
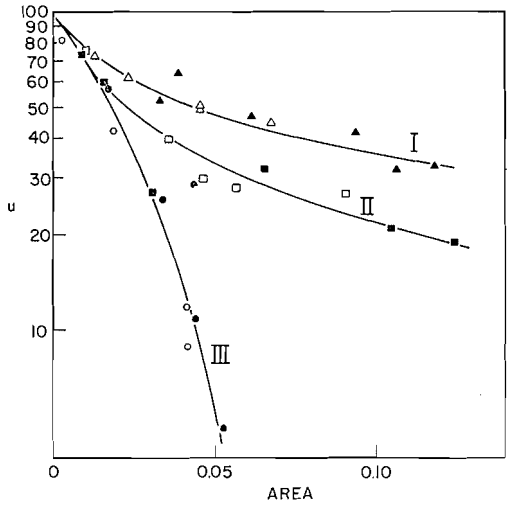

FIG. 3. Plot of equation [3] for three samples (I, II, and III) of the catalyst. (Catalyst weight: 40 mg of 5% Pt on asbestos. The arbitrary unit of the active areas shown on the abscissa corresponds to 1.9×10^{-2} micromoles of butene desorbed. Open and filled symbols indicate two different sets of experiments on the same catalyst samples.)

by poisoning. Qualitatively the trend is as predicted, and a correlation is evident between the activity and the active area measured from the amount of the displaced butene-1. However, there is an appreciable scatter of points and the plots are not linear. Moreover, both convex and concave curvatures are obtained.

In conclusion, it appears that, in spite of the difficulties indicated above, the described technique is capable of providing useful information. More extensive observations with a variety of olefins and, in particular, with simultaneous use of isotopic labelling are likely to enhance further its usefulness. These extensions were not feasible in the course of the preliminary work reported in this communication.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Y. Amenomiya for much helpful discussion and Mr. M. Bednas for assistance in setting up the gas chromatographic part of the apparatus.

Cl^{35} PURE QUADRUPOLE RESONANCE FREQUENCIES IN THE CYCLIC PHOSPHONITRILIC CHLORIDE POLYMERS

M. A. WHITEHEAD
Chemistry Department, McGill University, Montreal, Quebec
Received July 11, 1963

ABSTRACT

Pure nuclear quadrupole resonance frequencies of Cl^{35} in the cyclic phosphonitrilic chloride polymers, $(PNCl_2)_n$ have been observed for $n = 3$, 4, 5, and 6. For both the tetramer and hexamer two different crystal structures were studied. The observed frequencies are discussed assuming that the phosphorus–nitrogen ring system possesses a polyallylic bond structure. Several substituted polymers were examined ($P_3N_3Cl_4\phi_2$, $P_4N_4Cl_7\phi_4$, $P_3N_3(i\text{-}PrNH)_4Cl_2$, $P_3N_3Cl_2\phi_4$) but only diphenyl-tetrachloro trimer, $P_3N_3Cl_4\phi_2$, gave a frequency measurement. The ratio of the Cl^{35} quadrupole frequencies in two compounds is compared with the ratio of the effective orbital electronegativities of the phosphorus atom in the compounds.

INTRODUCTION

The pure nuclear quadrupole (n.q.r.) resonance of Cl^{35} has been observed in the cyclic phosphonitrilic halide polymers $(PNCl_2)_n$, for $n = 3$, 4, 5, and 6. The resonances were detected with a self-quenching super-regenerative oscillator unit, of the type described by Dean (2, 3). Low frequency (30–60 c.p.s.) frequency modulation across the resonance frequency allowed direct oscilloscope display of the signal. The signal was recorded using an on–off antisymmetric square wave of magnetic field over the sample, a phase-sensitive detector, and a narrow band amplifier. The resonance frequencies were measured with a BC 221 frequency meter; they are listed in Table I. The average frequency of the closely spaced lines from a given polymer is listed in Table II, which also lists the frequencies for comparable compounds.

TABLE II

Average Cl^{35} nuclear quadrupole resonance frequencies at 77° K in Mc

Ring compounds		Linear compounds	
Formula	Frequency in Mc/second	Formula	Frequency in Mc/second
$(PNCl_2)_3$	28.4564	SO_2Cl_2	37.7
$a\text{-}(PNCl_2)_4$	28.6483	$SOCl_2$	31.9
$b\text{-}(PNCl_2)_4$	28.6483	$POCl_3$	28.96
$(PNCl_2)_5$	28.15	PCl_3	26.2
$a\text{-}(PNCl_2)_6$	28.42	$COCl_2$	35.7
$b\text{-}(PNCl_2)_6$	27.97	CCl_4	40.6
$(SNCl)_3$	29.8	BCl_3	21.62
$(CNCl)_3$	36.3	$\phi POCl_2$	25.357
$(BNHCl)_3$	19.937		

Van Wazer (4) reports that from atom–atom distances the trimer and tetramer have 0.2 π character in the P—N bond and 0.1 π character in the P—Cl bond, but no such results are available for the higher polymers. Since all the polymers display similar chemical properties (5), it is to be expected that all will have similar amounts of π bonding, and that the frequencies will be in the same region throughout the series, as is the case (Table II). The actual shape of each polymer differs (6, 7), however, and their frequencies differ in detailed structure due to crystal field effects (Table I). The P—N ring is slightly

puckered in the solid state, the exact shape depending on which polymer is examined (8–14). In all the polymers the chlorine atoms are in a plane perpendicular to the P—N ring. When these molecules are packed together in a crystal, models show that several possible crystallographically inequivalent lattice sites are available to the chlorine atoms. These are responsible for the closely spaced lines in the quadrupole resonance (15). Two crystal forms of the tetramer $(PNCl_2)_4$ and hexamer $(PNCl_2)_6$ were examined. These have been differentiated in this work as *a*- and *b*-forms. The *a*-$(PNCl_2)_4$ is obtained from crystallization of the polymer from benzene near room temperature and is metastable. All the P—N bonds are of identical length. The ring is tub shaped. The *b*-$(PNCl_2)_4$ is obtained by crystallization from solvents at 60°, or from the melt. It has the same space group (P_{4_2}/n) as the *a*-form but different unit cell dimensions. In the hexamer both *a*-$(PNCl_2)_6$ and *b*-$(PNCl_2)_6$ are triclinic with different unit cell dimensions (13).

The puckered ring has several possible structures divisible into "tub" and "chair" forms (16); both forms are expected to be possible in the tetramer; the chair form may therefore be responsible for the second crystal structure, since the *a*-form is known to be tub shaped. This is true in $(PN(NMe)_2)_4$ and $(PN(CH_3)_2)_4$, but $(PNF_2)_4$ has a planar ring, due to special considerations.

In the trimer no such variable crystal structures occur (17). The trimer structure has been fully elucidated by X-ray analysis (17). The ring is almost planar and has ring angles of approximately 120°, is orthorhombic, and belongs to the *Pnma* space group.

The two crystal forms of the tetramer give almost identical n.q.r. frequencies at the liquid nitrogen temperature; they distinctly differ at room temperature. At room temperature the *b*-$(PNCl_2)_4$ lines are broad and indistinct, while the *a*-$(PNCl_2)_4$ lines are well separated and sharp.

The change in frequency with temperature of the *a*- and *b*-tetramer shows an interesting phenomenon. Both crystal forms show a frequency increase with temperature decrease. This is quite normal (18, 19). However, the *a*-form has line separations of 0.1314 mc/second at 293° K, and 0.0225 at 77° K, while the *b*-form appears to have a very small separation (if one at all) at 293° K and 0.0207 at 77° K. The *a*-$(PNCl_2)_4$ line separation depends on temperature as predicted by Gutowsky and McCall (20), while the *b*-$(PNCl_2)_4$ shows a dependence similar to that previously found in 2,2,2′,2′-tetrachlorobicyclopropyl, $Cl_2C_3H_3C_3H_3Cl_2$ (21). The *a*-$(PNCl_2)_4$ lines should coalesce at even lower temperatures and the *b*-$(PNCl_2)_4$ should separate further.

Neither crystal form of $(PNCl_2)_4$ displayed four lines similar to those reported by Negita and Satou for the $(PNCl_2)_4$ sample that they examined at room temperature (22). Initially it was assumed that they must have examined *a*-$(PNCl_2)_4$ since the sample displayed distinct lines. However, if the two distinct crystal forms are due to the molecule being in the tub and chair configurations, then the frequency differences between them would be due to molecular inequivalence rather than crystallographic inequivalence of the chlorine atoms. Thus if the two molecular configurations were to occur together, the lines due to both would be observed, and due to molecular dilution of one configuration by the other, the spectrum could have a larger signal-to-noise ratio and a sharper spectrum for each than in the pure molecular form. If, as discussed above, the *b*-lines approach as the temperature is raised, while the *a*-lines diverge, then at room temperature the mixed *a*- and *b*-$(PNCl_2)_4$ would have a pattern very similar to that of Negita and Satou. We have failed to resolve the absolute frequency difference (Fig. 1(*b*)) (22). Our results agree with those of Torizuka (23) both to the number of lines, and absolute frequency at room temperature.

TABLE I

Cl^{35} pure quadrupole resonances at room and liquid nitrogen temperatures

Compound	Frequency (megacycles per second)	Temperature	Approximate signal-to-noise ratio	Method of measurement	Comments*
$(PNCl_2)_3$	27.5391	293° K	2:1		
	27.6201		1:1	Visual	The lines at room temperature were broad. They narrowed but did not increase size at liquid nitrogen temperature

TABLE I (*concluded*)

Compound	Frequency (megacycles per second)	Temperature	Approximate signal-to-noise ratio	Method of measurement	Comments*
a-$(PNCl_2)_6$ Crystal A	28.4	77° K	2:1	Recorder	Broad and diffuse, and difficult to fix
b-$(PNCl_2)_6$ Crystal B	27.6822 27.7470 27.7938 27.8262 27.8730 27.9216 27.9720 28.0260 28.0395 28.0890 28.3095 28.4157	77° K		Visual	
$P_3N_3Cl_4\phi_2$	27.4 27.8	77° K	3:1 1:1	Recorder Visual	Lines broad and indistinct. Both ϕ on same phosphorus atom
$P_4N_4Cl_4\phi_4$ $P_3N_3(i\text{-}PrNH)_4Cl_2$ $P_3N_3\phi_4Cl_2$	Failed to give any results or disturbance in region 20 → 35 Mc				
$(PNCl_2)_3.HClO_4$	28.3040 28.3296 28.6024 28.6888	77° K	1:1 2:1 1:1 2:1	Visual	Only broad disturbance at 293° K about 27.8 Mc distinct sharp lines at 77° K
$(PNCl_2)_3.HBF_4$	Disturbance at 293° K and very strong at 77° K, but no individual lines detectable visually or by recorder. 28.3 28.5 Mc				
$(CH_3NPCl_3)_2$	No signal 20 → 45 Mc				

* No attempt was made to measure line widths; lines are reported as sharp, broad, or diffuse in accordance with accepted n.q.r. nomenclature. (P. J. Bray, R. G. Barnes, and R. Bersohn. J. Chem. Phys. 25, 813 (1956).)

†H. Negita and S. Satou. J. Chem. Phys. 24, 621 (1956). K. Torizuka. J. Phys. Soc. Japan, 11, 84 (1956).

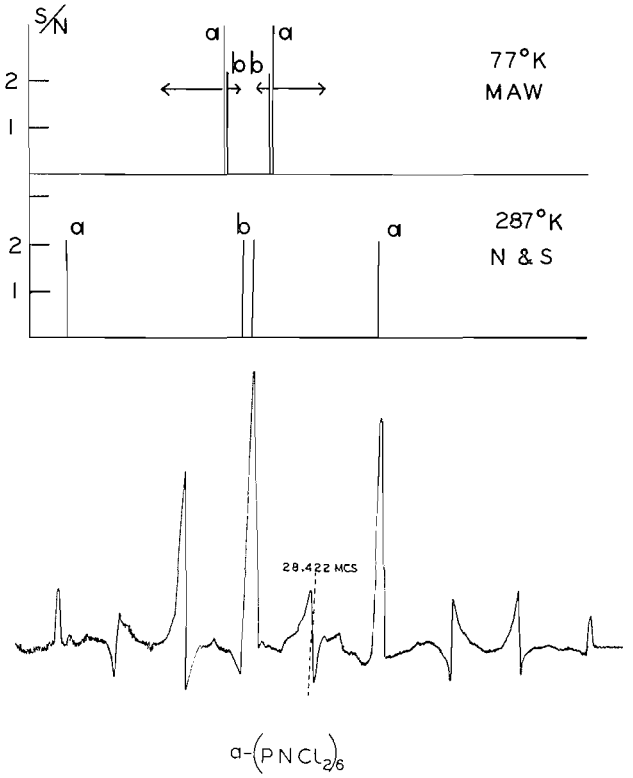

FIG. 1. (*a*) The superimposed spectra of *a*-$(PNCl_2)_4$ and *b*-$(PNCl_2)_4$ at 77° K and the predicted change of frequency with increasing temperature from the results and discussion in this paper. (*b*) The spacing of the four spectral lines in $(PNCl_2)_4$ at 287° K as measured by Negita and Satou, which may be due to their sample being a mixture of the two crystal forms *a*-$(PNCl_2)_4$ and *b*-$(PNCl_2)_4$. (*c*) Recorded nuclear quadrupole spectrum of *a*-$(PNCl_2)_6$, having only one resonance line, using a self-quenching superregenerative oscillator and 50 c/second antisymmetric square wave magnetic modulation. The quench frequency was 50 kc/second. Eight side bands are shown.

In the case of $(PNCl_2)_3$, the signal-to-noise ratio and the number of lines observed agree with the results of Negita and Satou at 293° K, but again an unresolved frequency shift is observed. When the temperature is changed to 77° K, the order of lines (as judged from their signal-to-noise ratio) changes, showing that the various frequencies have different temperature dependences. In the trimer Torizuka (23) reported only two lines which agree with two of the four lines reported in this paper.

While the relative signal-to-noise ratios describe the relative numbers of chlorine atoms in a given crystallographic situation, they do not show whether these chlorine atoms are on the same or different molecules; thus it is impossible to deduce whether there are twice as many molecules in one crystallographic situation as in another, or only twice as many chlorine atoms (15).

Only the diphenyl-tetrachloro-substituted trimer in which the disubstitution occurred on a single phosphorus atom gave a frequency. No frequencies were detected for the tetraphenyl-dichloro tetramer, $\phi_4P_4N_4Cl_4$, the tetra-isopropylamine-dichloro trimer, $P_3N_3(i\text{-}PrNH)_4Cl_2$, or the tetraphenyl-dichloro trimer, $\phi_4P_3N_3Cl_2$, as a result of any of the following effects: (i) the increased crystallographic disorder which results from packing non-symmetrical ring systems together, (ii) the strain occurring in the crystal,

and (iii) the dilution of the chlorine density in the crystal. The broadness and indistinctness of the diphenyl-tetrachloro trimer, $\phi_2P_3N_3Cl_4$, resonance, even at liquid nitrogen temperature, shows that the bulky phenyl groups cause not only a chlorine density dilution (which decreases the signal to noise ratio) but also either, or both, of effects (i) and (ii) (24).

EXPERIMENTAL

The phosphonitrilic chloride polymers were lent by Albright and Wilson Ltd., by arrangement with Dr. Childs, in the pure crystalline state and in sealed tubes of the exact size to fit the resonance coil; the substituted polymers were lent by Dr. R. A. Shaw, of Birkbeck College, London, and made in his Research School by S. K. Ray. They were spectroscopically pure and sealed in appropriate size tubes. Those samples for which resonance frequencies were not detected were recrystallized slowly from the melt in an attempt to obtain strain-free crystals, the work being carried out in a dry box under nitrogen gas, free of oxygen and hydrogen.

The $(PNCl_2)_3.HClO_4$ was made and purified by the procedure of Bode *et al.* (25), and preparation of the $(PNCl_2)_3.HBF_4$ followed the same procedure, replacing the 60% $HClO_4$ by 60% HBF_4 at the appropriate step. The crystals were subsequently filtered and dried under an atmosphere of pure dry nitrogen.

The super-regenerative oscillator (15) has a basic disadvantage when multiple lines are observed in a sample. Both self- and external-quenching produce frequencies on either side of the fundamental carrier, spaced at integral multiples of the quench frequency. Thus any side band of sufficient intensity can excite a quadrupole resonance as the oscillator carrier frequency is scanned. The actual frequency is obtained by re-examining the spectrum at a new quench frequency, when the side band frequencies will change but the fundamental frequency will remain unchanged. In the apparatus used, three side bands were observed on either side of the fundamental, or seven lines per true resonance. Thus for *b*-$(PNCl_2)_6$ a total of up to 84 lines could be seen. Actually 65 were observed at any one time, since side bands due to one true resonance can add to, or subtract from, side and fundamental lines due to another true resonance. Up to 10 different quench settings were needed to analyze the complex spectrum of $(PNCl_2)_5$ and *b*-$(PNCl_2)_6$. It was impossible to use the recording techniques available with either of these spectra. Figure 1(*c*) shows a recorded line from *a*-$(PNCl_2)_6$ which has only a single true resonance. The recording system was used to search for lines, but frequency measurement was made on the visual signals.

DISCUSSION I

The chemical condition of the chlorine atoms in the phosphonitrilic chlorides is quite similar to those in $(SNCl)_3$ trithiazyl chloride, the two frequency averages being alike (26, 27) (Table II). The differences appeared to be easily explained by recent work on orbital electronegativities (28, 29).

In both the phosphorus and sulphur compounds the central atom (P or S) is tetrahedrally(*te*) hybridized:* in the phosphorus compound to form four bonding orbitals, in the sulphur three bonding orbitals, and a lone pair orbital. The χ, orbital electronegativities, are (30):

$$\chi_{te}{}^{P} = 2.79$$

$$\chi_{te}{}^{S} = 3.21$$

for the atoms in the ($te^2tetete$) and (te^2te^2tete) state respectively. The promotion of one electron to the *d* orbital in the phosphorus atom may increase the $\chi_{te}{}^{P}$ slightly, but this will be similar to the change in $\chi_{te}{}^{S}$ when such a promotion occurs. However, in the phosphorus case the fourth bond is joined to chlorine and is not a lone pair orbital, so that the effective orbital electronegativity, $\chi_0{}^{eff}$, presented to a given chlorine, is changed

*The convention used in this paper is:
te = tetrahedral σ orbital,
tr = trigonal σ orbital,
di = digonal σ orbital,
π = pi orbital.
The superscript number designates the number of electrons in the orbital. Thus:
te = singly occupied tetrahedral orbital,
te^2 = doubly occupied tetrahedral orbital, or a lone pair orbital.

from the pure *te* value in both series but by different amounts. The change can be estimated from the empirically and theoretically established relation (30, 31)

$$\chi_o^{eff} = \tfrac{1}{2}(\chi_M^0)+\tfrac{1}{6}(\chi_A^0+\chi_B^0+\chi_C^0) \qquad [1]$$

where χ_M^0 is the orbital electronegativity of the central atom, and χ_A^0 etc. of the atoms joined to it. $(PNCl_2)_3$ and $(SNCl)_3$ only differ in one chlorine ligand as compared to a lone pair. Using the values of χ^0 for chlorine and nitrogen (29) and equation [1] a rough estimate of χ^{eff} for both the phosphorus and sulphur atoms can be made.

The nitrogen atom in the ring (1) is trigonally hybridized with a single p_π electron and a lone pair, *trtrtr*^{2} π; the chlorine can be assumed to be pure unhydridized $s^2p^2p^2p$; the sulphur and phosphorus are respectively *te*^{2}*tetetetd*, and *tetetetetd*. The various electronegativities (Table III) are:

$$\chi_N^{tr} = 4.13, \qquad \chi_{Cl}^{p} = 2.95, \qquad \chi_S^{te^2} = 2.01 \text{ (32)}.$$

TABLE III

Various orbital electronegativities used in the text given in Pauling units*

Atom	Orbital	χ°	Atom	Orbital	χ°
Cl	*s*	5.69	B	*s*	3.26
	p	2.95		*p*	1.26
				di	2.27
N	*s*	6.67		*tr*	1.93
	p	2.27		π	1.44
	di	5.05			
	tr	4.13	P	*s*	4.63
	π	2.47		*p*	1.84
	tr^2	1.58		*di*	3.58
				tr	3.05
C	*s*	4.84		*te*	2.79†
	p	1.75		*te*^{2}	1.59
	di	3.29			
	tr	2.75	S	*s*	5.12
	te	2.48		*p*	2.28
	π	1.68		*di*	3.96
				tr	3.46

				te^2	2.01†

* J. Hinze and H. H. Jaffe. J. Am. Chem. Soc. 84, 540 (1962).

†These values of χ are calculated for the states *te*^{2}*tetete* (*P*) and *te*^{2}*te*^{2}*tete* (*S*). They are used for the states *tetetetd* and *te*^{2}*tetetd* respectively in the text since no estimation of the change in χ under such a promotion is available.

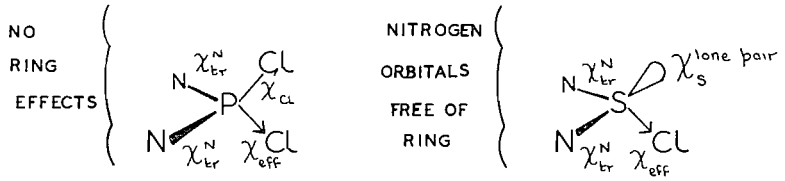

FIG. 2. The central atom is shown bonding either four ligands in the case of the phosphorus atom, or three ligands and a lone pair of electrons in the case of S. The nitrogen atoms are assumed to use pure trigonal hybrids towards the central atom and to be free of any ring influence.

To a first approximation the central atom can be considered as bonding four (P) or three ligands and a lone pair (S), independent of the rest of the ring, Fig. 2. Then using equation [1]

$$\chi_P^{eff} = 3.263, \qquad \chi_S^{eff} = 3.316,$$

giving $$\chi_P^{eff}/\chi_S^{eff} = 0.984,$$

while the n.q.r. frequency ratio is

$$[\nu_{(PNCl_2)_3}/\nu_{(SNCl)_3}] = 0.95.$$

This is quite good agreement when only σ bonds are considered and the ring ignored, but the electronegativity ratio is too high. The inclusion of the lone pairs of the nitrogen in any assessment of χ^{eff} would lower the value of χ^{eff}, to a slightly greater extent in the phosphorus than in the sulphur compound.

The disubstituted trimer, $P_3N_3Cl_4\phi_2$, has a frequency 0.86 Mc lower than the unsubstituted trimer. The pure p orbital electronegativity for chlorine, χ_o^p, is 2.95; if there is s hybridization in the orbital then the orbital electronegativity is given by (33)

$$\chi_{orbital} = s\chi_{orbital}^{s} + (1-s)\chi_{orbital}^{p} \qquad [2]$$

where s is the amount of s hybridization. The $\chi_{orbital}$ will exceed χ_o^p. The orbital electronegativity of the chlorine atoms is in consequence at least 2.95. Their replacement by phenyl groups (ϕ) means that the electronegativity is lowered. The phenyl group can display two electronegativities, the inductive χ^I, and conjugative χ^C. These are respectively (34):

$$\chi_\phi^I = 2.542, \qquad \chi_\phi^C = 1.68.$$

Measurement of the disubstituted trimers containing CH_3, C_2H_5, and $ClCH_2$ groups (as was possible in the $RPOCl_2$ series) would have decided whether the phenyl groups were inductively or conjugatively linked to the ring. This was not possible.

The following discussion allows a decision to be made. The change in frequency from $POCl_3$ to $\phi POCl_2$ is 3.6052 Mc when the phenyl group is conjugatively bonded; displaying $\chi_\phi^C = 1.68$. If it were inductively bonded then $\chi_\phi^I = 2.542$. Assuming the chlorine orbital to be pure p, $\chi_o^p = 2.95$, and thus a change in the electronegativity of 1.27 units changes the frequency by 3.6 Mc; a change of 0.41 units (the phenyl acting inductively) would be expected to cause, approximately, one-third the frequency change, 1.2 Mc. Allowing for the separation of the "phenyl phosphorus" from the phosphorus bonded to the chlorine atoms, a reduction of one-third per bond in the transmission of the effect, similar to that observed in organic ring systems, might be expected (35). Thus the conjugatively linked ϕ would cause a drop of 0.4 Mc per ϕ, or 0.8 Mc for the diphenyl, whereas the inductively linked ϕ would result in a drop of less than 0.3 Mc. It thus appears that the ϕ are conjugatively linked like the ϕ in the $RPOCl_2$ series. The absolute frequencies of the $(PNCl_2)_n$ compounds and the $RPOCl_2$ and R_2POCl series are also similar, suggesting that there is no fundamental difference between the bonding in the various types of compounds (27).

To explain the frequency behavior of the $RPOCl_2$ compounds, the use of the phosphorus d orbitals in d_π–p_π bond formation was stipulated; with the oxygen p_x and p_y orbitals two such bonds are formed, while only two of the remaining d orbitals have the correct symmetry to overlap the p orbitals on the RCl_2 atoms. The orbitals on all three groups can equally overlap the degenerate pair of d orbitals (Fig. 3(a)). The overlap will be less than that in the case of the phosphorus and oxygen orbitals because the RCl_2 atoms lie below the x–y plane containing the phosphorus–oxygen bond and also because the phosphorus–chlorine or phosphorus–R bond is longer than the phosphorus–oxygen bond (36). It was concluded that there would be weak conjugation between the orbitals

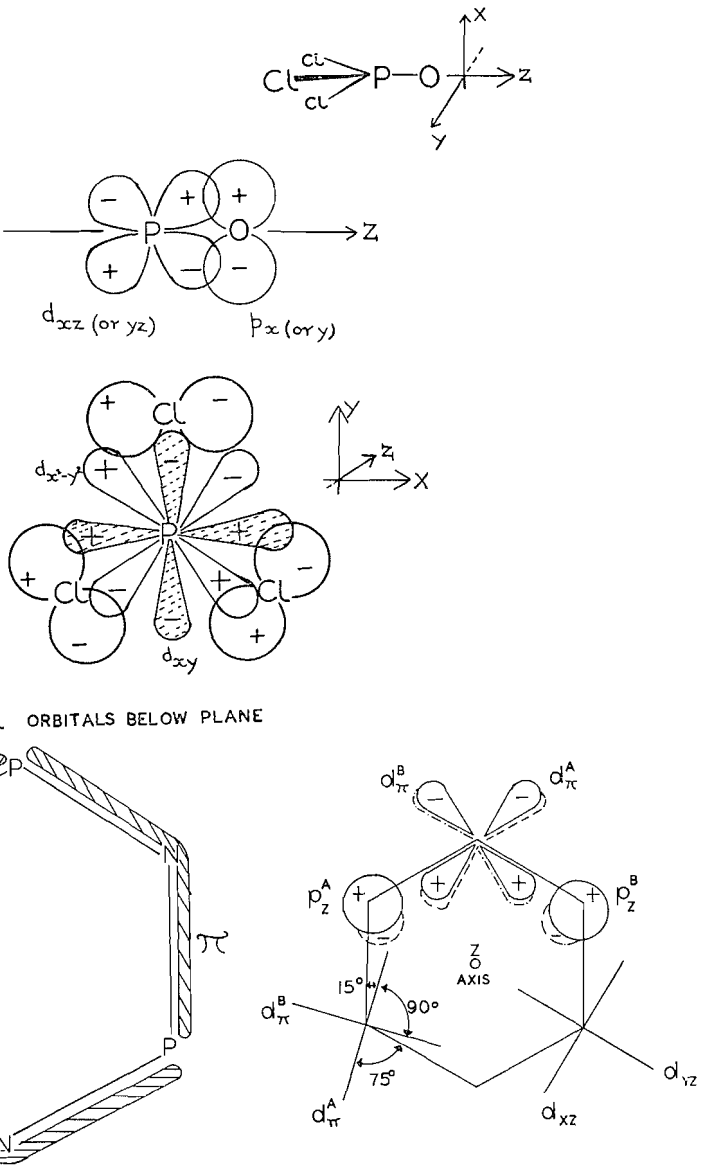

FIG. 3(*a*). The phosphorus oxychloride molecule has C_{3v} symmetry. With the z axis along the PO bond, the oxygen lone pair p orbitals lie in the xy plane. The transformation properties of the five d orbitals of phosphorus and these two p orbitals of oxygen, under both the C_{3v}, molecular, and C_v, bond, symmetry groups, show that the p_x and p_y orbitals can give a multiple π bond with d_{xz} and d_{yz} as shown in (*a*). It is a *triple* bond. The remaining d orbitals of phosphorus are of two symmetry types (i) the d_{z^2} orbital cannot d_π–p_π bond, (ii) the $d_{x^2-y^2}$ and d_{xy} orbitals can overlap with the chlorine orbitals, arbitrarily shown in (*b*). The chlorine orbitals can all equally well overlap, lie below the plane of the d orbitals and are further from the phosphorus than the oxygen atom orbitals.

FIG. 3(*b*). The polyallylic π bond structure of $(PNCl_2)_3$ and $(SNCl_2)_3$ showing the node present in the d_π–p_π system at each phosphorus (sulphur) atom. Any number of PN units may be combined either linearly or in rings and such an allylic structure will fit.

FIG. 3(*c*). The unhybridized d_{xz} and d_{yz} of a phosphorus or sulphur are shown. The hybridized

$$d_\pi^A = (1/\sqrt{2})\,(d_{yz} + d_{xz})$$

and

$$d_\pi^B = (1/\sqrt{2})\,(d_{yz} - d_{xz})$$

are shown and the angle between their lobes and the σ bond framework. The build-up of the allylic π bonds results from the overlap of a phosphorus d_π^A and nitrogen p_z^A which can overlap with the d_π^A of the next phosphorus atom. Since d_π^A and d_π^B are orthogonal orbitals there will be a break in the π orbital, or anode, at each phosphorus.

on the substituents and those on the phosphorus atom, and consequently between themselves, but that there would be no conjugation between the orbitals on the substituents and those forming the phosphorus–oxygen π bond.

In the phosphonitrilic halides it has been shown (1) that the stability of the phosphonitrilic halide ring can be explained by a polyallic structure for the ring. Each phosphorus atom makes use of two d_π orbitals in forming π bonds and these interact with the nitrogen atom p_π orbital to give a system of weakly interacting three-centered π bonds, embracing two phosphorus atoms and a central nitrogen atom (Fig. 3(*b*)).

Craig (16) criticized the formulation of Dewar *et al.* (1) on the grounds that it required the two *d* orbitals d_{xz} and d_{yz} to have identical electronegativities, which they could not, due to their different orientations towards the bonded atoms causing their polarization. However, in his papers (37–40) the effect of the ring nitrogen atoms is the only ligand effect considered. The other bonded ligands, whether halogen, aryl, alkyl, or another electronegative group (41–43) are not considered as affecting the size, or polarization, of the phosphorus *d* orbitals. While it is true that "we may expect, therefore, that d_{xz} will be more polarized than d_{yz} because of its greater overlap with the neighbor nitrogens" (40) it is equally true that we should expect the d_{yz} to be more polarized than the d_{xz} due to its greater overlap with the exocyclic ligand groups. This polarization will depend on the exocyclic group actually attached, or, more exactly, on the electronegativity of the σ orbital by which it is joined to the phosphorus, and these are comparable in electronegativity to the σ orbital of the ring nitrogen (30).

The difference between d_{xz} and d_{yz} orbitals should therefore be considerably less than suggested by Craig's arguments. Further, in the most recent paper (16), he postulates the inclusion of other *d* orbitals, as had been considered earlier by Dewar *et al.* (1). The inclusion of other *d* orbitals permits the non-planarity of the ring. The $d_{\pi a}$, $d_{\pi b}$ formed, have the form

$$d_{\pi a} = 1/\sqrt{(a^2+b^2+c^2+d^2)}\ \{ad_{yz}+bd_{xz}+cd_{xy}+dd_{x^2-y^2}\},$$
$$d_{\pi b} = 1/\sqrt{(a^2+b^2+c^2+d^2)}\ \{ad_{yz}-bd_{xz}-cd_{xy}-dd_{x^2-y^2}\}.$$

The hybridized orbitals do not have to be of precisely the same electronegativity but only similar electronegativities (i.e. energies or sizes), nor do they have to contribute equally to the hybrid. In forming two equal *sp*-hybrids at an angle θ_{ij} (44) where the *s* and *p* orbitals are not of the same χ, the orbitals

$$\phi_1 = s+ap_i$$
$$\phi_2 = s+bp_j$$

are constructed which are orthogonal if $\int \phi_1\phi_2 d\tau = \int (s+ap_i)(s+bp_j)d\tau = 0$ and normalized if

$$\int s^2 d\tau = \int p_i^2 d\tau = 1 \text{ and } \int p_i p_j d\tau = \cos\theta_{ij}.$$

Since any two perpendicular *p* orbitals or an *s* and *p* orbital are orthogonal, $\int sp_i d\tau = \int sp_j d\tau = 0$, so that orthogonality with equal hybrids requires $1+a^2\cos\theta_{ij} = 0$. Similar requirements can be applied to the various *d* orbitals and hybrids can always be constructed which are orthogonal. The polyallylic structure fits the ultraviolet spectra results for the linear and ring molecules, which show no increased conjugation path as the *n* in $(PNCl_2)_n$ increases, but a steady increase in ϵ, which is proportional to *n*.

The d_π orbitals are formed from the d_{yz} and d_{xz}, etc., orbitals by rehydridization. The d_π orbitals, $d_{\pi a}$ and $d_{\pi b}$, are orthogonal and do not conjugate with each other. The remaining orbitals on the phosphorus atom are the d_{xy}, $d_{x^2-y^2}$, and d_z orbitals. The phosphorus

atom is tetrahedrally bonded to the two nitrogen atoms and two chlorine atoms by sp^3 σ bonds, the chlorine atoms being above and below the plane of the ring (17). The $\widehat{ClPCl}$ is 109°. The d_{xy} orbital is therefore of the wrong symmetry to interact with the chlorine atom p_π orbital while both the d_{z^2} and $d_{x^2-y^2}$ orbitals can interact with one lobe of one of the chlorine p_π orbitals.

Thus, as in the $RPOCl_2$ case, there will be weak conjugative bonding between the chlorine atoms via the phosphorus atom, but not between the chlorine atoms and the allylic π bonding of the ring. Therefore the n.q.r. frequency would be expected to be similar in the phosphonitrilic halides and the phosphonyl halides.

The case of the $\phi_2P_3N_3Cl_4$ molecule is interesting. The phenyl groups are, as discussed above, weakly π bonded to the central phosphorus atom, displaying a conjugative rather than inductive electronegativity. This affects both the phosphorus σ and d_π electronegativities which transmit the effect to the next phosphorus atom, which is weakly conjugated to the chlorine atoms. The phenyl groups thus display conjugative electronegativity at the chlorine atoms via a conjugative path containing two nodes.

Similar arguments explain the resemblance between the $SOCl_2$ and $(SNCl)_3$ frequencies, the greater difference being due to the lone pair which has a greater "flexibility", than a bonded pair, to suffer rehybridization.

The perchlorate and borofluoride complexes of the phosphonitrilic chlorides have n.q.r. frequencies so close to those of pure $(PNCl_2)_3$ as to suggest that the $(PNCl_2)_3.HClO_4$ and $(PNCl_2)_3.HBF_4$ do not exist; their frequencies should differ greatly from those of the pure substance. If the bonding of the perchlorate and borofluoride were such as to give a salt, the proton adding to one of the ring nitrogen atoms, then there should be a distinct change in the pattern of the resonance. The four chlorine atoms on the phosphorus atoms adjacent to the protonated nitrogen atom should give higher frequencies, while the other two chlorine atoms should not. The increase of only 0.022 Mc from $(PNCl_2)_3$ to $(PNCl_2)_3.HClO_4$ seems rather small.

DISCUSSION II

It appeared at first as if the use of effective electronegativities could distinguish between π-bonded and non-π-bonded chlorine atoms, since when the ratio of the χ^{eff} was close to the frequency ratio then there would be no π bonding, but when π bonding was present, causing an abnormally low frequency to be measured, there would be a large discrepancy between the frequency and χ^{eff} ratios.

This was a fallacious expectation as the following sequence of results will show; these results confirmed the views expressed previously (21) that "quadrupole data may be correlated by means of χ^{eff} so long as a homologous series or family is maintained. Otherwise both hybridization and ionic character must be considered."

From Table II the following frequency ratios can be determined

$$(\nu_{POCl_3})/(\nu_{PCl_3}) = 1.105,$$

$$[\nu_{(PNCl_2)_3}]/(\nu_{POCl_3}) = 0.982,$$

and $$[\nu_{(PNCl_2)_3}]/(\nu_{PCl_3}) = 1.086,$$

while the χ^{eff} for the ring compound will be that calculated above, and for $POCl_3$ and PCl_3 with $\chi_P{}^{te} = 2.79$, $\chi_P{}^{te^2} = 1.59$, $\chi_O{}^{p} = 3.04$ and pure p chlorine orbitals of $\chi_{Cl}{}^{p} = 2.95$, then equation [1] yields $\chi^{eff}_{POCl_3} = 2.885$ and $\chi^{eff}_{PCl_3} = 2.643$, which give for the ratios

of the frequencies shown above

$$\chi^{eff}_{POCl_3}/\chi^{eff}_{PCl_3} = 1.092, \qquad \chi^{eff}_{(PNCl_2)_3}/\chi^{eff}_{POCl_3} = 1.131,$$

and

$$\chi^{eff}_{(PNCl_2)_3}/\chi^{eff}_{PCl_3} = 1.234.$$

The oxygen orbital is assumed to be pure p, since the inclusion of s character would increase the electronegativity and match the tetrahedral phosphorus orbital less well (45). However, a small amount of s character in either the chlorine or oxygen orbital would still permit a complete match of the frequency and effective electronegativity ratios in the case of $POCl_3$ and PCl_3; the lower $\chi^{eff}_{(PNCl_2)_3}$ resulting from the inclusion of ring effects would match the ratios in the other cases.

Despite the impressive match in the comparison of ν and χ of $POCl_3$ and PCl_3, there is some difficulty with using PCl_3 at all in this work, since it has yet to be established whether there is π bonding present between the chlorine atoms and the central phosphorus and hence between each other. It is possible to assume that the orbitals on the central atom point toward the ligand orbital (orbital following). Two estimates of PCl_3 have been made, with and without this assumption, and with and without π bonding. The various possibilities were:

(i) $\rho = 0.477 \quad \chi_P{}^{hyb} = 2.58 \quad s_P = 0.15$ from bond angles

$$\chi_{Cl}{}^{hyb} = 3.80 \quad s_{Cl} = 0.313$$

bond ionic character = 0.31;

(ii) if P is assumed to be pure "*te*"

$$\chi_P{}^{hyb} = 2.99 \quad s_P = 0.25$$

$$\chi_{Cl}{}^{hyb} = 3.89 \quad s_{Cl} = 0.343$$

bond ionic character = 0.28;

(iii) if π bonds are assumed present and estimated by Pauling's method (44) from bond length changes

$$\pi \text{ character} = 0.10$$

then

$$s_{Cl} = 0.231 \quad \chi_{Cl}{}^{hyb} = 3.64$$

$$i = 0.25.$$

This focusses the difficulties and dangers of correlating theories which ignore the individual nature of each molecule (21).

If the compounds $SOCl_2$ and SO_2Cl_2 are compared (Table II) then

$$(\nu_{SO_2Cl_2})/(\nu_{SOCl_2}) = 1.182$$

The χ^{eff} is estimated by the above method. The χ^{eff} is the effective σ orbital electronegativity displayed by the sulphur to a single chlorine atom which is not π bonded to the oxygen and only weakly π bonded to the sulphur. With $\chi_s{}^{te} = 3.21$, $\chi_s{}^{te^2} = 2.01$, $\chi_o{}^p = 3.04$, and with the chlorine orbital pure p in character (displaying the lowest possible χ) $\chi_{Cl}{}^p = 2.95$ and

$$\chi^{eff}_{SO_2Cl_2}/\chi^{eff}_{SOCl_2} = 1.058.$$

The inclusion of a small and different amount of s hybridization in the chlorine σ orbital

in the two compounds would make the agreement perfect. The comparison of $(SNCl)_3$ with $SOCl_2$ and SO_2Cl_2 gives for the frequency ratio 0.934 and 0.790. The corresponding χ^{eff} ratios are 1.154 and 1.066. These are high due to overassessment of the $\chi^{eff}_{(SNCl)_3}$ when the ring is not considered.

The interesting aspect of this approach is that the bond electronegativities seem to be qualitatively and semiquantitatively related to the n.q.r. frequency changes in all compounds where there is a small amount of conjugation between the chlorine and central atom, but no conjugation between the orbitals on the chlorine atoms and the π bonds of the system.

The compounds CCl_4, $COCl_2$, and $(CNCl)_3$ give nuclear quadrupole frequencies which are distinctly different from the phosphorus and sulphur compounds (27). It has been previously shown (45) that CCl_4 displays 9.7% s character in the chlorine σ orbital and 17.4% ionic character in the carbon–chlorine bond; assuming that the chlorine orbitals in $COCl_2$ are similar to those in CCl_4 with a similar amount of hybridization, then from Table II,

$$(\nu_{COCl_2})/(\nu_{CCl_4}) = 0.879$$

while $\chi^{eff}_{COCl_2}/\chi^{eff}_{CCl_4} = 1.004$ using a pure p orbital

or $= 1.028$ with 9.7% s hybridization.

The χ^{eff} are calculated using equation [1], modified in the case of $COCl_2$ to

$$\chi^{eff} = \tfrac{1}{2}\chi_c{}^{tr} + \tfrac{1}{4}[\chi_o{}^p + \chi_{Cl}{}^p].$$

The oxygen orbital is assumed to be pure p, the chlorine orbital to be pure p and hybridized respectively.

When χ ratio is less than the ν ratio, increased s hybridization in the chlorine σ orbital of $COCl_2$ could match the two ratios. However, s hybridization will increase the mismatch in this case. Any π bonding between the central carbon p orbital and the chlorine atom lone pair p would lower the $COCl_2$ frequency more than would be estimated from the χ^{eff} changes, and recent work supports the view that the chlorine atoms in $COCl_2$ are π bonded to the central carbon atom (36, 46–49).

It might be expected that the $(CNCl)_3$ molecule would resemble $COCl_2$ in its bonding to chlorine. The ratio

$$[\nu_{(CNCl)_3}]/(\nu_{CCl_4}) = 0.894$$

is very similar to the value for $COCl_2$ of 0.879. Treating $(CNCl)_3$ in the same way as the phosphorus and sulphur compounds, with trigonal carbon, the χ^{eff} ratio is 1.203, high due to the ring structure being ignored. If $(CNCl)_3$ is compared with $COCl_2$ then the frequency ratio is 1.017, while the χ^{eff} ratio is 1.171.

Finally in this series of comparisons one can consider $(BNHCl)_3$ and BCl_3 which with trigonal boron give a ν ratio of 0.922 and a χ ratio of 1.247.

CONCLUSION

In the compounds known to have aromatic ring character and π-bonded chlorine atoms, the χ^{eff} ratio differs from the ν ratio by 0.309, $(CNCl)_3$, and 0.325, $(BNHCl)_3$. In the single bonded cases $(PNCl_2)_3$ and $(SNCl)_3$ the differences are only 0.136 and 0.148 (compared to $POCl_3$ and PCl_3 respectively) but 0.22 and 0.27 (compared to $SOCl_2$ and SO_2Cl_2), while in $COCl_2$, now thought to have doubly bonded chlorine atoms and π bonding also

between the carbon and oxygen atoms (48, 49), the discrepancy between χ and ν for $COCl_2$ compared to CCl_4 is 0.149, in the singly bonded region.

The initially hopeful trend seen in comparing the $(SNCl)_3$ and $(PNCl_2)_3$ χ^{eff} ratio with their frequency ratio thus comes to naught. It does not appear possible to interpret structural differences from the comparison of the ratio of the nuclear quadrupole ratios with the ratios of the effective orbital electronegativity of the atom joined to the chlorine atom.

ACKNOWLEDGMENTS

We wish to thank Dr. Childs, of Albright and Wilson, and Dr. R. A. Shaw, of Birkbeck College, London, for the loan of samples, without which this research would never have occurred, and especially Dr. E. A. Lucken for useful views and discussion. The experimental measurements were performed at Queen Mary College, the University of London.

The author is indebted to the referee for very helpful criticism and suggestions.

NOTES

SYNTHESES OF ALPHA AMIDE AND PEPTIDE DERIVATIVES OF DL-ASPARTIC ACID

A. ZILKHA AND N. LERMAN

In previous work we have prepared α and β amide and peptide derivatives of aspartic acid starting with N-benzyl-aspartic acid as the anhydride hydrochloride (1) or as the mixed anhydride with chloroformic acid obtained by reaction with phosgene (2, 3, 4). Exclusive preparation of the β derivatives in good yield was obtained starting with maleic anhydride (5). In the previous methods, α amides and peptides were obtained sometimes exclusively, and sometimes in admixture with β derivatives (2, 3, 4). The use of active amines or aminoacid esters led to the formation of α derivatives, while with weak aromatic amines β derivatives were obtained (2, 4, 6). From weak aromatic amines, α derivatives were obtained only on using large excess of amine (6).

In the present work the use of β-benzyl N-benzyl-DL-aspartate (I) as starting material for the exclusive formation of α-aspartyl amides and peptides is described. In this compound the β-carboxyl group is masked with a benzyl group, which can be removed easily by hydrogenolysis. The use of other ester groups such as the methyl group [the corresponding N-benzyl derivative has been prepared (7)] did not seem feasible, as these can be removed only by hydrolysis, and it has already been shown that such hydrolysis leads to the formation of imide derivatives as cyclic intermediates, which afterwards may open to yield either the α or β derivatives (8, 9).

β-Benzyl N-benzyl-DL-aspartate (I) was prepared starting from benzyl maleate as follows:

$$\begin{array}{l} \mathrm{CHCOOCH_2C_6H_5} \\ \| \\ \mathrm{CHCOOH} \end{array} + \mathrm{C_6H_5CH_2NH_2} \rightarrow \begin{array}{l} \mathrm{CH_2COOCH_2C_6H_5} \\ | \\ \mathrm{CHCOOH} \\ | \\ \mathrm{NHCH_2C_6H_5} \end{array}$$

I

One equivalent of benzylamine was used, and it led exclusively to opening of the double bond without attacking the ester group, showing that addition to the double bond is preferable to amidation (7). DL-Aspartic acid was obtained on hydrogenolysis of (I). Reaction of (I) with phosgene in dioxane gave an active intermediate from which α-aspartyl amide and peptide derivatives were obtained on reaction with two equivalents of amine or amino-acid ester in dioxane. The product usually was difficult to crystallize, so that the dioxane solution was evaporated after filtration from the amine hydrochloride that precipitated, and the product was hydrogenolyzed with alcohol in the presence of palladium chloride (30% on carbon). In the case of cyclohexylamine, the intermediate product N^2-benzyl-N-cyclohexyl-α-asparagine β-benzyl ester was isolated. By this method the yields in many cases were much higher than those obtained previously (2, 4).

The α amides and peptides gave positive biuret reactions and purple spots on paper chromatograms as was found previously (2).

Structure of the Active Intermediate (II)

To ascertain the nature of the active intermediate (II), the known determinations (10) of acid chlorides, anhydrides, and amino acids by anhydrous titrations with sodium

methoxide and Triton B (trimethylbenzylammonium hydroxide) were used, as shown in the equations below:

$$RCOCl + NaOCH_3 \rightarrow RCOOCH_3 + NaCl \text{ (no back-titration with } HClO_4)$$

$$RCOCl + 2\,(CH_3)_3NC_7H_7OH \rightarrow RCOON(CH_3)_3C_7H_7 + (CH_3)_3NC_7H_7Cl + H_2O$$

$$\underset{\underset{NH_2}{|}}{RCHCOOH} + NaOCH_3 \rightarrow \underset{\underset{NH_2}{|}}{RCHCOONa} + CH_3OH \xrightarrow[\text{back-titration}]{2HClO_4} \underset{\underset{NH_2.HClO_4}{|}}{RCHCOOH} + NaClO_4$$

It may be noted that while 1 equivalent of sodium methoxide is required for the titration of a chloride or anhydride, 2 equivalents of Triton B are required. However, we found that a solution of carbon dioxide in dioxane required 1 equivalent of Triton B for titration, using thymol blue as indicator, the same as with sodium methoxide.

The intermediate (II) was prepared directly in dioxane solution (excess phosgene expelled) and aliquot portions analyzed. Volhard titration for chlorine showed the presence of approximately 1 equivalent of chlorine. Anhydrous titration with sodium methoxide using thymol blue as indicator required the use of 2 equivalents of reagent, while titration with Triton B required the use of 3 equivalents of reagent (10). Back-titration of the sodium methoxide titrated aliquot with perchloric acid in dioxane required the use of 2 equivalents of reagent, one to titrate the sodium carboxylate formed, and the other the amino group. Addition of *p*-toluidine to the dioxane solution of II led to the generation of 1 mole equivalent of CO_2. Also, the dioxane solution of the intermediate did not titrate directly with perchloric acid in dioxane with thymol blue as indicator, presenting evidence that the amino group was blocked.

All these results are consistent with the formation of an N-chloroformyl derivative (II*a*), but not a mixed anhydride with chloroformic acid (II*b*), which has a free amino group, or a simple anhydride hydrochloride between two molecules of the benzyl ester derivative.

$$\begin{array}{l} CH_2COOCH_2C_6H_5 \\ | \\ CHCOOH \\ | \\ NCOCl \\ | \\ CH_2C_6H_5 \end{array} \qquad \text{(II}a\text{)}$$

$$\begin{array}{l} CH_2COOCH_2C_6H_5 \\ | \\ CHCOOCOCl \\ | \\ NHCH_2C_6H_5 \end{array} \qquad \text{(II}b\text{)}$$

Such an N-chloroformyl derivative was formed in the reaction of phosgene with N-phenyl-β-alanine or N-*p*-tolyl-β-aminobutyric acid (11). It can cyclize (11) on reaction with amines to an N-carboxyanhydride, which decomposes with carbon dioxide evolution on reaction with additional amine.

We tried to obtain more evidence from examination of the infrared spectra of the active intermediate (II). A mixed anhydride structure, such as (II*b*), must have double absorption peaks at about 5.4 μ and 5.6 μ which are not given by the N-chloroformyl structure (II*a*). The dioxane solution was evaporated to dryness *in vacuo* at 30°, and the residue showed a double absorption peak in the infrared at 5.4 μ and 5.65 μ, which is consistent with either a mixed anhydride or an N-carboxyanhydride structure. However, during the evaporation, the compound must have undergone considerable transformation as its chlorine content was reduced by some 50%. The dry compound also evolved fumes of hydrogen chloride on standing. After several fractional crystallizations of the residue from dioxane – petroleum ether or chloroform–ether, the N-carboxyanhydride derivative of (I) was isolated. This was identical with that obtained on addition of an equivalent of

*Substances were recrystallized from ethanol or water.

triethylamine to the dioxane solution of the active intermediate, filtration of the precipitated triethylamine hydrochloride, evaporation of the dioxane, and crystallization of the N-carboxyanhydride from chloroform–ether. The N-carboxyanhydride showed absorptions at 5.4 μ and 5.65 μ besides the absorption at 5.8 μ (ester group).

EXPERIMENTAL

Melting points were determined in a Fisher–Johns apparatus, and the ascending method of paper partition chromatography (80% phenol) was used. A procedure for one typical example of each reaction step is given and the remainder are summarized in Table I. Benzyl maleate (12) m.p. 51–52°, was prepared in 92% yield by heating equimolar quantities of maleic anhydride and benzyl alcohol at 125°.

*β-Benzyl N-benzyl-*DL*-aspartate (I).*—Benzyl maleate (51.5 g, 0.25 mole) was dissolved in dry dioxane (400 ml) and cooled. Benzylamine (26.8 g, 0.25 mole) was added in one portion and the reaction mixture was stirred at 125° for 3 hours. The product started to precipitate after a few minutes. It was filtered and washed with acetone, yield 60 g (76%), m.p. 195° on recrystallization from water or better from 50% ethanol. Anal. Calc. for $C_{18}H_{19}NO_4$: C, 69.0; H, 6.1; N, 4.5. Found: C, 68.9; H, 5.9; N, 4.7.

*Reaction of β-Benzyl N-Benzyl-*DL*-aspartate with Phosgene.*—Dry, finely powdered β-benzyl N-benzyl-DL-aspartate (15.7 g, 0.05 mole) was suspended in dry dioxane (400 ml) in a three-necked flask equipped with a gas leading tube, a reflux condenser connected to a calcium chloride tube, and a mechanical stirrer. Dry phosgene was bubbled in with stirring for 90 minutes and the temperature was kept constant at 50°. After 10 minutes the solution cleared. Excess phosgene, but not the solvent, was removed *in vacuo* at 20° (4–5 hours). The solution was used as such for the preparation of the amides and peptides.

*N^3-Benzyl-N-cyclohexyl-α-*DL*-asparagine β-Benzyl Ester.*—To an ice-cold solution of the reactive intermediate (II) prepared from (I) (4.1 g, 0.013 mole) in dioxane (100 ml) was added cyclohexylamine (2.7 g, 0.028 mole). The reaction mixture was shaken in the cold for 30 minutes and left overnight at room temperature. The precipitate consisting of cyclohexylamine hydrochloride was filtered off, and the filtrate evaporated *in vacuo*. On cooling the residue crystallized. It was dissolved in a small volume of ethanol, water was added to incipient cloudiness, and the substance was left to recrystallize; yield 4.85 g. (95%), m.p. 80°. Anal. Calc. for $C_{24}H_{30}N_2O_3$: C, 73.1; H, 7.6; N, 7.1. Found: C, 73.4; H, 7.9; N, 7.1.

*N-Cyclohexyl-*DL*-α-asparagine.*—N^3-Benzyl-N-cyclohexyl-DL-α-asparagine (1 g) was dissolved in ethanol (100 ml) and 0.2 g of 30% palladium chloride on charcoal (2) was added. The hydrogenolysis was carried out in a Parr low-pressure hydrogenation apparatus for 10 hours at 50°. The product precipitated in the ethanol solution and was extracted from the catalyst by boiling water. The aqueous solution was evaporated, and the product which crystallized was washed with ethanol and filtered; yield 0.55 g. (quantitative), m.p. 247° on recrystallization from water, R_f 0.92. Anal. Calc. for $C_{10}H_{18}N_2O_3$: C, 56.1; H, 8.4; N, 13.1; N (Van Slyke), 6.6. Found: C, 56.0; H, 8.5; N, 13.2; N (Van Slyke), 6.6.

*N-Carboxyanhydride of β-Benzyl N-Benzyl-*DL*-aspartate.*—To a solution of the reactive intermediate (III) in dioxane prepared as above from 3.1 g (I), an equivalent amount of dry triethylamine (sufficient to react with the chlorine) was added dropwise in the cold with stirring. The reaction mixture was stirred for 2 hours and the precipitate of triethylamine hydrochloride was filtered. The dioxane filtrate was evaporated to dryness at 40°, and the N-carboxyanhydride crystallized on standing overnight in the cold under petroleum ether, yield 2.8 g (82%). It was recrystallized from chloroform – petroleum ether or chloroform–ether, m.p. 92°. Anal. Calc. for $C_{19}H_{17}NO_5$: C, 67.2; H, 5.0; N, 4.1; mol. wt. 339. Found: C, 66.9; H, 5.2; N, 4.3; mol. wt. 335, determined by anhydrous titration with 0.1 *N* sodium methoxide in dioxane using thymol blue as indicator (13).

ISOLATION OF 4,6-O-(1′-CARBOXYETHYLIDENE)-D-GALACTOSE FROM THE EXOCELLULAR POLYSACCHARIDE OF CORYNEBACTERIUM INSIDIOSUM[1]

P. A. J. GORIN AND F. J. T. SPENCER

In a previous publication the polysaccharide formed exocellularly by the alfalfa wilt organism, *Corynebacterium insidiosum*, was shown to yield two oligosaccharides and two unidentified acidic products on partial acid hydrolysis (1). The oligosaccharides were identified as 4-O-β-D-glucopyranosyl-L-fucose and O-β-D-glucopyranosyl-(1 → 4)-[O-D-galactopyranosyl-(1 → 3)]-L-fucose. The two unidentified acidic products consisted of a D-galactose residue (I) substituted by an unknown moiety and a trisaccharide (II) in which the D-galactose unit was also substituted.

(C.Et.GAL = 4,6-O-(1′-carboxyethylidene)-D-galactose)

I, II, III. Partial acid hydrolysis products of *Corynebacterium insidiosum* polysaccharide.

Re-examination of the crystalline galactose derivative, derived from I, by nuclear magnetic resonance spectroscopy (n.m.r.) indicated the presence of ethyl and uncoupled C-methyl protons. Since the compound appeared to be $C_{11}H_{20}O_9$ on the basis of carbon and hydrogen analysis and its neutral equivalent, the data were consistent with a carboxyethylidene galactose structure with 1 mole of ethanol of crystallization. The latter was removed by evaporation of an aqueous solution of the ethanolate. Further evidence for the structure was provided by the previous data (1), which showed a gradual consumption of lead tetraacetate by the ethanolate increasing to 1.32 moles after 20 minutes, indicating a 4-linkage (2). Compound I was converted to crystalline 4,6-O-(1′-carboxymethyl-ethylidene)-D-galactitol by treatment with sodium borohydride and then diazomethane. The product consumed 2 moles of sodium periodate with concomitant release of 1 mole of acid. Thus the structural assignment for the galactose derivate (I) was confirmed.

A third acidic component (III) was detected on re-examination of the partial hydrolysis products of the polysaccharide after charcoal and cellulose column chromatography. Its n.m.r. spectrum was indicative of the presence of a carboxyethylidene group. Compound III had a migration rate on paper chromatograms similar to that of glucose and was characterized as 3-O-[4,6-O-(1′-carboxyethylidene)-α-D-galactopyranosyl]-L-fucose as follows. Its hydrolysis products before and after sodium borohydride reduction indicated a fucose-reducing end. The lead tetraacetate oxidation characteristics of the reducing sugar showed it to be substituted in the 3-position. The specific rotation, +50°, of the derived fucitol derivative suggested an α-galactosidic linkage.

The data obtained show that a major structural component of the polysaccharide is O-β-D-glucopyranosyl-(1→4)-[4,6-O-(1′-carboxyethylidene)-α-D-galactopyranosyl-(1→3)]-L-fucose (II). The undegraded polymer consists of D-glucose, D-galactose, and L-fucose in

For personal use only.

the ratio 1:1:2 and has a neutral equivalent of 912 (1). Since acidic derivatives of sugars other than galactose have not been detected, 80% of the total galactose units must be substituted by a carboxyethylidene group. Also, the structure of II would indicate that the D-glucose units are the site of the periodate consumption (0.60 moles) and acid production (0.28 moles) in the polysaccharide (1). Therefore the D-glucose units are either non-reducing end-units or are glycosidically substituted at C-6.

The occurrence of 4,6-O-(1′-carboxyethylidene) groups in the exocellular polysaccharide of *Xanthomonas campestris* has been reported by Sloneker and Orentas (3). Hydrolysis of the product obtained by treatment of the polymer with sodium periodate and then sodium borohydride yielded 1,3-O-(1′-carboxyethylidene)-D-erythritol. This material appeared to be derived from the 4,6-O-(1′-carboxyethylidene)-D-glucosyl residues. Previous to this Hirase demonstrated the presence of 4,6-O-(1′-carboxyethylidene)-D-galactose linked to 3,6-anhydro-L-galactose in a disaccharide isolated from commercial red seaweed (4). Similar acidic substituents were detected in partial acid hydrolyzates of *C. michiganense* and *C. sepodonicum*. In all these materials the absolute configuration of the carboxyethylidene groups has yet to be determined.

EXPERIMENTAL

Evaporations were carried out under reduced pressure. Specific rotations were measured at 25° C. Acidic sugars were separated on paper chromatograms using ethyl acetate – acetic acid – water (9:2:2 v/v) as solvent. Galactose was identified by paper chromatography using the solvent, butanol–pyridine–water (3:1:1 v/v) and the spray reagent, *p*-anisidine hydrochloride (5). Nuclear magnetic resonance spectra were obtained in D_2O using tetramethylsilane as the external standard.

4,6-O-(1′-Carboxyethylidene)-D-galactose Ethanolate (Ethanolate of I)

The ethanolate was characterized previously as $C_{11}H_{20}O_9$ and had an equilibrium rotation of +49° in water (1). When examined by n.m.r. spectroscopy, the ethanolate gave a signal at 1.65 p.p.m. corresponding to uncoupled C-methyl protons and a triplet at 1.12, 1.23 and 1.35 p.p.m. from the methyl protons of an ethyl group. Re-examination of the product by n.m.r. spectroscopy after the material had been dissolved in water and the solvent then removed gave a spectrum in which there was no evidence of an ethyl group.

Partial Hydrolysis of C. insidiosum Polysaccharide

Crude polysaccharide (50 g) was stirred in *N* sulphuric acid (1 liter) at 70° C for 3 hours. The solution was neutralized ($BaCO_3$), filtered, decationized with Amberlite IR 120, and fractionated on a charcoal column. The monosaccharide components were eluted with water and the acidic components were eluted by increasing the concentration of ethanol in water to 10%. The acidic compounds were designated as I, II, and III, respectively, and had migration rates on paper chromatograms similar to those of arabinose, cellobiose, and glucose. Compounds I, II, and III were fractionated on a cellulose column using ethyl acetate – acetic acid – water (9:2:2 v/v) as solvent. This procedure gave I (0.48 g), corresponding to the previously isolated material (1), and III (0.30 g). Compound II (0.92 g) was obtained when the proportions of the solvent were changed to 3:1:1. Its n.m.r. spectrum contained a signal at 1.54 p.p.m. corresponding to an uncoupled methyl group.

Preparation of 4,6-O-(1′-Carboxymethyl-ethylidene)-D-galactitol

Compound I (0.17 g) was reduced with sodium borohydride (0.20 g) in water (5 ml). After 2 hours excess reagent was destroyed with acetic acid and cations were removed with Amberlite IR 120. The solution was filtered and the filtrate was evaporated to a crust which was repeatedly treated with methanol to remove boric acid as methyl borate, which was then evaporated. The residue was dissolved in methanol and ethereal diazomethane was added until the solution was neutral. The esterified product, when chromatographed in the solvent *n*-butanol–ethanol–water (40:11:19 v/v), was detected with ammoniacal silver nitrate spray reagent (6), and consisted mainly of a substance which had a migration rate similar to that of glycerol. Chromatography on cellulose with benzene–methanol–water (200:50:1 v/v) as solvent yielded the required material. Two recrystallizations of the product from ethyl acetate gave the methyl ester with m.p. 104–105° C and $[\alpha]_D$ −18° (*c*, 0.6, MeOH). Calculated for $C_{10}H_{18}O_8$: C, 45.1%; H, 6.8%; mol. wt., 266. Found: C, 45.3%; H, 6.9%; mol. wt. in ethanol, 260. The ester consumed 2.0 moles of sodium periodate after 30 minutes, 0.92 moles of acid being formed concomitantly. There was no change in the next 30 minutes.

Compound III

Compound III gave galactose and fucose on hydrolysis in *N* H_2SO_4 at 100° C for 3 hours. After reduction with sodium borohydride the product gave galactose and fucitol. Nuclear magnetic resonance spectroscopy

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

indicated the presence of uncoupled C-methyl protons at 1.55 p.p.m. similar to the signals found in compounds I and II. Compound III had $[\alpha]_D$ +25° (*c*, 1.0, MeOH) and consumed 0.85, 1.07, 1.14, and 1.26 moles of lead tetraacetate after 2, 5, 10, and 20 minutes, respectively. The derived fucitol derivative had $[\alpha]_D$ +50° (*c*, 1.0, MeOH).

REACTION OF PERFLUOROALKYL RADICALS WITH MOLECULAR HYDROGEN[1]

K. O. Kutschke

A certain ambiguity exists in the interpretation of data obtained in studies of reactions of the type $R + H_2 \rightarrow RH + H$ (and analogous reactions with D_2 and HD) in which R is some free radical. The discussion below is developed with those systems in mind in which R is a perfluoroalkyl radical. The ambiguity arises because it has not been possible to specify precisely the fate of the atom formed in the reaction.

In most studies the photolysis of the appropriate perfluoroketone was used as the radical source (R = CF_3, ((1), see also (2)); R = C_2F_5, (3); R = C_3F_7, (4)). Recently an investigation was made of the reaction, with R = C_2F_5 and C_3F_7, in which the radicals were generated by the photolysis of the corresponding aldehyde, RCHO (5). Values of the Arrhenius parameters obtained from the different studies involving the two radical sources are closely similar. However, Pritchard and Foote (5)[2] present evidence which indicates that the atoms disappear predominantly by reaction with aldehyde in their systems. Insofar as this evidence of a unique fate for atoms in the aldehyde systems is valid, the agreement between the results from the aldehyde and ketone systems indicates that the atoms enter only one reaction in the ketone system as well. The basis for this statement is given here; the argument is developed for the reaction $R + H_2$.

The mechanism appropriate to the ketone systems is given below. All combination reactions are written to show their dependence on pressure since the lifetime of the excited state will be considered later. In the mechanism, A represents a molecule of the radical source.

The basis for this statement is given here; the argument is developed for the reaction $R + H_2$.

The mechanism appropriate to the ketone systems is given below. All combination reactions are written to show their dependence on pressure since the lifetime of the excited state will be considered later. In the mechanism, A represents a molecule of the radical source.

[1]*Issued as N.R.C. No. 7849.*
[2]*I am indebted to Dr. Pritchard for a prepublication copy of this work and for useful correspondence in connection with it.*

$$R + R \underset{2b}{\overset{2a}{\rightleftharpoons}} R_2^*$$

$$R_2^* + A \xrightarrow{2c} R_2 + A \qquad R + H_2 \xrightarrow{3} RH + H$$

$$R_2^* + H_2 \xrightarrow{2d} R_2 + H_2$$

$$R + H \underset{4b}{\overset{4a}{\rightleftharpoons}} RH^* \qquad H + H \underset{5b}{\overset{5a}{\rightleftharpoons}} H_2^*$$

$$RH^* + A \xrightarrow{4c} RH + A \qquad H_2^* + A \xrightarrow{5c} H_2 + A$$

$$RH^* + H_2 \xrightarrow{4d} RH + H_2 \qquad H_2^* + H_2 \xrightarrow{5d} 2H_2$$

Deactivation by product species has been neglected in view of the low conversions usually employed. Combination on surfaces has also been neglected because the total pressures usually used have been relatively high. Finally, the alternative mechanism for combination (e.g. $H + M \rightleftharpoons HM^* \xrightarrow{H} H_2 + M$) has not been included; the application of such a mechanism leads to intractable algebraic relations.

If the mechanism describes completely the disappearance of R radicals and H atoms, the steady state treatment leads to [i] as the expression for the measured quantity $\rho \equiv R_{RH}/R_2^{\frac{1}{2}}[H_2]$ in which R_X is the rate of formation of the product X.

$$\rho = (k_3/k_{2a}^{\frac{1}{2}}\beta_2^{\frac{1}{2}})(2+2r)/(1+2r) \qquad [i]$$

Here $r = k_{5a}\beta_5[H]/k_{4a}\beta_4[R]$ and $\beta_n = (k_{nc}[A]+k_{nd}[H_2])/(k_{nb}+k_{nc}[A]+k_{nd}[H_2])$, the fraction of excited molecules formed in reaction [na] which suffer deactivation for the conditions used. Usually those conditions are such that the sequence [2] is in its high pressure region so that β_2 is unity and k_{2a} is replaced by k_2. Depending on the magnitude of $2r$ relative to the numerical constants, the correction factor in [i], i.e. $(2+2r)/(1+2r)$, tends to limiting values of two or unity. Usually it has been assumed that one or the other limit is valid over the whole range of temperature.

The correction factor can be independent of temperature if one of the following requirements is met (1). The disappearance of H atoms for all conditions is represented adequately by one of the sequences [4] and [5] (2). The temperature coefficient of r is zero; such a fortuitous cancellation of the temperature coefficient of [H]/[R] with that of $k_{5a}/\beta_5/k_{4a}/\beta_4$ is neglected.

If both sequences [4] and [5] should be included, it is anticipated that the correction factor varies with temperature. Since R_{RH}/R_{R_2} increases with temperature, it is expected that [H]/[R] will show a similar dependence so that the correction factor tends to 2 at low values of temperature (and for low $[H_2]$ and high I_a at a given temperature) and to unity for the opposite conditions. Thus, if both [4] and [5] are included, the temperature coefficient of ρ leads to an activation energy difference which is less than $E_3-\frac{1}{2}E_2$. It is difficult to assess the magnitude of the error in a real system. The maximum effect is obtained if the correction factor changes from 2 to unity over the temperature range studied; if the limits of that range are 300° and 450° K, the error is 1.4 kcal/mole.

When aldehydes are used as the source of free radicals, reaction [6] must be considered as well.

$$R + RCHO \rightarrow RH + RCO \qquad [6]$$

For this mechanism the correction factor contains a third additive term, $k_6[A]/k_{4a}\beta_4[R]$, in both the numerator and the denominator. If, as Pritchard and Foote suggest (5), [6] is the predominant fate of H atoms for all conditions, the correction factor cancels to unity and the temperature coefficient of ρ yields $E_3-\frac{1}{2}E_2$ unambiguously. Because of the relative smaller amount of R_2 formed in the aldehyde system, the value of $E_3-\frac{1}{2}E_2$ derived is possibly less precise than that obtained from ketone studies. On the other hand the agreement is quite good as shown below.

Reaction:	$C_2F_5 + H_2$		$C_3F_7 + H_2$		$C_3F_7 + D_2$	
System:	Ald. (5)	Ket. (3)	Ald. (5)	Ket. (4)	Ald. (5)	Ket. (4)
$E_3-\frac{1}{2}E_2$, kcal/mole	12.4	11.9	12.1	12.3	14.0	13.8
$A_3/A_2^{\frac{1}{2}}$, $(\text{mole/ml})^{\frac{1}{2}}$ $\text{sec}^{-\frac{1}{2}} \times 10^{-5}$	15.9	5.25	7.2	4.37	9.6	6.01

Values cited for the ketone systems have been calculated with the assumption that the correction factor is 2 and is independent of temperature as was done in the original publications. This agreement in the determinations of $E_3-\frac{1}{2}E_2$, especially for C_3F_7 reactions, is, in itself, indicative that one of the sequences [4] and [5] predominates in the ketone systems.

Unfortunately it is doubtful whether the data are sufficiently precise to permit a reliable decision about which of the limiting values of the correction factor should be used in the ketone systems. A comparison of the apparent values of $A_3/A_2^{\frac{1}{2}}$ from the two systems suggests that the correction factor should be unity, i.e. that sequence [5] predominates over [4] in the ketone systems, but the uncertainties are such as to inspire little confidence in this conclusion. The same conclusion was reached by Ayscough and Polanyi (1) in an experimental test involving the attack of CF_3 on an equilibrium mixture of the isotopes of hydrogen.

On the other hand, Miller and Steacie (4) gave theoretical reasons which suggested that [4] predominates over [5]. A rather more quantitative basis is now available for this argument in view of recent data (6)[3] which permits a calculation of the rate constant for the dissociation of CH_3D^* (formed from $CH_3 + D$); the value at room temperature is of the order $10^9\ \text{sec}^{-1}$. If RH^* in the present systems is assumed to have a similarly long life so that k_{4b} is also of this order, and if k_{4c} is taken near $10^{13}\ (\text{mole/ml})^{-1}\ \text{sec}^{-1}$, i.e. about 10% of the collisions are effective in deactivation, and if H_2 is assumed to have negligible deactivation efficiency, then, for the conditions used, β_4 is close to unity. However, it might be expected that k_{5b} would be closer to $10^{13}\ \text{sec}^{-1}$ so that, with similar rates of deactivation, β_5 is of the order 10^{-4}. Since there is no a priori reason to expect k_{4a} to differ greatly from k_{5a}, the long life of RH^* requires that [H]/[R] approach 10^4 if the $2r$ term in the correction factor of [i] is to compare in magnitude to the numerical constants. Such a large ratio of concentrations is most improbable in these systems. Thus the theoretical argument favors the predominance of [4] while the available experimental evidence suggests that [5] is the more important reaction consuming H atoms.

This disagreement between theoretical expectation and experiment might be resolved if the alternative mechanism for the combination of H atoms were involved. Experimental work to test this possibility has been undertaken.

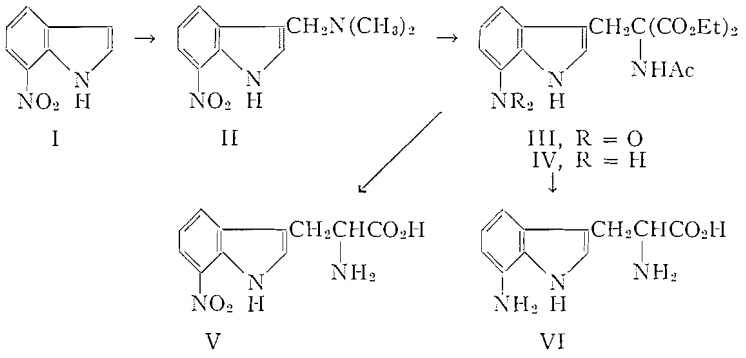
AN IMPROVED METHOD FOR DECARBOXYLATING INDOLE-2-CARBOXYLIC ACIDS AND ITS APPLICATION IN THE SYNTHESIS OF 7-AMINO-DL-TRYPTOPHAN

GIOVANNI CASINI* AND LEON GOODMAN†

A projected synthesis of 7-bis(2-chloroethyl)amino-DL-tryptophan in these laboratories required the preparation of large quantities of 7-nitroindole (I). The general procedure of Parmerter *et al.* (1) for the preparation of I was very convenient except for the final step, the decarboxylation of 7-nitroindole-2-carboxylic acid in boiling quinoline. When



the decarboxylation was effected in refluxing N,N-dimethylacetamide employing as catalyst the copper salt of the acid, prepared by the method of Piers and Brown (2), the yield of I was higher and the isolation was much simpler than in the conventional quinoline procedure. The dimethylacetamide method of decarboxylation should be generally useful in the preparation of substituted indoles.

While this work was in progress, Da Settimo (3) and Hiremath and Siddappa (4) reported the synthesis of 7-nitro-DL-tryptophan (V), utilizing the same intermediates, the gramine (II) and the acetamidomalonate ester (III), that were used to prepare VI. Catalytic reduction of the diester (III) afforded a good yield of the crystalline amino-ester (IV), which was hydrolyzed directly to 7-amino-DL-tryptophan (VI) isolated as

the hydrated dihydrochloride. Alternatively, 7-nitro-DL-tryptophan (V) (3) could be hydrogenated catalytically to the free base (VI), which was obtained as a crystalline solid and also converted to the dihydrochloride.

EXPERIMENTAL

7-Nitroindole (I)

A mixture of 4.0 g of 7-nitroindole-2-carboxylic acid (1), recrystallized from ethanol and *completely free* of inorganic salts, 0.4 g of the copper salt of 7-nitroindole-2-carboxylic acid, prepared by the method of Piers and Brown (2), and 20 ml of N,N-dimethylacetamide was refluxed, under nitrogen, until carbon dioxide evolution ceased (about 5 hours), then was poured onto 200 g of cracked ice. The yellow-green precipitate was washed and dried, then crystallized from 60 ml of boiling petroleum ether (60–110°) using Norit A, to afford 2.8 g (89%) of I, m.p. 96–97° (lit. (1) gives m.p. 95–96°).

7-Nitrogramine (II)

7-Nitrogramine (II) was prepared essentially as described by Da Settimo (3) although different physical constants were obtained. Thus, 7.0 g of 7-nitroindole (I) gave 11.2 g of crude II, m.p. 47–59°. Recrystallization of material by dissolving in 1 volume of hot methanol and adding 4 volumes of water gave the hydrate of II, m.p. 55–60°. Anal. Calc. for $C_{11}H_{13}N_3O_2.H_2O$: C, 55.7; H, 6.37; N, 17.7. Found: C, 55.7; H, 6.31; N, 17.9.

Alternatively, recrystallization from boiling toluene with azeotropic removal of any water gave the anhydrous compound, m.p. 91–92° (lit. (3, 4) give m.p. 69–71° and 79–80°, respectively). Anal. Calc. for $C_{11}H_{13}N_3O_2$: C, 60.3; H, 5.98; N, 19.2. Found: C, 60.4; H, 6.16; N, 18.8.

Ethyl α-Acetamido-α-carbethoxy-β-(7-amino-3-indolyl)propionate (IV)

A suspension of 3.0 g of ethyl α-acetamido-α-carbethoxy-β-(7-nitro-3-indolyl)propionate (III), prepared using the same procedure described by Da Settimo (3), 0.3 g of 5% palladium-on-charcoal, and 150 ml of absolute ethanol was treated with hydrogen at 25 p.s.i. and room temperature until the hydrogen uptake ceased (about 2 hours). The solution was filtered rapidly and the filtrate concentrated *in vacuo* to about 30 ml. The solution, after being chilled and scratched, deposited 2.3 g (82%) of crystalline product. The mother liquors were concentrated and treated with water, giving a second crop of crystals which raised the total crude yield to 95%. The analytical sample was recrystallized from ethanol and had m.p. 182–183°; $\lambda_{max\,(\mu)}^{Nujol}$ 2.90, 2.95, 3.10 (NH), 5.73 (ester C=O), 6.02 (amide C=O). Anal. Calc. for $C_{13}H_{23}N_3O_5$: C, 59.8; H, 6.42; N, 11.6. Found: C, 60.1; H, 6.62; N, 11.5.

7-Amino-DL-tryptophan (VI) and the Dihydrochloride

Method A

A stirred mixture of 0.13 g of 7-nitro-DL-tryptophan (3), 0.01 g of platinum oxide, and 50 ml of water was treated with hydrogen at atmospheric pressure until the theoretical amount of gas was absorbed (about 1 hour). The warm (50°) mixture was filtered rapidly and the filtrate was evaporated *in vacuo*, leaving a grey, crystalline powder which was dissolved in 20 ml of hot 60% aqueous ethanol. The solution was cooled, filtered through a thin layer of Norit A, and the filtrate concentrated *in vacuo*, affording 0.07 g (61%) of white crystals. The analytical sample, which slowly decomposed above 250°, was obtained by recrystallization from 3 ml of hot water; $\lambda_{max\,(\mu)}^{Nujol}$ 2.97 (NH), 3.6–4.0 and 4.75 ($NH_3\oplus$), 5.99 (NH_2), 7.04 ($CO_2\ominus$). Its paper chromatographic behavior in the isopropanol – 2 *N* hydrochloric acid system was identical with that of the dihydrochloride (see below). Anal. Calc. for $C_{11}H_{13}N_3O_2$: C, 60.3; H, 6.00; N, 19.2. Found: C, 59.8; H, 6.19; N, 18.9.

The dihydrochloride was obtained from the free base (VI) by dissolving it in a small volume of conc. hydrochloric acid. The chilled solution deposited crystals which were recrystallized from methanol–ether, affording a solid which decomposed slowly above 200°; $\lambda_{max\,(\mu)}^{Nujol}$ 3.08 (NH), 3.7–4.0 ($NH_3\oplus$), 5.69 (carboxyl C=O). The compound was homogeneous on paper chromatography (Whatman No. 1) in isopropyl alcohol – 2 *N* hydrochloric acid (65:35) with R_f 0.51, detected both by ninhydrin spray and ultraviolet examination. Anal. Calc. for $C_{11}H_{15}Cl_2N_3O_2.\frac{1}{4}H_2O$: C, 44.5; H, 5.27; Cl, 23.9; N, 14.2. Found: C, 44.7; H, 5.63; Cl, 24.0; N, 14.0.

Method B

A solution of 0.50 g of the aminoester (IV) in 4.0 ml of conc. hydrochloric acid was heated at reflux under nitrogen for 4 hours, then chilled. A crystalline solid, 0.26 g (65%), was collected and washed with acetone. The product was crystallized three times from methanol and ether, affording the analytical sample, which was identical with dihydrochloride prepared by method A (see above) according to infrared spectral and paper chromatographic comparison.

THE INITIAL RATE OF DECOMPOSITION OF WATER VAPOR BY AN ELECTRICAL DISCHARGE[1]

S. S. Barton, R. A. Jones, and D. E. Thyne[2]

Gill and Townsend (1), in a mathematical analysis, based on classical kinetic theory, of the motions of free electrons in a high-frequency gas discharge, developed an expression which predicts that the transfer of energy from the field to the gas molecules will have a maximum value when the frequency of the electrical field (ν) is equal to the kinetic theory frequency of elastic gas–molecule collisions (f).

If the density of free electrons remains constant with pressure for a high-frequency discharge in water vapor and if dissociative excitation of water molecules is the main consequence of the electron–molecule collisions while no further destruction of water occurs during subsequent reactions then the rate of decomposition should exhibit a maximum at the pressure where $\nu = f$.

In this work, $\nu < f$, except at very low pressures, and hence the maximum in the rate dependence on pressure may not be observed. However, the rate of decomposition should decrease with increasing pressure.

EXPERIMENTAL

The reaction cell was a 250-ml rectangular volumetric flask upon opposite sides of which were deposited two rectangular (4 × 6 cm) indium electrodes. The distance between the electrodes was approximately 5.7 cm. One electrode was grounded and the other connected to a Tesla coil (standard leak tester). The power

dissipated in the Tesla coil and the discharge was adjusted by the spark gap control and was measured with a voltmeter and an ammeter in the primary of the Tesla.

The frequency range over which the Tesla coil operated was determined with a General Radio Precision Wavemeter. The range extended from 200 kc to 800 kc with a maximum output at 500 kc.

The pressure rate of decomposition was recorded on a recording potentiometer (chart speed 8 in./minute) suitably connected to record the off-balance of a Consolidated Electrodynamics Corp. Micromanometer.

Water vapor from an outgassed sample of distilled water was allowed to enter the evacuated cell until a suitable pressure had been attained. The cell and the micromanometer were then isolated from the rest of the system and when pressure equilibrium had been reached the Tesla coil was turned on for 10–15 seconds. Initial rates of reaction were obtained from the slope of the initial straight-line portion of the recorded pressure vs. time curve. This straight-line portion extended over about a 0.1- to 0.5-fold pressure increase. When the discharge was allowed to continue for periods of up to 5 minutes, the pressure continued to rise past the 1.5-fold increase expected from the stoichiometry, $2H_2O = 2H_2 + O_2$. Presumably this excess pressure was due to absorbed water which left the surface of the cell as the reaction proceeded.

RESULTS AND DISCUSSION

Experiments were carried out at two levels of power consumption by the Tesla coil and discharge; 5.8 and 9.2 watts respectively. The pressure rates, dp/dt, were found to be proportional to the total power and in Fig. 1, which shows $2\,dp/dt$ vs. p_0 data from

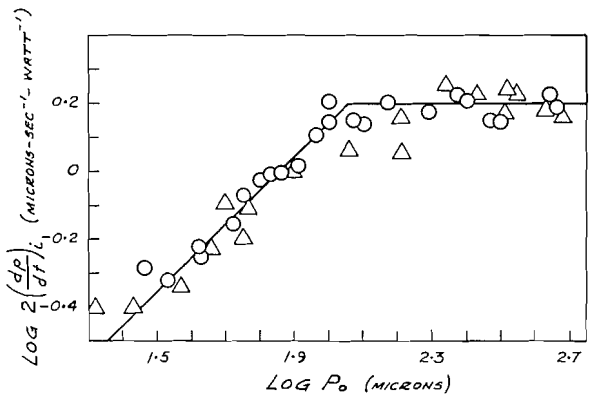

FIG. 1. Log–log plot of p_0 vs. $2\,dp/dt$ per watt data.

both sets of experiments in a log–log plot, the rates are expressed in microns sec^{-1} $watt^{-1}$. The initial pressure rate of reaction increases with increasing initial pressure and the reaction appears to be second order below $p_0 = 100$ microns. Above 100 microns the reaction becomes zero order.

If the Gill–Townsend mechanism is valid for this case and if the assumptions noted above hold then the rate should decrease with increasing pressure from a maximum value at about 2.4 μ, where $f = 4\times10^5$ sec^{-1}. It is not possible from the data to decide whether failure to follow this course can be ascribed to an increase in free-electron density with pressure or to decomposition reactions following the primary dissociation of water.

AN ESTIMATE OF THE HYDRONIUM ION ACTIVITY IN CONCENTRATED ACIDS

KEITH YATES

Deno and Spink (1) have suggested that H_R' (2) is the simplest acidity function since in equilibria of the type

$$[1] \qquad RH_2^+ \rightleftharpoons RH + H^+ \qquad K_{RH_2^+} = a_{RH} \cdot a_{H^+}/a_{RH_2^+}$$

where RH is a hydrocarbon base, for example a diarylolefin, and RH_2^+ is a carbonium ion, the ratio $f_{RH_2^+}/f_{RH}$ should be nearly invariant with acid concentration. Thus

$$H_R' = pK_{RH_2^+} - \log RH_2^+/RH = -\log a_{H^+} f_{RH}/f_{RH_2^+}$$

should be approximately equal to $-\log a_{H^+}$. The assumption about the invariance of $f_{RH_2^+}/f_{RH}$ is based on the fact that the hydrocarbons and their resulting carbonium ions are of practically the same size, that neither will strongly hydrogen bond to solvent, and that extensive charge delocalization in the large organic cations would be expected to minimize differences in electrostatic effects on $f_{RH_2^+}$ and f_{RH}. There is experimental evidence to support such a view (3) (see also last paper in (2)). However, in equilibrium (1) the conjugate acid RH_2^+ must transfer its proton to at least one water molecule, therefore $K_{RH_2^+}$ should involve some power of the water activity if it is to be considered as an equilibrium constant in any but a purely operational sense. From estimated values of the proton affinity of water (4) and from spectroscopic evidence (5) H_3O^+ can be regarded as a well-defined species in solution. Although other water molecules are undoubtedly fairly firmly held to H_3O^+ (6) the process $H^+ + H_2O \rightarrow H_3O^+$ involves formation of a very strong covalent bond (180–200 kcal mole^{-1}), whereas subsequent waters are attached through hydrogen bonds. Thus to a first approximation the olefin–carbonium ion type of equilibrium can be written in terms of H_3O^+ as a *formal* species,

$$RH_2^+ + H_2O \rightleftharpoons RH + H_3O^+.$$

In this case $K_{RH_2^+} = a_{RH} \cdot a_{H_3O^+}/a_{RH_2^+} \cdot a_{H_2O}$ and $H_R' = -\log a_{H_3O^+} f_{RH}/a_{H_2O} f_{RH_2^+}$. Thus $\log a_{H_3O^+} = -H_R' + \log a_{H_2O} + \log f_{RH_2^+}/f_{RH}$ and if the last term is nearly invariant with acid concentration a function H_R^* can be defined such that $H_R^* = H_R' - \log a_{H_2O} \approx -\log a_{H_3O^+}$. Values of H_R^* have been calculated for sulphuric, perchloric, and nitric acids in the range 0–70% acid and are shown in Table I. If calculations of H_R^* are extended

TABLE I

Calculated values for H_R^* for sulphuric, perchloric, and nitric acids

beyond 70% sulphuric acid it is interesting to note that H_R* reaches a maximum at almost exactly the equimolar composition of H_2SO_4–H_2O, where the concentration of H_3O^+ must also reach a maximum. This is shown in Fig. 2. The experimentally observed rise in indicator acidity above this region may be attributed to a continued large increase in $f_{H_3O^+}$, but can also be reasonably explained as being due to the drastic reduction in "free" water available and to the involvement of less basic species such as HSO_4^-, H_2SO_4 in the indicator equilibria.

To test the variance of $\log f_{RH_2^+}/f_{RH}$, the functions H_0 and H_R' can be combined to give

$$H_R' - H_0 - \log f_{BH^+}/f_B = \log f_{RH_2^+}/f_{RH}.$$

Experimental values of H_R' and H_0 are available and the recent work of Boyd (7) can be used to estimate $\log f_{BH^+}/f_B$ for the Hammett indicators. Hence estimates of $\log f_{RH_2^+}/f_{RH}$ can be made. Since Boyd's ionic activity coefficients are referred back to TEA^+ as standard ion, the estimated values of $f_{RH_2^+}$ will also be based on this standard. The variation of $\log f_{RH_2^+}/f_{RH}$ with acid concentration is shown in Fig. 1 with $\log f_{BH^+}/f_B$ for comparison.

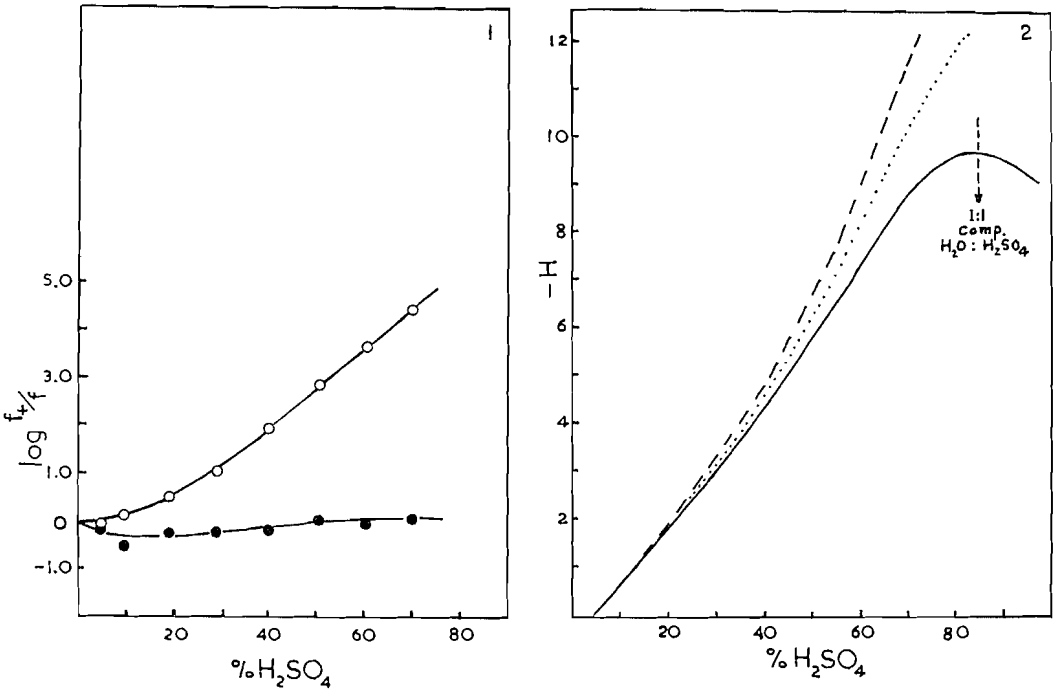

FIG. 1. Variation of activity coefficient ratios with acid concentration. Open circles, $\log f_{BH^+}/f_B$. Solid circles, $\log f_{RH_2^+}/f_{RH}$.

FIG. 2. Variation of hydrocarbon type acidity functions with concentration. – – – H_R, ... H_R', —— H_R*.

It can be seen that $\log f_{RH_2^+}/f_{RH}$ shows little change with concentration compared to the variation of $\log f_{BH^+}/f_B$. This provides support for Deno and Spink's suggestion but does not establish the invariance of $\log f_{RH_2^+}/f_{RH}$ since $f_{RH_2^+}$ is based on the reference f_{TEA^+}, which itself might show considerable variation with acidity. However, Boyd's study (7) of the effect of N-substitution on the activity coefficient of anilinium ion shows that the variation of $\log f_{BH^+}$ decreases with the number of N-alkyl groups. Therefore it seems reasonable that f_{TEA^+} might be expected to show little variation, presumably because of

For personal use only.

the shielding of the cationic charge on nitrogen by four tetrahedrally arranged ethyl groups.

It is therefore proposed that H_R^* can be used as an approximate measure of the hydronium ion activity in concentrated mineral acids. This function can be obtained for any acid for which H_R data and water activities are available, without the difficulties inherent in attempting to evaluate appropriate solute activity coefficients.

It is of interest to compare the H_R^* values in sulphuric acid with Boyd's values of log a_{H^+}/f_{TEA^+} (7) which are also shown in Table I. Some divergence is apparent in the high acidity region but the two sets of values agree within 0.19 log unit up to 60% acid. This agreement is surprising in view of the fact that log a_{H^+}/f_{TEA^+} values were derived without any reference to the water activity and must be at least partly fortuitous. It is possible that a more sophisticated treatment involving variable hydration numbers for all species may provide an explanation of this.

CALCULATIONS

Water activities in sulphuric acid at 25° C have been taken from the recent measurements of Giauque and co-workers (8). Average values of the water activity data at 25° C of Pearce and Nelson (9) and of Robinson and Baker (10) have been used for perchloric acid. Since Giauque (11) has criticized the available data for nitric acid at 25° C on the grounds that it does not obey the Duhem–Margules equation, the water activity data of Potier (12) at 0° C and 20° C have been extrapolated to 25° C. Calculations show that these results are in reasonable accord with the Duhem–Margules relation. Values of H_R and hence H_R' have been taken from Deno and co-workers (13). Estimates of log f_{BH^+}/f_B in 0–70% sulphuric have been made by averaging Boyd's (7) results for anilinium, *p*-chloroanilinium, and *p*-nitroanilinium to obtain log f_{BH^+} (relative to log f_{TEA^+}) and by averaging log f_B values for 2,4-dinitro-, 2,4-dichloro-6-nitro-, and 2,6-dichloro-4-nitro-anilines. These six indicators are typical of those which would be used to set up the H_0 scale in the 0–70% acid range. The equilibrium constant $K_{RH_2^+}$ as defined in this paper is only strictly correct if the activity of water is based on the same concentration scale as the activities of the solute species, namely the molarity scale, which is usually employed for indicator equilibria. However, if the water activity in

$$K_{RH_2^+} = a_{RH} \cdot a_{H_3O^+}/a_{RH_2^+} \cdot a_{H_2O}$$

is based on the mole fraction scale, it can be shown (14) that this expression is related to the true equilibrium constant by the relation

$$K^{true}_{RH_2^+} = 55.5 K_{RH_2^+} \cdot \left(\frac{d + 0.001(18\Sigma c_i - \Sigma c_i w_i)}{(\Sigma c_i) d_0} \right)$$

where d = the density of the solution, d_0 = the density of the pure solvent, c_i = molar concentration of the ith species. The summations are over all species present in solution. The factor of 55.5 enters in so that $a_{H_2O} \rightarrow 1$ in dilute solution on the molarity scale. Thus in dilute solution $K^{true}_{RH_2^+} = K_{RH_2^+}$ and in 70% sulphuric acid, assuming complete ionization of H_2SO_4, the above relation gives $K^{true}_{RH_2^+} = (1.31)\ K_{RH_2^+}$. This corresponds to a variation of 0.12 log units in $pK_{RH_2^+}$ over the range 0–70% sulphuric acid. Hence no serious error is introduced by using mole fraction water activities obtained directly from vapor pressure measurements. This is also illustrated by the fact that H_R' values derived from H_R using mole fraction water activities are directly applicable to olefin-carbonium ion equilibria (2).

ACID-CATALYZED REACTIONS OF VINYL COMPOUNDS

PART III. 2,7,9,10-TETRAMETHYLANTHRACENE FROM VINYL ACETATE AND TOLUENE

J. M. PEPPER, MARGARET HOWELL, AND B. P. ROBINSON

In previous communications (1, 2), the nature of the products obtained by the aluminum chloride catalyzed reaction of vinyl acetate and benzene was reported. As part of a subsequent, more detailed study of the mechanism of formation of the principal product, namely 9,10-dimethylanthracene, the similar reaction involving vinyl acetate and toluene was investigated. The isolation of 2,7,9,10-tetramethylanthracene rather than the 2,6,9,10-tetramethyl isomer supported a mechanism of formation of the anthracene derivatives which consisted of the initial synthesis of the 1,1-diarylethane followed by ring closure involving incorporation of a two-carbon fragment. Details of this mechanism will appear in a forthcoming publication. This note describes the synthesis and structure proof of the previously unreported 2,7,9,10-tetramethylanthracene.

Chromic acid oxidation of the purified reaction product gave a substance identical with 2,7-dimethylanthraquinone. An Elbs reaction performed upon 2,4,4′-trimethylbenzophenone, obtained from a Friedel–Crafts reaction of *p*-toluoyl chloride with *m*-xylene, afforded a mixture of 2,7-dimethylanthracene and 3,6-dimethylanthrone either of which, when oxidized with chromic acid, gave authentic 2,7-dimethylanthraquinone.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were measured using a Perkin–Elmer Model 21 spectrometer with sodium chloride optics.

ACID-CATALYZED REACTIONS OF VINYL COMPOUNDS

PART III. 2,7,9,10-TETRAMETHYLANTHRACENE FROM VINYL ACETATE AND TOLUENE

J. M. PEPPER, MARGARET HOWELL, AND B. P. ROBINSON

In previous communications (1, 2), the nature of the products obtained by the aluminum chloride catalyzed reaction of vinyl acetate and benzene was reported. As part of a subsequent, more detailed study of the mechanism of formation of the principal product, namely 9,10-dimethylanthracene, the similar reaction involving vinyl acetate and toluene was investigated. The isolation of 2,7,9,10-tetramethylanthracene rather than the 2,6,9,10-tetramethyl isomer supported a mechanism of formation of the anthracene derivatives which consisted of the initial synthesis of the 1,1-diarylethane followed by ring closure involving incorporation of a two-carbon fragment. Details of this mechanism will appear in a forthcoming publication. This note describes the synthesis and structure proof of the previously unreported 2,7,9,10-tetramethylanthracene.

Chromic acid oxidation of the purified reaction product gave a substance identical with 2,7-dimethylanthraquinone. An Elbs reaction performed upon 2,4,4′-trimethylbenzophenone, obtained from a Friedel–Crafts reaction of *p*-toluoyl chloride with *m*-xylene, afforded a mixture of 2,7-dimethylanthracene and 3,6-dimethylanthrone either of which, when oxidized with chromic acid, gave authentic 2,7-dimethylanthraquinone.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were measured using a Perkin–Elmer Model 21 spectrometer with sodium chloride optics.

Reaction of Vinyl Acetate and Toluene

Vinyl acetate (8.6 g, 0.1 mole) was added over a period of 1 hour to a cooled mixture of toluene (92 g, 1.0 mole) and aluminum chloride (40 g, 0.3 mole). The mixture was heated at 80° for 3 hours and the resulting complex decomposed and worked up in the usual manner. The crude product (18.9 g) was distilled and a fraction, boiling at 140–180° at 0.2 mm, was collected. This product solidified slowly and was recrystallized several times from absolute ethanol to yield 2,7,9,10-*tetramethylanthracene*, m.p. 124–125°. (Found: C, 92.74; H, 7.61. $C_{18}H_{18}$ requires C, 92.26; H, 7.74%.) Infrared spectrum (main peaks only): 2900, 1630, 1450, 1345, 910, 805, and 755 cm^{-1}.

Oxidation of 2,7,9,10-Tetramethylanthracene

Chromic acid (1.2 g) was dissolved in the minimum amount of water and this solution added slowly to 2,7,9,10-tetramethylanthracene (0.74 g) dissolved in glacial acetic acid (10 ml). The mixture was heated under reflux for 40 minutes and then poured into water (40 ml). The resulting precipitate was collected, partially purified by boiling in 5% sodium hydroxide solution, and recollected. Recrystallization from absolute ethanol gave 2,7-dimethylanthraquinone as colorless needles (0.55 g), m.p. 165–169°; no melting point depression with an authentic synthetic sample.

Synthesis of 2,7-Dimethylanthraquinone

2,4,4′-Trimethylbenzophenone.—A procedure similar to that reported by Morgan and Coulson (3) was used. A solution of *p*-toluoyl chloride (6.25 g) and *m*-xylene (4.3 g) in petroleum ether (b.p. 37–49°) (10 ml) was added slowly to aluminum chloride (6.3 g). The mixture was heated under reflux for 2 hours before decomposition of the complex. Distillation of the crude product gave 2,4,4′-trimethylbenzophenone (5.15 g, 57%), b.p. 208–210° at 19 mm; reported b.p. 169° at 4 mm (3).

Pyrolysis of 2,4,4′-Trimethylbenzophenone.—By application of the Elbs pyrolysis reaction by the method of Morgan and Coulson (3), two products were obtained: 2,7-dimethylanthracene, m.p. 240–243°, reported m.p. 241° (3), and 3,6-*dimethylanthrone*, m.p. 163–164°. (Found: C, 86.60; H, 6.56. $C_{16}H_{14}O$ requires C, 86.45; H, 6.35%.)

2,7-Dimethylanthraquinone.—Oxidation of either 2,7-dimethylanthracene or 3,6-dimethylanthrone, using chromic acid according to the method of Morgan and Coulson (3), gave 2,7-dimethylanthraquinone, m.p. 171–172°; reported m.p. 170° (4).

temperatures and initial concentrations. It was found that at initial concentrations of below 0.1 molar the first-order rate constants were independent of the initial concentration, as shown for the reactions at 168.7° C. The values at the lower temperatures are each averages of four runs with initial concentrations of 0.1 molar or less. It is believed that these represent true rates of unimolecular homolysis, uninfluenced by the complications of induced decomposition. 2,3,3-Trimethyl-2-butyl hydroperoxide is not much different in its rate of decomposition, at temperatures where this is conveniently measurable, from other hydroperoxides (1). We previously pointed out, however, that *t*-butyl hydroperoxide was different from other hydroperoxides in having a considerably higher ΔH^* and ΔS^* for thermal decomposition (2). 2,3,3-Trimethyl-2-butyl hydroperoxide is now found to be anomalous in these respects also. The products, too, show a similarity to those obtained from the decomposition of *t*-butyl hydroperoxide. The large amount of parent alcohol indicates a substantial lifetime for the 2,3,3-trimethyl-2-butoxy radical. To the extent that this radical cleaves, acetone is formed, as well as *t*-butyl radical, which appears as *t*-butyl alcohol and isobutylene. It is apparent that tertiary hydroperoxides at least may be classified in two groups: those which have high activation energies for unimolecular thermal decomposition (39–40 kcal) and give a large amount of the parent alcohol, and those with lower activation energies, which give little or no alcohol (1, 2). If the human time scale were such that the decompositions could be measured at 50° C, large differences in thermal stability would be manifest.

These arguments, which in the case of perester decomposition led to a proposed difference in mechanism of homolysis (3), would seem to make a similar difference for hydroperoxides not unlikely.

EXPERIMENTAL

2,3,3-Trimethyl-2-butyl hydroperoxide was prepared by the method of Criegee (4). The hydroperoxide, recrystallized from pentane (m.p. 109–111° C), gave an iodometric titration of 95%. Alternately it was extracted from the reaction mixture with benzene and not isolated. Rates of decomposition of this material did not differ from those obtained with hydroperoxide that had been crystallized.

The kinetic studies were done in benzene with initial concentrations of hydroperoxide ranging from 0.01 to 0.5 molar. It was found that the presence of air had a profound effect where concentrations were less than 0.05 molar, and all runs were carried out in evacuated sealed tubes.

Products from completely decomposed samples were determined gas chromatographically.

ON THE DIFFERENTIATION OF *endo*- AND *exo*-NORBORNYL DERIVATIVES BY CHEMICAL SHIFTS IN N.M.R. SPECTROSCOPY

EDWARD W. C. WONG* AND C. C. LEE

Recently, Fraser (1) investigated the possibility of correlating the chemical shift of a proton to its *endo*- or *exo*- position in the products of Diels–Alder reactions between cyclic dienes and derivatives of ethylene. Examination of the n.m.r. spectra of a number of bicyclo[2.2.1]hept-2-enes, and the corresponding dihydro compounds, led this author to conclude that the configuration of a proton, or proton-bearing substituent, in this bicyclic system can be ascertained by observing the change in its chemical shift when the double bond is removed by hydrogenation. It was suggested that the effect of the magnetically anisotropic double bond would shift the absorption frequency of the *exo*-proton downfield and that of the *endo*-proton upfield. Thus the change in chemical shift upon hydrogen, $\Delta\tau$, should be positive for an *exo*-proton and negative for an *endo*-proton. To test this hypothesis, we have measured the chemical shifts of the *endo*- and *exo*-protons in three pairs of *endo*- and *exo*-dehydronorbornyl derivatives and in the corresponding norbornyl compounds.

In the *endo*- and *exo*-dehydronorbornyl and norbornyl derivatives examined (I–IV),

ON THE DIFFERENTIATION OF *endo*- AND *exo*-NORBORNYL DERIVATIVES BY CHEMICAL SHIFTS IN N.M.R. SPECTROSCOPY

EDWARD W. C. WONG* AND C. C. LEE

Recently, Fraser (1) investigated the possibility of correlating the chemical shift of a proton to its *endo*- or *exo*- position in the products of Diels–Alder reactions between cyclic dienes and derivatives of ethylene. Examination of the n.m.r. spectra of a number of bicyclo[2.2.1]hept-2-enes, and the corresponding dihydro compounds, led this author to conclude that the configuration of a proton, or proton-bearing substituent, in this bicyclic system can be ascertained by observing the change in its chemical shift when the double bond is removed by hydrogenation. It was suggested that the effect of the magnetically anisotropic double bond would shift the absorption frequency of the *exo*-proton downfield and that of the *endo*-proton upfield. Thus the change in chemical shift upon hydrogen, $\Delta\tau$, should be positive for an *exo*-proton and negative for an *endo*-proton. To test this hypothesis, we have measured the chemical shifts of the *endo*- and *exo*-protons in three pairs of *endo*- and *exo*-dehydronorbornyl derivatives and in the corresponding norbornyl compounds.

In the *endo*- and *exo*-dehydronorbornyl and norbornyl derivatives examined (I–IV),

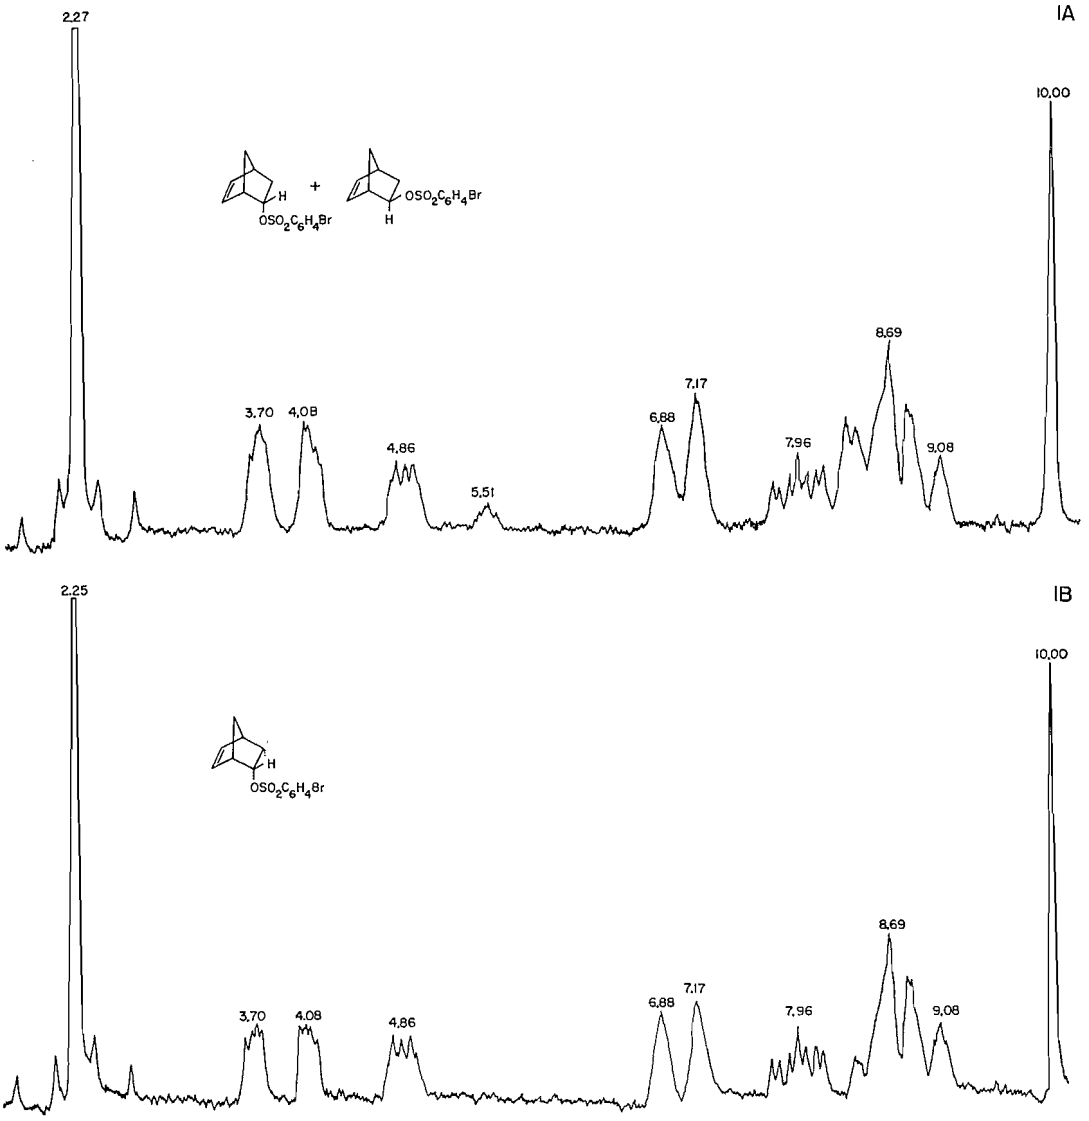

FIG. 1. Nuclear magnetic resonance spectra. A, B, C, and D are, respectively, a mixture of *endo*- and *exo*-dehydronorbornyl, *endo*-dehydronorbornyl, *endo*-norbornyl, and *exo*-norbornyl brosylates.

to the protons of the benzene ring. The multiplets centered at 3.70 and 4.08τ are assigned to the two olefinic protons. The multiplet at 4.86τ is due to the *exo*-proton (of the *endo*-brosylate) at C-2. The absorption of the C-2 *endo*-proton (of the *exo*-brosylate) is centered at 5.51τ. The peaks at 6.88 and 7.17τ are due to the bridgehead protons at C-1 and C-4. Following the reasonings of Fraser (1), the multiplet centered at 7.96τ is assigned to the *exo*-proton at C-3, while the peak at 9.08τ is part of the absorption of the *endo*-proton of C-3. The remaining peaks centered about 8.69τ may be assigned to the two protons of C-7.

As noted by Fraser (1), the saturated compounds show fewer well-resolved peaks. For *endo*-norbornyl brosylate (Fig. 1C), the absorption of the *exo*-proton at C-2 is centered

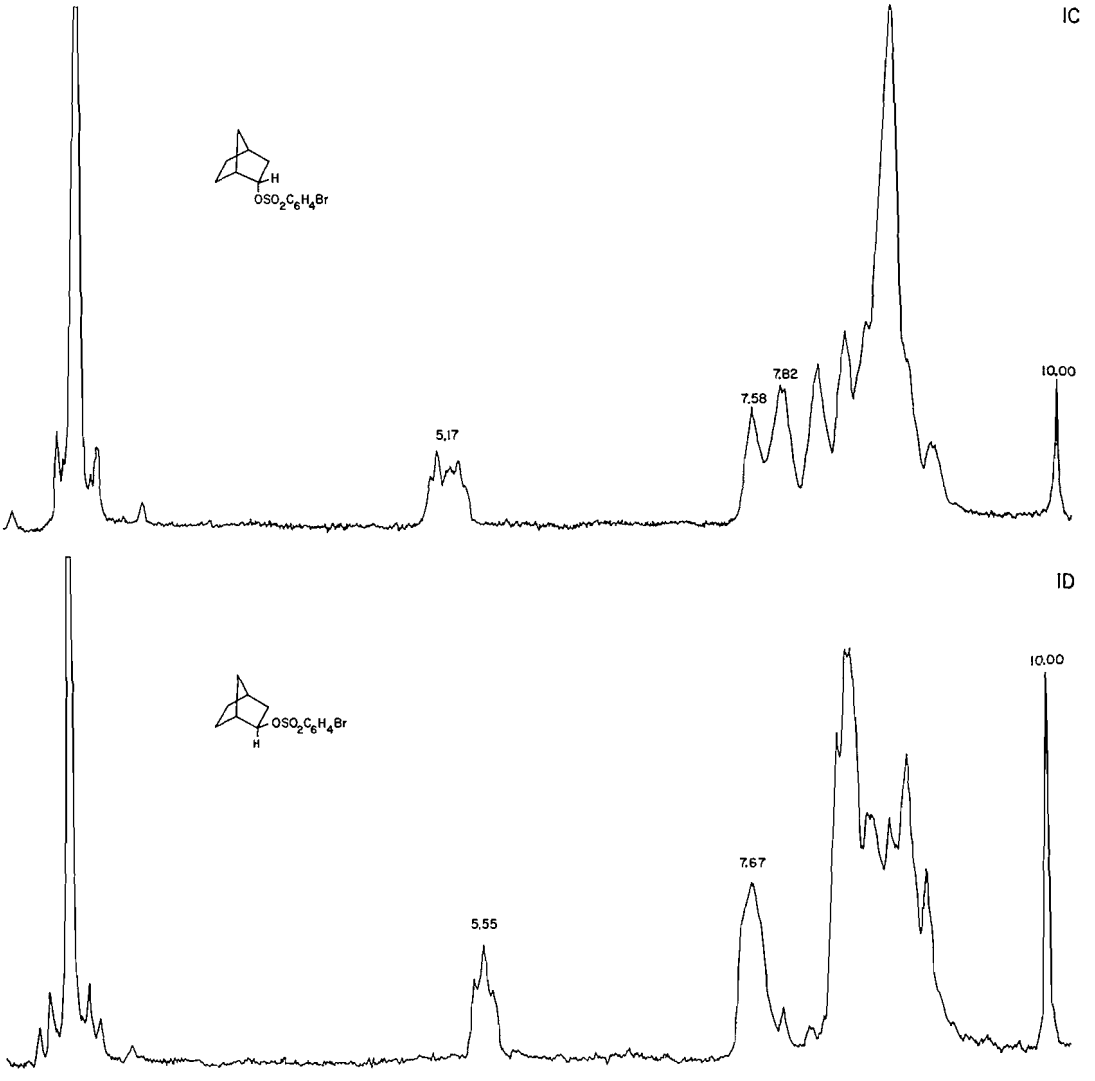

FIG. 1, C and D.

at 5.17τ. The other easily recognized peaks are those at 7.58 and 7.82τ due to the bridgehead protons. With *exo*-norbornyl brosylate (Fig. 2D), τ for the C-2 *endo*-proton is 5.55. Even the bridgehead protons are not resolved in this case.

The τ values for the *exo*- or *endo*-protons at the C-2 position of compounds I to IV were ascertained in a manner similar to that illustrated with the brosylates. These are summarized in Table I. It may also be pointed out that the correctness of the assignments is supported by the fact that the absorption of the C-2 proton of the norborneols disappeared in the spectrum of norborneol-2-*d* (chiefly *endo*) obtained from the reduction of norcamphor with lithium aluminum deuteride.

If the generalization of Fraser (1) regarding the effect of the double bond on chemical shifts of *exo*- and *endo*- protons were valid, the change in τ upon removal of the double

TABLE I

Chemical shifts of *exo*- and *endo*-protons at the C-2 position of dehydronorbornyl and norbornyl derivatives

	Alcohol		Acetate		Brosylate	
	τ	$\Delta\tau$*	τ	$\Delta\tau$*	τ	$\Delta\tau$*
endo-Dehydronorbornyl	5.54		4.81		4.86	
endo-Norbornyl	5.83	0.29	5.13	0.32	5.17	0.31
exo-Dehydronorbornyl	6.18		5.43		5.51	
exo-Norbornyl	6.34	0.16	5.46	0.03	5.55	0.04

*Change in τ upon removal of double bond.

bond, obtained by subtracting τ of the dehydronorbornyl derivative from that of the corresponding norbornyl derivative, should be positive if the proton at C-2 is *exo* and negative if this proton is *endo*. As can be seen from Table I, all values of $\Delta\tau$ obtained for the present cases are positive, regardless of whether the C-2 proton is *exo* or *endo*. Thus the suggestion that the *exo*- or *endo*-configuration may be established by the sign of $\Delta\tau$ does not hold for the dehydronorbornyl and norbornyl alcohols, acetates, and brosylates.

For the examples examined in the present study, the presence of the double bond shifted the absorption downfield for both *exo*- and *endo*-protons at C-2, although the magnitude of this shift is very small for the *endo*-proton (of the *exo*-epimer). While it is not possible to use $\Delta\tau$ to establish the *exo*- or *endo*-configuration, if both epimers were available, a differentiation can be made by the fact that the *exo*-proton at C-2 absorbs at lower field than the *endo*-proton. The finding that the C-2 *exo*-proton is deshielded relative to the *endo*-proton has also been noted by Musher (4) for a number of bicyclo [2.2.1]heptanols including *endo*- and *exo*-norborneols. Moreover, the absorption of the C-2 *exo*-proton appears to be a quintet, while that of the C-2 *endo*-proton is split into lesser number of peaks. The splitting into a quintet observed for the *exo*-proton of *endo*-2-nitronorbornane and *endo*-2-nitronorbornene (numbering of carbon skeleton as given in I–IV) has been ascribed by Fraser (1) to strong coupling with the *exo*-proton at C-3 and weaker coupling with both the *endo*-proton at C-3 and the bridgehead proton at C-1. More recently, the complexity of the couplings of the *exo*- and *endo*-protons of bicyclo [2.2.1]heptanols has been described by Musher (4). The less extensive splitting shown by the C-2 *endo*-proton may largely be due to its inability to couple with the bridgehead proton at C-1 (5).

It was mentioned earlier that norborneol-2-*d* (chiefly *endo*) showed no absorption for the C-2 proton. It may be of interest to record that after treatment in the presence of sodium and fluorenone in refluxing toluene to give an equilibrated mixture of *exo*- and *endo*-norborneols (2), some C-2 proton absorption reappeared, indicating loss of some deuterium and its replacement by hydrogen. This observation is consistent with the suggestion that such equilibrations may proceed via norcamphor as an intermediate (6).

EXPERIMENTAL

Preparations of compounds I–IV, either as mixtures of epimers or as individual pure compounds, have been described previously (2, 3).

The n.m.r. spectra were taken at 60 Mc on a Varian A-60 spectrometer. Samples were of 15–20% concentration dissolved in carbon tetrachloride containing 1% tetramethylsilane as internal standard.

The reproducibility of the chemical shifts was better than 0.02τ. The relatively high sample concentration of 15–20% was used to provide absorption peaks of good intensity for the C-2 protons. Chemical shifts of the *exo*- or *endo*-protons at C-2 were not affected by variations of sample concentration within the range

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of 5–20%. Chemical shifts of hydroxylic protons are known to be sensitive towards changes in concentration because of association (7). As expected, the absorptions of the hydroxylic protons of the norborneols and dehydronorborneols shifted markedly downfield with increasing concentration. However, the positions of other absorption peaks, corresponding to protons not bonded to oxygen, showed no association effects.

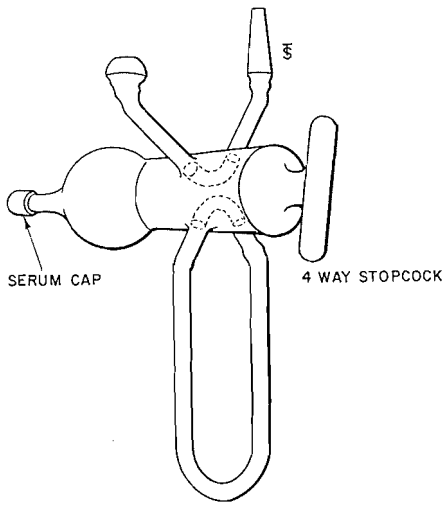
TRANSFER CELL FOR GAS CHROMATOGRAPHY

M. E. Bednas and D. S. Russell

In the literature there are few transfer cells (1–6) that enable a sample to be transferred from a vacuum manifold to a gas chromatograph in another location. Those designs which utilize two stopcocks are somewhat inconvenient to use and result in some peak broadening.



We have constructed a new transfer cell from a single four-way vacuum stopcock (see figure). In 1958, the first model had to be made with a non-vacuum stopcock; it leaked occasionally. Subsequently, Johns Glass Co., Toronto, has made some vacuum stopcocks according to the authors' design and they are now readily available. A serum bottle cap

is placed on the stopcock so that the barrel of the stopcock may be evacuated with a hypodermic needle cemented to a vacuum line.

Samples may be collected by one of the following methods:

(1) by evacuating the cell and filling it with the sample to some definite pressure.
(2) by evacuating the cell and freezing the whole sample from a vacuum manifold into it.
(3) by blowing or sucking the sample gas through a cold trap (as in the case of air pollutants).

The transfer cell may be used with any gas chromatographic apparatus. It may be connected directly to a four-way or six-way gas sampling valve. In these cases the connecting leads can be flushed with carrier gas first and, when equilibrium is re-established, the stopcock on the transfer cell can be turned to flush in the sample. To use the transfer cell with an instrument equipped with a septum, a hypodermic needle cemented to a 10/30 standard taper joint is fitted to the appropriate end of the cell and an auxiliary carrier gas line to the other end. The leads are flushed out, needle injected through the septum and stopcock turned to flush in the sample.

The authors have constructed cells with 4 to 20 ml capacity and used them under vacuum and up to 30 p.s.i.g. During 5 years of extensive use with these cells, 100% transfer of the sample has been achieved with an overall precision of $\pm 1\%$, including sample introduction, recording, and integration errors.

SOLVENT EFFECTS ON HYDROCARBON AUTOXIDATIONS[1]

J. A. Howard and K. U. Ingold

We have recently shown that the rate of the α,α'-azo-bis-isobutyronitrile- (AIBN-) initiated autoxidation of 0.42 mole/l. of styrene in oxidation-resistant solvents at 65° C increases with increasing dielectric constant of the solvent (1). The similarity between the effect of solvents on this reaction and their effect on the rate of the pyridine-catalyzed decomposition of *t*-butylperoxyformate at 90° C (2) led us to conclude that a dipolar transition state was probably involved in the addition of a peroxy radical to styrene, i.e., in the propagation reaction. It was suggested that the magnitude of the solvent effects on other oxidation reactions should indicate whether or not their propagation steps also involved dipolar transition states. Four other readily oxidizable hydrocarbons have now been examined in 11 of the solvents used in the previous work with styrene. The same experimental conditions were employed, i.e., 1 ml of reactant to 20 ml of solvent, initiated by 7×10^{-2} mole/l. [AIBN] at 65° C.

The rate of gas absorption is given by (1),

$$\rho_0 = (2e-1)k_1[\mathrm{AIBN}]+k_3[\mathrm{RH}]\left(\frac{ek_1[\mathrm{AIBN}]}{k_5}\right)^{1/2}$$

where RH represents the hydrocarbon, e is the efficiency of radical production by the initiator, k_1 is its rate constant for decomposition, and k_3 and k_5 are the propagation and self-termination rate constants. In calculating $k_3/k_5^{1/2}$ the same k_1 values were used as previously and e was taken to be 0.75 (1). The data are given in Table I for α-methyl styrene,* tetralin, 4-methyl cyclohexene, and cumene together with the data obtained previously for styrene. The $k_3/k_5^{1/2}$ values for the first three hydrocarbons have been plotted against $k_3/k_5^{1/2}$ for styrene in Fig. 1. The slopes of the best straight lines so

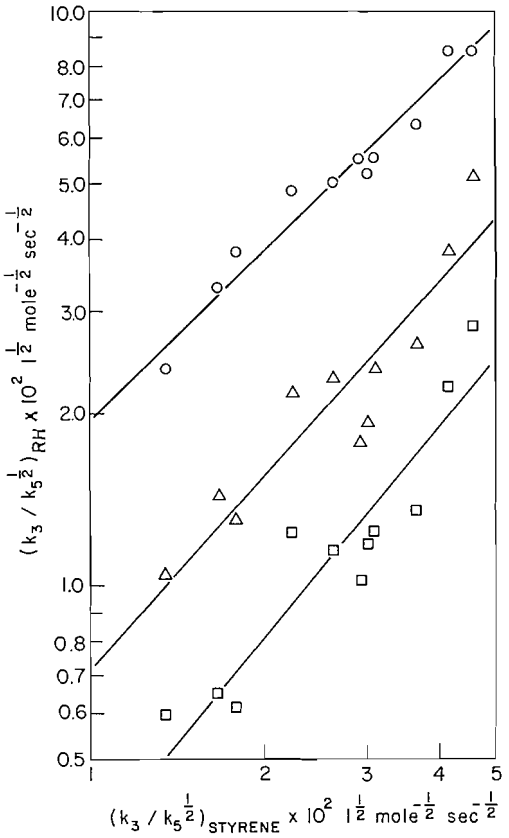

FIG. 1. $k_3/k_5^{1/2}$ for α-methyl styrene ○, 4-methyl cyclohexene △, and tetralin □, plotted against $k_3/k_5^{1/2}$ for styrene at 65° C.

obtained, together with their standard deviations (in $\log_{10}$ units), have been included in Table I.

The very close similarity of the solvent effects on the $k_3/k_5^{1/2}$ values for styrene and α-methyl styrene implies, as we originally suggested (1), that the solvent has a much greater influence on the propagation step (k_3) than on the termination step (k_5). That is,

*The oxygen pressure was kept constant at 740 mm in all the experiments with this hydrocarbon since its oxidation rate shows a slight variation with pressure up to at least 3200 mm (3).

the propagation steps must be quite similar for the two hydrocarbons since they will both involve the addition of a peroxy radical to a double bond. In contrast, the reactions involved in chain termination are probably quite different for the *secondary* styrene polyperoxy radicals and for the *tertiary* α-methyl styrene polyperoxy radicals (4). These results therefore provide confirmation that the increase in oxidation rate with increasing solvent dielectric constant results mainly from an interaction of the solvent with the dipolar transition state of the propagation reaction.

The similarity between the solvent effects on styrene and on tetralin and 4-methyl cyclohexene is not quite so close as the similarity between the two styrenes. However, the correlation is close enough to suggest that somewhat similar dipoles are involved in the transition states of both types of propagation reaction i.e., hydrogen abstraction and peroxy radical addition. There appear to be some specific differences in solvent effects for the two types of reaction. For example, $k_3/k_5^{1/2}$ is greater in CCl_4 than in *t*-butylbenzene for addition but is smaller for abstraction. Similarly, $k_3/k_5^{1/2}$ is enhanced in benzene and in acetonitrile for abstraction relative to addition but is depressed in *t*-butanol and in acetic acid.

The data for cumene is much less reliable than for any of the other hydrocarbons because the oxidation rates are so much smaller that the correction for nitrogen evolution from the AIBN (i.e. $(2c-1)k_I$[AIBN]) is a large fraction of the measured rate. Small errors in ρ_0, e, or k_1 will therefore be greatly magnified in the function $k_3/k_5^{1/2}$. This source of error is particularly important in the solvents of low dielectric constant where the rate is very low. For example, the measured rates in *n*-decane, *t*-butylbenzene, and CCl_4 were 8.8, 9.1, and 6.7×10^{-7} mole/l. sec, respectively, but the corrected rates were only 4.4, 2.8, and 2.1×10^{-7} mole/l. sec. Nevertheless, there appears to be a rough general correlation with the styrene data and a rather better correlation with the tetralin and 4-methyl cyclohexene data. A dipolar transition state is therefore probably involved in the propagation reaction with this substrate. This conclusion is supported by the recent correlation of the rate of oxidation of substituted cumenes with the σ^+ constants of the substituents (5).

Hendry (6) has recently measured $k_3/k_5^{1/2}$ at 60° C for 2.0 mole/l. of cyclohexene and for 2.0 mole/l. of cumene in several of the solvents used in this study. In spite of the different temperatures and the fact that oxidation rates tend to be very sensitive to trace

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

impurities there is an excellent correlation between his results and our own data on $k_3/k_5^{1/2}$ for styrene at 65° C. That is, the cyclohexene data (eight solvents) give a slope of 0.79 (standard deviation 0.024) and the cumene data (six solvents) give a slope of 0.25 (standard deviation 0.016) when plotted against $k_3/k_5^{1/2}$ for styrene.

In conclusion, the transition state for the propagation step in autoxidation reactions involves some contribution from a dipolar structure whether the peroxy radical abstracts a hydrogen atom or whether it adds to a double bond.

THE ELECTRONIC SPECTRA OF SOME ANIONIC POLYMERIZATION SYSTEMS[1]

S. BYWATER, A. F. JOHNSON,[2] AND D. J. WORSFOLD

Applied Chemistry Division, National Research Council, Ottawa, Canada

Received January 16, 1964

ABSTRACT

The ultraviolet absorption spectra of living anionic polymerizing systems have been measured with sytrene, butadiene, and isoprene as the monomers; with lithium, sodium, and potassium as the alkali metals; and with tetrahydrofuran, cyclohexane, and benzene as the solvents. For any monomer the similarity of the spectra obtained with the various metals and solvents leads to the conclusion that the alkali metal – carbon band has the same structure under the various conditions. From other evidence the bond is considered to be ionic in all cases. The diene monomer anions in tetrahydrofuran solution were found to undergo a series of isomerizations, some of them comparable in speed to the consumption of monomer.

Many polymerizations of olefins by anionic reagents occur by the addition of the metal–organic compound to the monomer molecule, M, as the chain initiation step. Chain propagation then proceeds by the addition of further monomer units to the carbon–metal bond at the end of the chain, re-forming the bond at each step.

$$R—M_n—Metal + M \rightarrow R—M_{n+1}—Metal$$

There is disagreement about the relative amount of ionic or covalent character of this bond when different alkali metals are used and when the polarity of the solvent is changed. With lithium in particular (1, 2), it has been suggested that in nonpolar solvents the carbon–lithium bond is largely covalent in character and that with dienes this covalency is the cause of the stereoregulating action found in nonpolar solvents. Addition of polar solvents such as tetrahydrofuran (THF) was supposed to promote ionization of the carbon–lithium bond, the ion-pair reacting to form a more random microstructure.

If the carbon–metal bond is essentially ionic, charge delocalization may be expected to occur with conjugated monomers, and the resultant polymer anions may be expected to show optical absorption in the near ultraviolet region at roughly the same wavelength as observed for the corresponding cations (3). The use of such an absorption band to measure the concentration of active centers in the butyllithium-catalyzed polymerization of styrene in benzene has been described previously (4). The effect of addition of tetrahydrofuran to such a system has been briefly mentioned (5). To learn more about the carbon–metal bond, a more general study of the changes in absorption spectra observed in the polymerization of styrene, butadiene, and isoprene has now been carried out in hydrocarbon solvents, in tetrahydrofuran, and in their mixtures with organo-lithium, -sodium, and -potassium reagents.

EXPERIMENTAL

The solvents and monomers were purified by standard methods described elsewhere (4, 6). The spectra were measured in the general type of apparatus (7) previously used involving greaseless high-vacuum apparatus to exclude moisture and air. Sodium and potassium films were used to initiate polymerization in THF and in cyclohexane; butyllithium was used to prepare the corresponding lithium compounds.

RESULTS

The absorption bands observed in the anionic polymerization of styrene are shown in Fig. 1. The positions of maximum absorption are given in Table I and show small changes

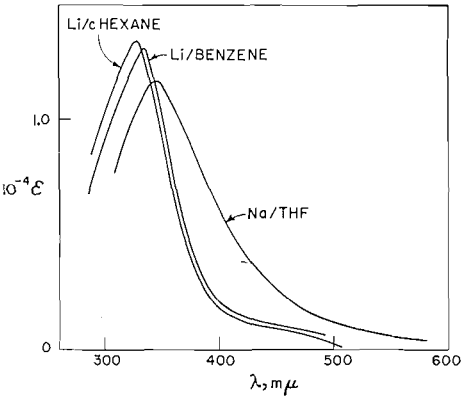

FIG. 1. Absorption spectra of polystyryl anions with different counterions in cyclohexane, benzene, and tetrahydrofuran.

"	"	Cyclohexane	275	

with alkali metal or with solvent. The absorption is proportional to the initiator concentration, and, since it is known that on complete initiation one polymer molecule is formed

per added initiator molecule, the absorption can be attributed to the reactive end grouping on the polymer chains. The absorption bands are very similar to those observed for benzyl-lithium or -sodium in the appropriate solvent (8, 9).

Similar absorption bands can be observed in the anionic polymerization of isoprene and butadiene; Table I shows the position of the maxima. With isoprene the measurements are complicated by rapid changes which occur in the spectra in tetrahydrofuran solution. After a time comparable to the time taken for the monomer to be consumed, a matter of minutes, the originally formed peaks have declined and other peaks of longer wavelength have appeared. With potassium as initiator, even in cyclohexane, complex spectra are observed. Initiation by metal films is rather slow and with potassium polyisoprene, for instance, the spectrum is already complex when first measured. Only the major band is shown in the table. It is possible that this band is not that of the species causing the polymerization, but is of some already isomerized product.

The effect of small amounts of tetrahydrofuran on the spectrum of polyisoprenyllithium in cyclohexane is a simple broadening of the band. In the presence of 1% tetrahydrofuran, the absorption maximum was still at 270 mμ, but slow isomerization occurred to give an absorption near 320 mμ.

DISCUSSION

Polystyryl–Alkali Metal Compounds

When the metal or solvent is changed, the similarity of the integral extinction coefficient and the positions of maximum absorption is strong evidence that the nature of the absorbing species is the same throughout. It seems likely that the carbon–metal bond is predominantly ionic in character, because in tetrahydrofuran the presence of conducting species has been observed for polystyrylsodium (7). The major part of this compound was shown to exist as ion-pairs in equilibrium with a small concentration of free ions at total concentrations around millimolar. The measured dissociation constant (1.5×10^{-7}) in this solvent is consistent with a simple dissociation process

$$R(M)_n^-Na^+ \rightleftharpoons R(M)_n^- + Na^+$$

rather than the more complex equilibria

$$R(M)_n—Na \rightleftharpoons R(M)_n^-Na^+ \rightleftharpoons R(M)_n^- + Na^+$$

which would also give the same dependence of equivalent conductance on total concentration of organometallic compound. This interpretation is confirmed by the absence in benzene solution of any temperature dependence of the extinction coefficient, which would be observed in the absorption spectrum if significant amounts of covalent form were present in equilibrium.

In tetrahydrofuran, solvation must add significantly to the stability of the ionic species. In hydrocarbon solvents stabilization of the ion-pair form by solvation will be reduced by about 50%, but the loss of solvation energy is apparently replaced by interaction energy between ion-pairs, which are known to be highly associated to dimers in solvents such as cyclohexane and benzene. This association has been demonstrated by kinetic methods (4, 11) and by direct light-scattering measurements on the active and deactivated polymer solutions (12). This phenomenon disappears at relatively low THF concentrations ($\sim$ 25:1 mole:mole calculated on total alkali metal) (5). As the major species changes from the ion-pair dimer to solvated ion-pairs, the ultraviolet absorption broadens without

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

changing the position of maximum absorption. At this point insufficient THF is present to materially affect the dielectric constant. The small change in the position of maximum absorption occurs as the bulk dielectric constant of the medium changes.

In nonpolar solvents the absorption spectrum reflects the properties of the ion-pair dimer, whereas the reactive species in polymerization has been shown (4) to be the small amount of free ion-pair present. The absorption in nonpolar solvents can thus give no evidence about the structure of the free ion-pair, which could conceivably differ from that of the associated form.

Polyisoprenyl– and Polybutadienyl – Alkali Metal Compounds

The wavelengths of the absorption maxima of the first peaks formed under the various conditions and assigned to the unisomerized polymer anion vary over a somewhat wider range than do those of the corresponding polystyryl compounds. But if that of the polyisoprenylpotassium in cyclohexane is rejected for reasons given earlier, the shifts are similar to those found in the spectrum of the benzophenone – alkali metal ketyls as the solvent and counterion were changed (13). Warhurst attributed the shifts caused by changing the counterion to perturbations of the energy levels of the anion by the field of the associated cation. This effect will increase as the cation radius decreases. However, it is not clear why the effect should be larger for the polyisoprenyl anion than for the polystyryl anion. McClelland (14) has made an approximate analysis of the cation field effect in the benzophenone compounds. This indicates that in the ground state the counterion is localized near the oxygen atom, but in the excited state the equilibrium position is centered on the aromatic rings. In an optical transition the counterion is therefore not in its equilibrium position after excitation and the transition energy is increased, by an amount which is a function of the cation field. For benzyl type anions a similar shift of effective charge from the side group to the aromatic ring might be expected on excitation, although the spectral shifts found are small.

It seems reasonable to suppose that in tetrahydrofuran the carbon–metal bond is again essentially ionic in nature and that the spectral shifts observed between alkali metals are due to the perturbing effect of the cation. The polymer microstructure in this solvent is predominantly 3:4 and varies little with the metal, suggesting the presence of similar reactive species at the chain ends.

In cyclohexane the polymer microstructure has changed to a predominantly *cis* 1:4 structure when the counterion is lithium and to a more mixed 1:4, 3:4 structure for the other counterions (2). Nevertheless, the spectral evidence suggests little change in the character of the major species present, because the spectral changes with change of alkali metal are very similar to those observed in THF. This similarity suggests that in cyclohexane the bulk of the isoprenyl – alkali metal compounds must have a largely ionic nature, too. Once again stabilization of the ion-pairs is effected through the formation of aggregates. Thus it would seem that there is no connection between the stereoregulating influence of the lithium counterion and the nature of the bond in the bulk of the polymerizing species present. Because of this aggregation, as mentioned before for styrene in hydrocarbon solvents, the spectra do not necessarily reflect the nature of the species active in the polymerization. The active species is probably a free ion-pair form (11), but it does seem likely that it is also ionic. In cyclohexane with 1% THF present, the polymer formed is no longer largely *cis* 1:4 with butyllithium. Although the ion-pairs are largely dissociated in the presence of such an amount of THF (11), the absorption is still at 270 mμ.

Diene–Carbanion Isomerization in THF

The absorption peaks first formed in tetrahydrofuran soon decay with the formation of peaks at longer wavelengths, and presumably this isomerization gives a more stable carbanion (Fig. 2). This occurs so rapidly for the sodium and potassium compounds, that even the very first spectrum measured one minute after the start of the reaction showed appreciable isomerization (Fig. 3). One isomerization possible with isoprene when 3:4

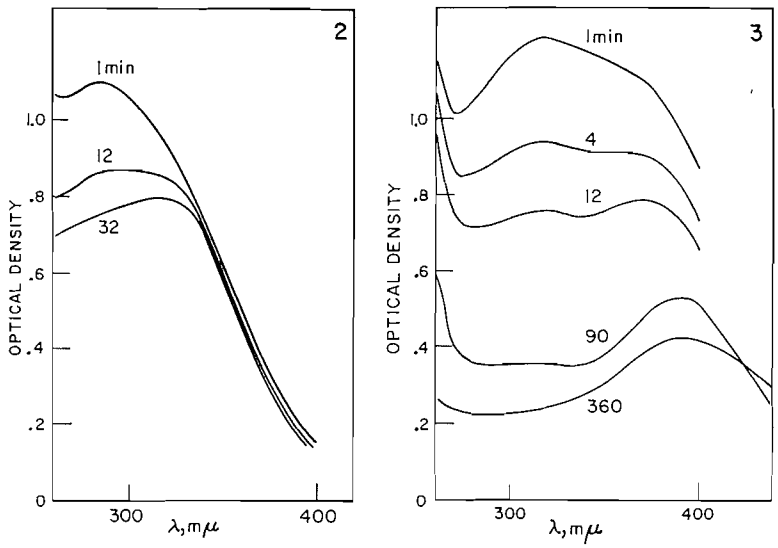

FIG. 2. Changes in spectrum with time after formation of polyisoprenyllithium in tetrahydrofuran.
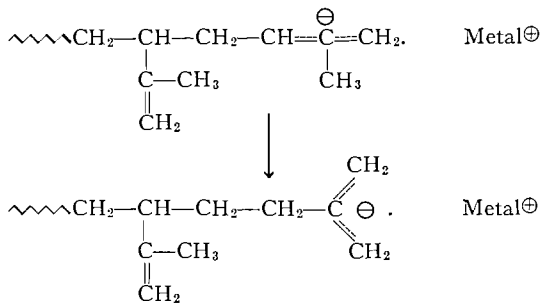
FIG. 3. Changes in spectrum with time shortly after formation of polyisoprenylpotassium in tetrahydrofuran.

structures are formed is as illustrated and gives a more symmetrical allylic type carbanion.



This mechanism is supported by measurements of the positions of the absorption maxima of comparably substituted allyllithiums in tetrahydrofuran solution.

Allylic carbanion	λ_{max}, this work	λ_{max} (10)
Allyllithium	317 mμ	315 mμ
Equilibrium mixture of α- and γ-methylallyllithium		291
β-Methylallyllithium	332	

The absorption maxima of the equilibrium mixture of α- and γ-substituted allyllithium is close to the initially formed, correspondingly substituted carbanion from butadiene and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

butyllithium and is also close to that from isoprene despite the extra methyl group. The β-substituted allyl carbanion absorbs close to the isomerized product from polyisoprenyllithium, the suggested isomerized structure above also having the β-substituent only. No such isomerization is possible in the polybutadienyl carbanion, and indeed it is found that polybutadienyllithium does not isomerize. Polybutadienylpotassium does show an isomerization, however, and this observation casts some doubt on the isomerization mechanism suggested above, but the carbanions from isoprene and butadiene with both sodium and potassium show far more complex behavior than do those with lithium, further isomerizations occurring after the initial rapid one. The initial isomerization may be a distribution of the carbanions among the various sites available, as has been suggested by Morton in alfin catalysis (15). Later isomerizations could well be of the type undergone by the polystyryl anion in ether solutions, with an increase in the stabilization by extra conjugation (16).

The rapid isomerization of polyisoprenyllithium in tetrahydrofuran is reversible in that the addition of another portion of monomer can cause the ion to revert temporarily to the original carbanion. There was little indication that this occurred with sodium or potassium as the counterions. It was found that the first isomerized form would react with styrene to give the polystyryl carbanion. Presumably there is a kinetic balance between the tendency to isomerize and the re-formation of the original ion by reaction of the isomerized form with monomer. The above isomerizations would lead to the presence of extraneous structures in the polymer chains. There is some evidence for abnormal structures in the infrared spectra of the alkali metal initiated polyisoprenes, where considerable deviations from the sum of the spectra of the individual expected (1, 4; 1, 2; 3, 4) structures occur (17).

The occurrence of rapid isomerization must cast some doubt on the usefulness of some of these systems for the production of narrow distribution polymers and block copolymers, unless the conditions are chosen to avoid these isomerizations. Kinetic studies in tetrahydrofuran will also be complicated by this type of rearrangement.

EXOCELLULAR BACTERIAL POLYSACCHARIDE FROM XANTHOMONAS CAMPESTRIS NRRL B-1459

PART III. STRUCTURE[1]

J. H. Sloneker, Danute G. Orentas, and Allene Jeanes
Northern Regional Research Laboratory,[2] U.S. Department of Agriculture, Peoria, Illinois

Received September 23, 1963

ABSTRACT

Periodate oxidation showed that the *O*-acetyl groups in the polysaccharide sterically affected the rate but not the extent of oxidation of the D-mannose residues, two-thirds of which were glycosidically substituted at C_2 by a D-glucuronic acid residue and one-third of which was linked as a terminal side-chain residue. The D-glucose and D-glucuronic acid residues oxidized by periodate were substituted at C_4, but both were more resistant to oxidation than were the D-mannose residues. One-third of the D-glucose residues and a significant quantity of the D-glucuronic acid residues were inert to vigorous periodate oxidation and may bear side-chain residues. Quantitative recovery of the periodate-stable D-glucose residues as 2-*O*-β-D-glucopyranosyl-D-erythritol, after the oxidized polysaccharide was reduced with sodium borohydride and hydrolyzed with mild acid, revealed that two-thirds of the D-glucose residues were in pairs linked (β, $1 \rightarrow 4$). The pyruvic acid linkage in the polysaccharide was established as a 4,6-*O*-1-carboxyethylidene ketal attached to a terminal D-glucose side-chain residue. The structure of the polysaccharide is discussed in relation to its anomalous viscosity behavior in salt solutions.

In a previous paper the polysaccharide elaborated by *Xanthomonas campestris* NRRL B-1459 was shown to be composed of the sugars D-glucose, D-mannose, and D-glucuronic acid in the ratio 2.8:3.0:2.0 (1). Acetic and pyruvic acid substituents are present in amounts of 4.7% and 3.0–3.5%, respectively. Acetic acid exists as the *O*-acetyl ester, whereas pyruvic acid is attached through a ketal linkage (2). Periodate oxidation of the polysaccharide under various oxidation conditions, followed by reduction with sodium borohydride and examination of the remaining products after acid hydrolysis, has provided further structural information.

RESULTS

Periodate consumption by the polysaccharide depends upon the reaction conditions. At 20° C, the native and deacetylated polysaccharides undergo oxidation at the same rate and to the same extent with either 0.02 *M* periodic acid or sodium metaperiodate. In 140 hours approximately 0.8 mole of periodate was reduced and 0.13 mole of acid produced per sugar residue (Fig. 1). After 140 hours at 4° C, the native polysaccharide had reduced only 0.56 mole of periodate per sugar residue, which is the approximate amount required for complete oxidation of the mannose residues, but the amount of acid produced was the same as that from the oxidation carried out at 20° C. When the periodate concentration was decreased to 0.005 *M* at 4° C, the deacetylated polysaccharide was oxidized at a significantly faster rate than native polysaccharide (Fig. 1), but acid production for both remained at 0.13 mole per sugar residue.

Both the native and deacetylated polysaccharides were oxidized to essentially the same extent by periodate at 20° C as shown by the determination of the residual sugars after borohydride reduction and acid hydrolysis (Table I). All the D-mannose residues

†0.02 *M* H_5IO_6 at 20° C for 140 hours.

and approximately 50% of the D-glucose and D-glucuronic acid residues were oxidized. The quantity of erythritol in the hydrolyzates of both samples was equivalent to the oxidized D-glucose residues. Glycerol, also present in the hydrolyzates, was not measured quantitatively.

When the native polysaccharide was oxidized at 4° C with 0.005 *M* sodium metaperiodate, two-thirds of the D-mannose residues were cleaved, whereas only a small portion of the D-glucose and D-glucuronic acid residues was oxidized. Reduction of this periodate-oxidized product followed by acid hydrolysis yielded a relatively large proportion of glycerol but only traces of erythritol. When this reduced polymeric product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

was acid hydrolyzed under conditions milder than those used for the sugar determination, approximately 7% of the D-glucose was recovered as cellobiose.

Anion-exchange chromatography of the polysaccharide degraded by periodate oxidation, borohydride reduction, and mild acid hydrolysis (3) led to the isolation of 50% of the pyruvic acid as 1,3-*O*-(1-carboxyethylidene)-L-erythritol along with other oxidation products, including L-erythronic acid, 2-*O*-β-D-glucopyranosyl-D-erythritol, and three glucuronic-acid-containing oligosaccharides.

DISCUSSION

Previous reports (4, 5) indicated that uronic-acid-containing compounds have a tendency to "overoxidize" with sodium metaperiodate but not with periodic acid. Therefore, both sodium metaperiodate and periodic acid were employed to study the oxidation behavior of the polysaccharide. As seen in Fig. 1, at 20° C both reagents oxidized the native and deacetylated polysaccharides similarly, and no "overoxidation" was indicated with either reagent under the conditions used (Table I).

A constant quantity of formic acid, 1 equivalent per 8 sugar residues, is produced either under severe oxidation conditions where all three sugars are oxidized or under more mild conditions where only D-mannose residues are oxidized. Presumably the formic acid originates from the oxidation of nonreducing D-mannose end residues. The quantity of formic acid produced is equivalent to one-third of the D-mannose residues in the polysaccharide. Also, one-third of the D-mannose residues is hydrolyzed from the polysaccharide by acid more readily than the other sugar residues (1). Such behavior indicates that these "acid-labile" D-mannose residues are nonreducing end residues that are bound to the polysaccharide chain by a single glycosidic bond. The remaining two-thirds of the D-mannose residues are substituted at C_2 as shown by the isolation of 2-*O*-β-D-glucopyranosyluronic acid-D-mannose (1).

At high concentrations of periodate the native and the deacetylated polysaccharide undergo oxidation at about the same rate, but with low concentrations of periodate the deacetylated polysaccharide is oxidized at a much faster rate. Therefore, the acetyl groups, which are not affected during the oxidation, must sterically hinder oxidation of the D-mannose residues. This conclusion was supported by the observation that removal of the acetyl groups resulted not only in an increased rate of oxidation of the terminal D-mannose residues (increased formic acid production), but also in an increased rate of cleavage of the D-mannose residues linked at C_1 and C_2.

Pyruvic acid appears to be a common substituent in the exocellular polysaccharides produced by members of the genus *Xanthomonas* (6, 7). In the polysaccharide from *X. campestris* the pyruvic acid was not affected by extensive periodate oxidation and was recovered as 1,3-*O*-(1-carboxyethylidene)-L-erythritol after the oxidized polysaccharide had been reduced with sodium borohydride and hydrolyzed with acid under mild conditions (3). Since D-glucose is the sole source of erythritol (Table I) in the polysaccharide, the only structure from which the pyruvic acid ketal can originate directly without rearrangement is a terminal side-chain 4,6-*O*-(1-carboxyethylidene)-D-glucose residue having free hydroxyls at C_2 and C_3. The pyruvic acid content requires approximately one such residue for every 16 sugar residues. This same ketal has been found previously in a pyruvic-acid-containing seaweed agar attached to a D-galactose residue linked at C_1 and C_3 (8).

Both structural and steric factors influence the periodate oxidation of the D-glucose and D-glucuronic acid residues. These two sugar residues were oxidized only slightly under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the conditions of low temperature and low concentrations of periodate that caused the D-mannose residues to oxidize readily. By increasing the temperature and the concentration of periodate, 50% of the D-glucose and D-glucuronic acid residues were oxidized (Table I). More than 50% of the D-glucose and D-glucuronic acid residues were oxidized when the polysaccharide was subjected to the oxidation conditions used to isolate the pyruvic acid ketal, 1,3-*O*-(1-carboxyethylidene)-L-erythritol. However, even with this extensive oxidation, approximately one-third of the total number of D-glucose residues and a significant portion of the D-glucuronic acid residues were inert. The D-glucose residues were isolated as 2-*O*-β-D-glucopyranosyl-D-erythritol and the D-glucuronic acid residues were recovered in several acidic oligosaccharides after the oxidized polysaccharide was reduced and hydrolyzed with acid under mild conditions (Table II). To be inert

to periodate oxidation, the glucopyranose residues must have either a glycosidic substituent at C_3 or substituents on at least two of the following positions—C_2, C_3, and C_4. Since the number of inert D-glucose residues is approximately equal to the number of terminal D-mannose side-chain residues, it is believed that the inert D-glucose residues constitute branch points in the polysaccharide and are, therefore, doubly substituted at C_2, C_3, or C_4. Similarly the D-glucuronic acid residues may be inert to periodate oxidation through glycosidic substitution by the side-chain residue, 4,6-*O*-(1-carboxyethylidene)-D-glucose.

The steric factors influencing the oxidation of the "periodate-labile" D-glucose and D-glucuronic acid residues in the polysaccharide are: both the D-glucose and D-glucuronic acid residues are linked in a β-configuration as indicated by the isolation of 2-*O*-β-D-glucopyranosyl-D-erythritol and 2-*O*-β-D-glucopyranosyluronic acid-D-mannose; both are glycosidically substituted at C_4 as shown by the isolation of erythritol and L-erythronic acid, respectively, after periodate oxidation, borohydride reduction, and acid hydrolysis. The *trans*-glycol group at C_2 and C_3 of β-glucosides is much more resistant to periodate oxidation than is that of the α-anomers because an equatorially oriented aglycone on the β-anomer is sufficiently close to the hydroxyl on C_2 to hinder the attack by periodate (9). A bulky equatorial glycoside at C_4 should exert similar steric hindrance on the hydroxyl at C_3. Thus the *trans*-glycol groups at C_2 and C_3 of both the D-glucose and D-glucuronic acid residues should be doubly hindered. The *trans*-glycol group at C_2 and C_3 of the 4,6-*O*-(1-carboxyethylidene)-D-glucose residues would also be doubly hindered if this side-chain residue is β-linked to the polysaccharide backbone, but the steric hindrance will be lessened by the cyclic nature of the carboxyethylidene substituent attached to C_4 and C_6.

In contrast, the D-mannose residues in the polysaccharide should be oxidized by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

periodate more rapidly than the D-glucose or D-glucuronic acid residues. Only a single glycoside substituent at C_2 sterically hinders the periodate oxidation of the *trans*-glycol group at C_3 and C_4 of the D-mannose residues linked at C_1 and C_2. Moreover, this substituent at C_2, although bulky, is in an axial conformation and would have steric effects similar to an aglycone of an α-glucoside (9). The terminal D-mannose side-chain residues have a *cis*, *trans*, triol group at C_2, C_3, and C_4 and should be oxidized rapidly with little hindrance by the substituent at C_1.

A structure consisting of a repeating unit of 16 residues (Fig. 2) is proposed for the

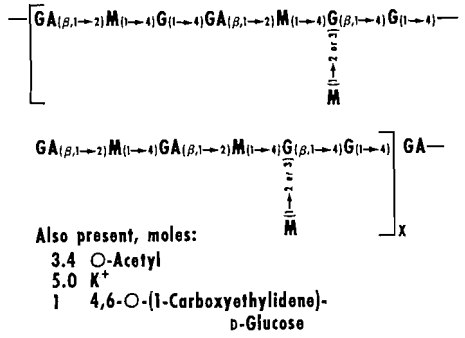

FIG. 2. Block of 16 hexose residues from the polysaccharide elaborated by *Xanthomonas campestris* NRRL B-1459, depicting order of arrangement and linkages: GA, D-glucuronic acid; M, D-mannose; G, D-glucose.

polysaccharide elaborated by *X. campestris* NRRL B-1459 on the basis of the experimental evidence. The linear portion of the polysaccharide consists of D-glucose, D-mannose, and D-glucuronic acid residues. The isolation of 2-*O*-β-D-glucopyranosyluronic acid-D-mannose (1) shows that the D-glucuronic acid residues are linked to C_2 of D-mannose residues. At least part of the D-mannose residues in the polysaccharide backbone are linked glycosidically to D-glucose residues as shown by the isolation of an aldotriouronic acid consisting of all three sugars with a D-glucose residue as the reducing end group (1). The remaining D-mannose residues in the polysaccharide backbone are probably linked to D-glucuronic acid residues, as shown in Fig. 2, although an aldotetraouronic acid containing two 2-*O*-β-D-glucopyranosyluronic acid-D-mannose units was not observed in acid hydrolyzates of the polysaccharide. Quantitative determination of 2-*O*-β-D-glucopyranosyl-D-erythritol indicates that two-thirds of the D-glucose residues are found in pairs linked (β, $1 \rightarrow 4$) to each other. The position of the remaining D-glucose residue in the polysaccharide backbone is not known. It may occur singly as in Fig. 2 or in a sequence of three D-glucose residues.

Six of the glycosidic bonds in the polysaccharide segment (Fig. 2) are known β-linkages. The remainder are presumed to be β also, because the polysaccharide has a low optical rotation [$[\alpha]_D^{25}$ 0°, (*c*, 1.0, water)] and except for the D-mannose side-chain residues is quite resistant to acid hydrolysis.

Studies of molecular models of ($1 \rightarrow 2$) linked sugar residues, such as occur in the main chain of the polysaccharide (Fig. 2), show that the ($1 \rightarrow 2$) linkages do not prevent a linear extension of the polysaccharide chain. However, in the extended molecule, the bulk of a sugar residue linked at C_1 and C_2 projects away from the axis of the main chain to produce a bulge approximately equivalent in size and steric properties to that of a nonreducing side-chain residue. The combined effect of the sugar residues linked

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

at C_1 and C_2 and the side-chain residues D-mannose and 4,6-*O*-(1-carboxyethylidene)-D-glucose confer upon the polysaccharide the character of a linear polymer with single unit side-chains, there being seven such apparent protruding groups for every 16 sugar residues (Fig. 2). The relatively frequent occurrence of single side-chain sugar residues and pseudo side-chain effects from $(1 \rightarrow 2)$ linkages does not prevent the polysaccharide from producing excellent water-soluble films with a high degree of flexibility (10). Such behavior is indicative of a polysaccharide which has few, if any, long side branches.

The *O*-acetyl groups are believed to be located on C_6 of the D-mannose residues which are linked at C_1 and C_2. The ratio of the *O*-acetyl groups to these D-mannose residues is 0.85 to 1. Furthermore, the *O*-acetyl groups must be located in a manner that interferes with the periodate oxidation of both forms of the D-mannose residues in the native polysaccharide. The steric hindrance of the D-mannose residues carrying the *O*-acetyl group is in accord with the known steric hindrance produced by bulky groups at C_6 on the periodate oxidation of the *trans* glycol group at C_3 and C_4 of the pyranose ring (9). The manner in which the *O*-acetyl group on the D-mannose residue in the main chain interferes with the oxidation of the D-mannose side-chain residue can be visualized by constructing a molecular model of a D-glucose residue substituted by two D-mannose residues as shown in Fig. 2. The two D-mannose residues are close together and the *O*-acetyl group attached to C_6 of the D-mannose residue in the main chain is in a position to hinder sterically the periodate oxidation of the D-mannose side-chain residue.

Solution viscosities of this anionic polysaccharide are atypically insensitive to the charge-neutralizing effects of electrolytes. Addition of salts to aqueous dispersions of the polysaccharide at concentrations of 0.25% or less resulted in a decrease in viscosity less than that shown by typical polyelectrolytes. For concentrations of polysaccharides greater than 0.25% the solution viscosity is increased markedly by addition of salt (11). Structural and steric factors appear to influence the behavior of the polysaccharide in solutions of electrolyte more than do charge effects. The large number of side-chain residues and $(1 \rightarrow 2)$ linkages restrict the flexibility of the long polysaccharide chains by steric hindrance. The role of side-chains in producing rigidity in polymer chains is well established (12, 13). This structural rigidity limits the loss in viscosity by permitting only a small decrease in the effective solution volume of the polysaccharide even though the coulombic repulsion of the carboxyl groups is reduced by salt (14, 15). The observed increases in viscosity of more concentrated solutions of the polysaccharide, after reduction of ionic repulsion by salt, may be due to an increase in intermolecular association. The rather rigid polysaccharide molecule remains in a more extended state, which favors intermolecular association as well as intermolecular entanglement, to produce a gel-like structure. However, the side-chain groups limit the amount of intermolecular association by steric hindrance (15) and prevent dehydration and precipitation of the polysaccharide from viscous solutions containing high concentrations of salt (16).

EXPERIMENTAL

Materials and Methods

The polysaccharide used for these experiments was an experimental pilot-plant preparation designated MP-3 (17). This material was identical in sugar and *O*-acetyl group content with a laboratory preparation designated T-42, which was used for compositional studies (1, 11). The laboratory preparation, however, contained 20% more pyruvic acid (1). Deacetylated polysaccharide was prepared from MP-3 as previously described (11).

The chromatographic solvents were: (A) ethyl acetate – acetic acid – water (3:1:3) (18); (B) *n*-butyl alcohol – pyridine – water (6:4:3) (19); and (C) *n*-butyl alcohol – ethyl alcohol – water (4:1:5) (20); all v/v. Ammoniacal silver nitrate was used to detect sugars on the developed chromatograms (21). Whatman

No. 1 paper* was used for quantitative and qualitative chromatography, and Whatman 3MM paper was used to separate and isolate larger quantities of pure sugars. All steps involving reduction of solution volume were carried out on a vacuum rotary evaporator at a bath temperature of 40° C unless otherwise stated.

Periodate Oxidation of Polysaccharide B-1459

For periodate oxidation studies, a portion of a solution containing the required amount of sodium metaperiodate or periodic acid was stirred into a homogeneous dispersion of polysaccharide in water, and the polysaccharide concentration was adjusted to 0.1% by adding a minimum amount of water. A periodate blank was prepared accordingly. Oxidations were carried out in the dark at either 20° C or 4° C. The periodate consumption was measured by the arsenite method (22) and the thiosulphtae method (23). Both methods gave identical values. The acid produced by periodate was measured titrimetrically with 0.01 *N* barium hydroxide (22). The results are shown in Fig. 1.

Sodium Borohydride Reduction of Periodate-oxidized Polysaccharide Samples

After oxidation, excess periodate was reduced with ethylene glycol. The reaction mixture was neutralized to pH 6.7 with solid sodium bicarbonate and dialyzed (Visking tubing) for 6 days against distilled water to remove salts. Toluene was added to each dialysis bag for asepsis. The retentate (24) was removed from the dialysis bag, sodium borohydride (20% by weight of polymer) was stirred in, and the mixture was allowed to react overnight at 25° C. Excess borohydride was destroyed by acidifying the reaction mixture to pH 5.5 with glacial acetic acid. The pH was adjusted to 6.7 with sodium bicarbonate and the solution was dialyzed against distilled water for 6 days. During dialysis the pH of the retentate dropped from 6.7 to between 4.5 and 5.0. Residual borate ions were removed by evaporating the solution to dryness, dispersing the residue in dry methanol, and removing the methanol by vacuum distillation. The oxidized and reduced polysaccharide, after drying over phosphorus pentoxide at room temperature, was a white or light tan powder insoluble in water. Yields of 90 to 95% were obtained.

Quantitative Determination of Residual Sugars and Oxidation Products

Samples of both the native and deacetylated polysaccharides which had been periodate oxidized and borohydride reduced were hydrolyzed in *N* hydrochloric acid for 2.5 hours at 100° C. The free sugars in the hydrolyzates were determined as previously described (1). Erythritol was isolated quantitatively by paper chromatography (solvent C) and determined colorimetrically (25). The results are given in Table I. Glycerol also was observed on the paper chromatograms but was not determined quantitatively.

Isolation of Cellobiose

A 2-g sample of the polysaccharide, which had reduced 0.5 mole of sodium metaperiodate per sugar residue and had been reduced with sodium borohydride, was hydrolyzed with *N* hydrochloric acid for 1 hour at 100° C. The hydrolyzate was neutralized to pH 7 with Dowex 1 (carbonate phase). The resin was filtered off, and the filtrate was concentrated to a small volume. Paper chromatography (solvent B) revealed that the concentrate contained glucose, glycerol, erythritol, and a slow-moving reducing sugar. Preparative paper chromatography (solvent B) and elution of the disaccharide fraction afforded 41 mg of a white amorphous powder after two precipitations from ethanol–water. Acid hydrolysis and chromatography of the disaccharide yielded only glucose. In solvents A and B the disaccharide co-chromatographed with cellobiose. An infrared spectrum of a small portion of the disaccharide, which had been crystallized from an ethanol–water–acetone system, was identical with the spectrum produced by cellobiose.

Mild Acid Hydrolysis and Ion-exchange Chromatography

A 1.5-g sample of the polysaccharide was oxidized with 0.2 *M* sodium metaperiodate, reduced with sodium borohydride, and then was hydrolyzed at room temperature for 24 hours in 150 ml of *N* hydrochloric acid. This material, which had reduced 1.2 moles of sodium metaperiodate per sugar residue, was insoluble in water but dispersed immediately in the acid. The solution was neutralized with silver carbonate, the precipitate was removed by filtration, and excess silver ions were removed as silver sulphide. The solution was concentrated to a small volume, filtered, and neutralized to pH 7 with 0.1 *N* sodium hydroxide. The neutral concentrate was poured onto a 2- × 40-cm ion-exchange column composed of Dowex 1X4, 200–400 mesh (acetate phase). After the concentrate had percolated into the resin, the column was washed with 100 ml of water, and the acidic fractions were separated by gradient elution. An adequate gradient was maintained by passing 5 liters of 3 *N* acetic acid into the mixing flask containing 1500 ml of water. Ten-milliliter fractions were collected at a flow rate of 1 ml per minute.

Pyruvic acid, D-glucuronic acid, and L-erythronic acid were detected qualitatively in the eluate fractions as follows: (A) Pyruvic acid was detected by a method similar to that used to measure the pyruvic acid in the intact polysaccharide (26). Portions of the column eluate (0.5 ml) were transferred to 18- × 150-mm test tubes containing 0.5 ml of 2 *N* hydrochloric acid and were hydrolyzed for 3 hours at 100° C. To the hydrolyzate, 1 ml of 2,4-dinitrophenylhydrazine reagent (2,4-DNP) was added, and the reaction was allowed to proceed for 5 minutes. Ethyl acetate (5 ml) was added, and the pyruvic acid 2,4-DNP was

extracted from the aqueous layer, which was then discarded. Fifteen milliliters of 10% sodium carbonate was added to the ethyl acetate, and the tube contents were thoroughly mixed. After the two phases separated completely, the absorbance of the carbonate layer was measured at 375 mμ. Aqueous acetic acid produced a slight background color but did not interfere with the assay. (B) The D-glucuronic acid was detected by the use of the carbazole reagent (27). (C) Erythronic acid was detected with fuchsin–sulphite after periodate oxidation (28). A 0.5-ml portion of column eluate was reacted 5 minutes at 23° C with 0.5 ml of periodic acid – B solution. The excess periodate was destroyed by adding excess sulphite solution and then several drops of fuchsin–sulphite solution were added with stirring. Periodate-oxidized erythronic acid produces an immediate pink color of a Schiff's base. Compounds readily oxidized by periodate, such as glycerol and erythritol, react similarly.

On the basis of the qualitative assays, the 10-ml fractions were combined into six different fractions, which were reduced in volume and recovered by lyophilization (Table II).

Components of neutral fraction A.—Glycerol, glycolaldehyde, glyceraldehyde, small quantities of glucose and erythritol, and a significant quantity of a slower moving disaccharide were observed in fraction A when a portion of it was chromatographed in solvents B and C. The remainder of fraction A was dissolved in 5 ml of water to which 5 ml of ethyl alcohol was added. A semicrystalline precipitate formed upon the slow addition of 15 ml of acetone. The precipitate was collected by centrifugation and redissolved in 1 ml of water. Upon paper chromatography in solvents B and C the precipitate appeared to consist primarily of the disaccharide that was observed in the neutral fraction. Preparative paper chromatography in solvent B afforded 114 mg of material which readily crystallized from a water–ethanol–acetone (2:10:30) system. After a second crystallization, the compound had a specific optical rotation of $[\alpha]_D^{25}$ −16 (*c*, 0.94, H_2O); m.p. 185.5–187° C. Glucose and erythritol were produced by acid hydrolysis of the crystalline material. Anal. Calc. for $C_{10}H_{20}O_9$; C, 42.3; H, 7.09. Found: C, 41.9; H, 6.85. These analytical data are in agreement with those reported for 2-*O*-β-D-glucopyranosyl-D-erythritol ($[\alpha]_D^{25}$ −17; m.p. 185–187° C) (29). Upon periodate oxidation, 2-*O*-β-D-glucopyranosyl-D-erythritol reduced 3.13 moles of sodium periodate and produced 0.93 mole of acid and 1.04 moles of formaldehyde; the theoretical values for 2-*O*-β-D-glucopyranosyl-D-erythritol are 3, 1, and 1, respectively.

The yield of 2-*O*-β-D-glucopyranosyl-D-erythritol from the periodate-oxidized, borohydride-reduced polysaccharide was determined on 111 mg of the same polysaccharide product used in the column chromatography experiment. Mild acid hydrolysis was conducted as described above. After neutralization, part of the hydrolyzate was quantitatively chromatographed in solvent C. The area containing 2-*O*-β-D-glucopyranosyl-D-erythritol was eluted and the contents determined by the phenol – sulphuric acid method (30). One mole of 2-*O*-β-D-glucopyranosyl-D-erythritol was produced for every 9.3 sugar units in the polysaccharide.

Components of glucuronic-acid-containing fractions B, D, and E.—These three fractions were subjected to paper chromatography in solvents A and B both before and after acid hydrolysis in *N* hydrochloric acid at 100° C. Each appeared as a single spot before hydrolysis. Paper chromatography in solvent A revealed that the acid hydrolyzates of fractions B, D, and E contained unoxidized D-glucuronic acid (Table II). These fractions appear to be aldobio-, aldotrio-, and aldotetrao-uronic acids in which one of the sugar residues has been oxidized with periodate and reduced with borohydride.

Fraction C, erythronic acid.—Fraction C, a waxy solid, with the chromatographic behavior of erythronic acid, was extracted with hot ethyl acetate to convert the acid to its lactone. Long needlelike crystals (32 mg) formed when the extract was evaporated. After a second crystallization from ethyl acetate, the waxy crystals melted at 100–101° C. The melting point of L-erythronolactone is 103–104° C (31). Pure D-erythronolactone mixed with the crystals depressed the melting point to 85–86° C. Anal. Calc. for $C_4H_6O_4$: C, 40.7; H, 5.12. Found: C, 40.1; H, 5.26. The remainder of the L-erythronolactone was converted to the corresponding crystalline brucine salt, melting point 211° C (reported 212° C (31)). Anal. Calc. for $C_{27}H_{34}N_2O_9$: C, 61.1; H, 6.46; N, 5.28. Found: C, 60.0; H, 6.32; N, 5.27. The lactone of L-erythronic acid also was found in fraction A. It apparently formed during the prolonged acid hydrolysis.

Fraction F, 1,3-O-(1-carboxyethylidene)-L-erythritol.—Fraction F contained 50% of the total pyruvic acid, which had been applied to the column, in a chemically combined state. The lyophilized fraction was dissolved in 2 ml of water and neutralized with saturated barium hydroxide. The barium salt, which precipitated as a soft gel from 70% aqueous ethanol upon addition of acetone, formed an amorphous powder when dried. Acid hydrolysis (*N* hydrochloric acid for 3 hours at 100° C) and quantitative estimation of the products revealed that the compound was composed of pyruvic acid and erythritol in a 1:1 ratio. Anal. Calc. for $(C_7H_{11}O_6)_2Ba$: C, 33.6; H, 4.27; Ba, 26.43. Found: C, 33.1; H, 4.77; Ba, 26.20. Infrared analysis of the barium salt in potassium bromide showed bands at 6.2 and 7.1 μ characteristic of a carboxyl ion and strong bands at 8.5 and 9.4 μ. These strong bands are reported to be characteristic of a six-membered ring structure containing a —C—O—C—O—C-group (32). A nuclear magnetic resonance spectrum shows several hydrogen resonances, CH_3— at 86, —CH—O— and —CH_2—O— at 218 and 226, and —OH at 332 c.p.s. ($(CH_3)_2Si(CH_2)_3SO_3H$ reference). The chemical and spectral evidence indicates that pyruvic acid is bound to erythritol by a ketal linkage. Because the barium salt of the ketal did not react with 0.01 *M* sodium metaperiodate at 4° C, the pyruvic acid must form the six-membered ring

ketal, 1,3-*O*-(1-carboxyethylidene)-L-erythritol. The remainder of the pyruvic acid, like L-erythronolactone, is suspected to be in fraction A as a lactone of 1,3-*O*-(1-carboxyethylidene)-L-erythritol. Evidence for this assumption is indicated by a positive test for pyruvic acid in this fraction.

ACKNOWLEDGMENT

We are gratefully indebted to Mrs. Clara McGrew and Mrs. Bonita Heaton for analytical analyses and to Mr. Curtis Glass for infrared analyses.

THE CONFIGURATION AND CONFORMATION OF "DI-D-FRUCTOSE ANHYDRIDE I"

R. U. LEMIEUX AND R. NAGARAJAN*
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received December 17, 1963

ABSTRACT

"Di-D-fructose anhydride I", obtained by acid depolymerization of inulin triacetate, was found to be 1′,2-anhydro-[1-(α-D-fructofuranosyl)-β-D-fructofuranose]. The high resistance to oxidation by periodate found for the α-D-fructofuranoside portion was related to the conformation for the ring wherein the 3′- and 4′-hydroxyl groups are in quasi-axial orientation. This and other conclusions about the conformations of the anhydride were based on a comparison of the 100 Mc.p.s. proton magnetic resonance spectra of the 6,6′-dideoxytetra-*O*-acetyl derivative of the anhydride, sucrose octaacetate, and 1,6-anhydro-α-D-galactofuranose triacetate.

DISCUSSION

When D-fructose reacts with aqueous acid, dimeric D-fructose anhydrides are formed which possess a central 1,4-dioxane ring. Six such di-D-fructose dianhydrides have been described (1). Although both the action of aqueous acid on D-fructose (2) or inulin (3) and the heating of a concentrated aqueous solution of D-fructose (4, 5) lead to mixtures of these anhydrides, the treatment of inulin triacetate in chloroform with fuming nitric acid yields only the hexaacetate of that isomer known as "di-D-fructose anhydride I" (6). The formation of the di-D-fructose anhydrides has been attributed (7, 8) to the stability of the 1,4-dioxane ring.

"Di-D-fructose anhydride I" was first reported almost simultaneously by Jackson and Goergen (3) and by Irvine and Stevenson (6). Methylation followed by hydrolysis to yield 3,4,6-tri-*O*-methyl-D-fructose established the compound to be the 1,2′:1′,2-dianhydride of D-fructose (7). The consumption of 2 moles of periodic acid by the compound provided additional support for this structure (9). The configurations of the anomeric centers in the di-D-fructose anhydrides have not been established.

The α,β-configuration was readily established for "di-D-fructose anhydride I" by application of proton magnetic resonance (NMR) spectroscopy. To achieve better chemical shifts between the various kinds of protons, the spectrum of the hexa-*O*-acetyl derivative (I) of II was determined at 100 Mc.p.s. with chloroform as solvent. Should the compound contain either the α,α- or β,β-configurations, the conformational equilibration would be expected to lead to time-averaging of the resonances for the protons at the corresponding positions in each of the rings. Certainly, the chemical shifts of the protons at the 1- and 1′-positions would be averaged out through rapid conformational change of the dioxane ring (10). This would result in the averaging of the resonances for protons at corresponding positions in the furanoside rings even though these rings should be conformationally rigid. Therefore, the NMR spectra for the 1,2′:1′,2-di-D-fructofuranose anhydride hexaacetates with the α,α- and β,β-configurations should show signals for only five kinds of protons on the sugar residue and three pairs of nonequivalent acetyl groups. However, as seen from the spectrum in Fig. 1, the hexaacetate (1) of "di-D-fructose anhydride I" (II) provided a much more complex spectrum. It is seen, for example, that even the methylenic protons of the dioxane ring are not equivalent. Also, the acetyl group region possessed

**Postdoctoral Fellow, 1961–1963.*

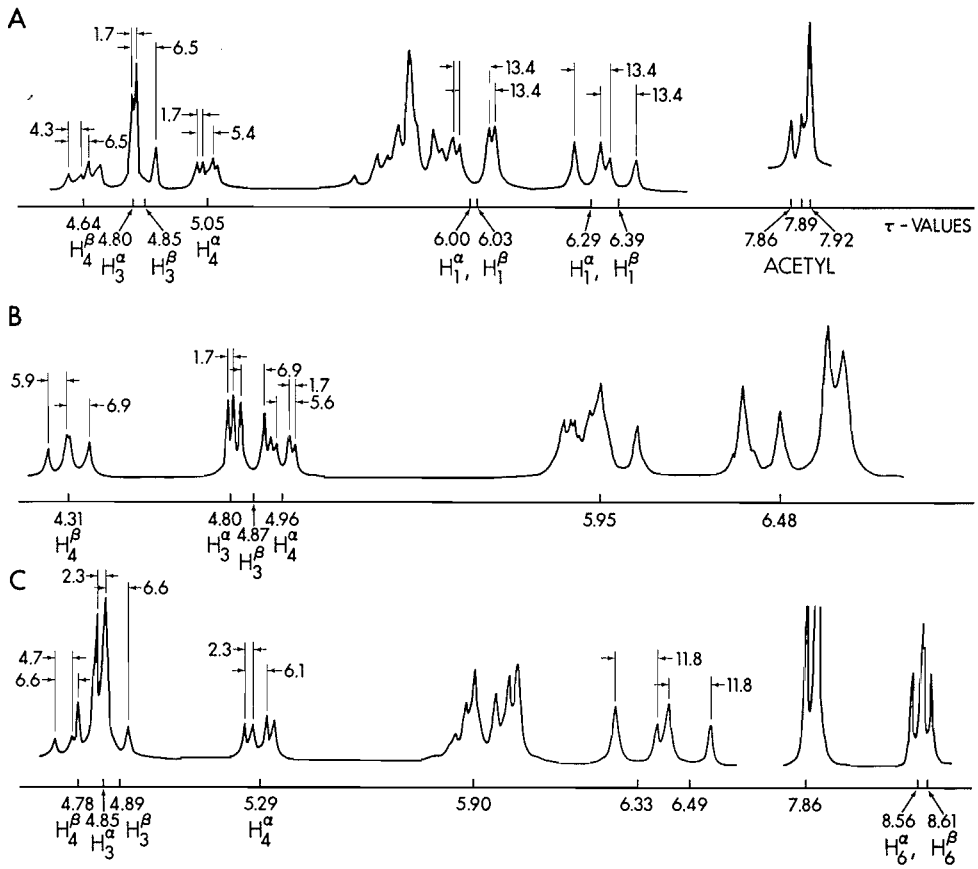

FIG. 1. NMR spectra at 100 Mc.p.s. in chloroform: (A) "di-D-fructose anhydride I" hexaacetate (I); (B) 6,6′-di-*O*-trityl "di-D-fructose anhydride I" tetraacetate (III); and (C) 6,6′-dideoxy-"di-D-fructose anhydride I" tetraacetate (V). The signals for the aromatic and acetyl-group protons are not shown in spectrum B. The spacings are in c.p.s. and the α and β designations refer to the furanoside ring with the corresponding anomeric configuration. The H_1^{α}, H_1^{β} and H_6^{α}, H_6^{β} assignments may in each case be reversed.

three signals of relative intensities 1:1:4. The indication was clear, therefore, that the compound has one of the anomeric centers in the α- and the other in the β-configuration. This conclusion was substantiated by the results obtained in a study of the periodate oxidation of II since, as discussed below, one of the furanoside rings proved to be much more resistant to oxidation than the other. To eliminate the possibility that II was not a 1,2′:1′,2-dianhydride, the compound was fully *O*-methylated and the product hydrolyzed in order that the hydrolyzate could be examined by the modern methods of paper chromatography. In fact, the hydrolyzate contained only one component which gave a color reaction with *p*-anisidine hydrochloride and possessed an R_f value close to that reported for 3,4,6-tri-*O*-methyl-D-fructose.

The formation of the hexaacetate (I) on acid treatment of the triacetate of the 1,2-linked β-D-fructosan (inulin) therefore involved a change in the configuration of the reacting anomeric center. In view of this stereochemical route, the course of the reaction can be depicted as an acid-catalyzed, transglycosidative depolymerization as shown below.

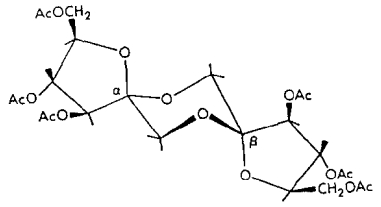
INULIN TRIACETATE



I

Although II consumed 1 mole of periodate at pH 4.05 in 4 hours, 127 hours were required for the consumption of the next 0.86 moles. This slow consumption of periodate by a vicinal glycol group situated on a *simple* five-membered ring appeared without precedent and provided the incentive to determine the conformation of the compound by application of high resolution NMR spectroscopy. Clearly, the high resistance to periodate oxidation exhibited by one of the rings requires a high degree of conformational rigidity. The previous experience with periodate-resistant vicinal glycols indicated a conformation wherein the hydroxyl groups define a dihedral angle greater than 120° (11–13).

McDonald and Jackson (14) subjected II to tritylation followed by acetylation to obtain a crystalline tetra-*O*-acetyl-di-*O*-trityl derivative (III) which was subsequently detritylated to yield a crystalline tetraacetate (IV) of II. The acetyl groups in IV were believed (14) to be at the 3-, 3′-, 4-, and 4′- positions. This conclusion was substantiated in the present investigation by tosylation of IV followed by reaction with sodium iodide to form a tetra-*O*-acetyl-6,6′-dideoxydiiodo derivative of II. Hydrogenolysis of the diiodide gave a crystalline tetra-*O*-acetyl-dideoxy derivative (V) of II. The NMR spectrum of V gave two doublets each of intensity three at 8.56 τ and 8.61 τ with spacings of 6.6 c.p.s. and 6.1 c.p.s., respectively, thus establishing the presence of two *C*-methyl groups each coupled to only one proton (15). It follows, therefore, that compound IV is 3,3′,4,4′-tetra-*O*-acetyl-1′,2-anhydro-[1-(α-D-fructofuranosyl)-β-D-fructofuranose]. As indicated in this name, the prime numbers will be used hereafter to refer to positions in the α-D-fructose residue.

The 100 Mc.p.s. spectra of compounds I, III, IV, and V were examined for information on the conformations of the furanose rings through application of the relationships that appear to exist between the coupling constant and the dihedral angle defined by vicinal protons (16–18). Most of the pertinent NMR data are presented in Fig. 1 and summarized in Table I. The chemical shifts of the protons at the 3-, 4-, and 5- positions in each of the furanose rings are in all cases large as compared to the observed spacings. It can therefore be concluded that the spacings found correspond closely to the coupling constants involved.

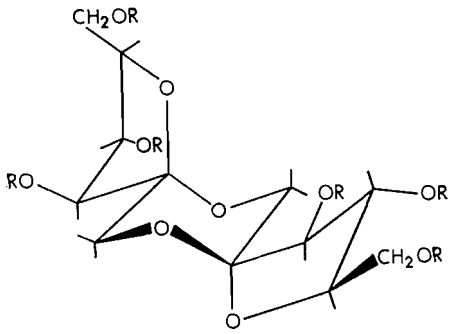
The purpose of this research was mainly to gain a better experimental basis for the conformational analysis of furanoside rings (19). The conformation indicated for compound I was suggested by conformational analysis for the following reasons. The two furanoside rings can in theory exist in a number of conformations wherein either one (C_s or envelope conformation) or two (C_2 or twist conformation) of the ring atoms is or are out of the plane of the other ring atoms. In view of the anomeric effect (19) and especially as demonstrated by the conformations of the *trans*-2,5-dichloro- and *trans*-2,3-dibromo-1,4-dioxanes (20), it must be anticipated that the furanoside-ring oxygens will be axially oriented on the dioxane ring of I. Also, in view of the anomeric effect, it can be anticipated that the oxygens of the dioxane will favor quasi-axial orientations on the furanoside rings. Furthermore, it is to be expected that the ring oxygen of a furanoside ring will tend to occupy a central position in that portion of the ring where four of the ring atoms are nearest to coplanarity (19). In other words, it is to be expected that *in general furanoside rings will tend to be puckered in such a manner as to have a carbon meta to the ring oxygen (either the 2- or the 3-carbon for aldofuranosides; either the 3- or 4-carbons for ketofuranosides) furthest out of the mean plane of the ring.* This conclusion is well borne out by the experimental evidence. It is established that the 2-carbon is out of plane in cytidine (21) and the 3-carbon is the atom out of plane in cytidine 3-phosphate (22) and 5′-bromo-5′-deoxythymidine (23). In the case of sucrose (24), it is the 4′-carbon which is out of plane. The 100 Mc.p.s. spectrum for methyl β-D-ribofuranoside was determined in chloroform and showed $J_{1,2} = 0.8$, $J_{2,3} = 4.9$, and $J_{3,4} = 6.3$ c.p.s. These coupling constants are well accommodated by the C_s conformation with the 3-carbon out of the plane of the other ring atoms. These considerations together with the avoidance of the eclipsing of large substituents lead to the conclusion that the conformations for the furanoside rings must be close to those depicted in the conformational formula II. This conformation would account for the periodate oxidation data since the hydroxyls of the two α-glycol groups would define dihedral angles of about 150° and 75° in the α- and β-furanoside rings, respectively.



I, R = Ac

II, R = H

The NMR spectral features for compounds I, III, IV, and V are in excellent agreement with this conformation for these compounds. The relevant data are presented in Table I. First of all, it should be noted that the coupling constants for the 3- and 4-protons (average 6.7 c.p.s.) are substantially greater than those for the 3′ and 4′-protons (average 1.8 c.p.s.).

Since the 3- and 4-protons are in *trans*-relationship on a five-membered ring, these hydrogens cannot conceivably define a dihedral angle of less than 60°. Therefore, the large coupling constant, according to the Karplus relationship (16), must arise from hydrogens which define a dihedral angle in the range 150° to 180°. Consequently, the dihedral angle defined by the 3- and 4-hydroxyls in this ring must be in the range 60° to 90° and comprise the glycol group readily susceptible to periodate cleavage. This conclusion was substantiated by treatment of II with 1.1 moles of periodate and reduction of the product with sodium borohydride. Acetylation gave an oil in 93% yield, based on the structure VI for the substance shown in Fig. 2,A. This structure was fully justified by its NMR spectrum. As expected, the coupling constant found for the protons at the 3- and 4-positions of the furanoside ring was small (1.5 c.p.s.). Deacetylation of VI followed by acid hydrolysis liberated fructose, glycerol, and dihydroxyacetone in agreement with the assigned structure.

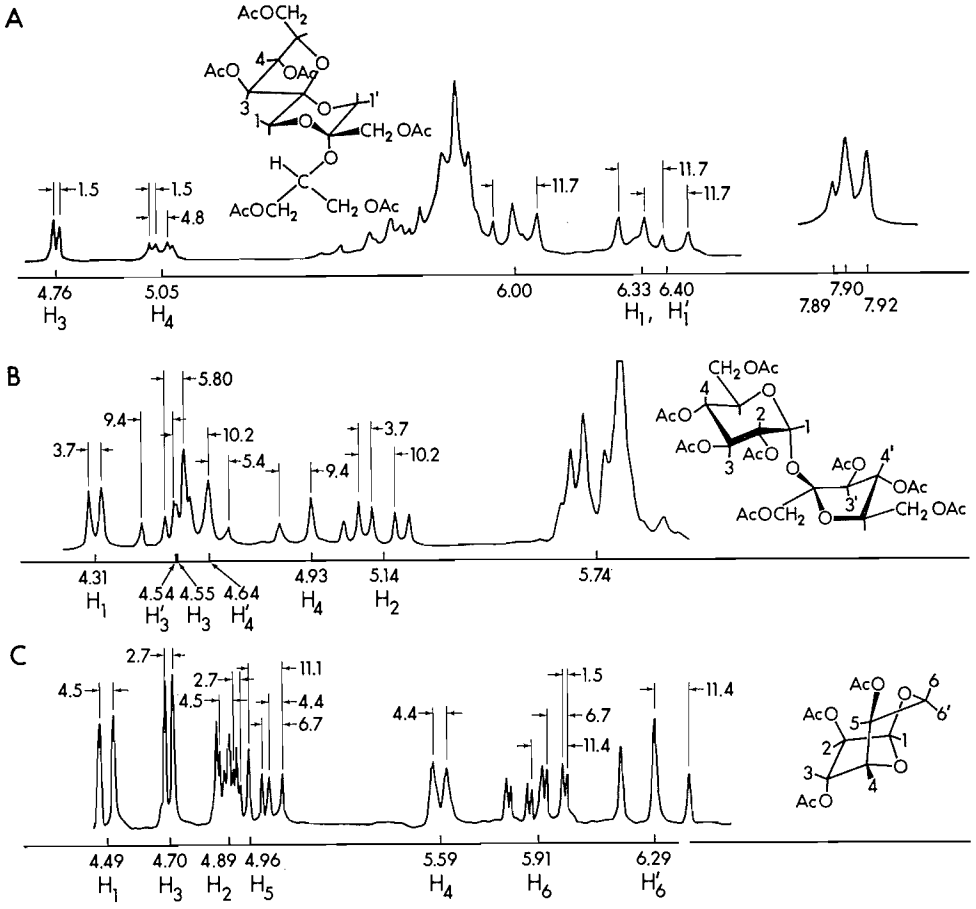


FIG. 2. NMR spectra at 100 Mc.p.s. in chloroform: (A) compound (VI); (B) sucrose octaacetate; and (C) 1,6-anhydro-α-D-galactofuranose triacetate. The signals for the acetyl groups are not shown in spectra B and C. In spectrum A, the H_1, H_1' signals are not specifically assigned.

To fully justify the conformation indicated in formula II for "di-D-fructose anhydride I", it was necessary to gain evidence that the periodate-resistant ring in fact possessed the α-D-configuration. The fact that VI showed a stronger dextrotation (+16°) than I (+0.5°)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

favored this assignment. However, the evidence provided by the NMR spectra of sucrose octaacetate and 1,6-anhydro-α-D-galactofuranose triacetate, reproduced in Fig. 2, provided more definitive evidence. The coupling constant for the 3′- and 4′-protons of the furanose ring in sucrose octaacetate was found to be 5.4–5.8 c.p.s. in agreement with expectations based on the conformation of sucrose (24) and the form for the Karplus expression normally found in carbohydrate structures. The β-D-furanoside ring of sucrose, although less susceptible to periodate oxidation than the α-D-glucopyranoside ring, is readily oxidized. The β-D-furanose ring undergoes lead tetraacetate oxidation extremely readily (25). The coupling constant for the 2- and 3-protons of the 1,6-anhydro-α-D-galactofuranose triacetate is 2.7 c.p.s. (see Fig. 2,C). Since these protons are in *trans*-relationship, this small coupling constant in itself cannot provide information on the dihedral angle defined by the protons. It was possible by double irradiation experiments to definitely locate the resonance for each of the protons in the molecule. The coupling constants found are indicated in Fig. 2,C and are $J_{1,2} = 4.5$, $J_{2,3} = 2.7$, $J_{3,4} \simeq 0$, $J_{4,5} = 4.4$, $J_{5,6} = 6.7$, $J_{5,6'} = 11.4$, and $J_{6,6'} = 11.4$ c.p.s. In addition, the signals for the 4- and 6-protons showed long-range coupling as was observed by Hall and Hough (26) in the spectra for a number of 1,6-anhydroaldopyranose triacetates. Spin-decoupling established that this long-range coupling involves the 2-proton and that $J_{2,4} = 1.1$ and $J_{4,6} = 1.5$ c.p.s. These coupling constants are best rationalized, on the basis of the type of relationship proposed by Karplus, by the conformation for the compound shown in Fig. 2,C wherein the 3-carbon is furthest out of the mean plane of the atoms in the ring. The fact that $J_{2,3}$ is larger than $J_{3,4}$ suggests that the furanose ring is somewhat distorted from the envelope conformation. The main point of interest is that the conformation has the 2- and 3-hydroxyls define a dihedral angle of about 150°, an angle compatible with the resistance to periodate oxidation exhibited by the parent alcohol (11).

In conclusion, "di-D-fructose anhydride I" definitely is 1′,2-anhydro-[1-(α-D-fructofuranosyl)-β-D-fructofuranose] and possesses a conformation close to that presented in structure II. The degree of conformational rigidity displayed by the α-furanoside ring in II is important in relation to the occurrence of furanoside rings in a wide variety of important biological compounds including coenzymes, nucleotides, and antibiotics.

EXPERIMENTAL

The melting points were determined on a Leitz heating stage and are not corrected. The optical rotations were measured at room temperature at the D-line of sodium. The NMR spectra were obtained with a Varian Associates model HR-100 spectrometer at 100 Mc.p.s. and the line positions calibrated by the side-band technique using a Hewlett-Packard audiofrequency oscillator model 200 AB and an electronic counter model 521C. Proton-proton spin decoupling was achieved in the manner previously described (18).

"Di-D-fructose Anhydride I" (II) and Its Hexaacetate (I)

The hexaacetate (I) was prepared according to Irvine and Stevenson (6). The melting point, 137°, optical rotation, +1.08°, and yield were in agreement with those previously reported. The hexaacetate (I), 20 g, was heated for 5 minutes with boiling 0.01 *M* methanolic sodium methoxide. The residue obtained on evaporation of the methanol soon crystallized and was purified by recrystallization from ethanol. The purified product (II) melted at 162–164° with $[\alpha]_D$ +27.6° (*c*, 7.5 in water). The values previously reported (3, 5) are m.p. 164°, $[\alpha]_D^{20}$ +26.9° (*c*, 8.45 in water).

The dianhydride (II) was methylated using dimethyl sulphate and barium hydroxide in dimethyl sulphoxide (27), and the product was separated from a small amount of contaminant by chromatography on a cellulose column using methylethylketone saturated with water as the developing phase (28). The purified product, R_{TG} 1.0, was found to be homogeneous on paper chromatography using *n*-butanol, ethanol, water (5:1:4) (29) and, on hydrolysis at 60° for 1 hour in 1 *N* hydrochloric acid, was converted to only one substance, $R_{TG} = 0.91$. The product of the hydrolysis was also homogeneous when chromatographed on paper using the aqueous methylethylketone (28) as developing phase. *p*-Anisidine hydrochloride was used as spray reagent (30).

3,4,3′,4′-Tetra-O-acetyl-"di-D-fructose anhydride I" (IV)

3,4,3′,4′-Tetra-*O*-acetyl-6,6′-dityrityl-"di-D-fructose anhydride I" (III) was prepared as described by McDonald and Jackson (14). The compound melted at 192–193° with $[\alpha]_D$ +20.1° (*c*, 8.8 in chloroform) in agreement with the values recorded, m.p. 194°, $[\alpha]_D^{20}$ +21.06 (*c*, 3.73 in chloroform). The NMR spectrum measured in chloroform is reproduced in Fig. 1 (see also Table I). The assignments were made on the basis of the structures of the signals and by comparison with the spectrum obtained for 6,6′-dideoxy-"di-D-fructose anhydride I" tetraacetate (V).

The dityrityl tetraacetate (III), 8.0 g, was hydrogenolyzed at atmospheric pressure in 500 ml of ethanol using 500 mg of 10% palladium on charcoal (purchased from Engelhard Industries Inc.). The compound (III) dissolved in the course of the reaction. When the hydrogen uptake was complete, the catalyst was removed by filtration. On evaporation of the ethanol *in vacuo*, the first crystalline deposit was triphenylmethane, m.p. 93°. After the latter compound was removed, the highly concentrated solution deposited the tetraacetate (IV) in crystalline condition and this product was purified by recrystallization from ethanol. The physical constants, m.p. 187–188°, $[\alpha]_D$ −1.94° (*c*, 20.8 in chloroform), were substantially higher than the values recorded in the literature (14), m.p. 173°, $[\alpha]_D^{20}$ −9.9° (*c*, 3.73 in chloroform).

6,6′-Dideoxy-"di-D-fructose Anhydride I" Tetraacetate (V)

Compound IV, 0.80 g, was dissolved in 15 ml of dry pyridine with 1.55 g of *p*-toluenesulphonyl chloride. After standing for 16 hours at room temperature, the reaction mixture was processed in the usual manner to obtain 1.23 g of a sirupy product. The NMR spectrum of the compound in deuterated chloroform showed signals at 2.43 (quartet), 7.57, and 7.95 τ, the regions characteristic for protons and methyl groups situated on the benzene ring and in acetoxy groups, respectively. The relative intensities of these signals was 4:3:6, respectively, as expected for presence of two tosyl groups in a tetraacetate. The sirup was dissolved in 30 ml of acetone with 11.5 g of sodium iodide and the solution was heated in a sealed tube for 20 hours at 110°. The reaction mixture was added to water and the product isolated by extraction with chloroform followed by evaporation of the chloroform in the usual manner. The yield was 1.02 g of a crystalline product whose NMR spectrum was devoid of signals characteristic for tosyloxy groups. The substance without purification was dissolved in 40 ml of methanol along with 0.45 g of diethylamine. Palladium (10%) on charcoal, 100 mg, was added and the solution was stirred in an atmosphere of hydrogen for 2 hours. After this time, the hydrogen uptake had ceased and the catalyst was removed by filtration. The solvent was removed and the residue was acetylated for 15 hours at room temperature in a mixture of 5 ml of pyridine and 5 ml of acetic anhydride. The product was isolated in the usual manner to provide a sirup which crystallized from ethanol. Purification by recrystallization from ethanol gave 345 mg of compound V, m.p. 169–170°, $[\alpha]_D$ −7.34° (*c*, 23.7 in chloroform). Calc. for $C_{20}H_{28}O_{12}$: C, 52.17; H, 6.13%. Found: C, 52.47, 52.26; H, 5.96, 5.78%.

The NMR spectrum (see Fig. 1) showed two doublets with spacings of 6.57 and 6.06 c.p.s. centered at 8.56 and 8.61 τ, respectively. When the sample was simultaneously irradiated at 5.90 τ, the above-mentioned doublets collapsed to two singlets. The total intensity of the two doublets was one half the intensity of the signal for acetoxy-group protons at 7.86 τ. The irradiation at 5.90 τ also led to the collapse of the two quartets at 4.78 and 5.29 τ. It followed, therefore, that the latter quartets arise from protons at the 4- and 4′- positions, respectively. Irradiation of the quartet at 4.78 τ collapsed the doublet with a spacing of 6.6 c.p.s. at 4.89 τ. Therefore this doublet must arise from the 3-hydrogen. Irradiation of the quartet at 5.29 τ caused a collapse of the doublet with 2.3 c.p.s. spacing at 4.85 τ and this doublet must arise from the 3′-hydrogen. Thus, the spin-decoupling experiments provided the assignment of signals anticipated from first-order analysis of the spectrum.

Periodate Oxidation of "Di-D-fructose Anhydride I" (II)

In a typical experiment, compound II, 151.9 mg (0.468 millimoles), and 289 mg (1.35 millimoles) of sodium metaperiodate were dissolved at zero time in 100 ml of acetate buffer solution at pH 4.05. The periodate consumption was subsequently determined after several intervals of time using the Fleury–Lange arsenite–iodometric method (31). Reaction blanks were determined and 0.391 millimoles of methyl-α-D-glucopyranoside was ozidized under the same conditions in a control experiment. After 3.7, 12.5, 42, and 131 hours at room temperature, compound II consumed per mole 1.03, 1.24, 1.56, and 1.86 moles of periodate, whereas the consumption by the methyl-α-D-glucopyranoside was 1.79, 2.01, 2.06, and 2.09 moles of periodate per mole after the same intervals of reaction time.

The oxidation of "di-D-fructose anhydride I", 0.648 g (2.0 millimoles) in 10 ml of water, with 0.46 g (2.2 millimoles) of sodium metaperiodiate was followed polarimetrically. The specific rotation dropped from +27.6° to a constant value of +5.4° in a period of 2 hours. The resulting solution was reacted with 0.190 g (5 millimoles) of sodium borohydride for 6 hours at room temperature. After this period, the excess of borohydride was destroyed by adding acetic acid and the pH was adjusted to 4.5. The solution was evaporated at 40° *in vacuo* to about 5 ml and then freeze-dried. To the resulting cake, 5 ml of methanol was added, the mixture was heated to the boiling point, and then evaporated to dryness. This procedure was repeated four times. To the dry cake, 10 ml of pyridine and 10 ml of acetic anhydride was added and the reaction mixture was left at room temperature for 15 hours. The usual work-up procedure afforded

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

1.08 g (93% yield) of a light sirup, $[\alpha]_D$ +16.2° (*c*, 1.21 in chloroform). The NMR spectrum is reproduced in Fig. 2. The chemical shifts and relative intensities of the various signals clearly required the compound to be essentially pure. The relative intensities of the three sets of signals for the protons in acetoxy groups agreed well with that expected for a hexaacetate (VI), namely 1:3:2. Further evidence of essential purity was provided by deacetylation in 50% aqueous methanol 10% in triethylamine and chromatographic examination. The sirupy product, $[\alpha]_D$ +20.1° (*c*, 6.07 in water), showed only one component in detectable quantity with $R_f = 0.28$ when chromatographed on paper using *n*-butanol, ethanol, water (5:1:4) as developing phase. Hydrolysis of the compound at 95° in 1 *N* sulphuric acid for 15 minutes and chromatographic analysis of the product using pyridine, *n*-butanol, acetic acid, water (4:6:1:3) revealed the formation of fructose, glycerol, and dihydroxyacetone.

ACKNOWLEDGMENTS

This research was made possible by a grant to R. U. L. from the Sugar Research Foundation, Inc., New York as their Project No. 88. The sample of 1,6-anhydro-α-D-galactopyranose triacetate was kindly provided by N. K. Richtmyer. The NMR spectra were determined by Mr. G. Bigam of this department.

PYRROLE CHEMISTRY

III. FRIEDEL–CRAFTS ISOPROPYLATION OF METHYL 2-PYRROLECARBOXYLATE

HUGH J. ANDERSON AND L. CAMERON HOPKINS
Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland
Received November 14, 1963

ABSTRACT

The reaction between isopropyl chloride and methyl 2-pyrrolecarboxylate catalyzed by aluminum chloride has been investigated. From the reaction mixture 4-isopropyl-, 5-isopropyl-, and 4,5-diisopropyl-2-esters have been isolated and identified. It has been found that while the 4-isopropyl-2-ester rearranged to 5-isopropyl-2-ester under alkylation conditions, neither the latter nor the 4,5-diisopropyl-2-ester underwent any change. Some suggestions as to the course of the reaction are made.

Interest in the substitution reactions of pyrrole derivatives which possess an electron-withdrawing group in the 2-position (1) has led us to begin an investigation of the Friedel–Crafts isopropylation of such compounds. Often yields in the alkylation of benzene derivatives with only an electron-withdrawing group are too low for preparative value (2), but deactivated furan and thiophene derivatives are still very reactive to electrophilic substitution and several have been alkylated in fair to good yield (3–6) with alkyl halides and aluminum chloride. However, there does not seem to have been any previous study of Friedel–Crafts alkylation using pyrrole or any of its simple derivatives.

The fact that methyl 4-isopropyl-2-pyrrolecarboxylate and the corresponding acid had been prepared and identified previously through ring-closure synthesis (7), while its isomer, methyl 5-isopropyl-2-pyrrolecarboxylate, appeared likely to be fairly easy to synthesize by another path, governed out choice of reactants.

Our starting material methyl 2-pyrrolecarboxylate was produced by the action of methyl chloroformate on pyrrylmagnesium bromide in a modification of the method of Maxim *et al.* (8). In addition to a very small amount of methyl 1-pyrrolecarboxylate (9), two other higher boiling substances were isolated as by-products of the reaction. One of these was methyl 1,2-pyrroledicarboxylate recently reported by Hodge and Rickards (10). The other was identified as methyl 1,3-pyrroledicarboxylate by mild base hydrolysis and partial decarboxylation to the known 3-pyrrolecarboxylic acid (11). The infrared spectrum of this acid was identical with that of an authentic specimen and the mixed melting point was not depressed. The n.m.r. spectrum of the 1,3-diester showed three aromatic type protons as well as two different ester CH_3's. The infrared spectrum showed a peak at 1720 cm^{-1} and another at 1760 cm^{-1}. The peak at higher frequency corresponds to the N-$COOCH_3$ carbonyl which appears at 1765 cm^{-1} in methyl 1-pyrrolecarboxylate.

The action of isopropyl chloride on pyrrylmagnesium bromide produced the known mixture of 2- and 3-isopropylpyrrole (12). Repeated fractionation gave a sample of 2-isopropylpyrrole of greater than 95% purity as determined by gas–liquid partition chromatography. After conversion of this compound to the corresponding Grignard reagent, reaction with methyl chloroformate produced a moderate yield of the desired methyl 5-isopropyl-2-pyrrolecarboxylate. The n.m.r. spectrum was in agreement with the assigned structure.

Our alkylation reactions were carried out in carbon disulphide using anhydrous aluminum chloride as the catalyst. The products were separated for identification by adsorption chromatography on alumina. Analysis of all reaction mixtures was done by gas–liquid partition chromatography. Standardization against a series of mixtures of known proportions showed that this method gave results accurate to about 2% when peak areas were determined by triangulation. The column used was a commercial Beckman one of Carbowax 4000 Dioleate on firebrick, operating at 220° C, and using helium as carrier gas.

The results of Spaeth and Germain (6) on methyl 2-thienyl ketone led us to expect the predominance of methyl 4-isopropyl-2-pyrrolecarboxylate. This proved to be correct. Column chromatography of early reaction products gave us two compounds as well as some unreacted starting material. One of the products was identified as the known 4-isomer by its melting point, by the n.m.r. spectrum, and by the melting point of the corresponding acid. The other product was shown by n.m.r. and later by elemental analysis to possess two isopropyl groups and to be the 4,5-diisopropyl derivative.

By following the eluate fractions from alumina by gas chromatography it was possible to isolate another major product. This was proved to be the expected methyl 5-isopropyl-2-pyrrolecarboxylate by mixed melting point and comparison of its infrared spectrum with an authentic specimen prepared as described above.

When the 2-isopropylpyrrole used to prepare methyl 5-isopropyl-2-pyrrolecarboxylate contained more than a small amount of 3-isopropylpyrrole then in the gas-chromatographic pattern of the Grignard reaction product two additional peaks were observed. One of these corresponded to the 4-isopropyl-2-ester and the other had the same retention time as an unknown trace peak which appeared in the reaction products from the isopropylation of the ester. The latter would thus appear to be methyl 3-isopropyl-2-pyrrolecarboxylate, the other possible monoisopropylation product. Miyazaki *et al.* (13) found that another Grignard synthesis from 3-isopropylpyrrole gave both 2- and 5-substitution. The amount of 3-substitution in our alkylations was usually of the order of 5% or less. It has not been possible to isolate this substance in a pure state.

Further Friedel–Crafts isopropylation of the now proved 4- and 5-isopropyl-2-esters produced the same diisopropyl-2-ester obtained in the original alkylation. The n.m.r. spectrum was in agreement with methyl 4,5-diisopropyl-2-pyrrole carboxylate. Bromination of the 2-ester has been shown to produce the 4,5-dibromo-2-ester (14). We therefore see no reason to doubt the assignment of the two isopropyl groups to the 4- and 5-positions.

Throughout our experiments no special purification of materials was attempted except for the starting ester which was not used until the gas-chromatographic pattern showed only a single peak. The aluminum chloride was kept in a desiccator but no particular care was used in handling it beyond that which ordinary use demands. Some trial experiments in which a controlled small amount of water was added seemed to have no particularly significant effect on the ratios of products. However, in a series of experiments where extra precautions were used to exclude all atmospheric moisture the extent of reaction was greatly decreased for the same time interval. The alkylation experiments were repeatable and gas–liquid partition chromatography gave consistent results except for some alkylations where the reaction time was quite short. In those experiments where all quantities were carefully measured a high percentage of the ester was accounted for as unreacted starting material or products. Thus there was very little destruction of the heterocyclic ring under these conditions.

Isopropyl chloride and aluminum chloride form a polarized complex in an equilibrium

with the corresponding ion-pair dependent upon the stability of the carbonium ion and the reaction conditions:

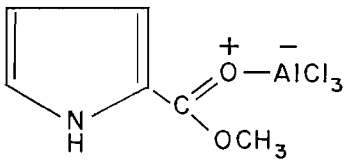
$$R\text{-}Cl + AlCl_3 \rightarrow R^{\delta+} \ldots . Cl \ldots . AlCl_3^{\delta-} \leftrightarrows R^+ + AlCl_4^-$$

which is then attacked (15) by the nucleophilic positions of the aromatic system.

Campbell and Spaeth (2) observed that Friedel–Crafts isopropylation of methyl benzoate produced almost exclusively the *meta* isomer, but in low yields. Similar observations on related compounds have been made by these and other authors. Usually the nitration of benzenes with an electron withdrawing group produces from 10 to 30% of the *ortho* plus *para* isomers (16). Other electrophilic substitution studies on such compounds are seldom comparable because of the poor yields. The much smaller proportion of *ortho-para* substitution observed in alkylation of these compounds has been attributed by Campbell and Spaeth to complexing of the carbonyl oxygen by the catalyst which would greatly enhance the electron-withdrawing character of the group. Complexing of carbonyl compounds, including esters, with aluminum chloride and other Lewis acids is well established (17).

Friedel–Crafts isopropylation of methyl 2-furoate and similar compounds was found by Gilman and Calloway (3) to produce only the 5-isomer. However, in the isopropylation of furfural the only product isolated was the 4-isomer (18), in low yield. In contrast, most electrophilic substitution reactions of thiophenes and pyrroles with electron-withdrawing groups in the 2-position have produced mixtures of 4- and 5-isomers (19, 20). Spaeth and Germain (6) observed in the isopropylation of methyl 2-thienyl ketone that more than 90% of the mixture obtained was the 4-isomer, while nitration of this ketone has been reported to produce equal amounts of the 4- and 5-isomers (21).

Although the α-directing influence of the heteroatom may be of some importance, the predominant electronic effect on orientation in our system is expected to be electron withdrawal by the carbomethoxy group, enhanced by complexing with the aluminum chloride, I. This would lead to 4-substitution through deactivation of positions 3- and 5-.



I

In contrast Rinkes (22) found that the reaction of this ester with nitric acid and acetic anhydride produced roughly equal amounts of 4- and 5-substitution.

Our initial observation was that the ratio of 4- to 5-alkyl substitution was roughly 4 or 4.5 to 1. However, it soon became apparent that the ratio varied with time, temperature, and initial concentrations. In addition, the formation of trace amounts of the 3-isopropyl isomer and substantial amounts of the 4,5-diisopropyl-2-ester complicated any explanations of the course of reaction. We also found that the overall reactivity of the pyrrole ring makes up for the strong deactivation of the complexed carbonyl group, and alkylation has preparative value for these products which are readily separated.

It was established that when pure methyl 5-isopropyl-2-pyrrolecarboxylate was refluxed for 1 to 2 hours in carbon disulphide with the appropriate quantity of anhydrous aluminum chloride, while a stream of anhydrous hydrogen chloride was admitted, no detectable change occurred. However, when methyl 4-isopropyl-2-pyrrolecarboxylate was subjected to the same conditions there was a rapid rearrangement in which roughly one-half of the 4-isomer was converted to the 5-isomer. At the same time there was a small amount of disproportionation in which nearly equal amounts of starting material and methyl 4,5-diisopropyl-2-pyrrolecarboxylate were formed. Finally it was shown that the diisopropyl-2-ester was also unchanged by the reaction conditions over an 18-hour period, in the presence of starting material.

A series of alkyation experiments was carried out to determine the course of the reaction with time when all other variables were held constant. These results are detailed in Table I. The observed behavior was that roughly equal amounts of 4- and 5-isopropyl-2-ester were formed, along with a rather small amount of diester, until about 1 hour had elapsed. The amounts of both 4-isopropyl- and of 4,5-diisopropyl-2-ester rose more rapidly during the second hour, while the 5-isopropyl-2-ester remained almost unchanged. The reaction was then nearly complete and not a great deal of change took place during the next 16 hours.

Throughout these reactions we have observed the formation of small amounts of yellow solid. In some trials using larger amounts of aluminum chloride a yellow oil separated. Other workers have investigated this type of material (23, 24) and found it to be a complex of aromatic, aluminum chloride and alkyl halide. We observed a more intense color with increased aluminum chloride or isopropyl chloride. Increasing the ester concentration seemed to have little effect.

TABLE I

Product distribution in alkylation experiments

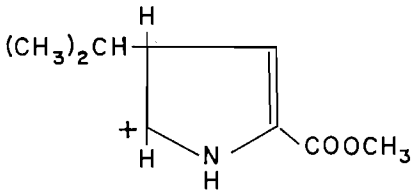
Time (hours)	Conversion (mole %)	Product distribution (mole %)*		
		4-Ipr-2-ester	5-Ipr-2-ester	4,5-Diipr-2-ester
0.25	5.7	4.3	trace	1.4
0.5	15.5	6.9	7.0	1.6
1.0	24.8	11.6	10.1	3.2
1.5	47.3	29.0	10.6	7.7
2.0	53.1	32.4	9.7	11.0
18.0	61.8	34.6	11.6	15.6

*The 3-isopropyl product was ignored in calculations.
Reactants: isopropyl chloride (0.01 mole)
methyl 2-pyrrolecarboxylate (0.01 mole)
aluminum chloride (0.012 mole)
Solvent: carbon disulphide (50 ml)
Temperature: 50° C.

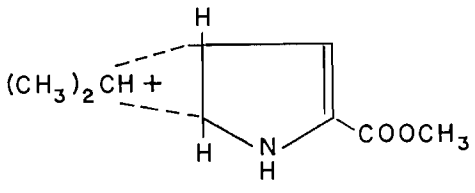
The pattern of our alkylation results is consistent with direct attack taking place primarily at the 4-position leading to the sigma complex II.* This may rearrange intramolecularly by way of a Wagner–Meerwein intermediate III (23, 25). Loss of a proton from these carbonium ions would produce the two monoisopropyl-2-esters. The highly reactive 4-position of the 5-isopropyl-2-ester would then acquire a second isopropyl group to form IV.

Support for this sequence was found in a series of observations in which it is assumed that the 4-position was always the most reactive one to electrophilic attack. Thus alkylation experiments where hydrogen chloride gas was admitted continuously throughout

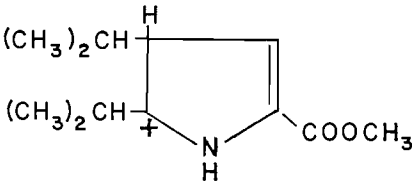
**The carbonyl groups of II through V undoubtedly remain complexed with aluminum chloride.*



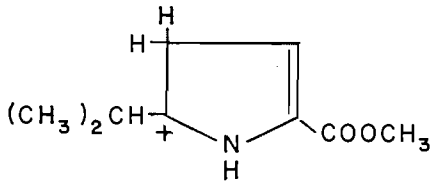
II



III



IV



V

led to very low yields, with the 5-isomer predominating. Here protonation of the 4-position exceeded alkylation and such II as was formed rearranged rapidly to the 5-isomer. In rearrangement experiments on the latter and on the diisopropyl-2-ester protonation of the 4-position would produce V and IV respectively, whose rearrangement or disproportionation would be expected to, and did, fail.

On the other hand methyl 4-isopropyl-2-pyrrolecarboxylate protonated to II and would rearrange. Attempts to carry out this rearrangement in the absence of a stream of hydrogen chloride gas produced little of the 5-isomer. The small proton concentration which must have been present was probably supplied by the hydrogen chloride usually associated with commercial grade aluminum chloride. Rearrangement experiments with the 4-isopropyl-2-ester gave, in addition to the 5-isopropyl isomer, equal amounts of methyl 2-pyrrolecarboxylate and 4,5-diisopropyl-2-ester. The fact that we observed no overall loss of isopropyl groups in these rearrangement reactions supports the idea of an intermediate such as III which loses its isopropyl group to a molecule of 5-isopropyl-2-ester in an intermolecular transfer (26). Some loss might have been expected to occur if a free isopropyl cation or its complex with the Lewis acid had formed.

The reactivity of the 4-position is also supported by alkylation experiments using the monoisopropyl-2-esters. Here it was observed that the 5-isomer was converted to 35% of the diisopropyl-2-ester in 15 minutes, while the 4-isopropyl-2-ester gave only 15% after 1 hour. In the latter experiment rearrangement probably preceded alkylation to a large extent. Alkylation experiments using swamping amounts of catalyst gave high yields of product where the 5-isopropyl-2-ester predominated by far and where diisopropylation was negligible.

A small amount of the supposed 3-isopropyl-2-ester was found among the rearrangement products of the 4-isopropyl isomer. While at least some direct attack may occur at the 3- and 5- positions during alkylation, it seems likely that most of the product having isopropyl groups at these positions arises through rearrangement from the kinetically favored 4-position.

Spaeth and Germain (6) did not examine the diisopropylated product at any time, although they indicated that higher boiling material was present after all alkylations. It may be that the very low percentage of 5-isopropyl-2-thienyl methyl ketone they observed was due to rapid further alkylation. In addition, in rearrangement studies they did not, apparently, use an external source of hydrogen chloride. However, further information is needed to determine whether their thienyl ketone did behave quite differently in Friedel–Crafts isopropylation to our pyrrole ester.

We hope to extend our studies of alkylation to other negatively substituted pyrroles, as well as to investigate the behavior when different Friedel–Crafts catalysts are employed.

EXPERIMENTAL

General

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Infrared spectra were recorded by a Unicam SP100 Spectrophotometer using the potassium chloride disk technique (2 mg of sample in 200 mg KCl).

Ultraviolet spectra were determined with a Beckman DK-2A recording spectrophotometer; samples were dissolved in ethanol (95%) at a concentration of 10 mg per liter. pK_a's were determined spectrophotometrically as described by Jaffé and Orchin (30).

The nuclear magnetic resonance spectra were determined at 60 Mc/second in carbon tetrachloride or in deuterochloroform. The chemical shifts are in p.p.m. from tetramethylsilane as internal reference.

Analyses of reaction mixtures were carried out by means of gas–liquid partition chromatography using a Beckman GC-2A gas chromatograph, equipped with a 30-in. column (number 70007) packed with Carbowax 4000 dioleate on firebrick and operated at 220° C with helium as the carrier gas (inlet pressure: 20 p.s.i.g.). Analyses were accurate to ±2% as shown by gas-chromatographic examination of a series of known mixtures. Retention times established for pure materials were methyl 2-pyrrolecarboxylate, 3.84 minutes; 5-isopropyl derivative, 4.55 minutes; 4,5-diisopropyl derivative, 5.88 minutes; 4-isopropyl derivative, 7.38 minutes. Another peak at 5.10 minutes is believed to represent the 3-isopropyl derivative.

Elemental analyses were determined by Alfred Bernhardt, Mülheim (Ruhr), Germany.

All Grignard reactions were carried out under an atmosphere of nitrogen.

Methyl 2-Pyrrolecarboxylate

This compound was prepared by an adaptation of the Grignard method of Maxim *et al.* (8) for the ethyl ester. The product was vacuum distilled: b.p. 115–120° at 12 mm; yield 25%. The methyl 2-pyrrolecarboxylate was crystallized from methanol, m.p. 72–73°, literature m.p. 73° (10).

From the forerun was obtained a small amount of methyl 1-pyrrolecarboxylate b.p. 57–59 at 14 mm (n_D^{22} 1.483). Gabel (31) reports b.p. 71–73 at 21 mm (n_D^{20} 1.487).

A higher boiling compound was separated from the 2-ester residue by fractional crystallization from hexane, to give a white crystalline solid, m.p. 142–143.5°. Infrared and n.m.r. spectra showed this compound to be methyl 1,3-pyrroledicarboxylate. Anal. Calc.: C, 52.46; H, 4.95; N, 7.65. Found: C, 52.53; H, 5.06; N, 7.82.

Dimethyl 1,3-pyrroledicarboxylate (0.2 g) was refluxed 2 hours in aqueous methanolic potassium hydroxide. The methanol was distilled and the aqueous solution was washed with ether to remove unreacted ester. Acidification with dilute hydrochloric acid resulted in copious evolution of carbon dioxide. The 3-pyrrolecarboxylic acid was extracted in ether and crystallized from methanol, m.p. 144.5–145.5°. Its infrared spectrum was identical with that of an authentic specimen of 3-pyrrolecarboxylic acid and the mixed melting point was not depressed.

Also isolated was the dimethyl 1,2-pyrroledicarboxylate reported by Hodge and Rickards (10), m.p. 44–45°.* Its infrared spectrum was identical with that of an authentic specimen and the mixed melting point was undepressed.

General Procedure for Alkylations

The reaction vessel was a 100-ml three-neck round bottom flask equipped with stirrer, condenser, and drying tube. The flask was immersed in an oil bath maintained at 50°. Methyl 2-pyrrolecarboxylate, 1.25 g (0.01 mole), and anhydrous aluminum chloride (Fisher Reagent Grade) 1.69 g (0.012 mole) were placed in the reaction vessel with 40 ml of carbon disulphide. Isopropyl chloride, 0.78 g (0.01 mole), in 10 ml of carbon disulphide was added at once and the reaction mixture was stirred for the required period. The reaction was quenched by pouring on ice. The aqueous layer was separated, saturated with sodium chloride, and extracted with ether. The combined organic extract was washed with sodium acetate (saturated aqueous solution) and dried over anhydrous sodium sulphate. The solvent was removed by distillation and the residue analyzed by gas chromatography.

**Dr. Rickards in a personal communication reports m.p. 48–49.5° C.*

Isolation of Alkylation Products

The unreacted starting material and its various isopropyl derivatives were separated by adsorption chromatography on alumina (Fisher Reagent Grade) and fractional crystallization from methanol. Methyl 4,5-diisopropyl-2-pyrrolecarboxylate, m.p. 120.5–121°. Calc.: C, 68.87; H, 9.15; N, 6.69. Found: C, 68.77; H, 9.43; N, 6.92. Methyl 4-isopropyl-2-pyrrolecarboxylate, m.p. 89–90° (lit. 90°). Calc.: C, 64.65; H, 7.84; N, 8.38. Found: C, 65.05; H, 7.74; N, 8.50. Methyl 5-isopropyl-2-pyrrolecarboxylate, m.p. 59.5–61°. Calc.: C, 64.65; H, 7.84; N, 8.38. Found: C, 64.67; H, 7.61; N, 8.29. Spectral properties are given in Table II.

2-Isopropylpyrrole

To a refluxing solution of 0.83 mole of pyrrylmagnesium bromide in 400 ml of ether was added an equimolar portion of isopropyl chloride in 50 ml of ether. Refluxing was continued for 18 hours and the reaction mixture cooled and hydrolyzed with 150 ml of a 10% ammonium chloride solution. The aqueous layer was separated and extracted with ether. The combined ether extracts were dried over anhydrous potassium carbonate, the solvent removed by distillation, and the residue vacuum distilled. Redistillation gave a fraction, b.p. 71–73° at 12 mm (n_D^{22} 1.4906), which was better than 95% pure in 2-isopropylpyrrole as determined by gas chromatography, the only other component being 3-isopropylpyrrole. Skell and Bean (12) report b.p. 80° at 25 mm, (n_D^{25} 1.4900) for pure 2-isopropylpyrrole.

Methyl 5-Isopropyl-2-pyrrolecarboxylate

To a cold solution of 0.171 mole of ethylmagnesium bromide in 300 ml of ether was added a solution of 0.171 mole isopropylpyrrole (>95% purity) in 25 ml of ether. The reaction mixture was refluxed for 1 hour and then cooled while methyl chloroformate (0.171 mole) in 25 ml of ether was added dropwise. The reaction mixture was again refluxed for 1 hour then carefully hydrolyzed with 100 ml of 10% ammonium chloride solution. The aqueous layer was separated and extracted with ether. After the combined ether extracts were dried over anhydrous sodium sulphate, the ether was removed by distillation and the product, methyl 5-isopropyl-2-pyrrolecarboxylate, vacuum distilled. Gas-chromatographic analysis showed that the material was homogeneous, the retention time (4.55 minutes) corresponding to that of the alkylation product to which we had tentatively assigned this structure. The 5-isopropyl-2-ester was crystallized from methanol, m.p. 59.5–61°, and was shown to be identical with the alkylation product by mixed melting point and comparison of infrared spectra.

Attempted Disproportionation of Methyl 4,5-Diisopropyl-2-pyrrolecarboxylate

Methyl 4,5-diisopropyl-2-pyrrolecarboxylate (0.001 mole) and methyl 2-pyrrolecarboxylate (0.001 mole) dissolved in 10 ml of carbon disulphide were refluxed for 4 hours in the presence of anhydrous aluminum chloride (0.0024 mole). A continuous stream of dry hydrogen chloride was passed through the reaction mixture. The reaction mixture was worked up in the usual manner and the product analyzed by gas chromatography. No elimination or disproportionation of isopropyl groups was observed.

Rearrangement of Methyl 4-Isopropyl-2-pyrrolecarboxylate

Methyl 4-isopropyl-2-pyrrolecarboxylate (0.001 mole) and aluminum chloride (0.0024 mole) in 10 ml of carbon disulphide were refluxed (50°) for 2 hours in the presence of a continuous stream of dry hydrogen chloride. The reaction mixture was worked up in the usual manner and the products analyzed by gas chromatography:

Product	Mole %
Methyl 4-isopropyl-2-pyrrolecarboxylate	35.2
Methyl 5-isopropyl-2-pyrrolecarboxylate	50.8
Methyl 2-pyrrolecarboxylate	6.9
Methyl 4,5-diisopropyl-2-pyrrolecarboxylate	7.0

Isopropylation of Methyl 5-Isopropyl-2-pyrrolecarboxylate

Methyl 5-isopropyl-2-pyrrolecarboxylate was isopropylated using the general procedure. After a reaction time of 15 minutes at 50° it was found that 35% of the starting material had been diisopropylated giving methyl 4,5-diisopropyl-2-pyrrolecarboxylate.

Isopropylation of Methyl 4-Isopropyl-2-pyrrolecarboxylate

Methyl 4-isopropyl-2-pyrrolecarboxylate was isopropylated using the general procedure. After a reaction time of 1 hour it was found that 15% dialkylation had occurred.

Preparation of acids

The corresponding acids of the alkylation products were prepared by refluxing the esters in 20% aqueous potassium hydroxide solution for 1 to 4 hours. The unreacted ester was extracted in ether and the aqueous layer acidified with dilute hydrochloric acid. The acid derivative was extracted in ether, dried, and

REACTIONS OF ORGANOTIN COMPOUNDS

III. ADDITIONS OF DIMETHYLTIN DIHYDRIDE TO SIMPLE OLEFINS[1]

H. C. CLARK AND J. T. KWON

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received January 27, 1964

ABSTRACT

The addition reactions of dimethyltin dihydride with ethylene, butadiene, and *cis*- and *trans*-butene are described. With ethylene and butadiene, the products $(CH_3)_2SnH(R)$ and $(CH_3)_2SnR_2$ are fully characterized, where R = C_2H_5, or $—CH_2CH=CHCH_3$, the latter being the first butenyltin compounds to be reported. The butenes were virtually unreactive towards the dihydride. From a consideration of these and previous results, the possible reaction mechanism is discussed, and the tentative conclusion is reached that the rate-determining factor involves the formation of radicals from the tin dihydride.

INTRODUCTION

In a previous paper (1) we showed that, contrary to earlier reports (2), simple olefins do add to organotin dihydrides, the systems examined involving the addition of some fluoro-olefins to dimethyltin dihydride. Not only was addition shown to occur, but the stepwise character of the addition was also established, so that for the reaction of tetrafluoroethylene to dimethyltin dihydride, both dimethyl(tetrafluoroethyl)tin hydride, $(CH_3)_2SnH(C_2F_4H)$, and dimethylbis(tetrafluoroethyl)tin, $(CH_3)_2Sn(C_2F_4H)_2$, were isolated. It seemed probable that similar addition products should also be formed from hydrocarbon olefins and, moreover, it now seemed worthwhile to re-examine the reaction of butadiene with a dihydride, despite the earlier report (2) that butadiene and hexadiene do not react with aliphatic organotin dihydrides. The extension to other olefins also allows some general statements to be made concerning the mechanism of these additions.

DISCUSSION

That olefins behave towards an organotin dihydride in much the same way as fluoro-olefins is shown by comparing the reactions of tetrafluoroethylene (1) and ethylene. Ethylene apparently reacts somewhat more slowly than tetrafluoroethylene, since the former did not react with dimethyltin dihydride at 50° in the dark during periods up to 180 hours, while tetrafluoroethylene and dimethyltin dihydride undergo 63% reaction at 25° in the dark after 160 hours (1). However, in both cases, the reaction is accelerated by ultraviolet irradiation, so that with ethylene in a 1:1 molar ratio with the dihydride, dimethylethyltin hydride, $(CH_3)_2SnH(C_2H_5)$, and dimethyldiethyltin $(CH_3)_2Sn(C_2H_5)_2$ were obtained in 37% and 31% yields respectively after 24 hours of irradiation at 25°. (In this discussion, experimental yields, calculated on the basis of the tin dihydride, have been rounded to two significant figures.) With a 2:1 molar ratio of ethylene to dimethyltin dihydride, a 69% yield of dimethyldiethyltin was obtained, with only a trace of dimethylethyltin hydride. The most notable difference from the reaction with tetrafluoroethylene is in the much lower stability of $(CH_3)_2SnH(C_2H_5)$ as compared with $(CH_3)_2SnH(C_2F_4H)$. The latter is apparently stable indefinitely at 25° *in vacuo*, but dimethylethyltin hydride decomposes under these conditions at a rate sufficiently rapid to make the determination

[1]*Presented in part at the Symposium on Current Trends in Organometallic Chemistry, Cincinnati, June 12–15, 1963.*

of accurate physical properties difficult. The products of decomposition were dimethyltin dihydride and dimethyldiethyltin, so that apparently a simple disproportionation occurs, similar to that proposed (1) for the decomposition of $(CH_3)_2SnH(C_2F_4H)$ at 160°. There is, however, no obvious reason for this difference in stability between $(CH_3)_2SnH(C_2H_5)$ and $(CH_3)_2SnH(C_2F_4H)$.

Since ethylene reacted readily with the tin dihydride, the reaction of butadiene with dimethyltin dihydride was examined, this being of further interest since a five-membered heterocyclic ring might be formed according to the reaction

$$(CH_3)_2SnH_2 + CH_2{=}CH{-}CH{=}CH_2 \rightarrow (CH_3)_2Sn\begin{array}{l}\diagup CH_2{-}CH_2\\ \diagdown CH_2{-}CH_2\end{array} \quad [1]$$

Reaction occurs more readily than with ethylene, since from 1:1 molar ratio mixture of dimethyltin dihydride and butadiene after 163 hours at 50° in the dark, only 34% of the reactants was recovered. Some decomposition products of the dihydride, notably hydrogen and an involatile white solid, were formed but the main product (34%) was dimethyl(2-butenyl)tin hydride, $(CH_3)_2SnH(CH_2CH{=}CHCH_3)$. This, like the corresponding product with ethylene, decomposed slowly at 25°, but characterization was possible by means of its proton magnetic resonance and infrared spectra, as well as by its conversion by mild chlorination to dimethyl(2-butenyl)tin chloride.

$$(CH_3)_2SnH(CH_2{-}CH{=}CH{-}CH_3) + CCl_4 \rightarrow (CH_3)_2SnCl(CH_2CH{=}CHCH_3) + CHCl_3 \quad [2]$$

The other product of the original reaction, formed in 19% yield, was dimethylbis(2-butenyl)tin, $(CH_3)_2Sn(CH_2CH{=}CHCH_3)_2$; this may form either by addition of butadiene to dimethyl(2-butenyl)tin hydride (equation [3]), or by disproportionation (equation [4]).

$$(CH_3)_2SnH(CH_2CH{=}CHCH_3) + C_4H_6 \rightarrow (CH_3)_2Sn(CH_2CH{=}CHCH_3)_2 \quad [3]$$

$$2(CH_3)_2SnH(CH_2CH{=}CHCH_3) \rightarrow (CH_3)_2SnH_2 + (CH_3)_2Sn(CH_2CH{=}CHCH_3)_2 \quad [4]$$

The reaction represented by equation [4] probably accounts for the spontaneous decomposition of $(CH_3)_2SnH(CH_2CH{=}CHCH_3)$. Ultraviolet radiation alone was not particularly effective in this addition of butadiene, since 92% of the reactants were recovered from a mixture of dimethyltin dihydride and butadiene after irradiation at 25° for 20 hours, although after 112 hours under these conditions, dimethyl(2-butenyl)tin hydride and dimethylbis(2-butenyl)tin were formed in 37% and 30% yields respectively. Reaction at 50° under ultraviolet irradiation for 20 hours, using a 1:1 molar ratio, leads to the consumption of 82% of the reactants and the formation of $(CH_3)_2SnH(CH_2CH{=}CHCH_3)$ and $(CH_3)_2Sn(CH_2CH{=}CHCH_3)_2$ in 6% and 32% yields respectively. Clearly under these conditions, the reaction proceeds so as to give extensive addition across both Sn—H bonds. Similarly, when a mixture of dimethyltin dihydride and butadiene in 1:2 molar ratio was irradiated at 50° for 23 hours, the corresponding yields of $(CH_3)_2SnH(CH_2CH{=}CHCH_3)$ and $(CH_3)_2Sn(CH_2CH{=}CHCH_3)_2$ were 6% and 71% respectively.

These are the first butenyl organotin compounds to be reported, and they are formed by a simple 1:4 addition to the conjugated system of butadiene. The configuration about the C=C bond is of interest, since *cis* and *trans* isomers are possible. The infrared spectra of $(CH_3)_2SnH(CH_2{-}CH{=}CHCH_3)$ and $(CH_3)_2Sn(CH_2CH{=}CHCH_3)_2$ show absorption at 1640 and 1639 cm^{-1} which can be assigned to the C=C stretching vibration, in comparison with the average values (3) of 1673 and 1657 cm^{-1} for $CHR_1{=}CHR_2$ (*trans*) and $CHR_1{=}CHR_2$ (*cis*). The C—H stretching vibrations of —CH=CH— are observed,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

as expected, at 3020 cm^{-1} in both compounds. The out-of-plane =CH deformation vibration is particularly significant, since only *trans* isomers give medium to strong bands at 990–965 cm^{-1}. For $(CH_3)_2SnH(CH_2CH{=}CCH_3)$ and $(CH_3)_2Sn(CH_2CH{=}CHCH_3)$, medium to strong bands are observed at 993 and 961 cm^{-1} and 991 and 960 cm^{-1} respectively. Although the correlation is much less certain, *cis* disubstituted ethylenes appear to show (3) the out-of-plane =CH deformation vibrations in the 675–728 cm^{-1} region. For the compounds being considered, a medium to strong band is observed in each case at approximately 725 cm^{-1}. The infrared evidence is therefore ambiguous, although the correlation of out-of-plane =CH deformation vibrations for *trans* isomers with absorption in the 990–965 cm^{-1} region has been found so reliable, that $(CH_3)_2SnH(CH_2CH{=}CHCH_3)$ and $(CH_3)_2Sn(CH_2CH{=}CHCH_3)_2$ may tentatively be assigned *trans* configurations. The nuclear magnetic resonance spectra are too complex, and hence at present do not allow any distinction between the isomers to be made.

As a final extension, the reactions of dimethyltin dihydride with *cis*- and *trans*-2-butene were examined. Mixtures were heated to 50°, or irradiated with ultraviolet light at 25°, but in all cases, the reactants were recovered virtually quantitatively. That the double bond in the 2,3 position should be inactive towards the tin hydride is consistent with all previous reports (2), which clearly indicate that addition occurs only with terminal olefinic bonds. Moreover, the lack of reactivity of the 2-butenes is also consistent with the observation that the C=C bond of $(CH_3)_2SnH(CH_2CH{=}CHCH_3)$ or $(CH_3)_2Sn(CH_2CH{=}CHCH_3)_2$ is apparently unreactive towards further addition with tin hydride.

It is clear that our earlier (1, 4) reports and this present work describe a general characteristic of organotin dihydrides, namely their ability to add under very mild conditions across terminal C=C bonds in a stepwise fashion. An examination of all these results leads to some general conclusions regarding the mechanism of these additions. The original workers (2) proposed an ionic mechanism, but more recently a radical mechanism has been suggested (5, 6), since it has been found that the addition can be catalyzed by radical sources which decompose at low temperatures, e.g. benzyl hyponitrite. Other workers (7) have investigated the addition of piperylene to trimethyltin hydride, and have suggested that the rate-determining step is the formation of radicals from the olefins. From our own results, the following statements can be made.

1. The addition of simple olefins to organotin dihydrides requires no solvent or catalyst, and in some cases (e.g. $(CH_3)_2SnH_2 + C_2F_4$) occurs at a reasonable rate in the dark at 25°. The addition to a dihydride is stepwise, and the rates of formation of $R_2Sn(R'H)H$ and $R_2Sn(R'H)_2$ seem to be comparable.

2. Ultraviolet irradiation always accelerates the reaction considerably. As the present results show, ethylene and dimethyltin dihydride in 1:1, 8:1, or 10:1 molar ratio were always recovered quantitatively after prolonged periods (up to 180 hours) at 50° in the dark. In a 1:1 molar ratio, after 23 hours at 25° under ultraviolet irradiation, the reaction was approximately 85–90% complete.

3. In the absence of ultraviolet irradiation, for cases where little or no reaction occurred, the percentage recovery of both olefin *and* dihydride was quantitative. However, in the presence of ultraviolet radiation, for cases where reaction was not complete (e.g. $(CH_3)_2SnH_2$ and ethylene), *only* olefin was recovered quantitatively, and involatile, tin-containing residues were formed. Moreover, we have previously shown (1) that ultraviolet irradiation greatly accelerates the decomposition of dimethyltin dihydride.

4. Under the same conditions of temperature and irradiation, an increase in the ratio olefin:tin dihydride from 1:1 to 14:1 has little effect on yields. Thus, for C_2F_4 with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$(CH_3)_2SnH_2$, in 4:1 and 14:1 molar ratio, the chief product was $(CH_3)_2Sn(C_2F_4H)_2$ in yields of 66% and 70% respectively. For C_2H_4 and $(CH_3)_2SnH_2$ in 2:1 and 8:1 molar ratio, the yields of $(CH_3)_2SnH(C_2H_5)$ and $(CH_3)_2Sn(C_2H_5)_2$ changed from 6 and 69% respectively, to 39 and 22% respectively. That is, the reaction proceeds more slowly when both the molar ratio and actual pressure of olefin are increased.

5. In no instance is there evidence for the formation of products containing $Sn[(C_2X_4)_nH]$ groups where $n > 1$.

All these factors argue convincingly against an ionic mechanism. It is less easy to distinguish between a process involving a four-center transition complex, and a free radical mechanism. However, contrary to previous suggestions (7), our evidence does indicate that the tin dihydride plays a major role and that the formation of radicals from the olefin is probably *not* the rate-determining step. The weight of evidence favors the formation of radicals from the tin dihydride as the determining factor, but detailed kinetic studies are necessary to provide conclusive evidence. It is assumed here that the same mechanism is involved in the addition of olefins to triorganotin monohydrides (5–7) as to diorganotin dihydrides. It must be conceded that there is no direct evidence showing that the same rate-determining step is involved. However, this may well be so since the rates of formation of $R_2Sn(R'H)H$ and $R_2Sn(R'H)_2$ from R_2SnH_2 seem comparable, although detailed kinetic studies are clearly necessary to justify this assumption and to provide conclusive evidence concerning the mechanism.

EXPERIMENTAL

The general experimental techniques have been described previously (1). Infrared spectra were recorded on model 137 sodium chloride and potassium bromide, and model 21 double beam Perkin–Elmer spectrophotometers, while n.m.r. spectra were obtained with Varian A60 and H.R. 60 spectrometers.

Reactions with Ethylene

(*a*) Dimethyltin dihydride (0.956 g, 6.30 mmole) and ethylene (0.384 g, 13.7 mmole) were allowed to react under ultraviolet irradiation for 24 hours at 25°. Vacuum fractionation gave a trace of hydrogen, unreacted ethylene (0.160 g, 5.0 mmole), fractions which condensed at −78° (0.031 g) and −46° (0.059 g, mol. wt. 150–179), and the major product which condensed at −23°. The latter (0.901 g, 69.0%) was dimethyldiethyltin (mol. wt. obs. 208, calc. 208; vapor pressure (25°) 14 mm; b.p. 132±3°, ΔH_v = 8.9 kcal mole^{-1}, lit. values (8) 131–132° and 144–146°. Calc. for $C_6H_{16}Sn$: C, 34.61; H, 7.69. Found: C, 34.64; H, 6.29%. The infrared spectrum of a liquid film showed the following absorption maxima: 2950 (sh), 2920 (s), 2880 (s), 1703 (vw), 1680 (vw), 1470 (m), 1460 (sh), 1428 (m), 1380 (m), 1234 (w), 1197 (m), 1190 (m), 1014 (m), 1000 (sh), 960 (w), 940 (m), 765 (sh), 744 (s), 700 (m), 668 (m), 556 (vw), 519 (s), and 509 (sh) cm^{-1}. The −78° fraction was shown spectroscopically to consist of unreacted dimethyltin dihydride and tetramethyltin. The −46° fraction decomposed at 25°, so that its molecular weight could only be determined approximately. Decomposition was rapid above 30° but the boiling point (extrapolated) was 95±2°, ΔH_v = 7.5 kcal mole^{-1}. The infrared spectrum showed bands at 2960 (s), 2910 (sh), 1837 (vs, Sn—H stretch), 1720 (vw), 1485 (sh), 1474 (w), 1432 (w), 1388 (w), 1205 (w), 1197 (w), 1014 (m), 947 (w), 800 (sh), 763 (s), 713 (m), 675 (sh), 550 (m), 517 (s), and 493 (sh) cm^{-1}. The proton magnetic resonance spectrum indicated one hydrogen attached to tin, this appearing as an unresolved multiplet with δ_{Sn-H} at −4.58 p.p.m. with respect to tetramethylsilane with Sn^{117} and Sn^{119} side bands at −13.60 and −14.20 p.p.m. (9). The ratio of intensities $Sn—H/\Sigma_i H_i$ was 1/10.6. The −46° fraction was therefore *dimethylethyltin hydride*, $(CH_3)_2SnH(C_2H_5)$.

(*b*) When dimethyltin dihydride (1.737 g, 11.5 mmole) and ethylene (0.322 g, 11.5 mmole) were allowed to react under conditions identical with those in (*a*), the products were hydrogen (5%), an involatile residue (0.30 g) containing metallic tin, unreacted ethylene (0.036 g), unreacted tin hidydride (0.136 g, mol. wt. obs. 150, calc. 150), a fraction (0.095 g) which condensed at −64°, dimethylethyltin hydride (0.757 g, 4.28 mmole, 37.1%) as an unstable fraction condensed at −46°, and dimethyldiethyltin (0.733 g, 3.54 mmole, 30.8%). The −64° fraction was shown spectroscopically to be largely $(CH_3)_4Sn$.

(*c*) Dimethyltin dihydride (1.605 g, 10.6 mmole) and ethylene (0.298 g, 10.6 mmole) were heated to 50° in the dark for 180 hours. The reaction mixture separated cleanly into fractions condensing at −125° (1.549 g, mol. wt. obs. 155, calc. for $(CH_3)_2SnH_2$, 150) and at −196° (0.291 g, mol. wt. obs. 28.7, calc. for C_2H_4, 28.0). There were no less volatile fractions and no residue, the total recovery of dihydride and ethylene being 97.3%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(*d*) A mixture of the dihydride (0.225 g, 1.49 mmole) and ethylene (0.422 g, 14.9 mmole) was heated at 50° in the dark for 92 hours. Both reactants were recovered quantitatively.

(*e*) Dimethyltin dihydride (0.572 g, 3.79 mmole) and ethylene (0.847 g, 30.3 mmole) were irradiated with ultraviolet light at 25° for 26 hours. The volatile fraction condensed at −23° (0.170 g) was dimethyldiethyltin (mol. wt. obs. 205, calc. 206, 22% yield), and the −46° fraction was dimethylethyltin hydride (0.265 g, 39%, mol. wt. obs. 150, calc. 178), both also identified spectroscopically. Unreacted dihydride (0.127 g, 22%) and ethylene (0.740 g, 87.2%) were also recovered.

Reactions with 1,3-Butadiene

(*a*) Dimethyltin dihydride (2.158 g, 14.3 mmole) and butadiene (0.774 g, 14.3 mmole) were irradiated with ultraviolet light at 25° for 20 hours. The reaction mixture contained no hydrogen, and all products were volatile. The volatile mixture was separated into fractions condensing at −23° (0.227 g, 7.8%, mol. wt. 210), and at −125° (2.692 g, mol. wt. approx. 110). The former fraction was characterized more fully in the later experiments, and the −125° fraction was shown spectroscopically to contain only dihydride and butadiene which could not be separated by fractional condensation. Hence 92% of the unchanged reactants were recovered.

(*b*) A mixture of dimethyltin dihydride (1.995 g, 13.2 mmole) and butadiene (0.697 g, 13.2 mmole) was kept at 50° under ultraviolet irradiation for 20 hours. The products were hydrogen (0.4 mmole), fractions which condensed at −23° (0.154 g, mol. wt. 247, vapor pressure (25°) 5 mm, 5.7%) and −125° (0.496 g) and a mixture of an involatile liquid with metallic tin, and other involatile solids. From this mixture, the involatile liquid (1.20 g, 32.4%) was separated by extraction. The −125° fraction was again an inseparable mixture of unchanged reactants. The −23° fraction decomposed slowly at 30° making characterization difficult, but careful refractionation in this and other experiments gave the same product, mol. wt. 203–210, b.p. (extrap.) approx. 200°, identified as *dimethyl(2-butenyl)tin hydride*, $(CH_3)_2SnH(CH_2CH{=}CHCH_3)$. Its infrared spectrum showed absorption bands at 3020 (sh), 2960 (sh), 2910 (m), 2860 (sh), 1823 (s), (Sn—H stretch), 1655 (sh) and 1640 (w) (C=C stretch), 1455 (w), 1444 (w), 1417 (w), 1398 (w), 1379 (vw), 1363 (w), 1302 (vw), 1254 (vw), 1192 (w), 1159 (w), 1095 (w), 1068 (w), 1037 (w), 993 (m), 961 (m), 906 (w), 762 (s) (CH_3—Sn rocking), 748 (sh), 727 (m), 570 (m), 513 (s), and 464 (w) cm^{-1}. The n.m.r. spectrum consisted of a pair of doublets at −5.36, −5.28, −5.26, and −5.19 p.p.m. assigned to —CH=CH—, an unresolved multiplet at −4.80 p.p.m. assigned to Sn—H (3), maxima at approximately −1.6 p.p.m. due to $—CH_2$ and $C—CH_3$, and a peak at −0.04 p.p.m. due to CH_3—Sn, all with respect to tetramethylsilane as internal standard. The intensities of these peaks, taken in the above order, was 1.8:1.2:5.0:6.0, compared with 2:1:5:6 for $(CH_3)_2SnH(CH_2CH{=}CHCH_3)$. Chlorination of this compound with carbon tetrachloride led to the formation of chloroform in the expected amount, and an increase in weight as expected for the formation of *dimethyl(2-butenyl)tin chloride*, $(CH_3)_2SnCl(CH_2CH{=}CHCH_3)$. The infrared spectrum of this product did *not* show absorption in the 1800–1850 cm^{-1} region, so that Sn—H groups were absent, and its n.m.r. spectrum was similar to that of the parent compound, with the exception that no multiplet at approx. −4.8 p.p.m. was observed.

The involatile liquid was shown to be *dimethylbis(2-butenyl)tin*, $(CH_3)_2Sn(CH_2CH{=}CHCH_3)_2$. Calc. for $C_{10}H_{20}Sn$: C, 46.37; H, 7.79. Obs.: C, 46.71; H, 7.70%. The infrared spectrum showed absorption at 3020 (s), 2955 (sh), 2910 (s), 2860 (sh), 1820 (vw), 1740 (vw), 1708 (vw), 1690 (vw), 1675 (vw), 1655 (w), 1639 (m), 1454 (m), 1442 (m), 1417 (m), 1397 (m), 1379 (m), 1362 (m), 1302 (w), 1254 (w), 1191 (m), 1156 (m), 1092 (m), 1066 (m), 1034 (m), 991 (s), 960 (s), 905 (sh), 902 (m), 788 (sh), 764 (s), 750 (sh), 720 (s), 550 (sh), 526 (s), 510 (m), and 480 (w) cm^{-1}. The n.m.r. spectrum showed a complex triplet at −5.36, −5.27, and −5.18 p.p.m., due to —CH=CH—, a series of peaks in the −0.5 to −2.00 p.p.m. region due to $—CH_2$ and $C—CH_3$ protons, and a large singlet at −0.0 p.p.m. due to CH_3—Sn, all with respect to tetramethylsilane. The areas of these peaks in the above order were in the ratio 2.2:1.7:3.2:5.5, compared with the expected ratio of intensities of 2:2:3:6 for $(CH_3)_2Sn(CH_2CH{=}CHCH_3)_2$.

(*c*) Dimethyltin dihydride (1.982 g, 13.1 mmole) and butadiene (0.707 g, 13.1 mmole) were exposed to ultraviolet radiation for 112 hours at 25°. The reaction mixture was separated into unreacted dihydride and butadiene (0.481 g), dimethyl(2-butenyl)tin hydride (0.994 g, mol. wt. obs. 203, 37%), involatile dimethylbis(2-butenyl)tin (1.005 g, 29.5%), and an involatile white solid (0.20 g).

(*d*) A mixture of dimethyltin dihydride (2.060 g, 13.6 mmole) and butadiene (1.470 g, 27.2 mmole) was irradiated for 23 hours at 50° C. The products were hydrogen (2.5 mmole, 19.0%), unreacted butadiene (0.241 g, 4.30 mmole, mol. wt. obs. 56.2, calc. 54), dimethyl(2-butenyl)tin hydride (0.152 g, 0.75 mmole, 5.5%), dimethylbis(2-butenyl)tin (2.562 g, 9.70 mmole, 70.6%), and a residue (0.50 g) composed largely of metallic tin.

(*e*) Dimethyltin dihydride (2.000 g, 13.2 mmole) and butadiene (0.718 g, 13.2 mmole) were heated at 50° in the dark for 163 hours. The products were identified as hydrogen (2.7 mmole), a mixture of unreacted dihydride and butadiene (0.926 g, 33.8%), dimethyl(2-butenyl)tin hydride (0.924 g, 4.50 mmole, 34.1%, mol. wt. obs. 201), dimethylbis(2-butenyl)tin (0.663 g, 2.56 mmole, 19.4%), and an involatile solid (0.205 g).

Reactions with cis-2-Butene

Four experiments were performed in which dimethyltin dihydride and *cis*-2-butene were allowed to react in either a 1:1 or 1:2 molar ratio under two sets of conditions: (*a*) at 50° in the dark for 23 hours, and (*b*)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

at 25° under ultraviolet irradiation for 22 hours. In all cases, the reactants were recovered virtually quantitatively (96% or higher recovery) as a mixture which condensed at −125°. The infrared spectrum of these mixtures showed only the dihydride and *cis*-2-butene to be present. Also, in each experiment, very small fractions (2–10 mg) were condensed at −23°, and −46°, the quantities being too small to allow characterization.

Reactions with trans-2-Butene

Three experiments were carried out using dimethyltin dihydride and *trans*-2-butene under the following conditions: (*a*) dihydride and the butene in a 1:2 molar ratio at 50° in the dark for 68 hours, (*b*) dihydride and the butene in a 1:1 molar ratio at 50° in the dark for 69 hours, and (*c*) dihydride and the butene in a 1:2 molar ratio at 50° in the dark for 70 hours, followed by exposure to ultraviolet radiation at 25° for 23 hours. In each experiment, virtually all of the volatile products was condensed at −125° and was shown spectroscopically and from molecular weight measurements to be just unreacted dihydride and the original olefin. The total recovery was 96.5% or higher. However, in each case, there were also small fractions separated at −23° and −46°, but in amounts (1–5 mg) too small to allow positive identification.

Reactions with Excess Tetrafluoroethylene

(*a*) Dimethyltin dihydride (0.47 g, 3.16 mmole) and tetrafluoroethylene (1.23 g, 12.3 mmole) were sealed in a Pyrex carius tube (100-ml capacity) to give an initial pressure of approximately 5 atmospheres. After being heated at 50° in the dark for 24 hours, the products were hydrogen (0.2 mmole), unreacted C_2F_4 (0.744g, 7.44 mmole), unreacted dihydride (0.053 g, 0.35 mmole), dimethyltetrafluoroethyltin hydride (0.021 g, 3% yield), dimethylbis(tetrafluoroethyl)tin (0.762 g, 65.5% yield), and involatile, yellow residue (0.17 g) which was apparently polymerized C_2F_4. The characterization of $(CH_3)_2SnH(C_2F_4H)$ and $(CH_3)_2Sn(C_2F_4H)_2$ followed previous work (1).

(*b*) Tetrafluoroethylene (2.47 g, 24.7 mmole) and dimethyltin dihydride (0.284 g, 1.87 mmole), giving an initial pressure of approximately 10 atmospheres, were heated at 50° in the dark for 22 hours; unreacted olefin (2.09 g, 84.5%) and unreacted dihydride (0.083 g, 29%) were recovered. Reaction products were dimethyltetrafluoroethyltin hydride (0.027 g, 5.4% yield), dimethylbis(tetrafluoroethyl)tin (0.457 g, 69.6% yield), a trace of hydrogen, and an involatile residue (0.13 g).

(*c*) After an exposure of 21 hours at 25° to ultraviolet irradiation, dimethyltin dihydride (0.270 g, 1.79 mmole) and tetrafluoroethylene (2.38 g, 23.8 mmole), at an approximately 8 atmosphere initial pressure, gave unreacted C_2F_4 (1.86 g, 78.0%), unreacted dihydride (0.061 g, 23%), dimethylbis(tetrafluoroethyl)tin (0.471 g, mol. wt. obs. 350, calc. 351, 75.0% yield), and involatile white residue (0.26 g).

REACTION MECHANISM STUDIES

2. REDUCTIVE ELIMINATION OF 1,2-DIHALIDES WITH LITHIUM ALUMINUM HYDRIDE

J. F. KING AND R. G. PEWS
Department of Chemistry, University of Western Ontario, London, Ontario

Received February 5, 1964

ABSTRACT

1,2-Dibromides and bromohydrin *p*-toluenesulphonates of favorable geometry are readily reduced by lithium aluminum hydride in good yield to the corresponding olefin. Small quantities of water are found to have a *temporary accelerating effect* on the reduction. The normal course of the reaction is a trans elimination, but when steric factors inhibit this, then substitution or *cis* elimination reactions may occur. It is shown that the *cis* elimination in the case of *cis*-1,2-dibromocyclohexane cannot involve reduction to the monobromide followed by dehydrobromination to the olefin. The reaction of some other 1,2-dihalides and related compounds with lithium aluminum hydride, and the reaction of a 1,2-dibromide with a number of other complex hydrides are reported.

A general scheme for the mechanism of the olefin-forming elimination reaction is proposed. The limits that this study places on the possible positions of the reductive elimination of 1,2-dibromides with lithium aluminum hydride within this general scheme are discussed.

The elimination reaction leading to the formation of an olefin may be expressed generally by the equation  . The conventional description of a reaction as either an oxidation–reduction or metathesis can be usefully applied to classify eliminations as oxidative (e.g. dehydrogenation, in which X, Y = H), reductive (e.g. X, Y = halogen) or metathetical (e.g. X = H, Y = halogen); correspondingly the formal reverse of each of these reactions would be reductive addition (e.g. hydrogenation), oxidative addition (e.g. addition of halogen), and metathetical addition (e.g. addition of hydrogen halide), respectively. Much study has been devoted toward an understanding of the metathetical addition and elimination reactions, but much less work has been carried out on the oxidative and reductive processes. Though some of the most commonly used examples of the latter group are heterogeneous phase reactions whose study is complicated by special problems, a substantial number of oxidative and reductive additions and eliminations take place in solution. Table I lists a number of conditions under which reductive elimination of dibromides has been reported to occur; the great majority of these, in fact, involve a homogeneous system.

Most of the work on the mechanism of homogeneous phase reductive eliminations that had been reported at the beginning of this study had been restricted to the reduction of 1,2-dibromides (and some related species) with alkali iodides.* But the number and variety of other reagents which could effect reductive elimination of 1,2-dibromides (see Table I) suggested the possibility that the mechanism of reaction of some of these reagents might be quite different from that of an alkali iodide. If this were the case it would not be possible to discover all the ramifications of the mechanism of the general reductive elimination reaction were the study to be restricted to the reduction induced by alkali iodides. Accordingly, we decided to investigate the reductive elimination with lithium

**While this work was in progress, an investigation of the reduction of similar compounds with mercaptides was reported (24).*

*An important preparative reaction with numerous variations of conditions; the example quoted is one of the earlier illustrations of its use.

aluminum hydride. From what little was known of this reaction at the beginning of this study, it appeared that this reagent effects reductive elimination of 1,2-dibromides in high yield, but it is otherwise different from alkali iodides in its reactions with organic compounds. Though lithium aluminum hydride is a much-used reagent in organic synthesis, there are serious technical and theoretical problems associated with a study of its mechanism of action. To a considerable extent these have limited the present study. At the same time it is hoped that this work has contributed toward their eventual solution.

Scope of the Reductive Elimination with Complex Metal Hydrides

Previous reports of reduction of 1,2-dihalides with lithium aluminum hydride are listed in Table II. In most of these examples reductive elimination is the only observed course of reaction, though substitution predominates with the following substrates: 1,2-dibromoöctane, ethyl β-chloroethyl ether, and *trans*-1,4-dibromo-2-butene. These anomalies are given further comment in the discussion of the mechanism of the reaction.

Table III summarizes the results of a number of experiments designed to show the range of compounds reducible with lithium aluminum hydride. The rest of this paragraph offers some general conclusions that may be drawn from these data. All of the 1,2-dibromides

*Reaction mixture also contained a small amount of sodium iodide.

listed in Table III gave the corresponding olefin, though in the case of *cis*-1,2-dibromocyclohexane the yield was low. Reductive elimination with formation of *trans*-stilbene took place fairly smoothly with all compounds derived from it including the meso dichloride. The two *trans*-2,3-dichlorocholestanes (I*d* and II*c*), however, both gave a remarkable mixture of products which included only small amounts of the reductive elimination product. It seems likely that the dichlorocholestanes are more representative of 1,2-dichlorides than *meso*-stilbene dichloride; in general, then, formation of the olefin from 1,2-dichlorides probably does not predominate over other possible reactions. A similar result was found with 2-fluorobromides; *trans*-stilbene was formed in good yield from the corresponding fluorobromide, but fluorocyclohexane was the only product obtained from *trans*-1-fluoro-2-bromocyclohexane. As expected, the two diaxial bromohydrin *p*-toluenesulphonates (I*b*) and (I*c*) both gave the corresponding olefin in high yield. Surprisingly, however, the diequatorial isomer II*b* yielded much the same complex mixture of products as that obtained from the dichlorocholestanes, whereas the *cis* isomer IV gave a fairly good yield of the olefin.

The quantity of lithium aluminum hydride consumed by the reduction of 1 mole of *meso*-stilbene dibromide and cholesterol dibromide (V) was estimated by iodometric titration of the unreacted hydride (31) to be 0.47 and 0.42 moles, respectively (see Experimental); this corresponds reasonably well with the equation

Gas (presumably hydrogen) is evolved in the reaction. The fate of the lithium, aluminum, and bromine atoms after the reduction has not been investigated, though a recent report on the reaction of lithium aluminum hydride with bromine suggests that the inorganic products may be LiBr and $LiAl_2Br_7$ (32).

The reaction of 2β,3α-dibromocholestane (I*a*) with a number of other complex hydrides was briefly investigated. Unreacted starting material was the principal constituent of the product obtained from the following conditions: (*a*) sodium borohydride in methanol at

room temperature, (*b*) commercial sodium "trimethoxyborohydride" in diglyme (diethylene glycol dimethyl ether) at room temperature, (*c*) lithium borohydride in ether or tetrahydrofuran under reflux, (*d*) lithium tri-*t*-butoxyaluminohydride in refluxing tetrahydrofuran, (*e*) diborane in diglyme at room temperature. With sodium borohydride in triglyme at 135°, sodium borohydride and aluminum chloride in diglyme at 100°, or lithium tri-*t*-butoxyaluminohydride in triglyme (triethylene glycol dimethyl ether) at 135°, neither starting material nor cholest-2-ene were isolated. Sodium "trimethoxyborohydride" in diglyme at 135° gave cholest-2-ene in 88% yield. Further work on some of these reactions will be described in a subsequent publication. Relevant to these observations is the recent report (17) that tri-*n*-butyltin hydride reduced certain 1,2-dibromides to the corresponding olefin (see Table I).

Rates of Reduction of Dibromides and Bromohydrin p-Toluenesulphonates

To gain further insight into the factors influencing the reductive elimination with lithium aluminum hydride, a study of the approximate rates of reduction of a number of dibromides and bromohydrin *p*-toluenesulphonates (tosylates) was initiated. The reaction was carried out in dry tetrahydrofuran at 0° in an atmosphere of oxygen-free, dry nitrogen under conditions designed to exclude water. Under these conditions the lithium aluminum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

hydride solution, though slightly turbid, was found to maintain the same reducing power (as measured by titration with iodine) over a period of at least 3 months. The rate of the reductive elimination was followed by stopping the reaction with excess water and titrating the bromide ion formed in the reaction. It was found, however, that only the most approximate comparisons of relative rates could be made under these conditions. Individual runs for a certain reaction time using the same lithium aluminum hydride stock solution and the same specimen of the substrate were reasonably reproducible, but the same experiment with similar materials of different origin often gave results incompatible with those obtained previously. In addition, the extent of reaction for different reaction times, even when carried out on the same day with the same materials, did not correspond to any simple rate expression. (These results are discussed in greater detail elsewhere (33).)

Previous investigators (34, 35) had reported that water exhibits a catalytic effect in the lithium aluminum hydride reduction of certain organic halides. It seemed not unreasonable that some of the difficulties described above might be due to traces of water being added with the organic substrate. To test this possibility, a small amount of water was added to the reaction mixture along with the substrate. A notable acceleration was observed, see Table IV, and also Table V experiments No. 1 vs. 9, and 5 vs. 7. However, when the same

TABLE IV

Effect of varying the amount of water added with the substrate in the reduction of *meso*-stilbene dibromide

Time (minutes)	Substrate (mmoles)	Water (mmoles)	$LiAlH_4$ solution* (conc.)	% Reaction of individual experiments	Average % reaction

*In tetrahydrofuran, 60 ml.

amount of water was added to the lithium aluminum hydride solution and the mixture allowed to stand for 15 minutes *before* adding the dibromide, then the rate of reduction was accelerated only slightly (if at all) over the case in which no water was added: compare experiment 12 (Table V) with 1 and 9, or 8 with 7 and 5. Addition of water, therefore, has a *temporary accelerating effect.* The reproducibility of the above results was checked in two ways: (i) A portion of the first lithium aluminum hydride stock solution (A) was stored under nitrogen for 3 months at room temperature; this solution (B) gave essentially the same results as had been obtained earlier. (ii) A new stock solution (C) was prepared from a fresh lot of lithium aluminum hydride and also gave similar results (see Table V).

It was apparent at this stage that the temporary accelerating effect of water introduces a complication into any attempt to compare the rates of reduction of different organic substrates. In the hope of obtaining a reaction mixture of constant reducing power, water was added gradually and continuously by passing a constant stream of wet nitrogen through the reaction mixture. The results obtained by this procedure using *meso*-2,3-dibromobutane as substrate are recorded in experiments 14–24 (Table V). A plot of log (100 − % reaction) vs. time indicates that under these conditions the reaction is approximately first order in dibromide, indicating that the constant addition of water to a large excess of lithium aluminum hydride produces a reagent of at least roughly constant

*6.3×10^{-3} *M* in tetrahydrofuran at 0°.

†Letters *A*, *B*, and *C* designate the stock solution of lithium aluminum hydride. Solution *B* was a portion of stock solution *A* that had been allowed to stand under nitrogen for 3 months. Solution *C* was prepared in the same way as *A* from a different lot of lithium aluminum hydride (from the same supplier).

reducing power in which the rate of reaction depends only on the concentration of the substrate. The detailed kinetics of the reduction are, without doubt, considerably more complicated, but the reproducibility of the above results with different stock solutions of lithium aluminum hydride gives confidence that the rates of reduction obtained by this technique would be at least semiquantitatively valid, and hence useful for comparing different organic substrates. It should be noted at this point that the amount of water added was not sufficient to destroy any more than about 10 to 25% of the lithium aluminum hydride, i.e. that the molar ratio of hydride to substrate changed at most from 20 to about 15.

In Table VI are summarized the results of the kinetic experiments which were carried out by passing wet nitrogen (saturated with water vapor at 0°) through solutions of lithium

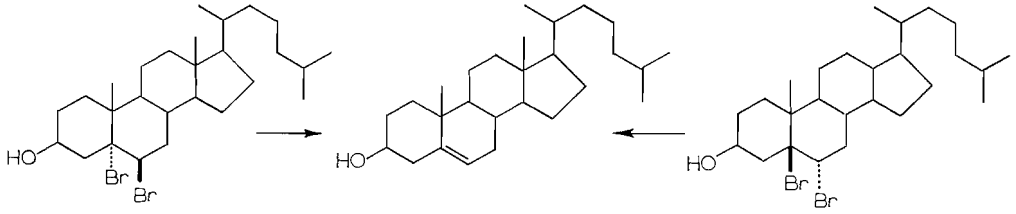
†After titration, the reaction mixture from one run was worked up in the same way that was used for that substrate to obtain the data in Table III. The numbers in the column give the percentage actually isolated of the quantity expected on the basis of the titration.

aluminum hydride and a variety of organic substrates in tetrahydrofuran. From these data it is readily apparent that those compounds reduce most readily in which the dihedral angle formed by the two carbons and the two leaving groups is 180°. In other words the preferred reaction is a trans elimination. Thus *meso*-stilbene dibromide reduces faster than *dl*-stilbene dibromide and the diaxial steroids reduce more readily than their diequatorial (or their cis) isomers. In most instances the rate differences were not very large, and with the 2,3-dibromobutanes there was no apparent rate difference at all. The products from the reduction of the 2,3-dibromobutanes, however, show that the reaction is strictly a trans elimination (see Table III). It is of interest that under the "anhydrous" conditions *meso*-2,3-dibromobutane apparently reduces slightly faster than the racemic isomer.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Under the "anhydrous" conditions also, 5α,6β-dibromocholestan-3β-ol (V), in which the bromine atoms are diaxial, apparently reduces more than 40 times faster than its di-equatorial isomer (VII).



V VI VII

For those compounds in which the dihedral angle of 180° is not readily formed, trans elimination may require extra activation energy, and other reactions, especially cis elimination and substitution, may compete. An example is the reduction of *dl*-stilbene dibromide, which at −10° in tetrahydrofuran gives 5% *cis*-stilbene (the trans elimination product) and 95% *trans*-stilbene (formally, at least, the product of a cis elimination). At higher temperatures a higher proportion of the cis isomer is formed. *cis*-Stilbene is gradually isomerized to *trans*-stilbene under the reaction conditions but the rate is too slow to account for the quantity of *trans*-stilbene produced in these reductions. In addition it was found that 1,2-diphenylethyl bromide yields no *trans*-stilbene under the conditions of the reaction; this clearly demonstrates that this reduction, unlike some cis reductions with sodium iodide (36), cannot be rationalized by a two-step process of initial substitution by one equivalent of the reducing agent followed by a trans elimination. The experiments do not exclude the possibility that under the reaction conditions the *dl*-stilbene dibromide rearranges to the *meso* isomer which is then rapidly reduced; the rearrangement of *dl*-stilbene dibromide above its melting point is well-known (37) but the likelihood of a rapid rearrangement at −10° seems small.

A second compound which undergoes cis elimination is *cis*-1,2-dibromocyclohexane which yields cyclohexane together with a larger amount of the monosubstitution product, bromocyclohexane. *cis*-1,2-Dibromocyclohexane is an apparently stable compound with no tendency to isomerize to the trans isomer; preliminary isomerization followed by trans elimination would seem very unlikely indeed. Again the possibility of substitution followed by metathetical elimination is excluded by the observation that bromocyclohexane yields no cyclohexene under the conditions of the reaction. In the sense that the reaction cannot be reasonably interpreted as involving a preliminary transformation followed by a trans elimination, the formation of cyclohexene from *cis*-1,2-dibromocyclohexane evidently must be regarded as a "true" cis elimination; further mention of this will be made in the discussion of the mechanism.

The reductive elimination of 2α-bromocholestan-3α-yl tosylate (IV), in which the bromine and tosyloxy groups are cis, would also appear to be a true cis elimination for the following reasons. Displacement of the bromine by hydride followed by dehydrohalogenation of the resultant tosylate (cholestan-3α-yl tosylate) is excluded because the latter compound does not give cholest-2-ene (III) under the reaction conditions. The alternative substitution–metathetical elimination pathway, which would require the intermediacy of 2α-bromocholestane, would seem extremely unlikely in view of the lack of olefin obtained from bromocyclohexane.

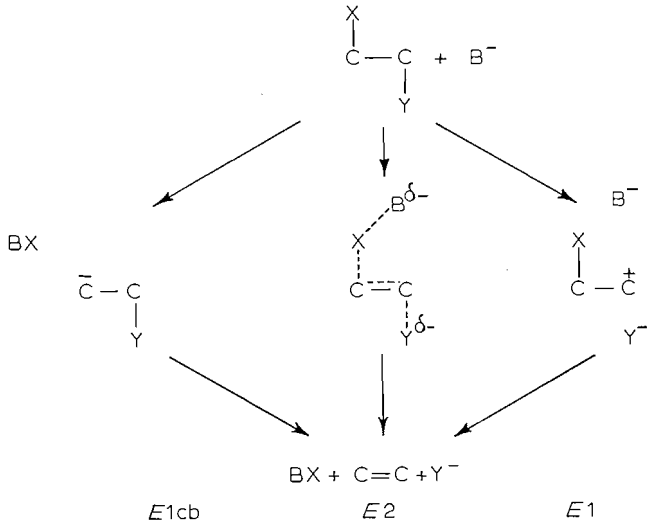
Referring again to Table VI, another point of interest is the fact that the two diaxial

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

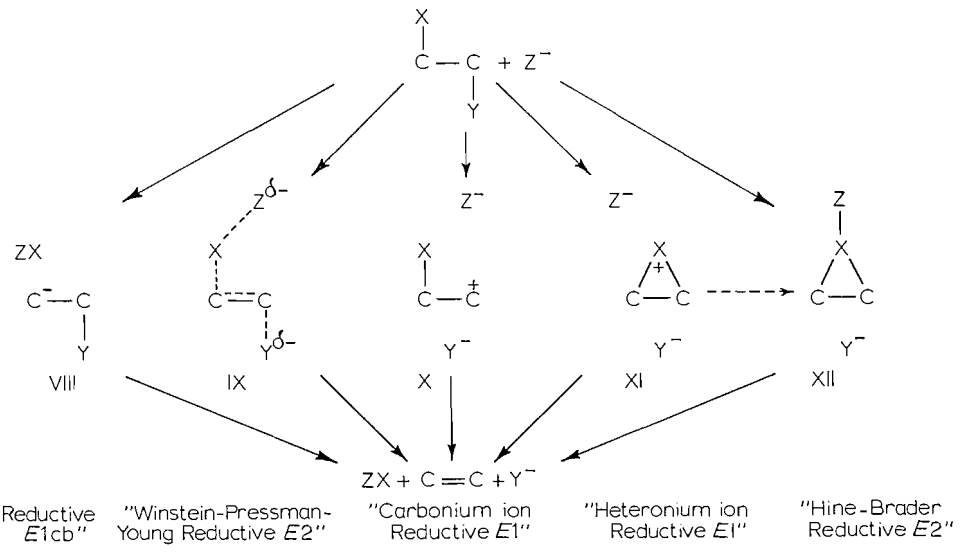
bromohydrin tosylates (I*b*) and (I*c*) reduce at about the same rate as the corresponding dibromide (I*a*). In this respect the reduction with lithium aluminum hydride differs from that with sodium iodide. With the latter reagent Cristol *et al.* (36) found that *trans*-2-bromocyclohexyl tosylate reduced about 20 times faster than *trans*-1,2-dibromocyclohexane.

Discussion of Mechanism

It would seem natural, in attempting to determine the mechanism of a reductive elimination reaction, to make use of the concepts which have been developed for the metathetical processes. Extension of the mechanisms of metathetical elimination to reductive



METATHETICAL ELIMINATION MECHANISMS



POSSIBLE REDUCTIVE ELIMINATION MECHANISMS

SCHEME 1

elimination is in some respects not trivial and some amplification is required at this point. In scheme 1 are set down the three mechanisms, which, together with mechanisms intermediate in character between these extremes, are currently regarded (38, 39) as describing all ionic metathetical eliminations which lead to the formation of olefins. Underneath are extensions which have been or may be made to apply to ionic reductive elimination. The arrangement in scheme 1 is such that between each mechanism and the one adjacent to it, one can easily visualize a continuous range of hybrid or "in between" processes. The five typical mechanisms shown, together with the hybrid mechanisms, constitute a continuous band or spectrum of reaction pathways. This scheme, though discussed here specifically with respect to reductive elimination, is probably general for all eliminations; the somewhat more restricted scheme for metathetical eliminations probably just reflects the inability of hydrogen to form species such as XI and XII, together with the fact that most of the work on metathetical eliminations has been carried out on compounds in which X = H.

At least three of the five reductive elimination mechanisms have been proposed previously. In 1939, Winstein, Pressman, and Young put forward (40) the mechanism involving species IX (scheme 1) to rationalize the observed kinetic and stereochemical data for the reduction of 1,2-dibromides with sodium iodide; since then it has been usual for most authors to discuss the mechanism of other reductive eliminations in terms of this process. Hine and Brader, however, put forward another reductive *E*2 mechanism (proceeding via species XII in scheme 1) for the reaction of dibromides with iodides (41); their chief point in favor of this mechanism is that it allows the halogenation and dehalogenation reactions to proceed via the same species (though, of course, in the reverse sequence). The "reductive *E*1cb" mechanism has been suggested (1) for the reduction of 1,2-dibromides with bivalent metals.* (The designation "reductive *E*1cb" is used in this discussion in order to show the parallel with the metathetical reaction; the literal significance of the term is lost, however, since the intermediate anion (VIII) is not the conjugate base of the starting material.)

To complete this mechanistic scheme it is apparently necessary to postulate mechanisms involving *both* the carbonium and "heteronium" ions, (X) and (XI) respectively, since depending on the nature of the substituent X and on the substitution of the carbon bearing Y, heterolysis of the starting material may lead to either of the extreme species and presumably also to a range of cations of intermediate character. It has recently been reported that an episulphonium salt is reduced to the corresponding olefin with sodium iodide (42). It is attractive to regard this reduction either as representing an example of the second stage of the "heteronium ion *E*1 reaction" (XI → olefin, directly), or alternatively as proceeding first to the Hine–Brader intermediate, as indicated by the dotted arrow, followed by olefin formation (i.e. XI → XII → olefin).

It should be emphasized that the possible reductive elimination mechanisms in scheme 1 are put forward in the hope of creating some order in the study of these transformations. Some of the mechanisms, though plausible, are nonetheless quite speculative. To our knowledge, in no case has *any* of the five mechanisms been established beyond question. It is in the context of this primitive state of the knowledge of these reactions that the following discussion of the lithium aluminum hydride reduction must be viewed.

Of the five mechanisms in scheme 1, two may be readily excluded for the reductive

**These authors do not draw a clear distinction between the "reductive E1cb" and the "Winstein–Pressman–Young reductive E2" mechanisms, but their discussion of the non-stereospecific reduction of the stilbene dibromides and related compounds is, in effect, in terms of the E1cb mechanism.*

elimination with lithium aluminum hydride. Neither the "reductive *E*1cb" mechanism nor the "carbonium ion reductive *E*1" mechanism satisfactorily accounts for the observed predominance of trans elimination and hence cannot be important routes for the reduction. The available data do not allow any definite conclusions to be drawn concerning the other three reductive elimination mechanisms. The "heteronium ion reductive *E*1" and, perhaps more particularly, the "Hine–Brader reductive *E*2" mechanisms might be expected to be strictly trans eliminations,* so that any scheme involving either of these would probably require the postulation of one of the other mechanisms to explain the cis eliminations. On the other hand it has recently been proposed (43, 44) that the metathetical *E*2, reaction takes place most readily when the leaving groups and the carbons to which they are directly attached form a dihedral angle of either 0° or 180°. If the geometrical requirements for the "Winstein–Pressman–Young *E*2" reaction are the same, then it by itself would account for all of the reductive eliminations described in this paper. The fact that the cis elimination is somewhat slower than the trans would be regarded simply as a reflection of the extra energy required for the compound undergoing cis elimination to achieve the totally eclipsed conformation (44). The ability of the "Winstein–Pressman–Young *E*2" mechanism to account for all of the observed elimination products is an attractive feature favoring this possibility, but it cannot be regarded as conclusive evidence.

There does not appear to have been any previous mention of the "heteronium ion reductive *E*1" mechanism,† and lest it be dismissed too lightly it is perhaps worth pointing out that such a mechanism fits readily into the pattern of the reactions of lithium aluminum hydride with organic halides generally. It was early recognized (25) that *substitution* at a saturated carbon with lithium aluminum hydride was a nucleophilic attack on carbon by a hydride ion or its complex equivalent. In addition it has been clearly shown that the displacement in simple secondary bromides and tosylates is predominantly a S_N2 reaction (45). Nonetheless there are a number of cases in which it seems likely that the reaction proceeds via a S_N1 mechanism. Corey and co-workers (46) have observed that the products formed in the reduction of cholesteryl tosylate are not compatible with a S_N2 process but are readily accounted for by assuming that the homoallylic carbonium ion is an intermediate. Other phenomena more readily explained by a S_N1 rather than a S_N2 mechanism are: (i) the high reactivity of triphenylmethyl chloride (25), (ii) the formation of rearranged products from 2-phenyl-3-pentyl tosylate (47), 7-chloronorbornadiene (35, 48), and 1-bromo-7-norbornanone (49) as well as cholesteryl tosylate (46, 50). In addition it may be noted that the tropylium ion is reduced to tropilidene (51), showing that an undoubted carbonium ion can, in fact, be reduced to the hydrocarbon with lithium aluminum hydride.

This expectation rests on two assumptions: (i) that the formation of the intermediates XI and XII involves displacement of Y^- with inversion of configuration, and (ii) that no geometrical isomerization takes place before or during reduction of the intermediate (XI or XII) to the olefin. It is reasonable to expect that these assumptions would be valid in most instances, but it is possible to imagine exceptions, especially with the "heteronium ion E1" reaction; to the extent that such exceptions are plausible in the present instance, then the force of the argument favoring the "Winstein–Pressman–Young E2" mechanism is diminished. The distinction that is being drawn at this point is that there are real *cis eliminations in a reaction which is believed to be analogous to the "Winstein–Pressman–Young E2" reduction, whereas any cis eliminations in the other two eliminations are, at present, hypothetical.*

†NOTE ADDED IN PROOF: *Such a mechanism, as we have belatedly discovered, has, in fact, been proposed by J. W. Cornforth, R. H. Cornforth, and K. K. Mathew (J. Chem. Soc. 112 (1959)). Specifically these authors suggest that a three-membered ring iodonium is an intermediate in the reduction of iodohydrins to olefins by means of a mixture of stannous chloride and phosphorus oxychloride in pyridine. The data in this admirable paper are not sufficient to establish the mechanism rigorously (they would fit equally well with the "Hine–Brader reductive E2" mechanism, for example), and at the moment the proposal would appear to be best described as an attractive and reasonable suggestion.*

Ionization of a 1,2-dibromide or bromohydrin tosylate is believed to lead to a bromonium ion (52, 53). Such an ion, in principle, could be attacked by hydride either at carbon or bromine; the former would lead to formation of the monobromide, the latter to the olefin (which reaction is, of course, simply the "heteronium ion *E*1" reduction of scheme 1). Such a direct reduction of a bromonium ion to an olefin is not implausible and finds parallel in the formation of olefins by the reduction of episulphides with lithium aluminum hydride (54) or triethyl phosphite (55), and also the reduction, referred to above, of an episulphonium ion with sodium iodide (42). It is perhaps of interest that the bromonium ion mechanism can account for the formation of 2-bromoöctane (as well as 1-octene) from 1,2-dibromoöctane (see Table II). In this case since one of the carbons of the bromonium ion is primary, attack on that carbon might be expected to be an important reaction path. (Another rationalization of the formation of 2-bromoöctane is mentioned below.)

To sum up this discussion of the three stereospecific mechanisms in scheme 1, it appears that attractive cases may be made for both the "Winstein–Pressman–Young *E*2" and the "heteronium ion *E*1" mechanisms but there is no reason to fault the "Hine–Brader *E*2" mechanism. The possibility either of two or more concurrent mechanisms* or of a hybrid or "in between" mechanism exists but does not warrant discussion until more data are obtained.

Another question raised by this study is the cause of the temporary accelerating effect of water. A priori it is conceivable that reaction of water with lithium aluminum hydride produces a reagent of greater reducing power than lithium aluminum hydride itself. But it has been reported that the lithium alkoxyaluminohydrides in general are weaker reducing agents than lithium aluminum hydride (57); this is in agreement with our finding that lithium tri-*t*-butoxyaluminohydride does not react with $2\beta,3\alpha$-dibromocholestane in refluxing tetrahydrofuran. Eliel and Prosser (34) have called attention to this point in connection with the effect of added water and alcohols in the reduction of chlorohydrins, and have concluded that the accelerating effect in their system may be due to the formation of a more active Lewis acid in the mixture. Such a Lewis acid could accelerate these reactions by adding onto the halide (or tosylate) group to give an easily heterolyzed complex. Such a process would fit in with any of the mechanisms in scheme 1, it would simply mean that the Y groups would be complexed leaving groups rather than the original halide or tosylate functions. A preliminary complexing with a Lewis acid is probably necessary for either the *E*1 or the S_N1 reactions with lithium aluminum hydride (assuming that they exist), since most halides or tosylates do not ionize spontaneously and rapidly in the solvents used for these reactions. Aluminum hydride has been suggested as the active Lewis acid facilitating the formation of an ionic intermediate (58), but the complex of aluminum hydride with tetrahydrofuran is apparently stable under the conditions of our study (59, 60) and therefore is a poor candidate to explain the comparatively short lifetime of the accelerating effect observed in our case. The present data are consistent with the possibility that the accelerating effect of water is due to an hydroxyaluminohydride ($Al(OH)_nH_{4-n}$) which rapidly disproportionates, reacts with solvent, and (or) polymerizes. The inorganic products formed in the reaction do not show any noticeable catalytic activity: a solution of lithium aluminum hydride in which *meso*-stilbene dibromide had been completely reduced showed no greater reactivity than one that had had no stilbene dibromide added to it.

**It has recently been suggested that reduction of ethylene dibromide with sodium iodide in acetone involves* both *the "Winstein–Pressman–Young E2" and the "Hine–Brader E2" mechanisms (56).*

Among the data in Tables II and III are a number of cases in which direct displacement of halogen by hydride predominates over reductive elimination. These are, in particular, the reactions of (*a*) 1,2-dibromoöctane, in which the displaced bromine is primary, (*b*) *trans*-1,4-dibromo-2-butene, in which the displaced bromine is allylic, and (*c*) ethyl β-chloroethyl ether, in which the displaced chlorine is on the same carbon as the ether oxygen; in each of these cases the relatively fast displacement is easily rationalized in terms of known properties of the S_N2 reaction. The cycloöctatetraene dibromide reduction is readily explained if it is assumed that the reduction proceeds through the monocyclic valence tautomer, in which both bromine atoms are allylic. The formation of bromocyclohexane from *cis*-1,2-dibromocyclohexane presumably reflects the ability of displacement to compete with reductive elimination when steric factors retard the latter reaction.

The reduction of the *trans*-2,3-dichlorocholestanes leads to cholest-2-ene, together with roughly the same amount of what appears to be cholestane, and a smaller amount of a mixture consisting of all four of the 2- and 3-cholestanols in approximately equal proportions. The surprising formation of the cholestanol mixture would appear to result from displacement of chlorine by hydroxide or oxygen bound in some form to aluminum. The most likely source of the oxygen is hydrolyzed reagent though the ratio of mixed cholestanols to other materials in the product is not sensitive to the extent of hydrolysis of the reagent: carrying out the reaction with carefully dried apparatus and solvent gives the same mixture as that obtained in the presence of wet nitrogen. It is not difficult to devise a scheme which accounts for the cholestanols being formed, but it is not particularly obvious why the four isomers should be formed in similar quantities. A similar mixture of cholestanols is also formed in low yield from 2α-bromocholestan-3β-yl tosylate. With this compound the hydroxyl group in the products might conceivably arise by S—O fission of the ester, but the similarity of the composition of the mixture of cholestanols to that obtained from the dichlorocholestanes suggests that they arise by a similar mechanism. Experiments are now being carried out which, it is hoped, will provide evidence as to the origin of the cholestanol mixture.

EXPERIMENTAL

Infrared spectra were obtained using Beckman IR-5 or IR-7 spectrophotometers equipped with sodium chloride optics; all values quoted for the frequencies of infrared maxima were determined with the IR-7 instrument. Melting points, which were determined on a Kofler hot stage, and boiling points are uncorrected. Optical rotations refer to chloroform solutions at room temperature ($c \sim 1.0$). The refractive indices were determined with a thermostatically controlled Bausch and Lomb refractometer. Thin-layer chromatography was carried out using Camag Kieselgel D5 or DF5. Petroleum ether, unless otherwise specified, refers to the fraction of boiling range 35–60°. All glassware used for rate measurements and the distillation of solvents was dried at 200° or more for not less than 2 hours.

The tetrahydrofuran used in this study was Fisher Certified Reagent refluxed for not less than 4 hours with lithium aluminum hydride and then distilled. Triglyme was purified as previously described (61). Dioxane was purified by the method of Vogel (62) and stored under dry nitrogen; it was tested for peroxides before use and if these were found present, it was redistilled from lithium aluminum hydride. The benzene for the iodometric titrations was BDH "Analar" grade refluxed over calcium hydride and distilled. Mallinckrodt "ether anhydrous analytical reagent" was used in reductions without further purification.

2β,3α-Dibromocholestane

Prepared from cholest-2-ene as described by Alt and Barton (63); m.p. 123–124°, $[\alpha]_D$ +76°; reported m.p. 123–124°, $[\alpha]_D$ +76°.

2α,3β-Dibromocholestane

Prepared from 2β,3α-dibromocholestane as described by Alt and Barton (63); m.p. 143–145°, $[\alpha]_D$ −29°; reported m.p. 144–145°, $[\alpha]_D$ −29°.

2β,3α-Dichlorocholestane

Prepared from cholest-2-ene as previously described (63); m.p. 105–108°, $[\alpha]$ +61°; reported m.p. 108–112°, $[\alpha]$ +63°.

2α,3β-Dichlorocholestane
Prepared from cholest-2-ene as previously described (63); m.p. 148–150°, $[\alpha]_D$ −4°; reported m.p. 150–152°, $[\alpha]_D$ −7°.

5α,6β-Dibromocholestan-3β-ol
Prepared as previously described by Fieser (64). Recrystallization from ether – petroleum ether gave a product m.p. 115–117°, $[\alpha]_D$ −45°; reported m.p. 112–114°, $[\alpha]_D$ −44° (65).

5β,6α-Dibromocholestan-3β-ol
The following procedure was found to be more convenient than that of Barton and Miller (65). 5α,6β-Dibromocholestan-3β-ol (3.5 g) was refluxed in spectroscopic grade carbon tetrachloride (100 ml) for 24 hours. About 60 ml of the solvent was removed *in vacuo* and the solution was then diluted rapidly with methanol. The first crop of crystals was unchanged starting material. Further dilution with methanol furnished, after recrystallization from ether–methanol, 5β,6α-dibromocholestan-3β-ol (1.3 g), m.p. 141–143°, $[\alpha]_D$ +45°; reported m.p. 143°, $[\alpha]_D$ +47°.

2β-Chlorocholestan-3α-ol
Prepared from 2α,3α-epoxycholestane as previously described (63); m.p. 118–121°, $[\alpha]_D$ +40°; reported m.p. 118–120°, $[\alpha]_D$ +39°.

2α-Bromocholestan-3α-ol
Prepared by reduction of 2α-bromocholestan-3-one with sodium borohydride as previously described (66); m.p. 116–118°, $[\alpha]_D$ +36°; reported m.p. 117–118°, $[\alpha]_D$ +33°.

2α-Bromocholestan-3α-yl p-Toluenesulphonate
Prepared from the alcohol in the usual way (61); recrystallized four times from acetone, m.p. 237–240°, $[\alpha]_D$ +40°. Calc. for $C_{34}H_{53}O_3SBr$: C, 65.68; H, 8.59; S, 5.16; Br, 12.85%. Found: C, 65.74; H, 8.45; S, 4.97; Br, 13.02%.

2β-Chlorocholestan-3α-yl p-Toluenesulphonate
Prepared from the alcohol in the usual way (61); recrystallized four times from acetone, m.p. 182–183°, $[\alpha]_D$ +46°. Calc. for $C_{34}H_{53}O_3SCl$: C, 70.73; H, 9.25; S, 5.55; Cl, 6.14%. Found: C, 71.20; H, 8.91; S, 5.59; Cl, 5.91%.

2β-Bromocholestan-3α-yl p-Toluenesulphonate
Prepared as previously described (67), m.p. 168–170°, $[\alpha]_D$ +49°; reported m.p. 168–170°, $[\alpha]_D$ +49°.

3α-Bromocholestan-2β-yl p-Toluenesulphonate
Prepared as previously described (61), m.p. 174–177°, $[\alpha]_D$ +49°.

2α-Bromocholestan-3β-yl p-Toluenesulphonate
Prepared as previously described (61), m.p. 135° and around 165°, $[\alpha]_D$ −38.5°.

Derivatives of 1,2-Diphenylethane
meso-Stilbene dibromide: crystallized from toluene, m.p. 237°. *dl*-Stilbene dibromide: m.p. 113–114°. *meso*-Stilbene dichloride: m.p. 191–193°. *dl*-1,2-Diphenylethanol: m.p. 65–67°. *dl*-1,2-Diphenylethyl bromide: prepared by the method of Curtin and Kellom (68): n_D^{20} 1.6015. *erythro*-1,2-Diphenyl-2-bromoethyl fluoride: prepared by Dr. J. Newton (69): m.p. 104–105°. *erythro*-1,2-Diphenyl-2-bromoethyl methyl ether: prepared as described by Bartlett and Tarbell (70): m.p. 117–120°.

Derivatives of Butane
(a) meso-2,3-Dibromobutane.—*trans*-2-Butene (99 mole % minimum, supplied by Phillips Petroleum Company, Special Products Division, Bartlesville, Oklahoma) was bubbled slowly into an ether solution (150 ml) of bromine (16 g) cooled in a dry-ice and carbon tetrachloride bath, until the solution became colorless. The reaction mixture was then poured into water and extracted with ether. The ether extract was washed with dilute sodium sulphite solution, dilute potassium bicarbonate solution, and water, and dried over sodium sulphate. Removal of the solvent and distillation of the residue gave after a small forerun, *meso*-2,3-dibromobutane (8.0 g); b.p. 72–73° (51 mm); n_D^{20} 1.5120; reported b.p. 72.7–72.9° (50 mm), n_D^{20} 1.5116 (71).
(b) dl-2,3-Dibromobutane.—This compound was prepared from *cis*-2-butene (99.97 mole % minimum supplied by Phillips Petroleum Company, Special Products Division, Bartlesville, Oklahoma) by the same procedure as described above for *meso*-2,3-dibromobutane; b.p. 72.5–73.5° (50 mm), n_D^{20} 1.5143; reported b.p. 75.6–75.8° (50 mm), n_D^{20} 1.5147 (71).

Derivatives of Cyclohexane
(*a*) *trans*-1,2-Dibromocyclohexane was prepared by the addition of bromine to cyclohexene in carbon tetrachloride as previously described (72); n_D^{25} 1.5507; reported n_D^{25} 1.5507 (73).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(*b*) *cis*-1,2-Dibromocyclohexane was prepared by the free radical addition of hydrogen bromide to 1-bromocyclohexene as described by Goering *et al.* (74). Recrystallization from pentane gave the product, m.p. 6–8°; reported m.p. 9–10°.

(*c*) *trans*-1-Bromo-2-fluorocyclohexane was supplied by Mr. F. H. Dean (69), n_D^{20} 1.4820; b.p. 88–90° (84 mm).

Lithium Aluminum Hydride Stock Solutions

Lithium aluminum hydride (Metal Hydrides Inc.) sufficient to give an approximately 0.8 ± 0.2 *M* solution was placed in a Soxhlet extractor and extracted with anhydrous tetrahydrofuran. The stock solution was then attached to the burette assembly as in Fig. 1. The molarity of the stock solution was determined by the addition of excess standardized iodine in anhydrous benzene, followed by back titration with sodium thiosulphate as described by Felkin (31).

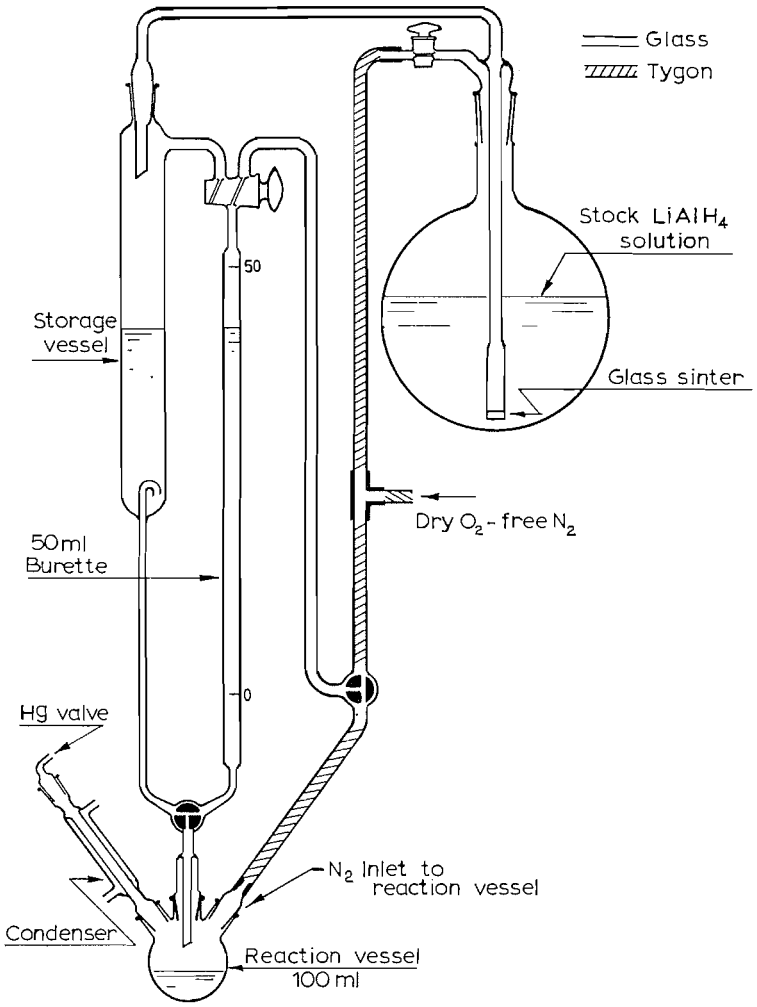

FIG. 1.

Procedure for the Determination of the Stoichiometry

Anhydrous tetrahydrofuran (approx. 150 ml) was distilled under a nitrogen atmosphere into a three-necked flask (300 ml) containing the dibromide (approx. 8 mmoles) and fitted with reflux condenser, magnetic stirrer, and drying tube. The flask was quickly transferred from the distillation assembly to the burette containing the stock solution of lithium aluminum hydride (see Fig. 1), and excess hydride added. After the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

addition of the hydride was complete, the reaction mixture was refluxed for 1 hour in the *meso*-stilbene dibromide experiments and 2 hours in the 5α,6β-dibromocholestan-3β-ol experiments. The active hydride remaining after reduction was titrated with a standardized solution of iodine in benzene (31). Blank experiments with stilbene and cholesterol, respectively, were carried out to determine the amount of hydride lost during the operations. For these experiments both the 5α,6β-dibromocholestan-3β-ol and the cholesterol were recrystallized from ether – petroleum ether and carefully dried. The results are recorded in Table VII.

After the iodine titration, the reaction mixture was poured into water and extracted with ether. The ether extract was washed with dilute sodium sulphite solution, dilute sulphuric acid, and water, dried over sodium sulphate, and the solvent evaporated. The olefin was then recrystallized from ether–ethanol. The yields are summarized in Table VII.

General Procedure for Rate Measurements with Lithium Aluminum Hydride (Tables IV to VI)

(a) The Reaction

The glassware was heated in an oven (minimum temperature 200°) for not less than 4 hours before use. A three-necked, round-bottomed flask (100 ml) equipped with condenser, magnetic stirrer, stopper, and nitrogen inlet tube was quickly assembled and heated with a Bunsen burner flame while dry nitrogen was passed through the apparatus. When the apparatus had cooled to room temperature, the stopper was quickly removed and the substrate (0.366 mmole) and tetrahydrofuran (50 ml) added to the reaction vessel under positive nitrogen pressure. The reactants were cooled in an ice bath to 1±1°. The reaction vessel was quickly transferred from the ice bath to the burette assembly (see Fig. 1) and lithium aluminum hydride (7.32 mmoles) in tetrahydrofuran added. The reduction was stopped by pouring the reaction mixture into water (150 ml). In the kinetic experiments in which water was initially present before the addition of lithium aluminum hydride, the water was mixed with the anhydrous tetrahydrofuran. In all other experiments involving addition of water, nitrogen saturated with water vapor by passage through an ice–water trap was bubbled into the reaction vessel at a constant flow rate. The flow rate (6.6 ml/second) was measured with a burette (50 ml) as a soap bubble flow meter.

(b) Method of Bromide Ion Analysis

The reaction mixture, after being quenched with water, was acidified with glacial acetic acid (approx. 20 ml). The amount of bromide ion was then determined by potentiometric titration with *N*/10 silver nitrate using an Electronic Instruments Ltd. (Surrey, England) Model 23A pH meter, and the following electrode system: silver electrode in contact with the bromide ion solution, with a calomel reference cell in a separate beaker and connected to the titration vessel through an ammonium nitrate bridge. To inhibit gumming of the silver electrode by the organic precipitate, benzene (ca. 50 ml) was added to the titration mixture. Under the titration conditions the organic substrates do not react with silver nitrate. A blank titration of the hydrolyzed reagent showed the presence of a small amount of halide ion (presumably lithium chloride); the quantity of silver nitrate consumed by the hydrolyzed reagent was determined before each run and was subtracted from the titer of that run.

Reaction of Lithium Aluminum Hydride with Water

The following experiments were carried out to measure the amount of lithium aluminum hydride (or active hydride) destroyed by bubbling moist nitrogen into the solution under the conditions described in the above section. In two experiments wet N_2 (saturated at 0°) was bubbled into the mixture at the rate of 6.6 ml/second for an interval and the mixture then titrated immediately with I_2 in benzene. In the other two experiments a quantity of water equal to that calculated to have been added in the wet N_2 experiments was added directly and the mixture allowed to stand for the same length of time as the N_2 had been bubbled in and the mixture then titrated with I_2 in benzene. The results are summarized in Table VIII.

Reaction of Lithium Aluminum Hydride with 1,2-Dihalides and Related Compounds (Table III)

General Procedure

A number of the reactions gave a crystalline product in good yield. In each of these cases, the substrate (ca. 50 mg) was refluxed for 1 hour in 1.0 *M* lithium aluminum hydride (ca. 4 ml). The reaction mixture was poured into water and extracted with ether. The ether extract was washed with dilute sulphuric acid and water, dried with sodium sulphate, and the solvent evaporated. Recrystallization gave a product which was identified by melting point, infrared spectrum, and where useful, optical rotation. The yields are summarized in Table III.

Other reactions are described individually below.

(a) 2α-Bromocholestan-3β-yl p-Toluenesulphonate.—Examination of the reaction product by thin-layer chromatography gave the following results: tile 1 (petroleum ether) indicated only trace amounts of cholestane and cholest-2-ene (identified by authentic samples run on the same tile); tile 2 (petroleum ether – benzene, 1:1) established the absence of starting material; tile 3 (benzene–ether, 3:1) showed the presence of not less than 10 products, four of which appeared to be the 2- and 3-hydroxycholestanes by their R_f values.

(b) 2β,3α-Dichlorocholestane.—In addition to a strong hydroxyl band at 3620 cm^{-1}, only unreacted starting

‡Time elapsed between water addition and I_2 titration.

material could be identified from the infrared spectrum (IR-7) of the reaction product. Thin-layer chromatography gave the following results: tile 1 (petroleum ether) showed, by comparison of the R_f values of authentic samples, the presence of unreacted starting material, cholestane and cholest-2-ene but none of the diequatorial isomer, 2α,3β-dichlorocholestane; tile 2 (benzene–ether, 3:1) showed, by comparison of the R_f values of authentic samples, the presence of the following alcohols, cholestan-2β-ol, cholestan-2α-ol, cholestan-3β-ol, and cholestan-3α-ol.

(c) 2α,3β-Dichlorocholestane.—The reaction product consisted mainly of unreacted starting material. Examination of the thin-layer chromatograms gave the same results as described for 2β,3α-dichlorocholestane with the exception that the six identifiable products were produced in lesser amounts.

(d) cis-1,2-Dibromocyclohexane.— *cis*-1,2-Dibromocyclohexane (3.5 g), lithium aluminum hydride (1.5 g), and anhydrous triglyme (80 ml) were placed in a three-necked, round-bottomed flask equipped with a nitrogen inlet and a reflux condenser. The condenser was connected to a trap cooled in liquid nitrogen. After wet nitrogen was passed through the reaction mixture at room temperature for 1 hour, the temperature was raised to 100° to distil off the volatile fraction (0.27 g) which was found by vapor-phase chromatography to contain 63% of cyclohexene. The reaction mixture was poured into wet ether to destroy the unreacted lithium aluminum hydride and the ether extract washed with dilute sulphuric acid and water, dried over sodium sulphate, and the solvent evaporated. The residue (1.90 g) was analyzed by vapor-phase chromatography and was found to consist of bromocyclohexane, 51%, and unreacted dibromide 49%. These results are equivalent to the following yields: cyclohexane, 26%, and bromocyclohexane, 49%, based on reacted *cis*-1,2-dibromocyclohexane.

(e) trans-1,2-Dibromocyclohexane.—Following the procedure and method of analysis as outlined for the cis isomer, *trans*-1,2-dibromocyclohexane (28 g) and lithium aluminum hydride (7.5 g) in anhydrous triglyme (100 ml) gave cyclohexane (0.5 g, 5%) and cyclohexene (7.3 g, 77%).

(f) meso-2,3-Dibromobutane.—Following the procedure outlined for *cis*-1,2-dibromocyclohexane, *trans*-2-butene was identified as the principal product of the reduction of *meso*-2,3-dibromobutane by comparison of the infrared spectrum (IR-7) with that of an authentic sample. From the absorption bands in the 2800–3000 cm^{-1} region and at 960 cm^{-1} and the lack of absorption at 975 cm^{-1} it was established that *cis*-2-butene was not produced in appreciable amounts if at all. In a separate experiment, the yield of *trans*-2-butene, isolated as the dibromide, was 90%.

(g) dl-2,3-Dibromobutane.—Following the procedure outlined for *cis*-1,2-dibromocyclohexane, *cis*-2-butene was identified as the principal product of the reduction of *dl*-2,3-dibromobutane by comparison of the infrared spectrum (IR-7) with that of an authentic sample. From the absorption bands in the 2800–3000 cm^{-1} region and at 975 cm^{-1}, and the lack of absorption at 960 cm^{-1}, it was established that *trans*-2-butene was not produced in appreciable amounts if at all. In a separate experiment, the yield of *cis*-2-butene, isolated as the dibromide, was 86%.

(h) 1-Fluoro-2-bromocyclohexane.—Following the procedure outlined in (*d*) 1-fluoro-2-bromocyclohexane (3 g), lithium aluminum hydride (1.5 g), and anhydrous triglyme (100 ml) gave fluorocyclohexane (0.8 g, 45%), identified by comparison of the infrared spectrum with an authentic sample and by retention time upon vapor-phase chromatography.

(i) meso-Stilbene Dichloride.—*meso*-Stilbene dichloride (400 mg) was reacted with lithium aluminum hydride (500 mg) in anhydrous tetrahydrofuran (50 ml) for 1 hour at room temperature. Wet nitrogen (as above) was bubbled gently into the solution during the reaction. Isolation of product as in the general procedure and recrystallization of the crude material from benzene–ethanol gave unreacted *meso*-stilbene dichloride (77 mg). Evaporation of the mother liquors and recrystallization from ethanol gave *trans*-stilbene (200 mg), 75% yield based on reacted dichloride.

(j) erythro-1,2-Diphenyl-2-bromoethyl Methyl Ether.—*erythro*-1,2-Diphenyl-2-bromoethyl methyl ether (300 mg) was refluxed for 5 hours in 1.0 *M* lithium aluminum hydride solution (25 ml). Work-up as in the general procedure and recrystallization from ether–methanol gave *trans*-stilbene (45%). Evaporation of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

mother liquors yielded an oil (85 mg) which gave a negative Beilstein test and had an infrared spectrum resembling that of the starting material; this material was not further investigated.

(k) erythro-1,2-Diphenyl-2-fluoroethyl Bromide.—*erythro*-1,2-Diphenyl-2-fluoroethyl bromide (300 mg) was reacted with 1.0 *M* lithium aluminum hydride in tetrahydrofuran solution (15 ml) for 45 minutes at room temperature while wet nitrogen was bubbled gently into the solution. Isolation of the product as in the general procedure and recrystallization from ether–methanol gave *trans*-stilbene (166 mg, 86%).

(l) dl-Stilbene Dibromide.—*dl*-Stilbene dibromide (50 mg) or *cis*-stilbene (35 mg) was reacted with 1.0 *M* lithium aluminum hydride (2.0 ml) in tetrahydrofuran as listed in Table IX. The reaction mixture was

TABLE IX

Reaction of $LiAlH_4$ in tetrahydrofuran with *dl*-stilbene dibromide and *cis*-stilbene

Compound	Time (hours)	Temp.	Product (±10%)
dl-Stilbene dibromide	24	−10°	5% *cis*-, 95% *trans*-stilbene
dl-Stilbene dibromide	24	25°	50% *cis*-, 50% *trans*-stilbene
dl-Stilbene dibromide	1	Reflux	65% *cis*-, 35% *trans*-stilbene
dl-Stilbene dibromide	0.5	25°	55% *cis*-, 45% *trans*-stilbene
cis-Stilbene	1	Reflux	70% *cis*-, 30% *trans*-stilbene
cis-Stilbene	24	25°	40% *cis*-, 60% *trans*-stilbene
cis-Stilbene	48	−10°	95% *cis*-, 5% *trans*-stilbene
cis-Stilbene	0.5	25°	95% *cis*-, 5% *trans*-stilbene

poured into water and extracted with ether. The ether extract was washed with dilute sulphuric acid, dilute potassium bicarbonate, water, dried, and the solvent evaporated. The relative amounts of *cis*- and *trans*-stilbene were determined by comparison of the intensities of the infrared absorption bands at 925 cm^{-1} (cis) and 962 cm^{-1} (trans) with those of authentic mixtures. The results are summarized in Table IX.

Reaction of Lithium Aluminum Hydride with Bromocyclohexane

Bromocyclohexane (10 g) and lithium aluminum hydride (5 g) in anhydrous triglyme (75 ml) were reacted under the same conditions as described for *cis*-1,2-dibromocyclohexane. Cyclohexane (0.6 g) was isolated from the liquid nitrogen trap and identified by infrared spectroscopy and vapor-phase chromatography. Cyclohexene was not detected by either method of analysis. The reaction mixture, worked up as previously described, yielded unreacted starting material (5 g).

Reaction of Lithium Aluminum Hydride with Cholestan-3α-yl p-Toluenesulphonate

This compound was reacted with lithium aluminum hydride under identical conditions as described for 2α-bromocholestan-3α-yl *p*-toluenesulphonate. The infrared spectrum of the product indicated little, of any, loss of the tosylate group. Thin-layer chromatography showed the absence of cholest-2-ene and that the reaction product was mostly unreacted starting material.

Reaction of Lithium Aluminum Hydride with dl-1,2-Diphenylethyl Bromide

dl-1,2-Diphenylethyl bromide (600 mg) was added to a solution of lithium aluminum hydride (600 mg) in tetrahydrofuran. The mixture was allowed to stand for 1 hour at room temperature, and then worked up by pouring into water and extracting with ether. The extracts were washed with water, dried with Na_2SO_4, and the solvent evaporated giving dibenzyl (385 mg); m.p. after recrystallization 49–52°. Thin-layer chromatography of the crude product of a second experiment, carried out in the same way, showed the absence of either starting material or any *trans*-stilbene.

ACKNOWLEDGMENTS

We thank the National Research Council of Canada for grants-in-aid and a scholarship, the Research Corporation for a Frederick Gardner Cottrell grant-in-aid, and Dow Chemical of Canada Limited for a scholarship. We are grateful to Professor F. L. M. Pattison, Mr. F. H. Dean, and Dr. J. Newton for generously supplying the fluoro compounds used in this study.

ELECTRODE POTENTIALS OF THORIUM TETRACHLORIDE IN ALKALI CHLORIDE MELTS

R. SRINIVASAN* AND S. N. FLENGAS
Department of Metallurgical Engineering, University of Toronto, Toronto, Ontario

Received January 10, 1964

ABSTRACT

The electrode potentials of the system Th, $ThCl_4$ (KCl, NaCl) were measured at various concentrations of thorium chloride, and at temperatures between 670° C and 850° C, using a silver – silver chloride reference electrode. It was shown by a direct gravimetric method that the reaction,

$$Th_{(metal)} + ThCl_{4(melt)} = 2ThCl_{2(in\ melt)},$$

postulated by previous investigators, did not take place.

The activity coefficients, and the other partial molal properties of the solutions of $ThCl_4$ in the equimolar mixture of potassium and sodium chlorides, were calculated as a function of temperature from the e.m.f. measurements.

INTRODUCTION

Measurements of the "apparent standard" potentials of several metal – metal chloride systems in dilute solutions in fused alkali chlorides have been reported in previous investigations (1, 2, 3, 13). Such measurements provide data on activities, help determine the equilibrium constants of chemical reactions in fused salts, and give some of the necessary information for the electrolytic recovery of metals by fused salt electrolysis. An equimolar mixture of potassium and sodium chlorides was used as the solvent melt in all these studies, and a silver – silver chloride electrode developed earlier in this work (1) was used as the reference electrode. In the present investigation, the technique has been applied to the determination of the reversible potentials of thorium tetrachloride, in the temperature range 670° C to 850° C.

The system has also been investigated recently by Yang, Hudson, and Chien (4) in KCl–LiCl melts, in the temperature range 490° C to 550° C, and by Smirnov *et al.* (5, 6, 7) in KCl–NaCl melts. However, the results obtained in these investigations were in complete disagreement. Thus, Smirnov and his associates, from potential–current curves, measured during the electrolysis of $ThCl_4$ in solution in a KCl–NaCl melt, predicted that thorium tetrachloride would be reduced almost quantitatively by thorium metal according to the reaction:

$$Th_{(s)} + ThCl_{4(in\ melt)} = ThCl_{2(in\ melt)}.$$

The redox potential of the Th^{3+}, Th^{4+} system was then measured and the Th, Th^{4+} system was also investigated by using a "non-reacting" Th–Zn alloy. The results of Yang *et al.* (4), however, did not indicate this reduction and, furthermore, Gruen, McBeth, Kooi, and Carnall (8), in an attempt to prepare Th(II) in chloride melts for the purpose of investigating the spectra of the species, did not find any evidence of its existence.

To resolve such conflicting information, it was therefore decided to begin this investigation by the determination of the solubility of thorium metal in a melt containing $ThCl_4$ in solution in the equimolar mixture of potassium and sodium chlorides. It should be noted that the existence of the redox equilibrium postulated by Smirnov *et al.* would make impossible the direct determination of the potentials of the Th, Th^{4+} system.

EXPERIMENTAL

Reduction of Thorium Tetrachloride

The method for the determination of the solubilities of thorium metal involved the direct observation of the decrease of weight of a piece of thorium metal, $\frac{1}{2}$ in. long by $\frac{1}{4}$ in. diameter, in contact with a molten solution of thorium tetrachloride, in the equimolar melt of potassium and sodium chlorides. The solution was contained in a platinum crucible and thorium metal was suspended from the end of a calibrated quartz spring balance by means of a platinum wire. The entire system was enclosed in a 2 in. diameter quartz tube under an atmosphere of purified argon, and the contraction of the spring, indicating the loss in weight of thorium metal, was measured by a cathetometer. The apparatus was capable of measuring a minimum loss of weight of 0.1 mg of thorium metal, corresponding to the production of 0.13 mg of thorium dichloride in the melt.

Solutions having compositions between 0.7 and 4.0% by weight of ThCl were investigated at reaction temperatures varying between 730° C and 800° C. The metal samples were immersed in the solutions for about 48 hours, and no loss of weight could be detected during this period of time. Furthermore, the melt remained colorless and there was no evidence of attack on the thorium metal. The reducing power of the melt, after cooling under argon, was also determined by back-titration with a ceric sulphate solution. Again, no trace of the reduced state of divalent thorium chloride could be found. It was therefore concluded that the reduction mechanism postulated by Smirnov *et al.* did not take place to any measurable extent, and that the direct determination of the potential of the Th, Th^{4+} system would be feasible.

Electromotive Force Measurements

The type of cell used for the measurements has been described in detail in previous publications (2, 3). The cell is represented as follows.

$$\begin{array}{c|c|c|c|c|c} \text{Th} & \text{ThCl}_4\ (X_2) & \text{Asbestos} & \text{AgCl}\ (X_1) & \text{Ag} \\ & & \text{fiber} & & \\ (-) & \text{KCl–NaCl (1:1 mole)} & & \text{KCl–NaCl (1:1 mole)} & (+) \end{array}$$

The cell reaction is:

$$Th_{(s)} + 4\,Ag^{+}\ (\text{as AgCl in KCl–NaCl}) = Th^{4+}\ (\text{as } ThCl_4 \text{ in KCl–NaCl}) + 4\,Ag_{(s)}.$$

The Nernst equation for the cell may be written as:

$$E_{cell} = (E^0_{ThCl_4} - E^0_{AgCl}) - \frac{2.303\,RT}{4F}\log\frac{X_2}{X_1^4} - \frac{2.303\,RT}{4F}\log\frac{\gamma_2}{\gamma_1^4} \qquad [1]$$

where $E^0_{ThCl_4}$ and E^0_{AgCl} are the "standard" potentials of thorium tetrachloride and silver chloride, respectively, in their standard states, and the γ's are the corresponding activity coefficients. Equation [1] may be further simplified by substituting the value of unity for the activity coefficient of silver chloride, as found in a previous investigation (2). Equation [1] then becomes:

$$E_{cell} = (E^0_{ThCl_4} - E^0_{AgCl} - \frac{2.303\,RT}{4F}\log\gamma_{ThCl_4}) - \frac{2.303\,RT}{4F}\log\frac{X_2}{X_1^4}. \qquad [2]$$

For dilute solutions obeying Henry's Law, γ_{ThCl_4} becomes constant and the "apparent standard" potential may then be defined as,

$$E^0_{app.} = E^0_{ThCl_4} - E^0_{AgCl} - \frac{2.303\,RT}{4F}\log\gamma_{ThCl_4}. \qquad [3]$$

The final form for equation [1] is:

$$E_{cell} = E^0_{app.} - \frac{2.303\,RT}{4F}\log\frac{X_2}{X_1^4}. \qquad [4]$$

Hence, by plotting E_{cell} against $\log(X_2/X_1^4)$, a straight line should be obtained having a slope of $-2.303\,RT/4F$ and an intercept equal to $E^0_{app.}$. It should be mentioned that the "apparent standard" potential represents the free energy of a hypothetical state of unit mole fraction of solute, having in all respects the properties of the solute in its state at infinite solution.

For the calculation of the activity coefficients of thorium tetrachloride from equation (3), the state of the "pure molten chlorides", at the temperature of the experiments, was chosen as the standard state. Standard potentials for molten silver chloride were obtained from data tabulated by Hamer *et al.* (9). Standard potentials for molten thorium tetrachloride were calculated from the corresponding free energies of formation of the compound. The latter were derived from the available data on the free energies of formation of the solid (10), and the free energies of fusion calculated from the vapor pressure data (11) of solid and liquid thorium tetrachloride, respectively.

In order to account for the entire temperature range of the experiments, i.e. 670° C to 850° C, the free energy equations representing the liquid state were extrapolated to temperatures below the melting point of thorium tetrachloride (765° C). Thus, below 765° C, the standard state is the supercooled liquid. Calculated standard potentials, with respect to the solid and the liquid states, are shown in Fig. 3.

PREPARATION OF MATERIALS

The equimolar mixture of potassium and sodium chlorides was prepared from analytical grade chemicals and dehydrated by heating under vacuum at 500° C for 20 hours.

Anhydrous thorium tetrachloride was prepared by chlorination of thorium oxide. Thorium oxide itself was prepared by calcination of pure thorium nitrate or oxalate. The thorium oxide was mixed with carbon and chlorinated at 800° C. The product was purified by double distillation *in vacuo* and had a purity of 99.3%. The crystalline sublimate was powdered and pelletised in a dry-box to facilitate easy addition to the melt.

The thorium electrode was a rod of reactor-grade thorium metal, cut from a 2 in. ingot supplied by Atomic Energy of Canada Ltd. The dimensions of the electrode were $\frac{1}{4}$ in. square by $2\frac{1}{2}$ in. long. It was threaded onto a copper-coated iron rod which served as the electrode connection. The electrode was cleaned with emery paper and dilute acid. It was then washed well with distilled water and dried with acetone. The cleaned electrode was kept in anhydrous carbon tetrachloride until its use.

The silver electrode was a rod ($\frac{1}{8}$ in) of pure silver connected to a silver wire. The electrolyte for the reference electrode was prepared by intimately mixing weighed amounts of the equimolar mixture of analytical-grade silver chloride with potassium and sodium chlorides, melting the mixture to form a homogeneous solution, and solidifying it, all under argon. The solid was powdered, thoroughly mixed, and kept under dry conditions.

RESULTS

The e.m.f. of Th/Th^{4+} cell was measured as a function of temperature for a given concentration, using the concentrations shown below.

		X_1	X_2
Run *a*	(1)	6.235×10^{-2}	6.468×10^{-3}
	(2)	6.235×10^{-2}	1.417×10^{-2}
Run *b*	(3)	1.05×10^{-2}	1.50×10^{-3}
	(4)	1.05×10^{-2}	5.20×10^{-3}
	(5)	1.05×10^{-2}	7.62×10^{-3}

The results are shown in Fig. 1.

Necessary corrections for the thermoelectric potential, which was measured separately, were made in plotting the results. The material was added in the form of pellets and, after each addition, the potential reached a steady state in about 30 minutes.

From Fig. 1 it is seen that the curves are linear over the temperature range involved, and the cell potentials have a negative temperature coefficient. Potential readings were taken at equilibrium while the temperature was being raised, and were in good agreement with those made while the temperature was decreasing. The duration of a complete heating and cooling cycle was about 24 hours.

Potentials in very dilute solutions of thorium tetrachloride, i.e. below 10^{-4} mole fraction, tended to drift with time as the result of a slow vaporization of thorium tetrachloride from the melt. Furthermore, a slight attack of the silica walls of the container was also observed. Thus, thorium tetrachloride reacted slowly with silica and produced a mirror-like coating, which, on X-ray diffraction analysis, was identified as ThO_2.

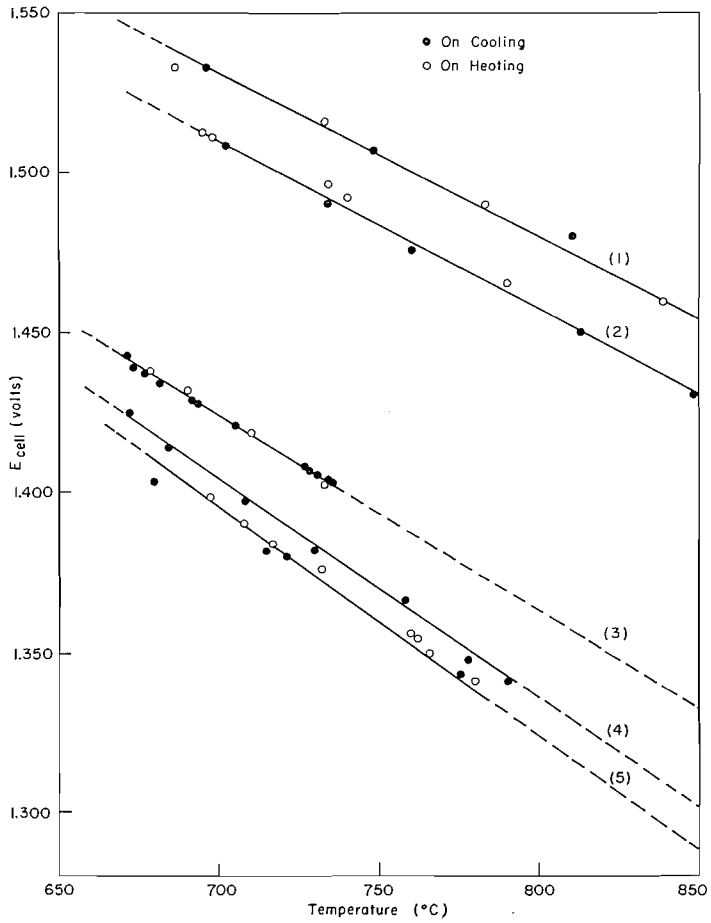

FIG. 1. Electromotive force of the cell Th, $ThCl_4$ (KCl, NaCl) as a function of temperature.

The e.m.f. of the Th/Th^{4+} cell was also measured as a function of $\log X_2/X_1^4$ at various temperatures. The results are shown in Fig. 2. The closed circles are data obtained at selected temperature from the results shown in Fig. 1. The half-closed circles are data representing an independent concentration run at 696° C covering the mole fraction range 4.093×10^{-4} to 2.103×10^{-2} of $ThCl_4$ ($X_1 = 6.235\times10^{-2}$). The slope of the lines in Fig. 2 corresponds fairly well with the theoretical slope for a four-electron electrode reaction calculated by the Nernst equation. For example, at 670° C, the theoretical slope should be 0.047, and the experimental slope is 0.042. At 850° C, the corresponding values are 0.056 and 0.050. The linearity of the curves indicates that the activity coefficient of thorium tetrachloride in dilute solutions is constant, and, at constant temperature, independent of concentration. The "apparent standard potentials" with respect to the silver – silver chloride electrode as the zero potential reference, were obtained by extrapolation of the straight lines to zero $\log (X_2/X_1^4)$ term, and are also shown in Fig. 2. To refer the "apparent standard" potentials to a chlorine electrode, it is only necessary to add to the values shown in Fig. 2 the corresponding standard potential of silver chloride (9).

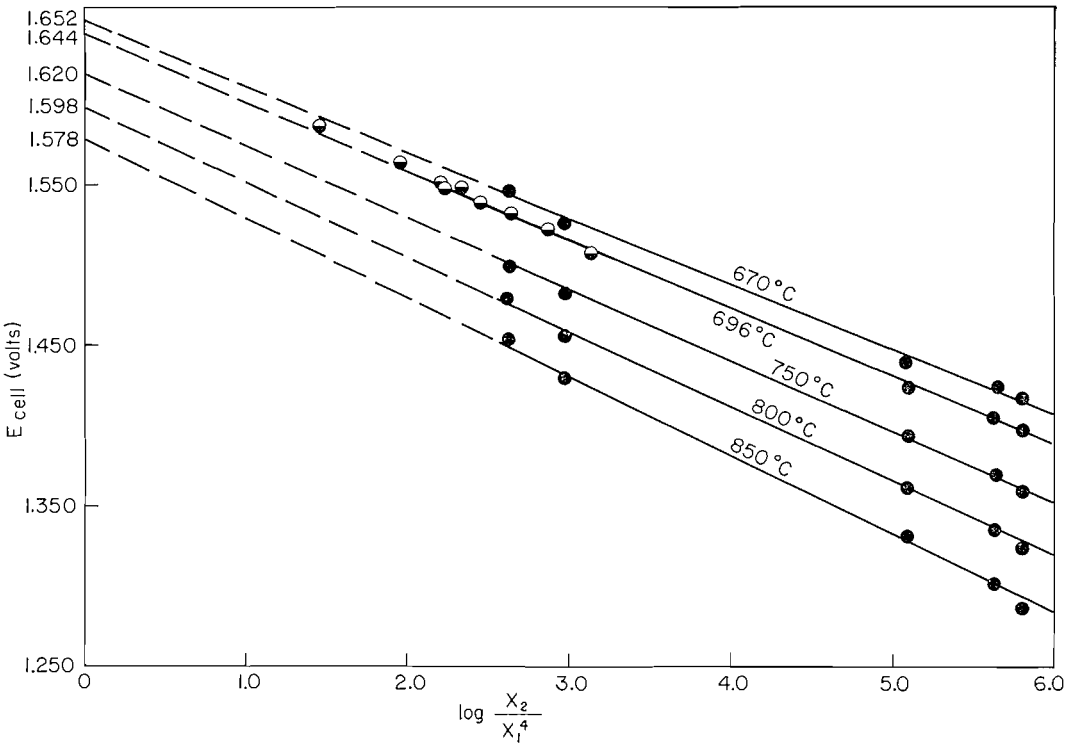

FIG. 2. Electromotive force of the cell Th, $ThCl_4$ (KCl, NaCl) as a function of log X_2/X_1^4 at various temperatures.

The results of these calculations are shown in Fig. 3. The plot is linear and the "apparent standard" potential of thorium tetrachloride, against a chlorine electrode as the zero potential reference, is given by the equation,

$$E^0_{app.} = 3.109 - 6.38\times10^{-4}T \qquad (923° K - 1123° K)$$

where T is in degrees Kelvin.

DISCUSSION

From the data given in Fig. 3, activity coefficients and the other partial molal properties of the solutions of thorium tetrachloride in the KCl–NaCl melt were calculated, and are given in Table I. The "apparent standard" and the standard potentials for thorium tetrachloride, calculated against a chlorine electrode, are also included in this table. The sign of the potentials is given as positive and represents the overall cell potential when one of the electrodes is a chlorine electrode. It will, however, assume a negative sign for the purpose of tabulating the thorium electrode potentials in an e.m.f. series, with respect to a chlorine electrode as the zero potential reference (I.U.P.A.C. convention). It may be noted that potentials calculated from the data of Smirnov and Yushina (7) are about 0.2 volts lower than the values obtained herein.

Within the accuracy of the measurements, the results indicate that the solutions follow Henry's law over a range of concentrations up to $X_{ThCl_4} = 10^{-2}$. Further, the magnitude of the activity coefficients indicates the tendency of thorium tetrachloride to form complex species in the melt. The activity coefficients increase with increasing temperature indicating the dissociation of these complexes at the higher temperatures, as expected.

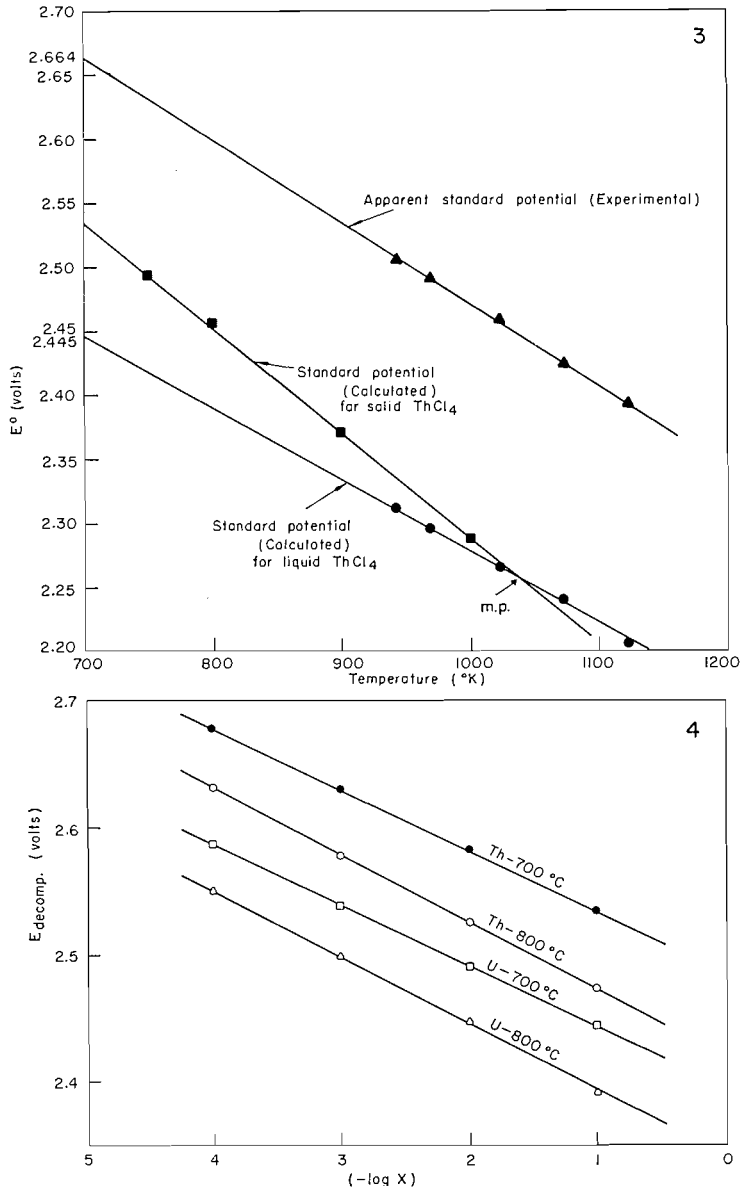

FIG. 3. Apparent standard potentials and standard state potentials of $ThCl_4$, as a function of temperature. All values refer to a chlorine electrode as the zero potential reference electrode.
FIG. 4. Decomposition potentials of UCl_3 and $ThCl_4$ in solution in a KCl–NaCl molten salt solvent, as a function of the mole fraction of the solute.

Activity coefficients of thorium tetrachloride in the KCl–LiCl melt at temperatures between 450° C and 550° C were also calculated by Yang *et al.* (4), and were of the order of 10^{-3}, indicating a weakening of the bonds in the complex species, due to the smaller Li^+ cations in the melt. It should be noted that similar effects were also observed with the complexes of the titanium tetrachloride with alkali metal chlorides. Thus the complex

TABLE I

Partial molal properties of dilute solutions of thorium tetrachloride in 1/1 mole KCl–NaCl

T (°K)	Apparent standard potential (volts)	Standard potential (calculated) (volts)	$\overline{\Delta F^*}$ kcal mole^{-1}	$\overline{\Delta H^*}$ kcal mole^{-1}	$\overline{\Delta S^*}$ e.u.	$\gamma \times 10^3$
943	2.505	2.312	−17.8	+9.6	29.02	0.72

1123	2.393	2.207	−17.16	+9.6	23.81	4.46

*Calculated from the well-known relationships

$$\overline{\Delta F} = RT \ln a_{ThCl_4}, \frac{\partial(\overline{\Delta F})}{\partial T} = -\overline{\Delta S}, \text{ and } \overline{\Delta F} = \overline{\Delta H} - T\overline{\Delta S}.$$

K_2TiCl_6 was readily prepared (12), whereas the corresponding lithium complex was found to be unstable.

With respect to the separation of thorium and uranium metals by electrolysis, from a solution containing both species as Th^{4+} and U^{3+} ions dissolved in the equimolar melt of potassium and sodium chlorides, the results obtained herein indicate that such a separation should be difficult.

Figure 4 shows the reversible decomposition potentials of the solutions (13) plotted as a function of concentration, at two temperatures. The corresponding curves are almost parallel in the mole fraction range 10^{-1} to 10^{-4}, with a potential difference of approximately 0.1 volt. Such a difference should not be considered as sufficient in actual practice for the separation and recovery of these two metals by fused-salt electrolysis, and would rather indicate co-deposition.

ACCURACY OF RESULTS

It is difficult to evaluate the limits of accuracy in the potentials measured. It could be said with confidence that the individual potential measurements as shown in Figs. 1 and 2 were stable and reproducible. Potential readings, taken after leaving the cell overnight, coincided within ±1 mv. The slight scattering of the points plotted in Figs. 1 and 2 may be attributed to the difficulties always present in high temperature systems: for example, concentration gradient because of thermal convection, small temperature gradients within the melt, the inevitable presence of some oxygen on the surface of the metal, side reaction in the refractory container, and traces of impurity in the electrolyte. However, it is reasonable to assume that the potential values obtained in this investigation are accurate to within ±2 mv. This variation would result in a change of only 0.4 kcal/mole in the free energy values as listed in Table I.

LCAO MO CALCULATIONS ON A SERIES OF NITRILES AND SOME RELATED MOLECULES BY A METHOD OF SELF-CONSISTENT FORMAL CHARGES

J. B. MOFFAT
Department of Chemistry, University of Waterloo, Waterloo, Ontario
Received November 29, 1963

ABSTRACT

A method of self-consistent charges has been applied to an LCAO MO calculation of a series of nitriles and some related molecules. The π-electron bond orders and π-electron densities were calculated for all the molecules considered. The entire calculation was programmed for operation on the IBM 1620 with alterations of the input data for the different molecules. The calculated bond orders yield bond lengths for C—C and C=C bonds in good agreement with experimental data, except when two or more triple bonds are present in the molecule. By the assumption of additivity of the bond orders obtained for the two orthogonal pi-electron systems, bond orders are obtained which yield bond lengths in satisfactory agreement with the experimental results for all CC bonds. For the nitrile bonds the calculated bond orders were fitted to a linear equation with the experimental bond lengths.

INTRODUCTION

It is now well known that the simple LCAO MO method with Huckel approximations yields results for aromatic molecules containing carbon only which are in general in good agreement with experimental data. In the simple LCAO MO method as applied to molecules containing atoms in addition to carbon, data such as electronegativities and effective nuclear charges may be introduced. Such data is usually that obtained for the uncombined atoms. When calculations are then pursued which have the effect of mathematically combining the atoms to form molecules, perturbations of a given atom will occur as a result of the presence of other atoms bonded to it. It is then no longer legitimate to employ the data for the uncombined atoms. In the present work an attempt has been made to allow for such perturbations which will be particularly important where heteroatoms are present in the molecule. In the present calculations the pi-electron density (formal charge) obtained is used to provide "perturbed" values of the Slater nuclear charge and the electronegativity. The calculation is then repeated with these new values included and the pi-electron density again obtained. This process is repeated until a self-consistent pi-electron density is obtained. In the present work, for convenience of programming the calculations, values of the bond orders rather than the pi-electron densities were tested by the computer for self-consistency.

In recent years increased attention has been given to the application of the simple LCAO MO method to heteroatomic molecules. However, as has been pointed out (1), little work has been done on the application of molecular orbital methods to nitriles. Penfold and Lipscomb (2) have carried out some calculations on tetracyanoethylene and 1,1-diamino-2,2-dicyanoethylene in connection with their crystallographic studies. Peacock and Wilkenson have done LCAO MO SCF calculations on benzonitrile (3). As Penfold and Lipscomb point out, reliable estimates of pi-bond orders in nitrile molecules would be most valuable.

Lofthus (4) has considered the values of parameters appropriate for use in molecular orbital calculations on various molecules containing nitrogen and has prepared a bond length:bond order plot for CN bonds. However, the curve for bond order greater than two

is fixed by only one point, namely that obtained by assuming that the bond order for the CN bond in hydrogen cyanide is three.

It therefore seemed worthwhile to attempt to apply the self-consistent method mentioned above to a series of nitrile molecules to determine if bond orders yielding bond lengths in agreement with experimental bond lengths could be obtained. For purposes of comparison, some related molecules have also been considered.

METHOD OF CALCULATION

The method employed here is similar to that suggested by Nagakura (5), and subsequently employed by Brown (6), Orville-Thomas and Jones (7), and Morris and Orville-Thomas (8). However, in the present work, an attempt was made to set up a computer program which could be employed for all "linear" molecules without adjustments, except in the input data.

The program requires the following input data: (1) electronegativities of the atoms, (2) number of atoms in the molecules, (3) experimental bond lengths, (4) value of the overlap integral for the CC bond, (5) effective nuclear charge on the atoms, (6) values of constants in relations for electronegativity and effective nuclear charge. The entire program was set up for operation on an IBM 1620 computer.

The present work considers the π-electron system only and assumes that any interaction with the σ-electron system may be neglected. In the calculation, molecular orbitals are assumed to be capable of representation as a linear combination of atomic orbitals (9)

$$\Psi_r = \sum_i C_{ir}\phi_i \qquad [1]$$

This relation is subsequently introduced into the stationary state form of the Schrodinger equation

$$\hat{H}\Psi = E\Psi$$

and a set of linear equations, one for each molecular orbital, is obtained. For such a set of linear equations, solutions other than those equal to zero are obtained only if the determinant

$$\begin{vmatrix} \alpha_1 - E & \beta_{12} - ES_{12} & \cdots & \beta_{1n} - ES_{1n} \\ \beta_{21} - ES_{21} & \alpha_2 - E & & \vdots \\ \vdots & & \ddots & \vdots \\ \beta_{n1} - ES_{n1} & \cdots & & \alpha_n - E \end{vmatrix} = 0$$

The Coulomb integrals α_i are $(i|H|i)$, the resonance integrals β_{ij} are $(i|H|j)$, and the overlap integrals S_{ij} are $(i|j)$. The polynomial which results from the expansion of the determinant has n real roots. Hence n values of the energy, E, are obtained, each of which may be associated with one of the molecular orbitals. Of course, according to the variational principle the value of the energy which would be obtained by such a calculation is not the "true" eigenvalue as could in principle be obtained from the Schrodinger equation, but rather an upper bound to such an energy. It follows that the wave functions are approximations to the "true" eigenfunctions.

Throughout the present paper, the resonance integrals β_{ij} are taken to be zero, for $j-i > 1$. That is, for atoms which are not nearest neighbors, β_{ij} is assumed to be negligible. On the basis of the exponential decay of the wave functions with distance from the nucleus,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

this seems intuitively correct. In addition the overlap integrals, S_{ij}, where $i \neq j$, are neglected in the so-called secular determinant. This is done so here primarily for mathematical convenience. Although this appears to be a poor approximation at best, it can be shown that this assumption amounts to the introduction of orthogonal atomic orbitals.

For the heteroatoms it is assumed that the Coulomb integral may be written as

$$\alpha_i = \alpha_c + \delta_i \beta_{cc}$$

where β_{cc} is the resonance integral for the CC bond in benzene, α_c is the Coulomb integral for a benzene carbon atom and δ_i is related to the electronegativity of the ith atom. This relation is equivalent to representing the Coulomb integral of the ith atom as a perturbation of that of the carbon atom in benzene with such a change being expressed in units of β_{cc}.

For the purposes of the computer programming, each term in the determinant is divided by β_{cc}. Diagonal terms for a heteroatom then become, by making use of the above substitutions,

$$(\alpha_c - E)/\beta_{cc} + \delta_i$$

or

$$x + \delta_i$$

It is assumed that the Coulomb integral is proportional to the electronegativity (10) so that for a heteroatom such as nitrogen

$$\alpha_i = (\chi_i/\chi_c)\alpha_c.$$

This is equivalent to

$$\begin{aligned} \alpha_i &= \alpha_c + [(\chi_i/\chi_c) - 1]\alpha_c, \\ &= \alpha_c + 4.1\beta_{cc}[(\chi_i/\chi_c) - 1], \end{aligned}$$

where $\alpha_c = 4.1\ \beta_{cc}$ (ref. 11).

Hence

$$\delta_i = 4.1[(\chi_i/\chi_c) - 1].$$

Further it is assumed that the resonance integral is proportional to the overlap integral (12), so that

$$\begin{aligned} \beta_{ij} &= (S_{ij}/S_{cc})\ \beta_{cc}, \\ &= \gamma_{ij}\beta_{cc} \end{aligned}$$

where S_{cc} is the overlap integral for the CC bond in benzene. The off-diagonal terms in the determinant then become γ_{ij}.

The same functional relationships are used for carbon atoms, so that

$$\delta_c' = 4.1[(\chi_c'/\chi_c) - 1]$$

and

$$\beta_{cc}' = (S_{cc}'/S_{cc})\ \beta_{cc}$$

where χ_c is the electronegativity of the uncombined carbon atom and S_{cc} is as defined previously. χ_c' and S_{cc}' are allowed to vary.

The assumptions of the proportionality of the Coulomb integral to the electronegativity, and of the resonance integral to the overlap integral appear to be not unreasonable. The Coulomb integral is related to the density of electrons near the core of the ith atom, which is in turn related to the electronegativity of the ith atom. Both the resonance and overlap integrals are related to the density of electrons near the cores of the ith and jth

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

atoms. It should be pointed out that, whereas in the case of the secular determinant the overlap integrals were taken to be zero, for the purposes of determining the resonance integrals, the overlap integrals are now assumed to be non-zero.

The "secular determinant" is now obtained in the reduced form

$$\begin{vmatrix} x_1+\delta_1 & \gamma_{12} & \cdots & \cdots & 0 \\ \gamma_{12} & x_2+\delta_2 & \ddots & & \vdots \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ \vdots & \vdots & & \ddots & \gamma_{n-1,n} \\ 0 & 0 & \cdots & \gamma_{n-1,n} & x_n+\delta_n \end{vmatrix} = 0$$

The computer is programmed to calculate first values of δ_i for each of the carbon, nitrogen, or oxygen atoms in the molecule by employing the initial values of the electronegativity given in the input data. The initial value of δ_c is just 0.

The values of the overlap integrals are calculated from the interatomic distances and the Slater effective nuclear charges (13, 14) by using the equations obtained by Mulliken (15). As has been mentioned, values of the observed interatomic distances and initial values of the Slater charges are contained in the input data. With these values, Mulliken's p and t are calculated within the machine and then are introduced into the appropriate equations for the overlap integrals. A check statement is included to test for the size of t in order that the appropriate relation may be used. These calculated values for the overlap integral are then used with the value of the overlap integral for the CC bond to calculate γ_{ij} values for each of the carbon, nitrogen, and oxygen atoms in the molecule. Of course, the initial value of γ_{cc} is 1.

With these values the secular determinant is transformed to the corresponding polynomial in x. The roots of this equation are obtained by employing the recursion formula of Laguerre as suggested by Pritchard and Sumner (16). The program is set up so that any desired starting value from which the machine may commence to look for roots may be fed into the computer as input data. In practice it was found convenient to insert the value -10.000000. The last two roots are found by solution of the appropriate quadratic equation. The roots are then ordered beginning with the largest negative root first and terminating with the largest positive root.

The eigenvectors are found by the Richardson method (17). If one introduces the value found for the x_1 into the secular determinant and then operates on the resulting determinant with the column matrix composed of the atomic orbital coefficients appropriate to the molecular orbital with that particular value of x, then this product should vanish. Hence if one considers any column matrix or vector as a linear combination of such vectors then on multiplying it by the secular determinant (with x_i introduced), the ith component will be made to vanish. This process may be continued until only one component of the vector remains. This component may then be reintroduced into the start of the process and the calculation continued until repetition of the operation does not alter this component to any assigned degree. The whole operation is then repeated with another value of x_i until all the atomic orbital coefficients have been obtained. In the present programme the initial vector was taken to have all components equal to one. The atomic orbital coefficients so obtained were normalized before further calculations were carried out.

The values of the atomic orbital coefficients so obtained were then employed to calculate mobile π-electron bond orders and π-electron charge densities.

The π-electron bond order, p_{rs}, for the bond between the r atom and the s atom, is defined as

$$p_{rs} = 2\sum_j C_{jr}C_{js}$$

where the sum is over the j occupied molecular orbitals. The π-electron charge density on the atom r in the ground state is defined as

$$q_r = 2\sum_j C_{jr}C_{jr}.$$

The calculated bond orders were then compared, within the computer, with those calculated in the previous iteration, or in the case of the first iteration with fictitious values (4.5) which were read into the computer at the start of the programme. If the sum of the differences is greater than 0.001, the computer is asked to continue, otherwise it is directed to print the answers, and stop.

In the event that the computer is asked to continue, new values of the Slater function and the electronegativity are determined from the calculated π-electron charges. Slater's rules (13, 14) for obtaining the effective nuclear charge on a given atom are used to relate the Slater nuclear charge to a function of the π-electron density:

$$u_i = u_i' - 0.175\, Q_i$$

where u_i is the value of the Slater function to be used in the next iteration step, u_i' is the appropriate constant for each atom calculated by Slater's method, and Q_i is the π-electron density of the ith atom. This is, of course, equivalent to the assertion that the effective nuclear charge, or the charge on the atom as "seen" by an electron approaching it, will depend on the number of electrons shielding the positively charged nucleus.

Values of the electronegativity adjusted for the π-electron densities are obtained by making use of Pauling's definition of electronegativity. Kurito (18) has obtained a relation from such a definition. This relation is used to obtain an equation,

$$\chi_i = \chi_i' - \tfrac{1}{3}Q_i$$

where χ is the electronegativity on the ith atom adjusted for the π-electron density Q_i, and χ_i' is a constant for the ith atom which contains the value of the "unperturbed electronegativity". Values of u_i' and χ_i' are contained in the input data.

With these adjusted values of the electronegativity and Slater functions, the computer is directed to the start of the program where the entire computation is repeated with these new values. The iterative steps are repeated until the requirements on the bond orders previously mentioned have been satisfied. In practice about 10 iterations were required to achieve the required degree of self-consistency.

RESULTS AND DISCUSSION

Table I shows the experimental bond lengths, the calculated mobile bond orders, and the bond lengths calculated from the latter for the CC and the CN bonds in the various molecules studied. The relationship between the pi-bond order (P_{11}) and bond length (R_{11})

$$R_{11} = 1.511 - 0.173\, P_{11}$$

as found for carbon–carbon bonds by Dewar (19) was assumed to be valid for all CC bonds. The bond lengths for CC bonds were calculated from the bond orders by means of this relation. It should be noted that this relation was derived for sp^2–sp^2 CC bonds. However, throughout this paper it is assumed that the bond lengths are independent of

Acetylenedinitrile	1.14	0.896	1.292

the σ-electron structure of the molecule. The bond orders shown in Table I are those obtained by considering "in-plane" orbitals only.

As may be seen from Table I, good agreement between the observed and calculated bond lengths of the carbon–carbon 'single' bonds is obtained in all cases where only one triple bond appears in the molecule. However, in those cases where two or more triple bonds appear in the molecule, and where the carbon–carbon 'single' bond separates at least two of these triple bonds, the observed bond length is much smaller than the calculated value. A semiquantitative hypothesis which appears to explain this discrepancy would suggest that in the latter type of molecule there is some delocalization of pi-electrons across the single bond in each of the in-plane and the out-of-plane orbitals. If it be assumed that these two, presumably mutually perpendicular, sets of orbitals are to a first approximation non-interacting one with the other, then the shortening of the bond as a result of the pi-electron delocalization should be additive in the two sets of orthogonal orbitals.

On this basis it should be possible to obtain predicted bond lengths in better agreement with the observed values by a simple addition of the bond orders for the single bond, where such bond orders are obtained from the orthogonal pi-electron systems, and where such a single bond is located between triple bonds. This was done for molecules containing such single bonds in Table I and the results shown in Table IV were obtained. The agreement between observed and calculated bond lengths can be seen to be much improved.

Malononitrile	0.670	1.29	0.961
Methyl isocyanide	0.342	1.63	0.941
Methyl cyanoacetylene	0.672	1.23	0.978
Propionitrile	0.674	1.31	0.965
Acetylenedinitrile	0.670	1.21	1.016

To employ the above hypothesis in a consistent manner, the bond orders for the CC 'triple' bonds must also be doubled, since presumably both the in-plane and out-of-plane orbitals will contribute to the contraction of the bond. The bond lengths for the CC 'triple' bonds calculated on the basis of this doubled bond order are also shown in Table IV. An improvement in the agreement between calculated and observed results may again be noted.

For the CN bonds the relation (20) $R_{ij} = 1.478 - 0.208\ P_{ij}$ was initially used for the calculation of bond lengths from bond orders. Examination of the bond lengths calculated for the CN bonds using this equation as found in Table I will indicate a lack of agreement between calculated and experimental values. The bond lengths calculated using this same relation but with doubled bond orders to allow for the in-plane and out-of-plane orbitals are shown for the CN bond in column (1) of Table IV. Although the agreement between calculated and experimental bond lengths has been improved, substantial differences still exist.

It may be argued that changes in the ratio of pi-electron densities of the nitrogen and carbon atoms as one passes from the CN 'double' bond to the CN 'triple' bond may preclude the use of a single relation between bond length and bond order for these two types of bonds. Conveniently, Julg (21) has provided an equation involving the effective charges, Z,

$$R_{ij} = \sqrt{\{3.25/[\tfrac{1}{2}(Z_i+Z_j)]\}}\ (1.52-0.19\ P_{ij})$$

CN bond lengths calculated using this relation are shown in column (2) of Table IV.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Double bond orders were again employed. The values of Z_C and Z_N for each molecule were calculated from the pi-electron densities given in Table III. It may be seen that in most cases satisfactory agreement between calculated and observed bond lengths is obtained with the Julg relation.

TABLE III

Pi-electron densities

Molecule	Framework	Pi-electron density					
		C_1	C_2	C_3	C_4	N_1	N_2
Vinyl cyanide	$C_1C_2C_3N_1$	0.842	0.970	0.815		1.37

Acetylenedinitrile	$N_1C_1C_2C_3C_4N_2$	0.772	0.941	0.941	0.772	1.29	1.29

It was thought to be of interest to find the linear relationship between bond order and bond length giving the best fit of the calculated and observed data for the cyano group. Such an equation was found to be

$$R_{ij} = 1.478 - 0.183\ P_{ij}$$

where the constant was assumed to be the same as that employed in the Miller relation. The bond lengths calculated using this fitted relation are given in column (3) of Table IV.

TABLE IV

Revised bond lengths from mobile bond orders

Calculated values of the parameters are shown in Table II. The values of δ_N and γ_{CN} are 1.2 ± 0.1 and 1.0 ± 0.05 respectively. It is interesting to note that Fraenkel adopted the values 1.0 and 2.0 respectively for these parameters for the nitriles which he studied. Table V gives a summary of the data on bond lengths and the source of the values which have been used in the present work.

TABLE V

Sources of bond length data

Molecule	Bond C=C	Bond C—C	Bond C≡N	Bond C≡C	Reference
Vinyl cyanide	1.339	1.426	1.164		22
Methyl cyanide		1.4582	1.1572		23
Cyanoacetylene		1.378	1.157	1.205	24
Cyanogen		1.371	1.127		25
Vinylacetylene	1.335	1.430		1.206	26

Methyl isocyanide			1.166		29
Methyl cyanoacetylene		1.454 1.375		1.205	30
Propionitrile		1.5479 1.4735	1.1566		31
Acetylenedinitrile		1.37	1.14	1.19	32

The method employed in this work appears to yield reliable values for bond order and pi-electron densities for the compounds considered provided the assumption of additivity of bond order under the conditions described in this work is employed. However, the existence of a systematic variation of bond length of CN 'triple' bonds remains in doubt. Further work is necessary to provide support for any bond order:bond length relationship which is to be applied to the nitrile group.

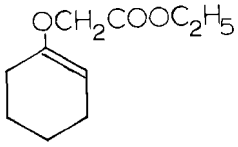
β-KETO ESTERS FROM REACTION OF ETHYL DIAZOACETATE WITH KETONES

W. T. TAI AND E. W. WARNHOFF[1]
Department of Chemistry, University of Western Ontario, London, Ontario
Received January 16, 1964

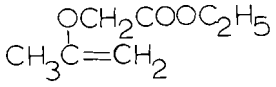
ABSTRACT

The Lewis acid catalyzed reaction of diazoacetic ester with ketones has been extended. Convenient conditions have been found for the preparation of some pure β-keto esters in fair to good yields by reaction of ethyl diazoacetate with ketones in the presence of boron trifluoride at −40° to −70°. The reaction is apparently general since cyclopentanone, cyclohexanone, and acetophenone gave nearly pure β-keto esters in 44%, 79%, and 38% yields, respectively, based on diazoacetic ester. In the case of acetophenone the phenyl group migrated. Acetone gave 78% of a mixture of β-keto ester and glycidic ester.

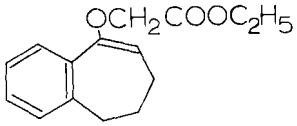
Although diazomethane and its alkyl derivatives have served extensively in the homologation of aldehydes and ketones (1), the closely related, but more sluggish, ethyl diazoacetate has been less useful. Several aldehydes bearing electronegative substituents have been reported to yield β-keto esters and (or) glycidic esters with this reagent (2, 3, 4). However, in the few cases studied, ketones and diazoacetic ester in the absence of a Lewis acid catalyst have given enol ethers as the product isolated and no noticeable amount of β-keto ester. Thus, cyclohexanone at 95° in the presence of copper gave 43% of I, and acetone at 93° in the presence of copper gave 23% of II (5). While neither ketone reacted below 120° in the absence of copper, at higher temperatures the same major product was formed as in the copper-catalyzed reactions. Finally, benzosuberone at 120° in the presence of copper gave 50% of III (6). To explain the formation of enol ethers it has been suggested (6) that diazoacetic ester may decompose in the presence of copper or at high temperatures to carbethoxycarbene which could react with the ketone to give the observed product.



I



II

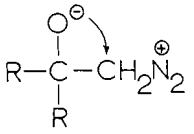


III

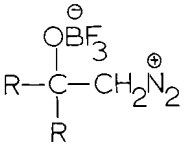
Recent work on catalysis of the reactions of ketones with diazoalkanes (7, 8) has revealed means of overcoming the relative inertness of diazoacetic ester and avoiding the formation of enol ethers. While the catalytic action of water and alcohols on the reactions of diazomethane has long been known, it has lately been observed that the catalytic action of boron trifluoride and other Lewis acids is more profound, even altering the course of reaction. Methyl *t*-butyl ketone gave no measurable reaction with diazomethane in methanol at room temperature, but in the presence of boron fluoride etherate at 0° it produced a mixture of homologous ketones and oxide (7). Normally, α,β-unsaturated

[1]*Fellow of the Alfred P. Sloan Foundation.*

ketones and diazomethane give pyrazoline derivatives or else no reaction (1). Δ^4-Cholesten-3-one was found not to react with diazomethane except in the presence of boron trifluoride or fluoboric acid when the homologous ketone was formed (9). Mesityl oxide and benzalacetone with diazomethane each gave a Δ^2-pyrazoline in the absence of a catalyst, but in the presence of the above two catalysts the only products were those of ketone homologation (7, 9). It was also noted that oxide formation was suppressed in the boron trifluoride catalyzed reaction of ketones with diazomethane (7). This result was tentatively ascribed to the decrease in importance of intermediates such as IV with a more nucleophilic alkoxide ion in favor of intermediates such as V with a less nucleophilic



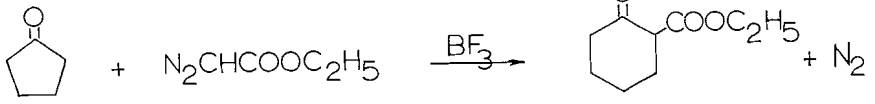
IV



V

complexed oxygen, thus diminishing oxide formation (assumed to occur by nucleophilic displacement of nitrogen) relative to rearrangement. In fact, the two examples of diazoacetic ester and a ketone not giving an enol ether but instead a β-keto ester are the aluminum chloride catalyzed reaction with cycloöctanone which gave the β-keto ester of unspecified purity (8), and the zinc chloride catalyzed reaction with 1,3-cyclohexanedione mono ethylene ketal, which gave 3,3-ethylenedioxy-7-carbethoxycylcoheptanone (21). Since the extension of this reaction could be a convenient synthesis of β-keto esters isotopically labelled on the α-carbon atom which were required for another study, the reaction of ethyl diazoacetate with ketones was examined with cyclopentanone as the model compound.

Several preliminary experiments agreed with previous conclusions. When cyclopentanone and diazoacetic ester were heated in the absence of solvent and catalyst, no nitrogen evolution occurred until 130–150°, and the mixture of products contained no β-keto ester (gas–liquid chromatography and negative ferric chloride test). With refluxing methanol as solvent and catalyst no nitrogen was liberated. On substitution of the higher boiling *n*-amyl alcohol (b.p. 138°) as solvent 86% of the theoretical amount of nitrogen was collected, but the mixture of products contained no β-keto ester (gas–liquid chromatography and a negative ferric chloride test). However, in the presence of boron trifluoride, cyclopentanone and ethyl diazoacetate rapidly evolved nitrogen at room temperature, and the mixture of products gave a positive ferric chloride test. With an excess of cyclopentanone at 0°, a 19% yield of 2-carbethoxycyclohexanone (VI) was separated from other products. There was also considerable (>10%) formation of VII



VI

by boron fluoride catalyzed self-condensation of cyclopentanone. This side reaction and others were largely eliminated by lowering the reaction temperature. Subsequent systematic variations of the reaction conditions are summarized in Table I.

TABLE I

Reaction	Moles DAE*	Moles  rel. to DAE*	Moles $BF_3.Et_2O$ rel. to DAE*	Solvent	Reaction temp., ° C	Time for DAE addn. (minutes)	% N_2 evolved	Yield VI (%)

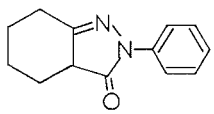
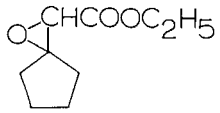
VII



VIII



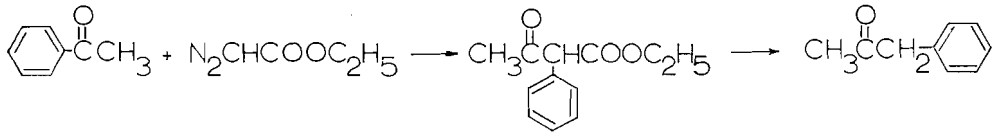
IX

The best results were obtained by the addition of ethyl diazoacetate to a threefold excess of 1:1 ketone:boron trifluoride mixture kept at −40° to −70°. Nitrogen evolution was rapid and almost quantitative.* Distillation of the crude product gave, after removal of excess cyclopentanone, reproducible 42–44% yields of almost pure 2-carbethoxycyclohexanone. There was present a small amount of an impurity which could be removed by fractional distillation. The identity and purity of the product were assured by a violet ferric chloride test, elemental analysis, comparison of the infrared spectrum, and gas–liquid chromatographic behavior with those of an authentic sample, and preparation of the known phenylpyrazolone VIII. The remainder of the diazoacetic ester was transformed into polymeric residue which incorporated cyclopentane groups and was not investigated further. That there was no glycidic ester IX in the once distilled product was demonstrated by comparison with the infrared and n.m.r. spectra of an authentic sample of IX. Nor did the 2-carbethoxycyclohexanone arise by Lewis acid catalyzed rearrangement of initially formed glycidic ester, because authentic IX, when subjected to the reaction conditions, gave a mixture of products containing not more than about 5%, if any, of β-keto ester VI. In addition, the other reaction products from IX would have

*In the absence of a ketone, diazoacetic ester evolved nitrogen only very slowly in the presence of boron trifluoride at −40° to −70°.

appeared in the diazoacetic ester product VI. In contrast to the uncatalyzed diazoacetic ester reactions, there was no evidence of formation of any enol ether analogous to I. Aluminum chloride is a somewhat less effective catalyst. Its substitution for boron trifluoride gave no nitrogen evolution until the reaction temperature was raised to −20°, and the yield of product was only 25%.

The low-temperature boron trifluoride catalyzed reaction is apparently general, since, under the best conditions found for cyclopentanone, other ketones gave fair to good yields of β-keto esters. Cyclohexanone gave 79% of 2-carbethoxycycloheptanone after separation from a small amount of a second product. This β-keto ester was identified from its infrared spectrum, a violet ferric chloride test, and the preparation of the known phenylpyrazolone. In the reaction between acetophenone and diazoacetic ester only the phenyl group migrated to afford in 38% yield ethyl α-phenylacetoacetate. The structure was proved by hydrolysis and decarboxylation to phenylacetone, which could not have



contained more than 2% of propiophenone. From acetone and diazoacetic ester was obtained 78% of a product which was recognized to be a mixture of ethyl α-methylacetoacetate and ethyl β,β-dimethylglycidate in the ratio 5:4 by infrared and n.m.r. spectral comparison of the product with authentic samples. Therefore, boron trifluoride does not always completely suppress oxide formation in this reaction. For those cases where oxide formation is negligible, the yields and convenience are such that the reaction should constitute an acceptable alternative method for preparation of β-keto esters.

EXPERIMENTAL

General

Melting points were taken on a Reichert microscope hot stage unless otherwise stated and are corrected. Infrared spectra were recorded with a Beckman IR-5 spectrophotometer. Only the principal sharply defined peaks are listed. Nuclear magnetic resonance spectra were determined in *carbon tetrachloride* solution on a Varian HR-60 spectrometer and were calibrated by the audio side band technique. Peak positions are given in p.p.m. from the tetramethylsilane peak (=0). The 1-m and 20-cm Nestor and Faust spinning band columns had efficiencies of 9 and 6 theoretical plates, respectively, at total reflux at atmospheric pressure. Petroleum ether refers to the fraction boiling at 60–80°. Microanalyses were by Dr. A. Bernhardt, Mulheim, Germany. Yields of β-keto esters are based on ethyl diazoacetate. For gas–liquid chromatography a Wilkens Aerograph, Model 350 B, was used with ¼ inch O.D. columns of (*a*) 10% Carbowax 20 M, or (*b*) 20–30% Dow Silicone 710, or (*c*) 3% UCON polar, each on 60–80 mesh Johns Manville Firebrick. Gas–liquid chromatography was not very useful with the β-keto esters in the present work. In some cases there were apparently peaks corresponding to keto and enol forms; the relative intensity of the two peaks varied with temperature and flow rate. In other cases decomposition occurred during chromatography. The n.m.r. spectrum was a more reliable criterion of purity.

Reagents

Ethyl diazoacetate was prepared by diazotization of ethyl glycinate according to the directions in Organic Syntheses (10).

Cyclopentanone (B.D.H.), cyclohexanone (B.D.H.), acetophenone, phenylacetone (E.K.C.), and propiophenone (E.K.C.) were redistilled if necessary. In each case the material used gave a single peak on gas–liquid chromatography.

Boron trifluoride etherate (M.C.B.) was redistilled.

Authentic 2-carbethoxycyclohexanone was prepared by the procedure in Organic Syntheses (11).

Ethyl α-methylacetoacetate (Aldrich) was fractionally distilled at reduced pressure.

Ethyl β,β-dimethylglycidate was prepared in 48% yield by condensation of acetone and ethyl chloroacetate according to the procedure of Rutowski and Dajew (19).

Reaction of Cyclopentanone and Ethyl Diazoacetate

(*a*) Cyclopentanone (30 g, 0.35 mole) was cooled to −40° by means of a Dry Ice – acetone bath and 50.7 g (0.35 mole) of redistilled boron trifluoride etherate was added at this temperature with mechanical stirring. Ether (10 ml, reagent grade) was added to prevent the mixture from solidifying. A solution of 13.6 g (0.12 mole) of ethyl diazoacetate in 30 ml of reagent grade ether was added dropwise with stirring over a period of 20 minutes while the temperature was maintained at −40° to −55°. Evolution of nitrogen was instantaneous and 2710 ml (93%) were collected. After addition was complete the cooling bath was removed and the stirring continued for 10 minutes.

The reaction mixture was diluted with ether and washed with saturated aqueous sodium chloride solution until the washings were neutral to litmus paper. The ethereal solution was dried over magnesium sulphate, filtered, and distilled through a 10-cm Claisen head. After removal of ether at atmospheric pressure, distillation gave recovered cyclopentanone, 13.9 g (46%), b.p. 57–62° (50 mm), followed by *2-carbethoxycyclohexanone* (VI), 8.9 g (44% based on diazoacetic ester), b.p. 110-112° (12 mm). The n.m.r. spectrum and gas–liquid chromatography on the UCON column (150 cm, t = 150°, pressure 30 p.s.i.g. He, 3 ml/second) revealed the pressure of ca. 9% of an impurity of retention time 19 minutes whereas VI had a retention time of 12 minutes. This impurity was removed by fractional distillation of the keto ester through a 1-m Nester and Faust spinning band column. The fraction boiling at 83–84° (3.0 mm) (lit. (12): b.p. 106–107° at 11 mm) was pure 2-carbethoxycyclohexanone whose infrared spectrum was identical with that of an authentic sample. R_f 0.70 (silica gel; ethyl acetate:petroleum ether, 50:50). The keto ester gave a deep violet ferric chloride test.

Anal. Calc. for $C_9H_{14}O_3$ (170.20): C, 63.51; H, 8.29. Found: C, 63.43; H, 8.46.

Infrared spectrum: $\nu_{max}^{CCl_4}$ 1745 (ester C=O)(m), 1721 (ketone C=O)(m), 1658 (ester C=O of enol)(s), 1618 (s), 1300 (s), 1261 (s), 1221 (s), 1179 (s), 1085 (s), and 1010 cm^{-1} (m).

The n.m.r. spectrum: δ = 1.27 p.p.m. (3H triplet, J=7 c.p.s., CH_3—[CH_2]); 1.63 p.p.m. (broad peak, ring CH_2); 2.20 p.p.m. (broad peak, CH_2—C=O, CH_2—C=C); 3.27 p.p.m. (broad peak, O=C—CH—C=O); 4.17 p.p.m. (2H quartet, J=7 c.p.s., O—CH_2—[CH_3]); 12.07 p.p.m. (1H singlet, chelated enolic OH).

The β-keto ester was shown to be stable under the reaction conditions by treatment of a 2:1 mixture of cyclopentanone and VI (5.10 g) with boron trifluoride etherate at −60° to −70° for 15 minutes. Work-up and distillation gave back 3.70 g (72%) of VI.

(*b*) From a similar reaction carried out at −2° to 2° there was distilled 19% of 2-carbethoxycyclohexanone followed by a high boiling (130–193° at 0.3 mm) oil that solidified. The solid was recrystallized twice from methanol to give colorless needles of *tris*-cyclopentenobenzene, m.p. 95–96° (lit.(13): m.p. 96–97°), ν_{max}^{melt} 2950 (C—H)(s), 2833 (C—H)(s), 1447 (methylene)(m), and 1425 cm^{-1}(w). The compound did not discolor permanganate solution.

The n.m.r. spectrum: δ = 2.07 p.p.m. (6H multiplet, non-benzylic CH_2); 2.73 p.p.m. (12H multiplet, benzylic CH_2).

(*c*) From a reaction of 13.6 g (0.119 mole) of diazoacetic ester in 200 ml of ether with a mixture of 30 g (0.35 mole) of cyclopentanone and 47.5 g (0.35 mole) of anhydrous aluminum chloride in 50 ml of ether at −20° to −4° there was isolated by distillation 5.15 g (25%) of not quite pure VI.

1-Phenylpyrazolone of Cyclopentanone–Diazoacetic Ester Product

To a solution of 0.85 g (5.9 mmoles) of phenylhydrazine hydrochloride and 1.2 g (14 mmoles) of anhydrous sodium acetate in 10 ml of water was added 1.00 g (5.88 mmoles) of the cyclopentanone – diazoacetic ester product. Sufficient ethanol was added to give a clear solution which was refluxed for 2.5 hours. The cooled solution deposited crystals which were filtered. Concentration of the filtrate gave a second crop from which a brown color was removed by washing with ether. The total yield of crude product, m.p. 172–180°, was 1.03 g (81%). Two recrystallizations from absolute ethanol gave colorless scales of VIII, m.p. 180–181°.

Anal. Calc. for $C_{13}H_{14}ON_2$ (214.26): C, 72.87; H, 6.59. Found: C, 72.79; H, 6.37.

The melting point and appearance of the crystals gradually changed over a period of several weeks to colorless needles, m.p. 163–165° (lit.(12): m.p. 165°) without any change in the infrared spectrum. The melting point of an authentic sample prepared from authentic VI behaved in the same way.

Infrared spectrum: $\nu_{max}^{CHCl_3}$ 1709 (s) (γ-lactam C=O and C=N), 1597 (s), 1379 (s), 1335 (s), 1312 (m), 1152 (m), and 1136 cm^{-1} (m); ν_{max}^{Nujol} 755 (s) and 690 cm^{-1} (s). The last two peaks are from monosubstituted phenyl.

Ethyl β,β-Tetramethyleneglycidate

A literature procedure (14) for cyclohexanone was adapted. A mixture of 16.8 g (0.20 mole) of cyclopentanone and 24.5 g (0.20 mole) of ethyl chloroacetate was cooled to −75° while the powdered sodium ethoxide from 4.6 g (0.20 g-atom) of sodium was added in small portions. After 10 minutes the mixture was allowed to come to room temperature and stand for several hours. The reaction mixture was then heated at 120–140° for 2.5 hours, poured into ice water, and extracted with ether. The combined ether extracts were washed with water, dried, and distilled through a 10-cm Claisen head. After a forerun, the glycidic ester, 8.9 g (26%) distilled as a colorless liquid, b.p. 88–94° at 3 mm. The product was fractionally distilled through a 20-cm Nestor and Faust spinning band column to give 5.97 g of IX, b.p. 92–94° (3.2 mm) (lit. (15): b.p.

90–95° at 3–4 mm). The glycidic ester decomposed during gas–liquid chromatography. Thin-layer chromatography (silica gel; ethyl acetate:petroleum ether, 50:50) gave a main spot, R_f 0.60, and very faint traces of impurities at R_f 0.32, 0.25, and 0.13 which were visible only under ultraviolet light and did not char.

Infrared spectrum: $\nu_{max}^{CCl_4}$ 1761 (s) and 1733 (s) (ester C=O), 1425 (m), 1372 (w), 1339 (w), 1284 (s), 1188 (s), and 1040 cm^{-1} (s). The doublet carbonyl peak probably results from different conformers of IX in solution; it is not caused by an impurity in view of the unambiguous n.m.r. spectrum of the same sample.

The n.m.r. spectrum: δ = 1.28 p.p.m. (3H triplet, J=7 c.p.s., CH_3—[CH_2]); 1.76 p.p.m. (8H apparent singlet, cyclopentane CH_2); 3.37 p.p.m. (1H singlet, O—CH—C=O); 4.17 p.p.m. (2H quartet, J=7 c.p.s. O—CH_2—[CH_3]).

Reaction of Ethyl β,β-Tetramethyleneglycidate with Boron Trifluoride

The glycidic ester IX (4.25 g, 0.025 mole) in 25 ml of reagent grade ether was cooled to −65° and redistilled boron trifluoride etherate (3.55 g, 0.025 mole) was added with stirring (magnetic bar). The temperature was kept at −65° to −55° for 20 minutes and then at −10° for 10 minutes.

The reaction was worked up as for the acetophenone – diazoacetic ester reaction. Evaporation of the ether left 4.2 g of colorless liquid whose infrared spectrum had strong hydroxyl absorption and was quite different from that of the starting material and VI. In particular, the distilled product had none of the strong infrared peaks at 1658, 1618, 1300, 1261, and 1221 cm^{-1} which appear in the spectrum of 2-carbethoxycyclohexanone. Thin-layer chromatography (silica gel; ethyl acetate:petroleum ether, 50:50) gave several spots, R_f 0.61, 0.52, 0.22, 0.10, and 0.03.

Reaction of Cyclohexanone and Ethyl Diazoacetate

A solution of 35.0 g (0.35 mole) of cylcohexanone in 20 ml of reagent grade ether was maintained at a temperature of −45° to −55° while 50.7 g (0.36 mole) of freshly distilled boron trifluoride etherate was added. Then a solution of 13.6 g (0.119 mole) of ethyl diazoacetate in 30 ml of reagent grade ether was added during 22 minutes with the temperature kept at −55° to −40°. The nitrogen evolved amounted to 3010 ml (98%).

The reaction mixture was worked up as for the cyclopentanone reaction. Distillation of the product through a 10-cm Claisen head gave 16.7 g (47%) of recovered cyclohexanone, b.p. 79–81.5° (60 mm), followed by 17.3 g (79%) of *2-carbethoxycycloheptanone*, b.p. 103–109° (3.3 mm) (lit. (16): b.p. 125–126° at 12 mm). Fractional distillation through a 20-cm Nestor and Faust spinning band column gave pure β-keto ester, b.p. 76–79° (1 mm), which produced a violet color with ferric chloride solution.

Anal. Calc. for $C_{10}H_{16}O_3$ (184.23): C, 65.19; H, 8.75. Found: C, 65.11; H, 8.66.

Infrared spectrum: $\nu_{max}^{CCl_4}$ 1748 (ester C=O)(m), 1715 (ketone C=O)(m), 1645 (ester C=O of enol)(s), 1616 (s), 1456 (m), 1404 (m), 1312 (s), 1242 (s), 1217 (s), 1200 (m), 1054 (s), and 975 cm^{-1} (w).

The n.m.r. spectrum: δ = 1.24 (1.29) p.p.m. (3H "doubled" triplet, J=7 c.p.s. for each triplet, CH_3—[CH_2]); 1.70 p.p.m. (broad peak, ring CH_2); 2.46 p.p.m. (broad peak, CH_2—C=O and CH_2—C=C), 3.31–3.53 p.p.m. (broad peak, O=C—CH—C=O); 4.12 (4.19) p.p.m. (2H "doubled" quartet, J=7 c.p.s. for each quartet, O—CH_2—[CH_3]); 12.64 p.p.m. (1H singlet, chelated enolic OH). The "doubling" of the methyl and oxymethylene proton groups is presumably due to slight differences in chemical shift of these groups in the enolic and non-enolic tautomers.

1-Phenylpyrazolone of Cyclohexanone – Diazoacetic Ester Product

The same procedure employed for the cyclopentanone adduct was used to prepare a derivative from 1.00 g (5.43 mmoles) of cyclohexanone–diazoacetic ester product, 0.797 g (5.50 mmoles) of phenylhydrazine hydrochloride, and 0.451 g (5.50 mmoles) of anhydrous sodium acetate in 7 ml of water. The crude product after filtration and drying amounted to 1.105 g (89%), m.p. 200–210°. Three recrystallizations from absolute ethanol gave colorless scales of the pyrazolone, m.p. 210–212° (lit. (17): m.p. 210°).

Infrared spectrum: $\nu_{max}^{CHCl_3}$ 1704 (s) (γ-lactam C=O and C=N), 1645 (m), 1600 (s), 1391 (w), 1340 (m), 1321 (m), and 1116 cm^{-1} (w); ν_{max}^{Nujol} 742 (m) and 690 cm^{-1} (m). The last two peaks are from monosubstituted phenyl.

Reaction of Acetophenone with Ethyl Diazoacetate

A solution of 72 g (0.60 mole) of acetophenone in 700 ml of reagent grade ether was maintained at −60° while 85.2 g (0.60 mole) of redistilled boron trifluoride etherate was added with mechanical stirring. A solution of 22.8 g (0.20 mole) of ethyl diazoacetate in 50 ml of ether was added dropwise at −50° to −30°* during 4 hours. Total nitrogen evolution over a period of 4 hours was 4690 ml (90%).

The reaction mixture was added with vigorous stirring to sodium bicarbonate solution which was then extracted with ether and worked up as for the cyclopentanone reaction. Distillation of the product through a 10-cm Claisen head gave 60.9 g (87%) of recovered acetophenone, b.p. 56–64° (2.8 mm) followed by 15.9 g (38%) of *ethyl α-phenylacetoacetate*, b.p. 120–124° (2.5 mm) (lit. (18): b.p. 145–147° at 11 mm), which gave a violet ferric chloride test. Thin-layer chromatography (silica gel; ethyl acetate:petroleum ether, 85:15) gave a single spot, R_f 0.49. The β-keto ester was fractionally distilled through the 1-m Nestor and Faust spinning band column for analysis and spectra.

**In this reaction evolution of nitrogen was slow at −70° to −50°.*

Anal. Calc. for $C_{12}H_{14}O_3$ (206.23): C, 69.88; H, 6.84. Found: C, 69.78; H, 6.76.

Infrared spectrum: ν_{max}^{film} 1745 (s) (ester C=O), 1721 (s) (ketone C=O), 1642 (s) (ester C=O of enol), 1621 (s), 1401 (w), 1335 (w), 1264 (s), 1225 (s), 1059 (m), 959 (w), 754 (w), 700 (s), and 665 (w).

The n.m.r. spectrum: δ = 1.16 p.p.m. (3H triplet, J=7 c.p.s., CH_3—[CH_2]); 1.80 p.p.m. (3H singlet, CH_3—C(=O)—C=C); 2.12 p.p.m. (3H singlet, CH_3—C=O); 4.14 p.p.m. (2H quartet, J = 7 c.p.s., O—CH_2—[CH_3]); 7.09–7.36 p.p.m. (5H multiplet, aryl H); 13.00 p.p.m. (1H singlet, chelated enolic OH). With better resolution the enolic hydroxyl was a quartet from coupling to the allylic methyl group which was in turn a doublet, $J \sim 0.5$ c.p.s.

Ketonic Cleavage of Acetophenone – Ethyl Diazoacetate Product

The fractionally distilled β-keto ester (6.30 g, 0.030 mole) was heated with 20 ml of 10% aqueous sulphuric acid at 100° for 16 hours at which point the ferric chloride test was negative. The water-insoluble oily layer was extracted with ether. The ethereal solution was washed with dilute sodium bicarbonate solution and with water before being dried over magnesium sulphate. Filtration and distillation of the ether left 3.4 g (83%) of liquid whose infrared spectrum was identical with that of an authentic sample of phenylacetone and quite different from that of authentic propiophenone. Gas–liquid chromatographic comparison (Dow Silicone 710 column, 250 cm, 175°, 50 p.s.i.g., 4.3 ml per second) of the product (retention time 9.6 minutes) with phenylacetone (retention time 9.6 minutes) and propiophenone (retention time 10.8 minutes) also confirmed the identification.

Infrared spectrum (acetophenone + diazoacetic ester product≡phenylacetone): ν_{max}^{film} 1715 (C=O) (s), 1603 (w), 1497 (m), 1456 (m), 1418 (w), 1359 (s), 1230 (m), 1160 (s), 1080 (w), 1033 (w), 730 (s), and 700 cm^{-1} (s) (last two peaks from monosubstituted phenyl).

Infrared spectrum (propiophenone): ν_{max}^{film} 1689 (conjugated C=O) (s), 1600 (m), 1585 (m), 1451 (m), 1416 (w), 1379 (w), 1355 (m), 1222 (s), 1183 (w), 1081 (w), 1016 (m), 1005 (w), 953 (s), 745 (s), and 689 cm^{-1} (s).

The infrared spectrum of a 2% solution (w/w) of propiophenone in phenylacetone gave a definite peak at 953 cm^{-1} from propiophenone. This peak was completely absent from the reaction product. Therefore the phenylacetone from the acetophenone–diazoacetic ester reaction could not have contained as much as 2% of propiophenone.

Reaction of Acetone with Ethyl Diazoacetate

Distilled boron trifluoride etherate (21.3 g, 0.15 mole) was added to 43.5 g (0.75 mole) of reagent grade acetone being stirred (magnetic bar) at −70°. Then 17.1 g (0.15 mole) of ethyl diazoacetate in 75 ml of reagent grade ether was added dropwise at −65° to −60° during 40 minutes. The nitrogen evolved amounted to 3715 ml (93%).

The reaction mixture was added with vigorous stirring to sodium bicarbonate solution and worked up as for the acetophenone reaction. Distillation of the product through a 10-cm Claisen head gave 16.8 g (78%) of colorless liquid, b.p. 73–82° (22 mm). Comparison of the n.m.r. and infrared spectra of the product with those of authentic *ethyl α-methylacetoacetate* and *ethyl β,β-dimethylglycidate* showed the product to be a mixture of these two compounds in the ratio of about 5:4. Fractional distillation of the product through a 1-m Nestor and Faust spinning band column at 22 mm did not separate the mixture.

Repetition of the reaction with a 3:3:1 ratio of acetone:boron trifluoride etherate:diazoacetic ester gave a 63% yield of a mixture of the same two compounds.

Infrared spectrum (ethyl α-methylacetoacetate): $\nu_{max}^{CCl_4}$ 1748 (ester C=O) (s), 1721 (ketone C=O) (s), 1650 (m), 1453 (m), 1245 (s), 1155 (m), 1100 (m), 1078 (w), and 862 cm^{-1} (w).

Infrared spectrum (ethyl β,β-dimethylglycidate): $\nu_{max}^{CCl_4}$ 1757 and 1730 (ester C=O) (s), 1456 (m), 1410 (m), 1381 (m), 1314 (m), 1289 (m), 1255 (w), 1196 (s), 1124 (m), 1112 (m), 1054 (m), and 1037 cm^{-1} (m) (cf. infrared spectrum of ethyl β,β-tetramethyleneglycidate).

The n.m.r. spectrum (ethyl α-methylacetoacetate): δ = 1.25 p.p.m. (3H doublet, J=7 c.p.s., CH_3—C—[H]); 1.26 p.p.m. (3H triplet, J = 7 c.p.s., CH_3–[CH_2]); 2.16 p.p.m. (3H singlet, CH_3—C=O); 3.40 p.p.m. (1H quartet, J = 7 c.p.s.., H—C—(CH_3]); 4.15 p.p.m. (2H quartet, J = 7 c.p.s., O—CH_2—[CH_3]). In addition there were minor peaks from a small amount of the enol tautomer.

The n.m.r. spectrum (ethyl β,β-dimethylglycidate): δ = 1.28 p.p.m. (3H triplet, J = 7 c.p.s., CH_3—[CH_2]); 1.32 p.p.m. and 1.37 p.p.m. (each a 3H singlet, $(CH_3)_2$C(O)—C); 3.14 p.p.m. (1H singlet, C(O)—CH—C=O); 4.17 p.p.m. (2H quartet, J = 7 c.p.s., O(O)—CH_2—[CH_3]).

A 3.00-g sample of the reaction product and a sample of authentic ethyl α-methylacetoacetate were each converted to the pyrazolone by heating with aqueous hydrazine sulphate solution for 11.5 hours. From the authentic sample there was obtained 45% of white prisms of pyrazolone, m.p. 243–263° (cap. uncorr.) (lit. (20): m.p. 268°). From the reaction product the yield was only 35%, m.p. 258–268° (cap. uncorr.).

ACKNOWLEDGMENTS

The financial support of the Alfred P. Sloan Foundation and the National Research Council is gratefully acknowledged. Mr. R. E. Klinck kindly determined most of the n.m.r. spectra.

THE STRUCTURES OF GALACTOSYL-LACTOSE AND GALACTOBIOSYL-LACTOSE PRODUCED FROM LACTOSE BY SPOROBOLOMYCES SINGULARIS[1]

P. A. J. GORIN, J. F. T. SPENCER, AND H. J. PHAFF[2]
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received December 12, 1963

ABSTRACT

Sporobolomyces singularis, when grown in a medium containing lactose, utilized the glucose portion as a carbon source and produced by transglycosylation as main products a trisaccharide *O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 4)-D-glucose (I) and a tetrasaccharide *O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 4)-D-glucose (II) (50% combined yield). Oligosaccharides of higher molecular weight were not detected.

INTRODUCTION

Sporobolomyces singularis was isolated by Phaff and do Carmo-Sousa (1) from frass of bark beetles attacking the western hemlock (*Tsuga heterophylla*). This yeast when grown on yeast nitrogen base, a chemically defined medium (Wickerham (2)), utilized lactose but not galactose. It was shown that the galactosyl moiety, instead of occurring free in the medium, was transferred to another lactose molecule to yield a trisaccharide.

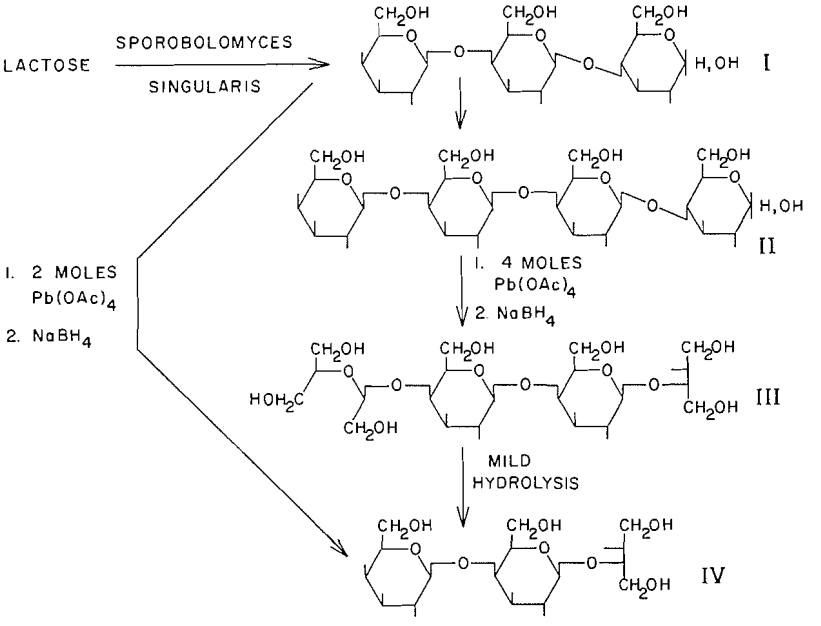
Phaff and do Carmo-Sousa showed that a yeast extract – lactose medium at pH 6 supported a more vigorous growth of the yeast, but did not result in any oligosaccharide formation (3). When the pH of the latter medium was adjusted initially to 3.75 the yield of the trisaccharide increased to substantial levels and a tetrasaccharide appeared. The tetrasaccharide is formed preferentially at pH values slightly higher than that optimal for trisaccharide formation.

The oligosaccharides thus formed were fractionated on a charcoal column to give a crystalline trisaccharide and an amorphous tetrasaccharide. The trisaccharide contained galactose and glucose. The latter was shown to be the reducing end-unit by acid hydrolysis before and after sodium borohydride reduction. Partial hydrolysis yielded 4-*O*-β-D-galactopyranosyl-D-galactose (4) and lactose, but in low yield. The *O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 4)-D-glucose (I) structure indicated by these data was confirmed by conversion to *O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 2)-D-erythritol (IV) by lead tetraacetate oxidation followed by sodium borohydride reduction (5). This material consumed 4 moles of sodium periodate and released 1 mole of acid.

The tetrasaccharide contained galactose and a glucose reducing end-unit, which was linked in the 4-position as shown by its lead tetraacetate oxidation characteristics (6). The oxidation was carried out on a larger scale and the product reduced with sodium borohydride. The resulting polyol appeared to be *O*-D-galactopyranosyl-(1 → 4)-*O*-D-galactopyranosyl-(1 → 4)-*O*-D-galactopyranosyl-(1 → 2)-D-erythritol since it consumed 5 moles of sodium periodate with concomitant formation of 1 mole of acid. Its specific rotation, which was close to that of galactobiosyl erythritol, suggested β-linkages. The identity of two of the three linkages in the tetrasaccharide was confirmed by prolonged oxidation

Canadian Journal of Chemistry. Volume 42 (1964)

[1]*Issued as N.R.C. No. 7869.*
[2]*Department of Food Science and Technology, University of California, Davis, California.*



with lead tetraacetate to give a trialdehyde. This was reduced with sodium borohydride to a polyol (III) which was partly hydrolyzed (7) to *O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 2)-D-erythritol (IV). It was shown that the other linkage in the tetrasaccharide was 1,4 as follows. Oxidation of the galactotriosyl erythritol with periodic acid gave a product which was reduced with sodium borohydride. The polyol was hydrolyzed to erythritol and glycerol, which were compared by gas-phase chromatography as their acetates and shown to be present in equimolar amounts. The tetrasaccharide fraction therefore contained, as a major component, the galactotriosyl glucose structure represented by II.

β-Transglycosyl activity of *Sporobolomyces singularis* under these conditions appears to be quite specific: a galactosyl moiety was transferred to the free 4-hydroxy group of lactose, the predominant sugar in the medium. The trisaccharide thus formed in turn contains a free 4-position which could be substituted with another galactose residue.

The final products have different structures from earlier reactions carried out using β-galactosidases. In general *O*-β-D-galactopyranosyl-(1 → 6)-*O*-β-D-galactopyranosyl-(1 → 4)-D-glucose has been found to be the main product. Pazur and co-workers (8, 9) have isolated this trisaccharide using a yeast lactase preparation. With culture filtrates or cell-free extracts of *P. chrysogenum*, appreciable quantities of this trisaccharide have been prepared by Ballio and Russi (10). When glucose was used as the acceptor, Wallenfels and co-workers (11) have shown with *E. coli* that the 1,6 link is formed in preference to 1,3 and 1,4 links. The only report of preferential synthesis of galactosyl glucoses, other than the 1,6 form has been that of Wallenfels and Fischer (12), who showed that a calf intestine enzyme synthesized 1,3 and 1,4 links rather than the 1,6 link.

The enzyme responsible for the transgalactosylation reaction appears to be associated with the cells. This fact may be responsible for the more quantitative nature of the transgalactosylation reaction in this system than that studied with soluble lactase preparations. Particularly at low pH values, it may be presumed that the galactosyl–enzyme complex,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

formed after one molecule of lactose is cleaved, remains intact until a second molecule of lactose approaches this site. At this stage the galactosyl moiety is transferred to lactose rather than to water. A second galactosyl–enzyme complex could be responsible for transferring an additional galactosyl unit to the trisaccharide, thereby forming a tetrasaccharide.

EXPERIMENTAL

Production of Oligosaccharides

The organism was grown on a medium containing 10% lactose and 0.75% Difco yeast extract. Inoculum was grown in 500 ml Erlenmeyer flasks containing 100 ml medium at 24° C on a Gump shaker (240 r.p.m., 1 inch eccentricity). Cultures 24–28 hours old (100 ml inoculum) were used to inoculate a 5-liter New Brunswick stirred fermentor containing 3 liters of medium at pH 3.75. Initial adjustment of the pH was essential. At pH values above 4, no oligosaccharides were obtained. The incubation temperature was 22° C, air flow rate 1 liter/minute and stirring speed 375 r.p.m. The progress of the fermentation was followed by means of paper chromatography, using ethyl acetate – acetic acid – water (6:2:2 v/v) as solvent and the silver nitrate – alkali dip reagent (13) for detection of the sugars. The process was complete in 3–4 days. The supernatant liquid was recovered by centrifugation and decolorized with activated charcoal (Darco G-60).

Isolation of Oligosaccharides

A portion of the filtered material corresponding to a starting weight of 35 g lactose was fractionated on a column of Darco G-60:Celite 545 (200 g:200 g) (14). This was washed with water, then 5% ethanol which eluted galactose and glucose (trace). Ethanol, 10%, eluted some lactose, then two oligosaccharides moving at a slightly faster rate than lactose on paper chromatograms. Later fractions contained the trisaccharide. Ethanol, 15%, removed the rest of the trisaccharide so that in all 12.0 g were obtained. Increasing the concentration to 20% developed the tetrasaccharide (5.1 g) and later fractions were contaminated with a paper chromatographically slower-moving sugar.

A more quantitative analysis was carried out by cellulose column chromatography. *n*-Butanol, one-half saturated with water, eluted galactose (0.25 g) and a trace of glucose. Acetone–water (4:1 v/v) gave lactose and a disaccharide which ran a little faster (0.64 g), trisaccharide (2.11 g), tetrasaccharide (1.17 g), and a material running slightly slower than the tetrasaccharide (0.21 g).

Characterization of the Trisaccharide (I)

The trisaccharide crystallized from 90% aqueous methanol, yielding a first crop of 5.1 g and a second crop of 2.0 g. Recrystallization from the same solvent gave material with m.p. 228–231° C and $[\alpha]_D$ +68° → +45° (*c*, 1.0, H_2O). Calculated for $C_{18}H_{32}O_{16}$: C, 42.9; H, 6.4. Found: C, 42.6; H, 6.45%.

Hydrolysis at 100° C for 3 hours in *N* sulphuric acid gave galactose and glucose on a paper chromatogram (solvent, butanol–pyridine–water 3:1:1; spray, *p*-anisidine hydrochloride (15)). A portion of the trisaccharide (5 mg) was reduced with sodium borohydride (5 mg) in water (5 cc) for 3 hours. The product on acid hydrolysis gave galactose only on a paper chromatogram with the reducing sugar spray.

The trisaccharide (1.0 g) was partially hydrolyzed in *N* sulphuric acid (5 ml) at 80° C for 45 minutes. The solution was neutralized ($BaCO_3$), filtered, and evaporated. Examination on a paper chromatogram in ethyl acetate – acetic acid – water (9:2:2 v/v) showed the presence of two disaccharides. These were separated on Whatman No. 3 paper sheets in an identical solvent to give lactose (72 mg) (m.p. and mixed m.p. 197–201° C after two recrystallizations from methanol) and faster running 4-*O*-β-D-galactopyranosyl-D-galactose (80 mg). The latter was recrystallized twice from methanol–ethanol to give material (10 mg) which had an X-ray powder diagram identical with an authentic specimen (4).

Lead tetraacetate oxidation showed the reducing end of the trisaccharide to be linked in the 4-position (6), since 0.19, 0.48, and 1.08 moles of oxidant were consumed after 2, 5, and 15 minutes respectively.

The trisaccharide (1.0 g) was oxidized with lead tetraacetate (2 moles) in acetic acid (100 ml), containing water (2 ml). After 1 hour the reaction mixture was treated with oxalic acid (2 moles) in acetic acid. The lead oxalate which formed was filtered off, and residual lead tetraacetate removed by addition of ethylene glycol (0.5 ml). Evaporation yielded a residue which was treated with sodium borohydride (1.0 g) in water (50 ml). After 1 hour excess reagent was destroyed with acetic acid and Amberlite IR120 was added to the solution. Filtration and evaporation gave a material from which boric acid was removed by repeated addition and evaporation of methanol. The resulting polyol mixture was fractionated on a cellulose column using acetone–water (6:1 v/v) as solvent. *O*-β-D-Galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 2)-D-erythritol (0.37 g) was obtained and two recrystallizations from methanol gave material with m.p. 180–183° C and $[\alpha]_D$ +13° (*c*, 1.0, H_2O). Calculated for $C_{16}H_{30}O_{14}$: C, 43.05; H, 6.8. Found: C, 43.1; H, 6.8%. The polyol consumed 3.23, 3.70, 3.97, and 4.26 moles of sodium periodate releasing 0.85, 0.97, 1.07, and 1.19 moles of acid after 1, 3, 5, and 23 hours respectively.

Characterization of the Tetrasaccharide (II)

Using methods identical with those used with the trisaccharide, the tetrasaccharide was shown to contain galactose and a glucose-reducing end. The tetrasaccharide had $[\alpha]_D$ +43° (*c*, 1.2, H_2O) and when oxidized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

with lead tetraacetate it consumed 0.47, 0.86, and 1.59 moles of oxidant after 2, 5, and 15 minutes respectively. The gradual uptake showed that the reducing end was 1,4-linked.

The tetrasaccharide was converted to its corresponding erythritol derivative by lead tetraacetate oxidation followed by sodium borohydride reduction by the method described above. For fractionation of the product on a cellulose column acetone–water (5:1 v/v) eluant was used. The product (0.41 g from 0.80 g starting material) was amorphous and had $[\alpha]_D$ +19° (*c*, 1.0, H_2O). On periodate oxidation it consumed 3.80, 4.40, 4.58, and 5.07 moles of oxidant after 1, 2.5, 4, and 23 hours respectively with concomitant formation of 0.85, 1.06, 1.13, and 1.23 moles of acid. Since these data showed that the two central units of the tetrasaccharide can be linked either 1,2 or 1,4 the following experiment was carried out.

The erythritol derivative (30 mg) was oxidized overnight in water (5 ml) containing periodic acid (100 mg). The reagent was then destroyed with barium carbonate and the solution filtered. The oxidation product was then reduced, with sodium borohydride (100 mg), and the reaction mixture worked up as previously described in this section. The resulting polyol was hydrolyzed by heating for 3 hours at 100° C in *N* sulphuric acid (1 ml). The acid was neutralized ($BaCO_3$) and the solution filtered and evaporated. The product contained erythritol and glycerol, but no hexose. The relative proportion of these polyols was compared by acetylation (hot NaOAc–Ac_2O method) and gas–liquid chromatography (G.L.C.) of the acetates at 150° C on a column of 2% LAC-IR296 on Chromosorb W. In terms of peak areas the glycerol and erythritol acetates were present in the ratio 1.67:1, respectively. When a similar experiment was carried out with galactobiosyl erythritol the polyol mixture on acetylation and G.L.C. examination gave peak areas of 3.63:1 for the glycerol and erythritol acetates. The erythritol:glycerol ratio was 2.2 times that obtained from the galactobiosyl erythritol mixture. This shows the central units of the tetrasaccharide to be 1,4-linked and the structure of the tetrasaccharide to be mainly *O*-D-galactopyranosyl-(1 → 4)-*O*-D-galactopyranosyl-(1 → 4)-*O*-D-galactopyranosyl-D-glucose.

O-β-D-Galactopyranosyl-(1 → 4)-O-β-D-galactopyranosyl-(1 → 2)-D-erythritol (IV) from O-β-D-Galactopyranosyl-(1 → 4)-O-β-D-galactopyranosyl-(1 → 4)-O-β-D-galactopyranosyl-(1 → 4)-D-glucose (II)

The tetrasaccharide (0.90 g) was dissolved in water (5 ml) and treated with lead tetraacetate (3.6 g) in acetic acid (250 ml). After 15 hours ethylene glycol (0.5 ml) was added, followed by oxalic acid (0.9 equivalents) in acetic acid (25 ml). The precipitate which formed was removed by filtration and the filtrate evaporated to dryness. A solution of sodium borohydride (1.0 g) in water (25 ml) was added and the reduction allowed to proceed for 2 hours. Excess reagent was then destroyed with acetic acid and the reduction product (III) was obtained by the method described previously in this section. On a paper chromatogram it ran slightly faster than galactobiosyl erythritol (solvent, acetone–water 4:1 v/v; spray, ammoniacal silver nitrate). Only a small amount of galactotriosyl erythritol was present.

The oxidized tetrasaccharide derivative was hydrolyzed at 60° C overnight in 0.1 *N* hydrochloric acid (25 ml). The solution was then neutralized (Ag_2CO_3), filtered, and the filtrate evaporated to a crust. This was fractionated on a cellulose column using acetone–water (4:1 v/v) as solvent. Galactobiosyl erythritol (0.30 g) was obtained and this was recrystallized twice from aqueous methanol to yield a product with m.p. 186–188° C and $[\alpha]_D$ +17° (*c*, 1.0, H_2O). Calculated for $C_{16}H_{30}O_{14}$: C, 43.05; H, 6.8. Found: C, 42.9; H, 6.8%. The X-ray diffraction patterns of the product and authentic material were identical.

ACKNOWLEDGMENTS

The authors wish to thank Miss E. Barker of the Department of Food Science and Technology, University of California, Davis, and Mr. N. R. Gardner for technical assistance. Thanks are due also to Mr. M. Mazurek for carrying out carbon and hydrogen analyses, and Mr. W. C. Haid for preparing X-ray crystal patterns.

MULTISTAGE DEACTIVATION IN THE PHOTOLYSIS OF HEXAFLUOROACETONE[1]

A. N. STRACHAN,[2] R. K. BOYD,[3] AND K. O. KUTSCHKE
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received December 23, 1963

ABSTRACT

In principle the vibrationally excited molecule in an upper electronic state, formed by absorption in the ultraviolet region of the spectrum, can attain vibrational equilibrium by two mechanisms. In most discussions of this degradation of vibrational energy it has been considered that the data are represented adequately by a single-step deactivation from high to low vibrational levels rather than by a multistep cascade from one group of vibrational levels to the next lower group. The present work suggests new treatments of the experimental data by which it is possible to distinguish between the single- and the multi-step deactivation processes. It is demonstrated that the literature data on the quantum yield for the decomposition of hexafluoroacetone is better interpreted in terms of a multistep deactivation. Some new data are presented which support this conclusion.

Methods to evaluate the efficiencies as deactivating agents of added inert gases are discussed. It is suggested that the deactivation of excited hexafluoroacetone by hydrocarbons might involve chemical rather than, or in addition to, purely physical quenching.

A few measurements were made of the rate of formation of carbon monoxide during the photolysis of hexafluoroacetone in the absence and presence of isobutane. In attempting to interpret these data in terms of the accepted mechanisms, some conclusions were reached concerning the deactivation processes occurring in the photolysis. These conclusions, which are supported by data already in the literature, are of more general interest and are reported here in some detail. The present report is, therefore, largely a reinterpretation of some of the details of the mechanism of the primary process of the photolysis; the few experimental results which give rise to this reconsideration form a relatively minor part of the report. Consequently experimental details are not given although some new results are recorded.

The major conclusion reached is that, contrary to opinions expressed elsewhere (1), there exist several graphical tests which can be used to decide whether deactivation in the upper electronic state reached by absorption involves a single-step process producing electronically excited molecules in low-lying vibrational levels from which dissociation does not occur, or whether a multistep cascade down the vibrational energy levels is involved. Existing data on the photolysis are better interpreted in terms of the cascade process. This conclusion has some bearing on the interpretation of data taken to show the deactivating effect of added gases; this also will be discussed in some detail. In addition a few remarks are offered on the mechanism responsible for the fluorescence observed in this photolysis.

PHOTOLYSIS PRODUCTS

Photoexcitation of hexafluoroacetone in the first absorption band near 3000 Å yields hexafluoroethane and carbon monoxide as photolysis products (2). There is no question that CF_3 radicals are involved (2, 3, 4) and the experiments in the presence of nitric oxide

(4) suggest that no intramolecular formation of C_2F_6 occurs although this latter point has not been definitely established. The relative instability of the trifluoroacetyl radical and the absence of abstractive attack on the ketone molecule permits the use of the quantum yield for the formation of carbon monoxide as a measure of that for decomposition of the molecule.

In earlier work (2, 5) the ratio $R_{C_2F_6}/R_{CO}$ has been taken as unity within experimental error; actually the average values reported are closer to 0.96 and are essentially independent of conditions. An explanation of this observation might be based on the detection (6) of $(CF_3)_3COCF_3$ as a reaction product although the deviation from unity of the ratio of the data in Table I is rather larger than might be expected on the basis of Gordon's rate

TABLE I

constants. That trifluoromethyl radicals are capable of rapid addition to carbonyl bonds is supported by the large decrements in material balance found when hexafluoroacetone was photolyzed in the presence of pivaldehyde or of *t*-butyl formate (7).

The evidence discussed above suggests that for most reaction conditions it is valid to assume that each molecule which decomposes yields one molecule of carbon monoxide so that the quantum yield of dissociation (ϕ) can be taken as R_{CO}/I_a.

DEACTIVATION IN THE PHOTOLYSIS

It has been well established (2, 8) that ϕ is a function of temperature, and of the concentration of ketone and that of other gases which might be present. Mechanisms to explain these effects have been advanced (2, 8). Giacometti, Okabe, and Steacie ((8); referred to as GOS) modified the original mechanism of Ayscough and Steacie ((2); referred to as AS). The modified mechanism is as follows.

$$A + h\nu \rightarrow {}^1A_n \quad [1]$$

$${}^1A_n \rightarrow \text{products} \quad [2]$$

$${}^1A_n + A \rightarrow {}^1A_0 + A \quad [3]$$

$${}^1A_0 \rightarrow A + h\nu^1 \quad [4]$$

$${}^1A_0 \rightarrow {}^3A_0 \quad [5]$$

$${}^3A_0 \rightarrow \text{products} \quad [6]$$

$${}^3A_0 \rightarrow A \quad [7]$$

A represents a molecule of hexafluoroacetone in the ground electronic state, ${}^1A_n$ is a molecule in the *n*th vibrational level of the upper singlet state, ${}^1A_0$ is a molecule in a low-lying, non-dissociating vibrational level of that singlet state, and ${}^3A_0$ is a molecule in a

low-lying vibrational level of an upper triplet state from which dissociation can occur with an activation energy. This mechanism requires that

$$(1-\phi)^{-1} = (1-\phi_\infty)^{-1} + (1-\phi_\infty)^{-1} k_2/k_3[\mathrm{A}] \qquad [\mathrm{i}]$$

in which $\phi_\infty = k_5k_6/(k_4+k_5)(k_6+k_7)$ and thus represents the quantum yield at infinite concentration of deactivating species.

Plots of the AS data, taken at 3130 Å, and of the GOS data, with 2640 Å excitation, show positive intercepts greater than unity as required by [i]. Evaluation of ϕ_∞ from the intercept of [i] is subject to large uncertainties because of the algebraic form involved. Nevertheless the values obtained are in good agreement with those derived from purely empirical plots of ϕ or ϕ^{-1} vs. $[\mathrm{A}]^{-1}$ in which the algebraic form of the quantities plotted does not lead to a magnification of errors. In those cases where data are available to check the point, the value of the intercept appears to be essentially independent of exciting wavelength at a given temperature.

Equation [i] requires that $(1-\phi)^{-1}$ vs. $[\mathrm{A}]^{-1}$ remain linear while the data show a pronounced upward curvature at low concentrations. Unfortunately, the algebraic form magnifies the experimental errors in the region of greatest curvature since ϕ approaches unity as [A] approaches zero. However, the consistency of the trend at all temperatures and wavelengths suggests that the curvature is not an experimental artifact. Such curvature might be a consequence of multistep deactivation from the nth vibrational level of the upper electronic state, which level is reached by absorption, to the lower vibrational levels from which the emission is thought to occur (8). If k_2/k_3 can be defined for each vibrational level, and if molecules in the zeroth, or highest non-dissociating, vibrational level undergo only reactions [4] and [5] suggested by GOS, then it can be shown that

$$(1-\phi)^{-1} = (1-\phi_\infty)^{-1} + (1-\phi_\infty)^{-1}\{[\textstyle\prod_{i=1}^{n}(1+p_i[\mathrm{A}]^{-1})]-1\} \qquad [\mathrm{ii}]$$

in which $p_i = k_{2,i}/k_{3,i}$. Porter and Connelly (9) give a detailed discussion of the concepts involved. The bracketed portion of [ii] is a power series in $[\mathrm{A}]^{-1}$, of which the first term is $\sum_{i=1}^{n} p_i[\mathrm{A}]^{-1}$, so that [ii] gives a qualitatively correct description of the observations.

Several other tests can be suggested to determine whether or not such multistep deactivation is required by the data. Porter and Connelly (9) use the occurrence of a point of inflection at low values of [A] in a plot of ϕ^{-1} vs. [A] as such a criterion; if $n = 1$, corresponding to a single step deactivation, plots of ϕ^{-1} vs. [A] have a finite initial slope ($\lim_{[\mathrm{A}]\to 0} (d\phi^{-1}/d[\mathrm{A}]) = (1-\phi_\infty)/p_1$), whereas if $n > 1$ the initial slope is zero. While the sensitivity of this test is not great, in the sense that experimental data are required at quite low pressures, the test uses experimental quantities directly. Other tests are proposed below which are more sensitive, in that trends are discernible at higher pressures; however, the algebraic forms involved are such as to amplify the experimental errors.

The characteristics of some plots used in such tests are summarized here.

$$g \equiv (\phi-\phi_\infty)/(1-\phi) = k_2/k_3[\mathrm{A}] \qquad \text{if } n = 1,$$
$$= [\textstyle\prod_{i=1}^{n}(1+p_i[\mathrm{A}]^{-1})]-1 \qquad \text{if } n > 1.$$

Plots of g vs. $[\mathrm{A}]^{-1}$ are predicted to be linear to $g = \infty$ if $n = 1$, but curve upward rapidly as $[\mathrm{A}]^{-1}$ increases ($dg/d[\mathrm{A}]^{-1} \to \infty$) if $n > 1$. Curvature is noted in the AS and GOS data at values of [A] and ϕ which are such that the experimental errors in the data should not introduce too large an error in g. Such plots require a determination of ϕ_∞, which also contributes to the uncertainties, but that particular contribution is minimal in the region

For personal use only.

of greatest curvature. The function g is readily differentiated graphically. Plots of g[A] vs. [A]$^{-1}$ are nearly linear for the AS data; this near linearity cannot be taken to prove that $n = 2$ in this system since the AS data do not extend to sufficiently low pressures.

$$f_1 = (1-\phi)[\mathrm{A}]^{-1} = (1-\phi_\infty)/([\mathrm{A}]+p_1) \qquad \text{for } n = 1$$
$$= (1-\phi_\infty)[\mathrm{A}]^{-1}/\prod_{i=1}^{n}(1+p_i[\mathrm{A}]^{-1}) \qquad \text{for } n > 1.$$

If $n = 1$, plots of f_1 vs. [A] start at $f_1 = (1-\phi_\infty)/p_1$ for [A] = 0 and decrease smoothly to zero as [A] $\rightarrow \infty$; the slope is always negative ($\lim_{[\mathrm{A}]\rightarrow 0} df_1/d[\mathrm{A}] = -(1-\phi_\infty)/p_1^2$) and continuously decreases in magnitude as [A] increases. On the other hand, if $n > 1$, $\lim_{[\mathrm{A}]\rightarrow 0} f_1 = 0$, and the function increases with [A] for small [A], passes through a maximum at a value of [A] such that $\sum_{i=1}^{n} p_i/([\mathrm{A}]+p_i) = 1$, and then decreases to approach $f_1 = 0$ asymptotically as [A] $\rightarrow \infty$. The condition for the maximum in plots of f_1 vs. [A] is such that the concentration at which the maximum appears is larger if n is greater, i.e. if more collisions are required for deactivation to a non-dissociating level of the upper singlet state. An increase in n can be achieved experimentally by doing the photolysis at a higher temperature or at a shorter wavelength. The shift of the maximum to larger concentrations is readily apparent in plots of the AS data (3130 Å; T = 27, 53, 78, and 107° C) and the GOS data (2640 Å; T = 27 and 53° C); such plots are shown in Fig. 1.

The effect of temperature on the position of the maximum probably is the result of two phenomena. (1) Because of the greater population of vibrationally excited molecules in the ground electronic state at higher temperatures and the fact that the photon energy absorbed from a monochromatic beam is independent of temperature, higher vibrational levels of the upper electronic state are reached by absorption. Hence n is larger at higher temperature. This effect will depend exponentially on temperature. (2) Each p_i increases as temperature increases; this increase probably is also exponential. Hence the value of [A] which satisfies the condition for the maximum must be larger at higher temperature. It is not easy to decide unambiguously which of the two effects is the more important or if they are of similar importance.

It might be pointed out that in plots of f_1 vs. [A], $\lim_{[\mathrm{A}]\rightarrow 0} df_1/d[\mathrm{A}] = (1-\phi_\infty)/p_1p_2$ (i.e. > 0) if $n = 2$, whereas if $n > 2$, $\lim_{[\mathrm{A}]\rightarrow 0} df_1/d[\mathrm{A}] = 0$. Therefore there will be a point of inflection if $n > 2$ which is absent if $n = 2$. It is doubtful whether experimental data can be obtained to demonstrate the existence of this point of inflection in an unambiguous way; rather low pressures would be required and such data are suspect because of possible surface effects.

Plots might also be made of f_1 vs. [A]$^{-1}$; a maximum is predicted to occur at a concentration defined by the same condition as that cited above for plots of f_1 vs. [A]. The characteristics of such a plot are that $f_1 = 0$ for [A]$^{-1} = 0$ regardless of the value of n; the initial slope is also independent of n and is equal to $1-\phi_\infty$. f_1 approaches an asymptotic value of $(1-\phi_\infty)/p_1$ for large values of [A]$^{-1}$ if $n = 1$, but passes through a maximum and returns to $f_1 = 0$ at [A]$^{-1} = \infty$ if $n > 1$. The AS data show these broad maxima at 107° and 78° C but the maxima are not distinguishable in the data taken at 53° and 27° C; the plots of the latter data can be interpreted equally well in terms of an approach to an asymptotic value. In plots of any function against [A]$^{-1}$ the data taken at low pressures, which are the least reliable, are emphasized. It might also be noted that values of ϕ_∞ determined from estimates of the initial slopes of f_1 vs. [A]$^{-1}$ are in good agreement with those obtained from plots of ϕ vs. [A]$^{-1}$.

For personal use only.

The function f_1 is the first member of a family of functions defined by $f_m = (1-\phi)[A]^{-m}$. Each such function ($m = 1$, 2, etc.) has the same general shape as that described for f_1 when plotted vs. [A]. In particular, $\lim_{[A]\to 0} f_m = 0$ if $m < n$, $= (1-\phi_\infty)\prod_{i=1}^{n} p_i$ if $m = n$ and $= \infty$ if $m > n$. The predicted values of the initial slopes also depend on the relative values of m and n. A general expression for the slope, which also applies to f_1 if m is set equal to unity in the expression, can be written as $df_m/d[A] = -(1-\phi_\infty)[\prod_{i=1}^{n}([A]+p_i)]^{-1}[A]^{n-1-m}\{m-\sum_{i=1}^{n} p_i/([A]+p_i)\}$. Hence $\lim_{[A]\to 0} df_m/d[A] = 0$ if $n > m+1$, $= +(1-\phi_\infty)/\prod_{i=1}^{m+1} p_i$ if $n = m+1$, $= -(1-\phi_\infty)(\sum_{i=1}^{m} p_i^{-1})/\prod_{i=1}^{m} p_i$ if $n = m$, and $= -\infty$ if m is chosen $> n$. Provided $m > 0$, $\lim_{[A]\to 0} df_m/d[A] = 0$ regardless of the value of n. From the general expression for the slope it is obvious that the maximum is predicted to occur at a value of [A] defined by $\sum_{i=1}^{n} p_i/([A]+p_i) = m$ provided that $m < n$; if $m = n$ the maximum coincides with the intercept at [A] = 0 and if m is chosen $> n$ the function f_m increases without limit as [A] decreases.

Thus a series of plots might be made of f_1, f_2, etc. vs. [A] for a given set of data; for some function there will no longer be any indication of a maximum although one exists in plots of all functions with smaller values of m. The value of m in the function for which the maximum disappears determines a minimum value of n which is compatible with the data in the range of pressures studied. To be of real value, data should be available at quite low pressures and the possibility of surface effects must be kept in mind. The AS and GOS data are not sufficiently extensive to permit a trial of this procedure.

Similar kinds of deductions can be made from plots of the functions f_m vs. $[A]^{-1}$.

Except for the relatively insensitive test involving the detection of a point of inflection in plots of ϕ^{-1} vs. [A], each of the tests suggested above indicates that the AS data and the GOS data are interpreted better in terms of multistep deactivation than by the single-step deactivation proposed originally. It is concluded, therefore, that the multistep deactivation process occurs in this photolysis. Data currently available are insufficiently extensive to permit the determination of the number of vibrational levels involved. Some initial experiments have been done in these laboratories to obtain more extensive data and are shown in Fig. 2. The agreement with the AS data at 78° C is excellent.

Although it provides a sensitive test for the occurrence of multistage deactivation, the function f_1 is subject to large experimental uncertainties. Indeed, the error $\delta f_1/f_1$ introduced into f_1 by an uncertainty $\delta\phi/\phi$ in ϕ is greater than that in ϕ by a factor $\phi/(1-\phi)$; such a factor increases rapidly as ϕ approaches unity. It might be pointed out, however, that ϕ is near 0.7 near the maximum shown in Fig. 2; hence the magnification factor is near 2 which is not unreasonably large. Considerable random scatter is to be expected at lower pressures, of course.

Moreover, it has been brought to our attention (10) that the observable characteristics of plots of f_1 vs. [A], which are ascribed here to the occurrence of multistage deactivation, would also be seen if the quantum yield measurements were systematically too large, i.e., if the quantity measured were $w = (1+\epsilon)\phi$ rather than ϕ, even if the single-stage deactivation process were occurring. With this hypothesis a plot of $(1-w)/[A]$ is predicted to pass through a maximum at $[A] = [A]_c$ such that

$$\epsilon = [A]_c^2(1-w_\infty)/p_1(2[A]_c+p_1). \qquad [iii]$$

Such an artifact type of maximum is not predicted if the measured quantity is systematically less than the true ϕ. It might also be noted that fictitious points of inflection

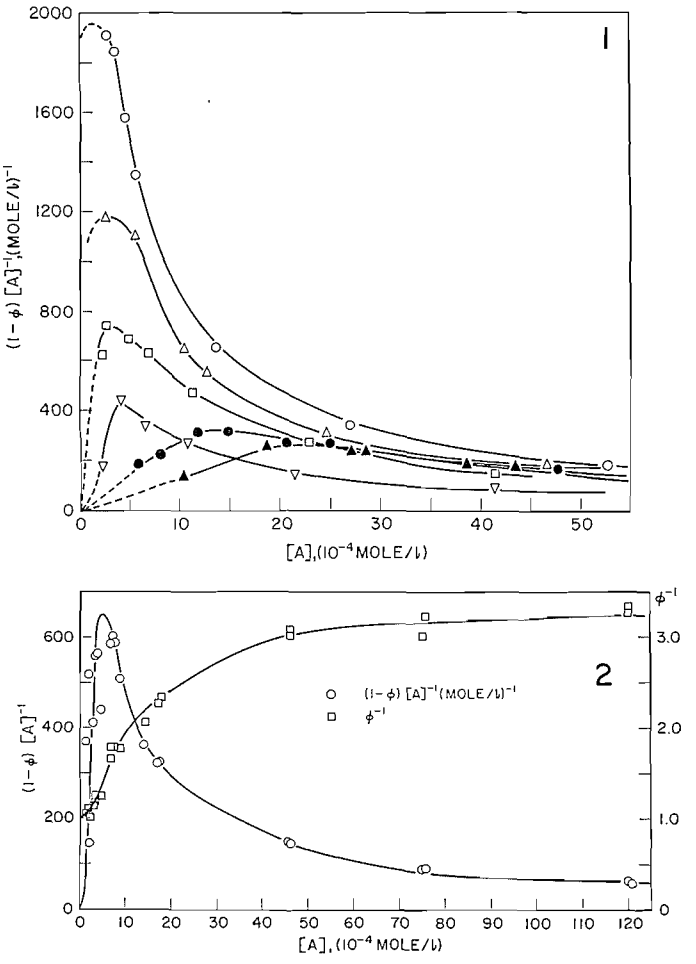

FIG. 1. Plots of $(1-\phi)/[A]$ vs. [A] for GOS and AS data. AS data at 3130 Å are open symbols; GOS data at 2640 Å are filled symbols. Circles, 27°; upright triangles, 53°; squares, 78°; inverted triangles, 107°.
FIG. 2. Plots of $(1-\phi)/[A]$ and ϕ^{-1} vs. [A]. This work, 3130 Å, 78°.

would be drawn in plots of w or w^{-1} vs. [A] if the systematic error in w were not recognized.

Attempts to determine ϵ are frustrated by the necessity of express p_1 in terms of measurable quantities. Four such expressions can be obtained from the initial slopes of plots in which the experimental data are used directly. Thus $p_1 = -(1-w_\infty+\epsilon)/s_1$, $= (1-w_\infty+\epsilon)/(1+\epsilon)^2 s_2$, $= s_3/(1-w_\infty+\epsilon)$ and $= -w_\infty^2 s_4/(1-w_\infty+\epsilon)$ where s_1 to s_4 are the initial slopes of w vs. [A], w^{-1} vs. [A], w vs. $[A]^{-1}$, and w^{-1} vs. $[A]^{-1}$, respectively. If pairs of these four expressions are equated, five quadratic equations in ϵ are obtained; in addition, each expression yields another equation for ϵ after substitution into [iii]. Some of the nine equations have only negative roots and those which yield positive roots lead to values of ϵ which extend from 0.01 to nearly unity. This great scatter arises because of the subjective errors involved in the estimation of an "initial" slope. For various reasons it appears that $s_3 \simeq 5\times10^{-4}$ mole/l. should be the most reliable of all the estimated initial

slopes. This taken together with the more directly observable $w_\infty = 0.27$ (from w vs. $[A]^{-1}$) and $[A]_e \simeq 5\times10^{-4}$ mole/l. (Fig. 2), leads to $\epsilon = 0.20$ after substitution into [iii].

Such a large value of ϵ is not consistent with other aspects of the data nor is it reasonable in view of the precautions taken in obtaining the data in Fig. 2. This is not the place to discuss those precautions; they will be considered in some detail when work now underway is reported.

The conclusion reached in this discussion is one of the first demonstrations of the occurrence of multistep deactivation in the photolysis of polyatomic molecules. Porter and Connelly (9) have discussed the photolysis of ketene and have made extensive calculations based on the theory of unimolecular reactions and the known spectroscopic properties of ketene. It is felt that such detailed considerations of the photolysis of hexafluoroacetone should await the more extensive data now being obtained.

LIGHT EMISSION

Regardless of the detailed mechanism of deactivation, the general GOS mechanism predicts that the function $(Q_\infty - Q)/Q$ (see GOS for the definition of Q; $Q_\infty = k_4/(k_4+k_5)$) should be numerically equal to the function $g = (\phi - \phi_\infty)/(1-\phi)$ for all [A]. Such numerical agreement is very nearly achieved near room temperature between the AS data on the photolysis and the GOS data on the emission; the agreement is increasingly poor as the temperature is raised. Unfortunately the two sets of data were not taken at identical temperatures in the range 25° to 110° C but it is felt that the small temperature differences do not negate the brief comments below.

As shown in Fig. 3 for data taken near 80° C, plots of $(Q_\infty - Q)/Q$ vs. $[A]^{-1}$ show a

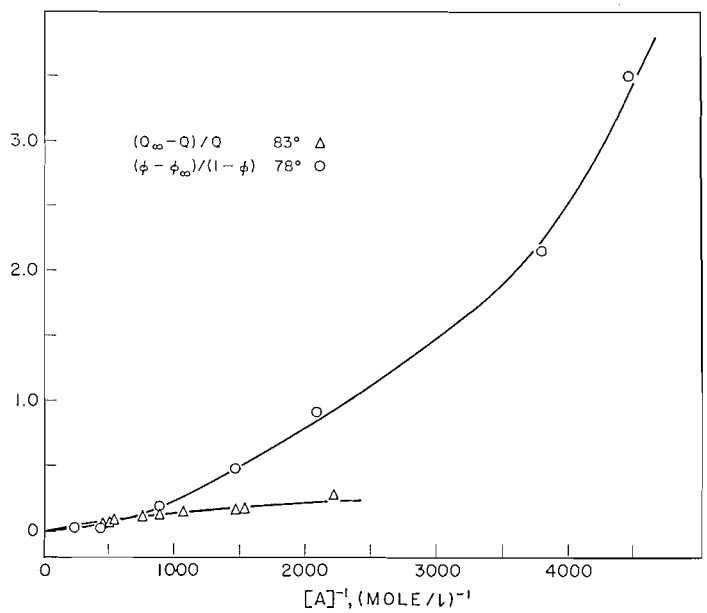

FIG. 3. Plot of $(\phi-\phi_\infty)/(1-\phi)$, AS data, and $(Q_\infty-Q)/Q$ vs. $[A]^{-1}$, GOS data. O, $(\phi-\phi_\infty)/(1-\phi)$ at 78°; Δ, $(Q_\infty-Q)/Q$ at 83°.

rather different dependence on concentration than do plots of g vs. $[A]^{-1}$. It is not our purpose to give a detailed discussion of the light emission in this system. It is, perhaps,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

sufficient to note that further modifications to the mechanism probably will be required to explain these data in detail. On the other hand, estimates of the quantum yield for the emission are rather small values of the order 0.01 (8). Thus, although there might be some ambiguity in the description of the emission, such uncertainties should not affect the conclusions reached in regard to the photodecomposition.

DEACTIVATION BY ADDED GASES

If other species are present which also remove energy from the excited molecule, reaction [8] must be included in the mechanism

$$A_n + M \rightarrow A_{n-1} + M. \qquad [8]$$

The following equation then should be obeyed.

$$\phi = 1 - (1-\phi_\infty)\pi_2\pi_3^{-1}$$

Here $\pi_2 = \prod_{i=1}^{n}(1+q_i[M][A]^{-1})$, $\pi_3 = \prod_{i=1}^{n}(1+p_i[A]^{-1}+q_i[M][A]^{-1})$, p_i has the significance given earlier and $q_i = k_{8,i}/k_{3,i}$. It is possible that the value of k_8/k_3 is independent of the vibrational level involved; this is more likely to be true if M is a polyatomic species. The more exact formulation will be retained for the present.

It is the usual practice to do a series of experiments at constant temperature and incident intensity with a fixed concentration of ketone, $[A]_1$, and various concentrations of the added gas; usually it is found that the absorbed intensity does not vary with [M]. The quantum yield for these conditions at a concentration of ketone $[A]_1$ but with [M] = 0 has been given the symbol ϕ' by AS. When multistep deactivation is included the mechanism requires that $\phi' = 1-(1-\phi_\infty)\pi_1^{-1}$ where $\pi_1 = \prod_{i=1}^{n}(1+p_i[A]_1^{-1})$. Plots of ϕ'/ϕ vs. [M] were made (2), and the relative efficiencies for various gases as deactivating agents were obtained from the slopes of the straight lines drawn through the data. The mechanism outlined here predicts that ϕ'/ϕ rises from unity at [M] = 0 with a finite initial slope given in [iv].

$$S_M^0 \equiv \lim_{[M]\rightarrow 0} d(\phi'/\phi)/d[M] = ((1-\phi')/\phi')\sum_{i=1}^{n} q_i p_i [A]_1^{-2}/(1+p_i[A]_1^{-1}) \qquad [iv]$$

The slope decreases as [M] increases and ϕ'/ϕ is predicted to approach an asymptotic value of ϕ'/ϕ_∞ at large values of [M]. Physical arguments indicate that there should be no point of inflection in such curves for most conditions (see below).

Although the scatter is rather large the AS data fit this general picture. An asymptote calculated from values of ϕ_∞ ($\simeq$0.30 at 78° C) and ϕ' ($\simeq$0.67 at 78° C, $[A]_1$ = 10 mm) derived from the data taken with [M] = 0 is compatible with the plots of ϕ'/ϕ vs. [M]. Some of the data are interpreted better if ϕ_∞ obtained from a plot of ϕ vs. [A] with [M] = 0 differs from that obtained in the limit of large [M], but the data are much too scattered to reach a firm conclusion on this point.

Since plots of ϕ'/ϕ vs. [M] are curves, only the initial slopes are useful for the evaluation of relative efficiencies for deactivation of the various gases. Even these are useful only if the value of q does not depend on the vibrational level, i.e. $q_i = q$ for all $i = 1, 2, \cdots n$, so that q may be removed from within the summation sign in [iv]. Because values are not available for n and the various p_i to permit a calculation of the factor $\sum_{i=1}^{n} p_i/([A]_1+p_i)$ contained in [iv], an absolute value for q cannot be obtained unless use is made of data taken with [M] = 0. One such method for calculating q is outlined below.

When [M] = 0, it can be shown that a plot of ϕ vs. $[A]^{-1}$ is a smooth curve, with no

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

point of inflection, which rises from ϕ_∞ at $[A]^{-1} = 0$ to an asymptotic value of unity at $[A]^{-1} = \infty$. The slope of this curve at $[A] = [A]_1$, S_K', may be evaluated graphically or otherwise. Since the general expression for the slope is $d\phi/d[A]^{-1} = (1-\phi)[A]\sum_{i=1}^{n} p_i/([A]+p_i)$, it follows that

$$\sum_{i=1}^{n} p_i/([A]_1+p_i) = S_K'/(1-\phi')[A]_1. \qquad [v]$$

This can be combined with [iv], taking $q_i = q$ for all i, to obtain

$$q = S_M^0\phi'[A]_1^2/S_K'. \qquad [vi]$$

Several other techniques, some possibly more reliable, might be available to evaluate the unknown factors in [iv]; the one outlined was chosen for its relative simplicity.

The AS data have been recalculated using an $S_K' = 1.2\times10^{-4}$ mole/l. obtained graphically, and other data cited above. Values of q obtained are: C_4F_{10}, 0.80; C_3F_8, 0.56; C_2F_6, 0.35; CF_4, 0.33; CO_2, 0.46. The only value of q which differs significantly from those reported by AS is that for C_3F_8 for which AS approximated the curved plot of ϕ'/ϕ vs. [M] by a straight line. The straight lines drawn in AS, Fig. 5, are essentially initial slopes, except that for C_3F_8, since the point at the highest pressure of C_4F_{10}, which indicates the curvature, was omitted from their figure, and the efficiencies of the other gases are so low that the data pertain only to the initial linear portion of the curve. Thus for all the species except C_3F_8 the linear approximation used by AS is close to S_M^0 defined in [iv]. Moreover the AS method of evaluating constants in the photolysis with [M] = 0 yields values which are closely equivalent to S_K'. Thus little difference was expected between values of q calculated by [vi] and those reported by AS.

One further concept should be mentioned. It is difficult to demonstrate mathematically whether or not a point of inflection occurs in plots of ϕ'/ϕ vs. [M]. A qualitative physical argument suggests that its presence or not depends on the value of $[A]_1$ used; the argument is as follows. In a plot of ϕ^{-1} vs. [A] with [M] = 0 at least one point of inflection occurs at some value of [A], say $[A]_p$. At the concentration $[A]_p$ the frequency and efficiency of collisions between excited and ground state molecules presumably are such that deactivation is "taking over" from decomposition as the major mode of disappearance of the "average" vibrationally excited molecule. If $[A]_1$ is chosen to be much greater than $[A]_p$, it seems obvious that deactivation by ketone will continue to keep the system on the "deactivation side" of $[A]_p$ regardless of how inefficient M might be as a deactivating agent. On the other hand, if $[A]_1$ is chosen to be less than $[A]_p$, the same type of argument predicts the existence of a point of inflection in the plots of ϕ'/ϕ vs. [M]. If $[A]_1$ is only slightly less than $[A]_p$ the point of inflection would be difficult to observe if q were large but might be detectable for those M which have a small value of q.

As is demonstrated in Fig. 2, the point of inflection in the plot of ϕ^{-1} vs. [A] for [M] = 0 at 78° C with excitation by 3130 Å occurs at a value of [A] somewhat larger than 5 mm and perhaps as large as the 10 mm which AS used as $[A]_1$. A point of inflection can be identified tentatively in the AS data for C_2F_6, CF_4, and CO_2 for which q is small, but is not discernible in the data involving C_4F_{10} and C_3F_8 for which q is relatively large. Obviously much more data are required before this point can be clarified experimentally.

DEACTIVATION BY HYDROCARBONS

The few data which stimulated the considerations discussed above are recorded in Table II. If these data are treated by the methods outlined in connection with [vi] above, the value of q obtained for isobutane is at least as great as 30 and may be a factor of two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

TABLE II

Effect of isobutane

$[CF_3COCF_3]$ = 46.5 mm; $T = 54 \pm 1°$ C; Vycor filter

[Isobutane] mm	0	4.08	8.53	17.06

ϕ'/ϕ*	1.0	2.76	3.04	3.49

*ϕ'/ϕ = ratio of the quantum yields of CO formation in the absence (ϕ') and presence (ϕ) of isobutane.

or three greater. The uncertainty arises in the estimate of $S_M{}^0$, which, because of the steepness of the extrapolated curve, might be grossly in error; the value of 30 was obtained by using a line joining the point at the lowest pressure of isobutane to the origin of the curve. Values of S_K' and ϕ' were taken from the GOS data at 53° C since the exciting wavelength used in that study is more representative, on the basis of energy, of the wavelength used to obtain the data in Table II. If S_K' and ϕ' for 3130 Å excitation were to be used, even larger values would be calculated for the q of isobutane.

This surprisingly large value cannot be considered to be established in view of the paucity of the data available. Nor can it be reconciled readily with concepts of collisional deactivation (physical quenching), which would predict a value near unity. However, similarly large values can be calculated for the efficiency for deactivation by benzene and toluene from the data obtained by Holmes and Kutschke (11). A possible explanation of these large values might be based on the occurrence of a chemical reaction between excited ketone molecules (precise excited state unspecified) and the hydrocarbon. Such chemical quenching is known to exist in several systems (12, 13).

ACKNOWLEDGMENT

Discussions of some of the details involved in this problem with various members of the staff of these laboratories have been of great benefit to the authors. They are particularly grateful for the views expressed by Dr. R. A. Back.

THE BEHAVIOR OF LEAD ELECTRODES IN SULPHURIC ACID SOLUTIONS[1]

K. EKLER
Department of Chemistry, Loyola College, Montreal, Quebec
Received August 1, 1963

ABSTRACT

Lead electrodes were anodically etched in NH_2SO_3H. Immersion potentials, self-passivation potentials, passivation times, PbO_2/O_2 potential, and the potential of the first discharge plateau were determined in H_2SO_4 solutions ranging from 0.5 to 20.0 *N* and were found to be concentration-dependent. Interruption of the anodizing current had no detectable influence on passivation time. Data obtained with the anodizing current turned on fall into three categories; those obtained with (1) short-immersion anodes, (2) anodes which had reached a hydrogen-like potential, and (3) anodes which were self-passivated before the current was switched on. An inflection in the relation between potential and time during charging was investigated. Its length was dependent upon acid concentration and current density, while its potential was $+300 \pm 30$ mv, and seemed to correspond to the self-passivation potential. The lengths of the first and second discharge plateaus increased with the number of coulombs passed and were dependent upon acid concentration, but were identical for electrodes treated by four different methods. The hydrogen-like potential appeared to be due to the presence of $PbO.PbSO_4$. The self-passivation potential seemed to be caused by formation of PbO.

INTRODUCTION

Although there is a voluminous literature on the reactions occurring at Pb electrodes in H_2SO_4 solutions during charge and discharge, there is still considerable uncertainty about the actual mechanism.

From their investigations Gladstone and Tribe (1) concluded that the overall reactions at the two electrodes may be represented by the so-called "double-sulphation" process:

$$Pb + PbO_2 + 2H_2SO_4 \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftharpoons}} 2PbSO_4 + 2H_2O$$

This was subsequently developed in more detail by Müller and Machu (2) and strongly supported by Thirsk and Wynne-Jones (3) as the only mechanism compatible with thermodynamics.

Lander (4) and Burbank (5) found PbO as a product of anodic oxidation in H_2SO_4 in contrast to the observations of Wynne-Jones *et al.* (6), who observed only $PbSO_4$ and PbO_2 as the reaction product. The transformation of $PbSO_4$ to PbO_2 has been assumed by Feitknecht and Gäumann (7) and by Thirsk and Wynne-Jones (3) to involve OH radicals. Two crystallographic modifications of PbO_2 have been noted (8). Feitknecht (9) has also reported PbO as a precursor to the formation of PbO_2 at the anode.

He explained that, during the discharge process, PbO_2 is first reduced to PbO, which is then slowly converted into $PbSO_4$ through the intermediate $PbO.PbSO_4$.

In the present study the conversion of $PbSO_4$ to PbO_2 and the reverse reaction were studied by making potential–time records during charge and open-circuit discharge of the anode.

Since the behavior of the anode during charge and discharge was sensitive to the *immersion time*, i.e. the time during which the anode had been in contact with H_2SO_4

[1]*This paper presented at the Colloquium on Electrochemistry, The Royal Society of Canada, June 1963, Laval University, Quebec.*

before anodization, it was necessary to study also the influence of immersion time on the electrode potential in absence of anodizing current.

EXPERIMENTAL

The measurements were made in a pyrex vessel 10 cm long, 5 cm wide, and 14 cm high, with a $\frac{1}{4}$ inch diameter hole drilled through each end, 6 cm from the top, to allow an electrode to be fastened by a screw and nut which served also to provide electrical contact.

The 2.5 cm × 10.0 cm electrodes were cut from $\frac{1}{4}$ inch rolled Pb sheet (Canada Metal Co., Montreal) of the following analysis: Cd < 0.0001%, Sb = 0.0002%, As < 0.0001%, Ag = 0.0004%, Cu = 0.0004%, Bi = 0.0005%, Fe = 0.0001%, Zn = 0.0001%.

An area of 10.0 cm^2 was measured off on the faces of the anode and cathode and the rest coated with paraffin wax (which had been shown to be chemically inert in H_2SO_4).

The H_2SO_4 used was Reagent Grade (Nicholls Chemical Co., Montreal) with the following analysis: Cl = 0.00002%, NO_3 = 0.00002%, NH_4 = 0.0001%, SO_2 = 0.0002%, As = 0.0000005%, Fe = 0.00002%, heavy metals = 0.00008%, non-volatile = 0.0004%.

The H_2SO_4 electrolyte was saturated with $PbSO_4$ before use. The cell was immersed in a water bath maintained at 25.2 ± 0.1° C. The direct current for the anodization was drawn from a Sorensen regulator (Nobatron 300 B, 150 ma capacity). The galvanostatic method was used for the polarization of the anode. Potential measurements were made with a portable potentiometer (Tinsley, type 3184-D) and a recording oscillograph (Brush RD 232100) in conjunction with a high-gain d-c amplifier (Brush RD 561500). Six chart-speeds were available: the normal speeds 5, 25, and 125 mm/sec and the slow speeds 50, 250, and 1250 mm/hour.

Polarization changes faster than 0.01 second were followed with a cathode-ray oscilloscope (Hewlett-Packard 120 A; P 7 screen) with a sweep-frequency variable from 2 c/sec to 50 kc/sec. Both the oscilloscope and oscillograph could be calibrated by their own internal standards, or against an external circuit consisting of a 1.5 volt battery with voltage divider.

A Luggin-capillary was used to make contact between the electrolyte and the reference electrode. It was filled with H_2SO_4 of the same concentration as that in the reaction vessel.

Electrode potentials were measured relative to the saturated calomel half-cell (Fisher 11-505-10), but are reported here with respect to the N.H.E.

The H_2O used was doubly distilled from KOH.

The anodes were prepared by grinding them on files of various roughness, followed by anodic etching for 32 minutes at a current density of 12.5 amp/dm^2 until the crystal structure of the matrix was exposed. Etching was interrupted every 2 minutes to allow for removal of debris from the electrode, and to dislodge gas bubbles. The electrolyte for etching was 5% aqueous NH_2SO_3H. To obtain satisfactory reproducibility, an anode that had been used once in an experiment had to be reground on the files before it was used in a second experiment. To minimize oxidation of the electrode, after it had been etched, it was washed in three changes of distilled H_2O and transferred, while wet, as rapidly as possible, to the experimental cell.

During the early parts of the study, the electrodes were chemically etched in HNO_3, but reproducibility of the data was very poor. Anodic etching in an electrolyte consisting of 30 g/l. $PbSiF_6$ and 70 g/l. H_2SiF_6 gave good reproducibility, but use of this bath was discontinued in favor of NH_2SO_3H, to rule out any possible influence of adsorbed F^- ion.

Accordingly, most of the electrodes used were etched anodically in the NH_2SO_3H bath, anodically polarized at a current density of 1.0 ma/cm^2 for 7 minutes (for convenience), and discharged on open-circuit, except where specifically stated otherwise.

A typical potential–time record is shown in Fig. 1*a* for an electrode which had been anodically polarized immediately after immersion in H_2SO_4 solution (short immersion).

RESULTS AND DISCUSSION

The potential of the electrode was noted immediately after immersion of the electrode in the H_2SO_4 solution, in the absence of anodizing current. This *immersion potential* ranged from −420 to −240 mv (Fig. 2).

The immersion potential remained constant during a period that ranged from hours to days, depending on the H_2SO_4 concentration, after which it spontaneously assumed a more anodic value of +300 ± 30 mv. The time required to reach this potential decreased with an increase in H_2SO_4 concentration (Fig. 3). After approximately 15 minutes this potential, in turn, slowly became more cathodic, until it reached +20 ± 40 mv, which will be designated the *hydrogen-like potential*. The potential remained constant at this value for

about 2 weeks (Fig. 4), after which it changed to the more anodic value of $+300 \pm 30$ mv, hereafter termed the *self-passivation potential.* The change from the immersion potential to the hydrogen-like potential was faster, the higher the concentration of H_2SO_4 into which the electrode was placed.

It appears from the value of $+20 \pm 40$ mv that the hydrogen-like potential might originate from the presence of $PbO.PbSO_4$. Ohse (11) gave a value of +34 mv for the

electrode potential of Pb, $PbSO_4/PbO.PbSO_4$ (at pH = 0). He states that: "it is probable that there is $PbO.PbSO_4$ present in the pores of the $PbSO_4$ layer".

The decrease of time required to reach the hydrogen-like potential, with increase in H_2SO_4 concentration, might be attributed to the increased solubility of $PbSO_4$ in more concentrated solutions (12).

The change from the $+300 \pm 30$ mv potential to the hydrogen-like potential could possibly take place by temporary elimination of the impurity centers in concentrated H_2SO_4 solutions, and formation of normal $PbSO_4$, thereby making the potential more cathodic. When sufficient time is allowed, such as on prolonged standing in H_2SO_4, adsorption of O-atoms, which are being formed (Casey and Campney (10)), can then take place to bring the potential to the more anodic self-passivation value. An alternative explanation for the attainment of the self-passivation potential might be the reaction of Pb with H_2O.

With the current turned on data were obtained with anodes which had (i) been immersed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

in the electrolyte for the shortest possible time (*short immersion*), (ii) attained the *hydrogen-like potential*, and (iii) reached the *self-passivation potential* before the current was switched on. When the current was turned on for short-immersion anodes (Fig. 1*a*, A) the potential passed through an "*inflection*" (CD). Interruption of the current had no detectable influence on *passivation time*, i.e. the time to reach the *overshoot* (E).

At constant current density, the passivation time decreased with an increase in H_2SO_4 concentration (Fig. 5). This is probably caused by a decrease in the diffusion coefficient

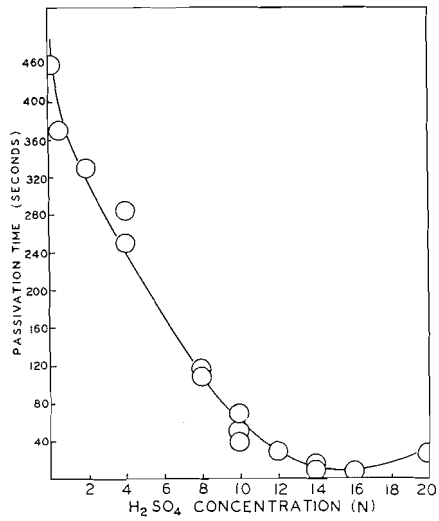

FIG. 5. Passivation time vs. H_2SO_4 concentration.

of $PbSO_4$. A difference in the character of the film may also be involved.

The inflection at CD (Fig. 1*a*) lasted from a fraction of a second to 17 seconds, depending on the current density and H_2SO_4 concentration (Fig. 6). Its potential amounted to $+300 \pm 30$ mv, depending on current density and the concomitant overvoltage, and was essentially identical with the self-passivation potential.

The inflection was absent in H_2SO_4 of less than 0.088 *N*, at which concentration, however, it was just noticeable. It increased in prominence with acid concentration up to 10.5 *N*, beyond which it decreased again. The 10.5 *N* H_2SO_4 gave the optimum inflection for a given current density. The electrochemical reactions which might take place at the inflection are:

(A) $$Pb + H_2O \rightleftarrows PbO_{red} + 2H^+ + 2e$$
$$E = 0.248 - 0.059\ pH$$

(B) $$Pb + H_2O \rightleftarrows PbO_{yellow} + 2H^+ + 2e$$
$$E = 0.253 - 0.059\ pH$$

(C) $$Pb + 2H_2O \rightleftarrows Pb(OH)_2 + 2H^+ + 2e$$
$$E = 0.277 - 0.059\ pH$$

Although present measurements were not sufficiently accurate to permit a decision on the probable occurrence of the above reactions, it might be noted that Burbank (5) reported X-ray identification of both PbO and $Pb(OH)_2$ in the potential range concerned.

■ 16.0 *N* H_2SO_4.
(*b*) Length of inflection vs. H_2SO_4 concentration: (current density = 2.5 ma/10 cm²).

Since the inflection is a maximum at 10.5 *N* acid, reactions A, B, and C, if they do occur, must have minimum rate for a given current.

When a *short-immersion* electrode was anodized to the inflection and then self-discharged, the potential dropped rapidly to a value that was 40 ± 10 mv more anodic than the immersion potential, the rate depending on acid concentration. When the current was turned on once more, a duplication of the foregoing trace was obtained. When the current was turned off at the inflection, the decay potential was now 80 ± 10 mv more anodic than the immersion potential. The procedure was repeated 3 times and each time the decay potential was more anodic. An interval of 5 minutes was allowed between switching the current off and on, so that concentration effects might dissipate. After the current was switched on for the fourth time no inflection was observable, and the potential rose at once to the overshoot. It may be concluded, perhaps, that more PbO or $Pb(OH)_2$ formed each time the potential was allowed to build up to the inflection, to give a more anodic mixed potential.

Since the potential at the inflection was maintained for a short time only during charging, the total amount of PbO or $Pb(OH)_2$ formed may be calculated to be quite minute.

When a *long-immersion* electrode was anodized, the potential increased at once to the PbO_2/O_2 level without an inflection, which is to be expected, since the electrode potential had already reached the Pb/PbO level before the current was turned on. When the current

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

was switched off, with either the short-immersion or long-immersion electrodes anodized for 7 minutes, there was a drop, within 40 seconds, of about 300 mv from the *charging-plateau* (Fig. 1*a*, FG) to a level that might be termed the first *discharge plateau* (Fig. 1*a*, HK). The potentials of the charging- and first discharge-plateaus were concentration dependent (Fig. 7).

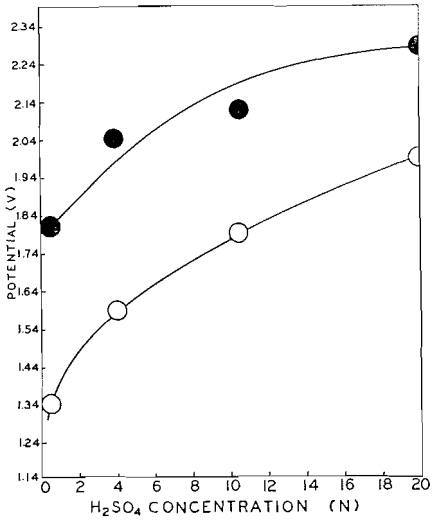

FIG. 7. Potential vs. H_2SO_4 concentration: ● PbO_2/O_2 potential during charging; ○ $PbO_2/PbSO_4$ potential (first plateau).

The duration of the first discharge plateau was concentration dependent with both *short-* and *long-immersion* electrodes, although to markedly different extents (cf. Figs. 8 and 9).

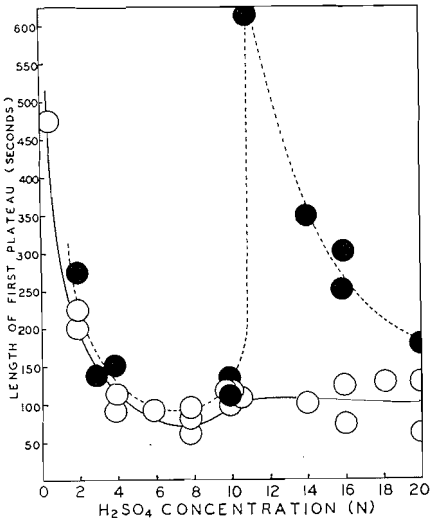

FIG. 8. Length of first plateau vs. H_2SO_4 concentration (short-immersion electrodes): ○ H_2SiF_6 etch; ◍ NH_2SO_3H etch.

In accordance with the results of Wynne-Jones *et al.* (13) the length of the first discharge plateau as well as that of the second decay (Fig. 1, KM) increased with the quantity of current passed, i.e. slow formation of PbO_2, in addition to that originating from the initial PbO_2 continued during anodization.

The two sublevels of the first discharge plateau were also observed by Ruetchi and Cahan (8), who associated the higher level with α (orthorhombic) and the lower with β (tetragonal) PbO_2 (Fig. 1*a*, HI and IK).

The behavior of the first discharge plateau for *long-immersion* electrodes was studied with four types of surfaces. The first of these was electrochemically etched, self-passivated in H_2SO_4, and anodized in H_2SO_4 of the same concentration as that used for self-passivation. The maximum plateau-length was observed in 10.5 *N* H_2SO_4 (Fig. 9). The thickness and character of the $PbSO_4$ layer formed might have varied, however, when the electrode was self-passivated in different acid concentrations. Experiments were made, therefore, with a second series of electrodes, self-passivated in 16.0 *N* H_2SO_4 (chosen merely for its relatively short self-passivation time). The electrodes were transferred after self-passivation to another vessel containing the appropriate H_2SO_4 concentration for anodizing. The longest plateau was again obtained in 10.5 *N* H_2SO_4. It was of interest then to check the behavior of a similar series of electrodes, self-passivated in 10.5 *N* H_2SO_4. The results were essentially the same as those obtained with electrodes self-passivated in 16.0 *N* acid. Since there remained the possibility that NH_2SO_3H, used for etching, or an oxidation product thereof, might be adsorbed by the electrodes and form a stabilizing agent, a fourth series of electrodes was prepared by grinding on files without the electrolytic etch. Nevertheless, the first discharge plateaus again showed their peculiar behavior.

It is possible that the length of the first discharge plateau is related to the solubility of $PbSO_4$ and that the slow step in the reaction is the rate of solution of $PbSO_4$ in H_2SO_4. The solubility was determined by Kameyama and Fukomoto (14) over the range 0.5 to 10.5 *N* H_2SO_4 and shows a maximum in 2.0 *N* and a minimum in 10.5 *N*.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The variation in the length of the first discharge plateau with change in H_2SO_4 concentration raised the question of whether it was caused by a change in the efficiency of PbO_2 formation for a fixed quantity of current or by a variation in the discharge rate. Experiments, in which the anodes were charged in one H_2SO_4 concentration and discharged in another, gave plateaus which reflected the acid concentration used during discharge and thus favor the second answer.

The second decay for *long-immersion* anodes occurred in either of two ways, depending on whether the potential prior to anodization had achieved the hydrogen-like potential $+20 \pm 40$ mv (Fig. 1*b*) or the self-passivation potential $+300 \pm 30$ mv (Fig. 1*c*). If the first condition prevailed, the second decay dipped to -40 ± 30 mv, which was slightly more cathodic than the hydrogen-like potential for the electrode under examination. On continued standing such an electrode gradually assumed the hydrogen-like, and eventually the self-passivation potential.

For the second condition, however, the potential reached a minimum of $+220 \pm 15$ mv, and then gradually regained its self-passivation potential. It would appear that, during the discharge of long-immersion electrodes, a change towards the immersion potential by formation of lower oxides of Pb and (or) $PbSO_4$ from PbO_2 occurs, in opposition to the formation of substances causing the hydrogen-like ($PbO.PbSO_4$) and the self-passivation (PbO or $Pb(OH)_2$) potentials. With short-immersion electrodes the oxidation products apparently were able to revert to $PbSO_4$, whereas this was not possible with the substances formed on long-immersion electrodes and responsible for the hydrogen-like and self-passivation potentials.

To reach the self-passivation potential, an electrode had to stand for an appreciable length of time in acid, giving the H_2SO_4 opportunity to attack the grain-boundaries. It might be that the establishment of the self-passivation potential produces PbO and (or) $Pb(OH)_2$ and that, since PbO is a poor conductor of electricity, it is not all oxidized to PbO_2, even during prolonged anodization, but remains embedded in the intergranular spaces of the surface. Its presence there, in conjunction with $PbSO_4$ formed during discharge, would then give rise to mixed potentials (the hydrogen-like potential). This view would seem to be supported by the observation that anodization experiments of 30 minutes and 2 hours gave results similar to those obtained with only 7 minutes anodization.

Moreover, when *short-immersion* electrodes were electrolytically etched in H_2SiF_6 or in NH_2SO_3H, a plot of the first discharge plateau against H_2SO_4 concentration showed the distinct discontinuity for electrodes treated in NH_2SO_3H (Fig. 8), and microscopic examination showed that NH_2SO_3H attacked the grain-boundaries more strongly than H_2SiF_6.

ACKNOWLEDGMENTS

The present investigation was made with financial assistance from the Defence Research Board of Canada, Grant Number 5480-14, to whom grateful acknowledgment is made.

Thanks are due to Messrs. V. Mimeault, G. Lanthier, R. Cook, J. Devlin, and H. Doherty (student assistants) who helped with the experiments.

The writer would like to express his appreciation to Drs. E. J. Casey and I. Henderson of the Defence Research Chemical Laboratories for several valuable discussions and private communications, Professor C. A. Winkler, Department of Chemistry, McGill University, Montreal, Quebec, for his continued encouragement and advice, and the Canada Metal Company, Ltd., Montreal, Quebec, for their generous gift of high-purity lead sheet.

D-MANNOFURANOSE 2,3-CARBONATE. PREFERRED SIZE OF THE SUGAR RING IN SOME FUSED-RING DERIVATIVES[1]

A. S. PERLIN

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received December 20, 1963

ABSTRACT

Treatment of 6-*O*-trityl-D-mannose with phosgene gives 6-*O*-trityl-D-mannose 2,3-carbonate (II), which on partial hydrolysis, yields D-mannose 2,3-carbonate (VI). Chemical properties of II and VI agree with the proposition that fusion of the cyclic carbonate group at the 2- and 3-positions of D-mannose converts the latter to a furanose derivative. Nuclear magnetic resonance spectral evidence supports the furanoid assignment and indicates also that in aqueous solution VI does not rearrange significantly to a pyranose form. Substantial disagreement is found between proton-proton coupling observed for VI and corresponding data predicted from the Karplus curve. A similar situation is encountered with a related fused-ring derivative, 2,3-*O*-isopropylidene-L-rhamnose.

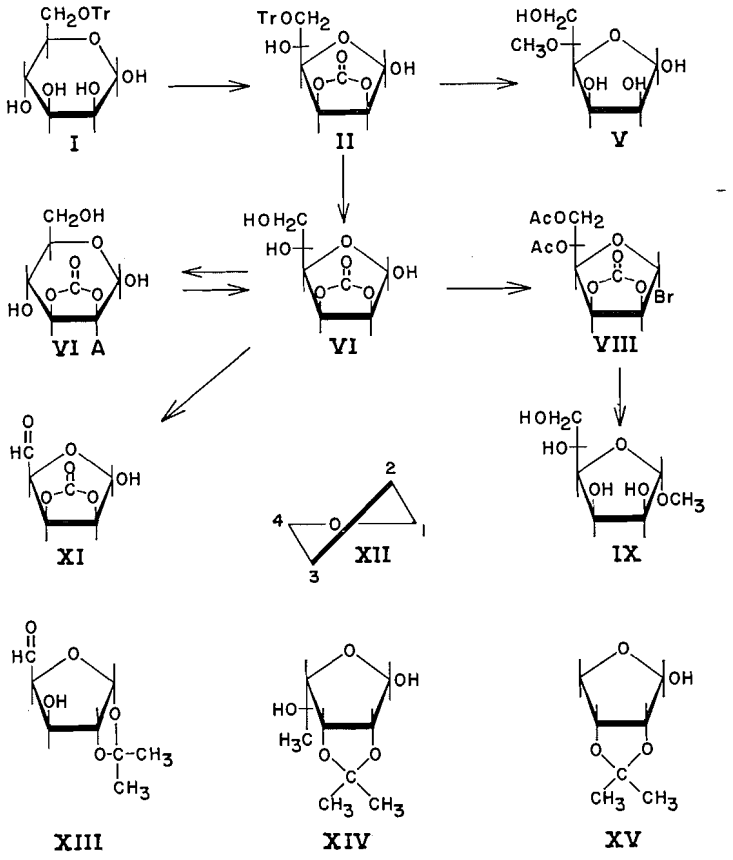
5-O-Methyl-D-mannofuranose has been synthesized via methylation of II. 5,6-Di-O-acetyl-α-D-mannofuranosyl bromide 2,3-carbonate (VIII), prepared from VI, permits synthesis of either of the anomeric methyl D-mannofuranosides. On treatment of VIII with methanol in the presence of excess sodium the α-D-glycoside is obtained, whereas in the presence of silver oxide a β-D-anomeric derivative is formed.

D-Mannofuranose 2,3;5,6-dicarbonate is formed by reaction of D-mannose with phosgene in pyridine (1). By analogy with this synthesis, 6-*O*-trityl-D-mannose (I) was treated in similar fashion in attempting to prepare 6-*O*-trityl-D-mannofuranose 2,3-carbonate (II). The reaction product was obtained in crystalline form after chromatography on silicic acid and, in accordance with expectation, it yielded a 5-*O*-methyl ether methyl glycoside (III). Removal of the carbonate group of III with barium methoxide gave 6-*O*-trityl-5-*O*-methyl methyl α-D-mannofuranoside (IV), the furanoside structure of which was clearly shown by a very rapid uptake of lead tetraacetate (2). Location of the ether group in IV was confirmed by acid hydrolysis to give 5-*O*-methyl-D-mannofuranose (V), which was converted to known 5-*O*-methyl-D-*arabino*hexophenylosazone (3).

D-Mannose 2,3-carbonate (VI) was obtained by partial acid hydrolysis of the 6-*O*-trityl ether (II). An α-D-triacetate (VII) of VI was prepared, which, on treatment with hydrogen bromide, afforded di-*O*-acetyl-α-D-mannosyl bromide 2,3-carbonate (VIII). The latter, in methanol containing excess sodium (4), was converted to methyl α-D-mannofuranoside (IX), thus establishing that acetate VII is a furanose derivative of D-mannose 2,3-carbonate. Preparation of IX parallels the conversion of tetra-*O*-acetyl-α-D-mannopyranosyl bromide to methyl α-D-mannopyranoside under the same conditions (4). In both instances, the observed retention of configuration presumably involves an intermediate 1,2-epoxide. When VIII was treated with methanol in the presence of silver oxide, inversion occurred and a β-D-glycoside (X) was obtained; this agrees with the observed behavior of related furanosyl halide 2,3-carbonates (5, 6, 7). Thus, D-mannose 2,3-carbonate is an intermediate suitable for synthesis of either the α- or β-anomer of methyl D-mannofuranoside, and its 6-*O*-trityl ether (II) permits ready synthesis of 5-*O*-methyl-D-mannofuranose (V), which does not appear to have been previously prepared (8).

These syntheses all accord with the original expectation (see (9)) that, in forming a 2,3-carbonate, D-mannopyranose is transformed into a furanose derivative (II and VI).

[1]*Issued as N.R.C. No. 7864.*



Moreover, D-mannose 2,3-carbonate rapidly consumes a mole of periodate, consistant with degradation of a furanose to a 5-aldo-derivative (XI). Nevertheless, such examples do not entirely eliminate the possibility that in solution the furanose sugar is in equilibrium with a high proportion of the pyranose isomer (e.g. VIA), but reacts preferentially or affords the more stable end-product. Certainly, when the pyranose ring is fixed by glycoside formation a 2,3-carbonate still may be prepared readily (10, 11). If both pyranose and furanose isomers are present in admixture, and if one assumes that they are interconvertible because of free hydroxyl groups at positions -1 and -4 or -5, their equilibrium ratio would depend on the relative stability of the fused-ring structure having two five-membered rings (furanose-carbonate) and the one having a six- and a five-membered ring (pyranose-carbonate).

It appears certain from the n.m.r. spectrum of D-mannose 2,3-carbonate (Fig. 1A) that one particular form of the sugar greatly predominates in aqueous solution.* Thus, the H_1 singlet, H_2 doublet, and H_3 and H_4 quartets are all approximately one proton signals; only the weak signal at 5.3 p.p.m. suggests the presence of a minor constituent. A choice of whether the dominant species is a furanose or pyranose form should be possible by analysis of proton–proton coupling in Fig. 1A, although differences between the two

**The spectrum of the crystalline 6-O-trityl derivative (II) in chloroform solution was more poorly resolved, even after the solution was shaken with deuterium oxide to eliminate OH coupling, but its general characteristics were similar to those of the detritylated derivative (VI).*

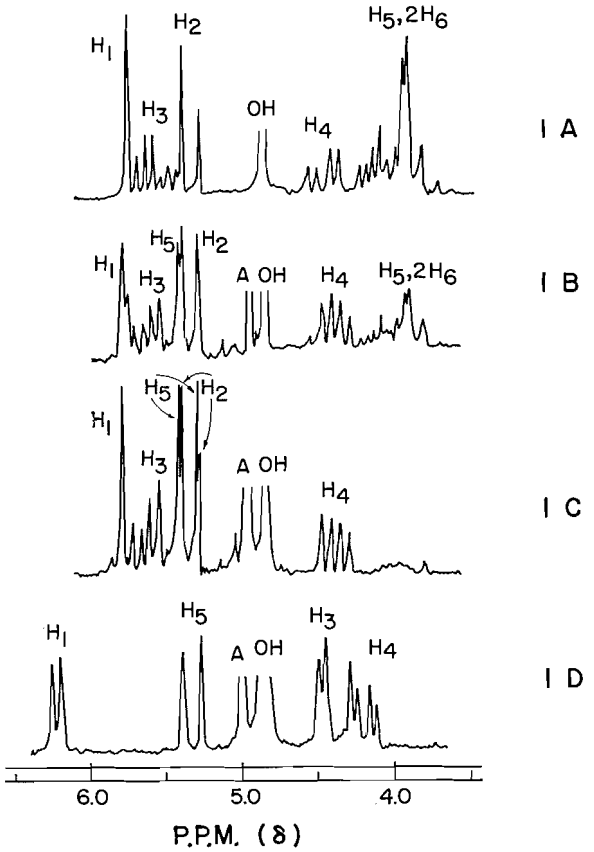

FIG. 1. Nuclear magnetic resonance spectra in deuterium oxide of (A) D-mannose 2,3-carbonate (VI); (B) the solution of VI, five minutes after addition of 0.4 moles of sodium metaperiodate per mole; (C) the product (XI) formed by treating VI with 1 mole of sodium metaperiodate per mole; (D) the product (XII) formed by treating 1,2-*O*-isopropylidene-D-glucofuranose with 1 mole of sodium metaperiodate per mole. Signal A is due to protons of formaldehyde produced.

forms *could* be rather small, depending on the mode of puckering of the furanose ring. This is seen by comparing the observed first-order coupling constants (J) for neighboring protons with corresponding dihedral angles given by the Karplus curve (12, 13).* As

		Dihedral angle		
CH—CH	$J_{H,H}$	α-D-Furanose	Karplus curve value	α-D-Pyranose
1,2	0	95°	90°	85°
2,3	6.5	28°	30°	35°
3,4	3.2	28°	50°, 130°	130°
4,5	9.0	—	180°	180°

shown in the table, the first two dihedral angles are readily approximated in a Barton conformational model (15) of the α-D-furanose isomer (VI) by puckering the ring so that C_2 is above and C_3 below the plane formed by C_4—O—C_1 (XII) ("skew" or cyclopentane

**A modified Karplus equation, derived for use in studies of sugar conformation in deuterium oxide, also gives values close to those listed in the table (14).*

"half chair" form (16, 17)); also there appears to be no restriction to a H_4—H_5 dihedral angle of 180°. In the model of the α-D-pyranose isomer (VIA) approximately the same dihedral angles pertain for the 1,2-, 2,3- and 4,5-proton pairs. Hence the major difference between the two molecules is the angle subtended by H_3 and H_4, although, even in this instance, the parabolic shape of the Karplus curve accommodates the possibility of two widely divergent dihedral values. There is much better agreement on this point between the predicted and found values for the pyranose derivative. A 3,4-dihedral angle larger than 30° appears prohibitive for the furanose isomer, irrespective of the mode of puckering.

If the Karplus curve in its original form is closely applicable to compounds such as D-mannose 2,3-carbonate, it may be inferred that the dominant species in solution is a pyranose form, in marked contrast to the chemical evidence cited above. The value for $J_{3,4}$ of 3.2 c.p.s. requires a gross displacement of the curve, i.e., by almost 3 c.p.s., to accommodate the furanose structure. Nevertheless, discrepancies of this magnitude have been shown for some types of compounds, as influences on proton-proton coupling other than dihedral angle are becoming recognized (18). To test the applicability of the curve in the present instance the spectra of several 2,3-carbonate derivatives were examined (furanoses VII and VIII as well as pyranosides (11)), but these have not yet been adequately interpreted. Pertinent reference data were obtained, however, from the n.m.r. spectrum of the product (XI) formed by periodate scission of VI. The 5,6-diol group of the latter should be readily accessible to the oxidant, whereas a pyranose form (VIA) would have to be converted to a furanose (or an acylcic) form in an equilibrium-displacement reaction; the expected product from either source is the 5-*aldo* derivative (XI). By examination of the spectrum at different stages the course of the oxidation reaction was conveniently followed: on partial oxidation there was a corresponding decrease in the signal intensity for the 5- and 6-protons (e.g. Fig. 1B), but with excess periodate present, cleavage of the diol was complete (Fig. 1C). The production of formaldehyde (signal at 4.95 p.p.m.) from C_6 increased proportionately over these stages, as did the relative intensity of a new doublet (J = 7.2 c.p.s.) overlapping the H_2 doublet. This new signal is attributed to the C_5 aldehydic proton.* Reference to the related 4-*aldo*-pentose (XIII) (Fig. 1D) formed by periodate oxidation of 1,2-*O*-isopropylidene-D-glucofuranose (19) supports the latter assignment by showing that H_5 gives a doublet of resonance frequency 5.35 p.p.m. and that its coupling with H_4 (J = 7.5 c.p.s.) also is clearly analogous to that in XI.† The observed value of 3.2 c.p.s. for $J_{3,4}$ (Fig. 1C) is particularly pertinent here as a guide to possible coupling between H_3 and H_4 in the furanose sugar VI, i.e., in both instances it is equally difficult to correlate the spectra with conformational models and the Karplus curve. Hence, the transformation of D-mannose 2,3-carbonate to XI, which cannot involve retention of a pyranose ring, causes only minute changes in chemical shift and coupling constant for each of the various ring protons. This clear indication of a close conformational similarity between starting material and oxidation product therefore strongly favors the conclusion that D-mannose 2,3-carbonate exists in solution almost entirely as a furanose sugar.‡

By acceptance of a furanose structure for D-mannose 2,3-carbonate, nevertheless the

**The aldehyde group, as well as formaldehyde, must be hydrated, to account for the occurrence of the signal at much higher field than usual for aldehydic protons.*

†Of further note in Fig. 1D are the characteristics of H_3 and H_5. Product XIII has been isolated as a crystalline dimer in which intermolecular bonding renders the 3- and 5-protons non-equivalent (20). Since only one signal is found here for each of these protons, the dimerization process undoubtedly does not take place as the aldehydo compound is generated by oxidation.

‡These data emphasize the difficulty inherent in applying the Karplus equation without a knowledge of the parameters required for the particular system (12, 13, 18).

n.m.r. spectrum cannot at present be used in turn for deducing the preferred conformation of the compound. The fused-ring system, however, permits relatively few possibilities as compared with a monocyclic compound. The "skew" form of the α-D-anomer depicted in XII has the merit of minimizing interactions between neighboring ring substituents and of a minimal number of *endo*-substituents (21). Also, in this form the cyclic carbonate ring likewise assumes a "skew" conformation which, according to X-ray crystallography, is preferred in ethylene carbonate (22).

There is a close structural analogy between cyclic carbonate and *O*-isopropylidene derivatives. Compounds of the latter class related to D-mannose 2,3-carbonate are 2,3-*O*-isopropylidene-L-rhamnose (XIV) (23, 24) and -D-lyxose (25), both of which have been assigned a furanose structure on chemical grounds. The n.m.r. spectrum of the L-rhamnose derivative (Fig. 2A) is slightly more complex than that of II, and suggests that a proportionately greater mixture of components is present in the solution. This is most evident from the multiplicity of signals for the C-methyl groups: a maximum of only four peaks would have been expected for the latter if a single component were present (two 3-proton singlets for the *O*-isopropylidene group (26; also see Fig. 2B) and a 3-proton doublet for the C_6 methyl group). Nevertheless, a substantial predominance of one component is indicated by major signals attributed to H_1 (singlet), H_2 (doublet), and H_3 (quartet). Of concern, especially to the above discussion, is the fact that values for $J_{1,2}$, $J_{2,3}$, and $J_{3,4}$ derived from these major signals are the same as found with D-mannose 2,3-carbonate. Hence, the current data support the furanose assignment already made, but suggest that a significant proportion of a different species is present in an aqueous solution of XIV.

The only type of fused-ring system possible for 2,3-*O*-isopropylidene-L-erythrose

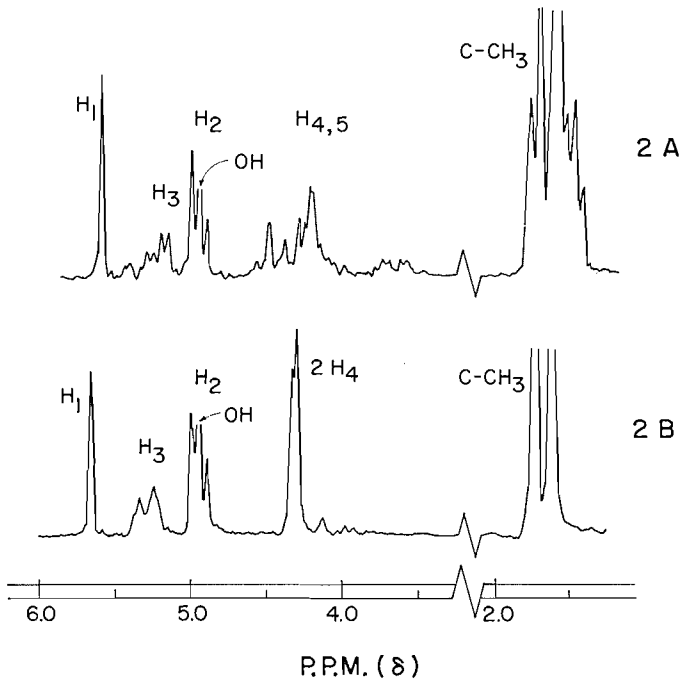

FIG. 2. Nuclear magnetic resonance spectra in deuterium oxide of (A) 2,3-*O*-isopropylidene-L-rhamnose; (B) 2,3-*O*-isopropylidene-L-erythrose.

(XV; D-isomer) (27) is one that contains two five-membered rings, and the n.m.r. spectrum, (Fig. 2B) as well, indicates that a single isomeric form of this derivative is present in the solution. By contrast, in a solution of D-erythrose itself, only about half of the compound appears to exist as the furanose form (28). Therefore, it may be inferred that the furanose ring is stabilized in XV by fusion of the second five-membered ring.

The strong similarity in general spectral characteristics of VI, XI, XIV, and XV, two of which cannot exist as pyranoses, adds to the chemical evidence in suggesting that this kind of bicyclic structure is more stable when the sugar ring is furanose than when pyranose. On conformational grounds the contrary would appear more reasonable. Thus, by manipulating models of VI and VIA in various ways, the same non-bonded interactions appear possible for both molecules in the region of the ring oxygen, C_1, C_2, and C_3. However, the C_5 group is *cis*-oriented relative to the C_3—O bond in VI and constitutes an unfavorable *endo*-substituent (21), whereas the equatorial C_4 hydroxyl group is *trans* in VIA. Although such interactions are clearly of primary importance in fused-ring systems (21, 29), it is probable that other types of factors also need to be considered when more than one ring size is permitted. The situation is similar for monocyclic sugars, though in a reverse sense: from the evidence available, it appears that most free sugars in solution exist predominantly as pyranose chair forms wherever possible, and various methods of conformational analysis concur in indicating assignment of most favorable chair conformations for the different pyranose sugars. However, the same principles do not necessarily explain why furanose forms should, at most, be minor components of the sugar solutions.

EXPERIMENTAL

Melting points are corrected. Solutions were evaporated *in vacuo* at 40–45° C.

Paper chromatography was carried out using Whatman No. 1 paper and butanol–ethanol–water (40:11:19) as solvent.

Proton magnetic resonance (n.m.r.) spectra were measured with a Varian A-60 spectrometer using tetramethylsilane as external or internal indicator.

6-O-Trityl-D-mannose 2,3-Carbonate (II)

6-*O*-Trityl-D-mannose was prepared according to Helferich and Leete (30): to a solution of D-mannose (10 g) in dry pyridine (60 ml) at 0° C, triphenylchloromethane (17 g) was added, the solution was stored at room temperature for 24 hours, and ice water was then added to turbidity. The suspension was poured with vigorous stirring into ice water containing excess of potassium bicarbonate, and the tacky precipitate was washed well with water.

The crude trityl derivative (10 g) was taken up in chloroform, the solution was passed through anhydrous magnesium sulphate, the chloroform evaporated off, and pyridine (70 ml) added. Phosgene (2.4 g) in toluene (20 ml) (31) was added to the pyridine solution at 0° C over a period of 30 minutes with good stirring, the coolant was removed, and after an additional 30 minutes the suspension was filtered and the filtrate concentrated. Chromatographic purification of the syrupy product (10 g) was carried out using a column of silicic acid (18 cm × 5 cm), the product being applied as a concentrated solution in chloroform and the column then developed with additional chloroform. Fractions of the eluate were concentrated and examined for the presence of a cyclic carbonate derivative by infrared absorption (32). After addition of ether–hexane to selected fractions, crystalline material (2.0 g) was recovered and recrystallized from this mixed solvent; m.p. 106–107° C (with gas evolution), $[\alpha]_D+10°$ (*c*, 1, $CHCl_3$). The product contained ether of crystallization. Calculated for $C_{26}H_{24}O_7 \cdot \frac{1}{2}(CH_3CH_2)_2O$: C, 69.26; H, 6.02; ethoxyl, 9.3. Found: C, 69.50; H, 6.10; ethoxyl, 7.7%. The compound absorbed strongly in the infrared region at 1800 cm^{-1}, characteristic of a cyclic 5-membered carbonate group (32).

6-O-Trityl-5-O-methyl Methyl α-D-Mannofuranoside 2,3-Carbonate (III)

A suspension of 6-*O*-trityl-D-mannose 2,3-carbonate (1.5 g), silver oxide (10 g), and anhydrous calcium sulphate (5 g) in methyl iodide (14 ml) was shaken at room temperature for 1 hour, and then heated under reflux for 24 hours.* The solids were filtered off and washed with chloroform. The filtrate and washings were

**Only product III was obtained when the methylation was carried out with methyl iodide and silver oxide. By using dimethylformamide as solvent for this reaction (33), an additional product was obtained which appeared from its infrared absorption spectrum (32) to contain an acyclic carbonate group.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

concentrated, and the residue methylated as above. The final product solidified (1.4 g) and, after recrystallization from benzene–ether–hexane, had m.p. 223.5–225° C; $[\alpha]_D$+35° (*c*, 1, $CHCl_3$). Calculated for $C_{28}H_{28}O_7$: C, 70.57; H, 5.92; methoxyl, 13.0. Found: C, 70.68; H, 5.92; methoxyl, 12.9%.

6-O-Trityl-5-O-methyl Methyl α-D-Mannofuranoside (IV)

A suspension of methylation product III (1.0 g) in methanol (50 ml) was heated and sodium methoxide solution (0.1 *N*) was added dropwise until excess of the base was present. The solution was neutralized with carbon dioxide and concentrated fivefold, water was added, the precipitate (0.75 g) was recovered, washed with water, and recrystallized from benzene–ether; m.p. 99–103° C; $[\alpha]_D$+37° (*c*, 2, dioxane) (M_D = +16,650; M_D of methyl α-D-mannofuranoside is +20,500). Calculated for $C_{27}H_{30}O_6$: C, 71.98; H, 6.71; methoxyl, 13.78. Found: C, 71.95; H, 6.74; methoxyl, 13.33%.

To a solution of IV (15 mg) in acetic acid (2 ml) was added lead tetraacetate solution (20 mg in 2 ml of acetic acid). The uptake of oxidant was 1.0 moles/mole, constant value at 2, 5, and 14 minutes reaction time. When oxidized in highly dilute solution as described elsewhere (34), the second-order rate constant found was 30,000 min^{-1} $mole^{-1}$ liter, as compared with a value of 37,800 for methyl α-D-erythrofuranoside (34).

5-O-Methyl-D-mannofuranose (V)

Product IV (0.6 g) in 50 ml of 70% acetic acid (35) was heated on the steam bath for 1 hour, the solution was cooled and concentrated to a volume of 5 ml. Water was added to the concentrate, the precipitated trityl alcohol was filtered off, and the solution was concentrated. Hydrolysis of the glycoside was completed at steam bath temperature with 0.1 *N* sulphuric acid for 1 hour, the solution was neutralized with Dowex-1 resin (bicarbonate form) and concentrated, affording a syrup (0.2 g); $[\alpha]_D$+30° (*c*, 1, H_2O). On paper chromatographic examination, the product was found to consist essentially of one component, travelling at 1.2 times the rate for L-rhamnose or 5-*O*-methyl-D-glucofuranose.

When treated with phenylhydrazine hydrochloride – sodium acetate in water for 1.5 hours on the steam bath, the sugar gave a dark oil which crystallized from ethanol–water; after recrystallization from this ethanol–water and twice from benzene, the yellow crystals had m.p. 131–133° C; the X-ray diffraction pattern was indistinguishable from that of 5-*O*-methyl D-*arabino*hexophenylosazone (m.p. 133–135° C) prepared from 5-*O*-methyl-D-glucofuranose.

D-*Mannose 2,3-Carbonate (VI)*

A solution of 6-*O*-trityl-D-mannose 2,3-carbonate (II) (100 mg) in 70% acetic acid (10 ml) was heated on the steam bath for 1 hour. Several volumes of cold water were added, the suspension was filtered, and the filtrate concentrated; water was again added and extracted material was concentrated to a syrup (35 mg); $[\alpha]_D$ −5° (*c*, 3.5, H_2O). On a paper chromatogram the product travelled at 1.6 times the rate of L-rhamnose.

A larger scale preparation of the carbonate was carried out without isolation of intermediate products: D-mannose (7 g) was tritylated as above, the pyridine solution was shaken thoroughly with excess of solid sodium bicarbonate, and then treated with phosgene as described above. After removal of solvent the final syrupy product was hydrolyzed with hot 70% acetic acid for 1 hour. The hydrolyzate, which was found by paper chromatography to contain VI, free mannose, and unidentified material having a high R_F, was concentrated and extracted with water. The aqueous extract was washed thoroughly with ether, and the water layer then extracted with ethyl acetate in countercurrent fashion in four stages. From those fractions containing chromatographically pure VI, 0.8 g of syrup was obtained. The product crystallized after prolonged storage at 3° C and was recrystallized from ethyl acetate; m.p. 110–112° C. Calculated for $C_7H_{10}O_7$: C, 40.78; H, 4.89. Found: C, 41.06; H, 4.84%. In the infrared region the product absorbed strongly at 1785–1790 cm^{-1} (cyclic carbonate group); the n.m.r. spectrum in deuterium oxide (Fig. 1A) was indistinguishable from that of the product obtained by hydrolysis of crystalline II.

1,5,6-Tri-O-acetyl α-D-Mannofuranose 2,3-Carbonate (VII)

Acetic anhydride (3 ml) and anhydrous sodium acetate (200 mg) were added to D-mannose 2,3-carbonate (200 mg), the suspension was shaken for 1 hour and then heated on the steam bath for 1 hour. Evaporation of the anhydride *in vacuo* at 60° C left a residue which was triturated thoroughly with ice water, dried, and taken up in ethanol from which it crystallized (180 mg). After recrystallization from ethanol the melting point was 110–111° C; $[\alpha]_D$ +40° (*c*, 1.1, $CHCl_3$). Calculated for $C_{13}H_{16}O_{10}$: C, 46.99; H, 4.85. Found: C, 46.94; H, 4.92%. The infrared absorption spectrum showed the presence of a cyclic carbonate group.

5,6-Di-O-acetyl-α-D-mannofuranosyl Bromide 2,3-Carbonate (VIII)

Triacetate VII (60 mg) in ethylene chloride (1 ml) was treated with hydrogen bromide in acetic acid (1 ml; 30%) for 4 hours, the observed rotation of the solution being constant over the period 2–4 hours; calculated for the product, $[\alpha]_D$ +115°. Chloroform (15 ml) was added, the solution was washed successively with ice water, cold sodium bicarbonate solution and ice water, dried, and concentrated. The residue solidified (63 mg), m.p. 117–120° C, and after recrystallization from ether–hexane had m.p. 123–124° C. Calculated for $C_{11}H_{13}O_8Br$: C, 37.41; H, 3.71. Found: C, 37.30; H, 3.99%.

Methyl α-D-Mannofuranoside (IX)

To a solution of bromide VIII (100 mg) in benzene (2 ml) was added methanol (2 ml) containing sodium (8 mg; 1.2 moles per mole of the acyl bromide (4)). After 15 minutes the alkaline solution was heated under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

reflux for 5 minutes, neutralized with carbon dioxide, and concentrated. The residue, in water, was treated with mixed-bed resins and concentrated to a syrup, $[\alpha]_D$ +102° (*c*, 2, H_2O), which was found chromatographically to consist almost entirely of methyl α-D-mannofuranoside. When taken up in 1-propanol (36) and seeded, the product crystallized; m.p. 118–120° C; the X-ray powder diagram was indistinguishable from that of methyl α-D-mannofuranoside.

5,6-Di-O-acetyl Methyl β-D-Mannofuranoside 2,3-Carbonate (X)

A mixture of bromide VIII (80 mg) and silver oxide (600 mg) was taken up in methanol (6 ml), shaken for several hours, filtered, and the solution was concentrated. The residue was taken up in chloroform, filtered, and on concentration a syrup was obtained (60 mg); $[\alpha]_D$ −93° (*c*, 2, $CHCl_3$), its infrared absorption spectrum showed the presence of a cyclic carbonate group and acetyl groups, and its n.m.r. spectrum (in chloroform) showed the presence of an O-methyl group. The non-reducing major product formed by treating the glycoside with sodium methoxide travelled on a paper chromatogram at 0.77 times the rate for methyl α-D-mannofuranoside, and was accompanied by a trace proportion of the latter; it was markedly acid labile, being hydrolyzed to mannose in aqueous solution when shaken with Amberlite IR-120 resin (H^+ form) for 5 hours.

ACKNOWLEDGMENTS

The author expresses his thanks to M. Mazurek and W. Haid, who carried out microanalyses and prepared n.m.r. and infrared absorption spectra. Dr. D. F. Mowery, Jr., very kindly provided a sample of methyl α-D-mannofuranoside.

TRANSFORMATIONS OF ICE VI AND ICE VII AT ATMOSPHERIC PRESSURE*

J. E. Bertie, L. D. Calvert, and E. Whalley
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received February 7, 1964

ABSTRACT

The irreversible transformations that occur when ices VI and VII are heated at atmospheric pressure from liquid-nitrogen temperature have been examined by simple thermal analysis and by X-ray diffraction. They transform first to cubic ice I (ice Ic) which subsequently transforms to hexagonal ice I (ice Ih). The rates of transformation depend on the temperature. The heat evolved is 16 ± ~2 cal/g for ice VI and 31 ± ~4 cal/g for ice VII.

I. INTRODUCTION

An investigation is being carried out of the properties of the high-pressure ices, and as part of this work the transformations of ices II, III, and V, when they are heated from a metastable state at liquid-nitrogen temperature and atmospheric pressure, have been investigated by simple thermal analysis and by X-ray diffraction (1). The X-ray powder photographs were reported for purposes of identification. In this paper the transformations of ices VI (2(*a*)) and VII (2(*b*)) are described.

II. EXPERIMENTAL METHODS

Ice VI was made using the high-pressure apparatus described earlier (1). Briefly, ice was compressed to ~7 kb at ~253° K in a thick-walled steel cylinder using a hydraulic press, and cooled to 77° K before the pressure was removed. It was removed from the vessel and handled either under liquid nitrogen or in the dry cold gas immediately above the surface of rapidly boiling liquid nitrogen, and was stored under the liquid until required. Ice VII was made (3) in a similar manner using a pressure vessel with one stage of external support (4) at ~253° K and 25 kb. Usually, large cylinders of ice were obtained, and these were washed with liquid nitrogen to remove small fragments, and then ground under liquid nitrogen before use. All of the ice studied in this work was made from H_2O.

When ice II is transformed to ice I on the I–II equilibrium line at 193° K it transforms not directly to the stable form ice Ih, but first to ice Ic (1). It was therefore worth testing whether ice VII transforms directly to ice VI on the equilibrium line. In fact, ice VII transformed at 23 kb and 250° K to ice VI with the same X-ray powder pattern as ice VI made by transformation of ice V at 7 kb and ~250° K.

It is assumed in all this work that the phase recovered at liquid-nitrogen temperature and atmospheric pressure is the same as that formed at high pressure and temperature. This can only be verified by, for example, X-ray diffraction at high pressure, and preparation is being made to do this.

The X-ray powder patterns were photographed as described earlier (1), except that to obtain better resolution a collimator giving a beam size at the specimen of 0.4 mm instead of 0.8 mm was used.

The apparatus and technique used for the thermal analysis has been described in detail elsewhere (1). Basically the temperature of a sample of ice contained in a dewar vessel

Issued as N.R.C. No. 7903.

of low heat capacity was measured as a function of time as the ice warmed from 77 to 190° K. The calorimeter was then re-cooled to 77° K and the heating curve of the ice I, which had been formed from the ice VI or VII, was measured. No attempt was made to ensure that ice Ih was formed, and the ice I was probably a mixture of ice Ih and ice Ic.

The heating curves were analyzed according to a first-order rate law

$$dT/dt = k(T_\infty - T)/C$$

where T is the temperature at time t, T_∞ is the temperature of the bath surrounding the calorimeter, k is the heating constant, and C is the heat capacity of the calorimeter and contents. T_∞ was 194.6° K.

III. RESULTS

The X-ray powder patterns for ices VI and VII are given in Table I. The values listed

The heating curve of ice VI is shown as curve 1 of Fig. 1. The transformation begins, at a heating rate of about 1.5 deg/min, at 147° K and is fast at 152° K. A large amount of heat is evolved and the temperature of the thermocouple lags the temperature of the ice by an unknown and uncontrollable amount, and thus the temperatures quoted may be low. Also, the large amount of heat evolved disturbs the pseudo-steady state of the system, causing a temperature peak to occur instead of a monotonic temperature change, and this made it difficult to obtain the temperature change required to calculate the heat evolution in the transition. To obtain this temperature change the heating curve of the ice I that was formed from the ice VI was followed for a long period, and the first-order plot was extrapolated graphically back to the transition temperature. This procedure is not, of course, very precise. It yields a temperature change of 25.4 ± ~0.5° C. From the heating curve of the same sample of ice after it had transformed to ice I, and the heating curve of the empty calorimeter, this temperature change yields a heat evolution of 16 ± ~2 cal/g,* if the heat capacities of ices Ih and Ic are assumed to be the same. From the heating curve of ice VI and the heating curve of the same sample in the form of ice I, the heat capacity of ice VI seems to be greater than that of ice I.

A sample of ice VI was heated in the X-ray camera for 4 minutes successively at the temperatures 106, 113, 127, 137, 146, and 158° K. After each heating it was cooled to ~90° K and the X-ray powder photograph was taken. Between 146° and 158° K the pattern changed from that of ice VI to that of ice Ic. Another sample of ice VI held at 143° K did not change in 10 minutes but had changed to ice Ic in 100 minutes. The rate of transformation is therefore temperature dependent.

The heating curve of ice VII is shown as curve 2 of Fig. 1. Ice VII starts to transform

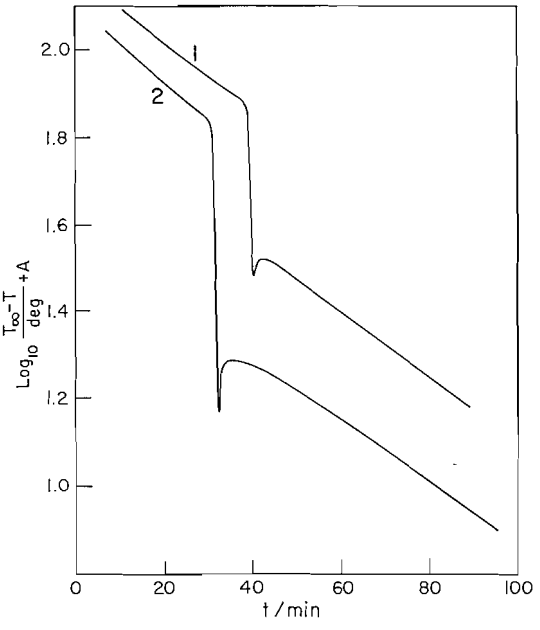

FIG. 1. First-order plot of the heating curves of the high-pressure ices. Curve 1: initially ice VI, A = 0.20. Curve 2: initially ice VII, A = 0.00.

In the previous paper in the series (1) the results for ice V were erroneously reported. The increase in temperature was 15.5 ± ~1° C and the heat evolved 11 ± ~2 cal/g.

at a heating rate of 1.5 deg/min at 123° K, and transforms rapidly at 131° K. The temperature lag between the thermocouple and the ice is likely to be greater for ice VII than for ice VI, because the heat evolved is greater, and the temperatures quoted are likely to be low. Similarly the pseudo-steady state is disturbed by the heat evolution, and the same techniques as outlined above for ice VI were used to find the "steady-state temperature change", which was 48.5 ± ~1° C, and this yielded 31 ± ~4 cal/g for the heat evolved.

A sample of ice VII was heated in the X-ray camera for 4 minutes successively at the temperatures 103, 119, 127, and 138° K. After each heating it was cooled to ~90° K and the X-ray powder photograph was taken. Between 127° and 138° K the pattern changed from that of ice VII to that of Ic with a trace of Ih. Another sample was held at 125° K for 21 hours and cooled to ~90° K and its X-ray powder photograph was taken. About half had transformed to ice Ic. The same sample was then kept at 133° K for 4 hours and cooled to ~90° K, and its X-ray powder photograph again taken. Only a trace of ice VII was left. The rate of transformation of ice VII to ice Ic is therefore temperature dependent. There is no inconsistency in the rates of transformation of ices VI and VII measured by the calorimetric and the X-ray methods. In the calorimetric experiments, the heat of transition autoaccelerates the reaction, and causes the thermocouple temperature to lag the ice temperature, so that the measured transition temperatures are probably low. Whereas in the X-ray experiments, the heat of transition is largely lost to the cooling gas without the ice warming greatly, and the measured temperatures are probably closer to those of the ice, and the transition temperatures are thus more reliable than those obtained in the calorimetric work.

The magnitude of the heat evolved cannot be compared in detail with the thermodynamic properties of the ices because too little is known about the thermodynamic properties. The magnitude is, however, consistent with the appropriate sum of the differences in internal energy on the equilibrium lines (2).

IV. DISCUSSION

For purposes of comparison, the X-ray powder patterns of all the phases of ice we have examined are represented in Fig. 2. As can be seen, they are readily distinguishable one from the other and are detectable in the presence of one another, except for ice Ic in the presence of Ih. The pattern for ice VII has a marked pseudo-cubic appearance and the strong lines can be formally referred to a body-centered cubic cell, $a = 3.45$ Å.

Rough values of the rates and heats of the irreversible transformation of several phases of ice that are metastable at 1 atm have now been obtained, and it is worthwhile to compare them. The data are summarized in Table II. The transformation rates for at least some of the transformations depends on the history of the sample (1), and this is not under perfect control. Nevertheless, the temperatures of transformation for the given heating rate, which is 1–2 deg/min, are probably roughly comparable for all the ices as they were all obtained in roughly the same way. In particular, the ice used was either freshly made or had been stored in liquid nitrogen since it was made.

There appears to be at least a rough relationship between the heat evolved and the temperature of transformation. There is also a rough relationship between these quantities and the infrared and Raman frequencies (3, 7, 8, 9). For example, the larger the O—H stretching frequencies, i.e. the nearer they are to those of the vapor, the lower usually is the transition temperature. Likewise, the dielectric relaxation times (10) correlate roughly with the data in Table II. In particular, ice II, which does not transform until

*Temperature of rapid transformation of a freshly made sample, or one that had not previously been heated above 80° K, for a heating rate of about 1–2 deg/min.
†Iv is vitreous ice I.
‡The correct value is given in this paper.

170° K at a heating rate of 1.5 deg/min (1), has no detectable relaxation under any accessible conditions (maximum temperature 243° K) at frequencies as low as 45 c.p.s. and has a low dielectric constant, whereas ices III, V, and VI all relax faster than ice I at the same temperature. There are, however, several exceptions to these correlations, which need not be detailed.

All these processes involve deforming hydrogen bonds, but involve different deformations. It is not surprising that there are rough correlations, nor that there are exceptions.

ACKNOWLEDGMENT

We are indebted to Mr. A. Lavergne for help with the high-pressure equipment, and to Dr. J. Marckmann who made the ices.

THE DIELECTRIC BEHAVIOR OF THE SYSTEM: ACETIC ACID – CHLOROFORM – WATER AT 25° C

A. N. CAMPBELL AND J. M. T. M. GIESKES[1]
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received January 20, 1964

ABSTRACT

The dielectric constants of mixtures of water and acetic acid, of chloroform and acetic acid, and of water, chloroform, and acetic acid have been determined at 25° C, over a range of concentrations. The apparent molar polarizations, but not the dipole moments, of acetic acid have been calculated and the results interpreted in the light of an assumed structure of the mixtures.

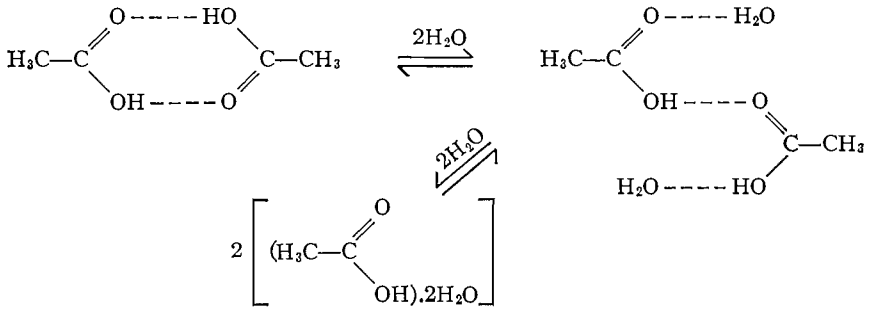
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The work detailed here is a continuing study of the system: acetic acid – chloroform – water. Earlier studies have embraced the isothermal vapor–liquid equilibrium at 25° and the volume changes on mixing (1). A more recent study (2) deals with the isobaric boiling point diagram. The guiding theme of this work is an attempt to find a connection between the very large miscibility gap which exists in this system, and other physical properties of the system. In this connection we thought that the dielectric constants and derived functions might be of interest.

The acetic acid – chloroform – water system stands in sharp contrast to the system acetone–chloroform–benzene, which we have previously investigated (3). In the latter system there is no miscibility gap and a compound is formed by hydrogen bonding between chloroform and acetone. We were able to prove the undoubted existence of this compound by a study of the freezing point curve, but, in addition, we demonstrated it by a study of the dielectric constant, or rather dipole moment, of acetone–chloroform mixtures, when increasing quantities of the inert solvent benzene were added. We have now carried out similar measurements on acetic acid – chloroform mixtures, with increasing additions of the inert, symmetrical carbon tetrachloride. In the case of acetic acid, however, the problem is complicated by the known association of acetic acid. Extrapolation of molar polarization to infinite dilution, in the usual way, becomes meaningless.

Because of the importance of acetic acid and its rather complicated structure, the literature is extensive and need not be gone into in detail. Smyth and Rogers (4) studied the dielectric behavior of acetic acid in benzene and in ethyl ether: Le Fevre and Vine (5) did similar work in the region of low concentration in benzene. More significant is the work of Pohl, Hobbs, and Gross (6), who studied acetic acid in very dilute solutions in benzene and heptane. They found an increase in the polarization of acetic acid at concentrations smaller than 0.004 mole fraction in benzene, and smaller than 0.001 mole fraction in heptane. These results they attribute to a dimer $\rightleftarrows$ monomer equilibrium. The dielectric constant of pure acetic acid increases with rising temperature and this is explained as being due to the favoring, at higher temperatures, of an open-chain polymeric form, rather than the cyclic dimer (7). Results of Raman spectra (8) of solutions of acetic acid in water suggest that an equilibrium exists between ring dimers and open-chain hydrogen bonded complexes with water, thus:

[1]*Holder of C.I.L. Fellowship, 1963–64.*



Work on the dielectric constants of acetic acid – water mixtures has been restricted to very dilute solutions (9) and nothing whatever appears to have been done on the dielectric constants of acetic acid – chloroform mixtures.

EXPERIMENTAL

For dielectric constant measurements we used a Sargent Oscillometer Model V and a Sargent Oscillometer Cell Compensator. The oscillometer works at a frequency of 5 megacycles per second. Because of its design, the cell is difficult to immerse in a liquid bath but we found that a well insulated air chamber could be controlled to 25.00 ± 0.05° C; such a temperature fluctuation is well within the accuracy of measurement (0.05%).

Fisher Certified Reagents were used throughout. Water was, therefore, the principal significant impurity, but, because of its high dielectric constant, every trace of it had to be removed. In the case of acetic acid, the freezing point was determined first and this gave a measure of the amount of water present. The calculated amount of acetic anhydride was then added and the mixture refluxed for 12 hours. After distillation, the distillate was submitted to repeated fractional crystallization, until a freezing point of 16.58° C was obtained; this is accepted as the freezing temperature of anhydrous acetic acid. The dielectric constant of this acid was 6.21, against the literature value of 6.18.

Chloroform was treated with concentrated sulphuric acid, washed with water until no acidity was detectable, dried over calcium chloride, and finally distilled from phosphorus pentoxide. The water used had a specific conductance of 5×10^{-6} mhos cm^{-1} at 25° C.

RESULTS

The System: Acetic Acid – Chloroform

1. The Concentrated Region

The accuracy of the measurements of dielectric constant is ±0.01.

A mixture containing 20.57 mole % $CHCl_3$ and 79.4 mole % HAc in CCl_4.—This is a pseudobinary system, in which the concentration of carbon tetrachloride is variable. To calculate the apparent polarization of the acetic acid, we made use of the Debye formula (as above) but for the polarization of the chloroform we used the value for chloroform at corresponding concentrations in carbon tetrachloride. This value is obtained from a graph of our measurements (not given) of the polarization of chloroform in carbon tetrachloride. Incidentally, this graph, when extrapolated to zero concentration, yields a value for the dipole moment of chloroform of 1.13 D, in good agreement with the literature value (10). The results are tabulated in Table III.

At a concentration of 20% by weight of water, the specific conductance has already risen to 1×10^{-4} mhos cm^{-1}. A conductivity of this magnitude is sufficient to interfere with the determination of dielectric constants, by ordinary methods. Johnson and Cole (11), in their study of formic acid, state that measurements below a frequency of 10^4 cycles and a conductance of 6×10^{-5} mhos cm^{-1} at 25° C, will lead to too large a value of the dielectric constant. In the present study a frequency of 5×10^6 cycles was used, so that, so long as the conductivity did not exceed 10^{-4} mhos, presumably no correction is needed. In this region (up to 20% water), therefore, we continued to use the Sargent Oscillometer. We went to considerable pains to obtain anhydrous formic acid and, having obtained it, we determined the dielectric constant in the Sargent apparatus, and we obtained a value in good agreement with that of Johnson and Cole. We therefore concluded that the Sargent apparatus gives good results up to a conductivity of 6×10^{-5} mhos and we have hopefully assumed that the apparatus continues to function accurately up to a conductivity of 10^{-4} mhos. It is claimed that corrections can be applied when the conductivity exceeds the above figure (12), but we are sceptical of such corrections and therefore we have not entered the region of higher conductivity. For this region of higher conductivity, an entirely different high frequency method is necessary.

Table VI contains data for the specific conductance and the dielectric constants as determined.

The Ternary System: Acetic Acid – Chloroform – Water

For this investigation we made up large amounts of stock solutions of chloroform and acetic acid of known compositions. To each of these stock solutions water was added in known amount, little by little, and the dielectric constant determined. For one set of experiments, in which the water content was allowed to go as high as 16–69% the specific conductances were also determined, to ensure that the allowable limit of conductance had not been exceeded.

DISCUSSION OF RESULTS

System: Acetic Acid – Chloroform

weight fraction of acetic acid, a minimum is found to occur at a concentration of about 20% by weight of acetic acid and dielectric value of 4.45, that is, the effective polarization of the mixture is reduced below those of its components. This negative deviation may indicate dipole association of chloroform with acetic acid, or alternatively, that the effect of adding chloroform to acetic acid is to decrease the number of open chain dimers in favor of ring dimers, which have very small dipole moments. The fact, however, that the dielectric constant of acetic acid itself is rather low suggests that the ring dimer form predominates, even in the pure acid.

When the molar polarizations of acetic acid in carbon tetrachloride, evaluated by the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Debye formula (Table II), are plotted as a function of mole fraction acetic acid, a striking increase in the apparent polarization of acetic acid is apparent, in the region of low concentration. This increase can only be explained on the basis of an increase in the relative amount of monomer, in dilute solution. The polarization of acetic acid in benzene and in heptane behaves in the same way, according to Pohl, Hobbs, and Gross (6): in the latter solvents, however, the effect is observed at a lower concentration. These observations are in agreement with the heats of dimerization as reported by Moelwyn-Hughes (13).

The apparent polarizations of acetic acid – chloroform mixtures, dissolved in carbon tetrachloride, were also obtained by the Debye method. This calculation makes the large assumption that the chloroform retains its molar polarization in the three-component mixture. To offset this assumption to some extent, we have used in our calculations, not the molar polarization of pure chloroform, but that of chloroform in carbon tetrachloride of corresponding concentration. Figures 1, 2, and 3 express the apparent molar polarization

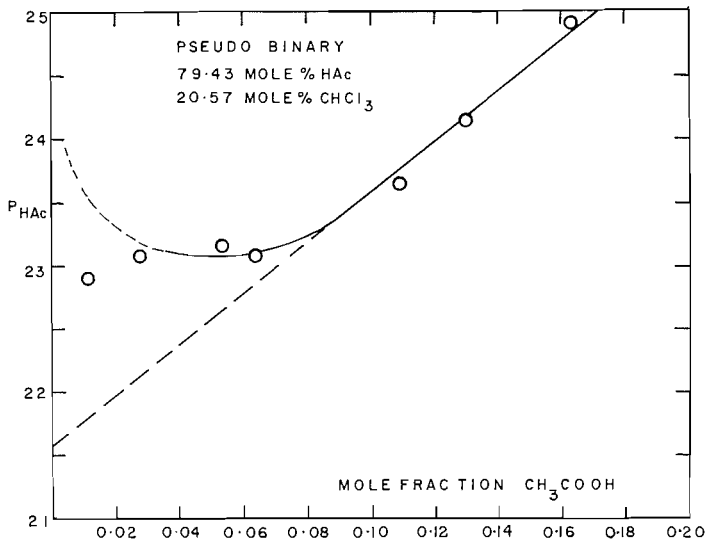

FIG. 1. Apparent polarization of acetic acid in carbon tetrachloride in system 79.43 mole % HAc, 20.57 mole % $CHCl_3$.

of acetic acid in acetic acid – chloroform – carbon tetrachloride mixtures, as a function of mole fraction of acetic acid in the ternary mixture. We have used the concentration of acetic acid as abscissa, rather than that of carbon tetrachloride, for the following reason. For a pseudobinary system of this type, the normal procedure would be to use the concentration of carbon tetrachloride as the obvious axis of reference, but, since the two types of graph (binary and pseudobinary) are very similar in character, it seemed to us that a plot in reference to the concentration of the acid was more instructive. Figures 1, 2, and 3 indicate the same behavior for the molar polarization of acetic acid, as that of acetic acid alone, in carbon tetrachloride. The apparent inaccuracy of the results in the low concentration region is due to the fact that a very slight error in the dielectric constant is very greatly multiplied in the process of calculation. There is no doubt, however, that the upward trend in the low concentration region is real. A striking feature of Figs. 1, 2, and 3 is that in all of them, if the linear portion of the curve is extrapolated to infinite dilution, the extrapolated value is the same, viz. 21.6 $\pm$ 0.1 ml.

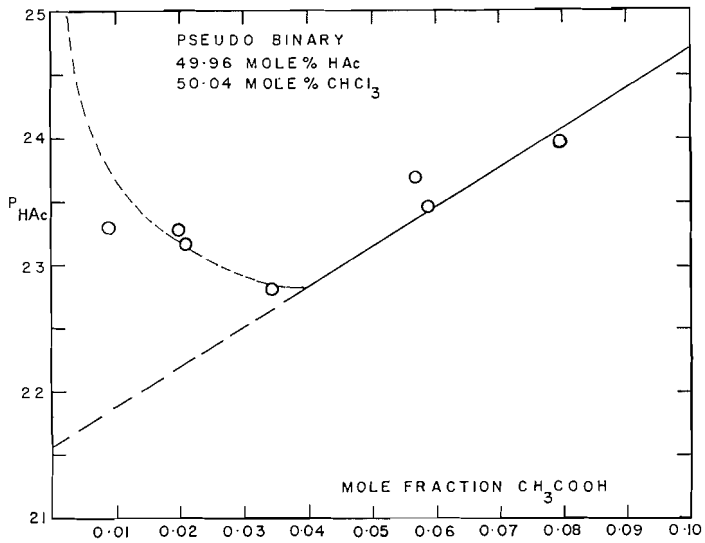

FIG. 2. Apparent polarization of acetic acid in carbon tetrachloride in system 49.96 mole % HAc, 50.04 mole % $CHCl_3$.

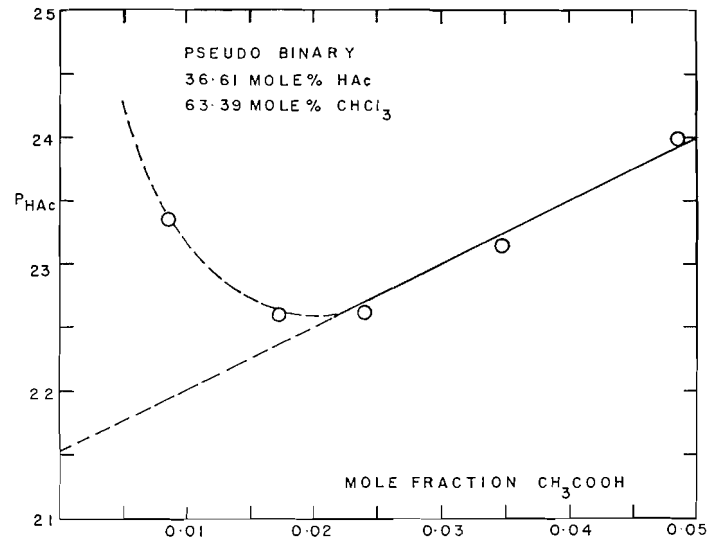

FIG. 3. Apparent polarization of acetic acid in carbon tetrachloride in system 36.61 mole % HAc, 63.39 mole % $CHCl_3$.

From the results of Davies, Jones, Patnaik, and Moelwyn-Hughes (14) on propionic acid in carbon tetrachloride and in chloroform, and also from the study by Brown and Mathieson (15), it appears that the heat of dimerization of acetic acid in carbon tetrachloride is greater than in chloroform and that the monomer concentration is greater in chloroform than in carbon tetrachloride. Similar results and conclusions were arrived at by Barrow and Yerger (16), who think that there is an association, via hydrogen bonding, between an acetic acid monomer and a chloroform molecule, the equilibrium constant being 0.2 at the lower limit.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

It seems to us that our dielectric work confirms the above view. The fact that the increase in polarization is delayed as chloroform is added to acetic acid can be explained on the assumption that the monomer forms a dipole associate with the chloroform. This assumption would also explain the minimum in the dielectric constant of acetic acid – chloroform mixtures. The fact that all extrapolations give the same value, viz. 21.6 ± 0.1 ml, for the polarization of acetic acid, may indicate that, of the two competing equilibria

$$(CH_3COOH)_2 \rightleftharpoons 2CH_3COOH \qquad \text{(i)}$$

and

$$CH_3COOH + CHCl_3 \rightleftharpoons H_3C{-}C(=O\cdots HCCl_3){-}OH \qquad \text{(ii)}$$

the former is still predominant and lies to the side of the dimeric form.

The System: Acetic Acid – Water

Figure 4 shows that up to a concentration of 10% by weight of water, the dielectric

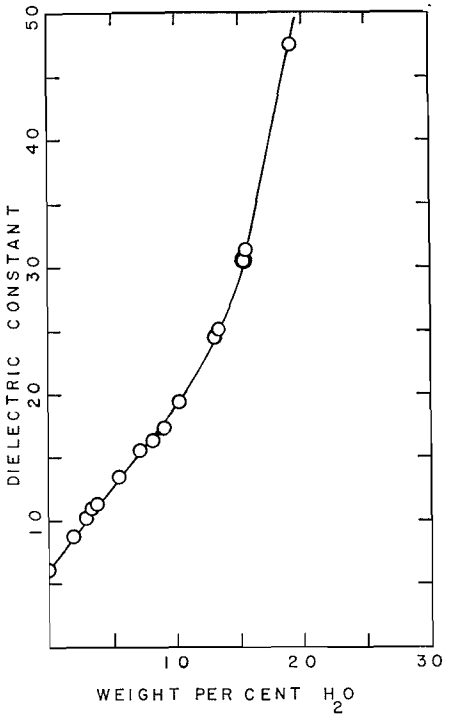

FIG. 4. Dielectric constant in system acetic acid – water at 25°.

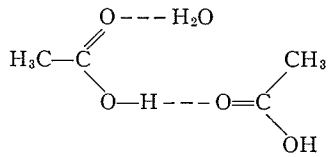
constant increases linearly. At higher concentrations of water the slope increases and then becomes linear again. Kozo Nagano (9), who studied the effect of small additions of water, up to 2% by weight, on the dielectric constant of acetic acid, at 30° C, had already noticed the rapid increase in dielectric constant. It has been suggested by S. Fénéant-Eymard (8) as a result of her studies of Raman spectra, that acetic acid, on dilution with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

water, first transforms from ring dimers into chain dimers, followed by hydration with formation of a dihydrated dimeric complex.

The behavior of Fig. 4 suggests that, at first, the ring dimers form open chain dimers, which then, via hydrogen bonding, form a complex with one molecule of water. We suggest this because the change of slope commences in the region of 33 mole % water. We, therefore, suggest a complex of the form



At higher concentrations, the hydroxyl group itself will commence to associate with a water molecule to form the dimeric dihydrate suggested by Fénéant-Eymard (8).

The System: Acetic Acid – Chloroform – Water

In all cases the relation between the dielectric constant and the weight per cent of water is linear. There is a sharp increase in dielectric constant at concentrations greater than 33 mole % of water, similar to the behavior of the system: acetic acid – water. The slopes of the straight lines decrease in the pseudobinary systems with increasing chloroform concentration. Our explanation of this behavior is the same as that offered for acetic acid – water mixtures, but the situation is complicated by the presence of the chloroform. Whereas water has a marked tendency to increase the dielectric constant of acetic acid, chloroform, on the assumption that it associates with the acid monomer to give a less polar complex, will tend to cause a decrease in the dielectric constant. These two competing effects could explain the lesser rate in the increase of the dielectric constant at higher chloroform concentrations.

INTRAMOLECULAR DIAZO COUPLING AND MOLECULAR REARRANGEMENT OF *o*-AMINOPHENYLCARBINOLS[1]

ROBERT L. COHEN[2] AND ANTHONY J. SISTI
Department of Chemistry, Adelphi University, Garden City, Long Island, New York
Received November 7, 1963

ABSTRACT

A number of 1-(2-aminophenyl)-1-(substituted aryl)ethanols were deaminated, yielding ketones, formed by a molecular rearrangement and, in some instances, azo ketones formed by intramolecular coupling and cleavage. The sensitivities of these two reactions, one characteristic of the aryl cation and the other of the diazonium group, to relatively small changes in the electrical nature of the migrating group were determined.

The products of decomposition of the aromatic diazonium ion (I) may be classified as resulting from the aryl cation (II) (produced by the irreversible loss of nitrogen from I),

I II

or from the diazonium group functioning as an electrophile. The available data in the literature indicate that the aryl cation (II) is a highly reactive, non-selective moiety (1, 2). Thus, the heterolytic acid-catalyzed decomposition of diazonium salts normally leads to substitution by solvent or other nucleophiles (3, 4), but in certain instances molecular rearrangement (2) and elimination, yielding benzyne intermediate (2, 5, 6), have been observed.

The well-known coupling reaction of aromatic diazonium ions yielding azo compounds illustrates the electrophilic property of the diazonium group. Other reactions indicating this property have been discussed elsewhere (7, 4 (p. 424 ff.)).

Recently, an interesting intramolecular coupling and cleavage of a diazotized amine was reported (8). Namely, when 1-*o*-aminophenyl-1-(2,5-dimethyl-4-methoxyphenyl)-ethanol (III, $R_1 = R_4 = CH_3$, $R_3 = OCH_3$) was treated with nitrous acid, in addition to phenol and the expected rearrangement product (2) (IV), an 18% yield of azo ketone (V)

[1] 
III IV V

was isolated (eq. 1). The intermolecular application of the aforementioned reaction led to an excellent synthesis of aldehydes and ketones (9, 10, 11).

[1]*Taken in part from the Ph.D. thesis of Robert L. Cohen, Adelphi College, 1963; presented at American Chemical Society Meeting, New York, N.Y., September 9–13, 1963.*

[2]*Present address: Jackson Laboratory, Organic Chemicals Department, E.I. du Pont de Nemours and Company, Inc., P.O. Box 525, Wilmington 99, Delaware.*

The present paper deals with a study of the factors (steric and (or) electrical) which promote the novel rearrangement of the anisyl group yielding azo ketone. It is also of interest to note that compounds of type III afford an excellent opportunity to study simultaneously the reactivity and selectivity of the aryl cation (II) and the diazonium group (I) with minor changes in the electrical nature of the migrating group (eq. 1).

RESULTS

The amino alcohols listed in Table I were prepared by treatment of the appropriately substituted *o*-aminobenzophenones with methylmagnesium iodide. The *o*-aminobenzophenones were prepared by conventional Friedel–Crafts acylations. Each compound was diazotized in acidic aqueous dioxane and the resulting diazonium salts were decomposed at room temperature. Three products were isolated: alkali-soluble material presumably phenol, ketones resulting from molecular rearrangement, and azo ketones (when produced) resulting from intramolecular coupling and cleavage. The two ketones were separated chromatographically on an alumina-packed column.

The results of the diazotization of various 1-(2-aminophenyl)-1-(substituted aryl)-ethanols (III), yielding ketone (IV) and azo ketone (V), are given in Table II (eq. 1). No fluorenol resulting from ring closure (2) could be isolated. The ketones (IV and V) were identified by infrared spectra and elemental analysis. Structure determinations were not carried out since ketones (2) and the azo ketone previously isolated (8) from similar reactions were synthesized unequivocally.

DISCUSSION

Inspection of the results presented in Table II reveals that *azo ketone* (V) was produced *only* by those amines which contain alkylated anisole rings (III*f*–III*i*). Significant amounts were produced from the diazotization of amines which bore two alkyl substituents in the anisole nucleus (compare III*e* and III*f* with III*g*–III*i*). The effect of the *ortho*-substituent (R_1) in promoting azo ketone formation cannot be primarily steric in nature (compare III*g* and III*i* with III*j* and III*k*). Specifically it should be noted that the azo coupling of the electrophilic diazonium group is particularly sensitive to the electrical changes in the migrating anisyl group (compare III*g*, III*h*, and III*i* with III*e* and III*f*, and with III*j* and III*k*). A rationalization for the results is best presented by assuming that the transition state for intramolecular azo coupling resembles the intermediate presented in equation 2. Maximum stabilization for the transition state is furnished by the *p*-methoxyl group, however, this substituent is not sufficient to yield a significant amount of coupling product. If the inductive stabilizing effect of the 1-methyl and 2- or 4-methyl groups are added, the rate of intramolecular azo coupling is fast enough to produce reasonable yields of the azo ketone. This interpretation of the results is in complete agreement with previously reported studies (12). The rate of coupling of *p*-nitrobenzenediazonium sulphate with various alkylated anisoles increased in the following order: *m*-methylanisole, 2,3-dimethylanisole, 2,5-dimethylanisole, and 3,5-dimethylanisole (anisole and *o*-methylanisole do not couple at all). Competitive coupling studies of phenols and substituted phenols with *p*-nitrobenzenediazonium sulphate revealed that chlorine and bromine deactivate whether *ortho* or *meta* to the coupling position (coupling occurs *para* to —OCH_3 or —OH group). Thus, the methyl, chloro, and bromo groups, which are sterically similar, whether *ortho* or *meta* to the coupling site exert effects consistent with their respective inductive electrical properties. A rationale for migration is therefore

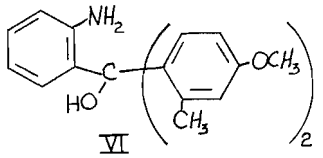
*Yields in parentheses refer to recrystallized ketone; those without parentheses to chromatographed yield.
†Yields refer to crystallized material.
‡1-(2-Amino-4,5-dimethylphenyl)-1-(substituted aryl)ethanol (VI).
§Yield of 2,4-dinitrophenylhydrazone.
‖The results of these compounds were reported previously (ref. (2)).

envisaged as an intramolecular electrophilic attack by the diazonium group upon the anisyl group (eq. 2).

[2] 
In a previously reported result (2), azo ketone was not isolated when amino alcohol VI was deaminated. Further substantiation of the selectivity and sensitivity of the electro-



philic diazonium group to relatively minor electrical changes was obtained upon diazotization of the amino alcohol (VII) which resulted in the isolation of a 7% yield of azo ketone (VIII) (eq. 3).*

[3] 
Further inspection of Table II reveals that the yields of ketone (IV), produced by migration of the aryl group to an electron-deficient carbon (2) (aryl cation), were essentially *constant* (III*f*–III*k*). These constant yields are significant since in those cases in which negligible amounts of azo ketone were produced (III*f*, *j*, and *k*), the increased portion of the reaction via aryl cation gave mainly phenol. Thus, the aryl cation is relatively insensitive to these electrical changes in the migrating group. Since it has been demonstrated that the lifetime of the aryl cation is very short (13) these results are not completely unexpected. However, they strongly support the mechanism previously offered for the formation of ketone (2). Thus, the electron-donor group (—OCH_3) in the *para*-position of the migrating group assists rearrangement provided an *ortho*-substituent is present (compare III*c*, *d*, and *e* with III*f*–*k*). This electrical assistance is to be expected in this type of rearrangement. Provided the *p*-methoxyl group is present, the yield of ketone is related to the number of free *ortho*-positions (III*f*–*k*). When the *p*-methoxyl group is absent the effect of an *o*-substituent upon ketone formation appears to be electrical (III*a*–III*d*). The rate of ketone formation, therefore, appears largely determined by the number of free *ortho*-positions, and the ground state electron density, of the migrating

*2,5-Dimethyl-4-methoxy-2'-(2,5-dimethyl-4-methoxyphenyl)benzophenone (27%) and 1,4-dimethyl-3-methoxy-9-(2,5-dimethyl-4-methoxyphenyl)-9-fluorenol (15.3%) were also isolated.

aryl group. As previously presented (2), the following reaction path is in accord with the data (eq. 4).

[4] 
EXPERIMENTAL

Synthesis of o-Aminobenzophenones

The following ketones were synthesized by the method of Kranzlein (14): 2′-chloro-4,5-dimethyl-2-aminobenzophenone, m.p. 121.5–123° (reported (14), 120°); *2′-bromo-4,5-dimethyl-2-aminobenzophenone*, m.p. 111–112.5°; yield, 61%, crystallized from 95% ethanol. Anal. Calc. for $C_{15}H_{14}BrNO$: C, 59.22; H, 4.64; N, 4.61. Found: C, 59.26; H, 4.62; N, 4.53.

2-Amino-4′methoxy-2′-methylbenzophenone

This was prepared according to the procedure of Sternbach *et al.* (15) by treating the Grignard reagent prepared from 4-iodo-3-methylanisole (16) with acetyl anthranil (17); yield, 17%; m.p. 60–61°, crystallized from aqueous ethanol. Anal. Calc. for $C_{15}H_{15}NO_2$: C, 74.66; H, 6.26; N, 5.81. Found: C, 74.53; H, 6.34; N, 5.69.

The following series of substituted benzophenones were prepared according to the procedure of Lothrup (18): 2,3-dimethyl-4-methoxy-2′-aminobenzophenone, m.p. 147–149° (reported (18), 144–145°); *2-ethyl-4-methoxy-5-methyl-2′-aminobenzophenone*, m.p. 116–118°; yield 49%, crystallized from 95% ethanol. Anal. Calc. for $C_{17}H_{19}NO_2$: C, 75.81; H, 7.11; N, 5.20. Found: C, 75.67; H, 7.16; N, 5.33.

2-Chloro-4-methoxy-5-methyl-2′-aminobenzophenone

2-Chloro-4-methoxy-5-methyl-2′-aminobenzophenone, m.p. 124–126°; yield, 29%, crystallized from absolute ethanol. Anal. Calc. for $C_{15}H_{14}ClNO_2$: C, 65.34; H, 5.12; N, 5.08. Found: C, 65.20; H, 5.20; N, 5.15.

2-Bromo-4-methoxy-5-methyl-2′-aminobenzophenone

2-Bromo-4-methoxy-5-methyl-2′-aminobenzophenone, m.p. 139–141°; yield, 22%, crystallized from 95% ethanol. Anal. Calc. for $C_{15}H_{14}BrNO_2$: C, 56.26; H, 4.41; N, 4.37. Found: C, 56.21; H, 4.25; N, 4.52.

The following anisoles were prepared by treating the corresponding phenols with methyl iodide for 5 hours in refluxing alcoholic potassium hydroxide: 2,3-dimethylanisole, b.p. 195–198° at 760 mm (reported (19), 199° at 760 mm), yield, 73%; 5-ethyl-2-methylanisole, b.p. 77–80° at 4.3 mm (reported (20), 96° at 16 mm), yield 81%; 5-chloro-2-methylanisole, b.p. 204–207° at 760 mm (reported (21), 206–208° at 760 mm), yield, 64%; 5-bromo-2-methylanisole, b.p. 75° at 1.4 mm (reported (22), 108° at 15 mm), yield, 83%. 2,3-Dimethylphenol was a commercial product, the other phenols were prepared by the methods described: 5-ethyl-2-methylphenol, b.p. 89° at 2.5 mm (reported (23), 224° at 760 mm); 5-chloro-2-methylphenol, m.p. 70–75° (reported (21), b.p. 225° at 760 mm); 5-bromo-2-methylphenol, m.p. 78–80° (reported (24), 78°).

Synthesis of Amino Alcohols

All of the amino alcohols listed in Table I were prepared from the appropriately substituted *o*-aminobenzophenone and methylmagnesium iodide, except compound VII which was prepared by treating the Grignard reagent of 4-iodo-2,5-dimethylanisole with methyl anthranilate. *4-Iodo-2,5-dimethylanisole* was prepared from 2,5-dimethylanisole by the procedure of Oki and Sato (25), m.p. 46–48°, yield, 60%. Anal. Calc. for $C_9H_{11}OI$: C, 41.25; H, 4.20. Found: C, 41.35; H, 4.36.

In each instance the ethereal solution of the Grignard reagent was cooled in an ice bath during addition of the carbonyl compound. The reactions were completed by refluxing for approximately 24 hours, with the exception of the preparation of VII in which case the reaction mixture was stirred overnight at room temperature. Hydrolysis was effected with aqueous ammonium chloride. All amino alcohols were crystallized from benzene – petroleum ether with the exception of III*h* which was crystallized from 95% ethanol.

Diazotizations

The amino alcohols (5–20 mmoles) were dissolved in a minimum quantity of *p*-dioxane and added to 100–200 ml of 5–10% sulphuric acid solution. The resulting solution or suspension was diazotized with stirring by the dropwise addition of an excess of sodium nitrite dissolved in 10 ml of water. The solution was allowed to stand from ½ hour to 3 hours at 0–10°; it was then permitted to warm to room temperature and stand overnight. The decomposition was completed by warming to 40–50°. The reaction mixture was extracted three times with ether, and the combined ether extracts washed, first with two 100-ml portions of 5% aqueous sodium hydroxide, and then with water, to remove phenolic material, which was not further

characterized. The neutral ether solution was dried over calcium sulphate, the solvent removed under vacuum, and the residue in each case treated as described below.

Products from IIIc

The residue was dissolved in 15% benzene – petroleum ether and placed on the column. Elution with 45% benzene – petroleum ether yielded 0.063 g (1.34%) of oil, ν 1692 cm^{-1} (chloroform). The ketone was completely converted to its 2,4-dinitrophenylhydrazone. There was obtained 0.062 g of hydrazone, m.p. 235–236°. This was equivalent to 0.036 g (0.8%) of *2-(2-chlorophenyl)-4,5-dimethylacetophenone*. Anal. Calc. for $C_{22}H_{19}ClN_4O_4$: C, 60.21; H, 4.36; N, 12.77. Found: C, 60.10; H, 4.41; N, 12.69. Further elution of the column produced only highly colored oils.

Products from IIId

The residue was dissolved in 20% benzene – petroleum ether, placed on a column, and eluted with 1:1 benzene – petroleum ether. There was obtained 0.066 g (1.4%) of oil, ν 1690 cm^{-1} (chloroform). It was completely converted to its 2,4-dinitrophenylhydrazone, which after purification, yielded 0.104 g of hydrazone, m.p. 231–234° (decomp.). This was equivalent to 0.065 g (1.4%) of *2-(2-bromophenyl)-4,5-dimethylacetophenone*. Anal. Calc. for $C_{22}H_{19}BrN_4O_4$: C, 54.67; H, 3.96; N, 11.59. Found: C, 55.46; H, 4.29; N, 11.98. Further elution of the column produced only highly colored oils.

Products from IIIf

The residue was dissolved in 30% benzene – petroleum ether, placed on a column, and eluted with the same solvent. There was obtained 0.845 g (17%) of light yellow oil, ν 1687 cm^{-1} (chloroform). The oil was completely converted to its 2,4-dinitrophenylhydrazone yielding 1.13 g of hydrazone, m.p. 150–152.5°, equivalent to 0.655 g (13.4%) of *2-(2-methyl-4-methoxyphenyl)acetophenone*. Anal. Calc. for $C_{22}H_{20}N_4O_5$: C, 62.85; H, 4.79; N, 13.33. Found: C, 62.64; H, 4.85; N, 13.20.

Elution of the column with chloroform gave a red oil which crystallized from aqueous ethanol to yield 0.095 g (1.7%) of red needles, m.p. 71–72.5°, ν 1685 cm^{-1} (chloroform). On the basis of previous work (8) it was assigned the structure of *2-acetyl-2'-methyl-4'-methoxyazobenzene*. Anal. Calc. for $C_{16}H_{16}N_2O_2$: C, 71.62; H, 6.01; N, 10.44. Found: C, 71.78; H, 6.19; N, 10.73.

Products from IIIh

The residue was dissolved in 1:1 benzene – petroleum ether, placed on a column, and eluted with petroleum ether. There was obtained 0.862 g (18.4%) of an oil, ν 1685 cm^{-1} (chloroform). The oil was crystallized from benzene – petroleum ether yielding 0.560 g (12%) of *2-(2,3-dimethyl-4-methoxyphenyl)acetophenone*, m.p. 60.5–61.5°. Anal. Calc. for $C_{17}H_{18}O_2$: C, 80.29; H, 7.13. Found: C, 80.17; H, 7.28. The 2,4-dinitrophenylhydrazone melted at 163–165°. Anal. Calc. for $C_{24}H_{22}N_4O_5$: C, 63.58; H, 5.11; N, 12.90. Found: C, 63.39; H, 5.03; N, 13.00.

Elution of the column with 1:1 benzene – petroleum ether gave a red oil which crystallized from ethanol to yield 0.808 g (15.6%) of *2-acetyl-2',3'-dimethyl-4'-methoxyazobenzene*, m.p. 134–135°, ν 1687 cm^{-1} (chloroform). Anal. Calc. for $C_{17}H_{18}N_2O_2$: C, 72.32; H, 6.43; N, 9.92. Found: C, 71.96; H, 6.32; N, 9.80.

Products from IIIi

The residue was dissolved in petroleum ether, absorbed on the column, and eluted with 10% benzene – petroleum ether. There was obtained 0.622 g (14.2%) of *2-(5-methyl-2-ethyl-4-methoxyphenyl)acetophenone*, m.p. 68–70°, ν 1683 cm^{-1} (chloroform), which was crystallized from petroleum ether. Anal. Calc. for $C_{18}H_{20}O_2$: C, 80.56; H, 7.51. Found: C, 80.53; H, 7.59. The 2,4-dinitrophenylhydrazone melted at 170–171.5°. Anal. Calc. for $C_{24}H_{24}N_4O_5$: C, 64.27; H, 5.39; N, 12.50. Found: C, 64.07; H, 5.38; N, 12.38.

Elution of the column with 1:1 benzene – petroleum ether gave a red oil which crystallized in red needles from 80% aqueous ethanol to yield 0.799 g (16.5%) of *2-acetyl-5'-methyl-2'-ethyl-4'-methoxyazobenzene*, m.p. 49–51°, ν 1687 cm^{-1} (chloroform). Anal. Calc. for $C_{18}H_{20}N_2O_2$: C, 72.95; H, 6.80; N, 9.45. Found: C, 73.06; H, 6.69; N, 9.41.

Product from IIIj

The residue was dissolved in 45% benzene – petroleum ether, placed on a column, and eluted with 25% benzene – petroleum ether. There was obtained 0.704 g (15%) of a light yellow oil. The oil was crystallized from ethanol to yield 0.550 g (11.7%) of *2-(2-chloro-5-methyl-4-methoxyphenyl)acetophenone*, m.p. 114–115°, ν 1697 cm^{-1} (chloroform). Anal. Calc. for $C_{16}H_{15}ClO_2$: C, 69.94; H, 5.50. Found: C, 69.92; H, 5.52. The 2,4-dinitrophenylhydrazone melted at 184–186°. Anal. Calc. for $C_{22}H_{19}ClN_4O_4$: C, 58.08; H, 4.21; N, 12.32. Found: C, 57.99; H, 4.15; N, 12.20. Further elution of the column produced only highly colored oils.

Products from IIIk

The residue was dissolved in 30% benzene – petroleum ether, placed on a column, and eluted with 40% benzene – petroleum ether. There was obtained 0.740 g (15.8%) of an oil. The oil was crystallized from benzene – petroleum ether yielding 0.610 g (13.1%) of *2-(2-bromo-5-methyl-4-methoxyphenyl)acetophenone*, m.p. 123–124°, ν 1686 cm^{-1} (chloroform). Anal. Calc. for $C_{16}H_{15}BrO_2$: C, 60.20; H, 4.74. Found: C, 59.98;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

H, 4.72. The 2,4-dinitrophenylhydrazone melted at 195–197°. Anal. Calc. for $C_{22}H_{19}BrN_4O_5$: C, 52.91; H, 3.84; N, 11.22. Found: C, 52.69; H, 3.70; N, 11.18. Further elution of the column produced only highly colored oils.

Products from VII

The residue was dissolved in 1:1 benzene – petroleum ether, placed on the column, and eluted with 2:1 benzene – petroleum ether. There was obtained 0.714 g (38%) of a light yellow oil, ν 1660 cm^{-1} (chloroform). The oil was crystallized from petroleum ether yielding 0.502 g (27%) of *2,5-dimethyl-4-methoxy-2'-(2,5-dimethyl-4-methoxyphenyl)benzophenone*, m.p. 97–99°. Anal. Calc. for $C_{25}H_{26}O_3$: C, 80.18; H, 7.00. Found: C, 79.98; H, 7.07.

Elution of the column with benzene produced a red oil which crystallized from ethanol to give 0.156 g (7.4%) of *2-(2,5-dimethyl-4-methoxybenzoyl)-2',5'-dimethyl-4'-methoxyazobenzene*, m.p. 133–134°, ν 1660 cm^{-1} (chloroform). Anal. Calc. for $C_{25}H_{26}N_2O_3$: C, 74.60, H, 6.51; N, 6.96. Found: C, 74.44; H, 6.58; N, 6.86.

Further elution of the column with 2:1 chloroform–benzene yielded an oil which crystallized from benzene – petroleum ether to give 0.286 g (15.3%) of *1,4-dimethyl-3-methoxy-9-(2,5-dimethyl-4-methoxyphenyl)-9-fluorenol*, m.p. 231–233°, ν 3600 cm^{-1} (chloroform). Anal. Calc. for $C_{25}H_{26}O_3$: C, 80.18; H, 7.00. Found: C, 80.29; H, 7.07.

GAS–SOLID EXCHANGE REACTIONS

ZINC VAPOR AND POLYCRYSTALLINE ZINC SULPHIDE

E. A. SECCO

Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia

Received December 19, 1963

ABSTRACT

The exchange kinetics of zinc vapor with polycrystalline zinc sulphide, wurtzite structure, have been studied in a static system in the temperature range 720–960° C.

Plots of $\log_{10}(1-\alpha^*)$, i.e. exchange fraction, versus time reveal two processes. The initial process is a rapid simple exchange, for which the data fit a first-order rate law and which persists to a depth of 15–18 molecular thicknesses. At this depth the second, slower process, which appears to be diffusion-controlled, sets in. Kinetic and structural interpretations of these results along with the existing data on Zn–ZnO exchange are discussed.

INTRODUCTION

Recent results (1, 2) on the exchange reaction between zinc vapor and polycrystalline zinc oxide showed that the exchange rate was controlled by two processes, an initial simple exchange followed by diffusion. The initial rate was not limited to the surface but extended to a depth of 25 molecular thicknesses. On the basis of these data a sequence of rate-controlling steps was postulated, i.e., exchange and interstitial mobility, and interstitial zinc diffusion. That is, the two processes of exchange and zinc mobility via interstices occurred simultaneously, but the exchange rate predominated because it was the slower of the two rates. As the exchange reaction progressed, the "effectively" available interstices became filled, with the result that a second transport mechanism involving a coupled interstitial-lattice type of movement, i.e. interstitial diffusion, became rate-controlling and superseded the exchange rate. The present investigation on the Zn–ZnS system was undertaken to elucidate the rate-controlling steps postulated for ZnO. Zinc sulphide was suitable for this study because it possesses a structure similar to ZnO, i.e. wurtzite, along with interstices available for interstitial mobility of zinc.

EXPERIMENTAL

The polycrystalline ZnS used in this work was from two sources: I, BDH Laboratory Reagent and II, crushed single crystals prepared by sublimation of the vapor (3). In both cases the X-ray diffractograms showed only peaks characteristic of the wurtzite structure. The surface area of sulphide II was found to be 1.2 m^2/g by nitrogen adsorption measurements. The particle radius is calculated to be ca. 6.1×10^{-5} cm. The sulphide samples were dried in an oven at 150° C overnight before use.

The exchange runs were carried out in a static system with the use of quartz vessels (4), and the extent of reaction was determined by the uptake of radiozinc, as previously described (1).

RESULTS

In Figs. 1 and 2 are shown typical $\log_{10}(1-\alpha^*)$ versus time plots at different temperatures for constant Zn pressure (0.11 atm) and constant mole fraction of zinc sulphide (0.50). The features of two distinct rate processes are evident. The logarithms of the rate constants, k_e' and k_e'', obtained from the slopes of the straight lines in Fig. 1(*a*) and 1(*b*),[1] are plotted against the reciprocal of the absolute temperature in Fig. 3, lines *a* and *b*. For the initial exchange process it is found that $k_e' = 3.3\times10^3 \exp(-32.5 \text{ kcal}/RT) \text{ sec}^{-1}$.

[1]*The plot for 780° C is not included, since these data are only slightly different from the data at 800° C, as evidenced by the k_e'' value in Fig. 3, line a.*

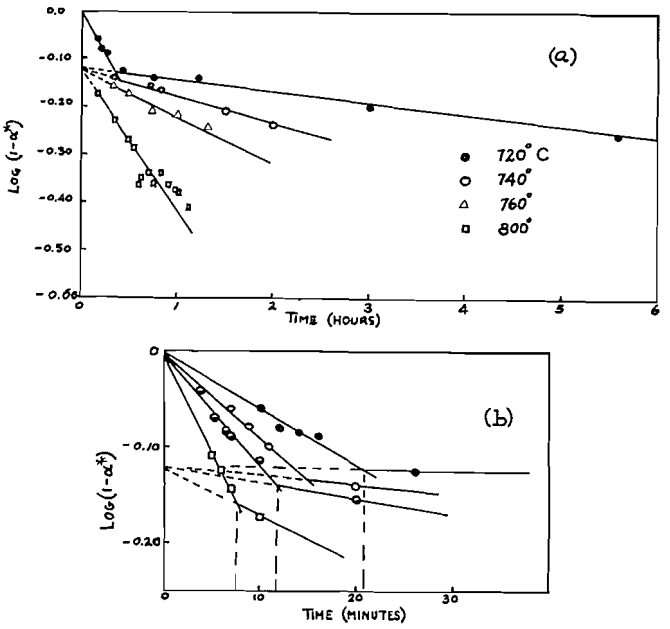

FIG. 1(*a*). Plot of $\log_{10}(1-\alpha^*)$ versus time showing two processes for sulphide I.
(*b*). Plot of $\log_{10}(1-\alpha^*)$ versus time for sulphide I, showing the first process on an expanded scale.

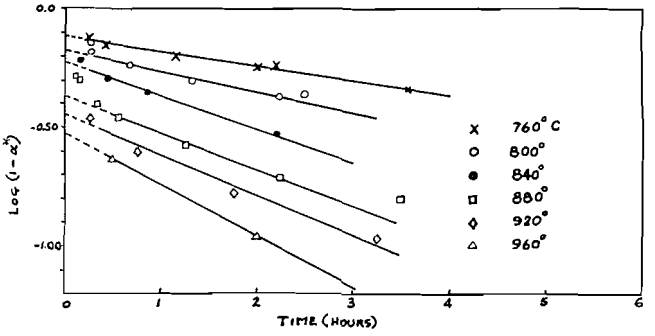

FIG. 2. Plot of $\log_{10}(1-\alpha^*)$ versus time for sulphide II.

The plot of $\log_{10} k_e''$, i.e. the second process, against $1/T$ yields a straight line corresponding to an energy of 61.5 kcal. An interesting fact is the common nonzero intercept of -0.12 corresponding to 25% reaction for the second process of sulphide I.

Figure 2 shows a similar $\log_{10}(1-\alpha^*)$ versus time plot for sulphide II. The slope for the second process at 760° C extrapolates to the same positive intercept value obtained for sulphide I, whereas the slopes above 800° C do not extrapolate to a common intercept. Above 880° C the plots do not show the distinct breaks evident at the lower temperatures.

It is most probable that the second process is a diffusion-controlled (5) transport mechanism whose rate is a function of depth. The particle radius for sulphide I was calculated to be 5.0×10^{-5} cm, using the particle size obtained from gas adsorption measurements of sulphide II, assuming a constant diffusion coefficient, D, at 760° C from the relationship $D = r^2 \times$ slope. The solutions to the diffusion equation for the case of small

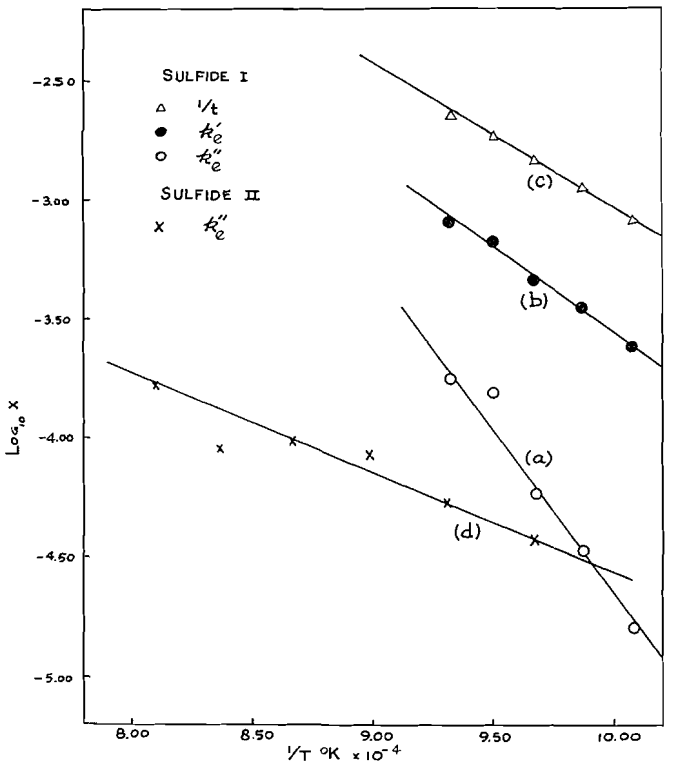

FIG. 3. Plot of $\log_{10} x$ (where $x = k_e'$, k_e'', or $1/t$) versus reciprocal temperature in °K.

spheres (1, 6), to which the polycrystalline sulphide powder approximate sufficiently well,[2] were used to calculate the diffusion coefficient for sulphide I,

$$D = 4.5 \exp (61.5 \text{ kcal}/RT) \text{ cm}^2 \text{ sec}^{-1}.$$

The plot of $\log_{10} k_e''$ versus $1/T$ (from Fig. 2) for sulphide II as given in Fig. 3 yields a straight line, *d*, corresponding to an activation energy of 20 ± 3 kcal. The k_e'' values were obtained from the best slope at a constant time of 2 hours.

DISCUSSION

The sequence of rate-controlling steps postulated for the zinc oxide exchange data may be invoked to explain the experimental results on the zinc sulphide exchange reaction reported here. The two processes of lattice exchange and zinc mobility via interstices occur simultaneously but the exchange process predominates, since it is the slower of the two. The "effectively" available interstices become filled, with the result that a transport mechanism of the interstitial diffusion type supersedes the exchange step. For zinc oxide (1) the activation energy for this latter process was found to be a composite quantity, consisting of an exchange term E_e and an interstitial mobility term, E_i, i.e.

$$E_D = E_e + E_i.$$

From the above data E_i is evaluated as 29.0 kcal, i.e. the activation energy for the direct

[2]*Since the initial and boundary conditions are somewhat ill-defined, use of the standard solutions to the diffusion problem involves some inaccuracy, which would be reflected in the pre-exponential term of the diffusion equation.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

interstice-to-interstice movement. If the time required for saturation of the sulphide interstices with zinc is taken as the time when interstitial diffusion begins, it is possible to check the value of 29.0 kcal for interstitial mobility. The plot of $\log_{10} 1/t$, i.e. the reciprocal of time (assuming a diffusion mechanism), against $1/T$ (°K) as given in Fig. 3 yields a straight line, c, corresponding to 28.0 ± 2 kcal. Furthermore, the simple relationship of $r^2 = 2Dt$, where r is the particle radius, is used to obtain the diffusion equation,

$$D_i = 10^{-2} \exp(-28 \text{ kcal}/RT) \text{ cm}^2 \text{ sec}^{-1},$$

where D_i is the interstitial mobility.

The diffusion equation for zinc in zinc sulphide differs from that for zinc in zinc oxide only in the pre-exponential factor. If the probability of an interstitial jump per second is given by

$$p_i = \nu_i \exp(-\Delta G_i^*/RT),$$

where ν_i is frequency or the number of attempts per second made by the interstitial zinc to cross the energy barrier ΔG_i^*; and since $\Delta G_i^* = \Delta H_i^* - T\Delta S_i^*$; then

$$p_i = \nu_i \exp(\Delta S_i^*/R - \Delta H_i^*/RT),$$

where ΔS_i^* is the entropy difference between the activated state and an equilibrium interstitial position and ΔH_i^* is the activation energy. The diffusion coefficient, $D_i = 10^{-2} \exp(-28 \text{ kcal}/RT) \text{ cm}^2 \text{ sec}^{-1}$, corresponds to $\Delta H^* = 26$ kcal and $\Delta S^* = -20$ cal deg^{-1} for the parameters of the Eyring diffusion equation,

$$D = (kT/h)\, \lambda^2 \exp -(\Delta H^* - T\Delta S^*)/RT,$$

with the jump distance $\lambda = 3.60$ Å. Therefore, the value of p_i is greater for ZnS than for ZnO by the difference in their entropic factors or, in structural terms, in the radii of their respective interstices.

The changing intercept value in Fig. 2 and the activation energy of 20 kcal obtained from Fig. 3, line b, indicate the appearance of another parameter which reduces the effect of temperature on the second slope. A very likely parameter is that of sintering or aggregation causing an increase in the particle size, which in turn is reflected on the slope, which is an inverse function of particle thickness, i.e. slope $\propto 1/r^2$. Assuming sintering to be the predominant process responsible for the increasing intercept value, we can evaluate the activation energy associated with sintering. The apparent temperature dependence of the diffusion-controlled exchange rate will depend on the extent of sintering that has occurred, but the actual temperature dependence is assumed to remain unchanged. In Fig. 3 the observed straight line, d, corresponding to 20 kcal is an apparent activation energy and represents a net value for the two processes. This interpretation suggests an activation energy of 41 kcal for the sintering process. This problem of sintering in an ambient of zinc vapor and in inert atmospheres is planned to be the subject of a future study.

NOTE ADDED IN PROOF: Sintering studies of zinc sulphide in an ambient of inactive zinc vapor by the radioactive-exchange method are now being carried out in this laboratory. Preliminary results show that the initial rapid exchange process persists after pretreatment in zinc vapor. These results are not concordant with the sequence of rate-controlling steps postulated for the zinc – zinc oxide exchange reaction.

THE INTERACTION OF *o*-DIPHENOLS WITH α-DIKETONES

THE REACTION OF 5,6-DIHYDROXY-*N*-METHYLINDOLE WITH DEHYDROASCORBIC ACID[1,2]

G. L. MATTOK AND R. A. HEACOCK
Psychiatric Research Unit, University Hospital, Saskatoon, Saskatchewan

Received February 3, 1964

ABSTRACT

5,6-Dihydroxy-*N*-methylindole readily reacts with dehydroascorbic acid in aqueous solution at room temperature. The *o*-diphenol system of the indole derivative interacts with the α-diketone function of dehydroascorbic acid to form a 1,4-benzodioxane derivative. This type of reaction appears to be a general one since similar interactions occur between other *o*-diphenols and α-diketones. The mechanism by which the 1,4-benzodioxane derivative is obtained when adrenochrome is reduced with ascorbic acid is discussed.

The reduction of adrenochrome (I) in aqueous solution by ascorbic acid was first described in 1948 by Beauvillain and Sarradin (1), who reported that at least two molecules of ascorbic acid were required to completely reduce 1 molecule of adrenochrome (I). Although these authors did not identify the products of the reaction they did report the spectral characteristics of the reaction mixture, which showed the presence of the typical indole chromophoric system in the ultraviolet region. Beauvillain and Sarradin also noted noted that a different "leuco" derivative was obtained from adrenochrome (I) with sodium bisulphite to that obtained with ascorbic acid. These findings were essentially confirmed 1 year later by Fischer (2); Gero and Parrot reported at about the same time that adrenochrome accelerated the decomposition of ascorbic acid solutions (3).

The products of this reaction (using an excess of ascorbic acid, i.e. five molecular equivalents) have been studied paper chromatographically (4, 5) and it was demonstrated that, along with some dehydroascorbic acid and unchanged ascorbic acid, there were three other products (with R_f values of ca. 0.42, 0.56, and 0.65 respectively when 2% acetic acid in water was used as the developing solvent) present in the reaction mixture. The first of these products was isolated as a crystalline solid and shown to be 5,6-dihydroxy *N*-methylindole (II) (i.e. DHMI)[3] (4). The second product (R_f = 0.56) (III), which could not be extracted from the reaction mixture with ether and which gave a characteristic blue-green color with Ehrlich's reagent, was not identified, although its ultraviolet spectral characteristics suggested that the indole chromophore remained intact (4). Recently it was reported in a preliminary communication that the substance giving the blue-green color with Ehrlich's reagent (R_f = 0.56) (i.e. III) was, in fact, a secondary product derived from the interaction of DHMI and dehydroascorbic acid (6). A consideration on the structure of the product (III) forms the basis of the present paper.

Paper chromatographic examination of samples of an adrenochrome – ascorbic acid reaction mixture, over a period of time, showed that the spot due to DHMI (R_f ca. 0.42) lessened in intensity whilst that due to (III) increased in intensity with increased reaction time (6); the DHMI spot eventually disappeared completely. Therefore, the substance

[1]*This investigation was supported by grants from the Department of National Health and Welfare (Ottawa) and the Government of Saskatchewan (Department of Public Health).*

[2]*Presented in part at the 46th annual conference of the Chemical Institute of Canada, Toronto, Ontario, June 1963.*

[3]*DHMI will be used as an abbreviation for 5,6-dihydroxy-N-methylindole throughout this paper.*

giving the blue-green Ehrlich spot is probably a secondary product resulting from an interaction of DHMI with ascorbic acid or one of its oxidation products. A substance chromatographically identical with (III) was produced by the interaction of DHMI and dehydroascorbic acid, but was not formed from DHMI with ascorbic acid or 2,3-diketogulonic acid (calcium salt), or from an interaction between adrenochrome and dehydroascorbic acid. The product (III) was decomposed (under nitrogen) by 40% aqueous sodium hydroxide and DHMI was regenerated (6).

Evidence which confirmed that (III) was a secondary product, derived from DHMI, was obtained from the reduction of adrenochrome by ascorbic acid in an ether–water system. In this system the DHMI was removed from the aqueous reaction mixture as soon as it was formed and in this case no secondary product was detected in the aqueous phase; only DHMI was found in the ether layer. 5,6-Diacetoxy-*N*-methylindole did not react with dehydroascorbic acid indicating that the *o*-diphenol system of DHMI must have been involved in the interaction. A paper chromatographic study showed that the 1-, 2-, 3-, and 7-positions of the 5,6-dihydroxyindole nucleus were not involved in this interaction, since chromatographically similar products, to that obtained from DHMI and dehydroascorbic acid, were obtained from dehydroascorbic acid and the following *o*-diphenols: (i) 5,6-dihydroxy-7-iodo-*N*-methylindole; (ii) 5,6-dihydroxy-7-iodoindole; (iii) 5,6-dihydroxy-2-methylindole, and (iv) adrenolutin (i.e. 3,5,6-trihydroxy-*N*-methylindole or 5,6-dihydroxy-*N*-methylindoxyl). A further indication that the interaction of DHMI with dehydroascorbic acid involved the α-dicarbonyl function of the dehydroascorbic acid molecule was obtained by treating DHMI with a sreies of α-dicarbonyl compounds (see Table I). All the α-dicarbonyl compounds used were found to react with DHMI.

TABLE I

Paper chromatography of products obtained from the interaction of: (A) several *o*-diphenols with dehydroascorbic acid, and (B) several α-diketones with 5,6-dihydroxy-*N*-methylindole (Solvent: 2% acetic acid – water; chromogenic reagent: Ehrlich's reagent)

The molecular composition of the product (III) was determined by allowing a known amount of dehydroascorbic acid to react with excess DHMI in aqueous solution. After the interaction was completed the unreacted DHMI was extracted and determined

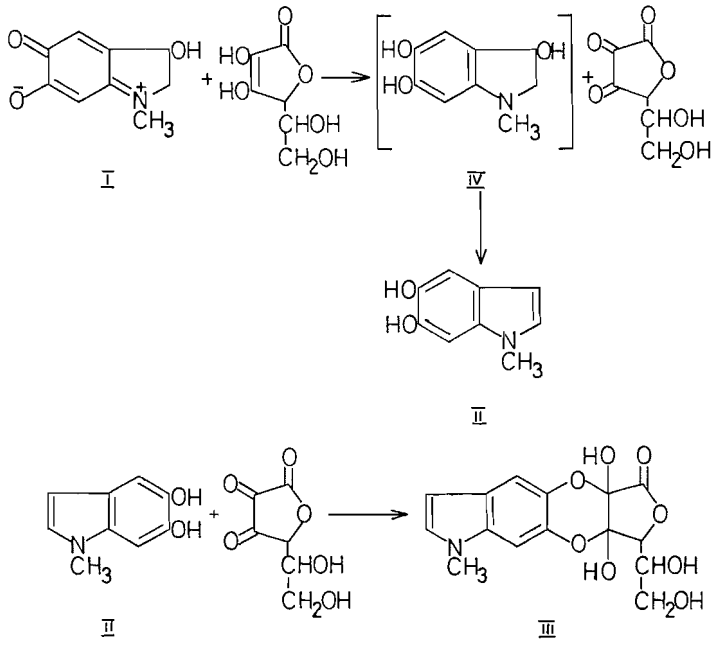
spectroscopically. By this procedure it was ascertained that the secondary product (III) was, in fact, derived from one molecule each of DHMI and dehydroascorbic acid.

Attempts to isolate the compound (III) in the solid state, from its aqueous solutions, were not successful as the compound decomposed on concentration of the solutions. However, it was possible to isolate a crystalline diacetate of (III) by acetylating the crude product obtained from either: (i) an adrenochrome – ascorbic acid reaction mixture (after removal of any unreacted DHMI by ether extraction), or (ii) a DHMI–dehydroascorbic acid reaction mixture. The acetylation procedure used was similar to that described by Walsh for the acetylation of adrenaline (7) (i.e. acetic anhydride in aqueous sodium bicarbonate). The fact that the same diacetate was obtained in both the aforementioned cases is further evidence that the compound (III), observed among the reduction products obtained from adrenochrome with ascorbic acid, is derived from the reaction of DHMI with dehydroascorbic acid. The diacetate could be readily converted into a crystalline tetraacetate by acetic anhydride and pyridine in chloroform solution.

Adrenochrome was readily reduced by 5,6-isopropylideneascorbic acid in acrylonitrile solution and gave DHMI and a secondary product analagous to (III). The chromatographic system used to examine the adrenochrome – ascorbic acid reaction mixtures (i.e. 2% acetic acid and Whatman No. 1 paper) was not satisfactory for the isopropylidene derivatives since hydrolysis of the isopropylidene group occurred. However, satisfactory separation of the products was obtained with a formamide – (ethyl acetate – chloroform) (1:4) system.

Although it had not proved possible to isolate the DHMI – dehydroascorbic acid product in the solid state, it was possible to isolate the corresponding compound derived from 5,6-isopropylidineascorbic acid as a white microcrystalline solid. However, this compound decomposed on storage and a completely satisfactory elemental analysis could not be obtained. A crystalline diacetyl derivative of this isopropylidene derivative of (III) was obtained, which, after removal of the isopropylidene group with aqueous acetic acid, gave a diacetate of (III) which was different to the diacetyl derivative obtained by acetylation of (III) by acetic anhydride in aqueous sodium bicarbonate. However, both diacetates, on further acetylation, were converted to the same tetraacetate. Acetylation of (III) by the acetic anhydride – sodium bicarbonate reagent, therefore, occurred at the 5- and 6-positions in the dehydroascorbic acid moiety of the molecule. Compound (III) (i.e. 2,3-*C*,*C*-(1′-methyl-5′,6′-indolodioxy)-L-threohexono-1,4-lactone) is probably formed in the following manner, when adrenochrome (I) is reduced by ascorbic acid. The initially formed "leucoadrenochrome" (i.e. 3,5,6-trihydroxy-*N*-methylindoline (IV)) rapidly loses water giving DHMI (II), which can then react with the dehydroascorbic acid, formed by oxidation of the ascorbic acid. The interaction between DHMI and dehydroascorbic acid occurs between the *o*-diphenol system of DHMI and the 2,3-dicarbonyl system of dehydroascorbic acid with the formation of the substituted 1,4-dioxane ring system in (III).

Although the nature of the reactions involved in the formation of the secondary product during the reduction of adrenochrome by ascorbic acid are clear, the relative positions involved are less certain. It is probably safe to assume that the lactone carbonyl of the dehydroascorbic acid molecule is not involved, but interaction could take place between the 2-carbonyl group and either of the 5- or 6-hydroxyl groups in the DHMI molecule and with similar possibilities existing for the 3-carbonyl group of the dehydroascorbic acid molecule. Structure (III) could, therefore, be written equally well with the indole system



inverted. There was no evidence that mixtures of such products were formed but it was not possible to favor either of these structures.

This type of interaction between an *o*-diphenol and an α-dicarbonyl system seems to be a general one. Paper chromatographically it has been shown that, as well as reacting with dehydroascorbic acid and 5,6-isopropylidenedehydroascorbic acid, DHMI reacts with 2,3-diketogulonic acid, diacetyl, and oxalic acid. Similarly dehydroascorbic acid has been shown to react with the following *o*-diphenols: 5,6-dihydroxy-7-iodo-*N*-methylindole; 5,6-dihydroxy-7-iodoindole; 5,6-dihydroxy-2-methylindole; 5,6-dihydroxy-*N*-methylindoxyl; adrenaline; and catechol. The products of such interactions (as yet unidentified) may have structures similar to (III).

This type of interaction is possibly of physiological significance, particularly in view of the very mild conditions under which it takes place. Ascorbic acid is known to protect catechol derivatives (e.g. adrenaline) against oxidation. This protection arises primarily from the preferential oxidation of the ascorbic acid. However, the formation of interaction products, such as those described above, could provide an additional explanation of the usefulness of ascorbic acid for the protection of catechol derivatives from oxidation. Stabilizations of this type have been reported by Gero (8, 9).

One of the most widely used chemical assay procedures for the catecholamines is the so-called "trihydroxyindole" (or "lutin") method (cf. 10). In this procedure the catecholamines (after extraction from the biological material) are oxidized to the corresponding aminochromes which are then rearranged, usually with a solution of ascorbic acid in strong alkali, to the highly fluorescent "lutins" (i.e. 5,6-dihydroxyindoxyls). The presence of ascorbic acid is necessary to "stabilize" the fluorescent products. The mechanism of this protective action is not clear. The simplest explanation, i.e. that ascorbic acid merely protects the fluorescent products against oxidation by being itself preferentially oxidized is not completely satisfactory. In view of the known instability of ascorbic acid in alkaline

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solution (11) the possibility that the protective action is due, at least in part, to some oxidation or degradation product of ascorbic acid (i.e. dehydroascorbic acid, 2,3-diketogulonic acid, or even oxalic acid) cannot be completely ruled out. Von Euler and Lishajko have, in fact, reported that alkali – ascorbic acid mixtures, of the type usually used in this procedure, spontaneously develop a reddish tint after about 7–10 minutes and this color progressively deepens with time with an accompanying increase in the "blank" fluorescence of this mixture (12), suggesting that the alkaline ascorbic acid reagent is not particularly stable.

The products of the interaction of the "lutins" with the transformation products of ascorbic acid mentioned above, which contain the α-dicarbonyl system, would retain the indoxyl structure, and consequently their intense fluorescence. The product obtained from adrenolutin (5,6-dihydroxy-*N*-methylindoxyl) by interaction with dehydroascorbic acid is still strongly fluorescent and appears to be more stable than adrenolutin. The excitation and emission wavelengths for maximum fluorescence of this interaction product are close to those of adrenolutin itself (excitation, 405 mμ; fluorescence, 535 mμ).

EXPERIMENTAL

All melting points were measured on a Leitz hot-stage instrument. The ultraviolet spectra were measured on a Beckman DK-2 spectrophotometer. The infrared spectra were recorded in chloroform solution on a Perkin–Elmer Model 137 spectrophotometer. Peroxide-free ether (or ether from freshly opened cans, Fisher reagent grade) was used throughout this investigation. The light petroleum used was B.D.H. AnalaR grade (b.p. 60–80°). Unless otherwise stated the paper chromatography was carried out on Whatman No. 1 paper with 2% acetic acid in water as running solvent with descending development. The Ehrlich's reagent used in this investigation was prepared by dissolving *p*-dimethylaminobenzaldehyde (1 g) in a mixture of methanol (75 ml) and conc. hydrochloric acid (25 ml).

A. Preparation of Starting Materials

Adrenochrome (13), 5,6-dihydroxy-*N*-methylindole (14), 5,6-diacetoxy-*N*-methylindole (15), 5,6-dihydroxy-7-iodiondole[4] (15), 5,6-dihydroxy-7-iodo-*N*-methylindole[4] (16), 5,6-dihydroxy-2-methylindole (17), adrenolutin (i.e. 5,6-dihydroxy-*N*-methylindoxyl) (18), and calcium diketogulonate (19) were prepared by the methods described in the literature. 5,6-Isopropylideneascorbic acid was prepared by the method of Vargha (20); colorless needles (m.p. 190.5–192°), Vargha reported a melting point of 220–222°). (Found: C, 50.24; H, 5.85; $C_9H_{12}O_6$ requires C, 50.00; H, 5.60%.) Dehydroascorbic acid was obtained as the methanol complex from the Nutritional Biochemicals Corporation.

B. Reduction of Adrenochrome by Ascorbic Acid

(i) In water

Ascorbic acid (60 mg) was added to a solution of adrenochrome (20 mg) in water (2 ml). Nitrogen was bubbled through the solution and after about 2 hours a sample of the reaction mixture was examined paper chromatographically (see Table I). After spraying the developed chromatogram with Ehrlich's reagent two main products (R_f's: ca. 0.42 and 0.57) and several minor products were detected (cf. 4, 6). The blue Ehrlich-staining substance (R_f 0.42), which had previously been characterized as DHMI (4), was removed by extraction with ether (6 × 1 ml) leaving an aqueous solution of the other major product (R_f 0.57: λ_{max}, 299 mμ) together with ascorbic and dehydroascorbic acids. The absence of DHMI in the aqueous mother liquors was confirmed by paper chromatography. This solution was then treated (under nitrogen) with 40% aqueous sodium hydroxide solution (1 drop), and after 1 minute, acidified with glacial acetic acid. DHMI was then detected in the reaction mixture by paper chromatography and the blue-green Ehrlich-staining substance (III) (R_f 0.57) was no longer present.

Isolation of (III) as its diacetyl derivative.—The product (III) was obtained in aqueous solution, as described above, and acetylated by the method described in section D (*ii*) to give a diacetyl derivative (m.p. 118–119°) identical with that obtained by acetylation, under similar conditions, of the DHMI – dehydroascorbic acid interaction product (III) (see section D (*ii*)).

The diacetate was fully acetylated by the method described in section D (*iii*) to give a tetraacetate (m.p. 108–109°), identical with the fully acetylated derivative of the interaction product (III).

(ii) In an Ether–Water System

Adrenochrome (5 mg) was added to a solution of ascorbic acid (25 mg) in water (1 ml) covered with ether

[4]*These compounds were erroneously referred to as 2-iodo derivatives in the references cited to the preparative procedures (cf. ref. 21).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(1 ml), and nitrogen bubbled through the system. After 2 hours, the ether and aqueous layers were separated and each layer was examined paper chromatographically, the ether extract was observed to contain DHMI, and in this case the aqueous phase contained no blue-green Ehrlich-staining substance (i.e. (III)). A control reaction mixture, prepared as above but omitting the ether, showed, on paper chromatographic examination, only a trace of DHMI and a strong blue-green spot due to (III).

C. Reduction of Adrenochrome by 5,6-Isopropylideneascorbic Acid

(i) Paper Chromatographic Examination

Adrenochrome (25 mg) and 5,6-isopropylideneascorbic acid (40 mg) were suspended in acrylonitrile (3 ml), and from time to time the mixture was shaken. The reaction mixture was kept at room temperature and the progress of the reaction was followed by paper chromatographic examination of small samples at various reaction times, using the ethyl acetate – chloroform (1:4) – formamide system (radial development) (15). The initial products were DHMI (R_f 0.48) (cf. 15), giving the usual blue color with Ehrlich's reagent and a compound (R_f 0.06) giving a brown spot with this chromogenic reagent, which quickly became dark green in color. After 24 hours virtually all the DHMI had disappeared from the reaction mixture.

(ii) Isolation of the Product

After 30 hours the reaction mixture was filtered and the filtrate evaporated to dryness at room temperature and under reduced pressure (nitrogen "leak"). The product was extracted from the syrupy residue by ether (5 ml), and obtained as a white crystalline solid (35 mg) by the addition of light petroleum and rapidly filtered in an atmosphere of nitrogen. The product (presumably a 1:1 interaction product of 5,6-isopropylidenedehydroascorbic acid and DHMI) on exposure to air became grey in color and finally turned black. It was not possible to obtain a melting point since the substance became black on heating. It was also impossible to obtain a completely satisfactory analysis. (Found: C, 57.18; H, 6.10; N, 3.58%; and mol. wt. 388. $C_{18}H_{19}NO_8$ requires C, 57.29; H, 5.08; N, 3.71%; and mol. wt. 377.)

(iii) Isolation of the Product as its Diacetyl Derivative

Acetic anhydride (0.15 ml) was added to a solution of the residue (obtained from the reduction of adrenochrome by 5,6-isopropylideneascorbic acid by the method described in section D (*ii*)) in a mixture of dry chloroform (3 ml) and pyridine (0.15 ml). After 20 minutes the reaction mixture was washed with 2 *N* hydrochloric acid (3 × 2 ml); saturated aqueous sodium bicarbonate (3 × 2 ml) and finally water (3 × 2 ml). The dried (Na_2SO_4) chloroform solution was then evaporated to dryness *in vacuo* (nitrogen "leak") at room temperature and the residue obtained was extracted with ether (5 ml); on addition of light petroleum to the ether extract a flocculent white precipitate (137 mg) was obtained. Recrystallization from ether: light petroleum raised the melting point of the diacetyl derivative of the 5,6-isopropylidene derivative of (III) to 135–136°. (Found:[5] C, 57.09; H, 5.19; N, 3.06%; and mol. wt. 471. $C_{22}H_{23}NO_{10}$ requires C, 57.26; H, 5.02; N, 3.04%; and mol. wt. 461.) The product showed the characteristic indole absorption maximum in the ultraviolet region at 284 mμ (in methanol).

(iv) Attempted Preparation of a Second Diacetyl Derivative of (III)

The diacetyl-isopropylidene derivative of (III), prepared by the method described in section C (*iii*) (15 mg), was dissolved in 30% acetic acid – water and the solution maintained at 60° for 1 hour. The reaction mixture was then extracted with chloroform (6 × 1 ml) and the combined, dried (Na_2SO_4), chloroform extracts concentrated, under reduced pressure (nitrogen "leak"), to about 0.2 ml. Ether was added to the concentrated chloroform extract and a white precipitate was then obtained, which decomposed (smelling strongly of acetic acid) on the filter.

A similar concentrate was treated with pyridine (0.3 ml) and acetic anhydride (0.15 ml); after standing for 10 minutes at room temperature, the reaction mixture was diluted with chloroform (1 ml) and washed successively with 2 *N* hydrochloric acid, saturated aqueous sodium bicarbonate, and finally water. The dried (Na_2SO_4) chloroform solution was concentrated to ca. 0.1 ml and light petroleum added. A white microcrystalline precipitate (yield: 0.9 mg; m.p. 109–110°) was obtained, which was identical with the tetraacetate of (III) obtained in Section D (*iii*).

D. Interaction of 5,6-Dihydroxy-N-methylindole with Dehydroascorbic Acid

(i) Paper Chromatographic Examination

DHMI (10 mg) and dehydroascorbic acid (methanol complex; 18 mg) were suspended in water (1 ml) and nitrogen bubbled through the suspension; after 15 minutes dissolution was complete. Chromatographic examination of the reaction mixture showed that the intensity of blue-green Ehrlich staining spot increased with time, with a corresponding decrease in the intensity of the spot due to DHMI. After 1 hour the spot due to DHMI had virtually disappeared.

(ii) Acetylation of (III)

A reaction mixture prepared as described in D (*i*) was allowed to stand at room temperature for 1½ hours, after which time it was extracted with ether (6 × 1 ml) to remove unreacted DHMI. The product (III) was then obtained in aqueous solution and acetylated by a procedure similar to that described by Walsh for the

[5]*Acetyl determinations on the same sample varied with the method used, presumably due to hydrolysis of the lactone ring and generation of catechol derivatives during the assay procedure.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

acetylation of adrenaline (7). Sodium bicarbonate (200 mg) and acetic anhydride (0.09 ml) were added to the aqueous mother liquors. The reaction mixture was allowed to stand for 20 minutes and then extracted with chloroform (6 × 1 ml). The dried (Na_2SO_4), combined, chloroform extracts were then concentrated on a water bath to about 0.2 ml and on addition of ether a white precipitate was obtained immediately (yield, 5 mg; m.p. 114–117°). After recrystallization from chloroform – light petroleum the product had a melting point of 118–119°. (Found:[6] C, 54.45; H, 4.76; N, 3.54%; and mol. wt. 419. $C_{19}H_{19}NO_{10}$ requires: C, 54.16; H, 4.55; N, 3.32%; and mol. wt. 421.) The infrared spectrum was consistent with that expected for a diacetate of (III), showing the expected carbonyl absorptions at 5.62 μ and 5.71 μ and hydroxyl absorption at ca. 2.85 μ, The ultraviolet spectrum showed a λ_{max} at 286 mμ (in methanol).

(iii) Further Acetylation of the Diacetate of (III)

The diacetate of (III) was obtained in chloroform solution by the procedure described in section D (*ii*). The volume of this solution was reduced to about 1 ml, and pyridine (0.2 ml) and acetic anhydride (0.1 ml) added. After 10 minutes, the reaction mixture was washed successively with 2 *N* hydrochloric acid (2 × 2 ml), aqueous sodium bicarbonate, and finally water. The dried (Na_2SO_4) solution was then evaporated to dryness and the residue extracted with ether (4 ml); addition of light petroleum to the ether extract gave a white precipitate (3 mg). After recrystallization from ether – light petroleum the product had a melting point of 108–109°. (Found:[7] C, 54.48; H, 4.70; N, 2.76%; and mol. wt. 521. $C_{23}H_{23}NO_{12}$ requires: C, 54.65; H, 4.55; N, 2.77%; and mol. wt. 505.) The infrared spectrum was consistent with that expected for a fully acetylated derivative of (III) showing no absorption in the OH stretching region and main carbonyl absorption peaks at 5.52 μ and 5.74 μ with shoulders at 5.60 μ and 5.70 μ; the ultraviolet spectrum showed a typical indole absorption with a λ_{max} of 285 mμ (in methanol). The tetraacetate obtained by this procedure was identical with that obtained by application of a similar acetylation procedure to the adrenochrome – ascorbic acid reduction product (see section B (*i*)).

E. Estimation of the Molecular Composition of the 5,6-Dihydroxy-N-methylindole – Dehydroascorbic Acid Interaction Product

The method used involved a reaction in water between dehydroascorbic acid and an excess (1 to 2 times) of 5,6-dihydroxy-*N*-methylindole (DHMI). The unreacted DHMI was extracted with ether and estimated from its absorbance at 298 mμ in water. Preliminary controls and calibrations that were carried out were as follows: (*i*) the efficiency of extraction of DHMI by ether from its aqueous solution in the presence of dehydroascorbic acid (using the procedure described below, this was found to be better than 95%); (*ii*) a calibration curve for DHMI (the absorbances of several aqueous solutions of DHMI were determined at its λ_{max} (298 mμ); the relation between absorbance and concentration for the solutions of DHMI was linear over the range studied); and (*iii*) the purity of the commercial sample of dehydroascorbic acid. The commercial sample of dehydroascorbic acid (as the methanol complex) available to the authors was analyzed by the 2,4-dinitrophenylhydrazine method described by Roe (22) and found to contain 74% dehydroascorbic acid.

In a typical determination, DHMI (8.5 mg, 5.22×10^{-2} mmoles) and dehydroascorbic acid (4.68 mg, 2.69×10^{-2} mmoles) were dissolved in water (1 ml); nitrogen was bubbled through the suspension and dissolution was complete in 15 minutes. After 2½ hours the solution was extracted with ether (5 × 1 ml); the combined ether extracts were concentrated (under nitrogen) and the residue dissolved in water (100 ml). The absorbance at 298 mμ was measured and the unreacted DHMI estimated from its extinction coefficient (ϵ, 7740 in water) at this wavelength. It was found that 4.40 mg of DHMI had reacted with 4.68 mg of dehydroascorbic acid, corresponding to an interaction product composed of one molecule of DHMI and 1 molecule of dehydroascorbic acid. (For such an interaction the calculated weight of DHMI to react with 4.68 mg of dehydroascorbic acid is 4.38 mg.) Similar determinations were carried out after reaction times of 3 and 3½ hours, and with various amounts of DHMI; in each case the results obtained corresponded to those expected for a 1:1 interaction.

F. Interaction of Other o-Diphenols and α-Diketones

Several other α-diketones were caused to react in aqueous solution with DHMI and, on the other hand, several *o*-diphenols were caused to react with dehydroascorbic acid. The reaction mixtures were prepared as described in Section D (*i*). In one series the dehydroascorbic acid was replaced in turn by: (*a*) calcium 2,3-diketogulonate, (*b*) oxalic acid, (*c*) diacetyl. In the series where the *o*-diphenol was varied, the DHMI, in the reaction mixture prepared according to section C (*i*), was replaced in turn by: (*a*) 5,6-dihydroxy-2-methylindole; (*b*) 5,6-dihydroxy-7-iodo-*N*-methylindole; (*c*) 5,6-dihydroxy-7-iodoindole; (*d*) adrenolutin; (*e*) adrenaline hydrochloride; and (*f*) catechol. The products of these interactions were, except in the case of catechol with dehydroascorbic acid, detected by paper chromatography (see Table I).

When catechol was allowed to react with dehydroascorbic acid no product was detected in the reaction mixture after 3 days reaction. However, when unreacted catechol was completely extracted, from the reaction mixture by ether, and the aqueous mother liquors treated with one drop of 40% aqueous sodium hydroxide, prior to acidification with glacial acetic acid, an ether extractable product (R_f 0.73 in 2% aqueous acetic acid), which gave a blue-black color with the ferric chloride reagent, was obtained. The chromatographic properties

For personal use only.

of this product were identical with those of catechol. No interaction between 5,6-diacetoxy-*N*-methylindole and dehydroascorbic acid was detected after a solution containing these two compounds had stood at room temperature for 3 days. *n*-Butanol – acetic acid – water (6:1:2) was used as the chromatographic solvent in this case. (The R_f of 5,6-diacetoxy-*N*-methylindole, in this solvent, was 0.90.)

ALIPHATIC CHEMISTRY OF FLUORENE

PART IX. SOME BIFUNCTIONAL DERIVATIVES

P. M. G. BAVIN[1]

Smith Kline and French Laboratories Ltd., Mundells, Welwyn Garden City, England

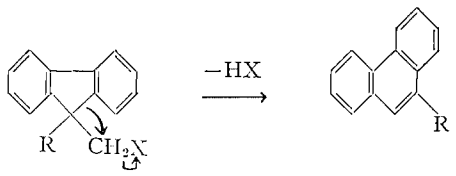
Received October 24, 1963

ABSTRACT

Methyl phenanthrene-9-carboxylate, dimethyl phenanthrene-9,10-dicarboxylate, and N,N-dimethyl phenanthrene-9-carboxamide have been prepared directly from fluorene by a novel route. Neighboring group participation by carbomethoxy has been clearly demonstrated in the reactions of some 9,9-disubstituted fluorenes.

This paper describes the preparation and reactions of a number of fluorene derivatives having two functional groups in the 9-position. The ultimate objective has been to provide a synthesis of 4-nitrophenanthrene from 4-nitrofluorene. As a necessary preliminary to experiments with nitrofluorenes, a route has been worked out to phenanthrene derivatives from fluorene without using reducing agents at any stage.

The formation of phenanthrene derivatives from substituted fluorenes is illustrated in Fig. 1. The group R may be hydrogen, alkyl, or aryl and X may be chlorine, bromine,



hydroxyl, *p*-toluenesulphonate, or similar leaving group. (For typical references see 1, 2, 3.) Examples where R is a functional group have not been recorded and are rare in the broad field of Wagner–Meerwein rearrangements. Methyl fluorene-9-carboxylate (I*a*) was chosen as starting point for these experiments because it is highly reactive (4, 5) and carboxyl groups are readily eliminated from phenanthrene carboxylic acids (6, 7). Initially, experiments were made with derivatives of the hydroxy-ester (I*b*). These were not successful and are briefly summarized later in this paper. More subtle methods appeared necessary and attention was turned to halo-esters. The bromo- and chloro-esters ((I*c*) and (I*d*) respectively) were prepared in excellent yields from the appropriate dihalomethanes. As expected, bromo-ester (I*c*) failed to react with a further molecule of fluorene ester and was recovered unchanged after it was heated with sodium iodide in methyl ethyl ketone. It was also unchanged after it was heated in 98% formic acid or dimethylformamide or alone at 220°. Like other neopentyl-type halides it reacted rapidly in the presence of silver ions,* for example with silver trifluoracetate in trifluoracetic acid to give diester (I*e*). The diester (I*e*) did not decompose at 220° but solvolyzed smoothly in 98% formic acid, giving methyl phenanthrene-9-carboxylate in 80% yield. Since Pschorr (6) saponified

[1]*Much of the work was carried out at The University, Hull, during the tenure of an I.C.I. Fellowship (1958–60).*

For personal use only.

and decarboxylated the phenanthrene ester, solvolysis of I*e* completes a novel synthesis of phenanthrene from fluorene without employing reducing agents. It also provides a new route to functionally substituted phenanthrenes which should prove valuable in the synthesis of hydrocarbons which show optical isomerism (cf. 11, pp. 472–478; 12). Chlorodiester (I*f*), prepared from methyl dichloroacetate, was converted similarly to dimethyl phenanthrene-9,10-dicarboxylate (62%), whilst N,N-dimethyl phenanthrene-9-carboxamide (53%) was obtained from bromo-amide (II*a*). Reactions of other halo-esters which did not lead to phenanthrene derivatives are discussed below.

In Part I of this series (13) we described some reactions of the chloride (III). It melted with decomposition up to 99° and underwent solvolysis in 98% formic acid, both decompositions giving good yields of 9-methyl-10-phenylphenanthrene. However, reaction with silver acetate in anhydrous acetic acid gave unrearranged acetate. The stabilization of neopentyl carbonium ions by an α-phenyl group has been noted elsewhere (14). The bromo-ester (I*c*) has also given only unrearranged products from reactions with silver salts: trifluoracetate (I*e*) from silver trifluoracetate in trifluoracetic acid; acetate (I*g*) from silver perchlorate in acetic acid; hydroxy-ester (I*b*) in poor and variable yield from silver perchlorate in 'moist' nitromethane. Both the bromides (IV*a*) and (IV*b*) decompose rapidly in the presence of silver salts to give 9-phenyl- and 9-methylphenanthrene respectively. Consequently the formation of unrearranged products from bromo-ester (I*c*) can be confidently attributed to neighboring group participation by the carbomethoxy group. Although it has been concluded (8, p. 120) that neighboring carboxylic ester has no significant effect in solvolytic reactions, an opposite view has been taken regarding silver-catalyzed reactions of certain aliphatic compounds (15) and, more recently, participation has been demonstrated for ester groups in the formation of 3-phenylphthalide (16). The striking neighboring group effect observed with bromo-ester (I*c*) has its origin in the very favorable stereochemistry associated with the rigid 9-disubstituted fluorene.

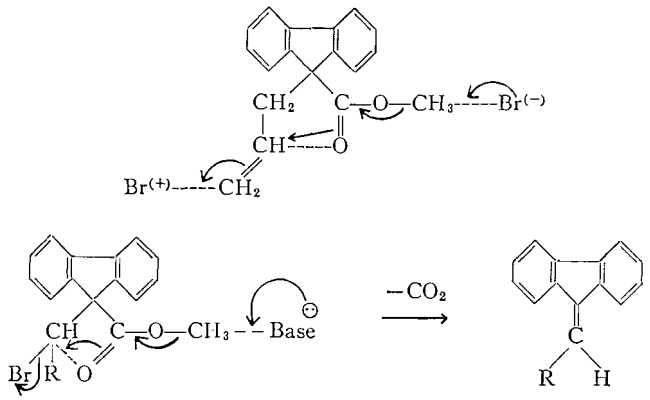
The contrast between the chemistry of bromo-ester (I*c*) and chloride (III) prompted the preparation of the chloro-ester (I*h*), which appeared to be a suitable intermediate for 9-phenyl-10-phenanthroic acid (13, 17, 18, 19).* Like III, the chloro-ester (I*h*) gave unrearranged diesters, e.g. the trifluoracetate (I*j*), in the presence of silver ion but, in contrast, gave unrearranged formate (I*k*) from solvolysis in formic acid and was recovered unchanged following attempted pyrolysis. The absence of rearrangement accompanying formolysis of (I*h*) can be attributed to additional stabilization by neighboring carbomethoxy. Formolysis of the trifluoracetate (I*j*) resulted in fragmentation to benzaldehyde and fluorene ester probably through a reversed aldol condensation (20) of hydroxy-ester (I*l*), cf. instability of I*b*, facile clearage by base of 9-fluorenyl ketones (13, 21, 22) and fragmentation of *t*-alkoxides (23), the driving force for all of these decompositions being the stability of fluorene anion. Related fragmentations of 9-fluorenylmethanols have been noted (24, 25, 26).

The secondary trifluoroacetate (I*m*), prepared from bromo-ester (I*n*), proved to be remarkably stable. It was recovered largely unchanged after being heated in 98% formic acid for several days or following attempted pyrolysis at 220°. Only slight decomposition occurred at 300–320° and phenanthrene derivatives were not detected by ultraviolet spectroscopy. Since the secondary *p*-toluenesulphonate (V*b*) undergoes formolysis 65 times as fast as the primary ester (V*a*) (27), the inertness of I*m* compared with I*e* is

**The formation of ethyl 9-phenylphenanthrene-10-carboxylate from 9-phenyl-9-bromofluorene and ethyl diazoacetate (19) may proceed by way of an unusual carbenoid insertion between carbon and bromine.*

surprising. As a check on the structure of I*n*, the isomeric bromo-ester (I*p*) was synthesized and non-identity established by comparison of melting points and infrared spectra.

Quinoline has already been used successfully to effect dehydrohalogenation and rearrangement of fluorenylalkyl halides (2), and it has now been shown to react with neopentyl-type halides, giving a good yield of 9-phenylphenanthrene from IV*a* and of 9-methylphenanthrene from IV*b*. The similar reactions of the halo-esters I*c*, I*h*, and I*n* gave only 9-methylene, 9-benzylidene, and 9-ethylidenefluorene, respectively. Previous experience with 9-fluorenylmethanols (1, 2, 3, 13, 21, 28) suggests that the formation of these olefins is anomalous and may proceed by way of the β-lactones (29, but see also 30, 31, 32, 33, 34). Decomposition of α,α-diphenyl-β-propiolactone to α,α-diphenylethylene has already been noted (35). Although the formation of β-lactones (29) and the (transient) α-lactones (9, pp. 117–119) is generally effected by intramolecular attack of carboxylate anion on carbon carrying halogen, examples are known of β-(36) and γ-lactone (37) formation involving explusion from carbomethoxy of methyl cation as methyl bromide. This process is illustrated in Fig. 2 for comparison with the formation of the alkylidene-



fluorenes (Fig. 3). Few examples have been recorded (38) of the decarboxylation of hindered acids in polyphosphoric acid. Consequently the decomposition in this reagent of hydroxy-ester (I*q*) may also proceed by way of the β-lactone.

The alkylation of N,N-dimethyl fluorene-9-carboxamide (II*b*) was successful only in *t*-butanol, esters being obtained in methanol or ethanol. Alkylation of 9-cyanofluorene (VI*a*) was effected under more general conditions (4), the 9-methyl (VI*b*), bromomethyl (VI*c*), and allyl (VI*d*) derivatives being obtained in satisfactory yields. Only a poor yield

of the 9-*t*-butyl compound (VII*e*) was obtained and, even under nitrogen, the major product was fluorenone. It was noted that some cyanide ion was liberated during these alkylations. This is interesting because it could have originated from anionic displacement of cyanide ion (39, 40) or, more probably, by autoxidation (41) followed by decomposition of the unstable cyanohydrin (42). The bromosulphone (VII*a*) was prepared by a modification of an earlier general method (43). Attempts to bring about rearrangement of bromonitrile (VI*c*) and bromosulphone (VII*a*) were not successful. A number of other compounds did not rearrange to give phenanthrene derivatives. These included the glycol (VIII*a*) and bistrifluoracetate (VIII*b*); hydroxyester (I*b*) and diester (I*g*); ether (I*r*) and the complex ethers (IX*a*) and (IX*b*) (see Experimental for details).

The infrared spectra of several of the derivatives of fluorene ester described in this paper have proved particularly interesting. In view of a recent publication (44), they will be discussed in detail elsewhere (45).

To provide reference compounds, 9-bromo-10-methylphenanthrene (46) was converted to the nitrile. Alkaline hydrolysis under forcing conditions stopped at the amide.

EXPERIMENTAL

Melting points are uncorrected. Microanalyses are by Weiler and Strauss (Oxford) or Mr. Michael Graham (Smith Kline and French Laboratories Ltd.).

Methyl fluorene-9-carboxylate was prepared as described earlier (3). 9-Cyanofluorene was prepared from fluorene-9-aldehyde without purifying intermediates (47). 9-Fluorenyl *p*-tolyl sulphone was available from earlier work (43).

N,N-Dimethyl Fluorene-9-carboxamide (IIb)

Fluorene-9-carboxylic acid (3) (20 g) and thionyl chloride (20 ml) were warmed gently until the acid had dissolved. Excess reagent was evaporated under reduced pressure, final traces being removed by codistillation with dry benzene. The residual oil in cold dry benzene (30 ml) was added slowly to a cold solution of dimethylamine (30 g) in dry benzene (200 ml). After half an hour, the mixture was evaporated under reduced pressure and the residue thoroughly washed with hot water. Crystallization of the dried product from toluene gave colorless prisms (11 g), m.p. 256.5–258.0°. Found: C, 81.21; H, 6.53. Calc. for $C_{16}H_{15}NO$: C, 80.98, H, 6.37%.

Derivatives of Methyl Fluorene-9-carboxylate

The following were prepared by alkylating (or acylating) fluorene ester in methanol (4).

*Methyl 9-acetylfluorene-9-carboxylate** (Is) crystallized from acetone–methanol as pale yellow prisms (40–70% for four preparations), m.p. 65–66°. Found: C, 76.91; H, 5.41. Calc. for $C_{17}H_{14}O_3$: C, 76.67; H, 5.30%.

Methyl 9-bromomethylfluorene-9-carboxylate (Ic) separated from methanol as flattened prisms showing extensive twinning (88%), m.p. 112–113°. Found: C, 60.92; H, 4.17. Calc. for $C_{16}H_{13}BrO_2$: C, 60.58; H, 4.13%.

Methyl 9-chloromethylfluorene-9-carboxylate (Id) formed colorless prisms (78%) from methanol, m.p. 96–97°. Found: C, 70.40; H, 4.75. Calc. for $C_{16}H_{13}ClO_2$: C, 70.46; H, 4.80%. Both this and the preceding compound were contaminated when crude with polymeric formaldehyde, easily removed during crystallization.

Methyl 9-methoxymethylfluorene-9-carboxylate (Ir) crystallized from benzene–hexane (1:10) as white prisms (84%), m.p. 129–131°. Found: C, 76.10; H, 6.15. Calc. for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01%.

Methyl 9-α-chlorobenzylfluorene-9-carboxylate (Ih) formed white felted needles (73%) from hexane, m.p. 127.0–127.5°. Found: C, 75.37; H, 4.94; Cl, 10.41. Calc. for $C_{22}H_{17}ClO_2$: C, 75.75; H, 4.91; Cl, 10.17%.

Methyl 9-1'-bromoethylfluorene-9-carboxylate (In) crystallized as colorless irregular prisms from hexane (72%), m.p. 129–130°. Found: C, 61.70; H, 4.48. Calc. for $C_{17}H_{15}BrO_2$: C, 61.64; H, 4.57%.

Methyl 9-2'-bromoethylfluorene-9-carboxylate (Ip) separated from hexane as colorless needles (67%), m.p. 189–190°. Found: C, 61.88; H, 4.72%.

Methyl 9-carbomethoxychloromethylfluorene-9-carboxylate (If) formed irregular prisms (81%) from cyclohexane, m.p. 102–103°. Found: C, 65.48; H, 4.68; Cl, 10.91. Calc. for $C_{18}H_{15}ClO_4$: C, 65.36; H, 4.57; Cl, 10.72%.

α-α'-bis-(9-Carbomethoxy-9-fluorenyl)-dimethyl ether (IXa), prepared by alkylating fluorene ester with α,α-dichlorodimethyl ether, crystallized from isopropyl alcohol as colorless prisms (89%), m.p. 170.5–171.0°. Found: C, 78.17; H, 5.54. Calc. for $C_{32}H_{26}O_5$: C, 78.35; H, 5.34%. The same compound (melting point, mixed melting point, and infrared spectra) was obtained in variable yield (30–60%) when fluorene ester was alkylated with impure chloromethy acetate, and was also isolated (10%) when methyl 9-hydroxymethylfluorene-9-carboxylate (VIIg) was acetylated with acetic anhydride and a trace of sulphuric acid. It was characterized by reduction with ethereal $LiAlH_4$ to IXb.

α,α'-bis-(9-Hydroxymethyl-9-fluorenyl)-dimethyl ether (IXb), which separated from benzene–heptane as fine white needles (91%), m.p. 158–159°, not identical with bis-9,9-hydroxymethylfluorene (VIIIa). Found: C, 82.84, 83.0; H, 6.36, 6.11. Calc. for $C_{30}H_{26}O_3$: C, 82.92; H, 6.03%.

bis-(9,9-Trifluoracetoxymethyl)-fluorene (VIIIb)

Dimethyl fluorene-9,9-dicarboxylate, prepared by acylating fluorene ester with methyl chloroformate, separated from cyclohexane as small colorless prisms (64%), m.p. 166–167° (lit. m.p. 167° (49)). Reduction with ethereal $LiAlH_4$ gave bis-9,9-hydroxymethylfluorene, identical with a sample supplied by Sprinzak (26). Found: C, 79.62; H, 6.24. Calc. for $C_{15}H_{14}O_2$: C, 79.56; H, 6.13%. Esterification of the glycol (3 g) with trifluoracetic anhydride (5 ml) gave *diester* (VIIIb), crystallizing as colorless needles (2.53 g, 45%) from hexane, m.p. 73–74°. Found: C, 54.87; H, 2.95. Calc. for $C_{19}H_{12}F_6O_4$: C, 54.55; H, 2.90%. Brief boiling with 98% formic acid regenerated the glycol, m.p. 146–147° (26), the ultraviolet spectrum of the crude product showing phenanthrene derivatives to be absent. The diester was recovered unchanged after attempted pyrolysis.

9-Hydroxy-9-fluorenylmethanol

Methyl 9-hydroxyfluorene-9-carboxylate was reduced with ethereal $LiAlH_4$, the *diol* crystallizing from benzene–hexane as long white needles (89%), m.p. 108–109°. Found: C, 79.45; H, 5.89. Calc. for $C_{14}H_{12}O_2$: C, 79.21; H, 5.69%. The diol was decomposed by phosphorus pentoxide under boiling xylene without formation of phenanthrene derivatives.

**Infrared measurements have established the keto-ester rather than the ketene–acetal–acylal structure for the corresponding ethyl ester (48).*

Experiments with Methyl 9-Bromomethylfluorene-9-carboxylate (Ic)

Methyl 9-Acetoxymethylfluorene-9-carboxylate (Ig)

The bromoester (4.2 g) reacted rapidly with silver perchlorate (5 g) in acetic acid (20 ml) which had been previously dried by boiling for 1 hour with 10% of its volume of acetic anhydride. Precipitation of silver salts was completed by the addition of an excess of dilute hydrochloric acid. Filtration and extraction with ether gave crude *diester* which crystallized from hexane as colorless prisms (3.1 g, 79%), m.p. 106–107°. Found: C, 72.72; H, 5.60. Calc. for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44%.

Reduction of the diester with ethereal $LiAlH_4$ gave the glycol (VIII*a*), identical with an authentic specimen (above).

The diester (0.5 g) was heated with polyphosphoric acid for half an hour at 160°. Chromatography of the products (hexane–alumina) gave phenanthrene (0.07 g), identical with an authentic specimen, together with traces of an unidentified substance, m.p. 164–168°.

Methyl 9-Trifluoracetoxymethylfluorene-9-carboxylate (Ie)

The bromoester (2.1 g) reacted rapidly with a warm solution of silver trifluoracetate (50) (2.1 g) in trifluoracetic acid (12 ml)*. The *diester* crystallized from hexane as irregular prisms (1.6 g, 69%), m.p. 72–75°, raised to 81–83° (not sharp) by several further crystallizations. Found: C, 61.66; H, 3.60. Calc. for $C_{18}H_{13}F_3O_4$: C, 61.72; H, 3.74%. The diester was recovered unchanged after attempted pyrolysis at 220°.

Formic acid (5 ml, 98%) and diester (0.5 g) were boiled under reflux for 2 hours. The product separated from methanol as white needles (0.28 g, 82%), m.p. 114–115°, identical with authentic (5, 51) methyl phenanthrene-9-carboxylate.

p-Toluenesulphonic acid monohydrate (30 g) was heated in a thick-walled test tube at 0.01 mm pressure until melting was complete, and was then maintained at 70–90° for 2 hours. To the cooled acid was added bromoester (1 g) and silver *p*-toluenesulphonate (52) (2 g) and the mixture maintained at 35–40° for 2 hours with occasional shaking. Moisture was excluded by maintaining an atmosphere of dry nitrogen. The product was precipitated by pouring into dilute hydrochloric acid, and was extracted into methylene chloride, purified by chromatography (hexane–alumina) and crystallized from methanol. Methyl phenanthrene-9-carboxylate crystallized as white needles (0.4 g), m.p. 113–115°, identical with the previous sample.

Methyl 9-Hydroxymethylfluorene-9-carboxylate (Ib)

The bromoester (1.5 g) reacted rapidly with silver perchlorate (2 g) in nitromethane (20 ml) containing water (0.5 ml). The product formed colorless needles from benzene, m.p. 117–118° (0.7 g, 58%). Found: C, 75.52; H, 5.53. Calc. for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55%. The yield was not reproducible and paraformaldehyde was always obtained.

Attempts to esterify the hydroxy-ester with methanesulphonyl or *p*-toluenesulphonyl chlorides were not successful. The reaction with acetic anhydride and a trace of sulphuric acid gave dimeric ether (IX*a*) (6–10%), isolated by crystallization from hexane, and acetoxy derivative (Ig) (27%), isolated by chromatography (hexane–alumina).

When heated with polyphosphoric acid at 160° or with phosphorus pentoxide under boiling xylene, the hydroxy-ester gave only tars.

The bromo-ester (Ic) was recovered unchanged after attempted pyrolysis at 220°, after it was heated with sodium iodide and boiling methyl ethyl ketone for 1 week, and after attempts at solvolysis in boiling dimethylformamide or 98% formic acid. It decomposed when heated with boiling quinoline for 1 hour, giving 9-methylenefluorene which, after purification by chromatography (hexane–alumina), crystallized from methanol as small colorless prisms (37%), m.p. 42–44°, strongly depressed by 9-methylfluorene (m.p. 45–46°). (Lit. m.p. 53° (53).) Found: C, 93.04; H, 6.58. Calc. for $C_{14}H_{10}$: C, 94.34; H, 5.66%. Calc. for $C_{14}H_{12}$: C, 93.29; H, 6.71%. The identity of the product as slightly impure 9-methylenefluorene was confirmed by its ultraviolet spectrum, which was almost identical with that of 9-ethylidenefluorene (54), and by hydrogenation over palladized charcoal to 9-methylfluorene.

Experiments with Methyl 9-α-Chlorobenzylfluorene-9-carboxylate (Ih)

Methyl 9-α-Formyloxybenzylfluorene-9-carboxylate (Ik)

Colorless prisms (0.9 g, 88%) separated after chloro-ester (Ih) (1 g) and 98% formic acid (10 ml) had been boiled under reflux for 1 hour. One crystallization from hexane gave the analytical sample, m.p. 164–165°. Found: C, 76.90; H, 5.16. Calc. for $C_{23}H_{18}O_4$: C, 77.08; H, 5.06%. Warming the diester with KOH in aqueous methanol gave benzaldyehde (2,4-dinitrophenylhydrazone, m.p. 232–234°) and fluorene-9-carboxylic acid (m.p. 226–228° decomp.).

Methyl 9-α-Trifluoracetoxybenzylfluorene-9-carboxylate (Ij)

The preparation was carried out as described for Ie but with the addition of 10% by volume of trifluoracetic anhydride to the trifluoracetic acid. The *diester* crystallized from hexane as colorless prims (71%), m.p. 128–129° after sintering at 120°. Found: C, 68.34; H, 4.47. Calc. for $C_{24}H_{17}F_3O_4$: C, 67.60; H, 4.02%. The analyses were not improved following further crystallizations.

**In later experiments silver trifluoracetate was replaced by the equivalent of silver oxide, which dissolved readily in trifluoracetic acid containing a slight excess of trifluoracetic anhydride.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The trifluoracetate solvolyzed in 98% formic acid with fragmentation (see above) and with formation of small amounts of the formate (I*k*), but, like the chloroester (I*h*), was recovered unchanged after attempted pyrolysis at 220°.

9-Benzylidenefluorene

The chloroester (0.2 g) was decomposed by boiling under reflux for 2 hours with anhydrous quinoline (4 ml). After purification by chromatography (hexane–alumina), the product formed colorless prisms (0.11 g, 75%) from hexane, m.p. 74–76°, identical with an authentic sample (lit. m.p. 76° (55)).

Experiments with Methyl 9-1'-Bromoethylfluorene-9-carboxylate (I*n*)

The bromoester (I*n*) was recovered unchanged after attempted pyrolysis or after attempted solvolysis in formic acid. It was decomposed by boiling quinoline with formation of 9-ethylidenefluorene (61%), identical with an authentic specimen (55), m.p. 103–104°.

Methyl 9-1'-Trifluoracetoxyethylfluorene-9-carboxylate (I*m*)

The *trifluoracetate* (I*m*), prepared in the usual way from bromoester (I*n*), crystallized from hexane as well-defined prisms (74%) m.p. 99.5–101°. Found: C, 62.39; H, 4.32. Calc. for $C_{19}H_{15}F_3O_4$: C, 62.64; H, 4.15%. It was remarkably stable, being recovered unchanged after boiling for 1 week with 98% formic acid or for 12 hours with dimethylformamide, and was not decomposed to phenanthrene derivatives by distillation in a nitrogen atmosphere at atmospheric pressure (300–320°), although some tar formation occurred.

Methyl 9-1'-Hydroxyethylfluorene-9-carboxylate (I*q*)

The ketoester (1 g) was reduced with sodium borohydride (0.5 g) in methanol (15 ml). The *hydroxyester* crystallized as colorless slender needles (0.94 g, 92%) from hexane, m.p. 104–105°. Found: C, 76.21; H, 5.96. Calc. for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01%. Attempts to prepare the methanesulphonate or toluenesulphonate in the usual way (3) failed but esterification with trifluoracetic anhydride gave the trifluoracetate (I*m*). The hydroxyester decomposed when boiled with phosphorus pentoxide under xylene, giving 9-ethylidenefluorene as the only crystalline neutral product.

9-Methyl-10-phenanthryl Nitrile

9-Bromo-10-methylphenanthrene (46) (1.3 g) was boiled under reflux for 3 hours with cuprous cyanide (1.5 g), pyridine (2 drops), and dimethylformamide (20 ml) (56). After it was cooled and diluted with water, the product was extracted into chloroform, purified by chromatography (hexane–alumina), and crystallized from benzene–heptane to give colorless prisms (0.7 g, 68%), m.p. 176.5–177.5°. Found: C, 88.66; H, 5.41. Calc. for $C_{16}H_{11}N$: C, 88.45; H, 5.10%. The infrared spectrum showed a C≡N stretching band at 2230 cm^{-1}.

9-Methylphenanthrene-10-carboxamide

The nitrile (0.4 g) and potassium hydroxide (2 g) were boiled under reflux for 6 hours with diethylene glycol (50 ml) and water (3 ml). The *amide* crystallized from toluene as slender colorless needles (0.15 g), m.p. 181–182°. Found: C, 81.25; H, 5.38; N, 5.67. Calc. for $C_{16}H_{13}NO$: C, 81.67; H, 5.57; N, 5.95%.

Derivatives of 9-Cyanofluorene

9-Methyl-9-cyanofluorene (VI*b*)

9-Cyanofluorene (1 g) was alkylated in the usual way (3, 4) with methyl iodide. After purification by chromatography (hexane–alumina) the product formed colorless well-defined prisms (0.6 g, 56%) from methanol, m.p. 92–93°. Found: C, 87.82; H, 5.53. Calc. for $C_{15}H_{11}N$: C, 87.77; H, 5.40% (C≡N stretching band at 2240 cm^{-1}). Acidification of the mother liquors remaining after isolation of the crude product liberated hydrocyanic acid, detected by its odor.

The following were prepared similarly:

9-Allyl-9-cyanofluorene (VI*d*), crystallizing as rhombohedral plates (69%) from methanol, m.p. 74–76°. Found: C, 88.56; H, 5.88. Calc. for $C_{17}H_{13}N$: C, 88.27; H, 5.67% (C≡N stretching band at 2240 cm^{-1}).

9-t-Butyl-9-cyanofluorene (VI*e*), which formed small colorless needles (8%) from hexane, m.p. 144–145°. Found: C, 87.11; H, 6.65. Calc. for $C_{18}H_{17}N$: C, 87.41; H, 6.93% (C≡N stretching band at 2230 cm^{-1}). Fluorenone, m.p. 69–72° (63%) was isolated by chromatography.

9-Bromomethyl-9-cyanofluorene (VI*c*)

9-Cyanofluorene (3.8 g) dissolved in dry *t*-butyl alcohol (30 ml) containing potassium *t*-butoxide (from 1.2 g potassium) to give a deep green sloution. The color was rapidly discharged following the addition of dibromomethane (8 g). The product separated from isopropyl alcohol as irregular prisms (3.9 g, 68%), m.p. 125–127°, raised to 126–127° by one crystallization from benzene. Found: C, 63.52; H, 3.55; N, 5.19. Calc. for $C_{15}H_{10}BrN$: C, 63.40; H, 3.55; N, 4.93%. Reaction with silver trifluoracetate gave the trifluoracetate (carbonyl stretching band: 1790 cm^{-1}), which decomposed in hot 98% formic acid during 4 hours with formation of the formate (carbonyl stretching band: 1725 cm^{-1}). Comparison of infrared spectra showed that 9-cyanophenanthrene was not formed. The bromo-nitrile decomposed in boiling quinoline to give tars in which 9-cyanophenanthrene was not detected.

Experiments with N,N-Dimethyl Fluorene-9-carboxamide

N,N-Dimethyl 9-Methylfluorene-9-carboxamide (II*c*)

Prepared by alkylation in *t*-butyl alcohol as described for (VI*c*), the *amide* crystallized as slender colorless needles (83%) from hexane, m.p. 161–162°. Found: C, 81.78; H, 6.94. Calc. for $C_{17}H_{17}NO$: C, 81.24; H, 6.82%. When the methylation was carried out in methanol, only methyl 9-methylfluorene-9-carboxylate was isolated, identical with an authentic specimen (3).

N,N-Dimethyl 9-Hydroxyfluorene-9-carboxamide (II*d*)

The only product isolated from attempts at *t*-butylation in methanol or *t*-butyl alcohol was the *hydroxy-amide* (55%), m.p. 121.5–122.0°. Found: C, 75.69, 75.94; H, 5.99, 6.08. Calc. for $C_{16}H_{15}NO$: C, 75.87; H, 5.97%.

N,N-Dimethyl 9-Bromomethylfluorene-9-carboxamide (II*a*)

The *bromo-amide* was prepared in *t*-butanol and formed very pale yellow prisms (91%) from hexane, m.p. 110–111°. Found: C, 61.66; H, 4.95. Calc. for $C_{17}H_{16}BrNO$: C, 61.83; H, 4.88%.

N,N-Dimethyl Phenanthrene-9-carboxamide

The crude product from the reaction between bromo-amide (II*a*) (1 g) and silver trifluoracetate (1.5 g) in trifluoracetic acid (10 ml) was boiled under reflux for 1 hour with 98% formic acid (8 ml). The phenanthrene amide formed small white needles (0.4 g, 53%) from ethanol, m.p. 185–186°, identical with an authentic specimen, m.p. 185–187° (lit. m.p. 182.5–183.0° (57)).

Preparation of 9-Phenylphenanthrene

9-Phenyl-9-fluorenylmethyl Bromide (IV*a*)

9-Phenylfluorene (17.5 g) was alkylated in ether with dibromomethane (40 g), using phenyllithium as base (58), the red color of the anion disappearing during 5 minutes. The product was obtained as well-defined colorless prisms (14.8 g, 61%) from benzene–hexane, m.p. 142–143°. Found: C, 71.55; H, 4.67; Br, 23.85. Calc. for $C_{20}H_{15}Br$: C, 71.65; H, 4.51; Br, 23.84%.

The bromo compound (1 g) reacted very rapidly with silver perchlorate (1 g) in anhydrous acetic acid (15 ml). 9-Phenylphenanthrene crystallized from ethanol as white needles (0.5 g, 66%), m.p. 103–104° (lit. m.p. 105–106° (17)).

The bromo compound (0.5 g) was boiled under reflux for 1 hour with quinoline (5 ml). Crystallization of the product from ethanol gave 9-phenylphenanthrene (0.28 g, 74%), m.p. 104–105°. The picrate formed orange needles from ethanol, m.p. 116–117° (lit. m.p. 115° (17)).

Preparation of 9-Methylphenanthrene

9-Methyl-9-fluorenylmethyl Bromide (IV*b*)

9-Methylfluorene (6.24 g) (13) was alkylated in the usual way (58) (preceding compound). The product crystallized as colorless prims (4.2 g, 49%) from methanol, m.p. 53–54°. Found: C, 65.89, 66.17; H, 4.65, 4.65. Calc. for $C_{15}H_{13}Br$: C, 65.95; H, 4.80%.

The bromide (IV*b*), (1 g), was warmed with silver perchlorate (1 g) in acetic acid (20 ml). The product crystallized from methanol as colorless prismatic needles (0.54 g, 77%), m.p. 91–92°, identified as 9-methylphenanthrene by comparison with an authentic specimen (3). 9-Methylphenanthrene (70%) was also obtained by decomposition of the bromide in boiling quinoline.

Experiments with 9-Bromomethyl-9-fluorenyl p-Tolyl Sulphone (VII*a*)

9-Bromomethyl-9-fluorenyl p-Tolyl Sulphone (VII*a*)

9-Fluorenyl *p*-tolyl sulphone (1 g) was alkylated with dibromomethane (5 ml) in a mixture of dimethylformamide (15 ml) and methanol (8 ml) containing sodium methoxide (from 0.4 g sodium). The product crystallized from benzene–hexane as small colorless prisms (0.6 g, 48%), m.p. 200–202°, raised to 202–203.5° by a further cyrstallization. Found: C, 60.97; H, 4.68; S, 7.44. Calc. for $C_{21}H_{17}BrO_2S$: C, 61.02; H, 4.15; S, 7.76%. Decomposition of the bromo-sulphone in boiling quinoline did not yield phenanthrene derivatives.

9-Hydroxymethyl-9-fluorenyl p-Tolyl Sulphone (VII*b*)

The bromosulphone reacted rapidly with silver trifluoracetate in trifluoracetic acid, but, even in the presence of trifluoracetic anhydride, the trifluoracetate was not obtained pure. Brief solvolysis of the crude product in 98% formic acid gave the *hydroxy-sulphone* (VII*b*) which, after chromatography (hexane–alumina), crystallized as colorless well-defined prisms (59%) from benzene–hexane, m.p. 158–159°. Found: C, 71.77, 71.89; H, 5.15, 5.39. Calc. for $C_{21}H_{18}O_3S$: C, 71.98; H, 5.18%. The hydroxy-sulphone did not give phenanthrene derivatives when boiled with phosphorus pentoxide and xylene.

FISSION FRAGMENT IRRADIATIONS OF HYDROCARBONS

I. YIELD AND ISOTOPIC COMPOSITION OF HYDROGEN FROM MIXTURES OF CYCLOHEXANE AND BENZENE WITH THEIR DEUTERATED ANALOGUES[1]

A. W. Boyd and H. W. J. Connor
Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario

Received January 20, 1964

ABSTRACT

Cyclohexane and benzene and mixtures of each of these with cyclohexane-d_{12} and benzene-d_6 have been irradiated with fission fragments using thin sources of $U_3^{235}O_8$. The hydrogen yield $G(H_2)$ for cyclohexane is 7.73, and is only slightly reduced by the addition of benzene. $G(H_2)$ for benzene is 2.14. The isotopic composition of the hydrogen from the four mixtures indicates that most is formed in bimolecular processes.

To correlate these results with those obtained in gamma radiolysis, a mechanism is proposed based on hydrogen formation by reactions between transient species in both cyclohexane and benzene.

INTRODUCTION

The linear energy transfer (LET) of ionizing radiation is defined as the rate of energy loss per unit length of track. An increase in LET increases the concentration of the primary products along the track and thus favors reactions between these products over their reactions with the substrate. The determination of the effect of LET on product yields may therefore aid in the formulation of a mechanism for the radiolysis of a compound.

LET dependence in the radiolysis of cyclohexane has been investigated by Schuler, Allen, and Dewhurst (1–3), who found the yields of hydrogen and the liquid products to be constant within 10% over the range 0.02–2 eV/Å.

Burns (4) assumed that the hydrogen formed in the radiolysis of cyclohexane is due to reactions [1]–[3]

$$C_6H_{12} \curvearrowright\!\!\!\!\rightarrow C_6H_{11} + H \qquad [1]$$

$$H + C_6H_{12} \rightarrow H_2 + C_6H_{11} \qquad [2]$$

$$H + H \rightarrow H_2 \qquad [3]$$

and calculated that at low LET values reaction [3] is not likely to compete with [2] but at 50–100 eV/Å the hydrogen yield should be lower due to the favoring of [3] over [2].

Gaumann and Schuler (5) and Burns *et al.* (6, 7) have found, in contrast to the behavior of cyclohexane, that in irradiations of benzene the yields of hydrogen and acetylene increase with increasing linear energy transfer.

The yield of hydrogen from benzene using fast electrons (LET ~0.02 eV/Å) is 0.036–0.04 (6) and increases to 0.075 at ca. 3 eV/Å and to 0.57 at ca. 15 eV/Å. Burns (6) has suggested that the increase is due to the favoring of reaction [4] over [5]

$$B^* + B^* \rightarrow H_2 + \text{radicals or stable products} \qquad [4]$$

$$B^* + B \rightarrow B + B \qquad [5]$$

at higher track densities, where B* is an excited molecule.

In this mechanism the intermediate is deactivated by the substrate instead of reacting with it to produce hydrogen as is assumed to occur in the radiolysis of cyclohexane.

[1]*Issued as AECL No. 1943.*
Presented in part at the American Chemical Society Meeting in New York, September 1960.

Fission fragments have an LET of about 400 eV/Å so that they provide a means of testing Burns' calculations of the LET dependence of hydrogen yield in cyclohexane. They also make it possible to determine if there is a further increase in decomposition yields of benzene with LET. We have therefore irradiated cyclohexane, benzene, and mixtures of these with their deuterated analogues with fission fragments. The irradiations of the mixtures were done for comparison with the analogous gamma-ray irradiations of Dyne and Jenkinson (8, 9).

EXPERIMENTAL

The benzene and the cyclohexane were both Fisher Spectrograde and the benzene-d_6 and cyclohexane-d_{12} were obtained from Merck and Co. The isotopic purity, as given by the manufacturer, of the former was 99.5% and of the latter, 99%.

The samples, which were 5–8 ml in volume, were thoroughly outgassed by five cycles of melting, freezing, and evacuating in quartz capsules. The uranium was 93% U^{235} in the form of a thin layer of U_3O_8 on stacked aluminum disks. An irradiation capsule with the aluminum disks is shown in Fig. 1. Chemically polished

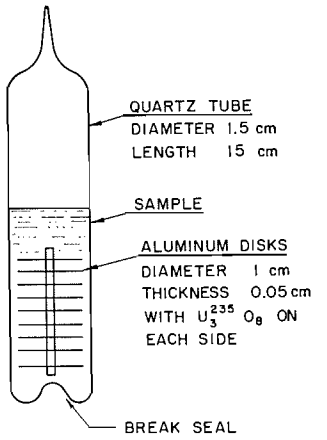

FIG. 1. Fission fragment irradiation capsule.

superpure aluminum was used for these sources and the layer of U_3O_8 was formed using the method of Glover and Burrell (10). The isotopic composition of the uranium, which was obtained from Oak Ridge National Laboratory, measured with a Consolidated Model 21–702B mass spectrometer, was U^{234} 0.984 atom %, U^{235} 93.18 atom %, U^{236} 0.471 atom %, U^{238} 5.37 atom %.

Each source was counted using a windowless proportional alpha counter, and the amount of U^{235} calculated from the alpha activity and the isotopic composition assuming the following half-lives: U^{234} 2.50×10^5 yr, U^{235} 6.985×10^8 yr, U^{236} 2.435×10^7 yr, and U^{238} 4.53×10^9 yr. The alpha counter was calibrated using a standardized Pu^{239} source.

The amount of fission fragment energy deposited in the sample was calculated from the weight of U^{235} and the integrated thermal neutron flux, assuming that half of the total energy of the fission fragments was released in the hydrocarbon. The integrated thermal neutron flux was determined using Johnson and Matthey spectroscopically pure 0.005 in. diameter cobalt wire. The following effective cross sections were used: $\hat{\sigma}$ $Co^{59}(n,\gamma)Co^{60}$ 36.1 b, $\hat{\sigma}$ $U^{235}(n,f)$ 551 b; total energy of fission fragments per fission 165 MeV. The values for these cross sections were taken from Westcott's compilation (11).

The maximum average thickness of the U_3O_8 on the sources was 64 $\mu g\ cm^{-2}$, and, as the range of fission fragments in U_3O_8 is 10 mg cm^{-2}, the loss of energy of the escaping fragments in the sources was negligible (12). The total uncertainty in the energy deposition values due to counting errors and to the uncertainties in the values of cross sections and half-lives is estimated to be less than ±10%.

The quartz capsules were placed in aluminum cans and suspended in an air annulus (the J-rod annulus) in the graphite reflector of the NRX reactor. Irradiation times were 1–2 minutes for the cyclohexane samples. As the yield of hydrogen from benzene is independent of dose (6), the benzene was irradiated for 30–60 minutes in order to obtain more easily measured volumes of gas. The thermal flux was approximately 1×10^{13} n $cm^{-2}\ sec^{-1}$, and the dose rate due to gamma rays and fast neutrons was approximately 30 mW g^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

To correct for the decomposition due to reactor radiation, samples without uranium were irradiated at the same time. The total dose in the cyclohexane samples from both fission fragments and reactor radiation was ca. 4×10^{19} eV g^{-1}, with 75% being due to the former. In the benzene samples, the corresponding values were $(1–2)\times10^{20}$ eV g^{-1} and 50%.

The volumes of hydrogen evolved were measured on a conventional gas analysis apparatus. The isotopic composition was determined with a calibrated Consolidated 21-610 mass spectrometer.

Samples of benzene and cyclohexane were given doses of the same order as those above in a Co^{60} source as a check upon the methods of sample preparation and analysis. The hydrogen yields were 5.5 and 0.04 for cyclohexane and benzene, respectively, in good agreement with the accepted values (13, 6).

RESULTS

The data for cyclohexane and the mixtures with C_6D_{12} and C_6D_6 are given in Table I. They have been corrected for the reactor radiation contribution so that the G values are for fission fragments only.

The data from fission fragment irradiations of benzene–benzene-d_6 mixtures and benzene–cyclohexane-d_{12} mixtures are shown in Table II.

TABLE I

Yields and isotopic composition of hydrogen from fission fragment irradiations of C_6H_{12}–C_6D_{12} and C_6H_{12}–C_6D_6 mixtures

Composition (volume %)	G (total hydrogen)	% HD	% D_2	G(HD)	$G(D_2)$	$G(D_2)/F$*
C_6H_{12}	7.73†	—	—	—	—	—
2% C_6D_{12}	8.11	2.63	0.095	0.25	0.0068	0.33
4% C_6D_{12}	8.21	5.14	0.226	0.46	0.018	0.43
6% C_6D_{12}	7.64	7.59	0.376	0.65	0.28	0.44
C_6D_{12}	5.96	5.06	94.94	—	—	—
2% C_6D_6	8.09	1.83	0.044	0.14	0.0035	0.14
6% C_6D_6	7.31	5.05	0.106	0.40	0.0082	0.103
6% C_6D_6	6.97	5.25	0.130	0.40	0.0098	0.125

*F is the mole ratio of the deuterated hydrocarbon to the light hydrocarbon.
†This is the average of five irradiations with an average deviation of 0.15. No significant difference in yields was observed between irradiations of frozen (−60–0°) and liquid (20–30°) cyclohexane.

TABLE II

Yields and isotopic composition of hydrogen from C_6H_6–C_6D_6 and C_6H_6–C_6D_{12} mixtures

Composition (volume %)	G(total hydrogen)	% HD	% D_2	G(HD)	$G(D_2)$	$G(D_2)/F$
C_6H_6	2.14*	—	—	—	—	—
	2.54†					
C_6D_6	1.45	—	—	—	—	—
2.5% C_6D_6–C_6H_6‡		4.15	0.1	0.089	0.002	0.078
2.5% C_6D_6–C_6H_6‡		4.19	0.088	0.090	0.0019	0.074

6% C_6D_{12}–C_6H_6	2.37	15.63	1.18	0.37	0.028	0.53

*This is the average of five determinations with an average deviation of 0.12. No significant difference in the yields was observed between frozen and liquid samples. The total dose was approximately 1×10^{20} eV g^{-1}.
†This is the average of four determinations with an average deviation of 0.32. The total dose was approximately 2×10^{22} eV g^{-1}.
‡The total hydrogen yields were assumed to be the same as in pure C_6H_6, i.e. 2.14.

In the calculation of the yields in Tables I and II it is assumed that 50% of the total energy of the fission fragments is deposited in the hydrocarbon. This percentage may if anything be lower so that the yields may be too low. The isotopic composition of acetylene from the fission fragment irradiation of benzene was also obtained. $G(C_2H_2)$ values are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of the same order as the hydrogen yields. An 8% solution of C_6D_6 in C_6H_6 gave 15.2% C_2HD and 7.3% C_2D_2, and 16% C_6D_6 in C_6H_6 gave 17.4% C_2HD and 15.5% C_2D_2.

DISCUSSION

The salient points shown by comparison of the fission fragment total hydrogen yields with those previously obtained are as follows.

(1) The hydrogen yield in the fission fragment radiolysis of cyclohexane is approximately 40% greater than that obtained in gamma radiolysis.

(2) The hydrogen yield in the fission fragment radiolysis of 6% C_6D_6–C_6H_{12} is 90% or more of the yield in pure cyclohexane, while in gamma radiolysis the addition of 6% C_6D_6 lowers the hydrogen yield by 50%.

(3) The hydrogen yield from benzene increases by a factor of 4 over the LET range 15–400 eV/Å compared to an increase of ~12 over the range 0.02–15 eV/Å.

In the following discussion we shall assume that the yields of the primary products (excited molecules, radicals, or ions) in the irradiation of both cyclohexane and benzene are independent of LET. This assumption is implicit in Burns' (4) discussion of the effect of LET on the hydrogen yield from cyclohexane, and if it is correct then the mechanism represented by reactions [1]–[3] must be wrong. The observed increase in the cyclohexane hydrogen yield with LET suggests that there is competition between a deactivation of the primary species by the substrate and the reaction of two of these species to form hydrogen. Thus the mechanism suggested by Burns (6) to explain the effect of LET in the irradiation of benzene can be used to explain the dependence of $G(H_2)$ values on LET in the irradiation of cyclohexane.

The reaction scheme for cyclohexane can be written as follows.

$$C_6H_{12} \rightsquigarrow C_6H_{12}' \qquad [6]$$

$$C_6H_{12}' + C_6H_{12}' \rightarrow H_2 + P \qquad [7]$$

$$C_6H_{12}' + C_6H_{12} \rightarrow P \qquad [8]$$

$$C_6H_{12}' + C_6H_6 \rightarrow P \qquad [9]$$

With high LET radiation reaction [7] is favored over reactions [8] and [9] so that the hydrogen yield is higher than at low LET values and is unaffected by the addition of benzene.[2]

Analysis of Isotopic Data

Let us consider what evidence can be derived for the above mechanism from the isotopic composition of the hydrogen from the mixtures of cyclohexane and benzene with C_6D_{12} and C_6D_6.

Dyne and Jenkinson (9) have derived equations for the HD and D_2 yields based on the following processes:

(1) a unimolecular decomposition yielding H_2 (or D_2)

(2) the formation of reactive intermediates which produce H_2, HD, or D_2 by abstraction from light or deuterated molecules.

We shall also assume that there is unimolecular decomposition as in reactions [10] and [11].

$$C_H \rightarrow H_2 + P \qquad \text{Yield } G_1(H) \qquad [10]$$

$$C_D \rightarrow D_2 + P \qquad \text{Yield } G_1(D) \qquad [11]$$

[2]*This mechanism is not inconsistent with the invariance of the H_2 yield over the range 0.02–2 eV/Å as the excited species and the spur sizes may be such that fission fragment track densities are needed to reduce reactions [8] and [9].*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The notation is theirs, with C_H and C_D being the light and the deuterated hydrocarbons, P other products, and $G_1(H)$ and $G_1(D)$ the yields of these reactions. Instead of abstraction we assume the bimolecular process producing hydrogen to be as follows.

$C_H \rightarrow C_H'$	Yield $G_t(H)$	[12]
$C_D \rightarrow C_D'$	Yield $G_t(D)$	[13]
$C_D' + C_H' \rightarrow HD + P$	Rate constant for HD formation, k_1	[14]
$C_D' + C_D' \rightarrow D_2 + P$	Rate constant for D_2 formation, k_2	[15]
$C_H' + C_H' \rightarrow H_2 + P$	Rate constant for H_2 formation, k_3	[16]

In solutions where $C_D \ll C_H$ the yields of D_2 and HD will be given by (i) and (ii).

$$G(D)_2 = FG_1(D) + \frac{F^2G_t(D)}{2}\frac{G_t(D)}{G_t(H)}\frac{k_2}{k_1} \qquad [i]$$

$$G(HD) = FG_t(D) \qquad [ii]$$

For the pure deuterated compound

$$G(D_2) = G_1(D) + \frac{G_t(D)}{2} \qquad [iii]$$

$G_1(D)$ can be obtained by determining the intercept in the plot of $G(D_2)/F$ against F. The yield of the transient species, $G_t(D)$, is given by the initial slope in the plot of $G(HD)$ vs. F, and is designated $g(HD)$ by Dyne and Jenkinson. It is important to note that an independent value of $G_t(D)$ can be obtained from equation (iii) above and is given by $2[G(D_2) - G_1(D)]$.

The values of $G_1(D)$ and $G_t(D)$ calculated from equations (i)–(iii) for all four of the isotopic mixtures used are given in Table III. Dyne and Jenkinson's values for gamma radiolysis are given in parentheses. The values for each of the mixtures in Table III are discussed below.

TABLE III

$G_1(D)$ and $G_t(D)$ values for mixtures of cyclohexane and benzene with their deuterated analogues

Mixture	$G_1(D)$	$G_t(D) = g(HD)$	$G_t(D) = 2[G(D_2)^* - G_1(D)]$
C_6D_{12}–C_6H_{12}	0.3 ± 0.05 (0.32)	12 (3.6)	11.3 (7.4)
C_6D_{12}–C_6H_6	0.3 ± 0.1 (0.06)	9.0 (0.17)	11.3 (8)
C_6D_6–C_6H_{12}	0.1 ± 0.05 (0.01)	5.6 (>2.9)	2.7 (0.006)
C_6D_6–C_6H_6	0.05 ± 0.01 (0.0032)	3.4 (0.027)	2.7 (0.02)

*This is the yield of D_2 from the pure deuterated hydrocarbon.

Cyclohexane-d_{12}/Cyclohexane Mixtures

Insofar as the two $G_t(D)$ values agree with each other our mechanism fits the fission fragment data. The overall increase in yield with LET can, as we have said, be explained by the favoring of reaction [7] over [8]. The disagreement between the $G_t(D)$ values in gamma radiolysis can be explained by an isotope effect in reaction [8] so that C_D' suffers more deactivation proportionally than C_H'. This isotope effect can be written as reaction [17]

$$C_D' + C_H \rightarrow C_D + C_H'. \qquad [17]$$

The $G_1(D)$ values appear to be independent of LET. This does not seem to exclude the possibility that the unimolecular and bimolecular processes have a common precursor.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Dyne and Jenkinson (14) have suggested the following reactions

$$C_6D_{12} \wwarrow\!\!\!\rightarrow C_6D_{12}^* \quad [18]$$

$$C_6D_{12}^* \rightarrow D_2 + P \quad [19]$$
$$\searrow X_D + P$$

$$X_D + C_6H_{12} \rightarrow HD + P \quad [20]$$

$$C_6D_{12} + C_6H_6 \text{ (or } I_2) \rightarrow P \quad [21]$$

to account for the similar reductions in both $G_1(D)$ and $g(HD)$ on the addition of benzene or iodine in the radiolysis of cyclohexane. Introducing a common precursor into the mechanism we have used, we have

$$C_6D_{12} \wwarrow\!\!\!\rightarrow C_D' \quad [22]$$

$$C_D' \rightarrow D_2 + P \quad [23]$$

$$C_D' + C_H' \rightarrow HD + P \quad [24]$$

$$C_D' + C_6H_{12} \text{ (or } C_6H_6) \rightarrow P \quad [25]$$

In the mechanism of Dyne and Jenkinson an increase in total yield of hydrogen in pure cyclohexane with LET can be explained by assuming that there is some deactivation of the precursor by cyclohexane. This deactivation would be reduced at high LET, but both $G_1(D)$ and $g(HD)$ should then increase, as the branching ratio in reaction [19] and the yield of [20] should not be affected by LET.

The mechanism represented by equations [22]–[25] does not appear to be inconsistent with the increase in $g(HD)$ and the invariance of $G_1(D)$ with increasing LET. At high LET values the substrate concentration in the track will be low; both reactions [23] and [24] will be favored over [25], and [24] will be favored over [23]. Therefore, the certain effects of increasing LET are to increase the yield of [24] and to decrease the yield of [25]. The yield of [23] may increase, decrease, or stay the same.

Cyclohexane-d_{12}/Benzene Mixtures

The values in Table III for these mixtures provide striking evidence of how great the difference can be between fission fragment and gamma radiolysis. In the gamma radiolysis of dilute solutions of C_6D_{12} in benzene $G_1(D)$ is 0.06 and $g(HD)$ only 0.17. In the fission fragment radiolyses of these solutions $G_1(D)$ is 0.3 and $g(HD)$ is 9.0, within 25% of the corresponding values for C_6D_{12} in cyclohexane. That is, the decomposition of C_6D_{12} in fission fragment radiolysis is much the same in 95% benzene as it is in 95% cyclohexane.

The 25% reduction in $g(HD)$ that is observed between C_6D_{12}–C_6H_{12} and C_6D_{12}–C_6H_6 can be explained by assuming that, even with fission fragments, reaction [9] occurs to some extent.

Benzene-d_6/Benzene Mixtures

The increase with LET in the $G_1(D)$ values for these mixtures is not in disagreement with a mechanism involving a common precursor similar to that given in reactions [22] to [25]. An increase in LET favors both reactions [23] and [24] over [25] but, since [24] is second order in the primary species, it should also increase relative to [23].

The difference between the two $G_t(D)$ values indicates that with benzene there is more interaction between the primary species and the substrate. That C_6D_{12}–C_6H_{12} mixtures behave "ideally" with fission fragments and C_6D_6–C_6H_6 mixtures do not is probably due to the greater reactivity of benzene in reactions such as [25].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Benzene-d_6/Cyclohexane Mixtures

The fission fragment value of g(HD) for these mixtures is twice the value of G_t(D) derived from the D_2 yield in pure C_6D_6. This can be explained by assuming as above that, even with fission fragments, benzene deactivates the primary products. Thus the hydrogen yield from benzene-d_6 is lower in 95% C_6H_6 than it is in 95% C_6H_{12}. The "true" yield of primary products from benzene, i.e. the yield before any deactivation of these products occurs, is, therefore, perhaps around 6 rather than 3.

The results from the gamma radiolysis of C_6D_6–C_6H_{12} mixtures are not consistent with hydrogen formation from the interaction of two primary species. The high value of g(HD) and the low values of G_1(D) in these mixtures and $G(D_2)$ in pure C_6D_6 are most easily explained by abstraction reactions such as [26]

$$X_H + C_6D_6 \rightarrow HD + P \qquad [26]$$

where X_H is an intermediate in the radiolysis of cyclohexane.

Further Comments

The mechanism we have discussed can be extended to explain the effect of HCl on the hydrogen yield in gamma ray irradiations of cyclohexane. If reaction [27] occurs and competes with reaction [8], then as has been found (15) the addition of HCl should increase the hydrogen yield.

$$HCl + C_6H_{12}' \rightarrow H_2 + P \qquad [27]$$

We have obtained a preliminary yield of G(cyclohexene) <1.5 and G(bicyclohexyl) <0.4, but have not identified the other hydrogen-deficient products. These values are supported by Burns and Parry (16) who obtained $G(C_6H_{10}) = 1.9$ and $G(C_6H_{11})_2 = 0.9$ using 1.5 MeV alpha particles. Falconer and Burton (17) found that the ratio of the yields of bicyclohexyl to cyclohexene decreased with increasing LET.

These results show that the reactions leading to the formation of liquid products in cyclohexane are different at high LET, but further speculation as to the mechanism of hydrogen formation should await identification of the other products.

The high C_2D_2 content of the acetylene from fission fragment irradiations of C_6D_6–C_6H_6 mixtures implies that the majority is formed by unimolecular decomposition. The increase in the total acetylene yield with LET is comparable to the increase in the hydrogen yield so that there is an apparent increase in unimolecular or first-order decomposition of 50- to 100-fold. This is much higher than the increase in the unimolecular yield of hydrogen with LET.

Again it is desirable to have the yields of the other products in the fission fragment radiolysis for the interpretation of these results.

ACKNOWLEDGMENTS

The mass analyses of the uranium were done by Dr. M. Lounsbury and Mr. R. W. Jones. It is a pleasure to acknowledge many helpful discussions with Dr. P. J. Dyne, Dr. R. H. Betts, and Dr. J. A. Stone.

THE MERCURY-PHOTOSENSITIZED DECOMPOSITION OF AMMONIA AND AMMONIA–PROPANE MIXTURES*

S. TAKAMUKU† AND R. A. BACK
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received January 30, 1964

ABSTRACT

A study of the mercury-photosensitized decomposition of ammonia, both with pure ammonia and with propane added as a scavenger for hydrogen atoms, suggests that the quantum yield of the primary decomposition into H and NH_2 is much less than unity at 33° C and rises with increasing temperature. The interaction of ammonia–propane mixtures with Hg $6(^3P_1)$ atoms cannot be explained in terms of simple competitive quenching; a tentative mechanism involving a long-lived Hg $6(^3P_1)$ – propane complex and Hg $6(^3P_0)$ atoms has been suggested. A temperature dependence in the relative quenching rates of C_3H_8 and C_3D_8 has also been observed.

INTRODUCTION

It was recently observed that the primary quantum yield in the mercury-photosensitized decomposition of methane was much less than unity at 33° C and was temperature dependent, rising with increasing temperature (1). The mercury-photosensitized decomposition of ammonia at room temperature also shows a quantum yield considerably less than unity which in the past has been attributed to efficient back reactions (2). The present experiments were undertaken to determine whether ammonia, like methane, might also show an inefficiency and a temperature dependence in its primary reaction with Hg $6(^3P_1)$ atoms.

EXPERIMENTAL

Apparatus and techniques have been described previously (1). The 200-cc cylindrical reaction vessel was part of a circulation system of about 4 liters volume. The intensity of light absorbed was about 2×10^{-9} einsteins/liter/second. Mercury was at its equilibrium vapor pressure at 0° C, which gave between 40 and 90% absorption of the 2537 resonance line in the reaction vessel. After irradiation, gases non-condensable at −196° C were removed and measured in a gas burette and analyzed for hydrogen content by diffusion through hot palladium. These analyses were confirmed by mass spectrometer and showed that H_2 and N_2 were the only non-condensable products from pure ammonia, while H_2 and CH_4 were the only ones from ammonia–propane mixtures.

Anhydrous ammonia was obtained from Matheson, while propane was Phillips' Research-grade, known to be free of olefins. Both gases were subjected to several bulb-to-bulb distillations. Deuterated ammonia and propane of high purity were obtained from Merck and Co. of Canada.

RESULTS AND DISCUSSION

Experiments with Pure Ammonia

The most thorough study of the mercury-photosensitized decomposition of ammonia was that of McDonald and Gunning (2) in which, with rather high light intensities, the following mechanism was shown to prevail in the initial stages:

$$Hg^* + NH_3 \rightarrow Hg + NH_2 + H \quad [1]$$

$$H + NH_2 \rightleftharpoons NH_3^* \quad [2]$$

$$NH_3^* + M \rightarrow NH_3 + M \quad [3]$$

$$H + H + M \rightarrow H_2 + M \quad [4]$$

$$NH_2 + NH_2 \rightarrow N_2H_4 \quad [5]$$

*Issued as N.R.C. No. 7879.

†*National Research Council of Canada Postdoctoral Fellow, 1961–62. Present address: Osaka University, The Institute of Scientific and Industrial Research, Osaka, Japan.*

As the reaction progressed further, very efficient secondary reactions (of H and NH_2) destroyed hydrazine, producing nitrogen, so that at conversions of about 0.1% and greater, the ratio N_2/H_2 equalled the stoichiometric value of 1/3. As conversion was reduced, this ratio fell towards zero; the lowest value actually attained was 0.017 at 0.005% conversion.

It was hoped in the present experiments, by reducing the light intensity and by maintaining very low conversions, that, first, reactions 2, 3, and 4 could be suppressed, and replaced by the reaction,

$$H + NH_3 \rightarrow H_2 + NH_2, \qquad [6]$$

and, second, that the yield of nitrogen could be reduced effectively to zero. Under these conditions the hydrogen produced would become a direct measure of the extent of the primary process.

These simplifying conditions were not in fact achieved. Table I shows quantum yields of

nitrogen and hydrogen (based on comparison with the propane decomposition) and it is seen that there is a marked increase with rising temperature. It is further seen that the yield of nitrogen, far from being zero, was never less than one-third of the hydrogen. Thus although the fraction of ammonia decomposed was about 10 times smaller than in the shortest experiments of McDonald and Gunning, in which nitrogen formation was largely suppressed, secondary reactions with hydrazine had in the present system apparently already led to a steady state in which nitrogen and hydrogen were effectively the only products. This seemingly contradictory behavior is, on closer examination, simply explained. In the earlier experiments, light intensities were about 5000 times higher than in the present ones, and reactions 2, 3, and 4, all second-order in radicals, predominated at low conversions over reactions of H or NH_2 with hydrazine. The much lower intensities used in the present experiments would favor the latter reactions. Reaction 6, if it were fast enough to scavenge all the hydrogen atoms, would suppress their reaction with hydrazine, but reaction of NH_2 with hydrazine would not be prevented, so that efficient destruction of hydrazine occurs in the present system despite the lower conversions.

Yields of nitrogen not only failed to fall below the value of $N_2/H_2 = 1/3$, but were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

actually considerably higher than this maximum stoichiometric limit. There was apparently a loss of hydrogen from the system; this was further investigated by experiments in which a few micromoles of pure hydrogen were irradiated in the reaction vessel. There was a steady loss of hydrogen observed comparable in magnitude to the missing hydrogen in the ammonia decomposition (about 1 micromole/day). Prolonged irradiation of hydrogen progressively reduced this loss to negligible proportions, but when ammonia was again irradiated in the hydrogen-conditioned vessel, loss of hydrogen was almost the same as before. This suggests a surface reaction of hydrogen atoms, perhaps catalyzed by adsorbed ammonia, resulting in permanent loss of hydrogen. The low light intensities used favor such a process.

The rise in quantum yield with rising temperature evident in Table I may arise in part from a temperature-dependent primary process, although it is impossible to separate this effect unequivocally from temperature dependence in the secondary reactions. The product yields in Table I were approximately independent of ammonia pressure, which suggests that most of the hydrogen atoms were disappearing by reaction 6, although the hydrogen deficit indicates that this process was not quantitative. Uncertainties in the mechanisms of the secondary reactions consuming hydrazine also complicate the interpretation of the data.

Experiments with Ammonia–Propane Mixtures

Failure to achieve the simple conditions in which hydrogen was a direct measure of the primary process in the decomposition of pure ammonia suggested the use of propane as an efficient scavenger for hydrogen atoms. In pure propane, under the prevailing conditions of low light intensity and low conversion, the decomposition followed the following simple mechanism (3).

$$RH + Hg^* \rightarrow R + H + Hg \quad [7]$$

$$H + RH \rightarrow R + H_2 \quad [8]$$

$$2R \rightarrow R_2 \text{ or } RH + \text{propylene} \quad [9]$$

Loss of hydrogen atoms by reaction with propylene product was negligible, so that the yield of hydrogen was a measure of reaction 7, which is known to have an efficiency close to unity. If then reaction 1 also has a quantum yield of unity, the addition of ammonia should simply replace reaction 7 by reaction 1, and the hydrogen yield should be unaffected. Any inefficiency in reaction 1, on the other hand, should be reflected in a decrease in the hydrogen production.

In Fig. 1 the hydrogen yields from ammonia–propane mixtures at three different temperatures are plotted against the calculated percentage quenching of Hg $6(^3P_1)$ by ammonia, based on cross sections of 2.94 and 1.30 Å^2 for ammonia and propane respectively (4, 5). Results are also shown for mixtures of ND_3 with C_3H_8 and of NH_3 with C_3D_8, assuming cross sections of 1.09 and 0.09 Å^2 for ND_3 and C_3D_8 respectively (4, 6). The latter mixture takes advantage of the very low quenching cross section of C_3D_8 to attain almost complete (93%) quenching by ammonia. In all these experiments, propane pressure was 150 mm, which should have been enough to scavenge all hydrogen atoms by reaction 8. Corrections were made to allow for measured variations in the absorption of the mercury resonance radiation in the reaction vessel with varying temperature and pressure, which were quite appreciable.

It appears superficially from Fig. 1 that reaction 1 has an efficiency which is much less than unity at 33° C, and which increases with increasing temperature until at 300° C it is about as efficient as reaction 7. It is evident, however, that the interaction between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

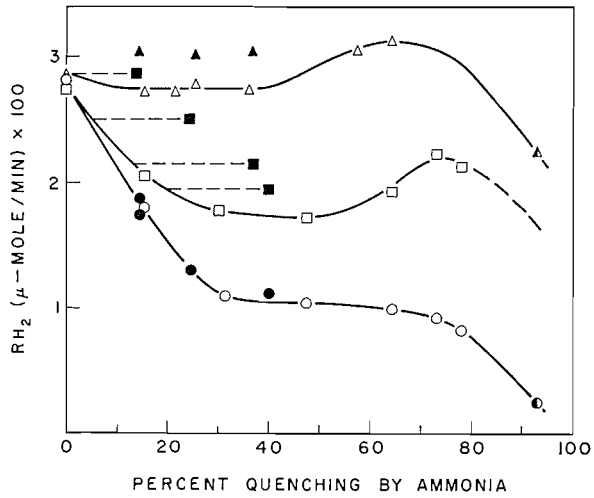

FIG. 1. Hydrogen yield from the mercury-photosensitized decomposition of ammonia–propane mixtures. The abscissae were calculated on the basis of simple competitive quenching. ○, □, △ = NH_3–C_3H_8; ●, ■, ▲ = ND_3–C_3H_8; ◐, ◭ = NH_3–C_3D_8. Circles = 33° C; squares = 200° C; triangles = 300° C.

ammonia and propane is much more complex than a simple competition between reactions 1 and 7. There is a common pattern of behavior at all three temperatures which may be separated into three parts.

(1) The initial effect of added ammonia is much greater than predicted from the quenching cross sections of ammonia and propane. Thus at 33° C the hydrogen yield had fallen by about 50% at a point where quenching by ammonia should have been only 20%. This deviation seems to be far beyond any possible errors in the values of the cross sections. The effect is less pronounced at 200° C and not evident at all at 300° C.

(2) There is an interaction in the region between 40 and 80% quenching by ammonia which leads to an enhancement of the hydrogen yield.

(3) There is a final decrease in hydrogen yield as complete quenching by ammonia was approached.

A simple competition between reactions 1 and 7, it might be noted, would have led to hydrogen yields linearly dependent upon the percentage quenching by ammonia.

The following mechanism can account for the general features of the ammonia–propane system:

$$Hg^* + RH \rightarrow (RH.Hg^*) \quad [10]$$

$$(RH.Hg^*) \rightarrow R + H + Hg \quad [11]$$

$$NH_3 + (RH.Hg^*) \rightarrow RH + NH_3 + Hg \quad [12]$$

$$Hg^* + NH_3 \rightarrow Hg^\circ + NH_3 \quad [13]$$

$$Hg^\circ + RH \rightarrow Hg + R + H \quad [14]$$

$$Hg^\circ + NH_3 \rightarrow Hg + NH_3 \quad [15]$$

$$NH_3 + (Hg^* \text{ or } Hg^\circ) \rightarrow Hg + NH_2 + H \quad [16]$$

where Hg, Hg*, and Hg° represent the ground state, the 6^3P_1 state, and the 6^3P_0 state, respectively. There are several pairs of concurrently competitive reactions in this sequence. At low pressures of ammonia, reaction 12 begins to compete efficiently with reaction 11, reducing the hydrogen yield. As ammonia pressure is further increased, reaction 13 begins to compete with 10, and reaction 14 causes a rise in the hydrogen production. Finally,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

reaction 15 competes more and more efficiently with 14, and the hydrogen yield falls again. Reaction 16 is required to account for the decomposition observed in pure ammonia. The temperature dependence in both ammonia and ammonia–propane mixtures can be explained if reaction 16 and perhaps reactions 11 and 14 increase in rate with rising temperature.

The isotopic composition of the hydrogen produced from the ND_3–C_3H_8 and NH_3–C_3D_8 mixtures (Tables II and III) lends some support to this mechanism. From ND_3–C_3H_8

TABLE II

300	60	150	92.9	3.8	52.2	44.0

mixtures, with calculated percentage quenching by ammonia ranging up to 40%, the decomposition of ND_3 as indicated by production of HD was never more than a few per cent of the total hydrogen, even at 300° C where there was no reduction in the hydrogen yield. This suggests that it was reactions 11 and 14, rather than 16, that were responsible for the increase in hydrogen yield with rising temperature on the left-hand side of Fig. 1. The experiments with NH_3–C_3D_8 mixtures, on the other hand, while complicated by a large yield of HD and H_2 arising from preferential decomposition of hydrogen-containing propane impurity, show that the increased hydrogen yield at 300° C arose largely from enhanced decomposition of NH_3. Thus reaction 16 must finally become important as "complete quenching" by NH_3 is approached. This, combined with the failure of reaction 16 to compete successfully in the ND_3–C_3H_8 experiments implies that Hg^0 rather than Hg^* is the effective reagent in reaction 16.

There are several further conclusions to be drawn from the experiments with ND_3–C_3H_8 and NH_3–C_3D_8 mixtures. One of these is that reactions 12 to 16 have relative rates which approximately parallel the cross sections for quenching of Hg^*. For example, the data

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

obtained with ND_3 at 33° C fits perfectly with the NH_3 data when corrected according to their known quenching cross sections. It also appears that C_3D_8 is very ineffective in reaction 14, as it is known to be in quenching Hg*. A further conclusion is that several of the quenching reactions show a marked variation with temperature. At 200° C, ND_3 appears to be much less efficient, relative to NH_3, in reducing the hydrogen yield (Fig. 1), although at 33° their relative efficiencies appeared to follow their quenching cross sections. This seems to imply a temperature dependence in the relative rates of NH_3 and ND_3 in reaction 12. Also notable are the two experiments with C_3D_8 alone (Table III). The yields of H_2 and HD at 33° C are quite compatible with the estimated isotopic purity of the C_3D_8 (> 98%) and the known preferential reaction of protiated propanes both in reaction 7 and to a lesser extent in reaction 8 (6, 7). At 300° C, the percentage yields of H_2 and HD were very much lower, apparently reflecting an increased quenching efficiency of C_3D_8 at the higher temperature. Quenching cross sections for Hg* have usually been measured at a single temperature, and no temperature dependence has been previously reported.

The experiments at 300° C shown in Fig. 1, in which the hydrogen yield in ammonia–propane mixtures apparently rose above that in pure propane, require a brief comment. There is a fairly large correction for incomplete absorption of light made to these data, and while the absorption was measured in each experiment, uncertainties arising in the correction may well account for the discrepancy. However, while the quantum yield of the propane decomposition is usually taken as close to 1.0 actual estimates of the yield (3, 8) lie closer to 0.9, which would make the highest yields in Fig. 1 about unity. A new absolute measurement of the yield of the propane decomposition is obviously desirable.

One final point concerns the fate of the NH_2 radicals in the ammonia–propane system. The complete absence of nitrogen as a product in these experiments suggests either that NH_2 radicals were efficiently removed by reaction with propane,

$$NH_2 + RH \rightarrow NH_3 + R \qquad [17]$$

or that hydrazine, if formed, was not converted to nitrogen by secondary reactions as it was in pure ammonia. There is further evidence that, at least at 300° C, NH_2 radicals reacted quantitatively by reaction 17; the yield of methane, which arose from decomposition of propyl radicals and hence reflects their concentration, was unaffected by the addition of ammonia (9).

The mechanism suggested for the ammonia–propane system is necessarily tentative. Its chief innovation is perhaps reaction 12; some reaction of this sort seems to be required to explain the abnormally high efficiency of ammonia in reducing the hydrogen yield at low temperatures. The existence of a propane–Hg* complex with sufficient lifetime to react with ammonia gains some support from recent evidence that with several alkanes, the initial rate-controlling quenching process, which involves a single C—H bond, is followed by formation of a reaction complex (perhaps cyclic) in which one of several C—H bonds may finally be broken (7, 10). A similar complex capable of deactivation by collision, might be invoked in the mercury-photosensitized decomposition of methane to explain the observed dependence on pressure and temperature (1). It is becoming increasingly evident that quenching of Hg $6(^3P_1)$ atoms by alkanes and probably by other hydrides such as ammonia and water is a fairly complex chemical reaction rather than a simple physical transfer of energy.

NUCLEAR MAGNETIC RESONANCE STUDIES OF THE PROTONATION OF WEAK BASES IN FLUOROSULPHURIC ACID

IV. PHENOLS AND AROMATIC ETHERS

T. Birchall, A. N. Bourns, R. J. Gillespie, and P. J. Smith
Department of Chemistry, McMaster University, Hamilton, Ontario

Received January 21, 1964

ABSTRACT

The n.m.r. spectra of phenol, anisole, and other phenols and aromatic ethers in solution in fluorosulphuric acid and in 70% perchloric acid show that in every case they protonate on an aromatic carbon. Earlier evidence from ultraviolet spectroscopy that phenol and anisole protonate on oxygen is reinterpreted.

INTRODUCTION

The protonation of methylbenzenes has been studied by a variety of techniques and it has been established that protonation occurs at the most electronegative aromatic carbon atom (1–6). The carbonium ions formed have characteristic absorptions at approximately 350 mμ and 250 mμ. The n.m.r. spectra of these compounds in solution in HF/BF_3 (7) and HSO_3F (8) confirm the spectrophotometric results.

Phloroglucinol and its methyl ethers in solution in concentrated acid have absorption bands at 365 mμ and 250 mμ suggesting that protonation occurs on the ring; this has been confirmed by n.m.r. evidence (9). In the case of anisole in strong acid solution Arnett and Wu (10) concluded that protonation occurs on the oxygen atom because they did not observe any new bands in the absorption spectrum down to 250 mμ. However the n.m.r. spectrum of anisole in HF/BF_3 (7) and HSO_3F (8) solutions at low temperature has been explained on the basis of protonation at the ring position *para* to the methoxy group, in complete contrast to the evidence from the ultraviolet spectra.

This discrepancy is discussed below and further evidence is presented which indicates that in aromatic bases where the ring is activated by an OR group protonation occurs on the most activated ring carbon atom and not on the oxygen atom.

N.M.R. SPECTRA

The chemical shifts of the compounds studied are given in Table I.

Anisole

Because of the large difference between the temperatures at which the original ultraviolet and n.m.r. measurements were made we attempted to observe the n.m.r. spectrum of the conjugate acid of anisole at room temperature. This can be done by increasing the acidity of the fluorosulphuric acid solvent by the addition of SbF_5. The n.m.r. spectrum of a solution of anisole in fluorosulphuric acid containing 7.55 mole % SbF_5 was recorded at 25° (Fig. 1); no new peaks appear on cooling the solution to −90°. If protonation occurred at the oxygen atom peaks of relative area 5:3:1 would result with the peak due to the methoxy protons being split into a doublet by the captured proton. However, the relative areas of the peaks A, B, and C were found to be 3.89:3.00:1.90 in good agreement with the relative areas of 4:3:2 expected for ring protonation; these peaks are therefore assigned to the ring protons and the OCH_3 and CH_2 groups respectively. No splitting of the methoxy peak was observed. The simple AB pattern of the signal given by the ring protons indicates that protonation occurs at the position *para* to the OCH_3 group; each component of the lower doublet has a triplet structure ($J \approx 2$ c.p.s.) indicating that it is spin–spin coupled to two protons, i.e. to the CH_2 group. No structure was observed in the CH_2 peak, possibly due to these protons having a shorter relaxation time and as a result broader lines.

Diphenyl Ether

The solution in fluorosulphuric acid when prepared at low temperatures (−85°) is yellow and gives an n.m.r. spectrum which has a peak B at −4.5 p.p.m. from an external tetramethylsilane reference which is characteristic of a CH_2 group (Fig. 2). That protonation occurs on the ring is confirmed by the relative areas of the absorptions A and B which are 9.0:1.93 and not 10:1 as would be the case for protonation on oxygen.

Phenol

A solution of phenol in fluorosulphuric acid at low temperatures gives an n.m.r. spectrum which can only be explained on the basis of protonation at the *para* position. This spectrum is shown in Fig. 3; the relative areas of A:B are 4.0:1.8. If protonation occurred at the oxygen atom the relative areas of the peaks would be 5:2 and the OH_2^+ signal would occur at lower field than the OH resonance of phenol itself. Moreover, the complicated A_2B_2C pattern of the ring protons of phenol is changed on protonation to give a relatively simple quartet pattern which is very similar to that given by the conjugate acid of anisole. The lower doublet is attributed to the ring protons adjacent to the protonated site. Each component of this lower doublet appears to have a triplet structure, as in the case of anisole. This is consistent with spin–spin coupling to the CH_2 protons: again no structure is observed in the CH_2 peak which has a width of approximately 7 c.p.s. No resonance for the OH proton is observed presumably because of rapid exchange with the solvent; this has been found to be the case for acid solutions of other phenols (9).

m-Cresol

The n.m.r. spectrum of *m*-cresol in fluorosulphuric acid is shown in Fig. 4. This spectrum can be accounted for only if protonation occurs at an aromatic carbon atom; the relative areas of the peaks A:B:C are 3.13:1.97:3.0. If protonation had occurred on the oxygen atom the relative areas would be 4:2:3. The spectrum of the ring protons which is an AB pattern overlapping a single peak is very similar to that obtained for the conjugate acid of *m*-xylene (7, 8). For *m*-cresol there are two possible sites for protonation, i.e. *ortho* or *para* to the OH group (I and II).

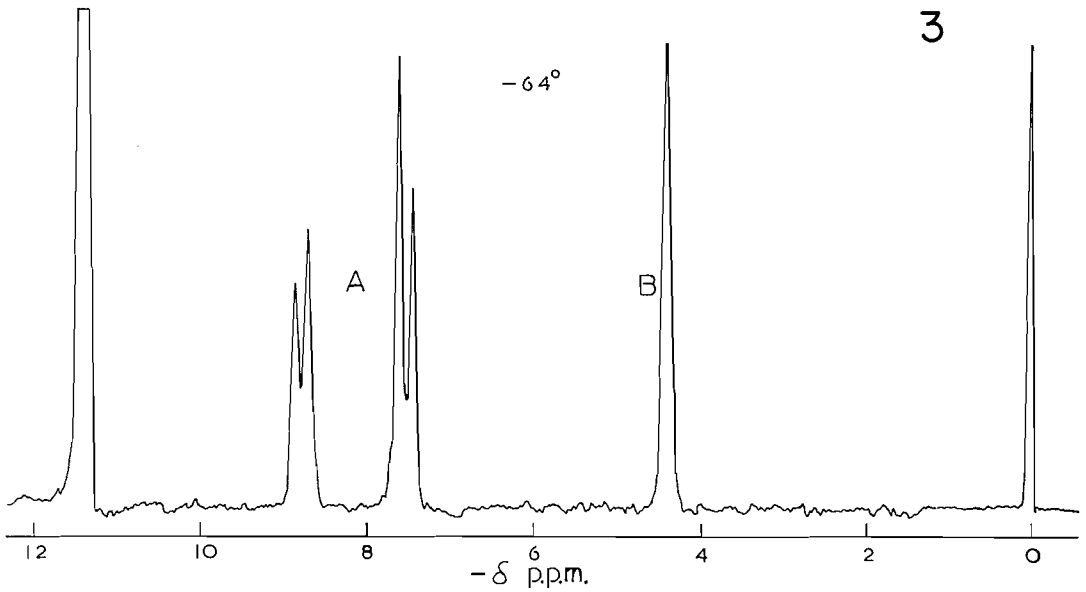

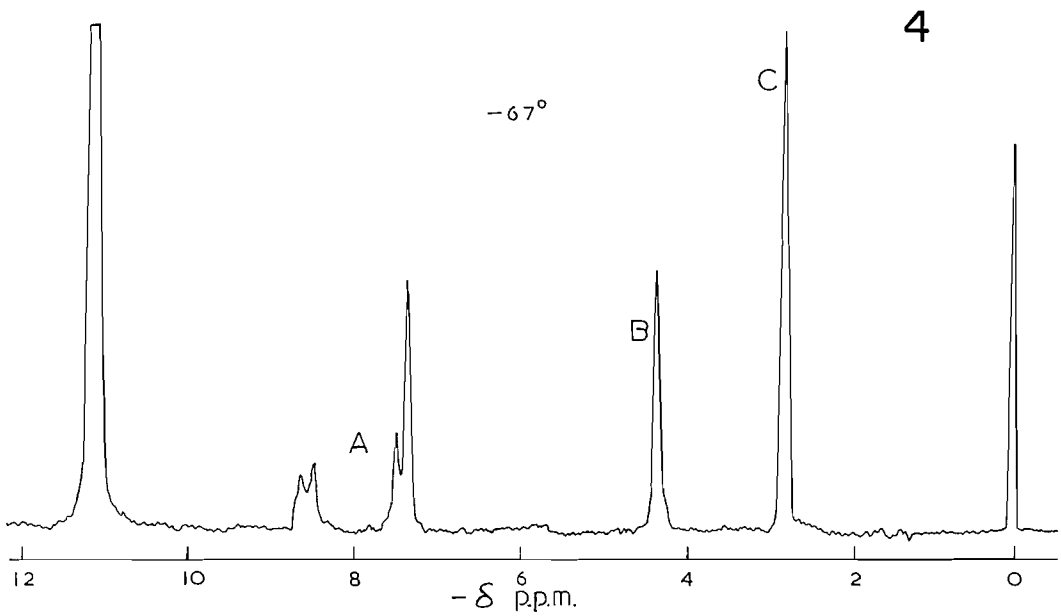

FIG. 3. The n.m.r. spectrum of a solution of phenol in fluorosulphuric acid.
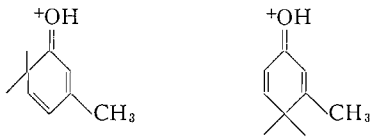
FIG. 4. The n.m.r. spectrum of a solution of *m*-cresol in fluorosulphuric acid.



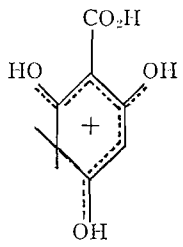
I II

It seems likely that II is the predominant form for reasons discussed below.

Polyhydroxy Compounds

In aqueous 70% perchloric acid phloroglucinol has only two peaks of equal area in its n.m.r. spectrum which have been attributed to the "aromatic" protons and the CH_2 group of the ring protonated base (9). We have obtained essentially the same n.m.r. spectrum in fluorosulphuric acid solution (Table I), although the peaks are much sharper because exchange is slower in the more acidic solvent. No resonance due to the OH proton was observed even on cooling the solution to $-100°$.

We have also examined solutions of 2,4,6-trihydroxybenzoic acid in 70% $HClO_4$ and in HSO_3F. No peaks, other than the solvent, are visible in the n.m.r. spectrum at room temperature but on cooling the 70% $HClO_4$ solution to $-55°$ two broad peaks appear. In the much stronger acid HSO_3F it is possible to slow down the exchange process so that these two peaks become much narrower. At $-63°$ the relative areas of these two peaks are found to be 1.0:1.77. From these relative areas and the chemical shifts of the two peaks they can be attributed to the single ring proton and the CH_2 group respectively showing that the conjugate acid has the structure III.



III

Under conditions of very slow exchange the areas should be 1:2. It was not possible to observe peaks due to OH or COOH protons presumably due to rapid exchange of these protons with the solvent.

ULTRAVIOLET SPECTRA

The ultraviolet spectra of these bases were recorded in neutral and strongly acid solution and the positions of the bands are given in Table II. Solutions of diphenylether in HSO_3F at low temperature were found to have a yellow color but we did not have suitable equipment for recording the spectrum at low temperatures; at higher temperatures ($> -10°$) a reaction, probably sulphonation, occurs between the solvent and the ether. Peaks in the 350 mμ region of the spectrum in acid solution were observed only in the cases of phloroglucinol and 2,4,6-trihydroxybenzoic acid. In 70% $HClO_4$ 2,4,6-trihydroxybenzoic acid is incompletely protonated and peaks due to both the free base and the conjugate acid are visible.

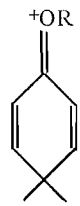
†70% $HClO_4$.

DISCUSSION

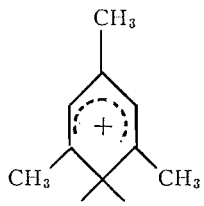
The conjugate acids of the methylbenzenes are found to give bands at 350 mμ and 250 mμ and protonation is known to occur at the most electronegative carbon atom (1–6), hence the appearance of these bands in the ultraviolet spectrum upon protonation has been taken to indicate ring protonation and the absence of these bands has been assumed to indicate protonation at a site other than the ring carbon atom. In the case of anisole it was assumed, on this basis, that protonation occurs on the ether oxygen (10).

In the cases of phloroglucinol, dimethoxybenzene, and trimethoxybenzene in 70% perchloric acid solution bands at 240 mμ and 350 mμ are present in the ultraviolet spectra. This has been assumed to indicate that protonation occurs on a ring carbon atom and this is confirmed by the n.m.r. evidence (9). We have obtained similar results for phloroglucinol and trihydroxybenzoic acid in both 70% perchloric acid and in fluorosulphuric acid.

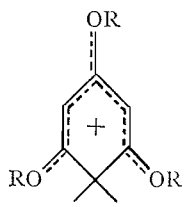
However, in the cases where there is only one OR group attached to the aromatic ring the conjugate acid does not have a band in the 350 mμ region of the ultraviolet spectrum but nevertheless the n.m.r. evidence can only be explained on the basis of ring protonation. It is suggested that protonation of ArOR compounds occurs at the position *para* to the OR group, the ion resulting having the quinonoid structure IV; this would result in a localization of the positive charge on the oxygen atom. The ultraviolet spectrum of IV



IV



V



VI

is quite consistent with other quinone systems reported in the literature, e.g., benzoquinone has peaks at 240 mμ, 290 mμ, and a weak band at 480 mμ, but none at 350 mμ (11); 2,4,6-tribromo-4-chloro-2,5-cyclohexadienone has a peak at 275–280 mμ (12); other similar compounds (13, 14) have peaks in the 275–280 mμ region but not in the 350 mμ region. The conjugate acid of *m*-cresol is assumed to have structure II rather than I since its ultraviolet spectrum closely resembles that of phenol and anisole in acid solution.

In contrast, in the case of the conjugate acids of the methylbenzenes, and the polyhydroxybenzenes and their ethers the positive charge is dispersed around the aromatic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

system (V and VI). Thus the bands at 250 mμ and 350 mμ which have been assumed to be characteristic of a protonated aromatic ring may be more satisfactorily regarded as arising from the positively charged conjugated systems present in V and VI. The absence of a band at 350 mμ in the ultraviolet spectrum of the conjugate acid of a base of the ArOR type cannot therefore be taken to indicate protonation on the oxygen atom.

In the case of a solution of diphenylether in fluorosulphuric acid at low temperature, the yellow color suggests the presence of a band at 350 mμ. This presumably arises as a result of some delocalization of the positive charge into the second ring.

EXPERIMENTAL

All of the bases were purified either by recrystallization or distillation and stored under a dry atmosphere. The n.m.r. samples were prepared as previously described (15) and recorded on a Varian H.R. 60 spectrometer equipped with a low temperature probe and integrator. The ultraviolet spectra were recorded on a Bausch and Lomb Spectronic 505 instrument.

ACKNOWLEDGMENT

We thank the Petroleum Research Fund of the American Chemical Society and the Directorate of Chemical Sciences of the United States Air Force Office of Scientific Research for financial support of this work. We also thank the Dow Chemical Company of Canada for the award of a fellowship (to T. B.) and the National Research Council for the award of a studentship (to P. J. S.).

BASE-CATALYZED DIMERIZATIONS OF ALKYLIDENEMALONONITRILES

MARY R. S. WEIR AND J. B. HYNE
Department of Chemistry, University of Alberta, Calgary, Alberta
Received December 23, 1963

ABSTRACT

The base-catalyzed dimerizations of several alkylidenemalononitriles have been studied, and proton nuclear magnetic resonance (n.m.r.) spectral evidence is presented in support of the suggested cyclic structures of these dimers.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The preparation of α,β-unsaturated dinitriles of the type $R_2C{=}C(CN)_2$ by base-catalyzed condensation of the corresponding carbonyl compound ($R_2C{=}O$) with malononitrile has been the subject of investigation from the time of Heuck onwards (1–9). In addition to the expected unsaturated dinitrile, however, a second substance, considered to be a dimer of the dinitrile, has been isolated in several instances (5). The formation of this dimeric product has previously led to confusion about the nature of the monomeric product. For example, cyclohexylidenemalononitrile (5) and isopropylidenemalononitrile (4) were originally reported to be crystalline solids and it was later shown (6) that they are, in fact, liquids.

These crystalline products are obtained in varying yields from the base-catalyzed condensations of both aromatic and aliphatic ketones with malononitrile. The structures of some of them have recently been investigated (7, 8, 9). Thus, Anderson, Bell, and Duncan (7) studied the solid products obtained from the base-catalyzed reactions of malononitrile with several carbonyl compounds including acetone, acetophenone, and benzil. They suggested, largely on the basis of infrared spectral analysis, that the structure of the dimer of isopropylidenemalononitrile was linear ($Me_2C{=}C(CN).C(NH_2){=}CH.CMe{=}C(CN)_2$). Williams later investigated some of the reactions of this dimer and concluded that it was cyclic (see Chart A (I*a*)(I*c*)). In a recent communication (9) we have suggested that the dimer of cyclohexylidenemalononitrile is likewise cyclic.

We have now investigated the base-catalyzed dimerizations of other alkylidenemalononitriles in an attempt to determine whether or not the formation of *cyclic* dimers can be considered to be a general reaction of these compounds. The proton n.m.r. spectral evidence which we have obtained leaves little doubt that the dimers are cyclic, but they appear to differ from isopropylidenemalononitrile dimer in the location of the carbon–carbon double bond.

The mechanism for cyclic dimer formation proposed for isopropylidenemalononitrile by Williams (8) can be expanded into the general form shown in Chart A. Compounds I in Chart A represent the reaction sequence for isopropylidenemalononitrile itself. Compounds II, III, and IV represent the three other alkylidenemalononitrile systems studied in this work. Our n.m.r. spectrum of the isopropylidenemalononitrile dimer is included in Fig. 1 for comparison with the spectra of the other dimers.

2-Butylidenemalononitrile Dimer (Chart A, $R = CH_3$; $R' = H$)

The linear form (Chart B, IV (*d*), IV (*e*)) of this dimer analogous to that first suggested for isopropylidenemalononitrile by Anderson, Bell, and Duncan (7) would arise from attack of the primary carbanion on a *nitrile* group of the second molecule rather than on

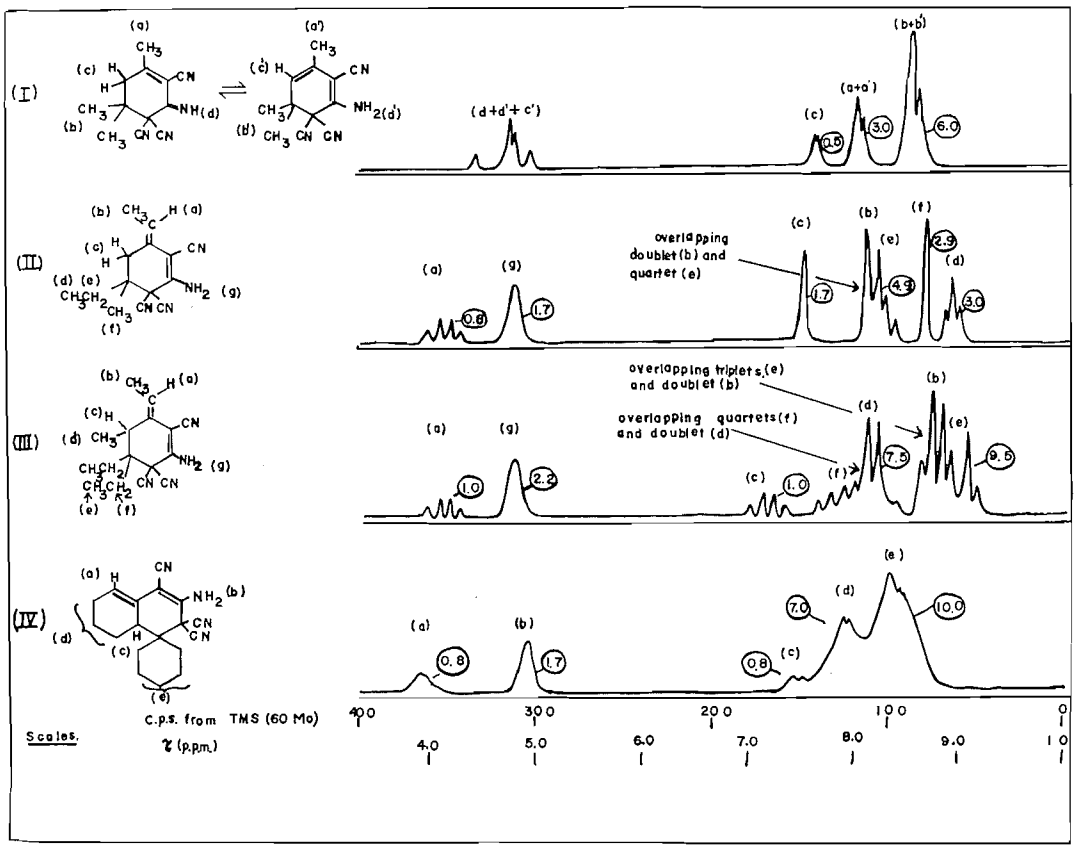

FIG. 1. (i) Assignments as shown by letters, (ii) relative peak areas circled numbers, (iii) spectra all 20% approximately in $CDCl_3$, and (iv) TMS internal standard.

the β-carbon atom. The n.m.r. spectrum (Fig. 1 (II)) of the dimeric product in this case suggests that the material is largely in the amino form II (*b*), the relative areas of the NH_2 absorption at 4.9τ and of the ethylenic hydrogen absorption at 4.1τ being 1.7 and 0.8 respectively. The linear structure can be ruled out since the 8.7τ value for the methyl singlet places it on a saturated carbon. This cannot be accommodated in structures VI (*d*) or VI (*e*). The amino form has been assigned structure II (*b*), with the double bond *exo*cyclic, rather than II (*c*), since the latter would be inconsistent with the 8.1τ doublet and with the 4.2τ quartet, which are due to the splitting in the CH_3—CH= group.

3-Pentylidenemalononitrile Dimer (Chart A, R = R′ = CH_3)

The n.m.r. spectrum (Fig. 1 (III)) of the dimer again suggests that it is largely in the amino form III (*b*) (relative area of NH_2 = 2.2). In the linear form VII (*d*), VII (*e*), only one H_3C—C—H group is present, while the spectrum shows *two* hydrogen quartets, which must arise from this kind of grouping. Hence the linear structure can be ruled out. The presence of these two quartets likewise rules out structure III (*c*).

Cyclohexylidenemalononitrile Dimer (Chart A, R + R′ = —$(CH_2)_5$—)

The proton n.m.r. spectrum has been reported and discussed in a recent communication (9). It is shown for comparison in Fig. 1 (IV).

CHART A

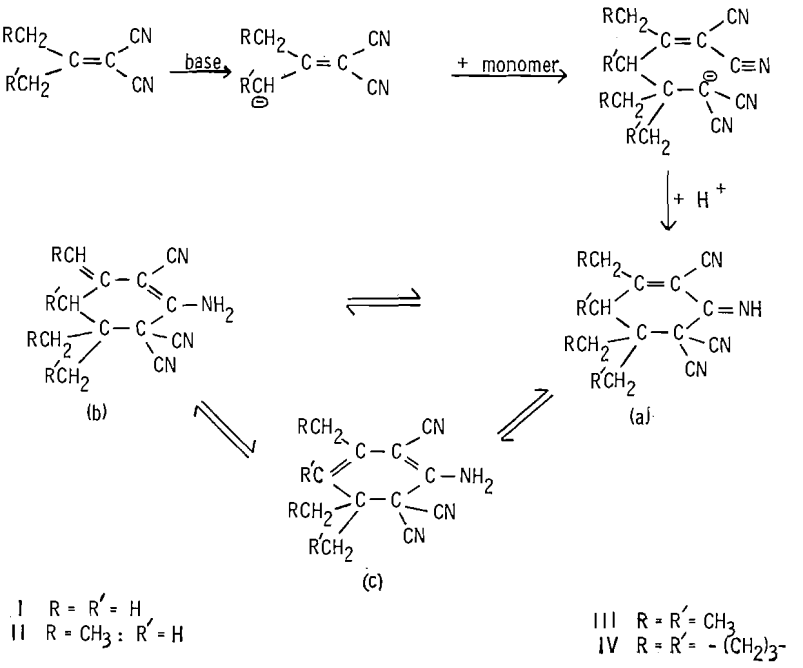

CHART B

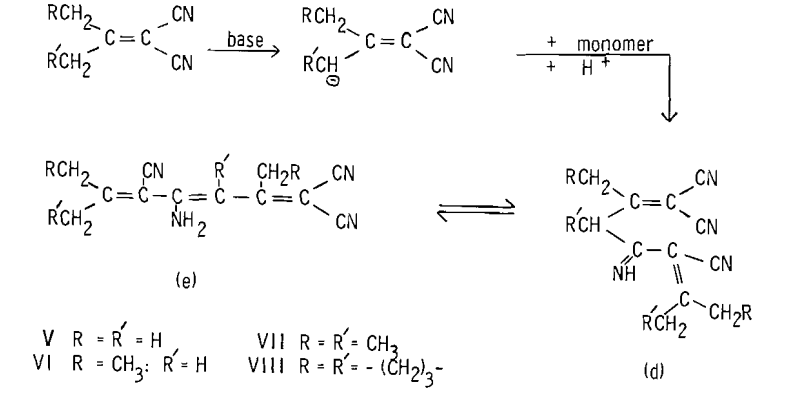


DISCUSSION

The evidence presented in support of the cyclic form of the dimeric products would appear to be conclusive. This implies that attack of the carbanion on the β-carbon of the ene-nitrile is preferred over attack on the cyano group in all the examples considered. The reasons for the observed product distribution among the three tautomeric forms indicated in Chart A remain to be discussed.

This product distribution may be explained in terms of (*a*) the steric repulsion of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

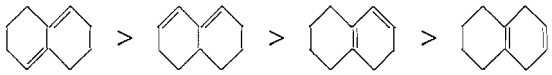
larger alkyl groups in II and III compared to I, and (*b*) the degree of substitution of the exocyclic double bond in II and III as compared to I.

The *amino* forms of dimers II and III can be written as either II (*b*), III (*b*) with the double bonds exocyclic, or as II (*c*), III (*c*) with the double bonds endocyclic. The n.m.r. evidence suggests that the (*b*) form with exocyclic double bonds is preferred here in contrast to the endocyclic structure I (*c*), favored in the isopropylidene case. It would appear that in II (*b*) and III (*b*) R and R′ have less steric interaction than would be the case in the corresponding (*c*) form. It also suggests that the preferred geometric isomer about the RCH=C(ring) double bond is that with the R group *trans* to the ring segment carrying the R′CH-entity. Steric interaction of this kind would not be important where R = R′ = H, i.e. in isopropylidenemalononitrile dimer.

The second major difference between dimer I and dimers II and III is in the nature of the substituents on the exocyclic double bond. The presence of a methyl substituent here appears to enhance the stability relative to that of an exocyclic methylene group. Thus, as a consequence of both of these factors, the (*b*) forms appear to be favored in the butylidene and pentylidene dimers, in contrast to the endocyclic double bond form (*c*) in isopropylidenemalononitrile dimer.

The apparent absence of *imino* forms II (*a*) and III (*a*) in the dimer products again points to the presence of a driving force favoring relief of steric repulsion between R and R′, possible with an exocyclic double bond as in II (*b*) and III (*b*). The presence of some 40% to 50% of the imino form in isopropylidenemalononitrile dimer (see Fig. 1 and Ref. 8) means that in itself the *imino* form is not significantly less stable than the *amino* form. It appears then that the dominant factors which determine the almost exclusive production of the amino form must be (i) the steric repulsion between R′ and R, and (ii) the added stability conferred by a methyl substituent on the exocyclic double bond.

Similar arguments may be applied to the structure of cyclohexylidenemalononitrile (IV). We previously suggested (9) that the structure of this dimer is the mixture IV (*a*), IV (*c*). However, there is also the possibility of the existence of form IV (*b*), analogous to II (*b*) and III (*b*), where the compounds were essentially 100% in these forms. Recent thermodynamic studies (10) have shown that the four hexahydronaphthalenes shown below have relative stabilities as indicated;



IX X XI XII

These studies might suggest that, in the amino form of cyclohexylidenemalononitrile dimer, IV (*b*) would be thermodynamically favored over IV (*c*). If the 3.9τ peak (Fig. 1 (IV)) were considered to be due to the hydrogen on the exocyclic double bond in IV (*b*) then the relative positions of the peaks in the n.m.r. spectrum of the dimer fit structure IV (*b*), if it is assumed that the material is essentially *all* in the IV (*b*) form. As previously noted (9), however, the broad and overlapping character of the cyclohexane hydrogen bands make accurate area correlations difficult.

Dimerization Mechanism

In the examples considered the ease of dimerization appears to depend on the availability of a base-extractable β-hydrogen in the monomeric ene-nitrile. Thus, the dimers of isopropylidenemalononitrile, 2-butylidenemalononitrile, and cyclohexylidenemalononitrile are produced rapidly (1–2 hours) by the action of base. It is also noteworthy that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in 2-butylidenemalononitrile the base attacks the methyl group exclusively rather than the ethyl CH_2. This agrees with the observation (11) that unsymmetrical ketones, such as ethyl methyl ketone, undergo enolization-controlled reactions on the ethyl CH_2 group in acid, and on the methyl group in base. On the other hand, the fourth monomer, 3-pentylidenemalononitrile, where the intermediate carbanion will be destabilized by the adjacent CH_3 group, and which is also more sterically hindered, undergoes dimerization much less rapidly. Some investigators (6) have, in fact, reported that they did not obtain any crystalline dimer from this compound. It may be noted in addition that 3-methyl-2-butylidenemalononitrile appears to react sluggishly, and we have as yet obtained only small amounts of the crystalline dimer. Presumably the steric effect of the isopropyl group is coming into play to a significant extent.

Of the base-catalyzed condensations considered here either the monomers or mixtures of the precursor ketones and malononitrile appear to give rise to simple cyclic dimers, except in the case of equimolar mixtures of acetone and malononitrile. In this case there is produced a crystalline solid which analyzes $C_{15}H_{14}N_6$ and which is reported (8) to arise from 1,4-addition of malononitrile to tautomer I (*a*). The production of more complex condensation products of this type from base catalyzed condensations of *arylidene-malononitriles*, such as benzalmalononitrile, appears to be common and will be the subject of a later communication.

EXPERIMENTAL

Preparation of Isopropylidenemalononitrile Dimer (7, 8)

Diethylamine (0.2 ml) was added to a solution of malononitrile (5 g, 0.07 mole) in acetone (19.8 g, 0.34 mole) at room temperature. The reaction mixture became very hot, and, on standing overnight, a solid product formed which was recrystallized from 95% ethanol to give needle crystals; m.p. 170–175° (lit. 171–174°). Anal. Calc. for $C_{12}H_{12}N_4$: C, 67.92; H, 5.67; N, 26.40. Found: C, 67.82; H, 6.08; N, 26.33. Mol. wt. Calc.: 212. Found: 204.

Preparation of 2-Butylidenemalononitrile Dimer

Malononitrile (3.3 g, 0.05 mole) was dissolved in 3.6 g (0.05 mole) of ethyl methyl ketone and 0.2 ml of diethylamine was added to the mixture, which rapidly became very hot. The mixture was left at room temperature overnight, and the solid thus produced was recrystallized from 95% ethanol; m.p. 167–169°. Anal. Calc. for $C_{14}H_{16}N_4$: C, 70.01; H, 6.67; N, 23.30. Found: C, 70.14; H, 6.92; N, 23.35. Mol. wt. Calc.: 240. Found: 255.

Preparation of 3-Pentylidenemalononitrile (6)

Malononitrile (26.4 g, 0.4 mole) and diethyl ketone (38 g, 0.44 mole) were dissolved in 50 ml of benzene, and 3.08 g (0.04 mole) of ammonium acetate plus 4.8 g (0.08 mole) of acetic acid were added to the solution. The mixture was refluxed for 40 minutes under a Dean Stark trap, and 7.8 ml of water was collected. It was then cooled, washed with water several times, and distilled under vacuum. Yield, 48.7 g, (90%); b.p. 150°/19 mm (lit. 122–125°/23 mm); $n_D^{20} = 1.4708$ (lit. $n_D^{25} = 1.4692$).

Preparation of 3-Pentylidenemalononitrile Dimer

Several initial attempts at the dimerization using different bases (piperidine, diethylamine, aqueous ammonia, aniline) resulted in the production of black tars. The following method eventually worked. To 3.4 g (0.025 mole) of 3-pentylidenemalononitrile was added 0.2 ml of diethylamine. The mixture did not become hot, but on standing overnight a glass was formed, which, on addition of 95% ethanol, could be crystallized. Recrystallization from 95% ethanol gave needles; m.p. 165–167°. Anal. Calc. for $C_{16}H_{20}N_4$: C, 71.60; H, 7.46; N, 20.85. Found: C, 71.83; H, 7.60; N, 2.70. Mol. wt. Calc.: 268. Found: 253.

Molecular weights were determined osmometrically.

THE ELECTRICAL POLARIZATION OF 1,4-BENZOQUINONE AND RELATED SUBSTANCES

HELMUT HUBER AND GEORGE F WRIGHT
Department of Chemistry, University of Toronto, Toronto, Ontario
Received August 28, 1963

ABSTRACT

A determination of the atom polarization of 1,4-benzoquinone from low-frequency infrared absorptions does not confirm the results of Becker and Charney. Therefore the total polarization of this substance must partly be due to orientation of a dipole. Also tetracyanoethylene and tetracyanoquinodimethane seem to have appreciable dipole moments although they both have abnormally high distortion polarization.

In the gaseous state (1) and in solution (2) the total polarization ($P_T = P_O + P_E + P_A$) of 1,4-benzoquinone has been found to about 37 cc, thus exceeding the electronic polarization (P_E) by about 6 cc. Originally (1) this difference was ascribed to abnormally high atom polarizations, an assignment in lieu of orientation polarization (P_O) which seemingly has been confirmed by observations that microwave absorptions (3, 4) are insufficient to account for a dipole moment and by absence of a negative Kerr effect (5). Most recently, optical dispersion theory (3, 5) has been applied by Becker and Charney (6) to the estimation of atom polarization (P_A) by calculation from absorption spectra of 1,4-benzoquinone in the 1700 to 50 cm^{-1} region. According to these workers the 6 cc difference between total polarization and electronic polarization is accounted largely in terms of this calculation as P_A.

On the other hand, some studies in this laboratory show that the atom polarization of benzoquinone does not exceed a few percent of the electronic polarization (2). Moreover, the total polarizations are both solvent and temperature dependent, and the polarization–temperature plots for several solvents intersect at the value of 37.6 cc, very close to the value obtained (1) from the gaseous state (36 cc) when the latter is extrapolated to lower temperature. Such behavior is presumptive of orientation polarization due to a dipole moment rather than to atom polarization, which ought to be, and has in general been found to be (7), temperature independent.

In view of the conflicting opinions in several laboratories we have elected to repeat with benzoquinone our direct determination of distortion polarization ($P_D = P_E + P_A$). This analysis is effected by capacitance measurements in respect of air on wafers of the solid substance finely ground for random particle orientation and compressed to maximum density. Because of the edge effect common to capacitors of this diameter (about 0.25 in.) a series of different thicknesses is measured and the apparent dielectric constants, if they are linearly related, are extrapolated to zero thickness. The original value for this extrapolation (2) was 30.1 cc. Our new value derived with more precise equipment is 31.4 cc.

This revised value for P_D does not vitiate our conclusion about the polarization of benzoquinone. However, the value of P_A included in it will depend upon the choice of P_E which is subtracted. The value of P_E derived from addition of bond or group polarizabilities at visible frequencies is 26.8 cc but a better evaluation is due to Syrkin *et al.* (8) from their measurements of refractive indices. These measurements led to molecular refraction at several wavelengths: 509 mμ (30.06 cc); 546 mμ (29.7 cc); 579 mμ (29.4 cc); and 644 mμ (29.0 cc). Extrapolation of these volumes to infinite wavelength by Sellmeier's formula led

to their value of 28.4 cc for MR_∞. The difference between this value and that derived by summation of atom (9) or bond (10) polarizabilities was not unreasonably attributed by Syrkin *et al.* to exhaltation.

Within experimental error their MR_∞ represents electronic polarization at radio frequencies. On this basis the difference between our experimental value for P_D and P_E at 10^6 c.p.s. may be assigned as $P_A = 3.0$ cc. This portion, almost 10% of the entire distortion polarization, is larger than is found for many substances but it is much less than is needed to account for 37 cc of total polarization. The alternative is orientation polarization due to a dipole moment.

Also because of the conflicting opinions, we have, like Becker and Charney, examined the spectrum of benzoquinone over the spectral range of 1700 to 50 cm^{-1}. We used the same type of spectrophotometer (PE-301) and altered their procedure only by using dispersions (15 wt. %) in polyethylene wax (7) for measurement of intensities.

Our results are shown in Table I. High accuracy cannot be claimed because there is

TABLE I

Calculation of atom polarization from spectral absorption (900–50 cm^{-1}) by *p*-benzoquinone

much distortion of the absorption bands on the low-frequency side. In view of this distortion we have calculated our intensities in two ways: integrated area of the entire bands as they were observed (unsymmetric) and also by assuming that the band contour on the low-frequency side ought to be identical with that on the high-frequency side (symmetrical), of course, with limitations imposed by the background of polyethylene wax in the same amount as has been used in the candidate samples.

According to the results of duplicate determinations with different samples we have found that for benzoquinone the absorption which is of principal interest occurs mainly at 117 cm^{-1}. This divergence from the 108 cm^{-1} reported by Charney and Becker (6) cannot be due to differences in the dilution medium because the absorption peak which we obtained from a 12% benzene solution also occurred at 117 cm^{-1}. Moreover the determination in benzene was carried out through the courtesy of the Eastman Kodak company on a duplicate 301 spectrometer. Our calibration was effected in terms of the band at 411 cm^{-1}, which corresponds with the frequency we observed for benzene solutions of benzoquinone in the Beckman IR-4 instrument.

The atom polarizations, P_{Aj} in Table I at each frequency for 1,4-benzoquinone, might be calculated from the equation of Whiffen (I) derived from the Kramers–Kronig relationship.

$$P_A = \frac{Nc}{3\pi^2} \int \frac{\alpha(\nu)d\nu}{\nu^2 C'} \qquad (I)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where α is the extinction coefficient integrated over the bandwidth $d\nu$, N is the Avogadro number, c is the vacuum velocity of light, C' is the concentration in moles per liter, and ν is frequency. Actually P_{A_j} values in Table I have been evaluated from Charney and Becker's form of equation I in which ν is expressed in wave numbers.

$$P_{A_j} = \int \frac{(I_0/I)d\nu}{3\pi^2\nu_j^2 C'(\mathrm{I})} \qquad \text{(II)}$$

and $P_A = \sum P_{A_j}$.

The deviation in P_{A_j} for the important 117 cm^{-1} band in different determinations makes it questionable whether meaningful results are possible with this spectrometer in its present state of development. Nevertheless for purposes of comparison the total of P_A calculated by inclusion of the complete bands (unsymmetrical) and including the high frequency contributions listed by Charney and Becker amounts to 3.5–4.5 cc. By a more realistic inclusion only of a symmetrical envelope of the bands the total P_A is 3.2–3.7 cc. Even the largest of these values (4.5 cc) is much less than the 6.97 cc reported by Charney and Becker.

Actually it is questionable whether equation II is applicable to a calculation of P_A for substances like benzoquinone. Whiffen's application of equation I was justified in the use of 3.1×10^{10} cm sec^{-1}, the vacuum velocity of electromagnetic radiation, because he applied it to gases for which the dielectric constants do not differ markedly from unity. But this approximation is not valid for condensed systems in which the dielectric constant usually exceeds 2. The velocity of radiation in such media has not been measured directly but theoretically (12) it ought to be less than the vacuum velocity by the factor $1/\sqrt{\epsilon}$ (i.e. $1/n$) in the spectral region in which P_A has been evaluated. When the reciprocal root of the dielectric constant of solid benzoquinone, $1/\sqrt{2.845}$, which is 0.5917, is applied to the P_{A_j} values of Table I then 4.5 cc (maximum of unsymmetrical band interpretation) and 3.2 cc (maximum for symmetrical band interpretation) become respectively 2.7 cc and 1.9 cc. But these values for P_A are both less than the magnitude determined as the difference between our measured distortion polarization and the measured electronic polarization by Syrkin *et al.* Contributions from overtones and minor absorptions over the entire spectral range is not expected to augment 1.9–2.7 cc to more than 3 cc.

Therefore our estimation of atom polarization from contributions due to absorption in the infrared region falls easily within the 31.4 cc of distortion polarization measured for the density and dielectric constant of the crystalline solid benzoquinone. Whether or not the estimation from spectra is reliable, it does not provide a contradiction of the value of distortion polarization derived by the wafer method. The estimation from spectra cannot account for the difference between this P_D and the total polarization found in the gas phase or in the solution. There is still no valid interpretation of the difference except as orientation polarization.

One may question our contradiction of Charney and Becker on the basis that our absorption coefficients were inordinately low (i) because of the difference in spectrometers or in their operation or (ii) because we used polyethylene wax suspensions rather than the benzene solution of Charney and Becker, or (iii) that our dispersion of the candidate substance in the wax was non-uniform. On the contrary, it may be seen in Table I that integrated intensity of the band at 411 cm^{-1} when determined by use of the PE-301 by use of polyethylene wax suspensions is much higher than that in benzene solution by IR-4 until it is corrected for asymmetry, after which the results from the two machines and the two media are comparable in magnitude.

Further evidence that spectral intensities observed with the PE 301 spectrometer tend to be high rather than low is provided by examination of *trans*-2,2,4,4-tetramethylcyclobutane-1,3-diol. The spectral data are recorded in Table II. In contrast to those of benzoquinone these bands are nicely symmetrical. Moreover, the absorption determined in the

TABLE II

Calculation of atom polarization from spectral absorption (900–50 cm^{-1}) of *trans*-2,2,4,4-tetramethyl-1,3-cyclobutanediol, in polyethylene wax

Freq., cm^{-1}	Concentration, %	Baseline, % T	Intensity, $cm^2 mol^{-1}$	Band width, cm^{-1}	P_{Aj}
512*	10	55	5,759	40	0.4
399*	10	70	7,134	28	0.6
317*	10	80	3,508	10	0.4
319	15	80	10,363	55	1.1
276	15	80	9,721	53	1.0
241	15	80	7,513	50	0.8
130	15	80	13,445	45	1.4

*These values were determined with the Beckman IR-4 spectrometer. The PE-301 machine was used for the remainder.

PE-301 spectrometer may be correlated reliably with those from the IR-4 by the overlapping frequency range at 317–319 cm^{-1}, especially since the data from the IR-4 spectroanalysis comprised results from six different samples with not more than 10% deviation among intensities. However, there is a wide discrepancy between the integrated intensities at the overlapping region, indicating that those determined with the PE-301 may be as much as 3 times too high. If P_{A_j} is calculated from the intensities as they were observed then $\sum P_{A_j}$ is 5.3 cc, while P_{A_j} is 2.4 cc if the intensities of bands observed in the PE-301 machine are weighted to conform with the IR-4 results in the ratio 3508/10363 of the 317–319 cm^{-1} absorptions.

Both of these values of P_A are larger than that calculated from the dielectric constant of compressed wafers of the solid substance. Actually the measured value of the distortion polarization is 0.9 cc less than that calculated from bond and atom polarizabilities (32.9 cc versus 40.1 cc). Since it is one of six alcohols for which the difference value, P_A, varies over a range of 2.5 cc (of which the *cis* diol at $P_A = +0.7$ cc is about average) it may be considered to have a minimal atom polarization comprising about 2% of P_D. It may be noted that a reduction of the intensity-corrected $\sum P_{A_j}$ (from the spectral study) by $1/\sqrt{\epsilon}$, i.e., $1/\sqrt{2.157} = 0.68$ provides a value of $P_A = 1.6$ cc, at least within magnitude of value obtained by wafer measurement. This apparent agreement does not increase our confidence in the value derived from spectral absorption.

The spectral studies have not altered the earlier conclusion (2) that part of the polarization of 1,4-benzoquinone is due to orientation due to a dipole in the electric field. However, the nature of this dipole has been obscure. In the hope of gaining an insight we have now examined tetracyanoquinodimethane, TCNQ (13) and its simpler vinylog, tetracyanoethylene, TCNE (14). The choice of TCNQ was made in the expectation that the quinonoid properties would be enhanced by the polar cyano groups, while TCNE was examined to evaluate these cyano groups in non-quinonoid attachment.

In contrast to benzoquinone the distortion polarizations of both substances, shown in Table III, are appreciably higher than would be expected from consideration of the electronic polarization calculated atom (Eisenlohr) or bond (Vogel) polarizabilities. It is of interest that the differences, P_A, are of the same order of magnitude for both of the tetracyano compounds.

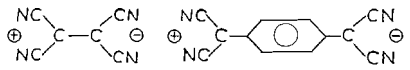
TABLE III
Dielectric constants of solid TCNQ and TCNE

Substance	d_4^{23}	ϵ	P_D, cc	MR_D, cc Eisenlohr	Vogel	Av.	$P_D - P_E$
TCNE	1.323	2.927	37.9	27.6	28.6	28.1	9.8
TCNQ	1.3185	2.976	61.5	51.7	53.0	52.4	9.1

The data showing the total polarizations of TCNQ and TCNE are presented in Table IV.

The dipole moments have been calculated after subtraction of the additive molecular refraction (μ_{MR}) and of the measured distortion polarization (μ_{P_D}) in order to show the hazard of reliance on the additive refraction. Only μ_{P_D} should be considered to be significant. Unfortunately this significance is limited by the low solubility of the substances to a precision of not better than ± 0.03 D.

Within this limitation certain qualitative comparisons may be made. The reality of the TCNE moment is attested by the higher moment of TCNQ which is to be expected from greater charge separation in the latter, even though the difference will be minimized by conjugation resonance. Also notable is the marked enhancement of moment in dioxane versus benzene. This difference (about 30%) is greater than is ordinarily observed and may be considered to be a consequence of the Lewis acid character of TCNE (15) exemplified by charge separation shown as TCNE-R. It may be remarked that the difference is about 3 times that which was observed for benzoquinone in benzene versus dioxane.



TCNE-R TCNQ-R

Unlike benzoquinone, the apparent moment of which was found (2) to decrease with respect to increasing temperature, the moment of TCNQ (within the precision of the determinations) seems to be invariant with respect to temperature. This invariance may be a consequence of the resonance hybrid exemplified by TCNQ-R or it may be due to a Lewis acid–base complex (16) with dioxane. Unfortunately TCNQ could not be examined in benzene because of inordinately low solubility. Undoubtedly the apparent moment in benzene would have been lower than in dioxane. But lower moments in benzene would not preclude the involvement of this solvent in a Lewis base complex with either TCNE or TCNQ. A better understanding of these apparent moments must await further studies.

Nevertheless the behaviors of TCNE and TCNQ in respect of solvent and temperature are sufficiently different from that of 1,4-benzoquinone that a lateral charge separation such as BP-R is not a reasonable postulation.

BP-R

On the basis of present evidence the polarization of benzoquinone is best explained in terms of a "bent" molecule. Nor is this unreasonable. The existence of an absorption band at 117 cm^{-1} (reported by Charney and Becker as 108 cm^{-1}) implies a condition at 20–40° C where about half of the molecules are in this state of excitation (17). This band has been designated as due to out-of-plane bending of carbonyl groups (6).

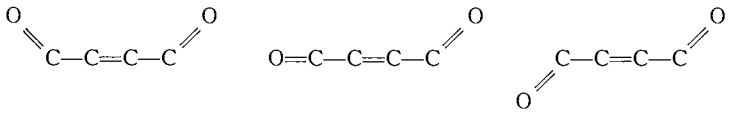
Charney and Becker, among others (1), have attributed to this oscillation an abnormally high atom polarization for benzoquinone. We have confirmed by our direct measurement of distortion polarization that abnormality does not exist. Indeed it would not be expected to exist if a large percentage of the benzoquinone molecules are already in resonance with the collision field around them since the frequency of this collision field will be higher than that of the electromagnetic field (10^6 c.p.s.) which is imposed on the substance for measurement of dielectric constant. On the other hand, that half of molecules which are excited at temperatures of 20–40° C will in solution be oriented in the field as a consequence of the dipole moment of the excited species.

The evidence against this argument heretofore has seemed to be in the fact that the apparent dipole moment of benzoquinone in benzene, dioxane, or carbon tetrachloride decreases to an extent dependent upon each solvent with increasing temperature. One might expect that if the carbonyl group out-of-plane oscillation were coupled, the amount of BP-2 would increase according to a simple Boltzmann distribution as the temperature was increased.



BP-2 BP-1 BP-3

If, on the other hand, the carbonyl oscillators are not coupled but, instead, are independent or mutually are only slightly perturbed, then one may expect an equilibrium among BP-1, 2, and 3. The temperature dependence of such an equilibrium, especially when it involves solvent effects, is not easily predictable. It is not unreasonable to expect that at higher temperatures the reversion of BP-2 and BP-3 to BP-1 would be greater than the rate at which BP-1 reverts to the ground state. If this were the fact the moment of the system would decrease with increasing temperature. Therefore the decreasing moment with increasing temperature does not necessarily contradict the explanation that the apparent moment of 1,4-benzoquinone is due to an excited state of bent molecules in the temperature region 20–40° C.

In view of the expectation that the benzoquinone molecule must partially be nonplanar at 20–40°C, the absence of appreciable Kerr effect (5) might seem to be anomalous. However, Charney's calculations show that a large effect would not be expected. Indeed a small effect has recently been noted (18). Moreover, a consideration of the thermally excited forms that are possible shows that the polarizabilities of BP-2 and BP-3 will be opposite in sign and thus compensatory. Therefore the findings in respect of dipole moment and Kerr effect need not be contradictory.

The discrepancy between the results of moment determination at low radio frequencies versus those at microwave frequencies (3, 4) must also be considered. The difference cannot be explained in terms of solute purity (19), at least in one instance, because the material used by Di Carlo and Smyth (4) and by Meredith *et al.* (2) was prepared in the same laboratory with the same criteria of purity.

Moreover, the discrepancy between microwave and radio frequency valuation extends to a number of other substances (4) such as 2,2,4,4-tetramethylcyclobutanedione for which the radio frequency (5×10^6 c.p.s.) reactance measurements assigns a dipole moment value of 0.7 D (20). On the other hand, the microwave frequency (2.40 and 0.93×10^{10} c.p.s.,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

1.25 and 3.22 cm) loss measurement does not indicate a moment. Yet a moment would be expected in this diketone if the cyclobutane ring is not planar. Evidence is accumulating that the tetramethylcyclobutane ring deviates by about 20–30° from planarity (summarized in Ref. 20). Also electrical polarization measurements (21) on *cis*- and *trans*-2,2,4,4-tetramethyl-1,3-diisonitriles and -dinitriles give polarizations of such magnitude that they cannot be explained away as atom polarizations. Moreover, the values for the moments of these *cis* diisonitriles and nitriles are best explained on the basis of a bending rather than a bent ring. This dynamic nonplanarity also explains the single proton absorption shown in the n.m.r. spectrum of tetramethylcyclobutanedione as a consequence of the slow reading rate of the latter measurement. The frequencies of the ring oscillations of the diketone, diisonitriles, and dinitriles have not yet been measured, but it may be expected that these cyclobutanes will absorb in the region of the band at 130 cm^{-1} found for 2,2,4,4-tetramethylcyclobutane-1,3-diol (Table II). This band probably is due to the out-of-plane bending of the tetramethylcyclobutane ring.

If a moment by microwave measurement cannot be discerned for tetramethylcyclobutanedione which seems, on the basis of the foregoing evidence, not to be strictly centrosymmetric, then one must seek an explanation for this apparent anomaly. An explanation which will apply equally well to benzoquinone is exemplified by consideration of BP-2 and BP-3 as ephemeral dipoles.

The reactance of all dipoles, even those of short life that are induced at frequencies of 10^{14} and higher c.p.s. will be integrated by the field at 10^6 c.p.s. in media of low viscosity such as are used for solution measurements, by the low-frequency method. Ordinarily the population of such induced dipoles is so small as to be unmeasurable. Only in the unique circumstance where absorption occurs in the thermal region will the population of induced dipoles be large enough to be measurable as in the case with benzoquinone.

By contrast with the same solvents at the higher frequencies of the microwave region the molecules lag behind the field; indeed the relaxation time is the basis for the loss measurement of the determination. But induced dipoles of shorter life than this relaxation time will not be appreciably measurable in the microwave field. This may well be the circumstance during the measurements made (3, 4) with benzoquinone and other substances which absorb strongly in the far infrared regions.

If the dipole moment of benzoquinone is indeed due to excitation in the thermal region it is a question of semantics whether one is justified in designating the geometry of the molecule as non-planar, i.e. as a bent molecule. In its ground state the molecule may be planar. But the circumstances in which the substance is chemically used and characterized places a majority of the molecules in the excited state where it is dipolar. It would seem that as chemistry becomes more sophisticated the necessity for designation of a substance in respect of its environment will increase.

The authors are grateful to the Defence Research Board for financial aid, to Drs. E. Whalley and J. Bertie of the National Research Council for use of their PE-301 spectrometer, and to Drs. Le Roy and Polanyi of this department for helpful discussions.

EXPERIMENTAL

Reagents

Tetracyanoquinodimethane (TCNQ, kindly supplied by Dr. W. R. Hertler, E. I. duPont de Nemours) melted at 288.5°–289.5° and was used as received. Tetracyanoethylene (TCNE) was crystallized from benzene (ca. 16 ml per g) to melt at 199°. Benzoquinone was crystallized repeatedly from ethanol and zone-refined to melt at 113.5°.

Spectral Studies

Both benzene solutions and polyethylene wax wafers were used for studies with the Beckman IR-4 spectrometer and both media were used in the Perkin–Elmer 301 spectrometer. These wafers were prepared according to the method already outlined (1) and reference wafers were made from the same thickness of polyethylene wax in the sample wafer despite the relatively high percentage (2) of candidate substance required for the low frequency spectrometer. The wafers containing benzoquinone were examined in the IR-4 spectrometer during a time interval of 48 hours to show that no appreciable loss by sublimation occurred. The benzene solutions were not used for intensity evaluation.

The PE-301 spectrometer was maintained dry by a positive pressure of gas from a liquid nitrogen container. Samples were examined by use of both globar and mercury arc energy sources with appropriate gratings and reststrahlen filters with scanning rates from 2.75 cm^{-1} per minute (grating No. 29) to 1 cm^{-1} per minute (grating No. 8).

The spectral intensities were obtained by summation of the 1 cm^{-1} increments on the chart and also by weight-integration of the graph paper.

Distortion Polarizations

The improved apparatus described recently (7) was used for measurements with benzoquinone, TCNE, and TCNQ. Density was determined for benzoquinone by air displacement (22) and for the other two substances by flotation. According to the present determination the extrapolated dielectric constant for benzoquinone is 2.842 (Fig. 1) instead of 2.730 while the density at 23° is 1.309 instead of 1.313. The dielectric constant extrapolations for TCNE and TCNQ are as linear as those shown in Fig. 1.

Total Polarizations

The measurements have been made according to earlier descriptions (2) and are recorded as Fig. 2 for TCNE and Fig. 3 for TCNQ.

THE ACID HYDROLYSIS OF GLYCOSIDES

I. GENERAL CONDITIONS AND THE EFFECT OF THE NATURE OF THE AGLYCONE

T. E. TIMELL[1]

Department of Chemistry, McGill University, and the Pulp and Paper Research Institute of Canada, Montreal, Quebec

Received December 23, 1963

ABSTRACT

First-order rate coefficients and energies and entropies of activation have been determined for the acid-catalyzed hydrolysis of a number of methyl D-glycopyranosides and disaccharides. The relation between the logarithm of the rate coefficients and values for Hammett's acidity function was linear, although different for different acids. All compounds had entropies of activation indicating a unimolecular reaction mechanism. Glucosides of tertiary alcohols were hydrolyzed very rapidly, triethylmethyl β-D-glucopyranoside, for example, 30,000 times faster than the corresponding methyl compound.

Increase in size of the aglycone caused a slight increase in the rate of hydrolysis of β-D-glucopyranosides, steric hindrance thus being of no significance. Electron-attracting substituents in the aglycone had little or no influence on the rate of hydrolysis, obviously because they would tend to lower the equilibrium concentration of the conjugate acid, while facilitating the subsequent heterolysis, the two opposing effects more or less cancelling out. These results were discussed in connection with recent studies on the acid hydrolysis of various phenyl glycopyranosides and with reference to the postulated occurrence of an activating inductive effect in oligo- and poly-saccharides containing carboxyl or other electronegative groups at C-5. It was concluded that there is little evidence for the existence of any such effect and that, for example, pseudoaldobiouronic acids should be hydrolyzed at the same rate as corresponding neutral disaccharides.

INTRODUCTION

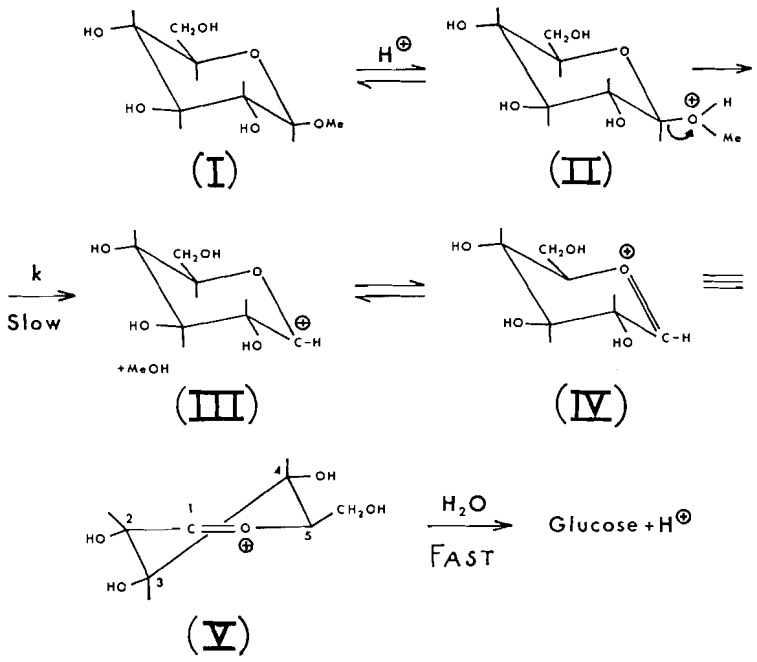
The acid-catalyzed hydrolysis of glycosides has attracted much attention in recent years. The mechanism now accepted was first suggested by Edward (1), experimentally proved by Vernon and co-workers (2–5), and later confirmed by Overend *et al.* (6, 7). For example, with methyl β-D-glucopyranoside (I), it involves a rapid, equilibrium-controlled protonation of the glycosidic oxygen to give the corresponding conjugate acid (II). In the slow, rate-determining step, the acid decomposes in a unimolecular heterolysis with formation of alcohol and a carbonium–oxonium ion (III, IV), which is most likely present in the half-chair conformation (V). Finally, water is rapidly added, giving glucose and hydronium ion.

It was the aim of the present series of investigations to study the effect of functional groups, and especially of carboxyl groups, on the acid hydrolysis of glycosides. Such a study, it was hoped, would provide information about the acid hydrolysis of polysaccharides containing such or similar groups. Because of the paucity of data available, it was decided first to study the hydrolysis of a few common methyl glycosides and disaccharides. This paper is concerned with this aspect and with the influence of the aglycone on the hydrolysis of glycosides. After completion of the experimental part of this study, an investigation by Overend, Rees, and Sequeira (6) on the acid-catalyzed hydrolysis of a number of glycosides has appeared.

RESULTS AND DISCUSSION

Most experiments were carried out with 0.05 *M* sugar solutions in 0.5 *M* aqueous sulphuric acid. The hydrolysis was followed with the aid of a photoelectric polarimeter.

[1]*Present address: Department of Forest Chemistry, State University College of Forestry at Syracuse University, Syracuse 10, New York.*



Final rotations usually agreed well with calculated values, although it is known that under the conditions used both disaccharides (6, 8) and 1,6-anhydro-β-D-glucopyranose (9) are formed to a small extent.

Hydrolysis of Some Methyl Glycosides and Disaccharides

The first compounds to be studied were methyl α- and β-D-glucopyranosides, which were hydrolyzed at seven temperatures, ranging from 60 to 120° C. Rate constants with their deviation from the mean and energies and entropies of activation are given in Table I. The Arrhenius plot of log k versus $1/T$ gave a straight line through all experimental points. The ratio of k_β/k_α decreased linearly with increasing temperature, reaching unity at 132° C on extrapolation. The corresponding temperature reported by Moelwyn-Hughes (8) was 116° C. Overend, Rees, and Sequeira (6) found the k_β/k_α ratio to vary very little with temperature.

In Table II a comparison has been made between energies of activation obtained by various investigators for the acid hydrolysis of methyl α- and β-D-glucopyranosides. With the exception of the values of Moelwyn-Hughes (10) and Nakano and Rånby (14), which were based on limited experimental data, the agreement between the various investigators is reasonably good.

A similar comparison between the rate coefficients, presented in Table III, gives a different result. Here, published values have been recalculated to be valid at 60, 70, and 80° C with the aid of the respective energies of activation and then referred to a value of +0.13 for H_0, Hammett's acidity function (15–17), valid for 0.5 M sulphuric acid (18). This treatment is justified because the acid hydrolysis of glycosides (2), and of acetals in general (19), has been shown to be proportional to h_0 rather than to H_3O^+. The agreement between the various investigators is not very good. The values of Easty (13) are conspicuously larger than the others. The fact that he alone used a chemical method (determination

of the methanol formed) for following the hydrolysis might be of relevance in this connection. The rate coefficients of Overend and co-workers (6) are almost twice as large as those obtained in the present study.

It was thought that this could perhaps be attributed to the fact that different acids were used in these two investigations. Rate constants were accordingly determined with four different mineral acids at concentrations ranging from 0.5 to 9 *M*. The results are presented graphically in Fig. 1. The logarithm of the rate coefficients vary linearly with H_0 as required by the Zucker–Hammett hypothesis. The requirement of slope unity, however, is only approximately fulfilled for three of the acids and not at all for phosphoric acid. Instead of coinciding, the plots are displaced with respect to each other, hydrochloric acid giving the highest and phosphoric acid the lowest rate coefficients at concentrations higher than 1 *M*. Data obtained with one of these four acids cannot accordingly be recalculated to be valid for another acid by referring to the same value for H_0, as has often been done in the past.

According to Hammett, a linear relationship in acid-catalyzed reactions between log k and H_0 implies that the rate-determining step involves a unimolecular decomposition of the conjugate acid without participation of water (A-1), while a bimolecular reaction (A-2) involving a molecule of water will lead to proportionality between log k and pH. This hypothesis has lately been critically reviewed by Bunnett (20) with special emphasis on the fact that many of the plots of log k against H_0 have slopes departing from unity. His treatment leads to the conclusion that, for example, methyl α-D-mannopyranoside should be hydrolyzed by the unimolecular mechanism, while methyl α-D-glucopyranoside should be hydrolyzed by an S_N2 mechanism, entailing a nucleophilic attack of water on

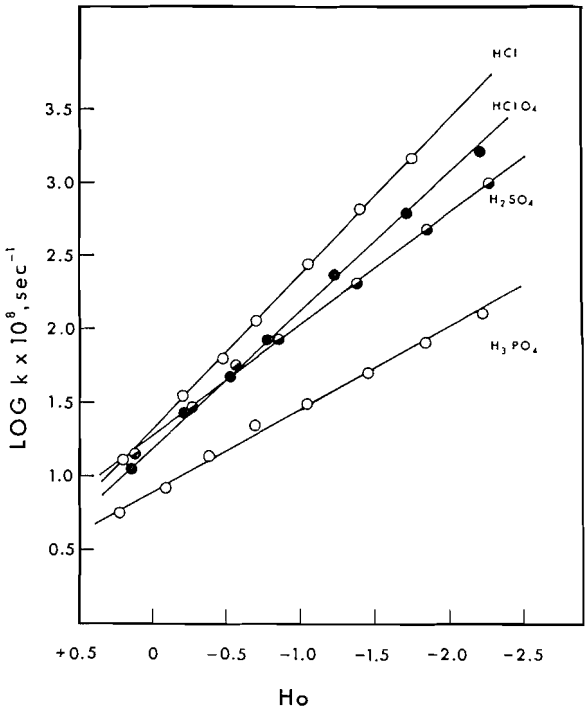

FIG. 1. Variation of log k with H_0 for hydrochloric, perchloric, sulphuric, and phosphoric acids.

the conjugate acid. As pointed out by Bunnett himself, this conclusion is difficult to accept in view of the similarity of the two compounds.

When the rate of hydrolysis of methyl α-D-glucopyranoside was measured at 60° C under exactly the same experimental conditions as those used by Overend, Rees, and Sequeira (6), a k-value of 5.56×10^{-6} sec^{-1} was obtained, compared with a value of 7.08×10^{-6} in the earlier study. A similar difference was found for all compounds studied in both of these investigations. This consistent discrepancy remained unexplained.

Kinetic data for five additional methyl α- and β-D-glycopyranosides are presented in Table IV. When referred to the rate constants valid for a single reference compound, such as methyl α-D-glucopyranoside, the present data agree well with those reported by Riiber and Søorensen (21) and by Overend, Rees, and Sequeira (6). If the reaction involved a

molecule of water (A-2), the transition state would constitute a more highly ordered structure than the ground state (the conjugate acid). This would involve a decrease in entropy, and $\Delta S^{\ddagger}$ would thus tend to be negative. In a unimolecular type of reaction, on the other hand, the structure in the transition state would be less ordered than in the ground state, and $\Delta S^{\ddagger}$ would be positive. Positive entropies of activation were obtained for all compounds investigated here. A unimolecular (A-1) type of mechanism is thus strongly indicated. Overend and co-workers (6) have previously reached a similar conclusion, basing their arguments both on their own data and on those reported by Heidt and Purves (11, 22). Recently, Withey and Whalley (23) have studied the effect of pressure on the rate of acid hydrolysis of methyl α-D-glucopyranoside. The value for the volume of activation thus obtained shows clearly that the reaction must be unimolecular.

Overend and his co-workers also observed that, with exception of the smallest aglycones, the rate differences between anomeric pairs of glycosides are caused by differences in the entropy rather than in the energy of activation, suggesting that the α-anomers are more highly oriented in the ground state than the β-anomers. Thus, the higher reactivity of the α- as compared to the β-glycosides is due to the greater change in entropy associated with the hydrolysis of the former compounds. An alternative explanation was previously offered by Edward (1), who pointed out that with large-size aglycones, such as a phenyl group, an α- (axial) aglycone would be less stable than the β-(equatorial) aglycone because of steric strain. In the present study, both the energies and entropies of activation are larger for the α- than for the β-anomer in the case of the methyl gluco- and galactopyranosides. The higher rate of hydrolysis of the β-anomer is accordingly in this case associated with its lower energy of activation, the entropy change having an opposite effect. The kinetic parameters observed for the two xylopyranosides are very close to those reported by Overend *et al.* (6). The energies of activation of the two anomers are the same, while $\Delta S^{\ddagger}$ is larger for the more labile β-compound.

Data for eight disaccharides are presented in Table V. For maltose, cellobiose, and gentiobiose the energies of activation are close to those previously reported by Moelwyn-Hughes (10). It is interesting to note that $\Delta S^{\ddagger}$ is larger for maltose (α-anomer) than for cellobiose (β-anomer) in accordance with the results of Overend and co-workers (6).

TABLE V

Rate coefficients and kinetic parameters for the hydrolysis of eight disaccharides (0.05 *M*) in 0.5 *M* sulphuric acid

Compound	$k \times 10^{-6}$ sec^{-1}			E	$\Delta S^{\ddagger}$
	60° C	70° C	80° C

4-*O*-β-D-Glucopyranosyl-D-mannose is hydrolyzed at the same rate as cellobiose, while mannobiose is almost twice as reactive. Xylobiose is hydrolyzed about three times faster than methyl β-D-glucopyranoside and seven times faster than cellobiose. A β-(1 → 4)-linked xylan has been reported to be hydrolyzed by acid four times faster than cellulose under homogeneous conditions (24).

Effect of the Nature of the Aglycone

The influence of the aglycone on the acid hydrolysis of glycosides has attracted little attention. Nath and Rydon (25) found that acid hydrolysis was facilitated by the presence of electron-repelling and impeded by electron-attracting substituents in the phenyl group of various phenyl β-D-glucopyranosides. The same observation has later been made with phenyl- and *p*-chlorophenyl β-D-gluco-, galacto-, and xylo-pyranosides (26).

The effect of the *size* of the aglycone was studied with nine β-D-glucopyranosides listed in Table VI. It is clear from the data that steric hindrance was of no importance, not even

TABLE VI

Rate coefficients and kinetic parameters for the hydrolysis of nine β-D-glucopyranosides (0.05 *M*) in 0.5 *M* sulphuric acid

	$k \times 10^{-6}$ sec^{-1}				
Compound	60° C	70° C	80° C	E	$\Delta S^{\ddagger}$
Ethyl	1.54	6.72	28.0	33.8	+14.8
Propyl	1.82	7.94	31.2	32.9	+15.1
Isopropyl	2.65	11.3	44.5	33.2	+14.0
n-Butyl	1.62	6.98	27.9	33.6	+14.3
Isobutyl	1.90	8.21	34.4	33.8	+15.2
Neopentyl	2.41	10.6	39.9	36.2	+22.9
Cyclohexyl	3.25	13.9	56.4	33.5	+15.3
Benzyl	1.56	6.75	28.3	33.6	+14.2
Allyl	1.83	8.02	32.8	33.8	+15.1

in the case of the neopentyl β-D-glucopyranoside. [The steric substituent constant, E_s, of the neopentyl group is as high as −1.74 (27).] The absence of steric hindrance is, of course, not unexpected, considering the unimolecular nature of the reaction mechanism. There is a slight and somewhat irregular increase in the rate coefficients with increasing size of the aglycone. This effect is undoubtedly due to the steric strain imposed on the molecule by the bulky aglycones. The higher rate of hydrolysis of isopropyl as compared to propyl β-D-glucopyranoside has been previously reported (28). The values for energy and entropy of activation are remarkedly constant, with exception of the neopentyl glucoside where both are larger than the average.

Three of the compounds investigated were hydrolyzed much more rapidly than the remainder namely *tert*-butyl β-D-glucopyranoside, triethylmethyl β-D-glucopyranoside, and sucrose. Measurements were carried out in both 0.5 *M* and 0.01 *N* sulphuric acid with the first glycoside, while the other two compounds could be studied only in the weaker acid. Experimental and extrapolated rate constants and kinetic parameters are given in Table VII. Sucrose is hydrolyzed by acids 4200 times faster than methyl β-D-glucopyranoside. The data of Heidt and Purves (29) indicate a factor of 3800. The low energy of activation is in agreement with previous results (10, 14). The value for $\Delta S^{\ddagger}$, +2.3 kcal deg^{-1} mole^{-1}, is not unexpected for this fructofuranoside considering that $\Delta S^{\ddagger}$ for ethyl β-D-galactofuranoside is −7.1 cal deg^{-1} mole^{-1} at the same temperature (6). Overend, Rees, and

*Value obtained by extrapolation.

Sequeira (6) have suggested that furanosides might be hydrolyzed by an A-2 mechanism, low or negative $\Delta S^{\ddagger}$ values being expected in this case.

Vernon and co-workers (4) have recently shown that the hydrolysis of *tert*-butyl β-D-glucopyranoside involves alkyl–oxygen cleavage, as it does in the acid hydrolysis of esters of tertiary alcohols. The reason is, in both cases, the great stability of this type of alkyl carbonium ion, which is far greater than that of the glycosyl carbonium ion. It is likely that all glycosides of tertiary alcohols hydrolyze by this mechanism. The rate of hydrolysis of the *tert*-butyl glucoside was 550 times higher than that of methyl β-D-glucopyranoside. The triethylmethyl β-D-glucopyranoside was hydrolyzed no less than 30,600 times faster than methyl β-D-glucoside, a truly astonishing rate which actually caused difficulties in the synthesis of this compound. The triethylmethyl carbonium ion is probably more stable than the *tert*-butyl carbonium ion. Part of the difference in stability might, however, reside in the greater release of steric strain on hydrolysis of the triethylmethyl glucoside.

The effect of polar groups in the aglycone was studied with six β-D-glucopyranosides. The kinetic data are given in Table VIII (30). The carboxymethyl β-D-glucopyranoside

TABLE VIII

Rate coefficients and kinetic parameters for the hydrolysis of β-D-glucopyranosides with polar aglucones (0.05 *M*) in 0.5 *M* sulphuric acid

	$k \times 10^{-6}$ sec^{-1}				
Compound	60° C	70° C	80° C	E	$\Delta S^{\ddagger}$
Carboxymethyl	4.11	16.2	61.0	31.4	+9.5
2-Carboxyethyl	1.58	6.40	26.9	33.1	+12.7

3-Hydroxypropyl	1.24	5.45	23.4	34.4	+16.1

was hydrolyzed three times faster than methyl β-D-glucopyranoside, a relatively small increase. The rate coefficients of the other five glucosides show that introduction into the aglycone of an electron-attractive group separated by two or more carbon atoms from the glycosidic oxygen has little or no effect on the rate of hydrolysis of the glycoside. These results are exactly those to be expected in a reaction of the present type. An electron-attracting substituent in the aglycone will decrease the electron density around the glycosidic oxygen, thus lowering the equilibrium concentration of the conjugate acid (II). The transfer of the electron pair to the oxygen in the heterolysis step (II → III), on the other hand, will be facilitated. The two opposing effects will tend to cancel out, and thus the overall rate should be almost unaffected by any polar group in the aglycone. This is a situation very similar to that found in the acid hydrolysis of esters by the A-2 mechanism. Contrary to Richards (31), Capon, Overend, and Sobell (32) have concluded that the rate of hydrolysis of the benzylidene group is approximately the same in methyl 4,6-*O*-benzylidene-α-D-glucopyranoside and in methyl 4,6-*O*-benzylidene-3-deoxy-α-D-glucopyranoside. This seemingly surprising fact is, as pointed out by the investigators, the result of the same two effects, one hindering and the other promoting the removal of the benzylidene group.

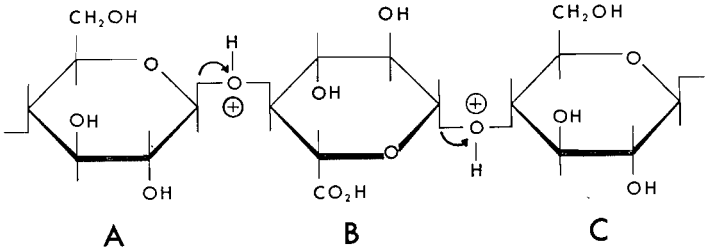
In a very strongly acidic solution the conversion of the glycoside to its conjugate acid should be more complete than in a more dilute solution, and an electron-attracting group

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

in the aglycone might accordingly increase the rate of hydrolysis of a glycoside under these conditions. The rate coefficients for the hydrolysis of 2-methoxyethyl and methyl β-D-glucopyranosides were 1.83 and 1.38×10^{-6} sec^{-1} at 60° C in 0.5 *M* sulphuric acid and 42.2 and 34.2×10^{-6} sec^{-1} in 5 *M* sulphuric acid, corresponding to a ratio of the rate constants of 1.33 and 1.23, respectively. There was accordingly no increase in the relative rate with increasing acid concentration. It is not known whether the glycosides were still only slightly protonated in the stronger acid, or whether the substituents did not affect the rate.

Hall, Hollingshead, and Rydon (33) have recently reported that the presence of polar groups in the aglycone has no effect on the rate of acid hydrolysis of phenyl α-D-glucopyranosides. As an explanation they suggest that the conjugate acid is protonated on the ring oxygen (34). Its decomposition would then involve the *trans*-elimination of two axial groups and would thus be sterically controlled. Substitution in the aglycone should under these circumstances be of little significance. This, they consider, is a more satisfactory explanation than a coincidentally exact cancellation of two opposing effects. This mechanism cannot be invoked for the equatorially substituted aryl β-D-glucopyranosides (25) or for the present alkyl β-D-glucopyranosides, yet, the influence of the aglycone on the rate of hydrolysis is in both series relatively minor. It should also be noted that the effects are opposite in these two cases. Thus, for example, *p*-chloro and *p*-methoxy substituents in the phenyl group slightly decrease the rate of hydrolysis of the phenyl β-D-glucopyranosides, while the same groups cause a small increase for the alkyl β-D-glucopyranosides. The operation of the same reaction mechanism in all three cases is therefore more likely, the net effect of the polar substituents being a matter of chance and always small.

The present results are of special interest in connection with a recent proposal by Marchessault and Råånby (35–37) concerning the influence of polar groups in general, and carboxyl groups in particular, on the acid hydrolysis of cellulose and other polysaccharides.



According to these investigators, the linkage (A → B) will be activated by the inductive effect of the carboxyl group, while the linkage (B → C) will be stabilized by the same effect which here will work in the opposite direction.

It is evident from the previous discussions that the concept of the "activating inductive effect" entails an oversimplification of the reaction mechanism involved, only the heterolysis step in the hydrolysis having been considered. The equilibrium concentration of the conjugate acid is certainly not a factor which can be ignored. In the present series, the 2-carboxyethyl β-D-glucopyranoside is an especially good model for unit A → B since both carry a carboxyl group in the aglycone portion, separated by two carbon atoms from the glycosidic oxygen. The 2-chloroethyl β-D-glucopyranoside can also be used as the HO_2CCH_2— and the $ClCH_2$— groups have the same polar substituent constant ($\sigma^* = +1.05$ (27)). The carboxy compound was actually hydrolyzed at the same rate as ethyl β-D-glucopyranoside and the chloroglucoside only slightly faster.

For personal use only.

Summarizing, there is no reason to believe that cellulose or any other polysaccharide should contain "weak links" because of the presence of carboxyl or any other electronegative group at C-5. Similarly, it is to be expected that pseudoaldobiouronic acids should be hydrolyzed at the same rate as the corresponding neutral oligosaccharides. Several acids of this type are presently being synthesized with a view of providing direct experimental evidence on this point (38).

EXPERIMENTAL

All melting points are corrected. Evaporations were carried out *in vacuo* at 50° C. Chromatographic separations were with ethyl acetate – acetic acid – water (9:2:2). The spray reagent was silver nitrate in acetone followed by ethanolic sodium hydroxide.

MATERIALS

Glycopyranosides

Methyl α-D-glucopyranoside, methyl α-D-xylopyranoside, and methyl β-D-xylopyranoside were commercial preparations, recrystallized once from methanol, 2-butanone, and ethanol, respectively. Methyl α- and β-D-galactopyranosides were obtained as a mixture after treatment of D-galactose with methanolic hydrogen chloride as described by Dale and Hudson (39). The anomers were separated by repeated crystallization from ethanol and ethanol – ethyl acetate. Methyl α-D-mannopyranoside was obtained in a yield of 97% by boiling D-mannose under reflux with *N* methanolic hydrogen chloride for 10 hours (40). All other β-D-glucopyranosides were synthesized by condensing acetobromoglucose in the presence of silver carbonate with the respective alcohol according to the method of Königs and Knorr (41), followed by de-*O*-acetylation with methanol in the presence of sodium methoxide according to Zemplén (42). Use of mercuric cyanide (43, 44) rather than silver carbonate always gave lower yields of the β-glucosides. Whenever possible, the condensation was carried out with the alcohol itself as the solvent. The following is a typical example.

Synthesis of Neopentyl β-D-glucopyranoside (45)

Neopentyl alcohol (35 g) was dissolved in anhydrous benzene (250 ml) and shaken in the dark at room temperature for 2 hours with silver carbonate (30 g) and Drierite (30 g). 1-Deoxy-1-bromo-2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranose (acetobromoglucose, m.p. 88–90° C, 20 g) was added, together with a little iodine, and shaking was continued for another 15 hours. After filtration through Celite and washing of the solid residue with benzene, the combined filtrate and washings were evaporated to a colorless sirup. When the latter was dissolved in hot ethanol, crystals formed immediately. After one recrystallization, the neopentyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (10.0 g, 49%) had m.p. 134.5–135.5° C and $[\alpha]_D$ −16.7° (*c*, 2.0 in chloroform). Anal. Calc. for $C_{19}H_{30}O_{10}$: C, 54.4; H, 7.22. Found: C, 54.5; H, 7.71%.

The tetraacetate was dissolved in 0.1 *N* methanolic sodium methoxide (200 ml) and the solution was allowed to stand at room temperature for 15 hours. After addition of some water, treatment with Amberlite IR-120 and IR-45 exchange resins and with Darco G-60 charcoal, filtration, and evaporation, the colorless sirup was dissolved in acetone (15 ml). On addition of benzene (10 ml) crystallization began slowly. The solid, crystalline mass finally formed was washed with acetone–benzene (1:1) and dried *in vacuo*. Yield: 5.0 g, 41%. The neopentyl β-D-glucopyranoside had m.p. 138–139° C and $[\alpha]_D$ −35.3° (*c*, 2.0 in water). Anal. Calc. for $C_{11}H_{22}O_6$: C, 52.8; H, 8.84. Found: C, 52.8; H, 8.80%.

The tetraacetate derivatives of the β-D-glucopyranosides with substituted aglucones were all crystalline, but only two of the glycosides were obtained in a crystalline state. The carboxyethyl β-D-glucopyranoside was prepared in the usual way from acetobromoglucose and methyl hydracrylate. The five sirupy glycosides were purified by preparative paper chromatography on Whatman No. 3 MM filter paper. The carboxymethyl and carboxyethyl compounds gave infrared spectra with the typical carbonyl absorption at 1735 cm^{-1}. Melting points and specific rotations of the glycosides and their tetraacetates (whenever synthesized) are summarized in Tables IX and X.

TABLE IX

Physical data for methyl D-glycopyranosides

Disaccharides

Maltose, cellobiose, lactose, melibiose, and sucrose were commercially available specimens. They were all recrystallized at least twice. Gentiobiose was synthesized according to Reynolds and Evans (46). Glucosyl mannose and mannobiose were obtained by partial acid hydrolysis of a wood glucomannan (47). Xylobiose was formed on enzymatic hydrolysis of a 4-*O*-methylglucuronoxylan (48). Accepted and found values for the melting points and specific rotations of the disaccharides are given in Table XI.

TABLE XI

Physical data for disaccharides

Compound	Melting point, °C		Specific rotation, $[\alpha]_D$*, degrees	
	Reported	Found	Reported	Found
Maltose		120–121	+130.4	+134.9
Cellobiose	225–231	242.5–243	+34.6	+34.1

Kinetic Measurements

Hydrolyses were carried out in a Townson and Mercer thermostat bath, accurate within ±0.01° C. When open flasks fitted with a reflux condensor were used, the data were exceedingly erratic, probably because of the varying amounts of water that condensed on the side of the flask and in the lower portion of the condensor. Good results were obtained throughout with ampoules, made from Pyrex glass tubing, 9 mm wide and approximately 12 cm long, which were sealed at both ends and completely immersed in the bath.

Polarimetric measurements were made at 405 mμ with a Zeiss precision photoelectric polarimeter, accurate within ±0.005°. The sample to be measured was quickly cooled to 25° C, the ampoule was opened, the sugar solution was transferred to the polarimeter tube, and the rotation was determined. These operations normally required only 2 to 3 minutes. On one occasion, hydrolysis was carried out directly in a jacketed polarimeter tube at 60° C. This technique gave more consistent values, required less material, and involved less manipulations. Unfortunately, however, the design of the polarimeter did not allow the use of temperatures higher than 60° C. Initial rotations were determined immediately after the glycoside solution had been prepared. In most cases the optical rotation to be expected at infinite time was checked by actual measurements. The few discrepancies observed were never large enough to affect the values of the rate constants significantly. As a check, the Shaffer–Hartmann–Somogyi (49, 50) alkaline copper reagent was used in three experiments to follow the hydrolysis. The results are presented in Table XII.

TABLE XII

Comparison between polarimetric and titrimetric determination of rate coefficients

Compound		$k \times 10^{-6}$ sec^{-1}	
		Polarimetric	Titrimetric
Methyl α-D-glucopyranoside	90	50.3	48.0
Carboxymethyl β-D-glucopyranoside	70	16.2	20.1
2-Carboxyethyl β-D-glucopyranoside	70	6.61	6.30

The same stock solution of 0.500 *M* (1.00 *N*) aqueous sulphuric acid was used throughout. Because of their rapid rate of hydrolysis, sucrose, and *t*-butyl- and triethylmethyl-β-D-glucopyranoside were studied in 0.01 *N* sulphuric acid solution. All measurements were carried out with 0.05 *M* solutions of the compounds. The following kinetic data (in min^{-1} and $_{10}$log) were typical.

Deviations from the mean were determined throughout and were usually in the range of 0.5 to 2.0%, with no value exceeding 5%. Data obtained on hydrolysis of methyl α-D-glucopyranoside in hydrochloric, perchloric, sulphuric, and phosphoric acid at 50° C are summarized in Table XIII.

Calculation of Energies and Entropies of Activation

Energies of activation were obtained from a minimum of three rate constants, usually determined at 60, 70, and 80° C. When log k was plotted against $1/T$, straight lines were obtained throughout.

Entropies of activation were calculated for 60° C from the relationship

$$T\Delta S^{\ddagger} = E - RT - RT \ln (kT/h) + RT \ln (k'/h_0),$$

where R = 1.9871 cal deg^{-1} $mole^{-1}$,
T = 333.16 °K,
k = 1.3805×10^{-16} erg deg^{-1} $molecule^{-1}$,
h = 6.6252×10^{-27} erg sec,
k' = first order rate coefficient, sec^{-1},
h_0 = +0.741 for 0.5 *M* sulphuric acid.

SYNTHESIS OF ALKYL 2-DEOXY-α-D-GLYCOPYRANOSIDES AND THEIR 2-DEUTERIO DERIVATIVES[1]

R. U. LEMIEUX[2] AND S. LEVINE[3]
Department of Chemistry, University of Ottawa, Ottawa, Ontario
Received December 17, 1963

ABSTRACT

The methyl, cyclohexyl, and *t*-butyl 2-deoxy-2-iodo-α-D-manno- and β-D-glucopyranoside triacetates were formed in near quantitative yield on reaction of equimolar amounts of the corresponding alcohol, iodine, D-glucal triacetate, silver perchlorate, and 2,4,6-trimethylpyridine (collidine) in dry benzene. The proportion of the α-D-*manno* isomer in the product increased in the order, *t*-butyl > cyclohexyl > methyl. Deuterolysis of the iodide in the presence of palladium proceeded with retention of configuration when the iodine was in equatorial orientation (β-D-*gluco*-configuration) but with near complete lack of stereospecificity when axially oriented (α-D-*manno*-configuration).

2-Deoxyglycopyranosides have been prepared by reaction of *O*-acylated 2-deoxyglycopyranosyl halides with alcohols (1, 2), acid-catalyzed addition of alcohols to acylated glycals (3–6), and the acid-catalyzed alcoholysis of 2-deoxysugars (7). Also, the condensation of *O*-acyl-2-deoxy-2-halogenoglycopyranosyl halides with alcohols followed by hydrogenolysis of the 2-deoxy-2-halogenoglycoside has been employed (8–12).

The syntheses involving substituted glycosyl halides are of most general application. Since anomeric halogens are normally in axial orientation and their replacement tends to proceed with inversion of the reacting center, 2-deoxyglycopyranosides with equatorial aglycons are the expected products. This corresponds to the β-configuration for the hexoses. The formation of the α-glycoside on reaction of 2,6-dideoxy-D-ribohexopyranosyl chloride tri-*p*-nitrobenzoate with digitoxigenin (1) is undoubtedly related to the instability of the α-configuration for the chloride in the presence of the axial 3-acyloxy group. The purpose of this research was to achieve a stereochemically controlled synthetic route to the 2-deoxy-α-glycopyranosides which would proceed in high yield.

It has long been recognized that the reaction of an alkene with a halogen in the presence of a source of carboxylate ion leads to the formation of *O*-acylated halohydrin (13, 14). The halogenation of an alkene in an alcohol results in formation of *O*-alkyl halohydrin (15, 16). The yields of these substituted halohydrins are enhanced through depression of the concentrations of halide ion by addition of silver ion (13, 14, 15, 17, 18). It was observed (17) that the reaction of cyclohexene with iodine and silver perchlorate in dry ether gave a product which was hydrolyzed to cyclohexene iodohydrin on the addition of water. This observation is in keeping with the now well-recognized inability of the perchlorate ion to form covalent bonds.

D-Glucal triacetate was converted to 1-*O*-benzoyl-2-deoxy-2-iodo-D-hexose triacetates on treatment with silver benzoate and iodine (19). The product was recently found to comprise an about equimolar mixture of the isomers with the α-*manno*- and β-*gluco*-configurations (20). Evidently, it could be expected that alkyl 2-deoxy-2-iodoglycopyranoside triacetates would form on reaction of an acetylated glycal dissolved in an alcohol with iodine and a silver salt. The preparation of *trans*-2-methoxycyclohexyl iodide in

90% yield on reaction of cyclohexene in methanol with iodine in the presence of silver perchlorate and calcium carbonate at −80° (17) would serve as a precedent. The use of silver perchlorate was found to be an unnecessary precaution in the iodomethoxylation of D-glucal triacetate when a large excess of methanol was used. Thus, the reaction in the presence of silver benzoate gave the methyl 2-deoxy-2-iodo-α-D-manno- and β-D-glucopyranoside triacetates in near quantitative yield. The isomer with the α-D-*manno*-configuration comprised about 55% of the mixture as evidenced by the relative intensities of the signals for the methoxy groups in the proton magnetic resonance (NMR) spectrum. The hydrogenolysis of these glycosides was previously shown (20) to yield the α- and β-methyl glycosides of 2-deoxy-D-glucose.

This approach to the synthesis of 2-deoxyglycopyranosides would likely not find useful application unless the acetylated glycal and the alcohol could be used in equimolar amounts to provide the 2-deoxy-2-halogenoglycoside in high yield. This goal was achieved through the anticipation that both glycosyl perchlorates and the *N*-glycosides of 2,4,6-trimethylpyridine (collidine) would prove to be unstable in the presence of an alcohol. Thus, the addition of iodine to equimolar amounts of D-glucal triacetate, silver perchlorate, collidine, and an alcohol (methanol, cyclohexanol, or *t*-butanol) provided the alkyl 2-deoxy-2-iodo-D-glycopyranoside triacetates as mixtures of α-D-*manno*- and β-D-*gluco*-configurations in near quantitative yields. The content of the isomer with the α-D-*manno*-configuration increased with increasing substitution of the α-carbon of the alcohol (methyl, 55%; cyclohexyl, about 70%; *t*-butyl, 85%). This result is reminiscent of the increased resistance displayed by 1,2-anhydro-α-D-glucopyranose triacetate with alcohols as the bulk of the group about the hydroxyl is increased (21). Thus, it seems likely that the amount of the α-D-*manno*-isomer increased because the formation of the intermediate iodonium ions is reversible and the diequatorial opening of the intermediate 1,2-α-D-*gluco* iodonium ion became less favored than the diaxial opening of the 1,2-β-D-*manno* iodonium ion with increasing size of the alkyl group.

The configurations of the iodoglycosides were established by application of NMR spectroscopy as previously described (12) and by hydrogenolysis to the corresponding α- and β-2-deoxy-D-glucopyranosides. It seemed of interest to investigate the stereochemical route of the reduction of these iodides with deuterium since it could be anticipated that the configurations of the 2-deoxy-2-deuterioglycosides could be readily interpreted from their NMR spectra. Deuterolysis of methyl 2-deoxy-2-iodo-β-D-glucopyranoside in deuterium oxide using palladium on charcoal as catalyst proceeded with apparent complete retention of configuration. The chemical shift and the triplet structure of the signal of intensity one at 1.78 p.p.m. requires the proton to be in axial orientation at the 2-position (see Fig. 1) and coupled with axial hydrogens at the 1- and 3-positions. As expected, the quartet signal (4.62 p.p.m. and spacings of 1.9 and 9.9 c.p.s.) for the anomeric hydrogen of the 2-deoxy-β-glucoside collapsed to a doublet with the larger spacing on introduction of the equatorial deuterium.

Treatment of the methyl 2-deoxy-2-deuterio-β-D-glucopyranoside with methanolic hydrogen chloride provided the α-anomer. The spectrum of this compound is shown in Fig. 2. A comparison of this spectrum with that shown in the same figure for methyl 2-deoxy-α-D-glucopyranoside clearly substantiates the configuration shown. The structure of the signal for the anomeric hydrogen allows the assignment of the larger spacing, 3.9 c.p.s., to the coupling of the anomeric hydrogen (H_1) with the axial hydrogen (H_2) at the 2-position. This result, on the basis of the Karplus relationship (22), indicates that H_1 defines a somewhat smaller dihedral angle with H_2 than with $H_{2'}$. This distortion of

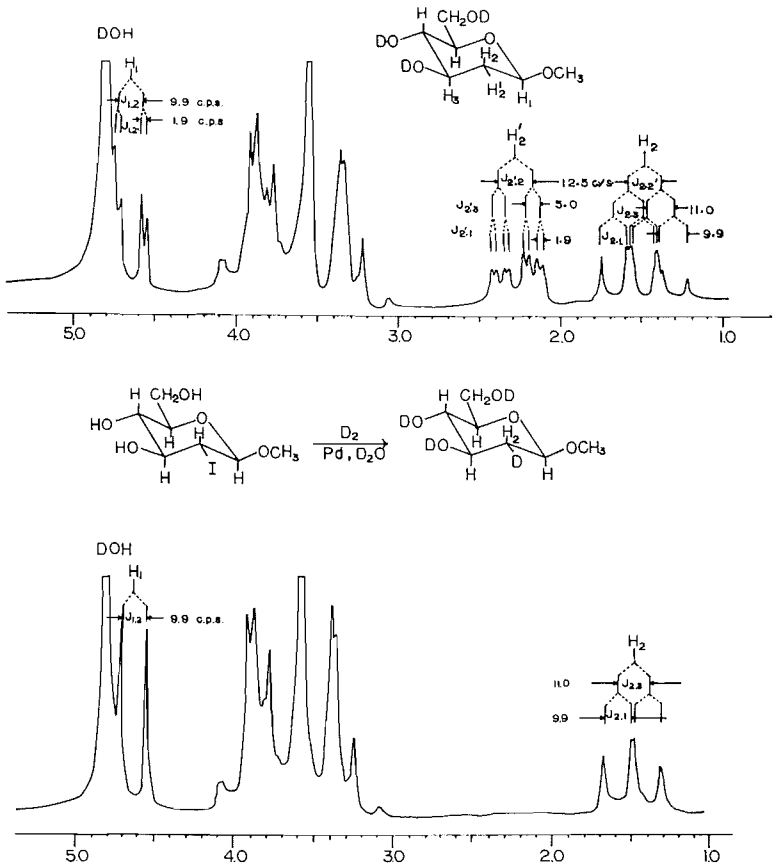

FIG. 1. NMR spectra at 60 Mc.p.s. in deuterium oxide of methyl 2-deoxy-β-D-arabohexopyranoside and methyl 2-deoxy-2-deuterio-β-D-glucopyranoside. The spacings are in c.p.s. and the chemical shifts in p.p.m. from tetramethylsilane used as an external reference.

the pyranose ring would be in the direction expected on the basis that the non-bonded interactions between the axial oxygen and the opposing axial hydrogens do not allow the oxygen to assume an exactly axial orientation. The spacings of 5.0 and 11.4 c.p.s. observed in the signals for the 2′- and 2-hydrogens, respectively, which arise from coupling with the 3-hydrogen, together with the above-mentioned spacings for the anomeric hydrogen obviously require the compound to possess the chair conformation.

The deuterolyses of both the methyl and *t*-butyl 2-deoxy-2-iodo-α-D-mannopyranosides both proceeded with extensive inversion (about 40%) of the reacting center. That the deuterium replaced the iodine is evident from the structures of the signals for hydrogens at the 2-position (see Fig. 3). The relative intensities of these signals provided the relative amounts of the two epimers in the mixture. Since the spacings found in the signals for these hydrogens are virtually the same for both the methyl and the *t*-butyl 2-deoxy-2-deuterio-α-D-glucopyranosides, it is clear that the size of the alkyl group of the aglycon has little if any influence on the conformation of the pyranose ring. The extent of racemization of the 2-position in the deuterolysis of the axially oriented iodine requires the reaction in this case to proceed by way of a configurationally labile intermediate such as a free radical or carbanion.

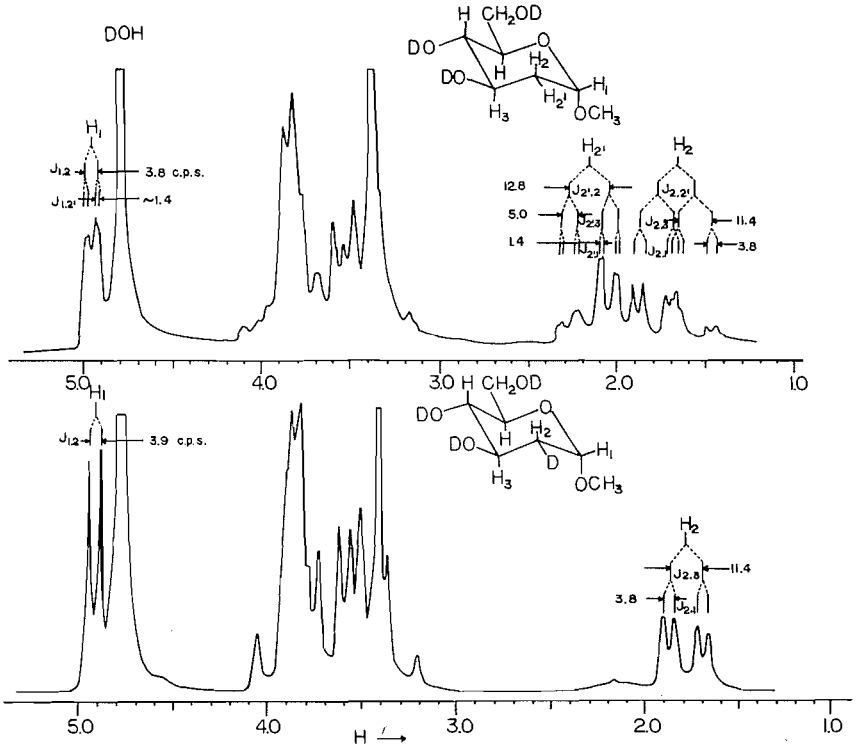

FIG. 2. NMR spectra at 60 Mc.p.s. in deuterium oxide of methyl 2-deoxy-α-D-arabohexopyranoside and methyl 2-deoxy-2-deuterio-α-D-glucopyranoside. The spacings are in c.p.s. and the chemical shifts in p.p.m. from tetramethylsilane used as an external standard.

Incidental to this research, the NMR spectrum of the methyl 2-deoxy-α-D-ribopyranoside was determined both in chloroform and deuterium oxide (see Fig. 4). It is of interest to note that the structures of the signals for the anomeric hydrogen changed from a triplet to a quartet on changing the solvent from chloroform to deuterium oxide. In view of the dependence of the coupling constant for hydrogens on vicinal carbons on the dihedral angles defined by the hydrogens (22), it is clearly apparent that the 1-axial conformation wherein the anomeric hydrogen is *gauche* to both the 2-hydrogens is much more favored in the non-hydroxylic solvent. It seems most probable that this conformation is favored in chloroform since it allows an intramolecular hydrogen bond between the 3-hydroxyl and the methoxyl. In the deuterium oxide solution, hydrogen bonding of the hydroxyl groups with the solvent is favored over intramolecular hydrogen bonding and therefore, the 1-equatorial conformation is preferred since it avoids non-bonded interaction between the 1- and 3-substituents.

EXPERIMENTAL

All melting points were determined on a heating stage and are uncorrected. The proton magnetic resonance spectra were determined in chloroform with a Varian Associates HR-60 spectrometer and the chemical shifts are reported in p.p.m. from tetramethylsilane.

Methyl 2-deoxy-2-iodo-β-D-gluco- and -α-D-mannopyranosides

(*a*) To a stirred suspension of 1.15 g (5 mmoles) of dry silver benzoate in a solution of 1.36 g (5 mmoles) of D-glucal triacetate (23) in 150 ml of dry methanol, 1.27 g (5 mmoles) of iodine were added over a period

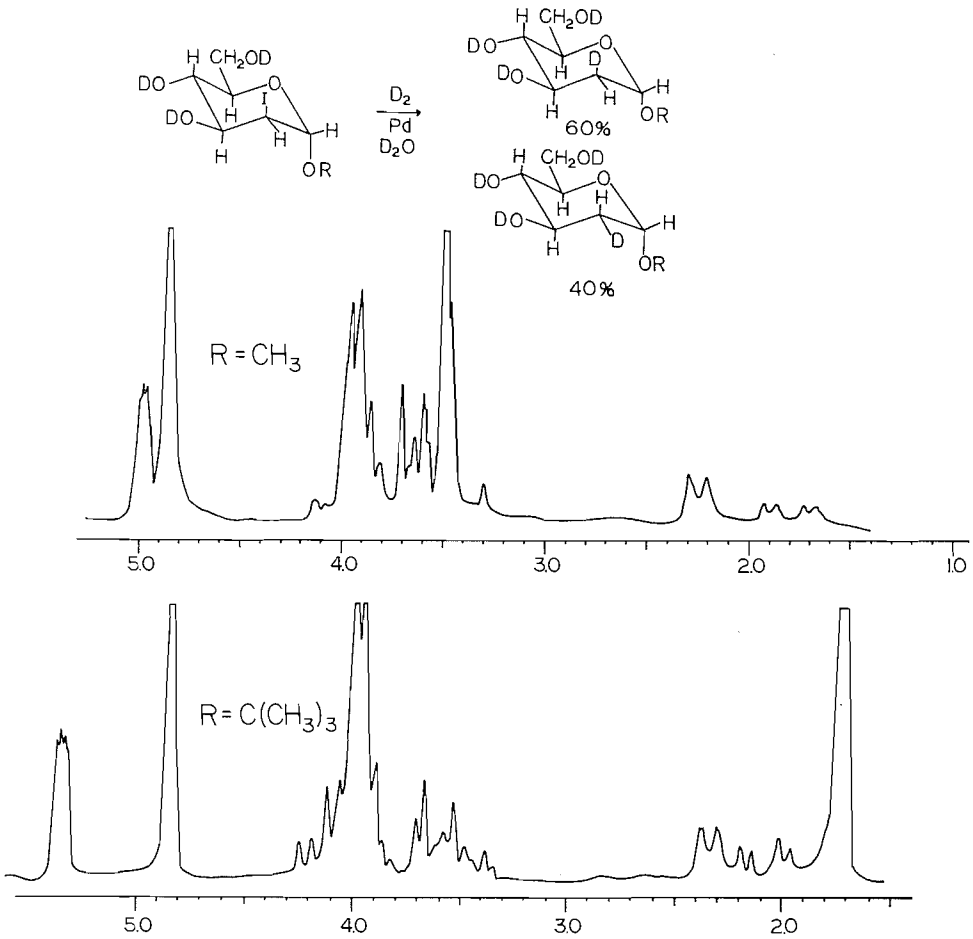

FIG. 3. The NMR spectra at 60 Mc.p.s. in deuterium oxide of the mixtures obtained on deuterolysis of the methyl and *t*-butyl 2-deoxy-2-iodo-α-D-mannopyranosides. The chemical shifts are in p.p.m. from tetramethylsilane used as an external standard. The doublets at 2.25 and 2.33 p.p.m. in the upper and lower spectra, respectively, are assigned to the equatorial 2-protons of the component with the *manno*-configuration. The lower intensity quartets to higher field centered at 1.8 and 2.1 p.p.m., respectively, are assigned to the axial 2-protons of the *gluco*-isomers.

of 5 minutes. Except for the last addition when slight coloration remained, the iodine coloration rapidly disappeared after each addition. After the suspension was stirred at room temperature for 30 minutes, the silver salts were removed by filtration, the filtrate was evaporated to near dryness, and the residue was dissolved in chloroform. The solution was washed with aqueous sodium thiosulphate, then with aqueous bicarbonate, and finally with water before drying. Removal of the chloroform left a viscous oil, 2.01 g (93.5% yield). The NMR spectrum showed two signals for methoxyl-group protons of relative intensities 10:13. The sirup was dissolved in 50 ml of dry methanol saturated with ammonia. After 1 day at room temperature, the solution was evaporated to dryness. The residue was freed of acetamide by chromatography on silicic acid using 5% methanolic chloroform as eluant. The acetamide-free sirup was dissolved in ethyl acetate. On seeding of the solution with methyl 2-deoxy-2-iodo-β-D-glucopyranoside (20), crystals of this material were deposited. The yield (based on the D-glucal triacetate) after one recrystallization from ethyl acetate was 21%. The sirup obtained on evaporation of the mother liquor was seeded with methyl 2-deoxy-2-iodo-α-D-mannopyranoside. After crystallization was complete, the crystals were washed with ethyl acetate and recrystallized from this solvent to provide a 30% yield of the mannoside. The identifications were based on melting points and mixed melting points with authentic samples (20).

(*b*) Anhydrous silver perchlorate, 0.451 g (2.19 mmoles) was added to a solution of 0.590 g (2.19 mmoles)

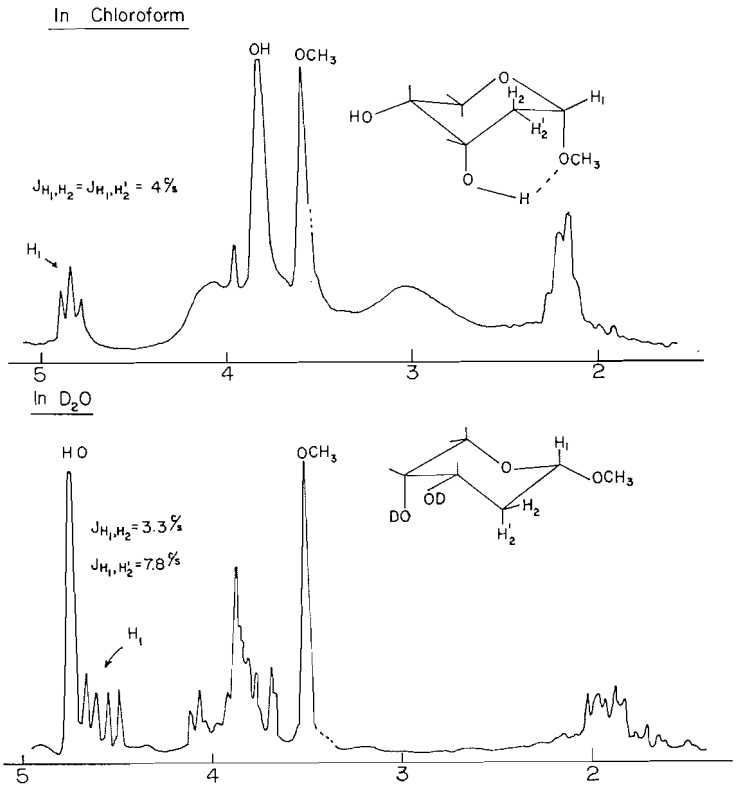

FIG. 4. The effect of solvent on the NMR spectrum at 60 Mc.p.s. of methyl 2-deoxy-α-D-ribopyranoside

of D-glucal triacetate, 0.071 g (2.23 mmoles) of anhydrous methanol, and 0.497 g (2.25 mmoles) of 2,4,6-trimethylpyridine (collidine) in 50 ml of dry benzene. A white precipitate was formed. Iodine, 0.55 g (2.19 mmoles) was added and the mixture was stirred at room temperature for 20 minutes. The reaction product was isolated in a manner similar to that described above. The yield was 0.895 g (95%) of a viscous oil which gave NMR and IR spectra almost identical with those obtained in the reaction described above using methanol as the solvent. The NMR spectrum indicated the product to contain 43% and 57% of the compounds with β-D-*gluco* and α-D-*manno* configurations, respectively. The mixture was deacetylated and the methyl 2-deoxy-2-iodoglycosides were isolated as described in the above preparation in pure condition for positive identification.

Cyclohexyl 2-deoxy-2-iodo-β-D-gluco- and -α-D-mannopyranosides

Reaction of 1.28 g (4.71 mmoles) of D-glucal triacetate, 0.480 g (4.80 mmoles) of dry cyclohexanol, 1.02 g (4.71 mmoles) of silver percholate, 1.20 g (4.71 mmoles) of iodine, and 0.431 (4.77 mmoles) of collidine in 50 ml of dry benzene for 20 minutes, followed by the isolation procedure described above, gave 2.28 g (97% yield). The NMR spectrum of the product required it to be free of D-glucal triacetate. The substance was deacetylated in methanol saturated with ammonia and chromatographed on silicic acid using chloroform as the developing phase. The faster moving of the components was isolated as an amorphous powder, in 50% overall yield, which resisted crystallization. The specific rotation was +68.7° (*c*, 1.9 in methanol). The slower moving component was eluted from the chromatographic column using 5% methanolic chloroform. This compound was obtained in crystalline condition on evaporation of the solvent in 23% overall yield. After purification by recrystallization from benzene, the melting point was 151–152.5° with $[\alpha]_D$ +16.0° (*c*, 2.1 in methanol).

Anal. Calc. for $C_{12}H_{21}O_5I$: C, 38.72; H, 5.69; I, 34.10. Found: C, 38.50; H, 5.83; I, 33.61%.

Cyclohexyl 2-Deoxy-α-D-glucopyranoside

The above-described cyclohexyl 2-deoxy-2-iodo-α-D-mannopyranoside, $[\alpha]_D$ +68.7°, 372 mg, was dissolved in 15 ml of methanol with 138 mg of diethylamine, and 40 mg of 5% palladium on charcoal was added to catalyze a hydrogenolysis. The theoretical amount of hydrogen was consumed within 30 minutes. After

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

filtration to remove the catalyst, silver carbonate was added to remove the iodide ion. The silver salts were removed and the filtrate was treated with hydrogen sulphide. Treatment with charcoal, filtration, and evaporation gave viscous oil, 206 mg (84% yield), which completely crystallized on trituration with benzene. Recrystallization from benzene gave white crystals, m.p. 123–124°, $[\alpha]_D$ +129.3° (*c*, 1.1 in methanol).

Anal. Calc. for $C_{12}H_{22}O_5$: C, 58.52; H, 9.00. Found: C, 58.71; H, 8.98%.

Cyclohexyl 2-Deoxy-β-D-glucopyranoside

The above-described cyclohexyl 2-iodo-2-deoxy-β-D-glucopyranoside, $[\alpha]_D$ +16.0°, 185 mg, was hydrogenolyzed and the product, 117 mg (95% yield), was isolated as described for the α-anomer. The crystalline compound melted at 126–127° with $[\alpha]_D$ + 46.3° (*c*, 0.9 in methanol) after recrystallization from benzene.

t-Butyl 2-Deoxy-2-iodo-β-D-glucopyranoside and -α-D-mannopyranosides

A mixture of the triacetates of these two compounds was obtained in 97% yield using the reaction conditions described above for the preparation of the cyclohexyl 2-deoxy-2-iodoglycoside triacetates except that dry *t*-butanol was used instead of the cyclohexanol. The product was deacetylated and chromatographed as reported for the corresponding cyclohexyl glycosides. The band eluted with chloroform provided a 59% yield of a crystalline product which, after one recrystallization from benzene, melted at 146–147° with $[\alpha]_D$ +65.2° (*c*, 2.1 in methanol).

Anal. Calc. for $C_{10}H_{19}O_5I$: C, 34.69; H, 5.53; I, 36.67. Found: C, 34.55; H, 5.30; I, 36.02%.

Elution of the chromatographic column with 5% methanolic chloroform gave a sirup from which a 4% yield of compound, m.p. 153–154°, $[\alpha]_D$ +13.2° (*c*, 0.08 in methanol), was obtained.

Anal. Calc. for $C_{10}H_{19}O_5I$: C, 34.69; H, 5.53; I, 36.67. Found: C, 35.02; H, 5.56; I, 36.20%.

A sample of the reaction mixture was deacetylated and its NMR spectrum in deuterium oxide showed a chemical shift for the *t*-butyl groups of the two components. The relative intensities of the signals required the mixture to comprise 85% of the α-D-mannoside and 15% of the β-D-glucoside.

t-Butyl 2-Deoxy-α-D-glucopyranoside

The above-described *t*-butyl 2-deoxy-2-iodo-α-D-mannopyranoside, $[\alpha]_D$ +65.2°, was hydrogenolyzed under the same conditions as described for the cyclohexyl mannoside except that water was used as solvent. The yield was 84% of a crystalline product which was recrystallized from benzene. On heating, the compound, $[\alpha]_D$ +123.0° (*c*, 0.7 in methanol), first melted at 136–138° then solidified to a crystal form which melted at 144–145°.

Anal. Calc. for $C_{10}H_{20}O_5$: C, 54.53; H, 9.15. Found: C, 54.42; H, 9.01%.

Deuterolysis of the Iodoglycosides

Methyl 2-deoxy-2-iodo-β-D-glucopyranoside and the methyl and *t*-butyl 2-deoxy-2-iodo-α-D-mannopyranosides after exchange of the active hydrogens using deuterium oxide, were treated with deuterium at atmospheric pressure and room temperature in the presence of 5% palladium on charcoal and diethylamine using deuterium oxide as solvent. The product in each case was isolated by first precipitating the iodide ion with silver carbonate as described above in similar preparations. The yields in each case were near quantitative. The NMR spectra of the 2-deoxy-2-deuterioglycosides are reproduced in Figs. 1 and 3. Methyl 2-deoxy-2-deuterio-α-D-glucopyranoside was obtained by allowing a solution of the β-anomer in 5% methanolic hydrogen chloride to achieve constant rotation. The α-glucoside was readily isolated in crystalline condition using the usual isolation procedure. Its NMR spectrum is reproduced in Fig. 2.

ACKNOWLEDGMENTS

The authors thank the Bristol Laboratories Incorporated and the National Research Council of Canada for the financial support of this research through grants to R.U.L. The nuclear magnetic resonance spectra were determined by Mrs. A. Westland and the microanalyses were conducted by Miss E. Busk of these laboratories. The methyl 2-deoxy-α-D-ribopyranoside was prepared by Mr. M. Saeed from a sample of 2-deoxy-D-ribose kindly donated by Hoffmann LaRoche Inc.

MOLECULAR SIEVE SORBENTS FROM CLINOPTILOLITE

R. M. Barrer and M. B. Makki
Chemistry Department, Imperial College, London, England
Received February 17, 1964

ABSTRACT

Clinoptilolite has been investigated as a source of porous, largely crystalline, molecular sieve sorbents. By treating the zeolite with mineral acid of different strengths a range of high area sorbents has been produced, in which all the original cations have been replaced by hydronium ions, and in which the aluminum has been progressively removed from the frameworks. The new sorbents and the original clinoptilolite have been characterized by sorption studies, and by X-ray, electron optical, differential thermal analysis, and thermogravimetric methods. The most open molecular sieve sorbents, able to imbibe considerable amounts of larger molecules such as benzene and isopentane, were obtained using 1 *N* and 2 *N* acid, but as acid strength increased further there was a decline in both crystallinity and sorption capacity until with 30 *N* acid an amorphous product resulted.

INTRODUCTION

Clinoptilolite is a silica-rich zeolite related to heulandite (1, 2). It has recently attracted attention because of its ability to scavenge Cs^+ from radioactive effluents (3, 4) and because it is one of several zeolites (including heulandite, laumontite, phillipsite, and erionite) which have been discovered in substantial deposits (5–8). Some natural crystalline zeolites are thus available as potential ion exchangers and molecular sieve sorbents in competition with synthetic crystalline zeolites.

When aluminosilicates are treated with mineral acids there may be exchange of their cations by hydronium ions, and there may be hydrolysis of Al—O—Si bonds. Hydrolysis occurs readily for the most aluminous minerals, and results in complete disintegration to colloidal silica and to aluminum salts. As the silica content increases, colloidal silica is replaced by silica gel (9). It could be anticipated that as the silica content increases still further the gel will retain more and more "memory" of the parent structure, so that highly specific silica-rich sorbents may be obtained. Clinoptilolite is one of the most siliceous aluminosilicates and accordingly sorbents obtained by acid treatment of the zeolite may have molecular sieve properties of special interest. To test this hypothesis we have investigated in various ways the products obtained from clinoptilolite treated with hydrochloric acid solutions.

EXPERIMENTAL MATERIALS AND METHODS

The original clinoptilolite and the products obtained from it were examined by X-ray diffraction, thermogravimetry, d.t.a., and as sorbents. Nitrogen sorption at the temperature of liquid nitrogen was measured in a volumetric sorption unit of standard design, and the sorption of a number of vapors was determined above room temperature using several silica spring balance sorption units. The sorbates were distilled water, 'AnalaR' methanol and ethanol, and benzene and isopentane. The hydrocarbons were supplied as pure chemicals by the National Chemical Laboratory, Teddington. Before sorption studies were made the sorbents were outgassed at 350° C for 15 hours.

CHARACTERIZATION OF THE CLINOPTILOLITE

Clinoptilolite, from Mount Hector, California, was supplied by the courtesy of Dr. L. L. Ames, Jr., of General Electric Company, Richland, Washington. The overall purity was

given as 85–95%, and the zeolite appeared as small hard fragments with conchoidal fracture to which a certain amount of pale green bentonite material was adhering. The main X-ray spacings from our sample are given in Table I, and are compared with the

corresponding spacings reported by Mumpton (2) for clinoptilolite and heulandite. There is a satisfactory correspondence after several lines due to quartz, which was a further impurity, are subtracted, although the similarity with heulandite is as close as that with clinoptilolite. The clinoptilolite powder pattern was still observed, somewhat weakened, after the zeolite was heated to 750° C for considerable periods. At still higher temperatures an amorphous, glassy phase was formed, although the quartz impurity was detectable up to 1000° C. Evidently clinoptilolite possesses very considerable thermal stability.

A differential thermal analysis curve is shown in Fig. 1. The endothermic reaction in the lower temperature range corresponds to the evolution of zeolitic water. A further endothermic change begins near 600° C and persists over a range of temperature. The loss of zeolitic water is a continuous process as shown by the full thermogravimetric curve of Fig. 2.

Because it was not easy to free the clinoptilolite from quartz and bentonite it was analyzed without further purification. The sample lost 15.2% by weight on ignition, which should primarily be water. The ratio Al_2O_3:SiO_2 was 1:10.8, and sodium was the main cation, with a little potassium and calcium. The latter may have been present as carbonate.

PREPARATION OF SORBENTS FROM CLINOPTILOLITE

Ten-gram samples of clinoptilolite were refluxed with 150 cm^3 of hydrochloric acid solutions for 4 hours at a temperature of a little above 100° C. The acid solutions used in different preparations were 0.25, 0.5, 1, 2, 5,

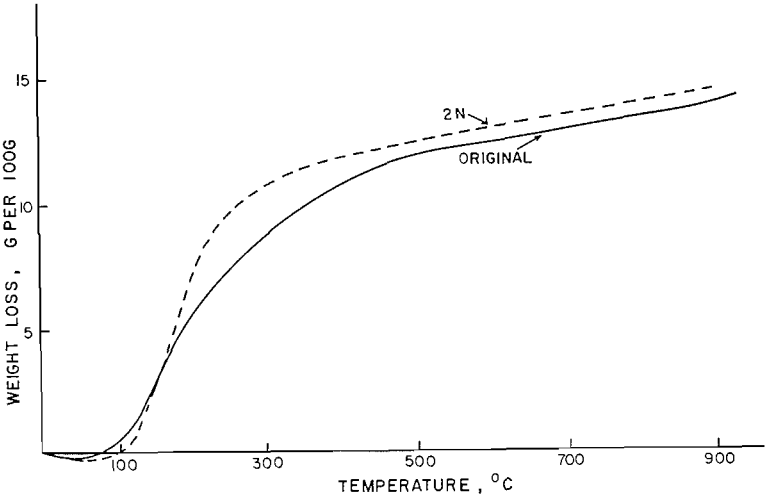

FIG. 2. Thermogravimetric curves of the original clinoptilolite (full line) and of clinoptilolite treated with 2 *N* HCl.

10, 15, and 30 *N*. After treatment the suspended particles were filtered off and washed first with cold and then with hot distilled water, until all traces of entrained acid were removed. The preparations were then air-dried and investigated as follows.

(a) Chemical Analysis

All exchangeable cations were found to be replaced by H_3O^+ by treatment with excess of 0.25 *N* HCl. With increasing acid strength Al and H_3O^+ were removed progressively, and in equal amount, until with the 5 *N* acid a hydroxylated silica free of Al or H_3O^+ remained. Removal of Al and H_3O^+ involves the intracrystalline reaction:

TABLE II

Compositions of acid-treated clinoptilolites

Treatment of sample	Molar ratio Al_2O_3:SiO_2	Approximate composition of crystalline product
Original	1:10.8	$Na^+[AlSi_{5.4}O_{12.8}]^-4.3_5H_2O$
0.25 *N* HCl	0.95:10.8	$H_3O^+_{0.95}[Al_{0.95}Si_{5.4}O_{12.6}(OH)_{0.2}]^-nH_2O$
0.5 *N* HCl	0.84:10.8	$H_3O^+_{0.84}[Al_{0.84}Si_{5.4}O_{11.96}(OH)_{0.64}]nH_2O$
1 *N* HCl	0.35_5:10.8	$H_3O^+_{0.35_5}[Al_{0.35_5}Si_{5.4}O_{10.02}(OH)_{2.58}]nH_2O$
2 *N* HCl	0.08_1:10.8	$H_3O^+_{0.08}[Al_{0.08_1}Si_{5.4}O_{9.1}(OH)_{3.7}]nH_2O$
5 *N* HCl	0.00 :10.8	$[Si_{5.4}O_{8.8}(OH)_4]nH_2O$

Table II shows the Al and H_3O^+ remaining after each treatment. The compositions in the last column will underestimate the total hydroxyl because partial hydrolysis which does not eliminate Al is not shown by the analysis. The elimination reaction produces nests of four hydroxyls in number equal to the Al removed.

(b) X-ray Diffraction

X-Ray powder photographs were taken with Guinier cameras, using filtered Cu K_α radiation, for all the products, after preparation as described above, and after the prepared samples had been outgassed at 350° C before their examination as sorbents. The results are shown in Fig. 3, in which the left-hand side shows the diffraction patterns before, and the right-hand side the same patterns after, the outgassing. Reading from top to bottom of the figure the samples are: original clinoptilolite and the products respectively obtained with 0.25, 0.5, 1, 2, 5, 10, and 15 *N* acid.

Complete replacement of Na^+ by H_3O^+ has no appreciable influence upon the powder pattern, and the hydrogen-ion exchanged clinoptilolite is quite stable to heating to 350° C. Moreover, one can replace some or all of the aluminum and H_3O^+ with hydroxyl, still leaving crystalline hydroxylated phases which are pseudomorphs of the parent clinoptilolite. This is the situation up to the treatment with 1 *N* HCl, for which there is noted merely some loss of intensity of the clinoptilolite lines. For the products derived by treatment with 2 *N* and higher strength acids, although virtually all Al is removed (Table II), considerable crystallinity still persists even to 15 *N*. The general weakening in intensity of the lines continues, however, and for 30 *N* acid the crystallinity of the original clinoptilolite has practically disappeared. Certain lines in Fig. 3 are unchanged by the acid treatments, but are due to the quartz impurities (Table I).

Heating the products to 350° C produces some further loss in intensity and number of diffraction lines for the products from which Al has been largely or wholly removed, but not for the products from 0.25 *N*, 0.5 *N*, and 1 *N* acid treatments (Fig. 3). Evidently defect-rich crystalline silicas of considerable stability can be prepared from clinoptilolite, in which the defects comprise hydroxyl groups appropriately distributed throughout the structure.

(c) Electron Optical Examination

The photomicrographs taken with a Philips 100 electron microscope showed no great difference among the samples until the product obtained by treatment with 15 *N* acid was reached, although aggregates of plates and laths were found to be progressively dispersed. The amorphous product of the treatment with 30 *N* acid was, however, much more finely divided.

(d) Thermogravimetry

In Fig. 2 we have compared the thermogravimetric curves for the original clinoptilolite and for the product obtained by treatment with 2 *N* hydrochloric acid. The dehydration of the latter sample is more rapid, so that at 300° C the original clinoptilolite had lost 9.5% of water, while the acid-treated product had lost 11%. The heating rate approached 10° C per minute.

BEHAVIOR AS SORBENTS

(a) Nitrogen Isotherms

Sorption isotherms for nitrogen and the vapors were of type II in the Brunauer classification (10). The monolayer equivalent areas were obtained from the isotherms at −195° C for nitrogen by the BET method, taking the area of a nitrogen molecule as 16.2 Å². The results are shown in Fig. 4. A very great increase is seen as the strength of the acid employed to treat the clinoptilolite is increased, until from a value of ~30 m² per g for the original clinoptilolite, the curve passes through a maximum of ~380 m² per g when the acid used is 2 *N*. Thereafter the monolayer equivalent area steadily declines to ~250 m² per g for the sorbent from 15 *N* acid and to ~90 m² per g for the sorbent from 30 *N* acid.

16. As 8, outgassed at 350° C for 15 hr.

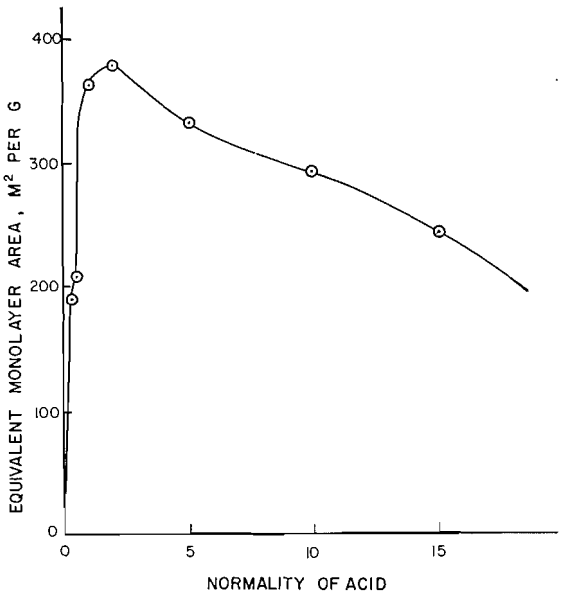

FIG. 4. The equivalent monolayer areas, determined using nitrogen sorption, for the original clinoptilolite and for clinoptilolites treated with HCl of different normalities.

Since the parent clinoptilolite crystals are not permeable to nitrogen, as shown by the area of only 30 m^2 per g, the exchange of Na^+ by H_3O^+, followed by outgassing, has rendered the intracrystalline volume of the crystals much more accessible to this gas. Outgassing at 350° C should remove the zeolitic water and most of the water of hydration of the protons (11), but should not remove significant amounts of hydroxyl water (in kaolin, for example, hydroxyl water is not evolved below about 500° C). The protons, on account of their small size, then offer little obstruction to diffusion of nitrogen into the crystals. The removal of ($Al + H_3O^+$) as shown in Table II improves still more the uptake of nitrogen in the intracrystalline channels, at least as far as the 2 *N* product.

(b) Molecular Sieve Aspects

While the intracrystalline channels of outgassed acid-treated clinoptilolites may be accessible to small molecules such as nitrogen, it by no means follows that they will be available to larger molecules. For this reason we have determined the sorption isotherms of a series of vapors of increasing molecular dimensions (H_2O, CH_3OH, C_2H_5OH, C_6H_6, and iso-C_5H_{12}). Except for water some hysteresis persisted between adsorption and desorption branches down to low relative pressures. The isotherms were measured at 55° C for all vapors save isopentane. In this instance sorption was measured at 30° C. From the adsorption branches at $p/p_0 = 0.5$, assuming that the co-volumes of sorbed molecules equal those of the same molecules in their liquids, one obtained the cm^3 of liquid sorbed per 100 g of outgassed sorbent which are recorded in Table III. For water, the smallest, most polar molecule, the volume sorbed did not vary greatly among all the sorbents. However, as the sorbate molecules became larger the volumes sorbed became progressively smaller both in the original clinoptilolite, and also in the silicas obtained by treatment with the stronger acid solutions. Maximum uptake tends to be observed with sorbents prepared by the action of 0.5, 1, and 2 *N* hydrochloric acids.

TABLE III

Liquid sorbate (cm^3) per 100 g outgassed clinoptilolite at $p/p_0 = 0.5$

Sorbate \ Sorbent	Original zeolite	0.25 *N*	0.5 *N*	1 *N*	2 *N*	5 *N*	10 *N*	15 *N*
H_2O	13.5	14	14.2	14	11.9	11.6	12.1	11.4
CH_3OH	10.1	15	17.5	15.5	15.9	15.5	13.7	13.9
C_2H_5OH	5.5	17	15.7	17.7	15.5	14.9	13.1	12.7
C_6H_6	2	4.5	5.7	8.7	10.7	8.9	3.7	2.8
iso-C_5H_{12}	0.65	3.5	4.5	6.5	5.4_5	3.8	2.0	1.4

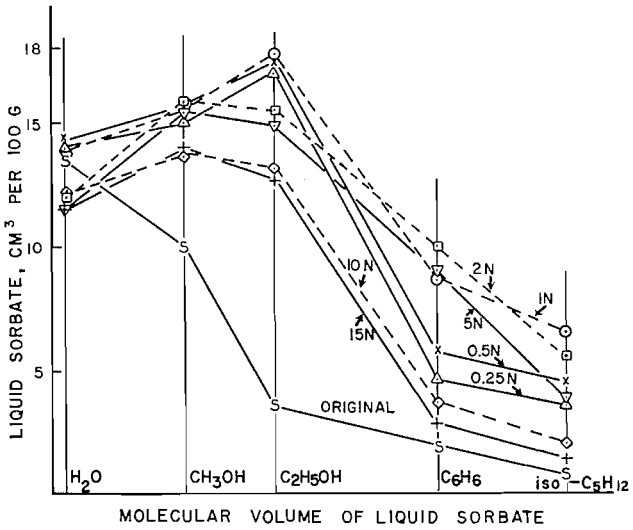

FIG. 5. The relation between sorption at $p/p_0 = 0.5$ of a range of sorbates and the molecular volume of the sorbates, for clinoptilolite and a range of acid treated clinoptilolites.

When the volumes sorbed (as cm^3 of liquid per 100 g of outgassed sorbent at $p/p_0 = 0.5$) are plotted as functions of the molecular volume of the sorbate, the curves of Fig. 5 are obtained. Except in the case of the original clinoptilolite, well-defined maxima appear; in all cases molecular sieve effects are seen which result in substantial reductions in the volumes sorbed for the larger sorbates.

DISCUSSION AND CONCLUSION

To check the reproducibility of the chemical treatment of the clinoptilolite a second treatment of a new sample of the zeolite with 1 *N* acid was given. For the two treatments the amounts of alumina were 3.5% and 3.6% respectively, the monolayer equivalent areas to nitrogen were 370 and 361 m^2 per g respectively, and the sorptions of methanol and ethanol were also almost unchanged. Thus, good control appears to be possible in the formation of sorbents from clinoptilolite. However, color changes, which may be evidence of catalytic activity, were observed in a number of instances. For example, after sorption of ethanol in the sorbent obtained with 15 *N* acid and outgassed at 350° C, the sorbent became blue. The '2 *N*' and '5 *N*' sorbents became black after adsorption of benzene and outgassing at 350° C, while '0.5 *N*' and '1 *N*' sorbents also darkened after occlusion of methanol and outgassing, although here the change of color was less marked. While the character of these reactions is so far unknown, they may in part correspond to deposition of carbon associated with catalytic cracking.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

From Table III about 10 cm³ of liquid benzene are seen to be imbibed per 100 g of H-clinoptilolite obtained by treatment with 1, 2, and 5 *N* acid, while a comparable uptake was observed also in H-mordenite (11). In the best H-clinoptilolite for the purpose, Table III also shows that 6.5 cm³ of liquid isopentane were imbibed, as compared with 7.5 cm³ of liquid neopentane in H-mordenite (11). Evidently the sorption capacity for these size-able hydrocarbon molecules is very similar for H-mordenite and for appropriate H-forms of clinoptilolite.

By condensation polymerization, starting with monosilicic acid, one may prepare extremely fine-pored but amorphous silicas (12). This procedure is the antithesis of that which we have used but has yielded sorbents with much molecular sieve character. Thus in a particular sample the pore volume accessible to small molecules such as nitrogen was 10 cm³ per 100 g, to benzene it was 4 cm³ and to carbon tetrachloride (equal in size to neopentane) only 2 cm³. Thus much of the porosity of this gel is less accessible to larger molecules than are either the crystalline H-clinoptilolites or H-mordenite, and certainly than sodium faujasite (13). The same also can be said of certain carbon sorbents (14). Thus amorphous sorbents can actually overlap substantially in pore accessibility and inaccessibility with some crystalline molecular sieves, although they show a less clear cut-off in accessibility of the pores as the molecular size of the sorbate is increased.

The behavior which we have observed and studied for clinoptilolite should be found with other siliceous zeolites such as mordenite, ferrierite, yugawaralite, or the synthetic lithium zeolite of Barrer and White (15). Although no details are available it is probable that hydrogen-"Zeolon" is produced by acid treatment of sodium-"Zeolon", which is a synthetic mordenite (16). The interesting possibility is thus revealed of multiplying the number of porous molecular sieve sorbents, and the range and type of these, by complete hydrogen ion exchange, and also of subsequently altering the hydrogen ion content in a regulated manner, and hence of modifying the catalytic activity, by removal of various amounts of aluminum from the framework. It is intended to study further, with other zeolites, the preparation and properties of such new molecular sieve materials, using the methods of this paper and other previously developed methods of hydrogen ion exchange of zeolites (17, 18).

One of us (M. B. M.) took part in this work while on sabbatical leave from the University of Aleppo, Syria. We are indebted to Dr. I. S. Kerr of these laboratories for the electron optical investigation.

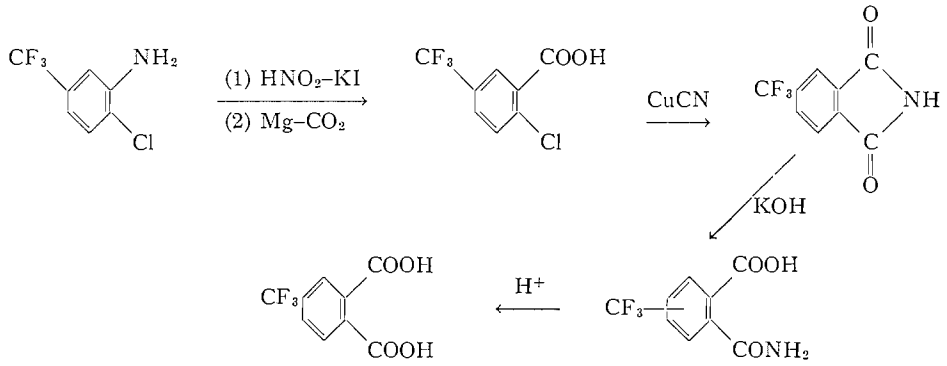
NOTES

SYNTHESIS OF 4-TRIFLUOROMETHYLPHTHALIC ACID

BERNARD LOEV

During a study of reactions of phthalic acids, it became necessary to prepare 4-trifluoromethylphthalic acid (I). This compound, not previously described, proved to be unexpectedly difficult to prepare; most of the standard methods either failed entirely or gave, at some stage in the reaction sequence, such low yields as to be unsuitable for preparative purposes. In this paper, we describe a convenient synthesis of this compound.

The synthetic scheme is outlined below and proceeds from the commercially available 3-amino-4-chlorobenzotrifluoride.

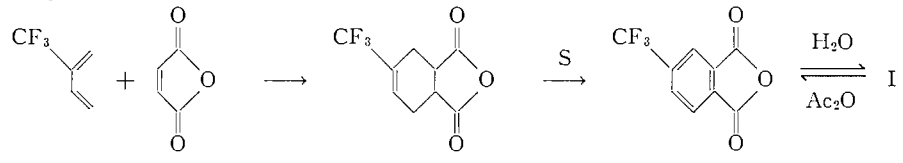


I

Reaction of 2-chloro-5-trifluoromethylbenzoic acid with cuprous cyanide gave 4-trifluoromethylphthalimide (70% yield) rather than the expected 2-cyano-5-trifluoromethylbenzoic acid.

4-Trifluoromethylphthalimide, on being stirred with base, gave the phthalamic acid, which, on being warmed with dilute acid, gave I. The hydrolysis of the imide can be carried out without isolation of the phthalamic acid; in this way, I is obtained in 90% yield.

Another far less satisfactory route to I involved the Diels–Alder reaction. Dehydrogenation of the adduct (II) was accomplished in 30% yield by heating it with sulphur at 230 to 250° C.



II

Adduct II could not be aromatized using chloranil, bromine, or palladium-on-carbon in refluxing quinoline or dimethylformamide. 4-Trifluoromethylphthalic anhydride, surprisingly, was a very fluid liquid; on being heated with water it was reconverted to the acid (I).

This route to I was not suitable on a preparative scale because of the difficulty of obtaining 2-trifluoromethylbutadiene; this difficulty has been observed by others (1, 2).

Some of the other methods that were investigated, unsuccessfully, for the synthesis of I were via diazotization of 3-nitro-4-aminobenzotrifluoride and 3,4-diaminobenzotrifluoride (in attempts to prepare the corresponding nitriles), via oxidation of 5- or 6-trifluoromethyl isatins,[1] via a Rosenmund–vonBraun reaction on 2-nitro-3-chlorobenzotrifluoride,[2] and via reaction of 4-carboxyphthalic ester and anhydride with sulphur tetrafluoride.

EXPERIMENTAL[3]

3-Iodo-4-chlorobenzotrifluoride

Two 22-liter three-necked round-bottom flasks equipped with an efficient stirrer, addition funnel, and thermometer were charged with 2 liters of concentrated sulphuric acid in 4 liters of water. To this hot solution was added rapidly 616.5 g (3 moles, 95% pure) of 3-amino-4-chlorobenzotrifluoride,[4] after which the solution was slowly cooled to 0–5° C with vigorous stirring. The suspension of the white sulphate salt was then diazotized with a solution of 207 g of sodium nitrite (3 moles) in 840 ml of water. After this addition was completed, there was added 549 g (3.3 moles) of potassium iodide in 815 ml of water over a period of 25 minutes. The brown oily mixture was then heated to 50° C for 1 hour, cooled in an ice water bath, and extracted with three 5 liter portions of ether. The ether extracts were washed with an aqueous solution of sodium thiosulphate, then water, and finally dried over anhydrous magnesium sulphate. The ether solution was filtered and concentrated, and the reddish-colored residue was distilled at 58–60° C (0.5 mm) to give 1620 g (83.5%) of a pink-colored liquid. Anal. Calc. for $C_7H_3ClF_3I$: C, 27.44; H, 0.98. Found: C, 27.37; H, 0.96.

2-Chloro-5-trifluoromethylbenzoic Acid

A 22-liter three-necked round-bottom flask equipped with an efficient stirrer, condenser, gas inlet tube, thermometer, and addition funnel was charged with 150 g (6.25 moles) of magnesium and 2 liters of ether. This solution was kept under a nitrogen atmosphere, as, with vigorous stirring, the solution was heated to reflux, at which time a few drops of ethylene bromide and 1620 g of 3-iodo-4-chlorobenzotrifluoride in 9400 ml of ether was added over a period of 2 hours. The mixture was refluxed and stirred vigorously for another 2 hours, and 1 ml of ethylene bromide was added after each hour. The mixture was cooled to −20° C in a dry ice – acetone bath and 800 g (18.2 moles) of dry carbon dioxide was bubbled into it over a period of 90 minutes. After it was allowed to stand overnight at room temperature, the reaction mixture was hydrolyzed at 0° C with 3 liters of cold 10% hydrochloric acid and was then extracted with three 2-liter portions of ether, and the ethereal solutions extracted with three 2-liter portions of a 10% potassium carbonate solution. The aqueous solution was treated with a small amount of charcoal and the solution filtered. Acidification of the filtrate with concentrated hydrochloric acid gave 663 g (49.5%) of an off-white material which was recrystallized from benzene–petroleum ether, m.p. 91–92° C. Anal. Calc. for $C_8H_4ClF_3O_2$: C, 42.78; H, 1.80. Found: C, 42.91; H, 1.89.

4-Trifluoromethylphthalimide

A mixture of 50 g (0.223 mole) 2-chloro-5-trifluoromethylbenzoic acid, and 30 g (0.335 mole) cuprous cyanide in 80 ml dimethylformamide was heated at reflux, with stirring, for 45 minutes. The resulting dark suspension was cooled slightly, and a solution containing 75 g of ferric chloride and 25 ml of concentrated hydrochloric acid in 125 ml of water was added over a period of 5 minutes. The mixture was then heated at 65° C for 15 minutes, chilled, diluted with 50 ml of ice water, and filtered. The dark brown solid was triturated with 5% sodium bicarbonate and filtered, giving 46.5 g of 4-trifluoromethylphthalimide, m.p. 164–166° C. A small sample recrystallized from benzene melted at 168.5–169.5° C. Anal. Calc. for $C_9H_4F_3NO_2$: C, 50.25; H, 1.87; N, 6.51. Found: C, 50.35; H, 1.85; N, 6.74.

4- (or 5)-Trifluoromethylphthalamic Acid

A suspension of 0.5 g 4-trifluoromethylphthalimide in 2.5 ml of 25% potassium hydroxide was stirred for 4 hours; then sufficient water was added to dissolve all the solid. The solution was cooled and acidified. The resulting waxy white solid was recrystallized from a mixture of isopropanol and hexane, m.p. 154–155° C. Anal. calc. for $C_9H_6F_3NO_3$: C, 46.36; H, 2.59. Found: C, 46.38; H, 2.94.

[1]*The oximino acetanilides could not be cyclized to the isatins as claimed by P. M. Maginnity and C. A. Gaulin. J. Am. Chem. Soc. 73, 3579 (1951).*

[2]*On mixture with potassium cyanide in dimethyl formamide there was no reaction. When sodium cyanide was used the reaction was almost explosively exothermic, but no product could be isolated.*

4-Trifluoromethylphthalic Acid

(a) From 4-Trifluoromethylphthalimide

A suspension of 1 g 4-trifluoromethylphthalimide in 5 ml of 25% potassium hydroxide was stirred for 10 hours, then the solution was made strongly acidic with concentrated hydrochloric acid. The solution was heated at reflux for 1 hour, filtered, then chilled, giving 0.9 g of a glistening waxy solid. Recrystallization from water gave the 4-trifluoromethylphthalic acid as a partial hydrate. Anal. calc. for $C_9H_5F_3O_4.3/4\ H_2O$: C, 43.83; H, 2.64. Found: C, 43.84; H, 2.38.

Prolonged drying at 100° C *in vacuo* did not remove the water. The melting point varied with the rate of heating and temperature at which the sample was placed in the melting point bath (phthalic acid shows the same behavior). After recrystallization from benzene, the sample analyzed the anhydrous form, and melted smoothly at melting point 169–170° C. The infrared was identical with that of a sample prepared via the Diels–Alder reaction, described below. Anal. calc. for $C_9H_5F_3O_4$: C, 46.17; H, 2.15. Found: C, 45.76; H, 2.50.

(b) Via Diels–Alder Reaction

A solution of 5 g (0.041 mole) 2-trifluoromethylbutadiene(2) and 4 g (0.041 mole) maleic anhydride in benzene was placed in a sealed bottle and kept at room temperature for 2 hours, then heated at 100° C for 8 hours. The solution was cooled and diluted with hexane. The precipitated 4-trifluoromethyltetrahydrophthalic anhydride was filtered (8 g) and recrystallized from benzene–hexane, m.p. 107–107.5° C (lit. (1) m.p. 107°).

The anhydride (5 g, 0.0228 mole) and 2 g sulphur were heated to 240° C in an oil bath, and maintained at 240–250° C for 3 hours. On cooling, the unreacted sulphur separated. Isopropyl ether was added and the sulphur was filtered off. The filtrate, on evaporation, left 4-trifluoromethylphthalic anhydride as a fluid oil. The oil was boiled with water until it all dissolved (approx. 15 minutes), then the solution was concentrated *in vacuo* leaving 5 g of a viscous oil. This was taken up in a large volume of benzene, then the solution was concentrated to 10 ml and cooled. The product separated as a white solid, m.p. 165–167° C. When a sample of the acid was refluxed with acetic anhydride for 1 hour, then concentrated, it was reconverted to the liquid anhydride.

addition of pyridine to the reactants. Such an enhancement of catalytic activity of cobalt carbonyls by the addition of tertiary amines has been noted previously (3, 4). An even more dramatic increase in yield of cyclized product was achieved by the inclusion of benzylamine with the reactants. The critical dependence of cyclized product on the quantity of hydrogen was clearly shown by the fact that when the mole ratio of hydrogen to substrate was greater than 1:1, then both N-benzylphthalimidine and ureas were simultaneously produced.

The inability of phenylacetonitrile to undergo cyclization with carbon monoxide and hydrogen might be explained by the fact that the nitrile group was not conjugated with the aromatic ring. A similar lack of reactivity of non-conjugated imino groups of Schiff bases towards carbon monoxide has been previously observed (5).

In an attempt to ascertain the probable mechanism of cyclization, benzonitrile was also reacted with mixtures of carbon monoxide, hydrogen, and deuterium, and the structures of the partially deuterated N-benzylphthalimidines determined by proton nuclear magnetic resonance analysis. In two different experiments in which the deuterium content was varied (as shown in the Experimental section) the cyclic methylene group contained less than 50% normal hydrogen and approximately the same amount as that of the exocyclic methylene group. It would therefore appear that the direct transfer of the ortho hydrogen on the aromatic ring to the carbon of the C≡N group cannot be simultaneous with the cyclization process as envisaged by Murahashi and Horiie (5), but rather the catalyst must first extract the ortho hydrogen to yield a cobalt hydrocarbonyl. The latter must then rapidly equilibrate with deuterium to yield a mixture of deuterated and normal hydrogen cobalt carbonyl. Subsequent transfer of hydrogen or deuterium to the carbon would then account for the fact that the cyclic methylene group had less than one normal hydrogen atom. As attempts to isolate the reactive intermediate by chromatographic procedures were unsuccessful, further work on a study of the mechanism was abandoned.

EXPERIMENTAL

General Considerations

These have been described previously (2, 10).

Reaction of Benzonitrile with Carbon Monoxide and Hydrogen

A typical experiment was as follows.

Benzonitrile (3 g) was allowed to react with carbon monoxide (2120 p.s.i. containing 0.04% hydrogen), hydrogen (70 p.s.i., 0.035 mole), benzylamine (3.5 g), and pyridine (0.5 g) in the presence of dicobalt octacarbonyl. Work-up of the product afforded 3.1 g of solid organic material (A) and 2 g of insoluble cobalt containing residue (B).

Alumina chromatography of material (A), using benzene–chloroform (4:1 by volume) as developer, yielded the following:

(1) 0.08 g of unreacted benzonitrile;
(2) 0.08 g of slightly impure N-formyl piperidine (indicated by n.m.r. analysis);
(3) 0.65 g (42%) of N-benzylphthalimidine;
(4) 0.25 g (16%) of N,N′-dibenzylurea.

Each of the fractions was confirmed by direct comparison with authentic samples.

Insoluble Material (B)

Anal. Found: C, 16.09; H, 1.86; N, 8.20. As the chemical analyses of different samples varied considerably, no further work was done on them.

Reaction of Benzonitrile with Carbon Monoxide and Deuterium

Procedure 1

This was similar to that described above except that 50 p.s.i. of deuterium was used instead of hydrogen, and benzylamine was excluded.

Nuclear magnetic resonance of partially deuterated N-benzylphthalimidine showed cyclic methylene group (0.50 H and 1.50 D); exocyclic methylene group (0.40 H and 1.60 D).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Procedure 2

This was the same as procedure 1 except that 40 p.s.i. of deuterium was used.

Nuclear magnetic resonance of deuterated N-benzylphthalimidine showed cyclic methylene group (0.76 H and 1.24 D); exocyclic methylene group (0.76 H and 1.24 D).

THE MOLECULAR CONFORMATION OF TRIPHENYLARSINE

M. J. ARONEY, R. J. W. LE FÈVRE, AND J. D. SAXBY

Trotter (1, 2) has recently shown, from an X-ray examination of tri-*p*-tolylarsine and tri-*p*-xylylarsine in the crystal state, that the aromatic rings in each molecule are similarly disposed relatively to the symmetry (C_3) axis. He defines the ring orientations within a molecule by angles of rotation, $\alpha°$, from an ideal model having maximum interaction of the arsenic lone pair and the aromatic π-electrons, the three rotations being in the same sense. For tri-*p*-tolylarsine the mean value of α is given as 36° and for tri-*p*-xylylarsine as 37° (the individual ring rotations for this molecule are reported as 34.6°, 37.0°, and 38.0°).

The conformations thus described agree remarkably well with that found by Aroney, Le Fèvre, and Saxby (3) for triphenylarsine in benzene solution. In our work, electric birefringence and polarity measurements [$_{\infty}(_{m}K_2) = -37.6 \times 10^{-12}$; $\mu = 1.23$ D] were interpreted as indicating a preferred conformation for triphenylarsine in which the angles of rotation (α) of the phenyl groups were 37 ± 3°. It should be noted that ϕ in ref. 3 is the complement of α. Solution of equation (3) in ref. 3 for ϕ required a knowledge of the bond angle C—As—C, which, for these calculations, was assumed to be 96° as quoted by Kuz'min and Kamai (4). If, however, the mean C—As—C angle (102°) newly reported by Trotter (1, 2) is utilized, then α for triphenylarsine as a solute in benzene is calculable as 40 ± 3°.

BONDING IN THE SULPHITE ION

E. A. ROBINSON

Recently (1), R. J. Gillespie and the author discussed the nature of bonding in compounds containing sulphur–oxygen bonds and obtained a linear correlation between their bond orders and force constants. The general applicability of such a relationship was discussed later (2).

A bond order of 1.13 was calculated for the S–O bonds in the sulphite ion on the basis of incorrect values of the stretching frequencies. Investigations of the Raman spectra of the sulphite ion in aqueous solution (and of solid Na_2SO_3) by Simon and Waldmann (3) led to assignments of the stretching frequencies at 925 cm^{-1} (symmetric stretch) and 966 cm^{-1} (asymmetric stretch). These authors calculate a force constant, k_{SO}, of 5×10^5 dynes cm^{-1} for the S–O bonds in SO_3^{2-} while direct calculation from the stretching frequencies by the simple method we used previously (1), gives $k_{SO} = 5.70 \times 10^5$ dynes cm^{-1} [i.e. $\nu_{SO} = (\nu_{sym} + \nu_{asym})/2 = 953\ cm^{-1}$, and $k_{SO} = 0.6282\ \nu_{SO}^2$].

On the basis of the linear relation between force constant and bond order [$n = 1.11\times 10^{-6}k_{SO} + 0.7$ (1)], $k_{SO} = 5.7\times10^5$ corresponds to a bond order of *1.33*, consistent with the valence bond formulation I, for which the bond length should be 1.54 Å.

It was suggested recently (4) that in sulphur–oxygen compounds a double bond orbital occupies approximately the same amount of space in the valency shell of the sulphur atom as does a lone pair orbital. Thus a bond order of 1.33 for the sulphite ion is consistent with this idea which would predict a structure for SO_3^{2-} similar to that established for the sulphate ion II (1), with a lone pair in place of one of the double bonds.

It was also shown that the bond order of the Cl–O bonds in the chlorate ion is also near to $1\frac{1}{3}$, consistent with structure III, which may be regarded as formed from the perchlorate ion IV by replacing a double bond by a lone pair of electrons. It thus appears likely that the sulphite ion and the chlorate ion, which are isoelectronic, have similar molecular structures.

Recently (1), R. J. Gillespie and the author discussed the nature of bonding in compounds containing sulphur–oxygen bonds and obtained a linear correlation between their bond orders and force constants. The general applicability of such a relationship was discussed later (2).

A bond order of 1.13 was calculated for the S–O bonds in the sulphite ion on the basis of incorrect values of the stretching frequencies. Investigations of the Raman spectra of the sulphite ion in aqueous solution (and of solid Na_2SO_3) by Simon and Waldmann (3) led to assignments of the stretching frequencies at 925 cm^{-1} (symmetric stretch) and 966 cm^{-1} (asymmetric stretch). These authors calculate a force constant, k_{SO}, of 5×10^5 dynes cm^{-1} for the S–O bonds in SO_3^{2-} while direct calculation from the stretching frequencies by the simple method we used previously (1), gives $k_{SO} = 5.70 \times 10^5$ dynes cm^{-1} [i.e. $\nu_{SO} = (\nu_{sym} + \nu_{asym})/2 = 953\ cm^{-1}$, and $k_{SO} = 0.6282\ \nu_{SO}^2$].

On the basis of the linear relation between force constant and bond order [$n = 1.11\times 10^{-6}k_{SO} + 0.7$ (1)], $k_{SO} = 5.7\times10^5$ corresponds to a bond order of *1.33*, consistent with the valence bond formulation I, for which the bond length should be 1.54 Å.

It was suggested recently (4) that in sulphur–oxygen compounds a double bond orbital occupies approximately the same amount of space in the valency shell of the sulphur atom as does a lone pair orbital. Thus a bond order of 1.33 for the sulphite ion is consistent with this idea which would predict a structure for SO_3^{2-} similar to that established for the sulphate ion II (1), with a lone pair in place of one of the double bonds.

It was also shown that the bond order of the Cl–O bonds in the chlorate ion is also near to $1\frac{1}{3}$, consistent with structure III, which may be regarded as formed from the perchlorate ion IV by replacing a double bond by a lone pair of electrons. It thus appears likely that the sulphite ion and the chlorate ion, which are isoelectronic, have similar molecular structures.

THE SYNTHESIS OF ANHYDROUS ZIRCONIUM TRICHLORIDE

B. SWAROOP AND S. N. FLENGAS

INTRODUCTION

Zirconium trichloride was first prepared by Ruff and Wallstein (1) by the reduction of zirconium tetrachloride with aluminum. The product, however, was contaminated with up to 4 weight % aluminum metal, and also contained oxygen. Larsen and Leddy (2) eliminated the aluminum contamination by carrying the reaction at 500° C in sealed pyrex ampoules containing stoichiometric amounts of zirconium tetrachloride, and aluminum or zirconium metal powders as the reductants. To prevent the explosion of the system, because of the vaporization of the excess zirconium tetrachloride during the initial stage of the reaction, the ampoules were placed within a stainless steel pressurized container filled with nitrogen gas. The gas pressure inside the bomb was then regulated to match the internal pressure of zirconium tetrachloride in the system, and pressures as high as 15 atmospheres were found necessary.

Under these conditions, $ZrCl_3$ of a maximum purity of only 85 weight % was obtained, the remainder being $ZrCl_2$ formed by disproportionation. The method was applied only to small quantities of zirconium tetrachloride (about 1 g) because of the obvious difficulty in balancing accurately the pressure in the system during the reaction.

In the present investigation, zirconium trichloride of a purity over 98 weight % was produced by the direct reaction between finely divided zirconium metal and zirconium tetrachloride at atmospheric pressure. The method, although essentially a batch process, could be adopted for preparation of larger quantities of the compound, if required.

EXPERIMENTAL AND RESULTS

Hafnium-free zirconium tetrachloride of commercial grade was further purified by double sublimation in vacuum in the presence of finely divided copper filings. The front and end tailings of the distillate were rejected and the middle portion was stored in sealed containers. Reactor grade zirconium metal containing less than 200 p.p.m. Hf was filed in a dry box filled with nitrogen gas to a particle size of about 80 mesh.

The zirconium trichloride was produced by the direct reaction:

[1] $$3ZrCl_{4\ (gas\ at\ 1\ atm)} + Zr_{(s)} = 4ZrCl_{3\ (s)}.$$

Figure 1 shows the reaction apparatus which was constructed from quartz glass.

The zirconium tetrachloride was placed in the right-hand compartment of the reaction cell, and the finely divided zirconium metal was placed in the left-hand compartment, which was completely lined with either zirconium or platinum foil. The cell was then evacuated and heated under vacuum to about 150° C for 6–8 hours, and then the ends were flame sealed under vacuum. The part of the reaction tube containing the zirconium metal was then heated slowly to about 700° C–750° C, while the compartment containing the zirconium tetrachloride in the system was heated to 330° ± 2° C. At this temperature, the pressure of zirconium tetrachloride vapor in the system was about 1 atm. To prevent the condensation of $ZrCl_4$, the two compartments were separated by a ¼ in. diameter quartz tube which was also heated to about 350° C.

THE SYNTHESIS OF ANHYDROUS ZIRCONIUM TRICHLORIDE

B. SWAROOP AND S. N. FLENGAS

INTRODUCTION

Zirconium trichloride was first prepared by Ruff and Wallstein (1) by the reduction of zirconium tetrachloride with aluminum. The product, however, was contaminated with up to 4 weight % aluminum metal, and also contained oxygen. Larsen and Leddy (2) eliminated the aluminum contamination by carrying the reaction at 500° C in sealed pyrex ampoules containing stoichiometric amounts of zirconium tetrachloride, and aluminum or zirconium metal powders as the reductants. To prevent the explosion of the system, because of the vaporization of the excess zirconium tetrachloride during the initial stage of the reaction, the ampoules were placed within a stainless steel pressurized container filled with nitrogen gas. The gas pressure inside the bomb was then regulated to match the internal pressure of zirconium tetrachloride in the system, and pressures as high as 15 atmospheres were found necessary.

Under these conditions, $ZrCl_3$ of a maximum purity of only 85 weight % was obtained, the remainder being $ZrCl_2$ formed by disproportionation. The method was applied only to small quantities of zirconium tetrachloride (about 1 g) because of the obvious difficulty in balancing accurately the pressure in the system during the reaction.

In the present investigation, zirconium trichloride of a purity over 98 weight % was produced by the direct reaction between finely divided zirconium metal and zirconium tetrachloride at atmospheric pressure. The method, although essentially a batch process, could be adopted for preparation of larger quantities of the compound, if required.

EXPERIMENTAL AND RESULTS

Hafnium-free zirconium tetrachloride of commercial grade was further purified by double sublimation in vacuum in the presence of finely divided copper filings. The front and end tailings of the distillate were rejected and the middle portion was stored in sealed containers. Reactor grade zirconium metal containing less than 200 p.p.m. Hf was filed in a dry box filled with nitrogen gas to a particle size of about 80 mesh.

The zirconium trichloride was produced by the direct reaction:

[1] $$3ZrCl_{4\ (gas\ at\ 1\ atm)} + Zr_{(s)} = 4ZrCl_{3\ (s)}.$$

Figure 1 shows the reaction apparatus which was constructed from quartz glass.

The zirconium tetrachloride was placed in the right-hand compartment of the reaction cell, and the finely divided zirconium metal was placed in the left-hand compartment, which was completely lined with either zirconium or platinum foil. The cell was then evacuated and heated under vacuum to about 150° C for 6–8 hours, and then the ends were flame sealed under vacuum. The part of the reaction tube containing the zirconium metal was then heated slowly to about 700° C–750° C, while the compartment containing the zirconium tetrachloride in the system was heated to 330° ± 2° C. At this temperature, the pressure of zirconium tetrachloride vapor in the system was about 1 atm. To prevent the condensation of $ZrCl_4$, the two compartments were separated by a ¼ in. diameter quartz tube which was also heated to about 350° C.

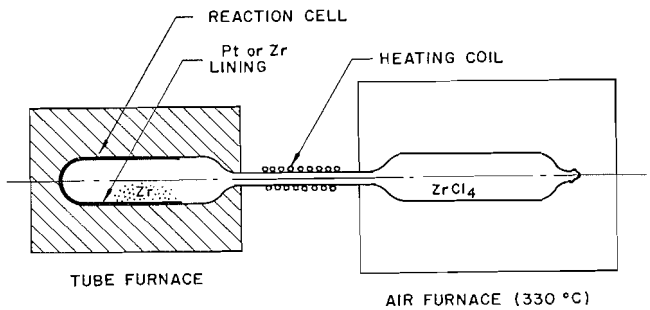

FIG. 1. Reaction apparatus.

It should be noted that all operations involving the handling and transfer of the reactive zirconium halides were done inside a dry box filled with nitrogen gas.

To drive reaction (1) to completion, and to avoid the possible disproportionation of the zirconium trichloride, an excess of zirconium tetrachloride was always present, i.e., 1.5 times the quantity required by the stoichiometry of the reaction. Thus, amounts of approximately 1 g of zirconium powder to about 12 g of zirconium tetrachloride were used in each of the preparations. The reaction time was about 72 hours. After the end of the run, the temperature of the zirconium trichloride compartment was gradually reduced to about 400° C, while that of the zirconium tetrachloride was reduced to about 250° C. When all the unreacted zirconium tetrachloride had been removed from the reaction site, the cell was rapidly cooled down, transferred to the dry box, and opened under an atmosphere of nitrogen gas.

The reaction products were free zirconium trichloride powder, and zirconium trichloride adhering to the surface of the unreacted zirconium metal. To separate the unreacted metal, the product was screened through a 200-mesh screen, and the zirconium trichloride was stored in sealed containers. The screened product was analyzed by three different methods.

(*a*) By the chlorine content determined by Volhard's method (3).

(*b*) By measuring the reducing power of the material with an $N/10$ ceric ammonium sulphate solution. To this purpose, 0.15 to 0.25 g of material was added to the solution containing the ceric salt, which was then back titrated with a $N/10$ sodium oxalate solution.

(*c*) By measuring the volume of hydrogen gas evolved when zirconium trichloride is added to distilled water, following the reaction:

$$[2] \qquad ZrCl_3 + H_2O = ZrOCl_2 + HCl + \tfrac{1}{2}H_2.$$

The results of analysis of the various batches are shown in Table I.

Zirconium trichloride is a blue-black powder which changes to brown when exposed to air. The compound dissolves in water to give a yellow-brown solution, but the color fades away when the solution is allowed to stand.

At high temperatures, both zirconium metal and zirconium tetrachloride react with the silica container in the reaction cell, and without the zirconium or platinum foil linings, all reaction efficiencies become much lower. The overall efficiency of the reaction before screening of the product is about 45%, and attempts to increase this efficiency by increasing the reaction temperature, failed. This is shown in Fig. 2, where the relative total efficiency of the reaction for the same amounts of reactants is plotted against temperature. The reaction time for the runs shown on the graph was always 72 hours. The effect of lining the reaction zone with zirconium and platinum foil is also indicated.

It is evident that the optimum temperature is about 700° C–750° C and that a platinum-lined cell gives only slightly higher efficiencies. The plateau of the efficiency curve in Fig. 2 indicates that the reaction reaches a pseudoequilibrium for that particular particle size of zirconium metal used in the study. It is probable that the reaction is diffusion controlled, and the use of more finely divided metal would increase the overall efficiency, and the purity of the product.

CONFORMATIONAL STUDIES OF THE CYCLOHEXANE RING BY NUCLEAR MAGNETIC RESONANCE. VII.* THE REACTION OF 1,4-CYCLOHEXANEDIOL WITH CONCENTRATED HYDROCHLORIC ACID

E. PREMUZIC AND L. W. REEVES

In our investigation of the chemistry of cyclohexane and its derivatives suitable for conformational analysis by n.m.r., we investigated a reported reaction for preparation of 4-chlorocyclohexanol. Owen and Robins (1) and Grewe *et al.* (2) reported a procedure in which a cis and trans mixture of 1,4-cyclohexanediol on treatment with an excess of fuming hydrochloric acid yields 4-chlorocyclohexanol in a good yield (more than 50%). We wish to comment on this reaction.

A mixture of *cis-* and *trans*-1,4-cyclohexanediol (0.98 moles) and concentrated hydrochloric acid (4.1 moles) was sealed in a Carius tube and then heated at 80–90° for 14 hours (1). On cooling of the reaction mixture an oily layer separated. The reaction mixture was then extracted with chloroform, washed with aqueous sodium bicarbonate, and dried over anhydrous sodium sulphate. Chloroform was removed by distillation. Fractional distillation of the residue at 4 mm yielded a colorless oil (75 g), b.p. 80–85°. The oily derivative was then cooled at −10°. A heavy white crystalline precipitate formed, which was collected and recrystallized from ethanol (F_1, m.p. 102–103°). The filtrate was redistilled at 5 mm, yielding 9 g of a colorless oil, b.p. 80–82°, n_D^{16} 1.4964, F_2, and 3 g of

* *VI in preparation.*

residue, F_3. The residue, on being cooled at $-10°$, yielded a small amount of white crystals identical with those collected in F_1 (mixed m.p. 102–102.8°). The mother liquor, F_4, was kept in cold for further investigation. The n.m.r. spectra of fractions F_1 to F_4 (30% solutions in carbon tetrachloride, with internal tetramethylsilane standard), recorded on a Varian A60 spectrometer, showed the following general pattern: F_1, no hydroxyl peak; F_2, hydroxyl peak present; F_3, crystals, identical spectra with F_1; F_4 showed presence of F_1 and a peak at low field. The F_2 fraction would thus seem to be consistent with the *cis–trans*-4-chlorocyclohexanol obtained by Owen and Robins (1). This fraction was then oxidized with chromic acid to 4-chlorocyclohexanone (b.p. 81–90° at 12 mm). Melting point of the semicarbazone, 178°, is consistent with the result obtained by Grewe *et al.* (2). 4-Chlorocyclohexanone was then adjacently deuterated in the usual manner (5). Nuclear magnetic resonance spectra (30% solution in carbon tetrachloride, tetramethylsilane internal standard, Varian A60 spectrometer) have shown the expected nine lines (6) in the —CHCl— region ($\tau = 5.5$), the coupling constants being $|J| = 4.10 \pm 0.1$ c.p.s. and $|J| = 5.6 \pm 0.1$ c.p.s. (Fig. 1). Unlike 3,3,4,4,5,5-hexadeuterocyclohexanol where the two

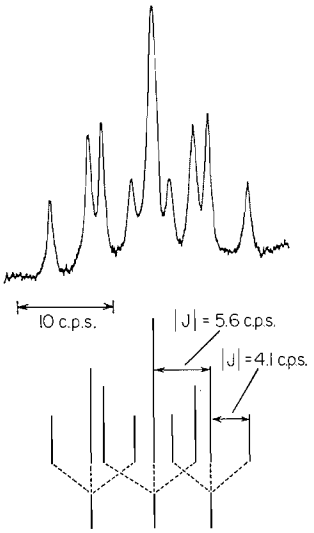

FIG. 1. C-4 proton resonance of 4-chlorocyclohexanone-2,2,6,6-d_4 at 60 Mc.

vicinal coupling constants are 9.77 and 3.93 c.p.s. (6), the ketone shows two almost equal coupling constants. The high-field $(AB)_2$ components of the spectrum were broad and marred by some 1,4-*trans*-dichlorocyclohexane, which was present as impurity. It was not possible to extract reliable chemical shift measurements in the high-field region. The values of these coupling constants in the ketone are indicative of two contributing pseudochair forms in which the carbon atoms of the cyclohexanone ring are much nearer a plane than in cyclohexane. This is reasonable in view of the trigonal carbon at the 1 position. An equally plausible explanation is the assumption that bond angles at the 3, 4, and 5 position are not appreciably distorted and the chlorine atom has ~60% probability of being axial. From the results obtained, it is evident that the reaction suggested by Owen and Robins (1) gives rise to only a small amount of 4-chlorocyclohexanol, viz., only 12% of the total yield.

Recently, Franzus and Hudson (3), and Russell and co-workers (4) reported an extensive study of 1,3-dibromocyclohexanes and 1,3- and 1,4-dichlorocyclohexanes. Acidic treatment, with either hydrobromic acid or hydrochloric acid of 1,4- (or 1,3-) cyclohexanediols yielded cis–trans mixtures of dihalogen-substituted cyclohexanes.

The bulk of our product (F_1), when isolated and recrystallized from ethanol, melts at 102–103°, in agreement with *trans*-1,4-dichlorocyclohexane prepared by Russell and co-workers by a similar procedure. Proton magnetic resonance spectra show a peak at $\tau = 5.9$ (Russell *et al.* $\tau = 5.82$), due to the methine protons in 1,4-dichlorocyclohexane, the C-1 and C-4 protons being predominantly diaxial. Proton magnetic resonance spectra of F_4 showed presence of *trans*-1,4-dichlorocyclohexane ($\tau = 5.9$) and a peak at $\tau = 5.67$, consistent with the signal due to methine protons of *trans*-1,3-dichlorocyclohexane (4). The reaction between 1,4-cyclohexanediol and hydrochloric acid was then followed up in the manner described below.

A series of Carius tubes each containing 0.98 moles of the diol and 4.1 moles of hydrochloric acid were sealed and heated at 80–90°. At regular intervals one tube was cooled, and the reaction mixture worked up as described at the beginning of the note. The isolated products were then analyzed by n.m.r. (30% carbon tetrachloride solution, int. TMS). In addition to unreacted material, 4-chlorocyclohexanol, 1,4-dichlorocyclohexane, peaks at $\tau = 4.45$ and $\tau = 2.9$ appeared. The $\tau = 4.45$ peak is consistent with formation of 1,4-cyclohexadiene and the $\tau = 2.9$ peak is consistent with formation of aromatic by-products. Presence of 1,3-dichlorocyclohexane in our F_4 fraction can thus be explained as due to the random addition of hydrochloric acid across the double bonds in 1,4-cyclohexadiene.

CONDENSATION OF HEXACHLOROCYCLOPENTADIENE WITH DIETHANOLAMINE*

Marwan R. Kamal and John E. Wicklatz

The reactivity of the allylic chlorine atoms in hexachlorocyclopentadiene and the ease of their displacement by nucleophiles had been previously demonstrated by other workers (1, 2). Recently, McBee and co-workers (3) demonstrated this type of reaction with secondary amines.

We wish to report the reaction between the amino alcohol diethanolamine and hexachlorocyclopentadiene. In this reaction the expected product (I) was not isolated. Instead, the spiro compound (II) resulting from the condensation of 1 mole of diethanolamine with hexachlorocyclopentadiene followed by a cyclization step with the elimination of a mole of hydrogen chloride was obtained.

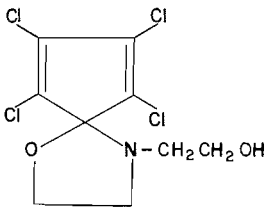
I

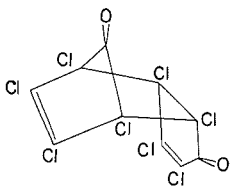


II

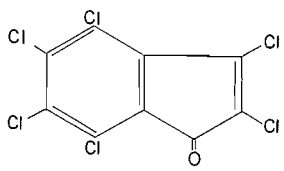
The structure of II was elucidated by mass spectrometry, nuclear magnetic resonance, and infrared spectra. The mass spectrum showed a parent peak at 303 (based on Cl^{35} isomer) with characteristic isotope peaks for an ion containing 4 Cl atoms. The n.m.r. spectrum showed a pair of triplets for the ring $—CH_2—N\langle$ and $—CH_2—O$ protons at 3.39 and 4.28 p.p.m. respectively. Another pair of triplets for the open chain $—CH_2—N\langle$ and $—CH_2—O$ protons was seen at 2.67 and 3.57 p.p.m. respectively. A single proton, attributed to —OH, was seen at 1.89 p.p.m. An examination of the n.m.r. spectrum of β-dimethylaminoethanol showed a pair of triplets at 2.38 and 3.50 p.p.m. for the $—CH_2—N\langle$ and $—CH_2—O$ protons respectively.

This cyclization is presumably favored over the further condensation of another diethanolamine molecule which would give the 5,5-bis-(dihydroxyethylamino)-1,2,3,4-tetrachlorocyclopentadiene (I). Steric factors probably contribute to the tendency toward cyclization.

The aminoketal product (II) is easily hydrolyzed in an acid medium to give octachloro-3a,4,7,7a-tetrahydro-4,7-methanoindene-1,8-dione (III). The diketone is undoubtedly the product obtained by the dimerization of the unstable intermediate tetrachlorocyclopentadienone (4).



III



IV

The diketone III was readily converted to hexachloroindone IV by treatment with aqueous acetone (5).

EXPERIMENTAL*

1-Oxa-4-hydroxyethylazaspiro[4.4]6,7,8,9-tetrachlorononona-6,9-diene [II]

Potassium hydroxide (22.4 g) was dissolved in 200 ml of isopropanol in a 500-ml, three-necked flask fitted with a stirrer, a thermometer, and a water-cooled condenser. Forty-two grams of diethanolamine and 54.6 g of hexachlorocyclopentadiene were added to the above solution. An immediate exothermic reaction occurred raising the temperature to about 75° C and a solid began to form. The flask was cooled with an ice-water bath to 30° C. The mixture was stirred for 48 hours while the temperature was maintained at 30° C ±5°. The solid which was formed was filtered and identified as potassium chloride. After removing the solvent under reduced pressure, the dark viscous residue was dissolved in benzene and extracted several times with a slightly acidic 20% sodium chloride solution until the aqueous phase was acidic. The organic phase was washed with water and then dried over anhydrous sodium sulphate. The solvent was then removed and pentane added to the residue.† After cooling in an ice bath 48.7 g of solid material was formed. The solid was dissolved in Skelly-B, the solution treated with charcoal, filtered, and the filtrate cooled to give 35.0 g (57%) of white needles II, m.p. 61–63° C. Anal. Calc. for $C_9H_9NO_2Cl_4$: C, 35.45; H, 2.97; N, 4.59; Cl, 46.51. Found: C, 35.76; H, 3.07; N, 4.91; Cl, 46.23.

The infrared spectrum of the product in carbon tetrachloride showed the following peaks between 6.17 and 10.47 μ: 6.17 (s), 6.29 (w-m), 8.28 (s), 8.54 (m), 8.86 (m), 9.32 (s), 9.97 (s), and 10.47 (s) μ.

Acid Hydrolysis of II

A solution of II (18 g) in 240 ml of acetone and 600 ml of concentrated hydrochloric acid was refluxed for 90 minutes. After the solution was cooled to room temperature, the precipitate was filtered. The solid was dried in a vacuum oven to give 11.9 g of III, m.p. 159–161° C dec. Recrystallization from hexane gave 11.7 g (92%) of pure product, m.p. 160–161° C dec.; λ_{max}^{KBr} 5.40 (s), 5.68 (s), 6.27 (s) μ; ϵ mol. = 9100 at 255 mμ in cyclohexane. Anal. Calc. for $C_{10}O_2Cl_8$: Cl, 65.09. Found: Cl, 64.90.

REARRANGEMENT STUDIES WITH ^{14}C. XX. SOME OBSERVATIONS ON REACTIONS BETWEEN GRIGNARD REAGENT, COBALTOUS BROMIDE, AND 2-PHENYLETHYL BROMIDE

C. C. Lee and D. P. Thornhill*

In a previous paper (1), it was demonstrated that contrary to an earlier report of Smith and Anderson (2), the reaction of 2-phenyl-1-^{14}C-ethyl bromide with magnesium and cobaltous bromide in refluxing ether gave ethylbenzene and styrene with no isotope position rearrangement. Since this reaction has some resemblance to the cobaltous halide catalyzed reaction between a Grignard reagent and an organic halide (designated by Slaugh (3) as the Kharasch reaction), which is believed to involve intermediate free radicals

**Holder of a Commonwealth Scholarship, 1961–63.*

(4), Smith and Anderson suggested an adaptation of the Kharasch mechanism, explaining the formation of ethylbenzene and styrene as arising from the 2-phenylethyl radical. It should be noted, however, that considerable differences exist between the experimental conditions of Kharasch and those of Smith and Anderson. In the Kharasch reaction, the organic halide is added to an ether solution of a Grignard reagent, usually phenylmagnesium halide, containing only a catalytic amount of cobaltous salt. The major products are saturated and olefinic hydrocarbons, and biphenyl. Under the conditions of Smith and Anderson (2), the organic halide, magnesium, and an *excess* of cobaltous halide are refluxed together in a relatively large volume of ether. As an attempt to shed some light on possible mechanistic differences between these reactions, interactions between Grignard reagent, cobaltous bromide, and 2-phenylethyl bromide (I) or 2-phenyl-1-^{14}C-ethyl bromide (I-^{14}C), under various experimental conditions, were studied and the results reported in this communication.

The observations from these studies are summarized in Table I. In the experiments where radioactive reactants were used, the mixtures of ethylbenzene (II) and styrene (III) were hydrogenated to II and then oxidized to benzoic acid whose activity measured the extents of ^{14}C-rearrangement (1).

The reaction conditions of expts. 1–3 were analogous to those used by Urry and Kharasch (5) in their study on the cobaltous chloride catalyzed reaction between phenylmagnesium bromide and neophyl chloride, which gave products attributable to rearrangement of the neophyl radical. The 0.5% isotope position rearrangement observed in expts. 1 and 2 (Table I) is real, indicating the occurrence of small amounts of a net 1,2-phenyl shift, possibly involving the 2-phenylethyl radical.

The Kharasch conditions were again used in expts. 4 and 5; but instead of phenylmagnesium bromide, phenylethylmagnesium bromide was employed. The 0.1% rearrangement may be of some significance as it corresponded to observed activities of about three times background for benzoic acid samples weighing about 15 mg. Such amounts of activity likely were beyond the experimental errors. The yields of II and III, as well as their relative compositions, are significantly different from those observed in expts. 1–3.

It is of interest to record that the specific activity of the 2-phenyl-1-^{14}C-ethylmagnesium bromide used in expt. 4 and that of the 2-phenyl-1-^{14}C-ethyl bromide (I-^{14}C) used in expt. 5 were the same, each equalling 5.40×10^5 c.p.m./mmole. The specific activities of the mixed products II and III from expts. 4 and 5 were, respectively, 3.02×10^5 and 2.08×10^5 c.p.m./mmole. If interchange of 2-phenylethyl groups between Grignard reagent and organic halide were complete before decomposition, the specific activities of II and III would be one-half of that of the active starting material. The data obtained suggest that complete interchange was not established before decomposition, as was observed recently by Parker and Noller (6) in their studies with isopropylmagnesium bromide and isopropyl bromide. Apparently, more of II and III were derived from the Grignard reagent than from the organic halide. Possibly, in expts. 4 and 5, two processes may be superimposed on each other. One of these might be a cobaltous bromide catalyzed decomposition of the Grignard reagent itself, which does not give any rearrangement. The other might be a cobaltous bromide catalyzed reaction between Grignard reagent and organic halide (the Kharasch reaction), which is capable of giving a small amount of rearrangement as observed in expts. 1 and 2.

In expts. 6–11, the use of excess cobaltous bromide and larger volumes of ether approximated the conditions of Smith and Anderson. In these trials, the Grignard reagent was first prepared and then the excess cobaltous bromide was introduced. This was followed,

*II and III are ethylbenzene and styrene, respectively.
†Percentage yields for expts. 1–5 were based on organic halide; those for expts. 6–12 were based on the Grignard reagent.
‡Yields of biphenyl or cobalt metal were based on the Grignard reagent.
§From treatment of reaction mixture with Dry Ice, indicating presence of unreacted Grignard reagent. No hydrocinnamic acid was obtained from Dry Ice treatment of reaction mixtures from expts. 4–11.

in some cases, by the addition of organic halide I or I-^{14}C (expts. 6–9). Most of the added I or I-^{14}C was recovered at the end of the reaction, indicating that the organic halide is not a reactant. The data from expts. 6–11 clearly show that reaction between 2-phenylethylmagnesium bromide and excess cobaltous bromide can take place, the identified products being II and III, with no rearrangement, and cobalt metal (there was no attempt to isolate cobalt metal from expts. 6 and 7). When 2-phenylethylmagnesium bromide in dilute ether solution was treated with only a small amount of cobaltous bromide (expt. 12), a very low yield of II and III was obtained, and the presence of unreacted Grignard reagent was indicated by its carbonation to hydrocinnamic acid.

The results discussed above strongly indicate that reaction of 2-phenylethyl bromide with magnesium and cobaltous bromide under the conditions of Smith and Anderson likely follow a course different from that of the Kharasch reaction. In the presence of excess cobaltous bromide, 2-phenylethylmagnesium bromide may give rise to unstable organocobalt (7), which decomposes to ethylbenzene (II), styrene (III), and cobalt metal. Such a decomposition may not even involve the actual liberation of free radicals (4). If the assumption is made that the 2-phenylethyl radical is an intermediate in all of the reactions investigated, the predominance of II over III in the products, the very small amount of 1,2-phenyl shifts under the Kharasch conditions, and the complete lack of such shifts under the conditions of Smith and Anderson might be rationalized, as discussed previously (1), on the basis of a predominance of hydrogen abstraction and a lack of sufficiently high reaction temperature to overcome the activation energy for the 1,2-shift. The complexity of the Kharasch reaction has been shown by some recent experiments (3, 6). In particular, Parker and Noller (6) have suggested that in the metal halide catalyzed reaction between alkylmagnesium halide and alkyl halide, part of the reaction may be due to decomposition of a molecular complex of Grignard reagent, alkyl halide, and catalyst to give equivalent amounts of saturated and olefinic hydrocarbons while another portion of the reaction proceeds via free radical hydrogen abstraction to give only saturated hydrocarbon. The net result is more alkane than alkene in the overall products. Such possible processes might also be applied in explaining the present results.

EXPERIMENTAL

Experiments 1–3

To a solution of phenylmagnesium bromide, prepared from 9.5 g (0.061 mole) of bromobenzene and 1.7 g of magnesium in 50 ml of ether, 0.4 g (0.0018 mole) of anhydrous cobaltous bromide was introduced. A solution of 10.0 g (0.054 mole) of I or I-^{14}C in 10 ml of ether was then added dropwise. After about one-half of this solution was added, a further introduction of 0.4 g of cobaltous bromide was made before the addition of the remaining solution of I or I-^{14}C was completed. The resulting mixture was heated under reflux for 3 hours. Following decomposition with dilute hydrochloric acid, the monomeric products II and III were isolated and their relative composition measured by vapor phase chromatography as previously described (1).

After removal of II and III, further distillation under reduced pressure gave a second fraction which solidified on cooling. After recrystallization three times from methanol, colorless crystals were obtained which melted alone or on admixture with authentic biphenyl at 69–70° C.

Experiments 4 and 5

The Grignard reagent was prepared from 10.0 g (0.054 mole) of I-^{14}C or I and 1.7 g of magnesium in 50 ml of ether. The solution was treated with catalytic amounts of cobaltous bromide and 10.0 g (0.054 mole) of I or I-^{14}C in 10 ml of ether as in expts. 1–3. Dry Ice was added to the reaction mixture before it was worked up in the usual way (1). No hydrocinnamic acid was obtained from the alkaline extract after the Dry Ice treatment. Following the removal of the mixed products II and III, attempted further distillation of the residue failed to give any 1,4-diphenylbutane.

Experiments 6–9

The Grignard reagent was prepared from 10.0 g (0.054 mole) of I or I-^{14}C and 1.7 g of magnesium in 250 ml of ether. The solution was decanted under nitrogen to remove any excess magnesium. A total of 14.5 g

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(0.066 mole) of anhydrous cobaltous bromide was introduced, either in one batch or portionwise. The mixture turned dark and refluxing occurred without external heating. A solution of 10.0 g of I or I-^{14}C in 50 ml of ether was then added, either rapidly or dropwise. The resulting mixture was heated under reflux for 3 hours, treated with Dry Ice, and worked up to give II and III. Further distillation under reduced pressure gave unreacted I or I-^{14}C, identified by conversion to a solid derivative, hydrocinnamic acid.

In expts. 8 and 9, after removal of unreacted I, the residue was subjected to repeated washing with aqueous acetone followed by centrifugation. When the washing was colorless, the finely divided cobalt metal that remained was dried under vacuum and stored under nitrogen. It showed magnetic and pyrophoric properties. After dissolution in dilute hydrochloric acid, treatment with hydrogen sulphide gave a black precipitate.

Experiments 10–12

The solution of Grignard reagent was prepared from 10.0 g of I and 1.7 g of magnesium in 250 ml of ether. It was decanted from excess magnesium and then treated with 14.5 g or 0.8 g of cobalt bromide. After refluxing of the mixture for 3 hours, Dry Ice was added and the mixture worked up to give II, III, and cobalt metal. When only 0.8 g of cobalt bromide was used (expt. 12), 3.7 g (45%) of hydrocinnamic acid was recovered from the sodium hydroxide extract after the reaction mixture was treated with Dry Ice.

SYNTHESIS OF POTENTIAL ANTINEOPLASTIC AGENTS. XII. SOME BIS(2-CHLOROETHYL)AMINES CONTAINING A *p*-FLUOROPHENYL GROUP AND RELATED COMPOUNDS[1,2]

FRANK D. POPP AND DRU W. ALWANI

During the past few years we have prepared a large number of nitrogen mustard Schiff bases of the type I (1, 2, 3). One of the most promising compounds in this series (4) (I, R = H, R′ = CH_3, R″ = *p*-FC_6H_4—) was derived from *p*-fluoroaniline. In a series of compounds of the type II (5) the one derived from *p*-fluoroaniline (II, R = *p*-FC_6H_4—) was ranked the highest of the series in screening against an established Dunning leukemia in Fischer rats (4). In view of these results, it was decided to prepare a number of other bis(2-chloroethyl)amines containing a *p*-fluorophenyl group.

Reaction of the readily available (6) *p*-[N-bis(2-chloroethyl)amino]benzhydrazide with *p*-fluorobenzaldehyde gave the compound III. At the same time a number of other hydrazides related to III were prepared and these are listed in Table I. None of these

SYNTHESIS OF POTENTIAL ANTINEOPLASTIC AGENTS. XII. SOME BIS(2-CHLOROETHYL)AMINES CONTAINING A *p*-FLUOROPHENYL GROUP AND RELATED COMPOUNDS[1,2]

FRANK D. POPP AND DRU W. ALWANI

During the past few years we have prepared a large number of nitrogen mustard Schiff bases of the type I (1, 2, 3). One of the most promising compounds in this series (4) (I, R = H, R′ = CH_3, R″ = *p*-FC_6H_4—) was derived from *p*-fluoroaniline. In a series of compounds of the type II (5) the one derived from *p*-fluoroaniline (II, R = *p*-FC_6H_4—) was ranked the highest of the series in screening against an established Dunning leukemia in Fischer rats (4). In view of these results, it was decided to prepare a number of other bis(2-chloroethyl)amines containing a *p*-fluorophenyl group.

Reaction of the readily available (6) *p*-[N-bis(2-chloroethyl)amino]benzhydrazide with *p*-fluorobenzaldehyde gave the compound III. At the same time a number of other hydrazides related to III were prepared and these are listed in Table I. None of these

compounds exhibited anything but minimal activity against an established Dunning leukemia (4), although III was active ($ED_{50} = 1.7 \times 10^0$, slope = -1.1) when screened against KB line tissue culture.[3]

Reaction of N-bis(2-chloroethyl)amine with *p*-fluorobenzenesulphonyl chloride and with *p*-fluorophenyl isocyanate gave compounds IV and V respectively. These agents were essentially inactive against the Dunning leukemia (4). An additional Schiff base of the type I was prepared from 4-fluoro-2-nitroaniline.

The reaction of *p*-fluorobenzoyl chloride and N-bis(2-chloroethyl)amine gave N-bis-(2-chloroethyl)-4-fluorobenzamide. This compound could be purified only with difficulty and was readily rearranged during purification to the corresponding 2-(2′-chloroethyl-amino)ethyl ester hydrochloride. Before this compound could be submitted for screening or reduced to the corresponding *p*-fluorobenzylamine its preparation was reported by Pettit.[4] In the same publication (7) Pettit speculates that the cycloalkyl amide mustards which we had prepared earlier (8) were actually the rearranged ester hydrochlorides. After publication of that paper (8) we had independently reached the same conclusion although these esters could never be obtained analytically pure. It should be emphasized, however,

[3]*Results supplied by the C.C.N.S.C. of the U.S.P.H.S.*
[4]*We would like to thank Professor Pettit for making this information available to us prior to publication (7). Professor Pettit has also indicated that the p-fluorobenzl bis(2-chloroethyl)amine was not superior to several related compounds in preliminary screening.*

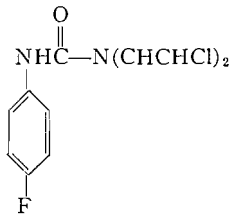
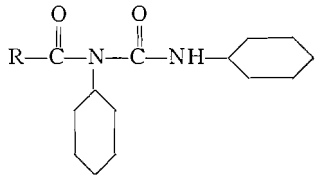
that no rearrangement was noted when purification was not attempted and that the materials reduced to the cycloalkyl mustards were indeed the unrearranged amides.

In an attempt to overcome the difficulties in the preparation and purification of mustard amides, we tried to react carboxylic acids and N-bis(2-chloroethyl)amine with dicyclohexylcarbodiimide as condensing agent. Such a condensation has been reported (9) in the synthesis of glycine bis(2-chloroethyl)amide. As indicated in the experimental section, our attempts led only to a substituted N-acylurea (VI). This type of compound has been noted by others (10–14) in the attempted preparation of amides.



V



VI

EXPERIMENTAL

1,1-Bis(2-chloroethyl)-3-(p-fluorophenyl)urea.—Reaction of *p*-fluorophenyl isocyanate and N-bis(2-chloroethyl)amine as previously described (15) gave, after recrystallization from carbon tetrachloride, an 82% yield of solid, m.p. 97–99°. Ultraviolet maximum 279–281 mμ and 241 mμ. Infrared (KBr): N–H, 3150–3200 cm^{-1}; C=O, 1625–1630 cm^{-1}. Anal. Calc. for $C_{11}H_{13}Cl_2FN_2O$: C, 47.33; H, 4.69; N, 10.04; Cl, 25.40. Found: C, 47.60; H, 5.12; N, 10.10; Cl, 25.65.

N,N-Bis(2-chloroethyl)-p-fluorobenzenesulphonamide.—A mixture of 0.02 mole of *p*-fluorophenylsulphonyl chloride, 5 ml of pyridine, 60 ml of anhydrous benzene, and the N-bis(2-chloroethyl)amine from 0.022 mole of the hydrochloride was allowed to stand for several days at room temperature and filtered. The filtrate was washed with water, dried, and concentrated to give after recrystallization from methanol a 78% yield of solid, m.p. 70–72°. Anal. Calc. for $C_{10}H_{12}Cl_2FNO_2S$: C, 40.00; H, 4.03; N, 4.67; Cl, 23.62. Found: C, 40.17; H, 4.11; N, 4.47; Cl, 23.30.

N′,N′-Bis(2-chloroethyl)-4-fluoro-2-nitro-2′-methyl-N,4′-methylidynedianiline.—The appropriate amine and aldehyde were refluxed in absolute ethanol for 30 minutes. After cooling of the solution, a solid was collected and recrystallized from benzene to give an 80% yield of solid, m.p. 135–136°. Anal. Calc. for $C_{18}H_{13}N_3Cl_2FO_2$: C, 54.28; H, 4.55; N, 10.55. Found: C, 54.43; H, 4.74; N, 10.46.

Hydrazides of p-[Bis(2-chloroethyl)amine]benzoic acid.—Equimolar quantities of p-[N-bis(2-chloroethyl)-amine]benzhydrazide and the appropriate aldehyde or ketone were refluxed for 30 minutes in absolute ethanol and cooled to give the compounds included in Table I.

Attempted amide formation with dicyclohexylcarbodiimide.—A mixture of 0.02 mole of the appropriate carboxylic acid in a minimum amount of a suitable solvent (benzene, dioxane, or tetrahydrofuran), N-bis(2-chloroethyl)amine, from 0.022 mole of the hydrochloride, in benzene, and 0.03 mole of dicyclohexylcarbodiimide was allowed to stand at room temperature for 24 to 48 hours. The mixture was filtered and the filtrate concentrated *in vacuo* to give a residue which was triturated with a solvent (ether, acetone, or ethanol) and recrystallized to give compounds of the type VI in 30 to 60% yields. When quinaldic acid was used the product was recrystallized from ethyl acetate and had m.p. 132–134°. Anal. Calc. for $C_{23}H_{29}N_3O_2$: C, 72.79; H, 7.70; N, 11.07. Found: C, 72.39; H, 7.72; N, 10.81. When levopimaric acid[5] was used the product was recrystallized from acetone and had m.p. 143–144°. Anal. Calc. for $C_{33}H_{52}N_2O_2$: C, 77.90; H, 10.30; N, 5.51. Found: C, 78.22; H, 10.31; N, 5.41.

Canadian Journal of Chemistry

Issued by THE NATIONAL RESEARCH COUNCIL OF CANADA

VOLUME 42 JULY 1964 NUMBER 7

COMPOUNDS OF THE TYPE M_5X_2: Pd_5As_2, Ni_5Si_2, AND Ni_5P_2[1]

G. S. SAINI,[2] L. D. CALVERT, AND J. B. TAYLOR

Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received January 13, 1964

ABSTRACT

Space group, lattice parameters, and powder data indicate that Pd_5As_2, Ni_5Si_2, and Ni_5P_2 are structurally related. Single crystal studies have established that Pd_5As_2 exhibits polytypism. Pd_5As_2 has $a = 7.31 \pm 0.01$ Å but c-values of 13.7, 10.34, 27.48, and 96.2 Å were observed on different crystals corresponding to a "single layer" repeat distance of 3.43 Å along the c-axis. The last three cells have trigonal symmetry, space group $P\bar{3}m1$, (D_{3d}^3), $P3m1(C_{3v}^1)$, or $P321(D_3^2)$ and the first cell has hexagonal symmetry, space group $P6_322(D_6^6)$. The Guinier focussing camera pattern of polycrystalline Pd_5As_2 can be indexed on a hexagonal cell with $a = 7.320 \pm 0.002$, $c = 96$ Å. Single crystal and focussing camera studies of Ni_5Si_2 showed it to be of trigonal symmetry with $a = 6.68 \pm 0.02$, $c = 12.28 \pm 0.03$ Å, and space group $P321$, $P3m1$, or $P\bar{3}m1$. A Guinier pattern of Ni_5P_2 can be indexed with hexagonal parameters $a = 13.220 \pm 0.002$ Å, $c = 24.632 \pm 0.002$ Å; a subcell with $a = 6.610$ and $c = 12.316$ Å can be used to index the strong lines. Comparison of the powder data for Pd_5As_2, Ni_5Si_2, and Ni_5P_2 with previously published data for Ni_5As_2 and Mn_5Ge_2 shows that the compounds are structurally related.

INTRODUCTION

Binary transition metal compounds with either pnigogens, chalcogens, silicon, boron, carbon, or germanium having the general formula M_5X_2 have been discussed previously (1). The present work concerns those compounds having hexagonal or trigonal symmetry, i.e. Pd_5As_2 (2), Ni_5Si_2 (3, 4), and Ni_5P_2 (5). Single crystal data have been used to establish the space groups for Pd_5As_2 and Ni_5Si_2 and Guinier patterns have been obtained for Pd_5As_2, Ni_5Si_2, and Ni_5P_2. Comparison of these has established a close structural relationship between them.

EXPERIMENTAL

The preparation techniques were different for the various M_5X_2 phases examined and details are contained under the relevant subheadings. High purity starting materials were used in all cases. Powder patterns were obtained in a Guinier–deWolff focussing camera using As_2O_3 as an internal standard. The intensities were estimated by comparison with a logarithmic interval density scale. Single crystal photographs were taken on a precession camera using zirconium filtered molybdenum radiation.

Pd_5As_2

Polycrystalline specimens were prepared by reacting palladium and arsenic powders in stoichiometric quantities in vacuum-sealed clear fused quartz ampoules. The bead resulting from the initial reaction was crushed and annealed *in vacuo* at 600 °C (2). Single crystal fragments were obtained by breaking up an ingot prepared by slow directional freezing of a melt of composition Pd_5As_2 contained in an evacuated, sealed clear fused quartz ampoule.

Preliminary investigation of the powder patterns showed that their quality was not sufficiently high to enable unambiguous indexing of what appeared to be a low symmetry cell. Accordingly single crystals were

[1]*Issued as N.R.C. No. 7912.*

[2]*Present address: Department of Chemical Engineering Technology, Panjab University, Chandigarh-3, India.*

studied and found to be trigonal or hexagonal with $a = 7.32 \pm 0.02$ Å but having different values for c ranging from 10.34 Å to 96.2 Å. Following the definition given by Strock and Brophy (6), these crystals are polytypes with a "single layer" repeat distance along the c-axis of 3.43 Å. Some crystals proved to be intergrowths of different polytypes and many were apparently of poor quality which could have resulted from the presence of giant polytypes or from imperfect annealing. One crystal gave sharp spots on precession photographs and the reciprocal lattice nets $hk.0$, $hk.1$, $hk.2$, $hk.3$, $hk.4$, $h0.l$, $h1.l$, $h2.l$, were recorded. For the other crystals the indices of the reciprocal lattice nets observed are listed in Table I, where the crystallographic data is summarized. The quantity N represents the multiplicity along the c-axis of the "single layer" repeat distance (3.43 Å).

TABLE I

Polytypes of Pd_5As_2

Multiplicity along c-axis, N	Cell parameters		Nets observed	Symmetry	Space group
	a	c			
3	7.32	10.34	$h0l$	Trigonal	$P\bar{3}m1$ (D_{3d}^3), $P3m1$ (C_{3v}^1) or $P321$ (D_3^1)
4	7.32	13.70	$h0l$	Hexagonal	$P6_322$ (D_6^6)
8	7.32	27.48	See text	Trigonal	$P\bar{3}m1$, etc.
28	7.32	96.2	$h0l$, $hk1$ $h1l$, $hk0$	Trigonal	$P\bar{3}m1$, etc.

A strongly marked subcell with $a = 2.44$ Å and $c = 6.87$ Å is visible in all the precession photographs. The intensities of the reflections corresponding to this subcell were very similar in all the specimens studied.

The crystal with $N = 28$ was re-examined after 2 months and found to have become a mixture of $N = 8$ and $N = 28$. It is assumed that this crystal had annealed at room temperature to form the mixture although it is worthy of record that the crystal had received a total X-ray exposure of 120 hours.

An indexed powder pattern of Pd_5As_2 is listed in Table II. Most of the lines have been indexed on the basis of hexagonal axes $a = 7.320 \pm 0.002$ Å; $c = 27.523 \pm 0.002$ Å. Two weak lines at d values of 4.712 and 4.401 Å were observed in photographs of three separate preparations and required the use of $c = 96$ Å to obtain satisfactory indexing. Two possible explanations are offered. Firstly, the preparations consistently contain a large amount of the polytype with $c = 27.523$ Å and a small amount of the polytype with $c = 96$ Å; secondly, the polytype present is the 96 Å one but the only lines requiring the 96 Å cell are the two weak ones at $d = 4.712$ and 4.401 Å.

Ni_5Si_2

Ni_5Si_2 was prepared by reacting stoichiometric quantities of nickel and silicon powders sealed in an evacuated clear fused quartz ampoule. After the initial reaction, the product was melted and then allowed to solidify slowly from 1300 °C. The ingot thus obtained was broken open and single crystal fragments separated. A portion of the ingot was crushed, screened through a 300-mesh sieve, and sealed under vacuum in a clear fused quartz tube with the minimum of void volume. This sample was annealed at 400 °C for 8 days, quenched, and used directly in the Guinier camera.

One single crystal was selected and the reciprocal lattice nets $hk0$, $hk1$, $hk2$, $h0l$, $h1l$ examined. It was found to be trigonal with diffraction symbol $\bar{3}mP\ldots$ The possible space groups are $P\bar{3}m1$, $P3m1$, and $P321$. The cell parameters from the single crystal photographs are $a = 6.68 \pm 0.02$, $c = 12.28 \pm 0.03$ Å.

The Guinier powder pattern of Ni_5Si_2 is given in Table III and has been indexed on hexagonal axes $a = 6.667 \pm 0.002$, $c = 12.277 \pm 0.002$ Å. Two very weak lines were observed in this pattern but could not be indexed even on a cell $a = 6.68$, $c = 85.94$ Å. These lines were not observed on patterns obtained from other preparations of Ni_5Si_2 but the measured pattern was considerably sharper than the others.

Ni_5P_2

Weighed quantities of nickel and phosphorus powders in stoichiometric proportions were sealed under vacuum in a clear fused quartz ampoule and reacted at 700 °C for 2 days. The product was subsequently crushed, resealed, and annealed at 700 °C for 8 days. This sample was used to obtain a Guinier pattern. Attempts to grow single crystals of this low temperature form of Ni_5P_2 by iodide vapor transport were not successful.

The Guinier pattern of Ni_5P_2 given in Table IV has been completely indexed with hexagonal parameters $a = 13.220 \pm 0.002$ Å, $c = 24.632 \pm 0.002$ Å. The strong lines can be indexed with parameters $a = 6.610$, and $c = 12.316$, and all but three lines at d values of 2.114, 1.7335, and 1.6581 can be indexed on the cell $a = 13.220$, $c = 12.316$.

DISCUSSION

The similarity between the structure of Ni_5As_2 and the structures of the various polytypes of Pd_5As_2 was established in the first instance by comparing the intensities of single crystal reflections. It was found that the intensities of corresponding reflections, referred to the subcell common to all the crystals, were very closely similar on both zero and upper level nets. Secondly, the similarity of the structures was established by comparing the powder data for Pd_5As_2, Ni_5Si_2, and Ni_5P_2 which have been plotted in Fig. 1 together with previously published data for Ni_5As_2 (1, 7) and Mn_5Ge_2 (8) (designated $Mn_{2.65}Ge$ by Ohoyama). The strong lines common to all the five compounds are shown in their observed positions with relative intensities and indices as indicated. It is apparent that the five structures are closely related.

It should be noted that all the lines in Fig. 1 can be indexed on the smaller cells having $a \approx 6$ Å and $c \approx 12$ Å. The larger cells are necessary in the cases of Pd_5As_2 and Ni_5P_2 to index some of the weak lines in these patterns. In the case of Pd_5As_2, the polytypism has been demonstrated by the single crystal work and the origin of the increase necessary in the c-axis parameter for satisfactory indexing is clear. The occurrence of polytypism implies a layered structure with layer planes at right angles to the c-axis. For Ni_5P_2 it is necessary to double both a and c parameters to index the pattern completely. No possible extension of c alone is satisfactory up to $c = 86$ Å.

In the absence of single crystal data on a number of crystals of Ni_5Si_2 and Ni_5P_2 it is not possible to draw any definite conclusions on the occurrence of polytypism in these compounds.

It is interesting to note that the β and β' phases of Ni_5As_2 reported by Heyding and

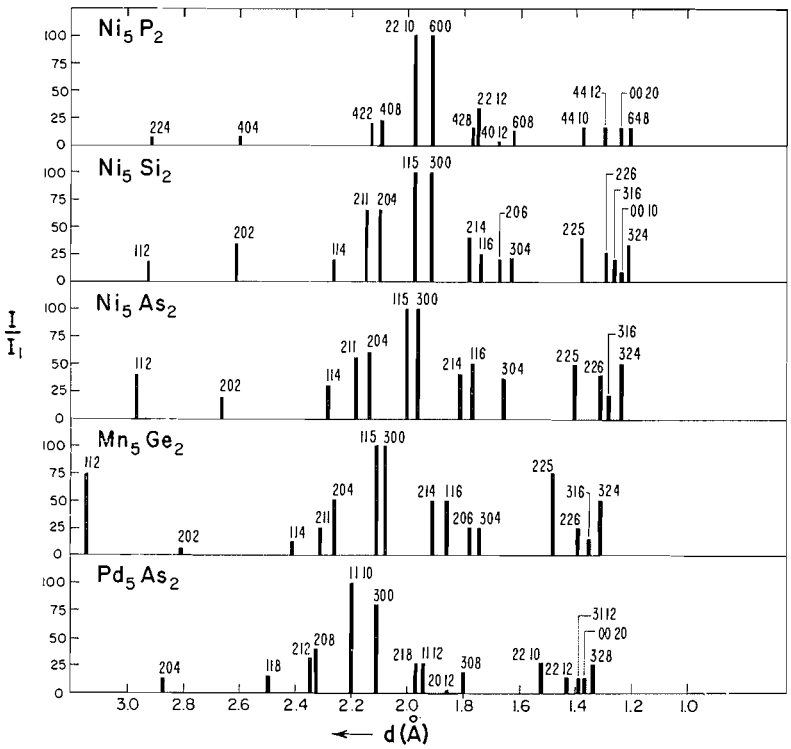

FIG. 1. Comparison of powder patterns of some M_5X_2 compounds.

Calvert (7) have powder patterns which are related in the same way as would be the powder patterns of hexagonal and trigonal polytypes of Pd_5As_2. The trigonal polytypes have reflections *h0l* for all values of *l* whereas the hexagonal polytypes have reflections *h0l* only where *l* is even.

THE RELATIVE ACCEPTOR POWER OF BORON TRIHALIDES AND BORANE TOWARD TRIMETHYLAMINE BY PROTON N.M.R. MEASUREMENTS[1]

J. M. MILLER[2] AND M. ONYSZCHUK
Inorganic Chemistry Laboratory, McGill University, Montreal, Quebec
Received January 29, 1964

ABSTRACT

Proton n.m.r. spectra of trimethylamine adducts of the boron trihalides and borane have been measured in chloroform solution. Chemical shifts of methyl protons relative to tetramethylsilane decrease in the order: $BBr_3 > BCl_3 > BH_3 > BF_3$, suggesting that this is the order of acceptor activity toward trimethylamine. This is supported by the existence of a linear relationship between methyl proton chemical shifts and the heats of formation, dipole moments, or infrared vibrational shifts of boron trihalide and borane adducts. Splitting of methyl proton resonances into quartets have been observed for $(CH_3)_3N \cdot BCl_3$ and $(CH_3)_3N \cdot BBr_3$ but not for $(CH_3)_3N \cdot BF_3$ and $(CH_3)_3N \cdot BH_3$.

INTRODUCTION

Nuclear magnetic resonance measurements have been used recently to determine relative stabilities of BX_3 (where X = F, H, CH_3, or C_2H_5) addition compounds (1–8). Relative basicities of donor molecules and relative acceptor powers of BX_3 molecules have been inferred from such data. Calorimetric (9, 10), dipole moment (11), infrared (12, 13), and displacement reaction (14) measurements have shown recently that the relative acceptor power of boron trihalides toward a variety of donor molecules is $BBr_3 > BCl_3 > BF_3$. Methyl proton chemical shifts of their trimethylamine adducts should also indicate this order. The measurements reported here were made to examine this possibility.

RESULTS AND DISCUSSION

Chemical shifts of methyl protons in trimethylamine adducts of boron trihalides and borane were found to decrease in the order: $BBr_3 > BCl_3 > BH_3 > BF_3$. The measured values for 1 mole % solutions of the adducts in chloroform were 190.8, 180.2, 159.5, and 157.3 c.p.s., respectively, below the proton resonance of dilute tetramethylsilane ($\delta = 0$ c.p.s.). The corresponding proton chemical shift of trimethylamine in chloroform was 132.2 c.p.s. Line diagrams of the measured spectra are compared in Fig. 1. Chemical shifts were affected to an extent of only 1 or 2 c.p.s. by changes of concentration in the range of 1.0 to 0.2 mole %. The difference between chemical shifts of the BH_3 and BF_3 adducts was only 2.2 c.p.s. in chloroform solution, but this appears to be significant because almost the same effect was obtained for measurements in benzene solution.

The observed order of decrease in chemical shift can be rationalized as follows. If the acceptor power increases progressively from BF_3 to BBr_3, the electron pair of the B–N bond of the trimethylamine complex should be drawn progressively closer to the boron atom. The resulting decrease in electron density at the nitrogen atom should be compensated in part by electron release from the attached methyl groups. This effect, in turn, should result in a decrease in the electron density about the methyl protons and their shielding should be reduced. Consequently, proton resonances should shift to lower field

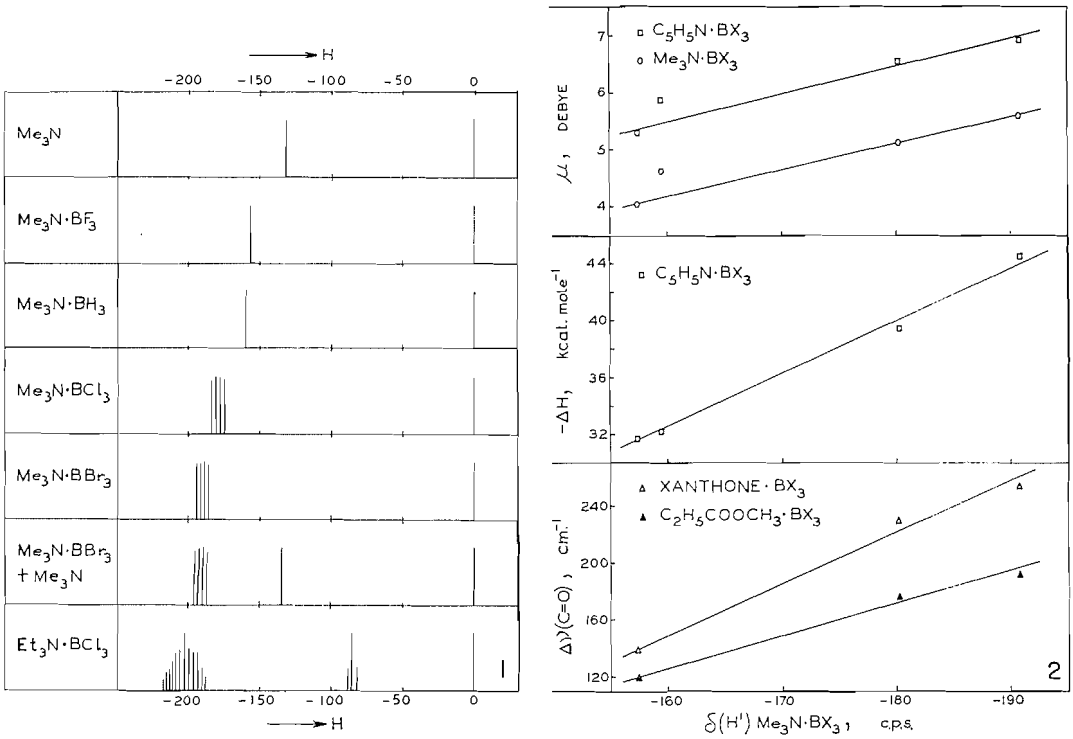

FIG. 1. Methyl proton n.m.r. spectra of $Me_3N \cdot BX_3$ (where X = H, F, Cl, Br) and $Et_3N \cdot BCl_3$.
FIG. 2. Correlations of methyl proton chemical shifts of $Me_3N \cdot BX_3$ with dipole moments, heats of formation, and infrared carbonyl shifts of various BX_3 complexes.

as the electron acceptor power of the boron species increases. Since methyl proton chemical shifts decreased in the order $BBr_3 > BCl_3 > BH_3 > BF_3$, we conclude that this is also the order of acceptor power toward trimethylamine.

The above explanation may not be the only one. Changes in electronegativity and (or) magnetic anisotropy due to substitution of one halogen atom for another might account for the observed order. Several workers (15, 16) have suggested that in some *n*-haloalkanes these effects produce shifts to lower field in the order I > Br > Cl > F for β protons and the opposite order for α protons. However, in the case of isopropyl halides the order in α and β proton chemical shifts is I > Br > Cl > F, whereas the reverse order applies for α protons in *n*-propyl halides. These unusual shifts have yet to be explained satisfactorily. Dr. M. A. Whitehead and his co-workers in this department are now trying to estimate theoretically the relative magnitudes of inductive, magnetic anisotropy, and hyperconjugative effects in $Me_3N \cdot BX_3$ and the isoelectronic Me_3CCX_3 compounds. Their results will be reported at a later date.

Coyle and Stone (5) found that with dichloromethane as solvent and concentrations of adduct of 10%, the methyl proton chemical shifts of $Me_3N \cdot BF_3$ was 0.02 p.p.m. greater than that of $Me_3N \cdot BH_3$. In the case of triethylamine adducts they observed a greater internal shift (measured as the difference between methyl and methylene proton resonances) for $(C_2H_5)_3N \cdot BF_3$ than for $(C_2H_5)_3N \cdot BH_3$; the difference was 0.14 p.p.m. corresponding to 8.4 c.p.s. at 60 Mc. In both cases BF_3 appears to be a slightly stronger acceptor than BH_3. Our chemical shift data agree with recent calorimetric (9, 10) and dipole

moment (11) measurements which indicate that BH_3 is a slightly stronger acceptor than BF_3.

As shown in Table I and Fig. 2, linear relationships exist between our chemical shift

data and dipole moments, heats of formation, and infrared shifts of various BX_3 (where X = H, F, Cl, Br) complexes, even though these values refer to different donor molecules. These linear correlations strongly suggest that proton chemical shifts reflect the same fundamental property of the complexes as do dipole moments, heats of formation, and infrared shifts. The property in common is probably the strength of the donor–acceptor bond, which, as suggested by Bax *et al.* (11) increases progressively from BF_3 to BBr_3 adducts because of a corresponding decrease in halogen valence shell electron-pair repulsions in the same order. Calorimetric and displacement results have been explained in terms of dative π-bonding and reorganization energies of boron trihalides (17, 14). This explanation cannot be used to account for dipole moment, infrared, and proton n.m.r. results because these data refer to properties of the complexes themselves and not to the energetics of their formation, as do heats of formation and displacement data. It is clear, nevertheless, that proton n.m.r. shifts, like heats of formation, dipole moments, and infrared shifts, indicate a relative acceptor power order of $BBr_3 > BCl_3 > BH_3 > BF_3$. Although displacement reaction studies showed that BF_3 is a slightly stronger acceptor than B_2H_6, it was evident that by taking the dimerization energy of BH_3 into account, BH_3 should be a stronger acceptor than BF_3. This expectation is confirmed by dipole moment, heat of formation, and our proton n.m.r. measurements.

Methyl proton n.m.r. spectra $Me_3N \cdot BH_3$ and $Me_3N \cdot BF_3$ consisted (Fig. 1) of slightly broadened singlets, whereas $Me_3N \cdot BCl_3$ and $Me_3N \cdot BBr_3$ gave quartets with peaks of almost equal intensity and a splitting constant $J = 2.7$ and 2.8 c.p.s., respectively (Fig. 3). These splittings were independent of concentration in the range 1.0 to 0.2 mole % and were the same in chloroform, *o*-dichlorobenzene, and benzene solutions. Chemical shifts for $Me_3N \cdot BCl_3$ and $Me_3N \cdot BBr_3$ were measured from the center of each quartet. Each peak of the quartet appeared to be a closely spaced doublet with $J \simeq 0.7$ c.p.s. Ohashi *et al.* (6) have also observed a quartet for $Me_3N \cdot BCl_3$ with a splitting constant of 2.6 c.p.s., in excellent agreement with our value. However, they did not detect further splitting of the quartet into doublets. They also reported that the peak at highest field was weaker than the other three. We found this effect depended upon the

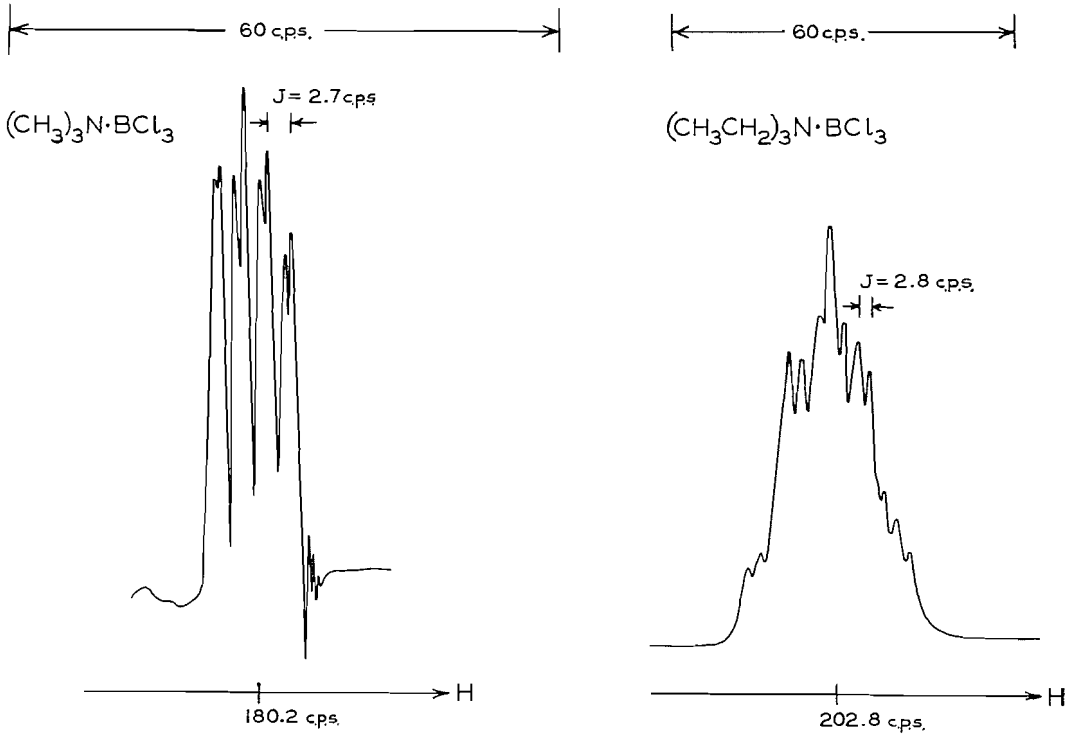

FIG. 3. Splitting of methyl proton resonances of $Me_3N \cdot BCl_3$ and of methylene proton resonances of $Et_3N \cdot BCl_3$.

direction of scan since it appeared at high field when scanned with increasing magnetic field and at low field when scanned in the opposite direction. This effect appears to be due to imperfect adjustment of the spectrometer.

If the main splitting was such as to produce a triplet with peaks of equal intensity, the effect could be ascribed to N^{14} spin–spin splitting, as has been proposed for anhydrous ammonia (18), $(CH_3CH_2)_4N^+I^-$ in D_2O solution (19), $(CH_3CH_2)_4N^+X^-$ (where X is Cl, Br, or OH) in Me_2SO, CH_3CN, and D_2O solution (19), and $(CH_3CH_2)_4N^+Br^-$ in H_2SO_4 solution (20). The same explanation has been suggested by Ohashi *et al.* (6) for the splittings in $Me_3N \cdot BCl_3$, even though they observed a quartet rather than a triplet. We think that N^{14} spin–spin coupling must be ruled out, because we observed quartets rather than triplets for $Me_3N \cdot BCl_3$ and $Me_3N \cdot BBr_3$.

Another possibility is coupling of methyl protons to B^{11} (spin 3/2) which should give a quartet with peaks of equal intensity. This effect should be just as likely to occur in $Me_3N \cdot BH_3$ and $Me_3N \cdot BF_3$ as in $Me_3N \cdot BCl_3$ and $Me_3N \cdot BBr_3$, but splittings were observed for the last two only. Perhaps restricted rotation about the B–N bond is necessary for coupling to be appreciable. Spatial models (of the Courtauld type) reveal that free rotation about the B–N bond is drastically restricted in $Me_3N \cdot BCl_3$ and $Me_3N \cdot BBr_3$ but not in $Me_3N \cdot BF_3$ and $Me_3N \cdot BH_3$. Hindered rotation might affect the electric field in such a way as to promote coupling of methyl protons with B^{11} and thereby give a quartet. An unambiguous test for B^{11} coupling could be made by double irradiation at the B^{11} resonance frequency. This test would be positive if a single methyl proton peak resulted. Unfortunately, we do not have the equipment to make this test. In an attempt

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

to examine the possibility of hindered rotation in $Me_3N \cdot BCl_3$, its proton resonance spectrum was measured at temperatures between 25 and 100°. There was no detectable change.

The observed quartets could conceivably be caused by coupling of methyl protons with chlorine and bromine, both of which have nuclear spins of 3/2, in the hindered molecules. However, this is unlikely because these nuclei do not normally produce first-order splitting of proton resonances in organic compounds. Moreover, three halogens should produce splittings more complex than a quartet. Further splitting of each peak of the quartet into a doublet might be due to non-equivalence of the methyl groups arising from a loss of axial symmetry along the B–N bond in the sterically hindered BBr_3 and BCl_3 adducts. Less likely is the possibility that spin coupling to B^{10} (present as 20% of natural boron, spin 3) superimposes new lines on the quartets. Such coupling should produce more complex splitting than the well-defined doublets observed. The same objection should apply to an explanation involving spin coupling of methyl protons to the Cl^{35},Cl^{37} and Br^{79},Br^{81} isotopic pairs (spin 3/2).

We observed that $Me_3N \cdot BBr_3$ and excess Me_3N in chloroform solution gave two separate methyl proton resonances, one for the free amine and the other for the complex. This clearly shows that there is no or only very slow exchange of BBr_3 between Me_3N molecules. The quartet splitting constant and chemical shift was unaffected by the excess Me_3N.

No unusual splitting of ethyl proton resonances in BH_3, BF_3, and BMe_3 complexes of triethylamine were reported by Coyle and Stone (5), and none for $Et_3N \cdot BCl_3$ by Ohashi *et al.* (6). We found that $Et_3N \cdot BCl_3$ in chloroform solution gave a methyl proton triplet centered at 84.3 c.p.s. and a complex band (Fig. 3) centered at 202.8 c.p.s. where methylene resonances are expected. The latter has 12 distinct inflections, but may well have more buried in the complex envelope. A splitting of the expected 1:3:3:1 methylene quartet into 12 peaks is expected if N^{14} spin–spin coupling occurred, and into 16 for B^{11} coupling. We are unable to decide between these possibilities. It is interesting to note that in $Et_4N^+I^-$ the methyl triplet and not the methylene quartet is split, and this has been attributed to N^{14} spin–spin coupling (19). Such coupling does not occur in $Me_3NH^+Br^-$ and $Et_3NH^+Br^-$, the spectra of which in H_2O (19) and chloroform solution show no unusual splitting.

EXPERIMENTAL

Materials

Trimethylamine complexes of BH_3, BF_3, BCl_3, and BBr_3 were prepared and purified as described previously (14). A solution of $Et_3N \cdot BCl_3$ in chloroform was prepared by bubbling BCl_3 (Matheson) into a solution of Et_3N (Eastman) in chloroform. Triethyl and trimethyl ammonium bromides were prepared by bubbling anhydrous HBr (Matheson) into chloroform solutions of the respective amines.

Chloroform (Fisher Spectral Grade) was purified of its ethanol preservative by extracting six times with distilled water and then drying over calcium hydride, followed by fractional distillation. An n.m.r. spectrum of the purified chloroform showed it to be completely free of ethanol. Benzene (Mallinkrodt) was first dried over sodium–lead alloy and then fractionally distilled. Tetramethylsilane (Anderson) was used without further purification.

Apparatus and Methods

Spectra were measured with a Varian HR-60 High Resolution NMR Spectrometer which has a fixed frequency of 60 Mc. Calibration was by means of 60 c.p.s. side bands on the tetramethylsilane peak. Each spectrum was scanned several times in each direction and average values of chemical shifts were taken relative to tetramethylsilane, the internal reference ($\delta = 0$ c.p.s.). Complexes were dissolved in purified chloroform or benzene such that concentrations were approximately 1 mole %.

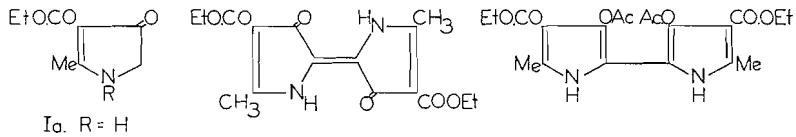
ABSTRACT

Ethyl 2-methyl-4-oxo-Δ^2-pyrroline-3-carboxylate (I*a*) is oxidized by one-electron oxidizing agents to a colored dimer which has been synthesized by an alternative route. Acetylation of (I*a*) and its N-methyl derivative (I*b*) gives a variety of products some of which show unusual infrared absorptions. The products of dimerization of (I*a*) and (I*b*) in strong acid show nuclear magnetic resonance absorptions at variance with previously claimed structures and alternatives are suggested.

The formation of dimeric compounds from pyrrolic monomers by reaction with one-electron oxidizing agents has been claimed only for certain oxygenated pyrrolic systems (1, 2). (The results of Siedel *et al.* (2) have recently been questioned (3).)

Benary (1) stated that oxidation of (I*a*) (which he formulated as a hydroxypyrrole (cf. ref. 4)) with ferric chloride gave a dimer (II), but had no evidence beyond analysis and the reversible reduction of the product.



Ia. R = H
b. R = CH_3

II

III

Many one-electron oxidizing agents produce (II) from (I*a*) (see Experimental section) and the reaction appears to be similar to the production of indigo from indoxyl. The product, however, shows few reactions typical of the indigo system and is very sensitive to acid and heat, both of which produce blue-black decomposition products. No crystalline derivatives of (II) have been reported previously, but we have now prepared a crystalline leuco-acetate (III) which, on treatment with base and subsequent neutralization, yields starting material. Dimerization of the iodo-acetate (IV*a*), under modified Ullmann conditions (5), gave (III) and thus proves Benary's formulation of the dimer (II). Infrared spectra of (II) in potassium bromide disks showed slight variations in different samples. The NH region varied considerably in the relative heights of the "bonded" and "unbonded" absorption bands and occasionally the single peak at 1647 cm^{-1} (extended-amide carbonyl) appeared as a close doublet. The rest of the absorptions were reproducible and since there were no variations in electronic spectra, the effect is probably due to polymorphism.

Treatment of (IV*a*) with base and air gave a purple salt which, after neutralization, yielded a compound showing superficial resemblance to (II), although its infrared and

electronic absorption spectra were significantly different. Reductive acetylation yielded (III) and we conclude, therefore, that this product is (or contains) the *cis*-isomer of (II).

Attempts to prepare the iodo-acetate (IV*a*) prompted investigation of the acetylation of (I*a*).

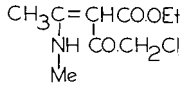
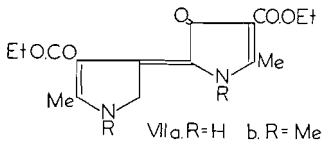
Other workers have assigned structures to some of the acetates described here, but the use of nuclear magnetic resonance spectroscopy (n.m.r.) shows that certain of the earlier formulations were incorrect. In particular, the number of acetate groups present has been difficult to establish by analysis but is obvious from the n. m. r. results. The O,N-diacetate (IV*b*) has previously been reported as an O-acetate (6) and a triacetate (7). The latter formula was based on the infrared absorption around 1700 cm^{-1} which shows four resolvable peaks which might reasonably be attributed to carbonyl groups. In fact, the O-acetate absorption is a doublet, as it is also in (III) and (IV*d*). This double absorption is probably due to the existence of the O-acetate group in two conformations relative to the pyrrole ring (8).

Other unreported acetates which can be prepared from (I*a*) are (IV*c*) and (V*a*). The N-acetates are very readily hydrolyzed and preparation of (IV*a*) from (IV*b*) with iodine and sodium acetate proceeds in one step. Similarly, the authentic triacetate (V*a*) is converted to (V*b*) (9) by treatment with aqueous sodium acetate. The O-monoacetate (IV*c*) undergoes Fries-type rearrangement to (V*c*) (10) either on heating or treatment with aluminum chloride. A similar lability of acetoxy residues has previously been reported for 2-acetoxypyrrole derivatives (11).

To eliminate a possible tautomeric structure for (II) we tried, unsuccessfully, to prepare the di-N-methyl analogue. Benary attempted the synthesis of ethyl 1,2-dimethyl-4-oxo-Δ^2-pyrroline-3-carboxylate (I*b*) by base induced cyclization of (VI), but reported that the only product was a hygroscopic oil.



VI



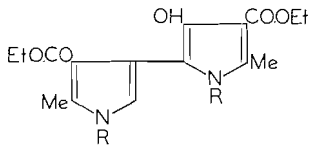
VII *a*. R = H *b*. R = Me

Our results are precisely similar, but we have good evidence that the oil is mainly the desired product. (For example, a group of acetates analogous to those of (I*a*) can be prepared by similar methods.) Attempts to synthesize a dimer analogous to (II) by oxidation were quite unsuccessful and the N-methyl iodoacetate (IV*e*) gave only (IV*d*) under Ullmann conditions.

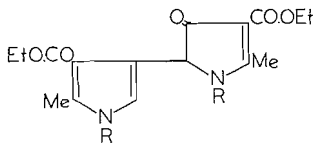
Acid treatment of (I*a*) gives a crystalline product which has been formulated as a dimer, either (VII*a*) or (VIII*a*) (1, 7). The N-methyl-oxo-pyrroline (I*b*) gives an analogous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

compound and examination of the n. m. r. spectra of the two products suggests that formulas (VII) and (VIII) are incorrect. Thus, apart from two non-equivalent ester groups, ring-methyl groups, and NH (or NMe) absorptions, both compounds show additional absorption equivalent to two protons. Compound (VII) requires that this absorption is either a singlet (intensity two) or an AB quartet, depending on the stereochemistry and rigidity of the ring containing the CH_2 group. Compound (VIII) requires that there be two singlets (intensity one each), one of which (the —OH) would exchange readily with heavy water. Both dimers showed two additional singlets, neither of which exchanged with D_2O, and hence both (VII) and (VIII) are incorrect.



VIII a. R=H b. R=Me



IX a. R=H b. R=Me

Further evidence comes from the fact that neither dimer gives a color with ferric chloride (which makes (VIII) unlikely) and that the ultraviolet absorption, especially of the N-methyl dimer, is extremely similar (in the longer wavelength bands) to the parent oxo-pyrroline (I*b*). The alternative formula (IX) is consistent with all of the observed properties. It is perhaps surprising that the substitution of the pyrryl-residue in the 2-position of ethyl 2-methyl-4-oxo-Δ^2-pyrroline-3-carboxylate does not convert the oxo-pyrroline to the hydroxypyrrole form but we have so far found only the acetyl-substituted compound (V*c*) in which the hydroxypyrrole structure is favored.

EXPERIMENTAL

Ultraviolet and visible spectra were recorded on Perkin–Elmer Model 137 UV and Unicam SP-700 instruments using ethanol solutions. Infrared data were determined on a Unicam SP 100 spectrometer and n. m. r. spectra on A.E.I. RS-2 or Varian A-60 instruments. Melting points (hot stage) are uncorrected.

Oxidation of Ethyl 2-Methyl-4-oxo-Δ^2-pyrroline-3-carboxylate (Ia)

The oxidation was carried out preparatively according to Benary (1). The yield of product is markedly reduced if less than 3 molar equivalents of ferric chloride are used. Using more than 3 moles per mole of pyrrole, the yield is 73%. The same dimer was obtained in varying yield when ferric chloride was replaced by potassium ferricyanide, Fremy's salt, lead tetraacetate, iodine in potassium iodide solution, silver nitrate, or selenium dioxide. A small yield of the sodium salt of the dimer was isolated when air was bubbled through an alkaline solution of (I*a*) for 24 h (precise analogue of indigo preparation).

The dimer gave little indication of similarity to indigo, e.g. direct acetylation gave no isolable product nor did attempts to prepare a dehydroindigo analogue. Oxidation gave no recognizable product. The compound was reversibly reduced by hydrogen over Adams' catalyst and by sodium dithionite.

Diethyl 2,2'-Dimethyl-4,4'-diacetoxydipyrrole-3,3'-dicarboxylate (III)

The oxidation product (0.2 g, see above) was suspended in 50% aqueous ethanol (20 ml) and treated with sodium dithionite (1 g). The reaction mixture remained heterogeneous but on shaking and warming (water bath) the red color of the oxidation product was slowly discharged. The mixture was filtered and the residual solid, after washing once with water, was dissolved in acetic anhydride (10 ml) containing a few drops of pyridine. The mixture was kept for 12 h when the white precipitate was separated and crystallized from chloroform–methanol to colorless needles; m. p. 265–266° (0.201 g, 80%). Calc. for $C_{20}H_{24}O_8N_2$: C, 57.13; H, 5.75; N, 6.66. Found: C, 57.40; H, 5.74; N, 6.60%. Ultraviolet spectrum: λ_{max} 222, 263 mμ; ϵ_{max} 31,200, 15,700 respectively. Infrared absorptions (KBr) at 3373, 1785, 1751, 1700 cm^{-1} (*inter alia*).

Ethyl 1-Acetyl-2-methyl-4-acetoxypyrrole-3-carboxylate (IVb)

This compound was prepared by the procedure reported to give a triacetate (7). The product formed colorless needles (94%); m. p. 123–124° (lit.123°). Calc. for $C_{12}H_{15}O_5N$: C, 56.91; H, 5.97; N, 5.53. Found: C, 56.80; H, 5.88; N, 5.60%. Ultraviolet spectrum: λ_{max} 223, 241 mμ; ϵ_{max} 21 450, 10 540. The infrared

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

absorptions included strong bands at 1765, 1744, 1709 cm^{-1} ($CHCl_3$); 1781, 1768, 1745, 1716 cm^{-1} (CCl_4). The n. m. r. spectrum ($CHCl_3$) showed peaks at τ 8.61 (ester CH_3); 7.65, 7.39 ($COCH_3$); 7.11 (—C—CH_3); 5.67 (ester CH_2); 2.99 (pyrrolic CH).

The product gave a red Ehrlich reaction slowly in the cold.

Ethyl 1,5-Diacetyl-2-methyl-4-acetoxypyrrole-3-carboxylate (Va)

The diacetate (IV*b* above, 0.5 g) was suspended in acetic anhydride (10 ml) and treated with 1 drop of 70% perchloric acid. The mixture was stirred in the cold for 10 min and then treated with cold water (30 ml). As the anhydride decomposed a crystalline solid separated. When the anhydride was completely decomposed, the solid was separated and recrystallized from ethanol–water to colorless needles (0.508 g, 87%); m.p. 105–107°. This compound gave no Ehrlich reaction. Calc. for $C_{14}H_{17}O_6N$: C, 56.94; H, 5.80; N, 4.74. Found: C, 56.80; H, 5.76; N, 4.69%. Ultraviolet spectrum: λ_{max} 228, 287 mμ; ϵ_{max} 19 340, 13 550 respectively. The infrared spectrum (CCl_4) showed strong peaks at 1780, 1711, 1654 cm^{-1} whilst n. m. r. absorptions ($CHCl_3$) occurred at τ 8.64 (ester CH_3); 7.59 (2) 7.53 (1) ($COCH_3$); 7.49 (—C—CH_3); 5.73 (ester CH_2).

Ethyl 2-Methyl-4-acetoxy-5-iodopyrrole-3-carboxylate (IVa)

The diacetate (IV*b*; 2.0 g) and potassium acetate (1 g) were dissolved in boiling ethanol (100 ml) and iodine (2 g) in ethanol (70 ml) was added from a dropping funnel over a period of 2 h. The solution was boiled for a further 1 h and the solvent removed. The residual solid was extracted with water to remove salts and then crystallized (charcoal) from aqueous ethanol (2.0 g, 76%) m. p. 140–143.5° (dec.). Calc. for $C_{10}H_{12}O_4NI$: C, 35.62; H, 3.56; N, 4.16; I, 37.69. Found: C, 35.20; H, 3.29; N, 3.82; I, 38.00. Ultraviolet spectrum: λ_{max} 208, 261 mμ; ϵ_{max} 30 410, 5075 respectively. The n. m. r. spectrum ($CHCl_3$) showed peaks at τ 8.93 (ester CH_3); 7.59 ($COCH_3$); 7.46 (C—CH_3); 5.90 (ester CH_2).

Ethyl 2-Methyl-4-acetoxypyrrole-3-carboxylate (IVc)

(i) The O,N-diacetate (IV*b*; 4 g) was heated under reflux with sodium acetate (4 g) in ethanol (60 ml) for 2 h. The solvent was removed and the residual solid was treated with water and ether. The ether extract was dried (sodium sulphate) and the solvent removed. The oily, reddish residue solidified on scratching with a glass rod and was distilled (96°/0.5 mm) to a colorless oil which solidified to a low-melting solid (3.01 g, 90%). The analytical sample was prepared by repeated distillation. Calc. for $C_{10}H_{13}O_4N$: C, 56.86; H, 6.20; N, 6.63. Found: C, 56.70; H, 6.33; N, 7.04%. The n. m. r. spectrum ($CHCl_3$) which showed peaks at τ 8.67 (ester CH_3); 7.80 ($COCH_3$); 7.66 (>C—CH_3); 5.73 (ester CH_2); 3.65, 3.69 (pyrrolic H); 0.55 (broad, NH), confirms the proposed structure. The pyrrolic hydrogen resonance is a doublet, possibly by interaction with the N–H proton; integration confirms that the two absorptions are together equivalent to one proton. The compound gave an intense Ehrlich reaction in the cold.

(ii) Hydrogenation of the iodoacetate (IV*a*) in ethanol over Adams' catalyst gave an oil which had ultraviolet, infrared, and n. m. r. spectra identical with those of the above product.

(iii) Fries rearrangement of IV*c*. Ethyl 2-methyl-4-acetoxypyrrole-3-carboxylate (IV*c*; 0.3 g) was mixed with anhydrous aluminum chloride (0.38 g) and heated at 110° for 20 min. The residue was treated with cold, dilute hydrochloric acid (20 ml) and the mixture extracted with ether. Extraction of the ether with aqueous sodium hydroxide, followed by acidification of the aqueous phase yielded a white solid. After purification by sublimation *in vacuo*, this product was shown to be identical with ethyl 2-methyl-4-hydroxy-5-acetylpyrrole-3-carboxylate (V*e*, (9)) by m. p., mixed m. p., and infrared spectrum. Yield: 69 mg, 23%.

Diethyl 2,2′-Dimethyl-4,4′-diacetoxydipyrrole-3,3′-dicarboxylate (III)

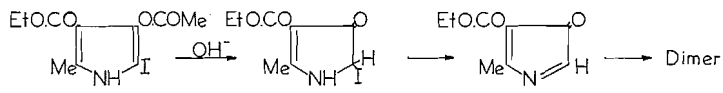
Ethyl 2-methyl-4-acetoxy-5-iodopyrrole-3-carboxylate (IV*a*; 1 g) was dissolved in dimethylformamide (20 ml) and stirred overnight at room temperature with copper powder (1 g). The solvent was removed *in vacuo* and the residue extracted with boiling chloroform from which a white solid was isolated by evaporation. Crystallization from chloroform–methanol gave a product (0.57 g, 92%) identical (m.p., mixed m.p., and infrared spectrum) with the leuco-acetate (III) described above.

Hydrolysis of the iodo-acetate (IV*a*). Ethyl 2-methyl-4-acetoxy-5-iodopyrrole-3-carboxylate (IV*a*; 1.15 g) in methanol (15 ml) was treated with aqueous sodium hydroxide (5 ml, 2.5 *N*). After standing in the cold for 2 h the solution, which had become purple, was neutralized (dilute hydrochloric acid) and the suspended solid (0.19 g) removed. The product showed a superficial resemblance to the normal oxidation product (II) but had rather different infrared and electronic absorption spectra, e.g. ultraviolet and visible spectrum showed bands at 253.5, 309.0, 473.0 mμ compared with 253.5, 300.6, 490.2 mμ for (II). Upon recrystallization from chloroform, the product became identical with (II). Reductive acetylation of this material yielded a substance identical with (III). We were unable to effect any controlled interconversion of the two compounds. The dimerization may proceed as follows: A dimerization sequence based on a similar 'indoleninone' intermediate has been suggested (12).

Ethyl 1,2-Dimethyl-4-oxo-Δ^2-pyrroline-3-carboxylate (Ib)

This compound was prepared, probably in rather impure form, by the method of Benary and Silbermann (1), by the base induced cyclization of ethyl α-chloroacetyl-β-methylaminocrotonate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



Ethyl 1,2-Dimethyl-4-acetoxypyrrole-3-carboxylate (IVd)

The yellow oil prepared above (15 g) was dissolved in acetic anhydride (20 ml) and treated with potassium acetate (1 g). The mixture was boiled for 1 min and cooled, and the anhydride was decomposed with cold water. The crystalline product (12.7 g, 69%) was separated and recrystallized from ethanol–water to colorless prisms; m. p. 96–97°. Calc. for $C_{11}H_{15}O_4N$: C, 58.65; H, 6.71; N, 6.22. Found: C, 58.90; H, 6.92; N, 6.44%. Infrared spectrum showed carbonyl absorption at 1759, 1698 cm^{-1} ($CHCl_3$) and 1782, 1764, 1709 cm^{-1} (CCl_4). Ultraviolet spectrum: λ_{max} 205.9, 234.0, 258.7; ϵ_{max} 16,750, 8870, 5270 respectively. The n. m. r. absorptions (CCl_4) occurred at τ 8.67 (ester CH_3); 7.80 ($COCH_3$); 7.55 ($\rangle C—CH_3$); 6.49 ($N—CH_3$); 5.77 (ester CH_2); 3.68 (pyrrolic H). The compound gave no color with ferric chloride, but a strong positive Ehrlich reaction in the cold.

Ethyl 1,2-Dimethyl-4-acetoxy-5-acetylpyrrole-3-carboxylate (Vd)

The monoacetate above (IV*d*; 1.0 g) was suspended in acetic anhydride (10 ml) in the cold and treated with 1 drop of 70% perchloric acid solution. After the solution was shaken for 10 min the anhydride was decomposed with water and the white crystalline product separated (0.95 g, 81%). The product was recrystallized from aqueous ethanol to white needles; m. p. 100–100.5°. Calc. for $C_{13}H_{17}O_5N$: C, 58.42; H, 6.42; N, 5.24. Found: C, 58.70; H, 6.28; N, 5.54%. The compound showed n. m. r. absorptions ($CHCl_3$) at τ 8.66 (ester CH_3); 7.67 (2) ($COCH_3$); 7.42 ($—C—CH_3$); 6.09 ($N—CH_3$); 5.68 (ester CH_2). The product gave no reaction with ferric chloride or Ehrlich's reagent.

Ethyl 1,2-Dimethyl-4-hydroxy-5-acetylpyrrole-3-carboxylate (Ve)

Ethyl 1,2-dimethyl-4-acetoxy-5-acetyl-pyrrole-3-carboxylate (V*d*; 0.2 g) was dissolved in cold ethanol (7 ml) and treated with 2.5 *N* sodium hydroxide solution (10 ml). The solution was neutralized after standing at room temperature and the resulting white solid (0.13 g, 85%) was crystallized from aqueous ethanol to colorless needles; m. p. 118–119°. Calc. for $C_{11}H_{15}O_4N$: C, 58.65; H, 6.71; N, 6.22. Found: C, 58.80; H, 6.71; N, 6.13%. The product gave an intense purple ferric chloride test but no color with Ehrlich's reagent.

Ethyl 1,2-Dimethyl-4-oxo-5-(1′,2′-dimethyl-3′-ethoxycarbonyl-pyrrol-4′-yl)-Δ^2-pyrroline-3-carboxylate (IXb)

The above monoacetate (IV*d*; 1 g) was treated with concentrated hydrochloric acid (15 ml) and then the mixture was allowed to evaporate to dryness *in vacuo* over solid sodium hydroxide. The residual oil crystallized on standing and was recrystallized from ethanol to white prisms; m. p. 137–142° (0.55 g, 71%). The product gave an intense purple color with Ehrlich's reagent. The n. m. r. spectrum ($CDCl_3$) peaks were observed at τ 8.91, 8.66 (ester CH_3); 7.55, 7.49 ($—C—CH_3$); 6.79, 6.48 ($N—CH_3$); 5.93, 5.70 (ester CH_2); and 3.54, 2.43 (singlets, unassigned). The spectrum was unchanged after treatment of the solution with D_2O. Calc. for $C_{18}H_{24}O_5N_2$: C, 62.05; H, 6.94; N, 8.04. Found: C, 62.00; H, 7.02; N, 8.38%. Ultraviolet spectrum: λ_{max} 205.4, 245.8, 296.7 mμ (inflection); ϵ_{max} 28 300, 24 550, 4370.

This compound was easily acetylated by acetic anhydride – potassium acetate to a mono-O-acetate which crystallized from aqueous ethanol to small white needles; m. p. 89–92°. Calc. for $C_{20}H_{26}O_6N_2$: C, 61.52; H, 6.71; N, 7.18. Found: C, 61.30; H, 7.03; N, 6.97%.

Ethyl 2-Methyl-4-oxo-5-(2′-methyl-3′-ethoxycarbonylpyrrol-4′-yl)-Δ^2-pyrroline-3-carboxylate (IXa)

Ethyl 2-methyl-4-oxo-Δ^2-pyrroline-3-carboxylate (I*a*; 5 g) in glacial acetic acid (25 ml) was heated under reflux for 15 min. The product was isolated by pouring the mixture on to ice and formed colorless prisms from aqueous acetic acid; m. p. 156–157° (lit. 157.5°). Calc. for $C_{16}H_{20}O_5N_2$: C, 59.99; H, 6.29. Found: C, 60.40; H, 6.26%. The n. m. r. spectrum ($CDCl_3$) showed peaks at τ 8.63 (ester CH_3); 7.54, 7.52 ($\rangle C—CH_3$); 5.69 (ester CH_2); 2.85, 2.81 (unassigned singlets); 1.87 (broad, NH). The ultraviolet spectrum: λ_{max} 203.3, 241.2, 274.2, 311.0 mμ; ϵ_{max} 17,230, 24,220, 6240, 6525 respectively.

A monoacetate was prepared as above and formed colorless needles; m. p. 171–173° (from chloroform – petroleum ether). Calc. for $C_{18}H_{22}O_6N_2$: C, 59.66; H, 6.12; N, 7.73. Found: C, 59.50; H, 6.06; N, 7.80%.

ABSTRACT

The 60 Mc/s proton spectra of methyl 2-bromo-3-fluoropropanoate and the 3-bromo-2-fluoro isomer have been analyzed completely with the aid of heteronuclear spin decoupling to illustrate an extension of the double resonance technique to ABCX spin systems. These results provide confirmatory evidence of the magnitude and relative signs of geminal and vicinal proton–proton and proton–fluorine coupling constants.

INTRODUCTION

This paper reports the complete analysis of the proton magnetic resonance spectra of methyl 2-bromo-3-fluoropropanoate and its isomer, methyl 3-bromo-2-fluoropropanoate. These spectra belong to the ABCX classification (1), for which A,B,C = H, X = F. The only previous example of a similar analysis is that of Banwell and Sheppard for vinyl fluoride (2). These authors discussed the general features of analysis of such systems and from its application determined the magnitude and sign of all parameters. In our case, the saturated aliphatic esters are particularly amenable to a simplified analytical approach. We have employed a standard ABC analysis, in conjunction with perturbation theory and heteronuclear spin decoupling, to obtain the complete set of parameters for each ester.

In the three-spin, ABC system, a complete analysis of the spectrum may be carried out if each of the nuclei are slightly shifted from one another. The choice of the best parameters is made by a careful comparison of the theoretical and experimental line positions and intensities. To check the results, this comparison should also be carried out for the spectrum obtained at a lower frequency. From this analysis the relative signs of the coupling constants as well as their magnitudes are obtained. An alternative method for the determination of relative signs, the double irradiation technique, may be employed in one of a number of ways depending on the complexity of the spectrum (3, and references cited therein, 4). The published reports of the use of this method for the study of relative signs for geminal and vicinal couplings have involved the simultaneous irradiation of one or more of the transitions within the spectrum while observing the changes in the rest of the spectrum (3, 4, 5 and references cited therein, 6). These may be termed "homonuclear" double irradiation experiments. If, however, the system is perturbed by the presence of another nucleus having a different magnetogyric ratio, γ, a "heteronuclear" double irradiation experiment can remove this perturbation and allow a complete analysis of the ABC system.

A suitable system for this approach is the ABCX, where $\gamma_{A,B,C} \neq \gamma_X$. In the present case for X = F, according to first-order perturbation theory,* the observed spectrum for the three protons will be a composite of two overlapping ABC patterns, one corresponding to each of the fluorine spin states, $\pm 1/2$. While analysis of each of these ABC patterns will yield the required parameters, it is helpful to have a further check on the results. Removal of the perturbation by the X nucleus on the spectrum produces a third ABC spectrum whose analysis must yield the same proton–proton coupling constants as the original systems. This may be accomplished by a "heteronuclear spin decoupling" experiment in which the X nucleus is strongly irradiated at its resonance frequency with a second radio frequency field which is at least strong enough to meet the requirement, $\gamma_X H_2/2\pi \approx \Sigma J_{HF}$, while observing the ABC portion of the spectrum. In this way, the peak positions and intensities in *three* patterns may be compared to provide confirmation of the choice of parameters.

Two examples of the use of this method are presented to illustrate its applicability and limitations. One of these cases has a strongly coupled ABC system, while the second case is one in which the A nucleus is only moderately coupled with the strongly coupled BC nuclei.

EXPERIMENTAL

Samples of methyl 2-bromo-3-fluoropropanoate and methyl 3-bromo-2-fluoropropanoate were kindly provided by Prof. F. L. M. Pattison, in whose laboratories these compounds were prepared in connection with other studies (8).

Carbon tetrachloride solutions of the two compounds were examined using ca. 25% (w/v) concentrations. All 60 Mc/s spectra were determined with a Varian DP-60 spectrometer and line positions measured by the usual audio side-band method. The audio oscillator was continuously monitored with a Hewlett–Packard 522B frequency counter. All measurements are reported as the average obtained from at least 10 separate spectra. The 15.085 Mc/s spectrum was obtained using the same basic instrument equipped with the necessary V4311 r. f. unit and the measurements given are those averaged from 12 spectra.

The heteronuclear spin decoupling experiments were performed with an NMR Specialties Inc. Model SD-60 spin decoupler equipped with modules to provide a strong variable frequency signal near 56.4 Mc/s. To carry out an experiment, the sample was simultaneously irradiated with the two r. f. signals required (60 and 56.4 Mc/s) and the proton spectrum examined by the field sweep method. Initially, the frequency of the 56.4 Mc/s signal was varied until the proton spectrum showed evidence of spin decoupling, i.e., the collapse of multiplets and a general narrowing of the entire pattern. This coarse adjustment was most easily performed with an oscilloscope presentation of the spectrum. Fine adjustments of the frequency were then made using a graphic recorder to locate the optimum setting of the variable frequency oscillator. Throughout these steps, the power of the fluorine oscillator was maximized to ensure complete decoupling. In the case of the α-fluoroisomer in which the components of the ABC system are well separated, it was necessary to readjust the fluorine resonance frequency to obtain complete decoupling of each multiplet. In these experiments, no measurement of the fluorine chemical shifts was done although this determination can be accomplished by the heteronuclear spin decoupling technique as described in Part V of this series (9).

RESULTS

A full description of the rigorous method of analysis for the ABC Spectrum has been given by Castellano and Waugh (10, 11). Following this method, a program for an IBM 650 computer has been written to carry out the computations, differing somewhat from that used previously by one of us (12, 13).

It has been pointed out by Castellano and Waugh that observation of the line positions does not determine the energy levels (E_i) of the system uniquely, but rather that there are 10 possible inequivalent assignments. We have obtained a simple prescription which, once

An elegant example of the use of perturbation theory for a similar purpose has been given by Anet (7).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

one assignment has been obtained, will generate the other nine. We put

$$\begin{aligned} F_1 &= -1/2(E_4 + E_7) \\ F_2 &= 1/2(E_7 - E_4 - 2E_3) \\ F_3 &= 1/2(E_7 - E_4 - 2E_2) \\ F_4 &= 1/2(E_4 - E_7 - 2E_1) \\ F_5 &= 1/2(E_4 - E_7 - 2E_6) \\ F_6 &= 1/2(E_4 - E_7 - 2E_5) \\ F_7 &= 1/2(E_7 - E_4 - 2E_1). \end{aligned}$$

It is simple to verify that $F_2 + F_3 + F_4 = F_2 + F_6 + F_7 = -F_1$ and that appropriate differences $F_i - F_j$ give the same 15 line positions as the $E_i - E_j$. Since the sets $\{E_2, E_3, E_4\}$ and $\{E_5, E_6, E_7\}$ can be permuted arbitrarily, E_4 and E_7 can be chosen in nine different ways, producing in general nine different values of E_1, and hence all the inequivalent assignments.

The quartic equation for the Castellano–Waugh parameter was solved using Ferrari's method rather than an approximation scheme. This is felt to be superior since in some cases the roots were almost degenerate. In predicting the line positions at a different field strength from a determined set of parameters it is necessary to solve a cubic secular equation. This was done using Cardan's method.

The intensities are well known functions of the components of the eigenvectors of H. Since the eigenvalues E_i of H are known, it is a simple matter to compute the eigenvectors; one way is to evaluate the vector cross product of the first two rows of $H - E_i$.

The effect on the molecular parameters of errors in the input parameters E_i is by no means clear. These effects could be determined by introducing unit increments in each of the E_i's separately and determining the resulting changes in each of the molecular parameters. Rather than do this, we considered the increments in the E's produced by unit increments in the molecular parameters. These changes are readily computed using first-order perturbation theory. Since the E's are not all independent but are related by

$$\begin{aligned} E_1 &= -(E_5 + E_6 + E_7) \\ E_8 &= -(E_2 + E_3 + E_4), \end{aligned}$$

the increments in E_3, E_4, E_5, E_6, E_7, E_8 only were computed. This provides a 6×6 matrix whose elements are

$$\frac{\partial E_i}{\partial P_j} \qquad \begin{aligned} i &= 3.8 \\ j &= 1,6. \end{aligned}$$

The inverse of this matrix determines the effect on P_j of a unit change in E_i or the quantity, $\partial P_j/\partial E_i$. If it is assumed that the E's are valid to within an amount ΔE the quantity,

$$\Delta E \sum_{i=3}^{8} \left| \frac{\partial P_j}{\partial E_i} \right|$$

provides an upper bound to the error in P_j. We have assumed for ΔE the value 0.1 c/s. The tolerances indicated on the molecular parameters represent what we believe to be the maximum possible deviations of the results.

The nomenclature used throughout this paper in reference to the analytical method is that given in the original description (10) and is indicated by italics.

Methyl 2-bromo-3-fluoropropanoate.—The 60 Mc/s proton spectrum of methyl 2-bromo-3-fluoropropanoate is shown in Fig. 1(*a*) and it can be seen that 18 of the maximum 30

transitions are resolved. By inspection, two "quartets" can be found in the group of seven lines towards lower field. These two multiplets must be a portion of one of the two overlapping ABC systems and would be expected to arise from the methylene protons on the β-carbon atom. The assignment of the third "quartet" for this system, however, is not so readily accomplished even though the required repeated spacings are known from the separations in the low field group. The assignment of the transitions for the remaining, higher field ABC system is still more difficult. The "spin decoupled" spectrum, shown in Fig. 2(*a*)

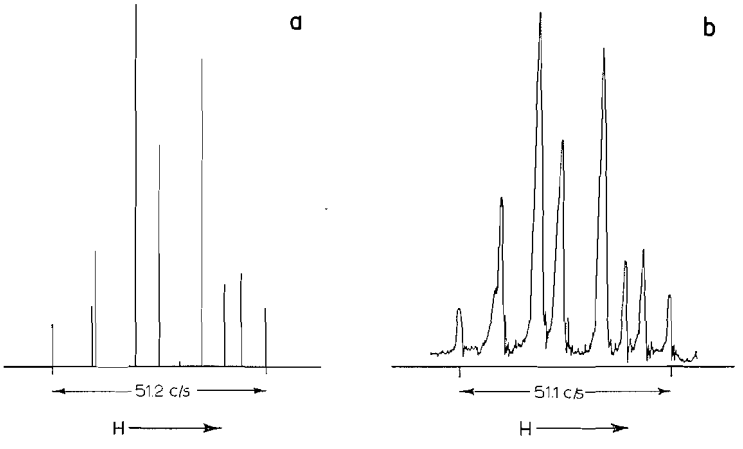

FIG. 2. Decoupled proton spectra of methyl 2-bromo-3-fluoropropanoate showing the ABC portion only. (*a*) Observed spectrum at 60 Mc/s while the fluorine nucleus was being irradiated at its resonance frequency and (*b*) theoretical spectrum calculated from the averaged data in Table I.

however, presents a way around this problem. The nine observable transitions may be assigned in the first-order approximation from the repeated spacings to the three ABC nuclei such that the four lines toward low field form one quartet as do the four lines at

For personal use only.

higher field, while the remaining quartet appears between these overlapping with one line of each of the others. From this assignment, one *grouping* is obtained which yields a possible set of energy levels for the ABC system. Computation of all of the possible arrangements results in a total of three *sets* of eigenvalues, from each of which there arises two sets of chemical shifts, $\nu_0\delta$'s, and coupling constants, J's. A comparison of the calculated intensities for all 15 possible transitions with the experimentally observed spectrum reduces the choice to three of these sets which differ, principally, in the relative signs of the coupling constants. Turning again to the original spectrum, the most probable position for the "missing" highest field quartet belonging to the lower field ABC system can now be found and a choice of suitable transitions made. This yields a set of energy levels for this ABC system from which all possible solutions were computed. A total of six possible solutions resulted, only two of which were found to fit well with the experimental spectrum upon comparing the calculated intensities with those observed. One of these sets of $\nu_0\delta$'s and J's was very close to one of the solutions for the decoupled spectrum. Having identified the C portion of the "low field" ABC, one can now make an assignment of the remaining lines for the other, "high field", ABC system and carry out the sequence of computations as before. This procedure yielded a total of six sets of parameters of which three were in reasonable agreement with the previous results. Only one of these sets, however, compares well with experiment when a comparison of line intensities is done. This set corresponds rather closely to the best results for each of the other two ABC systems. The three best sets of data are collected in Table I together with the averaged parameters. Since the most

precisely determined line positions are those obtained from the original spectrum, the calculated values of the chemical shifts and coupling constants for this spectrum were used for averaging. These averaged figures were then utilized to predict the line positions and intensities of each of the three separate ABC patterns (see Fig. 1(*b*) and 2(*b*)). A comparison of these calculated values with the experimental spectra gave agreement within 0.1 c/s for each line position (see Table II) and within 10% for their intensities.

The proton–fluorine coupling constants were obtained from the calculated chemical shifts after adjustment to a common frequency scale. This is illustrated in Fig. 3. A summary of these and the proton–proton coupling constants is given in Table III.

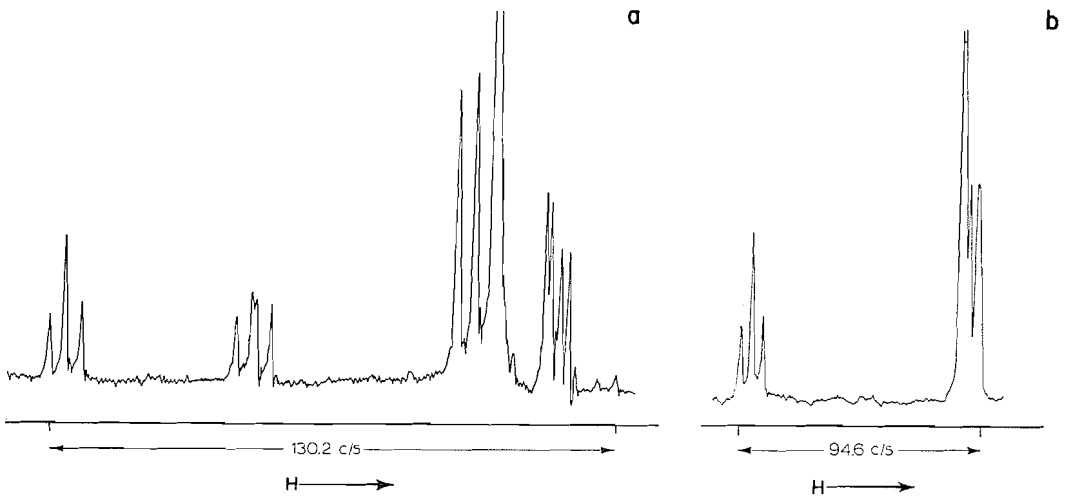

FIG. 4. 60 Mc/s proton spectra of methyl 3-bromo-2-fluoropropanoate. (*a*) Normal spectrum and (*b*) decoupled spectrum obtained by simultaneous irradiation of the fluorine nucleus at its resonance frequency. The strong signal toward higher field in each spectrum is due to the carbomethoxyl protons.

Methyl 3-bromo-2-fluoropropanoate.—The normal 60 Mc/s proton spectrum of methyl 3-bromo-2-fluoropropanoate is shown in Fig. 4(*a*) in which 16 lines are clearly discernible. The two ABC systems within this spectrum are more easily recognized than in the preceding case since one of the protons is shifted to much lower field than the others. Presumably this is the methine proton on the α-carbon. Of the two ABC systems within this spectrum, the one towards higher field is the better starting point for the analysis since more transitions are observed. Using the line positions for the "quartet" at lower field and the seven lines at highest field, an assignment was made from which one of the possible *arrangements* was found. Proceeding as before, all possible *arrangements* were analyzed to compute the physically possible sets of parameters. Four such sets were obtained, two of which gave satisfactory agreement with experiment and the principal difference was the relative sign of the vicinal coupling constant. A similar approach for the low field ABC pattern yielded three sets of parameters for this system. Again, two of these, differing only in the sign of the vicinal coupling constant, gave the most satisfactory agreement with experiment. The "decoupled" spectrum for this compound, shown in Fig. 4(*b*), is an extremely simple pattern having only five observed transitions and is an example of a "deceptively simple" ABX spectrum (14). (The largest peak toward higher field is due to the methoxyl protons.) Thus the data at 60 Mc/s do not allow a decision to be made regarding the relative signs of the coupling constants except by analogy with other similar systems. Furthermore, there are two equally satisfactory chemical shift assignments for the low field ABC pattern. This latter feature has virtually no effect on the proton–proton coupling constants obtained from the analysis but has a significant effect on the proton–fluorine coupling constants. To resolve this problem, the chemical shift data were converted to those expected at 15.1 Mc/s with both possible assignments for the low field ABC shifts included and the theoretical spectra were calculated. A comparison of the experimental 15.1 Mc/s spectrum, shown in Fig. 5(*a*), with those calculated allowed an unequivocal decision between the various possibilities (Table V). The agreement obtained for the best assignment is illustrated by the data in Table IV and schematic spectrum Fig. 5(*b*) for

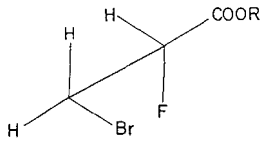
Proton Shifts

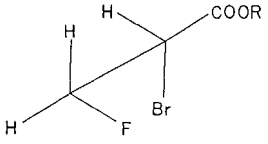
The proton chemical shifts relative to internal tetramethylsilane for the two esters were found to be as follows: methyl 2-bromo-3-fluoropropanoate, 3.82 p.p.m. ($COOCH_3$), 4.24 p.p.m. (—CHBr), 4.78 and 4.57 p.p.m. (CH_2F); methyl 3-bromo-2-fluoropropanoate, 3.80 ($COOCH_3$), 5.24 (—CHF), 3.76 and 3.72 p.p.m. (CH_2Br).

DISCUSSION

The question of the relative signs of geminal and vicinal proton–proton spin coupling constants has received much attention recently and the fact that the signs are opposite is well documented (3). For the analogous spin–spin couplings involving proton–fluorine interactions, the constants have been found to have the same sign (5). The present results (see Table III) are in complete agreement with the previous findings and thus confirm the original conclusions. The normal proton spectrum of the α-fluoro isomer (Fig. 4*a*) shows, simply by inspection, the geminal and vicinal proton–fluorine constants to be of the same sign, and while it is not immediately obvious from the spectrum of the β-fluoro isomer, the calculations unequivocally illustrate that this is indeed the case. The agreement between the calculated and observed 60 Mc/s spectra for methyl 2-bromo-3-fluoropropanoate, as shown in the preceding section, confirm the opposite sign relation for the geminal and vicinal proton couplings and the agreement between the calculated and observed 15.1 Mc/s spectra establishes this point for methyl 3-bromo-2-fluoropropanoate. It should be noted that the proton–fluorine coupling constants are given with the same relative sign as the vicinal proton–proton coupling constants, although this was not proved by our analysis. Tiers (15), however, has established that $J_{^{13}C-H}$ and geminal J_{H-F} have the same sign and since $J_{^{13}C-H}$ and geminal J_{H-H} are opposite in sign (16, 17), it follows that geminal J_{H-F} and vicinal J_{H-H} are of like sign.



A



B

The magnitudes of the proton–fluorine coupling constants reported here are within the limits of previously recorded ranges for similar systems (18–22) as are the proton–proton couplings. It is interesting that the electronegativity effect of substituents on the geminal coupling constants is negligible for the proton–fluorine interactions but is appreciable (2.5 c/s) for the proton–proton couplings and is in the expected direction (23) since geminal J_{H-H} = 12.0 c/s for the β-bromo ester and 9.5 c/s for the β-fluoro ester. The factors which affect the magnitude of vicinal J_{H-F} have not been extensively studied. Abraham and Bernstein (24) have concluded from a study of the temperature dependence of the spectrum of CCl_2F—$CHCl_2$ that $J_{trans} \sim 18$ c/s and $J_{gauche} \sim 1$ c/s. In a more recent paper, Fessenden and Waugh (25) report a similar study of $CClF_2$—$CHCl_2$ and were unable to determine with certainty which vicinal coupling constant is the larger. In the present cases, there is a large difference in magnitude for the vicinal J_{H-F} values. There is also an appreciable difference in vicinal J_{H-H} for the two esters. If we assume that the effect of the halogens due to electronegativity and hybridization is the same for both isomers then we can conclude from the Karplus relation (26) that the lower values for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

vicinal J_{H-H} in the α-fluoro isomer reflect a greater proportion of *gauche* interactions than in the β-fluoro isomer. This can only result from a greater contribution of rotamer A to the overall conformational equilibrium of the α-fluoro isomer than the contribution of rotamer B to the equilibrium of the β-fluoro ester. If A contributes more in the α-fluoro case than B for the β-isomer, it follows of necessity that there will be a greater contribution of $J_{trans\ H-F}$ vs. $J_{gauche\ H-F}$ in the α-isomer. Since the observed vicinal J_{H-F} is greater for the α-isomer, our results indicate that $J_{trans} > J_{gauche}$ for vicinal proton–fluorine interactions as concluded by Abraham and Bernstein (24). The above argument is subject to the restrictions recently reiterated by Karplus (27) and requires further work to substantiate it fully. Experiments to shed more light on this problem are in hand.

ON THE ANODIC OVERVOLTAGE IN ALUMINUM ELECTROLYSIS

JOMAR THONSTAD AND EIRIK HOVE
Technical University of Norway, Trondheim, Norway
Received October 2, 1963

ABSTRACT

The overvoltage on the carbon anode in aluminum electrolysis has been measured against a CO_2/C reference electrode placed in the cryolite melt. The behavior of the reference electrode was first investigated against the aluminum cathode. This galvanic cell showed a stable potential of 1.15 V, which was close to the reversible potential for the cell reaction in aluminum electrolysis. Similar measurements were made with CO/C and CO_2,CO/C electrodes. The potential of the CO/C electrode was in fair agreement with the reversible potential for the most probable cell reaction. The potentials obtained with CO_2–CO mixtures were intermediate between those for the pure gases, increasing with increasing CO_2 content. An explanation for the behavior of the CO_2,CO/C electrode is suggested.

The anodic overvoltage depended only to a limited extent on the chemical reactivity of carbon with respect to oxygen. Graphite anodes showed higher overvoltage than all other types of carbon anodes. Catalyzing and inhibiting additives to the carbon had small but significant influences on the overvoltage. Straight Tafel plots were obtained with slopes varying between 0.26 and 0.27. On this basis it is shown that the overvoltage may be due either to slow transport of oxygen ions through the double layer or to slow reaction between chemisorbed oxygen and carbon.

INTRODUCTION

Overvoltage

The decomposition voltage for the aluminum electrolytic cell has been found to be 1.40–1.70 V (1, 2, 3), which is considerably higher than the theoretical values for the two possible overall cell reactions shown below.

$$Al_2O_3 + (3/2)C \rightarrow 2Al + (3/2)CO_2, \qquad E^0_{1000°C} = 1.16 \text{ V (4)} \qquad [1]$$

$$Al_2O_3 + 3C \rightarrow 2Al + 3CO, \qquad E^0_{1000°C} = 1.03 \text{ V (4)} \qquad [2]$$

From measurements with an aluminum cathode Drossbach (5) and Piontelli (6) have shown that the cathodic overvoltage is negligible; hence the observed overvoltage must be confined to the anode.

From experimental evidence (7, 1, 8) it appears that CO_2 is the primary anode product during electrolysis at normal current densities. The anode reaction may tentatively be divided into the following consecutive steps.

Transfer of oxygen-carrying ions through the electric double layer:

$$O^{2-} \text{ (in melt)} \rightarrow O^{2-} \text{ (on surface)} \qquad [3]$$

Discharge and chemisorption: $O^{2-} + C \rightarrow C_xO + 2e$ [4]

Formation of CO_2: $2C_xO \rightarrow CO_2 \text{ (adsorbed)} + C$ [5]

Desorption of CO_2: $CO_2 \text{ (adsorbed)} \rightarrow CO_2 \text{ (g)}$ [6]

The occurrence of chemisorbed oxygen on carbon, usually denoted as C_xO, is also known from the theory of combustion of carbon in air (9, 10).

In measurements with graphite anodes, Welch and Richards (11) found that the anodic overvoltage follows the classical Tafel equation

$$\eta = a + b \log i \qquad (a = 0.52\text{–}0.64,\ b = 0.32\text{–}0.34)$$

and concluded that the overvoltage was caused by slow transport of oxygen-carrying ions through the double layer.

From potential decay measurements on industrial cells, Stern and Holmes (2) concluded that the slow step is a chemical reaction of approximately second order, e.g. reaction [5].

Mashovets and Revazyan (12) have suggested that the overvoltage consists of two components, one "non-inertial" due to slowness of reaction [3] and one "inertial" due to slowness of reaction [5].

Reference Electrodes

Mashovets and Revazyan (13) found that the galvanic element

$$Al/Na_3AlF_6 + Al_2O_3/CO_2/C \qquad [7]$$

gave a stable potential of 1.11 V at 1000° C, which is fairly close to the reversible potential for reaction [1].* Richards (14) has studied the CO_2,CO/C electrode and postulated that the oxygen pressure is determined by the equilibrium

$$CO + (1/2)\ O_2 \leftrightharpoons CO_2, \qquad [8]$$

as originally suggested by Drossbach (5). If p_{O_2} determined from equilibrium [8] is introduced into the formal expression for the cell reaction,

$$Al_2O_3 \rightleftharpoons 2Al + (3/2)O_2, \qquad E_{1000°C} = 2.19 + RT/4F \log p_{O_2}\ (4), \qquad [9]$$

the relation finally becomes

$$E_{1000°C} = 1.30 + 0.126 \log \frac{p_{CO_2}}{p_{CO}}. \qquad [10]$$

This relation is shown by curve I in Fig. 1 where E is plotted against $p_{CO_2}/p_{CO_2}+p_{CO}$.

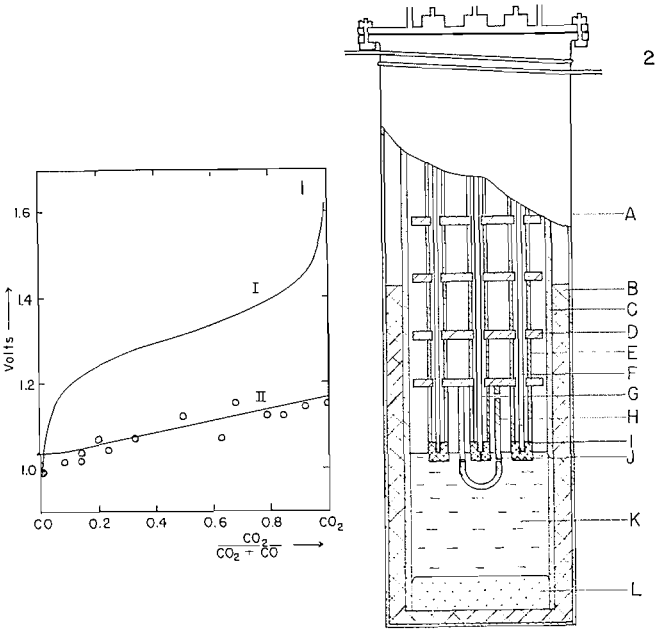

FIG. 1. The dependence of the potential on the ratio CO_2/CO_2+CO. Curve I, following equation [11]; curve II, following equation [16]; O, experimental points.

FIG. 2. Experimental cell.

**There is considerable inconsistency in the thermodynamic data which are used for the calculation of the reversible potentials for reactions [1] and [2]. In recent Russian literature (1) these potentials come out as 1.115 V and 0.98 V respectively at 1000° C, as against 1.16 V and 1.03 V when derived from other sources (4).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Richards (14), however, did not get potentials agreeing with equation [10]; the experimental values were much lower (e.g. 1.036 V as compared to 1.40 V for a CO_2/CO ratio of 3), but this was explained as being due to non-reliability of the aluminum cathode.

In the present investigation the CO_2,CO/C reference electrode has been studied. The potentials against the aluminum cathode were measured for the pure gases and for different gas mixtures. The main purpose of the overvoltage measurements has been to study the overvoltage dependence on the chemical reactivity of the carbon anode.

EXPERIMENTAL

The experimental cell for overvoltage measurements is shown in Fig. 2. The crucible consisted of a sintered-alumina tube C (60 mm I.D.) placed in a graphite crucible B, which was protected by an outer crucible A, made of heat-resistant steel. The bottom of the graphite crucible, which also served as the cathode contact, was covered by the aluminum cathode L. The electrolyte K consisted of cryolite saturated with alumina. A Kanthal furnace connected to a temperature controller maintained the temperature of 1000° C.

The reference electrode J (12 mm D), made of AUC grade graphite, was screwed on to a copper tube G and was surrounded by a sintered-alumina crucible H with narrow holes facing each of the anodes I. The anodes, which were accurately machined to the same size (12 mm D), were screwed on to copper rods F protected by sintered-alumina tubes E. Because the baffles, D, resulted in a symmetrical arrangement of the anodes around the reference electrode, possible errors due to a potential drop in the electrolyte would be the same for all anodes, so that the comparison between the measured overvoltage would not be affected.

The potentials were measured with a potentiometer.

REFERENCE ELECTRODE

Results

The reference electrode was tested against the aluminum cathode in separate runs prior to electrolysis. Gas mixtures were prepared in advance in a mercury gasometer.

The cell might be presented schematically as follows:

$$Al/Na_3AlF_6 + Al_2O_3/CO_2,CO/C. \qquad [11]$$

The measured potentials were corrected for the thermoelectrical potential of the cell, which was found to be 5 mV at 1000° C.

With pure CO_2 as the inlet gas, several measurements at 1000° C gave $E = 1.15$ V as the stable potential. This potential could be maintained for hours, the fluctuations not being more than 5–10 mV. When the gas flow was kept above 30 ml/min, the potential was independent of the flow rate.

The temperature dependence of the potential is shown on Fig. 3. The slope of the curve is 6.3×10^{-4} V/°K, which is fairly close to the theoretical value calculated for reaction [1], 5.9×10^{-4} V/°K.

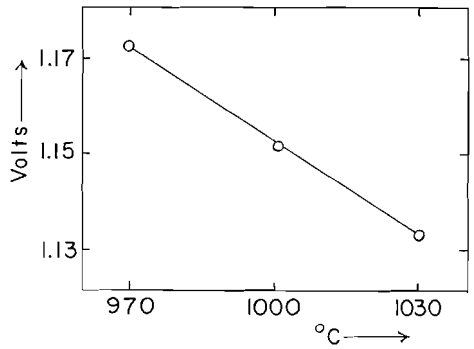

FIG. 3. Temperature dependence of the potential of cell [7].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

With pure CO as inlet gas, the potential values were less stable. The stability of each electrode was usually satisfactory (although not as good as for the CO_2 electrode) but different electrodes gave somewhat different values in the range 0.98 to 1.01 V.

The results obtained with mixtures of CO_2 and CO as inlet gas are plotted as circles on Fig. 1. Although there is considerable scattering of the results, it is evident that the results lie between the values for the pure gases, and that the potential increases with increasing CO_2/CO_2+CO ratio. No curve is drawn to represent the results. Curve II represents calculated potentials from thermodynamic data to be discussed below.

Discussion

The measured potentials for the pure gases agree with the theoretical values for reaction [1] and [2], within the accuracy of these values. It seems therefore reasonable to conclude that the potential-determining overall cell reaction is [1] or [2], depending upon the gas used.

The results for gas mixtures cannot in any way be explained by the theory of Richards (14), as is evident from curve I on Fig. 1. This theory implies that the carbon electrode acts as an inert conductor only, since the oxygen pressure is determined by equation [8]. It seems to be more likely that the oxygen pressure is determined by the following reactions:

$$C + O_2 \leftrightharpoons CO_2 \qquad [12]$$

$$C + (1/2)O_2 \leftrightharpoons CO. \qquad [13]$$

The carbon–oxygen system will not be in equilibrium except at one composition, which at 1000° C is about 99.2% CO, 0.8% CO_2, and 5.4×10^{-17}% O_2 (4).

The following calculation may be suggested: if $p_{CO_2} = x$ and $p_{CO} = 1 - x$, the overall cell reaction with a reversibly acting CO_2,CO/C electrode can be written as:

$$Al_2O_3 + \frac{3}{1+x}C = 2Al + \frac{3x}{1+x}CO_2 + \frac{3(1-x)}{1+x}CO. \qquad [14]$$

The free energy change for this reaction may be expressed in the usual manner from the free energies for reactions [1] and [2], ΔG_1^0 and ΔG_2^0 respectively,

$$\Delta G_x = \frac{2x}{1+x}\Delta G_1^{\,0} + \frac{1-x}{1+x}\Delta G_2^{\,0} + RT \ln \frac{p_{CO_2}^{\,3x/1+x}}{p_{CO}^{\,3(1-x)/1-x}}$$

$(a_{Al_2O_3} = 1, a_{Al} = 1)$

A similar treatment has been suggested by Piontelli (15). By converting the above equation to a Nernst equation, rearranging, and introducing numerical values (4), the final expression becomes:

$$E_x\ (1000°\ C) = 1.03 + \frac{0.26\,x}{1+x} + \frac{0.126}{(1+x)}\,(x \log x + (1-x)\log(1-x)). \qquad [15]$$

This equation is represented by curve II in Fig. 1. It gives a curve which is close to a straight line between E_1^0 and E_2^0.

As an alternative to the treatment above, the anode can be considered as made up of CO_2/C and CO/C half-cells in parallel, the half-cells being located at different spots on the carbon surface. The resulting mixed potential of the electrode towards the aluminum cathode cannot be calculated, but it must evidently lie between the potentials of the pure cells, E_1^0 and E_2^0.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

From the results it appears that the CO_2/C electrode is the best suited reference electrode, because it gives the most stable and reproducible potential. With this electrode the potential against the aluminum cathode is equal to the reversible potential for the overall cell reaction in aluminum electrolysis given by reaction [1].

OVERVOLTAGE MEASUREMENTS

Results

Anodes of different reactivity were obtained by using different kinds of anode materials, by applying different baking temperatures, and by additions of chemicals to the raw materials. The term "reactivity" can here most simply be defined as the tendency to react with oxygen at high temperatures. The reactivity generally decreases with increasing order of the carbon lattice, with graphite as the least reactive material. Addition of various chemicals is known to have substantial influence on the reactivity (17), some acting as catalysts and others as inhibitors.

In this work Fe_2O_3 and Na_2CO_3 were used as catalysts and H_3BO_3 as inhibitor. The additions were made to the raw materials in amounts of 0.4 to 1.3 wt.%. The different types of anodes used are summarized below.

I. Graphite anodes

II. Non-disintegrating anodes
(*a*) With 1.3 wt.% Fe_2O_3
(*b*) With no addition
(*c*) With 1.0 wt.% H_3BO_3

III. Non-disintegrating anodes
(*a*) With 0.6 wt.% Na_2CO_3
(*b*) With no addition
(*c*) With 0.6 wt.% H_3BO_3

IV. Non-disintegrating anodes
(*a*) Baked at 1000° C
(*b*) Baked at 1200° C
(*c*) Baked at 1400° C

V. Industrial type prebaked anodes
(*a*) With 0.4 wt.% Na_2CO_3
(*b*) With no addition
(*c*) With 0.4 wt.% H_3BO_3

All anodes were made by Elektrokemisk A.S. Most of them were of the non-disintegrating type, which earlier had proved not to disintegrate during electrolysis (8). The baking temperature was 1000° C except for type IV.

The current to all four anodes was delivered from the same D.C. source and regulated so that equal currents passed through each anode.

Table I shows a typical set of results on overvoltages obtained with three of the non-disintegrating type anodes, two of which had additions of Fe_2O_3 and H_3BO_3 respectively. In spite of the small differences between the data, there is a distinctive tendency to increasing overvoltage when passing from the most reactive to the least reactive anode. The reproducibility between different runs was not good enough to reveal such differences. However, comparison of the results between a set of anodes of different reactivity in any one experiment indicated clearly this trend.

Corresponding measurements had earlier been carried out in a similar apparatus with non-disintegrating anodes of a different make, type III. These anodes were more porous, and the catalyzing agent was Na_2CO_3 instead of Fe_2O_3. A pure graphite anode was also used. A set of results from these measurements is given in Table II. It is readily seen

TABLE I

Overvoltages (mV) on carbon anodes with chemical additions

Current density, A/cm²	Anode type		
	II(*a*)	II(*b*)	II(*c*)
0.067	160	162	161
0.10	210	211	212
0.13	219	224	225
0.20	298	300	300
0.26	318	318	319
0.29	334	336	336
0.34	354	354	355
0.44	379	380	381
0.67	433	435	435

that the same tendency of increasing overvoltage with decreasing reactivity is also observed in this case.

With anodes of the same type as those used in industrial cells (type V), the same general trend in the overvoltage was observed, as for the non-disintegrating anodes. The differences were of the same magnitude as in the results shown in Tables I and II, i.e. 1–7 mV.

TABLE II

Overvoltages (mV) on carbon anodes with chemical additions

Current density, A/cm²	Anode type			
	III(*a*)	III(*b*)	III(*c*)	I
0.25	265	265	265	281
0.30	283	284	284	302
0.40	289	290	292	334
0.60	361	363	362	—
0.70	371	373	374	405
0.90	410	412	412	432
1.00	427	429	430	472
1.20	460	463	466	518
1.50	526	528	531	593

The differences between the graphite anodes (type I) and types II, III, and V were approximately 20, 60, and 10 mV respectively, at the highest current density of 1.5 A/cm². This sequence was also confirmed in runs where the types I, II, and V were compared directly, as shown in Table III. Taking the overvoltage as a measure of reactivity provides

a reactivity scale, indicating for instance that type II was more reactive than type V. The comparatively great difference with type III was probably due to a larger active surface, because of the higher porosity of this anode material.

Measurements with non-disintegrating anodes baked at different temperatures, type IV, revealed no significant difference in overvoltage.

Discussion

The present results clearly show that the anodic overvoltage in aluminum electrolysis is dependent on the reactivity of the anode material. This dependence is, however, much less pronounced than in combustion of the same materials in oxygen (or CO_2).

In all cases the experimental results gave fairly good Tafel plots. In most measurements the linear relationship between overvoltage and log current density was observed over the entire range investigated (0.04–1.5 A/cm^2), but in a few cases marked inflections in the curves occurred. This phenomenon, which usually indicates that the reaction mechanism has changed, was not further investigated.

Two sets of experimental curves are given in Figs. 4 and 5. In order to keep the curves

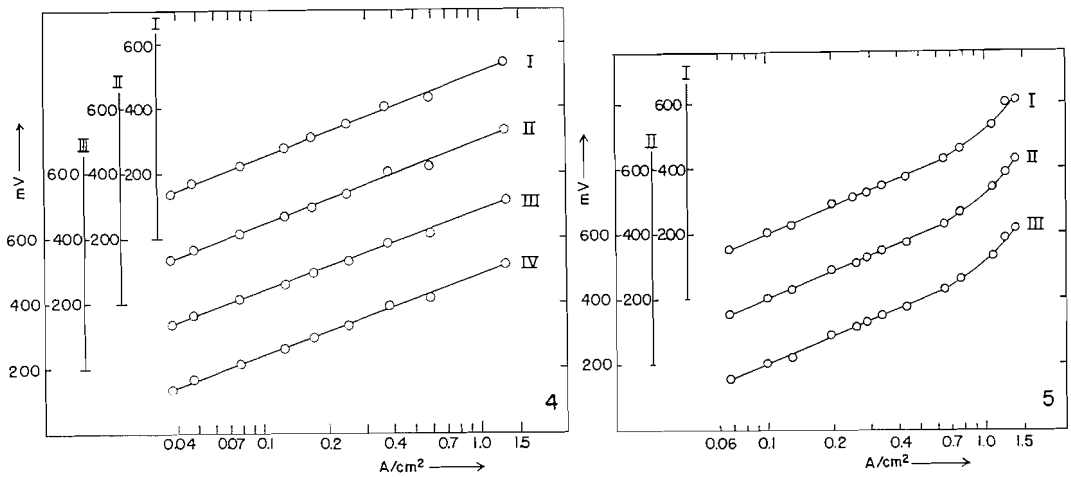

FIG. 4. Tafel plots. Curve I, graphite anode; curve II, industrial type anode; curve III, non-disintegrating anode; curve IV, as above with addition of Fe_2O_3.

FIG. 5. Tafel plots of non-disintegrating anodes. Curve I, with addition of H_3BO_3; curve II, without addition; curve III, with addition of Fe_2O_3.

apart, the ordinate has been displaced successively upwards. Fig. 4 shows the typical case whereas Fig. 5 gives curves which bend at about 0.65 A/cm^2.

The coefficients in Tafel's equation showed fairly constant values. The b value ranged between 0.26 and 0.27 in all runs but two, when it was 0.20. The a value was in the range 0.40–0.52.

Assuming that the overvoltage is caused by slow transport of oxygen-carrying ions through the double layer (reaction [3]), the relationship between overvoltage and current can be expressed by a Tafel equation in the form:

$$\eta = \frac{-RT}{\beta z F} \ln i_0 + \frac{RT}{\beta z F} \ln i \qquad [16]$$

where β is the symmetry factor, z the number of electrons and i_0 the "exchange current".

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Introducing the experimental value, $b = 0.26$–0.27, βz can be calculated as $\beta z = 0.97$–0.94. Assuming that the energy barrier through the double layer is symmetrical, i.e. $\beta = 1/2$, gives $z \simeq 2$, as expected for a reaction involving discharge of divalent oxygen ions.

If, on the other hand, the overvoltage is entirely due to slow formation of CO_2 from chemisorbed oxygen (e.g. reaction [5]), the overvoltage can be described as reaction overvoltage according to the general treatment introduced by Vetter (16). Under certain conditions the reaction overvoltage can be represented by a Tafel equation in the form:

$$\eta = \frac{-RT}{Fpn/\nu} \ln i_r + \frac{RT}{Fpn/\nu} \ln i \qquad [17]$$

where p is the order of reaction for the rate-determining chemical reaction and n/ν is the number of electrons required in the overall cell reaction for the formation of one activated complex. The term i_r is the "reaction limiting current" for the cell reaction going in the reverse direction, when $c \rightarrow 0$ at the interface.

In this case pn/ν would equal 0.97–0.94. The fraction n/ν cannot be less than two if one oxygen atom is involved, and the value of p must then be approximately one-half.

In an investigation of the kinetics of oxidation of graphite in oxygen at 800° C, Blyholder and Eyring (18) found that the order of reaction with respect to oxygen was zero when the reaction occurred only on the surface, and one-half when it also occurred in the pores in the graphite. A zero order of reaction with respect to oxygen indicates that the slow step is the breaking of the C–C bonds in the carbon network. In that case the present experimental results could also be interpreted in terms of the reaction overvoltage theory, providing that the anode reaction also takes place in the pores of the anode. Antipin and Dudyrev (19) observed that the linear dimensions of an anode increased by about 3% when the current density exceeded 0.1 A/cm^2. This expansion may indicate that oxygen becomes internally chemisorbed into the carbon material, so that the reaction could also take place within the pores of the anode.

From the treatment above it can be concluded that slow formation of CO_2 from the chemisorbed oxygen cannot be ruled out as the cause for the overvoltage. The experimental results show that the chemical reactivity of the carbon has a certain influence on the overvoltage. The overvoltage, therefore, can hardly be ascribed entirely to slow transport of oxygen ions through the double layer. It appears that the overvoltage is caused both by slow transport of oxygen ions through the double layer and by slow reaction on the carbon, although our experimental results do not allow the elucidation of the reaction mechanism in detail.

ACKNOWLEDGMENTS

The anodes used in this work were made by Elektrokemisk A/S, Research Department, Kristiansand S, Norway. The authors also wish to thank Prof. Rosenqvist, The Technical University of Norway, for helpful discussions and Prof. Flengas, University of Toronto, for critically reading the manuscript.

PLATINUM(II) COMPLEXES: INFRARED SPECTRA IN THE 300–800 CM^{-1} REGION

A. D. ALLEN AND T. THEOPHANIDES[1]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received February 6, 1964

ABSTRACT

Bands have been assigned to stretching frequencies of bonds between platinum and chlorine, nitrogen and oxygen which are observed in the far infrared region. The positions of these bands have been related to the structures of several complexes. Improved procedures are given for the preparation of complexes of the type $K[PtCl_3L]$ and *trans*-$PtCl_2L(am)$, where L is an unsaturated organic ligand and am is an aromatic amine.

As part of a study of the trans effect of unsaturated organic ligands in chloro-complexes of bivalent platinum, the infrared spectra of a series of such compounds have been examined in the 300-800 cm^{-1} region. Variations in the stretching frequencies, ν Pt–Cl, have been investigated and assignments made for the platinum – aromatic nitrogen stretching modes, ν Pt–N. From the spectrum of bis(acetylacetono) platinum(II) stretching frequencies ν Pt–O have been determined.

RESULTS AND DISCUSSION

(a) Chloro-complexes

In Table I are given details of the spectra of salts of the general form $K^+[PtCl_3L]^-$,

TABLE I

Complex	Cl–Pt–Cl, ν cm^{-1}	*trans*-Pt–Cl, ν cm^{-1}	Other bands, ν cm^{-1}
$K[C_3H_6PtCl_3]$†	330 vs	306 s	393 m, 535 vs
$K[C_2H_4PtCl_3]$	340 vs, 331 sh	306 vs	373 m, 403 ms, 492 s
K[olPtCl$_3$]	330 s, 335 sh	305 w	—
K[acPtCl$_3$]	326 vs	312 s	438 m, 486 m, 557 m, 600 s
K[ac*PtCl$_3$]	325 vs, 335 ms	314 s	474 m, 543 s, 618 s
$(MeC_2(OH)C\equiv)_2$	—	—	370 m, 535 s

where L is an unsaturated organic ligand. Since the complex ion is essentially square planar, with the platinum atom at the center, we expect to find two platinum–chlorine stretching frequencies: (*a*) the asymmetric stretching vibration of the linear Cl–Pt–Cl unit (the symmetric vibration being inactive in the infrared); and (*b*) the stretching frequency of the platinum–chlorine group trans to the ligand L. This latter frequency should be lower than the first because of the weakening of the bond by the high trans effect of the unsaturated ligand (1) as reported by Adams and Chatt (2) for the propene platinous chloride ion. We find that the stretching frequency of the trans chlorine (306–314 cm^{-1}) is some 20 cm^{-1} lower than that of the Cl–Pt–Cl unit (325–340 cm^{-1}), which is in accordance with expectations.

For the allyl alcohol complex the band at 305 cm^{-1} is rather weak and may be affected

[1]*Present address: Howard University, Washington, D.C.*

by any traces of water present, but if this is accepted there is a clear distinction between the *trans*-Pt–Cl stretching frequencies for the olefin and acetylene type complexes which indicates a greater bond weakening, and hence stronger trans effect, for the olefinic ligands.

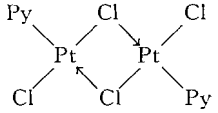
When salts of the above type are treated with one equivalent of a base such as pyridine a non-ionic product with the formula $[PtCl_2Lpy]^0$ is obtained (3, 4). The *trans* structure of this compound, which would be expected from the fact that the chlorine *trans* to the organic ligand is much more easily displaced than the other two, is shown by its far infrared spectrum. Details of the spectra of this type of compound are given in Table II.

TABLE II

Compound	ν Pt–Cl, cm^{-1}	ν Pt–N, cm^{-1}	Other bands, cm^{-1}
$[Ptpy_4]^{++}Cl_2 3H_2O$	—	474 m	793 m, 781 m, 735 s, 658 m, 302 m, 294 m
trans-$Ptpy_2Cl_2$	343 vs	480 m	778 m, 735 ms, 705 m
cis-$Ptpy_2Cl_2$	344 s, 330 ms	467 m, 454 m	776 m, 738 ms, 706 ms
$Pt_2py_2Cl_4$	349 s, 308 m	454 m	766 m, 736 ms, 688 ms
trans-acPtCl$_2$py	340 vs	474 m	690 m, 597 m, 549 ms, 532 ms, 438 w
trans-acPtCl$_2$(2,pic)	339 vs	477 m	602 m, 549 m, 532 ms, 440 m
trans-acPtCl$_2$(2,6-lu)	337 vs	450 m	645 m, 602 m, 549 m, 535 m, 411 w
trans-olPtCl$_2$(2,6-lu)	344 vs	463 w	855 w, 783 s, 606 s, 511 s, 413 w, 370 m

A single band at about 340 cm^{-1} is observed corresponding to the asymmetric vibration of the linear Cl–Pt–Cl unit, the band at about 310 cm^{-1}, due to the *trans* chlorine, having disappeared. These spectra also show a new band at about 470 cm^{-1}. We assign this band to the stretching mode of the platinum–pyridine bond on the basis of a comparison with the spectra of other compounds containing this bond, also shown in Table II. The ion $[Ptpy_4]^{++}$ has one band at 474 cm^{-1}, and the compound *trans*-$Ptpy_2Cl_2$ has a similar band at 480 cm^{-1}, corresponding to the asymmetric stretching vibration of the linear N–Pt–N unit, as well as the expected band at 343 cm^{-1} for the linear Cl–Pt–Cl unit. In the spectrum of the *cis* isomer of this compound each of these is split into two bands, since both the symmetric and asymmetric stretching modes of the angular *cis* $PtCl_2$ unit and *cis* $Ptpy_2$ unit are active in the infrared. The spectra of these two isomers form the basis of an excellent and simple method of distinguishing between *cis* and *trans* isomers, and for the detection of one in the presence of the other.

From these spectra it has been possible to determine the structure of the material which is formed when a solution of the complex *trans*-$PtCl_2$ac.py in dry benzene is allowed to stand at room temperature. After about 48 hours reddish-brown crystals begin to form, which are insoluble in common organic solvents. The spectrum of this material in the sodium chloride region contains typical pyridine frequencies only, showing that the acetylene has been displaced from the complex. The far infrared spectrum (Table II) shows bands at 308, 349, and 454 cm^{-1}. From these data, and from analyses for carbon, hydrogen, and chlorine, the following bridged structure is proposed:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The band at 454 cm^{-1} is the metal–pyridine stretching frequency, and the band at 349 cm^{-1} is the terminal platinum–chlorine frequency. The band at 308 cm^{-1} is similar to that observed by Adams (5) for the bridging chlorines in platinous chloride (312 cm^{-1}), and is assigned to that vibration. Two similar bands have also been observed (12) for the bridged complexes $[Cr_2Cl_9]^{3-}$ and $[V_2Cl_9]^{3-}$. The trans configuration of the two pyridines is suggested from the fact that only one band is observed for the two bridging chlorines, indicating that they are identical. If the pyridines were in the cis configuration the bridging chlorines would differ from each other and two bands would be expected. This particular compound has not been reported previously. Chatt and Venanzi (13) prepared a series of bridged compounds of bivalent platinum containing aromatic amines from the decomposition (2 months) of *trans*-ethyleneaminedichloroplatinum compounds. The use of the acetylene diol in place of ethylene greatly speeds up the preparation of these compounds since the starting material is easier to prepare and its decomposition in an inert solvent takes place more rapidly.

(b) Bis(acetylacetono) platinum(II)

The far infrared spectrum of bis(acetylacetono) platinum(II) is very similar to that reported by Nakamoto (6) for the analogous palladium(II) compound, who assigns a band at 464 cm^{-1} for the symmetric palladium–oxygen stretching frequency and gives a calculated value of 317 cm^{-1} for the asymmetric metal–oxygen stretching mode. We find (14) a band at 319 cm^{-1}, corresponding to the latter vibration in the platinum complex, and one at 478 cm^{-1} for the symmetric stretching mode. A correlation between this vibration and the stability constant (log K_1K_2) of the acetylacetonate complexes of several bivalent transition metals has been suggested (6). The stability constant of the platinum complex has not been reported, but by extrapolation from these other complexes, based on a stretching frequency for this vibration of 478 cm^{-1}, we obtain an estimated value for the logarithm of the stability constant of between 40 and 45 for this compound. This very high value is consistent with the well-known stability of complexes of bivalent platinum.

EXPERIMENTAL

The ligand 2,5-dimethyl-3-hexyne-2,5-diol was used as supplied by Air Reduction Chemical and Carbide Co. The dimethyl ether of this diol was prepared from it as described in ref. (4).

Potassium Trichloro(ethylene) Platinum(II) Monohydrate (Zeise Salt)

Prepared as described by Chatt and Duncanson (7), decomp. 175–180° (lit. (7)) decomp. about 165°.

Potassium Trichloro(2,5-dimethyl-3-hexyne-2,5-diol) Platinum(II)

In the procedure described by Bukhovets (4, 8) a concentrated aqueous solution of potassium chloroplatinite containing a twofold excess of the diol is allowed to stand at room temperature until the color changes from red to an orange-yellow. This takes from 1 to 2 weeks. It was found that by heating the solution on a water bath the change in color takes place in 2–3 minutes, but that further heating results in rapid decomposition. By cooling the solution in ice as soon as the change in color was observed this decomposition was prevented and the time taken for this step was reduced from several days to a few minutes. The filtered solution was evaporated at 30–40° at reduced pressure, and the procedure of Bukhovets was followed from this point. The yellow product was recrystallized from ether–acetone and dried *in vacuo* at room temperature, decomp. 140–145° (lit. (4, 8) decomp. 140–145°). Calc. for $C_8H_{14}O_2Cl_3PtK$: C, 19.9; H, 2.95. Found: C, 20.1; H, 3.05.

Potassium Trichloro-(2,5-dimethyl-2,5-dimethoxy-3-hexyne) Platinum(II)

Prepared as described by Bukhovets (4, 8). Recrystallization of the dark yellow product from ether–acetone gave yellow crystals, decomp. 154–156° (lit. (4) decomp. 140–145°). Calc. for $C_{10}H_{18}O_2Cl_3PtK$: C, 23.5; H, 3.55. Found: C, 23.3; H, 3.55.

Compounds of the type *trans*-$PtCl_2L(am)$, where am = pyridine, etc., were first prepared by the method of Gel'man, Bukhovets, and Meilakh (3, 4). A more convenient method was later used, as follows. To a concentrated solution of the potassium salt K $[PtCl_3L]$ in dry acetone was added a slight excess of the base

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(pyridine, etc.). A precipitate of potassium chloride formed immediately, and was removed by filtration. The filtrate was evaporated at room temperature, giving yellow crystals, which were thoroughly washed with cold water to remove traces of pyridine and potassium chloride, and dried *in vacuo* at room temperature. Further purification was not necessary, but recrystallization gave well-formed crystals. The following four compounds were prepared in this way:

trans-Dichloro-(2,5-dimethyl-3-hexyne-2,5-diol) (pyridine) platinum(II).—Bright yellow crystals, recrystallized from carbon tetrachloride or ether, m.p. 110–112° (decomp.) (lit. (3) m.p. 97° and (4) 114–116°). Calc. for $C_{13}H_{19}O_2NCl_2Pt$: C, 32.05; H, 3.95. Found: C, 31.8; H, 4.2.

trans-Dichloro-(2,5-dimethyl-3-hexyne-2,5-diol) (2-picoline) platinum(II).—Yellow crystals, recrystallized from ether or acetone, m.p. 127° (decomp.). Calc. for $C_{14}H_{21}O_2NCl_2Pt$: C, 33.55; H, 4.2. Found: C, 33.8; H, 4.1.

trans-Dichloro-(2,5-dimethyl-3-hexyne-2,5-diol) (2,6-lutidine) platinum(II).—This very stable compound has been stored in air for 1 year without detectable decomposition. Fine yellow prisms, recrystallized from benzene, m.p. 154°. Calc. for $C_{15}H_{23}O_2NCl_2Pt$: C, 34.95; H, 4.5. Found: C, 34.75; H, 4.7.

trans-Dichloro-(1-propen-2-ol) (2,6-lutidine) platinum(II).—Yellow crystals, recrystallized from carbon tetrachloride or ether, m.p. 102°. Calc. for $C_{10}H_{15}OCl_2NPt$: C, 27.85; H, 3.5. Found: C, 28.0; H, 3.65.

Tetrachloro-dipyridino-diplatinum(II)

The compound to which this formula is assigned was formed when a solution (3%) of the compound *trans*-dichloro-(2,5-dimethyl-3-hexyne-2,5-diol) (pyridine) platinum(II) in dry benzene was allowed to stand at room temperature. After 2 days reddish-brown crystals began to form. These are insoluble in common organic solvents except acetone (slightly soluble) and pyridine (soluble with reaction), m.p. 170° (decomp.). Calc. for $C_{10}H_{10}N_2Cl_4Pt_2$: C, 17.45; H, 1.45; Cl, 20.55. Found: C, 18.65; H, 1.55; Cl, 19.9.

The Compounds cis- and trans-Dichloro-dipyridino-platinum(II) and Tetrapyridino-platinum(II) Dichloride

These compounds were prepared as described by Kaufmann (9).

Bis(acetylacetono) Platinum(II)

Prepared as described by Werner (10). Recrystallization from benzene gave long yellow needles which begin to darken at 200° and turn black at about 240°. Calc. for $C_{10}H_{14}O_4Pt$: C, 30.5; H, 3.6. Found: C, 30.5; H, 3.45.

Infrared Spectra

The spectra were recorded with a Beckman IR-4 spectrometer, equipped with cesium bromide optics. The samples were prepared in polyethylene films (11). The instrument was calibrated against water vapor.

Microanalyses were done by Alfred Bernhardt, Mulheim.

We are indebted to Miss Mary Wright for assistance with some of the experimental work and to the National Research Council for financial support.

COMPLEXES OF STANNIC CHLORIDE WITH AROMATIC HYDROCARBONS AND OXYGEN-CONTAINING DONORS IN SOLUTION

J. J. Myher and K. E. Russell
Department of Chemistry, Queen's University, Kingston, Ontario
Received February 6, 1964

ABSTRACT

Complex formation between stannic chloride and various alkylbenzenes has been investigated by means of optical measurements. It is found that weak 1:1 complexes are formed in methylene chloride solution at 25 °C. The absorption at 355 mμ can be used to determine the concentration of free stannic chloride in benzene to which oxygen-containing donors have been added. The results are interpreted in terms of 1:1 and 1:2 complex formation between stannic chloride and donor. For the stronger donors such as tetrahydrofuran and acetone, the main complexes formed with excess of stannic chloride must contain equimolar amounts of stannic chloride and donor, and it is probable that they involve tin with a coordination number of five. Ethyl esters of chloroacids are very much weaker donors than ethyl esters of unsubstituted acids. The heat of reaction for the addition of a donor molecule to the 1:1 complex is usually close to the heat of reaction for the addition of the first donor molecule to stannic chloride. The decrease in entropy in each case is approximately 30 e.u./mole.

Extensive studies have been made of complexes between stannic chloride and both oxygen- and nitrogen-containing Lewis bases. In general stannic chloride forms 1:2 complexes with monofunctional donors such as simple aldehydes, ketones, ethers, and esters (1, 2, 3). In some studies, evidence has been obtained for 1:1 complexes; for example, molecular weight studies of complexes of stannic chloride and esters (4), ketones and ethers (2) were interpreted in terms of the dissociation of 1:2 complexes into 1:1 complexes and donor. More recently Kubota and Brown (5) have proved that 1:1 complexes between stannic chloride and aromatic nitriles persist in dilute solution and have determined equilibrium constants for their dissociation into the component donor and acceptor molecules. Laane and Brown (6) have extended this work to include diisobutyl ketone, 9-fluorenone, and ethyl pivulate. Brune and Zeil (7) have shown that both 1:1 and 1:2 complexes between stannic chloride and ethers, alcohols, and nitriles exist in the pure state and in concentrated solution. Satchell and Wardell (8) have interpreted absorption data of solutions of nitroanilines and stannic chloride in *o*-dichlorobenzene on the assumption that 1:1 complexes are formed.

There appears to be little quantitative information concerning the factors which govern the formation of 1:1 and 1:2 complexes between stannic chloride and simple oxygen-containing donors in solution. In principle equilibrium constants may be obtained by studying the infrared spectra of mixtures of stannic chloride and oxygen-containing donor in an inert solvent. The concentration of free donor can be estimated from the intensity of an appropriate infrared absorption band because complexing normally shifts the position of this band. In practice there is some difficulty with overlapping bands when aromatic nitriles are used as donors (5) and with some exceptions (6) the same difficulties are encountered with oxygen-containing donors. An alternative approach is suggested by Satchell's work (9) with toluene solutions of stannic chloride. Satchell confirmed Comyns, Howald, and Willard's observation (10) that such solutions absorb in the near ultraviolet and showed that the absorbance at 380 mμ was proportional to the concentration

of stannic chloride. The addition of acetic acid to a toluene solution of stannic chloride caused a reduction in the absorbance at 380 mμ; the concentration of free stannic chloride was determined from the measured absorbance. Satchell interpreted his results in terms of $SnCl_4 \cdot 3CH_3COOH$ and higher complexes but his conclusions are open to question because he neglected to consider the effects of hydrogen bonding and of dissociation.

Application of the method to other systems appeared attractive because ultraviolet measurements of fairly high precision can be readily made using solutions at controlled temperatures. If the only significant absorbance is due to the complex between stannic chloride and aromatic hydrocarbon, the free stannic chloride concentration can be readily estimated to $\pm 0.0005\ M$ and reasonably accurate estimates of equilibrium constants for the formation of 1:1 complexes between stannic chloride and many donors can be made. In this paper it is shown that weak 1:1 complexes are formed between stannic chloride and each of the aromatic hydrocarbons benzene, toluene, mesitylene, and hexamethylbenzene. Equilibria in dilute solution between stannic chloride and certain ethers and esters and the corresponding 1:1 and 1:2 complexes were studied using benzene as solvent and indicator. Calorimetric data were obtained for four donors and these were interpreted using the equilibrium constants estimated in the ultraviolet studies.

EXPERIMENTAL

Materials

Benzene and methylene chloride were dried over calcium chloride, degassed on the vacuum line and stirred with powdered Drierite for several hours. Mesitylene was treated with concentrated sulphuric acid, washed with sodium carbonate solution and water, and dried over calcium chloride; after standing over calcium hydride it was distilled *in vacuo*. Toluene and the oxygen-containing bases were dried and distilled into ampoules. Stannic chloride was degassed on the vacuum line, distilled three times, and stored at −78.5 °C.

Procedure

Complexes between stannic chloride and benzene, toluene, and mesitylene were investigated using 0.172 *M* solutions of stannic chloride and of hydrocarbon in methylene chloride. Spectra of mixtures containing y ml stannic chloride solution and $5 - y$ ml hydrocarbon solution were taken over the range 300–360 mμ using a Beckman DK1 recording spectrophotometer with cells of 1 cm path length. Complex formation between stannic chloride and hexamethylbenzene was studied using a series of solutions which contained one of the components at constant concentration and the other component at various concentrations; the spectra were recorded over the 300–420 mμ range. The effect of varying the temperature from 15 °C to 40 °C was examined with solutions of stannic chloride in benzene, and of hexamethylbenzene and stannic chloride in methylene chloride, contained in sealed corex cells.

Complex formation between stannic chloride and oxygen-containing donors was investigated with benzene as solvent. The reaction vessel consisted of a corex cell of 1 cm path length sealed to a 50-ml reservoir; ground joints at the top of the vessel provided entry for a small glass stirrer and a microburette. Twenty-five milliliters of an approximately 0.08 *M* solution of stannic chloride in benzene was placed in the cell and the absorbance at 355 mμ measured by means of a DK1 spectrophotometer when temperature equilibrium was reached. A small amount of base was added from the burette, the solution was vigorously stirred and the absorbance was recorded until a steady value was attained. The process was repeated for further additions of base, the maximum amount added generally being in the range of 0.5 ml to 1 ml. Separate experiments involving methylene chloride as solvent established that complexes of stannic chloride and these oxygen-containing donors do not absorb significantly at 355 mμ.

Heats of reaction were obtained by measuring the temperature rise on successive addition of small volumes of donor to 25 ml of stannic chloride solution in benzene. The simple calorimeter consisted of a Dewar flask, micromagnetic stirrer, and Beckmann thermometer. The heat capacity of the assembly was determined from electrical measurements.

Infrared spectra were recorded at room temperature using a Perkin–Elmer Model 21 spectrometer. The solutions were prepared by adding various amounts of ethyl formate, acetate, or propionate to an approximately 0.1 *M* solution of stannic chloride in benzene. The sealed cells were of 0.1 mm path length. Infrared spectra of benzene solutions of the pure esters were obtained under similar conditions.

RESULTS AND DISCUSSION

Complexes between Stannic Chloride and Aromatic Hydrocarbons

Mixtures of stannic chloride and benzene, toluene, mesitylene, or hexamethylbenzene in methylene chloride solution absorb significantly in the 320 to 360 mμ range, whereas solutions of the individual components show negligible absorption. Continuous variation plots for the absorbance of solutions of stannic chloride and mesitylene in methylene chloride at 25 °C are given in Fig. 1. At both 320 mμ and 340 mμ the absorbance passes

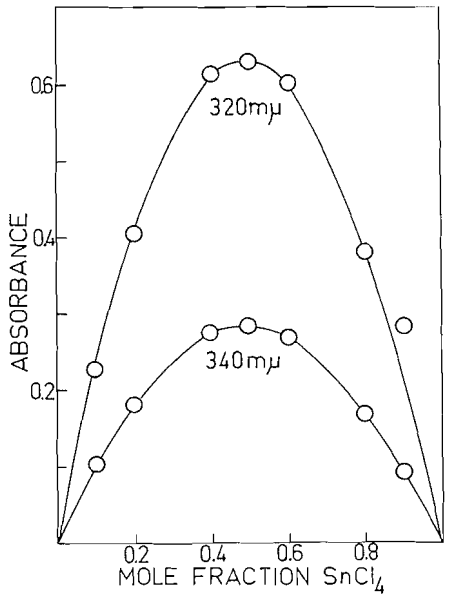

FIG. 1. Absorbance of solutions of stannic chloride and mesitylene in methylene chloride at 25 °C. Mole fraction of stannic chloride refers to the stannic chloride – mesitylene mixture, neglecting the solvent.

through a maximum when the mole fraction of stannic chloride is 0.5 indicating that a 1:1 complex is formed between stannic chloride and mesitylene. The curves are symmetrical, suggesting that only one complex with absorption in this region is formed and the rounded nature of the maximum shows that the complex is largely dissociated. Similar results are obtained with benzene and toluene. With hexamethylbenzene the absorbance in the range 320–410 mμ was found to be proportional to the stannic chloride concentration when the hexamethylbenzene concentration was constant and proportional to the hexamethylbenzene concentration for values up to 0.258 *M* when the stannic chloride concentration was constant (0.0178 *M*).

These observations are explained if a 1:1 complex is formed between stannic chloride and the aromatic hydrocarbon.

$$SnCl_4 + ArH \rightleftharpoons SnCl_4 \cdot ArH$$

In dilute methylene chloride solution the equilibrium is displaced well to the left, the results for hexamethylbenzene in particular indicating that the proportion of complexed stannic chloride is extremely small. Enthalpies of formation were estimated to be approximately −0.2 kcal/mole for the stannic chloride – hexamethylbenzene complex in methylene chloride solution, and 1.2 kcal/mole for the stannic chloride – benzene complex in benzene solution.

Earlier work in this field includes that of Tsubomura (11), who showed that a benzene solution of stannic chloride absorbs in the 330–360 mμ region. Ulich, Hertel, and Nespital (2) interpreted molar polarization data of such solutions in terms of complex formation between stannic chloride and benzene. Elliott, Evans, and Owen (12) have shown that a comparable 1:1 complex is formed between titanium chloride and benzene.

Complexes between Stannic Chloride and Ethers

The absorbance of benzene solutions of stannic chloride in the 355 mμ region is directly proportional to the concentration of stannic chloride. On the addition of a Lewis base such as tetrahydrofuran (THF), the optical density falls to a new value which is a measure of the concentration of free stannic chloride in the solution. Complexes of stannic chloride and tetrahydrofuran do not absorb in this region. Values of free stannic chloride concentration [$SnCl_4$] obtained at 25 °C are plotted against concentration of added tetrahydrofuran [THF] in Fig. 2. The dotted lines represent the hypothetical results for

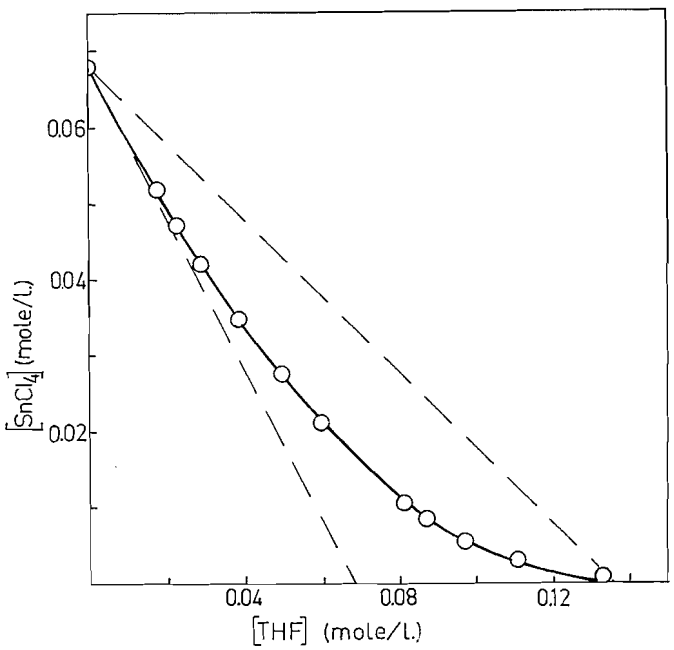

FIG. 2. Effect of added tetrahydrofuran on free stannic chloride concentration in benzene solution at 25 °C.

undissociated $SnCl_4 \cdot THF$ and $SnCl_4 \cdot 2THF$ in solution. The stannic chloride concentration decreases more rapidly with added tetrahydrofuran than is possible for even an undissociated 1:2 complex, and a lower complex must be present. The experimental results could be explained in terms of the complex $2SnCl_4 \cdot 2THF$ or a complex between $SnCl_4 \cdot THF$ and the solvent but the simplest possibility is $SnCl_4 \cdot THF$ in which tin shows a coordination number of five. It is reasonable to assume that the following equilibria are involved

[1] $$SnCl_4 + THF \rightleftharpoons SnCl_4 \cdot THF$$

[2] $$SnCl_4 \cdot THF + THF \rightleftharpoons SnCl_4 \cdot 2THF$$

The high degree of complexing precludes accurate estimates of the individual values of K_1 and K_2, the equilibrium constants for reactions [1] and [2], but the ratio K_1/K_2 is found to be equal to four if it is assumed that effectively all the tetrahydrofuran is present as $SnCl_4 \cdot THF$ and $SnCl_4 \cdot 2THF$ in the solution. Infrared spectra of solutions indicate that this assumption is reasonable for molar ratios of tetrahydrofuran to stannic chloride up to 1.4:1. The solid curve in Fig. 2 is calculated on the assumption that K_1/K_2 equals 4. Within experimental error the ratio K_1/K_2 is independent of temperature in the range 17 °C to 44 °C and the values of ΔH for reactions [1] and [2] must be approximately the same. In their thermometric studies of the reaction between tetrahydrofuran and stannic chloride in solution, Cioffi and Zenchelsky (13) showed that the heat evolved is proportional to the tetrahydrofuran added up to a molar ratio of tetrahydrofuran to stannic chloride of almost 2:1 and concluded that the only complex formed is $SnCl_4 \cdot 2THF$. Their experimental results can equally well be explained by the formation of 1:1 and 1:2 complexes and approximately equal values of ΔH for reactions [1] and [2]. The thermometric studies lead to a rough estimate of $K_1 K_2$ of 6×10^7 l^2 mole^{-2} but a rough estimate from the present ultraviolet studies is 2.25×10^6 l^2 mole^{-2} and this value has been used to obtain the approximate values of K_1 and K_2 given in Table I.

TABLE I

Equilibrium constants for the formation of complexes between stannic chloride and oxygen-containing donors at 25 °C

Donor	K_1 (l/mole)	K_2 (l/mole)
Ethyl formate	19	17
Ethyl acetate	61	6
Ethyl propionate	21	5
Ethyl chloroformate	0.13	—
Ethyl chloroacetate	1.1	0.1
Ethyl dichloroacetate	0.45	—
Diethyl carbonate	10.5	3
Tetrahydrofuran	3000	750
Dimethyltetrahydrofuran	50	200
Diethyl ether	3.5	15
Acetone	80	25

Most of the donors studied in this work are very much weaker than tetrahydrofuran and the observed stannic chloride concentration can be used to make estimates of the individual values of K_1 and K_2. The results for 2,5-dimethyltetrahydrofuran and diethyl ether are given in Table I. The estimated error in K_1 when its value is between 2 and 100 l mole^{-1} varies between 6 and 20%, a relatively high error being possible for 2,5-dimethyltetrahydrofuran because solutions of this ether and stannic chloride in methylene chloride show weak absorption.

The order of donor ability is tetrahydrofuran > 2,5-dimethyltetrahydrofuran > diethyl ether. Cioffi and Zenchelsky explain the lower base strength of 2,5-dimethyltetrahydrofuran compared with the unsubstituted compound in terms of steric effects. The weak basicity of diethyl ether compared with cyclic ethers has been observed in other systems e.g. boron trifluoride forms a far stronger 1:1 complex with tetrahydrofuran than with diethyl ether (14).

Complexes between Stannic Chloride and Esters

Table I records values of K_1 and K_2 at 25 °C for equilibria involving a number of ethyl

esters of monobasic acids. The experimental data have been interpreted on the assumption that only 1:1 and 1:2 complexes are formed. It is possible that the 1:1 complexes of stannic chloride and ester are solvated by benzene but the weakness of the complexes between stannic chloride and benzene suggests that such solvation is not significant. Analysis of the experimental data for ethyl formate, acetate, and propionate shows that the 1:1 complexes cannot be significantly dimerized.

The influence of inductive effects on the base strengths of esters is shown by chlorine substitution. The value of K_1 for the reaction between stannic chloride and ethyl chloroacetate is only about one-fiftieth of the equilibrium constant for the corresponding reaction involving ethyl acetate, and an even greater reduction in K_1 is observed in changing the donor from ethyl formate to ethyl chloroformate. The increase in K_1 when ethyl acetate replaces ethyl formate as donor may be ascribed to the inductive effect of the methyl group but the observation that K_1 is only slightly greater for ethyl propionate than for ethyl formate suggests that steric effects may also be involved. The value of K_1 for diethyl carbonate is derived on the assumption that only 1:1 and 1:2 complexes are formed; the weakening in base strength relative to ethyl formate is at least partly due to the inductive effect of the ethoxy group.

Some values of K_2, the equilibrium constant for the addition of a second molecule of ester to the 1:1 complex, are given in Table I. They are of relatively low accuracy but they show that K_2 for a given ester is generally smaller than K_1. Values of K_2 for esters of chloroacids are too small to be measured by the ultraviolet method, a result which is not surprising in view of the susceptibility of K_1 to chlorine substitution.

Infrared studies were confined to benzene solutions of stannic chloride and ethyl formate, acetate, or propionate. In such solutions two new bands appear in the 1620–1700 cm^{-1} range, one of strong intensity 85–105 cm^{-1} below the carbonyl stretching frequency of the pure ester and the other of weak intensity 40–45 cm^{-1} below the carbonyl stretching frequency of the pure ester. The variation of intensity of the strong band with amount of added ester suggests that it is made up of absorptions due to both the 1:1 and 1:2 complexes; the weak absorption probably originates from the 1:2 complex. The reductions in frequency are probably due to complex formation involving the carbonyl oxygen (15).

Absorbance measurements give the concentration of free ester in solution leading to independent estimates of K_1 and K_2. The measurements were made at 20 ± 1 °C and were complicated by the overlapping weak absorption band tentatively ascribed to the 1:2 complex. The values of K_1 and K_2, corrected to 25 °C, agree with those obtained from ultraviolet studies within the estimated experimental error of ±20% for K_1 and ±40% for K_2.

Calorimetric Data

Heats of reaction were measured for the donors ethyl formate, ethyl acetate, acetone, and tetrahydrofuran. Experimentally the heat evolved for a given amount of added donor is obtained and this is corrected for the heat of dilution of added base. The concentrations of 1:1 and 1:2 complexes present in solution are calculated from the spectrophotometric data and the heat of reaction per mole of complexed donor is thus obtained. The heats of reaction per mole of complexed ethyl formate and acetone were −10.9 kcal/mole and −11.0 kcal/mole respectively. The results for various amounts of added donor varied over a range of ±0.1 kcal/mole, which is well within the estimated experimental error of ±0.4 kcal/mole. Since the heat of reaction does not depend on whether primarily 1:1 or 1:2 complexes are being formed, the values of ΔH must be the same within experimental

Acetone	80	11.0±.4	2.60±.04	28.2±1.5	25	11.0±.4	1.9±.2	30.5±2.0

*Units of l/mole have been used for K_1 and K_2 in the calculation of ΔS_1 and ΔS_2.

error. The heat of reaction [1] for tetrahydrofuran was estimated to be -14.1 kcal/mole and the lack of temperature dependence of K_1/K_2 indicates that the heat of reaction [2] is also -14.1 kcal/mole. Cioffi and Zenchelsky estimated the sum of the two heats of reaction to be -27.5 ± 0.6 kcal/mole. For ethyl acetate the heat of reaction per mole of complexed donor varied from -10.1 kcal/mole to -10.9 kcal/mole over the range of additions. This variation may not be significant because it is still within the estimated experimental error and the heats of reactions [1] and [2] may both be -10.5 kcal/mole. It is possible, however, that for ethyl acetate the heat of reaction [2] is greater than the heat of reaction [1] or that the estimate of K_2 for this donor is low.

Table II summarizes the calorimetric data for reactions [1] and [2] and records the free energy and entropy changes for these reactions in benzene solution at 25 °C. The entropy decreases by approximately 30 e.u./mole in each of the two association reactions. Cioffi and Zenchelsky concluded that the entropy change in the formation of the 1:2 complex from uncomplexed stannic chloride and cyclic ethers is about -60 e.u./mole (13). Laane and Brown (6) observed an entropy decrease of -31.6 e.u./mole for the formation of the 1:1 complex between stannic chloride and diisobutyl ketone but the values for ethyl pivulate and 9-fluorenone were considerably smaller.

Received February 4, 1964

ABSTRACT

The results of a study of the resonance position of the carbonyl carbon nucleus in an extensive series of carbonyl derivatives are reported. A discussion of the major factors affecting the position of these carbon resonances is presented and some of the potential applications of these data to chemical problems are indicated.

INTRODUCTION

Earlier reports (1–6) of some preliminary studies of the C^{13} chemical shifts for the carbonyl carbon in a variety of organic compounds have clearly indicated that C^{13} nuclear magnetic resonance (n.m.r.) spectroscopy will prove to have valuable applications to chemical problems. An analogy between the C^{13} carbonyl carbon resonance position and the carbonyl infrared stretching frequency has already been noted (2, 4) since the C^{13} resonances are strong and appear in a relatively uncluttered region of the C^{13} spectrum. The fact that there is no obvious correlation between the C^{13} chemical shifts and the stretching frequencies of the various types of carbonyl group shows that the n.m.r. technique offers a method for studying these groupings which is dependent, at least in part, on different factors. The purpose of this paper is to present the results of a general survey of carbonyl compounds.

Our survey included an examination of more than 150 compounds selected to cover the commonly encountered functional groups such as aldehydes, ketones, carboxylic acids, esters, amides, anhydrides, and acid chlorides as well as a few bifunctional compounds. Examples were drawn from the aliphatic, alicyclic, and aromatic series. A number of general features were found which apply to each class of carbonyl compound, such as the effects of alkyl substitution, of conjugation, and of hydrogen-bonding (either intra- or inter-molecular).

EXPERIMENTAL

N.M.R. Spectra

The spectra were obtained using material containing C^{13} in natural abundance and were measured at either 8.50, 15.085, or 25.143 Mc/s using Varian spectrometers. Some samples were observed at each frequency to check the precision of the measurements. An external reference was used in most cases and was either CS_2 or CH_3I (the latter enriched to 58% C^{13}) contained in a small tube inserted in the larger (15 mm) sample tube. The resonance in CS_2 was taken as the origin of the chemical shift scale. No corrections for bulk magnetic susceptibility were made and the data are judged to be accurate to within ± 0.5 p.p.m. A detailed description of the experimental procedure has been given (7).

Samples

Most of the materials used in this study are commercially available and were purified by standard methods when the C^{13} or H^1 and infrared spectra showed gross amounts of impurities. Most of the members of the series of cyclic ketones (cyclodecanone to cycloheptadeconanone) were kindly supplied by Dr. J. Coops. Whenever possible, the C^{13} spectra were obtained using the neat liquids; otherwise, saturated solutions in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

appropriate solvents (noted in the text) were employed. Although this was done to realize the maximum signal: noise ratio, some preliminary studies of solvent effects for this class of compound were also carried out using 25% solutions.

RESULTS AND DISCUSSION

General

As noted previously (4), the resonances of carbonyl carbons occur over a total range of approximately 70 p.p.m. at the low-field end of the C^{13} spectral region. Some olefinic carbons (4, 5, 8) absorb within the upper portion of this region, as do oximes (4), carbon disulphide, and the central carbon of the allenic structure, $\diagup C{=}C{=}C \diagdown$ (8); otherwise, there is no interference with the C^{13} resonances of other classes of compounds for which data are presently available. As discussed later, it seems likely that a distinction between carbonyl peaks and those due to other carbons may be made on the basis of preferential solvent effects. Certainly, in the case of unknown structures, infrared spectroscopy allows one to determine whether or not a carbonyl group is present. Knowing this, one may be able to obtain further information concerning the environment of the carbonyl grouping from the C^{13} spectrum.

The carbonyl group in aliphatic ketones and aldehydes absorbs in the low-field region of the carbonyl range, -25 to -5 p.p.m. Although the regions are not well separated, no ambiguity arises between these two types because the aldehyde structure gives rise to a widely spaced doublet (J = 165–185 c/s) due to spin-coupling with the directly bonded formyl proton. The resonances of conjugated ketones and aldehydes are shifted to higher field than those in the saturated compounds and, for the most part, appear in the range, -5 to $+5$ p.p.m. Carboxylic acid peaks appear at still higher fields, 10 to 20 p.p.m., while the corresponding esters give rise to carbonyl peaks in the range, 20–30 p.p.m. A few acid anhydride resonances have been found in the upper portion of this ester region, 27–30 p.p.m. and the few amides studied absorb slightly higher, 30–35 p.p.m. Within the group of compounds included in this survey, the resonances of alkyl carbonates and acetylenic esters have been found at the highest field, i.e., 36–40 p.p.m. These general regions for the various carbonyl compounds are shown in Fig. 1 and the various classes are discussed in

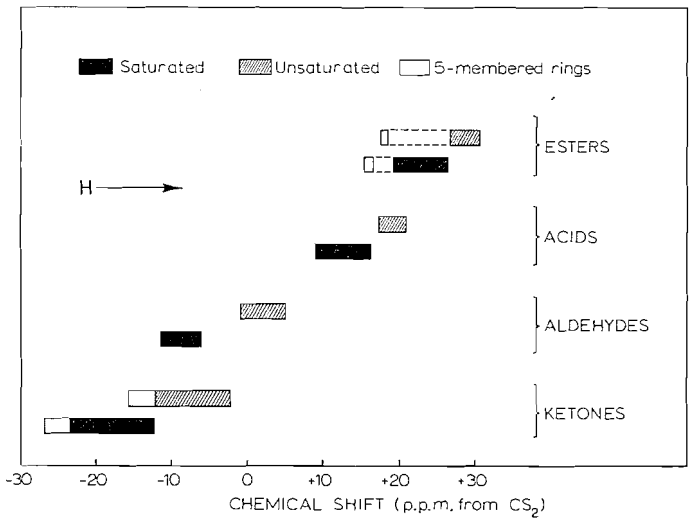

FIG. 1. Ranges of carbonyl carbon chemical shifts in various classes of compounds.

more detail in the following sections. For reference, it may be noted that the peaks for CO_2 and CO have been found at 68.6 and 11.5 p.p.m. respectively (9).

Aldehydes and Ketones

As mentioned above, the carbonyl carbons of these compounds absorb in approximately the same region of the C^{13} spectrum, but are easily distinguishable. For similar structural types, the ketone appears at the lower field by 5–8 p.p.m. The observed shift to lower field upon alkyl substitution for hydrogen, i.e. $-\overset{\overset{O}{\|}}{C}-H \rightarrow -\overset{\overset{O}{\|}}{C}R$, has been observed for carbon resonances in many different types of structure (1, 5, 7, 8, 10), although the reasons for this trend are not yet fully understood. It has been suggested (10, 11) that the major factor involved is a contribution from the diamagnetic anisotropy of the alkyl group. The difficulty with this explanation is that comparable shifts for protons are not observed although a change in screening due to the anisotropic nature of a substituent grouping should affect both C^{13} and H^1 nuclei equally, except for geometrical factors. To compare the effects of alkyl substitution on carbonyl shifts in some simple aldehydes and ketones, some typical data are collected in Table I. A comparison of the shifts for aldehydes with the corresponding methyl ketones shows that the effect of replacement of hydrogen by a methyl group of ca. −5 p.p.m. is somewhat less than that observed in other systems for a similar substitution. For example, in aliphatic cases, the change, $R\overset{*}{C}H_3 \rightarrow R\overset{*}{C}H_2-Me$, deshields the carbon nucleus marked by an asterisk by ca. −9 p.p.m. (5, 8, 10, 11), while methyl substitution at olefinic and aromatic carbons causes shifts of ca. −10 p.p.m. (8) and ca. −9 p.p.m. (4, 6, 7, 12, 13), respectively. It seems reasonable to suggest that the C—CH_3 bond in methyl ketones is more strongly polarized than that in these other systems resulting in a relatively higher electron density at the carbonyl carbon nucleus. If so, the net

result would be to offset, at least partially, the deshielding effect of the methyl grouping. Alkyl substitution at the α-position produces a small shift to low field (ca. 2 p.p.m.), but the effects of multiple substitution are not strictly additive. The effects of more distant substituents on alkyl groups are usually small. It may be noted that increased branching at the α-carbon reduces the number of hyperconjugative resonance structures which can contribute to the ground state and it is conceivable that these could be an important factor contributing to the observed chemical shifts since conjugative interactions have marked shielding effects on carbonyl carbon nuclei (see below). The trend to lower field with a decrease in the number of possibilities for hyperconjugation is consistent with this rationalization.

A marked variation in the chemical shift of the carbonyl carbon is found for the series of cycloalkanones, cyclobutanone to cycloheptadecanone. The resonance positions of the carbonyl carbon for this series are presented in Fig. 2 and some typical data are given in

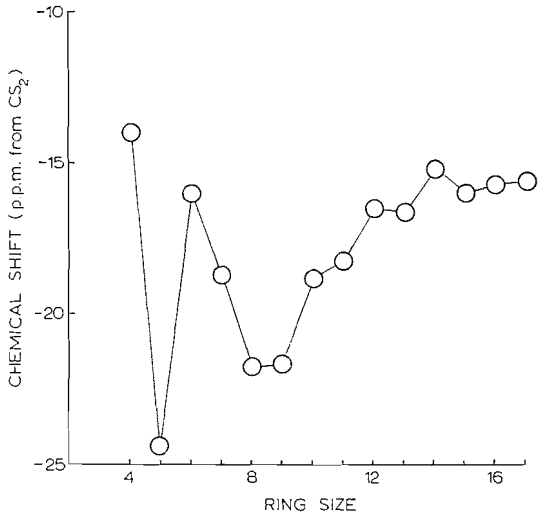

FIG. 2. Variation of carbonyl carbon chemical shifts of cyclanones with ring size.

Table II. Cyclopentanone exhibits the lowest field carbonyl shift of any so far examined (−24.4 p.p.m.). Curiously, the four-membered ring ketone, cyclobutanone, absorbs at approximately the same field as the six- and seven-membered ring ketones and it would appear, therefore, that the low-field position for cyclopentanone is not simply related to ring strain. Other evidence to support this conclusion is provided by the observation that the carbonyl carbons in more highly strained five-membered ring systems, thujone and camphor, are not appreciably different from the parent ketone. (The slightly lower field position for camphor is possibly due, in part, to hydrogen-bonding of the carbonyl group with the chloroform solvent.) Furthermore, the carbonyl resonances of cyclooctanone and cyclononanone appear at significantly lower field (ca. −21.7 p.p.m.) than that of the 6-, 7-, or 10-membered ring ketones, while it is generally assumed that ring strain is comparable in the 8- to 10-membered rings and significantly greater in these than in the five-membered cyclic cases (14). This peculiar effect on the five-membered ring carbonyl carbon is not restricted to the simple ketones but is also found for the corresponding lactone and lactam structures (see Table II) and constitutes one of the more puzzling

aspects of C^{13} chemical shifts observed to date, especially when it is compared with the shifts in the corresponding hydrocarbons (15).

The carbonyl resonance position for the large ring ketones, C_{12}–C_{17}, are comparable to those found for the acyclic ketones. This observation is in agreement with many other comparisons of large ring compounds with the corresponding aliphatic derivatives (14), except for the carbon chemical shifts in the cycloalkanes, which have a maximum at C_{12} (15). The trends in the carbonyl shifts of the medium ring cycloalkanones (C_8–C_{11}), however, indicate that a number of factors must contribute to the observed results only one of which is ring strain in the normal sense (i.e., an effect closely associated with changes in normal bond angles). One possible opposing effect could be associated with changes in the electronic structure of the C=O bond as ring size is varied. Further work is clearly required to resolve this difficulty.

Another important factor contributing to the carbonyl chemical shift is conjugation. Comparison of a conjugated system with an analogous saturated derivative shows that in the former the carbonyl peak appears at significantly higher field by ca. 10 p.p.m. (see Tables I and II). This shielding effect is comparable for α,β-unsaturated and aromatic systems, indicating that the electron density about the conjugated carbonyl carbon nucleus may be substantially greater than that about a saturated carbonyl carbon nucleus. If this is so, the electron-withdrawing effect of the carbonyl grouping on the carbonyl-methyl bond in methyl ketones will be reduced in a conjugated system relative to the saturated analogue, and a reduced polarization of this bond would increase the electron density at the methyl carbon nucleus. Evidence to support this view is provided by the observation that acetyl methyl carbons absorb at approximately 4 p.p.m. higher field in conjugated systems than in the corresponding saturated compounds, 168 p.p.m. vs. 164 p.p.m. (5, 6). Studies of proton spectra also indicate a greater electron density at the conjugated carbonyl carbon (16). Finally, it is well-known that conjugated carbonyl compounds are less reactive with the usual carbonyl reagents than are the saturated analogues, presumably because of the greater electron density at the carbonyl carbon in the former cases. In any event, the contribution due to the diamagnetic anisotropy of the aromatic ring cannot be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

important since the observed shifts are in the opposite direction to and much larger than that calculated using the usual ring-current model (17).

To examine the effect of polar substituents on the carbonyl chemical shift, a series of substituted benzaldehydes and acetophenones was examined. These data appear in the first two columns of Table III. It is clear that there is no correlation observed between the

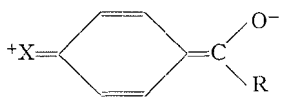
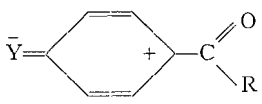
chemical shift and the Hammett parameters for the meta- and para-substituted examples. In fact, the total change in shift between the *p*-$N(Me)_2$ and the *p*-NO_2 acetophenone derivatives is only 0.7 p.p.m. although σ_p changes from −0.83 to +0.77 (18) for these substituents. This change may be compared to the chemical shift difference of 27.5 p.p.m. found for F^{19} in the corresponding *p*-substituted fluorobenzenes (19) and to the difference of less than 1 p.p.m. in the methyl C^{13} resonances of the corresponding toluenes (1). The results for the carbonyl shifts are in direct contrast to the findings from the F^{19} and H^1 nuclear magnetic resonance spectra of aromatic compounds for which the shieldings have been shown to be closely related to the separated σ-constants of Taft (20, 21, 22). There is, however, an important difference between the carbonyl compounds and the fluorobenzenes in that the two types of nuclei examined are not in comparable positions in the resonance system. For the carbonyl compounds, if one considers the resonance forms I and II for electron-releasing and electron-withdrawing substituents, respectively, it seems reasonable that the contribution of these forms would not alter the electron density at the carbonyl



I



II

carbon appreciably relative to the changes at the terminal nuclei and thus may not affect the carbonyl carbon shielding appreciably. In the fluorobenzenes, however, reasonable resonance forms with a charge on the terminal fluorine may be written, and the effect of substituents on the fluorine shielding should be much more pronounced. Support for this interpretation is provided by an examination of a few *p*-substituted styrenes for which it is found that the β-carbon resonance position shows a dependence on the polar characteristics

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of the substituent while the α-carbon does not (23). In addition, fairly good correlations between the C^{13} chemical shift of the para-carbon of the aromatic ring and the σ_p parameter of the substituent in mono-substituted benzenes (13, 24) have been found whereas a similar correlation is not observed for the meta-carbon shifts vs. σ_m.

More significant changes in the carbonyl shifts of the aromatic derivatives are found for the ortho-substituted acetophenones, particularly in those cases in which the substituent is large and (or) there is 2,6-disubstitution. In these examples, the shift to lower field is explicable in terms of steric inhibition of resonance. If the conjugated interaction of the aromatic nucleus with the carbonyl group is diminished, it follows from the results discussed previously that the carbonyl peak would appear towards lower field relative to an electronically similar, but unhindered, derivative. Furthermore, the acetyl methyl absorption also appears at lower field (6*a*) in the hindered acetophenones. Both of these changes are consistent with the occurrence of steric inhibition of resonance. It has been shown that the C^{13} carbonyl shieldings may be correlated with the angle of twist between the planes of the carbonyl bond and the aromatic ring (6*b*).

Completely analogous trends are found in the polycyclic ketones. Such compounds as 2-acetylnaphthalene and 3-acetylphenanthrene exhibit carbonyl peaks at -3.0 p.p.m., while 1-acetylnaphthalene and 9-acetylphenanthrene give rise to carbonyl peaks at -6.7 and -7.5 p.p.m., respectively, and 9-acetylanthracene shows a carbonyl band at -14.5 p.p.m. It appears, therefore, that the acetyl group in the last three examples is hindered from obtaining co-planarity with the aromatic system by interference with the peri-hydrogens. Further support for these conclusions regarding steric inhibition of resonance is given by a detailed examination of the aromatic ring carbon shifts (6*a*) and a full discussion of the use of C^{13} techniques for the study of steric hindrance in aromatic ketones is in preparation. Studies of similar steric effects in a variety of aromatic compounds have been reported (12).

For acyclic and alicyclic α,β-unsaturated carbonyl compounds, there are two conformations or configurations, respectively, which allow full conjugation between the unsaturated bonds. These are the S-*cis* and S-*trans* forms. The present results indicate that the carbonyl chemical shift is comparable for either of these provided the system is planar. For example, one can compare methyl vinyl ketone, 3-penten-2-one, and mesityl oxide in Table I, since it is generally agreed that the first two exist predominantly in an S-*trans* conformation (25) while mesityl oxide is S-*cis* (26). Further alkyl substitution tends to displace the carbonyl peak to lower field, indicating that such systems are no longer planar. In other words, the situation appears to be analogous to that in hindered aromatic systems. Supporting evidence is provided by the changes in the chemical shifts of the olefinic carbons in these compounds since these also appear to reflect the effect of any factor which hinders the system from attaining a planar conformation (5). A study of these C^{13} spectral changes clearly offers some advantage over the more conventional techniques such as Raman, infrared, and ultraviolet spectroscopies, which do not allow such a clear distinction between a planar S-*cis* form and a non-planar system. A full discussion of this aspect of C^{13} n.m.r. spectroscopy is in preparation.

The effects of a number of polar substituents on the carbonyl chemical shift in aliphatic systems can be seen from the data in Table IV. For comparative purposes, the effects of alkyl substitution are included. In the second column, the chemical shifts for the keto-carbonyl group in some diketones and keto-esters are given. If the second carbonyl group is separated from the first by two or more methylene groups, the shifts are unchanged from the normal saturated values, but the carbonyl shifts are affected in the α-diketo and

β-diketo examples. In the latter cases, of course, keto–enol tautomeric equilibria are involved and the chemical shift changes are readily rationalized. For example, acetyl acetone shows, in the neat liquid, an enol content of 76–80% (27) and the signals in the C^{13} spectrum (Fig. 3) are readily assigned to the two types of "carbonyl" carbon from the observed intensities. The weaker signal at −8.9 may be assigned to the keto form (A)

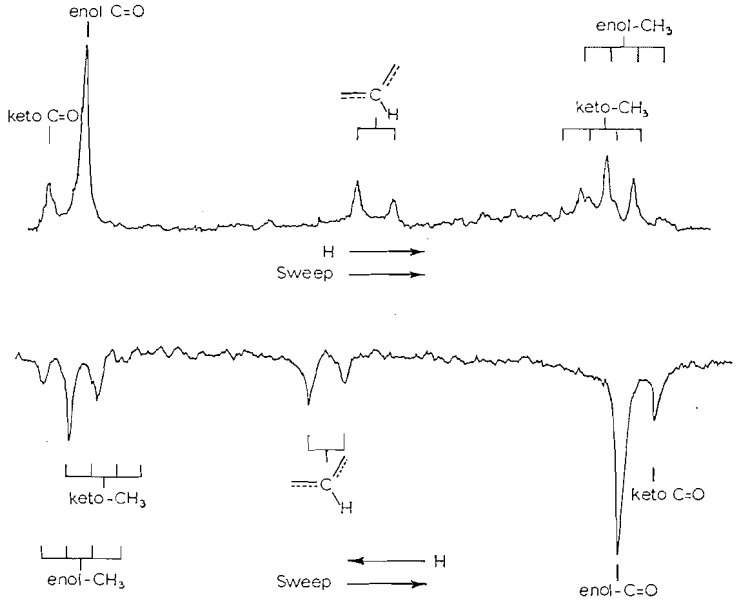

FIG. 3. The 15.085 Mc/s carbon-13 n.m.r. spectra of acetylacetone.

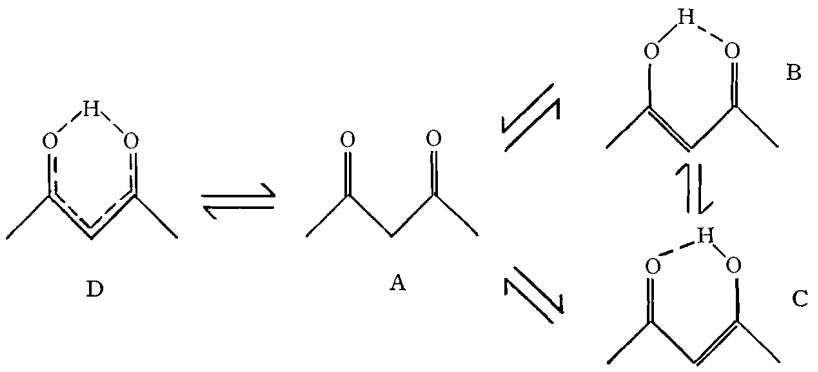
while the more intense peak at 1.9 p.p.m. (ca. 4 times as intense as the lower field signal) must be due to the enol form (B and C or D). The fact that only a single strong band which can be attributed to carbon bearing oxygen is observed indicates that either proton transfer between the two oxygens is rapid (B ⇌ C) or the proton is equidistant from each oxygen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



atom (D). The present evidence does not allow one to decide between these two alternatives. Presumably the observed peak position is an average for the chemical shift of a carbon nucleus in the two different environments, i.e., hydrogen-bonded carbonyl carbon and olefinic carbon bearing hydroxyl, of which the former would be expected to appear at the lower field. A number of proton n.m.r. studies of acetylacetone bearing on this phenomenon have appeared (28). Owing to the relatively low sensitivity of the C^{13} method using natural abundance material, coupled with the low enol content for the pure liquid (27), only the keto form is observed in the spectrum of ethyl acetoacetate with the carbonyl peak at −7.2 p.p.m. Thus, it appears that both the acetyl and carboethoxyl groups tend to shield a β-carbonyl carbon. This shielding effect is found to be greater for the α-diketo compounds. A possible interpretation of these results is that the electron withdrawing

$$\overset{+}{\text{C}}{=}\overset{-}{\text{O}}$$

substituents reduce the polarization of the C=O bond such that the electron density is increased at the carbonyl carbon and the nucleus is more screened. Variations in the stretching frequencies of carbonyl bonds have been accounted for in an analogous fashion, by assuming that a reduction in the polarization of the bond by electron-withdrawing groups tends to increase the force constant and, hence, the stretching frequency. Up-field shifts are found also for the α-chlorinated ketones, presumably for the same reason and, in addition, the observed shifts to higher field are approximately additive for each additional halogen atom. The feature of additivity of substituent effects on C^{13} chemical shifts has already been noted for a number of systems (4–8, 12). Further examples of the effects of chlorine substitution are discussed later.

For the case of hydroxyl substituents close to the carbonyl group, the observed shifts are in the opposite direction to those discussed above, i.e. toward lower field. Hydrogen-bonding possibilities, of course, arise for these cases and this effect would tend to increase the polarization of the carbonyl carbon–oxygen bond and thus decrease the screening at the carbon nucleus. Two aliphatic examples are included in Table IV and three examples are given in Table VI for aromatic cases. It is clear that the C^{13} chemical shift provides yet another means for studying hydrogen-bonding effects. One particular area of investigation, namely, solvent effects, is mentioned later in this paper.

Carboxylic Acids and Their Derivatives

Free carboxylic groups exhibit the carboxyl carbon resonance peak at somewhat higher field than aldehydes and ketones, i.e., 9 to 20 p.p.m., with the exception of formic acid at 27.0 p.p.m. Some data are presented in Table V. A comparison of this shift with that for

acetic acid, 15.6 p.p.m., shows the usual deshielding effect caused by replacement of hydrogen by a methyl group. Again, an increase in the chain length of the substituent alkyl group decreases the shielding slightly while branching at the α-carbon produces a more pronounced shift. It appears that conjugation tends to shield the carboxyl carbon, although the effect is not so large as that observed for simple carbonyl compounds. The position of the carboxyl carbon to higher field than a ketonic carbonyl carbon could be ascribed to the resonance stabilization of the carboxyl due to the additional oxygen atom. This interpretation is consistent with the foregoing while the substituent effects are comparable, at least directionally, to those discussed above. A diminution in the conjugative shielding effect is quite reasonable in view of the resonance stabilization within the carboxyl group itself.

The carboxyl carbon in a variety of carboxylic esters appears at higher field than the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

free acid, in the range 20 to 40 p.p.m. Since the available data for carboxylic acids, are, of necessity, obtained using either neat liquids or concentrated solutions, the observed shift for the free acid is that of the dimeric form rather than the monomeric, and the carbonyl oxygen will be strongly hydrogen-bonded. Hydrogen bonding at carbonyl groups serves to deshield the carbonyl carbon substantially and, thus, it is reasonable to suggest that this is a principal factor giving rise to the chemical shift difference between the carboxyl carbon of the free acid and its corresponding ester. It can be noted that, in general, methyl substitution of the type, $\diagdown\!\!\!\!\diagdown\!\!\!\!\diagdown\!\!\!\!

those in esters, whereas the resonance of the amide grouping appears at slightly higher field. These observations are consistent with the foregoing discussion since, presumably, the nitrogen atom in the amide structure is better able to donate electrons to the carbonyl group as shown, for example, by the lower reactivity of amides relative to esters. It is well known that the C—N bond has considerable "double-bond" character in amides due to contributions from forms such as $R_2—\overset{+}{N}=C(—O^-)—R'$, and the observed C^{13} chemical shifts reflect this effect relative to esters, etc.

To summarize, as well as to allow an intercomparison of the data, the effects of various substituents on "carbonyl" resonances are shown in Table VI. The key feature of this comparison is the remarkable consistency of the effects of various substituents on the different carbonyl groups, a clear indication that the observed variations are due to differences in degree rather than kind. For example, the effect of α-chlorine substitution for the various ketones is reasonably constant at ca. $+4.5 \pm 1$ p.p.m. per chlorine atom, and is found to be slightly less for the acid chlorides and somewhat larger for the aldehydes. It would appear that the electron-withdrawing power of the halogen offsets the same effect due to the carbonyl oxygen such that the electron density at the carbonyl carbon is substantially increased with an increasing number of substituents. The substitution of chlorine at the meta- or para-position of an aromatic ketone does not show the same shielding effect. For example, *p*-chloroacetophenone and *m*-chloroacetophenone absorb at -3.0 and -2.6 p.p.m. respectively, while the carbonyl carbon in acetophenone appears at -3.2 p.p.m. Some of this difference may be due to the diamagnetic anisotropy of the C—Cl bond, and some to a smaller inductive effect in the aromatic ketones, but it is not yet possible to factor the observed effect into its various components. The magnitude of the effect, (3–6 p.p.m. per chlorine atom), seems to be larger than one would expect due to bond anisotropy alone, for reasons mentioned previously.

Miscellaneous Carbonyl Derivatives

A few representative compounds of two other series were examined in the course of this study, namely, alkyl carbonates and metal carbonyls. The alkyl carbonates appear in the high-field region of the carbonyl range, 36–39 p.p.m., which, on the basis of the foregoing, could be attributed to the electron-releasing alkyl oxygen atoms directly bonded to the carbonyl analogous to the effect found for the esters. The two metal carbonyls were found to absorb in the ketone region. Iron pentacarbonyl at -15.6 p.p.m. and nickel tetracarbonyl at 1.2 p.p.m. Contrary to an earlier report (29) on the C^{13} spectra of these two materials, we submit that there is a significant difference between these two chemical shifts, although a better understanding of this difference must await a detailed study of these derivatives. Such an investigation is in progress (30). Since 1958, iron pentacarbonyl has been examined by a number of workers (29, 31, 32) using C^{13} n.m.r. techniques to attempt to establish the structure. No definite conclusions can be drawn as yet since only a single sharp peak is observed. A detailed discussion of this problem has been presented (29).

Hydrogen Bonding Effects

One of the more striking changes in the chemical shift of a carbonyl grouping occurs for hydrogen-bonded structures. In each case, the carbonyl carbon appears at lower field relative to an analogous but non-hydrogen-bonded carbonyl grouping. The effect is clearly illustrated by the data in Table VI for ortho-hydroxy aromatic derivatives. These

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

results would suggest that marked solvent shifts should be apparent in hydroxylic solvents relative to non-polar solvents and an examination of acetophenone clearly bears out this prediction. The pertinent data are given in Table VII, for a series of 25% (w/w) solutions

TABLE VII

Solvent effects on C^{13} chemical shifts of acetophenone (25% solutions; p.p.m. from CS_2)

Carbon nuclei	Solvent					
	Nil	CCl_4	C_6H_6	$C_4H_8O_2$	$CHCl_3$	MeOH

C_4	61.2	60.4	61.2	61.5	59.3	59.7
C=O	−3.2	−2.1	−2.9	−3.1	−4.5	−6.3

of acetophenone in a series of solvents. The largest change is noted for the carbonyl shifts in methanol while the down-field shift is also apparent in chloroform. In comparison, the other carbon atoms do not exhibit comparable changes, although there is an indication that the aromatic nuclei are slightly deshielded by hydrogen-bonding. In α,β-unsaturated aliphatic systems, the solvent shifts in methanol (relative to either neat liquid of CCl_4 solution) are comparable for the carbonyl carbons and, in addition, there is a significant shift of the β-olefinic carbon to lower field by ca. 2 p.p.m. (5). One benefit to be derived from these observations is an aid for the assignment of olefinic carbons for those compounds in which the α- and β-nuclei are similarly substituted. Other possible studies of hydrogen-bonding using C^{13} n.m.r. spectroscopy are also indicated, such as in structural studies and detailed solvent effect investigations.

CONCLUSIONS

In general, the C^{13} chemical shifts of organic carbonyl carbon nuclei may be rationalized in terms of the shielding effect of the local electrons about these nuclei. Contributions by neighboring nuclei, as well as the effects of neighboring anisotropic groups, appear to be of secondary importance. A number of potential avenues for investigation which should be rewarding are suggested by this general survey such as (*a*) applications to structural elucidations, (*b*) a new approach to studying steric inhibition of resonance, (*c*) solute–solvent associations, and (*d*) the use of C^{13} techniques for tracer studies. The results of more detailed studies of some of these will be published in the near future.

THE RADIATION CHEMISTRY OF SQUALENE

JEANNE DANON[1] AND MORTON A. GOLUB
Stanford Research Institute, Menlo Park, California
Received February 10, 1964

ABSTRACT

Squalene was irradiated with Co^{60} γ-rays at room temperature and with 1-MeV electrons at $-30°$ C. The main radiation-induced effects, and their *G*-values for the room temperature irradiations, were loss of unsaturation (4.6), crosslinking (1.35), *trans* → *cis* isomerization (0.83), and evolution of hydrogen (0.58). The *G*-values for the first three processes in the low temperature runs were 3.8, 0.82, and 0.83, respectively. The large drop in unsaturation is attributed in part to the formation of crosslinks involving double bonds, but principally to cyclization. The loss of double bonds occurs only in the immediate vicinity of the crosslinks and not at random throughout the irradiated squalene. This result has important implications for the radiolysis of diene polymers. Squalene in 10% benzene solution isomerizes with a much higher yield (apparent *G*-value of 2.6 *trans* double bonds converted initially per 100 eV absorbed by *both* solute and solvent) than that of the pure olefin, indicating very efficient energy transfer from excited benzene molecules to the squalene double bonds. The isomerization in the solution case was accompanied by a loss of double bonds in squalene (*G*-value of 0.98) due to phenylation as well as to the other indicated saturation reactions.

INTRODUCTION

Although there has been considerable interest in recent years in the radiation chemistry of polyisoprene (the pertinent literature will be summarized in reference 1), resulting, in fact, in much controversy regarding the loss of unsaturation in this polymer, very little work has been carried out on the irradiation of low or medium molecular weight prototypes of polyisoprene. This is somewhat surprising in view of the success achieved with appropriate model compounds in understanding the mechanisms of such reactions as vulcanization, crosslinking, and oxidation of natural rubber (2). Thus, while it might be difficult or impossible to characterize adequately the microstructural changes produced in the irradiation of a high polymer, because of intrinsic experimental difficulties with the polymer, the task of resolving some still unsettled questions might be greatly aided by a corresponding study of a small molecule model. From this point of view, we were interested in following up our work on the radiation-induced effects in polyisoprene (1) with a detailed examination of squalene. This compound, which is a hexaisoprene in which the internal double bonds are all of the *trans* configuration, constitutes a medium molecular weight counterpart of balata, but it can presumably serve also as a model for *cis* polyisoprene.

Apparently only two papers have been published to date in which the effects of ionizing radiation on squalene were mentioned. Turner (3), in one of them, has noted that squalene when irradiated *in vacuo* to a dose of 242 Mrad experienced about a 10% loss of double bonds, while Dale (4), in the other paper, reported lack of success in crosslinking squalene with radiation. In the present work, we have focussed attention on the principal radiation-induced reactions common to both squalene and polyisoprene, viz., hydrogen evolution, crosslinking, loss of unsaturation, and *trans* → *cis* isomerization. The aim has thus been to throw additional light on the overall radiation effects in polyisoprene and also to add, if possible, to our knowledge of radiation chemistry generally.

Further interest in a study of the irradiation of squalene derives from the fact that,

[1]*NATO Fellow, 1962–63, from Laboratoire de Chimie Physique, Faculté des Sciences, Orsay (S. et O.), France.*

like polyisoprene, it can be readily cyclized by a conventional carbonium ion mechanism (5, 6). Thus, to the extent that some radiation-induced reactions, such as polymerization of isobutylene (7) and various other monomers, have been found to proceed through an ionic mechanism which may well involve carbonium ions (8), the possibility existed that an ionic cyclization could be induced in squalene on exposure to ionizing radiation. Such a reaction, if realized, would serve as still another example in the increasing evidence for ion–molecule processes in the radiation chemistry of hydrocarbons in the condensed phase.

EXPERIMENTAL

The squalene (Eastman Kodak Co.) was chromatographed through a silica gel column and vacuum distilled prior to use. Portions of the pure squalene were sealed in ampoules *in vacuo* after three or four freeze-thaw outgassing cycles, and irradiated for various periods of time at room temperature using a 1500-curie Co^{60} γ-ray source, and at $-30°$ C using 1-MeV electrons from a G. E. resonant transformer. These samples were exposed to radiation intensities of about 0.3 and 200 Mrad/h, respectively. In addition, benzene solutions of squalene were γ-irradiated in ampoules or special n.m.r. tubes either in air or *in vacuo*.

The gases evolved in certain γ-irradiation runs were measured by compressing the volatile products into a known volume with a Toepler pump and then reading the pressure. They were subsequently analyzed with a mass spectrometer.

For purposes of characterization, some of the γ-irradiated squalenes were vacuum distilled, yielding a fraction which came over almost entirely at 180° C at a pressure of 10^{-5} mm Hg (fraction 1), and a residue which remained in the molecular still (fraction 2). Since the initial squalene gave no such residue on vacuum distillation, fraction 2 evidently comprised all of the crosslinked products present in the irradiated squalene. The relative amounts and molecular weights of fractions 1 and 2 as well as the viscosity of fraction 1 obtained from each irradiated sample were determined. Owing to the small amount of material used in the electron irradiations, it was not practical to carry out either vacuum distillation or viscosity measurements on the products in these runs, but their molecular weights were measured.

The number-average molecular weights of irradiated and unirradiated squalene samples were measured in benzene by means of a Mechrolab vapor pressure osmometer. The accuracy of this instrument in the molecular weight range considered here is claimed to be ±2–3%. However, variations in excess of this amount were found for the initial squalene (measured mol. wt.: 410 ± 38) which were believed to arise from systematic errors involved in the operation of the instrument. To minimize such errors for the irradiated samples, the molecular weight of the unirradiated material (M_0) was generally determined each time the molecular weight of an irradiated squalene (M) was measured. The ratio M_0/M was then essentially free from abnormal variations and could be employed reliably for calculating the degree of crosslinking in the irradiated squalene. The absolute viscosities of the γ-irradiated samples were measured by comparing their flow times in a Cannon–Fenske viscometer at 30° C to that of pure benzene.

To analyze the reaction products for microstructural changes, both infrared and n.m.r. spectra were obtained for irradiated and unirradiated samples of pure squalene as well as for the squalene recovered from some of the benzene solution irradiations. For added convenience, n.m.r. spectra were also run directly on the irradiated n.m.r. tubes containing benzene solutions of squalene.

The infrared spectra of the irradiated squalenes and the various fractions 1 were determined in duplicate in an optical cell of suitable path length, using a Perkin–Elmer Model 221 spectrophotometer. The reliability of the infrared results was verified by comparing the optical density of the 12 μ band (due to the C—H out-of-plane deformation of the *cis* and *trans* —$C(CH_3)$=CH— units) obtained in the given cell with that obtained in another cell of different path length: for each squalene sample examined, the ratio of optical density to path length in one cell was practically the same as in the other. The infrared spectra were examined for changes in the 12 μ band as well as changes in the 6 μ band (C=C stretching vibration of the double bonds) and the 8.7 μ band (C—CH_3 vibration of the *trans* —$C(CH_3)$=CH— unit). Since the fractions 2 were too viscous to be run in the cell, they were placed between salt plates and measurements made of the change in optical density of the 12 μ band relative to that of the 7.25 μ band (due to CH_3 groups) as an internal standard. These measurements were found to be quite satisfactory for the purposes intended, although less precise than the absolute measurements made in the cell. The infrared spectra of the irradiated squalenes, except for evidence of reduction of unsaturation, were only slightly different from that of the initial material. Consequently, there was no need to present them here (9).

The n.m.r. spectra were obtained at room temperature with a Varian HR-60 spectrometer operated at both normal and slow magnetic field sweep rates. The irradiated and unirradiated samples of pure squalene were run as 50% solutions by weight in benzene using tetramethylsilane as internal standard. The spectra obtained for an irradiated sample, before and after fractionation, are shown in Figs. 1 and 2. As can be seen, fraction 2 gives a more poorly resolved spectrum than either the prefractionated sample or fraction 1, a situation which must be related to the higher viscosity of fraction 2. In the case of benzene solutions of squalene (~10% concentration), the n.m.r. spectra were run directly on the irradiated solutions without

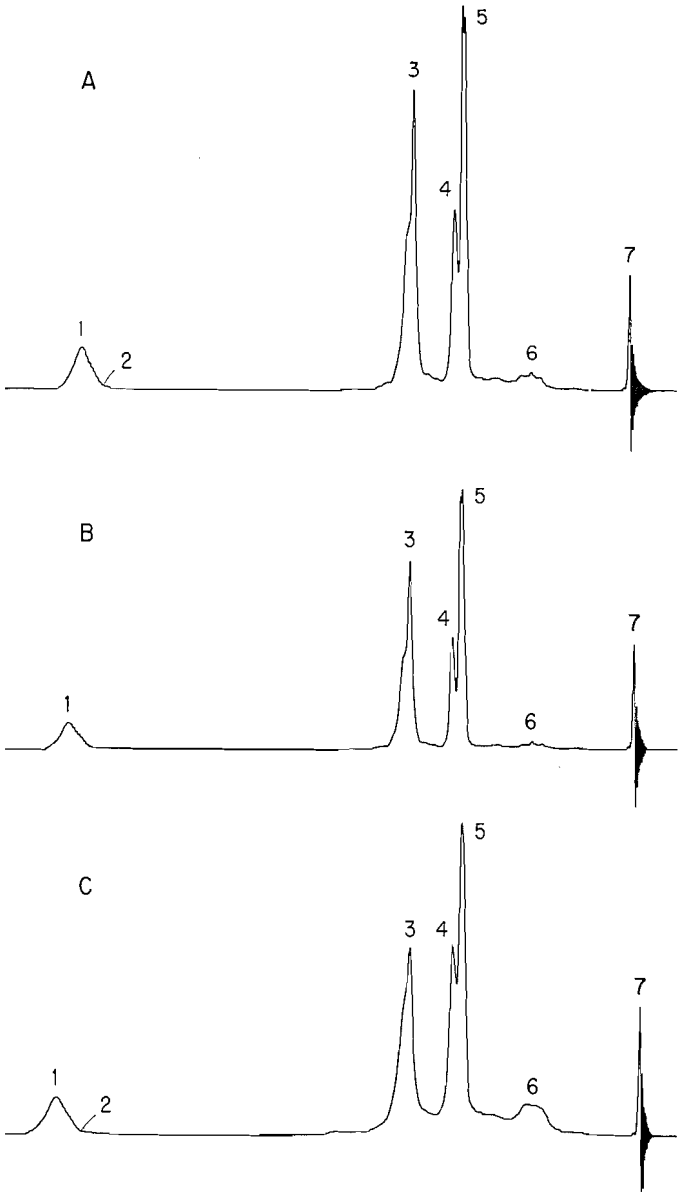

FIG. 1. N.m.r. spectra obtained at normal magnetic field sweep rate of pure squalene γ-irradiated to a dose of 195.5 Mrad: A, before fractionation; B, fraction 1; C, fraction 2. Peak 1, —CH═, 4.85 τ; peak 2, —C(═CH_2)— (?), 5.1 τ; peak 3, —CH_2—C═, 7.95 τ; peak 4, *cis* —C(CH_3)═, 8.34 τ; peak 5, *trans* —C(CH_3)═, 8.43 τ; peak 6, CH_3—C—, 9.0–9.2 τ; peak 7, tetramethylsilane, 10.0 τ.

using tetramethylsilane; since these spectra were very similar to those of Figs. 1 and 2, there was no need to present them here. The normal magnetic sweep spectra (~2 c.p.s./s) were used for the quantitative determination of the olefinic proton content—both planimetrically and by electronic integration—as well as for the qualitative examination for over-all microstructural changes in squalene. The slow sweep spectra (~0.5 c.p.s./s) were employed to give the best possible resolution of the *cis* and *trans* methyl proton

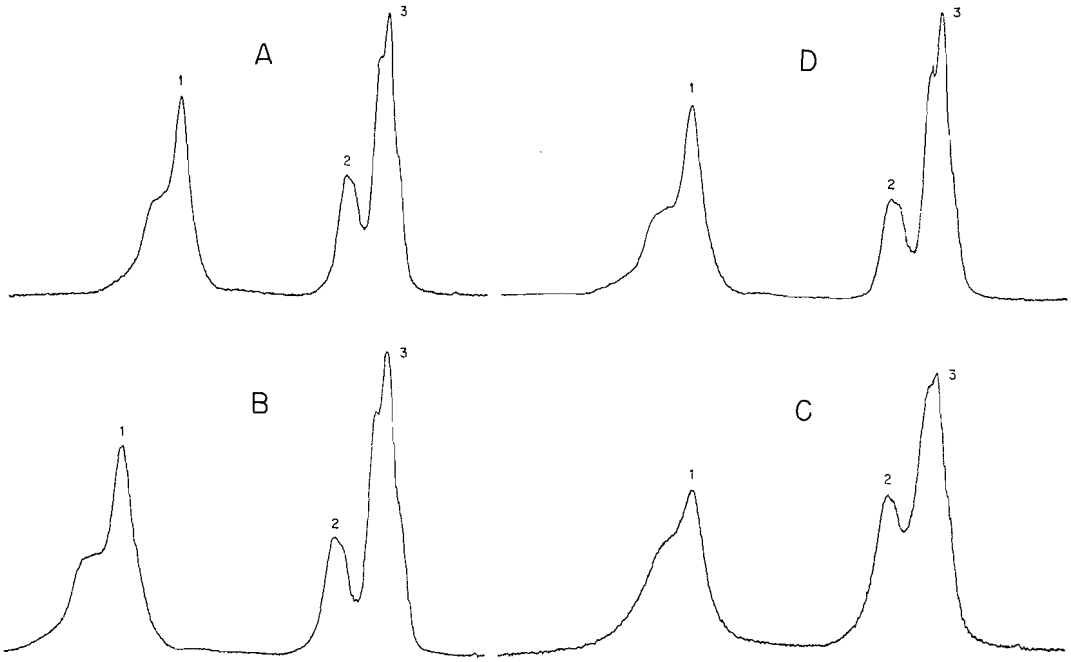

FIG. 2. N.m.r. spectra obtained at slow magnetic field sweep rate of pure squalene γ-irradiated to a dose of 195.5 Mrad: A, same sample as in Fig. 1, before fractionation; B, corresponding fraction 1; C, fraction 2. For comparison, D represents the spectrum of the unirradiated squalene. Peak 1, $-CH_2-\overset{|}{C}=$; peak 2, *cis* $-C(CH_3)=$; peak 3, *trans* $-C(CH_3)=$.

resonance peaks at 8.34 and 8.43 τ (10),[2] following the technique described by Chen (11) for polyisoprenes. The slow sweep spectra were thus used in conjunction with the normal sweep spectra to determine the extent of *trans* → *cis* isomerization of the internal double bonds in irradiated squalene. Two samples of distilled squalene were employed, A and B, which had 94.1 and 97.0% of the theoretical unsaturation, respectively (i.e., 11.25 and 11.65% olefinic proton content compared to the theoretical 12%). Corresponding to the indicated deficiency of double bonds in these samples, the n.m.r. spectra showed some "saturated" methyl protons at around 9.0–9.2 τ. Also, the internal double bonds in A and B were not completely *trans* initially; in fact, sample A, which was used the most, has 1.6% *cis* content.[3]

RESULTS

Gas Evolution

For doses up to 300 Mrad, the evolution of hydrogen, methane, and low molecular weight hydrocarbons in the γ-irradiation of pure squalene at room temperature was linear with dose. The 100 eV yields of these products were found to be $G(H_2) = 0.58$, $G(CH_4) = 0.015$, and G(lower hydrocarbons) = 0.015. These yields are substantiated by the work of Pestaner (12), who obtained $G(H_2) = 0.58$ and $G(CH_4) = 0.02$ for squalene irradiated to a dose of 0.5 Mrad. It is interesting to note that the ratio of hydrogen to methane from squalene (from 29 to 38) is roughly comparable to that from squalane [$G(H_2)/G(CH_4) = 3.4/0.12$ or $\sim$28] (13), which is fully saturated squalene. Moreover, the hydrogen yield

[2]*From an n.m.r. standpoint, two of the methyls on the terminal double bonds are cis and two are trans, the remaining four internal methyls being trans. This accounts for the fact that the initial squalene shows both cis-CH_3 and trans-CH_3 peaks in the ratio of about 25:75.*

[3]*The cis content was calculated from the cis-CH_3 proton values, taking into account the loss of unsaturation which is assumed to be statistically distributed over all six double bonds in squalene.*

from squalene is somewhat higher than the average value obtained recently in the γ-irradiation of several high molecular weight polyisoprenes [$G(H_2) = 0.48$][4] (14).

Crosslinking

Representative data on the molecular weight and viscosity changes produced in squalene on irradiation *in vacuo* with γ-rays at room temperature and with 1-MeV electrons at $-30°$ C are presented in Table I. From the slopes of the linear plots of M_0/M versus

dose for the prefractionated irradiated samples, shown in Fig. 3, the G-values for crosslinking were calculated, using the relation (15)

$$[1] \qquad 1/M_0 - 1/M = kD$$

where M_0 and M are the molecular weights before and after irradiation to dose D, and k is the number of crosslinks/g-unit dose. The use of this relation implies that the scissions which could occur in the irradiated squalene have been neglected. According to the findings on polyisoprene where the scission/crosslink ratio is very low (16) crosslinking can indeed be considered to have the greater effect by far on the molecular weight of squalene. $G(X)$ was thus found to be 1.35 and 0.82 for the room temperature and low temperature irradiations, respectively. These values are to be compared with the most probable $G(X)$ value for polyisoprene, viz, 0.9 (17). The fact that $G(X)$ for liquid squalene (room temperature runs) is higher than that for solid squalene (low temperature runs) or for polyisoprene is probably due to the greater mobility of the molecules in the liquid squalene case which is conducive to a higher frequency of crosslinking. As also shown in Fig. 3, the viscosity η of the prefractionated γ-irradiated squalenes is linear with dose up

[4]*This value is supported by Pestaner's work (12) and, moreover, satisfies, better than the value of 0.64 reported earlier by Turner (3), an empirical linear relation which appears to hold between $G(H_2)$ of different isoprenic compounds,* H—(CH_2—$C(CH_3)$=CH—CH_2)$_n$—H, *and the reciprocal of the number n of isoprenic units in these compounds.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

to ~150–200 Mrad, but becomes more than linear at higher doses. This situation is similar to that found with polymeric systems (15).

The data of Table I indicate that neither the molecular weight nor the viscosity of the various fractions 1 obtained from γ-irradiated squalene or from the unirradiated squalene is significantly different from the corresponding value for the unirradiated compound prior to fractionation. The variations in M_1 and η, although relatively large, are still within limits of experimental error. It would appear, therefore, that each fraction 1 must represent essentially unchanged squalene. This indication will be considered again in connection with infrared and n.m.r. data presented below.

The weight fraction of the crosslinked products (fraction 2 in each γ-irradiation run) when plotted against the dose gave a straight line. From the slope of this line, the G-value for production of crosslinked products was calculated to be 2.45 molecules of crosslinked squalene/100 eV absorbed. In view of the fact that $G(X) = 1.35$ for these runs, it would appear that on the average there is one crosslink per 1.81 squalene molecules. Evidently, the crosslinked products must have a complex structure consisting of dimers, trimers, and possibly even tetramers.[5]

An alternative approach to the structure of the crosslinked product involves a consideration of the molecular weights of the various fractions 2. Since the molecular weight determination of this series was unsatisfactory, it was necessary to get around this difficulty, as follows: For each irradiated sample, the relation

$$[2a] \qquad 1/M = (1 - x)/M_1 + x/M_2$$

is found to hold between the number average molecular weights of the irradiated squalenes before fractionation (M) and those of the corresponding fractions 1 and 2 (M_1 and M_2, respectively), where $(1 - x)$ and x represent the relative amounts of these fractions. Because of the difficulties encountered in measuring the molecular weights, as indicated earlier, it is desirable to use expression ($2a$) in the form

$$[2b] \qquad M_0/M = (1 - x)M_0/M_1 + xM_0/M_2.$$

Substituting the experimental values for M_0/M and x in equation ($2b$) and assuming $M_0/M_1 = 1$, we can calculate values for M_0/M_2, and hence M_2. The calculated values for M_2, given in the last column of Table I, compare satisfactorily with the experimental values in at least two cases and agree qualitatively with the previous observation that there was one crosslink/1.8 squalene molecules in the crosslinked products.[5] A slight upward trend in molecular weights with dose may be seen which, notwithstanding the absence of a corresponding upward curvature in the plot of the weight fractions of the crosslinked products versus dose, might indicate that the latter can undergo slow additional crosslinking on further irradiation. The effect of this additional crosslinking on the molecular weights of the crosslinked products can be eliminated by extrapolation to zero dose. An extrapolated molecular weight of 920 was found indicating that the complex structure of the crosslinked products is not entirely due to additional crosslinking.

Decrease in Original Unsaturation

By means of infrared and n.m.r. analysis of the irradiated unfractionated samples of pure squalene, we have observed a significant drop in the original unsaturation

[5]*This is based on the view that the crosslinked products (molecular weights in the range 935 to 1140, having one crosslink/1.8 squalene molecules) presumably are made up of dimers (mol. wt., 820; one crosslink/2.0 squalene molecules), trimers (mol. wt., 1230; one crosslink/1.5 squalene molecules), and possibly tetramers (mol. wt., 1640; one crosslink/1.33 squalene molecules).*

(—C(CH_3)=CH—, indicated by the 12, 6, and 8.7 μ bands and the 4.85 τ peak in the respective spectra) and production of some vinylene units (—CH=CH—, indicated by a very weak band at around 10.3 μ) and some vinylidene units (—C(=CH_2)—, indicated by a band at 11.3 μ and possibly also by a very minor peak at around 5.1 τ). Since the vinylene and vinylidene double bonds are of slight or negligible importance, as in polyisoprene (1), we will confine our attention here to the consumption of the original double bonds in pure squalene, as followed by changes in the 12, 6, and 8.7 μ infrared bands and the 4.85 τ n.m.r. peak.

Representative data for the decrease in the 12 μ band in pure squalene irradiated with γ-rays and electrons *in vacuo* are given in Table II. When these results for the irradiated

*Squalene sample A.
†Corresponding value for unirradiated sample is 0.47. The average loss of double bonds is then (1 − 0.37/0.47)100 = 21%, while the loss of unsaturation, based on the additivity, would be about 30%.

squalene before fractionation were plotted against dose, straight lines with negative slopes were obtained indicating that an important radiation-induced reaction in squalene is a zero-order consumption of double bonds. Straight lines with comparable slopes were obtained for the 8.7 and 6 μ bands. This last result as well as the fact that only very slight changes are observed in the range of wavelengths examined by Cunneen and co-workers (18) for squalene isomerized with sulphur dioxide suggests that if *trans* → *cis* isomerization occurs here, it is not very important. In fact, as we shall soon see, n.m.r. spectra indicated unambiguously that such a reaction does take place but only to a very small extent (1.4% increase in *cis* content after a dose of 200 Mrad). Under these conditions, it was justifiable to take an average value of the rate of decrease of the 12, 6, and 8.7 μ bands for the purpose of obtaining G-values for the loss of double bonds, G(-d.b.). Accordingly, the average decrease in unsaturation after a dose of 200 Mrad was found from infrared to be 7.0 and 5.5% for the room temperature and low-temperature irradiations, respectively; these data correspond to G(-d.b.) values of 4.6 and 3.7. Comparable G-values for the radiation-induced decrease in unsaturation in pure squalene can be obtained from the n.m.r. data given in Table III. Thus, from the slopes of the straight

§Based on additivity, unsaturation is 64.9.

line plots of n.m.r. unsaturation versus dose, G(-d.b.) for the irradiated squalene before fractionation was found to be 4.6 for the room temperature irradiations and 3.9 for the low temperature runs. Although the two samples of irradiated squalene, A and B, had different initial unsaturations, they gave linear unsaturation-dose plots with identical slopes, so that the zero-order reduction in unsaturation in these two samples proceeded at the same rate. The average G(-d.b.) value, from both infrared and n.m.r. data, can then be taken to be 4.6 and 3.8 for the room-temperature and low-temperature irradiations, respectively, indicating a small temperature effect. This corresponds to an activation energy of 0.53 kcal/mole.

It should be noted that the loss of original double bonds reported here for squalene irradiated at room temperature (7% at 200 Mrad) agrees qualitatively with that observed by Turner (~10% at 242 Mrad) (3). Moreover, our corresponding G(-d.b.) for squalene, 4.6, is of the same order of magnitude as that obtained recently for polyisoprene, 5.3 (1).

By comparing the infrared and n.m.r. data for the various fractions 1 with the corresponding data for the starting material (see Tables II and III), and taking into account the molecular weight and viscosity measurements discussed above (see Table I), it is evident that fraction 1 in each run is practically unchanged squalene, except for some *trans–cis* isomerization.

It follows from this last result that the radiation-induced decrease in unsaturation in squalene is localized only in the fractions 2, i.e., in the crosslinked products. At this point, it must be noted that the infrared and n.m.r. data obtained on these fractions were not very consistent with those obtained on the irradiated, prefractionated material and on fractions 1. The desired additivity breaks down,* presumably because of a lack of precision in the infrared analysis of fractions 2 and also because of complications arising in the n.m.r. spectra of samples containing crosslinked products (irradiated, prefractionated squalenes and fractions 2). The major source of difficulty in the n.m.r. case is that the olefinic proton region involves a new peak at around 5.1 τ (perhaps due to vinylidene units, —C(=CH_2)—, but possibly due instead to some other new structure) which broadens the regular 4.85 τ peak (due to —CH= protons), making the integration of these proton areas unreliable. This complication undoubtedly exists to some extent in the case of the irradiated, unfractionated samples, but is probably minor since the infrared and n.m.r. data are in reasonable agreement. This complication is quite serious, however, in the case of the crosslinked fractions 2 in which the production of vinylidene and other perturbing structures appears to be concentrated. At any rate, since the decrease in unsaturation is observed only in the crosslinked products, a simple consideration of the G-values for decrease in unsaturation (4.6) and crosslinking (1.35) in the room temperature irradiation of squalene enables us to find that some 3.4 double bonds are lost per crosslink. This result is difficult to understand on the basis of any known mechanism of crosslinking, and we are led therefore to suggest that some cyclization occurs along with crosslinking.

It may be noted that squalene in a 10% solution in benzene shows a somewhat more rapid linear decrease in unsaturation with dose than in the pure state (Table III), with a G(-d.b.) value of 0.98 double bonds consumed per 100 eV absorbed by both solute and solvent. This is equivalent to 9.8 double bonds/100 eV absorbed directly by the solute, calculated as though there is no energy transfer between excited benzene and squalene molecules. The loss of double bonds in the solution case is no doubt due in part to phenylation as well as to the same processes giving rise to decreased unsaturation in the pure

**See footnotes in Tables II and III for an idea on the discrepancies observed.*

squalene. Consequently, it is impossible to determine the extent to which the latter processes may have been enhanced in the solution case by benzene sensitization.

Isomerization

Nuclear magnetic resonance data on the radiation-induced *trans–cis* isomerization of squalene in the pure state and in benzene solution are assembled in Table III, and the essential results plotted in Fig. 4. It is immediately obvious that benzene has a profound effect on accelerating the squalene isomerization which approaches an equilibrium in which the *cis* content of the internal double bonds is around 45–50%. Unfortunately, there is no all-*cis* squalene available for studying the approach to equilibrium from the *cis* side. However, extensive γ-irradiation of high molecular weight *cis* or *trans* polyisoprene in benzene resulted in a common structure having a *cis* content ($\sim$50%) (1) which is similar to the above equilibrium value for squalene. Evidently, a parallelism exists between squalene and its high molecular weight counterpart, balata, insofar as radiation-induced isomerization in benzene is concerned. Since the isomerization of pure squalene, like that of solid polyisoprene (1), proceeds very slowly, it was not practicable to examine the equilibrium *cis/trans* ratio in that case; however, it is probably not significantly different from that in the squalene solution case.

In determining the percentage *cis*-1,4 content in the irradiated pure squalene by means of n.m.r. spectra, we encountered the same difficulty as with the unsaturation data, i.e., there is a lack of additivity of the measured *cis* contents of fractions 1 and 2 and prefractionated material. This problem arises in part because, as mentioned above, fractions 2 give spectra which are poorly resolved in the *cis* and *trans* methyl proton region. Much more serious, however, is the fact that the loss of unsaturation in the crosslinked fraction 2 and in the irradiated, prefractionated squalene, involving the reaction

[3] $$-CH_2-C(CH_3)=CH-CH_2- \longrightarrow -CH_2-\underset{|}{C}(CH_3)-\underset{|}{CH}-CH_2-$$

gives rise to "saturated" methylene groups which appear at higher field than the corresponding "unsaturated" methylene groups. The protons of the former groups, along with new tertiary protons, show up fortuitously in the same range of τ values as the "unsaturated" *cis* and *trans* methyl protons, thus perturbing the n.m.r. spectrum in the range of interest, viz., 8.0–9.2 τ (see Figs. 1 and 2). Although mechanistically, there is no reason for the rate of isomerization to differ in one fraction from that in another, the perturbation is such that the *cis* methyl peak, and hence *cis*-1,4 content, is apparently larger in the irradiated, prefractionated squalenes and in the fractions 2 than it is in the fractions 1. The latter, by virtue of not being crosslinked or showing any loss of unsaturation, give n.m.r. spectra which are free of perturbations from saturated methylene or tertiary protons and consequently indicate the actual *trans–cis* isomerization. The *cis* content – dose curves for the irradiated, prefractionated squalenes are curved upwards, as shown in Fig. 4, inasmuch as the perturbation is greater the higher the radiation dose and therefore the more crosslinked the squalene. Moreover, the curve for the room temperature γ-irradiation lies towards higher values of *cis* content than the low-temperature curve, due to the higher yield of crosslinks and hence greater perturbation difficulty in the former case. These curves are seen to originate at the same point on the ordinate, corresponding to the initial *cis* content, and their common tangent P passes through the points of fractions 1. It follows that the tangent line P defines the actual *trans–cis* isomerization of pure squalene and that this process depends neither on the physical state

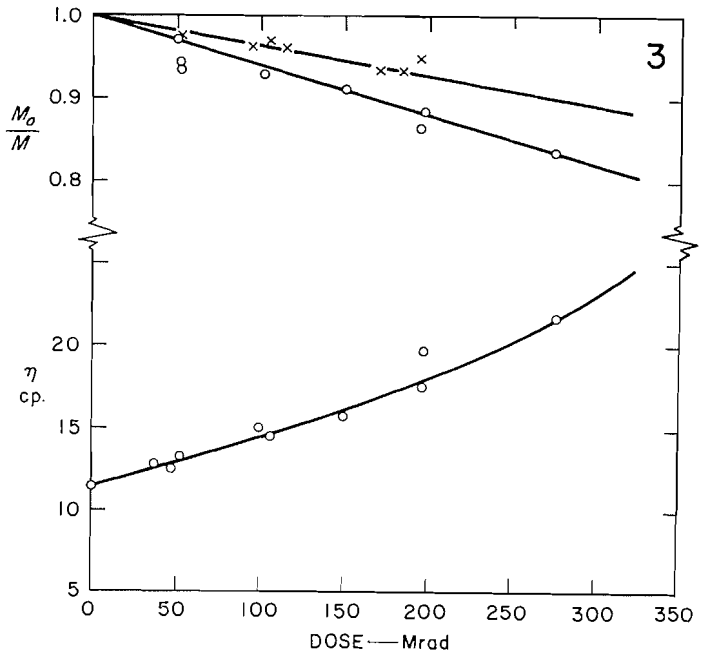

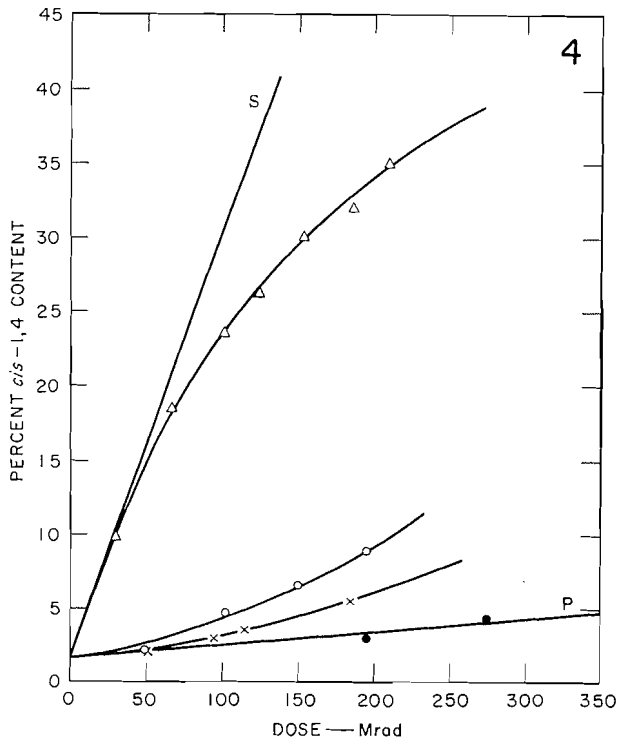

FIG. 3. The effect of dose on the molecular weight and viscosity of prefractionated γ-irradiated (○) and electron-irradiated (×) squalene.

FIG. 4. Radiation-induced *trans–cis* isomerization of squalene: pure squalene irradiated with γ-rays at room temperature (○) and with electrons at −30° C (×) but unfractionated; data on corresponding fraction 1, ●; squalene in benzene irradiated with γ-rays, △.

of squalene (liquid or solid) nor on the temperature. This latter aspect is in keeping with the observed temperature independence of the polybutadiene isomerization (19).

The upward curvature found in the plots for the pure squalene runs is clearly absent in the plot for the squalene solution runs. Here the perturbation effect is perhaps not any smaller than in the pure state but it is certainly obscured by the marked tendency for the plot to curve downward due to the relatively rapid approach towards equilibrium. The tangent line S can be considered to define *only* the upper limit of the initial rate of isomerization of squalene in a 10% benzene solution. The true value for this solution isomerization could thus be much lower than this, although still significantly higher than that in the pure liquid.

It is worth mentioning that, in contrast to the situation with the irradiated pure squalene, the infrared spectra of several samples of squalene recovered from solution irradiations provided qualitative confirmation of partial *trans–cis* isomerization. The infrared changes observed, which were subtle and unsuitable for quantitative purposes, were of the same form but not as extensive as those published for sulphur-dioxide-isomerized squalene (18).

As shown in Table III, the *cis* content in fraction 1 after a dose of 200 Mrad, for example, has increased from 1.6 to 3.0% of the internal double bonds in squalene, whereas in the solution case the *cis* content went from 1.6 to 23.6% for only one-half this dose. From the slopes of the lines S and P, the *G*-values for the *trans–cis* isomerization of squalene in benzene solution and in the pure liquid state were found to be $G_s(t\rightarrow c) \leq 2.6$ and $G_p(t\rightarrow c) = 0.83$, respectively. These energy yields represent the number of *trans* internal double bonds isomerized (initially) to *cis* configuration per 100 eV absorbed by both squalene and solvent, in the solution case, and by squalene alone, in the pure state. By way of comparison, it should be noted that the *G*-values for the *trans–cis* isomerization of balata in a 1% solution in benzene and in the pure solid state were found to be 0.97 and ~10, respectively (1). Evidently, there is a marked difference in ease of isomerization of squalene and balata in the pure state, although their solution isomerizations proceed at rates which have the same order of magnitude. Thus, the effective energy yields, $G_s'(t\rightarrow c)$, for squalene and balata in solution would be around 26 and 97, respectively, when calculated in terms of the energy absorbed directly by the solute, as though there were no energy transfer between solvent and solute.

DISCUSSION

Loss of Unsaturation and Crosslinking

As seen from the results presented above and summarized in Table IV, pure squalene and polyisoprene show considerable similarity in their response to ionizing radiation, quantitatively as well as qualitatively. Thus, for example, the most prominent microstructural change common to both materials is a fairly large consumption of double bonds, with *G*(-d.b.) values of 4.6 and 5.3 for the room temperature irradiations of squalene and polyisoprene, respectively. A somewhat lower *G*-value (3.8) was obtained for squalene in the case of irradiation at −30° C. These various values compare favorably with those calculated for the same compounds from the data of Turner (3) and Hayden (20).

Significantly, it was found in the present study that the loss of unsaturation occurs only in the immediate vicinity of the crosslinks (i.e., it is confined to the crosslinked fraction 2 and is not found in fraction 1), and does not occur randomly throughout the irradiated squalene, in contrast to *trans–cis* isomerization. This interesting result, derived from the

model compound approach pursued here and one which could not have been obtained from a study carried out solely on the high polymer, has important implications for the radiation chemistry of diene polymers. For one thing, it tends to rule out the addition of radiolytically produced hydrogen onto the double bonds of squalene (or polyisoprene) as a significant cause for the loss of unsaturation in the isoprenic compound. Otherwise, this loss would not be limited to the crosslinked products, since there is no reason for the addition of hydrogen to the double bonds to be anything but random. A further argument against this reaction making an important contribution to the loss of unsaturation is that it implies a high transient formation of hydrogen which, on the basis of the mechanisms considered below, would lead to a much higher *G*-value for crosslinking, or production of conjugated diene structures (21), than is actually obtained. It follows, therefore, that hydrogenation of double bonds must play a negligible role in the overall radiation chemistry of squalene or polyisoprene.

In the case of polyisoprene, Turner (3, 16, 17), has shown quite definitely from work with free radical scavengers that both crosslinking and hydrogen evolution involve non-radical as well as radical processes. Thus, he found that free radical scavengers can suppress the C—C crosslinks by about 40% and reduce the hydrogen yield by about 10%. These results afford a rough estimate of the relative contributions of non-radical (NR) and radical (R) processes to crosslinking and hydrogen evolution:

$$G(X)_{NR} = 0.54 \qquad G(H_2)_{NR} = 0.43$$
$$G(X)_{R} = \underline{0.36} \qquad G(H_2)_{R} = \underline{0.05}$$
$$G(X) = 0.90 \qquad G(H_2) = 0.48$$

where we make use of Turner's $G(X)$ value (16, 17) and our own $G(H_2)$ value (14). The non-radical processes, which evidently make a major contribution here, can be represented by the "molecular" reaction

[4] $$2\,RH \longrightarrow R{-}R + H_2$$

suggested by Turner for the radiolysis of polyisoprene (RH), since $G(X)_{NR} \simeq G(H_2)_{NR}$.

The radical processes, on the other hand, can be represented by either mechanism A or mechanism B, although the former appears to be by far the more important of the two, since $G(X)_R \gg G(H_2)_R$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Mechanism A

[5] $RH \rightsquigarrow R\cdot + H\cdot$

[6] $H\cdot + RH \longrightarrow RH_2\cdot$

[7] $RH_2\cdot + R\cdot \longrightarrow R_2H_2$

Mechanism B

[5] $RH \rightsquigarrow R\cdot + H\cdot$

[8] $H\cdot + RH \longrightarrow R\cdot + H_2$

[9] $R\cdot + R\cdot \longrightarrow R{-}R$

Consequently, the addition of a hydrogen atom onto a double bond involved in mechanism A (reaction 6) is found to occur much more readily than the abstraction of an α-methylenic hydrogen atom involved in mechanism B (reaction 8). Although this finding is in line with the general view regarding such reactions (22), it is nevertheless somewhat surprising for polyisoprene considering the high concentration of α-methylenic hydrogen atoms present in this macromolecule.*

Mutual combination is perhaps not the only fate of the allylic radicals ($R\cdot$) and the alkyl radicals ($RH_2\cdot$), and two other possibilities need to be considered, viz., disproportionation and addition of these radicals onto double bonds. In the case of the allylic radicals, if they undergo disproportionation a conjugated diene or triene structure would be formed, but such a reaction was shown to be of minor importance (21). Moreover, the two possibilities were ruled out by Moore and Watson (23) on the premise that in their study of the crosslinking of rubber with di-*tert*-butyl peroxide there was no detectable change in efficiency of crosslinking with variation in temperature. Accordingly, we can say quite definitely that the fate of the allylic radicals, apart from the trivial one of recombination with hydrogen atoms, is combination with an alkyl or another radical to form a crosslink.

In the case of the alkyl radicals, their disproportionation at room temperature cannot be very important since it would lead to new types of unsaturation, such as $-CH{=}CH_2$ units, but these are not formed to any appreciable extent. However, the addition of alkyl radicals to polyisoprene double bonds, resulting in further crosslinking

[10] $RH_2\cdot + RH \longrightarrow R_2H_3\cdot$

or their abstraction of α-methylenic hydrogen atoms present in the rubber molecule

[11] $RH_2\cdot + RH \longrightarrow RH_3 + R\cdot$

is not unlikely. Since the crosslinked products, even at very low doses, consist not only of dimers but of higher molecular weight material as well, it would appear that reaction 10 must occur to a certain extent. In fact, we may be dealing here with an allylic type polymerization in which the chain length is very small owing to a competition between reactions 10 and 11 (propagation and allylic termination, respectively). Such a "degradative chain transfer" is known with olefins containing allylic hydrogens (24). Whether or not reactions 10 and 11 take place, mechanism A involves the consumption of one double bond per crosslink formed, without evolution of hydrogen. From this, it may be deduced that the G-value for loss of double bonds involved in crosslinking is $G(\text{-d.b.})_X = G(X)_R - G(H_2)_R = 0.31$, where formation of hydrogen by

[12] $H + H \longrightarrow H_2$

accounts for the $G(H_2)_R = 0.05$.

*See ref. 3, p. 38.

For personal use only.

It is clear that crosslinking is responsible for only a small part of the consumption of double bonds. The major part, $G(\text{-d.b.})_C = G(\text{-d.b.}) - G(\text{-d.b.})_X$ or $5.3 - 0.31 \simeq 5$, is presumably due to cyclization, since the other obvious source of loss of double bonds, hydrogenation, has already been shown to be unimportant.

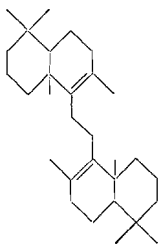
Since the radiation chemical data for squalene and polyisoprene are evidently very similar (Table IV), the arguments presented for polyisoprene may be considered to apply directly to the case of squalene, and for this reason it appeared necessary to develop them in some detail.

Cyclization

It is now of interest to examine the possible mechanisms for cyclization which must account for the large drop in unsaturation not related to crosslinking, $G(\text{-d.b.})_C \sim 5$. Conceivably, the cyclization takes place through a radical mechanism involving the intramolecular addition of an alkyl radical onto a double bond

[13] 
This intramolecular reaction cannot be ignored since the corresponding intermolecular addition of $RH_2\cdot$ radicals onto double bonds (reaction 10) has not been ruled out either. On the other hand, polyisoprene and isoprenoid structures have been known for a long time to undergo facile cyclization by a conventional carbonium ion mechanism

[14] 
although there has been considerable controversy about whether the product from polyisoprene consists of monocyclic or polycyclic structures (25). Without entering into this controversy, we should note that squalene, when similarly cyclized, gives rise to tetracyclosqualene



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

having a structure consisting of two bicyclic groups connected by two methylene groups (5). In any case, the cyclization reaction can be regarded as a chain process in which a proton, once released in the system, can lead to the consumption of many double bonds without producing crosslinks, hydrogen evolution, or other by-products. If the initially produced molecule ion from irradiated squalene can be converted into an appropriate carbonium ion, analogous to what has been suggested (8) for isobutylene and various other monomers known to undergo a radiation-induced ionic polymerization, it is quite possible that squalene can be cyclized by an ionic mechanism when exposed to ionizing radiation. In that event, the chain nature of the reaction could then be responsible for translating a very low rate of initiation (G_i of the order of 0.2, for example, in the case of isobutylene (7*b*)) into the observed rather high G-value for the cyclization ($\sim$5). If such a cyclization mechanism does operate, the analogous intermolecular reaction

[15] $$\begin{matrix} & -CH_2-\overset{+}{C}(CH_3)-CH_2-CH_2- & \longrightarrow & -CH_2-C(CH_3)-CH_2-CH_2- \\ -CH_2-C(CH_3)=CH-CH_2- & & & -CH_2-\overset{+}{C}(CH_3)-\underset{|}{CH}-CH_2- \end{matrix}$$

is likewise possible: it could, along with reaction 10, account for the higher molecular weight products found in the fractions 2. At any rate, the occurrence of reactions 14 and 15 (carbonium ion mechanism) or reactions 10 and 13 (free radical mechanism) could explain the observation that the cyclization is associated with the crosslinking reaction, i.e., the loss of unsaturation is observed only in the crosslinked products.

Another possible cyclization, involving allylic radicals, is one suggested by Moore and Watson (23)

[16] $$-CH_2-C(CH_3)=CH-CH_2-CH_2-C(CH_3)=CH-\dot{C}H- \longrightarrow$$
$$-CH_2-\dot{C}(CH_3)-CH-CH_2-CH_2-C(CH_3)=CH-CH-$$

to account for the loss of unsaturation observed in the crosslinked products obtained from the rubber-like compounds, dihydromyrcene and digeranyl, when these are reacted with di-*tert*-butyl peroxide. This suggestion does not appear valid, however, due to the small reactivity of allylic radicals and also to the fact that these same authors were led, on other grounds, to dismiss the corresponding *inter*molecular reaction (23). We consider that the loss of unsaturation in their experimental work remains without a satisfactory explanation.

Finally, it should be noted that the slight effect of temperature on G(-d.b.) argues against the free radical reactions 10 and 13 making an important contribution to the radiation chemistry of squalene and polyisoprene. But it would be unjustified to rule out such reactions entirely just as it would be to postulate exclusively a carbonium ion mechanism for cyclization. A study of the radiation-induced loss of unsaturation in the presence of free radical scavengers should help to elucidate this interesting question.

Isomerization

The similarity in the radiation chemistry of squalene and polyisoprene discussed in the foregoing sections clearly extends to the phenomenon of geometric isomerization about their isoprenic double bonds. However, these compounds show notable differences in their relative ease of isomerization in solution and in the pure state. Thus, the G-value for the *trans–cis* isomerization of squalene in the pure liquid (G_p(t$\rightarrow$c) = 0.83) is considerably smaller than that of balata (*trans* polyisoprene) in the solid state ($\sim$10), whereas the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

corresponding effective energy yields for the solution isomerizations ($G_s'(t\rightarrow c)$ of 26 and 97, respectively) are not fundamentally different.

The G_s' value for squalene in benzene is some 30 times the G-value for the pure compound (G_p), while in the case of balata the G_s' value is about 10 times the corresponding G_p value. A similar situation was described several years ago for the radiation isomerization of polybutadiene (26) where the effective yield in a 1% benzene solution is about eight times the yield in the pure polymer. The mechanisms advanced to explain the radiation-induced "unsensitized" isomerization of polybutadiene in solution and in the pure polymer appear to be directly applicable to that of squalene (or polyisoprene). Accordingly, the isomerization of squalene in the pure state can be considered to involve the excitation of the π-electrons of the isoprenic double bonds to an antibonding state where free rotation and hence geometric interconversion can occur. This excitation, resulting from collisions of energetic electrons with the squalene molecules, may take place directly at the double bonds or be produced there indirectly through intramolecular energy transfer out of adjacent methylene groups, or from neutralization of ionized species somewhere in the molecule. In the solution case, however, the important agency for promoting the isomerization can be assumed to be intermolecular energy transfer from excited or ionized benzene molecules to squalene double bonds. A similar explanation has been advanced recently for the radiation-induced isomerization of *cis* and *trans* butene-2 in benzene (27).

Two aspects of the squalene isomerization results deserve additional comment. Firstly, since there is no reason to expect the efficiency of intermolecular energy transfer from benzene to squalene to differ significantly from energy transfer from benzene to polyisoprene, we have to seek an explanation for the fact that the ratio of G_s' to G_p for squalene is around 30 while it is only around 10 for polyisoprene (and about 8 for polybutadiene). Although there is some uncertainty regarding the exact $G_s(t\rightarrow c)$ value for squalene, as noted earlier, it is quite unlikely that its true value would be low enough (say, about 1.0) to bring the G_s'/G_p ratio down from 30 to 10. In view of the work of Cundall and Griffiths (27) on *cis* and *trans* butene-2, a reasonable explanation for the difference between G_s'/G_p ratios for squalene and balata is that the particular values obtained for $G_s(t\rightarrow c)$ depend somewhat on the concentration of the isomerizing compound. In fact, our $G_s(t\rightarrow c)$ for squalene corresponds to a 10% benzene solution while the corresponding value for polyisoprene refers to a 1% solution.

Secondly, we are unable to explain the much lower isomerizability of pure squalene compared to that of pure polyisoprene, even if we allow for the fact that in the former compound only the four internal double bonds can isomerize. Apparently, squalene is less efficient than polyisoprene in using the available excitational energy for isomerization purposes. In this connection, it may be noted that preliminary work on pure *cis* 4-methylpentene-2 indicates that this compound isomerizes either not at all or at most very slightly (28). At first glance, it would seem that the efficiency of isomerization of the pure olefinic compound, in contrast to that of the material in benzene, depends on the size of the molecule, decreasing regularly from the macromolecule down to the very short molecule. Such a point of view appears consistent with the model depicted by Lorquet, ElKomoss, and Magee (29) in which electronic excitation localized in one of the double bonds of a polymer can migrate along the chain to induce the isomerization of several of them. However, both Kaufman (30) and Cundall (31) have recently observed rather high G-values for the isomerization of *cis* butene-2 in the pure state ($G_p\sim4.0$ and 14, respectively), so that the size of the isomerizing molecule per se is not sufficient to account for

For personal use only.

the low isomerizability of pure squalene compared to pure polyisoprene. Further work on this question seems worth while and we plan to extend this research to include dihydromyrcene which, having a diisoprene structure, is intermediate in molecular weight between squalene and pentene-2 or butene-2.

ACKNOWLEDGMENTS

This research was supported in part by Aeronautical Systems Division, U.S.A.F., and in part by Stanford Research Institute. We wish to express our appreciation to W. R. Anderson, Jr., for providing the n.m.r. spectra, to D. E. LeGoullon for the infrared spectra, to L. F. Nye who monitored the irradiations, and to other staff members for various analyses. We wish also to thank Professor P. J. Flory and Dr. A. H. Samuel for helpful discussions.

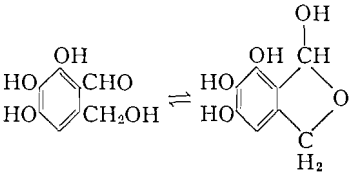
FOMECIN A AND B, PHENOLIC ALDEHYDES FROM THE BASIDIOMYCETE FOMES JUNIPERINUS

T. C. McMorris and Marjorie Anchel
The New York Botanical Garden, Bronx Park, Bronx 58, New York
Received February 11, 1964

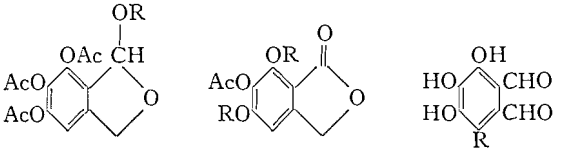
ABSTRACT

Fomecin A and B obtained previously from the basidiomycete *Fomes juniperinus* Schrenk have been characterized as 6-hydroxymethyl-2,3,4-trihydroxy benzaldehyde and 2,3,4-trihydroxy *o*-phthalaldehyde, respectively.

An investigation of antibacterial substances produced by higher fungi resulted in the isolation some time ago of a crystalline antibiotic from culture liquids of *Fomes juniperinus* Schrenk (1, 2). This compound, which was named Fomecin A, has now been identified as 6-hydroxymethyl-2,3,4-trihydroxy benzaldehyde (I*a*).



I*a* I*b*



II*a*, R = Ac
b, R = Me

III*a*, R = Ac
b, R = Me

IV*a*, R = H
b, R = Me

Fomecin A, $C_8H_8O_5$, was weakly acidic and gave a blue-black color with ferric chloride solution. It formed a red 2,4-dinitrophenylhydrazone, gave an orange condensation product with aniline, and it rapidly reduced ammoniacal silver nitrate in the cold, thus indicating the presence of an aldehyde function. In agreement, the n.m.r. spectrum showed a singlet at $-0.1\ \tau$.

Treatment of Fomecin A with acetic anhydride and pyridine gave a tetraacetate (II*a*) whose spectral properties indicated it to be a phenolic acetate having no aldehyde group. This reaction is readily explained if there is a hydroxymethyl *ortho* to the aldehyde so that acetylation can proceed through the tautomeric form (*Ib*).

When a methanolic solution of the tetraacetate was refluxed for a short time, solvolysis occurred giving the product (II*b*). The n.m.r. spectrum now showed a singlet at 6.65 (methoxyl) instead of one at 7.97 (acetate) and the unsymmetrical doublet at 2.65 due to the proton on the carbon bearing two oxygen functions had moved upfield to 3.77.

Treatment of (II*a*) with chromium trioxide in aqueous acetic acid gave a crystalline product shown to be 4,5,6-triacetoxy phthalide (III*a*). Thus, on deacetylation and then

methylation it gave a trimethoxy phthalide isomeric with authentic 3,4,5-trimethoxy phthalide. On oxidation, both isomers gave the same trimethoxyphthalic acid. The formation of phthalide (III*a*) establishes the orientation of substituents on the aromatic ring of (I*a*).

In later isolations of Fomecin A a second, less polar, substance called Fomecin B could also be obtained, though in much lower yield. This yellow crystalline compound, $C_8H_6O_5$, also gave a blue-black color with ferric chloride and reduced ammoniacal silver nitrate in the cold. The n.m.r. spectrum revealed the presence of six protons: sharp singlets at −0.8 and 0.05 due to two aldehyde protons, a singlet at 2.92 due to an aromatic proton and broad signals at about −2.66 and 0.4 due to one and to two hydroxyl protons, respectively, which disappeared on addition of deuterium oxide.

Peaks at 1685 and 1630 cm^{-1} in the infrared spectrum are assigned to free and chelated aldehyde groups.

The ultraviolet spectrum (λ_{max} 263, 336 mμ; ϵ 26 400 and 9200) is similar to that of Flavipin (IV*b*), (λ_{max} 261, 264, and 330 mμ; ϵ 23 500, 22 400, and 8700) a metabolite of *Aspergillus flavipes* (3).

The structure (IV*a*) for Fomecin B was confirmed by oxidation of its methylation product to 3,4,5-trimethoxy phthalic acid.

The Fomecins possess the same carbon skeleton as, for example, the well-known metabolite 6-methyl salicylic acid, which is known to be biosynthesized from acetate (4), and they are probably formed in a similar way. Their structures recall those of similarly related pairs of metabolites, dihydrogladiolic and gladiolic acids (5, 6), and cyclopolic and cyclopaldic acids (7).

EXPERIMENTAL

Melting points were taken on a Köfler block. Microanalyses were carried out by Dr. F. Pascher, Bonn, and n.m.r. spectra determined by Dr. D. P. Hollis, Varian Associates, California. Infrared and ultraviolet spectra were determined with Perkin–Elmer Model 21 and Carey Model 11 spectrophotometers, respectively. Petroleum ether refers to the fraction b.p. 66–75°.

The isolation and antibacterial properties of Fomecin A are described elsewhere (1). The final stage of the isolation was a countercurrent distribution between ethyl acetate and water. Fomecin A moved with the aqueous phase while the less polar Fomecin B remained in the ethyl acetate phase in the early funnels.

Fomecin A crystallized from ethanol–water as pale buff-colored spicules which did not melt but charred gradually above 160°. Found: C, 52.28; H, 4.49; O, 43.47; mol. wt. (Rast), 189; equiv., 173. Calc. for $C_8H_8O_5$: C, 52.18; H, 4.38; O, 43.44; mol. wt., 184. λ_{max} (EtOH) 241, 304 mμ (ϵ 10 800 and 15 300). ν_{max} (KBr) 3480, 3150 (broad), 1635, 1615 (shoulder), 1603, and 1510 cm^{-1}. τ (deuterated dimethyl sulphoxide) −0.1 (singlet, —CHO); 3.47 (singlet, aromatic H); 5.32 (singlet, —CH_2—O). The integral curve showed that the hydroxyl protons gave broad resonances overlapping the entire spectrum.

Fomecin B crystallized from ethyl acetate as yellow needles which darkened on heating and melted at about 230°. Found: C, 53.03; H, 3.79; O, 43.31. Calc. for $C_8H_6O_5$: C, 52.75; H, 3.32; O, 43.93. λ_{max} (EtOH) 263, 336 mμ (ϵ 26 400 and 9200). ν_{max} (KBr) 3450 (shoulder), 3100 (broad), 1685, 1630, 1603, and 1510 cm^{-1}. τ ($CDCl_3$) −0.8, 0.05 (singlets, 2 CHO); 2.92 (singlet, aromatic H); −2.66 and 0.4 (broad peaks, 1 and 2 OH, respectively).

Fomecin A Derivatives

(a) 2,4-Dinitrophenylhydrazone.—Addition of a hot solution of 2,4-dinitrophenylhydrazine (300 mg) in acetic acid (6 ml) to a solution of Fomecin A (200 mg) in ethanol (3 ml) gave quickly a red precipitate. It was recrystallized from ethyl acetate and it decomposed without melting. Found: C, 45.55; H, 3.68; N, 14.82. Calc. for $C_{14}H_{12}O_8N_4$: C, 46.16; H, 3.32; N, 15.38.

(b) Anil.—Aniline (0.5 ml) was added to a hot solution of Fomecin A (184 mg) in ethanol (2 ml). When it had been cooled orange crystals separated. It was recrystallized from ethanol and it decomposed without melting. Found: C, 64.60; H, 5.32; N, 5.29. Calc. for $C_{14}H_{13}O_4N$: C, 64.86; H, 5.06; N, 5.40.

(c) Acetate (IIa).—Fomecin A (200 mg) was treated with pyridine (5 ml) and acetic anhydride (2.5 ml) overnight. The solvents were removed *in vacuo* at room temperature, xylene added, and then removed similarly. Addition of ether to the residue caused crystallization. After recrystallization from ethyl acetate – petroleum ether it had m.p. 135°. Found: C, 54.53; H, 4.68; O, 40.98; Ac, 48.60. Calc. for $C_{16}H_{16}O_9$: C,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

54.55; H, 4.58; O, 40.87; 4 Ac, 48.87. λ_{max} (EtOH) 264, 270 (inf.) mμ (ϵ 830, 800). ν_{max} (Nujol) 1785–1755 cm^{-1}. τ ($CDCl_3$) 2.6 (unsymmetrical doublet, J 1.5 c.p.s.; —O—CH—O); 2.9 (somewhat broad singlet, aromatic H); 4.82 (AB spectrum, δ AB .22 p.p.m. J AB 12 c.p.s., —CH_2—O—. The signals of this methylene were broad and ragged indicating coupling to both the O—CH—O and aromatic proton; 7.77, 7.75, and 7.97 (2, 1, and 1 Ac, respectively).

Methanolysis of Tetraacetate

A solution of the tetraacetate (200 mg) in methanol (10 ml) was refluxed for 1 hour, then the solvent removed. The residue crystallized and on recrystallization from ethyl acetate – petroleum ether had m.p. 121–123°. Found: C, 56.08; H, 5.03; O, 39.14; OMe, 9.57; Ac, 39.57. Calc. for $C_{15}H_{16}O_8$: C, 55.55; H, 4.97; O, 39.47; 1 (OMe), 9.56; 3 Ac, 39.8. λ_{max} (EtOH) 263, 270 mμ (ϵ 740, 720). ν_{max} (Nujol) 1785–1765 cm^{-1}. τ ($CDCl_3$) 2.95 (somewhat broad singlet, aromatic H); 3.77 (unsymmetrical doublet, J = 1.5 c.p.s., —O—CH—O—); 4.87 (broad peak, —CH_2—O—. Here the satellite peaks of the AB spectrum were barely visible above the noise); 6.65 (OMe); 7.7 (3 Ac).

Oxidation of Tetraacetate

A solution of chromium trioxide (200 mg) in acetic acid (4 ml) and water (2 ml) was added to one of the tetraacetate (1 g) in acetic acid (12 ml) and water (6 ml). The resulting solution was kept overnight, then the solvents removed *in vacuo*, ethyl acetate added to the dark green residue, and the mixture boiled and filtered. When the filtrate had been concentrated, crystalline material (III) was obtained (prisms, 300 mg) which after recrystallization from ethyl acetate had m.p. 168–170°. Found: C, 54.89; H, 3.93; O, 40.28; Ac, 44.12; mol. wt. (Rast), 309. Calc. for $C_{14}H_{12}O_8$: C, 54.55; H, 3.92; O, 41.53; 3 Ac, 41.85; mol. wt. 308. λ_{max} (EtOH) 236, 277 (inf.), 283 mμ (ϵ 10, 400; 2300; 2500). ν_{max} (Nujol) 1785–1765, 1630, 1615 cm^{-1}. τ ($CDCl_3$) 2.72 (singlet, aromatic H); 4.72 (singlet, —CH_2—O—); 7.6 (Ac); 7.67 (2 Ac).

Hydrolysis and Methylation of Phthalide (III)

The phthalide (110 mg) dissolved in pyridine (4 ml) and water (2 ml) was kept overnight, then the solvents removed *in vacuo* below 30° leaving a residue which crystallized on adding ethanol. Since it tended to color in air it was dissolved in methanol and treated with ethereal diazomethane. There was vigorous effervescence and after 1 hour the excess diazomethane was destroyed and a crystalline product isolated which, after recrystallization from ethyl acetate, had m.p. 181–183°. Found: C, 57.21; H, 4.88; O, 37.78; OMe, 24.66; Ac, 17.01; mol. wt. (Rast), 238. Calc. for $C_{12}H_{12}O_6$: C, 57.14; H, 4.80; O, 38.06; 2 (OMe), 24.59; 1 Ac, 17.06; mol. wt. 252. The values indicate that two acetyl groups were removed in the hydrolysis. They must be the ones *ortho* and *para* to the lactone carbonyl, and the methylated product therefore has the structure (11*b*).

This compound (200 mg) dissolved in methanol (10 ml) was kept overnight with 0.1 *N* NaOH (5 ml). Next morning the solution was made just acid to litmus with dilute HCl then evaporated to dryness *in vacuo*. The residue was suspended in methanol and ethereal diazomethane added. After 1 hour excess diazomethane was destroyed, the methanol removed, water added, and the solution extracted with chloroform. This extract yielded an oil which quickly crystallized as rosettes of needles and after recrystallization from ethyl acetate – petroleum ether they had m.p. 136–137°. A sample was sublimed at 115°, 0.05 mm Hg for analysis. Found: C, 59.55; H, 5.62; O, 35.18; OMe, 41.16; mol. wt. (Rast), 238. Calc. for $C_{11}H_{12}O_5$: C, 58.92; H, 5.40; O, 35.68; 3 (OMe), 41.5; mol. wt. 224.2. λ_{max} (EtOH) 257, 288 mμ (ϵ 13 300; 2800). ν_{max} (KBr) 1755, 1605 cm^{-1}. τ ($CDCl_3$) 3.2 (singlet, aromatic H); 4.75 (singlet, —CH_2—O—) 5.8, 5.98, 6.07 (3 OMe).

3,4,5-Trimethoxy Phthalide

This compound prepared from 3,4,5-trimethoxy benzoic acid (8) had m.p. 135° and gave a depression of mixed melting point with the trimethoxy phthalide from Fomecin A. The infrared spectra of the two compounds were different. However, when both compounds were oxidized by treating the alkaline solutions (5% KOH) with dilute $KMnO_4$ (3%) at 60–65° for 1 hour, the same product, i.e., 3,4,5-trimethoxy phthalic acid was obtained, m.p. and mixed m.p. 174–176°. The infrared spectra were identical.

The phthalide from Fomecin A is, therefore, 4,5,6-trimethoxy phthalide, which is reported to have m.p. 136.5–137 (9).

Methylation and Oxidation of Fomecin B

The compound (100 mg), dry acetone (10 ml), K_2CO_3 (400 mg), and methyl sulphate (0.3 ml) were refluxed under N_2 for 2 hours. The mixture was filtered and the acetone removed from the filtrate leaving an oil. This was taken up in hot KOH solution (5%) and oxidized with dilute $KMnO_4$ as above. The crystalline product was identical (m.p. and infrared spectrum) with 3,4,5-trimethoxy phthalic acid.

SYNTHESIS OF SOME ALKYLATED ADENINES AS POTENTIAL ANTIMETABOLITES

C. J. ABSHIRE* AND L. BERLINGUET
Département de Biochimie, Faculté de Médecine, Université Laval, Québec, Québec
Received January 27, 1964

ABSTRACT

Several substituted adenines and (or) their salts have been prepared by condensing adenine in dimethylformamide with the following halides: benzyl chloride, *p*-methylbenzyl chloride, *n*-propyl bromide, (3-chloropropyl) benzene, α-bromo-γ-butyrolactone, allyl bromide, and cinnamyl chloride. The reaction may be carried out in large quantities and the salts were isolated in high yields.

Characterization of these compounds indicated that they are pure 3-substituted adenines with the possible exception of the allyl and the *n*-propyl derivatives, which may contain little, if any, of the 7- or 9-isomers.

It is well known that derivatives of adenine, such as 6-mercaptopurine, have interesting antimetabolic activities. This paper reports the synthesis of N-alkylated purines to evaluate their biological activities.

Within the recent past, various workers have succeeded in alkylating purines on the basic nitrogens of the heterocyclic rings (1, 2, 3). Some of these compounds have also been isolated as natural products (4–12). Most of the laboratory alkylation studies of purine derivatives have, to date, been achieved in basic media. Recently, however, workers have reported that the alkylation of purines occurs in dimethylformamide or dimethylacetamide without the addition of a basic reagent (1, 2). However, there still exists confusion concerning the site of alkylation. In a recent paper, Pal (13) states that "no correlation between alkylation sites and theoretically predicted relative basicities of the ring nitrogen atoms of adenine was observed." Recently, however, it has been proved by several authors that of all the common purines, adenine is the only one which is alkylated in position 3 (1), in neutral medium.

We have prepared several of these substituted adenines by reacting adenine with excess of an alkyl halide in dimethylformamide. Various halides were chosen, to include a variety of reactivity ranging from highly reactive, such as allyl bromide, to weakly reactive, such as *n*-propyl bromide (see Table I). In all cases, the yields were very good and the compounds could be isolated in fairly large quantities. We have isolated all of our compounds directly from the reaction mixture as the corresponding ammonium salts; these were obtained by removal of most of the solvent and trituration of the residue with acetone. Thus 3-benzyl adenine hydrochloride, 3-(*p*-methylbenzyl) adenine hydrochloride, 3-cinnamyl adenine hydrochloride, 3-(3′-phenyl-*n*-propyl) adenine hydrochloride, 3-(γ-butyrolactonyl-α) adenine hydrobromide, allyl adenine hydrobromide, and *n*-propyl adenine hydrobromide were isolated and characterized. In four cases, we isolated the free bases by neutralizing the salts with sodium hydroxide solution. Leonard and Fujii (2) recently reported the isolation of the free bases 3-benzyl adenine and 3-allyl adenine. The 3-benzyl adenine had also been synthesized previously by Denayer (14).

All of the analyses (C, H, N, halogen, titration) agree with the theoretical values, thereby suggesting purity of the compounds. However, because of the numerous possibilities that alkylation can take place at positions 1, 3, 7, or 9, we cannot disregard the

*Isomers present, therefore not all 3-substitution.

presence of two or several isomers. From the evidence accumulated by several authors (1, 2, 3, 13, 14, 15), we have assigned the alkylated chain on the 3-position of the adenine nucleus. The benzyl adenine which we have obtained has a melting point of 284–287 °C compared to 278–280 °C for 3-benzyl adenine reported by Leonard and Fujii (2). We were able to note a slight difference between the ultraviolet data for the free bases and their respective hydrohalides—in general, the free bases absorbed at a slightly lower wavelength than their corresponding hydrohalides. The pK_a' values of cinnamyl adenine and (3′-phenyl-*n*-propyl) adenine were 5.13 and 5.23 respectively, indicating that in both cases, the substitution on the adenine nucleus is in position 3 (3, 15). The allyl adenine and *n*-propyl adenine likewise showed pK_a' values of 5.43 and 5.45 respectively.

From the recent literature (1, 2, 3, 13, 14, 15) and our own work, it would seem that all of our compounds are 3-substituted adenines. To verify the presence or absence of isomers, all the compounds were analyzed by paper chromatography and electrophoresis in different buffers. This last method has proved to be very useful in observing the isomers which have different pK_a' values (see Fig. 1). All of the compounds as isolated showed

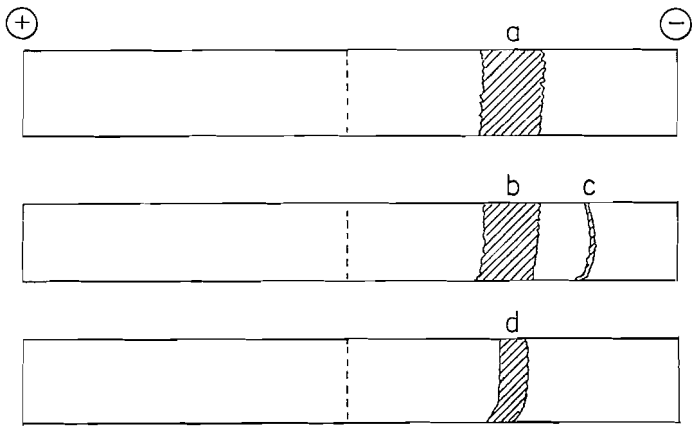

FIG. 1. Electrophoretic migration of adenine and alkylated adenines in buffer pH 1.9, 2 h at 10 mA. The spots are located by means of an ultraviolet lamp: (*a*) pure adenine, (*b*) 3-allyl adenine hydrobromide, (*c*) an uncharacterized allyl adenine isomer, and (*d*) 3-benzyl adenine hydrochloride.

one spotting except the following two: allyl adenine hydrobromide and *n*-propyl adenine hydrobromide. These two compounds showed two spots with both paper chromatography and electrophoresis. Since the elemental analyses and the titration data agreed for purity, the second spot which is somewhat weaker in intensity is obviously due to the presence of a position isomer. No attempts were made to identify the second isomers in question. For both the allyl and the *n*-propyl compounds, the ultraviolet data (λ_{max} = 277 mμ for both) and the pK_a' data (5.43 and 5.45 respectively) point to the fact that these compounds are both primarily 3-substituted.

Before realizing that we were dealing with a mixture of isomers, we prepared derivatives of the allyl compound. Treatment of this compound in acetic acid solution with bromine furnished the perbromide of (2,3-dibromopropyl) adenine hydrobromide (VIII). On heating, the bromine in the perbromide bonding was eliminated and (2,3-dibromopropyl) adenine hydrobromide (IX) resulted. Neutralization with aqueous sodium hydroxide yielded the free base (X). In all of these compounds the ultraviolet absorption peak remained virtually unchanged, indicating that the purine nucleus was not disrupted.

For personal use only.

Elemental analyses and titration data also all agreed. As with the starting material, paper chromatography and electrophoresis showed the presence of a major compound and a minor one (obviously a position isomer).

It is logical that allyl adenine hydrobromide should add bromide on the exocyclic olefinic bond and thus compounds IX and X are easily understood. Evidence for the existence of the heat labile perbromide (VIII) lies in the fact that the compound separates from solution as beautiful orange-colored crystals for which analyses of nitrogen and bromine agreed; the ultraviolet absorption spectra are also similar to that of IX, X, and the starting material. The heat lability of two bromine atoms further suggests that this is really a perbromide. It has similar properties with the perbromide of 2 (or 8)-bromoadenine first reported by Bruhns and Kossel (16).

We are presently doing extensive biological investigation of all the pure compounds.

EXPERIMENTAL

The carbon and hydrogen analyses were done by C. Daessle, Micro Analyses, Montreal. The nitrogen analyses were performed in our laboratory by the Kjeldahl procedure. The acid titrations were done by merely dissolving the compound in water and titrating with 0.1 *M* aqueous sodium hydroxide using phenolphthalein as indicator. The ultraviolet spectra were obtained in ethyl alcohol solution using a Cary Model 15 spectrophotometer. The melting points were determined on a Fisher–Johns melting point apparatus and were not corrected. All paper chromatograms were developed with the organic layer formed from a mixture of 1-butanol, water, and glacial acetic acid (75:20:5). Development was performed by the ascending method in a chamber saturated with solvent vapor. Comparison of samples were made on the same sheet and not by R_f values. Spots were detected by means of ultraviolet absorbance.

All electrophoreses were carried out using a Spinco Duostat apparatus and employing 10 mA for a period of 2 h. Two buffers were used, one at pH 1.9 (98–100% formic acid, glacial acetic acid, and water, 1:4:28) and one at pH 8 (0.667 *M* Na_2HPO_4 – 0.05 *M* borate – KCl – NaOH, 9:10). The pK_a' data for 3-cinnamyl adenine and 3-(3′-phenyl-*n*-propyl) adenine was obtained in dimethyl formamide (DMF), water solution (1:1). In the case of the allyl and *n*-propyl compounds, the salts were dissolved in water, titrated to neutralization with aqueous sodium hydroxide, and, since the free base did not precipitate, the solution was then used as such for pK_a' investigation.

Condensation of Adenine with Alkyl Halides

The halogen compound was added to a stirred solution of adenine in dimethyl formamide solvent at the reflux temperature. The resulting solution was refluxed for some time, then the solvent was removed by vacuum and gentle heat. Trituration of the residue with acetone yielded the ammonium salt in high purity. Table I gives the results obtained with seven different alkyl halides.

The products were analyzed for C, H, N, and either HCl or HBr. Ultraviolet spectral analysis was carried out on each compound; a 1% solution employing ethyl alcohol as solvent was used. Table II contains this data. Paper chromatography and electrophoresis were carried out on all compounds (salts and bases); only in the cases of the allyl and propyl compounds were two spots present. The pK_a' values of four of the compounds were determined as previously mentioned. The free bases 3-benzyladenine, 3-(*p*-methylbenzyl) adenine, 3-(3′-phenyl-*n*-propyl) adenine, and 3-cinnamyl adenine were obtained on neutralization in water of the acid salts. Table III lists the data obtained.

Reaction of Allyl Adenine Hydrobromide with Bromine

Two grams of allyl adenine hydrobromide were dissolved in 80 ml of boiling glacial acetic acid. After the solution was cooled to room temperature, bromine in glacial acetic acid was added. At first, the bromine was decolorized; the bromine solution was added until a slight excess was present. The total resultant solution was about 100 ml. Slight cooling caused precipitation. A 2.7 g yield of orange-colored crystals (perbromide of N-(2′,3′-dibromopropyl) adenine hydrobromide) (VIII) was obtained. These crystals began to change color from orange to white at about 130° and the white crystals subsequently melted with decomposition at 200–207°. Anal. Calc. for $C_8H_{10}N_5Br_3$: N, 12.15; Br, 69.28. Found: N, 12.40; Br, 68.68. The ultraviolet spectrum of this compound in ethyl alcohol showed a λ_{max} at 278 mμ with an ϵ of 19 100.

The above perbromide (800 mg) was dissolved in 25 ml of hot glacial acetic acid. This was heated and distilled. The distillate passed over at 118°; it was reddish in color and probably consisted of bromine and acetic acid. The residue in the distillation flask gradually decolorized from red to colorless. The distillation was stopped when the distillate was completely colorless (about 10 ml remained in the residue). This residue was cooled whereupon a white precipitate formed. This was filtered, washed with ether, and dried. A 550 mg yield of a product melting at 200–208° was obtained (N-(2′,3′-dibromopropyl) adenine hydrobromide) (IX).

REACTIONS OF PHENYL-SUBSTITUTED HETEROCYCLIC COMPOUNDS

V. NITRATIONS OF 1,3- AND 1,5-DIPHENYLPYRAZOLES[1]

BRIAN M. LYNCH AND YUK-YUNG HUNG[2]
Department of Chemistry, St. Francis Xavier University, Antigonish, Nova Scotia
Received February 17, 1964

ABSTRACT

Dinitration of 1,3- or 1,5-diphenylpyrazole in sulphuric acid yields the corresponding di(*p*-nitrophenyl) compounds, while nitric acid – acetic anhydride yields the 4-nitro-1-*p*-nitrophenyl compounds.

Mononitration at the 4-position occurs when the diphenylpyrazoles and several other 1-phenylpyrazoles are nitrated at 0° by nitric acid – acetic anhydride.

Possible explanations of the dependence of orientation on the nature of the nitrating agent are discussed.

Nuclear magnetic resonance (n.m.r.) spectroscopy was used in demonstrating the structures of many of the nitration products, and a general discussion of the n.m.r. spectra of substituted 1-phenylpyrazoles is given.

INTRODUCTION

In nitrations of aromatic compounds, the stages of successive substitution are usually well defined, since a nitro group is strongly deactivating towards further substitution (1). However, the 1-phenylpyrazole derivatives (IA–IC) are readily *dinitrated* to the 4-nitro-1-*p*-nitrophenyl compounds (IIIA–IIIC), under conditions similar to those employed for *mononitration* of 1-phenylpyrazole (2, 3). In an earlier paper (4), we suggested that 1-phenylpyrazoles (I) will undergo nitration in nitric acid – sulphuric acid as their conjugate acids (II), so that the para-position of the 1-phenyl group is the site of initial nitration. The resulting 1-*p*-nitrophenylpyrazoles (IV) will be far less basic than the parent species (I), and will undergo further nitration as the free bases, in which the 4-position is attacked. Dinitration is thus to be expected, since the various conjugate acids (II) and the 1-*p*-nitrophenylpyrazoles (IV) should be of approximately equal reactivity towards nitronium ion. The generalized conversion I → III is thus to be expected for all 1-phenylpyrazoles with readily accessible 1-para- and 4-positions.

Some assignments of structure to the dinitration products of 1,3- and 1,5-diphenylpyrazoles (ID and IE) conflict with this prediction, although it might be argued that a 3- or 5-phenyl group would shield the 4-position from attack; von Auwers and Mauss (5) suggested that dinitration of 1,3-diphenylpyrazole yielded 1,3-di(*p*-nitrophenyl)pyrazole (VA), while we assigned (4) the dinitro-1,5-diphenylpyrazole, m.p. 185°, obtained by nitric acid – sulphuric acid treatment of 1,5-diphenylpyrazole, as 1,5-di(*p*-nitrophenyl)-pyrazole (VB). In view of these apparent exceptions to the generality of the conversions I → III, we have reexamined the nitrations of 1,3- and 1,5-diphenylpyrazoles in detail. In addition, we have noted several further examples of initial 4-nitration of substituted 1-phenylpyrazoles by nitric acid – acetic anhydride (as predicted in an earlier paper (4)).

The proton nuclear magnetic resonance (n.m.r.) spectra of the various nitration products furnished particularly simple demonstrations of structure, supplementing or replacing classical degradations, syntheses, and conversions into known compounds.

RESULTS

(a) 1,3-Diphenylpyrazole

Nitration by nitric acid – acetic anhydride at 0° yielded 1,3-diphenyl-4-nitropyrazole (VC), m.p. 123°, together with 1-*p*-nitrophenyl-3-phenylpyrazole and 4-nitro-1-*p*-nitrophenyl-3-phenylpyrazole (IIID), m.p. 238–240°: the dinitro compound (IIID) was the sole product of similar nitration at 20°. Nitration by mixed nitrating acids at 0° yielded 1,3-di(*p*-nitrophenyl)pyrazole (VA), m.p. 228–230°, also obtained by similar nitration of 1-*p*-nitrophenyl-3-phenylpyrazole (cf. von Auwers and Mauss (5)).

The structural assignments were confirmed as follows. The mononitro compound of m.p. 123° has structure VC since its n.m.r. spectrum in dimethyl sulphoxide shows a signal at τ 0.20 integrating for a single proton, and a 10-proton envelope between τ 2.0 and 2.5. The low-field signal is typical of a 5-proton adjacent to a 4-nitro group in a 1-phenylpyrazole derivative (see Discussion section for examples). The assignment of structure VC is subject to little doubt in any case, since other likely nitration products are already known (1-*p*-nitrophenyl-3-phenylpyrazole, m.p. 169° (5), and 3-*p*-nitrophenyl-1-phenylpyrazole, m.p. 137° (6)). Structure VA for the dinitro compound of m.p. 228–230° also follows from its n.m.r. spectrum (measured in dimethyl sulphoxide at 50°), which shows two doublets (*J*, ca. 1 c/s) centered at τ 2.80 and 1.17 assigned to the 4- and 5-protons of the pyrazole ring, and a signal at τ 1.68 corresponding to the 8 (apparently equivalent) protons of the 1- and 3-*p*-nitrophenyl groups (see Discussion section for interpretations of the signal positions). The dinitro compound of m.p. 238–240° has structure IIID since it is obtained by nitration of VC by mixed acids and by nitric acid – acetic anhydride nitration of 1-*p*-nitrophenyl-3-phenylpyrazole, and it differs from the dinitro compound (VA).

For personal use only.

(b) 1,5-Diphenylpyrazole

Our present results confirm previous assignments (4) of structure to the various nitration products of 1,5-diphenylpyrazole, i.e.: 1,5-diphenylpyrazole — (HNO_3/Ac_2O)→VD, m.p. 150°, 1,5-diphenylpyrazole — (HNO_3/H_2SO_4)→VB, m.p. 185°, and confirm that 4-nitro-1-*p*-nitrophenyl-5-phenylpyrazole (IIIE), m.p. 147°, is the product of nitric acid – acetic anhydride nitration of 1-*p*-nitrophenyl-5-phenylpyrazole.

Structure VD for the mononitro-1,5-diphenylpyrazole of m.p. 150° was proved by converting it into 1,4,5-triphenylpyrazole via reduction, diazotization, and Gomberg arylation of benzene (cf. (4)). Furthermore, its n.m.r. spectrum in acetone was consistent with structure VD, in that a single proton signal assignable to the 3-proton, and two five-proton signals at τ 2.56 and 2.63, assignable to the 1- and 5-phenyl groups, are observed. The position of the signal assigned to the 3-proton (at τ 2.77) indicates the presence of some remarkable shielding effect (see Discussion section).

Structure VB for the dinitro-1,5-diphenylpyrazole of m.p. 185° is established, since it is formed by mixed-acid nitration of 1-*p*-nitrophenyl-5-phenylpyrazole, and it yields *p*-nitrobenzoic acid on prolonged oxidation by neutral potassium permanganate. Further confirmation is provided by its n.m.r. spectrum in acetone, which shows two doublets (J, ca. 1 c/s) centered at τ 2.10 and 3.13 assigned to the 3- and 4-protons of the pyrazole ring, together with an A_2B_2 pattern centered at τ 2.05 arising from the two *p*-nitrophenyl groups (which are apparently equivalent: see Discussion section). Similarly, structure IIIE for the dinitro-1,5-diphenylpyrazole of m.p. 147° follows from its n.m.r. spectrum in acetone, which shows a five-proton signal at τ 2.50 due to the 5-phenyl group, an A_2B_2 pattern centered at τ 2.08 arising from the four protons of the 1-*p*-nitrophenyl group, and a single proton signal at τ 1.50 from the 3-proton.

(c) Further Examples of 4-Nitration by Nitric Acid – Acetic Anhydride

Smooth 4-mononitration of the following compounds was effected by nitric acid in acetic anhydride at 0°: 1-*p*-bromo-, 1-*p*-chloro-, 1-*o*-methoxy-, and 1-*p*-phenyl-phenylpyrazoles, and 3-methyl-1-phenylpyrazole. The structures of the first three nitration products were established by comparison with samples synthesized by cyclizing the appropriate arylhydrazine with sodium nitromalonaldehyde hydrate; the structure of 1-*p*-phenylphenyl-4-nitropyrazole (1-*p*-biphenylyl-4-nitropyrazole), m.p. 200° (in previous experiments (4), a polymorphic form, m.p. 170°, having ultraviolet and infrared spectra identical with our present product, was obtained) was proved by synthesis via 1-*p*-aminophenyl-4-nitropyrazole using diazotization and Gomberg arylation (cf. (4)), while our nitro-3-methyl-1-phenylpyrazole had m.p. 110°, identical with that recorded for 3-methyl-4-nitro-1-phenylpyrazole by Finar and Hurlock (3), and its n.m.r. spectrum (see Discussion section) was consistent with the assigned structure.

DISCUSSION

(a) Dependence of Orientation upon the Nitrating Agents

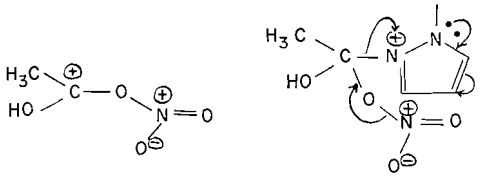
In the dinitrations of both 1,3,- and 1,5-diphenylpyrazoles, the orientations are seen to be reagent-dependent, in the sense that nitration at the para-positions of the N- and C-phenyl groups is favored in sulphuric acid, while 4-nitration is favored when nitric acid – acetic anhydride is used. These results could be rationalized in terms of our previous suggestions (4) if the conjugate acids of the diphenylpyrazoles, and also of the 1-*p*-nitrophenyl-3- and -5-phenylpyrazoles, are the entities undergoing nitration in the strongly acidic solvent, but such a postulate does not appear reasonable. In particular, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

1-*p*-nitrophenyl compounds would surely exist in measurable proportions as the free bases.

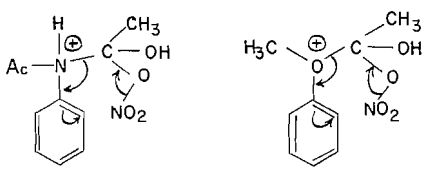
Our present results thus require an interpretation other than deactivation of the pyrazole ring through protonation, with resultant substitution by default in the phenyl rings, to account for the lack of substitution in the pyrazole ring. It is tempting to propose that the adjacent 3- or 5-phenyl group hinders the approach of nitronium ion, but such a suggestion replaces one difficulty by another, since the same factors would operate in the nitric acid – acetic anhydride nitrations, where 4-nitration is favored. However, if a specific interaction occurs between the pyrazole ring and the nitrating agent which is effecting substitution in the nitric acid – acetic anhydride system, such that attack in the pyrazole ring is favored over other sites, then the observed reagent-dependence can be explained.

Since Bordwell and Garbisch (7) have put forward convincing evidence that protonated acetyl nitrate (VI) is the effective species in nitrations by the nitric acid – acetic anhydride reagent, we suggest that the specific interaction suggested above takes the form of an addition of the nucleophilic N_2 of a pyrazole to the electron-deficient carbon of VI, yielding an intermediate (VII). The series of electron shifts shown would then lead to preferred 4-nitration.



Although an interpretation along these lines seems to be required to account satisfactorily for the results with the diphenylpyrazoles, the selective 4-nitrations of the simpler species noted in part (*c*) of the Results section, and some previous examples (4), may be accounted for in terms of our previous suggestion, i.e., in a simple 1-phenylpyrazole, where the 1-*para*- or 4-positions are the only probable sites of substitution, 4-substitution is favored for attack on the neutral molecule (4). Supporting evidence for this contention is furnished by the results of Friedel–Crafts nitration of 1-phenylpyrazole using nitronium tetrafluoroborate in tetramethylene sulphone, cf. Olah *et al.* (8(*a*), where 4-nitro-1-phenylpyrazole is the only detectable substitution product (8(*b*)).

Intermediates corresponding to VII account neatly for other selective nitrations effected by the nitric acid – acetic anhydride reagent: thus VIII would lead readily to the observed ortho nitration of acetanilide, and IX to the similar nitration of anisole.



Since previously suggested reaction pathways (9, 10) for these ortho nitrations do not take Bordwell and Garbisch's results into consideration, and the postulated intermediates are consistent with all previous evidence, we are currently engaged in a study (11) seeking to establish VIII as the general intermediate for the selective ortho nitrations of substituted acetanilides.

(b) Nuclear Magnetic Resonance Spectra

In addition to their value in facilitating and confirming assignments of structure, the n.m.r. spectra of 1-phenylpyrazole derivatives are of interest in their own right: little previous attention has been focussed either on the chemical shifts of ring protons in pyrazoles, or on the effects of heteroaromatic substituents on the chemical shifts of benzenoid protons. Many of the compounds examined by n.m.r. spectroscopy were 1-parasubstituted-phenyl pyrazoles, in which the presence of a readily recognizable A_2B_2 pattern due to the four protons of the substituted phenyl group facilitated identification of the signals from the pyrazole ring protons. Analyses of these A_2B_2 patterns so as to resolve the individual chemical shifts expected for the A and B protons in the absence of spin–spin coupling gave the results in Table I. The analyses employed the simplified approach adopted by Richards and Schaefer (12), in which it is assumed that $J'_{AB} = 0$ and $J_{AA} = J_{BB}$. It is evident from Table I that 1-pyrazolyl substituents usually have a marked deshielding influence on the protons of a parasubstituted-phenyl group. The deshielding is accounted for readily in terms of the effect of the ring current in the pyrazole ring on the adjacent protons of the 1-phenyl group (13). Although the qualitative effects of various substituents in the 1-phenyl group follow the order expected from the chemical shifts of ortho and meta protons in monosubstituted benzenes (14), no constant chemical-shift parameters could be assigned to the 1-pyrazolyl substituent, since the apparent deshielding contribution varies with the nature of the other substituent, and with the solvent. Fortunately, acetone and dimethyl sulphoxide (the most effective solvents for the compounds studied) appear to be closely comparable in their effects on the chemical shifts of the phenyl-group protons (see No. 1 in Table I).

With the 1-*p*-nitrophenyl-5-phenylpyrazole derivatives (Nos. 7–9 in Table I), where coplanarity of the 1-*p*-nitrophenyl and pyrazole rings is highly unlikely, marked changes from the A_2B_2 pattern typical of other 1-*p*-nitrophenylpyrazoles (e.g., Nos. 1, 3, 4–6) are found. The A–B chemical shift separation (δ_{A-B}), and the extracted A and B chemical shifts, are altered in the direction expected for a decreased deshielding contribution accompanying the increased angle between the planes of the 1-*p*-nitrophenyl and pyrazole rings (13). In No. 9, the 1- and 5-*p*-nitrophenyl groups must be magnetically equivalent, since only one A_2B_2 pattern, closely similar to those for Nos. 7 and 8, was resolved. A corresponding situation was observed with 1,3-di(*p*-nitrophenyl)-pyrazole, although in this instance the center of the system is at τ 1.68 (with $J_{AB} \gg \delta_{A-B}$), indicating that the three rings are coplanar in this compound. Further indications that the 5-phenyl groups in Nos. 7 and 8 are not coplanar with the pyrazole ring are provided by the appearance of discrete signals at τ 2.47 and 2.50, rather than the band envelopes between τ 2.0–2.6 observed for No. 4 and for 1,3-diphenyl-4-nitropyrazole (see Results section). Such differences are to be expected if the ortho protons of the 5-phenyl groups are shielded by comparison with the values characteristic of coplanar C-phenyl and pyrazole rings, and such differences are also noted with 1,5-diphenyl-4-nitropyrazole (see Results section).

The chemical shifts assigned to the pyrazole ring protons in a series of substituted pyrazoles are listed in Table II. In general the τ values fall in the order $4 > 3 > 5$, which is to be expected since (*a*) the 5-proton should be deshielded most effectively by the ring current of the adjacent 1-phenyl group, and (*b*) the 4-carbon should have a higher electron density than the 3-carbon (which will be influenced electrostatically by the adjacent pyridine-type nitrogen). The assignments are based upon the τ values noted for suitably substituted compounds (Nos. 3 and 6, 10 and 11), and upon the observed multiplicities

of signals for the compounds with three adjacent protons (Nos. 1, 2, *p*-di(1-pyrazolyl)-benzene, 1-*p*-bromophenylpyrazole): the 4-protons gave triplets, and the 3- and 5-protons doublets, as expected from simple first-order theory if spin–spin coupling is restricted to adjacent protons. Similarly, doublet signals were observed for compounds with two adjacent protons (Nos. 4, 7, 9, and 1,3-di(*p*-nitrophenyl)pyrazole). The apparent coupling constants between adjacent protons were ca. 1 c/s, and there was no evidence of coupling between non-adjacent protons (the signals from the pyrazole ring protons in Nos. 3, 5, 10, 12, 1-methyl-4-nitropyrazole, 4-bromo-1-phenylpyrazole and 4-bromo-1-*p*-bromophenylpyrazole were singlets). The influence of 4-substituents on the chemical shifts of the 3- and 5-protons qualitatively parallels their influence in monosubstituted benzenes, with one exception.

This exception is 1,5-diphenyl-4-nitropyrazole, where the 3-proton signal falls at τ 2.77 (with most 4-nitro-substituted pyrazoles, the 3-proton signal falls in the range τ 1.4–2.0). The three adjacent groups (the 1- and 5-phenyls, and the 4-nitro group) somehow lead to considerable shielding of the 3-proton. One rationalization of this extraordinary effect is that all three substituents are oriented perpendicularly to the pyrazole ring plane. Circulation of the π-electrons in the nitro group could then produce positive shielding above and below the plane containing the nitro group. Bullock (15) has noted the possibility of such an effect with nitrodurenes and nitromesitylenes, and we find that the n.m.r. spectrum of 3-nitro-*o*-xylene (as the pure liquid), a typical AB_2 system (13, p. 93; 16) may be resolved to give τ 2.67 for the A proton (adjacent to the nitro group) and τ 2.90 for the B protons, while the two methyl groups give a singlet at τ 7.79, thus lending support to the possibility of positive shielding of protons or methyl groups ortho to a nitro group which is in a plane perpendicular to that of an attached aromatic ring.

EXPERIMENTAL

Analyses are by the Schwarzkopf Microanalytical Laboratory, Woodside, N.Y., U.S.A. Melting points were observed using a Fisher–Johns apparatus and are uncorrected. Infrared spectra were recorded using a Beckman IR-8 spectrophotometer: samples were examined as suspensions in potassium chloride disks. Ultraviolet spectra refer to solutions in 95% ethanol, and were recorded using Beckman DK-2 or DK-2A ratio-recording spectrophotometers. Nuclear magnetic resonance spectra were obtained using a Varian A-60 n.m.r. spectrometer. Signal positions are expressed on the τ scale in parts per million from tetramethylsilane, present as an internal reference, and refer to saturated solutions.

Starting and Reference Materials

1-Phenylpyrazole, 1-*p*-biphenylylpyrazole, 4-bromo-1-*p*-bromophenylpyrazole, 4-bromo-1-*p*-nitrophenylpyrazole, 4-bromo-1-phenylpyrazole, 1-*p*-bromophenylpyrazole, 1-*o*-methoxyphenylpyrazole, and 1,5-diphenylpyrazole and its various nitro- and dinitro-derivatives had the properties described previously (4). 1-*p*-Chlorophenylpyrazole, m.p. 51°, 1-methylpyrazole, b.p. 126–127°, and *p*-di(1-pyrazolyl)benzene, m.p. 180° (anal. calc. for $C_{12}H_{10}N_4$: C, 68.55; H, 4.79; N, 26.65; found: C, 68.76; H, 4.83; N, 26.51%) (ultraviolet absorption: λ_{max} 283 mμ, log ϵ 4.37), were prepared by cyclizing the appropriate substituted hydrazine and 1,1,3,3-tetraethoxypropane (4). The 3-methyl-1-phenylpyrazole was purchased from the Aldrich Chemical Co., Inc., Milwaukee, Wisconsin, U.S.A. Authentic samples of 1-*p*-bromophenyl-, 1-*p*-chlorophenyl-, and 1-*o*-methoxyphenyl-4-nitropyrazoles (for melting points, see Table III), and of 1-methyl-4-nitropyrazole, m.p. 88–89° (anal. calc. for $C_4H_5N_3O_2$: C, 37.80; H, 3.96; N, 33.06; found: C, 37.79; H, 4.19; N, 33.11%), were prepared by cyclization using the appropriate substituted hydrazine and sodium nitromalonaldehyde hydrate. 1,3-Diphenylpyrazole, m.p. 85°, and 1-*p*-nitrophenyl-3-phenylpyrazole, m.p. 169° (ultraviolet absorption: λ_{max} 261.5, 337 mμ, log ϵ 4.16, 4.24), were prepared from the appropriate arylhydrazine and hydroxymethyleneacetophenone (5). 4-Nitro-1-*p*-nitrophenylpyrazole, m.p. 146° (ultraviolet absorption: λ_{max} 213.5, 305 mμ, log ϵ 4.22, 4.36), and 3-methyl-4-nitro-1-*p*-nitrophenylpyrazole, m.p. 208–209° (ultraviolet absorption: λ_{max} 216, 312.5 mμ, log ϵ 4.03, 4.30), were prepared by mixed acid nitrations of the parent 1-phenylpyrazoles (2, 3), and 1-*p*-aminophenyl-4-nitropyrazole, m.p. 190° (ultraviolet absorption: λ_{max} 262.5 mμ, log ϵ 4.14), and 1-*p*-aminophenyl-3-methyl-4-nitropyrazole, m.p. 169° (ultraviolet absorption: λ_{max} 261.5 mμ, log ϵ 4.18), were prepared from the corresponding dinitro compounds by partial reduction using ammonium sulphide solution (cf. Finar and Hurlock (3)).

Nitrations

(a) By Mixed Nitric – Sulphuric Acids

1,3-Diphenylpyrazole (2 g) was dissolved in the minimum volume of sulphuric acid (*d* 1.84), cooled to 0°, and a mixture of nitric acid (4 ml, *d* 1.42) and sulphuric acid (5 ml, *d* 1.84) was added at 0°, and the mixture was kept at 0° overnight, and then poured onto ice. The resulting precipitate was collected and purified by chromatography on alumina and repeated crystallization from methanol, finally yielding 1,3-di(*p*-nitrophenyl)pyrazole (0.7 g, 25%), m.p. 228–230° (anal. calc. for $C_{15}H_{10}N_4O_4$: C, 58.06; H, 3.25; N, 18.06; found: C, 57.85; H, 3.75; N, 18.02%) (ultraviolet absorption: λ_{max} 340 mμ, log ε 4.34; infrared absorption in the 650–1800 cm^{-1} region (cm^{-1}, intensity): 680w, 697w, 746s, 851s, 952m, 1045m, 1105m, 1269w, 1307sh(s), 1333s, 1513s, 1590s). This compound was also obtained in 87% yield by similar nitration of 1-*p*-nitrophenyl-3-phenylpyrazole. Similar nitration of 1,3-diphenyl-4-nitropyrazole yielded 1 g (43%) of 4-nitro-1-*p*-nitrophenyl-3-phenylpyrazole, m.p. 238–240°, after 1 h at 0°. The product was identical (m.p., mixed m.p., superimposable infrared spectra) with that obtained by nitric acid – acetic anhydride nitration of 1,3-diphenylpyrazole or of 1-*p*-nitrophenyl-3-phenylpyrazole (cf. section (*b*) below, and Table III).

(b) By Nitric Acid – Acetic Anhydride

The general procedure used was that adopted in our previous paper (4): A solution of nitric acid (*d* 1.52) in acetic anhydride, prepared at 15–20°, was cooled to 0° and added to the 1-phenylpyrazole derivative (dissolved in the minimum volume of acetic anhydride) over 30 min. The reaction mixture was poured onto ice and the precipitate was collected. Chromatography on alumina, followed by crystallization from methanol or ethanol, yielded the new products listed in Table III. The 4-nitro-1-*p*-nitrophenyl-3-phenylpyrazole (the final entry in Table III) was obtained by nitration of 1,3-diphenylpyrazole at 20°, and showed the following infrared absorption bands in the 650–1800 cm^{-1} region (cm^{-1}, intensity): 680w, 705w, 741s, 826w, 852s, 922w, 952m, 1099m, 1233m, 1307sh(s), 1335s, 1517s, 1590s. This dinitro compound, therefore, differs from 1,3-di(*p*-nitrophenyl)pyrazole (cf. above). 4-Nitro-1-*p*-nitrophenyl-3-phenylpyrazole was also obtained in 40% yield by similar nitration of 1-*p*-nitrophenyl-3-phenylpyrazole at 20°.

Proofs of Structure via Gomberg Reactions

(a) Conversion of 1,5-Diphenyl-4-nitropyrazole into 1,4,5-Triphenylpyrazole

1,5-Diphenyl-4-nitropyrazole (2.3 g) was reduced using tin and hydrochloric acid, and the crude amine thus obtained was diazotized in 10 *N* hydrochloric acid at 0°, and was stirred with benzene for 3 h after basification with sodium hydroxide at 0°. The benzene layer was separated and chromatographed on alumina: evaporation of the eluate followed by crystallization from ethanol yielded 1,4,5-triphenylpyrazole (0.2 g), m.p. 208–211°, undepressed on admixture with an authentic sample, and with infrared absorption identical with that of an authentic sample, showing the following bands in the 650–1800 cm^{-1} region: 654w, 662w, 694s, 718w, 761s, 767s, 773s, 856w, 920w, 952s, 1379s, 1429w, 1439w, 1493s, 1587s.

(b) Synthesis of 1-p-Biphenylyl-4-nitropyrazole

1-*p*-Aminophenyl-4-nitropyrazole (2 g) was diazotized and the basified diazonium salt solution was used to arylate benzene as in (*a*) above. Chromatography on alumina and crystallization from ethanol yielded 1-*p*-biphenylyl-4-nitropyrazole (0.7 g), m.p. 200°, having ultraviolet and infrared absorption identical with the polymorphic form, m.p. 170°, reported previously (4).

Oxidative Degradation of 1,5-Di(p-nitrophenyl)pyrazole

1,5-Di(*p*-nitrophenyl)pyrazole (0.5 g) was heated under reflux with an excess of alkaline potassium permanganate until no further reduction of permanganate occurred (ca. 100 h). Precipitated manganese dioxide was removed using sulphur dioxide, and the reaction mixture was acidified and extracted with hot benzene, re-extracted with sodium hydrogen carbonate, and re-acidified, giving *p*-nitrobenzoic acid (0.1 g), m.p. 237–240°, having infrared absorption identical with that of an authentic sample.

ACKNOWLEDGMENTS

We thank the National Research Council for grants in support of our work, and one of us (Y. H.) gratefully acknowledges the award of a summer scholarship from the Atlantic Provinces Inter-University Committee on the Sciences. The nuclear magnetic resonance and ultraviolet spectroscopic measurements were made during tenure of this scholarship, at the Atlantic Regional Laboratory, National Research Council, Halifax, and we thank Dr. A. G. McInnes for his courtesy in providing facilities for these measurements.

We also thank Dr. H. O. House (Massachusetts Institute of Technology) for a sample of 1,4,5-triphenylpyrazole, Dr. B. T. Newbold (University of Moncton) for a sample of 3-nitro-*o*-xylene, and Dr. H. S. Chang and Mr. M. A. Khan, who furnished several reference samples.

STUDIES ON THE THERMODYNAMICS AND CONDUCTANCES OF MOLTEN SALTS AND THEIR MIXTURES

PART II. THE VISCOSITIES, HEATS OF FUSION, AND HEAT CAPACITIES OF LITHIUM CHLORATE AND LITHIUM CHLORATE – LITHIUM NITRATE MIXTURES

A. N. Campbell and M. K. Nagarajan
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received February 6, 1964

ABSTRACT

The viscosities at different temperatures of pure molten lithium chlorate and of mixtures of lithium chlorate with lithium nitrate have been determined with high precision. The heats of fusion, and the molar heat capacities of both solid and liquid lithium chlorate, and of mixtures of lithium chlorate and lithium nitrate have also been determined. The heat of the transition $\alpha\ LiClO_3 \rightleftharpoons \beta\ LiClO_3$ has been obtained as the difference between the heats of solution in water of the two forms. The enthalpy, free energy, and entropy of mixing have been derived.

There is no simple theory which describes quantitatively the relationship between viscosity and composition of molten salt mixtures. Harrap and Heymann (1) determined the viscosity of a number of salt mixtures. They found that the viscosity isotherm was either "ideal", i.e. in conformity with the mixture rule, or exhibited a negative deviation from ideality. In some cases, their results suggested the formation of a complex between the two constituents of the mixture.

The only previous study of molten lithium chlorate is that of Klotschko and Grigorew (2): their value for the viscosity of molten anhydrous lithium chlorate (66.2 cP at 128 °C) is almost twice that found by us. No previous work has been done on the viscosities of mixtures of molten lithium chlorate with other salts.

Since the temperature range of the present investigation was sufficiently low, the conventional Ostwald viscometer, as modified by Campbell, Debus, and Kartzmark (3), was used. A small fritted glass disk was attached to the sidearm used for filling, to prevent any silt or suspended impurities entering the viscometer. The essential feature of the Campbell–Debus instrument is that it can be used at temperatures at which the vapor pressure is greater than 1 atmosphere (up to 20 atmospheres, if precautions are taken to thicken the glass appropriately), or when, as here, the system is extremely hygroscopic. Refilling is brought about simply by rotating the instrument through 180°, without the necessity of opening the viscometer. Our viscometers were calibrated with water in the range of 110° to 160 °C. In each case the water was frozen, evacuated, and remelted four times, to remove dissolved gases before final sealing off. A simple mechanical device, comprising a geared drive and a long handle, made it possible to rotate the viscometer without removing it from the hot thermostat. The nature and accuracy of the thermostat were mentioned in a previous communication (4). Time of flow was measured to $\pm$ 0.1 second, by means of an electrical stop clock. Flow times were measured in the region 100° to 160°. Using the known densities and viscosities of water, a calibration factor $C = \eta/\rho t$ was calculated (t = time). This calibration factor varies consistently with temperature: it was, therefore, plotted against temperature, so that C could be read off for any experimental temperature.

The viscometer was filled by exactly the same technique as was described for the

filling of the dilatometers (4). Here again, the fritted glass disk was of vital importance for removing any silt produced during the sealing operation. With molten salts, the reproducibility of the flow times was ± 5 s on a total time of about 10 000 s. The flow times were measured at different temperatures, for mixtures containing, respectively, the following mole fractions of lithium nitrate: 0.000, 0.030, 0.082, 0.131, 0.206, and 0.260. The appropriate density values were obtained by interpolation from the density data, given in a previous publication (4).

A careful estimate of the various sources of error indicates the error of our experimental work to be not more than $\pm 0.1\%$, but the viscosities of the water used as calibration standard are only known, in this temperature range, with an accuracy of $\pm 1\%$. At lower temperatures, the temperature fluctuation of the thermostat, though only amounting to $\pm 0.1°$, caused an observable change in the viscosity values, since the temperature coefficient of viscosity is large at low temperatures: the deviation due to this effect, however, is well within the accuracy of the determination.

The need for accurate values of the heats of fusion to interpret the results of crysoscopic measurements has been stressed by Janz and Goodkin (5). Since some solid salts undergo allotropic transformation below their melting points, it is necessary to know these heats of transition, to compare their entropies of fusion with those of other salts. The structural changes in the melt, in the immediate neighborhood of the melting point, can be better understood if the heat capacity of the melt is known. The entropy change in the melt from some standard state (e.g. the melting point) is evaluated from the equation

$$\Delta S = \int_{T_s}^{T} C_p \, (\mathrm{d}T/T)$$

where T_s is the temperature of the standard state. This entropy change will be considerable if the melt is associated, as is lithium chlorate. It is possible to make a theoretical calculation of ΔS, on the basis of an assumed structural model for the melt, if certain other data are available, and the comparison of this value of ΔS with the experimental value provides a test of the plausibility of the model.

Calorimetric data on mixtures of molten salts provide an understanding of the interactions in the melt. The heats of mixing (ΔH^m), of a large number of anion mixtures have been shown (6) to satisfy the equation

$$\Delta H^m/n_2 = \Delta H^t(t) + an_1$$

where n_1, n_2 are the mole fractions of the two components, $\Delta H^t(t)$ is the hypothetical heat of fusion of the higher melting component at the temperature of the mixture, and "a" is a constant, designated an "interaction parameter". Kleppa and Meschel (6) suggest that it may be possible to explain their results for the alkali halide – nitrate systems by taking into account, in addition to the electrostatic and van der Waals forces, the short range, anion–anion repulsive potential. They do not give any explicit equation for the interaction parameter "a".

The free energy of mixing can be obtained from the equation $\Delta F^m = \overline{\Delta F}_1 - \overline{\Delta F}_0 = \overline{\Delta H}_1 - \overline{\Delta H}_0 - T(\overline{\Delta S}_1 - \overline{\Delta S}_0) = RT \ln a$, where $\overline{\Delta F}_1$, $\overline{\Delta H}_1$, and $\overline{\Delta S}_1$, refer to the mixture and $\overline{\Delta F}^0$, $\overline{\Delta H}_0$, and $\overline{\Delta S}_0$ to one of its components in the pure state. The deviation of ΔF^m or ΔH^m from ideal behavior is generally related to some type of interionic action, which, in the extreme case, may amount to the formation of definite complexes. Unless, however, corroborative evidence is obtainable from other types of measurement, it is difficult to decide about complex formation in molten salt mixtures, from activity data alone.

No calorimetric data of any kind have been reported, either for lithium chlorate or its mixtures. The solid state transition from α lithium chlorate to β lithium chlorate was first reported by Kraus and Burgess (7) and later confirmed by Campbell and Griffiths (8). Campbell, Kartzmark, and Nagarajan (9) obtained a value of 99.1° for the transition temperature, in close agreement with the results of other workers. No determination of the heat of transition had previously been made.

A considerable amount of thermal work has been done on lithium nitrate (10). The heat of fusion of lithium nitrate has been reported as 6060 cal per mole. The molar heat capacity of solid lithium nitrate is 26.68 cal $mole^{-1}$ $degree^{-1}$ at 210° and that of liquid lithium nitrate 26.89 cal $mole^{-1}$ $degree^{-1}$ at 280 °C. No work has been done on the temperature dependence of the heat capacity of lithium nitrate.

Heats of fusion of salts are generally measured by the method of mixtures. A calorimetric assembly is described by Goodkin, Solomons, and Janz (11) for the determination of heats of fusion of inorganic compounds and for this they claim an accuracy of $\pm 2\%$. Our arrangement is quite similar to this, but we introduced a number of modifications to increase the accuracy.

An electric furnace of large heat capacity was kept at constant temperature, by means of the photoelectric control described by Campbell and Kartzmark (21). The furnace was mounted in a vertical position immediately above the calorimeter. The furnace had a swing door, which cut off the heated air space. Within the air space, the heated specimen, contained in a sealed glass container, was suspended by a thread. By swinging aside the door and applying a lighted match to the thread, the sample was precipitated into the calorimeter in a fraction of a second. An examination with a thermocouple probe showed that a band of uniform temperature, 5 inches long, existed in the furnace and within this band the sample was suspended. In the region 90 °C to 180 °C, the temperature was constant within $\pm 0.2°$.

The vacuum-jacketed calorimeter was entirely of glass and was placed in a heavily insulated box. The wooden box was mounted on wheels running on rails. Not until the last moment, that is when we were about to discharge the sample from the furnace, was the calorimeter run under the furnace. The water equivalent of the calorimeter was determined in the usual way from the electrical input necessary to produce an observed rise of temperature. Current was measured from the drop in potential across a standard resistance (about 1 ohm) in series with the calorimeter coil. The heat energy developed is, therefore, given by $E_1E_2t/4.186\,R_s$, where E_1 is the potential across the heating coil, E_2 that across the standard resistance, and R_s the value of the standard resistance. The source of energy was a 6-volt storage battery. The heat energy could be measured to ± 0.1 cal.

A 10-junction copper–constantan thermocouple was inserted in the calorimeter, the cold junctions being kept in a thermostat at 28.0 $\pm$ 0.01 °C. The junctions of the thermocouple were connected to a Varian recorder, which had a voltage span of 3 millivolts. This gave a potential difference of 0.073 °C per division of chart paper and, since it was possible visually to divide the chart paper division into 10 parts, there was an actual sensitivity of measurement of ± 0.007 °C. The calorimeter was stirred with a magnetic stirrer.

Actual temperature measurements were not made. The calculation reduced, after correction for radiation, to the comparison of two heights on the chart paper, one due to the calorimetric experiment and one to a known input of electrical energy. As a check on the accuracy of the apparatus, we determined the specific heat of pure copper, between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

room temperature and 160.0 °C and between room temperature and 198.8 °C. The values we obtained were 0.0959 cal g^{-1} and 0.0967 cal g^{-1}, as against literature values of 0.0953 and 0.0962, respectively.

Anhydrous lithium chlorate and lithium chlorate – lithium nitrate mixtures were loaded into pyrex glass tubes, 20 mm diameter and 5 cm long, using the technique described in Part I of this series (4). Because of the numerous sources of error in calorimetric measurements it is difficult to estimate the accuracy of the final measurement. The only guide, under the circumstances, is the variation from linearity, when molar heat capacity is plotted against temperature. On this basis, the probable error in the molar heat capacities of the solid salts appears to be about $\pm 1\%$ at higher temperatures and closer to $\pm 2\%$ at lower temperatures. The heat capacities of liquid salts and the heats of fusion will have a higher accuracy than this, since larger quantities of heat are involved.

For the heats of solution (in water) the samples were sealed in bulbs which had very thin bottoms and which could therefore be readily broken by the impact of a glass rod. Since the aim of these experiments was to determine the heat of the transition $\alpha \rightleftharpoons \beta$ of the two forms of lithium chlorate it was necessary to prepare both forms in a state of purity. The low temperature α form obtains inevitably in any preparation which has been kept at room temperature for a sufficient length of time. The β form was obtained by heating anhydrous lithium chlorate in a Vycor tube in the controlled furnace at the temperature of 110 °C (transition temperature = 99.1 °C) for 2 weeks. The tube was then dropped into liquid nitrogen, whereby the β form was preserved in the metastable form. We estimate the error of measurement in the determinations of heat of solution to be ± 5 cal on a total of about 400 cal or $\pm 1.5\%$.

RESULTS

The viscosity temperature data have been fitted to the equation

$$\eta = \eta_0 \, e^{(E_{vis}/RT)}$$

by the method of least squares on a computer. Table I gives the numerical values of this equation for pure lithium chlorate and for various values of n_2 = mole fraction of lithium nitrate. The actual experimental data are to be found in the Ph.D thesis of M. K. Nagarajan, University of Manitoba, 1963.

TABLE I

Viscosities of lithium chlorate and lithium chlorate – lithium nitrate mixture in the form of equation $\eta = \eta_0 \, e^{(E_{vis}/RT)}$

n_2 = mole fraction lithium nitrate	Equation	St. dev., P
0	$\eta = 1.979 \times 10^{-5} \, e^{7813/RT}$	±0.005
0.030	$\eta = 1.814 \times 10^{-5} \, e^{8002/RT}$	±0.003
0.082	$\eta = 1.202 \times 10^{-5} \, e^{8481/RT}$	±0.002
0.131	$\eta = 1.446 \times 10^{-5} \, e^{8401/RT}$	±0.003
0.206	$\eta = 1.848 \times 10^{-5} \, e^{8254/RT}$	±0.008
0.260	$\eta = 1.621 \times 10^{-5} \, e^{8399/RT}$	±0.006

Table II contains the values of η_0 and E_{vis} for different mixtures, as obtained from the "best" equation.

The variation of viscosity with composition at constant temperature is shown in Fig. 1. The interpolations at arbitrarily chosen temperatures were carried out by means of the computer, employing the equations of "best" fit. The data so obtained were analyzed

TABLE II

Activation energies for viscous flow

$\eta = \eta_0 e^{E_{vis}/RT}$

n_2	$\eta_0 \times 10^5$	E_{vis}, cal
0.000	1.979	7813
0.030	1.814	8002
0.082	1.202	8481
0.131	1.446	8401
0.206	1.848	8254
0.260	1.621	8399

TABLE III

Values of B_0, B_1, and B_2 in the equation $\eta = B_0 + B_1n_2 + B_2n_2^2$

T, °K	B_0	B_1	B_2	St. dev., P
390.0	0.479	2.676	−5.341	±0.014
400.0	0.372	1.958	−3.828	±0.009
410.0	0.292	1.451	−2.775	±0.006
420.0	0.233	1.088	−2.033	±0.003
430.0	0.187	0.825	−1.503	±0.002
440.0	0.152	0.632	−1.119	±0.001
450.0	0.124	0.489	−0.840	±0.001

by the method of least squares and were found to fit the equation $\eta = B_0 + B_1n_2 + B_2n_2^2$, satisfactorily. The values of B_0, B_1, and B_2 are tabulated in Table III.

Since the calculation of all our results involved a knowledge of the specific heat of Pyrex glass 7740, it was necessary to know this with accuracy. According to the Corning Glass Works (Pyrex Catalogue), this specific heat is 0.20 cal g^{-1}. This value, however, did not seem to satisfy completely all our calculations, and we found it advisable to redetermine the specific heat of Pyrex glass 7740 with the following results:

TABLE IV

Specific heat of Pyrex glass No. 7740

Temperature, °C	Specific heat, cal deg^{-1} g^{-1}
97.5	0.163
126.4	0.166
153.0	0.169
173.1	0.171

Apparently, the value 0.20 must refer to a temperature higher than those at which we have worked.

Table V contains the molar heat capacities of solid and of liquid forms, and the heats and entropies of fusion of pure lithium chlorate and of mixtures of lithium chlorate with lithium nitrate. The specific heats are assumed to be constant over the range of temperature investigated, viz. 156.5 °C to 127.8 °C for the liquid form and 127.8 °C to room temperature (say, 20 °C) for the solid form. It is also assumed that the specific heats of the α and β forms are the same, an allowable assumption, in view of the small heat of transition.

The heat of mixing of n_1 mole fraction of lithium chlorate and n_2 mole fraction of lithium nitrate was calculated as the difference between the observed and calculated

0.050	24.66±0.22	29.17±0.13	399.5	2811±13	7.04
0.105	24.81±0.23	29.11±0.17	397.8	3198±16	8.04
0.146	24.93±0.23	29.06±0.12	396.4	3490±15	8.80
0.196	25.03±0.20	28.98±0.13	394.3	3842±17	9.74
0.255	25.14±0.26	28.84±0.19	391.1	4248±17	10.86

values of heat contents at 401.0 °K (melting point of lithium chlorate), i.e. $\Delta H^m = \Delta H_{obs} - \Delta H_{calc}$. The observed heat content was defined as

$$\Delta H_{obs} = \Delta H_{f(mix)} + \int_{T_f}^{401.0} C_{p(l)} dT$$

where $\Delta H_{f(mix)}$, T_f, and C_p refer to the heat of fusion, freezing temperature, and molar heat capacity in the liquid state of the mixture. The calculated heat content was obtained from the equation:

$$\Delta H_{(calc)} = n_1 \Delta H_{(f)1} + n_2 \Delta H_{(f)2}$$

where $\Delta H_{(f)1}$ and $\Delta H_{(f)2}$ are the molar heats of fusion of lithium chlorate and of lithium nitrate at 401.0 °K. $\Delta H_{(f)2}$ was in turn obtained from the Kirchhof equation

$$\Delta H_{(f)2} = \Delta H_{f(p)} + \int_{T_p}^{401.0} \Delta C_p \, dT$$

where $\Delta H_{(f)p}$ is the heat of fusion of lithium nitrate at its melting point T_p and ΔC_p is the difference between the molar heat capacities of solid and liquid lithium nitrate, i.e. $\Delta C_p = C_{p\ solid} - C_{p\ liquid}$. It is assumed that C_p of lithium nitrate does not alter with temperature. The isothermal heats of mixing, correct to ±2%, are given in Table VI.

TABLE VI

Heats of mixing in lithium chlorate – lithium nitrate system at 401.0 °K (n_2 = mole fraction of lithium nitrate)

n_2	Heat content (calc.) ΔH_{calc}, cal mole^{-1}	ΔH_f of sample, cal mole^{-1}	$\int_{T_f}^{401.0} C_{p(l)}\,dT$, cal mole^{-1}	Heat content (obs.) ΔH_{obs}, cal mole^{-1}	ΔH^m, cal mole^{-1}	$\Delta H^m/n_2$ cal mole^{-1}
0.050	2648	2811	43.8	2855	+207	+4150

obtained from these free energies of mixing and the heats of mixing given in Table VI. Table IX contrasts the values of the free energy, enthalpy, and entropy of mixing (at different concentrations of lithium nitrate) at 401.0 °K. The ideal entropies of mixing were also calculated and are shown in the last column of Table IX.

DISCUSSION

We find the viscosity of pure molten lithium chlorate in the temperature range 128° to 170° is represented by the relation

$$\eta = 1.979 \times 10^{-5}\, e^{7813/RT}$$

NOTE: ΔF^M values obtained by interpolation.

Klotschko and Grigorew (2) reported the values of the viscosity of molten lithium chlorate as 66.2 and 52.2 cp at 128° and 136° respectively. The values consistently obtained by us at these temperatures are 38.3 and 29.8 cP, respectively.

The activation energy of viscous flow is 7.8 kcal, a value similar to those reported in the literature for a number of salts, in fact, the E_{vis} of lithium chlorate is closer to those of ionic melts (NaCl, KCl, etc.) than to those of associated melts, such as the alkali nitrates. It may be that a greater configurational change is involved in the viscous flow of molten lithium chlorate than in other associated melts. The activation energy for electrical conductance has been found by Dr. D. F. Williams of this laboratory, to be 6.13 kcal. Hence the ratio E_{vis}/E_Ω has a value of 1.27, and this is in good agreement with the values reported for associated melts, although this ratio is also affected by the relative sizes of anions and cations.

The presence of nitrate ion in the rather compact lithium chlorate lattice leads to an increase in viscosity and this suggests the possible formation of larger and more unsymmetrical clusters. In all other systems of molten salts hitherto studied, a decrease of viscosity only (negative deviation from ideality) has been noticed (1) and hence the positive deviation exhibited by the lithium chlorate – lithium nitrate system becomes interesting. Even at higher temperatures, the observed viscosity is higher than the ideal value calculated from the relation,

$$\eta_{calc} = n_1\eta_1 + n_2\eta_2$$

where η_1 and η_2 are the viscosities of pure lithium chlorate and of pure lithium nitrate (extrapolated for supercooled melt). Thus, at 440 °C, η_{obs} is 0.237 poise, whereas $n_1\eta_1 + n_2\eta_2$ is 0.154 P, for a mixture containing 0.2 mole fraction lithium nitrate.

We have no direct evidence about the nature of the interaction between nitrate ion and chlorate lattice. A suggested mechansim might be as follows:

1. The activation energy of viscous flow has increased.
2. The unit of viscous flow has become more complex.
3. The number of vacant sites or holes available for the migration of the particles has decreased.

It is possible that some kind of rearrangement takes place on addition of nitrate ion to the chlorate lattice, in such a way as to reduce the volume. Such a reduction in volume would result from the formation of more compact structures, due to the presence of the nitrate ion in the chlorate lattice. The abnormally high viscosity of molten lithium chlorate may be due to the existence of clusters, and the increase in viscosity on the addition of lithium nitrate could result from the bridging of two or more clusters by the nitrate ion.

These clusters, which are low energy preferred configurations moving as one unit during the process of transport, need not necessarily contain covalent bonds between the lithium and chlorate ions. The chlorate ion is pyramidal in shape with Cl—O distance of approximately 2.3 Å. Owing to its shape and large size, the chlorate units might give rise to close-packed anionic groupings, with Li^+ ions, ($r = 0.6$ Å) occupying the interspaces. During the process of transport, the chlorate sublattice and Li^+ ions may move as one unit, due to some kind of a co-operative (presumably rotational) effect, thus constituting, in effect, a cluster: thus, the size of the cluster will be partly determined by the co-ordination number and the non-availability of free space for rotation. Increase of temperature will allow more free space for rotation and hence give rise to a decrease in either the size or the number of clusters. The presence of unsymmetrical nitrate ion (flattened disk shape, with a height of 2.2 Å) could augment this co-operative effect, which is essentially a steric effect, yielding apparently bigger clusters.

The value of the entropy of fusion for lithium chlorate, 6.16 cal deg^{-1} $mole^{-1}$, is higher than that of most salts which give rise to an ionic melt, and falls within the general region of salts which are predominantly associated. The entropy of the transition at 99.1 °C, 1.70 cal deg^{-1} $mole^{-1}$, must be added to the entropy of fusion, when discussing the latter. The total entropy change is therefore 7.86 cal deg^{-1} $mole^{-1}$. The abnormally low melting point of lithium chlorate is probably due to entropy contributions from sources other than positional changes. It is possible that particularly low energy configurations occur in molten lithium chlorate which contribute an additional term (ΔS_{assoc}) to the total entropy of fusion. The molar heat capacity of molten lithium chlorate, 29.20 cal deg^{-1} $mole^{-1}$ is similar to those of molten alkali nitrates. It is generally agreed that association of some sort occurs in molten alkali nitrates. It therefore seems probably that similar association occurs in molten lithium chlorate.

The entropy of fusion of lithium chlorate – lithium nitrate mixtures increases sharply with increasing concentration of lithium nitrate (from 6.16 e. u. at $n_2 = 0$, to 10.86 at $n_2 = 0.255$). Although the entropy of fusion of lithium nitrate is itself very high (10.86 e. u.), the increase in entropy of fusion of lithium chlorate when lithium nitrate is added is much greater than that calculated from the mixture rule. For instance, at $n_2 = 0.255$, ΔS_f, calculated from $\Delta S_f = n_1\Delta S_{f(1)} + n_2\Delta S_{f(2)} = 7.51$ e. u., whereas the experimental value is 10.86 e. u. This sharp increase in entropy of fusion may result from some kind of interaction between nitrate ion and chlorate lattice. The change in the molar heat capacity of lithium chlorate – lithium nitrate mixtures also supports this view. If the ideal values of C_p are calculated from the mixture rule, it is found that the observed values exhibit positive deviation from ideality, in both the solid and the liquid states, the deviation being more pronounced in the liquid than in the solid state. The difference here, however, is small (<1%), not much greater than the experimental error, and so no attempt has been made to interpret these differences on a quantitative basis, as was done for molar volume (4). Nevertheless, the fact that the deviation is positive indicates that the nitrate ion (or the chlorate lattice) does not exist in the melt as such but is part of the structural unit resulting from a possible interaction of nitrate ion with chlorate lattice. The formation of a more complex cluster than that present in pure molten lithium chlorate, perhaps by a process of bridging by the nitrate ion, could account for the positive deviation of C_p from ideality, as well as the sharp increase in entropy of fusion.

The heat of mixing in the molten lithium chlorate – lithium nitrate system at 401.0 °K (the melting point of lithium chlorate) is positive and increases with increasing addition of lithium nitrate. This is in agreement with the findings of Kleppa and Meschel (6) that in all the anion mixtures studied by them, the heat of mixing was positive. They find it

useful to plot $\Delta H^m/n_2$ against n_2, the mole fraction of the addendum. They found that their thermal data on a number of systems satisfied the relation:

$$\Delta H^m/n_2 = \Delta H_{f(t)} + a(1 - n_2).$$

Where the "interaction parameter", a, is a constant. The limiting value of a at $n_2 = 0$, represents, according to Kleppa and Meschel, the partial molal enthalpy associated with the transfer of 1 mole of the second component from the pure crystalline state into admixture with the "pure" liquid state of the first component at the temperature of the mixture. They consider this value to be formally composed of two terms: (a) the enthalpy change, $\Delta H_{f(t)}$ of fusion of the second component, at the temperature of the mixture, and (b) the enthalpy change associated with the solution of this supercooled liquid in the pure liquid first component. Hence the value of $\Delta H^m/n_2 = \Delta H_{f(t)} + a$ at $n_2 = 0$, must be the sum of the above two quantities. The factor "a" thus represents the effect of any possible interaction between the two components.

The values of $\Delta H^m/n_2$ listed in Table VI are plotted against n_2 in Fig. 2. The data were

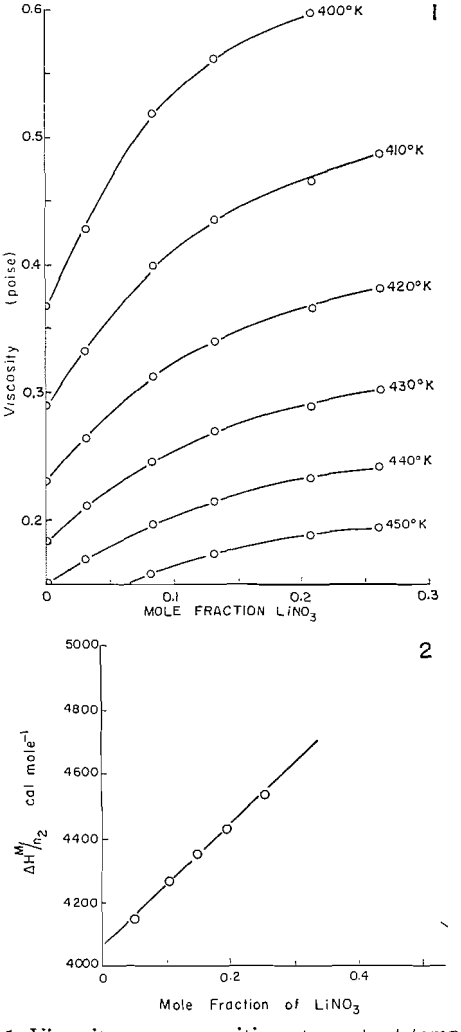

FIG. 1. Viscosity vs. composition at constant temperature.
FIG. 2. Plot of $\Delta H^m/n_2$ vs. n_2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

found (by least squares technique) to satisfy the linear relation

$$\Delta H^m/n_2 = (4.060 + 1.93\, n_2) \text{ kcal.}$$

Therefore,
$$\Delta H_{f(t)} + a = 4.060 \text{ kcal},$$
$$a = -1.93 \text{ kcal},$$
and
$$\Delta H_{f(t)} = 5.990 \text{ kcal}.$$

The value of $\Delta H_{f(t)}$ is given by the expression:

$$\Delta H_{f(t)} = \Delta H_{f(m.p.)} + \int_{401.0}^{T_p} \Delta C_p dT$$

where $\Delta H_{f(m.p.)}$ is the heat of fusion of pure lithium nitrate at its melting point, T_p, and $\Delta C_p = C_p$ (solid) $- C_p$ (liquid), for lithium nitrate. Using the value of 6060 cal mol^{-1} for $\Delta H_{f(m.p.)}$ the value of ΔC_p (assume to be constant in the temperature region 401.0 °C to T_p) results as -0.55 cal deg^{-1} mole^{-1}. The value of ΔC_p calculated from the data in the literature is -0.22 cal deg^{-1} mole^{-1}.

For the system under study, the interaction parameter, a, is negative and large; Kleppa and Meschal (6) found that the value of "a" is a small positive number (0.2 to 0.4) for the alkali nitrate system studied by them, but that it has decided negative values for the systems $AgNO_3$—AgCl and $AgNO_3$—AgBr ($-$ 1.13 kcal and $-$ 2.17 kcal respectively). They explain the small positive values of "a" as being due to the anion–anion (i.e. second nearest neighbor) core repulsion, in addition to coulombic and van der Waals forces. On the other hand, they explain the decidedly negative values obtaining in the silver salts systems as "evidence for a certain degree of chemical interaction in the mixture". A similar explanation may be offered for the large negative interaction parameter ($a = -1.93$ kcal) for lithium chlorate – lithium nitrate mixtures. Since "a" is a measure of the enthalpy change associated with the solution of undercooled lithium nitrate in molten lithium chlorate at 401.0 °K, a negative value of "a" indicates a negative enthalpy change for the possible interaction of nitrate ion with chlorate lattice.

Although the free energy of mixing given in Table VIII is only approximate and subject to a number of assumptions, it gives additional support to the arguments presented above. The fact that the free energy of mixing is negative shows that the interaction between nitrate ion and chlorate lattice is a spontaneous process. The data of Table VIII show that, in spite of a very large positive enthalpy of mixing ΔH^m, the mixing process is spontaneous (ΔF^m is negative) since $T\Delta S^m$ is also large. Since the entropy of mixing plays such an important role in this system there must be pronounced structural effects. The large positive deviation of ΔS^m from ideality suggests that more stable, low energy configurations result on the addition of nitrate ion to chlorate lattice.

AROMATIC SUBSTITUTION

PART VII.[1] COMPETITIVE REACTIONS OF PYRIDINE, 3-PICOLINE, AND 3-ETHYLPYRIDINE WITH PHENYLLITHIUM. ACTIVATION OF A NUCLEOPHILIC AROMATIC SUBSTITUTION BY ALKYL GROUPS

R. A. Abramovitch and Choo-Seng Giam[2]
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received February 2, 1964

ABSTRACT

The relative reactivities of pyridine, 3-picoline, and 3-ethylpyridine towards phenyllithium have been measured under various conditions by a competitive technique and have been found to be in the order: 3-picoline > pyridine > 3-ethylpyridine. A 3-methyl or ethyl substituent *activates* the 2-position relative to that in pyridine itself, while C_6 is deactivated as expected. A possible explanation is put forward for these observations and for the somewhat low yields that are obtained in such reactions. A method is described whereby arylation of pyridines with aryllithium compounds may be effected in high yields.

The predominant formation of 2-phenyl-3-methylpyridine in the reaction of phenyllithium with 3-picoline (1) has been shown to be the result of kinetic control of the addition step in this addition–elimination reaction rather than of thermodynamic control, since this step is irreversible to all intents and purposes (2). Possible explanations of the observed high ortho/para (with respect to the 3-alkyl group) ratio in this and related reactions have been discussed (1) and it clearly was important to establish whether this was due to a selective deactivation of the para position (C_6) with respect to the ortho position, or to some specific *activation* of the ortho position by the 3-substituent, which did not affect the 6-position. Reinheimer and Bunnett have reported cases of activation of an ortho position by a methyl group in certain nucleophilic aromatic substitutions, which they attributed to London dispersion forces between the polarizable approaching nucleophile and the methyl substituent (3).

Serious difficulties were encountered in attempts to study the kinetics of the reaction of phenyllithium with pyridine and with 3-picoline (4). It was, therefore, necessary to turn to competitive experiments in which an excess of equimolar amounts of pyridine and 3-picoline were allowed to react with a small amount of phenyllithium (from bromobenzene and lithium) under various conditions. The results so obtained paralleled those from the preliminary rough kinetic studies (4).

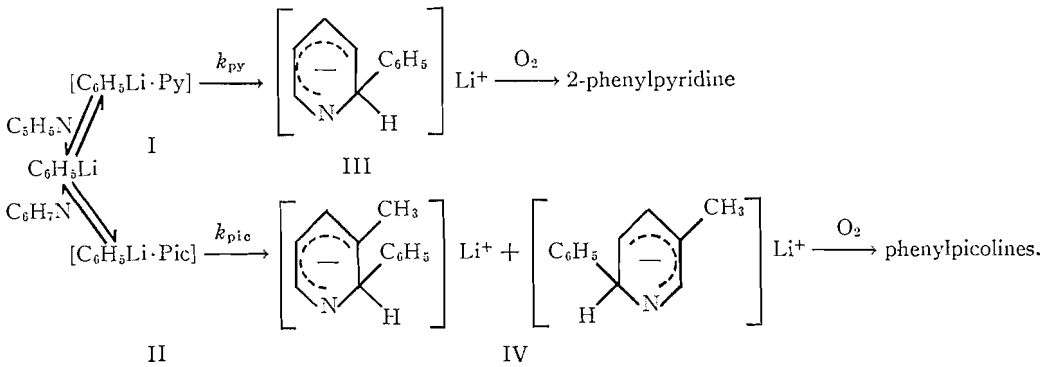
Three methods were used to work up the reactions. In the first (method A), the ether solvent was replaced by dry toluene and the temperature raised to ca. 110° to eliminate lithium hydride from the intermediate addition products. In method B, the ethereal suspension was boiled under reflux, cooled, and oxygen bubbled through to oxidize the intermediates. In method C, the mixtures in ether were stirred at room temperature for varying lengths of time before being oxidized with oxygen. An excess (1.5- to 10-fold, but generally 3-fold) of each pyridine was used and the products were analyzed by gas chromatography after the minimum amount of handling in the work-up. Though the combined yields of 2-phenylpyridine and 2-phenyl-3- and 2-phenyl-5-picoline varied according to the reaction method used, the 2,3-:2,5-isomer ratio remained virtually unchanged (ca. 95:5) within the limits of the experimental error. Table I summarizes a few of the results

[1]*Part VI. R. A. Abramovitch, F. Helmer, and J. G. Saha. Chem. Ind. London, 659 (1964).*
[2]*Present address: Imperial Oil Ltd., Sarnia, Ontario.*

thus obtained. The isomer ratios are correct to $\pm 2\%$ at the outside in most cases. The results of all the experiments described in this paper are the averages of a number of runs.

A number of features are apparent from a consideration of the results in Table I. The yields of products are on the low side and this leads one to worry about whether the isomer ratios and total rate ratios are meaningful or the intermediate σ-complexes are going to by-products at rates which differ according to the structure of the σ-complex. The relative constancy of the ratio of 2,3- to 2,5-phenylpicolines suggested that the isomeric σ-complexes from 3-picoline were not being removed at different rates.

The most striking feature of the results, however, was that it appeared as though, using method C and short reaction times, more phenylpicolines than 2-phenylpyridine were being formed, i.e., 3-picoline was reacting faster than pyridine with a nucleophilic reagent! It also appeared that, with increasing reaction time, the amount of 2-phenylpyridine formed increased with respect to that of the combined phenylpicolines. The following possible explanation had to be considered first, which would have had the merit of avoiding the assumption that 3-picoline was more susceptible to nucleophilic substitution than was pyridine and would account for the change in product ratios with time:



It seems most probable that each base rapidly forms a complex through the nitrogen atom with the organometallic compound.* Since the pyridines are present in excess they would compete for the phenyllithium available and, in view of the slightly greater basicity of 3-picoline over pyridine, one would expect somewhat more of complex (II) to be formed than of (I). These would then react irreversibly (2) to give the intermediate addition products (III) and (IV). Initially, therefore, one might expect more (IV) to be formed than (III). If, however, the 3-alkyl substituent deactivates the nucleus towards electrophilic attack by virtue of its (+I, +M) effect, i.e., $k_{py} > k_{pic}$, the amount of (III) would grow at a faster rate than that of (IV) and lead to the observed results.

To test this possibility an equimolar mixture of pyridine and 3-picoline was treated with *an excess of phenyllithium* to ensure that complexes (I) and (II) would be formed in about equal amounts. If, then, $k_{py} > k_{pic}$, more 2-phenylpyridine than 2-phenylpicolines should be formed from the outset. The results of such experiments are collected in Table II. A number of interesting conclusions may be drawn from the results. It is clear that initially more phenylpicolines are formed than 2-phenylpyridine, confirming that $k_{pic} > k_{py}$. Also, the yields of products obtained under these conditions are quite high (10 min

*This may either undergo intramolecular substitution, or the complex may be attacked by uncomplexed phenyllithium, or uncomplexed pyridine may be substituted by phenyllithium in equilibrium with the complex. Complexing should facilitate nucleophilic attack.

[a]Determined by titration with acid just prior to use.
[b]In the cases of methods B and C, the time is that between the moment the addition of phenyllithium is complete and that when oxygen is passed through the mixture.

TABLE II

Reaction of mixtures of equimolar amounts of pyridine and 3-picoline with an excess of phenyllithium at 24°[a]

Reaction time (min)	% yield of 2-phenylpyridine	% yield of phenylpicolines[b]	Ratio of phenylpicolines to 2-phenylpyridine
4	36.3	44.0	55:45
6	76.0	76.9	50.5:49.5
10	81.0	79.0	49.5:50.5
21	85.5	78.4	48:52
62	74.5	64.2	46.5:53.5

[a][Pyridine] = [3-picoline] = 0.0015 mole, added within 2 min to phenyllithium (0.02 mole).
[b]Ratio of 2,3- to 2,5-isomers = 95:5. Yields are based on pyridine and 3-picoline, respectively.

and 21 min runs), the highest that have been reported for such reactions. *This now provides a convenient method of obtaining high yields in reactions of organolithium compounds with pyridine derivatives*, i.e., using an excess of the lithium derivative at room temperature and a limited reaction time. The fact that even when the phenylpicolines are formed in 79% yield the ratio of the 2,3- to the 2,5-isomer is still 95:5 confirms that there is no, or almost no, *selective* removal of the isomeric dihydropicolyllithium intermediates to form by-products, but that both isomers undergo side reactions at virtually the same rate (2). From the last column of Table II, it is seen that, whereas more phenylpicolines than phenylpyridine are formed initially, the latter predominates after a reaction time of over 10 minutes. That this is not due to the hypothetical situation discussed above is seen from a brief consideration of the actual yields of products formed at various intervals of time. The phenylpicolines attain a maximum yield of about 80%, after which the actual yield *starts to fall*, while that of 2-phenylpyridine is still increasing and only starts to fall some minutes later. This shows that while intermediates (IV) are being formed more rapidly than is (III) they go to by-products, probably by polymerization, at a faster rate than does (III) (the intermediate dihydropyridine is a *cis*-butadiene-like system and, in the presence of a Ziegler-type catalyst, might be expected to polymerize readily). This explains the apparent increase with time in the amount of 2-phenylpyridine formed relative to the phenylpicolines. It also suggests that the relative reactivities of 3-picoline and pyridine (ratios of phenylpicolines to 2-phenylpyridine (Table I)) are, if anything, on the low side and may be taken as a rough, but conservative, estimate of the total rate ratio ${}^{CH_3}_{H}K$ (see also discussion below). Confirmation that 3-picoline was more readily substituted than pyridine in this reaction was obtained by analysis of the above reaction mixtures (Table II) for unreacted pyridine and 3-picoline. This gave a molar ratio of pyridine:3-picoline consumed of 47:53. From the known concentrations of starting amines and the concentrations of recovered unchanged amines and assuming that equation

$$\frac{\log[\text{picoline}]-\log[\text{recovered picoline}]}{\log[\text{pyridine}]-\log[\text{recovered pyridine}]}=\frac{k_{\text{pic}}}{k_{\text{py}}}={}^{CH_3}_{H}K$$

holds (5), a value of ${}^{CH_3}_{H}K = 1.3$ could be calculated.

It should now be possible to calculate partial rate factors for attack at C_2 and C_6 in 3-picoline, taking the rate of reaction at C_2 in pyridine as a standard. In the light of the above discussion, these partial rate factors should, if anything, be on the low side. As no attack appears to take place at C_4 in the examples studied so far, one can write ${}^{H}K = 2{}^{H}k_2$, where ${}^{H}k_2$ is the rate constant for the reaction at C_2 in pyridine, and ${}^{CH_3}K = {}^{CH_3}k_2 + {}^{CH_3}k_6$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where $^{CH_3}k_2$ and $^{CH_3}k_6$ are the rate constants for attack at C_2 and C_6 of 3-picoline, respectively. Then $^{CH_3}_{H}K = {}^{CH_3}K/{}^{H}K = (^{CH_3}k_2 + {}^{CH_3}k_6)/2{}^{H}k_2$, i.e., $2^{CH_3}_{H}K = {}^{CH_3}F_2 + {}^{CH_3}F_6$. If the 2-substituted isomer in the phenylpicoline mixture forms a fraction (α_2) of the mixture then $^{CH_3}F_2 = (\alpha_2)(2^{CH_3}_{H}K)$ and $^{CH_3}F_6 = (\alpha_6)(2^{CH_3}_{H}K)$. Partial rate factors calculated in this way for the reactions listed in Table I are given in Table III.

TABLE III

Partial rate factors determined from competitive reactions of "ordinary" phenyllithium with an excess of an equimolar mixture of pyridine and 3-picoline

Expt. No.	1	2	4	5	6	7	8
$^{CH_3}F_2$	1.5	1.5	2.9	2.9	2.5	2.3	2.4
$^{CH_3}F_6$	0.11	0.13	0.15	0.15	0.13	0.12	0.13

In all cases, C_6 in 3-picoline was deactivated about sevenfold compared with the same position in pyridine, a result consistent with the known electrical effect of an alkyl group in nucleophilic aromatic substitution reactions. Also, C_2 in 3-picoline was *activated*—albeit to apparently varying extents according to the reaction conditions—compared with C_2 in pyridine. At the lower temperature used in method C it appears that the selectivity of the attacking species for C_2 is greater than at the higher temperatures.

The solutions of "ordinary" phenyllithium used above contain one equivalent of lithium bromide. Since pyridine and 3-picoline form complexes with lithium bromide [volumetric analyses of the 3-picoline:lithium bromide complex indicate that it is a 2:1 complex (pyridine also forms a 2:1 complex with lithium chloride (6))], it was possible that in the above competitive reactions lithium bromide might have formed a complex with the slightly more basic 3-picoline present in excess. To equalize the influence, if any, of the lithium bromide upon the reactivities of the pyridine nuclei, the above competitive reactions were repeated, this time adding the "ordinary" phenyllithium solutions to solutions of the pyridines containing an excess of anhydrous lithium bromide. The results of these experiments are collected in Table IV. There is a small but probably significant increase in $^{CH_3}F_2$ in all of these reactions, but the overall yields were low compared with those obtained in those reactions in which lithium bromide was not present in excess.

TABLE IV

Reaction of "ordinary" phenyllithium[a] with an excess of an equimolar mixture of pyridine and 3-picoline[b] containing an excess of lithium bromide[c]

Expt. No.	Method of work-up	Combined yields (%) of phenylated pyridines	Ratio of 2,3- to 2,5-phenylpicoline	Partial rate factors	
				$^{CH_3}F_2$	$^{CH_3}F_6$
9	A	42	96:4	3.7	0.16
10	C (30 min)	6.4	94:6	3.8	0.24
11	C (60 min)	13.3	94:6	3.8	0.24

[a][Phenyllithium] = 0.005 mole.
[b][Pyridine] = [3-picoline] = 0.015 mole.
[c][Lithium bromide] = 0.061 mole.

This increase in the selectivity of the phenylating agent might be due to complexing of lithium bromide etherate with phenyllithium (7):

$$C_6H_5Li.LiBr.2(C_2H_5)_2O \rightleftarrows C_6H_5Li + LiBr.2(C_2H_5)_2O.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The presence of an excess of lithium bromide would shift the equilibrium towards the complex which might be less reactive but more selective. It has already been reported (2) that less heat is evolved in the reactions of phenyllithium with pyridines in the presence of an excess of lithium bromide and this would tend to support the above suggestion. Since, however, little is known concerning the structure of phenyllithium (it has been reported to be dimeric in ether solution (8)—contrast with ethyllithium which may be tetrameric or hexameric (9)) further speculation about the reactivity of the complex would be fruitless.

To eliminate the possible influence of lithium bromide similar reactions were carried out using halide-free phenyllithium and the results of these experiments are given in Table V.

TABLE V

Reaction of halide-free phenyllithium[a] with an excess of an equimolar mixture of pyridine and 3-picoline[b]

Expt. No.	Method of work-up	Combined yields (%) of phenylated pyridines	Ratio of 2,3- to 2,5-phenylpicoline	Partial rate factors	
				CH_3F_2	CH_3F_6
12	A	22	96:4	2.6	0.11
13	B (1 min)	6	96:4	2.7	0.11
14	B (30 min)	10	95:5	2.4	0.12
15	B (60 min)	39	96:4	2.5	0.10
16	C (6 min)	33	96:4	2.9	0.09
17	C (60 min)	36	96:4	2.5	0.11

[a][Phenyllithium] = 0.003 mole.
[b][Pyridine] = [3-picoline] = 0.01 mole.

The results indicate once again that the 2-position in 3-picoline is activated relative to that in pyridine in these reactions and that the 6-position is deactivated by the 3-methyl group. It is interesting to note the relative constancies of the partial rate factors when the three different methods of work-up are used. Unfortunately, yields are not very reproducible in those reactions in which halide-free phenyllithium is used.

Similar competitive experiments were carried out using mixtures of pyridine and 3-ethylpyridine under the three sets of conditions and using "ordinary" phenyllithium (Table VI), phenyllithium in the presence of an excess of lithium bromide (Table VII), and halide-free phenyllithium (Table VIII).

TABLE VI

Reaction of "ordinary" phenyllithium[a] with an excess of an equimolar mixture of pyridine and 3-ethylpyridine[b]

Expt. No.	Method of work-up	Combined yields (%) of phenylated pyridines	Ratio of 2,3- to 2,5-phenyl-ethylpyridine	Partial rate factors	
				Et_2F_2	Et_2F_6
18	A	41	91:9	1.5	0.15
19	A	50	91:9	1.5	0.15
20	B (60 min)	37	91:9	1.5	0.15
21	C (60 min)	27	91:9	1.4	0.14

[a][Phenyllithium] = 0.0075 mole.
[b][Pyridine] = [3-ethylpyridine] = 0.01 mole.

The results summarized in Tables VI–VIII indicate again that the 3-ethyl-substituent activates C_2 towards attack by phenyllithium compared with C_2 in pyridine itself. The activation seems to be slightly less in this case than with a 3-methyl-substituent, particularly when halide-free phenyllithium is used. On the other hand, C_6 in 3-ethylpyridine

[a][Phenyllithium] = 0.005 mole.
[b][Pyridine] = [3-ethylpyridine] = 0.015 mole.
[c][Lithium bromide] = 0.061 mole.

TABLE VIII

Reaction of halide-free phenyllithium[a] with an excess of an equimolar mixture of pyridine and 3-ethylpyridine[b]

Expt. No.	Method of work-up	Combined yields (%) of phenylated pyridines	Ratio of 2,3- to 2,5-phenyl-ethylpyridine	Partial rate factors	
				$^{Et}F_2$	$^{Et}F_6$
24	A	19	90:10	1.6	0.18
25	B (30 min)	13	91:9	1.5	0.15
26	B (60 min)	32	89:11	1.2	0.15

[a][Phenyllithium] = 0.0033 mole.
[b][Pyridine] = [3-ethylpyridine] = 0.01 mole.

would appear to be very slightly less deactivated than in 3-picoline; the difference is so small, however, that it may well be insignificant. Again it should be emphasized that these values of the partial rate factors would, if anything, be on the low side due to the greater ease of polymerization of the 3-ethylphenyldihydropyridine salt compared with the 2-phenyl-1,2-dihydropyridine salt. That a 3-methyl-substituent activates C_2 more than does a 3-ethyl one was confirmed by adding phenyllithium to an excess of an equimolar mixture of 3-picoline and 3-ethylpyridine. The four alkylated phenylpyridines so formed could be resolved by gas chromatography and thus analyzed simultaneously. The results obtained in these experiments are collected in Table IX.

TABLE IX

Reaction of phenyllithium with an excess of an equimolar mixture of 3-picoline and 3-ethylpyridine

Expt. No.	Method of work-up	Ratio of phenylpicolines to ethylphenylpyridines[c]	Combined yield (%) of phenylated pyridines	$^{CH_3}_{Et}K$
27[a]	A	66:34	36.5	1.9
28[a]	B (30 min)	63:37	4.7	1.7
29[b]	C (60 min)	64:36	13.7	1.8

[a]Halide-free phenyllithium (0.005 mole) used. [3-Picoline] = [3-ethylpyridine] = 0.015 mole.
[b]"Ordinary" phenyllithium (0.0032 mole) used. [3-Picoline] = [3-ethylpyridine] = 0.03 mole.
[c]The 2,3-:2,5-ratios for both sets of isomers were the same as in the non-competitive experiments.

Though it is conceivable that these figures may incorporate a reflection of a slightly greater tendency for the intermediate from 3-ethylpyridine to undergo polymerization than that from 3-picoline, this should only be a small effect. The main conclusion drawn from the results is that 3-picoline is more reactive towards phenyllithium than is 3-ethylpyridine. If anything, 3-ethylpyridine should be slightly more basic than 3-picoline, so

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

that complexing of the organometallic compound at nitrogen cannot be the factor which determines the apparent relative reactivities.

The reproducibility of competitive results appeared to depend to a small extent on the batch of phenyllithium reagent used. To compare more accurately the reactivities of pyridine, 3-picoline, and 3-ethylpyridine competitive reactions were carried out on the pairs: pyridine/3-picoline, pyridine/3-ethylpyridine, 3-picoline/3-ethylpyridine, under identical conditions, using phenyllithium from the same batch of stock reagent. Table X contains a summary of the results obtained.

TABLE X

Relative reactivities of pyridine, 3-picoline, and 3-ethylpyridine towards phenyllithium[a]

	Pyridine and 3-picoline	Pyridine and 3-ethylpyridine	3-Picoline and 3-ethylpyridine
Combined yields (%) of phenylated derivatives	29	27	14
Total rate ratios	${}^{CH_3}_{H}K = 1.30$	${}^{Et}_{H}K = 0.79$	${}^{CH_3}_{Et}K = 1.80$
Partial rate factors	${}^{CH_3}F_2 = 2.4$	${}^{Et}F_2 = 1.4$	—
	${}^{CH_3}F_6 = 0.13$	${}^{Et}F_6 = 0.13$	—

[a]Phenyllithium (0.0032 mole) added to the pairs of pyridines (0.03 mole of each) at 24°. Oxygen was passed into the mixtures after they had been stirred at that temperature for 1 h.

In addition to the factors already discussed which may lead to an underestimation of the magnitude of K it should be pointed out that this value, which in all the above and previous examples listed was equated with the product ratio, differs slightly from the more accurate value calculated (10) using the equation

$$\frac{k_Y}{k_X} = \log\left(1 - \frac{Z_0}{Y_0}\cdot\frac{R}{1+R}\right) \Big/ \log\left(1 - \frac{Z_0}{X_0}\cdot\frac{1}{1+R}\right)$$

where X_0, Y_0, and Z_0 are the initial amounts of the two pyridines and phenyllithium, respectively, and R is the product ratio (assuming the reactions are bimolecular and irreversible). The difference, however, is very small, e.g., the value calculated using this equation from the data from expt. 27 (Table IX) is 2.05 compared with the product ratio of 1.91; ${}^{CH_3}_{H}K$ calculated from the data in Table X is 1.31, while the product ratio is 1.30. For this reason, the product ratios were taken as the values of K throughout this paper, the difference between these and the values calculated from the Ingold and Shaw equation probably being smaller than the experimental error.

The overall reactivities of the three pyridines studied here towards phenyllithium are in the order 3-picoline > pyridine > 3-ethylpyridine, but both in the case of 3-picoline and 3-ethylpyridine F_2 is greater than unity. The values of the total rate ratios are adequately self-consistent as is indicated by the fact that the value of ${}^{CH_3}_{H}K$, calculated from the relation ${}^{CH_3}_{H}K = {}^{CH_3}_{H}K \cdot {}^{Et}_{H}K$, and from the results in Table X is ${}^{CH_3}_{H}K$ (calc.) = 1.40, in reasonably good agreement with ${}^{CH_3}_{H}K$ (expt.) = 1.30.

Of the possible proposals put forward (1) to explain the preferential formation of the 2,3-isomer in these reactions, only those can be retained which would account for the specific *activation* of C_2 by the alkyl substituent, though it is conceivable and likely that a combination of factors are involved which favor the formation of more 2,3- than 2,5-isomer, but only one of which causes the observed activation. Steric acceleration, resulting from a relief of steric compression of the C_2 proton (by the 3-alkyl substituent and a group complexed at nitrogen) as the phenyl anion attacks almost perpendicularly to the plane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

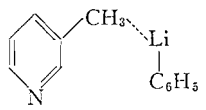
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of the ring, is ruled out by the fact that ${}^{CH_3}F_2 > {}^{Et}F_2$. The opposite would have resulted from steric acceleration. An attractive interaction, of the nature of London dispersion forces (3), was next considered. As an ethyl substituent is expected to be somewhat more polarizable than a methyl, it would have again been expected that activation by the former would have been the greater of the two, which was not the case. Steric hindrance might play a role here in decreasing the magnitude of ${}^{Et}F_2$. Preliminary studies on the relative reactivities of 2-bromopyridine, 2-bromo-3-methylpyridine, and 2-bromo-5-methylpyridine towards methoxide ion in methanol indicate that these are in the order 2-bromo- > 2-bromo-3-methyl- > 2-bromo-5-methyl- (11), and experiments are now under way using the more polarizable thiophenoxide ion. As has already been pointed out in previous parts of this series, coordination of the organolithium compound at the ring nitrogen is not necessary to explain the observed orientation in other similar cases, though it may be of importance here.

In the reaction of phenyllithium with 3-amino- and 3-methoxy-pyridine the exclusive formation of the 2-phenyl derivative was attributed to complexing between a lone-pair of electrons on the 3-substituent and the phenyllithium (12). It is suggested that a loose complex, e.g., V (in which a monomeric phenyllithium has been assumed for simplicity until further information is available concerning its structure), might be formed between the organolithium reagent and the methyl group of 3-picoline (the ring-nitrogen atom is probably also complexed with lithium bromide or with another molecule of phenyllithium). The attacking molecule would be favorably oriented for attack at C_2 and the energy of activation for the substitution would be sufficiently reduced to overcome the usual deactivation by the methyl group in nucleophilic aromatic substitutions, thus leading to



V

the observed activation. The lithium could be weakly bound to the methyl group by an electron-deficient-type bond. The presence of four-centered electron-deficient bonds have been postulated to explain the structures of tetrameric and hexameric ethyllithium both in solution and in the gas phase (9) and that of tetrameric *t*-butyllithium in solution (13). [See, however, 14 in which butyllithium in ether is believed to exist as a solvated dimer.] The existence of electron-deficient bonding is well established in polymeric alkyl beryllium (15) and dimeric aluminum trialkyls (16). The degree of polymerization in the last two systems is decreased by alkyl substitution at the alpha carbon atom and this has been discussed in terms of steric hindrance (17, 18) and of the decreased electronegative character of the branched alkyl groups (19). In either case, a slight decrease in the stability of the electron-deficient bond would be expected on going from 3-picoline to the more branched 3-ethylpyridine and would explain the observed reactivity sequence. It might then be predicted that a 3-isopropyl group would give rise to an even smaller value of F_2, probably less than unity, while with 3-*t*-butylpyridine, in which steric hindrance leads to attack mainly at C_6, ${}^{t\text{-Bu}}F_2$ should be appreciably smaller than ${}^{t\text{-Bu}}F_6$.

EXPERIMENTAL

Starting Pyridines

Commercial 2° pyridine (Reilly Tar and Chemical Co.) was dried (KOH) and fractionally distilled through a Podbielniak Mini-Cal Spinning Band Column, the fraction, b.p. 110–112° at 720 mm, being used. Commercial synthetic 3-picoline was similarly treated: the fraction, b.p. 138–140° at 720 mm, was used.

3-Ethylpyridine, b.p. 165–166° at 720 mm, was obtained in 80–87% yield by the reduction of 3-acetylpyridine with hydrazine hydrate and potassium hydroxide according to the procedure of Fand and Lutomski (20).

"Ordinary" Phenyllithium

This was prepared as usual and its concentration determined before every run by titration with 0.1 *N* hydrochloric acid using methyl orange as indicator.

Halide-free Phenyllithium

This was prepared as described in part V (2) and analyzed similarly.

The preparation of ethereal solutions of anhydrous lithium bromide has been described (2). The concentration of bromide was determined by Volhard titration.

Quantitative Analyses

The products formed in the phenylation reactions were resolved by gas chromatography and the compounds corresponding to the individual peaks identified (i) by comparing the retention times with those of authentic specimens, and (ii) by collecting each compound and comparing its infrared spectrum with that of an authentic phenylpyridine.

Calibration curves were then obtained by plotting areas under peaks vs. known concentration using standard solutions of the individual pyridines and under the conditions used in the quantitative analyses of the mixtures: linear plots were obtained in all cases. The accuracy of the method was checked by the analysis of a number of standard synthetic mixtures. The concentrations of the phenylated pyridines formed during the competitive runs could then be read directly from the calibration curves, provided the conditions established for the chromatographic analysis of each mixture of compounds were kept constant. These conditions are summarized below:

Mixtures of phenylpyridine and phenylpicolines.—A 20 ft × ¼ in. (i.d.) copper tube packed with silicone SE-30 (3%) on glass beads (60–80 mesh); column temperature 153°; injector temperature 230°; carrier gas (helium) inlet pressure 30 p.s.i. Under these conditions the retention times of 2-phenylpyridine, 2-phenyl-3-picoline and 2-phenyl-5-picoline were 13 min 36 s, 16 min 15 s, and 21 min 45 s, respectively.

Mixtures of phenylpyridine and phenylethylpyridines.—A 5 ft × ¼ in. (i.d.) copper tube packed with "Apiezon N" (25%) on Gaschrom P (60–80 mesh); column temperature 220°; injector temperature 245°; helium inlet pressure 30 p.s.i. The retention times of 2-phenylpyridine, 3-ethyl-2-phenylpyridine, and 5-ethyl-2-phenylpyridine were 10 min, 12 min 22 s, and 23 min, respectively.

Mixtures of phenylpicolines and phenylethylpyridines.—A 20 ft × ¼ in. (i.d.) copper tube packed with silicone SE-30 (3%) on glass beads (60–80 mesh); column temperature 170°; injector temperature 235°; helium inlet pressure 30 p.s.i. Under these conditions, the retention times of 2-phenyl-3-picoline, 2-phenyl-5-picoline, 3-ethyl-2-phenylpyridine, and 5-ethyl-2-phenylpyridine were 3 min 9 s, 4 min 9 s, 3 min 45 s, and 5 min 5 s, respectively.

Competitive Reactions

The procedure used will be illustrated by one example of each of methods A, B, and C.

Reaction of "Ordinary" Phenyllithium with an Excess of an Equimolar Mixture of Pyridine and 3-Picoline

Method A.—A solution of pyridine (2.37 g, 0.03 mole) and 3-picoline (2.79 g, 0.03 mole) in anhydrous ether (25 ml) was treated dropwise under a dry oxygen-free nitrogen atmosphere with an ethereal solution of phenyllithium (8.2 ml ≡ 0.01 mole, prepared from bromobenzene and lithium), vigorous stirring being maintained throughout the reaction. The rate of addition was such that the mixture boiled gently under reflux. At the end of the addition the ether was distilled off and simultaneously replaced with dry toluene. The toluene suspension was then boiled under reflux for 6.5 h, cooled, treated carefully with water, and made strongly alkaline with potassium hydroxide; the toluene layer separated and the aqueous layer was extracted with several portions of ether. The combined organic layers were extracted with concentrated hydrochloric acid, the acid extract was made strongly alkaline with potassium hydroxide, and extracted repeatedly with ether. The dried (KOH) ether-extracts were concentrated and analyzed by gas chromatography.

Method B.—The addition of a phenyllithium solution (8.2 ml ≡ 0.01 mole) to a mixture of pyridine (2.37 g, 0.03 mole) and 3-picoline (2.79 g, 0.03 mole) was carried out as in method A. At the end of the addition, the reaction mixture was boiled gently under reflux for a given time (see tables), cooled, and dry oxygen gas bubbled through the mixture until a white suspension had formed. Water was added and the mixture worked up as above.

Method C.—The procedure was essentially the same as that described under method B except that the temperature of the reaction mixture was never allowed to rise above 24° during the addition or after.

The same procedures were used in the runs in which halide-free phenyllithium was used. The concentrations of the phenyllithium solutions were determined by acid titration before every run and the required volume of the solution measured out with a burette, all the transfers being carried out under oxygen-free dry nitrogen.

When the reactions were carried out in the presence of an excess of anhydrous lithium bromide the procedures were identical with those described above, except that a solution of two molar equivalents of anhydrous lithium bromide in dry ether per mole of pyridine used was added to the solution of the pyridines before the phenyllithium solution was introduced. No appreciable evolution of heat was noted when the phenyllithium solution was added.

ACKNOWLEDGMENTS

This work was carried out during the tenure (by C.-S. G.) of a National Research Council Studentship, and was supported financially by a grant from the National Research Council. The authors thank Dr. K. J. McCallum for reading the manuscript and for helpful comments.

THE KINETICS OF THE REACTION OF ATOMIC HYDROGEN WITH METHANE

J. W. S. JAMIESON AND G. R. BROWN
Department of Chemistry, St. John's College, University of Manitoba, Winnipeg, Manitoba
Received July 29, 1963

ABSTRACT

Reinvestigation of the reaction of hydrogen atoms, produced by electric discharge, with methane in a fast flow system has given an activation energy of 7.4 ± 1.1 kcal/mole and a steric factor of about 10^{-3} for the primary reaction, $H + CH_4 \rightarrow H_2 + CH_3$.

INTRODUCTION

Earlier studies of the reaction of atomic hydrogen with methane were reviewed by Steacie (1), who concluded that the reliable early investigations led to a mean activation energy of about 12.5 kcal/mole, with the usual assumption of the time that the steric factor was about 0.1. More recently, however, Berlie and Le Roy (2, 3) published very much lower values of both P and E, obtained by production and measurement of the recombination of hydrogen atoms on filaments with and without methane. Steacie (1) also discussed the investigations of the reverse reaction, $CH_3 + H_2 \rightarrow CH_4 + H$, and concluded that the activation energy is 10.0 ± 0.5 kcal/mole. From the known dissociation energy of the H_3C—H bond in methane and from the heat of dissociation of hydrogen, the heat of reaction has been found to be 2.2 ± 1 kcal/mole.

Both the high and low values for the activation energy of the forward reaction are inconsistent with the apparently accurate activation energy of the reverse reaction and the heat of reaction. Thus further study seemed to be warranted and reinvestigation of the reaction of hydrogen atoms, produced by electric discharge, with methane in a fast-flow system became feasible recently as a result of a new method by Demchuk and Gesser (4) for quantitatively trapping methane in such a system.

EXPERIMENTAL

Materials

Reagents were obtained from the following sources:
hydrogen from the Linde Gases Division, Union Carbide Canada Limited,
methane (99% minimum purity) from Matheson Company Inc., East Rutherford, N.J., U.S.A.,
silica gel (28–200 mesh) from the Fisher Scientific Co. Ltd.

Apparatus and Methods

The apparatus was a fast-flow system of the conventional Wood–Bonhöffer type, containing two stopcocks of 15 mm bore and no tubing of smaller inside diameter than 16.6 mm between the reaction vessel and the Welch Duo-seal pump, 1402B, two-stage (vented exhaust), 0.1 micron, 140 liters/min. Hydrogen gas flowed into both ends of the discharge tube, across the aluminum electrodes of which was a potential drop of about 1100 V a-c. at 300 mA, provided by two Hammond 717 × 60 transformers with the primaries in parallel and the secondaries in series.

A mixture of atomic and molecular hydrogen flowed from the discharge tube down through a tube 12 cm long and 23 mm inside diameter to a 500-cc reaction vessel, into the center of which methane flowed. Products condensable at liquid nitrogen temperature were removed by a large trap immediately below the reaction vessel, while a second large trap surrounded by liquid nitrogen and having the inner wall of its outer tube coated with silicone grease and a layer of silica gel (previously degassed at 170 °C) adsorbed methane quantitatively from the gas stream. This gas was removed readily from the silica gel by reheating at 170 °C (4). It is, of course, possible that desorption of methane was complete at a much lower temperature. The flow of methane at room temperature was measured by the pressure drop in a manometer connected to a calibrated volume while the methane recovered from the second trap was allowed to expand into another

known volume of about the same size, where its pressure was measured in a manometer, again at ambient temperature. Products of the reaction were measured in a gas burette and analyzed by gas chromatography using helium as carrier gas, a Gow-Mac thermal conductivity cell Model 9193, TE-II, a Leeds and Northrup Speedomax Type G, Model "S", one second recorder, and a 4-ft molecular sieve 5A column or an 8-ft Beckman No. 17329 di-*n*-butyl maleate column.

RESULTS AND DISCUSSION

The methane used was analyzed by gas chromatography, using both the molecular sieve column and the di-*n*-butyl maleate column. No evidence of impurity was found. Under our fast-flow conditions no hydrogen was collected in either trap. In the high temperature experiments analysis by gas chromatography showed that ethane was the only product collected in the first trap, where it was trapped quantitatively. The quantity of ethane was measured in a gas burette. The methane collected in the second trap was shown by gas chromatography to be free of contamination by other gases. In several blank experiments with the hydrogen discharge off it was shown that the recovery of methane from the second trap was quantitative over the entire range of methane flow rates used in our experiments.

The results of experiments at various temperatures and methane flow rates are given in Table I. In Fig. 1 the amounts of methane reacted per second at various temperatures

TABLE I

Experimental data for the reaction of atomic hydrogen with methane

Expt. No.	T, °C	Atomic hydrogen	Methane flowed	Methane recovered	Methane reacted	Ethane produced
		All flow rates in μmoles/s				
1	227	5.2	5.23	4.67	0.56	
2	218	5.2	6.21	5.57	0.64	
3	212	5.2	12.45	11.56	0.89	
4	213	5.2	16.78	15.67	1.11	
5	317	5.0	3.56	2.92	0.64	
6	315	5.0	10.45	9.44	1.01

16	514	4.4	24.25	19.87	4.38	2.19

are plotted against the methane flow rate and the amounts of ethane produced per second at the high temperature are also shown. In all experiments the flow rate of molecular hydrogen was 88.2 micromoles/s, which gave a pressure in the reaction system of 1.10 mm.

The atomic hydrogen flow rate was estimated at several temperatures from the reaction of ethylenimine (5) and other cyclic imines (6) with atomic hydrogen in the same system. Thus it was found that the hydrogen atom flow rate decreased approximately linearly with increasing temperature, according to the expression:

$$\text{H-atom flow rate in micromoles/s} = 5.84 - 0.0028\ T\ ^\circ\text{C}.$$

With the use of this relation the applicable hydrogen atom flow rate has been calculated for the temperature of each experiment, as shown in Table I.

For the purpose of calculating specific reaction rates it is customary to make the assumption that the reaction is bimolecular and thus second order. Vance and Bauman (7) have derived theoretical equations from which specific reaction rates may be calculated for the case of a stationary state in a streaming, diffusing, and reacting gas mixture. Unfortunately their apparatus was substantially different from the usual Wood–Bonhöffer flow system, particularly since their hydrogen atoms were introduced into the center of the reaction vessel and were carried into the vessel by the other reacting gas, which was assumed to be in great excess so that its concentration could be taken as constant throughout the reaction zone. The treatment of Vance and Bauman does not appear to be applicable to the present experiments and thus the specific reaction rates have been calculated from the usual second-order rate expressions for conditions of both streamline and turbulent flow.

For streamline flow the integrated form of the rate expression is

$$k_s = V/[Nt^2(A - B)] \ln [B(A - X)/A(B - X)] \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

where k_s is the second-order rate constant for streamline flow,
V is the volume of the reaction vessel in cm^3,
N is Avogadro's number,
t is the reaction time,
A is the flow rate of atomic hydrogen in moles/s,
B is the flow rate of methane in moles/s, and
X is the number of moles of methane reacted/s.

The reaction time, assumed to be the time spent by the reactants in the reaction vessel, may be expressed as:

$$t = n/r$$

where n is the number of moles of gas in the reaction vessel, calculated from the ideal gas law, and r is the total flow rate in moles/s.

For experiments 1 and 9 in which the methane flow rates were virtually equal to the estimated flow rates of atomic hydrogen, the simpler rate expression

$$k_s = V/NAt^2[X/(A - X)] \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

was used.

Rate constants for conditions of turbulent flow have been calculated without integrating the rate equation by assuming that the reactant concentrations were uniform throughout the reaction zone, using the expression:

$$k_t = XV/[Nt^2(A - X)(B - X)] \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

where k_t is the second-order rate constant for turbulent flow.

The second-order rate constants and other data for the kinetic calculations are given in Table II. An Arrhenius plot of the data for streamline flow is shown in Fig. 2, for which the line of best fit, calculated by the method of least squares, and also plotted, is

$$-\log k_s = (1.4640 \times 10^3)/T + 12.39.$$

The standard deviations of the slope and intercept of the line may be calculated by statistical analysis (8) of the data. Thus the variance is

$$\sigma^2 = \sum d_i^2/n = 0.01291$$

TABLE II
Data for kinetic calculations

Expt. No.	$10^3/T$, °K	Second-order rate constants, cm^3 molecule^{-1} s^{-1}		$-\log k_s$	$-\log k_t$
		Streamline	Turbulent		
1	2.00	5.63×10^{-16}	6.33×10^{-16}	15.25	15.20
2	2.04	6.02×10^{-16}	6.05×10^{-16}	15.22	15.22
3	2.06	4.16×10^{-16}	4.80×10^{-16}	15.38	15.32
4	2.06	4.33×10^{-16}	5.04×10^{-16}	15.36	15.30
5	1.69	1.33×10^{-15}	1.65×10^{-15}	14.88	14.78
6	1.70	9.07×10^{-16}	1.06×10^{-15}	15.04	14.98
7	1.70	1.04×10^{-15}	1.31×10^{-15}	14.98	14.88
8	1.69	8.74×10^{-16}	1.07×10^{-15}	15.06	14.97
9	1.26	4.58×10^{-15}	6.15×10^{-15}	14.34	14.21
10	1.32	5.58×10^{-15}	9.43×10^{-15}	14.25	14.03
11	1.25	6.89×10^{-15}	1.30×10^{-14}	14.16	13.89
12	1.27	6.62×10^{-15}	1.26×10^{-14}	14.18	13.90
13	1.31	7.43×10^{-15}	1.68×10^{-14}	14.13	13.78

where the d_i are the deviations in Y (or $-\log k_s$) from the least squares line, and n is the number of experimental points.

The standard deviation, σ, then is 0.1136. For convenience a quantity Δ is defined as

$$\Delta = n\sum X_i^2 - (\sum X_i)^2$$

where the X_i are the values of $1000/T$. Therefore

$$\Delta = 16.89.$$

The variance of the slope may then be expressed as

$$\sigma_m^2 = n\sigma^2/\Delta = \sum d_i^2/\Delta = 0.009935$$

and the standard deviation of the slope, $\sigma_m = 0.09967$. The slope, then, may be reported as

$$m = 1.4640 \pm 0.1.$$

Similarly, the variance of the intercept is

$$\sigma_b^2 = (\sigma^2\sum X_i^2)/\Delta = 0.02779$$

and the standard deviation of the intercept, $\sigma_b = 0.1667$, so that the intercept may be written

$$b = 12.39 \pm 0.17.$$

Thus the data of the Arrhenius plot indicate that for streamline flow the activation energy is 6.7 ± 0.5 kcal/mole and the frequency factor is about 4×10^{-13} cm^3/molecule s. Similar calculations for turbulent flow give an activation energy of 8.0 ± 0.6 kcal/mole and a frequency factor of about 1.7×10^{-12} cm^3/molecule s. Since the flow pattern in a Wood–Bonhöffer system has not yet been established it seems desirable to use the mean values: 7.4 ± 1.1 kcal/mole for the activation energy and a frequency factor of about 1×10^{-12} cm^3/molecule s. These values would apply to the primary reaction

[1] $$H + CH_4 \rightarrow H_2 + CH_3$$

provided that the methyl radicals so produced did not regenerate methane either by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

combination with excess hydrogen atoms or by participation in the reverse reaction with molecular hydrogen.

If, however, either the reverse reaction or the $H + CH_3$ combination occurred to even a slight extent the measured rate of consumption of methane by atomic hydrogen would be less than the true value. Thus the measured rate of reaction [1] should tentatively be regarded as minimal and the calculated activation energy should be taken as the upper limit of the true value.

The amounts of methane reacted and ethane produced in experiments at temperatures near 500 °C do, however, provide further evidence that regeneration of methane by either of the two reactions mentioned is negligible. In such experiments, the ethane recovered was found to be one-half the methane reacted. This relation alone might only represent the attainment of a steady state involving several reactions, but at very high methane flow rates not only was the amount of methane reacted per second equal to the estimated hydrogen atom flow rate of 4.4 micromoles/s but the maximum amount of ethane produced was 2.2 micromoles/s, which could only have been formed by combination of 4.4 micromoles/s of methyl radicals, produced by reaction [1]. Thus it appears that, at least under these conditions, all the available hydrogen atoms are consumed by methane, so that none are left to combine with methyl radicals, and the only subsequent reaction is the combination of methyl radicals

$$[2] \qquad 2CH_3 \rightarrow C_2H_6$$

which probably occurs readily in the first cold trap.

In experiments at the high temperature there was no evidence that any of the ethane produced by reaction [2] reacted with hydrogen atoms, since at this temperature there was a material balance between hydrogen atoms and methane reacted, methyl radicals thus formed, and ethane produced by their combination. Furthermore, compounds such as propane, *n*-butane, and higher hydrocarbons, which might have been formed by reactions of ethyl radicals, were not found among the products.

Evidently the reaction

$$CH_3 + H_2 \rightarrow CH_4 + H$$

did not occur at the high temperature and since it has a positive temperature coefficient it would not be expected to occur at the lower temperatures. Therefore the calculated activation energy and frequency factor seem to be applicable to the primary abstraction reaction.

The frequency factor A can be expressed as

$$A = PZ/n_An_B = PZ'$$

where P is the steric or probability factor,

n_A and n_B are the concentrations of the reactants in molecules/cm^3,

Z is the number of molecules colliding/cm^3 s, and

Z' is Z/n_An_B in cm^3/molecule s.

Calculation of Z' at the mean temperature of 389 °C, using 2.1 Å as the collision diameter of the hydrogen atom (9) and 3.75 Å as the collision diameter of methane (10), gives the value 2.06×10^{-9} cm^3/molecule s. Division of the mean frequency factor, 1×10^{-12} cm^3/molecule s, by Z' gives a mean steric factor P of 4.86×10^{-4} for reaction [1].

The present activation energy and steric factor are in substantial agreement with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

preliminary results of Le Roy (2). The steric factor is within the range predicted by Eyring (11) and the activation energy agrees reasonably well with the activation energy of the reverse reaction and the heat of reaction.

It should, however, be noted that, in a sense, all the kinetic results cited for the reaction of atomic hydrogen with methane are consistent since errors in P and E compensate one another. Thus a plot of the logarithm of the steric factor against the activation energy should be linear. As shown in Fig. 3, this is the case when the present results are plotted

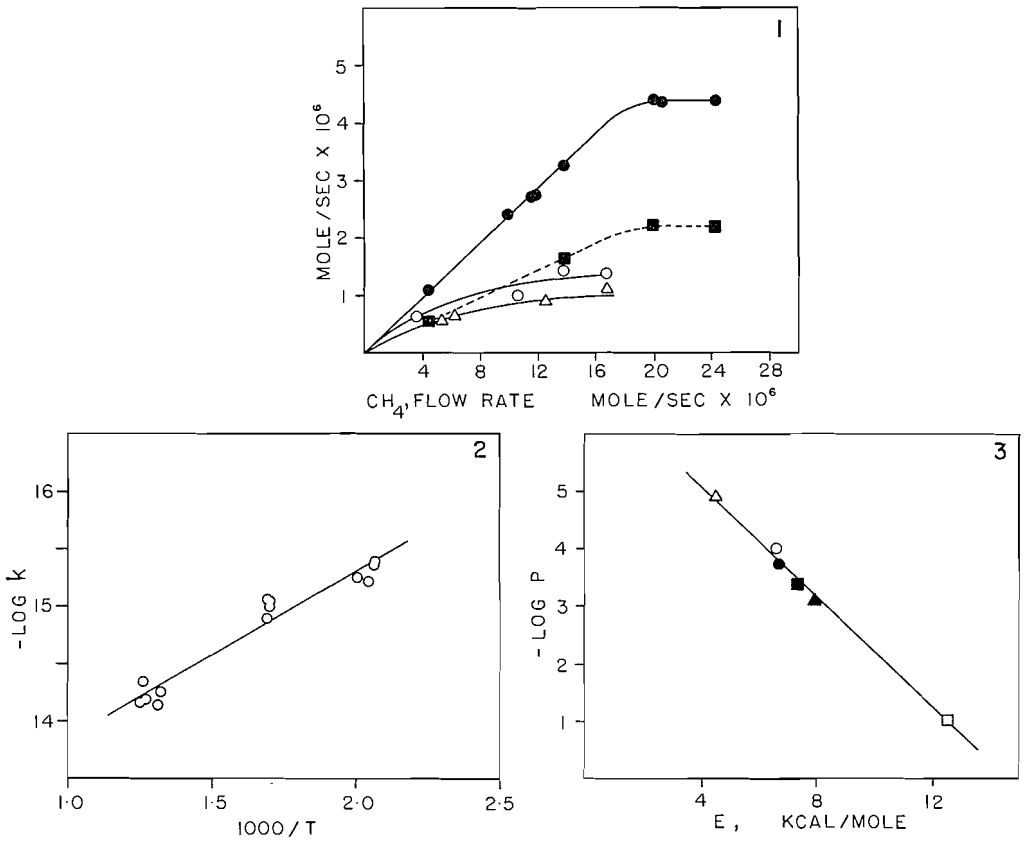

FIG. 1. Methane reacted at 218 °C (△), 316 °C (○), and 512 °C (●); ethane produced at 512 °C. (■).
FIG. 2. Arrhenius plot (streamline flow assumed) for the reaction of atomic hydrogen with methane.
FIG. 3. Logarithm of steric factor vs. activation energy for various studies of the reaction of atomic hydrogen with methane. Early investigations (□), preliminary results of Le Roy (○), Berlie and Le Roy (△), present results, streamline flow (●), present results, turbulent flow (▲), average present results (■).

together with the mean values for the early investigations (1), the preliminary results of Le Roy (2), and the more recent results of Berlie and Le Roy (3).

The results of a recent study (12) of the reaction

$$D + CH_4 \rightarrow HD + CH_3$$

appear to be inconsistent with the various results for reaction [1]. While the activation energy of 7.8 ± 0.6 kcal/mole seems to have the right magnitude, the steric factor, $P = 0.025$ ($-\log P = 1.60$) is too high to fit the line of Fig. 3. These values, however, were

obtained by the method of competing reactions and thus depend not only on correct values of P and E for the reaction

$$D + D_2CO \rightarrow D_2 + DCO$$

but also on the absence of other reactions which form either D_2 or HD.

A GROUP ORBITAL STUDY OF LITHIUM HYDRIDE[1]

I. G. CSIZMADIA,[2] B. T. SUTCLIFFE,[3] AND M. P. BARNETT[2]

Cooperative Computing Laboratory and Solid State and Molecular Theory Group, Department of Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts

Received November 14, 1963

ABSTRACT

A quantum mechanical treatment of lithium hydride in the group orbital approximation is presented. Some excited states and an improved ground state are obtained by means of configuration interaction within a single group.

The total energy obtained for the ground state at several interatomic distances (R = 2.0–8.0 a.u.) omitting and including configuration interaction and for the first excited singlet state compare very well with the values reported by Karo in a comparable simple molecular orbital calculation.

The chemical significance of the group orbital method is discussed. The results of the present calculations are related to some chemical reaction mechanisms and to some spectroscopic phenomena.

1. INTRODUCTION

The molecular orbital treatment of molecular systems allows chemical insight to be used in the choice of the analytical forms for the one-electron wave functions. The most accurate calculations that can be performed with a given set of basis functions in the molecular orbital approximation entails a complete configuration interaction treatment that includes all the electronic states which can be formed from those functions and which satisfy the space and spin symmetry requirements. This can lead to vast computations for relatively small numbers of one-electron basis functions. The "chemical integrity" of the "chemically recognizable" parts of the molecule becomes blurred in this full configuration interaction treatment. McWeeny (1) recently described an approximation that can be used, within the molecular orbital approach, to preserve the conceptual integrity of chemically recognizable molecular fragments such as a π electron cloud, a σ bond, or an atomic core. He calls these fragments "groups", and the approximation, which is defined formally in Section 2, is called the group function approximation. It extends some earlier work of Parr *et al.* (2–4). It allows a "mixing of states" within the individual groups, but requires less computation than the most general molecular orbital configuration interaction calculation which uses the same set of basis functions.

In the treatment of lithium hydride that is reported here, the core electrons on the lithium atom are treated as one group, and the electrons of the lithium hydrogen bond are treated as another group. Variational parameters are included in only the latter group, so that the calculation can be considered as just a conventional molecular orbital treatment in which the lithium 1s orbitals are not varied. A one-determinant, and a multi-determinant calculation have been performed, in a way that allows the results to be compared with those of Karo and Olson (5, 6), who varied all the parameters including those of the lithium core. The agreement is very good. The group function formalism of (1) is followed for convenience, and as an example on which corresponding treatments of larger systems can be modelled.

The group function approach has been applied to the ground states of some small molecules, which include H_2O (7), NH_3 (8), and NH_2 (9). The present paper applies the group function approach to the ground and excited states of the LiH molecule for a range of internuclear distances. The study was undertaken for several reasons. Lithium hydride is of inherent interest as the smallest neutral heteronuclear molecule. As such it will continue to provide the object of study by theoretical and experimental techniques that are developed to probe molecular structure and behavior with greater detail and precision. Past spectroscopic studies of LiH provide experimental material for several states (10–13). The present calculations have yielded results that may be compared with this material and also some results for states that have not yet been studied experimentally. Experimental corroboration of these latter results would be interesting. Lithium hydride has been studied extensively in different theoretical approximations, so that reference material exists for comparison with the results of a group function treatment, that can give insight into the relative merits of the group function and the other theoretical approaches (14–24). Lithium hydride forms crystals that may provide an interesting subject for subsequent theoretical study. The electronic structure of lithium hydride may also provide a model for the qualitative discussion of certain reactions of organo lithium compounds.

The one electron wave functions that we use are linear combinations of numerical Hartree–Fock functions that were used previously by Karo and Olson in a molecular orbital treatment of the ground state of lithium hydride (5). This has made it possible to use the integrals over basis functions that were computed by Karo and Olson, and hence to obtain a clear comparison of the group function and direct molecular orbital approaches in this instance.

The calculations were performed on an IBM 709 computer, and the programs were coded in FORTRAN. The cathode ray attachment to the computer was used to plot the charge distributions.

The mathematical formulation of our studies is summarized in Section 2. The results are discussed in quantum chemical terms in Section 3. The reaction mechanistic and spectroscopic implications are discussed in Sections 4 and 5. Further details of the mathematical formulation and the computational procedures are provided in a laboratory report that is organized as a set of Appendices to the present paper (25).

2. MATHEMATICAL FORMULATION

In the group function approximation, the electronic wave function for a molecule, molecular fragment or assembly of molecules, and (or) molecular fragments, is approximated by a function Ψ_K that is of the form [1].

$$[1] \qquad \Psi_K(1,2,\ldots,N_t) = \mathscr{A}[\Phi_{R_1,r_1}(1,\ldots,N_1)\Phi_{R_2,r_2}(N_1+1,\ldots,N_2)\ldots \ldots\Phi_{R_t,r_t}(N_{t-1}+1,\ldots,N_t)].$$

Here $\mathscr{A}$ is the normalizing antisymmetry operator (26), and the Φ's are the "group wave functions," which describe the "chemically recognizable" portions of the molecule. Each group function is labelled by two subscripts. The first subscript specifies the group, and conventionally is a capital letter. The second subscript specifies the electronic state of the group, and conventionally is a lower case letter. Equation [1] refers to a system in which there are N_t electrons and t groups. The integers 1 to N_t refer to the space and spin coordinates of the individual electrons. N_t denotes the number of electrons in the groups R_1 to R_t inclusive.

The group wave functions satisfy the orthonormality condition

$$[2] \qquad \int \ldots \ldots \int \Phi^*_{R,r'}(1, \ldots, N)\Phi_{R,r}(1, \ldots, N)d\tau_1 \ldots d\tau_N = \delta_{rr'}.$$

Equation [2] refers to a group R, in states r and r', which contains N electrons. Integration over the space and spin coordinates of the ith electron is denoted by $\int \ldots dv_i$ and $\int \ldots d\omega_i$ respectively and $d\tau_i = dv_i d\omega_i$.

The group wave functions are orthogonalized in the "strong" sense discussed in reference (1). This orthogonality condition refers to the integral [3].

$$[3] \qquad \int\int \Phi^*_{R,r}(i_1, i_2, \ldots, i_N)\Phi_{R',r'}(i'_1, i'_2, \ldots i'_{N'})d\tau_i = 0.$$

In this integral R and R' label two groups that contain N and N' electrons respectively. The groups may or may not be the same. The integrand contains the wave functions for these groups in states r and r' respectively. In the arguments of the wave functions, i_1 to i_N stand for the labels of some N electrons of the molecule, and i'_1 to $i'_{N'}$ stand for the labels of some N' electrons of the molecule. One or more of these labels may be common to the two sets of argument. The integration is over the space and spin of an electron with such a common label, which we denote by i:

$$[4] \qquad i = i_p = i'_{p'} \text{ for some } p, p', 1 \leqslant p \leqslant N, 1 \leqslant p' \leqslant N'.$$

Then the integral [3] is zero, for strong orthogonality, if

$$[5] \qquad R \neq R'.$$

The meaning and effects of this condition have been discussed by Löwdin (27).

As mentioned in the Introduction, we have studied the lithium hydride molecule theoretically, in the group function approximation [1], by considering the electrons of the lithium core as one group, and the electrons of the lithium–hydrogen bond as a second group. We call these groups A and B respectively. We use the letters a and b to designate their states in the early stages of the treatment, extending this notation when necessary. The symbols Φ_{Aa} and Φ_{Bb} are used for the group wave functions of the two groups, with an elaboration of the latter symbol when necessary.

The total wave function Ψ_K thus can be written as

$$[6] \qquad \Psi_K(1, 2, 3, 4) = \mathscr{A}[\Phi_{Aa}(1, 2)\Phi_{Bb}(3, 4)].$$

The integers 1, 2, 3, 4 are used as electron labels.

It is reasonable to assume that the lithium core electrons are affected to only a small extent by the bonding. A wave function that provides an adequate description of the core electrons in the isolated lithium atom therefore is used for Φ_{Aa}. Formally,

$$[7] \qquad \Phi_{Aa}(1, 2) = \phi_A(1)\phi_A(2)\theta_{0,0}(1, 2).$$

The function ϕ_A is the $1s$ one-electron orbital of the lithium atom. It is called a group orbital as it is a one-electron orbital that forms part of a group wave function. $\theta_{0,0}$ is the spin function

$$[8] \qquad \theta_{0,0}(1, 2) = \frac{1}{\sqrt{2}}[\alpha(1)\beta(2) - \beta(1)\alpha(2)].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The lithium–hydrogen bond is described by a group wave function that has the same general structure as the core function

$$\Phi_{Bb}(3, 4) = \phi_B(3)\phi_B(4)\theta_{0,0}(3, 4). \quad [9]$$

The function ϕ_B is also called a group orbital. It is a linear combination of $2s$ and $2p_z$ orbitals on the lithium atom and a $1s$ orbital on the hydrogen atom. These are denoted by χ_{2s}, χ_{2p_z}, and χ_h, respectively, to indicate their chemical nature. They are orthogonal to the lithium $1s$ orbital χ_{1s} and to each other. The z axis on the lithium atom points towards the hydrogen atom.

$$\phi_B = c_1\chi_{2s} + c_2\chi_{2p_z} + c_3\chi_h. \quad [10]$$

The $c_\nu(\nu = 1 \text{ to } 3)$ are variational parameters that are chosen to minimize the total energy of the molecule.

The orbitals χ_{2s}, χ_{2p_z}, and χ_h are linear combinations of the orbitals η_{1s}, η_{2s}, η_{2p_z}, and η_h, which are defined by equations [11*a–c*]. In these equations, the P's are the numerical Hartree–Fock functions obtained by Fock and Petrashen for the lithium atom (28). The letter i is used here as an electron label. The distances of the electron from the lithium and hydrogen atoms are denoted by r_i and r'_i respectively. The polar angle of the electron, measured from the lithium atom as origin and the lithium hydrogen bond as polar axis is denoted by θ_i.

$$\eta_{1s}(i) = (1/4\pi)^{1/2}P_{1s}(r_i) \quad [11a]$$

$$\eta_{2s}(i) = (1/4\pi)^{1/2}P_{2s}(r_i) \quad [11b]$$

$$\eta_{2p_z}(i) = (1/4\pi)^{1/2}P_{2p_z}(r_i)\cos\theta_i \quad [11c]$$

$$\eta_h(i) = (1/\pi)^{1/2}e^{-r'_i} \quad [11d]$$

The relationship between the χ's and the η's can be summarized in matrix form as follows. Replace the chemical subscripts $1s$, $2s$, $2p_z$, and h by the integer labels 1, 2, 3, and 4 respectively. Let $\boldsymbol{\chi}$ be the column vector whose successive components are χ_1, χ_2, χ_3, χ_4. Let $\boldsymbol{\eta}$ be the column vector whose successive components are η_1, η_2, η_3, η_4. Then

$$\boldsymbol{\chi} = \mathbf{Z}\boldsymbol{\eta} \quad [12]$$

$$\mathbf{Z} = \mathbf{V}\mathbf{S}_\zeta^{-1/2} \quad [13]$$

where

$$\mathbf{S}_\zeta = \mathbf{V}'\mathbf{S}\mathbf{V} \quad [14]$$

and

$$\mathbf{V} = \begin{Vmatrix} 1 & 0 & 0 & S_{14}/[1-(S_{14})^2]^{1/2} \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & S_{14}/[1-(S_{14})^2]^{1/2} \end{Vmatrix} \quad [15]$$

and $\mathbf{S}$ is the overlap matrix for the η's, that is

$$S_{ij} = \int \eta_i(1)\ \eta_j(1)\ d\nu_1. \quad [16]$$

The subscripts i and j here refer to orbitals, and the integer 1 is used as the electron label. The matrix $\mathbf{S}_\zeta$ is just the overlap matrix for the orbitals formed from the η's by Schmidt

For personal use only.

orthogonalization. The orbitals χ_2, χ_3, χ_4 must be orthogonal to χ_1 to satisfy the strong orthogonality condition that is discussed in Section 2 by reference to the integral [3]. The orbitals χ_2, χ_3, χ_4 are made orthogonal to each other for computational convenience. This orthogonalization procedure leaves the lithium $1s$ orbital unchanged. It is consistent with the assumption that the core electrons are affected very little by binding. Moreover, a recent calculation of a similar nature to this (7) suggests that, unless such an orthogonalization procedure is adopted, negative binding energies may result.

Karo and Olson (5, 6) used linear combinations of the orbitals η_1 to η_4 in a molecular orbital treatment that varied the coefficients of all four orbitals. Our calculations required less effort, as the form of wave function that we used allowed the variation of just two of the coefficients in the orbital ϕ_B, the third coefficient depending on the other two as a consequence of the normalization condition [2]. In our calculation, the orbitals of the lithium core electrons were not varied. Our results agree closely with those of Karo and Olson, where a comparison can be made. This encourages further use of the group function method.

We determined the coefficients c_1, c_2, c_3 in the orbital ϕ_B in two ways. The first involved a direct variation of parameters. The c_ν were varied until a set of values was found which minimized the energy. This method made it possible to plot contours of the energy surface as a function of the coefficients c_ν. The second method involved a modified self-consistent field (SCF) procedure. The solution of the SCF problem consists of three eigenvectors that are denoted by $\{c_{\nu 1}\}$, $\{c_{\nu 2}\}$, and $\{c_{\nu 3}\}$, and that correspond respectively to the eigenvalues ϵ_1, ϵ_2, ϵ_3, which are labelled so that $\epsilon_1 < \epsilon_2 < \epsilon_3$. These three eigenvectors define three group orbitals, when they are substituted in equation [10]. If the notation

$$\phi_{Bi} = c_{1i}\chi_{2s} + c_{2i}\chi_{2p_z} + c_{3i}\chi_h \qquad [17]$$

is used, then ϕ_{B1} should be identical with the ϕ_B orbital that is obtained by the direct variation of parameters. This is found to be the case.

The three orbitals ϕ_{B1}, ϕ_{B2}, ϕ_{B3} were used in a configuration interaction calculation to construct an improved ground state and a number of excited singlet and triplet states.

The detailed formulation of the computing procedure made extensive use of the concepts and notation of density matrices. The relevant formulae and some related technical matters are reviewed in Appendix 1. Further details of the direct variation of parameters, self-consistent field, and configuration interaction procedures are given in Appendices 2 to 4. The computations are described briefly in Appendix 5. As mentioned in the Introduction these appendices are available as a laboratory report (25). The results and their chemical implications are discussed in the Sections 3 to 5 that follow.

3. COMPUTATIONAL RESULTS

Figures 1A, 1B, and 1C illustrate the relationship between the individual atomic orbitals (η_i), the orthogonalized orbitals (χ_i), and the group orbitals (ϕ_i) respectively. The inflections that are due to the orthogonalization, and which can be seen in Fig. 1B, resemble those which were observed by McWeeny and Ohno, in their study of the water molecule (7). The elements of the orthogonalization matrix $\mathbf{Z}$, which is defined in equation [13], are given for a range of internuclear distances in Table AV of the appendices (25). Figure 1C shows the ϕ_A group orbital, which represents the lithium $1s$ core, and the ϕ_B group orbital, which represents the lithium–hydrogen bond.

The results of the variation of parameters calculation are shown in Table I. This

compares the coefficients (c_1, c_2, c_3) defined in equation [10], with the elements (c_{11}, c_{21}, c_{31}) of the lowest eigenvector found in the self-consistent field calculation (see equation [17]). Results are given for a few internuclear distances in Table I. The corresponding results for a greater range of internuclear distances are given in Table AI of the appendices (25). The agreement between the variation of parameter and the self-consistent field calculations is very good. Table AV of the appendices lists the elements of all three eigenvectors that are computed by the self-consistent field procedure, for a range of internuclear distances.

The coefficients of the χ's that we find in the group orbitals cannot be compared directly with the coefficients that were found by Karo in his molecular orbital calculation (6), as he varied linear combinations of all four basis orbitals, whereas we kept two electrons in the unchanged lithium 1*s* orbitals throughout, in accordance with the group function approximation. The energy that is computed by the two methods may be compared, however, and this comparison shows that the group orbital approach gives results that are very close to those obtained by the comparable molecular calculations of Karo.

The accuracy with which the results can be made self-consistent is shown by the entries in the rows of Tables I and AI that are marked "Reproducibility of iteration". The difference between the energies computed in the last two iterations of the matrix diagonalization is given in this row for each of the internuclear distances at which the calculation was performed. The diagonalization subroutine automatically ended its computation when the results began to oscillate. It can be seen that the accuracy which could be obtained deteriorated with increasing internuclear distance. The dependence of the energy function on the variational parameters is shown graphically in Fig. 2. The energy value becomes extremely shallow at large internuclear distances so that locating the minimum becomes difficult.

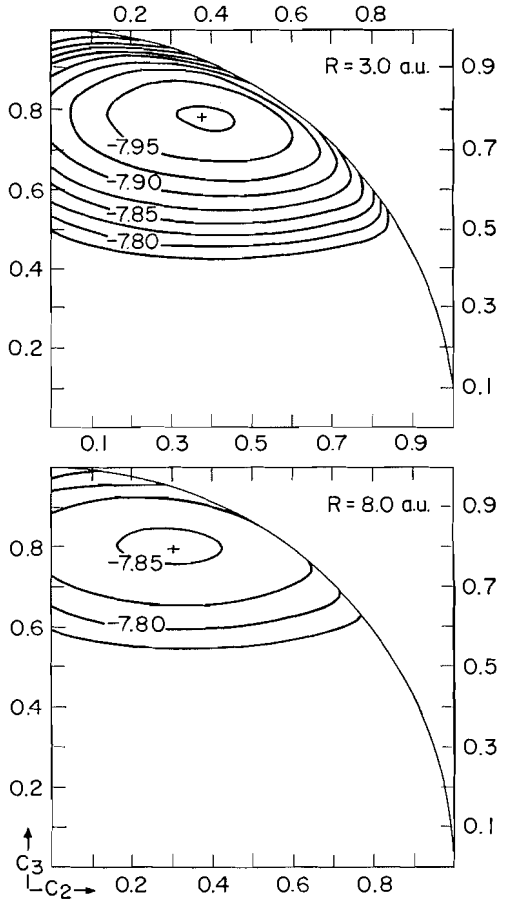

FIG. 2. Contour map of total energy of LiH vs. coefficients c_2 and c_3, for fixed R.

Figure 3 shows that the generalized product wave function [6] tends to the representation of separated Li^+ and H^- ions at infinite internuclear distance, as does the single determinant wave function of Karo and Olson. To construct a wave function that represents interacting neutral Li and H atoms at large separations, it is necessary to mix the solutions of the self-consistent field calculation (or, equivalently, products of the original χ's) in a configuration interaction treatment. This can still be considered to fall within the group function approximation, in that the orbitals of the bond electrons are mixed independently of the orbitals of the core electrons. In fact, the orbitals of the bond electrons only were mixed, as it seemed that this was most necessary on physical grounds. The configuration interaction treatment seems necessary for reasonable agreement with spectroscopic data.

Table II lists the energy values and Table AIII lists the coefficients that are found in this configuration interaction calculation. The results are given in these tables for a few internuclear distances, for the ground state and for the first and second excited singlet and triplet states. The last two rows of Table II contain the results obtained by Karo for the ground state and for the first excited singlet state. These are taken from Tables VI and VI*a* of reference (6). Tables AI and AII of the appendices (25) have the same format as Tables I and II, and contain the results for a larger set of internuclear distances. These results are plotted in Figs. 3 and 4, as graphs of energy versus internuclear distance.

The results of our configuration interaction calculation for the first excited singlet and triplet states suggest that energy minima occur at about 4.6 and 4.2 atomic units respectively. An experimental value of 4.906 atomic units (2.596 A) has been reported for the first excited singlet.

The second excited singlet and triplet states show no minima within the range of internuclear distances which we considered, which is 2 to 8 atomic units. The curves do show definite inflexions, however, which may be attributed to rather weak binding in these dissociating states.

The energy versus internuclear distance curves that we obtain resemble those which were found by Fraga and Ransil (20). The hump that we found in the lowest triplet state, at about 7 atomic units, was unexpected. It was thought at first that it was a numerical artefact due to the difficulty of making the results self-consistent at large internuclear distances. The height of the maximum above the asymptotic value of the energy curve in its neighborhood is about 0.02 atomic units. This is substantially greater than the

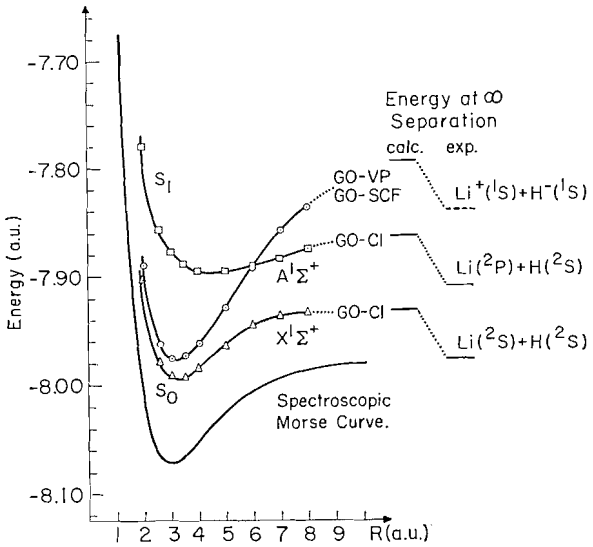

FIG. 3. Total energy vs. internuclear distance for LiH from GO-VP, GO-SCF, and the two lowest singlet GO-CI calculations. (The experimental Morse curve is also shown.)

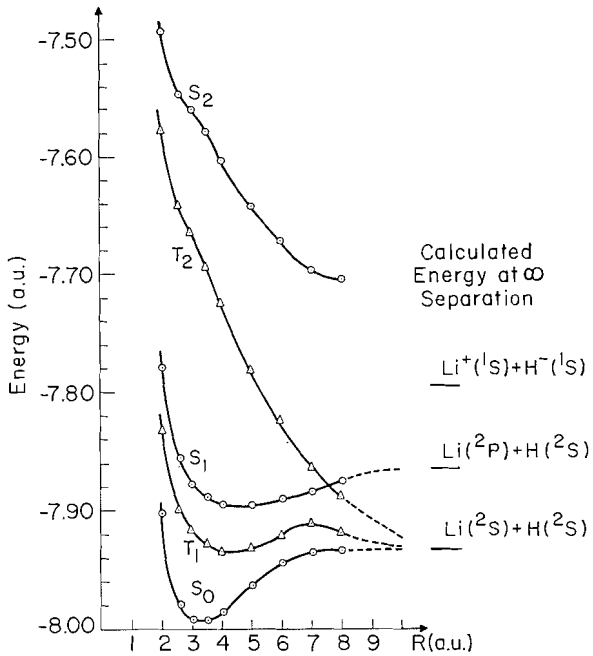

FIG. 4. Total energy vs. internuclear distance for LiH from the singlet and triplet GO-CI calculations.

"reproducibility of iteration", which is less than 0.00004 atomic units at the relevant internuclear distance. We conclude therefore that the hump is significant. Similar humps have been found by other workers in theoretical studies of homonuclear diatomic molecules (29, 30). Examples include H_2 in the $^1\Pi$ state (31), He_2 in the $^3\Sigma$ state (32), and O_2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

in the $^3\Pi$ state (33). Spectroscopic observations of predissociation of the BH species provide experimental evidence for such a hump in the energy curve of this molecule in the $^1\Pi$ state (34). The phenomenon has not yet been explained, however, in terms of any simple physical model.

Figure 4 shows that according to our calculations, the lowest singlet excited state dissociates to an unexcited hydrogen atom and an excited lithium atom in the ^2P state. The lowest excited triplet state of the molecule, however, dissociates, like the ground state, to the unexcited atoms. The energies of the ground state and of the first excited triplet state thus approach asymptotically.

The group orbital approach allows the one-electron densities for the individual groups to be calculated separately. The total electron density of the molecule is the sum of the group densities [28]. Figure 5 is a plot of the electron density distribution along the lithium–

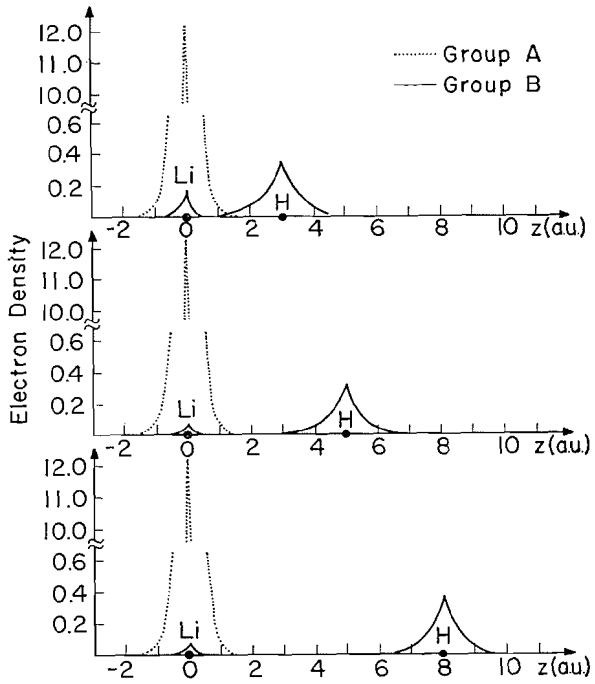

FIG. 5. Group orbital electron densities along the molecular axis (z) of LiH at R = 3.0, 5.0, and 8.0 a.u.

hydrogen bond, as calculated in the self-consistent field group function approximation. Figure 6 contains contour plots of the electron density, in a plane containing the bond, at two internuclear distances. These plots emphasize the group function approximation that we have used, in that the group of core electrons is not changed between the two figures. The density contours of the group of bond electrons in Fig. 6 correspond to the orbital ϕ_{B1}, which is assumed to be doubly filled. Figure 7 shows contour plots of electron density for hypothetical states of the molecule in which the orbitals ϕ_{B2} and ϕ_{B3} are doubly occupied. These states correspond to the states which Karo and Olson label 3σ and 4σ. The geometry of the ϕ_{B2} and ϕ_{B3} antibonding orbitals may have a stereochemical significance, which is discussed in the section that follows.

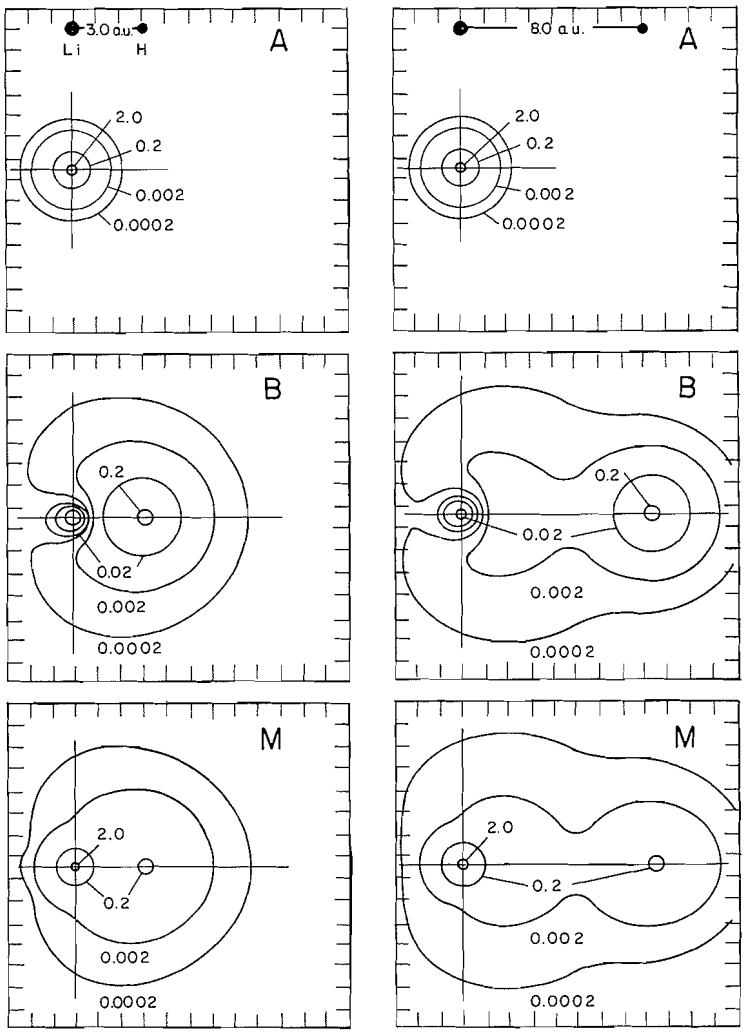

FIG. 6. Group orbital density contours of LiH at $R = 3.0$ and 8.0 a.u. (A) Group A, (B) group B, (M) total electron density.

Electron densities of the group B electrons in the various excited states in the configuration interaction were also found from equations [67] and [68] of Appendix 4 (25). Figure 8 contains plots of density along the Li–H axis for the three lowest singlet states at an internuclear distance of 3 atomic units. Figures 9 and 10 contain contour plots of electron density at several interatomic distances for the ground and several excited states.

These contour plots show that in the first excited states (S_1 and T_1) charge is decreased on both centers and built up in the region behind the lithium atom. In the second excited states (S_2 and T_2) charge is transferred from the lithium to the hydrogen atom. The arrangement of the valence electrons in the excited states may be summarized by simple formulae that depict electrons by arrows whose directions distinguish spin.

[18]

Li↓↑H	↓Li↑H	↑Li↑H	Li↑H↓	Li↑H↑
S_0	S_1	T_1	S_2	T_2

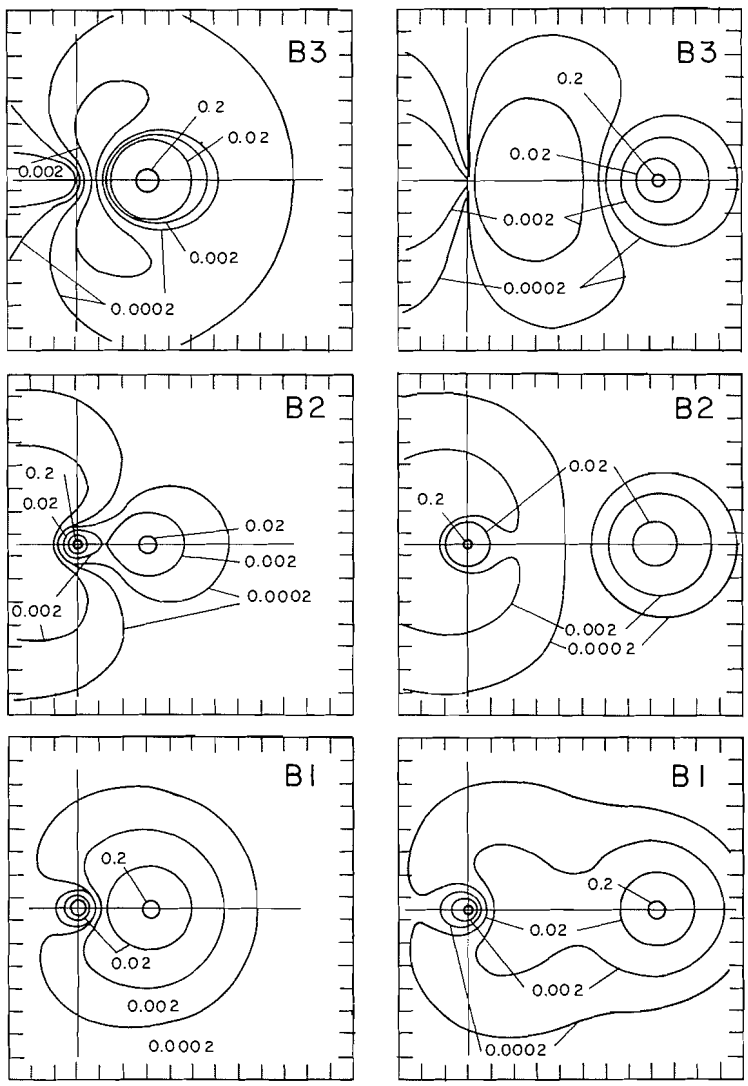

FIG. 7. Group B electron density contours for $B1$, $B2$, and $B3$ of LiH assuming each orbital doubly occupied, at $R = 3.0$ and 8.0 a.u.

Figure 10 contrasts the asymptotic behavior that is predicted by the self-consistent field and configuration interaction calculations. The former leads to ionic dissociation (as does the single determinant molecular orbital wave function) while the latter leads to neutral atom (free radical) dissociation. The fact that self-consistent field wave function goes over into the separated ion wave function at infinite internuclear distance is in a sense accidental. A generalized product function [6] of this form need not represent any particular state of the separated fragments at infinite separation. Nevertheless, advantage may be taken of this accident and the contours ($B1$) shown in Fig. 10 may be taken as representing the behavior of the molecule dissociating into Li^+ and H^- ions.

Contour plots of electron density for several further internuclear distances are given in the Appendix (Figs. A1 to A8). These illustrate the above discussion in greater detail.

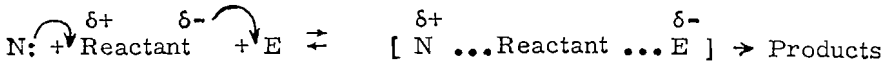
4. A MODEL FOR SOME CHEMICAL REACTIONS

The results that were described in the preceding section may be used to provide a tentative explanation of certain aspects of the chemical behavior of lithium hydride. This explanation is developed, within the framework of the transition state concept, that in every chemical reaction there exists at least one transition state (activated complex) whose electronic structure determines the nature of the reaction products, and the rate with which these products are formed. It is generally assumed that one reactant donates an electron pair to the other reactant to form the transition state in a reaction which proceeds by an ionic mechanism. This is often expressed by the statement that a nucleophilic reagent (Lewis base) attacks the more positive site of a substrate, and an electrophilic reagent (Lewis acid) attacks the more negative site.

[19]



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

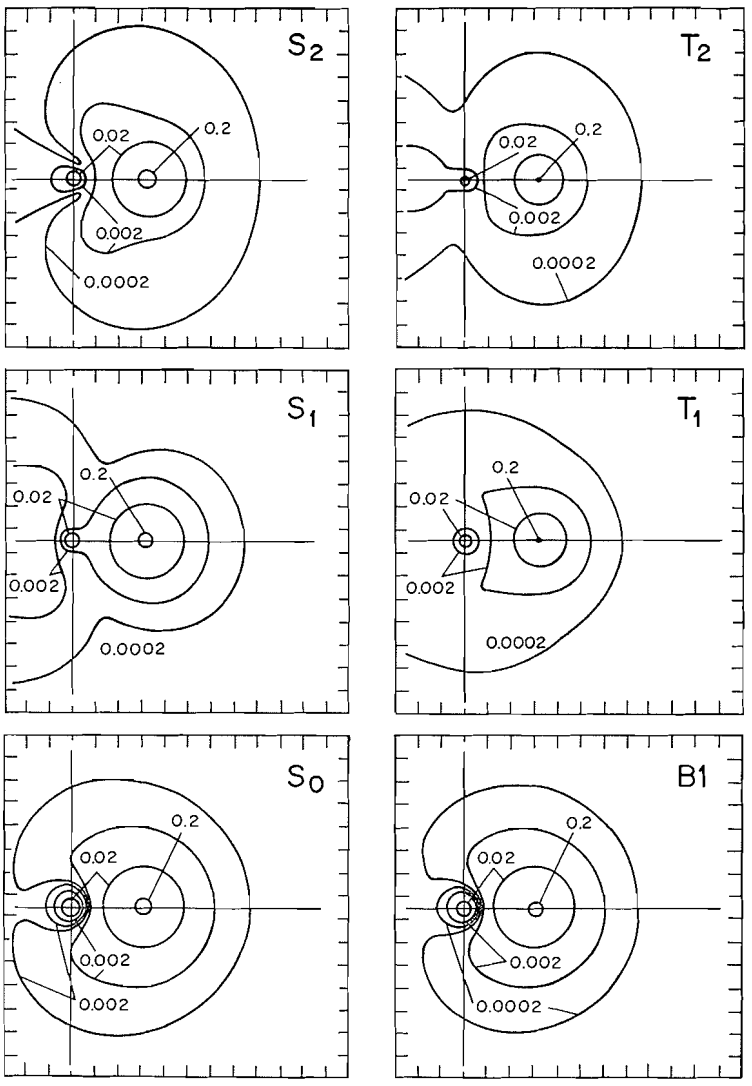

FIG. 9. Group B electron density contours for singlet (S_0, S_1, S_2) and triplet (T_1, T_2) states of LiH, at R = 3.0 a.u. The contour map of $B1$ is shown for comparison.

It is reasonable to assume further that the formation of a transition state in an ionic reaction resembles the formation of a coordination complex with the nucleophilic reagent playing the part of a ligand (35).

We now assume that the center with a net positive charge which is attacked by a nucleophilic agent must also have an unfilled orbital that is energetically accessible to the electron pair of the attacking agent. It would follow that the stereochemical arrangement of such unfilled orbitals affects the structure of the transition state and hence the course of the reaction. When several unfilled orbitals are available at the site of the attack, the orbital of lower energy presumably is occupied in the transition state. The assumptions of this paragraph have meaning within the simple orbital model of chemical structure, and the idea that a pair of electrons forms a chemical bond is implicit. These assumptions now are applied to the reactions of lithium hydride.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

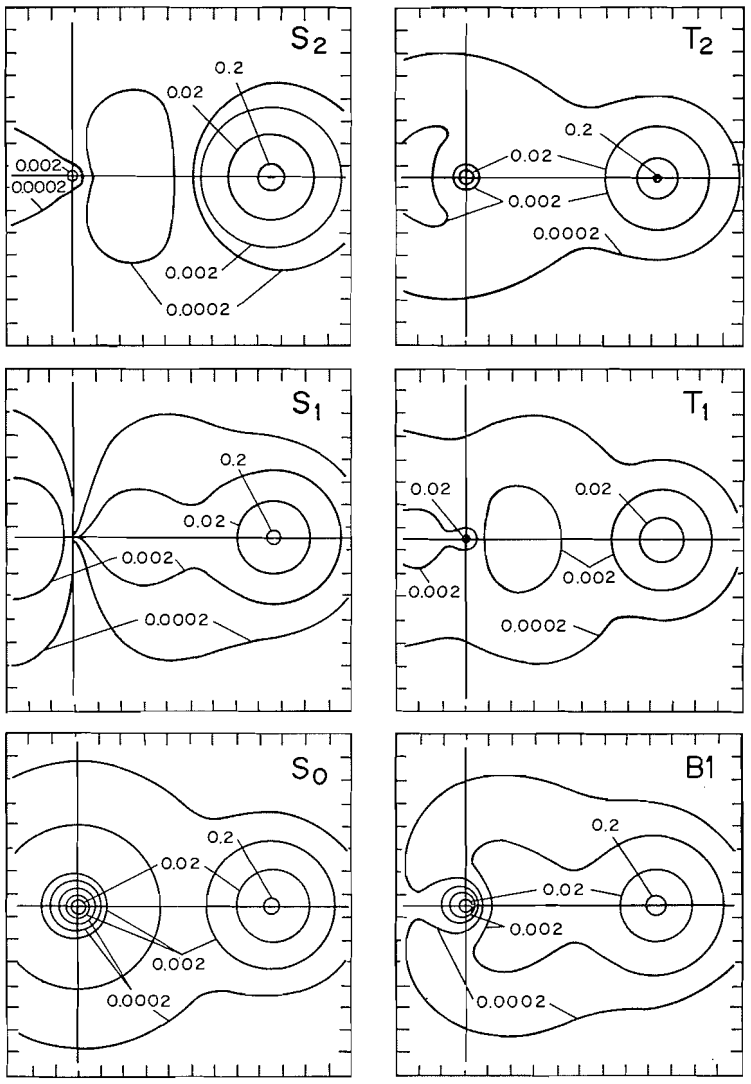

FIG. 10. Group B electron density contours for singlet (S_0, S_1, S_2) and triplet (T_1, T_2) states of LiH, at $R = 8.0$ a.u. The contour map of $B1$ is shown for comparison.

When a molecule of lithium hydride reacts, its atoms separate, and, in accordance with the calculated potential energy curve and electron density maps, it may be assumed that the molecule polarizes $Li^{\delta+} \ldots H^{\delta-}$ in ionic reactions. A nucleophilic reagent therefore should attack the lithium atom, and an electrophilic reagent should attack the hydrogen atom. In accordance with the assumptions of the preceding paragraph, the formation of a linear transition state between LiH and a nucleophilic reagent requires an unfilled orbital on the Li atom whose axis is collinear with the LiH bond.

[20]

In the bond-breaking step of this proposed mechanism, the valence electrons shift towards the hydrogen atom, where they participate in the formation of a bond with the electrophilic reagent. The valence electrons are described by the orbital ϕ_{B1} in our calculation, and the behavior of the electron density contours plotted for ϕ_{B1} at different internuclear distances probably gives a good representation of the distortion of the valence electron cloud during electrophilic substitution. The antibonding orbital ϕ_{B2} would be assumed to act as an electron acceptor in our scheme, as its geometry favors attack by the nucleophilic agent from the side that is opposite to the hydrogen atom. The orbital ϕ_{B3} is energetically less favorable than ϕ_{B2}, and it points in the opposite direction. We conclude that the orbitals ϕ_{B1} and ϕ_{B2} are of importance in reactions of LiH. Qualitatively, it may be said that as the internuclear distance increases, the region of maximum density of ϕ_{B1} moves away from the Li atom, while the region of maximum density of ϕ_{B2} moves into the region surrounding the Li atom (Fig. 11). Two specific chemical reactions will

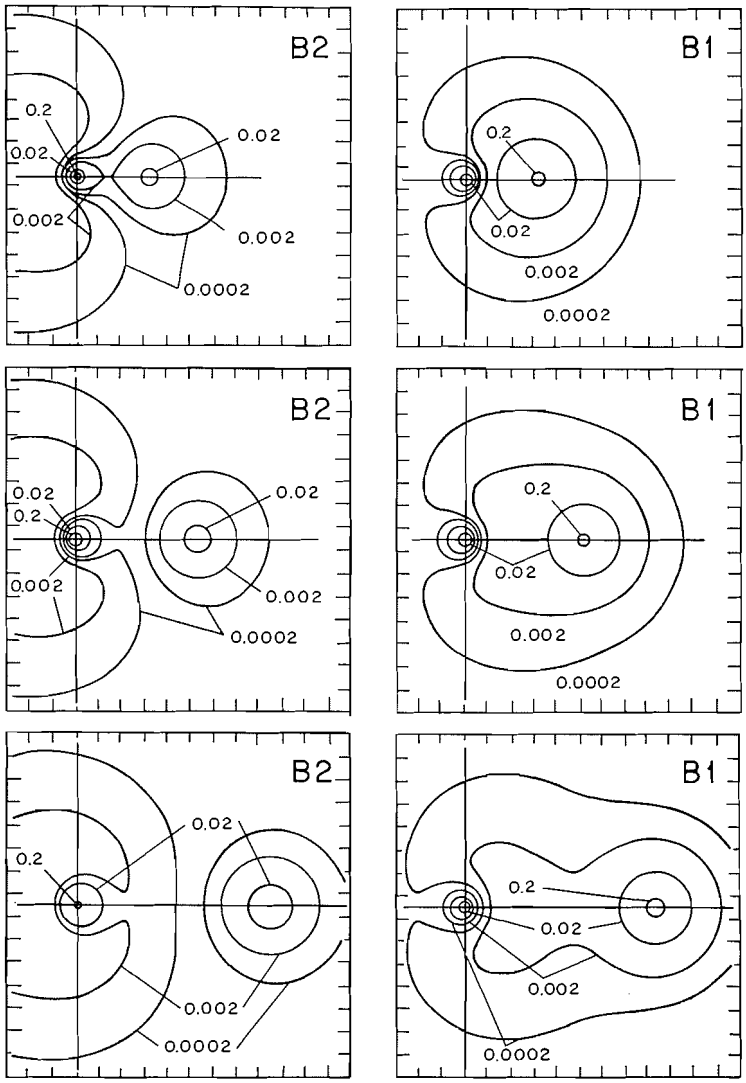

FIG. 11. Group B electron density contours for $B1$ and $B2$ of LiH at R = 3.0, 5.0, and 8.0 a.u.

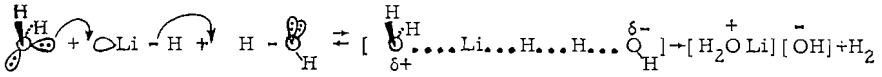
For personal use only.

now be considered which, it is suggested, proceed by ionic mechanism [20] and in which the ϕ_{B2} orbital acts as an electron acceptor.

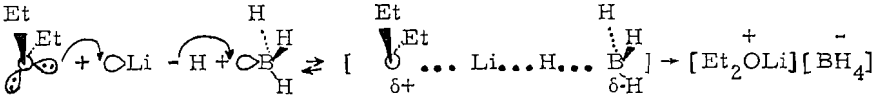
The first reaction is the solvolysis of LiH. Molecular hydrogen is formed in this reaction, and not nascent hydrogen. This suggests that molecular hydrogen is formed directly in the decomposition of the activated complex, as would be the case if the reaction proceeded by the following ionic mechanism.

[21]



The second reaction is the formation of lithium borohydride from lithium hydride and diborane. Diborane is known to dissociate to BH_3 (36). This would act as an electrophilic reagent. The lithium hydride diborane reaction requires an ether-type solvent (37). It seems reasonable then to assume that the solvent's participation in the reaction involves its lone pair of electrons.

[22]



Although this hypothesis is stereochemically plausible, no final conclusion can be drawn as yet from the present calculation since it is not known whether the lowest σ^* or the empty p_x and p_y orbitals of Li are energetically better for electron acceptance. Knowledge of this fact is necessary in the approximation we are using because it is assumed (see above) that of the several unfilled orbitals, the one of lowest energy will be occupied. The utilization of the empty p_x and p_y orbitals in the formation of the transition state would lead to a "bent" or "cyclic" activated complex as opposed to the linear complex presented above [20], [21], [22]. Which orbitals are in fact involved, can only be determined from a separate calculation of the possible transition states in which all three $2p$ orbitals ($2p_x$, $2p_y$, $2p_z$) of Li as well as the reagents are included.

It has, however, been suggested recently, as a result of kinetic measurements (38), that the transition state in butyl lithium – alkyl halide reactions is linear. This suggestion may perhaps be taken as support for a linear transition state in lithium hydride reactions.

5. SPECTROSCOPIC CONSIDERATIONS

The first excited singlet Σ state of lithium hydride is well known (10). We have not found reports of any observations of a triplet state, however. Our calculations predict only one stable triplet Σ state (see Fig. 3). Transition to this state from the ground state, of course, is spin forbidden. Furthermore this state cannot be reached by a radiationless transition from the S_1 state (which could be produced by irradiation), since the curves for S_1 and T_1 do not cross.

If the triplet state T_1 could be generated, however, it might be possible to confirm existence of the potential "hump", by observing rotational predissociation. This is so called "type III" predissociation (34). Although the triplet state cannot be excited directly, two indirect ways may be suggested.

The first involves a perturbation of the LiH molecule by an appropriately selected

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

species of unpaired spin, to cause the requisite forbidden transition. The singlet → triplet transition of benzene that occurs in the presence of O_2 and NO molecules is a phenomenon of this type. Theoretical explanations of this process have been given by several authors (39, 40, 41).

The second possible way of exciting LiH to the triplet involves photosensitization. An intermolecular triplet → triplet energy transfer could produce the required $\sigma \rightarrow \sigma^*$ triplet LiH state as shown in Fig. 12. It has been shown that this type of process is responsible

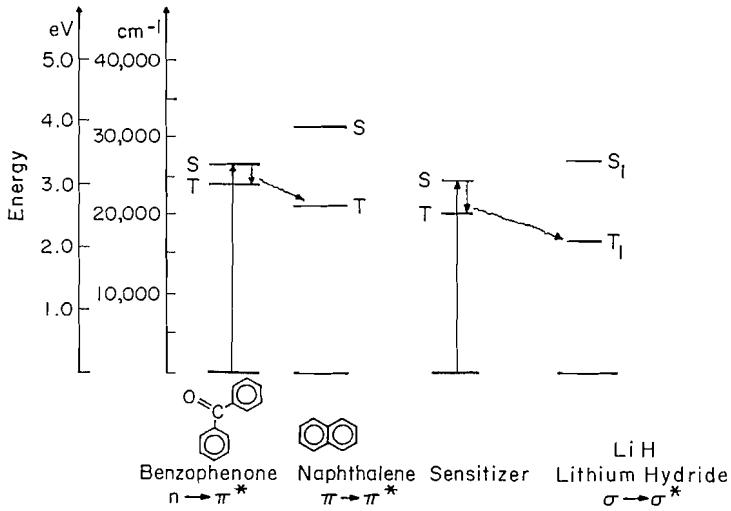


FIG. 12. Photosensitization by means of triplet → triplet energy transfer.

for the production of the $\pi \rightarrow \pi^*$ triplet in naphthalene with the aid of benzophenone (42, 43, 44). An appropriate photosensitizer for LiH would need suitable energy levels, a triplet state with a long enough lifetime for interaction, and should not react chemically with LiH in either its ground or excited states.

If the required triplet state can be obtained by the photosensitization method in an inert matrix at a low temperature (4.2 °K or 77 °K) the possibility of observing e.s.r. signals from both the photosensitizer and the lithium hydride can be considered. The signal from the photosensitizer should decrease as the signal from the lithium hydride increases.

In practice, however, it would be impossible to observe either signal if the lifetimes of the triplet states were too short. Furthermore Weissman suggests that triplet signals from small molecules cannot be observed because of magnetic dipolar coupling between the unpaired electrons (45). Even if the lifetimes of the triplets in the predissociation process were not too short, the signal from the lithium hydride might therefore be unobservable. Observation of a decaying signal from the photosensitizer, however, could still provide evidence for the occurrence of the triplet → triplet energy transfer.

ACKNOWLEDGMENTS

This work forms part of a program of research that is supported by the Army, the Navy, and the Air Force of the United States, and the National Science Foundation. One of us (I.G.C.) would like to thank the National Research Council of Canada for the

NEW REARRANGEMENTS OF THE CARYOPHYLLENE SKELETON: THE DINITROPHENYLHYDRAZONES FROM CARYOPHYLLENE OXIDE

E. W. WARNHOFF[1]
Department of Chemistry, University of Western Ontario, London, Ontario
Received January 27, 1964

ABSTRACT

Caryophyllene oxide (I) and dihydrocaryophyllene oxide (II) have been found to give 2,4-dinitrophenylhydrazones. Structures IV, V, and VII are assigned to three of these compounds on the basis of nuclear magnetic resonance data, other spectral and chemical data, and mechanistic considerations. Structure VII is the product of a new cyclization–rearrangement of the caryophyllene system. The dinitrophenylhydrazone previously obtained from isocaryophyllene oxide-*a* (III) is probably identical with VII. Three other new derivatives of caryophyllene are described, one of which (VI) is an intermediate in the conversion of I to VII.

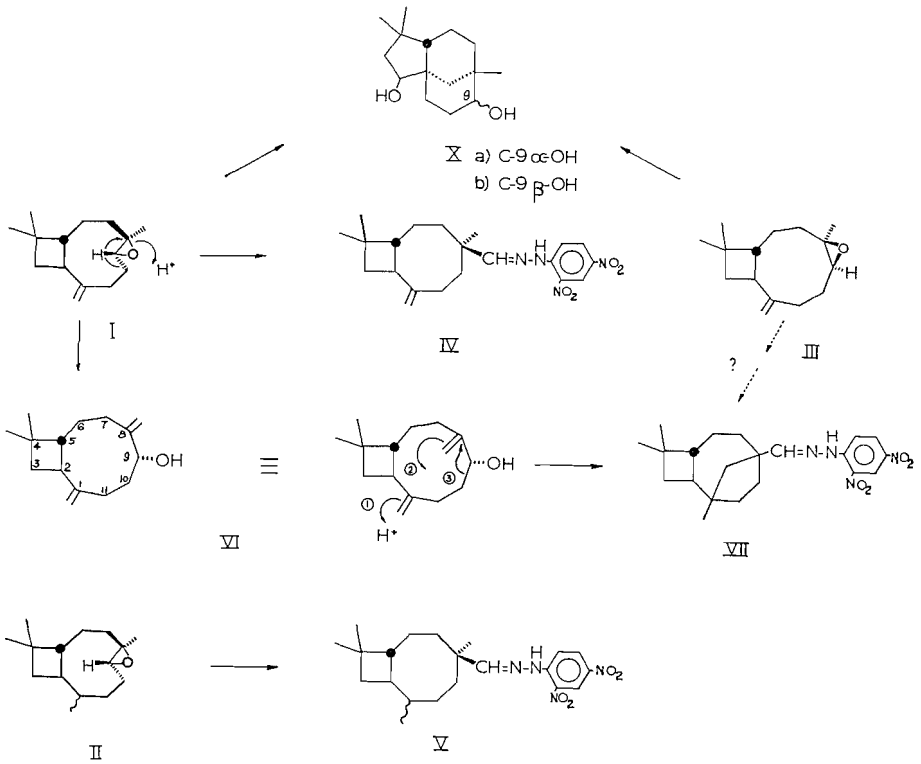
The chemistry of caryophyllene is a rich source of interesting reactions which is not yet exhausted. Among these reactions is the cyclization–rearrangement which occurs when the caryophyllene oxides are treated with aqueous acid (1). The product isolated is a C-9 epimer of the glycol X, but in addition there are carbonyl compounds formed. In the case of caryophyllene oxide (I), the crude hydration product exhibits infrared absorption at 1730 cm^{-1}. In the case of isocaryophyllene oxide, it has been reported (2) that isocaryophyllene oxide-*a* (III) reacts with 2,4-dinitrophenylhydrazine under unspecified conditions to give a derivative, $C_{21}H_{28}O_4N_4$, m.p. 185°. The carbonyl compounds probably result from rearrangement of the oxide ring, and any rearrangement might also have involved the exocyclic methylene group or a transannular reaction. These possibilities prompted the present investigation of the carbonyl compounds formed during the acid-catalyzed hydration of caryophyllene oxide (I) and dihydrocaryophyllene oxide (II).

The carbonyl compounds are most readily isolated by precipitation as the 2,4-dinitrophenylhydrazones. A mixture of the same derivatives was obtained by addition of 2,4-dinitrophenylhydrazine solution to previously acid-treated I, or, more conveniently, by addition of acidic 2,4-dinitrophenylhydrazine solution directly to I. When caryophyllene oxide was treated with a sulphuric acid solution of 2,4-dinitrophenylhydrazine, an orange precipitate formed in low yield (15%). This proved to be a mixture of three derivatives which was partially separated by thick-layer chromatography into a slower-moving component, m.p. 171°, and a faster-moving component. The faster-moving band was resolved by crystallization into two compounds, m.p. 186° and m.p. 191°. All three derivatives had the molecular formula $C_{21}H_{28}O_4N_4$ (I + 2,4-DNPine-H_2O), and each was revealed to be a true dinitrophenylhydrazone by its infrared and ultraviolet spectra (see Experimental), but these physical constants did not allow a distinction between aldehyde and ketone derivatives (3, 12).

However, the n.m.r. spectrum (Fig. 1*a*) of the 171° compound had a 1-H singlet at 7.39 p.p.m. (tetramethylsilane = 0) from the unsplit proton of an aldehyde dinitrophenylhydrazone —CH=N— system with no α-hydrogen (4). In addition the C-methyl region contained a new 3-H singlet at 1.14 p.p.m. corresponding to a methyl group on

[1]*Fellow of the Alfred P. Sloan Foundation.*

a quaternary carbon atom. The 7 c.p.s. displacement of these methyl protons to lower field relative to the *gem*-dimethyl group at 1.01 p.p.m. can be accounted for by proximity to the —CH=N—dinitrophenyl group.[2] The two olefinic protons at 4.50 and 4.71 p.p.m. showed the exocyclic methylene group to remain undisturbed. A mechanistically reasonable formula consistent with these facts and involving the least structural change is IV, formed by rearrangement of the oxide ring (I → IV) to an 8-membered carbocycle.



Confirmation for the rearranged structure was sought from dihydrocaryophyllene oxide (II), which should react in the same manner with dinitrophenylhydrazine solution. Only a single derivative, $C_{21}H_{30}O_4N_4$, m.p. 187.5°, was obtained from II in a yield (6%) about equal to that of the 171° compound from I. Again, both the infrared and ultraviolet spectra corresponded to those of a ketone or aldehyde dinitrophenylhydrazone. The n.m.r. spectrum (Fig. 1*b*) of the 187.5° compound also had a 1-H singlet at 7.36 p.p.m. from the unsplit proton of a quaternary aldehyde dinitrophenylhydrazone —CH=N— function. A quaternary methyl substituent adjacent to the —CH=N— dinitrophenyl function gave a 3-H singlet at 1.10 p.p.m., whereas the *gem*-dimethyl group was still present at 0.96 and 0.99 p.p.m. A doublet from the CH_3—CH of the fourth methyl group was centered at 0.82 p.p.m. with an apparent coupling of 6.5 c.p.s., and this doublet was also present in the spectrum of dihydrocaryophyllene oxide (Table I). In the infrared region the only notable difference between the 171° and the 187.5° compounds was the presence of a peak at 890 cm^{-1} (C=CH_2) in the spectrum of the 171° derivative but not of the 187.5° compound. Therefore, the 187.5° dinitrophenylhydrazone has the structure V analogous to that proposed for the derivative IV from

[2]*Proximity to the double bond is excluded by the derivative from II. See below.*

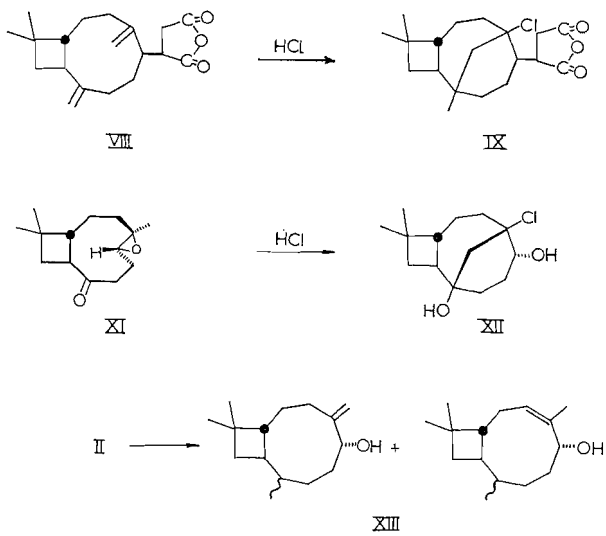
*Chemical shifts are given in p.p.m. from tetramethylsilane (=0) for deuterochloroform solutions. The number of protons in the peak(s) and the apparent multiplicity are given in parentheses; s = singlet, d = doublet, d of d = doublet of doublets, m = multiplet.

caryophyllene oxide. The stereochemistry of IV and V follows from the expected inversion during oxide rearrangement.

The 186° dinitrophenylhydrazone from caryophyllene oxide (I) appeared more interesting in that the exocyclic methylene group was missing. Both the peak at 890 cm^{-1} in the infrared spectrum and those at 4.50 and 4.71 p.p.m. in the n.m.r. spectrum were absent. This compound was also derived from an aldehyde with no α-hydrogen since a 1-H singlet at 7.52 p.p.m. was present in the n.m.r. spectrum (Fig. 1*c*). However, the absence of a 1.10–1.14 p.p.m. peak revealed that there was no quaternary methyl substituent on the α-carbon atom of the aldehyde. Instead, close to the *gem*-dimethyl group at 1.00 p.p.m. was a third quaternary methyl group at 0.96 p.p.m. not deshielded by any functional group. Furthermore, in the 2.00–3.10 p.p.m. region there was no absorption from allylic methylene or methine protons such as is present in n.m.r. spectra of unsaturated caryophyllene derivatives (see Table I). With no vinyl or allylic hydrogen present, the 186° compound is necessarily the dinitrophenylhydrazone of a completely saturated cyclization product. The simplest formulation for this derivative is VII arising by the sequence I → VI → VII,[3] which represents a new cyclization–rearrangement of the caryophyllene skeleton. The cyclization itself is not new; this type has been proposed (5) for the reaction of caryophyllene – maleic anhydride adduct with electrophilic reagents, e.g. VIII → IX, and proved (6) for the reaction of caryophyllene keto oxide with hydrogen chloride, XI → XII.



VIII IX XI XII XIII

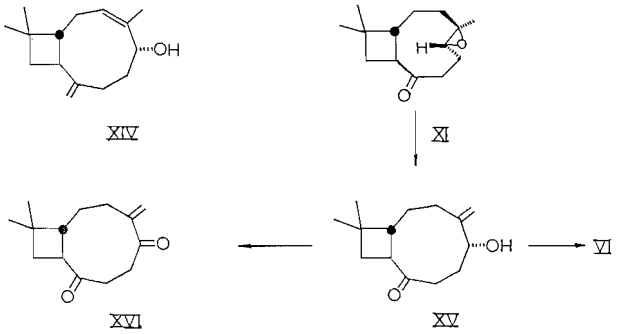
This interpretation was tested by determining whether VI could be an intermediate, since it has already been demonstrated (7) that the oxide ring of II can be opened to a mixture of allylic alcohols XIII. The allylic alcohol VI was prepared in 80% yield by mild opening of the oxide ring of caryophyllene oxide (I) on passage through a column of alumina. Although the product gave a single spot on thin-layer chromatography, and its infrared spectrum had hydroxyl absorption, increased methylene absorption (C=CH_2, 890 cm^{-1}) relative to I, and no carbonyl absorption, still the n.m.r. spectrum in the olefinic hydrogen region indicated the presence of an impurity. In particular, a small

[3]*More complex changes involving transannular hydride shifts, multiple rearrangements, etc. are regarded as less likely (see below).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

amount of XIV or the hydroxyl epimer of VI might be difficult to detect. Therefore, a sample of VI was synthesized by a different route.

The oxide ring of caryophyllene keto oxide, XI (8), was opened on alumina to give as the major product the keto allylic alcohol XV, which crystallized. Its structure is substantiated by its infrared spectrum with hydroxyl (3600 and 3440 cm^{-1}), carbonyl (1692 cm^{-1}), and asymmetric disubstituted ethylene (896 cm^{-1}) absorption, and by its n.m.r. spectrum (Table I) with peaks corresponding to two olefinic protons and one H—C—O group. As further structural evidence manganese dioxide oxidation of XV produced the crystalline cisoid conjugated ketone XVI, λ_{max} 227 mμ (ϵ 6150), whose n.m.r. spectrum (Table I) still had two olefinic hydrogens. The Wittig reaction of XV with the ylide from methyltriphenylphosphonium iodide gave VI[4], which, although not crystalline, gave a single spot on thin-layer chromatography with the same R_f value as VI prepared by opening the oxide ring of I. The n.m.r. spectrum (Table I) of VI from the Wittig reaction corresponded with that expected. It had a total of four olefinic protons, one proton (doublet of doublets) on carbon bearing oxygen, and only two methyl groups.



When VI, prepared by either method, was treated with 2,4-dinitrophenylhydrazine under the same conditions used for I and II, orange crystals precipitated in 33–44% yield. These were proved to be the 186° dinitrophenylhydrazone from I by mixture melting point and by comparison of infrared and n.m.r. spectra, optical rotations, and thin-layer chromatographic behavior. No trace of IV could be detected by thin-layer chromatography of the crude precipitate. Nor could any IV or 191° derivative be detected in the n.m.r. spectrum of the crude precipitate, although these would have been readily apparent at 1.14, 1.20, 1.56, and 1.73 p.p.m. if present. The fact that the 186° compound can be obtained from VI, and in much better yield than from I, provides strong support for the proposed structure VII and the reaction sequence leading to it.

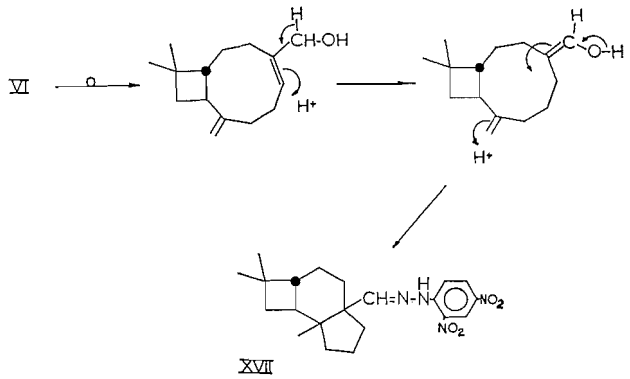
Another structure derivable by a more complex transformation of VI, but which also fits the interpretable features of the n.m.r. spectrum (Fig. 1*c*), is XVII formed as outlined below.[5] This possibility was tested by determination of the extent of deuterium incorporation when the cyclization–rearrangement was carried out in deuterium oxide and ethanol-*O*-d_1 solution. The VII formed was found to contain an average of 0.88 atom of deuterium per molecule. Since the 0.96 p.p.m. methyl peak in the n.m.r. spectrum of the deuterated derivative decreased from three to approximately two protons, there

[4]*It has been demonstrated that the 'trans' fusion of the 4- and 9-membered rings with adjacent ketone function is the more stable. Furthermore, in Wittig reactions on ketones of type XV the ring fusion is not altered (9).*

[5]*This possibility was suggested by Professor P. de Mayo.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

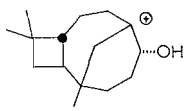
was only one deuterium atom in the deuterated molecules and it was located in the newly formed methyl group.* The formation of XVII would require the introduction of *two* C-deuterium atoms per molecule, and hence this formula is excluded.



XVII

Consideration of the proposed reaction paths leading to IV and VII suggests that isocaryophyllene oxide-*a* (III), the *cis* epoxide with the same configuration at C_8 as I, could give the same dinitrophenylhydrazones as caryophyllene oxide. In agreement the melting point (185°) of the one derivative reported (2) from III matched the melting point (186°) of VII, and the two compounds may well be identical.

In VII the stereochemistry of the methylene bridge with respect to the C-5 hydrogen is unknown; according to Stuart–Briegleb models, cyclization is possible either above or below the 9-membered ring. Since only one cyclized product was obtained, probably the methylene bridge is *cis* to the C-5 hydrogen as has been found by X-ray crystallography for XII (6). The models also raise an interesting question. The cyclization as depicted in VI cannot be completely concerted without the third "electronic movement" occurring *cis* to the second. On the other hand, a non-concerted cyclization would lead to the bridgehead (S = 8) carbonium ion XVIII of the same [4.3.1] type as that from caryolan-1-ol (β-caryophyllene alcohol). Models indicate that this particular bridgehead ion would not be very strained. There is as yet no evidence whether the cyclization-rearrangement is concerted or not.



XVIII

Since the dienol VI does not give IV, this derivative and also V must be formed directly from the corresponding oxide by rearrangement, in the case of IV by a reaction competitive with the I → VI → VII path. The 1,2-glycol from hydration of I would not be an intermediate in this rearrangement since the backside of the oxide ring is completely shielded.

The third dinitrophenylhydrazone, m.p. 191°, obtained from I results from more extensive rearrangement of the caryophyllene framework. It is also the derivative of an aldehyde with no α-hydrogen and has *five* methyl groups; the structure is as yet unknown. However, the compound is not formed from the dienol VI.

*NOTE ADDED IN PROOF: *Professor K. Biemann has very kindly determined the mass spectra of both the deuterated and undeuterated VII. No molecules containing two deuterium atoms could be detected.*

It was demonstrated that the reactions leading from I to the carbonyl compounds *accompany* the acid-catalyzed cyclization to the glycol X*a*. The filtrate from a preparation of X*a* contained no unreacted I, and yet the addition of dinitrophenylhydrazine gave IV, VII, and the 191° derivative. Furthermore, from the filtrate of the reaction of I with acidic dinitrophenylhydrazine solution at room temperature there was isolated the glycol X*a*. This glycol did not give a precipitate with acidic dinitrophenylhydrazine solution. The dienol VI is not a precursor of glycol X*a* since treatment of VI under conditions yielding 20% of the easily crystallized X*a* from I gave no diol X*a*. More convincingly, the hydration of caryophyllene oxide in acetone-d_6 – deuterium oxide solution with phosphoric acid-d_3 gave glycol X*a* which contained no deuterium. Therefore, at no stage during the hydration of I to X*a* is a proton from solvent incorporated onto carbon; hence X*a* is probably formed directly from I.

The apparent absence of carbonyl products from transannular reactions such as those observed with cycloöctene oxides (10, 11), can probably be ascribed to the peculiarities of the caryophyllene structure. Not only will hydride abstraction from C-2 and C-5 be opposed by the fused cyclobutane ring, but the carbonium ion formed by breaking the oxide ring at the preferred tertiary carbon atom may stabilize itself by proton loss from the C-8 methyl group, or by reaction with the double bond at C-1.

EXPERIMENTAL

General

Melting points were taken on a Reichert microscope hot stage and are corrected. Optical rotations were observed on chloroform solutions in a 1-dm tube with a Schmidt–Haensch polarimeter. Ultraviolet spectra were taken on a Bausch and Lomb Spectronic 505 instrument. Infrared spectra were recorded with a Beckman IR-5 spectrophotometer. Nuclear magnetic resonance spectra were determined in deuteriochloroform solution (10–20% w/v concentration) on a Varian HR-60 or A-60 spectrometer and were calibrated by the audio side band technique. Integrations were by the cut-and-weigh method. Silica gel with calcium sulphate binder was used for thin-layer chromatography. Petroleum ether refers to the fraction boiling at 60–80°. Microanalyses were by Dr. A. Bernhardt, Mulheim, Germany. Combustion deuterium analyses by the falling drop method were by Josef Nemeth, Urbana, Illinois.

Caryophyllene Oxide (I)

Caryophyllene isolated by fractional distillation from clove oil terpene fraction was epoxidized with monoperphthalic acid (2). The crude oxide was recrystallized from methanol to constant m.p. 63.5–64° and constant $[\alpha]_D^{20}$ −79° (*c*, 2.32)(lit. (8): m.p. 63–64°, $[\alpha]_D^{20}$ −68°). It gave a single spot on thin-layer chromatography in ethyl acetate:petroleum ether (15:85).

Dihydrocaryophyllene Oxide (II)

A solution of 2.640 g (12.0 mmoles) of caryophyllene oxide in 30 ml of reagent grade ethyl acetate was hydrogenated over 300 mg of 5% palladium-on-carbon catalyst (Matheson, Coleman and Bell) at atmospheric pressure and room temperature. One equivalent of hydrogen was absorbed in 1 hour. After filtration and evaporation of solvent the oily residue [2.622 g, $[\alpha]_D^{21}$ −81° (*c*, 2.24)] was recrystallized four times from methanol to give 738 mg (29%) of pure dihydrocaryophyllene oxide, m.p. 66.5–68°, $[\alpha]_D^{24}$ −67° (*c*, 2.00) [lit. (8): m.p. 67°, $[\alpha]_D$ −55° (ethanol)]. The pure II gave a single spot on thin-layer chromatography in ethyl acetate:petroleum ether (15:85).

Reaction of Caryophyllene Oxide (I) with 2,4-Dinitrophenylhydrazine Reagent

To a solution of 413 mg (1.88 mmoles) of pure caryophyllene oxide in 1 ml of 95% ethanol was added the reagent prepared from 380 mg (1.92 mmoles) of 2,4-dinitrophenylhydrazine, 0.3 ml of concentrated sulphuric acid, 0.1 ml of water, and 2 ml of 95% ethanol. An exothermic reaction occurred and a voluminous orange precipitate appeared in 10–15 seconds. After 30 minutes the precipitate was separated by centrifugation, washed with ethanol–water and water–pyridine, and dried to yield 116 mg (15%) of orange powder, m.p. 136–160°. Thin-layer chromatography in ethyl acetate:petroleum ether (10:90) gave two spots, R_f 0.30 and R_f 0.36, in about equal amounts. Two other reactions in which the amount of I was varied and the amount of dinitrophenylhydrazine decreased gave no significant change in yield (11–14%).

The combined crude derivative from the reactions was first chromatographed on a thick plate (20 g silica gel per 20×20 cm plate) in benzene to separate the mixture of the main components from traces of slower-moving impurities. The main yellow band (163 mg) was then chromatographed on thick plates (30 mg per

plate) in ethyl acetate : petroleum ether (10:90). Careful manual separation of bands and extraction gave 82 mg of the faster-moving material and 64 mg of the slower-moving derivative.

Three recrystallizations of the slower-moving component (R_f 0.30) from chloroform – 95% ethanol gave matted golden needles of IV, m.p. 170–171°, $[\alpha]_D^{24}$ −14.7° (*c*, 1.77), $\lambda_{max}^{CHCl_3}$ 362 mμ (ε 22,600), $\nu_{max}^{CHCl_3}$ 3300 cm^{-1} (NH), 890 cm^{-1} (C=CH$_2$).[6] Thin-layer chromatography in ethyl acetate : petroleum ether (10:90) showed the IV to be free of VII.

Anal. Calc. for $C_{21}H_{28}O_4N_4$ (400.47): C, 62.98; H, 7.05; N, 13.99. Found: C, 62.84; H, 7.04; N, 14.13.

Five recrystallizations of the faster-moving component (R_f 0.36) from chloroform – 95% ethanol gave matted golden needles of VII, m.p. 184–186°, capillary m.p. 186–188°, $[\alpha]_D^{25}$ +27.5° (*c*, 1.78), $\lambda_{max}^{CHCl_3}$ 369 mμ (ε 20,300), $\nu_{max}^{CHCl_3}$ 3300 cm^{-1} (NH).[6] A mixture of IV and VII melted with depression at 151–173°.

Anal. Calc. for $C_{21}H_{28}O_4N_4$ (400.47): C, 62.98; H, 7.05. Found: C, 63.15; H, 6.91.

From the mother liquors of recrystallization of the upper thick-layer band could be crystallized a third dinitrophenylhydrazone. However, it was more easily obtained from the mother liquors of the original dinitrophenylhydrazone precipitation. These mother liquors were diluted with water and extracted with chloroform. The chloroform solution was washed with water and dilute sodium bicarbonate solution. Evaporation of the chloroform left an oily residue which was extracted with petroleum ether and then with benzene. Evaporation of the benzene solution left 24 mg of dinitrophenylhydrazone. Three recrystallizations from chloroform – 95% ethanol gave matted yellow needles, m.p. 189.5–191°, $\lambda_{max}^{CHCl_3}$ 363 mμ (ε 20 800). On admixture with VII (m.p. 184–186°) the melting point was depressed to 159–186°.

Anal. Calc. for $C_{21}H_{28}O_4N_4$ (400.47): C, 62.98; H, 7.05; N, 13.99. Found: C, 62.81; H, 7.24; N, 14.12.

Reaction of Dihydrocaryophyllene Oxide (II) with 2,4-Dinitrophenylhydrazine Reagent

To a solution of 70 mg (0.315 mmole) of II in 0.8 ml of 95% ethanol was added at room temperature a solution of 63 mg (0.315 mmole) of 2,4-dinitrophenylhydrazine in 1.2 ml of 95% ethanol containing 8 drops of concentrated sulphuric acid and 4 drops of water. The copious orange precipitate which formed after 10 seconds was separated by centrifugation, washed with ethanol–water and water–pyridine and dried to give 7.0 mg (5.5%) of golden powder, m.p. 182–186.5°. Larger-scale reactions (180–230 mg of II) in which the amount of 2,4-dinitrophenylhydrazine was decreased gave no significant change in yield. Three recrystallizations from chloroform – 95% ethanol gave matted golden needles of V, m.p. 186.5–187.5°, $[\alpha]_D^{24}$ +8.5° (*c*, 1.52), $\lambda_{max}^{CHCl_3}$ 363 mμ (ε 22,300), $\nu_{max}^{CHCl_3}$ 3300 cm^{-1} (NH).[6] A mixture of V and VII melted at 159–185°. Thin-layer chromatography in ethyl acetate : petroleum ether (10:90) gave a single spot, R_f 0.36.

Anal. Calc. for $C_{21}H_{30}O_4N_4$ (402.48): C, 62.66; H, 7.51; N, 13.92. Found: C, 62.62; H, 7.51; N, 14.04.

Caryophyllene Keto Oxide (XI)

Caryophyllene oxide was oxidized with permanganate according to Treibs (8) and the product XI purified by chromatography on activity II *basic* Woelm alumina, m.p. 61.5–63°, $[\alpha]_D^{22}$ −148° (*c*, 1.95) (lit. (8): m.p. 61–62°, $[\alpha]_D^{20}$ −124° [methanol]), $\nu_{max}^{CS_2}$ 1695 cm^{-1} (C=O).

Keto Allylic Alcohol XV

A solution of 25 mg of pure caryophyllene keto oxide (XI) in benzene was added to a column of 0.9 g of activity I *neutral* Woelm alumina packed in benzene. Elution with 8 ml of benzene gave 6 mg of recovered XI; further elution with 10 ml of ether gave 17 mg (89%) of keto allylic alcohol XV. Thin-layer chromatography in ethyl acetate : cyclohexane (50:50) showed that XV and recovered XI were the only products of the reaction. Larger-scale reactions gave the same results. Three recrystallizations from chloroform – petroleum ether gave long thin needles of XV, m.p. 110–111°, $[\alpha]_D^{27}$ −46° (*c*, 2.14), $[\alpha]_D^{21}$ −49° (*c*, 2.01), ϵ_{220} 615 (end absorption only), $\nu_{max}^{CHCl_3}$ 3600 and 3440 cm^{-1} (OH), 3030 cm^{-1} (C=CH), 1692 cm^{-1} (C=O), 1640 cm^{-1} (C=C), 916 cm^{-1} (C=CH$_2$).

Anal. Calc. for $C_{14}H_{22}O_2$ (222.32): C, 75.63; H, 9.97. Found: C, 75.43; H, 9.79.

Unsaturated Diketone XVI

A solution of 1.000 g of pure XV in 30 ml of chloroform was stirred (magnetic stirring bar) with 7.0 g of active manganese dioxide (13) for 16 hours. Filtration and evaporation of chloroform left 922 mg of product, which was recrystallized twice from petroleum ether. The recrystallized material (605 mg) was then chromatographed on 5 g of activity II neutral Woelm alumina to remove some unoxidized XV. Elution with petroleum ether gave 470 mg of XVI, which was recrystallized twice from petroleum ether affording colorless prisms, m.p. 48–50°, $[\alpha]_D^{22}$ −14.7° (*c*, 3.06), $\lambda_{max}^{95\%\ EtOH}$ 227 mμ (ε 6150), $\nu_{max}^{CS_2}$ 1703 cm^{-1} (C=O), 1680 cm^{-1} (conjugated C=O), 1622 cm^{-1} (C=C), 925 or 935 cm^{-1} (C=CH$_2$). The compound slowly decomposed to an oil on standing for several weeks.

Anal. Calc. for $C_{14}H_{20}O_2$ (220.30): C, 76.32; H, 9.15. Found: C, 76.47; H, 9.33.

Dienol VI

(a) From the keto allylic alcohol XV.—To a suspension of 6.29 g (15.6 mmoles) of methyl triphenylphosphonium iodide in 50 ml of tetrahydrofuran (freshly distilled from sodium) was added 22 ml (15.6

[6]*Each of the 2,4-dinitrophenylhydrazones IV, V, and VII also had infrared peaks at 1620, 1590, 1510, 1463, 1425, 1333, 1311, 1140, 927, and 846 cm^{-1}, most of which have been found to be characteristic of this derivative (12).*

mmoles) of an ethereal solution of phenyllithium. The mixture was refluxed for 5 hours. Then 1.100 g (4.95 mmoles) of XV was added and the reaction mixture refluxed for 19 hours. Dilution of the reaction mixture with ether and extraction with water and dilute sodium bicarbonate solution left a clear-brown organic layer. Steam distillation of this solution left 3.29 g of viscous brown syrup which was chromatographed on 40 g of Woelm neutral alumina, activity I. Fractions eluted with solvents from pure benzene to ether : benzene (25:75) contained dienol VI along with other impurities. These fractions, 991 mg, were chromatographed on thick fluorescent silica-gel plates (20 g silica gel per 20×20 cm plate) and the dienol fraction extracted to give 131 mg (0.60 mmole, 12%) of pure dienol VI as a viscous colorless liquid, $[\alpha]_D^{24}$ +20.8° (*c*, 2.11), $\nu_{max}^{CS_2}$ 3600 and 3370 cm^{-1} (OH), 3060 cm^{-1} (vinyl H), 1640 cm^{-1} (C=C), and 903 cm^{-1} (C=CH_2). The dienol gave a single spot, R_f 0.25, on thin-layer chromatography in ethyl acetate : petroleum ether (30:70).

Anal. Calc. for $C_{15}H_{24}O_2$ (236.34): C, 81.76; H, 10.98. Found: C, 81.91; H, 10.94.

(b) From caryophyllene oxide (I).—To a column of 30 g of activity I *neutral* Woelm alumina packed in petroleum ether was added a solution of 2.000 g of pure I in petroleum ether. Elution with petroleum ether gave 676 mg of recovered I. Further elution with benzene–ether mixtures removed 212 mg of mixed minor products, and pure ether eluted 1.081 g (80%) of liquid dienol VI, $[\alpha]_D^{23}$ −15° (*c*, 2.87), $\nu_{max}^{CS_2}$ 3600 and 3370 cm^{-1} (OH), 3060 cm^{-1} (vinyl H), 1640 cm^{-1} (C=C) and 903 cm^{-1} (C=CH_2). This material gave a single spot, R_f 0.25, on thin-layer chromatography in ethyl acetate : petroleum ether (30:70). However, the dienol was not pure since its optical rotation differed from that of the Wittig reaction product, and its n.m.r. spectrum contained a small additional peak in the olefinic hydrogen region at 4.86 p.p.m., possibly from the hydroxyl epimer of VI.

Reaction of Dienol VI with 2,4-Dinitrophenylhydrazine Solution

(a) With VI from the Wittig reaction.—A solution of 106 mg (0.48 mmole) of pure VI in 1.5 ml of 95% ethanol was treated with the reagent prepared from 96 mg (0.48 mmole) of 2,4-dinitrophenylhydrazine, 10 drops of concentrated sulphuric acid, 4 drops of water, and 1 ml of 95% ethanol. The mixture became cloudy after a minute and crystals precipitated. After several hours the precipitate was separated by centrifugation, washed with ethanol–water and water–pyridine, and dried. There was obtained 67 mg (35%) of orange powder, m.p. 150–173°. Thin-layer chromatography (ethyl acetate : petroleum ether, 10:90) and the n.m.r. spectrum of the crude derivative revealed no trace of IV or the 191° derivative. Four recrystallizations of the crude derivative from chloroform – 95% ethanol gave 24 mg of orange needles of VII, m.p. 184–186°, $[\alpha]_D^{24}$ +27.8° (*c*, 1.94), $\nu_{max}^{CHCl_3}$ 3300 cm^{-1} (NH).[6] On admixture with VII from I the melting point was undepressed, m.p. 181–185°.

Anal. Calc. for $C_{21}H_{28}O_4N_4$ (400.47): C, 62.98; H, 7.05; N, 13.99. Found: C, 63.07; H, 6.98; N, 14.07.

(b) With VI from β-caryophyllene oxide (I).—To a solution of 181 mg (0.82 mmole) of the impure VI in 2 ml of 95% ethanol was added the reagent prepared from 163 mg (0.82 mmole) of 2,4-dinitrophenylhydrazine, 0.5 ml of concentrated sulphuric acid, a few drops of water, and 2 ml of 95% ethanol. There was an immediate precipitation. After several hours the reaction was worked up as in (*a*) above to give 108 mg (33%) of orange powder, m.p. 138–163°. Successive recrystallizations from chloroform – 95% ethanol gave either metallic orange flakes or orange needles, eventually yielding 34 mg of VII, m.p. 184–186°, identical with VII from (*a*) above and from I.[7] Thin-layer chromatography (ethyl acetate : petroleum ether, 10:90) of the recrystallized derivative gave a single spot, R_f 0.36. In another reaction 154 mg of VI gave 124 mg (44%) of crude dinitrophenylhydrazone.

Reaction of Dienol VI with 2,4-Dinitrophenylhydrazine in Deuterated Solvent

Dienol VI (200 mg, 0.91 mmole) was dissolved in 4 ml of ethanol-*O*-d_1 (~99% D) containing 0.25 ml of deuterium oxide (>99.5% D). To this solution was added a solution of 180 mg (0.91 mmole) of 2,4-dinitrophenylhydrazine (NH not previously exchanged for D) in a mixture of 2.0 ml of syrupy phosphoric acid-d_3 (prepared by dissolving phosphorus pentoxide in 99.5% deuterium oxide) and 5 ml of ethanol-*O*-d_1 (99%). The reaction mixture was heated to boiling for a few seconds and then allowed to stand at room temperature for 3 days. The precipitate was centrifuged, washed with ethanol–water and water–pyridine, and dried. The crude product was chomatographed on a thick plate (20 g of silica gel on a 20×20-cm plate) in benzene. The uppermost band was extracted with chloroform to yield 53 mg of orange solid. Recrystallization from chloroform – 95% ethanol gave 34 mg of orange needles, m.p. 182–186°. The n.m.r. spectrum of this material differed from VII only in having a less intense and broadened peak at 0.96 p.p.m. (ca. 2 protons). Integration gave only 8 protons in the methyl groups as compared with 9 protons in the spectrum of VII. The area ratio of the 1.01:0.96 peaks in the non-deuterated derivative was 2:1; in the deuterated derivative 3:1.

Anal. Calc. for $C_{21}H_{27}DO_4N_4$: D, 3.57 atom %. Found: D, 3.18 atom %.

Acid Isomerization of Caryophyllene Oxide (I)

(*a*) Caryophyllene oxide (112 mg) in 1 ml of 95% ethanol was treated with a solution of 3 drops of water and 6 drops of concentrated sulphuric acid in 0.5 ml of ethanol. The reaction mixture was warmed for a minute in

[7]*If the impurity in VI made by opening the oxide ring of I is the hydroxyl epimer of VI, this would also be expected to produce VII in a yield comparable to that from VI.*

a 70° water bath and then allowed to stand at room temperature for 30 minutes. Dilution with water and ether extraction gave 105 mg (93%) of colorless viscous liquid, $\nu_{max}^{CS_2}$ 1730 cm^{-1}. Thin-layer chromatography in ethyl acetate : petroleum ether (10:90) showed the absence of any I.

Addition of an acidic solution of 2,4-dinitrophenylhydrazine to 75 mg (0.34 mmole) of the acid isomerization product in 2 ml of 95% ethanol produced 5.5 mg (4%) of yellow precipitate. Thin-layer chromatography of this derivative in ethyl acetate : petroleum ether (15:85) gave two spots, R_f 0.51 and 0.58, corresponding to authentic IV and VII spotted on the same plate.

(*b*) Following the procedure of Aebi, Barton, and Lindsey (1), a solution of 240 mg of I in 1 ml of reagent grade acetone containing 0.25 ml of water and 0.05 ml of sulphuric acid (1:1, v/v) was refluxed for 2 hours. Dilution with water and extraction with ether gave 246 mg (98%) of colorless viscous oil. Two recrystallizations of a 204-mg sample from chloroform – petroleum ether gave 54 mg (20%) of colorless needles of X*a*, m.p. 150.5–151° (lit. (1): m.p. 152–153°). The glycol X*a* gave no precipitate on treatment with acidic 2,4-dinitrophenylhydrazine solution even at 80°.

The mother liquors from crystallization of X*a* were treated with acidic 2,4-dinitrophenylhydrazine solution whereupon a red oil separated. Thick-layer chromatography of this in benzene gave 32 mg of dinitrophenylhydrazone in the uppermost band. The n.m.r. spectrum of this material had sharp peaks at the positions of the unsplit methyl groups of IV, VII, and the 191° derivative. Thin-layer chromatography (ethyl acetate : petroleum ether, 10:90) gave two spots which had the same R_f as IV and VII plus the 191° derivative.

(*c*) A 150-mg sample (0.68 mmole) of I was treated at room temperature with sulphuric acid–2,4-dinitrophenylhydrazine solution as described earlier. Centrifugation yielded 18.5 mg (7%) of crude dinitrophenylhydrazone mixture. The supernatant mother liquor was diluted with water and extracted with chloroform. Evaporation of the chloroform left a residue which was extracted with petroleum ether. On standing this petroleum ether extract deposited 5.5 mg (2%) of glycol X*a*, m.p. 151.5–152°, after two recrystallizations from chloroform – petroleum ether. The melting point was undepressed on admixture with authentic X*a* prepared in (*b*) above.

Acid Isomerization of Caryophyllene Oxide (I) in Deuterated Solvent

A solution of 600 mg (2.72 mmoles) of I in a mixture of 2.4 ml of acetone-d_6 (>99.5% D), 0.3 ml of deuterium oxide (>99.6% D), and 0.10 ml of phosphoric acid-d_3 : deuterium oxide (3:1) was refluxed for 2.5 hours. The reaction mixture was diluted with water and extracted with ether. The ether extracts were washed with water, sodium bicarbonate solution, and saturated sodium chloride solution and dried. Evaporation of the ether left 580 mg of colorless residue. Recrystallization from chloroform – petroleum ether gave 274 mg (42%) of colorless matted needles of X*a*. A second recrystallization from the same solvent raised the melting point to 150.5–151°. The n.m.r. spectra of this material and the glycol X*a* prepared in protic solvent were compared at 100 mg/0.35 ml concentration in *pyridine* solution for greater solubility. The spectra were identical, and the relative intensities of the unsplit methyl peaks at 1.15 and 1.10 p.p.m. to the unsplit methyl peak at 0.90 was 1.93:1 (protic solvent) and 1.99:1 (deuterated solvent).

Anal. Calc. for $C_{15}H_{25}DO_2$: D, 3.85 atom %. Found: D, 0.00 atom %.

Reaction of Dienol VI with Sulphuric Acid

Dienol VI (200 mg) previously shown by thin-layer chromatography to contain no glycol X*a* was dissolved in 1 ml of reagent grade acetone containing 0.25 ml of water and 0.05 ml of sulphuric acid (1:1, v/v). The solution was refluxed for 2 hours. Dilution with water and extraction with ether gave 222 mg (100%) of colorless viscous oil. The product did not crystallize on trituration with petroleum ether and seeding with X*a*. Thin-layer chromatography in ethyl acetate : petroleum ether (67:33) gave three spots, one of which corresponded closely to authentic glycol X*a*, R_f 0.15. However, the colors developed by this spot on sulphuric acid charring were different from those of X*a*. Also, the infrared spectrum of the acid isomerization product (separated by thick-layer chromatography) corresponding closely in R_f to X*a* was quite different from that of X*a*.

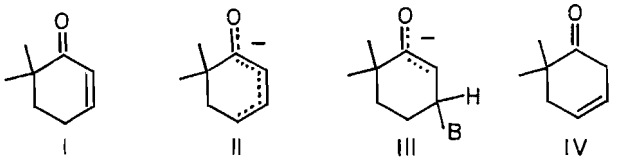
RELATIVE RATES OF BASE-CATALYZED EXCHANGE OF ALPHA- AND GAMMA-HYDROGEN IN AN α,β-UNSATURATED KETONE

J. WARKENTIN AND L. K. M. LAM
Department of Chemistry, McMaster University, Hamilton, Ontario
Received January 24, 1964

ABSTRACT

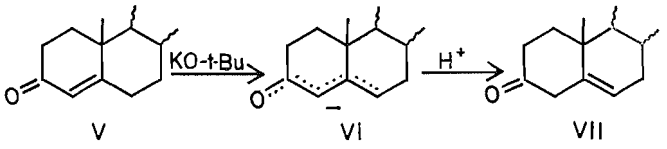
Relative rates of base-catalyzed exchange of vinylic and allylic hydrogen, in an α,β-unsaturated ketone, have been determined. In refluxing heavy water, with OD^- catalyst, vinyl hydrogen was exchanged about 170 times as rapidly as allyl hydrogen. In CD_3OD containing CD_3O^- the two rates were equal or nearly equal at ambient temperature. Factors which may contribute to the observed difference between the relative rates are discussed and results of simple molecular orbital calculations are presented.

We have studied base-catalyzed, hydrogen–deuterium exchange in 6,6-dimethyl-2-cyclohexene-1-one I. Three reactions which might be expected between base and I are (*a*) abstraction of γ-hydrogen to form dienolate II, (*b*) addition to carbonyl carbon, and (*c*) addition at the β-carbon to form III.



In hydroxylic solvents, II would be converted to enol, to I, and to ketone IV by protonation at oxygen, at C_4 and at C_2, respectively. In basic medium IV would rapidly be isomerized to I. Similarly, III might be destroyed by protonation at oxygen or at C_2 forming products which would not accumulate, but which would readily revert to I. In basic, deuterated, hydroxylic solvent one would therefore expect that I would become labelled at C_2 and at C_4. Reaction (*b*), above, is not of interest in connection with hydrogen–deuterium exchange.

There is evidence that protonation of II should be faster at C_2 than at C_4.* Deconjugation of α,β-unsaturated steroidal ketones can be accomplished in excellent yield by protonation of the corresponding anions with aqueous acetic acid. For example, yields of 17α-methyl-Δ^5-androstene-17β-ol-3-one VII, from 17α-methyltestosterone V, were as high as 95% (1). Alkylation of anions of α,β-unsaturated ketones has also been shown to

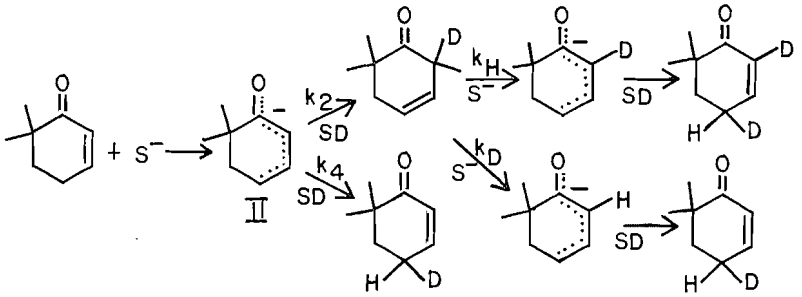


give predominantly the corresponding α-alkyl-α,β-unsaturated ketones and the α,α-dialkyl-β,γ-unsaturated products (2*a* and *b* and references cited therein). Of the two

**We are not concerned here with the rate of protonation at oxygen. That reaction is probably the fastest of all those that destroy II.*

anionic carbons in an ion such as VI, the α-carbon is clearly much more reactive than the γ-carbon, at least in the reactions cited above.

It is readily seen, however, that the rate of exchange of α-hydrogen in our system should not exceed the rate of exchange of γ-hydrogen if both processes involve enolization in the first step. This follows from the fact that α-deuterated IV, in isomerizing to I in deuterated solvent, must pick up deuterium at C_4. Such isomerization could involve loss of either hydrogen or deuterium from C_2 with an associated isotope effect k_H/k_D. From the equations below, for exchange by an enolization mechanism, it is seen that there is only one route leading to exchange at C_2 whereas there are three paths for exchange at C_4.



If we designate the rate of labelling at C_2 by dC_2/dt and that of labelling at C_4 by dC_4/dt, then the *initial* rates of exchange are

$$dC_2/dt = [k_2k_H/(k_H + k_D)][SD][II]$$

and

$$dC_4/dt = (k_2 + k_4)[SD][II].$$

Division gives the ratio of initial rates

$$dC_4/dC_2 = [(k_H + k_D)/k_H][1 + (k_4/k_2)].$$

We can set the limits $2 > (k_H + k_D)/k_H > 1$, since k_D will be smaller than k_H. For $k_4 = k_2$, we would then expect $4 > dC_4/dC_2 > 2$, if all exchange occurred via an enolization mechanism. On the other hand, if $k_4 \ll k_2$, then $2 > dC_4/dC_2 > 1$, and if $k_4 \gg k_2$ the rate ratio would be large.

EXPERIMENTAL

General

Rates of exchange were followed by n.m.r. spectrometry with a Varian HR-60 instrument. Exchange with heavy water was followed by periodic withdrawal of samples of ketone from the upper layer of the heterogeneous system. These samples were dissolved in $CDCl_3$ for recording of the n.m.r. spectra (60 Mc). The signals from nonexchangeable groups, such as the methyl groups at C_6 or the C_5 methylene group were used to determine the area per proton. The C_2 proton signal was a doublet at $\tau = 4.03$ while the C_3 proton signal was a sextet centered at $\tau = 3.06$, relative to internal tetramethyl silane. Proton signals centered at $\tau = 8.15$ (triplet) and $\tau = 7.59$ (multiplet) were assigned to the C_5 and the C_4 methylene groups, respectively. Four integrations per sample were averaged to calculate deuterium content.

Exchange with CD_3OD–CD_3O^- was carried out in an n.m.r. tube. Successive integrals of the spectral signals were recorded as rapidly as possible after addition of ketone to the tube.

The number of gram atoms of deuterium per mole incorporated in a given position of the ketone was calculated from the integrated area of the proton signal for that position. Such numbers were plotted against time and initial rates were estimated from the slopes of tangents drawn to the curves at the zero time.

Synthesis of 6,6-Dimethyl-2-Cyclohexene-1-one

6,6-Dimethyl-2-cyclohexene-1-one was synthesized according to a method described in the literature (3). The crude ketone was purified by preparative gas–liquid chromatography (g.l.c.) using a 20 ft × $\frac{3}{8}$ in.

column packed with 30% SE30 on Chromosorb P in the Aerograph A-700 instrument. The ultraviolet spectrum had $\lambda_{max} = 227$ and the semicarbazone of the hydrogenation product had m.p. 196–198° (3).

Exchange in D_2O

The ketone (10.0 g, 0.087 mole) was refluxed with 15 ml of heavy water (atom % D over 50) containing one pellet of NaOH. Samples of ketone were withdrawn at the intervals shown in Fig. 1.

Exchange in CD_3OD

Deuteromethanol (99 atom % D) was obtained from Merck Sharp and Dohme of Canada. To a sliver of freshly cut sodium in an n.m.r. tube was added 0.35 ml of the alcohol. When the sodium had dissolved, the tube was chilled with dry ice and about 40 mg of 6,6-dimethylcyclohexenone was added from a small syringe. The tube was sealed while cold and it was then warmed rapidly to room temperature. Integration of the n.m.r. signals was begun about 4 minutes after introduction of the ketone. The base strength was found to be 1.8×10^{-4} *M* by titration of the mixture at the end of the kinetic run.

RESULTS AND DISCUSSION

The results indicate that the relative rates of exchange depend on the base and on the medium employed. When exchange was catalyzed by OD^- in D_2O, γ-hydrogen was exchanged about 0.0059 times as rapidly as α-hydrogen (Fig. 1).

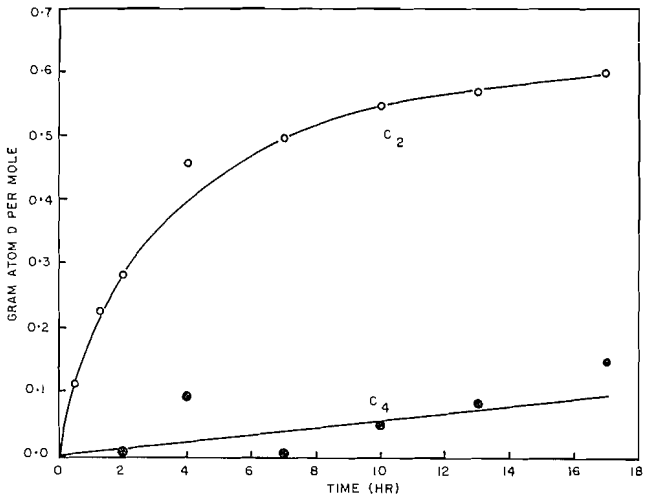


FIG. 1. Rates of exchange, catalyzed by OD^- in D_2O.

Due to the rapidity of exchange in the medium CD_3OD–CD_3O^-, rate data were not obtained in the region below 50% reaction. As our kinetic expression applies to the ratio of initial rates only, it was necessary to estimate that ratio from the experimentally available portion of the rate curves. The fact that these curves lie close together and appear to be nearly parallel allowed us to extrapolate them smoothly to the origin. Although absolute values of initial rates, obtained in this way, would depend critically on the manner of extrapolation, relative values should be more reliable if both curves are extrapolated in the same manner, The ratio of rates dC_4/dC_2, in methanolic medium, was estimated to lie between 1 and 1.7 (Fig. 2).

One way of accounting for the small ratio, dC_4/dC_2, in aqueous medium is to postulate an addition–elimination mechanism as depicted below. Analogy for the reaction is found in the well-known Michael additions of carbanions to α,β-unsaturated ketones. The

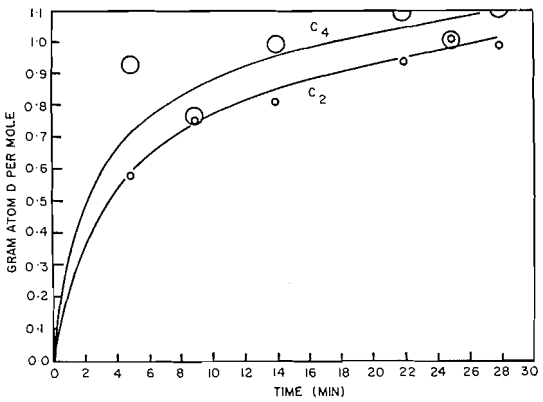

FIG. 2. Rates of exchange, catalyzed by CD_3O^- in CD_3OD.

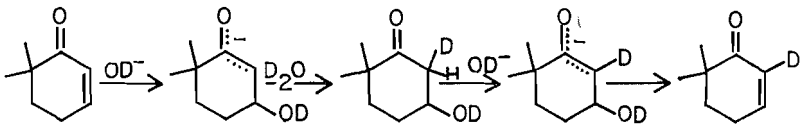
addition–elimination mechanism has been advanced to account for exchange of α-hydrogen in nonenolizable α,β-unsaturated ketones (4).*



The radically different behavior in the methoxide–methanol system cannot be explained satisfactorily at this time. Factors which may contribute are (*a*) steric hindrance to β-addition and (*b*) different relative nucleophilicities, toward hydrogen and toward unsaturated carbon, of hydroxide and methoxide.

Models of I and III show that steric hindrance to axial-like approach of a base toward the β-carbon of I is not severe for small ions like the ones in question. However, it should be emphasized that exchange with D_2O–OD^- was carried out at about 100°, while that with methoxide occurred at about 20°. Thus any difference between the entropies of activation for β-addition of the two bases to I would exert an effect, on the relative rates of the two addition processes, which would be magnified by the temperature difference. This suggestion is subject to experimental test and we are studying the temperature dependence of the relative rates of exchange at C_2 and C_4.

Nucleophilic reactivity has recently been reviewed (6). The reactivities of nucleophiles toward hydrogen correlate well with their basicities (6), with some exceptions (7, 8, 9).† However, the basicities of hydroxide and methoxide are probably not greatly different (9, p. 45) and the difference is solvent dependent. The relative nucleophilicities of hydroxide and methoxide in Michael-type additions do not appear to be recorded in the literature. Therefore it does not seem possible at this time to predict the magnitude or even the direction of the effect, on rates of exchange, of a difference between the relative nucleophilicities of hydroxide and methoxide toward γ-hydrogen and β-carbon of I.

If the action of methoxide on I, for whatever reason, is primarily the abstraction of

**It has been pointed out by a referee that intramolecular, base-catalyzed isomerization (5) of IV-αd_1 to I-αd_1 may contribute to the enhanced rate of α-exchange relative to that of γ-exchange. Such a process, however, must be unimportant in the aqueous exchange since the isotope effect, k_H/k_D, that would be required to accommodate the data in terms of such a mechanism alone, is too large by more than an order of magnitude.*

†Notable exceptions are some bimolecular eliminations in which thioalcoholate and thiophenolate anions surpass alcoholate and phenolate ions, respectively, as catalysts (7, 8). The effectiveness of carboxylate ions in catalyzing bromination of ketones is also not reliably correlated with their basicities (9).

γ-hydrogen, then the observed rate ratio, $1.7 \geqslant dC_4/dC_2 \geqslant 1$, (see above for predicted ranges of values) requires that the dienolate anion be protonated more rapidly at C_2 than at C_4. Such a rate difference must be responsible for the isomerization of V to VII and finds further analogy in the alkylation reactions of such ions (*vide supra*). Kinetic, rather than thermodynamic, control of the protonation step can be rationalized in terms of a transition state resembling the dienolate anion (10), with the latter having a nonuniform distribution of charge.

We have carried out Hückel molecular orbital calculations (11, 12) to estimate the charge distribution in the anion. In the simplest calculation, with an uncharged system such as the dienol or a dienol ether as the model, we used $\alpha_O = \alpha_C + 2\beta$ for the Coulomb integral of oxygen and $\beta_{CO} = \beta_{CC}$. The following charge densities were obtained.

O	C_1	C_2	C_3	C_4
−0.872	+0.125	−0.155	+0.015	−0.116

An improved calculation for the anion recognizes that oxygen probably bears more of the charge than any of the carbons and that its electronegativity is decreased more as a consequence. Calculation using $\alpha_O = \alpha_C + 1.5\beta$ and $\beta_{CO} = 0.8\beta_{CC}$ gave the charge densities below.

O	C_1	C_2	C_3	C_4
−0.892	+0.107	−0.114	−0.045	−0.057

These qualitative results, for the relative charge densities at C_2 and C_4, support the rationale for the relative reactivities at C_2 and C_4 of the anion of an α,β-unsaturated ketone.

Current work is directed toward testing for the origin of the difference in relative rates of exchange reported here and toward investigation of exchange rates in other systems.

ACKNOWLEDGMENTS

We are indebted to the National Research Council for financial support of this work. Mr. Oswald Tee carried out the second molecular orbital calculation.

STRONGLY BASIC SYSTEMS

III. THE H_- FUNCTION FOR VARIOUS SOLVENT SYSTEMS[1]

ROSS STEWART AND J. P. O'DONNELL[2]

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received January 13, 1964

ABSTRACT

The Hammett acidity function concept has been used to determine simultaneously the pK_a values of 24 substituted anilines and diphenylamines and the H_- values of various solvent systems. The following solvent systems were examined (the most basic H_- value obtained for each is shown in parentheses): water containing benzyltrimethylammonium hydroxide (16.20); pyridine–water containing tetramethylammonium hydroxide (18.91); sulpholane–water containing tetramethylammonium hydroxide (19.18); dimethyl sulphoxide – water containing tetramethylammonium hydroxide (18.61); water containing lithium hydroxide (14.31).

In addition to these results adjustments have been made to previously published scales for hydrazine–water (15.08) and ethylenediamine–water (15.48).

INTRODUCTION

During the past few decades there has been intense interest in the chemistry of strongly acid systems. Studies of the equilibrium protonation of weak bases and of acid catalysis continue to contribute to our knowledge and to a widening of our understanding of the concept of acidity. There is a continuous acidity scale that runs from pure water to pure sulphuric acid and beyond and covers a range in which the acidity varies by a factor of about 10^{20}. Until very recently only a few attempts had been made to extend the region of measurable acidities to strongly basic systems.

Pioneer measurements of the strength of very weak acids using an equilibrium approach were made by Conant and Wheland (3) and McEwen (4). They used ether solutions of carbanions, produced by reaction with metallic potassium, to determine the relative strength of weak acids through the equilibrium

$$HA_1 + A_2^- \rightleftarrows A_1^- + HA_2.$$

They deduced the position of equilibrium by colorimetric methods and so were able to determine acidity constants. They used methanol as a standard, assigning it a value of 16. It should be noted here that apparent acid strengths and even the order of acidity of acids can be different in solvents of low dielectric.

Stearns and Wheland (5) measured the strengths of some very weak acids by measuring the small amount of ionization that is detectable in aqueous or alcoholic alkali and assuming that this is the beginning of an ideal ionization curve. This method is unreliable with certain compounds such as *p*-nitrobenzyl cyanide.

Schwartzenbach and Sulzberger (6) tackled the problem of determining the basicity of concentrated alkalies. They found that the extreme insolubility of indicators prevented a normal spectrophotometric approach. They then added solvents, which contained indicators, to the various aqueous hydroxide solutions and determined the fraction ionized in the solvent layer. The drawbacks of this method have been discussed by Edward and Wang (7), who used thioacetamide as indicator in order to overcome salting-out problems.

[1]*A preliminary account of part of this material has appeared elsewhere (ref. 1); a joint paper dealing with a rate–equilibrium correlation and making use of some of the results reported herein has also appeared elsewhere (ref. 2). These papers can be considered Parts I and II of the series.*

Taken in part from the Ph.D. thesis of J. P. O'Donnell, University of British Columbia, 1962.

[2]*Present address: Imperial Oil Co. Ltd., Sarnia, Ontario.*

In 1952 Deno (8) made the first attempt to construct the H_- function in a mixed solvent system, using water containing various concentrations of hydrazine up to 65% hydrazine in water. The H_- scale for this system reached 16.0 for 65% hydrazine. Deno's pK_a values are also found in Table I. A priori, hydrazine seems to be the best choice of

TABLE I

Summary of previously determined pK_a values

System	Ethylene diamine/ water	Ethanol-amine/ water	Hydra-zine/ water	*t*-Amyl alcohol	Hydra-zine/ water	Sulpho-lane/ water	Etha-nol/ water

2-Nitrodiphenylamine	>19	18.85	—	18.80	—	—	—

solvent for this type of work from the standpoint of its physical properties: low acidity, high dielectric, suitable optical clarity, freezing point, boiling point, and viscosity. It is, however, difficult to find indicators for this system. Hydrazine reacts rapidly with many nitro compounds which are useful indicators in other systems; with some anions very large shifts in the wavelength of light absorption are observed. For example, Shatenshtein (9) has observed a wavelength shift of 120 mμ for the metanitrophenolate anion between 0.005 N sodium hydroxide and anhydrous hydrazine, with lesser but still troublesome shifts for other anions. In general, Shatenshtein found the comparable shifts in liquid ammonia to be much less and concluded that the shifts in hydrazine were probably due to the formation of molecular compounds. In all, it will be difficult to improve Deno's original choice of indicators for the hydrazine system. Some of the indicators studied by Deno, however, were not fully ionized since, as will be subsequently seen, there is a levelling of the H_- function for hydrazine near 65% composition.

Schaal and co-workers entered this field in 1955, using solutions of ethylene diamine in water as the basic system (10), and since then have published many papers (11–16) covering the systems ethanolamine in water, hydrazine in water, and tertiary amyl alcohol containing its sodium salt. They provided pK_a values for many weak acids, many of which are listed in Table I. Schaal and his co-workers obtained limiting values of 15.35 for anhydrous ethanolamine, 18.2 for ethylenediamine, and 19.4 for the tertiary amyl alcohol solutions.

Langford and Burwell (17) recently investigated sulpholane–water mixtures containing phenyltrimethylammonium hydroxide. They obtained an H_- value near 20 for a solution 95 mole % in sulpholane, 5 mole % in water, and 0.013 molar in phenyltrimethylammonium hydroxide. Sulpholane appears to be a good solvent in which to study a wide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

range of acidities since, as they point out, a 0.01 M solution of sulphuric acid in sulpholane is a much stronger acid than the same concentration of sulphuric acid in water. Similarly, sulpholane containing 5% water is a million times more basic than pure water when both contain 0.01 M hydroxyl ion. Langford and Burwell suggest that most of the difference is due to the increased activity coefficient of the hydroxyl ion.

The pK_a values determined by all these investigators are summarized in Table I. A critical comparison of these values shows that our knowledge of the pK_a values of weak acids is indeed in a state of confusion. Paul and Long (18), in comparing the values reported by Schaal and Deno state "this large discrepancy casts considerable doubt on the assumption that these H_- scales are independent of the indicator used and makes it imperative that this be tested by studies with other indicators."

Kinetic methods have frequently been used to compare acidities (19–23) and this technique has been augmented by the use of deuterium isotope exchange experiments. Shatenshtein (9, 19) concludes that there is usually a direct connection between the point of equilibrium in protolytic reactions and its rate of attainment and that the rate of hydrogen exchange may serve as one method of determining the strengths of very weak acids. He and his colleagues have published extensively in this field, using hydrogen exchange reactions in liquid ammonia. Streitwieser *et al.* (21) have used lithium cyclohexylamide – cyclohexylamine systems to measure deuterium exchange and so determine hydrocarbon acidities. Hofmann, Muller, and Schriesheim (22) have used tritiated dimethyl sulphoxide to measure the acidities of several aromatic hydrocarbons; Dessy, Okuzumi, and Chen (23) have determined relative acidities for a series of weak acids using dimethylformamide as solvent, triethylamine as catalyst, and deuterium oxide as deuterium source. Hart and Crocker (24), using α-deuterioethylbenzene as a deuterium source, measured the rate of deuterium transfer to other related hydrocarbons in the presence of potassium and concluded that cumene was 13 times more acidic than 2,2-dimethyl-3-phenylbutane.

An examination of Table I shows that existing measurements of the acidity constants of very weak acids have led to many differing results. The agreement for 4-nitrobenzyl cyanide will be shown in a subsequent paper to be only apparent. The prime purpose of this work, therefore, was to discover whether consistent values for these weak acids could be found and in so doing determine the H_- function for as many systems as possible.

It was decided to use indicators as closely allied in molecular structure as possible. The substituted anilines and diphenylamines provided a series of compounds of varying acidity well suited to our purpose. A parallel study was therefore initiated on the relation between structure and acidity in these compounds and this is reported in a subsequent publication. Because of the conflicts in values reported by other investigators it was necessary to reexamine their systems in order to pinpoint sources of disagreement.

The term acidity function and the symbol H_- are used to designate the equilibria studied in this work. The well-known Hammett acidity function, H_0, refers to the ability of a solvent to protonate a neutral base.

$$B + H^+ \rightleftharpoons BH^+$$

Hammett (25) pointed out that a different function, H_-, might govern the protonation of an anionic base, and this has proved to be the case in acid solution (26, 27).

$$A^- + H^+ \rightleftharpoons HA$$

In strongly basic systems the ionization of the aniline and related indicators would normally be written as follows.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$ArNH_2 \rightleftharpoons H^+ + ArNH^-$$

$$\text{or } ArNH_2 + OH^- \rightleftharpoons H_2O + ArNH^-$$

One can conveniently express these equilibria in terms of the H_- function, however, and this has been done by us and by most other workers in the field. (See Experimental section.)

RESULTS

Establishment of the H_- Function and Acidity Constants

The experimental data on the compounds used as indicators is summarized in Table II.

It shows the wavelength of maximal absorption and the extinction coefficient at that wavelength for each compound for both the molecular and anionic species in various solvents.

The pK_a value of 2,4,6-trinitroaniline was determined in aqueous buffers and sodium hydroxide to be 12.20, in good agreement with the work of Schaal (28), who reported 12.25. This indicator was then used to determine the H_- value for several different mixtures of pyridine in water containing 0.011 molar benzyltrimethylammonium hydroxide. It was then possible to determine in the same solutions the fraction ionized for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

2,4,4′-trinitrodiphenylamine. A best fit straight line was then drawn through these measured points to determine the pK_a difference from 2,4,6-trinitroaniline. This procedure could be applied repeatedly for successive indicators. Thus, 2,4,6-trinitroaniline is the compound analogous to 4-nitroaniline which was used in building the H_0 scale in acid solutions (18, 25).

Now pK_a values were assigned to the indicators. These individual pK_a values were then used to calculate the H_- value for each solution in which the position of its ionization equilibrium was measurable. This procedure resulted in several measured H_- values for each solution. These values were averaged, and the results are summarized in Table III.

The H_- values for the various concentrations of pyridine in water were now considered known, and Fig. 1 was produced by plotting the original values of log $[A^-]/[AH]$ against

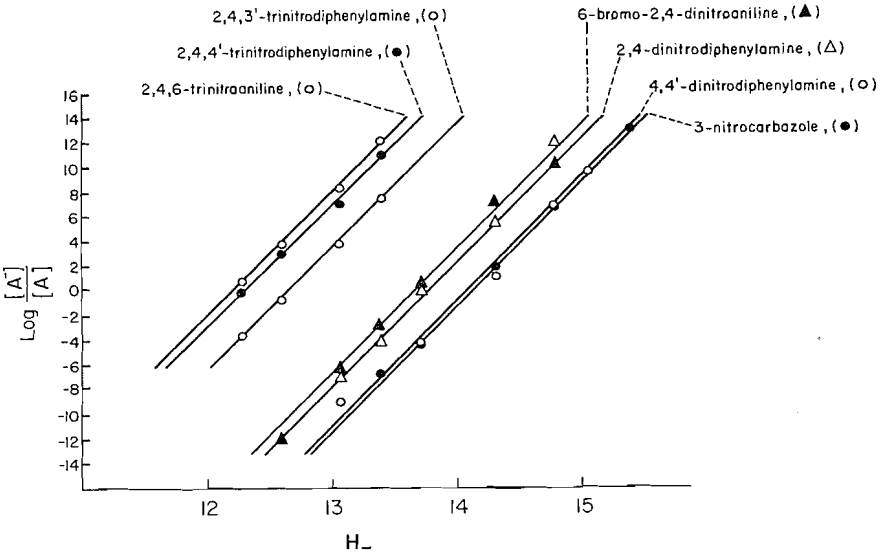

FIG. 1. The ionization of several indicator amines as a function of the basicity of the solution.

H_-. H_- appears to be an acceptable function for the system since the plots are parallel straight lines of unit slope, although it should be pointed out that these indicators are closely similar in molecular structure.

For this system it was not found possible to make determinations above 60 mole % pyridine. Near this point the indicator plots are found to be no longer parallel, and immiscibility problems arise.

Presumably, the irregularities in the ionization plots are chiefly due to decreasing dielectric constant. If it is assumed that change in dielectric is linear with mole fraction in a mixture of the two liquids, the dielectric of 60 mole % pyridine in water will be less than 40. The effects observed in this work seem greater than the expected effect of dielectric on $\log f_{A^-}/f_{AH}$, and it is possible that some effects due to ion pairing or molecular association are present. Hummelstedt and Hume (29) have concluded there is no hope for successful pK_a measurements in solvents such as benzene where association phenomena are very pronounced.

Operations were carried out in the same way for aqueous sulpholane as for aqueous pyridine systems, using the same indicators. The higher dielectric of sulpholane allowed continuance of the measurements from 100% water to 95 mole % sulpholane. The

The broken lines are the calculated values of the basicity of aqueous ethylene diamine (A) and aqueous hydrazine (B) solutions containing no added base, using the data of Schaal *et al.* (11, 13, 28).

FIG. 3. The variation of H_- for aqueous benzyltrimethylammonium hydroxide with the hydroxyl ion molarity (○), and with the logarithm of the hydroxyl ion molarity (●).

quaternary base was added in aqueous solution to bring the base concentration to 0.011 molar. The results are summarized in Table III and Fig. 2.

The entire operation was repeated using solutions of benzyltrimethylammonium hydroxide in water. This quaternary base has high water solubility and may be prepared in 2.38 molar solution. Figure 3 and Table III show the results obtained in this system.

Table IV shows a complete summary of the pK_a values determined in the present work and shows the average values obtained in these basic systems. It may be noted that better agreement is actually found between determinations in different solvents than the variations in log $[A^-]/[AH]$ for an individual indicator would lead one to expect.

Use of Acidity Constants to Establish H_- for Other Solvent Systems

Once an established list of acidity constants, such as Table IV, is available, it can be used to measure H_- values in other solvent systems. An investigation was carried out on the effect of increasing the base concentration in water–pyridine mixtures. Benzyltrimethylammonium hydroxide is available as a 2.19 molar solution in anhydrous pyridine. Thus, by mixing these two solutions in calculated proportions with pyridine or water, one can obtain any desired proportion of pyridine–water containing up to 2.0 molar base. Measurements in each solution were carried out with several indicators. The results are included in Table III. The indicators were also used in this manner to establish the H_- function for dimethyl sulphoxide – water mixtures containing 0.011 molar tetramethylammonium hydroxide. The extinction coefficients of maximal absorption were determined in solutions as close as possible in composition to those in which the measurements were carried out.

The indicators employed in this work possess marginal solubilities in aqueous lithium hydroxide. Measurements were made up to 5 molar (saturated) lithium hydroxide by use of 10 cm cells. Even with this path length optical densities were very low, and the results are accordingly not of high accuracy but are believed to represent at least roughly the H_- function in these systems.

Measurements were even more difficult in aqueous sodium and potassium hydroxides. For 1 molar sodium hydroxide the results agree with those for lithium hydroxide, within

the experimental error, but attempts to make measurements in more concentrated solutions with these indicators had to be abandoned. (See, however, refs. 6 and 7.)

DISCUSSION

How can we be sure we are actually dealing with a proton removal process producing an anion? At present no cryoscopic work has been done in any of the solvents, so no direct statement of the number of particles present is possible. Partly for these reasons an examination of several compounds which could not lose a proton under the reaction conditions was undertaken. These were *N*,*N*-dimethylpicramide, 1,3,5-trinitrobenzene, the picrate anion, and nitrobenzene. Each of these showed a spectral change when dissolved in a solution of sufficiently high basicity. However, all of them reacted at a finite rate, and for all of them the reverse reaction was also slow when the basicity of the solution was reduced.

This then became one of our main criteria: we accepted as simple proton removal only those reactions which were apparently instantaneous and which reversed instantaneously. All compounds whose pK_a value we have reported obey this criterion. 3,5-Dinitroaniline, for example, reacted slowly in our most basic solutions to produce a stable species, and the reverse reaction was also slow. Because of these observations it was decided that a pK_a determination would not be meaningful.

Difficulties of a similar nature were encountered for 4-nitrophenylhydrazine, 2,4-dinitrophenylhydrazine, and 2,4,6-trinitrophenylhydrazine.

Correlation of Results with Those of Other Investigators

It will be shown in a subsequent publication that the indicator 4-nitrobenzyl cyanide is an unsatisfactory compound on which to build an acidity scale. We have reevaluated the pK_a quantities in Table I by choosing new starting points for the scales of Schaal *et al.* and Langford and Burwell. Accordingly, the value of 13.63 for 6-bromo-2,4-dinitroaniline, as determined in this work, was used as a starting point for Langford and Burwell's work instead of the slightly different value of 13.71, obtained by comparison with 4-nitrobenzyl cyanide (17). The pK_a differences determined by them were then used to build up Table V. (It can be seen that the alteration in pK_a value is very small for every case except 2,4-dinitroaniline.)

Schaal's data for ethylenediamine were replotted after assigning the value of 13.84 instead of 14.65 to 2,4-dinitrodiphenylamine (11, 28).

An examination of Table V shows that disagreements in pK_a determinations are largely removed by these procedures. Also included in Table V are values obtained by Schaal *et al.* in ethanolamine (12) and tertiary amyl alcohol (14). These were determined by an extrapolation procedure since full ionization was not attained. It is satisfying that these values are in at least rough agreement. These values have all been adjusted by 1.02 pK units since we have adjusted 2,4-dinitroaniline by that amount. Hydrazine–water systems were treated in the same way (13).

Interpretation of Solution Basicity

The enhanced basicity of the solutions studied in this work appears to be due chiefly to an enhancement of the hydroxyl ion activity, as suggested by Langford and Burwell (17).[3] The following equilibrium,

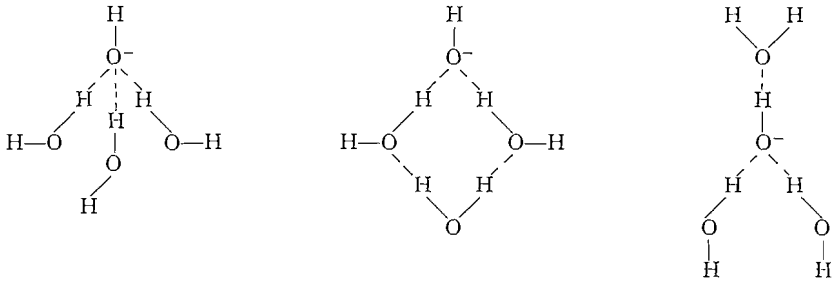
$$ArNH_2 + OH^- \rightleftharpoons ArNH^- + H_2O,$$

shifts to the right as water is replaced by a polar aprotic solvent, not merely because of

[3]*See also refs. 30–32.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

a mass action effect but principally because of the altered activities of the ions involved. As water is replaced by the second solvent, the activity of both OH^- and $ArNH^-$ will rise, since water is very effective at stabilizing anions by hydrogen bonding. The hydroxyl ion is probably coordinated to three water molecules (32–35); three such arrangements are shown below.



(The third structure above is similar to that of $H_9O_4^+$ (35, 36) less two protons. However, as Yagil and Anbar point out, the OH^- proton is unlikely to form a strong hydrogen bond to water (32)). The larger anion, $ArNH^-$, with extensive internal charge delocalization, is less sensitive to solvation changes and the equilibrium, above, shifts to the right. (In the case of the pyridine, sulpholane, and dimethyl sulphoxide systems it was necessary to add a strong base, but for aqueous hydrazine and ethylenediamine the hydroxyl ion is present because of the intrinsic basicity of the solvent molecules themselves.) It has recently been shown that the rates of nucleophilic displacements and other base-catalyzed reactions are sharply increased by addition of polar aprotic solvents, and similar explanations have been offered (30).

The above ideas explain satisfactorily the general effect of polar aprotic solvents on solution basicity, but they do not account for the individual variations that exist in the effects of the various added solvents (Fig. 2). Specific interactions probably occur between the molecules of added solvent and molecules of water on the one hand and the cations and anions on the other. Ion pairing is probably important only in the solutions that are rich in pyridine (or ethylenediamine), since all the other solvents have reasonably high dielectrics.

The purely aqueous system, containing benzyltrimethylammonium hydroxide (Fig. 3), also shows exalted basicity at high concentrations of the base. The broken line is simply a linear H_- versus log [OH^-] plot and represents the H_- value expected if the various ion activities remained unity. Beyond about 2 molar base the solution basicity rises dramatically, and this rise presumably reflects a decrease in the number of available water molecules for the solvation spheres of the ions.

EXPERIMENTAL

Preparation of Solvent Systems

Sulpholane (tetramethylene sulphone) was purchased from the Shell Development Company and distilled over sodium hydroxide according to the procedure of Langford (17). This solvent, b.p. 112° at 1 mm, was optically clear above 250 mμ. Dimethylsulphoxide was Baker reagent grade and was distilled over sodium hydroxide pellets before use. Fischer reagent grade pyridine was distilled over barium oxide to remove water, and had b.p. 115° at 760 mm. Eastman White Label 95% hydrazine was used without further purification. The percentage hydrazine was determined by the iodine titration procedure given by Audreith and Ogg (36). Eastman 98% ethylenediamine was distilled over sodium to remove water. This solvent does not remain optically clear during storage even if protected from sunlight, moisture, and oxygen. Anhydrous methanol was prepared by distillation over magnesium.

Potassium acid phthalate buffers covering the pH range from 2.2 to 6.2 (37) and potassium dihydrogen phosphate buffers covering the range from 5.8 to 8.0 were prepared. For the range 8.45 to 12.77 glycine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

buffers were used. These buffers were diluted so that the ionic strength was not greater than 0.1. Sodium hydroxide, 0.1 *N*, prepared from commercial standard sodium hydroxide, was used as a 12.88 pH standard. All pH measurements were made using a Beckman model G pH meter, equipped with a calomel reference electrode and a standard glass electrode. The Beckman E_2 "blue" electrode was used for all measurements above pH 11. Benzyltrimethylammonium hydroxide (40% in water) was used as purchased from British Drug Houses. Tetramethylammonium hydroxide (10% in water), tetra-*n*-propylammonium hydroxide (10% in water), and phenyltrimethylammonium hydroxide (20% in methanol) were Eastman White Label. Benzyltrimethylammonium hydroxide (40% in pyridine) was prepared according to the method of Sprinzak (38) from a methanol solution of benzyltrimethylammonium hydroxide, which was purchased from Columbia Organic Chemicals.

The solvent systems were prepared in the following way. Aqueous benzyltrimethylammonium hydroxide (40%) was diluted with freshly distilled water to obtain a series of 10 solutions containing various concentrations of the base. These were then titrated with standard sulphuric acid to a phenolphthalein end point. A series of similar solutions were then prepared by mixing the 10 solutions with varying amounts of pyridine to obtain a set whose pyridine to water mole ratio was 50:50 and a second set in which the pyridine to water mole ratio was 30:70. To keep the base concentration as high as possible, a 40% benzyltrimethylammonium hydroxide solution in pyridine was prepared. The pyridine to water ratio was calculated from a knowledge of the amounts of pyridine and water added, and the final base concentration was determined by titration. Pyridine–water mixtures were prepared by weighing calculated amounts of the components, as were the sulpholane–water mixtures and the dimethyl sulphoxide – water mixtures.

Solutions of lithium and sodium hydroxides were prepared by dissolving a weighed amount of the hydroxide in the calculated amount of water and filtering to remove carbonate. Weighed aliquots of these solutions were then titrated to determine the concentration of hydroxide. The potassium hydroxide solutions were already clear and no carbonate removal step was carried out.

Preparation of Indicators

References to syntheses of indicators are listed in Table II. All other compounds were available commercially.

N-t-butylpicramide had not been prepared previously and was obtained by refluxing 0.02 moles of tertiary butylamine with 0.01 moles of picryl chloride for 1 hour in ethanol. The product, after several recrystallizations from ethanol, was orange needles, m.p. 94–95°. Anal. Calc. for $C_{10}H_{12}N_4O_6$: C, 42.56; H, 4.22; N, 19.31. Found: C, 42.26; H, 4.16; N, 19.71.

Measurement of Spectra

A sample of each indicator was weighed and dissolved in acetone to make a 10^{-3} molar stock solution. Aliquots were pipetted from this solution directly into a 1 cm quartz cell equipped with a ground stopper. The acetone was then evaporated at an aspirator, and 2 ml amounts of the solvent under examination were added by means of a volumetric syringe. This technique was easily adaptable to an oxygen-free method. The cell was sealed with a silicone-rubber stopper of the type used in vapor phase chromatography. The cell was then flushed with dry nitrogen by an inlet and outlet pair of syringe needles. The solvent under consideration could then be added through the silicone stopper. This stopper proved satisfactorily leakproof even after several puncturings by small-gauge needles. Provided the solutions used are degassed previously, this technique prevents oxygen from seriously affecting the equilibria.

It was found that the bases employed reacted reasonably rapidly with sulpholane to produce a species which showed appreciable light absorption below 400 mμ. This reaction was accompanied by a drop in the basicity of the solutions. Because of this change, stock solutions of sulpholane containing the base could not be kept, and the following procedure was adopted. The indicator sample was first dissolved in a solution of known sulpholane–water concentration and the base added in water solution (20 microliters) immediately before taking the spectral measurements. The solvent composition was corrected for the added water. For consistency, this same procedure was adopted for pyridine–water systems and dimethyl sulphoxide – water systems. Also, it was not considered advisable to keep the highly basic solutions for any length of time. Calculation, based on known densities of the mixtures, then provided the final mole % values as reported.

For these systems it was possible to record the molecular spectrum and the anion spectrum in solutions of nearly identical composition. For other systems (buffers, benzyltrimethylammonium hydroxide in water, or hydrazine) the unionized spectrum was recorded in at least two solutions above the point where ionization appeared to be complete. These solutions were shown to be of higher basicity by their effect on a weaker acid. In this way it was possible to be certain that all compounds were fully ionized and to obtain extinction coefficients for both the molecular and anionic form in solutions of reasonably similar composition. All solvents were tested for optical clarity in the regions used, and a solvent blank of the same concentration as that containing the indicator was used.

The spectrum of the indicators employed varied little over the solvent composition range necessary to fully ionize the molecule. This was checked by making measurements at two different positions on the anion spectrum. A good check of this point is the agreement of the ionization equilibria of one indicator with the next. If an indicator shows serious anomalies, the difference in the quantity log $[A^-]/[AH]$ between it and the next indicator will not be constant.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

From one solvent system to another, however, certain significant differences were found for both extinction coefficients and wavelength maxima. (Table II does not include spectral data for all the solvent systems studied; these details may be found in the Ph.D. thesis of J. P. O'D., University of British Columbia, 1962.)

Visible and ultraviolet absorption spectra of the indicators were measured with a Cary Model 14 recording spectrophotometer to locate the wavelengths of maximal absorption of both the molecular and anionic forms. The actual optical density measurements were carried out at two or more wavelengths, using a Beckmann DU spectrophotometer whose cell compartment was maintained at 25° by means of thermospacers. All spectral changes were checked for reversibility.

Treatment of Data

The calculation of H_- and pK_a is carried out using the equation

$$H_- = pK_a + \log [A^-]/[AH].$$

In this work the good agreement of one indicator with another—parallel straight lines of virtually unit slope were obtained in all cases—has been taken as an indication that no serious media effects were encountered.

In aqueous solution calculations in this work were based on the theoretical-curve method because most of the indicators used in the pH range showed considerable absorption by the molecule at the wavelength of maximal absorption for the ion.

This method states that

$$\log [A^-]/[AH] = \log \alpha/(1-\alpha) = \log (\Delta D - \Delta D_u)/\Delta D_i - \Delta D)$$

where the symbols have the following significance.

α is the fraction ionized.

D_u is the difference between the optical density at the wavelength of maximal absorption for the anion and the optical density at the wavelength of maximal absorption of the molecule, when measurements are made in a solution where the amount of ionization is effectively zero.

D_i is the same difference measured in a solution where ionization is effectively complete.

D is this same difference measured in some intermediate test solution.

For many of the indicators in the mixed-solvent systems used in this work, the absorption of the molecule at the anion wavelength was negligible, or very small. In these cases the method described by Schaal (28) was used. In this procedure all measurements are made at the anion wavelength, and the fraction ionized is

$$\alpha = (D - D_{mol})/(D_{ion} - D_{mol})$$

where the symbols have the following significance.

D_{mol} is the optical density of the molecular form measured at the anion wavelength.

D_{ion} is the maximum optical density measurable at this same wavelength when the species is fully in the ionic form.

D is the optical density at this same wavelength measured in some intermediate test solution.

The first of these two methods may be expected to correct somewhat for medium effects on spectra, provided the medium effect on the molecule spectrum is in the same direction as on the anion spectrum.

The second method was favored in this work because of the time-dependent absorption in the blank and the resulting possibility of error in balancing. This error is negligible above 400 mμ, and all anions employed absorbed above this wavelength. Thus, with the second method all measurements could be made in an undisturbed region. Again, provided the Hammett postulate was closely followed, that is, that different solutions gave the same pK_a difference between two indicators, it was felt that medium effects could not be serious.

Probable Error

It is difficult to estimate a precise experimental error, but where simple spectra and good plots are obtained it is estimated to be about 0.05 units. In setting up a scale this error may be cumulative. Considerable effort was expended to measure each pK_a difference in many different solutions and to obtain closely spaced indicators, so that many measurements could be made of H_- for each test solution used. No observations have been used to determine H_- values where $\log [A^-]/[AH]$ was greater than 1.0 or less than -1.0 since the observational experimental error begins to increase rapidly outside this range.

The biggest single problem in obtaining high accuracy was insufficient solubility of the molecular form of the indicator. Particular attention was paid to this problem in aqueous solutions and in the most dilute of the mixed-solvent systems. This problem forced work at lower optical densities than was desired. Whenever work was carried out near the solubility limit, careful checks were made to ensure that complete solution had occurred, so that observational error was as small as possible. For the pH region it was found that several solutions of different but known pH gave the same calculated pK_a value.

No attempt was made to apply a thermodynamic correction. Such corrections are generally less than 0.1 log units and are probably much less than this in the present work, since the ionic strengths of the buffer solutions used were limited to 0.1 (39, 40).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Some error is probably introduced by solvent effects on spectra, but this error is believed to be small because of the good ΔpK_a agreements among the closely spaced indicators. The solubility problem became serious for solutions of benzyltrimethylammonium hydroxide in water but, fortunately, sufficient solubility to make reasonably accurate measurements was retained. In lithium hydroxide, even though 10 cm cells were employed, only small optical densities could be obtained and the results must be considered of marginal accuracy.

STRONGLY BASIC SYSTEMS

IV. SUBSTITUENT EFFECTS ON THE ACIDITY OF AROMATIC AMINES

ROSS STEWART AND J. P. O'DONNELL
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received January 13, 1964

ABSTRACT

The effect of ring substituents on the acidity of anilines and diphenylamines is examined. In general the effects are similar to those found in the analogous ionization of phenols. The acidities of diphenylamines having two or three nitro groups in one ring and variable substituents in the other ring can be correlated by the Hammett relation.

A good correlation is found between the acidities and basicities of aromatic amines, although basicity is more sensitive to the presence of ring substituents than is acidity. The relation of these results to the general question of first and second dissociation constants of dibasic acids is considered.

In Part III of this series (1) the acidity constants of a great many aromatic amines were reported, together with the H_- functions for several strongly basic solvent systems. The validity of any acidity scale for mixed solvents depends, in turn, on the validity of the general Hammett stepwise method of determining H_- and indicator pK values, a method which involves a considerable extrapolation from the standard state of pure water. Any structure–reactivity or rate–equilibrium correlations that can be tested are important, then, as independent checks of the validity of the scale. A rate–equilibrium correlation was reported previously (2). In this paper we should like to report some structure–acidity correlations that have emerged from this work. These are interesting in their own right, but in addition they strengthen our confidence in the validity of the scale and of the indicator acidities previously reported.

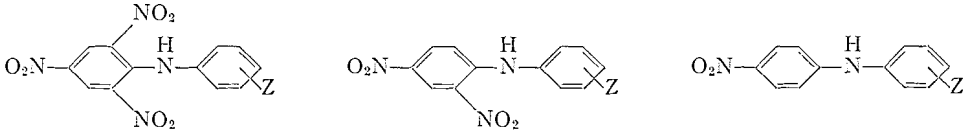
RESULTS AND DISCUSSION

Electron-withdrawing groups in the aromatic rings of the amines increase the acidity of the amino hydrogens and displace the following equilibria to the right.

$$ArNH_2 + OH^- \rightleftharpoons ArNH^- + H_2O$$

$$Ar_2NH + OH^- \rightleftharpoons Ar_2N^- + H_2O$$

If the general Hammett sigma–rho treatment is applied to the ionization of diphenylamines, it is found that the best correlation exists when σ^0 substituent constants (3, 4) are used. Figure 1 shows the correlation obtained for the three series A, B, and C, where Z is a meta or para substituent in all cases. (There is not enough data available to examine the anilines in this way, since all but one of these contain ortho substituents, which frequently produce anomolous effects. Similarly, since only two points are available for series C, below, no decision can be reached about the kind of sigma function being obeyed.)



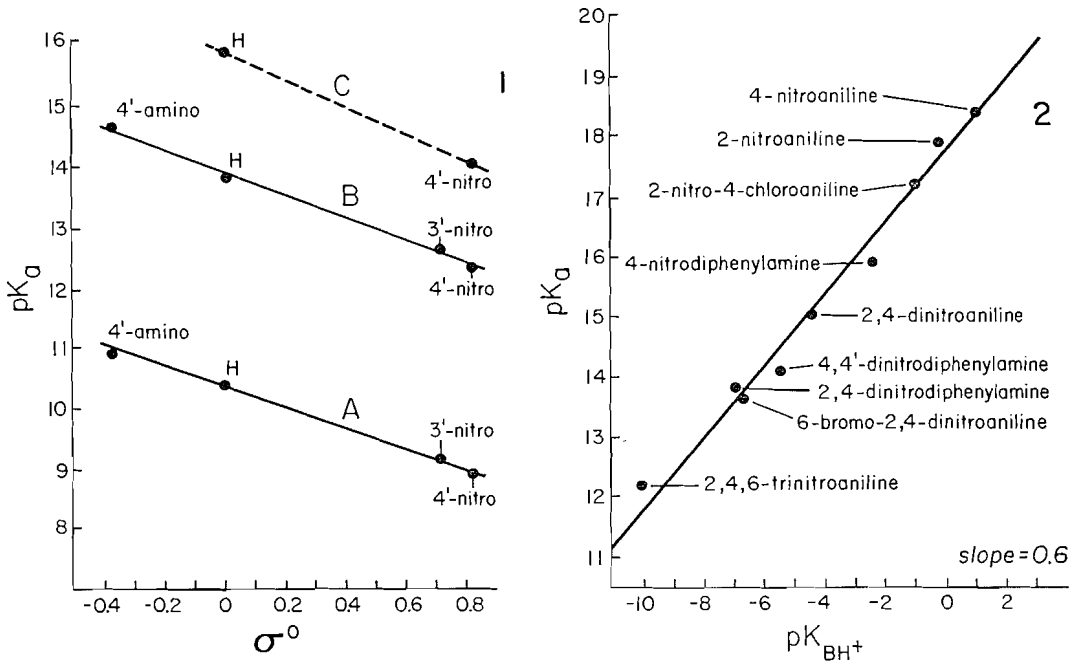


FIG. 1. Effect of an additional substituent on the acidities of nitrodiphenylamines: series A is 2,4,6-trinitrodiphenylamine, series B is 2,4-dinitrodiphenylamine, and series C is 4-nitrodiphenylamine.
FIG. 2. Acidities of aromatic amines (ordinate) plotted against their basicities (abscissa).

The substituent constants, σ^0, normally correlate reactivities for reactions in which conjugation between the substituent and the reactive center is absent (3, 4), whereas σ^- is used for reactions in which there is direct conjugation and σ for systems that possess the limited amount of conjugation present in benzoic acids (5, 6). It seems surprising, at first, that σ^0 constants give the best fit, since ortho and para nitro groups should interact strongly with the central $\rangle$NH and $\rangle$N$^-$ groups. It should be pointed out here that the present correlations are based on four substituents only, and the better agreement with σ^0 may be fortuitous. Nevertheless, it is worth speculating briefly on other possible causes of the less satisfactory correlation that exists for σ and σ^-. This correlation may result from a low degree of conjugation between the amino group and the substituent, simply because of the high degree of conjugation between the amino group and the ring, which is highly nitrated. Thus, for series A the ring with the Z-substituent may be oriented in such a way that much of its contribution to charge delocalization is sacrificed in order that the trinitro ring can interact powerfully with the central nitrogen. Only two points are available for series C, but it is probably significant that the apparent ρ is higher for this series suggesting that the substituent Z exerts a larger effect than in series A or B. (The next series, based on diphenylamine, undoubtedly has a much higher ρ, since work in progress shows that diphenylamine, itself, has a pK near 21.9 (7).)

The effect of substituents on the acidity of substituted anilines and diphenylamines resembles that found with phenols (6). The rho values for diphenylamine and phenol acidities are not strictly comparable, since, as we have seen, the former seem to correlate best with σ^0 values and the latter with σ^- values. Nevertheless, the effects of substituents are similar in the two series.

There are not enough compounds available to determine ρ for the acidity of anilines, but Table I shows that the effects of substituents on aniline and phenol acidities are also similar.

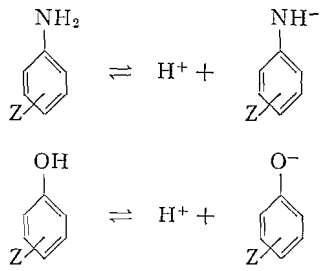

TABLE I

Comparison of the acidities of anilines and phenols

Substituent	pK_a Aniline	pK_a Phenol	ΔpK_a
2-Nitro-	17.88	7.08	10.80
4-Nitro-	18.37	7.15	11.22
2,4-Dinitro-	15.00	4.07	10.93
2-Nitro-4-chloro-	17.22	6.36	10.86
2,6-Dichloro-4-nitro-	15.55	3.48	12.17
2,4,6-Trinitro-	12.20	0.3	11.9

The extraordinary acidity of 2,4,6,2′,4′,6′-hexanitrodiphenylamine, which has a pK_a of 2.63 (1), suggests that both rings contribute strongly to the delocalization of charge (see, however, ref. 8). Charge delocalization may occur if the ion has the planes of its two aryl rings at right angles, so that maximum overlap occurs between the π-orbitals of each ring and two p-orbitals on nitrogen. This structure would require the central nitrogen to be sp hybridized, but the gain in resonance energy may be enough to make sp hybridization the most satisfactory arrangement. (An X-ray diffraction study of the potassium salt of 2,4,6,2′,4′,6′-hexanitrodiphenylamine was kindly undertaken by Dr. J. Trotter of this department, but the diffraction pattern was such that no decision could be reached with regard to the ion's geometry (9).)

TABLE II

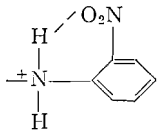
ΔpK for various nitro-substituted diphenylamines, showing the effect of nitro groups entering "other" ring

Amine	Position			
	3	4	2,4	2,4,6
4-Nitrodiphenylamine	—	1.82	3.59	7.02
2,4-Dinitrodiphenylamine	1.21	1.50	3.01	7.11
2,4,6-Trinitrodiphenylamine	1.23	1.50	3.66	7.75

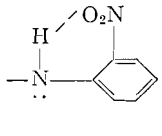
The addition of an ortho nitro group to 2,4,2′,4′-tetranitrodiphenylamine and to 2,4,6,2′,4′-pentanitrodiphenylamine also produces very large acidity increases; an important contributing factor in all these cases may be the relief of steric strain as the trigonal nitrogen of the amine is converted to the digonal nitrogen of the anion.

Fairly regular increases in acidity result from the introduction of nitro groups into diphenylamine. These effects are shown in Table II.

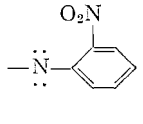
It is of interest to compare the effect of substituents on the acidity and basicity of diphenylamines. In Fig. 2 the pK_a and pK_{BH^+} values are plotted against one another, and a surprisingly regular effect is observed; surprising because many of the substituents are in the ortho position, and greater irregularities, caused by specific interactions such as the following (10), might have been expected (5, 6, 11, 12).



Strong H-bond



Weak H-bond



No H-bond

The slope of the line in Fig. 2 is approximately 0.7, meaning that substituents have a larger effect on the amines' basicity than on their acidity.

The matter of amine acidity and basicity is in essence the question of primary and secondary dissociation of a dibasic acid, $ArNH_3^+$ (or $Ar_2NH_2^+$), and it is of interest to see how the information gained in the present work fits into our general knowledge about these processes (13–15).

$$ArNH_3^+ \overset{K_1}{\rightleftharpoons} H^+ + ArNH_2$$

$$ArNH_2 \overset{K_2}{\rightleftharpoons} H^+ + ArNH^-$$

Much of the available information on dissociation of dibasic acids of various charge types is shown in Fig. 3. The filled circles (and the straight line) refer to dibasic acids with a gem diol grouping, that is to HO—Z—OH, where the atom Z may bear other groups and where the charge on the dibasic acid may be +1, 0, or −1. (Sulphuric, which is sometimes included in correlations of this type, has been omitted here because of doubt about the value of its primary dissociation constant.)

It is clear that, in contrast to the HO—Z—OH case, dissociation of dibasic acids of the type H_2Z (open circles) depends very strongly on the nature of the atom Z. This is not unexpected, since for H_2Z the atom Z must bear the charge that is being increased or

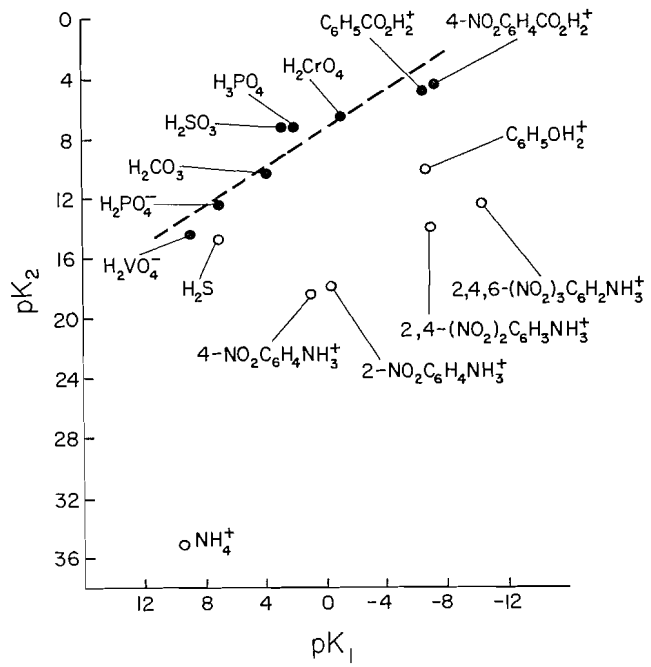

FIG. 3. pK_2 plotted against pK_1 for a variety of dibasic acids: ●, acid of general structure HOZOH; ○, acid of general structure H_2Z.

decreased as a result of the dissociation. (Of all the compounds studied herein only the nitroanilines are included in Fig. 2 for purposes of illustration.)

ANTINEOPLASTIC AGENTS

XI. N-BIS(2-BROMOETHYL)AMINES[1-3]

GEORGE R. PETTIT, MAURICE R. CHAMBERLAND, DAVID S. BLONDA, AND MARTYN A. VICKERS

Department of Chemistry, University of Maine, Orono, Maine

Received February 17, 1964

ABSTRACT

A novel halogen exchange reaction was found to accompany condensation of an acyl chloride with N-bis(2-bromoethyl)amine. Reaction between an acyl bromide and N-bis(2-bromoethyl)-amine, however, gave the expected N-bis(2-bromoethyl)amide. A number of N-alkyl-N-bis(2-bromoethyl)amines were prepared by lithium aluminum hydride reduction of the corresponding N-bis(2-bromoethyl)amides. The overall transformation from N-bis(2-bromoethyl)amine presents a convenient route to certain bromo nitrogen mustards. An efficient synthesis of N-bis(2-iodoethyl)amine hydroiodide is also described.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The earliest example of a bromo nitrogen mustard[4] appears to have been N-bis(2-bromoethyl)amine hydrobromide, described by Gabriel and Eschenback (2) in 1897. The bromo mustard was obtained by treating 2,2′-iminodiethylphenyl ether with hydrobromic acid. More recent methods ((3); see ref. 1 for an early example) involve modifications of the reaction between hydrobromic acid and 2,2′-iminodiethanol. The small number (4) of known N-substituted-N-bis(2-bromoethyl)amines have generally been prepared from the corresponding diol employing either hydrobromic acid (5), phosphorus tribromide (6), or thionyl bromide (7). A few procedures of more limited scope have also been recorded (3(*c*), 3(*d*), 5(*b*), 8).

Reaction of N-bis(2-bromoethyl)amine with an acyl chloride followed by reduction of the corresponding amide, employing a complex metal hydride reagent, would in principle provide a useful route to bromo nitrogen mustards. Analogous procedures have been developed in these laboratories for obtaining N-alkyl-N-bis(2-fluoroethyl)[1]- and N-alkyl-N-bis(2-chloroethyl)-amines (9). The present study was undertaken in order to explore this potentially useful and relatively mild route to N-alkyl-N-bis(2-bromoethyl)amines and to extend our knowledge of N-bis(2-bromoethyl)amines as potential cancerocidal agents.[5]

Syntheses of N-bis(2-bromoethyl)-derivatives of 3,5-dimethoxy-, 3,4-methylenedioxy-, and 3,4,5-trimethoxy-benzylamines were considered of particular interest as the corresponding chloro nitrogen mustards proved of interest in the Dunning leukemia test-system (9). Preparation of these bromo nitrogen mustards would also allow comparison of biological properties with several of the corresponding fluoro,[1] chloro (9), and iodo[1] (9(*a*)) derivatives. Initially, conversion of 2,2′-iminodiethanol (I*a*) to amine II*a* hydrobromide by the hydrobromic acid method was improved and during this work it was noted that certain acid:alcohol molar ratios lead instead to morpholine (III*a*).[6] Although

substitution of hydriodic acid for hydrobromic acid, in the procedure used to obtain bromo nitrogen mustard II*a*, afforded an efficient synthesis of N-bis(2-iodoethyl)amine hydriodide (cf. 11), the modified procedure may be limited in scope since analogous reaction between hydrobromic acid and N-*t*-butyl diol I*b* led to morpholine III*b*.

Transformation of N-bis(2-bromoethyl)amine to, e.g., a substance believed to be 3,4-methylenedioxybenzamide, IV*a* and subsequent aluminum chloride – lithium aluminum hydride reduction of the amide gave an unexpected result. Elemental analytical results obtained for the hydrochloride derivative of the product were in poor agreement with theoretical values for benzylamine (V*a*). Repeating the sequence (II*a* → V) with several other benzoyl chlorides was similarly unrewarding. In each case, the bromine content was lower and the chlorine component higher than calculated. Under these circumstances partial exchange of bromine for chlorine present during the reduction step seemed plausible.[7] Introduction of chlorine during isolation of the tertiary amine (V*a*) with hydrogen chloride, or during preparation of the amide precursor, was considered less likely. When the synthesis was repeated employing 3,4,5-trimethoxybenzoyl chloride and an aluminum bromide – lithium aluminum hydride reagent for amide reduction, the problem was rapidly defined. One half of the crude reduction product was converted to a hydrochloride salt, while the second half was isolated as the hydrobromide salt. Microanalyses indicated that chlorine (7.92%) was present in the hydrobromide derivative. A corresponding increase of chlorine in the hydrochloride salt was also apparent. The results of these experiments clearly demonstrated that interchange of chlorine for bromine had occurred during formation of the amide precursor: a novel reaction. In one series of experiments employing 3,4-methylenedioxybenzoyl chloride and aluminum chloride –

[7]*For example, recently a halogen exchange reaction between aluminum chloride and n-propyl bromide has been observed (reference 12).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

lithium aluminum hydride for reduction of the amide intermediate, nearly one equivalent of chlorine was introduced. The product's elemental composition was consistent with a N-2-bromethyl-N-2′-chloroethyl-3,4-methylenedioxybenzylamine structure. However, the exact course or scope of this interesting halogen-exchange reaction was not pursued further in the present investigation.

Recently, Satchell (13) has predicted the possibility of acylating halogen in alkyl halides (i.e., $RX + R'COY \rightarrow R'COX + RY$) and suggested that "rather powerful acylating agents should be necessary". We have no knowledge of an experimentally verified example of this reaction other than the possibly related transformations noted here. Since attack by an acyl chloride on the bromine–carbon unit of N-bis(2-bromoethyl)-amine occurs under mild conditions, the new reaction may proceed via a transition state such as VI. Under similar conditions, halogen exchange was not noted when N-methyl-N-bis(2-bromoethyl)amine (II*b*) was treated with benzoyl chloride, and this observation lends support to the general reaction pathway suggested by intermediate VI. A more definitive explanation of the reaction will require further study.

As soon as displacement of bromine by the acyl chloride was substantiated, the reaction sequence was restudied employing an acyl bromide. For this purpose benzoyl bromide was prepared from benzoic acid, employing phosphorous tribromide, and the acid bromide was easily converted to N-bis(2-bromoethyl)benzamide (IV*b*). The oily, water-sensitive amide was readily characterized by rearrangement (9), in the presence of aqueous ethanol, to crystalline ester VII.[8] Reduction of amide IV*b* employing lithium aluminum hydride alone or combined with aluminum chloride or aluminum bromide afforded bromo nitrogen mustard V*b*. In each case, the amine was isolated as the crystalline hydrobromide derivative. From these experiments it was ascertained that addition of an aluminum halide was unnecessary.

With exception of amine V*b*, the N-bis(2-bromoethyl)amines summarized in Table I were prepared as follows. The carboxylic acid was treated with oxalyl bromide and the resulting acyl bromide was allowed to react with two equivalents of N-bis(2-bromoethyl)-amine in benzene solution. After removing precipitated amine II*a* hydrobromide, the amide was reduced using an ethereal solution of lithium aluminum hydride. The nitrogen mustard was isolated as the hydrobromide salt.

All of the benzylamines described in Table I were selected for preparation on the basis of interesting biological responses displayed by the corresponding chloro nitrogen mustards (9). For example, preliminary biological studies[9] have shown N-bis(2-chloroethyl)-3,5-dimethylbenzylamine hydrochloride[10] to be capable of markedly inhibiting growth of Walker 256 (subcutaneous) in random-bred albino rats and slowing development of Dunning leukemia (solid) in Fisher 344 rats. Useful results (ca. 98% inhibition) were obtained with the Walker system at a dose of 25 mg/kg (in saline solution given intraperitoneally) beginning on the first day of tumor transplant and continued each of 5 days (tumor growth measured on the tenth day). The same dose regimen was employed in the Dunning experiments. In this case a dose level of 10 mg/kg (in carboxymethylcellulose by the intraperitoneal route) resulted in life extension from 16 days (controls) to 30 days (test).

[8]*A reaction between benzoyl chloride and N-bis(2-bromoethyl)amine, under Schotten–Baumann conditions, was reported (reference 14) in 1934 to yield N-bis(2-bromoethyl)benzamide hydrobromide. The amide salt should now be reassigned the 2-(2′-bromoethylamino)ethyl benzoate hydrobromide (VII) structure.*

EXPERIMENTAL

Dry benzene was prepared as follows: the solvent was heated at reflux over sodium for 2 h, distilled and then stored over sodium. Glass apparatus used for preparation and subsequent reduction of the moisture-sensitive benzamides was dried at 120°. Ethyl ether (Fisher, A.R. grade) used in the reduction procedures was distilled from lithium aluminum hydride directly into the reaction flask. Solvent extracts were dried over magnesium sulphate.

Melting points are uncorrected and were observed using open Kimble glass capillaries in a silicone oil bath. Elemental microanalyses were performed in the laboratories of Dr. A. Bernhardt, Max Planck Institute, Mülheim, Germany, and Drs. Weiler and Strauss, Oxford, England. Dr. R. A. Hill of these laboratories recorded the infrared data. The infrared spectrum of each pure substance was consistent with the assigned structure.

N-Bis(2-Bromoethyl)amine (IIa) Hydrobromide

The following procedure is a modification of one reported by Bobranski and colleagues (3(*c*)). Commercial 2,2′-iminodiethanol (210 g) was added slowly with cooling to 48% hydrobromic acid (950 ml) contained in a 2-l flask equipped with a 50-cm Vigreaux column. Water was then removed by azeotropic distillation until the distillate temperature rose to approximately 125°. A total of 500 ml of distillate was collected during the 7.5-h heating period. Removal (*in vacuo*, steam bath) of the remaining hydrobromic acid yielded an orange oily residue which crystallized upon cooling. Recrystallizing the crude product from ethanol – ethyl ether gave colorless needles; yield, 322 g (52%), m.p. 199–201°. The reported (3(*c*)) melting point is 199–200°.

Morpholine (IIIa) Hydrobromide

The preceding experiment was repeated employing a reduced volume (670 ml) of 48% hydrobromic acid. In this case, the reaction mixture was heated during 12 h while collecting 590 ml of distillate. The remaining reaction mixture was diluted with methanol, treated with Norit-A, filtered and cooled. The colorless crystals which separated weighed 165 g (49%) and melted at 203–206°. Diluting the mother liquor with ethyl ether led to a second crop weighing 131 g (39%) and melting at 200–201°. Both products were identical[11] with an authentic sample.

N-Bis(2-iodoethyl)amine Hydriodide

A mixture of 2,2′-iminodiethanol (25.0 g) and 47% hydriodic acid (350 ml) was allowed to react as illustrated for preparation of N-bis(2-bromoethyl)amine hydrobromide. After collecting 200 ml of distillate during an 8-h period, the reaction mixture was cooled. The crystalline hydriodide which quickly separated as long colorless needles was collected and washed with ethyl ether; yield, 106 g (97%), m.p. 173–176°. Five recrystallizations from 95% ethanol gave rectangular crystals melting at 183–184°. Calc. for $C_4H_{10}I_3N$: C, 10.61; H, 2.23; I, 84.07; N, 3.09. Found: C, 10.89; H, 2.41; I, 84.00; N, 2.65%.

Upon exposure to light, the iodo nitrogen mustard hydriodide rapidly became light-yellow and subsequently changed to a purple color reminiscent of iodine.

N-t-Butyl-morpholine (IIIb) Hydrobromide

Reaction between N-*t*-butyl-N-bis(2-hydroxyethyl)amine (10.0 g, from Rohm and Haas Co.) and 48% hydrobromic acid (200 ml) was allowed to proceed as described for preparation of N-bis(2-bromoethyl)amine hydrobromide. Recrystallizing the crude hydrobromide from methanol – ethyl ether led to 10.5 g (76%) of colorless crystals decomposing at 253°. Two recrystallizations from the same solvent provided an analytical sample, d.p. 265°. Calc. for $C_8H_{18}BrNO$: C, 42.86; H, 8.09; Br, 35.65; N, 6.25. Found: C, 42.81; H, 8.01; Br, 35.65; N, 6.13%.

Reaction Between N-bis(2-bromoethyl)amine and 3,4,5-Trimethoxybenzoyl Chloride

In a typical experiment, N-bis(2-bromoethyl)amine hydrobromide (78.0 g) in cold water (100 ml) was treated with a cold solution of 20% sodium hydroxide (100 ml). The oily amine[12] which separated was rapidly added to benzene and the remaining aqueous solution was extracted with benzene (2 × 100 ml).

The amine solution was stirred and treated with 3,4,5-trimethoxybenzoyl chlodide (23.1 g, reference 9(*b*)) in dry benzene (100 ml). Addition of the acid chloride was performed over 0.5 h. After a 2-h period at reflux the mixture was cooled and filtered (22.5 g of hydrohalide salt was collected). Concentrating the filtrate *in vacuo* yielded 37.3 g of an oily amide. Several attempts to crystallize the amide were unsuccessful; therefore, the crude substance was used in the following reduction reaction.

A 6.5-g (0.015 mole) sample of the amide in dry benzene (100 ml) was added over a 0.5-h period to a mixture of lithium aluminum hydride (0.35 g, 0.01 mole) and aluminum bromide (4.0 g, 0.015 mole) in

[11]*Identity was established by mixture melting point determination and infrared spectral comparison (potassium bromide).*

[12]*In another experiment, approximately 1 ml of the oily amine was isolated and added to a glass container exposed to the atmosphere. After ca. 1 min a vigorous exothermic reaction ensued. Almost immediately the amine was converted to a black residue and gaseous products.*

diethyl ether (150 ml). Stirring at room temperature was continued for 2 h. Water was then cautiously added dropwise until solid and clear liquid phases were obtained. Following filtration, one-half of the dry filtrate was treated with ethereal hydrogen chloride. The hydrochloride derivative separated as a colorless granular solid; yield, 1.9 g, m.p. 168–172°. Three recrystallizations from methanol – ethyl ether yielded colorless needles melting at 172–173°. Calc. for $C_{14}H_{22}Br_2ClNO_3$: Br, 35.71; Cl, 7.92. Found: Br, 23.13; Cl, 14.92%.

The second half of the amine filtrate was treated with ethereal hydrogen bromide. The resulting hydrobromide derivative weighed 2.3 g and melted at 165–168°. Following three recrystallizations from methanol – ethyl ether, colorless needles melting at 170–173° were obtained. Calc. for $C_{14}H_{22}Br_3NO_3$: Br, 48.72; Cl, 0.00. Found: Br, 36.49; Cl, 7.09%.

Reaction Between N-bis(2-bromoethyl)amine and 3,4-Methylenedioxybenzoyl Chloride

Reaction between piperonyl chloride (16.0 g, reference 9(*b*)) and the amine corresponding to 62.4 g of N-bis(2-bromoethyl)amine hydrobromide was performed as described in the preceding experiment. The resulting amide weighed 30.5 g. A 10.3-g specimen of the amide was reduced employing an aluminum chloride (3.6 g) – lithium aluminum hydride (1.0 g) procedure as illustrated (9(*a*)) in a prior study. The crude product was isolated as a hydrochloride derivative which weighed 5.2 g and melted at 158–161°. Five recrystallizations from methanol – ethyl ether led to a sample of colorless needles melting at 162.5–164°. Calc. for $C_{12}H_{26}BrCl_2NO_2$: C, 40.38; H, 4.52; Br, 22.38; N, 3.92. Found: C, 40.36; H, 4.23; Br, 21.90 to 23.80; N, 3.83%.

N-Methyl-N-bis(2-bromoethyl)amine (IIb) Hydrobromide

A solution composed of 37% formaldehyde (5 ml), 98% formic acid (2 ml) and N-bis(2-bromoethyl)amine hydrobromide (7.5 g) was heated at reflux for 2 h. The mixture was concentrated *in vacuo* to a colorless oil. After removing residual water by azeotropic distillation with benzene, the product crystallized; yield, 8.8 g (65%), m.p. 145–148°. Three recrystallizations from methanol – ethyl ether gave pure needles melting at 147–148°. Calc. for $C_5H_{12}Br_3N$: C, 18.43; H, 3.71; Br, 73.56; N, 4.30. Found: C, 18.65; H, 3.62; Br, 73.68; N, 3.90%.

Applying a similar procedure, Bobranski (3(*c*)) also obtained a hydrobromide melting at 147° but confirming elemental analytical data were not reported.

Treatment of N-Methyl-N-bis(2-bromoethyl)amine (IIb) with Benzoyl Chloride

A sample of amine II*b* hydrobromide (1.0 g) in water (50 ml) was treated with 20 ml of 6 *N* sodium hydroxide solution. The liberated amine was extracted with benzene (2 × 50 ml) and the combined extract was dried. A solution of benzoyl chloride (0.4 g) in benzene (50 ml) was added to the amine solution during 0.25 h. No apparent reaction occurred during a subsequent 2-h period at reflux. Treating the reaction mixture with ethereal hydrogen bromide led to 0.83 g (83%) of colorless solid, m.p. 141–143°. Three recrystallizations from methanol – ethyl ether afforded a specimen of N-methyl-N-bis(2-bromoethyl)amine (II*b*) hydrobromide melting at 145–147°. Calc. for $C_5H_{12}Br_3N$: Br, 73.56; Cl, 0.00. Found: Br, 73.80; Cl, 0.22%.

N-Bis(2-bromoethyl)benzamide (IVb)

The free amine (see above) corresponding to 63.0 g of N-bis(2-bromoethyl)amine hydrobromide in 300 ml of dry benzene was treated dropwise (0.5 h) with a benzene (100 ml) solution of benzoyl bromide (15.8 g, b.p. 218°) prepared (15) from benzoic acid and phosphorous tribromide. Before collecting regenerated amine II*a* hydrobromide (26.1 g, 97%), stirring was continued 2 h at room temperature. Removal of solvent *in vacuo* led to the colorless oily amide (28.3 g). The amide exhibited the following infrared absorption bands: ν_{max}^{neat} 3100, 1670, 1490–1420 (broad), 1295, and 1125 cm^{-1} but several attempts to crystallize this substance were unsuccessful. Consequently, the oily amide was employed without further purification in subsequent experiments.

2-(2′-Bromoethylamino)ethyl Benzoate Hydrobromide (VII)

A solution of N-bis(2-bromoethyl)benzamide (IV*b*, 2.8 g) in 90% ethyl alcohol (50 ml) was heated (steam bath) 2 h. Following concentration *in vacuo* to ca. 5 ml, dilution with ether, and cooling, the ester hydrobromide (VII) was obtained as colorless needles; yield, 2.6 g (93%), m.p. 133–135°. Three recrystallizations from the same solvent afforded an analytical sample melting at 137–139°; ν_{max}^{KBr} 2975, 2900, 2800, 2700, 1720, 1548, 1450, 1125, and 710 cm^{-1}. Calc. for $C_{11}H_{15}Br_2NO_2$: C, 37.42; H, 4.28; Br, 45.27; N, 3.97. Found: C, 37.54; H, 4.43; Br, 45.39; N, 3.87%.

The substance reported by Peacock and Dutta (14) to be N-bis(2-bromoethyl)benzamide hydrochloride, m.p. 135°, most probably corresponds to hydrobromide VII.

N-Bis(2-bromoethyl)benzylamine (Vb) Hydrobromide

Procedure A

A solution of N-bis(2-bromoethyl)benzamide (IV*b*, 6.7 g, 0.02 mole) in benzene (75 ml) was added over a 0.5-h period to a suspension of lithium aluminum hydride (0.8 g, 0.02 mole) in diethyl ether (100 ml). Before eliminating excess lithium aluminum hydride by careful addition of water (until a clear liquid phase

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

appeared), stirring was continued 1.5 h at room temperature. The solution was filtered, dried, and treated with hydrogen bromide. Amine V*b* hydrobromide was obtained as colorless crystals; yield, 5.9 g (64%), m.p. 175–178°. Three recrystallizations from methanol – ethyl ether afforded an analytical sample as colorless needles melting at 190–192.5°; ν_{max}^{KBr} 2850, 2500, 1450, 1425, 1370, 1242, 1005, 950, 930, 758, and 700 cm^{-1}. Calc. for $C_{11}H_{16}Br_3N$: C, 32.86; H, 4.01; Br, 59.64. Found: C, 33.13; H, 3.96; Br, 60.17%.

Cerkovnikov (5(*b*)) has reported a melting point of 187–188° for benzylamine V*b* hydrobromide.

Procedure B

The reduction reaction described in Procedure A was repeated with the following modification: Aluminum chloride (2.8 g, 0.02 mole) in ethyl ether (100 ml) was employed as reported earlier (9(*a*)). The crude amine hydrobromide weighed 3.0 g (37%) and melted at 179–183°. The analytical sample, m.p. 190–192°, was obtained as colorless needles following three recrystallizations from methanol – ethyl ether. Found for $C_{11}H_{16}Br_3N$: C, 33.05; H, 3.93; Br, 60.07%.

Procedure C

The preceding experiment (Procedure B) was repeated using aluminum bromide (5.6 g, 0.02 mole) in place of aluminum chloride. The crude hydrobromide derivative of amine V*b* weighed 1.5 g (19%) and melted at 174–178° Recrystallization (3 times) from methanol – ethyl ether raised the melting point to 189–191°. Found for $C_{11}H_{16}Br_3N$: C, 33.17; H, 4.07; Br, 60.02; N, 3.38 (calc. N, 3.49%).

The specimens of N-bis(2-bromoethyl)benzylamine (V*b*) hydrobromide prepared by Procedures A–C were identical.[11]

General Procedure for Preparation of the N-Bis(2-bromoethyl)amines Summarized in Table I

The amine hydrobromides, summarized in Table I, were prepared in good overall yields as illustrated below for synthesis of N-bis(2-bromoethyl)-3,4-methylenedioxybenzylamine (V*a*) hydrobromide. The acid bromide precursors were prepared (16) from the corresponding carboxylic acids and oxalyl bromide. Neither acyl bromides nor their amide derivatives required extensive purification and both were employed soon after formation.

N-Bis(2-bromoethyl)-3,4-methylenedioxybenzylamine (Va) Hydrobromide

A mixture of oxalyl bromide (6 g), prepared (17) from oxalyl chloride and hydrogen bromide, and piperonylic acid (2.5 g) was heated at reflux for 2 h. Removal of excess oxalyl bromide *in vacuo* yielded 3,4-methylenedioxybenzoyl bromide as a pale-yellow solid.

A solution of the acyl bromide in benzene (50 ml) was added dropwise (0.5 h) to a benzene (150 ml) solution of N-bis(2-bromoethyl)amine corresponding to 12.6 g of the bromo nitrogen mustard hydrobromide. Before collecting the regenerated nitrogen mustard hydrobromide which separated, the reaction mixture was stirred at room temperature for 2 h. The benzene filtrate was added over a 0.5-h period to a suspension of lithium aluminum hydride (0.57 g) in diethyl ether (150 ml). Stirring was continued for 2 h at room temperature and then excess lithium aluminum hydride was destroyed by cautious dropwise addition of water until distinct solid and clear liquid phases appeared. The solution was then successively filtered, dried, and dihited with ethereal hydrogen bromide. The colorless crystalline hydrobromide weighed 5.5 g (84%) and melted at 159–160°. Three recrystallizations from methanol – ethyl ether led to an analytical sample in the form of needles (see Table I): ν_{max}^{KBr} 2980, 2625, 2575, 1505, 1488, 1448 (shoulder at 1430), 1385, 1265–1245 (broad), 1105, 1045, 945, and 930 cm^{-1}.

THE ACTIVATION PROCESS IN SOLVOLYSIS[1,2]

R. E. ROBERTSON
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received December 6, 1963

ABSTRACT

The structural nature of water is a major factor in determining the solvent isotope effect and the apparent heat capacity of activation for solvolysis. The consequences of this assumption are examined for the S_N2 mechanism in terms of solvation changes at the transition state and the probable make-up of the activation energy.

Our studies of solvolysis (1) have forced us to question certain widely held hypotheses concerning the solvation of the transition state. Most of the current working hypotheses relating to this problem may be traced to the papers in which Hughes and Ingold (2, 3) discussed the solvation differences between the S_N1–S_N2 mechanisms and a series of related papers (4, 5)* in which Polanyi and his students attempted to analyze the components of the activation energy in such reactions. Briefly the latter treated E_{act} (for S_N1) reactions as the residual, Q, determined by the equation

$$[1] \qquad Q = D + I - E - S^+ - S^-$$

where D = heat of dissociation of C—Hal bond, E = electron affinity of Hal atom, I = ionization potential of R, S^+ = heat of solvation of R^+, S^- = heat of solvation of Hal ion. Robertson, Heppolette, and Scott carried out similar calculations for the S_N2 hydrolysis of the methyl halides and showed that the residual, Q, corresponded to the derived experimental activation energy, provided charge development, α, is about 0.8 e (8). While the cumulation of uncertainties in the terms of eq. 1 vitiated the practical value of such a calculation, the principle seemed to be generally accepted.

Since these reactions are exothermic, it will be obvious that there must always be some particular value of α which satisfies this type of calculation, hence apparent agreement cannot be persuasive. If such a calculation approximated reality, it would seem a reasonable corollary to expect evidence of solvation differences characteristic of the product ions. Such anticipated differences are not observed.

For this and other reasons, we have concluded that for the solvolysis of primary and secondary halides and sulphonates in water, exothermic solvation† of the developing anions is only beginning at the transition state. This unfamiliar concept is the logical consequence of the Laughton–Robertson hypothesis for the kinetic solvent isotope effect (9, 10, 11) and the related interpretation of the large negative heat capacity changes which characterize the ionogenic reactions studied (1). The experimental background is outlined in the following section.

DISCUSSION OF EXPERIMENTAL BACKGROUND

Although the kinetic solvent isotope effect (k_{D_2O}/k_{H_2O}) is not a sharp tool for exploring fine differences in solvent reorganization associated with hydrolysis, we have found

unmistakable indications of groupings of effects related to the structure of the solute. Thus Laughton and Robertson have shown that the k_{D_2O}/k_{H_2O} ratio for simple primary and secondary sulphonates was 0.92 ± 0.03, the difference between a methanesulphonate and a toluenesulphonate being about 0.02. The ratio for the corresponding halides was 0.80 ± 0.05. The systematic difference between the sulphonates and the halides was attributed to interaction of the sulphonic oxygens with the initial state solvation shell—a conclusion supported by the recent calorimetric studies of Arnett (12). Laughton and Robertson concluded that the major factor determining such solvent isotope effects was the difference in the structural stability of the respective initial state solvation shells compared to the smaller differences in the disrupted state. This assumption and the recognition that part of the activation energy is the work required to break down the initial state solvation shell are the major premises which distinguish the present treatment. Because the assumption of an initial state solvation shell appears to create a semantic stumbling block for some, it is desirable to emphasize that this assumption in no way excludes the existence of a dynamic equilibrium between the solvent shell and the bulk solvent. Our kinetic measurements give only an indication of the time independent difference between the initial and transition states. For convenience we treat this difference as static.

The assumption that the initial state solvation shell has some degree of structural stability follows from our knowledge of the nature of aqueous solutions of weakly polar molecules. Evidence for enhanced initial state water–water interaction due to the presence of the weakly polar solute is drawn from the similarity between the solvation parameters for dissolved gases and the formation of gas hydrates (13); from the negative ΔH and ΔS for solvation but the large positive ΔC_p which characterizes gas–liquid equilibria (14); from the steeper temperature dependence of the k_{D_2O}/k_{H_2O} ratio for the hydrolysis of isopropyl bromide compared to that for the relative fluidity (15); and from the larger partial molar volume of MeBr in such solutions in spite of the existence of empty holes in water structure (16, 17). The reduced temperature dependence for the k_{D_2O}/k_{H_2O} ratio for the sulphonates compared to the halides, as well as the value of the ratio itself, are consistent with the enhanced solute–solvent interaction of the former in the initial state. Limited data indicate that sulphates and phosphates would give values of k_{D_2O}/k_{H_2O} similar to those for sulphonates (10).

The above interpretation has been challenged by Swain and Thornton (17), who would attribute this solvent isotope effect largely to differences in the degree of solvent–ion interaction in the transition state, i.e. a hypothesis consistent with the traditional views concerning solvation of the transition state to which reference has been made above. In principle this is possible but it is snagged by at least one important experimental fact: i.e. the fluorides show similar k_{D_2O}/k_{H_2O} ratios to the remaining halides (Table I), whereas

TABLE I

Comparison of kinetic and ionic coefficients

Halide	k_{D_2O}/k_{H_2O}*	$\gamma_{H_2O}/\gamma_{D_2O}$†
F^-	0.82	1.20
Cl^-	0.77	−0.51
Br^-	0.80	−0.59
I^-	0.81	−0.68

*Typical values for k_{D_2O}/k_{H_2O} (9).
†Ratio of activity coefficients $\Delta F_s = F_s(H_2O) - F_s(D_2O) = R \ln \gamma_{H_2O}/\gamma_{D_2O}$, Table V, ref. 18 based on calorimetric investigation of Lange and Martin (20).

the arguments of Swain and Bader (18) and of Swain and Thornton would lead to a value of $k_{D_2O}/k_{H_2O} > 1$. Another more obvious weakness in the latter analysis is the neglect of the evidence for difference in structural stability between D_2O and H_2O in the absence of a solute. The significance of this omission is made apparent by the fact that when the initial state structure is broken down by the addition of a miscible solvent, the solvent isotope effect is greatly reduced (19).

The heat capacity of activation ($\Delta C_p^{\neq}$) is inherently a more sensitive probe of solvation changes than the solvent isotope effect in that it reflects not only the degree of reorganization but also is more sensitive to the number of molecules involved. In spite of this, there is the same grouping of sulphonates and halide values (Table II) (for the primary and

TABLE II

A comparison of $\Delta C_p^{\neq}$ values for solvolysis involving displacement from primary and secondary carbon centers

	Ions

secondary sulphonates -35 ± 5 cal/mol deg. and for the halides -55 ± 8 cal/mol deg.) already noted in the k_{D_2O}/k_{H_2O} ratios. The narrow range of values for $\Delta C_p^{\neq}$ found for the primary and secondary halides or sulphonates suggests that approximately the same number of water molecules are involved in the reorganization accompanying activation and that these have approximately the same initial and transition state relationships. The differences in $\Delta C_p^{\neq}$ for displacement of the same ion from primary and secondary centers apparent in Table II are not significant. There is no apparent correlation with expected differences in the degree of nucleophilic interaction. This may indicate that such interaction is small, or more likely that it appears to have a small effect on $\Delta C_p^{\neq}$. Certainly the introduction of a hydrogen bonding group close to the seat of reaction will show a much larger effect, presumably due to a modification in the initial state solvation shell (21). Similar evidence is seen in the large reduction in $\Delta C_p^{\neq}$ for those systems where sufficient miscible solvent is added to break down the initial state solvation shell (22). The counterpart with respect to the k_{D_2O}/k_{H_2O} value has already been noted (19).

These well-established characteristics for solvolytic reactions of primary and secondary halides and sulphonates in water support the conclusion that a significant component of the activation energy for the hydrolysis in water of alkyl halides and similar compounds is the work, $F_s^{\neq}$, required to break down the initial state solvation shell. The differences in $\Delta F_s^{\neq}$ between H_2O and D_2O already noted for the bulk solvents (23, 24) provide a natural basis for the observed rate difference in the two solvents and for the temperature dependence of this ratio. The second derivative of $\Delta F_s^{\neq}$ with respect to temperature can account for an important part of $\Delta C_p^{\neq}$. It is comparable in sign but larger in magnitude than the temperature dependence of the activation energy for such physical processes as viscosity (24), or time of dielectric relaxation (25), physical processes which necessarily involve the breakdown of water structure. Recent calorimetric studies by Arnett (26) support this interpretation. The familiar changes which are found in $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

solvolysis in a series of alcohol–water, and similar mixtures at the high-water end of the series, 26–29 may be regarded as another demonstration of changes in the work to organize the initial state solvation shell $\Delta F_s^{\neq}$. This reduction in $\Delta F_s^{\neq}$, as reflected in $\Delta C_p^{\neq}$ in ethanol–water solutions, lends further support to our hypothesis. It should be noted, however, that $\Delta F_s^{\neq}$ forms but part of the total observed free energy change on activation.

Charge Development at the Transition State

Neither the kinetic solvent isotope effect nor the heat capacity of activation provides a measure of the degree of charge development at the transition state, though each of these phenomena is related to the effect which such charge development has on the initial state solvation shell. The common basis for these diverse effects may be summarized in the composite equation

$$[2]\quad \left\{\text{Water–water interaction}\right\} \begin{matrix} > \\ = \\ < \end{matrix} \left\{\text{water–solute interaction}\right\} \begin{matrix} (a)\ \text{initial state} \\ (b)\ \text{transition state} \\ (c)\ \text{final state} \end{matrix}$$

This statement implies that in the activation process for solvolysis by an S_N2 mechanism, at some point along the reaction co-ordinate the inequality (*a*), characteristic of the initial state, disappears (*b*), then reverses (*c*). As a working hypothesis we have arbitrarily chosen the point of equality as the transition state. Up to the degree of charge development sufficient to satisfy this condition (*b*), work must be supplied to activate the solute and to break down the initial state solvation shell. Charge development beyond this level leads to the familiar complementary making and breaking of bonds without requiring any further increase in free energy but with increasing charge separation to the limiting value.

The Activation Energy in Solvolysis

Equation 2 implies that the activation energy is not a small residual from differences between large heats of ionization and heats of solvation reflecting a position of balance at some 80–100% charge development with a corresponding degree of solvation of both primary ions (8). Rather, E_{act} may be expressed as the sum of terms formally indicated by the following equation.

$$[3]\quad E_{act} = \begin{matrix}\text{Energy to achieve charge} \\ \text{separation to satisfy the} \\ \text{condition of eq. 2}\end{matrix} + \begin{matrix}\text{Energy to break down} \\ \text{the initial state} \\ \text{solvation shell}\end{matrix}$$

Critical charge development for the displacement of a particular anion, X^-, may be achieved by a number of paths depending on the structure of the solute R—X. Where thermal activation is sufficient to achieve critical charge development, S_N1 characteristics are observed. For the solutes under consideration here some degree of nucleophilic interaction is required to achieve this condition.

The first term on the RHS of eq. 3 is complex and probably involves in some measure those factors summarized by Caldin (30) for bimolecular reactions in solution. Some degree of cancellation is necessarily involved in such interaction, but until exothermic solvation is established between the developing anion and the solvent, such interaction will not predicate reaction.

The second term is normally neglected. The evidence of k_{D_2O}/k_{H_2O} and $\Delta C_p^{\neq}$ according to our interpretation, and that arising from the recent work of Arnett (26), shows that for solvolysis in water $\Delta H_s^{\neq}$ is a significant component in $\Delta H^{\neq}$. It is probably largest for reactions in water and tends to assume a constant value in mixed solvents where solvent structure in the initial state is of less importance.

ULTRASONIC ABSORPTION IN CRITICAL BINARY LIQUID SYSTEMS. II

PEETER KRUUS
Department of Chemistry, University of Toronto, Toronto, Ontario
Received February 26, 1964

ABSTRACT

The results of ultrasonic absorption measurements for the systems perfluoromethylcyclohexane – carbon tetrachloride and triethylamine–water are presented. A pulse reflection method was used for the measurements. Intermolecular correlation lengths were calculated from the absorption data for these and two other systems. They are in reasonable agreement with lengths calculated from light scattering data. The absorption results also substantiate the suggestion that, in the critical solution region, the system may already be in two phases. However, these are not present in the form of two distinctly separated phases, but as regions in a type of emulsion.

INTRODUCTION

From the results of ultrasonic absorption measurements in the critical solution region, it is possible to calculate values of an intermolecular correlation length l (1) by using the theory of Fixman (2). Values of l can also be calculated from experimental light-scattering and heat-capacity results.

As both light-scattering (3) and heat-capacity (4) data are available for the system perfluoromethylcyclohexane – carbon tetrachloride, ultrasonic absorption measurements were carried out for this system. An attempt was also made to test the frequency dependence of Fixman's theory by comparing the theory with measurements for the system triethylamine–water.

In addition, some unexpected features in the composition and temperature dependence of the absorption in the system perfluoromethylcyclohexane – carbon tetrachloride were found; these can be explained using the physical picture of the critical solution region suggested by Hildebrand *et al.* (5).

EXPERIMENTAL

Apparatus

The apparatus and the measuring techniques were the same as those described previously (6).

Velocity measurements were made in addition to absorption measurements in some cases. A delayed trigger signal from the pulsed oscillator was sent into the oscilloscope, and the setting of the delay dial was varied to make the delayed trigger signal coincide with the start of the signal of the reflected ultrasonic pulses. The delay dial was calibrated with the velocity of ultrasound at 10 mc in water at 1497 ms^{-1} as reference.

Materials

Perfluoromethylcyclohexane – Carbon Tetrachloride

The perfluoromethylcyclohexane (C_7F_{14}), density 1.789 and purity estimated to be 98.4% from a gas chromatography trace, was obtained from the Imperial Smelting Co. The value of the pressure absorption coefficient divided by the square of the frequency, α/f^2, is $584 \cdot 10^{-17}$ $cm^{-1}s^2$ at 20 mc, 28 °C and $502 \cdot 10^{-17}$ at 60 mc, 20 °C. It is evident from the rather large decrease of α/f^2 with an increase in frequency that C_7F_{14} relaxes in this frequency region. It should be noted that the velocity of ultrasound in C_7F_{14} is the lowest to be found, about 580 ms^{-1}.

Merck analytical grade carbon tetrachloride was used as the other component. It has an α/f^2 of $553 \cdot 10^{-17}$ at 20 mc, 28 °C, compared to $546 \cdot 10^{-17}$ at 107 mc, 25 °C, from ref. 7.

Figure 1 shows a phase diagram (Zimm (3)) for the system. The experimental critical solution temperature is 28.0$_5$ °C compared with 28.3 °C (3) and 26.2 °C (4).

Triethylamine–Water

The second system, triethylamine–water, is an example of a system with a lower critical solution temperature. Ion-exchanged water and Merck "Lab" grade triethylamine were the components of this system.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The absorption data is as follows: (*a*) Water: $\alpha/f^2 = 24.5 \cdot 10^{-17}$ at 60 mc, 25 °C, compared with $21.2 \cdot 10^{-17}$ at 192 mc, 25 °C (7). Measurements at lower frequencies (8) are in better agreement, but are less precise. (*b*) Triethylamine: $576 \cdot 10^{-17}$ at 17 mc, 18 °C, compared with $410 \cdot 10^{-17}$ at 23 mc, 20 °C (9). When data from ref. 9 is extrapolated to 17 mc, 18 °C, the value of α/f^2 is about $580 \cdot 10^{-17}$.

Values of the critical solution temperature for this system are reported from 12.4 to 19.9 °C (10); the experimental critical solution temperature for the system investigated is 17.8 °C. A phase diagram (10) is shown in Fig. 4.

Results

The results of the measurements are shown in Figs. 1–5. When the precision of the absorption measurements is outside the range given by the size of the symbol indicating points on the graph, the possible range of values is shown by a vertical line, and the most probable value by the symbol.

DISCUSSION

The Critical Solution Region

Investigations of light-scattering (3, 11) and heat capacity (4) indicate that these quantities show an abnormally large increase as the critical solution point is approached.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

When a centrifugal force is applied to a system (5), the critical solution temperature is changed because of hydrostatic and sedimentation effects. The critical solution temperature is here defined as the temperature at which the system first separates into two distinct phases.

The experimental results seem to indicate that the following physical picture of the critical solution region is reasonable.

In the extremely opalescent region, which occurs in some systems just before phase separation takes place, the system is in a form similar to an emulsion (5). It is made up of regions which contain the components in different proportions and are, thus, separated by composition gradients. As the critical solution temperature is approached, the regions become larger and the composition gradients steeper. Separation of the system into two distinct phases is caused by the action of gravity upon the regions of different density when Brownian motion can no longer keep these dispersed.

Related to this composition variation, there are probably also fluctuations (12) which occur inside the regions themselves. Near the critical solution point, these fluctuations can become very large. It is these fluctuations which correspond to the ordinary type of critical fluctuations in a one-component system near the critical point, and which give rise to the high ultrasonic absorption in the critical solution region.

This picture gives a reasonable explanation for all the experimentally observed phenomena. As the critical solution temperature is approached, light-scattering increases because of the critical fluctuations (11, 13), and also because of reflection from the composition gradients between the regions of different composition (5) close to the critical temperature. The heat capacity increases because of entropy changes associated with the inhomogeneities. Since the effective gravitational force is changed in a centrifugal field, it is to be expected that the observed critical solution temperature is also dependent on the centrifugal force.

Qualitative Discussion

Composition Dependence

Figure 1 shows the absorption at temperatures just above and just below the critical solution temperature. In the range of composition where the system is visibly opalescent at the higher temperature, the absorption varies about linearly with composition. When a line is drawn between the absorption–composition points at the lower temperature, the result is a good approximation to the absorption at the higher temperature.

This suggests that at the higher temperature, the system is already in two phases. But the phases are present in the form of regions which are too small and too similar in composition to fall into two completely separated phases. Instead, they remain in a dispersed form because of Brownian motion and absorb separately according to the proportion of the phase present in the total system. The ultrasonic absorption hence arises from effects present inside the phases themselves.

The absorption in the system triethylamine–water (Fig. 4) is much greater than in any of the systems which have an upper critical solution temperature. When a system has a lower critical solution temperature, it consequently has a large negative excess entropy. The large negative excess entropy in such a critical binary system is thought to arise from the large critical fluctuations (13). Thus it seems reasonable that the ultrasonic absorption is, at least to a large degree, dependent upon the critical fluctuations, as postulated by Fixman (2).

Because of the high absorption, the measurements are less precise in this second system. This, together with the lack of observed opalescence, makes it impossible to draw any conclusions regarding the physical structure of the system.

Temperature Dependence

Figure 2 shows that in the visibly opalescent temperature range, the absorption decreases slightly as the critical solution temperature is approached. The value just before phase separation is close to the value obtained in an unstable system in which a meniscus is forming. It is also approximately the same as the value obtained by interpolating coefficients of the two separated phases at a temperature slightly below the critical solution temperature. This supports the previous suggestion that in the visibly opalescent region, the system already is in two phases in the form of an emulsion.

Frequency Dependence

The experimental points in Figs. 3 and 5 were fitted with the use of least-squares computer programs. Two theoretical expressions were used: (i) the absorption equation due to a single relaxation frequency,

$$[1] \qquad \frac{\alpha}{f^2} = \frac{A}{1 + f^2/f_c^2} + B;$$

and (ii) the equation obtained from Fixman's theory,

$$[2] \qquad \frac{\alpha}{f^2} = Cf^{-5/4} + B.$$

The fitting was carried out by adjusting the frequency-independent parameters A, B, and f_c in [1] and C and B in [2] to get the lowest value of the relative root-mean-square deviation σ.

The results are shown in Table I and the resulting theoretical curve using equation 2 for triethylamine–water is shown in Fig. 5. It is seen that even though equation 2 has

TABLE I

	Equation 1				Equation 2			B (estimated from graph)
Case	$A \cdot 10^{14}$	$B \cdot 10^{17}$	f_c(mc)	σ	$C \cdot 10^{14}$	$B \cdot 10^{17}$	σ	B
1*	1.4	460	7.1	0.08	3.1	520	0.07	430.10^{-17}
2†	0.85	470	6.4	0.05	6.1	500	0.09	$430 \cdot 10^{-17}$
3‡		No reasonable fit			125.	7600	2.2	$50 \cdot 10^{-17}$

*Case 1: 56% by volume CCl_4 with C_7F_{14}; T = 28.3$_7$ °C.
†Case 2: 56% by volume CCl_4 with C_7F_{14}; T = 33.9$_3$ °C.
‡Case 3: 47 to 69% by volume water with triethylamine; data from (15, 16, 17) included; T = 17.1 °C.

one adjustable parameter less than equation 1, the values of σ obtained using it are of the same order of magnitude as for equation 1. The frequency dependence of the absorption is thus given reasonably well in this frequency range by Fixman's theory.

Quantitative Relationships

Values of an intermolecular energy distance parameter l (1) can be calculated from the temperature dependence of the absorption. The contribution to the absorption, B, due to all effects other than that discussed, is estimated and subtracted from the experimental curve, and the theoretical curve (2) is then fitted to the adjusted experimental curve in two points, giving values for l and C. The parameter C contains too many unknown quantities for a meaningful analysis.

The results of calculations for four systems are given. Values of B for the calculations are taken from Table I and from ref. 6. Since the dependence of B on temperature and frequency is unknown, but small in comparison to the total absorption in these systems, no allowance is made for any such variation of B.

(1) *n*-Heptane–nitrobenzene (6): l = 6 to 7 Å for a range of B-values $270 \cdot 10^{-17}$ to $40 \cdot 10^{-17}$ at 20 mc.

(2) Aniline–cyclohexane (14): l = 7 to 10 Å for a range of B-values $80 \cdot 10^{-17}$ to $180 \cdot 10^{-17}$ at two frequencies, 9 and 27 mc. The value from light-scattering experiments (11) is 12.7 Å.

(3) Perfluoromethylcyclohexane – carbon tetrachloride: l = 6.6 to 14.6 Å for B = $200 \cdot 10^{-17}$ to $520 \cdot 10^{-17}$. The critical solution temperature used in the calculations was 1.5 °C higher than the observed critical solution temperature, as in this 1.5 deg range, the system is probably already in two phases microscopically. The value of l obtained from light-scattering data (3) is 14.7 Å (13), and from heat-capacity data (4), 4.9 Å (13).

(4) Triethylamine–water (15, 16, 17): $l = 2.0 \pm 0.3$ Å for systems at frequencies 0.6 to 9 mc and at varying compositions. The values of l in this system are lower, indicating an interaction range which is shorter than in the other systems.

CONCLUSIONS

The results indicate that near the critical solution temperature, a system may exist as a type of emulsion which already contains two phases in the form of regions of different compositions.

The theory of Fixman postulates that the absorption arises from the interaction of critical fluctuations present in the system with the local temperature changes in the system caused by the passage of the ultrasonic wave. This theory is in reasonable agreement with experimental results, and gives calculated values of l of the same magnitude as those from light-scattering.

Measurements in a lower frequency range and in a greater number of systems would be helpful in finding out whether Fixman's theory and the physical picture of the critical solution region are more generally valid.

ACKNOWLEDGMENTS

This work was performed in the laboratory of Professor T. A. Bak at the H. C. Ørsted Institute, University of Copenhagen, Denmark, as part of the requirements for the lic. techn. degree from the Technical University of Denmark. The author is indebted to Professor T. A. Bak for his interest and help.

The Ontario Research Foundation gave financial support for this research through a scholarship to the author.

METHYLATION OF METALATED INDENE AND METHYLINDENE[1]

A. Bosch and R. K. Brown
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received February 12, 1964

ABSTRACT

The reaction of metallic lithium and potassium with indene and fluorene in refluxing 1,2-dimethoxyethane (DME) yields reduction products of indene and fluorene, 1-metalated indene, and 9-metalated fluorene, and as well is accompanied by the production of some hydrogen gas due to the acidic methylene group. The amount of hydrogen is small for fluorene but quite substantial for indene.

Metalation of indene, 1-methylindene, and 3-methylindene in refluxing DME, followed by methylation of these metalated indenes at 0°, gave a mixture consisting of starting material, the corresponding indan, monomethylindene, dimethylindene, and in some cases trimethylindene. Two competing reaction mechanisms resulting in the formation of the metalated indenes are suggested and possible routes for the formation of the di- and tri-methylindenes are examined.

INTRODUCTION

The weakly acidic nature of the methylene group of indene (1) has permitted the preparation of the 1-metalated derivative by use of a variety of basic reagents (2–8). The alkali metal salts of such pseudo acids can also be prepared by direct reaction of the metal with the hydrocarbon in tetrahydrofuran (9) as well as indirectly via metal–aromatic hydrocarbon adducts prepared in ethereal solvents (10–13).

A recent study of the alkylation of the alkali metal salt of fluorene has shown that the proportion of mono- to di-alkylation depends upon both the metal and the solvent employed (14–16). In this work one of the products obtained during the reaction of fluorene with the alkali metals was hydrogen gas. However, it has recently been stated that the reaction of alkali metals with such compounds as fluorene (13) and triphenylmethane (17) produces no hydrogen, but proceeds by initial metal–hydrocarbon adduct formation followed by proton exchange between this adduct and more of the hydrocarbon.

The purpose of this paper is to present results of an investigation of the metalation of indene and alkylation of the resulting salt, and as well of an examination of the question of hydrogen formation during reaction of alkali metals with both fluorene and indene.

RESULTS AND DISCUSSION

A. Hydrogen Evolution vs. Birch Reduction in the Reaction of Lithium or Potassium Metal with Indene or Fluorene

The results of experiments concerning hydrogen formation are shown in Table I.

The blank runs, containing only metal and solvent, produced a volume of gas, due nearly completely to the expansion and displacement of air, equal to 195–200 ml when potassium was used. This gas contained 1–2% of hydrogen as determined by mass spectrometry. When lithium was substituted for potassium, 210 ml of gas was obtained which contained only traces of hydrogen. Gas "evolution" was usually complete within 2 to 3 hours for potassium and 4 to 5 hours for lithium and no further increase in volume of collected material was found in the several runs made where blanks were refluxed for half a day.

TABLE I

Production of hydrogen during the reaction of indene or fluorene with lithium or potassium metal in refluxing dimethoxyethane (DME)*
(0.1 mole of hydrocarbon + 0.1 gram-atom of metal in 100 ml of DME)

Expt. No.	Hydrocarbon	Metal used	Amount of metal consumed, %	Time of reflux for complete gas evolution, h	Volume of gas collected, ml	Amount of H_2 in collected gas, %
1	Nil	K	Very little	2–4	200	1–2
2	Nil	K	Very little		195	1–2
3	Nil	Li	Very little		210	Trace
4	Nil	Li	Very little		210	Trace
5	Indene	K	85	3–4	700	At least 50
6	Indene	K	88		725	(No analysis)
7	Indene	Li	80		900	At least 60
8	Indene	Li	77		800	(No analysis)
9	Fluorene	K	Nearly all	3–4	350	35
10	Fluorene	K	Nearly all		390	(No analysis)
11	Fluorene	Li	80	22	220	2
12	Fluorene	Li	85–90	17	215	10
13	Fluorene	Li	(Not estimated)	4 (Incomplete reaction)	200	11

*Generally the reflux was carried out until gas evolution ceased. In some cases reflux time was extended further even though more evolution of gas failed to take place.

A mixture of *indene* and potassium in DME gave 700–725 ml of gas, over 50% of which was hydrogen (presumably 500 ml), while indene and lithium evolved 800–900 ml, over 60% of which was hydrogen (presumably 600–700 ml). Gas evolution ceased in both cases after 3–4 hours. When a mixture of *fluorene* and potassium in DME was refluxed, 350–390 ml of gas was collected (an increase of 150–190 ml above the blank value), at least 35% of which was hydrogen. However, the reaction between lithium and fluorene gave a total volume of gas, 200–220 ml, which mass spectrometry showed to contain about 10% of hydrogen, although in one case out of the three cited only 2% of the collected gas was hydrogen.

Fluorene thus does react with *potassium* to give substantial amounts of hydrogen—but not in the amount equal to that expected if the only reaction between fluorene and the metal were one of hydrogen evolution according to equation *a*.

(a) 
Roughly 11–14% of that theoretically required by equation (*a*) was actually produced. On the other hand, the reaction of *lithium* with fluorene definitely gave hydrogen, but only in small amounts—about 1.5% of that theoretically required by equation *a*. The detection of hydrogen evolution in the present case, but none in the work reported by Eisch and Kaska (13) can be accounted for by the different conditions employed. The latter authors used a larger volume of solvent (400 ml of tetrahydrofuran containing 0.1 mole of fluorene) and room temperature conditions, while the present work employed 100 ml of solvent (DME) containing the same amount of fluorene, and reflux temperature. The latter conditions would promote elimination of small amounts of dissolved hydrogen.*

It is quite evident that a second reaction, consuming the bulk of the metal, has occurred—nearly completely (98–99%) in the case of lithium and fluorene, but to a somewhat lesser extent (85%) with potassium and fluorene. Undoubtedly this occurs by way of reaction *b*, as pointed out by Eisch and Kaska (13), leading to a Birch-type reduction (18) of a portion of the fluorene,

(b) 
since evidence for the occurrence of such reduction products of fluorene has been presented (13).

The reaction of *indene* with either potassium or lithium metal in DME gave much more hydrogen gas. If the blanks are taken into consideration, the amount of hydrogen evolved when potassium metal reacted with indene was about 40% of the theoretical amount, while reaction with lithium gave about 50% of that required by equation *a*. In these two cases as well, the metal was consumed by the route expressed by equation *a*

**O. F. Beumel, Jr. and R. F. Harris, J. Org. Chem. 28, 2775 (1963) have shown that in the reaction of lithium metal with ethylenediamine in benzene, a competition occurs between (a) direct reaction of the lithium with the diamine to produce hydrogen gas and the lithium amide (b) addition of the metal to the benzene followed by Birch-type reduction of the benzene and lithium amide formation without hydrogen evolution. Hydrogen evolution according to process (a) is less important at lower temperatures, but above 85° a vigorous reaction occurs with evolution of considerable hydrogen.*

and also by one such as shown in equation *b*. This is supported by the isolation of indan as one of the products of the reaction, to the extent of 15–17% of the product when potassium was used, but only 8–10% with lithium metal* (Table II).

B. Methylation of Indenyllithium and Indenylpotassium

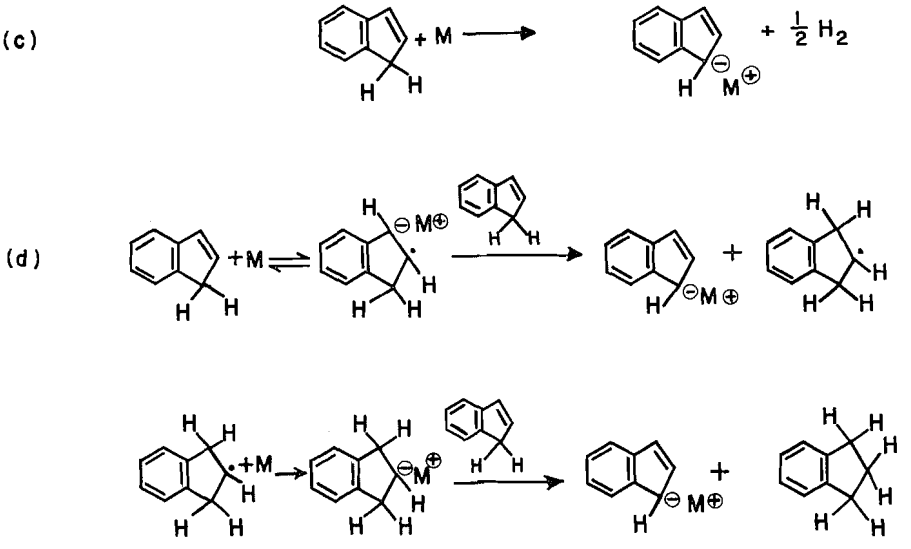
The following observations are made from the methylation data recorded in Table II.

(*i*) The amount of metal consumed appears to be nearly the same regardless of the duration of the reflux period during the metalation, within the limits shown. Whenever equivalent amounts of lithium and indene were employed, 80–90% of the metal reacted, whether the mixture was refluxed 5 or 22 hours, while with potassium 85–90% of the metal was consumed within the limits of 2 to 16 hours. However, in the case of potassium, when a 2:1 molar ratio of metal to indene was used, more than one equivalent amount of metal disappeared and this only when the reflux period was extended to 20 hours. In no case where excess lithium was employed was more than one equivalent of metal consumed even though the reflux time was extended to 72 hours (Table VI).

(*ii*) The amount of indan formed is nearly reproducibly the same regardless of the time of reflux of metal with indene or the use of a twofold excess of metal. The reaction with lithium gave 8–10% of indan while that of potassium yielded 15–17% of the product as indan.

These two observations (*i*) and (*ii*), coupled with the fact that the reaction of both lithium and potassium with indene produced substantial amounts of hydrogen (Table I), strongly support the concept of a competition between two different reactions of the metal with indene. One involves the reaction of indene as an "acid", producing hydrogen (equation *c*) and the other involves the formation of the metal adduct which then metalates more indene with simultaneous formation of reduced indene (equation *d*) via a Birch-type reduction (18).

Equation *c* predicts that equimolar amounts of indene and metal react to produce 0.5



**The source of the lithium metal, as well as particle size, is apparently important. Larger pieces of BDH lithium metal (98%), after 24 hours of heating in refluxing DME, were consumed to the extent of 50%, and gave 23% of the product as indan. Tiny pieces of Fisher Scientific lithium were 90% consumed in 20 hours, but yielded only 9% of the product as indan. In this work only Fisher Scientific lithium was used throughout.*

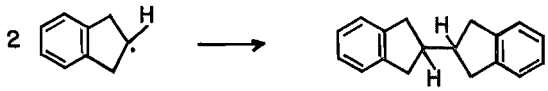
*0.1 mole of indene was dissolved in 100 ml of dimethoxyethane and refluxed with the appropriate amount of metal. Methylations were performed at 0–5°.
†Methylations were done at room temperature in these two cases.
‡In these two cases a material balance was made to estimate total recovery, using *t*-butylbenzene as an internal standard. The upper line of figures represents the percentages of each substance based on the total amount of isolated product. The lower line is the percentage of each substance based upon the indene used originally.

mole of hydrogen. Equation (*d*) predicts that 1 mole of indene will react with $\frac{2}{3}$ of a gram atomic weight of metal yielding $\frac{1}{3}$ of a mole of indan and $\frac{2}{3}$ of a mole of the metalated indene. Since the amount of metal consumed actually lies between $\frac{2}{3}$ and 1.0 of a gram atomic weight, and hydrogen as well as indan is produced, both reactions *c* and *d* are required. Furthermore, from the reaction of lithium with indene there has been isolated a small amount of the compound 2,2′-biindanyl, identified by comparison of its n.m.r., i.r., mass spectrum, and melting point (and mixed melting point) with those of an authentic specimen prepared from α,α'-dibromo-*o*-xylene and diethylmalonate (19). The formation of 2,2′-biindanyl is feasible from the indanyl free radical, an intermediate suggested in equation (*d*).



Attempts to isolate this biindanyl from the reaction involving potassium were fruitless. The failure to obtain biindanyl in this instance might be due to the greater electropositive nature of the potassium metal, resulting in *reduction* of the indanyl-free radical before it could dimerize. There was in all cases some unreacted metal left which could do this. The larger amount of indan found in the metalation with potassium (15–17%) than from the metalation with lithium (8–10%) can be rationalized in terms of the greater reducing capability of potassium metal.

(*iii*) The amount of recovered starting material, indene, is nearly constant, regardless of the length of time for metalation, when equivalent amounts of indene and metal are used. No significant change in the amount of recoverable indene occurred when a 2:1 ratio of metal to indene was heated in refluxing DME for a relatively short time (up to 3 hours with potassium metal and 20 hours with lithium metal—Table VI). But extended time of reflux resulted in lowered recovery of starting material (2% rather than 8% recovery of indene when a 2:1 ratio of *potassium* to indene was heated for 20 hours in refluxing DME; 6% rather than 9% of indene recovered when a 2:1 ratio of *lithium* to indene was heated in refluxing DME for 72 hours—Table VI). The decreased indene did not show up as a corresponding increase in the amount of indan, but might have appeared, via further methylation by some route as an increase in the quantity of dimethyl- or trimethyl-indene. A larger amount of the polyalkylated indene did in fact occur under these conditions.

(*iv*) The total amount of monomethylindene (both 1-methylindene and 3-methylindene) is nearly constant regardless of the length of time of metalation. This is to be expected from a reaction involving two competing pathways, *c* and *d*, which would then lead to the formation of a definite amount of metalated indene. For lithium, the total varied between 67% and 74% of the product. At 0 °C, methylation of 1-indenyllithium gave both 1-methylindene and 3-methylindene in the approximate ratio of 2:1, but methylation at room temperature reversed this since the ratio of 1-methylindene to 3-methylindene was now 2:5.

For potassium metal, the total amount of monomethylindene was 59–60% of the product except when the ratio of potassium metal to indene during metalation was 2:1, and then only for reflux periods considerably greater than 15 hours. In this case, 54% of the product was monomethylindene (Table II). The accompanying increase in di- and tri-methylated indene could readily account for this. A 2-hour metalation period yielded less (53%) of the monomethylindene, but also more recoverable indene. This result is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

quite likely due to incomplete metalation in this time. It is significant that all of the monomethylindene obtained is the 3-isomer, whether the methylation was carried out at 0° or at room temperature.

The Isomerization of 1-Methylindene

The isolation of both 1-methylindene and 3-methylindene from the methylation of 1-indenyllithium, but only 3-methylindene from the methylation of 1-indenylpotassium is no doubt due to the isomerization of the initially formed 1-methylindene in the presence of basic reagents (equation *e*).

(e) 
In the presence of the strong base, 1-indenylpotassium, this conversion was rapid (~10 sec) and the equilibrium (equation *e*) appeared to be completely on the side of 3-methylindene. Increase in temperature accelerated this conversion as shown by the greater proportion of 3-methylindene obtained in the methylation of 1-indenyllithium at room temperature than at 0 °C.

1. Thermal Isomerization of 1-Methylindene

The isomerization can be accomplished by heat alone. When 1-methylindene was refluxed in DME (83°/700 mm) for 24 hours, no change to 3-methylindene was perceived. But when 1-methylindene itself was heated to reflux (~184°/700 mm) and aliquots, withdrawn periodically, were analyzed by gas–liquid chromatography the material was converted 94% to 3-methylindene in 80 minutes as shown in Table III.

TABLE III

Isomerization of refluxing 1-methylindene to 3-methylindene (initial reflux temperature, ~184°/700 mm)

Reflux time, min	Product analysis, %	
	1-Methylindene	3-Methylindene
0	99	1
10	93	7
20	79	21
30	62	38
40	47	53
50	27	73
60	22	78
70	13	87
80	6	94
120	4	96
180	4	96

The data do not fit any simple kinetic order, no doubt because of the polymerization which accompanied isomerization at this temperature, as well as change of reflux temperature as the isomerization progressed. After 80 minutes much of the material has polymerized as shown by the viscous material clinging to the walls of the flask. Indenes are known to polymerize readily when exposed to light and heat (20).

The thermal isomerization appears to involve an equilibrium, since no change in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

4:96 ratio of 1-methylindene to 3-methylindene occurred during the period of reflux between 120 and 180 minutes. The same proportion of these two isomers was obtained when 3-methylindene was refluxed for 7 hours (Table IV).

TABLE IV

Isomerization of refluxing 3-methylindene to 1-methylindene
(initial reflux temperature, ~200°/700 mm)

Expt.	Reflux time, hours	Product analysis, %	
		1-Methylindene	3-Methylindene
1	0.5	2	98
	1.0	3	97
	2.0	4	96
	3.0	4	96
	4.0	4.5	95.5
2	3.0	3	97
	5.0	4	96
	6.0	4	96
	7.0	4	96

The exact position of the equilibrium is not certain since it is not known what the relative rates of polymerization are for 1-methylindene and 3-methylindene. The isomerization, however, occurs much more rapidly than does the polymerization.

2. Base-catalyzed Isomerization of 1-Methylindene

As expected, the base-catalyzed isomerization of 1-methylindene proceeded much more rapidly than did the thermal isomerization, and the rate of this transformation depended upon the strength of the base. The results of several qualitative tests are shown in Table V, and indicate that the effectiveness of the bases used were, in order of decreasing catalytic power, 1-indenylpotassium > methanolic NaOH > 1-indenyllithium > pyridine.

The base-catalyzed isomerization of 1-methylindene eventually yielded only 3-methylindene since only 3-methylindene was obtained from the reaction of 1-indenylpotassium

TABLE V

Isomerization of 1-methylindene in the presence of base
(each run was made with 0.3 ml of 1-methylindene in 1 ml of DME and the base added)

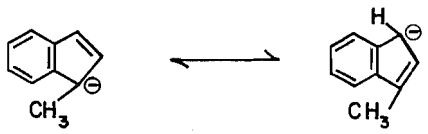
For personal use only.

with methyl iodide. Further support for this view was obtained from the treatment of a solution of *3-methylindene* in DME with methanolic sodium hydroxide. Addition of the base gave an instantaneous yellow color, due to the indenyl carbanion, which became darker when the mixture was shaken for 2 minutes. No conversion of the 3-methylindene to 1-methylindene was detectable by gas–liquid chromatography. Further shaking of the mixture for an additional 15 or 30 minutes failed to alter the result (cf. expt. No. 5, Table V).

The difference between the base-catalyzed and the thermal isomerization may be that in the former case we are dealing with the two contributing structures below, wherein the right-hand form is practically completely predominant. The thermal isomerization,



on the other hand, involves the relative stabilities of the neutral molecules, 1-methylindene and 3-methylindene, in which the 3-methylindene, containing the more highly alkylated olefinic bond, is the more stable (21, 22).

No isomerization whatsoever occurred when a solution of 1-methylindene (1.5 g) in 5 ml of DME containing 3 ml of 6 *N* HCl was refluxed for 1.5 hours.

(*v*) Dimethylindene (both 1,1- and 1,3-dimethylindene) was produced in both cases when the metalated indene, obtained from the reaction of equivalent quantities of metal and indene, was treated as usual with a 50% excess of methyl iodide. Under the conditions used, somewhat more dimethylindene was obtained from 1-indenylpotassium (12–16%) than from 1-indenyllithium (11–13%).

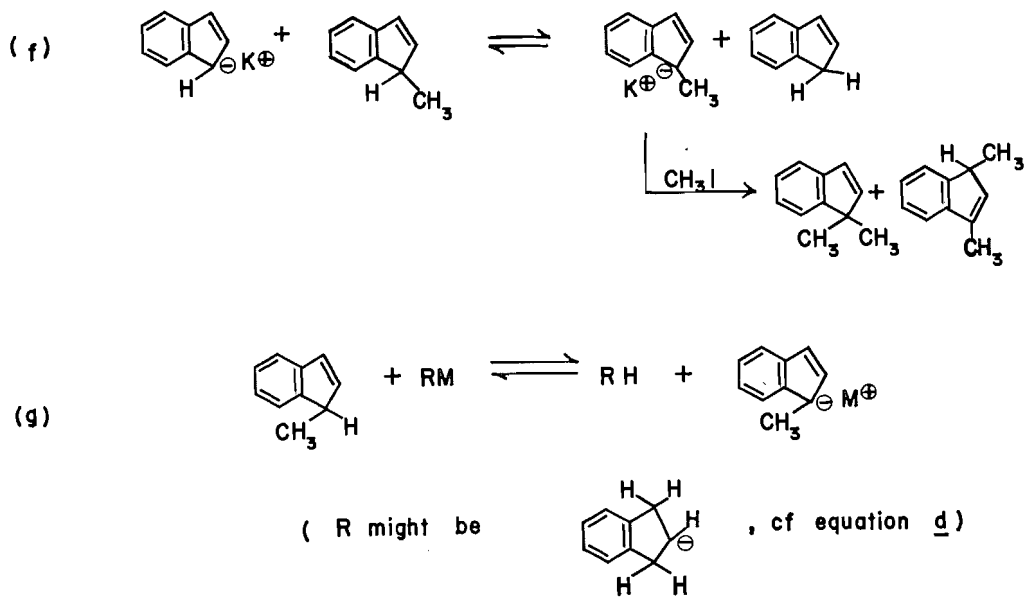
About 15–25% of the dimethylindene was the 1,1-dimethyl isomer. This rose to 33% when the metalated indene was prepared by heating an excess of potassium with indene for 20 hours. But, generally, long or short periods of reflux during metalation with an equivalent quantity of metal and indene did not change this proportion (15–25%) much. Further, from the results in Table II, no clear indication exists of the effect of temperature during methylation on the proportion of 1,1-dimethylindene to 1,3-dimethylindene.

Possible Routes Leading to Dimethylindenes

1. Via metal exchange according to equation *f*.
2. Via reaction of residual metal adduct with monomethylated indene (equation *g*).
3. The presence of some unremoved, unreacted metal which, via reactions similar to those in equation *c* and *d* could convert 1-methylindene into the metalated 1-methylindene. The presence of unreacted potassium metal, during methylation of fluorene, has been shown to produce a greater proportion of the dimethylated fluorene (16).
4. Prolonged heating of the metal in refluxing solvent (DME) might produce basic materials which could cause further alkylation of 1-methylindene. Evidence for reaction of alkali metal with a solvent such as dioxane (23) or aryl ethers (24) has already been reported.

The recovery of substantial amounts of indene, but failure to find the expected methylindan (e.g. 2-methylindan) supports the metal exchange process according to equation *f*. But since less indene was recovered than that expected by equation *f* (the ratio of indene to dimethylindene actually found varied between 7/13 and 10/12), formation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



some of the dimethylindene must have taken place by some additional route—for example because of the presence of unreacted metal, or basic decomposition products resulting from metal attack on the solvent DME. We have found that when *potassium* metal was heated in refluxing DME for several hours, a basic material was obtained. This material in the DME, freed from unreacted metal as much as possible, followed by treatment with both indene and methyl iodide simultaneously, gave a product consisting of 3–4% indan, 62% of recovered indene, 4% of 1-methylindene, and 31% of 3-methylindene. The source of the indan is obviously from some unreacted metal present (cf. equation *d*). The amount of methylindene was more, by about one half, than could be obtained from the amount of unreacted metal present (as calculated from the amount of indan found using the data in Table II to obtain an expected ratio of indan to mono- and di-methylindene). When lithium metal was treated similarly, no basic material was obtained and no alkylation of indene was detected.

It is our view that the dimethylindenes are obtained primarily by route 1 above, but assisted by route 3 and, possibly, in the case of the more reactive metal, potassium, by route 4.

Alkylation of the Product Obtained from Metalation of Indene with Two Equivalents of Metal

When metalation was accomplished using a molar ratio of metal to indene of 2:1, alkylation produced the results shown in Table VI. Conclusions drawn from this information can be summarized briefly as follows.

1. When metalation was carried out for short periods (3 hours for potassium, 5–20 hours for lithium) results were nearly identical with those obtained by the use of equivalent amounts of metal and indene (cf. Table II).

2. With potassium, as the time of metalation was increased, the amount of recoverable indene, as well as the newly formed monomethylindene decreased, while the quantity of dialkylated and trialkylated indene increased. The quantity of metal consumed was larger for the longer metalation period.

*Methylation was done at 0 °C.

†In these two cases a material balance was made to estimate total recovery, using *t*-butylbenzene as an internal standard. The upper line of figures represents the percentages of each substance based on the total amount of isolated product. The lower line is the percentage of each product based upon the indene originally used.

3. With lithium, increase in metalating time gave results about the same as those obtained for shorter metalating periods except that more of the 1-methylindene was isomerized to 3-methylindene.

Metalation and Alkylation of 3-Methylindene

Metalations and alkylations were carried out according to the procedures used for indene itself. The results are compiled in Table VII. Similar reactions were done using 1-methylindene and these results are given in Table VIII. Comparison of the information shown in these tables with those for the analogous reactions involving indene (Table II) lead to the following conclusions.

1. As for the reactions of metal with *indene*, long or short reflux time during metalation produced results which were nearly identical with each other, except that for potassium metal, somewhat more trialkylated indene was formed when the longer reflux time for metalation was used.

2. Total recovery from the metalation and alkylations of the 1-methylindene was 95% for the potassium, and 98% for the lithium. These are substantially higher than those obtained for the analogous reaction using indene.

3. A substantial proportion of the product was the reduced form, 1-methylindan. This was greater (22–27%) than the proportion of indan found from reactions involving indene (Table II).

4. For lithium, the total amount of monoalkylation of methylindene (~70% of product) was about the same as the proportion of monoalkylation of indene while the dialkylation of methylindene to produce 1,1,3-trimethylindene was much less (about 2 to 4% of the product), than that found for indene (about 9–10%). The amount of 1,1,3-trimethylindene from the dialkylation reaction is the *same* as the amount of recovered monomethylindene, suggesting that dialkylation occurs via the metal exchange route shown by equation *f*.

5. With potassium, the amount of monoalkylation (to dimethylindene) is about 30% of the product whereas similar monoalkylation of indene gave about 60% of the product as the monomethylindene. However, the 1,1,3-trimethylindene (from dialkylation) occurred to the extent of 24–29% while recovered unalkylated monomethylindene was found to the extent of 16–18% of the product, indicating that other routes as well as that of metal exchange, brought about dialkylation.

6. Results of the reactions with 1-methylindene (Table VIII) and 3-methylindene (Table VII) are nearly identical. The only significant differences are the slightly higher amounts of metal consumed by the reaction with 1-methylindene, and the recovery of only 3-methylindene rather than the original 1-methylindene as "starting material" (Table VIII).

EXPERIMENTAL

Solvents and Chemicals

1,2-Dimethoxyethane, commercially available, was distilled twice from potassium metal before use. Analysis by gas–liquid chromatography showed it to be free from contaminants.

Potassium metal (BDH reagent) and *lithium metal* (Fischer Scientific Co.) were freed from encrusting oxide or nitride while under Skellysolve B or paraffin oil.

Indene (Eastman Kodak Co.), practical grade, was treated with Drierite, then distilled twice at atmospheric pressure. Analysis by gas–liquid chromatography showed it to be free from impurities and water.

Fluorene (Eastman Kodak Co., 98%) was crystallized six times from 95% ethyl alcohol and then heated for 4 hours at 65° under vacuum in an Abderhalden drier to remove solvent. It was then dried under the same conditions but in the presence of phosphorus pentoxide. The product was stored in a desiccator over phosphorus pentoxide.

Indan (practical grade) was obtained commercially from Matheson Chemical Co.

Gas–Liquid Chromatography (G.L.C.)

A Burrell Model K-2 Kromo-Tog was used for all g.l.c. analyses, utilizing the following 2.5 m columns.

Silicone rubber, 25% by weight on Gas-Chrom P (60–80 mesh). This column separated the following *groups* of compounds from each other but failed to separate the individuals of each group where mixtures are indicated: (*a*) indan and indene, (*b*) 1-methylindene; 1,1-dimethylindene and 1-methylindan, (*c*) 3-methylindene, (*d*), 1,3-dimethylindene and 1,1,3-trimethylindene.

neo-Pentylglycol succinate, 25% by weight on Gas-Chrom P (60–80 mesh). This column separated the following groups from each other but not the individual members of each group: (*a*) indan, (*b*) 1,1-dimethylindene and 1-methylindan, (*c*) indene and 1-methylindene, (*d*) 1,1,3-trimethylindene, (*e*) 3-methylindene and 1,3-dimethylindene.

Apiezon L, 25% by weight on Gas-Chrom P (60–80 mesh). This column separated the following groups from each other but not the individuals contained in each group: (*a*) indan and indene, (*b*) 1,1-dimethylindene, (*c*) 1-methylindene and 1-methylindan, (*d*) 1,1,3-trimethylindene and 3-methylindene, (*e*) 1,3-dimethylindene.

For complete separation of the products of metalation and alkylation it was necessary to change from one column to another. Apiezon L did give better separation than the other two columns, but the peaks were broad and in some cases did not return to the base line satisfactorily, hence quantitative analysis with the integrator attached was not sufficiently satisfactory with this column. The other two columns gave well-resolved, sharp peaks.

Helium, at a flow rate of about 100 ml/min, was the carrier gas. Column temperatures varied with the different packings, but were adjusted to give maximum separation of the products (120–175°). Products were identified by comparison of their retention times with those of authentic samples, as well as by their isolation via the Kromo-Tog and subsequent analysis by n.m.r. and i.r. spectral determinations. These spectra were obtained with a Varian A 60 spectrometer and a Perkin–Elmer Model 421 spectrophotometer respectively.

The paper areas of the various product peaks were measured by an integrator. Analysis of carefully weighed authentic mixtures of the reaction products showed that these paper areas could be used as a direct measure of molar compositions of the reaction mixtures. The addition of a carefully weighed amount of *t*-butylbenzene as an internal standard allowed the calculation of the weights of each individual product and hence determination of the absolute per cent recovery.

General Procedure for the Formation and Collection of Hydrogen Gas

A 250-ml, round-bottom, 3-neck flask equipped with a magnetic stirrer was heated with a bunsen flame to remove adhering moisture. After it was allowed to cool (calcium chloride tube), it was equipped with a short water-condenser and a gas collecting apparatus. To the flask was added 100 ml of DME, 0.10 gram-atom of metal (if the metal was lithium it was cut up into small pieces) and 0.10 mole of the hydrocarbon in the order specified. But in the case of fluorene, 0.10 mole of the hydrocarbon was first dissolved in 100 ml of solvent and the metal added last. The reaction mixture was refluxed till no more gas was evolved (from 2 to 22 hours, see Table I). All gases were collected by the downward displacement of water. Small samples of this gas were taken and analyzed for molecular hydrogen content by mass spectrometry with a Metropolitan Vickers instrument, Model MS-2H, AEI, Manchester. Blanks were run under identical conditions except that the hydrocarbon was not added to the reaction flask.

General Procedure for the Metalation and Methylation of the Indenes

To a dried, 3-neck 250-ml round-bottom flask, equipped with a magnetic stirrer and a reflux condenser, were added 100 ml of DME and 0.10 (or 0.20) gram-atom of metal (Li was cut into small pieces). The redistilled indene (11.6 g, 0.10 mole) was added at once to the mixture, protected by an atmosphere of purified, dry nitrogen. The mixture was refluxed for a specific length of time (see Tables II, VI–VIII), then cooled in an ice-water bath. Any unreacted metal was removed mechanically as completely as possible and weighed. To the cold residual solution, now at 0–5°, was added dropwise over a period of 30–45 minutes, an excess (approximately 1.5 equivalents) of methyl iodide. After the addition was completed, the reaction mixture was stirred for 30 minutes at room temperature, then decomposed with excess dilute aqueous hydrochloric acid. The mixture was then extracted twice with ether (total volume ~400 ml), the ether extract dried ($MgSO_4$), filtered, and freed from solvent. The remaining dark oil was then analyzed by gas–liquid chromatography.

Preparation of Methylated Indenes and Indan

(All melting points are uncorrected.)

3-Methylindene was prepared in 60–75% yield by the method of Parham *et al.* (25), starting with commercially available 1-indanone (Eastman Kodak Co.). The product was a colorless liquid boiling at 56°/2.0 mm; η_D^{23}, 1.5621. Lit. b.p., 76–78°/11 mm; η_D^{25}, 1.5587 (25). The n.m.r. spectrum of this compound is shown in Fig. 1(*a*).

1-Methylindene was synthesized from 3-methyl-1-indanol in 40% yield according to the scheme given by Yarboro, Karr, and Estep (26). Since experimental details were lacking, the procedure is described below.

By a Friedel and Crafts reaction, benzene, crotonic acid, and 3 equivalents of anhydrous aluminum chloride gave 3-methyl-1-indanone (27). B.p., 103°/3.9 mm. Lit. b.p., 132–137°/15 mm (27). Reduction of this ketone with 40–50% excess of lithium aluminum hydride in ether according to general procedure (28) afforded 3-methyl-1-indanol, m.p., 70–72°. Lit. m.p., 71–72° (28).

In the absence of solvent, the alcohol was stirred and heated with 25% of its weight of solid oxalic acid, either in the anhydrous or the dihydrate form, at reflux temperature for 15–20 minutes. After cooling, the substituted indene was extracted from the solidified acid with Skellysolve B. The hydrocarbon layer was dried and fractionally distilled giving a 40% yield of 1-methylindene as a colorless liquid boiling at 54°/3.5 mm; η_D^{25}, 1.5540. Lit. b.p., 55–56°/3.75 mm (or 186°/735 mm); η_D^{20}, 1.5565 (26).

The n.m.r. spectrum of this compound, shown in Fig. 1(*b*), corroborates the structure designated.*

1,3-Dimethylindene was prepared from the 3-methyl-1-indanone, mentioned above, by the method suggested in the literature (29) with the following modifications. After the usual ammonium chloride – water work-up, the ether layer was dried and distilled at reduced pressure yielding both 1,3-dimethyl-1-indanol, m.p., 67–69°; lit. m.p. 72° (29) and 1,3-dimethylindene (colorless oil) b.p., 68°/3 mm; η_D^{21}, 1.5486. Lit. b.p., 66°/3 mm; η_D^{20}, 1.5477 (26).

The n.m.r. spectrum of 1,3-dimethylindene is shown in Fig. 1(*c*).

1,1-Dimethylindene has not been reported in the literature to our knowledge. Its preparation is described below and is similar to the preparation of 1-methylindene. By a Friedel and Crafts reaction a mixture of

**The C_1 proton of 1-methylindene (neat) gives a signal at τ = 6.78 (quartet, J = 8 c.p.s.) while the C_1 proton of indene (neat) shows a signal at τ = 6.98 (triplet, J = 2.0 c.p.s.). This is in agreement with the results found for fluorene and 9-methylfluorene (G. W. H. Scherf and R. K. Brown, Can. J. Chem. 38, 1388 (1961) showing a greater deshielding effect upon the C_1 proton in 1-methylindene and suggesting that it is more "acidic" than is the C_1 proton of indene.*

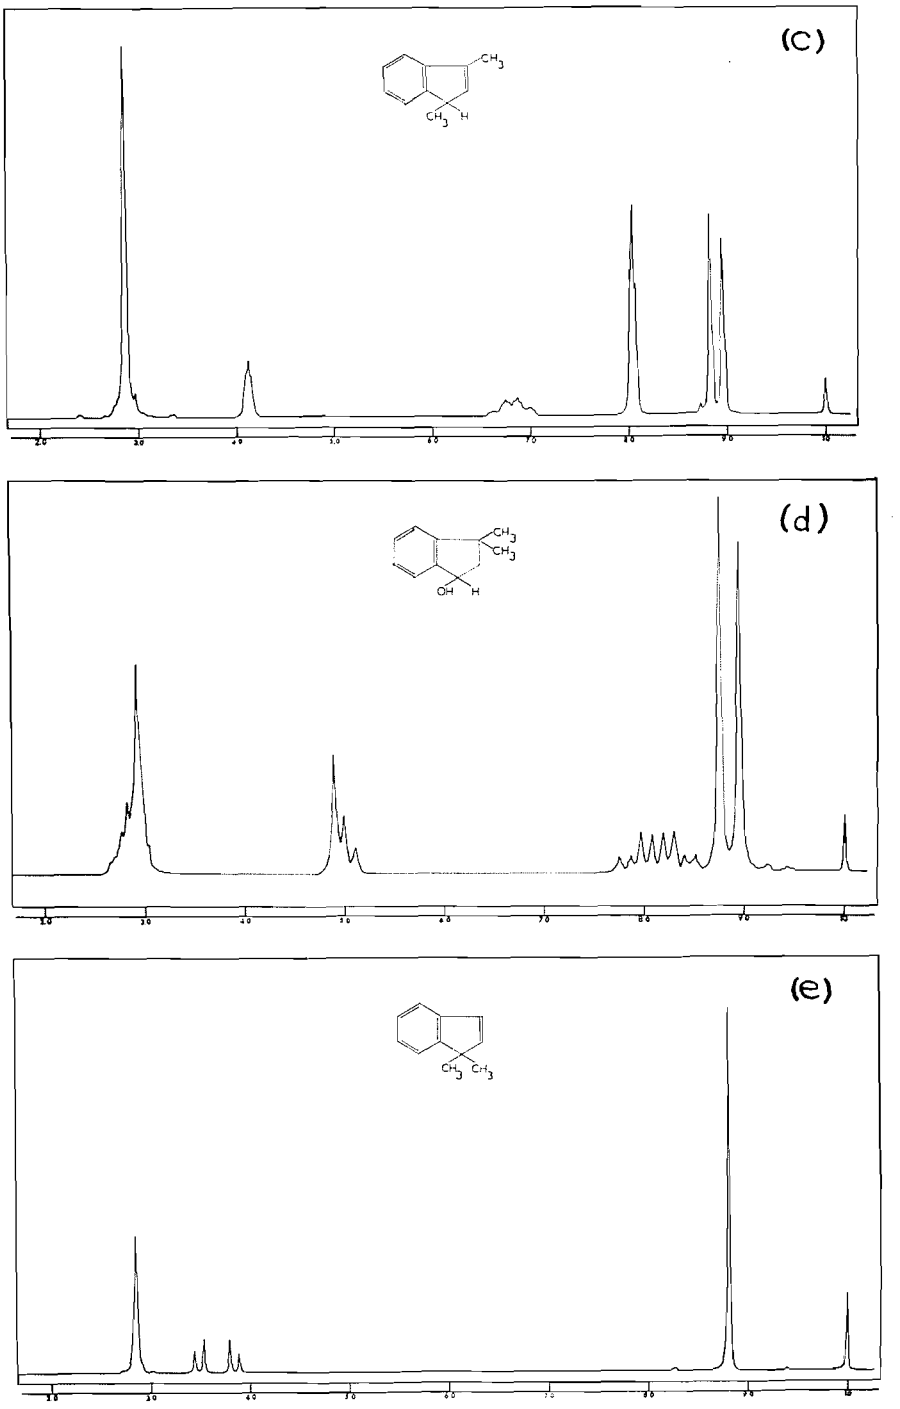

FIG. 1. Nuclear magnetic resonance spectra of indene derivatives (referred to tetramethylsilane, $\tau = 10.00$). All spectra were obtained on the pure liquids, neat, except in the case of 3,3-dimethyl-1-indanol which was diluted with an equal volume of carbon tetrachloride to reduce the viscosity of the hydrocarbon; (*a*) 3-methylindene, (*b*) 1-methylindene, (*c*) 1,3-dimethylindene, (*d*) 3,3-dimethyl-1-indanol, (*e*) 1,1-dimethylindene.

benzene, 3-methyl crotonic acid (Aldrich Chemical Co.) and 3 equivalents of aluminum chloride gave 3,3-dimethyl-1-indanone in 82% yield. B.p. 107°/4.7 mm. Lit. b.p. 130–132°/18 mm (30). Reduction of the ketone with lithium aluminum hydride according to the usual procedure (28) afforded 3,3-dimethyl-1-indanol in 80% yield as a colorless, viscous oil boiling at 107°/4.2 mm; η_D^{24}, 1.5340. Anal. Calc. for $C_{11}H_{14}O$: C, 81.44; H, 8.70. Found: C, 81.75; H, 8.66. The n.m.r. spectrum, shown in Fig. 1(*d*), is consistent with the formulation of this compound as 3,3-dimethyl-1-indanol.

A mixture of 3,3-dimethyl-1-indanol (25 g) and 10 g of solid oxalic acid dihydrate was heated to reflux for 1 hour. The cooled reaction mixture was extracted with Skellysolve B to remove the oil from the solidified oxalic acid. The dried extract ($MgSO_4$) was fractionally distilled and afforded 11 g (yield, 50%) of a colorless oil boiling at 57°/4.8 mm; η_D^{23}, 1.5379. Anal. Calc. for $C_{11}H_{12}$: C, 91.61; H, 8.39. Found: C, 91.47; H, 8.20. The n.m.r. spectrum of the 1,1-dimethylindene is shown in Fig. 1(*e*) and agrees with the structure assigned.

1,1,3-Trimethylindene was prepared quite readily from 3,3-dimethyl-1-indanone (see above) according to published procedure (31). It was a colorless oil boiling at 68°/3.6 mm; η_D^{24}, 1.5348. Lit. b.p., 52–61°/0.5 mm; η_D^{25}, 1.5353 (31).

1-Methylindan was obtained as a colorless oil by the reduction of 3-methylindene in methyl alcohol using a platinum oxide catalyst and hydrogen at an initial pressure of 50 p.s.i. The procedure was similar to directions already published (29) for the reduction of 1,3-dimethylindene. Yield, 81%. B.p. 98°/43 mm; η_D^{24}, 1.5266. Lit. b.p., 189.5/739 mm; η_D^{25}, 1.5241 (32).

2,2′-Biindanyl was prepared according to published directions (19, 33) from α,α'-dibromo-*o*-xylene and diethylmalonate. After three crystallizations from 95% ethyl alcohol, the final product (needles) melted at 168–170°. Lit. m.p., 165–166° (19). Its n.m.r. spectrum showed a peak at $\tau = 2.86$, and a broad, poorly resolved multiplet centered at $\tau = 7.18$. The areas were in the ratio of 4:5. Mass spectral and infrared data were also in complete agreement with the structure.

The above compound was shown to be identical in all respects (n.m.r. and i.r. spectra, melting point, and mixed melting point) with the solid obtained from the metalation of indene with lithium.

ACKNOWLEDGMENT

The authors thank the National Research Council of Canada for their financial support during this work. One of us (A. Bosch) gratefully acknowledges the receipt of a scholarship from the Cities Services Research and Development Company which enabled him to continue his work. We also thank R. Swindlehurst and Mrs. G. Conway for the infrared and n.m.r. spectral determinations of compounds prepared, and R. Taylor for the mass spectrometer analyses.

CLEAVAGE OF XANTHENE ETHERS

A NEW ROUTE TO 9-SUBSTITUTED XANTHENES

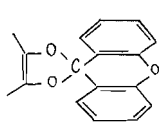
N. LATIF, I. FATHY, AND N. MISHRIKY
National Chemical Research Centre, Dokki, Cairo, United Arab Republic

Received January 3, 1964

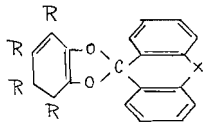
ABSTRACT

9,9-(Tetrachloro-*o*-phenylenedioxy) xanthene (II*a*) and its thio-analogue (II*b*) are cleaved by hydrazines to give the corresponding hydrazones of xanthone and thiaxanthone, respectively, together with tetrachlorocatechol. The unsaturated nitriles (V*a*), (V*b*), and (V*c*) are produced similarly by the action of malononitrile and cyanoacetic ester. Dixanthenyl ether itself reacts in a similar manner with active hydrogen compounds to give the corresponding 9-xanthyl derivatives. (II*b*) is prepared by the action of 9-diazothiaxanthene on tetrachloro-*o*-benzoquinone and is readily cleaved by lithium aluminum hydride to give thiaxanthene and tetrachlorocatechol. The reaction mechanisms are discussed.

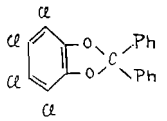
9-Substituted xanthenes have found wide application in biology and industry, and special attention has been directed recently to the study of the chemistry of this group of compounds. It has been shown, in this laboratory, that xanthene ethers of the type (I) have unusual chemical reactivity unrelated to that of previously reported analogous compounds. For example, it is known that ethers are ordinarily not reactive enough as substrate to be hydrolyzed easily; however, it has been found (1) that 9,9-(tetrachloro-*o*-phenylenedioxy) xanthene (II*a*), in contrast to other analogous methylenedioxy derivatives such as (III), is easily cleaved by dilute mineral acids under very mild conditions to give xanthone. Also, it has been reported (2) that xanthene ethers of the type (I) exceptionally undergo reductive cleavage by lithium aluminum hydride yielding xanthene. The unusual reactivity of (I) has been rationalized by assuming that a carbonium ion is first formed as an intermediate and is stabilized by resonance with the unshared electron pair on the oxygen of the xanthylene residue.



(I)



(II*a*): R = Cl, X = O.
(II*b*): R = Cl, X = S.
(II*c*): R = Br, X = S.



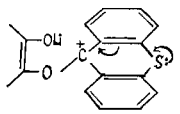
(III)

In the present investigation, it is found that the thiaxanthene analogues have similar reactivity. Thus, when (II*b*) is allowed to react with lithium aluminum hydride in boiling ether, thiaxanthene and tetrachlorocatechol are produced (3). It is assumed that cleavage proceeds by the initial attack of a positive ion such as Li^+ or AlH_2^+ on the oxygen of the dioxole ring followed by the heterolytic fission of the C—O bond to give a resonance stabilized carbonium ion (cf. IV) which readily picks up a hydride ion yielding finally xanthene. A similar mechanism has been previously proposed for the cleavage of the analogous cyclic ether (II*a*) (2). (II*a*) is prepared in good yield by the reaction of 9-diazothiaxanthene with tetrachloro-*o*-benzoquinone. The bromo-analogue (II*c*) is similarly obtained from tetrabromo-*o*-benzoquinone.

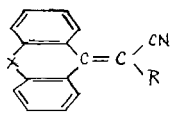
This remarkable reactivity of xanthene and thiaxanthene ethers stimulated us to extend our investigations and study their reactivity towards active hydrogen compounds. It is found (3, 4, 5) that when (II*a*) or (II*b*) is allowed to react with phenylhydrazine or benzoylhydrazine in boiling ethanol, the corresponding hydrazones of xanthone and thiaxanthone, respectively, are obtained together with tetrachlorocatechol. However, with hydrazine hydrate, the corresponding hydrazones and ketazines are produced.

It is found also that malononitrile reacts readily with (II*a*) and (II*b*) under similar conditions to give the highly colored unsaturated dinitriles (V*a*) and (V*b*), respectively, in excellent yields, together with tetrachlorocatechol. However, a higher reaction temperature has been found necessary to cleave the cyclic ether by cyanoacetic ester. For example, (V*c*) is only produced when the higher boiling *n*-butyl alcohol is used as a solvent. (V*a*), (V*b*), and (V*c*) have been previously obtained by condensing malononitrile or ethyl cyanoacetate with the corresponding thione in presence of yellow mercuric oxide (6).

Two possible suggestions might be proposed to explain the production of the xanthylene and thiaxanthylene derivatives by the action of active hydrogen compounds on xanthenic ethers. For example, in the case of the reaction of malononitrile with (II*a*), it is assumed

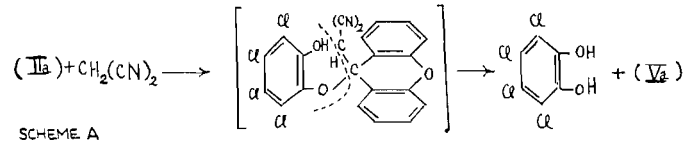


(IV)

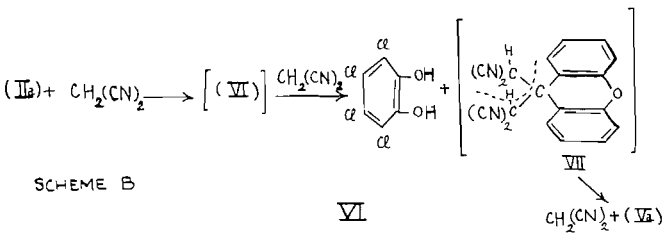


(V*a*): R = CN, X = O.
(V*b*): R = CN, X = S.
(V*c*): R = $OCOC_2H_5$, X = S.

that an intermediate (VI) is first formed which cleaves to give directly Δ^9,α-xanthenemalononitrile by a β-elimination process as shown in Scheme A. The other alternative which immediately suggests itself is that (VI) might react further with another molecule of malononitrile to give a second intermediate (VII) which decomposes under reaction conditions yielding the product as shown in Scheme B. However, the first possibility seems to be more feasible. In this connection, it is worth mentioning that the yield of (V*a*) is found to be the same whether using one or two moles of malononitrile in this reaction.



SCHEME A



SCHEME B

The production of the corresponding ketazines in the reaction between (II*a*) or (II*b*) with hydrazine hydrate might be explained by assuming that part of the hydrazone first formed reacts further with the cyclic ether to give the azine. This view is supported by the fact that xanthone hydrazone is found to react readily with (II*a*) under the same conditions to give xanthone azine in excellent yield.

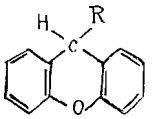
In an attempt to generalize this reaction, the reactivity of dixanthenyl ether itself has been investigated. It is found (4, 5) that the ether reacts readily with active hydrogen compounds to give the corresponding 9-xanthyl derivatives which have been previously obtained by the acid-catalyzed reaction of these compounds with xanthydrol. For example, (VIII*a*), (VIII*b*), and (VIII*c*) are produced, in good yield, by the action of benzoylhydrazine, ethyl cyanoacetate, and malononitrile, respectively, on dixanthenyl ether in boiling ethanol.



(VIII*a*): R = $HN.HNCOC_6H_5$
(VIII*b*): R = $CH.CN.COOC_2H_5$
(VIII*c*): R = $CH(CN)_2$

Cleavage of xanthene ethers by active hydrogen compounds provides a new method for the direct synthesis of 9-substituted xanthenes which enhances the value of xanthene ethers as synthetic intermediates.

EXPERIMENTAL

Reaction of 9,9-(tetrachloro-o-phenylenedioxy) xanthene (IIa) with hydrazine hydrate.—The xanthene ether (1) (1 g) and hydrazine hydrate (98–100%, 1 ml) in absolute alcohol (25 ml) were refluxed together for 5 hours. The solution was filtered while hot, and the orange crystals obtained (0.01 g) were shown to be xanthone azine (m.p. and mixed m.p. 295 °C). The filtrate was concentrated and left to cool. The yellow solid formed was filtered off and recrystallized from methanol to give xanthone hydrazone (0.1 g) m.p. 126 °C (undepressed when admixed with an authentic sample). The main ethanolic mother liquor was poured onto ice-cold water and acidified with hydrochloric acid. The precipitate formed was filtered off, dried, and refluxed with acetic anhydride (10 ml) for 30 minutes. The solution was left to cool, poured onto ice, and the separated solid was filtered off and washed with water. This was dried and crystallized from methanol to give the diacetate of tetrachlorocatechol, m.p. 184° (undepressed when admixed with an authentic sample prepared as described by Zincke and Kuster (7)).

Reaction of (IIa) with phenylhydrazine.—The cyclic ether (1 g) and phenylhydrazine (1 g) in absolute ethanol (20 ml) were refluxed together for 3 hours. The solution was filtered while hot, concentrated, and left to cool. The solid formed was filtered off and recrystallized from ethanol to give golden yellow crystals, m.p. 152 °C (0.5 g), which proved to be xanthone phenylhydrazone (m.p. and mixed m.p.). Tetrachlorocatechol was produced in the reaction and identified as before.

Reaction of (IIa) with benzoylhydrazine.—The reaction was carried out as above using half a gram of the ether and one-fifth of a gram of the hydrazine. The solution was cooled and the yellow solid formed was crystallized from benzene to give xanthone benzoylhydrazone as yellow crystals, m.p. 150 °C. Calc. for $C_{20}H_{14}O_2N_2$: C, 76.43; H, 4.46; N, 8.91. Found: C, 77.00; H, 4.65; N, 8.66%.

Reaction of (IIa) with xanthone hydrazone.—A suspension of (II*a*) (1 g) and the hydrazone (1 g) in absolute alcohol (20 ml) were refluxed together for 5 hours and the mixture was left to cool. The solid formed was crystallized from xylene to give xanthone azine (0.56 g) as orange yellow crystals, m.p. 295 °C (undepressed when admixed with an authentic sample).

Reaction of malononitrile with (IIa).—Malononitrile (0.3 g) was added to a suspension of (II*a*) (1 g) in absolute alcohol (20 ml) and the reaction mixture was refluxed for 4 hours. During this period the cyclic ether went gradually into solution and a yellow crystalline solid was formed. This was filtered off and recrystallized from benzene to give Δ^9,α-xanthenemalononitrile (V*a*) as green yellow crystals (0.35 g), m.p. 244–245 °C (undepressed when admixed with a sample prepared by condensing 9,9-dichloroxanthene with malononitrile (6)). Tetrachlorocatechol was identified in the ethanolic mother liquor as before. When the reaction was carried out using equimolecular amounts of the reactants, almost the same yield of (V*a*) was obtained.

Preparation of 9,9-(tetrachloro-o-phenylenedioxy) thiaxanthene (IIb).—Tetrachloro-*o*-benzoquinone (0.8 g) was added portionwise, at room temperature (25 °C), to a solution of 9-diazothiaxanthene (8) (1 g) in dry ether (20 ml). A vigorous reaction with evolution of gas took place after each addition and the red color of the quinone disappeared. When all the quinone had been added, the product formed was filtered off, washed with acetone, and recrystallized from the same solvent to give (II*b*) as colorless crystals, m.p. 221 °C (undepressed when admixed with an authentic sample prepared by the reaction of 9,9,dichlorothiaxanthene

with tetrachlorocatechol (9)). Both products have identical infrared spectra. Calc. for $C_{19}H_8O_2SCl_4$: C, 51.58; H, 1.81; S, 7.24; Cl, 32.12. Found: C, 51.75; H, 1.99; S, 7.16; Cl, 31.59%.

Preparation of 9,9-(tetrabromo-o-phenylenedioxy) thiaxanthene (IIc).—The reaction was carried out as in the case of the chloro-analogue when (II*c*) was obtained as colorless crystals, m.p. 245 °C (undepressed when admixed with an authentic sample prepared by the reaction of tetrabromo-*o*-benzoquinone with thiaxanthone hydrazone (9)).

Reaction of (IIb) with lithium aluminum hydride.—One gram of (II*b*) was added in small portions to a suspension of lithium aluminum hydride (1 g) in dry ether (40 ml). When all the cyclic ether had been added, the reaction mixture was refluxed for 6 hours on the water bath, and left to cool. It was decomposed with alcohol then with dilute hydrochloric acid, and extracted several times with ether. The combined ethereal extracts were dried over anhydrous sodium sulphate, and the ether was then driven off. The solid left was dissolved in the least amount of boiling methanol and the solution was filtered while hot and left to cool. The separated colorless crystals were shown to be thiaxanthene (m.p. and mixed m.p.). The alcoholic mother liquor was poured onto ice-cold water and acidified with a few drops of hydrochloric acid. The precipitate formed was shown to be tetrachlorocatechol as before.

Reaction of hydrazine hydrate with (IIb).—Hydrazine hydrate (99–100%—0.5 ml) and (II*b*) (0.5 g) in absolute alcohol (20 ml) were refluxed together for 3 hours. The reaction mixture was filtered while hot, and the solid obtained (0.002 g) was shown to be thiaxanthone azine (m.p. and mixed m.p.). The filtrate was concentrated and cooled. The pale yellow solid formed (0.16 g) was filtered off, crystallized from ethanol, and shown to be thiaxanthone hydrazone (m.p. and mixed m.p.). Tetrachlorocatechol was identified in the main alcoholic mother liquor as before.

Reaction of phenylhydrazine with (IIb).—The reaction was carried out as above using half a gram of phenylhydrazine and half a gram of (II*b*). The solution was filtered while hot, concentrated, and left to cool. The crystalline solid formed (0.31 g) was filtered off, and recrystallized from methanol to give thiaxanthone phenylhydrazone as yellow crystals, m.p. 150–151 °C. It gives an olive green color with deep green fluorescence with concentrated sulphuric acid. Calc. for $C_{19}H_{14}SN_2$: C, 75.49; H, 4.63; S, 10.59; N, 9.27. Found: C, 75.27; H, 4.83; S, 10.55; N, 9.25%. Tetrachlorocatechol was produced in the reaction and identified as above.

Reaction of benzoylhydrazine with (IIb).—The reaction was carried out as above. The solution was filtered while hot and evaporated to dryness under reduced pressure, and a few milliliters of methanol was added to the oily residue. The light yellow solid formed (0.24 g) was filtered off and crystallized from methanol to give thiaxanthone benzoylhydrazone as straw yellow crystals, m.p. 177 °C. Calc. for $C_{20}H_{13}OSN_2$: S, 9.72; N, 8.51. Found: S, 10.41; N, 8.36%. Tetrachlorocatechol was identified in the alcoholic mother liquor as above.

Reaction of malononitrile with (IIb).—Malononitrile (0.5 g) and the cyclic ether (II*b*) (0.5 g) in absolute alcohol (30 ml) were refluxed together for 6 hours. The orange yellow crystalline solid formed during the reaction was filtered off, washed with acetone, and crystallized from benzene to give Δ^9,α-thiaxantheneomalononitrile (V*b*) (0.2 g) as orange yellow crystals, m.p. 300–301 °C (undepressed when admixed with an authentic sample prepared by the reaction of 9,9-dichlorothiaxanthene with malononitrile (6)). Tetrachlorocatechol was produced in the reaction and identified as above.

Reaction of ethyl cyanoacetate with (IIb).—A mixture of (II*b*) (1 g) and ethyl cyanoacetate (1 ml) in *n*-butyl alcohol (20 ml) was refluxed for 6 hours. The solution was filtered while hot, evaporated to dryness under reduced pressure, and a few milliliters of methanol was added to the oily residue. The yellow crystalline solid formed (0.35 g) was filtered off, washed with methanol, and crystallized from the same solvent to give Δ^9,α-thiaxantheneacetic acid, α-cyanoethyl ester (V*c*) as yellow crystals, m.p. 129–130 °C (undepressed when admixed with an authentic sample prepared by the reaction of 9,9-dichlorothiaxanthene with ethyl cyanoacetate (6)). Tetrachlorocatechol was identified in the main methanolic mother liquor as before.

Reaction of malononitrile with dixanthenyl ether.—To a suspension of dixanthenyl ether (1.8 g) in absolute alcohol (25 ml), malononitrile (0.6 g) was added, and the reaction mixture was refluxed for 4 hours. During this period the ether went gradually into solution and a crystalline solid was formed. This was filtered off, and the filtrate was concentrated, and left to cool. The solid separated was filtered off, and crystallized from ethanol to give 9-xanthyl malononitrile (VIII*c*) (1.1 g) as colorless crystals, m.p. 186–188 °C (undepressed when admixed with an authentic sample prepared by the reaction of xanthydrol with malononitrile (10)).

Reaction of ethyl cyanoacetate with dixanthenyl ether.—Ethyl cyanoacetate (2.5 g) and dixanthenyl ether (3.7 g) in absolute alcohol (25 ml) were refluxed together for 6 hours. The solution was filtered while hot, and evaporated to dryness. The oily residue obtained was extracted several times with cold petroleum ether (b.p. 40–60°). The solid obtained (1.4 g) was filtered off, washed with methanol, and crystallized from ethanol to give (VIII*b*) (11) as colorless crystals, m.p. 125–127 °C. Calc. for $C_{18}H_{15}O_3N$: C, 73.72; H, 5.11; N, 4.77. Found: C, 74.04; H, 4.97; N, 4.22%.

Reaction of benzoylhydrazine with dixanthenyl ether.—The reaction was carried out as above using 0.8 g of benzoylhydrazine and 1.8 g of the ether. The solution was filtered off, concentrated, and left to cool. The solid separated was filtered off, and crystallized from ethanol to give (VIII*a*) (12) as colorless crystals, m.p. 176–178 °C (yield 1.7 g). Calc. for $C_{20}H_{16}O_2N_2$: C, 75.94; H, 5.10; N, 8.86. Found: C, 75.52; H, 5.37; N, 8.98%.

REACTION OF 2-METHYL-2-NITRO-1,3-PROPANEDIOL WITH ALKALI[1]

A. M. UNRAU
Department of Plant Science, University of Manitoba, Winnipeg 19, Manitoba
Received November 25, 1963

ABSTRACT

Hydrolysis of 2-methyl-2-nitro-1,3-propanediol with strong alkali (20% NaOH) resulted primarily, as expected, in a reverse aldol decomposition, although a small but significant quantity of free nitrite ion was detected. Hydrolysis with alkaline borate (pH 10) gave high yields of nitrite ion. Possible mechanisms to explain these results are presented. The major product formed in the borate hydrolysis was identified as 2-C-methyl glycerol (2-methyl-1,2,3-propanetriol). A number of minor products were also detected by vapor-phase chromatography.

DISCUSSION

Mechanisms have been advanced by Haas and Riley (1) and Lippincott (2) for the alkaline hydrolytic removal of the nitro group from primary nitroalkanes and it appears likely the suggested mechanisms were operative in the removal by alkali of the nitro group from β-nitropropionic acid (3). It has been reported (3) that 20 to 25% of the nitro group was removed from this naturally occurring nitro acid to give nitrite ion, when an alkaline borate buffer was used. It was found that the addition of formaldehyde greatly facilitated the removal of the nitro group from β-nitropropionic acid (3, 4) and primary aliphatic nitro compounds (4) and possible mechanisms leading to the greater ease of nitro group elimination have been suggested (4). It is known that 2 moles of formaldehyde may be condensed in an aldol fashion with 1 mole of a primary aliphatic nitro compound, thus removing both acidic α-hydrogens. In the mechanisms proposed by Haas and Riley (1) and Lippincott (2), the presence of α-hydrogens is required. If the α-hydrogens are replaced by hydroxymethyl groups, another mechanism would have to be operative.

An approach which might produce further information regarding the mode of removal of the nitro group would involve suitable model compounds. It was believed that 2-methyl-2-nitro-1,3-propanediol, a crystalline compound commercially available, would serve as a fairly adequate model at this stage. This compound, the nuclear magnetic resonance (n.m.r.) characteristics of which have recently been reported (5), is very soluble in water, methanol, and ethanol; less soluble in acetone; and only sparingly soluble in less polar solvents. The infrared and ultraviolet spectral characteristics of this type of nitro diol have been investigated (6) in some detail. Whereas it was found that 1,3-propanediol has bonded hydroxyl (hydroxyl bands at 2.83 μ in dichloromethane at a number of different concentrations), this feature was reported to be absent for mononitro diols. It has been suggested (6) that the close proximity of the hydroxyl groups and the nitro group might favor an interaction between these groups. Depending on the relative stability of such an interacting system, the ease whereby these nitro diols might be decomposed by alkali could be influenced. It is reasonable that weak alkali would not appreciably disrupt this hydroxyl – nitro group interacting system. Under these conditions, the tertiary, electron-deficient carbon atom might be more easily approached by a nucleophile. A planar intermediate or transition state could lead to a Walden inversion which, however, would not be observable in the optically inactive compound used.

The ultraviolet spectra of the nitro diol in methanol with varying concentrations of sodium hydroxide and sodium borate indicated different interactions for these two conditions. A solution of the nitro compound in methanol alone had a well-defined absorption band at 276–278 mμ. Addition of water to the solution caused no appreciable change in the position of the absorption band, although the maximum became progressively less well defined. In water alone, the band at 276–278 mμ appeared as a shoulder. Similar observations have been made (6) for a similar nitro compound, namely 2-hydroxymethyl-2-nitro-1,3-propanediol. This was verified further in this laboratory when the above nitro triol was dissolved in methanol, in methanol containing water, and in water alone. Addition of sodium hydroxide to the methanol solution of the nitro diol caused a marked shift in the absorption band. At low concentrations of this alkali (0.01 to 0.1% w/v), a well-defined band was observed at 296–297 mμ. With increasing base strength (0.08 to 2.0%) this band became obscured with a shoulder evident about 288–290 mμ. In contrast, addition of similar concentrations of sodium borate gave rise to an absorption band at 274–275 mμ at lower concentrations while at higher borate concentrations, a shoulder was observed at 273–274 mμ. These rather different spectra indicated that the nitro group in the nitro diol interacted in a rather different manner under the described conditions (see Fig. 1).

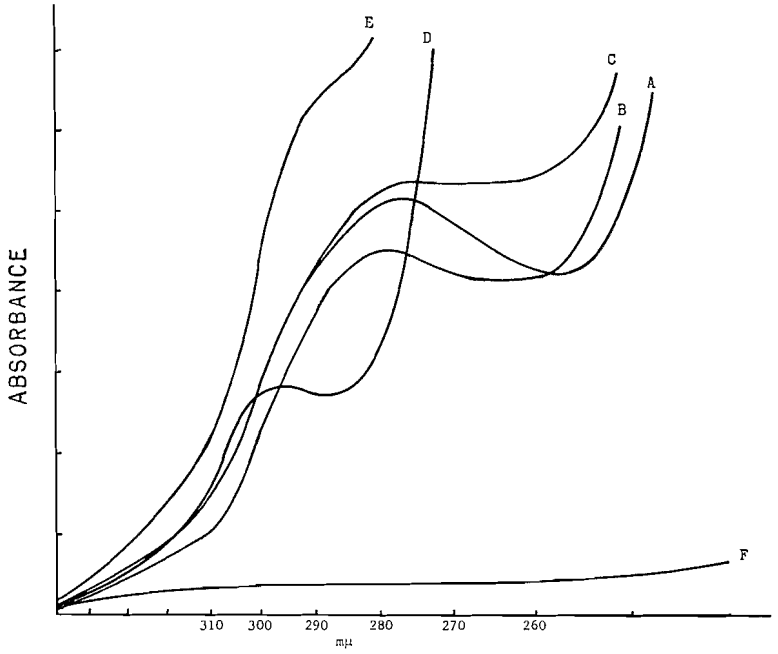

FIG. 1. Ultraviolet absorption spectra of 2-methyl-2-nitro-1,3-propanediol in various solvents. A, in MeOH, B, in water, C, in water and borate (0.02%), D, in MeOH and NaOH (0.01%), E, in MeOH and NaOH (0.08%), F, MeOH – borate blank.

Alkaline hydrolysis (20% NaOH – 15 lb pressure) of the nitro diol resulted in a 5 to 7% release of nitrite ion. A considerable amount of dark-brown, water insoluble polymeric material was formed. It was presumed that the tar consisted of a mixture of formaldehyde and nitroethylene polymers, since nitroethylene and formaldehyde would be formed in the reverse aldol decomposition of the parent compound. The release of a small amount

of nitrite could possibly come about by a direct substitution of the nitro group by hydroxyl or an attack on the tertiary carbon by the neighboring potential oxygenate anion to form an intermediate epoxide. In the experiments involving weak alkali solutions consisting of sodium bicarbonate and dilute sodium hydroxide, considerably less tar was formed and as much as 35% free nitrite was formed. Under these conditions it would be less likely that the neighboring hydroxyl groups would be ionized.

Treatment of the nitro compound with sodium borate buffer resulted in minimal tar formation while nitrite ion release was found to be as high as 90%. It was apparent that under these conditions the reverse aldol decomposition was of minor consequence and the nitro group was rather efficiently eliminated by some other mechanism. As indicated above, the ultraviolet spectrum under these conditions suggests a different interaction. It is known that borate will form charged complexes with *cis* 1,2-diols or form an intermolecular complex with polyhydroxylated compounds (7, 8, 9). Involvement of the nitro group and a hydroxyl with borate could facilitate removal of the nitro group by hydroxylation (nucleophilic attack) of the electron-deficient β-carbon and finally lead to the formation of 2-C-methyl glycerol (2-methyl-1,2,3-propanetriol). An alternative reaction route might involve intermolecular borate complexing of both hydroxyl groups with no direct participation of the nitro group. The nitro group could then be displaced in the same manner as suggested above, namely, nucleophilic displacement by hydroxide.

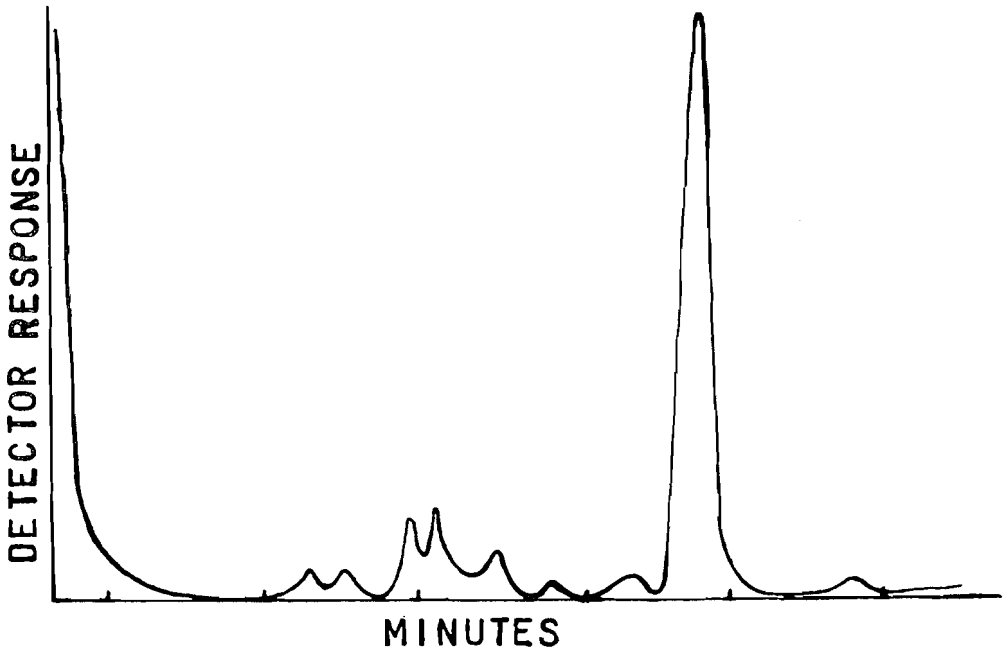

FIG. 2. Gas chromatography of product from alkaline borate hydrolysate. Column temperature programmed from 90 to 190 °C at 10°/min; helium flow 90 ml/min.

The product, a pale-yellow oil, obtained from the alkaline borate hydrolyzate exhibited no absorption bands generally ascribed to the nitro group in its infrared spectrum. Analysis of the product by gas chromatography gave (see Fig. 2) a complex spectrum in which at least eight minor components were evident together with one major peak. The major component, emerging as a sharp, symmetrical peak with a retention time of 8 min

For personal use only.

at a programming rate of 10 °C per min (starting temp. 90 °C), was collected and identified as 2-C-methyl glycerol (2-methyl-1,2,3-propanetriol).

EXPERIMENTAL

Evaporations were carried out under reduced pressure at bath temperatures of 35 °C to 45 °C. Melting points of derivatives were determined on a hot stage apparatus and are uncorrected. The descending technique was used in paper chromatography and solvent systems employed were: (A) ethyl acetate – acetic acid – water (8:2:2) and (B) ethyl acetate – pyridine – water (8:3:2). Ammoniacal silver nitrate solution (10) was used as a spray reagent for detection of polyols. Ultraviolet spectra were obtained with a Perkin–Elmer 4000A spectrophotometer in matched silica cells.

Hydrolysis of Nitro Compound with NaOH and $NaHCO_3$

The nitro compound, 2-methyl-2-nitro-1,3-propanediol, was hydrolyzed with a series of concentrations of sodium hydroxide and sodium bicarbonate. The solutions were boiled at atmospheric pressure for 10 h. In another series of experiments the reactions were carried out in an autoclave under pressure (15 lb/sq. in.) for 2 h. At the end of each run, suitable aliquots (2–5 ml) of the brownish liquid were withdrawn and nitrite determined colorimetrically using sulphanilic acid and naphthylamine reagents (11). The results are summarized in Table I.

TABLE I

Nitrite ion produced in hydrolysis of nitro compound with NaOH and $NaHCO_3$ solutions

Conc. of NaOH (%)	% NO_2^- released	
	Reflux	Autoclave
1	13.5	17.0
5	8.9	10.5
10	7.5	8.8
15	7.1	8.5
20	7.0	8.5
30	7.0	8.4
Conc. of $NaHCO_3$		
0.5	25	35
2	21	30

Hydrolysis of Nitro Compound with Sodium Borate

Analytical runs as described in the previous section were done using 0.7 *M* sodium borate as the alkaline hydrolytic agent (4). Refluxing gave 70 to 75% nitrite while autoclaving gave 80 to 90% nitrite.

Characterization of Hydrolysis Products

A quantity (3 g) of nitro compound in borate buffer (250 ml) was refluxed for 13 h. The small amount of water-insoluble tar was removed and the brownish solution evaporated. Borate was removed by several additions and evaporations of methanolic hydrogen chloride. The reaction product was separated from the inorganic residue by exhaustive extraction with acetone. The extract was evaporated, the thick, brownish liquid taken up in water, and treated with decolorizing charcoal. The filtrate was evaporated leaving a thick, straw-colored liquid (2.2 g). Paper chromatography of the product gave extensive streaking in both solvent systems with at least two darkly staining areas with R_f values of 0.60 and 0.62 in solvents A and B, respectively. The parent compound had an R_f of 0.85 and 0.91 in solvents A and B, respectively.

(a) Vapor-phase chromatography

The product was separated by gas chromatography in the following manner. A 3.5-ft. column (0.25 in. diameter) was packed with silanized Chromosorb W* containing 10% Versamid† as liquid phase. The helium flow was adjusted to 90 ml per min. Figure 1 shows a typical run with the column temperature programmed at 10° per min from a starting temperature of 90° to a temperature of 190°, then held isothermally at the latter temperature until the end of the run. In the separation of the major component, aliquots of 30 μl were injected.

(b) Identification and characterization of 2-C-methyl glycerol as the main component

To a quantity (150 mg) of the substance was added 0.1 *M* sodium periodate (50 ml) and water (50 ml) and the solution stored in the dark at 3 °C. Formaldehyde production (12) and periodate uptake were

determined periodically. After 30 min, 84 mg formaldehyde had been liberated with little or no increase observed thereafter. Periodate consumption became constant (2.80 mmoles) after the above time interval at 2 moles per mole of 2-methyl 1,2,3-propanetriol. Formaldehyde evolved was further characterized as the dimedone derivative which after recrystallization from dilute ethanol had m.p. and mixed m.p. 188–189 °C. Another portion (130 mg) of the compound was treated with bromine after periodate oxidation and the products oxidized with mercuric oxide. Carbon dioxide evolved was trapped in barium hydroxide solution and barium carbonate weighed. From 130 mg of starting material, two proportions of carbon dioxide (484 mg barium carbonate) were obtained. The acidified reaction mixture was extracted with ether and the solution dried with magnesium sulphate. Evaporation of the ether left a small amount of liquid which had a strong odor of acetic acid. The acid was neutralized with dilute alkali and a small quantity (20 mg) of the salt degraded by the Schmidt (13) procedure. The first step yielded 46 mg barium carbonate or one-half of the original carbon, while permanganate oxidation of the remaining amine gave the other half of original carbon (44 mg barium carbonate). The remaining salt (85 mg) was treated with thionyl chloride and the acyl halide reacted with suitable aroyl amines. The *p*-toluide had m.p. and mixed m.p. 145–146 °C and the anilide had m.p. and mixed m.p. 113–114 °C. These constants agree with those of the respective derivatives of acetic acid.

To a quantity (200 mg) of the component in pyridine (5 ml) was added a 10% theoretical excess of *p*-nitrobenzoyl chloride. A solid isolated in the usual fashion had, after recrystallization from acetone, m.p. 170–171 °C. Anal. Calc. for $C_{25}H_{19}O_{12}N_3$: N, 7.6. Found: N, 7.57 and 7.58%. A portion (150 mg) of compound in hot ethanol (100 ml) was saponified (NaOH), alcohol was evaporated, and the solution acidified (HCl). The precipitated *p*-nitrobenzoic acid was washed, dried, and weighed (135 mg). The results showed that the parent alcohol was in fact a trihydric alcohol, namely 2-C-methyl glycerol.

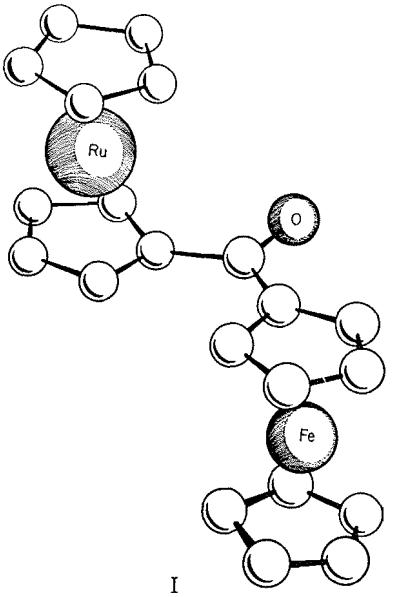
NOTES

THE STRUCTURE OF FERROCENYL RUTHENOCENYL KETONE

G. J. Small and J. Trotter

Since previous studies have suggested that the cyclopentadienyl rings are staggered in derivatives of ferrocene and eclipsed in ruthenocene derivatives (1), we have investigated the structure of ferrocenyl ruthenocenyl ketone (I) where both entities are contained within the same molecule.



I

Crystals of ferrocenyl ruthenocenyl ketone are orange-red needles elongated along b.

Crystal Data ($\lambda_{Cu\,K_\alpha}$ = 1.5418 Å)

$C_{21}H_{18}OFeRu$, M = 444; m.p. = 216 °C.

Monoclinic, a = 13.29 ± 0.02, b = 6.12 ± 0.01, c = 10.51 ± 0.02 Å, β = 111°17′.

V = 797 Å^3.

D_m (flotation in aqueous $AgNO_3$) = 1.86 g cm^{-3}.

Z = 2.

D_x = 1.85 g cm^{-3}.

$F(000)$ = 444.

Absorption coefficient for Cu K_α X-rays, μ = 160 cm^{-1}.

Absent spectra: $h0l$ when h is odd. In addition hkl weak when $(h + k)$ is odd. Space group is Pa, $P2/a$, or $P2_1/a$.

Intensity data for $h0l$ reflections were recorded on Weissenberg films and estimated visually; no absorption corrections were applied. The heavy atom positions were determined from the Patterson projection assuming space group Pa, and a Fourier series was

summed with phases based on these positions. The resulting electron-density map could best be interpreted as having molecules situated on diad axes of space group $P2/a$, the apparent twofold molecular symmetry being achieved by a disordered arrangement of molecules. The x- and z-coordinates of all the atoms were derived and are listed in Table I; structure factors were calculated with these parameters, with the scattering factors of

TABLE I

Positional parameters (fractional)

Atom	x	z
$\frac{1}{2}$(Ru + Fe)	0.4067	0.2525
C(1)	0.262	0.130
C(2)	0.293	0.251
C(3)	0.296	0.343
C(4)	0.267	0.286
C(5)	0.247	0.145
C(6)	0.520	0.151
C(7)	0.558	0.254
C(8)	0.580	0.382
C(9)	0.556	0.363
C(10)	0.518	0.217
C(11)	$\frac{1}{4}$	0
O	$\frac{1}{4}$	0

the *International Tables* (2) and $B = 3.0$ Å^2 for Fe and Ru and 4.0 Å^2 for the other atoms, and R was 0.14 for 151 observed reflections (a table of measured and calculated structure factors is available from the authors (1)). An electron-density projection along b is shown in Fig. 1. Since hkl reflections are weak when $(h + k)$ is odd, y of $\frac{1}{2}$(Fe + Ru) is about $\frac{1}{4}$.

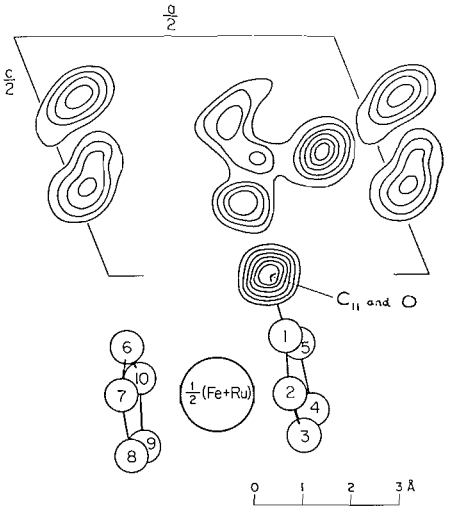


FIG. 1. Electron-density projection along b; contours at intervals of 2 eÅ^{-2}, starting at 4 eÅ^{-2}, except at the heavy atom, where contours are at intervals of 10 eA^{-2}.

Since no superlattice reflections or diffuse scattering are apparent on the films the two molecular orientations, related by a twofold axis, are distributed at random throughout the crystal. The electron-density projection (Fig. 1) indicates that both parts of the molecule have the rings similarly oriented (otherwise the density would be much more

For personal use only.

smeared out), the configuration being about midway between eclipsed and staggered, as in biferrocenyl (3). As a result of the disorder, the further refinement required to establish the structure and configuration more precisely is not profitable; we hope to obtain more accurate information from a study of diferrocenyl ketone. The fact that the rings bonded to the iron atom do have the same disposition as those bonded to the ruthenium suggests that the configuration is influenced to a great extent by intermolecular interactions. The central rings are not quite coplanar, each being rotated a few degrees out of the $C_1C_1'C_{11}O$ plane. No accurate molecular dimensions are available from this study, but all the intra- and inter-molecular distances appear to be normal.

HYDROGENOLYSIS OF CARBOHYDRATES. X. HYDROGENOLYSIS OF (±)-EPI-INOSOSE-2[1,2]

P. A. J. GORIN

Posternak has shown that catalytic hydrogenation of scyllo-inosose using a platinum catalyst in 5% aqueous sulphuric acid results in the formation of scyllo-quercitol (1). More recently Post and Anderson found that hydrogenation of (+)-vibo-inosose (I) under similar conditions yields (+)-vibo-quercitol (II) and 1,3/2,4-cyclohexanetetrol (III), that is, the tetrol is formed from the inosose by reductive removal of the keto and its adjacent hydroxyl group. This reaction is general among substituted inososes having an axial hydroxyl vicinal to the keto group (2).

In the present work it was observed that by-products were formed during the preparation of (±)-epi-quercitol (VI) from (±)-epi-inosose-2 (V) (purified via its phenylhydrazone (3)). Fractionation of the product on a cellulose column gave tetrol and triol fractions as well as (±)-epi-quercitol. The former consisted mainly of (±)-1,2,3/4-cyclohexanetetrol (VII), which was identified, subsequent to measurement of its periodate characteristics, by comparison with an authentic specimen (4). Oxidation of the triol fraction with sodium periodate resulted in consumption of 2.0 moles of oxidant with concomitant production of 0.9 moles of acid. After crystallization the triol had a melting point corresponding to 1,3/2-cyclohexanetriol (5) (VIII) and differing from those of the 1,2,3- (6) and 1,2/3-isomers (5). Although an authentic specimen was not available the identification was

smeared out), the configuration being about midway between eclipsed and staggered, as in biferrocenyl (3). As a result of the disorder, the further refinement required to establish the structure and configuration more precisely is not profitable; we hope to obtain more accurate information from a study of diferrocenyl ketone. The fact that the rings bonded to the iron atom do have the same disposition as those bonded to the ruthenium suggests that the configuration is influenced to a great extent by intermolecular interactions. The central rings are not quite coplanar, each being rotated a few degrees out of the $C_1C_1'C_{11}O$ plane. No accurate molecular dimensions are available from this study, but all the intra- and inter-molecular distances appear to be normal.

ACKNOWLEDGMENTS

The authors are indebted to the National Council of Canada for financial support, to Dr. M. D. Rausch for the crystal sample, to Dr. F. R. Ahmed for kindly making available his I.B.M. 1620 programs, and to the staff of the U.B.C. Computing Centre for assistance.

HYDROGENOLYSIS OF CARBOHYDRATES. X. HYDROGENOLYSIS OF (±)-EPI-INOSOSE-2[1,2]

P. A. J. GORIN

Posternak has shown that catalytic hydrogenation of scyllo-inosose using a platinum catalyst in 5% aqueous sulphuric acid results in the formation of scyllo-quercitol (1). More recently Post and Anderson found that hydrogenation of (+)-vibo-inosose (I) under similar conditions yields (+)-vibo-quercitol (II) and 1,3/2,4-cyclohexanetetrol (III), that is, the tetrol is formed from the inosose by reductive removal of the keto and its adjacent hydroxyl group. This reaction is general among substituted inososes having an axial hydroxyl vicinal to the keto group (2).

In the present work it was observed that by-products were formed during the preparation of (±)-epi-quercitol (VI) from (±)-epi-inosose-2 (V) (purified via its phenylhydrazone (3)). Fractionation of the product on a cellulose column gave tetrol and triol fractions as well as (±)-epi-quercitol. The former consisted mainly of (±)-1,2,3/4-cyclohexanetetrol (VII), which was identified, subsequent to measurement of its periodate characteristics, by comparison with an authentic specimen (4). Oxidation of the triol fraction with sodium periodate resulted in consumption of 2.0 moles of oxidant with concomitant production of 0.9 moles of acid. After crystallization the triol had a melting point corresponding to 1,3/2-cyclohexanetriol (5) (VIII) and differing from those of the 1,2,3- (6) and 1,2/3-isomers (5). Although an authentic specimen was not available the identification was

confirmed by examination of the nuclear magnetic resonance (n.m.r.) spectrum of the derived triacetate. It gave one acetoxy-proton signal in the n.m.r. at 2.0 p.p.m., thus indicating three equatorial acetoxy groups. In polyacetoxycyclohexanes which do not interconvert readily from one chair form to the other, equatorial acetoxy protons give signals at 2.0–2.1 p.p.m. Axial acetoxy protons produce signals at slightly lower field. This relation of chemical shift to conformation has been demonstrated with myo-, levo- (7), epi-, and neo-inositol hexaacetates (8) and the acetates of stereoisomeric quinic acid and quinicol derivatives (9).

The mixture, formed by hydrogenolysis of (±)-epi-inosose-2, was acetylated and examined by gas phase chromatography. On a molar basis the composition of the acetate mixture was as follows: (±)-epi-inositol (7%), (±)-epi-quercitol (53%), (±)-1,2,3/4-cyclohexanetetrol (21%), 1,3/2-cyclohexanetriol (9%). Smaller amounts of an unidentified tetrol acetate (5%) and two triol acetates (1% each) were detected. The (±)-1,2,4/3-cyclohexanetetrol tetraacetate was shown to be absent from the mixture.

In the light of the results obtained by Posternak (1) and Post and Anderson (2) it was not anticipated that hydrogenation of (±)-epi-inosose-2 would give appreciable amounts of tetrols and triols. Reductive elimination of the equatorial hydroxyl at C-1 and the keto group takes place, to yield (±)-1,2,3/4-cyclohexanetetrol (VII). A similar elimination at C-3 to form (±)-1,2,4/3-cyclohexanetetrol (IV) does not occur. Instead it appears that the platinum–cyclitol intermediate involving C-2 and C-3 is further hydrogenolyzed at C-4 to give 1,3/2-cyclohexanetriol. In this case the C-4 substituents have a reactivity comparable to those containing an axial hydroxyl group vicinal to a keto group in inososes.

EXPERIMENTAL

The (±)-epi-inosose-2 was prepared by the method of Posternak (10). A crude sample had C, 39.30; H, 5.84. Calc. for $C_6H_{10}O_6$: C, 40.45; H, 5.66%. After purification via its phenylhydrazone and two recrystallizations from water a sample had C, 39.92; H, 5.79%. Examination of the phenylhydrazone and semicarbazone (3) reaction mixtures on a paper chromatogram (solvent: *n*-butanol–ethanol–water 40:11:19 v/v; spray: ammoniacal silver nitrate) did not indicate the presence of any disubstituted derivatives. Melting points are corrected to the nearest degree.

Hydrogenation of (±)-*epi-Inosose-2*

The (±)-epi-inosose-2 (2.0 g) was suspended in 5% sulphuric acid (50 ml) and shaken overnight with platinic oxide (0.20 g) in the presence of hydrogen. The solution was filtered, neutralized with barium carbonate, filtered, and evaporated. The product gave on a paper chromatogram (solvent and spray as above)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

a main spot corresponding to epi-quercitol, and two others running at a faster rate. A trace of epi-inositol was present also.

The product was acetylated and examined by gas phase chromatography using 2% LAC IR296 on Chromosorb W as column packing (11). The gas–liquid chromatograph unit was of conventional design using thermal conductivity cells for detection. At 200 °C a satisfactory separation of epi-inositol, epi-quercitol, and tetrol acetates was obtained and at 160 °C the triol, tetrol, and epi-quercitol acetates gave suitable signals.

The responses of the machine were calibrated using authentic cyclitol acetates. On a molar basis the product consisted of the acetates of (±)-epi-inosose (7%), (±)-epi-quercitol (53%), (±)-1,2,3/4-cyclohexanetetrol (21%), 1,3/2-cyclohexanetriol (9%). An unidentified tetrol acetate (5%), with a slightly higher retention time than the main tetrol acetate, and two triol acetates (1% each), which had higher and lower retention times than the main triol acetate, respectively, were also detected.

The acetate of (±)-1,2,4/3-cyclohexanetetrol (4) was shown to have a lower retention time than the (±)-1,2,3/4-isomer (4).

Isolation of Hydrogenolysis Products

The above hydrogenolysis product was fractionated on a cellulose column using *n*-butanol one-half saturated with water as eluant. The following materials were isolated:

(i) *Triol*—140 mg was isolated and oxidation of this material with aqueous sodium periodate resulted in the consumption of 1.97 moles of oxidant in one day with concomitant production of 0.94 moles of acid.

One crystallization from ethyl acetate yielded 104 mg of material and a further recrystallization from the same solvent gave 1,3/2-cyclohexanetriol with m.p. 107–108 °C. Calc. for $C_6H_{12}O_3$: C, 54.5; H, 9.15. Found: C, 54.6; H, 9.4%. McRae *et al.* (5) report m.p. 107.7–108.2 °C for the 1,3/2-isomer, whereas the 1,2,3-isomer has m.p. 145 °C (6) and the 1,2/3-isomer m.p. 125 °C (5). After 5 h the triol consumed 1.97 moles of sodium periodate releasing 1.05 moles of acid.

The triacetate, obtained by the hot sodium acetate – acetic acid anhydride method, was recrystallized twice from hexane to give a product with m.p. 128–129 °C. Calc. for $C_{12}H_{18}O_6$: C, 55.8; H, 7.0. Found: C, 55.6; H, 7.0%. In the n.m.r., using chloroform as solvent, it gave one signal for acetoxy protons at 2.00 p.p.m. (tetramethyl silane standard).

(ii) *Tetrol*—324 mg was isolated from the column and this was recrystallized from ethanol. The product (0.23 g) was recrystallized and had m.p. 158–159 °C. Calc. for $C_6H_{12}O_4$: C, 48.6; H, 8.2. Found: C, 48.75; H, 8.2%. After 5 and 24 h the tetrol consumed 3.0 moles of sodium periodate, yielding 2.0 moles of acid. The tetrol gave an X-ray diffraction pattern identical with (±)-1,2,3/4-cyclohexanetetrol (4). The derived tetraacetate was recrystallized twice from ether–hexane and had m.p. 113–114 °C. Calc. for $C_{14}H_{20}O_8$: C, 53.3; H, 6.4. Found: C, 53.0; H, 6.45%.

(iii) (±)-*epi-Quercitol*—The majority of the product was represented by epi-quercitol (1.05 g) with m.p. 187–190 °C after two recrystallizations from aqueous ethanol. Calc. for $C_6H_{12}O_5$: C, 43.9; H, 7.4. Found: C, 43.9; H, 7.35%.

ACKNOWLEDGMENTS

The author thanks Prof. T. Posternak for the gift of (±)-1,2,3/4- and (±)-1,2,4/3-cyclohexanetetrols. Thanks are also due to Dr. E. Challen of the University of New South Wales and Mr. M. Mazurek for carrying out carbon and hydrogen analyses, and Mr. W. C. Haid for an n.m.r. determination.

POLYSACCHARIDES FROM THE SEEDS OF THE HUACRA PONA PALM (IRIARTEA VENTRICOSA)[1]

W. SOWA[2] AND J. K. N. JONES

Many plants produce seeds containing polysaccharides with a high proportion of D-mannose residues. In some cases D-glucose or D-galactose is joined to the main chain of D-mannose units (1). Early studies of ivory nut, the seed of the ivory nut palm (*Phytelephas macrocarpa*), established that mannose was the main carbohydrate component (2). Later work showed that at least two mannans (A and B) were present (3) and that both polymers were linear chains of D-mannopyranose units with β-1 $\rightarrow$ 4 linkages (4). More recently the mannans have been reinvestigated by Aspinall and coworkers (5). Mannan A, $[\alpha]_D$ $-46°$ (*c* 0.7 in *N* sodium hydroxide), was composed of D-mannose (97.6%), D-galactose (1.8%), and D-glucose (0.8%). From methylation studies it was deduced that two types of molecules were present, both comprising an average of 10 to 13 residues, one terminated at the non-reducing end by a D-mannopyranose residue and the other by a D-galactopyranose residue. The majority of the D-mannopyranose units were linked through C1 and C4 with some 1 $\rightarrow$ 6 linkages. A small amount of di-*O*-methyl mannose was found. Mannan B, $[\alpha]_D$ $-26°$ (*c* 0.8 in anhydrous formic acid) was chemically similar to mannan A but of greater molecular size (38 to 40 residues). Partial acetolysis (6) of the polymers yielded a homologous series of mannose oligosaccharides with β-1 $\rightarrow$ 4 linkages. Small amounts of 4-*O*-α-D-mannopyranosyl-D-mannose and β-1 $\rightarrow$ 4 linked oligosaccharides containing mannose and glucose were also found.

The present work describes preliminary results of an investigation of the seeds of the huacra pona tree (*Iriartea ventricosa*), a palm which grows in tropical South America. The fruit of this tree yields a jelly which is used locally as a base in medicinal preparations (7). The seeds are dark brown, about half an inch in diameter, and somewhat cone-shaped. They are extremely hard and in this respect resemble the seeds of the ivory nut palm.

Following the procedure of Aspinall *et al.* (5) for ivory nuts, the seeds were extracted first with 7% and then with 14% potassium hydroxide solutions to obtain polysaccharides. Fraction I, $[\alpha]_D$ $-42°$ (*c* 1.0 in 5 *N* sodium hydroxide), and fraction II, $[\alpha]_D$ $-30°$ (*c* 1.0 in 5 *N* sodium hydroxide), amounted to 15% and 9% of the seeds respectively. Further extraction of the seed residues with 21% potassium hydroxide, then with 14% potassium hydroxide plus 3% boric acid (8) and finally with 14% sodium hydroxide yielded an additional 17.5% of polysaccharide. Most of this (fraction V, 16%) was extracted by the sodium hydroxide solution. Paper chromatographic examination of the hydrolysates of the first four fractions indicated the presence of mannose accompanied by small amounts of galactose, glucose, uronic acid, and a trace of pentose. Fraction V appeared to be a neutral polymer of mannose and glucose. All fractions, especially fraction V, were very unreactive and difficult to hydrolyze.

Fractions I and II moved as discrete spots at slightly different rates when examined by glass paper electrophoresis in a borate buffer (9), suggesting that they were similar in structure but perhaps different in molecular size. The conditions employed for the formation of oligosaccharides from fractions I and II by acid hydrolysis were similar to those used for the formation of oligosaccharides from ivory nut mannan. The change in optical

[1]*Abstracted from the M.Sc. thesis of W.S. (1958 Queen's University).*

For personal use only.

rotation of the solutions during hydrolysis was also of the same order. Fraction I contained 6% of uronic acid anhydride. On periodate oxidation the polysaccharide consumed approximately 1 mole of periodate per mole of hexose and yielded traces of formic acid. Chromatographic examination of the hydrolysate of the oxidized polymer indicated that a small amount (1–2%) of the hexose residues had not been oxidized.

Fraction II was only partially acetylated with pyridine as catalyst and dimethyl formamide as swelling agent (10). Acetylation was effected with trifluoroacetic anhydride as catalyst (11). Attempted methylation of the acetylated product was unsuccessful even after eight treatments by the Haworth procedure (12). On graded hydrolysis of fraction II several oligosaccharides were obtained. These were separated by chromatography on a column of charcoal–Celite (13) and on paper. The major oligosaccharide was identified as 4-*O*-β-D-mannopyranosyl-α-D-mannopyranose. A small amount of an unidentified syrupy disaccharide, containing galactose and mannose, was also isolated. A trisaccharide, according to data obtained from partial hydrolysis and periodate oxidation, appeared to be a mannosyl-mannobiose containing $1 \rightarrow 6$ and $1 \rightarrow 4$ linkages.

The above results suggest that the polysaccharide reserve of the seeds of the huacra pona palm is a β-$1 \rightarrow 4$ linked mannan containing small amounts of D-galactose. The polymer may also contain some $1 \rightarrow 6$ linkages. The significance of the uronic acid portion is unknown but it may be part of an associated polymer, the presence of which may also explain the detection of traces of pentose residues. The polysaccharide fractions occurring in seeds of the huacra palm are thus structurally similar to those in seeds of the ivory nut palm.

EXPERIMENTAL

Paper chromatography was performed by the descending method on Whatman No. 1 paper using the following solvent systems (v/v): (A) ethyl acetate, acetic acid, formic acid, water (18:3:1:4); (B) ethyl acetate, acetic acid, water (9:2:2); (C) butan-1-ol, pyridine, water (10:3:3); (D) butan-1-ol, ethanol, water (3:1:1). Sugars were detected with the *p*-anisidine hydrochloride spray (14), the silver nitrate spray (15) or with a 0.1 *M* solution of 2-aminobiphenyl hydrogen oxalate in acetone (16).

Glass paper electrophoresis was carried out in borate buffer at pH 10.0 (9). Polysaccharides were applied in a 10% solution of sodium hydroxide and detected by spraying the glass paper with a solution of α-naphthol in methanol (3% w/v) followed by concentrated sulphuric acid.

Solutions were concentrated under reduced pressure at a water bath temperature of 40° or less. Optical rotations were determined in water at 20° ± 2° unless otherwise stated.

Isolation of Polysaccharide Fractions

Finely divided seeds (50 g) of huacra pona (*Iriartea ventricosa*) were extracted in a Soxhlet apparatus with benzene for 14 h and then with methanol for 14 h. The residue (32.5 g, 65%) was delignified by the sodium chlorite – acetate acid technique (17). The delignified material (27 g, 54%) was shaken at room temperature with successive solutions (200 g) of alkali of increasing concentration. Each polysaccharide fraction was isolated by pouring the extract into an equal volume of ethanol acidified with acetic acid. The results are shown in Table I.

TABLE I

Polysaccharide fractions obtained by alkaline extraction of seeds

Fraction	$[\alpha]_D$ (*c* 1.0 in 5 *N* NaOH)	Extraction solution	Yield (g)	Yield (% of seeds)
I	−42°	7% KOH	7.5	15
II	−30°	14% KOH	4.5	9
III	−36°	21% KOH	0.3	0.5
IV	−34°	14% KOH + 3% H_3BO_3	0.6	1
V	—	14% NaOH	7.7	16

Fractions I and II were examined for homogeneity by glass paper electrophoresis. Both fractions travelled as single spots with fraction I moving at a slightly greater rate than fraction II.

Hydrolysis of Fractions

Fraction I (1.00 g) was heated with formic acid (50 ml, 90%) in a boiling water bath. The hydrolysis was followed chromatographically and by the change in optical rotation, which was as follows: $[\alpha]_D$ −18° (10 min); −10° (30 min); −1° (1 h); +9° (2 h); +18° (3 h); +21° (8 h), constant value. The concentration of oligosaccharides was a maximum after 3 h hydrolysis. Disaccharides were still present in small amounts after 10 h. Traces of galactose, glucose, pentose, and uronic acids were also present. A colorimetric method employing carbazole (18) showed that fraction I contained 5.8% uronic acid. Fraction II on hydrolysis showed a similar change in optical rotation and in the chromatographic pattern of oligosaccharides. Hydrolysis of small samples of fractions III and IV with 2 *N* sulphuric acid in sealed tubes at 100°, followed by chromatographic examination, showed the presence of the same monosaccharides as in fractions I and II. Fraction V was difficult to hydrolyze with formic acid, 5 *N* sulphuric acid or trifluoroacetic acid at 100°. It was partially dissolved in 72% sulphuric acid and after 5 h the mixture was diluted to 5% sulphuric acid. After the diluted mixture was heated at 100° for 12 h, half the polysaccharide was recovered unhydrolyzed. The sugars in solution were examined chromatographically in solvents (A), (C), and (D) and consisted of glucose and mannose in the approximate ratio 1:1.

Mannan A, obtained by extracting ivory nut shavings with 5% sodium hydroxide solution (3), was hydrolyzed under the same conditions as fraction I. The following change in optical rotation was observed: $[\alpha]_D$ −28° (3 min); −13° (33 min); 0° (50 min); +12° (2.25 h); +15° (3.5 h); +18° (6.5 h); +19° (9.75 h). Paper chromatographic examination showed that the maximum yield of oligosaccharides was obtained after hydrolysis for 50 min.

Oxidation of Fraction I by Sodium Periodate

Samples (100 mg) were suspended in potassium chloride solution (5 ml, 3% w/v) and water (10 ml) was added followed by sodium periodate solution (5 ml, 0.3 *M*). Samples and blanks were shaken at 5° and removed at intervals for the determination of periodate consumption and formic acid yield (19). Found: moles of periodate consumed and formic acid produced per hexose unit ($C_6H_{10}O_5$): 0.66, 0.04 (6 h); 0.68, 0.05 (16 h); 0.81, 0.06 (74 h); 0.97, 0.07 (150 h). A sample of polysaccharide (100 mg) was oxidized for 150 h and excess periodate was then destroyed by the addition of ethylene glycol. The solution was neutralized (barium carbonate) and filtered and sodium borohydride (50 mg) was added. After 18 h the solution was acidified (acetic acid) and evaporated to dryness. The residue was boiled with methanolic hydrogen chloride (100 ml, 1.5%) for 30 min and then evaporated to a syrup. The residue was hydrolyzed for 18 h with *N* sulphuric acid (30 ml) at 100°, cooled, neutralized (barium carbonate), and filtered. The filtrate was concentrated and examined chromatographically in solvents A, B, and C. Erythritol and traces of glycerol, glucose, and mannose were present. The yield of monosaccharides by visual comparison with standards was 1–2%.

Acetylation and Attempted Methylation of Fraction I

Method I (10)

The polysaccharide (0.25 g) was swollen in dimethyl formamide (6 ml) at 20° for 16 h and at 50° for 1 h. Pyridine (10 ml) was then added dropwise at 45° during 1.5 h, followed by acetic anhydride (8 ml). After 1 h at 50° and 14.5 h at 20°, the product was isolated. It contained 7.3% acetyl and the method of acetylation was, therefore, unsatisfactory.

Method II (11)

The polysaccharide (4.00 g) was shaken in acetic acid (75 ml) at 20° for 24 h. Trifluoroacetic anhydride (100 ml) was then added and the mixture was heated at 50° for 2 h. After a further 20 h at 20°, the clear yellow solution was evaporated to 50 ml and poured into sodium bicarbonate solution (500 ml, 2% w/v). The precipitate was collected by filtration, washed well with water, and dried. The product (5.77 g) had $[\alpha]_D$ −18° (*c* 1.0 in acetone) and −34° (*c* 1.0 in chloroform). The acetyl content was 42.9%.

The acetate (5.67 g) was dissolved in acetone–dioxane mixture (150 ml; 2:1 ratio) and methylated with sodium hydroxide (30%) and dimethyl sulphate in the usual way (12). The product (2.4 g) was very difficult to methylate and even after eight treatments was only partially methylated.

Hydrolysis of Fraction II

Fraction II (3.50 g) was hydrolyzed by heating it with formic acid (175 ml, 90%) in a boiling water bath for 1.25 h. The solution was filtered from a small amount of unhydrolyzed material and then evaporated to a syrup (3.61 g). A solution of the syrup in water was placed on top of a column of charcoal–Celite (3 × 30 cm) and fractionated by the method of Whistler and Durso (13). The following 3 major fractions were obtained:

Fraction A

The first fraction (1.70 g), obtained by eluting the column with water, consisted mainly of D-mannose together with traces of a disaccharide, galactose, and xylose.

Fraction B

The second fraction (0.30 g), also obtained by eluting the column with water, was the disaccharide observed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in fraction A. It was chromatographically indistinguishable from an authentic specimen of 4-*O*-β-D-mannopyranosyl-α-D-mannopyranose. It crystallized from ethanol–water and had m.p. 194–195° and $[\alpha]_D$ −4° → −9° in 1.75 h (*c* 3.3). The X-ray diffraction patterns of the crystals and of the authentic specimen were identical.

Fraction C

Fraction C (0.68 g), $[\alpha]_D$ −14° (*c* 6.7), was a mixture of oligosaccharides, mainly 4-*O*-β-D-mannopyranosyl-D-mannose, which was eluted from the column with water containing from 2% to 50% ethanol (v/v). Paper chromatography of this fraction in solvent (D) yielded two additional oligosaccharides. One was a disaccharide (0.045 g) with $[\alpha]_D$ +11° (*c* 2.2). In solvents A, C, and D it had $R_{galactose}$ 0.38, 0.23, and 0.43, respectively. On partial hydrolysis of the disaccharide with 0.5 *N* sulphuric acid at 100° for 4 h, galactose, mannose, and starting material were observed chromatographically. It was not identified.

The other oligosaccharide (0.14 g) in fraction C had $[\alpha]_D$ −12° (*c* 1.2) and $R_{galactose}$ 0.11 in solvent A. On partial hydrolysis with 0.5 *N* sulphuric acid at 100° for 4 h it yielded D-mannose and a disaccharide which was indistinguishable from 4-*O*-β-D-mannopyranosyl-D-mannose by chromatography in solvents B, C, and D. The degree of polymerization was 3 by the method of Peat, Whelan, and Roberts (20). The trisaccharide (4.0 mg) was oxidized with sodium periodate solution and the yield of formaldehyde was determined using chromotropic acid (21). Found: moles of formaldehyde per mole of trisaccharide: 0.86 (1 h); 0.96 (3 h); 1.33 (5 h); 1.33 (18 h). In a parallel experiment the trisaccharide (4.0 mg) first was reduced in water with sodium borohydride (12 mg) for 1 h. After acidification with *N* sulphuric acid (0.4 ml), the product was oxidized with sodium periodate solution and the yield of formaldehyde was determined. Found: moles formaldehyde per mole of reduced trisaccharide: 1.11 (1 h), 1.47 (3 h), 1.76 (5 h), 1.95 (18 h). The consumption of periodate during oxidation of the trisaccharide was determined spectrophotometrically by the method of Aspinall and Ferrier (22). Found: moles periodate per mole of trisaccharide: 5.0 (2 h); 5.1 (3 h); 5.3 (4 h); 6.7 (6 h); 7.0 (30 h).

INTRODUCTION

During the preparation of methyl and ethyl aluminum hydride complexes (1), a reaction between lithium aluminum hydride and trimethylamine was observed that yielded aluminum hydride bis-trimethylamine. The treatment of dimethyl or diethyl aluminum chloride with lithium aluminum hydride and trimethylamine in ethyl ether yielded the alkyl aluminum dihydride trimethylamine complexes (1). The route of the reaction, shown here, was determined by combining an excess of lithium aluminum hydride with

$$LiAlH_4 + R_2AlCl \xrightarrow{Et_2O} R_2AlH + [LiAlH_3Cl] \searrow AlH_3 + LiCl$$

$$R_2AlH + AlH_3 \rightarrow 2RAlH_2 \xrightarrow{Me_3N} 2RAlH_2 \cdot NMe_3$$

trimethylaluminum in ether. When trimethylamine was added to the $LiAlH_4$–Me_3Al reaction mixture to produce the stable amine adduct of the methylaluminum hydride product, a substantial amount of aluminum hydride bis-trimethylamine was formed in addition to $Me_2AlH \cdot NMe_3$. Treatment of lithium aluminum hydride with trimethylamine in ether solution afforded $AlH_3(NMe_3)_2$, confirming the suspicion that the source of the $AlH_3(NMe_3)_2$ in the $LiAlH_4$–Me_3Al reaction was the direct reaction of the amine with lithium aluminum hydride.

The isolation of aluminum hydride bis-trimethylamine is inconsistent with the results of Wiberg and co-workers (2), who report that the reaction of lithium aluminum hydride with trimethylamine yields only $LiAlH_4(NMe_3)_x$ where x is 1, 2, or 3. Only the monoamine adduct is reported to be stable at room temperature.

An attempt was made to resolve the inconsistency by a study of the reaction of lithium aluminum hydride with trimethylamine. The study revealed a complex reaction yielding, in addition to aluminum hydride bis-trimethylamine, ether-insoluble solids whose compositions are dependent upon the stoichiometric ratios of the reactants. The study was extended to include the reaction of lithium aluminum hydride with Me_2NH where, with equimolar stoichiometry, dimethylamino aluminum hydride is produced in moderate yield, a result unpredictable from the literature in this area.

EXPERIMENTAL

Starting Materials

Lithium aluminum hydride was obtained from Metal Hydrides, Inc. Trimethylamine and dimethylamine were supplied by the Matheson Company, Inc., and the ethyl ether was provided by Mallinckrodt Chemical Works.

Reactions of Lithium Aluminum Hydride and Trimethylamine

The general procedure may be illustrated by one example: An ether solution of 0.16 mole of trimethylamine was added by drops to the stirred ether solution of $LiAlH_4$ (0.16 mole) in a round-bottom flask. A precipitate began to form immediately. The reaction mixture was stirred for a day, after which time it was filtered in a drybox.[1] The ether was removed from the filtrate and the remaining solid sublimed at 25 °C and 10^{-3} mm

[1]*Model He-43/He-73, D. L. Herring Co., Inc., Sherman Oaks, California.*

Hg onto a cold finger maintained at −78 °C. Five grams (0.034 mole) $AlH_3(NMe_3)_2$ was isolated. The compound melts at 92–94 °C (uncorrected). Anal. Calc. for $C_6H_{21}AlN_2$: C, 48.6; H, 14.3; N, 18.9; Al, 18.2. Found: C, 48.3; H, 14.0; N, 18.9; Al, 18.1. The molar ratio of lithium to aluminum in the sublimation residue was 1 to 1. A sample of the dry sublimation residue was pyrolyzed in a closed system at 120–150 °C for 7 h. A large quantity of hydrogen was evolved and a negligible amount of condensable gas.

An elemental analysis of a sample of the dried reaction residue indicated that the lithium to aluminum molar ratio was 2.5 to 1. Hydrolysis of a sample of the solid with methanol showed a hydridic hydrogen ('H') to aluminum ratio of 4.5 to 1. A strong, broad band in the Al—H frequency range (1600–1900 cm^{-1}) was observed in the infrared spectrum[2] of the reaction residue in Nujol. Pyrolysis of a sample of the reaction residue 3 h at 95–120 °C yielded hydrogen and a condensable gas identified as diethyl ether by its infrared spectrum. No amine was found nor was $AlH_3(NMe_3)_2$ or $AlH_3 \cdot NMe_3$ formed.

Experiments representing a variety of stoichiometries ranging from a large molar excess of Me_3N to a large excess of $LiAlH_4$ were conducted, and the results are summarized in Table I.[3]

Reactions of Lithium Aluminum Hydride and Dimethylamine

1. A solution of 0.24 mole of Me_2NH in ethyl ether was added by drops to a stirred ether solution of 0.24 mole $LiAlH_4$ at room temperature. As each drop of amine solution made contact with the hydride solution, hydrogen was evolved and solid precipitated. There was no noticeable heating of the reaction mixture. The solid was very bulky, and the reaction mixture could be stirred only with difficulty. The reaction mixture remained at room temperature for a day after the amine had been added. No additional hydrogen was formed during this period. The reaction mixture was filtered and the ether removed from the filtrate under vacuum. When the ether-soluble residue was heated in vacuum at 75 °C, 3.4 g of solid (m.p. 75 °C) sublimed and an air-sensitive residue remained. A mixed melting point of the sublimate with an authentic sample of AlH_2NMe_2 showed no depression. Anal. Calc. for C_2H_8NAl: C, 32.9; H, 11.0; N, 19.2; Al, 36.9. Found: C, 32.8; H, 10.8; N, 19.3; Al, 36.6.

2. A reaction of dimethylamine (0.16 mole) and $LiAlH_4$ (0.08 mole) was conducted in ether solution in a manner similar to that used in the previous experiment. Only a few crystals sublimed from the ether-soluble residue at 100 °C and 10^{-3} mm Hg. No sublimate formed when the reaction residue was heated at 100 °C for several hours.

3. The reaction of 0.15 mole Me_2NH and 0.05 mole $LiAlH_4$ in ether solution yielded no sublimable products.

DISCUSSION

Reaction of Lithium Aluminum Hydride and Trimethylamine

The addition of up to 4 moles of trimethylamine to an ether solution of 1 mole of lithium aluminum hydride gives precipitates rich in lithium and aluminum hydride bis-trimethylamine that is sublimed from the ether solution. A non-subliming residue whose lithium to aluminum molar ratio decreases as increasing amounts of trimethylamine are used remains in the sublimation apparatus following the isolation of aluminum hydride bis-trimethylamine. As more than 4 moles of amine to 1 of lithium aluminum hydride are used, the yield of $AlH_3(NMe_3)_2$ approaches zero, the amount of ether-soluble non-volatile material decreases, and the quantity of precipitate increases correspondingly. When 10 moles of amine are used nearly all of the lithium aluminum hydride appears in the non-volatile precipitate containing lithium and aluminum in an approximate 1 to 1 molar ratio, hydrogen, and loosely bound trimethylamine. This precipitate may be the same material that Wiberg, Nöth, and Usón observed in their reaction of a large excess of trimethylamine with lithium aluminum hydride in ether (2). However, their product, reported to be $LiAlH_4 \cdot NMe_3$, was stable in vacuum at 180 °C, whereas the solid obtained here evolves a large non-stoichiometric amount of trimethylamine and a small amount of ether at room temperature (10^{-3} mm Hg), leaving a hydrolytically active substance free of amine.

The solids that are precipitated in the course of the reaction increase in aluminum

X	10/1 (1.0/0.10)	None		1.0‡	1.5‡	4.7‡				The reaction residue evolved Me_3N at $25°/10^{-3}$ mm. No additional Me_3N was observed in the hydrolyzate

*Hydridic hydrogen 'H' was determined by hydrolysis with methanol. Al was determined as Al_2O_3.
†These nitrogen values are probably low because of amine evolution from the samples prior to analysis. See footnote 3.
‡The mole ratio of nitrogen was determined from HCl–NaOH titration of the Me_3N that evolved at $25°/10^{-3}$ mm prior to hydrolysis of the sample. Hydridic hydrogen was determined with methanol. Al was determined with EDTA and $ZnSO_4$, using Eriochrome black T as indicator.

content as the quantity of trimethylamine used increases. Thus the $AlH_3(NMe_3)_2$ or a species yielding $AlH_3(NMe_3)_2$ present in solution must be able to react with additional amine and dissolved lithium aluminum hydride to give additional solid of different composition than that first deposited (see Table I). (However, aluminum hydride bis-trimethylamine does not react with an ether solution of trimethylamine, nor with an ether solution of lithium aluminum hydride.) Experiment IV illustrates this phenomenon. The reaction mixture was initially equimolar in amine and $LiAlH_4$, a condition known from previous experiments to yield $AlH_3(NMe_3)_2$ from the ether solution (for example, experiment III). The precipitate (IV*a*) had the composition previously found in precipitates from other 1 to 1 reactions, namely 2.5 to 1 lithium to aluminum. The filtrate (IV*a*) was treated with an additional 3 moles of amine. The reaction yielded precipitate (IV*b*) of molar composition 1.7 to 1 lithium to aluminum. The only source of the additional aluminum found in the precipitate is an aluminum-containing species other than $LiAlH_4$ in the ether solution, formed from the earlier encounter of $LiAlH_4$ and Me_3N (IV*a*). As expected, the filtrate from reaction IV*b* contained only a trace of aluminum hydride bis-trimethylamine.

Reaction of Lithium Aluminum Hydride and Dimethylamine

Lithium aluminum hydride reactions with ammonia and primary and secondary amines have been characterized by the elimination of stoichiometric quantities of hydrogen and the formation of amides of undetermined composition (3, 4, 5). If a tetrahydrofuran solution of $LiAlH_4$ is treated with dimethylamine until hydrogen evolution ceases, a precipitate is formed and $LiAl(NMe_2)_4$ solvated with tetrahydrofuran may be isolated from solution (6). The work in this laboratory has demonstrated that the equimolar reaction of lithium aluminum hydride and dimethylamine in ethyl ether solution yields hydrogen, a precipitate, and dimethylamino aluminum hydride. When 2 or 3 moles of amine are used for each mole of $LiAlH_4$, no sublimable products are formed. Amides may be formed in all three reactions. Perhaps in the case of the equimolar reaction of Me_2NH and $LiAlH_4$ the source of AlH_2NMe_2 is the disproportionation of an unstable lithium aluminum amide. The more highly substituted amides formed in the other reactions may be stable to 100 °C or more. Recently Longi, Mazzanti, and Bernardini (7) found that in the reactions of large excesses of Et_2NH and Ph_2NH with $LiAlH_4$, the non-volatile products $LiAl(Et_2N)_3H$ and $LiAl(Ph_2N)_3H$ were formed, the anilide being stable to 140 °C.

THE REACTION OF SULPHUR TETRAFLUORIDE WITH SOME NITROGEN COMPOUNDS*

B. Marinier and Jean L. Boivin

The reactivity of sulphur tetrafluoride has been studied with compounds rich in nitrogen, such as urea, cyanamide, guanidine, dicyandiamide, melamine, and tetrazoles, and in each case trifluoromethyliminosulphur difluoride was a reaction product.

EXPERIMENTAL

Materials

Sulphur tetrafluoride was obtained from DuPont and was used without further purification. It contained about 5% thionyl fluoride. All other compounds were used as received but had a purity better than 99%.

General Procedure

The reactions with sulphur tetrafluoride were carried out in chrome–vanadium steel pressure vessels of 300-ml capacity. Solid reactants were placed in the bomb, the head was screwed into place, and the air was removed with a vacuum pump. Heat was applied to remove the last traces of water. The bomb was cooled in a dry ice – acetone bath and a known weight of SF_4 was condensed into it. A manometer was attached to the vessel to monitor the variations of pressure with temperature.

After the pressure vessel was heated for the desired period of time, it was cooled, the gases condensed at −196 °C, and weighed. The gases were expanded at 25 °C and analyzed by gas–liquid chromatography and mass spectrometry. The proportion of trifluoromethyliminosulphur difluoride was calculated from the peak areas of the gases present and the yield was reported in Table I for one carbon, whatever the number

of carbon atoms in the starting material. The yield of cyanuric fluoride was found by weighing the liquid obtained.

After each experiment, the bomb contained a solid residue of sulphur, iron salts, and ammonium fluoride.

Analytical Methods

The gas–liquid chromatography was performed with a Perkin–Elmer gas chromatograph Model 154 using a 9-ft long by $\frac{1}{4}$ in. diameter spiral copper column packed with standard Perkin–Elmer Chromosorb A

*Issued as CARDE Tech Memo 725/62 under Project No. D46-10-28-34.

(containing diisodecyl phthalate as liquid stationary phase), then by a 20-ft long by ¼ in. diameter spiral copper column packed with 33% by weight of grade No. 10 Kel-F polymer oil (3M Co.), supported by 35- to 80-mesh Firebrick C-22 (Johns Manville Co.).

The effluent gases were identified on a Bendix time-of-flight mass spectrometer, model 12-101, which was coupled with the gas chromatograph. The mass spectrum of CF_3NSF_2 was identical with that published (1), and CF_4 showed peaks at *m/e* 69 (CF_3^+), 50 (CF_2^+), and 31 (CF^+), as in the spectrum published by the American Petroleum Institute (serial No. 401).

Cyanuric fluoride obtained by the reaction of melamine with SF_4 (experiment No. 8) was identified by different methods. Its boiling point (74 °C) was the same as that reported (2). Its infrared spectrum, as a liquid film, was identical with that published (3).

The mass spectrum of cyanuric fluoride showed strong peaks in decreasing order of intensity at *m/e* 135 ($C_3N_3F_3$, "parent" ion), 31 (CF^+), 90 ($C_2N_2F_2^+$), 45 (CNF^+), 71 ($C_2N_2F^+$), and 116 ($C_3N_3F_2^+$). Much less abundant ions had mass/charge ratios of 76 ($C_2NF_2^+$), 26 (CN^+), 52 ($C_2N_2^+$), 12 (C^+), 50 (CF_2^+), and 38 (C_2N^+). Upon reducing the ionizing voltage of the mass spectrometer, the peaks due to the smaller charged fragments disappeared very rapidly, except the "parent" ion which disappeared at 9 V only.

THE ALKALOIDS OF ASPIDOSPERMA OBLONGUM A.D.C.

K. H. Palmer

The stem bark of *Aspidosperma oblongum* A.D.C., a tree growing in British Guiana, has been found to contain 0.8–1.0% of alkaloids. From the heptane and methanol extracts of the powdered bark, two crystalline and one amorphous base have been obtained. Thin-layer chromatography (t.l.c.) of alkaloid I, obtained from the heptane extract, was found to be identical in all respects with aspidocarpine (1), which was initially extracted from *Aspidosperma album* root bark. Alkaloid II was obtained by column-partition chromatography (of the total alkaloidal fraction) of the bases obtained from the methanol extract and was shown to be yohimbine. Yohimbine styphnate was found to be an easily prepared and stable derivative. It is of a somewhat unusual composition consisting of two moles of yohimbine and one mole of styphnic acid. Alkaloid III, obtained in extremely low yield as an amorphous powder, had all the physical and chemical characteristics of pseudoyohimbine (2). Four other minor bases, as shown by t.l.c., were not further investigated due to lack of primary plant material.

EXPERIMENTAL

Ultraviolet spectra were determined in 95% ethanol, using a Unicam SP700 spectrophotometer; the infrared spectra were obtained using a Perkin–Elmer DB21 instrument. Melting points are corrected. Thin-layer chromatography employed a 0.25 mm layer of Silicagel G (Merck) on glass plates, using the supersaturated chamber technique of Stahl (3). The solvent was chloroform–hexane–diethylamine (10:20:3) (4). The alkaloids were detected with a modified Dragendorff reagent for alkaloids or a 5% w/v ceric sulphate in 10% sulphuric acid spray.

(containing diisodecyl phthalate as liquid stationary phase), then by a 20-ft long by ¼ in. diameter spiral copper column packed with 33% by weight of grade No. 10 Kel-F polymer oil (3M Co.), supported by 35- to 80-mesh Firebrick C-22 (Johns Manville Co.).

The effluent gases were identified on a Bendix time-of-flight mass spectrometer, model 12-101, which was coupled with the gas chromatograph. Much less abundant ions had mass/charge ratios of 76 ($C_2NF_2^+$), 26 (CN^+), 52 ($C_2N_2^+$), 12 (C^+), 50 (CF_2^+), and 38 (C_2N^+). Upon reducing the ionizing voltage of the mass spectrometer, the peaks due to the smaller charged fragments disappeared very rapidly, except the "parent" ion which disappeared at 9 V only.

THE ALKALOIDS OF ASPIDOSPERMA OBLONGUM A.D.C.

K. H. Palmer

The stem bark of *Aspidosperma oblongum* A.D.C., a tree growing in British Guiana, has been found to contain 0.8–1.0% of alkaloids. From the heptane and methanol extracts of the powdered bark, two crystalline and one amorphous base have been obtained. Thin-layer chromatography (t.l.c.) of alkaloid I, obtained from the heptane extract, was found to be identical in all respects with aspidocarpine (1), which was initially extracted from *Aspidosperma album* root bark. Alkaloid II was obtained by column-partition chromatography (of the total alkaloidal fraction) of the bases obtained from the methanol extract and was shown to be yohimbine. Yohimbine styphnate was found to be an easily prepared and stable derivative. It is of a somewhat unusual composition consisting of two moles of yohimbine and one mole of styphnic acid. Alkaloid III, obtained in extremely low yield as an amorphous powder, had all the physical and chemical characteristics of pseudo-yohimbine (2). Four other minor bases, as shown by t.l.c., were not further investigated due to lack of primary plant material.

EXPERIMENTAL

Ultraviolet spectra were determined in 95% ethanol, using a Unicam SP700 spectrophotometer; the infrared spectra were obtained using a Perkin–Elmer DB21 instrument. Melting points are corrected. Thin-layer chromatography employed a 0.25 mm layer of Silicagel G (Merck) on glass plates, using the super-saturated chamber technique of Stahl (3). The solvent was chloroform–hexane–diethylamine (10:20:3) (4). The alkaloids were detected with a modified Dragendorff reagent for alkaloids or a 5% w/v ceric sulphate in 10% sulphuric acid spray.

The Extraction Aspidosperma oblongum

Finely powdered stem bark (200 g) was continuously extracted in a soxhlet apparatus, first by heptane, then by methanol. Upon concentration of the heptane extract, a light-brown, semicrystalline material (0.14 g) was precipitated. Crystallization of this material from methanol gave (0.065 g) colorless, crystalline prisms, m.p. 166–168°, of alkaloid I. Thin-layer chromatography of the crystals showed one component (R_f 0.46), whereas the mother liquors showed, in addition, a further base (R_f 0.26) alkaloid II. Alkaloid I was vacuum sublimed (0.05 mm/140°) to give colorless prisms, m.p. 168.5–169.5°, $[\alpha]_D^{26}$ +141° (c = 1.0, $CHCl_3$). Found: C, 71.32; H, 8.19; N, 7.54; O, 12.89; OCH_3, 8.30. Calc. for $C_{22}H_{30}O_3N_2$: C, 71.32; H, 8.16; N, 7.56; O, 12.96; 1 OCH_3, 8.38. The sublimed sample was identical in all respects (mixed melting point, ultraviolet, infrared, nuclear magnetic resonance) with an authentic sample of aspidocarpine.

The dark-brown viscous mass (20 g), left after the concentration of the methanol extract *in vacuo*, was dissolved in the minimal volume of boiling glacial acetic acid (30 ml) and the resultant dark-brown syrup was poured into ice-cold water (300 ml). The precipitated dark-brown non-alkaloidal resin was filtered off leaving an amber-brown mother liquid. To this was added strong solution of ammonia to give the pH 9.0 and the resultant solution exhaustively extracted with chloroform. The chloroform extract after evaporation gave a brown viscous alkaloidal residue (0.8 g). This material was fractionated on a 50 g/50 ml Kieselguhr/phosphate buffer (pH 5.8) partition column, first with ether and then chloroform as eluting solvents. The column was then stripped of basic material with ammoniacal chloroform. Both the ether and chloroform eluates were collected in constant volume fractions (10 ml), the progress of the elution was followed by both titrametric and t.l.c. techniques.

The major component of the ether eluate (fraction Nos. 9–21) consisted of a single component, alkaloid II (R_f 0.26). Three other compounds were detected in later fractions (24–40, 43–60, 65–82); these were present in extremely small quantities and were not further investigated. Fractions 4–7 consisted of mainly aspidocarpine and after they were processed gave a further amount of t.l.c. pure aspidocarpine (0.04 g). The chloroform eluate yielded only traces of basic material which was mainly alkaloid II.

Eluate Fractions 9–21

Concentration of these eluate fractions gave a crop of long, colorless needles (0.3 g) m.p. 236–237° of alkaloid II. Further concentration of the mother liquors gave more crystals, m.p. 234–235° of alkaloid II. When the mother liquor evaporated to a very small volume (15 ml), an off-white amorphous powder (0.06 g) m.p. 264–267° (alkaloid III) was deposited. The pale-yellow glass obtained by complete evaporation of the final mother liquors failed to crystallize from the usual solvents and consisted of alkaloid II (R_f 0.26) with traces of probably I (R_f 0.46).

Alkaloid II

Recrystallization of crop m.p. 236–237° from aqueous methanol gave colorless needles of the same melting point identical in all respects (infrared, ultraviolet, nuclear magnetic resonance, and mixed melting point) with yohimbine. The styphnates of alkaloid II and yohimbine were prepared and found to be identical. The styphnate, in contrast to the picrate, easily crystallized in yellow plates, m.p. 204° (dec.), from aqueous ethanol. Found: C, 60.22; H, 5.9; N, 10.2. Calc. for $C_{42}H_{52}O_6N_4$, $C_6H_3O_8N_3$: C, 60.43; H, 5.77; N, 10.2.

Alkaloid III

Recrystallization of the amorphous powder from methanol gave microplates (0.045 g) m.p. 265–266°. Found: C, 71.06; H, 7.40; N, 7.83; mol. wt. (titrametric) 348. Calc. for $C_{21}H_{26}O_3N_2$: C, 71.16; H, 7.39; N, 7.90; mol. wt. 354. Max. 2255 Å (4.49), 2805 Å (3.80), infrared (Nujol mull). Max. 3502 cm^{-1} (NH indole), 3333 cm^{-1} (OH bonded), 1746 cm^{-1} (carbonyl) 1605 and 1589 cm^{-1} (aromatic ring); $[\alpha]_D^{23}$ +29 (pyridine, c = 0.5). Pseudoyohimbine (2, 5) $C_{21}H_{26}O_3N_2$, m.p. 265–266°, $[\alpha]_D^{19}$ +27° (pyridine c = 1). Max. 2250 Å (4.53), 2900 Å (3.79). The infrared spectra appeared to be identical in all respects (5).

ACKNOWLEDGMENTS

I wish to express my thanks to Dr. Léo Marion for the sample of aspidocarpine.

AN ELECTRON IMPACT STUDY OF METHYLMERCAPTOBENZYL CHLORIDES

F. MEYER AND A. G. HARRISON*

A recent study (1) has shown that the appearance potentials of the $CH_3OC_7H_6^+$ ion from the isomeric meta- and para-methoxybenzyl chlorides differ by 1.15 eV, the meta isomer having the higher appearance potential. This difference is in reasonable agreement with the difference of 0.99 eV predicted for formation of the respective substituted benzyl ions and indicates that rearrangement to the symmetrical tropylium structure (2) does not occur at the appearance potential threshold. This conclusion is supported by the observation of large differences in the mass spectra of the isomeric methoxybenzyl chlorides. Similar differences have also been observed recently (3) in the spectra of the isomeric methoxybenzyl bromides.

We now report a similar study of the related compounds, meta- and para-methylmercaptobenzyl chloride. Partial mass spectra are given in Table I for these two compounds, where the spectra of the methoxybenzyl chlorides (1) are also presented for comparison. The largest peak in the mass spectra of the methylmercaptobenzyl chlorides occurs at $m/e = 137$ corresponding to the $CH_3SC_7H_6^+$ ion formed by loss of Cl. The appearance potential of $m/e = 137$ was found to be 11.20 ± 0.1 eV from the meta isomer and 10.45 ± 0.1 eV from the para isomer. From the correlation (4) of the ionization potentials of substituted benzyl radicals with the σ^+ value for the substituent, we estimate $I(m\text{-}CH_3SC_6H_4CH_2) = 7.97$ eV and $I(p\text{-}CH_3SC_6H_4CH_2) = 7.06$ eV using σ^+ (M-CH_3S) $= +0.158$ and σ^+ (p-CH_3S) $= 0.604$ (5). Since the bond dissociation energies of substituted benzyl derivatives are independent of the nature or position of the substituent (6) the difference of 0.91 eV in the ionization potentials is a measure of the difference expected in the appearance potentials if the benzyl structure for the $CH_3SC_7H_6^+$ ion is retained without migration of the substituent. The experimentally measured difference of 0.75 ± 0.2 eV is in good agreement with the predicted difference and strongly indicates retention of the benzyl configuration at the appearance potential threshold. If rearrangement to the symmetrical tropylium structure had occurred, the orientation of the substituents would have been lost and identical appearance potentials would have been expected. Such a behavior has been found when the ring substituent is CH_3, F, or OH (1).

TABLE I

Partial mass spectra of methylmercaptobenzyl chlorides and methoxybenzyl chlorides

	Methylmercaptobenzyl chlorides (X = S)			Methoxybenzyl chlorides (X = O)

The spectra of the methylmercaptobenzyl chlorides and the methoxybenzyl chlorides are quite similar and both show the differences expected on the basis of different structures and energy contents for the $CH_2XC_7H_6^+$ ions from the meta- and para-isomers. The $CH_3XC_7H_6^+$ ion from the meta isomer has a much higher energy content than the ion from the para isomer; thus for the meta isomer the abundance relative to the parent ion or the fragmentation product, $C_7H_7^+$ ($m/e = 91$), is greatly reduced compared to the para isomer. Not only is more energy required for formation of the $CH_3XC_7H_6^+$ ion from the meta isomer but also the energy barrier for further decomposition to the $C_7H_7^+$ ion is smaller. The main decomposition path for the $CH_3XC_7H_6^+$ ion appears to be by reaction [1] for both the methoxy- and methyl-mercapto compounds. The $C_7H_7^+$ ion presumably has the tropylium structure.

$$[1] \qquad CH_3XC_7H_6^+ \rightarrow C_7H_7^+ + CH_2X$$

A metastable transition is observed for this decomposition in the case of the methoxy compounds (1); however, for the methylmercapto compounds the metastable transition expected at $m/e = 60.4$ could not be identified with certainty because of a doubly charged ion at $m/e = 60.5$.

The above observations strongly support the conclusion that the methylmercaptobenzyl chlorides behave in a similar manner to the methoxybenzyl chlorides on electron impact and that, in both cases, the ion formed by loss of Cl retains the benzyl configuration.

EXPERIMENTAL

The mass spectra and appearance potentials were measured with an A.E.I. MS-2 mass spectrometer which has been described previously (1). Appearance potentials were determined in the usual manner (7) using xenon to calibrate the voltage scale.

The *p*-methylmercaptobenzyl chloride was prepared from thioanisole and chloromethylmethyl ether by the method of Buu-Hoi (8). The *m*-methylmercaptobenzyl chloride was prepared by reduction of *m*-methylmercaptobenzoic acid with $LiAlH_4$ and treatment of the resulting alcohol with PCl_3 (9). The *m*-methylmercaptobenzoic acid was prepared by the method of Smiles and Stewart (10). The chlorides were purified by fractional distillation.

METHOXYCARBOSTYRILS

GEORGE R. PETTIT AND ALEXANDER B. NEILL[1]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The central nervous sytem activity occasionally displayed by carbostyrils (1) led us to prepare several methoxy-substituted 2-hydroxyquinolines (cf. I) and a number of 2-quinolyl esters (Table I) for pharmacological evaluation. In general, the quinoline derivatives were based on structural features[2] of the hypotensive and sedative *Rauwolfia* alkaloids reserpine and resinnamine (2). Certain other 2-quinolyl esters (Table I), ethers, and 2-chloroquinolines were synthesized for comparison purposes.

Initially, it was considered necessary to prepare 6-methoxy-(I*a*), 7-methoxy-(**I*b*)**, and 6,7-dimethoxy-carbostyril (I*c*). Of these, only 7-methoxycarbostyril was previously undescribed and synthesis was accomplished by the following reaction scheme (II → I).[3]

Chromyl chloride oxidation of 2-nitro-4-methoxytoluene (5) gave 2-nitro-4-methoxybenzaldehyde (II) as described by Boon (6). Condensation of benzaldehyde II with malonic acid led to 2-nitro-4-methoxycinnamic acid (III). Ferrous sulphate reduction of nitrobenzene III afforded 2-amino-4-methoxycinnamic acid (IV), which cyclized to 7-methoxycarbostyril (I*b*) in hot 2-propanol – hydrochloric acid solution. Phosphorus oxychloride readily converted carbostyril I*b* to 2-chloro-7-methoxyquinoline (I*d*).

Preparation of 2-chloroquinoline I*d* illustrates the general reaction sequence employed for synthesis of 6,7-dimethoxycarbostyril (7) from 6-nitroveratraldehyde and subsequent conversion to 2-chloro-6,7-dimethoxyquinoline (I*e*). Dimethylformamide was found a superior solvent for effecting facile transformation of chloroquinoline I*e* to 2,6,7-trimethoxyquinoline (I*f*) with sodium methoxide. With methanol, Diglyme, or xylene as

[1]*Eaton Laboratories.*
[2]*A number of recent investigations, directed toward preparation of useful ataractic agents, have been inspired by various aspects of the reserpine molecule: see for example, reference 3.*
[3]*Three years after the present investigation was completed, Sidhu (ref. 4) and colleagues reported a similar route to 7-methoxycarbostyril.*

solvent, extended reaction periods were necessary.[4] The butyl (I*g*) and dimethylaminoethyl (I*h*) ethers of dimethoxycarbostyril I*c* were prepared in an analogous manner. In addition, 2,6,7-trihydroxyquinoline (I*i*) was obtained by treating carbostyril I*c* with 48% hydrobromic acid.

The 2-quinolyl esters (Table I) were prepared by warming the respective carbostyril and acyl chloride in pyridine. The infrared spectrum of each ester revealed a single strong band in the 5.78–5.82 μ region, compatible with O-alkylation. Evidence in favor of N-alkylation was not demonstrated.[5]

EXPERIMENTAL[6]

6-Methoxycarbostyril (Ia)

A solution of 6-methoxyquinoline-N-oxide (37.0 g, ref. 11) in 300 ml of acetic anhydride was heated at reflux for 5 h before removal of excess solvent *in vacuo*. The dark residue was warmed (steam bath) for 1 h with 200 ml of 2 *N* sodium hydroxide. After cooling, the product was collected and washed with dilute hydrochloric acid and water. The grayish-brown colored crystals weighed 12.6 g (33%) and melted at 208–216°. Recrystallization from ethanol (Darco) afforded colorless crystals of 6-methoxycarbostyril melting at 220–221°. The product was shown to be identical with an authentic sample (12) by mixture melting point determination and infrared spectral comparison.

2-Nitro-4-methoxycinnamic Acid (III)

To a solution of malonic acid (224 g) in 750 ml of pyridine were added piperidine (20 ml) and 2-nitro-4-methoxybenzaldehyde (127 g, ref. 5 and 6). After a 3-hr period of heating (steam bath), evolution of carbon dioxide appeared to be complete and the solution was poured into 3.2 l of 10% hydrochloric acid. The tan-colored crystalline product weighed 120 g (77%) and melted at 245–247° (with sintering from 190°). Recrystallization from ethanol (Darco) gave pale yellow needles, m.p. 246–248°. A melting point of 240° has been reported (4) for this substance. Anal. Calc. for $C_{10}H_9NO_5$: C, 53.81; H, 4.06; N, 6.28. Found: C, 53.90; H, 3.97; N, 6.56.

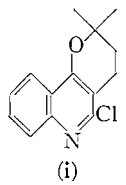
7-Methoxycarbostyril (Ib)

A solution of 2-nitro-4-methoxycinnamic acid (120 g) in 1.3 l of 28% aqueous ammonia was added, with stirring, to a warm solution of ferrous sulphate heptahydrate (1.3 kg) in 2 l of water. After the mixture was heated to 80° for 10 min, it was allowed to cool and was filtered through Celite. The filtrate was acidified to pH 6.5 with glacial acetic acid to furnish 44 g (43%) of light brown crystalline product (IV), m.p. 238–242° (dec.). A solution of the amino acid (44 g) in 500 ml of isopropyl alcohol containing concentrated hydrochloric acid (200 ml) was heated at steam bath temperature for 15 min, cooled, and filtered. The greyish-brown crystalline product was dissolved in 2 *N* sodium hydroxide (500 ml) and precipitated with 2 *N* hydrochloric acid. The tan-colored microcrystals weighed 18.3 g (45%) and melted at 198–200° (with sintering from 170°). Recrystallization from ethylene chloride gave colorless needles, m.p. 204–205.5°. An elemental analysis for nitrogen and a melting point of 199° has been reported (4) for carbostyril I*b*. Anal. Calc. for $C_{10}H_9NO_2$: C, 68.56; H, 5.18; H, 8.00. Found: C, 68.30; H, 4.91; N, 7.96.

2-Chloro-7-methoxyquinoline (Id)

A solution of 7-methoxycarbostyril (1.9 g) in 20 ml of phosphorus oxychloride was heated at reflux 3 h. The remaining phosphorus oxychloride was removed *in vacuo*. After addition of ice and aqueous ammonia, the basic mixture was extracted with chloroform. Removal of solvent from the dry (sodium sulphate) extract afforded 1.2 g (59%) of crystalline product; m.p. 96–97°, following recrystallization from benzene

[4]*The unexpected resistance displayed by chlorodeoxydihydroflindersine (ref. 8) (i) to nucleophilic attack by methoxide in methanol or xylene may be cited as another example: cf. also ref. 9.*



(i)

[5]*An imide structure, arising from N-alkylation, would be expected to exhibit a second band due to carbonyl absorption in the 5.85–6.00 μ region (ref. 10).*

[6]*Unless otherwise indicated, melting points were determined with a Fisher–Johns apparatus and are uncorrected. Elemental analyses were provided by the microanalytical laboratory of Eaton Laboratories. Infrared spectra were measured in chloroform solution using a Perkin–Elmer model 21 infrared spectrophotometer.*

[a]Yield based on a pure specimen.
[b]The ester was recrystallized from benzene (1), or benzene – petroleum ether (2).
[c]Melting point of the analytical sample.

(Darco)–hexane. The analytical sample crystallized as colorless needles from benzene–hexane, m.p. 97–98°. Anal. Calc. for $C_{10}H_8ClNO$: C, 62.02; H, 4.16; Cl, 18.31. Found: C, 62.20; H, 4.14; Cl, 18.05.

2-Chloro-6,7-dimethoxyquinoline (Ie)

A suspension of 6,7-dimethoxycarbostyril (100 g, ref. 7) in 300 ml of refluxing phosphorus oxychloride was stirred 3 h. Excess phosphorus oxychloride was removed *in vacuo* before the residue was cautiously added to an ice – aqueous ammonia mixture. The gray-colored crystalline product was collected and washed with water; yield 104.5 g (96%), m.p. 118–120°. Recrystallization from benzene (Darco) – petroleum ether gave colorless needles melting at 122–124°. Anal. Calc. for $C_{11}H_{10}ClNO_2$: C, 59.07; H, 4.51; Cl, 15.85. Found: C, 59.40; H, 4.50; Cl, 15.82.

2,6,7-Trimethoxyquinoline (If)

To a solution of 2-chloro-6,7-dimethoxyquinoline (I*e*, 5 g) in 100 ml of dimethylformamide was added 6.2 g of sodium methoxide. Before pouring the hot reaction mixture into 1 l of water, the resulting suspension was stirred and heated at reflux for 15 min. Collecting the colorless needles afforded 4.1 g (84%) of product melting at 116–117°. After further recrystallization from petroleum ether, the melting point remained at 116–117°. Anal. Calc. for $C_{12}H_{13}NO_3$: C, 65.74; H, 5.98; N, 6.39. Found: C, 65.75; H, 5.60; N, 6.24.

A fair yield (68%) in Diglyme was obtained after 24 h at reflux, while 48 h in refluxing xylene was needed to obtain a comparable yield (77%). The reaction in refluxing methanol, at periods up to 24 h, gave only crude starting material and was not further investigated. When a methanol solution of 6,7-dimethoxycarbostyril was treated with ethereal diazomethane and allowed to stand at room temperature for 24 h, only starting material was recovered.

2-Butoxy-6,7-dimethoxyquinoline (Ig)

Dimethylformamide (150 ml) and 20 g of 2-chloro-6,7-dimethoxyquinoline (I*e*) were added to solid sodium butoxide, prepared by adding sodium (12.4 g) to 200 ml of refluxing *n*-butyl alcohol (excess alcohol was removed *in vacuo*). Before the mixture was poured into 1.5 l of water, heating was maintained at 110–120° for 15 min. Heating the mixture to reflux caused excessive foaming. The crystalline product weighed 22.9 g and melted at 74–78° (with sintering from 65°). Distillation through a Claisen flask afforded 17.5 g (75%) of viscous oil, b.p. 175–179° (0.02 mm), which crystallized from benzene–petroleum ether as colorless crystals melting at 83–85°. An analytical sample, m.p. 85–86°, was crystallized from the same solvent. Anal. Calc. for $C_{15}H_{19}NO_3$: C, 68.74; H, 7.33; N, 5.36. Found: C, 68.74; H, 6.98; N, 5.08.

2-(2′-Dimethylamino)ethoxy-6,7-dimethoxyquinoline (Ih)

Sodium (12.4 g) was added in small portions to 150 ml of refluxing dimethylaminoethyl alcohol. Excess solvent was removed *in vacuo* and to the crystalline residue was added dimethylformamide (200 ml) and 20 g of 2-chloro-6,7-dimethoxyquinoline (I*e*). Before the mixture was poured into 2 l of cold water, stirring and heating at reflux was continued for 15 min. The aqueous solution was saturated with sodium chloride and extracted with chloroform. Removal of solvent from the dry (sodium sulphate) organic extract left a dark brown mobile oil. A portion of the oily residue (1.7 g) in benzene–hexane (1:1) was chromatographed on 50 g of activated alumina (Merck "Suitable for Chromatography"). Elution with 750 ml of the same solvent gave 0.42 g of colorless crystals. Further elution with 1 l of benzene afforded 0.28 g. After recrystallization from benzene – petroleum ether, the two crystalline fractions melted, respectively, at 108–110° and 112-114°. An analytical sample crystallized as colorless platelets from benzene – petroleum ether, m.p. 113–114°. Anal. Calc. for $C_{15}H_{20}N_2O_3$: C, 65.19; H, 7.30; N, 10.14. Found: C, 65.65; H, 7.23; N, 10.05.

The remaining reaction product was distilled through a Claisen flask. The main fraction boiled at 184-186° (0.01 mm) and separated from benzene – petroleum ether as colorless crystals (8.8 g), m.p. 100–107°. Several additional recrystallizations from benzene – petroleum ether raised the melting point to 109–111°. A mixture melting point determination with the chromatographed product showed no depression. The total yield of crystalline material amounted to 9.5 g (38%).

6,7-Dihydroxycarbostyril (Ii)

A stirred suspension of 6,7-dimethoxycarbostyril (I*c*, 30 g, ref. 7) in 600 ml of 48% hydrobromic acid was heated at reflux 24 h. The dark-colored solution was cooled and the brown needles (27.6 g) collected, washed with water, and recrystallized from glacial acetic acid (Darco). The straw-colored crystalline salt weighed 19.5 g and melted at 268–270° (with sintering from 260°). Precipitation from 450 ml of 2 *N* sodium hydroxide solution, with 2 *N* hydrochloric acid, gave 13 g of tan-colored *6,7-dihydroxycarbostyril*, m.p. 330–334° (dec.) with sintering from 315° .The yield was increased to 17.5 g (68%) by diluting the hydrobromic acid filtrate with ca. 100 ml of water and converting the second crop of hydrobromide to 6,7-dihydroxycarbostyil as previously described. An analytical sample was obtained as colorless crystals from glacial acetic acid, m.p. 338–340° (dec.) with darkening from 315°.[7] Anal. Calc. for $C_9H_7NO_3$: C, 61.01; H, 3.98; N, 7.91. Found: C, 60.90; H, 3.90; N, 7.82.

2-Quinolyl Esters (Table I)

Details for the preparation of 2-quinolyl-3′,4′,5′-trimethoxybenzoate will illustrate the general procedure

(13). To a warm solution of carbostyril (263 g) in 1.2 l of pyridine was added 418 g of 3,4,5-trimethoxybenzoyl chloride (14). Before pouring the solution into 13 l of water, heating was maintained at steam bath temperature for 1 h. The crude product was collected, dissolved in 2 l of chloroform, and washed successively with five 300 ml portions of 2 *N* sodium hydroxide and then with water. After removal of solvent from the dry organic extract, the residue was recrystallized (Table I).

Nicotinyl chloride was prepared as described by Clark-Lewis and Thompson (15). The following method was employed for preparation of *3,4,5-trimethoxycinnamoyl chloride*. Oxalyl chloride (35 ml) was added to 3,4,5-trimethoxycinnamic acid (39 g) and, after the initial reaction had subsided, the mixture was heated at reflux 1 h. Removal of excess oxalyl chloride *in vacuo* left a dark-colored crystalline residue which recrystallized from benzene – petroleum ether as yellow-colored crystals; yield 37 g (88%), m.p. 88–90°.

SYNTHESIS OF TRYPTOPHAN-CARBOXYL-^{14}C[1]

G. P. Slater

Tryptophan labelled in the carboxyl group with carbon 14 was required for studies on the biosynthesis of a fungal metabolite, but was not commercially available. The synthesis was achieved from indole-3-aldehyde and hydantoin-4-^{14}C* using a modification of the procedure described by Bond (1) for the corresponding ^{13}C-labelled compound.

In the modified method, the indolylidenehydantoin (I) was reduced by the action of Raney nickel alloy in dilute sodium hydroxide solution, instead of using Raney nickel catalyst in sodium hydroxide (2). The reduction product, indolylmethylhydantoin (II),

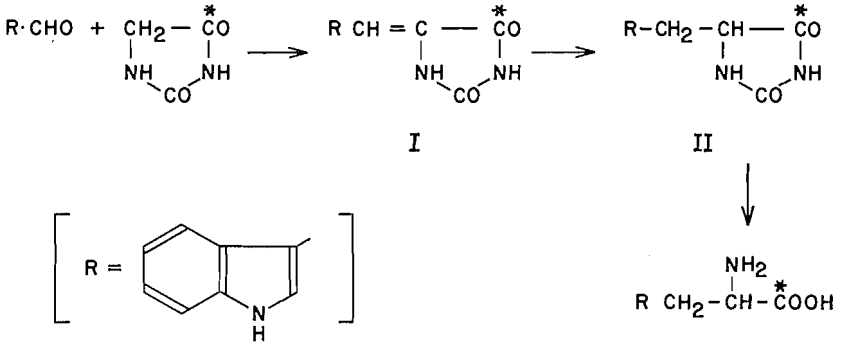
was not isolated, but its aqueous solution was hydrolyzed with barium hydroxide (2) and the tryptophan isolated by ion-exchange chromatography. This procedure constitutes a facile synthesis of tryptophan and gives a better yield (73%) than that reported by Bond (1) [59% based on hydantoin].



EXPERIMENTAL

Indolylidenehydantoin (I)

Hydantoin-4-^{14}C (45.5 mg, approximately 0.5 mC) and carrier (54.5 mg, total 1 mmole) was mixed with indole-3-aldehyde (160 mg, 1.1 mmole) in a 5-ml round-bottom flask. Piperidine (0.5 ml) was added, the flask fitted with a 6-in. air condenser, and immersed in an oil bath at 150–155 °C (1) until a yellow solid had formed (7 min). The product was suspended in water, the mixture acidified with acetic acid, filtered, and washed to give indolylidenehydantoin (208 mg, 92%).

DL-*Tryptophan-carboxyl-*^{14}*C*

The crude indolylidenehydantoin (208 mg, 0.92 mmole) was dissolved in water (50 ml), containing sodium hydroxide* (800 mg, approximately 20 mmole) in a 250 ml beaker, and stirred at 50–55 °C while Raney nickel alloy (1 g) was added, in portions, until the solution became colorless (6 min). After a further 10 min the mixture was filtered and the pH of the filtrate adjusted to 7.2 with 4 *N* hydrochloric acid to precipitate aluminum hydroxide (3). The mixture was centrifuged and the precipitate washed with water until the washings showed no ultraviolet absorption at 278–386 mμ. Barium hydroxide octahydrate (5.81 g, 18.4 mmole) was added to the combined washings and the mixture boiled for 48 h. The hot mixture was saturated with carbon dioxide (2) and filtered immediately. The filtrate was cooled to room temperature, made alkaline with 5 *N* ammonia, and passed through a Dowex 1 resin (X8, 200–400 mesh, 120 × 28 mm) in the hydroxyl form. The resin was washed with distilled water until the effluent was neutral to litmus and the tryptophan was eluted with 1 *N* acetic acid.† The latter solution was passed through a Dowex 50W resin (X4, 200–400 mesh, 120 × 28 mm) in the hydrogen-ion form, and the column washed as before. The tryptophan was eluted with 1 *N* ammonia and the eluate concentrated under reduced pressure at 50 °C until the product commenced to separate. Dilution of the mixture with ethanol and cooling in ice gave DL-tryptophan-carboxyl-^{14}C (127 mg, 0.386 mC), dec. 255–260 °C. The residue (30 mg) from the mother liquor was dissolved in 1 *N* sodium hydroxide (2 ml), the pH adjusted to 7 with 1 *N* acetic acid, and the solution absorbed on a Dowex 1 resin (220 × 22 mm) in the acetate form. Elution of the column with water and 0.05 *N* acetic acid gave a further quantity of tryptophan (22 mg, total yield 149 mg, 0.73 mmole), dec. 250–255 °C.

The two fractions gave infrared spectra (KBr) identical with that of an authentic sample of DL-tryptophan. Paper chromatography [*n*-butanol – acetic acid – water, 12:3:5] (4) of the product gave a single spot, corresponding to DL-tryptophan, and scanning of the chromatogram showed that the radioactivity was located in the spot of tryptophan only.

Decarboxylation of the product by the method of Van Slyke (5), using pH 4.7 buffer, gave barium carbonate (98% of theory) containing 96% of the radioactivity.

ACKNOWLEDGMENTS

The author wishes to thank Dr. J. C. MacDonald for the decarboxylation of the tryptophan, and Mr. M. Mazurek and Mr. J. Dyck for the radioisotope determinations.

**Barium hydroxide can also be used, but the reaction time is longer (40 min) and more alloy (3 g) is required.*

†The chromatography was followed by ultraviolet spectroscopy to ensure that no tryptophan was lost in the washings or by incomplete elution.

REARRANGEMENT STUDIES WITH ^{14}C

XXI. SIDE CHAIN REARRANGEMENT AND FRAGMENTATION FOLLOWING FRIEDEL–CRAFTS ALKYLATION OF BENZENE WITH β-^{14}C-ETHYL IODIDE

ABSTRACT

The aluminum chloride catalyzed reaction between β-^{14}C-ethyl iodide and benzene in 1,2,4-trichlorobenzene as solvent was studied under different conditions of temperature and reaction time. Yields of ethylbenzene were estimated by isotopic dilution. Up to 20% rearranged product, α-^{14}C-ethylbenzene, was found. The trend indicated that yield of ethylbenzene was lower and side chain rearrangement greater when the reaction mixture was heated at higher temperature for longer time. The rearrangement apparently occurred after the initial formation of β-^{14}C-ethylbenzene. After a reaction time of 5 min at 154 °C, only 0.1–0.3% unreacted and unrearranged β-^{14}C-ethyl iodide was recovered while the ethylbenzene obtained from the reaction showed about 2% rearrangement. When β-^{14}C-ethylbenzene was heated with aluminum chloride in 1,2,4-trichlorobenzene for 2 or 24 h, rearrangement to α-^{14}C-ethylbenzene was observed. In some experiments, a fragmentation product, toluene, was isolated. Its specific activity suggested that 1 mole of active ethylbenzene gave 2 moles of toluene only one of which was active. The mechanistic implications of these findings are discussed.

INTRODUCTION

The Friedel–Crafts reaction of β-^{14}C-ethyl chloride (1) or β-^{14}C-ethyl iodide (2) with excess benzene gave β-^{14}C-ethylbenzene with no isotope position rearrangement in the side chain. This observation is consistent with the proposed mechanism of Brown and co-workers (3) that Friedel–Crafts alkylations may be analogous to other substitutions on saturated carbon, with primary alkyl halides reacting by a direct displacement process. Since the Friedel–Crafts catalyst can, by itself, induce rearrangements in alkyl halides, it has been suggested (4, 5) that rearranged products could have arisen from reactions with alkylating agents that have undergone rearrangement prior to the alkylation step. Treatment of β-^{14}C-ethyl chloride or β-^{14}C-ethyl iodide with aluminum chloride (1, 2), or of β-^{14}C-ethyl bromide with aluminum bromide (6), has been shown to cause extensive rearrangement of the ^{14}C-label. However, consideration of reaction rates indicated that no rearrangement of the ethylating agent could take place prior to alkylation when the Friedel–Crafts reaction was effected in excess benzene (2). In the present work, the aluminum chloride catalyzed alkylation of benzene with β-^{14}C-ethyl iodide was carried out in 1,2,4-trichlorobenzene under various conditions. It might then be ascertained if the use of an inert solvent would decrease the alkylation rate sufficiently to allow the aluminum chloride induced rearrangement of the β-^{14}C-ethyl iodide to take place, so that isotopically rearranged ethylbenzene would result. Significant extents of rearrangement were observed only in reactions effected at relatively high temperatures. Experiments were then carried out to show that these rearrangements occurred subsequent to the

formation of ethylbenzene. In addition, a fragmentation product, toluene, was isolated in certain cases and its ^{14}C-contents determined.

RESULTS AND DISCUSSION

The molar ratio of the reactants was 1.0:3.0:3.2 for $AlCl_3$:C_6H_6:C_2H_5I. The solvent, 1,2,4-trichlorobenzene, has previously been used by Brown and co-workers (3). The reaction mixture was heated at different temperatures for various lengths of time. A known amount of ordinary ethylbenzene was then added as carrier, and the crude product was isolated by distillation. Pure ethylbenzene was finally separated by preparative vapor-phase chromatography (v.p.c.). The ethylbenzene recovered was oxidized to benzoic acid, whose activity, relative to that of ethylbenzene, measured the extent of rearrangement of the ^{14}C-label from the β- to the α-positions in the ethyl side chain. The results are summarized in Table I.

In most of the experiments, the specific activity of the original β-^{14}C-ethyl iodide was also determined. Since the amount of added ethylbenzene carrier and the specific activity of the diluted product were known, the yields of ethylbenzene for various runs were estimated by isotope dilution calculations. The basis of these calculations is as follows.

For every experiment, the theoretical yield of ethylbenzene was 3.18 g and the amount of carrier added was 1.73 g (2.0 ml).

Let x = g of ethylbenzene formed; if no carrier had been used, the specific activity of the ethylbenzene would have been the same as that of the β-^{14}C-ethyl iodide.

(Specific activity of $C_2H_5I)x$ = (observed specific activity of $C_6H_5C_2H_5)(1.73 + x)$. Solving for x, % yield = $(x/3.18) \times 100$. The yields calculated in this way are also included in Table I.

The data in Table I show that both yield of ethylbenzene and ^{14}C-rearrangement in the side chain are dependent on reaction temperature and reaction time. Under the relatively milder conditions of lower temperature and shorter reaction time, reproducibilities in yields and extents of rearrangement were fair. When the reaction mixtures were heated at higher temperatures for 24 h, results with much greater deviations were obtained. The general trend indicated by the data of Table I is that higher temperature and longer reaction time could cause greater amounts of rearrangement and lower yields of ethylbenzene. These observations strongly suggest the occurrence of processes which destroyed part of the ethylbenzene subsequent to its formation, and gave rise to side chain rearrangements in the ethylbenzene that remained.

To show more definitely that rearrangement did occur after ethylbenzene formation, first of all it was demonstrated that rearrangement did not arise prior to alkylation. In expt. 7 and 8 (Table I), which involved heating the reaction mixture at 154 °C for 5 min, besides the usual inactive ethylbenzene carrier, 2.0 ml of inactive ethyl iodide carrier was also added. The ethyl iodide fraction obtained by distillation would then contain unreacted β-^{14}C-ethyl iodide. This fraction was used for a Friedel–Crafts alkylation of an excess of benzene to give ethylbenzene, a process which does not cause appreciable rearrangement (2). From the activities of the ethylbenzene so obtained, calculations based on isotope dilution showed that only 0.1% and 0.3% of unreacted β-^{14}C-ethyl iodide were recovered in expt. 7 and 8. Moreover, oxidation of the ethylbenzene derived from the recovered ethyl iodide gave inactive benzoic acid, indicating no rearrangement of the β-^{14}C-ethyl iodide during the course of expt. 7 and 8. Thus the possibility of slowing down the alkylation by inert solvent to allow β-^{14}C-ethyl iodide to rearrange before alkylation was not realized.

‖Estimated by isotope dilution calculations.

When the Friedel–Crafts alkylation was carried out at 154° for 2 or 24 h with ordinary ethyl iodide, but with some β-^{14}C-ethylbenzene added at the beginning of each trial, the ethylbenzene finally recovered gave, on oxidation, radioactive benzoic acid, indicating rearrangement of the added active ethylbenzene. Moreover, when β-^{14}C-ethylbenzene in trichlorobenzene containing aluminum chloride was heated at 154 °C for 2 or 24 h, the ethylbenzene re-isolated with the aid of carrier also showed side chain ^{14}C-rearrangement. The results are summarized in Table II. The extents of rearrangement obtained in these

*From recovered ethylbenzene.
†Estimated by isotope dilution calculations. In expt. 24 and 26, β-^{14}C-ethylbenzene was heated while an inactive alkylation was carried out. Besides the inactive ethylbenzene carrier added, an unknown amount of inactive ethylbenzene derived from the alkylation reaction was also present; hence no isotope dilution calculations could be made.

trials are of about the same magnitude as those observed in the corresponding experiments 9–10 and 11–14 (Table I). These findings, therefore, support the conclusion that the side chain ^{14}C-rearrangement recorded in Table I arose after the initial formation of unrearranged alkylation product, β-^{14}C-ethylbenzene.

In the course of the v.p.c. separation of ethylbenzene from various experiments, peaks corresponding to benzene and toluene were observed (no attempt was made to identify or separate diethylbenzenes). Probably, benzene resulted from dealkylation and toluene from fragmentation. In some of the experiments with a reaction time of 24 h, sufficient amounts of toluene were present to allow its collection and determination of its specific activity. The results are shown in Table III. As expected, the yield of this fragmentation product was higher when the reaction mixture was heated at higher temperature. It may be of interest to note that under the most drastic conditions employed (expt. 22 and 23), the yields of toluene were comparable to the yields of surviving ethylbenzene.

In these experiments, the toluene was obtained without the addition of any carrier. When the specific activity of the toluene is compared with that of the corresponding ethylbenzene before any dilution of the latter by inactive carrier, the specific activity ratio is about 0.5 in all cases. This is an interesting observation, as it suggests that each mole of active ethylbenzene gave rise to 2 moles of toluene, one of which is active and the other is not. Such a situation would result if the toluene arose from 1,2-diphenyl-1-^{14}C-ethane, which could be derived from either β-^{14}C-ethylbenzene or α-^{14}C-ethylbenzene. In their studies on dealkylation and fragmentation of alkylbenzenes, Roberts, Baylis, and Fonken (7) reported the isolation of *meso*-2,3-diphenylbutane as a minor product after treatment of *sec*-butylbenzene with water-promoted aluminum chloride. A mechanism for fragmentation involving diphenylalkane as intermediate was suggested (7). Such a mechanism applied to ethylbenzene would involve 1,2-diphenylethane as intermediate, which is consistent with the observed specific activity ratio for toluene to ethylbenzene of

23	208	295 000	151 000	0.51	241	8.7	11

*In expt. 27, β-^{14}C-ethylbenzene was added as such; in the other experiments, the specific activity of the undiluted $C_6H_5C_2H_5$ was assumed to be equal to the specific activity of the C_2H_5I initially used (see Table I).

†For expt. 27, based on the β-^{14}C-ethylbenzene added; for the other experiments, based on the limiting reactant, benzene, in the Friedel–Crafts reaction mixture.

‡From Table I, also based on the benzene in the Friedel–Crafts reaction mixture.

about 0.5. The activity data of Table III may, therefore, be regarded as evidence in support of the fragmentation mechanism of Roberts, Baylis, and Fonken.

The disproportionation of ethylbenzene under conditions less severe than those used in the present experiments has been extensively investigated. The pertinent literature has been summarized in a recent paper by Ünseren and Wolf (8). The possibility of side chain rearrangements proceeding through π-complexes has been discussed by Roberts and co-workers (9, 10). It is noteworthy that in the present work, more rearrangement as well as more fragmentation were observed under conditions of higher temperature and longer reaction time. Both of these processes could result from the same intermediate. 1,2-Diphenyl-1-^{14}C-ethane might revert to equal amounts of α-^{14}C-ethylbenzene and β-^{14}C-ethylbenzene, giving rise to the side chain rearrangements observed in the surviving ethylbenzene (Tables I and II). The 1,2-diphenylethane could arise either directly from ethylbenzene or via 1,1-diphenylethane, an intermediate postulated by Streitwieser and Reif (11) for ethylbenzene disproportionation. Isotopically rearranged ethylbenzene via 1,2-diphenylethane would also be consistent with the conclusions of Ünseren and Wolf (8) and of Streitwieser and Reif (11) that disproportionation of ethylbenzene involves considerable extents of intermolecular *trans*-alkylation.

EXPERIMENTAL

The β-^{14}C-ethyl iodide was obtained from New England Nuclear Corp. The β-^{14}C-ethylbenzene was prepared by a Friedel–Crafts reaction between β-^{14}C-ethyl iodide and an excess of benzene, the product showing less than 0.3% ^{14}C rearrangement in the side chain (2). Degradation of ethylbenzene from various experiments to benzoic acid was effected by oxidation with alkaline potassium permanganate (12).

Friedel–Crafts Reactions (Expt. 1–23, Tables I and III)

All reactions were carried out in a pyrex vessel fitted with mechanical stirrer, reflux condenser, and Drierite tube. The vessel was enclosed in a pyrex jacket which was also fitted with a reflux condenser and connected to a pot of boiling liquid. The vapor from the refluxing liquid heated the reaction mixture and maintained a constant temperature.

A mixture of 2.34 g (30 mmoles) of anhydrous benzene, 1.33 g (10 mmoles) of sublimed, anhydrous aluminum chloride, and 50 ml of redistilled 1,2,4-trichlorobenzene was placed in the reaction vessel and brought to the desired temperature. A solution of 5.0 g (32 mmoles) of β-^{14}C-ethyl iodide in a small amount of 1,2,4-trichlorobenzene was then added through the top of the reflux condenser. Heating was continued for the desired length of time and then the reaction stopped by the addition of 50 ml of ice water. Two ml (1.73 g) of inactive ethylbenzene was introduced as carrier. The organic layer was separated and washed successively with 50-ml portions of 5% hydrochloric acid, 2% sodium hydroxide solution containing 5 g of sodium thiosulphate, and water. The washings were extracted with ether and the extract combined with the original organic layer. After the solution was dried over anhydrous magnesium sulphate, it was fractionated. The major portion of the product distilled at 130–135 °C, but the fraction boiling over the range 100–160 °C was collected. Recoveries were of the order of 2–3 g. Final purification was effected by passage through a preparative column packed with Apiezon L on firebrick in a Beckman GC-2A gas chromatograph. Ethylbenzene was recovered in all experiments, while in some cases, toluene, in addition to ethylbenzene, was also collected. The identities of these products were confirmed by n.m.r. spectroscopy. The spectra of the recovered ethylbenzene and toluene were the same as those of corresponding authentic samples. The typical triplet–quartet splitting was shown by the ethyl protons of ethylbenzene and a singlet was observed for the methyl protons of toluene. The τ-values also agree with those given by Tiers (13) for ethylbenzene and toluene.

In expt. 7 and 8, which involved stopping the reaction after heating at 154 °C for 5 min, 2.0 ml of inactive ethyl iodide, in addition to the inactive ethylbenzene carrier, were also added before the mixture was worked up as described above. Two fractions were collected, one contained the ethylbenzene and the other, boiling over the range of 40–80 °C, contained unreacted β-^{14}C-ethyl iodide diluted by carrier. The ethyl iodide fraction was used for a Friedel–Crafts reaction with excess benzene. The ethylbenzene obtained was purified by v.p.c. Its activity measured the amount of unreacted β-^{14}C-ethyl iodide recovered and its oxidation to inactive benzoic acid indicated no rearrangement in the unreacted β-^{14}C-ethyl iodide.

Treatment of β-^{14}C-Ethylbenzene with Aluminum Chloride (Expt. 24-27, Tables II and III)

Two procedures were used. In expt. 24 and 26, a mixture of 1.70 g (22 mmoles) of anhydrous benzene, 1.33 g (10 mmoles) of sublimed, anhydrous aluminum chloride, and 50 ml of redistilled 1,2,4-trichlorobenzene was heated to 154 °C. Inactive ethyl iodide (3.64 g, 23 mmoles) and β-^{14}C-ethylbenzene (0.86 g,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

8 mmoles) were introduced and the reaction mixture heated for 2 or 24 h. The reaction was stopped by addition of ice water. After the introduction of 1.0 ml of inactive ethylbenzene as carrier, the resulting material was worked up as in the Friedel–Crafts reactions to give pure ethylbenzene.

In expt. 25 and 27, 1.33 g (10 mmoles) of sublimed, anhydrous aluminum chloride and 50 ml of 1,2,4-trichlorobenzene were heated to 154 °C and then 2.60 g (24 mmoles) of β-^{14}C-ethylbenzene was introduced. Heating was continued for 2 or 24 h. Ice water was added followed by 1.0 ml of inactive ethylbenzene as carrier. The resulting material was worked up the usual way to give pure ethylbenzene. In expt. 27, which involved 24 h of heating, both ethylbenzene and toluene were recovered in the final purification by v.p.c.

Radioactivity Determination

All activities were measured by a liquid scintillation counter. Active ethyl iodide, ethylbenzene, toluene, and benzoic acid were counted in toluene solution containing PPO and POPOP. Sample concentrations were about 15 mg/20 ml. Ethyl iodide showed appreciable quenching and correction factors were determined by use of a known amount of ^{14}C-toluene as internal standard.

STUDIES ON THE THERMODYNAMICS AND CONDUCTANCES OF MOLTEN SALTS AND THEIR MIXTURES

PART III. DENSITIES, MOLAR VOLUMES, VISCOSITIES, AND SURFACE TENSIONS OF MOLTEN LITHIUM CHLORATE, WITH SMALL ADDITIONS OF WATER, AND OTHER SUBSTANCES

A. N. Campbell and D. F. Williams
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received March 10, 1964

ABSTRACT

The density (2.088 g cc^{-1}) at 131.8 °C and viscosity (0.35 P at 131.8 °C) and their temperature dependence, of molten lithium chlorate, have been determined. Similar results have been obtained for lithium chlorate melts containing small quantities of water. The surface tension and its temperature dependence have been determined for lithium chlorate and for several lithium chlorate – water and lithium chlorate – lithium nitrate mixtures. From these measurements the surface heat has been calculated.

The results for pure lithium chlorate indicate that the melt is complex, this complexity probably caused by association of some kind. This is especially evident just above the melting point, since there the temperature change in properties is greatest.

Addition of water to the lithium chlorate melt causes the melt properties, especially the viscosity, to alter considerably. These changes are in part caused by a breakdown of the structural entities in the melt.

In this paper we report our experimental data on the density, viscosity, and surface tension of lithium chlorate (a single-salt melt). As well we report some results for mixtures in which a second component (water or lithium nitrate) was added to lithium chlorate, to assess the sensitivity of these physical properties to the addition of polar molecular species, as well as inorganic salts, as foreign species. It is allowable to discuss these effects in terms of structure, although such a discussion cannot be considered as proving any hypothetical structure.

EXPERIMENTAL

The theoretical implications and the experimental methods used in determining density and viscosity have been described in Parts I and II of this series (1, 2). It should be mentioned, however, that since water was added in these experiments, it was essential that the lithium chlorate be originally completely anhydrous. Accordingly, the residual water, if any, in our preparation was determined by gas chromatography. A precision Chromofrac VP-7 unit was calibrated for water detection by injection of samples of 0.01 ml ethyl alcohol containing known amounts of water. The lower limit of detection was found to be 1 part water in 500 parts alcohol by volume. The dried, powdered lithium chlorate was weighed, mixed with dry sand, and heated strongly. Under the catalytic action of the sand, the lithium chlorate decomposed rapidly, evolving oxygen together with any moisture it contained. The gases were trapped in a liquid nitrogen trap. A test of the residue showed that decomposition was complete. The trapped gases were allowed to warm up slowly to 0 °C and a measured quantity of ethyl alcohol then added. This solution was allowed to warm up to room temperature and a portion passed through the chromatograph. The result showed that the lithium chlorate contained less than 0.006% water by weight. The specific conductivity at 131.8 °C of a sample of this lithium chlorate was found to be $0.1150 \pm 0.0002\ \Omega^{-1}$ and, for all subsequent preparations, this conductance was used as the criterion of the absence of moisture in the specimen. The conductivity water used had a specific conductance of $1.5 \times 10^{-7}\ \Omega^{-1}$.

The method of capillary rise was used for the determination of surface tension. The apparatus is shown in Fig. 1. The inner tube was a precision-bore capillary tube, internal diameter 0.5 ± 0.001 mm. An extension 5 cm wide at the foot of the outer tube made possible a satisfactory reading of the level of the lower meniscus, always a matter of uncertainty in the capillary rise method. The capillary rise was measured by means of a micro-cathetometer, which could be read to 0.01 mm.

The cell was loaded in a dry box with a weighed amount of lithium chlorate, sufficient in amount to cover, when molten, the maximum area of the bottom extension. Weighed amounts of additional substances were

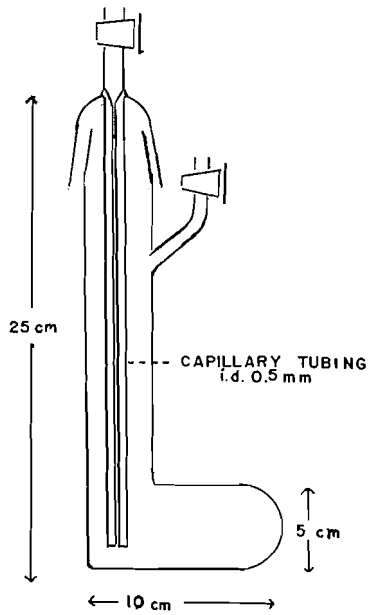

FIG. 1. Surface tension apparatus.

added when necessary. After transference of the apparatus to the thermostat and attainment of temperature equilibrium, the liquid was caused to rise and fall in the capillary by suitably altering the external pressure through the vacuum cocks. After each rise and fall, the capillary rise was measured. To test the apparatus, the surface tension of conductance water was determined in it, at 25 °C, and found to be reproducible to ± 0.5 dyn cm^{-1}.

RESULTS

Density and Molar Volume

The density of pure molten lithium chlorate was determined at temperatures ranging between ca. 130° to 150°, as well as those of mixtures containing 0.046, 0.130, and 0.223 mole fraction water. There is a maximum possible error of 8.0×10^{-4} g cc^{-1} in these measurements. The results are shown in Table I.

The density in each case was found to be linear with respect to temperature, the coefficient of expansion decreasing with increasing water content. The molar volumes, together with the coefficients of expansion, calculated from the relation $V_t = V_0(1 + \alpha t)$ are shown in Table II.

Equations of forms which have been shown experimentally to represent the density–temperature relationship for fused salts have been calculated by a least squares fit of the experimental results of Table I, using a computer. These equations are given in Table III.

Viscosity

The viscosities of pure molten lithium chlorate, and of mixtures containing 0.079, 0.197, and 0.251 mole fraction water, were determined at temperatures between 130° and 180°. The results are given in Table IV.

Both for pure lithium chlorate and the three mixtures with water, a linear relation exists between $\log \eta$ and $1/T$. The activation energies of viscous flow were obtained from these graphs, as $\Delta E_{vis} = 4.576 \times$ slope. The values of the constants are given in Table V. The Arrhenius equations used to represent the viscosity–temperature relations were determined by least squares fit, and they are also included in Table V.

Surface Tension

The surface tensions of pure molten lithium chlorate and of mixtures of lithium chlorate with water and with lithium nitrate are given in Table VI. The surface heat of lithium chlorate at different temperatures, calculated from the equation $H^s = \gamma - T(d\gamma/dT)$ (14, 15) was constant at 118 erg/cm^2 in the region 130 to 170 °C. The analytical representations of the temperature dependence of the surface tension of pure lithium chlorate and of the mixtures were obtained from a least squares fit of the results of Table VI. The constants of the equation are shown in Table VII.

Analytical representation of the surface tension variation with temperature for lithium chlorate, lithium chlorate – water, and lithium chlorate – lithium nitrate mixtures

Additive	Mole fraction additive	Eq. of general type $\gamma = a - bt$	
		a	b
Pure salt	0.000	96.7	6.3×10^{-2}
Water	0.038	96.2	7.7×10^{-2}
Water	0.090	103.2	13.3×10^{-2}
Water	0.155	101.6	13.0×10^{-2}
Water	0.236	101.7	13.6×10^{-2}
Lithium nitrate	0.032	94.9	4.6×10^{-2}
Lithium nitrate	0.075	97.4	5.6×10^{-2}
Lithium nitrate	0.172	97.7	4.4×10^{-2}
Lithium nitrate	0.213	100.5	6.0×10^{-2}

The surface tension of an equimolar mixture of lithium chlorate and water was determined at 132.4 °C and found to be 78.4 dyn cm^{-1}, using a density calculated from the mixture rule and the densities of the pure components at the temperature of determination. The surface tension of this mixture can be calculated from an ideal surface tension relationship proposed by Guggenheim (3).

$$\gamma = \tilde{\gamma} - \frac{kT}{a} \log \cosh \frac{\Delta \delta a}{2kT}$$

where $\tilde{\gamma} = \frac{1}{2}(\gamma_A + \gamma_B)$, $\Delta = \gamma_A - \gamma_B$ and a = area per molecule. Using this relation, the ideal surface tension of the mixture is found to be 69.8 dyn cm^{-1}.* It is obvious that the above relation gives the surface tension of the mixture as being equal to the arithmetic mean surface tension of the two liquids, minus a correction factor. This correction factor will not be very large, unless (*a*) the difference between the surface tensions of the two liquids is very great, (*b*) the temperature is very low on the Kelvin scale, or (*c*) there is a great difference between the surface areas per molecule. In the present case, (*a*) is not large and (*b*) not small, so that the value of the factor is determined by δa, the difference between the surface areas per molecule. This difference is obtained as follows: If we take the densities, at 132.4 °C, of lithium chlorate and of water as 2.0863 and 0.9331, respectively, the molar volumes are 43.33 ml and 19.31 ml, respectively. If these volumes are corrected for the free space in closest packing, they result as 32.06 and 14.29, respectively, but it makes very little difference to the end result whether this is done or not. When we divide by the Avogadro number, the molecular volumes are 5.317×10^{-23} and 2.370×10^{-23} cm^3, respectively. If we assume the molecules to be spherical, the radii are 2.330×10^{-8} and 1.785×10^{-8} cm, respectively. The hemispherical surfaces of such molecules are 3.412×10^{-15} and 2.002×10^{-15} cm^2, respectively. Hence $\delta a = 1.410 \times 10^{-15}$ cm^2. The surface tension of lithium chlorate at 132.4 °C is 87.41 dyn/cm and that of water, by a slight extrapolation from the figure for 130 °C, is 52.36 dyn/cm. Hence $\Delta = 35.05$. With the insertion of these values, together with the value of the Boltzmann constant, the value of the correction factor is 0.11. If the correction in molar volume for the free volume is not made, the correction factor is 0.15. Hence the calculated value of the surface tension of an equimolecular mixture is found to be 69.8, while the experimental value is 78.4.

**For an ideal liquid pair, this relation simplifies to* $\gamma = \tilde{\gamma} - \Delta\,(\delta a/8kT)$.

DISCUSSION OF RESULTS

The density of lithium chlorate at 131.8 °C, 2.0880 g cc^{-1}, agrees with the earlier result of Campbell, Kartzmark, and Patterson (4). The value of Klotschko and Grigorjew (5), (1.998 at 128°) is low, probably because of the presence of water in this highly hygroscopic salt. The relation between the density and temperature of molten lithium chlorate can be expressed by either of the following equations

$$\rho = 2.463 \exp(-4.12 \times 10^{-4})T \quad \text{or} \quad \rho = 2.188 - 7.672 \times 10^{-4}t.$$

The general trend of increasing density in the series, chloride–nitrate–chlorate, which is observed with sodium and potassium salts, applies also to the comparable lithium salts. The density of lithium chlorate – water mixtures decreases with increasing water content. The density–temperature variation of these mixtures is represented by equations of the same form as those applicable to pure lithium chlorate. The deviation from the ideal linear relation between molar volume and mole fraction (6, 7, 8) is negligible for the mixtures studied (Fig. 2). Since large deviations have been found for systems in which complex

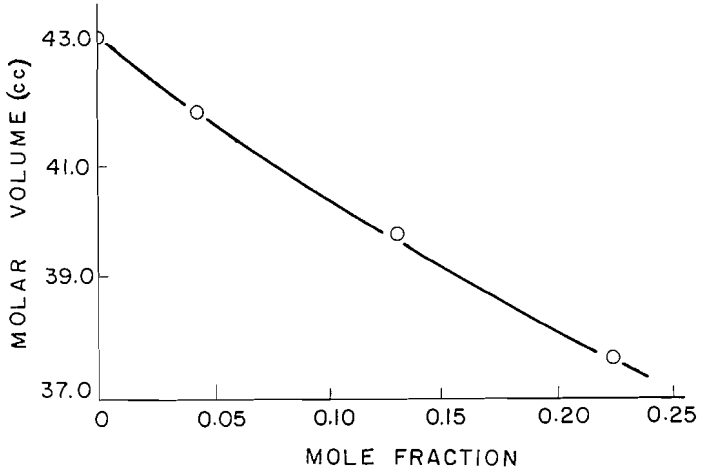

FIG. 2. Molar volume at 130 °C vs. mole fraction water.

formation occurs (9, 10, 11), it appears that there is little immediate association between the water and the lithium chlorate. The decrease in the coefficient of expansion α with increase in water content may be due in part to an increase in the overall ionic character of the melt. A graph of the coefficient of expansion against mole fraction of water (Fig. 3) shows this effect graphically. The viscosity of pure molten lithium chlorate can be represented in its temperature variation by

$$\eta = 1.979 \times 10^{-5} \exp(7813/RT).$$

The value of the viscosity at 131.8 °C, viz. 33.0 cP, is slightly larger than that obtained by Campbell, Kartzmark, and Patterson (4), perhaps because of the improved technique we are now using. On the other hand, Klotschko and Grigorjew (5) report a value of 52.5 cP, almost twice the value obtained by us. There is little doubt that the value of Klotschko and Grigorjew is inaccurate. We suggest as the most probable cause of this discrepancy

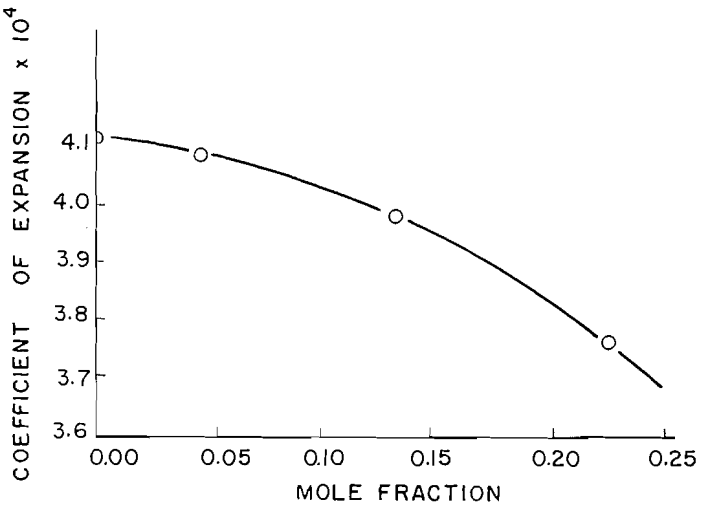

FIG. 3. Coefficient of expansion vs. mole fraction water.

the fact that the Russian workers took no precautions to exclude from their viscometer any decomposition products, formed in the sealing of the apparatus. We have obviated this difficulty by including in the viscometer itself a sintered glass disc, so that the fluid can be filtered as often as desired after sealing (2). If this is not done, the flow times are most erratic, because the capillary of the instrument is more or less choked with insoluble decomposition products.

The viscosity of molten lithium chlorate is much larger than that of simple ionic salts at corresponding temperatures (i.e. taking the melting point of the salt, on the Kelvin scale, as the basis of comparison): e.g. the viscosity of silver nitrate is 2.3 cP at 450 °C against 15 cP for lithium chlorate at 168 °C. Zinc chloride exhibits the very high viscosity of 350 cP at 400 °C, but this is interpreted on the basis of a model in which fragments of the original double layers of crystalline $ZnCl_2$, together with $ZnCl_6^{-4}$ ions, are the predominant species. A marked decrease with temperature of the activation energy for viscous flow is observed for such viscous melts but this is not observed for lithium chlorate, the activation energy being almost constant at 7.8 kcal $mole^{-1}$ between 130 and 170 °C. This is within the range of activation energy of viscous flow for most ionic melts, viz. 3–10 kcal $mole^{-1}$.

Yaffe and van Artsdalen (8) consider that the heat of activation for viscous flow is dependent on two opposing factors. As a melt expands with rising temperature, the total coulombic forces among the constituent ions tend to decrease and hence the activation energy for mass migration also decreases. Opposing this effect and because of the increase in the number of holes in the melt, the average number of nearest neighbors to a given ion may decrease, and hence increase the attractive force per nearest neighbor, with consequent increasing activation energy. In melts in which there is a large disparity in ionic size, such as lithium chlorate, the latter effect should predominate. In fact, however, little change is observed in the activation energy of lithium chlorate: this may be due to the association in the melt breaking down as the temperature rises. If this is so, fewer bonds will be broken in mass transfer at higher temperatures, and this may compensate for the increase in ion-neighbor attractive forces caused by a decrease in coordination number.

The addition of water to a lithium chlorate melt causes a considerable decrease in the viscosity of the melt. At temperatures slightly above the melting point, the decrease following the initial addition of water is greater than that caused by subsequent additions: at higher temperatures this large difference is not so marked.

Over the temperature range investigated, the viscosity isotherm for each mixture shows a negative deviation from linear dependence on molar composition. Harrap and Heymann (12) have found that this negative deviation is exhibited by all molten salts, regardless of type.

The viscosity–temperature relationship for lithium chlorate – water mixtures is represented by the Arrhenius equations of Table V. The activation energy of viscous flow becomes considerably smaller as the water content increases. The decrease of activation energy is not a linear function of the mole fraction of water. The initial rate of change decreases as water content increases and this indicates that the average size of the mass unit of viscous flow becomes smaller as water is added.

At temperatures slightly above the melting point, and at which, therefore, associated groups may be present in the melt, the effect of water addition on viscosity is pronounced, probably because of the immediate break-up of these groups. At higher temperatures, where associated groups do not exist or exist only to a lesser extent, water additions lower the viscosity to a lesser extent. The changes of activation energy may be interpreted in the same way.

The surface tension of lithium chlorate is typical of group I salts of polyatomic anions. If association occurs within a melt, the associated groups will probably affect the surface energy of the melt considerably, and, if these "associates" lower the surface energy, they will be preferentially adsorbed at the surface. The surface tensions of all group I nitrates are observed to be about the same. The surface tension of lithium chlorate at its melting point, 88.6 dyn cm^{-1}, is much the same as that of potassium chlorate at its melting point, 81.0 dyn cm^{-1} (13). If it is true that the anion determines the surface energy of the group I chlorates, as the nitrate ion does that of the group I nitrates, then it is possible that in these melts the anions pack in contact, with the cations in crevices where their effect on surface tension is slight.

The surface heat, $H^s = \gamma - T(d\gamma/dT)$ is not temperature dependent: it is thought to provide a measure of the covalent character of the melt (14). For nonpolar liquids the surface heat varies between 40 and 65 erg cm^{-2}. Salts which are essentially ionic have the highest values, e.g. sodium chloride 216.7, whereas molten salts which consist largely of covalent molecules have lower values, approaching those of non-polar liquids, e.g. magnesium chloride 76.7. The surface heat of lithium chlorate is 118 erg cm^{-2}, intermediate between the values for ionic melts and those of covalent melts, and indicates that at least some covalent character exists in the lithium chlorate melt.

The temperature coefficient of molecular surface energy is found to be 0.468. Although the calculation has little meaning, since lithium chlorate decomposes at temperatures not much above the melting point, we have used this coefficient to find a hypothetical critical temperature (L $\rightleftarrows$ V) for lithium chlorate, assuming, of course, that the so-called "Law" of Eotvos is applicable, viz. that molecular surface energy is a straight line function of temperature up to the critical temperature. The figure obtained is 2430 °C.

The surface tension of pure lithium chlorate and also those of the mixtures with water and with lithium nitrate decrease linearly with temperature. At any fixed temperature, the lithium chlorate – lithium nitrate mixtures have surface tensions greater than that of pure lithium chlorate, while the mixtures with water have surface tensions lower than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

that of lithium chlorate. This, however, is an almost necessary consequence of the fact that the surface tension of water at, say, 130 °C is lower than that of lithium chlorate while that of lithium nitrate (extrapolated for the supercooled state) is higher (126.0 dyn).

The relation between the isothermal surface tension and mole fraction of either lithium nitrate or water is not linear. Initial additions up to 0.05 mole fraction affect the surface tension of the melt to a greater extent than subsequent additions, both for lithium nitrate and water.

The temperature coefficient of surface tension changes considerably as the water content of the mixture increases. The temperature coefficient of water is much higher than that of molten salts and this accounts for the increase of the temperature coefficient of surface tension when water is added to molten lithium chlorate. On the other hand, the temperature coefficient of lithium nitrate is almost the same as that of lithium chlorate and this accounts for the observed fact that the addition of lithium nitrate hardly affects the temperature coefficient of lithium chlorate.

The surface tension of an ideal equimolecular mixture of lithium chlorate and water (calculated by Guggenheim's relation (3) 69.8 dyn cm^{-1}) is quite different from the experimental value (78.4). Hence the melt is not ideal with respect to surface tension behavior, at higher concentrations of water.

THE ELECTROLYSIS OF ω-BROMOCARBOXYLIC ACIDS

II. PREPARATION OF LONG-CHAIN ω-BROMOCARBOXYLIC ESTERS BY MIXED COUPLING REACTIONS[1]

R. G. Woolford, W. Arbic, and Ann Rosser
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received January 20, 1964

ABSTRACT

An attempt to synthesize long-chain ω-bromocarboxylic esters from the mixed electrolyses of ω-bromocarboxylic acids and half-esters is described. Methyl 15-bromopentadecanoate was successfully prepared in this way in 37% yield, but other reactions producing methyl 16-bromohexadecanoate (by two different routes) and methyl 14-bromotetradecanoate gave low yields (6–18%) and difficulties in purification of products. The product analysis of these electrolyses (symmetrical and unsymmetrical coupling products, methyl esters of starting materials) is given. It is concluded that this method is more likely to be of specific rather than general use.

The use of halogenated carboxylic acids for Kolbe electrolysis reactions has received little study (1). Most of the successful reactions have involved ω-chloro- and ω-bromocarboxylic acids (2–4). Under appropriate conditions the ω-chloro- and ω-bromo-acids with chains of six or more carbon atoms couple normally to produce ω,ω′-dihalides in good (usually 60–70%) yield. The preparation of 1,28-dibromooctacosane by electrolysis of 15-bromopentadecanoic acid is an example (see Experimental section). This dibromide has not been made previously by the Kolbe reaction.

The number of reported mixed electrolyses involving halogenated acids to produce long-chain esters and halides is small. Pattison *et al.* (3) produced 13-fluorotridecyl chloride in 24% yield from the electrolysis of 10-fluorodecanoic acid and 5-chlorovaleric acid. A series of esters have been produced by mixed coupling reactions of ω-fluoroacids (3, 5, 6). However, fluorine is not a typical halogen. The only mixed electrolysis of an ω-bromoacid is the preparation of 1-bromo-2,4-dimethyldocosane from 3,5-dimethyl-6-bromohexanoic acid and stearic acid but no experimental details are given (7).

ω-Bromo-acids and esters are useful as intermediates in multi-step syntheses (e.g. the bromodocosane just mentioned), but their preparation often involves long, tedious routes and low overall yields. Thus a study of the mixed electrolysis of some ω-bromoacids and half-esters seemed appropriate as a possible method offering a one-step route to the longer chain ω-bromoesters. A promising initial reaction seemed to be a mixed electrolysis of 11-bromoundecanoic acid (I; $n = 10$) and methyl hydrogen adipate (II; $m = 4$), both of which are commercially available as fairly inexpensive compounds.

$$\underset{\text{I}}{Br(CH_2)_nCOOH} + \underset{\text{II}}{HOOC(CH_2)_mCOOCH_3} \xrightarrow[\text{d-c. current}]{CH_3OH\ \text{solvent}}$$

$$\underset{\text{III}}{Br(CH_2)_{n+m}COOCH_3} + \underset{\text{IV}}{Br(CH_2)_{2n}Br} + \underset{\text{V}}{CH_3OOC(CH_2)_{2m}COOCH_3}$$

$$+ \underset{\text{VI}}{Br(CH_2)_nCOOCH_3} + \underset{\text{VII}}{CH_3OOC(CH_2)_mCOOCH_3}$$

This reaction produced the primary reaction products III ($n + m = 14$), IV ($n = 10$), and V ($m = 4$) and, in addition, the products VI ($n = 10$) and VII ($m = 4$), methyl

[1]*For Part I, see reference 4.*

esters of the starting materials, resulted from attack of the carboxylate radicals on the solvent. Control reactions showed a negligible tendency to form esters under the reaction conditions if no current were passed. The desired long-chain ω-bromoester, methyl 15-bromopentadecanoate (III; $n + m = 14$) was easily separated from the other products by distillation. The yield of 37% (Table I) is good, considering the number of products possible and bearing in mind that there are few recorded examples in which mixed coupling products are produced in significantly better yields. Moreover, the reaction represents a simpler and more effective means of obtaining this bromoester than hitherto reported (8).

It was previously shown (4) that experimental conditions have to be carefully controlled in reactions of long-chain ω-bromoacids to avoid the almost complete esterification of starting material. Further work indicates that the most critical factor is the temperature of reaction. At temperatures above ca. 54° the yield of coupled product is lowered considerably. Other factors normally considered critical, such as current density, concentration, and solvent, do not affect this yield nearly so much. Therefore, in the present experiments, the temperature was kept between 45 and 54°, while maintaining as high a current density as possible.

The success of this mixed coupling reaction led to its extension to other ω-bromoacids and half-esters. A number of possible combinations were ruled out because of anticipated difficulties in separating products, especially the long-chain bromoester, by distillation. Three reactions were tried: 8-bromooctanoic acid (I; $n = 7$) and methyl hydrogen sebacate (II; $m = 8$) to give methyl 16-bromohexadecanoate (III; $n + m = 15$); 6-bromohexanoic acid (I; $n = 5$) and methyl hydrogen sebacate (II; $m = 8$) to give methyl 14-bromotetradecanoate (III; $n + m = 13$); and 12-bromododecanoic acid (I; $n = 11$) and methyl hydrogen adipate (II; $m = 4$) to give also methyl 16-bromohexadecanoate. In these cases the products IV and V were usually obtained in greater yield, and separation of the products was much more difficult than in the previous reaction producing methyl 15-bromopentadecanoate. A summary of product yields is given in Table I.

TABLE I

Mixed coupling reactions of ω-bromocarboxylic acids

Reagents		Product yield (%)				
I	II	III	IV	V	VI	VII
$n = 10$	$m = 4$	37	39	39	11	5
$n = 11$	$m = 4$	6	21	51	34	1
$n = 5$	$m = 8$	18	23	1	51	50
$n = 7$	$m = 8$	7	24	6	32	30

It must be concluded that, while specific reactions of ω-bromoacids and half-esters may produce a successful mixed coupling, e.g. the preparation of methyl 15-bromopentadecanoate (and thus 15-bromopentadecanoic acid), the method is not likely to be a good general one for the preparation of pure long-chain ω-bromoesters in reasonable yield.

EXPERIMENTAL

General

Melting points, which were corrected, were recorded on a Leitz hot-stage microscope. Boiling points were uncorrected. Analyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside, New York.

A previous article (4) describes the commercial sources or the preparations of ω-bromoacids, methyl hydrogen adipate, and authentic reference samples used in the present work. The electrolytic cell was also fully described, as well as the general method of working up the reaction products into neutral and acidic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

fractions. Methyl hydrogen sebacate was prepared by half-esterification of sebacic acid. Following standard procedure in mixed electrolyses, the half-ester was usually in 1–2 molar excess, so as to improve chances for optimum yield of mixed coupling product. Percentage yields for the mixed electrolyses are recorded in Table I and are based on moles of bromoacid or half-ester reacting (in each case, on whichever was the limiting reagent).

Gas chromatographs used were a Beckman GC-2A and an F and M model 720 with TC3 fraction collector; columns were 6–8 ft Carbowax 20, diethylene glycol succinate, and silicone rubber on Chromosorb-W or its equivalent. Infrared spectra were obtained with a Beckman model IR-5.

Mixed Electrolysis of 11-Bromoundecanoic Acid and Methyl Hydrogen Adipate

11-Bromoundecanoic acid (50 g, 0.19 mole), methyl hydrogen adipate (100 g, 0.63 mole), and sodium (0.9 g, 0.04 g-atom) were dissolved in 95% methanol (130 ml). A current of 1.5–1.7 A was passed for 42 hours (3 × theoretical) at a temperature of 45–50°. A negligible amount of unreacted acid was isolated.

Distillation of the neutral fraction through a short Vigreux column yielded the following fractions: (i) b.p. 80–100° (0.6 mm), 13.8 g; (ii) b.p. 108–111° (0.6 mm), n_D^{25} 1.4346, 28.0 g; (iii) 125–130° (0.6 mm), n_D^{25} 1.4630, 6.0 g; (iv) 130–168° (0.6 mm), 29.5 g; and an undistilled residue of 15.8 g.

Fraction (i) was shown, by gas chromatography, to contain dimethyl adipate, 5.7 g. Fractions (ii) and (iii) were shown by gas chromatography and infrared spectrum analysis to be dimethyl sebacate and methyl 11-bromoundecanoate respectively; Trent *et al.* (9) give b.p. 175° (20 mm), n_D^{25} 1.4342 for dimethyl sebacate, and methyl 11-bromoundecanoate has b.p. 112–116° (0.3 mm), n_D^{25} 1.4630 (4). Fraction (iv) was methyl 15-bromopentadecanoate and was redistilled to yield a white solid, 23.4 g, of b.p. 142–147° (0.25 mm), m.p. 36.5–38.5°. Recrystallization from methanol yielded a solid with m.p. 38.5–39.5°. Anal. Calc. for $C_{16}H_{31}BrO_2$: C, 57.32; H, 9.32; Br, 23.84. Found: C, 57.41; H, 9.32; Br, 23.60. The infrared spectrum was consistent with the structure assumed. The original residue from distillation plus a 3.1 g residue from redistillation of fraction (iv) was recrystallized from methanol to yield 1,20-dibromoeicosane (16.3 g) of m.p. 66.5–68°; Korsching (2) reports m.p. 67.4–68°. A mixed melting point with an authentic sample showed no depression.

Mixed Electrolysis of 12-Bromododecanoic Acid and Methyl Hydrogen Adipate

12-Bromododecanoic acid (23.6 g, 0.085 mole), methyl hydrogen adipate (40.6 g, 0.25 mole), and sodium (0.040 g., 0.017 g-atom) were dissolved in methanol (100 ml) and electrolyzed at 2.0 A for 21 hours (4 × theoretical) at 50–54°. The neutral extract was 46.9 g, and unreacted acids were 5.7 g (1.8 g bromoacid and 6.3 g half-ester, by gas chromatography).

Distillation of the neutral extract and redistillation of each fraction gave the following: (i) b.p. 110–113° (13 mm), n_D^{25} 1.4264, 1.1 g; (ii) b.p. 108–110° (0.6 mm), n_D^{25} 1.4346, 14.1 g; (iii) b.p. 130–135° (0.6 mm), n_D^{25} 1.4625, 7.5 g; (iv) b.p. 152–157° (0.6 mm), m.p. 24–26°, 1.5 g; (v) undistilled residue, 5.4 g.

Gas chromatography and infrared spectrum analysis showed fraction (i) to be dimethyl adipate, fraction (ii) to be dimethyl sebacate, and fraction (iii) to be methyl 12-bromododecanoate; Hunsdiecker and Hunsdiecker (8) give b.p. 130° (0.5 mm). Fraction (iv) was methyl 16-bromohexadecanoate. Seven recrystallizations from methanol gave a white solid of m.p. 28–29° which could not be raised further; Hunsdiecker and Hunsdiecker (8) give m.p. 31°. For fraction (iv) Anal. Calc. for $C_{17}H_{33}BrO_2$: C, 58.46; H, 9.52; Br, 22.88. Found: C, 58.31; H, 9.43; Br, 22.90. Fraction (v) was recrystallized from petroleum ether (30–60°) and methanol to give a white solid (3.6 g) of m.p. 69–70°, undepressed on admixture with authentic 1,22-dibromodocosane.

Mixed Electrolysis of 8-Bromooctanoic Acid and Methyl Hydrogen Sebacate

8-Bromooctanoic acid (40.0 g, 0.18 mole), methyl hydrogen sebacate (78.0 g, 0.36 mole), and sodium (0.21 g, 0.009 g-atom) were dissolved in methanol (150 ml) and electrolyzed at 1.0–1.5 A for 40 hours (3 × theoretical) at 40–50°. At the end of this time the reaction mixture was thick with a solid white precipitate and the temperature could no longer be held below 50°. Gas chromatography showed the recovered acids to be 13.0 g 8-bromooctanoic acid and 25.0 g methyl hydrogen sebacate.

The neutral extract of 44.2 g was distilled and the main fractions redistilled. The following fractions were collected: (i) b.p. 88–90° (0.7 mm), n_D^{25} 1.4605, 8.7 g; (ii) 105–110° (0.6 mm), n_D^{25} 1.4348, 16.7 g; (iii) b.p. 155–160° (0.4 mm), m.p. 24–26°, 2.8 g; (iv) b.p. 165–172° (0.2 mm), m.p. 45–47°, 5.2 g; (v) residue in distilling flask, 2.3 g.

Fraction (i) was shown by gas chromatography and infrared spectrum analysis to be methyl 8-bromooctanoate; Cavanna and Ställberg-Stenhagen (10) give b.p. 91° (0.8 mm). Fraction (ii), identified in the same way, was dimethyl sebacate. Recrystallization of fraction (iii) from methanol gave a white solid of m.p. 28–29°, undepressed on admixture with authentic methyl 16-bromohexadecanoate. Recrystallization of fraction (iv) from petroleum ether (30–60°) gave a solid of m.p. 47.5–48.0°, undepressed on mixing with authentic 1,14-dibromotetradecane. The residue, fraction (v), on recrystallization from low-boiling petroleum ether gave a white solid of m.p. 59–60°, undepressed on admixture with authentic dimethyl 1,16-hexadecanedicarboxylate.

For personal use only.

Mixed Electrolysis of 6-Bromohexanoic Acid and Methyl Hydrogen Sebacate

6-Bromohexanoic acid (25.0 g, 0.13 mole), methyl hydrogen sebacate (83.0 g, 0.39 mole), and sodium (0.6 g, 0.025 g-atom) were dissolved in 150 ml of 1:1 methanol–water. Electrolysis was carried out at 1.5–3.5 A for 28 hours (3 × theoretical) at 45–54°. Products were a neutral extract of 65.5 g and unreacted acids 6-bromohexanoic acid, 1.8 g, and methyl hydrogen sebacate, 6.3 g.

The neutral extract was fractionated and the fractions redistilled to yield: (i) b.p. 66–69° (0.3 mm), n_D^{25} 1.4625, 12.9 g; (ii) 95–102° (0.3 mm), 43.4 g; (iii) 145–150° (0.6 mm), 6.9 g; (iv) undistilled residue, 0.7 g.

Fraction (i) was shown by gas chromatography and infrared spectrum analysis to be methyl 6-bromohexanoate; Skinner, Johnston, and Fisher (11) give b.p. 72° (1 mm), n_D^{22} 1.4635. Fraction (ii) was shown by gas chromatography to be a mixture of 1,10-dibromodecane (4.1 g) and dimethyl sebacate (39.3 g). Fraction (ii) could not be separated further by distillation, but fractionation by gas chromatography yielded small samples of the two compounds; these had the expected infrared spectrum and the correct physical constants: n_D^{25} 1.4265 for dimethyl sebacate, and n_D^{28} 1.4914, m.p. 25–26° for 1,10-dibromodecane (melting point undepressed on admixture with an authentic sample). Fraction (iii) was identified by gas chromatography and infrared spectrum analysis to be methyl 14-bromotetradecanoate; Hunsdiecker and Hunsdiecker (8) give b.p. 164° (0.8 mm), m.p. 22°. Careful recrystallization from methanol gave m.p. 23–23.5°. Fraction (iv), on recrystallization from petroleum ether (30–60°), gave 0.6 g of a white solid of m.p. 59–60°, undepressed on admixture with authentic dimethyl 1,16-hexadecanedicarboxylate.

15-Bromopentadecanoic Acid

Methyl 15-bromopentadecanoate (6.0 g, 0.016 mole) was dissolved in 150 ml of 4 *N* hydrogen bromide in glacial acetic acid and heated under reflux for 24 hours. 5.3 g (95%) of 15-bromopentadecanoic acid of m.p. 65–66° (from low-boiling petroleum ether) was isolated; Hunsdiecker and Hunsdiecker (8) report m.p. 66°. Because of the low solubility of this ester in aqueous systems, attempts to use 48% hydrobromic acid in glacial acetic acid gave less than 0.5% hydrolysis in the same time period.

1,28-Dibromooctacosane

15-Bromopentadecanoic acid (2.00 g, 0.0006 mole) in methanol (50 ml) was electrolyzed at 0.8 A for 10 hours at 45–50°. There was 0.24 g of unreacted acid. The neutral fraction was recrystallized from methanol to yield 0.70 g (51%) of 1,28-dibromooctacosane of m.p. 78–79°. Anal. Calc. for $C_{28}H_{56}Br_2$: C, 60.84; H, 10.23; Br, 28.93. Found: C, 60.54; H, 10.21; Br, 28.62. Gas chromatography of the recrystallization residue indicated 0.38 g, 21%, of the ester methyl 15-bromopentadecanoate.

CHEMICAL REACTIONS IN ELECTRICAL DISCHARGES*

I. THE SPECTRUM OF THE METHANE–OXYGEN SYSTEM AT LOW PRESSURE IN THE POSITIVE COLUMN OF A D-C. GLOW DISCHARGE

PIERRE A. BOIS D'ENGHIEN† AND JACQUES M. DECKERS
Department of Chemistry, University of Toronto, Toronto, Ontario

Received March 13, 1964

ABSTRACT

A technique is described which permits the study of changes in the spectra emitted by fast flowing reacting gas mixtures in the plasma of the positive column of a weak d-c. glow discharge. In certain cases a quantitative relationship is shown to exist between the concentration of a species and the intensity of emission of its spectrum. In particular such a correlation exists between the emission intensity of CO and its concentration. Use of this fact is then made to follow the rate of formation of carbon monoxide in methane–oxygen mixtures flowing through a discharge. The mechanism of formation of the various emitters either by means of a chemical reaction or by electron impact on molecules or radicals is discussed. It is concluded that to account for the rate of formation of CO, at least in the early stages of the presence of the gases in the discharge, before the steady state concentrations of atoms, radicals, and molecules have been approached, most of the energy of the electrons is used in breaking chemical bonds. The electric field values needed to impart the necessary amount of energy to the electrons are of the same magnitude as those measured in this laboratory ($\sim$60 V cm^{-1}).

PART 1. INTRODUCTION

This paper describes a method by which it is possible to obtain quantitative information on the rates of reactions occurring in the positive column of a glow discharge. It is by now well established that in the positive column the number of positive and negative charges are approximately equal and form a partially ionized quasi-neutral plasma (1). The chemical reactions occurring under these conditions are indicative of the physical conditions prevailing in this plasma, supplementing or confirming knowledge gained from other types of investigations.

By means of discharges it is possible to induce reactions in a wide variety of gases or gas mixtures over a wide range of pressures and compositions. Because of the flow of electrons and ions and the presence of an electric field, the gas is maintained in a steady state of non-equilibrium. The degree of this non-equilibrium can be changed to a certain extent by varying the overall current through the discharge. By changing the physical parameters of the discharge one can assess the relative importance of changes due to reactive or inelastic collisions, transport phenomena, and relaxation processes. Compared with other non-equilibrium systems, such as flames, in which the enthalpy of the chemical reaction is the only source causing departure from equilibrium, the discharge in gases is clearly a more flexible and versatile method of investigation.

In this laboratory a program has been initiated designed to study the kinetics and mechanisms of reactions in discharges, and assess the influence of these reactions upon the physical parameters of the discharge. After a short description of the apparatus, the spectra emitted by methane, oxygen, and mixtures of these gases, while flowing through a d-c. glow discharge, will be described and discussed.

In this paper we shall restrict ourselves to the description of the influence of a number of parameters, both physical and chemical, upon the emission spectrum of the methane–oxygen system. Our purpose is to illustrate the type of problems which can be solved by

*Supported by grants from the U.S. Air Force Office of Scientific Research, the National Research Council of Canada, and the University of Toronto.

†Present address: Department of Chemistry, Université de Louvain, 96 Rue de Namur, Louvain, Belgium.

using this technique; we reserve detailed kinetic studies of a number of applications outlined in this paper for a later publication.

In particular, the influence of the current, the composition of the gas mixture, and the time spent by the gases in the discharge on the emitted spectrum is discussed. The emission intensity of carbon monoxide has been correlated with its absolute concentration. The overall rate of reaction can hence be measured. We have also been able to show that, during the first few milliseconds that the gases spend in the discharge, most of the energy gained by the electrons under the influence of the electric field is used in breaking chemical bonds. We also discuss the likelihood of a number of reaction mechanisms which could explain some of the observed changes in the spectrum.

Although ion–molecule reactions often are very fast we have assumed that they do not contribute appreciably to the observed overall changes in composition. Electron and ion concentrations, which are equal in the positive column, vary from 10^{10} to 10^{13} ions cm^{-3} (1). In view of the weak currents in the discharge ($<10^{-2}$ A) we can assume that the ion concentrations in our discharge were near the lower limit which makes the above assumption reasonable.

We have limited our observations to the positive column of the discharge because it is known that in this region the electrical field and the density of ions and electrons are the same at all points of the column. Hence the value of the electrical parameters remains constant while the gases proceed downstream through the discharge.

We have also assumed that self-absorption or blockaded radiation could not introduce any significant error in our measurement.

PART 2. EXPERIMENTAL

The gas, or gas mixture, metered by calibrated rotameters, enters a Pyrex observation tube, 80 cm long and 0.7 cm wide through the positive electrode (Fig. 1). The visible and near ultraviolet spectrum emitted

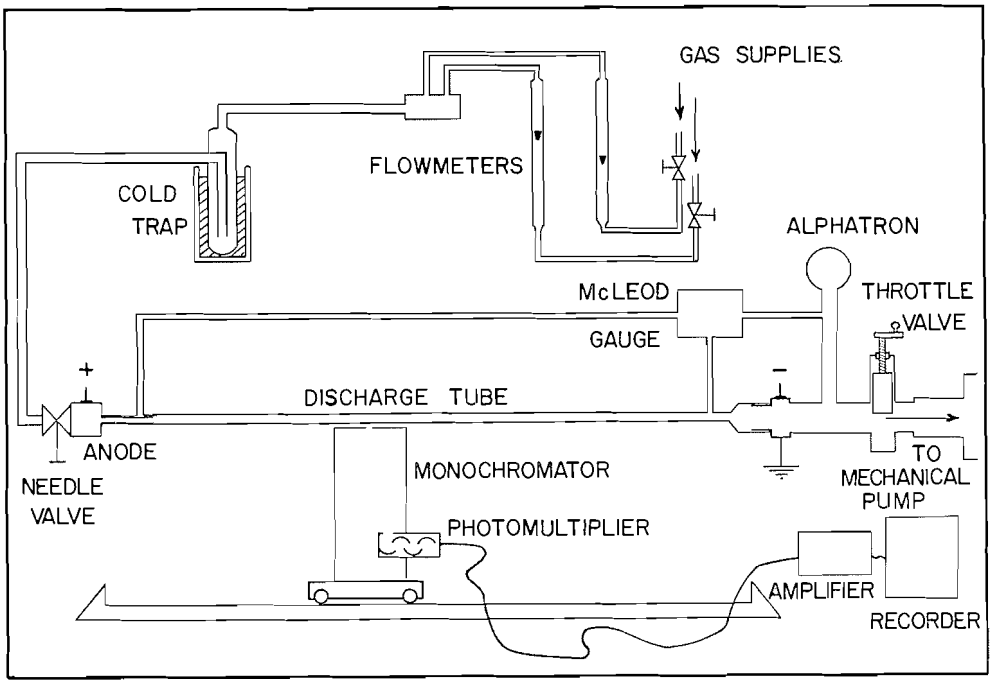

FIG. 1. Schematics of the apparatus.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

by the fast flowing ($\sim$50 m s^{-1}) gas mixture has been analyzed and its intensity measured for various emitters at various distances from the entrance point in the positive column of the discharge.

The gases (methane: Matheson C.P. grade; oxygen: British Oxygen of Canada Ltd.) were passed through dry-ice – acetone cooled traps and used without further purification. After they had passed through the discharge tube the gases were pumped out by means of an N.R.C. model S 30 rotary mechanical pump. Between the pump and the downstream end of the discharge tube a throttling valve allowed us to alter the velocity and the pressure in the discharge tube.

The d-c. glow discharge was sustained by means of an N.J.E. regulated power supply model S 328 (1000 to 10 000 V; 0 to 10×10^{-3} A). A chain of resistors in series with the discharge tube permitted us to adjust the resistance of the overall circuit and limit the current through the discharge tube. The spectrum was analyzed by means of a Jarrell–Ash model 82 000 grating monochromator. At the exit a 1P28 R.C.A. photomultiplier tube measured the light intensity. The monochromator was mounted vertically underneath the discharge tube with its slit parallel to the tube. It was placed on a small carriage rolling on two rails precisely parallel to the tube. This arrangement made it possible to record the spectrum at various positions in the discharge. The output of the photomultiplier tube was fed into a Keithley Model 414 micromicroammeter.

The pressure, both upstream and downstream of the discharge tube could be measured by means of a MacLeod gauge. An alphatron vacuum gauge, mounted downstream of the discharge tube, indicated any changes in pressure during a single run. The pressure gradient along the discharge tube was also measured by constructing a discharge tube similar to the one used for optical observations except for a number of side tubes at which the pressure could be taken.

PART 3. RESULTS

(a) General Remarks

The salient features of the emission spectrum consisted of the 4300 Å and 3900 Å bands of CH, the third positive, 5 B, Angstrom and Herzberg bands of CO, the 3064 Å band system of OH, the C_2 Swann bands, and the atomic lines of hydrogen and oxygen. Since nitrogen was always present as an impurity its second positive band system was always emitted as well. The presence and intensity of the various bands mentioned above were determined by the experimental conditions.

At no time did the intensity of the Swann bands of C_2 exceed the background scatter by more than a factor of three, so that we have not investigated in detail the emission due to this radical.

In addition to the features mentioned above we sometimes noticed a weak continuum in the blue region of the spectrum. A similar continuum appears much more strongly when hydrogen–oxygen mixtures flow through the discharge tube. In pure hydrogen a similar continuum has also been observed (1). It is possible that the origin of this continuum is, at least in part, of the same origin as the blue continuum observed in the emission from hydrogen–oxygen flames, which has been described by Padley (2) and ascribed by him to the radiative association of a hydrogen atom and an OH radical.

In the 3400–3100 Å region some further weak emission bands have been observed, which do not seem to belong to the OH band system. The wavelength of the maximum of emission intensity does correlate with a number of *absorption* maxima reported for ozone, which as far as we know have not yet been observed in emission. However, in view of the poor resolution of the monochromator under our working conditions (see next paragraph) we feel that further work is needed before a definite identification of these bands can be made.

Because of the weakness of the light source we had to use large slit widths on the monochromator which resulted in poor resolution. Hence, we have systematically measured the intensity of emission at the maximum peak height. At no time have we attempted to use integrated line or band intensities. It is probable that various experimental circumstances might affect the rotational populations and that a small error could enter into our measurements in this way. Furthermore, we have attempted to correct the intensities measured at different wavelengths for the variation in sensitivity of the photomultiplier

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tube with wavelength, because we are only interested in relative intensities at one wavelength.

We shall now review in turn the ways in which the time spent by the gases in the discharge tube (as determined by the distance from the entrance electrode), the current through the discharge, and the composition of the gas mixture influence the spectrum.

Unless otherwise indicated, the pressures reported are those at the entrance point of the gas in the discharge.

(b) Variation in the Intensity of Emission over the Length of the Positive Column of the Discharge

Since the gases enter the tube through the electrode and flow through the discharge at a known speed, the various positions downstream of the electrode correspond to the time spent by the gases in the discharge. Hence, the intensity of emission of various bands has been measured at various distances S from the point at which the gases enter the discharge for a wide range of composition of methane–oxygen mixtures. The spectra of the two pure gases have also been investigated as well as those of mixtures containing small known amounts of carbon monoxide.

In pure oxygen the intensity of the atomic oxygen lines shows a linear increase along the length of the positive column as seen in Fig. 2 where the intensity of the 4368.3 Å oxygen line has been plotted as a function of S for three different values of the discharge current. The variation of intensity of the CH emission in pure methane is quite different; as seen in Fig. 3 the intensity is very intense even for small values of S and increases only slightly for larger values. In Fig. 3 the emission intensity of the H_β line and of the 3371.3 Å band of the nitrogen impurity (second positive band system) is also plotted against S.

The behavior of a methane–oxygen mixture is illustrated in Fig. 4. The emission from CO increases in smooth, almost linear, fashion, while the emission of CH and H_β is similar to that in methane alone. The emission of OH increases sharply (but not as fast as the CH emission) at low values of S and more slowly afterwards. For other compositions of methane and oxygen, the behavior is similar. The nearly linear increase of the CO emission has been verified for the Angstrom, the Herzberg, and the triplet bands. We have also added small amounts of carbon monoxide to oxygen, methane, and mixtures of these gases. In Fig. 5 this CO emission from methane or oxygen is shown and that from mixtures in Fig. 6.

(c) Influence of the Current upon the Emission Intensity

The influence of the current upon the emission intensity of the various radicals at fixed distances S has been investigated for the gas mixtures mentioned above.

In Fig. 7 the intensity of emission of the 4368.3 Å oxygen line is plotted as a function of the current for various values of S. In Fig. 8 similar data are given for a discharge through methane, and Fig. 9 shows the linear relationship between the current and the intensity of emission in the case of methane–oxygen mixtures. However, when small amounts of carbon monoxide were added to the above gases and gas mixtures, the variation of the CO emission as a function of the current was not linear (Fig. 10).

(d) Influence of the Composition upon the Emission Intensity

In Fig. 11 the influence of the composition is illustrated; in this graph the intensities of emission of various radicals are plotted against the mole fraction X of methane. One sees that the intensity of the atomic oxygen line becomes negligible at $X = 0.67$; OH and CO emission is at a maximum for $X = 0.55$; the intensity of the H_β line, however, increases very quickly as soon as small amounts of methane are added to a discharge

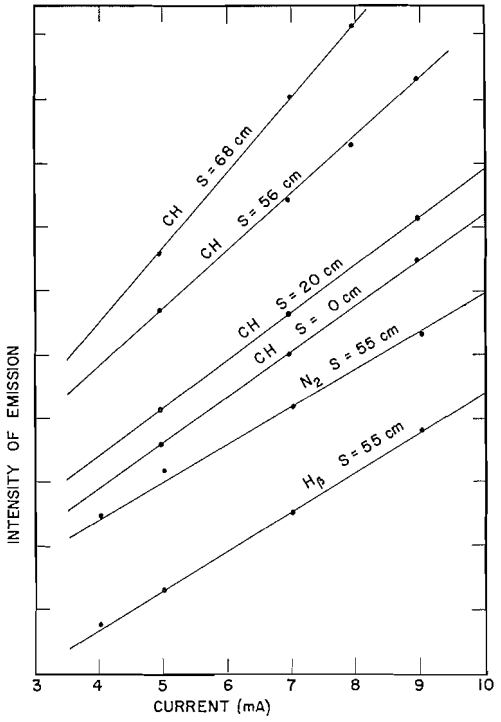

FIG. 8. Intensity of emission of the CH 4314.2 Å band in pure methane as a function of the current through the discharge for four different values of S. The emission of the N_2 3371.3 Å band and of the H_β line is also shown. Pressure at $S = 0$ cm: 1 torr.

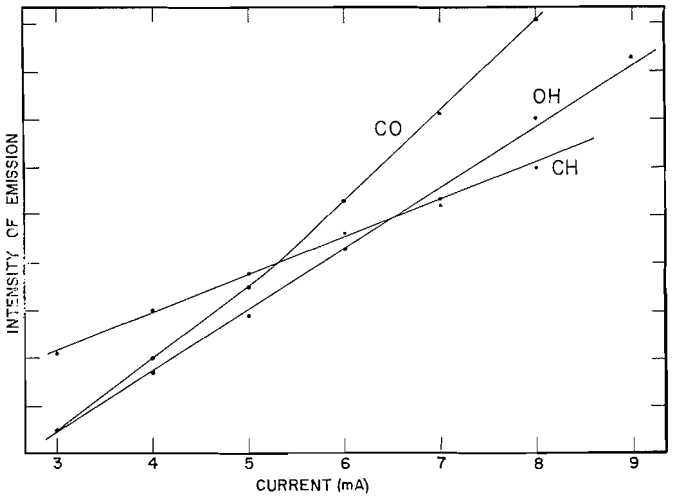

FIG. 9. Intensity of emission of the CH 4314.2 Å band, the CO 3134.4 Å band, and the OH 3089 Å band in a 33% methane 67% oxygen mixture at $S = 40$ cm as a function of the current through the discharge. Pressure at $S = 0$: 1 torr.

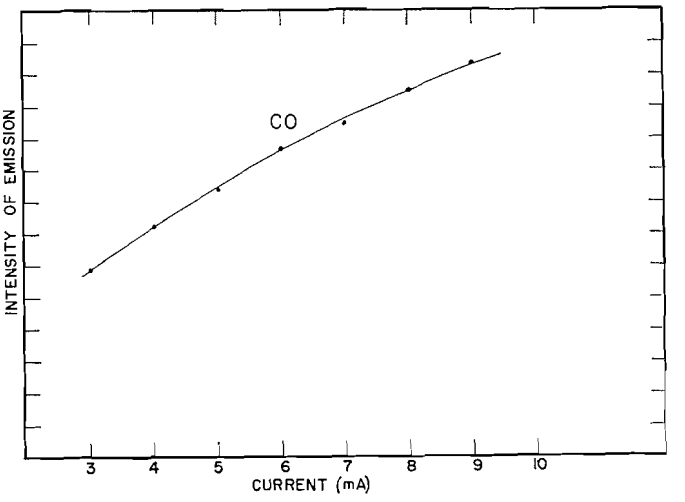

FIG. 10. Intensity of emission of the CO 3134.4 Å band in a mixture of 0.55% carbon monoxide and 99.45% oxygen as a function of the current through the discharge at $S = 40$ cm. Pressure at $S = 0$: 1 torr.

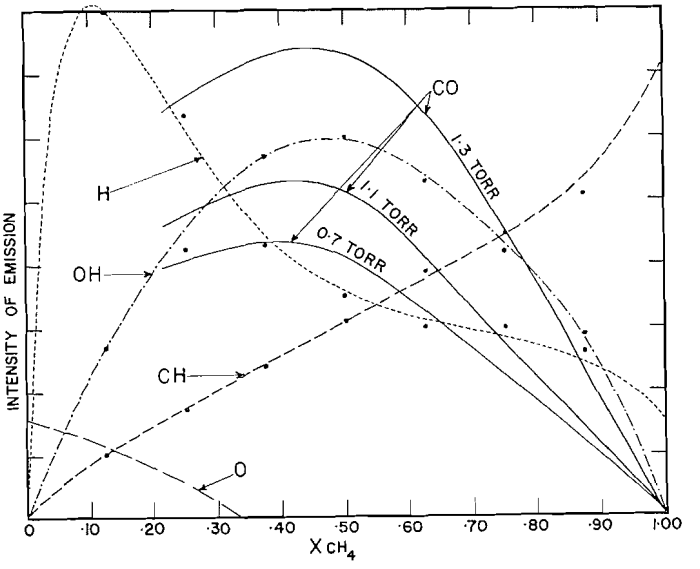

FIG. 11. Influence of the methane–oxygen ratio upon the emission intensity. The intensity of the OH 3089 Å, CH 4314.2 Å bands, and of the H_β and O 4368.3 Å lines is shown for 0.7 torr. The emission of the CO 3134.4 Å is shown at the three indicated pressures.

through pure oxygen and for large concentrations of oxygen, a maximum intensity is reached near $X = 0.88$. The CH emission increases smoothly as the methane concentration increases.

Small, increasing amounts of carbon monoxide were also added to discharges in methane and oxygen (Fig. 12(A) and 12(B)) and the intensity of emission of the CO bands was recorded. We can see that within the range of concentration explored the relation between the percentage of CO added in the mixture and the CO emission is linear. Finally, a

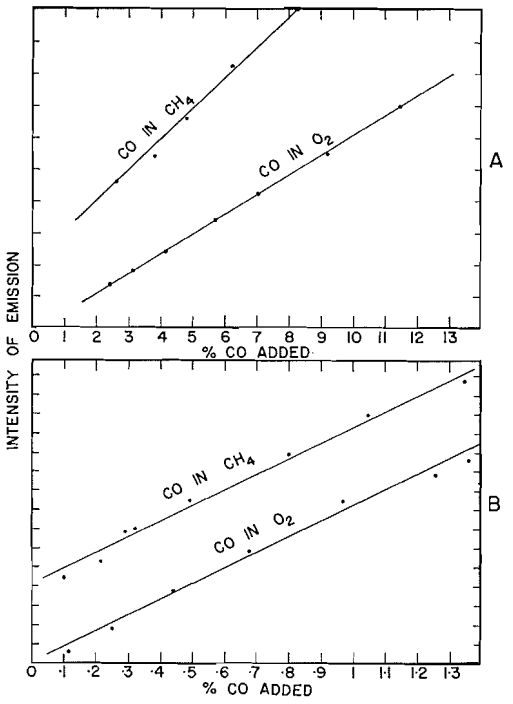

FIG. 12. Influence of the % CO added to methane or oxygen on the intensity of emission of the CO 3134.4 Å band. $S = 40$ cm. Pressure at $S = 0$: 1 torr.

constant amount of carbon monoxide was also added to methane–oxygen mixtures in which the mole fraction of methane varied from 0 to 1 and the intensity of the CO emission was measured. In Fig. 13 the intensity of emission due to the added CO alone (this is the total intensity of CO emission less the emission coming from the CO produced by the reaction) is plotted as a function of the mole fraction; this quantity is equal to the difference separating the two curves shown in Fig. 6. One notices the highly non-linear character of this curve.

(e) Pressure Gradient and Flow Velocity in the Discharge Tube

The total gas flow for all experiments reported in this paper was 150 ml min^{-1} N.T.P. At a pressure of 1 torr this corresponds to an average flow velocity of 50 m sec^{-1}. At that pressure a molecule travels 1 cm along the discharge tube in approximately 2×10^{-4} sec.

Because of the existence of a pressure gradient along the discharge tube, the flow velocity increases with S. This pressure gradient is illustrated in Fig. 14. The ordinate corresponds to the pressure at the entrance point of the gases in the discharge. *Within the limits* that the pressure, flow, or current through the discharge were varied in the experiments reported in this paper, this curve was found to be independent of the absolute value of these parameters. This curve also represents the relative amounts of time spent by a molecule in different sections of the discharge tube. It might also be useful to mention that a molecule, at 1 torr, assuming a collision diameter of 2 Å, suffers approximately 300 collisions during the time it takes to move 1 cm downstream. We have assumed the translational temperature of the gases to remain near 300 °K in the discharge. This last assumption warrants comment because the temperature of a gas in a discharge is not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

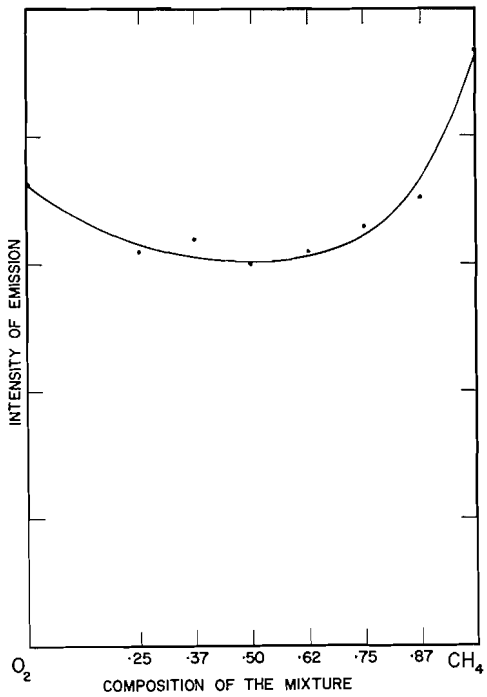

FIG. 13. Intensity of emission of the *added* carbon monoxide as a function of the methane–oxygen ratio at $S = 40$ cm, $p = 1$ torr. The value in ordinate corresponds to the difference separating the two curves in Fig. 6. Amount of CO added 2% (approx.).

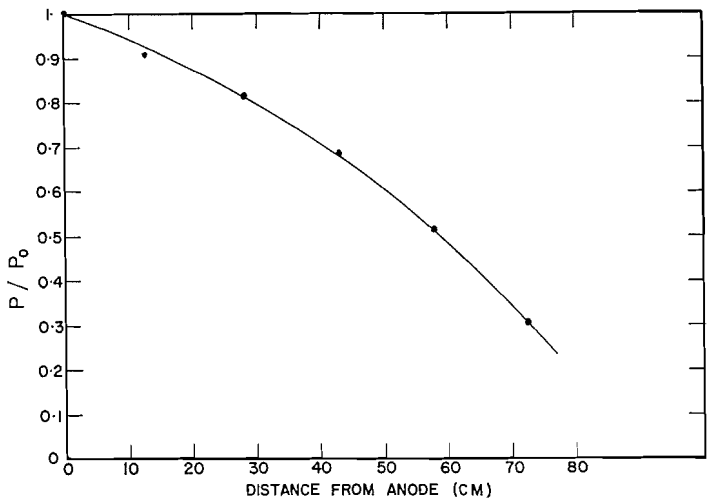

FIG. 14. Reduced pressure drop as a function of S for all experiments reported in this work.

necessarily in equilibrium with the walls. Because of the fast flow and the short residence time of the gases in the discharge it is felt that no appreciable heating of the gas can occur. Electron molecule collisions are very inefficient in transferring translational energy. Heating can hence only result from the succession of two inelastic collisions, the first

between an accelerated electron and a molecule or radical, followed by an inelastic collision of the second kind between two molecules or radicals. This last process competes with the possibility of loss of energy by emission of a photon. The linear increase in the emission of some radicals, further discussed in Part 4, is a further indication that this assumption is a reasonable one.

As was pointed out by the referee* of this paper, the effects of molecular diffusion should be negligible because of the high velocity of the flow.

PART 4. DISCUSSION OF THE RESULTS

A. Characteristics of the Emission

When we compare the emission of the species which have been studied in some detail we notice that we can separate them into two groups, each having a number of features in common. The emission intensity of CO, H, and O was nil at the entrance point of the gases in the discharge and increased monotonically as the gases proceeded further downstream in the observation tube. On the contrary the emission of CH and OH was substantial as soon as the gases entered the discharge tube and increased only very slightly further downstream (more for OH than for CH).

In the reaction zone of a flame a large emission of OH and CH has been observed (3). The origin of this emission is chemiluminescent, the radicals being produced in an excited state by a reactive collision. Vaerman, Nenquin, and Van Tiggelen (4) have indicated the conditions under which one can relate the emission intensity to the concentration of *excited* radicals. No appreciable emission of any of the emitters in the first group has been observed in a flame front.

As can be inferred from Fig. 12 at one point in the discharge tube, the emission due to CO is proportional to the amount of carbon monoxide added to methane or oxygen (up to 12%). This is also the case for methane–oxygen mixtures, provided the emission due to the CO formed in the discharge has been subtracted from the total CO emission (Fig. 6). From a number of similar graphs it was concluded that the emission of CO in mixtures is also proportional to the local carbon monoxide concentration, but the proportionality coefficient is a function of the position in the discharge tube at which the spectrum is recorded and of the methane–oxygen ratio (Figs. 6 and 13).

In this laboratory, Yealland (5) measured the concentration of oxygen atoms in the gases streaming out of a discharge through oxygen as a function of the length of the discharge. He found that this concentration increased linearly with the length of the positive column. We conclude that the emission intensity of the atomic oxygen lines is proportional to the atomic oxygen concentration.

We shall also assume that the emission intensity of the Balmer series of atomic hydrogen is proportional to the atomic hydrogen concentration, because its emission characteristics are rather similar to those of carbon monoxide and of atomic oxygen. For the radicals in group I (CO, H, O) the emission intensity is, we believe, proportional to the *total* concentration, while for the group II radicals (CH, OH) this is not necessarily so.

B. The Pressure Gradient, the Emission, and the Number of Collisions in the Discharge Tube

In most of the experiments the pressure in the discharge tube at the entrance point was 1 torr and the gas flow 150 cc min^{-1} N.T.P. Under these conditions the stream velocity of the gas was about 5×10^3 cm s^{-1}. Because of a pressure drop of about 70% (Fig. 14) the velocity of the gas downstream increased to about 1.5×10^4 cm s^{-1}. The time

*We thank the referee for raising this point.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

spent, on the average, by a molecule in 1 cm of discharge decreased from 2×10^{-4} s to 6.7×10^{-5} s. As a result, the number of collisions suffered by one molecule as it travelled 1 cm depended on the position and under the above conditions this number decreased from about 300 collisions cm^{-1} upstream to about 30 downstream (assuming an average collisional diameter of 2 Å).

For a current of 6 milliamperes there were 3.75×10^{16} electrons s^{-1} crossing a section perpendicular to the axis of the tubes; this number was independent of the pressure; to arrive at this number we assumed that the fraction of the current transported by ions was negligible because of the large difference in velocity between electrons and ions. The number of molecules flowing through a section of the discharge tube, in unit time, was also independent of the value of S throughout the tube because the decrease in density was offset by a corresponding increase in the velocity of the gas stream. Excluding metastable states, the lifetime of an electronically excited radical ($\sim 10^{-8}$ or less) was small compared to the time spent by a molecule in a segment of the tube whose length was comparable to that of the spectrograph slit (1 cm). The intensity of emission at various distances from the entrance point was therefore representative of the number of molecules being excited in that segment.

C. The Production of Excited Species

(a) Oxygen Atoms

The production of excited oxygen atoms could conceivably take place in a single collision:

[1] $$O_2 + e^-(>15.8 \text{ eV}) \rightarrow O + O^* + e^-$$

[2] $$O^* \rightarrow O + h\nu.$$

Emission from the ^5P, ^3P, ^5S, ^5D levels was observed. The intensity of all lines originating from these levels followed closely the behavior of the 4368.3 Å line. If reactions of type [1] were responsible for the observed emission to an appreciable extent, the rates of the production of these various states should increase or decrease proportionately under all experimental circumstances and increase linearly as the gases proceed through the tube. That these two conditions would be fulfilled at the same time is highly improbable; we would have to assume linear changes in the electric properties of the positive column which are contrary to all other observations. The disappearance of the emission of atomic oxygen upon addition of methane (Fig. 11) cannot be explained without assuming unreasonably large collision cross sections, if mechanism [1] is responsible for the production of O*.

It is much more probable that the observed emission is due to the excitation by electrons of oxygen atoms produced in previous collisions.

[3] $$O_2 + e^- (>5.1 \text{ eV}) \rightarrow O + O + e^-$$

[4] $$O + e^- (>12 \text{ eV}) \rightarrow O^* + e^-.$$

If reaction [4] is the only reaction producing excited atoms to any appreciable extent, the emission resulting from such collisions would indeed be proportional to the *total* oxygen atom concentration.

If deactivation of excited atoms by other molecules occurs according to:

[5] $$O^* + M \rightarrow O + M + \text{kinetic energy},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

this reaction will be first order with respect to the excited oxygen atoms.

Kaufman and Kelso (6) have suggested that the dissociative collision [3] proceeds via a $^3\Sigma_u^-$ oxygen molecule:

[6] $$O_2 + e^- (>7 \text{ eV}) \rightarrow O_2 (^3\Sigma_u^-) + e^-$$
$$O_2 (^3\Sigma_u^-) \rightarrow O (^3P) + O (^1D).$$

Such a mechanism would produce a ^1D metastable oxygen atom for every ground state atom. The existence of metastable oxygen atoms in the discharge is probable (7, 8) but it seems improbable that they are present in large concentration. It thus seems that as a result of electron impact, a substantial amount of dissociation occurs either from the ground state molecule or via one of the numerous excited states which dissociate into two ^3P oxygen atoms.

Chanin, Phelps, and Biondi (9) have measured the rate coefficient for the reaction

[7] $$O_2 + e^- (>3.5 \text{ eV}) \rightarrow O + O^-.$$

Kaufman and Kelso (6) have calculated that this reaction might account for the small dissociation that they measure in very pure oxygen; in the presence of small amount of impurities (they find N_2, H_2, and H_2O to be very effective) the production rate of oxygen atoms by this process alone is too small to account for the observed dissociation. In their papers these authors also suggest a number of other possible schemes for the production of atoms involving catalytic activity of impurities.

(b) Production of CH Radicals

The intensity of emission of CH in pure methane was fairly uniform throughout the discharge tube. CH emission was observed right at the entrance point of the gases in the discharge even at low pressures ($\sim 4 \times 10^{-2}$ torr). At such pressures a molecule, during the time it drifts 1 cm, suffers only a few collisions (<10) with other molecules. Thus the excited CH radicals must be produced, at least in part, from the methane molecule by electron impact. It is not possible at this stage to decide whether the removal of three hydrogen atoms occurs under the impact of a single electron or, as seems more probable, by successive impacts, as indicated in diagram [8].

[8] $$CH_4 \xrightarrow[e^-]{} CH_3 \xrightarrow[e^-]{} CH_2 \xrightarrow[e^-]{} CH$$
with e^- arrows from CH_3 to CH and from CH_4 to CH.

[9] $$CH + e^- \rightarrow CH^* + e^-$$

[10] $$CH^* \rightarrow CH + h\nu.$$

Excited CH radicals can be produced either directly from methane, or from one of the intermediates or by electron impact with CH radicals in the ground state, via mechanism [9].

At higher pressures some of the hydrogen could be removed from the methane or the radicals CH_3 and CH_2 by reactive collision with H, O, or other radicals which combine with hydrogen.

[11] $$CH_m + M \rightarrow CH_{m-1} + MH.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

CH can also be produced by disproportionation of two CH_2.

[11*a*] $$CH_2 + CH_2 \rightarrow CH + CH_3.$$

The reaction $C_2 + OH \rightarrow CO + CH^*$, which has been postulated as being responsible for the CH emission in flames, cannot account for the observed emission because:

(i) at the origin OH concentration is very small,

(ii) emission of C_2 is exceedingly weak and its concentration is too small.

In the case where pure methane flows through the discharge tube the slightly larger rate of increase of the CH emission with S as compared to that in methane–oxygen mixtures is due to the fact that when oxygen is present the CH is consumed by other reactions. It is also possible that some of the CH radicals, produced by reactions of type [11] are formed in excited states.

The fact that the CH emission increases approximately linearly with the concentration of CH_4 is an indication that a substantial amount of the CH might be produced in an excited state.

(c) The Excitation of CO

It can be inferred that no appreciable amount of CO is formed in an excited state, in much the same way that production of excited oxygen atoms in a single collision was excluded. The emission intensity of CO increases linearly with S, and parallel behavior of the emission from the $b_1\Sigma$, $B_1\Sigma$, and $C_1\Sigma$ states has been observed. It is therefore very probable that nearly all the observed emission arises from

[12] $$CO + e^- \rightarrow CO^* + e^-$$

the endothermicity of the process varying from 10.4 to 11.3 eV. Excitation of CO via [12] would make the CO intensity proportional to the total CO concentration.

In the presence of oxygen atoms some CO might be oxidized to CO_2. This possibility is discussed in more detail in the next paragraph. The emission of CO is not directly related to the mole fraction of CO in the discharge. We measure in fact an emission proportional to the sum of the mole fractions of CO and CO_2.

D. Reactions in the Discharge

(a) The Disappearance of CO

In Fig. 5 we notice that the CO emission drops near the origin, both in oxygen and in methane. We ascribe this drop in emission intensity to oxidation or reduction of CO in the discharge. We will discuss first the interaction of carbon monoxide with oxygen.

No reaction occurs at room temperature between CO and O_2 in their ground states. It is highly improbable that electronically excited non-metastable states of CO or O_2, formed under electron impact, are responsible for the formation of CO_2 from CO, because the probability of a collision occurring during the lifetime of an excited CO or O_2 molecule is too small. Although it is known (10, 11) that sizeable concentrations of the metastable $^1\Delta_g$ O_2 are formed in the discharge, this state lies only about 1 eV above the ground state and consequently the reaction

[13] $$CO + O_2^* (^1\Delta) \rightarrow CO_2 + O$$

would still be more than 1.2 eV endothermic. The only reasonable alternative leading to further oxidation of CO would be the reaction

[14] $$CO + O \rightarrow CO_2^*$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

This reaction has been studied by Mahan and Solo (12), who obtained a rate constant of 10^{10} exp $(-400/RT)$. The possibility that the CO_2* may dissociate is mentioned and discussed. If the decrease in CO emission is due to reaction [14] the value of Mahan and Solo's rate constant is too small. Even the value obtained by Avramenko and Kolesnikova (13), which is about 10 times larger, would be too small.

It is also possible that the initial decrease in the CO emission is due to a rapid removal of CO in the discharge. If this is the explanation of the initial decrease in CO emission in oxygen CO would be broken down under electron impact. The steady state CO emission reached downstream is then the result of the balancing of the breakdown reaction and the further reaction between a carbon atom and an oxygen molecule, regenerating CO.

(b) The Formation of CO

In Part 3(*c*) we assumed the temperature of the gas in the discharge to remain approximately at room temperature; reactions which normally occur in slow combustion or in flames do not occur in this work to any appreciable extent if they have appreciable activation energies.

Fok and Nalbandyan (14) have shown that for large flows at temperatures below 100 °C the only product from reaction between CH_3 and O_2 is a peroxide:

[15] $$CH_3 + O_2 \rightarrow CH_3OO.$$

Only above 100 °C are aldehydes formed as well. Hence the oxidation of a CH_3 radical formed under electron impact according to [8] or [11] will not produce a CO molecule. Similarly a CH_2 radical will probably disproportionate [11*a*] rather than undergo further oxidation. The only reactions which can produce CO are then

[16] $$CH + O_2 \rightarrow CO + OH$$

or

[17] $$CH + O \rightarrow CO + H$$

Most reactions involving H, OH, or CH_3 have activation energies which are large enough to make their occurrence unlikely under our conditions. These activation energies have been summarized by Semenov (15).

In a 50% methane 50% oxygen mixture under the usual conditions, after 5×10^{-3} s (40 cm) 12% CO has been formed. This means that during the time the gas moves 1 cm 4.1×10^{13} molecules have been formed. Since each CO comes from a previously formed CH radical this means that at least 4.1×10^{13} CH radicals were formed in this period of time. As mentioned earlier the only way that CH is produced from CH_4 is either under electron impact (8), or through a reaction of the type

[17*a*] $$CH_m + O \rightarrow CH_{m-1} + OH,$$

which involves an oxygen atom previously formed under electron impact by mechanism [3]. The endothermicity of a CH being produced via mechanism [8] is 12.5 eV while via mechanism [17*a*] it is only 7.7 eV; it only takes 2.55 eV to produce one oxygen atom.

If we assume that the current through the discharge is solely due to the flow of electrons and that the number of additional electrons being produced by ionizing collisions is small, the flux of electrons through a section of the discharge during the time the gas moves 1 cm is 7.5×10^{12} electrons; 4.1×10^{13} CH radicals have thus to be produced during that time. If f is the average number of C—H bonds broken during one electron impact, $(3/f)$ reactive collisions result in a CH being produced from a CH_4. If no reactions of type

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

[17*a*] were taking place, each electron must suffer on the average $5.5 \times 3/f$ collisions per centimeter displacement along the axis of the discharge to account for the above calculated rate of formation of CH radicals. In order that the electrons acquire enough energy to produce the calculated number of CH radicals via mechanism [8] the minimum field value has to be 69 V cm^{-1}. If CH were formed completely via mechanism [17*a*], on the other hand, the field value would be decreased to about 38 V cm^{-1}. The experimental values found by Rundle and Miller (16) in this laboratory were intermediate between these values ($\sim$60 V cm^{-1}).

Taking the previous discussion into account, the linear increase of emission with S of the CO emission intensity can be expressed as

$$(dI_{CO}/ds) = (k'd(CO)/ds) = k(i)$$

where I_{CO} is the emission intensity, (CO) the CO concentration, and ds an element of length along the axis of the discharge tube. The proportionality constant k is a function of the current i.

In view of the large pressure gradient in the discharge we have to assume that the rate-controlling step in the production of CO molecules is of zero overall order in the pressure. The right-hand term in the above expression is hence independent of the concentrations of the reagents. This is consistent with the facts reported earlier that the primary step leading to the formation of CO must be the breaking of three C—H bonds by electron impact or by a process such as [17*a*]. Because of the large mass difference electrons do not lose kinetic energy to any significant extent in an elastic collision; they only lose energy in inelastic or reactive collisions. If N_t is the total number of collisions suffered by an electron during the time it moves 1 cm, N_r the number of inelastic and reactive collisions suffered during this time by the electron, and g the average number of collisions it takes an electron before it suffers an inelastic or reactive collision, once it has acquired the minimum amount of energy necessary to excite or break a bond, provided $N_t \geqslant N_r g$, the rate of production of excited species, atoms, or radicals should be pressure independent. This explains the apparent zero order of the above rate law. Since the excitation processes leading to the production of excited CO or O atoms are similar processes, they too should be of zero order in the pressure.

Reactions [16], [17], and [17*a*] must be very fast reactions, occurring within a very few collisions in order to account for the observed rate of formation of the CO, so that the production of the radicals CH or O under electron impact should be rate determining, and thus the overall production of CO be pressure independent, as observed.

If [16] and [17] are fast reactions the concentration of CH should not vary appreciably along the discharge tube; the pressure gradient in the tube will decrease the overall number of collisions taking place per unit length of the discharge tube and result in an increase in the CH concentration. This might explain the slight increase in CH emission seen in Fig. 4.

It might be worthwhile to mention also that ds can be converted into a time dependency when the pressure gradient is known.

It is evident from the above discussion that any process involving accelerated electrons will also have an apparent zero pressure dependency, as long as the condition $N_t \geqslant N_r g$ is met. As was pointed out in Part 4(*a*), the emission of CO, O, or H was found to be proportional to the concentration of that species (to be more precise to the mole fraction of the component). Due to the existence of the pressure gradient in the discharge tube the total number of molecules at various points in the discharge tube varies. Strictly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

speaking the emission intensity is thus not proportional to the absolute concentration but, as long as $N_t \geqslant N_r g$, only to the mole fraction of the emitter in the gas.

The linear increase in the production of CO in methane–oxygen mixture is further evidence that the rate-controlling step in the CO production involves the breakdown of a molecule or radical under electron impact and that under our operating conditions the relation $N_t \geqslant N_r g$ holds.

Ions having comparable masses to the molecules will dissipate their kinetic energy in a few collisions and it is unlikely that a significant amount of energy would be gained by them under the influence of the electric field.

One molecule suffers approximately 300 collisions during the time the gas moves 1 cm (at 1 torr). Schmoluchowsky's formula

$$Z = 3\pi d^2/4\lambda^2$$

gives the average number of collisions suffered by a molecule as it diffuses a distance d with a mean free path of λ.

Assuming an average mean free path of 10^{-2} cm at 1 torr and $d = 0.35 \times 2$ cm as the average distance a radical will diffuse before hitting the wall a molecule suffers about 600 collisions. Hence if appreciable losses or recombinations on the wall are excluded the reactions [16] and [17] should occur within 600 collisions or less.

The relative importance of reactions [16] and [17] will vary with the composition of the gas mixture which flows through the discharge. In oxygen-rich mixtures a significant amount of atomic oxygen is present so that the formation of CO via reaction [17] might become significant.

(c) Other Reactions Involving H, OH, or O Atoms

It has been proposed in the previous sections that the emission of atomic oxygen is due to the collisions of electrons with oxygen atoms (4). When increasing amounts of methane were added to the gas mixture, the emission of atomic oxygen diminished steadily until for 33% methane no emission could be observed. This value is only approximately known because of the weakness of oxygen atom emission and partial overlapping of the N_2 second positive system.

The disappearance of free oxygen atoms might be due to a variety of reasons. If CH is formed from methane it might be that too few electrons are left with enough energy to dissociate an oxygen molecule. Alternately, the oxygen atoms produced may be consumed in further very fast chemical reactions. Recently, Young and Sharpless (17) indicated that the rates of some trimolecular processes might be significant in flow experiments at pressures of 1 torr. However, under our conditions, we doubt that their contribution could be significant.

Reactions likely to occur are:

[18] $\mathrm{CH} + \mathrm{O} \rightarrow \mathrm{CO} + \mathrm{H},$

[19] $\mathrm{OH} + \mathrm{O} \rightarrow \mathrm{O_2} + \mathrm{H},$

[20] $\mathrm{H_2} + \mathrm{O} \rightarrow \mathrm{OH} + \mathrm{H}.$

It is doubtful whether other reactions involving OH take place. Similarly H atoms will not propagate chain reactions at low temperatures because of their relatively large activation energy (15). Reactions [18], [19], and [20] each produce H atoms and together they account for the large H atom emission observed for small amounts of methane in oxygen. We are now attempting to measure the rate of some of the reactions which have been suggested.

CONCLUSIONS

In this work we have described a technique which permits the study of changes in the spectra emitted by fast flowing, reacting gas mixtures in the positive column of a d-c. glow discharge. We have shown that it is possible in certain cases to obtain a quantitative relation between the emitted intensity and the concentration of the emitting species. To account for the observed reaction rate, we have to postulate a high rate of production of atoms or radicals under electron impact. The electric field values needed to impart the necessary amount of energy to the electrons are of the same magnitude as those measured in this work ($\sim$60 V cm^{-1}). We have thus shown that, at least in the early stages of a discharge, before the steady state of concentrations of atoms, radicals, and molecules has been approached, most of the energy of the electrons is used in breaking chemical bonds.

ACKNOWLEDGMENTS

It is a real pleasure to acknowledge support in the form of grants from the United States Air Force through the Office of Scientific Research (Propulsion Research Division), from the National Research Council of Canada and from the University of Toronto.

Dr. J. F. Vrebosch designed the apparatus and Messrs. J. J. Ryan, R. F. Ferguson, and J. Noolandi were helpful in obtaining part of the data. One of us (P. B d'E.) is indebted to Professor A. Van Tiggelen of the University of Louvain for allowing a year's leave of absence to carry out this work at the University of Toronto.

THE REACTION OF UNSATURATED CARBOHYDRATES WITH CARBON MONOXIDE AND HYDROGEN

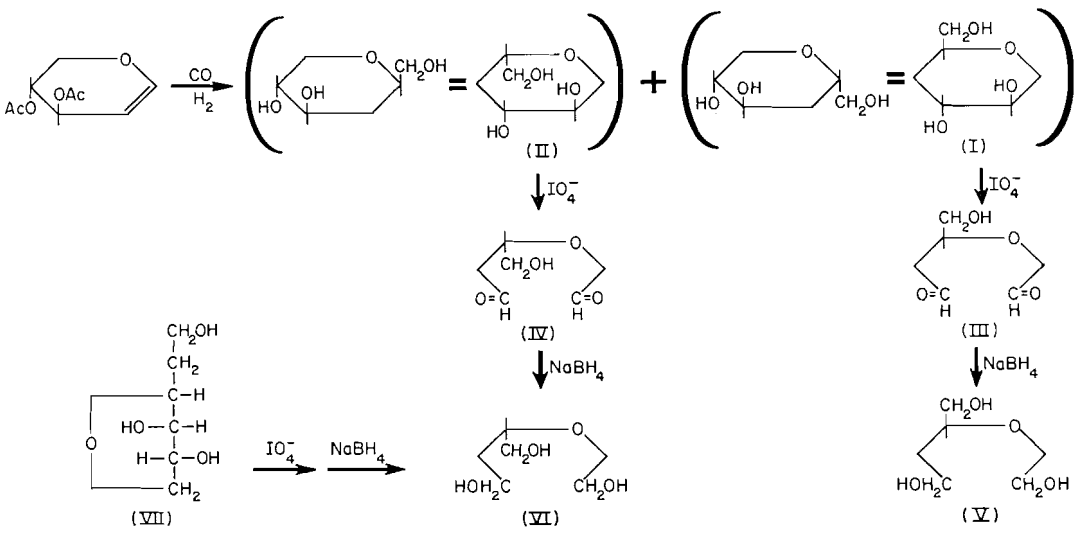
II. STRUCTURE AND STEREOCHEMISTRY OF THE ANHYDRODEOXYHEXITOLS FROM 3,4-DI-*O*-ACETYL-D-XYLAL

ALEX ROSENTHAL AND DEREK ABSON
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received January 20, 1964

ABSTRACT

3,4-Di-*O*-acetyl-D-xylal reacted with carbon monoxide and hydrogen in the presence of dicobalt octacarbonyl to yield 1,5-anhydro-4-deoxy-D-*arabino*-hexitol (I) and 1,5-anhydro-4-deoxy-L-*xylo*-hexitol (II). The stereochemistry at C-5 of the hexitols was elucidated by correlation with the triol ether (VI) obtained by sodium borohydride reduction of the periodate oxidation product of 1,4-anhydro-5-deoxy-D-*arabino*-hexitol (VII). Reaction of 3,4-di-*O*-acetyl-D-xylal with carbon monoxide and deuterium afforded 1,5-anhydro-4-deoxy-D-*arabino*-hexitol-4,6,6-H_3^2 (VIII) and 1,5-anhydro-4-deoxy-L-*xylo*-hexitol-4,6,6-H_3^2 (IX). Examination of the nuclear magnetic resonance (n.m.r.) spectra of the normal and deuterated anhydrodeoxyhexitols confirmed the structural assignments and showed that *cis*-addition to the double bond takes place to give (IX).



It has been reported previously (1, 2) that 3,4,6-tri-*O*-acetyl-D-galactal reacted with carbon monoxide and hydrogen under oxo conditions (3) to yield an anhydrodeoxyheptitol of unknown stereochemistry. It has now been found that pentals react similarly to yield anhydrodeoxyhexitols in which a hydroxymethyl group has been added to C-1 of the pental. The present paper in the series deals with the oxo reaction of 3,4-di-*O*-acetyl-D-xylal and offers conclusive proof by chemical means of the stereochemistry of the hexitols obtained. In addition, the mechanism of the addition of carbon monoxide and hydrogen to the glycal has been determined by the use of tracer studies.

The 3,4-di-*O*-acetyl-D-xylal, prepared by a modification of the procedure of Helferich and co-workers (4), was reacted with a mixture of carbon monoxide and hydrogen at a

pressure of about 4000 p.s.i. and at a temperature of about 130° in the presence of preformed dicobalt octacarbonyl as catalyst to yield a mixture of products. This was freed from catalyst by filtration through Florisil. After the solvent was removed, the mixture was deacetylated with sodium methoxide in methanol to yield the anhydrodeoxyhexitols (I) and (II). These were subsequently separated by paper chromatography.

The stereochemistry of C-5 of each of the hexitols (I) and (II) was resolved in the following way. Periodate oxidation of these hexitols yielded the dialdehydes (III) and (IV). Sodium borohydride reduction of these dialdehydes afforded the enantiomorphic triol ethers (V) and (VI), having similar infrared spectra and equal but opposite optical rotations. In addition, (V) and (VI) were converted into crystalline *p*-nitrobenzoates having similar infrared spectra and melting points. In connection with the problem of determining the structures of the *p*-nitrobenzoates of the triol ethers, it was noted that Gorin had previously reported (5) the preparation of a *p*-nitrobenzoate of a triol ether which appeared to have the same structure as that of the *p*-nitrobenzoate of either (V) or (VI). Direct comparison (m.p., mixed m.p., and infrared spectra) revealed that the tris-*p*-nitrobenzoate of Gorin's compound (III) was identical with the tris-*p*-nitrobenzoate of compound (V).

The configuration of C-3 of the triol ether (VI) was then correlated with that of C-4 of 1,4-anhydro-5-deoxy-D-*arabino*-hexitol (VII). The latter new compound was prepared by sodium borohydride reduction of the known 3,6-anhydro-2-deoxy-D-*lyxo*-hexose (6). Periodate oxidation of (VII) followed by sodium borohydride reduction of the dialdehyde yielded a triol ether having an optical rotation and infrared spectrum respectively similar to those of the triol ether (VI). Further confirmation of the identity of the two triol ethers was obtained by comparing the crystalline *p*-nitrobenzoates of each (same m.p., mixed m.p., and infrared spectra). Thus, the configuration of C-5 of the hexitol (II) is identical with that of C-4 of 1,4-anhydro-5-deoxy-D-*arabino*-hexitol, and compounds (I) and (II) are 1,5-anhydro-4-deoxy-D-*arabino*-hexitol and 1,5-anhydro-4-deoxy-L-*xylo*-hexitol, respectively.

In conjunction with the study of the structure of each of the hexitols (I) and (II) by classical chemical methods, a parallel investigation of their structures by use of proton n.m.r. has also been carried out. The interpretation of the n.m.r. spectra of (I) and (II) (shown in Fig. 1(A) and (B)) was greatly aided by the excellent n.m.r. analyses of the structures of chalcose (4,6-dideoxy-3-*O*-methyl-D-*xylo*-hexose) and of its methyl glycoside (7), and by comparison of the spectra of (I) and (II) with those of their deuterated analogues prepared by reacting 3,4-di-*O*-acetyl-D-xylal with carbon monoxide and deuterium. The n.m.r. spectra of the deuterated analogues (VIII) and (IX) are shown in Fig. 1(C) and 1(D). Based on the fact that the equatorial C-4 hydrogen of the methylene group of chalcose absorbed at around $\delta = 2.05$ and the axial C-4 hydrogen at around $\delta = 1.0$ to 1.58 (7), the signal at $\delta = 2.0$ in Fig. 1(D) might be attributed to the single equatorial hydrogen on C-4 of the deuterated compound (IX). In Fig. 1(B) both the equatorial and the axial C-4 hydrogen signals at $\delta = 2.0$ and 1.5, respectively, are clearly distinguishable. To account for the wide signal of the axial C-4 hydrogen (about 34 c.p.s.), it is suggested that the hydrogens on C-5 and on C-3 are axial. The three coupling constants of the axial C-4 hydrogen would therefore be $J_{4a,3a}$ $J_{4a,5a}$, and $J_{4a,4e}$ since it would be coupled with the two neighboring hydrogens on C-3 and C-5 and to the equatorial hydrogen on C-4. The fact that the axial C-4 hydrogen of chalcose (7), which gave a series of peaks having a width of 34.5 c.p.s., is also coupled to axial hydrogens on C-5 and on C-3 supports the above postulation. The splitting of the equatorial hydrogen signal around $\delta = 2.0$ clearly

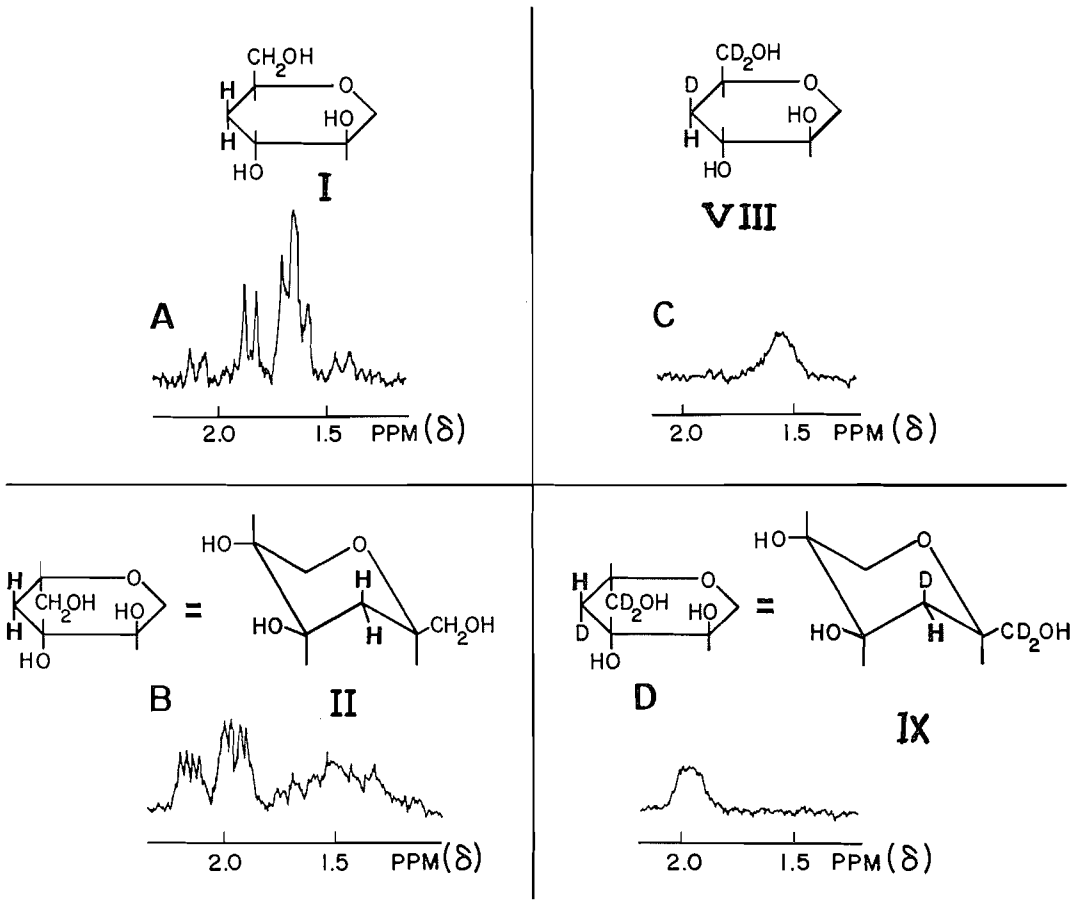

FIG. 1. Proton n.m.r. spectra in D_2O solution at 60 mc with chemical shifts given in p.p.m. from tetramethylsilane as zero: (A) 1,5-anhydro-4-deoxy-D-*arabino*-hexitol; (B) 1,5-anhydro-4-deoxy-L-*xylo*-hexitol; (C) 1,5-anhydro-4-deoxy-D-*arabino*-hexitol-4,6,6-H_3^2; (D) 1,5-anhydro-4-deoxy-L-xylo-hexitol-4,6,6-H_3^2. (Only signals of protons attached to C-4 are shown.)

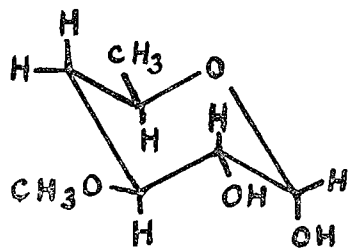

shows the large spin coupling to the geminal hydrogen ($J_{4a,4e}$ approximately 12.5 c.p.s.), and further small splittings by coupling to the adjacent axial hydrogens on C-3 and C-5. Therefore, the hydroxymethyl group in (II) must be in an equatorial position. It is apparent that analysis of the n.m.r. spectra 1B and 1D reveals the stereochemistry of

the hexitol (II) and of the deuterated analogue (IX). An important part of the evidence for axial deuterium in (IX) is the narrowness (~9 c.p.s.) of the signal at 2.0 p.p.m. (had the proton in (IX) been axial, the signal would have been wider (~20 c.p.s.) as well as being at higher field). It is also noteworthy that the deuterated analogue (IX) must have been formed by a *cis*-addition of the hydroxymethyl group and of the deuterium to the 1,2-unsaturated bond of 3,4-di-*O*-acetyl-D-xylal.

The n.m.r. spectra of the normal and deuterated hexitols (I) and (VIII) (Fig. 1(A) and 1(C)) do not reveal the stereochemistry of C-5 because of overlapping of the C-4 axial and equatorial hydrogen signals.

EXPERIMENTAL

General Considerations

The solvent used for paper chromatographic separations was water-saturated 1-butanol containing 5% ethanol and 1% concentrated ammonium hydroxide. The hexitols were detected with ammoniacal silver nitrate (8) or with sodium metaperiodate – Schiff's reagent (9).

The oxo product, first freed from catalyst, was also separated into slightly impure fractions by chromatography on neutral alumina using benzene–methanol (98:2/v:v) as developer. Analysis of the product–mixture was readily carried out using thin layer chromatography on alumina with benzene:methanol (96:4) as developer.

The Florisil was obtained from the Floridin Company, Tallahassee, Florida, United States.

The oxo product was dried by azeotroping with anhydrous benzene followed by methanol, and then deacetylated (10) with 0.1 *N* sodium methoxide in methanol (or in a 1:1 mixture of anhydrous chloroform – methanol) at about 5° for 1 day. Sodium ions were removed by stirring (or elution through a column) with Amberlite IR-120 (H^+) resin. Solutions were evaporated under reduced pressure.

The n.m.r. spectra were obtained in a Varian A-60 instrument using tetramethylsilane as the external standard (set at $\delta = 0$). The infrared analyses were done on a Perkin–Elmer spectrophotometer, Model 21, using a sodium chloride crystal. Microanalyses were done by Mrs. Aldridge of this department and by Dr. A. Bernhardt, Mikroanalytisches Laboratorium im Max-Planck-Institut für Kohlenforschung, Mülheim (Ruhr), West Germany.

Preparation of 3,4-Di-O-acetyl-D-xylal

The 3,4-di-*O*-acetyl-D-xylal was prepared according to a modification of the procedure of Helferich and co-workers (4). During the addition of the tri-*O*-acetyl-α-D-xylosyl bromide to the zinc – acetic acid mixture, the reactants were kept at −5 to −10° for 3 h. Prior to filtration, Celite was added to coagulate the zinc and hasten filtration. Pieces of solid carbon dioxide were added during the filtration process to keep the reaction mixture at −10°. It was imperative that the crude 3,4-di-*O*-acetyl-D-xylal be distilled immediately under reduced pressure to prevent undue decomposition of the product; yield about 60%. All operations in the preparation of 3,4-di-*O*-acetyl-D-xylal were carried out in the same day.

Reaction of 3,4-Di-O-acetyl-D-xylal with Carbon Monoxide and Hydrogen to Yield 1,5-Anhydro-4-deoxy-D-arabino-hexitol (I) and 1,5-Anhydro-4-deoxy-L-xylo-hexitol (II)

To a mixture of 3,4-di-*O*-acetyl-D-xylal (5.6 g) in dry, purified benzene (25 ml) contained in a 300-ml shaker bomb was added preformed dicobalt octacarbonyl (1–2 g). After flushing the bomb with carbon monoxide, carbon monoxide (500 p.s.i.) and hydrogen (2500 p.s.i.) were added and the reactants heated with rocking at 125–130° for about 2 h. The reactants were then added to a column of Florisil (8 × 8 cm diam.) and after the solvent had passed through the dicobalt octacarbonyl was eluted with 30–60° petroleum ether. The product was then eluted with benzene–ethanol (10:1/v:v). Evaporation of the eluent under reduced pressure yielded 6.0 g of sirup. The product contained the anhydrohexitols and traces of sugars. When the same substrate was reacted under similar conditions except at a temperature of about 115° for 0.5 h, the product consisted of 50% unreacted 3,4-di-*O*-acetyl-D-xylal, about 20% of sugars, and about 30% of the same anhydrohexitols as obtained in the 130° experiment.

The oxo product was then deacetylated with sodium methoxide in methanol (10). Fractionation of the deacetylated product was carried out by preparative paper chromatography or by cellulose column chromatography; ratio of fraction (I) and (II) was about 1:1. When the deacetylated product contained appreciable quantities of sugars, better separation of the hexitols was obtained if the mixture was first treated with sodium borohydride in water to reduce the sugars.

Characterization of Fraction (I)

Fraction (I) (1,5-anhydro-4-deoxy-D-*arabino*-hexitol) was crystallized from methanol – isopropyl ether; m.p. 102°; $[\alpha]_D^{20}$ −13° (*c*, 6.3 in water); $R_F = 0.47$. Calc. for $C_6H_{12}O_4$: C, 48.64; H, 8.16. Found: C, 48.35; H, 8.10.

Preparation of 1,5-Anhydro-4-deoxy-2,3,6-tri-O-p-nitrobenzoyl-D-arabino-hexitol

1,5-Anhydro-4-deoxy-D-*arabino*-hexitol was converted into a tris-*p*-nitrobenzoate according to the procedure used by Gorin (5); m.p. 215°; $[\alpha]_D^{20}$ −50° (*c*, 1.0 in chloroform). Calc. for $C_{27}H_{21}O_{13}N_3$: C, 54.60; H, 3.60. Found: C, 54.56; H, 3.86.

Characterization of Fraction (II)

Fraction (II) (1,5-anhydro-4-deoxy-L-*xylo*-hexitol) could not be crystallized; $[\alpha]_D^{20}$ −44° (*c*, 6.4 in water); R_F = 0.41. Calc. for $C_6H_{12}O_4$: C, 48.64; H, 8.16. Found: C, 48.36; H, 8.39.

Preparation of 2,3,6-Tri-O-acetyl-1,5-anhydro-4-deoxy-L-xylo-hexitol

The 1,5-anhydro-4-deoxy-L-*xylo*-hexitol (70 mg) was acetylated with acetic anhydride – pyridine to yield 109 mg of 2,3,6-tri-*O*-acetyl-1,5-anhydro-4-deoxy-L-*xylo*-hexitol. Recrystallization of the crude acetate from ether – petroleum ether (30–60°) afforded the pure acetate; m.p. 80–81°; $[\alpha]_D^{22}$ −41° (*c*, 0.8 in chloroform). Calc. for $C_{12}H_{18}O_7$: C, 52.55; H, 6.62. Found: C, 52.82; H, 6.58.

Structure and Stereochemistry of Hexitols (I) and (II)

Compound (I) was oxidized with 0.1 *M* periodic acid to yield the dialdehyde (III), which was reduced with sodium borohydride in water, according to the procedure of Gorin (5), to the triol ether (V); $[\alpha]_D^{23}$ −19° (*c*, 2.0 in water). The triol ether was *p*-nitrobenzoylated to afford a tris-*p*-nitrobenzoate, m.p. 102–103°; $[\alpha]_D^{22}$ −28° (*c*, 1.1 in chloroform). Calc. for $C_{27}H_{23}O_{13}N_3$: C, 54.30; H, 3.99. Found: C, 54.57; H, 3.95. The infrared spectra of the tris-*p*-nitrobenzoate of the triol ether (V) and of the tris-*p*-nitrobenzoate of the triol ether obtained from 1,4-anhydro-5-deoxy-D-*arabino*-hexitol (described in the following part of the experimental) were identical.

In a similar way to that described above, compound (II) was oxidized with periodic acid and the dialdehyde (IV) then reduced with sodium borohydride to yield the triol ether (VI) as a sirup; $[\alpha]_D^{25}$ +17° (*c*, 1.7 in water). The triol ether (VI) was then *p*-nitrobenzoylated; m.p. 102–103°; $[\alpha]_D^{24}$ +26° (*c*, 1.4 in chloroform). Calc. for $C_{27}H_{23}O_{13}N_3$: C, 54.30; H, 3.99. Found: C, 54.63; H, 4.09. The mixed m.p. of this *p*-nitrobenzoate and the *p*-nitrobenzoate obtained from 1,4-anhydro-5-deoxy-D-*arabino*-hexitol was 100–102°. The infrared spectra of the two nitrobenzoates were similar.

Synthesis of 1,4-Anhydro-5-deoxy-D-arabino-hexitol (VII)

An amount of 95 mg of "3,6-anhydro-2-deoxy-D-galactose" (6) was reduced with sodium borohydride (50 mg) in water (1 ml) for 1 h. The product, 1,4-anhydro-5-deoxy-D-*arabino*-hexitol (86 mg) was a colorless oil; $[\alpha]_D^{25}$ +21° (*c*, 1.7 in ethanol).

Preparation of 1,4-Anhydro-5-deoxy-2,3,6-tri-O-p-nitrobenzoyl-D-arabino-hexitol

1,4-Anhydro-5-deoxy-D-*arabino*-hexitol was reacted with *p*-nitrobenzoyl chloride in the usual way to yield 1,4-anhydro-5-deoxy-2,3,6-tri-*O*-*p*-nitrobenzoyl-D-*arabino*-hexitol, m.p. 159–160°; $[\alpha]_D^{22}$ −96° (*c*, 0.7 in chloroform). Calc. for $C_{27}H_{21}O_{13}N_3$: C, 54.46; H, 3.56. Found: C, 54.61; H, 3.86.

Conversion of 1,4-Anhydro-5-deoxy-D-arabino-hexitol into 2-Deoxy-3-O-(2-hydroxyethyl)-L-glycero-tetritol (VI)

1,4-Anhydro-4-deoxy-D-*arabino*-hexitol (55 mg) was oxidized with 0.1 *M* periodic acid and the product then reduced with sodium borohydride; yield: 51 mg; $[\alpha]_D^{24}$ +17° (*c*, 2.0 in water). The infrared spectrum of this product was similar to those of the triol ethers (V) and (VI).

A 30-mg portion of the triol ether obtained from 1,4-anhydro-5-deoxy-D-*arabino*-hexitol was *p*-nitrobenzoylated in the usual way; m.p. 101–102°; $[\alpha]_D^{24}$ +27° (*c*, 1.1 in chloroform). Calc. for $C_{27}H_{23}O_{13}N_3$: C, 54.30; H, 3.99. Found: C, 54.61; H, 4.00.

Reaction of 3,4-Di-O-acetyl-D-xylal with Carbon Monoxide and Deuterium to Yield 1,5-Anhydro-4-deoxy-D-arabino-hexitol-4,6,6-H_3^2(cis) (VIII) and 1,5-Anhydro-4-deoxy-L-xylo-hexitol-4,6,6-H_3^2 (cis) (IX)

The 3,4-di-*O*-acetyl-D-xylal was reacted with carbon monoxide and deuterium at 130° under similar conditions to those described in the first experiment to yield the above-mentioned deuterated hexitols (VIII) and (IX). The stereochemistry of the deuterium atoms was determined by proton n.m.r. analysis (see Discussion).

ACKNOWLEDGMENTS

The authors gratefully acknowledge the financial assistance of the National Cancer Institute of Canada, the National Research Council, and the University of British Columbia Research Grant. One of us (D. A.) gratefully acknowledges the Standard Oil Fellowship and the University of British Columbia Research Fellowship.

The authors wish to thank Dr. P. A. J. Gorin for furnishing a sample of the tris-*p*-nitrobenzoate of his triol ether (III).

One of us (A. R.) spent the academic year 1963–64 as a guest of the University Chemical

DIAMAGNETIC SUSCEPTIBILITIES OF SOME COMPOUNDS CONTAINING OXYGEN LINKED TO NITROGEN OR PHOSPHORUS

M. W. Lister and R. Marson
Department of Chemistry, University of Toronto, Toronto, Ontario
Received February 7, 1964

ABSTRACT

The diamagnetic susceptibilities of a number of compounds containing oxygen linked to nitrogen or phosphorus have been measured. The results are interpreted in terms of the apparent contribution of the oxygen atoms to the susceptibility in these and other series of compounds, and are compared with other evidence on the nature of the bonds to oxygen. The results support the usual formula of an amine oxide as $R_3N \rightarrow O$, but phosphine oxides behave as would be expected for $R_3P = O$. Phosphorus oxyhalides have molar susceptibilities about 4.6 (in units of -10^{-6} e.m.u.) larger than the corresponding trihalides, a difference close to that for singly bound oxygen in ethers or alcohols. Each oxygen contributes 4.4 in trialkyl phosphites, as might be expected for $P(OR)_3$; but the value in dialkyl phosphites is 4.9 per oxygen, thereby showing behavior similar to that of carboxylic esters. The extra oxygen in trialkyl phosphates as compared with trialkyl phosphites contributes 9.4, a surprisingly large amount.

It has been known since the time of Pascal's extensive work on diamagnetic susceptibilities (1) that the molar susceptibilities of diamagnetic compounds are approximately additive in terms of the atoms they contain, and of certain structural features such as double bonds. Organic compounds of oxygen, in particular, require different values to be assigned to the contribution of an oxygen atom in a ketone, or an ether, or an ester, etc. The object of the present work was to examine the susceptibilities of compounds containing oxygen linked to phosphorus or nitrogen, and to see whether they followed the same pattern as in compounds with oxygen linked to carbon. The interpretation in some cases requires a decision as to whether a given bond is predominantly single or double, and this has been made in the usual way from other properties of the bond, such as its length.

EXPERIMENTAL

Apparatus

The susceptibility measurements were made on a Goüy balance (2). The apparatus was calibrated by oxygen-free benzene, which was assumed to have a susceptibility of -0.7081×10^{-6} e.m.u./g, or -0.6187×10^{-6} e.m.u./ml, as reported by Eggleston, Evans, and Richards (3). The apparent change in weight of the benzene sample in the magnetic field was about 15 mg, and this was measured on a Sartorius microbalance sensitive to 2–3 μg. It was found that the magnetic force for a given magnet current on any particular sample was reproducible to within 0.25%. Since the determination of the molar susceptibilities involves a comparison of the magnetic forces on the sample and on benzene, and since five or six readings of the magnetic forces were always made, it seems reasonable to claim an accuracy in the result of $\pm 0.5\%$.

In order to convert volume susceptibilities to molar susceptibilities, it is necessary to know the density of the substance. Where no reliable value was available in the literature, it was measured in a 10-ml or 25-ml pyknometer, with special precaution against evaporation of volatile liquids. The reproducibility was 0.01% for a non-volatile liquid, but with volatile compounds it was 0.05 to 0.1%.

With solid samples the apparent density was measured directly in the tube used for the magnetic measurements, from the weight and length of the sample. The solid samples were always distilled into the tube, melted, and then allowed to cool. This therefore allows for any shrinkage away from the walls on freezing.

Chemicals

The samples used were prepared as follows. Where a middle fraction of a commercial sample is mentioned, this was always about 20 ml from an initial volume of at least 250 ml. In every case the susceptibility tube was filled by vacuum distillation, and nitrogen was then admitted up to atmospheric pressure.

Triethylamine oxide was prepared by oxidizing triethylamine with 3% hydrogen peroxide for 2 days (4).

The solution was evaporated under reduced pressure to leave an oily residue, which was dried over sodium sulphate and distilled *in vacuo*. It stood in a vacuum desiccator over phosphorus pentoxide for several weeks, and was then redistilled at reduced pressure.

Attempts to prepare trimethylamine oxide in a sufficiently pure state were unsuccessful. Decomposition occurred on melting, and recrystallization from various solvents led to persistent contamination by the solvents. Its instability on melting also prevented filling the susceptibility tube with the molten compound, which gives a uniform column of sample.

Triethylamine from the Eastman Chemical Company was dried over potassium carbonate, and distilled in nitrogen to give a middle fraction boiling at 89.2 °C.

Tripropylamine from the Pennsalt Chemical Company was treated in the same way. The middle fraction boiled at 156 °C.

Tripropylphosphine oxide was prepared by a modification of Pickard and Kenyon's method (5) from phosphorus oxychloride and propyl magnesium bromide in ether. Six hours of refluxing were necessary to give a reasonably complete reaction. After removal of the ether and addition of alkali, the product was distilled off at atmospheric pressure. It was then redistilled *in vacuo*, and dried in a vacuum desiccator. Repeated redistillation under vacuum eventually gave a middle fraction with a constant melting point of 45 °C. Pickard and Kenyon (5) give 38 °C. The compound is very deliquescent.

Trioctylphosphine oxide from Distillation Products Industries Ltd. was fractionally distilled under vacuum to give a sample melting at 57 °C. The melting point was not changed by redistillation.

Phosphorus trichloride from the Eastman Kodak Company was fractionated under reduced pressure, and a middle sample was used which boiled at 76 °C in agreement with earlier measurements (6).

Phosphorus oxychloride from the British Drug Houses Ltd. was fractionally distilled in nitrogen to give a product with a constant b.p. of 106 °C, and m.p. of 1.0 °C. Reference 7 gives m.p. 1.17 °C, b.p. 105.3 to 107.2 °C.

Dialkyl and trialkyl phosphites from the Victor Chemical Company were dried over calcium chloride, and fractionally distilled at low pressures in a slow stream of nitrogen. On redistillation, the middle 10% of the original samples were taken for the susceptibility measurements. The boiling points were checked against the values summarized by Kosolopoff (8) and Van Wazer (9).

Trialkyl phosphates from the Electric Reduction Company were dried briefly over calcium chloride, and redistilled. The boiling points were checked against the values summarized in ref. 8, p. 258; or ref. 9, p. 582.

Phosphorus tribromide was distilled to give a middle fraction boiling at 173 °C in agreement with earlier values (7).

Phosphorus oxybromide was prepared as described in Inorganic Syntheses (10). It was purified by partial crystallization from a melt to give a colorless product melting at 52 °C (ref. 7 gives 51.3 °C).

EXPERIMENTAL RESULTS

The densities were either measured or obtained from the literature. The values used are collected in Table I. The values for tripropylphosphine oxide, trioctylphosphine oxide, and phosphorus oxybromide are effective, and not true, densities, obtained from the length of a known weight of material in the susceptibility tube. The density of solid phosphorus oxybromide had been previously reported (7) as 3.25 g/ml. This is probably too high, as the apparent density was 3.025 g/ml at 25 °C, and the solid showed very little sign of shrinking from the walls of the tube. A density close to 3.025 g/ml is also more consistent with the molar volumes of other phosphorus halides and oxyhalides.

Table I also gives the molar susceptibilities, obtained by multiplying the directly measured volume susceptibilities by the molar volumes. In this table, and in the subsequent discussion, the molar susceptibilities are given in units of -10^{-6} e.m.u.

DISCUSSION OF RESULTS

Earlier measurements have been made on some of the compounds reported above, but these were remeasured either because earlier values disagreed with each other, or as a check on various members of a homologous series. In particular, Francois and Horrau (13) obtained 81.4 for triethylamine, as compared with 83.3 in the present work. Early results (11) gave 66 for phosphorus trichloride, and 68.9 for the oxychloride; more recently Nevgi obtained 61.8 for the oxychloride (14).

Other relevant results in the literature are: phosphorus triethyl, 90.0 (15); triethyl

phosphine oxide, 91.6 (15); triethyl phosphate, 115.3 (16); triethyl phosphite, 104.6 (15); and monoethyl phosphate, 68.9 (15).

In comparing members of a homologous series, it is necessary to estimate the contribution of a CH_2 group. Pacault (1) suggests 11.86 for this, and Angus and Hill (17) suggest 11.69. Other workers have used slightly different values, and it is in fact probable that this quantity is somewhat variable. Where possible, this question will be avoided by comparing compounds with the same number of carbon atoms; in other cases a value of 11.7 can be taken as an average.

The contribution of oxygen atoms linked to carbon has been measured in a wide variety of organic compounds. The average of a number of results (1, 17–22) can be summarized as follows: oxygen in alcohols 4.9; ethers 5.1; aldehydes -0.7; ketones -1.2; carboxylic acids 8.2 (two oxygen atoms); and carboxylic esters 7.4 (two oxygen atoms). These results mean that the difference between an ester, RCOOR′, and a ketone, RR′CO, is 8.5; while between an acid, RCOOH, and an aldehyde, RCHO, the difference is 8.9. These values can serve as a basis for comparison with the contributions of oxygen linked to nitrogen or phosphorus.

In interpreting the susceptibility results, we must first consider what evidence is available about the order of the bonds to oxygen. If we first consider triethylamine oxide, the usual view that nitrogen cannot have more than eight valency electrons suggests the formula $(C_2H_5)_3N \rightarrow O$, with singly bound oxygen. This is supported by the length of the N—O bond in trimethylamine oxide, which is about 1.40 Å (23, 24), and by the force constant of the bond which is in the range 3.8 to 4.8×10^5 dyn/cm (25). The susceptibilities of triethylamine and triethylamine oxide differ by 5.1, a value equal to that for singly bonded oxygen in ethers. Consequently the magnetic results support the formula above. The difference between triethylamine and tripropylamine (11.03 per CH_2) is a little low, but the results are consistent with Francois and Horrau's (13) value of 221.7 for trihexylamine.

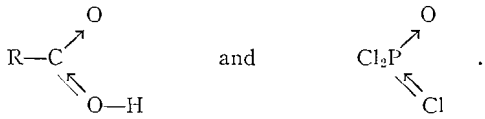
The behavior of phosphine oxides is different, presumably because phosphorus can expand its valency shell at least as far as 12 electrons. The vibration frequency assigned to P—O stretching in trimethylphosphine oxide is 1176 cm^{-1} (26), which would correspond to a force constant of 8.6×10^5 dyn/cm. Robinson (27) has related P—O force constants to bond order in a variety of compounds, and assigns a P—O bond order of 1.76 to this compound. The susceptibilities of phosphine oxides indicate a low contribution by the oxygen. If we allow 11.7 per CH_2, and compare the susceptibilities of triethyl, tripropyl, and trioctyl phosphine oxides with that of triethyl phosphine, the average contribution by the oxygen is 1.2. This is between the values for oxygen in alcohols and ethers (5.0) on the one hand, and aldehydes and ketones (−1.0) on the other, being somewhat closer to the latter. This result is therefore consistent with Robinson's estimate of the bond order.

The phosphorus oxyhalides have stretching force constants of 10.35×10^5 in $POCl_3$, and 9.89×10^5 in $POBr_3$ (27), to which Robinson assigns bond orders of 1.95 and 1.92 respectively. The bond lengths are 1.45 Å in $POCl_3$ (28), and 1.41 Å in $POBr_3$ (29), though the experimental errors are too large to attribute any significance to the apparently shorter bond in $POBr_3$. These distances are much shorter than a single bond, which might be expected to be about 1.71 Å (30). However the susceptibility measurements show a large contribution by oxygen: the difference $\chi(POCl_3) - \chi(PCl_3)$ is 4.7, and $\chi(POBr_3) - \chi(PBr_3)$ is 4.6. This is roughly the contribution of singly bound oxygen, but it is probably better to compare these results with the large contribution of oxygen in oxyacids, and to suggest that in both the electrons are somewhat delocalized by resonance with such structures as



This is supported by the phosphorus halogen distances (see ref. (30), p. 642), which are shorter in $POCl_3$ (1.995 Å) than in either PCl_3 (2.043 Å) or PCl_5 (2.04 and 2.19 Å), and are shorter in $POBr_3$ (2.06 Å) than in either PBr_3 (2.18 Å) or PBr_4^+ (2.13 Å). Against this may be set the fact that the susceptibilities of benzoyl chloride (75.8) and benzyl chloride (82.0) indicate a contribution of −0.4 by the oxygen in benzoyl chloride (if hydrogen has its usual value of 2.9), yet analogous resonance should be possible in compounds of formula RCOCl.

Similarly if we subtract the value for triethyl phosphine from the phosphite and phosphate esters, and allow 11.7 for each extra CH_2, we get the following values for the average contributions of the oxygen atoms: three oxygens in R_2HPO_3, 14.7; three oxygens in $P(OR)_3$, 13.3; four oxygens in R_3PO_4, 22.7. Each oxygen in the trialkyl phosphites contributes 4.4, which is nearly the value for an oxygen in an ether. The bonding of oxygen in trialkyl phosphites and ethers is similar, except for the possibility that the phosphorus can enlarge its valency shell by partial double bonding to the oxygen; if this occurs, it must have only a small effect on the susceptibility.

The usual formula given to dialkyl phosphites is $(RO)_2PH{=}O$, but the contribution of each oxygen is large, being 4.9 on the average. The force constant of the P=O bond in these compounds is about 9.9×10^5 dyn/cm (26, 27), indicating nearly a double bond. Hence their magnetic behavior is like that of the carboxylic esters, whose oxygen contribution is also fairly large (3.7 per oxygen); and their structures are, of course, similar.

The difference $\chi(R_3PO_4) - \chi(R_3PO_3)$ averages 9.4, and is surprisingly large. Here again

the infrared frequency of vibration of the P—O bond is quite high, being about 1275 cm^{-1} (26), corresponding to a force constant (27) of about 10.1×10^5 dyn/cm. This is a much greater susceptibility difference than that for the extra oxygen in going from an ether to a carboxylic ester, which is a somewhat comparable change, since it involves introduction of a doubly bound oxygen. In this latter case the average susceptibility of the extra oxygen is only 2.3. Hence the large increase in the phosphates is not paralleled in compounds with oxygen bound only to carbon. At present no really satisfactory explanation can be offered for this difference.

A MODEL FOR THE HYDROGEN BOND AND PROTON TRANSFER REACTIONS

R. F. W. BADER*

Burke Chemical Laboratories, Department of Chemistry, McMaster University, Hamilton, Ontario

Received March 3, 1964

ABSTRACT

A simple extension of Platt's model for determining the force constants in diatomic hydrides is used to investigate the properties of transition states for proton transfer reactions. The model is first tested by comparing the predicted and observed changes in bond lengths and stretching and bending frequencies for O—H···O systems. The quantities predicted for the transition state are the geometry and the perpendicular bending frequencies. The implications of the results with regard to the interpretation of hydrogen–deuterium kinetic isotope effects are discussed. In particular, the variations in both the isotope effect and the geometry of the transition state with changing acid or base strength are considered in detail.

I. INTRODUCTION

In 1950 Platt (1) proposed a simple but successful method for determining the force constants of diatomic hydrides. It is the purpose of the present work to show that a simple extension of Platt's theory provides useful insights into the nature of the hydrogen bond and into the properties of transition states for the transfer of a proton. Platt's method is essentially an application of the Hellmann–Feynman theorem with simplifying assumptions regarding the form and rigidity of the electron density distribution. In the molecule HX the proton is assumed to be imbedded in a spherical electron density distribution of the united atom with nuclear charge $Z_X + 1$ (or in the density of the corresponding ion, X^-). The equilibrium bond length is therefore equal to the radius of a sphere which contains Z_X electrons, for at this position the force on the proton is zero. In addition, if the assumption of the rigidity of the united atom (or negative ion) charge distribution is postulated to hold when the proton undergoes small displacements from its equilibrium position, then by Poisson's equation the force constant is given by

$$k = 4\pi\rho(\mathrm{H})$$

where $\rho(\mathrm{H})$ is the total electron density at the position of the proton. Longuet-Higgins and Brown (2) have successfully applied the same method to binary hydrides. An explanation for the success of the method in the face of the severe assumption regarding the rigidity of the charge density during a vibration has recently been given by Salem (3) (along with an excellent account of the theoretical interpretation of force constants from a number of approaches). Salem's discussion of the method will be referred to during the development of the model for the hydrogen bond.

II. THE MODEL

The proton is considered initially to be imbedded in the charge density of the ion A^- to give the acid species A—H. This initial condition of electrostatic equilibrium is perturbed by the approach of a base molecule B with its accompanying charge density. The final hydrogen-bonded species is A—H···B, which will be characterized by the new equilibrium distances r_a, r_b (and $R = r_a + r_b$) as shown in Fig. 1.

For personal use only.

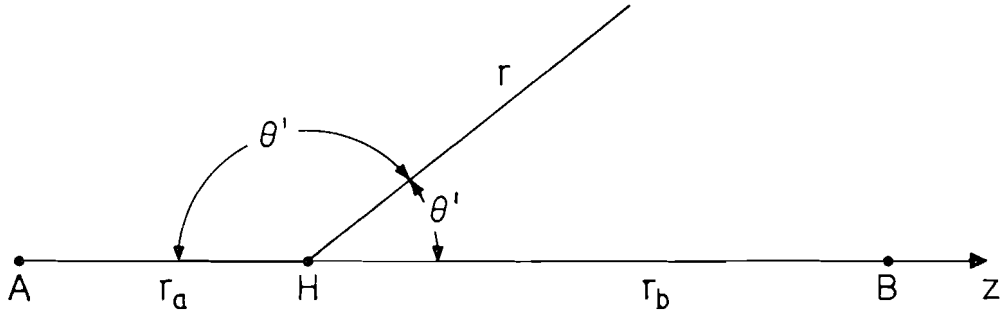

FIG. 1. The coordinate system. The A—B distance is denoted by R in the text.

The atoms A and B may be bonded to atoms other than the proton and the theory will also cover those cases in which the charge densities on A and B are not spherically symmetric.

The potential V of the proton is such that the force exerted on the proton in the z-direction is given by

$$[1] \qquad F_z = -\frac{\partial V}{\partial z_H} = \frac{Z_A}{r_a^2} - \int \frac{\cos\theta'}{r^2}\rho_A d\tau - \frac{Z_B}{r_b^2} + \int \frac{\cos\theta}{r^2}\rho_B d\tau$$
$$= F_{zA} + F_{zB}$$

where ρ_A and ρ_B are the charge densities centered on the acid and base species A and B. Equation [1] assumes that the total charge density is simply

$$\rho = \rho_A + \rho_B.$$

The total charge density correct to the second order in S, the overlap integral for orbitals on A and B is (4)

$$\rho = \rho_A + \rho_B - 2\sum_{i,j}\{2S_{ij}\phi_{iA}\phi_{jB} - S_{ij}^2(\phi_{iA}^2 + \phi_{jB}^2)\}$$

where ϕ_{iA} and ϕ_{jB} are atomic orbitals centered on A and B respectively. The overlap integral for values of R of interest here is 0.02 or less and thus the error in ρ at the position of the proton is less than 0.2%. In addition, applying Mulliken's approximation to the cross term reduces it to

$$S_{ij}\phi_{iA}\phi_{jB} \sim \tfrac{1}{2}S_{ij}^2(\phi_{iA}^2 + \phi_{jB}^2).$$

Thus the bracketed terms in ρ will make no contributions to the electric field and field gradient integrals *evaluated at the proton* when Mulliken's approximation is employed.* The small difference that actually exists between the contribution of $\phi_{iA}\phi_{jB}$ and $(\phi_{iA}^2 + \phi_{jB}^2)$ to these integrals will be multiplied by approximately S_{ij}^2, a very small number.

For a spherical charge distribution

$$\int \frac{\cos\theta}{r^2}\rho_A d\tau = \frac{Q_A}{r_a^2}$$

where Q_A is the total electronic charge contained in a sphere of radius r_a. Thus in this case

**The electric field and field gradient integrals together with the value of ρ at the proton are the only quantities required in the subsequent analysis.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the force F_z reduces to

$$[2] \qquad F_z = \frac{1}{r_a^2}(Z_A - Q_A) - \frac{1}{r_b^2}(Z_B - Q_B).$$

Initially, for the isolated acid molecule A—H, $Z_A = Q_A$ (or the two corresponding terms in equation [1] are equal) and there is no net force on the proton. However, when r_b is finite, the density on the base exerts a resultant positive force on the proton. The original value of r_a must increase to the hydrogen-bonded value until the forces exerted on the proton by A and B are again balanced. Thus the formation of a stable hydrogen bond should always result in a lengthening of r_a over the free acid value, as is indeed observed.

A second differentiation of V with respect to z_H will yield the force constant for the linear displacement of the proton. This can be identified with the force constant for the asymmetric motion of the three-atom system A—H$\cdots$B with A and B held fixed. Consider the case of the spherical distributions first and assume further that the charge densities are rigid.

$$[3] \qquad k_\parallel = \frac{\partial^2 V}{\partial z_H^2} = \frac{2}{r_a^3}(Z_A - Q_A) + \frac{2}{r_b^3}(Z_B - Q_B) + 4\pi(\rho_A(H) + \rho_B(H))$$

where $\rho_A(H)$ and $\rho_B(H)$ are the electron densities at the position of the proton due to A and B. (The $4\pi\rho(H)$ terms are a necessary consequence of Poisson's equation. See equation [4] below.)

Initially, for the free acid A—H, $Z_A = Q_A$ at equilibrium and $k_\parallel = 4\pi\rho_A(H)$. In the presence of the base, as explained above, $Q > Z$ for both acid and base at the hydrogen-bonded equilibrium position for the proton. Thus the final perturbed value for $k_\parallel$ is given by the difference between the positive quantity $4\pi(\rho_A(H) + \rho_B(H))$ and the negative field gradients (the first two terms on the R.H.S. of equation [3]). For values of R encountered in hydrogen bonding the overall value of $4\pi(\rho_A(H) + \rho_B(H))$ is less than the initial value of $4\pi\rho_A(H)$ since the increase in r_a on hydrogen bonding leads to a decrease in $\rho_A(H)$ and $\rho_B(H)$ is not large enough to counteract it.* Furthermore, the creation of the negative field gradients at the proton also leads to an overall decrease in $k_\parallel$. The model therefore predicts a decrease in the A—H stretching frequency $\nu_\parallel$ on hydrogen bond formation. This is in fact one of the most striking characteristics of hydrogen bond formation. From Poisson's equation we have

$$\frac{\partial^2 V}{\partial z^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial x^2} = 4\pi\rho(H)$$

or

$$[4] \qquad k_\parallel + 2k_\perp = 4\pi(\rho_A(H) + \rho_B(H))$$

where $k_\perp$ is the force constant for the displacement of the proton perpendicular to the bond. For spherical (or axially symmetric) distributions on A and B the two perpendicular frequencies will form a degenerate pair with identical force constants. For the above case $2k_\perp$ is in fact just the negative of the parallel field gradient at the proton.

$$2k_\perp = -\frac{2}{r_a^3}(Z_A - Q_A) - \frac{2}{r_b^3}(Z_B - Q_B)$$

**The electron density falls off exponentially from both centers. Thus, $|d\rho_A/dr_A| > |d\rho_B/dr_B|$ since $r_A < r_B$ and the final value of $\rho(H)$ will therefore, be less than $\rho_A(H)$ initial.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Initially, for $Z_A = Q_A$, $k_\perp$ will be zero, but the hydrogen bond formation leads to negative values for the parallel field gradient at the proton and thus to positive values for the perpendicular frequencies. The magnitude of these frequencies will increase as the field gradient becomes more negative and this in turn occurs with increasingly stronger hydrogen bonds. Thus the model predicts the appearance of (or increase in, if A—H was initially polyatomic) the perpendicular bending frequencies and the increase in these frequencies at the direct expense of the parallel frequency (see equation [4]) as the strength of the hydrogen bond increases. This is again in direct accord with observation.

For non-spherical charge distributions, differentiation of equation [1] without assuming the charge clouds to be rigid gives

$$k_\parallel = \frac{2Z_A}{r_a^3} + \frac{2Z_B}{r_b^3} - \int\left(\frac{3\cos^2\theta - 1}{r^3}\right)(\rho_A + \rho_B)\,d\tau + 4/3\pi(\rho_A(H) + \rho_B(H)) - \int\left(\frac{\cos\theta}{r^2}\right)\left(\frac{\partial}{\partial z_H}[\rho_A + \rho_B]\right)d\tau \quad [5]$$

as first shown by Salem (3) for the case of a diatomic molecule. For the correct density distribution ρ, this is an exact equation and follows directly from the Hellmann–Feynman theorem (3). Salem has pointed out that the success of Platt's model is in the fortuitous cancellation of the last term in [5], which arises from the change in the density due to the motion of the proton, with the amount by which the total electron density at the proton is underestimated in the united atom (or negative ion) model. That is, $4\pi\rho(H)$ is underestimated in Platt's model and the last term in [5] is discarded. The result is close to the truth due to the approximate cancellation of these two effects for motions of a hydrogen atom. Thus equation [5] reduces to

$$k_\parallel = \frac{2Z_A}{r_a^3} + \frac{2Z_B}{r_b^3} - \int\left(\frac{3\cos^2\theta - 1}{r^3}\right)(\rho_A + \rho_B)d\tau + 4/3\pi(\rho_A(H) + \rho_B(H)) \quad [6]$$

which in turn reduces to [3] when ρ_A and ρ_B are spherical charge distributions. The discussion of equation [6] for ρ_A and ρ_B of arbitrary symmetry parallels that of equation [3]. Equation [4], of course, holds true for non-symmetrical charge distributions as well.

It can be seen that this simple model embodies all of the important changes which occur on hydrogen bond formation. The close proximity of the base creates an imbalance in the forces operating on the proton with the net result that the original bond length r_a must *increase* to the hydrogen-bonded value. Accompanying this is a decrease in the local electron density in the vicinity of the proton and thus a *decrease* in the frequency of the original A—H stretching mode, one of the most characteristic features of hydrogen bond formation. In addition the parallel field gradient at the proton becomes more negative, leading to an increase in the perpendicular frequencies of vibration, another characteristic feature of hydrogen bond formation.

An even closer approach of the base from its position in the hydrogen-bonded system can result in the transfer of the proton. Thus the same model may be employed for an investigation into the properties of transition states for the transfer of a proton. The model for the transition state is thus a perturbed hydrogen bond, with the special requirement that the force constant $k_\parallel$ go to zero.

We wish to determine, with the aid of this model, what effects changes in the electron densities of the acid and base species have on the properties of a transition state. For this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

reason we retain the electron density ρ as the one flexible parameter. There are more detailed treatments of the hydrogen bond itself, for example, that of Reid (5), but this is accomplished at the expense of employing empirical potential functions with adjustable parameters which can be related to the electronic situation only in terms of "ionic" and "covalent" character. The present model is an attempt to obtain direct relationships between assumed electron densities and the properties of the hydrogen bond and proton transition states.

We shall proceed by first testing the ability of the model to predict the changes in r_a, $\nu_\parallel$, and $\nu_\perp$ brought about by hydrogen bond formation. Since there is a great deal of experimental data regarding O—H···O bonds we consider such a system. Using the same models for the A and B species developed for the hydrogen-bonded systems we then predict values of r_a, $\nu_\perp$, *and* R for transition states involving the transfer of a proton between two oxygen atoms.

III. APPLICATION TO HYDROGEN-BONDED SYSTEMS

Pimentel and Sederholm (6) have shown that an approximate linear relation holds between $\Delta\nu_\parallel$, the shift in the A—H stretching frequency, and R the overall length of the hydrogen bond for O—H····O bonds in crystals. In a crystalline hydrate, the crystal structure is primarily determined by the large forces operative between the ions and the relative sizes of the ions. The net result of these primary effects is the placing of an O—H bond at some distance from an adjacent $\diagup\!\!\diagdown$O atom and thus hydrogen bonds are formed at a number of different R values for different crystals. This situation provides a good opportunity to test the theory, as a single acid and a single base model may be chosen and the calculation carried out at a number of different values of R.

The electron density distribution for the acid species is that of O^- and this is taken to be spherically symmetrical. The fact that the ion is one electron short of a truly spherical density distribution does not change the calculated values by any large amount. The effective nuclear charge for $2s$ and $2p$ orbitals of an O^- ion by Slater's rules is 2.10. This gives a value of $\nu_\parallel = 3840$ cm^{-1} for the free A—H species at the equilibrium bond length for water. The observed value of ν_3 for a free water molecule is 3760 cm^{-1}. It is not necessary to consider the two inner shell electrons in these calculations as

$$\int \frac{\cos\theta}{r^2}\rho(1s_A{}^2)\,d\tau \text{ and } \int\left(\frac{3\cos^2\theta - 1}{r^3}\right)\rho(1s_A{}^2)\,d\tau$$

both reduce simply to $2(1/r_a{}^2)$ and $2(2/r_a{}^3)$ respectively. Thus the inner shell electrons effectively screen two units of the nuclear charge. This follows because the $1s$ electrons are so tightly bound to the nucleus that their entire charge density lies well within the sphere defined by r_a or r_b.* The model for the base must be more sophisticated as a neutral base species with a spherical charge density will not exert an attractive force on a positive charge at any distance. Instead, a density distribution corresponding to some valence state of an oxygen atom is employed. When engaged in hydrogen bonding, the most effective valence state density distribution for an oxygen atom is that corresponding to sp^3 hybridization with two orbitals (the lone pairs) fully occupied and two orbitals (the bonds to the hydrogens) singly occupied. In addition, further polarization of the total

**There is no need to make the 2s orbital orthogonal to the 1s orbital. The required integrals for the force and field gradient change only in the third place due to this nonorthogonality. This again is due to the fact that the 1s electron density is vanishingly small at the proton.*

charge density may occur through the unequal sharing of the density in the bonding orbitals. This can be taken into account in this simple valence state model by assigning occupation numbers greater than unity to the two bonding orbitals. The final electron density expression for the oxygen atom then becomes

$$\rho_B = \left(1 + \frac{1}{2}n\right)s^2 + \left(5/3 + \frac{1}{6}n\right)p_\sigma{}^2 + 4/3(1 + n)p_\pi{}^2 + \frac{1}{\sqrt{3}}(2 - n)sp_\sigma$$
