalyses were determined by Dr. C. Daessle, Montreal, Quebec.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Method A.—Cyclohexanone (19.6 g, 0.2 mole) and urea (24 g, 0.4 mole) in *o*-xylene (20 ml) were heated at reflux for 40 minutes. Water was distilled azeotropically and it was collected in a Barrat trap. The reaction was cooled and water (50 ml) and benzene (25 ml) were added. The precipitate (m.p. 199–205°) was recovered by filtration, yield 19.9 g (90%). Recrystallization from 46% aqueous ethanol (175 ml) gave pure cyclohexylidene 2-carbamylcyclohex-1-enylamine (m.p. 224–225°), yield 13.8 g. A mixed melting point determination with a known sample gave no depression.

Method B.—Cyclohexanone (19.6 g, 0.2 mole) and urea (24 g, 0.4 mole) in a solution of *o*-xylene (20 ml) and dimethylformamide (75 ml) were heated under reflux for 2.6 hours. During the reaction period water was collected azeotropically in a Barrat trap. The solution was evaporated *in vacuo* to one-half of its original volume and the residual solution was diluted with water (150 ml). The product (m.p. 215°) was collected by filtration, yield 18.5 g (84%). Recrystallization from 45% aqueous ethanol (270 ml) gave pure product (m.p. 225–226°), yield 15.2 g. A mixed melting point determination with a sample of product from method A showed no depression.

Cyclohexyl 2-Carbamylcyclohexylamine Hydrochloride and Free Base

The hydrochloride (m.p. 276°) and free base (m.p. 128°) of this compound were prepared as previously described (1).

Cyclohexyl 2-Carbamylcyclohexylnitrosamine

Cyclohexyl 2-carbamylcyclohexylamine hydrochloride (0.4 g, 0.0015 mole) in aqueous hydrochloric acid (5 drops of concentrated hydrochloric acid in 25 ml water) was treated with an aqueous solution of sodium nitrite (1 g sodium nitrite in 5 ml water). This solution was allowed to stand at room temperature for 24 hours. Crystals (m.p. 162–165°) gradually separated from the solution, yield 0.14 g (36%). One recrystallization from aqueous ethanol raised the melting point to 165–167°. Anal. Calc. for $C_{13}H_{23}N_3O_2$: C, 61.63; H, 9.15; N, 16.59. Found: C, 61.44; H, 9.00; N, 16.55.

Equilibration of Cyclohexyl 2-Carbamylcyclohexylamine

Cyclohexyl 2-carbamylcyclohexylamine (1 g, 0.004 mole) in 20 moles of potassium *t*-butoxide solution (1.3 g of metallic potassium in 33 ml *t*-butanol) was heated under reflux for 1 hour. At the end of the reaction period the solution was diluted with 7 volumes of water and exhaustively extracted with chloroform. Evaporation of the chloroform extract *in vacuo* gave an oil which crystallized into needle-like crystals (m.p. 94–95°) on standing, yield 1 g (100%). Several recrystallizations of the product from ethyl acetate gave crystals with melting ranges varying between 75° and 90°. Anal. Calc. for $C_{13}H_{24}N_2O$: C, 69.60; H, 10.78; N, 12.49. Found: C, 69.45; H, 11.00; N, 12.21. This experiment was repeated several times with the same results.

Nitrosation of Equilibration Product from Cyclohexyl 2-Carbamylcyclohexylamine

To a solution of this equilibration product (1.9 g, 0.008 mole) in water (40 ml) containing concentrated hydrochloric acid (1.7 g, 0.017 mole) was added a solution of sodium nitrite (1.25 g, 0.017 mole) in water. After standing overnight at room temperature crystals (m.p. 156–158°) of the nitrosamine separated, yield 0.71 g (33%). Two recrystallizations from aqueous ethanol raised the melting point to a constant value of 158°. Anal. Calc. for $C_{13}H_{23}N_3O_2$: C, 61.63; H, 9.15; N, 16.59. Found: C, 61.61; H, 9.33; N, 16.94. The melting point of this epimeric nitrosamine was depressed on admixture with a sample of the nitrosamine (m.p. 167°) which was prepared from cyclohexyl 2-carbamylcyclohexylamine melting at 128° (*vide supra*).

4-t-Butylcyclohexyl 2-Carbamyl-4-t-butylcyclohexylamine

A solution of 4-*t*-butylcyclohexylidene 2-carbamyl-4-*t*-butylcyclohex-1-enylamine (2 g, 0.006 mole) in absolute ethanol (150 ml) containing concentrated hydrochloric acid (0.6 g) and platinum oxide (0.1 g) catalyst was hydrogenated at room temperature. The first mole equivalent of hydrogen was absorbed very rapidly and then hydrogenation proceeded very slowly. After 20.5 hours only 1.6 mole equivalent of hydrogen was absorbed. The reaction mixture was filtered and the filtrate was evaporated to dryness *in vacuo*. The amorphous residue was dissolved in water and the solution made alkaline with 5% aqueous sodium hydroxide solution. A white precipitate separated from solution. This mixture was extracted with chloroform and the chloroform extract was evaporated to dryness *in vacuo*. The residue (m.p. 189°) weighed 0.8 g (41% yield). Four recrystallizations from ethyl acetate raised the melting point to 194°. Anal. Calc. for $C_{21}H_{40}N_2O$: C, 74.94; H, 11.98; N, 8.33. Found: C, 75.04; H, 12.02; N, 8.10.

Attempt to Epimerize 4-t-Butylcyclohexyl 2-Carbamyl-4-t-butylcyclohexylamine

Several attempts to epimerize 4-*t*-butylcyclohexyl 2-carbamyl-4-*t*-butylcyclohexylamine (m.p. 194°) under the conditions employed for the equilibration of cyclohexyl 2-carbamylcyclohexylamine gave almost quantitative recoveries of unchanged starting material.

4-Methylcyclohexyl 2-Carbamyl-4-methylcyclohexylamine Hydrochloride

4-Methylcyclohexylidene 2-carbamyl-4-methylcyclohex-1-enylamine (6 g, 0.024 mole) in absolute ethanol (250 ml) containing concentrated hydrochloric acid (2.04 ml) and 109 mg of platinum oxide was hydrogenated at ambient temperature and pressure. Approximately two mole equivalents of hydrogen were absorbed in 35 minutes. The catalyst was removed by filtration and the filtrate was evaporated to a volume

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of 25 ml *in vacuo*. After the residual solution was treated with ether (75 ml) and a few drops of concentrated hydrochloric acid, a crystalline precipitate (m.p. 216–217°) was obtained, yield 4.9 g (70%). A sample (1 g) was purified by several crystallizations from ethanol–ether solution, yield 0.41 g. The final melting point was 223–224°. Anal. Calc. for $C_{15}H_{29}ClN_2O$: C, 62.36; H, 10.12; Cl, 12.28; N, 9.70. Found: C, 62.00; H, 10.04; Cl, 12.68; N, 9.61.

A portion (1 g, 0.003 mole) of this hydrochloride salt in 15 ml of water was treated with excess aqueous sodium hydroxide solution. The resulting alkaline mixture was extracted with chloroform and the chloroform extract was dried over anhydrous sodium sulphate. Evaporation of chloroform solution gave 0.8 g (93%) of solid (m.p. 108–109°). One recrystallization from ether–pentane solution raised the melting point of 4-methylcyclohexyl 2-carbamyl-4-methylcyclohexylamine to 114–115°. Anal. Calc. for $C_{15}H_{28}N_2O$: C, 71.37; H, 11.18; N, 11.10. Found: C, 71.51; H, 11.00; N, 11.47.

Cyclopentyl 2-Carbamylcyclopentylamine Hydrochloride

Cyclopentyl 2-carbamylcyclopentylamine hydrochloride (m.p. 210–211°) was prepared in 61% yield by the hydrogenation of cyclopentylidene 2-carbamylcyclopent-1-enylamine under the conditions described for the preparation of 4-methylcyclohexyl 2-carbamyl-4-methylcyclohexylamine hydrochloride. Two recrystallizations from ethanol–ether solution raised the melting point to 223–224°. Anal. Calc. for $C_{11}H_{21}ClN_2O$: C, 56.76; H, 9.09; Cl, 15.24; N, 12.04. Found: C, 57.02; H, 9.02; Cl, 15.23; N, 12.04.

Cyclopentyl 2-Carboxylcyclopentylamine Hydrochloride

A solution of cyclopentyl 2-carbamylcyclopentylamine hydrochloride (0.2 g, 0.001 mole) in concentrated hydrochloric acid (5 ml) was heated on a steam bath for 1 hour. The solution was evaporated to dryness *in vacuo* and the residue was dissolved in methanol (6 ml). On addition of ether (15 ml) to the methanolic solution a precipitate (40 mg) of ammonium chloride was obtained. The filtrate was evaporated to dryness and the residual oil readily crystallized (m.p. 165–170°), yield 0.2 g (99.6%). One recrystallization from methanol–ether solution raised the melting point to 180.5–181°. Anal. Calc. for $C_{11}H_{20}ClNO_2$: C, 56.52; H, 8.63; Cl, 15.17; N, 5.99. Found: C, 56.55; H, 8.57; Cl, 15.33; N, 6.25.

Cyanocyclopent-1-ene

Cyanocyclopent-1-ene (b.p. 70° at 20 mm, n_D^{23} 1.46978) was prepared in 62% yield by the method of Wheeler and Lerner (8).

Cyclopent-1-enecarboxylic Acid

Cyanocyclopent-1-ene was converted in 63% yield into cyclopent-1-enecarboxylic acid (m.p. 121–122°; lit. (8) 121°) by the procedure of Wheeler and Lerner (8).

Cyclopentylamine

A solution of cyclopentanone (67.2 g, 0.8 mole) and hydroxylamine hydrochloride (69.5 g, 1 mole) in water (120 ml) was treated with an aqueous solution of sodium carbonate (53 g sodium carbonate in 130 ml water). After stirring for 30 minutes, the crystalline cyclopentanone oxime (m.p. 56.5–57.5°)was recovered by filtration, yield 53 g (67%).

The oxime (30 g, 0.3 mole) in absolute ethanol (700 ml) was treated with small portions of sodium metal (100 g). This mixture was refluxed for 12 hours until all the sodium disappeared. The viscous syrup was treated with an equal volume of water and the solution was exhaustively extracted with ether. After the ether extract was acidified with dry hydrogen chloride, it was evaporated to dryness. The residue was treated with 15% aqueous sodium hydroxide solution and this solution was extracted with ether. The ether was removed by fractional distillation through a Widmer column and the residual amine was fractionated in a spinning band column. Cyclopentylamine (b.p. 106–108°, n_D^{25} 1.44691; lit. (9) b.p. 106–108°, n_D^{25} 1.4478) was obtained in 47% yield.

Attempts to Prepare Cyclopentyl 2-Cyanocyclopentylamine

A solution of cyanocyclopent-1-ene (0.94 g, 0.001 mole) and cyclopentylamine (0.86 g, 0.001 mole) in glacial acetic acid (3 ml) was heated at 113° for 19 hours. The dark solution was made alkaline with 15% aqueous sodium hydroxide solution (20 ml) and extracted with ether. Washing the ether phase with 10% hydrochloric acid gave 1.12 g (91%) of cyclopentylamine hydrochloride (m.p. 200–202°).

The ether phase was washed with aqueous sodium bicarbonate solution and water and dried over anhydrous sodium sulphate. Evaporation of the ether solution gave 0.88 g (94%) of unchanged cyanocyclopent-1-ene.

The results were the same after the above reagents were heated for 22 hours at 113°.

Attempt to Prepare Cyclopentyl 2-Carboxycyclopentylamine

A solution of cyclopentylamine (2.34 g, 0.027 mole) and cyclopent-1-enylcarboxylic acid (1 g, 0.009 mole) in water (5 ml) was heated in a sealed tube at 155° for 48 hours. The resulting mixture was extracted with ether and the ether extract was washed with 10% hydrochloric acid and water. The ether extract on evaporation gave a solid which melted at 80–95°, yield 0.6 g (37%). Two recrystallizations from aqueous ethanol raised the melting point to 141–141.5°. This compound was identified as N-cyclopentyl cyclopent-1-enylcarboxamide by analysis and its infrared spectrum. Anal. Calc. for $C_{11}H_{17}NO$: C, 73.69; H, 9.56. Found:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

C, 73.48; H, 9.47. Infrared spectrum of the solid in Nujol mull showed absorption bands at 1328, 1604, 1620, 1641, and 3330 cm^{-1}.

A mixture of oil and cyclopentylamine hydrochloride was obtained from the acidic aqueous washings of the ether extract. The crystals (m.p. 199–200°) were identified as cyclopentylamine hydrochloride by a mixed melting point determination, yield 0.4 g. Attempts to purify the remaining dark brown oil were unsuccessful. It did not have the properties expected for cyclopentyl 2-carboxycyclopentylamine.

2,2′-Methylene-bis-cyclohexanone

A modification of the procedure described by Wick and Becke (10) was used for the preparation of 2,2′-methylene-bis-cyclohexanone.

Cyclohexanone (98 g, 1 mole), dimethylamine hydrochloride (18 g, 0.2 mole), and 30% formalin (20 g, 0.2 mole) were mixed and heated gradually on an oil bath. An exothermic reaction occurred at a bath temperature of 120° and the reaction was allowed to proceed without further heating. After the reaction had subsided, the product was cooled to room temperature and 20% aqueous sodium hydroxide solution (45 g) was added. After thorough agitation, the organic layer was separated and the water and unreacted cyclohexanone were removed by distillation. When the distillation temperature reached 155°, the residue was refluxed until the reflux temperature reached 162° after which the residue was distilled *in vacuo*. The main fraction (b.p. 168–170° at 5 mm, yield 38.3 g) was refractionated in a spinning band column. The first fraction (b.p. 120° at 0.05 mm, yield 9.7 g) remained an oil while the second fraction (b.p. 104° at 0.02 mm) crystallized (m.p. 52°; lit. (11) 58°), yield 15 g (36%). Anal. Calc. for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68. Found: C, 74.34; H, 9.39.

1,2,3,4,5,6,7,8-Octahydroacridine

A solution of 2,2′-methylene-bis-cyclohexanone (2 g, 0.02 mole) and urea (2 g, 0.03 mole) in dimethylformamide (15 ml) – xylene (5 ml) solution was heated under reflux until no more water separated in the Barrat trap. The reaction mixture was diluted with water and extracted with chloroform. The chloroform extract was evaporated to dryness and the residual oil was dissolved in methanol, diluted with an equal volume of water, and acidified with concentrated hydrochloric acid. The solution was extracted with ether and the aqueous phase was made alkaline with aqueous sodium hydroxide solution. The alkaline solution was exhaustively extracted with chloroform and the chloroform extract was evaporated *in vacuo*. The residual oil was dissolved in a small amount of ethyl acetate and the solution was filtered. Evaporation of the filtrate to dryness gave an oil which crystallized at room temperature, yield 1.75 g (97%). This crude product melted at 50°. It was dissolved in benzene and the benzene solution was passed through a column of neutral alumina. Evaporation of the benzene eluate *in vacuo* gave 1.2 g of crystals melting at 65–68°. These crystals were sublimed *in vacuo* and the sublimate melted at 69–71° (lit. (4, 5) 69° and 73.4–74°). Anal. Calc. for $C_{13}H_{17}N$: C, 83.37; H, 9.15; N, 7.48. Found: C, 83.65; H, 9.01; N, 7.19.

Ultraviolet absorption spectrum in ethanol gave λ_{max} 216, 222, 272, 276.5, 281, 285, and 290 mμ with $\epsilon_{max} \times 10^{-3}$ 6.3, 4.5, 4.3, 6.5, 7.8, 7.1, and 5.6 respectively.

A picrate (m.p. 195°) was prepared in 94% yield in the usual manner from a methanolic solution of the free base. Two crystallizations from ethanol raised the melting point to 200° with dec. (lit. (5) m.p. 200–201.5°). Anal. Calc. for $C_{19}H_{20}N_4O_7$: C, 54.80; H, 4.84; N, 13.46. Found: C, 54.96; H, 4.96; N, 13.31.

The hydrochloride (m.p. 201–202°) was prepared in 98% yield by passing dry hydrogen chloride through an ether solution of the free base. Anal. Calc. for $C_{13}H_{18}ClN$: C, 69.79; H, 8.10; Cl, 15.85; N, 6.26. Found: C, 69.83; H, 7.46; Cl, 15.79; N, 6.31.

ON THIOSEMICARBAZONE–COPPER (I) COMPLEXES. PART IV[1]

B. A. GINGRAS AND A. F. SIRIANNI
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received August 8, 1963

ABSTRACT

The structure of thiosemicarbazone–copper (I) complexes has been studied further and new data have been obtained. The most probable structure has the metal linearly coordinated to a sulphur atom of a thiosemicarbazone molecule and a nitrogen atom of a second molecu e. The diamagnetism of the complexes can be accounted for by a copper–copper interaction. Molecular weights of two typical complexes have been measured by a vapor pressure lowering method in benzene. The complexes were found to associate in this solvent but appeared as dimers at infinite dilution.

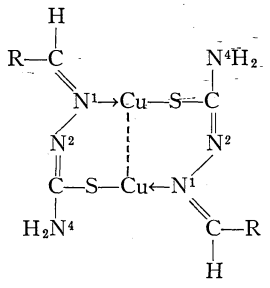
For personal use only.

In earlier publications we have reported the preparation of some thiosemicarbazone–copper (I) complexes (1, 2) and discussed their possible structures (2). A number of polymeric structures in which the metal was tetrahedrally coordinated were considered but eventually rejected on the ground of steric strain. Other possibilities involved linearly coordinated copper, also in a polymer.

Many attempts to determine molecular weights of these complexes by the cryoscopic and ebullioscopic methods failed because of their extremely low solubility in suitable solvents. However, using a considerably more sensitive method (vapor pressure lowering) and working at low concentrations, we have now been able to measure molecular weights of two typical copper complexes: *o*-fluoro- (I*a*) and *m*-fluoro- (I*b*) benzaldehyde thiosemicarbazone – copper (I). These were chosen because they can be recrystallized from acetone and, therefore, were particularly pure specimens.

This paper reviews various data obtained earlier and along with the molecular weight observed in benzene, a more probable structure (I) is suggested for these complexes.



(I)

(I*a*) R = *o*-FC_6H_4— (I*b*) R = *m*-FC_6H_4—

EXPERIMENTAL

Molecular weight determinations were made using milligram quantities of solute and about 10 milliliters of benzene which was previously dried and distilled over calcium hydride. The complexes were recrystallized from acetone to constant melting point and were freed of volatiles by evacuation at room temperature prior to use. The solute was dispersed in the solvent by ultrasonic irradiation for 3 minutes using a 40-kc circo ultrasonic generator. The solutions were shaken periodically and allowed to equilibrate overnight at room temperature before measurements were taken, with a Mechrolab vapor pressure osmometer model 301, to

[1]*Presented at the forty-sixth annual meeting of the Chemical Institute of Canada, Toronto, Ontario, June 1963. Issued as N.R.C. No. 7623.*

determine vapor pressure lowering at 37° C. The instrument was calibrated with benzil solutions over a similar concentration range used for the copper complexes. The operating procedure of the "osmometer" and the calculation of the apparent molecular weights were carried out as described elsewhere (3).

RESULTS AND DISCUSSION

The variation of the apparent molecular weight with solute concentration (g solute/100 g solvent) is shown in Fig. 1. The closed and open circles were obtained for the meta and

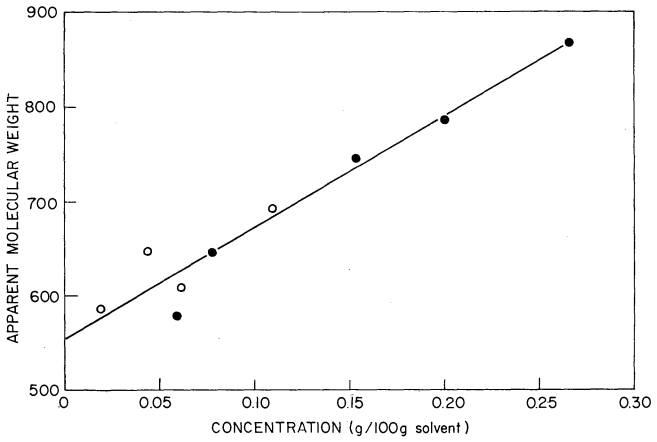


FIG. 1.

ortho isomers respectively. The latter isomer appeared to be less soluble and attempts were not made to carry out measurements over a much wider concentration range. The apparent molecular weight increases with solute concentration, indicating association in benzene. A straight line drawn through the experimental points extrapolated to infinite dilution indicates a molecular weight about twice the value of the monomer. These results suggest that the materials exist in the dimeric form, at least in very dilute solutions.

It was shown in Part II (2) that the complexes are in a 1:1 ratio (1 thiosemicarbazone to 1 copper) and are diamagnetic and that the metal is linked to the sulphur atom. The importance of the N^2 hydrogen atom was also stressed. Indeed, it has been shown that in cases where the N^2 atom was substituted with a methyl group, the resulting 2-methyl thiosemicarbazones failed to form complexes (2). It was suggested in this report that copper was coordinated to the N^4 atom on the ground that 4,4-dimethyl thiosemicarbazones formed 2:1 complexes and thus behaved in a different manner than the original thiosemicarbazones. However, it was found later that 4,4-dimethyl derivatives also formed 1:1 complexes, so that the argument no longer holds and it is now believed that copper is coordinated to the N^1 atom as in (I). This agrees with other findings that thiosemicarbazide and its derivatives form metallic complexes in which the metal is coordinated to the N^1 atom (4, 5, 6, 7, 8). Furthermore, there is little doubt that in the case of dithiosemicarbazone–copper (II) and nickel (II) complexes, coordination is also through the N^1 atom (9, 10).

Copper (I) is a d^{10} ion and to undergo linear coordination, one electron has to be promoted from the $3d$ orbital to the $4s$. A covalent bond would then be formed with an electron from the sulphur atom filling the $4s$ orbital. One $4p$ orbital would be filled by a doublet from the N^1 atom, resulting in sp hybridization, thence, linearly coordinated copper (I). This leaves the $3d$ orbitals with one unpaired electron and since the complexes are diamagnetic, a copper–copper bond is suggested. Atomic models of such a structure

For personal use only.

show that the copper atoms lie so close to each other that they can actually be linked, resulting in two strainless six-membered rings.

Complexes having copper–copper bonds are not too common but in the last few years, a number of reports have been published in which this possibility exists. For instance, the diamagnetism of bis-diazoaminobenzene–copper (II) is explained by a copper–copper bond (11). It is interesting to note that this complex is dimeric. The corresponding complex with copper (I) is also dimeric and X-ray analyses indicate that the metal is linearly coordinated. The possibility of Cu–Cu bonding in this compound has been considered (12) since the distance between copper atoms is 2.45 Å, shorter than that in metallic copper (2.56 Å), and that in cupric acetate (2.64 Å) where a Cu–Cu interaction is known to occur (13). Coates and Parkin suggest the possibility of Cu–Cu bonds in ethynyl–copper (I) complexes with tertiary phosphines where the distance between copper atoms is 2.45 Å (14). A copper–copper interaction would also contribute to the insolubility of the compounds as pointed out by Frasson *et al.* (15) for the dimethylglyoxime complexes of various metals.

The association with increasing concentration in benzene solution may be due to further coordination of a metal atom to a sulphur atom of another dimeric molecule, resulting in a tetramer or even a hexamer by coordination of two metal atoms to two sulphur atoms. Further coordination of metals to sulphur atoms of other molecules is known to occur in the complexes of dialkyldithiocarbamates with the univalent coinage metals, e.g. silver (I) (hexamer), copper (I) (tetramer), and gold (I) (dimer) (16). The crystal structure of these complexes has been studied by Hesse (17), who discussed the degree of polymerity with respect to several factors including the tendency of the metal atoms to coordinate with more than two sulphur atoms. It is interesting to note that similarly to the thiosemicarbazone–copper (I) complexes discussed in this work, the dithiocarbamate–gold (I) complexes have a linear metal–sulphur coordination, are dimeric, and the possibility of metal–metal interactions exists (17).

It is realized that the interaction between copper atoms in thiosemicarbazone–copper (I) complexes may be rather weak and the dimeric structure is broken down by merely dissolving the complexes in dimethyl sulphoxide. Molecular weight determinations by the cryoscopic method in dimethyl sulphoxide showed the complexes to be monomers, which is likely due to dissociation of the dimer followed by coordination of the solvent around the copper atoms; this will be the subject of a subsequent publication.

SYNTHESIS OF METHYL 4-ACETAMIDO-4-DEOXY-L-ERYTHROFURANOSIDE:* A SUGAR WITH NITROGEN IN A FIVE-MEMBERED RING

W. A. SZAREK AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario
Received July 31, 1963

ABSTRACT

The synthesis of methyl 4-acetamido-4-deoxy-L-erythrofuranoside from D-ribose is described. The structural features that are believed to be necessary for the replacement of the ring oxygen of sugars by nitrogen are discussed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The replacement of the ring oxygen of sugars by nitrogen has been achieved recently by a number of investigators. In this laboratory 5-acetamido-5-deoxy-L-arabinopyranose* and 5-acetamido-5-deoxy-D-xylopyranose have been synthesized from L-arabinose and D-xylose, respectively (1, 2). The same compounds have been obtained independently by Hanessian and Haskell (3). The latter compound has also been synthesized by a somewhat different route by Paulsen in Germany (4). In that work the compound was named 5-acetamido-5-deoxy-D-xylopiperidinose. Chemical Abstracts recommended the nomenclature used in the present paper.

All of the work cited above involved the introduction of nitrogen into pyranose rings. The present publication describes the synthesis of methyl 4-acetamido-4-deoxy-L-erythrofuranoside, a sugar derivative with nitrogen as the hetero atom in a five-membered ring.

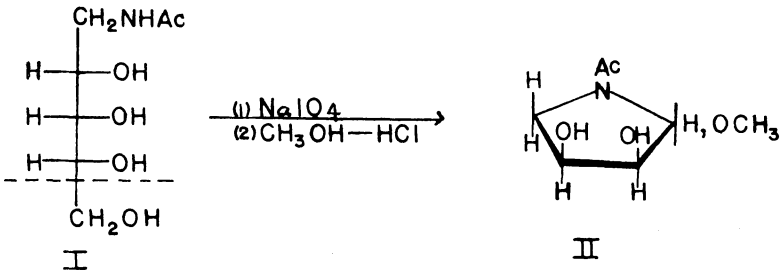
1-Amino-1-deoxy-D-ribitol was prepared from D-ribose by the reductive alkylation of ammonia method of Kagan *et al.* (5) and purified through the crystalline salicylidene Schiff base. *N*-Acetylation of the pure 1-amino-1-deoxy-D-ribitol with aqueous acetic anhydride then gave 1-acetamido-1-deoxy-D-ribitol (I) (6).

Schwarz (7) has shown that the oxidation of mannitol, dulcitol, and sorbitol with a limited quantity of sodium metaperiodate involved preferential attack on threo-glycol groups (i.e., "trans"-glycol groups on the Fischer convention). These results suggested that sodium metaperiodate would oxidize 1-acetamido-1-deoxy-D-ribitol (I) initially between C-4 and C-5, and that a large excess of the ribitol derivative would diminish further oxidation of the initial fission product. Consequently, 1 mole of 1-acetamido-1-deoxy-D-ribitol was oxidized with 0.1 mole of sodium metaperiodate. Under these conditions 81% of the 1-acetamido-1-deoxy-D-ribitol which was oxidized underwent oxidation between C-4 and C-5 as determined by the production of formaldehyde. Clearly, in the major carbohydrate moiety produced in the oxidation, there existed the possibility of formation of a nitrogen-containing furanose ring by ring closure of the terminal aldehyde group on to the nitrogen atom of the amide group.

A large proportion of unreacted 1-acetamido-1-deoxy-D-ribitol was removed by crystallization, and the residual colorless syrup from the periodate oxidation was treated with methanolic hydrogen chloride. Chromatographic examination of the syrupy product indicated that in addition to 1-acetamido-1-deoxy-D-ribitol one major component and two minor components were present. The major component was separated and obtained as a yellow syrup which was a mixture of two compounds. These were separated by

**Nomenclature used by Chemical Abstracts.*

partition between chloroform and water. The chloroform phase yielded a small amount of a pale yellow syrup, the infrared spectrum of which showed carbonyl absorption at 1737 cm^{-1}, but no absorption attributable to OH, NH, or the amide linkage. The identity of this material is as yet unknown. From the water phase there was obtained a clear colorless syrup which gave absorptions in the infrared corresponding to OH and N—Ac, but no absorption attributable to NH. The compound, on periodate oxidation in unbuffered aqueous solution, consumed periodate (1 mole) very rapidly but did not liberate any formic acid even after 48 hours. These results are consistent with the structure proposed for methyl 4-acetamido-4-deoxy-L-erythrofuranoside (II).



I II

Compound II gave a syrupy di-*O*-acetyl derivative which on gas–liquid chromatographic analysis gave a single symmetrical peak (see Fig. 1).

The proton magnetic resonance spectrum of methyl 4-acetamido-4-deoxy-L-erythrofuranoside is presented in Fig. 2. The spectrum contains two doublets at 5.09 and 5.00 p.p.m. in the general region characteristic of anomeric hydrogens (8, 9). In addition there are two peaks at 3.46 and 3.42 p.p.m. which may be assigned to the methoxyl protons (10), and peaks at 2.16 and 2.13 p.p.m. which may be assigned to the protons of the *N*-acetyl group (10). The n.m.r. spectrum can be interpreted in two ways. The substance may be an approximately 1:1 mixture of α- and β-anomers. Alternatively, the *N*-acetyl group might display restricted rotation, with the rotational isomers showing different chemical shifts for the substituents at C-1. These two possibilities are being investigated.

The preparation of the acyclic 2-pentuloses 5-acetamido-5-deoxy-D-*threo*-pentulose and 5-acetamido-5-deoxy-L-*erythro*-pentulose by the microbiological oxidation of 1-acetamido-1-deoxy-D-arabinitol and 1-acetamido-1-deoxy-D-ribitol, respectively, has been reported from this laboratory (6). These compounds were obtained as crystalline solids. Significantly, the formation of a five-membered ring involving the nitrogen atom was not observed. In the present work each of these ketoses was heated in a dilute acid solution in order to achieve a possible formation of a nitrogen-containing furanose ring. In both cases paper chromatography indicated the presence only of the original ketose sugar. These results suggest that a terminal aldehyde group is required for the formation of a nitrogen-containing furanose ring. An aldehyde group is believed also to be a necessary structural feature for the introduction of nitrogen into a pyranose ring on the basis of some results of Jones and Turner (11). These workers treated 6-acetamido-6-deoxy-D-*arabino*-hexulose with methanolic hydrogen chloride in the cold and at reflux temperature. A mixture of the α- and β-glycofuranosides of the ketose rather than a nitrogen-containing pyranose ring was obtained under both sets of conditions. Very recently Whistler and co-workers (12) reported that methanolysis of 5-amino-5-deoxy-1,2-*O*-isopropylidene-β-L-idofuranose gave methyl 5-amino-5-deoxy-α,β-L-idofuranoside, but no six-membered

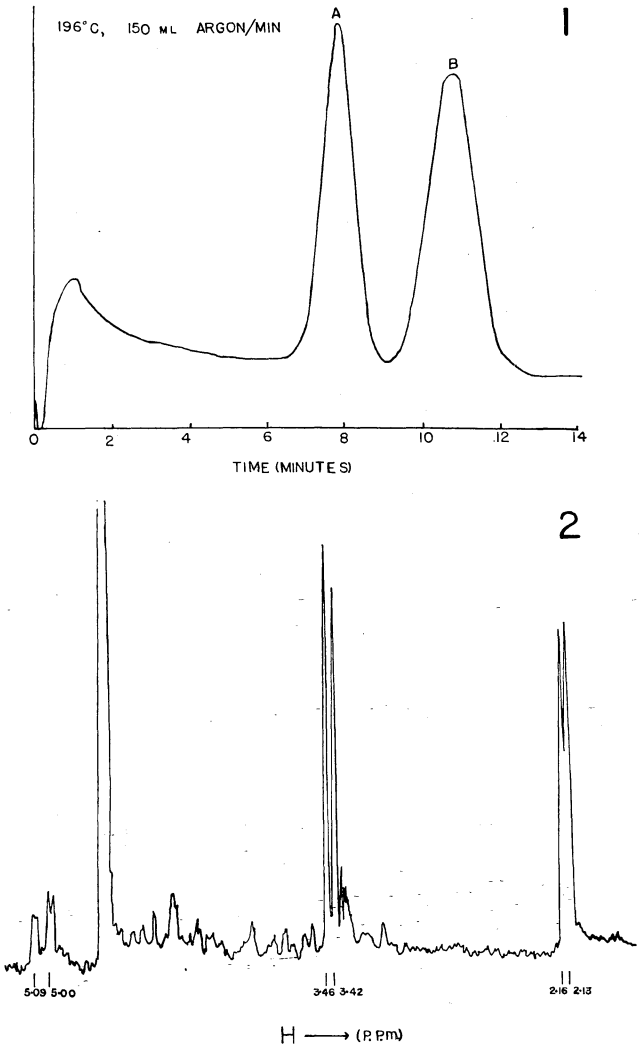

FIG. 1. Gas–liquid chromatogram of (A) methyl 4-acetamido-4-deoxy-2,3-di-*O*-acetyl-L-erythrofuranoside and (B) penta-*O*-acetyl-D-arabinitol.

FIG. 2. N.m.r. spectrum of methyl 4-acetamido-4-deoxy-L-erythrofuranoside measured at 60 Mc/s in deuterium oxide, with tetramethylsilane as an external reference.

nitrogen-containing ring compound was obtained. It appears, therefore, that the requisite structural features for the replacement of the ring oxygen of sugars by nitrogen are an aldehyde group and a *N*-acetyl group on a primary carbon atom.

EXPERIMENTAL

Solutions were concentrated under reduced pressure below 40° with a rotating vacuum-type evaporator. Melting points were determined on a Fisher–Johns melting point apparatus. Optical rotations were measured at 23±3° with a Hilger Standard Polarimeter. Infrared spectra were measured with a Perkin–Elmer Model 21 spectrophotometer. The n.m.r. spectrum was determined at 60 Mc/s with a Varian A-60 n.m.r. spectrometer using an approximately 10% by weight solution of the compound in deuterium oxide; tetramethylsilane was used as an external standard. Paper chromatography was carried out by the descending

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

method at room temperature on Whatman No. 1 filter paper; the solvent system was butan-1-ol:ethanol: water, 3:1:1 (v/v). Sugars were detected on paper chromatograms by the following spray reagents: (*i*) alkaline silver nitrate (13); (*ii*) *p*-anisidine hydrochloride (14); (*iii*) sodium metaperiodate – potassium permanganate (15). Rates of movement of the sugars on paper chromatograms are given relative to that of rhamnose (R_{rh}). The gas–liquid chromatographic analysis was carried out using a Pye Argon Chromatograph fitted with an ionization detector (80 μc radium D) and employing straight glass columns (117×0.5 cm I.D.). The column consisted of 38 cm of an intimate mixture of (*a*) 1 part of 20% w/w butanediol succinate polyester on 60–80 mesh Chromosorb W, (*b*) 0.7 part of 20% w/w methylated Damson Gum (OMe 40%) on 60–80 mesh Chromosorb W, placed on top of 79 cm of methyl silicone rubber gum SE-30, 1% w/w, on 60 plus mesh glass beads.

1-Acetamido-1-deoxy-D-ribitol

1-Amino-1-deoxy-D-ribitol was prepared by the reductive alkylation of ammonia method of Kagan *et al.* (5) in which D-ribose (100 g) was dissolved in liquid ammonia and hydrogenated with Raney Nickel catalyst at 1600 p.s.i. at 85° for 4 hours. The crude product was purified through the crystalline salicylidene Schiff base. The purified salicylidene derivative (67.4 g) was suspended in a mixture of 500 ml of water and 45 ml of concentrated hydrochloric acid, and the mixture was heated on a water bath for 15 minutes with vigorous stirring. After being cooled to room temeprature the reaction mixture was extracted three times with 100-ml portions of methylene chloride. The aqueous phase was evaporated to dryness, the residual 1-amino-1-deoxy-D-ribitol hydrochloride was dissolved in 1 l. of water and the solution was passed through a column of Amberlite IRA 400 (OH form) anion exchange resin (900 ml). The eluate was evaporated to dryness under reduced pressure to yield a light brown syrup (37.6 g). This material was dissolved in water (250 ml) and treated with acetic anhydride (37.3 ml). The solution was allowed to stand for 20 minutes with occasional shaking, then evaporated to dryness under reduced pressure to leave a syrup (46.2 g) which crystallized when left standing. Two recrystallizations of this material from methanol–ether gave white needles (27.1 g) which melted at 90–91° and had $[\alpha]_D = -24.5°$ (*c*, 3.14 in water) and R_{rh} 0.88 (spray *i*). Jones *et al.* (6) report m.p. 91.5–92°, $[\alpha]_D = -24°$ and R_{rh} 0.89 (butan-1-ol:ethanol:water, 3:1:1) for 1-acetamido-1-deoxy-D-ribitol.

Periodate Oxidation of 1-Acetamido-1-deoxy-D-ribitol

Preliminary Experiment

1-Acetamido-1-deoxy-D-ribitol (0.0268 g) (1.4×10^{-4} mole) was dissolved in water (12.5 ml), mixed with an equal volume of an aqueous solution of sodium metaperiodate (0.0030 g) (1.4×10^{-5} mole), and left to stand at room temperature. After 30 minutes the solution gave a negative test for periodate. Formaldehyde was then estimated by the chromotropic acid method (16); 0.081 mole formaldehyde per mole 1-acetamido-1-deoxy-D-ribitol had been produced.

Preparative Experiment

1-Acetamido-1-deoxy-D-ribitol (26.45 g) was dissolved in water (270 ml), mixed with an equal volume of a solution of sodium metaperiodate (2.93 g), and left to stand at room temperature for 30 minutes. The solution was then deionized by passing it through a column of Amberlite IR 120 (H form) cation exchange resin (40 ml) and then a column of Duolite A 4 (OH form) anion exchange resin (40 ml). The eluate and washings were then evaporated to dryness under reduced pressure to leave a colorless syrup. This material was taken up in methanol–ether, seeded with a crystal of 1-acetamido-1-deoxy-D-ribitol and set aside in a refrigerator. The crystalline 1-acetamido-1-deoxy-D-ribitol which separated was removed by filtration and washed with methanol. The filtrate and washings were evaporated to dryness under reduced pressure to yield a clear colorless syrup (7.25 g) which was examined on paper chromatograms. Spray *i* showed the presence of components at R_{rh} 0.88 (1-acetamido-1-deoxy-D-ribitol) and 1.13. The latter spot was also detected with spray *ii*.

Reaction with Methanolic Hydrogen Chloride

The clear colorless syrup (7.25 g) obtained above was dissolved in methanolic hydrogen chloride (1.2%, 60 ml) and allowed to stand at room temperature for 2 hours. The solution was then neutralized with silver carbonate and filtered. The clear solution was evaporated under reduced pressure to yield a syrupy product (7.06 g) which was examined on paper chromatograms. Spray *ii* showed one intense spot, R_{rh} 1.7, and two faint spots, R_{rh} 1.3 and 2.0. Spray *i* showed an additional component with R_{rh} 0.88 which was unchanged 1-acetamido-1-deoxy-D-ribitol.

The component having R_{rh} 1.7 was separated on a cellulose column (54×4.5 cm) with butan-1-ol half-saturated with water as the irigant and obtained as a pale yellow syrup (1.6 g). The infrared spectrum of this material in chloroform showed strong absorption at 3375 cm^{-1} attributable to OH, weak absorption at 1735 cm^{-1}, and strong absorption at 1640 cm^{-1} owing to N—Ac, but no absorption due to NH. The syrupy product was partitioned between chloroform and water. The chloroform phase yielded a pale yellow syrup (0.04 g), the infrared spectrum of which in chloroform showed absorption at 1737 cm^{-1}, but no absorption attributable to OH, NH, or the amide linkage. From the water phase there was obtained a clear colorless syrup. This syrup, methyl 4-acetamido-4-deoxy-L-erythrofuranoside, gave a strong absorption in the infrared in chloroform at 3375 cm^{-1} attributable to OH, and strong absorption at 1640 cm^{-1} owing to N—Ac, but no

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

absorption due to NH. The compound showed up on paper only faintly with the alkaline silver nitrate spray reagent (*i*), but an intense spot appeared within a few seconds with spray *iii*.

Periodate Oxidation of Methyl 4-Acetamido-4-deoxy-L-erythrofuranoside

Methyl 4-acetamido-4-deoxy L-erythrofuranoside (0.0173 g) was dissolved in water containing 0.3 *M* sodium metaperiodate solution (1 ml). The total volume was made up to 25 ml with additional water. A blank experiment was carried out at the same time. The oxidation was carried out in the dark and at room temperature. Formic acid yield and periodate uptake were determined in the usual fashion (17). After 0.38 hour 0.98 mole periodate per mole methyl 4-acetamido-4-deoxy-L-erythrofuranoside had been consumed and no formic acid had been liberated. The same results were obtained after 48 hours.

Methyl 4-Acetamido-4-deoxy-2,3-di-O-acetyl-L-erythrofuranoside

Methyl 4-acetamido-4-deoxy-L-erythrofuranoside (0.200 g) was dissolved in dry pyridine (1.5 ml), the solution cooled at 0°, and treated with acetic anhydride (0.5 ml). The solution was allowed to stand at room temperature for 24 hours. The di-*O*-acetyl derivative isolated in the usual manner was a syrup (0.258 g, 88%). The infrared spectrum in chloroform showed strong absorption at 1745 cm^{-1} attributable to the carbonyl group of an *O*-acetyl group, and strong absorption at 1660 cm^{-1} owing to N—Ac, but no absorption attributable to NH or OH. When subjected to gas–liquid chromatographic analysis, the acetate gave a single symmetrical peak (Fig. 1) with a retention time of 0.72 relative to penta-*O*-acetyl-D-arabinitol (=1.00). The acetate was readily purified by vacuum distillation to yield a clear, colorless syrup, $[\alpha]_D = -9°$ (*c*, 3.09 in chloroform containing 0.75% ethanol). Calc. for $C_{11}H_{17}O_6N$: C, 51.0; H, 6.6; N, 5.4; OCH_3, 12.0%. Found: C, 50.5; H, 6.8; N, 5.1; OCH_3, 10.8%.

Treatment of 5-Acetamido-5-deoxy-D-threo-pentulose and 5-Acetamido-5-deoxy-L-erythro-pentulose with Dilute Acid

To a 2% aqueous solution (1 ml) of each compound was added glacial acetic acid (0.1 ml). The solutions were heated at 80° for 1.5 hours and examined on paper chromatograms. In each case sprays *i*, *ii*, and *iii* showed the presence of only one component the R_{rh} value of which was the same as that quoted by Jones *et al.* (6) for the original ketose sugar.

ACKNOWLEDGMENTS

The authors thank the National Research Council for a grant (N.R.C.T-19) which made this work possible, and for a scholarship (to W. A. S.). They also wish to thank Dr. D. G. M. Diaper of the Royal Military College for the use of an autoclave, Mr. H. G. Jones of Queen's University for the gas chromatographic analysis, and Dr. S. Wolfe for helpful suggestions.

1,1′-SPIROBIINDANES[1]

L. R. C. Barclay and Ralph A. Chapman[2]
Department of Chemistry, Mount Allison University, Sackville, New Brunswick
Received June 24, 1963

ABSTRACT

The product from both the acid-catalyzed cyclodehydration of 4-methyl-4-phenyl-2-pentanone (I*a*) described by Hoffman (1) and by Barnes and co-worker (2) and the reaction of the saturated cyclic dimer of α-methylstyrene with aluminum chloride reported by Adams and co-workers (3) was shown to be 3,3,3′,3′-tetramethyl-1,1′-spirobiindane (IX*a*) by Curtis (4). A mechanism is postulated to explain the formation of the 1,1′-spirobiindane system. The reactions of several polyalkylindenes with α-methylstyrene and triphenylcarbinol were investigated. Several new polyalkyl-1,1′-spirobiindanes and a new polyalkylindene[1,2-*a*]indene were produced. Two of the 1,1′-spirobiindanes investigated were synthesized by unequivocal methods.

In 1929 Hoffman (1) reported the formation of a hydrocarbon from the treatment of 4-methyl-4-phenyl-2-pentanone (I*a*) with anhydrous zinc chloride at 180°. Later Barnes and co-worker (2) observed the formation of a hydrocarbon in low yield from refluxing 4-methyl-4-(*p*-tolyl)-2-pentanone (I*b*) with 50% sulphuric acid. Relating their work to that of Hoffman, they proposed after a thorough study that the compound he obtained was 4*b*,9,9,10,10-pentamethyl-4*b*,9,9*a*,10-tetrahydroindeno[1,2-]indene (VI*a*) and postulated the mechanism illustrated in Chart I to explain its formation.

Barnes and co-worker proposed that the beta-aryl ketone (I*a*) can undergo two simultaneous reactions. It can eliminate acetone by acid cleavage to yield the protonated α-methylstyrene (II*a*) and it can undergo cyclodehydration to yield the 1,1,3-trimethylindene (IV*a*). The carbonium ion II*a* then attacks the indene (IV*a*) at carbon 2 so as to produce the new carbonium ion (V), which alkylates the adjacent benzene ring to produce VI*a*.

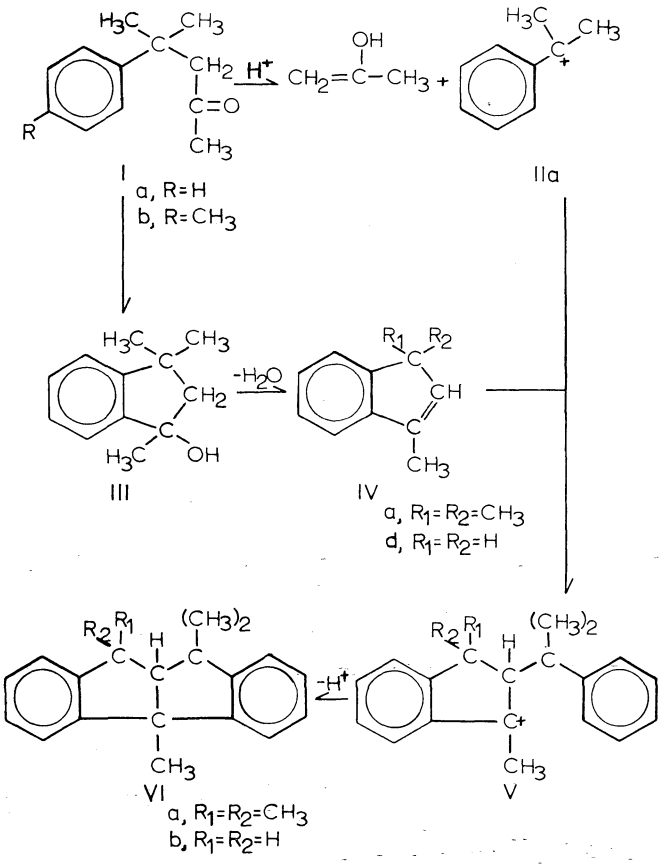
In 1959 Adams and co-workers (3) reported the formation of (VI*a*) by the treatment of the saturated cyclic dimer of α-methylstyrene (1-phenyl-1,3,3-trimethylindane) with aluminum chloride at 180°. The mechanism proposed involved the formation of protonated α-methylstyrene (II*a*) and indene (IV*a*) from the indane by acid cleavage. These were postulated to react as illustrated in Chart I.

More recently Curtis (4) demonstrated by nuclear magnetic resonance (n.m.r.) studies that the product obtained by all these workers was not the polyalkylindeno[1,2-*a*]indene (VI*a*) but really the 3,3,3′,3′-tetramethyl-1,1′-spirobiindane (IX*a*). He later substantiated this (5) by carrying out a number of interconversions of the 1,1′-spirobiindanes.

In the light of this evidence, the mechanisms of the above reactions became of interest since those postulated by Barnes and Adams could not account for the formation of IX*a*. However, it is interesting to note that in the mechanisms proposed by these workers, two reactants, the indene (IV*a*) and the carbonium ion (II*a*), are present. The following new mechanism for the formation of (IX*a*), illustrated in Chart II, is proposed.* An equilibrium can be set up in the acid medium between the endocyclic form of the 1,1,3-trimethylindene (IV*a*) and the exocyclic form (VII*a*) ($R_1 = R_2 = H$). (The 1,1,3-trimethylindene could form as illustrated in Chart I or could be added as one of the starting

[1]*Presented in part before the Division of Petroleum Chemistry, Symposium on Aromatic Compounds at the 142nd meeting of the American Chemical Society, Atlantic City, September 1962.*
[2]*Recipient of a National Research Council Studentship.*
**This mechanism has also been independently proposed by R. A. Barnes, private communication.*

CHART I



reagents.) This equilibrium is expected to favor the endocyclic form. However, the relatively bulky protonated α-methylstyrene (either formed as shown in Chart I or added as α-methylstyrene) can alkylate the exocyclic form more readily than the hindered endocyclic form. When alkylation occurs, it causes a continual shift in the endocyclic–exocyclic equilibrium because of removal of the exocyclic form as the new carbonium ion (VIII). This carbonium ion has the charge suitably situated to alkylate the second aromatic ring producing the 3,3,3′,3′-tetramethyl-1,1′-spirobiindane (IX*a*).

To substantiate the above mechanism we found that the indene (IV*a*) reacted with α-methylstyrene in sulphuric acid to produce the 1,1′-spirobiindane (IX*a*) in 54% yield. The product has identical physical properties to that prepared by Barnes and Adams. The n.m.r. spectrum of the compound (Fig. 1) was interesting. It showed a complicated multiplet integrating for 8 aromatic protons, a singlet at 7.72 p.p.m. for the 4 methylene protons, and a doublet at 8.61 and 8.65 p.p.m. corresponding to 12 methyl protons. The aromatic proton multiplet was divided into two signals one with maximum intensity at 2.89 p.p.m. (corresponding to 6 protons) and another at 3.30 p.p.m. (corresponding to 2 protons). The examination of a molecular model helped to clarify several points about the spectrum. A possible explanation of the two groups of partially resolved multiplets in the aromatic proton signal is based on the fact that the conformation of the molecule places

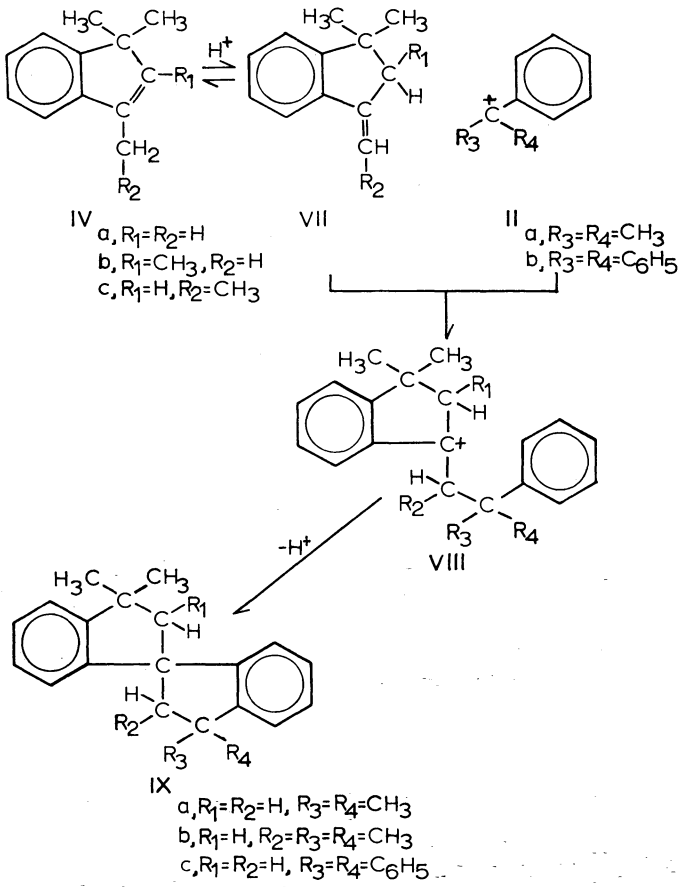
CHART II



the two aromatic rings nearly at right angles to one another and reasonably close together. In such a situation the proton on carbon 7 (and 7′) would lie in a position more or less over the plane of the ring to which it was not directly attached. Thus it would be shielded and would resonate at higher field than the other aromatic protons, that is, near 3.30 p.p.m.

The fact that the methyl proton resonance is a doublet can be attributed to the fact that one of the methyl groups of each of the *gem* dimethyl systems on carbons 3 and 3′ lies in the plane of the aromatic ring to which it is less closely attached while the remaining methyl group lies slightly above the plane of the ring to which it is more closely attached. In such a situation, the group in the plane of the ring would be expected to be deshielded relative to the other group and thus resonate at slightly lower field.

On closer examination of the proposed reaction mechanism, it is obvious that any effect which tends to stabilize the endocyclic form of the indene would tend to prevent the formation of the 1,1′-spirobiindane system while any effect which tends to stabilize the exocyclic form would have the opposite effect.

With the former effect in mind, 1,1,2,3-tetramethylindene (IV*b*) was prepared. In such a system the methyl group on carbon 2 should tend to stabilize the double bond in the endocyclic form and one would expect less 1,1′-spirobiindane to form in a reaction of this indene with α-methylstyrene than was produced under similar conditions with

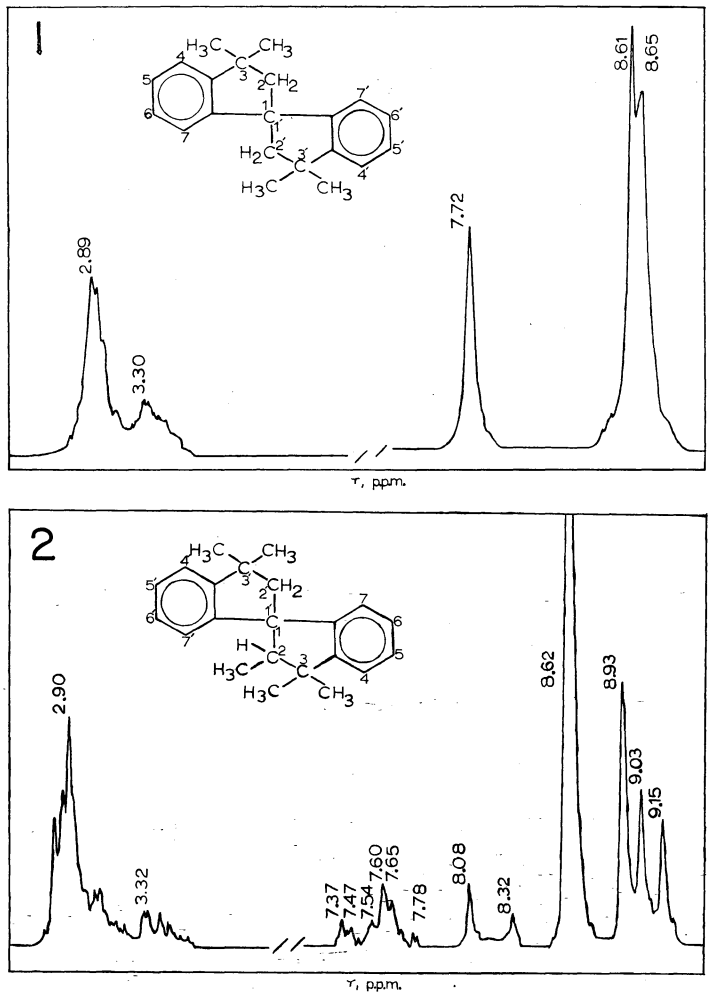

FIG. 1. Nuclear magnetic resonance spectrum of 3,3,3′,3′-tetramethyl-1,1′-spirobiindane.
FIG. 2. Nuclear magnetic resonance spectrum of 2,3,3,3′,3′-pentamethyl-1,1′-spirobiindane.

1,1,3-trimethylindene and α-methylstyrene. When the indene (IV*b*) and α-methylstyrene were reacted with sulphuric acid at −5° none of the 2,3,3,3′,3′-pentamethyl-1,1′-spirobiindane (IX*b*) was produced. The only high molecular weight compound formed was the saturated cyclic dimer of α-methylstyrene which under the conditions used does not react further to produce (IX*a*).

In order to test the stabilizing effect of an additional methyl group on the exocyclic form of an indene, 3,3-dimethyl-1-ethylindene (IV*c*) was prepared. In such a compound the exocyclic form would be expected to be more stable than in 1,1,3-trimethylindene. Reaction of the indene (IV*c*) with α-methylstyrene in sulphuric acid produced a colorless crystalline solid (m.p. 118–119°) in 67% yield. The ultraviolet spectrum gave bands at 2730 Å (log ϵ = 3.33), 2660 Å (log ϵ = 3.29), and 2590 Å (log ϵ = 3.08). The infrared spectrum gave a doublet in the 1385–1365 cm^{-1} region attributed to the *t*-butyl skeleton and two strong bands at 765 and 750 cm^{-1} attributed to *o*-disubstituted aromatics. The

For personal use only.

mass spectrum showed a parent mass of 290. The analytical results agreed with the formula $C_{22}H_{26}$. This evidence indicated the compound was the 2,3,3,3′,3′-pentamethyl-1,1′-spirobiindane (IX*b*). The n.m.r. spectrum (Fig. 2) was complex but confirmed this. The eight aromatic protons absorbed as a complex multiplet with maximum intensities of the two separate branches at 2.90 and 3.32 p.p.m. respectively. The signals at 3.32 p.p.m. were again attributed to the shielding effect on the protons at carbons 7 and 7′ causing them to resonate at higher fields as they did in compound (IX*a*). An AB type quartet at 7.37, 7.60, 8.08, and 8.32 p.p.m. was attributed to the methylene protons of carbon 2′. These protons are not equivalent because of the interaction of one of them with the methyl group on carbon 2 which actually lies very close to it. A quartet at 7.47, 7.54, 7.65, and 7.78 p.p.m. was attributed to the methine proton on carbon 2. The quartet is a result of its spin–spin coupling with the protons of the methyl group and thus represents the methine proton's contribution to the AB_3 system. A doublet at 9.03 and 9.15 p.p.m. was attributed to the methyl protons attached to carbon 2. It formed the remainder of the AB_3 system. The singlet at 8.93 p.p.m. was attributed to one of the methyl groups on carbon 3 which appears at higher field than the other because of the shielding effect of the methyl group on the adjacent carbon 2. The singlet at 8.62 p.p.m. was attributed to the protons of the remaining three methyl groups on carbon 3 and 3′. It is interesting to note that this is not resolved as a doublet as was observed for IX*a* perhaps, because the signal of the three methyl protons on carbon 3′ that lie in the plane of the non-adjacent aromatic ring is only half as intense as that of the six methyl protons on carbons 3 and 3′ out of the plane of the adjacent aromatic rings, and is thus not resolved from the larger signal considering that the shift for two such groups in compound (IX*a*) was only 0.04 p.p.m.

Positive evidence in favor of the proposed mechanism is given by the non-reactivity of 1,1,2,3-tetramethylindene (IV*b*) with α-methylstyrene, and the fact that 3,3-dimethyl-1-ethylindene (IV*c*), in a reaction similar to the one in which compound (IX*a*) was produced from 1,1,3-trimethylindene (IV*a*) and α-methylstyrene, gave the expected product (IX*b*) in higher yield.

Several questions arise concerning the generality of these reactions. It was desirable to determine if an unhindered endocyclic form of an indene (Chart I, IV*d*) would alkylate even if an exocyclic form could exist. If the reaction producing the spirobiindanes is a general one, other suitable olefins and other alkylating agents (besides α-methylstyrene) should enter into the reaction. In attempts to investigate the generality of these reactions, further work was undertaken as described below.

The reaction of 1-methylindene with α-methylstyrene in sulphuric acid yielded a colorless liquid in 50% yield. The ultraviolet spectrum of this product gave bands at 2730 Å (log ϵ = 3.22), 2660 Å (log ϵ = 3.25), and 2600 Å (log ϵ = 3.06). The infrared spectrum gave a doublet at 1390 and 1385 cm^{-1} attributed to the *t*-butyl skeleton, as well as a strong band at 760 cm^{-1} indicating *o*-disubstituted aromatics. The analytical results agreed with a formula $C_{19}H_{20}$ which was substantiated by the mass spectrum which indicated a parent mass of 248. The n.m.r. spectrum (Fig. 3) consisted of a multiplet of maximum intensity at 2.91 p.p.m. corresponding to 8 protons, a series of 10 signals between 6.70 and 7.66 p.p.m. integrating for 3 protons and three singlets at 8.39, 8.62, and 9.05 p.p.m. corresponding to 3 protons each. On the basis of this spectrum, the compound was apparently not a 1,1′-spirobiindane but the 4*b*,9,9-trimethyl-4*b*,9,9*a*,10-tetrahydroindeno[1,2-*a*]indene (VI*b*). This product would form if the protonated α-methylstyrene (II*a*) alkylated the 1-methylindene (IV*d*) at carbon 2 and subsequent reaction

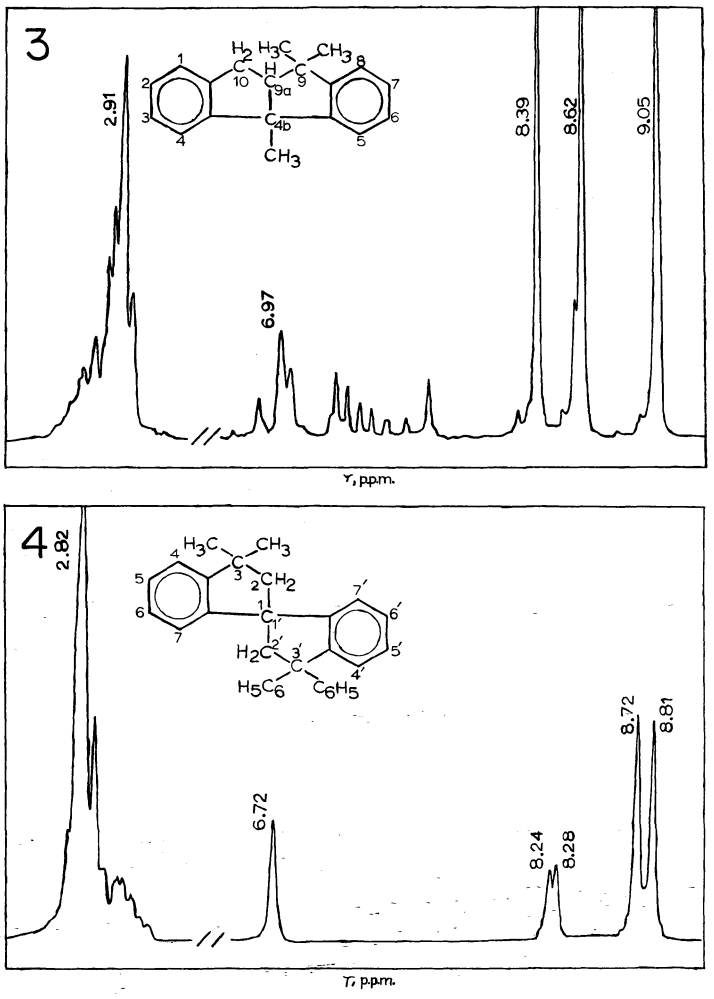

FIG. 3. Nuclear magnetic resonance spectrum of 4*b*,9,9-trimethyl-4*b*,9,9*a*,10-tetrahydroindene[1,2-*a*] indene.

FIG. 4. Nuclear magnetic resonance spectrum of 3,3-dimethyl-3′,3′-diphenyl-1,1′-spirobiindane.

followed the mechanism outlined in Chart I. The multiple signal in the n.m.r. between 6.70 and 7.66 p.p.m. was attributed to an ABC or ABX system consisting of the methine proton on carbon 9*a* and the methylene protons on carbon 10. The singlet at 8.39 p.p.m. was apparently due to one of the methyl groups on carbon 9, which, because of its position relative to the two aromatic rings, is deshielded. The singlet at 8.62 p.p.m. was then attributed to the other methyl group on carbon 9 while that at 9.05 p.p.m. was associated with the protons of the group on carbon 4*b* which, because of the type of fusion along the carbon 4*b* to carbon 9*a* bond, lie well away from either of the aromatic rings and thus resonate at higher field.

The product from the reaction of 1,1,3-trimethylindene (IV*a*) with triphenylcarbinol in sulphuric acid was a crystalline solid, m.p. 171–173° (41% yield). The ultraviolet spectrum gave bands at 2733 Å (log ϵ = 3.19), 2663 Å (log ϵ = 3.31), and a slight inflection at 2610 Å (log ϵ = 3.21). The infrared spectrum gave strong bands at 768, 755, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

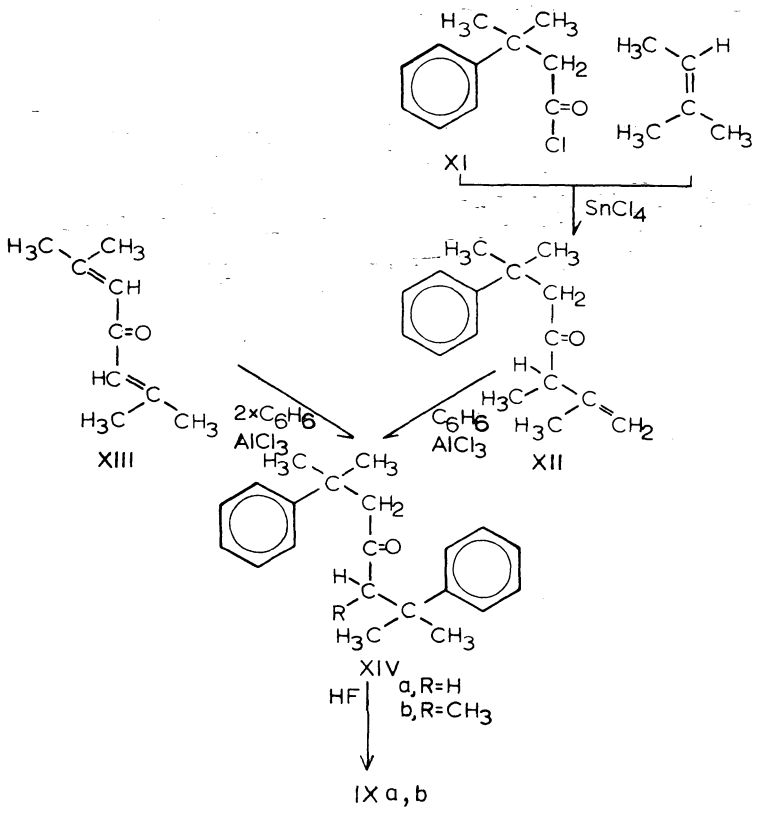
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

702 cm^{-1} indicative of both *o*-disubstituted and monosubstituted aromatics. The mass spectrum showed a parent mass of 400. This was substantiated by an analytical result which agreed with the molecular formula $C_{31}H_{28}$. This evidence suggested the compound was the expected 3,3-dimethyl-3′,3′-diphenyl-1,1′-spirobiindane (IX*c*). This was substantiated by the n.m.r. spectrum (Fig. 4) which gave an 18 proton multiplet at 2.82 p.p.m. A singlet at 6.72 p.p.m. integrating for 2 protons was attributed to the methylene protons on carbon 2′ which are deshielded by the adjacent aromatic ring attached to carbon 3′. A doublet at 8.24 and 8.28 p.p.m. integrated for 2 protons and was attributed to the methylene protons on carbon 2. The two methyl groups on carbon 3 gave signals at 8.72 and 8.81 p.p.m. respectively. The chemical shift of one of the methyl groups to lower field is attributed to that methyl group being in the plane of an aromatic ring as it was in compound IX*a*. The fact that the shift is greater in this case than was observed for compound IX*a* is attributed to the fact that a buttressing effect of the two bulky phenyl groups on carbon 3′ causes the other aromatic ring attached to that carbon to approach the methyl group on carbon 3 more closely than in compound IX*a* with the result that it is significantly more shielded.

As proof of the structures of two of the compounds prepared, namely, the 3,3,3′,3′-tetramethyl (IX*a*) and the 2,3,3,3′,3′-pentamethyl-1,1′-spirobiindane (IX*b*), these compounds were synthesized by unequivocal methods as outlined in Chart III.

The synthesis of (IX*a*) was realized by first treating benzene with phorone (XIII) in

CHART III



the presence of aluminum chloride to produce the 2,6-dimethyl-2,6-diphenyl-4-heptanone (XIV*a*) reported by Colonge and Pichat (6) in 70% yield. This compound had the expected n.m.r. spectra. Cyclization of this ketone with anhydrous hydrogen fluoride yielded (IX*a*) in 78% yield.

The synthesis of the 2,3,3,3′,3′-pentamethyl-compound (IX*b*) was carried out by first treating 3-methyl-3-phenylbutanoyl chloride (XI) with 2-methyl-2-butene and stannic chloride to yield 2,3,6-trimethyl-6-phenyl-1-heptene-4-one (XII). Reaction of this with benzene and aluminum chloride furnished 2,3,6-trimethyl-2,6-diphenyl-4-heptanone (XIV*b*). Treatment of this ketone with hydrogen fluoride yielded (IX*b*) identical with the (IX*b*) from the reaction of 3,3-dimethyl-1-ethylindene with α-methylstyrene.

EXPERIMENTAL

Apparatus and Methods

The ultraviolet spectra were recorded on a Beckman DK-2 ratio recording spectrophotometer using spectro grade cyclohexane as solvent. The infrared spectra were recorded on a Perkin–Elmer Model 137 "Infracord" spectrophotometer. Gas–liquid chromatography analyses were carried out on a Perkin–Elmer 154-D vapor fractometer or on an F & M Model 500 programmed temperature gas chromatograph equipped with a dual column attachment. Small samples of pure compounds were obtained by repetitive chromatography of a mixture followed by collection of pure components. The mass spectrometer analyses were done at an independent laboratory. Nuclear magnetic resonance spectra were recorded at the National Research Council, Halifax, Nova Scotia, on a Varian A-60 spectrometer using tetramethylsilane as internal standard and carbon tetrachloride as solvent. Melting points were determined on a Fischer–Johns melting point apparatus equipped with a microscope or on a Thomas–Hoover "Unimelt" capillary melting point apparatus. Reactions with anhydrous hydrogen fluoride were carried out in a 12-in. stainless steel MD test tube reactor equipped with stainless steel gaskets made by Autoclave Engineers Inc. Ultimate analyses were determined by Dr. E. Thommen, Basel, Switzerland and Dr. C. Daessle, Montreal.

*Preparation of 1,1,3-Trimethylindene (IV*a*)*

Benzene (800 ml) and aluminum chloride (360 g) were mixed at room temperature. Mesityl oxide (200 ml) was added dropwise to the stirred mixture over 45 minutes without external cooling. After 4 hours at room temperature, the mixture was hydrolyzed on ice. The organic material was separated and the aqueous layer was extracted with benzene. The combined organic layer and benzene extract were washed with 10% sodium carbonate, water, and dried over sodium sulphate. The solvent was distilled and the residue was further distilled *in vacuo* yielding 14.08 g of 1,1,3-trimethylindene, b.p. 50° at 0.65 mm, n_D^{25} = 1.5346 (literature (7), n_D^{25} = 1.5346), and 40.37 g of 4-methyl-4-phenyl-2-pentanone, b.p. 78–81° at 0.85 mm. Gas–liquid chromatography of the two products on an 8 ft silicone gum rubber column showed they were pure.

*3,3,3′,3′-Tetramethyl-1,1′-spirobiindane (IX*a*)*

The procedure for preparing IX*a* was essentially that of Barnes (2) except that phenyldimethylcarbinol was replaced by α-methylstyrene. The sulphuric acid catalyzed reaction between 1,1,3-trimethylindene (5 g, 0.031 mole) and α-methylstyrene (3.6 g, 0.031 mole) yielded 5.5 g of crude solid shown to be 81% compound IX*a* (a 54% yield) and 19% the saturated cyclic dimer of α-methylstyrene by gas–liquid chromatography.

The compound IX*a*, after recrystallization from methanol, had a melting point of 133–134° (literature (1) 133–134°). The ultraviolet spectrum gave bands at 2730 Å (log ε = 3.12), 2660 Å (log ε = 3.05), and 2595 Å (log ε = 2.99). This compound proved to be identical, by mixed melting point and infrared spectra, with the hydrocarbon prepared directly from 4-methyl-4-phenyl-2-pentanone according to the procedure of Hoffman (1). The infrared spectrum was identical with that reported by Adams and co-workers (3). The n.m.r. spectrum gave an 8-proton multiplet at 2.89 and 3.30 p.p.m., a 4-proton singlet at 7.72 p.p.m., and a 12-proton doublet at 8.61 and 8.65 p.p.m. The mass spectrum showed a parent mass of 276.

*Preparation of 1,1,2,3-Tetramethylindene (IV*b*)*

(a) Preparation of 3,4-Dimethyl-3-pentene-2-one

Acetyl chloride (55.75 g, 0.71 mole) and 2-methyl-2-butene, b.p. 38–41° (76.6 g, 1.09 mole), were reacted with anhydrous stannic chloride (7.1 g) according to the procedure of Colonge (8). The olefin and the acid chloride were cooled in ice and salt and the stannic chloride was added dropwise while the temperature was maintained below 0°. The mixture was then allowed to warm slowly to room temperature and finally was heated at 60–80° for 2 hours and allowed to cool slowly.

After hydrolysis on ice, extraction with ether, and washing the ether extract free of acid and drying, the solvent was distilled. Distillation of the residual liquid yielded 41.14 g of colorless liquid, b.p. 148–150°

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(with the evolution of a great deal of hydrogen chloride) $n_D^{14} = 1.4491$ (literature (8), $n_D^{14} = 1.4506$). Gas–liquid chromatography showed a 99% pure product.

(b) Preparation of 1,1,2,3-Tetramethylindene

Twenty-eight grams (0.25 mole) of 3,4-dimethyl-3-pentene-2-one was cooled below 0° and hydrogen chloride (10 g) 0.27 mole, was bubbled in, thus forming the 4-chloro-3,4-dimethyl-2-pentanone. This was added dropwise to a stirred mixture of benzene (100 ml, 1.15 mole) and aluminum chloride (50 g, 0.37 mole) while the temperature was maintained at 0–10°. After it was stirred for an additional 3 hours in the cold, the mixture was hydrolyzed on ice and hydrochloric acid. The organic layer was separated, washed free of acid, and dried over sodium sulphate. Distillation yielded 19.96 g of 1,1,2,3-tetramethylindene, b.p. 76–82° at 1.6 mm, $n_D^{25} = 1.5384$ (literature (9), $n_D^{25} = 1.5431$.

Reaction of 1,1,2,3-Tetramethylindene with α-Methylstyrene

The 1,1,2,3-tetramethylindene (5.30 g, 0.031 mole) and α-methylstyrene (3.6 g, 0.031 mole) were cooled to −5° in ice and salt. Sulphuric acid (41 ml) was added dropwise with vigorous stirring as described above. After the procedure was repeated as for 1,1,3-trimethylindene, distillation of the solvent yielded 3.66 g of viscous liquid. Gas–liquid chromatography showed it to be mostly the saturated cyclic dimer of α-methylstyrene with no higher boiling material.

Preparation of 3,3-Dimethyl-1-ethylindene (IVc)

(a) 3,3-Dimethyl-1-indanone

3-Methyl-3-phenylbutanoic acid, prepared by the alkylation of benzene with 3-methyl-2-butenoic acid (10), had a melting point of 55–57° (literature (11), m.p. 58–59°). This acid was converted to 3,3-dimethyl-1-indanone according to the procedure of Koelsch and Le Clair (11).

(b) Preparation of 3,3-Dimethyl-1-ethylindene

A Grignard reagent was prepared from 4.86 g (0.045 mole) of ethyl bromide and 0.72 g (0.032 mole) of magnesium in 30 ml of anhydrous ethyl ether. Crude 3,3-dimethyl-1-indanone (from part *a*) (4.31 g, 0.026 mole) in 15 ml of ether was added to the reagent over 45 minutes while the temperature was maintained at 0–5°. The mixture was then refluxed for 2 hours and hydrolyzed on ice. The crude product isolated by extraction with ether was refluxed for 2 hours with 10% aqueous oxalic acid and the oil obtained by ether extraction was chromatographed from petroleum ether on alumina. The first fraction from the alumina column yielded 1.71 g of an oil which was mainly the desired indene according to the similarity of its ultraviolet and infrared spectra with those of 1,1,3-trimethylindene. There was a slight contamination with the starting ketone as shown by a weak band for carbonyl absorption at 1700 cm^{-1}.

2,3,3,3′,3′-Pentamethyl-1,1′-spirobiindane (IXb)

The 3,3-dimethyl-1-ethylindene (0.50 g, 0.0029 mole) and α-methylstyrene (0.34 g, 0.0029 mole) were cooled to −15° and sulphuric acid (5.0 g) was added as described before. Distillation of the solvent after completion of the reaction and extraction with petroleum ether yielded 0.52 g of solid. Gas–liquid chromatography indicated that the major component (90%) was not compound IX*a* but a higher boiling one. The solid was fractionally sublimed *in vacuo*. Recrystallization of the fractions from absolute ethanol yielded colorless crystals, m.p. 118–119°. The ultraviolet spectrum gave bands at 2730 Å ($\log \epsilon = 3.33$), 2660 Å ($\log \epsilon = 3.29$), and 2590 Å ($\log \epsilon = 3.08$). The infrared spectrum gave a doublet in the 1385–1365 cm^{-1} region attributed to the *t*-butyl structure and two bands of equal intensity at 765 and 750 cm^{-1} attributed to *o*-disubstituted aromatics. The n.m.r. spectrum showed an 8-proton multiplet with maximum intensities at 2.90 and 3.32 p.p.m., a 2-proton quartet at 7.37, 7.60, 8.08, and 8.32 p.p.m., a single proton quartet at 7.47, 7.54, 7.65, and 7.78 p.p.m., a 3-proton singlet at 8.93 p.p.m., a 3-proton doublet at 9.03 and 9.15 p.p.m., and a 9-proton singlet at 8.62 p.p.m. The mass spectrum indicated a parent mass of 290. Analysis—Found: C, 90.30, 90.38; H, 9.31, 9.29. Calculated for $C_{22}H_{26}$: C, 90.98; H, 9.02.

4b,9,9-Trimethyl-4b,9,9a,10-tetrahydroindeno-[1,2a]-indene (VIb)

The 1-methylindene was prepared following the procedure of Stoermer and Laage (12) using the modification of Parham and co-workers (13). The product distilled at 84° at 11 mm, $n_D^{25} = 1.5630$ (literature (13), b.p. 76–78° at 11 mm, $n_D^{25} = 1.5587$) yielding 7.63 g of 1-methylindene.

The 1-methylindene (0.78 g, 0.006 mole) and the α-methylstyrene (0.71 g, 0.006 mole) were reacted with sulphuric acid as described above to yield 0.66 g of viscous liquid. Gas–liquid chromatography on a silicone grease column showed it to be 12% the saturated cyclic dimer of α-methylstyrene and 62% a compound which was not IX*a*. An attempt to separate the major component by molecular distillation was unsuccessful. Small samples were then repeatedly chromatographed on the F & M Model 500 and the compound collected as a colorless liquid. The ultraviolet spectrum gave bands at 2730 Å ($\log \epsilon = 3.22$), 2660 Å ($\log \epsilon = 3.25$), and 2600 Å ($\log \epsilon = 3.06$). The infrared spectrum gave a doublet at 1390 and 1385 cm^{-1} characteristic of a *t*-butyl group and also showed a strong band at 760 cm^{-1} for *o*-disubstituted aromatics. The mass spectrum showed a parent mass of 248. The n.m.r. spectrum gave an 8-proton multiplet at 2.91 p.p.m., a complex 3-proton 10-band ABC or ABX multiplet between 6.70 and 7.66 p.p.m., and three

3-proton singlets at 8.39, 8.62, and 9.05 p.p.m. Analysis—Found: C, 91.07, 90.92; H, 8.11, 8.07. Calculated for $C_{19}H_{20}$: C, 91.54; H, 8.46.

3,3-Dimethyl-3',3'-diphenyl-1,1'-spirobiindane (IXc)

The 1,1,3-trimethylindene (1.0 g, 0.006 mole) and triphenylcarbinol (1.56 g, 0.006 mole) were reacted with 8 ml of sulphuric acid as described above. After 2 hours' stirring the temperature had risen to 10°. The mixture was extracted with benzene after standing overnight at room temperature. Subsequent washing, drying, and distillation of the solvent yielded 1.0 g (41% yield) of solid. The solid was chromatographed from benzene on alumina to yield a thick oil which crystallized on treatment with acetone. Recrystallization from acetone yielded colorless crystals, m.p. 171–173°. The ultraviolet spectrum gave bands at 2733 Å (log ϵ = 3.19), 2663 Å (log ϵ = 3.31), and an inflection at 2610 Å (log ϵ = 3.21). The infrared spectrum showed strong bands at 768, 755, and 702 cm^{-1} apparently due to both *o*-disubstituted and monosubstituted aromatics. The mass spectrum showed a parent mass of 400. The n.m.r. spectrum showed an 18-proton multiplet at 2.82 p.p.m., a 2-proton singlet at 6.72 p.p.m., a 2-proton doublet at 8.24 and 8.28 p.p.m., and two 6-proton singlets at 8.72 and 8.81 p.p.m. Analysis—Found: C, 92.83, 92.90; H, 7.08, 7.20. Calculated for $C_{31}H_{28}$: C, 92.95; H, 7.04.

Synthesis of 3,3,3',3'-Tetramethyl-1,1'-spirobiindane (IXa)

(a) Preparation of 2,6-Dimethyl-2,6-diphenyl-4-heptanone (XIVa)

Benzene (64 g, 0.82 mole) and aluminum chloride (26.0 g, 0.27 mole) were cooled to 15–20°. Phorone (27.6 g, 0.20 mole) was added with stirring over 45 minutes at 15–20°. The mixture was stirred for 4 hours and allowed to stand for 43 hours at room temperature. After hydrolysis on ice, extraction, drying, and distillation of the solvent, the residue was distilled to yield 41.5 g of the desired ketone, b.p. 158–160° at 0.45 mm, n_D^{19} = 1.5462 (literature (6), n_D^{17} = 1.5465). The infrared spectrum indicated a monosubstituted aromatic ketone. The carbonyl absorption appeared at 1700 cm^{-1} and two strong bands at 700 cm^{-1} and 830 cm^{-1} were attributed to a monosubstituted aromatic. The ultraviolet spectrum gave bands at 2640 Å (log ϵ = 2.70), 2585 Å (log ϵ = 2.77), and 2535 Å (log ϵ = 2.71). The n.m.r. spectrum gave a 10-proton singlet at 2.95 p.p.m., a 4-proton singlet at 7.73 p.p.m., and a 12-proton singlet at 8.76 p.p.m.

(b) Reaction of 2,6-Dimethyl-2,6-diphenyl-4-heptanone with Hydrogen Fluoride

The hydrogen fluoride (10.0 g) was condensed in the cold reactor tube. The ketone (9.11 g, 0.031 mole) was added rapidly. The tube was sealed and stirred for 24 hours. It was then cooled and opened. The contents were solid. Petroleum ether was added to dissolve the solid. The ether extract was washed free of acid with water and dried. Distillation of the solvent yielded 7.35 g of solid. Gas–liquid chromatography on a 2-m silicone grease column indicated the solid was 89% compound IX*a* (75% yield). Recrystallization from methanol gave colorless needles, m.p. 135–136°. A mixed melting point and infrared spectrum showed this product to be identical with IX*a* produced from 1,1,3-trimethylindene and α-methylstyrene.

Synthesis of 2,3,3,3',3'-Pentamethyl-1,1'-spirobiindane (IXb)

(a) Preparation of 2,3,6-Trimethyl-6-phenyl-1-heptene-4-one (XII)

Ten grams (0.051 mole) of 3-methyl-3-phenylbutanoyl chloride and 2-methyl-2-butene (4.68 g, 0.068 mole) were cooled below −5°. Anhydrous stannic chloride (1.5 g) was added dropwise with stirring while the temperature was maintained below 0°. The mixture was then allowed to warm slowly to room temperature. After 7 hours, the reaction was hydrolyzed on ice. After extraction with benzene, washing, drying, and distilling the solvent, the residual liquid distilled at 120° at 1.8 mm yielding 6.88 g of a colorless liquid. Gas–liquid chromatography indicated two components which were found by infrared and ultraviolet spectra to be the two isomeric olefins possible. The infrared spectrum of the major component showed carbonyl absorption at 1700 cm^{-1} and a strong band at 900 cm^{-1} attributed to out-of-plane deformations of the protons of the terminal methylene group of XII. The ultraviolet spectrum of this component showed fine structure in the absorption at 2640, 2585, and 2525 Å typical of a substituted (non-conjugated) aromatic compound. On the other hand, the ultraviolet spectrum of the minor component separated on the chromatograph showed a broad band at 2400–2420 Å, presumably indicative of the conjugated isomer of XII.

(b) Preparation of 2,3,6-Trimethyl-2,6-diphenyl-4-heptanone (XIVb)

Benzene (4.68 g, 0.06 mole) and aluminum chloride (2.66 g, 0.020 mole) were mixed and cooled to 5–10°. The 2,3,6-trimethyl-6-phenyl-1-heptene-4-one (3.44 g, 0.015 mole) was added over 30 minutes while the temperature was maintained by cooling. The mixture was allowed to warm slowly to room temperature. Gas–liquid chromatography of an aliquot after 3 hours indicated little starting olefin. The mixture was hydrolyzed at once on ice. After the usual extraction and subsequent treatment, the residue distilled at 172–174° at 0.8 mm to yield 2 g of a viscous yellow oil, n_D^{17} = 1.5460. The product showed strong carbonyl absorption at 1700 cm^{-1}, lacked the olefinic proton absorption of the starting material at 900 cm^{-1}, and was generally very similar to the spectrum of 2,6-dimethyl-2,6-diphenyl-4-heptanone. Analysis—Found: C, 86.35; H, 9.35. Calculated for $C_{22}H_{28}O$: C, 85.66; H, 9.12.

(c) Reaction of 2,3,6-Trimethyl-2,6-diphenyl-4-heptanone with Hydrogen Fluoride

The hydrogen fluoride (10 g) was condensed in the cooled reactor. The ketone (1.0 g, 0.003 mole), dissolved

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in 6 ml of carbon tetrachloride, was added rapidly. The tube was sealed, stirred for 1 hour, and allowed to stand for 8 hours at room temperature. After the reactor was cooled and opened in the usual way, the contents were poured on ice. Subsequent treatment yielded 0.90 g of solid. Gas–liquid chromatography of this on an 8-ft silicone gum rubber column showed four components with the major one having a retention time identical with that of a sample of IX*b*. Recrystallization from ethanol yielded a colorless crystalline solid, m.p. 116–119°. A mixed melting point with a sample of IX*b* from the reaction of 3,3-dimethyl-1-ethylindene with α-methylstyrene showed no depression. The infrared spectra of the two samples were identical.

ACKNOWLEDGMENTS

The authors wish to thank Dr. G. McInnes of the National Research Council, Halifax, Nova Scotia, for recording the n.m.r. spectra. Financial assistance from the National Research Council is gratefully acknowledged.

ABSTRACT

Infrared spectra of various types of organosulphur compounds have been examined and group frequencies arising from C—S, S—S, N—S, O—S, and C=S stretching vibrations have been assigned and discussed. The C—S bands of thioketals and S—S bands of tri- and tetra-sulphides show splittings due to vibrational coupling. The O—S and N—S stretching frequencies are found around 890 and 820 cm^{-1} respectively, values which are much higher than the C—S stretching frequencies. Potassium alkyl xanthates exhibit the asymmetric and symmetric stretching frequencies of the CS_2^- ion. The splitting of C—O and C=S stretching bands in dialkyl dixanthogens have been interpreted in terms of the Fermi interaction with the combination tone of C—S and S—S stretching vibrations and with the overtone of S—S stretching vibrations respectively. The relative intensity of the C=S stretching bands in a few derivatives show marked dependence on the electronegativities of the elements directly linked to the thiocarbonyl group. It is found that the earlier assignments of the "—N—C=S bands" due to mixed vibrations in thioamide type derivatives have been found to be well justified on the basis of the recent normal coordinate treatment. Another band tentatively designated as the "—N—C=S IV band" has been assigned for these derivatives in the region 850–680 cm^{-1}. Examination of the spectra of a number of thioamide type derivatives has shown no evidence for the presence of thiol tautomers. All of them exist as thiones exhibiting characteristic N—H absorption and "—N—C=S bands".

INTRODUCTION

Infrared spectra of organosulphur compounds have been recently reviewed by Bellamy (1). The uncertainty regarding the assignment of C=S stretching frequency in the literature has been examined by Rao and Venkataraghavan (2), who have carried out detailed correlations and have distinguished two groups of thiocarbonyl derivatives: the first group, where the thiocarbonyl group is linked to atoms such as carbon, sulphur, oxygen, and chlorine; and the second group, where the thiocarbonyl group is linked to one or two nitrogen atoms. An unambiguous assignment of the C=S stretching frequency seems to be possible only when the C=S group is attached to atoms other than nitrogen. Strong vibrational coupling is operative in the case of nitrogen-containing thiocarbonyl derivatives and three bands seem to consistently appear in the regions 1397–1570 cm^{-1}, 1260–1420 cm^{-1}, 940–1140 cm^{-1} due to mixed vibrations ("—N—C=S bands"). In this communication we have reported and discussed the assignments of infrared group frequencies

associated with the C—S, S—S, O—S, N—S, and C=S stretching vibrations in several types of organosulphur compounds. We have also discussed the "—N—C=S bands" in the light of the results of the normal coordinate treatment.

EXPERIMENTAL

Preparation of Compounds

Ethylene-thioketals of (i) 3,20-dioxo-4-oxa-5α-pregnane, (ii) cholestane-3-one, and (iii) methyl *i*-butyl ketone were prepared by the methods described in the literature (3–5). The general method consists in treating a solution of the corresponding ketone in ethane-1,2-dithiol with borontrifluoro-ethereate. Compounds (i) and (ii) are solids melting at 237–239° C and 146–147° C respectively. The last one is a liquid boiling at 72–73° C at 1.5 mm. Dialkyl dixanthogens were obtained by the oxidation of the corresponding potassium alkyl xanthates with iodine (5, 6). Potassium alkyl xanthates were prepared by the addition of carbon disulphide to the corresponding potassium alkoxide at 0° C. Isoperthiocyanic acid was prepared by the decomposition of thiocyanic acid (7). The hydrochloride of 3,5-diimino-1,2,4-dithiazoline was prepared by the oxidation of dithiobiuret (8). Piperidine mono- and di-sulphides were prepared by the reaction of sulphur dichloride and sulphur monochloride respectively with piperidine in petroleum ether solution (9). The two sulphides were purified by crystallization from alcohol and obtained as needle-shaped crystals melting at 74° C and 64° C respectively. Piperidine tri- and tetra-sulphides were prepared by dissolving piperidine and sulphur in benzene and treating with lead oxide at 0° C and 50° C respectively and were purified by recrystallization from absolute alcohol solution (9). Piperidine trisulphide is a crystalline solid melting at 74° C and the tetrasulphide is an amorphous solid melting at 78° C. Dimethoxy disulphide and tetraethyl dithiodiamine were kindly given to us by Professor A. R. V. Murthy.

Thiofenchone was prepared by refluxing fenchone with phosphorus pentasulphide in heptane. *n*-Butyl-dithioacetate was prepared starting from acetonitrile and *n*-butylmercaptan (10). Thiatriazolinethiones were prepared by the reaction of carbon disulphide with azide ion and further esterification (11). Thiohydrazides were prepared by the reaction of hydrazine with the corresponding thioacids (12). Thiourethanes were prepared by refluxing isothiocyanates with ethyl alcohol (13). All the other compounds used in this study were commercially available.

Spectra

Infrared spectra were recorded employing Perkin–Elmer, Model 221 and Grubb–Parsons double-beam spectrometers fitted with NaCl and KBr prisms. Some of the spectra were also recorded with a Perkin–Elmer 137B spectrometer. The samples were in the form of solutions in CCl_4 and $CHCl_3$ or solids dispersed in Nujol mulls or KBr pellets.

RESULTS AND DISCUSSION

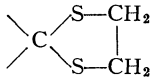
C—S Stretching Frequency

The C—S stretching vibration has been assigned to a weak band in the region 700–600 cm^{-1} (14). We have examined the infrared spectra of several alkyl thiocyanates (I) and have found

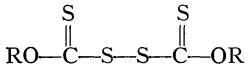
R—S—C≡N

I

weak to medium intensity bands in the region 772–622 cm^{-1}. In these compounds one should probably expect the C—S—C asymmetric and symmetric stretching vibrations instead of C—S stretching vibrations. In fact we observe two bands in all these compounds in the 772–622 cm^{-1} region, possibly due to the asymmetric and symmetric stretching vibrations. Infrared spectra of thioketals show broad bands with several maxima in the region 745–650 cm^{-1}, probably due to vibrational coupling in the thioketal unit (II), just as in ketals (15). Dialkyl dixanthogens (III) show the C—S stretching between 690 and



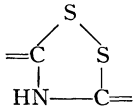
II



III

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

685 cm^{-1}. 1,2,4-Dithiazoline derivatives (IV) have been found to show at least two



IV

bands in the range 635–602 cm^{-1} which may be due to C—S stretching vibrations.

S—S Stretching Frequency

The S—S linkage generally gives rise to a weak stretching band in the range 500–400 cm^{-1} (14). We have examined the infrared spectra of several compounds containing S—S bonds and the results are summarized below.

Compound	Band position, cm^{-1}
Dialkyl dixanthogens (III)	510–505
$H_{10}C_5N—(S)_n—NC_5H_{10}$ (n = 2, 3, 4)	448–418
Dithiazolines (IV)	440–418

It is interesting to find that dipiperidine tri- and tetra-sulphides show multiplicity in the bands, probably due to vibrational coupling.

O—S and N—S Stretching Frequencies

The S—O stretching frequency has been observed as a strong band around 900 cm^{-1} in the spectra of sulphonic acids (16) and around 860 cm^{-1} in sulphinic acids (17). In sulphonic acid esters this band appears around 780 cm^{-1} (16, 18). In covalent sulphites the in-phase and out-of-phase S—O stretching frequencies have been assigned in the regions 720–690 and 760–730 cm^{-1} (16). In dimethyl sulphate, the S—O stretching absorptions are found at 752 and 875 cm^{-1} (16). We have examined the infrared spectrum of the disulphide, $H_3CO—S—S—OCH_3$ and find the O—S stretching frequency as a strong band at 890 cm^{-1}.

The N—S stretching vibration has been assigned in several sulphonamide derivatives. In methane sulphonamides this appears as a medium intensity band in the region 912–866 cm^{-1} (19). In N-methyl-*p*-tolyl sulphonamides the N—S stretching frequency has been assigned at 839 cm^{-1} (20). In N,N′-disubstituted-N-benzenesulphonyl and N-methanesulphonyl formamidine derivatives the N—S stretching band appears between 906 and 828 cm^{-1} (21). Dipiperidine mono-, di-, tri-, and tetra-sulphides exhibit an intense band around 830 cm^{-1} probably due to the N—S stretching vibration. The compound $(C_2H_5)_2—N—S—S—N—(C_2H_5)_2$ shows the N—S stretching band at 807 cm^{-1}.

C=S Stretching Frequency

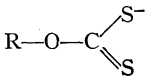
Rao and Venkataraghavan (2) have recently assigned the C=S stretching frequency to the region 1225–1025 cm^{-1} in thiocarbonyl derivatives where the C=S group is linked to elements other than nitrogen. We have now examined the infrared spectra of a few potassium alkyl xanthates and dialkyl dixanthogens (III) in detail. In potassium alkyl xanthates (V), we should have the limiting case of the dependence of the C=S stretching frequency on the double bond character of the thiocarbonyl linkage just as in the case of the carboxylate anion. One should therefore expect to find the asymmetric and symmetric CS_2^- stretching frequencies. We have tentatively assigned a medium intensity band in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the range 1060–1045 cm^{-1} to the asymmetric stretching vibration and a weak band between 833–819 cm^{-1} to the symmetric stretching vibration. The asymmetric stretching bands show splitting in solid state probably due to crystal field effects. The C—O stretching frequency in potassium alkyl xanthates is considerably reduced (1186–1140 cm^{-1}) compared to that in dialkyl dixanthogens (~1260 cm^{-1}). These results are hard to understand since one would expect an increase in C—O frequency due to the different canonical structures V*a*, V*b*, and V*c* of the xanthate ion. It is not clear whether we should again reverse the assignments of C—O and C=S stretching frequencies in dialkyl dixanthogens (22). Although the arguments regarding the relationship between double bond character

V*a*

V*b*



V*c*

and C—O and C=S group frequencies favor the low frequency assignment (1045–1010 cm^{-1}) to C—O and high frequency assignment (1270–1255 cm^{-1}) to C=S as reported by Shankaranarayana and Patel (23), it would still be very difficult to accept such a low frequency for C—O stretching in structures of this type where one would expect "contiguous" C—O bands (24).

The C—O and C=S stretching bands in dialkyl dixanthogens (III) show considerable splitting. On closer examination, we find that this may be due to Fermi interaction. The combination tone of C—S (690–685 cm^{-1}) and S—S (510–505 cm^{-1}) stretching vibrations seems to interact with the C—O stretching vibration (1270–1255 cm^{-1}), while the overtone of the S—S stretching frequency seems to interact with the C=S stretching vibration (1045–1010 cm^{-1}).

We have studied the relative intensities of the C=S bands in a few thiocarbonyl derivatives where the C=S stretching vibration is highly localized and the results are summarized below. In general, it appears that the C=S stretching band intensity varies fairly markedly with the electronegativity of the elements directly linked to the thiocarbonyl group.

Compound	*X*	*Y*	ϵ^{a}_{max}	$\Delta\nu^{a}_{\frac{1}{2}}$ cm^{-1}	Intensity ratio*
Thiofenchone	C	C	140	26	1
n-Butyl-dithioacetate	C	S	1538	21	7
Ethylenetrithiocarbonate	S	S	5350	21	16
Diisopropyldixanthogen	O	S	3890	46	54

*With respect to thiofenchone taken as unity.

"—*N*—*C*=*S Bands*"

Rao and Venkataraghavan (2) assigned three —N—C=S bands due to mixed vibrations in the regions 1395–1570 cm^{-1}, 1270–1420 cm^{-1}, 940–1140 cm^{-1} in thiocarbonyl derivatives where the C=S group is linked to one or two nitrogen atoms and pointed out the need for normal coordinate treatment to establish the nature of the mixed vibrations responsible for the —N—C=S bands. Recently, Suzuki (25) has carried out extensive normal coordinate calculations of thioformamide, thioacetamide, N-methylthioformamide, and N-methylthioacetamide. It is heartening to find adequate correlations between the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

—N—C=S bands suggested by Rao and Venkataraghavan and the assignments of Suzuki. All primary thioamides show a band around 1620 cm^{-1} which is completely due to the NH_2 deformation vibration. In primary thioamide derivatives, —N—C=S I band is mostly due to C—N stretching. In thiourea, it is probably due to N—C—N asymmetric stretching. In secondary thioamides, NH deformation and C—N stretching constitute the —N—C=S I band. The —N—C=S II band in primary thioamides is due to a mixed vibration involving CH deformation, C—N stretching, C—C stretching, NH_2 bending, and C=S stretching, depending on the nature of the compound. Thus, in thioformamide the band at 1325 cm^{-1} is due to CH deformation and C—N stretching and in thioacetamide the band at 1306 cm^{-1} has been shown to have contributions from NH_2 bending, C—C stretching, and C=S stretching (25). In thiourea this band may be mostly due to N—C—N symmetric stretching vibration. In secondary thioamides, —N—C=S II band is mostly due to C—N stretching, NH deformation, and CH deformation. Thus, in N-methylthioformamide, the band at 1297 cm^{-1} has contributions from CH deformation, NH deformation, and C—N stretching. In N-methylthioacetamide CH_3—C deformation, C—N stretching, and NH deformation contribute to the —N—C=S II band (25). In primary thioamides and in thiourea itself, the —N—C=S III band is due to C=S stretching and NH_2 bending. The —N—C=S III band in secondary thioamides involve contributions from C—N stretching, C=S stretching, and CH_3 bending. Suzuki's studies (25) indicate that in addition to the —N—C=S I, II, and III bands all the nitrogen containing thiocarbonyl derivatives also show a band in the region 850–680 cm^{-1} due to a mixed vibration involving considerable contribution from C=S stretching. This band may be tentatively designated as the —N—C=S IV band. The description of the —N—C=S IV bands for some of the derivatives are shown below. On closer examination, we find that many of the derivatives studied earlier by us (2) also show absorption in the region 900–670 cm^{-1} probably due to the —N—C=S IV band.

Compound	Band position, cm^{-1}	Assignment (25)
Thioformamide	843	$\nu_{C=S} + \nu_{NH_2}$
Thioacetamide	718	$\nu_{C=S} + \nu_{CC}$
N-Methylthioformamide	868	$\nu_{C=S} + \nu_{CN}$
N-Methylthioacetamide	690	$\nu_{C=S} + \nu_{CC}$
Thiourea*	732	$\nu_{C=S} + \nu_{NH_2}$

*Our assignment.

We have looked into the spectra of several other nitrogen containing thiocarbonyl derivatives and the assignments of the —N—C=S bands are summarized below. In the

case of thiourethanes (VI), one of the —N—C=S bands in the region 1507–1492 cm^{-1}

Compound	Number of derivatives	Band position, cm^{-1} —N—C=S I	—N—C=S II	—N—C=S III
Thiohydrazides	8	1545–1495	1325–1300	1050–1010
Thiatriazolinethiones	4	1495–1440	1340–1315	943–916
Thiourethanes	5	1507–1492	1341–1304	1134–1130

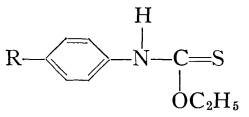
*Data taken from the reference indicated.

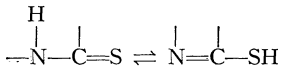


VI

seems to show slight dependence of its position on the electrical property of the para substituent. This may probably be due to the dependence of the Ph—N stretching vibration on the nature of the para substituent, since the transmission of electrical effects is through the Ph—N bond.

Thione–Thiol Tautomerism in Thioamides

Thione–thiol tautomerism (VII–VIII) has been suggested to occur in many thioamide



VII VIII

type derivatives based on the fact that many of them give rise to S-alkyl and N-alkyl derivatives depending on reaction conditions. But infrared evidence clearly shows that most of these derivatives exist only as the thiones (VII). During the course of our investigations, we have examined the infrared spectra of several of these derivatives, such as thiosemicarbazides, thiohydrazides, thiourethanes, 5-mercaptotetrazoles, 2- and 2,5-di-mercaptothiazoles, 5-mercapto-1,2,3,4-thiatriazoles, and 2-mercaptobenzthiazole and all these derivatives fail to show the S—H stretching frequency. Instead, they show N—H absorption and the —N—C=S bands. We have never come across a system which shows evidence for the mercapto structure VIII. Apparently, the proton always tends to go to the more electronegative nitrogen in such derivatives. The fact that one can prepare both S-alkyl and N-alkyl derivatives under suitable conditions is satisfactorily explained on the basis of proton transfer in these highly hydrogen bonded systems as suggested by Bellamy and Williams (26).

ACKNOWLEDGMENTS

The authors' thanks are due to Professor D. K. Banerjee and Professor M. R. A. Rao for their interest and to Professor A. R. V. Murthy for kindly giving some of the compounds studied by us.

ABSTRACT

Infrared spectra of 5-membered N- and N,S-heterocyclic derivatives such as triazoles, tetrazoles, thiazoles, thiadiazoles, thiatriazoles, and dithiazoles have been examined and empirical assignments have been made. The spectra of the two dithiazolidine derivatives, isoperthiocyanic acid and oxidation product of dithiobiuret, have been studied in detail. Assignments for benzthiazole derivatives are reported. The CH out-of-plane deformation bands of benzene rings fused to five-membered heterocyclic rings have been found to be in the region 760–740 cm^{-1}, characteristic of four adjacent benzenoid hydrogen atoms.

INTRODUCTION

Since the calculation of the normal vibrations of heterocyclic derivatives is rather tedious, the interpretation of the infrared spectra depends mainly on empirical correlations. Katritzky (1) has recently reviewed the infrared spectra of heteroaromatic compounds and classified the vibrations in terms of the ring-stretching, ring-breathing, CH in-plane deformation, and CH out-of-plane deformation modes. We have now examined the infrared spectra of several five-membered nitrogen- and nitrogen,sulphur-heterocyclic compounds in the light of Katritzky's review.

EXPERIMENTAL

Preparation of Compounds

The 1,2,3-triazole derivatives were prepared by the methods described by Lieber *et al.* (2, 3). The tetrazole derivatives were commercially available. All the thiazole derivatives were commercially available. The 1,2,3- and 1,2,4-thiadiazole derivatives were prepared by following the procedures described in the literature (4, 5). The thiatriazole derivatives were synthesized following the procedure described by Lieber *et al.* (6–8). Isoperthiocyanic acid was prepared by the decomposition of thiocyanic acid (9). The hydrochloride of 3,5-diimino-1,2,4-dithiazoline was prepared by the oxidation of dithiobiuret (10). Many of the benzthiazole derivatives were commercially available and some were synthesized in the laboratory following standard procedures.

Spectra

Infrared spectra were recorded employing Perkin–Elmer models 221 and 137B spectrometers fitted with NaCl prisms. The samples were in the form of solutions in $CHCl_3$ or solids dispersed in Nujol mulls or KBr pellets.

RESULTS AND DISCUSSION

Five-membered N-Heterocyclic Derivatives

The assignments for the first two five-membered nitrogen heterocyclic compounds,

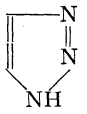
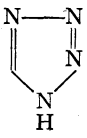
pyrrole (I) and imidazole (II), have been made by Katritzky (1). Making use of the infrared data of a few 1,2,3-triazole derivatives (III) reported by Hartzel and Benson (11),

I II



III

Katritzky (1) has assigned the ring-stretching frequencies around 1520, 1450, and 1410 cm^{-1}. We have examined the infrared spectra of several 1,2,3-vicinal-triazole derivatives, particularly in the region 1400–600 cm^{-1} and find that the following bands appear consistently in all of them: 1290–1150, 1130–1105, 1090–1010, 1000–900, and 850–700 cm^{-1}. The bands in the regions 1290–1105, 1090–900, and 850–700 cm^{-1} may be assigned to the CH in-plane deformation, ring-breathing, and CH out-of-plane deformation vibrations respectively. It should be mentioned, however, that assignments are difficult to make in many derivatives since they possess phenyl groups. We have examined the spectra of a few tetrazole derivatives (IV) and the following assignments may be made. The bands



IV

in the region 1640–1335 cm^{-1} may be due to the ring-stretching vibrations. The CH in-plane deformations occur in the region 1300–1110 cm^{-1}. The bands in the region 1095–900 and 810–715 cm^{-1} may be assigned to the ring-breathing and CH out-of-plane deformation vibrations respectively.

All the important characteristic vibrations of the five-membered N-heterocyclic derivatives have been summarized in Table I. It may be seen that the regions of absorption are very similar in all of them and infrared spectroscopy will not be of much use in qualitative analysis particularly in differentiating these compounds. The data only indicate what one should expect in the spectra of such five-membered N-heterocyclic derivatives. Further, it is not possible to assign C=N and N=N frequencies since these systems are aromatic in nature.

Examination of the spectra of the five-membered N-heterocyclic compounds in the N—H stretching region shows that pyrrole derivatives (12) exhibit the highest stretching frequency (~3488 cm^{-1}). The reported spectra of imidazoles (13) and triazoles (11) are all in the condensed phase and the N—H stretching absorption in both these kinds of derivatives appears around 3100 cm^{-1}. We have examined the spectra of tetrazoles in very dilute solution and find N—H stretching absorption around 3145 cm^{-1}. It is interesting to see that the N—H stretching frequency in tetrazoles is considerably lower than in pyrroles. This is what one would expect considering that the tetrazole ring is much more electronegative than pyrrole. Tetrazole is indeed an acid (pK_a = 4.89).

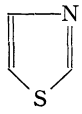
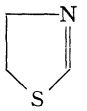
Five-membered N,S-Heterocyclic Derivatives

The simplest member of this group of derivatives is thiazole (V) and the characteristic frequencies of thiazole derivatives have been assigned by Katritzky (1) and Taurins,

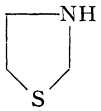


V

Fenyes, and Jones (14). We have examined the spectra of 2-substituted amino-thiazoles, thiazoline derivatives (VI), and thiazolidine derivatives (VII) and find that the assign-

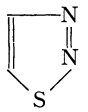


VI

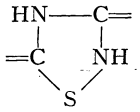


VII

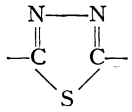
ments are very much similar to those in simple thiazole derivatives. All the assignments are summarized in Table II. We have examined the spectra of derivatives of 1,2,3-, 1,2,4-, and 1,3,4-thiadiazoles (VIII, IX, and X respectively) and have made the relevant



VIII



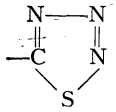
IX



X

assignments (Table II). The regions of absorption are similar in all these derivatives.

Recently, the existence of 1,2,3,4-thiatriazole ring system (XI) has been established by Lieber *et al.* (8, 15). We have examined the spectra of 5-(substituted)-amino-1,2,3,4-



XI

thiatriazoles (XII), 5-(substituted)mercapto-1,2,3,4-thiatriazoles (XIII), 4-substituted-1,2,3,4-thiatriazoline-5-thiones (XIV), salts of 1,2,3,4-thiatriazoline-5-thiones (XV), and 5-(substituted)phenyl-1,2,3,4-thiatriazoles (XVI) and find that all of them show similar

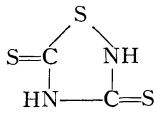
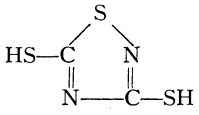
¶Data are not available in this region.

characteristic vibrations of the heterocycle. The relevant assignments are shown in Table II. The frequencies characteristic of the 1,2,3,4-thiatriazole ring system have been useful in distinguishing this structure from other alternatives proposed earlier (16 (*a*, *b*)).

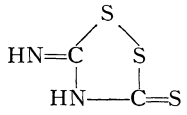
Isoperthiocyanic acid, $C_2H_2N_2S_3$, which is prepared by the decomposition of thiocyanic acid has been assigned various structures (XVII, XVIII, XIX) in the literature (17).



XVII

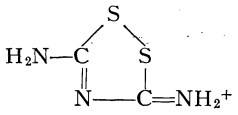


XVIII



XIX

Recently, based on chemical and X-ray evidence (18, 19), the 1,2,4-dithiazoline structure (XIX) has been established. We have studied the infrared spectra of isoperthiocyanic acid and its silver and barium salts and the relevant assignments are given below: 3175 ν_{N-H} (not present in salts), 1631 $\nu_{C=N}$, 1508 —N—C=S I, 1372 and 1325 ring-stretching, 1307—N—C=S II, 1144, 1082, and 1036 ring-skeletal, 1005—NC=S III, 630 ring-breathing or deformation, 600 ν_{C-S}, and 418 ν_{S-S}. The results further confirm the 5-imino-1,2,4-dithiazolidine-3-thione structure (XIX) for isoperthiocyanic acid. Another 1,2,4-dithiazoline derivative, whose structure has been established as XX (20), is produced



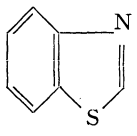
XX

by the peroxide oxidation of dithiobiuret. The tentative infrared assignments for this compound are shown below: 3333 and 3205 ν_{NH_2}, 2933 (triplet) $\nu_{NH_2}{}^+$, 1675 and 1639 $\nu_{C=N}$ and δ_{NH_2}, 1515, 1464, and 1372 ring-stretching, 1311 ν_{C-N}, 1046 ring-skeletal, 630 ring-breathing or deformation, 600 ν_{C-S}, and 418 ν_{S-S}.

The characteristic vibrations of the five-membered N,S-heterocyclic derivatives summarized in Table II are all found to be similar. Just as in the case of the five-membered N-heterocyclic derivatives, infrared data may not be of great value in qualitative analysis and since most of these derivatives are aromatic in nature it is difficult to assign characteristic ring N=N or C=N frequencies.

Benzene Ring Fused to a Five-membered Heterocyclic Ring

O'Sullivan (21) has studied the infrared spectra of several heterocyclic molecules possessing a benzene ring fused to a five-membered ring and has assigned the characteristic bands of such compounds. We have examined the infrared spectra of several benzthiazole derivatives (XXI) and the assignments are shown below: 1608–1580, 1577–1500, 1456–1440, and 1380–1340 cm^{-1}, ring-stretching vibrations; 1320–850 cm^{-1}, a number (~10)



XXI

For personal use only.

of bands due to the CH in-plane deformation, ring-breathing, and ring-skeletal vibrations. It is not possible to assign the C=N frequency in these conjugated systems.

O'Sullivan (22) has pointed out that the out-of-plane CH deformations of benzene rings fused to five-membered rings are found in the region 770–730 cm^{-1} characteristic of *o*-disubstituted benzenes (four adjacent hydrogen atoms). We have found that all the 2-substituted benzthiazole derivatives show a band around 750 cm^{-1} due to CH out-of-plane deformation. Examination of the data in the literature shows that fluorene (XXII) (23), carbazole (XXIII) (23), 3-substituted indoles (XXIV) (24, 25), thionaphthene (XXV) (26), and benzoxazoles (XXVI) (27) show a band in the region 760–740 cm^{-1}

SOME REACTIONS OF CHROMIUM TETRAFLUORIDE

H. C. Clark and Y. N. Sadana
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received July 31, 1963

ABSTRACT

The preparation of chromium tetrafluoride reported by von Wartenberg has been repeated, and some physical and chemical properties have been studied. Chromium tetrafluoride is surprisingly inert and does not react with ammonia, sulphur di- or tri-oxide, pyridine, halogen fluorides, or selenium tetrafluoride at ordinary temperatures. In boiling bromine trifluoride or selenium tetrafluoride, chromium tetrafluoride is reduced to lower fluorides, while a refluxing mixture of bromine tri- and penta-fluorides converts CrF_4 to $CrOF_3.0.25BrF_3$. Chromium (IV) fluoride complexes of the types $ACrF_5$ (A = K, Rb, or Cs) and A_2CrF_6 (A = K or Cs) have been prepared and their magnetic moments and lattice constants have been determined.

INTRODUCTION

The +4 oxidation state is uncommon for chromium; known simple compounds are tetra-*tert*-butoxychromium (IV) (1), the tetrafluoride CrF_4 (2), the corresponding bromide and chloride, $CrBr_4$ and $CrCl_4$, and the compound CrO_2 (3). In the latter case, the presence of Cr (IV) has recently been questioned (4) and it has been suggested that it is a Cr (III) – Cr (VI) compound, $(CrO)_2CrO_4$. The tetrabromide and tetrachloride appear to exist only in the vapor state. Von Wartenberg (2) prepared the tetrafluoride and small amounts of the pentafluoride by the direct fluorination of chromium metal, chromium (III) chloride, or fluoride at 300–350°, and very briefly described some of the properties of CrF_4. The only other reports on fluoride compounds of chromium (IV) have been concerned (5, 6) with the complexes M_2CrF_6 (M = K, Rb, or Cs). Hence, as Sharpe (7) has pointed out, there has been a need for more detailed study of chromium tetrafluoride and its derivatives, and following a similar investigation of vanadium tetrafluoride (8), we have now examined some properties of chromium tetrafluoride.

EXPERIMENTAL

Reactions were carried out in all-glass vacuum systems with taps replaced by combinations of capillary constrictions and break-seals. Reactions involving highly active fluorides (e.g. BrF_3, BrF_5) were performed in silica reaction vessels. All systems were baked out under vacuum before use to ensure the complete removal of moisture.

Magnetic susceptibilities were measured with a Gouy balance equipped with a cryostat which has been described previously (9). X-Ray powder photographs were taken on a G.E. unit with a camera of 14.4 cm diameter, using filtered Cu K_α radiation. Samples were sealed in 0.5 mm diameter, thin-walled capillaries (Pantak Ltd.) to avoid their decomposition by atmospheric moisture.

Fluorine was estimated by distillation as hydrogen fluoride from sulphuric acid at 130–135°, followed by precipitation as lead chlorofluoride, and the determination was then completed volumetrically. Other elements were determined by standard methods.

Preparation of Chromium Tetrafluoride

Chromium tetrafluoride was prepared by direct fluorination of powdered chromium metal at 300°–350° in a nickel apparatus described previously (8). Prior to fluorination, hydrogen was passed over the heated metal in an attempt to remove any oxide impurity. As fluorination proceeded, a mixture of chromyl fluoride and chromium pentafluoride condensed in the first of the series of traps connected to the nickel reactor, while a dark green solid mass of the tetrafluoride condensed at the reactor exit. Green chromium trifluoride remained in the nickel boat in the reactor. The tetrafluoride was removed under nitrogen and stored. The best conditions for fluorination involved a temperature of 350° and a moderate fluorine flow-rate. At higher temperatures or higher flow-rates, the reaction was sufficiently exothermic to cause fluorination and destruction of the nickel reactor.

Properties of Chromium Tetrafluoride

Chromium tetrafluoride is a very dark greenish-black solid, which, on exposure to moisture in the atmosphere, rapidly acquires a brown coating due to hydrolysis. It was hydrolyzed very rapidly in water but was insoluble in a wide range of organic solvents. Calc. for CrF_4: Cr, 40.63; F, 59.37. Found: Cr, 40.52; F, 59.63%. The magnetic moment at 294° K, with θ correction (Curie–Weiss law), was 3.02 B.m., the temperature dependence of the magnetic susceptibility of CrF_4 being shown in Table I. X-ray powder photographs of the tetrafluoride as prepared showed no diffraction lines, nor were any lines observed for samples which had been aged *in vacuo* at 80–100° for several days.

When chromium tetrafluoride was heated in a glass tube *in vacuo* at 100°, sublimation occurred and a bluish deposit was slowly formed on the cooler parts of the tube. At 150°, the rate of sublimation was more rapid, and after 15–20 hours at this temperature, the entire sample had sublimed.

Chemical Reactions with Chromium Tetrafluoride

(i) Dry ammonia was condensed in excess on to a sample of chromium tetrafluoride in an all-glass vacuum system. There were no signs of reaction with the liquid ammonia, and the residue after removal of ammonia was chromium tetrafluoride. Calc. for CrF_4: Cr, 40.63. Found: Cr, 39.8%.

(ii) In similar experiments, dry sulphur dioxide and sulphur trioxide were condensed on to separate samples of the tetrafluoride. In each case, after removal of the oxide, the residue was the original tetrafluoride.

(iii) Bromine trifluoride was condensed on to a weighed sample of chromium tetrafluoride in a silica reaction vessel, and was allowed to melt in contact with the tetrafluoride at atmospheric pressure. No reaction occurred and after the complete removal of bromine trifluoride at 100° *in vacuo*, the residue was unchanged tetrafluoride. Calc. for CrF_4: Cr, 40.63. Found: Cr, 40.55%.

(iv) A weighed sample of chromium tetrafluoride was refluxed with bromine trifluoride (b.p. 125.8°) in a silica reaction vessel for 20 minutes, at atmospheric pressure. The green residue left after removal of the trifluoride *in vacuo* at 120°, was shown to be $CrF_3.0.5BrF_3$. Calc. for $CrF_3.0.5BrF_3$: Cr, 29.4; equiv. wt. 25.0. Found: Cr, 30.0; equiv. wt. 25.5. The equivalent weight was calculated from the observed normality of an aqueous solution of known concentration of the sample, which had been passed through a Dowex-50 cation-exchange resin column. The molar susceptibility at 294° K was 6583×10^{-6} c.g.s. units, which gave a magnetic moment $\mu_{eff} = 3.96$ B.m., corresponding to three unpaired electrons.

(v) No reaction was observed between samples of chromium tetrafluoride and chlorine trifluoride (b.p. 12°), bromine pentafluoride (b.p. 40°), or iodine pentafluoride (b.p. 101°), either at room temperature or at the boiling points of the halogen fluorides. The residue from each experiment was identified analytically as chromium tetrafluoride.

(vi) A sample of chromium tetrafluoride was refluxed with a mixture of bromine tri- and penta-fluorides in a silica reaction vessel. A deep-red solution formed which, after removal of the bromine fluorides *in vacuo* at 100° gave a reddish solid, identified as $CrOF_3.0.25BrF_3$. Calc. for $CrOF_3.0.25BrF_3$: Cr, 32.71. Found: Cr, 32.9%. Magnetic measurements at 294° K gave a molar susceptibility of 1710×10^{-6} c.g.s. units and $\mu_{eff} = 2.01$ B.m., corresponding to one unpaired electron.

(vii) Although selenium tetrafluoride did not react with a sample of chromium tetrafluoride at room temperature, a reaction occurred on refluxing the mixture at atmospheric pressure (b.p. of SeF_4 106°) for 15 minutes. Removal of volatile material at 25° *in vacuo* left a heterogeneous solid. When the residue was heated at 80–90° to remove selenium tetrafluoride completely, the vapor of selenium tetrafluoride swept out of the residue a light buff-colored powder and left in the silica reaction vessel a pink solid. Analyses of the latter corresponded surprisingly well to $CrF_2.SeF_4$. Calc. for $CrF_2.SeF_4$: Cr, 21.24; F, 46.75. Found: Cr, 22.00; F, 47.50%. The molar susceptibility at 294° K was $11{,}900\times10^{-6}$ c.g.s. units giving μ_{eff} a value of 5.34 B.m. The buff-colored product which was much less susceptible to hydrolysis, corresponded in composition to $CrF_3.SeF_4$. Calc. for $CrF_3.SeF_4$: Cr, 19.7; F, 50.4. Found: Cr, 19.7; F, 50.0%.

Pentafluorochromium (IV) Complexes

(i) A mixture of chromium tetrafluoride and potassium chloride in a 1:1 molar ratio was heated in liquid bromine trifluoride. In different experiments, the excess trifluoride was distilled off *in vacuo* either (*a*) at 100°, or (*b*) at 160°. The product from method (*a*) was identified as $KCrF_5.0.5BrF_3$. Calc. for $KCrF_5.0.5BrF_3$: Cr, 20.43; F, 48.50. Found: Cr, 20.00; F, 49.10%. Magnetic measurements were made over the temperature range 98–294° K, as shown in Table I, giving a value for μ_{eff} at 294° of 3.22 B.m. (Curie law). The X-ray powder pattern was indexed on a tetragonal lattice with $a = 9.168$ Å, and $c = 13.49$ Å. The product from method (*b*) (removal of BrF_3 at 160°) was $KCrF_5$. Calc. for $KCrF_5$: Cr, 27.9; F, 51.0. Found: Cr, 26.0; F, 49.5%. The molar susceptibility at 294° K was 4193×10^{-6} c.g.s. units, giving μ_{eff} a value, without θ correction, of 3.16 B.m. The X-ray powder pattern was indexed on a hexagonal unit cell with $a = 8.739$ Å, and $c = 5.226$ Å.

(ii) Rubidium chloride and chromium tetrafluoride in a 1:1 molar ratio were heated in liquid bromine trifluoride, and the excess trifluoride was removed *in vacuo* at 160°. The product was $RbCrF_5$. Calc. for $RbCrF_5$: Cr, 22.4; F, 40.7. Found: Cr, 21.5; F, 40.7%. The variation of the molar susceptibility over the 98–294° K range is shown in Table I, and the value of μ_{eff} at 294° was 3.14 B.m. The X-ray pattern was indexed on the basis of a hexagonal lattice with $a = 6.985$ Å and $c = 12.12$ Å.

(iii) In a similar manner, chromium tetrafluoride and cesium bromide (1:1 molar ratio) were reacted with refluxing bromine trifluoride, the excess trifluoride then being removed at 160°, to give $CsCrF_5$. Calc. for $CsCrF_5$: Cr, 18.55; F, 33.95. Found: Cr, 18.00; F, 32.80%. The molar susceptibility at 294° was 4044×10^{-6} c.g.s. units giving a value of 3.09 B.m. for μ_{eff}. The X-ray powder pattern was indexed on the basis of a cubic lattice with $a = 8.107$ Å.

Hexafluorochromium (IV) Complexes

(i) The reaction of potassium chloride and chromium tetrafluoride in a 2:1 molar ratio, in bromine trifluoride solution gave, after removal of the trifluoride at 100°, the product $K_2CrF_6.0.5BrF_3$. Calc. for $K_2CrF_6.0.5BrF_3$: Cr, 16.62; F, 45.56. Found: Cr, 16.30; F, 46.93%. Magnetic measurements over the range 123–294° K, as shown in Table I, gave (θ correction applied) μ_{eff} at 294° K a value of 3.56 B.m. The X-ray powder pattern was indexed on a tetragonal lattice with $a = 4.339$ Å and $c = 5.500$ Å.

Samples of $K_2CrF_6.0.5BrF_3$ were heated *in vacuo* in sealed Pyrex tubes at 120° for 240 hours. The products gave X-ray powder patterns which could be indexed on a cubic lattice with $a = 8.104$ Å.

(ii) Chromium tetrafluoride and cesium chloride in bromine trifluoride solution gave, in a similar manner, the adduct $Cs_2CrF_6.0.5BrF_3$. Calc. for $Cs_2CrF_6.0.5BrF_3$: Cr, 10.40; F, 28.50. Found: Cr, 10.65; F, 28.10%. The molar susceptibility at 294° K was 4144×10^{-6} c.g.s. units giving μ_{eff} a value of 3.14 B.m. The X-ray powder pattern was indexed in terms of a cubic lattice with $a = 8.916$ Å. The indices of all the observed reflections were either even or odd indicating that the lattice was face-centered.

A sample of $Cs_2CrF_6.0.5BrF_3$, after being heated at 135° *in vacuo* for 72 hours, was converted to Cs_2CrF_6. Calc. for Cs_2CrF_6: Cr, 12.04. Found: Cr, 12.20%. The X-ray powder pattern was identical with that of $Cs_2CrF_6.0.5BrF_3$.

Potassium Pentafluoromanganese (IV)

A sample of $KMnF_5$ was prepared by the action of bromine trifluoride on potassium permanganate (10), and the X-ray powder pattern was indexed on a hexagonal unit cell with $a = 11.44$ Å and $c = 8.208$ Å.

DISCUSSION

The direct fluorination of chromium metal unfortunately gives a mixture, which is difficult to separate completely, of chromium tri-, tetra-, and penta-fluorides, as well as some chromyl fluoride. The formation of the latter, which cannot readily be separated from the pentafluoride, could be reduced but not prevented even by a prior high temperature reduction of the metal with hydrogen. These preparative difficulties have delayed study of the tetrafluoride, and particularly of the pentafluoride.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Chromium tetrafluoride, which is intermediate in volatility between the involatile trifluoride, and appreciably volatile pentafluoride, condenses as a dark-green, glassy solid. On exposure to air, it immediately is coated with a brown oxide layer, and this is presumably responsible for the cinnamon color reported for the tetrafluoride by von Wartenberg (2). Chromium tetrafluoride can be stored indefinitely *in vacuo* in well-dried Pyrex or silica vessels. In agreement with von Wartenberg, we have been unable to obtain samples of the tetrafluoride which would give X-ray diffraction lines, and the compound is probably amorphous. It can be sublimed *in vacuo* at ca. 150° and the steel-blue color of the vapor reported by von Wartenberg was particularly noticed during a fluorination of chromium metal in a silica vessel.

The volatility of chromium tetrafluoride, and in fact its general physical characteristics, are similar to those of titanium and vanadium tetrafluoride. To account for the anomalous properties of titanium tetrafluoride, Hückel (11) has suggested a chain-like structure, formed from condensed TiF_6 octahedra, in which each Ti atom has coordination number six. A similar structure has been proposed (8) for vanadium tetrafluoride, and may well occur in chromium tetrafluoride also. A coordination number of six for chromium in many of these chromium (IV) fluoro-compounds is supported by their magnetic properties which are discussed below. It should also be noted that the volatility and magnetic moment of chromium tetrafluoride are not consistent with formulations such as $CrF_5.CrF_3$ and $CrF_6.2CrF_3$, similar to those proposed (4) for CrO_2.

Chemically, chromium tetrafluoride is surprisingly inert, and does not react with ammonia, sulphur dioxide, sulphur trioxide, or pyridine. Thus chromium (IV) seems to differ markedly from chromium (III), which very readily forms coordination compounds. The tetrafluoride is, however, very rapidly hydrolyzed by water according to the equation

$$3Cr^{4+} \rightarrow CrO_4^{2-} + 2Cr^{3+},$$

as suggested by von Wartenberg (2).

The reactions of chromium tetrafluoride with reactive covalent fluorides, such as the halogen fluorides and selenium tetrafluoride, were investigated to see whether adduct formation or oxidation to a higher fluoride of chromium occurred. The tetrafluoride does not react with iodine or bromine pentafluorides, either at room temperature or at their boiling points, nor does it react with chlorine trifluoride at its boiling point of 12°. With bromine trifluoride, no reaction occurred at room temperature, but with refluxing bromine trifluoride, the green product was identified as $CrF_3.0.5BrF_3$. The reaction therefore differs from that of TiF_4 or VF_4 with bromine trifluoride. Titanium tetrafluoride forms (12) a very unstable adduct, $TiF_4.2BrF_3$, while vanadium tetrafluoride is oxidized (8) to the pentafluoride. It seems highly unlikely that chromium tetrafluoride can oxidize bromine trifluoride, and the more reasonable explanation would involve the thermal decomposition of the tetrafluoride to the trifluoride. This is consistent with the exothermic nature of this decomposition (13)

$$CrF_4 \rightarrow CrF_3 + \tfrac{1}{2}F_2, \Delta H = +22 \text{ kcal mole}^{-1}.$$

Whether the formula $CrF_3.0.5BrF_3$ represents true adduct formation, or just incomplete removal of the bromine trifluoride has not been determined. Certainly the experimental results indicate that vigorous conditions were generally necessary for the complete removal of BrF_3 from these chromium compounds.

As a more vigorous oxidizing agent than bromine trifluoride itself, a mixture of bromine tri- and penta-fluorides was refluxed with chromium tetrafluoride. A red solid was isolated from the solution, and was shown to be $CrOF_3.0.25BrF_3$, the oxygen presumably resulting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

from attack of the silica container. The magnetic moment of 2.01 B.m. at 23° corresponds to one unpaired electron and confirms the presence of chromium (V). A similar product was apparently obtained by Sharpe and Woolf (10), and in both their study and ours, attempts to remove completely the bromine trifluoride to give pure $CrOF_3$ caused decomposition. Further attempts to obtain $CrOF_3$ will be described in a later paper.

Selenium tetrafluoride does not react with chromium tetrafluoride at room temperature, but reaction occurred with refluxing selenium tetrafluoride. The results suggested that two products were obtained, $CrF_3.SeF_4$ and $CrF_2.SeF_4$. The reduction to chromium (III) and formation of an adduct $CrF_3.SeF_4$ is not unexpected for SeF_4. For example, the adduct $PdF_3.SeF_4$ on heating yields PdF_2 (14). In other cases, reduction does not occur and stable adducts are formed. Thus, vanadium tetrafluoride gives (8) the 1:1 adduct, $VF_4.SeF_4$. On the other hand, the apparent reduction of chromium (IV) to chromium (II) in $CrF_2.SeF_4$ is remarkable. The magnetic moment of 5.34 B.m. at 23° almost certainly indicates chromium (II) with four unpaired electrons, since there is no reason to suppose from all other magnetic measurements on chromium-fluorine compounds, that such a value would arise from three unpaired electrons with a very large orbital contribution to the moment. Further work on this interesting reaction will clearly be worthwhile.

Complex fluorides of chromium (IV) of the type $ACrF_5$ (where A = K, Rb, or Cs) have now been prepared for the first time, and some of their properties are shown in Table II. The X-ray evidence clearly showed the absence of free potassium fluoride, so

TABLE II

Complex fluorides of chromium (IV) of the $ACrF_5$ type, and $KMnF_5$

Compound	Magnetic moment (B.m.) (Curie law)	Crystal system	Lattice constants (Å)
$KCrF_5.0.5BrF_3$	3.22	Tetragonal	$a = 9.168$ $c = 13.49$
$KCrF_5$	3.16	Hexagonal	$a = 8.739$ $c = 5.226$
$RbCrF_5$	3.14	Hexagonal	$a = 6.985$ $c = 12.12$
$CsCrF_5$	3.09	Cubic	$a = 8.107$
$KMnF_5$	—	Hexagonal	$a = 11.45$ $c = 8.208$

that the formulae suggest the presence of the unusual penta-coordinate state. However, all evidence indicates that penta-coordination is usually avoided in the solid state, and structure determinations of various complexes of the type A_nMX_5 have revealed that in every case coordination numbers four or six have been attained. Thus Cs_2CoCl_5 contains (15) tetrahedral $CoCl_4^-$ and Cl^- ions, while Tl_2AlF_5 has been shown (16) to contain infinite chains of AlF_6^{3-} octahedra, each of which has two shared corners. In general for A_nMX_5 complexes, structural examination shows that M actually has a coordination of four if its oxidation state is +2, and if in a +3 state, octahedral coordination is observed. The most closely related case to the $ACrF_5$ complexes is that of $KMnF_5$ (10), but its structure has not yet been determined. On the basis of the close similarity of its infrared spectrum to that of K_2MnF_6, it has been suggested (17) that both complexes contain MnF_6 units. Likewise, it can reasonably be expected that these $ACrF_5$ complexes in fact contain CrF_6^{2-} octahedral units, each of which would share two corners with neighboring octahedra to maintain the observed stoichiometry.

Chromium (IV) complexes of the type A_2CrF_6 have been reported previously (5, 6).

Bode and Voss (6) found that the salts A_2CrF_6 (A = K, Rb) exist in hexagonal and cubic modifications, while Cs_2CrF_6 was found only in the cubic form. We have prepared K_2CrF_6 and Cs_2CrF_6 by a different method employing bromine trifluoride as fluorinating agent and solvent and it is of interest to compare the results. Table III indicates the products

TABLE III

Chromium (IV) complexes of the A_2MF_6 type

Compound	Bode and Voss (6)	Present investigation
K_2CrF_6	Cubic a = 8.15 Å Hexagonal a = 5.69, c = 9.34 Å	Cubic a = 8.104 Å
$K_2CrF_6.0.5BrF_3$	—	Tetragonal a = 4.339 c = 5.500 Å
Rb_2CrF_6	Cubic a = 8.506 Hexagonal a = 5.94, c = 9.67 Å	—

$Cs_2CrF_6.0.5BrF_3$	—	Cubic a = 8.916 Å

obtained and their unit cell dimensions. That the potassium and cesium salts in this present study were first obtained containing half a mole of solvating bromine trifluoride is, of course, just a result of the preparative method employed. However, it is clear that the presence of this BrF_3 causes distortion of the structure only for the potassium salt. For the cesium salt, the much larger cation presumably outweighs any distortion due to the bromine trifluoride in the crystal lattice. The values reported by Bode and Voss for the cubic modifications of K_2CrF_6 and Cs_2CrF_6 are higher than our values. Their preparations always contained excess alkali metal fluoride not discernible in the X-ray patterns, and this may be responsible for the slightly higher lattice constants. It is also of interest that the bromine trifluoride method of preparation leads only to the cubic form (i.e. high temperature form) of K_2CrF_6.

The magnetic properties of these chromium (IV) compounds described in Table I and in the experimental section are worth some discussion. Firstly, high values of θ are observed in many instances. As has been discussed (8) for vanadium tetrafluoride and some of its derivatives, such values may well arise from antiferromagnetic interactions, and similar arguments can clearly be applied for the Cr (IV) compounds. It is also clear that corrections for θ yield moments greater than the spin-only value (2.83 B.m.) for Cr (IV), and some spin–orbit interaction is therefore likely. This latter may also, of course, itself produce the large values of θ. Some conclusions regarding the stereochemistry about the chromium atoms in these compounds may be reached on the basis of the observance of a large orbital contribution to the magnetic moment.

The Cr^{4+} ion has a $^3F_2$ ground state which, in the presence of an octahedral field about the Cr^{4+} ion, is split (18) into two triplets and a singlet level, one triplet being the lowest and the singlet the highest energy level. For a Cr^{4+} ion in a tetrahedral environment, the splitting of the $^3F_2$ ground state is again into two triplets and a singlet, but in this case the singlet lies lowest (i.e. the Stark pattern is inverted). Only if a triplet lies lowest is there likely to be large spin–orbit interaction. The fact that our results indicate that there may be large spin–orbit interaction in CrF_4 and Cr (IV) fluoride compounds strongly suggests that, in all these cases, there is an octahedral field of fluoride ions about the Cr^{4+} ion.

Similar arguments also apply for D spectroscopic states. The Stark pattern for a D state has a low-lying triplet in the octahedral case and a low-lying doublet in the tetrahedral

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

case. A large spin–orbit interaction and a magnetic moment appreciably higher than the spin-only value can therefore only be expected for an octahedral environment. The observed (8) moments of VF_4 (in which V^{4+} has a D ground state) and related V (IV) compounds are all much higher than the spin-only values, suggesting the presence of octahedral coordination. The magnetic properties of Cr (IV) and V (IV) fluorides are thus consistent with an octahedral environment for the central metal atoms in these compounds.

Finally, it is now possible to compare briefly the tetrafluorides of titanium, vanadium, chromium, and manganese, although for MnF_4 (19) little detailed information is yet available. As shown in Table IV, there appears to be some increase in volatility in passing

TABLE IV

Tetrafluorides of titanium, vanadium, chromium, and manganese

	Color	Volatility	μ_{eff} (294° K) B.m.	$\theta(0°)$
TiF_4	White	760 mm at 284°	Diamag	Zero
VF_4	Lime-green	Subl. 100–120° *in vacuo* with disproportionation	2.17	198
CrF_4	Green-black	Subl. 150° *in vacuo*	3.02	70
MnF_4	Blue	(Volatile)	3.83	10

from TiF_4 to MnF_4 although precise vapor pressure measurements are lacking. It seems probable that TiF_4, VF, and CrF_4 have structures based on condensed octahedral MF_6 units and it may be that there is a tendency towards the formation of more discrete MF_4 molecules in passing towards MnF_4. There is also a remarkably regular decrease (*a*) in the deviation of the magnetic moment from the spin-only value, and (*b*) in the values of θ (Weiss constant) in passing from TiF_4 to MnF_4. Further structural information is necessary to interpret this although it may again indicate an increasing tendency to form molecular tetrafluorides.

INFRARED SPECTRA AND CRYSTALLINE PHASE TRANSITIONS OF AMMONIUM NITRATE

A. THÉORÊT AND C. SANDORFY
Département de chimie, Université de Montréal, Montréal, Québec
Received June 4, 1963

ABSTRACT

The infrared spectra of solid crystalline films of ammonium nitrate were measured at temperatures ranging between the melting point (169° C) and liquid air temperature (−190° C). Four different spectra were obtained which are shown to belong to phase I, II, IV, and (very probably) VII. Phases III and V were not encountered; only transitions I ⇄ II (125° C), II ⇄ IV (50° C), and IV ⇄ VII (−60° C) were observed. A spectrum measured at −190° C after rapid cooling is shown to correspond to a mixture of phases IV and VII. The symmetry properties of the different phases are discussed in relation with their infrared spectra.

INTRODUCTION

Ammonium nitrate has seven known crystalline modifications. These are the following.

Phase I	cubic	169°–125° C
Phase II	tetragonal	125°–84.5° C
Phase III	orthorhombic	84.5°–32° C
Phase IV	orthorhombic	32° to −16° C
Phase V	tetragonal	below −16° C
Phase VI		above 169° C, at pressures higher than 9000 kg/cm²
Phase VII		below −170° C

The related crystal structures and thermal properties were examined by Hendricks, Posnjak, and Kracek (1); West (2); Crenshaw and Ritter (3); Meerman (4); Jaffray (5); Goodwin and Whetstone (6); Hocart and Mathieu-Sicaud (7); Stephenson, Bentz, and Stevenson (8); Shinnaka (9); Amoros, Alonso, and Canut (10); and others. Volfkovich, Rubinchik, and Kozhin (11) re-examined all the phase transitions of ammonium nitrate and discovered the existence of phase VII. Disregarding phase VI, which was outside the reach of the experimental techniques used by the latter authors (and by the present ones), the following statements can be made.

1. The transition at 125° C (I ⇄ II) is easy to observe and does not lead to complications.

2. The occurrence of the transition at 84.5° C is highly dependent upon sample size and the speed of variation of temperature. Phase III is often missed and instead the transition II ⇄ IV occurs at 50° C.

3. Under certain circumstances the transition at −16° C is also missed, in which case an alternative transition is observed at around −60° C instead. Meerman (3) interpreted this phenomenon as a retardation of the transition IV ⇄ V. We shall examine this point later.

The infrared spectra of crystalline ammonium nitrate were studied by Keller and Halford (12); and then, under better resolution, by Newman and Halford (13, 14). The Raman spectra of phase IV were measured by Couture and Mathieu (15) and by Penot, Poulet, and Mathieu (16).

Since the occurrence of certain phases seems to depend on the way the samples are

prepared and since an appreciable number of new data became available after the original infrared work of Keller, Newman, and Halford was done, it seemed to us indicated to have a new look at the problem.

The present study was made on sublimed crystalline films and we attempted to measure the infrared spectra of all six phases of the same sample. As will be seen, however, only four different spectra were obtained.

EXPERIMENTAL

"Fisher Certified Reagent" ammonium nitrate was used. It was sublimed onto a silver chloride plate at 105° C under 0.1 mm Hg vacuum. In order to ascertain whether any exchange of ions occurred between the film and the AgCl plate (as it did with an NaCl plate), we repeated the experiments using Eastman-Kodak "IRTRAN II" plates. We obtained identical spectra.

A Perkin–Elmer model 21 spectrometer was used with a sodium chloride prism, supplemented in the 3 μ region with a Perkin–Elmer model 112 instrument with a lithium fluoride prism. The low-temperature cell has been described previously (17). Temperature was measured by a copper–constantan thermocouple introduced into a cavity made in the material of the silicon O-ring separating two silver chloride plates, onto one of which the film of ammonium nitrate had been deposited. The plates were pressed together between two copper rings inside of which heating wires were placed. Liquid air, liquid nitrogen + alcohol, and dry ice + alcohol were used as coolants.

RESULTS

Figure 1 gives the four different spectra which were obtained and Table I lists the observed frequency values. Figure 2 gives the spectrum measured at −190° C after rapid cooling.

DISCUSSION

Under T_d symmetry for NH_4^+ and D_{3h} for NO_3^- there would be the following fundamental vibrations.

Type	Description
ν_1' A_1	NH_4^+ sym. stretch, IR forbidden
ν_2' E	NH_4^+ sym. deformation, IR forbidden
ν_3' T	NH_4^+ asym. stretch
ν_4' T	NH_4^+ asym. deformation
ν_1 A_1'	NO_3^- sym. stretch, IR forbidden
ν_2 A_2''	NO_3^- out-of-plane deformation
ν_3 E′	NO_3^- asym. stretch
ν_4 E′	NO_3^- in-plane deformation

Our spectrum of phase IV of NH_4NO_3 is quite similar to the one of Newman and Halford (13). Phase IV has space group V_h^{13} (*Pmmn*) with two molecules per unit cell (2) and the site symmetries of both ions are C_{2v} (13). The strong bands at 3260 cm^{-1} and 1435 cm^{-1} are easily assigned to ν_3' and ν_4' respectively which are infrared active under T_d symmetry. ν_1' and ν_2' were found at 3130 cm^{-1} and 1656 cm^{-1} in the Raman spectrum by Penot, Poulet, and Mathieu (16). One may expect that these bands will at least weakly appear in the infrared under C_{2v} site symmetry but this does not seem to be the case. One may be tempted to assign the shoulder at 3070 cm^{-1} to ν_1' but Wagner and Hornig (18), who examined the spectra of crystalline ammonium chloride and bromide, gave strong reasons for believing that this band belongs actually to $\nu_2'+\nu_4'$ whose intensity is boosted by Fermi-resonance with ν_3'. It is equally difficult to assign the weak band at 1756 cm^{-1} to ν_2', its frequency being too high. It might belong to the combination $\nu_1+\nu_4$ of the nitrate ion or to a combination of ν_4' with a lattice mode. The argument concerning the ammonium-ion fundamentals has been critically reviewed by Mathieu and Poulet (19).

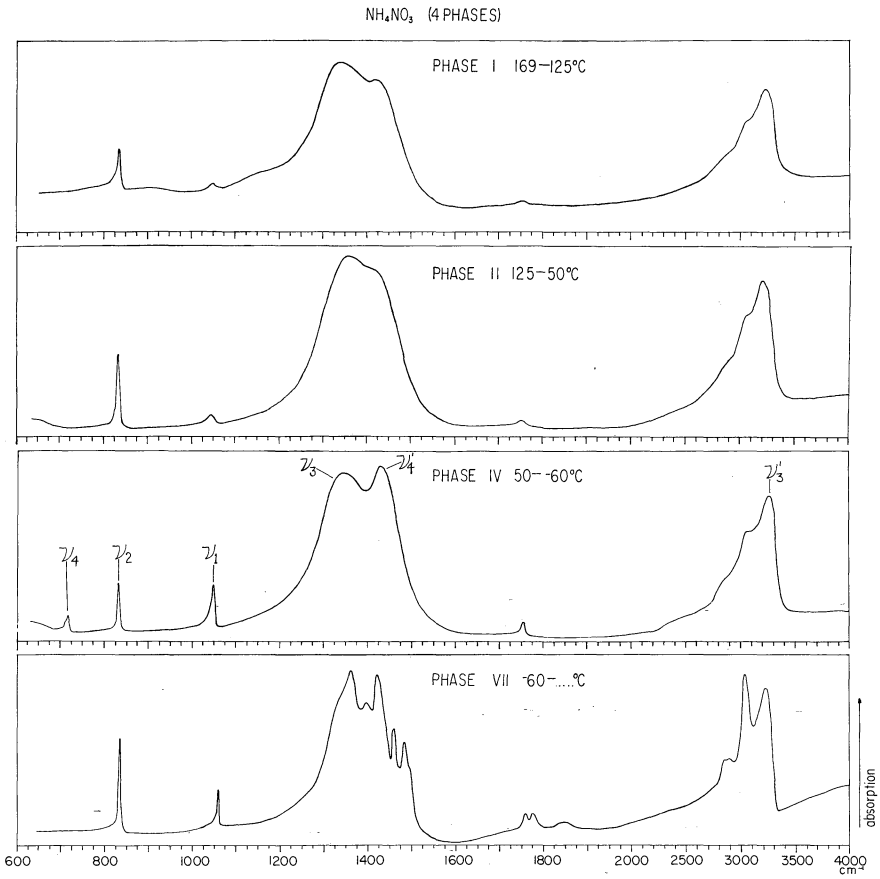

FIG. 1. The infrared spectra of solid crystalline films of ammonium nitrate: phases I, II, IV, and VII.

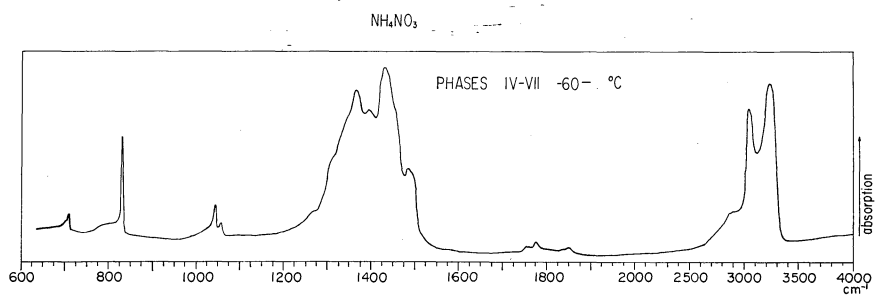

FIG. 2. The infrared spectrum of a solid crystalline film of ammonium nitrate rapidly cooled down to −190° C.

Nothing emerged from the present work that would elucidate these assignments further. We mention, however, that (i) the true intensity of the band at 3070 cm^{-1} may be much lower than its apparent intensity since it is highly overlapped by the much stronger ν_3' band and, (ii) that its intensity increases gradually with increasing departure from T_d symmetry in the order of phases I → II → IV → VII (Fig. 1). This seems to add some weight to its assignment to ν_1'. All we may conclude, however, is that there is no sure

ν_2	832	832	830	833
ν_4			715 713 sh.	

evidence for the presence of ν_1' and ν_2' in the infrared spectrum of phase IV and that the spectrum is compatible with space group V_h^{13} and C_{2v} site symmetry but it does not prove it.

There does not seem to be any such argument concerning the assignment of the frequencies of the nitrate ion. The observed frequencies are listed in Table I.

The spectra of phase I and phase II are very similar to each other (see ref. 12), the main difference being a 28 cm^{-1} shift in the frequency of ν_3. According to Hendricks, Posnjak, and Kracek (1) phase II is tetragonal with space group C_{4v}^2 ($P4bm$) and two molecules in the unit cell: a finding confirmed by Amoros, Alonso, and Canut (10), who suggested, however, that for the metastable state below 84.5° C the space group may be different. Phase I according to the former authors is cubic with only one molecule per unit cell. The site symmetries compatible with C_{4v}^2 are C_{2v} or C_4, much lower than any site symmetry compatible with a cubic structure. In view of this fact the great similarity between the two spectra is astonishing. ν_1 is present as a weak band in both spectra at 1047 cm^{-1} in violation of the selection rules applying to cubic symmetry, though it may be due to some residual phase IV. ν_4 is absent, but it is hard to draw any conclusions from this since, as will be seen below, it is also absent (or very weak) in the spectrum of phase VII whose symmetry is obviously much lower.*

In spite of all our efforts we were not able to obtain phase III. Even when cooling was as slow as 1° C per minute only the II $\rightleftarrows$ IV transition was observed at 50° C. Working with single crystals Newman and Halford (13) were able to measure the spectrum of phase III,

**The referee pointed out that "...the high temperature cubic phases of many crystals show orientational disorder. In that case the X-ray symmetry is a long range average symmetry and the appearance of ν_1 does not necessarily conflict with the X-ray structure." The authors wish to thank the referee for this and other helpful comments.*

and found it to be very similar to that of phase IV. According to Goodwin and Whetstone phase III has space group V_h^{16} (*Pbnm*) with four molecules per unit cel](6).

Phase V proved equally as elusive as phase III in our experiments on films. Instead of obtaining a transition at −16° C and another at about −170° C, we only obtained one at −60° C. The spectrum we obtained on slow cooling (1° C per minute) is the last one in Fig. 1; it remained unchanged down to −190° C. In this spectrum ν_3' (3230 cm^{-1}) is still strong and broad but the intensity of the band at 3040 cm^{-1} increases considerably and its apparent intensity is higher than that of ν_3'. At 2840 cm^{-1} $2\nu_4'$ is split into two components. The weaker but broad band observed at 1850 cm^{-1} may be $\nu_1+\nu_2$ or a combination involving a lattice mode. The band near 1756 cm^{-1} in phase IV is split into two components at 1760 cm^{-1} and 1780 cm^{-1} respectively. The 1400 cm^{-1} region is complicated because of the near coincidence of the triply degenerate deformation vibration, ν_4', of NH_4^+ and the doubly degenerate stretching, ν_3, of NO_3^-. Including shoulders we are able to distinguish seven bands in this part of the spectrum, some of which may be due to combinations of ν_3 with lattice modes. The observed splittings indicate a remarkable lowering of the site symmetry of the NH_4^+ and NO_3^- ions. Probably even more splitting would be found under higher resolution. Unfortunately, the crystal structure of this phase is not known.

We suggest that this spectrum (the last one in Fig. 1) belongs to phase VII, first obtained by Volfkovich, Rubinchik, and Kozhin (11), and that the transition occurring at −60° C is a IV ⇄ VII transition.

It may be argued that what we observed at −60° C is actually a retardation of the transition IV ⇄ V; but this view can be countered with the following consideration. Volfkovich, Rubinchik, and Kozhin (11) observed that when they "quenched" ammonium nitrate with liquid nitrogen they obtained a mixture of phases IV and VII. Now, after rapid cooling to −190° C we obtained the spectrum shown in Fig. 2. It is easily recognizable as being essentially a superposition of the spectra of phases IV and VII given in Fig. 1. When thick films were used this spectrum became practically identical with the one measured from 1200 to 700 cm^{-1} by Newman and Halford at −160° C for powdered NH_4NO_3.

To sum up, working with films, we have obtained the spectra of phases I, II, IV, and in all probability VII of ammonium nitrate.

We acknowledge financial support from the National Research Council of Canada. We are indebted to Mr. David Davies for correcting the English of our manuscript.

REACTION OF ANHYDROSEPEDONIN WITH ALKALI

SYNTHESIS OF A DEGRADATION PRODUCT AND SOME RELATED DIMETHYLHYDROXYBENZOIC ACIDS[1]

P. V. DIVEKAR[2] AND L. C. VINING[3]

Prairie Regional Laboratory, National Research Council, Saskatoon, Saskatchewan

Received August 9, 1963

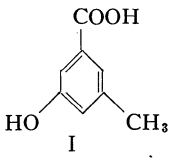
ABSTRACT

Two products have been isolated from the reaction of anhydrosepedonin with alkali and identified as 3-hydroxy-5-methyl benzoic acid and 3,4-dimethyl-5-hydroxybenzoic acid. The structure of the latter compound was established by unambiguous synthesis. In the course of this work the remaining *o*- and *m*-hydroxybenzoic acids derived from *o*-xylene were also prepared.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Sepedonin, a metabolic product of the fungus *Sepedonium chrysospermum*, was first isolated as the anhydro derivative by Divekar and Raistrick (1). From its chemical properties these authors suspected that their product might be a substituted tropolone, several examples of which are already known among the secondary metabolites of fungi. Subsequent studies in this laboratory have shown that treatment of anhydrosepedonin with alkali under conditions expected to cause rearrangement of a tropolone to a benzoic acid derivative (2) affords a small amount of product with the properties of a phenolic acid.

Difficulty was encountered in obtaining sufficient material from the reaction mixture for adequate purification and characterization of the components. However, analytical and spectroscopic evidence suggested the presence of a dimethyl *o*- or *m*-hydroxybenzoic acid. Attempts to synthesize these compounds were therefore begun. Subsequently paper chromatographic examination showed the product to be a mixture of phenolic acid and tropolone derivatives. Partition chromatography on a cellulose column allowed two of the former to be separated and isolated in a pure form. These compounds had similar ultraviolet and infrared spectra and differed only in the number of C-methyl substituents. The simpler of the two was identified by comparison with a synthetic specimen as 3-hydroxy-5-methylbenzoic acid (I).



I

On biogenetic grounds it was considered likely that the two methyl substituents of the second compound were vicinal. It was compared with the isomeric dimethylhydroxybenzoic acids synthesized by the routes outlined (III–IX, XI–XVII) and found to be indistinguishable from 3,4-dimethyl-5-hydroxybenzoic acid. The derived acetates and methyl ethers of the two compounds were also identical. The acid has previously been known as a degradation product of camphor, resulting from the action of warm sulphuric acid on dicamphorylic acid (3). The orientation of the substituents was established at

[1]*Issued as N.R.C. No. 7603.*

that time by decarboxylation to 2,3-xylenol, and by oxidation of the methyl ether to 6-methoxy-2-methylterephthalic acid, but does not appear to have been confirmed by synthesis.

The synthetic route used in the present work employed *o*-xylene as starting material. Nitration under suitable conditions gave mainly the dinitro derivatives in which each of the nitro groups can be selectively reduced to give the corresponding nitroxylidines. From these substances a series of *o*- and *m*-hydroxybenzoic acids containing two vicinal methyl substituents may be conveniently prepared by replacement of the amino and nitro with carboxyl and hydroxyl groups, respectively.

The three dimethylsalicylic acids derived from *o*-xylene were also prepared by other methods. 3,4-Dimethylsalicylic acid (XXXII), which has not been previously described, was obtained in good yield by carbonation (4) of 2,3-xylenol. When this reaction was applied to 3,4-xylenol, 4,5-dimethylsalicylic acid (XXXV) was the sole product. Earlier workers (4, 5) have observed a similar result which is evidently due to steric factors. Use of 3,4-xylenol in the Tiemann–Riemer reaction, on the other hand, is reported (6) to yield a mixture of 4,5- and 5,6-dimethylsalicylaldehydes (XXXVI and XXXI) which can be oxidized to the corresponding acids by fusion with alkali. Separation of the two aldehydes is difficult and Hunsberger and co-workers (5) in attempting to repeat Clayton's synthesis were able to obtain only one of them in pure condition. This was presumed to be the 5,6-derivative since 4,5-dimethylsalicylaldehyde was prepared by an alternative route and proved to be different. We have found, as did Auwers (7), that the main product from the Tiemann–Riemer reaction on 3,4-xylenol is the cyclohexadienone (XXXVII). Only a small amount of the mixture of aldehydes was obtained but these were separated

and each obtained in a pure form. Oxidation of one of them gave 4,5-dimethylsalicylic acid in good yield. The other under more vigorous conditions afforded a little 5,6-dimethylsalicylic acid, the identity of which was established by comparison with a sample synthesized from 3-amino-4-nitro-*o*-xylene (XXII–XXIX).

Isolation of the two related hydroxybenzoic acids from the action of alkali on anhydrosepedonin provides strong evidence that this compound has a tropolone structure. It is, moreover, of interest that such a tropolone would have hydroxyl and carbon substitution at the same positions on the ring as found in stipitatonic acid, a tropolone derivative isolated from *Penicillium stipitatum* (8). Since anhydrosepedonin has a molecular formula $C_{11}H_{10}O_4$, one oxygen and two carbon atoms remain to be accounted for.

EXPERIMENTAL

Alkaline Degradation of Anhydrosepedonin

To anhydrosepedonin (100 mg), dissolved in *N* potassium hydroxide (0.25 ml) in a nickel crucible, pellets of potassium hydroxide (2 g) were added. The crucible was covered and placed for 5 minutes in a Woods metal bath preheated to 250°. After it had cooled, the reaction mixture was dissolved in water (10 ml), acidified carefully with concentrated HCl, while being stirred in an ice bath, and extracted with four portions (25 ml) of ether. The extracts were dried over anhydrous sodium sulphate and evaporated to dryness. The residue (70 mg) was heated in high vacuum at 160° C for 12 hours and the white sublimate (13 mg) collected. Paper chromatography using *sec*-butanol – 10% aqueous ammonia (4:1) showed two main components, R_f's 0.55 and 0.64, which gave orange-colored zones when the paper was sprayed with an aqueous solution of Fast Bordeaux Salt (9).

Similar fusions carried out at higher and lower temperatures, and for different periods of time, gave lower yields of the mixture of these two products.

The combined product (95 mg) from a number of experiments was dissolved in a small amount (1 ml) of the upper phase from an equilibrated mixture of *n*-butanol – toluene – 3% aqueous ammonia (5:1:3) and applied to a column (15 in. × ¾ in. diam.) of cellulose powder through which 1 liter of the upper phase of the solvent mixture had already been passed. The column was developed with the same solvent and 3 ml fractions collected. The desired compounds were located by paper chromatography of eluate fractions. Appropriate solutions were pooled and evaporated to dryness.

Fractions 34–42 gave on sublimation at 25×10^{-6} mm Hg and 95° C colorless needles (11 mg) m.p., 211–212° C. Found: C, 65.16; H, 6.01. Neutralization equivalent in 80% ethanol, 174. Calc. for $C_9H_{10}O_3$: C, 65.05; H, 6.07%. Mol. wt. 166. This substance was indistinguishable in R_f values, color reactions, and absorption spectra from a specimen of 3,4-dimethyl-5-hydroxybenzoic acid (IX), and no depression of melting point resulted from admixture of the two compounds. It was esterified in ethereal solution at 4° C for 30 minutes with diazomethane. The product was sublimed at 70° C in high vacuum and crystallized from petroleum ether (b.p. 60–80°) as colorless cubes, m.p. 153.5°. Found: C, 66.63; H, 6.76; OCH_3, 16.43; CCH_3, 23.82%. Saponification equivalent 185. Calc. for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71; 1-OCH_3, 17.2; 2C—CH_3, 16.67%. Mol. wt. 180. A mixed melting point with methyl 3,4-dimethyl-5-hydroxybenzoate (VIII) caused no depression and the ultraviolet and infrared absorption spectra of the two substances were indistinguishable.

Fractions 55–80 gave on sublimation at 110° and 25×10^{-6} mm Hg colorless needles, m.p. 217° C. Found: C, 63.39; H, 5.22%. Neutralization equivalent in 80% ethanol, 155. Calc. for $C_8H_8O_3$: C, 63.15; H, 5.30. Mol. wt. 152. This substance had the same R_f values, color reactions, and absorption spectra as an authentic specimen of 3-hydroxy-5-methylbenzoic acid (I), m.p. 217° C. A mixed melting point also gave 217° C. Each compound was converted with diazomethane to the same methyl ester, m.p. 94°. Found for the product from anhydrosepedonin: C, 65.12; H, 6.18; C—CH_3, 9.6%. Calc. for $C_9H_{10}O_3$: C, 65.05; H, 6.07; 1C—CH_3, 9.04%.

2,3-Dimethyl-5-nitrobenzonitrile (XII)

o-Xylene was nitrated and the products separated by the procedure of Crossley and Renouf (10). Reduction of 3,5-dinitro-*o*-xylene (II) with 4 equivalents of stannous chloride in ethanolic hydrogen chloride (11) gave mainly 3-amino-5-nitro-*o*-xylene (XI) which, when purified by chromatography on alumina and crystallized from ethanol or benzene, had m.p. 113° C. This product (19.3 g) was dissolved by warming in concentrated sulphuric acid (35 ml) and water (175 ml) added. The solution was cooled rapidly with stirring and the fine suspension diazotized at 0° C with sodium nitrite (8.83 g) in water (40 ml). The diazonium salt was neutralized with calcium carbonate and the filtered solution added to a well-stirred mixture of toluene (100 ml) and potassium cuprocyanide (100 ml water, 20 g cuprous cyanide, and 40 g potassium cyanide) at 10° C (12). The temperature was allowed to rise to ambient and the mixture stirred vigorously at 60° C

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

until gas evolution ceased. The toluene layer was separated and extraction of the product from the aqueous phase completed with ether (3 × 100 ml). The combined extracts were washed successively with 4 *N* hydrochloric acid, *N* sodium hydroxide, and water, dried, and evaporated to dryness. The crude product was purified by chromatography on alumina and crystallized from ethanol as needles (10.6 g), m.p. 131–131.5° C, $\lambda\lambda_{max}^{KBr}$ 4.44, 6.54, 7.36 μ. Found: C, 61.37; H, 4.45; N, 16.13%. Calc. for $C_9H_8O_2N_2$: C, 61.36; H, 4.58; N, 15.90%.

3,4-Dimethyl-5-nitrobenzonitrile (IV)

5-Amino-3-nitro-*o*-xylene (III) was obtained from 3,5-dinitro-*o*-xylene by reduction with ammonium polysulphide as described by Noelting and Thesmar (13), or more simply with sodium hydrogen sulphide (14). It was separated from (XI) by fractional crystallization of the crude product from 4 *N* hydrochloric acid. The free base crystallized from ethanol as orange-red prisms, m.p. 69–71° C. The product (14 g) was diazotized and reacted with potassium cuprocyanide as above to give the nitrile as needles (7.6 g), m.p. 118.5–121° C, $\lambda\lambda_{max}^{KBr}$ 4.43, 6.52, 7.36 μ. Found: C, 61.31; H, 4.55; N, 16.08%.

2,3-Dimethyl-6-nitrobenzonitrile (XXIII)

3-Amino-4-nitro-*o*-xylene (XXII), prepared from 3,4-dinitro-*o*-xylene by the method of Burton and Kenner (15) was obtained as orange prisms, m.p. 120° C. The amine (14 g) was diazotized and treated with potassium cuprocyanide as in the preceding experiments to give the nitrile as needles (9.0 g), m.p. 111° C, $\lambda\lambda_{max}^{KBr}$ 4.46, 6.52, 7.41 μ. Found: C, 61.40; H, 4.54; N, 15.73%.

Hydrolysis of Nitriles

2,3-Dimethyl-5-nitrobenzonitrile (9.3 g) and 3,4-dimethyl-5-nitrobenzonitrile (7.0 g) were each hydrolyzed by heating in 100% phosphoric acid (50 ml) at a bath temperature of 150° C for 2 hours. The reaction mixture, which had set to a crystalline mass was diluted with water and filtered. The residue was separated into neutral and acidic fractions by distribution between chloroform and 5% sodium carbonate solution. Acidification of the aqueous layer yielded a crystalline product which was recrystallized from aqueous ethanol. The yield of 2,3-dimethyl-5-nitrobenzoic acid (XIII), m.p. 199–200° C, $\lambda\lambda_{max}^{KBr}$ 5.90, 6.58, 7.40μ, was 6.39 g. Found: C, 55.39; H, 4.68; N, 7.10%. Calc. for $C_9H_9O_4N$: C, 55.38; H, 4.65; N, 7.18%. The yield of 3,4-dimethyl-5-nitrobenzoic acid (V), m.p. 205–205.5° C, $\lambda\lambda_{max}^{KBr}$ 5.86, 6.50, 7.35 μ, was 5.0 g. Found: C, 55.46; H, 4.62; N, 7.11%.

The chloroform layers were evaporated and the products purified by sublimation in high vacuum followed by crystallization from ethanol. 2,3-Dimethyl-5-nitrobenzamide (XX) was obtained as needles (2.87 g) m.p. 198–199° C, $\lambda\lambda_{max}^{KBr}$ 2.88, 3.01, 3.11, 6.04, 6.17, 6.55, 7.45 μ. Found: C, 55.44; H, 5.06; N, 14.48%. Calc. for $C_9H_{10}O_3N_2$: C, 55.66; H, 5.19; N, 14.43%. 3,4-Dimethyl-5-nitrobenzamide (XIX) was obtained as prisms (2.15 g), m.p. 185–186° C, $\lambda\lambda_{max}^{KBr}$ 2.87, 3.14, 5.94, 6.15, 6.53, 7.46 μ. Found: C, 55.56; H, 5.06; N, 14.36%.

Attempts to hydrolyze 2,3-dimethyl-6-nitrobenzonitrile with phosphoric acid under these conditions caused extensive decarboxylation of the acid formed. Other vigorous methods of hydrolysis were similarly unsuccessful in converting the nitrile directly to the acid. The reaction was carried out in two steps. The nitrile (1.82 g) was heated for 3 hours at a bath temperature of 160° C in a mixture of glacial acetic acid (15 ml), sulphuric acid (15 ml), and water (15 ml). The cooled solution was diluted with water and the product extracted into chloroform. The residue from evaporation of the extract crystallized from ethanol as prisms (1.55 g), m.p. 182.5–183.5° C, $\lambda\lambda_{max}^{KBr}$ 2.96, 3.12, 6.03, 6.58, 7.40 μ of 2,3-dimethyl-6-nitrobenzamide (XXIV). Found: C, 55.66; H, 5.19; N, 14.43%.

2,3-Dimethyl-6-nitrobenzoic Acid (XXV)

2,3-Dimethyl-6-nitrobenzamide (1.83 g) was dissolved in 25% (v/v) aqueous sulphuric acid at a bath temperature of 160° C. Sodium nitrite (1.30 g) in water (25 ml) was then added slowly through a narrow funnel reaching to the bottom of the solution (16). On cooling, the reaction mixture deposited long needles (1.64 g), m.p. 175.5°, $\lambda\lambda_{max}^{KBr}$ 5.90, 6.58, 7.39 μ, after recrystallization from aqueous ethanol. Found: C, 55.38; H, 4.65; N, 7.18%.

Methyl Dimethylnitrobenzoates

The acids, suspended in ether, were each treated with excess of an ethereal solution of diazomethane, crystallized from aqueous ethanol and sublimed in high vacuum to give the following compounds.

(*a*) Methyl 2,3-dimethyl-5-nitrobenzoate (XIV), m.p. 76–76.5° C, $\lambda\lambda_{max}^{KBr}$ 5.80, 6.59, 7.45 μ. Found: C, 57.54; H, 5.43; N, 6.82%. Calc. for $C_{10}H_{11}O_4N$: C, 57.41; H, 5.30; N, 6.70%.

(*b*) Methyl 3,4-dimethyl-5-nitrobenzoate (VI), m.p. 59–60° C, $\lambda\lambda_{max}^{KBr}$ 5.82, 6.51, 7.39 μ. Found: C, 57.31; H, 5.26; N, 6.67%.

(*c*) Methyl 2,3-dimethyl-6-nitrobenzoate (XXVI), m.p. 86.5–87.5° C, $\lambda\lambda_{max}^{KBr}$ 5.77, 6.58, 7.43 μ. Found: C, 57.4; H, 5.30; N, 6.75%.

Methyl Aminodimethylbenzoates

The nitrobenzoates were each dissolved in 2.5% (w/v) methanolic hydrogen chloride and reduced with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

hydrogen over palladium on charcoal catalyst at atmospheric pressure and room temperature. After hydrogen uptake ceased the filtered reaction mixtures were concentrated to a small volume under reduced pressure and neutralized with sodium bicarbonate solution. The product was extracted into ether and the dried ethereal solution evaporated to give three compounds.

(*a*) Methyl-5-amino-2,3-dimethylbenzoate (XV) as needles, m.p. 72°, $\lambda\lambda_{max}^{CHCl_3}$ 2.90, 2.96, 5.84, 6.17 μ, after crystallization from benzene – petroleum ether (b.p. 60–80° C). Found: C, 66.94; H, 7.23; N, 7.90%. Calc. for $C_{10}H_{13}O_2N$: C, 67.02; H, 7.31; N, 7.82%.

(*b*) Methyl-5-amino-3,4-dimethylbenzoate (VII), as fine needles, m.p. 80.5° C, $\lambda\lambda_{max}^{CHCl_3}$ 2.87, 2.94, 5.88, 6.17 μ after crystallization from benzene – petroleum ether (b.p. 60–80° C). Found: C, 66.99; H, 7.27; N, 7.97%.

(*c*) Methyl-5,6-dimethylanthranilate (XXVII) as a liquid $n_D^{25°\ C}$ 1.5626, $\lambda\lambda_{max}^{CHCl_3}$ 2.86, 2.94, 5.87, 6.19 μ after distillation *in vacuo*. Found: C, 67.12; H, 7.40; N, 7.65%.

Methyl Dimethylhydroxybenzoates

The aminobenzoates (1–2 g) suspended in *N* sulphuric acid (25 ml) were each diazotized at 0° C under vigorous stirring by the dropwise addition of a solution of sodium nitrite (0.41 g) in water (5 ml). Urea was added to destroy excess nitrite and the solution added slowly to a boiling solution of copper sulphate (100 g) in water (100 ml). The reaction mixture was then diluted with two volumes of water, cooled, and extracted with ether. The ether was washed with sodium bicarbonate solution, dried, and evaporated to give three compounds.

(*a*) Methyl-2,3-dimethyl-5-hydroxybenzoate (XVI) as prisms, m.p. 104–105° C, $\lambda\lambda_{max}^{CHCl_3}$ 2.79, 5.83 μ after crystallization from benzene – petroleum ether (b.p. 60–80° C) (yield 77%). Found: C, 66.80; H, 6.72%. Calc. for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71%.

(*b*) Methyl-3,4-dimethyl-5-hydroxybenzoate (VIII), m.p. 153.5°, $\lambda\lambda_{max}^{CHCl_3}$ 2.79, 5.85 μ after crystallization from benzene followed by sublimation in vacuum (yield 92%). Found: C, 66.81; H, 6.78%.

(*c*) Methyl-5,6-dimethylsalicylate (XXVIII) as needles, m.p. 26–27° C, $\lambda\lambda_{max}^{CHCl_3}$ 3.23–4.17, 5.78 (w), 6.00 (s) μ, by spontaneous crystallization of liquid obtained when the crude product was distilled in vacuum (yield 94%). Found: C, 66.81; H, 6.81%. The absorption maximum at 5.78 μ did not disappear on dilution of the chloroform solution and was present at the same intensity in a sample purified by saponification, recrystallization of the acid to constant melting point (147.5–148° C) and re-esterification with diazomethane.

Dimethylhydroxybenzoic Acids

The esters were each saponified by heating with *N* potassium hydroxide at 50° C for 5 hours to give three compounds.

(*a*) 2,3-Dimethyl-5-hydroxybenzoic acid (XVII), $\lambda\lambda_{max}^{CHCl_3}$ 2.79, 3.20–4.21, 5.83 μ after crystallization from benzene followed by sublimation in high vacuum. The sample melted and resolidified at 189–190° C, and gave a second m.p. at 196–197.5° C. Found: C, 65.06; H, 6.02%. Calc. for $C_9H_{10}O_3$: C, 65.05; H, 6.07%.

(*b*) 3,4-Dimethyl-5-hydroxybenzoic acid (IX), m.p. 212° C, $\lambda\lambda_{max}^{CHCl_3}$ 2.77, 3.32–4.27, 5.86 μ after crystallization from benzene followed by sublimation in high vacuum. Found: C, 65.11; H, 6.06%.

(*c*) 5,6-Dimethylsalicylic acid (XXIX), m.p. 147.5–148°, $\lambda\lambda_{max}^{CHCl_3}$ 2.86–4.27, 6.03 μ, after sublimation in high vacuum. Found: C, 65.09; H, 6.11%.

Acetoxydimethylbenzoic Acids

The hydroxy acids were acetylated by heating with acetic anhydride and anhydrous sodium acetate on a steam bath for 3 hours. Excess acetic anhydride was decomposed with ice. The product was separated and recrystallized from aqueous ethanol to give four compounds.

(*a*) 5-Acetoxy-2,3-dimethylbenzoic acid (XVIII) as needles, m.p. 162.5–163° C. Found: C, 63.35; H, 5.93%. Calc. for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%.

(*b*) 5-Acetoxy-3,4-dimethylbenzoic acid (X) as needles, m.p. 162–163° C. Found: C, 63.35; H, 5.84%.

(*c*) Acetyl-5,6-dimethylsalicylic acid (XXX) as plates, m.p. 138–140° C. Found: C, 63.18; H, 5.79%.

(*d*) Acetyl-3,4-dimethylsalicylic acid (XXXIII) as needles, m.p. 143–145° C. Found: 63.21; H, 5.82%.

3,4-Dimethylsalicylic Acid (XXXII)

Kolbe–Schmitt carbonation of 2,3-xylenol (6.1 g) by the Marassé procedure (4) yielded a product which, after sublimation in high vacuum and crystallization from water, gave needles, m.p. 200–202° C, $\lambda\lambda_{max}^{CHCl_3}$ 2.86–4.17, 6.06 μ. Found: C, 65.05; H, 6.24%.

Methyl-3,4-dimethylsalicylate (XXXIV)

3,4-Dimethylsalicylic acid in ether was treated with a slight excess of ethereal diazomethane. The product, purified by sublimation in high vacuum, had m.p. 49.5° C. Found: C, 66.53; H, 6.77%.

Tiemann–Riemer Reaction with 3,4-Xylenol

The reaction was carried out according to the directions of Clayton (6). The main product separated from the steam distillate as long needles, m.p. 97° C (18% yield). Auwers (7) reported m.p. 102–103° C for 4-dichloromethyl-3,4-dimethylcyclohexa-2,5-dienone. Found: C, 52.45; H, 5.02; Cl, 33.91%. Calc. for $C_9H_{10}OCl_2$: C, 52.70; H, 4.91; Cl, 34.57%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

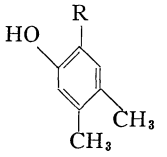
The material regenerated from the bisulphite derivative was crystallized from petroleum ether (b.p. 60–80° C) in 4% yield and the crystals sorted mechanically into two groups.

(*a*) Pale yellow needles, m.p. 67.5°, $\lambda\lambda_{max}^{CHCl_3}$ 2.8–3.7, 6.10 μ after several recrystallizations from petroleum ether and methanol. Found: C, 71.95; H, 6.76%. Calc. for $C_9H_{10}O_2$: C, 71.98; H, 6.71%. Clayton reported m.p. 72° for 5,6-dimethylsalicylaldehyde (XXXI).

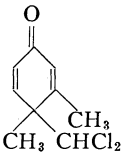
(*b*) Colorless plates, m.p. 69.5–70° C, $\lambda\lambda_{max}^{CHCl_3}$ 2.8–3.7, 6.04 μ after several recrystallizations from petroleum ether. Found: C, 72.13; H, 6.84%. Clayton reported m.p. 71° for 4,5-dimethylsalicylaldehyde (XXXVI).

Oxidation of Dimethylsalicylaldehydes

When the plates, m.p. 69.5–70° C, were heated in a fusion mixture of sodium hydroxide – potassium hydroxide at 180° C for 1.5 hours (6) an acid, m.p. 202° C, was obtained in 84% yield. This was indistinguishable from the 4,5-dimethylsalicylic acid (XXXV), isolated as the sole product after carbonation of 3,4-xylenol (4).



XXXV R = COOH
XXXVI R = CHO



XXXVII

Oxidation of the needles, m.p. 67.5° C under the same conditions, gave only unchanged starting material. More vigorous conditions (210° and 4 hours) gave a small yield (1%) of an acid, m.p. 146° C, separated from unreacted aldehyde by solubility in sodium bicarbonate solution, followed by fractional crystallization from aqueous ethanol. This product was spectroscopically indistinguishable from and did not depress the melting point of a sample of 5,6-dimethylsalicylic acid synthesized from 3-amino-4-nitro-*o*-xylene. Attempts to improve the yield by increasing the temperature and reaction time, or by using the procedure of Pearl (17) were not successful.

ACKNOWLEDGMENTS

The authors wish to express their sincere appreciation to Professor H. Raistrick for his continued interest and helpful advice. They are also indebted to Dr. Guy Talbot for the gift of an authentic sample of 3-hydroxy-5-methylbenzoic acid, and to Miss M. J. A. Gates for competent technical assistance. Microanalyses were performed by Mr. E. Mazurek.

THE CHEMISTRY OF APIOSE. PART I[1]

D. T. WILLIAMS AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario
Received August 27, 1963

ABSTRACT

D-Apiose, D-xylose, and 2-*O*-methyl D-xylose have been identified as components of polysaccharides of *Zostera marina* L.

D-Apiose has been synthesized by a new procedure which clarifies the stereochemistry at C_3 of the D-apiose molecules and which gives a new general method for the synthesis of branched chain sugar alcohols.

INTRODUCTION

D-Apiose has been found in the seaweed *Posidonia australis* L. (1). It also occurs in trace amounts in many plants (2, 3). Bell pointed out that its rate of movement on chromatograms and color reactions might lead to its confusion with rhamnose, a very common constituent of many plant materials. As a result of discussion with Dr. D. J. Bell, it was decided to test the hypothesis that D-apiose might be a constituent of plants of the family Potomagoneacae.

RESULTS

One of the seaweeds most readily available to us (apart from *Posidonia australis* L.) was *Zostera marina* L. After hydrolysis of this plant, D-apiose, D-xylose, and 2-*O*-methyl D-xylose were isolated and characterized. A third sugar tentatively identified as an *O*-methyl apiose was also isolated in small quantity. This is the first time that 2-*O*-methyl D-xylose has been encountered in a seaweed. A polysaccharide composed of D-apiose and D-xylose in the ratio of approximately one to one and an unidentified uronic acid were also isolated from *Posidonia australis* L.

In order to identify the D-apiose, attempts were made to synthesize the D- and L- forms by procedures described in the literature (5, 6). As these methods gave poor yields in our hands, a new synthesis was devised which has the advantage that it will enable us to solve the problem of the stereochemistry at C_3 of the D-apiose molecule in apiin. This problem was first discussed by Bell (1). The method of synthesis yielded a branched chain sugar alcohol as an intermediate (cf. Schaffer (6)).

In this synthesis di-*O*-isopropylidene *aldehydo* L-arabinose (7) was treated with formaldehyde and sodium hydroxide in aqueous solution when the branched chain sugar alcohol (I) was produced (cf. ref. 6). Cautious hydrolysis with dilute acetic acid removed one *O*-isopropylidene residue from (I) and the product (II*a*) purified via its crystalline acetate (II*b*), on oxidation with periodate, yielded *O*-isopropylidene D-apiose (III), the stereochemistry of which is fixed at C_3 yielding (III*a*), not (III*b*), which possesses transfused five-membered rings. The product (III) after hydrolysis yielded D-apiose which was characterized as its benzylphenylhydrazone. The periodate oxidation of this hydrazone and of methyl apioside have been examined. Attempts to synthesize D-apiose via 2,3-di-*O*-benzyl 3,4-*O*-isopropylidene *aldehydo* L-arabinose were unsuccessful.

It is of interest that D- and L-apiose gave di-*O*-isopropylidene derivatives which were not identical, presumably because of the formation of isomers of the type IV and V.

EXPERIMENTAL

The general experimental details and paper chromatography procedures have been described previously (8).

Isolation of D-*apiose and 2-O-methyl* D-*xylose from Zostera marina L.*

The seaweed (air dried, 500 g) was extracted in a Waring blender with (*a*) methanol (1 l.), (*b*) butan-1-ol saturated with water (1 l.), and (*c*) water saturated with butan-1-ol (1 l.), according to the procedure described to us by Dr. E. E. Percival (personal communication). These extracts contained colored material and amino acids but no D-apiose-containing material was present. The residue was divided into two equal parts. The first portion was hydrolyzed with *N* sulphuric acid at 70° for 4 hours. After filtration the cooled solution was neutralized ($BaCO_3$), filtered, and the filtrate was concentrated to a syrup (2 g). Paper chromatographic examination of the material showed the presence of apiose (mainly), plus trace amounts of sugars tentatively identified as xylose and glucose and (or) galactose. The second part (A) was extracted with cold 2% sodium hydroxide solution (2×500 ml) and the combined extracts were dialyzed for 4 days. Concentration of the solution gave a green residue (2.5 g), a small portion of which, after hydrolysis with 2 *N* sulphuric acid for 5 hours at 100°, showed only apiose and xylose in the approximate ratio 1:1 on chromatographic examination. Later work has shown that higher yields of polysaccharide are obtained if the seaweed is first given a treatment with ice-cold *N* hydrochloric acid before the alkaline extraction procedure (4). After alkaline extraction of the second portion (A), the insoluble residue, which still contained apiose, was hydrolyzed using the procedure described for the hydrolysis of the first portion of seaweed. The resulting reducing sugars were combined with those from the first hydrolysis, and the whole was fractionated on a cellulose column (9) using butan-1-ol half saturated with water as effluent. There resulted D-apiose (2.3 g), with R_{RH} 0.85; 2-*O*-methyl D-xylose, with R_{RH} 1.43, and *O*-methyl apiose (?) with R_{RH} 1.43 (solvent A).

D-Apiose was characterized as its *N*-benzyl *N*-phenylhydrazone (10) (1.4 g from 0.8 g D-apiose), which had m.p. 137–139° and $[\alpha]_D$ −68° (*c*, 1.3 pyridine) after recrystallization from chloroform. Analysis: Calc. for $C_{18}H_{22}O_4N_2$: C, 65.4; H, 6.7; N, 8.5%. Found: C, 65.3; H, 6.8; N, 8.6%. It was also characterized as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

apiose 2,5-dichlorophenylosazone of m.p. 189–190°, not depressed on admixture with an authentic sample prepared from L-apiose by the method of Schaffer (6). On periodate oxidation D-apiose *N*-benzyl *N*-phenylhydrazone consumed 1.95 moles of periodate and yielded 1.06 moles of acid and 1.05 moles of formaldehyde per mole in 14 hours (constant values). During the oxidation pale yellow crystals of glyoxal *N*-benzyl *N*-phenylhydrazone were precipitated. They had m.p. 93° after recrystallization from methanol–water. Analysis: Calc. for $C_{15}H_{14}ON_2$: C, 75.6; H, 5.9; N, 11.8%. Found: C, 75.4; H, 5.7; N, 12.0%.

The 2-*O*-methyl D-xylose fraction crystallized and the recrystallized sugar (4 mg) had m.p. 132–133° not depressed on admixture with an authentic specimen (11). It yielded xylose on demethylation with boron trichloride (12) and the reduced acetylated product was indistinguishable from 1,3,4,5-tri-*O*-acetyl 2-*O*-methyl D-xylitol by gas–liquid chromatographic analysis.

The methylated apiose (?) fraction (10 mg) was admixed with 2-*O*-methyl D-xylose. Because of the small amount of sugar available it was not possible to characterize it completely. The fraction on demethylation (12) (boron trichloride) yielded apiose and xylose which were detected chromatographically (solvent A).

Synthesis of D-*apiose*

*4-C-Hydroxymethyl-1,2-3,4-di-O-isopropylidene 2,3-*D*-erythropentitol*

2,3-4,5-Di-*O*-isopropylidene *aldehydo*-L-arabinose (from 25 g of the corresponding diethyl dithioacetal) (7) was dissolved in ethanol (300 ml), and formaldehyde (20 ml of a 37% solution) and sodium hydroxide (12 g in ethanol) were added. After 5 days at ambient temperatures the solution was neutralized (formic acid) and evaporated to dryness. The residue was extracted with chloroform and the extracts were counter-extracted with an equal volume of water. The chloroform solution was dried and then concentrated to a syrup (12.5 g) which was taken up in ether and the solution was extracted with an equal volume of water. The ethereal solution was dried and evaporated to a syrup which crystallized. The product 4-*C*-(hydroxymethyl)-1,2–3,4-di-*O*-isopropylidene 2,3-D-*erythro*-pentitol had m.p. 91–92° and $[\alpha]_D$ +14° (*c*, 2.0 in methanol). Yields varied from 12 to 36%. Analysis: Calc. for $C_{12}H_{22}O_6$: C, 55.0; H, 8.4%. Found: C, 54.9; H, 8.2%.

*4-C-(Hydroxymethyl)-3,4-O-isopropylidene 2,3-*D*-erythropentitol*

The crystalline di-*O*-isopropylidene derivative (above, 2.0 g) was hydrolyzed with 65% acetic acid for 18 hours at room temperature. The reaction mixture was diluted with cold water (200 ml), neutralized ($BaCO_3$), filtered, and the filtrate was evaporated to dryness. The residue was extracted with acetone; the extracts were evaporated to a syrup which was again extracted with acetone. The extracts on concentration yielded a syrup (1.4 g) which, on extraction with ether, yielded some (200 mg) starting material. The overall yield of crude product was 79%. It was purified by acetylating it (1.2 g) in acetic anhydride (3 ml)–pyridine (3 ml) mixture. After 16 hours at room temperature and 1 hour at 60°, the acetate was isolated in chloroform solution in the usual way. The product crystallized and was recrystallized from ethanol. It had m.p. 82° and $[\alpha]_D$ −22° (*c*, 2.0 in ethanol). Analysis: Calc. for the tetraacetate $C_{17}H_{26}O_{10}$: C, 52.3; H, 6.7%. Found: C, 52.1; H, 6.6%.

De-*O*-acetylation was achieved by the Zemplen procedure (13). The tetraacetate (1.1 g) yielded a syrup (500 mg) which had $[\alpha]_D$ 0° (*c*, 1.1 in acetone).

2,3-O-Isopropylidene D-*Apiose*

The above *O*-isopropylidene pentitol derivative (485 mg) was dissolved in water (25 ml) and oxidized with sodium metaperiodate (500 mg) in water (25 ml). After 1 hour at room temperature, (a trial experiment (formaldehyde determination) had shown that reaction was complete in this time) ethylene glycol was added to the solution. After 1 hour water (25 ml) was added and the solution was continuously extracted with chloroform. Concentration of the extracts yielded a syrup (390 mg) which had $[\alpha]_D$ −35° (*c*, 0.87 in methanol). Analysis: Calc. for $C_8H_{14}O_5$: C, 50.5; H, 7.4%. Found: C, 50.8; H, 7.6%.

D-*Apiose N-benzyl N-phenylhydrazone*

2,3-*O*-Isopropylidene D-apiose (350 mg) was hydrolyzed in *N* sulphuric acid (5 ml) at 70° for 4 hours. The product was isolated after the solution had been neutralized ($BaCO_3$) and treated with a solution of *N*-benzyl *N*-phenylhydrazine (1 g) in ethanol (10 ml) at ambient temperatures. After 18 hours the product (300 mg) was isolated (10) and recrystallized from chloroform. It had m.p. 138–139° not depressed on admixture with an authentic specimen, and $[\alpha]_D$ −29° (*c*, 1.1 in methanol). Analysis: Calc. for $C_{18}H_{22}O_4N_2$: C, 65.4; H, 6.7; N, 8.5%. Found: C, 65.35; H, 6.4; N, 8.2%.

*Methyl-*D-*apiosides*

D-Apiose (500 mg) was heated under reflux with methanolic hydrogen chloride (50 ml, 1%) for 16 hours. The acid was neutralized (Ag_2CO_3) and the filtered solution was evaporated to a syrup (510 mg) which contained at least two components of R_{RH} 1.41 and R_{RH} 1.32. The syrup was fractionated on a cellulose column and yielded one syrupy component which appeared to be chromatographically pure. It had R_{RH} 1.41 solvent (A) and $[\alpha]_D$ −101° (*c*, 1.3 in methanol). On periodate oxidation it yielded 1 mole of acid and consumed 2 moles of periodate per mole. The fraction of R_{RH} 1.32 was not obtained pure. In addition a small quantity of a third component of R_{RH} 1.30 previously undetected was also noted.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Di-O-isopropylidene D-*apiose*

D-Apiose (150 mg) was shaken with dry acetone (60 ml) containing concentrated sulphuric acid (3 ml) for 5 hours. The acid was neutralized (Na_2CO_3) and the product, isolated as a syrup (180 mg), crystallized. The crystals were recrystallized (40 mg) and had m.p. 80–82° $[\alpha]_D$ +58° (*c*, 1.17 in ethanol). Bell (1) gives m.p. 81–83° and $[\alpha]_D$ +55.6° (*c*, 1.35 in ethanol). On hydrolysis with dilute acid the product regenerated D-apiose with $[\alpha]_D$ +7.6° (*c*, 0.7 in water).

Di-O-isopropylidene L-*apiose*

L-Apiose (250 mg) was concentrated to the di-*O*-isopropylidene derivative by the procedure described above. The product crystallized; it could not be purified by recrystallization but could be purified by sublimation. It had m.p. 56–58° and $[\alpha]_D$ −16° (*c* 1.14 in ethanol). It depressed the melting point of the D-isomer and its infrared spectrum was different from that of the D-isomer.

ACKNOWLEDGMENTS

RAPID ANALYSIS OF STRONTIUM AND RUBIDIUM IN MINERALS

A. A. MILLS
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia
Received August 22, 1963

ABSTRACT

Methods are described for the rapid analysis of strontium and rubidium in micas and alkali feldspars by emission spectrography. The elements are determined in a common matrix, excess barium carbonate acting as buffer and internal standard. The techniques are applicable to the analysis of 5–500 p.p.m. strontium in the minerals, with relative deviations of ±5–8%. Semiquantitative results are obtained for 100–1500 p.p.m. rubidium in the same materials. These methods have also been successfully applied to the analysis of strontium and rubidium in certain whole rocks. Results obtained with the standard granite G-1 and standard diabase W-1 show satisfactory agreement with the recommended values.

INTRODUCTION

One method for the determination of geological age depends upon the decay of the naturally occurring radioactive nuclide rubidium-87 to strontium-87 (1). Whether this technique is applicable to a given rock or mineral depends upon the ratio of rubidium to total strontium in the sample, its age, and the accuracy desired. A comparatively high concentration of rubidium accompanied by a minimum of common strontium (which tends to mask the radiogenic strontium-87) is required. Micas (especially biotite and muscovite) and alkali feldspars have proved to be the most generally useful minerals for the dating of igneous rocks by the rubidium–strontium method.

A complete age determination, involving isotope dilution, ion exchange separation, and solid-source mass spectrometry, is time-consuming and expensive. A rapid method was therefore sought (2) which would indicate whether a given sample contained a suitable ratio of rubidium to strontium. An analysis yielding absolute quantities, rather than the ratio of the elements, was preferred to allow calculation of optimum 'spike' concentrations in any subsequent isotope dilution assay (3). The concentration of strontium was the more critical of the two determinations.

CHOICE OF TECHNIQUE

Method

A simple, rapid, sensitive technique necessitating minimum sample preparation was required. A method based on emission spectrography was therefore selected, relevant descriptions in the literature employing flame (4–6), arc (7–11), or spark (12) excitation of solid or liquid samples. Direct excitation of the powdered material at the anode of a d-c. arc was chosen as the technique to be developed.

Matrix Effects and Internal Standard

A notorious cause of inaccuracy in spectrographic analysis is the effect of a varying matrix (11). Turekian, Gast, and Kulp (10) showed that for the analysis of strontium in silicate rocks this effect may be minimized by the addition of an equal weight of calcium carbonate to the sample. The strontium content was then obtained from the Sr 4607/Ca 4578 intensity ratio, the calcium content of the original silicate being known from a previous analysis.

The basis of the present method was to mix the sample with an excess of barium carbonate; this acted as spectroscopic buffer, flux, and internal standard (11, 13, 14). Barium carbonate was preferred to the calcium salt for the following reasons:

(*i*) Traces of barium in the original samples would make a negligible contribution to the total barium in the mixture. The concentration of barium may therefore be considered constant, and comparatively weak lines in the spectrum of this element paired with sensitive lines of strontium and rubidium. Barium would be expected to be an excellent internal standard for strontium, less ideal for rubidium (11). 'Moving-plate' runs (11) and the experimental results confirmed this.

(*ii*) Barium carbonate gave a better burn than calcium carbonate, an observation previously reported by Marks and Potter (15). Adding an equal weight of graphite powder to the mix still further improved the steadiness of the arc.

(*iii*) Strontium was present in commercially available* spectrographic grades of both calcium and barium carbonate, but the latter contained less of this impurity.

A preliminary series of experiments confirmed that barium carbonate exhibited a buffering action comparable to that of calcium carbonate. A mixture of 1:1:2 by weight of sample, barium carbonate, and powdered graphite showed no matrix effect to over twice the range in concentrations of alumina, silica, potassium, and magnesium found in natural micas and alkali feldspars. A disadvantage was that bands due to molecular emission produced a heavy background in parts of the spectrum.

Systematic Error and Concentration Standards

Another possible cause of inaccuracy in spectrographic analysis is in the values assigned to the standards used to construct working curves. In the present work, standards were derived from selected samples analyzed by an isotope dilution technique (16) thought to be accurate to within ± 2–3% (2, 17).

EXPERIMENTAL

Sample Preparation

Clean, unweathered rock specimens were crushed in a roller crusher and sifted through nylon bolting cloth (18). The 40–80 mesh fraction was washed with deionized water to remove dust, then dried at 80° C.

Minerals were separated in a Frantz Isodynamic Separator; first arranged vertically to rapidly effect a coarse separation, and then sloped to the optimum angle. Three or four passages, monitored by optical microscopic examination of the products, were normally sufficient to yield one constituent in $>98\%$ purity. Selected minerals were carefully washed and dried. Samples (50–100 mg) were taken for spectrographic analysis, and reduced to a fine powder by vibrating for 2 minutes in a tool-steel micro ball-mill.

A stock mix was prepared from 1 g barium carbonate (J.M. 92) intimately ground with 2 g graphite powder (J.M. 9). Three parts by weight of this stock mix were combined in a plastic vial with one part by weight of the powdered mineral, and vibrated in the micro mill to give a uniform 1:1:2 mixture of sample, barium carbonate, and graphite. A mixture was stored in the plastic vial until required, 80 mg being adequate for the preparation of four electrodes.

Spectrography

Anodes were turned from graphite rod (J.M. 4B) to the dimensions shown in Fig. 1, the cavity holding about 15 mg of sample mix. Cathodes were of carbon rod, sharpened to a blunt point.

The following parameters were common to all determinations.

Spectrograph:	Hilger fully automatic large quartz-glass spectrograph, Littrow type.
Optics:	That part of the arc selected by a diaphragm was imaged on the collimating lens of the spectrograph, ensuring uniform illumination of the slit.
Rotating sector:	6-step, 2:1 transmission ratio.
Slit:	0.01 mm.
Arc length:	9 mm.
Potential drop across arc:	250 v on open circuit, falling to 50 v when operating.

**Johnson, Matthey and Co. Ltd., 73–83 Hatton Garden, London, E.C.1.*

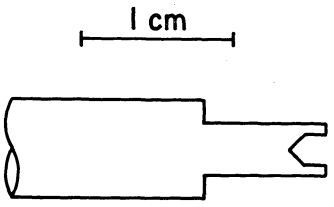

FIG. 1. Graphite anode.

Number of analyses: Normally in duplicate.
Photometer: Hilger non-recording microphotometer.

Plates were calibrated by the self-calibration method (11) on a plotting board of Seidel function (19) against intensity (sector steps). Relative intensities were read off from the straight line plots at Seidel function = 10, correction for background being made where required.

Strontium in Micas

Plates: Ilford ordinary.
Current: 5.7 amp.
Shutter: Opened just after striking arc. Average burning time 80 seconds.
Lines: Sr (I) 4607.3, Ba (I) 4700.4.
Correction for background was required.

It has been mentioned above that the barium carbonate contained strontium as an impurity. This was found by the addition method (11) to be equal to 8 p.p.m. strontium, and this quantity was therefore subtracted in all analyses for this element.

The resultant working curve is shown in Fig. 2: the range covered is from 5–100 p.p.m. strontium. The relative deviation was ±8% for single determinations in the 50 p.p.m. region. Analyses were normally carried out in duplicate, giving an error of the mean of ±6% at the 68% confidence level.

Strontium in Alkali Feldspars

Plates, current, and shutter as above.
Lines: Sr (II) 4077.7, Ba (II) 4166.0.
Correction for background not required.

The resultant working curve is shown in Fig. 3, being usable from 15–500 p.p.m. strontium. Precision at the 68% confidence level was ±5% for single determinations in the 100 p.p.m. region, equivalent to ±4% for duplicate analyses.

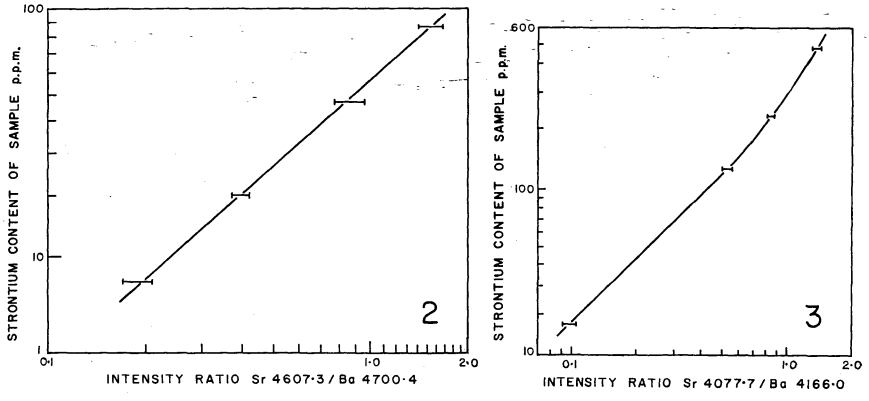

FIG. 2. Working curve for the determination of strontium in micas.
FIG. 3. Working curve for the determination of strontium in alkali feldspars.

Rubidium in Micas and Feldspars

Plates: Kodak I.R.E.R.
Current: 3.5 amp.
Shutter: Opened just before striking arc. Average burning time 2 minutes.
Lines: Rb (I) 7800.2, Ba (I) 7780.4.
Correction for background was required.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The resultant working curves are shown in Fig. 4, the range covered being from 100–1500 p.p.m. rubidium. The dispersion was assumed to follow a log-normal distribution (11), with the geometric mean of a set of analyses providing the best estimate of the correct value. The upper and lower 68% confidence limits were given by 3/2 G and 2/3 G respectively, where G represents the geometric mean.

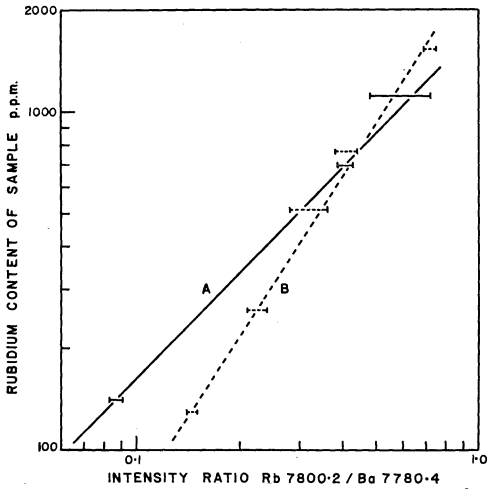

FIG. 4. Working curves for the determination of rubidium in: curve A, micas; curve B, alkali feldspars.

DISCUSSION

Strontium

In order to measure the very low concentrations of strontium sometimes found in biotites it was necessary to employ the most sensitive line in the spectrum of this element at 4607.3 Å. This atom line was paired with a barium-atom line at 4700.4 Å. Both lines lay in a region of comparatively high background ascribed to BaO molecular emission (20), and correction for this was required.

The greater concentrations of strontium associated with alkali feldspars permitted the use of the less intense ion line at 4077.7 Å, which was paired with a barium-ion line at 4166.0 Å. Correction for background was then unnecessary, provided registration of the cyanogen band spectrum was minimized. Self-absorption became apparent in the Sr 4077.7 line above 150 p.p.m., as shown by the deviation from linearity of the working curve above this concentration (Fig. 3). The slopes of the linear portions of the working curves were close to the expected value of 45° (11). A satisfactory degree of precision is indicated by relative deviations of ±5–8% for single determinations.

Rubidium

It was desirable to determine rubidium in the same sample mix, although this could not be expected to be as precise as a technique employing another alkali metal as internal standard.

The emission spectrum of rubidium contains four intense lines; two in the blue at 4201.8 and 4215.6 Å, and two in the red at 7800.2 and 7947.6 Å. The short-wavelength lines were not applicable because of the possibility of interference from Fe 4202.0 and Sr 4215.5 respectively. Use of a red line was therefore obligatory, although both are known to be very susceptible to self-absorption. Rb 7800.2 was chosen because the weaker Rb 7947.6 line lay in a region of heavy background.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Linear calibration curves were obtained (Fig. 4), although the precision was insufficient to preclude the presence of some self-absorption. The use of a barium carbonate matrix as an internal standard for rubidium is much less satisfactory than for strontium, but the accuracy was sufficient for the required purpose.

ANALYSIS OF STANDARDS G-1 AND W-1

The strontium contents of the standard granite G-1 and standard diabase W-1 (21) were determined by the method given for strontium in feldspars. The rubidium content of granite G-1 was also determined. The results are shown in Table I. The 'recommended' values are those of Fleischer and Stevens (22), the lower concentrations being derived from isotope dilution and neutron activation analyses, whilst inclusion of earlier spectrographic determinations gave the higher average. The results obtained in this work agree well with the lower recommended value in each case.

TABLE I

Analysis of standards G-1 and W-1

	Strontium, p.p.m.			Rubidium, p.p.m.		
Sample	Experimental results	Arithmetic mean	Recommended value	Experimental results	Geometric mean	Recommended value
G-1	258 250 250	253	250 or 280	195 210 255 160 230 270	217	220
W-1	166 182 179	176	175 or 220	Below detection limit	—	22

ACKNOWLEDGMENTS

I thank Mrs. N. Garton for the experimental work and Drs. B. J. Giletti and C. M. L. Bowler for their advice. The work was conducted at Oxford University as part of the geological age and isotopes research programme being carried out under the direction of Professor L. R. Wager, with support from the Department of Scientific and Industrial Research and the Overseas Geological Surveys, London.

PHOTOCHEMICAL TRANSFORMATIONS OF DIENES

I. THE PHOTOLYSIS OF 3-ALKOXYCHOLESTA-3,5-DIENES

GEORGE JUST AND CLIFFORD C. LEZNOFF[1,2]
Department of Chemistry, McGill University, Montreal, Quebec

Received August 16, 1963

ABSTRACT

The photolysis of 3-alkoxycholesta-3,5-dienes in an alcohol has been found to result in a stereospecific addition of the alcohol to the Δ^3 double bond with formation of β,γ-unsaturated ketals. On silica gel, the non-cyclic β,γ-unsaturated ketals gave cholest-5-en-3-one.

As part of an investigation of the photoinduced transformations of heteroannular dienes, an ethanolic solution of 3-ethoxycholesta-3,5-diene (1) (I) was irradiated with a high-pressure mercury lamp. The reaction was very fast as evidenced by the disappearance of the chromophore at 239 mμ. Evaporation and purification by chromatography on alumina resulted in a 60% yield of a crystalline compound (II), $C_{31}H_{54}O_2$, m.p. 49–50°. Treatment with acid resulted in the formation of cholest-4-en-3-one (VIII). Chromatography of II on silica gel gave cholest-5-en-3-one (IV).

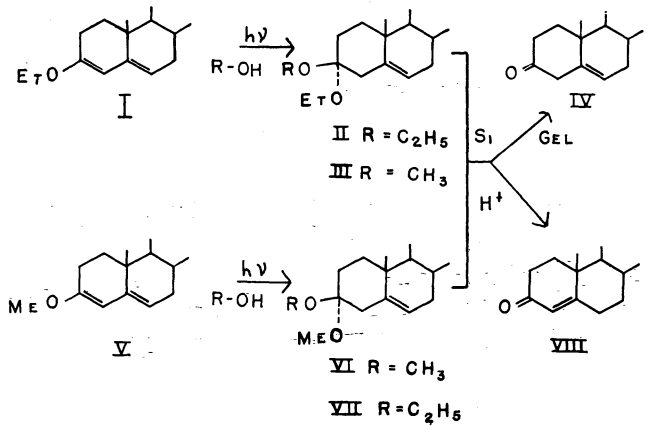

FIG. 1.

These results, in accord with the infrared (Fig. 2) and nuclear magnetic resonance (n.m.r.) data (Table I), indicated that the photoproduct was 3,3-diethoxycholest-5-ene (II). The structure was confirmed by synthesis in which cholest-5-ene-3-one was reacted with absolute ethanol in the presence of malonic acid (2).

Similarly, photolysis of 3-methoxycholesta-3,5-diene (V) in methanol gave 3,3-dimethoxycholest-5-ene (VI) in 50–60% yield, identical in all respects with a synthetic sample (2).

When 3,3-diethoxycholest-5-ene was recrystallized from methanol, a new compound

TABLE I

Nuclear magnetic resonance data of photolysis products II, III, VI, and VII
(T.M.S. = 0, chemical shifts in p.p.m.)

Compound	Methylene group at C_4 singlet	3α-MeO singlet	3β-MeO singlet	3α-EtO quartet center	3β-EtO quartet center	Vinyl proton at C_6 singlet
3,3-Diethoxycholest-5-ene	2.25	—	—	3.40_5	3.33	5.25
3,3-Dimethoxycholest-5-ene	2.23	3.12_5	3.04_5	—	—	5.25
3α-Ethoxy-3β-methoxycholest-5-ene	2.25	—	3.05_5	3.44	—	5.25
3β-Ethoxy-3α-methoxycholest-5-ene	2.25	3.15	—	—	3.33	5.25

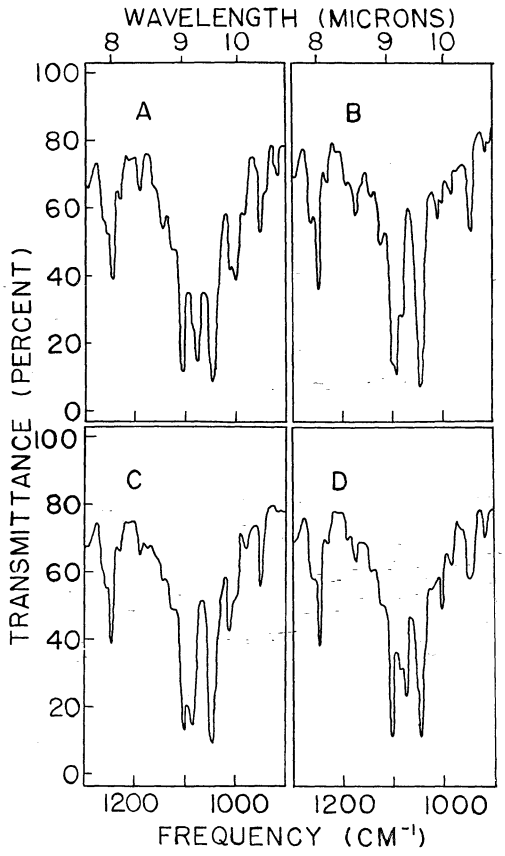

FIG. 2. The infrared spectra of (A) 3,3-diethoxycholest-5-ene; (B) 3,3-dimethoxycholest-5-ene; (C) 3α-ethoxy-3β-methoxycholest-5-ene; (D) 3β-ethoxy-3α-methoxycholest-5-ene.

(III), $C_{30}H_{52}O_2$, m.p. 105–106°, was obtained. The infrared spectrum (Fig. 2) showed strong absorption in the ether region and the n.m.r. spectrum showed the presence of one methoxy group, a singlet, and of one ethoxy group, a quartet (Table I), as well as a vinyl proton. The C_4 methylene group of these ketals at 2.25 p.p.m. is easily recognized and consistent with the structural assignments.

Since 3,3-dimethoxycholest-5-ene gives two distinct, unsplit signals for the two methoxy groups, compound III is a 3-ethoxy-3-methoxycholest-5-ene, in which one ethoxy group has been exchanged specifically for one methoxy group.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

It is a well-known fact (4, 5, 7) that in solvolytic reactions of the cholesteryl type, the Δ^5 double bond participates to give a homoallylic carbonium ion and that the incoming group attaches itself at the 3β position in a stereospecific manner. It hence seems reasonable to assume that in this exchange reaction, the Δ^5 double bond assists preferentially the departure of the 3β substituent and that the resulting dialkoxy compound is 3α-ethoxy-3β-methoxycholest-5-ene (III).

It was fortuitous that compound III was obtained in the pure state since a more detailed investigation of the exchange reaction of 3,3-diethoxy and 3,3-dimethoxycholest-5-ene in methanol and ethanol respectively revealed that the 3α-alkoxy group also exchanges. The rate of exchange of the 3β substituent is twice that of the 3α substituent.

In order to obtain some insight into the mechanism of the photolysis reaction, 3-methoxycholesta-3,5-diene (V) was photolyzed in absolute ethanol. The main product (VII) of the reaction, obtained in 60% yield, was isomeric with compound (III), obtained by the methanolysis of II. Nuclear magnetic resonance (Table I) showed the presence of one methoxy and one ethoxy groups. The chemical shifts of the methoxy and ethoxy groups coincide with one of the methoxy and ethoxy groups in VI and II. On silica gel, VII gave cholest-4-ene-3-one and cholest-5-ene-3-one. The compound is, hence, assigned the structure 3β-ethoxy-3α-methoxycholest-5-ene (VII).

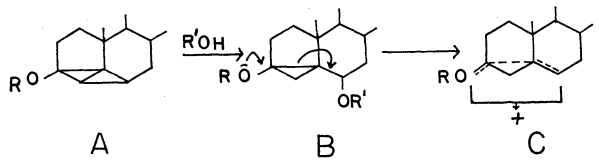
When 3-ethoxycholesta-3,5-diene (I) was photolyzed in methanol, 3,3-dimethoxycholest-5-ene (VI) was obtained. Obviously, the solvolysis exchange reaction was rapid. However, when the reaction was repeated in the presence of a small amount of pyridine, 3α-ethoxy-3β-methoxycholest-5-ene (III) was obtained. The product was identical with the methanolysis product of 3,3-diethoxycholest-5-ene (II). The n.m.r. of the crude photolysis product revealed that the reaction was not completely stereospecific, but that 5–10% of the isomeric mixed ketal (VII) was present.

It should be noted that n.m.r. and infrared spectra were taken on all crude photolysis products, in order to ensure that no isomerizations occurred during chromatography and crystallization.

The n.m.r. and infrared spectra were very characteristic for photolysis products II, III, VI, and VII, and resulted in unambiguous identification (Table I and Fig. 2).

If the assignment of stereochemistry of the epimeric mixed ketals is correct, the chemical shifts of the 3α- and 3β-methoxy groups are 3.12_5 and 3.04 p.p.m. and of the 3α- and 3β-ethoxy groups are 3.40_5 and 3.33 p.p.m. respectively. The methoxy groups give signals which appear as singlets while the ethoxy groups give signals which appear as quartets.

All of these results are consistent with the intermediacy of the carbonium ion C, formed either directly by interaction of a photoexcited species with solvent, or indirectly by sequence A → B → C.



A similar sequence has been proposed some time ago by Dauben and Willey (8) to explain the photolysis of cholesta-3,5-diene (8, 9) in which an intermediate of type A (OR = H) was isolated. We were not able to isolate an intermediate of this nature, using the conditions described (8). In particular, the n.m.r. of the photolysis product (pentane, He atmosphere) did not show any peaks characteristic of alkoxy groups. Further work to determine the mechanism of the reaction is being carried out.

EXPERIMENTAL

The melting points were determined on a Kofler microscope hot-stage and are corrected. The analyses were carried out by Dr. C. Daesslé, Montreal. The infrared spectra were determined on a Perkin–Elmer 421 grating spectrophotometer using 1 millimeter sodium chloride cells and carbon disulphide as solvent. The ultraviolet absorptions spectra were measured by means of a Beckman recording spectrophotometer Model DK1. Nuclear magnetic resonance spectra were recorded on a Varian H.R. 60 instrument at 60 megacycles using carbon tetrachloride as solvent and tetramethylsilane (0 c.p.s.) as an internal standard. Optical rotations were performed with a Carl Zeiss automatic polarimeter using a 0.5-dm tube. All irradiations were performed with a Hanovia 450-watt lamp in a water-cooled immersion apparatus. Unless otherwise stated, Woelm alumina, activity II–III, was used for chromatography.

Irradiation of 3-Ethoxycholesta-3,5-diene (I) in Ethanol

A solution of 3.0 g of I, λ_{max}^{EtOH}, 239 mμ (ϵ 17,900), was irradiated until no absorption could be detected in the ultraviolet (1.5 hours). After evaporation, one-half of the crude material was chromatographed on silica gel (Davidson No. 923). Elution with hexane, hexane–benzene, and benzene–ether gave 0.5 g of crude cholest-5-ene-3-one (IV), m.p. 118–120°. Recrystallization from cyclohexane afforded 0.1 g of IV, m.p. 119–125°. The melting point was not depressed upon admixture of authentic IV (6*a*). The infrared spectra were superimposable.

The other half of the crude photolysis product was chromatographed on alumina. Elution with pentane gave crude 3,3-diethoxycholest-5-ene (II) in 60% yield. Several crystallizations from ethanol gave II, m.p. 49–50°, $[\alpha]_D$ −28.4° (*c*, 1.06 in chloroform). Calc. for $C_{31}H_{54}O_2$: C, 81.16; H, 11.87%. Found: C, 81.26; H, 11.96%.

Further elution with benzene gave 20% of cholest-4-en-3-one (VIII), m.p. 81–82° not depressed upon admixture of authentic (VIII). Infrared and ultraviolet spectroscopy further proved the identity of the two products.

Further elution with ether gave 25 mg of cholest-4-en-6β-ol-3-one (IX) (6*b*), m.p. 181–182°, λ_{max}^{EtOH}, 237 mμ (ϵ 12,800), ν_{CHCl_3} 3570 cm^{-1} (free O—H), 3380 cm^{-1} (hydrogen-bonded O—H), 1685 cm^{-1} (α,β-unsaturated ketone). The melting point was not depressed on admixture with authentic IX.

3,3-Diethoxycholest-5-ene (II) and 3,3-Dimethoxycholest-5-ene (VI)

Following the procedure described by Ueberwasser *et al.*, a solution of cholest-5-en-3-one (1.0 g) and 0.5 g of malonic acid in 60 ml absolute ethanol was stirred for 20 hours at 20–25°. The solution was worked up as described and the resulting oil chromatographed on alumina. Elution with pentane yielded 0.38 g of pure 3,3-diethoxycholest-5-ene (II), m.p. 48–49°, in 32% yield, identical (infrared, melting point, mixed melting point) with that obtained by photolysis.

Similarly, the reaction of cholest-5-en-3-one, 1.0 g, and 0.5 g of malonic acid in 60 ml of absolute methanol yielded 0.685 g of pure 3,3-dimethoxycholest-5-ene (VI), m.p. 96°, identical (infrared, melting point, and mixed melting point) with that obtained by photolysis.

3-Methoxycholesta-3,5-diene (V)

To cholest-4-en-3-one (10 g) and 10 ml of trimethylorthoformate in 50 ml of dioxane, was added two drops of concentrated sulphuric acid in 1.5 ml of dioxane and the mixture refluxed for 0.5 hours. Pyridine (0.25 ml) was then added and the solution evaporated to an oil which was covered with methanol and allowed to crystallize. Recrystallization from ether–methanol yielded 5.8 g of pure V, m.p. 67–68°, $[\alpha]_D$ −97.1 (*c*, 1.12 in pyridine), λ_{max}^{EtOH}, 239 mμ (ϵ 19,900). Calc. for $C_{28}H_{46}O$: C, 84.35; H, 11.63%. Found: C, 84.19; H, 11.97%.

Irradiation of 3-Methoxycholesta-3,5-diene (V) in Methanol

Irradiation of 0.5 g of V in 1800 ml of absolute methanol for 30 minutes yielded, after evaporation, 0.6 g of an oil. Chromatography on alumina and elution with pentane gave 200 mg of 3,3-dimethoxycholest-5-ene (VI), m.p. 93°. Recrystallization from acetonitrile–ether gave pure VI, m.p. 95.7–96.0°, $[\alpha]_D$ −35.5° (*c* 1.07 in chloroform), identical (infrared, melting point, and mixed melting point) with that described above. Calc. for $C_{29}H_{50}O_2$: C, 80.87; H, 11.70%. Found: C, 81.19; H, 11.82%.

Methanolysis of 3,3-Diethoxycholest-5-ene (II)

The crude irradiation product of 1.65 g of 3-ethoxycholesta-3,5-diene (I) in ethanol was chromatographed on alumina. The oily hexane eluate (0.90 g) was covered with methanol. After a few days, 0.36 g of 3α-ethoxy-3β-methoxycholest-5-ene (III), m.p. 88–91°, was obtained. Two recrystallizations from methanol raised the m.p. to 105–106°. Calc. for $C_{30}H_{52}O_2$: C, 81.02; H, 11.79%. Found: C, 80.70; H, 12.05%.

In a second run, 100 mg of pure 3,3-diethoxycholest-5-ene (II) was heated for 12 hours in methanol on a steam bath and the solvent allowed to evaporate. Crystallization of the reaction product from methanol gave 40 mg of III, m.p. 96–98°. The very characteristic infrared and n.m.r. spectra of the products, m.p. 96–98°, and m.p. 105–106°, were indistinguishable.

Cholest-4-en-3-one (VIII) from 3α-Ethoxy-3β-methoxycholest-5-ene (III)

When a 90-mg sample of III in carbon tetrachloride was taken to dryness on the steam bath, an oily

mixture was recovered. Chromatography on aluminum oxide and elution with hexane–benzene mixtures gave cholest-4-en-3-one (VIII), m.p. 81–82°. The melting point was not depressed on admixture of authentic (VIII). Comparison of the infrared spectra confirmed the identity of the two compounds.

Further elution with ether gave 25 mg of a crystalline material, which melted at 182–183° after recrystallization from hexane. The melting point was not depressed on admixture with the material obtained in the chromatogram of the photolysis product of I in ethanol and V in methanol.

Rate of Alcoholysis of the 3,3-Dialkoxycholest-5-enes

Ketals VI and II were heated under reflux with ethanol and methanol respectively. Aliquots were withdrawn periodically and their n.m.r. spectra recorded.

In the methanolysis of II the 3β-ethoxy group was replaced at a rate twice as fast as the 3α-ethoxy group. The 3β group was replaced after 10 hours, the 3α group after 20 hours.

When 3,3-diethoxycholest-5-ene in 55 ml of methanol plus two drops of pyridine was refluxed overnight, 3,3-dimethoxycholest-5-ene was obtained.

Irradiation of 3-Methoxycholesta-3,5-diene (V) in Absolute Ethanol

Irradiation of 2.0 g of V in 1800 ml of absolute ethanol for 3 hours gave 2.3 g of product, which, on chromatography on alumina, yielded 1.1 g of 3β-ethoxy-3α-methoxycholest-5-ene (VII). The n.m.r. spectrum of this material indicated the presence of some epimeric 3α-ethoxy-3β-methoxycholest-5-ene (III) in small amounts. Recrystallization from ethanol gave pure VII, m.p. 98–99°, $[\alpha]_D$ −32.3 (*c* 1.26 in chloroform). Calc. for $C_{30}H_{52}O_2$: C, 81.02; H, 11.79%. Found: C, 81.43; H, 12.07%.

Effect of Silica Gel on β,γ-Unsaturated Ketals

3β-Ethoxy-3α-methoxycholest-5-ene (70 mg) was chromatographed on 20 g of silica gel (Davidson No. 923). A mixture of cholest-4-en-3-one (VIII) and cholest-5-en-3-one (IV) was obtained as indicated by the infrared spectrum of the eluate, ν 1735 cm^{-1} (saturated ketone), 1690 cm^{-1} (α,β-unsaturated ketone).

Chromatography of pure cyclic diethylene ketal of cholest-5-ene-3-one (3) resulted in complete recovery of starting material.

Irradiation of 3-Ethoxycholesta-3,5-diene (I) in Methanol with Pyridine

Irradiation of 0.8 g of I in 1500 ml of methanol for 30 minutes and subsequent slow evaporation of the solvent resulted in the formation of 0.28 g of pure 3α-ethoxy-3β-methoxycholest-5-ene (III), m.p. 110–112°. Recrystallization from ether–methanol gave pure III, m.p. 112–113°, $[\alpha]_D$ −30.1 (*c* 1.13 in chloroform). The infrared and n.m.r. spectra further proved the identity of this material.

ACKNOWLEDGMENTS

We wish to thank the National Research Council and Bristol Laboratories for financial support and Dr. C. Stammer, Department of Chemistry, McGill University, for taking the n.m.r. spectra.

INFRARED ABSORPTION OF SOLID PHOSPHINE

A. H. HARDIN AND K. B. HARVEY
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received August 13, 1963

ABSTRACT

The infrared absorption of solid phosphine has been measured in the region of 4° K to 68° K. An hitherto unreported transition at about 10° K has been observed. Above this temperature the spectrum is characteristic of a disordered system; below 10° K the absorption arising from the symmetric vibrational modes exhibits a fine structure composed of sharp lines. The large number of lines attributed to ν_2 are interpreted as arising from inversion doubling, indicating a residual disorder in the system.

INTRODUCTION

The crystal structure of solid phosphine is as yet unknown but it has been shown that it undergoes a number of transitions at low temperatures (1). The present investigation was undertaken to study the changes in the infrared spectrum expected to accompany these transitions.

The data of Stephenson and Giauque (1) are summarized in Fig. 1, reproduced from

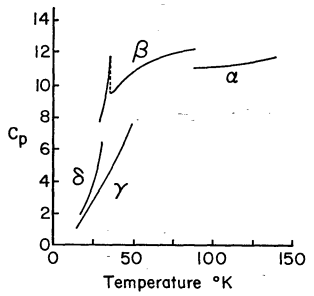

FIG. 1. Heat capacity of phosphine in cal/deg mole (from Stephenson and Giauque).

their paper. Three first-order transitions were observed at 30.29, 49.43, and 88.10° K and, in addition, they report a second-order transition in the region of 31–35° K. The transition from the α form to the β form (these designations are those of the present authors) at 88.10° K occurred rapidly and was readily observed. In contrast, the β to γ transition was an extremely slow one and Stephenson and Giauque found it necessary to hold the sample at 40° K for several days to obtain complete conversion. As a result, the β form could be readily supercooled to 30.29° K where a transition took place to the δ form. Stephenson and Giauque interpreted the heat capacity curves of the β and δ modifications as characteristic of the type associated with molecular rotation in the solid. Presumably the δ form is a disordered form of the γ phase.

The infrared spectrum of gaseous phosphine has been the subject of a number of investigations (2–6). McConaghie and Nielson (5) have partially analyzed the vibration–rotation spectrum in the region of the fundamentals and their structural data for the ground vibrational state are in good agreement with the microwave results (7, 8). The molecular parameters, as defined in Fig. 2, have the following values:

$$r = 1.42 \text{ Å}, h = 0.764 \text{ Å}, \alpha = 93°50', \text{ and } \beta = 57°30'.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

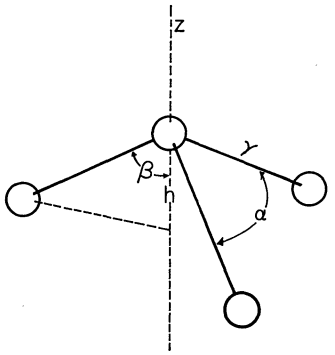

FIG. 2. Structural parameters of the PH_3 molecule.

The principal moments of inertia are

$$I_{xx} = 6.29\times10^{-40} \text{ g cm}^2 \text{ and } I_{zz} = 7.23\times10^{-40} \text{ g cm}^2,$$

so that phosphine is an oblate symmetric top.

It is also worth mentioning that no evidence has been obtained for inversion doubling in either the ground or first excited vibrational states of PH_3. This places upper limits on the splitting of 2×10^{-5} cm^{-1} in the ground state (8) and about 0.2 cm^{-1} for the first excited vibrational levels.

EXPERIMENTAL

The phosphine was prepared by adding PCl_3 dropwise to a vigorously stirred ethereal solution of $LiAlH_4$ under an inert atmosphere of nitrogen (9–11). A cold-finger at dry-ice temperature was used to prevent the ether from escaping the reaction vessel and the reaction products were trapped at 78° K. Separation of the PH_3 from P_2H_4, the other principle product, was accomplished by double distillation at 117° K (*n*-pentane slush) and the PH_3 produced was stored in the gaseous form. A slow reaction with stopcock grease was observed in the storage bulb, but this did not appear to introduce volatile impurities. As an added precaution, however, the phosphine was freshly distilled before each run. No impurities could be detected in the infrared spectrum of the gaseous phosphine. The latter was observed to explode on contact with air.

The low-temperature infrared absorption cell used in this work has been described previously (12). Temperatures intermediate between those attainable with liquid nitrogen and liquid helium were obtained by transferring quantities of helium just sufficient to maintain the desired temperature. It was found that the temperature of the copper block, in which the cesium iodide deposition plate is mounted, could be held to within ±3° K of the desired temperature by this method.

Spectroscopic measurements were carried out on a Perkin–Elmer 112G spectrometer with a modified source unit. Calibration was effected through established grating spectra and the reported frequencies are estimated to be accurate to within ±2 cm^{-1}. Spectral slit widths are indicated on the individual spectra.

RESULTS

The phosphine films investigated were deposited on the cesium iodide plate at about 65° K by admitting phosphine gas in short bursts. Spectra were recorded in the region of the fundamentals at a number of temperatures between 4° K and 65° K (approximately every 10 degrees), both while cooling and afterward during the warm-up. Several runs were made with deposits of different thicknesses and the results are summarized in Table I and Fig. 3. Attempts to deposit the PH_3 at temperatures above 88.10° K were unsuccessful because of the high vapor pressure of the solid so that we were unable to observe the spectrum of the α form. The high vapor pressure also limited the maximum annealing temperature to 65° K or 70° K.

At temperatures above 10° K the spectrum of each of the fundamentals consists of

$\nu_4 e$	1122.4	1101 m	1097 m	1102 m

NOTE: s = strong, m = medium, w = weak, vw = very weak.

only a single absorption peak and, surprisingly, none of these peaks underwent any significant changes as the temperature was varied. It seems certain that under our conditions of deposition and rate of cooling we obtained the β form between 65° K and 30° K and the δ modification between 30° K and 10° K. Our results indicate therefore that no significant spectral changes accompany the first- and second-order transitions in this region.

On the other hand, the spectrum of the fundamental ν_2 underwent a marked change at about 10° K to give a series of 10, very sharp, closely spaced lines. The overlap of ν_1 and ν_3 introduces some confusion, but it seems likely that ν_1 also exhibits fine structure below 10° K, although not to the same extent as ν_2. Since the fine structure disappeared at 10° K on warm-up, it can be concluded that the transition producing these changes is a reversible one.

DISCUSSION

Assignments

The assignment of the absorption due to the symmetric bending mode ν_2 and the degenerate, asymmetric bending mode ν_4 is straightforward. Some confusion arises from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

overlap of the other two fundamentals but, in the case of PH_3, intermolecular interactions in the solid would not be expected to result in a reversal of order of the frequencies of ν_1 and ν_3 so that we have assigned them in the same order as in the gas phase. At 4° K the problem is a more difficult one, but it is reasonable to assume that the fine structure in the 2300 cm^{-1} region is due to ν_1, which is of the same symmetry (a_1) as ν_2, the other mode giving rise to fine structure at this temperature. We have, therefore, assigned the single strong peak at 2312 cm^{-1} to ν_3. At the same time, the assumption that all of the remaining lines in this region are due to ν_1 must be treated with some reservation. Similarly, the strong absorption due to ν_3 may mask some of the ν_1 fine structure.

Frequency Shifts and Force Constants

All four fundamentals of phosphine shift downward in frequency as a result of condensation. This behavior is in contrast to that in crystalline ammonia (13) where the symmetric bending mode shifts upward in the crystal by over 100 cm^{-1}. It is unlikely therefore that hydrogen bonding, in the usual sense, plays any significant role in determining the crystal structure of phosphine. This conclusion is in agreement with the observed melting and boiling points of PH_3.

These relatively small downward shifts in crystalline PH_3 are reflected in the potential function, for internal vibrations. Assuming the coupling between the lattice vibrations and internal vibrations to be small, we may treat the internal problem separately and apply the same type of potential function as that used in the gas phase. We employed a simple valence–force potential function of the form

$$2V = k(\Delta r_1^2+\Delta r_2^2+\Delta r_3^2) + k_\delta(\Delta\alpha_1^2 +\Delta\alpha_2^2 +\Delta\alpha_3^2).$$

Since no corrections were made for anharmonicity, a more general potential function was unnecessary. The equations for the valence–force treatment of pyramidal XY_3 molecules have been derived by Lechner (14) and are tabulated by Herzberg (15). Since the frequencies of all four fundamentals are known in both the crystal and the gas it is possible to calculate two independent sets of values for k and k_δ in each case. Assuming the structural parameters to be the same as in the gas phase, the values listed in Table II are obtained.

TABLE II

Valence force constants for PH_3 (in units of 10^{-5} dynes/cm)

	From ν_1 and ν_2		From ν_3 and ν_4	
Gas	3.11	0.295	3.08	0.367
4° K	3.06	0.288	3.04	0.350

In view of the approximations involved, the agreement between the independent pairs of values is reasonable. At any rate there is little doubt that the stretching force constant k is about 1% smaller in the crystal as a result of crystal field perturbations, while the bending constant k_δ is about 3.5% smaller. In the case of ammonia the bending force constant was estimated by Hornig (13) to be about 5% larger in the crystal so that again we are led to the conclusion that hydrogen bonding is absent in crystalline PH_3.

Crystal Structure and the 10° K Transition

At temperatures above 10° K the lines assigned to ν_1, ν_2, ν_3, and ν_4 have band widths of approximately 7, 8, 15, and 17 cm^{-1} respectively; all far in excess of the spectral slit

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

width of the instrument. By absolute standards, these lines are not excessively broad for crystal spectra but the line widths are certainly far larger than the approximately 1 cm^{-1} line widths of the fine structure below 10° K. The latter are, in fact, of the same order as the resolution of the spectrometer.

We are led to conclude, then, that there is some degree of disorder in the β and δ forms right down to 10° K. This conclusion is in accord with the data of Stephenson and Giauque but it is surprising that no spectral changes accompany the transitions in the 30 to 35° K region. Furthermore, if as the calorimetric work indicated, the PH_3 molecules are executing rotational motion in the β and δ phases, a narrowing of the absorption peak would be expected as the temperature was lowered. We have been unable to detect any change in band width to confirm this. Such an effect might be masked, however, by the broadening due to additional disorder.

The transition at 10° K and the spectrum of the low temperature phase exhibit some interesting features. Since the transition is a reversible one and the β form is obtained on warming, the crystalline modification we observed at 4° K must also be metastable with respect to the γ form. Some degree of disorder might be expected then, even at 4° K. This is in accord with the broadness of the ν_3 and ν_4 absorption peaks (about 15 cm^{-1}) in the 4° K spectrum. On the other hand, the sharpness of the lines in the fine structure of the absorption due to ν_1 and ν_2 would indicate an ordered structure.

Apart from their sharpness, one must also account for the large number of lines in the ν_2 absorption band. Under a factor or unit cell group analysis, the number of absorption peaks arising from a single non-degenerate, internal vibrational mode may have a maximum value equal to the number of molecules in the unit cell. It is unlikely, however, that there are as many as 10 molecules in the unit cell of phosphine. A figure of two, four, or six seems more reasonable. Noting, in addition, that in the absorption assigned to ν_2 there are about twice as many components as there are in the ν_1 fine structure, one infers that some effect is giving rise to a doubling in the case of ν_2.

The effect observed is, in fact, consistent with inversion-doubling arising from the two equilibrium positions of the PH_3 molecule. In gaseous ammonia, for example, a splitting of some 35 cm^{-1} is observed for the $v_2 = 1$ level and 1 cm^{-1} for the $v_1 = 1$ level. On the other hand, the inversion doubling in gaseous phosphine is too small to be measured. It is clear, however, that the height of the barrier to inversion will be related to the magnitude of the bending force constant so that an increase in k_δ will decrease the magnitude of the splitting. This is observed in crystalline ammonia where the doubling is too small to be observed. In the case of phosphine, however, k_δ decreases on condensation so that the barrier to inversion will be lower than in the gas phase.

It is difficult to assign a specific value to the magnitude of the doubling in crystalline PH_3. On the basis of the two strong doublets (975, 976 cm^{-1} and 981, 983 cm^{-1}) the 10 peaks of the ν_2 absorption can be divided in two ways to give two sets of five lines differing by about 2 cm^{-1} or 6 cm^{-1}. Without single crystal spectra there is no criterion to decide which of these values is correct but the smaller one seems more reasonable. The ν_1 fine structure is of little value for comparison because of the overlap with ν_3.

ACKNOWLEDGMENTS

The authors are indebted to Mr. Rudolf Muehlchen for his assistance in the construction and maintenance of the apparatus. We wish also to acknowledge the financial assistance of the National Research Council of Canada and the University of British Columbia in carrying out this work.

RÉSUMÉ

On a mesuré l'absorption infrarouge de la phosphine crystalline entre 4° K et 68° K. Une nouvelle transition dans la région de 10° K a été observée. Aux températures plus élevées que 10° K, le spectre est caractéristique d'une système désordonnée; au-dessous de 10° K, l'absorption des vibrations symétriques a une structure composée de plusieurs lignes étraites. Dans le cas de ν_2 la multiplicité des lignes a été interprétée comme le résultat de deux positions d'équilibre occasionnées par l'inversion.

STEADY-STATE THEORY OF ADSORPTION PSEUDOCAPACITANCE IN ELECTROCHEMICAL RADICAL–ION REACTIONS

B. E. CONWAY AND E. GILEADI[1]
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received July 24, 1963

ABSTRACT

The theory of adsorption pseudocapacity behavior is developed for a sequence of electrochemical reactions involving an ion discharge step which produces an adsorbed radical, followed by an "ion–atom" recombination reaction with or without desorption of the product of this step. The adsorption pseudocapacity behavior is deduced analytically particularly for the steady-state case and distinguished from the results obtained for assumed quasi-equilibrium in the ion discharge step when the succeeding step is rate-controlling. The effect of variation of the relative values of the rate constants of the discharge and of succeeding steps is investigated. It is shown that the capacity-potential behavior is sensitively dependent on the ratio of these rate constants, particularly for the case of adsorption isotherms involving a large value for the "heterogeneity parameter", r, defining the variation of energy of adsorption of the intermediates with coverage. Under the latter conditions, limiting coverages of the electrode by the adsorbed species are reached with increasing potential, depending on the relative values of the rate constants and the value of r.

1. INTRODUCTION

Most electrochemical reactions not involving simple metal–ion redox reactions proceed by two or more consecutive steps. Under these circumstances, adsorbed intermediates are involved, the surface concentrations of which are usually potential dependent. Since Faradaic charge is involved in the formation of the layer of intermediates, the potential dependence of the coverage leads to an adsorption pseudocapacitance (1, 2).[2] The importance of studies of charging curves was already recognized by Bowden and Rideal (3) with regard to the ionic double-layer and the method was developed by Slygin and Frumkin (4–6) for the study of H atom adsorption in the hydrogen evolution reaction; at about the same time, Butler and Drever (7) used this method for the study of oxide films and Pearson and Butler (8) examined electrochemical hydrogen adsorption at the platinum metals by means of charging curves. Studies of charging curves and the corresponding adsorption pseudocapacitance can provide an important method, complementary to direct kinetic current–potential studies, for elucidation of electrode reaction mechanisms. Much contemporary interest in electrochemical kinetics centers around the study of charging curves and the measurement of electrode capacitance, but further work is required in the interpretation of such data.

In a previously published paper (9), we have shown how studies of the dependence of adsorption pseudocapacitance upon potential can lead to information on the type of isotherm governing the adsorption of reaction intermediates, and to information about the potential dependence of coverage by such intermediates in two or multistep electrochemical reactions. In another paper (10), we have shown how these theoretical considerations can be applied to the elucidation of the adsorption behavior of intermediates involved in electrochemical decarboxylation reactions reported elsewhere (11–13).

[1]*Present address: John Harrison Laboratory, University of Pennsylvania, Philadelphia.*

[2]*The term pseudo-capacitance was introduced by Grahame (1) to distinguish the capacitance arising from adsorption of intermediates (and diffusion effects) from the strictly "non-Faradaic" capacitance associated with the dependence of ionic and electron charge in the double-layer on potential. In the present case, the capacitance arises from a Faradaic discharge process across the ionic double-layer producing an adsorbed radical intermediate, the surface concentration of which varies with potential.*

Examples of reactions in which the desorption step is electrochemical (in distinction to heterogeneous chemical radical recombination or disproportionation) are the hydrogen evolution reaction under certain conditions and the formate decarboxylation reaction (11). The kinetic sequence of steps in these reactions may be written:

$$H_3O^+ + M + e \xrightarrow{k_1} MH^\cdot + H_2O + e \qquad I$$

followed by

$$MH^\cdot + H_3O^+ + e \xrightarrow{k_2} H_2 + H_2O + M, \qquad II$$

and in the anodic decarboxylation of formate ions

$$HCOO^- + M \xrightarrow{k_3} MHCOO^\cdot + e \qquad III$$

followed by

$$MHCOO^\cdot \xrightarrow{k_4} M + CO_2 + H^+ + e. \qquad IV$$

Analogous steps to I and II occur in the oxygen evolution reaction (9). Evidence has been given that the pathway I and II is the mechanism of the hydrogen evolution reaction from aqueous acids at a number of transition metals (14–17), while III–IV is the mechanism of formate decarboxylation at high anodic potentials (10–13). In the above reactions, the pseudocapacitance is associated with H$^\cdot$ adsorption in I–II and with HCOO$^\cdot$ adsorption in III–IV (10). We have chosen to examine the "radical-ion"[3] type of reaction sequence since this is the only one for which explicit steady-state analytical expressions can be obtained for the capacitance behavior.

The basis of previous calculations on adsorption pseudocapacitance (2, 9) has been the assumption of effective, or quasi-equilibrium, in an ion-discharge step in a sequence of electrochemical reactions, for which the following step was a rate-determining desorption or rearrangement process. The quasi-equilibrium assumption is the one often made in the kinetics of consecutive reactions, e.g. for certain solvolytic reactions in solution. Provided that one step is "rate-determining", it is usually not very important in homogeneous chemical reactions to what extent the equilibrium is disturbed in the pre-rate-determining step(s), and usually the extent of the disturbance of this equilibrium cannot be directly known unless independent knowledge of the rate constants of the individual steps is available. We shall show that in consecutive *electrochemical* reactions, the behavior of the adsorbed intermediates, as reflected in the potential-dependence of the pseudocapacitance, can be a sensitive measure of the extent of departure from equilibrium in the step prior to the rate-determining one. These conclusions will also affect the interpretation of the pseudocapacitance behavior in terms of the adsorption isotherm.

So long as effectively complete equilibrium in the ion discharge steps I or III is maintained, the pseudocapacitance can be directly calculated from the following abbreviated kinetic equations of the type given previously (9, 18):

$$[1] \qquad v_1 = k_1(1-\theta)C_{H^+} \exp\,[-\beta VF/RT] \exp\,-[\alpha r\theta/RT]$$

and

$$[2] \qquad v_{-1} = k_{-1}\,\theta \exp\,[(1-\beta)\,VF/RT] \exp\,[(1-\alpha)r\theta/RT]$$

for step I (or analogously for step III), where θ is the fractional surface coverage by the adsorbed intermediate, C_{H^+} is the reactant (H^+) ion concentration in the double layer,

[3]*The term is used here in a general sense similar to that of the term "atom-ion reaction" suggested by Parsons (18) for step II.*

V is the metal-solution potential difference, r the parameter defining the extent of linear (18–20) variation of the energy of adsorption with coverage (see footnote [4]) in a Temkin type of isotherm, and α and β are symmetry factors, where $\alpha = 1-\beta$. When double-layer ion distribution effects (21) are maintained constant, and for convenience at unit C_{H^+}, equations [1] and [2] give

$$-\frac{k'}{C} = \frac{dV}{d\theta} = \frac{RT}{F}\frac{d\ln[\theta/(1-\theta)]}{d\theta} + r/F \qquad [4a]$$

or

$$C = \frac{k'F}{RT}\frac{\theta(1-\theta)}{1+(r/RT)\theta(1-\theta)} \qquad [4b]$$

where k' is a geometrical and electrical constant giving the charge required to form a complete monolayer of adsorbed species. It must be emphasized that equation [4*a*] (or [4*b*]), which we have deduced previously (9), is an equilibrium equation for the general case of coverage-dependent energy of adsorption analogous to that deduced for *Langmuir* conditions (viz. $r = 0$) by Bockris and Kita (22) in their analysis of transients in metal deposition processes.

For the purposes of defining a rate-determining step in a sequence of reactions, it is usually sufficient that the rate constant for whatever step is rate-controlling is at least some 10 times smaller than that for other steps. In the cases considered above for rate-controlling desorption steps, this implies that steps I or III will have to be in quasi-equilibrium. For the purposes of purely kinetic studies (e.g. of the current–potential behavior), it will not be very important exactly to what extent these steps are in equilibrium provided the condition mentioned above regarding the relative values of k_1 and k_2, or k_3 and k_4 is satisfied.

It is the purpose of the theoretical calculations presented below, to show that the pseudocapacitance and coverage behavior is very sensitive to the relative values of the rate constants for the initial ion discharge and the subsequent electrochemical desorption steps. It will also be shown that the pseudocapacitance must preferably be derived from a *steady-state* equation relating θ to V rather than from a quasi-equilibrium type of equation which can normally be used as a satisfactory limiting approximation only in the analysis (e.g. see Bockris, ref. 23) of the kinetics of consecutive electrochemical reactions in terms of the Tafel slopes for the steady current–potential behavior.

2. NON-EQUILIBRIUM PSEUDOCAPACITY BEHAVIOR

(a) Introduction

We now consider the form of the C–V relationship in a case for which the assumption of quasi-equilibrium in the pre-rate-determining discharge step discussed above is no longer valid. We recall that when the standard free energy of activation of a given step in a consecutive reaction sequence is much larger than that of any other step, i.e. its specific rate constant is much smaller, the rate of the overall reaction will be governed by the rate constant for the slowest step, and all other steps prior to the rate-controlling step will effectively be in equilibrium. The fundamental requirement for the applicability of the quasi-equilibrium assumption in kinetics is, hence, that a rate-determining step will, unambiguously, exist. The rates of electrochemical reactions may, in general, depend on potential in different ways, so that, as the potential is changed, conditions may change from those where the quasi-equilibrium assumption is applicable to those where it is not.

For the purpose of discussing the kinetics of electrode reactions, we can usually assume

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

that a definite rate-determining step exists over a particular range of potentials studied, since (*a*) a relatively small difference in the standard free energies of activation of the various steps will generally be sufficient to make one of them rate-determining (thus if $\Delta G^{0\neq}$ for one step is 2.8 kcal mole^{-1} larger than that for another at the same metal-solution potential difference, the ratio of specific rate constants will be 10^2 at 25° C), and (*b*) the electrochemical rate constants for different steps will usually depend on potential to different extents (i.e., the Tafel slopes associated with these steps will be different) and the region of potential over which two steps can have comparable rates is strictly limited, as shown by Parsons (24). The arguments of Parsons apply, however, only to limiting Langmuir conditions, and we have shown elsewhere (9) that when a Temkin type of isotherm is applicable, several mechanisms may correspond to the same Tafel slope, i.e. the rates of different steps may vary with potential in the same way. Moreover, we shall show below that, while for the purpose of discussing electrode kinetics, a step may be considered rate-determining if its rate constant is, say, one or two orders of magnitude smaller than that for any other consecutive step, the ideal symmetrical shape of the C–V curve (9) may not be observed under certain circumstances (in particular when the heat of adsorption[4] varies excessively with coverage, i.e. $r/RT \gg 1$) unless the rate constant of the rate-determining step is *5 to 10 orders of magnitude* smaller than that for any other consecutive step in the given reaction sequence.

We shall proceed below to discuss a general anodic reaction sequence[5] such as III and IV occurring through an initial discharge step followed by a rate-controlling electrochemical desorption or an electrochemical recombination step, with a possible final desorption step which tends to be very fast, and not at equilibrium with respect to its products. The form of the dependence of pseudocapacity and coverage on potential will be evaluated first by means of a steady-state calculation (for non-equilibrium in the discharge step) assuming limiting Langmuir conditions for the adsorption of the intermediates and then using a general adsorption isotherm (including both Temkin and Langmuir terms), for various ratios of the specific rate constants of the initial discharge step and the following electrochemical desorption step. It is clear that a somewhat different set of equations will be obtained if a different sequence of consecutive electrochemical steps is considered.[6] Our *method* of treating the problem, as given below, will, however, be applicable in general. The present case serves both to exemplify this method and to demonstrate the much more limited applicability of the quasi-equilibrium assumption when calculations of C and θ, and their dependence on potential, are considered, than when the kinetics of the reaction steps themselves are considered.

(b) Limiting Langmuir Conditions (Non-equilibrium in the Discharge Step)

We consider the following general sequence of anodic reactions:

Ion discharge

$$\mathrm{M} + \mathrm{A}^- \underset{k_{-5}}{\overset{k_5}{\rightleftarrows}} \mathrm{MA} + \mathrm{e} \qquad \mathrm{V}$$

[4]*The variation of heat of adsorption and apparent standard free energy of adsorption with coverage has been discussed previously (9, 25) and it was assumed by Parsons (18) that the variation of these two quantities with coverage was the same; in the latter paper, however, the "free energy of adsorption" was regarded as varying with coverage, but it is clear that neither the free energy of adsorption (which is zero at equilibrium) nor the standard free energy of adsorption (which is a constant) can vary with coverage. It is, in fact, an apparent standard free energy of adsorption, calculated with respect to fractional surface coverages (rather than activities), which varies with coverage.*

[5]*While we have given I and II with III and IV as examples, the discussion henceforth will be a general one; the choice of an anodic reaction (such as III and IV) is purely for convenience in the mathematical development.*

[6]*In a forthcoming paper (30), it is intended to treat other reaction sequences. However, explicit analytical solutions for the relationship between the capacity and the potential cannot be obtained for these cases and digital computer calculations are required in order to obtain numerical solutions.*

For personal use only.

Electrochemical radical-ion step

$$MA + A^- \xrightarrow{k_6} MB + e + C \qquad VI$$

Final desorption

$$2MB \xrightarrow{k_7} 2M + B_2 \qquad VII$$

We shall assume first that the rate constant for reaction VII is much greater than that for either of the previous steps, so that $\theta_B \ll \theta_A$ and $\theta_A \doteqdot \theta_T$, the total coverage by A and B, which we shall write for simplicity as θ. With this assumption, we can proceed to calculate the *steady-state* coverage by 'A' radicals, determined by the condition

$$d\theta_A/dt = 0.$$

The rates of the relevant reaction steps can be written in an abbreviated form as

[5] $$v_5 = k_5\,(1-\theta)\exp\,[\beta VF/RT] = a_5\,(1-\theta)$$

[6] $$v_{-5} = k_{-5}\,\theta\exp\,[-(1-\beta)\,VF/RT] = a_{-5}\,\theta$$

[7] $$v_6 = k_6\,\theta\exp\,[\beta VF/RT] = a_6\,\theta$$

where k_5, k_{-5}, and k_6 are the specific rate constants; the equations have been written[7] for unit concentrations in the double-layer and for conditions under which the diffuse layer configuration is regarded as invariant. The terms a_5, a_{-5}, and a_6 are the corresponding electrochemical rate constants. We shall also define the Tafel slope parameter b as $2RT/F$ (assuming here that all symmetry factors are equal to 0.5).

The steady-state requirement leads to

[8] $$d\theta/dt = v_5 - v_{-5} - v_6 = 0$$

hence

[9] $$a_5(1-\theta) - a_{-5}\theta - a_6\theta = 0$$

or

[10] $$\theta = a_5/(a_5+a_{-5}+a_6).$$

Differentiating with respect to V gives

[11] $$\frac{d\theta}{dV} = \frac{(a_5+a_{-5}+a_6)a_5/b - (a_5-a_{-5}+a_6)a_5/b}{(a_5+a_{-5}+a_6)^2}$$

$$= \frac{2a_{-5}a_5/b}{(a_5+a_{-5}+a_6)^2}.$$

The Langmuir pseudocapacity (i.e. for $r = 0$) is hence given as

[12] $$C_L = k'(d\theta/dV) = k'\,\frac{2a_{-5}a_5/b}{(a_5+a_{-5}+a_6)^2}$$

where k' is the charge required to form a complete monolayer on the surface, as defined above. Substituting for the 'a' values from equations [5] to [7], gives

[7] *We consider only the forward directions of the rate-determining steps VI and VII, since the pseudocapacitance will be shown to vary over an appreciable range of polarizations, much greater than the approximately 30 mv potential range (from the reversible potential for the overall process $2A^- \leftrightarrows B_2 + 2e$) for which the back reactions of VI and VII can be significant in the kinetics. Thus we consider the pseudocapacitance in the regions of Tafel polarization behavior.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[13] $$C_L = k' \frac{2k_5k_{-5}/b}{[k_5 \exp(V/b)+k_{-5}\exp(-V/b)+k_6\exp(V/b)]^2}.$$

The maximum in capacity will occur at a potential V_m where the condition $dC_L/dV = 0$ is satisfied, that is when,

[14] $$\frac{dC_L}{dV} = \frac{2k'k_5k_{-5}}{b}\cdot\frac{d}{dV}(a_5+a_{-5}+a_6)^{-2} = 0.$$

Hence, V_m must satisfy the equation

[15] $$a_5-a_{-5}+a_6 = 0$$

so that

[16] $$(k_5+k_6)\exp(V_m/b) = k_{-5}\exp(-V_m/b)$$

or

[17] $$\exp(2V_m/b) = k_{-5}/(k_5+k_6).$$

Equation [17] defines the potential[8] V_m at which C_L will reach its maximum value.

Combining equations [12], [15], and [16], we obtain

[18] $$C_{L(max)} = \frac{k'k_5}{2bk_{-5}}\exp[2V_m/b] = \frac{k'}{2b}\times\frac{k_5}{k_5+k_6}.$$

Substituting the value[9] of b into this equation, gives

[19] $$C_{L(max)} = \frac{k'F}{4RT}\times\left(\frac{k_5}{k_5+k_6}\right).$$

Equations [13] and [19] are the general expressions for the Langmuir adsorption pseudo-capacity and its maximum value when a single intermediate is adsorbed on the surface of the electrode. If step VI is rate-determining, and for the particular condition $k_5, k_{-5} \gg k_6$

[20] $$C_L = \frac{k'F}{RT}\cdot\frac{k_5/k_{-5}\exp(VF/RT)}{[1+(k_5/k_{-5})\exp(VF/RT)]^2}$$

which is the quasi-equilibrium result; the corresponding maximum value for C_L under these conditions, is (cf. ref. 22),

[21] $$C_{L(max)} = k'F/4RT.$$

The constant k' has been defined above as the charge associated with formation of a monolayer of adsorbed intermediates per unit real surface area. Taking the number of sites per square centimeter, for example, as 10^{15}, we obtain

$$k' = 1.6 \times 10^2 \text{ microcoulomb cm}^{-2};$$

and

$$C_{L(max)} = 1.6 \times 10^3 \ \mu\text{f cm}^{-2}.$$

[8]*The potential considered here, and in all the calculations, is expressed on an arbitrary scale dependent on the value of K_5, as discussed previously (9).*

[9]*In the above derivation we have assumed $\beta = 0.5$ and defined accordingly $b = 2RT/F$. The limiting results (equations [20] and [21]) do not depend on this assumption, since the symmetry factor β cancels out between terms in β and $(1-\beta)$. This must be so since θ, and consequently its derivative C_L, are quantities defined by (quasi)-equilibrium conditions considered for this limiting case and cannot therefore depend on the form of the energy barrier. However, the steady state expression for C_L will still depend on β, although for convenience we have assumed the usual value of $\beta = \frac{1}{2}$.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The numerical value of k' obviously depends on both the size and "electrochemical valency" of the adsorbate, and the geometry of the adsorbent surface involved. We shall arbitrarily use the value given above for k' for our general calculations, since the discussion and conclusions do not depend on this value.

The coverage θ_m at which C_L reaches its maximum value is obtained by substituting equation [15] into equation [10] giving

$$\theta_m = \frac{a_5}{a_5+a_{-5}+a_6} = \frac{a_5}{2(a_5+a_6)} = \frac{1}{2}\left(\frac{k_5}{k_5+k_6}\right). \quad [22]$$

When step VI is rate-determining, with the particular condition $k_5 \gg k_6$, $\theta_m = 0.5$. The resulting expressions in terms of the steady-state assumption are thus reduced to those that would be obtained using the quasi-equilibrium assumption when $k_5 \gg k_6$ and v_5 can be almost equal to v_{-5}. This is to be expected since the above inequality applies when step VI is *unambiguously* rate-determining, and this is also the requirement for the applicability of the quasi-equilibrium assumption.

Equation [13] can be written for $\beta = 0.5$ as

$$C_L = \frac{k'F}{RT}\cdot\frac{(k_5/k_{-5})\exp(VF/RT)}{\left[1+\left(\frac{k_5+k_6}{k_{-5}}\right)\exp(VF/RT)\right]^2}. \quad [23]$$

For steady-state, rather than quasi-equilibrium conditions, the maximum in the C–V plot occurs at a potential given from the steady-state "Langmuir" equation [23] as

$$V_m = (RT/F)\ln[k_{-5}/(k_5+k_6)] \quad [24]$$

where the corresponding value of C_L is

$$C_{L(max)} = \frac{k'F}{4RT}\left(\frac{k_5}{k_5+k_6}\right). \quad [25]$$

We have used equation [23] to calculate C_L as a function of V taking three values for the rate constant ratio k_6/k_5, which determines the relative "extent" to which the discharge step is not in true equilibrium. Results of these calculations are shown in Fig. 1, taking the quasi-equilibrium constant $K_5 = k_5/k_{-5}$ as 10^{-2} (cf. previous calculations by Conway and Gileadi (9); choice of other values for K_5 only shifts the C–V profiles along the potential axis without changing their shapes). The quasi-equilibrium assumption obviously corresponds in the limiting case to $k_6/k_5 = 0$. As the latter ratio is increased, the pseudocapacities corresponding to each potential decrease, and the maximum is shifted towards less anodic potentials (or, in general, to lower values of the over-potential). The shapes of the curves remain, however, unchanged. This can be demonstrated by normalizing the curves in Fig. 1, so that they all have the same maximum (this is done by multiplying each capacity value by a factor $(k_5+k_6)/k_5$ and shifting the curves parallel to one another along the potential axis so that all maxima will occur arbitrarily at the same potential). The capacity curves normalized in this manner are then found to be identical. The coverage vs. potential relationships[10] corresponding to the pseudocapacitance behavior shown in Fig. 1, are illustrated in Fig. 2.

In the case when limiting Langmuir behavior is assumed to prevail, the conditions for a given step to be rate-controlling are similar to those required in the discussion of the

[10]*Experimentally, the coverage–potential relationship can be obtained by integration of the capacity-potential profile (10) or directly from charging or discharging transients (4, 5, 6, 11, 12).*

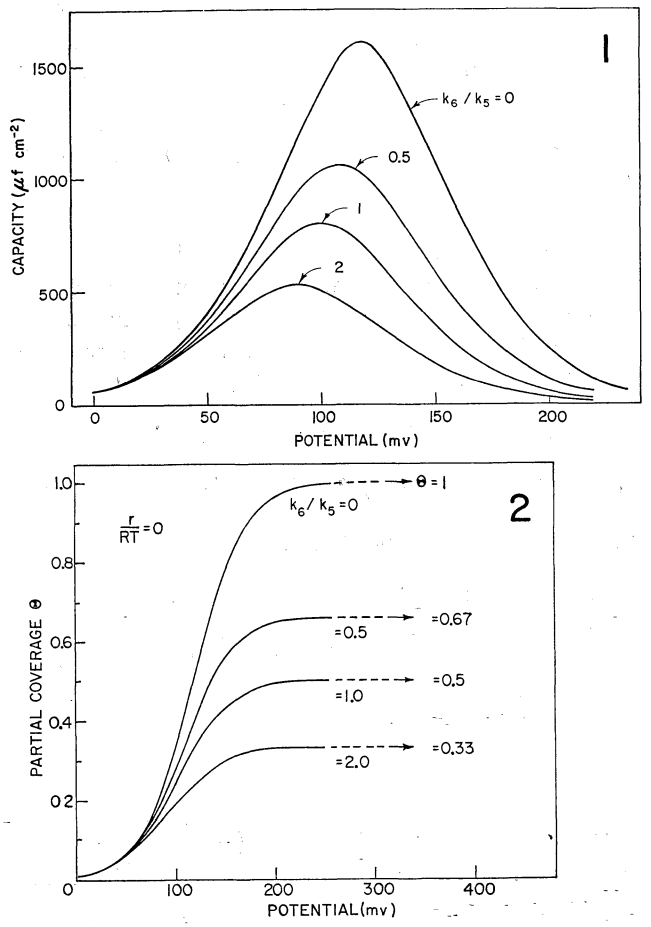

FIG. 1. Pseudocapacity–potential relationships calculated for Langmuir ($r = 0$) steady-state conditions for various values of the rate constant ratio k_6/k_5 equal to 0 (equilibrium case), 0.5, 1, and 2.

FIG. 2. Coverage–potential relations calculated for Langmuir ($r = 0$) steady-state conditions for various values of the rate constant ratio k_6/k_5 equal to 0 (equilibrium case), 0.5, 1, and 2. Note *limiting* coverages which are attained at high potentials.

electrode kinetics of the consecutive reactions involved. Thus when k_6/k_5 equals, say, 10^2 (which is a condition for the *discharge* step to be rate-determining),

$$C_{L(max)} = 0.01\ (k'F/4RT),$$

which is of the order of magnitude of the double-layer capacity, and, in addition, C_L will go from practically zero to its maximum and back to zero in a range of about 6 mv (cf. equation [24] and the argument above about the symmetrical form of the C–V curve for any value of k_6/k_5). Hence, when $k_6/k_5 = 10^2$ (as above), *no* significant pseudocapacity will be observed. Taking the other extreme case, when $k_6/k_5 = 10^{-2}$, $C_{L(max)}$ becomes equal to $0.99\ k'F/RT$ and the maximum occurs at a potential $V_m = 115$ mv if we take $k_{-5}/k_5 = 10^2$ (i.e., the equilibrium constant K_5 for the discharge step) as in our previous calculations (9). The maximum capacity thus obtained is 99% of the value deduced assuming complete quasi-equilibrium, and the potential range over which the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

pseudocapacity is appreciable is only some 6 mV less than in the complete equilibrium case; thus, when $k_6/k_5 = 10^{-2}$, the quasi-equilibrium assumption may be considered valid for most practical purposes. It is important to emphasize, however, that these conclusions will apply only under limiting Langmuir conditions, as we now show below.

(c) A General Case (Combined Langmuir and Temkin Terms) for Non-equilibrium Conditions in the Discharge Step

(i) Pseudocapacitance Equations

We proceed now to calculate the total effective adsorption pseudocapacitance, using the steady-state treatment, i.e. without any limiting assumption regarding quasi-equilibrium but also now without any special assumption (Langmuir case) about the two-dimensional thermodynamic ideality of the ad-layer. We write the rate equations for reactions V and VI now as (see Conway and Gileadi (9), Parsons (18), and Thomas (26)):

$$[26] \qquad v_5 = k_5(1-\theta)\exp(-\alpha r\theta/RT)\exp(\beta VF/RT)$$

$$[27] \qquad v_{-5} = k_{-5}(\theta)\exp[(1-\alpha)r\theta/RT]\exp[-(1-\beta)VF/RT]$$

$$[28] \qquad v_6 = k_6\theta\exp[(1-\alpha)r\theta/RT]\exp(\beta VF/RT)$$

In the above equations, [26] to [28], the term r has the significance defined above introducing coverage-dependent terms arising in a dependence of energy of activation for the various steps upon coverage when a Temkin type of isotherm applies to the adsorption of the intermediates.

In the steady state $v_5 = v_{-5}+v_6$, hence

$$[29] \qquad k_5(1-\theta)\exp(-r\theta/2RT)\exp(VF/2RT) = k_{-5}\theta\exp(r\theta/2RT)\exp(-VF/2RT)+k_6\theta\exp(r\theta/2RT)\exp(VF/2RT)$$

where all symmetry factors have again been taken as equal to 0.5. Equation [29] can be rearranged to have the form

$$[30] \qquad k_5\left(\frac{1-\theta}{\theta}\right)\exp(-r\theta/RT) = \left[\frac{k_{-5}\exp(-VF/2RT)+k_6\exp(VF/2RT)}{\exp(VF/2RT)}\right] = k_6+k_{-5}\exp(-VF/RT).$$

Hence

$$[31] \qquad \left[k_5\left(\frac{1-\theta}{\theta}\right)\exp(-r\theta/RT)-k_6\right]/k_{-5} = \exp(-VF/RT)$$

and

$$[32] \qquad V = \frac{RT}{F}\ln\left[\frac{k_{-5}}{k_5\left(\frac{1-\theta}{\theta}\right)\exp(-r\theta/RT)-k_6}\right].$$

The total effective adsorption pseudocapacity can be obtained explicitly by differentiating the above equations; thus

$$[33] \qquad \frac{k'}{C} = \frac{dV}{d\theta} = -\frac{RT}{F}\frac{d}{d\theta}\ln\left[k_5\left(\frac{1-\theta}{\theta}\right)\exp(-r\theta/RT)-k_6\right]$$

or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$$[34] \qquad \frac{k'}{C} = \frac{(1-\theta)\theta r + RT}{F\theta^2} \times \frac{k_5 \exp(-r\theta/RT)}{\left[k_5\left(\frac{1-\theta}{\theta}\right)\exp(-r\theta/RT) - k_6\right]}$$

$$= \frac{(1-\theta)\theta r + RT}{F\theta^2} \times \frac{1}{[(1-\theta)/\theta] - (k_6/k_5)\exp(r\theta/RT)]}.$$

The total adsorption pseudocapacitance is hence related to the coverage in the most general case (subject only to the assumption that the apparent standard free energy of adsorption decreases linearly with coverage through the r terms) by the equation

$$[35] \qquad C = (k'F/RT)\left[\frac{\theta^2}{(1-\theta)\theta r/RT + 1}\right][(1-\theta)/\theta - (k_6/k_5)\exp(r\theta/RT)].$$

It is apparent that this equation has the correct form, since if we assume $k_6/k_5 = 0$, i.e. when the discharge step is, in the limiting case, at quasi-equilibrium, equation [34] becomes (see eq. [4*b*])

$$[4c] \qquad \frac{k'}{C} = \frac{r}{F} + \frac{RT}{F} \times \frac{1}{\theta(1-\theta)},$$

which is the expression obtained previously (9) using the quasi-equilibrium assumption and is equivalent to equation [4*a*] or [4*b*].

(ii) Attainment of Limiting Coverages

Frumkin (29) was the first to show that for the radical-ion type of mechanism in hydrogen evolution, a limiting coverage of H would be reached dependent on the relative values of the rate constants for the discharge and desorption steps but the pseudocapacitance was not investigated and the case was developed for implicit Langmuir conditions.

When $r = 0$ is substituted into equation [35] above,

$$[36] \qquad C_L = (k'F/RT)[(1-\theta)\theta - \theta^2 k_6/k_5].$$

The first term in the square bracket is the usual term obtained for the quasi-equilibrium assumption ($k_6/k_5 = 0$). When we take, for example, $k_6 = k_5$, the pseudocapacity becomes

$$[37] \qquad C_L = 2(k'F/RT)\,[(0.5-\theta)\theta],$$

which varies symmetrically with coverage between $\theta = 0$ and a *limiting* value of coverage $\theta = 0.5$ with $C_{L(max)} = k'F/8RT$, i.e. half the quasi-equilibrium maximum value. This result is to be expected since when $k_6 = k_5$ the coverage cannot rise above 0.5, and the value of $C_{L(max)}$ is exactly half the value obtained for the case when $k_6/k_5 = 0$ (quasi-equilibrium assumption). The limiting coverages attained under these conditions are shown in Fig. 2 for various values of k_6/k_5.

We may observe that equation [36] for the Langmuir pseudocapacitance C_L as a function of coverage is equivalent to equation [23], where C_L was expressed as a function of potential. While in the Langmuir case, the pseudocapacitance can be expressed as an explicit function of potential (equation [23]), we obtain it here as a special case of equation [35] in terms of coverage, since it is not possible in the general steady-state case to derive an equation analogous to [35] expressed explicitly in terms of potential; the same situation is encountered for the expression of the quasi-equilibrium pseudocapacitance as a function

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of potential (9), where C as $f(V)$ must be calculated from an explicit $f(\theta)$ together with an equation giving θ as $f(V)$.

We presume that equation [35] relating the total effective adsorption pseudocapacity to coverage for the general case, applies only over the range of coverage where the resulting pseudocapacity is not negative, that is when

$$[38] \qquad (1-\theta)/\theta > k_6/k_5 \exp(r\theta/RT).$$

Hence, for the general case, the highest attainable coverage for given values of k_5/k_6 and r/RT is defined by the equation

$$[39] \qquad \theta/(1-\theta) \exp(r\theta/RT) = k_5/k_6.$$

The function on the left hand side of equation [39] is plotted in Fig. 3 against θ, for three

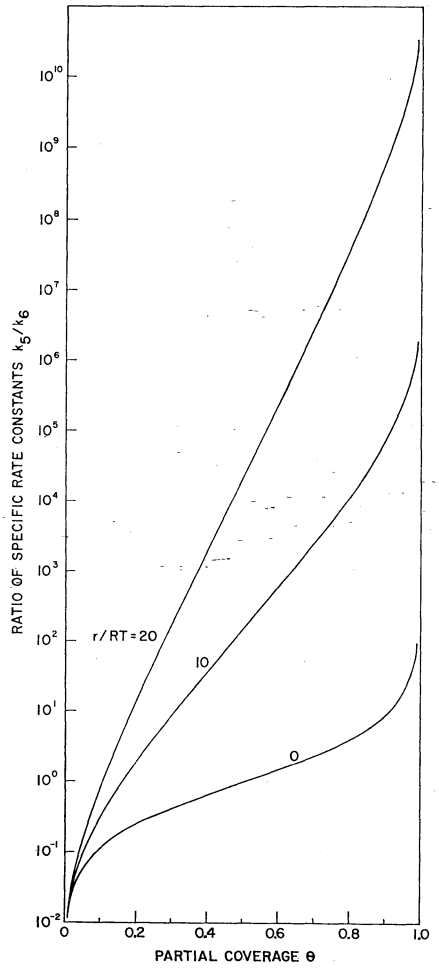

FIG. 3. The values of the ratio k_5/k_6 required for various limiting coverages to be attained at high potentials, calculated for three values of r/RT equal to 0 (Langmuir case), 10, and 20.

values of r/RT (0, 10, 20). The values of θ obtained from this graph constitute the various *limiting* coverages ($\theta < 1$) approached at high overpotentials for given values of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

parameters k_5, k_6, and r. As r/RT is increased, the ratio k_5/k_6 required for the limiting coverage to reach a given value increases rapidly, i.e. it becomes harder to realize a state of quasi-equilibrium (which obviously corresponds to a θ value approaching unity at sufficiently high overpotentials). Thus, for the limiting value of the coverage to be, for example, 0.9 with $r/RT = 20$ we require $k_5/k_6 = 6 \times 10^8$ corresponding to a difference of about 12 kcal mole^{-1} in the standard free energies of activation of the two consecutive steps. It must be recalled that these conclusions refer to the general type of mechanism shown in the scheme of reactions V, VI, and VII where an electrochemical "radical-ion" desorption step is rate-controlling.

(iii) Relation between Pseudocapacitance, Coverage, and Potential

We have used equation [35] to calculate the adsorption pseudocapacity for monovalent radicals as a function of coverage for different rate-constant ratios k_6/k_5 and two values of r/RT of 10 and 20. These results are shown in Figs. 4*a* and 4*b*. On the low coverage

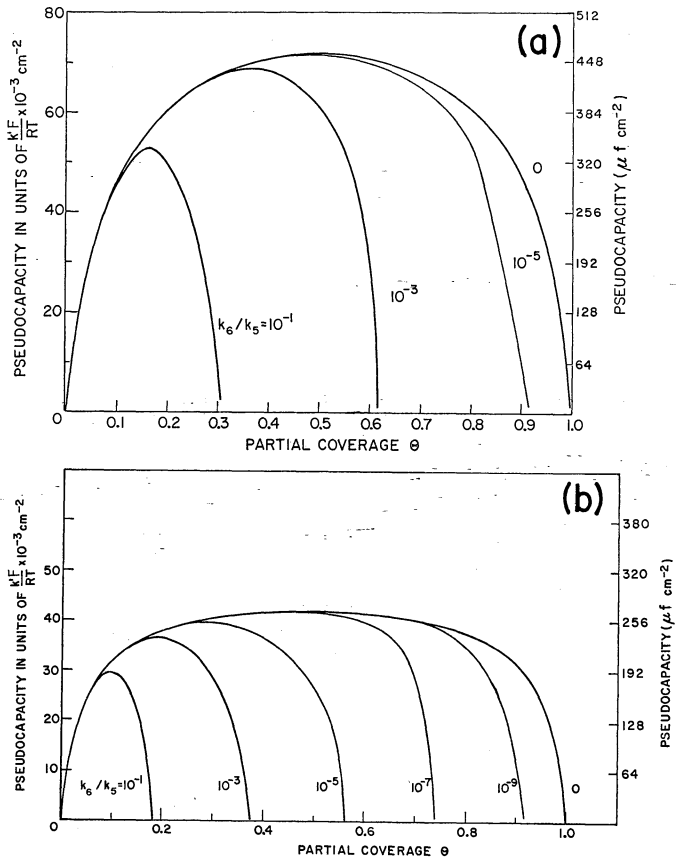

FIG. 4*a*. Adsorption pseudocapacitance as a function of coverage for various values of the rate constant ratio k_6/k_5 with $r/RT = 10$.

FIG. 4*b*. Adsorption pseudocapacitance as a function of coverage for various values of the rate constant ratio k_6/k_5 with $r/RT = 20$.

branch, the curves are almost identical with the one obtained for $k_6/k_5 = 0$ (the limiting quasi-equilibrium case), while on the high coverage side they deviate markedly from the quasi-equilibrium curve to an extent dependent on the values of r/RT and k_6/k_5.

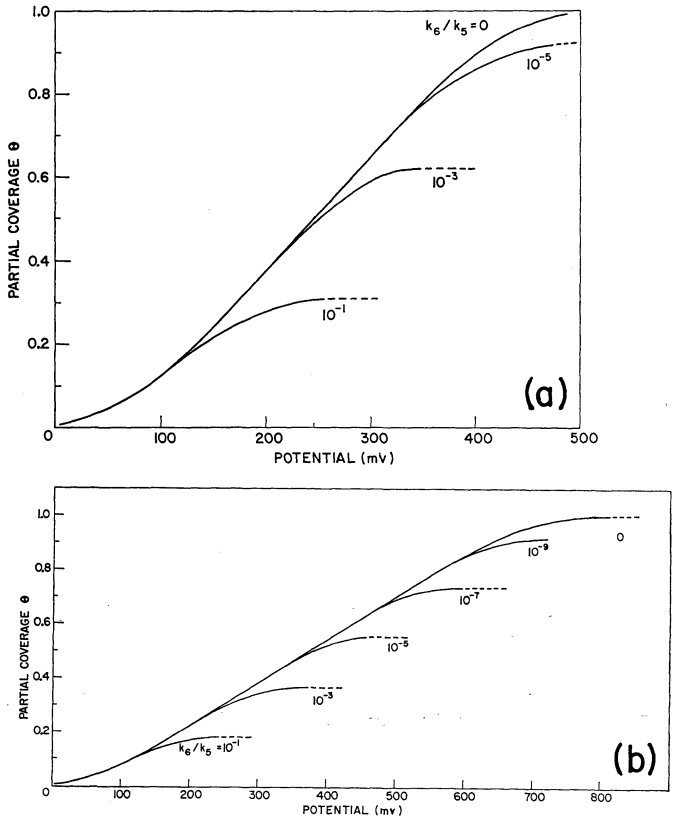

FIG. 5*a*. Coverage–potential relationships calculated for various values of the rate constant ratio k_6/k_5 with $r/RT = 10$ (compare Fig. 2).

FIG. 5*b*. Coverage–potential relationships calculated for various values of the rate constant ratio k_6/k_5 with $r/RT = 20$ (compare Fig. 2).

The corresponding variation of coverage with potential was calculated for the same values of r/RT and k_6/k_5, using equation [32], and is plotted in Figs. 5*a* and 5*b*. By combining equations [32] and [35], we can obtain numerically the dependence of pseudocapacity on potential, as shown in Figs. 6*a* and 6*b*. It is seen that for intermediate values of k_6/k_5, when this ratio is small enough for the discharge step to be considered practically at quasi-equilibrium for the purpose of discussing the kinetics of the reaction, the pseudocapacity will reach values comparable, but not identical, with those obtained for complete quasi-equilibrium for corresponding values of r, but the potential range over which the pseudocapacity will be appreciable will be greatly decreased.

It is clear from the above results, that while in many cases complete quasi-equilibrium may, without serious error, be assumed for the purpose of discussion of the current–potential behavior of the reactions considered, the relationship between the capacity and potential can, however, be quite different from that corresponding to quasi-equilibrium conditions, and is thus a more sensitive indication of the kinetic behavior in a sequence of consecutive reactions.

(d) Method of Application to Experimental Results

In a previous publication (10), we have proposed and applied a method by which the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Temkin parameter r and the roughness factor f of an electrode surface could be obtained from the shape of the experimental profile relating C to V. This calculation was carried out for the formate decomposition reaction assuming complete equilibrium in the initial formate ion discharge step but it is clear that such a procedure may be less applicable if k_6/k_5 were appreciably greater than zero, i.e. if the equilibrium in the initial ion discharge step were significantly disturbed. For the type of electrochemical reaction sequence considered here, a limiting coverage ($\theta < 1$) will be reached (equation [39]) and the pseudocapacity values will depend on k_6/k_5 as well as on r for given values of θ or V.

Experimental data can, in principle, be obtained for C from e.m.f. decay curves, from electronically differentiated charging curves (27), and from a.-c. impedance measurements (2). Corresponding coverage information can be obtained from charging curves and from integration of the $C-V$ relationship. At the present time, there are no data of sufficient precision to apply our calculations directly to experimental results for electrodes at which the mechanism considered here operates, although an atom–ion desorption mechanism is indicated in the hydrogen and oxygen evolution reactions at certain metals (14, 16, 17). However, we show below how the method may be applied to appropriate experimental results if information on surface coverage by intermediates and the associated pseudocapacity is available.

Apart from θ and V, three parameters are involved which determine C as $f(\theta, V)$, viz. r, f, and k_6/k_5. If the real surface area is known independently, e.g. from krypton B.E.T. adsorption measurements or from ionic double-layer capacity data, as used, for example, by Brodd and Hackerman (28), these deviations from quasi-equilibrium in the ion discharge step may be detected, and both r and k_6/k_5 can, in principle, be estimated, as shown below.

We consider the case of the atom-ion desorption type of mechanism for which both the relationship between C and V and the limiting coverage θ_{lim} could be obtained experimentally for an electrode, the surface area of which was known by the methods mentioned above. From the value of C at its maximum, $C_{\max}$, we can first estimate the value of the parameter r assuming, as a first approximation, that $k_6/k_5 = 0$ (cf. refs. 9 and 10). We note that the relationship in Fig. 6 indicates that $C_{\max}$, for a given value of r, will tend to decrease as k_6/k_5 increases, but this change of $C_{\max}$ does not become very large until k_6/k_5 is quite close to unity. Hence, the value obtained for r on the basis of the initial assumption that $k_6/k_5 = 0$ (equilibrium case) will tend to be too large[11] and would, in fact, constitute an upper limit for the estimate of r for the particular conditions involved.

In the light of the above discussion, it follows now that deviations from quasi-equilibrium conditions could be easily detected by considering the shape of the $C-V$ profile. Thus, we have shown previously (10) that the width ΔV_γ (in units of potential) of the $C-V$ profile at a value of $C = {}_\gamma C_{\max}$ (where γ is a fraction $0 < \gamma < 1$) is approximately linearly related to r when quasi-equilibrium conditions apply. We can use this relationship here to obtain an estimate of what would be the value of ΔV_γ (at, say, $\gamma = 0.5$) corresponding to the value of r estimated above from $C_{\max}$, if k_6/k_5 were, as a first approximation, zero. This quantity ΔV_γ could also be obtained experimentally from a $C-V$ profile; it is evident from Fig. 6 that ΔV_γ would be sensitively dependent on the kinetic parameter k_6/k_5 (much more so, for example, than the quantities $C_{\max}$ and the resulting r). Hence any departure from quasi-equilibrium conditions could readily be detected and

[11]*This conclusion follows from the fact, which we have discussed elsewhere (9), that C decreases with increasing r for a given value of θ or V in the equilibrium case. Some depression of C arises when* $k_6/k_5 \neq 0$ *and this would hence be counted as due to a higher apparent value of r.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

evaluated semiquantitatively by comparison of the experimentally determined ΔV_γ and that calculated from a value of r as estimated by the approximate procedure discussed above.

After the evaluation of r (or rather its upper limit), we can use equation [39] (cf. Fig. 3) to obtain k_6/k_5. Since the value of r used would be an upper limit, the corresponding calculated value for k_6/k_5 would be a lower limit.

A numerical example will help to clarify the use of the above procedure: let us consider the calculated profiles in Fig. 6*a* for $r/RT = 10$ and assume, for the purposes of this

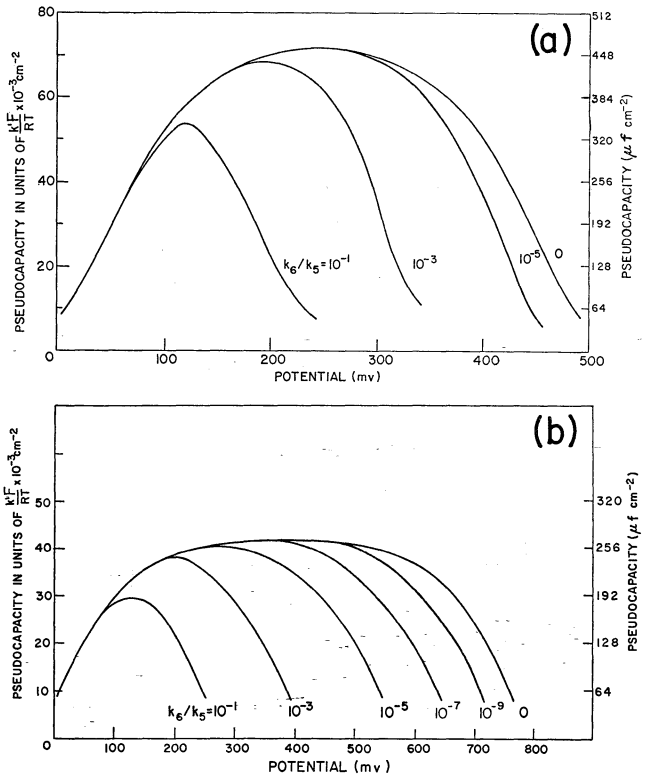

FIG. 6*a*. Adsorption pseudocapacitance as a function of potential for various values of the rate constant ratio k_6/k_5 with $r/RT = 10$.

FIG. 6*b*. Adsorption pseudocapacitance as a function of potential for various values of the rate constant ratio k_6/k_5 with $r/RT = 20$.

example, that a curve identical with that shown for $k_6/k_5 = 10^{-1}$ had been obtained experimentally. Assuming as the first approximation that $k_6/k_5 = 0$, a value of $r/RT = 15$ would be obtained. Using this value with the corresponding limiting coverage θ_{lim} (equation [35] and Fig. 3) which would arise with this mechanism, would give $k_6/k_5 = 2\times10^{-2}$. Also the experimental value of ΔV_γ ($\gamma = 0.5$) for this example would be approximately 0.12 v, while the theoretically expected value for $r/RT = 15$ and $k_6/k_5 = 0$ would be about 0.5 v; hence an appreciable deviation from quasi-equilibrium conditions would be directly evident.

A more accurate numerical evaluation of the parameters r and k_6/k_5 could be obtained from equations [35] and [39] if both $C_{\max}$ and θ_{lim} were experimentally available. Thus, in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

equation [35] let C be equal to C_{max}, so that θ will be the value of the coverage at a potential corresponding to the maximum in the curve relating C to V (for example, obtained by integrating an experimental $C-V$ curve (10) up to that potential). With C and θ numerically known, equation [35] would have the two required parameters (r and k_6/k_5) as unknowns. Similarly, equation [39]—in which θ is the limiting coverage attained at high overpotentials —has the same two unknowns, so that r and k_6/k_5 could be evaluated numerically between these two equations, from experimental data for C_{max} and θ_{lim}.

(e) Conclusions

We may conclude that the adsorption pseudocapacity function appears to be much more sensitive to the various assumptions made in deriving the rate equations than the resulting overall current–potential behavior. Thus, while the pre-exponential terms in θ can be neglected (cf. 18, 26) with respect to the exponential terms when the $V - \ln i$ relationship is considered at intermediate coverage, this is hardly ever justified for the purpose of calculating the total effective adsorption pseudocapacitance.

Secondly, we observe that a step which, without serious error, could be considered *kinetically* at quasi-equilibrium, may nevertheless give rise to very different pseudocapacity behavior from that corresponding to complete equilibrium ($k_6/k_5 = 0$) in the primary discharge step when the steady-state treatment is applied. This effect is greater, the greater is the value of the parameter r defining the variation of energy of adsorption of the intermediate A (in reactions V and VI) with coverage.

Finally, we recall that the actual form of the variation of heat of adsorption with coverage (i.e. when the heat of adsorption is proportional to θ^n and $n \neq 1$) does not affect the observed kinetic parameters (as shown previously (9)), but qualitatively affects the form of the dependence of pseudocapacity and coverage on potential as shown elsewhere (10).

GUM JEOL: THE STRUCTURE OF THE DEGRADED GUM DERIVED FROM IT

A. K. Bhattacharyya and C. V. N. Rao
The Department of Macromolecules, Indian Association for the Cultivation of Science, Calcutta-32, India
Received May 15, 1963

ABSTRACT

Gum Jeol has been shown to be composed of residues of D-galactose, L-arabinose, and D-galacturonic acid. On mild acid hydrolysis the gum gave an aldobiouronic acid, viz. 3-*O*-(D-galactopyranosyl uronic acid)-D-galactopyranose. Hydrolysis of the fully methylated degraded gum yielded 2,3,4,6-tetra-(3 moles); 2,3,4-tri-(2 moles); 2,4-di-(1 mole); and 2-*O*-methyl-D-galactose (1 mole) in the neutral fraction of the hydrolyzate. The reduced acidic fraction yielded 2,3,4-tri-(2 moles) and 2,4-di-*O*-methyl-D-galactose (2 moles). Based on these results a partial structure of the degraded gum has been proposed, the additional evidence of which was deduced from periodate oxidation studies of the degraded gum.

The sample of the Jeol gum (*Odina wodier, Roxb*) investigated was obtained as an exudate from the plants commonly known in Bengal as "Jeol trees" (1, 2). The gum was investigated by Mukherjee *et al.* (3), who reported arabinose, galactose, and galacturonic acid as constituent units. An aldobiouronic acid has also been isolated and identified. In the present work a beginning has been made on a study of the detailed molecular architecture of the repeating unit of the degraded gum.

The gum examined had been purified by repeated precipitation by ethanol from an aqueous solution and alkaline solution was avoided to protect from deesterification. Even after taking this precaution the methoxyl content (0.51%) was found to be very low and was therefore not considered to have any structural significance. A purified sample of the gum had an equivalent weight, 1150 (by titration with alkali) and uronic anhydride (4) 14.5% (uronic anhydride content for a polysaccharide of equivalent weight 1150 should be 15.3%). The pentosan content (5) of the gum was 21.7%. On complete hydrolysis, the gum yielded L-arabinose and D-galactose in the neutral hydrolyzate; these were characterized by isolating the crystalline sugars. Hydrolysis and quantitative estimation (6) of the sugars showed them to be present as arabinose 19.5% and galactose 63.7%.

The gum was hydrolyzed under milder conditions (0.1 *N* sulphuric acid) and the acidic fraction was separated from the neutral one by ion exchange resin and was found to be a mixture. The aldobiouronic acid was isolated in a homogeneous state from the mixture. Methyl ester methyl glycoside of the aldobiouronic acid, on reduction with lithium aluminum hydride and subsequent hydrolysis, yielded galactose, showing that the aldobiouronic acid is composed of galactose and galacturonic acid residues. The structure of the aldobiouronic acid was finally established to be 3-*O*-(D-galactopyranosyl uronic acid)-D-galactopyranose, by methylation, reduction, and remethylation of the acid and subsequent identification of the methyl sugars, viz., 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,4,6-tri-*O*-methyl-D-galactose, liberated on hydrolysis. The structure of the aldobiouronic acid obtained is in agreement with the one deduced by Mukherjee *et al.* (3).

As the natural gums are highly complex in their molecular architecture, these are generally degraded to relatively stable and smaller molecules, by removing some sugar residues connected by labile linkages, for structural investigation. Autohydrolysis is one of the convenient processes for such degradations.

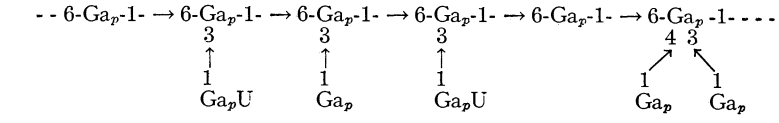
In order to isolate the degraded gum, the gum was subjected to autohydrolysis, the course of which was followed by examining the supernatant liquid chromatographically. In the earlier stages of hydrolysis arabinose was detected, then arabinose and an oligosaccharide, and after 25 hours, galactose started appearing. The hydrolysis was stopped at this stage and the degraded gum was precipitated by pouring the solution into ethanol. The isolated degraded gum had $[\alpha]_D^{32}$ $-2°$, equivalent weight 920, and uronic anhydride 18.54% (corresponding to a calculated equivalent weight 950), and on hydrolysis yielded galactose and a trace of arabinose. The amount of anhydro galactose was estimated to be 76.5%. Jeolic acid (degraded gum) was converted to its fully methylated derivative by treatment with dimethylsulphate and alkali (7, 8) and methyl iodide and silver oxide (9) successively. The fully methylated polysaccharide was subjected to methanolysis under conditions known to effect no cleavage of aldobiouronic acid. The methyl ester was hydrolyzed with barium hydroxide solution (10) and the acidic fraction was separated from the neutral one by absorbing the former on Dowex-1-X4 anion exchange resin (11). The neutral glycosides were converted to the corresponding mixture of methyl sugars which were separated and identified as 2,3,4,6-tetra-*O*-methyl-D-galactose (3 moles), 2,3,4-tri-*O*-methyl-D-galactose (2 moles), 2,4-di-*O*-methyl-D-galactose (1 mole), and 2-*O*-methyl-D-galactose (1 mole). The acid portion was displaced from the resin column and was shown to be 3-*O*-(2,3,4-tri-*O*-methyl-D-galactopyranosyl uronic acid)-2,4-di-*O*-methyl-D-galactose (2 moles) since reduction (12, 13) of the methyl ester methyl glycoside and subsequent hydrolysis afforded two methyl sugars, viz., 2,3,4-tri-*O*-methyl-D-galactose and 2,4-di-*O*-methyl-D-galactose in an equimolecular proportion. The length of the repeating unit, which contains two uronic acid residues, is calculated to be 11 anhydro hexose units. From the above results a structure for the repeating unit of the degraded gum can be deduced.

Demonstration of the presence of only 2,3,4-tri-*O*-methyl-D-galactose in the trimethyl fraction indicates that the backbone chain is composed of $1 \rightarrow 6$ linked galactose residues. Some of the galactose residues in the main chain are linked through C_1, C_3, and C_6 and some through C_1, C_3, C_4, and C_6 as indicated by the presence of 2,4-di-*O*- and 2-*O*-methyl-D-galactose respectively in the neutral fraction of the hydrolyzate. It is evident that tetramethyl galactose originated from the non-reducing ends. The number of branch points (3) are equal to the number of non-reducing end groups (3), as required by the theory. Besides these considerations, the aldobiouronic acid (2 moles per repeating unit) is to be accommodated. From the structure of the aldobiouronic acid it is evident that the galactose moiety of it is joined through C_1 and C_6 in the main chain with single unit side chain of the galacturonic acid linked to C_3 of this galactose residue. Two such units are present per repeating unit of the degraded gum. The simplest structure, which can accommodate all the above facts, is as follows:



(Ga_p represents galactopyranose residues and Ga_pU represents galactopyranosyl uronic acid residue.)

The possibility of linking one galactopyranosyl uronic acid unit and one galactopyranose unit to the same galactose unit of the main chain is ruled out because of the failure to isolate a monomethyl galactose from the hydrolyzate of the reduced aldobiouronic acid obtained from the methylated degraded gum. It should be pointed out that at

the present state of our knowledge it is not possible to determine the exact sequence of the different sugar units in the repeating unit of the degraded gum.

The negative rotation of the degraded gum as well as its methylated derivative shows that the majority of the glycosidic linkages are of β-type.

Further support for the proposed structure of the repeating unit of the degraded gum was obtained from the periodate oxidation of the degraded gum. The uronic acid residues, when present in the polysaccharide molecules as non-reducing end units, undergo over-oxidation. However, by using periodic acid instead of sodium metaperiodate the over-oxidation during the reaction can be controlled (13, 14, 15). The periodic acid oxidation data show that each anhydro hexose unit consumed 1.20 moles of the oxidant after 25 hours liberating 0.67 mole of formic acid. Considering the fact that a non-reducing hexopyranose unit (which may be a galactopyranose or galactopyranosyl uronic acid unit) and $1 \rightarrow 6$ linked hexopyranose unit of the back bone chain consume 2 moles of periodic acid liberating 1 mole of formic acid and that hexopyranose units linked through C_1, C_3, and C_6 or C_1, C_3, C_4, and C_6 cannot react with periodic acid, the consumption of the oxidant and the liberation of formic acid per hexopyranose unit, assuming the above structure, work out to be 1.27 and 0.64 moles respectively.

The periodate-oxidized degraded gum after reduction with sodium borohydride (16) followed by usual treatments was precipitated by ethanol. The percentage weight of galactose (as anhydro sugar) unattacked by periodate was found to be 32.4%. This result is in good agreement with the calculated value (35.7% assuming the above structure).

EXPERIMENTAL

All specific rotations are equilibrium values. Unless otherwise stated, all evaporations were carried out *in vacuo* at 30–40°. Whatman No. 1 filter papers were used for paper partition chromatography. The solvent mixtures (v/v) used for partition chromatography for sugars and their derivatives were:

(A) ethyl acetate:pyridine:water (8:2:1),
(B) *n*-butanol:acetic acid:water (4:1:5), upper layer,
(C) *n*-butanol:ethanol:water (40:11:19),
(D) *n*-butanol:ethanol:water (5:1:4), upper layer,
(E) methyl ethyl ketone – water azeotrope,
(F) ethyl acetate:acetic acid:water (9:2:2),
(G) ethyl acetate:acetic acid:water (3:1:3), upper layer.

The spray reagents used were:

(*a*) aniline hydrogen oxalate (saturated aq. solution),
(*b*) *p*-anisidine hydrochloride (3% solution in *n*-butanol),
(*c*) aniline hydrogen phthalate.

Isolation and Purification of the Gum

The crude gum (140 g) was allowed to swell in water (700 ml) and the viscous solution formed was vigorously stirred for 6 hours at room temperature. The brown viscous solution was filtered through fine cloth and then passed through Cepa-supercentrifuge for further clarification. The solution was slowly added to acidified (pH 4–5) ethanol (2 l.) when a white amorphous precipitate was formed. This was filtered and triturated with absolute ethanol and dry ether. The product after second purification as above was dried *in vacuo* at 40°; yield 48 g.

The figures given below are mean values from a series of analyses carried out with two separately prepared batches; no significant differences in the properties were observed between the two preparations: moisture 8.8%; ash 0.79%; $[\alpha]_D$ −44° (*c*, 0.5 in 4% aqueous sodium hydroxide solution); equivalent weight by acidimetry, 1150; anhydro uronic acid, 14.5%; pentosan content, 21.7% (calc. from the amount of furfuraldehyde evolved under standard conditions (17), account being taken of the furfuraldehyde yielded by the uronic acid residues); nitrogen, nil; methoxyl, 0.51%. The gum on complete hydrolysis followed by deionization with Amberlite IR-120(H) and Amberlite IR-400(OH) yielded a neutral sirup, which contained D-galactose and L-arabinose. The mixture was separated and the sugars were isolated in their crystalline states. L-Arabinose, m.p. and mixed m.p. 153–154°, $[\alpha]_D^{30}$ +108° (*c*, 1.05 in water) and D-galactose, m.p. and mixed m.p. 163–164°, $[\alpha]_D^{30}$ +84° (*c*, 1 in water). The gum (102.6 mg) was hydrolyzed and the neutral sugars were estimated (6) quantitatively using D-ribose as reference sugar. The percentages of galactose and arabinose, as anhydro sugars, were 63.7 and 19.5 respectively.

Isolation and Characterization of the Aldobiouronic Acid

The gum (10 g) was heated on a boiling water bath with 0.1 *N* sulphuric acid (250 ml) for 60 hours. After neutralization and usual treatments, the acid fraction was separated from the neutral one by Dowex 1-X4 resin. The resulting acid mixture containing aldobio- and aldotrio-uronic acid was separated on a cellulose column and the aldobiouronic acid was obtained in a homogeneous state (equiv. wt. 340). The methyl ester methyl glycoside of the aldobiouronic acid on reduction with lithium aluminum hydride followed by hydrolysis yielded D-galactose, which was characterized through crystalline *p*-nitroaniline derivative m.p. and mixed m.p. 216–217°, lit. 217–218° (18); $[\alpha]_D^{30}$ −244° (in dry pyridine).

The methyl ester methyl glycoside of the methylated aldobiouronic acid was reduced with lithium aluminum hydride in dry ether and remethylated to yield a fully methylated disaccharide. Found: —OCH_3, 54.1%. Calc. $C_{20}H_{38}O_{11}$: —OCH_3, 54.6%. This, on hydrolysis, gave a mixture of two methyl sugars which were separated on filter sheets and were identified as 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,4,6-tri-*O*-methyl-D-galactose through their crystalline aniline derivatives. N-Phenyl-2,3,4,6-tetra-*O*-methyl-D-galactosylamine, m.p. and mixed m.p. 186–188°, lit. 187° (18), $[\alpha]_D^{30}$ +40° (*c*, 0.5 in acetone), lit. +39° (19). N-Phenyl-2,4,6-tri-*O*-methyl-D-galactosylamine, m.p. and mixed m.p. 173–175°, lit. 175° (20) $[\alpha]_D^{30}$ +36° (*c*, 0.9 in acetone), lit. +38° (21).

Autohydrolysis of the Purified Gum and Isolation of the Degraded Gum

An aqueous solution of the gum acid (1 g, 10%) was heated on a boiling water bath. Paper chromatographic examination of the solution, using solvents A and G, at regular intervals of time, after removal of the precipitated polysaccharide by ethanol, showed that arabinose started splitting off in the beginning, and then arabinose and an oligosaccharide (R_{gal} 1.36 in solvent G). After 25 hours, galactose appeared in the hydrolyzate. A 10% aqueous solution of the gum acid (20 g) was subjected to autohydrolysis for 25 hours as stated above and the solution was filtered, concentrated to half its volume, and was poured into ethanol. The precipitated polysaccharide was washed with hot ethanol and dry ether and finally dried to give a white amorphous powder; $[\alpha]_D^{32}$ −2° (*c*, 1.2 in water); equiv. wt. (by acidimetry) 920; anhydrouronic acid 18.54% and moisture 9.5%. Paper chromatographic examination of the neutral sugars liberated on complete hydrolysis of the degraded gum indicated the presence of galactose and a trace amount of arabinose. Galactose was estimated, as anhydrosugar, to be 76.5% in the hydrolyzate.

Methylation of the Degraded Gum (7, 8)

The degraded gum (10 g) was methylated by treatment first with methylsulphate and alkali in an atmosphere of nitrogen and then with methyl iodide and silver oxide to yield a fully methylated derivative showing no hydroxyl absorption band in the infrared spectrum, $[\alpha]_D^{32}$ −30° (*c*, 1.05 in chloroform); —OCH_3 41.5%; yield 6.5 g.

Methanolysis and Separation and Identification of the Neutral Sugars of the Methylated Degraded Gum

A solution of the methylated degraded gum (1.5 g) in 2.5% dry methanolic hydrogen chloride (50 ml) was refluxed for 16 hours (till constant optical rotation). The solution was neutralized, filtered, and evaporated to a sirup which was heated with 2% aqueous barium hydroxide solution (30 ml) for 4 hours at 80°. The resulting solution was neutralized by passing carbon dioxide gas; then it was filtered and passed through a column of Amberlite IR 120(H) and the acidic portion was absorbed on a column of Dowex 1-X4 (bicarbonate form) resin. The column was thoroughly washed with water (5 l.) and the neutral solution was concentrated and hydrolyzed with *N* sulphuric acid for 12 hours (constant optical rotation). The solution after neutralization, filtration, and deionization, was evaporated to give a sirup (656 mg). On paper chromatographic examination of the sirup using solvents C and D four methyl sugars, viz. 2,3,4,6-tetra-, 2,3,4-tri-, 2,4-di-, and 2-*O*-methyl-D-galactose, were found to be present in it.

The sirup (ca. 600 mg) was separated on a cellulose column (22) (75×3.5 cm) using solvent E (23) as eluants to give five fractions. The following table shows the different fractions obtained by column chromatography.

TABLE I

Fraction No.	Tube No.	Methyl sugars	Yield (mg)
1	30–38	2,3,4,6-Tetra-*O*-methyl-D-galactose	238
2	39–43	Mixture of 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,3,4-tri-*O*-methyl-D-galactose and traces of methyl arabinose	32
3	44–64	2,3,4-Tri-*O*-methyl-D-galactose	158
4	80–102	2,4-Di-*O*-methyl-D-galactose	76
5	121–133	2-*O*-Methyl-D-galactose	64

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Fraction 1

The sirup (238 mg) had $[\alpha]_D^{31}$ +110° (*c*, 1 in water) lit. +109.5 (24) and —OCH_3 51.9% and was chromatographically homogeneous. The sugar was identified as 2,3,4,6-tetra-*O*-methyl-D-galactose by conversion into the anilide derivative, m.p. and mixed m.p. 187–189°, lit. 187° (18), $[\alpha]_D^{30}$ +40° (*c*, 0.5 in acetone) lit. +39° (19).

Fraction 2

The sirup (32 mg) on paper chromatography using solvents C and D separated into spots corresponding to 2,3,4,6-tetra- and 2,3,4-tri-*O*-methyl-D-galactose with a trace of methyl arabinose. Demethylation (25) gave galactose and a trace of arabinose.

Fraction 3

The chromatographically pure sirup (158 mg) had $[\alpha]_D^{30}$ +108° (*c*, 0.8 in water) lit. +114° (26). Found: —OCH_3, 41.1%. Calc. for $C_9H_{18}O_6$: —OCH_3, 41.8%. Demethylation gave only galactose. The sugar was identified as 2,3,4-tri-*O*-methyl-D-galactose through its aniline derivative which was crystallized (27) from acetone – petroleum ether, m.p. and mixed m.p. 162–163°, lit. 166° (27), $[\alpha]_D^{30}$ +41° (*c*, 0.9 in methanol) lit. +43° (28).

Fraction 4

This component (78 mg) was obtained as chromatographically pure solid and had $[\alpha]_D^{30}$ +82° (*c*, 1 in water) lit. +85° (29). Found: —OCH_3, 28.8%. Calc. for $C_8H_{16}O_6$: —OCH_3, 29.8%. The solid was crystallized from a small volume of ethanol, m.p. and mixed m.p. (with 2,4-di-*O*-methyl-D-galactose) 101–102° lit. 103° (28). It was further characterized as 2,4-di-*O*-methyl-D-galactose through its crystalline anilide, which on repeated crystallization from ethanol, had m.p. and mixed m.p. 217–218°, lit. 216° (29).

Fraction 5

The chromatographically pure sirup (64 mg) had $[\alpha]_D^{30}$ +78° (*c*, 0.6 in water) lit. +80° (30). Found: —OCH_2, 16.7%. Calc. for $C_7H_{14}O_6$: —OCH_3, 16.0%. On trituration with dry ether the sirup yielded a solid which on crystallization from glacial acetic acid showed m.p. and mixed m.p. (with 2-*O*-methyl-D-galactose) 142–144°, lit. 145–148° (26). It was further confirmed by conversion to N-phenyl-2-*O*-methyl-D-galactosylamine which after repeated crystallization from acetone – petroleum ether, had m.p. 159–161°; when mixed with an authentic sample of m.p. 163–164°, the melting point was 161–162°, lit. 165° (26).

A small quantity of the mixture was separated quantitatively by paper chromatography and the amount of each methyl sugar was estimated by alkaline hypoiodite method (31). The results were confirmed by duplicate experiments and were as follows: 2,3,4,6-tetra-*O*-methyl-D-galactose, 43.84%; 2,3,4-tri-*O*-methyl-D-galactose, 29.82%; 2,4-di-*O*-methyl-D-galactose, 13.39%; and 2-*O*-methyl-D-galactose, 12.95%.

Examination of the Acidic Fraction

The acidic fraction was displaced from the resin column in the usual way $[\alpha]_D^{32}$ +54° → +62° (*c*, 1.05 in chloroform); equiv. wt. 420. The methyl ester methyl glycoside of the methyl aldobiouronic acid was reduced with lithium aluminum hydride and then hydrolyzed to yield a mixture of methyl sugars. The mixture was separated on filter papers and the sugars obtained in equimolecular proportion were identified as 2,3,4-tri- and 2,4-di-*O*-methyl-D-galactose through their crystalline anilides. N-Phenyl-2,3,4-tri-*O*-methyl-D-galactosylamine, m.p. and mixed m.p. 164–166°, $[\alpha]_D^{31}$ +38° (*c*, 0.95 in acetone). N-Phenyl-2,4-di-*O*-methyl-D-galactosylamine, m.p. and mixed m.p. 218–219°.

Periodate Oxidation of the Degraded Gum

The degraded gum (118.5 mg) was dispersed in water (50 ml) and oxidized by shaking with 0.2 *M* periodic acid (50 ml) in dark at 15°. The liberated formic acid (after correcting for the titratable acidity of the gum) and the amount of periodic acid consumed during the reaction were estimated in the usual way (32) at regular intervals of time. The liberation of formic acid became constant after 25 hours, corresponding to 0.67 mole of formic acid per anhydro hexose residue and the periodate uptake became constant after 25 hours, corresponding to 1.20 moles of the oxidant per anhydro hexose unit.

The periodate-oxidized gum (114.4 mg) was neutralized with barium hydroxide and filtered, and to the clear solution sodium borohydride (200 mg) was added, and kept overnight at room temperature. The solution was acidified with acetic acid and then subjected to dialysis in running water to remove inorganic ions (5 days). The solution was concentrated (5 ml) and poured into ethanol. The amorphous white precipitate obtained was recovered at the centrifuge, triturated, and dried *in vacuo* at 40° (76 mg). The periodate-oxidized reduced polysaccharide (30 mg) was hydrolyzed with 2 *N* sulphuric acid and the percentage of galactose unattacked by periodate was estimated using D-ribose as reference sugar to be 32.4%.

ACKNOWLEDGMENT

The authors are thankful to Dr. P. Bagchi, Director, Research, East India Pharmaceutical Works Ltd., Calcutta, for suggesting the problem and his valuable advice and interest in the work reported in this paper.

THE SYNTHESIS OF AROYL METHYL KETONES AS LIGNIN MODEL SUBSTANCES

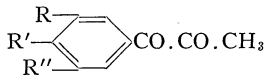
J. M. Pepper and Maitreyi Saha
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan
Received August 9, 1963

ABSTRACT

A series of aroyl methyl ketones ($ArCOCOCH_3$ in which Ar was phenyl, *p*-hydroxyphenyl, *p*-methoxyphenyl, 4-hydroxy-3-methoxyphenyl, 3,4-dimethoxyphenyl, 4-hydroxy-3,5-dimethoxyphenyl, and 3,4,5-trimethoxyphenyl) has been prepared by the oxidation, using selenium dioxide, of the correspondingly substituted benzyl methyl ketones.

INTRODUCTION

Two diketones, vanilloyl methyl ketone (IV) and syringoyl methyl ketone (VI), have been isolated from the products obtained by the acid-catalyzed solvolysis of wood or isolated lignins (1, 2). The characterization of such derivatives has contributed to the present knowledge of the chemical structure of lignin. They serve, too, as interesting model substances for lignin research. The reported syntheses of IV by Brickman, Hawkins,



I R = R′ = R″ = H
II R = R″ = H, R′ = HO
III R = R″ = H, R′ = CH_3O
IV R = CH_3O, R′ = HO, R″ = H
V R = R′ = CH_3O, R″ = H
VI R = R″ = CH_3O, R′ = HO
VII R = R′ = R″ = CH_3O

and Hibbert (3) and of VI by Kulka, Hawkins, and Hibbert (4) involve many steps and low overall yields. An investigation was made to find a more suitable mode of synthesis of such aroyl methyl ketones in order that a sufficient amount might be obtained for an extended study of their properties and chemical reactions.

The method that was investigated involved the synthesis of ketones of the formulae $ArCOCH_2CH_3$ and $ArCH_2COCH_3$ and their subsequent oxidation, using selenium dioxide, to the corresponding α-diketones. The latter route was shown to be preferable and compounds IV and VI were obtained with little difficulty. The method was then extended to include the synthesis of five other related diketones (I, II, III, V, VII), only one of which (I) had been made previously by this method.

RESULTS AND DISCUSSION

Initially, monoketones of the formula $ArCOCH_2CH_3$ were prepared by the silver oxide oxidation of the corresponding alcohols, $ArCH(OH)CH_2CH_3$, which had been synthesized from the aryl aldehyde and ethyl magnesium bromide. Following the method of Roberti, York, and MacGregor (5), the required 1-(4-hydroxy-3-methoxyphenyl)-1-propanol was prepared in 68% yield. Similarly, but using tetrahydrofuran instead of diethyl ether, syringaldehyde was converted to 1-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanol in 52% yield. Both compounds gave the characteristic color reaction with quinone monochloroimide which is indicative of a *p*-hydroxybenzyl alcoholic group (6, 7).

The oxidation of the alcohol to the corresponding keto compound using silver oxide

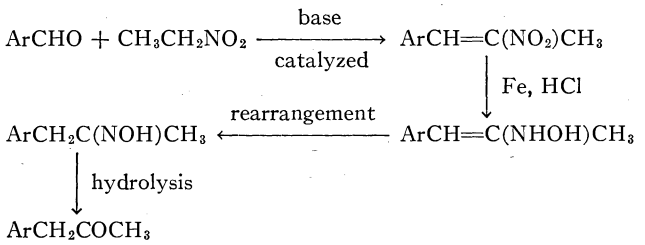
For personal use only.

had been shown by Pearl (8) to proceed readily in the case of 1-(4-hydroxy-3-methoxyphenyl)-1-propanol in 89% yield. Initially some difficulty was experienced in repeating these results, especially in crystallization of the syrupy product. This was overcome partly by increasing the reaction time from 1½ hours to 5 hours and using freshly generated sulphur dioxide. Under these conditions, the highly viscous product solidified slowly and could be recrystallized from petroleum ether to yield the required ketone (propiovanillone) in 50.5% yield. 1-(4-Hydroxy-3,5-dimethoxyphenyl)-1-propanone (propiosyringone) was prepared by the same method. This product solidified readily and could be recrystallized to give the required ketone in 40.3% yield. Subsequently it was found that the synthesis and oxidation of monoketones of the formula $ArCH_2COCH_3$ gave better yields of the required α-diketones and attention was directed, therefore, to the synthesis using this route.

The synthesis of monoketones of the formula, $ArCH_2COCH_3$, was based on the procedure reported by Kulka and Hibbert (9) and outlined as follows:



No difficulty was encountered in the condensation of vanillin with nitroethane using the methylamine hydrochloride – sodium carbonate method, but the similar reaction using syringaldehyde gave yields of product which varied widely from run to run. A more successful condensation was achieved using the method reported by Kaufmann (10) in which the methylamine hydrochloride was replaced by aqueous ethylamine. The condensation of other substituted benzaldehydes was then effected using one or other of these methods. The yields of the resulting 1-aryl-2-nitro-1-propenes are given in Table I.

TABLE I

Percentage yields of $ArCH=C(NO_2)CH_3$

Aldehyde	Methylamine method (9)	Ethylamine method (10)
p-Hydroxybenzaldehyde	49	65
Anisaldehyde	—	76
Vanillin	72	—
Veratraldehyde	—	76
Syringaldehyde	52	56
3,4,5-Trimethoxybenzaldehyde	66	52

The conversion of the 1-aryl-2-nitro-1-propenes to the substituted benzyl methyl ketones offered no difficulty. Purification of the monoketones was effected through the formation of the sodium bisulphite addition product. The yields are given in Table II.

It had been reported by Wegmann and Dahn (11) that benzyl methyl ketone could be oxidized, using selenium dioxide in dioxane, to the corresponding benzoyl methyl ketone. Since it was found possible to readily duplicate these results, attention was directed to this method as a means of synthesis of the required α-diketones from the correspondingly

substituted benzyl methyl ketones. The conversion of 4-hydroxy-3-methoxybenzyl methyl ketone to 4-hydroxy-3-methoxybenzoyl methyl ketone was chosen as a typical system with which to study the optimum conditions for oxidation and the most satisfactory procedure for the isolation and purification of the product.

Using, initially, the conditions reported by Wegmann and Dahn (11), the oxidation was carried out for 4 hours in dioxane at reflux temperature. The resulting crude reaction product was studied by gas–liquid chromatography using a 6-ft, 1/4-in., 15% Apiezon N on Fluoropak column at 220° C. Three well-separated peaks, with retention times of 4.0, 5.5, and 6.8 minutes, indicated the presence of three compounds in this product. By comparison with authentic samples the peaks were shown to correspond to vanillin, unchanged 4-hydroxy-3-methoxybenzyl methyl ketone, and the required vanilloyl methyl ketone* respectively. Since approximately 65% of the eluted material was the α-diketone, this method of synthesis warranted a more detailed investigation to determine the optimum conditions for a maximum yield of vanilloyl methyl ketone.

An equimolar ratio of selenium dioxide to the monoketone was adopted and a study made of the effect of varying the time of oxidation, at reflux temperatures, and the nature of the solvent system. Reaction times of 4, 8, 12, 18, and 24 hours gave rise to the diketone in yields which represented percentage relative abundances of 32, 46, 64, 64, and 64 respectively. Having, therefore, chosen 12 hours as the most suitable reaction time, a similar study was made of the effect of the solvent system. For dimethyl sulphoxide, dioxane, tetrahydrofuran, acetic acid, acetic anhydride, and ethanol the percentage relative abundances were 75, 65, 53, 36, a trace, and zero respectively. For simplicity, dioxane was chosen as the solvent system for all subsequent oxidations.

Two separate methods of isolation and purification of the required vanilloyl methyl ketone were investigated. In the first instance, a study was made of the separation of the nickel glyoxime salt and its subsequent decomposition with dilute sulphuric acid to liberate the free diketone (4). The second method involved a column chromatographic separation of the crude oxidation product and was found to be more successful. Silica gel was used as the column packing and petroleum ether (b.p. 40–60°) followed by petroleum ether containing 5% diethyl ether, effected the elution of the vanilloyl methyl ketone. Using these conditions of oxidation and isolation, seven substituted benzyl methyl ketones were oxidized successfully to the corresponding α-diketones. The yields are given in Table II.

On hydrolysis of the precipitated nickel glyoxime salt of vanilloyl methyl ketone, a white precipitate separated. This compound was characterized as vanillic acid. Further

The donation of an authentic sample of vanilloyl methyl ketone by Dr. J. A. F. Gardner, Superintendent, Forest Products Laboratory, Vancouver, B.C., was much appreciated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tests showed that the vanillic acid did not arise as a product of this hydrolysis or by oxidation of any vanillin that may have been present but rather that it was produced directly by oxidation of either the 4-hydroxy-3-methoxybenzyl methyl ketone or the vanilloyl methyl ketone. In subsequent syntheses involving the oxidation of *p*-methoxybenzyl methyl ketone and of 3,4,5-trimethoxybenzyl methyl ketone the two corresponding acids, anisic acid and 3,4,5-trimethoxybenzoic acid, were isolated and characterized. The mechanism of formation of these acids was not determined. A closer examination of a probable oxidation by air or peroxides in the dioxane must be made before a benzyl–acyl bond cleavage can be attributed to the action of selenium dioxide under these conditions.

The electronic absorption spectrum of each of the substituted benzoyl methyl ketones was determined using ethanol as the solvent. Table III records the λ_{max} and log ϵ_{max} for each diketone. The reported spectral bands of benzil and diacetyl are included for comparison.

TABLE III

Electronic absorption spectra of $ArCOCOCH_3$

Ar =	λ_{max}	log ϵ_{max}
1. Phenyl	255	4.36
2. *p*-Hydroxyphenyl	296	4.06
	225	3.82
3. *p*-Methoxyphenyl	294	4.00
	223	3.81
4. 4-Hydroxy-3-methoxyphenyl	320	4.93
	291 (sh)	—
	235	4.86

	370	1.89
Diacetyl ($CH_3COCOCH_3$)	435	1.30

The spectral data recorded in Table III are in general agreement with the theory regarding the effect of ring substituents on the absorption spectra of aromatic compounds.

EXPERIMENTAL

All melting points are uncorrected. Ultraviolet spectra were measured using a Cary Model 14 spectrometer. Infrared spectra were determined using a Perkin–Elmer Model 21 spectrometer with sodium chloride optics. Gas–liquid chromatography was performed using a Beckman GC-2 chromatograph with a thermal conductivity detector unit. This machine had been modified by placing the injection system as close as possible to one end of the column and by modifying it to make it more comparable electronically to the GC-2A.

Synthesis of 1-Aryl-1-propanones

(i) 1-(4-Hydroxy-3-methoxyphenyl)-1-propanone

1-(4-Hydroxy-3-methoxyphenyl)-1-propanol was prepared according to the method of Roberti, York, and MacGregor (5) and then oxidized, using silver oxide, to 1-(4-hydroxy-3-methoxyphenyl)-1-propanone as described by Pearl (8). For the latter step it was found necessary to increase the time of reflux to 5 hours and to use freshly prepared sulphur dioxide otherwise no crystalline product was obtained. Under the modified conditions, the crude oily product solidified on standing and was recrystallized from petroleum ether (30–60°) to yield colorless needle-shaped crystals, m.p. 59–60; reported m.p. 61–62 (8). Calc. for $C_{10}H_{12}O_3$: OCH_3, 17.22%. Found: OCH_3, 17.10%.

(ii) 1-(4-Hydroxy-3,5-dimethoxyphenyl)-1-propanone

Synthesis of 1-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanol.—Syringaldehyde (10 g) was dissolved in dry

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tetrahydrofuran (150 ml) and the solution treated with another solution of ethyl magnesium bromide (prepared from ethyl bromide (42 g) and magnesium (10 g)). The resulting oily product crystallized on standing, yield 6.1 g (52.3%). Recrystallization from benzene gave white crystals, m.p. 94–95°; reported m.p. 98° (12). Calc. for $C_{11}H_{16}O_4$: C, 62.25; H, 7.61; OCH_3, 29.3%. Found: C, 62.40; H, 7.48; OCH_3, 29.0%.

Oxidation of 1-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanol.—1-(4-Hydroxy-3,5-dimethoxyphenyl)-1-propanol (3.0 g) was treated with sodium hydroxide (7 g) and silver nitrate (8 g) and a similar procedure followed to that used for the oxidation of 1-(4-hydroxy-3-methoxyphenyl)-1-propanol. The yield of crude product was 1.2 g (40.3%). Recrystallization from aqueous ethanol gave white crystals, m.p. 108–109°; reported m.p. 109–110° (4).

Synthesis of 1-Aryl-2-propanones

2-Nitro-1-aryl-1-propenes

The experimental details are given for the preparation of a typical compound. Other compounds of the same series but differing in the ring substituent pattern were prepared by a similar procedure. The necessary data for each such individual synthesis are recorded in Table IV.

(i) Using the method of Kulka and Hibbert (9).—Vanillin (6 g) was dissolved in ethanol (10 ml) and to the solution, nitroethane (3 ml), methylamine hydrochloride (0.2 g), and sodium carbonate (0.016 g) were added. After 2 days at room temperature in the dark, the reaction mixture was cooled to 0°, the yellow needle-like crystals removed by filtration, washed with dilute sulphuric acid and with water, and dried. The yield was 5.9 g (71.5%). After recrystallization from a mixture of ethanol and ether the 2-nitro-1-(4-hydroxy-3-methoxyphenyl)-1-propene melted at 101–102°; reported m.p. 101–102° (9).

In Table IV are the experimental data for the similar condensations of *p*-hydroxybenzaldehyde, syringaldehyde, and 3,4,5-trimethoxybenzaldehyde.

(ii) Using the method of Kaufmann (10).—Veratraldehyde (15 g) was added to nitroethane (8 ml) and 20 drops of aqueous (75%) ethylamine added to the mixture. An initial turbidity slowly disappeared and a yellow oil separated which crystallized on standing. After 8 days, the crystals were removed by filtration and dried. The yield was 15.2 g (75.5%). After recrystallization from ethanol the 2-nitro-1-(3,4-dimethoxyphenyl)-1-propene melted at 73° (10).

In Table IV are the experimental data for the similar condensations of syringaldehyde, *p*-hydroxybenzaldehyde, and anisaldehyde.

1-Aryl-2-propanones

The experimental details are given for the preparation of a typical compound. All other compounds were prepared by a similar procedure, the necessary data for which are recorded in Table V.

(i) Using the method of Kulka and Hibbert (9).—2-Nitro-1-(4-hydroxy-3-methoxyphenyl)-1-propene (20 g) was dissolved in hot ethanol (200 ml) and hot water (500 ml), iron powder (40 g), ferric chloride (1.6 g), and concentrated hydrochloric acid added. The reaction mixture was refluxed, with stirring, for 6 hours and then concentrated to half the volume by removal of ethanol. The precipitated black iron oxide was filtered and washed with hot water. The combined filtrate and washings were extracted with benzene. From this extract was obtained an oil which was distilled to yield a clear, yellow product of 1-(4-hydroxy-3-methoxyphenyl)-2-propanone (13.4 g) (77.7%), b.p. 125° at 0.45 mm; reported b.p. 115° at 0.15 mm (9).

In Table V are the experimental data for the similar reduction and subsequent hydrolysis of the five other 2-nitro-1-aryl-1-propenes.

Synthesis of Aroyl Methyl Ketones

Vanilloyl Methyl Ketone

Selenium dioxide (2.4 g, 0.02 mole) was dissolved in dioxane (12 ml) and water (2 ml). 1-(4-Hydroxy-3-methoxyphenyl)-2-propanone (3 g, 0.02 mole) was added and the mixture refluxed for 12 hours. Initially the reaction mixture became red in color but gradually metallic selenium precipitated as a black powder. The selenium was removed by filtration and the dioxane and water removed by distillation. The residue, a dark brown tarry material, was distilled to give a clear yellow oil weighing 2.1 g, b.p. 115° at 0.6 mm. This product only partially crystallized.

(i) Purification of vanilloyl methyl ketone via the nickel glyoxime salt method.—From 3 g of the crude reaction product, prepared as above, the nickel glyoxime salt of the α-diketone was precipitated according to the method of Kulka, Hawkins, and Hibbert (4). The yield was 1.32 g. To hydrolyze this salt, it was added to 12 *N* sulphuric acid (400 ml), and the mixture was allowed to stand at room temperature for 24 hours and then at 40° for 4 hours. During hydrolysis a white precipitate separated (see below) which was removed by filtration. The filtrate was extracted with benzene in a continuous liquid–liquid extractor, the extract dried over anhydrous sodium sulphate and sodium bicarbonate, and concentrated to remove the excess benzene. A further slight precipitation of the white solid occurred during the concentration and it was removed by filtration. The residual oil was purified by fractional crystallization from benzene to give vanilloyl methyl ketone (0.55 g, 7%), m.p. 65–69°; reported m.p. 70–71° (9).

The white solid that precipitated during the hydrolysis was recrystallized from aqueous ethanol and characterized as vanillic acid on the basis of the following evidence: m.p. 204°, reported m.p. 207°; no melting

(ii) Purification of vanilloyl methyl ketone via the column chromatography method.—A chromatographic column (2 in.×30 in.) was half filled with dry petroleum ether (b.p. 40–60°) and silica gel (200 g) was added slowly with constant stirring. During this addition the petroleum ether was slowly drawn off from the bottom and the loss replaced through the top. When an air-bubble-free, well-packed column was obtained, the petroleum ether was drawn off until a 0.5-cm layer of solvent remained above the column packing. The crude oxidation product (2.0 g) was dissolved in a minimum amount of diethyl ether and placed on the top of the column. Elution with petroleum ether (40–60°) resulted in the slow separation of a yellow band. After the passage of 2 liters of the eluant, the band had moved one-third the length of the column. At this stage 5% diethyl ether was added to petroleum ether and 1.5 liters of this mixed solvent eluted the band completely. Evaporation of the solvent left yellow crystals of vanilloyl methyl ketone (0.92 g, 33%). After recrystallization from ethanol–water the melting point was 70–71°; reported m.p. 70–71° (9). The quinoxaline derivative melted at 160–161°; reported m.p. 162–163° (3).

In a similar manner six other aroyl methyl ketones were synthesized and isolated. The experimental data are given in Table VI.

THEORETICAL STUDIES ON THE ELECTRONIC SPECTRA OF SUBSTITUTED AROMATIC MOLECULES

PART II. SEMIEMPIRICAL SELF-CONSISTENT FIELD CALCULATIONS ON ANILINE

J. E. Bloor, P. N. Daykin, and P. Boltwood

British Columbia Research Council, University of British Columbia, Vancouver, British Columbia

Received July 15, 1963

ABSTRACT

The results of 14 calculations on the aniline molecule using different choices of parameters within the framework of the semiempirical SCFMO method have been carried out using an automatic Fortran 1A program written for an I.B.M. 1620 computer. It has been shown that the approximation of using the valence state ionization potential as a measure of the core integral of a heteroatomic substituent underestimates the amount of electron transfer between substituent AO and the benzene MO's. By adjusting this core integral empirically or by using a variable electronegativity MO approach it has been found possible to obtain, for the same set of parameters, agreement between experiment and theory for: the first two electronic transitions in the vapor state (4.23–4.38 ev and 5.22–5.41 ev), the change in ionization potential relative to benzene (AI = 1.54 ev), and the electron density para to the amino group (ρ_4^{π} = 1.059). It was not found possible to calculate values for the π-electron dipole moment and oscillator strengths which agreed, for any reasonable choice of parameters, with experimental values.

The semiempirical Self Consistent Field Molecular Orbital (SCFMO) theory as formulated by Pariser and Parr and Pople (1–4) is known to give calculated transition energies in fairly good agreement with those obtained experimentally for hydrocarbons. The reliability of the method for molecules with polar substituents in cases other than the replacement of a ring carbon atom by a nitrogen atom (5–9) have not been very thoroughly tested. We have therefore carried out a number of calculations on the SCFMO's of aniline using different approximations for the calculation of repulsion integrals and core integrals to try to obtain some insight as to the sensitivity of the SCFMO method to the values used for the basic parameters of the theory.

METHODS OF CALCULATION

The details of the approximations introduced by Pople and Pariser and Parr into the closed shell Hartree Fock method (9) in order to make it feasible to carry out calculations on conjugated systems have been described elsewhere many times (1–8) and only a summary necessary for the discussion will be given here. If the molecular orbitals (MO's) are expressed as linear combinations of atomic orbitals (AO's) ϕ_p [1],

$$\psi_i = \sum_{p}^{N\pi} C_{ip}\phi_p \qquad [1]$$

then the one-electron Hartree Fock problem for closed shell π-electron systems reduces to a matrix having elements [2] and [3].

$$F_{pq} = H_{pq}{}^{c} - \tfrac{1}{2}P_{pq}\gamma_{pq}, \quad p \neq q \qquad [2]$$

$$F_{pp} = H_{pp}{}^{c} + \sum_{q} P_{pq}\gamma_{pq} - \tfrac{1}{2}P_{pp}\gamma_{pp}, \qquad [3]$$

where P_{pq} is an element of the bond order matrix [4]

[4] $$P_{pq} = 2\sum_{i}^{N_{occ}} C_{ip}C_{iq};$$

the sum extending only over the occupied MO's N_{occ}. The eigenvectors C_{ip} and the orbital energies E_i are determined by the secular equation [5]:

[5] $$\sum_{p}^{N\pi} C_{ip}F_{pq} = E_iC_{iq}.$$

Since the eigenvectors used in [4] must also satisfy [5] some form of iterative procedure must be adopted. The numerical process used in the I.B.M. 1620 Fortran 1A program constructed for this investigation is described in the appendix. The process provides virtual as well as occupied MO coefficients and energies.

The central problem of assigning semiempirical values to the core terms $H_{pq}{}^{c}$ and atomic repulsion integrals γ_{pq} is discussed below.

Calculation of Core Matrix Elements

The off-diagonal elements $H_{pq}{}^{c}$ in [2] are very difficult to calculate theoretically so we have followed the common practice of treating them as empirical parameters β_{p-q} which have a value within the range -2.0 to -3.0 ev for the core where p and q are adjacent atoms contributing π-electrons. All other elements $H_{pq}{}^{c}$ are then neglected.

The diagonal elements $H_{pp}{}^{c}$ may be expanded as in [6]:

[6] $$H_{pp}{}^{c}(i) = \int \phi_p(i)\left|T_{(i)} + \sum_{q\neq p} U_q{}^{n_{q+}}(i) + \sum_{S} U_S(i) + \sum_{p} U_p{}^{n_{p+}}(i)\right|\phi_p(i)dv.$$

Where $U_q{}^{n_{q+}}$ represents the potential due to the core of atom q (with the n electrons contributing to the π-electron system removed) U_S represents the potential due to an atom S which does not contribute π-electrons to the system under consideration. T is the kinetic energy operator. The Goeppert–Mayer–Sklar approximation (10) [7] is utilized for the evaluation of the contribution of $(T+U_p{}^{n_{p+}})$

[7] $$\int\phi_p(i)|T(i)+U_p{}^{n+}(i)|\phi_p(i)dv = E_p = -I_p{}^{(n-1)+}$$

where $I_p{}^{(n-1)+}$ is the ionization potential of atom p in the appropriate valence state calculated using valence state tables (11).

The core terms in the first summation in [6] can be written in terms of a potential due to a neutral atom $U_q{}^{0}$ and a correction term allowing for the repulsion of the π-electrons contributed by that atom. Thus for an atom q contributing n π-electrons to

[8] $$U_q{}^{n+}(i) = U_q{}^{0}(i) - \sum_{j\neq i}^{n}\int\frac{\phi_q{}^{2}(j)}{r_{ij}}dv_{ij}$$

[9] $$H_{pp}{}^{c} = -I_p{}^{(n-1)+} - \sum_{p\neq q}(U_q{}^{0}{:}pp + n_q\gamma_{pq}) - \sum_{S} U_S{:}pp$$

the system we can write [8]. Then for the diagonal element $H_{pp}{}^{c}$ we can write [9]. The terms $U_S{:}pp$ and $U_q{}^{0}{:}pp$ are penetration integrals for neutral atoms following the convention that

$$U_S{:}pp = -\int U_s(i)\phi_p{}^{2}(i)dv(i).$$

The presence of the summation term over the number (n_r) of π-electrons contributed by atom r when $n_r > 1$ has led to some confusion in the literature (12). For example in the early work by Dewar and Paolini (13) it appears that only the repulsion of one

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

π-electron was included. In the case of Brown and Heffernan's work on pyrrole (8) the repulsion term for only one π-electron was included but then the penetration integrals for the nitrogen were calculated using an effective nuclear charge corresponding to N^+ rather than the neutral atom. In some of the more recent work (14–15) not enough data has been included to decide which approximation has been used. In the present work the core integral for the nitrogen (N^{2+}) has been approximated to that of a neutral nitrogen corrected by the repulsion of two π-electrons. The penetration integrals for nitrogen, carbon, and hydrogen have then been neglected. Some justification for this procedure has been given in the case of aniline by Peradejordi (17), who has shown that the penetration integrals, to be included in the core term of the nitrogen, add up to the same value as those for the carbon atoms. Leaving them out is tantamount to adjusting the energy zero of the orbitals and will not affect either the excited state energies or the charge distribution, although, as discussed later, this omission does alter the absolute value of the orbital energies.

Calculation of Repulsion Integrals

The calculation of the repulsion integrals γ_{pq} defined by [10],

$$\gamma_{pq} = \int \phi_p(i)\phi_p^*(i)(1/r_{12})\phi_q(2)\phi_q^*(2)dv_1dv_2, \qquad [10]$$

is probably the part of the theory which is at present the least satisfactory. It was shown by Pariser and Parr (1, 2) that if the values calculated theoretically using Slater orbitals are used then the calculated excited states even for hydrocarbons turn out to be far too high. They therefore proposed a method of calculating them empirically using data obtained from atomic spectra. For the one-center integrals γ_{pp} they proposed [11],

$$\gamma_{pp} = I_p - A_p, \qquad [11]$$

where I_p is the ionization potential of atom p in the valence state appropriate to the particular molecule under consideration and A_p is the electron affinity for the same valence state. For the two-center integrals γ_{pq} ($r_{pq} \geqslant 2.8$ Å) they proposed the formulae [12] and [13] based on treating the π-electronic charge distribution as charged spheres so giving [12] and [13] where Z_p is the Slater effective nuclear charge for atom p.

$$\gamma_{pq}(r) = \frac{7.1975}{r}\left\{\left[1+\left(\frac{R_p-R_q}{2r_{pq}}\right)^2\right]^{-\frac{1}{2}}+\left[1+\left(\frac{R_p+R_q}{2r_{pq}}\right)^2\right]^{-\frac{1}{2}}\right\} \qquad [12]$$

$$R_p = (4.597/Z_p). \qquad [13]$$

For distances shorter than 2.8 Å an extrapolation procedure [14] was adopted.

$$\gamma_{pq} = \tfrac{1}{2}[\gamma_{pp}+\gamma_{qq}]-ar-br^2 \qquad [14]$$

where a and b are found by using the values calculated from [12] for $r = 2.80$ Å and $r = 3.7$ Å. This method of calculating repulsion integrals has been adopted in the great majority of semiempirical SCF calculations published up to date. However it is clear from the work of Pariser (1) and the more recent work of Lykos (17) that even for hydrocarbons this method of calculating the two-center repulsion integrals is not suitable for calculations on excited states. To obtain satisfactory results for polyacene hydrocarbons it is necessary (1, 18, 19) to construct an empirical $\gamma_{pq}{}^r/r_{pq}$ curve from values obtained for benzene by equating the theoretical excited state energies to the experimental values. This curve can then be extended to greater r_{pq} values using either the values calculated from Slater orbitals or by using equation [14]. If [14] is used it should be noted that for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

values >4.0 Å, the value obtained is very insensitive to the nature of p and q and the repulsion integral becomes independent of the nature of atoms p and q, and depends only on the distance r_{pq}.

An alternative to the Pariser–Parr formulation for the calculation of repulsion integrals, which has been used quite successfully in calculating the excited states of polyacene hydrocarbons (20), is that proposed by Mataga (6). In this method the one-center integrals are evaluated from [11] or by the Paolini approximation [18] discussed below. The two-center integrals are assumed to be of the form [15–16]:

$$\gamma_{pq}(r) = \frac{14.397}{a_{pq}+r_{pq}} \text{ ev}, \qquad [15]$$

$$a_{pq} = \frac{28.794}{(\gamma_{pp}+\gamma_{qq})} \text{ ev}. \qquad [16]$$

This method has been used apparently successfully on calculations described elsewhere (21) and was used as the starting point in many of the earlier calculations described below. It, however, has been found to be unsatisfactory (21) in cases where the substituent attached to the benzene ring ions is polyatomic (e.g. —HC, $=CH_2$, —C≡N, and $—NO_2$).

The Variable Electronegativity Method

As will be reported elsewhere, the simple SCF methods described above were found to be unsatisfactory for molecules where there was an uneven charge distribution due to the presence of more than one hetero atom in the molecule, e.g. in nitrobenzene and *p*-nitroaniline. The chief source of this error appears to lie in the choice of I_p which is assumed to be independent of the environment of atom p in the molecule. It has recently (8) been suggested that an improvement over the simple SCF method may be obtained by assuming both I_p and γ_{pp} to be dependent on the charge distribution at atom p in the particular molecule under consideration. We have therefore carried out two calculations using this method in the case of aniline. The dependency of I_p and γ_{pp} on the charge density P_{pp} is formulated in terms of the Slater effective nuclear charge Z_p which is related to the π-electron density P_{pp} by [17],

$$Z_p = N_p+K_1^p+K_2^pP_{pp}, \qquad [17]$$

where N_p is the atomic number of atom p, K_1 is a constant incorporating the constant part of Z_p due to the σ bonds and the lone pairs, and K_2 is a constant equal to -0.35 for atoms in the first row of the periodic table.

The one-center integrals were calculated from Z_p using the relationship [18] suggested by Paolini (7):

$$\gamma_{pp} = 3.294Z_p. \qquad [18]$$

The two-center integrals γ_{pq} were either found from the Mataga approximation [15] using the π_{pp} obtained from [18] at each iteration or, since their variation is quite small, they were kept constant after being calculated at the first iteration. The elements I_{pp} were calculated from the parabolic relationship [19],

$$I_{pp} = K_2Z_p^2+K_3Z_p+K_4, \qquad [19]$$

where K_2, K_3, and K_4 were constants obtained by fitting the Z values for an isoelectronic series calculated from valence state tables (11) and correcting for the valency of the atom

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

using the method suggested by Brown (8). The final values of the repulsion integrals provided by the SCF calculation were used in the configuration interaction calculations described below.

Calculation of Excited State Energies

The excited states of a molecule, e.g., Ψ_I can be expressed as a linear combination [20] of individual configurations ψ_i^k in which an electron has been excited from MO ψ_i into MO ψ_k. The mixing coefficients $A_I^{(ik)}$ and the excitation energies are obtained by diagonalizing a configuration interaction matrix with elements given by [21]. In [21] E_i is the orbital energy of the SCFMO ψ_i. $\langle ik|jl\rangle$ and $\langle ij|kl\rangle$ are molecular repulsion integrals defined by [22]. For the two lowest excited excitation energies of aniline it was found necessary to include only the configurations involving excitations from the two highest occupied MO's to the lowest unoccupied MO's.

The oscillator strength f_I of the Ith excited state of energy E_I was calculated using [23] where $Q_{0\to I}$ is the transition moment (1). The π-electron dipole moment of the ground state was calculated using [24].

[20] $$\Psi_I = \sum A_I^{(ik)} \psi_i^k$$

[21] $$({}^1\psi_i^k|H|{}^1\psi_j^l) = \delta_{ij}\delta_{kl}(E_k - E_i) + 2\langle ik|jl\rangle - \langle ij|kl\rangle$$

[22] $$\langle ik|jl\rangle = \sum_p \sum_q C_{ip}C_{kp}C_{jq}C_{mq}\gamma_{pq}$$

[23] $$f_I = 8.753\times 10^{-2} Q_{0\to I}^2 E_I. \quad (Q_{0\to I} = \int \Psi_0 e\mathbf{r}\Psi_I dv)$$

where L_{xp} L_{yp} L_{zp} are the co-ordinates of atom p, and Z_p is the number of electrons contributed by atom p to the π-electron system.

[24] $$\mu^\pi = 4.8\left[\left\{\sum_j^{x,y,z}\left[\sum_p^{N\pi} L_{jp}(z_p - p_{pp})\right]^2\right\}^{\frac{1}{2}}\right]$$

EXPERIMENTAL DETERMINATION OF TRANSITION ENERGIES

The primary purpose of this investigation was to obtain a set, or sets, of parameters which gave calculated transition energies fairly close to the observed ones for aniline so that these parameters for the amino nitrogen in aniline could be used in interpreting the spectra of other aromatic amino compounds. Since, for monosubstituted benzenes, the actual changes in the transition energies of the parent molecule on substitution are quite small (e.g. the change in the transition energies of the first and second transitions of benzene on substituting one hydrogen for a dimethylamino group, which is one of the strongest electron donating groups, are only 0.76 and 1.1 ev respectively (measurements in iso-octane solution)), it is necessary to obtain accurate experimental results. We have therefore re-examined the spectra of aniline in the vapor state using a Cary 14 spectrophotometer. As previously reported by Matsen (22) the first transition contains a large number of vibronic lines. The 0–0 transition is located at 34,130 cm^{-1} (4.23 ev) and the line of maximum intensity, corresponding to the Frank–Condon transition, is at 35,340 cm^{-1} (4.38 ev). Fine structure was also observed for the second transition and is reported apparently for the first time. The fine structure consisted of a shoulder at 42,100 cm^{-1} (5.22 ev), a well-defined peak at 42,510 cm^{-1}, a shoulder at 43,100 cm^{-1}, a pronounced peak at 43,670 cm^{-1} (5.41 ev), and two ill-defined shoulders at 44,200 cm^{-1} and 44,640 cm^{-1}. Because of the small number of bands observed no vibrational analysis was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

attempted and the 0–0 transition was arbitrarily taken to be at the first shoulder, i.e., at 5.22 ev.

The theoretical calculations of the transition energies are based on virtual orbitals obtained from a solution of the Schroedinger equation using parameters dependent on the ground state physical dimensions. Consequently an exact correspondence between the experimental 0–0 transition energies and the theoretical transition energies should not be expected since the latter correspond to a Frank–Condon transition to a hypothetical excited state possessing the same dimensions as the ground state. We have therefore assumed that a satisfactory theoretical transition energy should be greater than the observed 0–0 transition energy and probably less than the experimentally observed line of maximum intensity. Thus in the case of aniline a satisfactory calculation would give the first transition between 4.23 ev and 4.38 ev and the second transition between 5.22 ev and 5.41 ev.

DISCUSSION AND RESULTS

The results of 14 calculations using the methods described above are summarized in Tables I and II. In these calculations the parameters were not varied entirely syste-

matically but were largely based on values reported in the literature for calculations on amino compounds. The starting point in the calculations was the rigid set of rules suggested by Pariser and Parr (2, 4) for choosing the parameters I_{N^+}, γ_{NN}, and γ_{CN} while the γ_{C-C} value was chosen by reference to the benzene spectrum (1). β_{C-N} was then regarded as an empirical parameter. As will be discussed in detail below such a procedure did not give satisfactory results since it underestimated the amount of electron transfer from the amino nitrogen to the benzene ring. Agreement with experiment can be achieved by treating I_{N^+} as an empirical parameter, as suggested by McWeeny for calculations on pyridine type compounds (5). However the introduction of two empirical elements I_{N^+} and β_{C-N} has considerably reduced the fundamental significance of the approach. It is known from calculations using the simple Huckel LCAO method with two similar empirically chosen parameters α and β that it is possible to adjust these values to fit almost

*Experimental quantities: $\mu^\pi = 1.02$ D, $\Delta I = 1.54$ ev, $\rho_4^\pi = 1.059$.

any set of experimental data. The situation was somewhat improved by using the VESCF method of obtaining I_{N^+}. In this method I_{N^+} is allowed to vary with the Slater effective nuclear charge according to [19]. The procedure described by equations [17] and [19] may be regarded as taking into consideration correlation effects between the two π-electrons on the nitrogen and between the nitrogen π-electrons and the carbon π-electrons. As P_{pp} increases the effective Z_p decreases so lowering the effective "electropositivity" of the nitrogen nucleus resulting in a lower value of $H_{pp}{}^c$.

When these calculations were started it was hoped that some information about the valence state of the amino nitrogen would be obtained by comparing the calculated and experimental results of the various physical quantities discussed below. There is a considerable body of evidence from infrared spectroscopy (24, 25), microwave absorption (26), and structural determinations (27, 28, 29) that the bonds about an amino group are not planar even in an amide such as formamide, where considerable conjugation between the amine group and the electron attracting carbonyl group is to be expected. The valence state of the nitrogen lone pair in the planar configuration would be that of a $2p$ π-electron and in the pyramidal configuration it would be sp^3. This difference in the valence state would be expected to be reflected both in the I_{N^+} value and the β_{C-N} value. Thus I_{N^+} $(\pi) = 28.17$ ev and I_{N^+} $(sp^3) = 33.3$ ev (11). If we assume the resonance integral β_{C-N} to be proportional to the overlap integral S_{C-N} we would expect β_{C-N} for sp^3 nitrogen to be only 0.61 of β_{C-N} for sp^2 nitrogen at $r = 1.36$ Å. Since, however, we have only been able to obtain agreement between experiment and theory by taking I_{N^+} much lower than either of the two values obtained from valence state tables it has not been possible to come to any conclusion regarding this problem.

The results of the calculations treating NH_2 as a monatomic substituent contributing two π-electrons to the system, are set out in Table I. In calc. 1, I_{N^+} was obtained using valence state tables (11), γ_{NN} was obtained using [11], and the two-center γ_{pq} were calculated using the Mataga approximation [15, 16]. For β_{C-N} an empirical value of -2.0 ev was chosen as being compatible with other work on substituted benzenes (21).

The calculated excitation energies (columns 5–12, Table I) were found to be much too high and were more like the values expected for a weakly interacting substituent such as Cl or OH rather than for the supposedly strongly interacting NH_2 group. In calc. 2 the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

I_{N^+} value was dropped considerably to 23.0 ev and β_{C-N} was raised to -2.50 ev. This causes the value for the second excited state to be lowered outside the satisfactory limits. Raising I_{N^+} by 0.5 ev (calc. 3) now gives quite good agreement between experiment and theory. Since a value of I_{N^+} used in calc. 3 is quite close to that suggested by McEwen (23) for an amino nitrogen in nitramine (NH_2NO_2) (i.e., 24.38 ev) calculations using this value and $\beta_{C-N} = -2.5$ ev (calc. 4) and $\beta_{C-N} = -2.0$ ev (calc. 5) were carried out. The value of the first excited state now has become rather higher than the experimental value. To make a fairer comparison with McEwen's work however a calculation was carried using the same value for γ_{NN} as used by McEwen (calc. 6). The result was a considerable increase in the transition energies of both the first two excited states placing the energies well outside our criteria for a satisfactory calculation.

Calculations 4, 6, and 10 in which the only variation is the value of γ_{NN} show the appreciable sensitivity of the SCF method to the values used for the repulsion integrals. Previous workers have tended to ignore this factor (30), although it is of course implicit in Pariser's (1) work since he was unable to fit experimental values of the benzene transitions without choosing his γ_{CC} values very carefully.

In earlier calculations on aniline using equations [1–13] for the calculations of γ_{pq}, Peradejordi (16, 21) found the values $I_{N^+} = 28.16$, $\gamma_{NN} = 15.92$ ev, and $\beta_{C-N} = -2.59$ ev to be quite suitable parameters for aniline. Calculation no. 7 utilized these parameters but used the Mataga method [14–15] for determining the two-center integrals. It can be seen that again the calculation cannot be regarded as satisfactory since the transition energies are much higher than our limits for a satisfactory calculation.

The I_{N^+} was then reduced to 25.0 ev (calc. 8) and then to 24.38 ev (calcs. 9–11). In calcs. 9–11 I_{N^+} was kept constant but β_{C-N} was decreased gradually through the values -2.0, -2.5, and -2.75 ev. These last three calculations show that although the first transition energy is very insensitive to β_{C-N} the second transition energy is lowered in energy as β_{C-N} decreases. This rather unexpected increase in transition energy with decrease in the resonance integral β_{C-N} is apparently due to the increase in the energy of the second lowest unoccupied MO (E_6) as β_{C-N} is increased, due to the term F_{17} (as defined in equation [2]) in [25] for the orbital energy E_i which outweighs the increase in energy of E_4. In a molecule where the interaction of the substituent X is not as great as in

$$[25] \qquad E_i = \sum_{p}^{N\pi} \sum_{q}^{N\pi} C_{ip} C_{iq} F_{pq}$$

aniline an increase in β_{C-X} would raise the energy of the highest interacting occupied MO more than any of the unoccupied MO's so that increase in β_{C-X} would result in a lowering of transition energy. However, in the case of aniline the mixing of the substituent AO with the benzene MO's is so great that it is no longer correct to relate any of the aniline MO's with those of the parent benzene.

Calculations 1–11 have been carried out using the Mataga approximation for γ_{pq}. In calc. 12 we have used values for γ_{cc} obtained from an empirical curve of $\gamma_{cc}{}^r$ against the C—C distance r obtained by equating the calculated transition energies for benzene to the experimental values quoted by Pariser (1). The γ_{CN} values were then obtained using equations [12–14]. The results using $I_{N^+} = 25.0$ ev, i.e. a value much lower than that usually proposed for amino nitrogen, were in satisfactory agreement with experiment for the transition energies. Since the empirical lowering of I_{N^+}, until agreement with experiment is found, is not a very satisfactory procedure, and since calculations on other mono- and di-substituted benzenes (21) had also demonstrated deficiencies of the simple

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

SCF method calculations were next carried out using the VESCF method. In calc. 13 the Mataga method was used to calculate the γ_{pq} values and both the γ_{pp} values and the γ_{pq} values were allowed to change with the charge density according to equations [15–16] and [18]. The final result for I_{N^+} and γ_{NN} are recorded in Table I (calc. 13) together with the excitation energies. It is seen that both I_{N^+} and γ_{NN} are quite close to those suggested by McEwen for amino nitrogen but much lower than the values usually used. However the excitation energies are considerably higher than the experimental values. In carrying out this calculation it was noted that the final off-diagonal γ_{pq} values of the repulsion integrals (R matrix) differed only slightly from the starting values so that variation of these off-diagonal elements at each iteration seems an unnecessary refinement. In calc. 14, therefore, only the diagonal elements of the R matrix were varied. However, the calculation differed from calc. 13 in that the off-diagonal elements of the R matrix were those obtained as in calc. 12 for γ_{c-c} and equations [13–15] were used for the γ_{CN} values. It can be seen from Table I that the agreement between experiment and theory for the energy of second transition is very good but for the first transition the energy is a trifle high. Relative to the approximations used in the theory however the results cannot be described as poor.

As far as the transition energies of the third and fourth transitions are concerned it is not possible to say very much. They appear at greater energies than 6.0 ev but the absorption curves given by Klevens and Platt (32) reveal only a very broad absorption from which it is impossible to infer a 0–0 transition energy of even a clear cut maximum. However, the value 6.3 ev has often been quoted in the literature and it can be seen from Table I that the theory, whatever the parameters used, does predict two transitions of high intensity in the region 6.2–6.8 ev.

Although the oscillator strengths of the first two transitions are known for aniline in solution, namely 0.03 for the first transition and 0.17 for the second, agreement between theory and experiment should not be expected since even for benzene, where the repulsion integrals were adjusted to give a good fit for the energy levels, the calculated oscillator strengths of the first two allowed transitions are much too high. (Calc. $f = 2.215$, exp. $f = 0.74$.) Similar discrepancies between experimental and calculated results have been reported for other polyacene hydrocarbons (1). High results may therefore be expected for the calculated oscillator strengths of aniline but the questions of whether an appropriate correction factor to the calculated f values can be applied (e.g. Baba (33) has suggested 0.3) and if so what is its magnitude can only be answered when more calculations and more experimental data on oscillator strengths (preferably in the vapor state) are made available. From the results of Table I however it can be seen that the calculated f values are not very sensitive to variation in parameters and that the ratio of f_{II}/f_I is usually a factor of two higher than the experimental value ($f_{II}/f_I = 5.4$). More calculations on other molecules using the same methods are required to find out whether this factor is specific to aniline or whether it can be carried over to other monosubstituted benzenes.

Calculation of π-Electron Dipole Moments

It is usual for π-electron dipole moments calculated by the Hückel theory to be rather higher than those estimated from experimentally determined dipole moments but it has been claimed that the SCF theory and the VESCF theory (8) will produce more realistic values. We have tabulated the calculated dipole moments of the π-electrons (μ^π) in column 2 of Table II. To compare these values with the experimentally determined

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

value it is necessary to adjust the latter for the dipole moment of the N—H bonds, any moment due to other σ bonds and for the spatial distribution of the hydrogen, the lone pair and the phenyl ring about the amino nitrogen.

To do this we have accepted the arguments of Everard and Sutton (34) which lead to a π-electron dipole moment of 1.02 D. This value is based on a μ (N—H) bond moment of 1.31 D and a tetrahedral distribution of bonds about the nitrogen.*

The results of the theoretical calculations of μ^π given in Table II show that in general the calculated contribution of the electrons to the total dipole moment is too high compared with the estimate obtained by experiment. However, it is clear that μ^π is very sensitive to the parameters used in the calculations. Thus, in reducing β_{C-N} from -2.75 ev (calc. 8) to -2.0 ev (calc. 11) we have lowered μ^π to one-third of its original value while changing I_{N^+} from 23.0 ev (calc. 2) to 23.5 ev (calc. 3) decreases μ^π by 16% and increasing I_{N^+} further to 24.38 ev decreases μ^π by 30%. The calculation using the VESCF method (calc. 14) has also quite a high value for μ^π which is no better than the ordinary SCF method for parameters which give good values for excited state energies. The calculations (1, 7, 13) which have low μ^π values are calculations using (except for calc. 13 which is a VESCF calculation) high I_{N^+} values and which give high transition energies and a small lowering of the ionization potential compared to benzene. With the exception of the last two (calc. 1 and 7) discussed above, all the μ^π values are much higher than those experimentally estimated. One must therefore conclude that it is not possible to choose parameters to obtain good agreement between theoretically calculated and experimentally estimated μ^π electron dipole moments and at the same time obtain agreement between theory and experiment for other quantities.

Charge Densities and Bond Orders

There is unfortunately, as yet, no reliable experimental method of obtaining data which are directly comparable with the elements of the charge density matrix, the elements of which are given by [4]. It has been suggested (35) that C^{13} nuclear magnetic resonance chemical shifts may be related to π-electron densities. Such a relationship appears to be obeyed by both alternant and non-alternant hydrocarbons. The linear relationship [27] has been obtained (36) by using hydrocarbons (C_6H_6, C_7H_{7+}, C_5H_{5-}) of known π-electron density (ρ^π) and the C^{13} chemical shift δ_C (p.p.m.)

$$\rho^\pi = (\delta_C/160)+1. \qquad [27]$$

The electron density at all the carbon atoms in a monosubstituted aromatic hydrocarbon can in principle be obtained if the δ_C values could be measured and [27] is assumed applicable to such compounds. Unfortunately, as pointed out by Spiesecke and Schneider (35), magnetic anisotropic effects play an important part in determining the chemical shift of both the carbon atom to which a substituent is attached and the neighboring one. For aniline therefore we only obtain reliable experimental values for ρ_4^π and ρ_3^π. Moreover (35) ρ_3^π in insensitive to the nature of the substituent on the C_1 atom. Using the experimental value for $\delta_C = 9.5$ (rel. to benzene) (35) for the C_4 atom in [27] we arrive at the value $\rho_4^\pi = 1.0594$. We can either relate this directly to that calculated by an SCF calculation or,

**There are many other estimates of μ^π to be found in the literature. They mostly lie within the range of 1.0–1.6 D. The main exception is a value of 0.7 D quoted by Fischer (14 and 41). This value, however, is probably subject to rather a large degree of uncertainty because it is based on a comparison of the dipole moments of alkyl amines and alkyl anilines, both ring and N-substituted, and no attempt is made to consider changes in bond angles and sigma bond moments in the various compounds.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

since in these calculations we have not taken into consideration any direct field effect or any inductive effect transmitted by the sigma electrons, we can attempt (38) to split the chemical shift into two contributions by an empirical method using standard substituent constants such as σ_I and σ_R suggested by Taft (37). Since, however, it seems likely (38) that the predominant factor determining the C^{13} chemical shift in the para position is a π-electron effect we have directly related ρ_4^π to the calculated π-electron density, therefore neglecting any sigma electron inductive effect or any direct electrostatic (field) effects.

Comparison of the experimental value for ρ_4^π with the theoretical values in column 5 of Table II shows that quite a number of calculations give ρ_4^π values quite close to 1.059. The calculations which disagree are those which quite clearly are underestimating the electron transfer from the NH_2 group to the ring (calc. 1, 7, and 13). For values of I^+_N in the region of 23–25 ev the calculated ρ_4^π values are not sensitive with change of I^+_N. Therefore, although ρ_4^π can be used to select parameters of the right order which, considering the many approximations in the semiempirical π-electron theory used here, is perhaps all that can be expected, it is not very reliable for pinpointing the best I^+_N value. The VESCF calculation (14) gives a ρ_4^π value of 1.029 predicting an electron transfer to the C_4 atom only one-half of that estimated experimentally.

The ratio ρ_2^π/ρ_4^π is of interest. No quantitative experimental estimation of this value is available but it is now generally accepted that the ortho position in a monosubstituted benzene C_6H_5X, where X is an electron donating group, is much more sensitive to electrophilic reagents than the para position. The Hückel theory tends to give a much lower value for this ratio than the SCF method so one can make the tentative conclusion that the SCF method of calculating electron densities is more in accord with experiment than the Hückel theory. The bond orders ρ_{pq} of aniline have also been calculated. Unfortunately there do not appear to be any experimental determinations of bond distances with which to compare the bond orders. All values of the parameters give ρ_{pq} values which correspond to a marked lowering of the bond order of the C_1—C_2 and C_1—C_6 bonds, where the amine group is attached to the C_1, while the C_2—C_3 and C_3—C_4 bond orders are relatively little changed. It would be of very great interest to have available accurate bond distance measurements, preferably in the vapor state, for C_6H_5X, where X is a fairly strong electron donating agent, to see whether the prediction of a longer C_1—C_2 bond is fulfilled experimentally.

Ionization Potential

Assuming Koopman's theorem to be correct for polar molecules (9) we can relate the ionization potential of a molecule to the energy of the highest occupied MO. However, the absolute value of energy of this MO is determined by the values of the parameters used for the kinetic energy and potential energy of the core and if constant factors (e.g. the penetration integrals and many integrals due to the sigma electrons) relating to these are omitted from the diagonal elements of the F matrix they will alter the absolute values of the orbital energies but not their relative values. In comparing calculated orbital energies with experimental energies then it is very important to use relative values. In Table II column 4 we report the difference between the orbital energies of the highest occupied MO's of benzene and aniline, the benzene energies being calculated using [28].

[28] $$E_3 = -I_C+\beta_{C-C}+\tfrac{1}{6}(3\gamma_{11}-2\gamma_{12}-\gamma_{14})$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

These values should be compared with the experimental difference of (9.24 ev -7.7 ev) = 1.54 ev.

From the results of Table II it can be seen that the calculated ionization potential difference ΔI is quite sensitive to the parameters used but that a number of calculations give a reasonably correct value (e.g. calc. 3, 8, 11, 12). It can be seen that calculations which give poor agreement for other properties (calc. 1, 6, 7, 13) also give poor values for ΔI. Calculations 6, 9, 10, 11 indicate that ΔI is not very sensitive to change in β_{C-N} although it is probable that this condition would not be found in cases where the electron interaction between substituent and ring are not so great. In general it does appear that ΔI values could be used as a guide in choosing parameters for substituents. The effect of changes in electron distribution of the ion $(C_6H_5NH_2)^+$ making use of the method formulated by Roothaan (39) for open shells and applied to hydrocarbons by Hoyland and Goodman (18) is under investigation in order to test the validity of Koopman's theorem for polar molecules.

COMPARISON WITH PREVIOUS CALCULATIONS

Prior to the work reported here there have been three semiempirical SCF calculations reported for aniline (14, 16, 40). No details of the work of Peradejordi have yet been published so comment will be restricted to the calculations by Peacock (40) and Fischer (14). In reference 40 the first two transition energies were both given as being at 4.3 ev. These should be discussed in conjunction with the values calculated for the excited states of the parent molecule benzene using the same values for the γ_{CC} repulsion integrals (5), these were found to be at 4.90 ev and 5.66 ev. Thus the relative change of the first transition energy corresponds well to the experimental value ($\Delta\epsilon$ exp. = .67 ev, $\Delta\epsilon$ calc. = 0.6 ev) while the effect of the amino group on the second transition is considerably overestimated (calc. 1.36 ev, exp. 1.0 ev). Since the calculation predicts that the first two transitions are completely superimposed on each other whereas they are observed to be quite separate then it would appear to be inadvisable to use Peacock's parameters, especially the repulsion integrals, in calculations designed to aid in assigning bands of unknown origin. No data were given on the ionization potential and charge densities. In the other SCF calculation on aniline (14) the parameters β_{CC} and γ_{CC} were chosen to fit the transition energies of benzene and the I_C and I_{N^+} value was obtained by reference to the ionization potential of benzene and ethylamine respectively. The remaining parameter β_{C-N} was then calculated in terms of the other parameters and found to be -1.452 ev, i.e., rather lower than the range used in the present calculations. The first two transition energies were calculated to be at 4.7 ev ($f = 0.15$) and 5.58 ev ($f = 0.19$), the ionization potential relative to benzene was calculated as 1.05 ev and ρ_4^π was found to be 1.015. Comparison of these results with the corresponding experimental ones (Tables I and II) indicate that the parameters used underestimate considerably the interaction of the amino group with the benzene ring. However, the calculated dipole moment $\mu^\pi = 0.78$ D compares very favorably with that estimated experimentally ($\mu^\pi = 0.7$ D) by a different procedure (41) from that used in the present work. It is because of the difficulties in extracting a reliable μ^π from the experimental dipole moment that we prefer to use transition energies, ionization potentials, and charge densities as criteria for selecting parameter values in semiempirical calculations. Unfortunately, for polar molecules, there are available very few experimental measurements of these properties, and of bond lengths, which are free from environmental effects, such as crystal forces and solvent effects. Such results, which can be used to compare with theoretical calculations, are badly needed.

CONCLUSIONS

The main conclusions of the present work may be summarized as:

1. The Pariser–Parr method described in [12–14] for calculating two-center repulsion integrals does not give values which may be used in calculations of transition energies of monosubstituted benzenes. However, satisfactory results can be obtained if the γ_{CC} values are obtained by equating the observed transition energies to the corresponding theoretical expressions for benzene and then calculating the repulsion integrals involving the hetero atoms by means of the Pariser–Parr formulation.
2. Two-center repulsion integrals for monosubstituted benzenes C_6H_5X where X is a monatomic substituent can be calculated satisfactorily for both γ_{CC} and γ_{C-X} if the Mataga approximation [14, 15] is used.
3. The usual method of obtaining the core integral I_X in C_6H_5X from valence state ionization potentials yields a value which when used in the Pariser–Parr–Pople SCF method for calculating physical properties yields results which indicate considerable underestimation of the interaction between the benzene MO's and the substituent X.
4. If I_X is treated as an empirical parameter then a value can be found which, when used in the simple SCF method and applied to aniline, yields values for the first two transition energies: the ionization potential, relative to that of benzene (i.e. ΔI), and the charge density at the para position (ρ_4^π), which are in good agreement with experimental values. On the other hand it has not been possible to find parameters which would also give satisfactory agreement between calculated oscillator strengths and the μ_4^π electron dipole moment and the values obtained from experimental data which would also give satisfactory results for the other physical properties.
5. Parameters suitable for use in simple SCF calculations for compounds using an amino type nitrogen are $I_{N^+} = 25.0$ ev, $\beta_{C-N} = -2.5$ ev, and $\gamma_{NN} = 14.36$ ev.
6. The undesirable feature of treating I_{N^+} as an empirical parameter can be avoided by using the VESCF method devised by R. D. Brown (8). However, even here, the results for the transition energies are barely within the admittedly rather stringent requirements for a satisfactory calculation as defined above and the amount of charge transfer between the substituent and ring appears to be only about a half of that required to give satisfactory results for ρ_4^π and ΔI.

Further work is in progress by one of us (J. E. B.) in an attempt to improve the agreement between theory and experiment for the physical properties of conjugated systems containing hetero atoms. Preliminary results indicate that an improvement in the choice of I_X is achieved by taking into consideration the shielding of the effective nuclear charge acting on the π-electrons caused by polarization of the σ bonds attached to the atom X.

The financial aid given by the National Research Council of Canada and the British Columbia Research Council is gratefully acknowledged. Thanks are extended to the staff, particularly Mr. W. Dettwiler, of the Computing Center of the University of British Columbia, for their cooperation and help in preparing and running the computer programs for the IBM 1620.

APPENDIX: COMPUTER SOLUTION OF MOLECULAR SCF EQUATIONS

A program has been constructed for completely automatic solution of the restricted molecular SCF problem for π-electron spectra. Because the available computer, an IBM

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

1620, is comparatively slow, some thought was given to developing a procedure which would economize in computing time. Those time-saving procedures likely to be of general use are reported in this note.

The self-consistent field problem may be expressed in the following condensed form:

$$P_{rs} = \sum_{i}^{m} C_{ri}\tilde{C}_{is} \qquad [1]$$

$$F_{pq} = H_{pq}+G_{pq}(P_{rs}) \qquad [2]$$

$$\sum_{p,\,q}^{n} \tilde{C}_{ip}F_{pq}C_{qk} = E_i\delta_{ik} \qquad [3]$$

In [1] the sum extends over the $m < n$ eigenvectors, C_{ri}, representing the occupied orbitals. If the eigenvectors are arranged in sequence corresponding to an ascending order of the corresponding eigenvalues E_i, then the occupied orbitals are designated by a set of integers $(i_1, i_2, \ldots i_m)$. For the ground state of the molecule the occupied orbitals are represented by the first m ordered eigenvectors.

The eigenvalue problem (3) can be solved rapidly with the Jacobi method (42) in which a unitary transformation **C** which diagonalizes **F** is constructed. The matrix **C** so obtained is used in [1] and the sequence [1, 2, 3] repeated until self-consistency, as judged by some suitable criterion, is reached.

The process is elementary from a purely mathematical viewpoint, but some modifications in it can reduce substantially the required computing time. First, the **C** matrix used in [1] to construct the bond order matrix **P** can also be used in [3] to partially diagonalize H:

$$\tilde{\mathbf{C}}\mathbf{F}\mathbf{C} = \mathbf{F}_1.$$

This step requires about half of the time consumed by the Jacobi method to achieve the same degree of diagonalization. At this point the off-diagonal elements of $\mathbf{F}_1$ can be examined. If the greatest is less than some tolerance, t, which may be some chosen fraction of the largest diagonal element of **F**, then self-consistency has been obtained; otherwise the diagonalization is continued by the Jacobi method. (The above step is omitted on the first iteration because an accurately orthornormal **C** matrix is not usually available; instead **F** is diagonalized directly by the Jacobi method to the tolerance t.) Second, there is little merit in continuing the Jacobi process, in any one iteration, until the tolerance t has been reached, because **F** itself is constructed from an approximate matrix **C**. Instead, the Jacobi process should be terminated when the off-diagonal elements of $\mathbf{F}_1$ have been reduced to a fraction k, which appears to be 0.3 on the basis of the number of iterations required for average size molecules. Further economy in computing time could undoubtedly be realized by treating k as a variable whose value is related to the degree of self-consistency currently obtained. Third, the rate of convergence can be increased, substantially in favorable cases, by making use of Aitken's acceleration (43). The most convenient function to accelerate is the bond order matrix **P**. If $\mathbf{P}_1$, $\mathbf{P}_2$, $\mathbf{P}_3$ are three successive estimates of **P**,

$$\begin{aligned} \boldsymbol{\Delta}_1 &= \mathbf{P}_2-\mathbf{P}_1, \\ \boldsymbol{\Delta}_2 &= \mathbf{P}_3-\mathbf{P}_2, \\ \boldsymbol{\delta} &= \boldsymbol{\Delta}_2-\boldsymbol{\Delta}_1; \end{aligned}$$

then an estimate of the limit **P** of the sequence is

$$P_{ik} = P_{3ik}-(\Delta_{2ik})^2/\delta_{ik}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Since the computation, once started, is outside the control of the program user, it is essential to include some automatic restriction on the acceleration. The acceleration is convergent in a broad sense provided

$$|\Delta_{2ik}| < |\Delta_{1ik}|.$$

However, consideration of a few well chosen examples will show that this condition is not stringent enough to prevent "wild" estimates of **P** from occurring. A more stringent convergence condition,

$$|\Delta_{2ik}| < |\delta_{ik}|,$$

has been written into the program. Acceleration can be elected beforehand by the program user for any suitable subsequence of the sequence of iterations, but its implementation is automatically subject to this convergence condition.

After the SCF problem for the ground state has been solved, the automatic calculation of π-electron excited states by configuration interaction is straightforward.

A typical calculation for aniline required eight iterations and a computing time of 35 minutes to give a bond order matrix self-consistent to the fourth significant figure. The computing times compare favorably with the times reported by Amos (34) for some hydrocarbons, using the method of steepest descents with a Mercury computer, whose basic multiplication speed is about 30 times that of the I.B.M. 1620.

THE STRUCTURE AND STEREOCHEMISTRY OF ATISINE[1]

D. DVORNIK[2] AND O. E. EDWARDS
Division of Pure Chemistry, National Research Council, Ottawa, Canada

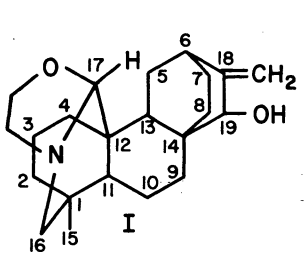
Received August 9, 1963

ABSTRACT

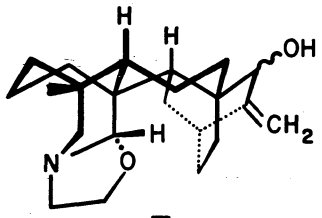
A stereospecific hydration of the exocyclic methylene group of a derivative of the alkaloid atisine has been observed. The product was used to degrade the alkaloid to a tetracyclic phenol. This enabled rigorous proof of the structure and relative and absolute stereochemistry of atisine and related alkaloids. A detailed explanation of the abnormal basic strength and the isomerization of atisine is given. Long-range influence of polar groups on the basic strength of derivatives of the alkaloid is reported.

When the investigations described herein were undertaken a structure (I) had been suggested by Wiesner and co-workers for the aconite alkaloid atisine (1) on the basis of the dehydrogenation and oxidation evidence of Jacobs and colleagues (2) and analogy to the structures assigned to the very similar Garrya alkaloids (1,3). Further evidence was later produced in support of this structure (4–7) but rigorous proof of the skeleton and location of the functional groups was lacking and the stereochemistry was unknown.

We now amplify our preliminary report (8) on work which led to proof that structure I is correct and that the stereochemistry of atisine is correctly represented by II (9, 10, 11).[3]



I



II

The initial object of this investigation was to prove by systematic degradation the environment of the allyl alcohol system in atisine. The starting material chosen was the very useful azomethine alcohol III prepared from atisine as described earlier (6).[4] It was found that in 10% aqueous hydrochloric acid III was converted to a mixture of two azomethine ketones, IV and the product of stereospecific hydration of the terminal

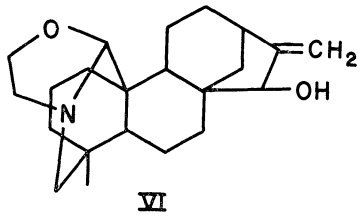
[3]*The numbering system is based on that suggested for pimarane by Klyne (6).*
[4]*This azomethine alcohol was also obtained as an oxidation product of atisine by Pelletier and Jacobs (7).*

methylene, the azomethine diol V. The isomerization of the allyl alcohol system to a methyl ketone under the influence of acid was observed by Jacobs and Huebner (12). Later Djerassi and co-workers (13) reported a similar transformation of the allyl alcohol system in garryfoline (VI) and Dreiding and Hartman showed the generality of the reaction [5] using simple models (14).

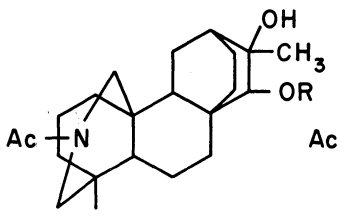


VI

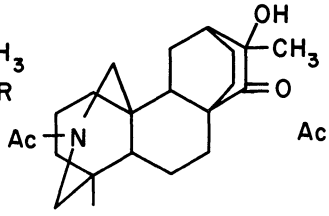
The higher melting azomethine ketone IV had been isolated from the products of thermal decomposition of atisine in the presence of nickel on alumina (12) and of selenium (15). Pyrolysis of atisine hydrochloride (5*a*) gave a mixture of the two azomethine ketones which had been obtained from the action of acid on III. The formation of comparable amounts of the two ketones reflects a high degree of symmetry about the allyl alcohol system consonant with its presence on a bicyclo[2,2,2]octane.[6]

The hydration to the diol is a new reaction for this type of allyl alcohol. The maximum conversion to this compound was 54%. This could only be realized by successive separation of the diol from the mixture of methyl ketones and unrearranged allyl alcohol and recycling of the latter. If this was not done the diol was slowly converted to methyl ketones, with consequent reduction of the final yield.

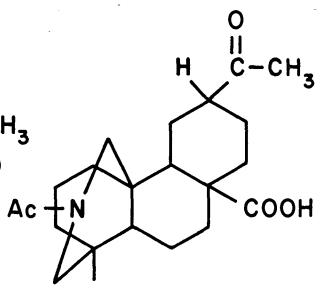
The next step in the degradation sequence was reduction of the azomethine double bond in diol V. This was accomplished with sodium borohydride, or preferably, by catalytic hydrogenation. The resulting secondary aminodiol was acetylated and the diacetate selectively hydrolyzed to the *N*-acetyl diol VII (R = H). Sodium dichromate in acetic acid rapidly oxidized VII (R = H) to a mixture of the ketol VIII and the keto acid IX.



VII



VIII



IX

Cleavage of VIII with lead tetraacetate also gave IX. The best method of preparation of IX, however, was by oxidation of VIII with the Kiliani reagent (16). This reaction probably proceeds by the illustrated mechanism.

[5]*It has been reported, without experimental details, that veatchine does not isomerize under comparable conditions and an explanation based on intermediacy of a non-classical ion in the garryfoline case advanced to account for this (3). It is very unlikely that such ions are important in the other cases of the rearrangement, since the charge can be delocalized by the vicinal hydroxyl; hence this warrants further investigation.*

[6]*The lower degree of symmetry of the bicyclo[3,2,1]octane system of the Garrya alkaloids (e.g. VI) is manifested in the formation of only one isomer in the parallel reaction (13).*

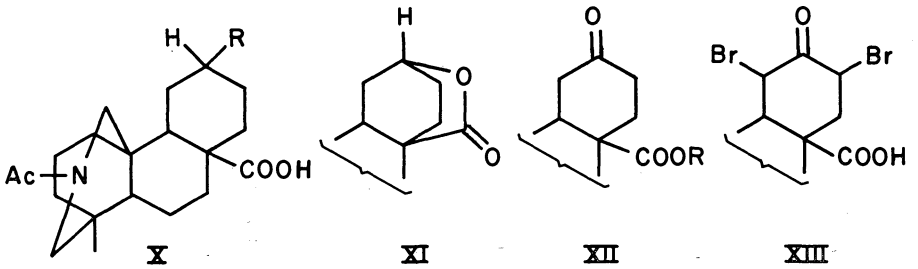
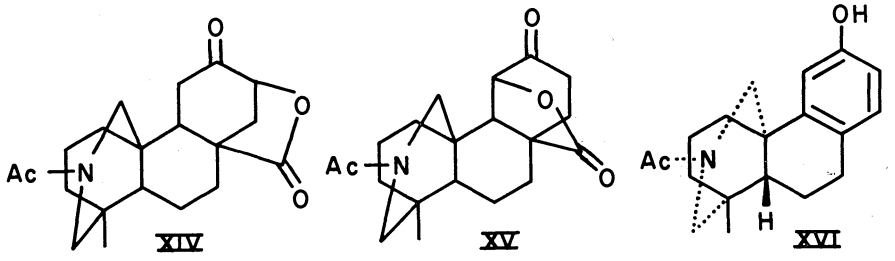
Trifluoroperacetic acid (17) oxidized IX to the acetoxy acid (X,R = $OCOCH_3$), which was then hydrolyzed to the hydroxy acid (X,R = OH). In the presence of traces of mineral acid the latter very readily lactonized to XI. The hydroxy acid was rapidly oxidized by sodium dichromate in acetic acid to the keto acid XII (R = H).



With two moles of bromine in dry acetic acid containing hydrogen bromide, XII (R = H) was converted to a dibromoketo acid. After 42 hours' contact with the hydrogen bromide we expected by analogy with steroidal ketones (18) that this would be predominantly XIII. However, no crystalline dibromo derivative was obtained from XII or its methyl ester. When the dibromoketo acid was treated with collidine at reflux temperature it was converted into a mixture of products. These were separated into acidic, phenolic, and neutral components. One neutral and one phenolic product crystallized.

The neutral substance proved to be a γ-lactone ketone (ν_{max} 1639, 1734, and 1796 cm^{-1}). The frequency of the ketone carbonyl is unusually high for a cyclohexanone with axial electronegative substituent on the α-carbon (19). However, we formulate this on grounds of its analysis and origin as XIV or XV. The bromoketone mixture must have contained



some monobromoketone, the bromine of which was displaced by the carboxylate anion to give the lactone. The lactone size proves a 1,4 relation between the carbon carrying the carboxyl and the carbonyl carbon, a fact consistent with, but not proving, ring *C* in atisine to be six-membered.

The phenol XVI, formed in around 8% yield had an ultraviolet spectrum with λ_{max} 282 mμ (log ϵ 2100), which shifted to λ_{max} 300 mμ in alkali. Its infrared absorption spectrum had a band at 828 cm^{-1} (nujol mull), a position characteristic of 3,4-disubstituted phenols

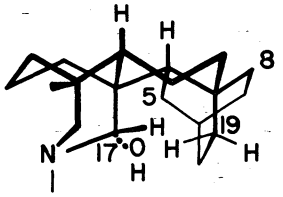
(20). Hence, barring the unlikely event of skeletal rearrangement during the dehydrobromination step, this proves ring *C* to be six-membered and, coupled with the evidence from the γ-lactone formation, establishes the presence of a bicyclo[2,2,2]octane system in atisine.

The location of the exocyclic methylene group on the bicyclooctane follows from the formation of the acetate of a secondary alcohol (X,R = $OCOH_3$) in the Baeyer–Villiger oxidation.[7] The chemistry of the closely related *Delphinium* alkaloid ajaconine (10) and the transformations of the heterocyclic ring of atisine (11) supported the rest of the skeletal assignment shown in I. Proof of the structure was completed by synthesis of the enantiomer of *N*-acetylphenol XVI from podocarpic acid (9). Independent proof of the structure comes from the synthesis of DL-kaurene (22) since the *Garrya* alkaloids have been related to L-kaurene (23) and to atisine (24).

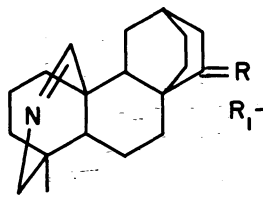
The stereochemistry of atisine as designated by II is assigned on the basis of the following evidence. The *trans A*:*B* fusion is proved by the chemistry of ajaconine (10), which had been related to atisine, and by the synthesis of the mirror image of phenol XVI from podocarpic acid. An anti coupling of rings *A* and *C* is demanded by the chemistry of ajaconine (10,25) and in addition provides a satisfying explanation of the high basic strength of atisine and its isomerization by base into isoatisine (see below).

With the ring fusion established our earlier tentative conclusion (8) about which branch of the bicyclooctane system carried the allyl alcohol system was made rigorous. The argument follows.

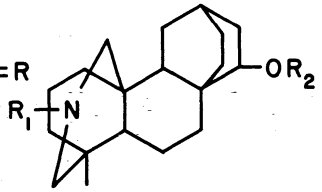
The hydroxyl must be on C-8 or C-19. Inspection of Courtauld molecular models of the atisine skeleton (see XVII) showed that a hydrogen on C-19 oriented toward the hetero ring is in strong non-bonded interaction with one hydrogen on C-17. Clearly if the atisine



XVII



XVIII



XIX

hydroxyl were on C-19 it would have to be oriented away from the hetero ring since the 19-epimeric alcohol, if it were capable of existence, would be extremely hindered. To test this point the azomethine ketone XVIII (R = O) (6) was reduced with sodium borohydride. Comparable amounts of two epimeric secondary amino-alcohols XIX (R_1= R_2=H) were produced.[8] Both could be readily acetylated to the *O*,*N*-diacetates, and the ester function in both diacetates was easily hydrolyzed. This result was consistent only with the oxygen function of the alkaloid being on C-8.

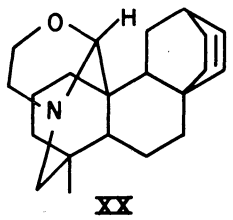
Another piece of evidence which led us to the same conclusion (8) came from the oxazolidine XX (6), with a double bond in the branch of the bicyclooctane system which originally carried the allyl alcohol system.[9] The repulsive interaction of the C-17 and C-19

[7]*Subsequent work by Pelletier (21) in which 6-isopropyl-1-methylphenanthrene was obtained by dehydrogenation of an atisine derivative is consistent with this assignment, although the isopropyl group could conceivably have arisen by rearrangement of a n-propyl group.*

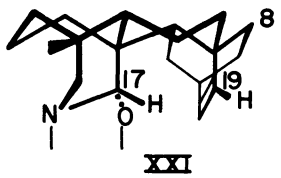
[8]*One of these proved identical with the amino alcohol obtained by borohydride reduction of the C_{19}-azomethine alcohol described earlier (6). Since almost exclusively this one epimer was formed in the degradative sequence from atisine, its hydroxyl must have the same configuration as was originally present in the alkaloid.*

[9]*The double bond arose from Wolff–Kishner reduction of an α-acetoxy ketone, derived by acetylation and osmium tetroxide – periodate oxidation of the allyl alcohol system of III (6).*

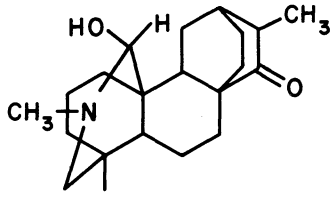
hydrogens discussed below (see XVII) is a large factor in determining the high basic strength of the oxazolidines and carbinolamines with the oxygen on C-17. Had the double bond in XX been between C-18 and C-19, this interaction would have been absent (see XXI) and the base would have been weaker than atisine and the corresponding carbinolamines. Actually XX has the same extremely high basic strength as its saturated



XX



XXI



XXII

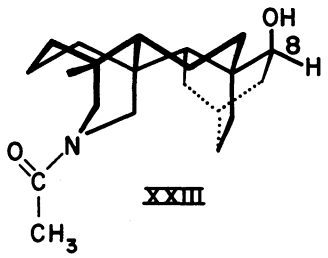
analogue; hence the double bond is in the branch *trans* to the hetero ring.

A similar argument can be used relative to the keto carbinolamine XXII derived from the methiodide of azomethine ketone IV. This is an extremely strong base. Had the carbonyl been on C-19, the 17–19 hydrogen interaction would have been absent, and the base would have been much weaker.

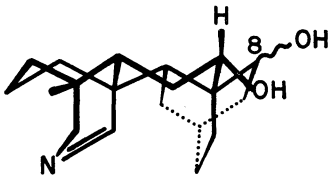
Wiesner and Edwards (3) used pK_a evidence to assign the allyl alcohol function to the *trans* branch of the bicyclooctane system of the *Garrya* alkaloids. Subsequently Pelletier produced similar evidence for atisine derivatives (21).

The absolute stereochemistry designated by II was first suggested on the basis of comparison of the molecular rotation of phenol XVI with that of similar phenolic diterpenes (8, 10). Further molecular rotational and rotatory dispersion information on ajaconine derivatives substantiated this conclusion (10) as did rotatory dispersion studies of the *Garrya* alkaloids and phyllocladene group of diterpenes (23). Rigorous proof of the antipodal character relative to the common resin acids was finally provided by the mirror image relation of phenol XVI and the molecule of this structure synthesized from podocarpic acid (9).

The structure of atisine is thus defined in every respect but the configuration of the 8-hydroxyl. Solo and Pelletier (26) and Whalley (27) advanced the argument that the hydroxyl had the configuration shown in XXIII since this compound was less strongly adsorbed on alumina than its 8-epimer. They attribute this to the possibility of simultaneous *cis* adsorption of the hydroxyl and acetamido group in the case of the epimer. This is tenuous since the nature of the adsorption process is not clearly defined.[10] Our evidence bearing on this point which might lead to the same conclusion is the fact that the diol



XXIII



XXIV

[10]*See for example the conclusions of Pines regarding adsorption in alumina pores (28). It was found necessary to postulate simultaneous trans catalytic action of the alumina to account for some eliminations.*

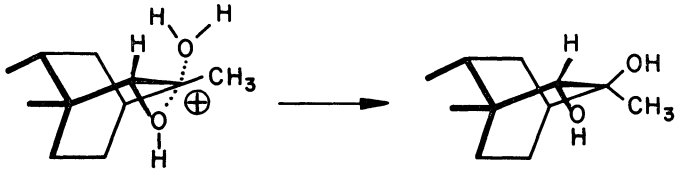
XXIV derived from ajaconine failed to give *p*-nitrobenzylidene derivative (29).[11] However, a comparative study of the 8-epimers in this reaction is needed before a firm conclusion can be reached.[12]

A number of interesting chemical points were uncovered in the course of this work.

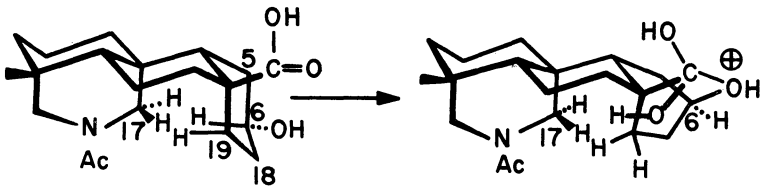
(*a*) The hydration of the allyl alcohol system of III is stereospecific despite the high symmetry of the bicyclooctane system. Strong evidence for the *trans* relation of the two hydroxyl groups in the resulting diol is provided by the very low rate of lead tetraacetate cleavage of VII[13] ($k_2 = 3.3\times10^{-2}$ l. mole^{-1} sec^{-1}) and by its failure to give an isopropylidene



XXV

derivative. This stereochemistry could result from hydroxyl participation shielding one side of the carbonium ion formed by protonation of the double bond (as in XXV) or, in the extreme, formation of the epoxide as an intermediate in the reaction. The acetate of III gave very little if any diol when treated at room temperature with 7.5% sulphuric acid in 60% acetic acid. This is probably the result of proton capture by the nearby carbonyl instead of by the less basic double bond.

(*b*) The lactonization of hydroxy acid X(R = OH) is much more facile than that of simple *cis* 4-hydroxycyclohexane carboxylic acids (32). Much lactone was formed when the acid was liberated from its sodium salt, extracted into methylene chloride, and recovered by distillation of the solvent. It appears possible that traces of mineral acid carried over from the extraction catalyzed the reaction since the amount of lactone formed varied in apparently identical runs. The unique factors responsible for the unusual reactivity are the relief of the carboxyl vs. 5βH and 18βH interactions and the 6αH:17H interactions in going from chair to boat conformation of ring *C* (XXVI → XXVII) as the transition state for lactone formation develops.[14]



XXVI XXVII

(*c*) A phenomenon somewhat related to that described in (*b*) is the remarkable ease of alkaline hydrolysis of the bisnorketo ester XII (R = CH_3). The ester hydrolyzes as readily as that of a carboxyl group on a primary or secondary carbon. Carbomethoxy

[11] *Unpublished observations by Dr. D. Dvornik.*

[12] *Photolysis of the nitrite esters of the epimeric alcohols XIX (*R_1 = Ac, R_2 = H*) failed to give the oximino alcohols, which it was hoped would distinguish between the hydroxyl configurations. We warmly thank Dr. K. K. Purushothaman for these experiments.*

[13] *The angle between cis hydroxyls on a bicyclo[2,2,2]octane system is less than 10° (30). Even ditertiary glycols with similar geometry have values of* k_2 *around* 3×10^5 *l. mole*$^{-1}$ *sec*$^{-1}$ *(31).*

[14] *This is offset in part by development of a* 5αH:17H *interaction.*

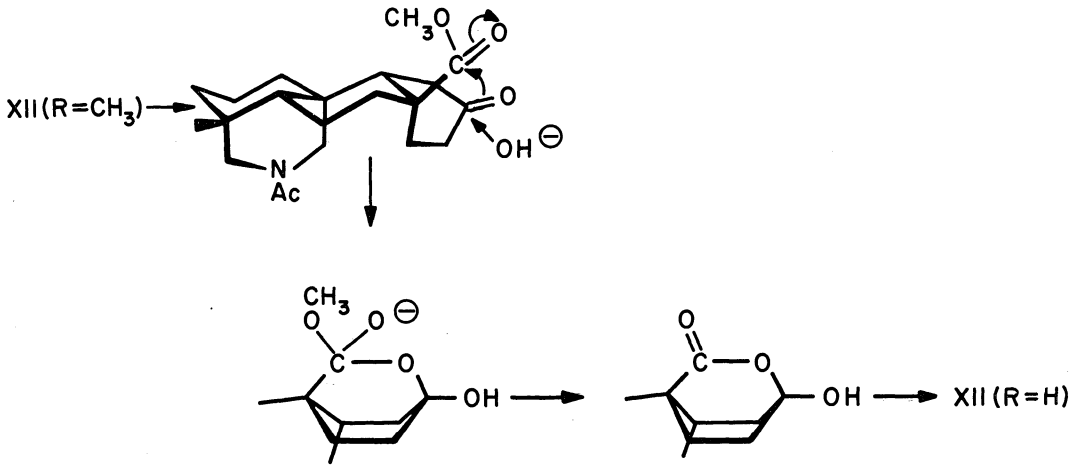
groups on fully substituted carbon require prolonged heating with alkali under sealed tube conditions for hydrolysis (33). The boat form of ring *C* in XII is favored by absence of the 1,4 bowsprit interaction and by the absence of the 1,3-diaxial interactions of the carbomethoxyl group and the 5β and 18β hydrogens present in the chair form. Hence this conformation is present in sufficient concentration that the ketone carbonyl can markedly accelerate the hydrolysis as shown. A similar accelerated hydrolysis of the ester of a



triterpene keto-acid was observed by Djerassi and Lipmann (34) and of keto and aldehydo aromatic esters by Bender and Silver (35) and Newman and Hishida (36).

(*d*) The basic strength of various azomethines prepared in this and related work varied with the substituents present on the bicyclooctane system. The pertinent data are summarized in Table I.

TABLE I

Base	pK_a'*	pK_a†
XVIII R = H_2	5.2	–
XVIII R = H,OH	5.3	+0.1
XVIII R = O	4.6	−0.6
III	5.0	−0.2
III acetate	4.8	−0.4
IV	4.6	−0.6

*In 95% ethanol.
†Difference from the pK_a' of XVIII (R = H_2).

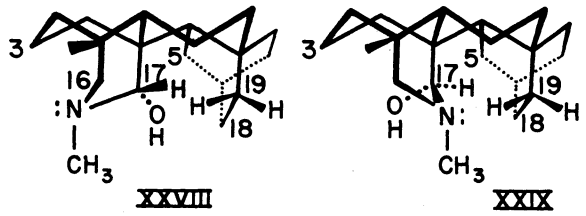
It seems very unlikely that the C-8 substituent would significantly affect the steric environment of the nitrogen. We hence conclude that the pK_a differences are the result of electrical effects operating over the long distance (ca. 5.6 Å) between the nitrogen and C-8. The largest effect was observed in the 8-ketones. This may be ascribed to the orientation of the carbonyl dipole with the positive end facing the nitrogen, thus opposing the charging of the latter by protonation. Comparable effects on basic strength at shorter range have been observed for other diterpenoid alkaloids (37) and Roberts and Moreland (38) have reported a trans-spatial effect of polar groups on the strength of carboxylic acids.

The general conception that steric hindrance of C-17 accounts for the extremely high basic strength of atisine and for its base-catalyzed isomerization into isoatisine was enunciated some time ago (3, 39). However, the detailed explanation of these phenomena

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

has been the subject of some controversy (6, 10, 40). We now present a full account of our analysis of the steric factors involved.

There are only two conformations of ring *E* with an oxygen substituent on C-17 which need be considered (see also refs. 27, 40). These are illustrated in XXVIII and XXIX for

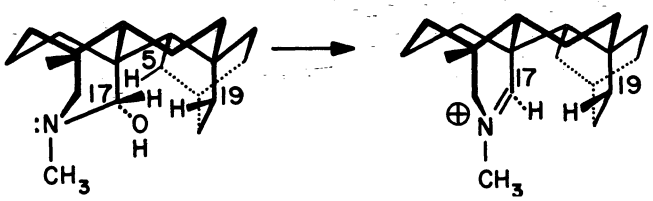


XXVIII XXIX

the *N*-methyl carbinolamines, which have the same properties as atisine itself. Using space-filling Courtauld molecular models the relative stability of these conformational isomers could be deduced. Since the interactions of the unshared pair of electrons on the nitrogen with the nearest hydrogen should be nearly the same for the two conformations, the serious repulsive hydrogen interactions determining their relative stability are:

for XXVIII (*a*) 17-oxygen:5αH,
(*b*) 17H:19H,
for XXIX (*a*) 17-oxygen:3αH,
(*b*) 16H:3αH,
(*c*) 17H:18H,
(*d*) 17H:19H,
(*e*) 17H:5αH.

We conclude that XXVIII is the stable conformational isomer.[15] In view of the above destabilizing interactions, the cause of the high basic strength of atisine and the analogous *N*-methyl carbinolamines is the relief of the 17:19 hydrogen interactions and the 17-oxygen:5αH interaction (10, 41) in going from the bases to the immonium salt form.



The pK_a of atisine is greater than 12 (5*a*, 39). Even if it is as high as 12.5 the concentration of the ionic form in a 1 *M* solution in methanol containing 1 *N* NaOH is negligible (ca. $3\times10^{-2}M$). Isoatisine (pK_a' 10) will be even less ionized, hence in considering the equilibrium of the two bases only the oxazolidine forms need be considered.[16] Under the above conditions the equilibrium lies nearly 90% in the isoatisine side (42); hence ΔF (isomeriz.) = -1.3 kcal/mole. The major difference between the two isomers is the replacement of a 17-oxygen:5α-hydrogen repulsive interaction by a 17H:5αH repulsion. The difference between the interactions of two 1,3 diaxial hydrogens and that of 1,3 diaxial hydrogen and hydroxyl is 0.4 to 0.5 kcal/mole (43, 44). But in the atisine series the 17-hydrogen and 5α-hydrogen are forced closer than the sum of the van der Waals radii and this compression is even more exaggerated for the 17-oxygenated case. Since the

[15]*Solo and Pelletier concluded that the two conformers have nearly equal stability (40).*
[16]*This is contrary to the argument of Solo and Pelletier (40).*

For personal use only.

interacting atoms are thus in a region where the repulsion vs. distance curve rises steeply, the energy difference between the H:H and H:OH interactions will be magnified and may easily be as large at the 1.3 kcal/mole required to account for the position of the atisine–isoatisine equilibrium.[17]

EXPERIMENTAL

Rotations were of absolute ethanol solutions. Infrared spectra are of nujol mulls unless otherwise specified. Ultraviolet spectra are of solutions in 95% ethanol. The pK_a' values cited are the pH at half titration of solutions in the solvent specified using a glass electrode – calomel electrode pair. Alumina for chromatography was Woelm brand (neutral), with activity expressed on the Brockman scale.

Action of Acid on Azomethine Alcohol III

A solution of 1.44 g of the unsaturated azomethine alcohol III (6) in 20 ml of 10% hydrochloric acid was left at room temperature for 18½ hours. The solution was extracted with chloroform, and the chloroform back-washed with 3 *N* sulphuric acid. The combined aqueous layers were made strongly alkaline and extracted with chloroform. The recovered base crystallized from benzene giving 555 mg, m.p. 230–250°. The benzene-soluble material was treated again with 10% hydrochloric acid for 19 hours giving 216 mg of the benzene-insoluble crystals, m.p. 230–250°. A further recycling of the benzene-soluble fraction yielded 63 mg more crystals. The total yield of crude diol was 834 mg.

The benzene-soluble product was adsorbed on a 15-fold weight of alumina activity 1. Benzene and 1:1 benzene–ether eluted azomethine ketones, which crystallized from pentane.

Azomethine Diol V

The crude diol was recrystallized by solution in methanol, addition of benzene, then removal of the methanol by boiling until crystallization commenced. It had m.p. 264°, $[\alpha]_D$ +3° (*c*, 0.89), and ν_{max} ($CHCl_3$) 3600, 1651 cm^{-1}. Found: C, 75.48; H, 9.66. Calc. for $C_{20}H_{31}NO_2$: C, 75.67; H, 9.84. A solution of the azomethine diol in 10% hydrochloric acid was left at room temperature for three days. Thirty percent was converted to a mixture of methyl ketones (see below) with ν_{max} ($CHCl_3$) 1710 and 1650 cm^{-1}.

Methyl Ketones IV

The least soluble methyl ketone crystallized as prisms from a pentane solution of the readily eluted fractions. After repeated recrystallization from hexane this melted at 143.5–144.5, $[\alpha]_D$ −7° (*c*, 1.76) and had ν_{max} 1708 and 1651 cm^{-1}. Found: C, 80.13; H, 9.69. Calc. for $C_{20}H_{29}ON$: C, 80.22, H, 9.76. The ketone did not depress the melting point of the azomethine ketone, m.p. 141°, from pyrolysis of atisine hydrochloride (5*a*). If formed a methiodide when treated at room temperature with methyl iodide in ether. This crystallized as rectangular plates from methanol which became brown and amorphous at 340°. This has ν_{max} 1715 and 1677 cm^{-1}. Found: C, 57.20; H, 7.28. Calc. for $C_{21}H_{32}ONI$: C, 57.15; H, 7.31.

The more soluble methyl ketone crystallized from pentane. After several recrystallizations it melted at 93–99°, $[\alpha]_D^{26}$ −13° (*c*, 1.53), and had ν_{max} 1716 and 1650 cm^{-1}. Found: C, 80.17; H, 9.67. Calc. for $C_{20}H_{29}NO$: C, 80.22; H, 9.76. This was a mixture since it gave a methiodide separable by recrystallization from methanol–acetone into rectangular plates which became amorphous around 325° (crude methiodide of the 145° ketone) and needles m.p. 285–295°. The methiodide of the low melting point ketone from pyrolysis of atisine hydrochloride likewise gave less soluble plates (no true melting point, becoming amorphous at 330°) and needles, m.p. 290°. The latter had ν_{max} 1710 cm^{-1} and 1685 cm^{-1}.

O,N-Diacetate VII (R = Ac)

The azomethine double bond of the diol V could be reduced slowly by sodium borohydride in aqueous methanol. The product was hard to extract from water, hence the following catalytic reduction was preferable.

Azomethine diol V (880 mg) in 12 ml of acetic acid was reduced in the presence of platinum from 115 mg of Adams' platinum oxide. The hydrogen uptake in 4 hours was 61.6 ml at N.T.P. (1 molar equivalent). The catalyst was removed by filtration and the bulk of the acetic acid removed under reduced pressure. Fifteen milliliters of 1:1 mixture of acetic anhydride and pyridine was then added. After 7 hours at room temperature the reagents were removed under reduced pressure. Methanol was added to react with residual anhydride. After 10 minutes this was removed under reduced pressure, the product dissolved in methylene chloride, then the solution extracted successively with dilute sulphuric acid and dilute sodium carbonate solution. The 1.1 g of froth recovered from the methylene chloride crystallized readily from methanol. The first crop (1.0 g) melted at 206–215°. After two recrystallization from acetone this melted at 212–214° and had $[\alpha]_D$ 0° (*c*, 1.17), ν_{max} 3280, 1735, and 1620 cm^{-1}. Found: C, 71.36; H, 9.21. Calc. for $C_{24}H_{37}O_4N$: C, 71.43; H, 9.24.

[17]*Solo and Pelletier overlooked the extra compression (40). Furthermore, they argued that it is the oxazolidine ring in atisine which, by restricting rotation of* C-17 *increases the total steric hindrance relative to isoatisine. They consider this to be the major source of the energy difference between the two isomers. This explanation is invalidated by the fact that the N-methylcarbinolamine XXVIII (11) and the methiodide of III (see experimental part) are converted to the isomeric carbinolamines under the conditions of the atisine rearrangement.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

N-Acetyl Diol VII (R = H)

A solution of 966 mg of *O,N*-diacetate VII (R = Ac) and 600 mg of potassium hydroxide in 10 ml of methanol and 3 ml of water was left at room temperature for 5 hours. The solvent was removed under reduced pressure, the residue taken up in water, and the product extracted into chloroform. The froth remaining after evaporation of the chloroform was dissolved in acetone and ether added, giving 846 mg of crystals. These showed three melting points depending on crystallization conditions; 161–164°, 176–179.5°, and 205°. Sometimes the transition from a lower melting to a higher melting form took place after partial melting. $[\alpha]_D$ −17° (*c*, 1.38), ν_{max} ($CHCl_3$) 3580, 3380, and 1623 cm^{-1}. Found: C, 73.06; H, 9.74. Calc. for $C_{22}H_{35}O_3N$: C, 73.09; H, 9.76.

A solution of 51.5 mg of the *N*-acetyl diol in 10 ml of acetic acid containing 0.061 mole/liter of lead tetraacetate was titrated at intervals. One molar equivalent of reagent was consumed in approximately 9 hours but the uptake continued. After 68 hours 2.74 moles had been used. The bimolecular rate constant for the uptake of the first mole was 3.3×10^{-2} l. $mole^{-1}$ sec^{-1}.

In an attempt to form an isopropylidene derivative 46 mg of the *N*-acetyl diol was dissolved in 10 ml of dry acetone containing 81 mg of *p*-toluenesulphonic acid monohydrate. After 17 hours at room temperature 3 ml of 5% sodium carbonate solution was added, then the solution taken to small volume under reduced pressure. Chloroform extracted 56 mg of material which crystallized from acetone–ether to give 28 mg of pure and 10 mg of cruder starting material.

N-Acetyl Ketol VIII

To a solution of 106 mg of *N*-acetyl diol VII (R = H) in 2 ml of acetic acid was added quickly a solution of 61 mg of sodium dichromate dihydrate in 2 ml of acetic acid. After 1 hour at room temperature the excess dichromate was reduced with sodium hydrogen sulphite and the acetic acid removed under reduced pressure. The residue was taken up in dilute sulphuric acid, the organic matter extracted into methylene chloride, then this solution was washed twice with dilute sodium carbonate solution. The methylene chloride layers yielded 89 mg of neutral material and the carbonate solutions after acidification and extraction gave 16 mg of acid. The neutral fraction crystallized from acetone. After three recrystallizations from this solvent it melted at 226° and had $[\alpha]_D$ −30° (*c*, 1.24) and ν_{max} 3360, 1729, and 1626 cm^{-1}. Found: C, 73.63; H, 9.02. Calc. for $C_{22}H_{33}O_3N$: C, 73.50; H, 9.25.

N-Acetyl Keto Acid IX

(*a*) 2 ml of Kiliani chromic acid mixture (16) was added to a cold solution of 180 mg of *N*-acetyldiol VII (R = H) in 1 ml of acetic acid. A gum precipitated, which slowly dissolved after addition of 1 ml of acetic acid and stirring. After a total reaction time of 15 minutes sodium hydrogen sulphite solution was added until the solution was green. After further dilution with water, the mixture was thoroughly extracted with chloroform. The chloroform extracts were extracted twice with sodium carbonate solution, dried, and evaporated, yielding 27 mg of *N*-acetyl ketol VIII. The sodium carbonate solutions yielded 150 mg of acid. The latter crystallized from aqueous acetone giving 120 mg of hexagonal plates, m.p. 207–218°. After recrystallization from aqueous acetone and drying at 100° it melted at 218° and had $[\alpha]_D$ +19° (*c*, 1.32), ν_{max} 1705, 1693 cm^{-1}. Found: C, 69.99; H, 8.70. Calc. for $C_{22}H_{33}O_4N$: C, 70.37; H, 8.86.

(*b*) A solution of 15 mg of the *N*-acetylketol VIII in 10 ml of 0.054 *M* lead tetraacetate in 90% acetic acid – 10% water consumed 1 molar equivalent of the reagent after approximately 15 hours at room temperature. The resulting keto acid crystallized from acetone as six-sided plates, m.p. 214°. This did not depress the melting point of the keto acid described in (*a*).

Acetoxy Acid X (R = OAc)

To a solution of 735 mg of the methylketo acid IX in 12 ml of 1:1 chloroform – methylene chloride mixture (dry alcohol-free) was added 700 mg of anhydrous disodium hydrogen phosphate followed by 2 ml of a trifluoroperacetic acid solution (prepared from 0.2 ml of 98% hydrogen peroxide, 0.8 ml of trifluoroacetic anhydride, and 2 ml of methylene chloride). The suspension was refluxed for 15 minutes. After cooling, a solution of sodium hydrogen sulphite was added and the mixture vigorously shaken. The layers were separated, and the aqueous solution extracted three times with chloroform. The product crystallized readily from acetone, giving 673 mg of acid, m.p. 309° (decomp.). The material in the mother liquor was treated again with trifluoroperacetic acid as above, and a further 42 mg of crystalline acid obtained, m.p. 302°. Recrystallization from methanol did not raise the melting point above 309°. It had ν_{max} 1725 cm^{-1} (OAc). 1711 cm^{-1} (COOH), 1605 cm^{-1} (amide); $[\alpha]_D$ −21° (*c*, 0.68). Found: C, 67.37; H, 8.39. Calc. for $C_{22}H_{33}O_5N$: C, 67.49; H, 8.50.

Hydroxy Acid X (R = OH)

Acetoxy acid X (R = OAc) (900 mg) in solution in 20 cc of 50% aqueous methanol containing 800 mg of potassium hydroxide was left for 4½ hours at room temperature. The bulk of the solvent was removed under reduced pressure, the residue diluted with water and acidified. The hydroxy acid was extracted into chloroform, and this solution washed with water. The product recovered from the chloroform crystallized readily from acetone, giving 737 mg, m.p. 195°. The mother liquor contained mainly lactone (see below). The hydroxy acid, after recrystallization from methanol had m.p. 201–203°, $[\alpha]_D$ −5° (*c*, 1.4); ν_{max} 3160, 1709,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

1619 cm^{-1}. Found: C, 68.62; H, 8.83. Calc. for $C_{20}H_{31}O_4N$: C, 68.74; H, 8.94. In apparently identical runs the proportion of lactone produced was as high as 60%. A solution of 20 mg of the hydroxy acid in 2 ml of methanol containing 0.1 ml of 6 *N* sulphuric acid was maintained at 50° for ½ hour. The product gave 18 mg of lactone, m.p. 167°.

δ-Lactone XI

The lactone formed from the hydroxy acid X (R = OH) as described above melted at 167° after recrystallization from acetone–ether. It had $[\alpha]_D$ −53° (*c*, 1.6); ν_{max} 1740 cm^{-1} (δ-lactone), 1640 cm^{-1} (amide). Found: C, 72.76; H, 8.75. Calc. for $C_{20}H_{29}O_3N$: C, 72.47; H, 8.82. The lactone (56 mg) after hydrolysis at room temperature for 2 hours in an 8% solution of potassium hydroxide in methanol gave 35 mg of pure hydroxy acid X (R = OH).

Bisnorketo Acid XII

A solution of 155 mg of bisnorhydroxy acid X (R = OH) in 4 ml of acetic acid was prepared. To this was added 0.5 ml-portions of a solution of 61 mg of chromium trioxide in 5 ml of acetic acid and 1 ml of water. As each portion was reduced the next was added. After addition of 4 ml of the chromic acid solution (in 3 hours) excess oxidant persisted for ¾ hour. After addition of sodium hydrogen sulphite to reduce the excess reagent, the solution was taken to dryness under reduced pressure. The residue was dissolved in methanol, 1 drop of 6 *N* sulphuric acid added, then left at 40° for 15 minutes. The methanol was removed under reduced pressure, then the product separated into 27 mg of neutral and 125 mg of acidic materials. The acid fraction crystallized from acetone giving 101 mg of keto acid, m.p. 245–255°. Recrystallization failed to raise the melting point, hence the acid was reoxidized with chromium trioxide in acetic acid. The acid then softened at 255° and melted at 266°. Further recrystallization from methanol–acetone mixtures raised the melting point to 268° with $[\alpha]_D$ −35° (*c*, 1.83) and λ_{max} 280 mμ (ε 21), λ_{min} 260 mμ (ε 16). It had ν_{max} 1711 and 1602 cm^{-1}.

The methyl ester of the keto acid prepared using diazomethane was not obtained crystalline. It had ν_{max} ($CHCl_3$) 1720 and 1632 cm^{-1}.

Dibromoketo Acid XII and its Dehydrobromination

To 67 mg of bisnorketo acid XII in 1 ml of dry acetic acid was added 0.05 ml of acetic acid containing 3.8 mg of hydrogen bromide. Over a period of 20 minutes 0.6 ml of a solution of bromine in acetic acid (64 mg Br_2) was added with stirring. A small amount of oil separated. After addition of a further 0.05 ml of the hydrogen bromide solution the reaction mixture was left in the dark at room temperature for 42 hours. The solvent was then removed under reduced pressure near room temperature, the residue taken up in chloroform, and this solution washed thoroughly with water. The chloroform solution on evaporation left 109 mg of froth which would not crystallize.

The bromo acid was dissolved in 3.5 ml of dry collidine and the solution refluxed under nitrogen for 1 hour. The bulk of the collidine was removed under reduced pressure, then the residue dissolved in chloroform. The solution was extracted twice with 2 *N* sulphuric acid, then twice with dilute sodium hydroxide in a nitrogen atmosphere. The chloroform gave 60 mg of neutral product (trace of collidine). The sodium hydroxide solution was adjusted to pH 8 and extracted with chloroform, yielding 7.5 mg of phenol. The aqueous layer was then acidified and extracted, giving a few milligrams of acid.

Keto-γ-lactone XIV or XV

The neutral fraction crystallized readily from concentrated acetone solution giving 17 mg, m.p. 270°. After two recrystallizations from methanol–acetone this separated as hexagonal plates with m.p. 275°, $[\alpha]_D^{24}$ −25° (*c*, 0.65). It had only end absorption in the ultraviolet and ν_{max} 1796, 1734, and 1639 cm^{-1}. Found: C, 69.62; H, 7.75. Calc. for $C_{20}H_{27}NO_4$: C, 69.54; H, 7.88.

Phenol XVI

The phenolic fraction crystallized from acetone, giving 4.8 mg, m.p. 272–275°. This was combined with material from other runs and recrystallized twice giving tiny prisms with m.p. 277–279°, $[\alpha]_D^{24}$ −105±9° (*c*, 0.35). It had λ_{min} 250 mμ (ε 450); λ_{max} 282 mμ (ε 2100). In alkaline ethanol the spectrum shifted to λ_{min} 270 mμ, λ_{max} 300 mμ. It had ν_{max} 828 (3,4-disubstituted phenol), 1586, and 1638 cm^{-1}. Found: C, 76.07; H, 8.25. Calc. for $C_{19}H_{25}NO_2$: C, 76.22; H, 8.42.

Methiodide of III and its Isomerization

The azomethine alcohol III (230 mg) was dissolved in 15 ml of 1:1 ether–benzene mixture. After addition of 0.8 ml of freshly distilled methyl iodide the mixture was left 2 hours at room temperature. The crystalline methiodide was collected by filtration, giving 386 mg, m.p. 250°. After one recrystallization from methanol–acetone combination it melted at 254° and had $[\alpha]_D^{26}$ −14° (*c*, 1.65), pK_a' greater than 12 (95% ethanol) and ν_{max} 3370, 1684, 1653, and 898 cm^{-1}. Found: C, 57.09; H, 7.20. Calc. for $C_{21}H_{32}INO$: C, 57.15; H, 7.31.

The methiodide (232 mg) was dissolved in 7 ml of methanol containing 400 mg of potassium hydroxide. The solution was refluxed for 3 hours, then the solvent removed under reduced pressure. The residue was dissolved in water and extracted with benzene giving 189 mg of pale yellow gum. This was converted to its iodide by careful titration with hydriodic acid in methanol. The crystalline *iso*methiodide was recrystallized

For personal use only.

twice from acetone containing a little methanol; m.p. 246° (partially liquefied when placed on the hot stage at 220°, resolidified), $[\alpha]_D^{26}$ −13° (*c*, 1.74); pK_a' 10.6 (95% ethanol), ν_{max} 3380, 1696, 1634, 895 cm^{-1}. Found: C, 56.56; H, 7.24; Calc. for $C_{21}H_{32}INO$: C, 57.15; H, 7.31.

C_{19}-Secondary Amino Alcohol (XIX, $R_1 = R_2 = H$)

To a solution of 67 mg (0.23 m*M*) of the C_{19}-azomethine alcohol XVIII (R = H, OH) (6) in 4 ml of 80% aqueous methanol 250 mg of sodium borohydride were added. After being kept for 6 hours at room temperature, the solution was evaporated to dryness under reduced pressure, water was added, and the base extracted with ether. Evaporation of the solvent gave 54 mg (80%) of the crude dihydro derivative, which crystallized spontaneously on spraying with ether. After three recrystallizations from acetone–hexane and sublimation at 160–165° at 0.5 mμ it melted at 158–161°. $[\alpha]_D^{26}$ −49±2° (*c*, 0.84), $[M]_D$ −141±6°. Found: C, 78.63; H, 10.67. Calc. for $C_{19}H_{31}NO$ (289.45): C, 78.84; H, 10.80. ν_{max} 3425, 3320, 3180 cm^{-1}.

Acetylation of the C_{19}-Secondary Amino Alcohol (XIX, $R_1 = R_2 = H$)

A solution of 59 mg (0.20 m*M*) of the C_{19}-secondary amino alcohol in 3 ml of a mixture of pyridine and acetic anhydride (1:1) was kept at 40° for 5 hours. The residue obtained on evaporation to dryness under reduced pressure was distributed between ether and 3 *N* aqueous sodium carbonate solution. The ethereal phase was washed with 6 *N* aqueous sulphuric acid and water respectively. Evaporation of the solvent gave 71 mg (93%) of the crude diacetate, which after three recrystallizations from acetone–hexane melted at 175.5–177°; $[\alpha]_D^{26}$ −55±1° (*c*, 0.80); $[M]_D$ −205±4°. Found: C, 74.10; H, 9.37. Calc. for $C_{23}H_{35}NO_3$ (373.52): C, 73.95; H, 9.45. ν_{max} (CCl_4) 1742, 1247 cm^{-1} (OAc), 1648 cm^{-1} (>N—CO).

Sodium Borohydride Reduction of the C_{19}-Azomethine Ketone XVIII (R = O)

To a solution of 88 mg (0.31 m*M*) of the C_{19} azomethine ketone in 5 ml of 80% aqueous methanol 250 mg of sodium borohydride was added, the mixture being kept at room temperature for 3½ hours. The solution was evaporated to dryness under reduced pressure, water was added, and the solution extracted with ether. Evaporation of the solvent gave 68 mg (76%) of a product which crystallized partially on spraying with ether. After three recrystallizations from aqueous acetone the 8-epi secondary amino alcohol XIX ($R_1 = R_2 = H$) (26 mg) melted at 181.5–182.5°. $[\alpha]_D^{26}$ +1.2° (*c*, 0.83), $[M]_D$ +3.5°. Found: C, 78.98; H, 10.70. Calc. for $C_{19}H_{31}NO$ (289.45): C, 78.84; H, 10.80. ν_{max} 3330, 3280 cm^{-1} (—OH and >NH).

The combined mother liquors were dissolved in a pyridine – acetic anhydride mixture (1:1) and kept at room temperature for 92 hours. The solution was evaporated to dryness under reduced pressure, and the residue distributed between ether and 3 *N* aqueous sodium carbonate solution. The ethereal phase was then washed with 6 *N* aqueous sulphuric acid and water respectively. The residue after evaporating the solvent crystallized spontaneously. After three recrystallizations from acetone–hexane the product ($[\alpha]_D^{25}$ −49±2° (*c*, 0.90); $[M]_D$ −183±7°) showed no melting point depression (174–176°) with a sample of the diacetate obtained by reduction and acetylation of XVIII (R = H, OH). In addition the infrared spectra (carbon tetrachloride solution) of both compounds were superimposable.

Acetylation of the 8-epi Alcohol (XIX, $R_1 = R_2 = H$)

A solution of 30 mg (0.11 m*M*) of the 8-epi C_{19} alcohol (XIX, $R_1 = R_2 = H$) in 3 ml of a mixture of pyridine and acetic anhydride (1:1) was kept at room temperature for 90 hours. The solution was evaporated to dryness under reduced pressure and the residue dissolved in Et_2O. The ethereal solution was shaken with 3 *N* aqueous sodium carbonate solution, 6 *N* aqueous sulphuric acid, and water respectively. Evaporation of the solvent gave 38.5 mg (97%) of a *n*-pentane-soluble colorless oil. After passage through a column of neutral aluminum oxide (1:35, activity 1) from which it was eluted with benzene, this had $[\alpha]_D^{25.5}$ −14±1° (*c*, 1.25), $[M]_D$ −52±4°; ν_{max} (CCl_4) 1737 cm^{-1}, 1249 cm^{-1} (OAc), 1648 cm^{-1} (>N—CO). Except for a missing shoulder at 1150 cm^{-1} the I.R. spectrum was superimposable on that of the normal analogue.

Hydrolysis of the 8-epi O,N-Diacetate (XIX, $R_1 = R_2 = Ac$)

25 mg (0.067 m*M*) of the 8-epi *O,N*-diacetate was refluxed for 30 minutes with 2 ml of 70% aqueous methanol containing 5% of potassium hydroxide. The methanol was partially removed *in vacuo*, water was added, and the solution extracted with methylene chloride. Removal of the solvent gave 21 mg of an oily product, which crystallized on being sprayed with ether. After two recrystallizations from acetone–hexane the product melted at 191–192.5; $[\alpha]_D^{25}$ −14.5±1° (*c*, 0.90); $[M]_D$ −48±3°. Found: C, 76.15; H, 9.95, Calc. for $C_{21}H_{33}O_2N$ (331.48): C, 76.09; H, 10.03. On reacetylation the oily product had $[\alpha]_D^{23}$ −12±1° (*c*, 1.67); $[M]_D$ −45±4°. The ΔM_D for acetylation of the 8-epi hydroxyl is hence near 0°.

Hydrolysis of the O,N-Diacetate (XIX, $R_1 = R_2 = Ac$)

By the same procedure as mentioned above, XIX ($R_1 = R_2 = Ac$) gave an oily product with $[\alpha]_D^{24}$ −37±1°; $[M]_D$ −122±3°. The ΔM_D for acetylation of the *normal* 8-hydroxyl is hence −83°.

COMPOUNDS OF THE TYPE M_5X_2: DETERMINATION OF THE SPACE GROUP OF PENTA NICKEL DIARSENIDE (Ni_5As_2) USING VAPOR-GROWN SINGLE CRYSTALS[1]

G. S. SAINI,[2] L. D. CALVERT, AND J. B. TAYLOR
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received July 30, 1963

ABSTRACT

Single crystals of Ni_5As_2 have been grown by vapor transport reactions involving the use of either bromine or iodine. Crystals and whiskers have also been grown in the absence of halogen. In neither case did the maximum dimensions of the crystals exceed 0.5 mm. Ni_5As_2 is hexagonal with space group $P6_322$: $a = 6.81$, $c = 12.48$ Å.

INTRODUCTION

There are many references in the literature to compounds having the general formula M_5X_2. This particular study has been confined to cases where M is a transition metal and X is either a pnigogen, a chalcogen, silicon, boron, carbon, or germanium. Crystallographic information is not available for all of the known compounds, e.g. Pt_5Sb_2 (1), Pd_5Te_2 (2), Pd_5Se_2 (2), and Pd_5P_2 (3) are reported to exist but the crystal symmetry is not known. In other cases, the lattice parameters and space group are known but the exact composition is not always certain. When analysis is reported the stoichiometry is found to fall within the range $M_{5.30}X_2$ to $M_{4.77}X_2$. The known compounds fall into three crystal classes but there is, at present, no necessary reason to regard the compounds in each system as isostructural. The data found in a literature survey are summarized below. All cell parameters are in Ångström units.

Tetragonal	Ti_5Sb_2 (4)	As Ti_2Sb C 38 type	$a = 4.01$; $c = 14.5$
	Ni_5Sb_2 (5)	As Ni_2Sb	$a = 5.80$; $c = 6.01$
	Cu_5As_2 (6)	Tentative indexing	$a = 7.48$; $c = 7.12$
	$Ni_{12}P_5$ (7)	$I4/m$ (C_{4h}^5)	$a = 8.646$; $c = 5.070$
Monoclinic	Pd_5B_2 (8)	$C2/c$	$a = 12.786$; $b = 4.955$; $c = 5.472$; $\beta = 97° 2'$
	Mn_5C_2 (9)	$C2/c$	$a = 5.086$; $b = 4.573$; $c = 11.66$; $\beta = 97° 45'$
Hexagonal	$Mn_{2.65}Ge$ (10)	($B8_2$?)	$a = 7.18$; $c = 13.08$
Hexagonal or trigonal	Ni_5As_2 (11)		$a = 6.815$; $c = 12.498$ (for $Ni_{4.77}As_2$)
Trigonal	Ni_5Si_2 (12, 14)		$a = 6.670$; $c = 12.267$ (in equilibrium with Ni_2Si)
Hexagonal	Ni_5P_2 (13)		$a = 13.220$; $c = 24.632$

It is interesting to note that in the case of the first two members of the tetragonal group the 5:2c ompounds have the same structure as the respective 2:1 phases. In fact Welsbach, Nowotny, and Kohl wrote Ti_5Sb_2 as Ti_2 [$Ti_{0.15}$ $Sb_{0.85}$]. Although the cell parameters for Ni_5Si_2 and Ni_5P_2 were based on single-crystal studies, no details, other than those given above, were published. The powder pattern of Ni_5Si_2 published by Osawa and Okamoto (14) is probably unreliable. The symmetry and the lattice parameters for Ni_5As_2 and

$Mn_{2.65}Ge$ were obtained by powder methods. In addition to the latter compound, the pattern of $Mn_{2.5}Ge$ was reported but was not indexed.

The present series of investigations has been directed towards an examination of structural similarities among these 5:2 compounds and this paper describes the preparation of single crystals of Ni_5As_2, derivation of a definite space group, and modification of the indexed powder pattern published earlier.

Many 5:2 compounds have incongruent melting points but Ni_5As_2 is an exception in that it melts congruently at 998° (15). Thus it would be theoretically possible to grow single crystals of Ni_5As_2 by freezing a liquid of stoichiometric composition. However, the crystals used in this study were prepared by a halide vapor transport reaction of the type reported by Brixner (16) and Nitsche, Bölsterli, and Lichtensteiger (17), which may be represented as follows:

$$Ni_5As_{2(s)} + \text{halogen}_{(g)} \rightleftharpoons Ni(\text{halide})_{(g)} + As_{(g)}.$$

There is a possibility that this method is generally applicable to the preparation of single crystals of all 5:2 compounds whereas preparation of a phase with an incongruent melting point from a liquid of carefully controlled composition by the method of zone leveling (18) is difficult in practice and requires detailed knowledge of the liquidus curve.

PREPARATIVE—EXPERIMENTAL

The nickel was supplied as sponge by Johnson Matthey and Co. and contained less than 0.8 p.p.m. total impurities as Fe, Cu, Si, and Mg. The sponge was completely reduced in hydrogen at 600° C prior to use. Arsenic was obtained from Cominco and had a purity of 99.999% as determined by spectrographic methods. This material was fractionally sublimed *in vacuo* at 450° C to remove carbon and oxide contaminants which are not recorded in the spectrographic analysis. Other chemicals employed were laboratory reagent grade. The bromine was vacuum sublimed from a source at −80° C to a receiver at −196° C before it was finally distilled into the reaction tube.

The tube furnace used was 62 cm long and 4 cm inside diameter. A center-tapped winding of "Kanthal" resistance tape was used. This was fed with two variable transformers to provide independent heating zones. No temperature control was used but the equilibrium temperature attained by the furnace on a given voltage supply was sufficiently constant for these experiments. The furnace operated horizontally and the ends were closed with tightly packed quartz wool plugs. The tubes in which the transport reactions occurred were made of clear quartz, 35 cm long, 2.0 cm diameter, with a 0.2-cm wall. Two chromel vs. alumel thermocouples were attached to the tubes to record "hot" and "cold" zone temperatures. The tubes were fitted with thin wire spiders which supported them away from the walls of the furnace. This method of support is distinctly preferable to the alternative of allowing the tube to lie on the inside wall of the furnace.

Three alternative methods of loading the tube were used. (1) A previously prepared polycrystalline sample of Ni_5As_2 was placed in the tube at one end. (2) A mixture of nickel and arsenic powders in the atomic proportion 5:2 was placed at one end of the tube. (3) Arsenic was placed at one end of the tube and nickel powder at the other end. The correct 5:2 atomic proportions were still maintained.

Either iodine or bromine was used in the transport reaction. The former was added as crystals and the bromine was distilled into the tube on a high vacuum system. The tube was cooled in liquid nitrogen and evacuated to 10^{-4} mm Hg prior to being sealed off. It was supported horizontally in the furnace, as described earlier, with the cold end at 650° C and the hot end containing the Ni_5As_2 or the Ni at 750° C.

One tube was also prepared which contained polycrystalline Ni_5As_2 at one end but into which no halogen was introduced. The tube was sealed at a pressure of 10^{-5} mm Hg and heated so that the Ni_5As_2 was at 800° C and the other end at 550° C.

RESULTS

In the experiments described, with the exception of the last case in which no halogen was used, there was an appreciable transport of material from the hot end towards the cooler end of the tube and clusters of crystals with a metallic luster were observed on the walls after a period of 3 days. The same results were obtained for each method of loading the tube and for concentrations of iodine or bromine of 0.03 mg per cc or 5 mg per cc. The majority of the crystals grew close to the initial charge and Debye–Sherrer photographs confirmed that these were Ni_5As_2. Large lustrous black flakes of NiI_2 were observed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

at the cooler end of the tube in the case of iodide transport. In one iodide transport experiment, dark green crystals of NiO grew at the hottest end of the tube. With the exception of these two compounds (and the elements composing the starting materials) no other phase besides Ni_5As_2 was ever observed. Many of the Ni_5As_2 crystalline samples contained NiI_2 and the content of the impurity increased as the iodine concentration in the tube was raised.

The experiment using no halogen was performed after NiO was obtained in one transport tube. The part played by oxyhalides and even by oxygen itself in the transport reactions is at present open to conjecture. No bulk transport was observed in this tube but the polycrystalline Ni_5As_2 was found to have completely changed in appearance. Its surface had become covered with a variety of crystal growths which on X-ray powder examination proved to be composed entirely of the Ni_5As_2 phase.

CRYSTALLOGRAPHY

The most common habits of the Ni_5As_2 crystals grown with low pressure iodine transport were pyramidally terminated needles, rectangular based pyramids, and multifaceted beads. On X-ray examination, selected crystals were found generally to be imperfect multiple crystals with some apparently twinned. A few of the needles were found to be perfect. The overall maximum dimension of any crystal did not exceed 0.5 mm. In the case of crystals grown in the absence of halogen there were large numbers of multifaceted beads and flat hexagonal plates. Occurring less frequently were dendritic blades and whiskers about 1 mm long. The growth in this case appeared to have taken place upwards out of the substrate since the whiskers carried small fragments of the substrate polycrystalline material along their length.

Three crystals grown by iodine transport reactions were examined on a precession camera using zirconium-filtered molybdenum radiation. Zones recorded were $h0*l$, $\bar{h}2h*l$, $h1*l$, $hk*0$, and $hk*1$ and the only systematic absences were $00*l$ where l is odd.

The crystals were hexagonal, diffraction symbol $6/mmm\ P6_3..$, which uniquely determines the space group as $P6_322(D_6^6)$. The average observed unit cell dimensions were $a = 6.81 \pm 0.02$, $c = 12.48 \pm 0.02$ Å, $c/a = 1.833$, $D_x = 8.80$ for Ni_5As_2 (F.W. = 443.39), $V = 502$ Å^3, $Z = 6$.

The axial lengths are shorter than those recorded by Heyding and Calvert for $Ni_{4.77}As_2$ and as the lattice is reported to contract with increasing arsenic concentration it must be concluded that the crystals examined in this work were even richer in arsenic. The exact composition was never determined. The space group $P6_322$ modifies the aspect symbol previously suggested on the basis of the indexed powder photograph and requires that all indices of the type $h0*l$ be considered in indexing the powder pattern.

Examination of the intensities of reflections on the single crystal photographs indicates that one extra index should be added to the previous indexing of the line at $d = 1.96$ Å. The previous line in the powder pattern at $d = 2.01$ Å can be uniquely indexed as 11*5. Since the intensities of 30*0 and 11*5 are very similar on the single crystal photographs the indexing of the line at $d = 1.96$ Å should include 30*0.

The complete indexing of the two strong lines is as follows:

I_{obs}	$hk*l$	d_{obs}	d_{calc}
100	11*5	2.01	2.02
100	21*3	1.96	1.969
	30*0		1.967
	10*6		1.964

THE STRUCTURES OF TWO NEW ALKALOIDS: CHASMACONITINE AND CHASMANTHININE[1]

O. ACHMATOWICZ, JR.[2] AND LÉO MARION
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received August 28, 1963

ABSTRACT

A re-examination of the root of *Aconitum chasmanthum* Stapf has shown that it contains several alkaloids. Of these, besides indaconitine, the presence of which had been reported long ago, four new alkaloids have been isolated: base A ($C_{26}H_{43}O_6N$), base B ($C_{25}H_{41}O_6N$), chasmaconitine ($C_{34}H_{47}O_9N$), and chasmanthinine ($C_{36}H_{49}O_9N$). Chasmaconitine gives rise to bikhaconine on hydrolysis, and has been shown by conversion to delphinine to be N-ethyl-N-desmethyl-delphinine. Chasmanthinine is also hydrolyzable to bikhaconine. Whereas in chasmaconitine bikhaconine is esterified with acetic and benzoic acid, in chasmanthinine it is esterified with acetic and *trans*-cinnamic acid. The complete structures and absolute configurations of both bases are derived.

The Indian plant *Aconitum chasmanthum* Stapf was examined many years ago by Dunstan and Andrews (1), who isolated from it the alkaloid indaconitine ($C_{34}H_{47}O_{10}N$). To study the structure of this alkaloid (2) a quantity of the root of this plant was obtained from India.[3]

A careful examination of the methanolic extract of the root has shown that it contains several alkaloids, and five of these have now been isolated in crystalline and pure form (single spots in thin layer chromatography). The five alkaloids are the following: base A, $C_{26}H_{43}O_6N$, m.p. 105–107°; base B, $C_{25}H_{41}O_6N$, m.p. 90–91°, which is the major component of the mixture; base C, $C_{34}H_{47}O_9N$, m.p. 181–182°, also obtained in a low-melting form, m.p. 165–167°; base D, $C_{36}H_{49}O_9N$, m.p. 160–161°; and base E, $C_{34}H_{47}O_{10}N$, m.p. 189–191°. The first two alkaloids came mostly from the strong bases fraction while the remaining three were present in the fraction containing the weak bases (cf. Experimental).

Base E has been identified with indaconitine (II, R = C_2H_5, R_1 = OH, R_2 = C_6H_5) by direct comparison. In this paper we report work concerned with the establishment of the structures of bases C and D which we propose to designate as chasmaconitine and chasmanthinine respectively.

Chasmaconitine ($C_{34}H_{47}O_9N$), according to its infrared absorption spectrum, contains one free hydroxyl (3470 cm^{-1}), an aromatic ring (1600 cm^{-1}), ester carbonyls (strong band at 1718 cm^{-1}), and an acetate (1275 cm^{-1}). The n.m.r. spectrum of the base shows that it contains four methoxyls (δ 3.53, 3.28, 3.27, 3.16), one N-ethyl group (triplet centered at δ 1.08), and one acetoxy group (δ 1.27), and that the aromatic group is monosubstituted (signals corresponding to five aromatic protons at δ 7.35–8.20). The spectroscopic evidence, therefore, indicates that chasmaconitine is a diester of benzoic acid and acetic acid with an alkamine ($C_{25}H_{41}O_7N$) containing four methoxyl groups.

This is confirmed by the hydrolysis of chasmaconitine with alkali which produces benzoic acid, acetic acid, and an amorphous alkamine which on treatment with acetic

[1]*Issued as N.R.C. No. 7656.*

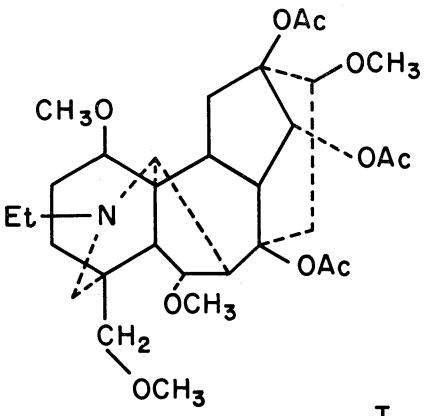
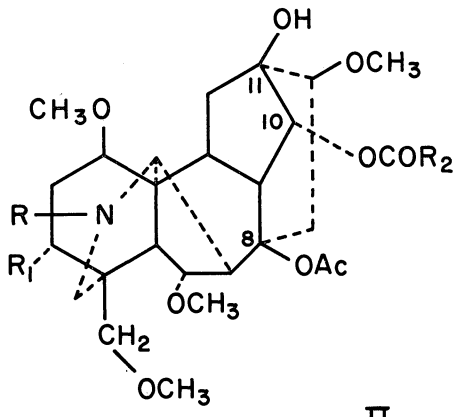
[3]*Obtained through the courtesy of Mr. K. L. Handa, Regional Research Laboratory, Jammu, India, to whom we express our most cordial thanks. In two lots of the root, the major alkaloid was indaconitine. In this particular lot, however, the quantity of indaconitine was appreciably smaller.*

anhydride and *p*-toluenesulphonic acid, gave a derivative, $C_{31}H_{47}O_{10}N$, crystallizing as needles, m.p. 149–150°, or prisms, m.p. 159–161°, $[\alpha]_D$ −7.8°. This product proved to be identical in every way with an authentic sample (3) of triacetylbikhaconine I (melting point, that of the mixture, infrared and n.m.r. spectra, and mobility in thin-layer chromatography, as well as optical rotation). Hence the alkamine is bikhaconine and,



I



II

consequently, chasmaconitine should be identical with deoxyindaconitine, i.e. N-ethyl-N-desmethyl-delphinine (II, R = Et, R_1 = H, R_2 = C_6H_5). It has the same empirical formula and its properties (m.p. 181–182°, $[\alpha]_D^{25}$ +10.3°) are similar to those previously reported for deoxyindaconitine (m.p. 175–180°, $[\alpha]_D^{25}$ +14°). The infrared spectra of the two, however, showed some very slight differences, but the identity was confirmed in the following manner.

The imino-ethyl group of chasmaconitine was removed by oxidation with potassium permanganate in acetone–water solution at room temperature.[4] N-Desethylchasmaconitine, m.p. 161–164°, showed no triplet at δ 1.08 in its n.m.r. spectrum. That the removal of the ethyl group was the only effect of the oxidation was proved by the reconversion of a small quantity of the N-desethyl-base into chasmaconitine by the action of ethyl iodide. An analogous reaction with methyl iodide gave rise to a product which was identical with delphinine (II, R = CH_3, R_1 = H, R_2 = C_6H_5) in every respect (melting point, that of the mixture, infrared spectrum, and mobility in thin-layer chromatography). Consequently chasmaconitine has structure II (R = Et, R_1 = H, R_2 = C_6H_5). It is probable that the slight differences in properties of deoxyindaconitine (cf. ref. 2) are due to the presence of a small quantity of a compound arising in the course of the catalytic hydrogenation of anhydroindaconitine by elimination of the allylic methoxyl. A similar side reaction has been observed in the catalytic hydrogenation of the anhydropseudaconitine (3).

In the n.m.r. spectrum of chasmaconitine, the signal of the three protons of the acetoxy group occurs as a singlet at δ 1.27, which is at much higher field than normal. This shift of the signal to unusually high field has been observed previously in the n.m.r. spectra of aconitine, indaconitine, pseudaconitine, delphinine, and bikhaconitine and is due to the fact that the protons of the acetoxy group come within the shielding range of the aromatic nucleus, the anisotropic effect of which causes the shift (4). Consequently, the orientation

[4]*This oxidative dealkylation procedure will be fully described in a forthcoming paper.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of the two ester groups in chasmaconitine is exactly the same as in aconitine and delphinine. In fact, the conversion of chasmaconitine into delphinine by the simple replacement of its N-ethyl group by an N-methyl not only confirms this, but proves that the absolute configuration is the same for both alkaloids (6).

Chasmanthinine (base D) ($C_{36}H_{49}O_9N$) has an empirical formula that contains C_2H_2 more than that of chasmaconitine. The R_F values of the two bases are very close, although different. The infrared spectrum of chasmanthinine, like that of chasmaconitine, shows the presence in the alkaloid of a hydroxyl (3440 cm^{-1}), of two ester carbonyl groups (1725 and shoulder at 1715 cm^{-1}), of an aromatic ring (1578 cm^{-1}) which is monosubstituted (765, 710 cm^{-1}) and of an acetate ester (1277 cm^{-1}). It differs in containing a sharp band at 1643 cm^{-1} indicative of an isolated double bond, and another band at 980 cm^{-1}, characteristic of a trans double bond.

The presence of an isolated double bond is also shown by the n.m.r. spectrum of chasmanthinine, which contains an AB type quartet (δ 6.42, 7.72, J_{AB} = 16 c.p.s.) corresponding to two protons characteristic of trans olefines. It further contained signals corresponding to five aromatic protons (δ 7.43), to four methoxyls (δ 3.50, 3.27, 3.24, 3.19), to an N-ethyl group (triplet at δ 1.08), and an acetoxy group (δ 1.77).

Consequently, the spectroscopic evidence indicates the presence in chasmanthinine of the features characterizing chasmaconitine, but shows the presence of an additional double bond in the former.

Hydrolysis of chasmanthinine with alkali gave rise to an alkamine isolated as its triacetate, $[\alpha]_D$ −7.9°, m.p. 159–161°, identical in every respect with bikhaconine triacetate, to acetic acid (not isolated), and to a crystalline acid which was not benzoic acid. The acid melted at 137–139°, either alone or in admixture with an authentic sample of *trans*-cinnamic acid. The identity of the acid was confirmed by comparison of its X-ray powder diagram with that of the authentic sample which was exactly alike.

The isolation of the cinnamic acid accounts for the additional C_2H_2 present in chasmanthinine and for the trans olefinic bond. Consequently, the structure of chasmanthinine (II, R = Et, R_1 = H, R_2 = $CH{:}CHC_6H_5$) is the same as that of chasmaconitine except that the benzoyl group of the latter is replaced by a *trans*-cinnamoyl group. That the aromatic ester group occupies the same position as in chasmaconitine follows from the n.m.r. evidence.

Just like the n.m.r. spectrum of pseudaconitine, delphinine, and bikhaconitine (4), the spectrum of chasmanthinine contains a doublet at δ 4.80, $J \sim 4.5$ c.p.s. corresponding to a single proton split by a single neighboring proton. This signal must be attributable to a proton attached to the carbon carrying the aromatic ester group (cf. ref. 4). Because the alkamine derived from chasmanthinine is identical with bikhaconine, it can be concluded that the cinnamic ester group must be located at C_{10} (formula II) since, of the three possible positions for esterification (C_8, C_{10}, C_{11}), that is the only carbon that would carry a proton accompanied by a single neighboring proton.

The signal for the acetoxy protons in the n.m.r. spectrum of chasmanthinine occurs at δ 1.77, which is at higher field than the normal signal (5) but is at lower field than the corresponding signal in chasmaconitine (δ 1.27) and of a number of other aconite alkaloids previously examined (4). It is possible to see from an examination of scale models that in chasmaconitine as in aconitine the acetoxy group stands very close to the plane of the benzene ring of the aromatic ester group and is subject to its anisotropic action which causes the shift. In chasmanthinine, which is esterified with cinnamic acid, the benzene ring is further away from the acetoxy group which, however, is close to the double bond.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Hence the smaller shift (δ 1.77) in the acetoxy protons signal must be due to the anisotropy of the double bond, which is not as strong as that of the aromatic ring. It can, therefore, be concluded that the location and the orientation of the two ester groups in chasmanthinine is exactly the same as in chasmaconitine and delphinine.

Since chasmaconitine has been shown to have the same absolute configuration as delphinine, and since both chasmaconitine and chasmanthinine are hydrolyzed to bikhaconine, it follows that chasmanthinine also has the same absolute configuration as delphinine.

Chasmanthinine is the first alkaloid reported in the highly oxygenated diterpenoid series that is esterified with cinnamic acid. In all the bases of the aconitine type so far studied the alkamine is esterified with acetic acid and one or the other of the following acids: benzoic, veratric, or anisic acid.

EXPERIMENTAL

All the infrared absorption spectra were measured on a Perkin–Elmer double beam spectrophotometer model 21B and unless otherwise mentioned, in a Nujol mull. The n.m.r. spectra were obtained on a Varian A-60 instrument.

Separation of Alkaloids

The dried, ground root of *Aconitum chasmanthum* Stapf (1.36 kg) was extracted by percolation with methanol and the extract evaporated under reduced pressure. The residue was dissolved in 3% hydrochloric acid, and the filtered acid solution extracted with methylene dichloride to remove the neutral and acid material (26.5 g).

Sodium carbonate was added to the aqueous solution (to pH 8), which was again extracted with methylene dichloride (extract 2). The aqueous solution was then made strongly basic with sodium hydroxide (pH 12) and extracted further with methylene dichloride (extract 3).

Extract 3 on evaporation left a residue of crude strong bases (22 g). Extract 2 was evaporated to dryness and the residue dissolved in ether. The ether solution was filtered to remove the insoluble material and the filtrate evaporated to dryness. The residue consisted of the crude weak bases (80 g).

The Strong Bases

The residue from extract 3 (22 g) was dissolved in hot benzene (200 ml) and the insoluble material (4.2 g) was filtered off. The benzene solution was passed through a column of alumina and the eluate evaporated. It left a residual yellowish oil (16.1 g) which partially crystallized. Two crystallizations from *n*-hexane yielded base B (10.6 g), m.p. 90–91°, $[\alpha]_D^{25}$ +23.6° (*c*, 2.5 in EtOH). Found: C, 66.31; H, 9.09; N, 3.14. Calc. for $C_{25}H_{41}O_6N$: C, 66.49; H, 9.15; N, 3.10%; ν 3460, 3365, 3260 cm^{-1}.

The mother liquor from the crystallization of base B was evaporated to dryness. It left a gum (5.4 g) which thin-layer chromatography showed to be a mixture of some base B and another component (base A). Chromatography on alumina (grade III) failed to effect a clean separation but gave a fraction enriched in base A. Separation was effected on this fraction by the use of thin-layer chromatography on a preparative scale. The mixture of bases A and B (136 mg) was adsorbed on silica gel spread on two plates (40×40 cm) and developed with cyclohexane–diethylamine (9:1). The strip of silica gel containing base A was eluted with chloroform–methanol (20:1) and the eluate evaporated. There was left a residue (118 mg) which was dissolved in benzene and chromatographed on alumina.[5] The base obtained (112 mg) crystallized immediately and consisted of pure base A. After two recrystallizations from *n*-hexane, it consisted of clumps of colorless prisms, m.p. 105–107°, $[\alpha]_D^{25}$ +19.2° (*c*, 2.4 in EtOH). Found: C, 67.32; H, 9.07; N, 2.96. Calc. for $C_{26}H_{33}O_6N$: C, 67.06; H, 9.31; N, 3.01%; ν 3420 cm^{-1}.

The Weak Bases

The crude weak bases (80 g) were dissolved in chloroform (500 ml) and shaken with three portions (1000 ml) of a buffer solution consisting of disodium orthophosphate (290 g) and citric acid (90 g) dissolved in water (4 l.) and adjusted to pH 5.4. Each portion of buffer solution extract was back extracted with chloroform (200 ml). The combined aqueous extract was made basic with alkali and extracted with chloroform. This last chloroform extract, after drying and evaporation, left a residual white foam (10 g) which thin-layer chromatography showed to consist mostly of base A and base B together with small quantities of other components.

The first chloroform solution (which had been extracted with buffer solution) was dried and evaporated to dryness. The gummy residue (70 g) was dissolved in benzene and chromatographed on a column (6×40 cm) of alumina (grade IV, 1000 g). The column was eluted first with benzene–chloroform (4:1), then a 1:1

[5]*In all cases of column chromatography, Woelm alumina was used as the adsorbent.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

mixture, afterwards with chloroform, and finally with chloroform–methanol (9:1). The eluate was collected in fractions of 500 ml.

Indaconitine

Fractions 1–4 (benzene–chloroform 4:1) left on evaporation a residue (36.1 g) which crystallized on contact with ether. Recrystallization from ether gave colorless crystals (6.2 g), m.p. 189–191°, undepressed by admixture with an authentic sample of indaconitine. The identity was confirmed by comparison of the infrared and n.m.r. spectra of both the isolated base and the authentic sample.

Fractions 5–8 (benzene–chloroform 1:1) afforded a further quantity of crude indaconitine (20.1 g).

Chasmaconitine

The mother liquors from the crystallization of indaconitine were combined and evaporated to dryness. The gummy residue (29.9 g) was dissolved in benzene–*n*-hexane (1:1), chromatographed on alumina (grade IV, 300 g), and eluted with benzene collected in 300-ml fractions. Fractions 4–7 (1200 ml) yielded an alkaloid which appeared homogeneous in thin-layer chromatography. This alkaloid (4.01 g), for which the name chasmaconitine is proposed, was crystallized from *n*-hexane from which it separated as colorless prisms, m.p. 181–182° (decomp.). When chasmaconitine was rapidly recrystallized from ether it formed fine needles, m.p. 165–167°. Either form could be obtained by cross-seeding, $[\alpha]_D^{25}$ +10.3° (*c*, 1.26 in EtOH). Found: C, 66.59; H, 7.67; N, 2.36. Calc. for $C_{34}H_{47}O_9N$: C, 66.54; H, 7.72; N, 2.28%.

Chasmanthinine

Fraction 8 (373 mg) obtained from the chromatogram that yielded chasmaconitine was rechromatographed over alumina (grade IV, 7 g). Fractions 1–7 (eluted with benzene–hexane 1:1, 80 ml, and with benzene, 60 ml) contained mainly the new base chasmanthinine (thin-layer chromatography). The residue after evaporation of the eluate (237 mg) was dissolved in methylene dichloride and adsorbed on preparative scale thin-layer chromatography plates. The chromatogram was developed on the plates with cyclohexane–diethylamine (9:1) and the strips of silica gel containing chasmanthinine were eluted with chloroform–methanol (9:1). The filtered eluate was evaporated and the residue dissolved in benzene and passed through a column of alumina. The benzene solution was evaporated and the residue (215 mg) crystallized twice from *n*-hexane and once from ether from which chasmanthinine separated as colorless needles, m.p. 160–161° (decomp.), $[\alpha]_D^{25}$ +9.6° (*c*, 1.09 in EtOH). Found: C, 67.48; H, 7.51; N, 2.31. Calc. for $C_{36}H_{49}O_9N$: C, 67.58; H, 7.72; N, 2.19%.

Hydrolysis of Chasmaconitine

Chasmaconitine (200 mg) was refluxed in 3% methanolic sodium hydroxide (20 ml) for 1 hour. The methanol was evaporated under reduced pressure, water was added, and the mixture extracted with chloroform. After drying and evaporation the extract left a basic gummy residue (148 mg) which, in the infrared, showed no carbonyl absorption.

The alkaline aqueous solution was acidified with dilute sulphuric acid and thoroughly extracted with ether. The ether extract on evaporation yielded a white solid (39 mg) which, after two crystallizations from water, consisted of colorless needles (20 mg), m.p. 123° either alone or in admixture with benzoic acid.

Triacetylbikhaconine

The alkamine formed in the hydrolysis of chasmaconitine and obtained as a gummy residue (148 mg) could not be induced to crystallize. It was heated with acetic anhydride (3 ml) and *p*-toluenesulphonic acid (100 mg) on a steam bath for 1 hour. The reaction mixture was poured onto cracked ice, made basic with sodium carbonate, and extracted with chloroform. Evaporation of the dried extract left a solid which was dissolved in benzene and passed through a column of alumina. The benzene eluate was evaporated to dryness and the crystalline residue (192 mg) recrystallized from *n*-hexane from which it separated as colorless needles, m.p. 149–150°. Needles are obtained if the crystallization is rapid, but from a more dilute solution when the crystallization is slow, colorless prisms, m.p. 159–161°, separate, $[\alpha]_D^{25}$ −7.8° (*c*, 2.5 in EtOH). The melting point of the prisms was not depressed when mixed with an authentic sample of triacetylbikhaconine, m.p. 159–161° (3). The identity was confirmed by comparison of the infrared absorption spectra which were superimposable.

N-Desethylchasmaconitine

Chasmaconitine (248 mg) was dissolved in acetone (35 ml) and a solution of potassium permanganate (248 mg) in acetone (35 ml) and water (35 ml) was added rapidly. The reaction mixture was stirred for 10 minutes, the excess permanganate decomposed with sulphurous acid and the filtered solution evaporated under reduced pressure to about one-third of its volume to remove the acetone. The aqueous solution was alkalized with sodium carbonate and extracted four times with chloroform. Evaporation of the dried chloroform extract left a residue which was dissolved in 1% sulphuric acid (10 ml) and the solution extracted with benzene to remove neutral products. The aqueous solution was alkalized with sodium carbonate and again extracted with chloroform. This last extract when evaporated to dryness left a foam (226 mg) which was dissolved in benzene and chromatographed an alumina (grade IV). Elution of the column with *n*-hexane–benzene 1:1 (fractions 1–2) yielded unchanged chasmaconitine (111 mg). Further elution with a mixture of

For personal use only.

benzene and methylene dichloride (fractions 3–7) yielded the expected secondary base (92 mg) which gave one spot only in thin-layer chromatography. The secondary base crystallized from ether as colorless needles, m.p. 161–164.5°, $[\alpha]_D^{25}$ +25.7° (*c*, 1.4 in EtOH). Found: C, 65.76; H, 7.72. Calc. for $C_{32}H_{43}O_9N$: C, 65.62; H, 7.40%. Its n.m.r. spectrum did not contain the triplet characteristic of the ethyl group.

Treatment of the N-desethyl base (30 mg) dissolved in ether–methanol (1:1, 6 ml) with excess ethyl iodide and finely powdered potassium carbonate converted the base back to chasmaconitine, m.p. 180–182° either alone or in admixture with the starting material. The identity was also confirmed by comparison of the infrared absorption spectra.

N-Methyl-N-desethylchasmaconitine (Delphinine)

N-Desethylchasmaconitine (100 mg) was dissolved in ether–methanol (1:1, 10 ml) and an excess methyl iodide was added to the solution together with finely powdered potassium carbonate. The reaction mixture was refluxed for 1 hour and the solvent distilled off. Water was added to the residue and the solution was extracted with chloroform. The extract on evaporation left a foam which was dissolved in benzene and chromatographed on alumina. The benzene eluate was evaporated to dryness; it left a residue which crystallized on contact with ether (96 mg). The product, after two recrystallizations from ether, consisted of colorless prisms, m.p. 187–189° (decomp.), $[\alpha]_D$ +26.0° (*c*, 1.45 in EtOH). The melting point was not depressed by admixture with an authentic sample of delphinine, and the infrared absorption spectra were superimposable. Further, the product and delphinine had the same mobility on a chromatoplate.

Hydrolysis of Chasmanthinine

Chasmanthinine (101 mg) was refluxed with 3% methanolic sodium hydroxide (20 ml) for 1 hour. The methanol was evaporated under reduced pressure, water added, and the mixture extracted with chloroform. The dried extract on evaporation left a gum (92 mg) which did not show any carbonyl absorption in the infrared.

The aqueous solution, which had been extracted with chloroform, was acidified with dilute sulphuric acid and extracted with ether. Evaporation of the extract left a yellowish crystalline residue (22 mg), which, after two crystallizations from aqueous ethanol, consisted of colorless prisms (12 mg), m.p. 137–139°, not depressed in admixture with *trans*-cinnamic acid. The X-ray powder diagrams of both the acid from the hydrolysis and the authentic sample were identical.

The gummy alkamine (92 mg) was heated with acetic anhydride (3 ml) and *p*-toluenesulphonic acid (100 mg) on a steam bath for 1 hour. The mixture was poured into ice water, alkalized with sodium carbonate, and extracted with chloroform. The extract was dried and evaporated; it left a solid residue which was dissolved in benzene and passed through a column of alumina. The benzene eluate, on evaporation, left a crystalline product (90 mg) which, after crystallization from *n*-hexane, consisted of colorless prisms, m.p. 158–161°, $[\alpha]_D^{25}$ −7.9° (*c*, 1.2 in EtOH). This acetylated product proved to be identical with triacetylbikhaconine by comparison of melting point, that of the mixture with an authentic sample, infrared and n.m.r. spectra.

ACKNOWLEDGMENTS

We wish to express our thanks to Mr. A. Knoll who prepared the crude alkaloid extract, to Mr. R. Lauzon who measured the infrared spectra, to Mr. M. Lesage for the n.m.r. spectra, and to Mr. H. Séguin for the microanalyses.

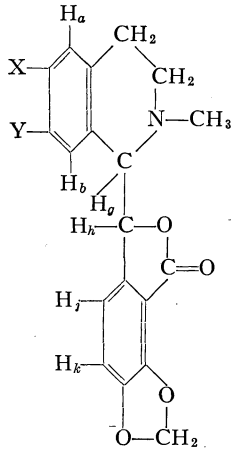
NOTES

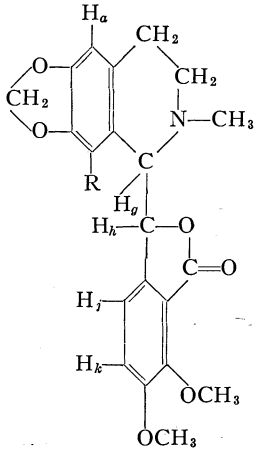
STEREOCHEMICAL CONFIGURATION OF SOME PHTHALIDEISOQUINOLINE ALKALOIDS

S. Safe and R. Y. Moir

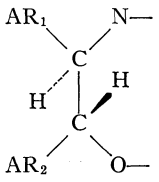
A study of the proton magnetic resonance spectra of adlumine (I), corlumine (I), bicuculline (II), hydrastine (III), and narcotine (IV) (I) shows that adlumine has the configuration A (or its mirror image), and that the four other alkaloids have configuration B (or its mirror image).



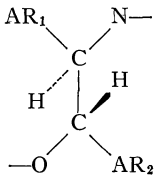
I X = Y = OCH_3
II X, Y = $-OCH_2O-$



III R = H_b
IV R = OCH_3



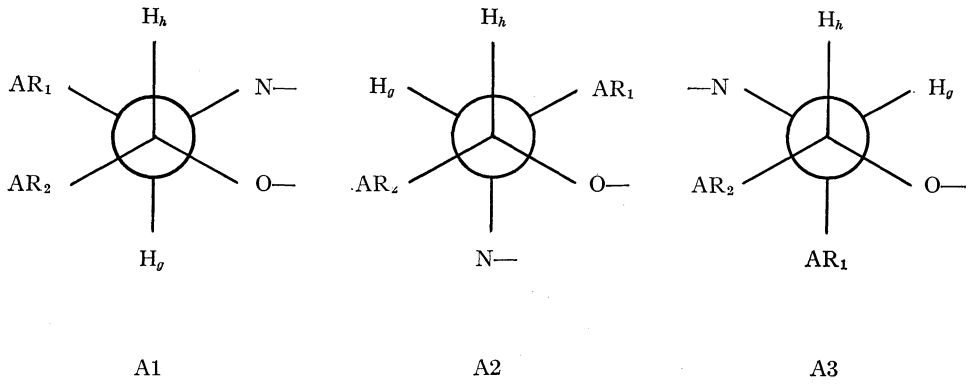
A



B

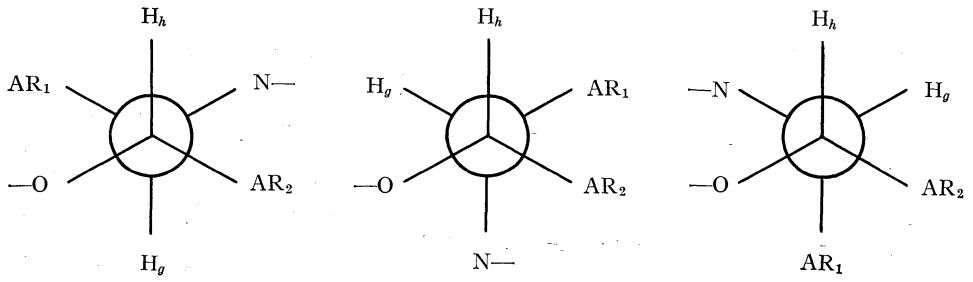
Since conformations with low steric interactions exist for both A and B when the tetrahydropyridine ring is a half-chair, the phthalide moiety is equatorial, and the asymmetric carbons are in a staggered conformation, it seems certain that conformations having these structural features will predominate greatly. Furthermore, the conformations A1 and B1, having H_g and H_h antiparallel, show large interactions and can contribute only slightly to the total population. This is borne out by the low coupling constant of these hydrogens (3.4–4.3 cycles per second). Thus only conformations A2 and A3, and B2 and B3, need be considered in the first approximation, and indeed a consideration of the minor conformations does not alter the following argument.

A proton in the region above or below an aromatic ring is magnetically shielded by the "supercurrent" in the ring (2, 3, 4). In configuration A, neither of the conformations A2 or A3 allows H_j to enter the shielding region of the benzene ring of the isoquinoline portion, but in configuration B, the conformation B2 places H_j well into the shielding region of one aromatic ring, while the other conformation B3 places H_b in a similar position with respect to the other aromatic ring. Thus structures might be assigned to the stereoisomers adlumine and corlumine on the basis of the relative shielding of H_j or of H_b; in the event,



A1 A2 A3

Staggered conformations of configuration A.



B1 B2 B3

Staggered conformations of configuration B.

only the effect on H_j could be used since the signal from H_b could not be distinguished with certainty from that of H_a.

In Table I are reported the mid-band frequencies of the relevant hydrogens, measured in deuterochloroform solutions containing tetramethylsilane as the internal standard at 60 megacycles per second on the Varian A-60 spectrometer.

TABLE I

Proton magnetic resonance frequencies

Alkaloid	H_j	H_k	H_a(?)	H_b(?)
Adlumine	431.5	412.5	384	404
Corlumine	374.5	416.5	386	397
Bicuculline	380	415.5	390	395
Hydrastine	390	425.5	394	384
Narcotine	364.5	418.5	378	—

Values are in cycles per second downfield from the standard, higher values representing lower shielding. The values for H_j and H_k of adlumine have been corrected for the quantum mechanical mixing of the states.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The signals from H_j and H_k were identified with certainty by their characteristic ortho-splitting constant of 7.9–8.3 cycles per second; they could be distinguished from each other since that from H_j suffered a further splitting of 0.8 cycles per second due to the presence of H_h. A similar phenomenon has been observed in this laboratory with a series of phthalides.

It is clear that the configurations given are correct, bicuculline acting as a link in the argument connecting corlumine, hydrastine, and narcotine. The large increase in the shielding of H_j in narcotine, compared to that in hydrastine, adds to the strength of the argument, since with narcotine (but not with hydrastine) the conformation B3 is blocked by the interaction of the R group and the phthalide group; thus the conformation B2, in which H_j is shielded, is occupied a much greater part of the time than with hydrastine.

Robinson (5) felt that hydrastine and narcotine have different configurations (from considerations based on optical rotations, conformational effects being ignored). From Table I, this could only mean that hydrastine should have configuration A, contrary to our conclusions. One would then have to say that the change observed in the frequency for H_j in going from adlumine to hydrastine was due to inductive and resonance effects from the change in substituents, that these effects were large, and that they acted in the opposite direction upon the signal for H_k. But these effects would be expected to be small and in the same direction, as indeed they were for H_k, and for H_a and H_b in the corresponding change from corlumine to bicuculline. Fortunately, other work of Robinson gives decisive support to our structure B for hydrastine, and *a fortiori* to the structures suggested for the other alkaloids. Synthetic hydrastine-*a* was shown to be the racemate of natural hydrastine (6). Aminohydrastine-*a* was easily converted to hydrastine-*a* by the same reactions that coupled the aromatic rings in aminohydrastine-*b*, the other racemic stereoisomer (7). A study of models shows that the ring coupling is easy for configuration A, but would involve tremendous distortion for configuration B. Hence the natural alkaloid, belonging to the series in which coupling did not occur, must be B.

Proton magnetic resonance assignments for hydrastine (8), and for corlumine and bicuculline (9), have been published previously. After the first submission of this note, there appeared the determination by another method of the absolute configuration of hydrastine by Ohta, Tani, and Moruzumi (10). Our work agrees with theirs.

We wish to express our gratitude to Dr. R. H. Manske, whose gift of adlumine, corlumine, and bicuculline made the work possible.

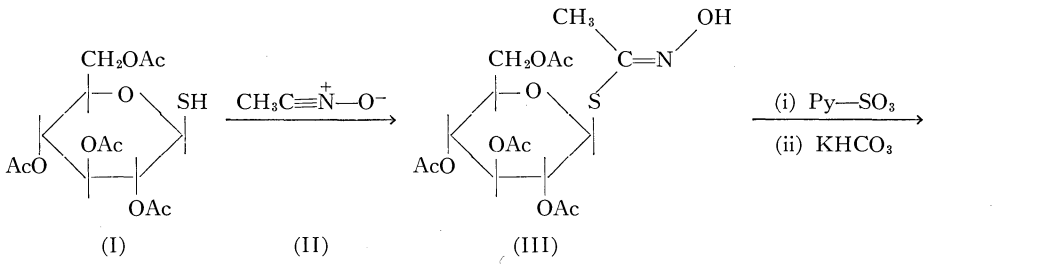
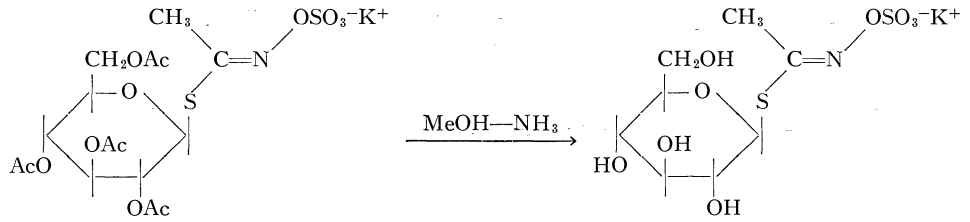
THE SYNTHESIS OF GLUCOAPPARIN

M. H. Benn

First isolated, from *Cleome spinosa* Jacq., by Kjaer and Gmelin (1), glucoapparin (V) is a mustard oil glucoside apparently widely distributed in plants of the family Capparidaceae (2). It is the progenitor of methyl isothiocyanate, the simplest mustard oil, in these plants. We wish to report here the first synthesis of glucoapparin, achieved by the general route developed by us for the synthesis of mustard oil glucosides and already illustrated by the synthesis of glucotropaeolin (3).



(I) (II) (III)



(IV) (V)

2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosylthiol (I) was added to acetonitrile oxide (II), generated in situ from 1-chloroacetaldoxime, to form S-2′,3′,4′,6′-tetra-O-acetyl-β-D-glucopyranosyl methylthiohydroximate (tetraacetylproglucoapparin) (III). Sulphonation of this compound with pyridine – sulphur trioxide complex and isolation of the product as the potassium salt yielded tetraacetylglucoapparin (IV). Deacetylation of the tetraacetate with methanolic ammonia produced crystalline glucoapparin (V). Both the synthetic glucoapparin and its tetraacetate were identical with specimens of natural origin.

EXPERIMENTAL

Tetra-O-acetylproglucoapparin (III)

Acetaldoxime (3.0 g) was dissolved in chloroform (20 ml), the solution cooled to 0° in ice–salt and a slow stream of chlorine bubbled through the solution for 20 minutes. Removal of the solvent under reduced pressure (bath ⩾ 40°) left a pale blue oil containing a little colorless crystalline material. The total product was added in dry ether (30 ml) to a solution of tetraacetylglucosylthiol (1.00 g) in dry ether (130 ml). Triethylamine (8 g) in ether (10 ml) was added to the gently stirred reaction mixture. After 30 minutes at room temperature, the reaction mixture was poured into ice cold, ca. 1 *N* aqueous sulphuric acid. The ether layer was separated, the aqueous layer re-extracted with ether (1 × 50 ml) and the combined, dried ($MgSO_4$) ether extracts evaporated to small volume. The suspension of crystals was stored at 0° overnight and then filtered. Concentration of the mother liquors gave more product, total yield 1.02 g., m.p. 158–162°. Recrystallization from ethanol gave pure tetra-*O*-acetylproglucoapparin as colorless needles, m.p. 163–164°, $[\alpha]_D^{23}$ −16.8° (*c*, 2 in $CHCl_3$). Found: C, 45.94; H, 5.82; N, 3.66; S, 7.86. $C_{16}H_{23}NO_{10}S$ requires C, 45.60; H, 5.50; N, 3.34; S, 7.61%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Tetra-O-acetylglucoapparin (IV)

Pyridine – sulphur trioxide complex (447 mg) was added to a solution of tetraacetylproglucoapparin (522 mg) in dry pyridine (6 ml). The reaction mixture stirred at room temperature for 20 hours, then poured into water (15 ml) containing potassium bicarbonate (675 mg). When effervescence had ceased the clear solution was freeze-dried and the amorphous residue rapidly extracted with boiling 95% aqueous ethanol* (3 × 30 ml). The combined, filtered extracts which rapidly deposited crystalline solid were stored overnight at 0°, then filtered to yield crude tetra-*O*-acetylglucoapparin (422 mg). Recrystallization from aqueous ethanol* gave the pure compound, m.p. 215–217° (*d*), $[\alpha]_D^{22}$ −29° (*c*, 2 in H_2O). Lit. (2) m.p. 209–210°; $[\alpha]_D^{25}$ −31° (*c*, 1.8 in H_2O). The infrared spectrum, in KBr disk, was identical with that of an authentic specimen of tetraacetylglucoapparin.

Glucoapparin (V)

Tetraacetylglucoapparin (100 mg) was dissolved in methanol (10 ml) saturated with ammonia. The solution was kept at room temperature for 18 hours, then evaporated under reduced pressure (bath ⩾ 40°), to yield a crystalline residue. Recrystallization was best achieved by dissolving this material in a few drops of water and then adding ethanol until the solution became turbid. Glucoapparin separated as tiny needles (51 mg), m.p. 207–209° (*d*), $[\alpha]_D^{22}$ −28° (*c*, 1.9 in H_2O). Lit. (2) m.p. 208–210° (*d*), $[\alpha]^{25}_D$ −31° (*c*, 2.2 in H_2O). The infrared spectrum of the synthetic material was superimposable upon that of an authentic specimen of the natural product. The synthetic material was homogeneous when examined by paper chromatography (4) on Whatman No. 1 paper in *n*-butanol – acetic acid – water (4:1:5), top phase, ascending, giving a single spot R_F 0.09, as did the natural product.

ACKNOWLEDGMENTS

We thank Professor Anders Kjaer for the gift of authentic specimens of glucoapparin and its tetraacetate. We are also grateful to the National Research Council for financial support of this work.

THE POSSIBLE USE OF ^{14}C-LABELED *N*-ETHYLMALEIMIDE FOR THE ESTIMATION OF SULPHYDRYL GROUPS

C. C. LEE AND E. R. SAMUELS[1]

In earlier communications (1, 2), we have reported that under certain conditions of hydrolysis whereby the peptide bonds of the glutathione-*N*-ethylmaleimide adduct were cleaved, some L-cysteine-*N*-ethylmaleimide adduct (I) was recovered after the hydrolysis. These findings suggested that if a protein labeled with ^{35}S were allowed to react with *N*-ethylmaleimide (NEM) and then hydrolyzed, any sulphydryl groups originally present in cysteine residues would give rise to ^{35}S-labeled I whose activity could be a measure of the original sulphydryl content. Alternatively, ^{14}C-labeled NEM may be used to treat an ordinary protein. After hydrolysis, the activity of the recovered I-^{14}C would also be a measure of the amount of sulphydryl groups originally present in the protein. If the total

activity of the recovered ^{14}C- or ^{35}S-labeled I were to be used for a quantitative determination of sulphydryl content, either the recovery of I must be complete, or the fraction of I recovered must be constant. Since hydrolytic cleavage of the imide bonds of I should give rise to *S*-succinyl-L-cysteine (II), it is to be expected that under conditions of protein hydrolysis, some decomposition of I to II would occur. The extent of this decomposition was studied by subjecting I-^{14}C to various hydrolytic treatments.

Adduct I-^{14}C, prepared (1) from the reaction of L-cysteine with *N*-ethylmaleimide-1-^{14}C, showed a single active spot on paper chromatography. It is, however, of interest to point out that Dr. R. Tkachuk (3) of the Grain Research Laboratory, Winnipeg, has found that I may be resolved into two components by means of resin ion exchange columns. Possibly, the two components may be diastereoisomers as addition of L-cysteine to NEM creates a second asymmetric carbon. After I-^{14}C was subjected to hydrolytic treatment, two active spots corresponding to I-^{14}C and II-^{14}C were obtained. Typical results on the effect of hydrolysis temperature on the recovery of I-^{14}C are shown in Fig. 1. It can be

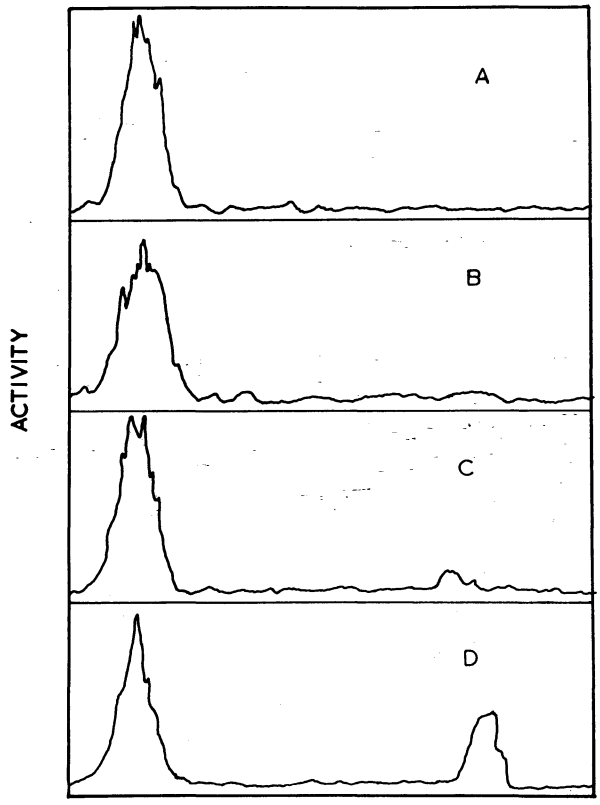

FIG. 1. Effect of temperature of hydrolysis on the decomposition L-cysteine-NEM-^{14}C adduct as measured by a Nuclear-Chicago Actigraph II chromatogram scanner. *A*, *B*, *C*, *D* are chromatograms of the adduct before hydrolysis and after hydrolysis at 75–78° C, 100–103° C, and 110–113° C, respectively, in 6 *N* hydrochloric acid for 18 hours.

seen that decomposition of I-^{14}C to II-^{14}C increased with increasing temperature of hydrolysis. As reported earlier (2), the recovery of I-^{14}C after hydrolysis at 100–103° C for 18 hours was fairly constant at $81 \pm 1\%$.

Conversion of I to II is apparently dependent on both reaction temperature and reaction time during acid hydrolysis. Moore and Ward (4) have reported the presence of II in paper chromatograms of the acid hydrolyzate of NEM-treated wool keratin, indicating that there was some decomposition of I to II during hydrolysis in 5 *N* hydrochloric acid at 125° C for 5 hours. Extensive destruction of I has resulted after prolonged hydrolysis. Thus Blemenfeld and Perlmann (5) found 84% destruction of I after hydrolysis at 110° C for 66 hours, while Tkachuk (3) observed complete decomposition of I to II on hydrolysis at 120° C for 60 hours. However, since our results indicated a constancy in the fraction of I recoverable after hydrolysis under a fixed set of conditions, the relative activity of I-^{14}C recovered after hydrolysis of a sulphydryl-bearing substance, which had been treated with NEM-^{14}C, should be directly related to the sulphydryl content of that substance.

To establish the applicability of this radiochemical method for the estimation of sulphydryls, tests were carried out using NEM-^{14}C on solutions of reduced glutathione or L-cysteine hydrochloride of known concentrations. The results are given in Table I. It

TABLE I

Data from experiments with glutathione or L-cysteine solutions of known concentration

Compound	Concentration, m*M*	Activity of I-^{14}C,* c.p.m.	Activity ratio†
Glutathione	0.20	45	0.23
	0.50	101	0.53
	0.70	130	0.69
	1.00	189	1.00
Cysteine	1.00	187	0.99

*Each value is the average of at least duplicate experiments.
†Relative to 1.00 m*M* glutathione as 1.00.

was realized that because the specific activity of the NEM-^{14}C available was quite low and because only a very small aliquot of the total hydrolyzate was chromatographed each time, it was more accurate to compare the relative activities of the chromatogram spots rather than attempt to calculate the total activity present in each hydrolyzate. As can be seen from Table I, the activity ratios obtained are in good agreement with expectation from the known sulphydryl concentrations of the glutathione and L-cysteine solutions.

Tests with NEM-^{14}C on compounds of known sulphydryl content have also been extended to include trials with thiolated gelatin. The results are summarized in Table II.

TABLE II

Data from experiments with thiolated gelatin

From the observed activities of the chromatogram spots corresponding to I-^{14}C, it can be seen that a 2-fold increase in the amount of thiolated gelatin resulted in activity ratios of 137/70 and 354/180, or 1.96 and 1.97, respcetively, for the two trials. Moreover, an increase of 2.5-fold in the specific activity of the NEM-^{14}C increased the observed activities by factors of 180/70 and 354/137, or 2.57 and 2.58, respectively. These results are again in good agreement with expectation.

The results outlined in this communication indicate that the radiochemical approach to the determination of minute concentrations of sulphydryls is quite feasible, particularly if NEM-^{14}C of higher specific activity could be used. As already pointed out, the experimental conditions must be controlled so that a constant fraction of adduct I-^{14}C will be recovered after hydrolysis. It is, of course, also possible to use the activity of the recovered ^{14}C-labeled *S*-succinyl-L-cysteine (II-^{14}C) as a measure of sulphydryl groups provided the conditions of hydrolysis are so chosen as to convert I-^{14}C to II-^{14}C completely.

EXPERIMENTAL

N-Ethylmaleimide (NEM), *N*-ethylmaleimide-1-^{14}C (NEM-^{14}C), and thiolated gelatin (14 SH groups per molecular weight of 100,000) were obtained from Schwarz BioResearch Inc., Mount Vernon, New York. The L-cysteine-NEM-^{14}C adduct (I-^{14}C) was prepared according to the procedure previously reported from this laboratory (1). Paper chromatographic separation of I-^{14}C in the various hydrolyzates has also been previously described (1, 2).

Hydrolysis of Adduct I-^{14}C

Ten milligram samples of adduct I-^{14}C were each hydrolyzed by heating under reflux in 2.5 ml of 6 *N* hydrochloric acid for 18 hours at 75–78° C, 100–103° C, or 110–113° C, using heated glycerine baths. Each hydrolyzate was filtered and made up to 5.0 ml for use in subsequent paper chromatographic analyses.

Experiments with Glutathione and with L-*Cysteine*

To 10 ml of 0.20, 0.50, 0.70, or 1.00 m*M* solution of reduced glutathione were added 10 ml of a 2.00 m*M* solution of NEM-^{14}C containing 2.0 μc of activity. The resulting solution was allowed to stand overnight at room temperature and then evaporated almost to dryness on a steam bath under reduced pressure. The residue was transferred to a 10 ml flask with 3.0 ml of 6 *N* hydrochloric acid and hydrolyzed by heating under reflux at 100–103° C for 18 hours. A 1.0 m*M* solution of L-cysteine hydrochloride was similarly treated with NEM-^{14}C and hydrolyzed.

Experiments with Thiolated Gelatin

A 10-ml aqueous solution of 5.0 mg (0.04 mmoles) of NEM-^{14}C containing 2.0 or 5.0 μc of activity was added to 25 or 50 ml of a thiolated gelatin solution (2.0 g thiolated gelatin per liter of water). After standing overnight, the resulting solution was concentrated to a small volume under reduced pressure and then hydrolyzed in 4.0 ml of 6 *N* hydrochloric acid at 100–103° C for 18 hours.

THE KINETICS OF REACTION BETWEEN L-CYSTEINE HYDROCHLORIDE AND SOME MALEIMIDES

C. C. LEE AND E. R. SAMUELS[1]

Work in this laboratory (1, 2) on a possible radiochemical method of estimating sulphydryls in proteins involving the addition of the sulphydryl to *N*-ethylmaleimide (NEM) suggested that it may be of interest to investigate the kinetics of this addition reaction. In work based on the U.V. absorption of NEM at 300 mμ, Roberts and Rouser (3) and Alexander (4) have reported that an excess of NEM reacts rapidly with sulphydryls in buffered solutions and have made use of this fact as basis of a quantitative determination of sulphydryls. Also utilizing the absorption at 300 mμ, Gregory (5) has followed the rate of reaction of NEM with sulphydryls as well as the stability of NEM at various pH values. Although no reaction order or rate constants were worked out, it was found that sulphydryls react with NEM faster in neutral than in acidic media and that a slow hydrolysis of NEM occurs in basic medium (5). In the present study, these findings were confirmed and extended, and, besides the reaction of L-cysteine hydrochloride (I) with NEM, reactions of I with maleimide (M) and with *N*-phenylmaleimide (NPM) were examined.

Because NPM is insoluble in water, its reaction with I was studied in 99.75% ethanol – 0.25% water. The reactions with M or NEM were studied both in aqueous solution and in 99.75% ethanol. The kinetics were followed spectrophotometrically. Since equal initial concentrations of the two reactants were used in all cases, for a second order reaction, $1/(a-x) = kt+C$, where $(a-x)$ is the concentration of the reactants at time t. Plots of the reciprocals of the concentrations of M, NEM, or NPM at time t vs. t gave straight lines from which the specific rate constants were obtained.

To study the effect of pH on the rate of reaction between NEM and I, water adjusted to a desired pH with either hydrochloric acid or sodium hydroxide solution was used as solvent. The results are shown in Table I. The reactions of M, NEM, or NPM with I,

TABLE I

Effect of pH on the second order specific rate constant for the reaction between L-cysteine hydrochloride and NEM at room temperature

pH of aqueous solvent	1.0	2.0	3.0	4.0	5.0	6.0	7.0	8.0	9.0	10.0

in aqueous or 99.75% ethanolic solution, were followed at 25, 35, and 45° C. From the straight line plots of log k vs. the reciprocals of absolute temperature, the Arrhenius activation energies were obtained from which the enthalpies and entropies of activation, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, were calculated (6). The results are summarized in Table II.

The addition of sulphydryls to double bonds has been discussed in terms of polar or free radical mechanisms (7). The dependency of the rates on pH and the fact that reactions in water are faster than in ethanol indicate that the present cases likely have a polar

[1]*Holder of a Province of Saskatchewan Graduate Research Scholarship, 1961–62.*

TABLE II

Specific rate constants and activation parameters for the reactions of M, NEM, or NPM with L-cysteine hydrochloride

Solvent	Maleimide	10^3k (l. mole^{-1}sec^{-1}) 25°	35°	45°	$\Delta H^{\ddagger}$ (kcal mole^{-1})	$\Delta S^{\ddagger}$ (cal mole^{-1} deg^{-1})
Water	M	120	210	360	9.8	−29.8
"	NEM	196	350	670	11.0	−25.1
99.75% ethanol	M	0.42	0.93	1.28	10.7	−33.5
"	NEM	1.25	2.16	3.12	8.0	−40.5
"	NPM	4.40	6.67	8.33	5.3	−47.0

rather than a free radical mechanism. Actually, the effect of pH is so pronounced that when L-cysteine free base instead of the hydrochloride (I) was used as reactant in aqueous medium, reaction with M or NEM was too fast for kinetic measurement (complete in less than 2 minutes). Similarly, reactions of M or NEM with I in phosphate buffers of pH 5.4, 6.0, or 6.6 also reached completion in less than 2 minutes. All the results thus suggest the probability of a rate-determining nucleophilic addition of the thiol or thiolate ion to the double bond of the maleimides. This is in accord with expectation as the electron-withdrawing effects of the carbonyl groups adjacent to the double bond would enhance the possibility of nucleophilic attack. In aqueous solution of low pH, formation of thiolate ions would be suppressed, hence retarding the reaction rate. The highly negative entropies of activation are also consistent with a rate-determining addition, as the transition state leading to the addition product would be much more restricted in freedom and randomness than the initial reactants.

EXPERIMENTAL

For reactions in aqueous medium, a 2.00 m*M* solution of M or NEM was added to an equal volume of 2.00 m*M* L-cysteine hydrochloride (I). The initial concentration of each reactant in the reaction mixture was thus 1.00 m*M*. At various time intervals, the concentration of M or NEM remaining was determined spectrophotometrically.

For reactions in ethanolic medium, 2.00 m*M* solution of I was made up by first dissolving I in a small amount of water and then diluting the solution with absolute ethanol. This was added to an equal volume of 2.00 m*M* M, NEM, or NPM in absolute ethanol. The final solvent composition was 99.75% ethanol – 0.25% water by volume.

A Cary recording U.V. spectrophotometer was used to draw all the spectra. The concentration of M or NEM in aqueous medium was measured by the absorbance at 277 mμ or 300 mμ, respectively. In ethanolic medium, concentrations of M, NEM, and NPM were determined, respectively, at 275 mμ, 294 mμ, and 308 mμ. These correspond to the wavelengths of maximum absorption of the maleimides in either aqueous or ethanolic solution. The adducts formed between L-cysteine and M, NEM, or NPM (8, 9) were also examined spectrophotometrically. The L-cysteine-NEM and L-cysteine-NPM adducts show no appreciable U.V. absorption in the region of interest. Thus in the reaction of NEM or NPM with I, λ_{max} for NEM or NPM remained unchanged and the absorbance at λ_{max} decreases as the reaction proceeds according to expectation. On the other hand, in the course of the reaction of M with I, there was a progressive shift of λ_{max} of the reaction mixture from 275 or 277 mμ towards shorter wavelengths because of interference by an appreciable absorption by the L-cysteine-M adduct in the U.V. region under study. Nevertheless, Beer's law was still obeyed and the concentration of M in the reaction mixtures was measured at 275 or 277 mμ, although these wavelengths no longer corresponded to maximum absorption.

THE PHOTOCHEMICAL ADDITION OF CYCLOHEXENE TO DIACETYL AND ETHYL PYRUVATE[1]

P. W. JOLLY AND P. DE MAYO

The photochemical addition of cyclohexene to saturated ketones (1) and a β-diketone (acetylacetone) (2) has, so far as products are concerned, been investigated. The present brief study was undertaken to ascertain if, in non-enolized α-dicarbonyl derivatives, specific addition would take place at one carbonyl group leaving the other available for chemical transformation such as cyclization.

The reaction of cyclohexene with diacetyl under mercury or tungsten light proceeded as expected (3, 4), the structure of the ketol (II) being demonstrated by periodate cleavage and characterization of the fission products. Compound (II) was probably a mixture of stereoisomers. The accompanying pinacol (5, 6, 7) (I) was recognized by the infrared spectrum, but the n.m.r. spectrum was particularly informative: this showed sharp singlets at τ 8.84 (3H), 7.76 (3H), and 5.54 (1H) for the CH_3—C—O, CH_3CO—, and hydroxyl protons, respectively. By-products formed in the irradiation were acetylcyclohexane and bicyclohexenyl.

Similar reaction of cyclohexene with ethyl pyruvate gave the stereoisomeric hydroxy-ester (III, R = Et) mixture expected.[2] Separation of the two stereoisomers was achieved by gas–liquid chromatography (g.l.c.) and the separated esters hydrolyzed to the corresponding crystalline acids (III, R = H).

Treatment of the hydroxy-ester mixture (III, R = Et) with *p*-toluene sulphonic acid in refluxing acetic acid gave a mixture of neutral and acidic products. From the neutral material, which from infrared spectra consisted of a mixture of hydroxylated and unsaturated lactones, a single crystalline hydroxy-lactone was isolated (IV) in about 10% yield. The presence of the hydroxyl and carbonyl groups was attested to by the infrared spectrum. The n.m.r. spectrum showed a singlet (3H) at τ 8.58 (CH_3—C—O) and a multiplet (1H) at τ 5.58 (methine hydrogen on carbon bearing oxygen).

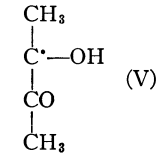
The decay of excited singlets of α-dicarbonyl compounds, it is well known, may proceed through triplets, that of diacetyl being well documented (see, for instance ref. 9). Since the present activation of diacetyl may be achieved with light from a tungsten lamp it may be presumed that $n \rightarrow \pi^*$ excitation is involved. This is followed by intersystem crossing and hydrogen abstraction by the resultant triplet (from the cyclohexene) to give the ketyl (V). The subsequent reactions of the ketyl are unexceptional. There is inferential evidence that the direct irradiation of ethyl pyruvate also gives, by intersystem crossing, a triplet state (10). The present observations indicate this triplet will also abstract hydrogen from cyclohexene to give a ketyl.



(V)

EXPERIMENTAL

Reagents were fractionated in a 40-in. spinning band column and their purity confirmed by g.l.c. The columns used were diethyleneglycol succinate (DEGS) and Carbowax.

Diacetyl–Cyclohexene Irradiation

Diacetyl (4 g) and cyclohexene (150 ml) were irradiated for 150 minutes in a quartz immersion apparatus with a Hanovia CH3 (80 w) lamp (quartz envelope). After this time the absorption at 450–500 mμ disappeared. The products from four such irradiations were combined and fractionated. The fraction with b.p. 62–66°/4 mm was crystallized from ether – light petroleum (1.3 g) to give the pinacol (1) m.p. 95–96° (literature (4), m.p. 95–96°). Calc. for $C_8H_{14}O_4$: C, 55.16; H, 8.10. Found: C, 55.36; H, 7.97%. Passage of the pinacol through a DEGS column at 175° resulted in its conversion to diacetyl, n_D^{23} 1.3929, identical in infrared spectrum and retention time with an authentic specimen.

The fraction collected between 44–49°/4 mm (1.4 g) consisted mainly of acetylcyclohexane. A pure specimen was isolated by g.l.c., n_D^{25} 1.4468, and was identical in infrared spectrum with an authentic specimen. It was characterized as the semicarbazone m.p. 172–173°.

The fraction of b.p. 50–80°/4 mm (including the mother liquors of the pinacol) consisted essentially of bicyclohexenyl (7 g), n_D^{25} 1.5056, identified by retention time and infrared spectrum with an authentic specimen.

The material distilling at 90–92°/3.5 mm (8.4 g) consisted of the ketol (II) contaminated by a small amount of bicyclohexenyl. Redistillation gave the ketol, n_D^{24} 1.4851. Calc. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59. Found: C, 71.42; H, 9.40%. The semicarbazone had m.p. 195–197°. Calc. for $C_{11}H_{19}O_2N_3$: C, 58.64; H, 8.5; N, 18.65. Found: C, 58.37; H, 8.78; N, 18.75%. Cleavage of the ketol (51 mg) with periodic acid resulted in the uptake of 1 atom of oxygen. The product (37 mg) was heated with *N* hydrochloric acid and then converted to the 2,4-dinitrophenylhydrazone in the usual way. Crystallized from ethanol – ethyl acetate the product had m.p. 200–202° undepressed on admixture with an authentic specimen of the derivative of acetylcyclohexene.

In a similar experiment steam distillation of the reaction mixture after cleavage gave acetic acid characterized as the *p*-bromophenacyl derivative, m.p. and mixed m.p. 83–84°.

Irradiation of diacetyl (2 g) in cyclohexene (150 ml) with an external 500 w T.D. Tungsten lamp in Pyrex apparatus gave a similar mixture.

Ethyl Pyruvate–Cyclohexene Irradiation

Ethyl pyruvate (4 g) in cyclohexene (150 ml) was irradiated for 7.5 hours with a Hanovia CH3 lamp in a Pyrex well acting as a cutoff below ~280 mμ, after which time the absorption at ca. 320 mμ was barely detectable. The product from two such irradiations was fractionally distilled. The material of b.p. 64–66°/0.2 mm (5.0 g) was collected and consisted of about 80% of mixed hydroxy esters. The pure esters were separated by g.l.c. on a preparative DEGS column (10 ft × 1/2 in. 20%) to give keto-ester A, n_D^{25} 1.4698. Calc. for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15. Found: C, 66.41; H, 8.78%, and keto-ester B, n_D^{25} 1.4706. Found: C, 66.82; H, 9.18%.

Hydrolysis of the esters at room temperature (*N* NaOH; 2 hours) and acidification gave the corresponding acids: keto-acid A, m.p. 78–79°, from ether – light petroleum). Calc. for $C_9H_{14}O_3$: C, 63.51; H, 8.29. Found: C, 63.48; H, 8.38%. The *p*-bromophenacyl derivative (from aqueous ethanol) had m.p. 95–96. Calc. for $C_{17}H_{19}O_4Br$: C, 55.60; H, 5.17. Found: C, 55.77; H, 5.19%. keto-acid B, m.p. 110–111° (from ether – light petroleum). Found: C, 63.2; H, 8.25%.

Formation of Hydroxy-lactone (IV)

The mixed esters (1.4 g) in acetic acid (25 ml) were refluxed with *p*-toluene sulphonic acid (800 mg) for 18 hours. The acetic acid was removed *in vacuo* below 40° and after addition of water to the residue it was extracted with ether. Evaporation of the ether gave an oil (800 mg) from which acidic material was removed by extraction of an ethereal solution with sodium carbonate to give a neutral residue (400 mg). This was separated on a Carbowax column at 200°. The largest peak was collected (25%) and the material crystallized from ether – light petroleum to give the hydroxy-lactone, m.p. 113° (IV), described below. Infrared spectroscopy indicated that the remaining fractions were unsaturated or hydroxy-lactones.

Continuous ether extraction of the original aqueous phase for 24 hours gave material (390 mg) which, after extraction in ethereal solution with small amounts of aqueous sodium carbonate, gave a crystalline neutral product (IV) (180 mg), m.p. 112–113°, ν_{max} 3550, 1780 cm^{-1}. Calc. for $C_9H_{14}O_3$: C, 63.57; H, 8.29. Found: C, 63.70; H, 8.34%.

SOME CHEMISTRY OF HETERATISINE[1]

O. E. EDWARDS AND C. FERRARI[2]

The minor alkaloid heteratisine from *Aconitum heterophyllum* is of special interest as the only base from aconite and delphinium species known to contain a lactone ring. A recent note outlines the determination of its structure by X-ray crystallography[3] (1). Simultaneous with this determination a number of simple transformation products of the alkaloid were prepared. A study of the physical properties of these enabled recognition of the environment of most of the functional groups of the alkaloid, but fell short of permitting unambiguous assignment of total structure. This evidence is now shown to be completely consistent with the assigned structure.

The early work of Jacobs and Craig on heteratisine (2) demonstrated the presence of a lactone ring, a methoxyl group, an N-alkyl group (presumed to be methyl), and two hydroxyl groups (Zerewitinoff). No easily reduced double bond was found, hence if none is present the empirical formula $C_{22}H_{33}NO_5$ corresponds to a 6-ring structure.

The present work showed that only one hydroxyl of heteratisine was readily acetylated, and that chromium trioxide in acetic acid oxidized the same hydroxyl giving a keto base. The alkaloid hence contains one secondary and probably one tertiary hydroxyl group. Chromium trioxide pyridine complex oxidized heteratisine to a keto-lactam $C_{22}H_{29}NO_6$, thus showing the presence of a methylene group attached to nitrogen. In the infrared spectra of chloroform solutions of the keto-base and keto-lactam, the lactone carbonyl

Formation of Hydroxy-lactone (IV)

The mixed esters (1.4 g) in acetic acid (25 ml) were refluxed with *p*-toluene sulphonic acid (800 mg) for 18 hours. The acetic acid was removed *in vacuo* below 40° and after addition of water to the residue it was extracted with ether. Evaporation of the ether gave an oil (800 mg) from which acidic material was removed by extraction of an ethereal solution with sodium carbonate to give a neutral residue (400 mg). This was separated on a Carbowax column at 200°. The largest peak was collected (25%) and the material crystallized from ether – light petroleum to give the hydroxy-lactone, m.p. 113° (IV), described below. Infrared spectroscopy indicated that the remaining fractions were unsaturated or hydroxy-lactones.

Continuous ether extraction of the original aqueous phase for 24 hours gave material (390 mg) which, after extraction in ethereal solution with small amounts of aqueous sodium carbonate, gave a crystalline neutral product (IV) (180 mg), m.p. 112–113°, ν_{max} 3550, 1780 cm^{-1}. Calc. for $C_9H_{14}O_3$: C, 63.57; H, 8.29. Found: C, 63.70; H, 8.34%.

SOME CHEMISTRY OF HETERATISINE[1]

O. E. EDWARDS AND C. FERRARI[2]

The minor alkaloid heteratisine from *Aconitum heterophyllum* is of special interest as the only base from aconite and delphinium species known to contain a lactone ring. A recent note outlines the determination of its structure by X-ray crystallography[3] (1). Simultaneous with this determination a number of simple transformation products of the alkaloid were prepared. A study of the physical properties of these enabled recognition of the environment of most of the functional groups of the alkaloid, but fell short of permitting unambiguous assignment of total structure. This evidence is now shown to be completely consistent with the assigned structure.

The early work of Jacobs and Craig on heteratisine (2) demonstrated the presence of a lactone ring, a methoxyl group, an N-alkyl group (presumed to be methyl), and two hydroxyl groups (Zerewitinoff). No easily reduced double bond was found, hence if none is present the empirical formula $C_{22}H_{33}NO_5$ corresponds to a 6-ring structure.

The present work showed that only one hydroxyl of heteratisine was readily acetylated, and that chromium trioxide in acetic acid oxidized the same hydroxyl giving a keto base. The alkaloid hence contains one secondary and probably one tertiary hydroxyl group. Chromium trioxide pyridine complex oxidized heteratisine to a keto-lactam $C_{22}H_{29}NO_6$, thus showing the presence of a methylene group attached to nitrogen. In the infrared spectra of chloroform solutions of the keto-base and keto-lactam, the lactone carbonyl

[1]*Issued as N.R.C. No. 7630.*

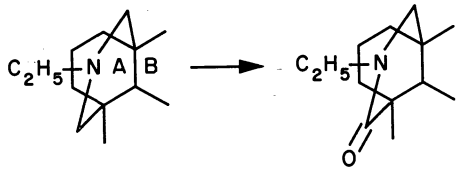
absorbed at 1735 cm^{-1} (δ-lactone) and the ketone carbonyl absorbed above 1725 cm^{-1}. In mull spectra of various derivatives the carbonyl absorbed near 1750 cm^{-1}. The secondary hydroxyl of the alkaloid thus appeared to be on a 5-membered ring.

The pK_a of the keto-base (6.6) was two units below that of heteratisine (8.6). This dramatic difference is characteristic of the hydroxyl to carbonyl transformations when the oxygen is on rings A or B of diterpenoid alkaloids (3, 4, 5), and is identical with that for delpheline which has a 6-hydroxyl.

Potassium permanganate in acetone converted heteratisine monoacetate to a complex mixture from which a lactam and a N-desethyl lactam could be isolated. The analysis of the latter and the absence from its spectrum of the characteristic 3-hydrogen triplet which appears near $\delta = 1$ in the n.m.r. spectra of the bases and $\delta = 1.2$ in that of the lactam proved the N-alkyl group to the ethyl.

An unsplit methyl group resonated at $\delta = 1$ in the n.m.r. spectrum of heteratisine and at slightly higher field in that of the keto base and O-acetate. However, the methyl was deshielded markedly in the keto-lactam, resonating at $\delta = 1.25$. The evidence about the hetero ring was thus consistent with the presence of the usual ring A arrangement of the diterpenoid alkaloids:



That the lactone ring and the hydroxyl groups were isolated from one another was demonstrated by the inertness to lead tetraacetate of the tetrahydroxy base produced by lithium aluminum hydride reduction of heteratisine.

The above evidence is consistent with structure I deduced in the X-ray crystallographic study. The remaining structural information obtained in this work was derived by analysis of the n.m.r. spectra of heteratisine and its transformation products. For economy of presentation this will be described using structure I. The chemical shift assignments that could be made with confidence are noted on the formulae:

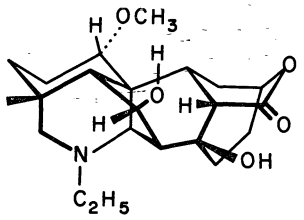
The 11-hydrogen gave a very broad (~20 c.p.s.) signal, relatively invariant in chemical shift as the nitrogen and secondary hydroxyl functions were modified. The chemical shift corresponded to tertiary hydrogen on carbon carrying an acyloxy group. The width of the signal suggested coupling with three or more α-hydrogens. The 15-hydrogen signal was always a doublet (J = 2 c.p.s.). The downfield shift on lactam formation identified this as due to a tertiary hydrogen on carbon carrying the nitrogen, and the multiplicity indicated at least one α-hydrogen. The 6-hydrogen gave a rather complex signal in the base and lactam, shifting downfield and becoming a doublet with J = 6.5 c.p.s. on acetylation and disappearing when the secondary hydroxyl group became a ketone. Thus at least one α-hydrogen was again present. A fourth low field hydrogen could be assigned to the carbon carrying the lactone carbonyl (C-9) or the methoxyl group (C-1). It was a doublet (J = 7 c.p.s.) and was strongly shielded by the ketone carbonyl. The possibility that this hydrogen was adjacent to and coupled with the 6-hydrogen, since the splitting of the doublet in each case was nearly the same, was discounted by spin-decoupling experiments. It was found that the 6-hydrogen was coupled with a hydrogen 161 c.p.s. upfield (hence probably tertiary) and the other was coupled with a hydrogen 91 c.p.s. upfield (again probably tertiary).* On the basis of I this signal corresponds unambiguously to the 9-hydrogen.

Two points, the negligible coupling of the 5- and 6-hydrogens ($\theta \simeq 90°$) and the marked shielding of the 9-hydrogen by the carbonyl on C-6, are beautifully accounted for by formula I.

The perfect correspondence of all the above properties with those expected for the X-ray structure I leaves no doubt about its correctness.

An attempt to test the structure by elimination of the 8-hydroxyl to give an analogue of the very characteristic pyroderivatives of pseudaconitine (6) and delphinine (7) was made. The major component of the resulting mixture proved so unstable, however, that no useful information was obtained from it.



II

Evidence is available that the absolute stereochemistry of heteratisine is correctly represented by I and II. The 6-hydroxyl of heteratisine has the same relative configuration as that of delpheline, whose absolute stereochemistry is known (8, 9, 10). The ΔM_D on oxidation of this hydroxyl in delpheline derivatives is large and negative (−200° to −670°) (11). Since the ΔM_D on oxidation of the 6-hydroxyl of heteratisine is −370°, the absolute stereochemistry is undoubtedly the same as delpheline and all other known diterpenoid alkaloids.

A chair form of ring A has been illustrated in II although the X-ray study showed this ring to be a boat in the crystals of the hydrobromide. Two factors stabilize the boat conformation in the salt: (*a*) hydrogen bonding between the proton on the nitrogen and

We are grateful to Dr. L. Hall, University of Ottawa, who obtained the spin-decoupled spectra.

the 1-oxygen; (*b*) repulsive interaction of the 1-methoxyl and the 12-β hydrogen in the chair conformation of ring A which destabilizes this relative to the boat. Whether or not factor (*b*) is enough to make the boat or a half-boat conformation stable in the case of the free base is not certain.

The biogenesis of heteratisine must involve a Baeyer–Villiger type oxidation of a precursor having the commonly occurring lycoctonine skeleton and a 10-carbonyl group.

EXPERIMENTAL

Heteratisine

A solution of the total alkaloids of *Aconitum heterophyllum* in dilute sulphuric acid was adjusted to pH 8 using sodium carbonate, then extracted with benzene. The "weak" bases which were recovered from the benzene extracts crystallized in part from methanol solution. The colorless prisms melted at 267–268° (lit. m.p. 267°) and had $[\alpha]_D$ +29° (*c*, 1.55 in $CHCl_3$), ν_{max}^{Nujol} 3380, 1741 cm^{-1}. Found: C, 67.63; H, 8.41. Calc. for $C_{22}H_{33}O_5N$: C, 67.47; H, 8.50. The perchlorate of heteratisine crystallized as needles, m.p. 252–256° (dec.). Found: C, 53.90; H, 6.46. Calc. for $C_{22}H_{34}ClNO_9$: C, 53.70; H, 6.96. The pK_a' of the base (pH at half titration of the hydrochloride in 50% aqueous ethanol) was 8.6.

Heteratisine Monoacetate

Heteratisine (100 mg) was dissolved in 1 ml of pyridine, and 1 ml of acetic anhydride was added. The solution was left at room temperature overnight and then taken to dryness under reduced pressure. The crystalline residue was dissolved in boiling cyclohexane and when it was cooled 90 mg of white crystals separated, m.p. 155–165°. A second recrystallization from the same solvent raised the melting point to 161–166°. The compound retained solvent and before analysis had to be dried 9 hours at 120°, *in vacuo*. Heteratisine monoacetate sublimed at 145° at 10^{-4} mm, m.p. 161.5–167°. It had ν_{max}^{Nujol} 3430, (tertiary OH), 1738 (δ-lactone), and 1707 cm^{-1} (O-acetyl); pK_a' 7.8 (in 50% ethanol); $[\alpha]_D$ +16° (*c*, 1.66 in $CHCl_3$). Found: C, 66.10, 65.89; H, 8.01, 7.99; N, 3.35. Calc. for $C_{21}H_{35}O_6N$: C, 66.49; H, 8.14; N, 3.23.

N-Desethyl Lactam Acetate and Lactam Acetate

Heteratisine monoacetate (250 mg) was dissolved in 25 ml of acetone, at room temperature. A few drops of acetic acid was added followed by small amounts of finely ground potassium permanganate until the color was permanent for 30 minutes. The small excess was reduced with a few drops of alcohol, and the solution filtered through a bed of diatomaceous earth. The manganese dioxide was thoroughly washed with acetone, and the solution taken to dryness. The oily residue was dissolved in hot methanol and, when it was cooled, 50 mg of colorless platelets of N-desethyl lactam acetate were obtained, m.p. 268–272°. Recrystallization raised the melting point to 271–274°. This gave only one spot on thin-layer chromatography (TLC). It had ν_{max}^{Nujol} 3190 (OH and NH), 1737 (lactone), 1727 (O-acetyl), and 1647 cm^{-1} (lactam). Found: C, 62.80; H, 6.97; N, 3.47. Calc. for $C_{22}H_{29}O_7N$: C, 62.99; H, 6.97; N, 3.34.

The mother liquors of the first crystallization were taken to dryness, and chromatographed on a column of grade IV neutral alumina. Elution with benzene–chloroform 1:1 gave two fractions, the second of which was mainly the above N-desethyl lactam. The first fraction was dissolved in hot methanol; when it had been cooled 40 mg of colorless crystals of the lactam acetate appeared, m.p. 282–286°. A second recrystallization gave m.p. 286–288°. TLC showed only one spot. ν_{max}^{Nujol} 3380 (tertiary OH), 1732 (lactone and O-acetyl), and 1623 cm^{-1} (lactam). Found: C, 64.57; H, 7.42; N, 3.15. Calc. for $C_{24}H_{33}O_7N$: C, 64.41; H, 7.47; N, 3.13. Further elution of the column with 1% methanol in chloroform gave another crystalline fraction that was shown by TLC to be a mixture. This was not investigated further.

N-Desethyl Lactam

N-Desethyl lactam acetate (80 mg) was dissolved in 10 ml of methanol. One milliliter of 10% aqueous solution of sodium hydroxide was added, and the whole boiled 1 hour under reflux. Water was added and the methanol evaporated under reduced pressure. The remaining solution was acidified with sulphuric acid and extracted with chloroform. Evaporation of the extract left an oily residue that crystallized from methanol. TLC showed impurities that could not be removed by crystallization. The product was therefore chromatographed on a large silica gel plate. The main band was scraped off and extracted, giving approximately 50 mg of N-desethyl lactam. Crystallization from methanol gave colorless crystals melting at 266–269°. It had ν_{max}^{Nujol} 1733 (lactone) and 1630 cm^{-1} (lactam) and several peaks above 3000 cm^{-1}. Found: C, 63.66; H, 7.51. Calc. for $C_{20}H_{27}O_6N$: C, 63.64; H, 7.21. (Sample dried 48 hours at 120°.)

Dehydroheteratisine

Heteratisine (200 mg) was dissolved in 4.5 ml of acetic acid, and a suspension of 155 mg of chromium trioxide in 6 ml of acetic acid was added. The mixture was left 50 minutes at room temperature, with occasional shaking. It was then diluted with 3 *N* sulphuric acid and the excess chromic acid reduced with sulphur dioxide. The resulting green solution was extracted with methylene chloride and the extracts discarded. The remaining solution was made alkaline with solid sodium carbonate and then extracted with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

methylene chloride. The extracts were taken to dryness, giving approximately 200 mg of slightly brown froth. This was shown by TLC to be mainly one product, with a small amount of starting material. The mixture failed to crystallize, so it was chromatographed on large silica gel plates, using chloroform–*n*-hexane–diethylamine (10:10:3) as developing solvent. The main band was scraped off and extracted. This afforded 140 mg of keto-base, that again failed to crystallize. It was then dissolved in methanol and a dilute solution of perchloric acid in methanol added until the pH was near 5. The perchlorate which separated immediately as a gel was dissolved by boiling and addition of more solvent. When the solution had been cooled, bulky white needles formed. These were collected and again crystallized from methanol–water, m.p. 266–269.5°. Weight: 85 mg. This had ν_{max}^{Nujol} 3390 (tertiary OH), 1750 (cyclopentanone), and 1715 cm^{-1} (lactone). Found: C, 53.88; H, 6.68; N, 2.98. Calc. for $C_{22}H_{31}O_5N.HClO_4$ ($C_{22}H_{32}ClNO_9$): C, 53.92; H, 6.58; N, 2.85. The free base finally crystallized from cyclohexane, m.p. 135–139°. A second recrystallization gave m.p. 130–135°; pK_a' 6.6 (in 50% ethanol); $[\alpha]_D$ −66° (*c*, 1.42 in $CHCl_3$). Found: C, 67.76; H, 7.93; N, 3.81. Calc. for $C_{22}H_{31}O_5N$: C, 67.84; H, 8.02; N, 3.60. The ultraviolet spectrum of dehydroheteratisine perchlorate only showed a very small peak at 302 mμ, $\epsilon \simeq 30$ unchanged on addition of sodium hydroxide.

Keto Lactam

Heteratisine (100 mg) was dissolved in 1.5 ml of pyridine, and the suspension of the complex from 80 mg of chromium trioxide in 2 ml of pyridine was added. The suspension was left overnight at room temperature, diluted with 3 *N* sulphuric acid, and the excess chromic acid reduced with sulphur dioxide. A base-neutral separation gave a basic fraction that was shown using TLC to be dehydroheteratisine. The neutral fraction (55 mg) contained two main components. Crystallization of this mixture from methanol gave colorless crystals, m.p. 268–275°. A second recrystallization gave m.p. 270–274°. The compound had ν_{max}^{Nujol} 3480 (tertiary OH); 1748 (cyclopentanone); 1735 (lactone); and 1635 cm^{-1} (lactam). Found: C, 65.46; H, 7.41; N, 3.38. Calc. for $C_{22}H_{29}O_6N$: C, 65.49; H, 7.25; N, 3.47.

Dehydration of Heteratisine with $POCl_3$–Pyridine

A solution of 100 mg of alkaloid in 3 ml of pyridine was cooled to 0°. One milliliter of phosphorus oxychloride was added dropwise during 15 minutes, and the resulting solution left 1 hour at room temperature. It was then slowly poured over ice, made alkaline with solid sodium carbonate, and extracted with methylene chloride. On evaporation to dryness under reduced pressure the solution turned purple, possibly due to oxidation. A thin layer chromatogram showed one main component that was separated on a preparative plate. The n.m.r. spectrum of this fraction showed possibly one olefinic proton, but a new TLC revealed that the compound had decomposed giving a complex mixture.

N-SULPHONYLIMINO ESTERS

Bernard Loev and Minerva F. Kormendy

Orthoaminobenzenesulphonamide (I*a*) and orthoaminobenzylsulphonamide (I*b*) cyclize readily on heating with an orthoester to give, respectively, the six-membered benzothiadiazinedioxide (II*a*) (1) and the seven-membered benzothiadiazepinedioxide (II*b*) (2).

methylene chloride. The extracts were taken to dryness, giving approximately 200 mg of slightly brown froth. This was shown by TLC to be mainly one product, with a small amount of starting material. The mixture failed to crystallize, so it was chromatographed on large silica gel plates, using chloroform–*n*-hexane–diethylamine (10:10:3) as developing solvent. The main band was scraped off and extracted. This afforded 140 mg of keto-base, that again failed to crystallize. It was then dissolved in methanol and a dilute solution of perchloric acid in methanol added until the pH was near 5. The perchlorate which separated immediately as a gel was dissolved by boiling and addition of more solvent. When the solution had been cooled, bulky white needles formed. These were collected and again crystallized from methanol–water, m.p. 266–269.5°. Weight: 85 mg. This had ν_{max}^{Nujol} 3390 (tertiary OH), 1750 (cyclopentanone), and 1715 cm^{-1} (lactone). Found: C, 53.88; H, 6.68; N, 2.98. Calc. for $C_{22}H_{31}O_5N.HClO_4$ ($C_{22}H_{32}ClNO_9$): C, 53.92; H, 6.58; N, 2.85. The free base finally crystallized from cyclohexane, m.p. 135–139°. A second recrystallization gave m.p. 130–135°; pK_a' 6.6 (in 50% ethanol); $[\alpha]_D$ −66° (*c*, 1.42 in $CHCl_3$). Found: C, 67.76; H, 7.93; N, 3.81. Calc. for $C_{22}H_{31}O_5N$: C, 67.84; H, 8.02; N, 3.60. The ultraviolet spectrum of dehydroheteratisine perchlorate only showed a very small peak at 302 mμ, $\epsilon \simeq 30$ unchanged on addition of sodium hydroxide.

Keto Lactam

Heteratisine (100 mg) was dissolved in 1.5 ml of pyridine, and the suspension of the complex from 80 mg of chromium trioxide in 2 ml of pyridine was added. The suspension was left overnight at room temperature, diluted with 3 *N* sulphuric acid, and the excess chromic acid reduced with sulphur dioxide. A base-neutral separation gave a basic fraction that was shown using TLC to be dehydroheteratisine. The neutral fraction (55 mg) contained two main components. Crystallization of this mixture from methanol gave colorless crystals, m.p. 268–275°. A second recrystallization gave m.p. 270–274°. The compound had ν_{max}^{Nujol} 3480 (tertiary OH); 1748 (cyclopentanone); 1735 (lactone); and 1635 cm^{-1} (lactam). Found: C, 65.46; H, 7.41; N, 3.38. Calc. for $C_{22}H_{29}O_6N$: C, 65.49; H, 7.25; N, 3.47.

Dehydration of Heteratisine with $POCl_3$–Pyridine

A solution of 100 mg of alkaloid in 3 ml of pyridine was cooled to 0°. One milliliter of phosphorus oxychloride was added dropwise during 15 minutes, and the resulting solution left 1 hour at room temperature. It was then slowly poured over ice, made alkaline with solid sodium carbonate, and extracted with methylene chloride. On evaporation to dryness under reduced pressure the solution turned purple, possibly due to oxidation. A thin layer chromatogram showed one main component that was separated on a preparative plate. The n.m.r. spectrum of this fraction showed possibly one olefinic proton, but a new TLC revealed that the compound had decomposed giving a complex mixture.

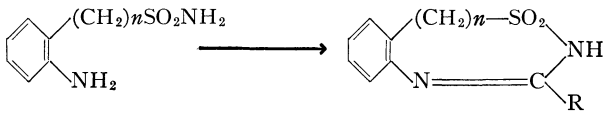
N-SULPHONYLIMINO ESTERS

Bernard Loev and Minerva F. Kormendy

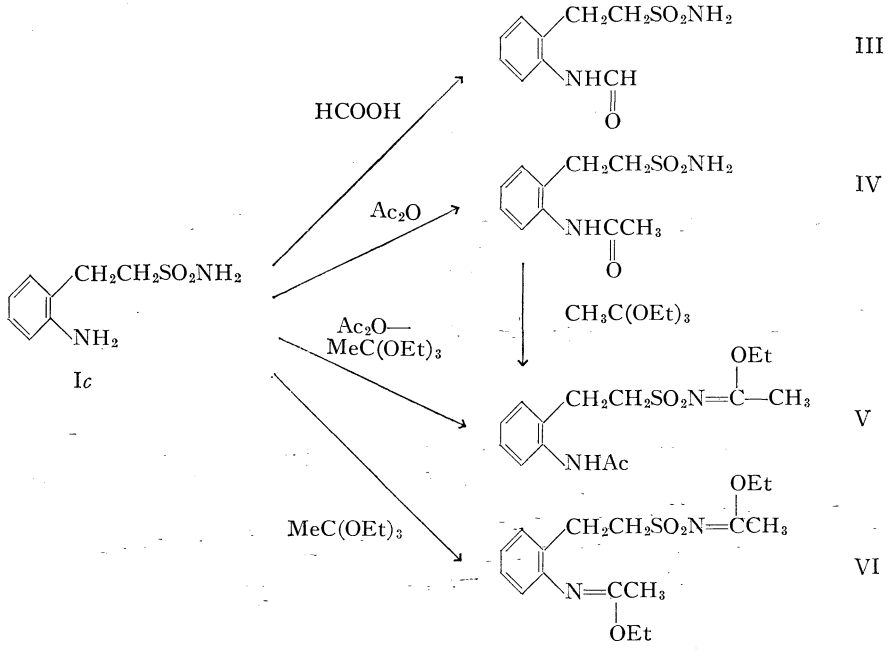
Orthoaminobenzenesulphonamide (I*a*) and orthoaminobenzylsulphonamide (I*b*) cyclize readily on heating with an orthoester to give, respectively, the six-membered benzothiadiazinedioxide (II*a*) (1) and the seven-membered benzothiadiazepinedioxide (II*b*) (2).



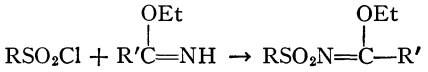
I
a, $n = 0$
b, $n = 1$
c, $n = 2$

II
a, $n = 0$
b, $n = 1$
c, $n = 2$

Under the same or modified conditions, orthoaminophenethylsulphonamide (I*c*) (3) has been found to give only the uncyclized products shown below, rather than the eight-membered analogue (II*c*).



Iminoesters prepared by the reaction of aromatic amines with orthoesters are well known (1, 4); however, there are few examples of *sulphonyl*iminoesters. N-Sulphonylacetimidic and benzimidic acid esters were first described by Barber in 1943 (5); he prepared them by the reaction of a sulphonyl chloride with an iminoester. The utility of this



method may be gauged by the fact that subsequent workers (6) report that changes in experimental technique led to "greatly improved (to 25–30% total) yields". In another reference to such compounds, a small amount of VII was isolated as a by-product in the reaction of acetobromogalactose with the silver salt of *p*-toluenesulphonamide (7). This same compound has now been prepared in 80% yield simply by heating the sulphonamide and the orthoester.

VII

Recently, Novello *et al.* (8), observed the formation of a sulphonyliminoester during the synthesis of 6-chloro-7-sulphamyl-1,2,4-benzothiadiazine-1,1-dioxide by reaction of 5-chloro-2,4-disulphamylaniline with ethyl orthoformate.

EXPERIMENTAL[1]

o-Formamido-β-phenethylsulphonamide (III)

A solution of 2.0 g (0.001 mole) of *o*-amino-β-phenethylsulphonamide (3) in 20 ml of 98–100% formic acid was refluxed for 18 hours. The solution was concentrated, *in vacuo*, to give a thick oily residue which crystallized on contact with ethanol. It was recrystallized from ethanol and from isopropanol to give 0.75 g of white solid, m.p. 122–124°. Anal. Calc. for $C_9H_{12}N_2O_3S$: C, 47.45; H, 5.27; N, 12.30. Found: C, 47.50; H, 5.38; N, 12.30.

o-Acetamido-β-phenethylsulphonamide (IV)

Four grams (0.002 mole) of *o*-amino-β-phenethylsulphonamide (3) was treated with 20 ml of acetic anhydride. There was some heat evolution and the solid dissolved momentarily and another solid separated. This material was recrystallized from ethanol to give 2.6 g of white crystalline solid, m.p. 158–160°. Anal. Calc. for $C_{10}H_{14}N_2O_3S$: C, 49.57; H, 5.82; N, 11.56. Found: C, 49.85; H, 5.93; N, 11.62.

N-(1-Ethoxyethylene)-o-acetamido-β-phenethylsulphonamide (V)

To 4.0 g (0.02 mole) of *o*-amino-β-phenethylsulphonamide (3) was added 20 ml of acetic anhydride; the solid dissolved completely with heat evolution. To this solution was then added 20 ml of ethyl orthoacetate, and the mixture was refluxed for 18 hours. The solution was concentrated *in vacuo* to give a residual oil which slowly solidified. The solid was recrystallized from a mixture of ethylacetate and hexane to give 2.6 g of white solid, m.p. 97–98°. Anal. Calc. for $C_{14}H_{20}N_2O_4S$: C, 53.93; H, 6.42; N, 8.98. Found: C, 53.99; H, 6.29; N, 9.29.

A sample of IV, on being heated with ethyl orthoacetate, gave a product identical with V.

N-(1-Ethoxyethylidene)-2-(1-ethoxyethylidene-amino)-phenethylsulphonamide (VI)

A mixture of 1.0 g (0.005 mole) of *o*-amino-β-phenethylsulphonamide in 10 ml of triethyl orthoacetate was heated to reflux; slowly all the solid dissolved. Reflux was continued for 3 hours. The solution was concentrated *in vacuo* to give a residual oil which slowly solidified. This solid was recrystallized from petroleum ether to give 0.6 g of N-(1-ethoxyethylidene)-2-(1-ethoxyethylidene amino)-phenethylsulphonamide, m.p. 45–46°. Anal. Calc. for $C_{16}H_{24}N_2SO_4$: C, 56.45; H, 7.11; N, 8.22. Found: C, 56.68; H, 7.28; N, 8.15.

Methyl N-(p-toluenesulphonyl)-iminoacetate (VII)

A mixture of 8.5 g (0.05 mole) of *p*-toluenesulphonamide and 15 ml of trimethyl orthoacetate was heated to reflux. Slowly the solid dissolved; heating was continued for 3 hours. The resulting solution was concentrated *in vacuo* and the residue crystallized. The solid (80% yield) was recrystallized from cyclohexane; white crystalline solid, m.p. 73–74°. (Lit. (7) m.p. 74–75°.)

SYNTHESIS OF BISNAPHTHOXAZOLES[1]

CHARANJIT RAI AND JOHN B. BRAUNWARTH

The usefulness of polyphosphoric acid as an effective condensing agent for intra- and inter-molecular condensations has been extensively demonstrated. Hein, Alheim, and Leavitt (1) extended its application to the benzoxazole synthesis and to similar related reactions (2). Several workers (3, 4, 5) reported the synthesis of heterocyclic compounds in improved yields by conducting the cyclizations in the polyphosphoric acid medium. The present study was undertaken to investigate whether polyphosphoric acid would successfully catalyze the intermolecular condensation of 1-amino-2 naphthol with diabasic acids, to give a new series of heterocyclic compounds, bisnaphth-(1,2)-oxazoles, which were needed for our studies.

Bis[2-naphth(1,2)oxazolyl]alkanes were readily prepared by the polyphosphoric acid catalyzed reaction of 1-amino-2-naphthol hydrochloride and dicarboxylic acids. The yields of α,ω-bis[2-naphth(1,2)oxazolyl]alkanes varied from 22 to 92% of the theory. It was observed that as the connecting alkylene chain length was increased, the preparation of the compounds became easier and in some cases the yields were higher.

The condensation reaction involving terephthalic acid and fumaric acid required higher temperatures (175° to 220°). Thus 1,4-bis[2-naphth(1,2)oxazolyl]benzene was prepared by conducting the reaction at 200° in 30% yield, whereas trans-1,2-bis[2-naphth(1,2)oxazolyl]ethylene was prepared at 175° in 35% yield.

The reaction of 3,3′-thiodipropionic acid and 1-amino-2-naphthol hydrochloride gave 2,2′-bis[2-naphth(1,2)-oxazolyl]diethyl sulphide in 22% yield. The reaction was catalyzed by polyphosphoric acid.

EXPERIMENTAL

The procedure for the syntheses of bis[2-naphth(1,2)oxazolyl]alkanes is described below. The data on the preparation, yields, melting points, and analysis are summarized in Table I. All melting points reported here are uncorrected. Commercially available polyphosphoric acid, also known as phospholeum, obtained from Monsanto Chemical Company, was used in this work.

Preparation of α,ω-Bis[2-naphth(1,2)oxazolyl]alkanes

1-Amino-2-naphthol hydrochloride (0.026 mole) was mixed with dicarboxylic acid, or its anhydride (.013 mole) and the mixture was poured into well-stirred polyphosphoric acid (approximately 75 ml) contained in a three-necked flask at room temperature. The reaction mixture was heated at 130° to 200° C for 1 to 2 hours. The α,ω-bis[2-naphth(1,2)oxazolyl]alkanes were isolated by pouring the cooled reaction mixture on ice. The precipitate was filtered, washed with water, then dilute sodium bicarbonate solution and water, and dried in a vacuum desiccator. The crude product was recrystallized from ethanol or dioxane until a constant melting point was obtained.

Preparation of 1,4-Bis[naphth(1,2)oxazolyl]benzene

A mixture of 1-amino-2-naphthol hydrochloride (0.05 mole) and terephthalic acid (0.025 mole) was added to polyphosphoric acid (100 ml) at 80° C. The reaction mixture was heated at 175° to 220° C for 2 hours. The product was isolated according to the procedure described for α,ω-bis[2-naphth(1,2)oxazolyl]alkanes. The compound was recrystallized from a mixture of methanol and benzene.

Preparation of 2,2′-Bis-[2-naphth(1,2)oxazolyl]diethyl sulphide

This compound was prepared by reacting 1-amino-2-naphthol hydrochloride (0.026 mole) with 3,3′-thiodipropionic acid (0.013 mole) in polyphosphoric (75 ml) at 130° C. The reaction was complete in less than an hour and the product was worked up by the normal procedure described earlier.

THE ACTIVITY PRODUCT OF FERRIC HYDROXIDE BY TURBIDIMETRY

R. F. PLATFORD

Electrometrically determined values for the activity product of ferric hydroxide vary from $10^{-35.5}$ to $10^{-38.7}$ (1,2,3,4) and show changes with aging of the precipitate (5). Turbidimetry has been used by other workers (6) in the study of complex formation and was used in the present work to detect the initial appearance of the precipitate produced by adding hydroxyl ions to solutions of ferric salts. Knowledge of initial ferric-ion activity and hydroxyl-ion activity at the point of initial precipitation allowed the calculation of an activity product for the reaction $Fe^{+++} + 3OH^- \rightarrow Fe(OH)_3$.

EXPERIMENTAL

Reagents

All chemicals used were reagent grade or better. Solutions of ferric salts were prepared (*a*) from $FeCl_3 . 6H_2O$, (*b*) from $FeNH_4(SO_4)_2 . 12H_2O$, and (*c*) by dissolving A.R. iron wire in HCl and oxidizing it with hydrogen peroxide. All solutions thus prepared contained sufficient HCl (usually 0.01 *N*) to prevent precipitation of $Fe(OH)_3$.

Instruments

A Radiometer pH meter 4 with glass electrode and saturated calomel reference electrode was used for pH measurements. The instrument was standardized before and after each run using 0.05 *M* potassium tetroxalate (pH 1.68 at 25° C) and 0.05 *M* potassium acid phthalate (pH 4.01 at 25° C).

Light scattering measurements were made with a Brice-Phoenix Universal 1000 Series light scattering photometer using a semioctagonal cell (7). The light scattering by a solution was calculated from the expression:

$$\tau = A(I_S)/h(I_T)$$

where:

τ = turbidity of solution in meters^{-1},
A = a constant related to the geometry of the instrument and equal to 9.85 for the light of 436 mμ wavelength used in these measurements,
I_S = intensity of light scattered at right angles to an incident beam,
I_T = intensity of light transmitted through the solution,
h = thickness of scattering solution in meters seen by photometer measuring I_S, i.e., width of incident beam.

In a typical experiment 100 ml of ferric solution in the scattering cell was stirred magnetically and standard NaOH or NH_4OH was added from a semimicro burette. The pH was measured after each addition and the temperature of the liquid in the scattering cell was controlled at 25±0.3° C by means of water circulated through a thin hollow plate atop the magnetic stirrer. Following each pH measurement the cell was transferred to the photometer and I_S/I_T was measured. Increases in I_S/I_T (indicating precipitation of $Fe(OH)_3$) were accepted only when it was possible to repeat the readings after the solution was restirred. The induction period for precipitate formation was short compared to the time for reagent addition.

THE ACTIVITY PRODUCT OF FERRIC HYDROXIDE BY TURBIDIMETRY

R. F. PLATFORD

Electrometrically determined values for the activity product of ferric hydroxide vary from $10^{-35.5}$ to $10^{-38.7}$ (1,2,3,4) and show changes with aging of the precipitate (5). Turbidimetry has been used by other workers (6) in the study of complex formation and was used in the present work to detect the initial appearance of the precipitate produced by adding hydroxyl ions to solutions of ferric salts. Knowledge of initial ferric-ion activity and hydroxyl-ion activity at the point of initial precipitation allowed the calculation of an activity product for the reaction $Fe^{+++}+3OH^- \rightarrow Fe(OH)_3$.

EXPERIMENTAL

Reagents

All chemicals used were reagent grade or better. Solutions of ferric salts were prepared (*a*) from $FeCl_3.6H_2O$, (*b*) from $FeNH_4(SO_4)_2.12H_2O$, and (*c*) by dissolving A.R. iron wire in HCl and oxidizing it with hydrogen peroxide. All solutions thus prepared contained sufficient HCl (usually 0.01 *N*) to prevent precipitation of $Fe(OH)_3$.

Instruments

A Radiometer pH meter 4 with glass electrode and saturated calomel reference electrode was used for pH measurements. The instrument was standardized before and after each run using 0.05 *M* potassium tetroxalate (pH 1.68 at 25° C) and 0.05 *M* potassium acid phthalate (pH 4.01 at 25° C).

Light scattering measurements were made with a Brice-Phoenix Universal 1000 Series light scattering photometer using a semioctagonal cell (7). The light scattering by a solution was calculated from the expression:

$$\tau = A(I_S)/h(I_T)$$

where:

τ = turbidity of solution in meters^{-1},
A = a constant related to the geometry of the instrument and equal to 9.85 for the light of 436 mμ wavelength used in these measurements,
I_S = intensity of light scattered at right angles to an incident beam,
I_T = intensity of light transmitted through the solution,
h = thickness of scattering solution in meters seen by photometer measuring I_S, i.e., width of incident beam.

In a typical experiment 100 ml of ferric solution in the scattering cell was stirred magnetically and standard NaOH or NH_4OH was added from a semimicro burette. The pH was measured after each addition and the temperature of the liquid in the scattering cell was controlled at 25±0.3° C by means of water circulated through a thin hollow plate atop the magnetic stirrer. Following each pH measurement the cell was transferred to the photometer and I_S/I_T was measured. Increases in I_S/I_T (indicating precipitation of $Fe(OH)_3$) were accepted only when it was possible to repeat the readings after the solution was restirred. The induction period for precipitate formation was short compared to the time for reagent addition.

RESULTS AND DISCUSSION

Plots of τ vs. pH were made for a series of solutions of varying initial ferric ion concentration $[Fe^{+++}]_0$, and typical results are shown in Fig. 1. The initial break in each curve was taken as the onset of formation of colloidal $Fe(OH)_3$. No attempt was made to remove suspended matter initially present in the solution as it was found to have no effect on the

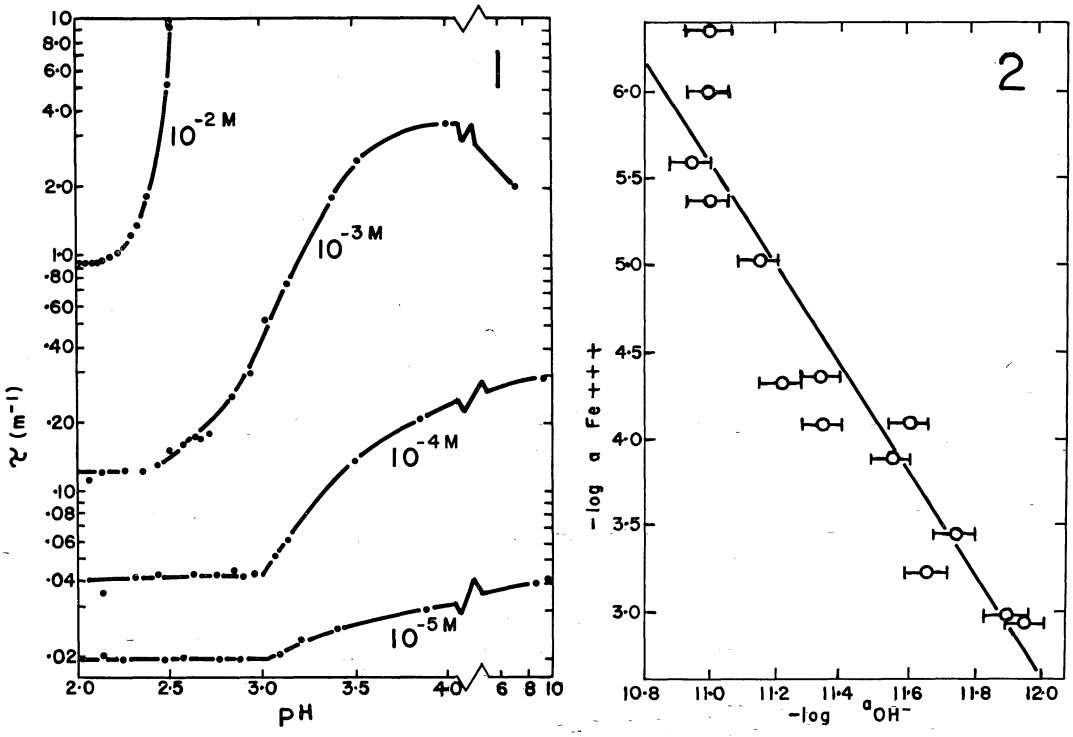

FIG. 1. Turbidity of solutions of ferric salts as a function of pH.
FIG. 2. Hydroxyl ion activity vs. ferric ion activity at point of initial precipitation.

overall results. It was unnecessary to correct for the color caused by the ferric ions in solution. The activity $a_{Fe^{+++}}$ was assumed to equal $[Fe^{+++}]_0\, fF$ where f was calculated from Kielland's expression for individual activity coefficients (8) and F was the fraction of "free" Fe^{+++} not bound to OH^-, Cl^-, or $SO_4^=$(9,10,11). Since association constants for possible complexes were not known at all ionic strengths employed, some interpolation was necessary in the evaluation of F. It was assumed that $-\log a_{OH^-} = 14.00 - pH$. The data are summarized in Table I and plotted in Fig. 2. The activity product, calculated from Fig. 2, is $10^{-38.6\pm0.4}$ at 25° C.

In spite of the questionable use of "individual" activity coefficients the method described gave reasonably constant values for $a_{Fe^{+++}} \times a^3_{OH^-}$ over a thousandfold range of $a_{Fe^{+++}}$. This indicated that the "free" Fe^{+++} was participating in the process:

$$Fe^{+++} + 3OH^- \rightarrow Fe(OH)_3$$

although the processes:

$$FeOH^{++} + 2OH^- \rightarrow Fe(OH)_3$$

and

$$Fe(OH)_2^+ + OH^- \rightarrow Fe(OH)_3$$

were presumably occurring simultaneously.

*Precipitate with NH_4OH.

The events occurring at the point of initial precipitation of $Fe(OH)_3$ are not well known (5) and the complexity of the solutions treated here, and the assumptions made, limit this method as a means of measuring activity products. Because of the variation of K_w with temperature an error of 0.3° C in the temperature of the solution will lead to an error of $\pm 10^{0.01}$ in a_{OH^-} and a resultant error in K_{sp} of $Fe(OH)_3$ of $\pm 10^{0.03}$.

The author is grateful to Dr. D. E. Ryan of Dalhousie University for helpful criticism.

*Precipitate with NH_4OH.

The events occurring at the point of initial precipitation of $Fe(OH)_3$ are not well known (5) and the complexity of the solutions treated here, and the assumptions made, limit this method as a means of measuring activity products. Because of the variation of K_w with temperature an error of 0.3° C in the temperature of the solution will lead to an error of $\pm 10^{0.01}$ in a_{OH^-} and a resultant error in K_{sp} of $Fe(OH)_3$ of $\pm 10^{0.03}$.

The author is grateful to Dr. D. E. Ryan of Dalhousie University for helpful criticism.

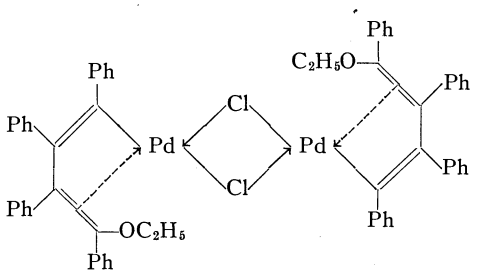
A MODIFIED SYNTHESIS OF TETRAPHENYLCYCLOBUTADIENE PALLADIUM HALIDES

P. M. Maitlis and M. L. Games

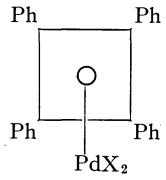
In view of the current interest in the properties and reactions of tetraphenylcyclobutadiene–metal complexes, in particular those of palladium (B, X = halogen), we wish to describe a simplification of the original preparation of (A)[1] and also the preparation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of the bromide and iodide of (B; X = Br, I). The modification entails reaction of sodium (or ammonium) chloropalladite with tolan (diphenylacetylene) in aqueous ethanol and avoids the necessity of preparing bis(benzonitrile) palladium chloride.* Further, the yield of (A) using sodium chloropalladite is rather better (92%) than that obtained with the benzonitrile complex (83%).



A



B

The conversion of complex A into tetraphenylcyclobutadiene palladium chloride (B, X = Cl) has already been noted (1); (A) can also be converted into the bromide (B, X = Br) using anhydrous hydrogen bromide (82% yield) and, less conveniently, with aqueous hydriodic acid, into the iodide (B, X = I) (50% yield). In the case of the bromide, particularly, appreciable amounts of hexaphenylbenzene were also sometimes formed. This was removed by boiling the mixture with benzene. The halides also tend to crystallize with solvent (chloroform or dichloromethane) of crystallization; these solvents were also removed on boiling of the mixtures with benzene or cyclohexane. Drying under high vacuum at 100° did not suffice.

Attempts were also made to use other palladium complexes to prepare (A); it was found that $[(\pi\text{-allyl})PdCl]_2$, $[(C_4H_9)_3P \cdot PdCl_2]_2$, and (dipyridyl)$PdCl_2$ were ineffective under normal conditions. The ligands in these complexes are presumably too firmly bound to be replaceable by acetylenes.

It was possible to prepare tetraphenylcyclobutadiene palladium bromide (B, X = Br) directly from tolan and palladium chloride in ethanol and hydrobromic acid. The yields under the best conditions, 4 hours refluxing, were much poorer than for the two-step reaction, and the product, while having the correct infrared spectrum, gave very high palladium analyses. In addition, a 41% yield of desoxybenzoin was obtained. More vigorous conditions (17 hours refluxing) gave poorer yields, while milder conditions (3 days at 25°) gave low yields of complexes A and B (infrared spectra). Use of hydrochloric instead of hydrobromic acid gave analogous results.

The formation of desoxybenzoin (none was formed in the absence of palladium salts, in the absence of acid, or in reactions at 25°) by hydration of tolan parallels the interesting recent discovery of a similar mercuric perchlorate catalyzed reaction (3). It therefore appears that palladium salts can react with tolan in at least two different ways, either to oligomerize it to (A), (B), or hexaphenylbenzene (1), depending on conditions, or to hydrate it to desoxybenzoin.

**Although numerous references (2) in the literature claim high yields for the preparation of this complex, we find that it is never possible to dissolve all of a given sample of palladium chloride (99.98% pure) in benzonitrile, thus resulting in low conversions. Addition of a solvent does not appear to improve the yield.*

EXPERIMENTAL

All melting points were carried out in evacuated capillaries and are uncorrected.

Complex A

Sodium chloride (2.5 g; 42.7 mmoles) and palladium chloride (3.75 g; 21.1 mmoles) were dissolved in hot water (25 ml) and filtered into a solution of tolan (8.25 g; 46.4 mmoles) in ethanol (95%; 130 ml). The solution was stirred at 25° for 1 hour, then filtered to give small yellow-brown crystals (8.22 g). The mother liquors were evaporated to small volume (<50 ml) on a rotary evaporator at 40° and gave a further crop of crystals of crude complex A (3.49 g). When the combined solids had been dissolved in dichloromethane and filtered, sodium chloride (1.17 g) was recovered. The filtrate gave the purified complex A (10.54 g; 92%). This was twice recrystallized from dichloromethane solution by addition of ethanol to give orange-red prisms, m.p. 181° (decomp.). The material had an infrared spectrum identical with that of the material prepared previously (1) and analyzed correctly. Calc. for $(C_{30}H_{25}OPdCl)_X$: Pd, 19.6%. Found: Pd, 19.7%. No desoxybenzoin was formed in this reaction.

Tetraphenylcyclobutadiene Palladium Bromide (B, X = Br)

Anhydrous hydrogen bromide was passed for 20 minutes into a solution of complex A (10.0 g) in chloroform (210 ml). Some complex B (solvated) crystallized out and the remainder was precipitated with light petroleum (b.p. 30–60°) to give crude (solvated) tetraphenylcyclobutadiene palladium bromide (10.4 g). Chloroform of crystallization and hexaphenylbenzene were removed by boiling the crude product with benzene (100 ml) for 30 minutes. Filtration gave pure tetraphenylcyclobutadiene palladium bromide (9.4 g, 82%). An analytical sample was prepared by dissolving the complex in dichloromethane saturated with hydrogen bromide; then the solution was filtered and allowed to crystallize. After removal of dichloromethane of crystallization by boiling with benzene and vacuum-drying, the compound analyzed correctly. Calc. for $C_{28}H_{20}PdBr_2$: Pd, 17.1%. Found: Pd, 17.1%. The infrared spectrum (KBr disk) of this complex was identical with that of tetraphenylcyclobutadiene nickel bromide (1) and tetraphenylcyclobutadiene palladium chloride (1) in the region measured (2–16 μ). The bromide (B, X = Br) had m.p. 347–348° (decomp.), the chloride (B, X = Cl) m.p. 297–298° (decomp.).

Tetraphenylcyclobutadiene Palladium Iodide (B, X = I)

Because of the expense of anhydrous hydrogen iodide the following method was used.

Complex A (5.0 g, 9.2 mmoles) dissolved in chloroform (50 ml) was refluxed with aqueous hydriodic acid (47%; 25 ml) for 17 hours. Filtration gave black needles (3.97 g) which, after being boiled with cyclohexane, gave the pure solvent-free iodide (B, X = I; 3.31 g; 50%) m.p. 287–290° (decomp.). Calc. for $C_{18}H_{20}PdI_2$: Pd, 14.9%. Found: Pd, 14.7%. The infrared spectrum was again identical with those of the bromide and chloride above.

Reaction of Tolan with Palladium Chloride in Aqueous Ethanolic Hydrobromic Acid

A solution of palladium chloride (1.78 g; 10 mmoles) in aqueous hydrobromic acid (48%; 5 ml) and ethanol (20 ml) was added to a solution of tolan (3.56 g; 20 mmoles) in ethanol (175 ml) and refluxed for 4 hours. Filtration gave crude tetraphenylcyclobutadiene palladium bromide (3.32 g). Calc. for $C_{28}H_{20}PdBr_2$: Pd, 17.1%. Found: Pd, 20.22, 20.87%, identified by infrared spectrum. The filtrate was evaporated to dryness, boiled with light petroleum (b.p. 100–120°), filtered, and concentrated to give desoxybenzoin (1.6 g, 41%), which was recrystallized from carbon tetrachloride, m.p. 54–55°, unchanged on admixture of a synthetic sample (4), m.p. 54–55°. The infrared spectra of the two samples were identical.

Longer periods of refluxing gave the same products in poorer yields. Reaction at 25° for 3 days gave poor yields of complex B (X = Br) containing large amounts of hexaphenylbenzene and complex A, even when a large excess of hydrobromic acid was used. No desoxybenzoin could be detected in this last reaction.

The authors thank the National Research Council of Canada and the Research Corporation of New York for supporting this work.

THE ISOBARIC BOILING POINTS OF THE SYSTEM: ACETIC ACID – CHLOROFORM – WATER AT A PRESSURE OF 760 mm Hg

A. N. CAMPBELL AND J. M. T. M. GIESKES

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In previous papers where complete bibliographies are given, Campbell, Kartzmark, and Gieskes (1) have studied the isothermal vapor pressures at 25° C, and Campbell and Kartzmark (2) the critical phenomena of the system acetic acid – chloroform – water. It seemed a desirable sequel to the above work to determine the isobaric boiling points under one atmosphere pressure. Little discussion is necessary since the boiling point diagram is largely a consequence of the vapor pressure diagram. Further work is proceeding on the dielectric constants and heats of mixing of this system.

EXPERIMENTAL

Pressure was controlled with an accuracy of ±0.02 mm, by means of a two-stage barostat of the type described by Campbell and Dulmage (3). For the study of the liquid–vapor equilibria of the acetic acid – chloroform system, we used the equilibrium still of Scatchard, Raymond, and Gillman (4). This still, however, was found not to be satisfactory for the ternary mixtures, because in these mixtures the distillates usually separate into two layers so that no proper equilibrium can be established. For this purpose, therefore, we used the apparatus of Reinders and de Minjer (5); instead of their bell stirrer, we introduced a Scatchard pump. Nevertheless, the accuracy of this apparatus is not high and the boiling temperatures of the ternary system are not more accurate than ±0.5° C. The corresponding accuracy with the Scatchard still is ±0.1° C. Analyses were carried out by the method described by Campbell, Kartzmark, and Gieskes (1). Temperatures were measured with a double junction copper–constantan thermocouple and a precision potentiometer with an accuracy of ±0.1° C. The materials were purified by the methods described by Campbell, Kartzmark, and Gieskes (1).

RESULTS

Acetic Acid – Chloroform

TABLE I

Boiling points of acetic acid – chloroform mixtures at P = 760 mm

Liquid wt. % HAc	Vapor wt. % HAc	Boiling point, ° C
0.0	0.0	61.4
1.2	0.2	61.5
9.1	1.6	63.3
32.5	6.9	69.8
35.2	7.6	71.0
57.0	18.0	81.5
58.5	17.6	81.8
78.6	32.9	93.5
82.0	39.2	96.8
91.0	63.9	106.0
98.6	87.0	113.7
99.0	97.4	117.0
100.0	100.0	118.1

When the above figures are plotted in the usual way, the simplest type of boiling point diagram is obtained, without maximum or minimum; in other words, complete separation of chloroform and acetic acid is possible by fractional distillation.

Acetic Acid – Chloroform – Water

Since the vapor phase from ternary mixtures almost always separates into two layers on liquefaction, the analytical figures for vapor composition are unreliable and therefore we do not reproduce data for vapor composition. The boiling point data are reported in Table II. The experiments were carried out in series, starting with a mixture of given composition. The removal of condensed vapor phase caused the composition of the system as a whole to change, so that each set gives an indication of the course of progressive distillation.

TABLE II

Boiling points of mixtures of acetic acid, chloroform, and water, P = 760 mm

Series No.	Wt. % HAc	Wt. % H_2O	Boiling point	Series No.	Wt. % HAc	Wt. % H_2O	Boiling point

	72.2	5.8	84.6				
	73.1	6.0	85.2				

DISCUSSION

The isobaric behavior of the system: acetic acid – chloroform is what would be expected from the previous isothermal work (1, 2), where it is shown that, provided that due allowance is made for the fact that acetic acid is dimerized, the behavior is ideal. Figure 1 has been constructed for the ternary system from the known data and the data of this paper to give a graphical representation of the equilibria and relative liquid and vapor compositions. The isothermal sections (consolute solutions) are taken from Brancker, Hunter, and Nash (6) and from Campbell and Kartzmark (2). We have not attempted to find the ternary minimum boiling point, if it exists, because it must be very close to the minimum in the binary system, chloroform–water (5), and the accuracy of our apparatus was not sufficient to detect it. Figure 2 represents diagrammatically the distillation paths, derived from the data of Table II. The form of the distillation paths is what would be expected. Reinders and de Minjer (7) discuss in detail the several possible types of distillation path diagrams. The present system shows some similarity to their Fig. 3, with the difference that in the present case a miscibility gap exists. Systems of the latter type are discussed by Haase (8).

Δ^{11}-STEROIDS

P. ZIEGLER AND A. A. AMOS

During attempts at introduction of a Δ^{11} double bond into some steroids, we had occasion to prepare 3,20-dioxo-12α-tosyloxypregnane. This compound has previously been reported as having m.p. 130–132° (1, 2), 120–125° (3), 129–131° (4), but has otherwise not been characterized satisfactorily. In this laboratory, 3,20-dioxo-12α-hydroxypregnane was treated with *p*-tosyl chloride to yield 90% of crystalline material which, after purification, had m.p. 155–156.5°. Elemental analyses and ultraviolet absorption data indicated that our compound is authentic 3,20-dioxo-12α-tosyloxypregnane. The discrepancy in melting point might be due to polymorphism, which is known (3) to occur in this particular series of steroids. The steroid tosylate was then converted to 3,20-dioxo-12α-tosyloxypregnane bis-ethylene ketal, a crystalline compound which gave correct analyses and exhibited the expected ultraviolet absorption data (ϵ = 12,900 at 224 mμ in isooctane). This compound, obtained in the form of an amorphous solid, has been reported (4) to have ϵ = 25,120 at 225 mμ in ethanol.

Dehydrotosylation of 3,20-dioxo-12α-tosyloxypregnane to 3,20-dioxo-Δ^{11}-pregnene has been effected (1) by refluxing with collidine, but the yields of product were low (32%). A more recently developed procedure (2, 3, 4), consisting of dehydrotosylation by chromatography through a column of activated alumina, gave much improved yields (70–85%). In order to carry out this conversion on a larger scale, it seemed desirable to find an alternative method which would avoid chromatography and, at the same time, provide adequate yields. It has now been found that this can be accomplished (50–60% yield) by dehydrotosylating in N-methylpyrrolidone containing a small amount of water and 10% potassium acetate. It seems that this reaction proceeds readily in a slightly basic medium of high dielectric constant.

EXPERIMENTAL

3,20-Dioxo-12α-tosyloxypregnane

3,20-Dioxo-12α-hydroxypregnane (4 g), m.p. 182.5–184.5° and $[\alpha]_D^{25}$ +135.8° (*c*, 0.41, ethanol), was dissolved in dry pyridine (8 ml). After addition of *p*-tosyl chloride (4.5 g) the mixture was kept at 37° for 5 days. By that time the solution had turned brown and long crystals of pyridine hydrochloride had deposited. The solution was then cooled to 0°, the excess reagent was destroyed by addition of water (1 ml) and the mixture was poured into dilute hydrochloric acid. The products were extracted with ether, the solvent extract was washed with dilute acid, then with water until neutral. After it was dried over sodium sulphate, filtered, and evaporated, there remained 5.72 g of residue which crystallized from ether–hexane. In two crops, 5.17 g (89%) of crystals, m.p. 148–153°, were obtained. Three further recrystallizations from ether–hexane provided the analytical specimen, m.p. 155–156.5° (decomp. at 160°), $[\alpha]_D^{25}$ +66.1° (*c*, 0.61, ethanol), $\lambda_{max}^{isooctane}$ 224 mμ (ϵ 12,020). Calculated for $C_{28}H_{38}O_5S$: C, 69.10; H, 7.87; S, 6.59. Found: C, 69.14; H, 7.84; S, 6.43.

This compound has previously been reported as having m.p. 130–132° (1, 2), 120–125° (3), 129–131° (4), but has otherwise not been characterized satisfactorily. In this laboratory, 3,20-dioxo-12α-hydroxypregnane was treated with *p*-tosyl chloride to yield 90% of crystalline material which, after purification, had m.p. 155–156.5°. Elemental analyses and ultraviolet absorption data indicated that our compound is authentic 3,20-dioxo-12α-tosyloxypregnane. The discrepancy in melting point might be due to polymorphism, which is known (3) to occur in this particular series of steroids. The steroid tosylate was then converted to 3,20-dioxo-12α-tosyloxypregnane bis-ethylene ketal, a crystalline compound which gave correct analyses and exhibited the expected ultraviolet absorption data (ϵ = 12,900 at 224 mμ in isooctane). This compound, obtained in the form of an amorphous solid, has been reported (4) to have ϵ = 25,120 at 225 mμ in ethanol.

Dehydrotosylation of 3,20-dioxo-12α-tosyloxypregnane to 3,20-dioxo-Δ^{11}-pregnene has been effected (1) by refluxing with collidine, but the yields of product were low (32%). A more recently developed procedure (2, 3, 4), consisting of dehydrotosylation by chromatography through a column of activated alumina, gave much improved yields (70–85%). In order to carry out this conversion on a larger scale, it seemed desirable to find an alternative method which would avoid chromatography and, at the same time, provide adequate yields. It has now been found that this can be accomplished (50–60% yield) by dehydrotosylating in N-methylpyrrolidone containing a small amount of water and 10% potassium acetate. It seems that this reaction proceeds readily in a slightly basic medium of high dielectric constant.

EXPERIMENTAL

3,20-Dioxo-12α-tosyloxypregnane

3,20-Dioxo-12α-hydroxypregnane (4 g), m.p. 182.5–184.5° and $[\alpha]_D^{25}$ +135.8° (*c*, 0.41, ethanol), was dissolved in dry pyridine (8 ml). After addition of *p*-tosyl chloride (4.5 g) the mixture was kept at 37° for 5 days. By that time the solution had turned brown and long crystals of pyridine hydrochloride had deposited. The solution was then cooled to 0°, the excess reagent was destroyed by addition of water (1 ml) and the mixture was poured into dilute hydrochloric acid. The products were extracted with ether, the solvent extract was washed with dilute acid, then with water until neutral. After it was dried over sodium sulphate, filtered, and evaporated, there remained 5.72 g of residue which crystallized from ether–hexane. In two crops, 5.17 g (89%) of crystals, m.p. 148–153°, were obtained. Three further recrystallizations from ether–hexane provided the analytical specimen, m.p. 155–156.5° (decomp. at 160°), $[\alpha]_D^{25}$ +66.1° (*c*, 0.61, ethanol), $\lambda_{max}^{isooctane}$ 224 mμ (ϵ 12,020). Calculated for $C_{28}H_{38}O_5S$: C, 69.10; H, 7.87; S, 6.59. Found: C, 69.14; H, 7.84; S, 6.43.

3,20-Dioxo-12α-tosyloxypregnane Bis-ethylene Ketal

3,20-Dioxo-12α-tosyloxypregnane (10 g) and *p*-toluenesulphonic acid (0.35 g) were stirred and refluxed for 7 hours in benzene (160 ml) and ethyleneglycol (30 ml). A Dean–Stark trap was used to separate the water formed. The mixture was cooled, neutralized with sodium bicarbonate, and diluted with water; the benzene extract was separated, then washed with water, dried, and evaporated. The residue (12.5 g) crystallized from ether to provide 9.3 g (85%) of ketal, m.p. 148–150° (decomp.). Repeated recrystallizations from ether gave the pure compound, m.p. 150° with decomp. (the melting point depends on the rate of heating), $[\alpha]_D^{25}$ +66.4° (*c*, 0.76, ethanol), and $\lambda_{max}^{isooctane}$ 224 mμ (ε 12,900). Calculated for $C_{32}H_{46}O_7S$: C, 66.87; H, 8.07; S, 5.58. Found: C, 67.03; H, 8.12; S, 5.49. This compound has been described (4) to be amorphous with $\lambda_{max}^{ethanol}$ 225 mμ (ε 25,120).

3,20-Dioxo-Δ¹¹-pregnene

Potassium acetate (3.75 g), water (1.25 ml), and N-methylpyrrolidone (37.5 ml) were stirred and heated to 110°. After addition of 3,20-dioxo-12α-tosyloxypregnane (5 g), the temperature was kept at 115–120° for 3.5 hours. The reaction mixture was then poured into water, the products were extracted with ether, the solvent extract was washed, dried, and evaporated. The residue crystallized from ether–hexane to yield, in two crops, 1.77 g (55%) of material, m.p. 130–133°. Two recrystallizations gave the pure compound, m.p. 138.5–140° and $[\alpha]_D^{25}$ +94.0° (*c*, 0.424, ethanol).

When 3,20-dioxo-Δ¹¹-pregnene was dissolved in methanol containing traces of mineral acid, the corresponding 3-dimethylketal precipitated as white crystals. Repeated recrystallization from ether gave m.p. 137–139° and $[\alpha]_D^{26}$ +89.0° (*c*, 0.551, chloroform). Calculated for $C_{23}H_{36}O_3$: C, 76.62; H, 10.04; O, 13.31. Found: C, 76.45; H, 10.04; O, 13.49.

REACTIONS OF BENZYLIDENETRIPHENYLPHOSPHORANE WITH SOME DICARBONYL COMPOUNDS

J. Parrick

The reactions of Wittig reagents with certain dicarbonyl compounds is of proved synthetic utility (1). We have found that the reaction of benzylidenetriphenylphosphorane (I) with some 1,2-dicarbonyl compounds gave 2-benzylidene ketones, even when 2 molar equivalents of the phosphorane were used.

Phosphorane (I) reacted with phenanthraquinone to give 9,10-dihydro-9-benzylidene-10-oxophenanthrene but no reaction was observed with anthraquinone, and only intractable tars were obtained with diacetyl, *p*-benzoquinone, and 1,2- and 1,4-naphthoquinone. A mixture of what was assumed to be the two geometrically isomeric 1,2,3-triphenylprop-1-en-3-ones was obtained from benzil.

The reaction of Wittig reagents with compounds having a carbonyl group in a heterocyclic ring has been little investigated. Isatin was found to react readily with 1 molar equivalent of benzylidenetriphenylphosphosphorane to give 3-benzylidene oxindole, the same as that prepared from oxindole and benzaldehyde. Thus, the two reactions give the same pure stereoisomer. Reduction of 3-benzylidene oxindole with lithium aluminum hydride gave 3-benzylindole.

3,20-Dioxo-12α-tosyloxypregnane Bis-ethylene Ketal

3,20-Dioxo-12α-tosyloxypregnane (10 g) and *p*-toluenesulphonic acid (0.35 g) were stirred and refluxed for 7 hours in benzene (160 ml) and ethyleneglycol (30 ml). A Dean–Stark trap was used to separate the water formed. The mixture was cooled, neutralized with sodium bicarbonate, and diluted with water; the benzene extract was separated, then washed with water, dried, and evaporated. REACTIONS OF BENZYLIDENETRIPHENYLPHOSPHORANE WITH SOME DICARBONYL COMPOUNDS

J. Parrick

The reactions of Wittig reagents with certain dicarbonyl compounds is of proved synthetic utility (1). We have found that the reaction of benzylidenetriphenylphosphorane (I) with some 1,2-dicarbonyl compounds gave 2-benzylidene ketones, even when 2 molar equivalents of the phosphorane were used.

Phosphorane (I) reacted with phenanthraquinone to give 9,10-dihydro-9-benzylidene-10-oxophenanthrene but no reaction was observed with anthraquinone, and only intractable tars were obtained with diacetyl, *p*-benzoquinone, and 1,2- and 1,4-naphthoquinone. A mixture of what was assumed to be the two geometrically isomeric 1,2,3-triphenylprop-1-en-3-ones was obtained from benzil.

The reaction of Wittig reagents with compounds having a carbonyl group in a heterocyclic ring has been little investigated. Isatin was found to react readily with 1 molar equivalent of benzylidenetriphenylphosphosphorane to give 3-benzylidene oxindole, the same as that prepared from oxindole and benzaldehyde. Thus, the two reactions give the same pure stereoisomer. Reduction of 3-benzylidene oxindole with lithium aluminum hydride gave 3-benzylindole.

EXPERIMENTAL

The reactions were performed in apparatus which was thoroughly purged with dry nitrogen.

Benzylidenetriphenylphosphorane (I)

An ethanolic solution was prepared as described by Trippett (2).

9,10-Dihydro-9-benzylidene-10-oxophenanthrene

Addition of a hot benzene solution (200 ml) of phenanthraquinone (2.08 g, 0.01 mole) to a warm (0.4 *M*) ethanolic solution of phosphorane (I) (0.023 mole) gave a red solution, which was allowed to stand at room temperature for 1 day and then boiled under reflux for 5 hours. The solvent was distilled off and the residue extracted with hot petroleum ether (b.p. 60–80°). The extract deposited triphenylphosphine oxide on cooling and, after filtration, the mother liquor yielded 9,10-dihydro-9-benzylidene-10-oxophenanthrene on evaporation. Crystallization from a large volume of ethanol yielded colorless prisms, m.p. 146–147° (1.3 g, 46%). λC_6H_{12} 229, 248, 280, 320, 352, 370 mμ, log ε 4.33, 4.4, 4.11, 3.94, 3.91, 3.42, 3.51. Carbonyl stretching frequency: 1628 cm^{-1}. (Found: C, 89.1; H, 5.25. $C_{21}H_{14}O$ requires C, 89.4; H, 5.5%.)

1,2,3-Triphenylprop-1-en-3-one

A hot ethanolic solution of benzil (2.1 g, 0.01 mole) was added to the ethanolic phosphorane solution (I) (0.02 mole) and the red solution boiled under reflux for 6 hours. Isolation by the procedure described above afforded a pale yellow solid (1.8 g). Fractional crystallization from ethanol gave a less soluble fraction as colorless needles (0.9 g, 32%), m.p. 98–99°. Carbonyl stretching frequency: 1649 cm^{-1}. (Found: C, 88.7; H, 5.7. $C_{21}H_{16}O$ requires C, 88.8; H, 5.6%.) The more soluble fraction deposited as colorless prisms (0.4 g), m.p. 89–90°. Carbonyl stretching frequency: 1666 cm^{-1}. (Found: C, 89.0; H, 6.0%.)

3-Benzylidene Oxindole

Addition of a hot ethanolic solution of isatin (2.94 g, 0.02 mole) to the ethanolic phosphorane (I) (0.02 mole) gave a deep red solution, but the color faded after 2 hours with the formation of bright yellow needles of 3-benzylidene oxindole (78%), m.p. 177–178°. (Found: C, 81.0; H, 4.9. Calc. for $C_{15}H_{11}NO$: C, 81.5; H, 5.0%.) The compound prepared from oxindole and benzaldehyde had m.p. 176–177° (lit. m.p. 176° (3)), and showed no depression of melting point on admixture with the first specimen.

3-Benzylindole

Reduction of 3-benzylidene oxindole with lithium aluminum hydride in ether at room temperature gave 3-benzylindole, m.p. 106–108° (lit. m.p. 107° (4)).

For personal use only.

optical rotation, with that obtained by degradation of I*d*, proved that both alkaloids possessed the same structure in the saturated part of the molecule and had the same absolute configuration. A different reason had then to be found for the difference in optical rotation between the two alkaloids.*

A further examination of a series of derivatives of these alkaloids brought to light three significant differences between those N(1)-acyl derivatives with an OH group at C-17 and those with an OMe group at this position: the former show the hydrogen-bonded carbonyl near 1635 cm^{-1} in the infrared while the corresponding absorption is near 1660 cm^{-1} in the latter; the phenolic alkaloids show the C-2 proton at about 5.9 τ in the n.m.r. while the methoxy analogues show this signal near 5.5 τ (1, 2, 3); optical rotations of the phenolic alkaloids have large positive values whereas the O-methyl derivatives have large negative values. Values recorded for a number of derivatives prepared in the present study are listed in the table and compared with values recorded elsewhere for alkaloids which retain the aspidospermidine (4) skeleton. Comparison shows that the phenomenon is quite general; pyrifolidine (2) has, of course, a completely antipodal relationship. In fact the changes in optical rotation are also reflected in alkaloids in which the saturated part of the molecule has been modified, although it is not surprising to find, with molecules in which an extra asymmetric center has been introduced (II, III), that the values for the rotations no longer match the earlier pattern completely.

Conversion of an N-acyl-17-hydroxyaspidospermidine to its 17-acetoxy derivative produces a shift in rotation in the same direction as does conversion to a 17-methoxy derivative, but the effect is less pronounced (I*l*, *m*, *n*). N-Deacylation has a similar effect, and now the nature at the substituent at C-17, has little influence on the rotation (I*o*, *p*, *q*).

It is reasonable to consider it likely that these three parallel effects, i.e. shifts in the infrared, n.m.r., and specific rotation, have a common cause; that is to say, the presence or absence of a hydrogen-bonded acyl group, a feature that readily accounts for the change in the infrared spectrum, also leads to the possibility of other more subtle differences in the molecular environment and these are reflected in the n.m.r. spectrum and the optical rotation. It is, however, difficult to relate cause and effect in a detailed way. The unlikely possibility that changes in the conformation of ring C are involved can be disposed of since, although the *position* of the C-2 proton signal in the two series is different, its *pattern* is the same and shows the C-2 proton signal split by two vicinal protons with identical orientations with respect to the C-2 proton in both series (J values are approximately 6 and 11 c.p.s.) (5).

The effect observed must, therefore, be directly related to changes in the orientation of the N-acyl group. The n.m.r. differences would then arise from the different amount of diamagnetic shielding produced at the C-2 proton by the acyl carbonyl in two different conformations.†‡ The differences in optical rotation can then be traced to a conformational asymmetry (8) effect of the acyl group. It seems possible that the effect may be simply conformational or it may be that the contribution of the asymmetric center at C-2 is also influenced by a variation in the polarizability (8) of the C—N bond depending on whether or not the N-acyl group is hydrogen-bonded. It any event the system does not appear to be amenable to explicit analysis on the basis of available data and perhaps

**Ironically, an alkaloid belonging to the antipodal series was soon reported when it was shown that pyrifolidine is the enantiomer of O-methylaspidocarpine (Ib) (2). (The structures shown do not necessarily indicate the true absolute configurations.)*

†It is, however, difficult to see from models that the sense of this change is in the direction anticipated (6).

‡It is significant that Anet has recently reported a detailed n.m.r. study of strychnospermine in which he demonstrates that the N-acetyl group has a high conformational stability (7).

the most significant point at present is that a fairly small change in a molecule at a position well removed from an asymmetric center can have a large influence on the optical activity.

EXPERIMENTAL

O-Acetyl-O-demethylaspidospermine

Aspidospermine (Inland Alkaloid Co.) (0.616 g) was treated successively with hydrobromic acid and acetic anhydride by the method described for the preparation of O,O-diacetyl-O-demethylaspidocarpine (1). The isolation of the product was also the same as for the aspidocarpine derivative. The crude residue (0.550 g) was recrystallized from a mixture of hexane and acetone, and formed a product (0.478 g), m.p. 155–157°, which, on further recrystallization from the same solvent, was obtained as fine white rods, m.p. 157–158°, $[\alpha]_D^{25}$ +24.3° (*c*, 1.03; $CHCl_3$); infrared (chloroform), 1760(s), 1662(s) cm^{-1}.

Witkop (18) has obtained this compound, which he describes as birefringent prisms, m.p. 158–158.5° by a lightly different technique. His published spectral data correspond closely with the spectrum of our material.

O-Demethylaspidospermine

O-Acetyl-O-demethylaspidospermine (79 mg) was dissolved in methanol (5 ml) to which was added 20% aqueous sodium hydroxide (0.5 ml) and partial hydrolysis carried out in the manner described for the preparation of O-demethylaspidocarpine (1). The crude product (46 mg) was recrystallized with difficulty from hexane and obtained as white prisms, m.p. 120–131°. Anal. Calc. for $C_{21}H_{28}N_2O_2$: C, 74.08; H, 8.28.

For personal use only.

Found: C, 74.23; H, 8.21. $[\alpha]_D^{25}$ +132° (*c*, 0.37; $CHCl_3$). Infrared ($CHCl_3$), 1634(s) cm^{-1}; no OH absorption apparent (compare with aspidocarpine (1); the spectrum is very similar to that of aspidocarpine, but the latter has an additional strong peak at 1080 cm^{-1}).

Witkop (18) has prepared this compound by a different technique, but he failed to obtain it crystalline. However, the infrared characteristics which he describes appear to confirm the identity of the two products.

ACKNOWLEDGMENT

ION–MOLECULE REACTIONS STUDIED BY TIME-OF-FLIGHT MASS SPECTROMETRY

Clifford W. Hand and Hanns von Weyssenhoff

Many reactions between ions and molecules in the gas phase have been studied during the last ten years; this field has been extensively reviewed by Lampe, Franklin, and Field (1), and by Talroze (2). The usual experimental method (1) of obtaining rate constants for such reactions has been to operate a mass spectrometer at relatively high pressure (10^{-4}–10^{-1} Torr.) in the source region. The primary ions (those formed by electron impact in the mass spectrometer) undergo reactive collisions with neutral species as they pass from their point of formation to the exit slit under the influence of the electric field. The average residence time of an ion in the high pressure source region can be calculated from a knowledge of the source geometry and the electric field; the rate constant for the reaction under investigation is then obtained from the residence time, the experimentally determined pressure, and the ion currents measured at the detector.

Found: C, 74.23; H, 8.21. $[\alpha]_D^{25}$ +132° (*c*, 0.37; $CHCl_3$). Infrared ($CHCl_3$), 1634(s) cm^{-1}; no OH absorption apparent (compare with aspidocarpine (1); the spectrum is very similar to that of aspidocarpine, but the latter has an additional strong peak at 1080 cm^{-1}).

We have developed a method in which time, rather than pressure or potential gradient, is the experimental variable. The basic instrument is a Bendix Model 14 time-of-flight mass spectrometer which has been modified as follows. *1.* A stainless steel box of dimensions 1.5 in.$\times$1.5 in$\times$0.240 in. was constructed around the ion source region, forming a reaction chamber with the short side parallel to the ion trajectories. The chamber is provided with a 0.1 in. diameter ion exit orifice, 0.030 in.$\times$0.200 in. electron beam entrance and exit slits, a 0.125 in. diameter gas inlet tube, and a 0.250 in. diameter orifice for pressure measurement. An auxilliary 6 in. diffusion pump was installed so that the source region could be differentially pumped. The instrument can be operated with up to 0.080 Torr. in the source region, while the pressure in the rest of the instrument remains less than 2×10^{-5} Torr. Pressures in the source region are measured with a McLeod gauge and (or) a Consolidated micromanometer. *2.* A delay circuit (available from the Bendix Corp. as the Time Lag Focus Modification) was provided to allow the introduction of a variable and accurately known delay between the ionizing electron pulse and the pulse which withdraws the ions for analysis. Thus primary ions formed in the electron beam react for a known time at thermal velocities in a field-free space.

To test the method we have reinvestigated the reaction $CH_4^+ + CH_4 = CH_5^+ + CH_3$. With the usual assumptions that competitive and consecutive reactions are negligible (3), that the ions CH_4^+ and CH_5^+ are collected by the detector with equal efficiency, and that these ions are lost at equal rates by neutralization at the walls and by flow out of the reaction chamber, the kinetic equation may be integrated to

$$\log_{10}(I_{16}+I_{17})/I_{16} = k[CH_4]t/2.303,$$

where I_m is the measured intensity of the ion current of mass m, k is the bimolecular rate constant, and t is the time.

Figure 1 shows a typical plot of $\log(I_{16}+I_{17})/I_{16}$ vs. time between formation and

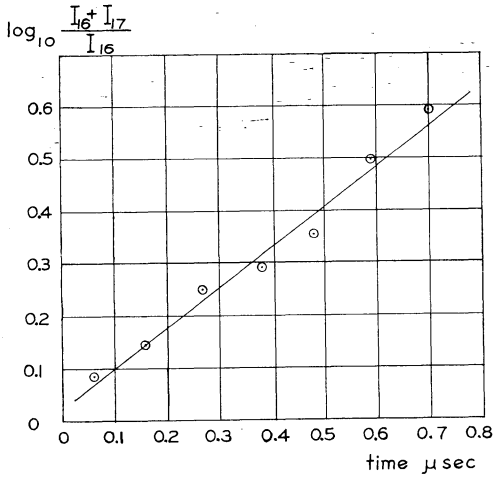

FIG. 1. $\log_{10}(I_{16}+I_{17})/I_{16}$ vs. time. Source pressure 0.049 Torr. $k = 10.3\times10^{-10}$ cc/molecule-sec.

analysis of the ions; the data were obtained at a source pressure of 0.049 Torr. and result in a rate constant of $k = 10.3\times10^{-10}$ cc/molecule-sec. Table I shows rate constants for this reaction determined at various pressures. The average value of the rate constant, 11×10^{-10} cc/molecule-sec, is in good agreement with the value $k = 8.9\times10^{-10}$ cc/molecule-sec, obtained by Franklin, Field, and Lampe (3), over a pressure range of 10^{-4}–10^{-2}

A REMARK ON THE ULTRAVIOLET SPECTRUM OF CHRYSENE

P. Sauvageau and C. Sandorfy

It has been shown previously (1, 2, 3) by the measurement of low-temperature absorption spectra and fluorescence spectra of benzo[*a*]anthracene derivatives (1,2-benzanthracene in the old nomenclature) that in the case of this molecule the two longest wavelength electronic band systems (α and p according to Clar's nomenclature) overlap to a large extent so that the α-band system continues amongst or underneath the bands belonging to the p-band system.

The work of Jones and Spinner (4, 5) on anthracene, phenanthrene, and benzo[*c*]-phenanthrene (3,4-benzophenanthrene in the old nomenclature) did not yield similar results and it was suggested (3) that such a situation is likely to occur only with molecules intermediate between the "long field" and "round field" type (6) where the p-band system approached very closely but did not entirely overtake the α-band system. The lack of a good mirror-image relationship between the absorption and fluorescence spectra of chrysene (7) seemed to indicate that this molecule is of this type. We have therefore measured the absorption spectra at 83° K (in a 6:1 mixture of isopentane and 3-methylpentane) and the fluorescence spectra (in cyclohexane solution) of chrysene (Fig. 1),

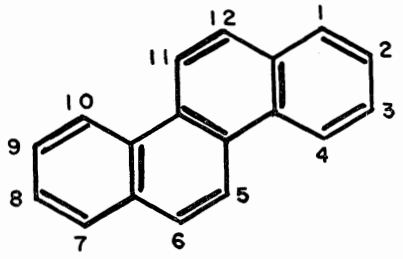

FIG. 1. The numbering of carbon atoms in the chrysene molecule.

5-methyl-, 6-methyl-, and 5,6-dimethyl-chrysene, samples of which were made available to us by Professor M. S. Newman of Ohio State University.

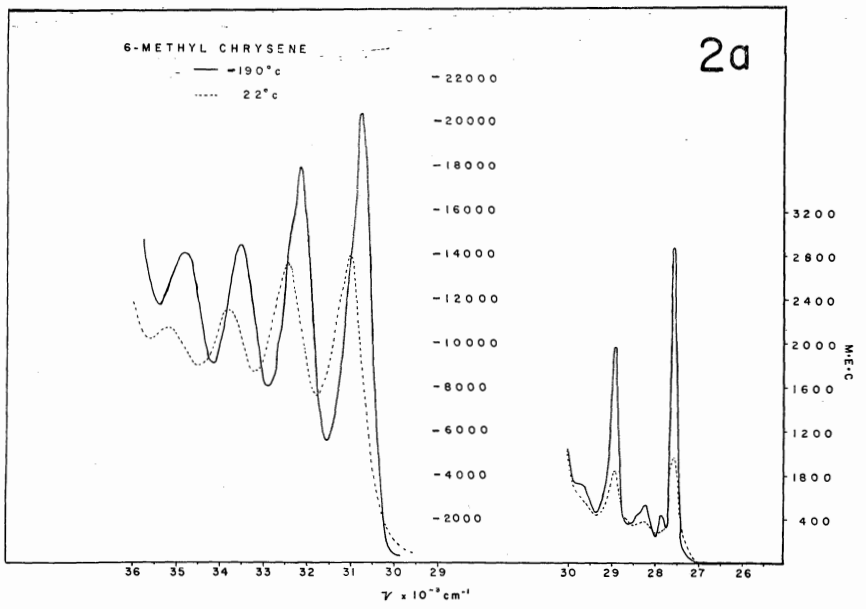
Only the results for 6-methylchrysene (Fig. 2) will be discussed here but the observations made on the other compounds were essentially the same.

1. The low-temperature absorption spectrum shows a somewhat improved resolution of the vibrational fine structure with respect to the room temperature spectrum but it does not give any significant new indications.

2. Taking the first apparent peak (of lowest and highest frequency respectively) for the 0–0 band in both the absorption of fluorescence spectra we find that they are shifted with respect to each other by 383 cm^{-1} for 6-methyl-, 144 cm^{-1} for 5-methyl-, and 407 cm^{-1} for 5,6-dimethyl-chrysene. Schoental and Scott (7) found 150 cm^{-1} for chrysene itself. These differences tend to be greater than for most other aromatic hydrocarbons.

3. The spacing between the main peaks is of the order of 1350 to 1400 cm^{-1} for the α- (and p-) band systems in absorption but only about 1150 to 1200 cm^{-1} in fluorescence where the bands are broader.

4. While the apparent spread of the weak α-band system is only about 2000 cm^{-1} in absorption, in fluorescence it is about 4000 cm^{-1} where four main peaks are observed



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

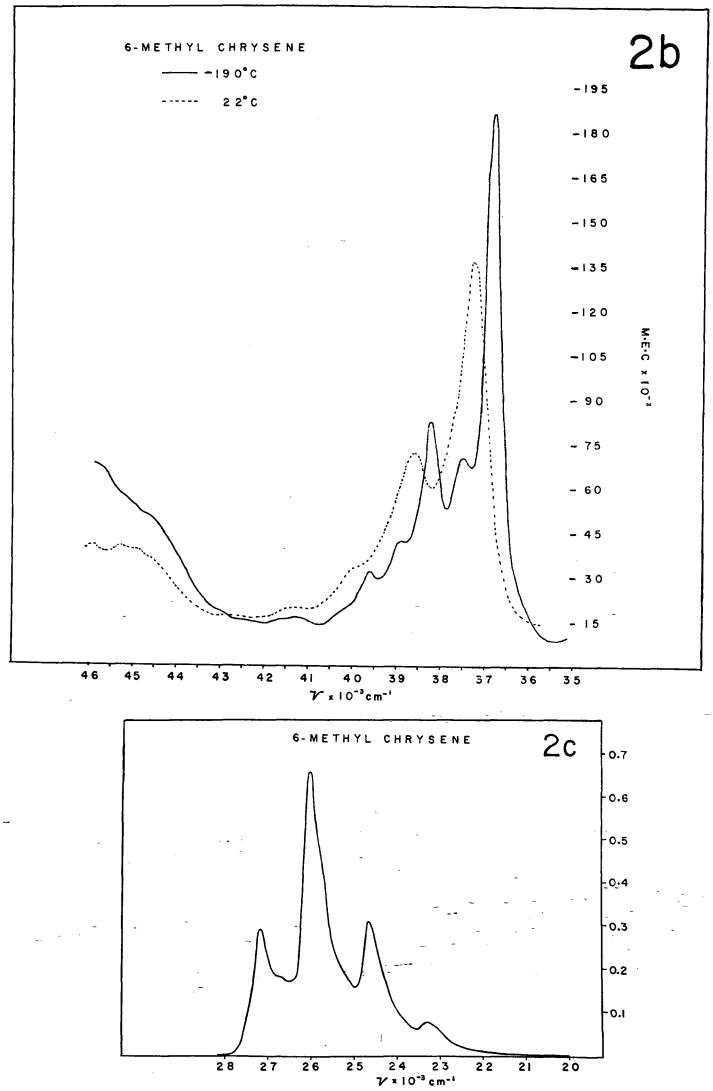

FIG. 2. (*a*) and (*b*) The ultraviolet absorption spectrum of 6-methylchrysene in a 6:1 mixture of isopentane and 3-methylpentane. Wave numbers against molecular extinction coefficients: - - - (*c*) The fluorescence spectrum of 6-methylchrysene at 21° C in cyclohexane solution. Wave numbers vs. arbitrary units.

against two in absorption. (For 6-methylchrysene the related wave numbers are, in cm^{-1}, fluorescence: 27196, 26042, 24661, 23256; absorption (−190° C): 27578, 28943.)

We conclude from these observations that, as expected, the case of chrysene is similar to that of benzo[*a*]anthracene inasmuch as the α- and p-band systems overlap to an appreciable extent, a part of the bands of the α-system being hidden below the bands of the p-band system. The extent of this overlapping is lesser, however, than in the case of benzo[*a*]anthracene. It may be concluded too that in the first excited singlet state the chrysene molecule differs more from its ground state than do most other aromatic molecules.

Experimental details and further references were given in paper (3).

DOUBLE-MINIMUM POTENTIAL FOR INTRAMOLECULARLY HYDROGEN-BONDED PROTONS IN ORTHO-SUBSTITUTED ANILINES[1]

P. J. KRUEGER

Department of Chemistry, University of Alberta, Calgary, Alberta

Received August 12, 1963

ABSTRACT

The concentration and temperature-independent splitting of the first overtone NH_2 symmetric stretching band in 31 ortho-substituted anilines in which intramolecular hydrogen bonding is possible is interpreted in terms of a double-minimum potential for the hydrogen bonded proton. The intensity ratio of the doublet and the extent of the splitting is related to the basicity of the ortho-substituent, modified by the rigid geometrical restrictions of the intramolecular system. The absence of band splitting in the corresponding fundamental mode suggests that the secondary minimum lies in the vicinity of the $v = 2$ vibrational level. The antisymmetric mode appears to be less sensitive to perturbations.

Deuteration studies, the spectra of some *o*-substituted *N*-methyl anilines, and the first overtone bands of *N*-methyl aniline in very basic solvents support these views.

INTRODUCTION

Among the many contributions that have been made to our present understanding of the nature of hydrogen bonding (1, 2) there has recently been considerable support for the idea that the motion of the proton in an A—H···B system may be governed by a potential-energy function with two minima separated by a low barrier. This is represented schematically in Fig. 1(*a*) for a symmetrical hydrogen bond where the two minima have

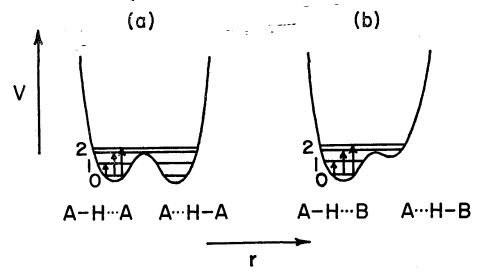

FIG. 1. Schematic representation of double-minimum potentials for hydrogen bonded protons where proton tunnelling (or a resonance splitting) occurs at the vibrational level $v = 2$. (*a*) Symmetric double-minimum potential. (*b*) Asymmetric double-minimum potential.

equal depth, and in Fig. 1(*b*) for the more common situation where the proton would always remain more firmly bonded to A than to B. Both sketches show the intermediate barrier height in the region of the $v = 2$ vibrational level. A potential system such as that in Fig. 1(*a*), where the minima are of sufficiently equal energy so that the lowest energy

[1]*Paper presented at the 46th Annual Conference of the Chemical Institute of Canada, Toronto, Ontario, June 6–8, 1963.*

levels of both are appreciably populated at room temperature, is applicable to tautomeric equilibria. This paper deals with unsymmetrical double-minimum potentials in some intramolecular systems.

Not only does the double-minimum concept have a sound theoretical basis (3, 4), but Bell and Barrow (5) presented the first experimental verification in 1959 by showing that the first and second overtone OH bands in ethanol and phenol in solvents of various proton-accepting abilities show a pair of solvent-dependent absorption bands. The observed spectra were held to arise from a potential energy function in which the second minimum lies in the region of the $v = 2$ vibrational level. It was shown that the height of the second potential minimum depends on the hydrogen bonding strength of the alcohol and on the acceptor strength of the solvent. In strongly basic solvents the higher overtones were characteristic of a broad potential well. Subsequent work by Bell and Barrow (6) showed that in phenol-*d* and *p*-nitrophenol-*d* the splitting of the fundamental OD stretching bands could be interpreted in terms of a second low-lying potential minimum and its effect on the $v = 0$ and $v = 1$ levels. For *p*-nitrophenol-*d* and very strong bases in non-dissociating solvents tautomeric equilibria between proton transferred and nonproton transferred species were found.

Pshenichnov and Sokolov (7) concluded independently that hydrogenic band splitting of the type observed could be interpreted in terms of quantum effects near the top of the barrier in double-minimum potential curves. Further, Bratoz and Hadzi (8) found that a potential energy surface with two minima for hydrogen bonded molecules occasionally played a significant part in the consistent interpretation of their spectra. On this basis doubling of the OH fundamental stretching band in the infrared spectra of carboxylic acids in pyridine solution has been ascribed to tunnelling of the proton between interacting double minima separated by a small barrier (9).

The detailed results of a general solution for the case of a proton moving in a potential field of two equal minima, given by Blinc and Hadzi (10), cover a wide range of physically possible parameters. The same authors have also described (11) the quantum-mechanical treatment of the case of two unequal minima, and interpreted the complex spectra in the OH stretching region for a number of ferroelectric compounds in the solid phase on the basis of proton tunnelling. By using the temperature dependence of resonance line widths in the proton magnetic resonance spectra of solid substances containing very short hydrogen bonds, Hadzi *et al.* (12, 13, 14) have demonstrated that the band splitting in infrared spectra is supported, and that the protons are either tunnelling between two minima of potential energy (e.g., in potassium hydrogen bis-*p*-nitrobenzoate) or that they are symmetrically situated midway between the electronegative atoms and are not moving appreciably (e.g., in potassium hydrogen bis-phenylacetate). The classification of the compounds investigated into these two categories could not be related simply to the length of the hydrogen bond; for compounds with an O···O distance of about 2.5 Å, where the potential barrier separating the minima should disappear and a flat single-bottomed type of curve should be attained, according to Reid's model (15), examples of both classes coexist.

There are obvious dangers inherent in the interpretation of experimentally observed doubling of hydrogenic stretching bands in infrared spectra of hydrogen bonded solids in terms of double-minimum potentials, as Somorjai and Hornig (16) have pointed out. They emphasize the necessity for obtaining sufficient experimental evidence, since it is well recognized that crystalline forces may play a large role in determining the potentials for hydrogen-bonded protons in the solid state (17).

In his review of the status of the double-minimum potential concept in interpreting experimental data Barrow (18) has shown that the relative heights of the potential minima can be correlated semiquantitatively with the pK_a values of the acids and bases involved.

To date there appears to have been no systematic study of infrared band splitting which may arise because of double-minimum potentials for intramolecularly hydrogen bonded protons, although Hambly (19) has suggested that the splitting of the first overtone symmetric NH_2 stretching vibration, first observed by Whetsel (20) for *o*-nitroaniline and *o*-phenylmethylsulphone in dilute CCl_4 solution, may arise from this phenomenon. Recent work in this laboratory has shown that a doubling of the first overtone symmetric NH_2 stretching band occurs in all ortho-substituted anilines where intramolecular NH···X hydrogen bonding is conceivable (21). No splitting is observed in the fundamental symmetric and antisymmetric NH_2 stretching bands in these compounds (22). The overtone data have now been amplified, and the suggestion is made that a second potential minimum lying at approximately the level $v = 2$, and with a low potential barrier, may indeed be responsible. The intramolecular hydrogen bond may actually be favorable for the experimental observation of this phenomenon because of the relatively fixed molecular geometry, and the absence of factors like the continuum of lattice vibrations which broaden each transition in the spectra of hydrogen bonded crystals (16). It is also well known that bands arising from intramolecularly hydrogen-bonded systems tend to be narrower than analogous intermolecularly hydrogen-bonded bands. Intramolecular systems may lead to more refined calculations on the nature of the potential function since the A—H···B distance is known. As Barrow (18) has pointed out, the lack of knowledge of the AB distance in intermolecular hydrogen bonds is a major obstacle in such calculations.

EXPERIMENTAL

The experimental details have been described for measurements in both the fundamental and overtone regions (21, 22). The compounds used were largely commercial materials purified by fractional distillation, recrystallization, or vacuum sublimation. A few were synthesized by standard methods described in the literature. Commercial spectroscopic quality solvents were employed. For spectra in the fundamental region the aniline concentrations were kept down below 0.01 *M*; in the first overtone region they were below 0.07 *M* in CCl_4. Overtone spectra in other solvents had to be obtained at higher concentrations. These are given in the captions to Figs. 5 and 6.

Table I lists the experimental data relevant to this discussion.

RESULTS AND DISCUSSION

The composite Fig. 2 shows the ν_{01} and ν_{02} NH_2 stretching band contours observed for:

(*a*) a typical *o*-substituted aniline with a small "inert" substituent (*o*-$CH_3C_6H_4NH_2$),

(*b*) a typical *m*- or *p*-substituted aniline (*m*-$BrC_6H_4NH_2$),

(*c*) a typical *o*-substituted aniline with a relatively weak NH····X bond (*o*-$IC_6H_4NH_2$),

(*d*) a typical *o*-substituted aniline with a moderately strong NH····X bond (*o*-$NO_2C_6H_4NH_2$), and

(*e*) a typical *o*-substituted aniline with a very strong NH····X bond (*o*-$COCH_3C_6H_4NH_2$).

The most significant feature is that although the resolution of a grating spectrophotometer (Beckman IR-7, slit width ~2 cm^{-1}) does not resolve either the symmetric or antisymmetric ν_{01} bands into components, the lower resolution of the near infrared quartz prism instrument (Beckman DK-1A) shows that the symmetric ν_{02} band is a doublet where the possibility of NH···X bonding exists, and that in general the separation

[a]Values from Hambly and O'Grady (23). Differences from present measurements may be due to methods employed to obtain positions of poorly resolved components. In this work the major band was reflected about the ordinate at the maximum and subtracted from the experimental curve to obtain the peak frequency and absorbance of the subsidiary band appearing as a shoulder.
[b]Values from Hambly and O'Grady (24).
[c]On the basis of deuteration studies Hambly and O'Grady (25) have proposed a repulsive interaction between the NH_2 and the adjacent CF_3 group. See text.
[d]Values from Hambly (19).
[e]Additional shoulder at 6603 cm^{-1} on high-frequency side of low-frequency component.
[f]Values from Whetsel (20).
[g]Values from Whetsel, Roberson, and Krell (26).

between the components increases and the apparent absorbance ratio (low-frequency component/high-frequency component) decreases dramatically as the NH···X interaction increases. The relationship between the doublet separation and the absorbance ratio is shown in Fig. 3, and appears to be asymptotic to both axes. As the NH···X interaction commences the intensity switches rapidly from one component into the other with only a slight increase in doublet separation. Infrared intensities are usually more sensitive to interaction effects than are vibrational frequencies. After the high frequency component predominates a further increase in the strength of the NH···X interaction alters the absorbance ratio little, but increases the doublet separation markedly.

Although the order in which the compounds are listed in Table I (increasing doublet separation) appears to be approximately that in which one would expect increasing hydrogen-bonding interaction between the NH_2 group and a single *o*-substituent, a precise correlation would have to take into account:

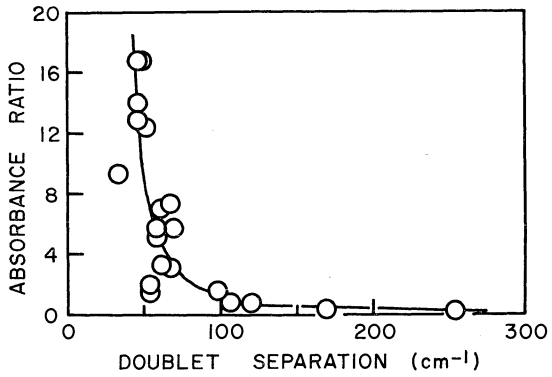

FIG. 3. Relationship of absorbance ratio in the first overtone symmetric mode doublet (low-frequency component/high-frequency component) to the doublet separation in *o*-substituted anilines.

Further, there are almost certainly factors operating in 2,6-disubstituted anilines which are not present in mono-2-substituted anilines. For example, Hambly and O'Grady (28) have shown on the basis of the failure to observe cis–trans isomerism of the NHD group in 2,4,6-trinitroaniline, a technique due to Moritz (29), that bilateral hydrogen bonding exists in this compound. Similar bilateral hydrogen bonding was suggested for 2,6-dicarbomethoxyaniline (24), and for 2,6-diiodo-4-methylaniline, but both the fundamental NH_2 stretching bands as well as the NH and ND bands of the NHD group in 2,6-dihalo-4-nitroanilines showed shoulders (23). Although Hambly and O'Grady suggest rotational isomerism with the NH_2 group rotated out of conjugation with the benzene ring because the two members of each of the stretching bands of the 2,6-dihalo-4-nitroanilines are respectively higher and lower than those of the corresponding 2,4,6-trihaloanilines, this may be band splitting observed in the fundamental region because of a secondary potential minimum in the $v = 1$ region in this particular compound. The effect of temperature on these spectra would probably decide between these two possibilities. With respect to twisting of the NH_2 group out of conjugation with the benzene ring, the work of Wepster (30) shows that even very bulky groups in the 2 and 6 positions do not appear to be capable of doing this.

A plot of the ν_{02} symmetric frequencies for a large number of *o*-, *m*-, and *p*-substituted anilines vs. the substituent σ values (see Fig. 3 of Ref. 21) shows that for weak proton acceptors like *o*-alkoxy groups the low-frequency component of the doublet lies close to the correlation line for *m*- and *p*-substituents while the high frequency component lies above it, but for substituents like 2-NH_2, 2-I, 2,4,6-tri-Br, 2-NO_2, 2,6-di-Cl-4-NO_2, and 2,4-di-NO_2 one component lies at a higher frequency and the other at a lower frequency than the general correlation. This suggests resonance separation of vibrational levels as a very likely cause of the doubling. Even if bilateral hydrogen bonding does not occur in all 2,6-di-*o*-substituted anilines both substituents would probably have a pronounced effect on the potential energy curves for the protons. A comparison of the symmetric ν_{02} band splitting for 2,6-dicarbomethoxyaniline (52 cm^{-1}) with that for methyl anthranilate (154 cm^{-1}), and the splitting for 2,6-dinitroaniline (53 cm^{-1}) with that for 2-nitroaniline (106 cm^{-1}) suggests that the intramolecular NH···O hydrogen bonds are weaker for bilaterally bonded NH_2 groups than they are if only one NH bond is involved (31).

In the overtone spectra a relatively weak absorption band is found in the approximate range 6560–6600 cm^{-1} for all anilines (band D in Fig. 2). This has tentatively been assigned

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to a difference band involving the torsional vibration of the NH_2 group (23), although this may not prove to be entirely satisfactory. In ethyl anthranilate and *o*-aminoacetophenone the low-frequency component of the doublet is displaced downward sufficiently far as to overlap with the difference band, which led to early conclusions that the symmetric band was *single* in these compounds. With improved resolution the difference band and the low-frequency symmetric component can be resolved (Fig. 2(*e*)), the latter lying at a *lower* frequency than the difference band. This assignment is based on the solvent dependence of these frequencies; the low-frequency symmetric component shifts to higher frequency by 10–25 cm^{-1} on going from CCl_4 to $CHCl_3$, whereas the high-frequency component and the difference band lie at nearly the same positions respectively in these two solvents. Deuteration removes band D from this region of the spectrum (24).

The results of Whetsel (20) for *o*-nitroaniline and *o*-aminophenylmethylsulphone and the present measurements on ethyl anthranilate show that not only is the doublet separation decreased in the transition from CCl_4 to $CHCl_3$, but there is also a decrease in the relative intensity of the high frequency component. Both points strongly suggest that the intramolecular $HNH\cdots X$ interaction is weakened in $CHCl_3$ as might be expected because the H atom of chloroform complexes with the lone pair electrons of the amino N atom (32), thereby decreasing the acidity of the NH_2 protons as the sp^3 character of the N atom increases.

The basic criteria for a double-minimum potential for a hydrogen-bonded proton, with the second minimum at approximately the $v = 2$ level, appear to be as follows.

(1) No splitting of the ν_{01} hydrogenic stretching vibration, but a splitting of ν_{02}.
(2) A band splitting which is independent of concentration (to show that the effect originates in monomer species).
(3) An increase in the separation of the observed bands as the strength of the interaction increases.
(4) A strong dependence of the separation of the doublet on the mass of the hydrogen atom, i.e., a reduction on deuteration. Bell and Barrow (5, 6) have shown that the $v = 1$ or $v = 2$ level can be split only with a considerably stronger acid and base when deuterium rather than protium bonds are involved.
(5) A relative intensity in the doublet which is independent of isotopic substitution.
(6) A temperature-independent intensity ratio for the pair of bands since both transitions originate in the ground state.
(7) Second and higher overtones characteristic of a very broad potential well. It may not be valid to interpret changes in energy levels in terms of anharmonicity since the potential is no longer a sufficiently regular function. Overtones higher than the first should appear at frequencies very different from multiples of the fundamental frequency.
(8) A splitting which increases as the height of the intermediate barrier rises.

There appears to be sufficient evidence to substantiate a double-minimum potential for *o*-substituted anilines. Criterion (1) has already been discussed, and is illustrated in Fig. 2. The overtone splitting is these compounds is concentration independent. An examination of the order in which mono-*o*-substituted compounds appear in Table I in relation to an increase in the splitting shows that criterion (3) is met reasonably well, if one bears in mind the geometrical restrictions of intramolecular hydrogen bonds.

A sample of *N*,*N*-dideutero-*o*-nitroaniline, prepared by repeated equilibration with methanol-*d*, showed an antisymmetric ND_2 stretching band at 5263 cm^{-1}, and a symmetric ND_2 doublet at 5072 and 5039 cm^{-1} (separation 33 cm^{-1} as compared with 106 cm^{-1} in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the undeuterated compound). This pronounced importance of the mass of the particle in the tunnel effect is in agreement with item (4). Within experimental error, the absorbance ratio for the doublet was the same as that for *o*-nitroaniline, as required by criterion (5).

Temperature studies over the range 0–60° C for *o*-nitroaniline, *o*-iodoaniline, *o*-phenylenediamine, and ethyl anthranilate in CCl_4 solution led to no significant changes in intensity ratios for any of the pairs of bands, in agreement with item (6).

No second overtone spectra were obtained to test item (7), since the high aniline concentrations which are required (at the maximum convenient path length of 10 cm) introduce the possibility of intermolecular hydrogen bonding. Also, difficulties are sometimes encountered in the unambiguous assignment of these higher overtones. All knowledge about the height of the intermediate barrier in double-minimum potential systems is very speculative at the present, so that criterion (8) cannot be applied.*

The question which remains to be answered is the failure to observe splitting in the ν_{02} antisymmetric NH_2 stretching bands if the double-minimum potential is a valid interpretation for the symmetric mode splitting. It is known that these two modes respond differently to substitution effects, including *o*-substituents (21, 22). Applying a classical method of Kohlrausch (33), Wolff and Staschewski (34) have calculated how these two stretching modes in primary amines react as the HNH···X interaction increases, assuming that only one NH bond is weakened in this way, and that the other NH bond remains at a fixed strength (Fig. 4). Although this is clearly an approximation, there appears to

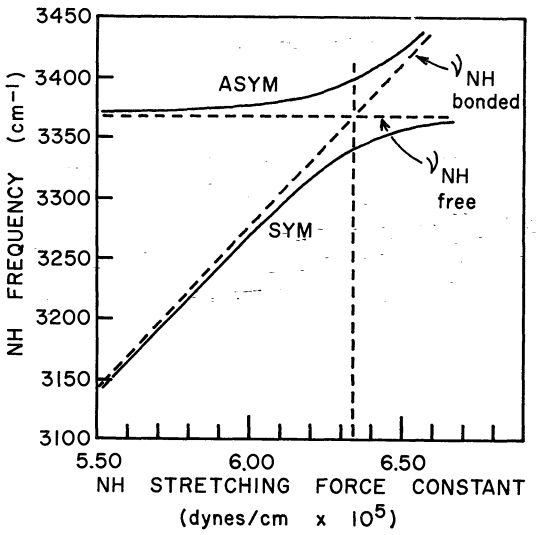

FIG. 4. Effect of HNH···X interaction on the NH_2 stretching frequencies, after Wolff and Staschewski (32). The broken vertical line corresponds to a completely "free" NH_2 group where both NH force constants are 6.34×10^5 dynes/cm. One of the force constants is kept at this value while the other is progressively reduced.

be little doubt that ν_{sym} is more sensitive to such interaction effects, which is reflected in larger frequency displacements. Thus the splitting of the levels for the antisymmetric mode in *o*-substituted anilines may be too small to be observed. It should be noted in this connection that even in cases where splitting of OH stretching bands has been

**The calculations of McKinney and Barrow (3) for an* OH···O *bond with an* O *to* O *distance of 2.8* Å *lead to a barrier height of 25 kcal/mole, with the secondary minimum lying 18 kcal/mole above the main minimum.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

observed and ascribed to double-minimum potentials, analogous doubling has not been observed for other OH vibrations, e.g. OH deformation (9).

In order to remove some of the ambiguities which the complex vibrational pattern of the NH_2 group may introduce, the methyl ester of *N*-methyl anthranilic acid, *o*-nitro-*N*-methylaniline, and *o*-nitro-diphenylamine were investigated. These spectra are shown in Fig. 2(*f*), (*g*), and (*h*) respectively. In all cases a single sharp fundamental NH stretching band is observed, whereas the first overtone band shows additional structure. For methyl-*N*-methyl anthranilate the ν_{01} band lies at 3382 cm^{-1} ($\Delta\nu_{\frac{1}{2}} = 27$ cm^{-1}). The fact that it is 71 cm^{-1} lower than the NH frequency in the methyl ester of *p*-aminobenzoic acid indicates the former is intramolecularly bonded. In the first overtone region an extremely weak pair of bands (6752 cm^{-1}, 6572 cm^{-1}, separation 180 cm^{-1}) is observed, with an unexplained low-frequency shoulder. *o*-Nitro-*N*-methylaniline is also known to exist exclusively with the CH_3 group trans to the NO_2 group, with a sharp intramolecularly bonded NH band at 3399 cm^{-1} (35, 29*b*) (present measurements located this band at 3401 cm^{-1}, $\Delta\nu_{\frac{1}{2}} = 19$ cm^{-1}) as compared with 3456 cm^{-1} in *p*-nitro-*N*-methylaniline (36). In the ν_{02} region this compound shows an NH overtone at 6625 cm^{-1} with a *high frequency* shoulder at 6792 cm^{-1}. For *o*-nitrodiphenylamine the fundamental NH band lies at 3354 cm^{-1} ($\Delta\nu_{\frac{1}{2}} = 33$ cm^{-1}), and the overtone region shows a band at 6536 cm^{-1} with a *low frequency* shoulder at 6423 cm^{-1}. If the secondary aromatic amines follow the same pattern as observed for the primary amines, i.e., the high frequency component becomes more intense as the intramolecular hydrogen bonding interaction increases, the overtone results for *o*-nitro-*N*-methylaniline and *o*-nitrodiphenylamine are consistent with the higher acidity of the latter. Also, the ν_{02} symmetric absorbance ratios for methyl-*N*-methyl anthranilate and *o*-nitro-*N*-methylaniline can be reconciled with greater intramolecular hydrogen bond strength in the six-membered chelate ring in the former compound.

Examination of Fig. 2 shows that the intensities of the fundamental bands increase on intramolecular hydrogen bond formation, whereas the first overtone bands become a little weaker. For the *N*-methylanilines the fundamentals are exceptionally intense, and the overtones very weak and broad. This behavior is well recognized in the spectra of hydrogen-bonded systems (p. 101, Ref. 2).

The possibility of overtone band splitting in some *o*-substituted anilines because of steric repulsion between substituents cannot be overlooked. Previous studies have shown that the symmetric ν_{02} band is plit in 2-*t*-Bu- and 2,5-di-*t*-Bu-aniline, but not in 2,4,6-tri-*t*-Bu-aniline where the NH_2 group has its symmetrical environment restored (21). Hambly and O'Grady (25) have demonstrated that rotational isomerism of the NHD group occurs in 2-*t*-Bu-anilines, as well as in 2-trifluoromethylaniline. Doubling of the NH bands of the NHD group is thus not a specific test for hydrogen bonding, but only for a difference in the environment of the two H atoms of the amino group. Since the separation between the symmetric and antisymmetric ν_{01} bands for 2-trifluoromethylaniline is smaller than that predicted by the modified Bellamy and Williams relationship (37), just as it is for 2,6-dimethylaniline, Hambly and O'Grady (23) ascribe the cis–trans isomerism of the NHD group in the former compound to a repulsive interaction.

Figures 5 and 6 show ν_{02} bands for *N*-methylaniline and aniline respectively in various solvents. These were obtained in an attempt to induce first overtone NH band splitting by means of intermolecular interaction with very basic solvents. For *N*-methylaniline the NH band appears to be symmetrical in CCl_4, toluene, and acetone (cf. the results for phenol in these solvents, where the proton donor is of sufficient strength to cause band splitting in the last two solvents, Ref. 5). In pyridine a shoulder appears at about 6557 cm^{-1},

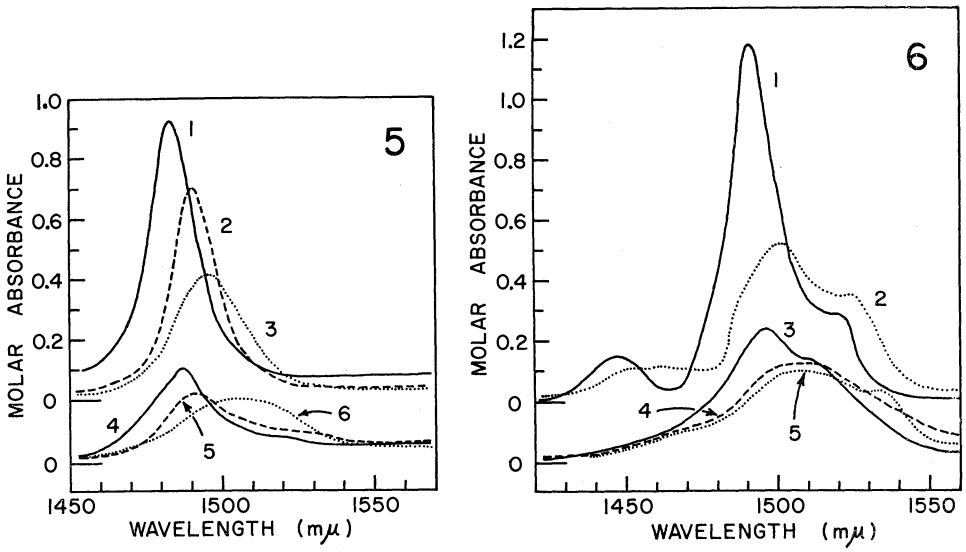

FIG. 5. First overtone NH bands of *N*-methylaniline in various solvents. The zero axis is displaced downward by 0.2 absorbance units for curves 4, 5, and 6. (1) Carbon tetrachloride (0.059 *M*). (2) Toluene (0.070 *M*). (3) Acetone (0.072 *M*). (4) Triethylamine (0.230 *M*). (5) Pyridine (0.234 *M*). (6) *N*,*N*-Dimethylformamide (0.072 *M*).

FIG. 6. First overtone NH_2 bands of aniline in various solvents. The zero axis is displaced downward by 0.2 absorbance units for curves 3, 4, and 5. (1) Carbon tetrachloride (0.058 *M*). (2) Acetone (0.101 *M*). (3) Triethylamine (0.173 *M*). (4) Pyridine (0.134 *M*). (5) *N*,*N*-Dimethylformamide (0.128 *M*).

displaced downward by 150 cm^{-1} from the main peak at 6707 cm^{-1}. In triethylamine a shoulder appears at 6623 cm^{-1}, down 102 cm^{-1} from the main peak at 6725 cm^{-1}. In dimethylformamide the very broad, flat-topped band centered at about 6638 cm^{-1} suggests unresolved bands. For the corresponding aniline spectra very broad bands are obtained, the envelopes involving the antisymmetric band and the difference band D as well. In acetone, triethylamine, pyridine, and dimethylformamide the main symmetric maximum appears doubled (this assumes that band D does not shift to shorter wavelength on going from CCl_4 to these basic solvents). In general, the NH bonds are not acidic enough to provide well-resolved symmetric ν_{02} doublets on intermolecular hydrogen bond formation.

SUR LA DOUBLE ÉNOLISATION DE LA DIMÉTHYL-3,3 CYCLOHEXANONE

J. CHAMPAGNE,[1] H. FAVRE, D. VOCELLE,[2] ET MLLE I. ZBIKOWSKI

Département de chimie, Université de Montréal, Montréal, Québec

Reçu le 13 août 1963

RÉSUMÉ

On montre dans cet article, par l'étude des acétates énoliques et des ène-pyrrolidines de la diméthyl-3,3 cyclohexanone, par la mise en équilibre des diméthyl-3,3 et diméthyl-4,4 cyclohexènes et par l'oxydation nitrique de la diméthyl-3,3 cyclohexanone que l'énolisation de la diméthyl-3,3 cyclohexanone est double et qu'elle se fait de préférence dans la direction opposée aux groupes méthyles, le rapport entre les isomères formés étant de 3 à 1. De plus la diméthyl-4,4 cyclohexanedione-1,3 s'énolise aussi de préférence avec la double liaison C=C en 1,2 donc éloignée des groupes méthyles.

La diméthyl-3,3 cyclohexanone présente, selon la bibliographie, la particularité de ne réagir qu'en position 6, que l'on fasse agir le brome sur la cétone (1), l'acrylonitrile sur l'énamine correspondante (2) (méthode de Stork), le formiate d'éthyle (3) ou l'iodure de méthyle (4) sur le sel sodé de la cétone. Ceci peut être dû à deux causes: soit que l'énolisation ne se donne que vers la position 6 seulement pour donner l'énol, l'énamine, ou l'énolate, II*a*, II*b*, ou II*c* respectivement, soit que l'énolisation soit double pour donner les énols, énamines, et énolates II*a*, *b*, *c* et III*a*, *b*, *c*, un encombrement stérique empêchant la réaction de se faire ensuite en α du groupe *gem*-diméthyle. Nous avons voulu trancher cette question, en stabilisant la double liaison énolique par la formation d'un acétate énolique ou d'une énamine et en mettant en évidence la présence d'un ou de deux composés d'énolisation; pour fins de comparaison, nous avons mis à l'équilibre le diméthyl-4,4 cyclohexène (II*e*) et le diméthyl-3,3 cyclohexène (III*e*). Dans une discussion nous mettrons en parallèle les résultats ainsi obtenus, l'oxydation nitrique de la diméthyl-3,3 cyclohexanone et finalement l'énolisation de la diméthyl-4,4 cyclohexanedione-1,3.

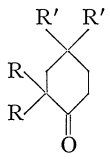
Les acétates énoliques de la diméthyl-3,3 cyclohexanone

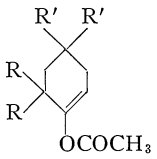
En faisant réagir la diméthyl-3,3 cyclohexanone (I) avec l'acétate d'isopropényle en présence d'acide sulfurique concentré, selon Dauben et ses collaborateurs (5), nous avons obtenu deux acétates énoliques, mis en évidence par chromatographie en phase gazeuse, dans le rapport de 62–38%. Ils se séparent facilement par chromatographie en phase gazeuse à l'échelle du gramme; l'acétate de diméthyl-5,5 cyclohexényle (II*d*) est identifié par son spectre de RMN: triplet à τ 5.1 p.p.m.; J 4 c.p.s.; l'acétate de diméthyl-3,3 cyclohexényle (III*d*) présente un singulet comme attendu, à τ 4.9. Les bandes caractéristiques

[1]*Boursier de l'Office de la Recherche Scientifique de la Province de Québec, 1959.*
[2]*Boursier de l'Office de la Recherche Scientifique de la Province de Québec, 1960.*

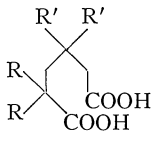
des acétates énoliques, dans l'infrarouge, sont à 1754 cm^{-1} et 1751 cm^{-1} pour II*d* et III*d* respectivement. Le spectra de RMN du mélange II*d*–III*d* permet d'établir que l'acétate II*d* représente 62% du mélange. Une corroboration chimique de ces résultats a été faite de la manière suivante: les acétates purs II*d* et III*d* ont été ozonolysés; les acides diméthyl-3,3 et diméthyl-2,2 adipiques VIII et IX respectivement obtenus ont été estérifiés par le diazométhane et les diesters caractérisés et dosés par CPG. Les diesters de référence ont été préparés à partir des acides VIII et IX qui sont connus (6) et que nous avons préparés par ozonolyse des acétates énoliques VI et VII issus respectivement de la diméthyl-4,4 et de la diméthyl-2,2 cyclohexanone IV et V. L'acétate énolique de la diméthyl-4,4 cyclohexanone (un seul est attendu) se forme sans difficultés; celui de la diméthyl-2,2 ne se forme pas complètement: il est toujours accompagné de la cétone de départ.



IV
V



VI
VII



VIII
IX

R = H; R' = CH_3
R = CH_3; R' = H

Une autre manière de former des acétates énoliques est de traiter la cétone par de l'anhydride acétique et de l'acide perchlorique aqueux dans un mélange de tétrachlorure de carbone et de benzène (7, 8). Appliquée à la diméthyl-3,3 cyclohexanone cette méthode a conduit aux deux acétates énoliques II*d* et III*d*, dans un rapport de 73–27%, mais la réaction n'est pas complète, 12% de cétone de départ se retrouvant à côté des acétates énoliques.

Il nous a semblé intéressant de mettre en évidence les modes de contrôle ("cinétique et thermodynamique") de ces deux modes opératoires. A cet effet nous avons traité chaque acétate énolique pur II*d* et III*d* par l'acétate d'isopropényle et l'acide sulfurique; dans chaque cas l'acétate énolique est inchangé. Il n'y a pas de changement si l'on ajoute en plus de l'acétone. Lorsque l'acétate énolique III*d* est traité par l'acétate d'isopropényle et l'acide sulfurique en présence de diméthyl-3,3 cyclohexanone, l'acétate II*d* se forme, mais dans des proportions strictement équivalentes à la quantité de diméthyl-3,3 cyclohexanone présente dans le mélange. Nous tirons la conclusion que le contrôle est cinétique lorsque la cétone est traitée par l'acétate d'isopropényle et l'acide sulfurique concentré.

En revanche, lorsque l'acétate énolique III*d* est traité par de l'anhydride acétique et de l'acide perchlorique aqueux (78%) nous retrouvons 10% de diméthyl-3,3 cyclohexanone et 90% du mélange des acétates énoliques II*d* et III*d* dans les proportions de 75–25%, soit le mélange que l'on obtient à partir de la diméthyl-3,3 cyclohexanone elle-même. Nous tirons la conclusion que le contrôle est ici "thermodynamique".

Les ène-pyrrolidines de la diméthyl-3,3 cyclohexanone

L'action de la pyrrolidine sur la diméthyl-3,3 cyclohexanone a déjà été décrite par l'un de nous (2). Le produit brut a été ozonolysé, puis saponifié, et finalement traité par le diazométhane: la CPG a révélé les deux diesters méthyliques des acides diméthyl-3,3 et diméthyl-2,2 adipiques (VIII et IX). Du rapport 80–20% de ces diesters, nous concluons que les deux ène-pyrrolidines II*b* et III*b* se trouvaient présentes dans le mélange des énamines et qu'elles étaient dans ces proportions. Nous considérons, d'après Stork et ses collaborateurs (9), que les deux ène-pyrrolidines sont à l'équilibre.

Mise en équilibre des diméthyl-4,4 et 3,3 cyclohexènes

Nous avons déterminé la position d'équilibre des diméthyl-4,4 et diméthyl-3,3 cyclohexènes (II*e* et III*e*). En traitant chacun de ces composés par de l'acide *p*-toluène sulfonique dans de l'acide acétique glacial (10, 11) nous avons obtenu, par dosage en chromatographie en phase gazeuse, les résultats du Tableau I. Les mélanges d'isomérisation sont très complexes (cf. partie expérimentale): si nous admettons toutefois qu'au bout de 257 heures les hydrocarbures éthyléniques II*e* et III*e* sont à l'équilibre, bien qu'ils disparaissent progressivement au cours de l'isomérisation, nous obtenons un ΔF de −0.73–0.78 kcal/mole, le diméthyl-4,4 cyclohexène étant le plus stable. Turner,* par l'étude des chaleurs d'hydrogénation, a trouvé que le ΔH entre ces hydrocarbures est de 1.0 kcal/mole, le diméthyl-4,4 étant le plus stable également.

TABLEAU I

Isomérisation des diméthyl-4,4 et diméthyl-3,3 cyclohexènes

		Isomérisation du diméthyl-3,3 cyclohexène III*e*			Isomérisation du diméthyl-4,4 cyclohexène II*e*		
Durée (heures)		1	17	257	1	17	257
Pourcentage de diméthyl-3,3 et diméthyl-4,4 cyclohexènes, III*e* et II*e*, retrouvés		47.0	14.0	9.0	53.0	19.0	7
Composition du mélange en % de III*e* et II*e* retrouvés	III*e*	62	30	26	26	33	27
	II*e*	38	70	74	74	67	73

DISCUSSION ET COROLLAIRES

Les résultats précédents, rangés au Tableau II, montrent une prépondérance de composé à double liaison *loin* des groupes *gem*-diméthyles dans les mélanges d'acétates énoliques, d'ène-pyrrolidines et dans les diméthyl-4,4 et diméthyl-3,3 cyclohexènes à l'équilibre.

TABLEAU II

Pourcentages d'isomères d'énolisation de la diméthyl-3,3 cyclohexanone

	Isomères obtenus		
Composés	II	III	R =
Acétates énoliques (contrôle cinétique)	62%	38%	$-OCOCH_3$
Acétates énoliques (à l'équilibre)	73%	27%	$-OCOCH_3$
Ene-pyrrolidines (à l'équilibre)	80%	20%	$-NC_4H_8$
Enols de la diméthyl-3,3 cyclohexanone (par oxydation nitrique)	78%	22%	(—OH)

Turner et Garner (13) ont très bien résumé les arguments qui rendront une double liaison plus stable dans une position que dans l'autre dans des composés alicycliques: on ne peut encore trancher définitivement entre l'hyperconjugaison et les facteurs conformationnels. L'hyperconjugaison stabilisera plus le diméthyl-4,4 cyclohexène (deux groupes $—CH_2—$) que le diméthyl-3,3 cyclohexène (un seul groupe $—CH_2—$). Si l'on avance au

**Communication orale faite au 139ième Congrès de l'American Chemical Society (12).*

For personal use only.

contraire les facteurs conformationnels seuls, la seule explication valable pour le moment (10) est que l'hydrogène en position 2 cause une interaction non liée défavorable avec le groupe méthyle quasi-équatorial (14) en position 3 (Fig. 1), défavorisant ainsi le diméthyl-3,3 cyclohexène par rapport au diméthyl-4,4 cyclohexène: dans cette dernière molécule les interactions créées par les groupes méthyles axial et équatorial en position 4 avec les hydrogènes en position 5, qui sont gauches dans une conformation demi-chaise (Fig. 2), sont moins dévaforables que l'interaction décrite pour le diméthyl-3,3 cyclohexène. Il est cependant très difficile de faire un choix entre les interactions non liées pour dire avec

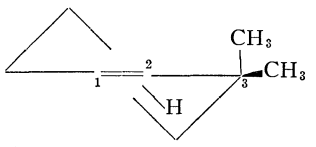

FIG. 1.

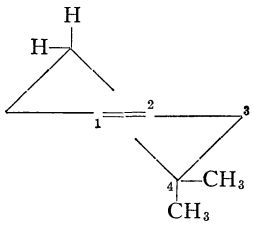

FIG. 2.

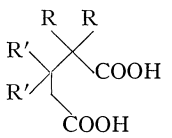
certitude que le diméthyl-4,4 cyclohexène est plus stable, par l'effet de ces seules interactions non liées, que le diméthyl-3,3 cyclohexène.

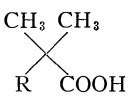
Pour ce qui est de la réactivité de ces doubles liaisons énolique et énaminique nous discuterons deux cas.

1. La cyanoéthylation des énamines II*b* et III*b*. Nous avons montré (2) qu'une seule cétone cyanoéthylée résulte de l'action de l'acrylonitrile sur le mélange de ces deux énamines: tout se passe comme si l'énamine II*b* réagissait seule pour donner la diméthyl-5,5 cyanoéthyl-2 cyclohexanone. Le refus de réagir de l'énamine III*b* peut être attribué à un encombrement stérique dû au groupe *gem*-diméthyle. Nous reviendrons sur la nature de cet encombrement stérique, qui a été mis en évidence par Conia et ses collaborateurs (15), dans une prochaine publication.

2. L'oxydation nitrique de la diméthyl-3,3 cyclohexanone. Nous l'avons conduite dans l'acide nitrique concentré bouillant et obtenu 70% des acides diméthyl-2,2 et diméthyl-3,3 adipiques (IX et VIII) dans le rapport de 22–78%, à côté des acides diméthyl-2,2, et diméthyl-3,3 glutariques (X et XI), de l'acide diméthyl-2,2 succinique (XII), et de l'acide diméthyl malonique (XIII). Tous ces acides ont été caractérisés en chromatographie en phase gazeuse, sous forme d'esters méthyliques. Nous avons vérifié que dans les mêmes conditions d'oxydation, la diméthyl-2,2 cyclohexanone (V) ne conduit qu'à quatre des diacides issus de la diméthyl-3,3 cyclohexanone, les diacides VIII et XI ne pouvant se former et la diméthyl-4,4 cyclohexanone ne conduit qu'à cinq des diacides de la diméthyl-3,3 cyclohexanone, le diacide IX ne pouvant se former.



X, R = CH_3; R′ = H
XI, R = −H; R′ = $-CH_3$



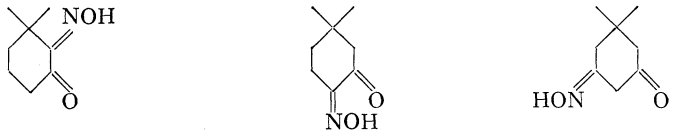
XII, R = $-CH_2COOH$
XIII, R = −COOH

On avance que l'oxydation nitrique se fait sur l'énol (ou les énols) correspondant à la cétone (16, 17, 18). Les énols de la diméthyl-3,3 cyclohexanone seraient ainsi formés dans

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

le rapport II*a*—78%/III*a*—22%, très voisin de celui que nous décrivons pour les acétates énoliques II*d*/III*d*, les ènes-pyrrolidines II*b*/III*b* et les diméthyl-4,4 et diméthyl-3,3 cyclohexènes à l'équilibre II*e*/III*e* (Tableau II). Il n'y aurait pas d'empêchement stérique du groupe *gem*-diméthyle dans l'oxydation nitrique.

Toutefois les travaux de van Asselt et van Krevelen (19, 20) sur l'oxydation nitrique à basse température, qui ne se fait qu'en présence d'acide nitreux et passe par des isonitroso cétones, montrent que l'oxydation sur l'énol est pour le moins un point de vue très simplifié. Selon eux, il faudrait admettre que les isonitroso cétones A et B (Fig. 3) se formeraient dans le rapport de 22–78% et qu'il se formerait encore d'autres nitroso cétones, par exemple C. Nous travaillons ici avec l'hypothèse que l'oxydation nitrique à température élevée est semblable à l'oxydation à basse température, ce qui n'est pas prouvé.

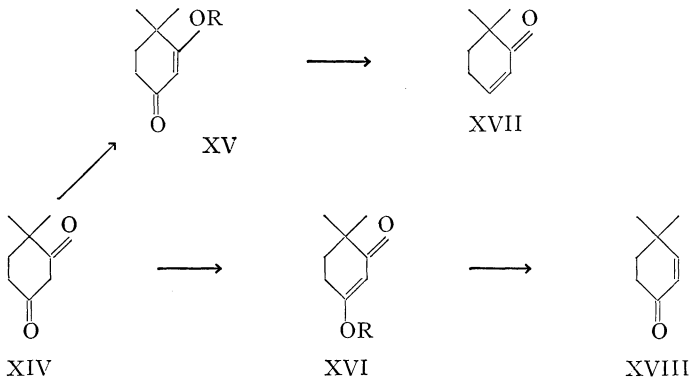


A B C

FIG. 3.

En définitive, pour prévoir l'isomère principal résultant de l'oxydation nitrique d'une cétone, il semble que l'on puisse continuer à dire que tout se passe comme si l'énol (ou les énols) étaient oxydés.

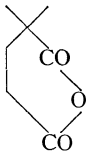
Nous décrivons maintenant un travail qui est un corollaire de ce que nous venons d'étudier et qui porte sur la diméthyl-4,4 cyclohexanedione-1,3 (XIV). Cette cétone peut conduire à deux céto-énols (XV, XVI, R = H), dans lesquels la double liaison énolique reflète la double énolisation de la diméthyl-3,3 cyclohexanone. Bien que nous ayons dans les céto-énols XV et XVI un groupe carbonyle qui doit certainement affecter la géométrie et les tensions internes de ces molécules, nous avons trouvé que la dicétone XIV s'énolise doublement et dans le rapport 35/65%—XV/XVI, donc dans le même sens que l'énolisation de la diméthyl-3,3 cyclohexanone, c'est-à-dire plus de double liaison loin des groupes méthyles. Nous avons montré ceci en stabilisant les céto-énols sous forme de céto-éthers XV to XVI (R = CH_3) par réaction avec le diazométhane; par le méthode maintenant classique de Frank et Hall (21), le mélange de ces céto-éthers a été réduit par l'hydrure de lithium et d'aluminium en diméthyl-4,4 et -6,6 cyclohexène-2 ones (XVIII et XVII),



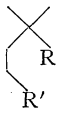
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

qui ont été réduites à leur tour en diméthyl-4,4 et -2,2 cyclohexanones (IV et V). Ce sont ces cétones saturées que nous avons dosées par chromatographie en phase gazeuse: nous avançons que leur rapport reflète le rapport des éthers céto-énoliques et ce rapport celui des céto-énols de la dicétone XIV, car nous admettons avec Tamm et ses collaborateurs (22) que le diazométhane réagit avec les céto-énols conformément à leurs vitesses de formation à partir de la dicétone.

La diméthyl-4,4 cyclohexanedione-1,3 (XIV) a été préparée selon la méthode classique (23) de cyclisation d'un méthyl-céto-ester; la séquence XIX → XX → XXI → XXII → XIV illustre cette synthèse. La dicétone XIV n'a pas donné une bonne analyse carbone–hydrogène, mais les céto-éthers correspondants l'ont fait. Leur preuve de structure découle essentiellement du fait de leur transformation en diméthyl-2,2 et diméthyl-4,4 cyclohexanones.



XIX



XX, R = COOEt; R′ = COOH
XXI, R = COOEt; R′ = COCl
XXIII, R = COOEt; R′ = $COCH_3$

PARTIE EXPERIMENTALE*

Les spectres infrarouges ont été déterminés à l'aide d'un spectrophotomètre Perkin–Elmer, modèle 21, double faisceau, prisme de chlorure de sodium.

Les analyses par chromatographie en phase gazeuse (CPG) ont été réalisées à l'aide d'un appareil "Kromo-Tog" de Burrell Corporation, modèle K–2, et les séparations préparatoires à l'aide d'un appareil "Prep/Partitioner" de Fisher, modèle 24. Sauf indications contraires, les colonnes sont en verre, diamètre intérieur 6 mm.

Les analyses élémentaires ont été effectuées par C. Daesslé, Organic Microanalyses, Montréal, et W. Manser, ingénieur, Herrliberg (Suisse).

Les spectres de résonance magnétique nucléaire (RMN), ont été pris avec un Spectromètre modèle A–60 de Varian. Les déplacements chimiques, τ, sont exprimés en parties par million (p.p.m.) du champs total. On utilise le tétraméthylsilane comme référence interne. Les constantes de couplage des spins J sont exprimées en cycles par seconde (c.p.s.).

1. Diméthyl-2,2, -3,3, et -4,4 cyclohexanones

Ces cétones ont été préparées par de nombreuses méthodes; nous décrivons brièvement ici les méthodes que nous avons mises en œuvre; elles permettent de préparer des cétones en grande quantité et d'une pureté de 99.6±0.2%, déterminée par CPG sur des colonnes de glycérol (20% sur brique), à température de 110°.

Diméthyl-2,2 cyclohexanone.—La méthode de Bailey et Madoff est très appropriée (24).

Diméthyl-3,3 cyclohexanone.—Pour préparer cette cétone à grande échelle nous recommandons la méthode suivante. Réduire le dimédon en diméthyl-3,3 cyclohexanol selon la méthode (25). Oxyder cet alcool: on prépare une solution de 210 g de bichromate de potassium dans 1100 ml d'eau à laquelle on ajoute, lentement, 254 ml d'acide sulfurique conc. Cette solution est ajoutée goutte à goutte à 203 g d'alcool en solution dans 417 ml d'acide acétique glacial. La température ne doit jamais dépasser 0°. On extrait par de l'éther et isole à la manière habituelle 191.2 g de cétone, p.é. 120–122° sous 142 mm (rendement de l'oxydation: 95.5%).

Diméthyl-4,4 cyclohexanone.—Cette cétone se prépare très bien, en grande quantité, par réduction catalytique sur palladium – carbonate de calcium selon (26) de la diméthyl-4,4 cyclohexène-2-one préparée selon (27). Elle fond à 38–40°. On donne p.f. 39–40° (28) et 38–41° (29).

2. Acétates énoliques

2.1. Acétates énoliques de la diméthyl-3,3 cyclohexanone (IId et IIId)

2.11. Méthode I (5)

18 ml d'acétate d'isopropényle et 0.08 ml d'acide sulfurique concentré sont ajoutés à 5.2 g de diméthyl-3,3 cyclohexanone. Le mélange est chauffé à reflux sous atmosphère d'azote pendant 1 heure, après quoi 6 ml

**Les p.f. ont été déterminés en tubes capillaires, à l'aide d'un thermomètre étalonné avec des composés purs de p.f. connus.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

de solvant sont distillés sous pression réduite à environ 400 mm en maintenant constamment une atmsophère d'azote dans le ballon. Le résidu refroidi est dissous dans l'éther et lavé successivement avec une solution glacée de NaOH 2% et de l'eau saturée de NaCl jusqu'à neutralité. La phase éthérée est séchée sur du Na_2SO_4 anhydre, l'éther est évaporé sous une colonne de Widmer et le résidu est distillé: p.é. 102–103° à 34 mm, $n_D^{26.5}$: 1.4498, rendement 90%.

La chromatographie en phase gazeuse sur une colonne de 2.5 mètres de polyester succinique de Craig, 20% sur Kromat FB, temp. 158°, débit 50 ml par min. He, indique la présence de deux acétates énoliques, III*d* et II*d*, dans des proportions de 38% et 62% respectivement; III*d* est élué avant II*d*: temps de rétention, 19.5 et 23 minutes. Une colonne de 2.5 mètres de Carbowax 20M, 20% sur Chromosorb P, temp. 154°, débit environ 50 ml par min. He, conduit au même résultat. L'analyse par RMN (tétrachlorure de carbone) indique la présence des deux composés: 38% de l'acétate III*d* et 62% de l'acétate II*d*.

Le mélange brut a été séparé en ses constituents II*d* et III*d* par chromatographie en phase gazeuse préparative. On injecte le mélange dans un appareil "Fisher Prep/Partitioner" modèle 24.

Les conditions utilisées sont les suivantes: (*a*) 4 colonnes de 50 cm chacune, chargées de Chromosorb P sur lequel est adsorbé 20% de Carbowax 20M. (*b*) Températures: colonnes, 142°; "flash evaporator", 230°; cellule, 200°. (*c*) Pression à l'entrée des colonnes: 18 livres par p.c., azote.

Après deux passages sur les colonnes, chacune des fractions recueillies est distillée et la chromatographie en phase gazeuse analytique indique l'homogénéité des échantillons.

Acétate de diméthyl-3,3 cyclohexényle (IIId).—Calculé pour $C_{10}H_{16}O_2$: C, 71.39; H, 9.58%. Trouvé: C, 71,60; H, 9.28%. Le spectre I.R. révèle des bandes à 1689 cm^{-1} et 1751 cm^{-1} (liquide pur); n_D^{23}: 1.4501. RMN: singulet, 5.1.

Acétate de diméthyl-5,5 cyclohexényle (IId).—Calculé pour $C_{10}H_{16}O_2$: C, 71.39; H, 9.58%. Trouvé: C, 71.15; H, 9.47%. Le spectre I.R. révèle des bandes à 1691 cm^{-1} et 1754 cm^{-1} (liquide pur); n_D^{23}: 1.4510. RMN: triplet, τ 4.9; J = 4 c.p.s.

2.12. Méthode II (8)

Une solution glacée de 6 ml d'anhydride acétique et 8 gouttes d'acide perchlorique 78% est ajoutée à une solution refroidie de 434 mg de diméthyl-3,3 cyclohexanone dans 80 ml de benzène et 30 ml de tétrachlorure de carbone. Le tout est agité à la température de la pièce pendant 4 heures et abandonné pour la nuit. On ajoute alors de l'eau glacée et du CCl_4 et la phase organique est lavée avec une solution de $NaHCO_3$ 5% et avec de l'eau saturée de NaCl, séchée sur le Na_2SO_4 anh. et les solvants sont distillés. Le résidu brut foncé est chromatographié en phase gazeuse comme en 2.11 (sur Carbowax 20M). La proportion des acétates énoliques est de 27% de l'acétate III*d* et 73% de l'acétate II*d*, et le mélange contient environ 12% de cétone de départ.

2.2. Acétate de diméthyl-6,6 cyclohexényle (VII)

A 2 g de la diméthyl-2,2 cyclohexanone on ajoute 9 ml d'acétate d'isopropényle et 0.04 ml d'acide sulfurique concentré. On isole comme rapporté en 2.11, après la distillation, un liquide incolore avec un rendement de 68%, p.é. environ 126° à 150 mm. La chromatographie en phase gazeuse sur polyester succinique de Craig semble indiquer la présence de 20% de cétone de départ. Le spectre I.R. a des bandes à 1707 cm^{-1} (cétone non réagie), 1755 et 1696 cm^{-1} (acétate énolique). Ce mélange n'a pas été analysé. Un temps de chauffage de 2 et 3 heures ne permet pas d'obtenir l'acétate exempt de cétone de départ.

2.3. Acétate de diméthyl-4,4 cyclohexényle (VI)

La diméthyl-4,4 cyclohexanone (4.91 g) est transformée en acétate énolique VI par la méthode rapportée en 2.11. On obtient 5.1 g d'un liquide incolore (78% du rendement théorique), p.é. 104–105° à 105 mm, $n_D^{26.5}$: 1.4512. Le spectre I.R. a des bandes à 1690 et 1748 cm^{-1} (liquide pur). Calculé pour $C_{10}H_{16}O_2$: C, 71.39; H, 9.58%. Trouvé: C, 71.72; H, 9.66.

3. Ozonolyse des acétates énoliques

3.1. Méthode générale

On dissout 1.6 g d'acétate énolique dans 75 ml d'éther de pétrole (p.é. 30–38°) exempt d'alcènes, on refroidit la solution dans un bain de glace sèche et d'acétone et on fait passer dans cette solution, en maintenant la réfrigération, un courant d'oxygène contenant environ 3% d'ozone jusqu'à obtention de la coloration bleue caractéristique d'un excès d'ozone (durée de l'opération: environ une heure et demie). On évapore alors l'éther de pétrole, en faisant passer un courant d'azote, sous un léger vide, et au résidu on ajoute 18 ml d'eau, 18 ml d'acétate d'éthyle, 18 ml d'acide acétique glacial, et 6 ml de peroxyde d'hydrogène à 30%. On agite pendant la nuit à la température ambiante. Les solvants sont évaporés en chauffant sous vide de 11 mm à une température ne dépassant pas 100°. On dissout le résidu brut dans de l'éther et on ajoute à cette solution refroidie, une solution éthérée de diazométhane jusqu'à coloration jaune persistante. L'éther est évaporé et le résidu chromatographié en phase gazeuse: colonne de 1 mètre, polyester succinique de Craig 15% sur Kromat FB; débit de l'éluant (hélium), environ 50 ml à la minute; température 162°. Dans ces conditions le diester méthylique de l'acide diméthyl-2,2 adipique est élué au bout de 10.5 minutes, celui de l'acide diméthyl-3,3 adipique au bout de 14.2 minutes.

For personal use only.

3.2. Ozonolyse de l'acétate énolique IIId

Selon le mode général d'opération 3.1, 300 mg de l'acétate sont ozonolysés. La chromatographie en phase gazeuse du diester final ne donne qu'un pic, superposable à celui obtenu plus loin en 3.4.

3.3. Ozonolyse de l'acétate énolique IId

500 mg de l'acétate II*d* sont ozonolysés suivant le mode général d'opération 3.1. La chromatographie en phase gazeuse du diester final ne révèle qu'un pic, superposable à celui obtenu plus bas en 3.5.

3.4. Ozonolyse de l'acétate énolique VII

1.24 g de l'acétate énolique VII (préparé en 2.2 et contenant 20% de diméthyl-2,2 cyclohexanone) sont traités par l'ozone suivant le mode général 3.1. Après l'évaporation des solvants (suivant l'oxydation de l'ozonide) et un séchage sous vide, l'acide diméthyl-2,2 adipique ne se solidifie pas. Le p.f. rapporté est de 89–90° (6). L'acide brut est alors méthylé et la chromatographie en phase gazeuse du produit final indique un pic majeur (10.5 minutes d'élution) et une impureté de l'ordre de 5%.

3.5. Ozonolyse de l'acétate énolique VI

2.5 g de l'acétate de diméthyl-4,4 cyclohexényle, préparé en 2.3, sont ozonolysés suivant le mode général 3.1. Après l'évaporation des solvants qui suit l'oxydation par H_2O_2, le résidu est séché sous vide. Le diacide brut est recristallisé dans le chloroforme et l'éther de pétrole, p.f. 85.5–87° (litt. (6) 86–87°). L'acide diméthyl-3,3 adipique VIII est méthylé par le diazométhane et le diester ne fournit qu'un pic en chromatographie en phase gazeuse. (14.2 minutes d'élution).

4. Mises en équilibre des acétates énoliques de la diméthyl-3,3 cyclohexanone

4.1. Mise en équilibre de l'acétate de diméthyl-3,3 cyclohexényle IIId par un mélange anhydride acétique–acide perchlorique

Environ 150 mg de l'acétate énolique III*d* sont dissous dans 40 ml de benzène et 15 ml de CCl_4. A cette solution refroidie on ajoute une solution glacée de 3 ml d'anhydride acétique et 4 gouttes d'acide perchlorique 78%. Le mélange est ensuite traité de la même façon que lors de la préparation des acétates énoliques à partir de la diméthyl-3,3 cyclohexanone (voir plus haut, section 2.12). La chromatographie en phase gazeuse indique la présence d'environ 10% de diméthyl-3,3 cyclohexanone et 90% d'acétates énoliques dans un rapport de 25% de III*d* et 75% de II*d*.

4.2. Essai de mise en équilibre par l'acétate d'isopropényle – acide sulfurique

4.21. A partir de l'acétate de diméthyl-3,3 cyclohexényle IIId

A 600 mg de l'acétate de diméthyl-3,3 cyclohexényle (III*d*) on ajoute 2 ml d'acétate d'isopropényle et 0.01 ml d'acide sulfurique concentré et le mélange est chauffé à reflux pendant 75 minutes sous atmosphère d'azote, après quoi environ 30% du solvant est distillé sous pression légèrement réduite. Le produit est extrait de la même façon que lors de la préparation des acétates énoliques à partir de la diméthyl-3,3 cyclohexanone (voir plus haut, 2.11). La chromatographie en phase gazeuse indique que le composé de départ III*d* est resté inaltéré.

On a repris la même expérience en ajoutant 200 mg d'acétone au produit de départ mais ceci n'amène aucune isomérisation de l'acétate de départ.

4.22. A partir de l'acétate de diméthyl-5,5 cyclohexényle (IId)

600 mg de l'acétate énolique II*d* sont traités de la même façon que l'acétate III*d* (cf. 4.21). La chromatographie en phase gazeuse du produit final indique que c'est l'acétate de départ inchangé.

4.23. A partir de l'acétate énolique IIId en présence de la cétone I

Un mélange de 82 mg de diméthyl-3,3 cyclohexanone (I) et 132 mg d'acétate de diméthyl-3,3 cyclohexényle (III*d*) dans 1 ml d'acétate d'isopropényle et 0.005 ml de H_2SO_4 concentré, est traité suivant le même mode opératoire qu'à la section 4.21. La chromatographie en phase gazeuse du produit brut révèle la présence de 71.5% de l'acétate III*d* et 28.5% de l'acétate II*d*.

Ces pourcentages représentent: acétate III*d* = 132 mg au départ + 40.6 mg formés à partir de la cétone; et acétate II*d* = 68.7 mg formés à partir de la cétone. La cétone a donc engendré les acétates II*d*/III*d* dans le rapport 62.8/37.2. Nous concluons de ceci que l'acétate de départ III*d* ne s'est pas isomérisé et que la cétone a donné les acétates énoliques II*d*/III*d* comme en 2.11.

5. Oxydation nitrique des diméthyl-2,2, -3,3, et -4,4 cyclohexanones

La cétone (1.5 g) est ajoutée lentement à 6.0 ml d'acide nitrique concentré chauffé à reflux (30). Après l'addition on laisse refluer pendant 10 minutes puis on évapore l'acide nitrique en chauffant. Le résidu jaune, très visqueux, n'est pas purifié. On le dissout dans l'éther et on ajoute à cette solution refroidie, une solution éthérée de diazométhane jusqu'à ce que l'évolution d'azote cesse et la coloration jaune persiste. Le solvant est évaporé sur bain-marie et le produit brut est chromatographié en phase gazeuse, sur polyester succinique de Craig (15% sur Kromat FB, température 162°, hélium 50 ml par min.

Les acides diméthyl malonique (XIII), diméthyl-2,2 succinique (XII), diméthyl-3,3 glutarique (XI), et diméthyl-2,2 glutarique (X) ont été obtenus de la Maison Aldrich Chemical Co., Inc. Les diesters méthyliques correspondants ont été préparés en ajoutant une solution éthérée de diazométhane à une solution éthérée

TABLEAU III

Oxydation nitrique des cétones I, IV, et V

Cétone de départ	Diacides obtenus et temps de rétention (minutes) des diesters méthyliques correspondants					
	XIII 2.3	XII 3.8	XI 6.4	X 7.3	IX 10.5	VIII (diacides) 14.2 (minutes
I	+	+	+	+	22%	78%
IV	+	+	+	+		+
V	+	+		+	+	

de chacun des acides. Les esters des acides diméthyl-2,2 et -3,3 adipiques (IX et VIII) ont été préparés plus haut (cf. 3.4 et 3.5).

Les composants des mélanges indiqués au Tableau III ont été identifiés en faisant des mélanges avec les produits connus qui dans chaque cas, se superposent avec un des composants d'un mélange d'oxydation.

Seul le rapport des acides diméthyl-2,2 et -3,3 adipiques a été déterminé: il est de 22/78 (Tableau III). On remarque qu'à partir de la diméthyl-4,4 cyclohexanone, l'acide diméthyl-2,2 adipique (IX) ne se forme pas et à partir de la diméthyl-2,2 cyclohexanone, les acides diméthyl-3,3 adipique (VIII) et diméthyl-3,3 glutarique (XI) ne se forment pas. Nous n'avons pas dosé chaque constituant dans chaque mélange: en première approximation, en calculant simplement les surfaces de chaque pic, l'acide IX à partir de la cétone V, VIII à partir de IV, et les acides IX et VII à partir de I, représentent environ 70% du mélange brut.

6. Ozonolyse des ène-pyrrolidines IIIb et IIb

On effectue l'ozonolyse sur 1 g du mélange des énamines II*b* et III*b*. préparé selon (2) suivant la méthode générale 3.1. Après l'évaporation des solvants (qui suit l'oxydation par H_2O_2) le produit brut est saponifié en chauffant à reflux pendant 4 heures avec 20 ml de solution de NaOH 10%. Une forte odeur de pyrrolidine se dégage. La solution refroidie est acidifiée avec l'acide chlorhydrique concentré, jusqu'au bleu Congo, et on extrait avec de l'éther. La phase éthérée est lavée à l'eau saturée de NaCl et séchée sur le sulfate de sodium anhydre. Le solvant est évaporé et les acides bruts sont méthylés avec une solution éthérée de diazométhane. Après l'évaporation de l'éther, le résidu est chromatographié en phase gazeuse comme en 3.1: les deux diesters des acides IX et VIII sont présents dans un rapport de 20% et 80% respectivement.

7. Isomérisation des diméthyl-3,3 et diméthyl-4,4 cyclohexènes

7.1. Diméthyl-3,3 cyclohexène (IIIe)

On chauffe à l'ébullition à reflux pendant 20 heures, 2.2 g de diméthyl-2,2 cyclohexanol (31), 20 ml de toluène anhydre, et 1.0 g de sodium coupé en petits morceaux. On refroidit à 0°, enlève l'excès de sodium avec des pincettes, et ajoute 50 ml d'éther anhydre puis 3.3 g de sulfure de carbone fraîchement distillé; il n'y a pas de précipitation de sel sodé. On ajoute alors 6.3 g d'iodure de méthyle dans 20 ml de méthanol anhydre et chauffe à l'ébullition à reflux pendant 4 heures. Après refroidissement à 0°, on extrait par de l'éther et isole à la manière habituelle 6.9 g (rendement 81.2%) de xanthogénate, p.é. 102° sous 1.4 mm, $n_D^{26} = 1.5390$.

Le xanthogénate (6.9 g) est ajouté goutte à goutte dans un ballon de Claisen, contenant des anneaux de verre et chauffé à 270°. Le diméthyl-3,3 cyclohexène brut qui distille est redistillé: p.é. 113–114° sous 740 mm, $n_D^{21} = 1.4447$ (on donne (32): $n_D^{20} = 1.4426$). Cet hydrocarbure est homogène en chromatographie en phase gazeuse: colonne 5 mètres, 5 mm de diamètre interne, 35% de β,β'-oxydipropionitrile sur Kromat-FB, température 55°, hélium 40 ml par minute; temps d'élution: 32 minutes.

7.2. Diméthyl-4,4 cyclohexène (IIe)

Par la méthode 7.1 décrite plus haut, on transforme le diméthyl-4,4 cyclohexanol (27) en diméthyl-4,4 cyclohexène, p.é. 115° sous 740 mm. $n_D^{25} = 1.4383$, homogène en chromatographie en phase gazeuse (temps d'élution dans les conditions décrites en 7.1: 36 minutes). On donne (33): $n_D^{20} = 1.4414$; (34): $n_D^{20} = 1.4435$.

7.3. Isomérisation des diméthyl-3,3 et diméthyl-4,4 cyclohexènes (IIIe et IIe)

Ces deux hydrocarbures furent isomérisés selon la méthode de Cope (11).

Dans chaque cas, 360 à 390 mg de l'hydrocarbure en question furent dissous dans 10 ml d'acide acétique glacial en présence de 1.0 g d'acide *p*-toluène sulfonique. Le mélange fut porté à reflux sous une atmosphère d'azote pendant 1, 17, et 257 heures. A la fin du chauffage, les produits de la réaction sont extraits par de l'éther de pétrole. Cette solution est lavée par de l'eau, jusqu'à neutralité puis séchée. L'éther de pétrole est distillé (colonne de Widmer). L'analyse par chromatographie en phase gazeuse comme plus haut en 7.1, permit à la fois d'identifier les produits de réaction et de calculer les proportions relatives de chacun des deux isomères. Les résultats sont rapportés au Tableau I. L'isomérization des deux hydrocarbures donne naissance à un mélange fort complexe d'hydrocarbures (au moins 8) et d'acétates (au moins 4), comme le

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

montrent la chromatographie en phase gazeuse sur colonne de Ucon Polar (20% sur Kromat FB, 2.5 mètres, *T*: 85° pour les hydrocarbures et 137° pour les acétates) et la spectroscopie infrarouge.

8.1. Diméthyl-4,4 cyclohexanedione-1,3 (XIV)

L'anhydride diméthyl-2,2 glutarique, p.f. 38–40° (on donne (35) 38.5°), 5 g, est porté à l'ébullition à reflux dans 5 ml de méthanol. On reprend par de l'éther, extrait par une solution aqueuse de bicarbonate de sodium 10%, acidifie la solution aqueuse, extrait par de l'éther, sèche et évapore l'éther. On recueille, par distillation, 11.7 g de mono-ester XX, p.é. 120° sous 1.6 mm, $n_D^{24} = 1.4395$. Rendement 85.2%.

On agite pendant 15 heures, à température de la pièce, 16.5 g de mono-ester XX et 14.4 g de chlorure de thioyle (30% d'excès). Par distillation on obtient 17.4 g de chlorure d'acide XXI, p.é. 70° sous 1.2 mm; rendement 97%.

A une solution, refroidie à 0°, de bromure de méthyle magnésium (formée à partir de 4.5 g de magnésium, 30.0 g de bromure de méthyle liquide et 150 ml d'éther) on ajoute 19 g de chlorure de cadmium anhydre en l'espace de 20 minutes, puis on agite à température de la pièce durant 45 minutes. On évapore 100 ml d'éther, puis ajoute 150 ml de benzène anhydre. Le mélange est porté à l'ébullition à reflux. On interrompt le chauffage, ajoute aussi rapidement que possible 17.4 g du chlorure d'acide XXI dans 30 ml de benzène anhydre. On reprend l'ébullition durant 30 minutes, refroidit à 0° et ajoute lentement 150 ml d'acide sulfurique 0.15 *M* refroidi à 0°. On extrait par de l'éther, lave les solutions éthérées réunies par de l'eau, une solution de bicarbonate de sodium 10%, puis à l'eau saturée de chlorure de sodium. On distille les solvants, puis le céto-ester XXII, 11.3 g, p.é. 72° sous 2 mm, $n_D^{24} = 1.4347$; rendement 73%.

A 7 g de sodium pulvérisé, juste recouvert de xylène, on ajoute 2.6 ml de méthanol anhydre et 65 ml d'éther anhydre. On agite durant 12 heures à température ambiante. On ajoute ensuite 5.0 g du céto-ester XXII, puis reprend l'agitation durant 2 heures; on essore le précipité, on le lave avec de l'éther anhydre et le dissout, par petites portions, dans 100 ml acide chlorhydrique concentré – eau 1:1. On extrait par de l'éther, lave avec de l'eau saturée de chlorure de sodium, sèche, distille l'éther, et recueille 3.0 g de diméthyl-4,4 cyclohexanedione-1,3 (XIV), p.f. 105° après cristallisation dans de l'éther de pétrole; rendement 75%. Calculé pour $C_8H_{12}O_2$: C, 67.32; H, 8.37%. Trouvé: C, 68.54; H, 8.63%. Spectre infrarouge (Nujol): –OH, bande large 3400–2660 cm^{-1}, avec max. à 2620 et 2550 cm^{-1}; C=O, 1610 cm^{-1}; C=C 1535 cm^{-1} (36).

8.2. Ethers méthyliques céto-énoliques de la diméthyl-4,4 cyclohexanedione-1,3 (XV et XVI, R = $-CH_3$)

On ajoute à 2.2 g de dicétone XIV, en solution dans 100 ml d'éther anhydre, une solution de diazométhane jusqu'à coloration jaune persistante, puis en excès (26); on abandonne pendant 2 heures à température ambiante. On évapore l'éther, reprend par de l'éther pur, que l'on lave avec une solution aqueuse d'acide chlorhydrique 5% (rapidement), puis à l'eau, avec une solution aqueuse de bicarbonate de sodium 5% et enfin à l'eau. Après distillation de l'éther, le résidu est distillé: 2.05 g, p.é. 81° sous 2 mm, $n_D^{22} = 1.4969$; rendement 85%. Calculé pour $C_9H_{14}O_2$: C, 70.03; H, 9.05%. Trouvé: C, 70.10; H, 9.15%.

8.3. Double réduction des éthers céto-énoliques XV et XVI en diméthyl-2,2 et diméthyl-4,4 cyclohexanone

On suit fidèlement les indications données pour la réduction des éthers céto-énoliques de l'oxo-4 homocamphre en cétones α,β-éthyléniques par l'hydrure de lithium et d'aluminum, puis de ces cétones en cétones saturées en présence de palladium sur carbonate de calcium (26). C'est ainsi que 2.0 g des éthers céto-énoliques XV et XVI (R = CH_3) donnent 1.45 g des cétones XVII et XVIII, qui conduisent elles-mêmes à 1.10 g de diméthyl-2,2 et diméthyl-4,4 cyclohexanones en mélange. Par chromatographie en phase gazeuse (colonne de 2.5 mètres, 30% de graisse Apiezon sur cellite, 140°, hélium 65 ml par minute) nous avons montré, par la méthode du rehaussement des pics avec des cétones authentiques, la structure de ces cétones et nous les avons dosées: 65% de diméthyl-4,4 cyclohexanone et 35% de diméthyl-2,2 cyclohexanone, ±3%.

REMERCIEMENTS

Nous remercions vivement le Conseil National de Recherches du Canada d'une subvention de recherches (H. F.) et l'Office de la Recherche Scientifique de la province de Québec de bourses d'étude (J. C. et D. V.).

ABSTRACT

The major condensation product of benzoic acid with formaldehyde in the presence of sulphuric acid was shown to be diphenylmethane-3,3′-dicarboxylic acid.

When benzoic acid is condensed with formaldehyde in the presence of sulphuric acid there is formed in small and variable yield a diphenylmethanedicarboxylic acid. Because the product is not identical with known diphenylmethanedicarboxylic acids and because of the predominantly meta directing nature of the carboxyl group Schöpff assigned the 3,3′-positions to the carboxyls (1).

We have had occasion to repeat the condensation of benzoic acid with formaldehyde and have succeeded in isolating the major condensation product in a pure form and in establishing its structure.

The pure acid melts at 270°* and this was oxidized to the corresponding benzophenone-dicarboxylic acid. The oxime of the methyl ester of the latter on Beckmann rearrangement yielded the dimethyl ester of 3,3′-dicarboxybenzanilide identical with a synthetic specimen and therefore the structural assignment of Schöpff is correct. The above benzanilide was also prepared as follows: *m*-aminobenzoic acid was reacted with *m*-toluoyl chloride under Schotten–Baumann conditions and the resulting *m*-tolu-3-carboxyanilide was oxidized with permanganate. Further proof of the structure of the dicarboxybenzanilide came from its hydrolysis to isophthalic acid.

EXPERIMENTAL

Dimethyl Diphenylmethane-3,3′-dicarboxylate

The mixture of acids as obtained by the procedure of Schöpff was esterified with methanol in the usual manner. Upon distillation there was obtained a first fraction of methyl benzoate followed by one boiling at 200–210° at 1.5 mm which constituted about one-third of the entire ester. There was considerable higher boiling material, evidently higher condensation products. The above middle fraction was a viscous oil which crystallized after many months standing at ambient temperature. Adhering oil was pressed out on filter paper and the ester then recrystallized from methanol; m.p. 64°. Found: C, 72.21, 72.31; H, 5.42, 5.56. $C_{17}H_{16}O_4$ requires: C, 71.83; H, 5.63.

The free *acid* obtained by alkaline hydrolysis, when recrystallized from methanol, melted at 270°. Found: C, 70.68, 70.76; H, 4.59, 4.87. Calc. for $C_{15}H_{12}O_4$: C, 70.31; H, 4.69.

Benzophenone-3,3′-dicarboxylic Acid

An alkaline solution of the above diphenylmethane-3,3′-dicarboxylic acid (5 g) was digested on the steam bath for several hours with potassium permanganate (5.35 g). The acid isolated by acidification, filtration, and drying (5.1 g) was recrystallized by adding isopropanol to the concentrated solution of it in dimethylformamide. The fine colorless crystals melted at 356°. Found: C, 66.83, 66.82; H, 3.93, 3.69. $C_{15}H_{10}O_5$ requires C, 66.66; H, 3.70.

Owing to the extremely low solubility of this acid in methanol its esterification with that solvent in excess required several days heating under reflux with a trace of sulphuric acid. The *dimethyl ester* crystallized from benzene in stout colorless prisms melting at 130°. Found: C, 68.72, 68.46; H, 4.68, 4.70. $C_{17}H_{14}O_5$ requires: C, 68.46; H, 4.70.

**All melting points are corrected.*

The *oxime* of the dimethyl ester, prepared by reaction with excess hydroxylamine hydrochloride and potassium acetate in methanol, was recrystallized from methanol; m.p. 130°. Found: C, 64.94; 64.64; H, 4.72, 4.79; N, 4.43, 4.41. $C_{17}H_{15}O_5N$ requires: C, 65.18; H, 4.79; N, 4.47.

When 2 g of this oxime was heated under reflux in 40 cc benzene with 2 g phosphorus pentachloride for 3 hours it was converted to dimethyl benzanilide-3,3′-dicarboxylate. The cooled benzene solution was washed with aqueous alkali and the solvent removed by evaporation. The residue (1.6 g) when recrystallized from methanol melted at 159° and this melting point was not depressed when the ester was admixed with that prepared as described below. Found: C, 65.42, 56.47; H, 4.82, 4.88; N, 4.44, 4.54. $C_{17}H_{15}O_5N$ requires: C, 65.18; H, 4.79; N, 4.47.

The acid, obtained by hydrolysis of the above ester, was recrystallized from dimethylformamide–water and then melted at 342°. This melting point was not depressed when the acid was admixed with the evidently less pure product (m.p. 333°) described below.

Further authentication of the above anilide was achieved by heating 1 gram of it for 50 hours in a mixture of 100 cc glycol and 13 cc concentrated hydrochloric acid. The reaction mixture was then rendered akaline with sodium hydroxide and most of the glycol removed by evaporation *in vacuo*. The residue was dissolved in water, the filtered solution acidified, and the precipitate recrystallized from aqueous ethanol. It then melted at 338–339° either alone or in admixture with an authentic specimen of isophthalic acid similarly recrystallized.

m-Tolu-3-carboxyanilide

The acid chloride prepared from 9 g of purified *m*-toluic acid and excess thionyl chloride was added to a cooled solution of 9 g *m*-aminobenzoic acid in 50 cc water containing 3 g sodium hydroxide; a 40% solution of sodium hydroxide was added in small portions to maintain constant alkalinity. A slight turbidity was removed by filtration and the filtrate diluted to 500 cc with hot water. The precipitate obtained upon acidification was separated by filtration and washed with a liter of boiling water. When dried it melted at 248° and when recrystallized either from ethanol, or from dimethylformamide-methanol it melted at 250°. Found: C, 70.30, 70.99; H, 5.20, 5.03. $C_{15}H_{13}O_3$ requires: C, 70.59; H, 5.10.

Dimethyl Benzanilide-3,3′-dicarboxylate

The above anilide (6.4 g) was suspended in 100 cc water to which had been added several pellets of sodium hydroxide. The hot solution was treated with powdered potassium permanganate until further oxidation was very slow (ca. 9.5 g). The mixture was filtered with the aid of 'filtercel' and the hot filtrate acidified. The washed and dried precipitate melted not quite sharply at 333°. This crude acid required 48 hours boiling under reflux with methanol and a trace of sulphuric acid to affect complete esterification. The *dimethyl ester* was crystallized first from benzene (m.p. 152–154°) and then from methanol; m.p. 158°.

A STUDY OF MOLECULAR INTERACTIONS IN MOLECULAR BEAMS ISOLATED FROM THE EXHAUST OF SUPERSONIC NOZZLES

JOHN P. VALLEAU AND JACQUES M. DECKERS
Department of Chemistry, University of Toronto, Toronto, Ontario
Received June 12, 1963

ABSTRACT

In high density molecular beams, such as those isolated from supersonic nozzles, collisions between beam molecules may have an important effect on the beam behavior. This paper uses the classical kinetic theory to discuss the effect of these collisions on the intensities and velocity distributions in a beam. Initially, intensities are calculated assuming unchanging Maxwellian velocity distributions. However, the beam collisions will, in fact, alter the velocity distributions in a way that could be described as an "asymmetric cooling" of the beam; a start has been made on examining the effects of this phenomenon.

In the case of beams of mixed composition, the analysis indicates that an enrichment of the heavier component will take place as a result of collisions within the beam.

Formulae relating beam density profiles to the geometry of the beam-defining elements are also deduced. Numerical examples are worked out for an illustrative case in which the diameter of the beam diaphragms is 0.1 cm and the distance between them is 10 cm, assuming the beam to be isolated from the exhaust of a 7.5 mach expansion with a stagnation temperature of 300° K.

Section 1—Introduction

An ideal molecular beam could be described as a stream of molecules which move in rigorously parallel paths without undergoing collisions. However, all attempts to obtain molecular beams in the laboratory have yielded devices in which the beam molecules only approximate this behavior. In any beam, there are two reasons for molecular encounters: collisions with residual molecules in the environment and collisions among the molecules in the beam itself. The low background pressures achieved with modern large-capacity vacuum pumps have, however, reduced the number of collisions between beam and residual molecules to a very large extent.

Recently beam densities much higher than before have been achieved by isolating molecular beams from the core of the exhaust of small supersonic nozzles. The technique was originally suggested by Kantrowitz and Grey (1), and realized experimentally first by Kistiakowsky and Slichter (2) at Harvard University, and later by Becker *et al.* (3) in Germany (Marburg and Karlsruhe) and by groups at Princeton University (4) and at the University of Virginia (5). At the beam densities thus achieved the number of collisions between the beam molecules may affect the behavior of the molecular beam in a way that cannot be neglected. The purpose of the present paper is to discuss the effect of these collisions in the beam and in particular to make some estimate of the resulting variation of intensity and velocity distribution throughout the beam. Most measurements on "nozzle beams" have recorded the *total flux* at a *fixed* detection station. It will be shown that the flux at other positions in the beam can, as a result of collisions, differ significantly from the results of such measurements. The intensity profiles within the beam are also investigated.

It might be useful to point out that the variation of velocity distribution and density profiles as a function of the distance from the point of origin of the beam will have far-reaching influences on the beam experiments which are presently being carried out or

contemplated in various laboratories. Although surface-scattering experiments involving a single beam might not be too much affected provided all targets are mounted at exactly the same location and the beam is not too wide, the study of gas phase collisions and scatter will be especially sensitive to the detailed density distribution within the beam.

In section 2 beam formation is described, and the velocity distribution functions in the beam are discussed with reference to some assumptions basic to the later calculations. In the following section the purely geometrical factors affecting the behavior of molecular beams will be studied. We then go on to consider beams in which collisions may occur, examining first the central "core" region of a one component beam (section 4), and then the intensity profiles in the remaining peripheral region of the beam (section 5). Finally we make some remarks on beams composed of a mixture of heavy and light molecules.

Section 2—Formation of a Supersonic Beam

Only the experimental features relevant to the analysis will be given here, since a complete description of the method has appeared elsewhere (4).

As seen in Fig. 1 a converging nozzle exhausts into chamber I evacuated to a pressure

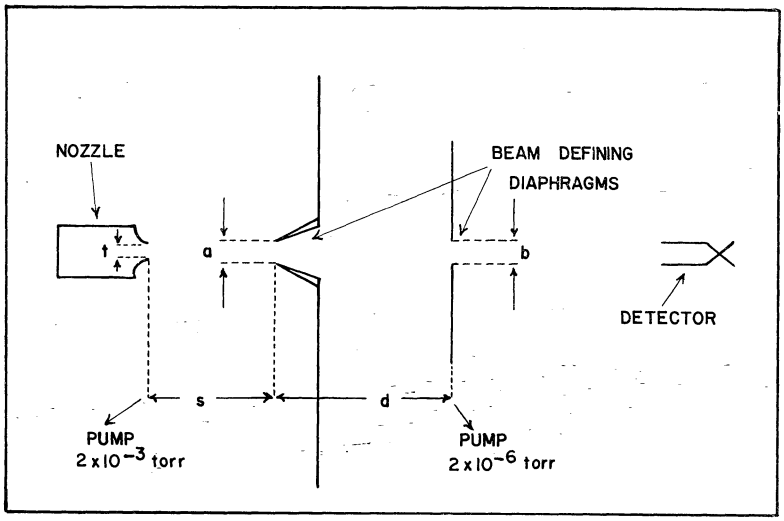

FIG. 1. Production of a "nozzle beam" (schematic).

of about 10^{-3} torr. Part of the core of the exhaust gases flows through a hole in the tip of a conical diaphragm into a second enclosure in which the pressure is maintained near 2×10^{-6} torr. In this enclosure is located a second diaphragm which further defines the molecular beam. The mean free path in the second chamber at those working pressures is larger than 10^3 cm, so the number of collisions between beam and background molecules is very small and might be neglected.

The fluid mechanical description of flow through nozzles may be found in adequate textbooks.* According to this the bulk mass velocity of a pure gas expanded through a nozzle will be

$$\bar{v} = \sqrt{\frac{2C_p(T_0-T)}{M}}, \qquad [2.1]$$

where the following symbols are used:

*For example, see ref. (6).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$\bar{v}$ is the bulk mass velocity or "beam velocity",
C_p is the specific heat per mole, at constant pressure,
M is the molecular weight,
T_0 is the temperature before expansion (stagnation temperature),
T is the temperature within the beam after expansion, with respect to an observer moving with the beam velocity $\bar{v}$.

The temperatures T_0, T will be related by

$$T_0/T = 1+[(\gamma-1)/2]\mathscr{M}^2 \qquad [2.2]$$

where $\mathscr{M}$ is the mach number of the gases expanded through the nozzle.

These equations assume isentropic flow and imply the retention, throughout the expansion, of a Boltzmann velocity distribution isotropic with respect to the local bulk velocity. We have adopted this Boltzmann distribution as a reasonable (and furthermore workable) basis for our calculations (cf. appendix 3). It must be admitted that this distribution will in fact be distorted, between the diaphragms, in two ways. The first concerns merely the spreading of the beam and leads, on a simple-minded view, to the distribution

$$f(v) \propto v^2 \exp\{-m(v-\bar{v})^2/2kT\}. \qquad [2.3]$$

The purely Maxwellian distribution we are using neglects,* in the words of Kantrowitz and Grey (1), "the influence of the random velocity on the probability of a molecule's getting through the slit, compared to the predominant effect of the mass flow velocity". The distortion is in fact not very great since most of the velocities $v \approx \bar{v}$, and it is smaller the higher the mach number of the beam. In any case it will become apparent from our analysis (section 4) that the beam's velocity distribution will be simultaneously subjected to a second, equally serious, distortion by collisions between the molecules. In view of this the above distribution [2.3] is not of special relevance. In section 4 we will consider how we may make some correction for the effect of collisions on the velocity distribution in the beam.

A beam is isolated from the expanded gas by two apertures, of diameters a and b, which are separated by a distance d. At the second aperture, no molecule in the beam will have a trajectory forming an angle with the beam axis greater than arctan (b/d). All smaller angles will, however, be present, and will result in the gradual spreading of the beam envelope. This "geometrical" effect will lead to no change in the *total* flux in the beam, of course, but only to a decrease of molecular density within the beam. At the same time, collisions will occur, and most such collisions will result in the removal from the beam of the colliding molecules. This leads to a decrease of total molecular flux in the beam, and thus results in a further reduction of the beam density.

It will be convenient to present some numerical examples in this paper. For this purpose we have chosen a sample beam of typical dimensions to which all illustrative examples will refer. This beam is defined by equal apertures $a = b = 0.1$ cm, separated by a distance $d = 10$ cm. The stagnation and beam temperatures will be taken as $T_0 = 300°$ K and $T = 15°$ K, respectively. The gas is assumed to be monatomic and ideal. The temperatures assumed are those of a mach 7.5 expansion.

Section 3—Geometrical Effects

We wish to calculate the molecular density at any point in the beam, and we consider in this section the purely geometrical effects. That is, we attempt to obtain the density

*We are grateful to R. P. Andres of Princeton University for raising this question.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in the absence of any collisions in the beam (for point particles, for example, or for photons).

This calculation is much simplified as a result of the following considerations. Suppose a particular molecule is moving with the beam velocity $\bar{v}$. If it is to remain in the beam after isolation by the two apertures, its *transverse* velocity, v_{tr}, must be less than $(b/d)\bar{v}$; i.e.

$$v_{tr} < \frac{b}{d}\bar{v} = \frac{b}{d}\mathscr{M}\sqrt{\frac{[C_p(\gamma-1)T]}{M}}. \qquad [3.1]$$

For most cases of interest this velocity is very small. In particular, $(b/d)\bar{v}$ is much less than the r.m.s. transverse velocity, $\sqrt{2(RT/M)}$, of the gas behind the apertures; for our "sample beam" ($(\gamma-1)C_p = 5R/3$, $\mathscr{M} = 7.5$)) we find a ratio of 0.068 for these quantities. Figure 2 shows a Boltzmann velocity distribution function, and indicates that even at

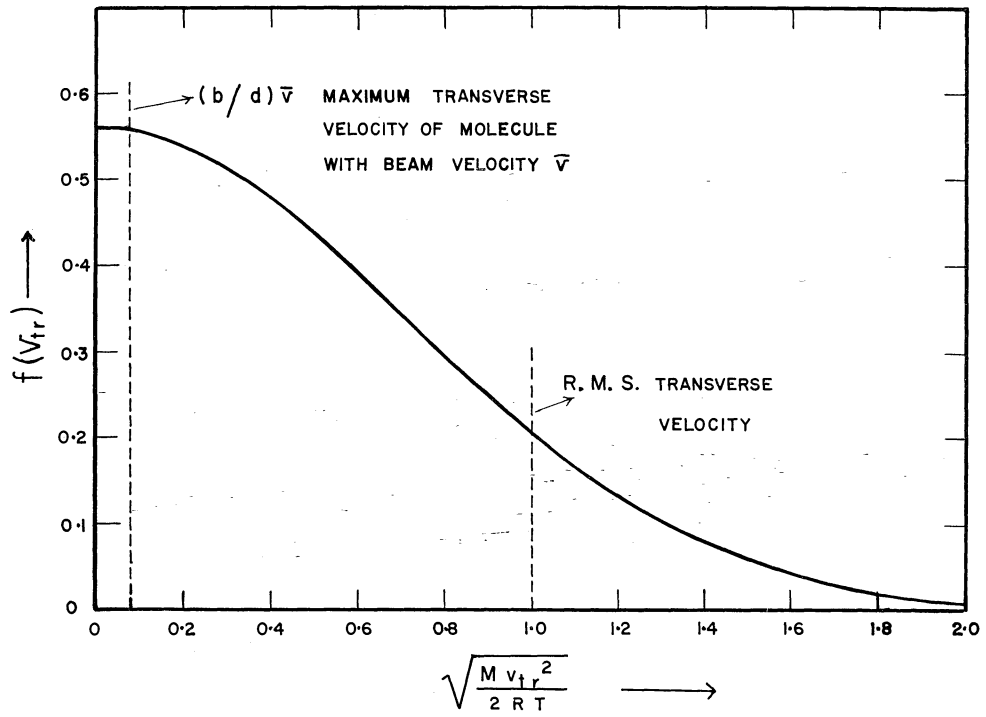

FIG. 2. A normalized Maxwell velocity distribution, showing the r.m.s. transverse velocity behind the apertures, and also the maximum transverse velocity of a molecule in the beam and travelling with the beam velocity $\bar{v}$ (for the sample beam).

the maximum value $(b/d)\bar{v}$ of v_{tr} the velocity probability is down only to 0.99_5 of its peak value. It is therefore a very fair approximation to take equal probabilities for all the (very small) transverse velocities attainable within the beam, and this approximation is the basis of the following calculations.

As shown in Fig. 3, the molecular beam consists of a central region, or "core", and a surrounding "off-core" or "peripheral" region. Points in the core "see" the whole of the first aperture. Since points in the first aperture are, according to the above approximation,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

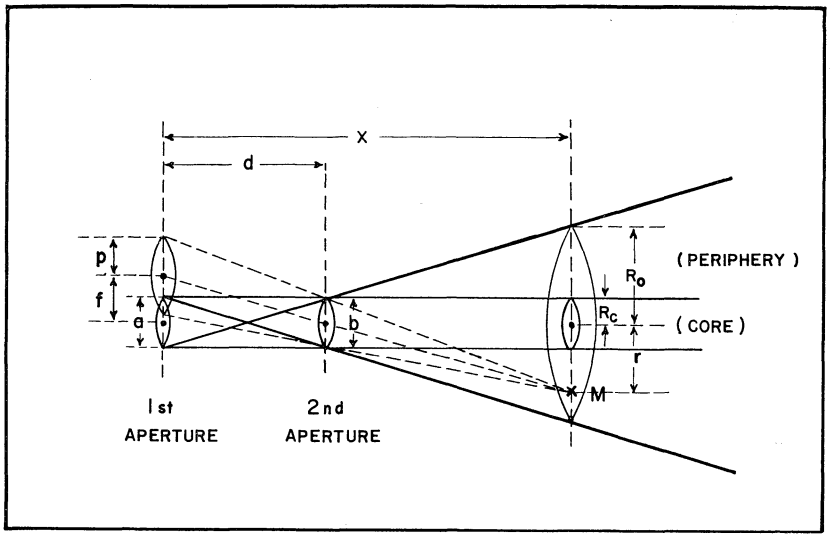

FIG. 3. Structure of the beam. Here $a = b = 2R_c$; if $a \neq b$, the core becomes conical.

regarded as isotropic point sources, the molecular density in the core will fall off according to the inverse square law:

$$n_c' = n_b d^2/x^2, \qquad [3.2]$$

$$dn_c'/dx = -2n_c'/x, \qquad [3.3]$$

where x is the distance, measured along the beam axis, from the first aperture, n_c' is the density in the core, and the prime refers to the calculations of this section, in which collisions are ignored; n_b is the value of the density in the second aperture. (Since the first aperture is finite, the above equations really involve the additional assumption that we may ignore the deviation from unity of the cosines of all angles less than arctan (b/d). For our sample beam, cos arctan (b/d) is 0.9999_5, and the approximation is entirely justified.)

According to the above, the intensity is uniform across the core of the beam at a given value of x; one may say that the intensity profile has a flat top. Turning now to points inside the beam, but at a distance r, greater than the radius of the core, from the beam axis, only a fraction $\sigma'(x,r)$ of the first aperture will be visible. The molecular density at this distance r will be related to that in the core by

$$n'/n_c' = \sigma'. \qquad [3.4]$$

In appendix 1, this ratio σ' has been evaluated as a function of x and r. It proves convenient to introduce the quantities R_c and R_o, which are respectively the radius of the core and that of the outer envelope of the beam. At a distance x from the first diaphragm $(x > d)$, these may be written

$$R_c = \frac{b}{2}\left(\frac{x}{d}\right) - \frac{a}{2}\left(\frac{x-d}{d}\right), \quad R_o = \frac{b}{2}\left(\frac{x}{d}\right) + \left(\frac{a}{2}\right)\left(\frac{x-d}{d}\right). \qquad [3.5]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

When these quantities, along with [A.1.5], are introduced into [A.1.4], we find that

$$\sigma' = \frac{1}{\pi}\text{arc cos}\left(\frac{r^2-R_oR_c}{r(R_o-R_c)}\right)+\left(\frac{x}{x-d}\right)^2\left(\frac{b}{a}\right)^2\frac{1}{\pi}\text{arc cos}\left(\frac{r^2+R_oR_c}{r(R_o+R_c)}\right) - \frac{2}{\pi}\frac{\sqrt{(R_o^2-r^2)(r^2-R_c^2)}}{(R_o-R_c)^2}. \qquad [3.6]$$

We may describe the off-core values of r by the dimensionless quantity

$$\xi = (r-R_c)/(R_o-R_c); \qquad [3.7]$$

ξ ranges from zero at the edge of the core to unity at the outer edge of the beam.

In Fig. 4 is shown σ', for our sample beam, as a function of ξ for various values of x

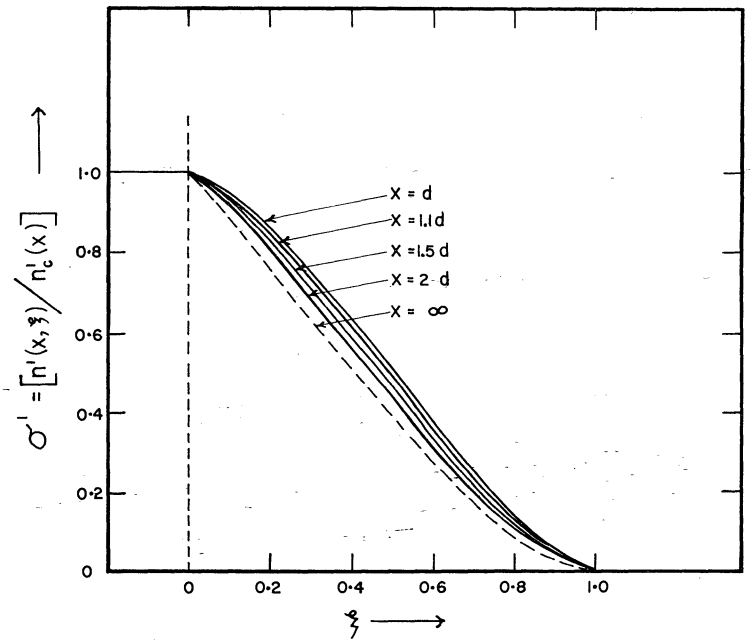

FIG. 4. Beam profiles, in the absence of collisions, for the sample beam: $a = b = 0.1\ d$.

from d to infinity. What seems remarkable is the consistency of this profile, which means that at constant ξ, the density falls off very closely as the inverse square of x. We shall later find this a helpful approximation (section 5).

At the second aperture there is no peripheral region (Fig. 3), and the beam flux is merely spread uniformly across the core of the beam. Considering points further along the beam ($x > d$), one could inquire into the distribution of the flux as a function of the distance, r, from the center of the beam. To do this one must evidently multiply the intensity profile (Fig. 4) by $2\pi r$. One then easily sees that, at least for a parallel beam, most of the flux very soon takes place through the peripheral region rather than through the core. We shall find that collisions in the beam will further increase the proportion of the flux appearing in the peripheral region. This is somewhat unfortunate, for one's estimates of collisional attenuation are apt to be rather better in the core than outside it. This migration

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of the flux from the core to the periphery can be reduced by the use of a diverging beam, of course, and this may sometimes prove useful.

Section 4—Effect of Collisions on Density in the Core

Almost every molecule that collides with a similar molecule within the beam will be given a new trajectory which quickly carries it out of the beam (some further consideration of this statement will be found in appendix 2). Combining this collisional effect with the inverse square depletion [3.3], we obtain a corrected equation for attenuation of the core density:

$$dn_c/dx \equiv (1/\bar{v})(dn_c/dt) = -\lambda n_c^2/\bar{v} - 2n_c/x, \qquad [4.1]$$

where $\lambda n_c^2/2$ is the collision frequency in the core of the beam. If the velocity distribution functions are Maxwellian, the collision frequency may easily be calculated; this is done in appendix 3, where no allowance is made for the effect of the small transverse velocities. This result is

$$\lambda n^2/2 = 2n^2\rho^2\sqrt{(4\pi RT/M)}, \qquad [4.2]$$

where T is again the temperature within the beam, and where it has been assumed that the collision probability may be described in terms of a velocity-independent collision radius ρ. It has been found experimentally that ρ is strictly dependent on the relative velocity and it may prove necessary to take some account of this. On the other hand the relative velocities are, of course, mostly rather small in the molecular beams, so that we might expect ρ to be large, but not to vary greatly.

Equation [4.1] is easily solved when λ is independent of x; the result (cf. appendix 3) is

$$n_c = \frac{n_b d^2}{x^2\left\{1+\frac{\lambda n_b d(x-d)}{\bar{v}x}\right\}}, \qquad [4.3]$$

where n_b is again the density in the second aperture. According to this, the initial decrease in density is large, due to collisions; as the density gets smaller, however, the number of collisions quickly diminishes, and the attenuation approaches that of the inverse-square law. This is illustrated in Fig. 5, for two values of $\lambda n_b d/\bar{v} = \Lambda$. These values of Λ are not unrealistic. It appears that fluxes of about 5×10^{17} molecules cm^{-2} sec^{-1} can be achieved in nozzle beams (9). Taking this figure we find

$$\Lambda \equiv \frac{2\rho^2\sqrt{(4\pi RTM)}\times10^{18}\times d}{2C_p(T_o-T)} \doteq 2\times10^{13}\rho^2\sqrt{M},$$

where the final form applies to our sample beam. If we assign argon a collision radius of 15 Å, we find $\Lambda = 3$; the parameter Λ will be smaller for beams of higher mach number, however.

The above result [4.3] depends on the assumption that λ is independent of x. Unfortunately this is not the case. The complication arises in the following way. The beam is being depleted by collisions. Molecules moving rapidly relative to the mean motion of the beam are naturally most apt to collide; that is, the very slow and very fast molecules will be depleted more quickly than those moving with a velocity close to $\bar{v}$. This evidently corresponds to a "cooling" of the beam as it moves, but it also leads, as we shall see, to increasingly non-Maxwellian velocity distributions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

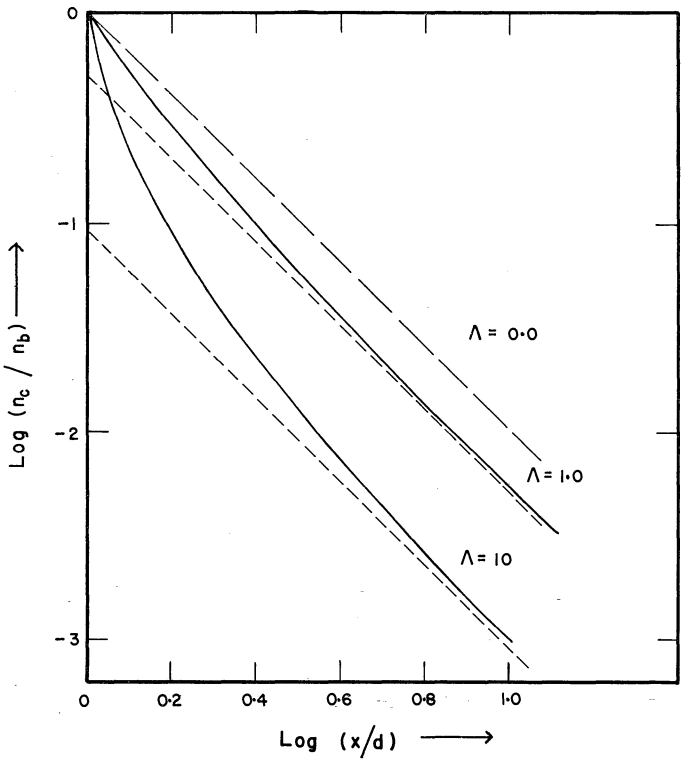

FIG. 5. Attenuation [4.3] of the core density, taking account of collisions, for two values of $\Lambda \equiv \lambda n_b d/\bar{v}$, along with the asymptotic inverse square laws.

We write an equation analogous to [4.1], but describing only the density $n_c f(v)$ of molecules with a particular velocity v:

$$\frac{d\, n_c f(v)}{dx} = -\frac{\lambda^*(v) n_c^2 f(v)}{v} - \frac{2 n_c f(v)}{x} \qquad [4.4]$$

In [4.4], $f(v)$ is the normalized probability of a molecule's having a velocity v; the integral $\lambda^*(v)$ is derived in appendix 3 [A.3.7]. Notice the denominator v in the collisional term of [4.]. Because of this, the *spatial* attenuation of the very slow molecules ($v \ll \bar{v}$) is greater than that of the very fast ($v \gg \bar{v}$). This is understandable, in that slower molecules remain a longer time in the high density part of the beam. It leads, of course, to an "acceleration" of the mean velocity of the beam and also to a skewed velocity distribution, having a long low-velocity wing. The existence of these effects can be seen in the curves published by Becker and Henkes (3(*c*)). It may be worth mentioning that the extent of the increase in the mean velocity, $\bar{v}$, is of course limited by the width (speaking loosely) of the thermal spread in the velocities. Detailed theoretical study of this effect has not been attempted here and further quantitative experiments are needed.

It is of interest, however, to make some estimate of how seriously this affects our result [4.3]. To do this we have examined the "cooling" effect of the collisions in an approximate way, ignoring the accompanying asymmetry: we suppose the velocity

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

distribution to remain Maxwellian. The approximations are discussed in appendix 3, where a set of differential equations for n_c and λ are derived and solved. The result is

$$n_c = \frac{n_b d^2}{x^2\left[1+\frac{(1+G)\,\lambda_b n_b d(x-d)}{\bar{v}x}\right]^{1/(1+G)}}. \qquad [4.5]$$

Here λ_b is the value of λ [4.2] at the second aperture. G is a constant, which may be chosen to give a rate of "cooling" close to that which a Boltzmann function would actually undergo (but which takes no account of the asymmetry that would simultaneously appear). This is discussed more fully in the appendix, and it is shown that a value $G = 0.29_3$ gives a reasonable account of the cooling effect in the molecular beams. Adopting this value, we may calculate by how much our new estimate [4.5] differs from [4.3]. The new result [4.5] may be regarded as a slightly better approximation, though the discrepancy will often be small, when compared with the total effect of the collisions as predicted by either. The two results are compared, in Fig. 6, for various beams, corresponding to $\Lambda_0 = \lambda_b n_b d/\bar{v} = 1.5$, 1, 0.75, and 0.5, as a function of position x in the beam. The discrepancy amounts, in these cases, to less than 10% at x equal infinity, and it is smaller for the useful parts of the beam ($x \sim 2d$).

Section 5—Effect of Collisions on Density outside the Core

The molecular density in the beam but outside the core varies both along the beam and in a radial direction. It could be described, knowing the density in the core, by a function σ:

$$\sigma(\xi,x) = n(x,\xi)/n_c(x) \qquad [5.1]$$

analogous to σ' [3.4]. Our task is to make some estimate of the form of σ, but this is not a simple problem.

It is easy to see qualitatively how σ will differ from σ'. The core density has been reduced below that in the absence of collisions, and this will be equally true for the density outside, but close to, the core. All paths leading to points near the outer envelope of the beam, on the other hand, pass only through low density regions, so that collisions will have had little effect; the density profile near the edge of the beam will therefore be very similar to that in the absence of collisions. It is thus evident that σ, when plotted against ξ, will be somewhat convex upwards for middle values of ξ, unlike the nearly linear σ'.

By noting that the total flux in the beam is attenuated only by collisions, it is possible to derive a somewhat complicated integral equation for $d\sigma/dr$; this equation has not been solved. Instead we write the following approximate equation

$$\left(\frac{dn}{dx}\right)_\xi = -\frac{\lambda n^2}{\bar{v}} + \frac{n}{n'}\left(\frac{dn'}{dx}\right)_\xi, \qquad [5.2]$$

where the subscripts signify that the differentials are to be taken along paths of constant ξ, and the primes once again signify the collision-free beams discussed in section 3. In [5.2], the first term describes the collisional depletion of the beam, in the same approximation as in [4.1]. The second term describes the convective contribution to $(dn/dx)_\xi$, but it

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

takes only partial account of the secondary effect of collisions on this convective contribution. This equation is derived in appendix 4, and the nature of the approximations is made more precise.

To solve [5.2], we set

$$n = Sn' \qquad [5.3]$$

when we obtain the new equation

$$\frac{1}{S^2}\left(\frac{dS}{dx}\right)_\xi = -\frac{\lambda n'}{\bar{v}}. \qquad [5.4]$$

To simplify the solution of this equation we introduce a further approximation. As mentioned at the end of section 3, the profile of σ' is remarkably unchanging as a function of x; this means that the attenuation of $n' = \sigma' n_c'$, at constant ξ, is very nearly that of n_c' only, [3.3]:

$$n_c' = n_b d^2/x^2 \qquad [5.5a]$$

or

$$\left(\frac{\partial n'}{\partial x}\right)_\xi \approx \sigma' \frac{\partial n_{c'}}{\partial x} = -\frac{2\sigma' n_c}{x}. \qquad [5.5b]$$

If this approximation is made, [5.4] is readily integrated; when it is combined with [5.3], [3.20], and [3.4] we obtain

$$n = \frac{\sigma' n_b d^2}{x^2\left[1+\sigma' \dfrac{\lambda n_b d(x-d)}{\bar{v}x}\right]} = n_c\sigma. \qquad [5.6]$$

We could also write, using [4.3],

$$\sigma = \sigma' \frac{\left[1+\Lambda\dfrac{x-d}{x}\right]}{\left[1+\sigma'\Lambda\dfrac{x-d}{x}\right]} \qquad [5.7]$$

showing that σ is everywhere greater than σ', as expected. The effect of collisions on the shape of σ is shown in Fig. 7, where the dimensions a, b, d are those of our sample beam, and $\Lambda = \lambda n_b d/\bar{v} = 1$.

This result, while approximate, has desirable characteristics. It correctly predicts $n = n'$ in the absence of collisions. It has the distortion from σ' which was expected, and it remains continuous at the edges of the beam and the core.

The effect of "beam cooling" could be allowed for as before, introducing a $(1+G)$ modification like that of [4.5].

Section 6—Mixture of Light and Heavy Gases

When expanding a solution of a heavy gas (argon) in a light gas (hydrogen), Becker and Henkes (3(*c*)) observed that the velocity of the heavy molecules was larger than that obtained in the expansion of the pure heavy gas. One pictures the heavy gas "carried along" by the much faster light molecules. This is only to say that during the expansion—i.e., while the gases are undergoing hydrodynamic flow—any average motion of one gas

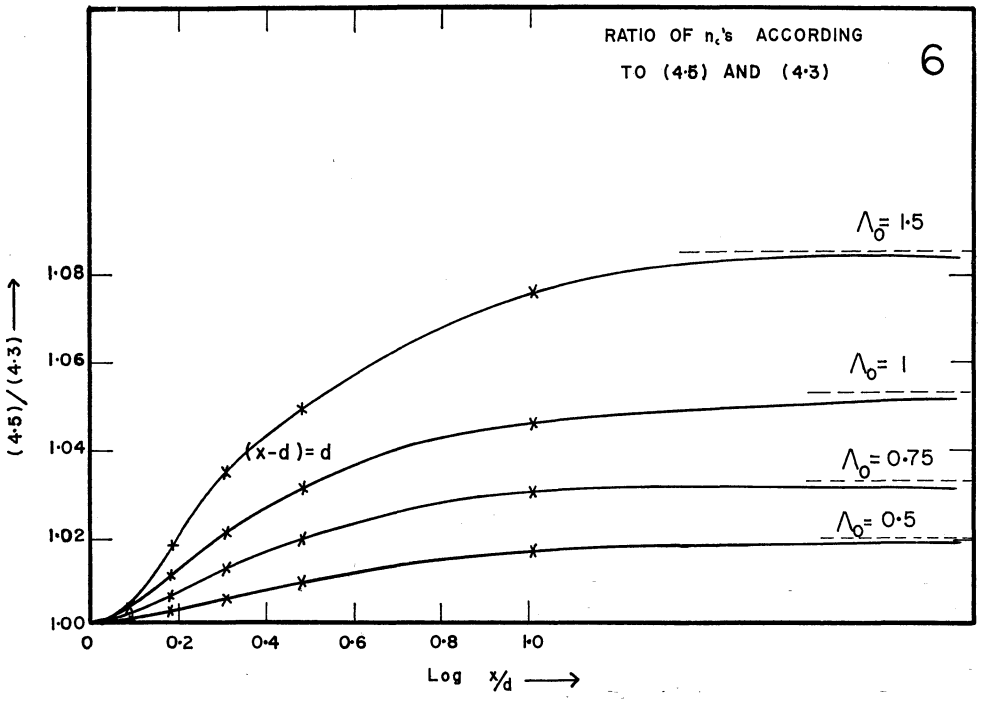

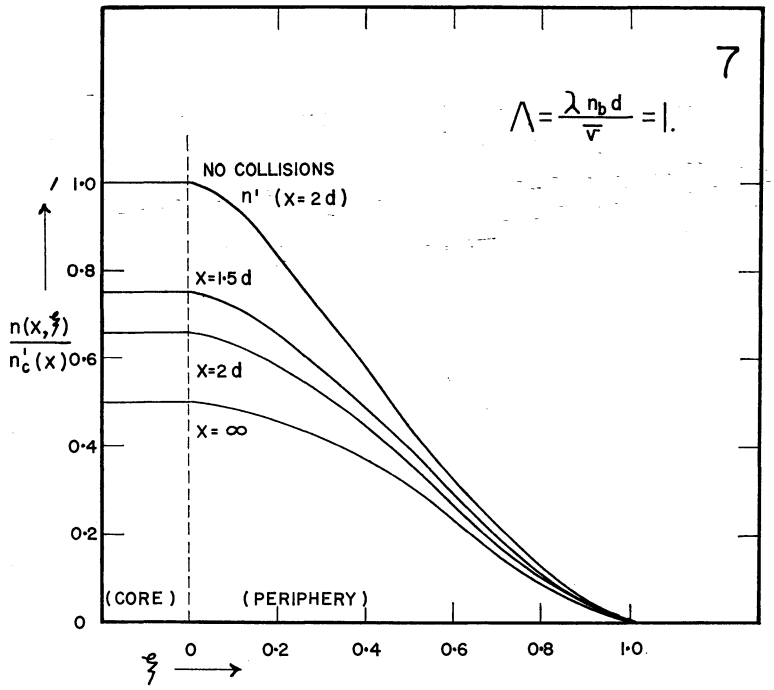

FIG. 6. Effect of the beam cooling; the figure shows the ratio of the densities according to [4.5] and [4.3], for several values of $\Lambda_0 = \lambda_b n_b d/\bar{v}$.

FIG. 7. Effect of collisions on the beam profiles. The number density, n, is compared with that in the core and in the absence of collisions, n_c'. (It is consistent with the approximation that the top curve, n', holds for all x in the absence of collisions. The actual small variation of σ' may be seen in Fig. 4.)

relative to the other must rapidly be dissipated. The same will be true of any temperature difference between the two gases. This appears to be in keeping with the physical model implied by the hydrodynamic description of flow through a nozzle (section 2 and ref. (6)).

We therefore assume that, as a good approximation, the two gases, immediately after expansion, share the same mean velocity $\bar{v}$ and the same temperature T within the beam. Then $\bar{v}$ and T will be related by [2.1] where C_p and M are replaced by $(X_1C_{p1}+X_2C_{p2})$ and $(X_1M_1+X_2M_2)$, X_1 and X_2 being the mole fractions of the two components. Evidently if $M_1 \gg M_2$ the resulting beam velocity will be greater than that for the pure heavy gas 1, but less than that for the light gas 2.

Becker, Bier, and Burghoff (3(*b*)) also reported that an almost pure argon beam was obtained from the originally dilute solution of argon in hydrogen. The relatively rapid disappearance of the light gas can again be ascribed partly to "geometrical" and partly to "collisional" effects. The geometrical effect (see Waterman and Stern (7)) may be explained as follows. If the two gases are described by the same temperature within the beam, the thermal velocities of the light molecules, including their transverse velocities, will be on the whole considerably greater than those of the heavy molecules. As a result the light gas will "spread", behind the diaphragms, much more rapidly than the heavy gas, and only a relatively small proportion of its molecules will have transverse velocities sufficiently small that they get through both apertures and into the beam.

In addition, however, one can see that the collisional attenuation of the light molecules will be much greater than that of the heavy, Nearly all collisions between molecules of equal weight lead (appendix 2) to the disappearance of both molecules from the beam. By contrast, the collision of a very light molecule with a very heavy molecule will be expected to lead to the departure of the light, while the path of the heavy molecule is scarcely altered. We can express this by a set of equations for the core densities, analogous to [4.1]:

$$dn_1/dx = -(\lambda_{11}n_1^2/\bar{v}) - (2n_1/x) \qquad [6.1]$$

$$dn_2/dx = -(\lambda_{12}n_1n_2/\bar{v}) - (\lambda_{22}n_2^2/\bar{v}) - (2n_2/x) \qquad [6.2]$$

where $M_1 \gg M_2$. The absence of a λ_{12} term from [6.1] (which is correct in the limit $M_1/M_2 \to \infty$) expresses the ineffectiveness, for the removal of the heavy molecules, of collisions with light molecules. The coefficients λ_{11}, λ_{12}, λ_{22} may be written [A.3.6]

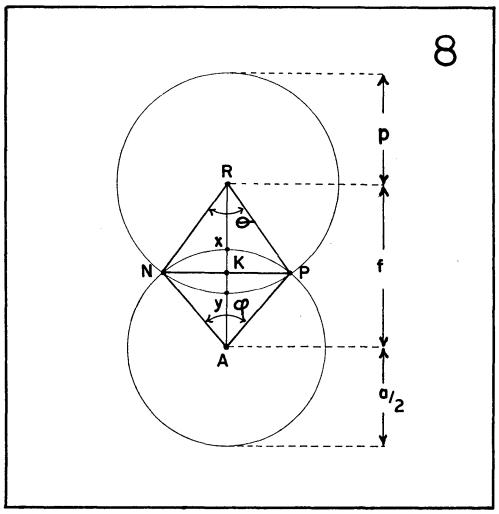
$$\lambda_{11} = 4\rho_1^2\sqrt{(4\pi RT/M_1)},\ \lambda_{22} = 4\rho_2^2\sqrt{(4\pi RT/M_2)},$$

$$\lambda_{12} = (\rho_1+\rho_2)^2\sqrt{[2\pi RT(M_1+M_2)/M_1M_2]}.$$

We see that for $M_1 \gg M_2$, λ_{12} will certainly exceed λ_{11}; if the collision radii are well-behaved, λ_{22} will also be considerably greater than λ_{11}. The attenuation of the light gas will be correspondingly great.

The logarithmic decrements $(1/n_1)(dn_1/dx)$ and $(1/n_2)(dn_2/dx)$ are obtained on dividing [6.1] and [6.2] by n_1 and n_2 respectively. Figure 11 shows the ratio of the collisional contributions to these logarithmic decrements for various mole fractions: the curve has been drawn for the mass ratio $M_1/M_2 = 20$ (as for argon and hydrogen) and assumes equal collision radii. It can be seen that at low argon concentrations the collisional depletion of the hydrogen will be enormously more rapid than that of the argon. However, even in the limit of low hydrogen concentration ($X_2 \to 0$), the fractional decrease of the hydrogen remains considerably more rapid than that of the argon. It follows that an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



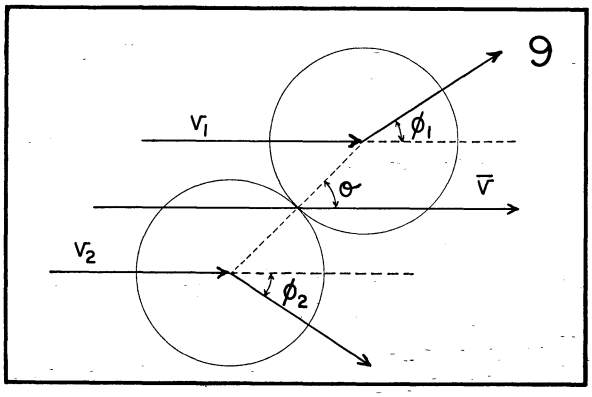


FIG. 8. Calculation of the fraction of the first aperture seen from a peripheral point M in the beam (cf. Fig. 3).

FIG. 9. Hypothetical collision discussed in appendix 2.

almost pure beam of a heavy gas could thus be obtained: no limit exists to the enrichment by collisions.

Equation [6.1] is exactly like [4.1] and has the same form of solution [4.3]; it is possible, using this result, to solve [6.2]. The "asymmetric cooling" effects will of course occur in the mixed beam. It is rather amusing that the light gas will thus be at first accelerated ahead of the heavy gas, but as the density of the light gas becomes small most of its collisions will begin to be with the heavy molecules—at this time the mean velocity of the light gas must return toward that of the heavy gas.

It is incidentally evident that for molecules of equal weight (so that a λ_{12} term will appear in [6.1]), the difference in collision radii will lead to a collisional depletion of the "larger" component. The relevant experiments on isolated beams have not been carried out. Immediately after expansion, nitrogen–ethylene mixtures show a separation in the *opposite* direction (Waterman and Stern (7)). This was ascribed to a perturbation of the isentropic expansion model of nozzle flow, such that the larger molecule acquires a larger mean velocity and a lower temperature in the beam.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

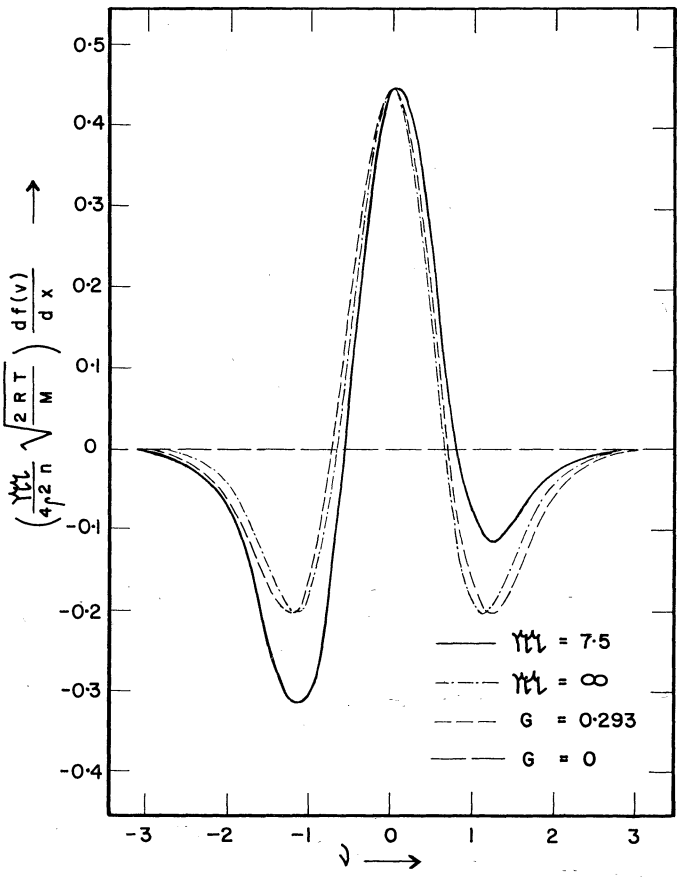

FIG. 10. "Asymmetric cooling". This shows the initial rate of the collisional distortion of a normalized Maxwellian velocity distribution (with $\mathcal{M} = 7.5$). The curve shows the cooling and accelerating effects, and also that the Maxwell distribution is destroyed. Also shown is the limit $\mathcal{M} = \infty$. The broken line shows the "cooling" approximation derived here ($G = 0.293$), in which the Maxwell distribution is retained but the temperature is allowed to diminish; the first approximation, [4.1], [4.3], (i.e. $G = 0$) is also shown by the dashed horizontal line.

Section 7—Conclusion

The calculations of this paper must be regarded as only a beginning of a classical kinetic theory of high density molecular beams. It is hoped that it provides a valuable qualitative description of some beam phenomena, and allows certain useful quantitative predictions. Less drastic assumptions can certainly be introduced, but the resulting equations will probably require numerical solution.

We have been especially interested in the effects of collisions within the beam, but have restricted our attention to the beam itself—i.e. to the region outside the second aperture. This was done to make the mathematical problems palatable, but it is, of course, precisely in the high density region behind the diaphragms that collisions will have their greatest effects in distorting the velocity distributions, reducing the beam density, and enriching the heavier gas of a mixture. The situation is much complicated by the fact that behind the first diaphragm, and to some extent between the diaphragms, there will also occur collisions which result in molecules *entering* the beam. That is to say that there exists,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

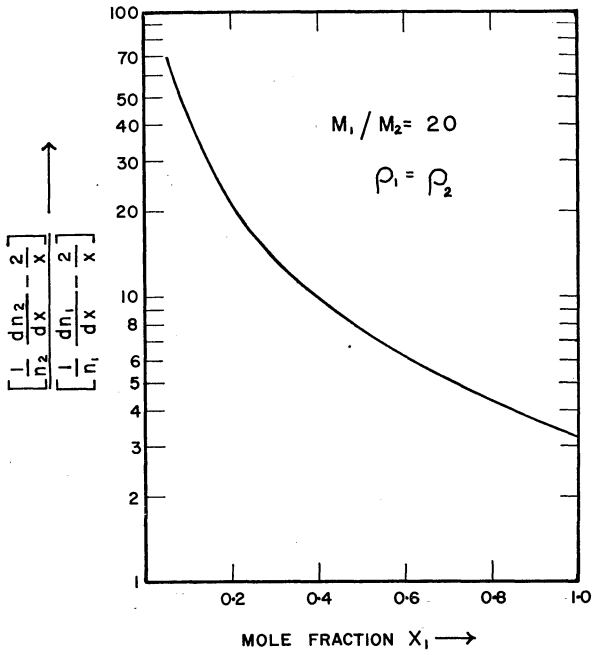

FIG. 11. Ratio of the collisional contributions to the logarithmic decrements of the light and the heavy gas in a mixed beam.

behind the diaphragms, a region not adequately described by either a hydrodynamic or a molecular collision treatment; we have shirked the study of this transition region.

It should be emphasized that, although the velocities with respect to laboratory coordinates may be very large, the relative velocities of molecules in the beam are small. Hence we may expect rather large values of the collisional radii.

The illustrations in the text have been for a sample beam of mach 7.5. For higher mach numbers it is easy to see that the approximations of section 3 and of appendix 2 slightly deteriorate, while the "Boltzmann" approximation to the beam cooling (section 4 and appendix 3) will improve.

Troitskii (8) has calculated that the mean free path in a beam having a velocity distribution uniform over a limited range Δv, is inversely proportional to this width Δv. This corresponds to the proportionality [A.3.6] of collision frequency to $\sqrt{(T/M)}$, found with the more realistic distribution assumed in this paper.

ACKNOWLEDGMENTS

The authors wish to thank Professor M. J. Dignam and Professor D. J. Le Roy, of this Department, for very valuable discussions. Some preliminary calculations were made while one of us (J. M. D.) was a research associate in Princeton University. He wishes to thank Professor R. M. Drake, Professor J. B. Fenn, and Professor M. Boudart for advice and discussion. Mr. Gordon Albright read the manuscript.

Acknowledgment for support of this research is made to the donors of "The Petroleum Research Fund", administered by the American Chemical Society, and to the National Research Council of Canada for a major equipment grant and for a grant in support of the molecular beam research. We are also grateful to the University of Toronto for special financial assistance with the molecular beam program.

APPENDIX 1

Calculation of σ'

In Fig. 8, the smaller circle, of radius $a/2$, represents the first aperture, and the larger circle, of radius p, that portion of the first diaphragm, including part of the aperture, seen from a point M (Fig. 3). The circle of radius p is of course the projection, by the point M, of the second aperture.

The ratio of the overlap of the two circular surfaces to the area of the first aperture is equal to σ' [3.4], the ratio of the beam intensity at M to that in the core. We now calculate this ratio.

Referring to Fig. 8, we are interested in the area $N_y^x P$, which can evidently be written

$$\text{area } N_y^x P = \left(\frac{a}{2}\right)^2 \frac{\phi}{2} + p^2 \frac{\theta}{2} + f\left(\frac{a}{2}\right) \sin\frac{\phi}{2}. \qquad [A.1.1]$$

In triangle RNA,

$$\cos(\phi/2) = [f^2+(a/2)^2-p^2]/af = \sqrt{[1-\sin^2(\phi/2)]}, \qquad [A.1.2]$$

while

$$\cos\frac{\theta}{2} = \frac{RK}{p} = \frac{f-(a/2)\cos(\phi/2)}{p} = \frac{f}{p} - \frac{a}{2p}\left[\frac{f^2+(a/2)^2-p^2}{af}\right]. \qquad [A.1.3]$$

If we divide [A.1.1] by the area, $\pi(a/2)^2$, of the first aperture, we obtain σ', which we can write, introducing [A.1.2] and [A.1.3], as

$$\sigma' = \frac{1}{\pi}\arccos\left\{\frac{f^2+(a/2)^2-p^2}{af}\right\} + \frac{p^2}{\pi(a/2)^2}\arccos\left\{\frac{f}{p} - \frac{f^2+(a/2)^2-p^2}{2pf}\right\} - \frac{f}{\pi(a/2)}\sqrt{1-\left(\frac{f^2+(a/2)^2-p^2}{af}\right)^2} \qquad [A.1.4]$$

It is easy to see, in Fig. 3, that f and p are related to the position of the point M by

$$f = \left(\frac{d}{x-d}\right) r, \quad p = \left(\frac{x}{x-d}\right)\frac{b}{2}. \qquad [A.1.5]$$

The introduction of [A.1.5] and the definitions [3.5] transforms σ' [A.1.4] to the form [3.6] quoted in the text.

APPENDIX 2

Probability of Ineffective Collisions

Some of the collisions between beam molecules will be "ineffective", in the sense that they do not lead to the rapid removal from the beam of the colliding molecules. We could define the collision radii ρ ([4.2] and appendix 3) so that they described only effective collisions, but in that case ρ would depend on the beam geometry. If we regard ρ as a true molecular parameter, then we are agreeing to neglect the fact that a small number of collisions is not effective. It is interesting to make a rough estimate of the importance of such an assumption.

To do this we consider a simple and highly hypothetical case, of two hard spherical molecules of equal weight travelling, before collision, in paths parallel to the beam axis (Fig. 9). Suppose their velocities v_1, v_2 differ by $V = v_2 - v_1$ and that the line joining their centers forms an angle θ with the beam direction. It is easy to show that the trajectories of the two molecules after collision form, with the beam direction, angles ϕ_1, ϕ_2 given by:

$$\tan \phi_1 = (V \sin \theta \cos \theta)/(v_1 - V \cos^2 \theta), \qquad [A.2.1]$$

$$\tan \phi_2 = (V \sin \theta \cos \theta)/(v_2 - V \cos^2 \theta). \qquad [A.2.2]$$

The molecules will leave the beam unless these tangents are less than b/d—that is unless the molecules just graze ($\theta \approx \pi/2$) or collide head-on ($\theta \approx 0$). Characteristically, the denominators above will be near $\bar{v}$, the beam velocity, so that the condition for ineffective collisions is very roughly

$$\sin \theta \cos \theta < \frac{\bar{v}}{V}\left(\frac{b}{d}\right). \qquad [A.2.3]$$

A typical relative velocity V for a collision is $\sqrt{(2RT/M)}$. (This relative velocity gives, in fact, the maximum in the integrand of the one-dimensional collision integral.) Using this, and [3.1], we find, for a perfect gas,

$$\sin \theta \cos \theta < \frac{b}{d}\mathscr{M}\sqrt{\frac{5}{6}} \sim \frac{b}{d}\mathscr{M} \qquad [A.2.4]$$

For our example, $\mathscr{M} \sim 7.5$, $b/d = 0.01$, so $\sin \theta \cos \theta < 0.07$, roughly.

Regard the slow-moving molecule 1 as a circular target for molecule 2. An element of area in this target is given by

$$2\pi(2\rho)^2 \sin \theta \cos \theta \, d\theta,$$

where ρ is the radius of the spheres. Thus, the whole target area is

$$\int_0^{\pi/2} 8\pi\rho^2 \sin \theta \cos \theta \, d\theta = 4\pi\rho^2,$$

while that for ineffective collisions is approximately

$$\left\{\int_0^{\text{arc sin } 0.07} + \int_{\text{arc cos } 0.07}^{\pi/2}\right\} 8\pi\rho^2 \sin \theta \cos \theta \, d\theta \doteqdot 0.01(4\pi\rho^2).$$

The resulting error in our estimate, [4.1] [4.2], of the number of effective collisions thus appears, in the above case, to be around 1%. In addition, of course, molecules for which $\tan \phi$ is only slightly greater than (b/d) will remain in the beam some distance before escaping. Unlike the assumptions discussed in appendix 3, the present one deteriorates

for beams of low temperature and high mach number; this can be seen from [A.2.4], and is physically obvious.

APPENDIX 3

Collision Integrals and the "Cooling" of the Beam

Part I

We wish to calculate the frequency of collisions in the molecular beam. Suppose that n_I,n_J are the number densities of components I,J, having molecular weights M_I,M_J. We suppose that the collision probability may be described in terms of velocity-independent collision radii ρ_I,ρ_J, and we ignore the small transverse velocities within the beam, so that molecular velocities are regarded as parallel to $\bar{v}$, the mean motion of the beam.

Consider a molecule of component I having a velocity in dv_i at v_i; the number density of such a molecule is $n_I f_I(v_i)\, dv_i$, where $f_I(v_i)$ is a normalized one-dimensional velocity distribution.

Suppose that a J molecule of velocity v_j lies, with respect to the I molecule, in an element of solid angle dl, forming an angle θ with the molecular velocities. Then the speed of approach of the two molecules is $v = (v_i-v_j)\cos\theta$; this must be greater than zero if there is to be a collision:

$$v = (v_i-v_j)\cos\theta > 0. \qquad [A.3.1]$$

If they are to collide within a short time dt, the distance between their centers, r_{ij}, must fall in the range

$$(\rho_I+\rho_J) < r_{ij} < (\rho_I+\rho_J)+v\,dt, \qquad [A.3.2]$$

so that the element of volume available to such a J molecule is

$$(\rho_I+\rho_J)^2\, v\, dt\, dl. \qquad [A.3.3]$$

The probability of the configuration described, per unit volume, is therefore

$$(n_I f_I(v_i)dv_i)(n_J f_J(v_j)dv_j(\rho_I+\rho_J)^2\, v\, dt\, dl, \qquad [A.3.4]$$

where $v > 0$. The total rate of I,J collisions is therefore

$$\lambda_{IJ} n_I n_J = \oint_{(v_i-v_j)\cos\theta>0} \int\int n_I n_J f_I(v_i) f_J(v_j)(\rho_I+\rho_J)^2 (v_i-v_j)\cos\theta\, dl\, dv_i dv_j \qquad [A.3.5]$$

where the integration is carried over all directions of l, and may be taken over all values of v_i and v_j consistent with the indicated restriction, $(v_i-v_j)\cos\theta > 0$. If the velocity distributions f_I, f_J are Maxwellian,

$$f_I(v_i) = \sqrt{\left(\frac{M_I}{2\pi RT}\right)} \exp\left\{-\frac{M_I}{2RT}(v_i-\bar{v})^2\right\},$$

and are determined by the same temperature, [A.3.5] is easily integrated to give

$$\lambda_{IJ} n_I n_J = (\rho_I+\rho_J)^2 n_I n_J \sqrt{\left(\frac{2\pi RT(M_I+M_J)}{M_I M_J}\right)}. \qquad [A.3.6]$$

Where $I = J$, so that we consider collisions between like molecules, the above integral counts every collision twice; on the other hand, every such collision removes two I molecules from the beam, so that [A.3.6], with $I = J$, is the correct expression for λn^2 in [4.1] and [5.2].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Part 2

In [4.4] we are interested in the frequency of collisions involving molecules of a specified velocity $v_i = v$. The appropriate collision integral is like [A.3.5], but without integration over the velocity v_i. That is, the frequency of such collisions, per unit volume and time, is given by

$$(2\rho)^2 n^2 f(v_i) \oint\int_{(v_i-v_j)\cos\theta>0} f(v_j)(v_i-v_j)\cos\theta\, dl\, dv_j = \lambda^*(v) n^2 f(v_i), \qquad [A.3.7]$$

where the second form comes from comparison with [4.4], noting that

$$\frac{d}{dx}[nf(v_i)] = \frac{1}{v_i}\frac{d}{dt}[nf(v_i)]. \qquad [A.3.8]$$

This result could be used to investigate the distortion of the distribution functions in the beam. One might suppose that the changing distribution function $f(v_i)$ would at least approach a limiting form at large distances. One can see that this is not the case by first assuming it to be so, when we could set

$$0 = \frac{1}{f}\frac{df}{dx} = \frac{1}{nf}\frac{d(nf)}{dx} - \frac{1}{n}\frac{dn}{dx}$$
$$= -\frac{n\lambda^*}{v} + n\int\frac{\lambda^* f}{v}\,dv \qquad [A.3.9]$$

in which we have used the form [4.4]. It follows from [A.3.9] that λ^*/v is independent of the velocity v. Thus we would expect $d\lambda^*/dv$ to be independent of v in the postulated limiting case. It is not difficult, however, to show from [A.3.7] that

$$\frac{d\lambda^*}{dv} = -\pi(2\rho)^2\left\{\int_v^\infty f(v_j)dv_j - \int_0^v f(v_j)dv_j\right\} \qquad [A.3.10]$$

which cannot be independent of v for any non-trivial velocity distribution $f(v_j)$. We have proceeded no further with the general case.

Instead we consider the special case in which the velocity distribution functions are instantaneously Maxwellian, and of temperature T. Then [A.3.7] may be written

$$\lambda^*(v) = (2\rho)^2\sqrt{\left(\frac{2\pi RT}{M}\right)}\left[e^{-\nu^2} + 2|\nu|\int_0^{|\nu|} e^{-z^2}\,dz\right], \qquad [A.3.11]$$

where ν is the reduced velocity, relative to the beam velocity $\bar{v}$:

$$\nu = \sqrt{(M/2RT)}(v-\bar{v}). \qquad [A.3.12]$$

In Fig. 10 the solid line shows

$$\frac{\mathscr{M}}{4\rho^2}\sqrt{\left(\frac{2RT}{M}\right)}\left[\frac{\lambda^*}{v} - \frac{\lambda}{\bar{v}}\right] = \frac{\mathscr{M}}{4\rho^2 n}\sqrt{\left(\frac{2RT}{M}\right)}\left[\frac{df(v)}{dx}\right], \qquad [A.3.13]$$

as a function of ν, for the sample beam ($\mathscr{M} = 7.5$). This is a dimensionless form of the variation of the normalized velocity distribution function, and demonstrates the "asymmetric cooling" mentioned in the text; the high velocity wing ($\nu > 0$) of the normalized velocity distribution is reduced less than the low velocity wing ($\nu < 0$). The figure also shows [A.3.13] in the limit $\mathscr{M} \to \infty$; in this limit the asymmetry vanishes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

We wish to compare with the above calculation a mathematically tractable approximation. In this we assume that the distribution functions remain Maxwellian and of mean velocity $\bar{v}$, but we allow the temperature of the beam to change. We thus take some account of the cooling, but not of the acceleration, of the beam. Then, in view of the form

$$f(v) = \sqrt{\left(\frac{M}{2\pi RT}\right)} \exp\left\{\frac{-M(v-\bar{v})^2}{2RT}\right\} \qquad [A.3.14]$$

of the normalized velocity distribution, we can set

$$\frac{1}{4\rho^2 n}\frac{df(v)}{dx} = \frac{f(v)}{4\rho^2 n}(\nu^2 - \tfrac{1}{2})\frac{d\ln T}{dx}. \qquad [A.3.15]$$

Furthermore we restrict the temperature variation to the form

$$\frac{d\ln T}{dx} = -\frac{8\rho^2 n}{\bar{v}}\sqrt{\left(\frac{4\pi RT}{M}\right)}\, G, \qquad [A.3.16]$$

which defines the constant G. In order to fix the value of G, we make [A.3.15] coincide with [A.3.13] for molecules travelling at the beam velocity ($\nu = 0$); this gives $G = 1-(1/\sqrt{2}) = 0.293$. It should be noted that this result for G is independent of the temperature and mach number of the beam. The broken line in Fig. 10 shows the resulting value of [A.3.15] as a function of ν. Although this approximation takes no account of the asymmetry, it is certainly an improvement over the approximation of [4.1], [4.2], which corresponds to $G = 0$. The approximation improves for higher mach numbers.

It remains to determine the effect of the beam cooling [A.3.15], [A.3.16] on the density attenuation, dn_c/dx, in the core of the beam. We write again equations [4.1], [4.2]:

$$dn_c/dx = -(\lambda n_c^2/\bar{v}) - (2n_c/x) \qquad [A.3.17]$$

$$\lambda/\bar{v} = (4\rho^2/\bar{v})\sqrt{(4\pi RT/M)}. \qquad [A.3.18]$$

However, it follows from [A.3.16] that

$$\frac{d}{dx}\left(\frac{\lambda}{\bar{v}}\right) = \frac{\lambda}{2\bar{v}}\frac{d\ln T}{dx} = \left(\frac{\lambda}{\bar{v}}\right)^2 n_c G. \qquad [A.3.19]$$

We proceed to solve the set of equations [A.3.17], [A.3.19]. The latter may be integrated to give

$$\frac{\lambda}{\bar{v}} = \frac{(\lambda_b/\bar{v})}{1+(G\lambda_b/\bar{v})\int_d^x n_c\, dx} \qquad [A.3.20]$$

where λ_b is the value of λ at $x = d$, the second aperture. If this is put into [A.3.17] we obtain, making the substitution

$$n_c = S/x^2, \qquad [A.3.21]$$

$$\frac{d\ln S}{dx}\left[1+\frac{G\lambda_b}{\bar{v}}\int_d^x n_c\, dx\right] = -\frac{\lambda_b S}{\bar{v}x^2}. \qquad [A.3.22]$$

By differentiating this equation once more we can obtain

$$\frac{d^2\ln S}{dx^2} - (1+G)\left(\frac{d\ln S}{dx}\right)^2 + \frac{2}{x}\left(\frac{d\ln S}{dx}\right) = 0, \qquad [A.3.23]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

which can be solved to give

$$S = \frac{n_b d^2}{\left\{1+(1+G)\,\frac{\lambda_b n_b d(x-d)}{\bar{v}x}\right\}^{1/1+G}}. \qquad [A.3.24]$$

This expression is combined with [A.3.21] at [4.5]; when $G = 0$ there is no cooling of the beam and [A.3.24] reduces to [4.3], a result which has also been obtained by a direct integration of [4.1].

APPENDIX 4

The Approximation [5.2]

Consider an element of volume δV, outside the core, defined by the ranges $\delta\xi$, δx, and $\delta\phi$, where ϕ describes rotation around the beam axis. Suppose that δV moves in the x-direction with beam velocity $\bar{v}$, but keeping ξ and ϕ fixed. The total number of molecules in δV changes in two ways: due to a collisional loss $-\lambda n^2$ cc^{-1} sec^{-1} (cf. [4.1]), and due to the flux, J_ξ of molecules through the $\delta x\delta\phi$ faces of δV. We may write this

$$\frac{d(n\delta V)}{dx} \equiv (\delta V)\frac{dn}{dx}+n\frac{d(\delta V)}{dx} = -\frac{\lambda n^2}{\bar{v}}-\frac{1}{\bar{v}}\left(\frac{\partial J_\xi}{\partial\xi}\delta\xi\right)\delta x\, r\,\delta\phi; \qquad [A.4.1]$$

$J_\xi(x,\xi)$ is the radial component of the molecular flux.

This equation is complete in the same approximation as [4.1]. The corresponding equation for the collision-free case (ξ3) is, in an obvious notation,

$$\frac{d(n'\delta V)}{dx} \equiv (\delta V)\frac{dn'}{dx}+n'\frac{d(\delta V)}{dx} = -\frac{1}{\bar{v}}\left(\frac{\partial J\xi'}{\partial\xi}\delta\xi\right)\delta x\, r\,\delta\phi. \qquad [A.4.2]$$

These equations [A.4.1,2] combine to give

$$\frac{1}{n}\frac{dn}{dx} = \frac{1}{n'}\frac{dn'}{dx}-\frac{\lambda n}{\bar{v}}-\frac{1}{\bar{v}}\left[\frac{1}{n}\frac{\partial J_\xi}{d\xi}-\frac{1}{n'}\frac{J\partial\xi'}{d\xi}\right]\frac{r\,\delta\xi\,\delta x\,\delta\phi}{\delta V}. \qquad [A.4.3]$$

Now in [5.2] the final term of this equation has been dropped. This clearly corresponds to assuming that the radial gradient of the flux J_ξ is proportional in all cases to the molecular density. If the direction and velocity of molecular flow were invariable, the approximation would become

$$\frac{1}{n}\frac{\partial n}{\partial\xi} = \frac{1}{n'}\frac{\partial n'}{\partial\xi}, \qquad [A.4.4]$$

a relation which agrees quite well with the derived beam profiles (cf. Fig. 7). However, we must expect that the flow pattern in the beam will in fact be affected by collisions, so that this agreement is not a valid justification of the approximation [5.2].

RELATION ENTRE LA DISSYMETRIE DES RAIES DE RESONANCE MAGNETIQUE NUCLEAIRE ET CERTAINS PARAMETRES STRUCTURAUX

PIERRE J. VAN TIGGELEN[1]
Laboratoire de Chimie Physique, Université de Louvain, Louvain, Belgique
Reçu le 27 mai 1963

ABSTRACT

We give here an equation describing the dissymmetry of nuclear magnetic resonance lines by means of the dipolar influence of the paramagnetic centers. In simple cases this equation coupled with the value of the second moment, will give us two structural parameters from spectra taken on powder samples.

1. INTRODUCTION

Certains auteurs ont déjà remarqué à plusieurs reprises que les spectres de poudres de substances paramagnétiques apparaissaient sous la forme de raies dissymétriques (1, 2, 3, 4, 5), du type schématisé à la Fig. 1. Cependant, à notre connaissance, aucun auteur

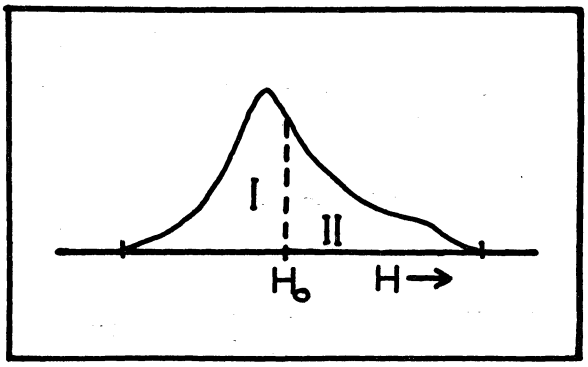

FIG. 1. Aspect d'un spectre dissymétrique.

n'a jusqu'à présent essayé d'exprimer cette dissymétrie en fonction de la structure des composés étudiés.

Nous nous proposons, dans cet article, de relier la dissymétrie des raies à des paramètres structuraux se rapportant aux centres paramagnétiques et ceci, par l'intermédiaire d'une fonction: le troisième moment. Cette grandeur dépend non seulement des distances séparant le centre paramagnétique du noyau en résonance mais encore de la valeur moyenne du moment magnétique du centre paramagnétique envisagé et, par conséquent, est fonction de la température et du champ magnétique directeur appliqué.

La détermination des distances interatomiques requiert un troisième moment précis qui peut être obtenu par la répétition de la mesure de cette grandeur.

Nous calculerons l'expression théorique du troisième moment sur la base d'une méthode statistique en moyennant les diverses fluctuations du champ à l'endroit du noyau en résonance.

2. INTERACTIONS ET CHAMPS AGISSANT SUR LE NOYAU

Avant d'exprimer le champ magnétique "vu" par le noyau, nous examinerons les interactions dont il faut tenir compte dans un cristal paramagnétique à structure figée.

[1]*Actuellement à l'Université Laval, Québec, Qué.*

L'hamiltonien du système $\mathscr{H}_{tot}$ peut s'écrire comme suit:

$$\mathscr{H}_{tot} = \mathscr{H}_{ZeN} + \mathscr{H}_{ZeP} + \mathscr{H}_{N} + \mathscr{H}_{PP} + \mathscr{H}_{E} + \mathscr{H}_{PN} + \mathscr{H}_{S} \qquad [1]$$

Ces sept termes sont représentés à la Fig. 2.

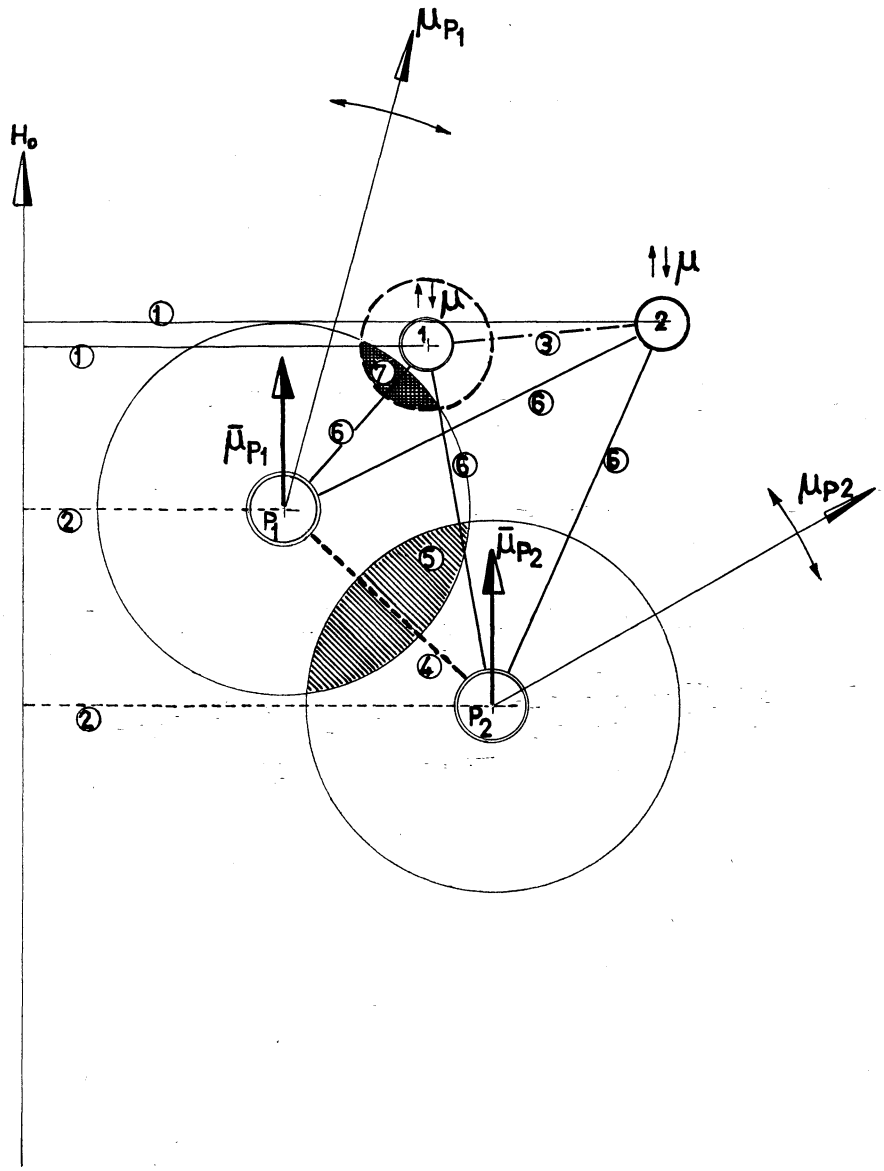

FIG. 2. Interactions auxquelles sont soumis les noyaux en résonance dans une substance paramagnétique: (1) interaction Zeeman nucléaire (H_0 – noyaux); (2) interaction Zeeman electronique (H_0–electron des centres para-magnétiques); (3) interaction spin–spin nucléaire (dipolaire–quadrupolaire); (4) interaction dipolaire entres les centres paramagnétiques; (5) interaction d'échange entre spins électroniques; (6) interaction dipolaire entre centre paramagnétique et noyau; (7) interaction de superéchange (couplage hyperfin de contact) entre le paramagnétique et le noyau.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Nous constatons donc qu'en plus des interactions Zeeman nucléaires ($\mathscr{H}_{\text{ZeN}}$) et électroniques ($\mathscr{H}_{\text{ZeP}}$) il y a lieu de tenir compte tout d'abord de l'interaction entre noyaux $\mathscr{H}_{\text{N}}$, soit dipolaire magnétique $\mathscr{H}_{\text{ND}}$, soit quadrupolaire électrique $\mathscr{H}_{\text{NQ}}$.

(*a*) L'interaction dipolaire magnétique nucléaire a été étudiée par Pake (6) dans le cas de deux noyaux i et j. Elle peut s'écrire:

$$\mathscr{H}_{\text{ND}} = \frac{\boldsymbol{\mu}_i\boldsymbol{\mu}_j}{r_{ij}^3} - 3\frac{(\boldsymbol{\mu}_i\mathbf{r}_{ij})(\boldsymbol{\mu}_j\mathbf{r}_{ij})}{r_{ij}^5}. \qquad [2]$$

Le résultat exprimé en unité de champ, est plus grand d'un facteur 3/2 pour des noyaux i et j semblables que pour des noyaux différents. Ceci provient de l'interaction "flip-flop" présente uniquement entre noyaux semblables.

(*b*) L'interaction quadrupolaire électrique $\mathscr{H}_{\text{NQ}}$ étudiée par Pound (7) apparait dans le cas d'interaction entre noyaux de nombre de spin I supérieur à $\frac{1}{2}$. Nous nous limiterons dans la suite aux noyaux $I = \frac{1}{2}$ et donc le terme $\mathscr{H}_{\text{NQ}}$ sera nul.

L'interaction dipolaire entre centres paramagnétiques $\mathscr{H}_{\text{PP}}$ n'aura pas d'influence directe sur le spectre de résonance nucléaire. Cependant, l'interaction dipolaire des centres paramagnétiques avec les noyaux $\mathscr{H}_{\text{PN}}$ sera influencée par $\mathscr{H}_{\text{PP}}$. En effet, $\mathscr{H}_{\text{PN}}$ devrait provoquer, par suite de la grandeur des moments magnétiques électroniques, une scission du spectre en $(2m_p+1)$ raies (si m_p désigne le nombre quantique magnétique total du centre paramagnétique) et, de cette manière, élargir considérablement le spectre. Dans la plupart des cas cependant, la réorientation rapide des moments des centres paramagnétiques μ'_p dans le champ (réorientation obtenue par l'échange de quanta d'énergie entre centres d'une part, entre centre et réseau d'autre part) donne au moment magnétique de l'ion une valeur moyenne $\bar{\mu}'_p$. Ce processus de réorientation est beaucoup plus rapide que le phénomène de résonance nucléaire et, par conséquent, le moment magnétique nucléaire "voit" une valeur moyenne de l'ion paramagnétique qui diffère de zéro par suite de l'écart de population entre les niveaux Zeeman électroniques. On peut, pour des températures pas trop faibles, estimer le moment magnétique $\bar{\mu}'_p$ sur la base d'une théorie classique du paramagnétisme. $\bar{\mu}'_p$ dépend de la température et du champ magnétique directeur appliqué.

Mais, à côté des interactions dipolaires entre centres paramagnétiques, il faut envisager l'interaction d'échange $\mathscr{H}_{\text{E}}$, responsable de la tendance des moments magnétiques à s'aligner parallèlement ou antiparallèlement les uns par rapport aux autres. Ces forces d'échange provoquent à la limite l'apparition des états ferro- et antiferro-magnétique. Cette interaction peut se représenter dans l'hamiltonien par une interaction scalaire:

$$\mathscr{H}_{\text{E}} = \sum_{k>p} A_{kp}\mathbf{S}_k\mathbf{S}_p \qquad [3]$$

où A_{kp} est la constante de couplage proportionnelle aux intégrales de recouvrement des fonctions d'onde des centres paramagnétiques p et k. Il est cependant possible de tenir compte de cette interaction d'échange en corrigeant le facteur $\bar{\mu}'_p$. Celui-ci, en effet, dépend de la température. En introduisant une température de Curie T_c dans l'expression de $\bar{\mu}'_p$ on aura donc, comme moment magnétique des centres paramagnétiques "vu" par les noyaux la valeur $\bar{\mu}_p$ qui résume à la fois l'influence des interactions $\mathscr{H}_{\text{ZeP}}$, $\mathscr{H}_{\text{PP}}$ et $\mathscr{H}_{\text{E}}$.

Ce moment magnétique moyen $\bar{\mu}_p$, localisé aux sites occupés par les centres paramagnétiques va provoquer une perturbation sur les noyaux en résonance. Cette interaction est représentée par $\mathscr{H}_{\text{PN}}$; il s'agit d'une interaction dipolaire entre $\bar{\mu}_p$ et les moments nucléaires μ_i. Cette interaction sera du même type que celle décrite par l'équation [2].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Mais, dans le calcul des niveaux d'énergie, il convient de remarquer que, pour le moment magnétique $\bar{\mu}_p$, la position parallèle au champ directeur H est seule permise et qu'il s'agit bien ici d'une interaction entre partenaires dissemblables (un noyau et un électron). Par conséquent, nous observerons un glissement de la position de résonance au lieu d'une scission de la raie, et le facteur numérique 3/2 n'apparait pas dans l'expression du champ résultant de cette interaction.

Il reste encore à considérer le dernier terme de l'hamiltonien total, c'est-à-dire $\mathcal{H}_S$ qui symbolise l'interaction de superéchange ou couplage hyperfin de contact. Cette interaction résulte de la non annulation de la fonction d'onde de l'électron responsable des propriétés paramagnétiques à l'endroit du noyau en résonance. Cette interaction est également de forme scalaire.

$\mathcal{H}_S = \sum_p A_{ip}\mathbf{I}_i\mathbf{S}_p$ où la constante A_{ip} est proportionnelle à la densité de probabilité de l'électron célibataire du paramagnétique p à l'emplacement du noyau i. Ce couplage a été introduit par Townes *et al.* (8) pour expliquer le "Knight shift" dans les métaux. Cette interaction joue également un role important dans des composés du type MnF_2 et $KMnF_3$, comme l'ont remarqué Shulman *et al.* (9, 10). Nous négligerons cependant ce couplage hyperfin car, en l'absence de liaison chimique entre le paramagnétique et le noyau, on peut supposer avec une bonne approximation que la fonction d'onde électronique s'annule à l'endroit du noyau en résonance. Shulman fait d'ailleurs la même approximation pour le proton dans le $CuF_2.2H_2O$ (11).

Dans l'étude de la dissymétrie de la raie, nous nous bornerons donc à l'effet des interactions dipolaires nucléaires et dipolaires électroniques statiques. Pour le système de noyaux en résonance, l'hamiltonien s'écrit sous la forme suivante où les interactions quadrupolaires nucléaires et de superéchange sont négligées:

$$\mathcal{H} = \mathcal{H}_{ZeN} + \mathcal{H}_{ND} + \mathcal{H}_{FN}. \qquad [5]$$

N. Bloembergen (12) a calculé les niveaux d'énergie d'un système à deux noyaux et plusieurs centres paramagnétiques ainsi que les transitions permises entre ces niveaux. Il a déterminé de cette manière la position et l'intensité des raies de résonance. Nous utiliserons le résultat de Bloembergen à la section 5 et nous verrons qu'il amène à une valeur du troisième moment identique à celle obtenue au moyen d'un raisonnement semi-classique. Nous pouvons donc supposer la simple additivité des effets dipolaires de sorte que chacune des perturbations $\mathcal{H}_{ND}$ et $\mathcal{H}_{FN}$ puisse être traitée comme si elle etait seule à influencer le spectre. Dans le cas de cristaux diamagnétiques, Pake (6) a étudié $\mathcal{H}_{ND}$ par un calcul quantique de perturbation. Le champ produit à l'endroit du noyau en résonance i par le noyau j s'écrit alors:

$$h_j = \pm k_{ij}\mu_j \cdot r_{ij}^{-3}(3\cos^2\theta_{ij} - 1) \qquad [6]$$

où le signe $\pm$ dépend de la position parallèle ou antiparallèle du spin j à H_0. $k = 1$ pour des noyaux diffèrents et $k = 3/2$ pour des noyaux semblables: la diffèrence représente la contribution de l'interaction "flip-flop" réalisable uniquement pour des noyaux identiques. μ_j désigne la valeur absolue de la projection suivant H_0 du moment magnétique du noyau j distant de r_{ij} du noyau i. θ_{ij} est l'angle entre la direction de H_0 et de r_{ij}. Pour plusieurs noyaux, le champ résultant en i sera:

$$H_j = \pm \sum_j h_j \qquad [7]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Un calcul classique de l'interaction $\mathscr{H}_{PN}$ donne pour le champ provoqué par les centres paramagnétiques la valeur de:

$$H_p = +\sum_p k_{ip}\bar{\mu}'_p \cdot R_{ip}^{-3}(3\cos^2\theta_{ip}-1) \qquad [8]$$

où

$$\bar{\mu}_p = \frac{\mu^2_p \cdot H_0}{3k(T-T_c)} \qquad [9]$$

expression où seul le signe + est permis et où le facteur k_{ip} vaut l'unité.

Nous aurons donc, à l'endroit du noyau en résonance i, à coté du champ directeur H_0, la contribution des centres paramagnétiques H_p et celle des autres noyaux, H_j:

$$H_i = H_0 + H_p + H_j. \qquad [10]$$

3. MOMENTS ET MOYENNES

La notion de moment permet de déterminer certaines grandeurs de la distribution spectrale et de les relier à des paramètres structuraux. Dans ce qui suit, nous exprimerons les moments en unité de champ. De façon générale, pour toute distribution spectrale $g(H)$, on peut définir deux types de moment: les moments centraux S_n rapportés au champ moyen H_m de la distribution, et les moments Σ_n rapportés au champ de résonance H_0 d'un noyau isolé, c'est-à-dire soustrait à toute interaction autre que celle du champ magnétique directeur H_0. Dans la plupart des cas, les deux types de moments coïncident par suite de l'égalité entre H_m et H_0. On notera les différents types de moment par les équations:

$$S_n = \langle (H-H_m)^n \rangle \qquad [11]$$

et

$$\Sigma_n = \langle (H-H_0)^n \rangle \qquad [12]$$

où n indique l'ordre du moment, H la variable du spectre enregistré et les crochets la moyenne effectuée en tenant compte de la fonction de distribution $g(H)$.

Ces expressions peuvent être appliquées aux spectres obtenus à l'enregistreur. Il existe entre ces types de moments des relations. Pour les moments d'ordre un: $S_1 = 0$ par définition de la grandeur H_m et $\Sigma_1 = H_m - H_0$, qui représente le glissement du centre de gravite de la distribution par rapport à H_0. Pour les moments d'ordre deux, où $\Sigma_2 = S_2 + \Sigma_1^2$, le second moment central S_2 indique la dispersion de la distribution. Enfin la relation entre les troisièmes moments s'écrit:

$$\Sigma_3 - S_3 = 3\Sigma_1\Sigma_2 - 2\Sigma_1^3. \qquad [13]$$

Ils mesurent la dissymétrie de la distribution spectrale.

A l'échelle nucléaire, au champ H du spectre correspond un champ instantané H_i à l'endroit du noyau i, champ tel que la condition de résonance est réalisée pour ce noyau. Le champ magnétique H_i à l'emplacement d'un noyau est le champ H_0 de l'électroaimant, modifié par les perturbations H_p et H_j dues aux interactions magnétiques dipolaires avec les centres paramagnétiques et d'autres moments nucléaires, respectivement. Ce champ H_i variera dans le temps pour un même site et les moyennes dans le temps seront par ailleurs différentes à priori d'un site à l'autre.

Dans le calcul des moments, nous aurons donc à prendre divers types de moyennes, les unes pour déterminer le champ moyen que connait un noyau, les autres pour déterminer le champ moyen règnant sur l'ensemble des sites non equivalents au point de vue de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

l'entourage. Enfin, dans le cas des poudres, une troisième moyenne devra être faite pour tenir compte des différentes orientations des cristallites.

(a) Cas du monocristal

La moyenne à effectuer est double dans ce cas ci. Il s'agit de prendre tout d'abord la moyenne de $(H_i-H_0)^n$ sur le temps. On peut remarquer que calculer une moyenne sur le temps revient, conformément à l'hypothèse de Gibbs, à effectuer la moyenne d'ensemble à un moment donné. En effet, au même instant, les divers noyaux de type i répartis dans le monocristal sont soumis à tous les champs directeurs qu'un noyau i peut subir suite aux fluctuations du champ dans le temps. Dans la suite des calculs, cette moyenne sera symbolisée par une barre horizontale ne dépassant pas les crochets. La seconde moyenne est à prendre sur les noyaux de l'espèce en résonance, différents par leur position dans la maille de l'édifice cristallin. Elle sera représentés par des crochets entourant l'expression à moyenner. Le calcul de ces deux moyennes revient à scinder en deux parties la moyenne étendue à tous les noyaux du type étudié, contenus dans l'échantillon. Cependant, nous séparerons très nettement les deux moyennes.

(b) Cas des poudres

Ici les cristallites sont, en principe, orientés au hasard et de manière uniforme. L'angle que forme le champ directeur H_0 avec le vecteur liant les deux particules en interaction dipolaire, peut prendre toutes les valeurs. Il faut donc en plus moyenner sur la fonction angulaire. Ceci sera représenté par une barre horizontale débordant les crochets. Finalement, nous effectuerons les moyennes dans l'ordre suivant:

1. moyenne sur le temps,
2. moyenne sur les noyaux en des sites inéquivalents,
3. moyenne sur la fonction angulaire.

Les moments à l'échelle microscopique s'écriront donc:

pour un monocristal:	pour une poudre:
$S_n = \langle\overline{(H_i-H_m)^n}\rangle$ [14]	$\bar{S}_n = \overline{\langle(H_i-\bar{H}_m)^n\rangle}$ [16]
$\Sigma_n = \langle\overline{(H_i-H_0)^n}\rangle$ [15]	$\bar{\Sigma}_n = \overline{\langle(H_i-H_0)^n\rangle}$ [17]

où la valeur de H_i est donnée par [9]. De plus $H_m = \langle\bar{H}_i\rangle = H_0+\langle H_p\rangle$ [18] pour un monocristal et $\bar{H}_m = \overline{\langle\bar{H}_i\rangle} = H_0$ [19] pour une poudre. Par conséquent, pour des échantillons polycristallins, les deux types de moment $\bar{\Sigma}_n$ et $\bar{S}_n$ sont égaux. Par ailleurs, en l'absence de paramagnétiques, H_m et H_0 coincident même pour un monocristal ainsi que le signale également Kroon (1).

Le premier moment pour un monocristal vaut:

$$\frac{1}{N}\sum_i\sum_p \frac{\bar{\mu}_p}{R_{ip}^3}(3\cos^2\theta_{ip}-1) \qquad [20]$$

expression où la moyenne sur les sites inéquivalents est symbolisée par $1/N\sum_i$ et où la moyenne sur le temps est déjà inclue dans le facteur $\bar{\mu}_p$. Ce premier moment s'annule pour une poudre ainsi qu'en témoigne l'équation [19]. L'effet des centres paramagnétiques pour un échantillon polycristallin se fera donc uniquement sentir sur les moments d'ordre supérieur.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Des définitions [16] et [17] et des équations [9] et [19], le second moment d'une poudre s'exprimera par:

$$\bar{S}_2 = \bar{\Sigma}_2 = \overline{\langle H_p^2 \rangle} + \overline{\langle H_j^2 \rangle}.$$

Cette relation amène à un résultat semblable à celui de Van Vleck (13) une fois les moyennes effectuées.

Le résultat final pour $\bar{S}_2$ peut s'écrire:

$$S_2 = \frac{1}{N} \sum_i \left[\frac{4}{5} \sum_j k_{ij}^2 \mu_j^2 r_{ij}^{-6} + \frac{4}{5} \sum_p \bar{\mu}_p^2 R_{ip}^{-6} + \frac{2}{5} \sum_p \sum_{p' \neq p} \bar{\mu}_p \bar{\mu}_{p'} R_{ip}^{-3} R_{ip'}^{-3} (3 \cos^2 \lambda_{p\,ip'} - 1) \right] \quad [21]$$

Les deux derniers termes, qui représentent la contribution des centres paramagnétiques au second moment, sont équivalents aux équations [17] et [18] de Kroon (1) lorsqu'on y néglige l'effet d'anisotropie des cristallites qui, de toute façon, reste un effet fort difficile à déterminer quantitativement.

4. CALCUL DU TROISIEME MOMENT

Cette fonction caractérise la dissymétrie de la distribution; elle est donc nulle dans le cas des raies symétriques, par exemple pour des profils gaussiens et lorentziens, qui sont les plus fréquents en résonance. Par contre, dès que l'échantillon contient des centres paramagnétiques (paramagnétisme métallique, ions paramagnétiques), leur influence se marque sur le profil de la raie en provoquant une dissymétrie. Il est donc bien justifié d'utiliser le troisième moment pour chiffrer l'écart à la symétrie et, par là, l'influence du paramagnétisme.

Si, pour des monocristaux, le premier moment de type Σ est plus facile à utiliser (14), dans le cas d'une poudre polycristalline, l'annulation de $\bar{\Sigma}_1$ exige l'emploi des moments d'ordre supérieur et, entre autres, du moment d'ordre trois $\bar{S}_3$.

Celui-ci a pour expression générale, lorsqu'on utilise les définitions [16] et [17] et les équations [9] et [19]:

$$\bar{S}_3 = \bar{\Sigma}_3 = \overline{\langle H_p^3 \rangle} + 3\overline{\langle H_p \bar{H}_j^2 \rangle} \quad [22]$$

où, en remplacant H_p et H_j par leur valeur, il vient:

$$\bar{S}_3 = \overline{\frac{1}{N} \sum_i \left[\sum_p \bar{\mu}_p \cdot R_{ip}^{-3} (3 \cos^2 \theta_{ip} - 1) \right]^3} + \frac{3}{N} \overline{\sum_i \left[\sum_p \bar{\mu}_p R_{ip}^{-3} (3 \cos^2 \theta_{ip} - 1) \right] \cdot \left[\sum_j k_{ij}^2 \mu_j^2 r_{ij}^{-6} (3 \cos^2 \theta_{ij} - 1)^2 \right]}. \quad [23]$$

Pour évaluer ces moyennes sur les directions, nous remarquerons tout d'abord que le terme au cube peut se décomposer en:

$$\overline{\left(\sum_p A_p \right)^3} = \overline{\sum_p A_p^3} + 3\overline{\sum_p \sum_{p' \neq p} A_p^2 A_{p'}} + \overline{\sum_p \sum_{p' \neq p} \sum_{\substack{p'' \neq p' \\ \neq p}} A_p A_{p'} A_{p''}} \quad [24]$$

où A_p représente toute la fonction

$$\bar{\mu}_p R_{ip}^{-3} (3 \cos^2 \theta_{ip} - 1).$$

D'autre part le second terme de [23] s'écrit:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$\overline{\sum_p A_p \sum_j B_j^2} = \sum_p \sum_j \overline{A_p B_j^2} \qquad [25]$$

où

$$B_j = k_{ij}\mu_j r_{ij}^{-3}(3\cos^2\theta_{ij}-1)$$

Pour effectuer la moyenne de ces diverses sommes, il suffit de prendre un terme caractéristique de chacune des sommes, d'en faire la moyenne et, enfin, de sommer les résultats obtenus.

Dans l'équation [25], la fonction angulaire,

$$(3\cos^2\theta_{ij}-1)^2(3\cos^2\theta_{ip}-1)$$

moyennée sur l'angle θ de 0 à π et sur l'angle φ de 0 à 2π amène au résultat

$$\frac{8}{35}(3\cos^2\lambda_{pij}-1)$$

où λ_{pij} représente l'angle entre les directions i–p et i–j.

Finalement le second terme de [23] se met sous la forme:

$$\frac{3}{N}\sum_i \sum_p \sum_j \overline{A_p B_j^2} = \frac{24}{35}\frac{1}{N}\sum_i \sum_p \sum_j \bar{\mu}_p k_{ij}^2 \mu_j^2 R_{ip}^{-3} r_{ij}^{-6}(3\cos^2\lambda_{pij}-1). \qquad [26]$$

La moyenne du cube de la somme s'effectue comme suit:

1. La moyenne sur un terme caractéristique de la simple somme en p du second membre de [24] devient après intégration sur θ_{ip}:

$$\overline{A_p^3} = \frac{16}{35}\bar{\mu}_p^3 R_{ip}^{-9}. \qquad [27]$$

2. La moyenne sur un terme caractéristique de la double somme en p et en p' se traite comme la moyenne sur le terme mixte $A_p B_j^2$. Après calcul on obtient un résultat similaire:

$$\overline{A_p^2 A_{p'}} = \frac{8}{35}\bar{\mu}_p^2 \cdot \bar{\mu}_{p'}(3\cos\lambda'-1) \qquad [28]$$

où λ' désigne l'angle entre les vecteurs i–p et i–p'.

3. Les termes $A_p A_{p'} A_{p''}$ font intervenir trois angles par rapport au champ magnétique H_0 et, pour effectuer la moyenne d'un terme caractéristique, nous utiliserons le système de référence comme indiqué à la Fig. 3. Dans le trièdre, nous plaçons le noyau i à l'origine des coordonnées, le vecteur ip suivant l'axe Z et le vecteur ip' dans le plan XOZ. Le vecteur ip'' est fixé par les constantes du réseau cristallin. La direction de H_0 est exprimée par la colatitude θ et la longitude φ mesurée par rapport à X. λ'' et λ''' représentent respectivement les angles entre ip et ip'', et entre ip' et ip''. χ est l'angle dièdre entre les plans ipp' et ipp''. λ', λ'', λ''' et κ sont des constantes de la structure cristalline du composé étudié.

Dans une telle représentation, les angles θ_{ip}, $\theta_{ip'}$ et $\theta_{ip''}$ deviennent, en fonction de φ et de θ:

$$\begin{cases} \cos\theta_{ip} = \cos\theta \\ \cos\theta_{ip'} = \cos\lambda'\cdot\cos\theta + \sin\lambda'\cdot\sin\theta\cdot\cos\varphi \\ \cos\theta_{ip''} = \cos\lambda''\cdot\cos\theta + \sin\lambda''\cdot\cos\kappa\cdot\sin\theta\cdot\cos\varphi + \sin\lambda''\cdot\sin\kappa\cdot\sin\theta\cdot\sin\varphi \end{cases} \qquad [29]$$

où

$$\cos\kappa = \frac{\cos\lambda''' - \cos\lambda'\cos\lambda''}{\sin\lambda'\sin\lambda''}.$$

For personal use only.

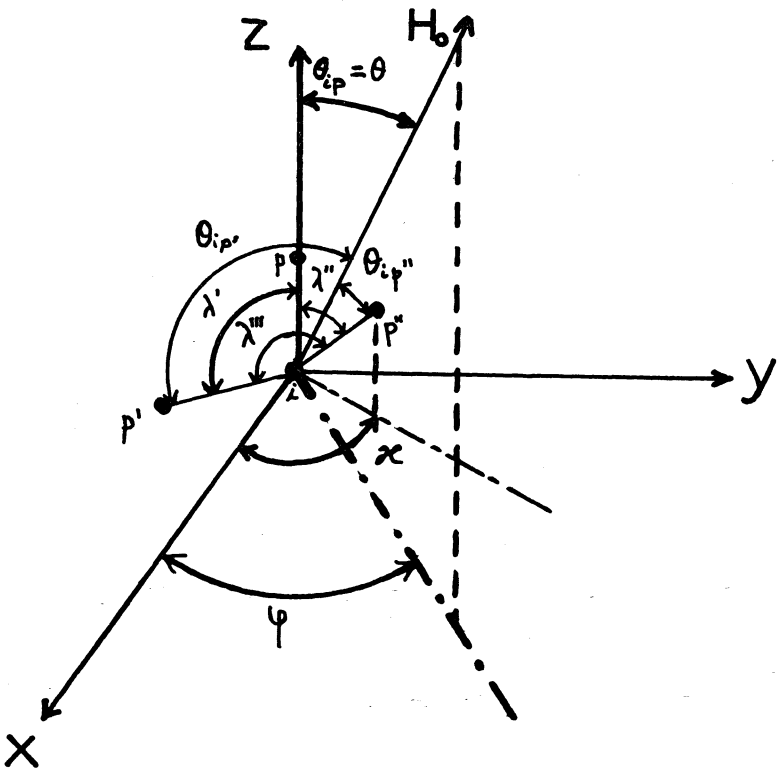

FIG. 3. Angles intervenant dans le calcul du troisième moment.

La partie angulaire de l'expression à moyenner $A_pA_{p'}A_{p''}$ peut se développer comme suit:

$$\bar{E} = 27\bar{E}_1-9\bar{E}_2-9\bar{E}_3-9\bar{E}_4+3\bar{E}_5+3\bar{E}_6+3\bar{E}_7-1. \qquad [30]$$

Les moyennes, après intégration en θ et en φ, donnent:

$$-9\bar{E}_2 = -\frac{3}{5}(2\cos^2\lambda'+1), \qquad +3\bar{E}_5 = +1$$

$$-9\bar{E}_3 = -\frac{3}{5}(2\cos^2\lambda''+1), \qquad +3\bar{E}_6 = +1$$

$$-9\bar{E}_4 = -\frac{3}{5}(2\cos^2\lambda'''+1), \qquad +3\bar{E}_7 = +1$$

et $$27E_1 = \frac{9}{35}(1+2\cos^2\lambda'+2\cos^2\lambda''+2\cos^2\lambda'''+8\cos\lambda'\cos\lambda''\cos\lambda''').$$

$\bar{E}$ s'écrit après simplification:

$$\frac{8}{35}[2-3(\cos^2\lambda'+\cos^2\lambda''+\cos^2\lambda''')+9\cos\lambda'\cos\lambda''\cos\lambda''']. \qquad [31]$$

En introduisant dans l'expression du troisième moment les équations [31, 26, 27, 28] il vient finalement:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$\bar{S}_3 = \bar{\Sigma}_3 = \frac{1}{N}\sum_i \left[\frac{16}{35}\sum_p \bar{\mu}_p^3 R_{ip}^{-9} + \frac{24}{35}\sum_p \sum_{p'} \bar{\mu}_p^2 \bar{\mu}_{p'} R_{ip}^{-6} R_{ip'}^{-3}(3\cos^2\lambda' - 1)\right.$$

$$+\frac{8}{35}\sum_p \sum_{p'} \sum_{p''} \bar{\mu}_p \bar{\mu}_{p'} \bar{\mu}_{p''} R_{ip}^{-3} R_{ip'}^{-3} R_{ip''}^{-3}(2 - 3(\cos^2\lambda' + \cos^2\lambda'' + \cos^2\lambda''')$$

$$\left. +9\cos\lambda'\cos\lambda''\cos\lambda''') + \frac{24}{35}\sum_p \sum_j \bar{\mu}_p \mu_j^2 k_{ij}^2 R_{ip}^{-3} r_{ij}^{-6}(3\cos^2\lambda_{pij} - 1)\right] \quad [32]$$

Cette longue expression se simplifie considérablement dans le cas où un seul paramagnétique fait sentir son influence sur les noyaux. Les sommes en p se réduisent à un terme, de telle sorte que [32] devient:

$$\bar{S}_3 = \frac{1}{N}\sum_i \left[\frac{16}{35}\bar{\mu}_p^3 R_{ip}^{-9} + \frac{24}{35}\sum_j \bar{\mu}_p k_{ij}^2 \mu_j^2 R_{ip}^{-3} r_{ij}^{-6}(3\cos^2\lambda_{pij} - 1)\right]. \quad [33]$$

Pour une paire de noyaux identiques et équidistants du paramagnétique:

$$R = R_{1p} = R_{2p},\ \lambda = \lambda_{p12} = \lambda_{p21},\ k_{ij} = \frac{3}{2} \text{ et } \mu_j = \mu$$

si bien que le troisième moment sera pour une telle disposition:

$$\bar{S}_3 = \frac{16}{35}\frac{\bar{\mu}_p^3}{R^9} + \frac{54}{35}\frac{\bar{\mu}_p \mu^2}{r^6 R^3}(3\cos^2\lambda - 1) \quad [34]$$

Cette équation simplifiée est à rapprocher de l'équation suivante du second moment, valable dans les mêmes conditions:

$$\bar{S}_2 = \frac{9}{5}\frac{\mu^2}{r^6} + \frac{4\bar{\mu}_p^2}{5R^6}. \quad [35]$$

Pour fixer l'ordre de grandeur de $\bar{S}_3$, nous prendrons le cas d'un centre paramagnétique tel que l'ion Cu^{++}, placé dans un champ de 13,200 g à la température de 300° K. Le moment magnétique moyen de l'ion cuivre vaut alors 7.24 magnétons nucléaires ($K = 2.6$). Si cet ion est situé à 2.60 Å de deux protons distants de 1.60 Å, on trouve pour les second et troisième moments

$$\bar{S}_2 = \overline{\langle H_p^2\rangle} + \overline{\langle H_j^2\rangle} = 3.4 + 21.0 = 24.4g^2$$

$$\bar{S}_3 = \overline{\langle H_p^3\rangle} + 3\overline{\langle H_p H_j^2\rangle} = 4.1 - 29.2 = -25.1g^3.$$

Transformons l'équation [34] en exprimant $\bar{S}_3$ en fonction d'un paramètre K, qui représente le rapport du moment magnétique $\bar{\mu}_p$ du centre paramagnétique au moment μ du noyau. Pour la résonance du proton, il vient:

$$\bar{S}_3 = 8.03\cdot 10^{+71}\left[16\frac{K^3}{R^9} + 54\frac{K}{R^3 r^6}(3\cos^2\lambda - 1)\right]$$

A la Fig. 4, nous avons mis en graphique le troisième moment $\bar{S}_3$ en fonction de K pour différentes valeurs de R et de r.

	R	r	$\bar{S}_3$
I	2.60	1.56	$0.237\,K^3 - 12.5\,K$
II	2.60	1.60	$0.237\,K^3 - 11.2\,K$
III	3.00	1.56	$0.0650\,K^3 - 8.91\,K$
IV	3.00	1.60	$0.0650\,K^3 - 8.03\,K$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

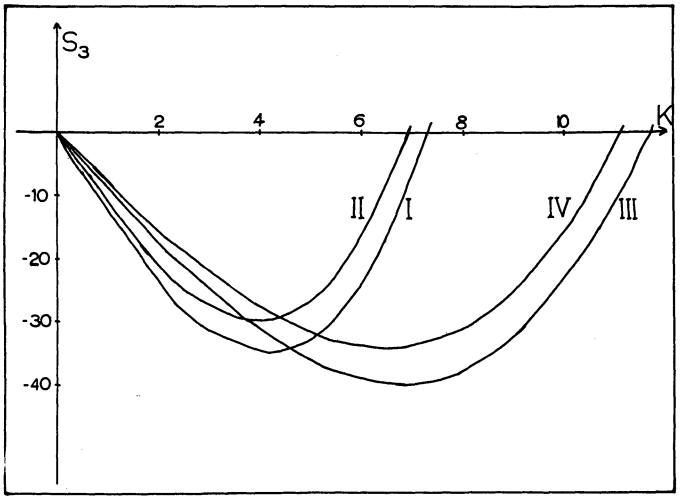

FIG. 4. Variation du troisième moment $\bar{S}_3$ en fonction du paramètre $K = \bar{\mu}_p/\mu$.

Remarquons toutefois que la dissymétrie d'une distribution reste une grandeur délicate à mesurer. L'erreur expérimentale à laquelle est soumis le troisième moment peut s'estimer comme suit.

Supposons la distribution de champ de la figure 1. Si $h = H - H_0$, de par la définition de S_3, nous aurons:

$$\bar{S}_3 = \frac{\int_{-\infty}^{+\infty} g(h)h^3 dh}{\int_{-\infty}^{+\infty} g(h)dh} = \bar{S}_{3II} - \bar{S}_{3I}$$

avec

$$\bar{S}_{3I} = \frac{\int_{-\infty}^{0} h^3 g(h)dh}{\int_{-\infty}^{+\infty} g(h)dh}$$

où $g(h)$ représente la fonction de normalisation et où l'indice I indique qu'il est question de l'aile à bas champ. La précision de la mesure sur l'aile I d'un spectre peut être de $\pm \bar{S}_{3I}/20$ et sur l'aile II, à haut champ, de $\pm \bar{S}_{3II}/20$. Et donc, la précision du troisième moment total sera exprimée par $\bar{S}_3 \pm (\bar{S}_{3I} + \bar{S}_{3II})/20$. De plus, si $\bar{S}_{2I} \sim \bar{S}_{2II} \sim \bar{S}_2/2$ et si $(\bar{S}_{2I})^{3/2} \sim \bar{S}_{3I}$, nous obtenons alors pour $\bar{S}_3$ une valeur précise à $\pm 5g^3$, dans le cas de l'exemple du paragraphe précédent. Or, l'ordre de grandeur de $\bar{S}_3$ est de $-30\ g^3$, comme nous l'avons vu plus haut. $\bar{S}_3$ est donc connu à $\pm 15\%$. On peut, par des mesures sur un plus grand nombre de spectres, préciser les valeurs de $\bar{S}_{3I}$ et de $\bar{S}_{3II}$ et, par là, diminuer l'erreur commise sur $\bar{S}_3$.

Par conséquent, en utilisant simultanément les valeurs de $\bar{S}_2$ et de $\bar{S}_3$, il est possible de déterminer deux paramètres structuraux si l'on enregistre, à *une* température et à *une* valeur du champ magnétique H_0, les spectres de résonance d'un noyau dans un échantillon à l'état de poudre.

5. CALCUL DE $\bar{S}_3$ À PARTIR DES RESULTATS QUANTIQUES

Au moyen d'un calcul de perturbation, N. Bloembergen (12) a déterminé la position et l'intensité des raies de résonance d'un système à deux protons entourés de plusieurs ions paramagnétiques.

Le spectre calculé comporte quatre raies (Fig. 5):

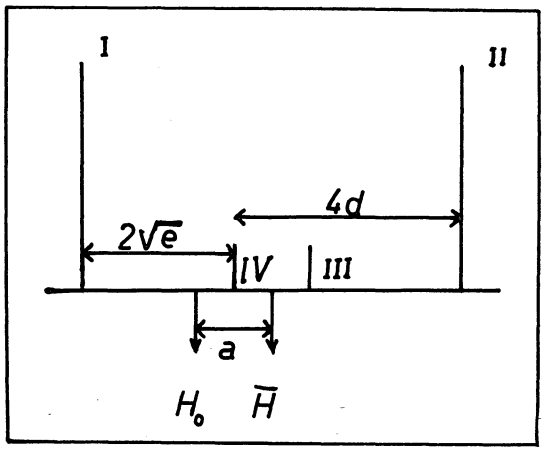

FIG. 5. Spectre de résonance nucléaire d'une paire isolée de protons soumis à l'interaction de plusieurs ions paramagnétiques.

	Position	Intensité
I	$H_1 = H_0 + a + 2d + \sqrt{e}$	$i_1 = \dfrac{(b - d - \sqrt{e})^2}{e - b\sqrt{e}}$
II	$H_2 = H_0 + a - 2d - \sqrt{e}$	
III	$H_3 = H_0 + a - 2d + \sqrt{e}$	$i_2 = \dfrac{(b - d + \sqrt{e})^2}{e + b\sqrt{e}}$
IV	$H_4 = H_0 + a + 2d - \sqrt{e}$	

[36]

Les positions des raies sont données en unité de champ et

$$a = \frac{1}{2}\left[\sum_p \bar{\mu}_p R_{1p}^{-3}(3\cos^2\theta_{1p} - 1) + \sum_p \bar{\mu}_p R_{2p}^{-3}(3\cos^2\theta_{2p} - 1)\right] = \frac{A+B}{2} \qquad [37]$$

$$b = \frac{1}{2}\left[\sum_p \bar{\mu}_p R_{1p}^{-3}(3\cos^2\theta_{1p} - 1) - \sum_p \bar{\mu}_p R_{2p}^{-3}(3\cos^2\theta_{2p} - 1)\right] = \frac{A-B}{2} \qquad [38]$$

$$H_{12} = 3d = \frac{3}{2}\mu r_{12}^{-3}(3\cos^2\theta_{12} - 1),\ e = b^2 + d^2,\ H_m = H_0 + a \qquad [39]$$

Les indices 1 et 2 concernent les deux protons de la paire et l'indice p se rapporte à l'ion paramagnétique p de l'entourage.

Calculons d'abord les seconds moments pour une orientation du monocristal:

$$S_2 = \sum_i p_i (H_i - H_m)^2$$

où i représente l'indice de la raie considérée et où p_i est le poids de cette raie.

I et II ont même poids: $p_1/2$ et $p_1 = i_1/(i_1 + i_2)$.

III et IV ont même poids: $p_2/2$ et $p_2 = 1 - p_1$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Après calcul, il vient:

$$S_2 = 8dp_1\sqrt{e+4d^2+e-4d\sqrt{e}}$$

et $p_1 = (e^{1/2}+d)/2e^{1/2}$.

Enfin $S_2 = 9d^2+b^2$ [40]

A partir des relations: $\Sigma_2 = S_2+\Sigma_1^2$ et $\Sigma_1 = H_m-H_0 = a$ [41]

Σ_2 s'écrira donc:

$$9d^2+b^2+a^2 = 9d^2+\tfrac{1}{2}(A^2+B^2). \quad [42]$$

Nous pouvons maintenant passer au cas du second moment pour une poudre. En effet, le champ moyen de référence $\bar{H}_m$ est le même pour toutes les orientations et vaut H_0.

$$\bar{S}_2 = \bar{\Sigma}_2 = 9\overline{d^2}+\overline{b^2}+\overline{a^2} = 9\overline{d^2}+\frac{\overline{A^2}+\overline{B^2}}{2}$$

Cette expression donne un résultat identique à l'équation

$$\bar{S}_2 = \overline{\langle H_p^2\rangle}+\overline{\langle H_j^2\rangle}$$

pour une paire de protons entourés de plusieurs ions paramagnétiques.

D'après l'équation [13], Σ_3 s'écrit: $\Sigma_3 = S_3+3\Sigma_1\Sigma_2-2\Sigma_1^3$

Or, S_3 pour une orientation du monocristal est nulle.

Donc, en remplaçant Σ_1 et Σ_2 par les équations [42] et [41], il vient:

$$\Sigma_3 = 27d^2a+3b^2a+a^3$$

et, pour une poudre, après simplification, on obtient:

$$\bar{\Sigma}_3 = \bar{S}_3 = 3\overline{(3d)^2a}+\frac{\overline{A^3}+\overline{B^3}}{2}. \quad [43]$$

Ce qui peut s'écrire sous la forme suivante:

$$\bar{S}_3 = \overline{\langle H_p^3\rangle}+3\overline{\langle H_p\overline{H_j^2}\rangle} \quad [22]$$

car la somme est ici étendue à deux noyaux en résonance (protons).

L'expression du troisième moment d'un tel système est donc bien identique à celle calculée sur la base d'un résultat semi-classique.

Le facteur 3/2, qui exprime l'écart entre les raisonnements quantique et classique pour les interactions dipolaires entre partenaires semblables, intervient dans l'expression du second moment au carré. Cependant, pour les moments d'ordre n, la correction est, à priori, différente de $(3/2)^n$, ainsi que le signale Van Vleck (13). Ceci se vérifie bien dans l'expression du troisième moment. Le facteur 3/2 n'affecte en rien les termes en H_p^3 et H_p mais intéresse uniquement H_j^2 où la correction $(3/2)^2$ est présente sous forme de k_{ij}^2 dans les équations [32] et [33].

6. CONCLUSION

Le troisième moment $\bar{S}_3$ décrit la dissymétrie de la distribution spectrale. Cette dissymétrie est généralement imputable à la présence de centres paramagnétiques dans la substance étudiée.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Nous nous sommes bornés, ici, à voir l'influence sur le troisième moment de l'interaction dipolaire des noyaux ($I = \frac{1}{2}$) avec les centres paramagnétiques. Dans le cas d'un modèle simple, nous avons vu comment la mesure simultanée de $\tilde{S}_3$ et de $\tilde{S}_2$ pouvait déterminer deux paramètres structuraux R et r, à l'aide de spectres pris sur un échantillon polycristallin.

Il est possible d'étendre l'expression du troisième moment à des cas où l'interaction hyperfine $\mathscr{H}_S$ n'est plus négligeable. $\tilde{S}_3$, couplé aux autres moments ($\overline{\Sigma}$, et $\tilde{S}_2$), permettrait de distinguer les contributions au profil de la raie, des interactions dipolaires et des interactions hyperfines anisotropiques.

Le troisième moment pourrait également être appliqué au couplage de contact dans les métaux et dans les alliages où apparaissent aussi des raies dissymétriques (15).

Enfin, la dissymétrie pourrait mesurer le pourcentage de couplage quadrupolaire de second ordre dans le cas où celui-ci n'est plus négligeable (16).

REMERCIEMENTS

Je remercie tout particulièrement Monsieur le Professeur M. Van Meerssche pour l'intérêt qu'il a bien voulu porter à cette étude et j'exprime ma reconnaissance au Dr. D. J. Kroon pour les fructueuses discussions que nous avons eues ensemble.

Mes remerciements vont également au Fonds National de la Recherche Scientifique (Belgique) pour le mandat d'aspirant qu'il a bien voulu m'octroyer.

L'EFFET RÉFLEXE DANS LE BICYCLO[3.2.1]OCTANEDIOL-2β,4β

J. G. DUROCHER[1] ET H. FAVRE
Département de Chimie de l'Université de Montréal, Montréal, Québec

Reçu le 4 juillet 1963

RÉSUMÉ

Les bicyclo[3.2.1]octanediols-2β,4β, -2α,4β et 2α,4α ont été préparés. Le diol diaxial -2β,4β a servi de substance molèle pour l'étude de l'effet de contrainte et de l'effet réflexe. Par l'étude du pont hydrogène interne de ce diol, il est confirmé que si l'on rapproche (effet de contrainte) les substituants diaxiaux sur les carbones 1 et 5 d'un cyclohexane, les substituants axiaux sur les carbones 2 et 4 s'écartent l'un de l'autre (effet réflexe).

En 1958, Sandris et Ourisson (1) signalaient un effet stérique, qu'ils appelaient *effet réflexe*, opérant dans un noyau cyclohexanique lorsque deux substituents axiaux subissent une contrainte. Deux groupes méthyles se repoussent: ils n'occupent pas, comme l'indique la Fig. 1, les positions *a*, mais les positions *a'*. En passant de *a* à *a'*, deux substituants

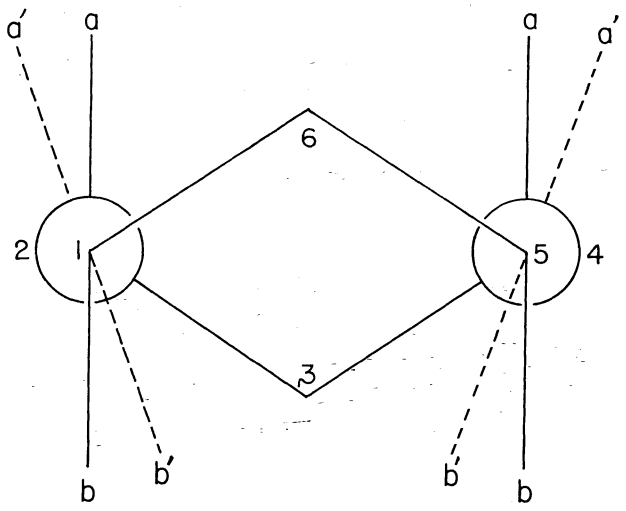

FIG. 1. Cyclohexane en projection de Newman et effet réflexe.

axiaux entraînent les substituants *b* qui se rapprochent l'un de l'autre pour occuper les positions *b'*: c'est l'effet réflexe, qui joue d'ailleurs dans deux sens, car si l'on rapproche les substituants *b* on écarte du même coup les substituants *a*. Les mouvements décrits sont facilement observables sur un modèle de Barton (2); la Fig. 1 les illustre. Si l'effet réflexe a été mis en évidence par les expériences d'Ourisson, il n'en reste pas moins que son aspect quantitatif est encore obscur. On peut en effet envisager que cet effet réflexe (stérique) est analogue à l'effet inductif (électronique); on sait que ce dernier diminue, pour finalement s'éteindre, à mesure que l'on s'éloigne du centre d'induction (3). On peut donc se poser la même question pour l'effet réflexe: quel est son ordre de grandeur à proximité des centres de contrainte, et ensuite, en fonction de la distance? On retrouve

For personal use only.

ainsi le problème plus général de la transmission conformationnelle soulevé par Barton (4, 5). Nos études sur les dérivés du bicyclo[3.2.1]octane, en particulier celles des diols (6, 7), nous ont amenés à entreprendre quelques travaux sur les déformations que subit un noyau cyclohexanique contraint en deux points et à approfondir les notions d'effet réflexe et de transmission conformationnelle.

Ce mémoire traite essentiellement du bicyclo[3.2.1]-octanediol-2β,4β (I), et accessoirement de ses isomères-2α,4β (II) et -2α,4α (III).

Nous envisageons le diol diaxial I (Fig. 2) comme un cyclohexanediol-1,3 *cis* diaxial

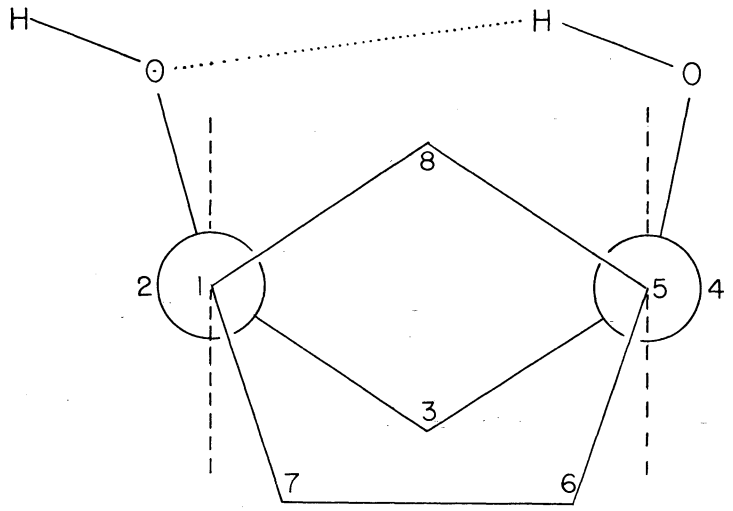

FIG. 2. Projection de Newman du bicyclo[3.2.1]octanediol-2β,4β.

idéal[2] (Fig. 1, a = OH, b = H, on néglige a', b') dans lequel la distance idéale de 2.51 Å H—H (= b—b) aurait été amenée à 1.54 Å, qui est la longueur de la liaison C_6—C_7 dans le diol I. On s'attend donc, par l'effet réflexe, à ce que les groupes OH soient plus éloignés l'un de l'autre dans le diol I que dans le cyclohexanediol-1,3 *cis* diaxial. La vérification en est aisée, car Kuhn (8) a montré que la différence ($\Delta\nu$, exprimé en cm^{-1}) entre les bandes infrarouges de vibration des groupes —OH libre et engagé dans un pont hydrogène intramoléculaire de nombreux diols est fonction de la longueur du pont hydrogène: plus ce dernier est court, plus le $\Delta\nu$ est grand. Nous avons trouvé que le $\Delta\nu$ du bicyclo[3.2.1]octanediol-2β,4β (I) est de 39 cm^{-1}, pour 76 cm^{-1} (8) pour le cyclohexanediol-1,3 *cis* (diaxial). Qualitativement donc nous sommes en mesure de confirmer l'effet réflexe d'Ourisson, puisque la diminution de $\Delta\nu$ en passant du diol non contraint (cyclohexanediol-1,3 *cis*) au diol contraint (diol I) correspond à un écartement des groupes —OH.

Un travail récent de Mühle et Tamm (10) corrobore nos résultats et justifie nos conclusions. Ces auteurs ont en effet observé une augmentation de $\Delta\nu$ en passant du cholestanediol-1α,3α ($\Delta\nu$ 87 cm^{-1}) au diméthyl-4,4 cholestanediol-1α,3α ($\Delta\nu$ 107 cm^{-1}), la répulsion entre les groupes méthyles β diaxiaux amenant par effet réflexe un rapprochement des groupes —OH diaxiaux en 1 et en 3.

[2]*La conformation du cyclohexanediol-1,3 cis diaxial idéal est représentée par la Fig. 1 (a = —OH, b = —H; on néglige a', b'). Des travaux récents (9, 10) indiquent toutefois qu'une certaine répulsion entre les groupes* —OH *fait que la forme (conformation réelle) est plutôt représentée par la Fig. 1 (a' = —OH, b' = —H; on néglige a, b); la grandeur de la déformation n'est pas connue.*

(IV) (V) (VI)

SYNTHÈSE DES TROIS BICYCLO[3.2.1]OCTANEDIOLS-2,4

Nous avons préparés les diols à partir: 1. de la bicyclo[3.2.1]octanedione-2,4 (IV), qui s'obtient facilement en faisant agir le diazométhane sur la norcamphoquinone et en hydrolysant l'éther céto-énolique obtenu, à l'image de la synthèse de l'oxo-4 homocamphre à partir de la camphoquinone (12, 13); 2. de l'époxyde 3β,4β de la bicyclo[3.2.1]octène-3 one-2, (VI) qui résulte de l'action du peroxyde d'hydrogène sur la cétone α,β-éthylénique correspondante (V).

Le diol diaxial résulte de la réduction de la β-dicétone IV par le nickel de Raney et le diol diéquatorial de la réduction par le sodium et l'éthanol de cette β-dicétone, à l'image des réductions de l'oxo-4 homocamphre (7). Le diol axial-équatorial s'obtient par réduction par l'hydrure de lithium et d'aluminium de l'époxyde-cétone VI (méthode de Tamm et de ses collaborateurs (10, 11). Dans les trois cas le diol pur a été obtenu par chromatographie sur alumine des diols bruts. D'une manière assez surprenante, dans ces chromatographies, nous avons toujours obtenu dans les fractions de tête un diol pur, que ce soit le diaxial (I), le diéquatorial (III), ou l'axial-équatorial (II); les trois diols n'ont donc pas de caractéristiques d'adsorption sur l'alumine bien marquées. La pureté de chaque diol a été établie en chromatographiant en phase gazeuse le diéther méthylique correspondant, que l'on obtient aisément en traitant le diol par le diazométhane en présence d'acide fluoroborique (14). Les temps de rétention des diéthers diaxial et diéquatorial sont identiques; ces deux diéthers sont élués après le diéther axial-équatorial. Nous n'avons ainsi pas pu doser chaque diol dans les mélanges bruts de réduction: nous ne pouvons que connaître le pourcentage de diol axial-équatorial qui se retrouve dans les 3 mélanges: 42% dans la réduction catalytique, 28% dans la réduction chimique de la dicétone et 90% dans la réduction de l'époxyde-cétone. Dans ce dernier cas les 10% qui restent sont nécessairement formés du diol diaxial, l'époxyde 3β,4β (VI) étant le seul formé au cours de l'époxydation.

Cette configuration 3β,4β a été déduite du fait que l'attaque du réactif doit so faire sur la face β, la plus dégagée de la cétone α,β-éthylénique V, celle qui n'est pas soumise à l'empêchement stérique causé par le pont C_6—C_7 diaxial. Ceci est conforme au travail récent de Mühle et Tamm (10), qui signalent que l'époxydation de la diméthyl-4,4 cholestène-1 one-3 (et même de la cholestène-1 one-3 (11)) se fait par la face α, non par la face β influencée par les groupes méthyles axiaux en 4 et 10. L'analogie entre le bicycle que nous décrivons et les stéroïdes se complète par le fait que l'oxydation périodique ne révèle pas de diol-1,2, mais elle s'arrête là, car dans la série stéroïde on obtient par réduction de l'époxyde-cétone principalement le diol-1,3 diaxial.

PREUVES DE CONFIGURATION DES DIOLS I, II ET III

Les preuves des configurations de ces diols sont les suivantes (voir Tableau I): dans l'*infrarouge* un seul des trois diols présente une bande OH libre et une bande OH associé,

TABLEAU I

Diol	Mode de préparation	Spectre IR ν —OH cm^{-1}	Résonance magnétique nucléaire*	Vitesses relatives d'oxydation chromique†
I Diaxial	Dicétone + H_2/NiRa	3615 (OH libre) 3576 (OH ass.) $\Delta\nu$ = 39 cm^{-1}	6.08 p.p.m. (2H) pic/unique	117.2
II Axial-équatorial	Epoxyde-cétone + $LiAlH_4$	3615 (OH libre)	5.94 p.p.m. (1H) pic/unique 5.55 p.p.m. (1H) multiplet	55.1
III Diéquatorial	Dicétone + Na/EtOH	3615 (OH libre)	6.05 p.p.m. (2H) multiplet	25.8

*Tétraméthylsilane, comme standard interne.
†*Tert*-butyl-4 cyclohexanol *trans* = 1.

d'après la méthode de Kuhn (8); ce ne peut être que le diaxial (I);[3] en *résonance magnétique nucléaire* (15) deux des diols présentent un type de proton H—C(OH), le troisième en a deux; les deux premiers doivent donc avoir un élément de symétrie qui rendra les deux protons identiques, le troisieme en est dépourvu: ce dernier composé est donc l'isomère axial-équatorial (II); des deux premiers diols l'un (I), est déjà connu par l'infrarouge (le diaxial), l'autre sera donc le diéquatorial (III); ces configurations sont confirmées *par oxydation chromique*, selon nos travaux antérieurs (6, 7) qui prévoyaient que le diol axial-équatorial devait s'oxyder plus rapidement que le diéquatorial, et le diaxial plus rapidement que l'axial-équatorial: c'est ce que nous observons en effet.

On peut envisager pour le bicyclo[3.2.1]octane deux conformations, chaise et bateau cyclohexanique, représentées respectivement par les formules des diols I–III et IA–IIIA. La conformation chaise est favorisée, en première approximation, par 7–10 kcal/mole (16). Il est donc évident que le diol diéquatorial chaise III n'aura pas tendance à passer au diol diaxial bateau IIIA, et aussi que le diol axial-équatorial chaise II ne gagnera rien à passer à la conformation diol axial-équatorial bateau IIA. Pour le diol diaxial chaise I $\rightleftarrows$ diéquatorial bateau IA, si la conformation diéquatoriale bateau IA était prédominante aucun des trois diols IA, II et III ne donnerait de pont hydrogène intramoléculaire. Ceci n'étant pas le cas, la conformation I doit exister de préférence à IA, ce qui est d'ailleurs confirmé par les vitesses d'oxydation chromique. A supposer que le diol bateau IIIA existât et que ce soit lui qui donnât le pont hydrogène intramoléculaire observé, sa vitesse d'oxydation chromique devrait être nettement plus élevée que celle du diol diéquatorial, supérieure à 4, de l'ordre de 25 au moins. Le triméthyl-1,8,8 bicyclo[3.2.1]octane diol-2,4 diaxial s'oxyde 25 fois plus rapidement que son isomère diéquatorial alors que l'interaction méthyle-hydroxyde diaxiale est 1–3 (7); l'on s'attendrait à ce qu'une interaction méthyle-hydroxyle diaxiale soit au moins aussi forte en 1–2 qu'en 1–3.

En définitive, les conformations I, II et III nous semblent tout à fait appropriées pour

[3]*Le triméthyl-1,8,8 bicyclo[3.2.1]octanediol-2β,4β n'a pas de pont hydrogène intramoléculaire, mesurable tout au moins dans l'infrarouge (7). C'est la raison pour laquelle nous avons dû préparer le diol diaxial I, dépourvu de groupes méthyles, pour étudier l'effet réflexe.*

I	X = Y = −OH;	W = Z = −H	IA
II	X = Z = −OH;	W = Y = −H	IIA
III	W = Z = −OH;	X = Y = −H	IIIA

décrire ces diols. La conformation chaise cyclohexanique est d'ailleurs généralement acceptée pour les alcools de la série du bicyclo[3.2.1]octane (17, 18).

PARTIE EXPÉRIMENTALE[4]

1. Bicyclo[3.2.1]octanedione-2,4(IV)[5]

La norcamphoquinone préparée selon (19) est traitée par le diazométhane selon la méthode (12): 17.5 g donnent 11.5 g d'éther céto-énolique brut, liquide jaune qui est hydrolysé en β-dicétone IV selon la méthode (13), à la différence près que la dicétone est très soluble dans l'eau et qu'il faut l'extraire d'une manière continue au moyen d'un appareil de Kutscher-Steudel. On obtient ainsi 5 g de dicétone IV, p.f. 128–129°, après cristallisation dans le benzène et sublimation à 100° sous 1 mm. Calculé pour $C_8H_{10}O_2$: C, 69.54; H, 7.30%. Trouvé: C, 69.39; H, 7.24%. Le spectre infrarouge dans le nujol présente une bande forte à 2500 cm^{-1}: —OH à 1610 cm^{-1}: C=C et 1530 cm^{-1}: C=O. La dioxime fond à 182°. Calculé pour $C_8H_{12}O_2N_2$: C, 57.13; H, 7.19; N, 16.66%. Trouvé: C, 57.16; H, 7.22; N, 16.47%.

2. Bicyclo[3.2.1]octanediol-2β,4β (I)

On agite en atmosphère d'hydrogène 2 g de β-dicétone (IV) en solution dans 40 ml d'éthanol 95%, en présence de 2 g de nickel de Raney, à 20° et à la pression atmosphérique. Le nickel de Raney est préparé selon (7). En 10 heures, il y a absorption de 800 ml d'hydrogène (calculé 700 ml). Le catalyseur est éliminé par filtration; on le lave avec un peu de méthanol, évapore les filtrats réunis. Au résidu on ajoute 100 ml d'une solution aqueuse de NaOH 5%; on extrait cette solution par de l'éther, d'une manière continue, dans un appareil de Kutscher–Steudel, pendant 18 heures. L'évaporation de l'éther abondonne 2 g de diols bruts, que l'on dissout dans 200 ml de chloroforme et adsorbe sur 200 g d'alumine Woelm d'activité I. On élue ensuite par des portions de 200 ml de chloroforme. Les fractions 1 à 12 (477 mg) représentent le diol I pur, p.f. 265–267° après 6 cristallisations dans le benzène. Calculé pour $C_8H_{14}O_2$: C, 67.57; H, 9.92%. Trouvé: C, 67.46; H, 9.75%. Di-*p*-nitrobenzoate, p.f. 191–193° (EtOH). Calculé pour $C_{22}H_{20}O_8N_2$: C, 60.00; H, 4.58; N, 6.36%. Trouvé: C, 59.81; H, 4.43; N, 6.14%.

Les fractions 13 à 59 (chloroforme) (1.233 g) représentent des diols en mélange; on élue finalement par 200 ml de méthanol, fraction 60 (317 mg).

3. Bicyclo[3.2.1]octanediol-2α,4α (III)

A 671 mg de β-dicétone en solution dans 30 ml d'éthanol anhydre, on ajoute peu à peu 1.6 g de sodium coupé en petits morceaux. On agite à température de la pièce pendant 3 heures, on ajoute avec prudence 50 ml d'éthanol étendu d'eau (1:1) et évapore l'alcool à pression de 12 mm. La solution aqueuse résiduelle est extraite par de l'éther, d'une manière continue, pendant 18 heures. L'évaporation de l'éther abandonne 306 mg de diols bruts. Pour la chromatographie, on dissout 4 g de diols bruts dans 400 ml de chloroforme, on les adsorbe sur 400 g d'alumine Woelm d'activité I et élue par des portions de 400 ml de chloroforme. Les fractions 1 à 8 (460 mg) représentent le diol III pur, les fractions 9 à 30 (1.10 g) et la fraction 31 (éluée par du méthanol) (1.95 g) des diols en mélange que l'on rechromatographie sur 300 g d'alumine pour obtenir 138 mg (fractions 1 à 5) de diol III pur et 2.823 g de diols en mélange. Le diol III pur fond à 225–226°, après

[4]*Les points de fusion ont été déterminés en tubes capillaires, au moyen d'un thermomètre étalonné avec des substances pures de points de fusion connus. Les analyses sont de W. Manser, ing., Herrliberg (Suisse) et C. Daesslé, Organic Microanalyses, Montréal. Les chromatographies en phase gazeuse ont été réalisées au moyen d'un appareil, Kromo-Tog K–2, de Burrell Corporation.*

[5]*Nous devons la synthèse de cette dicétone à MM. J. Champagne et N. Dufort, candidats chimistes.*

cristallisation dans le benzène. Calculé pour $C_8H_{14}O_2$: C, 67.57; H, 9.92%. Trouvé: C, 67.42; H, 9.65%. Di-*p*-nitrobenzoate, p.f. 184–185°. Calculé pour $C_{22}H_{20}O_8N_2$: C, 60.00; H, 4.58; N, 6.36%. Trouvé: C, 59.84; H, 4.64; N, 6.16%.

4. Bicyclo[3.2.1]octène-3 one-2 (V)

Nous avons procédé de la manière suivante. La bicyclo[3.2.1]octanone-2, préparée selon (20), a été bromée selon (21) puis déshydrobromée selon la méthode (22); la cétone α,β-éthylénique brute a été purifiée par chromatographie en phase gazeuse, en utilisant un appareil Prep-Partitioner de Fisher (20% polyester succinique de Craig, sur brique, 185°, azote comme éluant). Le rendement en cétone pure est de 54% à partir de la cétone saturée: p. éb. 86° sous 12 mm: dinitro-2,4 phénylhydrazone, p.f. 139–140° (litt. 140.4–141.5° (23)).

5. Oxydo-3β,4β bicyclo[3.2.1]octanediol-2α,4β (II)

Nous avons adapté la méthode (24). Dans un bécher de 250 ml, muni d'un agitateur magnétique et placé dans un bain maintenu à 40°, on met 2.02 g de bicyclo[3,2,1]octène-3 one-2 (V) en solution dans 100 ml de méthanol aqueux 80%. On ajoute au compte-goutte, quelques gouttes de NaOH 1.5 *N* en solution dans du méthanol aqueux 80% pour que le pH, lu sur un pH-mètre, soit de 11.5. A l'aide d'une ampoule on ajoute, goutte à goutte, une solution de 10 ml de peroxyde d'hydrogène 30% dans 30 ml de méthanol. Pendant l'addition on maintient le pH du milieu réactionel en ajoutant au besoin quelques gouttes d'une solution de NaOH (0.2 *N*, méthanol–eau 8:2). L'addition terminée, on poursuit l'agitation et le chauffage à 40° pendant une heure en maintenant le pH constant par addition de la solution de NaOH 0.2 *N*. Puis on abandonne au réfrigérateur pendant une heure. On projette le tout sur 500 ml d'eau glacée saturée de NaCl. Le pH de l'eau est alors de 7, lu sur le pH-mètre. On extrait le produit à l'éther et on sèche le solution éthérée sur sulfate de sodium anhydre. On évapore l'éther sous vide. On reprend le résidu par du benzène qu'on évapore aussi sous vide pour éliminer les traces d'eau et de méthanol. On recueille un solide amorphe de 2.20 g, 90°–108°, après cristallisation dans l'éther de pétrole refroidi à −60°. Calculé pour $C_8H_{10}O_2$: C, 69.54; H, 7.30%. Trouvé: C, 69.29; H, 7.30%.

Le spectre infrarouge présente une bande forte à 1725 cm^{-1} (CCl_4).

6. Bicyclo[3.2.1]octanediol-2α,4β (II)

L'époxyde-cétone (336 mg) en solution dans 25 ml d'éther anhydre a été réduite par l'hydrure de lithium et d'aluminium, (2.0 g en suspension dans 50 ml d'éther anhydre), en chauffant à reflux pendant 3 heures. L'excès d'hydrure est détruit par de l'eau; on ajoute ensuite de l'eau (25 ml) et de l'acide chlorhydrique concentré (20 ml), extrait d'une manière continue par de l'éther pendant 18 heures. On recueille à la manière habituelle 333 mg de diols bruts. On chromatographie 2.1 g de ces diols bruts en les dissolvant dans 200 ml de chloroforme, sur 200 g d'alumine Woelm d'activité I. On élue par des portions de 200 ml de chloroforme. Les fractions 1 à 31 (1.328 g) représentent le diol II pur, p.f. 252–255° après 2 cristallisations dans le benzène. Calculé pour $C_8H_{14}O_2$: C, 67.57; H, 9.92%. Trouvé: C, 67.36; H, 9.88%. Di-*p*-nitrobenzoate, p.f. 161–163°. (EtOH). Calculé pour $C_{22}H_{20}O_8N_2$: C, 60.00; H, 4.58; N, 6.36%. Trouvé: C, 59.70; H, 4.61; N, 6.25%. Les fractions 31–36 de la chromatographie, éluées par du chloroforme contenant de 1 à 10% de méthanol (660 mg) représentent des diols en mélange.

L'oxydation des diols bruts par le periodate de sodium ne donne pas de composés de coupure (11).

7. Chromatographie en phase gazeuse des diéthers des diols I, II et III

Les diéthers correspondant aux diols se chromatographient bien, soit sur Tergitol, soit sur le polyester succinique de Craig.

Les diéthers des diols purs ou des mélanges de réduction ont été préparés selon la méthode (14) simplifiée. Un échantillon de 10 à 15 mg de diol(s) est dissous dans 1.5 à 2.0 ml de chloroforme. On refroidit à 0° dans un bain de glace, puis ajoute 5 à 6 ml de la solution de diazométhane dans le chlorure de méthylène. Puis on ajoute une goutte de la solution aqueuse d'acide fluoroborique 15 *N*. On continue d'ajouter de la solution de diazométhane dans le chlorure de méthylène jusqu'à coloration jaune persistante durant 30 secondes. On ajoute alors deux pastilles de KOH, du sulfate de sodium anhydre. On filtre. L'évaporation du solvant sous pression de 12 mm abandonne quelques gouttes de liquide jaune-brun, présentant une bande forte à 1097 cm^{-1} dans l'infrarouge (C—O—C) et aucune bande —OH. On chromatographie tel quel soit sur Tergitol (colonne 2.5 mètres, diamètre intérieur 6mm, 20% sur brique, 225°) soit sur polyester succinique de Craig (colonne 2.5 mètres, diamètre intérieur 6mm, 20% sur brique, 180°). Temps de rétention des diéthers issus des diols purs:

Tergitol: diéther de I et diéther de II: 20½ minutes;
diéther de II 17⅔ minutes.

Polyester succinique de Craig: diéther de I et diéther III 11 minutes;
diéther de II 9 minutes.

Les diols bruts de réduction ont donné, par cette méthode:

Réduction catalytique de la dicétone: 42% axial-équatorial;

Réduction chimique de la dicétone: 28% axial-équatorial;

Réduction de l'époxyde-cétone: 90% axial-équatorial.

Il n'est pas possible de séparer les diéthers des diols diaxial et diéquatorial par cette méthode.

For personal use only.

8. Points de fusion des mélanges des diols et des di-p-nitrobenzoates

Tous les mélanges sont 1:1.
Diol I + diol II: 246–255° (dépression)
Diol I + diol III: 245–250° (pas de dépression)
Diol II + diol III: 238–241° (pas de dépression)
Di-*p*-nitrobenzoates de I + II: 141–149° (dépression)
Di-*p*-nitrobenzoates de I + III: 156–163° (dépression)
Di-*p*-nitrobenzoates de II + III: 144–150° (dépression)

9. Spectres infrarouges des diols I, II et III

Les spectres infrarouges des diols I, II et III ont été mesurés selon la méthode (8), dans la région de 3600 cm^{-1} au moyen d'un spectromètre Perkin Elmer, modèle 112; optique LiF; longueur de la cellule: 30.9 mm. Concentration des solutions 2.6×10^{-3} *M* (CCl_4). Les résultats sont rapportés au Tableau I.

10. Spectres de résonance magnétique nucléaire des diols I, II et III

Ils ont été mesurés au moyen d'un appareil Varian A60, dans la pyridine, selon les indications (15). Le tétraméthylsilane est pris comme système de référence. Les signaux caractéristiques sont rapportés au Tableau I.

11. Oxydations chromiques des diols I, II et III

Nous avons utilisé la technique déja décrite (25). La méthode de calcul a cependant été modifiée par le professeur Richer, qui la publiera bientôt *in extenso*. Nous rapporterons ici les données expérimentales: température 25°; système de référence, *tert*-butyl-4 cyclohexanol pour lequel *K* (litre $mole^{-1}$ sec^{-1}) = 2.502×10^{-3}. Les vitesses relatives pour le cyclohexanol et les diols I, II et III sont rapportées au Tableau I, la valeur de *K* pour le *tert*-butyl-4 cyclohexanol *trans* étant prise comme unité. Le détail des mesures apparaît au Tableau II.

TABLEAU II

Oxydation chromique des diols I, II et III

Diols	Essais	Concentrations molaires en CrO_3	Concentrations molaires des diols	*K*, litre $mole^{-1}sec^{-1}$	*K* Moyenne
I	1	4.076×10^{-4}	2.883×10^{-3}	296×10^{-3}	293×10^{-3}
	2	4.021×10^{-4}	3.007×10^{-3}	290×10^{-3}	
II	1	3.962×10^{-4}	2.937×10^{-3}	136×10^{-3}	
	2	3.855×10^{-4}	2.903×10^{-3}	133×10^{-3}	138×10^{-3}
	3	4.217×10^{-4}	2.889×10^{-3}	144×10^{-3}	
III	1	3.715×10^{-4}	2.920×10^{-3}	66×10^{-3}	67×10^{-3}
	2	3.654×10^{-4}	3.165×10^{-3}	68×10^{-3}	

REMERCIEMENTS

Nous remercions le Conseil National de Recherches du Canada pour une subvention de recherches (H. F.) et une bourse d'études (J. G. D.). Nous remercions également M. le professeur J. C. Richer et M. Cl. Gilardeau de l'aide apportée dans les mesures des vitesses d'oxydation chromique.

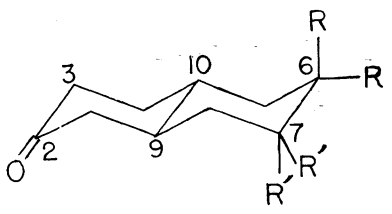
LES ACÉTATES ÉNOLIQUES DES DIMÉTHYL-6,6 ET DIMÉTHYL-7,7 DÉCALONES-2 CIS ET TRANS

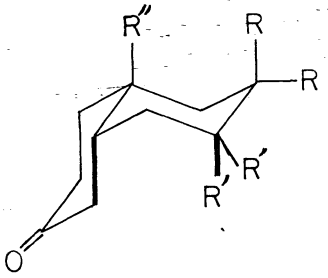
H. Favre et A. J. Liston
Département de chimie, Université de Montréal, Montréal, Qué.
Reçu le 22 juillet 1963

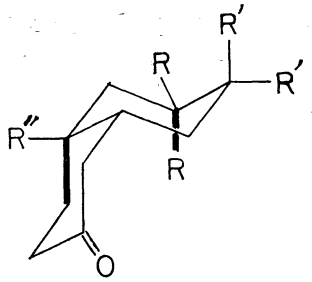
RÉSUMÉ

Les quatre décalones mentionnées dans le titre conduisent chacune à deux acétates énoliques lorsqu'on les traite par l'acétate d'isopropényle et l'acide sulfurique concentré. Ces derniers ont été dosés et leurs structures déterminées. Des quatre décalones, seules les décalones cis donnent des acétates énoliques lorsque l'agent d'acétylation est un mélange d'anhydride acétique et d'acide perchlorique. La condensation des quatre décalones avec l'oxalate d'éthyle est également rapportée.

Nos études sur la stéréochimie des terpènes et des stéroides nous ont amenés à étudier le comportement chimique des décalones-2 cis et trans* pour préciser les facteurs stériques qui contrôlent l'énolisation et déterminer la façon dont un squelette alicyclique se modifie et se déforme sous les contraintes exercées par la présence d'une double liaison sur le cycle. Ce mémoire traite des acétates énoliques des diméthyl-6,6 et diméthyl-7,7 décalones-2 trans (I et II) et cis (III et IV) (1). Comme la triméthyl-7,7,10 décalone-2 cis (V) de Halsall et Thomas (2), que l'on doit tenir pour *nst* puisque la conformation *st* présente une interaction défavorable entre le groupe méthyle axial et l'embranchement décalinique; alors, la diméthyl-7,7 décalone-2 *cis* pour ces mêmes raisons doit être *nst*. Au contraire, la diméthyl-6,6 décalone-2 *cis* (III), doit être *st*, puisque c'est la conformation *nst* qui présente l'interaction défavorable entre le groupe méthyle axial et l'embranchement décalinique.†







I R = —CH_3; R′ = —H
II R = H; R′ = —CH_3

III*st* R = —CH_3; R′ = R″ = —H
IV*st* R′ = —CH_3; R = R″ = —H
V*st* R″ = R′ = —CH_3; R = H
VI*st* R″ = —CH_3; R = R′ = —H
VII*st* R = R′ = R″ = —H

III*nst*
IV*nst*
V*nst*
VI*nst*
VII*nst*

**Dans ce mémoire le numérotage des décalones est indiqué à la formule I; celui des stéroïdes sera le numérotage officiel.*

†Le travail de Djerassi et de ses collaborateurs (3), qui permet de tirer la conclusion que la méthyl-10 décalone-2 cis (VI) est st, jette quelque doute sur la validité de l'argument thermodynamique (4) pour déterminer la conformation st–nst d'une décalone-2 cis. Jusqu'à preuve du contraire, nous considérerons que la diméthyl-6,6 décalone-2 cis est st, ou tout au moins un mélange des conformations st et nst dans lequel prédomine la conformation st; de même la diméthyl-7,7 décalone-2 cis sera nst, ou tout au moins un mélange st–nst dans lequel prédomine la conformation nst.

Préparation des acétates énoliques

En traitant les décalones trans I et II et cis III*st* et IV*nst* par l'acétate d'isopropényle en présence d'acide sulfurique concentré (5) nous avons obtenu dans chaque cas un mélange des deux acétates énoliques Δ^1 et Δ^2 correspondant à la double énolisation de la décalone, que nous avons dosés par chromatographie en phase gazeuse (Tableau I). La conversion

TABLEAU I

Pourcentages respectifs d'acétates énoliques obtenus à partir des décalones I, II, III*st*, et IV*nst*

Décalones de départ	Rapports des acétates énoliques formés Δ^1, Δ^2, et pourcentages de décalones de départ qui les accompagnent (C=O)								
	Méthode 1			Méthode 2			Méthode 3		
	Δ^1	Δ^2	C=O	Δ^1	Δ^2	C=O	Δ^1	Δ^2	C=O
I	36.7	63.2	0	0	0	100	0	0	100
II	33.8	66.2	0	0	0	100	0	0	100
III*st*	56.6	43.4	0	60.0	40.0	8	60.0	40.0	8
IV*nst*	59.0	41.0	0	74.0	26.0	6	74.0	26.0	6

Méthode 1: acétate d'isopropényle + acide sulfurique.
Méthode 2: anhydride acétique + acide perchlorique (24 heures, 25°).
Méthode 3: anhydride acétique + acide perchlorique sur les mélanges obtenus par la méthode 1 (36 heures, 25°).

en acétates énoliques est complète, comme l'indiquent l'infrarouge et la c.p.g. (chromatographies en phase gazeuse). Dans un cas, celui de la diméthyl-7,7 décalone-2 cis (IV*nst*) nous avons montré qu'il s'agissait bien des deux acétates énoliques correspondant à la décalone, en séparant le mélange par c.p.g. et en convertissant chaque acétate énolique en décalone de départ par l'hydroxyde de potassium méthanolique.

En traitant durant 24 heures les décalones cis III*st* et IV*nst* par l'anhydride acétique, en présence d'acide perchlorique aqueux, dans un mélange de tétrachlorure de carbone et de benzène (6, 7), nous avons obtenu dans les deux cas les acétates énoliques correspondants, que nous avons dosés par c.p.g., après avoir déterminé par infrarouge la teneur en décalone de départ qui se trouve présente dans les mélanges (Tableau I). Les décalones trans I et II ne donnent pas du tout les acétates énoliques attendus. L'un de nous ayant montré (8) que cette méthode donnait des acétates énoliques en équilibre, contrairement à la première méthode à l'acétate d'isopropényle qui est régie par un contrôle cinétique, nous avons soumis chacun des mélanges obtenus par contrôle cinétique aux conditions isomérisantes de la deuxième méthode, avec les résultats suivants pour un contact de 36 heures: dans la série trans, les mélanges d'acétates énoliques sont entièrement convertis en décalones; dans la série cis, les mélanges se mettent à l'équilibre et sont finalement semblables à ceux que l'on prépare directement à partir des décalones (voir Tableau I).

Preuves des structures des acétates énoliques

Il existe une preuve de structure absolue, illustrée par le Schéma 1, valable pour la série trans et pour la série cis, chacune prise séparément, fondée sur le principe suivant. La décalone trans I donne naissance à deux acétates énoliques VIII et IX trans, qui à leur tour engendrent deux composés de coupure XII et XIII trans. La décalone trans II, à son tour, engendre les acétates X et XI trans et les composés de coupure XIII et XIV trans en mélange. Les deux mélanges de composés de coupure, à partir de I et de II, contiennent donc un composé commun, qui ne peut être que XIII trans. Reconnaître et doser ce dernier dans les mélanges des composés de coupure permet donc sans ambiguité

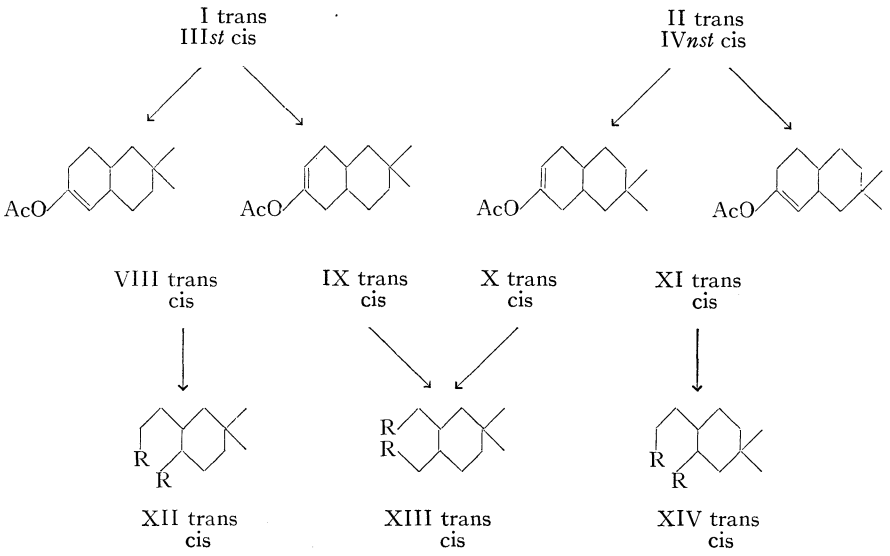


SCHÉMA 1. Preuves de structure des acétates énoliques issus des décalones I, II, III, et IV.

de déterminer les structures des acétates énoliques et finalement de doser ces derniers, si les proportions des composés de coupure reflètent celles des acétates énoliques. Le même raisonnement se fera dans la série cis, au départ des décalones *III*st et IV*nst*.

La c.p.g. semblait prometteuse pour résoudre facilement ce problème, puisque les mélanges binaires XII et XIII trans (et cis) et XIII et XIV trans (et cis) devaient donner un mélange ternaire dans lequel le composé commun XIII devait être facilement repérable à partir des temps de rétention des composés des mélanges binaires. Mise en œuvre cette méthode n'a pas donné des résultats définitifs. Nous avons d'abord choisi le type de composé de coupure le plus adapté à une analyse par c.p.g.: notre choix s'est arrêté sur les diéthers méthyliques XII, XIII, et XIV trans (et cis) (R = —CH_2OCH_3). On obtient aisément, et avec de bons rendements ces diéthers en ozonant les acétates énoliques, en réduisant les ozonides par l'hydrure de lithium et d'aluminium en diols XII, XIII, XIV trans (et cis) (R = —CH_2OH) et en éthérifiant ces derniers par la méthode de Williamson. Les mélanges binaires XII–XIII et XIII–XIV des diéthers des séries trans et cis montrent bien, en c.p.g., les deux pics attendus, suffisamment espacés pour permettre un dosage dans chaque cas (les résultats sont rapportés au Tableau II pour les diéthers issus des acétates énoliques en mélange préparés selon la méthode à l'acétate d'isopropényle).

TABLEAU II

Dosages des diéthers XII, XIII, et XIV issus des mélanges d'acétates énoliques résultant de l'action de l'acétate d'isopropényle sur les décalones I, II, III*st*, et IV*nst*

Acétates énoliques	Diéthers obtenus		
Δ^1 et Δ^2	XII	XIII	XIV (R = —CH_2OCH_3)
VIII et IX trans	30%	70%	
X et XI trans		72%	28%
VIII et IX cis	63.5%	36.5%	
X et XI cis		44%	56%

Les mélanges ternaires sont flous et mal définis en c.p.g., dans la série trans et dans la série cis: dans la série trans, nous pouvons en déduire que c'est le composé commun XIII trans qui prédomine dans chaque mélange binaire, d'où la conclusion que les acétates Δ^2 se forment en prépondérance à partir des décalones I et II; dans les mélanges binaires de la série cis, au contraire, le composé commun XIII cis est minoritaire, ce qui fait que les décalones III*st* et IV*nst* engendrent plus d'acétate Δ^1 que d'acétate Δ^2. Ces résultats cependant demandaient à être vérifiés d'une autre manière.

Dans la série trans, Schéma 2, en traitant les décalones I et II, sous forme de sel sodé, par

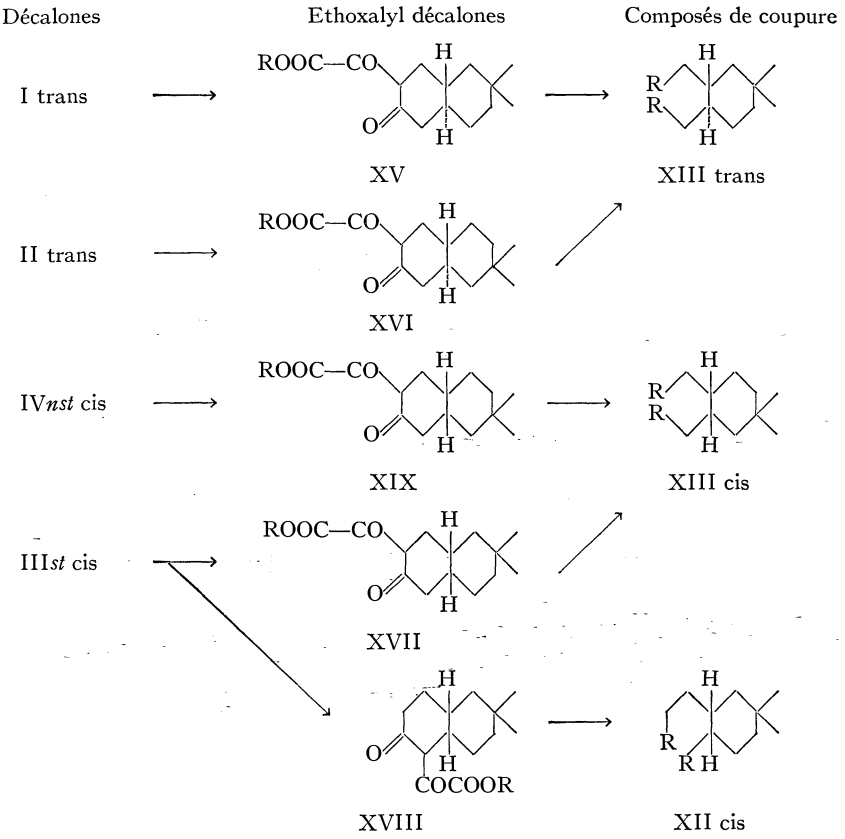

SCHÉMA 2. Ethoxalylation des décalones I, II, III, et IV et preuves de structure.

l'oxalate d'éthyle, puis en oxydant le composé de condensation par le permanganate de potassium, nous n'avons obtenu qu'un seul et même diacide de coupure, p.f. 154.5°, qui ne peut être que le diacide XIII trans (R = —COOH). Ce diacide a été estérifié par le diazométhane, le diester réduit par l'hydrure de lithium et d'aluminium en diol, le diol éthérifié par la méthode de Williamson en diéther XIII trans (R = —CH_2OCH_3). Par la méthode du rehaussement des pics en c.p.g. nous avons pu montrer que les mélanges binaires des diéthers XII–XIII et XIII–XIV trans contiennent bien en majorité le composé XIII trans, corroborant ainsi nos conclusions antérieures.

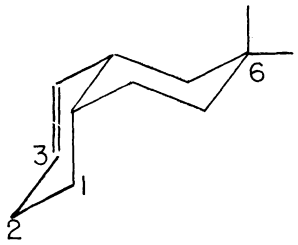
Dans la série cis, Schéma 2, nous avons procédé comme dans la série trans, soit éthoxalylation et oxydation permanganique. La diméthyl-7,7 décalone-2 cis (IV*nst*) conduit à

un acide bien cristallisé, p.f. 151.5°, que nous avons réduit en diol, puis éthérifié en diéther (XIII cis, R = —CH_2OCH_3). La diméthyl-6,6 décalone-2 cis (III*st*) conduit par les mêmes étapes, à un mélange de deux diéthers, nécessairement XII et XIII cis (R = —CH_2OCH_3). La c.p.g. montre que le diéther issu de la diméthyl-7,7 décalone-2 cis correspond, par superposition parfaite des pics, au diéther minoritaire issu de la diméthyl-6,6 décalone-2 cis, ce diéther doit donc être le diéther commun XIII cis, ce qui fait du diacide p.f. 151.5° le diacide XIII cis (R = —COOH). Par la méthode du rehaussement des pics, en c.p.g., il est facile de montrer que le diéther XIII cis est le diéther minoritaire dans les mélanges binaires XII–XIII cis et XIII–XIV cis issus des acétates énoliques en mélanges, d'où la conclusion que les acétates énoliques qui se forment en prépondérance, par la méthode à l'acétate d'isopropényle et par la méthode à l'anhydride acétique – acide perchlorique, sont bien, comme établi plus haut, VIII cis à partir de la décalone III*st* et XI cis à partir de la décalone IV*nst*.

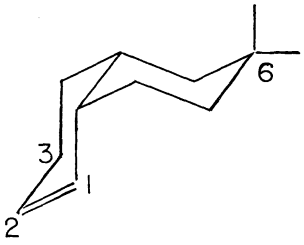
Nous pouvons également tirer les conclusions suivantes: le groupe -COCOOR se fixe, dans les condensations avec l'oxalate d'éthyle, en position 3 des décalones trans I et II, pour donner XV et XVI respectivement (cf. Schéma 2), et de la décalone cis IV*nst* pour donner XIX. On obtient un mélange des deux composés de condensation XVII et XVIII à partir de la décalone cis III*st*, dans lequel l'isomère de substitution en position 1 (XVIII) prédomine (cf. Schéma 2).

DISCUSSION

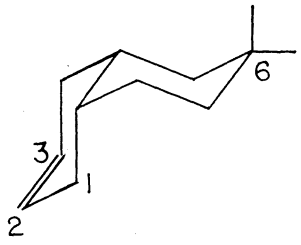
Nos travaux mettent d'abord en évidence le parallélisme chimique évident dans la formation des acétates énoliques des décalones trans I et II et de la nor-19 androstanol-17β one-3 (9) par la méthode à l'acétate d'isopropényle, puisque dans chaque cas les deux acétates énoliques se forment, dans un rapport voisin de 2–1 avec prépondérance de double liaison éloignée des carbones de jonction. Ce parallélisme chimique doit être la conséquence directe de la superposabilité des décalones I et II et des anneaux A et B du stéroide en question et de la rigidité conformationnelle de ces anneaux condensés. Pour ce qui est de la série cis nos travaux indiquent qu'il n'y a que très peu de différence d'énergie entre les acétates Δ^1 et Δ^2 étudiés, et finalement entre les Δ^1, Δ^2, et Δ^3-octalines diméthylées en 6,6, dont l'ordre de stabilité serait $\Delta^3 > \Delta^1 > \Delta^2$ (XX > XXI > XXII) en première approximation, en négligeant le groupe —$OCOCH_3$.



XX



XXI



XXII

On sait que l'étude des ènes-pyrrolidines correspondant à la décalone-2 cis (VII) avait conduit Stork et ses collaborateurs (10) à signaler le peu de différence d'énergie entre les octalines Δ^1 et Δ^2. Il est aussi frappant de constater que la décalone III*st* ne donne pas plus d'acétate énolique Δ^1, comme les conclusions de Dreiding (11) le faisaient prévoir. Pour cet auteur, la différence très significative de comportement chimique, bromation

(12, 13, 14, 15), alkylation (16), et énolisation (5) entre la cholestanone et la coprostanone est due au fait que chez cette dernière l'introduction de la double liaison en position 3, 4 amène une décompression stérique notoire. Il faut toutefois tenir compte ici que nous ne pouvons comparer à priori la décalone III*st* et la coprostanone, et à plus forte raison la décalone IV*nst* et la coprostanone, car la présence du groupe méthyle en 10 doit certainement jouer un rôle à l'image de la série trans (6). Certainement d'autres expériences s'imposent pour comprendre l'influence du groupe méthyle angulaire et pour établir la distinction entre le comportement d'une décalone-2 cis *st* et *nst*: il est possible en effet que dans les décalones cis III*st* et IV*nst* le groupe méthyle axial ne soit pas suffisant pour assurer la stabilité conformationnelle *st* et *nst*.

Nos expériences infirment également, à notre avis, l'explication de Stork et Hill (17), qui, pour rendre compte de l'introduction du groupe —COCOOR dans la décalone-2 cis en position 3 seulement, ont avancé que l'état de transition étant volumineux dans une réaction de type Claisen, la réaction n'allait pas se faire du côté de l'embranchement décalinique (position 1) pour des raisons d'encombrement stérique. La réaction préférentielle de la décalone III*st* en position 1 et celle de la décalone IV*nst* en position 3 réfutent l'encombrement stérique comme facteur déterminant et font de la décalone-2 cis une décalone qui réagit dans sa conformation *nst*. Nos résultats sont encore trop fragmentaires pour pousser plus loin l'analyse dans ce domaine. Dans la série trans, les décalones I et II réagissent comme la décalone-2 trans (VII) elle-même, soit en position 3 (18).

Il est intéressant en revanche de souligner les différences marquées qui existent dans les mises en équilibre des acétates énoliques dans les séries cis et trans décaliniques, quand on n'a pas de méthyle angulaire. Si l'on considère l'équilibre décalone $\rightleftarrows$ acétates énoliques et le caractère semicyclique de la liaison C=O et cyclique de la liaison C=C, nous voyons qu'une décalone-2 cis s'accomodera mieux d'une double liaison cyclique qu'une décalone-2 trans: cette constatation prend son importance lorsqu'on considère le choix d'un réactif d'acétylation énolique.

PARTIE EXPÉRIMENTALE

Les p.f. ont été déterminés en tubes capillaires, au moyen d'un thermomètre étalonné avec des substances pures de p.f. connus. Les analyses sont de C. Daesslé, Organic Microanalyses, Montréal. Les c.p.g. ont été réalisées au moyen d'un appareil Kromo-Tog K-2 de Burrell Corporation. Les spectres infrarouges ont été mesurés sur un appareil Perkin–Elmer, modèle 21, prisme NaCl.

1. Acétates énoliques VIII, IX, X, et XI cis et trans

1.1. Méthode à l'acétate d'isopropényle

1.11. Méthode générale.—À 1.8 g de décalone on ajoute 8.0 ml d'acétate d'isopropényle et 0.02 ml d'acide sulfurique concentré. On chauffe à reflux, en atmosphère d'azote, pendant 1 heure, puis distille 3 ml de la solution en une demi-heure. On refroidit à 0°, reprend par 100 ml d'éther, lave la solution éthérée à 0° avec une solution aqueuse d'hydroxyde de sodium 0.5 *M* et avec de l'eau jusqu'à neutralité. On sèche sur sulfate de sodium anhydre, distille l'éther puis le résidu. Les acétates énoliques sont dosés en c.p.g. dans les conditions suivantes: colonne 2.5 mètres, température 195°, éluant hélium 60 ml par minute, 20% de polyester succinique de Craig sur brique.

1.12.—A partir de la diméthyl-6,6 décalone-2 cis 72% du mélange des deux acétates énoliques, Δ^1 (VIII cis) et Δ^2 (IX cis), p.éb. 98° sous 1 mm, $n_D^{27} = 1.4823$, spectre infrarouge: bandes à 1762 et 1690 cm^{-1}. Calculé pour $C_{14}H_{22}O_2$: C, 75.63; H, 9.96%. Trouvé: C, 75.42; H, 9.93%. En c.p.g.; il apparaît d'abord 43.4% d'acétate Δ^2 (IX cis) et ensuite 56.6% d'acétate Δ^1 (VIII cis), temps de rétention: (IX cis) 53.2 minutes, (VIII cis) 66.4 minutes.

1.13.—A partir de la diméthyl-7,7 décalone-2 cis, 94% du mélange des deux acétates énoliques Δ^1 (XI cis) et Δ^2 (X cis), p.éb. 106° sous 0.9–1.1 mm, $n_D^{22} = 1.4830$, spectre infrarouge, bandes à 1755 et 1692 cm^{-1}. Calculé pour $C_{14}H_{22}O_2$: C, 75.63; H, 9.96%. Trouvé: C, 75.56; H, 9.71%. En c.p.g. il apparaît d'abord 59.0% d'acétate Δ^1 (XI cis), puis 41.0% d'acétate Δ^2 (X cis), temps de rétention: (XI cis) 36.5 minutes, (X cis) 40 minutes. La cétone de départ a été regénérée des acétates énoliques de la façon suivante: 100 mg du mélange est dissout dans 20 ml de 2% d'hydroxide de potassium méthanolique, après 5 minutes on évapore

le solvent sous vide et on ajoute 30 ml d'éther et d'eau. La solution éthérée est lavée jusqu'à neutralité. On identifie la cétone par c.p.g. tel que décrit en 1.11 et par infrarouge, bande à 1715 cm^{-1}.

1.14.—La diméthyl-6,6 décalone-2 trans conduit à 89% du mélange des acétates énoliques Δ^1 et Δ^2, p.éb. 81.5° sous 0.48 mm, $n_D^{22} = 1.4758$; spectre infrarouge, bandes à 1752 et 1687 cm^{-1}. Calculé pour $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%. Trouvé: C, 75.93; H, 9.74%. En c.p.g. il apparaît d'abord 63.2% d'acétate Δ^2 (IX trans) et ensuite 36.7% d'acétate Δ^1 (VIII trans), temps de rétention (IX trans) 42.2 minutes, (VIII trans) 49.2 minutes.

1.15.—La diméthyl-7,7 décalone-2 trans conduit à 89.2% du mélange des acétates énoliques Δ^1 et Δ^2, p.éb. 106° sous 1.2 mm, $n_D^{24} = 1.4903$; spectre infrarouge, bandes à 1763 et 1693 cm^{-1}. Calculé pour $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%. Trouvé: C, 75.41; H, 10.24%. En c.p.g. il apparaît d'abord 33.8% d'acétate Δ^1 (XI trans) et ensuite 66.2% d'acétate Δ^2 (X trans): temps de rétention (XI trans) 56.2 minutes, (X trans) 62.0 minutes.

1.2. Méthode à l'anhydride acétique et acide perchlorique

Méthode générale.—On dissout 100 mg de décalone dans 16 ml de benzène anhydre et 6 ml de tétrachlorure de carbone anhydre; on y ajoute 1.2 ml d'anhydride acétique fraîchment distillé et 2 gouttes d'acide perchlorique – eau 75–25. On agite la solution pendant 24 heures à température de 25°. On ajoute alors 10 ml de tétrachlorure de carbone et 30.0 g de glace; on lave avec une solution aqueuse de bicarbonate de sodium 15%, puis avec une solution saturée de chlorure de sodium jusqu'à neutralité. On sèche sur sulfate de sodium anhydre et distille les solvents sous vide. Le résidu est analysé tel quel. Dans le série trans l'infrarouge n'indique pas d'acétates énoliques et la c.p.g. comme en 1.11 ne montre que la présence des décalones de départ. Dans la série cis, l'infrarouge montre la présence d'acétates énoliques (bandes à 1753 cm^{-1} et 1690 cm^{-1}) et de la décalone de départ (1715 cm^{-1}); le pourcentage de décalone est déterminé ainsi par l'infrarouge à partir de mélanges de proportions connues décalones – acétates énoliques; les résultats sont rapportés au Tableau I. Puis les acétates énoliques sont dosés par c.p.g. comme en 1.11, en faisant la correction pour la décalone présente dont le pic coincide avec celui d'un des acétates énoliques; les résultats sont rapportés au Tableau I.

1.3. Mise en équilibre des acétates énoliques

Méthode générale.—On dissout 100 mg des mélanges d'acétates énoliques préparés en 1.12, 1.13, 1.14, et 1.15 dans 16 ml de benzène et 6 ml de tétrachlorure de carbone anhydre; on y ajoute 1.2 ml d'anhydride acétique fraîchement distillé et 2 gouttes d'acide perchlorique – eau 75–25. On agite la solution pendant 36 heures à 25°. On isole les composés d'isomérisation comme en 1.2. Les résultats sont rapportés au Tableau I. Si l'on n'agite que 24 heures, dans la série trans, 85% environ des acétates énoliques sont déjà transformés en décalones. Au bout de 36 heures, l'isomérisation est totale.

2.1. Acide diméthyl-4,4 cyclohexane diacétique-1,2 cis (XIII cis, R = —COOH)

Selon la méthode de Cook et Lawrence (19), 5 g de diméthyl-7,7 décalone-2 cis (IV) et 5 g d'oxalate d'éthyle en mélange sont refroidis à −15°; on ajoute 16 ml d'éthanol anhydre dans lesquels on a fait réagir 0.8 g de sodium. Le tout est maintenu à −10° pendant 20 heures, puis traité par 20 ml d'acide sulfurique 3 *N*. On extrait à l'éther et obtient à la manière habituelle 5.8 g d'une huile jaune (diméthyl-7,7 éthoxalyl-3 décalone-2 cis brut) qui ne se cristallise pas et que l'on soumet immédiatement à l'oxydation permanganique.

L'oxalate brut (2.5 g) est mis en suspension dans 50 ml d'eau, à laquelle on ajoute une quantité suffisante de NaOH aqueux 10% pour obtenir un pH de 12. On ajoute ensuite une solution saturée de permanganate de potassium tant qu'il y a décoloration. Le tout est agité vivement et maintenu à 60° pendant 45 minutes. La solution à 60° est acidifiée par addition lente d'acide chlorhydrique concentré; le chauffage est maintenu jusqu'à ce que le dégagement de CO_2 cesse. On ajoute pendant la décarboxylation de la solution concentrée de permanganate de potassium de façon à garder la couleur pourpre. Après la décarboxylation on refroidit, détruit l'excès de permanganate de potassium et le bioxyde de manganèse par addition d'une solution saturée de $NaHSO_3$ et extrait la solution qu'on maintient à pH 2 par addition d'HCl, par trois portions d'éther, que l'on réunit, lave avec une solution saturée de NaCl, sèche sur sulfate de sodium anhydre; la distillation de l'éther abandonne un résidu huileux, de diacide diméthyl-4,4 cyclohexane diacétique-1,2 cis, p.f. 151.5° après ramollissement à 124°. Calculé pour $C_{12}H_{20}O_4$: C, 63.15; H, 8.77%. Trouvé: C, 63.14; H, 8.81%.

2.2. Acide diméthyl-4,4 cyclohexane diacétique-1,2 trans (XIII trans, R = —COOH)

2.21. A partir de la diméthyl-7,7 décalone-2 trans (II).—En suivant fidèlement le mode opératoire décrit en 2.1, 2.5 g de diméthyl-7,7 décalone-2 trans sont condensés avec l'oxalate d'éthyle, et l'ester dicétonique obtenu oxydé par le permanganate de potassium. On obtient 1.8 g (88%) de diacide brut, qui après recristallisation dans le mélange chloroforme – éther de pétrole fond à 154.5°. Calculé pour $C_{12}H_{20}O_4$: C, 63.15; H, 8.77. Trouvé: C, 63.34; H, 8.68%.

2.22. A partir de la diméthyl-6,6 décalone trans (I).—On obtient l'acide XIII trans décrit plus haut en 2.21, p.f. 154.5°, avec un rendement de 69% à partir de la décalone.

2.3. Diméthyl-4,4 bis-(hydroxy-2 éthyl)-1,2 cyclohexane cis (XIII cis, R = —CH_2OH)

On dissout 1.75 g du diacide XIII cis, p.f. 151.5°, obtenu en 2.1, dans 25 ml d'éther on ajoute une solution éthérée de diazométhane préparée selon (20), jusqu'à coloration jaune persistante et distille l'éther. Le

résidu (ester méthylique) est repris par 50 ml d'éther anhydre et ajouté goutte à goutte à une suspension de 2.5 g de lithium et d'aluminium dans 200 ml d'éther. On chauffe à reflux pendant 45 minutes, détruit l'excès d'hydrure par de l'eau, ajoute de l'acide chlorhydrique 3 *N*. Par extraction continue durant 6 heures par l'éther on épuise la phase aqueuse; on évapore l'éther et distille le résidu. On obtient le diméthyl-4,4 bis-(hydroxy-2 éthyl)-1,2 cyclohexane cis huile incolore, visqueuse, 1.2 g (76%), p.éb. 162° sous 0.9 mm. Calculé pour $C_{12}H_{24}O_2$: C, 71.96; H, 12.69%. Trouvé: C, 72.32; H, 12.45%.

2.4. Diméthyl-4,4 bis-(hydroxy-2 éthyl)-1,2 cyclohexane trans (XIII trans, R = —CH_2OH)

En suivant le mode opératoire décrit en 2.3, 1.2 g de diacide trans obtenu en 2.21 conduisent à 0.74 g (70%) de diol liquide, p.éb. 165° sous 0.8 mm. Calculé pour $C_{12}H_{24}O_2$: C, 71.98; H, 12.69%. Trouvé: C, 72.01; H, 12.38%.

2.5. Diméthyl-4,4 bis-(méthoxy-2 éthyl)-1,2 cyclohexane cis (XIII cis, R = —CH_2OCH_3)

On dissout 1.2 g du diol préparé en 2.3 dans 50 ml de toluène anhydre et ajoute 1.5 g de sodium métallique. On chauffe à reflux durant 4 heures et élimine l'excès de sodium après refroidissement. On ajoute alors 3.0 g d'iodure de méthyle et, en agitant, chauffe à reflux pendant 8 heures. On lave avec de l'eau pour enlever l'iodure de sodium, sèche la solution toluénique sur sulfate de sodium anhydre. On distille le toluène, puis sous 0.3 mm, le diéther qui passe à 82.5°, $n_D^{26} = 1.4562$, bande caractéristique R—O—R à 1117 cm^{-1} dans le spectre infrarouge. Calculé pour $C_{14}H_{28}O_2$: C, 73.68; H, 12.28%. Trouvé: C, 73.32; H, 12.26%.

2.6. Diméthyl-4,4 bis-(méthoxy-2 éthyl)-1,2 cyclohexane trans (XIII trans, R = —CH_2OCH_3)

En suivant le mode opératoire décrit en 2.5, 0.8 g de diol trans obtenu en 2.4 conduit à 0.69 g (76%) de diéther liquide, $n_D^{24.5} = 1.4566$, p.éb. 82.5° sous 0.3 mm; bande dans l'infrarouge à 1117 cm^{-1}. Calculé pour $C_{14}H_{28}O_2$: C, 73.68; H, 12.28%. Trouvé: C, 73.49; H, 12.14%.

2.7. Condensation de la décalone IIIst avec l'oxalate d'éthyle

On condense la décalone III*st* avec l'oxalate d'éthyle comme décrit plus haut en 2.1. On oxyde le mélange de condensation par le permanganate de potassium comme décrit plus haut en 2.1. On transforme les diacides en diesters méthyliques, puis en diols comme décrit plus haut en 2.3. On prépare les diéthers méthyliques comme décrit plus haut en 2.5. Les diéthers sont dosés en c.p.g. comme décrit plus loin en 3.0, avec les résultats suivants: diéther cis XIII 20%, diéther cis XIV 80%.

3.0. Ozonolyse des acétates énoliques et obtention des diéthers XII, XIII, et XIV cis et trans (R = —CH_2OCH_3)

On ozonolyse les mélanges des acétates énoliques (préparés en 1.12, 1.13, 1.14, et 1.15) en dissolvant 1.0 g de mélange dans 150 ml d'éther de pétrole (p.éb. 38–40°) et en faisant passer un courant d'oxygène chargé de 1.8% d'ozone dans la solution plongée dans un bain de CO_2–acétone jusqu'à coloration bleue persistante. On évapore ensuite l'éther de pétrole en faisant passer un courant d'azote dans l'appareil. Le résidu huileux est séché sous vide.

Les ozonides bruts sont dissous dans 100 ml d'éther anhydre; cette solution est ajoutée goutte à goutte à une suspension de 2.0 g d'hydrure de lithium et d'aluminium dans 200 ml d'éther anhydre. On chauffe à reflux durant 45 minutes, détruit l'excès d'hydrure par de l'eau, ajoute de l'acide chlorhydrique concentré jusqu'à disparition de tout précipité et extrait d'une manière continue à l'éther. En évaporant la solution éthérée on recueille le mélange de diols que l'on sèche sur P_2O_5 jusqu'à poids constant (rendement de 70–90%).

Pour la méthylation on procède selon les indications données en 2.5, plus haut. Les mélanges bruts cis sont chromatographiés (c.p.g.): colonne 2.5 mètres, 195°, 20% de polyester succinique de Craig sur brique, hélium 60 ml par minute. Les mélanges bruts trans sont chromatographiés sur une colonne de 1.5 mètre, 20% de Tergitol sur brique, 212°, hélium 50 ml par minute. Dans ces conditions les diéthers ont les temps de rétention suivants:

XIII trans pur (préparé en 2.5): 10 minutes, fluctue de 9 à 11 minutes, selon l'usure de la colonne.
XIII cis pur (préparé en 2.5): 15.8 et 19.2 minutes selon l'usure de la colonne.
XII et XIII trans: 9.1 et 10.0 minutes; XIII et XIV trans: 9.5 et 13.5 minutes.
XII et XIII cis: 21.8 et 19.2 minutes.
XIII et XIV cis: 15.8 et 16.9 minutes.

Les résultats sont rapportés au Tableau II. Les diéthers XIII cis et trans purs, préparés plus haut en 2.6 et 2.5, ont servi à l'analyse qualitative (méthode du rehaussement des pics) des mélanges binaires.

REMERCIEMENTS

Nous remercions le Conseil National de Recherches du Canada d'une subvention de recherches (H. F.).

ÉTUDE INFRAROUGE DES ACIDES FLUO- ET CHLORO-SULFURIQUES

RODRIGUE SAVOIE[1] ET PAUL A. GIGUÈRE
Département de Chimie, Université Laval, Québec, Qué.

Reçu le 13 août 1963

RÉSUMÉ

Les spectres d'absorption infrarouge entre 4000 et 150 cm^{-1} des acides fluosulfurique HSO_3F et chlorosulfurique HSO_3Cl à l'état solide, liquide, et gazeux montrent les douze vibrations fondamentales de ces molécules. De plus, ils révèlent l'existence de fortes liaisons hydrogène (quelque 6 kcal) qui conduisent à la formation de dimères cycliques, même dans la vapeur. Contrairement aux prévisions l'acide chlorosulfurique est plus fortement dimérisé que l'acide fluosulfurique. La rotation du groupe OH dans les molécules libres est empêchée par un seuil de potentiel à triple maximum d'environ 1.3 kcal. Le calcul des fonctions d'état à partir des présents résultats donne 71.4 cal deg^{-1} $mole^{-1}$ pour l'entropie standard de HSO_3F à 25° C, et 74.9 pour HSO_3Cl.

Les acides halosulfuriques sont beaucoup plus volatils que l'acide sulfurique parce que dans ce dernier les liaisons hydrogène (aussi de 6 kcal) relient toutes les molécules en un réseau à trois dimensions.

Le spectre moléculaire de l'acide fluosulfurique liquide a été étudié récemment par Gillespie et Robinson (1). Ces auteurs ont également repris le spectre Raman de l'acide chlorosulfurique qui avait fait l'objet de travaux antérieurs (2–4). Comme il n'existait pas de données sur les spectres de vibration de ces deux molécules à l'état libre, nous avons entrepis de mesurer leur absorption en infrarouge, aussi bien dans la vapeur que dans les phases condensées, et sur un intervalle de fréquence assez étendu pour observer toutes les fondamentales. Outre leur intérêt pour le calcul des fonctions d'état de ces molécules et d'autres analogues, en particulier H_2SO_4 (5), ces recherches ont fourni des précisions intéressantes et parfois inattendues sur la structure et l'association moléculaire par l'intermédiaire de liaisons hydrogène.

PARTIE EXPÉRIMENTALE

Pour l'acide fluosulfurique on a utilisé directement le produit commercial ("Technical Grade", Allied Chemical Co.). Le spectre montrait quelques faibles bandes dues à des impuretés ou à des produits de dissociation. En effet, cet acide tend à se dissocier suivant la réaction

$$HSO_3F = HF + SO_3,$$

et à s'hydrolyser

$$HSO_3F + H_2O = HF + H_2SO_4.$$

L'acide fluorhydrique ainsi formé peut ensuite attaquer le verre pour donner le composé volatil SiF_4 décelable en infrarouge par une forte bande à 1030 cm^{-1} (6). L'acide chlorosulfurique, un produit de la "British Drug Houses, Ltd.", titrant 99.5% au minimum, a été employé tel quel. Dans le spectre du liquide et du solide les bandes les plus fortes de H_2SO_4 provenant de l'hydrolyse étaient visibles. Dans la vapeur, par contre, on pouvait observer des concentrations appréciables, surtout à 60° C, de HCl grâce à la bande de vibration–rotation à 2886 cm^{-1} (7) ou encore aux bandes de rotation pure dans l'infrarouge lointain (8). L'autre produit de dissociation, SO_3, apparaissait dans le spectre d'absorption sous forme d'épaulement vers 525 cm^{-1} (9).

Les cellules d'absorption et les spectrophotomètres étaient les mêmes que précédemment (10), sauf pour l'étude des vapeurs dans l'infrarouge lointain (au-delà de 450 cm^{-1}) où il a fallu construire une cellule à double parcours pour augmenter l'absorption sans trop élever la température, et partant la dissociation. Cette cellule (Fig. 1) comprend deux miroirs concaves (*A* et *B*), diam. 9 cm, distance focale 20 cm, montés en opposition dans le tube d'absorption en Pyrex (*C*) au moyen d'une sorte de cage en tiges de Pyrex (*D*). Le petit miroir plan (*E*), de 14×18 mm, au centre de la cellule est aluminisé sur ses deux faces. A sa partie supérieure il se prolonge en une mince tige qui permet de le fixer à frottement (avec un manchon de Teflon) dans un petit tube de Pyrex scellé dans l'axe d'un bouchon à joint rodé 24/40 (*F*). Ce dernier est monté au

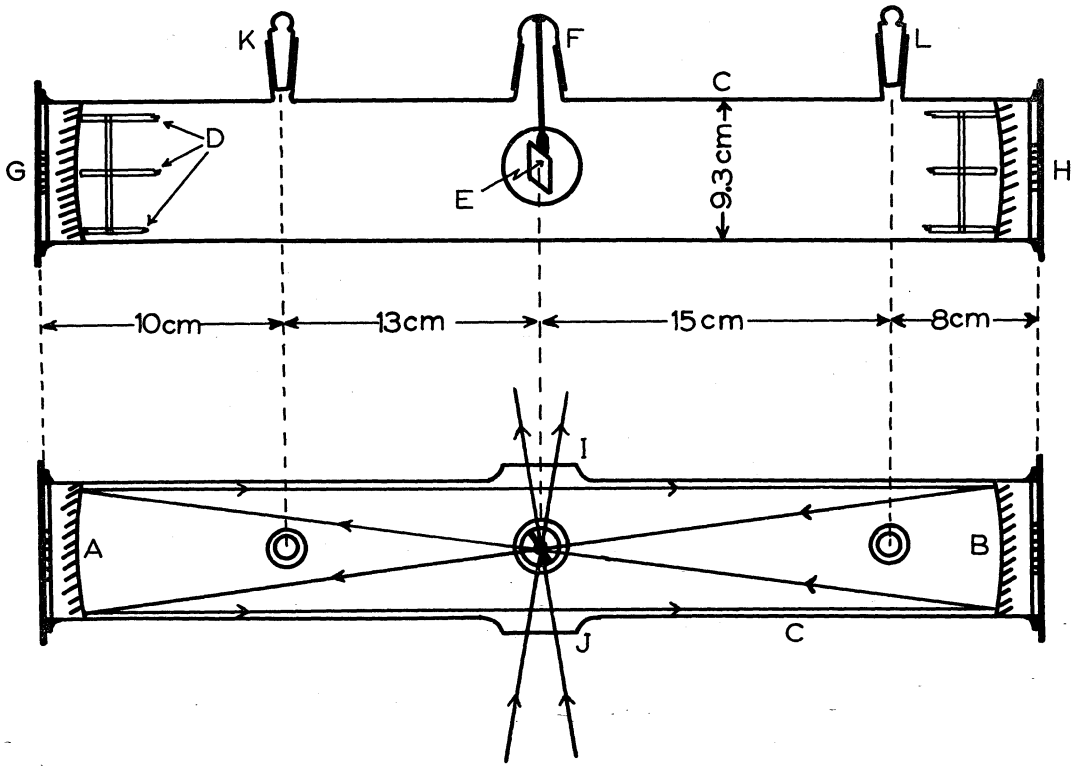

FIG. 1. Cellule à absorption pour le spectromètre infrarouge de Perkin–Elmer (*N*° 201-C).

centre de la cellule d'absorption, de sorte qu'une simple rotation permet d'orienter le faisceau lumineux. On réalise ainsi un parcours optique de quelque 92 cm, et la transmission peut atteindre jusqu'à 90% dans les conditions optima.

La cellule est fermée aux deux extrémités par des plaques d'aluminium (G et H) recouvertes de feuilles de Teflon et maintenues en place par trois tiges métalliques à l'extérieur. Deux ouvertures (*I* et *J*) de 50 mm de diamètre sont ménagées de chaque côté de la cellule pour le passage du faisceau infrarouge. Comme fenêtres on a utilisé, soit des films de Teflon, soit des disques de quartz cristallin. Enfin, deux tubulures (*K* et *L*) munies de joints rodés servent à introduire l'échantillon et à assécher la cellule d'absorption en y faisant circuler assez longtemps (environ une heure) un courant d'azote sec. Cette dernière précaution était d'une importance capitale dans le cas présent, non seulement parce que la vapeur d'eau absorbe fortement la radiation entre 400 et 150 cm^{-1}, mais encore à cause du caractère très hygroscopique des deux acides halosulfuriques. Effectivement, pour l'étude de l'acide fluosulfurique on enlevait les dernières traces d'humidité en introduisant d'abord une goutte d'acide chlorosulfurique qui absorbe très peu dans l'infrarouge au-delà de 400 cm^{-1}, du moins à température ordinaire. Lorsque nécessaire, la cellule pouvait être chauffée au moyen d'un enroulement de fil de résistance.

RÉSULTATS

Bien que la structure des deux molécules HSO_3F et HSO_3Cl n'ait pas encore été déterminée par une méthode directe, on peut sans hésitation la supposer du même type que celle de H_2SO_4 (11) ou encore SO_2F_2 (12) et SO_2Cl_2 (13). Selon l'orientation du groupe OH, diverses configurations sont possibles (Fig. 2), avec ou sans élément de symétrie. De toute façon une molécule XSO_3H quasi-tétraédrale doit avoir douze vibrations fondamentales, toutes actives en infrarouge.

Les spectres de HSO_3F

Les neuf bandes observées dans le spectre Raman de l'acide liquide se retrouvent

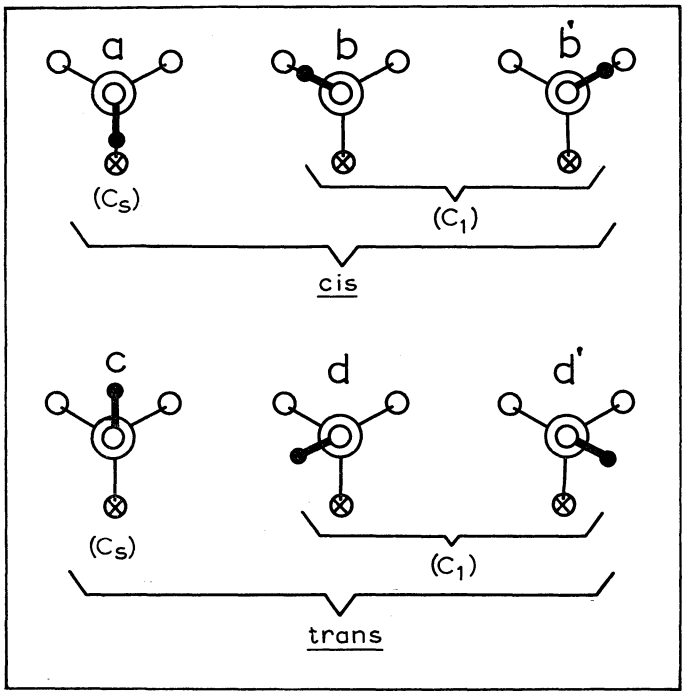

FIG. 2. Configurations possibles des molécules HSO_3X.

naturellement dans les présents spectres (Tableau I), avec en plus la bande de valence O—H à 3125 cm^{-1}, et un léger épaulement vers 650 cm^{-1} dû au mode de torsion ν_{12} du groupe OH. Ce dernier donne naissance à une bande beaucoup plus intense et plus nette dans le cristal (Fig. 3), sans doute parce que les variations de moment polaire qui l'accompagnent ne s'annulent pas, ou à peu près, comme dans le liquide. L'identification des diverses fondamentales par Gillespie et Robinson nous semble correcte, sauf pour ν_7, la fréquence de balancement de S—OH, qu'ils situent vers 560 cm^{-1} comme pour le balancement de S—O. La présente interprétation est cependant plus logique pour les raisons suivantes: (*a*) qualitativement on doit s'attendre à une fréquence de balancement moins élevée pour S—OH que pour S—O, vu la distance interatomique plus grande dans le premier cas; (*b*) la fréquence de balancement S—F (390 cm^{-1}) est dans le même rapport à la fréquence de balancement S—OH (409 cm^{-1}) dans la vapeur, que les vibrations de valence de ces deux groupes (896 et 955 cm^{-1}). D'ailleurs, ce rapport (0.94) est presque identique à la racine carrée du rapport des masses OH/F, ce qui est normal car les distances S—F et S—OH sont à peu près les mêmes dans ces molécules et d'autres analogues; (*c*) enfin, la fréquence 409 cm^{-1} a son équivalent à 407 cm^{-1} dans HSO_3Cl et à 412 cm^{-1} dans H_2SO_4 (5).

Les spectres de la vapeur (Fig. 4) révèlent des particularités intéressantes, entre autres quant à l'effet de la température sur l'intensité et le contour de certaines bandes. Ainsi la région des vibrations O—H montre deux types de bandes; l'une à 3600 cm^{-1}, avec branches *P*, *Q*, et *R*, et dont l'intensité croît avec la température; l'autre, de fréquence beaucoup plus basse, 3100 cm^{-1}, assez large, et dont l'intensité varie en sens inverse de la première avec la température. L'explication la plus obvie de ces résultats est que dans

la vapeur les molécules HSO_3F sont en partie associées par liaisons hydrogène formant des dimères cycliques comme dans le cas classique des acides carboxyliques. D'ailleurs, il apparaît à l'examen que la structure probable de la molécule HSO_3F se prête bien à ce genre d'association (Fig. 5). Nous discuterons plus loin des modalités de ce phénomène. Signalons ici qu'il permet de comprendre d'autres détails des spectres comme, par exemple, la bande de valence S—O (ν_2) dont les deux composantes à haute fréquence, 1491 et

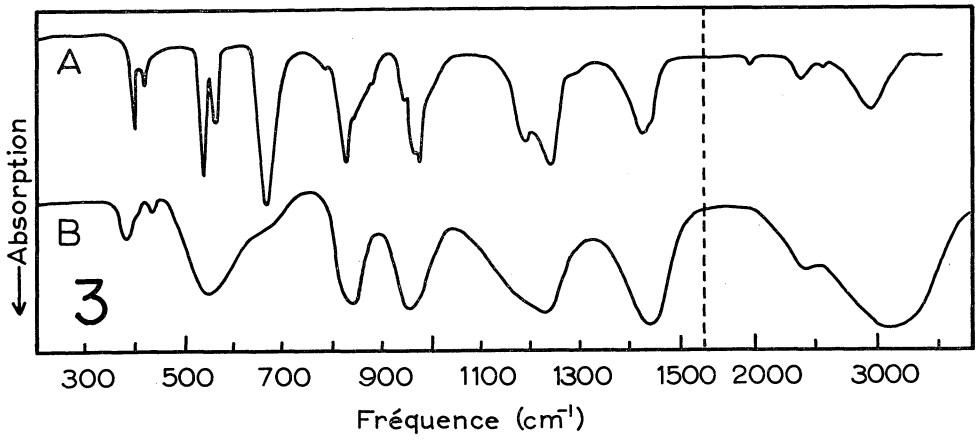

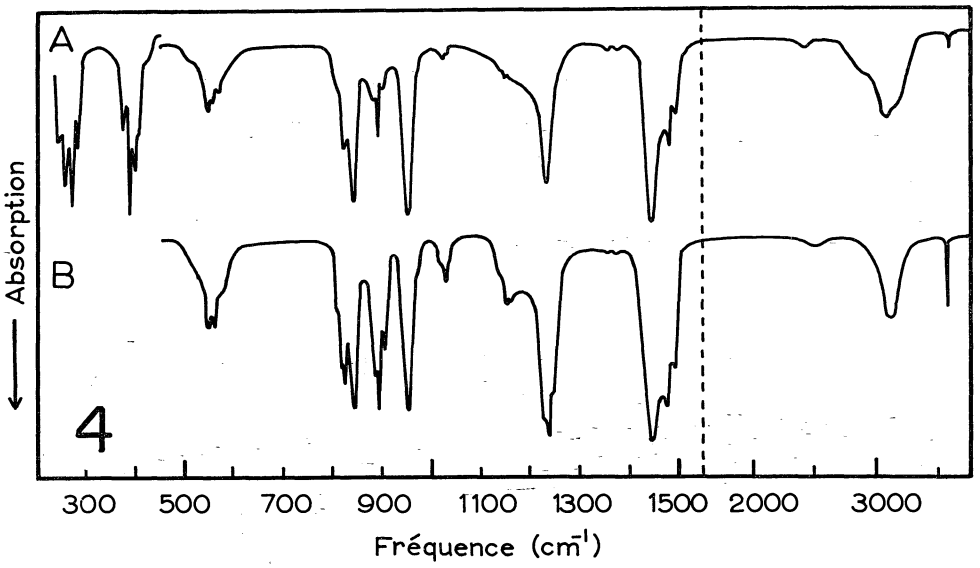

FIG. 3. Spectres infrarouges de HSO_3F à l'état solide (A) et liquide (B).
FIG. 4. Spectres infrarouges de la vapeur de HSO_3F à 25° C (A) et à 60° (B).

1480 cm^{-1}, augmentent d'intensité avec la température, contrairement à la troisième à 1450 cm^{-1}. Les deux premières doivent appartenir aux groupes S—O libres, et la dernière, aux groupes formant des liaisons hydrogène. On retrouve le même comportement pour les bandes S—F (ν_5) à 906–896–887 cm^{-1} et 844 cm^{-1} respectivement.

Enfin le mode de torsion interne du groupe OH, qui produit une bande à structure complexe vers 260 cm^{-1} dans la vapeur, apparaît à une fréquence beaucoup plus élevée, 550–650 cm^{-1}, dans les molécules dimères et les états condensés. On connaît plusieurs autres cas semblables.

Les spectres de HSO_3Cl

Pour diverses raisons les présents résultats pour l'acide chlorosulfurique (Tableau II) sont moins abondants que ceux de l'acide fluosulfurique. Ainsi, malgré plusieurs tentatives il n'a pas été possible d'obtenir le solide à l'état parfaitement cristallisé; d'où l'apparence

For personal use only.

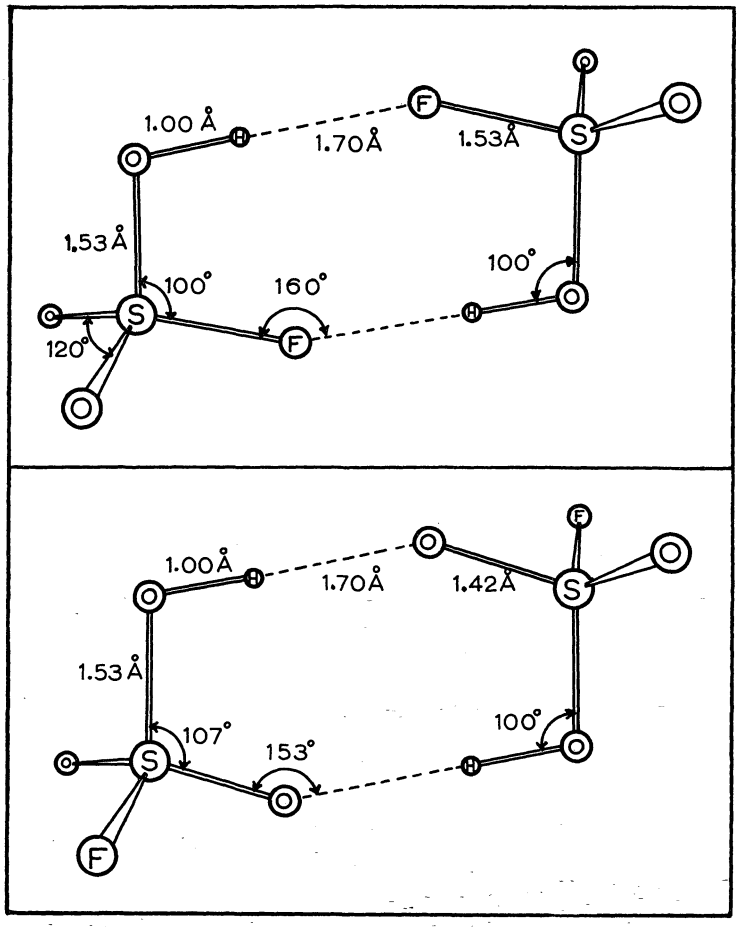

FIG. 5. Structures hypothétiques des dimères cycliques de HSO_3F.

plutôt diffuse des bandes (Fig. 6C). Du côté des basses fréquences, au delà de 250 cm^{-1}, l'absorption non sélective augmente rapidement dans le liquide aussi bien que dans le solide. Quant à la vapeur, l'association moléculaire y est si forte, même à 60°, que les vibrations des molécules HSO_3Cl libres sont à peine perceptibles. D'ailleurs à cette température la dissociation chimique devient assez importante pour que le spectre de rotation pure de HCl nuise à l'observation des vibrations de basse fréquence. Ainsi, la bande de balancement de S—Cl, à 200 cm^{-1} en Raman, n'a pu être aperçue en infrarouge.

Pour le reste, le spectre du liquide (Fig. 6B) ressemble de très près au spectre Raman, à l'exception de la bande à 413 cm^{-1} qui est beaucoup moins intense en infrarouge. Par conséquent on ne saurait l'attribuer à la vibration de valence S—Cl, tel que suggéré précédemment (1, 4). Elle doit plutôt appartenir au mode de balancement S—OH puisqu'on la retrouve à la même fréquence et avec la même intensité dans HSO_3F et dans H_2SO_4 (5). Quant à la vibration S—Cl, nous avons le choix entre les deux fortes bandes à 510 et 615 cm^{-1}. Cette dernière est à préférer car la bande correspondante en Raman est polarisée. D'ailleurs cette fréquence est assez rapprochée des valeurs 577 et 586 cm^{-1} dans SO_2Cl_2 selon la plus récente interprétation (14). Les deux bandes à 510 et 480 cm^{-1} pourraient convenir pour les modes de balancement et de déformation de SO_2, bien que

( ) Fréquence incertaine.

ces fréquences soient notablement plus basses que dans HSO_3F. Aussi la présente interprétation n'est-elle pas définitive.

Signalons encore les particularités suivantes dans le spectre de la vapeur. Les trois pics vers 1400 cm^{-1} n'appartiennent pas à une seule bande (branches PQR), leur séparation étant trop grande, mais plutôt à deux bandes distinctes: celles des groupes S—O libres et S—O····H. Par contre, le faible triplet à 850 cm^{-1} doit être une bande fondamentale de la molécule HSO_3Cl libre, soit la bande de valence S—OH. Le décalage de quelque 60 cm^{-1} par rapport à la bande des dimères semble raisonnable par comparaison avec les acides carboxyliques et leurs dérivés fluorés (15). On a sans doute la même situation dans HSO_3F, mais alors la bande ν_4 des molécules libres est probablement cachée par la bande ν_5 à 900 cm^{-1}.

La structure des molécules HSO_3F et HSO_3Cl

La structure la plus probable pour les molécules des acides halosulfuriques permet diverses configurations selon l'orientation du groupe OH (Fig. 2). A ce sujet rien n'est connu avec certitude et on en est réduit à des hypothèses. Suivant que l'hydrogène est vis-à-vis d'un atome du groupe SO_2X ou entre deux de ces atomes, on aura des formes appelées ici cis- ou trans-. Etant donné le caractère électronégatif de l'oxygène et des halogènes la première alternative est la plus probable. Des trois formes cis- l'une (*a*)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

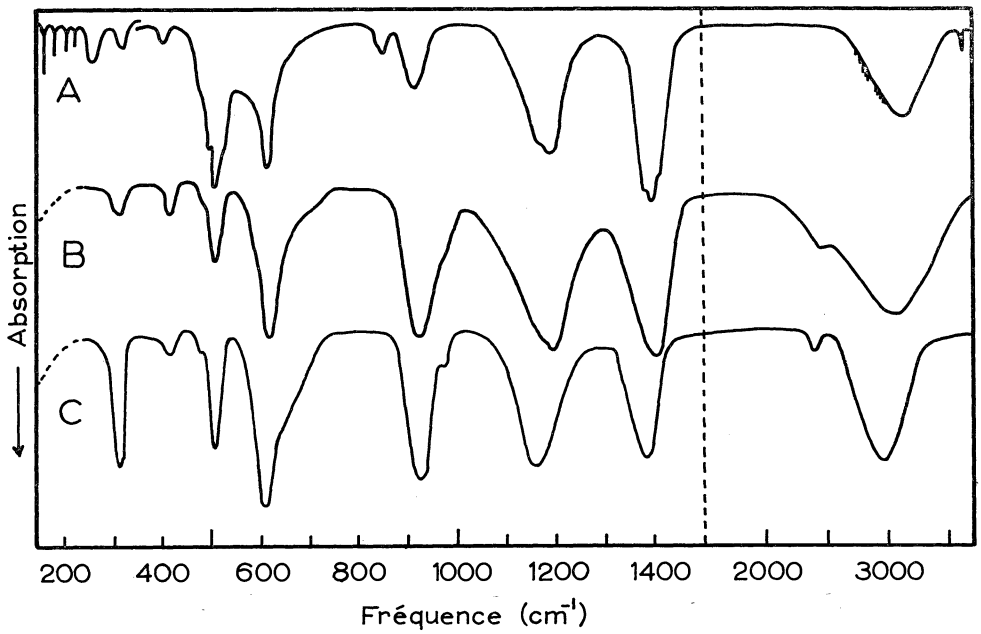

FIG. 6. Spectres d'absorption de HSO_3Cl en infrarouge: (A) gazeux à 60° C, (B) liquide à 25°, (C) solide à −185°.

possède un plan de symétrie C_s; les deux autres (b et b'), sans symétrie C_1, sont des énantiomorphes. Nous adopterons arbitrairement la première comme la plus stable, bien que les deux autres soient également possibles. En réalité, on doit avoir un mélange d'isomères; la structure complexe de certaines bandes dans la vapeur de HSO_3F est une indication en ce sens. Une étude plus détaillée de la structure de ces bandes, et en particulier des effets de la température fournirait des données utiles sur la stabilité relative de ces divers isomères. Le seuil de potentiel qui les sépare semble assez bas; environ 1.3 kcal d'après la fréquence de torsion $\nu_{12} = 275$ cm^{-1} (16). Cette valeur est un peu surprenante si l'on songe au caractère partiellement double de la liaison S—OH. Par ailleurs le fait que ce seuil soit triple contribue à abaisser notablement le maximum (par rapport à une molécule comme HNO_3, par exemple). De toute façon il s'agit ici d'une valeur moyenne puisque l'un des maxima (et aussi l'un des minima) doit être différent des deux autres.

Liaisons hydrogène et association moléculaire

La présence de fortes liaisons hydrogène dans les acides halosulfuriques était à prévoir, du moins dans les phases condensées. Les corrélations empiriques basées sur la fréquence de la vibration O—H dans les solides, ou encore sur le décalage de cette fréquence en passant de la molécule libre aux molécules associées (17, 18) indiquent des énergies de l'ordre de 6 kcal, et des distances O—H de 1.02 Å et O···O de 2.70 Å pour ces liaisons hydrogène. Par ailleurs, selon les mêmes critères, les liaisons hydrogène seraient un peu plus fortes dans HSO_3F que dans HSO_3Cl (Tableau III). Ceci est en accord avec la force relative des deux acides (19) et avec d'autres relations indirectes comme les fréquences caractéristiques du groupe S—OH (1). Etant donné les fortes liaisons hydrogène et les structures moléculaires favorables il n'est pas surprenant que ces deux acides soient associés en phase vapeur. Comme dans les acides carboxyliques on doit avoir surtout des dimères cycliques plutôt que des chaînes. Les paramètres indiqués ici (Fig. 5) sont basés

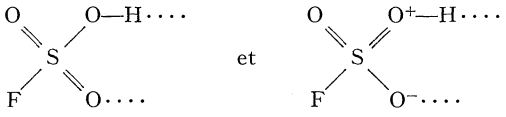
Valence S—OH	970 cm^{-1}	925 cm^{-1}
Déformation SOH	1195 cm^{-1}	1165 cm^{-1}
Constante d'ionisation (25° C)	2.3×10^{-3}	9×10^{-4}
Point de fusion	−87.3° C	−80° C
Point d'ébullition	165.5° C	158° C

sur le modèle purement arbitraire de cycles plans. Une évaluation d'après l'intensité relative des bandes de valence O—H des molécules simples et doubles dans HSO_3F (Fig. 4) donne une enthalpie d'association de 11.5 kcal, environ le double de l'énergie de liaison mentionnée plus haut.

D'après ces considérations, on devrait trouver à peu près le même degré de dimérisation dans les deux acides à l'état de vapeur. Au contraire, les bandes de valence O—H révèlent une concentration relative de molécules libres HSO_3F aussi grande, sinon plus, à 25° C que celle de HSO_3Cl à 60°. Il est vrai que dans ce dernier cas la température plus élevée favorise la décomposition de l'acide, mais ce facteur est d'importance secondaire ici, comme on peut en juger par le peu d'intensité de la bande de vibration–rotation de HCl vers 2880 cm^{-1}. (Il n'existe malheureusement pas de données thermodynamiques sur la stabilité de ces deux acides; nos observations, purement qualitatives, confirment que l'acide fluosulfurique résiste mieux à la décomposition thermique que l'acide chlorosulfurique.)

Notons ici que le cas de HSO_3F est plus complexe que celui de HSO_3Cl. En effet, dans ce dernier composé les liaisons hydrogène sont toutes du même type, soit O—H···O, vu que l'atome de chlore ne participe pratiquement pas à ce phénomène. Au contraire dans HSO_3F, on peut imaginer trois sortes de dimères: (*i*) avec deux liaisons O—H···F, (*ii*) avec deux liaisons O—H···O, et enfin, (*iii*) avec une liaison de chaque sorte. Du simple point de vue statistique les trois possibilités sont dans les rapports 1:4:4 respectivement, mais il est clair que l'énergie de résonance n'est pas la même dans les trois cas. Ainsi le dimère asymétrique (*iii*) doit être moins stable que les deux autres. Quant à ceux-ci (Fig. 5), on ne peut dire ce qui l'emporte, de la plus grande électronégativité du fluor, ou de la stabilisation par résonance selon le schéma de Pauling (20),



lequel ne s'applique pas aux liaisons O—H···F. Effectivement la bande de valence O—H des dimères dans la vapeur de HSO_3F à 25° C montre deux maxima à 3050 et 3150 cm^{-1} provenant sans doute de deux isomères différents. Le second, de moindre énergie, est à peu près disparu à 60°. Pour élucider cette question il faudrait compléter les données actuelles, soit par une étude à haute résolution de la région de 3 μ dans la vapeur à plusieurs températures et pressions, soit par l'étude de solutions dans un solvant approprié. Des mesures de densité de vapeur seraient également utiles, quoique d'exécution et d'interprétation difficiles à cause de la corrosion et de la décomposition thermique.

Il est instructif de comparer les acides halosulfuriques avec l'acide sulfurique du point de vue association moléculaire. Bien que leurs liaisons hydrogène soient de même énergie en première approximation, la différence entre leurs propriétés physiques est considérable. Ainsi l'acide sulfurique est beaucoup moins volatil (point d'ébullition évalué à 300° C) et plus visqueux que les acides halosulfuriques. L'explication réside dans la présence de deux protons par molécule dans l'acide sulfurique, ce qui conduit à un réseau de liaisons hydrogène à trois dimensions, comme c'est le cas pour H_2O. Au contraire, dans les acides halosulfuriques les molécules doubles (ou les chaînes?) ne sont retenues entre elles que par des forces de Van der Waals. A noter que les points d'ébullition de HSO_3F et HSO_3Cl sont dans l'ordre inverse de leur masse moléculaire; cependant il faut tenir compte ici de la décomposition thermique, sans doute importante à ces températures.

Les fonctions d'état du Tableau IV ont été calculées par les méthodes statistiques

TABLEAU IV

Paramètres de structure et fonctions d'état des acides halosulfuriques

usuelles pour le gaz parfait, composé de molécules simples, à pression et température normales. Pour le calcul des moments d'inertie on a pris les distances et les angles les plus probables par analogie avec des molécules de structure connue comme H_2SO_4, SO_2F_2, et SO_2Cl_2.

SUMMARY

The infrared spectra of fluorosulphuric and chlorosulphuric acids were measured over the range 150–4000 cm^{-1} and in the three physical states. All 12 fundamental vibrations of both molecules were observed. Strong hydrogen bonds (some 6 kcal) lead to association through cyclic dimers in the vapor. The chloro-acid is more strongly associated than the fluoro-acid although the hydrogen bonds seem slightly stronger in the latter. Internal rotation of the OH group in the free molecules is hindered by a threefold barrier of about 1.3 kcal. Statistical calculations of the thermodynamic functions give 71.4 cal deg^{-1} mole^{-1} for the standard entropy of free HSO_3F molecules at 25° C, and 74.9 for HSO_3Cl.

These halosulphuric acids are much more volatile than sulphuric acid because in the latter the hydrogen bonds (also 6 kcal) form a three-dimensional network.

SPECTROSCOPIC STUDIES OF ALCOHOLS

I. METHANOL-BASE ADDUCTS IN DILUTE CCl_4 SOLUTION

P. J. KRUEGER AND H. D. METTEE
Department of Chemistry, University of Alberta, Calgary, Alberta
Received September 17, 1963

ABSTRACT

The fundamental ν_{OH} shifts and association constants for methanol hydrogen bonded to some relatively weak proton acceptors (alkyl halides, aryl halides, aromatic hydrocarbons) are reported for standardized conditions in CCl_4 solution, and the data are compared with similar measurements involving some relatively strong bases (containing N or O acceptor atoms) under the same conditions. The general usefulness of hydrogenic frequency displacements of the donor species as a measure of the basicity of the acceptor species is questioned.

INTRODUCTION

In a recent experimental study of conformational equilibria in 2-haloethanols (following paper) it was necessary to have available for comparison the association constants and the fundamental ν_{OH} frequency displacements for ROH . . . base adducts involving covalently bound halogen atoms as proton acceptors. Although the chemical literature abounds with spectroscopic evaluations of hydrogen-bonded systems (1), most of them are for systems which involve hydrogen-bond energies of 3- kcal/mole or more, and which are associated with fundamental hydrogenic frequency displacements in excess of 100 cm^{-1}. Further, many of the reported measurements have been made with spectrophotometers offering poor resolution in the 3 μ region, or they apply to conditions other than those desired for our studies. Hence this series of measurements was made under carefully standardized conditions with a grating stectrophotometer, since the data desired were for weak intermolecular hydrogen bonds and small frequency shifts.

The measurements of Allerhand and Schleyer (2) show that, contrary to popular belief, ν_{OH} shifts encountered in hydrogen-bonded systems where a proton donor ROH interacts with a proton acceptor B in an "inert" solvent depend on the concentration of B. For the measurements described in this paper the concentration of B was, with few exceptions, held at 1.00 M in CCl_4.

While this work was in progress, Allerhand and Schleyer (3) reported the effect of quaternary ammonium halides on the OH stretching frequency of methanol, the magnitude of the shifts depending on the halide anion in the order of $Cl^- > F^- > Br^- > I^-$. Since, with the exception of the anomalous position of the fluoride ion, this order is the inverse of that found when *covalent* halides were used as proton acceptors (4), it was of interest to extend these measurements to more covalent halides with varying degrees of partial ionic character.

Methanol was chosen as the proton donor because the free methanol OH absorption band is known to be almost perfectly symmetrical (5).

EXPERIMENTAL

A Beckman IR-7 infrared spectrophotometer employing a NaCl foreprism and a 75 lines/mm grating blazed at 12 μ was used. The frequency calibration of this instrument has been described (6, 7). Measurements were made in the fourth grating order at a spectral slit width of 1.0 cm^{-1}. The entire optical path and the enclosed sample compartment was flushed with dry air partially freed from atmospheric CO_2. Matched 2.00-cm quartz ("Infrasil") absorption cells were used in double beam operation. The average cell temperature was 28° C.

n-Amyl fluoride was prepared by a method previously described (8). The other proton acceptors were commercial products purified by drying and fractional distillation. "Spectroquality" materials available were used directly; these included the solvent CCl_4 and the proton donor methanol.

Solutions of proton acceptors were made up to exactly 1.00 *M* concentration in CCl_4 in 50-ml volumetric flasks. Part of this solution was used to fill the reference cell, the rest of it was used to make up a sample beam solution containing 8.0 μl of methanol in 25 ml of solution (0.0079 *M*). The methanol was delivered with a screw-type micropipette. Some of the initial measurements were made on solutions made up on twice this scale to minimize pipetting errors. This was found to be unnecessary. The results reported are averages of three independent trials in most cases. During the course of the experimental work frequent "standard" solutions of methanol in CCl_4 (without base) were used to establish a peak absorbance of 0.882 ± 0.013 (average deviation from the mean). The association constants were based on the residual absorbance of the 'free" methanol peak in the presence of base.

RESULTS AND DISCUSSION

The frequency data and the derived association constants for hydrogen bond formation are collected in Table I. Figure 1 gives a comparative view of spectra obtained with weak bases (bonding to covalent halogen atoms or aromatic π-electrons), while Fig. 2 shows the experimental curves obtained in the presence of some stronger bases.

*Allerhand and Schleyer (3) report the monomeric OH band in methanol at 3643 ± 2 cm^{-1}. The value determined in this work is the average of 20 independent measurements spread out over the period during which the other measurements were made. The maximum deviation from the mean was ± 0.4 cm^{-1}, which reflects in part the subjective error in locating the band center. The calibration procedure for the instrument has been described (6, 7).

†"Free" and "bonded" components determined by mathematical resolution of the experimentally observed asymmetric band, assuming a Lorentz shape for the components, and adjusting the band parameters to obtain the best fit. See Ref. (5) for previous application of this method.

‡Corresponding values reported by Schleyer and West (4) for *n*-BuF, Cl, Br, and I are 19, 37, 41, and 47 cm^{-1} respectively.

Table II summarizes trends in $\Delta\nu$ and K observed for variation of X on a given R group, and for variation of R on a given X group. Using the Taft σ^* parameter (9) for the group R in a covalent halide RX, the ionic character of the RX bond would be expected to increase in the order R = C_6H_5 < $C_6H_5CH_2$ < *n*-Bu < *t*-Bu (for a given X

TABLE II

Summary of $\Delta\nu$ and K trends for methanol adducts of weak bases in CCl_4 solution at ~28° C

Base	Trends
(*a*) For variation of X on a given R group:*	
C_6H_5X	$\Delta\nu$: F ≈ Cl < Br < I = benzene
	K: F < Cl ≈ Br < I < benzene
$C_6H_5CH_2X$	$\Delta\nu$: Cl < benzene < Br
	K: Cl < Br < benzene
n-Butyl X	$\Delta\nu$: (F <)Cl < Br < I
(*n*-Amyl)	K: (F >)Cl > Br > I
t-Butyl X	$\Delta\nu$: Cl < Br
	K: Cl ≈ Br
$R_4N^+X^-$†	$\Delta\nu$: $Cl^- > F^- > Br^- > I^-$
(*b*) For variation of R on a given X atom:	
RF	$\Delta\nu$: C_6H_5 > *n*-Am
	K: *n*-Am > C_6H_5
RCl	$\Delta\nu$: *t*-Bu > *n*-Bu = $C_6H_5CH_2$ > C_6H_5
	K: *n*-Bu > $C_6H_5CH_2$ > *t*-Bu > C_6H_5
RBr	$\Delta\nu$: *t*-Bu > *n*-Bu > $C_6H_5CH_2$ = C_6H_5
	K: $C_6H_5CH_2$ > *n*-Bu > *t*-Bu > C_6H_5
RI	$\Delta\nu$: *n*-Bu > C_6H_5
	K: *n*-Bu > C_6H_5
(*c*) For variation of R in aromatic systems:	
	$\Delta\nu$: Benzene < toluene < *m*-xylene < mesitylene < durene < hexamethylbenzene
	K: Benzene ≫ toluene > *m*-xylene < mesitylene < durene < hexamethylbenzene(≈toluene)

*Bases in this section grouped and listed in the order of increasing negative charge on the X atom e.g. the Taft σ^* parameter (9) for R is +0.600, +0.215, −0.130, and −0.300 for C_6H_5, $C_6H_5CH_2$, *n*-Bu, and *t*-Bu respectively.

†Data from Ref. (3).

atom). As the ionic character of the halogen atom increases the ν_{OH} shift trend might be expected to revert to that observed for halide anions. Table II(*a*) shows that for the halides investigated the trend remains F < Cl < Br < I. A radical break in the order thus appears to exist as the halogen becomes completely ionized. For covalent halides the polarizability of the C—X bond may be a major factor in determining the ν_{OH} shift.

The methanol proton could conceivably bond to either the ring π-electrons or the halogen *n*-electrons in phenyl and benzyl halides, or be involved in equilibria involving both sites. For the halobenzene bases the order of increasing basicity deduced from $\Delta\nu$ and from K are identical, and in agreement with the conclusions of Olah *et al.* (10) and Josien and Sourisseau (11) based on frequency shifts. Josien and Sourisseau have indicated that in plots of ionization potential vs. $\Delta\nu$ for various proton donors with series of bases the data for C_6H_5Br and C_6H_5Cl do not correlate with the data for aromatic hydrocarbons. This would be consistent if the ionization potential of a halobenzene is due to the removal of a halogen non-bonding electron. Similar basic behavior differences have been noted by Caldow and Thompson (12) for HCN interaction with aromatic hydrocarbons and halogenated aromatics. These results suggest strongly that the proton is bonded to the halogen atom. On the basis of nuclear magnetic resonance shifts observed for the chloroform proton in chlorobenzene or bromobenzene solutions, Reeves and Schneider (13) had earlier allowed the possibility of some complexing to the π-electrons.

For the phenyl and benzyl halide bases the order of K is the same as $\Delta\nu_{OH}$, whereas for *n*-BuX bases the order of K is the reverse of the $\Delta\nu_{OH}$ trend. For halobenzenes other

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

physical measurements have also failed to lead to consistent basicity correlations. Thus, on the basis of solubilities of HCl in halobenzenes as determined from vapor pressure measurements Brown and Brady (14) found that the basicity of $C_6H_6 > C_6H_5F > C_6H_5Cl > C_6H_5Br > C_6H_5I$. On the other hand, assuming that lowering of ionization potential means increasing basicity of an aromatic, the results of Watanabe (15) show that the relative basicity order is $C_6H_5I > C_6H_5Br > C_6H_5Cl > C_6H_5F$.

Section (*b*) of Table II shows that, with the exception of the limited measurements with RF, the ν_{OH} shift increases as the ionic character of the C—X bond increases (for a given X atom). The same consistent behavior pattern is not observed for the corresponding K values.

The extensive early work on association constants for hydrogen-bonded systems has been summarized and analyzed (1). As stated earlier, most of the data apply to relatively strong hydrogen bonds. Some of the previous findings indicate that there exists a linear relationship between log K_{assoc} (or ΔF) and the frequency shift for strongly hydrogen-bonded systems.* Since the enthalpy and the entropy changes on hydrogen bond formation are related to the free energy change through the relationship $\Delta F = \Delta H - T\Delta S$, it follows that a linear dependence of ΔF on the frequency shift must mean that both ΔH and ΔS are also proportional to the frequency shift. This has been recognized and the linear ΔH vs. ΔS, ΔH vs. $\Delta\nu$, and ΔS vs. $\Delta\nu$ behavior has been demonstrated for certain systems. It thus appears that a decrease in enthalpy is counteracted by a decrease in entropy (more restricted configuration in the associated species), with the net result that K_{assoc} is not particularly sensitive to changes in hydrogen-bond strength.

Joesten and Drago (18) report that the monotonic ΔH vs. $\Delta\nu_{OH}$ relationship holds to ± 0.5 kcal/mole for adducts of phenol with nitrogen and oxygen donors ($\Delta H > 3$ kcal/mole); but that the log K vs. $\Delta\nu_{OH}$ relationship for the same system is limited to similar bases where no unusual entropy effects are observed. The review by Josien (19) suggests that there is no general correlation of the Badger–Bauer type (20) that will have widespread applicability, even if the same proton donor is used in conjunction with bases that differ only little.

For the data reported in this paper log K and $\Delta\nu$ do not correlate with sufficient precision to make the relationship useful, particularly when the high accuracy of frequency measurements is considered. No significant improvements in the correlation result when only closely related bases are used.

For aromatic hydrocarbons as bases (Table II (*c*)) the $\Delta\nu_{OH}$ shift increases with increasing methyl substitution, while K goes through a minimum for *m*-xylene in the series. It is tempting to suggest that this minimum is the result of two opposing factors:

(*i*) slight steric restriction in the approach of the angular CH_3OH molecule to the π-electron density because of methyl substitution, and

(*ii*) an increase in K as the number of electron-donating methyl groups increases.

Factor (*i*) would be absent for benzene itself, and may account for the observation that K for benzene as a base exceeds that for the other hydrocarbons. Factor (*ii*) rapidly overcomes (*i*), and is dominant beyond *m*-xylene in the series. Factor (*i*) presupposes that the OH bond will prefer to be perpendicular to the plane of the aromatic ring in the adduct. Reeves and Schneider (13) speculate that chloroform complexes with aromatic rings in this fashion. Solubility measurements of HCl in aromatic solvents (14) show that

**See for example the work of Grunwald and Coburn (16) on ethanol complexes of ethyl acetate and acetic anhydride, and of Aksnes and Gramstad (17) on the association of phenol with a large number of organophosphorous compounds.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the order of increasing basicity is benzene < toluene < *m*-xylene < mesitylene. The difference in this order from that of the K's for methanol complexes may be in the absence of factor (*i*) for the HCl complexes because of the small spatial requirements of the proton donor.

The data reported in Table I for methanol complexes of bases containing O or N atoms as proton acceptors require little further comment. In general, the ν_{OH} shifts and the K's are larger than for methanol complexes formed with halogen atoms or π-electrons. Again a linear correlation between these quantities is absent. Nitromethane appears to be a poor proton acceptor, in agreement with some other spectroscopic studies of the nitro group (21).

More definite conclusions concerning the relationship of the ν_{OH} shift and the strength of the AOH. . .BY interaction could no doubt be drawn if complete thermodynamic data for these systems were available. However, the results described here provide further evidence to indicate that the decrease in ν_{OH} on hydrogen bond formation does not give a true picture of the overall strength of the hydrogen bond, since it only reflects the decrease in the OH stretching force constant, and neglects compensating changes in the A—OH, B—Y, and OH. . .B bonds, as Bernstein (22) has pointed out.

PYROLYSIS STUDIES

X. RATES OF THE THERMAL DECOMPOSITION OF ortho-SUBSTITUTED ETHYL BENZOATES IN THE GAS PHASE[1,2]

GRANT GILL SMITH[3]

Received September 20, 1963

ABSTRACT

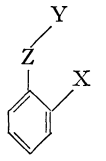
Eight ortho-substituted ethyl benzoates (with substituents varying from *o*-NH_2 to *o*-NO_2) have been partially pyrolyzed to ethylene and the corresponding benzoic acid. By gas chromatographic measurement of the amount of ethylene produced, the relative rates of the thermal decomposition of the various ethers have been determined. There are minor steric effects (primary or secondary) in the reaction and direct field influences are negligible. The varying reactivity, therefore, is attributed to changes in polar effects of the substituent. This reaction appears to be a useful method of determining, quantitatively, to a good first approximation, polar effects of ortho substituents.

The Hammett equation and its various modifications have proved useful in correlating reaction rates and equilibria with variations in structure at the *m* and *p* positions, but little success has been attained so far in applying it to ortho-substituted derivatives and obtaining σ values (1). The reasons for the deviations with ortho substituents are well known and are combined under the heading, proximity effects. These include primary and secondary steric effects, direct field interactions, hydrogen bonding, and, in condensed phase reactions, solvation of the reaction site, of the reagent, and of the ortho substituent (2).

Taft (3) has approached the problem of obtaining polar substituent constants for ortho substituents by applying a suggestion of Ingold (4) that steric hindrance and resonance effects in the transition state of both acidic and basic hydrolyses of esters were the same and formulated the equation

$$\sigma^\circ \equiv (1/2.48)[\log(k/k_0)_B - \log(k/k_0)_A].$$

This approach, however, requires data from two different reactions. Mammalis and Rydon (5) and more recently Charton (6) have suggested that constants for ortho substituents can be defined by reaction series in which the reaction site is not adjacent to the substituent but rather several atoms removed from the aromatic ring.



Z = —CH_2—CH_2—, —CH=CH—, —O—CH_2—

[4]*Part of this study is abstracted from a thesis presented to the Graduate School, Washington State University, by David F. Brown in partial fulfillment of the requirements for the degree of Master of Science, August 1961.*

In the present vapor phase study of the thermal decomposition of alkyl benzoates, proximity complications have been eliminated or markedly reduced even though the reaction site is directly attached to the aromatic ring. Because the pyrolyses are carried out in the vapor phase, all solvent interactions are eliminated. Inasmuch as the reaction is unimolecular and intramolecular, primary steric effects are essentially precluded. Also, it is known that the pyrolysis of ethyl benzoates follows a σ° correlation (7) so resonance interactions between the substituent and the reaction site, including steric inhibition of resonance, are negligible. Hydrogen bonding can not occur with most substituents studied. The pyrolyses of esters are known to proceed via a cyclic transition state intermediate in which there is only a small amount of charge separation (8 (*a*, *b*)); therefore, there are no pole–pole or pole–dipole interactions and very likely only minor dipole–dipole interactions.

Eight ortho-substituted ethyl benzoates (with substituents varying from *o*-NH_2 to *o*-NO_2) have been pyrolyzed to ethylene and the corresponding benzoic acid in a static system under identical conditions in such a manner that not all of the ester decomposed. The relative rates for the thermal decomposition have been determined by gas chromatography and are given in Table I. The results reported earlier (7) for the meta and para

TABLE I

Relative rate data for the pyrolysis of *o*-, *m*-, and *p*-substituted ethyl benzoates at 515° C

Substituent	ortho	meta	para	*o*:*p* ratio	Infrared frequency cm^{-1} for *o*-substituted ester C=O	C—O
2,6-Me_2	0.88				1717	1243 (1213)
OMe	0.97	1.07	0.96	1.01	1719	1178
NH_2	0.98	1.01	0.86	1.14	1683	1163 (1155)

OH	1.16	0.98	0.91	1.27	1669	1152 (1131)
Cl	1.34*	1.28	1.28	1.04	1725	1131
I	1.35	1.32	1.32	1.02	1721	1096
NO_2	1.61	1.50	1.42	1.13	1728	1069

*This value was obtained from the ratio of the absolute reaction rate data for ethyl *o*-chlorobenzoate and ethyl benzoate. Grateful acknowledgment is given to Dr. David A. K. Jones for determining these data. Decarboxylation is not sufficient to present a serious problem with these esters, therefore, studies could be made in a static reactor.

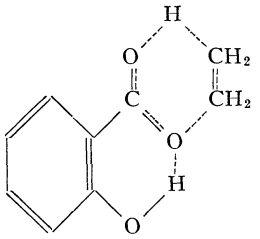
isomers are listed for comparison. Also included in the table are the frequencies of the C—O stretching in the 1100–1150 cm^{-1} region and the frequencies of the C=O stretching in the 1715 cm^{-1} region. At the temperatures necessary to cause the pyrolysis of ethyl benzoates, aromatic acids undergo decarboxylation. For this reason the absolute reaction rates are not readily determined by measuring the increase in pressure in a static reactor as reported from this laboratory on the studies of arylethyl acetates (8(*a*)), isopropyl benzoates (8(*c*)), and carbonates (8(*d*)). The present studies, however, were successfully made in a dynamic reactor, the design of which has been described (9).

This study is the first of a series on the pyrolyses of ortho-substituted benzoates in which the alkyl group is increased in size from ethyl, isopropyl, to *t*-butyl.

The most striking observation is that the *o*:*p* ratios for all but three of the substituents were in the range 1.00–1.06. To our knowledge, there is only one other similar reaction of σ° type reported (10) that does not show a marked difference in reactivity of the substituent in the ortho and para positions (3(*b*)). This demonstrates that the proximity effects for *o*-substituents are excluded in the pyrolysis of esters.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The three substituents that showed somewhat enhanced *o*:*p* ratios were NH_2 (1.14), OH (1.27), and NO_2 (1.13). Two of these (NH_2, OH) show hydrogen bonding in solution at room temperature as indicated by the occurrence of additional low frequencies of the C=O absorption in the infrared spectra (see Table I). This may explain the enhanced reactivity of these substituents in the ortho position, though bonding of this type will be much less important at high temperatures. Hydrogen bonding can help to stabilize the slight charge separation reported to occur in the transition state of this thermal decomposition reaction.



The nitro group, which has a strong —I and —R effect, would be expected to show an *o*:*p* ratio greater than 1.00 and greater than the *o*:*p* ratio for Cl and I. The size of the nitro group is considerable [$E_s = -0.75$] (3(*b*)) but there is little evidence that the slightly increased ortho reactivity is due to steric acceleration. Certainly the 2,6-dimethyl-substituted ester would be expected to show a marked difference in reactivity from the standard ethyl benzoate if steric effects were pertinent. The two groups reduce the rate only slightly ($k_{rel} = 0.88$). Bailey and Turek demonstrated that ethyl 2,4,6-trimethyl-benzoate could be pyrolyzed readily to the free acid and ethylene in 76% yield (11). This indicates very little steric hindrance or acceleration in this reaction as compared to many reactions run in the condensed phase such as in the esterification of 2,6-dimethylbenzoic acids (and the reverse, hydrolysis) where the rate is markedly affected by the presence of two ortho substituents (12).

Therefore, it is concluded that in the pyrolysis of ethyl benzoates the proximity effect appears to be minimal or non-existent, and changes in reactivity are primarily due to the changes in polar effects of the substituent. This reaction appears to be a useful method of determining, at least to a good first approximation, quantitative polar effects of ortho substituents. Such polar substituent values for ortho substituents will be reported in future papers.

EXPERIMENTAL

Ester Preparation

Esters were, in general, prepared from commercially available acids and ethanol, using either sulphuric acid or dry hydrogen chloride as a catalyst. *o*-Iodobenzoic acid was made using the method of Wachter (13) from anthranilic acid. Ethyl 2,6-dimethylbenzoate was prepared from 2,6-dimethylbromobenzene using a Grignard synthesis following the procedure outlined by Bailey and Turek (11). The esters were purified by careful fractionation, and the physical constants of the pure esters were found to agree with the best literature values.

Method of Pyrolysis

Each ester was pyrolyzed under identical conditions in such a manner that not all of the ester decomposed, otherwise a relative rate could not be determined. The extent of pyrolysis was determined by measuring the amount of ethylene produced using gas-phase chromatography and was found to be in the range of 50–60%. The details of the method have been described (9) as well as other applications (7).

A fixed volume of ester was injected into the hot zone of the reactor using a 10-μl syringe fitted with a Chaney adapter. The reactor was an 8-in. stainless tube inserted in the constant flow helium line leading to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the gas chromatograph. The temperature of the reactor was maintained by a well-lagged copper block surrounding the stainless steel tube. Although the temperature used was 515°, the time (0.7 second) that the ester was in the hot zone was not sufficient to cause complete pyrolysis.

The product from the pyrolysis and the unpyrolyzed ester were carried with the helium stream through an ice-cooled trap to remove the unpyrolyzed ester and the acid. The ethylene and carbon dioxide (produced by partial decarboxylation of the acid) were carried on through a 15-ft 40–60 mesh silica gel column maintained at 56°.

The amount of ethylene produced by a given ester was directly proportional to the rate of decomposition, as the stoichiometry of ester to olefin is one. Throughout the series studied the reaction temperature and time were held constant. The reference compound, ethyl benzoate, was pyrolyzed at regular intervals to check reproducibility. Triplicate or more runs were averaged to obtain mean values.

The relative rates are given in Table I. The results reported earlier for the meta and para isomers are listed for comparison (7).

Also included in Table I are the frequencies of the C—O stretching vibrations in the 1100–1150 cm^{-1} region and the frequency of the C=O stretching in the 1715 cm^{-1} region (measured in CS_2 solutions).

SPECTRAL AND CHEMICAL PROPERTIES OF β- AND γ-FUNCTIONAL SILANES

A. G. Brook and J. B. Pierce
Department of Chemistry, University of Toronto, Toronto, Ontario
Received June 28, 1963

ABSTRACT

The synthesis of β- and γ-hydroxy- and keto-silanes is described, together with that of their carbon analogues. Unlike the α-isomers. the hydroxysilanes do not rearrange to silyl ethers, and the ultraviolet spectra of the silyl ketones is essentially the same as those of the carbon analogues, and unlike that of α-silyl ketones. β-Silyl ketones have a carbonyl-stretching frequency midway between that of ordinary ketones and α-silyl ketones. These effects are discussed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

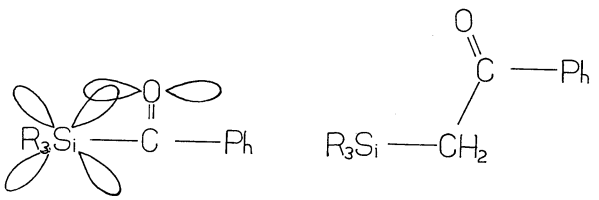
Previous studies from this laboratory have shown that organosilicon compounds having functional groups (OH, C=O) on the carbon atom adjacent (alpha) to silicon exhibit properties considerably different in behavior from those of their carbon analogues. Thus alpha-silyl ketones have anomalous infrared and ultraviolet spectra (1, 2), and both α-silyl ketones (3) and α-silyl carbinols (4, 5) (α-hydroxysilanes) undergo rearrangements unknown in carbon chemistry.

The ultraviolet spectra of benzoylsilanes are characterized by absorption in the visible region at about 403–417 mμ, so that all the compounds are bright yellow regardless of whether methyl (1), phenyl (1), hydroxyl (2), methoxyl (2), or halobenzyl (2) groups are attached to the silicon atom, whereas, in all cases the carbon analogues are colorless, absorbing at some 80–100 mμ's shorter wavelength. At the same time the infrared carbonyl stretching vibration of α-silyl ketones is at remarkably low frequency: 1618 cm^{-1} (6.18 μ) for benzoylsilanes (1, 2) and 1645 cm^{-1} (6.08 μ) for acetyl (1) or propionylsilanes, whereas the carbon analogues absorb at about 1686 cm^{-1} (5.93 μ) and 1715 cm^{-1} (5.83 μ) respectively. Again the position of the absorption band is rather insensitive to the nature of the groups attached to silicon (2).

It has been suggested that these anomalous spectral effects might be due to interaction of the unshared electrons of the oxygen atom of the carbonyl group with the unoccupied but accessible *d*-orbitals of silicon (1). Such interactions appear to be well established for oxygen attached directly to silicon (6). It might be anticipated that if such *n*–*d* interactions were associated with the anomalous spectra of α-silyl ketones (I), while little effect would be observed with β-ketosilanes (II) due to poor overlap, this type of interaction could also arise in a γ-ketosilane (III) in a suitable cyclic conformation.

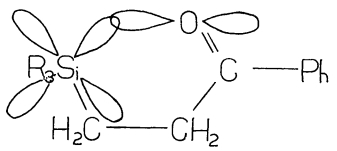
While a number of carbon-functional silanes have been synthesized where the functional group is beta or gamma to the silicon atom (7(*a*)), no detailed investigation of their properties has been reported. Hence it appeared to be of interest to synthesize keto- and hydroxysilanes where the functional group was not next to silicon to see what effect position had on the infrared and ultraviolet absorption, and on the tendency of the compound to undergo rearrangement.

The ketones chosen were phenacyltriphenylsilane, a β-silyl ketone, and 1-triphenylsilyl-3-phenylpropan-3-one, a γ-silyl ketone, together with their carbon analogues, prepared to ensure absence of any unpredicted behavior. A by-product of one of the reactions also yielded what is believed to be 1,3-bis(triphenylsilyl)-5-phenylpentan-5-one, which is both



I

II



III

a γ and an ε ketone. The corresponding alcohols were also prepared to establish whether rearrangement to the isomeric silyl ethers occurred.

The spectral data for the various ketones are recorded in Table I.

†Ultraviolet spectrum run in $CHCl_3$ due to solubility problems.
S = Shoulder.

With respect to the infrared absorption, it is found that the characteristic carbonyl absorption at 1618 cm^{-1} of α-ketosilanes is raised to 1667 cm^{-1} in the β-ketosilane, and is still further raised to 1692 cm^{-1} in the γ-silyl ketones, the normal value for an alkyl phenyl ketone, as demonstrated by the results from the carbon analogues. This effect is typical of a simple inductive electron release from the relatively electropositive triphenylsilyl group to the carbonyl group, which diminishes as methylene groups are interposed between silicon and the electron-accepting group.

No anomalous ultraviolet absorption effects are observed for the β-, γ-, or ε-silyl ketones, as demonstrated by the similarity of their spectra to the appropriate carbon analogues. Thus only when the silicon atom is directly attached to the carbonyl group are anomalous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ultraviolet spectra obtained. While we wish to defer a detailed discussion of the interpretation of these absorption effects to a later paper, it seems obvious that some direct interaction between the carbonyl group and the silicon *d*-orbitals is occurring, probably involving contributions in the excited state from structures such as IV.

$$R_3SiCOPh \xrightarrow{h\nu} R_3Si^- = \overset{O^+}{\overset{|}{C}}—Ph$$

IV

West (7*b*) has recently interpreted these effects similarly in terms of resonance interaction between the silicon atom and the π orbitals of the carbonyl group, in which interaction with the π^* orbital is most important.

A characteristic of α-silyl carbinols is their ability to rearrange readily to the isomeric silyl ether under mild conditions (4). This has been shown to be an intramolecular reaction occurring with retention of configuration at silicon (8). It was of interest to establish whether β- or γ-silyl carbinols would rearrange similarly. Since the hydroxy compounds were readily available from the ketones, both 1-triphenylsilyl-2-phenylethan-2-ol and 1-triphenylsilyl-3-phenylpropan-3-ol were treated over several hours with sodium–potassium alloy in ether, conditions which, with α-silyl carbinols, would have been more than adequate to convert them to silyl ethers (4). However, in neither case was any evidence for isomerization observed and the starting materials were recovered in excess of 75%.

Hence it appears that β- and γ-functional silanes are devoid of the interesting physical or chemical properties that characterize alpha-hydroxy- or alpha-ketosilanes.

Synthesis of the β- and γ-silyl ketones and their carbon analogues presented some difficulties. The synthesis of the γ-silyl ketone, 1-triphenylsilyl-3-phenylpropan-3-one, followed closely the methods employed for the synthesis of α-silyl ketones (1, 2). Coupling of 3-phenylpropyllithium with triphenylchlorosilane gave 3-phenylpropyltriphenylsilane, which was dibrominated with N-bromosuccinimide and then hydrolyzed to the ketone with silver acetate and water. Alternatively, the compound was prepared in low yield by the photochemical-induced addition of benzaldehyde to vinyltriphenylsilane, using conditions previously described for the synthesis of 1-triphenylsilyl-butan-3-one (9).

A second major product was also isolated from this reaction. Although the structure was not rigorously proved, it seems reasonable from the infrared spectrum (1692 cm^{-1}), molecular weight determination, and analysis to ascribe to this compound the structure 1,3-bis(triphenylsilyl)-5-phenylpentane-5-one. Such a structure is reasonable from a radical reaction involving triphenylvinylsilane where the intermediate 1-triphenylsilyl-3-keto-3-phenylpropyl radical either abstracts hydrogen, giving 1-triphenylsilyl-3-phenylpropan-3-one, or attacks a second vinyltriphenylsilane molecule.

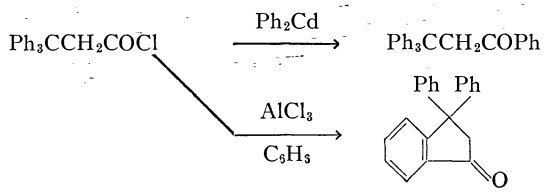
The β-silyl ketone, phenacyltriphenylsilane, was prepared by oxidation of 1-triphenylsilyl-2-phenylethan-2-ol, prepared by the method of Gilman *et al.* from triphenylsilyllithium and styrene oxide (10). Attempts to prepare the ketone following the methods described above for the γ-ketone failed.

Bromination with N-bromosuccinimide of 1-triphenylsilyl-2-phenylethane, prepared from 2-phenylethylmagnesium bromide and triphenylchlorosilane, gave the expected 1-triphenylsilyl-2-phenyl-2,2-dibromoethane. However, on some occasions, particularly with prolonged reflux, this compound spontaneously evolved hydrogen bromide, yielding instead 1-triphenylsilyl-2-bromo-2-phenylethene, characterized by carbon–carbon double bond absorption at 1587 cm^{-1}, and ultraviolet absorption at 260 mμ, ε 15,360, a position typical for an aryl-conjugated double bond with an alpha-bromine substituent (11). This result suggests that bromination followed by dehydrobromination occurred. Such behavior is not surprising for a β-bromosilane (12).

Attempts to hydrolyze 1-triphenylsilyl-2-phenyl-2,2-dibromoethane with silver acetate in the normal manner failed to yield any of the expected phenacyltriphenylsilane. Extensive silicon–carbon cleavage occurred, yielding triphenylsilanol and the only other material isolated appeared to be a mixture of α- and β-hydroxysilanes containing bromine, which could not be separated. Short refluxing of this material in ethanol gave low yields of 1-triphenylsilyl-2-bromo-2-phenylethene. These anomalous reactions have not been further investigated, but it is known from previous work that β-silyl halides frequently give rise to unusual reactions (7, 12).

The carbon analogues of the β- and γ-silyl ketones, viz. 1,1,1,3-tetraphenylpropan-3-one (13) and 1,1,1,4-tetraphenylbutan-4-one, were also synthesized by unambiguous routes, the latter not previously having been reported. Treatment of 3,3,3-triphenylpropionyl chloride with diphenylcadmium gave a good yield of 1,1,1,4-tetraphenylpropan-3-one, but attempts to convert the acid chloride to the phenyl ketone by Friedel–Crafts coupling with benzene using aluminum chloride gave only intramolecular cyclization to the previously reported 3,3-diphenylindanone (14).



The ketone 1,1,1,4-tetraphenylbutan-4-one was prepared by a route similar to that used for the γ-silyl ketone. Triphenylmethylsodium was coupled with 3-phenylpropylbromide to yield 1,1,1,4-tetraphenylbutane. This hydrocarbon was dibrominated with N-bromosuccinimide and the bromide was hydrolyzed with silver trifluoroacetate and water.

$$Ph_3CNa + Br(CH_2)_3Ph \rightarrow Ph_3C(CH_2)_3Ph \xrightarrow[(ii)\ AgO{-}C{-}CF_3,\ H_2O]{(i)\ 2NBS} Ph_3CCH_2CH_2COPh$$

In addition, in the course of this work, two additional ketones were synthesized by exploratory reactions involving the coupling of triphenylmethylmagnesium bromide with acid chlorides. It was considered probable that the hindered ketones formed by this coupling reaction would not readily add a second mole of Grignard reagent as normally

occurs, and this was confirmed to some extent, although the yields of ketone were low and numerous other products accompanied the desired product. Thus 1,1,1-triphenylpropan-2-one (15) was prepared in low yield when trityl Grignard reagent was treated with acetyl chloride and 1,1,1,3-tetraphenylpropan-2-one was similarly prepared by reaction with phenylacetyl chloride.

$$Ph_3CMgI \xrightarrow{ClCOMe} Ph_3CCOMe$$

$$Ph_3CMgI \xrightarrow{ClCOCH_2Ph} Ph_3CCOCH_2Ph$$

EXPERIMENTAL

Reactions involving organometallics were carried out under a dry oxygen-free nitrogen atmosphere. Infrared spectra were determined in carbon tetrachloride on a Beckman IR5 instrument calibrated against polystyrene. Ultraviolet spectra were determined in 95% ethanol.

1-Triphenylsilyl-3-phenylpropan-3-one

A. From 1-Triphenylsilyl-3-phenylpropane

1-Triphenylsilyl-3-phenylpropane was prepared from triphenylchlorosilane and 3-phenylpropyllithium in 61% yield by the method of Gilman and Miles (16), m.p. 66.5–67.5° (reported 62.5–64°). Anal. Calc. for $C_{27}H_{26}Si$: C, 85.6; H, 6.92. Found: C, 84.7; H, 6.60.

Dibromination of 3.78 g (0.01 mole) of 1-triphenylsilyl-3-phenylpropane over 18 hours with 3.8 g (0.0215 mole) of N-bromosuccinimide in 100 ml of refluxing carbon tetrachloride, to which small lumps on benzoyl peroxide were added every 15 minutes over the first hour, gave, on cooling, 1.94 g (98%) of succinimide identified by mixed melting point. Removal of the carbon tetrachloride and crystallization from petroleum ether (b.p. 90–100°) gave 2.51 g (47%) of 1-triphenylsilyl-3,3-dibromo-3-phenylpropane, m.p. 111–113°.

Hydrolysis of 2.51 g (0.0047 mole) of the dibromide was accomplished by stirring its solution in 20 ml of benzene, 58 ml of acetone, and 2 ml of water with 1.57 g (0.0094 mole) of silver acetate for 22 hours in the dark at room temperature. After filtration of 1.69 g (96%) of silver bromide the solution was treated with water and extracted with benzene. After drying, and removal of the solvent under reduced pressure, the orange residue was recrystallized from ethanol to give 1.19 g (65%) of colorless 1-triphenylsilyl-3-phenylpropane-3-one, m.p. 84–84.5°. Anal. Calc. for $C_{27}H_{24}SiO$: C, 82.6; H, 6.16. Found: C, 82.2; H, 6.03.

B. From Vinyltriphenylsilane and Benzaldehyde

A solution of 5.3 g (0.05 mole) of benzaldehyde and 5.72 g (0.02 mole) of vinyltriphenylsilane and a trace of benzoyl peroxide in 75 ml of cyclohexane was irradiated with ultraviolet light from General Electric 40-watt Black Light fluorescent lamps, for a period of 2 weeks. After removal of the solvent, the residue was chromatographed on silica gel, using 50% benzene – petroleum ether (b.p. 90–100° C) and then benzene as eluants. The first fractions gave 3% of a high melting ketone (m.p. 189–191° C) after two recrystallizations from a 90–100° C petroleum ether – benzene mixture. This material is tentatively identified is 1,3-bis(triphenylsilyl)-5-phenylpentane-5-one. Anal. Calc. for $C_{47}H_{42}Si_2O$: C, 83.1; H, 6.23; mol. wt. 679. Found: C, 82.1; H, 6.28; mol. wt. (osmometer) 706.

The next fractions (benzene) yielded 1.0 g (12%) of 1-triphenylsilyl-3-phenylpropan-3-one, m.p. 84–84.5°, after crystallization from ethanol, shown to be identical with the material described above by mixed melting point.

Phenacyltriphenylsilane

A. To 2.0 g (0.0052 mole) of 1-triphenylsilyl-2-phenylethan-2-ol, prepared by the method of Gilman *et al.* (10), in 25 ml of ether and 20 ml of acetone was added over 45 minutes 3.8 ml of an oxidizing mixture made up from 25.80 g (0.25 mole) of 96% sulphuric acid and 16.67 g (0.167 mole) of chromium trioxide in water to a total volume of 100 ml. After it was stirred for 1 hour at room temperature, the reaction mixture was drowned in water, and was ether extracted. After drying and removal of the ether, an oily solid, smelling strongly of benzaldehyde, was obtained. Recrystallization from carbon tetrachloride removed 0.39 g (27%) of triphenylsilanol, m.p. 148–152°, identified by mixed melting point. Recrystallization from ethanol of the residue after removal of the carbon tetrachloride gave 0.52 g (27%) of phenacyltriphenylsilane, m.p. 89–91°. Anal. Calc. for $C_{26}H_{22}SiO$: C, 82.5; H, 5.86. Found: C, 82.5; H, 6.09.

B. Dibromination of 1-Triphenylsilyl-2-phenylethane

1-Triphenylsilyl-2-phenylethane, m.p. 147–149°, was prepared in 44% yield from 2-phenylethylmagnesium bromide and triphenylchlorosilane according to the method of Gilman and Miles (16); reported m.p. 146–147°.

A mixture of 5.0 g (0.018 mole) of 1-triphenylsilyl-2-phenylethane in 50 ml of carbon tetrachloride was refluxed with 4.87 g (0.0274 mole) of N-bromosuccinimide for 2 hours with periodic additions of small amounts of benzoyl peroxide. The bromination was distinctive in terms of the brown color which developed,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

suggesting liberation of free bromine. After cooling and removal of 92% of succinimide, identified by mixed melting point, the solvent was removed under reduced pressure and the resulting oil was dissolved in cyclohexane and cooled to give 2.75 g (38%) of crude 1-triphenylsilyl-2,2-dibromo-2-phenylethane, m.p. 103–112°. Recrystallization from heptane raised the melting point to 115–117°. Anal. Calc. for $C_{26}H_{22}SiBr_2$: C, 59.8; H, 4.21. Found: C, 60.3; H, 4.23.

A variety of other compounds, whose identity has not been established, were isolated in low yield from the mother liquor.

Similar runs to the above gave on at least one occasion a vigorous evolution of HBr after about 2.5 hours reflux. Workup as above gave as the main product 2.0 g (32%) of 1-triphenylsilyl-2-bromo-2-phenylethene, m.p. 156.5–158° after recrystallization from benzene–petroleum ether (b.p. 90–100°). Anal. Calc. for $C_{26}H_{21}SiBr$: C, 70.7; H, 4.80. Found: C, 71.4; H, 4.92. Infrared ($CHCl_3$) 1587 cm^{-1}; ultraviolet λ_{max} 260.5, ϵ 15,360.

Hydrolysis of 1-Triphenylsilyl-2,2-dibromo-2-phenylethane

A mixture of 1.9 g (0.0036 mole) of the dibromo compound and 1.28 g (0.0077 mole) of silver acetate in 30 ml of acetone, 10 ml of benzene, and 1 ml of water was stirred for 18 hours. The insoluble silver salts were removed, water was added, and the material was extracted with ether. The ether layers were washed with water and dilute sodium bicarbonate and, after drying, the ether was removed. Recrystallization from heptane gave 0.46 g (46%) of triphenylsilanol, m.p. 150–152°, identified by mixed melting point, and 0.60 g of material melting 110–127°.

Recrystallization from heptane raised the melting range to 120–132°, but further recrystallization failed to alter the range. This material, which contains halogen, appeared to be a mixture of α- and β-hydroxy silanes based on the presence of two OH peaks at 3572 cm^{-1} (α) and 3636 cm^{-1} (β) in the infrared spectrum. If the material was refluxed in ethanol, about 50% of 1-triphenylsilyl-2-bromo-2-phenylethene, m.p. 154–157°, identified by mixed melting point with the material described above, could be isolated. None of the expected 1-phenacyltriphenylsilane was detected, and an infrared spectrum of the crude hydrolyzate showed no carbonyl absorption bands.

1-Triphenylsilyl-3-phenylpropan-3-ol

To a solution of 0.03 g (0.0007 mole) of lithium aluminum hydride in 25 ml of dry ether was added 1.0 g (0.0026 mole) of 1-triphenylsilyl-3-phenylpropan-3-one in 25 ml of ether. After stirring for 15 minutes at room temperature ethyl acetate was added and the mixture was then hydrolyzed. Removal of the ether from the ether layer gave 0.75 g (73%) of 1-triphenylsilyl-3-phenylpropan-3-ol, m.p. 80–80.5° after recrystallization from petroleum ether (b.p. 90–100°). Anal. Calc. for $C_{27}H_{26}SiO$: C, 82.2; H, 6.64. Found: C, 81.9; H, 6.35.

Attempted Isomerization of 1-Triphenylsilyl-3-phenylpropan-3-ol

To 0.30 g of the above carbinol in 5 ml of dry ether was added a drop of sodium–potassium alloy. Gas appeared to be evolved during the 4-hour reaction period. Workup by removal of the alloy and the solvent gave, after recrystallization, 0.24 g (80%) of recovered starting material, m.p. 80–81°.

Attempted Isomerization of 1-Triphenylsilyl-2-phenylethan-2-ol

To 0.56 g of the carbinol (10) in 5 ml of dry ether was added 1 drop of sodium–potassium alloy. A gas was slowly evolved. After occasional shaking over 4 hours the alloy was removed, the ether was removed under reduced pressure, and the resulting oil was crystallized from ethanol to give 0.42 g (75%) of recovered starting material, m.p. 134–137°.

1,1,1,3-Tetraphenylpropan-3-one

To 15.7 g (0.0347 mole) of 3,3,3-triphenylpropionyl chloride, prepared by the method of Hellerman (17), in 50 ml of dry benzene was added 0.0374 mole of diphenylcadmium (18) in benzene. The mixture was refluxed for 18 hours and then was drowned in ice and dilute hydrochloric acid and extracted with ether. After drying with sodium sulphate and removal of the ether, the residue was washed with petroleum ether (b.p. 90–100°) and the insoluble ketone was crystallized from ethanol – ethyl acetate to give 4.98 g (37%) of 1,1,1,3-tetraphenylpropan-3-one, m.p. 165–167°, Anal. Calc. for $C_{27}H_{22}O$: C, 89.4; H, 6.12. Found: C, 88.6; H, 6.12.

Attempted Synthesis of 1,1,1,3-Tetraphenylpropan-3-one by Friedel–Crafts Reaction

3,3-Diphenylindanone.—To a solution of 5.25 g (0.04 mole) of aluminum chloride in 40 ml of dry benzene was added 13.82 g (0.043 mole) of 3,3,3-triphenylpropionyl chloride in 20 ml of dry benzene. The mixture was heated carefully to near reflux, at which point a vigorous evolution of hydrogen chloride occurred. After 1 hour the reaction mixture was poured on ice and extracted with benzene. After removal of the solvent, recrystallization of the residue from ethanol gave 7.53 g (62%) of 3,3-diphenylindanone, m.p. 131–133°. Infrared of carbonyl, 1727 cm^{-1}. Reported (14) m.p. 130°. None of the expected product was obtained.

1,1,1,4-Tetraphenylbutane.—To 0.152 mole of triphenylmethylsodium in 1300 ml of ether, prepared from trityl chloride and sodium amalgam (19), was added 30.2 g (0.152 mole) of 1-phenyl-3-bromopropane in 100 ml of ether. The reaction mixture was stirred for 2 hours after addition was complete and then was hydrolyzed. The ether layers were dried, the ether was removed, and the residue was treated with hot

For personal use only.

ethanol. An insoluble residue weighing 1.72 g (4.8%) of *p*-benzhydryltetraphenylmethane, "Gomberg's isomer" (20), was obtained, m.p. 215–220°, identified by mixed melting point with an authentic sample, m.p. 215–219°. The ethanol solution, on cooling, gave 25.5 g (59%) of 1,1,1,4-tetraphenylbutane, m.p. 92–93.5°. Anal. Calc. for $C_{28}H_{26}$: C, 92.4; H, 7.63. Found: C, 92.4; H, 7.37.

1,1,1,4-Tetraphenylbutan-4-one.—To 5.0 g (0.0138 mole) of 1,1,1,4-tetraphenylbutane in 100 ml of carbon tetrachloride was added 4.92 g (0.0276 mole) of N-bromosuccinimide. The mixture was refluxed for 18 hours, several small portions of benzoyl peroxide being added. Removal of the succinimide and then the solvent gave a dibromide which failed to crystallize and which therefore was hydrolyzed directly by treatment with 5.19 g (.0234 mole) of silver trifluoroacetate in 75 ml acetone and 2 ml of water over 18 hours. After removal of the silver bromide, water and ether were added and the ether layer was thoroughly washed with water and dilute sodium hydroxide. After removal of the ether the residue was chromatographed on silica gel, with benzene as eluant. The desired ketone was eluted, after the first 250 ml of solvent, as an oil which crystallized from ethanol to give 0.51 g (11%) of 1,1,1,4-tetraphenylbutan-4-one, m.p. 139–140.5°. Anal. Calc. for $C_{28}H_{24}O$: C, 89.3; H, 6.43. Found: C, 88.5; H, 6.17.

1,1,1-Triphenylpropan-2-one.—To 0.0495 mole of triphenylmethylmagnesium iodide, prepared by the method of Gilman and Zoellner (21), was added 4.3 g (0.055 mole) of acetyl chloride. The reaction mixture was stirred at 0° during the addition and for an additional half hour, and then was allowed to warm to room temperature. After hydrolysis with aqueous acid, the dried ether layers yielded 0.61 g (4.7%) of triphenylmethyl peroxide, m.p. 170–172°, identified by mixed melting point, and a dark residue which was chromatographed on silica gel using 50% benzene – petroleum ether as eluant. Isolated were: (*a*) 2.7 g (22%) of triphenylmethane, m.p. 91–93°, identified by mixed melting point with an authentic sample and after recrystallization from ethanol; (*b*) 2.37 g (17%) of 1,1,1-triphenylpropan-2-one (15), m.p. 138.5–140°. Anal. Calc. for $C_{18}H_{18}O$: C, 88.3; H, 6.34. Found: C, 87.8; H, 6.47.

1,1,1,3-Tetraphenylpropan-2-one.—To 7.70 g (0.0498 mole) of phenylacetyl chloride in 50 ml of benzene was added 0.0415 mole of triphenylmethylmagnesium iodide in 100 ml of benzene and 215 ml of ether. The mixture was maintained at −5° during addition and for an additional half hour and then was allowed to warm to room temperature. After hydrolysis with dilute aqueous acid the mixture was ether-extracted; from the extract precipitated 1.54 g (12%) of triphenylmethyl peroxide, m.p. 174–182°, identified by mixed melting point. After removal of the ether, the dark oily residue was chromatographed on silica gel using 50% benzene – petroleum ether as eluant. Obtained were (*a*) 2.94 g (29%) of triphenylmethane, m.p. 90–95°, identified by mixed melting point, (*b*) 1.87 g (12.5%) of 1,1,1,3-tetraphenylpropan-2-one, recrystallized from ethanol, m.p. 114–115°, and finally (*c*) 0.97 g (9%) of triphenylmethanol, m.p. 157–160°, identified by mixed melting point. Anal. Calc. for $C_{27}H_{22}O$: C, 89.5; H, 6.13. Found: C, 89.4; H, 6.25.

THE RAMAN SPECTRA OF DEUTERATED METHYL LAURATES AND RELATED COMPOUNDS[1]

R. NORMAN JONES AND R. A. RIPLEY[2]
Division of Pure Chemistry, National Research Council of Canada, Ottawa
Received June 20, 1963

ABSTRACT

The Raman spectra of methyl laurate and five derivatives selectively deuterated in the terminal methyl group, the α-methylene group, and the carbomethoxy group have been examined in the liquid phase. Raman spectra of *n*-dodecane and *n*-dodecane-1,12-d_6 have also been determined. The spectra are compared with the infrared spectra, which have been reported previously, and are analyzed in terms of current views on the vibrations of compounds containing polymethylene chains.

Whereas the infrared spectra of the esters are dominated by absorption bands associated with the carbomethoxy group, this group has only a minor effect on the Raman spectrum; the implications of this in organic structural analysis are discussed.

INTRODUCTION

The Raman and infrared spectra of compounds containing methylene chains have been investigated extensively for solid phase systems, and the vibrations have been described in terms of models of increasing degrees of sophistication. The principal contributions prior to 1957 have been listed by Nielsen and Woollett (1), and the most detailed and recent analyses are by Tung Po Lin and Koenig (2), by Snyder and Schachtschneider (3, 4), and by Tasumi, Shimanouchi, and Miyazawa (5). It is generally assumed that the polymethylene chains pack in an all-trans conformation. If the end groups are identical, the compounds of even- and odd-chain length have C_{2h} or C_{2v} symmetry respectively, and if the chain is infinitely long, V_h symmetry is acquired. By the application of the appropriate selection rules, vibrational assignments have been made for most of the bands in both the infrared and Raman spectra of the *n*-alkanes and of polyethylene (loc. cit.).

As a result of vibrational coupling between successive methylene groups, "arrays" of bands are observed, which extend over defined regions of the spectrum. The array distribution pattern shown in Fig. 1 summarizes the vibrational assignments proposed several

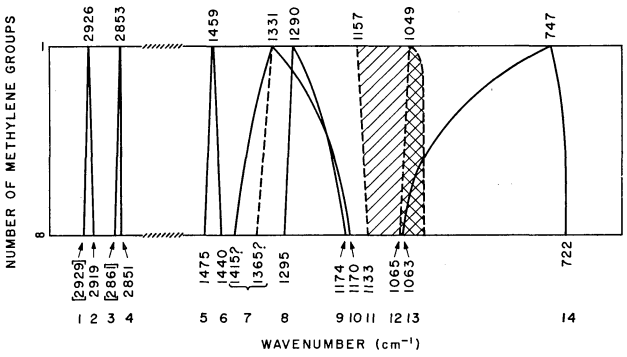

FIG. 1. Distribution of vibrational modes for an infinite polymethylene chain, according to Snyder and Schachtschneider (3, 4). The numbers 1–14 indicate the vibrations shown in Fig. 2.

[1]*Issued as N.R.C. No. 7622.*
[2]*National Research Council Postdoctoral Fellow, 1960–62.*

years ago by Sheppard and collaborators (6–8), as modified by the later measurements and normal co-ordinate calculations of Snyder and Schachtschneider for *n*-alkanes (3, 4). Within each array progressions of bands occur, the number increasing with the length of the chain. The relative intensities of consecutive bands in an array change progressively or alternatingly in accord with the selection rules for even or odd chain length. The peripheral bands usually have maximal or minimal infrared or Raman intensity, depending on the relevant selection rules. In the peripheral modes simple phase relationships usually exist between the vibrations of adjacent methylene units; these are illustrated in Fig. 2 for a section of an infinite methylene chain.* The array limits and symmetry characteristics are listed in Table I.

TABLE I

Characteristic vibrations of the infinite polymethylene chain

**See text.

While the vibrational analysis of highly oriented crystalline systems has intrinsic interest in molecular spectroscopy and polymer chemistry, the organic chemist frequently encounters polymethylene chains under conditions that do not conform to the idealized state considered above. If the chain is attached to a more bulky molecule, it will not necessarily orient in the same manner as in *n*-alkanes. Even such simple derivatives as the *n*-alkanoic acids exhibit polymorphism with which is associated striking changes in the infrared spectra (9, 10), and the spectroscopic changes associated with polymorphism in triglycerides are even more profound (11). The transfer of vibrational assignments from *n*-alkane spectra to the spectra of more complex molecules containing polymethylene chains must be approached cautiously.

In the liquid state the chain will be subject to less highly directed interchain force

**These considerations do not apply to the C—C stretching modes, for which the array folds back upon itself on the low wavenumber side. There may also be minor departures for the arrays terminating at 1295 cm^{-1} and 722 cm^{-1} which extend these limits to 1310 and 719 cm^{-1} respectively (3, 4).*

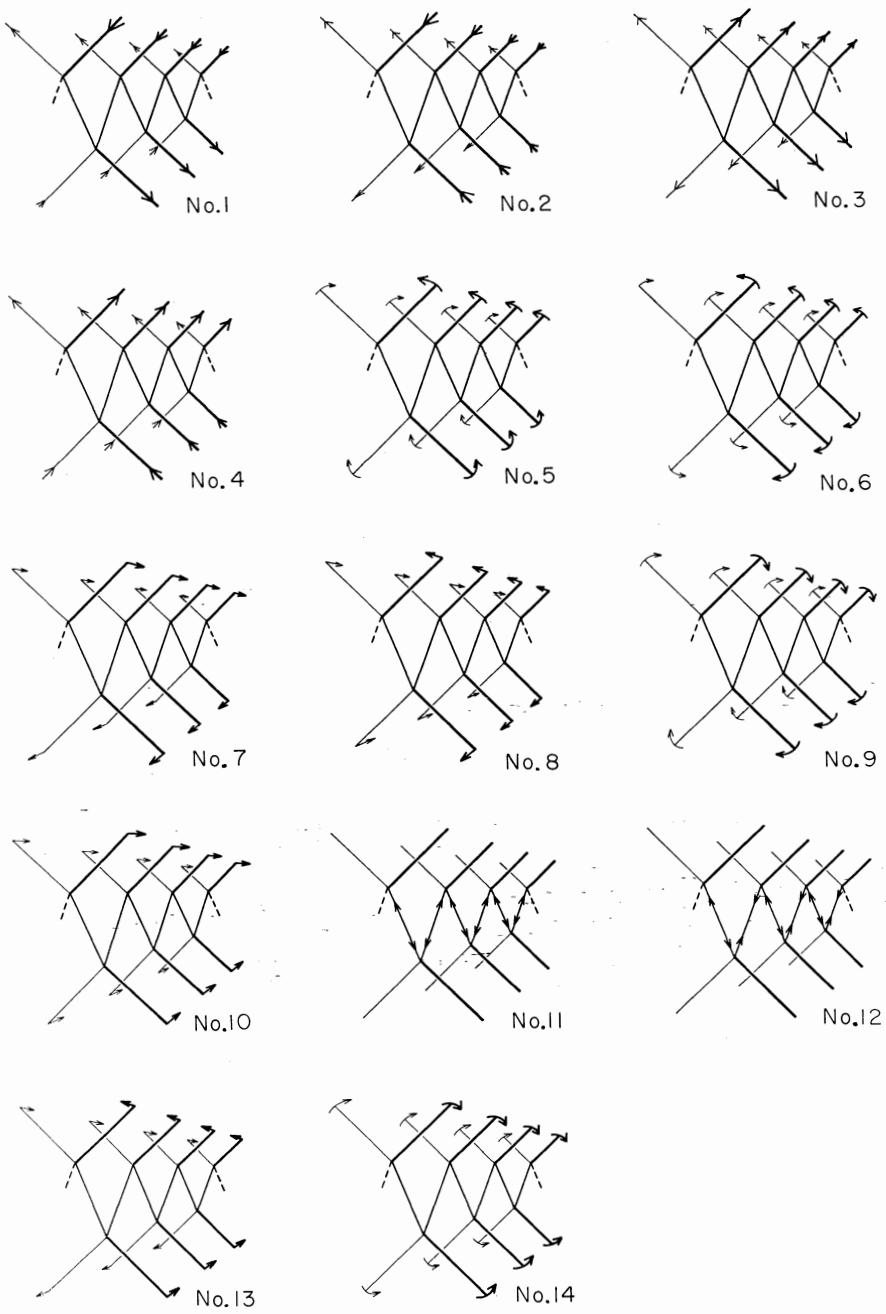

FIG. 2. Normal vibrations of an infinite polymethylene chain (the C—C bending vibrations are not included).

fields; the orientation will tend to randomize, and the vibrational frequencies, though less specific, should be more readily transferable among different types of compounds. Chain mobility in the liquid phase will permit nominal free rotation about C—C bonds, and bands characteristic of dimethylene units in gauche conformation may be observed (12, 13).

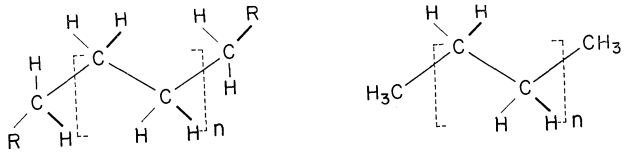
Thermodynamic considerations require that the trans linkages will predominate, and in general the gauche linkages will be randomly distributed along the chain. In some compounds, however, the statistical distribution of gauche-linked methylene groups in the chain may be determined by steric factors specific to the particular substance.*

In the liquid phase, it can be assumed that each trans-linked unit of the chain will vibrate approximately like an *n*-alkane methylene chain of the same length, and the vibrational frequencies will not be greatly affected by the nature of the terminal group, whether this be a gauche-linked methylene (I), a methyl group (II), or some other



I II

terminating substituent. The total contribution of the methylene chain to the vibrational spectrum will be determined by the sum of the contributions of the trans-linked methylene chain units supplemented by the statistically weaker contributions from methylene groups in gauche conformations. Normally the contributions from gauche–gauche-linked trimethylene units will be statistically insignificant.†‡

Each trans-linked polymethylene chain section will contribute a set of bands to the vibrational pattern within each array, at positions determined by its chain length. The superposition of bands from chain units of different length will produce the broad band systems typical of polymethylene compounds in the liquid state. Within each array the major contributions will group around one or other of the peripheral regions, and will differ in the Raman and infrared spectra in accord with the selection rules applicable to the particular array. The sharpness or diffuseness of the band system will depend on the curvature of the array boundaries. Where these are narrow and steep (as for the scissoring modes Nos. 5 and 6 of Fig. 1) the envelopes will be sharp, and will be recognized as individual "bands".

Organic chemists will probably find it more useful to deal with the vibrational spectra of polymethylene compounds in these terms than in terms of isolated, oriented chains, and these considerations have prompted our interest in the spectra of the liquid phase systems. Previous publications from this laboratory have dealt with the infrared spectra of *n*-alkanes

Note, for example, that a terminal halogen atom may favor a gauche conformation for the adjacent methylene group in —$(CH_2)_n$—CH_2—X *(14).*

†*The chair form of cyclohexane provides an example of a molecule in which all the methylene groups are gauche linked, but the overall* D_{3h} *symmetry makes this unacceptable as a general case (15, 16).*

‡*The referee has noted that assuming a reasonable value of 0.5–0.8 kcal per mole for the energy difference between a pair of trans- and gauche-linked carbon atoms in a* C_4 *chain unit, it would be anticipated that a considerable number of gauche bonds will occur in the n-dodecane chain in the liquid state. While we recognize the validity of this argument, it must be kept in mind that the conversion of a C—C linkage near the center of the chain from trans to cis conformation will require considerable movement of the other trans-linked methylene groups of the molecule, and this will introduce an entropy term that will become increasingly important as the chain lengthens. The* B_{2u} *infrared active band at 721* cm^{-1} *requires the presence of a chain of at least four trans-linked methylene groups. The intensity of this band has been shown to increase linearly with the chain length for various types of polymethylene compounds, from which it can be inferred that, in the liquid state, such compounds exist predominantly in conformational sets in which at least four consecutive methylenes are trans linked.*

Considered in toto, both the Raman and infrared spectra of these compounds agree surprisingly well with the assignments based on the vibrational analysis of the all-trans methylene chain. The Raman band o near 1079 cm^{-1} *and the infrared triplet* ζ, η, *N near 1368, 1353, and 1340* cm^{-1} *are the only peaks that can be assigned with any degree of assurance to a non-trans conformation of methylene groups. Although this is conventionally regarded as "gauche" it may in fact be considerably distorted from the geometrical gauche configuration by interactions between neighboring non-bonded hydrogen atoms.*

in the liquid phase (17), and with the effect on the infrared spectrum of replacing one of the terminal methyl groups by a carbomethoxy group (18). In these investigations use has been made of selective deuteration and chlorination to distinguish the absorption of the main chain from that of the terminal substituents. It was also recognized that the α-methylene group adjacent to the carbomethoxy group is atypical, and esters specifically deuterated or chlorinated at this position were prepared.

The Raman spectra of a selection of these compounds (III–XI) have now been investigated; the object of this paper is to draw attention to the similarities and differences among these Raman and infrared spectra, and to consider the significance of these differences in evaluating the role of Raman spectroscopy in organic structural analysis.

EXPERIMENTAL

The compounds were provided by Isabelle and Leitch, and their preparation and characterization have been described previously (18, 19). The Raman spectra were measured on a Cary Model 81 Raman spectrophotometer using 4358 Å Hg irradiation, and capillary sample tubes of 1 mm internal diameter (20). Above 900 cm^{-1} the spectra were determined on solutions prepared by adding 1.5–2.0 millimoles of the compound to 0.25–0.3 millimoles of carbon tetrachloride; the spectra at lower wavenumbers were obtained on the pure liquid.† The wavenumber scale of the spectrometer was calibrated against the emission spectra of argon and neon, and a small systematic cam correction was applied; this nowhere exceeded 2 cm^{-1}. The band intensities were corrected for the spectral response of the photomultiplier tubes. The background slopes of the spectra were corrected by tangent constructions to the bases of the bands. The spectral slit width increased progressively from 4 cm^{-1} at 3000 cm^{-1} to 5 cm^{-1} at 459 cm^{-1}.

The band intensities were corrected for the mole fraction of carbon tetrachloride, and the peak height scattering coefficients relative to the CCl_4 band at 459 cm^{-1} were calculated, but these data are not considered accurate enough to warrant publication. The illustrative curves for the ester spectra have been normalized with respect to the peak height of the C=O stretching band at 1743 cm^{-1}, and since the intensity of this band is not likely to vary much in the series, it serves to put the spectra on a semiquantitative intensity basis adequate for comparison purposes.

Polarization data were obtained by the use of cylindrical Polaroid filters; the convergence errors of the source optical system were measured by the method of Rank and Kagarise (21) and corrections applied. The peak intensity depolarization ratios (ρ_{peak}) reported for the more highly polarized bands are averaged values for all the esters. The reproducibility of the band positions is ± 1 cm^{-1}, but various instrumental factors make it difficult to assess the absolute errors of these measurements. It is considered that these do not exceed ± 3 cm^{-1} and they will be discussed in more detail in a later publication dealing with the general aspects of the technique.

RESULTS AND DISCUSSION

The spectra are illustrated in Figs. 3–11, and the positions of the band maxima are reported in Tables II–IV. No comparisons are available for ester spectra, but the spectrum of *n*-dodecane agrees with the spectra published by earlier investigators (13, 22, 23).

**The structural formula numbers given in parenthesis provide cross reference to the paper on the infrared spectra (18).*

†To facilitate comparative discussion with the infrared spectra, band positions are expressed as wavenumbers, the displacement character of the Raman bands being implied, but not stated.

Region 3100–2700 cm^{-1} (Bands a–g)

Structure characteristic of the methylene chain is best observed in the spectrum of the hexadeuterated dodecane (IV), shown in Fig. 4. The bands *c* and *f* at 2928 and 2851 cm^{-1} are obviously related to bands at 2926 and 2857 cm^{-1} in the infrared spectrum, but there is a strong additional Raman band *d* at 2891 cm^{-1}. A very weak infrared band near this position has been observed for *n*-alkanes of long chain length (17). A representative illustration of the polarized spectra is shown in Fig. 12; it indicates that band *f* is strongly polarized ($\rho_{peak} \sim 0.07$) and band *d* considerably less so ($\rho_{peak} \sim 0.4$).

The presence of a third strong band in this spectrum invalidates a simple explanation in terms of the two array patterns, each with one Raman and one infrared active edge, as suggested by Fig. 1. The positions of these array limits are in any case circumspect, since the array edges No. 1 and No. 3 are based only on normal coordinate calculations (4). For crystalline polyethylene Nielsen and Woollett (1) place the Raman active edges at 2883 and 2848 cm^{-1} respectively. This would reduce the symmetric array (Nos. 3–4) almost to a line, and reverse the direction of the antisymmetric array, putting the infrared active edge on the high wavenumber side. The identification of band *f* with the No. 3 array edge is consistent with the strong polarization of this band. Bernstein, however, regards bands *d* and *f* as resulting from Fermi resonance coupling between the No. 3 vibration and an overtone of the A_g scissoring mode (No. 6) (24), and Snyder and Schachtschneider speculate along similar lines (4). When these considerations are introduced, the commonly accepted assignment of the infrared band near 2850 cm^{-1} to a pure C—H stretching mode (No. 4) also becomes suspect. The same bands are clearly discerned in the spectra of the other compounds, and, in addition, all the compounds exhibit a weak Raman band *g* near 2730 cm^{-1} which may be a combination of No. 6 and No. 8 (A_g+B_{3g}), which is allowed.* A shoulder is observed at 2860 cm^{-1} in the Raman spectra of III and IV, but is not detected in the ester spectra.

Comparison of the Raman spectra of III and IV indicates that bands *b* and *e* of III at 2961 and 2876 cm^{-1} are associated with methyl vibrations and are assigned to antisymmetric and symmetric C—H stretching modes of the terminal methyl group. Band *e* is also present in the Raman spectra of V, VII, VIII, and X, but not in VI, IX, and XI.

**The forbidden Raman and infrared combination and overtone bands associated with V_h symmetry have been conveniently summarized by Cleveland (25).*

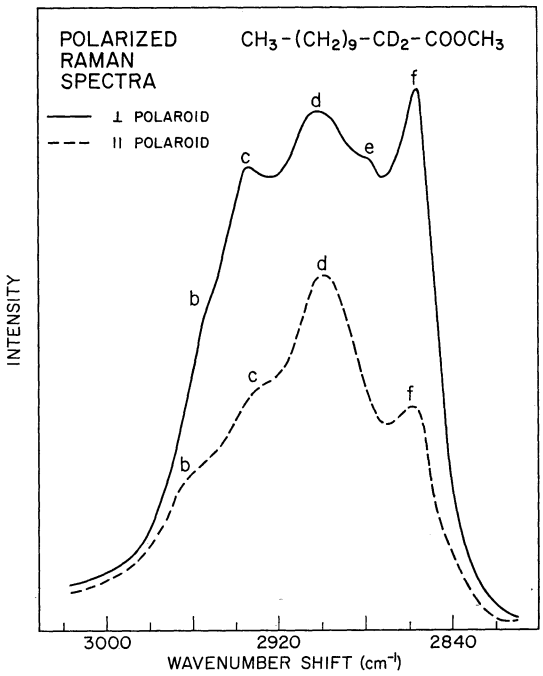

FIG. 12. Raman spectra of VII in the C—H stretching region obtained with polarized radiation. — Exciting radiation polarized transversely to the direction of observation. --- Exciting radiation polarized parallel. These curves are not corrected for convergence errors.

It disappears in the spectra measured through a parallel-oriented polarizer (Fig. 12), which suggests that it is strongly polarized, as expected for an A_1 vibration. Band *b* is displaced to 2956–2940 cm^{-1} in the ester spectra, and reduced to an inflection. Comparison among the ester spectra suggests that the carbomethoxy methyl contributes a weaker band (*b'*) at a lower wavenumber than the terminal methyl band *b*. Compounds containing —$COOCH_3$ also exhibit a prolongation of the —C—H stretching band envelope above 3000 cm^{-1}, suggestive of additional unresolved structure (band *a*). This is consistent with more clearly delineated structure in the infrared spectra.

Region 2300–2050 cm^{-1} (C—D Stretching Bands)

Compounds containing no deuterium exhibit no Raman bands in this region. The bands of the other compounds are presumed to involve C—D stretching motions and are listed in Table III. Bands associated with CD_3—, α—CD_2—, and —$COOCD_3$ are best illustrated in the spectra of IV, VII, and VIII respectively (Figs. 4, 7, 8).

The infrared and Raman spectra associated with CD_3— occur at the same positions within experimental error. In both spectra there are three bands, that at the highest wavenumber is depolarized and more intense than the other two. The two at lower wavenumber are both strongly polarized (ρ_{peak} ~0.1). The upper band is the antisymmetric C—D stretching vibration and the lower pair probably result from a Fermi resonance splitting of the symmetric mode. Bands associated with C—D deformation vibrations occur in the ranges 1115–1100 cm^{-1} and 1065–1054 cm^{-1} in both the infrared and Raman spectra (*vide infra*) and the overtone and combination bands of these vibrations will be suitably located to participate in the resonance. Similar splitting has been noted by Noether (26) in the Raman spectrum of $CD_3.OD$.

The α-CD_2— group of VII produces two weak bands at 2228 and 2144 cm^{-1} the upper of which is depolarized (ρ_{peak} ~0.78) and the lower polarized (ρ_{peak} ~0.2). There is no evidence of the third weak band at 2312 cm^{-1} seen in the infrared spectrum. The upper and lower bands of the Raman active pair can be reasonably assigned to the antisymmetric and symmetric C—D stretching modes respectively.

As in the infrared spectra, the —$COOCD_3$ group of VIII yields a complex group of five bands at 2277, 2252, 2194, 2126, and 2075 cm^{-1} the lower three of which are very strongly polarized (ρ_{peak} ~0.1) and the two upper depolarized (ρ_{peak} ~0.8). Since the deuterium exchange in these compounds is not complete, some —$COOCD_2H$ could be present, and could conceivably account for the weaker bands at 2277 and 2252 cm^{-1}. Alternatively, splitting of the degeneracy of the asymmetric —OCD_3 stretching mode in a planar structure could explain the increase in the number of bands, as has been suggested to account for the analogous bands of —$COOCH_3$ at 2995 cm^{-1} and above (18, 27).

The Raman spectra of the compounds containing more than one deuterium-substituted group are consistent with simple additivity. The polarized spectrum of XI is shown in Fig. 13 and illustrates the polarization differences among these bands. In particular this

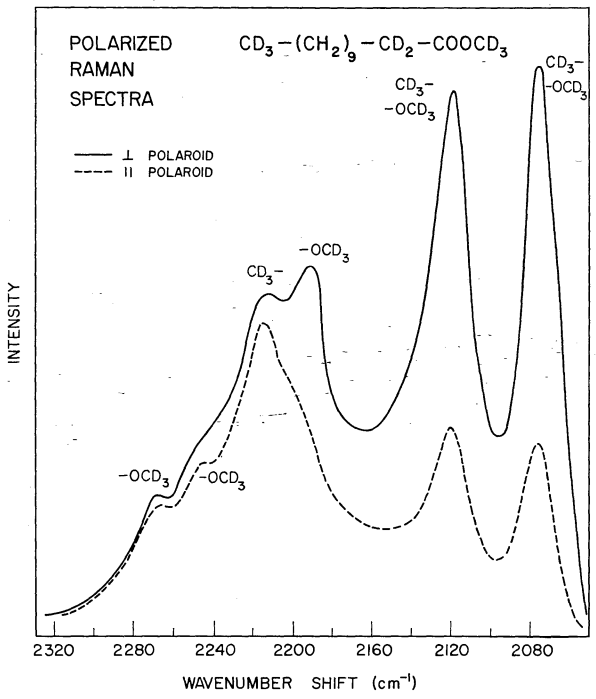

FIG. 13. Raman spectra of XI in the C—D stretching region. Experimental conditions as for Fig. 12.

diagram emphasizes the difference in the polarization characteristics of the CD_3— band at 2215 cm^{-1} and the —$COOCD_3$ band at 2196 cm^{-1}.

Region 1745–1740 cm^{-1} (Band h)

The C=O stretching band *h* in the ester spectra occurs in the range 1743–1740 cm^{-1}. It is strongly polarized (ρ_{peak} ~0.15) and relatively weaker in the Raman than the infrared spectra. The infrared band shifts appreciably from 1742 cm^{-1} to 1739 cm^{-1} on substitution

of —$COOCD_3$ for —$COOCH_3$. The failure to observe this displacement in the Raman spectra may not be significant, as the Raman bands are measured at a wider slit width and the determination of the exact peak position is less certain.

Region 1500–1290 cm^{-1} (Bands i–l)

Vibrations associated with the methylene scissoring array occur between 1475 and 1440 cm^{-1}; the infrared active peripheral mode No. 5 is observed at 1467 cm^{-1}, superimposed on methyl absorption (17, 18). This infrared band evelope is asymmetric, rising steeply on the high wavenumber side and falling less steeply to lower wavenumbers, where it shows evidence of partly resolved structure (cf. Fig. 9 of reference 17). The slow fall off may be due to contributions from less strongly infrared active modes within the scissoring array, and from scissoring modes of gauche-linked methylene units.* The Raman spectra of *n*-dodecane and the methyl laurates exhibit a strong band envelope with maximum near 1440 cm^{-1} (band *j*) and opposite skewness, rising sharply on the low wavenumber side and trailing at higher wavenumbers with an inflection (band *i*) near 1456 cm^{-1}. This pattern is consistent with the assignment of band *j* to the low wavenumber edge of the scissoring array, viz. the Raman active vibration No. 6 of Fig. 1, accompanied by diminishing contributions from other coupled scissoring modes of lesser Raman activity. It is to be noted, however, that the No. 6 vibration has A_g symmetry so that the Raman band should be polarized. In fact, the observed band can be polarized only slightly, if at all, the values obtained for ρ_{peak} range between 0.73 and 0.85. The inflection near 1456 cm^{-1} may be due in part to the antisymmetric C—H deformation vibration of the methyl group, but this cannot be the full explanation, since the band is retained with diminished intensity in the Raman spectra of IV, VI, and IX. Scissoring modes of methylene groups in gauche conformation may also be contributing.

In the infrared spectra of the methyl esters there is a prominent band at 1436 cm^{-1}, which is associated with the carbomethoxy group, and has been assigned to the symmetric C—H bending mode. There is no indication of any similar band in the Raman spectra, thus the spectra of V and VIII and of IX and X show no differences in this region. Assuming C_{3v} symmetry for the internal motions of the methyl group this band should be allowed in the Raman spectrum as well as in the infrared, and the failure to observe it will be further considered in the concluding part of this paper.

According to Nielsen and Woollett (1), the Raman active edge of the methylene wagging array occurs at 1415 cm^{-1} in polyethylene, but we have failed to observe any band near this position in these dodecane and ester spectra, nor is such a band recorded in the *n*-alkane spectra published by Mizushima and Shimanouchi (12, 13) or by Rea (23). It must therefore be extremely weak, and it is difficult to accept it as a Raman active fundamental. If the 1415 cm^{-1} band is rejected, the alternative would be to assign the Raman active (B_{2g}) edge of the wagging array to band *k*, which is observed at 1369 cm^{-1} in IV and in the range 1367–1373 cm^{-1} in the other spectra. Though measurement of the depolarization ratio was not practical, this band appears by inspection to be depolarized. A band at 1367 cm^{-1} in the infrared spectrum of polyethylene has been intensively investigated by Nielsen and Holland (28), who rejected its assignment to the B_{1u} infrared active wagging mode. We might note also that Snyder and Schachtschneider failed to observe any infrared components of the methylene wagging array of *n*-alkanes above the 1370's and we would prefer to regard the 1415 cm^{-1} location of the upper end of the wagging array as *sub judice* until more positive Raman evidence for the extension of this

**The gauche-linked methylene groups of cyclohexane have infrared active scissoring vibrations at 1453 cm^{-1} (15, 16).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

array above 1375 cm^{-1} is forthcoming. It is also relevant to note that the Raman spectra of III and IV are quite similar in the region of 1375 cm^{-1} and there is no indication of any contribution from the symmetric C—H deformation vibration of the terminal methyl groups of III, either as a distinctive group vibration, or in coupling with the wagging mode as is preferred by Snyder and Schachtschneider (3). Very weak and incompletely resolved structure between 1355 and 1340 cm^{-1} is observed in the Raman spectra of III, IV, and X which may be associated with wagging modes of gauche-linked methylene groups (cf. reference 28).

All the Raman spectra exhibit a strong largely depolarized band *l* at 1303–1301 cm^{-1} (ρ_{peak} ~0.7) which is identified with the high wavenumber edge of the twist–rock array. The peripheral band corresponds approximately with the pure twist mode No. 8 of Fig. 1. Snyder and Schachtschneider conclude from their normal coordinate analysis (4) that the arrays terminating at 1295–1175 cm^{-1} and 1063–722 cm^{-1} both involve combinations of rocking and twisting motions and, in good approximation, can be regarded as pure twisting modes at the high wavenumber edges and rocking modes at the low edges.* This constitutes the major departure of Snyder and Schachtschneider's analytical treatment from the vibrational patterns for polymethylene chains proposed by Sheppard (8), Krimm (29), Lin and Koenig (2), and other prior investigators.

Though the No. 8 twist vibration is forbidden in the infrared spectrum, a weak band at 1305–1300 cm^{-1} invariably appears in the infrared spectra of polymethylene compounds (17). Nielsen and Woollett assign this to the amorphous component of polyethylene, and, by inference, to a vibration of a gauche conformer. However, it always appears in the spectra of crystalline *n*-alkanes (12, 13) and could be a twist–rock vibration of a trans form arising under conditions where the selection rules break down.

Region 1290–1140 cm^{-1} (Band m)

The infrared spectrum of methyl laurate exhibits three strong absorption bands at 1245, 1196, and 1169 cm^{-1}. These are commonly designated "C—O stretching bands", but in fact involve coupled vibrational modes extending through the —CH_2—$COOCH_3$ "zone" of the molecule (18); they are the most characteristic feature of this structural unit in the whole infrared spectrum. The Raman spectrum of methyl laurate is singularly empty between 1290 and 1140 cm^{-1}. The esters V, VI, and VIII exhibit only a single weak band *m* between 1160 and 1140 cm^{-1}, which could be assigned to the Raman active B_{1g} rocking end of the twist–rock array (No. 9), though it is extremely weak. The esters VII, IX, and X, which contain a —CD_2— group possess a weak band at 1201–1190 cm^{-1}.

The failure to observe any Raman bands that can be specifically associated with the —CH_2—$COOCH_3$ structure in this region of the spectrum is one of the most notable distinctions between the Raman and infrared spectra of these esters. Since this structural unit has low symmetry the absence of these Raman bands does not result from the operation of selection rules and must stem from the low polarizability characteristics of the bonds involved.

Region 1140–1100 cm^{-1} (Band n)

A prominent, weakly polarized Raman band *n* (ρ_{peak} ~0.4) occurs at 1134 cm^{-1} in III, displaced to 1122 cm^{-1} in IV. In the esters containing the CH_3—$(CH_2)_9$— chain it occurs at 1127–1122 cm^{-1} and is displaced to lower wavenumber by a terminal CD_3—

**More precisely the pure twist vibration No. 8 occurs at 1295 cm^{-1} for a —$(CH_2)_{18}$ chain on the basis of Snyder and Schachtschneider's analysis, and the peripheral modes extend to 1310 cm^{-1} with a small rocking component. This rocking component reappears below 1295 cm^{-1} and becomes increasingly prominent at lower wavenumber. The low wavenumber edge is a pure No. 9 vibration.*

group. This is presumably the high wavenumber edge of the C—C skeletal array (No. 11 of Fig. 1) coupled weakly with terminal group vibrations.* In the infrared spectra, band S occurs in the same general region of the spectrum (18) and is displaced similarly to band *n* by change in the terminal group. In most of the compounds band S occurs some 8–10 cm^{-1} below band *n*. This is outside the experimental error; it is therefore not likely that the same vibration is involved though they may represent different modal combinations within the same array. The No. 11 skeletal vibration is infrared inactive though it may pick up infrared activity by coupling with the methyl rocking modes (4).

The esters VI, IX, and XI contain a terminal CD_3— group, and exhibit an additional weak band at 1109–1103 cm^{-1} which also occurs as an inflection in IV; it is presumably the antisymmetric C—D deformation mode and is also observed in the infrared spectra.

Region 1090–1050 cm^{-1} (Bands o, p)

n-Dodecane exhibits a moderately strong Raman band *o* at 1081 cm^{-1} and a weaker band *p* at 1067 cm^{-1}, both of which are slightly polarized (ρ_{peak} ~0.7); similar bands occur in the spectra of V, VII, VIII, and X. Deuteration of the terminal methyl group in IV, VI, and IX causes the relative intensities of the two peaks to invert. A band at the same position is observed in the liquid phase infrared spectra (17, 18). Band *o* does not occur in the Raman spectra of crystalline *n*-alkanes (12, 13), and Nielsen and Woollett (1) assign absorption at 1077 cm^{-1} in the infrared spectrum of polyethylene to the amorphous fraction, and attribute it to a C—C skeletal mode. If this band is a C—C skeletal mode associated with a gauche-linked chain, it constitutes the most prominent feature of the gauche conformer in the whole spectrum.

Band *p* is well recognized in the Raman spectra of polymethylene chains, and has been assigned by Nielsen and Woollett to a skeletal stretching vibration. In terms of Fig. 1 this would be the B_{2g} vibration, No. 12 of Fig. 2.† Snyder and Schachtschneider also locate the upper end of the second twist–rock array at 1063 cm^{-1}, but this vibration (No. 13 of Fig. 1) should be inactive in both the infrared and Raman spectra. The observed Raman band *p* is more probably the skeletal band, and the fact that band *p* is appreciably less polarized than band *n* supports Snyder and Schachtschneider's assignment of the higher frequency to the more symmetric A_g mode.

The intensification of the 1068 cm^{-1} band on replacement of the terminal CH_3— by CD_3— suggests the superposition by a CD_3— band.

Region Below 1050 cm^{-1} (Bands q–y)

The Raman spectra of these compounds are weak at the lower wavenumbers, and the band positions are variable. All show weak irregular structure between 1050 and 920 cm^{-1}. Compounds VII and XI possess a more prominent polarized band at 1005 cm^{-1} which could involve the —CD_2— group, though it is not observed in IX.

Most of the Raman spectra possess two bands in the ranges 909–883 and 875–859 cm^{-1} (bands *u* and *v*). Band *u* is consistent with Brown, Sheppard, and Simpson's identification of a Raman active band near 890 cm^{-1} in *n*-alkanes (7), which they assign to a C—C skeletal vibration coupled with a methyl rock. Band *u* is absent from the Raman spectrum of IV, supporting its association with a methyl group.‡ Band *v* is present in the spectrum

**In the Raman spectrum of CCl_3—$(CH_2)_9$—$COOCH_3$ this band occurs at 1106 cm^{-1}, which gives some indication of the extent to which it is displaced by coupling with the terminal methyl rocking vibration.*

†Note that Liang, Sutherland, and Krimm (30) and Nielsen and Woollett (1) assigned the peripheral vibrations of the C—C skeletal array of Fig. 1 in the reverse sequence, with the B_{2g} mode at the upper end and the A_g mode at the lower. Tasumi, Shimanouchi, and Miyazawa's assignments (5) agree with those of Snyder and Schachtschneider.

‡Absorption in the infrared at 875 and 845 cm^{-1} has been associated with the —$COOCH_3$ group (18). If these vibrations are Raman active they will complicate the interpretation of this region of the spectrum.

For personal use only.

of IV, but is not seen in the Raman spectra of crystalline *n*-alkanes (12, 13), and Sheppard and Simpson have assigned it to a skeletal vibration involving gauche-linked methylene groups (6). These authors note a similar Raman band between 840 and 810 cm^{-1} for liquid *n*-alkanes, and this also is present in most of our spectra (band *w*). Bands *u*, *v*, and *w* should all be polarized (6) but they appear too weakly in our spectra to establish this.

Compounds containing a terminal CD_3— group all possess a pair of characteristic bands at 753 and 726 cm^{-1} which probably involve CD_3— rocking vibrations. The other compounds exhibit only weak ill-defined bands below 750 cm^{-1}. In most of the spectra there is some evidence of structure between 650 and 600 cm^{-1} and a better defined band is present in the range 430–400 cm^{-1}; this is presumably associated with a C—C—C bending mode. The rocking vibration (No. 14) which delineates the low wavenumber end of the lower twist–rock array at 719 cm^{-1} is not detected in the Raman spectra.

CONCLUSIONS

In Table V the assignments for both the infrared and the Raman bands of methyl laurate are summarized, and the characteristic vibrations of the deuterated substituent groups are listed in Table VI. Most details of the spectra can be rationally interpreted in terms of previous theoretical and experimental studies on simpler molecules, though some features call for comment since they have more general implications.

The intense Raman band *d* in the C—H stretching region is difficult to reconcile with a fundamental vibration, and suggests that the conventional analysis of this part of the spectrum in terms of antisymmetric and symmetric C—H stretching vibrations may be an oversimplification; Fermi resonance with overtones and combination tones of the scissoring deformation modes may play a larger part in these spectra than has generally been recognized. The almost complete depolarization of the Raman band *j* at 1440 cm^{-1} is

unexpected, and is difficult to reconcile with the A_g edge of the methylene scissoring array to which other evidence points as the correct assignment of this band. The location of the high wavenumber edge of the B_{2g} wagging array in the 1415–1350 cm^{-1} range still remains to be positively established.

From the point of view of the organic chemist, the comparison of the Raman and infrared spectra of these compounds emphasizes that selection rules based on symmetry are inadequate to account for relative intensities in the two types of vibrational spectra. The introduction of strongly polarized bonds into an alicyclic or aliphatic molecule has a profound effect on the infrared spectrum, and, in the presence of such polar substituents, it becomes increasingly difficult to detect small changes in the purely hydrocarbon parts of the molecule (cf. Figs. 2, 3 of reference (31)). In the infrared spectrum of methyl laurate bands J, P, Q, and R are prominently associated with the carbomethoxy group, but they are not detected in the Raman spectrum. On the other hand we observe a Raman band profile extending from 1200 to 800 cm^{-1} which is characteristic of the aliphatic chain, and which is absent from the infrared spectrum or totally obscured by the strong absorption centered in the carbomethoxy group.

This distinction is a general one, thus it has been observed that the strongly infrared active "amide II" band of N-methyl acetamide is extremely weak in the Raman spectrum (32). Regions of the infrared spectra of carboxylic acids and of monosaccharides that are dominated by broad absorption bands associated with hydrogen bonds exhibit Raman structure characteristic of the alicyclic or aliphatic parts of the molecule because the hydroxyl vibrations are only weakly active. There are also indications that the Raman spectra of steroids are more sensitive than the infrared spectra to conformational and other stereochemical differences in the ring system for a similar reason.

In none of these cases is it plausible to attribute the weakness of the Raman bands to the operation of selection rules based on symmetry. In these complex compounds we are dealing with vibrating molecular systems that are grossly asymmetric, but they are systems in which the bonds are strongly polarized at their equilibrium lengths. The vibrational motions of the polar bonds will induce the large dipole moment changes required for intense infrared absorption, but the weak Raman scattering indicates that the change in the bond polarizabilities during the vibrations are small. This characteristic of polarized bonds was recognized by the early investigators of the Raman effect, and has been discussed in a more theoretical context by Placzek (33), Volkenstein and Elyashevich (34), Edgell (35), and Shorygin (36), among others. Although early attempts were made to use this effect in the structural analysis of complex molecules (37, 38) it was not pursued and should be more extensively investigated.

When the current technical problems associated with the routine measurement of Raman spectra are overcome, the organic chemist will acquire structural information that he cannot now obtain from the infrared spectra alone. From the more fundamental work on small molecules, we know that neither the Raman nor the infrared spectrum can by itself provide a complete picture of the vibrating system. To do this, both techniques must be employed, and, at a more empirical level, the same is also true for more complex organic compounds.

ACKNOWLEDGMENTS

We are grateful for the opportunity of discussing certain aspects of these spectra with H. J. Bernstein and N. Sheppard.

SPECTROSCOPIC STUDIES OF ALCOHOLS

II. THE CONFORMATION OF 2-HALOETHANOLS IN CARBON TETRACHLORIDE SOLUTION*

P. J. KRUEGER AND H. D. METTEE
Department of Chemistry, University of Alberta, Calgary, Alberta
Received August 23, 1963

ABSTRACT

Of the five conformers predicted for 2-haloethanols, only two (halogen and OH trans and gauche) can be positively identified by high resolution infrared spectroscopy. From the temperature dependence of the relative intensities of the fundamental OH stretching bands of the trans and gauche forms of the compounds XCH_2CH_2OH, where X = F, Cl, Br, and I, the gauche conformers are shown to be energetically favored in dilute carbon tetrachloride solution, with enthalpy differences between the two conformers of 2.07 ± 0.53, 1.20 ± 0.09, 1.25 ± 0.08, and 0.81 ± 0.09 kcal/mole respectively. Equilibrium constants and the conformational free energy and entropy differences are reported. Inter- and intra-molecular OH. . .X hydrogen-bond interactions are found to be similar in that the enthalpy increases in the order X = I < Br < Cl < F, and is linearly related to a *decrease* in the fundamental OH band shift, in contrast to the Badger–Bauer relationship. The molecular and thermodynamic factors governing conformational equilibria involving intramolecular hydrogen bonds are discussed.

INTRODUCTION

Since 1936, when the thermodynamic properties of hydrocarbons calculated on the basis of restricted internal rotation about a single bond were first shown to be in agreement with the experimental values (1), a large amount of information has been accumulated about the nature of the potential minima which exist for those molecular conformations in which the bonds to the atoms on the axis of rotation have taken up a staggered orientation (2). As the barriers to rotation are usually relatively low, aliphatic hydrocarbons and their derivatives exhibit a high degree of conformational heterogeneity in the gaseous or liquid state. In the crystalline state such rotational freedom is lost, and the molecule is frozen in its most stable form. Much of the early work in this field involved halogenated ethanes.

Recently Kuhn, Luettke, and Mecke (3) showed that in 2-haloethanols in CCl_4 solution only two conformers (trans and gauche) could be identified by means of infrared spectra in the OH stretching region obtained with a prism spectrophotometer. The two gauche forms in the equilibria are mirror images and thus spectroscopically equivalent. The low frequency ν_{OH} component is assigned to the gauche forms.

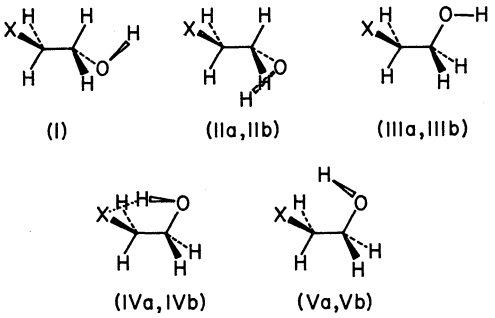
consideration rotation about C—C and C—O bonds. In four of these the OH group is in an identical environment with respect to the X atom as in one of the other five conformers because of the mirror-image relationship across the XCC plane, and hence a maximum of five conformers remain to be considered:



This work was begun with the object of checking whether the improved resolution of a grating spectrophotometer, together with temperature studies, would permit the identification of more than two conformers of XCH_2CH_2OH in dilute CCl_4 solution, where X = F, Cl, Br, and I. The temperature dependence of the infrared spectra should permit the determination of the enthalpy differences between the rotational isomers involved, and the effect of intramolecular hydrogen bonding on the equilibria. It was also of interest to compare the nature of intra- and inter-molecular hydrogen bonding of OH groups to covalently bound halogen atoms. A preliminary survey showed that the OH stretching vibration would be potentially the most useful band for the characterization of alcohol conformers.

EXPERIMENTAL

The spectra in the fundamental region were obtained with a Beckman IR-7 infrared spectrophotometer employing a NaCl foreprism and a 75 lines/mm grating in the fourth order. With a scanning speed of 6.4 cm^{-1} per minute, it was shown that bands obtained by scanning in the direction of decreasing frequency were identical in shape with those obtained by scanning in the conventional direction of increasing frequency. The frequency calibration of the instrument has been described (5). The frequencies reported by Kuhn, Luettke, and Mecke (3) are about 11.5 cm^{-1} lower than those found with our calibrated instrument. The calculated slit width in this region was approximately 0.7 cm^{-1} under the operating conditions. Higher resolution could be attained only at the expense of the signal-to-noise ratio, or by an unrealistic decrease in the scanning speed.

Double-beam operation was employed, using a pair of matched 2.00-cm fused quartz cells. Both the reference and the solution cell were jacketed with a closely fitting hollow brass block which was insulated from the spectrophotometer mounting and the rest of the sample compartment. Methylated spirits were circulated through the brass blocks, connected in parallel, from a Haake thermostat. For measurements below room temperature a dry ice – acetone mixture was used as a heat sink in conjunction with the thermostat. The entire spectrophotometer, including the sample compartment, was carefully purged with dry air to prevent condensation on the cell windows at low temperatures.

Temperatures were monitored during the course of a run by means of calibrated iron–constantan thermocouples inserted directly into the liquid in each of the two cells through Teflon stoppers in the filling ports. A Rubicon B-1 potentiometer, with a limit of error of ±1 microvolt in the low range, was used for the electromotive force measurements. The limiting factor in the temperature stabilization was the slight temperature rise experienced by the alcohol solution due to absorption of radiation. In general, temperatures are believed to be accurate to ±0.1° C above room temperature, and to ±0.2° C for those below room temperature.

Solutions were made up volumetrically with CCl_4 of spectroscopic quality, keeping concentrations below 0.006 *M* to avoid intermolecular hydrogen-bonding complications. The 2-iodoethanol was synthesized according to Norland and Hartmann (6) and 1-fluoropentane according to Vogel *et al.* (7); the others were commercial products which were carefully dried and purified by fractional distillation through a 23 theoretical-plate spinning band column. For the competitive inter- and intra-molecular OH . . . X studies both

For personal use only.

the sample and reference solutions were 1.00 M with respect to RX′ and the sample solution was 0.005 M with respect to XCH_2CH_2OH.

Measurements in the first overtone region were made with a Beckman DK-1 spectrophotometer, using matched 10-cm quartz absorption cells held at 25.0±0.1° C, and alcohol concentrations below 0.05 M in CCl_4. Some error may be introduced into the overtone measurements because of the presence of a small amount of intermolecular hydrogen bonding, although no evidence of broad association peaks was found.

RESULTS AND DISCUSSION

Conformational Enthalpy Differences and Equilibrium Constants

The spectra obtained in the 3 μ region (Fig. 1) in the temperature range −20° C to

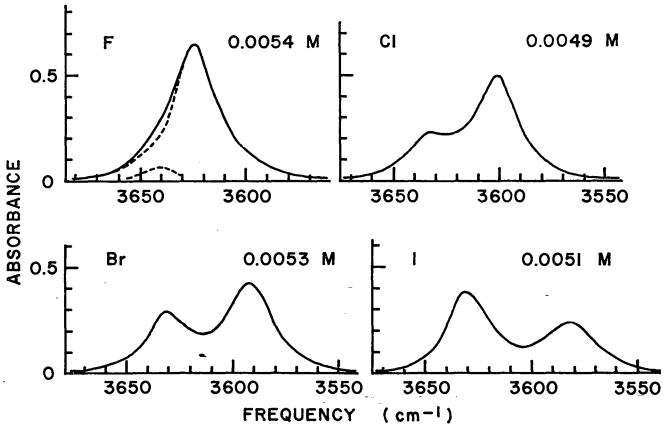

FIG. 1. The fundamental OH stretching bands of the trans and gauche conformers of 2-haloethanols in dilute CCl_4 solution. Path length = 2.00 cm.

+45° C exhibit only a partially resolved doublet for 2-chloro-, 2-bromo-, and 2-iodoethanol, of which the low frequency component is consistent with a hydrogen-bonded gauche form, and the high frequency component with a trans form having a "free" OH group. There is no evidence, such as pronounced band asymmetry, which would indicate further unresolved submaxima corresponding to other conformers.* For 2-fluoroethanol only one band showing pronounced asymmetry on the high frequency side is observed. By reflecting the low-frequency side of the band across the ordinate at the maximum and subtracting the mirror image from the observed envelope, the existence of a relatively weak trans component, which decreases as the temperature is lowered, can be established. The precision of this method is quite poor, but the components are too closely spaced (~15.5 cm^{-1}) and too wide (trans $\Delta\nu_{\frac{1}{2}}^{a}$ ~16 cm^{-1}; gauche $\Delta\nu_{\frac{1}{2}}^{a}$ ~24 cm^{-1}) to be resolved.

For 2-fluoroethanol a further broad component, of very low intensity, is found at about 3709 cm^{-1} at temperatures above 0° C only. It seems very doubtful whether such a high frequency can be assigned to an OH stretching band of an alcohol conformer. It is likely an overtone or a combination band.

The presence of only one distinguishable gauche-type conformer in these compounds implies that in the gauche orientation the hydrogen bonds are strong enough to hold the

**The contribution of conformers IIIa, IIIb, Va, and Vb (gauche with "free" OH groups) to the high frequency component or to its wings cannot be excluded completely. Since this contribution is probably small and cannot be estimated, this paper discusses the results in terms of trans conformers with "free" OH groups (I, IIa, and IIb) and gauche conformers with intramolecularly hydrogen-bonded OH groups (IVa and IVb). Although Mecke et al. (3) favor electrostatic interaction in these molecules as opposed to intramolecular hydrogen bonding, the data can be accommodated by the operational definition of the "hydrogen bond" as given by Pimentel and McClellan (25).*

For personal use only.

hydrogen atom of the OH group in that position (of the three which arise due to restricted rotation about the C—O bond) where it is nearest the X atom. Spectral studies by Mizushima and by Edgell and Glockler (8) have demonstrated that substituted ethanes consistently assume trans and gauche forms rather than trans and cis types. The azimuthal angle in the gauche form may, however, be larger than 60° because of the oxygen–halogen repulsion due to electrical and steric factors. According to electron diffraction investigations of Bastiansen (9) the azimuthal angle in ethylene glycol and 2-chloroethanol appears to be 74°. This corresponds to an O to O distance of 2.96 Ångstroms in ethylene glycol, and an O to Cl distance of 3.17 Ångstroms in 2-chloroethanol. Similar investigations of Yamaha and Igarashi (10) led to angles of 75° in 2-chloroethanol and 60–70° in 2-fluoroethanol. They concluded that the latter compound was completely in the gauche form. The presence of only one distinguishable trans-type conformer suggests that in the trans orientation the OH group is so far removed from the halogen atom that the three potential minima governing rotation about the C—O bond are equivalent.

In the application of the Beer–Lambert absorption law to spectroscopic data involving an equilibrium like [1], the following expressions may be derived (11):

$$\ln (I_0/I)_t = E_t N_t l, \quad [2]$$

$$\ln (I_0/I)_g = E_g N_g l, \quad [3]$$

where I_0 and I are the intensities of incident and transmitted radiation respectively, E_t and E_g are the molecular extinction coefficients for the trans and gauche forms (at different frequencies), N_t and N_g are the numbers of molecules in the trans and gauche forms, and l is the path length. From these expressions

$$N_t/N_g = (E_g/E_t) \ln (I_0/I)_t/\ln (I_0/I)_g. \quad [4]$$

Experimental evaluation of (N_t/N_g) and hence the equilibrium constant is not usually possible by this method since E_g and E_t, the intrinsic molecular absorption coefficients for molecules known to be gauche and trans respectively, cannot be obtained, except perhaps by analogy with some model compounds.

If the number of molecules in one of the gauche forms involved in equilibrium [1] is N_g', and the number of molecules in the mirror-image gauche form is N_g'', then

$$N_g = N_g' + N_g'' = (N_t/K) + K'N_t \quad [5]$$

since $K = (N_t/N_g')$ and $K' = (N_g''/N_t)$. From the reciprocal relationship of K and K' it follows that $N_g = (2N_t/K)$, or

$$K = (2N_t/N_g) = 2(E_g/E_t)\ (D_t/D_g), \quad [6]$$

where D_t and D_g are the absorbances at the trans and gauche band maxima respectively. Provided the assumption $E_t = E_g$ is made, the equilibrium constants at 28° C calculated from [6] are 0.20, 0.92, 1.36, and 3.22 for X = F, Cl, Br, and I respectively. If a Lorentz band shape is assumed for both the trans and the gauche bands, then band areas can be estimated from the analytical expression

$$A = 2.303\ (\pi/2)D(\Delta\nu_{\frac{1}{2}}^{a}) \quad [7]$$

using the approximate $\Delta\nu_{\frac{1}{2}}^{a}$ values in Table I.* The K values (28° C) obtained on this basis are 0.13, 0.96, 1.20, and 2.08 for X = F, Cl, Br, and I respectively.

**For 2-fluoroethanol these band widths were obtained from the components established by graphical resolution. For the other alcohols the band widths reported in this table were obtained by doubling $\frac{1}{2}\Delta\nu_{\frac{1}{2}}^{a}$ as measured to the ordinate at the apparent band maximum on that side of the band which is relatively free from overlap.*

If the reasonable assumption is made that (E_g/E_t) is relatively temperature independent over a small temperature range,* the van't Hoff equation is applicable in the following form:

$$[8] \qquad \log (D_t/D_g) = -\Delta H/(2.303\,RT) + [\Delta S/(2.303\,R) - \log (2E_g/E_t)]$$

where ΔH is the enthalpy difference between the conformational isomers, and ΔS is the corresponding entropy difference. From graphs of log (D_t/D_g) versus $1/T$ (Fig. 2), the

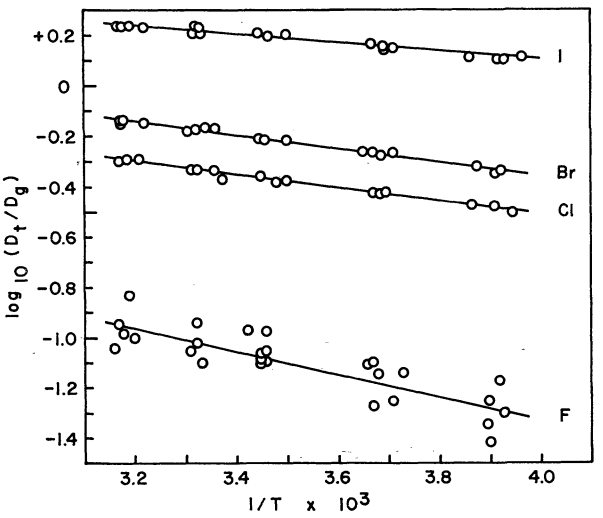

FIG. 2. The effect of temperature on the trans/gauche absorbance ratio in 2-haloethanols in dilute CCl_4 solution.

quantity ΔH can be obtained directly from the slope, and ΔS can be estimated if the assumption is made that $E_g = E_t$. This is certainly not true in intermolecular association, but is probably a better approximation in intramolecular association involving weak hydrogen bonds in five-membered rings. Baker and Kaeding (13) have argued that in the latter system the hydrogen bond may be largely an electrostatic effect, and that charge transfer phenomena, which are mainly responsible for increases in band intensity, are only of secondary importance in cases where highly bent hydrogen bonds to halogen atoms are involved. Table I includes the thermodynamic values obtained by a least squares analysis of the data on the basis of equation [8]. For the ΔH values 95% confidence limits are also given (18).

The conformational enthalpy difference increases in the order X = I < Br ≈ Cl < F, in all cases the gauche form having the greatest stability, as based on the decrease of the ratio D_t/D_g with decreasing temperature. This is in contrast to the qualitative deductions of Kuhn, Luettke, and Mecke (3), who suggest, on the basis of spectra at ambient temperature only, that in 2-bromoethanol the conformational energy difference must be nearly zero since $D_t \approx D_g$, and in 2-iodoethanol the trans form appears to be more stable since this is the only one of the compounds under consideration where $D_t > D_g$. However, it must be borne in mind that absorption band areas (A) should be compared rather than

*Over the small temperature range employed in this work the temperature dependence of the molar extinction coefficient of an absorption band arising in a given conformer is expected to be small. See, for example, the results reported by Lisitsa and Khalimonova (12) for CH stretching vibrations in a number of aromatic compounds.

*The frequencies, band widths, and absorbance ratios reported are for measurements close to 28° C to simplify the table. The form of the equilibrium is: gauche ⇌ trans; $K = 2[\text{trans}]/[\text{gauche}]$.

†Shifts for XCH_2CH_2OH observed by Schleyer and West (14): 12, 32, 38, and 46 cm^{-1} for F, Cl, Br, and I respectively. Corresponding intermolecular shifts for MeOH...*n*-BuX bonding (14): 19, 37, 41, and 47 cm^{-1} respectively for above X order.

‡Reported by Oki and Iwamura (15) at 3634.6 and 3620.9 cm^{-1}.

§The large 95% confidence limits for the ΔH value for 2-fluoroethanol are due to the low precision of the graphical resolution of the doublet.

¶Reported by Josien and Pineau (16) at 3623±5 cm^{-1} and 3597±4 cm^{-1}.

‖Using an optical method involving the relative intensities of the C—Cl stretching frequencies at 669 cm^{-1} and 760 cm^{-1} in the gauche and trans forms respectively, as well as the intensity of the C—H stretching band at 2890 cm^{-1} common to both conformers, Mizushima *et al.* (17) found $\Delta S = 3.7 \pm 0.4$ e.u. for experimental measurements in the gas phase.

apparent peak absorbances, and in 2-iodoethanol the gauche band has a half-intensity width which is more than 50% greater than that of the trans band, so that $A_g \approx A_t$ within the experimental error of the area measurements. In view of the resolution difficulties it seems unwise to attempt to use estimated band areas in the ΔH determinations. Also, since changes in the relative widths of these trans and gauche bands with temperature are not pronounced, the rate of change of D_t/D_g with temperature should approximate to the corresponding rate of change of A_t/A_g, leading to correct ΔH values.

In the 1,2-dihaloethanes thermodynamic calculations, dipole moment, infrared, and Raman studies all show that the trans isomers are energetically favored in the gas phase, with increasing population of the gauche form in the liquid state and in solution due to solvent stabilization of the form having the largest dipole moment (11). Only one recent gas phase ΔH value for the 2-haloethanols appears to have been published. Mizushima *et al.* (19) report that the gauche form of 2-chloroethanol is more stable than the trans form by 0.95 kcal/mole. The corresponding ΔH value in CCl_4 solution obtained in this work is 1.20 kcal/mole, also showing stabilization of the more polar form of the molecule in solution, even by non-polar although highly polarizable CCl_4 molecules.

The enthalpy differences between the gauche and trans forms are undoubtedly determined by a number of factors, among which the most important would be:

(*a*) steric repulsion between the oxygen and the halogen atoms in the gauche form, which would increase in the order F < Cl < Br < I, and thus tend to make the trans form more stable;

(*b*) electrostatic repulsion between the oxygen and halogen atoms (or between the C—X and C—O dipoles), which would also favor the trans form; and

(*c*) OH...X hydrogen bond interaction, which would stabilize the gauche form.

According to Parker (20) the idea that the proton-acceptor in hydrogen-bond formation must be an element of small atomic radius and high electronegativity, although true for the strong hydrogen bonding to anions (as in the bonding of water to halide ions, where the strength increases in the order $I^- < Br^- < Cl^- < F^-$), cannot automatically be extended to the much weaker hydrogen bonding to covalently bound electronegative atoms. Further, there is a deficiency of information about intramolecular OH...X hydrogen bonds, where the restricting geometry of the system may affect (*c*), and perhaps

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

even change the order of X in the bond strength series and make it different from the intermolecular order. In the formation of intramolecular hydrogen bonds between OH groups and halogen atoms, increasing size of the halogen atom may favor the bond strength since the minimum OH. . . X distance is fixed by the system. On the basis of n.m.r. spectroscopy Allan and Reeves (21) suggest that the flourine atom is too small to lead to measurable stability of a cis-isomer in *o*-fluorophenol. Similarly, the ultraviolet spectra of the *B*-bands of *o*-fluorophenol (22) and *o*-fluorobenzoic acid (23) indicate the absence of strong intramolecular hydrogen bonds in these compounds. However, these examples are not strictly analogous to the gauche form of FCH_2CH_2OH since the benzene ring modifies the character of the F atom and the OH group.

Intra- vs. Inter-molecular OH. . . X Hydrogen Bonding and the ν_{OH} Shift

In intermolecular hydrogen bonding, the extent by which the OH stretching frequency of the "bonded" molecule is displaced from the corresponding frequency of the "free" molecule has long been accepted as an approximate measure of the strength of the hydrogen bond (24, 25). The application of the Badger–Bauer rule to intramolecular hydrogen bonds in the *o*-halophenols has been criticized by Baker and Kaeding (13) on the grounds of a repulsive interaction between the OH bonding orbital and the donated lone-pair orbital of the halogen in the cis form of the molecule, so that the ν_{OH} shift observed is not a measure of the net energy of the resultant bonds.* This may be a valid argument for a rigid aromatic molecule where the OH group is preferentially constrained to the plane of the ring by resonance, making such repulsive interaction in the cis form a maximum, but in the more flexible saturated 2-haloethanols this should be of minor importance. In fact, a quasi-gauche form of the molecule allows for a certain amount of adjustment of the OH. . . X distance to attain the maximum hydrogen bond strength permitted by the geometry of the system.

On the basis of a large number of measurements on the 1,2-halohydrin steroid systems of known conformation, Nickon (26) has pointed out that, in the absence of other disturbing factors, the halogens follow the sequence I > Br > Cl in their ability to decrease the fundamental OH stretching frequency, whereas they adopt the reverse order in their power to increase the C—OH stretching frequency. Since the relationship for the bonded ν_{OH} shift is the reverse of the electronegativity sequence, Nickon suggests that the perturbing action of a halogen atom must be governed not only by electronegativity effects, but also by the proximity and polarizability of the electrons on the halogen.

On the basis of frequency shift data for the bonding of methanol and phenol to *n*-butyl and cyclohexyl halides, Schleyer and West (27) concluded in 1959 that the intermolecular hydrogen bond strength decreased in the order I > Br > Cl > F. These authors further concluded that although the ν_{OH} shifts for the intramolecular bonds in *o*-halophenols and 2-haloethanols indicated the same order of hydrogen bond enthalpy, the data for these systems could not be interpreted unambiguously because the groups were rigidly held. Recently West *et al.* (28) have reversed their arguments on the basis of more complete thermodynamic studies of the phenol – cyclohexyl halide system, and have shown that the Badger–Bauer rule is invalid for this system.

Bernstein (29) has offered an explanation for the lack of general correlation of $\Delta\nu$ with ΔH. The enthalpy change measures the total interaction energy of the system AH. . . BY, i.e. the strength of the H. . . B bond compensated in part by A—H and B—Y weakening, whereas $\Delta\nu$ measures only the weakening of the A—H bond. For the same proton donor

They deduced the order of intramolecular OH . . . X bond strength in o-halophenols to be Cl > Br > F > I.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$\Delta\nu$ and $-\Delta H$ may correlate for minor changes in the proton acceptor (in Y), but not necessarily for changes of the acceptor atom B. In this connection it may be noted that Nickon (26) has observed an increase in C—OH frequencies in steroid 1,2-halohydrins in the order I < Br < Cl.

The extended work of Josien and her associates (30) clearly shows that although a linear "correlation zone" of increasing $-\Delta H$ with increasing $\Delta\nu$ exists for a series of hydroxylic proton donors bonded to various bases, it is by no means a precise relationship. Taken over a large range of $\Delta\nu$ (up to and exceeding 300 cm^{-1}) and up to enthalpies of 6 kcal/mole, the Bauer–Badger relationship is a very approximate one. For relatively low enthalpies and small frequency shifts, Josien's work shows that good linear enthalpy vs. $\Delta\nu$ relationships are obtained for the bonding of phenol and *p*-chlorophenol to cyclohexyl halides, but that the slope is *in opposition* to the Bauer–Badger correlation.

Figure 3 (*a*) shows a comparative plot of ΔH vs. $\Delta\nu$ for the intermolecularly hydrogen-

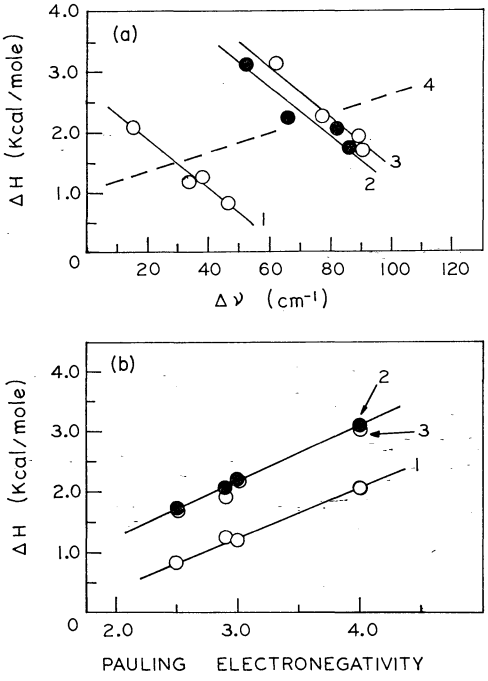

FIG. 3. (*a*) Enthalpy change vs. OH frequency shift correlations on OH ... X bond formation. (1) Intramolecular bonds in XCH_2CH_2OH. (2) Intermolecular phenol ... cyclohexyl X bonds (28). (3) Intermolecular *p*-chlorophenol ... cyclohexyl X bonds (30). (4) Broken line indicates approximate Bauer–Badger "correlation zone" taken from Fig. 19, p. 51, ref. 30. The scatter of points along this zone is sufficient to include the 12 points on this graph.
(*b*) Enthalpy change vs. Pauling electronegativity for X atom. Points have same significance as above.

bonded systems of phenol and *p*-chlorophenol with the cyclohexyl halides, as well as the present data for the intramolecular bonds in 2-haloethanols. All three correlations have identical slope; from this parallel behavior it is reasonable to conclude that the order of increasing intramolecular hydrogen bond strength in the 2-haloethanols is F > Cl > Br > I, this being the order established by West *et al.* (28) for intermolecular OH hydrogen bonds to halogens by a method not open to question. Figure 3 (*b*) confirms the parallelism of intra- and inter-molecular OH...X bonds, since both exhibit the same linear ΔH

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

dependence on the halogen electronegativity. It is interesting to note that both the intermolecular systems lie on the same line in this graph.

Becker (31) has discussed the Badger–Bauer relationship in the light of experimental data on a variety of alcohol complexes with strong bases, and reports only approximate behavior. In this context the work of Joesten and Drago (32) shows that the Bauer–Badger rule holds to ± 0.5 kcal/mole for adducts of phenol with nitrogen and oxygen donors, but here again $\Delta\nu$ values range from 144 to 553 cm^{-1}, with accompanying enthalpies from 3.2 to 9.2 kcal/mole. It appears that the prediction of hydrogen-bond enthalpies from frequency shifts is least reliable in the weak hydrogen bond range.

Figure 4 shows that in 2-haloethanols ν_t increases in an approximately linear manner

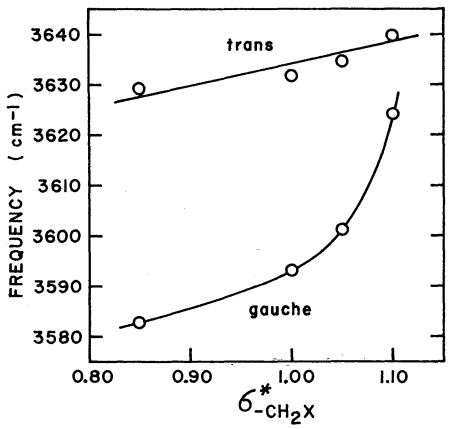

FIG. 4. The inductive effect of the halogen atom on ν_{OH} in the trans 2-haloethanols, and the frequency lowering due to hydrogen bonding in the gauche 2-haloethanols.

with the Taft inductive parameter σ^* of the substituent (33), whereas the ν_g behavior is non-linear. Bellamy's recent analysis (34) of group frequency shifts suggests that, in general, frequencies arising in groups well removed from the substituent in aliphatic systems follow the order of σ^* values, which measure the true inductive effect, but that where non-bonded interactions predominate the order of effectiveness of the substituent groups will more closely follow the order of the Pauling electronegativities since these include both inductive and polarizability effects. Figure 5 shows that ν_g is linearly related to the electronegativity of the X atom; as far as ν_t is concerned the frequency change is too small to distinguish this correlation from that with σ^*. Many group-frequency shifts are still poorly understood; in this series ν_t increases approximately linearly with increasing polarity of the OH group.

With increasing temperature, ν_{OH} for both the trans and gauche forms increases by approximately 0.8 cm^{-1} per 10° temperature rise, as shown in Fig. 6. This is probably related to the decreasing density of the solvent, which means that, on the average, the solvent molecules will be further removed from the solute molecules, and their influence will be reduced.

Rotational Entropy Differences

The review by Mizushima (2*a*) indicates that steric repulsion between movable groups is the major factor in determining the nature of the potential function hindering internal rotation, and that electrostatic interactions play a less significant role, except if hydrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

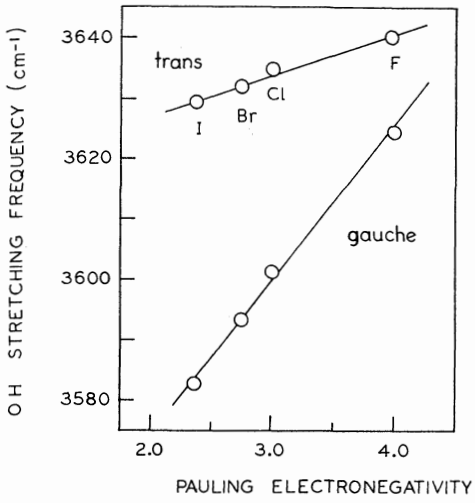

FIG. 5. The relationship of ν_{OH} in the trans and gauche XCH_2CH_2OH conformers to the Pauling electronegativity of the X atom.

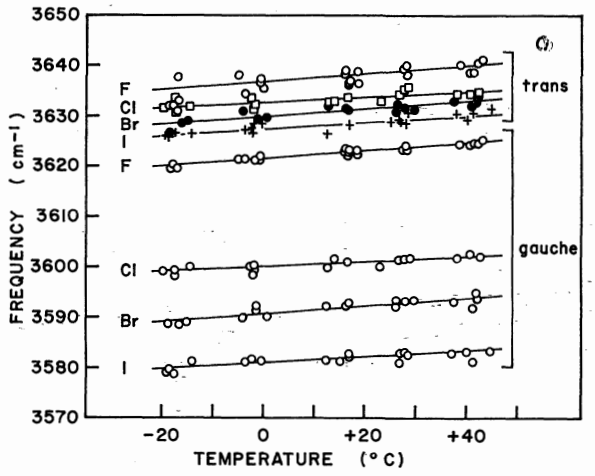

FIG. 6. The temperature dependence of the trans and gauche OH stretching frequencies in 2-haloethanols in dilute CCl_4 solution.

bonding is involved. In considering rotational isomerism in 2-haloethanols it is important to distinguish between the strength of the hydrogen bond and the population of the hydrogen-bonded conformation.

Jaffe (35) has pointed out that, in general, entropy changes in intermolecular hydrogen bond formation exceed those in intramolecular hydrogen-bond formation, and Mizushima (2(*b*)) has discussed the entropy differences of trans and gauche forms of 2-chloroethanol, which arise mainly from differences in the internal rotation about the C—C and C—O bonds. The calculated entropy differences arising from overall rotation and normal vibrations are less than 1/10th of the observed value (17). The fact that one of the conformers has a hydrogen bond is regarded as the main reason for the entropy difference. In the trans form rotation of the H atom about the C—O bond leads to three equivalent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

stable positions, whereas in the gauche form this leads to one OH position which is much more stable than the other two, so that $S_g < S_t$. Further, the torsional oscillation frequency would be increased in the gauche form, also making the entropy of the gauche form smaller than that of the trans form. The ΔS values calculated in this work on the basis that $E_g = E_t$ increase as the strength of the intramolecular OH...X bond decreases. One factor which may lead to greater "ordering" of the system on hydrogen-bond formation in the series F < Cl < Br < I may be the increasing size of the halogen atom, which in the gauche conformation progressively comes closer to the hydroxyl proton, and may bind it more effectively during librational motion. The geometric factor involved in intramolecular hydrogen bonding shows up clearly here since the data of West *et al.* (28) on intramolecular OH...X bonds reveal the opposite ΔS order, i.e. largest for bonding to the strongest proton acceptor (F) since the optimum OH...F distance can be achieved. Solute–solvent interaction may also enter into the picture for the intramolecular hydrogen bonds, since the polarity of the OH bond depends on X and therefore the trans form may "order" the polarizable CCl_4 molecules in the vicinity in the series I < Br < Cl < F. The ΔS change on intramolecular hydrogen bond formation would be affected by such interaction in the trans conformer.

At present there is no information on the potential barriers to internal rotation in these molecules (36). It is possible that these barrier heights could be evaluated from the torsional frequencies in the far infrared region.

Competitive Inter- and Intra-molecular OH...X Bonding

Figure 7(*a*) shows the spectra of 2-iodoethanol (0.005 *M*) in the presence of a 1.00 *M* concentration of 1-iodobutane and 1-fluoropentane respectively in CCl_4 solution. Figure

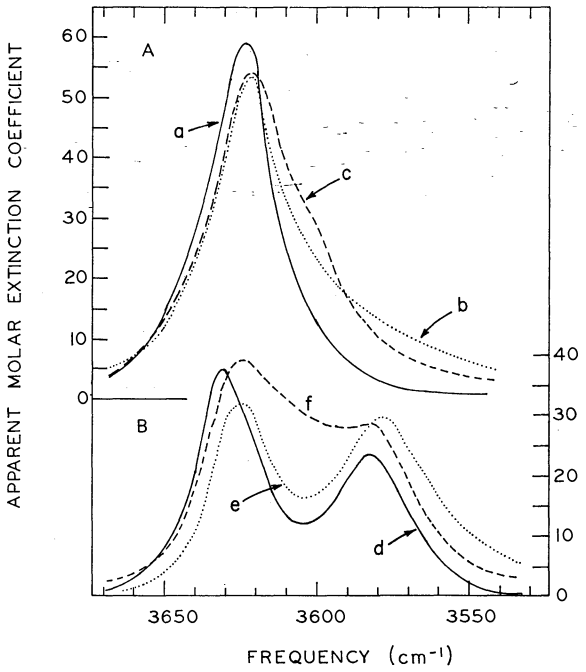

FIG. 7. Competitive inter- and intra-molecular OH ... X interactions. 7 (*b*) shows the effect of the same two alkyl halides on 2-fluoroethanol under the same conditions. In the competing equilibria

K_{intra} = 2[trans]/[gauche] and K_{inter} = [complex]/[trans][RX′]. Since K_{intra} = 2.08 for X = I and 0.13 for X = F, and K_{inter} = 0.28 for X′ = I and 1.5 for X′ = F (intermolecular methanol K values from preceding paper) it is easy to show that under the conditions of these experiments the ratio [complex]/[gauche] should be ≈1.5 for 1.00 *M* RF in 0.005 *M* ICH_2CH_2OH, and ≈0.02 for 1.00 *M* RI in 0.005 *M* FCH_2CH_2OH. Although these are only crude estimates, the experimental curves show that the intramolecular ICH_2CH_2OH equilibrium is upset more by intermolecular bonding to RF than is the intramolecular FCH_2CH_2OH equilibrium by the addition of either RF or RI. No band resolution was attempted, but in all cases the third component appears in the expected region of the spectrum. These studies provide further evidence that in this system covalently bound halogen atoms follow the order of electronegativity in their ability as proton acceptors.

First Overtone Measurements on 2-Haloethanols

In the first overtone OH stretching region trans/gauche doublets very similar to those shown in Fig. 1 are observed. The overtone band widths are increased with respect to the corresponding fundamental band widths by a factor of about 2.7. The overtone data are summarized in Table II, together with the calculated mechanical anharmonicities (x_e).

TABLE II

First overtone OH band parameters of trans and gauche conformers of XCH_2CH_2OH in CCl_4 solution

	Frequencies (cm^{-1}) (25° C)		Band widths (cm^{-1}) (25° C)		Mechanical anharmonicity (x_e)		
X =	trans	gauche	trans	gauche	trans	gauche	D_t/D_g (25° C)
F	7113	7079	38	57	0.0218	0.0224	0.15
Cl†	7097	7036	73	64*	0.0226	0.0222	0.53
Br	7096	7012	63	71	0.0221	0.0232	0.71
I	7086	6983	60	85	0.0227	0.0242	1.62

*2-Chloroethanol appears to be exceptional in that the gauche band width is less than the trans band width for both the fundamental and the first overtone vibrations.
†Piccolini and Winstein (37) have reported three components at 7101, 7072, and 7029 cm^{-1}.

It is seen that the x_e is constant for both conformations of all four compounds, having an average value of 0.0227±0.0015 (maximum deviation from the mean). These values are in agreement with those reported by Moccia and Thompson (38) for a large number of substituted phenols and aliphatic alcohols. The XCH_2CH_2OH trans and gauche enthalpy differences also correlate linearly with the overtone $\Delta\nu$ shifts.

The fundamental to first-overtone integrated intensity ratio (A_{01}/A_{02}) for a vibrational band is governed by both the mechanical and the electrical anharmonicity. Electrical anharmonicity in a diatomic molecule implies that the dipole moment (M) does not change linearly as the bond distance (r) is altered, but that M must be replaced by

[9] $$M = M_0 + M_1 r + M_2 r^2 + \ldots$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

If terms higher than quadratic are ignored, the quantity $B = M_2/M_1$ may be calculated according to Russell and Thompson (39), who showed that for a diatomic oscillator approximation with $x_e \ll 1$, both the methods of Dunham (40) and of Heaps and Herzberg (41) lead to the expression

$$[10] \qquad (A_{O2}/A_{O1}) = x_e\,(1-2B/ar_e)^2$$

where a is the constant in the Morse potential and r_e is the equilibrium OH bond length. As x_e is constant for both conformers in the 2-haloethanols, and changes in both a and r_e will be relatively small, differences in (A_{O2}/A_{O1}) must arise because of different B values for the two conformers.

Since, because of band overlapping, neither A_{O1} nor A_{O2} could be measured, they were estimated by using the peak absorbances and the approximate half-band widths (Tables I and II), on the assumption that both the fundamental and first overtone band envelopes conform to the Lorentz band shape. This has been shown to be a relatively satisfactory assumption for the fundamental OH band of methanol (42). The application of this method to our spectra of methanol in CCl_4 solution to obtain B led to a root of [10] which was within 5% of the value obtained by Moccia and Thompson (38) by rigorous methods, and which they supported by quantum mechanical calculations. Despite uncertainties in estimating r_e, there appears to be little doubt that for all four 2-haloethanols $|B_{trans}| > |B_{gauche}|$, the average values being 0.9 and 0.7 respectively. For NH bonds in secondary amines it has been shown (39) that the dipole moment change becomes more linear as the ionic character of the bond increases. For a completely ionic bond B should be zero. This concept is consistent with hydrogen bonding in the gauche form of the 2-haloethanols.

ABSTRACT

The OH stretching region was examined for the compounds F_3CCH_2OH, Cl_2CHCH_2OH, Cl_3CCH_2OH, and Br_3CCH_2OH in dilute CCl_4 solution. The first two compounds exhibit temperature-dependent band asymmetry which is due to trans–gauche equilibria arising from rotation about the C—O bond, with relatively small populations in the trans forms. Enthalpy differences of 3.3 and 2.4 kcal/mole between the conformers were obtained for these two compounds respectively. Although symmetrical at lower temperatures, the band for Cl_3CCH_2OH shows the presence of a small amount of the trans conformer at temperatures above 45° C. These results are discussed in terms of intramolecular OH ... X hydrogen bond interaction, inductive effects, non-bonded interactions, O—H bond polarization, C—X bond polarizability, and the size of the halogen atoms in a geometrically constrained system.

INTRODUCTION

Recent work in this laboratory (1) has shown that 2-haloethanols in dilute CCl_4 solution exhibit an equilibrium between trans and gauche forms arising because of restricted rotation about the C—C bond. Thermodynamic studies have shown that the gauche form is more stable, and that the enthalpy difference (ΔH) between the two forms decreases in the order X = F > Cl ~ Br > I, whereas the frequency difference ($\nu_t - \nu_g$) increases in the order F < Cl < Br < I. The ΔH versus ($\nu_t - \nu_g$) behavior is linear, and parallels the behavior observed for intermolecular hydrogen bonding of phenol to cyclohexyl halides (2, 3) where it has been demonstrated that the OH frequency displacement does not measure the strength of hydrogen bond formation. Both the inter- and intra-molecular hydrogen bonding of OH groups to halogen atoms thus appears to disagree with the accepted Bauer–Badger relationship (4), but correlates with high precision in the opposite sense.

As an extension of this work some 2,2-di- and 2,2,2-tri-haloethanols have been examined under the same experimental conditions. On the basis of the measurements on FCH_2CH_2OH described in the preceding paper (1), it was expected that F_3CCH_2OH would be completely intramolecularly bonded. However, Cannon and Stace (5) have reported a "free" OH stretching band for trifluoroethanol in CCl_4 solution (3617 cm^{-1}), which persisted even in the pure liquid state (3628 cm^{-1}) and in dilute solution in perfluorocarbon (3644 cm^{-1}). Their interpretation did not support intramolecular OH...X bonding. Oki and Iwamura (6), working with a grating spectrophotometer and a spectral slit width of 1 cm^{-1}, found an OH band for F_3CCH_2OH in 0.003 *M* CCl_4 solution, which was asymmetric on the high frequency side, and interpreted it in terms of an unresolved doublet due to trans–gauche isomerism because of restricted rotation about the C—O bond. From mathematical resolution of the doublet (area of trans band/area of gauche band = 0.042) they concluded that trifluoroethanol was predominantly in the intramolecularly bonded gauche form. In some earlier work Haszeldine (7) had also considered intramolecular OH...X hydrogen bonding in primary and secondary haloalcohols, but his spectra, obtained with the poor resolving power of a NaCl prism, did not permit him to come to detailed conclusions about the nature of the "free" OH band. The recent work of Rao

and his associates (8, 9) on the acidity of the hydroxyl proton and the basicity of the hydroxyl oxygen, as deduced from solvent effect studies, together with the uncertainty in the interpretation of the OH absorption as described above, led to this investigation of a larger number of di- and tri-haloethanols at several temperatures.

EXPERIMENTAL

A Beckman IR-7 infrared spectrophotometer was employed under the conditions described previously (1). Alcohol concentrations were always below 0.006 *M*. A Lauda UltraKryostat UK 70 was used to regulate the temperature of the cells over the range 0–60° C. The haloethanols were all commercial materials purified by sublimation, recrystallization, or fractional distillation through a 23 theoretical-plate spinning band column. Analytical reagent grade CCl_4 was dried over P_2O_5 and distilled through a 50 theoretical-plate spinning band column.

RESULTS AND DISCUSSION

Figure 1 shows the nature of the OH bands obtained for F_3CCH_2OH, Cl_2CHCH_2OH,

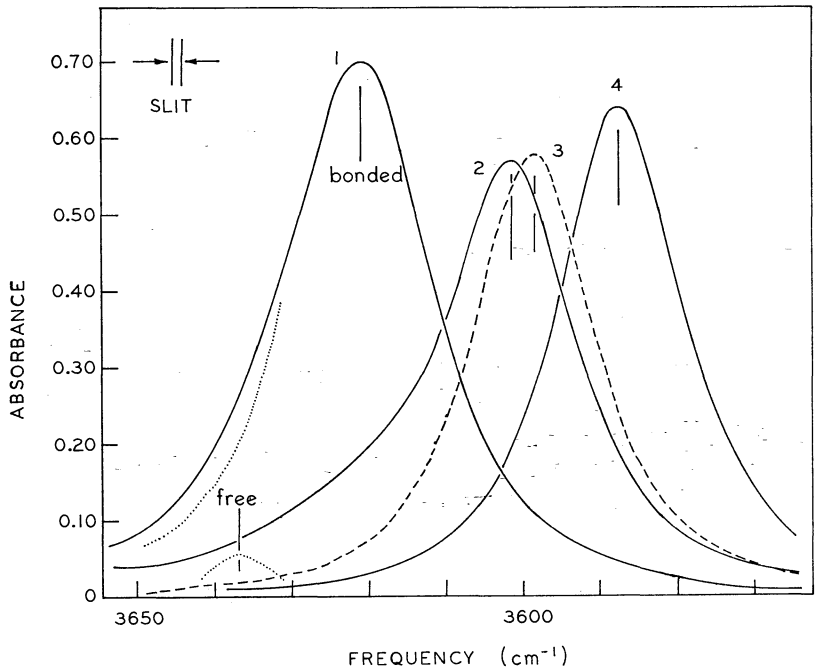

FIG. 1. Representative O—H stretching bands of di- and tri-haloethanols in CCl_4 solution. Path length = 2.00 cm.
(1) 2,2,2-Trifluoroethanol, 0.0030 *M*, t = 46° C. Dotted lines indicate residual "free" band obtained by reflection of the "bonded" band across the ordinate at the maximum.
(2) 2,2-Dichloroethanol, 0.0031 *M*, t = 48° C.
(3) 2,2,2-Trichloroethanol, 0.0022 *M*, t = 22° C.
(4) 2,2,2-Tribromoethanol, 0.0028 *M*, t = 27° C.

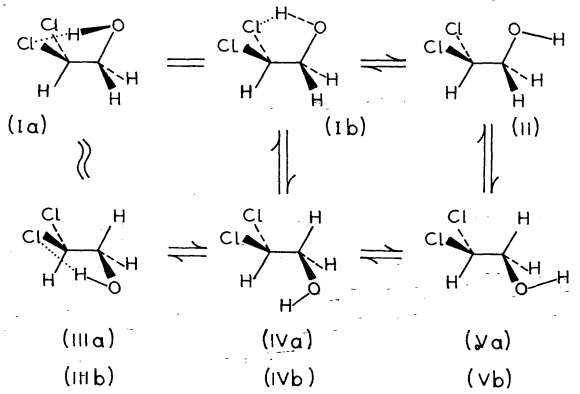
Cl_3CCH_2OH, and Br_3CCH_2OH in dilute CCl_4 solution. The band for Br_3CCH_2OH was found to be completely symmetrical over the temperature range investigated. The Cl_3CCH_2OH band was also symmetrical at lower temperatures, but exhibited slight asymmetry on the high frequency side at 45° C. On the other hand, F_3CCH_2OH and Cl_2CHCH_2OH show small but significant asymmetry on the high-frequency side over the entire temperature range investigated. By reflecting the major component of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

doublet about the ordinate at the maximum and subtracting the mirror image from the experimental spectrum, it can be demonstrated that the residual absorption causing asymmetry is due to a secondary band lying at higher frequency (example in Fig. 1). This method is satisfactory where the secondary component is relatively weak so that its contribution to the peak height of the principal band is negligible. The experimental data are summarized in Table I.

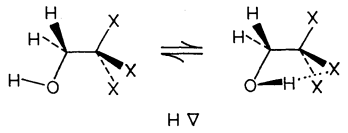
Examination of the frequency data shows that the major bands for all the di- and tri-haloethanols lie within 5 cm^{-1} of the corresponding values (ν_g) for the monohaloethanols. For trifluoroethanol the secondary band lies within 4 cm^{-1} of the corresponding value (ν_t) in FCH_2CH_2OH, while the secondary band for Cl_2CHCH_2OH differs from the corresponding value (ν_t) in $ClCH_2CH_2OH$ by the greatest amount, but even that is only 12 cm^{-1}. This frequency correspondence with the ν_t and ν_g bands respectively in the monohaloethanols indicates an equilibrium involving intramolecular OH...X hydrogen bonds,* with all molecules in the bonded form in Br_3CCH_2OH and Cl_3CCH_2OH (except at temperatures of 45° C or higher for the latter).

Considering rotation about both the C—C and the C—O bond, and staggering all bonds on the axes of rotation, the following equilibrium scheme can be formulated for 2,2-dichloroethanol (and other dihaloethanols):



The low-frequency major component would be due to forms I*a* and III*a* (and their mirror images I*b* and III*b*). Conformer II would not be favored because both of the oxygen lone pair orbitals are directed toward chlorine atoms. The minor high frequency component must be due to the mirror image pairs IV*a*, IV*b* and V*a*, V*b*.

For 2,2,2-trihaloethanols only a very simple equilibrium is conceivable:



It should be noted that in 2,2-dihaloethanols the OH group always remains gauche to at least one halogen atom, whereas in 2,2,2-trihaloethanols the OH group is always gauche

**Intermolecular OH ... X or OH ... O bonding is ruled out because of the low alcohol concentrations used. No evidence of such interaction (broader concentration-dependent bands at reduced frequency) was found in any spectrum, even at 0° C.*

to two halogen atoms. The hydroxylic proton can get away from the gauche halogen(s) only by rotation about the C—O bond.

The temperature dependence of the relative absorbances of the two components of the doublet (D_t/D_g) shows that these are true equilibria; in both F_3CCH_2OH and Cl_2CHCH_2OH this ratio increases with increasing temperature.* From measurements at three different temperatures and plots of $\log_{10}(D_t/D_g)$ versus $1/T$, the enthalpy difference (ΔH) between bonded forms (I*a*, I*b*, III*a*, and III*b*) and non-bonded forms (II, IV*a*, IV*b*, V*a*, and V*b*) as well as the corresponding ΔS and ΔF values, can be determined (Fig. 2 and Table I).

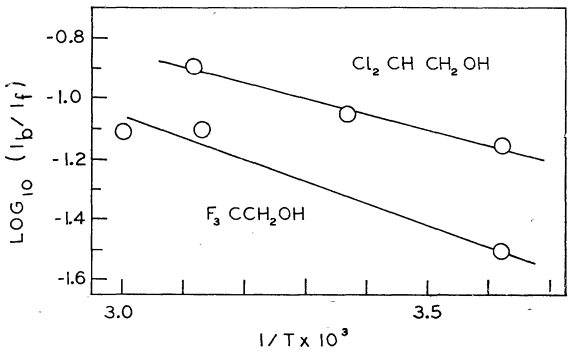

FIG. 2. The temperature dependence of the "free"/"bonded" OH absorbance ratio in 2,2-dichloroethanol and 2,2,2-trifluoroethanol in dilute CCl_4 solution.

The ΔH, ΔF, and ΔS values for the bonded $\rightleftharpoons$ free OH equilibrium in F_3CCH_2OH are uniformly much larger than the corresponding values for FCH_2CH_2OH, in harmony with the concept of stronger intramolecular OH...F bonding in the trifluoro compound. One of the contributing factors would be the increase in acidity of the alcohol, as revealed by the pK_a's (7). An increase in the effective positive charge on the hydroxyl H atom would make it more available for hydrogen bonding, assuming that the base strength of the acceptor remains the same. This may not be the case, since an F atom in an F_3C— group may have a smaller effective negative charge than an F atom in an FCH_2— group. Another factor which would favor the gauche form would be the repulsion between the oxygen atom lone pair orbitals and the F atoms, since in F_3CCH_2OH these orbitals are both approximately directed to an F atom when the OH bond takes up a staggered orientation with respect to the methylene CH bonds in the conformer where the OH is trans to the $-CF_3$ group. However, progressive substitution of fluorine on the same carbon atom is known to lead to C—F bond shortening (11). This would tend to reduce such repulsion. The overall interplay of such factors leads to a greater stability of the intramolecularly bonded form with respect to the free form of F_3CCH_2OH in comparison with FCH_2CH_2OH. Statistically the population of the intramolecularly bonded form is favored in F_3CCH_2OH in comparison with FCH_2CH_2OH. The intramolecular hydrogen bonds in Cl_2CHCH_2OH are also stronger than those in $ClCH_2CH_2OH$.

The fact that the unbonded OH peak disappears in the trihaloethanols in the order $F_3C- > Cl_3C- > Br_3C- = 0$ can be understood in terms of the following factors which override the OH...X hydrogen bonding order F > Cl > Br:

(*a*) Increasing size of the halogen atoms in the order F < Cl < Br, which makes it easier for OH...X bonds to form to the larger atoms in an intramolecular system.

**Here, and in the subsequent discussion, "trans" and "gauche" refer to the relative orientations of the OH group and the -CHX_2 or -CX_3 group respectively, and involve rotation about the C—O bond.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(*b*) Halogen–halogen repulsion, which increases with the size of the halogen atoms, opening up the $—CX_3$ umbrella and bringing the X atoms nearer to the OH group. It is known that such angle deformations occur. (See, for example, the increasing XCX angle for CHF_3, $CHCl_3$, $CHBr_3$, and CHI_3, as given by Sutton (12).)

(*c*) Increasing polarizability of X in the order F < Cl < Br. As a result the repulsion between the X atoms and the oxygen lone pair orbitals (in the conformation where the hydroxyl proton is pointing away from the $—CX_3$ group) will increase in the order F < Cl < Br, favoring the hydrogen-bonded form in which the accessibility of X orbitals to the proton will also increase in the order F < Cl < Br. It appears therefore that in F_3CCH_2OH the presence of some unbonded molecules rests chiefly in the small size of the F atoms, which are held at a certain distance from the OH group.

The fact that the self-association constant of F_3CCH_2OH is less than that of ethanol, as reported by Rao *et al.* (8), can readily be interpreted in terms of the reduced basicity of the oxygen due to the electron-withdrawing trifluoromethyl group. Further, most of the OH groups are already tied up in intramolecular OH...F bonds and therefore not readily available for intermolecular association. However, as far as the proton-donating ability to good proton-acceptors is concerned, it is enhanced in F_3CCH_2OH, as Rao *et al.* (9) have shown on the basis of $n \rightarrow \pi^*$ blue shifts in ketones and nitro compounds when these are dissolved in trifluoroethanol.

Concerning half-band widths of ν_g, it is interesting to note that in all the di- and trihaloethanols investigated they are slightly less than for the corresponding monohaloethanols.

When conformational problems are investigated by infrared spectroscopy, an assumption must usually be made concerning the relative magnitudes of the intrinsic molar extinction coefficients (ϵ) (actually, the intrinsic integrated molar intensities) of bands arising in some functional group in the two conformers. Rarely can suitable model compounds be prepared which hold the molecule in a given conformer without perturbing the electron distribution in the group that is being studied. For Cl_3CCH_2OH and Br_3CCH_2OH ϵ_g values were found to be 132 and 114 cm^2 $mole^{-1}$ respectively, and for F_3CCH_2OH a value of >140 can be estimated. Since the band widths are roughly comparable, this indicates that the dipole moment changes involved during the OH stretching vibration increase in the order $OH...Br_3C— < OH...Cl_3C— < OH...F_3C—$, which is expected for increasing OH bond polarity due to the inductive effect, and for increasing strength of the OH...X bond.

Failure of ν_t for the trihaloethanols to correlate with the linear relationship established between ν_t for the monohaloethanols and the Taft σ^* values (1) is almost certainly due to non-bonded interactions between the X atoms and the oxygen atom, since in X_3CCH_2OH the O atom cannot rotate away from a halogen atom, i.e. molecules with "free" OH groups arise by rotation about the C—O bond. Non-bonded interactions have now been shown to play a very important role in determining frequencies (13).

SPECTROSCOPIC STUDIES OF ALCOHOLS

IV. CONFORMATIONAL HETEROGENEITY OF 1-PROPANOL IN DILUTE CCl_4 SOLUTION*

ABSTRACT

High-resolution infrared spectroscopy indicates that the fundamental OH stretching band of 1-propanol in dilute CCl_4 solution is composed of three components caused by rotational isomerism about the C—C and C—O bonds. Although the conformer with the CH_3 and OH groups trans to each other is most heavily populated at room temperature, one of the two conformers having gauche CH_3 and OH groups is thermodynamically most stable. A conformational equilibrium scheme is postulated in which the most stable conformer has a methyl C—H interacting with one of the lone pairs of electrons on the oxygen atom.

INTRODUCTION

Recent studies in this laboratory have led to the spectroscopic evaluation of the enthalpy differences between the trans and the intramolecularly hydrogen-bonded gauche forms of some substituted alcohols of the type XCH_2CH_2OH, X_2CHCH_2OH, and X_3CCH_2OH in dilute CCl_4 solution (1). Of the 2,2,2-trihaloethanols examined, tribromoethanol was found to be exclusively intramolecularly bonded over the range 0–50° C. Trichloroethanol exhibited similar behavior at the lower temperatures, but a trace of "free" OH absorption appeared at 45° C. Trifluoroethanol showed temperature-dependent OH band asymmetry over the range 0–60° C, indicating a small but significant population of the conformer with the OH group directed away from the CF_3 group.

As an extension of this work, we have now investigated 1-propanol by means of high-resolution infrared spectroscopy, and have found three rotational isomers. Prior to this rotational isomerism was advanced to explain the *doublet* OH absorption observed for 1-propanol by Oki and Iwamura (2) in the fundamental region (CCl_4 solution), by Piccolini and Winstein (3) in the first overtone region (CCl_4 solution), and by Badger and Bauer (4) in the second overtone region (gas phase).

EXPERIMENTAL

The details of the instrumental procedure have been described (5, 6).

Reagent grade 1-propanol was dried over anhydrous sodium sulphate and fractionally distilled through a 23-plate spinning band column (b.p. 93.5° at 670 mm, n_D^{20} = 1.3849, lit. 1.38453). Commercial "spectrograde" CCl_4 was used.

RESULTS AND DISCUSSION

The fundamental OH stretching band observed exhibits three partially resolved components with temperature-dependent relative intensities. Figure 1 shows a representative spectrum, with the apparent band maxima at 3638.5 (I), 3632.5 (II), and 3626.7 cm^{-1} (III). The results of quantitative measurements of the changes in the relative absorbances of the peaks with temperature are illustrated in Fig. 2. The slopes of these plots permit the determination of the enthalpy differences between the different pairs of conformers that must exist in simultaneous equilibrium .This treatment suffers from the disadvantage

**A preliminary report of this work was presented at the 46th Annual Conference of the Chemical Institute of Canada, Toronto, June 6–8, 1963.*

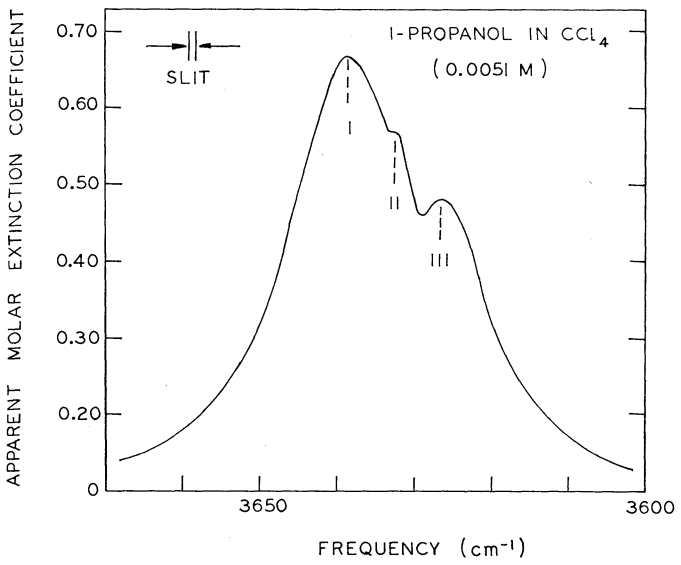

FIG. 1. Fundamental OH stretching bands for conformers of 1-propanol in dilute CCl_4 solution (0.0051 *M*). Path length = 2.00 cm. Temperature = 15° C.

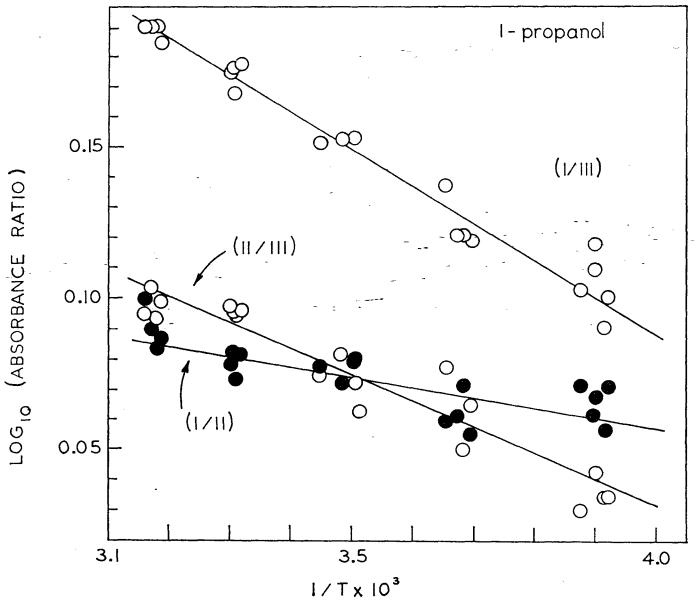

FIG. 2. Temperature dependence of relative absorbances of OH stretching band components in 1-propanol in dilute CCl_4 solution.

that the components of the band overlap badly and therefore make contributions to the peak absorbances of the neighboring band(s). If the assumption is made that the intrinsic molar extinction coefficient of the OH group is independent of its spatial orientation with respect to the CH_3 group, the thermodynamic quantities ΔS and ΔF can also be evaluated. This is a justified approximation since the effect of a hydrocarbon group on

the polarity of an OH bond due to non-bonded interactions must be small. The thermodynamic quantities are summarized in Table I.

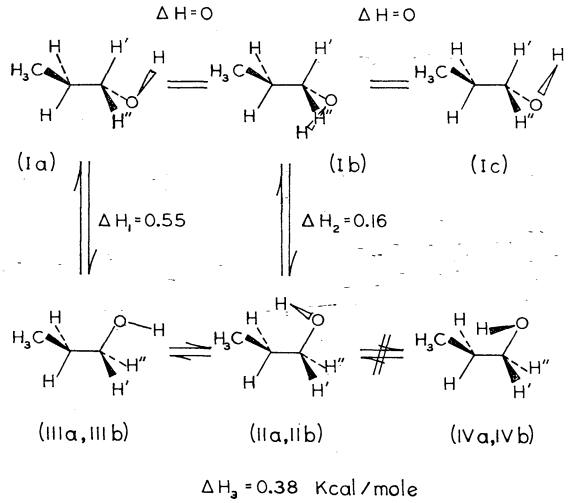
TABLE I

Thermodynamic and spectral properties of 1-propanol in dilute CCl_4 solution

Equilibrium*	ΔH (kcal/mole)†	$\Delta S^{25°\,C}$ (e.u.)	$\Delta F^{25°\,C}$ (kcal/mole)	$\nu_{OH}^{15°\,C}$ shift (cm^{-1})‡
(1) III $\rightleftharpoons$ I	0.55	3.97	−0.63	5.8
(2) II $\rightleftharpoons$ I	0.16	2.28	−0.52	6.0
(3) III $\rightleftharpoons$ II	0.38	1.65	−0.49	11.8

*Components identified in Fig. 1 and in equilibrium scheme. A statistical factor of 2 is included in the calculations for the first two equilibria because there are two equivalent gauche forms for every trans form as far as rotation about the C—C bond is concerned. In the third equilibrium this factor is not required.
†Obtained by least squares fit of the data.
‡Apparent shifts due only to band overlapping. Temperature of 15° C selected for data in this column because of optimum resolution.

Despite the appreciable scatter of the experimental points in Fig. 2, the fact that $\Delta H_1 = \Delta H_2 + \Delta H_3$ (0.54 vs. 0.55 kcal/mole) confirms the validity of treating this system as a set of three simultaneous conformational equilibria. The data are consistent with the following scheme, which makes allowance for the nine conformers predicted by the general treatment of Funck (7). Rotation about both the C—C and the C—O bond is considered, and in each conformer the bonds to atoms on the axis of rotation are staggered.



Conformers I*b* and I*c*, II*a* and II*b*, III*a* and III*b*, and IV*a* and IV*b* are mirror-image pairs and thus spectroscopically indistinguishable. The mirror plane passes through the three C atoms.

In (I*a*): O—H staggered re C—H′ and C—H″.
In (I*b*): C—H′ staggered re lone-pair oxygen orbitals.
In (I*c*): C—H″ staggered re lone-pair oxygen orbitals.
In (II): C—H′ staggered re lone-pair oxygen orbitals.
In (III): O—H staggered re C—H′ and C—H″ (one of the oxygen lone-pair orbitals directed toward a methyl H atom).
In (IV): attempted staggering of C—H″ re lone-pair oxygen orbitals (hydroxyl H atom interferes with CH_3 group).

The recent review of threefold potential barriers to rotation about single bonds by Wilson (8) indicates that unshared pairs of electrons on an axial atom appear to contribute little to these barriers. Thus, in methylamine with two NH bonds and one lone pair the barrier (1.94 kcal/mole) is about 2/3 that of ethane (2.7–3.0 kcal/mole), whereas in methanol with one OH bond and two lone pairs the barrier (1.07 kcal/mole) is about 1/3 the ethane value. However, staggering of the O—H with respect to the C—C and C—H bonds in the above conformers corresponds to staggering of the oxygen lone-pair orbitals with respect to the methylene C—H bonds.

The highest frequency component in the spectrum is assigned to form I where the CH_3 group cannot interfere with the trans OH group. Rotation about the C—O bond in this form, although involving a small barrier, would have a negligible effect on the energy so that I*a* is equivalent to the mirror-image pair I*b*, I*c*. If all three conformers absorb at the same frequency one might expect the high frequency component to be most intense. In III one of the oxygen lone-pair orbitals is directed toward a methyl H atom in close proximity. Form IV can be ruled out because the hydroxyl H atom interferes spatially with one of the methyl H atoms. Form II is relatively free from methyl interference with the hydroxyl proton, and neither of the oxygen lone-pair orbitals is directed toward the methyl group.

It is known that in the vapor phase the gauche form of 1-chloropropane is more stable than the trans form (9). Szasz (10) has suggested that the steric repulsive force between the CH_3 group and the chlorine atom has been overcome by an electrostatic attractive force between the chlorine atom (or the C—Cl bond) and the polarizable methyl group. Pentin and Tatevskii (11) have advanced a similar explanation. The azimuthal angle of $59\pm5°$ between the C—Cl and the C—CH_3 groups (12), compared with the 60° value for gauche C—H bonds in ethane, and with $71\pm5°$ estimated between the C—Cl bonds in 1,2-dichloroethane (13) agrees well with this concept. Since one of the methyl H atoms is directed toward the Cl atom and almost in direct contact (Fisher–Herschfelder model), conditions may be favorable for a CH. . .Cl interaction resembling weak hydrogen bonding.

On this basis the lowest frequency component in 1-propanol (most stable) is assigned to conformer III*a* and its mirror image III*b*, where a C—H of the methyl group could interact with one of the oxygen lone-pair orbitals (weak intramolecular CH. . .O hydrogen bonding). That leaves the intermediate component in the spectrum for the mirror-image pair II*a*, II*b*. The stretching frequency of a terminal OH group in a hydrogen-bonded ROH dimer or polymer is probably not very different from that of a ROH monomer (14). It is therefore difficult to make a prediction about the relative OH frequencies of II and III, particularly since the CH. . .O interaction is very weak.

Table I shows that for the reaction III→I (most stable form to highest energy form) the ΔS value is largest, corresponding to maximum disordering. This is expected, since I actually consists of three rotational isomers that are due to restricted rotation about the C—O band. Further, the torsional oscillation about the C—C bond is probably greatest in I. The reaction III→II corresponds to minimum disordering (smallest ΔS), whereas II→I corresponds to intermediate disordering (intermediate ΔS).

Pennington *et al.* (15) have investigated 1-propanethiol in the gas phase and have found the trans form more stable by 0.4 kcal/mole. Since steric interactions must be fairly similar to those in 1-chloropropane, this situation may be accounted for by the reduced attraction between the C—S bond and the methyl group. It is not known whether the gauche form of 1-propanethiol would be stabilized sufficiently by a solvent like CCl_4 to make it the most stable form in solution.

On the basis of photographic measurements of the temperature dependence of the relative intensities of four pairs of bands in the Raman spectra of liquid 1-propanol in the range 300–1500 cm^{-1} at 32° and −80° C, Berthelot (16) found an average $\Delta H = 820 \pm 180$ cal/mole, which he ascribes to the enthalpy difference between conformers which differ because of rotation about the C—C bond since the value is so similar to that obtained by Szasz *et al.* (17) for butane (785 ± 165 cal/mole). For 1-butanol Berthelot found $\Delta H = 670 \pm 190$ cal/mole, compared with 615 cal/mole reported for pentane (18). On the other hand Berthelot reports a higher value ($\Delta H = 1024 \pm 210$ cal/mole) for the enthalpy difference between rotational isomers in ethanol, where the rotation must be about the C—O bond. Undoubtedly these Raman values are affected by the strong intermolecular interaction in the pure liquid alcohols. Nevertheless the lower limit for 1-propanol ($820 - 180 = 640$ cal/mole) is reasonably close to the largest ΔH determined in this work (0.55 kcal/mole) for rotational isomerism involving only rotation about a C—C bond.

Recently Sutor (19) has summarized the available data on bond lengths and angles in crystals where "short" inter- and intra-molecular C. . .O distances exist, and has found considerable evidence for CH. . .O hydrogen bonds involving methylidyne groups, and probably also methylene and methyl groups. For systems involving CH_2 and CH_3 groups the CH. . .O angles range from 102° to 147°, with H . . .O distances between 2.07 and 2.77 Ångstroms. Assuming an azimuthal angle of 60°, our calculations show that in 1-propanol the CH. . .O angle is 94°, and the H. . .O distance is 2.6 Ångstroms. This distance is equal to the sum of the Van der Waals radii for an oxygen atom and a hydrogen atom (19). Although the CH. . .O angle is only slightly in excess of a right angle, the need for the H atom to be directed toward one of the lone-pair orbitals of the oxygen atom for most effective interaction cannot be overlooked.

The recent study of C—H groups as proton donors in intermolecular hydrogen bonds by Allerhand and Schleyer (20) shows that the proton-donating ability of the C—H group depends on the carbon hybridization ($sp > sp^2 > sp^3$), and increases with the number of adjacent electron-withdrawing groups. They conclude that a single electron-withdrawing group attached to a sp^3-hybridized carbon atom is not sufficient to make the hydrogens attached to such a carbon proton donors. Undoubtedly the favorable geometry is responsible for the detection of a weak intramolecular CH. . .O hydrogen bond in 1-propanol.

FLUORANTHENE STUDIES

E. H. Charlesworth and B. J. Blackburn
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received October 7, 1963

ABSTRACT

3-Acetamido- and 3-amino-fluoranthene are brominated in the 2-position. Two new fluoranthene compounds are reported: 2-bromo-3-acetamidofluoranthene and 2-bromofluoranthene. The theoretical implications of these results are discussed.

INTRODUCTION

Comparatively few disubstituted derivatives of fluoranthene* have been made by further reaction on monosubstituted derivatives and not too much is known regarding the directive influence of these substituents. It is known that, in general, compounds containing meta-directing groups in the 3-position undergo further substitution in the 9-position. 3-Bromofluoranthene on further bromination gives the 3,8-dibromo compound. On the basis of these data, Campbell and Keir (3) postulated in 1955, that a meta-directing group in ring A would direct to position 9 and an ortho–para directing group would direct to position 8. In the following year Kloetzel, King, and Menkes (4) showed that the above rule was over-simplified, as 3-acetamidofluoranthene was found to nitrate in the 2-position. They considered that the greater activating influence of the acetamido group activates the ring to which it is attached and substitution occurs in the same ring. It seemed desirable to study further examples of strongly activating directors such as the acetamido and amino groups under brominating conditions.

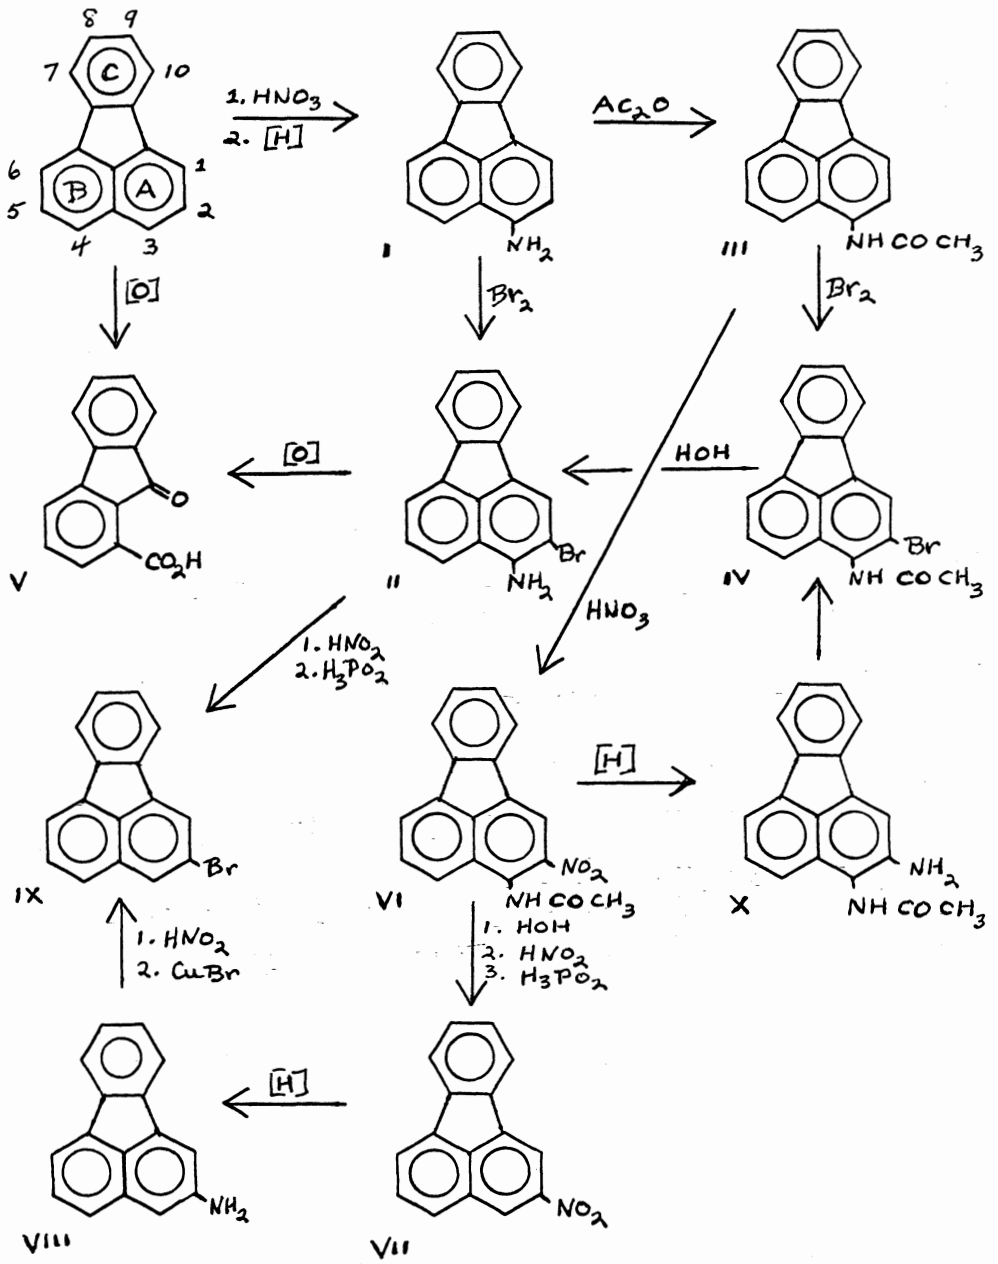
3-Acetamidofluoranthene (III) was brominated at room temperature in pyridine to give the 2-bromo-3-acetamido derivative (IV). Hydrolysis of IV in pyridine – methanol – sodium hydroxide gave 2-bromo-3-aminofluoranthene (II).

Attempts to establish the orientation of the bromine in IV by diazotization and a Sandmeyer reaction on 2-amino-3-acetamidofluoranthene (X) failed. The usual high sulphuric acid concentration required for diazotization of weak, insoluble amines of this type resulted in tar formation. This was due to the instability of the amine sulphate, as this salt, prepared in ether, decomposed when separated from the ether.

The 2-position of the bromine atom has been established in the following manner. If the two substituents are in the same ring, oxidation of IV would destroy this ring, whereas if the groups were in different rings, only the ring containing the amino group could be destroyed and a bromo-1-fluorenonecarboxylic acid would result. Oxidation with chromic anhydride in glacial acetic acid gave 1-fluorenonecarboxylic acid (V) identical with an authentic sample. That the bromine is in the 2-position in the A ring has been established through the 2-nitro-3-acetamido compound (VI) whose orientation was previously established by Kloetzel *et al.* (4). By hydrolysis and deamination of VI they obtained 2-nitrofluoranthene (VII) and by reduction 2-aminofluoranthene (VIII).

Attempted diazotization of VIII under the conventional high-acid concentration required for weak insoluble amines gave an unsatisfactory product. In this diazotization (and in the diazotization of I for practice) side reactions were largely avoided by isolation of the amine sulphate which was then dissolved in a concentrated sulphuric and acetic

**For excellent reviews of fluoranthene chemistry up to 1951, see references 1 and 2.*



acid mixture and diluted for diazotization. This valuable method is fully described in the experimental preparation mentioned. A Sandmeyer reaction on the diazonium sulphate solution gave an authentic sample of 2-bromofluoranthene (IX). By deamination of II, IX is also obtained. Thus the orientation of the bromine in the original bromination has been established.

The direct bromination of 3-aminofluoranthene (I) is recorded in a German patent by Meyer and Falta (5), but they did not establish the orientation of the halogen. They

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

report a melting point of 166–167° C, but our purest product by their method melted at 152–158° C. Comparison of the nuclear magnetic resonance spectra indicates that this is an impure specimen of 2-bromo-3-aminofluoranthene which melts at 176–177° C. Thus direct bromination of 3-aminofluoranthene (II) occurs largely in the 2-position, but a purer product is obtained via the 3-acetamidofluoranthene (III).

These results substantiate those of Kloetzel *et al.* that an intensely activating substituent in fluoranthene causes further substitution in the same ring.

EXPERIMENTAL

3-Nitrofluoranthene was prepared by the method of Garascia, Fries, and Ching (6), reduced to 3-aminofluoranthene (I), and acetylated to the 3-acetamido derivative (III) by following the directions of Kloetzel, King, and Menkes (4).

2-Bromo-3-acetamidofluoranthene (IV)

Bromine (5 ml) was added, with stirring, to a solution of 3-acetamidofluoranthene (10.0 g) in technical grade pyridine (700 ml). The reaction was allowed to proceed at room temperature for 10 hours. The crude product was precipitated by addition of water (2 liters), filtered off, and washed successively with 10% aqueous solutions of sodium hydroxide and sodium bisulphite. The resulting material was placed in pyridine (200 ml) and heated to the boiling point. The insoluble material was filtered from the hot pyridine solution and discarded. The filtrate was treated with charcoal and then sufficient water was added to cause crystallization when the pyridine–water solution cooled. The 2-bromo-3-acetamidofluoranthene (7–8 g) was obtained as yellow flakes which melted at 266–267° C (decomp.). Found: N, 4.2; Br, 23.3; acetyl, 13.1%. Calc. for $C_{18}H_{12}NBrO$: N, 4.1; Br, 23.6; acetyl, 12.7%.

2-Bromo-3-aminofluoranthene (II)

The previous 2-bromo-3-acetamidofluoranthene (10.3 g) was hydrolyzed by heating under reflux for 12 hours in a solution of methanol (600 ml), pyridine (400 ml), and sodium hydroxide (30 g). A small amount of insoluble material was filtered off and discarded. The crude product was precipitated by dilution to 4 liters with water. The collected material was washed with water, dried, and dissolved in boiling pyridine. A small amount of insoluble material was filtered off and the filtrate was heated with charcoal. Sufficient water was added to cause crystallization when the solvent cooled. 2-Bromo-3-aminofluoranthene (7.2 g) was thus obtained as beautiful yellow needles, m.p. 176–177° C (decomp.). Found: N, 4.6; Br, 27.6%. Calc. for $C_{16}H_{10}NBr$: N, 4.7; Br, 27.0%.

Oxidation of 2-Bromo-3-aminofluoranthene

This was accomplished by heating 2-bromo-3-aminofluoranthene (2.0 g) under reflux for 5 hours with sodium dichromate (20 g) in glacial acetic acid (100 ml). This treatment caused evolution of bromine in gaseous form. The reaction mixture was poured into a solution of concentrated sulphuric acid (100 ml) in water (700 ml). The solid which precipitated was filtered off and heated in an aqueous solution of sodium carbonate. The insoluble material was filtered from the carbonate solution and discarded. The filtrate from the diluted reaction mixture was extracted with benzene. The benzene extract was in turn treated with carbonate solution, and the carbonate solutions combined. Acidification of the carbonate solution with sulphuric acid produced crude 1-fluorenonecarboxylic acid. The acid was dried and taken up in boiling *o*-xylene (100 ml). The acid was recovered by extraction with aqueous carbonate solution and acidified. Recrystallization from glacial acetic acid gave 1-fluorenonecarboxylic acid (0.53 g), m.p. 185–189° C. Admixture with an authentic sample prepared by oxidation of fluoranthene by the method of Fieser and Seligman (7) gave no depression in melting point. Comparison of the infrared spectra also proved the identity.

Treatment of the two samples of 1-fluorenonecarboxylic acid with *p*-nitrophenylhydrazine gave the same derivative as fine yellow-orange microcrystals which melted at 307–308° C and with no depression on mixing.

Preparation of 2-Bromofluoranthene (IX)

(a) from 2-Aminofluoranthene (VIII)

2-Nitrofluoranthene (VII) was made from 3-acetamidofluoranthene (III) as shown on the flow sheet according to the directions of Kloetzel *et al.* (4). Reduction of the nitro group gave 2-aminofluoranthene (VIII).

Crude 2-aminofluoranthene (2.0 g) was stirred in dry ether (170 ml) and the insoluble material filtered off. Concentrated sulphuric acid (1 ml) was added with stirring to the amine solution. The amine sulphate was filtered off, allowed to dry, and finely ground. The salt was dissolved in a vigorously stirred solution of concentrated sulphuric acid (75 ml) and glacial acetic acid (75 ml) with gentle warming. The solution was cooled and 150 g of ice and water were added rapidly with stirring to precipitate the amine salt in finely

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

divided condition. The salt was diazotized at 15–20° C by addition of sodium nitrite (1.6 g) in water (10 ml). The diazonium solution was poured, with stirring, into a solution of cuprous bromide (15 g) in 48% hydrobromic acid (70 ml) and water (30 ml). The mixture was heated slowly, with stirring, to 95° C. The cooled reaction mixture was diluted with water and the precipitate filtered off. The dried material was stirred with hot benzene and the insoluble material discarded. The aqueous filtrate from above was also extracted with benzene. The benzene extracts were combined and washed with an aqueous sodium hydroxide and sodium bisulphite solution. The benzene was then washed with concentrated sulphuric acid until further washing caused no visible change in the benzene solution. The benzene solution was now washed with an aqueous sodium carbonate solution, which was discarded. The benzene was removed by evaporation to dryness. Sublimation of the solid residue, at approximately 100° C under high vacuum, gave 2-bromofluoranthene (1.1 g) as a light yellow powder, m.p. 102–104° C. Found: C, 67.7; H, 3.39; Br, 27.3; N, 1.17%. Calc. for $C_{16}H_9Br$: C, 68.4; H, 3.23; Br, 28.4%. The analysis indicates some nitrogen containing impurity was present.

(b) Deamination of 2-Bromo-3-aminofluoranthene

Sodium nitrite (0.75 g) was added slowly with stirring to a solution of concentrated sulphuric acid and water (4.2 ml) at room temperature. The solution was then cooled to −5° C and finely ground 2-bromo-3-aminofluoranthene (1.16 g) was then added with vigorous stirring over a 15-minute period, the temperature being maintained at −5° C. Stirring was continued for another 45 minutes at this temperature. Then precooled 50% hypophosphorous acid (85 ml) was added to the stirred solution at such a rate that the temperature did not exceed 5° C. This took about 2½ hours. After 1 week, at 2–3° C, the reaction mixture was diluted with water to 1 liter. The precipitate was allowed to coagulate and then filtered off. The dried material was treated with benzene (250 ml) as previously described under (*a*). The sublimed pale yellow 2-bromofluoranthene (0.75 g) melted at 101–103° C. Found: C, 68.3; H, 3.32; Br, 28.8%. Calc. for $C_{16}H_9Br$: C, 68.4; H, 3.23; Br, 28.4%. A mixed melting point with sample (*a*) showed no depression.

THE REACTION OF CYCLOPENTANE VAPOR WITH Hg 6($^3P_1$) ATOMS AT ELEVATED TEMPERATURES: THE RECOMBINATION, DISPROPORTIONATION, AND DECOMPOSITION OF CYCLOPENTYL RADICALS[1,2,3]

HARRY E. GUNNING AND RICHARD L. STOCK
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received September 23, 1963

ABSTRACT

The static reaction of Hg 6($^3P_1$) atoms with cyclopentane vapor (c-C_5H_{10}) has been studied with temperatures from 26 to 376°, at constant c-C_5H_{10} concentration and at low light intensities.

From 26 to 250°, the only important products are hydrogen, cyclopentene, and bicyclopentyl. Above 250° new products appearing are ethylene, biallyl, and allyl cyclopentane, together with smaller yields of propylene, ethane, propane, and methane. To 250°, the reaction can be explained in terms of a 5-step paraffinic sequence, involving initial C—H scission to form H atoms and cyclopentyl (c-C_5H_9) radicals. The Arrhenius plot of a function equal to k_{disp}/k_{comb} for c-C_5H_9 radicals showed that $E_{disp}-E_{comb} = 0$. Above 250° c-C_5H_9 radicals decompose into C_2H_4 and C_3H_5 radicals. The activation energy for this process was determined from a number of product functions to be 36.9±1.2 kcal/mole. Evidence was also found for scission of c-C_5H_9 into cyclopentene and H atoms, above ca. 300°.

A brief examination was also made of the thermal decomposition of c-C_5H_{10} up to 457° in a quartz reaction vessel. The substrate is unstable above 350° forming ethylene, propylene, cyclopentene, cyclopentadiene, and hydrogen. The rate data can be satisfactorily explained by two intramolecular decompositions of the substrate into (*a*) ethylene and propylene and (*b*) cyclopentene and hydrogen with the cyclopentene further dehydrogenating to cyclopentadiene. From the data $E_a = 49.6\pm2.0$ kcal/mole and $E_b = 44.0\pm2.0$ kcal/mole.

INTRODUCTION

The reaction of cyclopentane vapor with Hg 6($^3P_1$) atoms, at 30°, has been previously studied (1, 2, 3). It has been shown that the primary reaction involves exclusively C—H bond scission, resulting in the formation of cyclopentyl radicals (c-C_5H_9) and H atoms with a quantum efficiency of at least 80% (3). At this temperature the mechanism of the reaction is

$$c\text{-}C_5H_{10} + \text{Hg } 6(^3P_1) \rightarrow c\text{-}C_5H_9 + H + \text{Hg } 6(^1S_0) \quad [1]$$

$$H + c\text{-}C_5H_{10} \rightarrow H_2 + c\text{-}C_5H_9 \quad [2]$$

$$2(c\text{-}C_5H_9) \rightarrow c\text{-}C_5H_8 + c\text{-}C_5H_{10} \quad [3]$$

$$2(c\text{-}C_5H_9) \rightarrow c\text{-}C_{10}H_{18} \quad [4]$$

$$H + c\text{-}C_5H_8 \rightarrow c\text{-}C_5H_9, \quad [5]$$

and in the most recent study (3) of the reaction, it has been found that the quantum yields at zero extent of reaction ($\Phi°$) for the products, hydrogen, cyclopentene (c-C_5H_8), and bicyclopentyl (c-$C_{10}H_{18}$), are respectively 0.8, 0.4, and 0.4. It follows then from the mechanism and the quantum yield data that $k_4 = k_3$; in other words cyclopentyl radicals show equal rates for disproportionation and recombination. Furthermore, with increasing duration of exposure the cyclopentene level builds up, rendering step [5] more important

and leading to a product stationary concentration in this product (2, 3). From the actual $(c\text{-}C_5H_8)/(c\text{-}C_5H_{10})$ ratio in the product stationary state, it has been estimated (3) that $k_5/k_2 \simeq 175$.

In view of the foregoing, the mercury-photosensitized decomposition of cyclopentane appeared to be a suitable system for studying the reactions of $c\text{-}C_5H_9$ radicals as a function of temperature. In this connection, previous studies (4, 5) on the behavior of $c\text{-}C_5H_9$ radicals, generated *in situ* by the abstractive attack of CD_3 radicals on $c\text{-}C_5H_{10}$, had shown that $c\text{-}C_5H_9$ is stable to ca. 250°, above which temperature thermolytic cleavage occurs largely via

$$c\text{-}C_5H_9 \rightarrow C_2H_4 + C_3H_5. \qquad [6]$$

In the present investigation the reaction of $c\text{-}C_5H_{10}$ with Hg $6(^3P_1)$ atoms has been examined in some detail over the temperature range from 26° to 375°—in the lower region of thermal instability of the substrate. Below ca. 250° the temperature coefficients of reactions associated with stable $c\text{-}C_5H_9$ radicals were studied, including the disproportionation and recombination processes. In addition activation energy data for the thermal decomposition of the $c\text{-}C_5H_9$ species were sought in the temperature range 250–375°. Finally the thermal decomposition of the substrate itself was briefly examined in the 351–457° region.

The details of the investigation follow.

EXPERIMENTAL

Cylindrical quartz reaction cells were used, 5 cm in diameter, 10 cm in length. The central stem of the cell connected to the high-vacuum manifold via a mercury U-valve, provided with a float valve in the arm on the manifold side. By raising the mercury level in the U-valve to a fixed mark, the cell could be isolated at constant volume from the remainder of the system. The furnace consisted of two brass cylinders, each 5.5 cm I.D. and 12.5 cm in length, wound with insulation and nichrome wire. The two sections were machined to fit around the cell as one unit, with Vycor 7910 ports at each end, opposite the cell windows. Iron–constantan thermocouples were installed close to each window. By mounting each furnace section on tracks parallel to the cylindrical axis of the cell, the two halves of the furnace could be united without altering the position of the cell. On the same tracks, the Hanovia, 87A45 mercury resonance source fitted into a lamp-housing, provided with a shutter on the cell side. Thereby the lamp-housing could be moved into a fixed position with respect to the incident window of the cell. The Vycor 7910 window attached to the furnace cut off radiation below 2200 Å, and thus the 1849 Å resonance line from the lamp was prevented from entering the cell.

Runs were carried out at a constant molar concentration of cyclopentane. Exactly 1120 μmole of substrate was measured in a gas burette, for each run, and transferred to the cell by immersing a small side-arm appendage of the cell stem in liquid nitrogen. This quantity of substrate, upon vaporization, provided a gas pressure of ca. 100 mm in the reaction cell at 25°. At the end of each run, liquid nitrogen was placed around the side arm, and the U-valve was opened. Non-condensable gases were transferred by a Toepler pump to a gas burette for measurement, after which the mole fraction of each component was determined by mass spectrometry.

For analysis of the condensable products, the section of the side arm, into which products and unreacted substrate had been condensed, was flame-cut from the cell, and inserted in a special crusher–preheater previously described (3). This unit could be connected in series with the H_2-carrier stream of the temperature-programmed gas chromatograph (G.L.C.) and complete vaporization of the condensables was assured by maintaining the unit at 150° (3). A by-pass system, downstream from the G.L.C., permitted trapping-out of any peak and removal for separate characterization. The molar, G.L.C. response factors, relative to $c\text{-}C_5H_{10}$, were determined directly for each product, with authentic samples, except for allyl cyclopentane. For this product, the response factor was obtained by interpolation on the linear plot of response factor vs. molecular weight for the naphthenes after Messner, Rosie, and Argabright (6).

The absorbed light intensity at 2537 Å was determined with propane as actinometer (7), taking $\Phi(H_2)$ for this reaction as 0.50 at propane pressures exceeding 40 mm. In our previous study (3) on the $c\text{-}C_5H_{10}$ reaction at 25°, it was shown that $\Phi(c\text{-}C_{10}H_{18})$ was invariant in exposure duration at 0.40 ± 0.01, on the basis of the propane standard (7). Hence the $\Phi(c\text{-}C_{10}H_{18})$ value at 25° was used as a secondary standard for the absorbed light intensity.

The cyclopentane used was Phillips, Research Grade (P.R.G.). Analysis by G.L.C. showed 0.051 mole %, cyclopentene as the only impurity. Repeated trap-to-trap distillation did not improve the purity. By check runs with an ultrapure c-C_5H_{10}, prepared by preparative G.L.C. (3), it was shown that the P.R.G. material gave identical rate data, when corrected for the small amount of c-C_5H_8 present in the starting material. The cyclopentene used was also P.R.G. material, containing, by G.L.C. analysis, 99.98 mole % of c-C_5H_8, with the impurities consisting of c-C_5H_{10} with traces of c-C_5H_6. The P.R.G. ethylene and propylene used were both further refined by several trap-to-trap distillations with retention of the middle fractions. Similar treatment was employed for further purifying the propane (Matheson, Instrument Grade). Bicyclopentyl was synthesized from cyclopentyl bromide by the Grignard route. A fraction, b.p. 181–183°, was taken which contained at least 99 mole % c-$C_{10}H_{18}$. The 1,5-hexadiene (biallyl) used for calibration was obtained from Matheson, Coleman, and Bell. G.L.C. analysis revealed hexenes as the only impurities.

RESULTS

The mercury-6($^3P_1$)-photosensitized decomposition of cyclopentane vapor was studied over the temperature range 26–376°. At several temperatures in this range, the reaction was examined as a function of duration of exposure (t), to determine the effect of t on the quantum yield ($\Phi(P)$) of each product (P), and to enable estimates to be made of $\Phi°(P)$—the $\Phi(P)$ values at $t = 0$. For the absorbed light intensity (I_a) at 2537 Å, propane actinometry gave $5.92 \pm 0.06 \times 10^{-7}$ einstein/minute. The I_a levels were repeatedly checked throughout the study by the primary propane standard, and by the measured rate of c-$C_{10}H_{18}$ formation, taking $\Phi(c\text{-}C_{10}H_{18}) = 0.40$, at 26° (3).

The significant products over all or part of the temperature region studied were hydrogen, ethylene, cyclopentene (c-C_5H_8), biallyl (C_6H_{10}), allyl cyclopentane (c-C_8H_{14}), bicyclopentyl (c-$C_{10}H_{18}$), methane, ethane, propylene, propane, cyclopentadiene (c-C_5H_6), and cyclopentyl cyclopentenes (c-$C_{10}H_{16}$).

In Figs. 1 and 2, the product yields in micromoles (μM), for runs with $t = 30$ minutes,

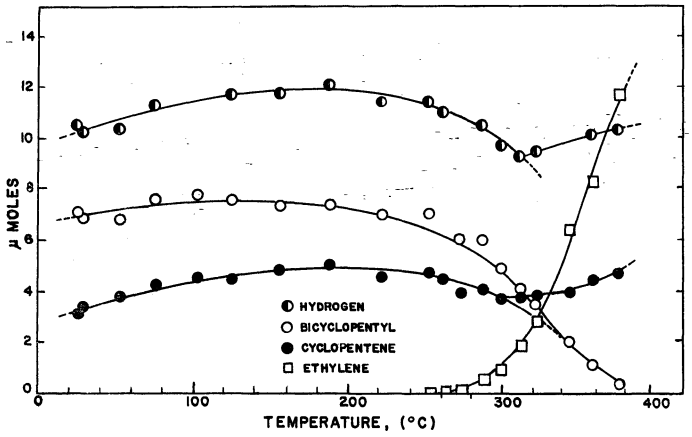

FIG. 1. Micromoles of major products formed for 30-minute runs as a function of cell temperature in the reaction of Hg 6($^3P_1$) atoms with P.R.G. cyclopentane.

are shown as a function of temperature for H_2, c-$C_{10}H_{18}$, c-C_5H_8, C_2H_4 (Fig. 1), and C_6H_{10}, c-C_8H_{14}, C_3H_6, C_2H_6 (Fig. 2). The mean quantum yields for the 12 products, as a function of exposure duration and reaction temperature are given as follows: H_2, C_2H_4, c-C_5H_8, C_6H_{10}, c-C_8H_{14}, c-$C_{10}H_{18}$ (Table I); CH_4, C_2H_6, C_3H_6, C_3H_8, c-C_5H_6, c-$C_{10}H_{16}$ (Table II). It is apparent from Figs. 1 and 2, and Tables I and II, that up to ca. 250°, the only important products are H_2, c-C_5H_8, and c-$C_{10}H_{18}$, as in the reaction at room temperature (3). Of the three minor products appearing below 250° (Table II), the most

NOTE: G = methane; H = ethane; J = propylene; K = propane; L = cyclopentadiene; M = cyclopentyl cyclopentenes.

significant is the cyclopentyl cyclopentene isomers, previously observed in the reaction at 24° (3). It should be noted that *c*-$C_{10}H_{16}$ follows, within the experimental error, the same temperature trend as the major product, *c*-$C_{10}H_{18}$ (Table I), with the rate achieving a gentle maximum at ca. 260°. Cyclopentadiene is a very minor product with Φ values about an order of magnitude lower than Φ(*c*-$C_{10}H_{16}$). Below 250°, CH_4 is a trace product, never exceeding 0.1% of the H_2 product.

Above 250°, new products begin to appear in measurable yields. The first group, which were detected at 252°, consisted of C_2H_4, C_6H_{10}, and *c*-C_8H_{14} (Table I). In the 270–290° region, three further products emerged: C_3H_6, C_2H_6, and C_3H_8 (Table II). The exponential nature of the temperature profile of the C_2H_4 rate is clearly shown in Fig. 1. The corresponding rate vs. temperature graphs for *c*-C_8H_{14}, C_6H_{10}, C_3H_6, and C_2H_6 are displayed in Fig. 2. In both figures the rates are total yields per 30 minutes of exposure.

Thermal Decomposition of Cyclopentane

In order firmly to establish the upper temperature limit to which the photosensitized reaction could be studied, it was necessary to determine the temperature coefficient of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the thermal reaction. In the photosensitized runs, the longest exposure was 60 minutes, after 3 hours of equilibration at the reaction temperature. The thermal runs were therefore each performed for a period of 240 minutes, representing the maximum time of residence of the substrate in the reaction system for the photosensitization runs. In all, the thermolytic reaction was examined at five temperatures in the range 351–457°.

At the highest temperature studied, 457°, the major products, in order of decreasing importance, were C_3H_6, C_2H_4, c-C_5H_8, and c-C_5H_6. The minor products consisted of C_2H_6, CH_4, and C_3H_8. The results, expressed as μM of product formed in 240 minutes, are given for the five temperatures in Table III.

DISCUSSION

The Photosensitized Reaction from 26 to 250°

The salient features of the reaction in this temperature region are as follows.

(1) The significant products of the reaction remain qualitatively unchanged, with the major products being H_2, c-C_5H_8, and c-$C_{10}H_{18}$.

(2) The average rates, for 30-minute runs, for H_2 and c-C_5H_8 rise slightly with increasing temperature, passing through a shallow maximum at ca. 200° (cf. Fig. 1). The corresponding curve for c-$C_{10}H_{18}$ appears also to have a slight upward concavity, with the same rates at each end of the curve (Fig. 1).

(3) Comparison of the A, C, and F columns of Table I reveals that, within the experimental error, the following relation obtains:

$$[6a] \qquad \Phi(H_2) = \Phi(c\text{-}C_5H_8) + \Phi(c\text{-}C_{10}H_{18}),$$

as stoichiometrically required for (1) (above) to be valid.

It is apparent that the mechanism ([1] through [5] above) previously proposed (3) for the room-temperature reaction is operative over the entire temperature region (i.e. to 250°). From the steady-state treatment of this five-step sequence, one of the consequences is the relation

$$[7] \qquad K/\Phi(c\text{-}C_{10}H_{18}) - 1 = k_3/k_4$$

where K is the fractional efficiency of [1], that is, the quantum yield of the primary step. It follows from [7] that a plot of log $[K/\Phi(c\text{-}C_{10}H_{18})-1]$ vs. $1/T°_K$ should be linear, with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

slope proportional to E_3-E_4, the difference in activation energy between the disproportionation and recombination reactions for c-C_5H_9 radicals. To calculate the L.H.S. of [7], K was taken as 0.8 from the previous study (3), and combined with the $\Phi(c\text{-}C_{10}H_{18})$ values in the F column of Table I. The results, presented in Fig. 3, yield a straight line

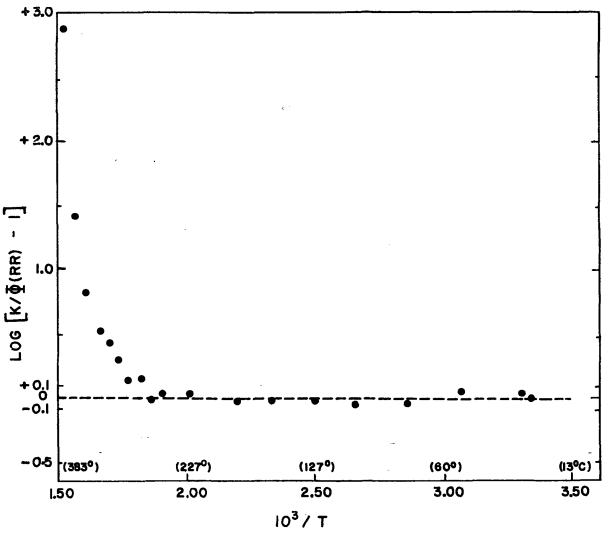

FIG. 3. Log $[K/\Phi(RR)-1]$ = log (k_{disp}/k_{comb}) for cyclopentyl radicals as a function of $1/T$ for runs of 30 minutes duration, in the reaction of Hg $6(^3P_1)$ atoms with P.R.G. cyclopentane.

of zero slope to ca. 250°, and therefore $E_3-E_4 = 0$, demonstrating that the disproportionation and recombination reactions have the same activation energies, presumably zero. A similar temperature behavior for the k_3/k_4 ratio has been found for ethyl, n-propyl, and isopropyl radicals (8–14).

Two factors contribute to the observed rise in $\Phi(c\text{-}C_5H_8)$ with temperature for the 30-minute run. At 26°, the product stationary concentration (P.S.C.) for c-C_5H_8 is reached after ca. 100 minutes of exposure. This period progressively shortens with rising temperature through an increase in the rate of diffusion, resulting in a larger c-C_5H_8 yield within the fixed time of irradiation. In addition the actual P.S.C. level of c-C_5H_8 moves upward with the temperature. This is a direct consequence of the mechanism which predicts for the P.S.C. of c-C_5H_8:

[8] $$(c\text{-}C_5H_8)_{SC} = k_2k_3(c\text{-}C_5H_{10})/k_4k_5.$$

Now, since $E_3 = E_4$ (Fig. 3), and $E_2 > E_5$, [8] will have a positive temperature coefficient at constant substrate concentration. The observed effect at constant exposure duration will be an enhanced c-C_5H_8 yield with increasing temperature.

The fact that $E_2 > E_5$ also accounts for the slight rise in $\Phi(H_2)$ with temperature, since increasing temperature will favor [2] over [5] and thus enhance $\Phi(H_2)$.

In the previous study (3) on the reaction at 24°, it was shown that $\Phi(c\text{-}C_{10}H_{18})$ was invariant in exposure time with a value of 0.40. Steady-state calculations for this quantity lead to the relation

[9] $$\Phi(c\text{-}C_{10}H_{18}) = Kr/(1+r)$$

where $r = k_4/k_3$, and thus since $r = 1$, K, the fractional primary efficiency is 0.8. Equation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

[6] is of course a rearrangement of [7], the relation used to demonstrate (Fig. 3) that r has no temperature coefficient. Now if K is 0.8 rather than unity at 24°, owing to substrate reformation by recombination of the primary fragments,

$$H + c\text{-}C_5H_9 \rightarrow c\text{-}C_5H_{10} \qquad [10]$$

one would expect [10] to become less important with rising temperature through the increased rate of [2]. Any such changes in K with temperature would, through [9], be directly reflected in $\Phi(c\text{-}C_{10}H_{18})$. While there may be a slight increase in this quantity with temperature (Fig. 1, Table I), the small variation in $\Phi(c\text{-}C_{10}H_{18})$ could reasonably be included in the experimental error. It seems unlikely therefore that [10] is important in this system. That K appears to be less than unity more probably is due to our imprecise knowledge of the absolute $\Phi(H_2)$ values for the propane actinometer, used here to determine the absorbed light intensity (I_a). In this connection, a rather detailed study has recently been made in this laboratory (15), on the propane actinometer. The results would suggest that our estimates of I_a may be 20% higher than the true value. Under such conditions K would become 0.96.

The Photosensitized Reaction above 250°

At ca. 250° three new products appear: C_2H_4, C_6H_{10}, and $c\text{-}C_8H_{14}$ (Table I, Figs. 1 and 2). The products are readily explained by the sequence:

$$c\text{-}C_5H_9 \rightarrow C_2H_4 + C_3H_5 \qquad [6]$$

$$2C_3H_5 \rightarrow C_6H_{10} \qquad [11]$$

$$c\text{-}C_5H_9 + C_3H_5 \rightarrow c\text{-}C_8H_{14} \qquad [12]$$

in agreement with previous work on the thermolysis of $c\text{-}C_5H_9$ (4, 5). The exponential increase in the C_2H_4 rate above 250° is accompanied by a corresponding drop in the rate for $c\text{-}C_{10}H_{18}$ (Fig. 1, Table I). This is as expected, since [6] would depress the $c\text{-}C_5H_9$ level in the system, thus reducing $c\text{-}C_{10}H_{18}$ formation via the radical combination step [4]. The resonance-stabilized allyl radicals formed in [6] undergo exclusively radical combination reactions in the 250–270° region, i.e. [11] and [12], a fact consistent with a high activation energy for the abstractive process

$$C_3H_5 + c\text{-}C_5H_{10} \rightarrow C_3H_6 + c\text{-}C_5H_9. \qquad [13]$$

For E_{13}, Gordon, Smith, and McNesby (5) estimate 31.8±3.6 kcal/mole and their data indicate [13] to be important only above 450°. Actually C_3H_6 becomes detectable at 273°, with $\Phi(C_3H_6) = 0.002$ at $t = 30$ minutes (Table II). The rate rises slowly with temperature, reaching a maximum Φ of 0.11 at 376° (Table II), at which temperature thermolysis of the substrate is becoming appreciable (Table III). Examination of the Φ vs. t-runs in the J column of Table II indicates C_3H_6 to be truly a primary, if minor, product of the reaction. Since the rates for C_3H_6 and $c\text{-}C_8H_{14}$ vary independently with temperature, C_3H_6 cannot arise by disproportionation between $c\text{-}C_5H_9$ and C_3H_5. Likewise mutual disproportionation of C_3H_5 radicals is eliminated as a C_3H_6 source since allene was sought as a product and found absent. Accepting the conclusion (5) that [13] is significant only above 450°, there remains the reaction

$$H + C_3H_5 \rightarrow C_3H_6 \qquad [14]$$

to explain C_3H_6 formation. Now, with increasing temperature, the H atoms, formed at constant rate in [1], encounter an increasing C_3H_5 level through the steep rise in the rate of [6] with temperature, thus rendering [14] more important. On this basis, C_3H_6 formation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

through [14], and C_6H_{10} formation through [11] should both be determined by the C_3H_5 level to a first approximation. The rate vs. temperature curves for the two products should therefore be similar, with the C_6H_{10} curve showing the steeper slope, since the rate here is proportional to $(C_3H_5)^2$. Inspection of Fig. 2 reveals that such is actually the case, thereby supporting [14] as the route to the C_3H_6 product.

Biallyl formation rises sharply and continuously with temperature (Fig. 2, Table I), as expected from the [6] and [11] sequence determining its rate of formation. In addition to [11] and [14], step [12] should also be favored by the increase in (C_3H_5) with temperature, dictated by the temperature dependence of [6]. However, any increase in the rate of [6] will simultaneously raise (C_3H_5) and depress $(c\text{-}C_5H_9)$. Thus it is not surprising that the $c\text{-}C_8H_{14}$ rate, which depends on (C_3H_5) $(c\text{-}C_5H_9)$ through [12], passes through a maximum (Fig. 2, Table I), and this occurs at ca. 350°. Ultimately, with increasing temperature, $(c\text{-}C_5H_9)$ should go to zero and the $c\text{-}C_8H_{14}$ should vanish. In fact $\Phi(c\text{-}C_8H_{14})$, at $t = 30$ (Table I), maximizes at 0.19 at 358°, and at 376° has only dropped to 0.15. Clearly it would be necessary to study the photosensitization reaction above 376°, where the substrate is thermally unstable (Table III), to find the temperature at which $(c\text{-}C_5H_9)$ is effectively zero. More specifically, the $c\text{-}C_{10}H_{18}$ rate through [4] is a direct monitor of $(c\text{-}C_5H_9)$. On this basis we estimate from Fig. 1 that $(c\text{-}C_5H_9)$ drops to zero at ca. 400°.

The minor products, C_2H_6 and C_3H_8, first detected at 273° and 288° respectively (Table II), presumably arise by addition of H atoms from [1] to the primary C_2H_4 and C_3H_6 products, followed by abstraction from the substrate:

$$H + C_2H_4 \rightarrow C_2H_5, \qquad [15]$$

$$C_2H_5 + c\text{-}C_5H_{10} \rightarrow C_2H_6 + c\text{-}C_5H_9, \qquad [16]$$

$$H + C_3H_6 \rightarrow C_3H_7, \qquad [17]$$

$$C_3H_7 + c\text{-}C_5H_{10} \rightarrow C_3H_8 + c\text{-}C_5H_9. \qquad [18]$$

Extrapolation of the Φ vs. t data at 358° (Table II) gives $\Phi°(C_3H_8) = 0.0015$, and $\Phi°(C_2H_6) = 0.005$, with zero being included for both $\Phi°$'s in the uncertainty range at $t = 0$. It is therefore concluded that both C_2H_6 and C_3H_8 are secondary products of the reaction.

The minor product, CH_4, is again mainly of secondary origin ($\Phi°(CH_4) = 0.0015$ at 358°, Table II). We attribute this product to the reaction (11, 12)

$$C_3H_7 \rightarrow C_2H_4 + CH_3 \qquad [19]$$

followed by

$$CH_3 + c\text{-}C_5H_{10} \rightarrow CH_4 + c\text{-}C_5H_9. \qquad [20]$$

Step [19] would reduce (C_3H_7), thus limiting C_3H_8 formation by [18]. Indeed $\Phi(C_3H_8)$ at $t = 30$ appears to maximize at 344° (Table II). Similarly at the higher temperature in the present range, (C_2H_5) should be reduced by

$$C_2H_5 \rightarrow C_2H_4 + H. \qquad [21]$$

From previous work (16), $E_{21} = 39.5$ kcal/mole. The effect of [21] on (C_2H_5) shows up in the C_2H_6 formation via [16]. Thus this rate flattens off above ca. 350° (Fig. 2, Table II).

Especial interest attaches to the temperature trends of the rates of H_2 and $c\text{-}C_5H_8$ formation. Both rates show similar behavior. Above 250° the rates decline slightly to shallow minima at ca. 300° (Fig. 1), and then begin gently to rise. With [3] the sole source of $c\text{-}C_5H_8$, the rate of this product should follow that of $c\text{-}C_{10}H_{18}$ to zero at ca. 300°, where

presumably (c-C_5H_9) becomes negligible. It follows that at ca. 300° and above a c-C_5H_8-forming reaction, other than [3], must come into play. In this connection McNesby and Gordon (17) studied the photolysis of a 1:1 mixture of acetone-d_6(Ad_6) and cyclopentane from 250 to 402°, thereby producing c-C_5H_9 by hydrogen abstraction from c-C_5H_{10} by CD_3 radicals. They found the hydrogen product of the reaction to be predominantly H_2 ($HD/H_2 = 0.04$), indicating that the H_2 must arise intramolecularly from c-C_5H_9:

$$c\text{-}C_5H_9 \rightarrow c\text{-}C_5H_7 + H_2. \qquad [22]$$

The fate of the c-C_5H_7 radicals was not discussed.

Our findings do not particularly support reaction [22], unless it is assumed that the c-C_5H_7 radicals, formed in [22], disappear almost exclusively by abstraction from the substrate to form c-C_5H_8. Here it is to be noted from Table II that $\Phi(C_{10}H_{16})$, which product likely forms by combination of c-C_5H_9 and c-C_5H_7 radicals (3), has a negative temperature coefficient above 300°, and the expected disproportionation product, c-C_5H_6, is not detectable above 288° (Table II). As the new source of c-C_5H_8 above ca. 300°, we postulate

$$c\text{-}C_5H_9 \rightarrow c\text{-}C_5H_8 + H. \qquad [23]$$

This reaction would explain the upturn in $\Phi(C_5H_8)$ above ca. 300° (Table I, Fig. 1), and also for the similar behavior (Table I, Fig. 1) of $\Phi(H_2)$, since [23] would increase the H-atom yield, thereby raising the rate of H_2 formation by [2]. The contribution which [23] makes to the observed $\Phi(c\text{-}C_5H_8)$ values can be estimated, at least at 350° from the Φ vs. t data in Table I. Thus from the data below 250°, where [3] and [4] are the respective sources of c-C_5H_8 and c-$C_{10}H_{18}$, it was found that $\Phi°(C_5H_8) = \Phi°(C_{10}H_{18})$. At 358°, direct extrapolation to $t = 0$, of the Φ vs. t data gives $\Phi°(C_5H_8) = 0.33$, and $\Phi°(C_{10}H_{18}) = 0.06$. Thus the $\Phi°$ for the c-C_5H_8 produced in [23] would be $0.33 - 0.06 = 0.27$.

Very recently Gordon (18) has re-examined the Ad_6–c-C_5H_{10} photolysis. Hydrogen and c-C_5H_8 were found as products, as well as those originating from [6]. He concludes that the formation of H_2 and c-C_5H_8 can best be explained by step [23], followed by [2], as in our system. From his temperature data he estimates E_{23} to be 28 kcal/mole.

The activation energy for reaction [6], the decomposition of c-C_5H_9 into C_2H_4 and C_3H_5, may be estimated from our data in several ways. Thus assuming that any of the primary C_2H_4 formed in [6] that is consumed during irradiation terminates as C_2H_6, we can calculate $\Phi(C_2H_4 + C_2H_6)$ at $t = 30$, ($\Phi(C_2)$), from Tables I and II. Now the total μM of products formed in 30 minutes of exposure (μM C_2) will be equal to $30\Phi(C_2)\ I_a$, when I_a is expressed in μeinstein/minute. In Fig. 4, log (μM C_2) is plotted against $1/T$. The plot is linear from 252° to 344°, and the best straight line gives $E_6 = 37.2$ kcal/ mole. Above 344°, a major fraction of the cyclopentyl radicals are decomposing by both [6] and [23], and under these conditions the exponential relation between rate of C_2 formation and temperature will no longer obtain.

Alternately E_6 can be calculated from a graph of $\log[\Phi°(C_2H_4)$ vs. $1/T$. To estimate $\Phi°(C_2H_4)$ from the data in Table I, extrapolation to $t = 0$ was used above 312°, and below this temperature the mean $\Phi(C_2H_4)$ values were used, since in this range $\Phi(C_2H_4)$ does not appear to depend on t. The Arrhenius plot is shown in Fig. 5 from which a value $E_6 = 36.2$ was obtained.

On the basis of the proposed mechanism several other relations can be used to determine E_6. Thus

$$\Phi°(C_2H_4)/[\Phi°(c\text{-}C_{10}H_{18})]^{\frac{1}{2}} = k_6/(I_a k_4)^{\frac{1}{2}}. \qquad [24]$$

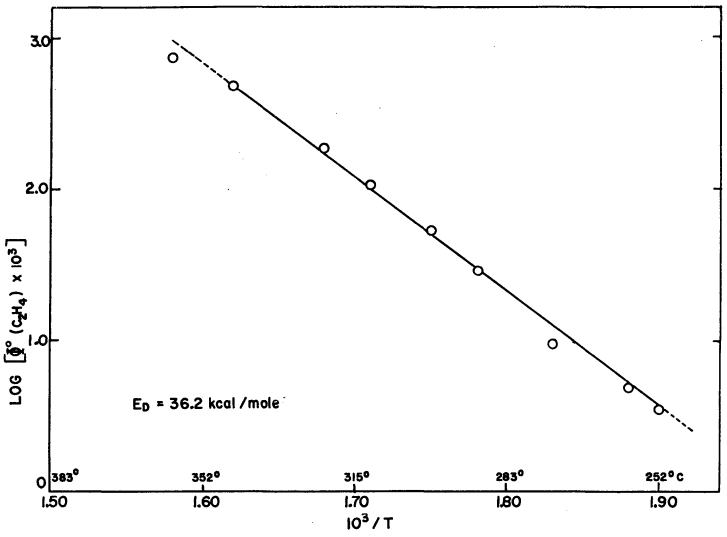

FIG. 4. Arrhenius plot for the decomposition of cyclopentyl radicals into ethylene and allyl radicals, using as monitor the total yield of C_2 products, in the reaction of Hg $6(^3P_1)$ atoms with P.R.G. cyclopentane.

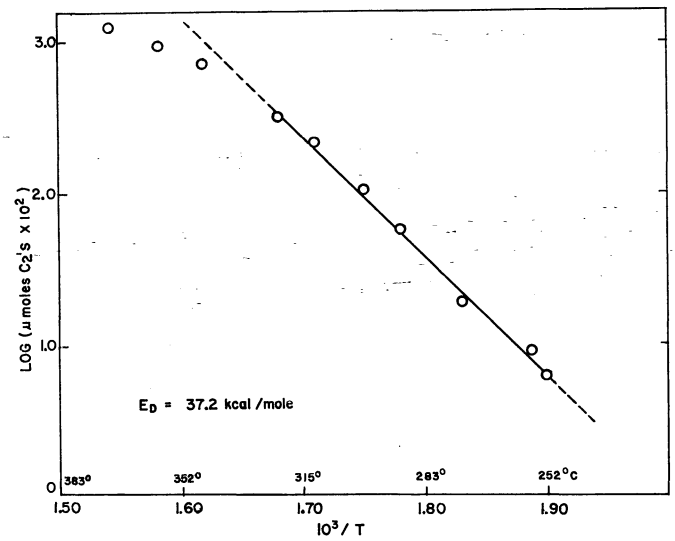

FIG. 5. Arrhenius plot for the decomposition of cyclopentyl radicals into ethylene and allyl radicals, using as monitor the primary quantum yield of ethylene formation, in the reaction of Hg $6(^3P_1)$ atoms with P.R.G. cyclopentane.

Since in the R.H.S. of [24] only k_6 is temperature-dependent, the plot log (L.H.S.) vs. $1/T$ should provide a value for E_6. A good straight line is obtained, from the slope of which $E_6 = 40.0$ kcal/mole. Again from the steady-state relations among the primary reactions, taking $K = 1$,

$$[25] \qquad \Phi^\circ(C_2H_4)/[1-\Phi^\circ(C_3H_6)-\Phi^\circ(C_6H_{10})-\Phi^\circ(c\text{-}C_8H_{14})]^{\frac{1}{2}} = k_6/[I_a(k_3+k_4)]^{\frac{1}{2}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and

$$[26] \qquad \Phi^\circ(C_2H_4)/[1-\Phi^\circ(C_2H_4)+\Phi^\circ(C_6H_{10})]^{\frac{1}{2}} = k_6/[I_a(k_3+k_4)]^{\frac{1}{2}}.$$

The log (L.H.S.) vs. $1/T$ plots for [25] and [26] were both linear and the slopes gave E_6 values of 35.0 and 36.3 kcal/mole, respectively.

Combining the five independent values, we find $E_6 = 36.9 \pm 1.9$ kcal/mole (standard deviation). Since extrapolation to $t = 0$ may lead to large errors, it is likely that the E_6 value of 37.2 kcal/mole, obtained from Fig. 4, is the most reliable. Pertinently Gordon (18) has recently determined E_6 from the Ad_6–c-C_5H_{10} system, and obtains 37.7 kcal/mole, in satisfactory agreement with our findings.

Bywater and Steacie (19), for the reaction

$$n\text{-}C_4H_9 \rightarrow C_2H_4 + C_2H_5, \qquad [27]$$

found $E_{27} = 23$ kcal/mole. This reaction involves scission of a C—C single bond, and formation of one olefinic bond. On the other hand decomposition of c-C_5H_9 via [6] requires two C—C single bond ruptures, and the formation of two olefinic linkages. To a first approximation one would expect, therefore, that E_6 should be roughly twice E_{27} or 46 kcal/mole. The fact that E_6 is actually 9 kcal/mole lower than this estimate can be readily explained in terms of the resonance energy of the C_3H_5 radical, and any strain energy associated with the cyclic c-C_5H_9 structure.

In the mercury $6(^3P_1)$-photosensitized decomposition of saturated hydrocarbons, the C—H bond energy may be as much as 20–25 kcal/mole lower than the 112.7 kcal/mole available from the Hg $6(^3P_1)$ atom. Thus the primary process may lead to energy-rich alkyl radicals. Indeed Back (20) has seriously considered this possibility to explain certain aspects of the propane reaction. It is equally conceivable that in our system the primary reaction [1] may generate an energy-rich c-C_5H_9 radical. Now one would expect such hot species to decompose with a lower activation energy than thermalized radicals. It is therefore of considerable interest to find that our value for E_6 agrees very well with that obtained by Gordon (18) from a system in which c-C_5H_9 was generated by the abstractive attack of CD_3 on c-C_5H_{10}, a reaction which should not transfer excess energy to the resulting c-C_5H_9 radical.

The Thermal Decomposition of Cyclopentane Vapor

For the 351–457° range studied, the major products were C_2H_4, C_3H_6, H_2, c-C_5H_8, and c-C_5H_6 together with very minor yields of CH_4, C_2H_6, and C_3H_8 (Table III). It will further be noted (Table III) that C_2H_4 and C_3H_6 are produced in roughly equimolar yields, suggesting the unimolecular decomposition

$$c\text{-}C_5H_{10} \rightarrow C_2H_4 + C_3H_6. \qquad [28]$$

Alternately C—H cleavage would occur.

$$c\text{-}C_5H_{10} \rightarrow c\text{-}C_5H_9 + H, \qquad [29]$$

followed by [6], with C_3H_6 forming either by [13] or [14]. However, militating against the importance of [13], here, is the fact (4, 5, 17) that C_3H_5 does not appreciably abstract from c-C_5H_{10} below 450°. Also the virtual absence of C_2H_6 in our products (Table III) suggests a low H-atom level in the system, thereby rendering C_3H_6 formation through [14] improbable. Furthermore, no C_6H_{10} was found, again indicating the absence of C_3H_5 radicals. We conclude, therefore, that in our specific temperature range, reaction [28] is the main ring-cleavage process operative, in agreement with earlier workers [21–26]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

who have used [28] to explain the c-C_5H_{10} thermolysis at much higher temperatures. In contrast, McNesby and Gordon (17) concluded that the reaction proceeded partly by [28] and partly by the free radical route. While our findings do not confirm their conclusions, the two studies are not completely comparable in that their work (17) was done above 500°.

If it is accepted that H atoms do not play an important role under our conditions, as discussed above, the c-C_5H_8 and c-C_5H_6 products must be attributed to intramolecular processes.

$$c\text{-}C_5H_{10} \rightarrow c\text{-}C_5H_8 + H_2 \qquad [30]$$

followed by further dehydrogenation of c-C_5H_8

$$c\text{-}C_5H_8 \rightarrow c\text{-}C_5H_6 + H_2. \qquad [31]$$

Now [31] and [32] would require that the H_2 yield be related to the amounts of c-C_5H_8 and c-C_5H_6 produced. From Table III, the ratio of H_2 found to that required by [30] and [31] varies from 0.6 to 0.98. The disparity is consistent with the experimental error and the incompleteness of the mechanism assumed. Insufficient data are available to discuss the origins of the minor products, CH_4, C_2H_6, and C_3H_8.

The activation energy for [28] can be estimated from the three Arrhenius plots log $[\mu M(C_2H_4)]$, log $[\mu M(C_3H_6)]$, and log $[\mu M(C_2H_4+C_3H_6)]$ all vs. $1/T$. The results give E_{28} values respectively of 50.4, 48.9, and 49.5 kcal/mole.

For reaction [30], the activation energy can be obtained by plotting log $[\mu M(c\text{-}C_5H_8) + \mu M(c\text{-}C_5H_6)]$ vs. $1/T$ on the assumption that c-C_5H_8 is the intermediate in the formation of c-C_5H_6, as indicated in [31]. For E_{30} we obtain 42.2 kcal/mole. Alternately we may plot log $[\mu M(H_2)-\mu M(c\text{-}C_5H_6)]$ vs. $1/T$. Here E_{30} is 46.4k cal/mole. Finally we may represent both the log $[\mu M(c\text{-}C_5H_8) + \mu M(c\text{-}C_5H_6)]$ and the log $[\mu M(H_2)-\mu M(c\text{-}C_5H_6)]$ points against $1/T$ on the same graph and put the best straight line through all points. Thereby we find $E_{30} = 43.7$ kcal/mole. Considering the paucity of the data and the inherent experimental error in the low temperature values for $\mu M(c\text{-}C_5H_8)$, we conclude E_{30} to be 44 ± 2 kcal/mole. For similar reasons we estimate E_{28} to lie within the range 49.6 ± 2 kcal/mole.

Finally it should be emphasized that in this brief ancillary study on the thermal decomposition of c-C_5H_{10} vapor, we may well be examining a reaction which is entirely heterogeneously catalyzed on the quartz surface of the reaction vessel.

MOLD METABOLITES

2. THE STRUCTURE OF GRISEOVIRIDIN[1,2]

M. CATHERINE FALLONA, P. DE MAYO, T. C. MCMORRIS, T. MONEY, AND A. STOESSL

Department of Chemistry, University of Western Ontario, London, Ontario

Received August 21, 1963

ABSTRACT

By a combination of selectively reductive and hydrolytic processes the structure of perhydrodethiogriseoviridin diacetate, obtained by Raney nickel reduction of griseoviridin diacetate, has been shown to be that of a macrocyclic lactonic peptide (III). Other hydrolytic and degradative experiments have ascertained the points of attachment of the cysteine moiety and the disposition of the functional groups in the aminodecanoic acid. The remaining three carbon atoms have been shown to be part of an unusual dehydro amino acid fragment, and the totality of this and other evidence has defined the structure of griseoviridin as represented in (XXVII).

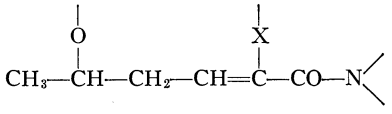
For personal use only.

The antibiotic griseoviridin, isolated from cultures of a strain of *Streptomyces griseus* (16), has been the subject of studies by Ames, Bowman, and their collaborators (3, 4, 5) and by ourselves (1). The results of these investigations may be summarized as follows.

Griseoviridin, $C_{22}H_{27}O_7N_3S$,* on reduction with Raney nickel gave perhydrodethiogriseoviridin (2).† This on hydrolysis under various conditions gave 5-hydroxyhexanoic acid (1), two molecules of alanine (5), and ω-aminodecanoic acid, the latter representing a chain from which all the originally present functional groups had been stripped (5). All the carbon atoms in griseoviridin itself could, therefore, be accounted for in terms of four distinct moieties. These were (*a*) a C_6 fragment the structure of which had been shown (1) to be (I), (*b*) a C_3 alanine precursor which had been identified as D-cysteine (4), (*c*) a second C_3 alanine precursor concerning the nature of which no direct evidence was yet forthcoming, and (*d*) an unsaturated ω-aminodecanoic fragment required to contain, also, at least one of the hydroxylic functions present in griseoviridin itself. Another pertinent observation was the fact that griseoviridin contained but one C-methyl group, present in the C_6 fragment (1), and, therefore, that both the methyl groups present in the two molecules of alanine derived from perhydrodethiogriseoviridin were artefacts. Other significant results were recorded and will be referred to at the appropriate point. It may



X = O, N, or S

(I)

be mentioned here that discussion of an important derivative of griseoviridin, namely its "hydrochloride," because it is not directly relevant to the structural elucidation of griseoviridin, will be deferred to the following paper.

[1]*Reference (1) is considered Part 1 in this series.*
[2]*A portion of the work here reported formed a preliminary communication (2).*

**The analytical figures did not permit selection of the number of hydrogen atoms to nearer than two; the final result awaited the structural clarification.*
†*This compound perhydrodethiogriseoviridin was originally termed octahydrodethiogriseoviridin, but has been renamed more appropriately. An authentic octahydro compound is referred to below.*

Since perhydrodethiogriseoviridin diacetate was obtainable from griseoviridin diacetate without the removal of any oxygen function and under mild conditions it seemed probable at the outset that this molecule contained the framework of carbon atoms originally present in griseoviridin. The relevant observation (4) that it was a neutral substance implied, considering the constituent functional groups, that the substance be cyclic, and be a lactone or, less likely, a diacylamide: the infrared spectrum (4) could be interpreted in either sense.

Perhydrodethiogriseoviridin diacetate prepared by Raney reduction of griseoviridin diacetate, and also by acetylation of perhydrodethiogriseoviridin (4) was hydrolyzed with dilute alkali at room temperature. Aside from the titrimetric requirements of the acetates one further equivalent of alkali was consumed. The product, which contained no acetyl group, was an acid and was characterized as the crystalline methyl ester. The latter consumed one equivalent of alkali on similar mild hydrolysis.

If the hydrolysis were that of a diacylimide, the functional groups revealed would necessarily be those of a carboxylic acid and an amide. In the case of a lactone a new hydroxyl function would be exposed. In any other circumstances an amino group would be released, and that this was not the case was shown by titration of the methyl ester with hydrochloric acid: no basic function could be detected. Acetylation of the ester gave an oily triacetate the nature of which was indicated by analytical data and also, persuasively, by the presence of three sharp closely spaced peaks (3H each) in the n.m.r. spectrum at τ 7.92, 7.94, and 7.96 for the three acetates. It was therefore to be concluded that perhydrodethiogriseoviridin diacetate was a lactone.

Three structures could then be written for the hydroxy acid corresponding to perhydrodethiogriseoviridin considering only, for the moment, the order of union of the four constituent moieties. These could be represented as in (II*a*, *b*, or *c*):

(II) (*a*) C_5—CO—Ala—Ala—NH—C_9—COOH,

(*b*) C_5—CO—Ala—NH—C_9—CO—Ala—OH,

(*c*) C_5—CO—NH—C_9—CO—Ala—Ala—OH.

In II*a* and II*c* the dipeptide alanylalanine was present whilst in II*b* and II*c* the terminal carboxyl was that of alanine. With these experimentally determinable features a solution was possible.

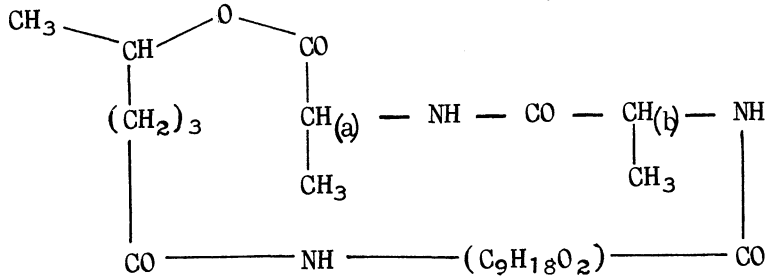
Milder acid hydrolysis of perhydrodethiogriseoviridin diacetate than had been previously used, afforded, after separation of the products by chromatography, alanylalanine isolated in crystalline form and further characterized by hydrolysis to alanine.

To distinguish between II*a* and II*c* advantage was taken of the selective reducing properties of lithium borohydride (6). Reduction of perhydrodethiogriseoviridin diacetate with this reagent, it was expected, would result in conversion of the lactonic carboxyl to primary alcohol and leave unaffected the remaining amide functions. The product obtained by this mode of reduction was hydrolyzed and the basified solution steam distilled. A volatile base was obtained, characterized as the crystalline 3,5-dinitrobenzoate, which behaved indistinguishably from *dl*-alaninol. Further, the active and racemic esters had identical infrared spectra. These observations allowed the rejection of (II*a*) as inappropriate, and required (II*c*) as the correct representation of the structure of the acid corresponding to perhydrodethiogriseoviridin.

Three hydroxyl groups were available as the site of lactonization. It will be shown later that, in parallel studies, it was ascertained that the two such functions in the C_{10} fragment

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

were not so involved, and that the C_6 hydroxyl provided the ethereal oxygen. With this anticipation perhydrodethiogriseoviridin could then be represented as (III).



(III)

It was recorded previously (1) that (III), on alkaline hydrolysis gave, as expected, δ-caprolactone (IV). Hexahydrodeoxygriseoviridin, a reduction product of griseoviridin hydrochloride (see following paper), did not give (IV) on hydrolysis (1) and the same observation was later made with respect to hexahydrogriseoviridin diacetate. This suggested (1) that the atom 'X' in the representation (1) might be sulphur, and substance was added to this conception when it was observed that, whilst griseoviridin on treatment with perbenzoic acid gave an amorphous and uncharacterized "oxide" which did not show absorption bands in the infrared corresponding to those expected for sulphones, hexahydrodeoxygriseoviridin (1) and, later, hexahydrogriseoviridin diacetate gave such sulphones readily. The interpretation drawn from these observations was that hydrogenation or hydrogenolysis in the vicinity of the sulphur rendered it open to oxidative attack. Since, in the preparation of hexahydrodeoxygriseoviridin and hexahydrogriseoviridin diacetate, the unsaturation from the C_6 fragment was removed, as shown by the non-formation of crotonaldehyde after ozonolysis and distillation, the formulation (I, where X = S) would be acceptable. That this interpretation was, in fact, required was shown by the further observation that whereas, as has been mentioned, neither of the hexahydro-compounds gave (IV) on alkaline hydrolysis, the corresponding sulphones did so, together with one molecule of sulphur dioxide. This is readily explicable when it is recalled that the sulphur atom forms part of a cysteine moiety. The course of the base-catalyzed decomposition of the thio ether and sulphone may then be represented as in (V) and (VI). The obvious consequence of this mechanistic interpretation was that the alkaline hydrolysis of hexahydrogriseoviridin diacetate should produce the thiol (VII). By the process described in the experimental section this substance was isolated as a colorless oil which analyzed correctly. The n.m.r. spectrum with a doublet (3H) centered at τ 8.61 ($J \sim 6$ c.p.s.) showed the presence of a methyl attached to carbon bearing hydrogen. The infrared spectrum, beyond showing the obvious carbonyl absorption at 1735 cm^{-1}, revealed the presence of a thiol grouping with a weak band at 2570 cm^{-1}. The only element of structural ambiguity remaining—the point of attachment of the thiol grouping—was removed when it was noted that the pK_a of the hydroxy acid corresponding to (VII) was 3.76. This represented an increase in acidity over 5-hydroxyhexanoic acid or acetic acid comparable with that reported for thioglycollic acid (pK_a 3.67) (7).

In (V) the cysteine moiety represented was the precursor of either alanine (*a*) or

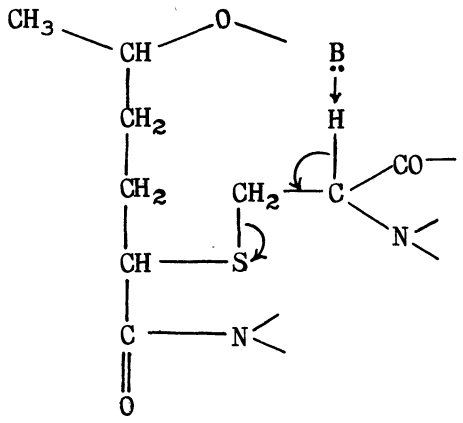
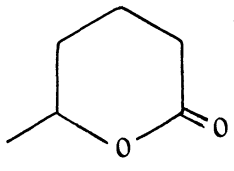
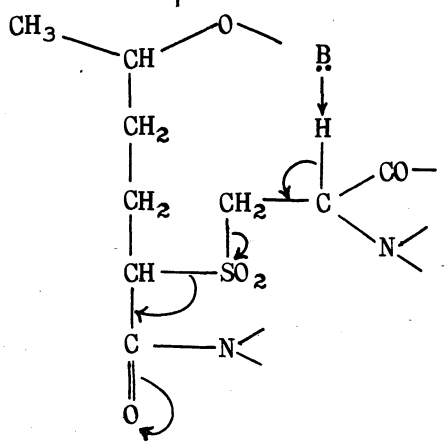
(VII)



(V)

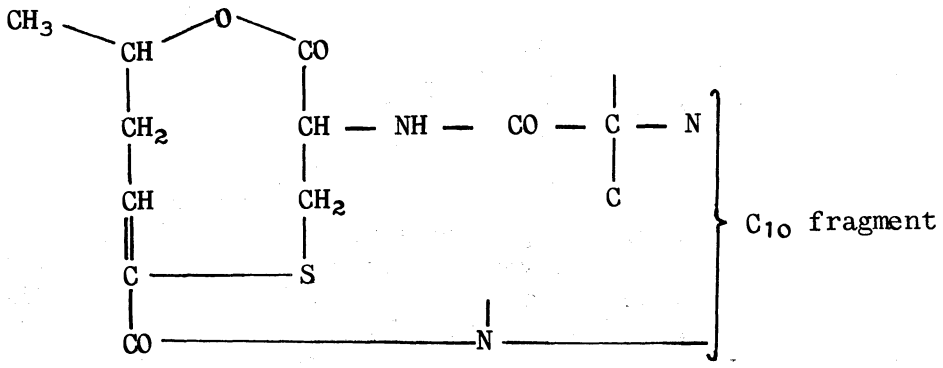


(IV)



(VI)

alanine (*b*) in (III). In the first case, represented in (VIII), the cysteine carboxyl would be involved in lactone formation. In the alternative (IX), the other, as yet unspecified C_3 fragment, would be the precursor of alanine (*a*), the cysteine being that of alanine (*b*), with its carboxyl involved, consequently, in amide formation.



(VIII)

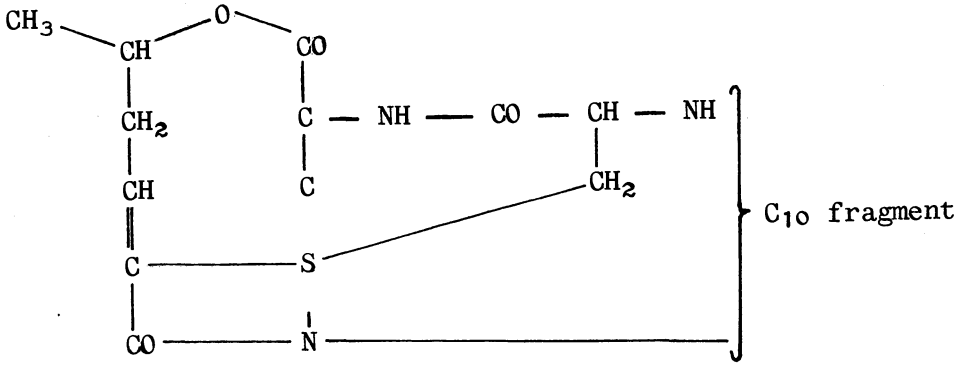
For personal use only.

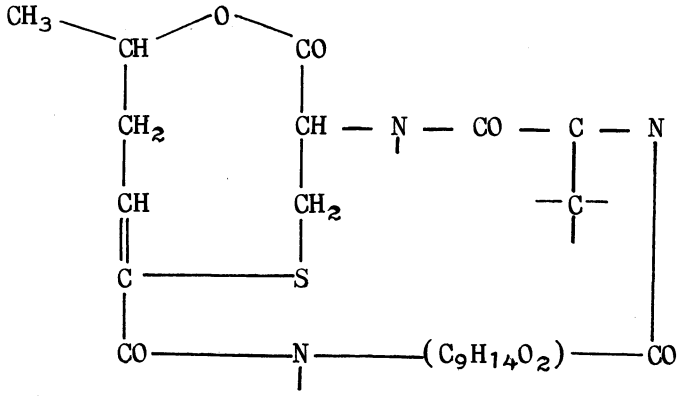


(IX)

In the event that (VIII) were correct, reduction of griseoviridin diacetate with lithium borohydride would, in reducing the lactone carbonyl specifically, be reducing the cysteine carboxyl. With (IX) the reverse situation would obtain. Since, however, it might cogently be argued that for the release of the sulphur from the C_6 fragment the unsaturation was a prerequisite, and that hydride reduction might, incidentally, remove this unsaturation, it was first shown that hexahydrogriseoviridin diacetate also gave cysteine on hydriodic acid – red phosphorus hydrolysis.

The decisive experiment could now be performed. Reduction of griseoviridin diacetate with lithium borohydride gave an oil in the infrared spectrum of which the amide carbonyl bands were unchanged in intensity, but in which the lactone carbonyl band was absent. Hydriodic acid – red phosphorus hydrolysis of this, followed by isolation of the amino acid fraction gave material which on paper chromatographic analysis showed the total absence of cysteine and cystine. Conditions were selected which would have revealed far smaller (less than 5%) amounts of the cystine obtained from the material not treated with lithium borohydride.

From these experiments it was concluded that alanine (*a*) was derived from cysteine and the part structure of griseoviridin could reasonably be expanded to that shown in (X).



(X)

For personal use only.

Although griseoviridin showed no well-defined high intensity absorption bands in the ultraviolet the intensity of the absorption between 200–225 mμ ($\epsilon \sim 39{,}000$), indicated that several chromophores must be absorbing in that region. One of these systems was contained in (X) and this, together with at least one other high-intensity band was removed upon hydrogenation to the hexahydro series leaving what was probably a single chromophore (λ_{max} 212 mμ; ϵ, 15,700). This, for reasons presented below, was to be attributed to the other C_3 fragment, so that a conjugated system of some kind was present in the aminodecanoic acid. Both a simple diene and an α,β-unsaturated amide could be entertained as possibilities for this chromophore, and a number of modes of distinguishing between these alternatives with varying degrees of finesse were considered. The simplest appeared the exposure of the molecule to reaction with maleic anhydride. In the event griseoviridin gave, with maleic anhydride in benzene solution, a crystalline adduct showing in the infrared spectrum the required anhydride bands.

Since reaction of a diene with maleic anhydride removes the dienic chromophore and adds only a single cis ethylene linkage, subtraction of the chromophore of an adduct from that of the starting material should reveal the nature of the chromophore removed by adduct formation. In the present instance such a check was necessary to ensure that no bond migration had occurred under the reaction condition prior to adduct formation. The difference spectrum is represented in Fig. 1, and is compatible with expectation.

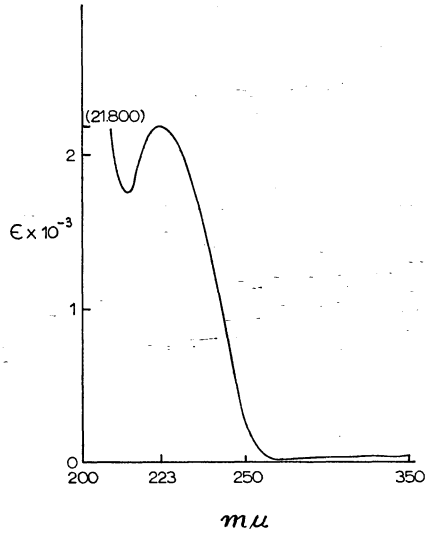

FIG. 1. Difference spectrum of griseoviridin diacetate and its maleic anhydride adduct.

Since the aminodecanoic acid moiety was now known to have four carbon atoms involved in a conjugated diene, and since it was further known that the hydroxyl groups were not vicinal (3) it seemed probable that one of these hydroxyl groups would be attached to a carbon atom adjacent to the dienic system, the probability being further increased by the fact that griseoviridin did not have the properties of a carbinolamine. An attempt to demonstrate this by forming an adduct of griseoviridin itself (instead of the diacetate) was partially successful in that the crude product after treatment with diazomethane showed the expected carboxylic and γ-lactone bands in the infrared spectrum, the lactone being formed by the internal attack of the vicinal hydroxyl on the anhydride. The product was, however, amorphous and intractable.

Griseoviridin lacked solubility in most solvents suitable for manganese dioxide allylic oxidation; it had however sufficient solubility in acetone for such to be attempted. By this means a crystalline dienone dehydrogriseoviridin, λ_{max} 277 mμ was obtained, further characterized as the crystalline acetate. The next object was the ascertaining of the spatial relationship of the second hydroxylic function with respect to the presently established five-carbon sequence. Since a vicinal position to the hydroxyl group was excluded a β- or vinylogous β-position seemed probable, and attempts were made to achieve β-elimination under mild conditions in dehydrogriseoviridin.

Addition of a small amount of alkali to an alcoholic solution of the dienone acetate produced, instantaneously, an absorption band in the ultraviolet at 415 mμ, moved to 355 mμ on acidification. The position of this absorption rendered interpretation somewhat uncertain since no distinction could be made between β- and vinylogous β-elimination. A preliminary removal of unsaturation from the dienone was therefore attempted. This was achieved in two ways.

Treatment of the dienone acetate very briefly (2 minutes) with activated zinc in acetic acid resulted in the complete disappearance of the long-wavelength-high intensity absorption band. Evidently electrons had been successfully transferred to the dienonic system, but the position of protonation was not revealed, it being possible mechanistically that the remaining ethylenic linkage be $\beta\gamma$ or $\gamma\delta$ to the carbonyl group. This subject will be returned to below.

This dihydrodehydrogriseoviridin acetate on treatment with alkali immediately produced, in alkaline solution an intense absorption at 387 mμ as shown in Fig. 2. This

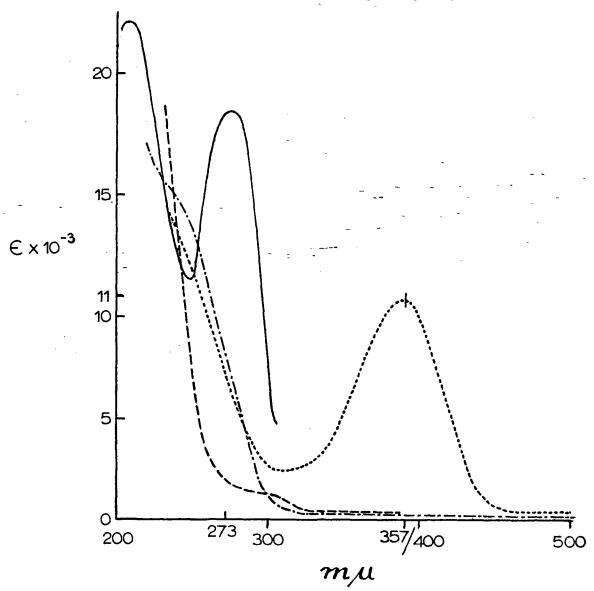

FIG. 2. Absorption spectrum of dehydrogriseoviridin (—), zinc – acetic acid reduction product before alkali treatment (- - -), after alkali treatment (· · ·), and after acidification of the alkali treated solution (·—·).

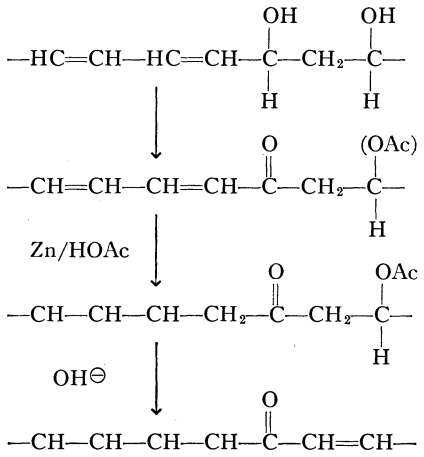
absorption was removed on acidification with acid but was reversibly generated. Isolation of the product gave an amorphous product which analyzed correctly for the loss of acetic acid, and whose infrared carbonyl absorption was clearly indicative of the loss of an acetoxyl group. Since in the zinc reduction product one ethylenic linkage had been

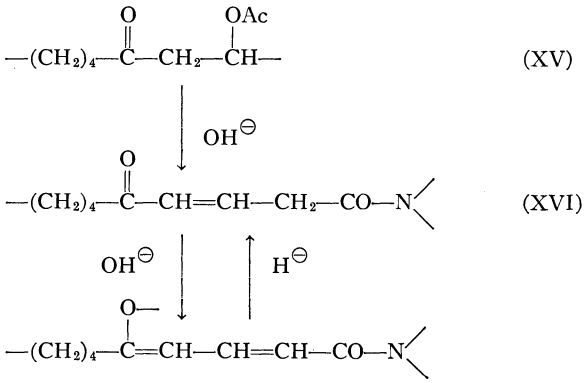
saturated, the possibility of vinylogous β-elimination could be clearly excluded, and the disposition and environment of seven contiguous carbon atoms in the ω-aminodecanoic acid be represented as in (XI) for griseoviridin, the further transformations being indicated in (XII)–(XIV). The loss of the acetoxyl was the surety of β-elimination in (XIV),



but the position of the absorption maximum in alkaline solution, and its reversibility, indicated the presence of an enolic system, and therefore of the participation of some other function. To simplify the interpretation a more saturated derivative than (XIII) was sought in which the putative β-elimination could be induced.

Hydrogenation of (XIII) resulted in saturation of the C_{10} ethylenic linkage and also of the C_6 unsaturation, to give a crystalline hexahydrogriseoviridin. The same crystalline substance was obtained by hydrogenation of (XII). Treatment of this substance having part structure (XV) with .05 *N* alkali for three seconds resulted in the ejection of the acetoxyl group. Acidification of the product with acetic acid and subsequent isolation gave a crystalline elimination product.

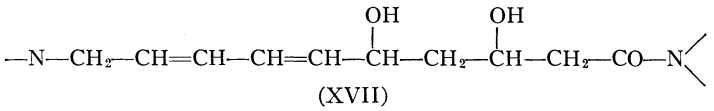
This substance showed absorption as represented in Fig. 3 and, since this was reversible, similarly contained an enolic system. The only group available for fulfilling this desired function was together with the unsaturated ketone produced by elimination, the terminal carboxyl; incorporation of this revealed the complex enolic function under discussion as that of a vinylogous β-ketoamide represented in (XVI). The rather longer wavelength of the enolate absorption maximum than perhaps expected is undoubtedly due to the cisoid disposition of the ethylenic linkage as required by the geometry of the molecule.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The incorporation of the chain of atoms represented by (XVI) into the framework of the ω-aminodecanoic acid led to a unique structure (XVII) for this fragment. However, it was realized that the disposition of these atoms in the chain were related, directly, only to one end, that of the carboxamide function, of the amino acid.

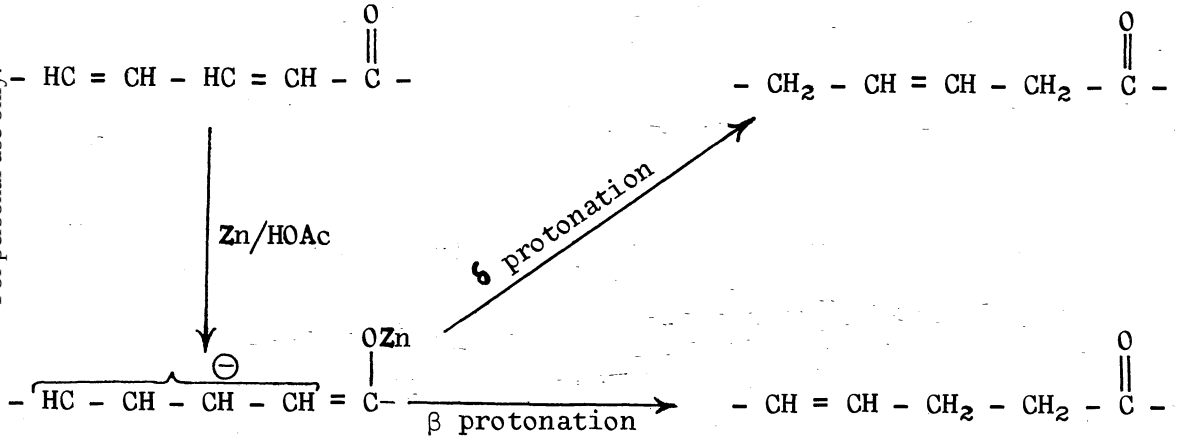
A consideration of the environment of the nitrogen atom at the other end of the chain suggested that, if the ethylenic linkages in the C_{10} and the C_6 fragments were cleaved by ozonolysis, quite mild acid hydrolysis would suffice to release glycine—an amino acid obtained by alkaline, but not by acid, hydrolysis of griseoviridin. This proved to be the case, and glycine was the only amino acid detected under the conditions used. Without



(XVII)

such prior ozonolysis no amino acids were revealed in the hydrolyzate by paper chromatography.

At this point it was of interest to subject the zinc reduction product, containing the part structure (XIII), to the same treatment to ascertain whether protonation of the carbanion (XVIII), produced by electron transfer from the zinc metal, was specific:



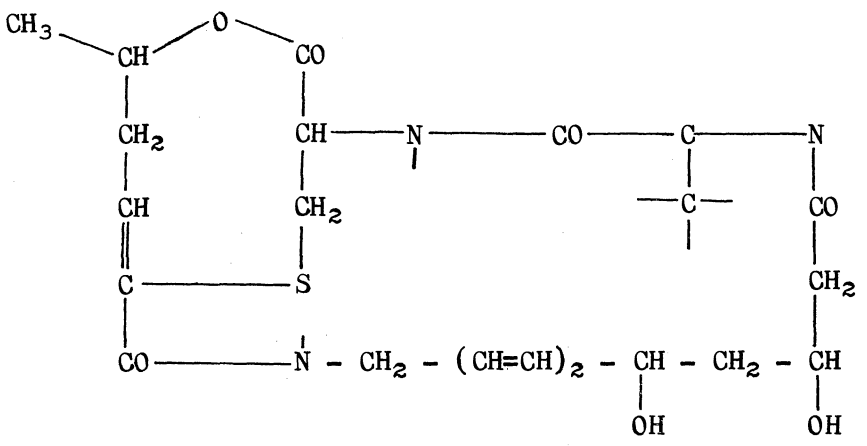
(XVIII)

Ozonolysis and mild acid hydrolysis in this case gave both glycine and β-alanine in roughly equal amounts, clearly indicating indiscriminate β and δ protonation.

At this point in our investigations the partial structure of griseoviridin (X) could be expanded to (XIX), and it was clear from this formulation why Bowman and his group obtained ω-aminodecanoic acid and an unidentified hydroxyaminodecanoic acid by Clemmensen reduction and hydrogenation–hydrolysis (5) respectively of perhydrodethiogriseoviridin. The hydroxyl groups were doubtless β-eliminated by activation of the appropriate protons by the terminal carboxamide function. Our attempts to induce such elimination with mild base were unsuccessful because under the general conditions necessary for such elimination, mild as they can be (8), the chromophore was destroyed and only a transitory formation of peaks of low intensity could be observed.

In the manipulations performed on the C_{10} fragment both hydroxylic functions had been transformed or affected without disturbance of the remote lactonic function. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



(XIX)

previous assumption made, in the determination of the structure of perhydrodethiogriseoviridin, that the ethereal oxygen of the lactone was that in the C_6 fragment could, therefore, be justified.

The final structural problem presented by griseoviridin was contained in the nature and arrangement of the three carbon atoms which appeared as alanine (*b*) in perhydrodethiogriseoviridin. It was not found possible to isolate these three atoms as one fragment in any form other than alanine, but a considerable amount of indirect evidence was forthcoming.

That this group of atoms contained unsaturation was known since it represented the residuum of ultraviolet absorption after saturation of the C_6 and C_{10} fragments in, for instance, hexahydrogriseoviridin diacetate. This unsaturation was resistant to further hydrogenation under the same condition, but conversion of the thioether to sulphone and subsequent hydrogenation in acetic acid over platinum oxide removed this unsaturation. The new substance perhydrogriseoviridin diacetate sulphone produced now contained an extra methyl group and on acid hydrolysis gave alanine. It appeared, therefore, that conditions of hydrogenation sufficiently severe to effect reduction also, directly or indirectly, effected hydrogenolysis.

Bands in the infrared spectrum at about 1600 cm^{-1} and 1500 cm^{-1} (Table I) were observed in all compounds which contained the C_3 unsaturation, which were absent in all compounds wherein such unsaturation had been removed, and which were therefore to be associated with this unsaturation.

These facts could be interpreted in terms of the part structure (XX*a*) which also explained in a simple manner the formation of glycine and formic acid (by β-addition and dealdolization) on alkaline hydrolysis of griseoviridin. The atom Y in (XX*a*) could not be hydrogen (as in XX*b*) because no spectral evidence for such a methylene group was obtainable—and such functions are readily detectable in the infrared and n.m.r. spectra—and no formaldehyde was produced on the ozonolysis of griseoviridin diacetate.

It was observed that in all substances which contained the C_3 unsaturation there was a sharp singlet (1 H) close to τ 1.9 in the n.m.r. spectra. This proton signal was to be

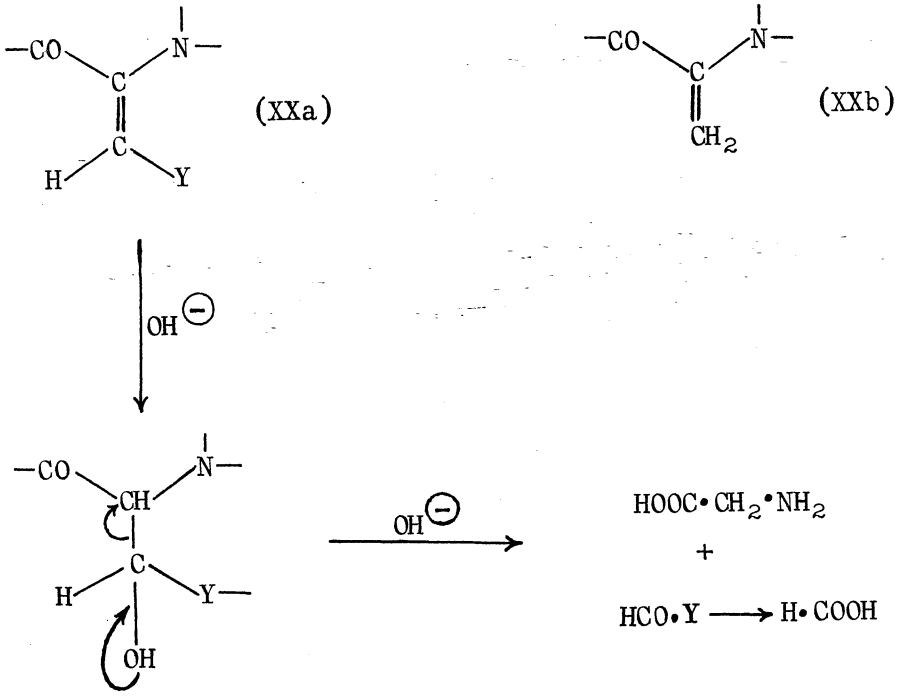
NOTE: A blank space indicates no determination made in that medium.

attributed to the proton in (XX*a*). Its position at very low field suggested that Y was an electron-withdrawing group, and that it was not the site of any proton. Bearing in mind the nature of hydrogenolysis of the C_3 fragment, which must be understood to proceed by hydrogenation, β-elimination, and further hydrogenation, then Y was required to be oxygen or nitrogen.



Support for the part-structure represented in (XX*a*) came from an unexpected source. The Raney desulphurization of griseoviridin diacetate gave an adequate yield of crystalline product, but purification was difficult and the final yield of pure perhydrodethiogriseoviridin diacetate was low. A careful examination of the mother liquors gave, after

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

tedious recrystallizations, a new substance which also had the requisite analysis for perhydrodethiogriseoviridin diacetate and which had an infrared spectrum virtually superposable on Bowman's substance. The melting point of the new substance, isoperhydrodethiogriseoviridin was close to that of perhydrodethiogriseoviridin diacetate, and the depression in mixed melting point though probably real was not impressive.

That these were, indeed, two substances was clearly shown by the large differences in specific rotation (84°) and by significant discrepancies in the n.m.r. spectra (Fig. 3). In

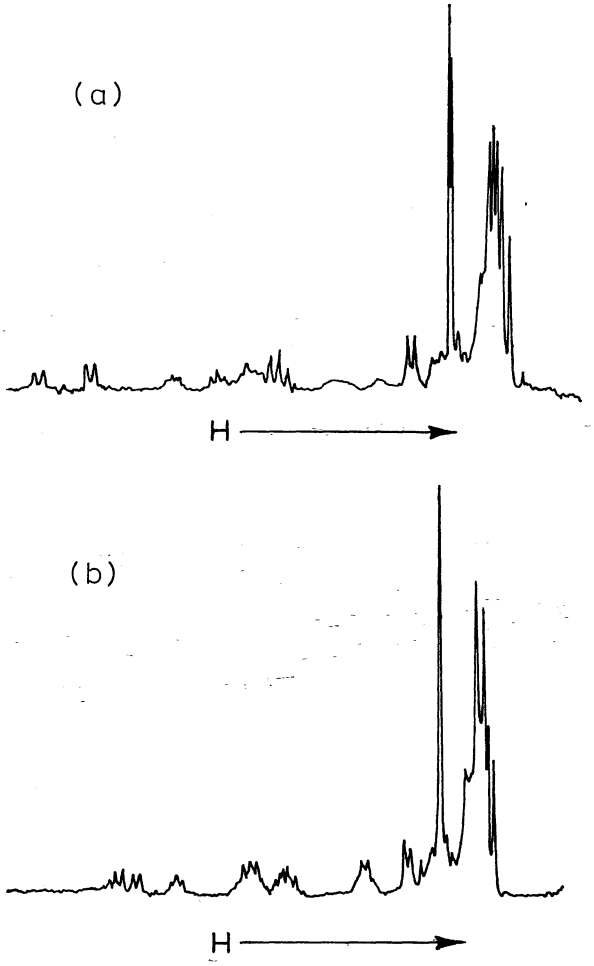


FIG. 3. Absorption spectrum of base eliminated compound (XVI) in neutral (—) and alkaline (···) solution.

particular divergencies were observed in the region where the methine hydrogen and amide hydrogen of the alanine moieties were displayed. These differences indicated alternative orientations of one of the alanine moieties and were explicable in terms of approach of the catalyst to either side of the ethylenic linkage in its final reduction stage:

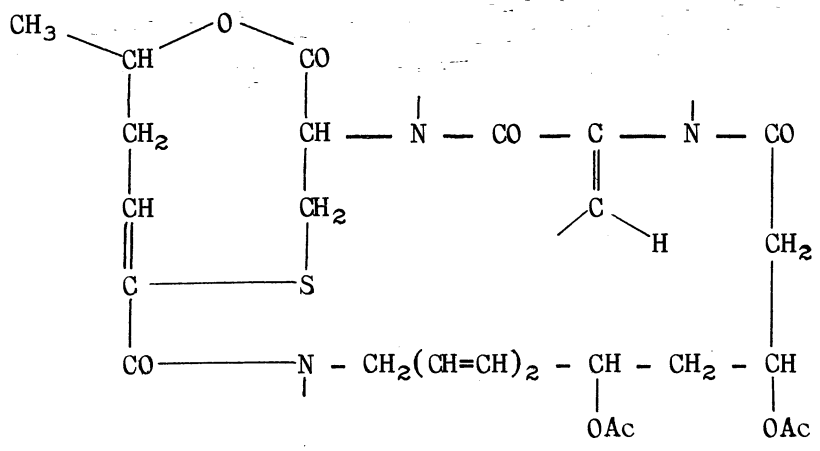
(XXb) (XXc)

Attempts to interrupt this sequence of hydrogenation–elimination–hydrogenation at an intermediate stage were unsuccessful. Using a weaker Raney catalyst (B.D.H. stabilized catalyst) under strictly defined conditions a substance octahydrodethiogriseoviridin (see footnote † on p. 371) was obtained which had lost the sulphur atom. All unsaturation appeared to have been removed with the exception of that contained in the C_3 fragment. Thus the compound exhibited high enol absorption in the ultraviolet spectrum and showed the appropriate bands at 1600 cm^{-1} and 1511 cm^{-1} in the infrared spectrum. On alkaline hydrolysis glycine, formic acid, and δ-caprolactone were obtained. However, attempted hydrogenation to the dihydro stage only (XXI) was unsuccessful: the substance took up two molecules of hydrogen with the formation of perhydrodethiogriseoviridin diacetate. Such behavior was not totally unexpected since the resistance of (XX*a*) to hydrogenation argued that this moiety was embedded in the molecular environment, whilst, in contrast (XX*c*) would be expected to be exposed.

The participation of nitrogen or oxygen in the function (XX*a*), it was recognized, would define the number of active hydrogen atoms present in griseoviridin diacetate which could at this stage be represented by (XXI). In principle any of the three nitrogen atoms,



(XXI)

directly or through the lactim ether, could be involved, and if such were the case, as followed from the above discussion, then (XXI) should have two active hydrogen atoms

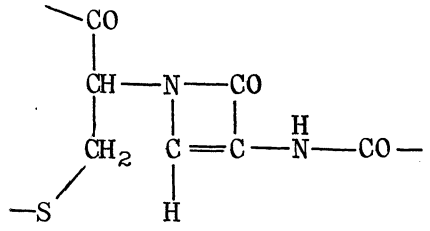
Hexahydrodeoxygriseoviridin	3.0			3
Hexahydrodeoxygriseoviridin acetate	2.2			2

*Modified procedure using lithium aluminum hydride.
†A standard, N-acetylcyclohexylamine was assumed to have one active hydrogen. A second standard, N-acetylbenzylamide, was calibrated against it and found to have 1.05 active hydrogen by comparison of the integrated areas at the same molecular concentration. No correction for slit width was made.
‡Deuterium exchange was effected by repeated evaporation from dioxan-D_2O, complete exchange being followed by intensity of the ND stretch in the infrared. The fully deuterated compound was assumed to have zero active hydrogen. The n.m.r. integration was referred to the τ 1.9 peak (one proton).

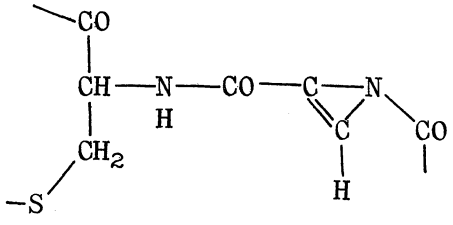
approximately four and two hydrogens for griseoviridin and its diacetate respectively. However, such determinations are not impeccably free from suspicion, and alternative methods were investigated for confirmation. In the first, the active hydrogen atoms in griseoviridin diacetate were exchanged with deuterium and the difference in the numbers of protons present estimated by integration in the appropriate areas with respect to the sharp singlet at τ 1.9. Again approximately two hydrogen atoms were detected. In the second procedure the NH stretch in the infrared was integrated directly,* with the same result.

Of the possibilities available two could be immediately dismissed (XXII*a* and XXII*b*) as requiring chemical behavior not consonant with that observed in griseoviridin. Amongst the various incompatibilities observed, the resistance of this unsaturated system to hydrogenation, and the similar resistance to moderately strong acid conditions (implied by such transformations as the formation of the hydrochloride) were particularly striking; the lability of such systems is well-known.

Similar arguments excluded all but two of the remaining possibilities. Of these the more superficially attractive was that represented in (XXIII). Much of the chemical evidence available could be interpreted in terms of (XXIII), and in addition a study of 4-carbethoxyoxazole (XXIV) as a model indicated that the vinyl hydrogen indeed appeared at approximately τ 1.9 and that a band in the infrared spectrum at 1590 ($CHCl_3$)



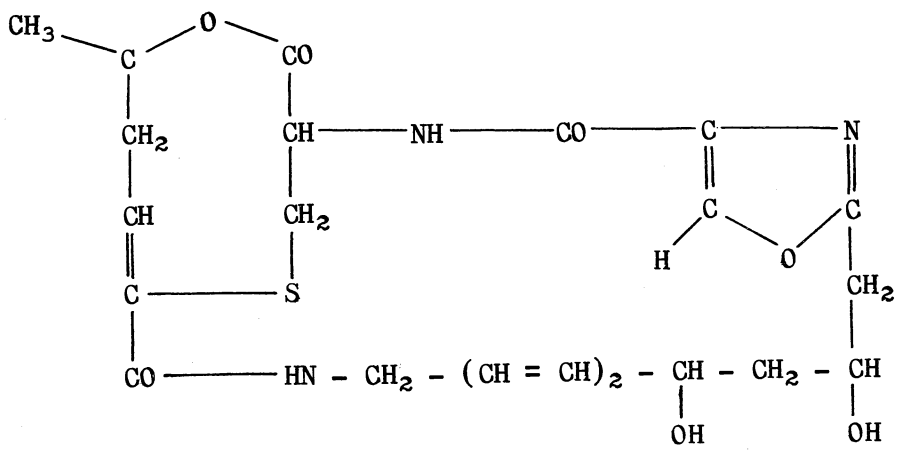
(XXIIa)



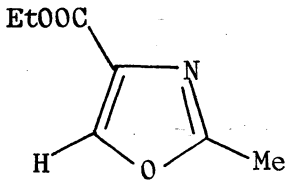
(XXIIb)

Such amide NH stretches appear to be remarkably independent of the nature of the substituents (9). As shown in the table a standard was taken, checked against a suitable model.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



(XXIII)



(XXIV)

was also observed, but the associated band at ca. 1500 was, significantly, absent. This formulation was rejected for the following reasons.

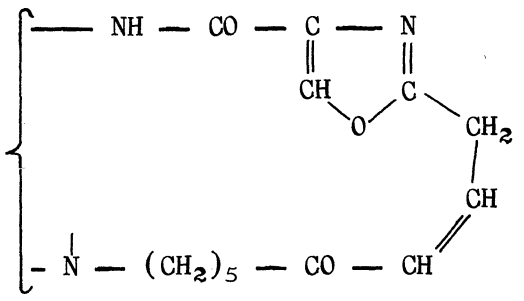
Although oxazoles are weak bases and (XXIV) would be expected to be even weaker, nevertheless it could be titrated in acetic acid solution when a pK_a of 3.3 was found. Under the same conditions a solution of griseoviridin diacetate was indistinguishable from the solvent.*

The presence of the unsaturated chromophore could be detected, as already discussed, both in the infrared and in the n.m.r. It was still present in the vinylogous β-keto amide from hexahydrodehydrogriseoviridin, which on the basis of (XXIII) was required to be represented as in (XXV). The behavior of this substance with dilute alkali is not compatible with (XXV) for which no such facile enolization as was noted could be expected. A similar observation could be made with regard to the ketone hexahydrodehydrodesoxygriseoviridin obtained from hexahydrodeoxygriseoviridin sulphone (1) which, in view of the nature of the hydrochloride, would be represented as (XXVI).

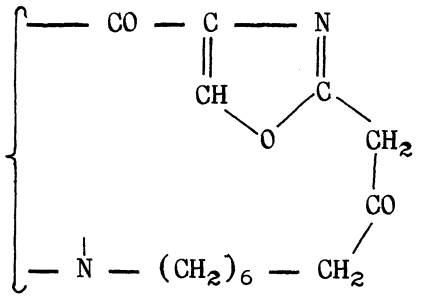
The most compelling evidence, however, devolved from the nature of the "hydrochloride" of griseoviridin (4). In this substance the unsaturated three-carbon unit remains intact whilst the nitrogen and carbon atoms required for oxazole formation could be demonstrated to be otherwise employed (see following paper).

**When left standing the 'perchlorate' separated out. As discussed in the following paper this slow process is a chemical reaction, and has no relevance to the present argument.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

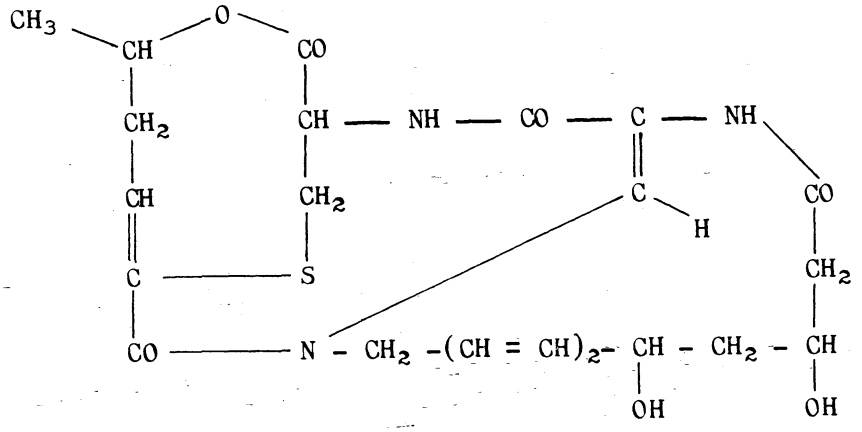


(XXV)



(XXVI)

For these reasons the formulation (XXIII) was rejected. Only one formulation remained which permitted the interpretation of the chemical and physical evidence; that is, (XXVII).



(XXVII)

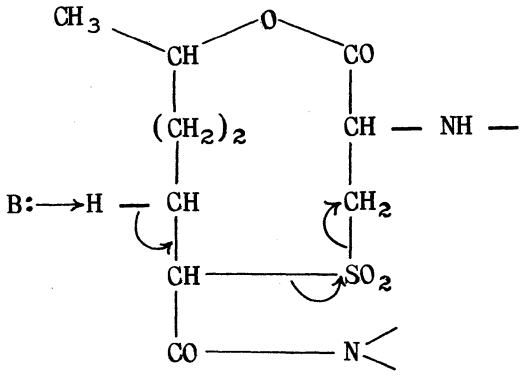
With this representation a number of other facts noted during the study of this problem could be rationalized. It was apparent that the absorption of the unsaturated alanine (*b*) system was at shorter wavelengths than expected; inspection of models suggested this was attributable to the considerable distortion of this bridge and its pi system with respect to the *p* electron on the substituting nitrogen. The model also indicated, that the appropriate geometry of the diene for adduct formation was easily attained.

Although acid hydrolysis of griseoviridin and hexahydrodeoxygriseoviridin produced no alanine we had observed that alkaline hydrolysis of hexahydrodeoxygriseoviridin sulphone diacetate did lead to the formation of this amino acid. This must be interpreted as a reverse elimination (XXVIII, arrows) and the formation of a primary carbanion.

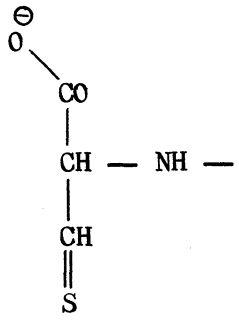
Whilst alkaline hydrolysis of griseoviridin followed by acidification gave about one-third mole of hydrogen sulphide (3) the alkaline solution did not contain sulphide ions since no precipitate was obtained with alkaline lead acetate. As presumed by Bowman the action of the alkali must be to produce a very acid-labile sulphur-containing moiety.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

One possible explanation could be formation of the thioaldehyde (XXIX) by an elimination process,* the substance being stabilized as enolate until acidification.

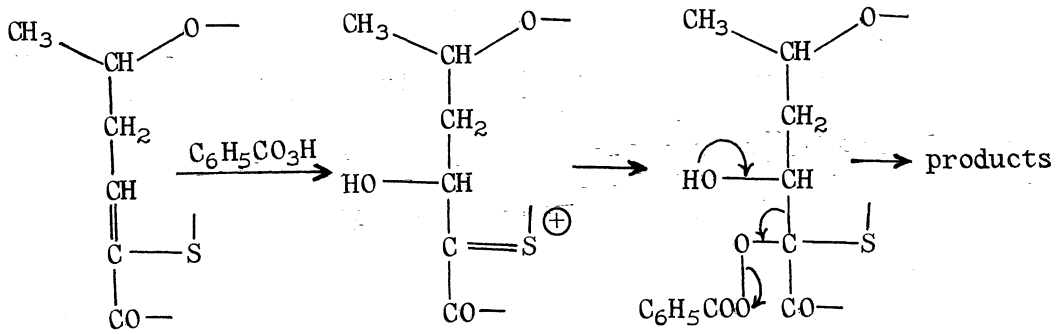


(XXVIII)



(XXIX)

A final observation requiring interpretation was that of Bowman (4) who noted that, whilst griseoviridin derivatives for the most part required ozonolysis followed by acid, alkali, or heat treatment for the release of crotonaldehyde, the product of oxidation of griseoviridin diacetate with perbenzoic acid (which was not a sulphone (1)) gave crotonaldehyde by simple acid hydrolysis. One interpretation is symbolized in the sequence (XXX).



(XXX)

The structure represented by (XXVII) therefore appeared uniquely capable of allowing interpretation of the presently known chemistry of griseoviridin.

At the time of study griseoviridin appeared to have properties placing it in no known class of mold metabolites. The recent structural elucidation of its associated metabolite viridogrisein (17) (etamycin) (10) suggested some relationship to the ostreogrycin complex (11) from *streptomyces* wherein, also, two main groups of metabolites are found. One group consists of relatively simple lactonic peptides, having a general resemblance to etamycin, whilst the other group contains more complex structures which, although none

Reverse elimination would give an α-thiono acid for which identical comments would apply. No distinction is here implied, (XXIX) being selected merely illustratively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

have as yet been completely structurally elucidated, have a superficial resemblance to griseoviridin. They are at least lactonic peptides containing an unsaturated aliphatic acid, dehydro amino acids, and a long-chain, unsaturated ω-amino acid (12).

EXPERIMENTAL

Except where otherwise indicated melting points were taken on the Köfler hot stage, infrared spectra as Nujol mulls, and ultraviolet spectra in 95% ethanol. Light petroleum was that of boiling range 60–80°. Rotations were in chloroform unless otherwise stated.

Perhydro- and Isoperhydro-dethiogriseoviridin Diacetate

(*a*) Griseoviridin diacetate (4.5 g) was refluxed with Raney nickel as described by Ames *et al.* (4). The crude crystalline (from ethyl acetate) product (1.94 g) was crystallized twice from ethanol – ethyl acetate – light petroleum (0.8 g, m.p. 192–215°), then from chloroform – light petroleum and finally the original solvent mixture to give the pure diacetate m.p. 220–223°, $[\alpha]_D$ −55° (*c*, 1.7). A sample provided by Dr. Bowman had m.p. 216–217°, $[\alpha]_D$ −52° (*c*, 1.7), mixed m.p. 216–220°.

Concentration of the first ethyl acetate mother liquors gave material which was crystallized from chloroform – light petroleum, then from ethanol, and finally repeatedly from ethanol – ethyl acetate – light petroleum to give the isomeric diacetate m.p. 215–218°, $[\alpha]_D$ +30° (*c*, 2.3). The infrared spectrum of this substance was closely similar to that of the normal diacetate and the mixed melting point was depressed to ca. 200°. Calc. for $C_{26}H_{43}O_9N_3$: C, 57.65; H, 8.00; N, 7.76; O, 26.59%. Found: C, 57.75; H, 7.88; N, 7.82; O, 26.41%.

(*b*) Perhydrodethiogriseoviridin was prepared as described by Ames *et al.* (4). It had the melting point previously reported (190–192°) but had $[\alpha]_D$ −7° (*c*, 0.55; MeOH). The rotation $[\alpha]_D$ −32° previously reported may be attributed to the presence of a small amount of an impurity (responsible for a band at 1730 cm^{-1}) which was removed on repeated crystallization from chloroform–ethanol with little change in the melting point.

Acetylation of the diol (3.7 mg) with acetic anhydride and pyridine (1:1) at room temperature overnight gave after repeated crystallization from ethanol – ethyl acetate – light petroleum the diacetate, m.p. 223–225° undepressed on admixture with the normal diacetate.

Mild Alkaline Hydrolysis of Perhydrodethiogriseoviridin Diacetate

(*a*) The acetate on standing overnight with an excess of 0.1 *N* aqueous ethanolic sodium hydroxide consumed 3.13 equivalents of base. Under the same conditions the isomeric diacetate consumed 3.0 equivalents of base and perhydrodethiogriseoviridin 1.07 equivalents.

(*b*) Perhydrodethiogriseoviridin diacetate (300 mg) was hydrolyzed as described under (*a*). The mixture was neutralized with 0.1 *N* hydrochloric acid, freed from sodium ions by passage through Dowex 50W-X2 (H^+), and the acidic eluate evaporated to a glass under reduced pressure. After conversion to the ester with ethereal diazomethane the product was repeatedly crystallized from methanol – ethyl acetate when it had m.p. 125–127°. Calc. for $C_{23}H_{43}O_8N_7$: C, 56.44; H, 8.79; N, 8.59; O, 26.18, OMe (1), 6.34%. Found: C, 56.73; H, 8.51; N, 8.73; O, 26.45; OMe, 6.28%. On potentiometric titration with hydrochloric acid the substance in aqueous ethanolic solution was indistinguishable from the solvent.

The ester (44 mg) in pyridine (0.6 ml) containing acetic anhydride (0.3 ml) was allowed to stand at room temperature overnight. The triacetate was obtained as an oil. Calc. for $C_{29}H_{49}N_3O_{11}$: C, 56.57; H, 8.02; N, 6.82; 3 Ac, 21.0%. Found: C, 56.53; H, 8.20; N, 7.14; Ac, 20.1%.

The Isolation of Alaninol

Perhydrodethiogriseoviridin diacetate (51.3 mg) in dry tetrahydrofuran (50 ml) at 0° was treated with lithium borohydride (500 mg) in portions over 20 minutes. It was then stirred at room temperature under nitrogen for 18 hours. The mixture was then diluted with *n*-butanol (30 ml) and concentrated to ca. 20 ml under reduced pressure. *n*-Butanol (20 ml) saturated with water was then added and the mixture warmed to 60–75° for 20 minutes. The solid was filtered off and washed with several portions of hot butanol. After acidification with a few drops of 6 *N* hydrochloric acid, filtrate and washings were evaporated to dryness *in vacuo* at 100°. The product, in 6 *N* hydrochloric acid, was refluxed for 17 hours, the hydrolyzate evaporated to dryness under reduced pressure, and the residue rendered basic with 5% sodium carbonate solution. The mixture was then distilled under reduced pressure and the distillate neutralized with .01 *N* hydrochloric acid (6.15 ml; 0.67 equiv.). The volume was then reduced to 1.2 ml. Paper chromatography showed the presence of two weak and one intense ninhydrin-positive substances, the latter being indistinguishable from that of *dl*-alaninol in three different solvent systems.* The aqueous solution was basified with sodium hydrogen carbonate and 3,5-dinitrobenzoyl chloride (45 mg) was added. The mixture was shaken for 3 hours and the product isolated with ethyl acetate. The crystalline product melted from 195–235° and after repeated crystallization from ethyl acetate – methanol and aqueous acetone melted at 236–237°. Its infrared spectrum was superposable with that of the derivative described below from *dl*-alaninol.

**We wish to thank Dr. J. Walker (M.R.C. London) for a generous specimen of dl-alaninol.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

dl-Alaninol (19 mg) in water (5 ml) containing sodium hydrogen carbonate (500 mg) was shaken for 3 hours with 3,5-dinitrobenzoyl chloride (230 mg) and the product then isolated with ethyl acetate. Concentration gave a crystalline product which after recrystallization from aqueous acetone had m.p. 216–217°. Calc. for $C_{17}H_{18}O_{11}N_6$: C, 44.07; H, 2.83; N, 15.12%. Found: C, 44.07; H, 3.02; N, 15.19%.

Partial Hydrolysis of Perhydrodethiogriseoviridin Diacetate

The diacetate (210 mg) was refluxed in sulphuric acid (1.0 *N*; 50 ml) under nitrogen for 10 hours. The solution was then added to a Dowex 50W-X2 (H^+) column (10 g) and the material retained eluted with 3 *N* ammonia solution. The eluate was evaporated to dryness (79 mg) and on paper chromatographic examination (upper phase of *n*-BuOH – water – acetic acid, 4:5:1) revealed the presence of several ninhydrin-positive substances only two of which were intense and which corresponded to alanine (R_f 0.26) and alanylalanine (R_f 0.37).

The material, in the upper phase of the above solvent system (5 ml), was added to a "chromax" LKB paper column and eluted with the same solvent, the eluate being collected in 10-ml fractions. The contents of tubes 25–32 were evaporated and the residue (8 mg) crystallized from absolute ethanol when it had m.p. 268–272° (capillary) $[\alpha]_D \pm 0°$ (*c*, 0.6, H_2O). It was identical in melting point, mixed melting point, and infrared spectrum and in paper chromatographic behavior with authentic *dl*-alanylalanine. After hydrolysis in refluxing 6 *N* hydrochloric acid for 24 hours the product gave on paper chromatograms a single spot corresponding to alanine.

Hexahydrogriseoviridin Diacetate Sulphone

Hexahydrogriseoviridin diacetate (400 mg) (3) was dissolved in chloroform (65 ml) containing perbenzoic acid (ca. 400 mg) and allowed to stand at room temperature for 3 hours. Isolation of the product in the usual way (uptake 2 atoms of oxygen) gave the sulphone which was crystallized from chloroform–methanol, m.p. 215–225°. Calc. for $C_{26}H_{37}O_{11}N_3S$: C, 52.08; H, 6.22; N, 7.00; S, 5.35; C-Me (3), 7.5%. Found: C, 51.60; H, 6.31; N, 6.95; S, 5.03; C-Me, 6.63%.

Alkaline Hydrolysis of Hexahydrogriseoviridin Diacetate Sulphone

The sulphone (66.5 mg) in sodium hydroxide solution (4 *N*; 8 ml) was refluxed for 45 minutes. Ammonia (0.83 molecular equivalent (mol. eq.)) was evolved. Acidification of the cooled hydrolyzate liberated sulphur dioxide which was entrained in a stream of nitrogen and estimated by iodine titration: found, 0.52 mol. eq. The aqueous residue was distilled at constant volume until no further acid distilled (55 ml). The neutralized distillate was evaporated to dryness and treated with chromic acid solution (0.2 *N* chromic acid in 2 *N* sulphuric acid; 4 ml) and allowed to stand overnight. Excess oxidant was destroyed with sulphur dioxide and aqueous 2,4-dinitrophenylhydrazine sulphate added. The resultant precipitate was collected and crystallized from benzene to give the 2,4-dinitrophenylhydrazine of γ-acetobutyric acid, m.p. 136–137° undepressed on admixture with an authentic specimen.

In another, similar, experiment the acidified hydrolyzate was passed over a column of Dowex 50W-X2 (H^+) resin and the retained material on the washed column eluted with 6 *N* ammonia. After evaporation the residue was examined by paper chromatography. Two ninhydrin-positive substances, corresponding to glycine and alanine, were present.

Alkaline Hydrolysis of Hexahydrogriseoviridin Diacetate

The diacetate (259 mg) was refluxed in aqueous sodium hydroxide (4 *N*; 20 ml) for 1 hour. The solution was acidified with sulphuric acid (6 *N*; 40 ml) and continuously extracted with carbon tetrachloride for 24 hours. Evaporation of the carbon tetrachloride gave an oil (53 mg) which was injected onto a silicone Dow 710 column (20% stationary phase on firebrick, 10 ft × ¼ in.) the only peak eluted (retention time 30 minutes) being collected to give the thiol-lactone. Calc. for $C_6H_{10}O_2S$: C, 49.31; H, 6.90; S, 21.90; equiv. 146. Found: C, 49.14; H, 7.07; S, 21.66; equiv. 156. Titration in water gave pK_a 3.76.

Alkaline Hydrolysis of Hexahydrodeoxygriseoviridin Sulphone

The sulphone (1) (17.4 mg) was refluxed in aqueous sodium hydroxide (4 *N*; 2 ml) for 30 minutes. The liberated ammonia was entrained in nitrogen and titrated with .00667 *N* hydrochloric acid. Found: 0.94 mol. eq. volatile base.

The cooled hydrolyzate was acidified with 6 *N* hydrochloric acid (2 ml), warmed to 50°, and the liberated sulphur dioxide collected in ice-cold iodine solution (3 hours). Found: 0.95 mol. eq. sulphur dioxide. The nature and stoichiometry of the process was confirmed by titration of the acids formed (according to the equation $SO_2+I_2+2H_2O \rightarrow H_2SO_4 + 2HI$. Found 3.80 equiv. alkali consumed) and by a precipitate ($BaSO_4$) given with barium chloride.

After removal of the sulphur dioxide the hydrolyzate was distilled at constant volume. The distillate (30 ml) was warmed with .02 *N* sodium hydroxide (3 ml) and neutralized with standard hydrochloric acid (ca. 1 mol. eq. base consumed). Paper chromatography (propanol–ammonia 3:2) of the salts revealed the presence of formic acid (R_f .51; reduced silver nitrate) and 5-hydroxycaproic acid (R_f .65). A solution of chromic acid in 2 *N* sulphuric acid (0.4 *N*; 0.5 ml) was added and the mixture allowed to stand overnight. The excess oxidant was destroyed with sulphur dioxide and 2,4-dinitrophenylhydrazine (7 mg in 1 ml 10% sulphuric acid)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

added. The precipitate was collected and crystallized from benzene to give the derivative of γ-acetobutyric acid melting point and mixed melting point 135–137°.

Reduction–Hydrolysis of Griseoviridin Diacetate and Hexahydrogriseoviridin Diacetate

(*a*) Griseoviridin diacetate (100 mg) in dry tetrahydrofuran (125 ml) was shaken for 18 hours under nitrogen with lithium borohydride (500 mg). *n*-Butanol was added to the mixture and the volume reduced to about 25 ml by evaporation under reduced pressure at 35°. A further quantity of water-saturated butanol (25 ml) was added and the mixture heated at 60° for 20 minutes. After filtration the filtrates were evaporated to dryness to give an oil (86 mg). The infrared spectrum of this material indicated that the ester had been reduced, but that the amide functions were unchanged.

The oil (300 mg, from several runs) was refluxed for 5 hours with hydriodic acid (15 ml; $d = 1.7$) containing red phosphorus (140 mg) (4). The filtered hydrolyzate was concentrated to small volume, diluted with water, and passed through a column of Amberlite IRA-400 (OH^-). The washed column was eluted with 10% aqueous acetic acid (400 ml) and the eluate evaporated to dryness under reduced pressure. A solution (A) of the product in 5% aqueous acetic acid (4 ml) was used for paper chromatography.

(*b*) A similar hydrolyzate was prepared directly from griseoviridin (510 mg), hydriodic acid (15 ml), and red phosphorus (105 mg) without prior lithium borohydride reduction (solution B).

(*c*) A similar hydrolyzate was prepared directly from hexahydrogriseoviridin diacetate (225 mg), hydriodic acid (15 ml), and red phosphorus (127 mg) (solution C).

Aliquots of the solutions and of those of authentic amino acids were chromatographed (*n*-BuOH–water–HOAc, 4:5:1) the chromatogram being developed with the ninhydrin reagent of Moffat and Lytle (13). Solutions B and C showed the presence of alanine, glycine, and cystine. Solution A showed the presence of alanine and glycine and no trace of cystine or cysteine could be detected even at vastly increased concentrations.

Griseoviridin Diacetate – Maleic Anhydride Adduct

Griseoviridin diacetate (503 mg) in benzene (10 ml) containing maleic anhydride (174 mg) was refluxed for 5 hours. The solvent and excess anhydride were removed under reduced pressure (80° at 0.2 mm), and the residue crystallized from ethyl acetate – light petroleum to give the adduct m.p. 266–269°, λ_{max} 209 mμ (ε, 27,000). The difference spectrum (Fig. 1) was determined directly by balancing equimolar solutions. Calc. for $C_{30}H_{33}O_{12}N_3S$: C, 54.62; H, 5.04; N, 6.37%. Found: C, 54.20; H, 5.23; N, 6.39%.

Attempted Diels–Alder Reaction with Griseoviridin

Griseoviridin (140 mg) was added to a melt of maleic anhydride (400 mg) and heated on the steam bath for 3 minutes. The yellow solution was cooled and diluted with ethyl acetate. The amorphous acidic precipitate was esterified with diazomethane and acetylated (acetic anhydride – pyridine). In solution ($CHCl_3$) there was a strong band at 1750 cm^{-1} with a pronounced shoulder at 1770 cm^{-1}.

Dehydrogriseoviridin

Griseoviridin (1 g) in acetone (400 ml) was stirred at room temperature with a slurry of active manganese dioxide (10 g) for 3 hours. Evaporation of the filtered solution gave the crystalline ketone, m.p. 245–248° (from ethanol), $\lambda\lambda_{max}$ 209, 277 mμ (ε, 25,300, 20,100). Calc. for $C_{22}H_{25}O_7N_3$: C, 55.55; H, 5.30; N, 8.84. Found: C, 55.63; H, 5.41; N, 8.33%. The dienone (13.6 mg) in methanol (5 ml) was treated with periodic acid (0.21 *M*; 0.5 ml). There was no uptake after 20 hours.

Acetylation of the ketone (50 mg) (acetic anhydride – pyridine at room temperature overnight) gave, after crystallization from methanol, the monoacetate, m.p. 238–241°, $\lambda\lambda_{max}$ 209, 277 mμ (ε, 28,000, 24,300). Calc. for $C_{24}H_{27}O_8N_3S$: C, 55.68; H, 5.26. Found: C, 55.49; H, 5.26.

Hexahydrodehydrogriseoviridin Acetate

Dehydrogriseoviridin acetate (120 mg) in ethanol (100 ml) was shaken over palladized charcoal (10%; 450 mg) for 4 hours. Repeated crystallization of the product from methanol gave the acetate, m.p. 173–175°, λ_{max} 214 mμ (ε, 20,400) in neutral solution. Calc. for $C_{24}H_{33}O_8N_3S$: C, 55.02; H, 6.35; N, 8.03; S, 6.12%. Found: C, 54.98; H, 5.95; N, 8.53; S, 6.12%.

Dihydrodehydrogriseoviridin Acetate

Dehydrogriseoviridin acetate (120 mg) in acetic acid (10 ml) was shaken with activated zinc dust (3 g) for 2 minutes. The filtered solution was evaporated, the residue taken up in ethyl acetate and washed with water. The product, a mixture of double-bond isomers, was precipitated as an amorphous colorless solid by addition of light petroleum to the ethyl acetate solution. λ_{max} 216 mμ (ε, 21,300) in neutral solution. Calc. for $C_{24}H_{29}O_8N_3S$: C, 55.48; H, 5.63; N, 8.09; S, 6.16; Ac(1), 8.28%. Found: C, 55.38; H, 5.72; N, 7.83; S, 5.91, Ac, 8.85%.

The zinc reduction product (100 mg) was hydrogenated in the manner described for dehydrogriseoviridin acetate and gave hexahydrodehydrogriseoviridin acetate identical in every respect with the material obtained by direct hydrogenation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Base-catalyzed Elimination in the Zinc Reduction Product

To the zinc reduction product (105 mg) in ethanol (50 ml) was added 0.1 *N* sodium hydroxide solution (21 ml). After 20 seconds the resultant yellow solution was acidified with acetic acid and evaporated to dryness at 35° under reduced pressure. The residue was extracted with ethyl acetate, the organic phase washed with water, and the product precipitated as a colorless solid by addition of light petroleum. Calc. for $C_{22}H_{25}O_6N_3S$: C, 57.50; H, 5.44; N, 9.14; S, 6.96. Found: C, 57.16, 57.23; H, 5.71, 5.66; N, 9.02; S, 6.86%. An acetyl determination indicated the presence of less than 0.1 acetyl groups. The ultraviolet spectrum of this product is shown in Fig. 2.

Base-catalyzed Elimination in Hexahydrodehydrogriseoviridin Acetate

The acetate (26.0 mg) in ethanol (10 ml) was mixed with rapid stirring with 0.1 *N* sodium hydroxide solution (3 ml). It was then acidified with acetic acid (0.1 *N*; 7.5 ml). The time taken for neutralization was 3–5 seconds. The product was extracted into chloroform and the organic phase washed with water, EDTA (4 Na) solution, and water. After removal of the solvent the product crystallized from methanol and chloroform–methanol m.p. 264–267°. Calc. for $C_{22}H_{29}O_6N_3S$: C, 56.95; H, 6.25%. Found: C, 57.48; H, 6.88%. Repeated analyses gave variable but not improved figures. The compound had no maximum in the ultraviolet above 215 mμ (Fig. 4).

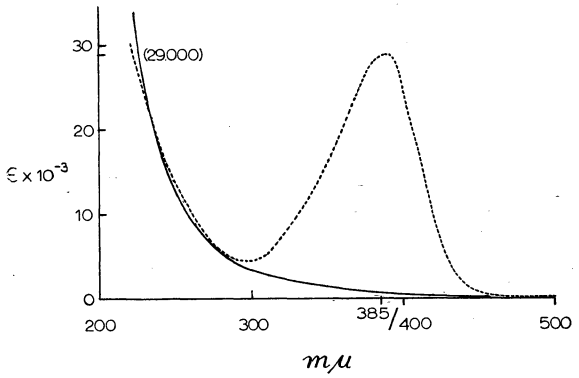


FIG. 4. N.m.r. spectra of (*a*) perhydro- and (*b*) isoperhydro-dethiogriseoviridin diacetate.

Ozonolysis–Hydrolysis of Griseoviridin Diacetate

Griseoviridin diacetate (506 mg) in ethyl acetate (30 ml) was treated with a stream of ozone for 75 minutes at −70°. Excess ozone was removed in a stream of oxygen and the solution evaporated at room temperature. The residue was heated on the steam bath with acetic acid (15 ml) and hydrogen peroxide (30%; 5 ml) for 90 minutes. The solution was concentrated under reduced pressure to about 3 ml, hydrochloric acid (*N*; 20 ml) added, and the mixture refluxed under nitrogen for 15 hours. The amino acid fraction was separated by ion-exchange on Dowex 50W-X2 (H^+) and on paper chromatography gave a single spot corresponding in R_f and color reaction to glycine.

The amino acid solution was rendered alkaline with *N* sodium hydroxide solution and shaken with benzoyl chloride (0.1 ml). After acidification benzoic acid was removed by filtration and extraction into chloroform. The residue from the aqueous layer was extracted with ethyl acetate and crystallized from ethyl acetate – light petroleum to give hippuric acid m.p. 183–190° undepressed on admixture with an authentic specimen.

Under identical conditions, but with omission of the ozonolytic step no trace of glycine could be detected by paper chromatography.

Ozonolysis–Hydrolysis of the Zinc Reduction Product

The substance (29 mg) in ethyl acetate (15 ml) was treated with ozonized oxygen for 1 hour. The solvent was removed under reduced pressure and the residue warmed on the water bath for 15 hours in acetic acid (10 ml) containing hydrogen peroxide (30%; 2 ml). After concentration under reduced pressure to ca. 0.5 ml hydrochloric acid (1 *N*; 10 ml) was added and the mixture refluxed for 1.5 hours. The amino acid fraction was isolated by Dowex 50W-X2 in the usual way. Paper chromatography of the product in hydrochloric acid (0.3 *N*; 1 ml) (upper phase of *n*-butanol:water:acetic acid, 4:5:1) using the polychromatic ninhydrin reagent of Moffat and Lytle (13) revealed the presence of glycine (R_f 0.17, orange brown) and β-alanine (R_f 0.25, blue-grey).

Alkaline Hydrolysis of Griseoviridin

Griseoviridin (120 mg) was refluxed under nitrogen for 1 hour with sodium hydroxide solution (4 *N*;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

5 ml). The cooled hydrolyzate was adjusted to pH 8–9 with carbon dioxide, the solution diluted with water (15 ml) and benzoyl chloride added (0.3 ml), and the mixture shaken. The resultant solution was extracted with chloroform, ether, and ethyl acetate, and the extract discarded. The aqueous phase was acidified and continuously extracted with ether, the residue from removal of the ether being added to a column of silica gel. Elution with ether–benzene (1:1) gave hippuric acid which after crystallization from ether–ethanol had melting point and infrared spectrum identical with those of an authentic specimen, and gave no depression in melting point on admixture.

Perhydrogriseoviridin Diacetate Sulphone

Hexahydrogriseoviridin diacetate sulphone (210 mg) in acetic acid (75 ml) was hydrogenated for 16 hours over platinum oxide (400 mg). Evaporation of the filtered solution and crystallization from methanol gave the perhydro derivative, m.p. 221–229°. It showed only end absorption in the ultraviolet. Calc. for $C_{26}H_{41}O_{11}N_3S$: C, 51.74; H, 6.84; N, 6.96; S, 5.31; C-Me (4), 8.93. Found: C, 51.82; H, 6.83; N, 6.78; S, 5.05; C-Me, 9.94%.

Alkaline hydrolysis of the perhydro sulphone, in the manner described for hexahydrogriseoviridin diacetate sulphone gave a solution which on paper chromatographic examination showed the presence of alanine only. No trace of glycine, found in the hydrolysis of the less reduced derivative, could be detected.

Octahydrodethiogriseoviridin (see footnote† on p. 371)

Griseoviridin (1.03 g) in ethanol (100 ml) was refluxed with catalyst from six pellets of B.D.H. stabilized Raney nickel. Two further, similar, portions were added during the course of 6.5 hours. The catalyst was removed by filtration and washed with hot ethanol. Filtrate and washings were evaporated, the residue taken up in methanol and crystallized by the addition of methyl ethyl ketone. The crude product (240 mg) was repeatedly crystallized to give the octahydro compound, m.p. 168–169° (decomp.), $[\alpha]_D$ +4° (*c*, 0.92 MeOH). The compound had λ_{max} 212 mμ (ϵ, 14,200) unchanged by the addition of alkali. Calc. for $C_{22}H_{35}O_7N_3$: C, 58.26; H, 7.78; N, 9.27; C-Me(2), 6.6. Found: C, 58.00; H, 7.47; N, 9.35; S, 0.00; C-Me, 6.4%.

Hydrogenation of Octahydrodethiogriseoviridin (see footnote † on p. 371)

The compound (51 mg) was acetylated (acetic anhydride – pyridine) and the gummy product hydrogenated over Adam's catalyst (50 mg). Reaction was complete after 5 hours with the uptake of 1.8 mol. eq. hydrogen. The product was repeatedly crystallized from ethanol to give perhydrodethiogriseoviridin diacetate, m.p. 223–224°, $[\alpha]_D$ −50° (*c*, 0.88). Found: C, 57.77; H, 7.97; N, 7.63%.

Alkaline Hydrolysis of Octahydrodethiogriseoviridin

The substance (11.9 mg) was hydrolyzed in 4 *N* sodium hydroxide solution (2 ml) in the manner described for hexahydrodeoxygriseoviridin sulphone. No volatile base was evolved. After acidification with sulphuric acid (6 *N*; 2 ml) the solution was distilled at constant volume. The distillate (30 ml) consumed 1.1 equiv. alkali on rapid titration and a further 0.83 equiv. on warming with excess alkali and back titration. Paper chromatography of the distillate in the system propanol–ammonia (3:2) revealed the presence of two compounds indistinguishable in every respect (R_f; acidity towards indicator, coloration and time of development with silver nitrate) from 5-hydroxyhexanoic and formic acids respectively.

The salt mixture was oxidized with chromic acid (0.2 *N* in 1 *N* sulphuric acid; 1 ml) at 70° (ca. 1 hour) and after standing overnight at room temperature the excess oxidant was destroyed with sulphur dioxide. Addition of 2,4-dinitrophenylhydrazine (10 mg) in sulphuric acid (20%; 0.5 ml) and recrystallization of the precipitate from ethanol gave the derivative of 5-oxohexanoic acid, m.p. 143–145°.*

The distillation residue was diluted with water and passed through a column of Amberlite IR120 (H^+). After washing the column was eluted with ammonia. Paper chromatography of the evaporated eluate in 77% aqueous ethanol gave a number of ninhydrin-positive spots the two most intense corresponding to alanine and glycine. The presence of glycine was confirmed by the color with *o*-phthalaldehyde. After running on a single large sheet the band corresponding to glycine was cut out, the amino acid eluted and run in the two dimensional systems *n*-BuOH–water–ammonia (4:5:1)/*n*-BuOH – water – acetic acid (4:5:1) and *n*-BuOH – water – acetic acid (4:5:1)/77% ethanol. Glycine was again present.

Potentiometric Titration of Griseoviridin Diacetate

The diacetate (146 mg) in acetic acid (25 ml) was titrated with 0.109 *N* perchloric acid against a calomel electrode in saturated lithium chloride – acetic acid solution using a glass electrode. The titration curve was indistinguishable from that of the solvent. Urea and 2 methyl-4-carbethoxy-oxazole (15) gave end points with pK_a' 4.2 and 3.3 respectively.

ACKNOWLEDGMENTS

The authors wish to thank Dr. R. E. Bowman (Parke, Davis, London) for supplies of griseoviridin and helpful discussions, and Drs. L. Long and Q. Bartz (Parke, Davis,

**The mixture with the authentic derivative (m.p. 137–138°) reset after melting at ca. 135° and melted at 142–146°. The authentic derivative, m.p. 137–138°, was shown to be the unstable form by seeding a melt with a trace of material m.p. 143–146° when the higher melting point was observed. The literature melting point (14) is 143–145°.*

MOLD METABOLITES

3. THE STRUCTURE OF THE GRISEOVIRIDIN SALTS

M. CATHERINE FALLONA, P. DE MAYO, AND A. STOESSL
Department of Chemistry, University of Western Ontario, London, Ontario
Received August 21, 1963

ABSTRACT

The conversion of griseoviridin (I) into its hydrochloride and into its perchlorate has been shown to involve the ejection of one of the hydroxyl groups in (I) and the formation of an imino-lactone salt.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

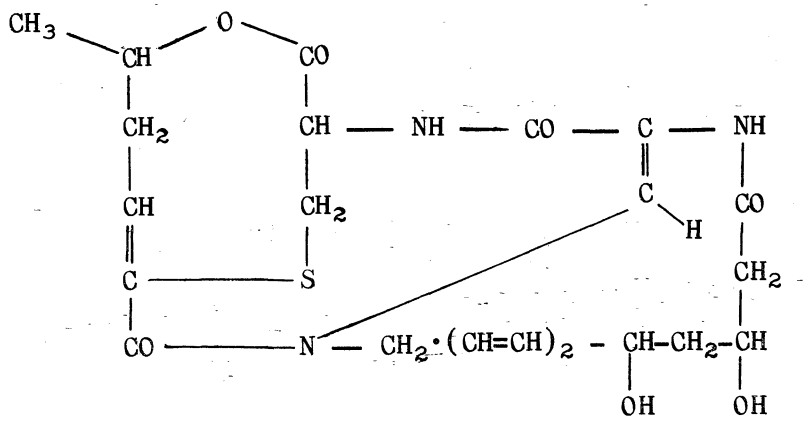
In the course of their characterization of, and preliminary studies on, griseoviridin, Bowman and his collaborators made the observation that although this substance was neutral, as judged by attempted titration with perchloric acid in acetic acid, it nevertheless under certain conditions gave crystalline salts (1–3). When heated with acetic anhydride and perchloric acid a substance designated a perchlorate diacetate was obtained, whilst using dioxan instead of acetic anhydride a simple perchlorate resulted. They also noted that griseoviridin dissolved rapidly in cold concentrated hydrochloric acid from which, by careful evaporation of the hydrochloric acid, a crystalline hydrochloride could be obtained, the analysis of which (2, 4) indicated that no loss of water had occurred in its genesis.

These salts differed from griseoviridin in having a lower intensity of ultraviolet absorption (Fig. 1) and, most importantly, they could now be titrated with alkali. Two titrable groups were disclosed ($pK_a' \sim 6.5$), one of which was the base hydrochloride, but on back titration only a single titrable group could be detected in this region. The second function at $pK_a' \sim 6.5$ was attributed to an enolic function because the perchlorate, after treating with hot water, gave a purple color with ferric chloride not given without preliminary heating. The significance of the potentiometric data was obscured by the fact that further reactions, such as hydrolysis, were undoubtedly proceeding under the titration conditions. This was clearly revealed in the case of the perchlorate which showed an ultraviolet absorption maximum at 218 mμ in water and at ca. 270 mμ in alkaline solution.

It was consequently difficult at the outset to be clear which physical properties were to be attributed to the salts themselves, and which to their decomposition products. Only one chemical transformation had been performed on the salts, in this case the hydrochloride, in which the chemical integrity of the reacting species seemed unequivocal. Ames and Bowman (2) found that hydrogenation of griseoviridin hydrochloride gave a substance which contained no chlorine and which was now neutral to titration with perchloric acid in acetic acid. At a later date this work was repeated (4) and the product, hexahydrodeoxygriseoviridin, was shown to differ from hexahydrogriseoviridin with respect to empirical formula, in the lack of one oxygen atom. Thus, whatever the nature of the basic function introduced through reaction with strong acid, it was removed irreversibly by hydrogenation; the deoxy compounds would not give salts under conditions adequate for griseoviridin.

With (I) proposed as a representation of the structure of griseoviridin (5), an interpretation of the facts concerning the salts was required if the validity of (I) was to be maintained.

A number of prerequisites were known for such salt formation. As mentioned, no salt could be obtained from hexahydrodeoxygriseoviridin indicating that the unsaturation in either the C_6 fragment or the aminodecanoic acid was required, or both. Then, since the maleic anhydride adduct (5) of griseoviridin diacetate also failed to give a salt with concentrated hydrochloric acid, the conclusion to be reached was that one of the ethylenic linkages in the aminodecanoic acid was essential, either in itself or because of some property to be associated with it. Further, the unsaturated C_3 fragment was clearly not involved in the salt formation since the singlet vinylic proton signal at low field ($\sim\tau$ 1.9) was still observable in the n.m.r. spectrum of the hydrochloride and of hexahydrodeoxygriseoviridin and its derivatives. Likewise the presence of the bands at ca. 1600 and 1500 cm^{-1} in the infrared spectrum (5) revealed that the unsaturation associated with this fragment was untouched in both series of compounds. In hydrolytic reactions the hydrochloride paralleled the behavior of griseoviridin (see Experimental). Finally, the unchanged situation of the C_6 unsaturation was confirmed by the obtention of crotonaldehyde by ozonolysis and distillation, and by the formation of acetaldehyde on base treatment of the hydrochloride. The formation of the basic function, therefore, involved an amide and some part of the C_{10} moiety encompassing at least one of the ethylenic linkages.



(I)

The decrease in the high-intensity ultraviolet absorption during hydrochloride formation noted by Bowman (2) has been mentioned. To ascertain more exactly the nature of the change, a plot of the difference curve between the absorption of griseoviridin and of its hydrochloride was constructed (Fig. 1). It was then apparent that concomitant with the decrease in absorption in the 220 mμ region a new absorption band had appeared at longer wave length. Furthermore, the chromophore removed from the 220 mμ region was not that of the diene (5) nor, since it was not apparently involved in the transformation, that of the C_6 fragment. It was, in fact, as closely as the errors inherent in such difference spectra would allow, the absorption associated with the unsaturated C_3 fragment and represented by, for instance, the absorption of hexahydrogriseoviridin diacetate; and this despite the fact that this particular arrangement of atoms, as concluded from infrared and n.m.r. spectra, had survived salt formation and subsequent hydrogenation intact.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

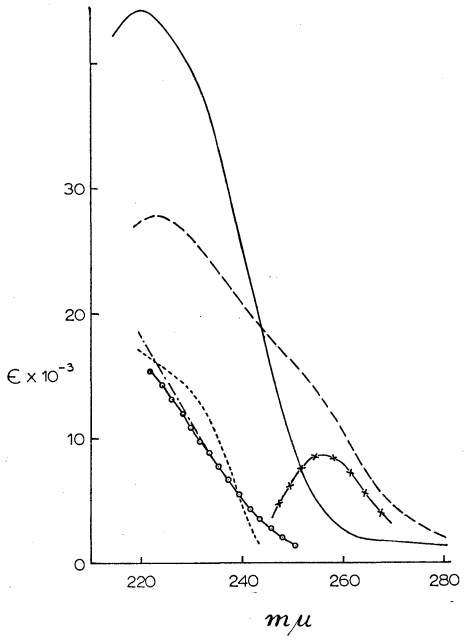

FIG. 1. Absorption spectrum of griseoviridin (—) and griseoviridin hydrochloride (– – –). The "disappearance" difference spectrum is given as (- - -), the "appearance" difference spectrum shown as (×—×). Hexahydrogriseoviridin and hexahydrodeoxygriseoviridin are (·—·) and (○—○).

The interpretation arrived at, compatible with these observations, was that the C_3 chromophore was extended in salt formation, but that in conversion to the hexahydrodeoxy series (the ultraviolet absorption of which was similar to that of hexahydrogriseoviridin diacetate) this extension of unsaturation was removed.

It was first assumed that the conversion of the salts to the hexahydrodeoxy series involved hydrogenolysis of an oxygen function, as suggested by the relevant analyses. Such supposition, it became evident, raised considerable interpretative difficulties. Careful preparation and analysis of the salts confirmed the empirical formula of the hydrochloride, but revealed that the perchlorate diacetate (I) was in fact a monoacetate. The fact was established, however, that the analytical values required that salt formation should not involve loss of water, and that where acetic acid was lost it was replaced by water. It was shown, also, that the acetate present in the perchlorate acetate was one originally present in griseoviridin diacetate by preparing the acetate perchlorate in propionic anhydride. Hydrolysis and paper chromatography showed no trace of propionate incorporation.

It was thus possible and necessary to presume that one of the oxygen atoms in the salts was present, simply as water of crystallization, water which, however, it was not possible to remove by prolonged drying. An observation relevant to this assumption was the fact that attempted repetitions of the perchlorate acetate preparation were subject to uncertainty until it was finally noted that traces of water were responsible for success. The addition of one equivalent of water (to the anhydride) after reaction resulted in spontaneous crystallization. With the assumption that one molecule of water (or acetic acid) was lost in salt formation, the necessity of postulating hydrogenolytic oxygen loss was removed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

During salt formation and the loss of an oxygen function, either the β or the δ oxygen could be the one ejected; the hydroxyl remaining was that present in hexahydrodeoxygriseoviridin. It had previously been shown that the sulphone of this substance could be oxidized to a ketone (4) which, whilst showing no long-wavelength absorption in neutral solution, in the presence of alkali exhibited a maximum at 298 mμ, which was reversibly formed in typical enolic fashion.

This clearly required that the β hydroxyl (in I) should be the one remaining. At this point sufficient data were available for unambiguous interpretation.

Protonation of the allylic hydroxyl group (or acetate) in the δ position followed by solvolysis would leave an allylic cationic charge which would be accessible to the non-bonded electrons of the aminodecanoic acid carbonyl oxygen.[1] Ether formation with participation of the nitrogen p electrons would complete the process. This sequence, shown in (II), would lead to (III) as a representation of the structure of the salts. Such a process is unexceptional and, in essentials, has adequate analogy (6, 7, 8).

The hydrogenation of allylic ethers leads frequently to carbon–oxygen bond fission. The product of such cleavage at the position '*a*' in (III) would be an amide of structure (IV, R = H) which would differ from hexahydrogriseoviridin diacetate (IV, R = OAc) only by the absence of one acetoxyl group. In Fig. 2 the infrared spectrum of hexahydro-

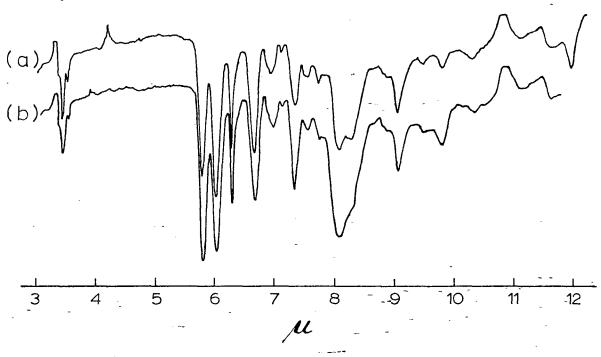

FIG. 2. Infrared spectra (*a*) of hexahydrodeoxygriseoviridin acetate and (*b*) hexahydrogriseoviridin acetate in equimolar solutions in chloroform.

griseoviridin diacetate and hexahydrodeoxygriseoviridin acetate are reproduced. With the exception of those frequencies associated with carbon–oxygen stretch the spectra are virtually identical.

The only impediment to the acceptance of this rationalization was the already mentioned persistent deviation of the analytical figures for the salts from those required by one molecule of water. Drying temperatures above 60° were not utilizable because of the decomposition which occurred over the prolonged periods necessary, so the retention of water under such condition by a salt was by no means inconceivable. However, the importance of this point did not allow of pious assumption.

Although the salts were not recoverable from pyridine solution, probably because of ready decomposition, no simple mechanism for the generation of water in this medium could be envisaged. Accordingly, Karl Fischer titration appeared to be an adequate tool for

[1]*If the stereochemistry of the diene is such as to give the maleic anhydride adduct (5) without geometrical inversion, then a study of models indicates that such inversion must occur in salt formation. Participation of the amide carbonyl in the solvolytic step is not thus possible.*

(IV)

water estimation in these circumstances. Titration with the reagent (see Experimental), in fact, revealed the presence of one molecule of water in the hydrochloride and in the monoacetate perchlorate.[2]

The last impediment to the acceptance of (III) was thus removed.

The enolic properties exhibited by the solutions of the hydrochloride in water after warming were not those, therefore, of the salt itself, but of some hydrolysis product. The aqueous hydrolysis of such imidate ethers had been studied and it appeared that an important mode of decomposition was formation of a carbinolamine followed by cleavage of the C—N bond. This is illustrated in the present instance by the process indicated in the part formula (V). Such a mode of reaction of an imino-lactone salt has ample analogy.[3] An opposite is the hydrolysis of the methyl benzimidate ion. The salt is stable in water for short periods, but on mild warming is converted to methyl benzoate and ammonium chloride (12).

The further transformation of (V) can only be interpreted tentatively. Two possibilities, at least, exist.

In the first, the vinylamine may be hydrolyzed to give (VI), whilst alternatively, water may add β to the amide carbonyl, followed by C—N bond cleavage in the carbinolamine to give the β-aldehydoamide (or tautomer) (VII). Both (VI) and (VII) may undergo further hydrolytic steps. Both could provide the requisite enolic system observed, but the evidence available does not justify further discussion.[4]

EXPERIMENTAL

(For general details see Part 2 (5))

Griseoviridin Hydrochloride

A solution of griseoviridin (200 mg) in methanol (10 ml) at 0° was saturated with hydrogen chloride over 1 hour. Evaporation under reduced pressure and crystallization from methanol–ether gave the hydrochloride identical in infrared spectrum with an authentic specimen (2).

[2]*A sample of the hydrochloride allowed to stand exposed to the atmosphere for 2 days contained approximately two molecules of water, but after redrying a figure of one molecule was again obtained.*

[3]*See, for example, the series of papers by McElvain (9) and many others including the hydrolysis of 2-cyclohexyliminotetrahydrofuran hydrobromide (10) and papers by Witkop (inter alia 11) on selective peptide cleavage.*

[4]*The phenylphenacyl derivative of the neutralized hydrochloride reported by Bowman may well be an enolate derivative. The analytical values reported (2) are in approximate agreement with this formulation.*

Alkaline Hydrolysis of Griseoviridin Hydrochloride

(*a*) The hydrochloride (245 mg) was hydrolyzed with 4*N* sodium hydroxide as described for griseoviridin (4). Acetaldehyde (isolated as the 2,4-dinitrophenylhydrazone (60 mg)), formic acid (0.64 molecular equivalent (mol. eq.)), and acetic acid (0.16 mol. eq.) were found.

(*b*) The hydrochloride (104 mg) was refluxed with barium hydroxide solution (0.46 *N*; 25 ml) for 4 hours. Ammonia (0.86 mol. eq.) was evolved. A 1-ml aliquot of the cooled hydrolyzate gave no sulphide reaction with alkaline lead acetate. A control indicated a positive response to 3×10^{-4} mmole. The barium carbonate precipitated (16 mg; 0.41 mol. eq.) was removed by filtration and the filtrate acidified. Hydrogen sulphide was immediately evolved in the cold. The solution was heated for 2 hours and the gases led into standard barium hydroxide by a stream of nitrogen. Barium carbonate (0.29 mol. eq.) was deposited and the filtrate was titrated with iodine: 0.33 mole H_2S had been absorbed. In a parallel experiment griseoviridin gave 0.97 mol. eq. ammonia and 0.47 mol. eq. carbon dioxide.

Griseoviridin Monoacetate Perchlorate

To griseoviridin (250 mg) in acetic acid – acetic anhydride (1:1, 2.5 ml) was added perchloric acid (70%; 0.1 ml), the solution kept at 55° for 30 minutes protected from the atmosphere, and then divided into two equal portions. To one of these water (0.12 ml) was added, whilst the other was protected from traces of water. On standing overnight, only the solution to which water had been added had deposited crystals (54 mg). These were collected, washed with acetic acid, and recrystallized from nitromethane–ether. After washing with ether, the crystals were dried at 97° under high vacuum for 3.5 hours and another 6 hours at 65°. Calc. for $C_{24}H_{28}O_{11}N_3SCl\cdot H_2O$: C, 46.48; H, 4.88; N, 6.78; S, 5.17; Cl, 5.72. Found: C, 45.94; H, 5.06; N, 6.33; S, 4.87; Cl, 5.47%.

The same compound was obtained from griseoviridin diacetate when the acetic anhydride – acetic acid mixture was replaced by propionic anhydride – propionic acid. Identity was established by ultraviolet and infrared spectroscopy and analysis. Found: C, 46.18; H, 5.05; N, 7.09; S, 5.38; Cl, 5.55%.

On acetyl determination (alkaline hydrolysis) the product liberated 1.42 mol. eq. volatile acid. Griseoviridin perchlorate (3) under the same conditions gave 0.18 mol. eq. volatile acid. Examination of the volatile acids by paper chromatography in three solvent systems revealed the presence of acetic and formic acids only, and no trace of propionic acid.

Estimation of Water of Crystallization (Karl Fischer Determinations)

The titrations were performed by the 'dead stop technique', using pyridine as solvent and standard water-in-methanol for back-titration (ref. 13 and references there cited).

		Calculated, %	Found, %
(1) Griseoviridin hydrochloride ($C_{22}H_{25}O_6N_3S\cdot HCl$)			
(*a*) Air-dried	($2\cdot H_2O$)	6.68	6.81
(*b*) Dried at 60°	($1\cdot H_2O$)	3.51	3.67[5]
(*c*) Sample (*b*) exposed to the atmosphere for 3 days		—	7.32
(*d*) Sample (*c*) redried		—	5.10
(2) Griseoviridin monoacetate perchlorate ($C_{24}H_{27}O_7N_3S\cdot HClO_4$)	($1\cdot H_2O$)	2.91	3.04

Titrations of Griseoviridin Salts

The compounds listed (ca. 0.02 mmole) were dissolved or suspended in water, sodium hydroxide (0.01 *N*; 10 ml) added, and the mixture left at room temperature overnight. The excess alkali was then titrated. Found (equivalent consumed in parentheses): griseoviridin hydrochloride (2.07); griseoviridin perchlorate (2.15); griseoviridin perchlorate acetate (3.21).

Hydrolysis–Hydrogenation of Griseoviridin Diacetate

The diacetate (250 mg) was dissolved in concentrated hydrochloric acid (1.0 ml). After evaporation under reduced pressure, the product was crystallized from methanol and methanol–ether. The product, for which a satisfactory carbon analysis could not be obtained, consumed 3.29 equivalents of alkali (see above) and gave an acetyl value of 1.15. Calc. for $C_{24}H_{28}O_7N_3Cl\cdot H_2O$: N, 7.56%; Cl, 6.38%. Found: N, 7.33; Cl, 6.00%. Hydrogenation of the salt (67 mg) over palladized charcoal (10%; 200 mg) in ethanol for 4 hours gave hexahydrodeoxygriseoviridin acetate identical in every respect with material obtained (4) by the acetylation of hexahydrodeoxygriseoviridin.

Hexahydrodeoxygriseoviridin

(*a*) The compound (43 mg) was dissolved in concentrated hydrochloric acid (0.5 ml). Evaporation and crystallization of the residue gave starting material (30 mg) identified by melting point and mixed melting point.

[5]*Average of two determinations.*

On hydrolysis in 0.46 *N* barium hydroxide, as described for griseoviridin hydrochloride, ammonia (0.99 mol. eq.) and carbon dioxide (0.81 mol. eq.) were liberated. No hydrogen sulphide was evolved on acidification.

Hydrolysis in 4 *N* sodium hydroxide, as described (4) for hexahydrodeoxygriseoviridin sulphone, gave ammonia (0.80 mol. eq.). Distillation of the acidified solution gave an oily lactone, which in paper-chromatographic behavior paralleled 2-mercapto-1,5-hexanolide (5), and formic acid.

In another comparable experiment the acidified hydrolyzate (from 318 mg hexahydrodeoxygriseoviridin) was distilled and the sodium salts of the volatile acid converted into the methyl esters by acidification and treatment with diazomethane in methanol–ether. The ether was distilled off and collected at −70°. Hydrolysis of the distillate, followed by reacidification and distillation, gave formic acid (0.18 mol. eq.) characterized by the melting point and infrared spectrum of the sodium salt.

THE pH AND pD DEPENDENCE OF THE SPONTANEOUS AND MAGNESIUM-ION-CATALYZED DECARBOXYLATION OF OXALACETIC ACID

GEORGE W. KOSICKI AND STANISLAVA N. LIPOVAC[1]
Department of Chemistry, University of Windsor, Windsor, Ontario
Received March 15, 1963

ABSTRACT

Spectrophotometric studies of the spontaneous and magnesium-ion-catalyzed decarboxylation of oxalacetic acid in H_2O and D_2O have been carried out over a range of pH, pD, and magnesium ion concentrations.

The rate of decarboxylation of oxalacetic acid depends on the proposed equilibrium system between the acid anion and magnesium chelate under a variety of conditions.

The absorbancy indexes and the apparent equilibrium constant of the keto and enol forms of the magnesium chelate were estimated from a combination of the kinetic and spectral data.

INTRODUCTION

Oxalacetic acid has been shown to decompose to CO_2 and pyruvic acid spontaneously (1, 2, 3), and catalytically by the action of polyvalent cations (1, 4, 5) and enzymes (6). The catalysis by metal ions has served as a model for the enzymatic reaction (7,8). The kinetics of the spontaneous decarboxylation of oxalacetic acid in aqueous solution have been studied over a range of temperature and at varying degrees of dissociation (9,10). Steinberger and Westheimer (8) have proposed that the keto form of the acid decarboxylates by using the α,α-dimethyl substituted oxalacetic acid, in which only the keto form can exist. In this paper the decomposition was followed spectrophotometrically as a function of pH and pD. The results indicate that the keto form of the monoanion of oxalacetic acid is the predominant species leading to decarboxylation.

The decarboxylation of oxalacetic acid is also catalyzed by a variety of multivalent cations (11–14). Magnesium ion was found to have a low catalytic activity compared to other divalent metals, but still it involves a change of spectrum indicating the formation of a chelate. The results of the present study show a direct correlation between the rate of decarboxylation of oxalacetic acid and the magnesium ion concentration as a function of pH and pD. The range of optimal activity (pH 5 to 6) for the magnesium-ion-catalyzed reaction coincides with the range found for the enzymatic decarboxylation (11, 15, 16).

EXPERIMENTAL

The following materials were commercial preparations: oxalacetic acid (OAA) (Sigma Chemical Co.), $MgCl_2.6H_2O$ reagent grade, Tris(hydroxymethyl)aminomethane (Tris) was primary standard grade. The D_2O (99.78 atom % excess D) was purchased from the Atomic Energy Commission of Canada Limited, Ottawa.

Measurements of pH and pD of each reaction mixture were made at the end of the experiment with a Beckman Model G pH meter standardized with pH 7 buffer. When D_2O was used as a solvent the measurements were made with the same glass and calomel electrodes and the pD was calculated by adding 0.4 units to the observed meter reading (17). The buffer system used was a Tris–acetate mixture. To adjust the pH, 1 *M* basic Tris and 1 *M* acetic acid were mixed in the proper proportions. For the D_2O systems all the reagents were made up in D_2O.

Absorption spectra were measured with a Bausch and Lomb Spectronic 505 spectrophotometer. Rates of reaction were followed either in the Beckman DU spectrophotometer or on the Gilford Instrument Model 2000

absorbance recorder (Beckman monochromator). The temperature of the reaction cell was kept at 25.0±0.2° C by a water-cooled circulating bath.

Rate measurements were made at 25.0° C and followed over a period of 3 half-times for the spontaneous decarboxylation of oxalacetic acid, and followed to the end of the reaction for the magnesium-ion-catalyzed reaction. The observed rate constants were calculated graphically from the slopes of the first order plots and from the equation:

$$[1] \qquad k_{obs} = \frac{2.303}{t} \log \frac{A_0 - A_e}{A_t - A_e}$$

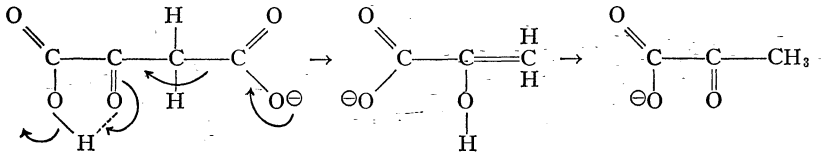
where A_0 is the absorbance at zero time, A_e is the absorbance at equilibrium, A_t is the absorbance at time t, t is the time in minutes and k_{obs} is the observed rate constant (minutes^{-1}).

RESULTS AND DISCUSSION

Spontaneous Decarboxylation

The observed first order rate constants for the spontaneous decarboxylation of oxalacetic acid measured at 255 mμ are plotted as a function of pH and pD in Fig. 1. The bell-shaped curve with a maximum of activity at pH 3.6 shows a shift to a higher pD value for the D_2O system of about 0.6 pH (pD) units. For the spontaneous decarboxylation of oxalacetic acid the buffer concentration definitely has an effect on the observed rate constant. Beyond a concentration of 0.7 M, however, further increases of buffer had no significant effect on the observed rate constant. For this reason the reactions were followed within the range of this plateau of buffer effect. At the optimal activities of decarboxylation, however, the deviations due to buffer effects are accentuated, and deviations from the first order plot are observed after a half-time of reactions. In the D_2O system from pD 6 to 8 the observed rates were corrected for initial ketonization.

The correspondence of the curve to the dissociation constants of oxalacetic acid of pK 2.5 and 4.37 (depending on ionic strength) indicates that the predominant species that decarboxylates is the monoanion:



$+ CO_2$ [2]

At pH 3.6 the keto form of oxalacetic acid is the predominant species (18). When the maximum activity is reached at about pH 3.6 the first dissociation (pK_1 2.5) is virtually complete (19). The rate of the reaction begins to decrease as the pH increases to where the second carboxyl group starts to dissociate (pK_2 4.37) and reaches a minimum rate when the fully dissociated form is predominant. The anion of pyruvic acid with a pK of about 2.5 is the product at pH 3.6. The activity plot as a function of pH (Fig. 1) confirms the kinetic studies of Pedersen (9) and Gelles(9), who conclude that oxalacetic acid as the monoanion decarboxylates much faster than in the undissociated form (44 times).

The shift of the bell-shaped activity curve of 0.6 units in D_2O to higher pD values gives further and direct evidence that the monoanion is the predominant active species that decarboxylates (10). To obtain the same concentration of the active monoanion in D_2O a higher pD is required than the corresponding pH because oxalacetic acid is a weaker acid in D_2O than in H_2O.

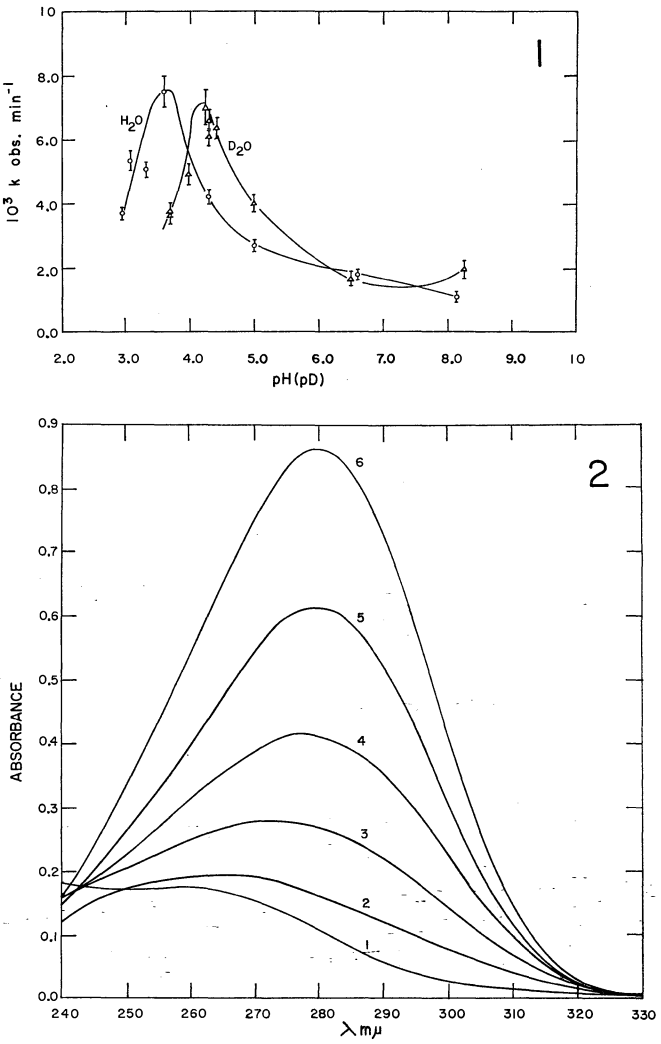

FIG. 1. Spontaneous decarboxylation of oxalacetic acid. Each cuvette (0.5 cm light path) contained $\sim 2\times10^{-4}$ *M* oxalacetic acid and 1.0 *M* Tris–acetate buffer of the appropriate pH made up in H_2O or D_2O. Solid oxalacetic acid was added last and its concentration measured immediately by its absorption at 255 mμ. The zero time absorbance was determined by extrapolation of the plot of absorbance versus time.

FIG. 2. The spectra of the magnesium chelate as a function of magnesium ion concentration. Solutions were prepared in 25 ml volumes adjusted to pH 7.40 ± 0.04 with Tris–acetate buffer 0.5 *M* and measured in 1.0-cm light path cuvettes within 2 minutes. The concentration of oxalacetic acid was 1.9×10^{-4} *M*. Magnesium chloride concentrations for the curves were: (1) 0.000, (2) 0.012, (3) 0.04, (4) 0.08, (5) 0.20, (6) 0.40 *M*, giving a molar ratio of Mg^{++}/OAA^{-} of 0, 64, 212, 424, 1060, 2120 respectively.

Magnesium Oxalacetic Acid Chelate

Addition of magnesium chloride to aqueous solutions of oxalacetic acid promotes decarboxylation of the acid, which can be measured by the changes in absorption. The changes in absorption are caused by the changes in the equilibrium concentration of the kinetically active keto and the spectrophotometrically active enol forms.

Each of the factors that affect the equilibrium, namely the concentration of the magnesium ion, pH, and ionic strength, or factors that are related to it, such as absorption,

observed rate constant of decarboxylation, overall association constant, and absorbing indexes will be discussed. The equilibrium itself will be treated in the 'General Discussion'.

(a) Absorption of the Chelate

The spectrum of oxalacetic acid (pH 7.4) as a function of magnesium ion concentration is plotted in Fig. 2, and indicates an increase in integral absorption and a shift of the 240–260 mμ plateau to a peak of absorption at 280 mμ, on the addition of magnesium ion. It appears from the high ratio of Mg^{++}/OAA (10^3) needed to form the complex that only a small fraction of the added magnesium chloride is effective in complexing with oxalacetic acid, probably because of the extensive hydration of the magnesium ion. The overall absorption of the complex in excess magnesium ion is also a function of pH (and pD).

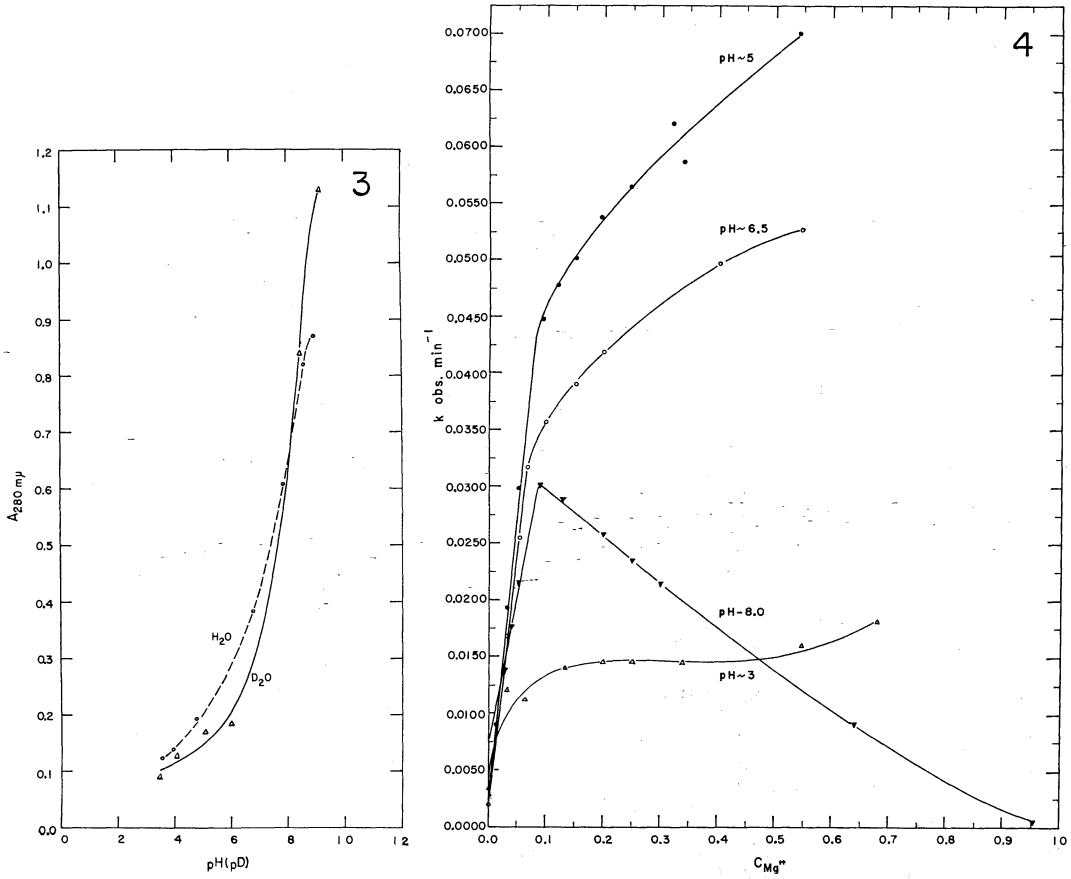

FIG. 3. The absorbance at 280 mμ of the magnesium chelate as function of pH and pD. For the H_2O system: solutions of 1.08×10^{-4} *M* oxalacetic acid, 0.2 *M* $MgCl_2$, and 0.1 *M* Tris–acetate buffer of the appropriate pH were made up to 25 ml in H_2O. Measurements were made within 1–1.5 minutes after each preparation in 1.0-cm light path cuvettes. For the D_2O system: $MgCl_2$, hydrated with heavy water, was prepared by partial dehydration at 98° C of the hexahydrate, dissolving it in D_2O, and repeating the process. Solutions of 1.14×10^{-4} *M* oxalacetic acid, 0.2 *M* $MgCl_2$, and 0.1 *M* Tris–acetate buffer of the appropriate pD were made up to 10 ml in D_2O and measured as above.

FIG. 4. The observed first order rate constant of decarboxylation as a function of magnesium ion concentration at various hydrogen ion concentrations (278 mμ). Each cuvette (0.5-cm light path) contained 0.5 *M* Tris–acetate buffers of the appropriate pH, $\sim2\times10^{-4}$ *M* oxalacetic acid, varying concentrations of $MgCl_2$ (expressed in molarity).

The absorption increases sharply in the region of pH 6 to 9 as shown in Fig. 3 as the concentration of the enol chelate increases. Other sets of measurements of the absorption at pH values up to 9.5 show no significant increase in the total absorption. Further increases of pH (and pD) caused precipitation of the system.

(b) Decarboxylation of the Chelate

The rate of decrease of absorption during the magnesium-ion-catalyzed decarboxylation of oxalacetic acid was measured spectrophotometrically (at 278 mμ for concentrations above 0.04 *M* $MgCl_2$ and at 255 mμ below 0.04 *M* $MgCl_2$). At magnesium ion concentrations below 0.1 *M* $MgCl_2$ (ratio of Mg^{++}/OAA of about 10^3), shown in Fig. 4, there is a linear relationship between the observed rare constant of decarboxylation and the magnesium ion concentration. In addition the rate becomes less dependent on pH as the concentration of magnesium ion decreases.

At concentrations of magnesium ion above 0.1 *M* $MgCl_2$ the reaction is strongly pH dependent (Fig. 4), with an apparent inhibition at pH 8.0 and stimulation at pH 5–6.5 as the $MgCl_2$ concentration is further increased. The depression and stimulation of the observed rate constants can be accounted for by the increase of ionic strength due to the excess magnesium chloride. The addition of KCl (equivalent to 0.25 *M* $MgCl_2$) to a system with optimal concentration of magnesium chloride (0.1 *M* $MgCl_2$) serves to increase the ionic strength and depress the observed rate constant at pH 8.0.

The observed first order rate constants for decarboxylation as a function of pH are plotted in Fig. 5, at varying concentrations of magnesium ion. For a given concentration of magnesium ion the ionic strength is constant. The bell-shaped activity curves show a maximum rate in the range of pH 5 to 6, with a convergence of k_{obs} (isokinetic point) at pH 7.4.

The rate of magnesium-ion-catalyzed decarboxylation was also measured in D_2O as a function of pD and magnesium ion concentration. The rate profile curve shows a shift to higher pD values (Fig. 6). The horizontal shift of the isokinetic point from pH 7.4 to pD 7.8 is evidence of the decreased dissociation constant of the α-C—D bond involved in the enolization of the magnesium oxalacetate complex. The spectrophotometric titration curve (Fig. 3) also indicates a similar shift of the equilibrium position between the keto and enol forms of the complex in D_2O.

(c) Absorbancy Index of the Chelate

The absorbancy index of the keto form of the magnesium-oxalacetate complex (a_K) in Tris–acetate buffer was calculated from kinetic and spectrophotometric measurements. On the basis of the kinetic experiments it is assumed:

(1) that the maximum concentration of the active species, the keto form of the magnesium oxalacetate complex (C_K), exists at pH 5.5, since the activity is maximal at pH 5.5 (Fig. 5).

(2) that the concentration of the active species is reduced to one-half its maximal concentration as the observed rate constant decreases to one-half of its maximal value as a function of pH. The average decrease to 50% activity was found to occur at pH 7.4 (isokinetic point) for magnesium ion concentrations above 0.1 *M* $MgCl_2$ (10^3 ratio of Mg^{++}/OAA).

On the basis of the spectrophotometric measurements (Fig. 3) made at greater than 1000-fold excess of magnesium ion as a function of pH, it is assumed:

(3) that the enol form of the magnesium oxalacetate complex predominates at pH 9.0.

Under such conditions, an approximate value for the apparent absorbancy index of the enol form of the magnesium oxalacetate complex (a_E) can be calculated to be 8.05×10^3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

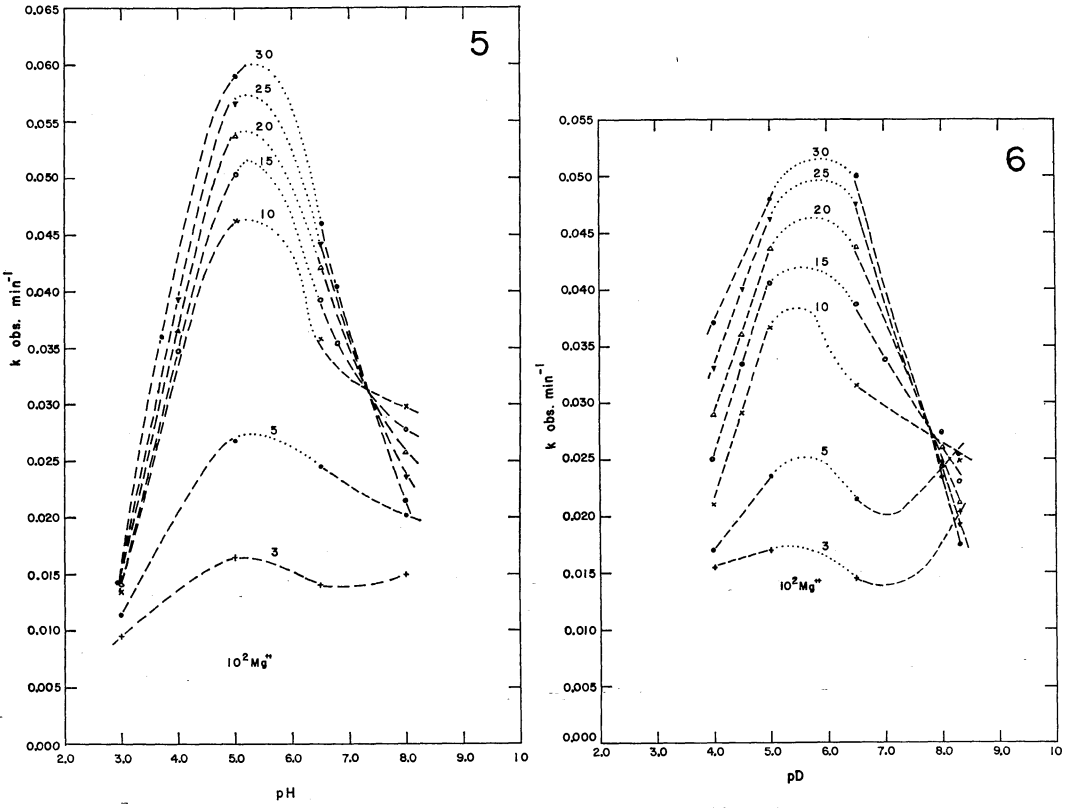

FIG. 5. The observed first order rate constant of decarboxylation as a function of pH at various magnesium ion concentrations (278 $m\mu$). Each cuvette (0.5-cm light path) contained 0.5 M Tris–acetate buffer of the appropriate pH, $\sim 2\times 10^{-4}$ M oxalacetic acid, varying concentrations of $MgCl_2$, 3, 5, 10, 15, 20, 25, 30 each $\times 10^{-2}$ M (see Fig. 4).

FIG. 6. The observed first order rate constant of decarboxylation as a function of pD and magnesium ion concentration (278 mμ). Each cuvette (0.5-cm light path) contained 0.3–0.5 M Tris–acetate buffer of the appropriate pD, $\sim 2\times 10^{-4}$ M oxalacetic acid, varying concentrations of $MgCl_2$, 3, 5, 10, 15, 20, 25, 30 each $\times 10^{-2}$ M.

(ionic strength conditions of Fig. 3). The absorbancy index for the keto form of the complex (a_K) can be then calculated from the following equations at pH $\geqslant$5.5, 1-cm light path:

[3] $$C_T = C_E + C_K = C_T' = C_E' + C_K'$$

[4] $$A_T = a_E c_E + a_K c_K$$

[5] $$A_T' = a_E c_E' + a_K c_K'$$

[6] $$C_K' = C_K/2$$

solving for a_K:

[7] $$a_K = \frac{a_E(A_T + C_T a_E - 2A_T')}{A_T + C_T a_E + 2A_T'}$$

where C_T is the total concentration of the complex and C_E and C_K are the concentrations of the enol and keto forms of the complex and A_T is the total absorbance at 280 mμ (pH 5.5). The primed numbers refer to the values at one-half maximal activity (pH 7.4).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

From these equations the molar absorbancy index for a_K is 5.38×10^2 in H_2O. For the D_2O system a_E is 10^4 and a_K is 6.3×10^2.

The above assumptions are supported by other evidence. Calculations of the percentage of keto and enol forms of the complex as a function of pH (pD), using the above absorbancy indexes, show that at pH 7.4 (pD 7.8), which appears to be the pK for the keto–enol complex, there is a 1:1 ratio of the concentrations of the keto to enol complexes (Table I).

TABLE I

The keto–enol equilibrium of the magnesium chelate as a function of pH (pD)

[b]Approximate values calculated using equation [18] and kinetic data from Figs. 5 and 7.

(d) Overall Association Constant of the Chelate

Further support for the assumptions in section (*c*) comes from the determination of the overall association constant for the magnesium oxalacetate complex at pH 7.4 in Tris–acetate buffer at constant ionic strength of 0.4. The calculations (20, 21) are based on the following equation (equation 8) where the magnesium ion concentration is much greater than the oxalacetate concentration and:

[8] $$\frac{C_{Mg^{++}}\,C_{OAA^{--}}}{A} = \frac{1}{K_C a_C} + \frac{C_{Mg^{++}}}{a_C}$$

where $C_{Mg^{++}}$ and $C_{OAA^{--}}$ are the concentrations of magnesium ion and the dianion of oxalacetic acid, A is the total absorbance at 280 mμ, a_C is the absorbancy index of the complex, and K_C is the overall association constant. The results are plotted in Fig. 7. Based on the overall absorbancy index of the complex at 3.85×10^3 and on the calculated absorbancy indexes for the keto and enol forms of the complex, the keto complex concentration at pH 7.4 is also found to be 51%.

The overall association constant (K_C) for the magnesium oxalacetic acid complex depends on pH and ionic strength as shown in Table II. The ionic strength was maintained at a fixed level by the addition of KCl for a given set of spectrophotometric measurements at varying magnesium ion concentrations and fixed concentrations of oxalacetic acid and hydrogen ion.

At pH 7.4 the association constant is almost independent of the ionic strength but at pH 6.7 and particularly at pH 8.0 there is a marked dependence of K_C, the value decreasing with higher ionic strength. This type of dependence of the K_C sensitivity on ionic strength seems to indicate that there are two distinct aspects of the equilibrium system affected by the ionic strength (cf. General Discussion).

GENERAL DISCUSSION

The changes in absorption observed during the magnesium-ion-catalyzed decarboxylation are caused by the changes in the equilibrium concentrations of the keto form of the

For personal use only.

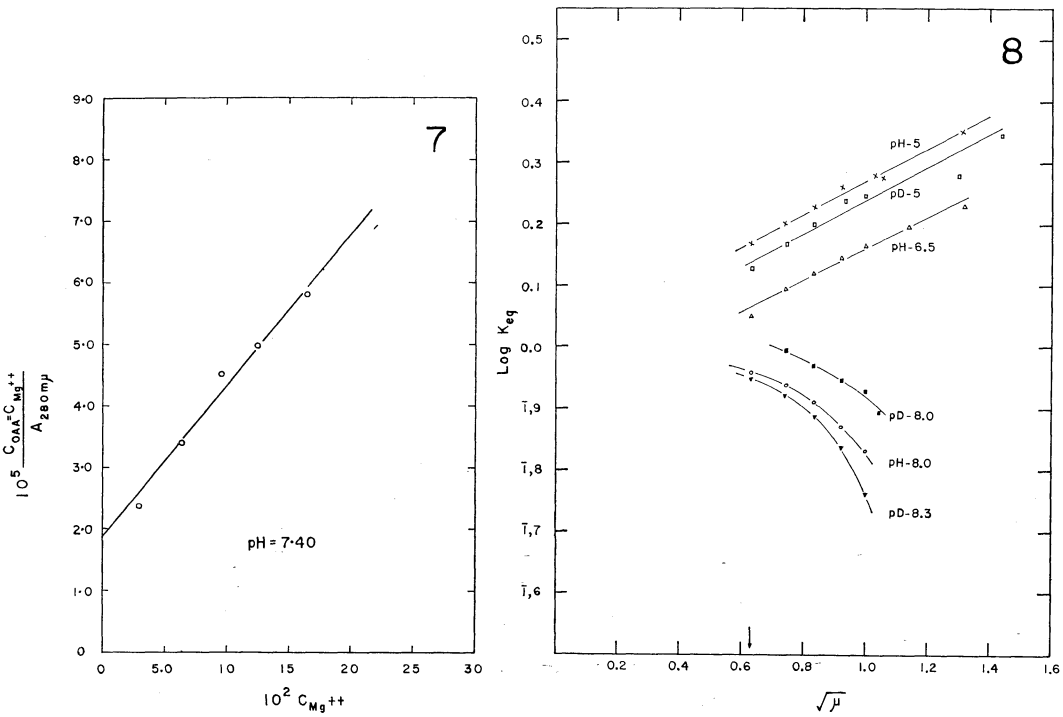

FIG. 7. Scott's plot (20) for the overall association constant for the magnesium chelate. Solutions of 8.66×10^{-5} *M* oxalacetic acid, varying concentrations of magnesium chloride, KCl to adjust the ionic strength to 0.4, and ~0.05 *M* Tris–acetate of the appropriate proportions to give a resultant pH of 7.40 ± 0.02 were made up to 50 ml H_2O. Measurements were made at 280 mμ 2 minutes after preparation of the solution in 1.0-cm light path cuvettes. For magnesium chloride concentrations of 3.20, 6.38, 9.57, 12.76, 16.74 each $\times 10^{-2}$ *M* the absorbancies at 280 mμ were 0.116, 0.163, 0.183, 0.222, 0.230 respectively.

FIG. 8. The keto–enol equilibrium of the magnesium chelate as a function of ionic strength, calculated from $K_{eq} = k_{obs}/k_1$ (18) at various ionic strengths. The arrow indicates the ionic strength which is equivalent to a ratio of Mg^{++}/OAA of 10^3.

TABLE II

Overall association constant of the magnesium chelate as a function of the ionic strength and pH

pH	Ionic strength	K_C, M^{-1}
8.0	0.2	43
	0.3	33
	0.4	18.5
	0.8	5.3
7.4	0.4	13
	0.6	10
	0.8	8.4
6.75	0.3	27.5
	0.6	11
	0.8	6.7

NOTE: The values were measured as described in the legend to Fig. 7.

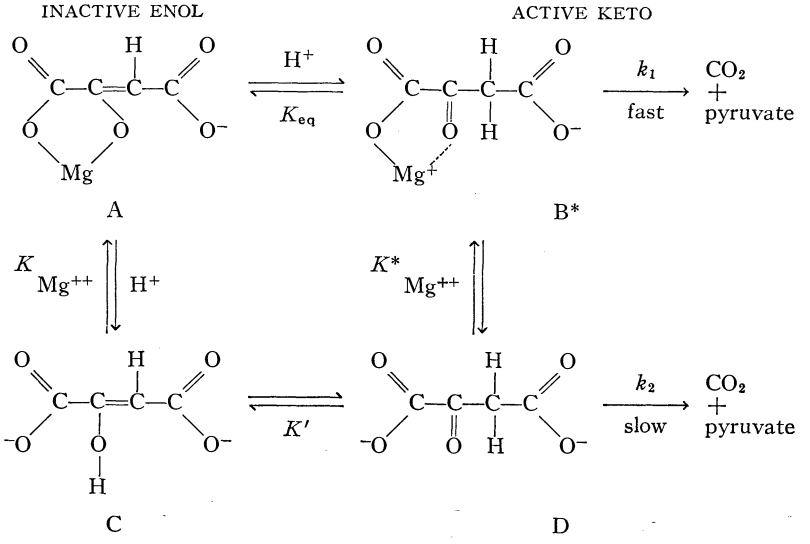
magnesium oxalacetic acid chelate. A general equilibrium scheme can represent the system above pH 5.5 and show its pH and magnesium ion dependence.



[9]

This equilibrium system can be considered under various conditions that displace the position of the equilibrium (indicated by heavy arrows) and so change the concentration of the active species [B*] and [D]. The apparent equilibrium constants are defined as:

$$K = \frac{[A]}{[Mg^{++}][C]}, \quad K_{eq} = \frac{[B^*]}{[A]}$$

and the equilibrium constants as:

$$K^* = \frac{[B^*]}{[Mg^{++}][D]} \text{ and } K' = \frac{[D]}{[C]}.$$

K' is constant in the pH range 5 to 10 (18). The overall association constant

$$K_C = \frac{[A][B^*][H^+]}{[Mg^{++}]^2[C][D]} = K^*K[H^+].$$

The rate of decarboxylation depends on the concentration of the active species.

[10] $$\text{Rate} = k_1[B^*] + k_2[D]$$

where $k_1 > k_2$.

Calculated values for K^* and K are reported in Table III for the isokinetic point.

TABLE III

The H_2O – OAA – Tris-acetate buffer system

$k_{obs} = k_1$	$K_{eq} = [B^*]/[A]^a$	K_C, M^{-1}	K^*, M^{-1b}	K, M^{-1b}

NOTE: [a]Calculated from spectrophotometric measurements (Fig. 3).
[b]Calculated from $K_C = K^* K[H^+]$ and $K_{eq} = (K^*/K)K'$ where $[H^+] = 3.98\times10^{-8}$ (pH 7.4), $K' = 9.3$ (22) and ionic strength = 0.6.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(*i*) At low magnesium ion concentrations (e.g. 0.03 *M* $MgCl_2$) the k_{obs} becomes less dependent on pH changes (Fig. 5) since the concentration of D is more significant than that of B* and the C⇄ D equilibrium is H^+ independent:

$$\begin{array}{l} A \rightleftharpoons B^* \rightarrow CO_2 \\ \downarrow \quad \downarrow \\ C \rightleftharpoons D \rightarrow CO_2 \end{array} \quad . \qquad [11]$$

(*ii*) At the maximum rate (pH 5–6) the magnesium chelate exists predominantly as B*, the active keto form (Table I). For a given concentration of magnesium ion (e.g. 0.1 *M* $MgCl_2$), k_{obs} is at a maximum since the concentration of B* is at a maximum:

$$\begin{array}{l} A \rightarrow B^* \xrightarrow{k_1} CO_2 \\ \uparrow \quad \uparrow \\ C \rightleftharpoons D \xrightarrow{k_2} CO_2 \end{array} \quad . \qquad [12]$$

The k_{obs} depends on the pre-equilibrium concentration of the active forms of B* and D, which in turn depend on the magnesium ion concentration. Increasing the concentration of magnesium ion will increase the concentration of B* until the concentration of D is insignificant and so the k_2[D] term is negligible.

$$\text{Rate} = k_1[B^*]. \qquad [13]$$

In terms of the spectrophotometrically active species A:

$$\text{rate} = k_1K^*/K.\ K'[A], \qquad [14]$$

$$k_{obs} = k_1K^*/K.\ K' = k_1\ K_{eq} = k_1[B^*]/[A]. \qquad [15]$$

Addition of more $MgCl_2$ (pH 6.7) will not only increase the concentration of B* but will also increase ionic strength. Increasing the ionic strength depresses both the overall stability constant (Table II) and the A ⇌ B* dissociation (Fig. 8). The depressed dissociation, however, favors the kinetically active species B* and thus stimulates the rate of decarboxylation (equation 13).

(*iii*) An increase in the pH above 5.5 for a given high concentration of magnesium ion (e.g. 0.1 *M* $MgCl_2$) shifts the position of the pH dependent equilibrium A ⇌ B*. The observed rate constant is decreased because the concentration of the active form (B*) is diminished (see Table I and equation 13).

$$\begin{array}{l} A \leftarrow B \rightarrow CO_2 \\ \uparrow \quad \uparrow \\ C \rightleftharpoons D \end{array} \qquad [16]$$

(*iv*) Simultaneously with the decrease of k_{obs} with pH (section *iii*) the absorption at 280 mμ increases. The increased absorption is due to the increase of the concentration of form A, the highly absorbing enolic form of the metal chelate which does not decarboxylate. This dependence of the rate on pH is further evidence that it is the lower absorbing keto form of the chelate that is the active species in decarboxylation of oxalacetic acid.

(*v*) As the pH is increased to pH 8.0, high concentrations of magnesium chloride cause an apparent inhibition of the observed rate constant, i.e., k_{obs} increases up to a certain critical level (a ratio of Mg^{++}/OAA of 10^3) and then decreases on the addition of more magnesium chloride. Several combined factors may be involved in this behavior. A certain amount of magnesium ion promotes the reaction because it forms the 1:1 complex. As more $MgCl_2$ is added, increasing the ionic strength, the overall association constant decreases. The k_{obs} is also diminished since the concentration of the active form (B*) is decreased as reflected in the decrease of K_{eq} at pH 8.0 (section *viii*). The increase in ionic

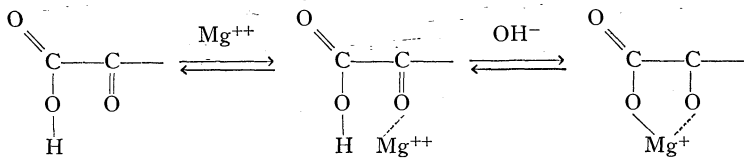
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

strength, by addition of KCl to an optimal concentration of magnesium, shows that ionic strength increases do diminish k_{obs}.

At high pH the presence of OH^- changes the extent of hydration around the magnesium ion, which would then affect the Mg^{++} in its sensitivity to ionic strength, as well as in its effective positive charge, which promotes the decarboxylation. Davies (22) points out that cations are hydrated with a layer of water protecting them from the anion: M^+,H_2O,X^- but with hydroxides this probably changes to M^+,OH^-,H_2O so that the protective hydration is lost. Magnesium ion is a particularly highly hydrated ion and would be sensitive to pH changes. The K_C values at pH 8.0 are seen to be most sensitive to ionic strength changes. At this pH the effect of ionic strength changes is probably mostly on the state of hydration of the magnesium ion, changing its effective radius and charge. The effect is analogous to the addition of a different metal of the same group (24) which binds the ligand with a lower K_C and establishes a different K_{eq}.

(*vi*) At pH 7.4 there is a convergence of the observed rate constants (isokinetic point) such that k_{obs} is constant above a certain critical level of magnesium ion (Mg^{++}/OAA = 10^3). The data in Fig. 5 (pH 7.4) indicate that increases of magnesium chloride concentrations above 0.1 *M*, needed to form the 1:1 complex, cause no apparent inhibition of k_{obs} within the concentration range investigated. The p*K* of the keto–enol chelate equilibrium A $\rightleftarrows$ B* was also found to be about pH 7.4 by spectrophotometric titration of the chelate (Fig. 3). This means that at this pH, [A] = [B*] so that $k_{obs} = k_1$ (equation 15). The apparent equilibrium constant and the overall association constant are almost independent of ionic strength; the effect on the various equilibria may balance each other (see section *ix*).

(*vii*) At pH 3.0 increases of magnesium ion above a molar ratio of magnesium ion to oxalacetate of 10^3 have no effect on the observed rate constant in the range investigated. At this pH there was found an intensification of the absorption at 260 mμ but no shift of the peak to 280 mμ. This can be interpreted as the formation of the saturated monoligand complex, which has a slower rate of decarboxylation.



[17]

With increasing pH the observed rate constant increases are within the range of pH where the second carboxyl group of oxalacetic acid dissociates. By pH 5.5 the second carboxyl group is fully dissociated so that the bidentate chelate with magnesium ion can form and the observed rate constant is at a maximum.

(*viii*) The apparent keto–enol chelate equilibrium constant (K_{eq}) can be calculated from the scheme illustrated in equation (9); rearranging equation [15] to:

[18] $$K_{eq} = k_{obs}/k_1.$$

The calculated K_{eq} values at various pH (pD) values as a function of ionic strength are plotted in Fig. 8. The value of k_{obs} at the isokinetic point (pH 7.4) is used as k_1. These K_{eq} values determined from kinetic measurements compare favorably (Table I) to the K_{eq} values measured spectrophotometrically under similar conditions of ionic strength. Increase of the ionic strength (above 0.1 *M* $MgCl_2$) increases K_{eq} below pH 7.4 (pD 7.8)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

but decreases K_{eq} above these values. This behavior of K_{eq} directly reflects the behavior of k_{obs} (equation 18).

(*ix*) The variation of the ionic strength sensitivity of K_{eq}, K_C, total absorption, and k_{obs} with pH changes gives indication that possibly two separate aspects of the equilibrium system are affected by ionic strength in different ways.

(*a*) In the acid range, increasing ionic strength diminishes the proton dissociation of the tautomeric equilibrium as indicated by the increase of K_{eq} favoring the active species B*. Although the increase of ionic strength also causes a decrease in K_C, the resulting effect on k_{obs} is balanced by the effect on K_{eq}.

(*b*) In the basic range, increasing ionic strength diminishes the positive charge of the less hydrated magnesium ion both in solution and in the chelate (see Section *v*) and decreases K_C and K_{eq}. The direction of the ionic strength effect on K_C supports the effect on K_{eq} and decreases [B*], resulting in a diminished k_{obs}.

(*x*) The decrease of the rate constant in D_2O at the isokinetic point, $k_{H_2O}/k_{D_2O} = 1.1$, is indicative of a secondary isotope rate effect. Such a secondary isotope effect might be expected in the keto form of the complex in which the two alpha hydrogens are replaced by deuterium. The fact that no primary isotope rate effect is observed is evidence that a C—D or O—D bond cleavage is not rate determining in the magnesium-ion-catalyzed decarboxylation of oxalacetic acid. This supports the mechanism in which the C—C bond cleavage is rate determining (16).

The nature of the shift of the isokinetic point in D_2O is further evidence that at the isokinetic point $k_{obs} = k_1$, since at pD 7.8 the ratio of [B*] to [A] is 1 (see equation 15). The general shift of the pD rate profile supports the explanation that whatever affects the equilibrium concentration of the active species B* affects the rate of the reaction.

(*xi*) It has been proposed (14) that the decrease in absorption observed when oxalacetate decarboxylates in the presence of metal ion is due to the ketonization of the enol–pyruvate complex which is the first product of decarboxylation. This interpretation was based on the assumption that the enol–pyruvate complex is a very strongly absorbing species compared to the oxalacetate complex, but no spectral evidence was presented for this assumption. The present calculations for the absorbancy indexes of the keto and enol magnesium complexes and for K_{eq}, which combine kinetic and spectral data, account for all the predominant absorption changes in the reaction without assuming a highly absorbing enol–pyruvate complex intermediate. The fast increase of absorption on the addition of magnesium ion to oxalacetate is interpreted as the fast formation of the more strongly absorbing magnesium oxalacetate complex. This fast formation was also observed for Al^{+++} (11), Cu^{++}, and Zn^{++} (14). The decrease of absorption during decarboxylation can be accounted for by the decrease in the concentration of the absorbing magnesium oxalacetate complex under various conditions of pH and magnesium ion concentration.

(*xii*) The magnesium-ion-catalyzed decarboxylation is analogous to the behavior of other metals, in its pH dependence to copper (10, 24), and in its inhibitory effect at higher concentrations to Pb^{++}, Cu^{++}, and La^{++} (4, 14).

Comparison of the effect of pH and pD on the rate of the magnesium-ion-catalyzed decarboxylation and the effect of pH and pD on the decarboxylation reaction catalyzed by oxalacetate carboxylase of *Micrococcus lysodeikticus* (15,16) shows that both systems have the same maximum of activity at about pH 5.5 and that both peaks are shifted to higher pD values in the D_2O systems (16). Other enzymes that decarboxylate oxalacetic acid also have certain common features in their mechanism. The malic enzyme (26) from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

pigeon liver, which depends on manganese ion or magnesium ion, has a maximal activity at pH 4.5 to 5.0 and the enzyme from wheat germ has a maximal activity at pH 5.2. The oxalacetate carboxylase of chicken liver (27), which depends on inosine triphosphate, has a maximal activity at about pH 6.0. The oxalacetate decarboxylase of rat liver (28) with a maximal activity at pH 7.4 depends on magnesium ion and is inhibited by manganese ion. The inhibition of the magnesium-ion-catalyzed decarboxylation of oxalacetate at high concentration of magnesium ion above pH 7.4 is analogous to the behavior of phosphoenol pyruvate carboxylase (29) from spinach leaves in the formation of oxalacetate where, at 7.4, the reaction is stimulated by the magnesium ion concentrations up to 2×10^{-3} M magnesium chloride and inhibited above this concentration. The present results indicate a parallelism between the mechanism of the metal-ion-catalyzed and enzyme-catalyzed decarboxylation of oxalacetic acid.

ACKNOWLEDGMENTS

The authors wish to thank the National Research Council of Canada for financial support, Mr. P. A. Kelly, for mathematical assistance, and Doctors R. J. Thibert and K. G. Rutherford for their valuable discussions.

ANTIMONY TETRAFLUORIDE MONOFLUOROSULPHATE: PREPARATION, PROPERTIES, AND STRUCTURE*

R. J. GILLESPIE AND R. A. ROTHENBURY
Department of Chemistry, McMaster University, Hamilton, Ontario
Received September 18, 1963

ABSTRACT

When antimony pentafluoride is refluxed with sulphur trioxide, a new compound with the composition $SbF_5.SO_3$ is formed together with sulphuryl fluoride, disulphuryl fluoride, and small amounts of the higher polysulphuryl fluorides. This compound is a colorless, very viscous liquid. From the chemical analysis, the F^{19} N.M.R. spectrum, and the Raman and infrared spectra of the liquid it was concluded that the compound is antimony tetrafluoride monofluorosulphate $SbF_4(SO_3F)$ and that it is highly polymerized in the liquid state by fluorosulphate bridges that can have either a cis or a trans orientation with respect to each other; the former occurring to a greater extent than the latter.

It has been reported that disulphuryl fluoride is formed when antimony pentafluoride is added dropwise to refluxing sulphur trioxide (1). The authors represented the reaction in the following manner:

$$2SbF_5 + 14SO_3 \rightarrow Sb_2O(SO_4)_4 + 5S_2O_5F_2.$$

We have found that when antimony pentafluoride (1 mole) is added slowly to refluxing sulphur trioxide (2 mole) and the resulting mixture distilled, unreacted sulphur trioxide, sulphuryl fluoride, disulphuryl fluoride, and small amounts of higher polysulphuryl fluorides were obtained, together with a relatively large amount of a colorless viscous liquid, with a boiling point of 227°. After distillation a white solid residue remained. When the reaction was repeated using considerable excess of sulphur trioxide, unreacted sulphur trioxide, disulphuryl fluoride, and some higher polysulphuryl fluorides were again obtained, but the viscous liquid was not obtained. A similar white solid residue remained behind. When heated in air at 1000° these solid residues afforded a mixture of Sb_2O_4 and Sb_2O_5. Analysis of the viscous liquid showed that it had the composition $SbF_5.SO_3$. During attempts to find a solvent for this substance it was found that it reacted with the common organic solvents and that it was insoluble in 1,2-dichloro-1,1,2,2-tetrafluoroethane (Freeon 114) and sulphur hexafluoride. It fumed in air and supercooled readily to give a glass-like solid.

The F^{19} nuclear magnetic resonance spectrum of the viscous liquid was determined at three temperatures (Table I); the three spectra were almost identical. The fluorine-on-antimony region is shown in Fig. 1; it consists of a pair of triplets *A* and *C* and a single line *B*. The relative areas of the peaks *A*:*B*:*C* were found to be 3.0:1.0:3.0. In the fluorine-on-sulphur part of the spectrum (Fig. 2) there are two main peaks *D* and *E* of relative areas 3.2:1.0 and four very small peaks *F*, *G*, *H*, and *I*. Peak *D* was at $+692\pm3$ c/second from an internal reference of SF_6. The chemical shift of the center of the triplet *A* (Fig. 1) with respect to the peak *D* (Fig. 2) was $+7729\pm28$ c/second.

The most obvious explanation for the two triplets in the fluorine-on-antimony region of the spectrum would be that the molecule contains pairs of fluorine atoms in the axial and

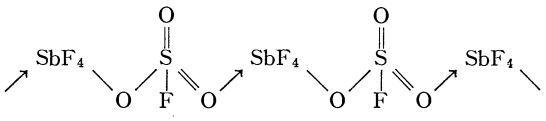
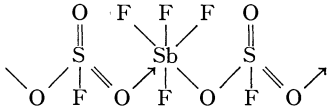
equatorial positions of a trigonal bipyramid molecule. However, this provides no explanation of the peak *B*, nor for the presence of more than one peak in the F^{19} on S region of the spectrum. The highly viscous nature of the liquid indicates extensive association or polymerization, as has been found in the case of antimony pentafluoride (2, 3). The observed spectrum is, however, not consistent with association by means of fluorine bridges

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

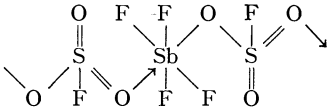
such as occur in liquid antimony pentafluoride, but only with association by means of fluorosulphate bridging groups (I). In such a polymeric chain the bridging fluorosulphate groups may be either cis or trans to each other. The fluorines in each cis unit of the polymer (II) would be expected to give an A_2X_2 spectrum of two triplets, while the four equivalent fluorines in each trans unit (III) of the polymer would be expected to give a single line, which we assume is *B*. Hence the polymers contain both cis and trans units in the ratio 6.0:1.0.



I



II



III

In any polymeric chain containing both cis and trans units a given fluorosulphate group can have one of three possible environments: the neighboring fluorosulphate groups can be both cis, both trans, or one cis and one trans. Since there is, on average, one trans unit for every six cis units, approximately 29% of the fluorosulphate groups would be expected to have cis–trans neighbors and approximately 2% to have trans–trans neighbors. Because of their appreciable overlap the areas of the peaks *D*, *E*, and *F* (Fig. 2) are difficult to measure accurately but they are in reasonable agreement with these predictions. Clearly peak *D* may be assigned to cis–cis fluorosulphate groups, *E* to cis–trans fluorosulphate groups, and *F* to trans–trans fluorosulphate groups. The small high-field peaks *G*, *H*, and *I* cannot be due to small amounts of the polysulphuryl fluorides since these give signals to low field of sulphuryl fluoride (5), which itself gives a peak at 360 c/second to low field of fluorosulphuric acid. They are assigned to terminal fluorosulphate groups; this assignment has been confirmed by more recent studies on solutions of $SbF_4.SO_3F$ in fluorosulphuric acid (6).

Further evidence in support of our interpretation of the n.m.r. spectrum is as follows: the coupling constant between the axial and equatorial fluorines in a cis unit of the polymer was found to be 128±3 c/second, which is close to the F–F coupling constant of 130 c/second for polymeric antimony pentafluoride (2, 3) and to the value of approximately 100 c/second found by Muetterties (4), and by the authors (3), for several SbF_5.base complexes. The chemical shift between the non-equivalent fluorines on antimony of 0.303 p.p.m. is also close to that of 0.260 p.p.m. found for antimony pentafluoride (3).

Since the peaks *G*, *H*, and *I* observed in the F^{19} on S region, and attributed to terminal fluorosulphate groups, are very small in comparison to *D* and *E*, attributed to the bridging

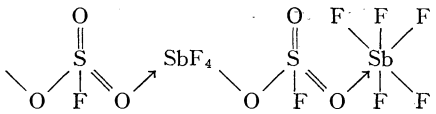
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

groups, it may be concluded that the average chain length is quite high, or that the polymers are mainly cyclic.

Two very small additional peaks were obtained in the spectrum of $SbF_4.SO_3F$ when the temperature was reduced to $-37°$; they occurred at 856 ± 9 c/second and 951 ± 10 c/second to high field of the center of triplet *A* (Fig. 1). They are probably due to the presence of a very small amount of antimony pentafluoride and presumably they do not appear at higher temperatures because of exchange processes. We assume that the two peaks are the X part of an AX_4 spectrum which would consist of a doublet and a quintet and that the quintet which would have only 1/4 of the intensity of the doublet is not resolved from the base-line noise. Such a spectrum could arise from an SbF_5 group occupying a terminal position in a polymeric chain (IV) and it would be expected to closely resemble the fluorine spectrum of an SbF_5.base complex. The observed fluorine–fluorine coupling constant of 95 c/second is in close agreement with values of approximately 100 c/second that have been found for various SbF_5.base complexes (3, 4). This SbF_5 could either be an impurity or it might possibly arise from the following self-dissociation process.

$$2SbF_4SO_3F = SbF_5 + SbF_3(SO_3F)_2.$$

However, no additional peaks were observed in the spectrum that could be attributed to $SbF_3(SO_3F)_2$ units in the polymer and we therefore believe that the SbF_5 was present as a very small impurity. From the areas of the peaks in the spectrum it was found that the amount of such impurity was less than 2 mole%. This amount of SbF_5 impurity could not have been detected by our analytical methods.



IV

Confirmation of the formulation of the compound as a fluorosulphate $SbF_4.SO_3F$ was obtained from a study of its infrared and Raman spectra. The lines observed in these spectra are listed in Table II. No lines are observed at frequencies higher than 750 cm^{-1}

TABLE II

Infrared and Raman spectra of antimony tetrafluoride monofluorosulphate

Raman	1430, 1080, 890, 695, 667, 654, 555, 425, 300, 270, 251, 200, 165, 143 cm^{-1}

in the spectrum of antimony pentafluoride (7) thus the line observed at 890 cm^{-1} in the Raman spectrum and at 865 cm^{-1} in the infrared spectrum can be unambiguously assigned as an SF-stretching vibration. This vibration has frequencies of 848 and 885 cm^{-1} in SO_2F_2 (8), and 850 cm^{-1} in HSO_3F (9). The lines at 1430, 1216, and 1080 cm^{-1} may be assigned as SO stretching vibrations.

EXPERIMENTAL

Preparation of Antimony Tetrafluoride Monofluorosulphate

Antimony pentafluoride (47.3 g, 1.0 mole) was added slowly, with constant shaking, to refluxing sulphur trioxide (35.9 g, 2.1 mole). The main product was a mixture of a clear viscous liquid and a white solid, together with material which was obtained as a liquid-air trap condensate; the latter was identified as sulphuryl fluoride by its boiling point and its chemical shift in the F^{19} n.m.r. spectrum (b.p. $-53°$, $\delta(S_2O_5F_2)$ $+861 \pm 4$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

c/second at −31° (3). Distillation of the mixture gave some more volatile material, which condensed in a liquid-air trap, a clear viscous liquid (45.7 g) b.p. 88° at 1.0 mm, and a white solid (8.2 g) (found: Sb, 62.6; F, 8.8; S, 4.7%), which when heated in air at 1000° for 7.5 hours afforded an off-white solid which was yellow when hot, and contained no fluorine or sulphur (found: Sb, 77.2; Sb_2O_4 requires: Sb, 79.2; Sb_2O_5 requires: Sb, 75.3%).

The liquid–air trap condensate contained a material which boiled below room temperature, and was identified as sulphuryl fluoride by its boiling point and its chemical shift in the F^{19} n.m.r. spectrum (b.p. −53°, $\delta(S_2O_5F_2)$ +861±4 c/seconds at −31° (3)) and a liquid which boiled above room temperature. This liquid was treated with 95% sulphuric acid to remove sulphur trioxide, and a sample distilled to afford a fraction, b.p. 51–62°, which has shown by means of its F^{19} n.m.r. spectrum to consist mainly of disulphuryl fluoride, plus a small amount of the trisulphuryl fluoride (5). The F^{19} n.m.r. spectrum of the residue was examined, and peaks were observed at −80, −109, −117, and −123 c/second from $S_2O_5F_2$ which could clearly be attributed to $S_3O_8F_2$, $S_4O_{11}F_2$, $S_5O_{14}F_2$, and $S_6O_{17}F_2$ respectively (5). A small unidentified peak was also observed at +366 c/second from $S_2O_5F_2$.

The clear viscous liquid (44.4 g) on distillation afforded a white solid residue (1.6 g) and a clear viscous distillate (36.5 g) (found: Sb, 40.6; F, 31.4; S, 10.3; $SbF_4(SO_3F)$ requires: Sb, 41.0; F, 32.0; S, 10.8%), b.p. 68° at 0.4 mm. The n.m.r. spectrum of this distillate is shown in Figs. 1 and 2.

Reaction of Antimony Pentafluoride with Excess Sulphur Trioxide

Antimony pentafluoride (32.2 g, 1.0 mole) was added slowly, with constant shaking, to refluxing sulphur trioxide (95.7 g, 8.1 mole) to afford a mixture of a clear liquid and a white solid. Distillation of the mixture gave 77.0 g of a distillate with b.p. 50°; further heating up to 360° at 1.0 mm yielded only a white solid residue (36.4 g) (found: Sb, 43.8; F, 11.7; S, 14.0%), which when heated in air at 1000° (12.5 hours) afforded a white solid which was yellow when hot, and contained no fluorine or sulphur (found: Sb, 78.8; Sb_2O_4 requires: Sb, 79.2; Sb_2O_5 requires: Sb, 75.3%).

The distillate was treated with 95% sulphuric acid to remove sulphur trioxide, and a sample distilled to afford pure disulphuryl fluoride, b.p. 50–51°, and a residue which the n.m.r. spectrum showed consisted of the higher sulphuryl fluorides (5).

Apparatus

The F^{19} n.m.r. spectra were obtained using a Varian high-resolution n.m.r. spectrometer and electromagnet at a frequency of 56.4 Mc and a field of 14,000 gauss. The infrared spectra were obtained with a Perkin–Elmer model 21 spectrometer using silver chloride cells and the Raman spectra were obtained with an apparatus that has been described previously (10).

ACKNOWLEDGMENT

We thank the Directorate of Chemical Sciences, United States Air Force Office of Scientific Research, and the Allied Chemical Company for financial assistance. We also thank Dr. K. Ramaswamy for obtaining some of the infrared and Raman spectra, and the Ozark Mahoning Co. for a gift of antimony pentafluoride.

THE SESQUITERPENE ALCOHOLS OF THE HEARTWOOD OF THUJA OCCIDENTALIS L.[1]

E. VON RUDLOFF AND G. V. NAIR[2]
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received September 27, 1963

ABSTRACT

γ-Eudesmol, a mixture of α- and β-eudesmol, and a new sesquiterpene diol, occidiol, were found to be minor components of the neutral extract of eastern white cedar heartwood. A tentative structure for occidiol is proposed. The biogenetic relationship between these compounds is discussed and a common precursor for the eudesmol and occidentalol series is suggested.

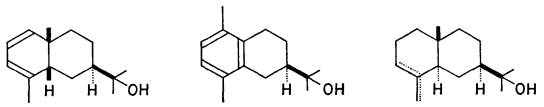
For personal use only.

Nakatsuka and Hirose (1, 2) have isolated from the heartwood of eastern white cedar (*Thuja occidentalis* L.) the two sesquiterpene alcohols occidentalol (I) and occidol (II).



I II III

Nakazaki (3) has reported that in (+)-occidol the isopropanol group has the R-configuration (as shown). By conversion to the dihydro and tetrahydro derivatives and comparison with eudesmol (III) and its dihydro derivatives, occidentalol has been shown by von Rudloff and Erdtman (4) to have cis-fused rings. This was based on the reasonable assumption that the isopropanol group is in the equatorial position, i.e., as in the trans-fused eudesmane-type of compound (5). Recently, Mislow and Moscowitz (6) have presented arguments which indicate that the isopropanol group of occidentalol at C-7 has the R-configuration. This lends support to Nakazaki's view (3, 7) that occidentalol and occidol are biogenetically closely related.

In view of the unusual cis-fused ring system found in occidentalol and a possible biogenetic relationship with the eudesmols, it was of interest to determine the nature of the minor sesquiterpenoid constituents of the wood of eastern white cedar. Gas–liquid chromatography (G.L.C.; cf. also Refs. 4 and 8) showed that the wood extract from a mature tree from the Winnipeg district, Manitoba, contained mainly occidentalol (peak 1) and occidol (peak 6), three minor, and two trace constituents (see Table I). The three minor constituents (peaks 2, 3, and 5) were isolated in milligram amounts and were shown to be a mixture of γ-eudesmol and an unidentified compound, a mixture of α- and β-eudesmol, and a new sesquiterpene diol respectively.

Peak 2 had the retention time of α-cadinol and γ-eudesmol. Its infrared spectrum was similar in all respects to that of α-cadinol, when these were recorded as liquid films (8). The weak, but distinct, absorption bands near 1650 and 815 cm^{-1} are indicative of the trisubstituted double bond found in α-cadinol. However, the fraction of the oil of araucaria identified as α-cadinol by one of us (8) mainly on this basis was shown to be essentially γ-eudesmol by Bates and Hendrickson, who employed nuclear magnetic resonance (n.m.r.) spectroscopy and obtained dihydroeudesmol by hydrogenation of the material.

TABLE I

Sesquiterpenoid components of the wood of *Thuja occidentalis* L.

Peak	Compound	R.R.T.*	%
1	Occidentalol	0.92	36
2	γ-Eudesmol and unidentified	1.02	3
3	α- + β-Eudesmol	1.46	10
4	Unidentified	2.08	0.5
5	Diol	2.20	3
6	Occidol	6.0	46–47
7	Unidentified	6.5	0.5–1.0

*R.R.T. = relative retention time (cedrol = 1.00) on a 6 ft × 1/4 in. O.D. adipate polyester column.

Since insufficient amounts of peak 2 were isolated in this study to permit the recording of an n.m.r. spectrum, the component was hydrogenated over platinum catalyst. The product crystallized on standing and was found to be mainly dihydroeudesmol. Therefore, peak 2 must contain γ-eudesmol. However, rechromatography of peak 2 showed that it contained a second component, but this could not be isolated.

Peak 3 was obtained crystalline and a mixed melting point and comparison of infrared spectra and G.L.C. retention data confirmed that this was identical with the mixture of α- and β-eudesmol, which is the major constituent of the oil of araucaria (8). G.L.C. analysis also showed that the ratio of α- to β-isomer was nearly the same as that in oil, i.e., about 1 to 3.

Peak 5 was a viscous liquid, which appeared to decompose gradually under atmospheric conditions. The infrared spectrum of the freshly isolated material indicated it to be an unsaturated alcohol (strong bands at 3440, 2920, 1650, with a shoulder at 1670, 1382, and 1370 cm^{-1}, weaker ones at 3080, 3040, 1035, 915, 875, 850–825, and 750 cm^{-1}) which may have a terminal methylene and an isopropyl or isopropanol group and possibly a trisubstituted double bond. The molecular weight (236), obtained by mass spectroscopy,* and the elementary analysis agreed fairly well with $C_{15}H_{24}O_2$. The unsaturated character was confirmed by a strongly positive tetranitromethane test, as may also be deduced from the relatively high optical rotation ($[\alpha]_D^{23}$ −125.5°) and refractive index (n_D^{23} 1.5129). No characteristic ultraviolet spectrum was recorded. Thus, the compound appears to be a diol with at least two isolated double bonds. Hydrogenation over palladium catalyst gave a liquid dihydro product, the infrared spectrum of which no longer showed the peaks at 3080 and 875 cm^{-1}. Hydrogenation over platinum catalyst gave inconclusive results, possibly because hydrogenolysis took place. Dehydrogenation over palladium-on-charcoal at 250° C gave a high yield of guaiazulene, which was also obtained in very low yield when the total mixture of terpenes was distilled at temperatures above 150 to 160° C.

Most remarkable was the behavior of peak 5 towards dilute acids. Treatment with aqueous oxalic or methanolic sulphuric acid resulted in the formation of a ketol (strong I.R. bands at 3420 and 1710 cm^{-1}, weaker ones at 1643, 910, and 825 cm^{-1}). When this ketol was dehydrogenated over either selenium or palladium no guaiazulene was obtained, but a low yield of an aromatic hydrocarbon with the same retention time as eudalene was recorded by G.L.C. Dehydration of the ketol with pyridine-modified alumina reagent (10) gave mainly an unsaturated ketone (strong I.R. bands at 1740, 1693, 1633, and 1377 cm^{-1}). The ultraviolet absorption at 290 and 228 mμ confirmed α,β-conjugation.

The formation of guaiazulene from the parent diol and its acid-catalyzed rearrangement to a eudalene precursor are reminiscent of the behavior of germacrone (11). Further,

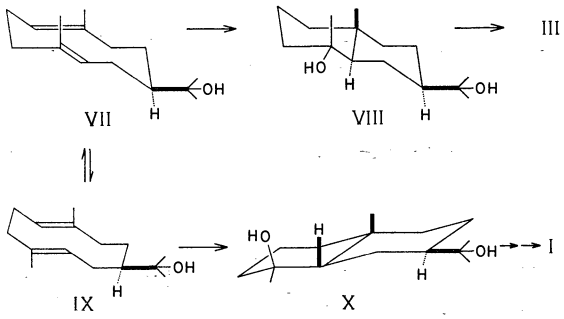
IV V VI

the above data can be reconciled with the properties of a diol having a 10-membered ring of type IV, which isomerizes to the ketol V under acidic conditions. Dehydration would produce the α,β-unsaturated ketone VI. The n.m.r. spectrum confirms the presence of an isopropanol group (singlet equivalent to 6 protons at 8.75), a trisubstituted double bond (triplet equivalent to 1 proton near 4.00) and two C-methyl groups. However, a complete interpretation of this spectrum was not possible. This may be due to some unusual properties of protons found in 10-membered rings. Also, the material isolated may be a mixture of double bond isomers. Further work to establish the structure more definitely will be carried out when the isolation of larger amounts of pure material has been achieved. The name "occidiol" is proposed for this component of the wood of *Thuja occidentalis* L.

Hendrickson (12) has discussed the stereochemical implications in sesquiterpene biogenesis and has shown that eudesmol may be formed from *trans*-farnesol via the 10-



membered intermediate VII, which would form the precursor VIII by a concerted cyclization. This would then lead to α-, β-, and γ-eudesmol as described by Bates and Hendrickson (9). If the two methyl groups are aligned on opposite sides of the 10-membered ring (IX), then by the same mechanism the cis-fused precursor X would obtain, which would then lead to occidentalol, and further to occidol (3, 7). Such a scheme would result in the R-configuration of the isopropanol group at C-7 in both cases, and would predict the absolute configuration of occidentalol to be I.* Furthermore, a single oxidative step with perhaps a double bond isomerization would account for the formation of the diol in *Thuja occidentalis*.

EXPERIMENTAL

Melting points were determined on a Leitz hot-stage microscope. Infrared spectra were recorded with a Perkin–Elmer model 21 double beam spectrophotometer, liquids being mounted as films between sodium chloride plates and solids as KBr disks, unless otherwise indicated. Nuclear magnetic resonance spectra were obtained with a Varian A-60 spectrometer, using tetramethyl silane as internal standard. The G.L.C. columns and apparatus have been described previously (4, 8). Known compounds were identified by comparison of infrared spectra, G.L.C. retention data, and mixed melting point. All retention times (R.T.) were measured relative to cedrol (= 1.00).

Isolation of Sesquiterpenes

The milled heartwood (5.5 kg) of eastern white cedar (part of a mature tree from the Winnipeg district, Manitoba (4)) was extracted with acetone in a Soxhlet extractor for 36 hours. The solvent was removed under reduced pressure from the extract in a rotary evaporator at 40–50° C. The dark brown, viscous residue

For personal use only.

(313 g, 6.3%) was poured with stirring into ether (3 liters) and the insoluble precipitate was filtered off. The ethereal solution was shaken with several aliquots of aqueous potassium hydroxide solution (10%) to remove all acidic and phenolic components. After it was washed with water and dried over anhydrous sodium sulphate, the ether was moved by evaporation. The residue (195 g, 3.5%) was composed mainly of sesquiterpenoid compounds and G.L.C. analysis gave the composition shown in Table I.

Aliquots (20 mg) of the total neutral material were injected repeatedly onto the 6 ft × 1/4 in. adipate polyester column (160° C, flow rate 120 ml He/minute) and components 1, 2, 3, 5, and 6 were isolated practically pure. Components 1 and 5 were obtained crystalline (m.p. 94–96° and 66–69° C. respectively) and were found to be occidentalol and occidol.

γ-Eudesmol

Component 2, $[\alpha]_D$ −34.3° (*c*, 2.0, $CHCl_3$) was reinjected (0.5 μl) onto a 6 ft × 1/4 in. polyethylene glycol (Carbowax 20 M at 160° C) column, when two partially resolved peaks were recorded. In runs using more than 1–2 mg aliquots these merged into one single peak.

Component 2 (8.7 mg) was hydrogenated over reduced Adams catalyst with acetic acid as solvent; consumed: 0.70 ml H_2 at N.T.P.; required for 1 mole H_2 per mole: 0.85 ml. The product, after filtration, crystallized on standing; m.p. 78–82° C. G.L.C. analysis of this product gave, besides starting material, a peak corresponding in R.T. to dihydroeudesmol.

Eudesmol

Component 3 was also obtained crystalline; m.p. 81–84° C, $[\alpha]_D$ +33° ($CHCl_3$). Hydrogenation gave dihydroeudesmol, m.p. 81–83° C. G.L.C. analysis gave two partially resolved peaks (area ratio approximately 1:3) with the same R.T. of the mixture of α- and β-eudesmol, m.p. 82.0–83.5° C, isolated from the oil of araucaria (8).

Occidiol

Component 5 was obtained as a viscous liquid, b.p. (at 11 mm) 135–140° C (air bath); n_D^{23} 1.5129; $[\alpha_D]$ −125.5 (*c*, 2.3, $CHCl_3$). It did not form a crystalline nitrobenzoate or phenylurethane. Treatment with tetranitromethane in ethanol gave a strong yellow-brown color immediately. Found (for the freshly isolated material); C, 76.97; H, 9.93%; mol. wt. (by mass spectroscopy) 236. Caculated for $C_{15}H_{24}O_2$: C, 76.88; H, 9.46%; mol. wt. 236.34. Infrared spectrum: 3420(s), 3080(w), 3040(w), 2930(s), 1668(m), 1650(s), 1452(s), 1377(broad, s), 1197(s), 1125 (s), 1100 (s), 918(m), 878(m), 750(m) cm^{-1}. In chloroform solution there was also a strong band at 3620 cm^{-1}, and that at 886 was strong. The n.m.r. spectrum was recorded in $CDCl_3$ solution.

Dihydrooccidiol

Occidiol (7.4 mg) in ethanol (1 ml) was hydrogenated in a microhydrogenation apparatus over palladium-on-charcoal catalyst (2 mg). Hydrogen was absorbed rapidly during 10 minutes and much more slowly thereafter. Hydrogen consumed: 0.74 ml at N.T.P.; required for 1 mole H_2 per mole of diol: 0.71 ml. The solution was filtered and the solvent evaporated to give the sirupy dihydro diol. Infrared spectrum: 3440, 2940–2860, 1465, 1377, 1265(m), 1120, 950(m), 915(m), and 815(m) cm^{-1}.

Guaiazulene

Occidiol (15 mg) was mixed with palladium-on-charcoal catalyst (15 mg) and heated at 250° C for 30 minutes. The blue-black product was taken up in petrol (b.p. 60–66° C) and filtered, and the derived azulene was extracted with phosphoric acid (85%). Dilution with water liberated the azulene; trinitrobenzene adduct m.p. 162° C, picrate m.p. 120° C (lit. 121–122° C (13)). G.L.C. analysis gave a single peak having the same R.T. as guaiazulene.

Ketol

Occidiol (20 mg) in methanol (10 ml) and a few drops of dilute sulphuric acid (10%) were heated on a steam bath for 5 minutes, when a pink color developed. The product was extracted into ether and worked up to give a viscous residue. Infrared spectrum: 3420, 2930, 2700(w), 1710, 1643(w), 1463, 1378–1363, 1110, 1020(m), 910(m), 825(w) cm^{-1}. The same product was obtained when the diol was heated with aqueous oxalic acid.

The ketol (3 mg) was dehydrogenated as above and the colorless product was analyzed by G.L.C.; major peak with the same R.T. as eudalene, several smaller peaks in the eudesmene–eudesmane (selinane) range.

The ketol (10 mg) was heated with twice its weight pyridine-modified alumina (10) at 230° C for 15 minutes. A viscous product was obtained after extraction, filtration, and evaporation of solvent; infrared spectrum: 2960–2920, 1740, 1693, 1633, 1455, 1377, 1110(m), 877(w); λ_{max}^{EtOH} 290 mμ and inflexion near 228 mμ.

ACKNOWLEDGMENTS

We are grateful to Prof. H. Erdtman for his interest and for having obtained the mass spectrum of occidiol. Microanalyses and n.m.r. spectra were carried out by Mr. M.

PORE STRUCTURES AND SURFACE AREAS OF HARDENED PORTLAND CEMENT PASTES BY NITROGEN ADSORPTION

R. Sh. Mikhail,[1] L. E. Copeland, and Stephen Brunauer
Portland Cement Association Research and Development Laboratories, Skokie, Illinois, U.S.A.
Received July 15, 1963

ABSTRACT

The investigations were performed on five hardened pastes of a type I (normal) portland cement, having initial weight ratios of water to cement of 0.35, 0.40, 0.50, 0.57, and 0.70, and hydrated for 12, 12, 12, 2½, and 2½ years, respectively. The percentage hydration ranged from 90 to 98%.

Nitrogen adsorption and desorption isotherms were determined for all pastes at the boiling point of nitrogen, from low pressures to almost the saturation pressure. The BET surface areas were calculated, and the pore space accessible to nitrogen was obtained by a slight extrapolation of the isotherms. In addition, pore structure analysis was made for three of the five pastes by the method of Cranston and Inkley.

The specific surface areas of the five pastes were also determined by water vapor adsorption, and the total porosity to water was measured. For every paste, the water areas and porosities were greater than the nitrogen areas and porosities.

The main conclusions from the results were as follows.

(1) There is a wide range of pore sizes in the pastes.

(2) Nitrogen is excluded from a part of the pore system by two mechanisms; some of the pores are too narrow and others have too narrow entrances to admit nitrogen.

(3) The hydraulic radius (the volume of the pore system divided by the surface area of the pore walls) for the system of small pores increases with increasing water to cement ratio.

(4) The hydraulic radius of the system of large pores also increases with increasing water to cement ratio, but the increase is smaller than for the small pores.

(5) The paste with water to cement ratio of 0.35 has enough pore space for complete hydration.

Some practical implications of the above conclusions are discussed.

INTRODUCTION

When portland cement is mixed with a limited amount of water, e.g., 0.5 of its own weight, and the paste is allowed to stand, it sets in a few hours and then continues hardening for months or even years. The hardened portland cement paste forms the matrix in which the grains of sand and pieces of coarse aggregate are embedded in concrete.

The hardened paste is not a compact solid mass but a porous material with a very large internal surface. The internal surface and the total porosity were first measured by Powers and Brownyard (1), using water vapor adsorption. Both water and nitrogen adsorption were employed later by others (2, 3). Powers and Brownyard demonstrated highly important correlations between such physical properties as specific surface area and porosity of the hardened paste on the one hand, and such vital engineering properties as strength, dimensional changes, permeability to water and freezing and thawing of water in the pore system, on the other. In the subsequent decade and a half, further work by Powers and many others has confirmed the validity and extended the scope of these correlations. During this period, much work has been done on the surface areas of hardened pastes but, as far as the authors know, a detailed study of the pore size distribution has not been made.

Nitrogen adsorption, in almost every instance, leads to a smaller specific surface area than water vapor adsorption. The smaller size and the strong dipole moment of the water molecule enable it to penetrate into pore spaces which are inaccessible to the larger

[1]*Present address: Chemistry Department, Faculty of Science, Ain Shams University, Cairo, Egypt, U.A.R.*

For personal use only.

nonpolar nitrogen molecules. Kalousek was the first to point out the existence of spaces which may exercise such selectivity (4). The main constituent of hardened portland cement paste is a calcium silicate hydrate, called tobermorite gel (5). This gel is responsible for at least 80% of the specific surface area of fully hydrated portland cement, as measured by water adsorption. Tobermorite gel is a layer crystal, and Kalousek assumed that water could penetrate between the layers but nitrogen could not. However, later work has shown that water can not penetrate between the layers of strongly dried tobermorite gel, even when the gel is soaked in water (6). Thus, the difference between water and nitrogen adsorption is not a consequence of the layer structure of tobermorite gel.

The authors have undertaken the investigation of the pore structures of hardened portland cement pastes both by nitrogen and water vapor adsorption. Nitrogen has been used by many investigators for pore structure determinations (7, 8); consequently, the authors started with nitrogen. The results are given in the present paper. Although nitrogen determines only a part of the pore structure, important conclusions can still be drawn from the results. The determination of the complete pore structure by water vapor adsorption is now in progress.

EXPERIMENTAL

The hardened pastes were all prepared from a single type I (normal) portland cement, designated as 15754. The major constituents of this cement, as determined by X-ray diffraction analysis, are tricalcium silicate, 54.1%; β-dicalcium silicate, 26.0%; tricalcium aluminate, 6.5%; and tetracalcium aluminoferrite, 8.6%.

The pastes were prepared with initial weight ratios of water to cement, w_0/c, covering the range 0.35 to 0.70. They were placed in test tubes and covered with water. The test tube was then sealed and kept at 24±1° C until almost complete hydration was reached. The pastes with w_0/c values of 0.35, 0.40, 0.50, 0.57, and 0.70 were hydrated for 12, 12, 12, 2½, and 2½ years, respectively.

After a paste was removed from the test tube mold, the top and bottom half inch were cut off with a small diamond saw and discarded. The remainder was dried for 2 days in a vacuum-drying apparatus (9). It was then transferred to a carbon-dioxide-free controlled atmosphere cabinet and ground there to pass a U.S. standard 20-mesh screen. The part retained on a 50-mesh screen was used in the present work.

The ground specimens, in tared weighing bottles, were placed in the vacuum-drying apparatus and were dried to equilibrium at the vapor pressure of ice at −78° C (5×10^{-4} mm). A specimen was then transferred to the nitrogen adsorption system and outgassed overnight at room temperature, using a mercury diffusion pump backed by a mechanical oil pump. The adsorption data were obtained in a volumetric apparatus of the conventional type. Cylinder nitrogen (99% purity) was purified by passing over hot copper and drying by magnesium perchlorate. A nitrogen vapor pressure manometer was used to obtain the saturation pressure of nitrogen at the temperature of the experiment. Surface areas were calculated with a value of 16.2 Å² for the area of a nitrogen molecule. The porosity of the paste for nitrogen was determined by a very slight extrapolation of the adsorption isotherm.

Surface areas and porosities were also determined with water. The adsorption data were obtained gravimetrically in modified vacuum desiccators (10). A different relative pressure, in the range from 0.07 to 0.33, was maintained in each desiccator by means of a saturated salt solution. The value of 11.4 Å² was used for the molecular area of water (6). The total porosity of the paste to water was measured before the paste was dried. The surface of the saturated paste was wiped off with a slightly moist tissue paper, and the paste was weighed. Ignition and reweighing of the paste gave the total water content, combined and uncombined. Total water minus combined water gave the water in the pore system. The combined water was determined by the method of Copeland and Hayes (9). This involves drying the specimen as for the nitrogen or water vapor adsorption and igniting it. The combined water contents indicated percentage hydrations ranging from 90% for the paste with $w_0/c = 0.35$ to 98% for the paste with $w_0/c = 0.70$.

The densities of the saturated pastes were determined with a specific gravity balance.

RESULTS

1. Figure 1 represents the nitrogen adsorption isotherms near −195.8° C. The adsorbed volume is given in cubic centimeters of nitrogen at S.T.P. per gram of adsorbent; the abscissa is the relative pressure p/p_s, where p is the measured equilibrium pressure, and p_s is the vapor pressure of nitrogen at the temperature of the measurement. The abscissas

For personal use only.

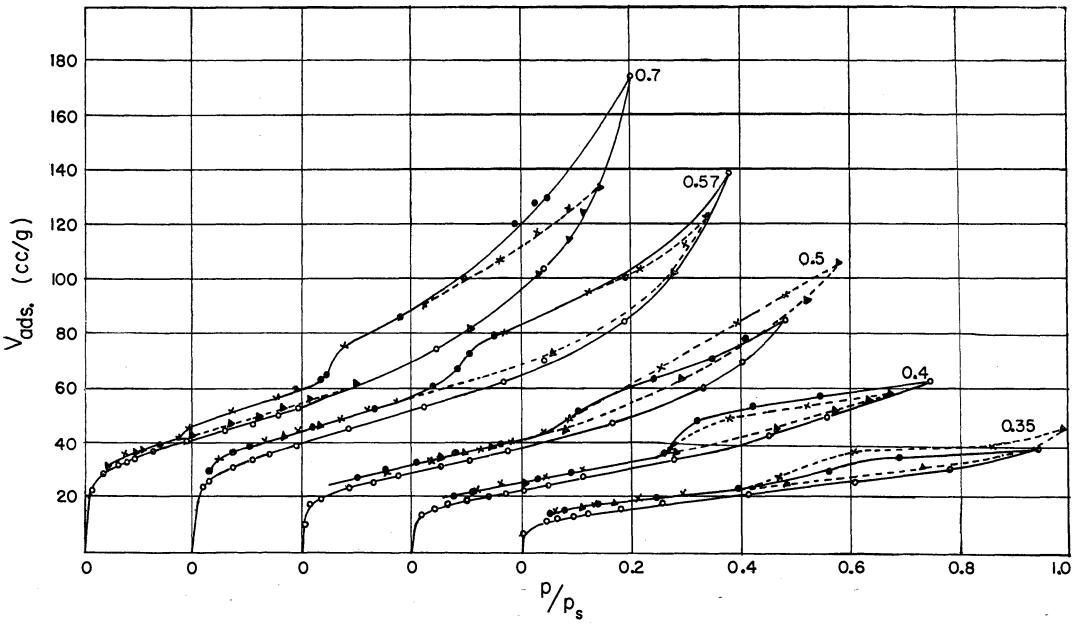

FIG. 1. Isotherms of nitrogen adsorption near the boiling point of nitrogen on hardened portland cement pastes.

are displaced for the different pastes, for clear representation. Two adsorption and two desorption isotherms were determined for each paste. The first adsorption isotherm is represented by empty circles, the first desorption isotherm by filled circles. In every instance, an open hysteresis loop was obtained down to low pressures. Then at some low pressure a second adsorption isotherm was started, represented by triangles in Fig. 1. The second adsorption isotherm, at lower relative pressures always coincided with the first desorption isotherm; which means that it indicated higher adsorption than the first adsorption isotherm. The second desorption isotherm, designated with crosses, formed a closed hysteresis loop with the second adsorption isotherm for four of the five pastes, the loop closing between $p/p_s = 0.41$ and 0.44. For the paste with $w_0/c = 0.7$, however, a double hysteresis loop was obtained. As Fig. 1 shows, the loop tended toward closing at $p/p_s = 0.44$, but it did not close completely until a p/p_s value slightly less than 0.2 was reached.

When the pastes were outgassed to remove nitrogen completely, both cycles of adsorption–desorption could be completely reproduced. It seems, therefore, that the adsorption of nitrogen itself causes a change in the pore structure. An expansion in the pore system is produced, which is not fully reversible; consequently, the hysteresis loop remains open in the first adsorption–desorption cycle. Subsequently, however, the structure remains stable, which is indicated by the closing of the hysteresis loop in the second cycle. At lower relative pressures, the first desorption, the second adsorption, and the second desorption isotherms coincide.

2. The pore structure was determined by the method of Cranston and Inkley (8). The determination involves three assumptions: (1) the pores are cylindrical capillaries with one end closed; (2) the amount of adsorbate in equilibrium with the gas phase is retained by the adsorbent by two mechanisms: (*a*) physical adsorption on the pore walls, and (*b*)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

capillary condensation in the inner capillary volume; and (3) the multilayer thickness in the pores is the same as that on a flat surface. The first assumption will be discussed later. The second assumption may be stated in the form that the capillary radius is equal to the sum of the thickness of the multilayer adsorbed on the pore walls plus the radius calculated from the Kelvin equation.

From adsorption data of nitrogen on a variety of non-porous adsorbents, Cranston and Inkley deduced a so-called *t*-curve, a plot of the thickness of the adsorbed layer (v_{ads} in milliliters divided by the BET specific surface area) against the relative pressure. The pore volumes and surface areas corresponding to different pore diameters are calculated from the difference between the *t*-curve and the actual isotherm obtained for the porous adsorbent. The pore structure analysis can be made for both the adsorption and the desorption isotherm. Cranston and Inkley found that for most adsorbents the analysis of the adsorption isotherm gave more reliable results, as judged by the agreement between the cumulative surface area in the pore volumes and the BET area. The present authors have come to the same conclusion. The pore structures were determined for the 0.35, 0.50, and 0.70 paste. (Henceforth, the designation of 0.35 paste will be used for the paste with $w_0/c = 0.35$.) The adsorption isotherms gave cumulative pore areas in very good agreement with the BET areas, whereas the desorption isotherms did not. This can be seen by comparing column 3 with columns 4 and 5 in Table I. The BET area obtained

TABLE I

by nitrogen adsorption is S_{N_2}, the cumulative areas in the pores, obtained from the adsorption and desorption isotherms are S_{cum}^{ads} and S_{cum}^{des}, respectively. In the analysis, the second adsorption isotherm was used. As was discussed earlier, a stable pore structure was obtained only in the second adsorption–desorption cycle.

Because of the poor agreement between S_{N_2} and S_{cum}^{des}, and because of other inconsistencies in the pore volume data based on the desorption isotherms, only the data obtained from the adsorption isotherms have been used. The Cranston–Inkley analysis starts with pores of 300 Å diameter and does not take larger pores in consideration. There is only a small surface in these larger pores, but there is a considerable volume, as will be seen. The surface in the larger pores is given in column 7 of Table I. These values may have a sizable error, because they represent small differences between two large numbers.

Table I, column 2, gives the BET surface areas obtained by water vapor adsorption. These values represent the total surface in the pores of the pastes (5). The values in column 3 represent the surface accessible to nitrogen molecules, and the values in column 6 represent the surface inaccessible to nitrogen molecules.

3. The pore structure analysis was kindly carried out by Dr. G. R. Lester of the Universal Oil Products Company, Research and Development Laboratories, Des Plaines, Illinois. The method he used was essentially that of Cranston and Inkley, with the

For personal use only.

inclusion of a computer interpolation procedure. This interpolation is from point to point, rather than over the entire isotherm, so that if any deviation is introduced by the interpolation, it will be at a minimum in the neighborhood of each experimental point.

The results for the pore volume distributions are shown in Fig. 2. The curves are plots of $V(D)$, the pore volume in milliliters per gram of paste per Å, against D, the pore diameter in Å. There is a high point in the 0.7 paste curve at the smallest pores, which is not found for the two other pastes. It may be real, but more probably it is caused by a small error in a single isotherm point. Aside from this anomalous maximum, the maximum for the 0.7 paste is at 32.5 Å, and the same is true for the 0.5 paste. The maximum, i.e., the largest pore volume per Å for the paste, is at 22.5 Å for the 0.35 paste.

The cumulative pore volumes for the three pastes are given in Table II, column 4.

The total pore space accessible to nitrogen is given in column 3, and it is greater than v_{cum}^{ads} for each paste. This is because the Cranston–Inkley analysis does not take into account pores larger than 300 Å in diameter. The volume of nitrogen in pores larger than 300 Å is given in column 6 of Table II.

Table II, column 2, gives the porosity to water, which is the total porosity of the paste. Column 3 gives the pore space accessible to nitrogen, and column 5 that inaccessible to nitrogen. The table also contains, in column 7, the densities of the saturated pastes.

In the calculations of pore volumes, two approximations have been made: (1) the densities of nitrogen and water were assumed to be the same as those of the liquids; and (2) the effect of shrinkage of the pastes caused by drying was neglected. Even if some error is introduced by these approximations, it cannot affect any of the conclusions reached in this paper.

DISCUSSION

1. The shapes of the hysteresis loops in Fig. 1 come closest to those classified as type D loops by de Boer (11). He points out that such loops can be produced, for example, by a heterogeneous assembly of plate-like capillaries with a varying range of widths. Electron microscopic examination of hardened portland cement pastes (12) shows that tobermorite gel, which is largely responsible for the pore structure of the paste, consists of very thin sheets. Such sheets may well produce plate-like or slit-shaped pores. Type D hysteresis loops can also be produced by a heterogeneous assembly of capillaries with wide bodies having a varying range of narrow short necks (11). This may also fit the pastes investigated. It will be shown that many of the larger pores have narrow openings, but the present investigations did not reveal anything about the variation in lengths and widths of these openings.

De Boer has pointed out that for type D hysteresis loops, scanning is possible from any

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

point of the sloping desorption branch. This has been found to apply in the present investigations.

The question may be raised regarding the validity of a pore volume analysis based on the assumption of cylindrical pores to a system in which the pores are likely to be slit-shaped. Certainly caution must be applied in drawing quantitative conclusions, but the qualitative conclusions, as will be seen, are most helpful in supporting and extending quantitative conclusions drawn from other data. The cylindrical pore approximation has found useful application in many instances for solids widely differing in nature, even though there is probably no solid which contains only cylindrical pores.

2. When portland cement sets, the paste acquires a stable volume, which is approximately equal to the volume of the cement solids plus the volume of the water initially mixed with the cement, w_0. Thus, the total porosity of the paste is determined by the w_0/c ratio. The hydration products of portland cement have a larger specific volume than unhydrated portland cement; consequently, the total porosity decreases as the hydration progresses.

Powers (1, 13) divided the pore system into two types of pores. He reasoned that the hydration of a definite weight of a given cement was accompanied by the formation of a definite pore volume, and he called this the gel pore volume. He called the rest of the pores capillary pores. He visualized two overlapping pore systems, each having a wide pore size distribution, but he concluded that the average diameter of the capillary pore system was much greater than that of the gel pore system.

The measurements reported here can distinguish between smaller and larger pores but they can not distinguish between gel pores and capillary pores of equal sizes. There is a considerable advantage in distinguishing between a system of small pores and a system of large pores, regardless of their origin. Nuclei of hydration products can not grow into crystals in small pores. Water can not freeze in small pores for the same reason. Capillary condensation can not occur in small pores. For these reasons, as well as for others, the pore system will be divided into two parts: a system of small pores, designated as S pore system, and a system of large pores, designated as L pore system. These two systems are not identical with the gel pores and capillary pores of Powers, but they are similar to them. Most of the gel pores of Powers are S pores, and most of the capillary pores are L pores.

3. There is no sharp dividing line between the S and L pore systems. In Fig. 2, the pore volume distribution curves are continuous, and no bimodal distribution is indicated. The high point in the curve for the 0.7 paste at very small pore diameters is probably caused by an error in a single isotherm point. However, even if the dip is real, it signifies only a break in the distribution within the S pore system and not the division between the S and L pore systems. A small dip in the same curve, in the vicinity of 175 Å, is within the L pore region.

On the basis of the curves for the 0.7 and 0.5 pastes, an arbitrary but useful division between the pore systems could be made in the region of the sharp drop, somewhere between 60 and 80 Å. The division for the 0.35 paste, however, is around 40 Å. Thus the average diameter of the S pores in this paste is smaller than in the two other pastes. Further evidence for this will be presented later.

The curves of Fig. 2 represent only the pores accessible to nitrogen and not the total pore system but, as a comparison of columns 2 and 4 in Table II shows, about 40% of the total pore system for the 0.35 paste and about 50% for the two other pastes is represented by the curves of Fig. 2. Small and large pores are included for all three pastes.

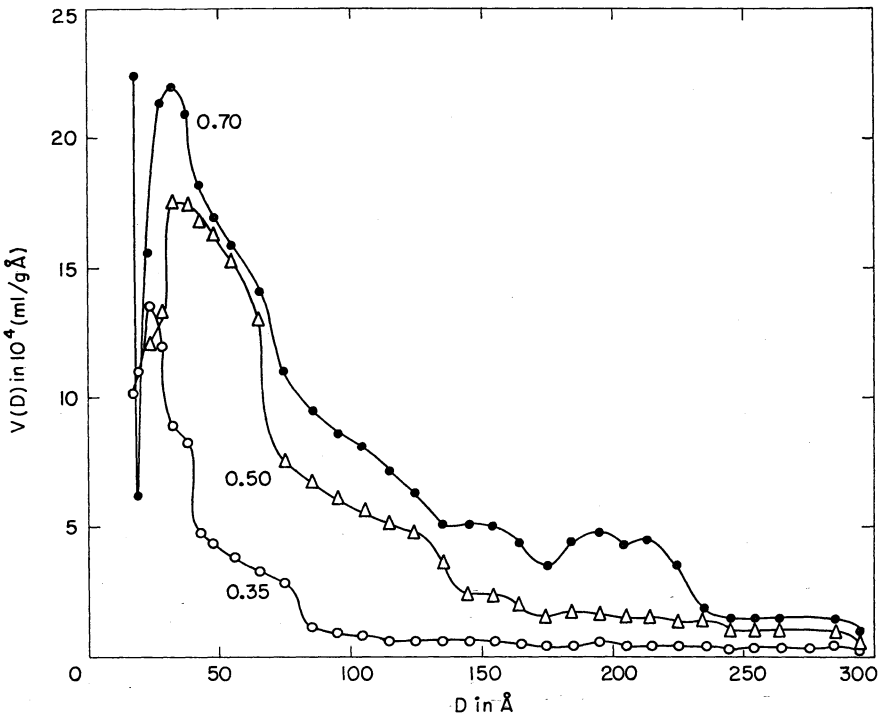

FIG. 2. Pore size distribution curves of hardened portland cement pastes.

Nevertheless, the question remains whether the "sample" is representative of the whole. This will be discussed later.

4. For pores of irregular or unknown shapes, an average radius called hydraulic radius can be calculated by dividing the volume of the pore system by its surface area. For a cylinder open at both ends, the hydraulic radius is one-fourth of the diameter, and for an open slit it is one-half of the width. The hydraulic radii for the five pastes are given in Table III. The values in columns 2, 3, 4, 5, and 6, designated as r_1, r_2, r_3, r_4, and r_5,

TABLE III

Hydraulic radii of pores (in Å)

are V_{H_2O}/S_{H_2O}, $(V_{H_2O}-V_{N_2})/(S_{H_2O}-S_{N_2})$, V_{N_2}/S_{N_2}, $V_{cum}^{ads}/S_{cum}^{ads}$, and $(V_{N_2}-V_{cum}^{ads})/(S_{N_2}-S_{cum}^{ads})$, respectively.

(*a*) First it should be noted that r_4 is the same for the 0.5 and the 0.7 paste. Two materials having the same hydraulic radii may have widely differing pore size distribution,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

but when the two materials are as similar as two pastes of the same portland cement, identity of hydraulic radii should imply at least a rough similarity of pore size distribution. This is actually so, as the two curves of Fig. 2 show. The maxima are at the same point; the sharp drops appear in the same region. The 0.35 paste curve, however, though in many respects similar to the two other curves, exhibits a shift toward smaller pore sizes. The value of r_4 for this paste is smaller than for the two others.

(*b*) For the 0.35 paste, the values of r_1, r_2, and r_3 are 6.1, 3.4, and 13.2 Å. This means that this paste possesses a large number of small pores inaccessible to nitrogen. If the pores are visualized as slits, the average width of the slits inaccessible to nitrogen is 2 r_2 or 6.8 Å; if the pores are visualized as cylinders, the average diameter is 4 r_2, or 13.6 Å. In either case, some of the pores are too narrow, and the others have too narrow entrances to permit access of nitrogen. It is important to note only that the hydraulic radius of the pore system accessible to nitrogen is about four times as large as that of the pore system inaccessible to nitrogen.

The situation is very different for the 0.7 paste. The values of r_1, r_2, and r_3 are 20.1, 20.8, and 19.8 Å, respectively. The hydraulic radius of the pores inaccessible to nitrogen is somewhat larger than that of the pores accessible to nitrogen, though this may be within experimental error. The exclusion of nitrogen from about half of the pore system must be a consequence of narrow entry ways to the pores. If there were a sizable fraction of pores into which nitrogen can not enter because of the small sizes of the pores, r_2 would be considerably smaller than r_3.

The conclusion from the last two paragraphs is that the small pores or *S* pores in the 0.7 paste have larger average diameters or widths than the small pores in the 0.35 paste. A comparison of columns 3 and 4 in Table III shows that the three other pastes are intermediate between these two. It was stated earlier that according to Powers (13) the gel pore system has a characteristic porosity. The present results show that the *S* pore system has no characteristic porosity valid for all w_0/c ratios of the same cement; on the contrary, the average widths or diameters of the *S* pores increase with increasing w_0/c ratio. However, the *S* pores can not be fully identified with the gel pores; consequently, the results do not disprove Powers' views.

Table III, column 3, shows that the hydraulic radius of the pore system inaccessible to nitrogen increases sixfold from the 0.35 paste to the 0.7 paste, and column 4 shows that the increase in the hydraulic radius of the pore system accessible to nitrogen is only about 50%. Especially slight is the increase in the hydraulic radius of the latter pore system from the 0.5 to the 0.7 paste; it is less than 8%. It follows, therefore, that the increase in the sizes of the *L* pores with increasing w_0/c ratio is considerably smaller than that of the *S* pores for these pastes.

The arguments advanced in this section (4*b*) are based solely on hydraulic radii. They assume nothing about the shapes of the pores, nor do they refer to the distribution curves of Fig. 2.

(*c*) It follows from the equality of r_1, r_2, and r_3 for the 0.7 paste that the distribution curve in Fig. 2 for this paste is probably representative for the entire pore system. This means that the distribution curve for water would not be very different from that of nitrogen, except that the ordinates would be roughly twice as large. The curves become less representative as one progresses to lower w_0/c ratios. The water distribution curves should show increasingly larger fractions of the total porosity at the small pore diameters.

5. A comparison of columns 3 and 6 in Table II shows that about one-fourth to one-third of the pore system accessible to nitrogen consists of pores larger in diameter than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the pores covered by the Cranston–Inkley analysis. The hydraulic radii of these largest pores, given in column 6, Table III, are questionable because of the uncertainty in $S_{N_2}-S_{cum}^{ads}$ (Table I, column 7) that was pointed out earlier. Nevertheless, they give a rough indication of the average diameters or widths of the pores.

The pores in Table II, column 6, for the 0.35 paste constitute 19.5% of the total porosity. In addition to these pores, a part of the pores shown in Fig. 2 belongs to the L pore system. One can estimate that the L pore system makes up at least one-fourth of the total porosity. This result has important implications.

According to Powers, for cement 15754 the weight of water in the gel pore system is 3.0 V_m, where V_m is the weight of water necessary to cover the surface with a monolayer of adsorbed water. It follows from this that for pastes with w_0/c ratios less than 0.38 there is not enough pore volume to accommodate the characteristic gel porosity at complete hydration; consequently, such pastes do not hydrate completely. Calculation gives 93% as the maximum hydration of the 0.35 paste.

It is possible that the pores of the S pore system are too narrow to permit growth of the nuclei of the hydration products, but this is not true of the L pores. The results cited above show that there is enough room in the L pore system of the 0.35 paste for complete hydration. This, in itself, would have little practical significance, because the hydration is so slow that it may take decades to reach even 93% hydration. It would have, however, great significance, if a way were found to accelerate the hydration process. The strength and dimensional stability of pastes possessing low porosities increase greatly with decreasing porosity. Thus, if the hydration could be accelerated, a marked improvement in concrete could be achieved. The authors consider this a distinct possibility.

Although there is enough room in the 0.35 paste for complete hydration, this may not be true of pastes with lower w_0/c ratios. Powers is doubtless correct in his view that the hydration of portland cement is accompanied by the formation of a gel pore system. The gel water content can not be as high as 3.0 V_m in all pastes of cement 15754. The 0.35 paste, if all the pores are assumed to be gel pores, has a gel water content of 2.46 V_m, and Powers cited a paste with a gel water content of 2.38 V_m (13). That paste had a w_0/c value of 0.235. If there is a minimum gel porosity, which is very likely, it necessarily leads to Powers' concept of a limiting w_0/c ratio, below which complete hydration can not occur.

6. There is another way of demonstrating the increase in the sizes of the S pores with increasing w_0/c ratio.

For adsorption on a plane surface, an average thickness can be defined for the adsorbed film, which is the volume of the adsorbed film divided by the surface area of the adsorbent. For nitrogen, the equation is

$$t = 15.47\ (v_{ads}/S_t) \qquad [1]$$

where the volume adsorbed is expressed in cc at S.T.P., S_t is in m^2 per g, and t in Å. A plot of v_{ads} against t is a straight line, the slope of which is 15.47 $/S_t$. The plot should be a straight line even for porous bodies at low relative pressures. It should remain a straight line until one of two things happens.* (*a*) Some of the narrowest pores become filled by multilayer adsorption. In this case, a part of the surface becomes unavailable for further adsorption, and the points of the plot should begin to drop below the straight line. (*b*) Capillary condensation starts in certain pores in addition to multilayer adsorption. In this case, the points of the plot should begin to deviate upward.

**We are greatly indebted to Professor J. H. de Boer for discussion of this point with one of the authors (R. Sh. M.).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Figure 3 shows such v_{ads} vs. t plots for four of the five pastes. As stated earlier, Cranston and Inkley (8) plotted the thickness of the adsorbed film, t (the volume of the adsorbed film divided by the BET surface), against the relative pressure for the adsorption of nitrogen on a great variety of non-porous adsorbents. On the basis of these data, they drew an average "t-curve", which represents the adsorption of nitrogen on a plane surface. The points in Fig. 3 were obtained in the following manner. The values of v_{ads} were taken from the adsorption branches of the isotherms of Fig. 1, and the values of t were taken from the t-curve of Cranston and Inkley, by reading the value of t corresponding to the relative pressure of the particular isotherm point.

First it should be noted that at small values of relative pressure (or of t) the curves are straight lines. From the slopes of the straight lines, S_t was calculated for the pastes, and good agreement was obtained with the BET surface areas. This means that the t-curve of Cranston and Inkley gives a good representation of the average thickness of the nitrogen film adsorbed at low relative pressures on the pastes investigated.

The curve for the 0.35 paste deviates from the straight line already at a thickness of 4 Å. The downward deviation shows that an appreciable fraction of the pores, having hydraulic radii of 4 Å, are already filled with adsorbate. (If the pores are slits, the width of the slit is 8 Å). If the S pores in the four pastes would have the same size distribution, all four curves of Fig. 3 would show a downward deviation at the same point. Instead, the 0.4 paste shows a downward deviation at a considerably larger value of t, and the two other curves show upward deviations. The conclusion is that the S pores increase in width with increasing w_0/c ratio.

The 0.5 and 0.7 paste curves clearly indicate capillary condensation at p/p_s values between 0.4 and 0.5. This is an interesting way to detect the beginning of capillary condensation from an *adsorption* curve. Ordinarily, the closing of the hysteresis loop of the desorption isotherm is employed for the indication of the beginning of capillary condensation. As Fig. 1 shows, the hysteresis loops confirm the conclusions drawn from Fig. 3.

The fact that the downward deviation for the 0.4 paste comes only at a t value of about 9 Å indicates that the two effects discussed occurred already at smaller values of t, but they balanced each other. As the closing of the hysteresis loop shows, capillary condensation in this paste must also have occurred at a t value in the vicinity of 6 or 7 Å, but this was balanced by filling of pores by multilayer adsorption.

7. Figure 4 represents the variation of surface area with w_0/c. Curves I and II give the surface areas per gram of paste obtained by nitrogen and water vapor adsorption, respectively. The water areas are almost constant, as they should be for almost completely hydrated pastes, but the nitrogen areas increase with increasing w_0/c. The difference is more striking if the surface areas are plotted per cubic centimeter of paste. The water areas decrease, as curve IV shows, because there is less solid and more pore space per cubic centimeter of paste with increasing w_0/c. In spite of the fact that there is less adsorbing solid, the nitrogen areas increase with increasing w_0/c.

The explanation is that the major part of the surface area resides in the small pores of each paste. The nitrogen and water points for the 0.35 paste on curves III and IV are far apart because there are many pores in this paste that are too narrow to admit nitrogen. The widths of the small pores increase with increasing w_0/c; consequently, curves III and IV approach each other.

8. The main conclusions of the present investigations will now be summarized. They are partly definite and partly tentative conclusions. The tentative conclusions await

confirmation or refutation by the work now in progress on the determination of the complete pore structure by water vapor adsorption and by other work in the future.

Definite Conclusions

(1) There is a wide range of pore sizes in almost fully hydrated portland cement pastes. There are pores in the 0.35 paste that have hydraulic radii of less than 3.4 Å, and there are pores in the 0.7 paste with hydraulic radii of greater than 200 Å.

(2) Nitrogen molecules are excluded from a part of the pore system by two mechanisms: some of the pores are too narrow and others have too narrow entrances to admit nitrogen.

(3) The system of small pores (the S pore system) increases in hydraulic radius with increasing w_0/c ratio.

(4) The system of large pores (the L pore system) also increases in hydraulic radius with increasing w_0/c ratio. The increase is smaller than the increase in the radii of the small pores for pastes in the w_0/c range 0.5 to 0.7.

(5) The L porosity of the 0.35 paste is greater than 25% of the total porosity. The hydration will not stop at 93% because of lack of room; there is enough room in the paste for complete hydration.

(6) If the gel porosity does reach a minimum short of zero, which is very probable, the minimum gel water content is less than 2.46 V_m.

Tentative Conclusions

(1) There is no bimodal distribution in the pore system, which would separate small pores and large pores. An arbitrary but useful separation may possibly be made at a hydraulic radius of about 15–20 Å for the 0.5 and 0.7 pastes and at 10 Å for the 0.35 paste.

(2) In the 0.7 paste, the small pores which exclude nitrogen because of their widths constitute a negligible fraction of the total porosity. Nitrogen is excluded because of narrow entrances to a part of the pore system.

(3) In pastes of lower w_0/c ratios than 0.35, hydration may stop and in pastes of very low w_0/c ratios, hydration will stop because of lack of room. However, it can not be predicted at what point hydration will stop because it is not known at present what is the minimum gel porosity that a paste can possess.

THE CHROMIC ACID OXIDATION OF ARYL TRIFLUOROMETHYL ALCOHOLS: ISOTOPE AND SUBSTITUENT EFFECTS[1]

ROSS STEWART AND DONALD G. LEE[2]
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received September 3, 1963

ABSTRACT

The mechanism of the chromic acid oxidation of eight aryltrifluoromethylcarbinols has been studied in acetic acid solution. Electron-donating substituents accelerate the reaction and a good correlation of rate with σ^+ values has been found. The rho value is -1.01. Deuterium isotope effects for the oxidation of five of these compounds have been determined and the magnitude of the isotope effect has been found to correlate inversely with the ease of oxidation of the alcohol.

The results are interpreted in terms of a unimolecular decomposition of the chromate ester of the alcohol.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Previous work in this laboratory showed that unusually large kinetic isotope effects were observed when a group of aryl trifluoromethyl alcohols ($ArCDOHCF_3$) were oxidized to ketones by alkaline permanganate (1, 2). The values of k_H/k_D of 16:1 found at 25° are more than double those expected for complete loss of the C—H (D) stretching mode in the transition state (3, 4). Since proton tunnelling did not seem to be the dominant factor in these and related reactions the anomalous isotope effects have been tentatively attributed to alterations in the C—H bending modes in the transition state. It was of interest, then, to determine if the unusual isotope effects observed in the permanganate oxidation also occur in the oxidation of these alcohols by chromic acid. A "normal" isotope effect of 6.6 at 25° was found for the chromic acid oxidation of isopropyl-*d* alcohol, $(CH_3)_2CDOH$ (5).

A great deal of work has been done in elucidating the mechanism of chromic acid oxidation of alcohols, particularly by Westheimer (5–10), Roček (11, 12), and Kwart (13–15) and their colleagues.

The work of Westheimer and his group on the oxidation of isopropyl alcohol can be summarized as follows: (*a*) the reaction is acid catalyzed with the rate being proportional to the first (or in some cases a higher) power of the hydrogen ion concentration (or h_0), (*b*) the reaction is much faster in acetic acid solution than in mineral acids of the same H_0 value, (*c*) the transition state is a monochromium, not a dichromium, species, (*d*) the C—H bond at the carbinol carbon is broken in the rate-controlling step. Chromate esters of alcohols are known to exist under the reaction conditions and the following mechanism, in which such an ester decomposes by proton loss to any available base (probably a water molecule), was put forward.

$$R_2CHOH + HCrO_4^- + 2H^+ \rightleftharpoons R_2CHOCrO_3H_2^+ + H_2O$$

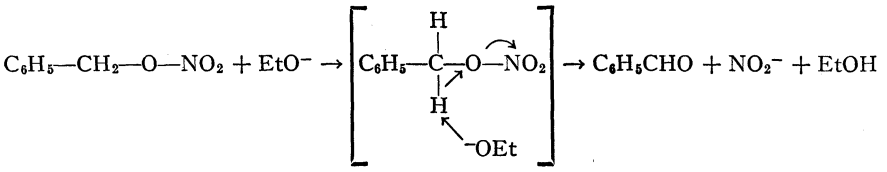
Some elegant work on the induced oxidation of added substrates has traced the fate of the chromium (IV) intermediate formed in such reactions and which is eventually converted to chromium (III) (16, 17).

It has not proved possible to detect the participation of base in the rate-controlling step of the oxidation and this has led to other mechanisms being suggested. Furthermore, the Hammett reaction constant, rho, for the chromic acid oxidation of arylmethylcarbinols has a value of -1.01 (13) and this is not very easily reconciled with a rate-controlling proton abstraction from the α-carbon of the ester, even when the pre-equilibrium step is considered.

The effect of substituents on such a reaction has been elegantly illustrated by Buncel and Bourns (18) in their work on the decomposition of benzyl nitrate by ethoxide ions.



This reaction shows a deuterium isotope effect of 5.04 at 60° and a ^{15}N isotope effect of 1.0196 at 30° indicating that the carbon–hydrogen and the nitrogen–oxygen bonds are broken simultaneously in the course of the reaction. In this case it is evident that the hydrogen is being abstracted as a proton and the large positive rho value of $+3.40$ shows that the effect of substituents on the cleavage of the α-carbon–hydrogen bond is greater than on the more remote oxygen–nitrogen bond.

In subsequent papers in this series evidence will be presented in support of the idea that the chromate ester is a reactive intermediate which decomposes unimolecularly to products.

$$R_2CHOCrO_3H_2^+ \rightarrow R_2C{=}O + H_3CrO_3^+$$

The results presented herein are in accord with such a mechanism although they do not uniquely require it.

A unimolecular decomposition of the ester by an internal proton transfer has been previously suggested by Kwart and Francis (14) and the possibility of an internal hydride transfer has been noted by Littler (19). The relative merits of the cyclic and acyclic mechanisms have been discussed by Roček, Westheimer, Eschenmoser, Moldovanyi, and Schreiber (20) and by Stewart (21).

RESULTS AND DISCUSSION

The rates of oxidation of eight aryltrifluoromethylcarbinols have been determined at 25° in a 77.2% acetic acid solution containing 3.20 *M* perchloric acid. The deuterium isotope effects for five of these alcohols were also determined. The results are presented in Table I. A Hammett plot for both the protio and deuterio compounds is shown in Fig. 1. The σ^+ values were used since they gave a somewhat better correlation with the measured rate constants.

Attempts were made to determine the rates of oxidation of *p*-methoxyphenyltrifluoromethylcarbinol and β-naphthyltrifluoromethylcarbinol. Since the difference between σ and σ^+ values for the *p*-methoxy and the α-naphthyl group are greater than for any of the other groups they are most useful in differentiating between reactions which follow σ^+

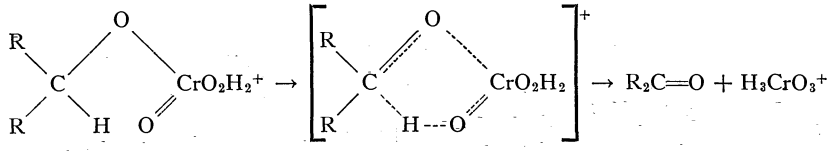
values and those which follow σ values. Unfortunately both of these alcohols reduced chromium (VI) at a very fast rate in the medium used. This can be attributed to the oxidation of these compounds at sites other than the hydroxylated carbon since it was later found that both anisole and naphthalene were very rapidly oxidized under these conditions.

A rho value of -1.01 was calculated from the slope of the plot in Fig. 1. While other interpretations (6, 13) have been suggested for the negative rho values observed in the oxidation of alcohols by chromic acid the most direct explanation for any reaction exhibiting a negative ρ^+ value is that considerable positive charge is located on the α-carbon atom in the transition state. Further, the observation of very pronounced isotope effects demands that any proposed mechanism include as a rate-determining step, fission of the α-carbon–hydrogen bond.

The oxygen–hydrogen bond of the alcohol is probably not intact in the transition state (ethers are relatively inert to chromium (VI) (6)) nor being broken in the transition state (because of the positive solvent isotope effect observed in this reaction (6)). Westheimer's conclusion, then, that the chromate ester is a reactive intermediate in the oxidation, seems reasonable. The recent study by Roček, Westheimer, Eschenmoser, Moldovanyi, and Schreiber (20) of the chromic oxidation of a hindered alcohol lends further support to the ester being an intermediate in the oxidation. They found that the substrate isotope effect for the hindered alcohol vanished in concentrated acid, i.e. ester formation became rate controlling.

A unimolecular decomposition of the ester can be written in which the hydrogen is bonded in the transition state to both the alcoholic carbon atom and the oxygen atom attached to chromium.



Kwart and Francis have written a similar transition state with the hydrogen being transferred as a proton (14). The question of electron flow in a cyclic transition state such as the above is a vexing one (22, 23) and we prefer to consider the conversion of ester to transition state in the following terms.

The transfer of electrons toward the chromium occurs by formation of carbon–hydrogen–oxygen bonds in the transition state as well as carbon–oxygen–chromium bonds, i.e. partly occupied orbitals are used to bind the transferred hydrogen to both carbon and oxygen in the transition state. The developing carbonyl group in the electron-deficient transition state will be stabilized by electron-donating substituents and this presumably accounts for the negative rho value. (See however Ref. 15.) Protonation of the chromate portion of the ester also increases the reaction rate. The conversion of ester to transition state is thus aided by the combined polarizing effects of an electron-donating aromatic ring and an electron-withdrawing metal cation.

An approximately linear relationship exists between the rates of oxidation of trifluoromethylcarbinols and the observed isotope effects. This relationship, which is illustrated in Fig. 2, fits in well with the suggestion, first made by Wiberg (3), that there should be a general correlation between rates and isotope effects within a group of analogous reactions, slow rates being accompanied by large isotope effects. Wiberg based his predictions on the

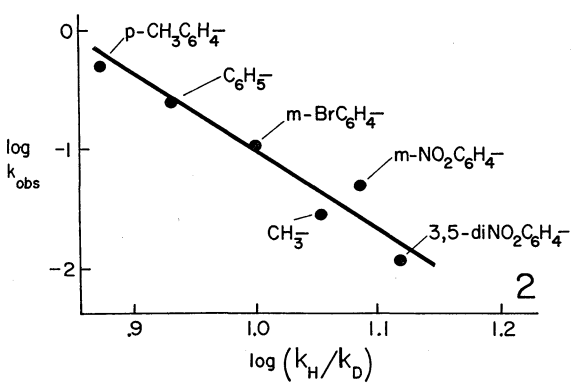

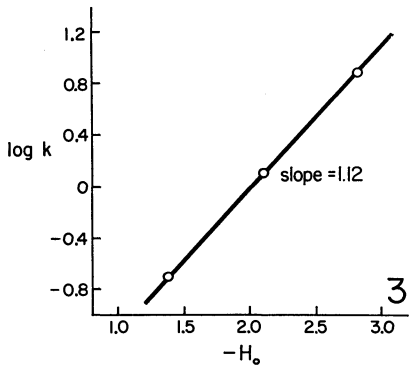

FIG. 2. The variation of isotope effect with rate constant for the chromic acid oxidation of $ArCHOHCF_3$.
FIG. 3. Variation of rate with acidity for the oxidation of phenyltrifluoromethylcarbinol in 77.2% acetic acid.

experimental observation that the isotope effects in the side-chain halogenation of para-substituted toluenes varied from 3.22 to 5.11 at 77°. Since the largest of these isotope effects is somewhat smaller than the maximum effect predicted from a consideration of zero-point energies of the carbon–hydrogen and carbon–deuterium bonds, the variation with rate was explained in terms of factors which could be related to C—H stretching frequencies (3, 24, 25).

In the present case, however, even the smallest isotope effect observed is larger than the maximal effect predicted from a consideration of carbon–hydrogen stretching frequencies. While it is not clear from the present results whether the large isotope effects are due to loss of bending frequencies in the transition state or to a tunnel effect it is interesting to note that a correlation between rate and isotope effect still exists. Such a correlation was not observed by Stewart and Van der Linden (1, 2) in the permanganate oxidation of these alcohols since the rho value for that reaction was almost zero. It does appear, however, that large isotope effects are intimately connected with the trifluoromethyl group or at least with the presence of strongly electron-withdrawing groups adjacent to the site of oxidation. (It should be pointed out here that in the chromic acid oxidation of fluorinated *aliphatic* alcohols a similar situation exists, i.e. the slower the oxidation rate (the more highly fluorinated the alcohol) the higher the isotope effect, with an important exception. 1,1,1,3,3,3-Hexafluoro-2-propanol is oxidized very slowly but its 2-deuterio derivative does not appear to show an anomalously large isotope effect (26).)

The rate of oxidation of phenyltrifluoromethylcarbinol was determined at three different acidities and was found to be linear with h_0 as indicated by the plot in Fig. 3. The acidity data reported in Table II were obtained by a comparative method using *p*-nitrodiphenylamine and 4-chloro-2-nitroaniline as indicators. (The pK_a's of these indicators were assumed to be −2.48 and −1.03 respectively (27).) This observed linearity with h_0, although based on three points only, is in accord with the rate law observed for the oxidation of isopropyl alcohol (9) and benzaldehyde (28) in acetic acid.

$$v = k[R_2CHOH][HCrO_4^-]h_0$$

The rho value observed for the oxidation of the aryltrifluoromethylcarbinols is also identical with the value observed for the corresponding oxidation of arylmethylcarbinols in acetic acid (13) and it is probable that they are oxidized via the same reaction path.

EXPERIMENTAL

Reagents

Many of the fluoro alcohols had previously been synthesized in this laboratory (2, 29). During the present investigation several of these compounds were resynthesized and good agreement with all the reported physical constants was found except in the case of *m*-nitrophenyltrifluoromethylcarbinol where the melting point was found to be 51–52° instead of the reported 47–48°. The preparation of other alcohols which were synthesized specially for this investigation are given below.

m-Tolyltrifluoromethylcarbinol

m-Bromotoluene (Eastman Organic Chemicals) (49 g, 0.286 mole) and magnesium (7 g, 0.286 mole) were converted to the Grignard reagent under anhydrous conditions. Then trifluoroacetic acid (10.5 g, 0.092 mole) in 25 ml of ether was added dropwise over a period of 2 hours. After refluxing for 1 hour the complex was decomposed in 10% sulphuric acid. The product (*m*-tolyltrifluoromethyl ketone) was extracted from the aqueous solution with ether, dried over anhydrous magnesium sulphate, and distilled. B.p. 58° at 8 mm. Yield: 8.5 g, 49%. ν_{max} (liq) 1717 cm^{-1} (C=O).

This ketone (6.0 g, 0.032 mole) was dissolved in 20 ml of dry ether and lithium aluminum hydride (0.38 g, 0.01 mole) in 20 ml of dry ether was added slowly under anhydrous conditions. After refluxing for 1 hour the complex was decomposed with dilute sulphuric acid and the product was extracted with ether, washed with water, and dried over anhydrous magnesium sulphate. Distillation yielded 3.5 g (57%) of *m*-tolyltrifluoromethylcarbinol. B.p. 95° at 14 mm. (Found: C, 57.0%; H, 3.6%. $C_9H_7OF_3$ requires: C, 57.4%; H, 3.7%.)

p-tert-Butylphenyltrifluoromethylcarbinol

Starting from *p-tert*-butylbromobenzene *p-tert*-butylphenyltrifluoromethylcarbinol (m.p. 75.0–75.5°) was prepared by the same procedure used to synthesize *m*-tolyltrifluoromethylcarbinol. (Found: C, 61.6%; H, 6.13%. $C_{12}H_{15}OF_3$ requires: C, 62.0%; H, 6.52%.)

β-Naphthyltrifluoromethylcarbinol

Magnesium (2.4 g, 0.1 mole) was placed in a flame-dried three-necked flask fitted with two dropping funnels, a reflux condenser, and a magnetic stirrer. Methyl iodide (0.5 g) dissolved in 10 ml of dry ether was added through the first funnel and after the reaction had started β-bromonaphthalene (13 g, 0.063 mole) dissolved in 50 ml of dry ether was added slowly. The mixture was refluxed for ½ hour after which 100 ml of dry ether was added. This was followed by the dropwise addition of trifluoroacetic acid (1.82, g 0.016 mole) dissolved in 20 ml of dry ether. After the addition was complete the solution was refluxed for 2 hours and then decomposed with cold dilute sulphuric acid, extracted with ether, and dried. The product (β-naphthyltrifluoromethyl ketone) was distilled under reduced pressure (b.p. 88° at 1.1 mm) and crystallized from low boiling petroleum ether. ν_{max} ($CHCl_3$) 1706 cm^{-1} (C=O). Yield: 5.0 g, 0.013 mole, 80%.

This ketone (2.5 g, 0.011 mole) was reduced with lithium aluminum hydride (0.25 g, 0.0066 mole), yielding, after recrystallization from petroleum ether, a fine white crystalline compound. M.p. 83–84°. A mixed melting point with naphthalene gave a depression of 20°. (Found: C, 63.4%; H, 3.64%. Required for $C_{12}H_9OF_3$: C, 63.76%; H, 4.01%.)

p-Chlorophenyltrifluoromethylcarbinol

Starting from 1-bromo-4-chlorobenzene *p*-chlorophenyltrifluoromethylcarbinol (b.p. 117–119° C at 22 mm) was prepared by the same procedure used to synthesize *m*-tolyltrifluoromethylcarbinol. (Found: C, 44.9%; H, 2.63%. Required for $C_8H_6OF_3Cl$: C, 45.6%; H, 2.87%.)

m-Nitrophenyltrifluoromethylcarbinol-α-d

m-Nitrophenyltrifluoromethyl ketone (29) was reduced with lithium diethoxyaluminodeuteride using the procedure developed by Brown and Tsukamoto (30). This produced a brown oil which distilled at 122° at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

0.4 mm. This product was recrystallized several times from benzene and petroleum ether to give pale yellow crystals. M.p. 51.5–52.5°. (Found: C, 43.1%; H, 2.00%; N, 6.28%. Required for $C_8H_5DNO_3F_3$: C, 43.2%; H, 2.72%; N, 6.32%.)

3,5-Dinitrophenyltrifluoromethylcarbinol

Fuming nitric acid (sp. gr. 1.15) was added dropwise to a stirred solution of trifluoroacetophenone (Columbia Organic Chemicals) (38.4 g, 0.216 mole) in 150 ml of concentrated sulphuric acid. External cooling was applied to maintain a temperature of 60–80° during the addition. The mixture was then heated on a steam bath for 4 hours. This was followed by cooling and the addition of another 40 ml of fuming nitric acid. The mixture was again heated on a steam bath for 4 hours and finally at 130–150° for 4 hours. The reaction mixture was then poured into crushed ice and extracted with ether. The ethereal extract was dried over anhydrous magnesium sulphate and evaporated leaving a yellow oil which was distilled under reduced pressure. The distillation yielded 2 g forerun, 10.6 g *m*-nitrophenyltrifluoromethyl ketone (b.p. 90° at 0.95 mm) and 3,5-dinitrophenyltrifluoromethyl ketone (b.p. 120–127 at 0.95 mm) (32.4 g, 0.123 mole, 57%). ν_{max} (film) 1733 cm^{-1} (C=O). Hydrolysis of this compound with dilute sodium hydroxide yielded 3,5-dinitrobenzoic acid (m.p. 203–205°, lit. 204–205°).

Attempted recrystallization of the crude 3,5-dinitrophenyltrifluoromethyl ketone from most common solvents such as ether, petroleum ether, and chloroform yielded a stable white solid which showed no carbonyl band in the infrared, but exhibited peaks at 3490 and 3270 cm^{-1} (m.p. = 85.0–85.5°). It was concluded that this compound was 3,5-dinitrophenyltrifluoromethyl ketone hydrate. (Found: C, 32.52%; H, 2.13%; N, 9.22%. Required for $C_8H_5N_2O_6F_3$: C, 34.01%; H, 1.78%; N, 9.94%.) The analysis is hardly satisfactory, however, and despite the sharp melting point the compound may be impure. The N.M.R. spectra is consistent with the hydrate assignment as is the facile hydrolysis to 3,5-dinitrobenzoic acid which occurs in dilute sodium hydroxide.

Dehydration of 3,5-dinitrophenyltrifluoromethyl ketone hydrate by phosphorous pentoxide at 50° yielded the corresponding ketone (m.p. 77–78°). ν_{max} ($CHCl_3$) 1737 cm^{-1} (C=O). (Found: C, 35.8%; H, 1.28%; N, 10.27%. Required for $C_8H_3N_2O_5F_3$: C, 36.4%; H, 1.14%; N, 10.60%.)

Recrystallization of the crude 3,5-dinitrophenyltrifluoromethyl ketone from ethanol yielded a white crystalline compound (m.p. 70–71°) which showed no absorption in the carbonyl region of the infrared spectra nor any in the region from 3200 to 3500 cm^{-1}, where the hydrate absorbs. (Found: C, 29.85%; H, 1.53%; N, 10.96%; O, 26.35%; F, 0.00%; m.w. = 243.) This compound was resistant to basic hydrolysis and as yet its exact structure has not been determined.

3,5-Dinitrophenyltrifluoromethylcarbinol was prepared from crude 3,5-dinitrophenyltrifluoromethyl ketone by reduction with lithium tri-*t*-butoxyaluminohydride in diglyme (31). Distillation of the yellow oil which resulted from this reaction yielded 3,5-dinitrophenyltrifluoromethylcarbinol (b.p. 108–174° at 8 mm) (9.2 g, 63%). This product was further purified by recrystallization from carbon tetrachloride. The resulting fine white crystalline compound gave an infrared spectrum similar to *m*-nitrophenyltrifluoromethylcarbinol and a nuclear magnetic resonance spectrum consistent with the assumed structure (m.p. 76–77°). (Found: C, 36.16%; H, 1.72%; N, 10.54%. Required for $C_8H_3N_2O_5F_3$: C, 36.10%; H, 1.89%; N, 10.53%.)

3,5-Dinitrophenyltrifluoromethylcarbinol-α-d

This compound was prepared by the reduction of 3,5-dinitrophenyltrifluoromethyl ketone with lithium tri-*t*-butoxyaluminodeuteride as described above (m.p. 76.8°). (Found: C, 36.07%; H, 1.78%; N, 10.78%. Required for $C_8H_2DN_2O_5F_3$: C, 36.00%; H, 1.89%; N, 10.50%.) The nuclear magnetic resonance spectrum was also consistent with the assignment of this structure.

Kinetic Methods

Oxidation rates were obtained by following the disappearance of Cr^{VI}. A plot of the reciprocal of [Cr^{VI}] against time yielded the second-order rate constant directly.

Good straight line plots to at least 70% completion were obtained for all rate constants reported (Fig. 4).

Typical kinetic runs were carried out as follows: 50 ml of a 4.035×10^{-3} *M* acetic acid solution of phenyltrifluoromethylcarbinol was mixed with 20 ml of 71% perchloric acid and thermostated at 25.0±0.1° for 10 minutes. A fast-delivery pipette was then used to add 4.94 ml of 0.01361 *M* potassium dichromate to this solution and 4.92 ml aliquots were withdrawn at intervals. The aliquots were quenched by adding them to 15 ml of 5% sodium bicarbonate solution containing a large excess of potassium iodide. Two milliliters of 6 *M* sulphuric acid was added and the solution was set aside to develop for 3 minutes. The iodine formed was then titrated with standardized thiosulphate using Thyodene as an indicator.

The magnitude of the equilibrium constant in dilute aqueous solutions is such that the amount of chromium in the bichromate form is appreciable only at fairly high concentrations and Westheimer has observed that in dilute solutions (0.0005–0.005 *M*) the rate is proportional to the gross Cr^{VI} concentration (10). Although no further investigation of this equilibrium was conducted during the present work, an attempt to minimize any deviations arising from this effect was made by using concentrations of Cr^{VI} that were always lower than 0.005 *M* and in cases where rates were used for comparison purposes attempts were made to keep the Cr^{VI} concentration constant throughout the whole series.

Product Analysis

It is well known that chromic acid oxidizes most secondary alcohols smoothly to the corresponding ketones with little or no carbon–carbon bond fission (10; see, however, ref. 32). Since the concentration of

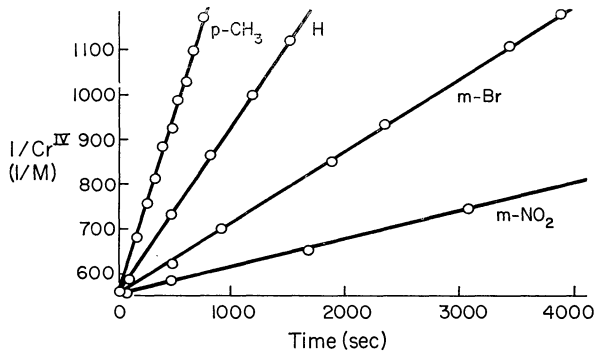

FIG. 4. Typical second-order rate plots for the oxidation of aryltrifluoromethylcarbinols in 77.2% acetic acid.

reactants was low in all of the kinetic experiments conducted in this investigation, it was found to be extremely difficult to isolate and identify the products of these reactions. However, when the concentrations of the reactants were increased to a preparative scale it was found that the aromatic alcohols gave almost quantitative yields of the corresponding ketones. The good second-order rate plots obtained also indicate that few side reactions are taking place.

PHOSPHONITRILIC COMPOUNDS

PART I. THE MECHANISM OF PHOSPHONITRILIC CHLORIDE POLYMERIZATION CAPACITANCE, CONDUCTANCE, AND ELECTRON-SPIN RESONANCE STUDIES[1]

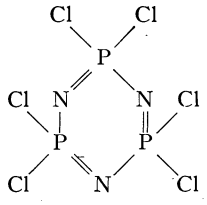
H. R. Allcock and R. J. Best
Central Research Division, American Cyanamid Company, Stamford, Connecticut
Received September 11, 1963

ABSTRACT

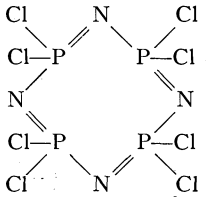
Capacitance and conductance measurements were carried out with molten $(NPCl_2)_3$ and $[NP(OC_6H_5)_2]_3$ and dipole moments were determined in benzene solution. Attempts to detect free radicals in molten samples of the same compounds were unsuccessful. Evidence was obtained that homolytic or heterolytic phosphorus–nitrogen ring cleavage is not involved in the primary initiation process. The results favor, instead, a polymerization mechanism for $(NPCl_2)_3$ in which phosphorus–chlorine ionization is a preliminary step.

INTRODUCTION

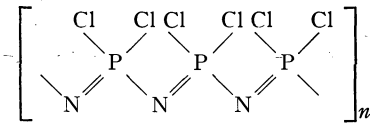
Phosphonitrilic chloride trimer, $(NPCl_2)_3$, (I) and tetramer, $(NPCl_2)_4$, (II) polymerize at temperatures between 200 and 300° C to yield a series of higher polymers which include linear oils and elastomers, $(NPCl_2)_n$, (III) (1–11). The higher polymers produced by this process are believed to have molecular weights in excess of 100,000 (2).



(I)



(II)



(III)

A similar behavior has been reported for phosphonitrilic fluorides and bromides (12–15). However, if phosphonitrilic chloride high polymer is heated above a temperature of 300 to 350° C, the material depolymerizes to low molecular weight oligomers which include the trimer (I) and tetramer (II). Under suitable conditions, a complete reversal of polymerization can be effected (5, 16, 17). By contrast, other phosphonitrilic compounds do not undergo polymerization–depolymerization reactions of this type (18). For example, the phenoxy derivative, $[NP(OC_6H_5)_2]_3$, does not polymerize to linear polymers at high temperatures and shows a high resistance to thermal degradation (19, 20).

Several authors have investigated the polymerization reactions of phosphonitrilic chlorides (4–10) but the different interpretations of the results have given rise to conflicting opinions concerning the reaction mechanism. In this paper, the polymerization mechanism is discussed in the light of capacitance, conductance, and electron-spin resonance experiments.

EXPERIMENTAL

Phosphonitrilic Chloride

Phosphonitrilic chloride trimer (Hooker Chemical Company) was recrystallized twice from reagent grade *n*-heptane and was then exhaustively dried in a vacuum oven at 60° C to give material having a melting

[1]*Presented at the Symposium on Inorganic Polymers held at the University of Western Ontario, September 4–6, 1963.*

For personal use only.

point of 113–114° C. Subsequent purification was effected by sublimation to yield a product with a melting point of 114° C. Zone refining was also used to purify 55×0.7 cm columns of the material. After 17 passes using a Fisher zone refiner, the melting point was 114–114.5° C.

Phosphonitrilic Diphenoxide Trimer

The compound $[NP(OC_6H_5)_2]_3$ was prepared by a route similar to that reported previously (19, 20). A solution of sodium phenoxide in tetrahydrofuran (500 ml) was prepared from phenol (84.6 g) and sodium (20.7 g) in an atmosphere of dry argon. To this stirred solution was added a solution of phosphonitrilic chloride trimer (52.2 g) in tetrahydrofuran (500 ml). The mixture was then refluxed for 8 hours and was allowed to stand at 25° C for a total of 56 hours. Filtration of the mixture yielded sodium chloride (55 g); evaporation of the filtrate and precipitation of the residue from acetone into a large excess of water yielded 88.5 g of a material having a melting point of 106–109° C. The product was then recrystallized twice from *n*-heptane and *n*-heptane–benzene mixtures, and was exhaustively dried in a vacuum oven at 60° C to yield phosphonitrilic diphenoxide trimer (83.2 g, 93%), m.p. 112–112.5° C. Found: C, 62.32; H, 4.47; N, 6.04; P, 13.61%. $C_{36}H_{30}N_3P_3O_6$ requires: C, 62.5; H, 4.34; N, 6.07; P, 13.42%. The molecular weight by cryoscopy in naphthalene was 702, and by mass spectrometry was 693. (Theory = 693.)

Electron-Spin Resonance Measurements

Electron-spin resonance measurements were performed using a Varian V 4500 spectrometer with a modulation frequency of 100 kc. The samples were contained in quartz tubes (4 mm outside diameter), and were heated at temperatures up to 250° C using standard Varian accessories. Experiments were carried out with the samples either exposed to air or in vacuum.

Conductance and Capacitance Measurements

The bridge used for the capacitance and conductance measurements was based on a design by Cole (21). It consisted essentially of a Wheatstone bridge with a closely coupled pair of secondary transformer windings used as the ratio arms. Balancing was achieved by the use of a low-inductance Helipot and a switching arrangement to include any one of five accurate resistors on the measuring side. The capacitance was balanced with one of two General Radio standard variable capacitance boxes, No. 722 CC or No. 722 MD. The bridge was supplied with an a-c. signal from a Hewlett–Packard oscillator, No. 200CD/CDR, and the signal from the bridge was amplified by a Rohde and Schwarz tunable indicating amplifier, type UBM BN 12121/2, and was displayed on a Hickok oscilloscope, model 387R. The frequency range of this assembly was 50 c.p.s. to 400 kc, the conductance range was 5×10^{-10} to 5×10^{-3} mho cm, and the capacitance range was from 0 to 1100 $\mu\mu$f in two ranges.

The dielectric cells were Balsbaugh liquid sample holders, one with an interplate air capacitance of 51.790 $\mu\mu$f and the other with a capacitance of 18.48 $\mu\mu$f. The respective cell constants were 0.001710 and 0.004791. During the measurements the samples were in contact with the Monel electrodes and with the Pyrex glass of the cell. An atmosphere of dry argon was maintained above the sample throughout the experiments by passage of a slow stream of the gas (Linde) through a liquid-nitrogen cooled cold trap which contained dry silica gel, before passage through the dielectric cell. The exhaust gas was then passed through a second trap, and was released into the atmosphere through a mineral oil bubbler. Sublimation of $(NPCl_2)_3$ was noticeable at the higher temperatures, and sufficient vapor was present in the dry gas stream to cause test papers to indicate acidity. The cells were contained in an aluminum block which could be heated electrically up to a temperature of 360° C. During the measurements, the cell temperature was held to within ±0.5° C.

At the beginning of each experiment the crystalline material was placed in the cell and air was removed by a stream of argon. The temperature was then raised to the melting point. Capacitance and conductance measurements were taken at progressively increased temperatures, and also as the temperature was subsequently lowered. With $(NPCl_2)_3$, four successive experiments were performed with recrystallized and zone-refined starting material, different cells, and, in one case, after replacement of the Monel by platinum electrodes. Reproducible results were obtained from these runs. Dielectric constants were then calculated from the air capacitance, benzene capacitance, and the capacitance of the sample.

Dipole Moments

The dielectric constant values of the samples at 120° C over the frequency range 1 kc to 50 kc, were used to calculate dipole moments by the Onsager equation. The refractive indices were determined by comparison with a set of standard glass powders at temperatures from 110° C to 130° C. Densities were determined in a 10 ml graduated cylinder held at 120° C in an aluminum block.

Dielectric constant values were also determined for 4%, or less than 4%, solutions of the two compounds in benzene at 30° C and 70° C and at 1 kilocycle frequency. The refractive indices and weight fractions of the solutions were then used to calculate dipole moments by means of the Guggenheim equation.

RESULTS

Electron-Spin Resonance Measurements

No electron-spin resonance was observed for purified $(NPCl_2)_3$ and $[NP(OC_6H_5)_2]_3$ between 25° C and 250° C in air or in vacuum. Under the same conditions, radicals could

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

be detected readily in liquid sulphur, which also undergoes a ring-chain equilibrium (22). This indicated the absence of free-radical species in the molten phosphonitrilic compounds under these conditions.

However, samples of $[NPCl_2]_3$ which had been purified by recrystallization only gave spurious resonances below $g = 2$. These peaks were attributed to trace amounts of transition metals. Sublimed samples of $[NPCl_2]_3$ did not behave in this way.

Capacitance Measurements

(a) $(NPCl_2)_3$

The dielectric constant of $(NPCl_2)_3$ did not change as the temperature was raised from the melting point (114° C) to 203° C. (The small decrease in dielectric constant shown in Table I can be explained solely by thermal expansion of the liquid.) However, as the temperature was raised from 203° C to 253° C, through the temperature range where polymerization becomes important, the dielectric constant rose rapidly. When the temperature was maintained at 253° C, the dielectric constant continued to increase slowly with time. Moreover, the value continued to rise as the cell temperature was lowered to 202° C, by an extent which could not be explained by thermal contraction or by a time lag in the cooling of the reaction mixture. As the temperature was elevated initially from 114° to 253° C, the dielectric constant was independent of frequency from 1 to 100 Kc. However, during the period of continuous dielectric constant increase with time at 202° C, and on cooling to 164° C, the capacitance decreased slightly as the frequency was raised from 1 to 50 Kc.

TABLE I

		120	4.35

*The dielectric constant rose continuously with time.

(b) $[NP(OC_6H_5)_2]_3$

The variation of dielectric constant with temperature for molten $[NP(OC_6H_5)_2]_3$ is also shown in Table I. Over a temperature range of 120° C to 350° C, a small decrease in dielectric constant occurred. This behavior was completely reversible when the temperature was lowered again, and could be accounted for entirely by the change in volume of the liquid due to thermal expansion and contraction.

Conductance Measurements

(a) $(NPCl_2)_3$

The variation of conductance with temperature for phosphonitrilic chloride trimer was complex, as shown by the data in Table II. The compound had a low conductance from 114° to 203° C, although above this temperature both the a-c. and d-c. conductance rose rapidly with temperature. At 253° C the conductance also showed a continuous increase

*The conductance rose continuously with time.

with time. The conductance fell slightly when the temperature was reduced to 202° C, but did not return to its original value at this temperature. Direct-current conductance measurements were taken simultaneously with the a-c. determinations and agreed satisfactorily with the a-c. values. The d-c. conductance decreased steadily when the current was maintained, a result which indicated a migration of charge carriers and a polarization at the electrodes.

(b) $[NP(OC_6H_5)_2]_3$

Conductance data for $[NP(OC_6H_5)_2]_3$ is also shown in Table II. Elevation of the temperature from 120° C to 252° C resulted in a small increase in conductance. This fivefold increase was approximately 400 times less than that observed with phosphonitrilic chloride trimer and was reversible when the sample was cooled. This behavior can probably be explained by increased solvation or ionic mobility at the higher temperatures. However, when the sample was heated to 350° C, about a 200-fold increase in conductance occurred. This increase was not completely reversible when the temperature was lowered to 120° C, and must be attributed to a decomposition at 350° C not connected with a polymerization process. Even so, the permanent increase in conductance at this temperature was considerably less than that observed with the chloro compound at 252° C.

Dipole Moments

The densities and refractive indices of the two compounds at 120° C were: $(NPCl_2)_3$, $d = 1.6891$, $n_D = 1.525$; $[NP(OC_6H_5)_2]_3$, $d = 1.2104$, $n_D = 1.564$. These values were used in conjunction with the dielectric constants to solve the Onsager equation for the dipole moment at this temperature. These values and the solution dipole moments are shown in Table III.

DISCUSSION

An understanding of the polymerization and depolymerization reactions of phosphonitrilic halides must take into account the unique structural and bonding characteristics of this system. Phosphonitrilic chloride trimer, tetramer, and polymer have been studied by X-ray and electron diffraction (23–28). The trimer exists as an almost planar six-membered ring, the tetramer as a puckered eight-membered ring, and the polymer as a linear chain which is arranged in the form of a helix. Other homologues, such as the pentamer and higher oligomers, exist as puckered ring or chain structures (29). Structural determinations indicate that the N—P—N and P—N—P bond angles are not significantly different in the trimer, tetramer, and polymer (about 120°) (23–28). The N—P bond lengths are also similar in the three derivatives (about 1.6 Å) (23–28). It is probable therefore, that in the phosphonitrilic series, no marked steric advantage to the system occurs by polymerization or depolymerization. This contrasts markedly with other inorganic polymer systems such as organosiloxanes, borazoles, and silicon–nitrogen compounds, where the preferred steric arrangement of the six- or eight-membered ring thermodynamically favors these species relative to the higher polymers. Furthermore, the existence of $d\pi$–$p\pi$ bonding between the phosphorus and nitrogen atoms in these compounds (30, 31) implies that changes in ring or chain size and planarity do not appreciably influence the stability of the system.

Polymerization and depolymerization may be different aspects of the same thermal equilibration process. Heating of the lower oligomers or the higher polymers would result in the establishment of a statistical equilibrium to give a range of species with degrees of polymerization between 3 and about 1500. If such a mixture is heated at high temperature under conditions where the lower molecular weight species are volatilized and removed, more of these oligomers will be formed by equilibration of the system. Thus, in time, removal of the more volatile components will effect a general depolymerization. Some evidence has been reported in favor of such a process (5, 7, 8, 11, 17).

Two types of mechanism have been proposed for the polymerization of cyclic phosphonitrilic chlorides. Patat and co-workers (6–8) described the reaction as a free-radical polymerization, in which the initiation step included a ring opening, phosphorus–nitrogen bond cleavage into a diradical or a stabilized resonance form. The free-radical reaction was reported to occur both in the presence and absence of oxygen, and with or without solvents. Konecny and coworkers (9, 10) and Gimblett (18) suggested an ionic mechanism which involved prior dissociation of a chloride ion from phosphorus. In theory, phosphonitrilic chloride trimer or tetramer could undergo a number of simple, reversible bond cleavage reactions. These are summarized in Fig. 1.

Reaction (*a*) involves a thermally induced homolytic phosphorus–nitrogen bond cleavage to form a diradical. This species could either revert to the starting material or combine with the cyclic trimer or other diradicals to form polymeric chains. Reaction (*b*) involves a heterolytic cleavage of a phosphorus–nitrogen bond. Polymerization of such species could involve ionic addition reactions. Reaction (*c*) involves dissociation of a chloride ion from phosphorus (either thermally or under the influence of a cation) followed either by heterolytic phosphorus–nitrogen ring cleavage of the unstable species formed, or by attack of this species on the starting material. It was considered likely that the results of the present work might distinguish between these possible steps.

The two compounds, $(NPCl_2)_3$ and $[NP(OC_6H_5)_2]_3$, were chosen for the present study for several reasons. Firstly, $(NPCl_2)_3$ polymerizes thermally to linear high polymers while, under the same conditions, $[NP(OC_6H_5)_2]_3$ is completely unaffected. Secondly, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

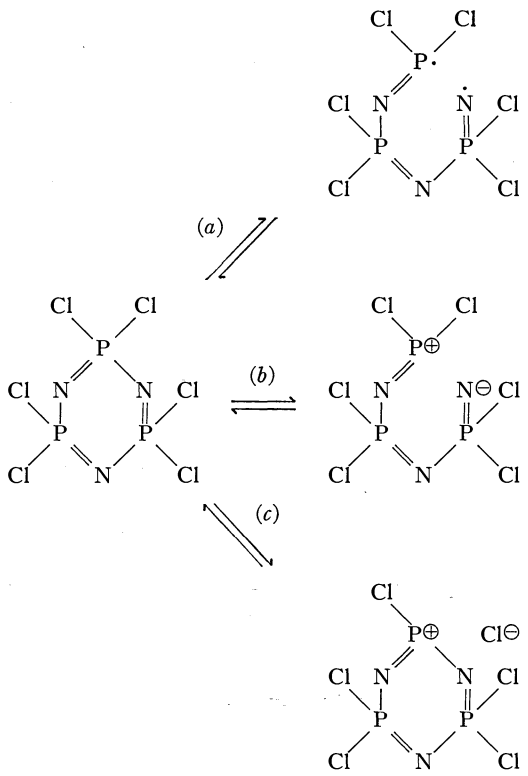

FIG. 1. Bond cleavage reactions of $(NPCl_2)_3$.

phosphorus–nitrogen bond strengths in the two compounds are expected to be similar, as indicated by the small shift in the phosphorus–nitrogen infrared absorption [$(NPCl_2)_3$, 1210 cm^{-1}; $[NP(OC_6H_5)_2]_3$, 1265 cm^{-1}]. This shift is indicative of a minor increase in π electron character within the phosphorus–nitrogen ring (29). The increase in P—N bond order is, however, less than for the compound $(NPF_2)_3$ (29). Thirdly, chlorine should ionize more readily than phenoxy from phosphorus.

It is of interest to compare the dipole moment values of $(NPCl_2)_3$ and $[NP(OC_2H_5)_2]_3$ shown in Table V. The low values for $(NPCl_2)_3$, (0.83–0.98 D) are consistent with the symmetry of the planar, cyclic structure in solution and in the melt. These values are somewhat higher than those reported for concentrated solutions in benzene (32). However, a surprisingly high value (about 3.0 D) was obtained for $[NP(OC_6H_5)_2]_3$ under the same conditions. This result indicates that the compound has a lower symmetry than does the chloride, and probably denotes that the phosphorus–nitrogen ring exists in a puckered form in this compound due to the steric crowding of the bulky phenoxy groups. The small increase of solution dipole moment with temperature for both compounds can be attributed to improved solvation at the higher temperature.

The failure to detect an electron-spin resonance spectrum in molten $(NPCl_2)_3$ and $[NP(OC_6H_5)_2]_3$ at temperatures where the polymerization of $(NPCl_2)_3$ takes place is an indication that a free-radical initiation (Fig. 1*a*) does not occur. The alternative explanation, that radicals are formed but are too labile to be detected, is considered unlikely. If this were the case, paramagnetic species should have been detected with $[NP(OC_6H_5)_2]_3$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where loss of radicals by polymerization cannot occur. Negative results of this type do not exclude the possibility of contributions from free-radical species, but the data provides strong evidence against a primary homolytic cleavage process.

Heterolytic cleavage of the phosphorus–nitrogen ring (Fig. 1*b*) would lead to the formation of dipolar species. If such species are present in appreciable concentrations, and do not polymerize rapidly, an increase in the capacitance of the system would be expected at higher temperatures. With $[NP(OC_6H_5)_2]_3$, no capacitance increase was detected between 120° C and 350° C. The evidence suggests that an initial heterolytic phosphorus–nitrogen ring cleavage is not involved in the polymerization of trimeric phosphonitrilic compounds within this temperature range.

The more complicated results obtained with $(NPCl_2)_3$ can be explained in terms of secondary processes. An irreversible rise in dielectric constant took place between 203° C and 253° C in the temperature range in which polymerization occurs. Furthermore, the dielectric constant rose continuously at constant temperature and continued to rise when the temperature was lowered to 202° C. A rough approximation of the rate of dielectric constant increase at 252° C and 202° C indicated that the activation energy of the process was about 19 kcal/mole. These results can be correlated with an increasing concentration of linear polymer. A decrease in molecular symmetry would accompany conversion of the cyclic trimer to linear polymers and would result in an increase in the polarizability of the system. Evidence in favor of this hypothesis was provided by the fact that, after the permanent dielectric constant increase had occurred, the capacitance was no longer independent of frequency. This small decrease in capacitance with increasing frequency was indicative of a slower relaxation process which would be expected for polarizable, polymeric species.

Eley and Willis (33) have recently reported the conductivity of crystalline $(NPCl_2)_3$, and suggested that the small conductance was due to ionization of chloride ions from phosphorus. If polymerization requires the prior ionization of a side-group from phosphorus, the conductance of molten $(NPCl_2)_3$ should increase with temperature. Furthermore, if polymerization is a slow step compared to ionization, the conductance increase with temperature should be reversible.

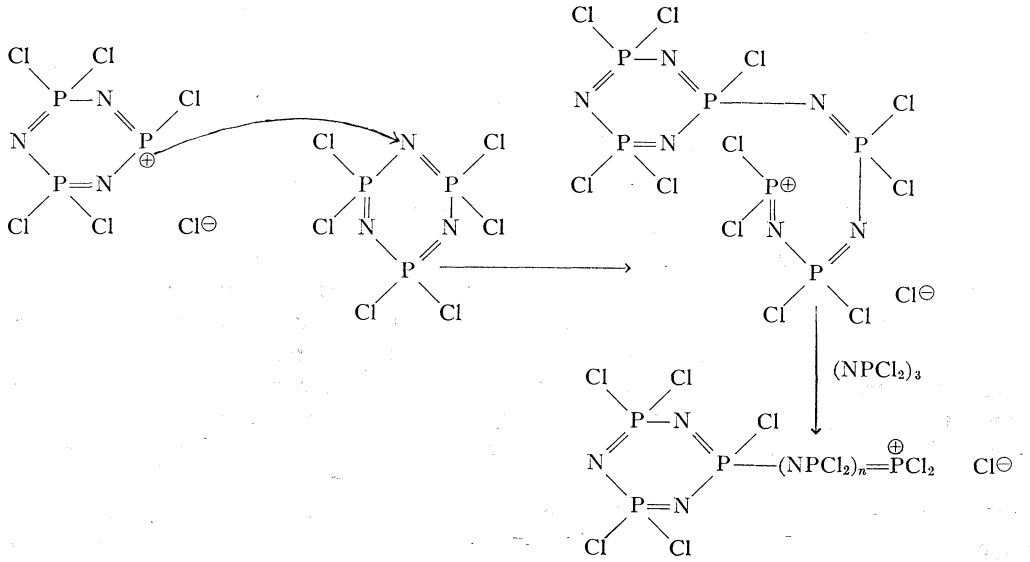
The compound $[NP(OC_6H_5)_2]_3$ was used as a control in these experiments also because thermal ionization of phenoxy from phosphorus was expected to be negligible below 250° C. As expected, the conductance of $[NP(OC_6H_5)_2]_3$ increased only slightly from 120° C to 252° C, and was completely reversible. The almost reversible conductance increase between 252° C and 350° C may be due to a small degree of phenoxy ionization.

The rising conductance of $(NPCl_2)_3$ with increasing temperature can be correlated with the polymerization process. The large, permanent conductance increase shown in Table III can similarly be attributed to the presence of polymer, although the fact that a part of the conductivity is reversible as the temperature is lowered suggests the presence of an ionization equilibrium. It is clear, however, that the increased conductance of $(NPCl_2)_3$ at higher temperature is due to some form of decomposition or release of charge-carrying species. If the assumption is made that chloride ion is one of the charge carriers, it is clear that the undissociated form is relatively stable at 253° C and the steady-state concentration of ionized species must be very low.

The results described suggest that a free-radical mechanism or one involving heterolytic phosphorus–nitrogen ring cleavage as *initial* steps are unlikely. The conductance data indicates that, for $(NPCl_2)_3$, ionization into charge-carrying species occurs concurrently with polymerization. Chloride ion is probably one of the charge-carriers, and an initial

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

step in the polymerization can be depicted as that shown in Fig. 1*c*. A description of subsequent steps beyond the initial ionization must be largely speculative. However, the results indicate that the polymerizing species have a high dielectric constant, a low relaxation frequency, and a permanently enhanced conductance. This evidence is consistent with the following initiation and chain-propagation steps.



The mechanism depicted assumes an electrophilic attack by the P^+ unit on nitrogen without participation of chloride ion. This is consistent with the permanently increased conductivity during polymerization and with the enhanced dielectric constant, the latter due to the greater polarizability of the growing polymer chain.

This mechanism differs from the one suggested by Konecny *et al.* (10) in that phosphorus rather than nitrogen is assumed to be the electrophilic center of the initiating species. The greater electropositivity of phosphorus (34) is consistent with this interpretation. The mechanism proposed by Gimblett (18), in which chloride ion is consumed as an initiating unit, is inconsistent with the high conductivity observed for this system. The free-radical or Zwitterion mechanisms proposed by Patat and co-workers (6–8) can also be reinterpreted in terms of prior ionization of chloride ion from phosphorus.

This comparatively simple interpretation of the reaction is valid only for pure phosphonitrilic chloride in an inert reaction vessel. The accelerating effect of many impurities has been reported (9, 10, 17, 18) and, at high temperatures, reaction of phosphonitrilic chlorides with the glass walls of the reaction flask may occur. Impurities which function as chloride ion acceptors presumably catalyze the reaction by facilitating the initial ionization. A radiation-induced ionization probably occurs during the X-ray catalyzed, solid-state polymerization of $(NPCl_2)_3$ (35). Ionization of chloride ion from phosphorus is clearly responsible for many of the features of phosphonitrilic chloride polymerization, and also provides an explanation for the allied processes of chain-branching, cross-linking, and depolymerization.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Mrs. K. K. Mead, who obtained much of the conductance and capacitance data, and to Dr. W. G. Hodgson, who performed

STEROIDS

V. THE SYNTHESIS OF 4,4-DIMETHYL-3α,5-CYCLOCHOLESTAN-6-ONE (XI)[1]

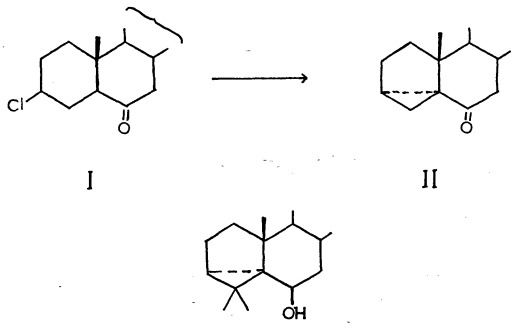
GEORGE JUST AND KEITH ST. C. RICHARDSON[2]
Department of Chemistry, McGill University, Montreal, Que.
Received August 20, 1963

ABSTRACT

The synthesis of the title compound is described.

By analogy with cholesteryl derivatives, one of the expected products of the solvolysis of 4,4-dimethyl-cholesteryl tosylate should be 4,4-dimethyl-3α,5-cyclocholestan-6β-ol (II*a*) (1). Since the nature of this compound is disputed (2–4), we were interested in synthesizing it in an unambiguous fashion. This paper describes the synthesis of its immediate precursor, 4,4-dimethyl-3α,5-cyclocholestan-6-one (XI).

FLOWSHEET I



I II IIa

The parent compound, 3α,5-cyclocholestan-6-one (II) (5) had been synthesized by Windaus by the action of potassium hydroxide on 3β-chlorocholestan-6-one (I). Our first objective therefore was the preparation of a 4,4-dimethylsteroid bearing a carbonyl function at C_6. Nitration (6) and other methods (7–11) for introducing functional groups at the 6 position of the readily available 4,4-dimethylcholesteryl acetate (III) (12) did not result in the formation of the desired product. However, *cis*-hydroxylation with osmium tetroxide gave 4,4-dimethylcholestane-3β,5α,6α-triol acetate (IV*a*) in good yield. The stereochemistry is assigned in conformity with the "rule of rear-attack" (13) and is corroborated by the positive Cotton-effect (14) shown by the oxidation product of the triol monoacetate (IV*a*), 3β-acetoxy-4,4-dimethyl-5α-hydroxy-cholestan-6-one (V).

The 5α-hydroxy group was not removed by the action of zinc in acetic acid (15). However, treatment with calcium in liquid ammonia (16, 17), followed by alkaline hydrolysis of the reaction product, resulted in the formation of the desired 3β-hydroxy-4,4-dimethyl-cholestan-6-one (VII) in 40–45% yield. Its structure and stereochemistry follow from its

[1]*This paper forms a part of the Ph.D. thesis of K. St. C. Richardson, to be presented to the Faculty of Graduate Studies and Research, McGill University.*

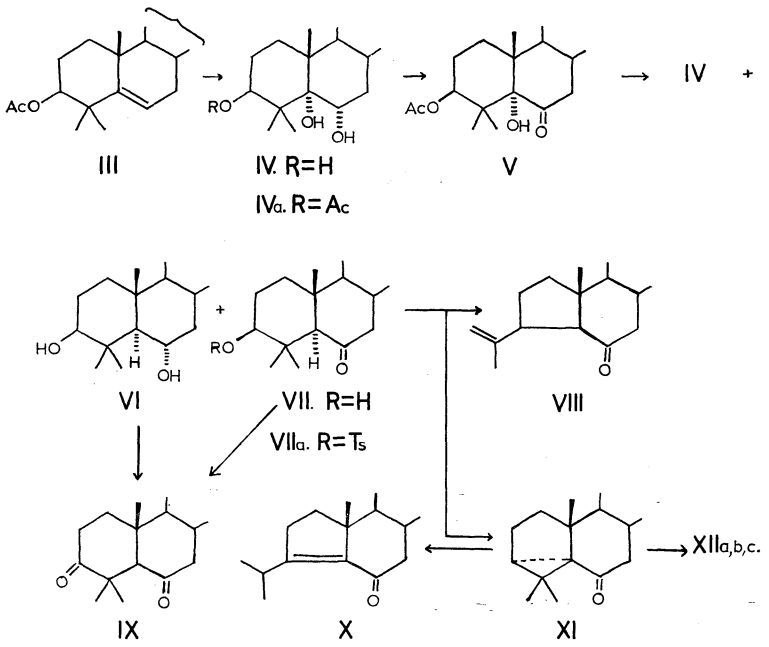
FLOWSHEET II



mode of formation, analysis, infrared spectrum (1708 cm^{-1}, 6-ketone) and optical rotatory dispersion curve (positive Cotton-effect), as well as the chemistry of the products derived from it. In the course of the calcium–ammonia reduction, there was obtained in addition to the 3-hydroxy-6-ketone VII, a diol VI, and a triol IV.

The structure of the diol VI was proved by conversion to 4,4-dimethylcholestane-3,6-dione (IX), also obtained by oxidation of VII. The stereochemistry of the hydroxyl group at C_6 is most probably α, since reductions of this type usually afford the thermodynamically more stable alcohols (18). Moreover, the magnitude of the rotatory power ($[M]_D$ 152°) is in agreement with the stereochemistry assigned[3]. Triol IV was shown to be identical with the hydrolysis product of IV*a* by melting point, mixed melting point, and comparison of their infrared spectra. Triol IV also exhibited the expected rotation[4], $[M]_D$ 97.8°.

Reaction of 4,4-dimethylcholestan-3β-ol-6-one (VII) with *p*-toluenesulphonyl chloride in pyridine gave the corresponding tosylate VII*a*. Treatment of the tosylate VII*a* with potassium *t*-butoxide for 3.5 hours afforded, after chromatography, two isomeric ketones XI, m.p. 107–108° and VIII, m.p. 116.5–118°. The latter ketone (VIII) was also obtained in 77% yield by treatment of tosylate VII*a* with potassium carbonate (19) in aqueous ethanol. Examination of the mother liquors of this reaction by infrared revealed the presence of ketone VIII only.

Ketone XI, $C_{29}H_{48}O$, absorbed in the ultraviolet at 203 mμ, ϵ4600 (20, 21) and in the infrared at 1696 cm^{-1}. This is indicative of a ketone in conjugation with a cyclopropane

[3]*Cholestane-3β-6α-diol, [M]D 154°; cholestane-3β-6β-diol, [M]D 52.7° (see ref. 5, p. 197).*
[4]*Cholestane-3β,5α,6α-triol, [M]D 88.5°; cholestane-3β,5α,6β-triol, [M]D 12.6° (see ref. 5, p. 192).*

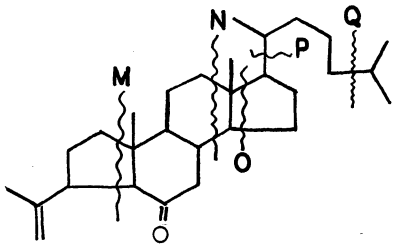
For personal use only.

ring (20–22). The nuclear magnetic resonance spectrum[5] reveals a poorly resolved multiplet centered at 0.19 p.p.m. (>C_3—H, cyclopropane) and thus confirms the structural assignment[6] (20).

Ketone VIII absorbed in the infrared at 1705 cm^{-1} (6-membered ketone) and at 3070, 1645, and 895 cm^{-1} (terminal methylene). There was no strong ultraviolet absorption above 215 mμ. The n.m.r. spectrum showed signals at 1.66 p.p.m. (3-H singlet, CH_3—C<) and 4.58 p.p.m. (2H, >C=CH_2). These data point to structure VIII, which is also plausible on mechanistic grounds.



VIII

Mass Spectrometry Fragmentation Pattern

Mass spectrometry is also in accord with this structural assignment (24, 25). In particular, process M places the double bond in the environment of ring A. Furthermore, process M would be unlikely if the double bond were at any position other than the position assigned.

Ketone VIII is not a product of isomerization of the 3α,5-cycloketone XI. Prolonged treatment of XI under conditions of tosylate displacement did not effect isomerization to ketone VIII. The formation of ketones VIII and XI is hence best explained by postulating a duality of reaction paths depicted below.

In the presence of a large excess of strong base, reaction (ii) is favored, whereas, in a weakly basic medium the solvolytic reaction (i) predominates to the virtual exclusion of cyclopropane formation.

I-ketone XI seems to be stable to base, but very labile to acid. Thus, chromatography on Davison silica gel and elution with hexane–benzene afforded an oil, which absorbed in the infrared at 1677 and 1620 cm^{-1} (α,β-unsaturated ketone) and in the ultraviolet at λ_{max}^{EtOH} 253 mμ. Both absorption patterns are consistent with the product of isomerization X. Alterations and elimination reactions in the steroid molecule on anhydrous silica gel have been reported in the literature (26), but comparatively little is known about the particular mechanisms involved.

Finally, reduction of ketone XI with lithium aluminum hydride gave, after chromatography, a hydrocarbon mixture XII*a*, ($\lambda_{max}^{C_6H_{12}}$ 233 mμ and 252 mμ, with rising end absorption) and two unidentified alcohols XII*b* and XII*c* (infrared determined). One of

[5]*T.M.S. was taken as internal standard and is equal to zero.*

[6]*Recently Tadanier and Cole (23) used a series of complex signals between 0–0.83 p.p.m. to characterize some 3α,5-cyclo-6-substituted steroids.*

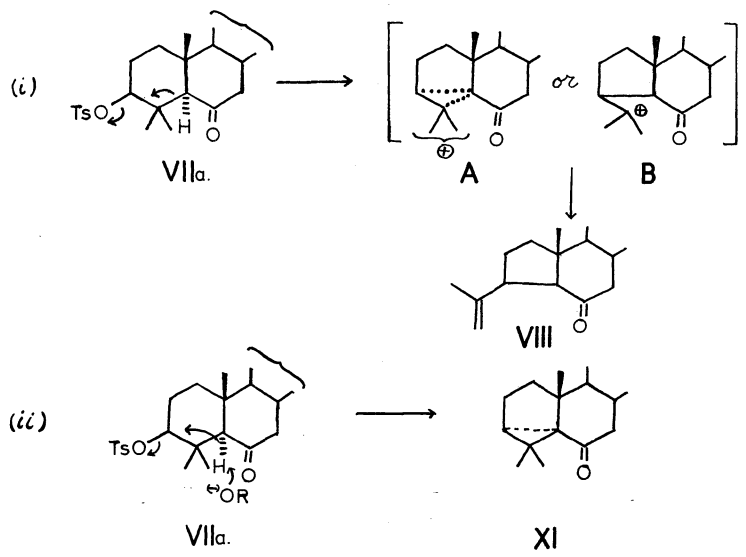
FLOWSHEET III



the latter alcohols could conceivably have the 3,5-cyclo structure. However, lack of an adequate supply of the starting ketone XI prevented a more detailed investigation of the products of reduction.

It might be pointed out that, whereas steroidal 6-ketones are reduced by lithium aluminum hydride in virtually quantitative yield to the 6β-hydroxy compound (27), 3,5-cyclocholestane-6-one is reduced to the 6α-alcohol (3*b*, 27, 28). A similar change in the stereochemistry of the reaction is also observed when 6-oxo and 3,5-cyclo-6-oxo steroids are submitted to a Grignard reaction (3*b*).

This "abnormal" stereochemistry of the lithium aluminum hydride reduction or Grignard addition to the *i*-ketones can best be explained by postulating an intermediate of type C, in which coordination of the carbonyl function with a Lewis acid (aluminum hydride, Grignard) leads to a homoallylic carbonium ion. The incoming nucleophile (hydride, Grignard, solvent in the case of solvolyses) attacks in the 6β-position, when R = H (formula C). However, with R = CH_3, it might be expected that attack might also take place at C_4, leading to more than one compound. Hence, this explains the multiplicity of products obtained above in the reduction of XI.

EXPERIMENTAL[7]

3β-Acetoxy-4,4-dimethylcholestane-5α,6α-diol (IVa)

A solution of 2.0 g (7.8 m mole) of osmium tetroxide in 94 ml of dry ether was poured into a solution of 2.5 g (5.6 m mole) of 4,4-dimethylcholest-5-en-3β-yl acetate (III), m.p. 136–137°, in 94 ml of dry ether (29). The reaction mixture was swirled briefly and set aside at room temperature for 7 days. The solvent was removed *in vacuo* at 25°. The dark residue was taken up in 340 ml of 70% aqueous ethanol, to which 0.99 g of sodium sulphite was added, and the mixture heated under reflux for 1 hour (30). The hot mixture was filtered through Celite and the filter-cake thoroughly washed with hot 80% aqueous ethanol. The volume was concentrated until partial crystallization was observed. Refrigeration overnight and filtration afforded 1.61 g (3.3 m mole) of colorless feathery needles, m.p. 186–189.5°. Crystallization of mother liquors gave an additional 713 mg (1.45 m mole) of IV*a*, m.p. 186–187.5°, for a total yield of 85%. Two recrystallizations for analysis raised the melting point to 190–191.5°, $[\alpha]_D^{23°}$ 35° (*c* 0.68). Anal. Calc. for $C_{31}H_{54}O_4$: C, 75.86; H, 11.0. Found: C, 75.64; H, 10.90. ν_{max} 3640 cm^{-1} (hydroxyl), 1735 cm^{-1} (acetate).

In a similar run, in which 3.5 ml of pyridine was added, the yield was not improved appreciably.

3β-Acetoxy-4,4-dimethyl-5α-hydroxycholestan-6-one (V)

Chromium trioxide (638 mg) in 6.38 ml of 90% aqueous acetic acid was added to a solution of 2.5 g (5.1 mmole) of the diol–acetate IV*a* in 180 ml of glacial acetic acid. The mixture was stirred continuously overnight at 25° C. Excess chromic acid was destroyed by addition of 3.5 ml of methanol, the entire mixture poured into 1 l. of ice water and the organic material extracted with ether. The ethereal solution was washed with dilute bicarbonate solution and with water; it was dried over magnesium sulphate and the solvent removed under reduced pressure. A colorless crystalline residue (2.42 g), m.p. 145–150°, was obtained. Recrystallization from ether–methanol afforded 2.04 g (82.2%) of needles, m.p. 158–160°. Three recrystallizations for analysis raised the melting point to 161–161.5°, $[\alpha]_D^{23°}$ −1.12 (*c* 0.73). Anal. Calc. for $C_{31}H_{52}O_4$: C, 76.18; H, 10.72. Found: C, 75.96; H, 10.59. ν_{max} 3650 cm^{-1} (5α-OH), 1735 cm^{-1} acetate) and 1710 cm^{-1} (C_6-ketone).

Treatment of V with Calcium – Liquid Ammonia

To 200 ml of liquid ammonia were added calcium turnings at −60°, until the solution became purple. A solution of 2 g (4.0 mmole) of the 5α-hydroxy ketone V in 15 ml of dry toluene was added to the stirred mixture, over a period of 6 minutes and the reaction allowed to proceed an additional 2 minutes. Bromobenzene (16 ml) was very cautiously added dropwise, followed in a similar manner by 50 ml of water. The temperature during the whole operation was maintained between −60° and −45°[8]. The excess ammonia was allowed to evaporate at room temperature. Concentrated hydrochloric acid was added with cooling, until the mixture was weakly acidic; the toluene layer was separated and the solvent removed *in vacuo*. Chloroform extraction gave a crimson product, the infrared analysis of which indicated partial hydrolysis of the 3β-acetate. Complete hydrolysis was subsequently effected by refluxing the residue overnight in 1.7 l. of 6% methanolic potassium hydroxide. The bulk of the solvent was distilled off and the remainder diluted with water. Ether extraction afforded 2.25 g of yellow viscous oil. The latter was combined with a similar oil (1.0 g, infrared analysis) obtained from a duplicate experiment run under identical conditions, and the whole chromatographed on alumina (Act. II–III).

Elution with benzene and benzene–ether (4:1) gave, after crystallization from ether–hexane, 4,4-dimethyl-3β-hydroxycholestan-6-one (VII), m.p. 173–175°, in 41.4% yield. Three recrystallizations for analysis raised the melting point to 175–175.5°, $[\alpha]_D^{23°}$ 8.4° (*c* 0.51). Anal. Calc. for $C_{29}H_{50}O_2$: C, 80.87; H, 11.70. Found: C, 80.53; H, 11.59. ν_{max} 3640 cm^{-1} (hydroxyl), 1708 cm^{-1} (>C=O).

The benzene–ether (1:1) eluates, after crystallization from methanol, gave 4,4-dimethylcholestane-3β,6α-diol (VI), m.p. 165–168° in 1.5% yield. Several crystallizations from ether–hexane for analysis raised the melting point to 167–168°, $[\alpha]_D^{23°}$ 35° (*c* 0.60). Anal. Calc. for $C_{29}H_{52}O_2H_2O$: C, 77.27; H, 12.08. Found: C, 77.71, H, 11.50[9]. $\nu_{max}^{CHCl_3}$ 3650 (hydroxyl), 3400 cm^{-1} (broad, hydrogen bonding).

A third crystalline product, 4,4-dimethylcholestane-3β,5α,6α-triol (IV), m.p. 208–210° C (20%), was

[7]*All rotations were taken in chloroform solutions on a Carl Zeiss Photoelectric Precision Polarimeter. Infrared (IR) spectra were determined with a Perkin–Elmer model 21 spectrophotometer. Unless otherwise stated, IR were taken in carbon tetrachloride solutions. Ultraviolet spectra were measured with a Beckmann spectrophotometer, model DK-1, except for i-ketone XI, which was measured on a Unicam, model SP500s. The commercially available aluminum oxide (Woelm) was used for chromatography. Microanalyses were carried out by Dr. C. Daessle, 5757 Decelles St., Montreal, Que., and by Dr. A. Bernhardt, Mulheim, Germany. Melting points were taken on a Kofler hot plate.*

[8]*In subsequent runs it was observed that maintaining the temperature well below −60° throughout the entire reaction period gave an optimum yield (46%) of the desired product VII.*

[9]*The diol VI proved quite hygroscopic and could have been analyzed as the monohydrate giving the calculated values in closer accord with the experimental values. $C_{29}H_{52}O_2.H_2O$: C, 77.27; H, 12.08.*

obtained directly from ether eluate. Recrystallization from ether–methanol for analysis did not alter the melting point, $[\alpha]_D^{23°}$ 21.8° (*c* 0.86). Anal. Calc. for $C_{29}H_{52}O_3$: C, 77.61; H, 11.68. Found: C, 76.53, 78.02; H, 11.49, 11.21. $\nu_{max}^{CHCl_3}$ 3640 cm^{-1} (hydroxyl), 3400 cm^{-1} (hydroxyl, broad hydrogen bonding).

4,4-Dimethyl-6-oxocholestan-3β-yl p-Toluenesulphonate (VIIa)

A solution of 1.06 g (2.4 mmole) of 4,4-dimethyl-6-oxocholestan-3β-ol (VII) and 1.06 g of *p*-toluenesulphonyl chloride in 45 ml of anhydrous pyridine was set aside at room temperature for 1 week. The mixture was poured into 550 ml of ice water and the tosylate extracted with previously chilled diethyl ether. The ethereal solution was washed successively with cold dilute hydrochloric acid, cold 5% sodium bicarbonate, and distilled water and finally with a saturated solution of sodium chloride. It was dried ($MgSO_4$) and the solvent removed *in vacuo*. A quantitative yield of tosylate VII*a*, m.p. 187–188.5° was obtained. Recrystallization from ether afforded 1.01 g (72.5%) of needles, m.p. 188–189°. Further crystallization of mother liquors gave an additional 159 mg (11.3%), melting also at 188–189°. Recrystallization for analysis afforded needles melting sharply at 189°, $[\alpha]_D^{23°}$ 6.9° (*c* 0.41). ν_{max} 1715 cm^{-1} (>C_6=O), 1345, 1190, 1180, 985, and 875 cm^{-1} (tosylate). $\lambda_{max}^{cyclohexane}$ 225 mμ, (ε 10,800). Anal. Calc. for $C_{36}H_{56}O_4S$: C, 73.92; H, 9.65; Found: C, 73.84; H, 10.02.

Treatment of VIIa with Potassium t-Butoxide

To a hot solution of 1.0 g (8.85 matom) of potassium in 100 ml of dry *t*-butanol was added, in one portion, a solution of 1.15 g (1.97 mmole) of VII*a* in 55 ml of dry *t*-butanol and the mixture heated under reflux for 3.5 hours. The cooled mixture was poured into 800 ml of ice water and the organic material extracted with ether. The ethereal solution was washed with cold dilute hydrochloric acid and with water; it was dried over magnesium sulphate and the solvent removed under reduced pressure. The recovered residual oil failed to crystallize.

Accordingly, the mixture was chromatographed on alumina (Act. II–III), effecting only partial separation of a single crystalline product (175 mg), the 3-isopropenyl-A-norcholestan-6-one (VIII). Recrystallization from ether–methanol gave 130 mg (18.2%) of colorless prisms, m.p. 115–117° C.

The remaining material was collected and rechromatographed on alumina (Act. II). Elution with hexane afforded 209 mg of 4,4-dimethyl-3α,5-cyclocholestan-6-one (XI). Crystallization from ether–methanol gave 132 mg (18.3%) of pure *i*-ketone, m.p. 104–107°. One portion of the hexane–benzene (95:5) eluate furnished 78 mg of a mixture of ketones VIII and XI (IR-spectra).

The remaining hexane–benzene eluates (95:5 and 4:1) gave 211 mg of crystalline material, m.p. 100–113°, exhibiting the same infrared spectral characteristics melting point and mixture melting point as an extra portion (57 mg) set aside from the first chromatogram and was not combined for rechromatography. The two identical portions were taken up together and crystallized from ether–methanol, furnishing 182 mg of VIII, m.p. 116–118°, for a total yield of 43.1%.

Repeated Potassium t-Butoxide Treatment of VIIa

To a hot solution of 181 mg (4.6 in atom) of freshly cut potassium in 40 ml of dry *t*-butanol was added dropwise and with stirring, a solution of 250 mg (0.43 mmole) of the tosylate VII*a* in 40 ml of dry *t*-butanol, over an extended period of time. The colorless reaction mixture was heated under reflux for 3 hours; it was cooled and poured into 250 ml of ice water. Ether extraction afforded 187 mg of an oily residue. Chromatography on alumina (Act. II) and elution with hexane afforded 77 mg of ketone XI (IR). One crystallization from ether–methanol gave 64 mg (31.5%)[10] of the pure product, m.p. 105–108°. Two recrystallizations for analysis raised the melting point to 107–108°, $[\alpha]_D^{23°}$ 35.4 (*c* 0.41). Anal. Calc. for $C_{29}H_{48}O$: C, 84.40; H, 11.72. Found: C, 84.36; H, 11.57. ν_{max} 1695 cm^{-1} (C_6-ketone in conjugation with a cyclopropane ring), 1308 cm^{-1} (31), 1025–1005 cm^{-1}, and 925 cm^{-1} (cyclopropane). λ_{max}^{EtOH} 203 mμ (ε 4650), (20). N.m.r. 0.19 p.p.m. (>C_3—H), 0.95 p.p.m. and 1.01 p.p.m. (C_4-*gem*dimethyl).[11]

Elution with hexane–benzene (5:1 and 2:1) gave, after four crystallizations from ether–methanol 20 mg (10.6%) of ketone VIII, m.p. 116.5–118°, $[\alpha]_D^{23°}$ −27.2° (*c* 0.41). Anal. Calc. for $C_{29}H_{48}O$: C, 84.40; H, 11.72. Found: C, 84.29; H, 11.89. ν_{max} 1705 cm^{-1} (>C_6=O), 3070, 1645, and 895 cm^{-1} (>C=CH_2). N.m.r. 1.66 p.p.m. (>C—CH_3), 4.58 p.p.m. (>C=CH_2) (32).

Solvolysis of VIIa in Aqueous Ethanol

To a refluxing solution of 150 mg (0.26 mmole) of tosylate VIIa in 100 ml of absolute ethanol was added 450 mg of potassium carbonate in 10 ml of water and 10 ml of absolute ethanol, and the colorless reaction mixture allowed to reflux overnight. The bulk of the solvent was distilled off and the remainder diluted with water. Ether extraction afforded 100 mg, (m.p. 113–115°) of ketone VIII. Recrystallization from ether–

[10]*Although the overall yield of the A-nor-ketone VIII and i-ketone XI appears less than it was before, the ultraviolet spectrum of the crude reaction product showed the presence of 75% content of i-ketone XI.*

[11]*Lehn and Ourisson (32) have attributed signals in the n.m.r. at 0.92 p.p.m. and 1.04 p.p.m. to the C_4-gemdimethyl groups in a 4,4-dimethyl-3-oxo triterpene derivative of the lupane series.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

methanol gave 65 mg (59%) of VIII, m.p. 115–116°. The mother liquors upon further crystallization furnished an additional 20 mg (18.5%), m.p. 115–116.5°, which did not depress upon admixture with an authentic sample. ν_{max} 1705 cm^{-1} ($>C_6{=}O$), 3070, 1645, and 895 cm^{-1} ($>C{=}CH_2$). Infrared analysis of subsequent mother liquors showed the presence of ketone VIII, only.

Lithium Aluminum Hydride Reduction of Ketone XI

Chromatographically pure 4,4-dimethyl-3α,5-cyclocholestan-6-one (XI, 145 mg) was treated with 800 mg of lithium aluminum hydride in 45 ml of dry ether at 25° (12). Excess hydride was destroyed by the dropwise addition of 1.7 ml of distilled water, followed in similar fashion by 1.5 ml of 10% sodium hydroxide solution. The solid inorganic material was filtered, the filter cake thoroughly washed with dry ether, and the filtrate evaporated to dryness under reduced pressure. Infrared analysis of the residue (146 mg), which resisted crystallization, established the complete reduction of the ketone. A portion of the residue (70 mg) was chromatographed on alumina (Act. II–III). Elution with hexane afforded 21 mg of a colorless oil XII*a*. No carbon–oxygen functions were observed in the infrared spectrum. $\lambda_{max}^{cyclohexane}$ 233 mμ and 252 mμ, with end absorption.

Hexane–benzene (95:5) eluted 14 mg of a crystalline product XII*b*, m.p. 92–96°. ν_{max} 3650 cm^{-1} (hydroxyl), 1033 cm^{-1}. Crystallization for analysis was unsuccessful.

Elution with hexane–benzene (9:1 and 2:1) gave 17 mg of a second crystalline product XII*c*, m.p. 105–107°. Two crystallizations from ether–methanol gave a few crystals and raised the melting point to 117–120°. $\nu_{max}^{CCl_4}$ 3665 cm^{-1} (hydroxyl), 1037 cm^{-1}.

Isomerization of Ketone X on Silica Gel

Mother liquors (78 mg) obtained from a previous crystallization of ketone XI were chromatographed on a column of Davison silica gel (commercial Grade No. 923). Elution with hexane–benzene afforded 24 mg of colorless oil, which failed to crystallize. $\nu_{max}^{CCl_4}$ 1677 and 1620 cm^{-1} (α,β-unsaturated ketone), 1740 cm^{-1} (unidentified weak shoulder).[12] λ_{max}^{EtOH} 253 mμ. The compound was formulated as XI from its infrared and ultraviolet data.

Further elution with benzene and benzene–ether (9:1 and 4:1) gave 44 mg of an intractable oil. $\nu_{max}^{CCl_4}$ 1740 cm^{-1}, 1696 cm^{-1}, 1675 cm^{-1}, and 1620 cm^{-1}. λ_{max}^{EtOH} 252 mμ and 236 mμ, with strong end absorption.

*Hydrolysis of 3β-Acetoxy-4,4-dimethylcholestane-5α,6α-diol (IV*a*)*

A solution of the diol acetate IV*a* (200 mg, 0.4 mmole) in 50 ml of 6% methanolic potassium hydroxide was heated under reflux overnight. Ether extraction afforded 176 mg of a crystalline product. Recrystallization from chloroform–ethanol gave 150 mg (75%) of the 3β,5α,6α-triol IV, m.p. 205–207°, which did not depress upon admixture with an authentic sample of IV obtained from the Ca–NH_3 reduction. The infrared spectra were essentially identical.

4,4-Dimethylcholestan-3,6-dione IX

A solution of 170 mg (0.4 mmole) of VI in 25 ml of glacial acetic acid was treated with 150 mg (15 mmole) of chromium trioxide in 1.5 ml of 90% aqueous acetic acid as described. Ether extraction afforded 163 mg of crystalline material. Recrystallization from chloroform–methanol gave only 50 mg of dione IX, m.p. 140–146°. Three successive crystallizations afforded less than 10 mg of needles, m.p. 149–151°. $\nu_{max}^{CCl_4}$ 1710 cm^{-1} (C_3 and C_6 ketones, double intensity). No hydroxyl bands were present in the infrared spectrum.

Treatment of VII with Chromium Trioxide

To a solution of 20 mg of VII in 5 ml of glacial acetic acid was added 0.2 ml (20 mg) of a solution of chromic trioxide in 90% aqueous acetic acid as described. The reaction followed the general procedure described above, affording 18 mg of a semicrystalline residue, which failed to crystallize. The infrared spectrum was identical with the crude residue obtained from chromic acid oxidation of VI.

ACKNOWLEDGMENTS

We wish to thank the National Research Council for generous financial support. We also wish to thank Mr. I. Wang of our laboratory for having taken the ultraviolet spectrum of the 3,5-cycloketone. We are indebted to Mr. J. Nicholson of the National Research Council, Ottawa, for the nuclear magnetic resonance spectra, Dr. R. Schaffer, American Oil Co., Whiting, Ind., for the mass spectrometry, and to Professor J.C. Richer of the University of Montreal for the ORD curves and to each for his very valuable interpretations.

[12]*It is interesting to note that when the tosylate VII*a *was treated with base as described above, and the reaction followed at intervals by infrared, the anomalous peak at 1740 cm^{-1} reached a maximum (medium to strong band) at 1.5 to 2 hours and gradually disappeared upon complete displacement of the tosyl group. Investigation of this anomalous band was not attempted.*

STEROIDS

VI. THE STEREOCHEMISTRY OF 4-ETHYL-4-METHYLCHOLEST-5-EN-3-ONE (II)[1]

GEORGE JUST AND KEITH ST. C. RICHARDSON[2]
Department of Chemistry, McGill University, Montreal, Que.
Received August 20, 1963

ABSTRACT

The stereochemistry of the title compound was determined.

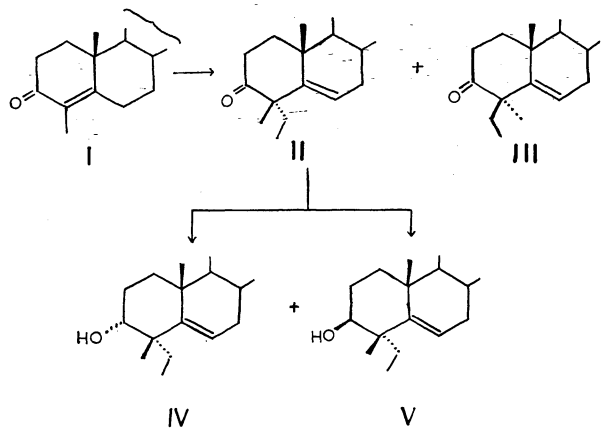
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In the course of the solvolysis of 4,4-dimethylcholesteryl tosylate, some 3,4-dimethylcholestane derivatives were isolated (1). It was shown (2) that their formation was probably due to a 1,3-diaxial interaction of the C_4- and C_{10}-methyl groups, resulting in deformation of the A-ring, since analogous 19-nor steroids give only the expected solvolysis products.

In order to establish whether the 4α or the 4β-methyl group migrated in this solvolysis, it was decided to prepare a 4-ethyl-4-methylcholesteryl derivative of known stereochemistry at C_4. The object of this paper is to describe the preparation and structure proof of such a compound.

Ethylation of 4-methylcholest-4-en-3-one (I) (3) with ethyl iodide and potassium *t*-butoxide in *t*-butanol resulted in the formation of a 70% yield of 4α-ethyl-4β-methylcholest-5-en-3-one (II), obtained by direct crystallization. In addition, small amounts of its isomer III were obtained with difficulty (see Experimental). Ultraviolet and infrared spectroscopy indicated the absence of conjugation in the two epimeric ketones.

FLOWSHEET I



In order to prove the stereochemistry at C_4, a sample of 3α-hydroxy-4-ethyl-4-methylcholest-5-ene was required.

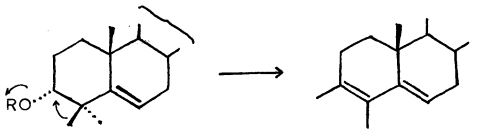
Reduction of ketone II with sodium borohydride in aqueous dimethyl formamide (4),

[1]*This paper forms a part of the Ph.D. thesis of K. St. C. Richardson, to be presented to the Faculty of Graduate Studies and Research, McGill University.*
[2]*Union Carbide Research Fellow 1961–62.*

followed by chromatography of the product gave, upon elution with hexane–benzene (2:1) and crystallization from ether–ethanol, the 3α-alcohol IV, in 17% yield. Elution with benzene ether afforded the 3β-epimer V in 67% yield. The stereochemistry of the alcohols was assigned by analogy with the reduction of the 4,4-dimethyl-3-oxo steroids (2), by their relative ease of elution on alumina (5), by their infrared spectral characteristics (6), and finally by the product derived from solvolysis of their respective mesylates[3].

When the ketone II was reduced with lithium aluminum hydride, the 3α-alcohol IV was obtained in 6% yield. In the corresponding 4,4-dimethyl series, lithium aluminum hydride reduction had resulted in the formation of more than 99% of 4,4-dimethylcholesterol (2).

FLOWSHEET II



VI R=H VII

VIa R=Ts

In the 4,4-dimethylcholestene series, it had been shown that acetolysis of the 3α-tosylate VI*a* gave in virtually quantitative yield 3,4-dimethylcholesta-3,5-diene (VII) (1, 7). In that instance, there was no doubt that the reaction involved the migration of the 4β-(axial) methyl group to C_3 (see flowsheet II). A similar acetolysis should result in the formation of either 3-methyl-4-ethyl- or 3-ethyl-4-methylcholesta-3,5-diene from the 4β-methyl- or the 4β-ethyl-3α-alcohol respectively.

Two dienes VIII and XII were therefore prepared by reaction of the ethyl and methyl Grignard reagents with 4-methyl- and 4-ethylcholest-4-en-3-one (I and X) respectively. The latter ketone X was obtained by monoethylation (3) of cholestenone IX. The infrared and ultraviolet spectra of the two isomeric dienes were very similar. However, the melting point of the two dienes was depressed upon admixture.

Alcohol IV was treated with *p*-toluenesulphonyl chloride in pyridine at room and elevated temperatures for extended periods of time. No tosylate was formed in these attempts. Next, the alcohol IV was treated with phosphorus oxychloride in dry pyridine. There was obtained from this reaction a mixture of dienes, readily separable by chromatography. The diene XIII, m.p. 98–98.5°, $[\alpha]_D$ −35°, obtained in 21% yield, showed no absorption in the ultraviolet above 220 mμ. The structure of diene XIII was assigned by analogy with a similar product obtained on treatment of 4,4-dimethyl-cholest-5-en-3α-ol (VI) with thionyl chloride by Shoppee and Johnson (7). The structural assignment is confirmed by n.m.r. data, which exhibited a complex signal centered at 5.46 p.p.m. (3H, olefinic protons).

The second diene XII, m.p. 101–102°, was obtained in 26% yield (65% by UV) and was identical in all respects with the sample obtained by direct synthesis.

When the 3α-alcohol was treated with methanesulphonyl chloride in pyridine at 0°, an oily, unstable mesylate was obtained. Its infrared spectrum showed the lack of hydroxyl absorption. The ultraviolet spectrum gave no evidence for a conjugated chromophore.

[3]*A report on the solvolysis of 4α-ethyl-4β-methylcholest-5-en-3β-yl mesylate will appear in a future publication.*

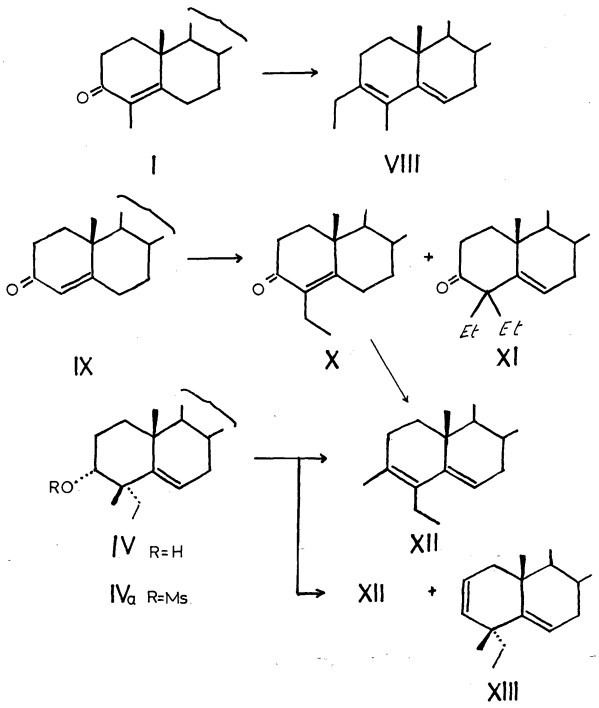
FLOWSHEET III



Solvolysis of the crude mesylate IV*a* in buffered glacial acetic acid gave a conjugated diene. Crystallization afforded 80% of pure 3-methyl-4-ethylcholesta-3,5-diene (XII), m.p. 100–102°, identical in all respects with the sample synthesized from 4-ethylcholestenone (X) and different from 3-ethyl-4-methylcholesta-3,5-diene (VIII). The infrared spectrum of the mother liquors of crystallization revealed only the presence of XII. The stereochemistry at C_4 is hence as depicted by ketone II.

This indicates that steric factors determine the entry of the alkylating agent (8–10). In the absence of steric hindrance, axial entry of the ethyl group (12, 13) would have been the preferred mode of the alkylation.

EXPERIMENTAL[4]

4α-Ethyl-4β-methylcholest-5-en-3-one (II)

A solution of 20g (50 mmole) of 4-methylcholestenone (I) (3), m.p. 101–104° C, λ_{max}^{EtOH} 250 mμ (ε 15,800) in 100 ml of dry *t*-butanol was treated with a solution of 6.3 g (160 matom) of potassium in 160 ml of dry *t*-butanol. To the vigorously stirred solution at 75° was added a solution of 20.3 ml (250 mmole) of ethyl iodide in 50 ml of dry *t*-butanol. The reaction mixture was heated under reflux for 1 hour; the bulk of the solvent was distilled off. The remainder was diluted with cold dilute hydrochloric acid and the organic material extracted with chloroform. The chloroform extract was washed successively with dilute hydrochloric acid, 5% sodium bicarbonate and water, and dried ($MgSO_4$) and the solvent removed under reduced pressure. The infrared spectrum of the yellow amorphous residue (22.5 g) showed carbonyl bands at 1710 cm^{-1} (saturated ketone) and at 1675 and 1610 cm^{-1} (unsaturated ketone). It contained approximately 10%

[4]*All rotations were taken in chloroform on a Carl Zeiss photoelectric precision polarimeter.*
Infrared spectra were taken in carbon tetrachloride solutions. Ultraviolet spectra were measured with a Beckman spectrophotometer, model DK-1.
Melting points were taken on a Kofler hot plate.
Microanalyses were carried out by Dr. C. Daessle, 5757 Decelles Street, Montreal, Quebec.
The commercially available aluminum oxide (Woelm) was used for chromatography.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of the starting Δ^4-ketone I, (λ_{max}^{EtOH} 250 mμ, ϵ 1550). Crystallization from chloroform–ethanol readily afforded 14.85 g (70%) of 4α-ethyl-4β-methylcholest-5-en-3-one (II), m.p. 158.5–160°. Recrystallization for analysis raised the melting point to 160–161°, $[\alpha]_D^{23°}$ 14.7° (*c* 0.33). Anal. Calc. for $C_{30}H_{50}O$: C, 84.44; H, 11.81. Found: C, 84.21; H, 11.83. ν_{max} 1710 cm^{-1} (C_3=O). The mother liquors were chromatographed on alumina (Act. II). Elution with hexane and hexane–benzene (19:1) gave 2.66 g (12.5%) of an intractable semicrystalline mixture of isomeric products II and III. Further elution with hexane–benzene (19:1 and 4:1) afforded 1.75 g (8.2%) of a more easily separable crystalline mixture, m.p. 131–137°. Six consecutive recrystallizations gave 140 mg of pure 4β-ethyl-4α-methylcholest-5-en-3-one (III), m.p. 153.5–154°; admixture of II resulted in depression of the melting point, $[\alpha]_D^{23°}$ 10.6° (*c* 1.08). Anal. Calc. for $C_{30}H_{50}O$: C, 84.44; H, 11.81; Found: C, 84.38; H, 11.70. The infrared spectra of II and III were essentially identical.

Benzene–ether (9:1) eluted 1.2 g (6%) of the starting material, (λ_{max}^{EtOH} 250 mμ, ν_{max} 1670 and 1610 cm^{-1}).

Sodium Borohydride Reduction of Ketone II

To a stirred solution of 4 g (9.4 mmole) of ketone II in 170 ml of redistilled N,N-dimethyl formamide (DMF) was added, dropwise, 4 g of sodium borohydride in 25 ml of water and 55 ml of DMF, at a rate which did not allow precipitation of the starting material. During the period of addition the temperature was maintained at 90–95°, thereafter at 100° for 3 hours, when bubbling ceased. The reaction mixture was then allowed to reflux overnight. The mixture was cooled and the excess hydride carefully destroyed with dilute hydrochloric acid. Water was added to ensure complete precipitation of the organic material. The latter was extracted with ether and the ethereal solution washed successively with cold dilute hydrochloric acid, twice with cold 5% sodium bicarbonate, and three times with water. It was dried ($MgSO_4$) and the solvent removed under reduced pressure, furnishing 4.06 g of a colorless semicrystalline residue.

Chromatography on alumina (Act. II) and elution with hexane–benzene (9:1 and 4:1) gave, after crystallization from chloroform–ethanol, 180 mg (4.5%) of the starting ketone II, m.p. 158–159°, $\nu_{max}^{CCl_4}$ 1710 cm^{-1}.

Elution with hexane–benzene (2:1) gave 800 mg of crystalline product, m.p. 139–144°. Crystallization from ether–ethanol yielded 610 mg (15.2%) of 4α-ethyl-4β-methylcholest-5-en-3α-ol (IV), m.p. 144–145°. The mother liquors gave an additional 70 mg (1.8%) of IV, m.p. 141–143°. Two crystallizations for analysis raised the melting point to 145–145.5°, $[\alpha]_D^{23°}$ −72.5° (*c* 0.85). Anal. Calc. for $C_{30}H_{52}O$: C, 84.03; H, 12.23. Found: C, 83.90; H, 12.32. ν_{max} 3640 cm^{-1} (C_3O—H), and 1080 cm^{-1} (C—O stretch) (13).

The benzene ether eluate (9:1) afforded 2.7 g (67%) of 4α-ethyl-4β-methylcholest-5-en-3β-ol (V), m.p. 120–122°. Crystallization for analysis raised the melting point to 123–123.5°; $[\alpha]_D^{23°}$ −61.5 (*c* 1.51). Anal. Calc. for $C_{30}H_{52}O$: C, 84.03; H, 12.23. Found: C, 84.28; H, 12.44. ν_{max} 3640 cm^{-1} (C_3O—H), 1050, 1040, and 1025 cm^{-1} (equatorial C—O stretch) (6).

Reduction of Ketone II with Lithium Aluminum Hydride

To a stirred suspension of lithium aluminum hydride (2.5 g) in 200 ml of anhydrous ether was added 6.2 g (14.5 mmole) of ketone II in 300 ml of anhydrous ether (14). Excess hydride was destroyed by the dropwise addition of water and 10% sodium hydroxide solution. Filtration of the inorganic solid and removal of the solvent under reduced pressure afforded 6.2 g of a colorless crystalline mixture, m.p. 110–112°, which could not be separated by fractional crystallization; 5.5 g of this mixture was hence chromatographed on alumina (Act. II). Crystallization from ether–ethanol of the hexane–benzene eluates gave 325 mg (5.3%) of 4α-ethyl-4β-methyl-cholest-5-en-3α-ol (IV), m.p. 143.5–145° C, and identified by melting point, mixed melting point, and infrared spectra with the product IV eluted with hexane–benzene from the sodium borohydride reduction. Crystallization of the mother liquors afforded an additional 56 mg (1%), m.p. 141–143°.

The benzene–ether eluate afforded, upon crystallization from ether methanol, alcohol V (2.75 g, 44.2%), m.p. 123–124°. Further recrystallization of mother liquors gave 31.8% of V, m.p. 121–123.5°. The alcohol was identified by the melting point, mixed melting point, and infrared spectra with the alcohol V similarly obtained from chromatography of the previous sodium borohydride reduction product.

4-Ethylcholest-4-en-3-one (X)

A solution of 3.3 g (78 matoms) of potassium and 10 g (26 mmole) of Δ^4-cholesten-3-one (IX), m.p. 82–83° (λ_{max}^{EtOH} 240 mμ, ϵ 16,600) in 450 ml of dry *t*-butanol was heated under reflux for 10 minutes. To the refluxing solution was added dropwise, over a period of 2 hours, a solution of 2.5 ml (31.2 mmole) of ethyl iodide in 200 ml of dry *t*-butanol. The reaction mixture was allowed to reflux an additional 30 minutes, the bulk of the solvent distilled off, and the remainder poured into 150 ml of dilute hydrochloric acid. Extraction with ether gave 10.01 g of yellow oil.

Chromatography on alumina (Act. II–III) and elution with hexane–benzene (19:1) gave 1.71 g (14.7%) of 4,4-diethylcholest-5-en-3-one (XI), m.p. 96–97°. Two crystallizations from ether–methanol for analysis raised the melting point to 96.5–97.5°, $[\alpha]_D^{23}$ 3° (*c* 0.81). Anal. Calc. for $C_{31}H_{52}O$: C, 84.48; H, 11.89. Found: C, 84.20; H, 11.75. $\nu_{max}^{CCl_4}$ 1705 cm^{-1}.

The hexane–benzene eluates (9:1 and 4:1) furnished, upon crystallization from ether–acetone, 2.55 g (24%) of 4-ethylcholest-4-en-3-one (X), m.p. 84–86°. Recrystallization from ether–acetone afforded 2.2 g of crystals, m.p. 87–88° C. Further crystallization for analysis did not raise the melting point, $[\alpha]_D^{23°}$ 93° (*c* 1.58). Anal. Calc. for $C_{29}H_{48}O$: C, 84.40; H, 11.72. Found: C, 84.66; H, 11.82. ν_{max} 1675 and 1610 cm^{-1} (α,β-unsat'd ketone). λ_{max}^{EtOH} 250 mμ (ϵ 17,700).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Further elution with hexane–benzene (1:1) afforded 1.58 g (17%) of the starting material, m.p. 79–81° (ν_{max} 1680 and 1620 cm^{-1}; λ_{max}^{EtOH} 240 mμ).

3-Methyl-4-ethylcholesta-3,5-diene (XII)

To 6 ml of an ethereal solution of methyl magnesium iodide formed from 350 mg of magnesium and 1.7 ml of methyl iodide was added at 0°, a solution of 100 mg (0.24 mmole) of 4-ethyl-cholestenone (X) in 8 ml of anhydrous ether (15). The temperature was gradually raised to the boiling point and the mixture heated under reflux overnight. Cold saturated ammonium chloride was added and the organic material extracted with ether. The ethereal solution was washed successively with cold dilute hydrochloric acid, with cold 5% sodium hydroxide, three times with water, and finally with a saturated sodium chloride solution; it was dried over magnesium sulphate and the solvent removed at reduced pressure. The residual oil exhibited three peaks in the ultraviolet spectrum ($\lambda_{max}^{cyclohexane}$ 283 mμ, 246 mμ, and 235 mμ), consonant with a mixture of heteroannular and homoannular dienes.

Accordingly, the residual oil (116 mg) was taken up in 200 ml of 95% aqueous ethanol, three drops of concentrated hydrochloric acid were added, and the mixture refluxed overnight. The ethanol was distilled off and 50 ml of water was added to the residue. Ether extraction of the organic material furnished 114 mg of crystalline product XII, which upon crystallization from ether–ethanol gave 86 mg (87.2%) of 3-methyl-4-ethylcholesta-3,5-diene (XII) as long needles, m.p. 101–103°. Two crystallizations for analysis raised the melting point to 102.5–103° C, $[\alpha]_D^{23°}$ −129° (*c* 0.32). Anal. Calc. for $C_{30}H_{50}$: C, 87.74; H, 12.27. Found: C, 87.79; H, 12.22. $\lambda_{max}^{cyclohexane}$ 237 mμ (ϵ 19,500), 244.5 mμ (ϵ 20,000), and 253 mμ (ϵ 12,800, inflection) (2,16,17).

3-Ethyl-4-methylcholesta-3,5-diene (VIII)

Ketone I (400 mg, 1 mmole) in 15 ml of anhydrous ether was reacted with ethereal ethyl magnesium iodide prepared from 1.2 g of magnesium and 8 ml (100 mmole) of ethyl iodide in 5 ml of ether as described above (15). Ether extraction of the acid isomerized product (400 mg) afforded, upon crystallization from ether–ethanol, 300 mg (73%) of 3-ethyl-4-methylcholesta-3,5-diene (VIII), m.p. 115–117.5°, as needles. Further crystallization of the mother liquors gave an additional 41 mg (10%), m.p. 117–118°. Recrystallization for analysis raised the melting point to 117.5–118°, $[\alpha]_D^{23°}$ −116° (*c* 0.36). Anal. Calc. for $C_{30}H_{50}$: C, 87.74; H, 12.27. Found: C, 87.55; H, 12.25. $\lambda_{max}^{cyclohexane}$ 237.5 mμ (ϵ 19,400), 245 mμ (ϵ 21,200), and 253 mμ (ϵ 13,400, inflection).

A mixture of diene XII, m.p. 102.5–103° and of diene VIII, m.p. 117.5–118°, melted at 100–104.5°.

Reaction of 4α-Ethyl-4β-methylcholest-5-en-3α-ol (IV) with Phosphorus Oxychloride

Ten milliliters of phosphorus oxychloride was added to a solution of 450 mg (1.0 mmole) of IV in 25 ml of dry pyridine at room temperature. The reaction mixture was kept at 40° for 12 hours. Infrared analysis of an aliquot indicated the presence of sizable amounts of starting material. The reaction mixture was, therefore, heated for an additional 24 hours at 60°, cooled, then carefully poured into 200 ml of ice water and extracted with ether. The ethereal solution was washed successively with dilute hydrochloric acid, 5% sodium bicarbonate, water, and finally a saturated solution of sodium chloride. It was dried over magnesium sulphate and the solvent removed at reduced pressure, affording 400 mg of yellow oil. The ultraviolet spectrum of the crude product showed the presence of about 65% of the conjugated diene XII ($\lambda_{max}^{cyclohexane}$ 244.5 mμ, ϵ 12,700).

Chromatography on alumina (Act. I) and elution with hexane afforded 104 mg of colorless oil. Crystallization from ether–ethanol gave 86 mg (20.9%) of leaflets, m.p. 95–97°, which depressed upon admixture with dienes VIII and XII. Recrystallization from the same mixed solvents gave a product melting sharply at 98–98.5°, $[\alpha]_D^{23}$ −35° (*c* 0.64)[5]. No absorption maxima above 220 mμ were recorded in the ultraviolet spectrum.

Further elution with hexane and hexane–benzene (19:1) afforded 124 mg of crystalline material, which, upon recrystallization from ether–ethanol, gave 101 mg (24.6%) of diene XII, m.p. 99.5–102°. Recrystallization gave sharply melting needles, m.p. 101–102°, which was depressed upon admixture with VIII, but not with the diene XII obtained by direct synthesis; $[\alpha]_D^{23°}$ −129° (*c* 0.37), $\lambda_{max}^{cyclohexane}$ 237 mμ (ϵ 18,800), 244.5 mμ (ϵ 19,600), and 253 mμ (ϵ 12,600 inflection).

4α-Ethyl-4β-methylcholest-5-en-3α-yl Methanesulphonate (IVa)

To a chilled solution of 200 mg (0.47 mmole) of alcohol IV in 2.5 ml of dry pyridine was added 1 ml of methanesulphonyl chloride and the mixture kept at 0° for 2 hours, with continuous stirring. The mixture was poured over crushed ice and extracted with ether after 30 minutes. The ethereal solution was washed successively with cold dilute hydrochloric acid, cold 5% sodium bicarbonate solution, water, and finally a saturated solution of sodium chloride. It was dried ($MgSO_4$) and the solvent removed under reduced pressure at 30°. A pale yellow crystalline residue IV*a* (293 mg) was obtained. The infrared spectrum showed medium to strong bands at 1415, 1385, 1340, 1180, 963, and 900 cm^{-1}, associated with the expected frequencies of

[5]*The non-absorbing diene XIII has been assigned on analogy with 4,4-dimethylcholesta-2,5-diene (m.p. 92–93° $[\alpha]_D$ −37°, rising ultraviolet end-absorption) obtained in the work of Shoppee and Johnson (7).*

For personal use only.

a mesyl group. The ultraviolet spectrum exhibited no absorption maximum above 220 mμ. Owing to the extreme instability of the mesylate IV*a*, the product could not be recrystallized.

Acetolysis of Mesylate IVa

A stirred solution of the crude mesylate IV*a* (293 mg) and 100 mg of anhydrous sodium acetate in 40 ml of glacial acetic acid was heated at 60° for 5 hours. The reaction mixture was cooled, poured into 400 ml of ice water, and extracted with ether. The ethereal solution was worked up in the usual manner, yielding 190 mg of crystalline product XII. Recrystallization from ether–ethanol afforded 145 mg (80%) of needles, m.p. 98–100°. Two recrystallizations raised the m.p. to 100–102°, $[\alpha]_D^{23°}$ −130° (*c* 0.34). $\lambda_{max}^{cyclohexane}$ 237 mμ (ε 18,400), 244.5 mμ (ε 19,000), and 253 mμ (ε 12,200 inflection). The product upon admixture with diene VIII gave a depression of the mixture melting point, which was not observed with the authentic sample of XII. The infrared and ultraviolet spectra of the mother liquors revealed the presence of diene XII only.

ACKNOWLEDGMENTS

We wish to thank the National Research Council for generous financial support, and Dr. Stammer of this Department for taking the n.m.r. spectra.

STEROIDS

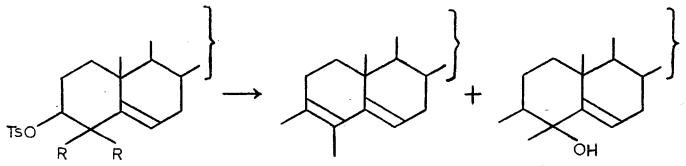
VII. THE SOLVOLYSIS OF 4,4-DIMETHYL-17β-ACETOXY-ESTR-5-EN-3-YL *p*-TOLUENESULPHONATE[1, 2]

GEORGE JUST AND F. E. SHORTLAND[3, 4]
Department of Chemistry, McGill University, Montreal, Quebec
Received August 20, 1963

ABSTRACT

The solvolysis of the title compound resulted mainly in products of ring contraction. No product of methyl shift could be detected.

In the solvolysis of 4,4-dialkylcholesteryl *p*-toluenesulphonate (I), it had been noticed that 6–20% of the 3,4-dimethylcholestane derivatives II and III were formed (1, 2). To establish if these unexpected rearrangement products were due to a deformation of ring



I R=CH_3 II III

A arising from the 1,3-diaxial interaction of the alkyl groups at C-4 and C-10, the solvolysis of 19-norsteroids was studied.

Starting Materials

A suitable intermediate for this investigation was the recently described 4,4-dimethyl-estr-5-en-17β-ol-3-one (IV)(3), which can be obtained by a 5-step reaction from estrone* (3, 4).

Acetylation of the 17β-alcohol IV gave 4,4-dimethyl-17β-acetoxyestr-5-en-3-one IV*a*, m.p. 135.5–136°, $[\alpha]_D$ −10.6°. The acetate IV*a* possessed infrared absorption maxima at 1707 cm^{-1} (ketone)and 1737 cm^{-1} (acetate) and the elemental analysis agreed well with the molecular formula $C_{22}H_{32}O_3$.

The reduction of 4,4-dimethyl-17β-acetoxyestr-5-en-3-one (IV*a*) using a slight excess of sodium borohydride in dimethyl formamide (5), followed by careful chromatography, resulted in the formation of very small amounts of 3α-alcohol VI, m.p. 144–147°, which was not depressed on admixture with the corresponding β-alcohol,* m.p. 184.5–185°. A comparison of infrared absorption curves in the 3400–3650 cm^{-1} region revealed small but constant differences between the two epimers. For example, with identical concentrations, 4,4-dimethyl-17β-acetoxyestr-5-en-3α-ol (VI) absorbed at 3642 cm^{-1} (CCl_4, hydroxyl) whilst 4,4-dimethyl-17β-acetoxyestr-5-en-3β-ol (V) possessed a maximum at 3635 cm^{-1} (CCl_4, hydroxyl).

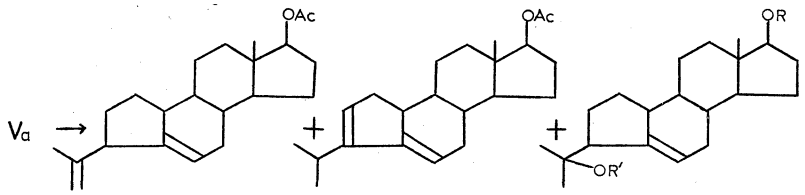
The 3α-alcohol VI was reacted with *p*-toluenesulphonyl chloride for 12 days at room temperature to give 4,4-dimethyl-17β-acetoxyestr-5-en-3α-ol 3-*p*-toluenesulphonate (VI*a*) in 75% yield. Because of decomposition of the tosylate when reacted for longer periods, the reaction was interrupted before completion. An oily residue was isolated which still contained 25% unreacted starting alcohol VI.

Reduction using aluminum isopropoxide in isopropanol (6) resulted in hydrolysis of the 17-acetate group without reduction of the carbonyl function.

Solvolysis of 4,4-Dimethyl-17β-acetoxyestr-5-en-3β-ol 3-p-Toluenesulphonate

The acetolysis of 4,4-dimethyl-17β-acetoxyestr-5-en-3β-ol 3-*p*-toluenesulphonate (V*a*) was effected by maintaining a sodium acetate buffered glacial acetic acid solution of the sulphonate at 50° for 50 hours. The resulting oil was chromatographed on aluminum oxide. Hexane eluted 11% of a non-conjugated diene monoacetate VII, followed closely by 22% of a conjugated diene monoacetate VIII. Hexane–benzene mixtures gave 53% of a diacetate IX*a*.

Acetone–water solvolysis of 4,4-dimethyl-17β-acetoxyestr-5-en-3β-ol 3-*p*-toluenesulphonate (V*a*) was carried out at the reflux temperature for 20.5 hours using sodium



VII VIII IX R=Ac, R'=H

IXa R=R'=Ac

IXb R=R'=H

acetate buffer. The resulting oil was chromatographed on aluminum oxide. Hexane and hexane–benzene (95:5) eluted 20% of a non-conjugated diene monoacetate which was identical with the acetolysis diene VII. A conjugated diene monoacetate was next eluted in 7.5% yield and was found to have the same ultraviolet spectrum as the conjugated

**For the β-alcohol V, see the experimental section.*

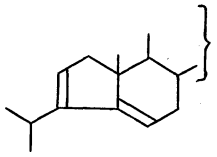
X



XI

diene VIII derived from the acetolysis. Continued elution with hexane–benzene (1:1 and 1:2) gave 66.5% of ring-contracted diol monoacetate IX.

Both ring-contracted dienes VII and VIII gave a water-soluble sodium salt on refluxing in methanolic sodium hydroxide. This behavior pointed to the formation of a cyclopentadienyl anion X. Under the same conditions the ring-contracted diol monoacetate IX quantitatively gave the diol IX*b*.

Diene monoacetate VII, derived from both solvolyses, did not absorb between 220 and 350 mμ and hence was not conjugated. Infrared analysis revealed, in particular, strong absorption at 3060, 1641, and 887 cm^{-1} (CCl_4) typical for an exomethylene double bond. The only structure compatible with the lack of significant absorption between 220 mμ and 350 mμ, the infrared evidence, and the formation of a cyclopentadienyl anion upon treatment with strong alkali, is that proposed in VII. As will be shown below, it is also compatible with the proposed mechanism of the solvolysis.

Diene monoacetate VIII exhibited a characteristic ultraviolet absorption pattern, λ_{max} 244 mμ (ϵ 9700), 252 mμ (10,000) and 262 mμ, inflection (6600), which was very similar to that assigned to the $\Delta^{2,5}$-diene XI, λ_{max} 244.5 mμ (ϵ 15,500), 252 mμ (16,600), and 261.5 mμ (10,400), encountered in the cholesterol series (1). This makes VIII the probable structure for this conjugated diene, although other formulations cannot be rigorously ruled out.

Hydrolysis of the diol monoacetate IX in 5% methanolic potassium hydroxide gave diol IX*b*, m.p. 168–168.5°, $[\alpha]_D$ −1.4°, for which the elemental analysis agreed with the empirical formula $C_{20}H_{32}O_2$. Reacetylation with acetic anhydride in pyridine for 16 hours at room temperature regenerated the diol monoacetate IX. This indicated that the unesterified alcohol was tertiary. Oxidation of IX with chromium trioxide in pyridine resulted in the recovery of unchanged starting material, further confirming the tertiary nature of the alcohol. A solution of the diol IX*b* in glacial acetic acid was hydrogenated using Adam's catalyst. One equivalent of hydrogen was absorbed. The resulting saturated alcohol XII was acetylated at room temperature, yielding a diol monoacetate XII*a* (ν^{CCl_4}, 3610 cm^{-1} hydroxyl and 1733 cm^{-1} acetate). The alcohol therefore did not suffer hydrogenolysis, a finding which was in direct contrast to results obtained in the cholesterol series (1).

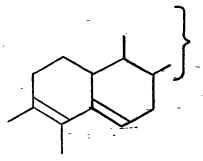
For personal use only.

The reaction of phosphorus oxychloride in pyridine on diol IX*b* resulted in the production of an oil which contained at least two dienes. Ultraviolet absorption analysis of the above oil revealed the following absorption maxima in cyclohexane: 244 mμ (ε 7800), 252 mμ (6700), and 262 mμ, inflection (5200). Comparison of ε-values with those obtained in the cholesterol series indicated the possible presence of approximately 40% of the $\Delta^{2,5}$-diene XIII. However, the relative ratios of ε-values were somewhat high between 240 mμ and 250 mμ, showing that some other diene similar to XIV (λ_{max} 250 mμ, ε 13,300) or XV (λ_{max} 243 mμ, ε 9250) might also have been formed. Substituted cyclopentadiene compounds have been shown (7) to absorb in the region of 243 mμ and could account for the enhanced ultraviolet absorption indicated. Too little material was available to investigate in detail the composition of this mixture.

Solvolysis of 4,4-Dimethyl-17β-acetoxyestr-5-en-3α-ol 3-p-Toluenesulphonate

The *p*-toluenesulphonate VI*a* was dissolved in glacial acetic acid, containing excess sodium acetate, and solvolyzed at 52° for 3 days. Examination of an aliquot showed that the reaction was not complete. Hence, the mixture was heated to reflux for 12 hours. A yellow oil was isolated which in addition to containing unchanged 4,4-dimethyl-17β-acetoxyestr-5-en-3α-ol (VI) also contained an olefinic acetate. The crude solvolysis oil possessed ultraviolet absorption maxima at 236 mμ (ε 11,000), 243 mμ (18,000), and 252 mμ, inflection (6930). A comparison of this absorption data with that obtained for 3,4-dimethylcholesta-3,5-diene (II), λ_{max} 236 mμ (ε 19,500), 243 mμ (19,900), and 252 mμ, inflection (12,800), indicated that the acetolysis of 4,4-dimethyl-17β-acetoxyestr-5-en-3α-ol 3-*p*-toluenesulphonate (VI*a*) produced 56% of methyl-shifted diene XVI. The absorption at 243 mμ is obviously elevated because of the presence of at least one more conjugated diene. As indicated previously, cyclopentadiene compounds absorb precisely in this range. Hence the presence of a cyclopentadiene contaminant cannot be ignored



XVI

in accounting for the remaining acetolysis products. Since only small amounts of the 3α-epimer were available, the study was discontinued.

However unsatisfactory these results are with respect to the identification of the products, they show clearly that 3α-hydroxyestrene derivatives also give products of methyl shift, similar to those obtained in the cholesteryl series, and that they could easily be detected. It can therefore be concluded that no significant amount of methyl-shifted product was formed in the solvolysis of 4,4-dimethyl-17β-acetoxyestr-5-en-3β-ol 3-*p*-toluenesulphonate.

EXPERIMENTAL

(*a*) All melting points were corrected.
(*b*) The commercially available aluminum oxide (Woelm) was used for chromatography.
(*c*) All ether solutions were dried over anhydrous magnesium sulphate.

Acetylation of 4,4-Dimethylestr-5-en-17β-ol-3-one (3) (IV)

A solution of 1.215 g of the 17β-alcohol IV, m.p. 143.5–144.5°, in 10 ml of pyridine and 10 ml of acetic anhydride was allowed to stand overnight at room temperature. The pyridine solution was poured into iced

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

5% hydrochloric acid and extracted with ether. Washing with water, followed by drying and evaporation, gave 1.315 g of colorless residue, m.p. 131–132°. A single recrystallization from acetone–water raised the melting point to 133.5–134° (1.03 g). Two further recrystallizations gave pure 4,4-dimethyl-17β-acetoxyestr-5-en-3-one, m.p. 135.5-136°, $[\alpha]_D^{15}$ −10.6° (*c*, 0.946), ν^{CCl_4} 1707 cm^{-1} (carbonyl) and 1737 cm^{-1} (acetate). Anal. Calc. for $C_{22}H_{32}O_3$: C, 76.74; H, 9.30. Found: C, 76.29; H, 9.34.

Sodium Borohydride Reduction of 4,4-Dimethyl-17β-acetoxyestr-5-en-3-one (IVa)

A solution of 1.03 g of ketone IV*a*, m.p. 135.5–136°, in 25 ml of methanol was added to a solution of 119 mg of sodium borohydride in 10 ml of methanol and 2 ml of water. The mixture was stirred for 20 minutes at room temperature and diluted with 40 ml of water. Extraction with ether followed by washing with water, drying, and evaporation to dryness gave 1.06 g of colorless residue, m.p. 174–175°. Difficulty was experienced in obtaining a suitable recrystallizing solvent system.

The reduced product (1.06 g) was chromatographed on 35 g of aluminum oxide (activity II–III). Hexane–benzene (4:1) eluted 244 mg of colorless residue, melting range 174.5–182.5°. Rechromatography of this fraction gave 114 mg of the 3β-alcohol, m.p. 184–186°, which did not give a melting point depression with the main alcohol fractions.

Further elutions with hexane–benzene (4:1) gave 846 mg of pure alcohol V, m.p. 184.5–185.5°, ν^{CCl_4} 3655 cm^{-1} (hydroxyl) and 1735 cm^{-1} (acetate). Anal. Calc. for $C_{22}H_{34}O_3$: C, 76.25; H, 9.83. Found C, 76.50; H, 9.91.

Repeated chromatography of the initial fractions on aluminum oxide and silica gel failed to produce any detectable amounts of the α-epimer VI.

Hydrolysis of 4,4-Dimethyl-17β-acetoxyestr-5-en-3β-ol (V)

A solution of the 17β-acetate V (30 mg, m.p. 184.5–185°) in 5% methanolic potassium hydroxide (20 ml) was refluxed for 60 minutes. The reaction mixture was poured into cold water and extracted with ether. After it was washed with water and dried, the ether solution, on evaporation, yielded 32 mg of an oily residue. Recrystallization from aqueous methanol gave 19 mg of diol V*b*, m.p. 193.5–194.5°, $[\alpha]_D$ +8° (*c*, 1.32) (m.p. 192–194°, $[\alpha]_D$ +4°) (3).

Preparation of 4,4-Dimethyl-17β-acetoxyestr-5-en-3β-ol 3-p-Toluenesulphonate (Va)

To a solution of 620 mg of alcohol V, m.p. 184.5–185°, in 20 ml of pyridine was added 1.0 g of *p*-toluenesulphonyl chloride and the mixture allowed to stand at room temperature for 6 days. The pyridine solution was poured on crushed ice and the ether extract washed initially with iced 5% hydrochloric acid and finally with iced water. Drying followed by evaporation *in vacuo* gave 0.98 g of colorless tosylate V*a*, m.p. 134° dec., ν^{CCl_4} 1735 cm^{-1} (acetate), 1188 cm^{-1}, and 1178 cm^{-1} (tosylate); $\lambda_{max}^{ethanol}$ 225 mμ, ε 13,500.

Acetolysis of 4,4-Dimethyl-17β-acetoxyestr-5-en-3β-ol 3-p-Toluenesulphonate (Va)

A solution of 100 mg of toluenesulphonate V*a*, m.p. 134° dec., in 30 ml of glacial acetic acid was buffered with 75 mg of sodium acetate and maintained at 50° for 50 hours. The reaction mixture was poured into a large volume of iced water and extracted with ether. Washing was carried out with 5% sodium bicarbonate solution and water. The ethereal layer was finally dried and evaporated to dryness. A yellow oil (80 mg) resulted.

On chromatography, using 5 g of aluminum oxide (activity II–III), hexane eluted 9 mg (11%) of oil which failed to crystallize and possessed no characteristic ultraviolet absorption. The infrared analysis (CCl_4) revealed absorption at 1735 cm^{-1} (acetate), 3080 cm^{-1}, 1641 cm^{-1}, and 887 cm^{-1}, strong (exomethylene). The compound was assigned structure VII.

Further elution with hexane gave 17 mg (22%) of oil, $\lambda_{max}^{ethanol}$ 244 mμ, ε 14,550, 252 mμ, ε 15,840, 261 mμ, inflection, ε 13,200. The ultraviolet absorption pattern for this compound was very similar to that of diene XI in the cholesterol series and was assigned the structure VIII.

Hexane–benzene mixtures eluted initially 9 mg of oil followed by 32 mg of oily crystals, representing a total of 53%. Infrared analysis (CCl_4) indicated absorption in the region of 1735 cm^{-1}, broad, very strong (diacetate). Diacetate IX*a* possessed no characteristic ultraviolet absorption.

Solvolysis of 4,4-Dimethyl-17β-acetoxyestr-5-en-3β-ol 3-p-Toluenesulphonate (Va) in Aqueous Acetone

To a solution of 750 mg of tosylate V*a*, m.p. 134° dec., in 180 ml of acetone was added a solution of 400 mg of sodium acetate in 18 ml of water. The mixture was refluxed for 20.5 hours, then cooled and most of the acetone was evaporated *in vacuo*. The residual aqueous oily liquor was extracted with ether, the ethereal layer washed well with iced water, dried, and evaporated to dryness. The resulting oil (0.52 g) possessed no infrared absorption (CCl_4) in the region 1175–1190 cm^{-1}, indicating complete solvolysis.

The solvolysis oil was chromatographed on 25 g of aluminum oxide (activity II–III). Hexane and hexane–benzene (95:5) eluted 126 mg, 25% (second run 15%), of a colorless oil (VII) which failed to crystallize, ν^{CCl_4} 1732 cm^{-1} (acetate), 3060 cm^{-1} (double bond), and 887 cm^{-1}, strong and sharp (exomethylene). Hydroxyl absorption was absent. Ultraviolet analysis revealed no recognizable characteristics.

Hexane–benzene (95:5) eluted 35 mg, 7% (second run 8%), of an oily residue (VIII), ν^{CCl_4} 1735 cm^{-1} (acetate), $\lambda_{max}^{ethanol}$ 244 mμ, ε 9700, 252 mμ, ε 10,000, and 262 mμ (inflection), ε 6000. The ultraviolet absorption

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

pattern is typical for the assigned $\Delta^{2,5}$-diene XI, $\lambda_{max}^{cyclohexane}$ 244 mμ (ϵ 15,000), 252 mμ (16,300), and 262 mμ (10,700), encountered in the cholesteryl series.

Hexane–benzene (1:1 and 1:2) and benzene eluted 325 mg, 63% (second run 70%), of colorless oil (IX) which readily crystallized on moistening with methanol, m.p. 88–91°, ν^{CCl_4} 3630 cm^{-1} (hydroxyl), 1735 cm^{-1} (acetate), and 1670 cm^{-1} (double bond). Attempted recrystallization from the normal solvents failed to give good crystalline form. Alcohol IX was therefore characterized by its diol derivative IX*b* described below.

Reaction of Diene VII with 5% Methanolic Sodium Hydroxide

Diene VII (50 mg) was dissolved in 15 ml of 5% methanolic sodium hydroxide and gently refluxed for 60 minutes. The solution turned from a pale yellow coloration to an intense brown-red. On extraction of the solution with ether, followed by three water washes, most of the colored material transferred to the aqueous phase. The ether layer was dried and evaporated *in vacuo* to yield 30 mg of pale yellow oil.

The aqueous layer was acidified with a few drops of concentrated hydrochloric acid and re-extracted with ether. After washing with water, the ether layer was dried and evaporated to give 17 mg of oil, a total of 47 mg.

Reaction of Diene VIII with 5% Methanolic Sodium Hydroxide

Diene VIII (33 mg) was refluxed in 15 ml of 5% methanolic sodium hydroxide for 60 minutes and extracted as given in the previous experiment. The neutral ether extract gave 22 mg of oil whilst the acidified alkaline extract gave 9 mg of oil, totalling 31 mg overall.

Reaction of Alcohol IX with 5% Methanolic Sodium Hydroxide

Alcohol IX (295 mg, m.p. 88–91°) was refluxed in 30 ml of 5% methanolic sodium hydroxide for 60 minutes. The reaction mixture was cooled and most of the methanol removed *in vacuo*. Ether (300 ml) was added and the ether solution washed with water until neutral. It was then dried and the ethereal solution evaporated *in vacuo* to yield 294 mg of a colorless residue, m.p. 164–167°. Successive recrystallizations from methanol–water (1:1) gave 183 mg of pure diol IX*b*, m.p. 168–168.5°, $[\alpha]_D^{27}$ −1.41° (*c*, 0.71), ν^{CCl_4} 3620 cm^{-1} (hydroxyl), 3030 cm^{-1}, and 1662 cm^{-1} (double bond), 1154 cm^{-1} (tert. alcohol), 1052 cm^{-1} (sec. alcohol). Anal. Calc. for $C_{20}H_{32}O_2$: C, 78.93; H, 10.52. Found: C, 78.71; H, 10.48.

Acetylation of Ring-contracted Diol IXb

Diol IX*b* (53 mg, m.p. 168°) was dissolved in 2 ml of pyridine and 1 ml of acetic anhydride added. After standing overnight at room temperature, the reaction mixture was poured on iced 5% hydrochloric acid. Extraction with ether followed by aqueous washes, drying, and evaporation to dryness gave 64 mg of crystals, m.p. 85–86°. Mixed melting points with the original solvolysis alcohol–acetate IX gave no depression. A comparison of the infrared absorption curves obtained from the solvolysis acetate and the synthesized acetate, in both carbon disulphide and carbon tetrachloride, indicated no detectable difference.

Chromium Trioxide – Pyridine Oxidation of Ring-contracted Acetate IX (8)

Acetate IX (13 mg, m.p. 88–91°) was dissolved in 0.25 ml of pyridine and a solution of 25 mg of chromium trioxide in 0.25 ml of pyridine added. The reaction mixture was gently agitated for 30 minutes and then allowed to stand at room temperature overnight. After pouring on iced 5% hydrochloric acid, extraction with ether was carried out. Three water washes rendered the ethereal layer neutral. After drying, evaporation to dryness yielded an oily residue. A comparison of infrared curves showed no difference between that of the reaction product and the starting material.

Hydrogenation of Ring-contracted Diol IXb

A glacial acetic acid solution of diol IX*b* (9 mg, m.p. 168°) was hydrogenated at room temperature using Adam's catalyst. One equivalent of hydrogen was quickly taken up. The hydrogenation was continued for a further 3 hours without detectable hydrogen uptake. The hydrogenation mixture was diluted with ether and filtered. Numerous washings with 10% sodium bicarbonate solution, followed by water washes, rendered the ether layer neutral. After drying, the ether solution was evaporated *in vacuo* to give 8 mg of a colorless oil.

Without further examination, the hydrogenation product XII was dissolved in 2 ml of pyridine, 2 ml of acetic anhydride added, and the mixture was allowed to stand at room temperature overnight. The pyridine solution was added to iced 5% hydrochloric acid, extracted with ether and the extract washed well with water. When the solution was dried and evaporated to dryness, a pale yellow oil (XII*a*) resulted; ν^{CCl_4} 3610 cm^{-1} (hydroxyl) and 1733 cm^{-1} (acetate). It was not possible to detect any absorption due to unsaturation.

Reaction of Phosphorus Oxychloride – Pyridine with Ring-contracted Diol IXb

A solution of 5 mg of diol IX*b* in 1 ml of pyridine was treated with 0.5 ml of phosphorus oxychloride and allowed to stand overnight at room temperature. With cooling, a careful addition of ice was made and the whole extracted with ether. After water washing, the ether solution was dried and evaporated *in vacuo*. A pale yellow oil (5 mg) was obtained; ν^{CCl_4} 3030 cm^{-1} (double bond), $\lambda_{max}^{cyclohexane}$ 244.5 mμ, ϵ 7800; 252 mμ,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ϵ 6700 and 262 mμ (inflection), ϵ 5200. On the basis of ultraviolet absorption values obtained for the assigned $\Delta^{2,5}$-diene XI, $\lambda_{max}^{cyclohexane}$ 244.5 mμ (ϵ 15,500), 252 mμ (16,600), and 261.5 mμ (10,400), the presence of 41% of diene XIII is indicated.

Anhydrous Sodium Borohydride Reduction of 4,4-Dimethyl-17β-acetoxyestr-5-en-3-one (IVa)

Ketone IV*a*, m.p. 139° (2.263 g), was dissolved in anhydrous dimethyl formamide (b.p. 152–153°) and 0.390 g (1.5 equivalents) of sodium borohydride added. Refluxing was carried out for 20 minutes. The cooled reaction mixture was poured on 300 ml of iced water containing 10 ml of concentrated hydrochloric acid. Extraction with ether was carried out and the ether solution washed four times with water before drying *in vacuo*. The resulting colorless residue (2.27 g) was chromatographed on 100 g of silica gel (Davison).

Careful elution with benzene–ether (98:2) at first gave 31 mg of oil followed by 62 mg of crystalline 3α-alcohol VI, m.p. 141–147°. Further elution with the same solvent system gave 412 mg of colorless residue, m.p. 162.5–164°, followed by 286 mg, m.p. 167–169°.

Ether (100%) gave 1.50 g of colorless residue, m.p. 167–169°. A 5% methanolic potassium hydroxide hydrolysis of a representative sample taken from the latter fractions gave a diol, m.p. 185–187°. The diol did not give a melting point depression on admixture with an authentic sample of diol V*b* and the infrared absorption curves were superimposable.

Rechromatography of 300 mg of material, m.p. 162.5–164°, on 60 g of silica gel (Davison) yielded a further 28 mg of 3α-alcohol, m.p. 148–150°.

The low melting fractions of 3α-alcohol were combined (90 mg) and recrystallized repeatedly from methanol to give pure material, m.p. 144–147°; ν^{CCl_4} 3642 cm^{-1} (hydroxyl), 1733 cm^{-1} (acetate), 3050 cm^{-1}, and 1652 cm^{-1} (double bond). Anal. Calc. for $C_{22}H_{34}O_3$: C, 76.26; H, 9.86. Found C, 76.30; H, 9.73.

Comparison of 4,4-Dimethyl-17β-acetoxyestr-5-en-3α- and -3β -ols

Upon admixture, no melting point depression was observed. Infrared curves were recorded for both epimers on the Perkin–Elmer 421 spectrophotometer. An enlarged scale for the 3000–3600 cm^{-1} region was used. Extreme care was taken in using identical concentrations. 3α-Hydroxy: ν^{CCl_4} 3642 cm^{-1} (hydroxyl). 3β-Hydroxy: ν^{CCl_4} 3635 cm^{-1} (hydroxyl).

Preparation of 4,4-Dimethyl-17β-acetoxyestr-5-en-3α-ol 3-p-Toluenesulphonate (VIa)

The 3α-alcohol VI (86 mg, m.p. 144–147°) was dissolved in 8 ml of pyridine and 100 mg of *p*-toluenesulphonyl chloride added. After standing at room temperature for 12 days, the pyridine solution was poured on crushed ice. Extraction with ether was carried out followed by iced 5% hydrochloric acid and water washes. The ethereal layer was dried and evaporated *in vacuo*. A yellow oily solid (100 mg) resulted, ν^{CCl_4} 3640 cm^{-1} (hydroxyl), 3050 cm^{-1} (double bond), 1733 cm^{-1} (acetate), 1189 cm^{-1}, and 1180 cm^{-1} (tosylate); $\lambda_{max}^{ethanol}$ 224–225 mμ, ϵ 9000.

Acetolysis of 4,4-Dimethyl-17β-acetoxyestr-5-en-3α-ol 3-p-Toluenesulphonate (VIa)

Toluenesulphonate VI*a* (100 mg) was dissolved in 15 ml of glacial acetic acid and 100 mg of sodium acetate added. The reaction mixture was maintained at 52° for 3 days. Examination of an aliquot indicated incomplete reaction, hence the acetolysis was continued at reflux temperature overnight. On cooling, the solvolysis mixture was extracted with ether and the extract washed twice with water, four times with 10% sodium bicarbonate solution, three times with water, dried and evaporated to dryness to give 75 mg of yellow oil; ν^{CCl_4} 3640 cm^{-1} (hydroxyl), 3050 cm^{-1} (double bond), and 1733 cm^{-1} (acetate); $\lambda_{max}^{cyclohexane}$ 236 mμ (ϵ 11,000), 243 mμ (ϵ 18,000), and 252 mμ, inflection (ϵ 6930). On the basis of ultraviolet absorption data derived from methyl-shifted diene II ($\lambda_{max}^{cyclohexane}$ 236 mμ, ϵ 19,500; 243 mμ, ϵ 19,000; and 252 mμ, inflection, ϵ 12,800), the presence of 56% methyl-shifted diene XVI is indicated.

NOTES

ON THE EQUILIBRIUM ATTAINED BY ELECTROLYTIC SOLUTIONS UNDER IONIZING RADIATION*

J. R. COLEMAN

Henderson *et al.* (1) irradiated a number of redox systems in aqueous solution and measured the resulting potentials at a platinum electrode. They observed in each case a potential of 0.83–0.88 v referred to a hydrogen electrode in the same solution, or approximately 0.85–0.06 pH, referred to the normal hydrogen electrode.† These results were advanced in support of a suggestion by Dainton and Collinson (2) that aqueous solutions under prolonged irradiation might attain a steady state in which the reducing and oxidizing actions of irradiation products and (or) intermediates were equal and opposed. Dainton and Collinson called the potential corresponding to this state the equivalent redox potential (e.r.p.). It was subsequently pointed out (3–5) that Bockris and Oldfield (6) had found a very similar behavior and pH dependence while measuring potentials produced by H_2O_2 solutions at a platinum electrode, and it was shown by Feates and Knight (5) that the potentials observed by Henderson *et al.* could be reproduced by adding H_2O_2 to aqueous H_2SO_4. It was decided to repeat certain of these experiments, analyzing where possible for substances that might affect or determine the potential.

Dainton and Collinson's original estimate of the e.r.p. (0.94 v) was based on the work of Lefort (7) on nitrite and nitrate systems. A later investigation of the nitrite system (8) suggested the necessity of repeating this work.

EXPERIMENTAL

The apparatus and experimental procedures have been described by Henderson *et al.* The apparatus was modified to permit sampling by expulsion of aliquots of solution with inert gas during brief intermissions in irradiation. All experiments were carried out in N_2- or argon-saturated solution. X- and Co^{60} γ-radiation were used at dose rates of 4 to 6×10^{14} ev ml^{-1} sec^{-1}. All potentials are reported with respect to a hydrogen electrode in the same solution.

H_2O_2 was determined by titanium sulphate reagent (9) and NO_2^- by a variation of the Griess method (10). I_2 was determined by the optical density maximum at 460 mμ in aqueous solution. As I_2 and I_3^- have the same extinction coefficient at 465 mμ (11), measurements at 460 mμ give $(I_2+I_3^-)$ as I_2 with sufficient accuracy. Ferric and ceric ion were determined spectrophotometrically at 305 and 330 mμ, at 24° (12, 13).

RESULTS

Nitrite–Nitrate

Lefort reported that $NaNO_2$ and $NaNO_3$ in neutral unbuffered solution (10^{-3} *M*) reached on irradiation an equilibrium in which about 4×10^{-4} *M* NO_2^- and 6×10^{-4} *M* NO_3^- were present, and this, together with the E_0 of the HNO_2/NO_3^- couple, 0.94 v (14), led Dainton and Collinson to propose 0.95 v for the e.r.p. Lefort analyzed for NO_2^- by determining the I_2 produced in acidified solution by the reaction

$$HNO_2 + I^- + H^+ \rightarrow NO + \tfrac{1}{2}I_2 + H_2O$$

when excess KI was added. H_2O_2, subsequently demonstrated to be present by Schwarz and Allen (8), would also oxidize I^- to I_2 by

$$2H^+ + H_2O_2 + 2I^- \rightarrow I_2 + 2H_2O.$$

*Issued as D.R.C.L. Report No. 419.
†European sign convention.

Lefort's experiments were therefore repeated, analyzing for NO_2^- and H_2O_2 as in the experimental part above. Analysis disclosed that, beginning with either 10^{-3} *M* $NaNO_2$ or $NaNO_3$, only about 1.1×10^{-5} *M* NO_2^- was present finally, while H_2O_2 built up to a concentration of 1.75×10^{-4} *M*. As H_2O_2 is twice as efficient as NO_2^-, mole for mole, in oxidizing I^- to I_2, it was concluded that Lefort's results could be accounted for by the presence of H_2O_2, the final ratio NO_2^-/NO_3^- being 1:90 and not 4:6.

Iron and Cerium Sulphates

When solutions of $FeSO_4$ (5×10^{-4} *M*) or $Ce(SO_4)_2$ ($2–5\times10^{-4}$ *M*) in 0.5 *M* H_2SO_4 were irradiated, oxidation of Fe^{+2} and reduction of Ce^{+4} went to completion. While oxidation (or reduction) was proceeding, the observed potentials and Fe^{+2}/Fe^{+3} (or Ce^{+3}/Ce^{+4}) ratios determined by analysis were related by the Nernst equation, the potentials being the same as those of unirradiated solutions of the same composition. When irradiation was continued past the point of complete oxidation or reduction respectively, H_2O_2 began to be formed in detectible amount, and the potential drifted to final steady values in the range 0.86–0.88 v for iron (12 runs) and 0.82–0.88 v for cerium (five runs). Final potentials were quite steady in any one run but varied within the limits given in a series of runs. Similar results were obtained when $FeSO_4$ or $Ce(SO_4)_2$ in H_2SO_4 was titrated with H_2O_2 until an excess of H_2O_2 had been added. Potentials rose (with $FeSO_4$) or fell (with $Ce(SO_4)_2$), after each H_2O_2 addition, to constant values which were related by the Nernst equation to the new Fe^{+2}/Fe^{+3} or Ce^{+3}/Ce^{+4} level. After addition of excess H_2O_2 potentials drifted to final steady values in the same range (0.83–0.88 v).

H_2SO_4 Alone

The observation of Zalkind and Veselovsky (15) and Feates (16) was confirmed, that when H_2SO_4 (1.0 *M*) without added redox system was irradiated, the potential fell first to a hydrogen-like value and then rose to values constant in any one run but varying between runs from 0.81 to 0.87 v, H_2O_2 again being observed in amounts of the order of 10^{-4} *M*.

These final peroxide-like potentials, whether obtained by prolonged irradiation or by addition of excess H_2O_2 to $FeSO_4$ or $Ce(SO_4)_2$, were affected by the presence or absence of irradiation, fluctuating by 10—20 mv as it is cut off or resumed, but there is little doubt that in all these systems they are ascribable to H_2O_2 acting at the platinum electrode, perturbed to some extent by radiation and by Fe^{+3} or Ce^{+3} if present.

Iodide–Iodine

When solutions of KI or I_2 ($1–3\times10^{-4}$ *M*) in 1 *M* H_2SO_4 were irradiated, oxidation of I^- or reduction of I_2 was observed, a quasi steady state being reached from both sides in which about 85% of the iodine was in the oxidized form, I_2. This steady state persisted for about 24 hours and was followed by a slow further oxidation of I^- to I_2, proceeding for as long as it was possible to irradiate continuously (120 hours). A Nernst plot (v vs. log $I_2/(I^-)^2$) coincided with that obtained by oxidation of KI in H_2SO_4 with H_2O_2, or by electrolytic oxidation and reduction of KI–I_2 solution in H_2SO_4 at an auxiliary electrode. Extrapolation of the Nernst plot to log $I_2/(I^-)^2 = 0$ gave an E_0 of 0.620 v, in agreement with Riddiford's value (17) for I_2 (in solution)/I^-.

The potential was unaffected by momentary removal of the source, or by the presence of H_2O_2, which accumulated from the beginning of irradiation.

Corresponding to the steady-state I_2/I^- ratio a constant potential of 0.76–0.77 v was observed during irradiation, rising slowly as the oxidation of I^- resumed. If irradiation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was cut off during the steady-state period the accumulated H_2O_2 rapidly oxidized the remaining I^- to I_2, and in the presence of sufficient H_2O_2 a rapid oxidation of I_2 to IO_3^- set in, after an induction period of several hours. Parallelling these postirradiation changes, the potential rose from 0.76–0.77 v to about 0.85 v, and, after an arrest of several hours, climbed rapidly to 1.15 v, with the beginning of IO_3^- formation. When the system had once passed from the I_2–I^- to the I_2–IO_3^- domain, further irradiation led only to complete oxidation of the remaining I_2 to IO_3^-, which was stable to doses $>10^{21}$ ev ml^{-1}.

DISCUSSION

In the earlier work (1) a steady potential of about 0.85 v was obtained in a relatively short time (<24 hours) on irradiation of KI–I_2 solution in H_2SO_4. This potential would correspond to complete oxidation of I^- to I_2, and is in fact observed when H_2O_2 is added to I_2 in H_2SO_4, during the induction period preceding the oxidation of I_2 to IO_3^-. The H_2O_2–I_2 system behaves in this respect as does H_2O_2 with Fe^{+3} and Ce^{+3}. However, in the present work under continuous irradiation I^- is not oxidized to I_2 completely even after 120 hours. No explanation has been found for this discrepancy.

In all the systems studied except iodine, the final potentials reached after prolonged irradiation can be reproduced simply by adding H_2O_2 to the original solution. There is then, as Feates and Knight suggested (5), no need to invoke a radiation-produced steady-state potential as explanation. Further, in the presence of a redox couple which is electromotively active on platinum, the potential observed during oxidation or reduction of the couple by irradiation is that of the couple itself. That is, all values are ascribable to molecular products of irradiation.

Two phenomena do not fit into this scheme: (*i*) In several systems the final potentials are affected by the presence of irradiation, fluctuating by 10–20 mv as it is cut off or resumed. This has been ascribed to photosorptions (1). (*ii*) In the I_2–I^- system a temporary arrest occurs under irradiation at about the 85% level of oxidation. Allen (18) suggested that in air-saturated KI solutions H (through HO_2 formation) might reduce I_2 by

$$HO_2 + I_2 \rightarrow I^- + I + H^+ + O_2,$$

as well as oxidizing I^- by

$$HO_2 + H^+ + I^- \rightarrow H_2O_2 + \tfrac{1}{2}I_2.$$

In the present work, although solutions were originally O_2 free, the formation and decomposition of H_2O_2 could provide O_2 for HO_2 formation. Alternatively, H_2^+ might reduce I_2 by some such reaction as:

$$H_2^+ + I_2 \rightarrow I + I^- + 2H^+.$$

The first or third reaction above, working in opposition to the second, could account for this arrest. The accumulation of H_2O_2 under irradiation and consequent increase in rate of the ordinary dark reaction

$$2H^+ + 2I^- + H_2O_2 \rightarrow 2H_2O + I_2$$

will result in the subsequent observed displacement of the steady state towards 100% I_2.

SYNTHESIS OF 2- OR 4,6-DINITRO-*sec*-PENTYL PHENOLS

G. G. S. DUTTON, M. E. D. HILLMAN, AND J. G. MOFFATT

In previous papers we have reported the synthesis and characterization of dinitro-*n*-alkyl and iso-alkyl phenols (1–3), compounds which have insecticidal and selective herbicidal properties. In view of the known superiority of 2,4-dinitro-6-*sec*-butyl phenol compared to the *n*-isomer (4, 5) it was of interest to prepare the *sec*-pentyl derivatives for physiological tests which will be reported elsewhere.

The isomeric *sec*-pentyl phenols were prepared by reacting a carbonyl compound with a

SYNTHESIS OF 2- OR 4,6-DINITRO-*sec*-PENTYL PHENOLS

G. G. S. DUTTON, M. E. D. HILLMAN, AND J. G. MOFFATT

In previous papers we have reported the synthesis and characterization of dinitro-*n*-alkyl and iso-alkyl phenols (1–3), compounds which have insecticidal and selective herbicidal properties. In view of the known superiority of 2,4-dinitro-6-*sec*-butyl phenol compared to the *n*-isomer (4, 5) it was of interest to prepare the *sec*-pentyl derivatives for physiological tests which will be reported elsewhere.

The isomeric *sec*-pentyl phenols were prepared by reacting a carbonyl compound with a

2-(4-Hydroxy-3,5-dinitrophenyl)-3-methylbutane	199	170	217 (decomp.)

Grignard reagent (e.g. 4-methoxypropiophenone and ethyl magnesium bromide), dehydrating the carbinol (6), and hydrogenating the alkene. The 4-alkyl anisoles were demethylated using pyridine hydrobromide and acetic acid but this method failed with the 2-isomers which were accordingly reacted with hydriodic acid and phenol. Nitration of the phenols was done in acetic acid and each dinitrophenol was characterized by the preparation of crystalline salts with morphine, piperidine, and cyclohexylamine.

The dinitrophenols, their derivatives, and intermediates are listed in the tables. All the compounds reported are new except where noted and satisfactory analyses were obtained for all the compounds. These analyses together with experimental details of the preparations are available elsewhere (7, 8).

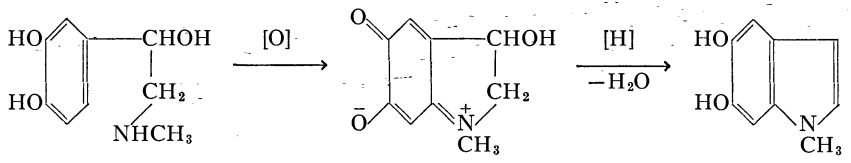
A SIMPLE PREPARATION OF 5,6-DIHYDROXY-*N*-METHYLINDOLE

G. L. Mattok and R. A. Heacock

5,6-Dihydroxy-*N*-methylindole (III) has previously been obtained in crystalline form by the reduction of adrenochrome (II) (1, 2, 3); the rearrangement of epinochrome (4) and the rearrangement (accompanied by decarboxylation) of *N*-methyldopachrome (5).



I II III

The present note describes an adaptation of the first of these methods to give a rapid and simple procedure for the preparation of (III). A solution of adrenochrome (II), prepared by oxidation of adrenaline (I) with buffered potassium ferricyanide (cf. 6), was reduced with excess ascorbic acid in the presence of ether. The use of a two-phase system ensured that (III) was extracted as soon as it was formed; thus preventing lowering of the yield by interaction of (III) with dehydroascorbic acid present in solution (7). The yields (based on adrenaline) obtained by this procedure (ca. 60%) are considerably better than those previously reported (ca. 30%) (cf. refs. 1–5).

EXPERIMENTAL

5,6-Dihydroxy-N-methylindole

Adrenaline bitartrate (2.5 g), in aqueous solution (25 ml), was oxidized by a solution of potassium ferricyanide (13 g) and sodium bicarbonate (4.2 g) in water (50 ml). After 5 minutes, peroxide-free ether

As before (1), all compounds reported are new unless otherwise noted and satisfactory analyses were obtained for all compounds. These figures, together with experimental details, may be found elsewhere (4, 5).

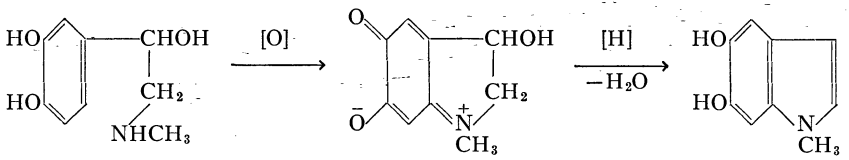
A SIMPLE PREPARATION OF 5,6-DIHYDROXY-*N*-METHYLINDOLE

G. L. Mattok and R. A. Heacock

5,6-Dihydroxy-*N*-methylindole (III) has previously been obtained in crystalline form by the reduction of adrenochrome (II) (1, 2, 3); the rearrangement of epinochrome (4) and the rearrangement (accompanied by decarboxylation) of *N*-methyldopachrome (5).



I II III

The present note describes an adaptation of the first of these methods to give a rapid and simple procedure for the preparation of (III). A solution of adrenochrome (II), prepared by oxidation of adrenaline (I) with buffered potassium ferricyanide (cf. 6), was reduced with excess ascorbic acid in the presence of ether. The use of a two-phase system ensured that (III) was extracted as soon as it was formed; thus preventing lowering of the yield by interaction of (III) with dehydroascorbic acid present in solution (7). The yields (based on adrenaline) obtained by this procedure (ca. 60%) are considerably better than those previously reported (ca. 30%) (cf. refs. 1–5).

EXPERIMENTAL

5,6-Dihydroxy-N-methylindole

Adrenaline bitartrate (2.5 g), in aqueous solution (25 ml), was oxidized by a solution of potassium ferricyanide (13 g) and sodium bicarbonate (4.2 g) in water (50 ml). After 5 minutes, peroxide-free ether

(150 ml) was added to the reaction mixture, followed by ascorbic acid (25 g). The system was shaken for several minutes until all the red color was discharged. The ether layer was separated, dried (Na_2SO_4), and concentrated, under nitrogen, to about 30 ml. Dry benzene (50 ml) was added and the solution concentrated under reduced pressure, at ca. 30°, (nitrogen "leak") to about 30 ml. This solution was then filtered and *n*-heptane (100 ml) added to the filtrate; a flocculent white precipitate was obtained, which was purified by dissolving in warm benzene (35°), reprecipitating with *n*-heptane giving 5,6-dihydroxy-*N*-methylindole (0.7 g; 57%) m.p. 131–132° in long colorless needles. Recrystallization of a sample from *n*-heptane raised the melting point to 133–134°. The melting points quoted for (III) in the literature range from 133° to 136° (refs. 1–6). However, the product obtained by the current procedure was sufficiently pure for most purposes.

A CONVENIENT PREPARATION OF TRYPTOPHOL

THOMAS NOGRADY AND TERRENCE W. DOYLE

Trytophol, 3-indolylethanol, is of considerable interest as an intermediate in indole chemistry. Its preparation in larger amounts is, however, not too convenient with the existing methods, and yields are sometimes poor.

Usually, it is prepared by the LAH reduction of ethyl 3-indolyl-acetate, in a near-quantitative yield. The ester, however, is rather difficult to obtain, through gramine, its methosulphate, indolylacetonitrile, and indolylacetic acid. This 6-step synthesis gives an overall yield of 59% only (cf. (1)).

The new procedure of Johnson and Crosby (2) makes indolylacetic acid available at a 90% yield, and from this acid tryptophol, in an overall yield of 79%, can be obtained. This method requires the use of a concentrated potassium hydroxide solution, and a heating period of 14–22 hours at 250° in an autoclave.

The reduction of ethyl indolylacetate suffers from the disadvantage that it has to be conducted at −20°, otherwise the reaction mixture becomes a tough gum which is impossible to stir.

In the method of Elderfield and Fischer (3) the indolylglyoxylyl chloride is obtained in one step from the indole, according to Speeter and Anthony (4). The chloride is then directly reduced by LAH in tetrahydrofuran at room temperature, and gives an overall yield of 74%. This elegant procedure, described for the 6-methoxy derivative, gave unsatisfactory yields and an impure product when applied to unsubstituted indolyl-3-glyoxylyl chloride.

(150 ml) was added to the reaction mixture, followed by ascorbic acid (25 g). The system was shaken for several minutes until all the red color was discharged. The ether layer was separated, dried (Na_2SO_4), and concentrated, under nitrogen, to about 30 ml. Dry benzene (50 ml) was added and the solution concentrated under reduced pressure, at ca. 30°, (nitrogen "leak") to about 30 ml. This solution was then filtered and *n*-heptane (100 ml) added to the filtrate; a flocculent white precipitate was obtained, which was purified by dissolving in warm benzene (35°), reprecipitating with *n*-heptane giving 5,6-dihydroxy-*N*-methylindole (0.7 g; 57%) m.p. 131–132° in long colorless needles. Recrystallization of a sample from *n*-heptane raised the melting point to 133–134°. The melting points quoted for (III) in the literature range from 133° to 136° (refs. 1–6). However, the product obtained by the current procedure was sufficiently pure for most purposes.

A CONVENIENT PREPARATION OF TRYPTOPHOL

THOMAS NOGRADY AND TERRENCE W. DOYLE

Trytophol, 3-indolylethanol, is of considerable interest as an intermediate in indole chemistry. Its preparation in larger amounts is, however, not too convenient with the existing methods, and yields are sometimes poor.

Usually, it is prepared by the LAH reduction of ethyl 3-indolyl-acetate, in a near-quantitative yield. The ester, however, is rather difficult to obtain, through gramine, its methosulphate, indolylacetonitrile, and indolylacetic acid. This 6-step synthesis gives an overall yield of 59% only (cf. (1)).

The new procedure of Johnson and Crosby (2) makes indolylacetic acid available at a 90% yield, and from this acid tryptophol, in an overall yield of 79%, can be obtained. This method requires the use of a concentrated potassium hydroxide solution, and a heating period of 14–22 hours at 250° in an autoclave.

The reduction of ethyl indolylacetate suffers from the disadvantage that it has to be conducted at −20°, otherwise the reaction mixture becomes a tough gum which is impossible to stir.

In the method of Elderfield and Fischer (3) the indolylglyoxylyl chloride is obtained in one step from the indole, according to Speeter and Anthony (4). The chloride is then directly reduced by LAH in tetrahydrofuran at room temperature, and gives an overall yield of 74%. This elegant procedure, described for the 6-methoxy derivative, gave unsatisfactory yields and an impure product when applied to unsubstituted indolyl-3-glyoxylyl chloride.

Therefore, we prepared ethyl 3-indolylglyoxylate from the chloride (4), by the action of ethanol, in the presence of triethylamine. The crude ester, obtained in a 95% yield and showing the melting point reported in the literature (5) was reduced with LAH in tetrahydrofuran to give tryptophol in a 95% yield. The overall yield from indole is therefore 85–86%.

EXPERIMENTAL

Melting points were taken in capillaries in a Gallenkamp aluminum block, and are corrected. Infrared spectra were determined in KBr disks on a Beckman IR8 grating instrument.

Ethyl 3-indolylglyoxylate

3-Indolylglyoxylyl chloride (4), 10.35 g (0.05 moles), was refluxed for 30 minutes in a mixture of 60 ml absolute ethanol and 5.30 g (7.2 ml, 0.052 moles) of triethylamine. The reaction mixture was chilled, and the crystals were filtered and washed with a little ethanol. Yield 7.60 g (70.0%), m.p. 186–187° (lit. m.p. 186°) (5).

The mother liquid was evaporated under reduced pressure, and the residue triturated with water. On filtration, an additional 2.70 g (25.0%) ester was obtained, m.p. 184–186°.

Infrared absorption (λ_{max}, μ): 3.11 (NH, vs), 3.37 (C—H, w), 5.87 (C=O, s), 6.20 (C=C, s), 7.95 (C—O, s).

3-Indolylethanol (Tryptophol)

Ethyl indolylglyoxylate (10.85 g (0.05 moles)) was refluxed for 2 hours with 6.6 g (0.175 moles) $LiAlH_4$ in 200 ml dry tetrahydrofuran, with mechanical stirring. We then added 20 ml water slowly while cooling the reaction mixture in ice water. The precipitate was filtered and washed several times with tetrahydrofuran, and the solvent evaporated after drying over Na_2SO_4. The white crystalline residue weighed 6.50 g (95.0%), m.p. 54–55°.

It can be recrystallized from benzene–petroleum ether, m.p. 56–58° (lit. m.p. 58–59° (6)).

Infrared absorption (λ_{max}, μ): 2.94 (NH, OH, vs), 3.40, 3.43, 3.50 (C—H, w), 6.20 (C=C, w), 9.52 (OH, s, broad).

H_0 ACIDITY FUNCTIONS FOR NITRIC AND PHOSPHORIC ACID SOLUTIONS CONTAINING ADDED SODIUM PERCHLORATE

Donald G. Lee and Ross Stewart

In connection with an investigation of the mechanism of the chromic acid oxidation of alcohols (1) we required the values of the Hammett acidity function, H_0, for nitric and phosphoric acid solutions containing equimolar amounts of sodium perchlorate and acid. The functions were determined by use of weak bases for indicators in the manner described by Paul and Long (2).

H_0 ACIDITY FUNCTIONS FOR NITRIC AND PHOSPHORIC ACID SOLUTIONS CONTAINING ADDED SODIUM PERCHLORATE

Donald G. Lee and Ross Stewart

In connection with an investigation of the mechanism of the chromic acid oxidation of alcohols (1) we required the values of the Hammett acidity function, H_0, for nitric and phosphoric acid solutions containing equimolar amounts of sodium perchlorate and acid. The functions were determined by use of weak bases for indicators in the manner described by Paul and Long (2).

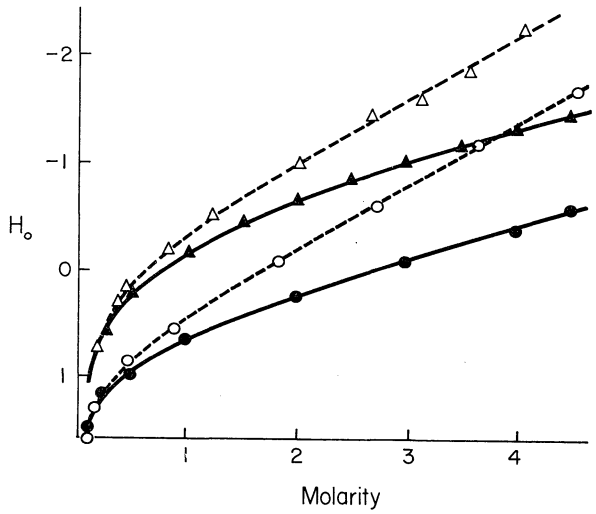

FIG. 1. Acidity functions for solutions of nitric acid ▲ and phosphoric acid ●, and for nitric acid – sodium perchlorate △ and phosphoric acid – sodium perchlorate. ○ All solutions are equimolar in acid and salt.

Figure 1 reveals that the functions obtained in dilute regions are identical with previously determined functions containing no added salt (2), the addition of small amounts of salt having very little effect on the acidity of these solutions. In more concentrated solutions, however, the addition of increasing amounts of salt results in a continuous increase in acidity as compared to solutions containing no added salt. This is in agreement with the work of Harbottle (3) and Paul (4), who have reported that the addition of varying amounts of sodium perchlorate to perchloric acid and hydrochloric acid solutions causes increases in the acidity of the media.

$-H_0$ is defined as

$$-H_0 = \log C_{H^+} + \log (f_{H^+}/f_{BH^+}) + \log f_B.$$

The more rapid increase in $-H_0$ as compared to C_{H^+} in acid solutions containing no added salt is due primarily to an increase in log (f_{H^+}/f_{BH^+}) as the acid concentration is raised. The additional effect of added sodium perchlorate is presumably due to a further increase in this term and probably an increase in the log f_B term since it is known that sodium perchlorate has a tendency to salt-out non-electrolytes (2, 4).

EXPERIMENTAL

The indicators used in this investigation (*p*-nitroaniline, *o*-nitroaniline, and 4-chloro-2-nitroaniline) were all obtained commercially and recrystallized from ethanol to constant melting points. The melting points were all found to agree favorably with the values reported in the literature (5).

Concentrated stock solutions containing equimolar ratios of either H_3PO_4 or HNO_3 and sodium perchlorate were prepared and then diluted to give a series of solutions of varying concentrations. Fifty microliters of an alcoholic solution of indicator was then added to a series of 5-ml volumetric flasks which were then filled to the mark with salt–acid solutions. The visible and ultraviolet spectral data were then obtained in the usual way using a Beckman DU Spectrophotometer, controlled to 25°±0.5° by means of thermospacers.

The data are shown in Tables I and II. In dilute solutions the H_0 determined from *p*-nitroaniline solutions was found to agree to within 0.03 units with pH measurements made with a glass electrode on a Beckman Model G pH meter.

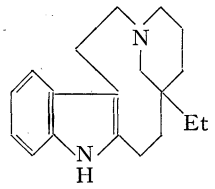
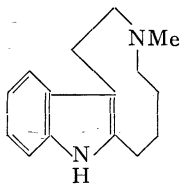
A QUEBRACHAMINE MODEL

ERNEST WENKERT,[1] SHEILA GARRATT, AND K. G. DAVE

Chemical studies, biogenetic considerations (1) and mass-spectrometric analysis (2) have led to the proposal of I as the structure of quebrachamine. While probably biogenetically related to the natural pentacyclic *Aspidosperma* bases (3), tetracyclic quebrachamine possesses an unusual nine-membered ring. This rare structural feature has now been incorporated in a synthetic model (II) by a method which, in principle, is applicable to the total synthesis of the indole alkaloid itself.

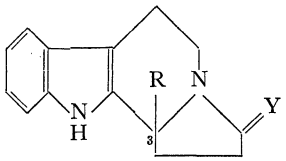


I

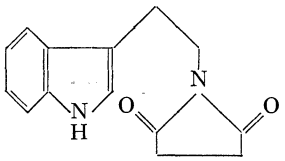


II

The first synthetic goal was the indolopyrrocoline system III. It was obtained in form of the lactam ester III*a* by the condensation of ethyl α-ketoglutarate with tryptamine. Alternatively, it was produced as the amine III*c* by the acid-catalyzed condensation of tryptamine and α-ketoglutaric acid, pyrolytic decarboxylation–dehydration, and lithium aluminum hydride reduction of the resultant lactam III*b*—a procedure published by Corsano and Algieri (4). The proton magnetic resonance spectrum of the base III*c* [a one-proton multiplet at 4.0–4.2 p.p.m. characteristic of C(3)—H] showed it to possess a cis-pyrrocoline configuration (5). An alternative synthesis of III*c*, via the intermediacy of IV and modelled after recorded reactions with tryptimides (6), failed in the crucial cyclization step.



III*a*, R = CO_2Et, Y = O
b, R = H, Y = O
c, R = H, Y = H_2



IV

Conversion of III*c* to its methiodide and treatment of the latter with lithium in liquid ammonia yielded the medium-sized ring, compound II (cf. 7).

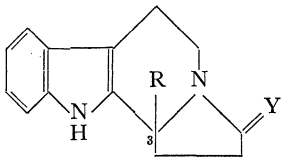
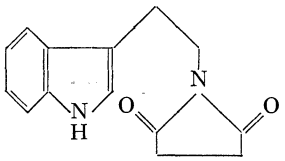
The first synthetic goal was the indolopyrrocoline system III. It was obtained in form of the lactam ester III*a* by the condensation of ethyl α-ketoglutarate with tryptamine. Alternatively, it was produced as the amine III*c* by the acid-catalyzed condensation of tryptamine and α-ketoglutaric acid, pyrolytic decarboxylation–dehydration, and lithium aluminum hydride reduction of the resultant lactam III*b*—a procedure published by Corsano and Algieri (4). The proton magnetic resonance spectrum of the base III*c* [a one-proton multiplet at 4.0–4.2 p.p.m. characteristic of C(3)—H] showed it to possess a cis-pyrrocoline configuration (5). An alternative synthesis of III*c*, via the intermediacy of IV and modelled after recorded reactions with tryptimides (6), failed in the crucial cyclization step.



III*a*, R = CO_2Et, Y = O
b, R = H, Y = O
c, R = H, Y = H_2



IV

Conversion of III*c* to its methiodide and treatment of the latter with lithium in liquid ammonia yielded the medium-sized ring, compound II (cf. 7).

EXPERIMENTAL

All melting points were observed on a Kofler microscope hot stage. Ultraviolet spectra were run on 95% ethanol solutions on a Cary model 12 spectrophotometer, while infrared spectra were obtained on a Perkin–Elmer infrared spectrophotometer. Proton magnetic resonance spectra were measured on deuterochloroform solutions with tetramethylsilane as internal standard on a Varian A-60 spectrometer (courtesy of the Department of Chemistry, Indiana University, Bloomington, Indiana, U.S.A.).

Lactam IIIa

A solution of 1.20 g of tryptamine hydrochloride and 1.00 g of ethyl α-ketoglutarate in 10 ml of ethanol was refluxed for 60 hours under nitrogen. Evaporation of the solvent left 0.88 g of crystalline residue whose recrystallization from methanol yielded colorless prisms of lactam ester III*a*, m.p. 225–226°; μ (Nujol) NH 3.00 (s), C=O 5.75 (s), 5.92 (s), C=C 6.30 (w); λ_{max} 223 mμ (log ϵ 4.60), 282 mμ (log ϵ 3.95), and 292 mμ (log ϵ 3.85); δ broad NH singlet 8.58 p.p.m., ester CH_2 quartet 4.25 p.p.m. (J = 7 c.p.s.), ester CH_3 triplet 1.29 p.p.m. (J = 7 c.p.s.). Anal. Calc. for $C_{17}H_{18}O_3N_2$: C, 68.45; H, 6.08. Found: C, 68.15; H, 6.02.

N-[β-(3-Indolyl)ethyl]succinimide (IV)

A suspension of an intimate mixture of 1.14 g of tryptamine and 0.70 g of succinic anhydride in 120 ml of benzene was refluxed for 5 hours. The cooled suspension was decanted and the solution extracted with 5% sodium hydroxide solution and with water. The solid residue from the decantation was dissolved in 5% sodium hydroxide solution and thereafter combined with the previous basic extract. The joint alkaline extracts were acidified with 5% hydrochloric acid and the resultant solid taken up in ethyl acetate. The organic solution was dried over anhydrous magnesium sulphate and evaporated under reduced pressure. Crystallization of the solid residue, 1.36 g, from ethyl acetate yielded N_b-succinoyl tryptamine, m.p. 138–139°. Anal. Calc. for $C_{14}H_{16}O_3N_2$: C, 64.58; H, 6.20; N, 10.77. Found: C, 64.77; H, 6.27; N, 10.62. An ether solution of an excess diazomethane was added to a solution of 82 mg of the amide acid in 10 ml of methanol and the mixture left standing for 30 minutes. Evaporation of the solvent and crystallization of the resultant solid, 85 mg, from methanol yielded colorless plates of the amide ester, m.p. 110–111°; μ (Nujol) NH 2.95 (s), 3.0–3.1 (m), C=O 5.80 (s), 6.03 (s); δ ester CH_3 singlet 3.62 p.p.m.

N_b-Succinoyl tryptamine, 1.44 g, was heated for 10 minutes at 200° under slightly reduced pressure. Crystallization of the dark brown reaction residue from methanol yielded the imide IV, m.p. 166–167°; μ (Nujol) NH 2.95 (s), C=O 5.60 (w), 5.85 (s); δ two succinoyl CH_2 singlet 2.58 p.p.m. Anal. Calc. for $C_{14}H_{14}O_2N_2$: C, 69.37; H, 5.82; N, 11.56. Found: C, 69.34; H, 5.92; N, 11.47.

Amine II

A solution of 188 mg of the amine III*c* and an excess of methyl iodide in 10 ml of ether was left standing for 8 hours. The resultant precipitate was filtered and dried. (Since this methiodide was exceedingly hygroscopic, its isolation had to be carried out rapidly.) The dried salt, 275 mg, was dissolved in 5 ml of absolute ethanol and 75 ml of liquid ammonia and enough lithium added to the stirring solution until the resultant blue color persisted for 1 hour. Then solid ammonium chloride was added, the ammonia allowed to evaporate, and the residue dissolved in water. Sodium hydroxide, 5%, was added and the aqueous solution extracted with ether. The extract was washed with water, dried over anhydrous magnesium sulphate, and evaporated under reduced pressure. Chromatography of the residue, 136 mg, on alumina and elution with 1:1 chloroform–benzene yielded 44 mg of crystals whose crystallizations from aqueous ethanol led to amine II, m.p. 128–130°; δ N—CH_3 singlet 2.38 p.p.m., no C—CH_3 present. Anal. Calc. for $C_{15}H_{20}N_2$: C, 78.89; H, 8.83; N, 12.27; C-alkyl, 0.00. Found: C, 78.70; H, 8.89; N, 12.28; C-alkyl, negative.

ACKNOWLEDGMENT

The authors are indebted to the U.S. Public Health Service for support of this work by grant MY-5815 and to Mr. L. Dorfman (Ciba Pharmaceutical Co., Summit, New Jersey, U.S.A.) for the C-alkyl determination.

TERPENOIDS

V. SENEGENIN: FUNCTIONAL GROUPS AND PART STRUCTURE

J. J. DUGAN, P. DE MAYO, AND A. N. STARRATT

Department of Chemistry, University of Western Ontario, London, Ontario

Received September 23, 1963

ABSTRACT

Senegenin, the sapogenin from *Polygala senega* has been shown to contain chlorine; it has the empirical formula $C_{30}H_{45}O_6Cl$. The oxygen atoms, contrary to earlier work, are contained in two carboxyl groups and two secondary hydroxyl groups. There is one isolated ethylenic linkage. The environment of the hydroxylic functions and one carboxyl group has been shown to be as in (XI).

Of the known triterpenoids of undetermined constitution remaining, senegenin has a claim to outstanding interest. Investigations directed to a study of the saponin of *Polygala senega* have spread over many years, but, as mentioned by Simonsen and Ross (1), such "investigations . . . have given rise to very divergent results". It is this confusion, and its present clarification, which exculpates us from a charge of literary proliferation in the presentation of incomplete work.

Although senega extract has been used medicinally for some time, chiefly as an expectorant (however, see ref. 2), the first results of chemical importance were obtained by Wedekind and Krecke (3). They isolated, by acid hydrolysis of the saponin, a product to which they assigned the formula $C_{26}H_{44}O_6$. It contained two hydroxyl groups, as indicated by the formation of a diacetate, and gave a dimethyl ester.

A more extensive study was later reported by Jacobs and Isler (4), who observed the presence of two crystalline sapogenins. That of lower solubility appeared to be senegenin, although the constants differed somewhat from those of Wedekind and Krecke: the diacetate, in particular, melted at a much higher temperature. The empirical formula $C_{30}H_{46}O_8$ or $C_{30}H_{44}O_8$ was proposed, and evidence for an isolated ethylenic linkage found in a weak tetranitromethane test. Titration with alkali indicated the presence of two carboxyl groups (again confirmed by the preparation of a non-crystalline dimethyl ester) and the presence of a lactone was inferred by the consumption of a third equivalent of alkali on heating. Senegenin could not be recovered from the acidified hydrolysis mixture.

The second sapogenin isolated from senega root by Jacobs and Isler was an acid, m.p. 257°, which appeared to have the empirical formula $C_{31}H_{50}O_6$ or $C_{31}H_{48}O_6$. This substance also gave a positive reaction with tetranitromethane, and was shown to give a diacetate. Hydrolysis revealed it to be the monoethyl ester of a dibasic acid. Both the sapogenins gave, on selenium dehydrogenation, the same substituted picene obtained previously from such triterpenoids as oleanolic acid, and shown to be (5) 1,8-dimethylpicene: results which strongly supported the supposition of Jacobs and Isler that they were dealing with a triterpenoid.

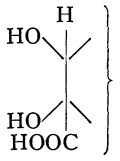
More recently senegenin has been the subject of study by Shamma and Reiff (6). The allocation of oxygen functions previously proposed (4) was accepted by these authors with the added qualification, because of the absence of an appropriate band for a γ-lactone, that the lactone be six (or more) membered. Confirmation of the presence of the double bond led them to assign the molecular formula $C_{30}H_{44}O_8$ to senegenin, an interpretation requiring that the substance be tetracyclic. Senegenin gave on lithium aluminum hydride reduction a product believed to be a hexaol from which a pentaacetate could be prepared. An important observation was that senegenin gave an isopropylidene derivative.

Senegenin consumed (6) 2 molecules of lead tetraacetate whereas the dimethyl ester consumed but 1 molecule. No crystalline or characterized compounds were, however, isolated from the cleavage. From their observations the conclusion was drawn that senegenin contained the grouping (I) which required it to be of a carbon skeleton different from that of the then known triterpenoids. It could, however, be incorporated into the carbon skeleton, recently established, of ceanothic acid (7) (II) and our interest in this substance led us to a study of senegenin.



(I)

A number of triterpenoids have been reported as having been isolated for *Polygala* species. *Polygala tenuifolia* Willd. has been shown to contain (8, 9) an acid, tenuifolic acid, to which the empirical formula $C_{30}H_{44-46}O_8$ has been attributed: the same substance has been isolated from *Bredemeyera floribunda* Willd. A similar substance has been isolated from *Polygala senega* L. var. *latifolia* Torr. and Gray (10) which may, however, be identical with senegenin. From *Polygala paenea* Polonsky has isolated polygalacic acid (11) and shown it to have the structure (III) whilst very recently, after the completion of the work to be described, Tschesche and his collaborators have modified their original findings and presented (IV) (12) as the structure of bredemolic acid, a substance found together with tenuifolic acid. The relevance of this related work will become apparent in the sequel.

The isolation procedure of Jacobs and Isler was modified (see Experimental), the crude sapogenin, obtained from the hydrochloric acid hydrolysis of the prosapogenin, being acetylated directly. The material extracted with aqueous bicarbonate solution gave senegenin monoacetate.* Acid hydrolysis afforded senegenin (see Table I).

Our first endeavor was to confirm the nature of the functional groups. The ultraviolet absorption (λ_{max} 205 mμ, ϵ = 6900) suggested the presence of an isolated ethylenic linkage (4), but no indication whatsoever could be found for the presence of a vinylic proton (6) in the n.m.r. spectra of several derivatives. The double bond was, therefore, fully substituted.

The n.m.r. spectrum of dimethyl senegenin showed two singlets (3H each) at τ 6.29 and 6.41 in agreement with the presence of two carbomethoxyl groups. In addition there was absorption at τ 5.81 and 6.10 (1H each). Senegenin monoacetate dimethyl ester, obtained by brief exposure to mild acetylating conditions, had two bands at τ 5.74 (1H, multiplet) and 4.77 (1H, doublet) whilst in the diacetate both bands had moved

**Professor W. D. Ollis (Sheffield) has isolated senegenin in a similar manner, and we would like to present our sincere thanks for a gift of a generous sample.*

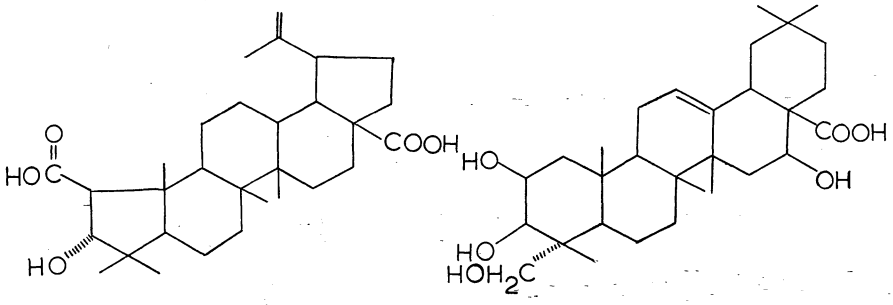
Compound	Present work	Jacobs and Isler (4)	Reiff (22)
Senegenin	M.p. 281–283°* $[\alpha]_D$+19° (EtOH)	290–292° $[\alpha]_D$+19° (EtOH)	280–283° $[\alpha]_D$+16° (EtOH)
Senegenin diacetate	M.p. 257–263° $[\alpha]_D$+29° (MeOH)	260–270°	225–230° $[\alpha]_D$+26° (EtOH)

*The melting point was determined on the Kofler block by placing the compound on the block about 15° below the melting point. This is the procedure indicated to us by Dr. S. W. Pelletier (Athens) as giving the recorded melting point on Dr. Jacob's samples. We are grateful to Dr. Pelletier for this information. Melting points determined on the block in the usual way were in the region 265–270° and varied with the rate of heating.

A direct comparison of the senegenin used in these experiments and that of Jacobs and Shamma has established identity in melting point, mixed melting point, infrared spectrum, and behavior on thin-layer chromatography. We are grateful to Professors Pelletier and Shamma for making the material available.

down field to τ 4.47 (1H, multiplet) and 4.68 (1H, doublet). These changes are those to be expected in the stepwise acetylation of two secondary hydroxyl groups. In confirmation, a diformate could be prepared by the action of formic acid. Further, since one of the methine hydrogens was a doublet, and senegenin dimethyl ester consumed one mole of periodic acid, the part structure (I) (6) must be rejected and replaced by (V), where $(HO)_b$ is the hydroxyl group acetylated first.



II

V

Six of the oxygen atoms in senegenin were thereby satisfactorily accounted for. The remaining two were those attributed by previous workers to a lactonic function essentially because of the consumption of an extra equivalent of alkali. This lactone was presumed to suffer ring change to a γ-lactone with perbenzoic acid (6) the exact nature of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

transformation being, however, unspecified. In an attempt to obtain direct spectral evidence for the lactone the sodium salt of senegenin was prepared and shown, by analysis, to be a disodium salt. However, the infrared spectrum of this salt showed no carbonyl absorption above 1550 cm^{-1} (carboxylate anion). The presence of a lactone in senegenin was, therefore, precluded.

The obstinate fact remained that one equivalent of alkali was consumed by senegenin, beyond the requirements of its carboxyl functions. Yet this potentially acidic function was generated from a non-carbonylic precursor. Whilst such a system, as an improbable grotesquerie, can be devised, the interpretive problem was considerably simplified when it was discovered that senegenin contained chlorine. The atomic weight of chlorine renders distinction from two oxygen atoms by carbon and hydrogen analysis alone a subtle one, and the presently proposed empirical formula, $C_{30}H_{45}O_6Cl$, has requirements close to the O_8 formula previously entertained.

For the further study of senegenin, and in particular for the investigation of the environment of the vicinal hydroxyl groups, the removal of the chlorine was required. This was achieved in two ways.

In the first, senegenin was refluxed in quinoline when de(hydrochloro)senegenin was obtained. This compound could also be obtained, under defined conditions, as the product of the alkali treatment of senegenin, the "extra" equivalent of alkali being consumed by the liberated hydrochloric acid. De(hydrochloro)senegenin was characterized as a diacetate and a dimethyl ester. From the ester a mono- and di-acetate were prepared. The ultraviolet absorption (see Experimental) showed the presence of a heteroannular diene. In the n.m.r. spectrum the de(hydrochloro)senegenin dimethyl ester showed the two bands (3H each) at τ 6.49 and 6.32 for the ester methyl groups and at 6.11 (doublet) and 5.92 (multiplet) for the continuing presence of the glycol system. There was also a band at 4.70 (1H) for a vinyl hydrogen. In addition it was still possible to prepare an isopropylidene derivative. Treatment of senegenin dimethyl ester with quinoline afforded a product identical with that obtained by the methylation of the product from senegenin. The molecular weight, 528, determined mass spectroscopically* further showed that only hydrogen chloride had been lost during the treatment with alkali or with quinoline.

De(hydrochloro)senegenin dimethyl ester was hydrogenated over platinum oxide, with the uptake of one molecule of hydrogen, to give a dihydro compound, termed isodechlorosenegenin dimethyl ester, showing end absorption (λ_{max} 199 mμ, ϵ = 6700) only, and which was characterized as a mono- and di-acetate. De(hydrochloro)senegenin, similarly, gave isodechlorosenegenin.

In the second method of eliminating the chlorine direct reduction of the monoacetate with lithium in liquid ammonia was employed; the product, dechlorosenegenin, was characterized as the diacetate.

A difference in the reactivity of the two carboxyl groups was noted when de(hydrochloro)senegenin dimethyl ester was heated for 2 hours in refluxing 5% alcoholic potassium hydroxide. The product proved to be a monomethyl ester. It has previously been observed in other triterpenoids (13, 14, 15, 16) that the presence of an appropriately situated oxygen function can greatly facilitate the hydrolysis of an otherwise very resistant ester. This observation suggested that the carbomethoxyl group which underwent hydrolysis should be placed as in (VI, R = Me), a part structure which already assumed a general familiarity, but a more direct demonstration of this relationship was required.

Oxidation of isodechlorosenegenin dimethyl ester with chromic acid in pyridine gave a

*We are grateful to Professor K. Biemann for this determination.

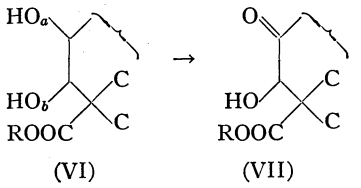
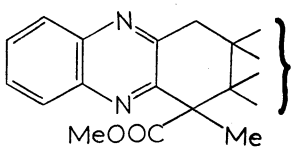
For personal use only.

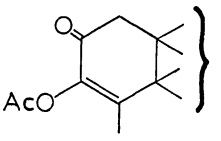


(VI) (VII)

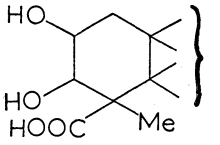
ketol showing hydroxyl absorption at 3495 cm^{-1} in the infrared and a band in the n.m.r. spectrum at τ 5.51 moved to 4.57 on acetylation. This band was a singlet, and therefore it is hydroxyl (*a*) which has been oxidized to the ketone (as in (VII, R = Me)). Since



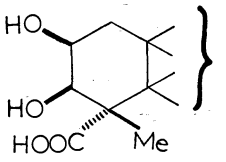
VIII



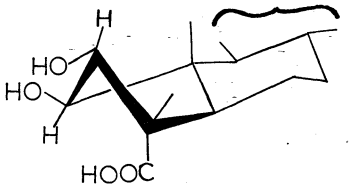
IX



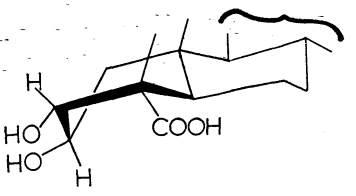
X



XI



XII



XIII

the carbonyl absorption of the keto-acetate was at 1728 cm^{-1} the possibility of a five-membered ring could not, at this stage, be dismissed. Attempts to hydrolyze the ester grouping in (VII, R = Me) were abortive, however, since the ketol underwent air-oxidation (17) and yielded no tractable product. (VII, R = Me) was converted by bismuth oxide (18) to the non-crystalline α-diketone characterized as the crystalline quinoxaline derivative (VIII).

An alternative approach to the establishment of the relationship of the hydroxyl and carboxyl functions was therefore sought. Isodechlorosenegenin dimethyl ester was converted to the monomethyl ester by alkaline hydrolysis. Oxidation with chromic acid in pyridine gave a gum. On warming in alkali, and acidification, a compound was obtained having the properties of a diosphenol and which had decarboxylated. It was characterized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

as the crystalline acetyl derivative (IX) (λ_{max} 247 mμ).* Since this compound showed ν_{max} for the unsaturated ketone at 1675 cm^{-1} a six-membered (or larger) ring was indicated.

The decarboxylation, that of a β-keto acid, confirms the position of the carboxyl function and the presence of a singlet (3H) at τ 7.76 in the diosphenol acetate indicates the position of a methyl group at this point. The part structure (V) may thus be reasonably expanded to (X)—that is, the normal triterpenoid ring A carbon skeleton. No evidence is presently available for the presence of the C_{10} methyl group.

The carboxyl group must be placed at the 4α, equatorial, position since the resistance of 4β carboxylic ester groups to hydrolysis at this position is well known (for example, ref. 19). Of the four possible arrangements of the glycol one, 2α,3β, can be immediately dismissed since this would require a large trans diaxial coupling of the methine protons ($J \sim$ 8–10 c.p.s.) (20) whereas that observed is ~3.8 c.p.s. Of those remaining only the 2α, 3α, and 2β,3β would be expected to give an isopropylidene derivative easily (21).

Since in senegenin monoacetate the low field (τ 4.83) methine proton is the doublet it is the C_3 hydroxyl that acetylates first. If the arrangement were 2α,3α then this would require the preferential acetylation of an axial 3-hydroxyl group over the far less hindered equatorial 2-hydroxyl group. Since this cannot be accepted the remaining 2β,3β stereochemistry follows (XI), and is consistent with the preferred oxidation of the 2β hydroxyl. It will be noted that a 2β configuration of a hydroxyl group requires a 4α configuration of the carboxyl group since no evidence of lactonization under a variety of conditions has been observed. The structure of what is presumably ring A of senegenin is therefore identical with that observed in medicagenic acid (13).†

The above discussion requires that ring A be a chair, but the possibility of twist or boat forms requires consideration. Of the three remaining possible assignments of glycol stereochemistry rejected, two, namely 2α,3β and 2α,3α, should show no tendency to assume conformations other than chair and so remain unacceptable. The third, 2β,3α, because of the three 1:3 hydroxyl and methyl interactions (present also in (XI)) and because of two 1:3 hydroxyl–hydrogen interactions could invert into a boat or twist form of which (XII) and (XIII) represent extremes. Whilst this might account for acetonide formation and the order of acetylation and oxidation of the hydroxyl groups, in (XII) and (XIII) or all conformations in between the methine protons at C_2 and C_3 are essentially trans-diaxial. The coupling constant here, as in the 2α,3β chair form, would therefore be larger than that actually observed.

Since the hydrolysis of the saponin was effected by all previous workers using hydrochloric acid it seemed probable that the introduction of chlorine into the senegenin moiety took place at this point. Isolation and halogen analysis of the crude saponin indicated the total absence of chlorine. Analysis of the crude prosapogenin on the other hand indicated the presence of 1.57% chlorine not removed by repeated precipitation from ethanol. It is therefore at this stage that the halide is most probably introduced.

Tenuifolic acid, previously referred to (9), has two unassigned oxygen atoms in the formula proposed. On treatment with quinoline it is converted to anhydrotenuifolic acid which, although not a conjugated diene as in the case of de(hydrochloro)senegenin, has analytical figures closely corresponding. It is possible therefore that tenuifolic acid may also contain chlorine, as may other "O_8 substances" from *Polygala* species (10).

Such a sequence has been reported in the chemistry of medicagenic acid (13).

†*That dechlorosenegenin is not medicagenic acid has been shown by a comparison of the acids. We thank Dr. R. J. Morris (Nevada) for a generous specimen of medicagenic acid.*

EXPERIMENTAL*

Extraction of Ground Root of Polygala senega

The ground root (6 kg, supplied by S.B. Penick and Co.) was extracted in methanol for approximately 1 day, after which time the solvent was drained off. This was repeated three times and the combined extract was concentrated. The saponin was precipitated by the addition of ethanol and removed by filtration. Crude saponin (2 g) was dissolved in methanol and treated with activated charcoal. After filtration the solution was concentrated to one-third volume and the saponin precipitated with acetone. Analysis showed the absence of chlorine.

The saponin (156 g) was dissolved in alcohol–water (1:1; 480 ml) and warmed on the steam bath for 1 hour with concentrated hydrochloric acid (320 ml). The solution was cooled and the precipitated prosapogenin filtered off.

Upon standing, a crystalline material was slowly deposited from the concentrated saponin mother liquors, m.p. 183–186° (alcohol), $[\alpha]_D$ +67° (*c*, 1.21; water). This compound was identified as sucrose by mixed melting point and infrared spectrum.

Prosapogenin (1 g) was dissolved in alcohol and treated with activated charcoal. After filtration the solution was concentrated and the prosapogenin precipitated with water. This process was repeated six times (with omission of treatment with activated charcoal) at which time the mother liquors no longer gave a positive test for chloride ion. The dried material contained 1.57% chlorine.

Without drying, the total prosapogenin was further hydrolyzed by refluxing 6 hours in a mixture of alcohol (960 ml), water (320 ml), and concentrated hydrochloric acid (320 ml). The solution was cooled and the precipitate collected. The precipitate was extracted exhaustively with ether and the ether extract washed with water and concentrated to dryness.

Acetylation of the Crude Sapogenin Mixture

To the above ether crude extract in pyridine (100 ml) was added acetic anhydride (50 ml) and the solution allowed to stand at room temperature for 6 hours. After isolation the product was dissolved in ether and extracted with sodium bicarbonate solution (5%). After acidification with dilute hydrochloric acid, the acidic product was crystallized from ether–chloroform solution to yield a crude monoacetate (6.8 g). Additional crystalline material (1.6 g) was obtained as a second crop. Recrystallization from methanol–chloroform gave senegenin monoacetate, m.p. 209–211°, $[\alpha]_D$ +23° (*c*, 1.32), ν_{max} 1743, 1700 cm^{-1} (Nujol mull), λ_{max}^{MeOH} 205 mμ (ϵ 6400). Calc. for $C_{32}H_{47}O_7Cl$: C, 66.26; H, 8.18; Cl, 6.12%. Found: C, 66.05; H, 7.95; Cl, 6.01%. Methylation with diazomethane yielded a non-crystalline ester, ν_{max} 1722 cm^{-1}, n.m.r. bands at τ 9.13, 9.07, 8.97, 8.80, 8.64, 7.95, 6.43, 6.37, 5.78 (multiplet), 4.83 (doublet).

On one occasion, the material not extracted by bicarbonate solution was purified by filtration through silica gel. A crystalline product was obtained which was recrystallized from alcohol to give an acetate, m.p. 164–166°, $[\alpha]_D$ +25° (*c*, 1.10), λ_{max} 200 mμ (ϵ 5560), n.m.r. bands of methyl ester at τ 7.98, 6.41, 5.98 (quartet), 4.97 (doublet). Found: C, 70.74; H, 8.97%.

Hydrolysis of the latter acetate (100 mg) by refluxing 30 minutes under nitrogen in methanolic potassium hydroxide solution (5%; 10 ml) afforded, upon isolation, a substance recrystallized from aqueous alcohol to give a product, m.p. 214–217°, $[\alpha]_D$ +20° (*c*, 0.70; alcohol). Found: C, 71.09; H, 9.32%. This compares favorably with the dihydroxy dicarboxylic acid monoethyl ester isolated together with senegenin by Jacobs and Isler (4) and reported to have m.p. 215–218°, $[\alpha]_D$ +24.5° (alcohol). This compound was found to contain no chlorine.

Senegenin

The monoacetate (1.33 g), m.p. 209–211°, was refluxed for 1 hour with methanol (83 ml), water (6 ml), and concentrated hydrochloric acid (18 ml). Isolation of the product and recrystallization from aqueous alcohol gave a product (962 mg) further recrystallized from aqueous alcohol and acetone–water to yield senegenin, m.p. 265–267° (gas evolution) (see Table I), $[\alpha]_D$ +19° (*c*, 0.74; alcohol), ν_{max} 3400, 1700 cm^{-1} (Nujol mull), λ_{max} 205 mμ, (ϵ 6950). The dimethyl ester (glass) exhibited n.m.r. bands at τ 9.15, 9.09, 8.98, 8.85, 8.62, 6.41, 6.29, 6.10, and 5.81. Calc. for $C_{30}H_{45}O_6Cl$: O, 17.87; Cl, 6.60%. Found: O, 17.87; Cl, 6.56%.

Senegenin Diacetate

Acetylation of senegenin at room temperature for 46 hours (acetic anhydride – pyridine) gave senegenin diacetate, m.p. 257–263° (decomposition), $[\alpha]_D$ +29° (*c*, 1.09; methanol), ν_{max} 1736, 1698 cm^{-1}. Calc. for $C_{34}H_{49}O_8Cl$: C, 65.73; H, 7.95; Cl, 5.71%. Found: C, 65.94; H, 7.99; Cl, 5.90%. The non-crystalline methyl ester showed n.m.r. bands at τ 9.14, 9.05, 9.00, 8.87, 8.62, 8.06, 7.93, 6.40, 6.34, 4.68 (doublet), 4.48 (multiplet), and 6.77, 6.58.

Acetonide of Senegenin

Senegenin (48 mg) in acetone (10 ml) was shaken 70 hours with anhydrous copper sulphate. The solution was filtered and the solvent evaporated to give a product which was recrystallized from aqueous alcohol

**For general procedure, see part IV (23).*

to yield the acetonide of senegenin, m.p. 282–284°, (Reiff (22) reports m.p. 261–264°) $[\alpha]_D$ +28° (*c*, 0.93; methanol), ν_{max} 1697 cm^{-1} (Nujol mull). Calc. for $C_{33}H_{49}O_6Cl$: C, 68.64; H, 8.56%. Found: C, 68.86; H, 8.53%.

Sodium Salt of Senegenin

Senegenin was titrated with sodium hydroxide solution (*N*/100 in methanol:water (1:1)). The solvent was evaporated and the residue, dissolved in methanol, was precipitated with ether. The product, $[\alpha]_D$ +5° (*c*, 1.16; methanol), decomposed over a wide range starting at about 260° and showed ν_{max} 1550 cm^{-1} (KBr disk) (carboxylate group). No absorption attributable to a γ or δ lactone was detected between 1550 and 1800 cm^{-1}. Calc. for $C_{30}H_{43}O_6ClNa_2$: Na, 7.92%. Found: Na, 7.34%.

Dechlorination of Senegenin Monoacetate

Senegenin monoacetate (1.2 g) dissolved in anhydrous ether (200 ml) was added over a period of 5 minutes to a stirred solution of an excess of lithium metal in liquid ammonia (200 ml) cooled by immersion in a dry ice – acetone bath. Stirring was continued for 20 minutes and then ammonium chloride was added carefully until the disappearance of the blue color. The ammonia was allowed to evaporate, water added, and the mixture acidified with hydrochloric acid. Isolation of the product by ether extraction and crystallization from methanol afforded dechlorosenegenin (760 mg), m.p. 279–281, $[\alpha]_D$ −15° (*c*, 1.57, methanol). Calc. for $C_{30}H_{46}O_6$: C, 71.68; H, 9.22; O, 19.10%. Found: C, 71.48; H, 9.14; O, 18.58%. The compound was converted into the non-crystalline dimethyl ester with diazomethane and the molecular weight determined by mass spectroscopy. Mol. wt. calc. for $C_{32}H_{50}O_6$: 530.7. Found: 530.*

Dechlorosenegenin Diacetate

Dechlorosenegenin (57 mg) was acetylated (acetic anhydride – pyridine) by standing 3 days at room temperature. Isolation of the product and recrystallization from ether – light petroleum gave dechlorosenegenin diacetate (45 mg), m.p. 281–285°, $[\alpha]_D$ −2° (*c*, 1.61). Calc. for $C_{34}H_{50}O_8$: C, 69.59; H, 8.59%. Found: C, 69.76; H, 8.44%.

De(hydrochloro)senegenin

Senegenin (290 mg) was refluxed 3 hours in quinoline (6 ml; freshly distilled from zinc dust) under nitrogen. The reaction mixture was poured into dilute acid and extracted with ether. The ether extract was then extracted with sodium bicarbonate solution (5%) and the bicarbonate-soluble material isolated (180 mg). This gave a crystalline product (146 mg), found to be free of chlorine, from aqueous alcohol. Further recrystallization gave de(hydrochloro)senegenin, softened ~240°, m.p. 294–296° (gas evolution; evacuated capillary), $[\alpha]_D$ +80° (*c*, 0.75; methanol), ν_{max} 3320, 1697 cm^{-1} (Nujol mull). Calc. for $C_{30}H_{44}O_6.0.5H_2O$: C, 70.68; H, 8.90%. Found: C, 70.61; H, 8.67%.

De(hydrochloro)senegenin Diacetate

De(hydrochloro)senegenin (60 mg) in pyridine (2 ml) was treated overnight at room temperature with acetic anhydride (1 ml). After isolation, the product was placed on a silica gel column (Davison) and eluted with benzene–ether (4:1) to yield a crystalline product which when recrystallized from aqueous alcohol gave de(hydrochloro)senegenin diacetate, m.p. 215–218°, $[\alpha]_D$ +84° (*c*, 0.72; methanol). Calc. for $C_{34}H_{48}O_8.0.5H_2$: C, 68.77; H, 8.32%. Found: C, 68.61; H, 8.64%.

Dimethyl Ester of De(hydrochloro)senegenin

Dehydrochlorosenegenin (93 mg) was methylated with diazomethane and chromatographed on alumina (3 g; Woelm). Elution with benzene:ether (19:1) and recrystallization from alcohol gave the dimethyl ester of de(hydrochloro)senegenin, m.p. 228–231° (evacuated capillary), $[\alpha]_D$ +78° (*c*, 0.99), ν_{max} 3500, 1716 cm^{-1}, λ_{max} 243, 249, 256 mμ (ϵ = 13,200; 14,900; 11,800), n.m.r. bands at τ 9.22, 9.12, 8.97, 8.79, 8.65, 6.49, 6.32, 6.11 (doublet), 5.92 (multiplet), 4.70 (multiplet). Calc. for $C_{32}H_{48}O_6$: C, 72.69; H, 9.15%. Found: C, 72.11; H, 8.99%. Molecular weight determined by mass spectroscopy 528. Mol. wt. calc. for $C_{32}H_{48}O_6$: 528.7.

Treatment of Senegenin Dimethyl Ester with Quinoline

Senegenin dimethyl ester (53 mg) in quinoline (2.5 ml) was refluxed 0.5 hour under nitrogen. The mixture was poured into dilute sulphuric acid and extracted by ether. The ether extract was washed with dilute hydrochloric acid and then with sodium bicarbonate solution (5%). Removal of the ether gave a crude product (48 mg) which was chromatographed on alumina (2 g; Woelm). Elution with benzene:ether (9:1) afforded a substance recrystallized from alcohol and shown by ultraviolet and infrared spectra and mixed melting point to be identical with de(hydrochloro)senegenin dimethyl ester obtained above.

Acetylation of De(hydrochloro)senegenin Dimethyl Ester

The dimethyl ester of de(hydrochloro)senegenin (97 mg) in pyridine (2 ml) was treated overnight with acetic anhydride (1 ml). Upon isolation, the product was filtered through alumina (Merck). Benzene eluted a crystalline fraction recrystallized from alcohol to give the dimethyl ester of de(hydrochloro)senegenin

**We wish to thank Professor K. Biemann (M.I.T.) for this determination.*

For personal use only.

diacetate, m.p. 179–181° (evacuated capillary), $[\alpha]_D$ +64° (*c*, 1.03), ν_{max} 1732 cm^{-1} ($CHCl_3$), n.m.r. bands at τ 9.21, 9.09, 8.94, 8.83, 8.69, 8.09, 7.96, 6.51, 6.37, 4.76 (broad composite band). Calc. for $C_{36}H_{52}O_8$: C, 70.55; H, 8.55%. Found: C, 70.49; H, 8.50%.

Elution with ether gave a product recrystallized from alcohol to yield the monoacetate of the dimethyl ester of de(hydrochloro)senegenin, m.p. 218–221° (evacuated capillary), $[\alpha]_D$ +75° (*c*, 1.02), ν_{max} 3500 1720 cm^{-1}, n.m.r. bands at τ 9.21, 9.07, 8.92, 8.87, 8.74, 7.95, 6.49, 6.42, 6.32, 5.98 (multiplet), 4.80 (composite band). Calc. for $C_{34}H_{50}O_7$: C, 71.55; H, 8.83%. Found: C, 71.25; H, 8.79%.

Acetonide of De(hydrochloro)senegenin

De(hydrochloro)senegenin (24 mg) was shaken 64 hours in acetone (6 ml) with anhydrous copper sulphate. Paper chromatography using Tschesche's mixture B (9) indicated reaction to be complete at this time. The copper sulphate was filtered off and the acetone evaporated to yield a product which upon recrystallization from alcohol gave the acetonide of de(hydrochloro)senegenin, m.p. 281–295° (gas evolution), $[\alpha]_D$ +89° (*c*, 0.64; methanol). Calc. for $C_{33}H_{48}O_6 . 0.5H_2O$: C, 72.07; H, 8.98%. Found: C, 72.52; H, 8.76%.

Dimethyl De(hydrochloro)senegenin Diformate

Senegenin (59 mg) was refluxed 4 hours with formic acid (15 ml; 97%). The formic acid was removed under reduced pressure on the steam bath and the residue filtered through silica gel with ether. The product furnished crystals from alcohol when methylated with diazomethane. The crude methyl ester was chromatographed on silica gel (1.5 g; Davison). Elution with benzene afforded crystalline fractions (41 mg) which were combined and recrystallized from alcohol to give the dimethyl ester diformate of de(hydrochloro)-senegenin, m.p. 235–240° (evacuated capillary), $[\alpha]_D$ +72° (*c*, 0.95), ν_{max} 1720 cm^{-1} (broad band), λ_{max}^{MeOH} 240, 248, 256 mμ, (ϵ 11,910; 13,850; 9440), n.m.r. bands at τ 6.34, 6.22, 1.82, 1.65. Calc. for $C_{34}H_{48}O_8$: C, 69.83; H, 8.27%. Found: C, 69.16; H, 8.39%.

Alkaline Hydrolysis of Senegenin Monoacetate

(*a*) Senegenin monoacetate (135 mg) was refluxed under nitrogen with methanolic potassium hydroxide solution (10 ml; 5%) for 15 minutes. Upon cooling, crystals of the potassium salt deposited on the surface of the flask. Isolation of the product after acidification and recrystallization from alcohol afforded senegenin showing no melting point depression on admixture with material obtained by acid hydrolysis of the monoacetate.

(*b*) Senegenin monoacetate (30 mg) was refluxed 24 hours under nitrogen with an aqueous alcoholic (1:3, water:ethanol) sodium hydroxide solution (10 ml; 5%). After acidification, isolation of the product, followed by methylation and recrystallization from alcohol, the dimethyl ester of de(hydrochloro)senegenin was obtained, m.p. 234–237° (evacuated capillary), which was undepressed on admixture with that obtained above and which exhibited identical behavior upon thin-layer chromatography.

Isodechlorosenegenin

Dehydrochlorosenegenin (28 mg) was hydrogenated in glacial acetic acid (5 ml) over platinum oxide catalyst for a period of 2.5 hours. Recrystallization of the product from aqueous alcohol gave isodechlorosenegenin, m.p. 289–292°, $[\alpha]_D$ +58° (*c*, 0.96; methanol), λ_{max} 199 mμ, (ϵ 6680). Calc. for $C_{30}H_{46}O_6 . 0.5H_2O$: C, 70.42; H, 9.26%. Found: C, 69.96; H, 9.22%.

Isodechlorosenegenin Dimethyl Ester

The dimethyl ester of dehydrochlorosenegenin (31 mg) in ethyl acetate was hydrogenated using palladium on charcoal (5%) catalyst. In 7 minutes 0.9 mole of hydrogen was absorbed. The product was recrystallized from alcohol to give the dihydro derivative, isodechlorosenegenin dimethyl ester, m.p. 221–223° (evacuated capillary), $[\alpha]_D$ +41° (*c*, 1.30), n.m.r. bands at τ 5.86 (multiplet), 6.05 (doublet), 6.29, 6.40 ($COCH_3$). Calc. for $C_{32}H_{50}O_6 . 0.5H_2O$: C, 71.20; H, 9.52%. Found: C, 71.41; H, 9.48%.

Acetylation of Isodechlorosenegenin Dimethyl Ester

Isodechlorosenegenin dimethyl ester (43 mg) in pyridine (2 ml) was treated with acetic anhydride (1 ml) for 6 hours. The product consisting of monoacetate together with some diacetate (see below) was separated by (silicic acid) thin-layer chromatography (3% methanol in chloroform). Recrystallization of the slower moving compound from methanol gave the monoacetate of isodechlorosenegenin dimethyl ester, m.p. 173–176°, $[\alpha]_D$ +33° (*c*, 1.15), ν_{max} 3490, 1720 cm^{-1}. Calc. for $C_{34}H_{52}O_7 . 0.5H_2O$: C, 70.19; H, 9.18%. Found: C, 70.55; H, 8.79%.

Isodechlorosenegenin dimethyl ester (74 mg) was allowed to react with acetic anhydride – pyridine for a period of 50 hours and yielded a product which was recrystallized from alcohol to give the dicaetate, m.p. 192–196° (evacuated capillary), $[\alpha]_D$ +53° (*c*, 0.96), ν_{max} 1725 cm^{-1}, n.m.r. bands at τ 8.04, 7.94, 6.39, 6.34, 4.66 (broad composite band) ($CDCl_3$). Calc. for $C_{36}H_{54}O_8$: C, 70.33; H, 8.85%. Found: C, 70.65; H, 8.77%.

De(hydrochloro)senegenin Monomethyl Ester

De(hydrochloro)senegenin dimethyl ester (34 mg) was refluxed for 2 hours under nitrogen with alcoholic potassium hydroxide solution (5%; 10 ml). The product was isolated by ether extraction after acidification

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and dilution with water. The acid obtained was recrystallized from aqueous alcohol to give the de(hydrochloro)senegenin monomethyl ester, m.p. 249–252° (evacuated capillary; gas evolution), $[\alpha]_D$ +58° (*c*, 0.79; methanol). Calc. for $C_{31}H_{46}O_6.H_2O$: C, 69.89; H, 9.08%. Found: C, 70.38; H, 9.03%.

Remethylation of the monoacid (6 mg) gave a crystalline compound with identical infrared spectrum and behavior upon thin-layer chromatography (silica gel) as was observed with de(hydrochloro)senegenin dimethyl ester.

Periodic Acid Titration of Senegenin Dimethyl Ester

Senegenin dimethyl ester (36 mg), dissolved in methanol (8 ml) and water (1 ml), was titrated with periodic acid (1 ml; approx. 0.32 *N*). After 1.25 hours, the uptake of oxidant had ceased with consumption of 1 mole. The product was isolated but could not be induced to crystallize.

Dehydroisodechlorosenegenin Dimethyl Ester

Isodechlorosenegenin (109 mg) in pyridine (1.1 ml) was added to chromic anhydride (108 mg) in pyridine (1.1 ml) and let stand at room temperature for 10 hours. The reaction mixture was dissolved in alcohol and dilute hydrochloric acid, diluted with water, and extracted with ether to yield the crude ketol (92 mg). This was recrystallized from alcohol to give dehydroisodechlorosenegenin dimethyl ester, m.p. 186–188° (evacuated capillary), $[\alpha]_D$ +31° (*c*, 0.97), ν_{max} 3495, 1723 cm^{-1} (CCl_4), n.m.r. bands at τ 6.43, 6.27, 5.51. Calc. for $C_{32}H_{48}O_6$: C, 72.69; H, 9.15%. Found: C, 73.11; H, 9.03%.

The above ketol (20 mg) was acetylated (acetic anhydride – pyridine; room temperature) to give a non-crystalline acetate, ν_{max} 1758, 1728 cm^{-1} (CCl_4), n.m.r. bands at τ 7.95, 6.46, 6.32, 4.57 (singlet).

Diketone from Isodechlorosenegenin Dimethyl Ester

The above ketol (42 mg) was refluxed 10 hours under nitrogen in glacial acetic acid (4 ml) with bismuth oxide (53 mg). The solvent was evaporated and the residue dissolved in ether and dilute hydrochloric acid. The ether solution was washed, dried, and evaporated, yielding a crude product, which appeared as mainly one spot upon thin-layer chromatography. This crude, non-crystalline, diketone in absolute alcohol (3 ml) and acetic acid (0.5 ml) was refluxed 3 hours under nitrogen with *o*-phenylenediamine. The product was isolated by ether extraction and the ether was washed with dilute hydrochloric acid. Recrystallization from alcohol afforded the quinoxaline derivative, m.p. 260–263° (evacuated capillary), $[\alpha]_D$ +40° (*c*, 0.99), ν_{max} 1728 cm^{-1} (CCl_4), λ_{max} 238, 322, 312 (shoulder) (ϵ 34,300; 10,200; 7900). Calc. for $C_{38}H_{48}O_4N_2.0.5H_2O$: C, 75.34; H, 8.15; N, 4.63%. Found: C, 75.61; H, 8.44; N, 4.79%.

Isodechlorosenegenin Monomethyl Ester

Isodechlorosenegenin dimethyl ester (40 mg) was refluxed 2 hours under nitrogen with alcoholic potassium hydroxide solution (5%; 5 ml). The acidic material was isolated and recrystallized from aqueous alcohol to give isodechlorosenegenin monomethyl ester, m.p. 284–286° (evacuated capillary), $[\alpha]_D$ +57° (*c*, 1.09; methanol). Calc. for $C_{31}H_{48}O_6$: C, 72.06; H, 9.36; O, 18.58%. Found: C, 71.82; H, 9.20; O, 18.61%.

Nor-diosphenol Acetate

Isodechlorosenegenin monomethyl ester (80 mg) in pyridine (0.8 ml) was added to chromic anhydride (88 mg) in pyridine (0.8 ml) and let stand 9 hours at room temperature. The oxidation product (53 mg) was isolated as previously but could not be induced to crystallize. The gum was then refluxed 1 hour with methanolic potassium hydroxide (10%; 10 ml). The crude product (49 mg) was isolated and found to give a positive ferric chloride test. It exhibited ν_{max} 3460 (hydroxyl), 1725 (methyl ester and ketone), 1675 (unsaturated ketone), 1648 (double bond) cm^{-1} (CCl_4), λ_{max}^{MeOH} 279 mμ (ϵ 4600) (band showed characteristic change to higher wavelength upon addition of alkali). It was then acetylated (acetic anhydride – pyridine, overnight). The crude acetate was chromatographed on a column of silica gel (Davison). Elution with benzene:ether (19:1) afforded the crystalline nor-diosphenol acetate, m.p. 190–192° (evacuated capillary), $[\alpha]_D$ +83° (*c*, 0.85), ν_{max} 1752 (acetate), 1718 (methyl ester), 1674 (unsaturated ketone), 1640 (double bond) cm^{-1}, λ_{max}^{MeOH} 246 mμ (ϵ 9630). Calc. for $C_{32}H_{46}O_5$: C, 75.26; H, 9.08%. Found: C, 74.87; H, 9.08%.

ACKNOWLEDGMENTS

The support of the National Research Council is gratefully acknowledged. We also wish to thank Mr. R. E. Klinck for the determination of the n.m.r. spectra.

NUCLEAR MAGNETIC RESONANCE STUDIES OF THE PROTONATION OF WEAK BASES IN FLUOROSULPHURIC ACID

III. METHYLBENZENES AND ANISOLE

T. Birchall and R. J. Gillespie
Department of Chemistry, McMaster University, Hamilton, Ontario

Received May 29, 1963

ABSTRACT

The proton magnetic resonance spectra of solutions of mesitylene, durene, pentamethylbenzene, hexamethylbenzene, *m*- and *p*-xylenes, and anisole have been studied in fluorosulphuric acid and protonation on the ring carbon atom established. Rates of proton exchange have been measured and activation energies calculated for the proton exchange process. Intermolecular exchange with the solvent is suggested as the most probable exchange process in all cases.

INTRODUCTION

The protonation and relative basicities of the various methylbenzenes has been discussed in a number of papers (1–5). It has been assumed that the proton adds to one carbon atom thereby forming an "aliphatic" CH_2 group as first suggested by Gold and Tye (2) in the case of anthracene. Definite evidence in support of this has been obtained from the n.m.r. spectra of the conjugate acids of a number of aromatic hydrocarbons obtained by dissolving the hydrocarbon in a strongly acidic medium such as $BF_3.H_2O/CF_3CO_2H$ or BF_3/HF (6). Although for pentamethylbenzene in BF_3/HF a rather broad line due to the CH_2 group was observed at room temperature; for hexamethylbenzene, mesitylene, and other weaker bases it was necessary to make measurements at low temperatures in order to observe the resonance of the CH_2 protons. This has been attributed to the exchange of the CH_2 protons by one or more of three processes.

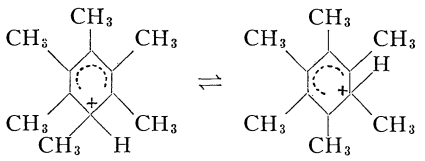
(i) Exchange with the solvent HS

$$AH^+ + S^- = A + HS.$$

(ii) Intermolecular exchange between the aromatic hydrocarbon and its conjugate acid

$$A + AH^+ = AH^+ + A.$$

(iii) Intramolecular exchange of the proton between positions of equal proton affinity on the same carbonium ion, for example,



From the results of their studies of the protonation of aromatic hydrocarbons in HF/BF_3 MacLean and Mackor (7) have concluded that for hexamethylbenzene, durene, and prehnitene, exchange proceeds by (iii); for mesitylene, by (ii) and (i); and for *m*-xylene by (ii) alone, while for pentamethylbenzene, they observed no exchange.

We have made similar measurements of the spectra of aromatic hydrocarbons in solutions in fluorosulphuric acid at temperatures down to −90°. In contrast to MacLean and

Mackors' conclusions we find that the observed spectra may in all cases be interpreted in terms of exchange by (i).

EXPERIMENTAL

The bases were commercial samples; solids were recrystallized. The n.m.r. spectra run at high gain showed no peaks that could be attributed to impurities. Fluorosulphuric acid was distilled twice in a dry atmosphere before use. The solutions were prepared at the temperature of an acetone – dry ice mixture.

The n.m.r. spectra were recorded with a Varian H.R. 60 spectrometer equipped with a variable temperature probe and an integrator. Chemical shifts were measured from an external reference of tetramethylsilane using the audio side-band technique.

RESULTS AND DISCUSSION

Spectra of Hydrocarbon Conjugate Acids

For each of the hydrocarbons studied it was found that at sufficiently low temperatures and under sufficiently acid conditions the lifetime of the hydrocarbon conjugate acid is long enough for its n.m.r. spectrum to be observed.

Mesitylene

The spectrum of a 6.16 mole % (1.2 molar) solution of mesitylene in fluorosulphuric acid at −79° C is shown in Fig. 1. It consists of three peaks A, B, and C of relative areas 2.02:1.96:9.08. These three peaks must arise from the two aromatic protons A, the two methylene protons B, and the three methyl groups C respectively, indicating that protonation has occurred on one of the ring carbon atoms. Since the three methyl groups are no longer equivalent the methyl resonance actually consists of two overlapping peaks of relative areas 2:1. The spectra of other solutions with concentrations in the range 2–6 mole% were all quite similar. No signals were observed for any of the solutions that could be attributed to the unprotonated mesitylene, indicating that, under our experimental conditions, the protonation of mesitylene is essentially complete. This is of some interest since MacLean and Mackor's (7) n.m.r. spectrum of a 3.5 molar solution of mesitylene in anhydrous hydrogen fluoride saturated with boron trifluoride indicated that only 60% of the mesitylene was present in the protonated form, the remainder being present as the free base.

No fine structure due to spin–spin coupling was observed in our spectra. In HF solution MacLean and Mackor found that the para-methyl group signal was a triplet and they attributed this to spin–spin coupling with the methylene group although the expected quartet splitting of the methylene signal was not observed.

Durene

Four peaks A, B, C, and D are observed in the spectrum of a solution of durene in fluorosulphuric acid at low temperature (Fig. 2). These may be attributed to the CH and CH_2 groups and two non-equivalent methyl groups respectively. The relative areas were found to be A:B:C+D = 0.87:1.79:12.0 in agreement with the proposed assignment.

Pentamethylbenzene

Protonation of pentamethylbenzene occurs at the only unsubstituted ring position. The spectrum of a fluorosulphuric acid solution at −49° is shown in Fig. 3; it consists of four peaks A, B, C, and D of relative areas A:B:C:D = 1.77:3.14:6.09:6.00 which may be attributed to the CH_2, p-CH_3, o-CH_3, and m-CH_3 groups respectively.

Hexamethylbenzene

A solution of hexamethylbenzene (2.7 mole %) in fluorosulphuric acid was found to give at −85°, a spectrum consisting of five peaks of relative areas A:B:C:D:E =

FIG. 2. Nuclear magnetic resonance spectrum of a solution of durene (1.12 mole%) in fluorosulphuric acid.

0.99:3.06:6.13:6.35:3.00 which may be attributed to the HCCH$_3$, p-CH$_3$, o-CH$_3$, m-CH$_3$, and HCCH_3 groups respectively (Fig. 4*a*). Under favorable conditions E was observed as a poorly resolved doublet due to coupling with the single proton A (J = 5.8 c/s) but no corresponding splitting of peak A was observed. In HF/BF$_3$ solution MacLean and Mackor found J_{AE} = 6.7 c/s and also J_{AB} = 3.5 c/s and J_{AC} = 1 c/s (6, 7). We were unable to observe any fine structure other than the doublet E.

m-Xylene

Figure 5 shows the spectrum of a solution of *m*-xylene in 1.2 mole % SbF$_5$/HSO$_3$F at

−50° C. The relative areas of the peaks were found to be A:B:C = 2.91:1.80:6.00. The spectrum is best explained by assuming protonation ortho to one methyl group and para to the other methyl group. The "doublet" C is due to the non-equivalent methyl groups and B arises from the methylene protons. The phenyl part of the spectrum A consists of a single peak due to the proton ortho to both methyl groups superimposed on an AB quartet arising from the other two ring protons. The unequal heights of the methyl peaks may be attributed to unresolved spin–spin coupling causing a greater broadening of one peak than the other.

p-Xylene

The much weaker base *p*-xylene was examined in a 13 mole% SbF_5/HSO_3F solution. At −63° C the lowest temperature at which a reasonable spectrum could be recorded due to the high viscosity of the solution, only two very broad lines were visible in the spectrum: one was due to the ring protons and the other to the methyl groups. From an integrated spectrum the relative areas of the two peaks were found to be 4.77:6.00, indicating that ring protonation had taken place.

Anisole

The spectrum of a solution of anisole in fluorosulphuric acid at 25° shown in Fig. 6*a* closely resembles that obtained in an organic solvent except that the spectrum is shifted 0.6 p.p.m. to lower field. Figures 6*b* and 6*c* show the effect of decreasing the temperature. A new peak appears at 4.4 p.p.m. below the tetramethylsilane reference which can be attributed to a methylene group formed by ring protonation. At 0° the lack of resolution in the phenyl spectrum indicates that exchange of the CH_2 protons with the solvent is still occurring but at −64° fine structure can be observed in the phenyl spectrum and as this does not change further at lower temperatures it is reasonable to suppose that exchange has become very slow. The spectrum is best explained by postulating protonation at the ring position para to the methoxy group as MacLean and Mackor have previously done in order to explain the results of their studies of HF solutions (7), and not on the oxygen atom as has been assumed to explain the results of ultraviolet spectroscopic measurements (8). Evidence for ring protonation has also been obtained recently in the cases of di- and tri-methoxybenzene (7, 9).

Rates of Proton Exchange

On increase of the temperature of the solutions the lifetime of the conjugate acid decreases and the spectrum changes correspondingly. The methyl spectrum collapses to a single line for all the solutes except pentamethylbenzene, which is the only one for which proton exchange does not lead to equivalence of the *o*-, *m*-, and *p*-CH_3 groups; the methylene (or $CH.CH_3$) and phenyl peaks broaden and eventually merge into the base line, and finally the solvent line broadens somewhat. The broadening of the solvent peak is especially noticeable when the concentration of the hydrocarbon is relatively large. The collapse of the methyl peaks of the conjugate acid of hexamethylbenzene with increasing rate of proton exchange is illustrated in Figs. 4*a–d*. The *o*-CH_3 group is the first to collapse since it has the smallest chemical shift and the methyl group on the site of protonation is the last since it has the largest chemical shift from the other methyl peaks.

These observations may be attributed to proton exchange by one or more of the processes (i), (ii), and (iii). The lifetime of the conjugate acid can be obtained from the widths of the CH and CH_2 (or $CH.CH_3$) signals. Under conditions where these signals can be observed the lifetime of the conjugate acid is large compared with the inverse of the separation of exchangeable sites and the condition for slow exchange may be applied.

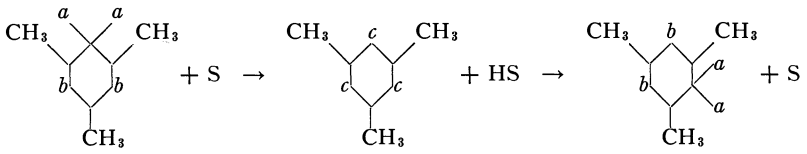
The relation between the lifetime of any particular proton in a hydrocarbon conjugate acid and the lifetime of the conjugate acid τ depends on the conditions under which exchange occurs and on the particular hydrocarbon under consideration. MacLean and Mackor (7) have dealt with the case when the concentration of the free base and of the conjugate acid are comparable. Under our conditions the concentration of free base is negligibly small. For the conjugate acid of mesitylene under these conditions exchange between the two proton sites *a* and *b* occurs by slow rate-determining loss of the proton to a solvent molecule followed by rapid addition of another proton from the solvent.



If τ_{as}^{-1} and τ_{ac}^{-1} are the probabilities that an *a* proton becomes an *S* proton or a *c* proton respectively then

$$\tau_{as}^{-1} = \tfrac{1}{2}\tau^{-1} \text{ and } \tau_{ac}^{-1} = \tfrac{1}{2}\tau^{-1}.$$

Since two-thirds of the *c* protons are rapidly reconverted to *b* protons

$$\tau_{ab}^{-1} = \tfrac{2}{3}\tau_{ac}^{-1} = \tfrac{1}{3}\tau^{-1}.$$

Hence

$$\tau_{CH_2}^{-1} = \tau_{ab}^{-1} + \tau_{as}^{-1} = \tfrac{5}{6}\tau^{-1}.$$

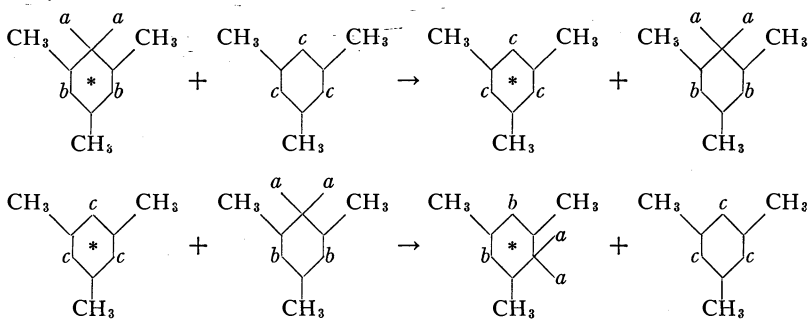
Now $\tau_{bc}^{-1} = \tau^{-1}$ and since one-third of the *c* protons are rapidly reconverted to *a* protons

$$\tau_{ba}^{-1} = \tfrac{1}{3}\tau_{bc}^{-1} = \tfrac{1}{3}\tau^{-1}.$$

Hence

$$\tau_{CH}^{-1} = \tau_{ba}^{-1} = \tfrac{1}{3}\tau^{-1}.$$

According to mechanism (ii) exchange between the protons sites *a* and *b* in the conjugate acid occurs by bimolecular reaction with the free base.



We have

$$\tau_{ac}^{-1} = \tfrac{1}{2}\tau^{-1} \text{ and } \tau_{bc}^{-1} = \tau^{-1}.$$

Since two-thirds of the *c* protons are rapidly reconverted to *b* protons and one-third to *a* protons

$$\tau_{ab}^{-1} = \tfrac{2}{3}\tau_{ac}^{-1} = \tfrac{1}{3}\tau^{-1} \text{ and } \tau_{ba}^{-1} = \tfrac{1}{3}\tau_{bc}^{-1} = \tfrac{1}{3}\tau^{-1}.$$

Hence

$$\tau_{CH_2}^{-1} = \tau_{CH}^{-1} = \tfrac{1}{3}\tau^{-1}.$$

The corresponding relations for other hydrocarbons may be derived similarly.

	Mechanism (i)		Mechanism (ii)
Mesitylene	$\tau_{CH_2}^{-1} = \frac{5}{6}\tau^{-1}$,	$\tau_{CH}^{-1} = \frac{1}{3}\tau^{-1}$	$\tau_{CH_2}^{-1} = \tau_{CH}^{-1} = \frac{1}{3}\tau^{-1}$
Durene	$\tau_{CH_2}^{-1} = \frac{3}{4}\tau^{-1}$,	$\tau_{CH}^{-1} = \frac{1}{2}\tau^{-1}$	$\tau_{CH_2}^{-1} = \frac{1}{4}\tau^{-1}$, $\tau_{CH}^{-1} = \frac{1}{2}\tau^{-1}$
Hexamethylbenzene	$\tau_{CH.CH_3}^{-1} = \tau^{-1}$		No broadening
Pentamethylbenzene	$\tau_{CH_2}^{-1} = \frac{1}{2}\tau^{-1}$		No broadening
m-Xylene	$\tau_{CH_2}^{-1} = \frac{3}{4}\tau^{-1}$		$\tau_{CH_2}^{-1} = \frac{1}{4}\tau^{-1}$

The width of the signal ($T_2'^{-1}$) from the protons at a site A is given by

$$T_2'^{-1} = T_2^{-1} + \tau_A^{-1},$$

where τ_A is the lifetime of the protons at A and T_2^{-1} is the natural line width in the absence of exchange. The first-order rate constant for proton loss by the conjugate acid is given by

$$k = \tau^{-1}.$$

In order to obtain a value for τ from the measured line widths it is necessary to know T_2. The CH and CH_2 line widths for mesitylene are plotted against the temperature in Fig. 7.

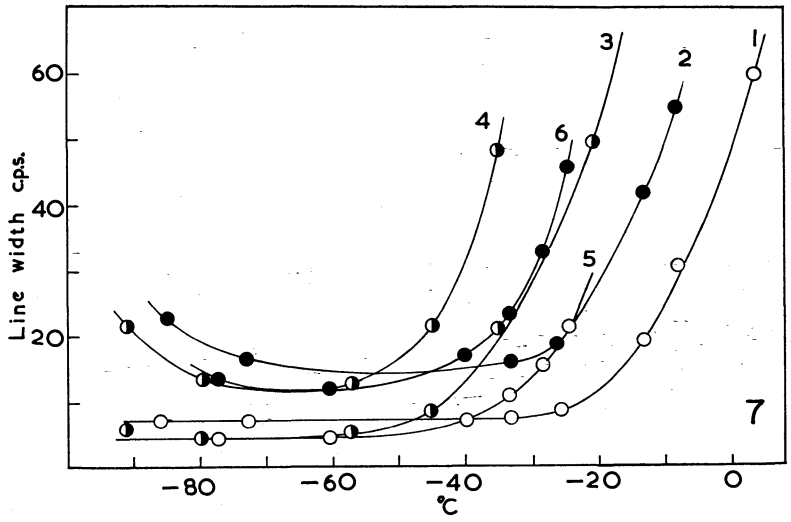

FIG. 7. Plots of line width against temperature for the CH and CH_2 peaks of solutions of mesitylene in fluorosulphuric acid.

They decrease with decreasing temperature and eventually reach a constant limiting value. It seems reasonable to assume that at these temperatures proton exchange is slow enough that it no longer affects these line widths and these limiting values were taken as a measure of the line width in the absence of exchange (T_2^{-1}). Values were obtained in a similar manner for the other hydrocarbons. At very low temperatures the CH_2 but not the CH line widths increase again somewhat. This may possibly be attributed to a decrease in the relaxation time as a consequence of an increase in η/T where η is the viscosity and T is the absolute temperature. The line width of the CH_2 peak is in all cases considerably

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

greater than that of the CH peak. This may be due to unresolved spin–spin coupling in the CH_2 signal or to the protons of the methylene group having a shorter relaxation time which might possibly be attributed to these protons being involved in rather strong hydrogen bonding with the solvent. The line widths of the CH and CH_2 peaks in SbF_5/HSO_3F solutions are greater than for solutions in HSO_3F alone, which is consistent with the greater viscosity of these solutions.

It is also clear from Fig. 7 that the line widths are dependent on the concentration of the hydrocarbon base. An increase in the concentration of hydrocarbon results in an increase in the CH and CH_2 line widths and a decrease in the temperature at which line broadening is first observed. Evidently the rate of proton exchange increases with increasing concentration of the hydrocarbon base. As the ionization of the hydrocarbon produces fluorosulphate ion which increases the basicity of the solvent we attribute this increase in exchange rate to an increase in the solvent basicity. A detailed comparison of the rates of proton exchange at −20° of all the compounds studied is given in Table I. The rate

increases in every case with increase in the concentration of the hydrocarbon. Our suggestion that this may be attributed to the effect of the increased concentration of fluorosulphate ion resulting from the protonation of the hydrocarbon is confirmed by the effect of added fluorosulphate ion in increasing the rate in the case of pentamethylbenzene and the effect of added antimony pentafluoride in reducing the rate in the cases of mesitylene, durene, hexamethylbenzene, and *m*-xylene. In this respect our results differ substantially from those of MacLean and Mackor (7), who claim that the rate of proton exchange for hexamethylbenzene and prehnitene are independent of the concentration of the BF_3 in a BF_3/HF solvent and they concluded that in these cases exchange occurs by the intramolecular process (iii). We found, in fact, that the addition of antimony pentafluoride to a solution of hexamethylbenzene in fluorosulphuric acid increased the lifetime of the conjugate acid to such an extent that the CH peak did not broaden sufficiently even at 25° to enable a lifetime to be measured. These results clearly exclude the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

possibility that (iii) is the only exchange process for any of the compounds that we have studied.

In the case of mesitylene we may note that mechanism (ii) predicts equal broadening for both the CH and CH_2 signals whereas mechanism (i) predicts a greater broadening for the CH_2 than the CH signal. Figure 7 shows that the CH_2 signal broadens more rapidly than the CH signal. Thus, in this case at least, mechanism (i) seems to be more important than (ii). Further evidence in favor of (i) is provided by the observation that the solvent peak broadens somewhat as the CH and CH_2 peaks broaden; some representative results are given in Table II. Because of the high concentration of the solvent in the

TABLE II

Dependence of the solvent line width on temperature

	(4.42% SbF_5)	−56	6.6

solutions the amount of broadening of the solvent peak is not great enough to enable exchange rates to be calculated with any accuracy but nevertheless our results clearly indicate that exchange cannot occur only by process (ii) because this does not involve the solvent. We conclude therefore that proton exchange occurs mainly via the solvent although one cannot entirely rule out the possibility that there might, in addition, be some exchange by (ii) and (iii) under suitable conditions.

The dependence of the rate of proton exchange on the temperature can be expressed by the Arrhenius equation

$$k = k_0 e^{-E/RT}.$$

Plots of log k against $1/T$ are shown in Fig. 8 for solutions of mesitylene in HSO_3F. We note that the rates obtained from both the CH and CH_2 line widths give reasonably straight and parallel lines; this provides some confirmation of the values chosen for T_2^{-1}.

Similar plots were made for the other bases, and the results are summarized in Table III. We note that except for pentamethylbenzene the activation energies fall in the range 13–15 kcal and are much higher than the values obtained by MacLean and Mackor for HF/BF_3 solutions which are in the range 7–8.5 kcal. This is possibly a reflection of the smaller basicity of our solvent media. However, there are other differences between our results and those of MacLean and Mackor that are difficult to explain. It seems remarkable, for example, that proton exchange involving the conjugate acid of hexamethylbenzene proceeds entirely by an intramolecular process in solution in hydrogen fluoride but predominantly, if not entirely, by intermolecular exchange with the solvent in solution in fluorosulphuric acid. Again, we find that in fluorosulphuric acid durene exchanges very much more rapidly than hexamethylbenzene, which is consistent with the relative

basicities of these compounds, whereas MacLean and Mackor obtained exchange rates in hydrogen fluoride that were almost the same under the same conditions.

ACKNOWLEDGMENT

We are grateful to the Directorate of Chemical Sciences, United States Air Force Office of Scientific Research, and the Petroleum Research Fund of the American Chemical Society for financial aid and to the Dow Chemical Company of Canada, Limited, for a Postgraduate Fellowship (to T. B.). We also thank Dr. E. L. Mackor for his very helpful comments on the manuscript.

THE PREPARATION OF THE HYDROXYSKATOLES AND 5,6-DIHYDROXYSKATOLE[1]

R. A. HEACOCK AND O. HUTZINGER
The Psychiatric Research Unit, University Hospital, Saskatoon, Saskatchewan
Received September 16, 1963

ABSTRACT

A new procedure for the preparation of the hydroxyskatoles has been devised. 4-, 5-, 6-, and 7-benzyloxyindole-3-carboxaldehyde and 5,6-dibenzyloxyindole-3-carboxaldehyde have been prepared and give the corresponding benzyloxyskatoles on reduction with either $LiAlH_4$ or $NaBH_4$/Pd–C. The 4-, 5-, 6-, and 7-hydroxyskatoles and 5,6-dihydroxyskatole are readily obtained on catalytic debenzylation of the relevant benzyloxy compound. An alternative method for the preparation of the hydroxyskatoles involving hydrogenolysis of the benzyloxygramines is also described.

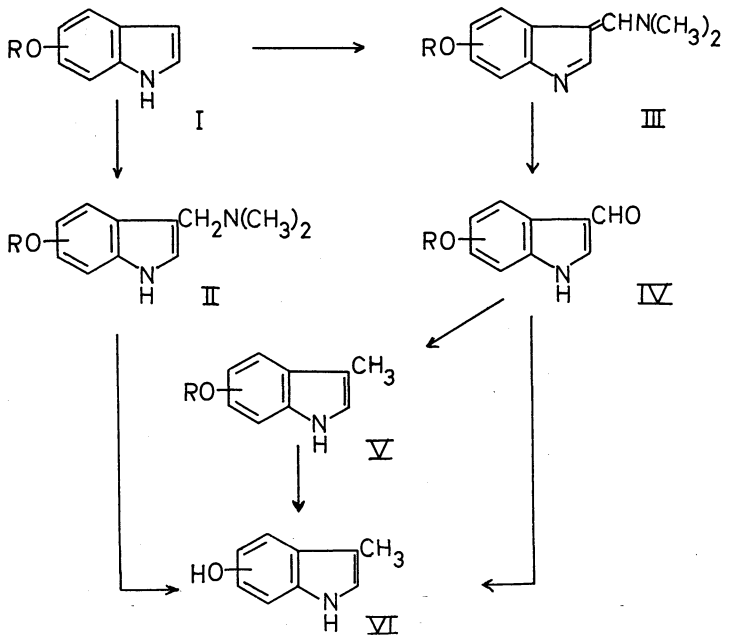
The possible structures of by-products obtained in some instances are discussed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The sulphate ester of a hydroxyskatole, usually considered to be the 6-isomer, has been reported to be excreted in the urine in certain pathological conditions (1, 2) including some forms of mental illness (cf. reviews by Sprince (3) and Rodnight (4)). However, until relatively recently none of the hydroxyskatoles had been described in the literature. In 1956 Teuber and Staiger reported obtaining a substance described as 5-hydroxyskatole (VI: HO— = 5-HO—) by the oxidation of 3-methylindoline with potassium nitrosodisulphonate although no proof of structure or analytical data was given (5). In 1959, Horning *et al.* claimed, without giving any details of their experimental procedure, that 6-hydroxyskatole (VI: HO— = 6-HO—) could be obtained from 6-benzyloxyskatole (V: RO— = 6-$C_6H_5CH_2O$—); the benzyloxyskatole having been obtained by an application of the Fischer indole synthesis (2). 5-Hydroxyskatole (VI: HO— = 5-HO—) has been obtained by the hydrogenolysis of 5-benzyloxygramine (II: RO— = 5-$C_6H_5CH_2O$—) (Acheson and Hands (6), Marchand (7), and Heacock and Hutzinger (8)). The hydrogenation of 6-benzyloxygramine (II: RO— = 6-$C_6H_5CH_2O$—) was initially reported to give a mixture of 6-hydroxyskatole (VI: HO— = 6-HO—), 6-benzyloxyskatole (V: RO— = 6-$C_6H_5CH_2O$—), and unchanged starting material from which the pure hydroxy compound was apparently not isolated (9) although this has recently been accomplished (8). It has now been established that this reaction is of general applicability and that all four hydroxyskatoles can be obtained from the corresponding benzyloxgramine (cf. preliminary report (8)). The reaction conditions for optimum yields of the hydroxyskatoles (cf. VI) from the benzyloxygramines (cf. II) were determined by examining test samples of the reaction mixture chromatographically on formamide-treated paper (cf. 10). This technique also indicated the degree of by-product formation under any particular set of reaction conditions. No significant by-product formation was detected during the preparation of the 5- and 7-hydroxyskatoles by this procedure; however, it was impossible to prevent by-product formation during the synthesis of the 4- and 6-isomers. (The nature of these products will be discussed later.)

In view of the fact that high yields of the hydroxyskatoles could not always be obtained by the method described above, a new procedure has been developed. The synthesis of

[1]*This investigation was supported by grants from the Government of Saskatchewan (Department of Public Health) and the Department of National Health and Welfare (Ottawa).*



the 5- and 6-benzyloxindole-3-carboxaldehydes (IV: RO— = 5- and 6-$C_6H_5CH_2O$— respectively) (11, 12) by procedures similar to that described for the formylation of indole (13, 14) with phosphorus oxychloride and dimethylformamide has been described in the literature. The intermediate 3-dimethylaminomethyleneindolenine (cf. III) giving the indole-3-carboxaldehyde (cf. IV) derivative on treatment with alkali. This procedure has now been applied to the preparation of 4- and 7*-benzyloxyindole-3-carboxaldehydes (IV: RO— = 4- and 7-$C_6H_5CH_2O$— respectively). In all cases good yields of the aldehydes were obtained, and the crude products were usually sufficiently pure to be used in the next stage of the procedure.

In one instance, 4-benzyloxygramine (II: RO— = 4-$C_6H_5CH_2O$—) was obtained on reduction of the crude formylation product; this must have arisen from the reduction of the undecomposed intermediate 4-benzyloxy-3-dimethylaminomethyleneindolenine (III: RO— = 4-$C_6H_5CH_2O$—). Hydrogenation of (II: RO— = 4-$C_6H_5CH_2O$—) then gave 4-hydroxyskatole (VI: HO = 4-HO—). Usually the intermediate (III: RO— = 4-$C_6H_5CH_2O$—) would be decomposed by alkali to give 4-benzyloxyindole-3-carboxaldehyde (IV: RO— = 4-$C_6H_5CH_2O$—), which would give (VI: HO— = 4-HO—) on reduction and debenzylation.

In 1953 it was reported that skatole, and not the expected 3-hydroxymethylindole, was obtained, on reduction of indole-3-carboxaldehyde with lithium aluminum hydride (Leete and Marion (15) and Rossiter and Saxton (16)). The current investigation has shown that all the benzyloxyindole-3-carboxaldehydes (cf. IV) described above can be reduced to the corresponding benzyloxyskatoles (cf. V) by this procedure. However, in some cases (i.e. with 5- and 6-benzyloxyindole-3-carboxaldehyde) (IV: RO— = 5- and 6-$C_6H_5CH_2O$— respectively) significant amounts of unidentified by-products were formed

**Although 7-benzyloxyindole-3-carboxaldehyde is available commercially (L. Light and Co.; Regis Chemical Co.) as far as the authors are aware details of the preparation of this compound have not been reported in the literature.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

at the same time as the desired benzyloxyskatole and consequently the possible use of different reducing systems was investigated in these cases. It has been reported that 3-hydroxymethylindoles are obtained on reduction of indole-3-carboxaldehydes with sodium or lithium borohydride (17, 18, 19, 20). Recently, it has been demonstrated that the reducing power of sodium borohydride is markedly enhanced by the addition of a suitable precious metal catalyst and that functional groups not usually attacked by sodium borohydride are reduced by this system (21, 22, 23, 24). Good yields of 5- and 6-benzyloxyskatole (V: RO— = 5- and 6-$C_6H_5CH_2O$— respectively) have now been obtained by the reduction of the corresponding aldehydes with sodium borohydride and 10% Pd–C in boiling isopropanol. The corresponding 4- and 7-benzyloxyskatoles (V: RO— = 4- and 7-$C_6H_5CH_2O$— respectively) could be obtained satisfactorily by reduction of the aldehyde with lithium aluminum hydride in boiling tetrahydrofuran. The only benzyloxyskatole which had previously been fully described in the literature was the 5-isomer (V: RO— = 5-$C_6H_5CH_2O$—) (6), which was obtained by the action of zinc and sodium hydroxide on 5-benzyloxygramine (II: RO— = 5-$C_6H_5CH_2O$—) (cf. 25). The desired hydroxyskatoles were readily obtained by catalytic debenzylation of the corresponding benzyloxyskatole.

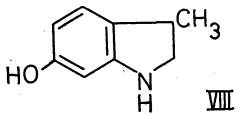
A by-product (VII) of unknown structure was invariably formed along with 4-hydroxyskatole on catalytic hydrogenation (Pd–C) of 4-benzyloxygramine. The presence of VII was indicated by the appearance of a second spot on paper chromatograms of the crude reaction mixtures. The unknown compound VII was also obtained on hydrogenation of 4-benzyloxyskatole and 4-hydroxyskatole, indicating that it was probably formed from the hydroxyskatole and not from either of the two possible precursors (i.e. 4-benzyloxyskatole or 4-benzyloxygramine). The formation of (VII) appeared to be facilitated if the hydrogenation was carried out in polar solvents (i.e. methanol). Elemental analysis and molecular weight determinations suggest that VII (a colorless crystalline solid, m.p. 205–206°) was a dihydrohydroxyskatole. However, it is probably not the corresponding indoline (i.e. 4-hydroxy-3-methylindoline), which might have been expected, in view of the well-known fact that indolines can be obtained by the hydrogenation of indoles (26), for the following reasons: (*a*) the ultraviolet absorption maximum of VII did not show the typical shift to higher frequency in acid solution expected for an indoline; (*b*) VII gave a pink-mauve color with Ehrlich's reagent (turning to a gray-blue overnight) and not the stable yellow color expected from an indoline; (*c*) VII does not appear to have any appreciable basic character and did not form a crystalline picrate, and (*d*) VII has a higher melting point than would have been expected for an indoline. The structure of the compound (VII), which may be a derivative of 4-hydroxyskatole, in which the benzene ring has been partially reduced, will be the subject of further investigations.

The hydrogenation of 6-benzyloxygramine or 6-benzyloxyskatole in ethyl acetate at $3\frac{1}{2}$ atmospheres pressure gave, besides the expected 6-hydroxyskatole, a smaller quantity of a second product (VIII). The formation of VIII, which gave a yellow color with Ehrlich's reagent, could be followed by paper chromatography. The compound (VIII) was probably 6-hydroxy-3-methylindoline for the following reasons: (*a*) the main ultraviolet absorption maximum showed the expected shift to shorter wavelengths in acid solution (i.e. 295 mμ → 279 mμ); (*b*) satisfactory microanalytical results; (*c*) the low melting point of VIII (it is a yellow oil at room temperature) is not inconsistent with its being an indoline; (*d*) catalytic dehydrogenation (Pd–C) gave 6-hydroxyskatole.

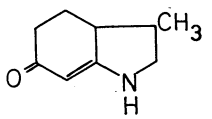
Under more vigorous hydrogenation conditions, 6-benzyloxygramine and 6-benzyloxyskatole, or their primary hydrogenation products 6-hydroxyskatole or 6-hydroxy-3-methylindoline (VIII), were converted into a new product (IX). The formation of IX

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

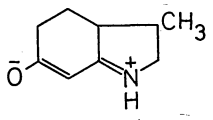
can be detected by paper chromatography (although IX did not react with Ehrlich's reagent, it could be detected by viewing of the chromatograms in short-wave ultraviolet light). Microanalytical and molecular weight data suggested that IX (a colorless crystalline solid, m.p. 194–195°) is a tetrahydro-6-hydroxyskatole. This compound is weakly basic in nature. The nitrogen atom must be involved in its chromophoric system since its single ultraviolet absorption maximum shifts from 285 mμ in neutral solution to 275 mμ in acid solution. Attempted catalytic dehydrogenation of IX was unsuccessful and the compound was recovered unchanged. Although more work will be needed to ascertain the structure of IX with certainty the evidence to date is not altogether incompatible with its being a 6-oxo-3-methyl-2,3,4,5,6,9-hexahydroindole (IX*a*), which probably exists mainly in the zwitterionic form (IX*b*). A similar product (the zwitterionic form (X) of



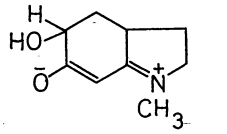
VIII



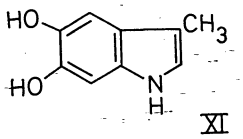
IX a



IX b



X



XI

which is depicted above) has previously been obtained, by Austin, Chanley, and Sobotka by the catalytic hydrogenation of 5,6-dihydroxy-*N*-methylindole (27).

5,6-Dihydroxyskatole (XI) previously obtained by the thermal decarboxylation of 5,6-dihydroxy-3-methylindole-2-carboxylic acid (28) was readily obtained by the hydrogenolysis of either 5,6-dibenzoyloxygramine or 5,6-dibenzyloxyskatole (this latter compound was prepared by the reduction of 5,6-dibenzyloxyindole-3-carboxaldehyde with sodium borohydride in the presence of a palladium–charcoal catalyst). The preparation of XI by the methods described above proceeded very readily with no detectable quantities of by-products being formed at the same time. The authors are unable to explain the claim by Acheson *et al.* that 5,6-dibenzyloxyskatole could not be debenzylated (29).

EXPERIMENTAL

All operations involving free hydroxyskatoles were carried out in an atmosphere of nitrogen. This is an important precaution to follow, otherwise yields are significantly reduced due to the formation of colored by-products, by air oxidation. The palladium-on-charcoal catalyst was added to the organic solvents in an atmosphere of nitrogen to prevent spontaneous ignition. The identity of compounds prepared by different procedures was established by mixed melting point determinations and by comparison of their infrared spectra, unless otherwise specified.

For personal use only.

The silica gel (200/400 mesh size) used for column chromatography was obtained from L. Light and Co. The following indole compounds were available commercially: 5-benzyloxyindole (Aldrich Chem. Co.); 6-benzyloxyindole (L. Light and Co.); 4- and 7-benzyloxyindole, 5,6-dibenzyloxyindole, and 5-, 6- and 7-benzyloxygramine (Regis Chemical Co.). The light petroleum used throughout this investigation was B.D.H. AnalaR grade (b.p. 80–100°).

4-Hydroxyskatole

(A) From 4-Benzyloxygramine

A suspension of 4-benzyloxygramine (250 mg) prepared by the method of Stoll *et al.* (30) and 5% palladium–charcoal (100 mg) in ethyl acetate (100 ml) was shaken at room temperature in an atmosphere of hydrogen at 30 p.s.i. for 3 hours. After this time the reaction mixture was filtered and the colorless solid obtained after concentration of the filtrate was dissolved in benzene and adsorbed on a silica gel column. Elution of the column with benzene – ethyl acetate (49:1) gave a solid product, which, on recrystallization from benzene – light petroleum, gave 4-hydroxyskatole, m.p. 123°, in colorless prisms (16 mg; 12%). (Found: C, 73.64; H, 6.18; N, 9.34. Calc. for C_9H_9NO: C, 73.45; H, 6.16; N, 9.52%). Further elution of the column with benzene – ethyl acetate (44:6) gave a colorless solid, which, on recrystallization from benzene, afforded colorless prisms, m.p. 205–206°, of the substance (VII) (28 mg), which analyzed well for a dihydrohydroxyskatole. (Found: C, 72.25; H, 7.40; N, 9.12%; mol. wt. 147. Calc. for $C_9H_{11}NO$: C, 72.47; H, 7.43; N, 9.39%; mol. wt. 149.) The ultraviolet absorption spectrum was measured in (i) methanol (λ_{max}: 247 mμ with a shoulder at 275 mμ) and (ii) methanol containing 3% perchloric acid (70%) (λ_{max}: 269 mμ).

A solution of 4-hydroxyskatole (2 mg) in methanol (5 ml) containing a 10% palladium–charcoal catalyst (1 mg) was shaken at room temperature in an atmosphere of hydrogen at 50 p.s.i. for 10 hours. Paper chromatographic examinations of the products indicated* that all the 4-hydroxyskatole had been converted to the dihydro derivative (VII).

(B) From 4-Benzyloxyindole-3-carboxaldehyde

4-Benzyloxyindole-3-carboxaldehyde.—Phosphorus oxychloride (2.88 ml) was added to a stirred solution of dimethylformamide at 0° followed by 4-benzyloxyindole (1.9 g) in dimethylformamide (2 ml), the temperature being kept below 35° during the addition of the indole derivative. After the mixture had been stirred at 30–35° for 30 minutes a solution of sodium hydroxide (3.8 g) in water (10 ml) was added and the reaction mixture boiled for 10 minutes; pale yellow crystals of 4-benzyloxyindole-3-carboxaldehyde separated out during this period. After the mixture had been cooled, water (100 ml) was added and the crystalline product removed by filtration and washed with water several times. The crude product (1.95 g; 91%), m.p. 165°, was sufficiently pure for lithium aluminum hydride reduction.† A sample for analysis was twice recrystallized from 80% ethanol, giving pure 4-benzyloxyindole-3-carboxaldehyde in colorless prisms, m.p. 168°. (Found: C, 76.32; H, 5.38; N, 5.54. Calc. for $C_{16}H_{13}NO_2$: C, 76.47; H, 5.22; N, 5.57%.)

4-Benzyloxyskatole.—A stirred suspension of 4-benzyloxyindole-3-carboxaldehyde (0.5 g) and lithium aluminum hydride (0.16 g) in dry tetrahydrofuran (30 ml) was boiled under reflux in an atmosphere of nitrogen for 6 hours. The excess lithium aluminum hydride was decomposed by the cautious addition of moist ether; the reaction mixture was filtered, dried (Na_2SO_4), and evaporated to dryness. Recrystallization of the residue from benzene – light petroleum gave 4-benzyloxyskatole (0.44 g; 93%) in pale yellow needles, m.p. 83–84°. (Found: C, 80.97; H, 6.26; N, 6.01. Calc. for $C_{16}H_{15}NO$: C, 80.98; H, 6.37; N, 5.90%.)

4-Hydroxyskatole.—A solution of 4-benzyloxyskatole (0.44 g) in ethyl acetate (80 ml) containing a 5% palladium–charcoal catalyst (0.15 g) was shaken in an atmosphere of hydrogen at room temperature and under atmospheric pressure for 4 hours. After this time the hydrogenation mixture was filtered, and the residue obtained on concentration of the filtrate (a mixture of crude 4-hydroxyskatole and VII) was dissolved in benzene and adsorbed on a silica gel column. Elution of the column with benzene – ethyl acetate (49:1) and recrystallization of the product obtained from benzene – light petroleum gave 4-hydroxyskatole (73 mg; 27%) identical with the material obtained from the hydrogenolysis of 4-benzyloxygramine. Further elution of the column with benzene – ethyl acetate (44:6) gave VII (88 mg; 32%), after recrystallization from benzene.

5-Hydroxyskatole

(A) From 5-Benzyloxygramine

The preparation of 5-hydroxyskatole by the hydrogenolysis of 5-benzyloxygramine has been described in the literature. Melting points and yields given are 116°, 72% (6); 114–115°, 45% (7). In the current investigation with hydrogenation in methanolic solution at 50 p.s.i. (room temperature; 10% Pd–C catalyst) a 62% yield of 5-hydroxyskatole, m.p. 114°, was obtained.

**All paper chromatographic data are given at the end of the experimental section.*

†*In some early experiments the mixture was boiled for 2 minutes only and the bulk of the water was added before heating was begun. Anomalous results were obtained on reduction of some of these crude aldehyde preparations; lithium aluminum hydride gave various amounts of 4-benzyloxygramine probably formed by reduction of some unhydrolyzed indolenine intermediate present in the reaction mixture.*

For personal use only.

(B) From 5-Benzyloxyindole-3-carboxaldehyde

5-Benzyloxyskatole.—A suspension of 5-benzyloxyindole-3-carboxaldehyde (1 g; prepared by the method of Young (12)), 10% palladium–charcoal (0.5 g) and sodium borohydride (2 g) in isopropanol (300 ml) was boiled under reflux, with stirring, for 2½ hours. After this time a further quantity of sodium borohydride (1 g) was added and the mixture was boiled under reflux for a further 2½ hours. The catalyst was then removed by filtration, water (100 ml) added to the filtrate, and most of the isopropanol removed by distillation under reduced pressure. The resulting aqueous solution was extracted with ether; the residue obtained on concentration of the dried (Na_2SO_4) ether extract was recrystallized from aqueous ethanol and gave 5-benzyloxyskatole (0.7 g; 74%) in colorless needles, m.p. 115–116°. (Found: C, 80.70; H, 6.50; N, 5.80. Calc. for $C_{16}H_{15}NO$: C, 80.98; H, 6.37; N, 5.90 %.) Acheson and Hands prepared this compound by a different route and report a melting point of 118° (6).

5-Hydroxyskatole.—A solution of 5-benzyloxyskatole (100 mg) in methanol (100 ml) containing 10% palladium–charcoal (50 mg) was shaken in an atmosphere of hydrogen at room temperature and under atmospheric pressure for 3 hours. 5-Hydroxyskatole (42 mg; 67.5%) was obtained on recrystallization of the residue obtained on concentration of the filtered hydrogenation mixture from benzene – light petroleum.

6-Hydroxyskatole

(A) From 6-Benzyloxygramine

A suspension of 6-benzyloxygramine (0.4 g) and 5% palladium–charcoal (0.2 g) in methanol (80 ml) was shaken in an atmosphere of hydrogen at 45 p.s.i. at room temperature for 2½ hours. The reaction mixture was filtered and the residue obtained on concentration of the filtrate was dissolved in benzene and adsorbed on a silica gel column. Elution with benzene – ethyl acetate (99:1) gave a white solid, which afforded 6-hydroxyskatole (63 mg; 30%) in colorless plates, m.p. 162° on recrystallization from benzene – light petroleum. (Found: C, 73.22; H, 6.24; N, 9.63. Calc. for C_9H_9NO: C, 73.45; H, 6.16; N, 9.52%.) Melting point recorded in the literature: 149–151° (2). Further elution of the column with benzene – ethyl acetate (97:3) gave a thick yellow oil (24 mg; 11%) (VIII). An analytical sample of VIII, probably 6-hydroxy-3-methylindoline, was obtained by distillation of a portion of this material in vacuum, b.p. 180° (bath temperature) at 2 mm. (Found: N, 9.35. Calc. for $C_9H_{11}NO$: N, 9.39%.) The ultraviolet absorption spectrum was measured in (i) methanol (λ_{max}: 295 mμ) and (ii) in methanol containing 3% perchloric acid (70%) (λ_{max}: 279 mμ and 223 mμ).

When the hydrogenation was carried out at 45° for 3 hours and at 50 p.s.i. a solid was obtained after removal of the catalyst and evaporation of the filtrate, which on recrystallization, firstly from ethyl acetate and secondly from benzene, gave colorless prisms of the tetrahydro-6-hydroxyskatole (IX), m.p. 194–195°. (Found: C, 71.54; H, 8.64; N, 9.01%; mol. wt. 156. Calc. for $C_9H_{13}NO$: C, 71.49; H, 8.67; N, 9.26%; mol. wt. 151.2.) The ultraviolet absorption spectrum was measured in (i) methanol (λ_{max}: 285 mμ) and (ii) methanol containing 3% perchloric acid (70%) (λ_{max}: 275 mμ).

(B) From 6-Benzyloxyindole-3-carboxaldehyde

6-Benzyloxyskatole.—A suspension of 6-benzyloxyindole-3-carboxaldehyde (2.5 g; prepared by the method of Young (12)), sodium borohydride (2.5 g) and 10% palladium–charcoal (1.2 g) in isopropanol (500 ml) was boiled under reflux for 5 hours. Crude 6-benzyloxyskatole (2.1 g; 89%) was obtained as a colorless solid on concentration of the reaction mixture to small bulk after filtration. An analytical sample was obtained by repeated recrystallization of a small quantity of the crude product from benzene. Colorless prisms: m.p. 148°. (Found: 81.10; H, 6.25; N, 5.65. Calc. for $C_{16}H_{15}NO$: C, 80.98; H, 6.37; N, 5.90%.)

6-Hydroxyskatole.—A solution of 6-benzyloxyskatole (1 g) in ethyl acetate (100 ml) containing 5% palladium–charcoal (0.3 g) was shaken in an atmosphere of hydrogen at room temperature and under atmospheric pressure for 8 hours. 6-Hydroxyskatole and the dihydro-hydroxyskatole were shown to be present by means of paper chromatography. The catalyst was removed by filtration, and the residue obtained on concentration of the filtrate was dissolved in benzene and separated into 6-hydroxyskatole (270 mg; 43.5%) and 6-hydroxy-3-methylindoline (VIII) (55 mg; 9%) by chromatography on a silica gel column by the procedure described above.

Dehydrogenation of 6-Hydroxy-3-methylindoline (VIII)

A solution of the 6-hydroxy-3-methylindoline (VIII) (2 mg) in xylene (3 ml) containing 10% palladium–charcoal (5 mg) was boiled under reflux for 5 hours whilst a stream of nitrogen was bubbled through the mixture. After this time the suspension was filtered and the solvent removed *in vacuo*; the residue obtained was recrystallized from benzene – light petroleum and gave a few crystals of 6-hydroxyskatole identical with an authentic specimen.

Attempted dehydration of IX by a similar procedure was not successful, the starting material being recovered in an essentially unchanged condition.

Methylation of 6-Hydroxyskatole

A solution of sodium methoxide in methanol (2.4 ml), prepared by dissolving sodium (1 g) in methanol (100 ml), was added to a solution of 6-hydroxyskatole (0.15 g) in methanol (10 ml) and the solvent removed *in vacuo*. Dimethyl sulphate (1 ml) in dry benzene (20 ml) was added to the crude sodio derivative and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

suspension stirred at 50° for 3 hours. After this time the reaction mixture was filtered, and the benzene solution shaken with 2 *N* sodium hydroxide solution and washed with water, dried (Na_2SO_4), and evaporated to dryness. Purification of the residue, firstly by sublimation in high vacuum (50° at 0.1 mm) and finally by recrystallization from light petroleum afforded 6-methoxyskatole, m.p. 125° in fine plates (Blaikie and Perkin prepared this compound by a different route but report the same melting point (31)).

7-Hydroxyskatole

(A) From 7-Benzyloxygramine

A suspension of 7-benzyloxygramine (250 mg) and 10% palladium–charcoal (125 mg) in a mixture of methanol (80 ml) and ethyl acetate (80 ml) was shaken in an atmosphere of hydrogen at room temperature and 55 p.s.i. for 5 hours. After it was treated as described above a waxy solid was obtained which was purified chromatographically on a silica gel column with adsorption from benzene – ethyl acetate (97:3). Recrystallization of the crude chromatographic product from light petroleum gave 7-hydroxyskatole (41 mg; 31%), m.p. 82.5° in colorless needles. (Found: C, 73.75; H, 6.43; N, 9.27. Calc. for C_9H_9NO: C, 73.45; H, 6.16; N, 9.52%.)

(B) From 7-Benzyloxyindole-3-carboxaldehyde

7-Benzyloxyindole-3-carboxaldehyde.—This compound was prepared in a fashion analogous to that described above for the synthesis of the corresponding 4-isomer. In this way 2.0 g (93.5%) of 7-benzyloxyindole-3-carboxyaldehyde, m.p. 158°, were obtained from 1.9 g of 7-benzyloxyindole. Recrystallization of a small sample for analysis from aqueous ethanol raised the melting point to 159° (melting point reported in the current catalogues of L. Light and Co. and the Regis Chemical Co., 157–159°). (Found: C, 76.57; H, 5.18; N, 5.65. Calc. for $C_{16}H_{13}NO_2$: C, 76.47; H, 5.22; N, 5.57%.)

7-Benzyloxyskatole.—A suspension of 7-benzyloxyindole-3-carboxaldehyde (0.9 g) and lithium aluminum hydride (0.3 g) in tetrahydrofuran (80 ml) was boiled under reflux for 30 minutes. After it was treated as described above for 4-benzyloxyskatole, 7-benzyloxyskatole (0.65 g; 77%) was obtained as a colorless oil which could be debenzylated satisfactorily without further purification. A small sample for microanalysis was purified by distillation in vacuum, b.p. 160° (bath temperature) at 0.2 mm. (Found: C, 81.22; H, 6.25; N, 6.09. Calc. for $C_{16}H_{15}NO$: C, 80.98; H, 6.37; N, 5.90%.)

7-Hydroxyskatole.—Hydrogenolytic debenzylation of 7-benzyloxyskatole (0.65 g) with 10% palladium–charcoal (0.3 g) in methanol (120 ml) (45 minutes; atmospheric pressure) gave 7-hydroxyskatole (180 mg; 44.5%).

5,6-Dihydroxyskatole

(A) From 5,6-Dibenzyloxygramine

A suspension of 5,6-dibenzyloxygramine (200 mg; prepared by the method of Schlossberger and Kuch (32, 33)) and 5% palladium–charcoal (120 mg) in ethyl acetate (80 ml) was shaken in a hydrogen atmosphere at room temperature and under atmospheric pressure for 3 hours. After filtration of the reaction mixture and concentration of the filtrate the residue was purified chromatographically on silica gel with adsorption from benzene and elution with benzene – ethyl acetate (49:1), followed by recrystallization from benzene – light petroleum. 5,6-Dihydroxyskatole was obtained in colorless prisms (18 mg; 38%) m.p. 151°. (Found: C, 66.00; H, 5.64. Calc. for $C_9H_9NO_2$: C, 66.24; H, 5.56%.) This compound had previously been prepared by a different route by Beer *et al.*, who reported a melting point of 152° (28).

(B) From 5,6-Dibenzyloxyindole-3-carboxaldehyde

5,6-Dibenzyloxyindole-3-carboxaldehyde.—5,6-Dibenzyloxyindole (0.7 g) in dimethylformamide (0.8 ml) was added to a well-cooled, stirred mixture of dimethylformamide (1 ml) and phosphorus oxychloride (0.325 g). A solution of sodium hydroxide (1.4 g) in water (3.8 ml) was added to the reaction mixture after it had been stirred at 30–35° for 30 minutes. The crude product obtained after the aqueous alkaline reaction mixture had been boiled for 10 minutes was recrystallized from 95% ethanol and gave 5,6-dibenzyloxyindole-3-carboxaldehyde, m.p. 195° in colorless fine plates (0.6 g; 79%). (Found: C, 76.98; H, 5.20; N, 4.23. Calc. for $C_{23}H_{19}NO_3$: C, 77.29; H, 5.36; N, 3.92%.)

5,6-Dibenzyloxyskatole.—A stirred suspension of 5,6-dibenzyloxyindole-3-carboxaldehyde (200 mg), 10% palladium–charcoal (100 mg), and sodium borohydride (200 mg) in isopropanol (20 ml) was boiled under reflux for 2 hours and the products worked up in a manner identical with that described above. Recrystallization of the crude product from benzene – light petroleum gave 5,6-dibenzyloxyskatole, m.p. 122° in colorless prisms (110 mg; 52%). (Found: C, 80.42; H, 6.27; N, 4.10. Calc. for $C_{23}H_{21}NO_2$: C, 80.44; H, 6.16; N, 4.08%.) Acheson *et al.* prepared this compound by a different route and quote m.p. 123° (29).

5,6-Dihydroxyskatole.—Debenzylation of 5,6-dibenzyloxyskatole (40 mg) in ethyl acetate (30 ml) with hydrogen in the presence of 5% palladium–charcoal (20 mg) gave 5,6-dihydroxyskatole (12 mg; 63%).

Paper Chromatography

Disks (diameter = 24 cm) of Whatman No. 1 paper were pretreated with formamide by the method previously described and radial development in a modified Kawerau apparatus was carried out with a benzene:chloroform (1:1) mixture containing 0.4% formamide (cf. (34)).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The benzyloxyindole-3-carboxaldehydes, which could be located on the developed chromatograms by the red- to orange-brown colors they gave with the 2,4-dinitrophenylhydrazine reagent, had the following R_f values in this system: 4-, 0.81; 5-, 0.75; 6-, 0.73; 7-, 0.88; and 5,6-di-, 1.0.

All these compounds could be detected by viewing the developed chromatograms in ultraviolet light. The 4-, 5-, and 7-benzyloxyindole-3-carboxaldehydes showed a distinct blue fluorescence and although the 6-benzyloxy- and 5,6-dibenzyloxy- derivatives did not fluoresce they could be located by the fact that they absorbed the ultraviolet light.

The benzyloxyskatoles, all of which gave blue or blue-green colors with Ehrlich's reagent, migrated to the solvent front under these conditions of chromatography. The hydroxyskatoles have previously been reported to have the following R_f's in this system 4-, 0.27; 5-, 0.21; 6-, 0.22; and 7-, 0.32 (10). 5,6-Dihydroxyskatole did not migrate at all in this solvent system.

The three products VII, VIII (i.e. 6-hydroxy-3-methylindoline), and IX had R_f's of 0.55, 0.34, and 0.32 respectively. They could be detected on the chromatograms by the fact that they all absorbed ultraviolet light. Compound VII gave a pink-mauve color with Ehrich's reagent, turning blue-gray overnight; 6-hydroxy-3-methylindoline (VIII) gave a yellow color with the Ehrlich's reagent.

PHOTOLYSIS OF POLYMETHACRYLIC ACID IN AQUEOUS SOLUTIONS

C. H. CHOU* AND H. H. G. JELLINEK
Department of Chemistry, University of Windsor, Windsor, Ontario
Received October 2, 1963

ABSTRACT

The photolysis of polymethacrylic acid was studied in aqueous solutions as a function of pH, polymer concentration, polymer chain length, and small additions of electrolytes in the absence of oxygen with light of wavelength 2537 Å. The random chain scission constants decrease with increasing pH values. Small variations in polymer chain length and concentration and electrolyte concentration have no effect on the photolysis. Changes in the ultraviolet spectra with irradiation time are more pronounced at low pH values than higher ones. It is shown that the decrease in susceptibility to photolysis with increasing degree of ionization of the acid is not proportional to the decrease or increase of the number of COOH or COO^- groups respectively. It is rather due to the same causes—that is changes in ionic atmosphere—which make the polymer chains uncoil with increasing ionization.

The photodegradation of polymethacrylic acid was studied by Baxendale and Thomas (1). Their work was mainly concerned with the photolysis in the presence of hydrogen peroxide; however, a few experiments were also performed in its absence. Völker (2) made a study of polymethacrylic acid copolymers exposed to daylight under various conditions, but he did not carry out detailed rate measurements. He concluded that the changes in the extent and rate of degradation are a function of the degree of coiling of the chain molecules as a function of pH.

In the present work, rate measurements were performed as a function of pH, electrolyte, and polymer concentration and also of chain length. All irradiations were carried out with light of wavelength 2537 Å.

No appreciable change in rate constants was found in a region of pH values where the intrinsic viscosities rise very sharply.

EXPERIMENTAL

(a) Materials

All chemicals were of analytical reagent grade quality.

Methacrylic acid, obtained from Matheson, Coleman, and Bell, was polymerized in carefully purified dioxane, using 0.5% w/v benzoylperoxide as described by Eisenberg and Katchalsky (3). The polymerization was carried out under oxygen-free nitrogen at 25° C. The polymer was dissolved in methanol and precipitated with ether. This procedure was repeated three times. The polymer was then dried *in vacuo* at 100° C until constant weight was attained. Percentage conversion was about 10%. Three samples were prepared, which had the following intrinsic viscosities in 5×10^{-4} *M* HCl aqueous solutions: $[\eta]_I = 0.45$, $[\eta]_{II} = 0.42$, and $[\eta]_{III} = 0.25$. All intrinsic viscosities are expressed in $(g/100\ ml)^{-1}$; viscosities were measured at 25±0.05° C. These samples are referred to below as I, II, and III.

(b) Apparatus

The apparatus was similar to the one used previously (4) except for a few minor modifications: (1) The distance between the lamp (low pressure Hg lamp; over 90% of its light output is at $\lambda = 2537$ Å; current 30 ma; total output ca. 3×10^{18} to 5×10^{18} quanta/sec) and the incident surface of the cylindrical Ultrasil cell (4 cm i.d., length 3 cm) was 5.5 cm; (2) the polymer was degraded in absence of air by passing cylinder nitrogen through alkaline pyrogallol, water, and finally through a drying tower into the polymer solution. The reaction cell was located in a thermostated water bath kept at 25±0.05° C.

**National Research Council of Canada Postdoctoral Fellow.*

PROCEDURE AND RESULTS

(a) Influence of pH

As already pointed out above, all irradiations were carried out with ultraviolet light of wavelength $\lambda = 2537$ Å. Data for solutions of polymers I and II, indicating their initial intrinsic viscosities, pH values, and composition, is given in Table I. The polymer concentrations were in all cases within 2.5% of 0.200% w/v; calculations were, of course, made using the exact polymer concentrations in each case. It will be shown subsequently that the photolysis is independent of polymer concentration over a range of concentrations.

TABLE I

Intrinsic viscosities as a function of pH values
(Polymer concentration 0.200±0.005% w/v; temperature 25±0.05° C)

Solvent	Intrinsic viscosity $[\eta]_0$ before irradiation	pH	Remarks
1×10^{-1} *M* HCl	0.41	1.1	
1×10^{-2} *M* HCl	0.41	2.1	
2×10^{-3} *M* HCl	0.42	2.7	
1×10^{-3} *M* HCl	0.42	2.9	
5×10^{-4} *M* HCl	0.45	3.2	
1×10^{-5} *M* HCl	—	3.6	$[\eta]$ cannot be measured
Buffer A	0.41	4.4	
Buffer D_1	0.45	5.4	
Buffer D_2	1.45	5.6	
Buffer D_3	3.50	5.8	
Buffer C	3.65	6.0	
Buffer B	3.60	7.1	
5×10^{-2} *M* NaOH	—	9.7	$[\eta]$ cannot be measured
Distilled H_2O	—	3.5	$[\eta]$ cannot be measured

NOTE: The buffers were made up from mixtures of *M*/15 Na_2HPO_4 and *M*/15 KH_2PO_4.

Figure 1 shows $(1/[\eta]_t)-(1/[\eta]_0)$ values plotted against the irradiation time t for the polymer in the various HCl solutions and the distilled water solution. $[\eta]_t$ and $[\eta]_0$ are the intrinsic viscosities at time t and $t = 0$ of the irradiation process. The intrinsic viscosities were obtained by adjusting all solutions, except the 1×10^{-1} and 1×10^{-2} *M* HCl solutions, to 2×10^{-3} *M* HCl and diluting with 2×10^{-3} *M* HCl solution.

The irradiation results for the 5×10^{-2} *M* NaOH solutions are also shown in Fig. 1. After irradiation these solutions were adjusted to pH 2.0 by adding to 15 ml of the irradiated solution 1 ml of 1 *M* HCl. The intrinsic viscosities were then determined by diluting with 2×10^{-3} *M* HCl. It is shown below that the presence of *M*/15 NaCl has a negligible effect on intrinsic viscosities and rate of degradation.

Figure 2 gives $(1/[\eta]_t)-(1/[\eta]_0)$ values as a function of irradiation time for polymer I in the buffer solutions. In these instances, the intrinsic viscosities were obtained by diluting with the respective buffer solutions. This, of course, dilutes the polymer and the pH values change somewhat with dilution, as the buffers are not strong enough, and approach eventually the pH values of the pure buffer solutions.

Rate constants were derived from the slopes of the straight lines shown in Figs. 1 and 2, using the relationship:

$$(1/[\eta]_t)-(1/[\eta]_0) = kt \qquad [1]$$

where $[\eta]_t$ and $[\eta]_0$ are the intrinsic viscosities at time t and the beginning of the irradiation respectively.

It is apparent that the degradation rate constants are not immediately comparable for the different types of solutions. In order to refer all rate constants to one reference solution, thus making the degrees of degradation and number of chain scissions comparable, the following procedure was adopted.

Irradiation was carried out in 5×10^{-4} *M* HCl solutions for various periods of time. Each irradiated solution was divided into four parts. One part was made 2×10^{-3} *M* with respect to HCl, to the other three parts, buffers A, B, and C were added respectively in such quantities that these solutions were equivalent with respect to buffer to those irradiated in previous experiments. In this way, calibration curves were obtained giving intrinsic viscosity values for the buffer solutions and the 5×10^{-4} *M* HCl solutions as a function of intrinsic viscosity values of the 2×10^{-3} *M* HCl solutions. Figure 3 shows these calibration curves. Calibration curves are not needed for the 1×10^{-1} *M* and 1×10^{-3} *M* HCl solutions as the intrinsic viscosities do not change with pH in this range.

5×10^{-4} *M* HCl solutions were chosen for obtaining calibration curves for the following reason. A polymer solution containing buffers A, B, or C plus 5×10^{-4} *M* HCl has a lower pH value than the respective polymer solution containing buffer only. However, by diluting buffer solutions also containing 5×10^{-4} *M* HCl with the buffer, a region is reached where the specific viscosity versus concentration curves coincide with those for the polymer solutions containing buffer only. If 2×10^{-3} *M* HCl had been used for irradiation, the region where solutions (buffer with and without HCl) show the same values would have been too dilute with respect to polymer to obtain intrinsic viscosity measurements. This is shown in Fig. 4.

Figure 5 shows $(1/[\eta]_t)-(1/[\eta]_0)$ values plotted against irradiation time for the buffer solutions referred to 2×10^{-3} *M* HCl.

Rate constants, referred to the 2×10^{-3} *M* HCl solutions are given in Table II; rate constants for the buffer solutions without reference to 2×10^{-3} *M* HCl are also indicated.

TABLE II

Degradation rate constants as a function of pH values
(Polymer concentrations 0.200±0.005% w/v, λ = 2537 Å, 25±0.05° C)

Solution irradiated	pH	Rate constant $min^{-1}\times$(g/100 ml)	Rate constant referred to 2×10^{-3} *M* HCl $min^{-1}\times$(g/100 ml)
1×10^{-1} *M* HCl	1.1	1.70×10^{-1}	1.70×10^{-1}
1×10^{-2} *M* HCl	2.1	1.70×10^{-1}	1.70×10^{-1}
2×10^{-3} *M* HCl	2.7	2.12×10^{-1}	2.12×10^{-1}
5×10^{-4} *M* HCl	3.2	1.64×10^{-1}	1.50×10^{-1}
Distilled water	3.5	—	1.40×10^{-1}
1×10^{-5} *M* HCl	3.6	—	1.32×10^{-1}
Buffer A	4.4	1.95×10^{-1}	1.30×10^{-1}
Buffer C	6.0	2.5×10^{-2}	0.90×10^{-1}
Buffer B	7.1	8.7×10^{-3}	0.78×10^{-1}
0.05 *M* NaOH	9.7	—	0.65×10^{-1}

(b) Influence of Polymer Chain Length

The rate constants for samples I ($[\eta] = 0.45$) and III ($[\eta] = 0.25$) are as follows:

(1) In 5×10^{-4} *M* HCl: $k_I = 1.64\times10^{-1}$ and $k_{III} = 1.55\times10^{-1}$.

(2) In buffer B (referred to 2×10^{-3} *M* HCl): $k_I = 0.78\times10^{-1}$ and $k_{III} = 0.77\times10^{-1}$.

There is no effect of polymer chain length on the rate of degradation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

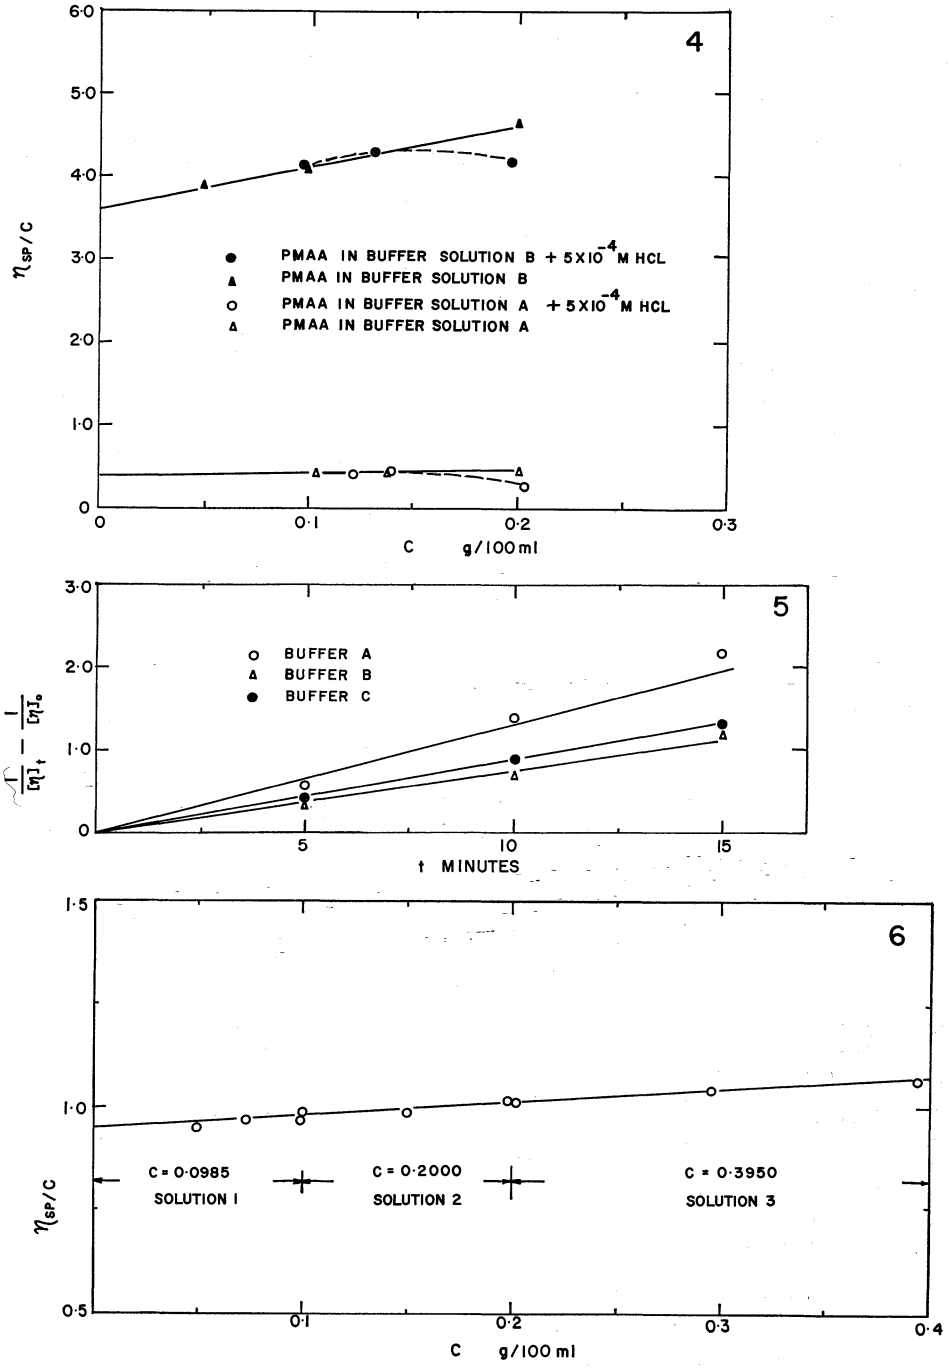

FIG. 4. Specific viscosities for buffers A and B with and without 5×10^{-4} *M* HCl.
FIG. 5. $(1/[\eta]_t)-(1/[\eta]_0)$ versus irradiation time for buffer solutions referred to 2×10^{-3} *M* HCl.
FIG. 6. Effect of polymer concentration on rate of degradation. Sample III irradiated for 10 minutes in each case. The same intrinsic viscosity is obtained irrespective of concentration.

(c) Influence of Polymer Concentration

Polymer solutions of sample III in buffer B were irradiated over a concentration range from 0.099 to 0.395% w/v for 10 minutes each. Figure 6 shows that the concentration has no effect on the rate.

(d) Influence of Electrolyte Concentration

A number of experiments were carried out on the effect of the addition of sodium chloride; sample III was irradiated for 10 minutes in each case. The results are given below:

	5×10^{-4} *M* HCl	5×10^{-4} *M* HCl + 1/15 *M* NaCl	Buffer B	Buffer B + 1/15 *M* NaCl
pH	3.1	3.1	7.15	7.15
$[\eta]_t$ = 10 minutes	0.17	0.17	0.90	0.90

Small additions of NaCl have no effect on the degradation rate.

(e) Ultraviolet Spectra

Ultraviolet spectra of the polymer in the various solutions have been determined for various stages of the irradiation process. In all cases the optical densities in 1-cm cells were measured. Figures 7 and 8, for example, show the spectra for 2×10^{-3} *M* HCl and buffer A solutions. The solutions were diluted 10 times before taking the spectra. The spectra in distilled water are of interest. Figure 9 shows these, including some longer irradiation periods. The extinctions first decrease and eventually increase again with a shift of the maximum absorption to shorter wavelengths for the water solutions. The spectrum for the monomer is given for comparison. In general, the spectra at higher pH values are not much different from those at lower pH values. The extinctions of the peak values of the absorption spectrum change much less with irradiation time at higher pH values than those at lower ones.

DISCUSSION

Figure 10 shows the intrinsic viscosities of the unirradiated solutions as a function of pH. It also shows the rate constants k referred to 2×10^{-3} *M* HCl. The optical densities of the unirradiated solutions were all similar except the value for the 2×10^{-3} *M* HCl solution, which was somewhat higher.

The fact that equation (1) is obeyed suggests a linear relationship between the intrinsic viscosity and polymer chain length, which does not agree with the relationship found by Eisenberg and Katchalsky (3) for polymethacrylic acid fractions measured in 2×10^{-3} *M* HCl solutions: $[\eta] = 6.16\times10^{-3} P^{0.5}$. However, Oth and Doty (7) have indicated that the relationship is dependent on the degree of ionization and the power to which P is raised varies according to them from 0.82 to 1.87 starting with a degree of ionization α of about 0.001 at pH 1.55 to $\alpha = 0.7$ at higher pH values. Baxendale and Thomas (1) found linear relationships between the number of chain scissions and irradiation time. Chain lengths were calculated from intrinsic viscosity values using Eisenberg and Katchalsky's relationship. However, their irradiation times were rather short.

It was shown in previous publications (5) that the rate constants for chain scission are directly proportional to the chain scission quantum yield for a random process, provided all other variables are kept constant. The relationship is as follows:

$$k = \phi_s \frac{(1-e^{-E})I_0}{n_0 l} \qquad [2]$$

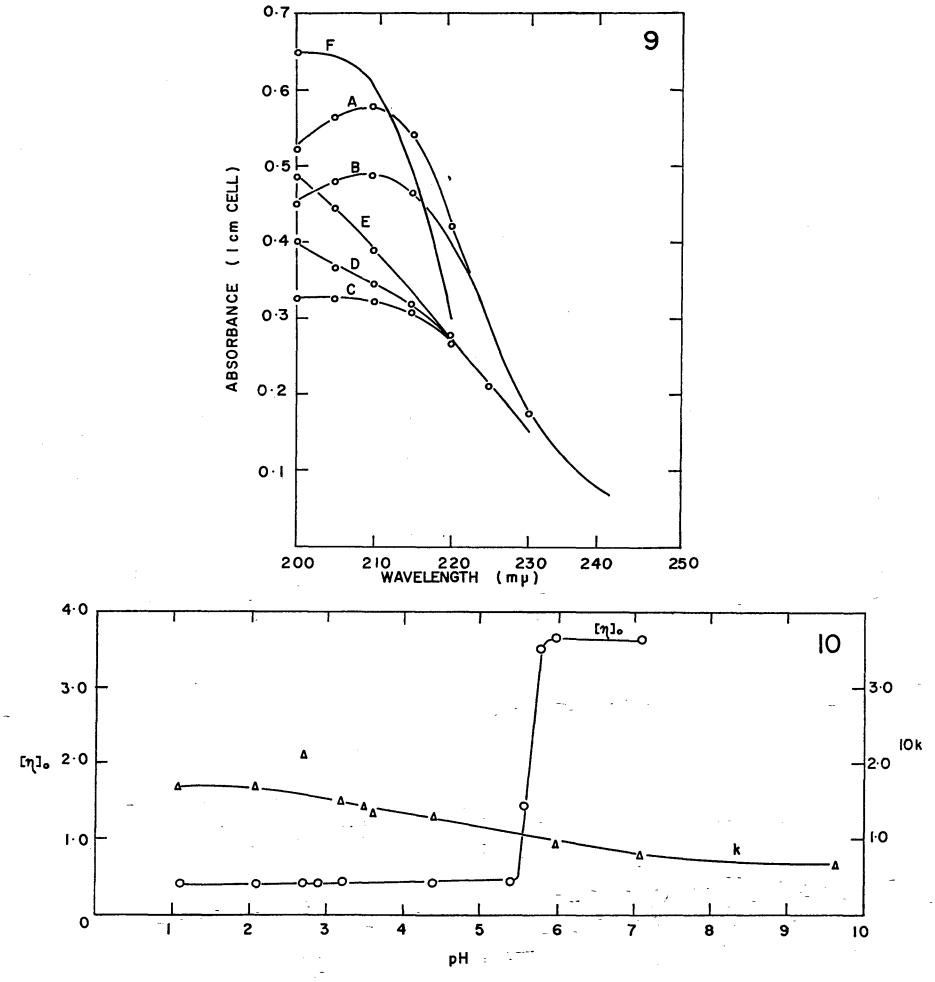

FIG. 9. Ultraviolet absorption spectra for various irradiation times in distilled water: A, unexposed; B, 15 minutes; C, 60 minutes; D, 2 hours; E, 3 hours; F, monomer; diluted 10 times after exposure, $c = 0.0203$ % w/v, sample I.

FIG. 10. Initial intrinsic viscosity $[\eta]_0$ as a function of pH and rate constants k referred to 2×10^{-3} M HCl as a function of pH.

where ϕ_s is the quantum yield for chain scission (number of main chain links broken for each quantum absorbed by the solution), E the optical density, I_0 the incident light intensity, n_0 the initial concentration of main chain links in the polymer solution, and l the length of the reaction cell. All these quantities were kept constant, hence k is a direct measure of the quantum yield.

It is apparent that the susceptibility of polymethacrylic acid to photolysis decreases with increasing pH values becoming practically constant at either end of the pH range. This means that the quantum yield for chain scission decreases with increasing degrees of ionization and also with increasing degrees of uncoiling (stretching) of the polymer chains.

If the rate of breaking main chain links were directly proportional to the number of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

COOH groups and COO^- groups respectively, each having its individual rate constant, the following equations should hold:

$$s_1/[(1-\alpha)P_0] = k_1 t \quad \text{and} \quad s_2/\alpha P_0 = k_2 t$$

where s_1 and s_2 are the average numbers of chain scissions per original chain molecule of length P_0 due to COOH and COO^- groups, respectively, k_1 and k_2 are the corresponding rate constants, and α is the degree of ionization.

Further
$$(s_1+s_2)/P_0 = k_{exp}t = (1-\alpha)k_1 t + \alpha k_2 t$$
or
$$\alpha = (k_{exp}-k_1)/(k_2-k_1)\,. \qquad [4]$$

Our experiments indicate that $[\eta] \propto P$; hence the ratio given by equation [4] can be evaluated directly. k_1 represents the rate constant at the low end of the pH range and k_2 that at the high range, k_{exp} are the experimental rate constants between the two extremes. As a guide, the degrees of ionization α_k as a function of pH may be given from Katchalsky *et al.* (6) (see Fig. 8, ref. 6).

pH	3	4	5	6	7	8
α_k	0.01	0.04	0.1	0.25	0.5	0.8
α_{calc}	0.19	0.38	0.53	0.67	0.86	1.0

The degrees of ionization α_{calc} calculated from equation [4] are also given. The rate constants were read off the graph in Fig. 10: $k_1 = 1.70\times10^{-1}$ and $k_2 = 0.65\times10^{-1}$. In actual fact the rate constant for photolysis decreases much faster with increase in degree of ionization than predicted by the above assumption of direct proportionality of rate of breaking links and number of COOH or COO^- groups respectively.

The ratio of the root mean extension R_α/R_0 of the chains (R_α root mean extension at degree of ionization α, R_0 at $\alpha = 0$) as a function of the degree of ionization was calculated for a polymethacrylic acid fraction by Oth and Doty (7) (see Fig. 7, ref. 7). In our case the experimental photolysis rate constants decrease with increasing α; however, R_α/R_0 increases with α. Hence $1/k$ was plotted against α. A curve is obtained of a similar type as that for the plot R_α/R_0 versus α. As a matter of fact, if the values of R_α/R_0 as a function of α are chosen which were obtained from titration data by Oth and Doty and these values are plotted against the corresponding $1/k$ values, a straight line is obtained. Not much significance should be attached to any quantitative aspects of these relationships; however, it is clear that the photolysis is influenced by the same causes which are responsible for the stretching of the polymer chains as a function of pH or degree of ionization. In other words, the ionic atmosphere produced by even a very small amount of ionization of the polymethacrylic acid seems to have an appreciable effect on the susceptibility to photolysis. The corresponding α, $1/k$, and R_α/R_0 values, the latter taken from Oth and Doty's paper (Fig. 7, titration values, ref. 7) are given below:

α	0.01	0.04	0.1	0.25	0.5
R_α/R_0	1.3	2.5	5.0	6.8	11.0
$1/k$	6.7	7.7	9.1	10.5	12.5

However, it must not be forgotten that the rate of photolysis of fatty acids (8) seems to be influenced by pH, but systematic investigations do not appear to have been made.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Also decomposition products such as CO_2 and gaseous hydrocarbons have been observed during the photolysis of fatty acids. It is likely that such gases are also produced during the photolysis of polymethacrylic acid; even some monomer may be evolved.

The primary photolytic process consists probably of the absorption of a light quantum by the carboxylic groups which may then lead to production of COOH radicals and also to some random chain scissions, as indicated by Baxendale and Thomas (1),

THE BROMINATION AND HALOGENOMETHOXYLATION OF D-GLUCAL TRIACETATE[1]

R. U. LEMIEUX AND B. FRASER-REID
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received September 19, 1963

ABSTRACT

The bromination of D-glucal triacetate gave a mixture of tri-*O*-acetyl-2-bromo-2-deoxyglycopyranosyl bromides containing about 60% and 30% of the compounds with the α-D-gluco and α-D-manno configurations, respectively. Reaction of the bromides with methanol in the presence of silver carbonate proceeded almost entirely with inversion of the reacting anomeric centers. Hydrogenolysis of the product of methanolysis gave methyl 2-deoxy-β-D-glucopyranoside. Reaction of D-glucal triacetate with either bromine, chlorine, or iodine in methanol containing silver acetate gave in each case about 60–65% and 35–40% yields of the corresponding methyl 2-deoxy-2-halogeno-α-D-mannopyranoside and -β-D-glucopyranoside triacetates. The mechanisms of the reactions are discussed.

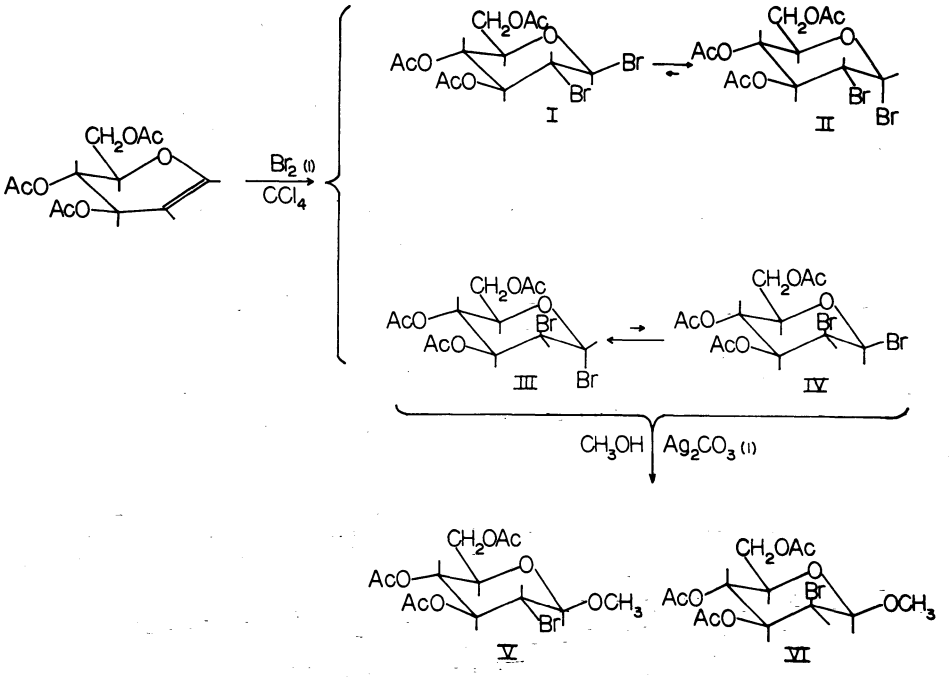
In 1920, Fischer, Bergmann, and Schotte (1) reported the bromination of D-glucal triacetate and methanolysis of the product to form two crystalline compounds termed the "triacetyl methyl glucoside-2-bromohydrins I and II". These reactions were reinvestigated since it was apparent (2) that application of nuclear magnetic resonance spectroscopy would readily allow the establishment of the configurations of these and the related compounds. The β-D-configuration was established for the anomeric centers of the "bromohydrins I and II" by reduction of each with sodium amalgam to methyl 2-deoxy-β-D-glucopyranoside (1). Also, the stereochemistry of the direct preparation of methyl 2-deoxy-2-halogeno-D-glycopyranosides by halomethoxylation of D-glucal was of interest as an alternative synthetic route to 2-halogeno-glycosides and their various possible derivatives (3–5).

Three publications related to this present contribution appeared in the course of this investigation. Manolopoulos, Mednick, and Lichtin (6) offered a proof of the configurations of the 2-positions of the "bromohydrins I and II" based on the rates of the iodide-catalyzed deoxymercuration of the methyl 2-acetoxymercuri-2-deoxyglycosides obtained on the reaction of D-glucal triacetate with methanolic mercuric acetate. The brominolysis of the acetoxymercuri-glycosides was assumed to yield the bromohydrins of related configuration. It will be seen below that the assignments of configuration were indeed correct although Inglis, Schwarz, and McLaren (7) have more recently contended that the compound characterized [by Monolopoulos and co-workers (6)] as methyl 2-acetoxymercuri-2-deoxy-β-D-mannopyranoside triacetate in fact has the α-D-manno configuration. Agaki, Tejima, and Nakamira (8) deacetylated the "bromohydrin I" and converted the product to the 4,6-benzylidene derivative which, on treatment with sodium methoxide, gave the known methyl 2,3-anhydro-4,6-benzylidene-β-D-mannopyranoside. It was therefore concluded that "bromohydrin I" possessed the D-gluco configuration.

D-Glucal triacetate was brominated as described by Fischer, Bergmann, and Schotte (1) to provide a syrupy product, the NMR spectrum of which required 90% of the mixture to be two glycosyl bromides. The major component (II) gave a doublet in the NMR spectrum with a 3.5 c.p.s. spacing at 6.47 p.p.m. The other compound (III) produced a

[1]*This research is to constitute a portion of a thesis to be submitted by B. F.-R. in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*

doublet at 6.65 p.p.m. with a spacing of 1.0 c.p.s. The general experience with NMR spectra (9) of acetylated glycosyl bromides clearly indicated that both these doublets because of their chemical shifts arose from anomeric hydrogens in equatorial orientation. Furthermore, the spacings indicated that compounds II and III possessed the α-D-gluco- and α-D-manno-configurations, respectively, since, in general, derivatives of α-D-glucopyranose and α-D-mannopyranose provide signals for the anomeric hydrogens with spacings of 3.0–3.6 c.p.s. and 1.0–1.5 c.p.s., respectively. As will be seen below, this conclusion was confirmed through characterization of the products formed on the methanolysis of the dibromides.



The formation of the 1,2-*trans*-α-D-manno dibromide (III) in about 30% yield is in accordance with the usual stereochemical route found in the halogenation of alkenes. However, the formation of the 1,2-*cis*-α-D-gluco dibromide (II) as the main product (about 60%) of the reaction is not a classical route of reaction. It is now well established that, in the absence of large axial substituents at the 3- or 5-positions, the thermodynamically stable anomer for glycopyranosyl halides is the anomer which has the halogen in axial orientation (10, 11). The dipole–dipole interaction responsible for this condition has been termed the "anomeric effect" and can provide a driving force of 1.5 to 2.0 kcal/mole (10). Therefore, it can be expected that, if formed, the β-D-gluco dibromide (I) would anomerize to II to an extent of 85 to 90%. The α-D-mannosyl bromide (III) would possess an even greater stability over that of its β-anomer (IV) since its formation from the β-anomer not only involves the driving force of the anomeric effect but also that derived from the interaction of vicinal bromine atoms in *gauche* relationship (12). Therefore, it can be concluded that the bromination of D-glucal triacetate gave an equilibrium mixture of the dibromides I–IV and judging from the NMR analysis for compounds II and III, the β-anomers I and IV are present to an extent of about 10%. The dibromide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

II may have formed directly in the bromination reaction since it is conceivable that an initially formed 1,2-cyclic bromonium ion rearranged directly to the glucosyloxonium ion, which then accepted bromide to form the thermodynamically stable α-D-anomer (II). This conjecture seems eliminated by the observation that the bromomethoxylation of D-glucal triacetate gave only the β-D-gluco (V) and α-D-manno (VII) glycosides. It does not seem likely that the change in solvent from chloroform for the bromination to methanol for the bromomethoxylation would profoundly alter the courses of these mechanistically closely related reactions. Nevertheless, we were not able to demonstrate the anomerization reaction of I to II by following the bromination in the NMR spectrometer. Equilibration must have been achieved within about 15 seconds. It is possible that the bromination in the case of D-glucal triacetate is a rapidly reversible reaction and that the composition of the product reflects the relative stabilities of the four dibromides.

Reaction of the mixture of dibromides with methanol in the presence of silver carbonate gave a mixture of *O*-acetylated methyl 2-deoxy-2-bromoglycosides containing 80–85% of the β-anomers V and VI. As normally observed in the NMR spectra of methyl glycosides, the equatorial methoxyl groups of V and VI gave their signals at substantially lower field, 3.60 p.p.m. (see Fig. 1), than the axial methoxyl groups of the α-anomers,

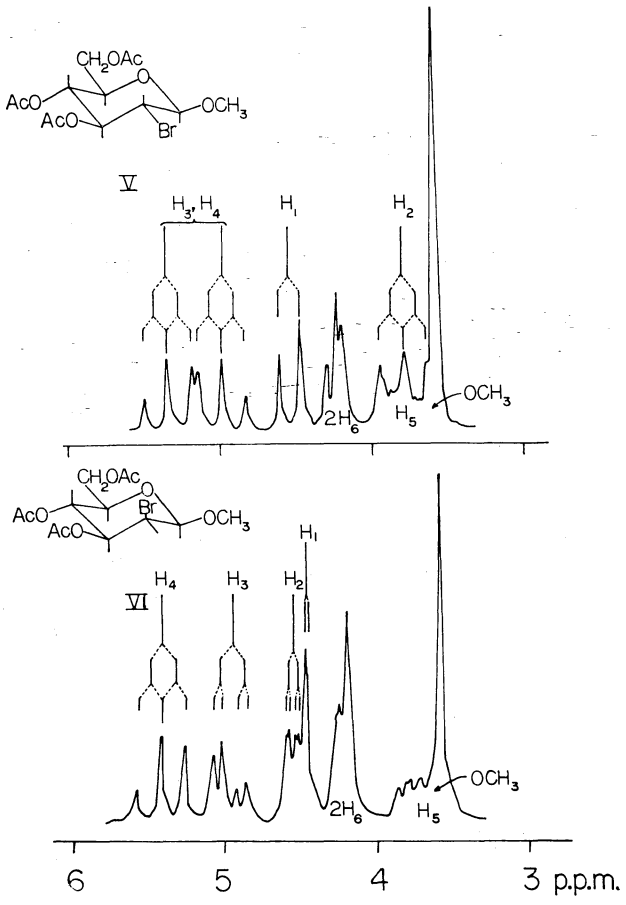


FIG. 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

3.44 and 3.48 p.p.m. The intensities of the latter signals required the α-anomers to be formed in nearly equal amounts. Hydrogenolysis of the mixture followed by deacetylation and deionization readily gave a 69% yield of methyl 2-deoxy-β-D-glucopyranoside. It is therefore clear that the glycosyl bromides, I–IV, underwent reaction with near quantitative inversion of the anomeric centers—the normal stereochemical route of reaction for 1,2-*cis*-glycosyl halides. Evidently, there was no appreciable tendency for the axial 2-bromine to participate in the reaction of the 1,2-*trans*-bromide (III). The NMR spectrum of the reaction product clearly indicated a high content of methyl 2-bromo-2-deoxy-β-D-glucopyranoside triacetate (V). The spectrum of V as well as that for the β-D-manno isomer (VI) are shown in Fig. 1. The assignments shown in the spectrum for compound V obviously require the β-D-gluco configuration. The β-D-manno configuration of compound VI was apparent from the chemical shifts for the methoxy group and anomeric hydrogen as compared to those shown in Fig. 2 for the α-anomer (VII). The latter

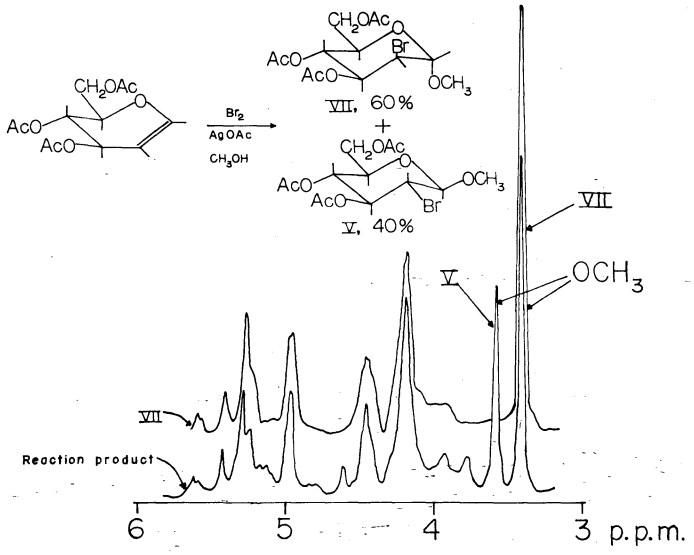

FIG. 2.

compound (VII) was the main product of the bromomethoxylation of D-glucal triacetate. Its configuration was apparent from the NMR spectrum shown in Fig. 2 and confirmed by hydrogenolysis followed by deacetylation to give methyl 2-deoxy-α-D-glucopyranoside. The bromomethoxylation of D-glucal triacetate is undoubtedly an irreversible process and it is of interest to note that, in contrast to the bromination reaction, the 1,2-diaxial-α-D-*manno*side (VII) was the main product (see Fig. 2).

The chloro- and iodo-methoxylation reactions followed virtually the same stereochemical routes as found for the bromomethoxylation. It was established that the "triacetyl methyl glucoside-2-chlorohydrin I," m.p. 149–150°, $[\alpha]_D$ +53°, reported by Fischer and co-workers (1) is methyl 2-chloro-2-deoxy-β-D-glucopyranoside triacetate (VIII). The α-D-manno isomer failed to crystallize. Treatment of VIII with titanium tetrachloride in chloroform (13) was shown to bring about anomerization to the α-D-isomer. The products formed on the iodomethoxylation of D-glucal triacetate have been reported (2). The preparation described here was found most convenient for the large scale preparation of the

For personal use only.

methyl 2-deoxy-2-iodo-β-D-gluco- and α-D-manno-pyranoside triacetates for brominolysis (4, 5). It was found that the addition of a mole of collidine per mole of iodine raised the yield of the α-D-mannoside from 63% to 75–80% and this procedure is recommended for the preparation of this compound.

EXPERIMENTAL

All melting points were determined on a heating stage and are uncorrected. The nuclear magnetic resonance spectra were determined, unless otherwise stated, in chloroform with a Varian A60 spectrometer and the chemical shifts are reported in parts per million from tetramethylsilane used as an internal standard. Unless otherwise stated, the paper chromatograms were made on Whatman No. 1 paper. The zones were detected with the silver nitrate – sodium hydroxide (14) or the permanganate–periodate (15) reagents.

Bromination of D-*Glucal Triacetate*

D-Glucal triacetate (16) was brominated in chloroform as described by Fischer, Bergmann, and Schotte (1). The product was obtained as a colorless syrup in 95% yield. Two doublets for anomeric hydrogens were present in the NMR spectrum of the product at 6.65 p.p.m. (1 c.p.s. spacing) (III), and at 6.47 p.p.m. (3.5 c.p.s. spacing) (II). The relative intensities of these signals were 1:2, respectively. The total intensity of these two signals as compared to the total intensities of the other signals, except for acetyl, required the two compounds to make up more than 90% of the mixture.

Methanolysis of Compounds II and III

The dibromide mixture was reacted with methanol and silver carbonate as described by Fischer and co-workers (1). The NMR spectrum of the product showed three signals for methoxyl groups at 3.60, 3.48, and 3.44 p.p.m. with relative intensities of 10:1:1, respectively. A portion of the product, 150 mg, was dissolved in 15 ml of a 10:9:1 mixture of methanol, water, and triethylamine, respectively, and reacted with hydrogen in the presence of 5% palladium on charcoal. The hydrogen was taken up within a half hour. After 12 hours, the catalyst was removed by filtration and the bromide ion by stirring with an excess of basic Amberlite IRA-400 resin. Evaporation left a residue which readily crystallized from ethyl acetate in 69% yield (71 mg). The compound, m.p. 121–122° did not depress the melting point of an authentic sample of methyl 2-deoxy-β-D-glucopyranoside (2).

The product partially crystallized when dissolved in ethanol to yield compound V, m.p. 135–136°, $[\alpha]_D$ +46.0° (*c*, 2 in chloroform), in 26% yield. Reported for "triacetyl methyl glucoside-2-bromohydrin I" (1), m.p. 138°, $[\alpha]_D$ +50.4°. The NMR spectrum of V is reported in Fig. 2. Deacetylation of V in methanolic ammonia provided methyl 2-bromo-2-deoxy-β-D-glucopyranoside, m.p. 182–184°, $[\alpha]_D$ +0.9 (*c*, 2.4 in methanol). Fischer and co-workers (1) reported the constants, m.p. 179–180° and $[\alpha]_D$ +0.87° for this product.

The mother liquor from the isolation of V was deacetylated at room temperature in methanolic ammonia and the product was fractionated by preparative paper chromatography on Whatman 3MM paper using *n*-butanol–ethanol–water (5:1:4). The chromatogram showed five main components with R_f values of 0.14, 0.33, 0.49, 0.66, and 0.80. The central zone, R_f = 0.49, provided a substance which crystallized on acetylation with acetic anhydride and pyridine. The melting point of the compound (VI), 110–111°, and $[\alpha]_D$ −89.5° (*c*, 1.2 in chloroform) were similar to those reported by Fischer and co-workers (1) for their "triacetyl methyl glucoside-2-bromohydrin II", m.p. 115–116° $[\alpha]_D$ −92.0°. The NMR spectrum of VI is shown in Fig. 1. The R_f value of the product formed on the deacetylation of V was 0.66 and this spot was more intense than that for deacetylated VI in the above-mentioned preparative chromatogram.

Bromomethoxylation of D-*Glucal Triacetate*

D-Glucal triacetate, 10.0 g (37 mmoles), was dissolved in 250 ml of dry methanol containing 8.76 g (52 mmoles) of silver acetate. The mixture was cooled to 0° and 8.4 g (52 mmoles) of bromine was added over a period of 10 minutes with stirring. After an additional 20 minutes, the silver salts were removed by filtration and washed with methanol. The filtrate was evaporated *in vacuo* to a syrup which was taken up in chloroform. The chloroform solution was washed with aqueous sodium bicarbonate and sodium thiosulphate solutions. The dried solution was evaporated to a clear dry syrup. The NMR spectrum of the substance contained two signals for methoxyl groups of relative intensities 1:2 at 3.60 and 3.45 p.p.m., respectively (see Fig. 2).

The syrup was dissolved in ethanol and, on cooling, a 26% yield of the above described methyl 2-bromo-2-deoxy-β-D-glucopyranoside triacetate (V) was deposited. The methoxy group of this compound was found to give its signal at 3.60 p.p.m. A portion, 4 g, of the material in the mother liquor was deacetylated with methanolic ammonia and chromatographed on a cellulose column using *n*-butanol saturated with water. The first fraction, 670 ml of eluate, contained 1.45 g of material which was acetylated with acetic anhydride in pyridine. From the relative intensities of the signals for the methoxy groups, it was concluded that the product which gave a strong methoxy signal at 3.45 p.p.m. was methyl 2-bromo-2-deoxy-α-D-manno-pyranoside triacetate (VII) contaminated 14% by the β-D-gluco isomer (V). The specific rotation of the mixture was +31.2° in chloroform. Catalytic hydrogenolysis of 450 mg of VII using palladium on charcoal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in methanol containing triethylamine gave 118 mg (57% from VII) of methyl 2-deoxy-α-D-glucopyranoside, m.p. 90–91 (2).

Chloromethoxylation of D-*Glucal Triacetate and Characterization of the Product*

Chlorine was passed through a stirred solution of D-glucal triacetate, 5.00 g (18.5 mmoles) in 125 ml of dry methanol containing 4.35 g (26 mmoles) of silver acetate at 0° until an excess was present. The reaction mixture was then left for 20 minutes before the product was isolated by the procedure described above for the bromomethoxylation reaction. The NMR spectrum of the syrupy product showed the presence of two methyl glycosides as main products of the reaction. The signals for the methoxy groups at 3.60 and 3.45 p.p.m. were in the ratio 2:3, respectively. The NMR spectrum also showed a weak signal for methoxy group at 3.48 p.p.m.

On trituration with methanol, a 19% yield of material (VIII), m.p. 141–145°, was obtained. After two crystallizations from ethanol the material possessed physical constants, m.p. 149–150°, $[\alpha]_D = 53°$ (*c*, 1 in chloroform) and undoubtedly was identical with the "triacetyl methyl glucoside-2-chlorohydrin I" of same melting point and $[\alpha]_D$ +40.2° reported by Fischer and co-workers (1). Deacetylation gave a material (IX) of same melting point, 164–165°, and specific rotation in water, −12.9°, as reported (1) for this compound. The NMR spectrum of VIII was very similar to that for the bromine analogue V shown in Fig. 2 and therefore required the compound to be methyl 2-chloro-2-deoxy-β-D-glucopyranoside triacetate. The substance, 0.51 g, was treated with a refluxing solution of titanium tetrachloride, 0.86 g, in 15 ml of dry chloroform for 15 hours. The product, isolated in the usual manner (13), possessed a specific rotation of 104° in chloroform and its NMR spectrum required the presence of the starting material and a second methyl glycoside with the signal for the methoxy group at 3.48 p.p.m. in the relative amounts 1:2, respectively. The latter substance, undoubtedly methyl 2-chloro-2-deoxy-α-D-glucopyranoside triacetate, resisted crystallization.

The residue from the crystallization of VIII was deacetylated with methanolic ammonia to give a syrupy product, 2.26 g of which was fractionated on a cellulose column using *n*-butanol saturated with water. The first fraction contained 1.30 g of a substance with $R_f = 0.87$ (the R_f value for IX was 0.76) and its NMR spectrum, measured in deuterium oxide, had a doublet, 1.2 c.p.s. spacing at 5.03 p.p.m., assigned to the anomeric hydrogen and a quartet at 4.44 p.p.m. with spacings of 1.2 and 3.5 c.p.s. assigned to the 2-hydrogen of methyl 2-chloro-2-deoxy-α-D-mannopyranoside. The position of the signal for the methoxy group was at 3.50 p.p.m. Its tri-*O*-acetyl derivative (X) produced a signal at 3.45 p.p.m. for the methoxy group. Although the substance appeared virtually pure, $[\alpha]_D$ +45.2° (*c*, 1.7 in chloroform), it resisted crystallization.

Iodomethoxylation of D-*Glucal Triacetate and Characterization of the Product*

To 5 g (18 mmoles) of D-glucal triacetate in 125 ml methanol containing 4.35 g (26 mmoles) silver acetate cooled to 0°, was added iodine, 6.6 g (26 mmoles), during 5 minutes. The mixture was allowed to stand for a further 10 minutes.

The syrupy product was isolated in the manner already described. The NMR spectrum had signals for methoxy groups at 3.58 and 3.43 p.p.m. with relative intensities 3:5. The material was deacetylated by solution in a mixture of 45 ml water, 50 ml methanol, and 5 ml of triethylamine. After 5 hours the solvents were removed by evaporation and the residue was dissolved in methanol for decolorization using charcoal. The methanol was removed and the residue was dissolved with heating in 30 ml of ethanol. Within 1 hour, 2.01 g (36%) of the glucoside crystallized. After two recrystallizations from ethanol, the compound had the physical constants, m.p. 187–188°, $[\alpha]_D$ +3.8° (*c*, 3.9 in water). The reported values (2) for methyl-2-deoxy-2-iodo-β-D-glucopyranoside are 189–189.5° and +6.9° respectively. Acetylation in the usual manner using acetic anhydride and pyridine provided methyl 2-deoxy-2-iodo-β-D-glucopyranoside triacetate, m.p. 94–95°, $[\alpha]_D$ +61.1° (*c*, 2.03 in chloroform).

The mother liquors from the glucoside were dissolved in ethyl acetate, 20 ml, and nucleation with an authentic sample afforded 1.15 g (20%) of crystalline methyl 2-deoxy-2-iodo-α-D-mannopyranoside contaminated (about 15%) with the glucoside. The product was extracted twice with 15 ml of cold ethanol, and the combined ethanolic extracts (which were shown by nuclear magnetic resonance to be free from the glucoside) on evaporation and crystallization from ethyl acetate gave 0.95 g of the pure mannoside, m.p. 147–8°, $[\alpha]_D$ +48.8° (*c*, 1.0 in water). The reported values (2) are 145–146° and +49.6°, respectively.

The residue from the first crop of crystalline mannoside was dissolved in methanol and treated with charcoal. The clarified solution was evaporated to dryness and taken up in a minimum of ethyl acetate to provide a further 0.73 g of crystalline mannoside. The mother liquors from the second crop of crystals were eluted through a short column of silicic acid with methanol. The concentrated eluate afforded a further 0.32 g of mannoside. The total yield of methyl 2-deoxy-2-iodo-α-D-mannopyranoside was 2.00 g (36%). The crystalline residue from the above-mentioned extractions with cold ethanol was recrystallized from ethanol to yield 0.17 g of methyl 2-deoxy-2-iodo-β-D-glucopyranoside and thus raise the yield of this compound to 39%.

THE BROMINOLYSIS OF CARBOHYDRATE IODIDES

I. ACETYLATED 6-DEOXY-6-IODO AND 2-DEOXY-2-IODO GLYCOSIDES[1]

R. U. LEMIEUX AND B. FRASER-REID
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received September 19, 1963

ABSTRACT

Reaction of methyl 6-deoxy-6-iodo-α-D-glucopyranoside triacetate with an excess of bromine in glacial acetic acid, *N* in potassium acetate, gave a 1.1:1 mixture of the products resulting from replacement of the iodine by bromine and by acetoxy group, respectively. When 2 moles of silver acetate were present per mole of bromine, the reaction was much more rapid and only methyl α-D-glucopyranoside tetraacetate was formed. The brominolysis of methyl 2-deoxy-2-iodo-α-D-mannopyranoside triacetate proceeded at a useful rate only when catalyzed by silver acetate. The main product of the reaction appeared to be methyl 3-acetoxy-2-bromo-2-deoxy-α-D-*arabino*-hexopyranoside triacetate. The compound could be converted by way of sodium borohydride reduction to methyl 2-bromo-2-deoxy-α-D-altropyranoside and by way of zinc dust reduction to methyl 2-deoxy-α-D-*erythro*-hexopyranoside-3-ulose diacetate. About 20% of the reaction proceeded with migration of the methoxy group to the 2-position to yield 2-*O*-methyl-D-glucose tetraacetate. The mechanisms of these reactions are discussed.

The reaction of alkyl iodides with bromine was discovered by Geuther (1) and, in 1865, Friedel (2) observed that the addition of bromine to isopropyl iodide led to the formation of isopropyl bromide and propylene dibromide. Recently, Keefer and Andrews (3) showed that the substitution of iodine chloride for bromine led to the formation of isopropyl chloride and chloroiodopropane. This "halogenolysis" reaction of alkyl iodides was adapted by Viebock and Schwappach (4) for the determination of the volatile alkyl iodides in the classical Ziesel alkoxy group determination (5). The alkyl iodide is distilled into a receiver containing bromine and potassium acetate dissolved in acetic acid. The reaction is described in books of quantitative analysis as involving replacement of the iodine by bromine to form iodine bromide which is subsequently oxidized to iodate—the substance ultimately determined by iodometric titration (6–8).

It would be expected that the driving force for the halogenolysis of an alkyl iodide would originate in the oxidation of the iodine by the halogen and thus provide a better leaving group. In fact, it has long been known that compounds of the type RIX_2 can have existence, ever since Willgerodt (9) isolated phenyl iodine dichloride from the reaction of phenyl iodide with chlorine. However, iodine dihalides appear to have appreciable stability only in the aromatic series (10). Their analogues have been detected in the aliphatic series only at exceedingly low temperatures (4, 11). Thus, the stabilities of the iodine dihalide salts are reminiscent of those for aromatic and aliphatic diazonium salts. As will be seen below, their reaction properties are very similar. Viebock and Schwappach (4) postulated the formation of alkyl iodine dibromides as intermediates in the brominolysis of alkyl iodides.

The stereochemistry and mechanism of the halogenolysis reaction of alkyl iodides has received considerable attention. Corey and Wechter (12) examined the extent of inversion in the reaction of optically active 2-octyl iodide with chlorine and iodine chloride in a number of solvents. The 2-octyl chloride formed was isolated by distillation in 30 to 50% yield and its rotation was measured under standard conditions. The extent of

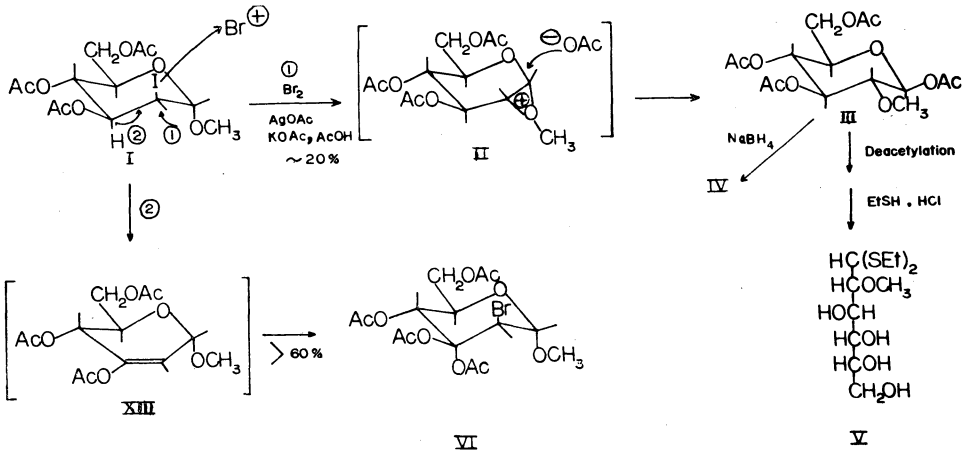
inversion with chlorine as the reagent was 1.5 to 2.3 times that of retention when inert, non-polar solvents were used (methylene chloride, ether, pentane, and ethyl acetate). The highest degree of inversion (10.25 times greater) occurred when a 3:1 mixture of methylene chloride and methanol, 4 *M* in hydrogen chloride, was used. In the absence of the hydrogen chloride, the extent of inversion was reduced to 5.8 times that of retention. In the presence of methanol, methyl 2-octyl ether was also formed.

Keefer and Andrews (3, 13) examined the kinetics of the reaction in carbon tetrachloride and concluded that the rate-controlling step involves attack by the halogen on a 1:1 complex (4, 14) of the alkyl iodide and the halogen. A direct nucleophilic attack on carbon by the halogen would then explain the inversions observed by Corey and Wechter (12). However, Keefer and Andrews (13) pointed out that the second molecule of halogen may make an electrophilic attack on a halogen of the complex. Thus, one can envisage the formation of a high-energy alkyl iodonium halide cation which presumably could rapidly decompose to a carbonium ion – iodine halide molecule pair. Nucleophilic attack on this pair by a nucleophile from the immediate environment could then account for the products of replacement. Increased solvent polarity would be expected to facilitate separation of the carbonium ion – iodine halide pair and the neighboring halide anion, and thus account for the increase in inversion noted with increasing polarity of the solvent (12). The departing iodine halide would be expected to help shield the carbonium ion from nucleophilic attack to produce products of retention.

The formation of a high-energy alkyl dihalide cationic intermediate is favored by the indiscriminate courses of reaction observed. First of all, it is to be noted that the substitution reaction is often the minor reaction. Instead, elimination can be the main course of reaction even in the absence of proton abstracting reagents (2). Also in line with carbonium ion formation is the fact that Meerwein–Wagner type rearrangement of the neopentyl to the *sec*-isobutyl carbon skeleton occurs when neopentyl iodide is treated with either bromine or chlorine (15). We were interested in the possibility of replacing the iodine of alkyl 2-deoxy-2-iodo-α-D-mannopyranoside triacetates by acetoxy and thus achieving a synthesis of α-D-glucopyranosides. This approach would be attractive since alkyl 2-deoxy-2-iodo-α-D-mannopyranosides are readily prepared (16). However, the iodide proved so highly resistant to nucleophilic attack on carbon that only elimination was obtained under a variety of solvolytic conditions. It was decided to examine the dark reaction of the iodide with bromine under the standard Viebock–Ziesel conditions used in methoxyl group determinations, namely, to react the iodide in the dark with bromine in glacial acetic acid, *N* in potassium acetate. In view of the relatively high concentration of acetate ion and polarity of the medium, it could be expected that the inversion mechanism would lead to replacement of the axial iodine atom by acetoxy group. The rate of the cleavage of the carbon–iodine bond could be conveniently followed by titration of the iodate content after various periods of time.

Although the rate of the reaction of simple alkyl iodides with bromine under the above conditions is extremely rapid, the methyl 2-deoxy-2-iodo-α-D-mannopyranoside triacetate (I) proved exceedingly resistant to reaction. In order to achieve reaction at a useful rate, silver acetate was added to the reaction medium. This procedure proved, in fact, to accelerate the reaction greatly and provided evidence that the rate-controlling stage in the brominolysis of an iodide involves the formation of a bromoiodonium cation. Inspection of the crude product by nuclear magnetic resonance showed the presence of at least five compounds (five different methoxy group signals). The major component (VI) produced

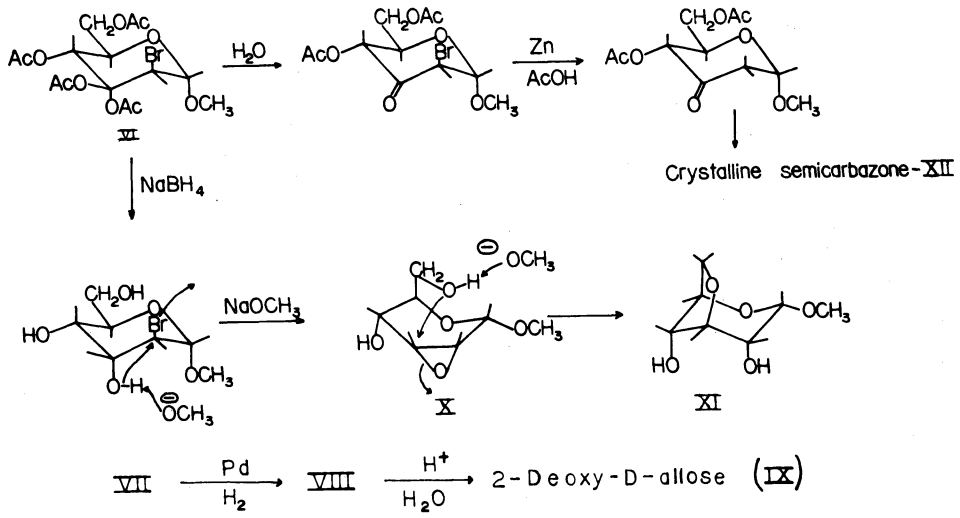
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



a signal for the methoxy group at 3.52 p.p.m. and constituted more than one-half of the product. Chromatography on dimethyl sulphoxide impregnated paper (17) showed the presence of at least 10 components, one of which was starting material.

The crude product was reduced and deacetylated with sodium borohydride. Column chromatography allowed the isolation of at least two of the five components. One of these substances (compound IV) represented about 20% of the product isolated from the borohydride reduction and appeared to be 2-*O*-methyl-D-glucitol when examined by periodate oxidation followed by paper chromatography (18). It was decided on this basis to examine the product of the brominolysis reaction for 2-*O*-methyl-D-glucose. The material was deacetylated with sodium methoxide in methanol and the resulting syrup was treated with ethanethiol and hydrochloric acid in the anticipation that the well-characterized and high-melting diethyl dithioacetal derivative of 2-*O*-methyl-D-glucose (V) could be isolated from the product of the mercaptolysis reaction. In fact, a crystalline product was readily isolated, which was identical with an authentic sample of 2-*O*-methyl-D-glucose diethyl dithioacetal (19). It is therefore clear that a course of the brominolysis reaction involved cleavage of the axial C_2–I bond, likely by way of a $[C_2—I—Br]^{\oplus}$ intermediate, with participation of the axial C_1-methoxy group, to lead to a 1,2-methoxonium ion (II). This ion would, of course, accept a nucleophile preferentially at the 1-position. Thus, one product of the reaction may be 2-*O*-methyl-β-D-glucopyranose tetraacetate (III). However, it is conceivable that the methoxonium ion is much less favorable than the glucosyloxonium ion. Thus, the latter ion may be an important intermediate in the reaction and its presence could lead to the formation of α- as well as β-anomer. It was not possible to obtain information on this matter. To our knowledge, this is the first example of a methoxy group migration in carbohydrate chemistry although Winstein and Ingraham (20) observed a methoxy migration in the silver ion assisted solvolysis of 2-methyl-2-methoxy-3-bromobutane. In both cases, the migration occurred because the intermediate ethylene oxonium ion was preferentially attacked at the center, which was originally bonded to the methoxyl group. The extent of the migration was at least 7.3% (the actual yield of 2-*O*-methyl-D-glucitol IV). However, judging from the intensities and sizes of the spots obtained in the chromatograms of the sodium borohydride – reduction product, compound IV and a second substance (compound VII) necessarily made up nearly all of the mixture. Also, only two methoxy group signals of appreciable intensity were present in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



the NMR spectrum of the product. On these bases, it can be concluded that the migration represented about 20% of the course of the brominolysis reaction, and the sequence of reactions leading to compound VI about 60%.

Compound VII failed to crystallize. The substance contained bromine, appeared pure on chromatograms, and possessed (NMR) three acetyl groups per methoxyl group. Hydrogenolysis of the bromine provided a methyl 2-deoxyglycoside, different from either methyl 2-deoxy-α- or β-D-glucopyranoside but possessing the specific rotation reported for methyl 2-deoxy-α-D-allopyranoside (VIII) (21). Acid hydrolysis gave a 2-deoxy sugar found identical, by direct comparison, with 2-deoxy-D-allose (IX) (22). It was therefore evident that compound VII was a methyl 2-bromo-2-deoxy-D-hexopyranoside possessing either the *altro* or *allo* configuration. The D-*altro* configuration was established by treatment of VII with sodium methoxide to form methyl 3,6-anhydro-α-D-glucopyranoside (XI) (23). This conversion requires the intermediary formation of methyl 2,3-anhydro-α-D-allopyranoside (X), which undergoes oxide-ring migration (23) to form the 3,6-anhydro sugar.

It was therefore clearly apparent that the major product (VI) of the brominolysis of I was an acetylated derivative of methyl 2-bromo-2-deoxy-α-D-*erythro*-hexopyranoside-3-ulose. This compound appeared (NMR) to make up about 60% of the reaction product. In order to confirm the structure for VI, a sample of the crude product of brominolysis was reduced with zinc dust in acetic acid. The main component in the reaction mixture (paper chromatography) was converted by sodium borohydride reduction with simultaneous deacetylation to a substance with the same R_f and color reactions as the above-mentioned methyl 2-deoxy-α-D-allopyranoside (VIII). When the crude product of the zinc dust reaction was treated with semicarbazide, a crystalline product was deposited, which possessed the elementary composition and NMR spectrum expected for methyl 4,6-di-*O*-acetyl-2-deoxy-3-oxo-α-D-glucopyranoside semicarbazone (XII). It was therefore concluded that the main course of reaction in the brominolysis of I involved elimination to form the acetylated enol (XIII), which subsequently underwent acetoxybromination to form VI. The formation of the acetylated enol as an intermediate found support in the observation that brominolysis of cyclohexyl iodide, under the same conditions as used

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

above except that silver acetate was not added, led to the formation of a substantial amount of *trans*-2-acetoxycyclohexyl bromide (54.6%) along with cyclohexyl bromide, cyclohexyl acetate, and *trans*-cyclohexene dibromide.

In order to achieve a better insight into the essential mechanism of the brominolysis reaction, a number of experiments were conducted starting from methyl 6-deoxy-6-iodo-α-D-glucopyranoside triacetate (24). First of all, the compound was treated with a 5 mole excess of bromine (0.13 *M*) in *N* potassium acetate in acetic acid. After 7 hours, reaction was complete and the product was a 1.1:1 mixture of methyl 6-bromo-6-deoxy-α-D-glucopyranoside triacetate and methyl α-D-glucopyranoside tetraacetate. When the reaction mixture was diluted with the potassium acetate in acetic acid solution to provide an initial bromine concentration of 0.013 *M*, the reaction after 7 hours was only about 44% complete (determined from the relative intensities of the methoxy group signals in the NMR spectrum taken at 100 Mc.p.s.). The relative amounts of the 6-bromo and 6-acetoxy reaction products was now 0.4:1, respectively. The brominolysis reaction under these dilute conditions was complete after 43 hours and the reaction product was a 0.6:1 mixture of the 6-bromo to 6-acetoxy products, respectively. These experiments clearly show that the 6-bromide is to some extent formed by way of an attack by external bromine and (or) bromide on the reactive intermediate. The reaction was then conducted under these same conditions of dilution but in the presence of 2 moles of dissolved silver acetate per mole of bromine in order to exclude any possibility of the presence of bromide ion. The reaction product was analytically pure methyl α-D-glucopyranoside tetraacetate. In view of the fact that the brominolysis reaction is second order in bromine (3), the reduction in the extent of replacement by bromine on a 10-fold dilution of the reaction mixture was much less than expected unless the bromide is formed extensively by attack on the reactive intermediate by a bromide ion from the immediate environment. It is evident therefore that the retention mechanism is operative to an important extent in these reactions. Evidently, the iodine may be replaced by acetoxy with retention in the reactions conducted in the presence of silver acetate. The brominolysis of the 6-iodide under the same conditions as were used for the 2-iodide (I) gave an 0.82:1 ratio of the 6-bromo and 6-acetoxy products, respectively.

EXPERIMENTAL

All melting points were determined on a heating stage and are uncorrected. The nuclear magnetic resonance spectra were determined, unless otherwise stated, in chloroform with Varian A60 or HR100 spectrometers and the chemical shifts are reported in parts per million from tetramethylsilane used as an internal standard. Unless otherwise stated, the paper chromatograms were made on Whatman No. 1 paper and developed with the lighter phase of an *n*-butanol, ethanol, and water mixture (5:1:4) (25). The zones were detected with the silver nitrate – sodium hydroxide (26) or the permanganate–periodate (27) reagents.

Brominolysis of Methyl 2-Deoxy-2-iodo-α-D-mannopyranoside Triacetate (I)

The starting material was a 9:1 mixture (NMR determination) of methyl 2-deoxy-2-iodo-α-D-mannopyranoside (I) and methyl 2-deoxy-2-iodo-β-D-glucopyranoside triacetates. The mixture, 3.24 g (7.5 mmoles, 6.75 mmoles of I), was dissolved in 150 ml of a 10% solution of potassium acetate in acetic acid which contained 24.0 g (150 mmoles) of bromine. Silver acetate, 12.5 g (75 mmoles), was added and the reaction mixture was kept in the dark. Titration of the iodate showed the reaction to be complete after 6 hours at room temperature. The reaction was much slower, about 10% reaction in 1 week, in the absence of the silver acetate. After a 7-hour reaction time, 150 ml of a 25% aqueous solution of sodium acetate was added and the bromine was reduced by the addition of formic acid (4). The product was isolated by filtration to remove insoluble salts and extraction of the filtrate in the usual manner. The brown-colored syrupy product, 2.4 g, was examined by chromatography on dimethyl sulphoxide impregnated paper (17) and found to be a complex mixture containing at least 10 components. The product obviously underwent profound degradation on deacetylation in methanolic ammonia. For this reason, it was deacetylated under reductive conditions using sodium borohydride.

A. Reduction with Sodium Borohydride

The mixture, 5 g, was treated with an excess of sodium borohydride, 10 g, in aqueous methanol at room temperature for 7 hours. An excess of acetic acid was then added and the solution was reduced to dryness. Methanol was distilled several times from the residue to remove the boric acid and then dissolved in water and the sodium ion was removed by sulphonic acid resin in the acid form. The dark-colored, water-soluble product was found on paper chromatography to contain five main components, one of which, $R_f = 0.71$, was identical with the deacetylated starting material. The other components showed R_f values of 0.18, 0.30, 0.53, and 0.65 and were separated by chromatography on a cellulose column using a *n*-butanol – Skellysolve B (4:1) mixture for development. The components with R_f values of 0.30 and 0.65 (compounds IV and VII, respectively) were obtained in yields of 0.23 g and 1.03 g, respectively.

Characterization of compound IV.—The compound was acetylated and the product was found by nuclear magnetic resonance to contain five acetoxy groups per methoxy group. IV, 15.4 mg, in 50 ml of 0.02 *M* sodium metaperiodate consumed 3.28 moles of periodate per mole and liberated 2.2 moles of formic acid and 1.1 moles of formaldehyde per mole (28). A portion of the oxidized material was analyzed by paper chromatography and a canary yellow spot was revealed by the aniline phthalate reagent (29) with the $R_f = 0.78$ of 2-*O*-methyl glyceraldehyde (18). It was therefore concluded that IV was a 2-*O*-methyl hexitol. The parent compound 2-*O*-methyl-D-glucose was characterized as described further on.

Characterization of compound VII.—The major component, VII, R_f 0.65, obtained from the cellulose column chromatogram was acetylated. The NMR spectrum in chloroform showed the presence of three chemically shifted *O*-acetyl groups and one *O*-methyl group. Qualitative tests revealed the presence of bromine. Hydrogenolysis of VII, 320 mg, over 5% palladium on charcoal in 50 ml of 50% aqueous methanol containing 0.2 ml of triethylamine, afforded 110 mg of a substance with $[\alpha]_D = 146°$ (*c*, 1.2 in methanol), which on paper chromatography gave the color reaction with the *p*-anisidine hydrochloride spray reagent (30) found characteristic for methyl 2-deoxyhexosides. The latter, VIII, was neither methyl 2-deoxy-α- or -β-D-glucopyranoside as shown by comparison of their NMR spectra measured in deuterium oxide. The specific rotation of methyl 2-deoxy-α-D-allopyranoside is reported to be 144° (21). Hydrolysis of VII with cold normal sulphuric acid was complete after 4 hours (constant optical rotation). Neutralization of the acid with basic Amberlite IRA-400 followed by filtration and evaporation *in vacuo* gave a syrup which crystallized from ethanol. The melting point after four recrystallizations from ethanol was 135–6°, $[\alpha]_D$ 55.2° (*c*, 1 in water), and was not depressed when admixed with an authentic sample of 2-deoxy-D-allose kindly provided by Professor J. K. N. Jones. The reported constants are m.p. 133–5° and $[\alpha]_D$ 57.9±2 (22).

Treatment of VII, 150 mg, with 5 ml of 0.75 *N* sodium methoxide in methanol for 19 hours followed by neutralization of the base with sulphonic acid resin in the acid form, filtration, evaporation, and fractionation of the resulting mixture, 99 mg, on Whatman 3 MM paper afforded 9 mg of a compound, $R_f = 0.84$, which had an infrared spectrum identical with that for methyl 3,6-anhydro-α-D-glucopyranoside (XI) prepared from methyl 6-*O*-tosyl-α-D-glucopyranoside (31) by the method of Haworth and co-workers (23).

B. Reduction with Zinc Dust

To a well-stirred mixture of 6 ml water, 3 ml glacial acetic acid and 0.6 g zinc dust at 0°, a 5-ml portion of VI, 4.4 g, in 20 ml of glacial acetic acid was added. After 1 hour, 1.2 g zinc dust, 5 ml water, and a further 5-ml portion of the above solution were added to the reaction mixture. Addition of similar quantities of these substances was made twice during the succeeding 2 hours, after which the mixture was allowed to stand, with stirring, at room temperature for an additional 15 hours. Excess zinc dust and precipitated salts were removed by filtration and the filtrate was exhaustively extracted with chloroform. The chloroform phase, after being washed to neutrality with water, was dried and evaporated *in vacuo* to yield 2.71 g of a syrupy halogen-free product which, according to its infrared spectrum, did not contain an olefinic double bond but contained a ketonic carbonyl group as indicated by absorption at 1740 cm^{-1}. The product was readily deacetylated on standing for 2 hours in a mixture of methanol, water, and triethylamine (50:45:5). Paper chromatography of the deacetylated material showed a very intense spot (30) with $R_f = 0.57$. Sodium borohydride reduction of the deacetylated material, and isolation as described above, led to a product which, on paper chromatograms, had color reactions characteristic of a methyl 2-deoxyhexoside.

The material from the zinc dust reduction, 1.30 g, was dissolved in 5 ml of ethanol and water was added until a turbid solution resulted. Semicarbazide hydrochloride, 0.75 g, and 1.19 g anhydrous sodium acetate were then added. After the mixture had been allowed to stand at room temperature for 30 minutes crystals were deposited and after it was cooled at 0° for a further 2 hours, 0.40 g of crystalline material was isolated. After four recrystallizations from ethanol, the material had a melting point of 195–196°, $[\alpha]_D = +146°$ (*c*, 0.75 in pyridine). Calc. for $C_{12}H_{19}N_3O_7$: C, 45.43; H, 5.99; N, 13.25%. Found: C, 45.67; H, 5.88; N, 13.08%.

Identification of 2-O-Methyl-D-glucose

The product, 0.5 g, of the brominolysis reaction was treated with 5 ml of 0.05 *N* sodium methoxide in dry methanol for 30 minutes. The solution was then neutralized with sulphonic acid resin in the acid form, filtered, and evaporated to dryness *in vacuo*. The resulting syrup, 110 mg, was treated with a mixture of 0.5 ml ethanethiol and 0.5 ml concentrated hydrochloric acid at room temperature. After 15 hours, 5 ml

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

water was added to the cooled solution and the excess ethanethiol was removed. The solution was neutralized with basic ion exchange resin (Amberlite IRA-400). After filtration and evaporation the product was dissolved in ethyl ether to deposit 13.2 mg of material which after four recrystallizations from ethanol had a melting point of 157–158° and a specific rotation of −22.4° (*c*, 0.52 in pyridine). An authentic specimen of V was prepared from D-glucose diethyl dithioacetal by the method of Lieser and Leckzyck (19). The two compounds had identical melting points (which were undepressed on admixture), infrared spectra, and NMR spectra.

Brominolysis of Cyclohexyl Iodide

Cyclohexyl iodide, 3.20 g (15 mmoles), was treated with 100 ml of a 10% w/v solution of potassium acetate in acetic acid containing 33 g (200 mmoles) of bromine. After 7 hours, 100 ml of 25% aqueous sodium acetate was added and the excess bromine was reduced by the addition of formic acid. The mixture was extracted with chloroform and the chloroform solution was thoroughly neutralized by washing with aqueous sodium bicarbonate. The dried chloroform solution was evaporated to an oily residue. The material was subjected to gas–liquid partition chromatography on a silicone oil – Celite column using a temperature program over the range 50° to 225°. Four components were detected comprising 4.3, 6.7, 34.4, and 54.6% of the material which passed through the column. These components were identified by direct comparison of their retention times with those of authentic samples and found to be cyclohexyl bromide, cyclohexyl acetate, *trans*-cyclohexane dibromide, and *trans*-2-bromocyclohexyl acetate, respectively.

Brominolysis of Methyl 6-Deoxy-6-iodo-α-D-glucopyranoside Triacetate (XIV)

The reaction was performed under conditions essentially identical with those described above for the 2-iodomannoside. A solution of the product in ethanol readily deposited a crystalline compound (XV), m.p. 109–111°, $[\alpha]_D = +144.1°$ (*c*, 1 in pyridine). Although these constants are not exactly those reported (32) for methyl 6-bromo-6-deoxy-tri-*O*-acetyl-α-D-glucopyranoside, the NMR spectrum could leave no doubt about this identity. The major difference between its spectrum at 60 Mc.p.s. and that for methyl tetra-*O*-acetyl-α-D-glucopyranoside (XVI) was the chemical shift for the methylenic 6-hydrogens from 4.15 p.p.m. for the 6-acetate to 3.4 p.p.m. for the 6-bromide. In the case of the 6-iodide (XIV), the starting material, this signal appeared at 3.28 p.p.m. Furthermore, on hydrogenolysis of XV with palladium as catalyst, followed by deacetylation, a substance with the same R_f value as methyl 6-deoxy-α-D-glucopyranoside was obtained. The other product formed in the brominolysis was readily isolated by fractional crystallization and found by direct comparison to be methyl tetra-*O*-acetyl-α-D-glucopyranoside (XVI). The signals for the methoxyl groups in compounds XIV, XV, and XVI occurred at 3.5, 3.48, and 3.42 p.p.m. and were well resolved by the spectrometer operating at 100 Mc.p.s. The relative intensities of these signals in the spectrum of the above described reaction product showed the absence of starting material and the ratio of XV to XVI to be 0.82:1.

In another experiment, compound XIV, 215 mg (0.5 mmole), was reacted in the dark with 2.6 mmoles of bromine in 18.5 ml of 10% potassium acetate in acetic acid. Reaction was complete after 7 hours. The product, 163 mg, isolated in the usual manner, was found by nuclear magnetic resonance to comprise a mixture of XV and XVI in the ratio 1.1:1.0. When the reaction was performed at higher dilution using 185 ml of the 10% potassium acetate in acetic acid, the reaction was only 47% complete after 7 hours and the ratio of XV to XVI was 0.4 to 1. After 43 hours, the reaction was complete and the ratio of XV to XVI in the product was 0.6:1.

In an experiment identical with that described immediately above at high dilution except that 5 mmoles of silver acetate was added, the reaction was complete within 3 hours and the product was pure XVI.

ACKNOWLEDGMENTS

The 60 Mc.p.s. NMR and infrared spectra were determined by R. N. Swindlehurst and Mrs. G. B. Conway. The 100 Mc.p.s. NMR spectra were obtained by G. B. Bigam of this department. The research was supported by two National Research Council of Canada Studentships to B.F-R. and National Research Council of Canada grants-in-aid of research (T-172) to R.U.L.

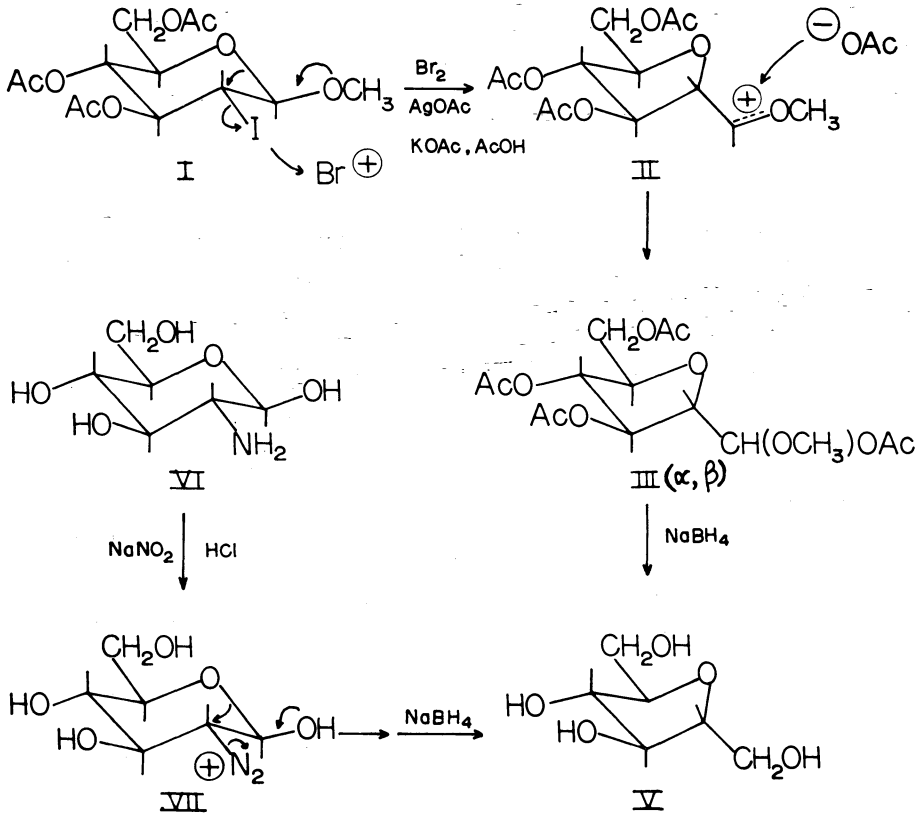
ABSTRACT

Reaction of methyl 2-deoxy-2-iodo-β-D-glucopyranoside triacetate with a 20-fold excess of bromine and a 10-fold excess of silver acetate in a 10% solution of potassium acetate in acetic acid gave a near-quantitative yield of an equimolar mixture of the anomeric forms of 1,3,4,6-tetra-*O*-acetyl-2,5-anhydro-1-methoxy-D-mannose. Treatment of the mixture with methanolic hydrogen chloride gave the dimethylacetal of 2,5-anhydro-D-mannose (chitose).

In the first paper in this series (1), the halogenolysis of alkyl iodides was reviewed and the products formed on the brominolysis in the presence of silver acetate of methyl 6-deoxy-6-iodo-α-D-glucopyranoside triacetate and methyl 2-deoxy-2-iodo-α-D-mannopyranoside triacetate were described. This communication reports the formation of 1,3,4,6-tetra-*O*-acetyl-2,5-anhydro-1-methoxy-D-mannose on the brominolysis of methyl 2-deoxy-2-iodo-β-D-glucopyranoside triacetate (I).



[1]*This research is to constitute a portion of a thesis to be submitted by B.F.-R. in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*

Brominolysis of I in 10% potassium acetate in acetic acid containing silver acetate led to the formation in quantitative yield of an about equimolar mixture of two compounds. The compounds were separated by column partition chromatography using dimethyl sulphoxide on silicic acid as static phase (2). Nuclear magnetic resonance (NMR) spectroscopy clearly required the compounds to be diastereoisomers differing only in configuration at the anomeric center. The more dextrorotatory compound (IIIα) was assigned the α-configuration and the other (IIIβ) the β-configuration following the original basis for naming anomeric compounds derived from D-sugars (3). Except for the spacings of doublets arising from the anomeric hydrogen, the NMR spectra of the two compounds were virtually identical and required the presence of four acetyl groups per methoxyl group. For IIIα, the doublet was at 5.90 p.p.m. with a spacing of 5.0 c.p.s. In the case of IIIβ, the doublet was at 5.91 p.p.m. with a spacing of 5.8 c.p.s. Since both IIIα and IIIβ underwent profound and rapid degradation on attempted deacetylation with base, the compounds were deacetylated under reductive conditions using sodium borohydride. Although several compounds were formed, the main product of the reaction was a substance identified as 2,5-anhydro-D-mannitol (V) by direct comparison with a sample prepared by borohydride reduction of 2,5-anhydro-D-mannose obtained by nitrous acid deamination of D-glucosamine (VI) (4, 5). It was therefore clear that the brominolysis of I proceeded with participation of the ring-oxygen as is established for the deamination of D-glucosamine (6). The fact that about equimolar amounts of IIIα and IIIβ were formed indicates that the oxocarbonium ion II was a discrete reaction intermediate. This course of reaction further illustrates that the brominolyses of iodides proceed by way of highly reactive intermediates (1) which possess properties very similar to the diazonium salts (VII) formed as intermediates in the nitrous acid deaminations of primary amines (7).

The great ease for the formation of hydroxymethylfurfuraldehyde and related compounds on treatment of 2,5-anhydro-D-mannose with bases or aqueous acid is well known (8–10). It is of interest in this regard that treatment of the mixture of IIIα and IIIβ with methanolic hydrogen chloride readily gave the dimethyl acetal (IV). This type of compound is stable to bases and may prove useful as intermediates in the preparation of 2,5-anhydrosugars (11–13).

EXPERIMENTAL

The melting points, nuclear magnetic resonance spectra, and paper chromatograms were established as described in the previous paper of this series (1). The methyl 2-deoxy-2-iodo-β-D-glucopyranoside triacetate (I) was prepared by iodomethoxylation of D-glucal triacetate (14).

1,3,4,6-Tetra-O-acetyl-2,5-anhydro-1-methoxy-α- and -β-D-mannose (IIIα and IIIβ)

Methyl 2-deoxy-2-iodo-β-D-glucopyranoside triacetate (I), m.p. 94–95° (14), 3.24 g (7.5 mmoles), was dissolved in 150 ml of a 10% solution of potassium acetate in acetic acid which contained 24.0 g (150 mmoles) of bromine. In separate experiments, titration for iodate in the reaction mixture showed that the brominolysis of the iodine was extremely slow (10% reaction in 1 week). However, on the addition of 12.5 g (75 mmoles) of silver acetate, reaction in the dark as shown by the appearance of iodate was complete in 6 hours at room temperature. After a 7-hour reaction time, 150 ml of a 25% aqueous solution of sodium acetate was added and the bromine was reduced by the addition of formic acid. The product was isolated by filtration to remove precipitated solids followed by extraction with chloroform and evaporation in the usual manner (1). The dried colorless syrupy product, 2.48 g, was found by chromatography on dimethyl sulphoxide impregnated paper (15), using Skellysolve B as the developing phase, to contain two components. This composition was substantiated by a comparison of the NMR spectrum of the mixture with those of the two components obtained by preparative chromatography on a column of silicic acid impregnated with dimethyl sulphoxide (2) using a 15% mixture of diisopropyl ether in Skellysolve B as developing phase. The mixture, 853 mg, was added to 2.5 cm × 27.5 cm column and the first pure component (IIIβ), 261 mg, $[\alpha]_D$ +46.3° (*c*, 2.26 in chloroform) was isolated in the 1500 to 1600 ml fraction of eluate. The next 75 ml provided 350 mg of a mixture of the two components. Compound (IIIα), 161 mg, $[\alpha]_D$ +49.4° (*c*, 2.7 in chloroform) was obtained in the following 80 ml of eluate. Both the pure compounds gave NMR spectra with sharp signals for four

acetoxy groups and one methoxy group at 2.12 and 3.51 p.p.m., respectively. The spectra were almost identical in the range 4.0 to 5.7 p.p.m. and could readily be assigned to the presence in both compounds of two methylenic hydrogens of an acetoxymethyl group (4.26 p.p.m.), two hydrogens on secondary carbons bonded to ring-oxygen (4.0–4.4 p.p.m.) and two hydrogens bonded to secondary carbons each substituted by acetoxy groups (5.37 and 5.14 p.p.m.). In addition, both compounds gave a doublet of intensity 1 at low field. For compound IIIβ, the doublet was at 5.91 p.p.m. and had a spacing of 5.8 c.p.s. In the other compound (IIIα) the doublet center was at 5.90 p.p.m. and the spacing was 5.0 c.p.s. The relative intensities of these doublets in the spectrum of the mixture required IIIβ and IIIα to be present in about equal amounts.

2,5-Anhydro-D-mannose Dimethyl Acetal (IV)

On reacting the mixture of IIIα and IIIβ (0.410 g) formed in the brominolysis reaction with 15 ml of 2% methanolic hydrogen chloride for 7 hours, followed by isolation in the usual manner, the material was converted to a single substance, $R_f = 0.67$, which produced a strong color reaction with *p*-anisidine hydrochloride on paper chromatograms. The compound rapidly consumed 1 mole of periodate per mole in agreement with the assumption that the substance is the dimethylacetal (IV) of 2,5-anhydro-D-mannose (chitose). The compound was acetylated with acetic anhydride in pyridine and the product, $[\alpha]_D$ +41.7° (*c*, 1.39 in chloroform), produced signals in its NMR spectrum for acetoxy- and methoxy-group hydrogens of intensities in the ratio 3:2. A sharp doublet of intensity 1 was present at 3.54 p.p.m. with a spacing of 5.5 c.p.s.

2,5-Anhydro-D-Mannitol (V)

A. From D-glucosamine.—A sample of D-chitose was prepared according to the directions prescribed by Bera, Foster, and Stacey (5) starting from D-glucosamine hydrochloride. Reduction of the product with sodium borohydride as described below for the alternate preparation led to the isolation of a substance which on analysis by paper chromatography showed the presence of at least six components using the periodate–permanganate spray reagent. The main component, $R_f = 0.66$, was isolated by chromatography on a cellulose column using *n*-butanol as developing phase. The substance was acetylated using pyridine and acetic anhydride and isolated in the usual manner. The clear syrupy product was dissolved in chloroform and the solution was passed through a short column of silicic acid and the column was washed with chloroform. The chloroform was removed *in vacuo* to leave a syrup, $[\alpha]_D$ +27.3° (*c*, 4.2 in chloroform). The NMR spectrum showed three sharp signals at 4.83 (3- and 4-hydrogens), 5.75, and 1.88 (acetyl hydrogens) p.p.m. of relative intensities 2:6:12 as expected for tetra-*O*-acetyl-2,5-anhydro-D-mannitol should the signals for the six hydrogens at the 1-, 2-, 5-, and 6-positions show no chemical shift and occur at 5.75 p.p.m.

B. From the mixture of IIIα and IIIβ.—The mixture of IIIα and IIIβ from the brominolysis reaction, 4.10 g, was treated with an excess of sodium borohydride, 10 g, in aqueous methanol at room temperature for 7 hours. An excess of acetic acid was then added and the solution was reduced to dryness. Methanol was distilled several times from the residue to remove the boric acid. The product was dissolved in water and the sodium ion was removed by sulphonic acid resin in the acid form. Paper chromatographic examination of the residue obtained on evaporation *in vacuo* showed the presence of at least six components with the main zone at $R_f = 0.66$. The R_f values and relative intensities of the zones were the same as those observed above on chromatography of the product from the borohydride reduction of D-chitose. The main component was isolated on a cellulose column and acetylated and purified as described above. The product $[\alpha]_D$ +26.4° (*c*, 3.9 in chloroform) had the same NMR and infrared spectra as the above described tetra-*O*-acetyl-2,5-anhydro-D-mannitol.

ACKNOWLEDGMENTS

The 60 Mc.p.s. NMR and infrared spectra were determined by R. N. Swindlehurst and Mrs. G. B. Conway. The research was supported by two National Research Council of Canada Studentships to B. F-R. and National Research Council of Canada grants-in-aid of research (T-172) to R. U. L.

KINETICS OF ETARD'S REACTION

PART III. EFFECT OF RING SUBSTITUTION

R. A. STAIRS

Department of Chemistry, Queen's University, Kingston, Ontario

Received September 27, 1963

ABSTRACT

The initial rates of reaction of a number of para- and meta-substituted toluenes with chromyl chloride in carbon tetrachloride solution have been measured and the results analyzed using Hammett's relation. The results are interpreted in terms of electrophilic attack by CrO_2Cl_2 molecules. The reaction appears to be marked by an unusually large effect of ring substitution on the entropy of activation. The mechanistic significance of this observation is discussed.

INTRODUCTION

Earlier papers in this series report the effects on the rate of reaction with CrO_2Cl_2 of varying number of phenyl substituents in methane (1), and of change of solvent (2). We have now measured the initial rates of the reaction of chromyl chloride with toluenes having para and meta methyl, fluoro, chloro, bromo, and nitro substituents at three temperatures.

EXPERIMENTAL

The method of measurement was by titration for Cr VI as previously described (1). The carbon tetrachloride solvent was Fisher Certified Reagent, used as purchased in small bottles. A portion was purified by treatment first with concentrated sulphuric acid and then with water, followed by drying over $CaCl_2$ and distillation through a short column, without perceptible improvement. The toluene and the substituted toluenes were Eastman or Fisher reagent grades, and were fractionally distilled before use, with the exception of *p*-nitrotoluene, which was recrystallized from ethanol.

All the experiments were carried out in subdued light, as it was found that the laboratory fluorescent lights had an easily noticeable effect on the rates, particularly of the slower reactions. Each reaction was carried out at a number of different initial concentrations of both reactants, and second-order rate constants were calculated from the initial rates. The constants were examined for trends that might suggest that any of the reactions were other than first order in each of the reactants. No such trends were found.

RESULTS

The rate constants recorded in Table I are averages of at least six runs each. In the

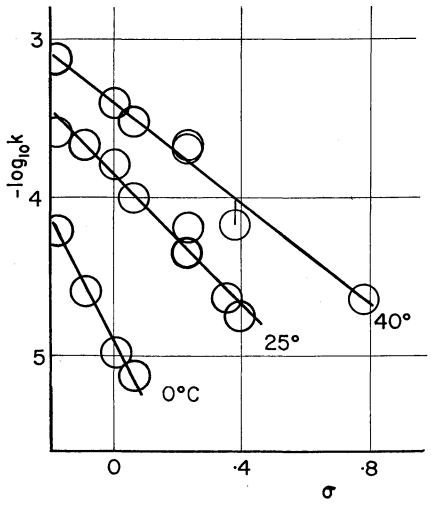

FIG. 1. Hammett plot for Etard's reaction. The common logarithm of the rate constant for each substituted toluene is plotted against the Hammett sigma for the substituent, at the three indicated temperatures. The constants for the two xylenes have been divided by two to allow for the fact that either methyl group may be attacked.

table are also noted the Hammett sigma values for each substituent (3). Figure 1 shows the same data, plotted as the common logarithm of the rate constant versus the corresponding values of σ, at three temperatures. The lines were fitted by the method of least squares, and the following constants were obtained:

(*a*) Hammett's ρ, -3.94 at 1° C, -2.06 at 25° C, -1.58 at 40° C, with overall standard deviation 0.15.

(*b*) Assuming that the enthalpy and entropy of activation are both independent of temperature, and writing H^σ for $d(\Delta H^\ddagger)/d\sigma$, etc., $H^\sigma = 25 \pm 1$ kcal; $S^\sigma = 72 \pm 10$ cal/deg; $F^\sigma{}_{298} = 2.81 \pm 0.20$ kcal. From the data of ref. (1) one may calculate for toluene $\Delta H^\ddagger = 14.3$ kcal; $\Delta S^\ddagger = -28$ cal/deg; $\Delta F^\ddagger{}_{298} = 22.6$ kcal.

The present data were also examined by the method of Bekkum, Verkade, and Wepster (4) as outlined by Wells (5) to determine whether direct resonance effects were present. There appeared to be no such effects, and $\Delta\Delta F_p$ values were zero within experimental error.

DISCUSSION

Leffler has pointed out (6) the dangers in interpreting Hammett ρ values obtained at a single temperature as criteria of mechanism. In the present case, it appears by extrapolation that ρ would change sign in the vicinity of 70° C, this being the approximate isokinetic temperature of this reaction series. The effect of substitution on the enthalpy of activation, represented here by $H^\sigma = 25$ kcal, however, is a clear indication of a substantial electron demand at the reaction site. This is clearly compatible with the known electrophilic nature of CrO_2Cl_2, and a fortiori of species such as CrO_2Cl^+ that have been invoked in proposed mechanisms (7, 8). The positive sign of the quantity S^σ is explained by what Brown has called the compensation law (9), i.e. the fact that a change in a reactant molecule that raises the enthalpy of activation by making the binding in the activated complex weaker would be expected to raise the entropy of activation for the same reason. Parallel changes in these two quantities have opposite effects on the rate,

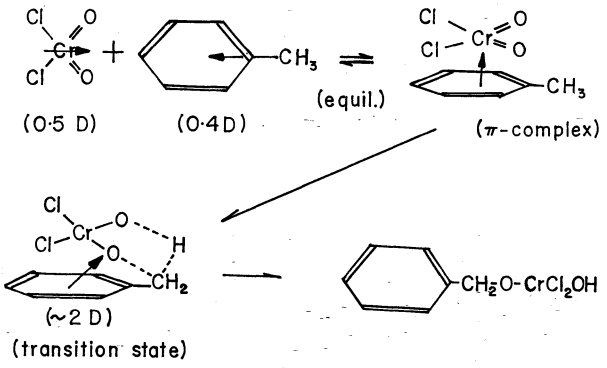
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and the degree of compensation depends on how close the experimental temperature is to the isokinetic temperature, which, if H^σ and S^σ are independent of temperature, is given by $\beta = H^\sigma/S^\sigma$, here about 340° K.

The rather large size of S^σ is probably explained by Wheeler's suggestion (10) that the reaction involves complex formation between CrO_2Cl_2 and the π-electrons of the ring. Electron-withdrawing substituents would reduce the strength of binding in such a complex, and if, as has been suggested earlier (1), this involvement of the ring persists in the activated complex there would be an additional positive contribution to S^σ.

Our earlier conclusion (2) that the formation of the activated complex does not involve a large change in polarity appears at first sight to be at variance with the foregoing discussion. However, it should be noted that the dipole moment of toluene presumably is in such a direction as to make the methyl group relatively positive. During the approach of the electrophilic attacking species, presumably CrO_2Cl_2, to the methyl group, this polarity will be reversed so that a fairly large movement of electrons can take place with only a moderate increase in dipole moment.

It is therefore proposed that the probable mode of reaction of chromyl chloride with toluene is as follows:
(The arrows and numbers in parentheses represent the dipole moments.)



The above scheme accounts for only one of the two molecules of chromyl chloride involved in the stoichiometric reaction. It has usually been assumed (7) that the second molecule reacts with another hydrogen of the methyl group in a similar manner in a subsequent step. A recent paper from Nenitzescu's laboratory (11) reports that the two chromium atoms are not both reduced, one being still in oxidation state VI (a conclusion based on measurements of electron spin resonance absorption intensity), and suggests that the second step of the oxidation does not take place until the hydrolysis. The second molecule of chromyl chloride, it is suggested, is bound to the first in an unknown manner, perhaps as in the dichromate ion (though this requires the unusual coordination number of five for Cr VI). This disagrees with Wheeler's magnetic susceptibility measurement (10), which indicated that all the chromium was quadrivalent. However, both magnetic susceptibility, when not measured over a range of temperature and of field strength, and e.s.r. intensity are difficult to interpret, so this point must still be considered open to discussion. Since the reaction is first order in CrO_2Cl_2 (1), it is improbable that both molecules of chromyl chloride are involved in the transition state.

OXIDATION–REDUCTION POLYMERS

III. STANDARD OXIDATION POTENTIALS OF 2,5-DIHYDROXYDIPHENYL SULPHONES[1]

I. H. SPINNER, H. P. KASSERRA,[2] AND W. METANOMSKI
Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario
Received October 8, 1963

ABSTRACT

The preparation of two new sulphonyl derivatives of methoxy- and naphtha-hydroquinone as possible intermediate compounds in the synthesis of redox monomers is described. The standard oxidation potentials of these and other sulphonyl derivatives of hydroquinones were determined and compared with the values for similar compounds, reported previously (1).

In Part II (1) we have described the preparation of redox polymers containing repeating hydroquinone units joined through a sulphone bridge to a polystyrene chain.

Although 2,5-dihydroxydiphenyl sulphones were first synthesized by Hinsberg (2, 3) in 1894–1895, and in some cases their oxidized forms prepared, no systematic study of redox potentials of these and similar derivatives of hydro- and naphthahydro-quinones has been made. The sulphones whose redox potentials have been reported are *p*-toluene-sulphonyl, *p*-bromobenzenesulphonyl, and *d*-camphor-10-sulphonyl derivatives of 1,4-naphthahydroquinone (4, 5) and the *d*-camphor-10-sulphonyl derivative of 2,5-dimethyl-hydroquinone (4). The redox potentials of these compounds are 121, 125, 114, and 135 mv, respectively, higher than the potentials of the corresponding parent quinones.

Data previously obtained from potentiometric titrations (1) on intermediate and model compounds of redox polymers of the sulphone type showed the effect of various substituent

groups on the standard oxidation potential (E_0) of the parent compound. The relative stability and reversibility of the compounds studied was also evaluated.

In our efforts to produce monomers and polymers of increased stability, two new sulphones derived from methoxy-*p*-benzoquinone and 1,4-naphthaquinone were synthesized. It was intended to have a $-CH_2CH_2Br$ side chain on the non-oxidizable benzene nucleus, which could be dehydrobrominated to a vinyl group (1, 6).

The addition of *p*-(β-bromoethyl)benzenesulphinic acid to methoxy-*p*-benzoquinone produced 2,5-dihydroxy-4-methoxy-4′-(β-bromoethyl)diphenyl sulphone (I). This compound was characterized by the preparation of diacetate and dibenzoate derivatives. Contrary to experience with toluquinone (1), only one isomer in a relatively high yield was isolated. Since in methoxy-*p*-benzoquinone the para position to the methoxy group is most reactive, the sulphinate ion would most probably react with quinone at this position. Therefore, the structure I has been assigned to the compound. Attempts to protect both hydroxyl groups by pyranylation, as in the schemes reported previously (1, 6), were not successful.

A second new sulphone, 2-[*p*-(β-bromoethyl)benzenesulphonyl]-1,4-naphthahydroquinone (II), was obtained through 1,4-addition of *p*-(β-bromoethyl)benzenesulphinic acid to 1,4-naphthaquinone. A diacetate derivative was prepared. Attempts to pyranylate the sulphone II resulted in the formation of a monopyranylated derivative. This behavior is in agreement with previously reported results for sulphones based on toluhydroquinone (1). The hydroxyl group which is in the ortho position to the sulphonyl group is sterically hindered because of the presence of a rigid naphthalene structure and does not react with 2,3-dihydropyran.

Attempts to add the same sulphinic acid to hydroxy-*p*-benzoquinone were not successful. This is in agreement with the original observation of Hinsberg (3), who, however, did not advance any explanation. A successful 1,4-addition to a quinone is usually accomplished by adding an aqueous suspension of the acid to a solution of the quinone and stirring the mixture for several hours. The hydroxy-*p*-benzoquinone decomposes very rapidly in water and a black polymeric material is formed before any other reaction can take place.

The solubility of *p*-(β-bromoethyl)benzenesulphinic acid in water is low. On the other hand, the presence of water was found essential for 1,4-addition to occur. The reaction did not take place in benzene or absolute ethanol. Water is primarily necessary for ionizing the sulphinic acid, the dissociation constant of which will be in the range 1×10^{-2} to 2×10^{-2} (7, 8). Even in an aqueous suspension there is enough sulphinic acid dissolved and dissociated for the reaction to go virtually to completion.

Two additional derivatives of unsubstituted hydroquinone, 2,5-dihydroxydiphenyl sulphone (III) and 2,5-dihydroxy-4′-methyldiphenyl sulphone (IV), were synthesized according to methods described in the literature (2, 9). 2,5-Dihydroxy-3-methyl-4′-(β-bromoethyl)diphenyl sulphone (V) described previously (1) has also been investigated.

The dihydroxy sulphones and their parent hydroquinones were potentiometrically titrated in 50% acetic acid (pH 1.2), unbuffered 80% acetic acid (pH 0.2), and 80% acetic acid buffered with sodium acetate (pH 2.0). The standard oxidation potentials (E_0) were essentially the same under these conditions. Representative examples of continuous and discontinuous titrations are shown in Table I. The parent hydroquinones are included for control and comparison purposes. The sulphones III and IV had to be titrated discontinuously. The decomposition of the oxidized form, as indicated by the potential decay index, was relatively slow in 80% acetic acid. This is also characteristic of other sulphones based on unsubstituted hydroquinone (1). The sulphones I and V, being

derivatives of methoxy- and methyl-hydroquinone, respectively, could be titrated continuously and their oxidized forms were relatively stable to about 85% oxidation. The oxidized sulphone II (derivative of naphthahydroquinone) was even more stable and the characteristic sharp rise in potential was observed at the equivalence point. It has been noted that all the sulphones gave generally a lower index potential (E_1) than that calculated for a theoretical bivalent oxidation.

The effect of substitution on the standard oxidation potential is also indicated in Table I. The addition of the $-SO_2C_6H_4R$ group to the quinone caused an increase in potential, as expected. Considering the originally substituted quinones (methyl-, methoxy-, and naphtha-), this increase (ΔE_0) ranged from 115 to 132 mv. This range is nearly the same as that reported (114–135 mv) for other sulphonyl-substituted naphtha- and dimethyl-hydroquinones (4, 5).

The increase in potential for the sulphone V (3-methyl isomer) is higher than that for the 4-methyl isomer (ΔE_0 = 77–88 mv), reported previously (1). This fact agrees well with the earlier observation of Conant and Fieser (14, 17), who investigated isomeric disubstituted quinones (dichloro- and dimethoxy-).

The increase in potential on the addition of the $-SO_2C_6H_4R$ group to unsubstituted *p*-benzoquinone is relatively smaller. Table II confirms the conclusion arrived at previously

TABLE II

Standard oxidation potentials of $2,5\text{-}(OH)_2C_6H_3SO_2C_6H_4R$

R (para position)	ΔE_0* (mv)	Reference
H	43	
CH_3	46	
C_2H_5	66	(1)
C_2H_4Br	52–60	(1)
iso-C_3H_7	44	(1)

*The difference between E_0 of the compound and that of hydroquinone.

(1) that the group R in the para position to the sulphonyl group on the non-oxidizable benzenoid ring does not influence the E_0 of the compound to any great extent. A slight trend towards a larger increase appears with the lengthening of the side chain (ethyl, bromoethyl), whereas for methyl and symmetrical isopropyl groups ΔE_0 has practically the same value as that for the simplest sulphone III.

In the case of naphthahydroquinone derivatives, ΔE_0 for the sulphone II (R = CH_2CH_2Br) is nearly the same as that for the sulphone having R = CH_3 (121 mv) (4, 5).

Potentiometric titrations were also carried out in 50% aqueous dioxane. Standard oxidation potentials of both parent quinones and their sulphonyl derivatives were higher by a nearly constant value (23–29 mv) than those measured in aqueous acetic acid. The interpretation of these data is difficult because of the lack of knowledge of activity coefficients and liquid junction potential in such a system. It might be noted that a similar increase in E_0 is well known for quinones in alcoholic solutions (18).

EXPERIMENTAL*

p-(β-Bromoethyl)benzenesulphinic Acid

The preparation of this compound has been reported in Part I (6). Since all attempts to provide a sample suitable for microanalysis failed, additional derivatives were prepared.

**Melting points are corrected. All alcohol solutions are reported on a percentage by volume basis. Microanalyses were done by Galbraith Laboratories, Inc., Knoxville, Tennessee, and Micro-Tech Laboratories, Skokie, Illinois.*

For personal use only.

Ferric *p*-(β-bromoethyl)benzenesulphinate was obtained on the addition of 15% ferric chloride solution to about 1% sulphinic acid in hot water (19). The light-orange precipitate was found insoluble in organic solvents and soluble in concentrated hydrochloric acid. It decomposed in alkaline solution. Anal. Calc. for $(C_8H_8BrO_2S)_3Fe$ (800.20): Fe, 6.98. Found: Fe, 7.05%.

Another derivative, C-[*p*-(β-bromoethyl)benzenesulphonyl]formamidine, was prepared according to a method of Farrar (20). Sodium sulphinate solution was first prepared by passing a hot aqueous solution of the sulphinic acid through a bed of Dowex 50W-X8 resin, converted to sodium form and maintained at 90–95° by means of an external hot water jacket. The addition of sodium cyanate to the effluent followed by acidification with acetic acid produced a white precipitate with the simultaneous evolution of carbon dioxide. Recrystallization from a large volume of water gave the product melting at 159–159.5° with decomposition. Anal. Calc. for $C_9H_{11}BrN_2O_2S$ (291.18): C, 37.12; H, 3.81; Br, 27.45; N, 9.62; S, 11.01. Found: C, 37.52; H, 3.72; Br, 27.11; N, 9.47; S, 10.88%.

2,5-Dihydroxy-4-methoxy-4′-(β-bromoethyl)diphenyl Sulphone (I)

A solution of methoxy-*p*-benzoquinone (13.3 g, 0.0964 mole) (prepared by the method of Ioffe and Sukhina (21), m.p. 144.5–145°) in dioxane (210 ml) was added dropwise to a suspension of *p*-(β-bromoethyl)benzenesulphinic acid (24 g, 0.0964 mole) in 1800 ml of water. The addition took about 4 hours and stirring was continued for an additional hour. The mixture was kept at 0–5°. The typical yellow color of quinone disappeared and the original fluffy white sulphinic acid particles changed gradually into heavy, sandy-colored particles of sulphone. Crystallization from 30% alcohol (3:1 ethanol–methanol), in the presence of a few milliliters of 6% stannous chloride in 6 *N* HCl as a reducing agent, gave a white powder (31 g, 85.5%) melting at 166.5–167°. Anal. Calc. for $C_{15}H_{15}BrO_5S$ (387.25): C, 46.52; H, 3.90; Br, 20.64; O, 20.66; S, 8.28; OCH_3, 8.01. Found: C, 46.79; H, 3.96; Br, 20.75; O, 20.44; S, 8.15; OCH_3, 8.19%. Infrared spectrum: 1148 (s) and 1267 (s) (—SO_2—) (22), 3390 (s) (—OH) cm^{-1}.

A derivative, 2,5-diacetoxy-4-methoxy-4′-(β-bromoethyl)diphenyl sulphone, was prepared by reacting the dihydroxysulphone I with acetic anhydride and a drop of concentrated sulphuric acid as a catalyst. Crystallization from 55% ethanol gave white crystals melting at 146.5–147°. Anal. Calc. for $C_{19}H_{19}BrO_7S$ (471.32): C, 48.42; H, 4.06; Br, 16.96; S, 6.80. Found: C, 48.74; H, 3.97; Br, 17.85; S, 6.98%.

Another derivative, 2,5-benzoxy-4-methoxy-4′-(β-bromoethyl)diphenyl sulphone, was prepared by reacting the dihydroxysulphone I with benzoyl chloride in dilute sodium hydroxide solution. Crystallization from 80% ethanol gave a white powder melting at 184–184.5°. Anal. Calc. for $C_{29}H_{23}BrO_7S$ (595.45): C, 58.50; H, 4.06; Br, 13.42; S, 5.38. Found: C, 58.56; H, 4.05; Br, 13.12; S, 5.32%.

2-[p-(β-Bromoethyl)benzenesulphonyl]-1,4-naphthahydroquinone (II)

A solution of 1,4-naphthaquinone (16 g, 0.101 mole) in 650 ml of ethanol was added dropwise to a suspension of *p*-(β-bromoethyl)benzenesulphinic acid (25 g, 0.100 mole) in 1500 ml of water. At the end of 3 hours, a gray, light precipitate settled, leaving the supernatant liquid clear and nearly colorless. The crude product was dissolved in 450 ml of cold dioxane, containing 10 ml of 6% stannous chloride solution, and precipitated by the addition of 1300 ml of water. A white powder (25 g, 61%) melted at 166–167° with decomposition to a red liquid. Anal. Calc. for $C_{18}H_{15}BrO_4S$ (407.28): C, 53.08; H, 3.71; Br, 19.62; S, 7.87. Found: C, 53.29; H, 3.35; Br, 19.62; S, 7.81%. Infrared spectrum: 1131 (s) and 1282 (s) (—SO_2—) (22), 3344 (s) (—OH) cm^{-1}.

A derivative, 2-[*p*-(β-bromoethyl)benzenesulphonyl]-1,4-diacetoxynaphthalene, was prepared. Crystallization from 33% ethanol gave a white product melting at 179.5–180.5°. Anal. Calc. for $C_{22}H_{19}BrO_6S$ (491.35): C, 53.77; H, 3.89; Br, 16.27; S, 6.53. Found: C, 53.71; H, 4.02; Br, 16.39; S, 6.61%.

Attempts to fully pyranylate this dihydroxysulphone failed. Only a monopyranylated derivative, 1-hydroxy-2-[*p*-(β-bromoethyl)benzenesulphonyl]-4-(2-tetrahydropyranyloxy)naphthalene, was obtained. The dihydroxysulphone II was dissolved in a large excess of 2,3-dihydropyran containing a drop of concentrated hydrochloric acid as a catalyst. The product precipitated on overnight shaking at room temperature. It was filtered, washed with 5% sodium hydroxide, and recrystallized from a dioxane–water mixture buffered to pH 7. A white product melted at 129–130°. Anal. Calc. for $C_{23}H_{23}BrO_5S$ (491.39): C, 56.21; H, 4.72; Br, 16.26; S, 6.53. Found: C, 56.28; H, 4.84; Br, 16.14; S, 6.46%.

Potentiometric Titrations

The assembly used as well as the techniques employed were similar to those described in the previous paper (1). The titration vessel and the calomel cell were placed in a constant temperature bath kept at 25±0.1° C. Another improvement was the use of a more accurate pH meter (Radiometer 4) permitting the measurement of pH to 0.001 unit. In titrations where unbuffered 80% acetic acid was used, the pH reading was taken after each potential reading. The cell potential was then corrected for any changes in pH.

FATTY ACID COMPOSITION OF SOME CUCURBITACEAE SEED OILS[1]

MARY J. CHISHOLM AND C. Y. HOPKINS
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received October 15, 1963

ABSTRACT

Seed oils of nine species of Cucurbitaceae were analyzed by gas chromatography and other techniques. The oil of *Ecballium elaterium* yielded 22% of punicic acid; *Cucumis dipsaceus* and *Cucurbita ficifolia* had the ordinary palmitic–oleic–linoleic composition; a variety of *Momordica charantia* had 57% of α-eleostearic acid. Occurrence of punicic acid as the major acid of *Trichosanthes anguina* was confirmed. No evidence could be found for the existence of an isomer of linoleic acid in *Telfairia pedata* oil. The fatty acid composition was determined quantitatively for the above oils and for those of *Cucumis melo*, *Lagenaria siceraria*, and *Luffa cylindrica*. The 4-bromophenacyl esters of α-eleostearic and punicic acids were prepared.

Seed oils of the Cucurbitaceae family fall into two distinct groups, one having the ordinary palmitic–oleic–linoleic composition, the other having a considerable proportion of conjugated triene fatty acids in the glycerides. The first group includes the common cultivated cucurbits. The second or conjugated oil group consists of certain species of *Cucurbita*, *Momordica*, *Telfairia*, and *Trichosanthes*.

Nine species of the family were examined in the present work to ascertain or confirm the identity of the conjugated acids and to resolve certain anomalies in previous studies. *Ecballium elaterium*, *Cucumis dipsaceus*, and *Cucurbita ficifolia* had not been analyzed previously. The percentage composition of each oil was determined by gas–liquid chromatography (GLC) of the methyl esters, in conjunction with ultraviolet absorption analysis. The conjugated acids, when present in substantial amount, were isolated and purified by crystallization at low temperatures. They were identified by orthodox chemical methods.

RESULTS AND DISCUSSION

Preliminary data are shown in Table I. The high refractive indices of the first three oils indicate conjugated unsaturation and this was confirmed by their ultraviolet spectra and by isolation of conjugated triene fatty acids (see Table II). None of the oils had an absorption peak in the region of 233 mμ; thus they contained no appreciable amount of conjugated diene acid.

In the analysis of the methyl esters by GLC, neither myristic nor linolenic acid was observed, although these two acids had been reported in some species by earlier workers (11, 15, 16). The results suggest that seed oils of Cucurbitaceae contain little or no linolenic acid. No acids other than those shown in Table II were observed. The infrared spectra did not disclose any evidence of oxygenated acids and GLC analysis showed that C_{20} and C_{22} acids were absent.

There was evidently some loss of conjugated triene ester on the GLC column during the analysis. Accordingly, the content of conjugated triene was determined by ultraviolet absorption analysis and the amount of each non-conjugated acid was calculated as a percentage of the remainder.

TABLE II

Estimated fatty acid composition

Species	Fatty acid, wt. % of total acids				
	Conjugated trienoic	16:0*	18:0	18:1	18:2
Ecballium elaterium	22.2†	9	3	9	57
Momordica charantia	56.9‡	2	34	4	3
Trichosanthes anguina	42.8†	6	7	23	21
Cucumis dipsaceus	0.8	10	5	6	78
Cucumis melo	0.5	11	4	15	70
Cucurbita ficifolia	0.1	12	4	26	57
Lagenaria siceraria	0.3	14	3	7	76
Luffa cylindrica	0.2	13	6	15	66
Telfairia pedata	0.4	35	14	7	44

*The figures indicate chain length and number of double bonds.
†Punicic acid.
‡α-Eleostearic acid.

The conjugated triene esters gave rise to a broad composite peak in the C_{22} region. This peak undoubtedly represents a mixture of the original conjugated ester and one or more of its geometric isomers, produced by cis–trans isomerization on the column, as observed with methyl α-eleostearate by Morris, Holman, and Fontell (1).

Some degree of uniformity can be seen in the fatty acid composition of this group of oils. In seven of the nine species, in spite of the variation in individual acids, the sum of the unsaturated acids fell within the range 81–88% of the total acids. (The exceptions were *Momordica charantia* and *Telfairia pedata*.) This suggests that the unsaturated acids, both conjugated and non-conjugated, may arise from a common substrate.

From a taxonomic viewpoint, it is noted that all species of *Momordica* and *Trichosanthes* reported to date have conjugated oils (three species of each) and all species of *Citrullus*, *Cucumis*, and *Luffa* studies so far have non-conjugated oils (three, three, and four species). On the other hand, one species of *Telfairia* has a conjugated oil (2) and one has not. Similarly, two species of *Cucurbita* have an appreciable amount of conjugated fatty acid (3) while three species have a negligible amount.

Ecballium elaterium

Punicic acid was isolated from the oil of this seed and identified by its spectral absorption and by mixed melting point with an authentic sample. Punicic acid constituted 22% of the total fatty acids but the largest component was linoleic acid.

Momordica charantia

Occurrence of α-eleostearic acid as the major acid of *M. charantia* seed oil has been established (4, 5). The present sample, variety "Long green monsoon", had a noticeably higher content of α-eleostearic acid (57%) than that of the unnamed varieties reported previously (40–48%). This was reflected in the higher refractive index and higher melting point of the oil. The oil is unusual in composition, since the fatty acids consist almost entirely of α-eleostearic acid (57%) and stearic acid (34%). There is less than 5% each of palmitic, oleic, and linoleic acids.

Trichosanthes anguina

The major acid of *T. anguina* was reported to be an isomer of α-eleostearic acid (6, 7) and was identified unequivocally by Crombie and Jacklin in 1957 as punicic acid (8). However, in 1960, Chowdhury (9) re-examined the oil of this species and found the major component to be α-eleostearic acid; conclusive evidence of its identity was given. Our sample of this seed yielded punicic acid as the major component of the oil (43% of the total acids) and there was no evidence of α-eleostearic acid. It is possible that Chowdhury had an unusual variety of *T. anguina.*

The strong infrared band at 752 cm^{-1} appears to be characteristic of the cis,trans,cis grouping in punicic acid and was not observed in the spectrum of α-eleostearic acid (cis,trans,trans).

Telfairia pedata

An early report of the occurrence of an isomer of linoleic acid in *T. pedata* oil (10) was refuted by several authorities (11, 12). However, in view of the recent discovery of linoleic acid isomers in a seed oil (13, 14), *T. pedata* was re-examined. The infrared spectrum of the oil showed no evidence of trans unsaturation, thus ruling out the presence of geometric isomers. The total mixed acids were subjected to oxidative splitting and the fragments were identified by gas chromatography over a wide range of column temperatures. The expected acids, hexanoic, nonoic, and azelaic (from the oxidation of oleic and linoleic acids), were found in quantity. The major dienoic acid is, therefore, linoleic acid. Other fragments were few and very small in amount. It was judged from the GLC data that traces of valeric, heptanoic, and glutaric acids were produced. It is possible, therefore, that traces of isomers of linoleic acid were present but it is estimated that the amount of any one isomer would not exceed 1% of the total fatty acids.

T. pedata oil differs markedly in composition from other Cucurbitaceae oils, having a much higher content of saturated acids (49%). The major acid is linoleic (44%). The data confirm the earlier analyses by Smit and van Loon (11) and by Hilditch and Meara (15) except that linolenic acid was not present in our sample.

Other Species

The other species in this study had the ordinary palmitic–oleic–linoleic composition, with minor amounts of stearic acid and less than 1% of conjugated triene acid. No other fatty acids were detected and it is judged that any minor component acid that may be present does not exceed 0.5% of the total. All of the non-conjugated oils had a relatively

high content of octadecadienoic acid. The fatty acids of *Cucumis dipsaceus* oil contained 78% of linoleic acid, identified as its tetrahydroxy derivative, and it is presumed that the dienoic acid in the other species is also linoleic.

A high refractive index, reported earlier for *Cucumis melo* oil (16), suggested the presence of conjugated acids. However, the present sample had a normal refractive index and contained only 0.5% of conjugated acids.

EXPERIMENTAL

Seed of *Telfairia pedata* (oyster nut) was supplied and its identity was verified through the kindness of Dr. D. H. S. Horn. The other seeds were obtained from reliable commercial sources. Ultraviolet spectra were determined in cyclohexane solution with a Beckman DU spectrophotometer. Infrared spectra were determined in carbon disulphide in a Perkin–Elmer model 21 spectrophotometer with sodium chloride prism. Melting points were determined in capillary tubes and were corrected. The oils were obtained by Soxhlet extraction with petroleum ether (b.p. 30–60°) except where noted otherwise. Iodine values were determined by the Wijs method (30 minutes).

The oils were converted to methyl esters by transesterification in methanol with hydrogen chloride catalyst. The esters were examined by GLC and the composition was estimated by measuring the peak areas. The GLC analyses were made using a copper column at 185° and a thermal conductivity (thermistor) detector. The liquid phase was a diethylene glycol – succinic acid polyester. The average of three determinations for each oil is reported in Table II. A slightly different procedure was followed with oils containing much conjugated acid, as explained above.

Ecballium elaterium

The seeds were ground and extracted by stirring with petroleum ether at 25° and the solvent was removed in a current of nitrogen at 25–30°. The oil had ultraviolet absorption λ_{max} 266, 275, 287 mμ and absorptivity $E^{1\%}_{1\,cm}$ 382 at 275 mμ, equivalent to 22.2% of conjugated triene acid. The oil was hydrolyzed by refluxing under nitrogen for 30 minutes with aqueous 6% potassium hydroxide. The acids (8.5 g) were dissolved in 85 ml of acetone and cooled. Crystals were taken off at −10, −30, and −55°. Ultraviolet absorption analysis showed that the −30° fraction had 68% and the −55° fraction 23% of conjugated triene acid. The −55° fraction (3.65 g) was crystallized three times from pentane at −25°, yielding 0.41 g of punicic acid, m.p. 43.5–44°. After one crystallization from acetone it had m.p. 44.5–45.5°, alone and mixed with authentic punicic acid of m.p. 45.0–45.5°. The ultraviolet spectrum was the same as that of punicic acid, λ_{max} 265, 275, 287 mμ.

Momordica charantia

Seed of *M. charantia*, var. Long green monsoon (from Poona, India), was hulled and the kernel oil was extracted at 25°. The oil had λ_{max} 262, 272, 283 mμ and negligible absorption at 233 mμ. The absorptivity, $E^{1\%}_{1\,cm}$, was 1007 at 272 mμ, equivalent to 56.9% of conjugated triene acid, calculated as α-eleostearic. Infrared maxima were at 987 (vs) and 959 (w) cm^{-1}. The mixed fatty acids were crystallized fractionally from acetone at low temperatures. There was a large yield of crystals at 10°, mainly stearic acid. After one crystallization from ethanol it had melting point and mixed m.p. 68–69°. Conjugated triene acid was collected at −15°. After further crystallization from acetone it melted at 45.5–46.5°. It formed an adduct readily with maleic anhydride by the usual method (17). The adduct melted at 63.5–64.5°, alone and mixed with the maleic anhydride adduct of α-eleostearic acid.

Trichosanthes anguina

Seed of *T. anguina* (from Poona, India) yielded an oil having λ_{max} 265, 275, 287 mμ and $E^{1\%}_{1\,cm}$ 739 at 275 mμ, equivalent to 42.8% of conjugated triene fatty acid. Absorption at 233 mμ was negligible. Infrared maxima were at 982 (s) and 931 (s) cm^{-1} (cis,trans,cis-triene), also at 752 cm^{-1}. There were no absorption bands attributable to hydroxy, keto, or isolated trans unsaturated groupings.

Twenty grams of the oil was hydrolyzed and the mixed acids were crystallized from acetone. Saturated acids were removed at −15° and the conjugated acid (6.5 g) at −38°. The latter, after three crystallizations from pentane melted at 44.5–45.5°, alone and mixed with punicic acid from pomegranate seed oil.

4-Bromophenacyl Esters

A solution of 0.5 g of punicic acid in 20 ml of ethanol was treated with 2,4′-dibromoacetophenone by the method of Neish and Lemieux (18). The crude product (0.8 g) was crystallized from ethanol at 0°, giving 4-bromophenacyl punicate, m.p. 61–63°. The ester is unstable like the acid. Its identity was confirmed by hydrogenation to the saturated ester by means of Adams catalyst in ethyl ether. The product, 4-bromophenacyl stearate, melted at 88–89° after two crystallizations from ethanol. The melting point was unchanged in admixture with an authentic sample of m.p. 88.5–89.0° (lit., 90°).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

α-Eleostearic acid was converted to its 4-bromophenacyl ester in the same way. The ester had m.p. 53–54° and was unstable. Anal. Calc. for $C_{26}H_{35}O_3Br$: C, 65.67; H, 7.42. Found: C, 65.33; H, 7.40.

Telfairia pedata

Oil from seed kernels of *T. pedata* (origin South Africa) was hydrolyzed and the mixed fatty acids were subjected to oxidative splitting by permanganate–periodate (19). The unchanged saturated acids were filtered off and esterified with methanol (A). The water-soluble monobasic and dibasic acids were extracted from the filtrate with ether in a continuous extractor. They were converted to methyl esters (B) by a method that avoids loss by evaporation of any component (20).

The A esters, examined by GLC at column temperatures of 140°, 160°, and 185°, gave peaks corresponding to palmitate and stearate. The B esters, examined at temperatures from 50° to 195°, gave major peaks corresponding to hexanoate, nonoate, and azelate. The minor peaks were very small. They indicated traces of valerate, heptanoate, and glutarate. There was no indication of other monobasic acids from C_3 to C_{15} inclusive, nor of dibasic acids from C_3 to C_{14} inclusive.

The infrared spectrum of *T. pedata* oil showed no absorption characteristic of a terminal double bond (ca. 910 cm^{-1}), nor of an αβ-unsaturated acid (ca. 1275 cm^{-1}).

Cucumis dipsaceus

The dienoic acid of the oil was identified as linoleic acid as follows. The mixed fatty acids (1.2 g) were oxidized by aqueous alkaline permanganate for 10 minutes at 10°. The solid product (0.92 g) was washed with hexane, then with ethyl acetate, and finally crystallized from ethanol, giving di-erythro-9,10,12,13-tetrahydroxystearic acid, m.p. 173–174°, alone and mixed with an authentic sample.

ACKNOWLEDGMENTS

The authors are indebted to Mr. R. Lauzon for determination of infrared spectra and to Mr. H. Seguin for microanalyses.

HINDERED CONFORMATIONAL ISOMERIZATION OF 9,10-DIHYDRO-9,9-DIMETHYL-10-METHYLENEANTHRACENES[1]

D. Y. Curtin, C. G. Carlson,[2] and C. G. McCarty[3]

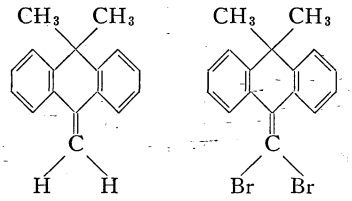
Received September 18, 1963

ABSTRACT

While the n.m.r. spectrum of 10,10-dimethyl-9-methylene-9,10-dihydroanthracene (I) shows the geminal methyl group absorption as a sharp singlet the spectrum of the dibromo derivative, 10,10-dimethyl-9-dibromomethylene-9,10-dihydroanthracene (II) shows the methyl absorptions as two sharp well-separated peaks at room temperature which coalesce at 91°. 10,10-Dimethyl-9-phenylbromomethylene-9,10-dihydroanthracene (III), and the methyl ester (V) of IV show a broad geminal methyl spectrum at room temperature which separates to a doublet at lower temperatures and sharpens to a singlet at higher temperatures. Rate constants for the first-order processes responsible for the change in spectrum of II, III, and V have been calculated at the coalescence temperatures to be 57 (364° K), 35 (305° K), and 61 (300° K) sec^{-1}, respectively. The ΔH^{+}'s were used to extrapolate the rates to 305° to give values of 1, 40, and 100 sec^{-1}, respectively. The process being studied is inferred to be the equilibrium between two boat conformations of the center ring in the dihydroanthracene system, rapid interconversion leading to identical environments for the two methyl groups. A comparison with the geometrically similar *o,o'*-disubstituted biphenyl racemization gives support for this explanation. A number of compounds with a proton and one substituent on the methylene carbon atom of I (substituents: bromine, chlorine, phenyl, carboxy, carbomethoxy, phenylmercapto) and also 10,10-dimethyl-9-phenylcarbomethoxymethylene-9,10-dihydroanthracene (XII) showed a single methyl absorption at room temperature. The methyl spectrum of the mono bromo compound VI did not broaden at temperatures down to 246° K.

INTRODUCTION

In a continuation of a study of the reaction of vinyl halides with lithium reagents (1) 10,10-dimethyl-9-methylene-9,10-dihydroanthracene (I) and a number of its derivatives were prepared. Examination of the n.m.r. spectrum of the parent compound I at room



I II

temperature showed, not unexpectedly, a single absorption maximum due to the protons of the two methyl groups in the 10-position. The derived dibromomethylene compound II, however, showed absorption attributable to the two methyl groups as a well-separated pair of lines. Examination of molecular models suggests that the two compounds I and II might be expected to have a boat conformation as that preferred by the center ring. The situation is somewhat similar to that of 9,10-dihydroanthracene which has been shown to exist in a boat conformation in the crystalline state (2) and whose derivatives show

chemical behavior which has been interpreted in terms of a preferred boat conformation for the ring system. In such a molecule as has been pointed out previously (3) the two methyl groups are non-equivalent, one being almost perpendicular to the plane which is approximately the plane of the ring system and the other methyl group nearly in that plane as is shown in Fig. 1.* These considerations suggested that the dibromide II, when

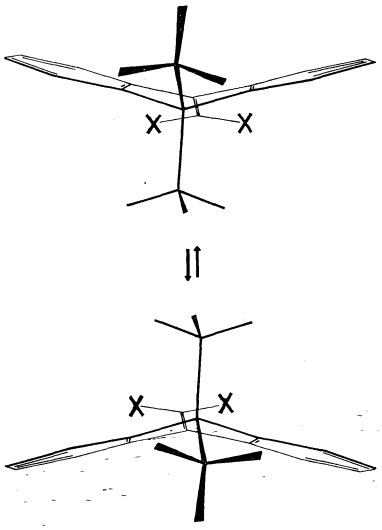

FIG. 1.

heated, might undergo a sufficiently rapid interconversion from one boat form to the other to average the magnetic environments of the methyl protons (4). Not only I and II but also a number of compounds (III–XII) with other substituents at the vinyl carbon atom have been submitted to examination with n.m.r. with results to be reported here.

EXPERIMENTAL

Preparation of Materials

The preparation and structure determination of each of the compounds studied will be published elsewhere. Details are available in the Ph.D. thesis of C. G. Carlson (see footnote 1 of this paper).

Nuclear Magnetic Resonance Instrumentation and Procedure

The spectra were obtained by use of a Varian Associates high-resolution n.m.r. spectrometer with a Model V-K 3506 super stabilizer and a Model V-4311 RF probe for operation at 60 Mc. The Varian Model V-4340 variable temperature probe accessory and the Model V-4331-THR Dewar probe insert were used in the high- and low-temperature studies. The spectra were recorded by a modified Varian Model G-10 recorder.

**Beckett and Mulley (3) proposed that atoms or groups in these positions be designated "perp" and "lin", respectively. However, "axial" and "equatorial" appear to us to be sufficiently descriptive to make it unnecessary to introduce new terminology.*

Sample temperatures from −40° to +30° were achieved by means of a nichrome immersion heater placed in a 25-l. Dewar flask of liquid nitrogen with an exit tube connected to the variable temperature probe accessory. The power input to the immersion coil determined the rate of vaporization of the liquid nitrogen and, thus, the temperature of the insert. A flow of compressed air, heated by the coils in the probe accessory, was employed to provide sample temperatures from +30° to +120°. A copper–constantan thermocouple, calibrated against National Bureau of Standards thermometers over the range of −35° to +150°, and a Leeds and Northrup Model 8662 precision potentiometer were employed for determining temperatures of the samples.

Solutions were 6% in carbon tetrachloride. Tetramethylsilane was used as an internal standard. Pyrex glass tubes, 6½ inches in length and 5 mm o.d., were filled to 3½ inches with the solutions of the samples. Air was replaced with nitrogen and the tubes sealed.

High resolution n.m.r. spectra of the dihydroanthracenes II, III, and V were obtained at a series of temperatures from −40° to +120°. Each sample was studied at room temperature before and after the high- and low-temperature work in order to check on the chemical and thermal stability of the compounds and the reproducibility of the spectra. Sufficient time was allowed for equilibration of temperature at each setting. Temperature was monitored with the copper–constantan thermocouple immersed in a dummy sample tube of carbon tetrachloride until a constant temperature was obtained. The sample tube was then inserted, allowed to come to thermal equilibrium, and the spectra obtained. The dummy tube was then returned to the probe insert in order to detect any change in temperature. In no case did the temperature change more than ±0.1°.

From four to six spectra were obtained at each temperature. Some were recorded with increasing and some with decreasing linear sweep fields but all were recorded at the same applied R_F field, H_1, which was well below the minimum value giving R_F saturation. Variables such as spinning rate, recorder input level, and sweep rate were adjusted to give the best spectra and the smallest percentage error in the measurement of signal separation. Audiofrequency side bands of tetramethylsilane generated with a Hewlett–Packard Model 200 CD audio oscillator which was calibrated by a Hewlett–Packard Model 521C electronic counter were used to determine the chemical shift difference, $\delta\nu_e$, between the maxima of the lines of the methyl doublet. Of the four to six spectra recorded at each temperature, usually one and sometimes two would yield values well away from the others due presumably to non-linearity in the sweep. This left three to five values which could be used to obtain an average value of $\delta\nu_e$ at each temperature. The deviation from the average, in every case, was $\leqslant \pm 0.30$ c.p.s.

The coalescence point of the methyl doublet in spectra of II, III, and V was taken as that temperature at which the spectrum consisted of a single broad flat top peak. This point was closely bracketed by spectra obtained at slightly higher and lower temperatures. In this manner the true coalescence temperature of each compound was obtained to within about ±0.8°. The limiting maximum separation, $\delta\nu_\infty$, was found from graphs of $\delta\nu_e$ vs. temperature. This was felt to be accurate to within ±0.2 c.p.s. in each case.

Sample data are presented in Table I.*

TABLE I

Variation with temperature of the methyl spectrum of the dibromide II*

†The range of values of $\delta\nu_e$ is indicated. The value in parentheses is the number of measurements averaged.

RESULTS

A study of the dibromide II showed that the twin methyl peaks found at room temperature coalesced to a single sharp peak at temperatures above 90°. It might be hoped that,

**Additional data and critical spectra are available in the theses referred to in footnote 1.*

conversely, the barrier to interconversion of the two boat conformations of the parent olefin I would be high enough so that at some temperature below room temperature the methyl singlet absorption could be observed to separate to a doublet. No change in the spectrum was observed down to −27°, however. Examination of the N.M.R. spectra of the series of compounds III–XII with various substituents attached to the methylene carbon atom showed that they fall into two distinct classes differing in the shape of the methyl proton spectrum. The first class (compounds III–V), containing one vinyl bromine atom and a second vinyl substituent showed methyl proton spectra which were broad but not separated into a doublet at room temperature. The methyl proton spectra of III and V separated to a doublet when the solutions were cooled to −27°, however. The second group of compounds VI–XII had the methyl absorption as a single peak. The mono bromo compound VI showed no significant broadening at temperatures down to −27°.

Of the methods available (5, 6, 7, 8, 9) for the calculation of rate constants of processes which lead to this type of change in the n.m.r. spectrum the method of Gutowsky and Holm (5, 11) was chosen in order to obtain a more detailed interpretation of the effect of temperature on the spectra of the dibromide II, the bromo phenyl compound III, and the bromo ester V. The maximum experimental separation, $\delta\nu_\infty$, and the coalescence temperature were measured and the rate constant, $k_1 = k_{-1}$, at the coalescence temperature was calculated using the following expression (4(*b*)) $k_1 = k_{-1} = \pi(\delta\nu_\infty)/\sqrt{2}$. From the equation (10) $k_1 = (kT_e/h)(-\Delta F^{\ddagger}/RT)$ was calculated the standard free energy of activation at the coalescence temperature for each of the compounds studied. These results are summarized in Table II.

TABLE II

Compound	Coalescence temperature (° K)	$\delta\nu_\infty$ (c.p.s.)	k_1 (sec^{-1})	$\Delta F^{\ddagger}$ (kcal/mole)
X = Y = Br (II)	364.4±0.5	25.6±0.2	56.9±0.4	18.6
X = Br, Y = C_6H_5 (III)	305.2±0.5	15.8±0.2	35.1±0.4	15.7
X = Br, Y = $COOCH_3$ (V)	300.3±0.5	27.6±0.2	61.3±0.5	15.1

Equations developed by Gutowsky and Holm (5) permit the calculation of the activation energy, E_a, for the boat–boat interconversion from the temperature dependence of the separation of the methyl peaks. Thus, from

$$\log_{10} 1/[2\pi\tau(\nu_A-\nu_B)] = \log_{10} A/[\pi(\nu_A-\nu_B)] - E_a/(2.30\,RT)$$

a plot of log $1/[2\pi\tau(\nu_A-\nu_B)]$ against $1/T$ gave a line from whose slope and intercept were evaluated E_a and the frequency factor, A, for the interconversion. The function log $1/[2\pi\tau(\nu_A-\nu_B)]$ was evaluated with the aid of the assumption that the signal widths are sufficiently small relative to the separation, $\nu_A-\nu_B$ so that $\tau(\nu_A-\nu_B)$ could be obtained (5) from the separation of the peaks at any temperature, $\delta\nu_e$ and the limiting separation approached at low temperatures, ν_∞, with the expression

$$\frac{\delta\nu_e}{\delta\nu_\infty} = \left[1 - \frac{1}{2\pi^2\tau^2(\nu_A-\nu_B)^2}\right]^{\frac{1}{2}}.$$

The results of this analysis of the data are presented in Table III with the designation Method A. A second method, Method B in Table III, which was both more rigorous and

	B	−7.2±1.3	+2.0±1.3	+2.7±1.3

more laborious than that just described gave substantially the same results. In this method the nuclear relaxation time, T_2, is determined from the line width at half maximum under conditions of rapid exchange, together with graphical solutions (5, 11) of the equations relating $1/\tau(\nu_A-\nu_B)$ with $1/T_2(\nu_A-\nu_B)$ for different values of $\delta\nu_e/(\nu_A-\nu_B)$. Values of E_a and A and their probable errors were obtained by the method of least squares (12). The questionable assumption in method A that line widths are small relative to $(\nu_A-\nu_B)$ suggests that the E_a's obtained by method B are the more reliable.

TABLE IV

Effects of vinyl substituents on the rate of conformational isomerization of 9,10-dihydro-9,9-dimethyl-10-methyleneanthracene

Substituents at the vinyl carbon atom		Rate at 305° K (sec^{-1})	$\Delta H^{\ddagger}$(305°) (kcal/mole)	$T\Delta S^{\ddagger}$(305°) (kcal/mole)
X	Y			
Br	Br (II)	1	16	−2
Br	C_6H_5 (III)	40	16	+0.6
Br	$COOCH_3$ (V)	100	16	+0.8
H	Br (VI)	>1000*	—	—

*This estimate has been arrived at in the following way. Assuming a limiting separation of 15 c.p.s. at a temperature of −30° or lower gives a rate constant ($k_1 = \pi\delta\nu_{ac}/\sqrt{2}$) of 35 sec^{-1}. Extrapolation to 305° K with an estimated energy of activation of 9 kcal leads to a rate constant greater than 1000.

DISCUSSION

The results as summarized in Table IV show the rather considerable dependence of the rate of the reaction being followed on substituents on the vinyl carbon atom. The spread of rates for the three compounds for which quantitative data are available is only a factor of 100, however, and it will be noted that, unfortunately, $\Delta H^{\ddagger}$ is constant to within the limits of experimental error, the difference in rates being due principally to differences in the entropies of activation of the three compounds. In a case of this kind, as has been pointed out by Hammett (13), it is unclear whether the potential energies of activation parallel the free energies or the enthalpies (or either one). There does, however, appear

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

to be a relationship of the type which would be expected from potential energy considerations between the rates and effective steric requirements of the substituents as judged by examination of molecular models. A comparison of the present system with the optically active *o,o'*-disubstituted biphenyls is of particular interest in view of the striking similarity of the geometry of the planar transition state of the methylenedihydroanthracene isomerization with that for the racemization of the biphenyls (Fig. 2). Although there

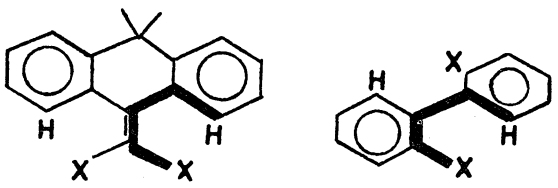

FIG. 2.

are minor differences in bond distances (for example, there is a C=C in one system instead of the C—C aromatic bond in the other) it is seen that the geometry is very similar and the same H—X interaction occurs twice in each transition state. There may, of course, be other important differences between the two systems such as any change in the resonance stabilization of either system resulting from a change in the overlap of the pi electron clouds of the two halves of the molecule in going from the non-planar initial state to the planar transition state. Nevertheless a comparison of the two systems is highly instructive, particularly because of the excellent discussion of the racemization of the *o,o'*-disubstituted biphenyls by Westheimer (14). This discussion applies to a large extent to the isomerization which is the subject of this paper. It is reassuring to note that the value of 17 kcal/mole estimated for the enthalpy of activation of the racemization of 2,2'-dibromo-4,4'-dicarboxybiphenyl is close to the value of 16 kcal for the isomerization of the dibromomethylene compound II. Also the order of effectiveness of substituents in interference with the attainment of the planar transition state, Br > COOH > H, is in agreement with the limited data available for the racemization of biphenyls (15).

Finally, the origin of the difference in chemical shift of the two methyl groups in the methylene derivatives II–V deserves comment. Inspection of models indicates that the position of the methyl groups with respect to the benzene ring currents differs sufficiently so that this ring current effect (16) should be a substantial factor in accounting for the observed differences of 16–28 c.p.s. (at 60 Mc). An estimation of the difference to be expected using the tables of Johnson and Bovey (17)* gives a value of 36 c.p.s. and suggests that the ring current effect may be the predominant or almost exclusive factor responsible for the separation.

ANTINEOPLASTIC AGENTS

X. N-BIS(2-FLUOROETHYL)AMINES[1,2]

GEORGE R. PETTIT AND ROBERT L. SMITH
Department of Chemistry, University of Maine, Orono, Maine

Received September 30, 1963

ABSTRACT

Successive conversion of N-bis(2-hydroxyethyl)-*p*-toluenesulphonamide (I*b*) to respective dimethanesulphonate and difluoro derivatives (II*a*, III*a*, and III*c*) was found to provide a convenient route to N-bis(2-fluoroethyl)amine. Reaction of N-bis(2-methanesulphonyloxyethyl)-*p*-toluenesulphonamide (III*a*) with limited quantities of potassium fluoride, in several protic solvents, was shown to yield N-(*p*-toluenesulphonyl)morpholine (IV). Utility of N-bis(2-fluoroethyl)amine as a precursor of fluoro-nitrogen mustards was illustrated by synthesis of two N-bis(2-fluoroethyl)benzylamines (IX*b* and X*a*). Application of an aluminum chloride – lithium aluminum hydride reagent for hydrogenolysis of carbon–fluorine bonds was also suggested.

Greater versatility in design of potential antineoplastic agents should be possible by utilizing predictable differences in the chemical reactivity expected for N-bis(2-fluoroethyl)amines, as compared to other N-bis(2-haloethyl)amines. For example, neighboring group displacement of halogen from a 2-fluoroethylamine should proceed substantially more slowly than with related 2-haloethylamines.[3] Intensive study of fluoro-nitrogen mustards might, therefore, lead to substances with more specific and prolonged antitumor activity.

Advantage might also be taken of the known ability of certain fluorine derivatives to inhibit the citric acid cycle (2, 3). The pronounced toxicity of fluoroacetic acid and several even-numbered linear homologs has been attributed to their eventual in vivo conversion to fluorocitric acid. Apparently, the odd-numbered homologs do not yield one of the necessary precursors, fluoroacetic acid, and are considerably less toxic. Fluorocitric acid, in turn, is believed to block the citric acid cycle during the tricarboxylic acid sequence. Although utilization of glycolytic products at this stage, by neoplastic tissue, appears less important than conversion to lactic acid, interruption of glycolysis during the citric acid cycle might be useful in control of certain neoplasms.

The above considerations and general paucity of information relating to synthesis and biological properties[4] of N-bis(2-fluoroethyl)amines has led to the present investigation. Syntheses of N-bis(2-fluoroethyl)-3,4-methylenedioxybenzylamine and N-bis(2-fluoroethyl)-3,4,5-trimethoxybenzylamine were first considered, as the corresponding chloro derivatives (5) gave encouraging results in the Dunning leukemia test system.

Synthesis of N-bis(2-fluoroethyl)amine (6) from 1-bromo-2-fluoroethane and ammonia illustrates the method employed for obtaining the two previously reported (6, 7) fluoro-nitrogen mustards. However, appropriate N-substitution of N-bis(2-fluoroethyl)amine was

[1]*Part IX. G. R. Pettit, D. S. Blonda, and E. C. Harrington. Can. J. Chem. 41, 2962 (1963).*

[2]*Abstracted in part from the Master of Science thesis submitted by R. L. Smith to the Graduate School, University of Maine, August, 1963.*

[3]*A proton magnetic resonance study of several N-bis(2-haloethyl)amines, in deuterium oxide, has indicated that the fluoro compounds undergo hydrolysis (see also ref. 1) and intermolecular condensation reactions at a markedly slower rate than, for example, the chloro derivatives. Details of this investigation will be reported by G. R. Pettit, J. A. Settepani, and R. A. Hill.*

[4]*Only one N-bis(2-fluoroethyl)amine appears in the comprehensive survey of alkylating agents prepared by R. B. Ross and colleagues (ref. 4). By contrast, over 2200 other nitrogen mustards are included in this valuable review.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

considered a more convenient approach to the required benzylamines and, in general, to fluoro-nitrogen mustards. Initially, N-bis(2-fluoroethyl)amine was prepared using the Childs procedure (6). When requirements for the amine increased, a more practical laboratory synthesis based on 2,2′-iminodiethanol (I) was undertaken.

A useful synthesis of N-bis(2-fluoroethyl)amine was eventually developed[5] employing the ready nucleophilic displacement of sulphonate esters by fluoride ion (12, 13). The bismethanesulphonate derivative (II*a*) of *p*-toluenesulphonamide I*b* was prepared, in cold pyridine solution (12), and allowed to react with excess anhydrous potassium fluoride. Treating the resulting N-bis(2-fluoroethyl)sulphonamide (III*a*) with hydrogen bromide (14), in glacial acetic acid, led to N-bis(2-fluoroethyl)amine (III*c*) hydrobromide. In this manner, substantial quantities (>50 g) of amine III*c* hydrobromide were routinely prepared. Similar transformation of methanesulphonamide II*b* to amine III*c* was less satisfactory.

Interestingly, an attempt to prepare the monofluoro derivative of sulphonate II*a* using almost equimolar quantities of ester (II*a*) and potassium fluoride, in diethylene glycol, gave N-(*p*-toluenesulphonyl)morpholine (IV) as major product. Repeating the reaction with formamide (13) as solvent led to a 72% yield of morpholine IV, while only unreacted sulphonamide II*a* was recovered when diglyme or dimethylformamide was used as solvent. These experiments suggest that potassium fluoride may first promote an exchange reaction (II*a* → V) between the sulphonate ester and protic solvent and then catalyze (15) intramolecular nucleophilic displacement (V → VI, see also ref. 16) of the second sulphonate group.[6]

Synthesis of the required benzylamines was initiated as described (5) for preparing the corresponding chloro analogs. Amine III*c* was easily converted to both 3,4-methylenedioxy- and 3,4,5-trimethoxy-benzamide derivatives (VII*a* and VIII*a*). Subjecting amide VII*a* to the aluminum chloride – lithium aluminum hydride reduction reaction, successfully used[1] (5) for obtaining N-bis(2-chloroethyl)benzylamines, unexpectedly caused nearly complete hydrogenolysis of the carbon–fluorine bond to yield N,N-diethyl-3,4-methylenedioxybenzylamine (IX*a*)[7] as major product. Subsequently, a reduction technique employing only lithium aluminum hydride was developed, using N,N-diethyl-3,4,5-trimethoxybenzamide (VIII*b*) as model substrate, and found suitable for reducing amides VII*a* and VIII*a* to N-bis(2-fluoroethyl)benzylamines IX*b* and X*a*.

Biological evaluation of the fluoro-nitrogen mustards has been undertaken by the Cancer Chemotherapy National Service Center (National Institutes of Health, U. S. Public Health Service). Initial biological studies have shown that amine III*c* is a very toxic compound. No animals survived when random-bred albino rats were treated with N-bis(2-fluoroethyl)amine hydrobromide at a dose of 3 mg/kg in saline (by the intraperitoneal route). While a dose of 0.6 mg/kg was tolerated, only two of three survived at 1 mg/kg. By analogous experimental methods, the maleic acid salt of N-bis(2-chloroethyl)-amine was tolerated at 100 mg/kg, N-bis(2-bromoethyl)amine hydrobromide at 4 mg/kg, and N-bis(2-iodoethyl)amine hydroiodide at 10 mg/kg. Interestingly, when similar animals bearing Walker 256 (subcutaneous) were treated (saline solution, intraperitoneally, beginning on the first day of tumor transplant) with the above nitrogen mustards,

[5]*The approach employed was selected from among a number of potentially valuable methods (ref. 8, 9, 10, and 11).*

[6]*The major side reaction during displacement of p-toluenesulphonate esters by potassium fluoride, in diethylene glycol, has been attributed to ether formation (12).*

[7]*The aluminum chloride – lithium aluminum hydride reagent, used in this experiment, may provide a mild and general method for hydrogenolysis of carbon–fluorine bonds. Complex metal hydrides do not readily affect the carbon–fluorine bond (cf. Hudlický, ref. 3 (p. 161) and ref. 17).*

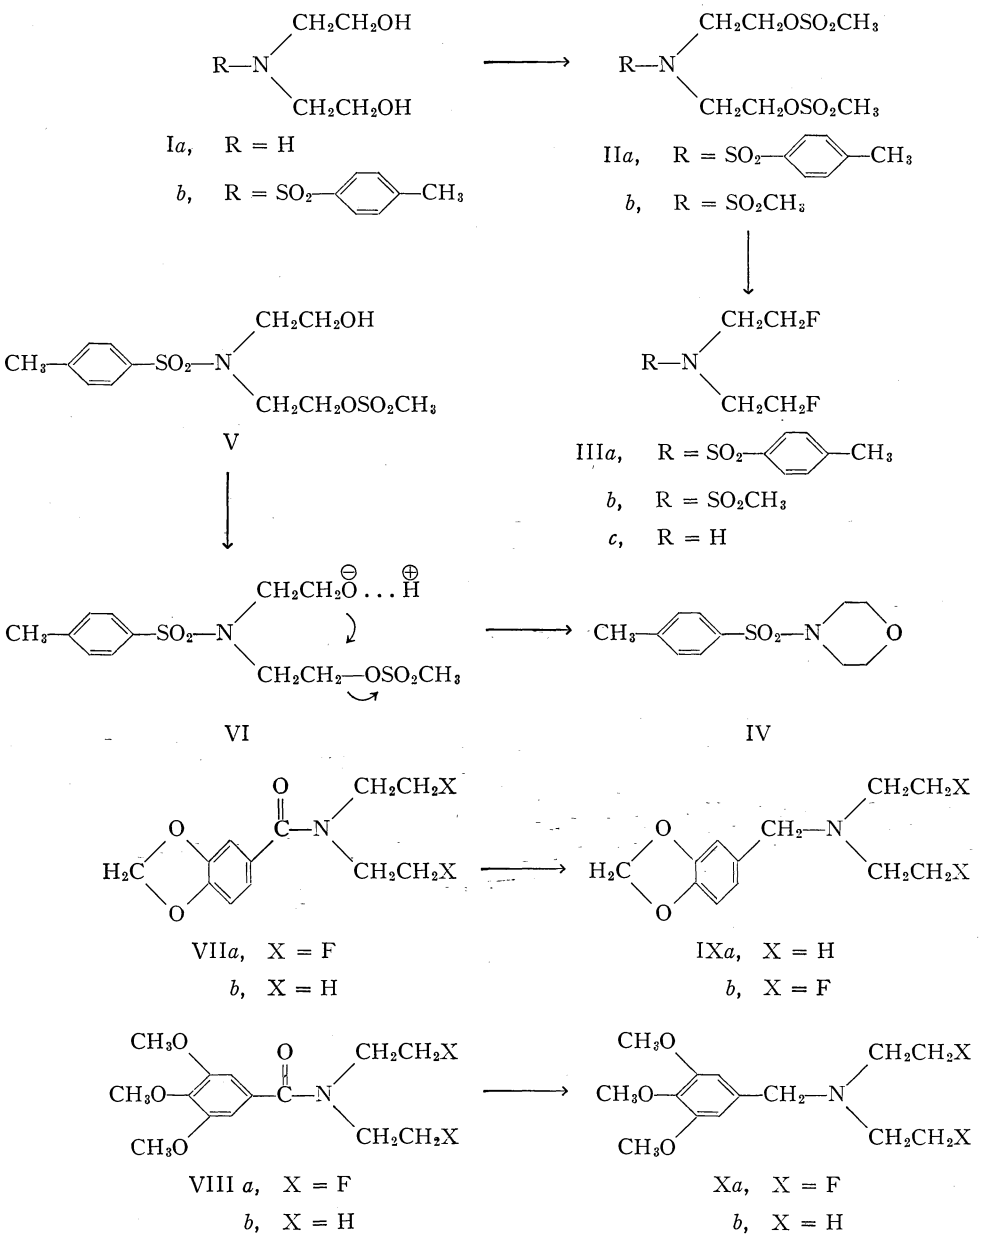
For personal use only.

tumor growth was inhibited; 40% by the fluoro mustard (0.6 mg/kg), completely by the chloro (22 mg/kg), completely by the bromo (4 mg/kg), and 88% by the iodo (6.5 mg/kg). Tumor growth was measured on the 10th day.



EXPERIMENTAL

Glass apparatus employed for preparation and subsequent reduction of the benzamides was previously dried at 120° C. Tetrahydrofuran used in the reduction procedure was heated at reflux over sodium for 4 hours and then distilled (from lithium aluminum hydride) into the reaction container. The formamide and dimethylformamide were both distilled *in vacuo* and stored over molecular sieve type 4-A. Potassium fluoride was dried in a vacuum oven at 165° for 24 hours. All solvent extracts were dried over magnesium sulphate.

Melting points were observed using a Kofler apparatus. Infrared spectral data was recorded by Dr. R. A. Hill of this laboratory. Microanalyses were provided by Dr. A. Bernhardt, Max-Planck Institute, Mülheim (Ruhr), Germany, and Drs. Weiler and Strauss, Oxford, England.

N-bis(2-methanesulphonyloxyethyl)-p-toluenesulphonamide (IIa)

Methanesulphonyl chloride (115 g) was added dropwise with stirring over a 5.5 hour period to a cold (ice bath) solution of N-bis(2-hydroxyethyl)-*p*-toluenesulphonamide (I*b*, 130 g, ref. 18) in dry pyridine (107 ml). The resulting pale yellow mixture was stirred with cooling for 1.5 hours and then allowed to stand 2.5 hours. After the mixture was washed with ice water and 6 *N* hydrochloric acid the residue was extracted with chloroform. The combined extract was washed successively with water, 6 *N* hydrochloric acid, and water. Following removal of solvent *in vacuo* and trituration with ether, the pale yellow residue solidified. Recrystallization from chloroform–benzene gave colorless crystals; yield, 136 g (66%), m.p. 58–62°. Four recrystallizations from benzene (Norit-A) afforded an analytical sample melting at 63–63.5°; ν_{max}^{KBr} 1355–1318 (broad), 1180–1154 (broad), 1015, 998, 980, 910, 820, and 720 cm^{-1}. Calc. for $C_{13}H_{21}NO_8S_3$: C, 37.58; H, 5.09; N, 3.37; S, 23.16%. Found: C, 37.30 to 41.68; H, 4.92 to 5.39; N, 3.08 to 3.19; S, 22.04 to 22.18%.

Three apparently pure analytical samples of sulphonamide II*a*, m.p. 63–64°, were prepared using different methods and submitted for elemental analysis. However, the product (II*a*) was generally accompanied by a tenacious impurity as evidenced by the above analytical data.

N-Bis(2-fluoroethyl)-p-toluenesulphonamide (IIIa)

A mixture of sulphonamide II*a* (18.0 g, 0.01 mole), anhydrous potassium fluoride (10.0 g, 0.17 mole) and diethylene glycol (180 ml) was stirred at 130–140° for 4.5 hours. The solution was cooled to room temperature and diluted with ice water (150 ml). The resulting mixture was extracted with chloroform and the extract was concentrated to a colorless oil, which crystallized upon trituration with ether. Recrystallization from benzene – ethyl ether yielded (4.0 g, 32%) colorless needles melting at 76–78°. Childs (6) reported a melting point of 79°. Four recrystallizations from ethyl ether (Norit-A) gave an analytical specimen melting at 79–79.4°; ν_{max}^{KBr} 1598, 1468, 1447, 1400, 1365, 1342–1330 (broad), 1293, 1172–1148 (broad), 1038, 937–922, 858, 720, and 700 cm^{-1}. Calc. for $C_{11}H_{15}F_2NO_2S$: C, 50.18; H, 5.74; F, 14.43; N, 5.32; S, 12.18%. Found: C, 50.40; H, 5.67; F, 14.29; N, 5.13; S, 12.36%.

N-Bis(2-methanesulphonyloxyethyl)methanesulphonamide (IIb)

Methanesulphonyl chloride (115 ml) was added (dropwise) over 1 hour to a cold (ice bath) solution composed of 2′,2′-iminodiethanol (52.6 g) and dry pyridine (160 ml). The resulting yellow suspension was stirred for 0.25 hours and then the solution was filtered. The solid phase was washed well with water, with 6 *N* hydrochloric acid (250 ml), and again with water. Following crystallization from acetone, the product (137 g, 81%), m.p. 110–112°, was recrystallized from chloroform to yield pale yellow needles melting at 114.5–115.5°; yield, 50.0 g (33%). Several recrystallizations from acetone raised the melting point to 117–118°; ν_{max}^{KBr} 1368–1320 (broad), 1176, 1148, 1135, 1020, 978, 900, 808, 778, 740, and 727 cm^{-1}. Calc. for $C_7H_{17}NO_8S_3$: C, 24.76; H, 5.05; N, 4.13; S, 28.34%. Found: C, 24.95; H, 4.97; N, 3.94; S, 27.98%.

N-Bis(2-fluoroethyl)methanesulphonamide (IIIb)

A mixture composed of anhydrous potassium fluoride (70.0 g, 1.2 mole), methanesulphonamide II*b* (10.0 g, 0.3 mole), and diethylene glycol (500 ml) was stirred and heated at 150–155° for 6 hours. As the reaction proceeded, the mixture began to gel and darken. After cooling, and dilution with cold water (750 ml), the mixture was extracted with chloroform. The extract was concentrated *in vacuo* to a brown oil and triturated with ethyl ether. Next, the waxy residue was extracted with benzene (50 ml) and the extract was treated with Norit-A. Following dilution with ethyl ether and cooling, two crystal crops were obtained: the first 5.9 g (10%), m.p. 42.5–45.5°, and the second 10.1 g (18%), m.p. 38–42°. Three recrystallizations of the higher melting specimen from carbon tetrachloride led to an analytical sample of colorless needles, m.p. 46.2–46.7°; ν_{max}^{KBr} 1346–1320 (broad), 1155–1144 (broad), 1012, 966, 922, 843, and 776 cm^{-1}. Calc. for $C_5H_{11}F_2NO_2S$: C, 32.08; H, 5.92; F, 20.03; N, 7.48; S, 17.13%. Found: C, 32.35; H, 5.72; F, 20.01; N, 7.73; S, 16.90%.

N-Bis(2-fluoroethyl)amine (IIIc) Hydrobromide

Procedure A

Toluenesulphonamide III*a* (1.32 g) was added to a solution of phenol (0.47 g) in anhydrous 3:7 hydrogen bromide – glacial acetic acid and the pale yellow solution was allowed to remain at room temperature for 13 hours. After dilution with ethyl ether (30 ml) the colorless crystalline hydrobromide weighed 0.25 g (26%) and melted at 186–188°. Increasing the reaction time to 2.5 or to 4 days afforded respectively 48 to 60% yields of amine III*c* hydrobromide.[8] Three recrystallizations from methanol – ethyl ether gave a pure sample, m.p. 187–189°; ν_{max}^{KBr} 3000–2900 (broad), 2760, 1563, 1455, 1422, 1273, 1058, 925, and 785 cm^{-1}. Calc. for $C_4H_{10}BrF_2N$: C, 25.28; H, 5.30; F, 19.99%. Found: C, 25.46; H, 5.23; F, 20.26%.

By mixture melting point determination and infrared spectral comparison in potassium bromide, the

[8]*Experiments conducted by T. P. Habif and M. Sciaraffa.*

For personal use only.

hydrobromide salt was found to be identical with a specimen prepared from N-bis(2-fluoroethyl)amine hydrochloride (see below). Fluoro-nitrogen mustard III*c* was further characterized by conversion to *N-bis(2-fluoroethyl)-3,4,5-triiodobenzamide.* The amide was prepared (cf. VII*a*) using the amine corresponding to 4.2 g of N-bis(2-fluoroethyl)amine hydrobromide and 5.2 g of 3,4,5-triiodobenzoyl chloride (19). The crude pale yellow solid was recrystallized from benzene (Norit-A) to yield 2.9 g (49%) of colorless needles melting at 152–154.5°. Concentrating the mother liquor gave a second crop (0.2 g) melting at 151–153.5°. Several recrystallizations from benzene–hexane afforded an analytical specimen melting at 154–155° with sublimation from 150°, ν_{max}^{KBr} 1630 cm^{-1}. Calc. for $C_{11}H_{10}F_2I_3NO$: C, 22.35; H, 1.71; I, 64.42; N, 2.37%. Found: C, 22.56; H, 1.64; I, 64.22; N, 2.23%.

Procedure B

When the general cleavage reaction over a 13 hour period described in procedure A was applied to methanesulphonamide III*b* (3.7 g), the yield of N-bis(2-fluoroethyl)amine hydrobromide (0.3 g), m.p. 183–187°, was 8%. Two recrystallizations from methanol – ethyl ether led to a pure sample, m.p. 187–189°, which was identical with the hydrobromide obtained using procedure A. The identical composition of both products was established by infrared spectral comparison (in potassium bromide) and mixture melting point determination.

N-Bis(2-fluoroethyl)amine Hydrochloride

A specimen of N-bis(2-fluoroethyl)amine prepared as described by Childs (6) was converted to the hydrochloride derivative by D. S. Blonda of this laboratory. Three recrystallizations from methanol – ethyl ether gave an analytical sample melting at 202°; ν_{max}^{KBr} 2990–2970, 2730, 2460, 1590–1578 (broad), 1460, 1058, 936–922 (broad), cm^{-1}. Calc. for $C_4H_{10}ClF_2N$: C, 33.00; H, 6.92; Cl, 24.35%. Found: C, 33.02; H, 6.84; Cl, 24.16%.

N-(p-Toluenesulphonyl)morpholine (IV)

Approximately 60 ml of a solution prepared from anhydrous potassium fluoride (1.4 g, 0.024 mole) and formamide (75 ml) was added dropwise over a 0.25 hour period to a warm (90°) solution of *p*-toluenesulphonamide II*a* (9.1 g, 0.22 mole) in formamide (50 ml). Before addition of the remaining potassium fluoride solution, over 0.25 hour, stirring and heating at 120–125° were continued 4 hours. Heating was then continued at 120–125° for 3 hours. The solution was cooled to room temperature and poured into cold water (125 ml). Following extraction with benzene the combined extract was concentrated *in vacuo* to a colorless solid; yield, 3.8 g (71.5%), m.p. 144.5°. Recrystallization from methanol gave colorless needles melting at 148–149°. By mixture melting point determination and infrared spectral comparison in potassium bromide, the product was found to be identical with an authentic sample (16).

When the above experiment was repeated essentially as described using diethylene glycol as solvent the crude yield of *p*-toluenesulphonamide IV was 5.6 g, m.p. 142–143.5°. Recrystallization from methanol gave 0.43 g of colorless needles melting at 147–148.5°. However, when the reaction was repeated using the dimethyl ether of diethylene glycol or dimethylformamide as solvent only starting material (II*a*) was isolated.

N-Bis-ethyl-3,4-methylenedioxybenzylamine (IXa) Hydrochloride[9]

(a) From N-bis(2-fluoroethyl)-3,4-methylenedioxybenzamide (VIIa)

In a typical experiment N-bis(2-fluoroethyl)amine hydrobromide (5.7 g) was treated with 1.3 g of sodium hydroxide in water (25 ml). The corresponding amine was extracted with benzene and the combined extract was dried. Next, a solution of 3,4-methylenedioxybenzoyl chloride (2.6 g, ref. 5) in benzene (25 ml) was added over a 1 hour period with cooling (ice bath). Stirring was continued while the mixture was heated at reflux for 5 hours. After it was cooled to room temperature, N-bis(2-fluoroethyl)amine hydrochloride was collected and the colorless filtrate was concentrated to a deep straw-colored oil; yield, 3.45 g, ν_{max}^{pure} 1640 cm^{-1}. Several attempts to crystallize the crude oily amide were unsuccessful.

The N-bis(2-fluoroethyl)amide (VII*a*, 9.2 g) was reduced using a mixture of aluminum chloride (4.8 g) and lithium aluminum hydride (1.2 g) as described for preparation of N-bis(2-chloroethyl)-3,4-methylenedioxybenzylamine hydrochloride in a prior investigation (5). In this case, addition of excess ethyl ether – hydrogen chloride solution did not precipitate the hydrochloride. However, removing the solvent *in vacuo* led to 3.5 g of colorless crystalline amine (IX*a*) hydrochloride, m.p. 190–195°. Four recrystallizations from methanol – ethyl ether raised the melting point to 203–204°, with darkening from 198°.

(b) From N-bis-ethyl-3,4-methylenedioxybenzamide (VIIb)

Preparation (cf. ref. 20) and conversion of amide VII*b* (9.7 g) to the corresponding amine (2.1 g, decomp. 210–211° with darkening from 209°) was accomplished essentially as described in the preceding experiment. Calc. for $C_{12}H_{18}ClNO_2$: C, 59.13; H, 7.44; N, 5.76%. Found: C, 59.39; H, 7.30; N, 5.86%.

Amine IX*a* hydrochloride prepared by procedure (*a*) was found to be identical (infrared spectral comparison) with the specimen prepared by this method. A mixture of both products melted at 206–207° (darkening from 203°). However, elemental analysis of the product from procedure (*a*) indicated that this specimen still contained a small amount (1.44%) of fluorine.

[9]*These experiments were performed by D. S. Blonda.*

N-Bis-ethyl-3,4,5-trimethoxybenzylamine (Xb) Hydrochloride

A solution of N-bis-ethyl-3,4,5-trimethoxybenzamide (3.0 g, 0.011 mole (ref. 21)) in tetrahydrofuran (20 ml) was slowly (0.5 hour) added to a cold (ice bath) suspension of lithium aluminum hydride (0.24 g, 0.006 mole). The ice bath was removed and stirring was continued at room temperature for 24 hours. The reaction was conducted in a nitrogen atmosphere. After cautious addition of ethyl acetate, 95% ethanol, and water, the reaction mixture was concentrated *in vacuo* at 40–50°. The residual mixture was treated with 40% sodium hydroxide (20 ml) and extracted with benzene. Diluting the combined and dried extract with dry hydrogen chloride in ethyl ether gave 2.28 g (70.4%), m.p. 179.5–181°, of amine X*b* hydrochloride. Three recrystallizations from methanol – ethyl ether (Norit-A) led to a pure sample as colorless needles, m.p. 183–184°; ν_{max}^{KBr} 2920, 2600, 1590, 1512, 1470, 1428, 1335, 1260–1243 (broad), 1122, 1018, 860, and 780 cm^{-1}. Calc. for $C_{14}H_{24}ClNO_3$: C, 58.03; H, 8.35; N, 4.83%. Found: C, 58.30; H, 8.42; N, 4.93%.

N-Bis(2-fluoroethyl)-3,4-methylenedioxybenzylamine (IXb) Hydrochloride

Lithium aluminum hydride (0.5 g) was used to reduce N-bis(2-fluoroethyl)-3,4-methylenedioxybenzamide (VII*a*, 3.1 g) as described for preparation of diethyl amine X*b*. The crude hydrochloride was obtained as colorless crystals; yield, 1.73 g (52%), m.p. 176–178°. Four recrystallizations from methanol – ethyl ether led to an analytical specimen melting at 185° (sublimation at 150°), ν_{max}^{KBr} 2900, 2600–2500 (broad), 1510, 1494, 1445, 1255, 1140, 922, and 905 cm^{-1}. Calc. for $C_{12}H_{16}ClF_2NO_2$: C, 51.53; H, 5.77; N, 5.01%. Found: C, 51.42; H, 5.87; N, 4.88%.

N-Bis(2-fluoroethyl)-3,4,5-trimethoxybenzamide (VIIIa)

A 6.1 g sample of bis(2-fluoroethyl)amine hydrobromide was converted to the free base and allowed to react with 3,4,5-trimethoxybenzoyl chloride (3.5 g) in dry benzene (100 ml) as described for synthesis of amide VII*a*. The crude amide crystallized from benzene–hexane as colorless needles weighing 4.4 g (96%), m.p. 80.5–83.5°. Two recrystallizations from the same solvent afforded a pure sample melting at 83.7–84.5°, ν_{max}^{KBr} 1638 cm^{-1}. Calc. for $C_{14}H_{19}F_2NO_4$: C, 55.44; H, 6.31; F, 12.53; N, 4.61%. Found: C, 55.55; H, 6.36; F, 12.30; N, 4.56%.

N-Bis(2-fluoroethyl)-3,4,5-trimethoxybenzylamine (Xa) Hydrochloride

Lithium aluminum hydride (0.14 g) reduction of amide VIII*a* (2.0 g) was accomplished as described for preparation of amine X*b* hydrochloride. Recrystallizing the crude hydrochloride from methanol – ethyl ether (Norit-A) gave a first crop (0.75 g) melting at 132–134.5° and a second crop (0.14 g, total yield 41%) melting at 129.5–131.5°. Three recrystallizations of the higher melting specimen from the same solvent gave a pure sample of colorless platelets melting at 133.5–135°, ν_{max}^{KBr} 1589, 1510, 1468, 1422, 1335, 1258, 1172, and 965 cm^{-1}. Calc. for $C_{14}H_{22}ClF_2NO_3$: C, 51.62; H, 6.81; F, 11.66; N, 4.30%. Found: C, 51.75; H, 6.91; F, 11.44; N, 4.29%.

ACKNOWLEDGMENTS

This investigation was aided by Grants Number T-79C and T-79D from the American Cancer Society. We also wish to thank Dr. R. B. Ross for providing a summary of the N-bis(2-fluoroethyl)amine toxicity studies.

FRIEDEL–CRAFTS REARRANGEMENTS

II. REARRANGEMENTS DURING CYCLIALKYLATION OF ε-ARYL-SUBSTITUTED COMPOUNDS[1]

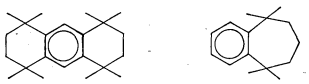
L. R. C. BARCLAY, B. A. GINN, AND C. E. MILLIGAN[2]
Department of Chemistry, Mount Allison University, Sackville, New Brunswick
Received October 3, 1963

ABSTRACT

Friedel–Crafts cyclialkylation of aromatics such as 1,1,4,4-tetramethyltetralin with 2,6-dichloro-2,6-dimethylheptane does not yield a benzsuberane as previously reported. Several 5-phenyl-substituted chlorides, alcohols, and olefins were synthesized for cyclialkylation studies. These included 2-chloro-2,6-dimethyl-6-phenylheptane (X*a*), 3-chloro-3,7-dimethyl-7-phenyloctane (X*b*), 2,6-dimethyl-6-phenyl-2-heptanol, 2,6-dimethyl-6-phenyl-2-hepten-4-one (XX), 2-chloro-6-methyl-6-phenylheptane, and 1-chloro-5-phenylpentane (XXIV). Cyclialkylation of X*a* (and the corresponding alcohol), X*b*, 2-chloro-6-methyl-6-phenylheptane, and XXIV produced alkyltetralins instead of benzsuberanes. Evidence is presented and discussed which indicates that the alkyltetralins form by rearrangements in the side chains of the aryl-substituted systems. The alternative mechanism involving rearrangement of a benzsuberane intermediate via a phenonium ion mechanism was unequivocally ruled out in at least one case—the cyclization of X*b*. Nuclear magnetic resonance evidence is presented and discussed for the structural assignments.

INTRODUCTION

In Part I (1), it was shown that the ortho-diquaternary aromatic hydrocarbon octamethyloctahydroanthracene (I) was stable under the usual Friedel–Crafts conditions. However, prolonged heating of I with aluminum chloride caused ring contraction involving a 1,2-aryl shift and a phenonium ion mechanism was favored to account for the rearrangement involving conversion of a tertiary to a secondary alkyl system.



I II

The present investigation was initiated to study rearrangements in systems homologous to I. In this connection the polyalkyl benzsuberane (II) would be of particular interest. Such systems were reported by Colonge (2). However, we found at the outset that ortho-diquaternarybenzsuberane systems such as II could not be prepared by Friedel–Crafts cyclialkylations with appropriate dichlorides. Rearrangement products (alkyltetralins) formed instead. It was desirable to find if such rearrangements take place through intermediate formation of II followed by a 1,2-aryl shift, as proposed in the case of I, or whether the rearrangement takes place in the alkylating agent before ring closure. The former mechanism would conform to the phenonium ion mechanism proposed by Schmerling and co-workers (3) and by Roberts and co-workers (4) for the isomerization of *t*-pentylbenzene into 2-methyl-3-phenylbutane. The latter mechanism would be analogous to that proposed by Friedman and co-workers (5), who cited evidence indicating that (at least in the alkylation of para-xylene) the *t*-pentyl cation may isomerize to a secondary pentyl system, as opposed to isomerization taking place through the arylalkane.

6(*c*)	XX (0.0023)	PPA	None	100	7	1,1-Dimethylindanone	65.2
7	$C_6H_5C(CH_3)_2(CH_2)_3$—$CHClCH_3$ (0.0047)	$FeCl_3$ (0.0047)	CH_3NO_2	0	¾–2	Unreacted chloride + 1,1-dimethyl-4-ethyltetralin (XXIII)	
					4	XXIII	89.2
8(*a*)	$C_6H_5(CH_2)_5Cl$ (XXIV) (0.0055)	$AlCl_3$ (0.0055)	Pet. ether, (b.p. 60–80° C)	Reflux	1	1-Methyltetralin	80
8(*b*)	XXIV (0.0027)	$AlCl_3$ (0.0027)	Pet. ether, (b.p. 60–80° C)	0	0.5	1-Methyltetralin XXIV	2 98

In cases Nos. 3–8, the percentage yields were calculated from gas–liquid chromatographic analyses.

A number of synthetic phenyl-substituted chlorides, related olefins, and alcohols were selected for cyclialkylation–rearrangement studies. Polyalkyltetralins rather than benzsuberanes were the products of cyclization and evidence is provided in favor of rearrangement in the side chain before ring closure.

DISCUSSION OF RESULTS

The structure for Colonge's reported 1,1,5,5-tetramethylbenzsuberane (II) (2) from cyclialkylation of benzene with 2,6-dichloro-2,6-dimethylheptane (IV) was based upon a reported oxidation of II to *o*-phenylenediisobutyric acid anhydride with a melting point of 116°. However, this anhydride was recently synthesized by unambiguous routes (6, 7) and found to have a melting point of 98–99°. The structure offered for II is therefore open to question and an initial cyclialkylation study was made using the dichloride (IV). 1,1,4,4-Tetramethyltetralin (III) was selected as the substrate since it is cyclialkylated under mild conditions and does not lead to complex mixtures as is the case with benzene. This cyclialkylation of III (Table I, No. 1) yielded two hydrocarbons—a saturated hydrocarbon (60%) (V) from the solvent (CS_2) layer and an unsaturated hydrocarbon (12%) (VI) from the complex layer of the reaction. The unsaturated hydrocarbon was related to V by catalytic reduction of the olefinic double bond. These hydrocarbons were shown to have structures V and VI shown below by spectroscopic evidence and a classical synthesis. The ultraviolet spectrum of V was very similar to that of octamethyloctahydroanthracene (I) (1) (see Table II for ultraviolet spectra). The infrared spectrum of V (CS_2) showed a strong band at 11.2 microns attributed to 1,2,4,5-tetrasubstitution. Hydrocarbon VI displayed an ultraviolet spectrum (Table II) typical of compounds containing a double

TABLE II

Ultraviolet spectra

	λ_{max} (mμ)	ϵ
Octamethyloctahydroanthracene (I)	278, 270	1096, 955
Saturated hydrocarbon (V)	279.6, 271	1362, 1227
Unsaturated hydrocarbon (VI)	262 (broad)	14,725
1,1,4,4-Tetramethyltetralin (III)	271, 264, 257	398, 457, 324
1,1-Dimethyl-4-isopropyltetralin (XII*a*)	272.5, 265	269, 330

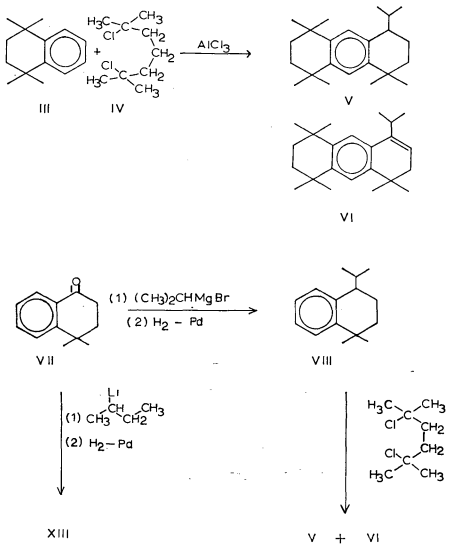
bond conjugated with a benzene ring. Its infrared spectrum showed a strong band at 11.2 microns attributed to 1,2,4,5-tetrasubstitution and a strong band at 12.5 μ attributable to the out-of-plane deformation of an olefinic proton. The latter band disappeared upon catalytic reduction of VI. The compounds showed the expected nuclear magnetic resonance spectra. Hydrocarbon V exhibited a multiplet in the region of C—CH_3 absorption between 9.28 and 8.76 p.p.m. of intensity corresponding to 24 protons. A band at 8.36 corresponded to eight methylene protons and one at 7.59 was attributed to the two methine hydrogens. The two aromatic protons absorbed as a doublet at 3.07 and 2.91. The unsaturated hydrocarbon (VI) had a doublet at 8.80–8.73 p.p.m. corresponding to 24 methyl protons, a peak at 8.34 for four methylene protons, a doublet at 7.92–7.81 for the methylene adjacent to the conjugated double bond, a doublet at 4.42–4.34 attributed to the olefinic proton, and a band at 2.82 attributed to the two aromatic protons.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

A classical synthesis confirmed the structures offered for V and VI (see Chart I). The previously reported 4,4-dimethyl-1-tetralone (VII) (8, 9) was converted to 1,1-dimethyl-4-isopropyltetralin (VIII). Cyclialkylation of VIII with 2,5-dichloro-2,5-dimethylhexane (Table I, No. 2) yielded a mixture of V and VI. These hydrocarbons were shown to be identical by mixed melting points and infrared spectra with the products formed in the cyclialkylation of 1,1,4,4-tetramethyltetralin with 2,6-dichloro-2,6-dimethylheptane (IV).

CHART I

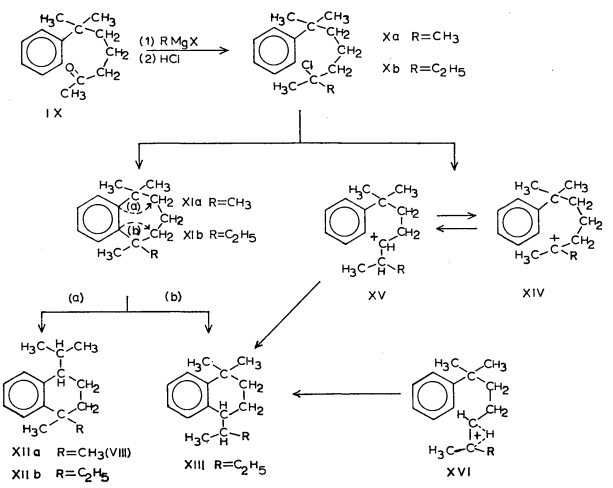


From the above results it seems unlikely that benzsuberanes can be prepared by Friedel–Crafts cyclialkylations with ditertiary halides. However, it was desirable to determine the mechanism whereby the rearrangement products (alkyltetralins) formed. Two distinct possibilities existed. Firstly, the ortho-diquaternarybenzsuberane system (i.e. II) could form as an intermediate in the reaction followed by rearrangement through a 1,2-phenyl shift as was demonstrated in the rearrangement of I (1). Secondly, the rearrangement could take place before cyclization, possibly in a phenyl-substituted chloride. A method of testing for both of these possibilities was worked out by cyclizations of 2-chloro-6-phenyl-2,6-dialkylheptanes (X*a* and *b*) (Chart II). A key intermediate in the synthesis of these chlorides was the ketone 6-methyl-6-phenyl-2-heptanone (IX) prepared by alkylation of benzene with 6-methyl-5-heptene-2-one. The ketone (IX) has been synthesized previously (10). Nevertheless it was desirable to establish the authenticity of our own sample by n.m.r. analysis. This ketone showed a singlet at 8.74 p.p.m. integrating for six protons and attributed to the *gem* dimethyls. A singlet at 8.13 of intensity corresponding to three protons was attributed to the methyl on the carbonyl carbon. A triplet at 7.93, 7.83, and 7.60 p.p.m. integrating for two protons was attributed to the methylene group adjacent to the carbonyl. The remaining four methylene hydrogens appeared in a multiplet with the prominent band at 8.57 p.p.m. The desired chlorides, 2-chloro-2,6-dimethyl-6-phenylheptane (X*a*) and 3-chloro-3,7-dimethyl-7-phenyloctane (X*b*), were synthesized from IX as outlined in Chart II.

The chloride X*a* provided a "control" to determine if cyclization of such a system would yield any benzsuberane (XI*a*). A rearrangement product (VIII) resulted as is discussed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

CHART II



below. In the chloride X*b* the ethyl group is in effect a "label". *If* the rearrangement takes place through an ortho-diquaternary benzsuberane (XI*b*), the 1,2-aryl shift can take place by two routes "*a*" and "*b*". One would expect equal proportions of two tetralins from this mechanism—dimethylsecondarybutyltetralin (XIII) and isopropylmethylethyltetralin (XII*b*). The alternative mechanism for this rearrangement involves rearrangement in the side-chain by equilibration of the tertiary carbonium ion XIV with the secondary carbonium ion XV followed by cyclization of the latter (see Chart II). This latter mechanism would be expected to produce only one tetralin (XIII) from X*b*.

Friedel–Crafts cyclization of the chloride X*a* (Table I, No. 3) or hydrogen fluoride cyclization of the corresponding alcohol (Table I, No. 4) produced 1,1-dimethyl-4-isopropyltetralin (VIII) as the only cyclic product. This compound was found by ultraviolet, n.m.r., and infrared analyses to be identical with a synthetic sample of VIII. It was similarly identical with VIII recently prepared by Wood and co-workers (10). The n.m.r. spectrum of VIII provided a useful characterization (Fig. 1(*a*)). The six protons of the *gem* dimethyl group appeared as a singlet at 8.75 p.p.m. A four proton doublet at 8.28 and 8.31 p.p.m. was attributed to the four methylene protons. The characteristic feature of the spectrum was the appearance of two doublets at higher fields—8.93–9.03 and 9.19–9.31 p.p.m.—and attributed to the methyl protons of the isopropyl group. The two doublets indicate that the two methyls are non-equivalent. This is probably due to restricted rotation of the isopropyl grouping so that one of the methyls (Fig. 2, R_1) lies over the aromatic ring and is subjected to diamagnetic shielding which causes these protons to absorb at higher field than those of the more remote methyl (R_2). Hindered rotation in the isopropyl group of VIII was evident in a Stuart–Briegleb model.

Cyclization of 3-chloro-3,7-dimethyl-7-phenyloctane (X*b*) with aluminum chloride (Table I, No. 5) yielded 1,1-dimethyl-4-secondarybutyltetralin XIII(identity discussed below) rather than a mixture of tetralins XII*b* and XIII. This result rules out the phenonium ion mechanism (through XI*b*) to account for the rearrangement. Thus the rearrangement in this case must have taken place in the side chain, for example by the isomerization of XIV $\rightleftarrows$ XV.

The identity of XIII was established by comparison of the ultraviolet (Table II) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

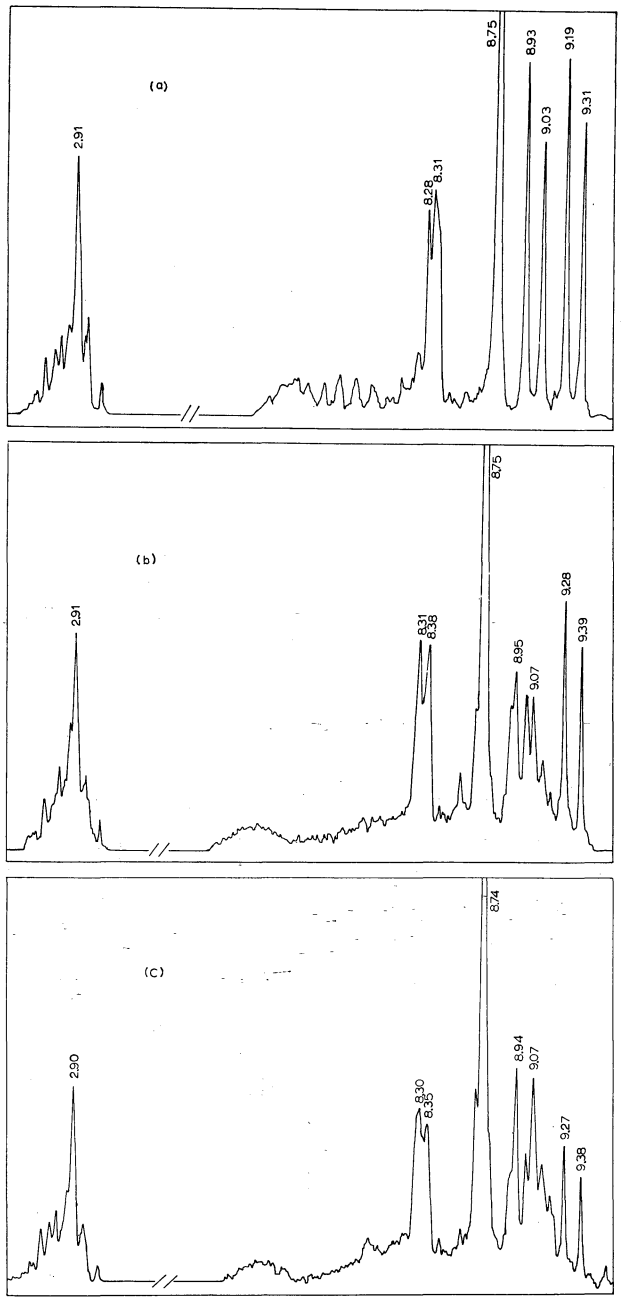

FIG. 1. Nuclear magnetic resonance spectra. (*a*) 1,1-Dimethyl-4-isopropyltetralin (VIII). (*b*) 1,1-Dimethyl-4-secondarybutyltetralin (XIII) from cyclization of (X*b*). (*c*) XIII synthetic.

infrared spectra with a synthetic sample prepared from 4,4-dimethyl-1-tetralone (VII) as is outlined on Chart I.

The n.m.r. spectra of XIII from the cyclization and also from the synthesis are shown in Fig. 1(*b*) and 1(*c*). The spectra were practically identical in the aromatic proton region

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

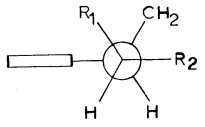

FIG. 2. (*a*) $R_1 = R_2 = CH_3$; (*b*) $R_1 = CH_3$, $R_2 = C_2H_5$; (*c*) $R_1 = C_2H_5$, $R_2 = CH_3$.

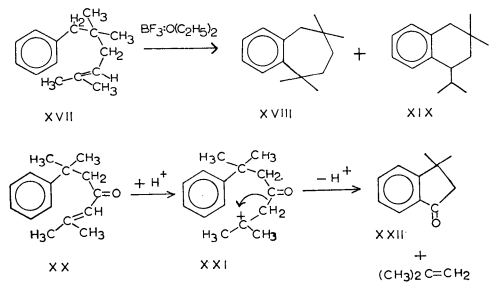
near 2.90 and in the doublet attributed to methylenes at 8.31–8.38 in Fig. 1(*b*) and 8.30–8.35 in Fig. 1(*c*). Both showed a six proton singlet at 8.75–8.74 attributed to the *gem* dimethyl grouping. The only significant difference in the spectra was in the intensities of the doublets at 9.39–9.28 (9.38–9.27) and 9.07–8.95 (9.07–8.94) in each. In the synthetic sample the high field doublet at 9.38–9.27 integrated for 1.4 protons. This might be taken to indicate that this sample consisted of approximately an equal amount of the two possible configurations in the conformations shown in Fig. 2(*b* and *c*). On the other hand, in the cyclization product the high-field doublet (Fig. 1(*b*)) integrated for 2.3 protons and indicates that this sample is enriched in configuration *b* (77%) which has the methyl group (R_1) over the field of the aromatic ring. If this speculation is correct, the cyclization of X*b* shows some stereospecificity. This would be expected if the cyclization takes place preferentially through a hydrogen bridged ion such as XVI (Chart II) since the phenyl group might be expected to approach the bridged ion (XVI) more easily on the side nearer the methyl rather than the ethyl group.

The mechanism established for the cyclization of X*a* and X*b* cannot be generalized to apply to other similar systems without unequivocal evidence. For example, Hart (11) found that cyclization of 2,5,5-trimethyl-6-phenyl-2-hexene (XVII) yielded some tetramethylbenzsuberane (XVIII) as well as 2,2-dimethyl-4-isopropyltetraline (XIX).

An attempt was made to synthesize a benzsuberane containing ortho-diquaternary carbons by cyclization of 2,6-dimethyl-6-phenyl-2-heptene-4-one (XX). Compound XX resisted cyclization (Table I, Nos. 6(*a*) and 6(*b*)). Vigorous conditions with polyphosphoric acid (No. 6(*c*) resulted in the formation of 4,4-dimethylindanone (XXII) (1). The carbonium ion (XXI) derived from XX could form XXII by a cyclization with elimination of isobutylene (Chart III).

CHART III



The failure of compounds X*a*, X*b*, and XX to cyclize to benzsuberanes can be attributed to strain in an ortho-diquaternarybenzsuberane system such as XI*a* or *b*. A Stuart–Briegleb model of the latter system showed very strong conformational interactions; for example, between the methyls and the ortho aromatic protons. An analogy can be made between XI*a* and derivatives of the strained aromatic system *o*-di-*t*-butylbenzene. For example, 4,5-benzo-3,3,6,6-tetramethyl-1-oxacycloheptene (which is isoelectronic with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

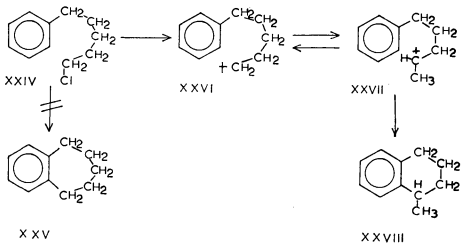
XI*a*) and 2,2,5,5-tetramethyl-3,4-benzo-ϵ-caprolactol lack the usual vibrational fine structure in their ultraviolet spectra and this has been taken as evidence of strain (6, 7). On the other hand, the tetramethylbenzsuberane (XVIII) prepared by Hart showed some fine structure in its ultraviolet spectrum (see Table II) although it was not so well developed as in the tetralins or in benzsuberane itself.

Cyclization of the secondary chloride 2-chloro-6-methyl-6-phenylheptane under mild conditions also yielded a tetralin, 1,1-dimethyl-4-ethyltetralin (XXIII) instead of a benzsuberane (Table I, No. 7). The structure of XXIII was determined by a classical synthesis from 4,4-dimethyl-1-tetralone (VII) using the Grignard method similar to the synthesis of XII*a*.

In view of the above results on cyclialkylations of chlorides X*a*, X*b*, and 2-chloro-6-methyl-6-phenylheptane, it was desirable to reinvestigate the cyclialkylation of the primary chloride 1-chloro-5-phenylpentane (XXIV). The generally accepted view (12, 13) is that this chloride cyclizes to yield benzosuberane (XXV). Contrary to this we found that XXIV does not yield benzsuberane under conditions reported in the literature (Table I, No. 8(*a*)). It yielded instead the rearrangement product 1-methyltetralin (XXVIII). The ultraviolet spectrum of XXVIII was clearly distinguishable from that of a synthetic sample of benzsuberane (Table II). The structure of XXVIII was confirmed by its n.m.r. spectrum. The most important feature of this spectrum was a three-proton doublet at 8.69 and 8.80 p.p.m. for the methyl group on carbon one. The synthetic benzsuberane showed only methylene absorption and aromatic proton absorption as expected. The methylene absorption appeared in two multiplets—one near 8.24 p.p.m. and assigned to the protons on carbons 2, 3, and 4 and the other at 7.13–7.29 and assigned to the protons on carbons 1 and 5.

Cyclialkylation of 1-chloro-5-phenylpentane (XXIV) under milder conditions (Table I, No. 8(*b*)) resulted in recovery of 98% of XXIV and 2% of 1-methyltetralin. The absence of benzsuberane even at this stage of the reaction indicates that it is probably *not* an intermediate in the rearrangement. This reaction may therefore take place by rearrangement in the side chain through equilibration of XXVI and XXVII prior to cyclization (see Chart IV). Experiments are now underway to test this postulated mechanism by using a deuterium tracer in the side chain of XXIV.

CHART IV



EXPERIMENTAL

The melting points were determined on a hot stage equipped with a microscope and are uncorrected. Ultraviolet spectra were recorded on a Beckman DK-2 spectrophotometer in spectrograde cyclohexane and infrared spectra on a Perkin–Elmer Model 137 Infracord. Reaction products were analyzed on a F & M Model 500 programmed temperature gas chromatograph equipped with a dual column attachment. The column packings contained silicone gum rubber. The percentage yields were determined by gas chromatography. Pure samples of liquid compounds for analyses were obtained by repetitive gas chromatography.

For personal use only.

Nuclear magnetic resonance spectra were measured on a Varian A-60 in carbon tetrachloride solvent. Values are reported in p.p.m. relative to tetramethylsilane equals 10. Ultimate analyses were determined by Dr. E. Thommen, Basel, Switzerland.

Syntheses of Compounds for Cyclialkylation Studies

(a) 2,6-Dichloro-2,6-dimethylheptane (IV)

The dichloride (IV) was prepared from 2,6-dimethyl-5-hepten-2-ol according to the method of Colonge (2). It gave a melting point of 41–42° (lit. (2) 43°).

(b) 1,1,4,4-Tetramethyltetralin (III)

Hydrocarbon III was prepared by reacting benzene with 2,5-dichloro-2,5-dimethylhexane by a modification of the Bruson procedure (14). Gas–liquid chromatographic analysis indicated 98% purity.

(c) 2-Chloro-2,6-dimethyl-6-phenylheptane (Xa)

6-Methyl-6-phenyl-2-heptanone (IX) was prepared by a procedure similar to that reported by Wood and co-workers (10). The infrared spectrum of this ketone showed carbonyl absorption at 1700 cm^{-1} and bands attributed to monosubstitution at 770 and 704 cm^{-1}. The ketone (IX) was converted by the Grignard method into 2,6-dimethyl-6-phenyl-2-heptanol as previously reported (10). The purified alcohol gave $n_D^{23.3}$ 1.5034 (lit. (10) n_D^{20} 1.5034). The hydroxyl absorption appeared at 3250 cm^{-1}.

The chloride X*a* was prepared in 81.3% yield by the action of hydrogen chloride gas and concentrated hydrochloric acid (25 ml) on 2,6-dimethyl-6-phenyl-2-heptanol. Hydrogen chloride was bubbled into the alcohol (24.0 g) for 1.5 hours. The organic layer was then washed with sodium carbonate solution and water and dried over anhydrous calcium chloride. The crude product was vacuum distilled at 0.72 mm and 110° to yield 21.3 g of liquid (n_D^{20} 1.5041). The infrared spectrum of this compound showed no hydroxyl absorption.

(d) 3,7-Dimethyl-7-phenyl-3-octanol

The alcohol was prepared by the reaction of an ethyl Grignard with IX. The Grignard reagent, ethyl magnesium bromide, was prepared in the usual manner from 2.4 g (0.10 mole) of magnesium and 10.9 g (0.10 mole) of ethyl bromide. The ketone (13.9 g, 0.068 mole) was added slowly to the Grignard reagent in anhydrous ethyl ether and the solution was then refluxed for 6 hours and then allowed to stand overnight at room temperature. After the solution was worked up in the usual way, 14.5 g of crude liquid was obtained. The infrared spectrum showed strong hydroxyl absorption at 3250 cm^{-1} and no carbonyl absorption. Gas–liquid chromatography indicated 98.5% purity. This product was used directly without distillation for the synthesis of the chloride X*b* described below.

(e) 3-Chloro-3,7-dimethyl-7-phenyloctane (Xb)

The chloride X*b* was prepared by treating 3,7-dimethyl-7-phenyl-3-octanol (14.0 g, 0.060 mole) with 15 ml of concentrated hydrochloric acid for 15 hours. The organic layer was then washed with sodium carbonate solution and water and dried over anhydrous sodium sulphate. The ether was distilled and the crude liquid was vacuum distilled at 1.1 mm and 128–133° to yield 8.33 g of a compound, the infrared spectrum of which showed no hydroxyl absorption. Gas–liquid chromatographic analysis indicated the compound to be pure (n_D^{20} 1.5053).

(f) 2,6-Dimethyl-6-phenyl-2-hepten-4-one (XX)

Benzene (15.6 g, 0.200 mole) and aluminum chloride (36.0 g, 0.270 mole) were placed in a 200-ml three-necked flask and cooled to 10–15°. 2,6-Dimethyl-2,5-heptadien-4-one (27.6 g, 0.200 mole) was added to the above mixture over a period of 50 minutes maintaining the above temperature limits. The mixture was then allowed to come to room temperature and 2 hours later gas–liquid chromatography indicated that the phorone had been consumed. The infrared spectrum of the major component (28.4%) was typical of a monoalkyl benzene with bands at 772 and 703 cm^{-1}. A band at 1670 cm^{-1} indicated a conjugated carbonyl. This material was distilled at 1.3 mm and 117–122° (n_D^{20} 1.5268) and was assumed to be 2,6-dimethyl-6-phenyl-2-hepten-4-one.

Another component of longer retention time on the gas chromatograph was found to be 2,6-diphenyl-2,6-dimethyl-4-heptanone (15).

(g) 2-Chloro-6-methyl-6-phenylheptane

The secondary alcohol, 6-methyl-6-phenyl-2-heptanol, was prepared by the reduction of 6-methyl-6-phenyl-2-heptanone (IX) with lithium aluminum hydride. The lithium aluminum hydride (0.95 g, 0.025 mole) and anhydrous ethyl ether were placed in a 65-ml three-necked flask equipped with a mechanical stirrer, addition funnel, and reflux condenser. The ketone (5.00 g, 0.025 mole) was added slowly to produce gentle reflux, after which the mixture was refluxed for 4.5 hours. The mixture was cooled and the excess lithium aluminum hydride was decomposed first with methanol and then water. Dilute hydrochloric acid was then added to dissolve the precipitated hydroxides. The mixture was then extracted with ether and the ethereal extracts were washed with water and dried over sodium sulphate. Evaporation of the ether left 4.23 g of liquid, the infrared spectrum of which showed strong hydroxyl absorption at 3230 cm^{-1}, bands at 770 and 703 cm^{-1} for monosubstitution and no carbonyl absorption.

The chloride was prepared by heating 2.00 g (0.0098 mole) of 6-methyl-6-phenyl-2-heptanol with 10 ml of concentrated hydrochloric acid – zinc chloride reagent at 100° C for 20 minutes with stirring. The mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was then allowed to stand at room temperature for several hours. The organic layer was then separated, washed free of acid with water, and dried over sodium sulphate. The infrared spectrum of the product did not show hydroxyl absorption but still showed the bands at 770 and 703 cm^{-1} for a monosubstituted benzene.

(h) 1-Chloro-5-phenylpentane (XXIV)

The alcohol, 5-phenyl-1-pentanol, was prepared by lithium aluminum hydride reduction of 5-phenylpentanoic acid (Aldrich Chemical Co.). Lithium aluminum hydride (11.4 g, 0.330 mole) and anhydrous ethyl ether were refluxed for 2 hours to effect solution. 5-Phenylpentanoic acid (17.8 g, 0.100 mole) in ethyl ether was added over a period of 3 hours, a rate which promoted gentle refluxing. After one additional hour of refluxing, the solution was cooled in ice. Water was then cautiously added to decompose excess lithium aluminum hydride, after which 150 ml of 10% sulphuric acid was added. The organic layer was separated, washed with water, and dried over sodium sulphate. After distillation of the ether, the liquid residue was vacuum distilled at 1.4 mm pressure and 114–118° to yield 10.9 g (67%) of pure 5-phenyl-1-pentanol (n_D^{20} 1.5182, lit. (16) n_D^{21} 1.5170). The infrared spectrum of this compound showed no carbonyl absorption. There was strong hydroxyl absorption at 3200 cm^{-1}.

The chloride, 1-chloro-5-phenylpentane (XXIV), was prepared by heating 3.66 g (0.023 mole) of 5-phenyl-1-pentanol and 25 ml of concentrated hydrochloric acid – zinc chloride reagent for 2 days. The organic layer was then washed free of acid with sodium carbonate solution and then water and dried over sodium sulphate. The crude product was then vacuum distilled at 2.4 mm and 95–96° to yield 1.87 g of pure 1-chloro-5-phenylpentane ($n_D^{23.2}$ 1.5149). The infrared spectrum of the product showed no hydroxyl absorption and had a strong band at 670 cm^{-1} attributed to the carbon-to-chlorine linkage.

Procedures for Cyclialkylation Experiments

Cyclialkylations catalyzed by aluminum chloride and ferric chloride were carried out in a three-necked flask equipped with a mechanical stirrer and a condenser fitted with a calcium chloride drying tube. The catalyst was placed in a small Erlenmeyer flask attached to the reaction flask with flexible rubber tubing to permit convenient addition of catalyst. The reagent and solvent were placed in the flask and the mixture was cooled in an ice–salt bath. The catalyst was then added slowly with stirring to maintain the temperatures listed in Table I. The reactions were terminated by pouring the mixtures on to ice. The organic products were extracted with peroxide-free ethyl ether, the extracts washed free of acid with sodium carbonate solution then washed with water and dried over anhydrous sodium sulphate.

Reactions with anhydrous hydrogen fluoride were carried out in a 12-in. stainless steel MD test tube reactor (Autoclave Engineers Inc.). After addition of the reagents, the tube was sealed by using two-way valves and fittings. Mixing of the reaction mixture was effected by rotating the tube slowly on the shaft of an electric motor. The catalyst polyphosphoric acid was prepared from phosphoric acid and phosphorous pentoxide in the flask to be used for the reaction. The compound to be cyclized was quickly added to this catalyst with stirring. When boron fluoride – etherate was used, it was cooled to 0° with the solvent. The reagent was then added in the solvent to the cooled catalyst with stirring.

Details on the reactants and catalyst used, solvent, temperature, time, and percentage yields of products are outlined in Table I. Ultimate analyses are summarized in Table III below.

TABLE III

Ultimate analyses

Classical Syntheses of Hydrocarbons

(a) 4,4-Dimethyl-1-tetralone (VII)

The ketone (VII) was prepared by the method of Arnold and co-workers (8) by alkylation of benzene with α-methyl-valerolactone. However, our product proved to be a mixture which was difficult to purify. The method of Campbell and Cromwell (9) involving a Willgerodt–Kindler reaction on 4-methyl-4-phenyl-2-pentanone was more successful. This reaction yielded 4-methyl-4-phenylbutanoic acid (n_D^{25} 1.5182, lit. (9)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

n_D^{25} 1.518; anilide, m.p. 115–116°, lit. (9) 116.5–117.5°). The latter was cyclized to 4,4-dimethyl-1-tetralone (VII) as reported (9). Vapor phase chromatography of VII indicated it was pure. The ultraviolet spectrum of VII had bands at 245 mμ, ϵ = 12,174; 285 mμ, ϵ = 1904; and 295 mμ, ϵ = 1492. The infrared spectrum showed carbonyl absorption at 1660 cm^{-1} and a strong band at 770 cm^{-1} attributed to *o*-disubstitution.

(b) 1,1-Dimethyl-4-isopropyltetralin (VIII)

The Grignard reagent, isopropyl magnesium bromide, was prepared from 7.13 g (0.058 mole) of isopropyl bromide and 1.41 g (0.058 mole) of magnesium in 50 ml of dry ethyl ether in an atmosphere of nitrogen. The Grignard reagent was cooled to −5° and 1,1-dimethyl-4-tetralone (5.0 g, 0.029 mole) in 50 ml of benzene was added over 1 hour. The reaction mixture was refluxed for 2½ hours. The product was hydrolyzed by pouring into aqueous ammonium chloride. Distillation of the solvent yielded a liquid residue which was shown to contain some starting ketone (42%) by gas–liquid chromatography. This crude product was freed of ketone by chromatography on alumina in petroleum ether. The first eluates yielded a hydrocarbon fraction (1.65 g) which showed a broad band in the ultraviolet spectrum near 260 mμ indicative of conjugation. The infrared spectrum showed a strong band at 757 cm^{-1} attributed to ortho-disubstitution and a band at 815 cm^{-1} assigned to an olefinic proton. This hydrocarbon was dissolved in methanol and reduced with hydrogen at 50 p.s.i. over palladium – calcium carbonate. The product 1,1-dimethyl-4-isopropyltetralin showed a strong band in the infrared at 760 cm^{-1} assigned to ortho-disubstitution. This compound proved to be identical with the cyclization product of 2-chloro-2,6-dimethyl-6-phenylheptane (X*a*) (Table I, No. 3) by infrared, ultraviolet (Table II), and nuclear magnetic resonance spectra (Fig. 1(*a*)).

(c) 1,1-Dimethyl-4-sec-butyltetralin (XIII)

4,4-Dimethyl-1-tetralone (4.33 g, 0.025 mole) and 50 ml of dry pentane were placed in a 200-ml three-necked flask equipped with graduated dropping funnel, nitrogen inlet, condenser, and calcium chloride drying tubes. Commercial *sec*-butyl lithium (19 ml of a 12.6% solution was added to the ketone with stirring at −5° C over 10 minutes. The reaction mixture was then allowed to stand for 24 hours and at the end of that time water was added to hydrolyze the alkyl lithium compounds. The organic layer was separated, washed with water, and dried over anhydrous sodium sulphate. The crude product showed hydroxyl absorption in the infrared spectrum and was heated with 10% oxalic acid for 18 hours to dehydrate the alcohol. After working up in the usual manner, the infrared spectrum of the product showed no hydroxyl absorption. Gas–liquid chromatography of the product after dehydration indicated that some starting ketone (39%) was still present. The product was freed of unreacted ketone by chromatography on alumina as in the previous experiment. There was obtained 2.0 g of hydrocarbon from the first eluates. This material was dissolved in methanol and hydrogenated at 60 p.s.i. over palladium calcium carbonate. After distillation of the methanol, the product was purified by repetitive gas–liquid chromatography. The infrared spectrum of the product had a strong band at 763 cm^{-1} attributed to ortho-disubstitution. The infrared and ultraviolet spectra of this hydrocarbon, 1,1-dimethyl-4-*sec*-butyltetralin, were identical with those of the cyclization product of 3-chloro-3,7-dimethyl-7-phenyloctane (X*b*) (see Table I, No. 5).

(d) 1,1,5,5,8,8-Hexamethyl-4-isopropyl-1,2,3,4,5,6,7,8-octahydroanthracene (V) and 1,1,5,5,8,8-Hexamethyl-4-isopropyl-1,2,5,6,7,8-hexahydroanthracene (VI)

1,1-Dimethyl-4-isopropyltetralin (VIII) (0.60 g, 0.003 mole) was alkylated in dry carbon disulphide solvent at 0° C with 0.55 g (0.003 mole) of 2,5-dichloro-2,5-dimethylhexane in the presence of 0.24 g (0.0018 mole) of aluminum chloride. After 6 hours reaction time, two layers were carefully separated by filtration and worked up separately to yield 0.43 g of white crystals from the carbon disulphide layer and 0.37 g of brownish white crystals from the solid complex layer. Recrystallizations from ethanol of the product from the solvent layer yielded crystals of m.p. 93.5–94.5° C. The mixed melting point of this compound with hydrocarbon V (Table I, No. 1) was 93.5–95° C. The infrared spectra of these two compounds in KBr pellets were identical. The product from the lower layer was recrystallized once from ethanol and sublimed to yield crystals of m.p. 122–124° C. The mixed melting point of this compound and hydrocarbon VI (Table I, No. 1) was 123–125° C. The infrared spectra of these two compounds in KBr pellets were identical.

(e) 1,1-Dimethyl-4-ethyltetralin

The Grignard reagent, ethyl magnesium iodide, was prepared in the usual manner from 2.68 g (0.017 mole) of ethyl iodide and 0.41 g (0.017 mole) of magnesium in 20 ml of anhydrous ethyl ether in an atmosphere of nitrogen. The Grignard reagent was cooled to 0° C and 4,4-dimethyl-1-tetralone (1.50 g, 0.0086 mole) in 20 ml of benzene was added over 20 minutes. The reaction mixture was then refluxed for 4.5 hours and at the end of that time it was worked up in the usual manner. The infrared spectrum of the crude product showed strong hydroxyl absorption. There was some carbonyl absorption indicative of some unreacted ketone. The crude product was then refluxed with aqueous oxalic acid for 21 hours to dehydrate the alcohol. The dehydrated product was chromatographed on alumina from petroleum ether to yield 0.88 g of hydrocarbon free of starting ketone. Gas–liquid chromatography indicated this material was pure.

This hydrocarbon was reduced in methanol over a palladium catalyst at 60 p.s.i. of hydrogen to yield pure 1,1-dimethyl-4-ethyltetralin. The hydrocarbon was further purified by repetitive gas–liquid chromatography. From infrared, ultraviolet, and n.m.r. spectra this compound was found to be identical with hydrocarbon XXIII produced by cyclization of 2-chloro-6-methyl-6-phenylheptane (Table I, No. 7).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(f) Benzsuberane

Benzsuberone was prepared by cyclization of 5-phenylvaleric acid (Adrich Chemical Co.) with polyphosphoric acid by the method of Muth and co-workers (17). The product was distilled at 3 mm, b.p. 122–123°, n_D^{20} 1.5659 (lit. (17) n_D^{20} 1.5642); λ_{max} 241 mμ, ϵ = 8382, λ_{max} 280 mμ, ϵ = 884. Carbonyl absorption appeared in the infrared at 1660 cm^{-1} and a strong band at 773 cm^{-1} was attributed to ortho-disubstitution. Benzsuberane was prepared by Clemmensen reduction of the above benzsuberone. The hydrocarbon was purified by gas–liquid chromatography for spectral analyses (Table II). The infrared band for ortho-disubstitution appeared at 754 cm^{-1}.

ACKNOWLEDGMENTS

This research was supported by grants from the National Research Council of Canada, the American Chemical Society (Petroleum Research Fund), Research Corporation (Frederick G. Cottrell grant), and Imperial Oil Limited.

We thank Dr. A. G. McInnes of the Atlantic Regional Laboratory, Halifax, Nova Scotia, for determining the nuclear magnetic resonance spectra. We thank Dr. T. F. Wood for a sample of 1,1-dimethyl-4-isopropyltetralin and Dr. H. Hart for a sample of 1,1,4,4-tetramethylbenzsuberane.

TOTAL SYNTHESIS OF STEROIDAL DERIVATIVES

III. SYNTHESIS OF HYDROCHRYSENE ANALOGUES AND RELATED COMPOUNDS[1]

JAMES P. KUTNEY AND ARNOLD BY
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

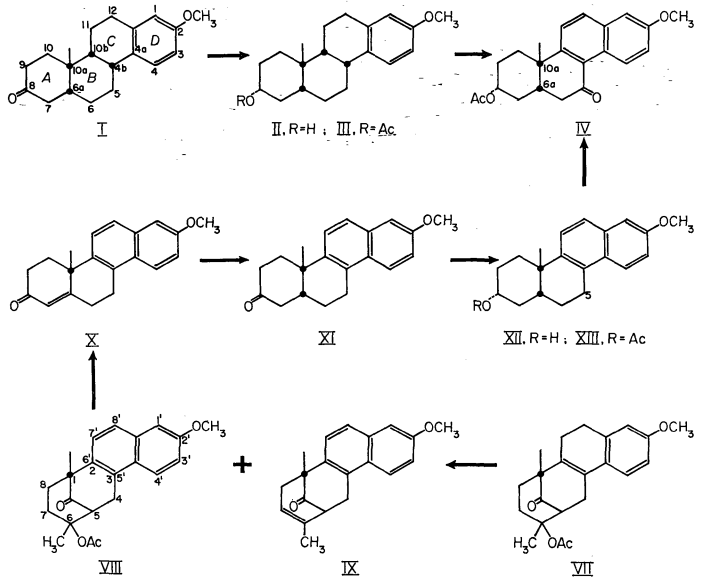
Received October 30, 1963

ABSTRACT

A synthetic sequence leading to the total synthesis of certain octahydrochrysene derivatives is described. The introduction of a ketonic function into ring B of these substances is also given and it is noted that these ketone intermediates allow entry into ring-B-modified steroidal analogues. The sequence indicates an interesting difference in the mode of reaction of cis–syn–cis and trans–anti–trans hydrochrysene analogues, which is undoubtedly due to the difference in the conformational structures of these compounds.

Recently we reported (1, 2) stereospecific syntheses leading to certain hydrochrysene analogues in both the trans–anti–trans and cis–syn–cis series. Having completed this phase of the investigation we then considered the introduction of functional groups into ring C of the hydrochrysene molecule (see I) to allow entry into intermediates where ring C had been opened. This goal was achieved in the trans–anti–trans series where a ketonic group was introduced at C_{12} (see I) by the use of the sterically large oxidant, namely *t*-butyl chromate (2). We would now like to present similar studies in the cis–syn–cis series which indicate a rather remarkable difference in reaction from that of the former series.

The ketone, I, synthesized previously (1) was reduced with lithium aluminum hydride to give a good yield of the cis–syn–cis alcohol, II. The assignment of the equatorial (8 α) hydroxyl group is well supported by previous work (3). The alcohol was acetylated by means of isopropenyl acetate and the corresponding acetate, III, was oxidized under



[1]*Presented, in part, at the Second International Symposium on the Chemistry of Natural Products, Prague, Czechoslovakia, August 27–September 2, 1962.*

conditions *identical* with those utilized for the preparation of the trans–anti–trans-2-methoxy-12-keto compound (2). To our surprise, the spectral properties of the reaction product suggested immediately that the expected cis–syn–cis-2-methoxy-12-keto compound was not being isolated. Indeed the data indicated that an aromatization of ring C had occurred and furthermore, on subsequent comparison with data already available from other work in our laboratory, established that the structure of this oxidation product was the octahydrochrysene analogue, IV. This latter substance had been synthesized by an unambiguous route for another purpose and its synthesis is presented below.

During the early course of our investigations it became apparent that the readily available keto acetate, VII (1) by virtue of its bridged structure, should provide an obvious access to octahydrochrysene derivatives possessing an aromatic C ring. It was clear that dehydrogenation studies may provide fruitful results since aromatization of ring C would take place rapidly but any further aromatization of the molecule must be preceded by bond fission at one of the bridged carbon atoms. Indeed when the keto acetate, VII, was treated with 10% palladium on carbon, it gave, in good yield, a new crystalline product. The spectral data provided strong evidence for the success of the dehydrogenation and was in complete agreement with the expected structure, VIII. In particular the ultraviolet spectrum was very informative here and showed the typical complicated spectrum of a naphthalenic chromophore (λ_{max} 231, 266, 277, 287, 307, ca. 315 (shoulder), 321, 330, and 335.5 mμ). Apart from the usual carbonyl absorption characteristic of the ketone and acetate functions in the infrared spectrum (5.84, 5.79 μ), the nuclear magnetic resonance (n.m.r.) spectrum of this substance also indicated some interesting features. For example, the C_1-methyl peak now occurred at 8.47 τ and the methoxyl signal at 6.10 τ represented a downfield shift when compared to the corresponding signals in the spectrum of the starting material. However, as would be expected, the signals for the methyl group at C_6 (8.32 τ) and for the acetate methyl group (8.0 τ) have not been effected to an appreciable extent. Furthermore the increase in the area under the aromatic signals indicated that aromatization of ring C had occurred. During the dehydrogenation reaction, some acetic acid was evolved and, as a minor product, an olefinic material was also isolated. This olefinic material was proved to be 1β,6-dimethyl-2,3-(2′-methoxy-6′,5′-naphtho)-$\Delta^{2,6}$-bicyclo[3.3.1]-nonadiene-9-one (IX) on the basis of the following evidence. The infrared spectrum of this olefin showed only ketonic function (5.84 μ) and the ultraviolet spectrum, which was superimposable on the spectrum of VIII, excluded any further skeletal degradation. The n.m.r. spectrum of this compound still retained the C_6-methyl signal at 8.32 τ but now also indicated a weak, broad absorption in the olefinic region (4.75 τ) due to the endocyclic olefinic proton. It is clear that the exocyclic olefin, which was also a possible product in this reaction, was not formed since it would not exhibit any signal at high field for the C_6-methyl group and would have an olefinic signal at higher field than observed in the above spectrum.

Having obtained the bridged intermediate with rings C and D aromatic, it was then desirable to convert this substance into the hydrochrysene skeleton. Consequently the keto acetate, VIII, was subjected to a retroaldol rearrangement (1) and the expected tetracyclic α,β-unsaturated ketone, X, was obtained in excellent yield. The success of the reaction was indicated by the appearance of a conjugated ketonic absorption in the infrared spectrum (6.04 μ) and also by the appearance of an additional chromophore (λ_{max} 236 mμ) in the ultraviolet spectrum. The n.m.r. spectrum of X now showed only *one* methyl signal at high field (8.37 τ) and a weak signal at 4.04 τ due to the olefinic proton.

In order to provide further desirable derivatives in this series, the unsaturated ketone,

X, was hydrogenated with 10% palladium on carbon in a benzene solution containing a trace of 48% hydrobromic acid. These reaction conditions are known to provide a ring A/B cis fusion in some related syn–cis series (1, 4) and it was felt that a similar situation may prevail here. The reduction product, XI, can, in fact, be assigned the A/B cis configuration since it was subsequently converted to the monoketone, IV, wherein the assignment of carbon atoms 6*a* and 10*a* can be made with certainty. The saturated ketone, XI, then reduced with lithium aluminum hydride to the saturated alcohol, XII, and this latter substance was acetylated by the use of isopropenyl acetate to provide a good yield of the crystalline acetate, XIII. This sequence completed the first phase of this investigation, namely the construction of hydrochrysene derivatives possessing aromatic rings C and D.

It was now necessary to consider the introduction of a carbonyl function at the benzylic position (C_5, see XIII) since this would allow entry into ring B—a desirable feature for other studies in our laboratory. For this purpose, three different reaction conditions were investigated: (1) a refluxing solution of *t*-butyl chromate in carbon tetrachloride and acetic anhydride, (2) a solution of chromium trioxide in aqueous acetic acid at room temperature, and (3) a refluxing solution of *t*-butyl chromate in carbon tetrachloride. The first set of conditions did not give the desired ketone, but instead some other oxidation products which were not investigated any further. The second method, similar to that used by Barnes and Beachem (5), gave only a 12% yield of the desired ketone and about 12% recovery of starting material, while the use of *t*-butyl chromate in carbon tetrachloride proved most satisfactory. Under optimum conditions, the latter oxidizing agent provided 30% of the desired ketone, IV, and allowed recovery of 19% of starting material. The infrared spectrum of the desired ketone showed the presence of a conjugated ketone and an acetate group (6.03, 5.79 μ) and the n.m.r. spectrum showed some interesting changes from that of the starting material, XIII. For instance, the angular methyl signal was shifted downfield to 8.63 τ and a considerable difference was noted in the aromatic region. In particular, a doublet corresponding to one proton was found at 0.78 τ and is suspected to be due to the C_4 aromatic hydrogen atom. It may be expected that this proton would be deshielded by virtue of its close proximity to the carbonyl oxygen at C_5. At this point, this sequence not only provided a good synthetic intermediate for the subsequent synthesis of ring B modified steroidal analogues but also allowed us to establish the structure of the oxidation product in the reaction of *t*-butyl chromate on the cis–syn–cis hydrochrysene analogue, III. This latter substance was identical in every respect with the monoketone, IV, from the above synthesis.

The formation of the monoketone, IV, from III is quite remarkable considering the fact that under *identical* conditions, the corresponding trans–anti–trans compound is converted to the expected ketonic substance. It is clear from numerous investigations in our laboratory, some of which are already published (2), that the introduction of a substituent at C_{12} always receives serious competition from the tertiary carbon designated as 4*b* since the latter, by virtue of its para relationship to the methoxyl group, is highly reactive. Indeed, as indicated previously (2), *t*-butyl chromate, which is an oxidizing agent possessing considerable bulk, is the only reagent which allows attack at C_{12} in preference to C_{4b} in the trans–anti–trans series. The isolation of IV indicates that this tertiary center (4*b*) in the cis–syn–cis series must be more accessible to attack even by *t*-butyl chromate than in the trans–anti–trans series. A study of molecular models of both series reveals information in support of this proposal. Consideration of the model for the trans–anti–trans series (XIV) shows the well-known rigid flat skeleton encountered in the steroid

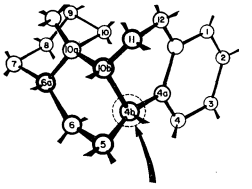
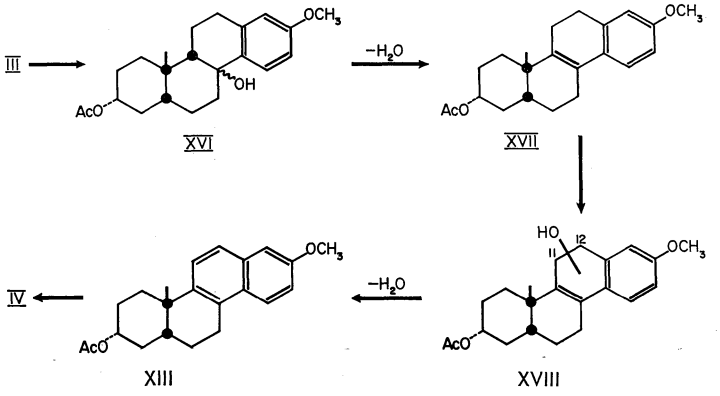
XIV



XV



series and reveals that any attack at C_{4b} is hindered particularly by the angular methyl group at C_{10a} and by atoms in a 1:3 diaxial relationship to the hydrogen atom at C_{4b}. On the other hand, although the cis–syn–cis skeleton is considerably less rigid and several conformations become possible, it is clear that any of these conformations must possess a "bent" structure so that C_{4b} is now more accessible. Furthermore the angular methyl group does not hinder any approach of the attacking reagent, which must certainly approach from the "side" of the molecule possessing the flat, aromatic ring. To illustrate this point, one possible conformation is reproduced in XV.

A mechanism for the formation of IV is presented below although it must be emphasized that this is merely speculation and we do not have any experimental evidence in support of this mechanism.

We feel that the initial step involves formation of the tertiary alcohol XVI, which would be expected to dehydrate readily to XVII. This latter intermediate possessing an allylic carbon (C_{11}) and a benzylic carbon (C_{12}) could be oxidized at either one of these positions to provide XVIII, which would immediately aromatize to XIII. Subsequent oxidation of XIII then yields the final product, IV.

We hope to present, in forthcoming publications, the value of intermediates such as IV in the synthesis of certain novel steroidal analogues.

EXPERIMENTAL

All melting points were determined on a Fischer–Johns apparatus and are uncorrected. The ultraviolet spectra were recorded in 95% ethyl alcohol on a Cary 11 or 14 recording spectrophotometer. Infrared spectra were recorded as potassium bromide pellets on a Perkin–Elmer Model 21 spectrophotometer. The n.m.r. spectra were taken at 60 Mc/second on a Varian A 60 instrument. In all cases, tetramethylsilane was the internal standard with its signal set at 10.0 τ units and the positions of all the signals are given in the Tiers τ scale. Integration of areas under the signals was carried out and the number of protons corresponding to each signal is indicated in parentheses. Deuteriocholoroform was the solvent used in all cases. The analyses were performed by Dr. A. Bernhardt and his associates, Mulheim (Ruhr), Germany, and by Mrs. A. Aldridge, University of British Columbia.

Synthesis of cis–syn–cis-2-Methoxy-8α-hydroxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene (II)

The saturated ketone, I (1.43 g) was dissolved in a mixture of benzene (20 ml) and dioxane (49 ml), and to this solution, anhydrous ethyl ether (98 ml) was added. A solution of lithium aluminum hydride (0.773 g) in anhydrous ethyl ether (19.5 ml) was added dropwise, over a 15-minute period, to the stirred refluxing mixture. After the addition was complete, the solution was refluxed for an additional hour after which time it was cooled and treated with ethyl acetate to decompose the excess hydride. The reaction mixture was made acidic by the addition of a solution of concentrated sulphuric acid (0.6 ml) in water (7 ml). Finally, the mixture was diluted with water and the organic layer was separated. The aqueous layer was extracted with ether and the combined ether extract was washed with a saturated solution of sodium bicarbonate, then with cold water, and finally dried over anhydrous magnesium sulphate. Removal of the drying agent and evaporation of the solvent *in vacuo* provided a slightly yellow gum (1.6 g). It was found that purification could not be successfully accomplished by recrystallization and the product was therefore chromatographed on alumina (40 g). Elution with benzene–chloroform (2:3) mixture gave the desired alcohol, II (1.11 g). Several recrystallizations from benzene – petroleum ether provided the analytical sample as colorless needles, m.p. 124–125°. Infrared: 2.93 μ; ultraviolet: λ_{max} 221 (log ϵ 3.88), 279 (log ϵ 3.31), and 287 mμ (log ϵ 3.31); λ_{min} 246 (log ϵ 2.46) and 285 mμ (log ϵ 3.23); n.m.r. signals: 8.90 τ (angular methyl, area = 3H), 6.25 τ (CH_3O—, area = 3H), broad signal ca. 6.43 τ (*H*—C—OH, area = 1H), multiplet centered at 3.15 τ (aromatic H, area = 3H). Found: C, 79.52; H, 9.32; O, 11.45. Calc. for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39; O, 10.65.

Synthesis of cis–syn–cis-2-Methoxy-8α-acetoxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene (III)

A solution of the saturated alcohol, II (1.822 g) in isopropenyl acetate (21 ml) and *p*-toluenesulphonic acid monohydrate (70 mg) was refluxed for 5 hours. The mixture was concentrated *in vacuo* and the residue was treated repeatedly with ether and water. The combined ether extract was washed with a saturated solution of sodium bicarbonate and then water. After drying over anhydrous magnesium sulphate, the solvent was removed to yield a crude gum (2.011 g). Recrystallization from benzene – petroleum ether gave colorless plates (1.404 g), m.p. 110°. Infrared: 5.81 μ; ultraviolet: λ_{max} 221 (log ϵ 3.89), 280 (log ϵ 3.29) and 287 mμ (log ϵ 3.29); λ_{min} 285 mμ (log ϵ 3.22); n.m.r. signals: 8.90 τ (angular methyl, area = 3H), 8.00 τ ($CH_3C(=O)$—, area = 3H), 6.27 τ (CH_3O—, area = 3H), broad multiplet centered at 5.22 τ (*H*—C—OAc, area = 1H), multiplet centered at 3.06 τ (aromatic H, area = 3H). Found: C, 77.22; H, 8.82; O, 14.21. Calc. for $C_{22}H_{30}O_3$: C, 77.15; H, 8.83; O, 14.02.

Oxidation of cis–syn–cis-2-Methoxy-8α-acetoxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene

A solution of *t*-butyl chromate in carbon tetrachloride was prepared according to the procedure of Heusler and Wettstein (6) except that the final solution was concentrated to 600 ml instead of 1000 ml. Aliquots of this solution were then used for the various experiments.

The acetate, III (550 mg) was dissolved in dry carbon tetrachloride (17.5 ml) and to this solution, acetic anhydride (8.7 ml) and *t*-butyl chromate (17.5 ml, about 0.003 moles CrO_3 per milliliter) were added. The mixture was refluxed for 3 hours during which time a green precipitate gradually formed. The reaction mixture was cooled and a solution of oxalic acid (5 g) in water (35 ml) was added. This mixture was then stirred at room temperature for 2 hours. The resulting mixture was diluted with chloroform and water, and the layers were separated. The aqueous layer was extracted twice with chloroform, and the combined reddish chloroform extract was washed twice with cold water and three times with a solution of sodium carbonate (10 g) in a saturated aqueous solution of sodium bicarbonate (100 ml). The basic aqueous layer was extracted once with chloroform and this extract was added to the main chloroform extract. The pink aqueous basic layer was made acidic with concentrated sulphuric acid to yield a yellow solution which was then extracted with chloroform. After this extract was dried over anhydrous magnesium sulphate, the solvent was evaporated to yield a yellow acidic gum (16 mg).

The chloroform extract containing the neutral materials was washed several times with cold water and then dried over anhydrous magnesium sulphate. Removal of the solvent provided the main neutral product (0.578 g). This neutral material was taken up in benzene (5 ml) and chromatographed on deactivated alumina (30 g, approx. activity II–III). Elution with benzene gave in the initial fractions an orange gum (75 mg) which contained some starting material and the keto-acetate, IV. Further elution with benzene gave more of the keto-acetate, IV (108 mg). This latter fraction was crystallized from benzene – petroleum ether to provide pure IV, m.p. 143–144.5°. A comparison of this product (mixed melting point, infrared, ultraviolet, and n.m.r.) with the compound IV, prepared unambiguously via the octahydrochrysene series below, showed both of these to be identical.

Synthesis of 1β,6-Dimethyl-6-acetoxy-2,3-(2′-methoxy-6′,5′-naphtho)-Δ²-bicyclo[3.3.1]nonene-9-one (VIII)

The unsaturated keto-acetate, VII (1.0 g) was mixed and powdered with 10% palladium on carbon (0.75 g) in a 250-ml three-necked flask. The flask was then heated for 3 minutes at 230–235° with nitrogen passing over the mixture. Bubbling generally took place in the first 2 minutes and some acetic acid was evolved near the end of the heating period. After it was cooled to room temperature, the residue was treated with hot benzene, the catalyst filtered, and the solvent removed *in vacuo* to yield 0.94 g of a product. This material was dissolved in benzene (7 ml) and chromatographed on deactivated alumina (60 g, approx. activity II–III). Elution with 2:3 benzene – petroleum ether yielded first a solid material which, on two recrystallizations from benzene – petroleum ether gave an analytical sample of 1β,6-dimethyl-2,3-(2′-methoxy-6′,5′-naphtho)-$\Delta^{2,6}$-bicyclo[3.3.1]nonadiene-9-one (IX), m.p. 181.5°–182. Infrared: 5.84 μ; ultraviolet: λ_{max} 231 (log ε 4.76), 266 (log ε 3.77), 276 (log ε 3.76), 286 (log ε 3.57), 307 (log ε 3.02), broad shoulder at 315 (log ε 3.06), 320 (log ε 3.72), 329 (log ε 3.16), and 335 mμ (log ε 3.34); λ_{min} 261 (log ε 3.72), 271 (log ε 3.71), 284.5 (log ε 3.58), 303 (log ε 2.96), 310 (log ε 2.99), 325 (log ε 3.12), and 331 mμ (log ε 3.15); n.m.r. signals: 8.48 τ (angular methyl, area = 3H), quartet centered at 8.32 τ (CH_3—C=C, area = 3H), 6.12 τ (CH_3O—, area = 3H), broad signal centered at 4.75 τ ( , area = 1H), multiplet centered at 2.47 τ (aromatic H, area = 5H). Found: C, 82.04; H, 7.10. Calc. for $C_{20}H_{20}O_2$: C, 82.15; H, 6.89.

Further elution with 3:2 benzene – petroleum ether gave the desired keto acetate, VIII (767 mg). Several recrystallizations from aqueous ethyl alcohol or benzene : petroleum ether gave colorless square plates, m.p. 185.5–186°. Infrared: 5.79 μ, 5.84 μ; ultraviolet: λ_{max} 231 (log ε 4.75), 266 (log ε 3.76), 277 (log ε 3.74), 287 (log ε 3.57), 307 (log ε 3.03), broad shoulder at 315 (log ε 3.09), 321 (log ε 3.25), 330 (log ε 3.18), and 335.5 mμ (log ε 3.36); λ_{min} 262 (log ε 3.72), 272 (log ε 3.69), 303 (log ε 2.97), 311 (log ε 3.00), 326 (log ε 3.14), and 331 mμ (log ε 3.18); n.m.r. signals: 8.47 τ (angular methyl, area = 3H), 8.32 τ (CH_3—C—OAc, area = 3H), 8.0 τ (CH_3—C(=O)—, area = 3H), 6.10 τ (CH_3O—, area = 3H), multiplet centered at 2.46 τ (aromatic H, area = 5H). Found: C, 74.89; H, 7.04. Calc. for $C_{22}H_{24}O_4$: C, 74.98; H, 6.86.

Synthesis of 2-Methoxy-8-keto-10a-methyl-5,6,8,9,10,10a-hexahydrochrysene (X)

The apparatus used in this experiment was set up exactly as in the tricyclic ketone preparation (1) in order to maintain anhydrous conditions and a nitrogen atmosphere at all times.

A 1-liter three-necked flask was charged with anhydrous methanol (318 ml) and then sodium (2.94 g) was added gradually in small pieces. After the sodium had reacted, the methoxide solution was cooled, and the entire apparatus evacuated until the solvent began to boil. Dry nitrogen was admitted, the system evacuated again, and the entire process repeated several times. To the stirred methoxide solution, a solution of the acetate, VIII (7.188 g) in dry benzene (81 ml) was added through a dropping funnel under a flow of escaping nitrogen. After the addition was complete, the system was evacuated, and dry nitrogen admitted to ensure complete removal of oxygen. The reaction mixture was then refluxed for 5 hours in this inert atmosphere. At the end of the reflux period, the solution was cooled in ice, glacial acetic acid (8.5 ml) was added, and the mixture was swirled for several minutes. Some water and benzene were added to the reaction flask, the layers were then separated, and the aqueous layer was extracted three times with benzene. The combined benzene extract was washed with a cold saturated solution of sodium chloride and then dried over anhydrous magnesium sulphate. Evaporation of the solvent *in vacuo* yielded a yellow crystalline product (5.808 g). Decoloration with Norite and three recrystallizations from benzene provided X, m.p. 198–199°. Infrared: 6.04 μ; ultraviolet: λ_{max} broad shoulder at 230 (log ε 4.83), 236 (log ε 4.86), broad shoulder at 262 (log ε 3.94), 274 (log ε 3.84), broad shoulder at 284 (log ε 3.65), 306 (log ε 3.05), broad shoulder at 314 (log ε 3.12); 319 (log ε 3.28), 327 (log ε 3.22), and 333.5 mμ (log ε 3.38); λ_{min} 270 (log ε 3.82), 301 (log ε 2.99), 308 (log ε 3.03), 324 (log ε 3.18), and 329 mμ (log ε 3.20); n.m.r. signals: 8.37 τ (angular methyl, area = 3H), 6.10 τ (CH_3O—, area = 3H), 4.04 τ ( , area = 1H), multiplet centered at 2.43 τ (aromatic H, area = 5H). Found: C, 82.45; H, 6.68; O, 11.08. Calc. for $C_{20}H_{20}O_2$: C, 82.15; H, 6.89; O, 10.95.

Synthesis of cis-2-Methoxy-8-keto-10a-methyl-5,6,6a,7,8,9,10,10a-octahydrochrysene (XI)

A solution of the α,β-unsaturated ketone, X (1.39 g) in benzene (94 ml) was treated with 10% palladium on carbon (0.338 g) and three drops of 48% hydrobromic acid. This mixture was hydrogenated at room temperature and atmospheric pressure for 3½ hours, after which time 1 mole of hydrogen had been absorbed. The catalyst was removed by filtration and was then washed with hot benzene. After evaporation of the solvent *in vacuo*, a gum (1.497 g) was obtained. This gum was dissolved in benzene (15 ml) and chromatographed on deactivated alumina (80 g, approx. activity II–III). Elution with 1:2 benzene – petroleum ether provided a fraction (1.405 g) which crystallized from ethyl ether. Two further recrystallizations from
