The ketone, XI (3.75 g) was dissolved in dry benzene (60 ml) and then put into the dropping funnel which already contained dry dioxane (100 ml) and anhydrous ether (50 ml). This solution was added dropwise, over a period of 12 minutes, to a stirred refluxing solution of lithium aluminum hydride (2.14 g) in a mixture of dry dioxane (34 ml) and ether (150 ml). The reaction mixture was refluxed for a further 65 minutes and then cooled to 0°. The excess hydride was destroyed by careful addition of water and the resulting mixture was acidified with concentrated sulphuric acid (7.2 ml) diluted with water (84 ml). The organic layer was separated and the aqueous layer was extracted several times with benzene. The combined benzene extract was washed with cold water and then dried over magnesium sulphate. Removal of the solvent yielded the crude product (3.737 g). This material was purified by chromatography on deactivated alumina (260 g, approx. activity II–III). Elution with 1:1 benzene – petroleum ether provided a small amount of starting material and further elution with 3:2 chloroform–benzene yielded the desired alcohol, XII. After two recrystallizations from benzene – petroleum ether, the pure product was obtained as colorless needles, m.p. 150–150.5°. Infrared: 2.97 μ; ultraviolet: λ_{max} 228 (log ϵ 4.82), 254.5 (log ϵ 3.67), 266 (log ϵ 3.75), 276 (log ϵ 3.76), 287 (log ϵ 3.60), 307 (log ϵ 3.08), broad shoulder at 315 mμ (log ϵ 3.15), 321 (log ϵ 3.31), 329 (log ϵ 3.24), and 335.5 mμ (log ϵ 3.40); λ_{min} 252 (log ϵ 3.66), 259 (log ϵ 3.66), 271 (log ϵ 3.70), 284 (log ϵ 3.59), 302 (log ϵ 3.01), 310 (log ϵ 3.08), 325 (log ϵ 3.20), and 331 mμ (log ϵ 3.23); n.m.r. signals: 8.83 τ (angular methyl, area = 3H), multiplet centered at 6.50 τ (*H*—C(OH)—, area = 1H), 6.17 τ (CH_3O—, area = 3H), multiplet centered at 2.58 τ (aromatic H, area = 5H). Found: C, 80.82; H, 8.19; O, 10.63. Calc. for $C_{20}H_{24}O_2$: C, 81.04; H, 8.16; O, 10.80.

Synthesis of cis-2-Methoxy-8α-acetoxy-10a-methyl-5,6,6a,7,8,9,10,10a-octahydrochrysene (XIII)

The alcohol, XII, (4.672 g) was treated with *p*-toluenesulphonic acid monohydrate (156 mg) and isopropenyl acetate (80 ml) and the mixture was heated on a steam bath for 4½ hours. The reaction mixture was cooled to room temperature and pyridine (10 drops) was added. The solvent was evaporated on a steam bath *in vacuo* and the residue was dissolved by the addition of benzene and water. The layers were separated and the aqueous solution was extracted twice with benzene. The combined benzene extract was washed twice with cold water and then dried over anhydrous magnesium sulphate. Removal of the solvent on a steam bath *in vacuo* gave the crude acetate (5.34 g). After four recrystallizations from benzene – petroleum ether, the pure acetate, XIII, m.p. 158–159° was obtained. Infrared: 5.82 μ; ultraviolet: λ_{max} 228 (log ϵ 4.82), 254 (log ϵ 3.64), 266 (log ϵ 3.73), 276 (log ϵ 3.75), 287 (log ϵ 3.58), 308 (log ϵ 3.06), broad shoulder at 315 (log ϵ 3.11), 321 (log ϵ 3.29), 329 (log ϵ 3.22), and 335 mμ (log ϵ 3.40); λ_{min} 251 (log ϵ 3.63), 259 (log ϵ 3.63), 271 (log ϵ 3.68), 284 (log ϵ 3.56), 302 (log ϵ 2.92), 310 (log ϵ 2.99), 325 (log ϵ 3.18), and 331 mμ (log ϵ 3.21); n.m.r. signals: 8.78 τ (angular methyl, area = 3H), 8.13 τ (CH_3—C(=O)—O—, area = 3H), 6.17 τ (CH_3O—, area = 3H), broad signal centered at 5.21 τ (H—C(OAc)—, area = 1H), multiplet centered at 2.55 τ (aromatic H, area = 5H). Found: C, 78.12; H, 7.61; O, 14.40. Calc. for $C_{22}H_{26}O_3$: C, 78.01; H, 7.69; O, 14.20.

Synthesis of cis-2-Methoxy-8α-acetoxy-5-keto-10a-methyl-5,6,6a,7,8,9,10,10a-octahydrochrysene (IV)

(a) By Oxidation with t-Butyl Chromate

The methoxy-acetate, XII (250 mg) was dissolved in dry carbon tetrachloride (9 ml) and *t*-butyl chromate solution (3 ml, about 0.009 moles CrO_3) was added. The mixture was refluxed, with stirring, for 4½ hours after which time, the mixture was cooled to 0°, and treated with a solution of oxalic acid (0.9 g) in water (10 ml). The reaction mixture was then stirred, with a little cooling, for 2 hours. Chloroform and water were added and the layers were separated. The aqueous solution was extracted several times with chloroform and the combined organic extract was washed successively with cold water, a 1:1 mixture of saturated aqueous sodium bicarbonate and 1 *N* sodium carbonate solution and finally water. The carbonate solution was extracted once with chloroform, then acidified with concentrated sulphuric acid, and the resulting aqueous acidic layer was extracted with chloroform to yield, after removal of solvent, 6 mg of an acidic product.

The original organic layer and the chloroform extract of the carbonate layer were combined and washed with cold water until the washings were neutral to litmus. The organic layer was dried over anhydrous magnesium sulphate and, after removal of the solvent, provided a crude neutral product (186 mg). The

For personal use only.

material was purified by chromatography on silica gel (12 g). Elution with 2:1 benzene – petroleum ether provided some starting material (48 mg, 19% recovery) and further elution with 3:1 benzene – petroleum ether yielded the desired ketone, IV (81 mg, 31% yield). After two recrystallizations from benzene – petroleum ether, a pure sample of IV was obtained, m.p. 143–144.5°. Infrared: 5.79 μ, 6.03 μ; ultraviolet: λ_{max} 220 (log ϵ 4.71), 247 (log ϵ 4.45), 316 (log ϵ 3.87), and broad shoulder at 348 mμ (log ϵ 3.61); λ_{min} 232 (log ϵ 4.28) and 278 mμ (log ϵ 3.35); n.m.r. signals: 8.63 τ (angular methyl, area = 3H), 8.13 τ (CH_3—$\overset{\overset{O}{\|}}{C}$—O—, area = 3H), 6.12 τ (CH_3O—, area = 3H), broad signal centered at 5.20 τ (H—$\overset{|}{C}$—OAc, area = 1H), multiplet centered at 2.52 τ (aromatic H, area = 4H), doublet centered at 0.78 τ (C_4 aromatic H, area = 1H). Found: C, 75.08; H, 6.93; O, 18.09. Calc. for $C_{22}H_{24}O_4$: C, 74.97; H, 6.86; O, 18.16.

(b) By Oxidation with Chromium Trioxide

The methoxy-acetate, XII (0.5 g) was dissolved in a mixture of glacial acetic acid (9.9 ml) and water (0.1 ml). A chromic acid solution (0.337 g CrO_3 in 0.63 ml 80% aqueous acetic acid) was added dropwise, over a period of 45 minutes, to the mixture kept at room temperature. The reaction mixture was stirred for a further 36 hours at room temperature, then 95% ethyl alcohol (15 ml) was added to destroy the excess chromic acid. Water and chloroform were then added and the layers separated. The aqueous solution was extracted several times with chloroform. The combined chloroform extract was washed twice with cold water, twice with saturated sodium bicarbonate solution, and then four times with a 1:1 saturated sodium bicarbonate – 1*N* sodium carbonate solution. The alkaline aqueous extracts were combined and extracted twice with chloroform. These chloroform extracts were combined with the original reddish-orange chloroform extract, washed with water, and then finally dried over anhydrous magnesium sulphate. Removal of the solvent *in vacuo* provided the crude neutral material (0.461 g). This material was dissolved in 3:2 benzene – petroleum ether (5 ml) and chromatographed on silica gel. Elution with benzene provided some starting material (59 mg, 12% recovery) and further elutions with the same eluant gave the desired ketone, IV (64 mg, 12% yield). This ketone was identical with that obtained from the *t*-butyl chromate oxidation.

A GENERAL SYNTHESIS OF NUCLEOSIDE-5′ TRIPHOSPHATES[1]

J. G. MOFFATT
Syntex Institute for Molecular Biology, Palo Alto, California
Received August 15, 1963

ABSTRACT

The reaction between ribo- and deoxyribo-nucleoside-5′ phosphoromorpholidates and tributylammonium pyrophosphate in molecular sieve dried dimethyl sulphoxide has been found to give the nucleoside-5′ triphosphates in 81–84% yields. A convenient work-up of the triphosphates following ion exchange chromatography permits isolation of the triphosphates in overall yields of 73–80% as the pure sodium salts. A number of examples of the reaction are given.

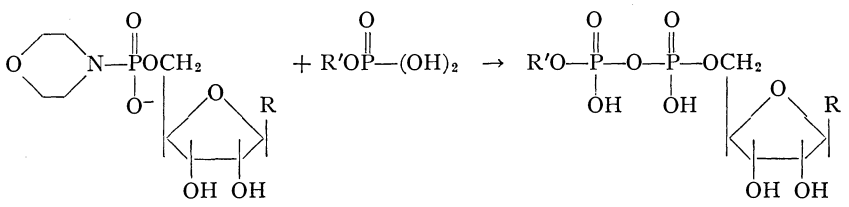
Progress in biochemical research during recent years has clearly pointed out the unique importance of ribo- and deoxyribo-nucleoside-5′ triphosphates in biological systems. Thus, in addition to the well-known role of adenosine-5′ triphosphate (ATP) as the primary energy source in many systems, the nucleoside triphosphates also serve as direct precursors of both ribonucleic (1) and deoxyribonucleic (2) acids, and of nucleotide coenzymes (3). Certain triphosphates also act as rather poorly understood specific cofactors for certain biological transformations (4). This multiplicity of function of nucleoside triphosphates has led to a demand for efficient synthetic routes to the compounds, and a considerable effort has been made in this direction (5). The general method which has been most widely used to date consists of the reaction of a nucleoside-5′ phosphate with a large excess of inorganic orthophosphate in the presence of dicyclohexylcarbodiimide (6). This method was much improved when it was realized that the reaction could be conducted in anhydrous pyridine if the tributylamine salts of the various acidic components were used (7). This modification allowed the reaction to be run for the first time in a homogeneous system and also led to the selective formation of the nucleoside triphosphates in considerably higher yield than the other mixed products. In order to achieve a satisfactory yield, however, it was necessary to use at least 10 molar equivalents of orthophosphate. The presence of the resulting large excess of mixed inorganic polyphosphates formed during the reaction necessitated selective adsorption of the nucleotides on carbon followed by elution with ethanolic ammonia prior to ion exchange chromatography. Such a step frequently leads to considerable losses of the nucleotidic material and usually the final isolated yields are far below those present in the crude reaction. In spite of this, the simplicity of the method has made this the most widely used route to nucleoside triphosphates (8).

The development of a simple general method for the conversion of nucleoside-5′ phosphates into activated but insolable phosphoramidate (9), and in particular phosphoromorpholidate (10), derivatives (I) has opened the way to syntheses, in high yield, of nucleoside-5′ diphosphates (III, R′ = H) and nucleotide coenzymes (III, R′ = sugars, etc.) by their reaction with orthophosphate (II, R′ = H) or various phosphate monoesters (II, R′ = sugar, etc.) in anhydrous solvents (10, 11, 12).

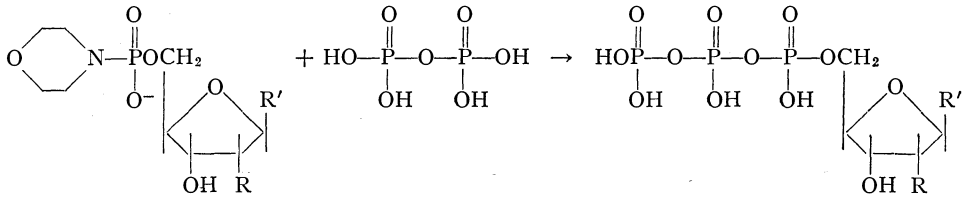
In an earlier paper (10), the attempted extension of the above reactions to the direct synthesis of a nucleotide-5′ triphosphate through the reaction of adenosine-5′ phosphoromorpholidate (IV, R = OH, R′ = adenine) with tributylammonium pyrophosphate in

[1]*Contribution No. 3 from the Syntex Institute for Molecular Biology, Palo Alto, California.*



I II III

anhydrous pyridine was described. This reaction led rather rapidly to a moderate yield (57%) of adenosine-5′ triphosphate (V, R = OH, R′ = adenine) within 2 hours but on prolonged reaction this initial product disappeared and was converted into adenosine-5′ diphosphate, which was present in 76% yield after 24 hours. Further studies on this reaction (13) have shown it to be quite general, the rate of disappearance of the initially



IV V

formed triphosphate being a function of the particular nucleotide under consideration (14).* It is, moreover, possible to conduct the reaction using only 3–4 molar equivalents of pyrosphosphate without appreciable formation of P^1,P^4-dinucleoside-5′ tetraphosphates (13). Since the excess pyrophosphate is not chemically activated, and hence remains substantially unchanged, it is possible to separate the resulting nucleotides by ion exchange chromatography without the necessity of charcoal absorption. Several other workers (15) have also studied the reaction of nucleoside-5′ phosphoramidates with pyrophosphate in a variety of solvents but only in a recent study by Ikehara and Ohtsuka (15(*d*)) has any mention been made of the disappearance of the initial products, and the final yields have not been sufficiently good to make this route superior to the carbodiimide reaction. Only in the work of Tanaka *et al.* (15(*b*)) was pure pyrophosphate free of large amounts of orthophosphate used, thus allowing a critical examination of the desired reaction.

It was of considerable importance to devise reaction conditions such that degradation of the initially formed triphosphates did not occur and this product could be isolated in high yield. As a result of another study in this laboratory (14), it was observed that while tributylammonium adenosine-5′ triphosphate was rapidly converted into a complex mixture of products in pyridine (10) it was virtually completely stable in a number of other anhydrous organic solvents. One such agent is dimethyl sulphoxide which offers particular interest in view of its high solvent power for nucleotides. Accordingly the reaction of deoxyadenosine-5′ phosphoromorpholidate (IV, R = H, R′ = adenine) with tributylammonium pyrophosphate was studied in dimethyl sulphoxide. Initially the two components were separately rendered anhydrous by coevaporation with pyridine and then mixed in distilled dimethyl sulphoxide. The reaction proceeded

**Verheyden and Moffatt will describe shortly a detailed study of the interesting decomposition of the nucleoside polyphosphates in certain anhydrous organic solvents.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

quite rapidly, the morpholidate having almost completely disappeared after 10 hours, and the product distribution remaining unchanged after 24 hours. The products were separated by ion exchange chromatography on a DEAE cellulose column in the bicarbonate form using a linear gradient of triethylammonium bicarbonate as eluant.* Under these conditions, the major product was indeed deoxyadenosine-5′ triphosphate (54%). Only small amounts (2% and 10% respectively) of deoxyadenosine-5′ phosphoromorpholidate and deoxyadenosine-5′ diphosphate were present but deoxyadenosine-5′ monophosphate comprised 34% of the total nucleotides. This picture was surprisingly reproducible under a variety of reaction conditions including further coevaporation of the final reaction mixture with pyridine and dropwise addition of the morpholidate. When, however, the dimethyl sulphoxide was dried by standing for several days with a molecular sieve† and then used in a similar reaction, the yield of deoxyadenosine-5′ triphosphate rose to 82% with only 6%, 7%, and 5% respectively of the unreacted morpholidate, monophosphate, and diphosphate. It appears, therefore, that, as was found earlier (10, 11) in experiments leading to the synthesis of nucleotide coenzymes in pyridine, it is essential to maintain conditions as anhydrous as possible to avoid simple hydrolysis of the morpholidate. It is interesting to note that when molecular sieve dried dimethyl sulphoxide was used the reaction becomes much slower, usually 48–72 hours being necessary for disappearance of nearly all the morpholidate.

Isolation of the product in a water-soluble, non-hygroscopic, solid form is readily accomplished by removal of excess triethylammonium bicarbonate by low temperature evaporation, and adding an excess of sodium iodide in acetone to a concentrated solution of the resulting triethylammonium salt of the nucleotide in methanol. Recoveries of the resulting sodium salt are generally excellent and the products as directly obtained are suitable for use in biochemical studies.

This general procedure has been used for the synthesis of all the normal deoxynucleoside-5′ triphosphates and also several ribonucleoside-5′ triphosphates. The results are summarized in Table I and it can be seen that in all cases the yield of pure isolated sodium

TABLE I

Product distribution of the various nucleoside polyphosphates

	% yields based on starting material				
Nucleoside	Morpholidate	$MonoPO_4$	$DiPO_4$	$TriPO_4$	Isolated Na salt of $TriPO_4$
Deoxyadenosine	6	7	5	82	73
Deoxycytidine	6	5	7	82	80
Deoxyguanosine	3	7	6	82	77
Thymidine	5	4	9	81	75
Cytidine	4	5	7	84	80

salt fell in the range 70–80% thus being much higher than those by any previous method. Several triphosphates have also been prepared from P^{32}-labeled ribo- and deoxyribonucleotides in connection with another problem which will be reported on at a later date (16).

It is our experience that it is very difficult to isolate nucleoside polyphosphates (particularly the tri- or higher phosphates) from columns in the chloride form without minor decomposition to the lower homologues. This does not appear to be a problem with the bicarbonate columns.

†*Type 10X obtained through the courtesy of the Linde Co., Los Angeles. More recently we have been informed by this company that type 4A might be the agent of choice for drying dimethyl sulphoxide.*

It is interesting to note the remarkable consistency of product distribution for the various reactions summarized in Table I. The small amount of diphosphate which invariably appears seems not to be due to the presence of orthophosphate in the reagent grade sodium pyrophosphate used in these experiments. Indeed measurement of the orthophosphate content by the method of Lowry and Lopez (17) shows that less than 0.1% of the total phosphorus is orthophosphate. It is particularly to be emphasized that in no case is there any contamination of the triphosphate peak by inorganic phosphates even without prior necessity of charcoal adsorption and elution. The combination of simplicity, high yield, and purity of the products clearly makes the procedure of unique value in the synthesis of nucleoside triphosphates. The efficient syntheses of nucleoside-5′ diphosphates previously reported using pyridine as the solvent (10) perhaps make the use of dimethyl sulphoxide unnecessary in these syntheses but an extension of the previous method to the direct synthesis of nucleoside-5′ tetraphosphates using tripolyphosphate will be described at a later date.

EXPERIMENTAL

Paper chromatography was conducted by the descending technique on Schleicher and Schuell No. 589 Orange Ribbon paper using the following solvent systems: solvent I, isobutyric acid : 1 *N* ammonium hydroxide : 0.1 *M* tetrasodium ethylenediamine tetraacetic acid (60:100:1.6); solvent II, *n*-propyl alcohol : ammonium hydroxide : water (6:3:1). R_f's of all pertinent compounds in solvent I are given in Table II

TABLE II

Compound	R_f in solvent I	Compound	R_f in solvent II
Deoxyadenosine-5′ phosphate	0.66	Thymidine-5′ phosphate	0.44
Deoxyadenosine-5′ diphosphate	0.53	Thymidine-5′ diphosphate	0.30
Deoxyadenosine-5′ triphosphate	0.41	Thymidine-5′ triphosphate	0.21
Deoxycytidine-5′ phosphate	0.55	Cytidine-5′ phosphate	0.43
Deoxycytidine-5′ diphosphate	0.40	Cytidine-5′ diphosphate	0.29
Deoxycytidine-5′ triphosphate	0.30	Cytidine-5′ triphosphate	0.21
Deoxyguanosine-5′ phosphate	0.36	6-Azauridine-5′ phosphate	0.24
Deoxyguanosine-5′ diphosphate	0.25	6-Azauridine-5′ diphosphate	0.16
Deoxyguanosine-5′ triphosphate	0.19	6-Azauridine-5′ triphosphate	0.12

with the exception of the morpholidates which decompose in this system. In all cases the disappearance of the morpholidate may be conveniently followed using solvent II in which they move far ahead of the corresponding monophosphates. Phosphorus-containing compounds were localized on paper chromatograms using the Hanes and Isherwood spray (18) followed by ultraviolet irradiation (19). Total phosphorus determinations were done by the method of King (20) and ultraviolet spectra were recorded on a Cary Model 15 spectrophotometer. Elemental analyses (other than for phosphorus) were obtained by Midwest Microlab Inc., Indianapolis, Indiana. All evaporations were done at approximately 1 mm pressure using a rotary-type evaporator in which the condensing bulb was cooled with circulating aqueous glycol at −10° to −20° C.

Deoxyadenosine-5′ phosphoromorpholidate (IV, R′ = adenine, R = H).—This material was prepared and isolated in 91% yield as its 4-morpholine N,N′-dicyclohexylcarboxamidinium salt by the general procedure previously reported (10). As directly obtained the chromatographically pure material (R_f 0.54 in solvent II) was a tetrahydrate (equivalent weight 776 by spectra) but after drying in 80° *in vacuo* the dihydrate was obtained. Calc. for $C_{31}H_{52}N_9O_7P \cdot 2H_2O$: C, 51.00; H, 7.73; N, 17.28. Found: C, 50.33; H, 8.23; N, 17.36.

Deoxyguanosine-5′ phosphoromorpholidate (IV, R′ = guanine, R = H).—Isolated as the tetrahydrate of its 4-morpholine N,N′-dicyclohexylcarboxamidinium salt in 95% yield by the usual procedure (10). R_f 0.35 in solvent II. Drying *in vacuo* at 80° gave the monohydrate. Calc. for $C_{31}H_{52}N_9O_8P \cdot H_2O$: C, 51.18; H, 7.48; N, 17.33. Found: C, 52.02; H, 8.23; N, 17.27.

6-Azauridine-5′ phosphoromorpholidate (IV, R′ = 6-azauracil, R = OH).—This material was obtained in the usual way (10) from 6-azauridine-5′ phosphate* and isolated in 89% yield as its chromatographically pure

**Prepared by phosphorylation of 2′,3′-O-isopropylidine 6-azauridine by the cyanoethyl phosphate method (see ref. (21)). Details will be published shortly.*

4-morpholine N,N′-dicyclohexylcarboxamidinium salt. R_f 0.36 in solvent II. Calc. for $C_{29}H_{50}N_7O_{10}P \cdot H_2O$: C, 49.38; H, 7.43; N, 13.90. Found: C, 49.04; H, 7.86; N, 14.08.

Nucleoside-5′ triphosphates. General procedure.—Reagent grade tetrasodium pyrophosphate $\cdot 10H_2O$ (1 mmole, 446 mg) is dissolved in water and passed through a column containing Dowex 50-W resin in the pyridine form (15 ml). The resin is then washed with water (30 ml) and the total effluent evaporated *in vacuo* to a volume of approximately 10 ml. Pyridine (30 ml) is then added followed by tri *n*-butylamine (1.0 ml, 4.2 mmoles). The resulting homogeneous solution is evaporated to a syrup and tendered anhydrous by four evaporations with 10-ml portions of pyridine (dried by distillation from, and stored over calcium hydride). The residual pyridine is then removed by two evaporations with 5-ml portions of calcium hydride dried benzene. Separately the 4-morpholine N,N′-dicyclohexylcarboxamidinium salt of the nucleoside-5′ phosphoromorpholidate (0.25 mmoles) is dried by two evaporations with 5-ml portions of pyridine followed by two evaporations of the residue with benzene (5 ml each). The pyrophosphate is then transferred onto the dried morpholidate with the aid of four 1.0-ml portions of dimethyl sulphoxide* which had been dried by distillation and storage for at least several days, over Linde Molecular Sieve Type 10X. The resulting clear solution is kept at room temperature for 2 to 4 days, the disappearance of the morpholidate being readily followed by chromatography in solvent II. Water (30 ml) is then added and the solution is directly applied to a 2×35-cm column of DEAE cellulose† in the bicarbonate form. The column is then washed with water until the optical density of the effluent falls to zero and the components are eluted using a linear gradient of triethylammonium bicarbonate. In each case the mixing vessel initially contains 1500 ml of water and the reservoir contains 1500 ml of 0.35–0.45 *M* triethylammonium bicarbonate depending upon the individual nucleotides being separated. In the cases of deoxyadenosine, thymidine, deoxycytidine, and cytidine-5′ triphosphate, 0.35 *M* salt is used while with deoxyguanosine and azauridine-5′ triphosphates 0.40 *M* and 0.45 *M* respectively are necessary. In each case four clearly separated ultraviolet-absorbing peaks are observed and the recovery of optical density is quantitative. The product distributions are shown in Table I. The pooled triphosphate peak is evaporated to dryness with a bath temperature of 30–35°, and all residual triethylammonium bicarbonate removed by four evaporations with 25-ml portions of methanol. The final residue is dissolved in approximately 5 ml of methanol and a 1 *M* solution of sodium iodide in acetone (6 equivalents relative to the nucleoside by spectra) is added followed by 75 ml of acetone. The precipitate is collected by centrifugation, washed three times with 30-ml portions of acetone, and dried overnight *in vacuo* over phosphorus pentoxide at room temperature. In each case the product is a white, freely water-soluble and non-hygroscopic powder which is chromatographically homogeneous in solvents I and II.

Deoxyadenosine-5′ triphosphate (V, R′ = adenine, R = H).—The final isolated yield of the tetrasodium salt hexahydrate was 73%. Calc. for $C_{10}H_{12}N_5O_{12}P_3Na_4 \cdot 3H_2O$: C, 18.97; H, 2.87; N, 11.06. Ratio of P:deoxyadenosine,‡ 3.0. Found: C, 19.06; H, 3.12; N, 10.91; P/dAdenosine, 3.12.

Deoxycytidine-5′ triphosphate (V, R′ = cytosine, R = H).—The tetrasodium salt monohydrate was isolated in 80% yield. Calc. for $C_9H_{12}N_3O_{13}P_3Na_4 \cdot H_2O$: N, 7.33; P/dCytidine, 3.0 Found: N, 7.29; P/dCytidine, 2.93.

Deoxyguanosine-5′ triphosphate (V, R′ = guanine, R = H).—The tetrasodium salt trihydrate was isolated in 77% yield. Calc. for $C_{10}H_{12}N_5O_{13}P_3Na_4 \cdot 3H_2O$: N, 10.79; P/dGuanosine, 3.0. Found: N, 10.78; P/dGuanosine, 2.90.

Thymidine-5′ triphosphate (V, R′ = thymine, R = H).—The tetrasodium salt dihydrate was isolated in 75% yield. Calc. for $C_{10}H_{13}N_2O_{14}P_3Na_4 \cdot 2H_2O$: N, 4.62; P/Thymidine, 3.00. Found: N, 4.65; P/Thymidine, 3.15.

Cytidine-5′ triphosphate (V, R′ = cytosine, R = OH).—The anhydrous tetrasodium salt was isolated in 80% yield. Calc. for $C_9H_{12}N_3O_{14}P_3Na_4$: N, 7.36; P/Cytidine, 3.00. Found: N, 7.30; P/Cytidine, 2.94.

6-Azauridine-5′ triphosphate (V, R′ = 6-azauracil, R = OH).—Isolated as the trisodium salt dihydrate in 77% yield. Calc. for $C_8H_{10}N_3O_{15}P_3Na_4 \cdot 2H_2O$: N, 7.11; P/Azauridine, 3.0. Found: N, 6.98; P/Azauracil, 3.12.

SYNTHESIS OF 5-ACETAMIDO SUBSTITUTED BARBITURATES

PRITAM SINGH AND LOUIS BERLINGUET
Department of Biochemistry, Faculty of Medicine, Laval University, Quebec, Quebec
Received July 26, 1963

ABSTRACT

A series of 22 5-acetamido and 5-amino barbituric acids as well as corresponding thiobarbiturates and N-methylated derivatives have been prepared for hypnotic activity evaluation. From comparative studies of their infrared spectra, various frequencies have been ascribed to the acetamido and amino groups at C-5 position. S-Alkylation resulted in the formation of unstable thioethers which hydrolyzed to give corresponding barbituric acids and mercaptans.

We were interested in preparing for biological evaluation, a new series of barbituric acids in which an amino group, free or acetylated, would be attached to carbon-5. A survey of the literature showed that of the many barbituric acids prepared, only a few have an amino group in the fifth position. These new compounds which we have prepared were obtained by condensing the alkylated acetamido malonic esters with urea or thiourea in the presence of sodium ethoxide. Tables I and II give the description of the various compounds prepared.

Some of these new barbiturates were methylated with dimethyl sulphate in alkaline solution.

With barbituric acids, N-methylated compounds were obtained as expected and isolated. They were characterized by distillation with soda lime. The methylamine thus formed was identified (1). The yields of N-methylated compounds were in the range of 40–60% (Table III).

With thiobarbituric acids, methylation can occur either on the nitrogen (N-1) or on the sulphur located on C-2. When 5,5-dialkylthiobarbiturates were methylated, N-methylation along with some methylation on the sulphur atom took place. However, it has been shown by Lee (2) that "5,5-dialkyl-2-alkyl-thiobarbituric acids are unstable substances evolving a strong thiol-like odor in air". It is not surprising, then, that we isolated, after the methylation of 5-acetamido-5-phenoxypropyl-2-thiobarbituric acid, 10% of the corresponding non-methylated 2-oxygen analogue and 40% of the N-methylated thiobarbiturate. 5-Acetamido-5-isobutyl thiobarbiturate gave, similarly, 45% of 5-acetamido-5-isobutyl barbituric acid.

The substitution of the sulphur atom by oxygen in these two attempts of methylation could only be explained by the labile nature of the intermediate methyl thioether formed at carbon-2.

To confirm this, sodium pentothal was refluxed in 95% ethanol with excess allyl bromide, and benzyl chloride. In both cases pentobarbital could be isolated in 68% yield.

Hydrolysis of some 5-acetamido barbiturates with 4 *N* HCl gave the 5-amino hydrochloride barbiturates which are listed in Table III along with the N-methylated derivatives.

The hydrolysis of the 5-acetamido group to an amine hydrochloride results in the disappearance of absorptions at 3400 cm^{-1} (free N—H stretching mode), 1650 cm^{-1} (amide I band), 1365 cm^{-1} (amide II band), and 1298 cm^{-1} (amide III band) (Table IV). There is also the disappearance of the lowest of the first three carbonyl frequencies in the region 1800–1640 cm^{-1} (3). In the 5-aminohydrochloride compounds, new bands around 1585–1555 cm^{-1} and 1340 cm^{-1} are probably due to NH_3 deformation frequency and symmetric mode respectively. There is also some displacement towards lower frequencies of 3100 cm^{-1} and 2900 cm^{-1} to 3000 and 2800 cm^{-1} (VI, XX; V, XIX).

Pharmacology.—All these barbiturates (Tables I, II, and III) were tested on mice in dosage of 100 mg/kilogram, as their sodium salts. No hypnotic activity was found in any case. The replacement of an alkyl chain in position-5 by a free or acetylated amino group resulted in the loss of hypnotic activity.

EXPERIMENTAL

All the melting points reported are uncorrected and some of them depend on the rate of heating. The infrared spectra were recorded with a Beckman IR4 spectrophotometer using KBr pellets containing 0.5% by weight of sample and reported spectra are all calibrated. Ultraviolet spectra were all recorded with a Beckman DB Spectrophotometer using 95% ethanol as solvent. Analyses were performed by Dr. C. Daessle of Organic Microanalysis, Montreal.

The method used for preparing alkylated acetamido malonic esters was mainly that reported by Snyder (4) and Albertson (5) as reviewed by Cope (6). The criterion used for the completion of the reaction was its neutral reaction towards litmus. If, on vacuum evaporation, the compound solidified, it was filtered, washed with water, and dried before crystallization. However, if, on vacuum evaporation an oil was obtained, small amount of water was added and the oil extracted with benzene. The benzene solution was dried with anhydrous sodium sulphate and vacuum evaporated.

For the preparation of barbiturates, 1 mole of the alkylated acetamido malonic ester was refluxed with 2 moles of sodium dissolved in absolute ethanol and 1.5 mole of urea. The condenser carried a $CaCl_2$ tube. The amount of absolute alcohol was so adjusted that the reaction mixture always retained enough fluid to be refluxed and stirred. After the reaction was completed, the mixture was cooled and vacuum evaporated. The semisolid was brought into solution by adding water and the mixture was acidified with 10% HCl to precipitate the barbiturate.

Methylation with dimethyl sulphate consisted in dissolving 5 g of the barbituric acid in 75 ml of 4% NaOH solution and then adding an equimolar amount of dimethyl sulphate. The mixture was stirred at room temperature for 0.5 hour and then acidified with cold 10% HCl.

Hydrolysis of acetamido group was performed with 4 *N* HCl. The complete dissolution of the compound indicated completion of the reaction. The reaction mixture was filtered, evaporated, and crystallized from a minimum amount of dilute HCl.

Attempted S-Alkylation of 5-Ethyl-5-(1-methylbutyl)-2-thiobarbituric Acid

Sodium pentothal, 5 g (0.021 mole), was dissolved in ethyl alcohol (150 ml, 95%), and allyl bromide (15 ml, excess) was added to it. The mixture was refluxed for 3 hours and then evaporated. The solid residue was extracted with benzene and repeatedly crystallized from benzene – petrol ether (b.p. 35–75°) (six times) to yield 3.5 g of pentobarbital m.p. 130.5° (lit. 131°). An easier way to purify the compound is by adsorption chromatography on alumina (B.D.H.) using as eluant benzene – ethyl acetate (1:1 mixture) or ethyl acetate alone. The pentobarbital thus obtained gave negative Lassaigne's test for sulphur and gave superimposable ultraviolet and infrared spectra with an authentic sample obtained from commercial Nembutal by precipitation with dilute HCl and crystallization from benzene – petrol ether mixture. It also showed no depression in mixed melting point determination. Mol. wt. (Rast) 235 (theory, 226). Anal. Calc. for $C_{11}H_{18}N_2O_3$ (226): C, 58.40; H, 7.97; N, 12.39. Found: C, 58.64; H, 8.16; N, 12.40.

Similarly sodium pentothal, 1 g (0.004 mole), on refluxing with benzyl chloride (3 ml, excess), in ethyl alcohol (30 ml, 95%) for 16 hours, and vacuum evaporation gave 0.5 g of pentobarbital. The characteristic smell of benzyl mercaptan and allyl mercaptan in the above case was noted but no efforts were made to isolate them. The characterization of the pentobarbital was done according to the method described in the case of allyl bromide.

Preparation of 5-Acetamido-5-isobutylbarbituric Acid (IV) from 5-Acetamido-5-isobutyl-2-thiobarbituric Acid (XII)

To a solution of 5.2 g (0.02 mole) of XII in 75 ml of 4% caustic soda solution was added 2.52 g (0.02 mole) of dimethyl sulphate. The mixture was stirred at room temperature for half an hour and then acidified with 10% HCl. If the mixture was kept in the refrigerator overnight, 2 g of the crystals of IV were obtained. Crystallization from dioxane–H_2O gave the analytical sample, m.p. 318°. Lassaigne's test for sulphur was negative. Anal. Calc. for $C_{10}H_{15}N_3O_4$ (241): C, 49.79; H, 6.22; N, 17.42. Found: C, 49.85; H, 6.07; N, 17.38. Mixed melting point with the sample prepared by condensation of urea and 5-acetamido-5-isobutyl malonic ester showed no depression. The two compounds also gave identical infrared spectra.

ISOTOPE EFFECTS IN METHYL RADICAL ABSTRACTION REACTIONS

MARK SALOMON
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received October 18, 1963

ABSTRACT

The high k_H/k_D ratio found experimentally for methyl radical abstraction reactions is explained on the basis of classical rate theory. It is shown that if the bending frequencies in the activated complex approach zero, good agreement is found between experimental and calculated k_H/k_D values. For abstraction of H and D from hydrocarbons, both the tunneling and classical rate theories predict acceptable k_H/k_D values. Abstraction of H and D from H_2 and D_2, however, can best be explained on the basis of a classical process.

INTRODUCTION

The ratio of rate constants, k_H/k_D, for the abstraction of H and D from hydrocarbons by methyl radicals has been found to be higher than that calculated from classical rate theory when the bending frequencies of the RC—H bond is assumed to remain constant from the initial to final states (1–6). To explain these high values for k_H/k_D, several workers (1, 2) have proposed that the rates are largely determined by appreciable participation of a quantum mechanical tunneling process. The basis for the tunneling mechanism is the theory of Johnston and Rapp (3), who give the relation

$$k_H/k_D = 0.99 \exp(1580/RT). \qquad [1]$$

for methyl radical abstractions based on proton tunneling (2). This theory is attractive since it does predict the experimental values of k_H/k_D with a good degree of accuracy, but the theory does not explain the lower values of k_H/k_D found for methyl radical abstraction from H_2 and D_2. In Table I, the k_H/k_D values for various reactions are given together with the ratio of frequency factors, A_H/A_D, and the difference in activation energies, ΔE, found experimentally. It will now be shown that these observed values can be correlated with classical rate theory and that quantum mechanical tunneling need not be invoked.

CALCULATIONS

From absolute reaction rate theory (9), the ratio of rate constants is given by

$$\frac{k_H}{k_D} = \frac{\prod^{3n^{\neq}-7} \sinh \tfrac{1}{2}U_{i_D}^{\neq}}{\prod^{3n^{\neq}-7} \sinh \tfrac{1}{2}U_{i_H}^{\neq}} \frac{\prod^{3n-6} \sinh \tfrac{1}{2}U_{i_H}}{\prod^{3n-6} \sinh \tfrac{1}{2}U_{i_D}} \qquad [2]$$

where the products and ratios of molecular mass and moments of inertia are assumed to be unity and U_i is $h\nu_i/kT$. We now examine several cases for the isotopic dependence of frequencies in the initial and activated states. If we first make the assumption that the frequencies associated with the activated complex are isotopically independent, then two limiting cases are obtained from equation 2. The first is that cleavage of a C—H bond occurs and the bending frequencies do not change from the initial to the activated state, that is, the only isotopically dependent vibration is the C—H stretch, so that equation (2) can be simplified to

$$k_H/k_D = \exp \tfrac{1}{2}(U_H - U_D). \qquad [3]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The second case arises when the C—H bond undergoing cleavage is stretched significantly so that the bending frequencies approach zero in the activated state. If this bending frequency is assumed to be doubly degenerate, equation 2 reduces (10) to

$$\frac{k_H}{k_D} = \tfrac{1}{2} \exp \tfrac{1}{2} \sum (U_{1H} - U_{1D}). \quad [4]$$

A third case arises for the $CH_3 + H_2$ reaction when the frequencies in the activated complex are isotopically dependent. If the simple pseudo-three-atom model, the activated complex has the linear form $C \ldots H \ldots H_{(2)}$. In bending frequencies (which would be absent if the $H_{(2)}$ atom were sufficiently far away from the C atom in (CH_3·) are neglected, there are two vibrations which exist (11). The first is the asymmetric one which leads to reaction and need not be considered. The second is the symmetric vibration which will result in the movement of the central H atom. Replacement of the central atom with D will then change this frequency and the symmetric vibration is therefore isotopically dependent. For abstraction from methane, the activated complex has the form C. . .H. . .C and the symmetric vibration does not involve any motion of the central H atom. For abstraction from a hydrocarbon, the activated complex has the same general form as that for methane and the symmetric vibration is assumed not to involve any motion of the central H or D atom. Hence replacement by D will have no effect and this frequency can, in principle, be neglected for this case. For $CH_3 + H_2$ and $CH_3 + D_2$ then, the ratio of rate constants is, from equation 2,

$$\frac{k_H}{k_D} = \exp \tfrac{1}{2}(U_D^{\neq} - U_H^{\neq}) \exp \tfrac{1}{2}(U_H - U_D). \quad [5]$$

We can now calculate the isotope effect for the abstraction of H and D from hydrocarbons. When the C—H and C—D stretch vibrations in CH_4 and CD_4 are assumed to be 3020 and 2258 cm^{-1} respectively (12), then from equation 3,

$$\frac{k_H}{k_D} = \exp (1090/RT), \quad [6]$$

which is 2.2 at 200° C. If the C—H and C—D bending frequencies of 1306 and 996 cm^{-1} (12) are doubly degenerate, then from equation 4

$$k_H/k_D = 0.5 \exp 1977/RT, \quad [7]$$

which equals 4.1 at 200° C. Equation 7 predicts satisfactory k_H/k_D values (see Table I). There is some discrepancy, however, for the k_H/k_D values for abstraction from methane (1). This large discrepancy was explained by assuming that the potential energy barrier for abstraction from methane is higher than for ethane, propane, etc., and therefore results in a larger contribution from tunneling (1). The bond dissociation energy of methane is reported to be between 100 and 102 kcal $mole^{-1}$ (13, 14) and the corresponding value of the C—H bond energy for ethane is 98 kcal $mole^{-1}$ (14). If this difference between the C—H bond dissociation energies causes an increase in tunneling, then one would expect that proton tunneling for the reaction $CH_3 + H_2$ would be greater. This would follow from the bond dissociation energy of 103 kcal $mole^{-1}$ for H_2 (15) and also on steric grounds. The H_2 or D_2 molecule could approach the CH_3 radical more closely than a hydrocarbon molecule so that the width of the potential energy barrier would be decreased and the tunneling probability increased. The k_H/k_D ratio for abstraction from H_2 and D_2 is, however, 2.0 (7) and therefore precludes any significant tunneling.

TABLE I

Kinetic parameters for abstraction reactions

Reaction	ΔE (kcal mole^{-1})	A_H/A_D	k_H/k_D (200°)	Reference
$CH_3 + CH_4 \rightarrow CH_4 + CH_3$ $CD_3 + CD_4 \rightarrow CD_4 + CD_3$	3.5	8.91	8.1	5 1
$CD_3 + C_2H_6 \rightarrow CD_3H + C_2H_5$ $CD_3 + C_2D_6 \rightarrow CD_4 + C_2D_5$	1.5	1.0	4.95	4 4
$CD_3 + CH_3CD_3 \rightarrow CD_3H + CH_2CD_3$ $CD_3 + CH_3CD_3 \rightarrow CD_4 + CH_3CD_2$	1.9	0.72	4.95	4 4
$CD_3 + (CH_3)_3CH \rightarrow CD_3H + (CH_3)_3C$ $CD_3 + (CH_3)CD \rightarrow CD_4 + (CH_3)_3C$	1.6	0.8	4.4	2 2
$CD_3 + CH_3CH_2CH_3 \rightarrow CD_3 + CH_3CHCH_3$ $CD_3 + CH_3CD_2CH_3 \rightarrow CD_4 + CH_3CDCH_3$	1.4	1.04	4.5	2 6
$CH_3 + H_2 \rightarrow CH_4 + H$ $CH_3 + D_2 \rightarrow CH_3D + D$	1.7	0.41	2.0	7 7
$CF_3 + CHD_3 \rightarrow CF_3H + CD_3$ $CF_3 + CHD_3 \rightarrow CF_3D + CHD_2$	2.2	0.51	5.0	8 8

If the vibrations for H_2 and D_2 are taken as 4395 and 3118 cm^{-1} respectively (16), k_H/k_D is calculated to be 6.7 from equation 3. We have seen, however, that the symmetric vibration in the activated complex is isotopically dependent and equation 5 must be used to calculate k_H/k_D. In addition to this symmetric frequency, a doubly degenerate bending frequency may be generated in the activated complex if the approach of H_2 to CH_3 is close enough. These uncertainties prohibit a quantitative evaluation of the frequencies in the activated state, but their effect is clear. The "tighter" the activated complex, the smaller is the isotope effect. An activated complex which shows this behavior is that which arises during the electrochemical discharge of a proton (or a deuteron) from acid solution onto a mercury cathode. The sum of the frequencies for the activated complex Hg. . . H. . .O has been calculated by Conway and Salomon (17) and is 3550 cm^{-1}. It is also possible that the bonding in the activated state becomes tight enough to cause an inverse isotope effect, i.e. k_H/k_D is less than unity (11). Swain *et al.* (18) have found such a case for the decarboxylation of *p*-methylbenzoylacetic acid where $k_H/k_D = 0.85$.

CONCLUSION

It has been found that the k_H/k_D ratios found for methyl radical abstraction reactions can be explained on the basis of classical rate theory. There are several discrepancies noted in the literature and the main one is the k_H/k_D value obtained for abstraction from CH_4 and CD_4. There are also some minor differences in the predicted and experimental ratio of frequency factors. This can be attributed to experimental error, since an error of $\pm 2\%$ in the measurement of k_H/k_D can give large errors in A_H/A_D and in ΔE. The C—H bend has been treated as consisting of a single stretching and a doubly degenerate bending frequency. If the symmetric and asymmetric vibrations are taken into account, the effect would be to increase k_H/k_D still more. In the reactions considered, it is found that the theory of quantum mechanical tunneling need not be invoked to explain the observed isotope effects.

ACKNOWLEDGMENTS

The author wishes to thank Professors K. J. Laidler and B. E. Conway and Dr. M. Back for their interest in this work. Grateful acknowledgment is also made to the Sprague Electric Company for the award of a Fellowship.

SYNTHESIS OF THE 2,4-DI-*O*-METHYL TETROSES

G. G. S. DUTTON AND K. N. SLESSOR
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received November 22, 1963

ABSTRACT

The four isomeric 2,4-di-*O*-methyl tetroses were prepared by periodate oxidation of known methylated sugars. 2,4-Di-*O*-methyl-D- and L-erythroses were prepared from 4,6-di-*O*-methyl-D-glucose and 3,5-di-*O*-methyl-L-arabinose respectively. 2,4-Di-*O*-methyl-D- and L-threoses were prepared from 3,5-di-*O*-methyl-D-xylose and 1,4,6-tri-*O*-methyl-L-sorbose.

The tetroses were characterized by their crystalline 2,4-dinitrophenylhydrazones. The R_F and R_G values of the free sugars were recorded in a variety of solvents including a silica gel thin-layer chromatography system.

In the structural investigation of *Virgillia oroboides* gum, Stephen (1) observed several chromatographically fast-running products obtained from periodate oxidations of partially methylated sugars. From consideration of the structure of the parent sugars, these compounds were assumed to be partially methylated tetroses. No attempt to isolate these products was made due to the small amount of material present. Periodate oxidation of partially methylated glucoses, obtained from hydrolysis of a methylated glucan (2), produced methylated reducing fragments, believed to be of the tetrose series. Had recognition of the structure of these fragments been possible by comparison with known compounds, the structural elucidation of the parent sugars would have been simplified. For this reason, the synthesis of reference compounds in the 2,4-di-*O*-methyl tetrose series was undertaken.

2,4-Di-*O*-methyl-D-erythrose was prepared by periodate oxidation of 4,6-di-*O*-methyl-D-glucitol. This hexitol was obtained by borohydride reduction of crystalline 4,6-di-*O*-methyl-D-glucose prepared by the method of Bell and Lorber (3). Its optical isomer, 2,4-di-*O*-methyl-L-erythrose was obtained by periodate oxidation of 3,5-di-*O*-methyl-L-arabinitol. The dimethyl pentitol was obtained by borohydride reduction of 3,5-di-*O*-methyl-L-arabinose (4).

Periodate oxidation of 3,5-di-*O*-methyl-D-xylitol yielded 2,4-di-*O*-methyl-D-threose which, upon purification, yielded a crystalline product. The pentitol was obtained from the known (5) 3,5-di-*O*-methyl-D-xylose by borohydride reduction. Periodate oxidation of the borohydride reduction product of 1,4,6-tri-*O*-methyl-L-sorbose yielded the isomeric 2,4-di-*O*-methyl-L-threose. Reduction of the known 1,4,6-tri-*O*-methyl-L-sorbose (6) may yield two hexitols (1,4,6-tri-*O*-methyl-L-sorbitol or 1,3,6-tri-*O*-methyl-D-glucitol and 1,4,6-tri-*O*-methyl-L-iditol or 1,3,6-tri-*O*-methyl-L-iditol). Examination of the reduction mixture by thin-layer chromatography indicated only one major product, the absolute structure of which remains unknown.

Incomplete periodate oxidation of reducing sugars has been reported (1) and was substantiated in this work. Periodate oxidation of the derived glycitol gave expected periodate uptakes for all the compounds studied. The resistance of 3-substituted aldoses to borohydride reduction has been reported (7). This effect has been attributed to steric hindrance of the borohydride as it approaches the 1,3 system. In the preparation of 3,5-di-*O*-methyl pentitols from the parent pentoses and 1,3,6-tri-*O*-methyl-glycitol from 1,4,6-tri-*O*-methyl-sorbose, borohydride reduction was not complete after 24 hours. If longer reduction times

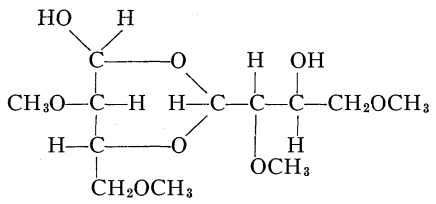
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

were used, detectable amounts of degradation products were formed; these were, presumably, due to Lobry de Bruyn – van Ekenstein transformations. Reductions were carried out overnight and subsequent separation of the product from the unreduced material was effected by chromatography on a silica gel column using butanone–water azeotrope as the solvent.

The use of silica gel columns originated with Bell (8), who estimated the chain length of methylated polysaccharides by use of this method. Elution of the fully methylated sugars, formerly end groups, allowed estimation of the ratio of end group to backbone residues. With the advent of cellulose chromatography, the use of silica gel columns was neglected. In purifications, such as described in this paper, silica gel column chromatography offers comparable resolution in approximately one-fourth of the time. It should be noted that thin-layer chromatography is a fast, efficient method of analyzing methylated sugar fractions (9) obtained from either cellulose or silica gel columns.

Attempts to prepare crystalline derivatives of the glycitols were unsuccessful. Although some acetates and *p*-nitrobenzoates were prepared and shown to be homogeneous by thin-layer chromatography (10), crystallization could not be induced.

Paper chromatography of the tetroses in some solvents and on silica gel thin-layer chromatography indicated the existence of two modifications of the tetroses, which were inseparable by silica gel column chromatography. Upon standing for extended lengths of time (3 months), sirupy tetroses were observed to become more viscous. Infrared spectra of the viscous sirup in contrast with those of the more mobile sirup, showed reduction in the carbonyl stretching band at 1750 cm^{-1} and enhancement of the hydroxyl band at 3400 cm^{-1}, with respect to the more mobile sirup. The infrared spectrum of the crystalline 2,4-di-*O*-methyl-D-threose showed no carbonyl stretching band but contained a hydroxyl band which was split into two equal-intensity absorptions at 3375 and 3480 cm^{-1}. The anomalous optical rotation of the threose isomers (D, $-14.8°$; L, $-14.3°$) in methanol is attributed to the existence of two or more modifications present in the solution of the sirupy L-threose compound. Upon solution of the isomers in 1 *N* sulphuric acid, the rotations dropped to near-zero values with opposite signs. These results suggest that 2,4-di-*O*-methyl tetroses easily undergo dimerization to a compound of structure similar to that from 5-aldo-1,2,-*O*-isopropylidene-D-*xylo*-pentofuranose (11). The structure of the crystalline modification of 2,4-di-*O*-methyl-D-threose may therefore be of the following nature:



Thin-layer chromatography of the tetroses isolated as sirups contained appreciable quantities of modifications of this type. Because of the small amounts of product, molecular weight and nuclear magnetic resonance studies were not undertaken.

Acceptable analytical values were seldom obtained for the sirupy di-*O*-methyl tetroses presumably because of occluded solvent. No attempt was made to distil them because of the small amounts obtained and their volatility. Several different reagents were tried for characterizing the tetroses but only 2,4-dinitrophenylhydrazine gave satisfactory crystalline derivatives in all four cases. This reagent was used in neutral solution to give

the phenylhydrazone rather than the osazone. In retrospect the difficulty of making crystalline derivatives may be due to the equilibrium with a dimer.

Because the importance of the partially methylated tetroses lies in their chromatographic recognition, R_F and R_G values were recorded in a large number of solvent systems (Table I).

TABLE I

Physical properties of 2,4-di-*O*-methyl tetroses

	2,4-Di-*O*-methyl D-erythrose	2,4-Di-*O*-methyl L-erythrose	2,4-Di-*O*-methyl D-threose	2,4-Di-*O*-methyl L-threose

[1]Descending paper chromatography was carried out using Whatman No. 1 paper and R_G values are relative to 2,3,4,6-tetra-*O*-methyl-D-glucose. Sugars were detected by use of *p*-anisidine trichloracetate spray reagent. Optical isomers showed identical chromatographic patterns in all solvents. R_F and R_G values quoted for D-threose refer to the sirup before crystallization. The crystalline modification gave only the slower running component.

Ascending silica gel thin-layer chromatography was adopted for rapid examination of column fractions. Detection was achieved by use of 5% HNO_3 in H_2SO_4. Subsequent heating at 150° was sufficient for development.

In view of the apparent tendency of the 2,4-di-*O*-methyl-tetroses to dimerize and the consequent difficulty in obtaining them pure or securing crystalline derivatives in high yield these compounds cannot be recommended for characterization purposes. A knowledge of their chromatographic behavior will, however, be useful in analysis of complex mixtures of methylated sugars.

EXPERIMENTAL

Evaporations were carried out under reduced pressure at a bath temperature of 40–45° C. Optical rotations are equilibrium values measured on either a Bendix ETL-NPL Automatic Polarimeter (Type 143A) or a Rudolph Polarimeter (Model 219) at 21±2°. Melting points quoted are uncorrected. Periodate oxidation estimations were carried out by quenching oxidation aliquots in buffered arsenite and back-titrating with iodine.

Preparation of the Silica Gel Column

To silica gel (Fisher S-157, 200 g) that had been screened to pass through 60 mesh was added butanone–water azeotrope (500 ml) with stirring. The slurry was allowed to sit for 1 hour, with occasional stirring.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The mixture was then slurried into a column (3×36 cm), fitted with a fritted disc, and the silica was packed tightly by tapping the outside of the column until no further settling was apparent. A 1-cm layer of sand was then carefully placed on top of the silica gel.

The column was equilibrated by passing butanone–water azeotrope through the column for 2 days. At the end of this time the flow rate was constant at 1.8 ml per minute.

The movement of the solvent can be approximated with Sudan IV dye which shows an R_F of about 0.95 on thin-layer plates. If this is used as a marker, the front time for the column was about 1 hour.

Fractions from the column were analyzed by running samples on silica gel thin-layer plates using the same solvent system as that used on the column.

*4,6-Di-O-methyl-*D*-glucose*

4,6-Di-*O*-methyl-D-glucose was prepared by the method of Bell and Lorber (3). After recrystallization from ethyl acetate the constants were: m.p. 154–156° $[\alpha]_D$ 116° → 70.5° (*c*, 1.23 in H_2O). Lit. (3), m.p. 156–157°, $[\alpha]_D$ 108° → 65.7° (*c*, 4 in H_2O).

*4,6-Di-O-methyl-*D*-glucitol (1,3-Di-O-methyl-*L*-gulitol)*

4,6-Di-*O*-methyl-D-glucose (2.7 g) was dissolved in water (50 ml) and sodium borohydride (0.5 g) was added. The solution was neutralized with acetic acid after 18 hours, and evaporated to dryness. The resulting solid was treated with 3% HCl in methanol (3×15 ml) and evaporated to dryness. The residue was dissolved in water (25 ml) and the solution deionized with Amberlite IR-120 (H^+) and Duolite A-4 (OH^-). Evaporation of the resulting solution gave a non-reducing sirup (2.6 g), $[\alpha]_D$ 7° (*c*, 1.5 in $CHCl_3$).

*2,4-Di-O-methyl-*D*-erythrose*

4,6-Di-*O*-methyl-D-glucitol (524 mg, 2.5 mmoles) in water (25 ml) was added to 0.12 *M* sodium periodate (50 ml, 6 mmoles). The oxidation was complete in 25 minutes with an uptake of 2.03 moles of periodate per mole of hexitol. The solution was neutralized with washed barium carbonate, and diluted with an equal volume of methanol, filtered, and evaporated to give a mobile sirup which was purified by chromatography on a silica gel column (297 mg) $[\alpha]_D$ 60.1° (*c*, 1.4 in MeOH).

*2,4-Dinitrophenylhydrazone of 2,4-Di-O-methyl-*D*-erythrose*

2,4-Di-*O*-methyl-D-erythrose (100 mg) was dissolved in 100% ethanol (3 ml) and recrystallized 2,4-dinitrophenylhydrazine (110 mg) was added. The mixture was refluxed on a steam bath for 5 hours, evaporated to dryness, dissolved in ethyl acetate (10 ml), and petroleum ether (30–60°) (10 ml) was added to precipitate excess reagent. The mixture was filtered after 10 minutes, the filtrate evaporated to a sirup, dissolved in chloroform (2 ml), and applied to an alumina column (3×20 cm). Collection of the light yellow band eluted with chloroform afforded yellow-orange crystals melting at 102–103°. Subsequent recrystallization from ethyl acetate – petroleum ether (30–60°) gave crystals melting at 105–106°. Calculated for $C_{12}H_{16}O_7N_4$: N, 17.07; OCH_3, 18.90%. Found: N, 17.04; OCH_3, 19.23%.

*3,5-Di-O-methyl-*L*-arabinose*

3,5-Di-*O*-methyl-L-arabinose was obtained by the procedure of Hirst, Jones, and Williams (4). The sirup showed only one component (R_F 0.59) upon paper chromatography in butanone–water azeotrope and had $[\alpha]_D$ −36° (*c*, 6.7 in MeOH). Lit. (4), $[\alpha]_D$ −39° (25% aqueous acetic acid).

*3,5-Di-O-methyl-*L*-arabinonolactone*

3,5-Di-*O*-methyl-L-arabinose (75 mg) in water (4 ml) was treated with bromine (4 drops) and the mixture was left at room temperature overnight. Aeration, and treatment with silver carbonate followed by filtration, gave a solution which was passed through IR-120 (H^+), and evaporated to a sirup. Sublimation at 65–70° (0.05 mm) gave crystals of 3,5-di-*O*-methyl-L-arabinonolactone, m.p. 72–73°. Lit. (4), m.p. 73°.

*3,5-Di-O-methyl-*L*-arabinonamide*

3,5-Di-*O*-methyl-L-arabinonolactone (6 mg) was dissolved in methanol saturated with ammonia (1 ml) and the solution was left overnight at room temperature. The solution was evaporated to give crystals, which, after recrystallization from acetone, melted at 144°. Lit. (4), m.p. 144°.

*3,5-Di-O-methyl-*L*-arabinitol (1,3-Di-O-methyl-*L*-lyxitol)*

3,5-Di-*O*-methyl-L-arabinose (1.7 g) dissolved in water (30 ml) was treated with excess sodium borohydride (1 g) and left at room temperature overnight. The solution was worked up in the same manner as described for 4,6-di-*O*-methyl-D-glucitol. The sirup containing 3,5-di-*O*-methyl-L-arabinitol and 3,5-di-*O*-methyl-L-arabinose (ca. 9:1) was separated completely on the silica gel column. The arabinose (R_F 0.56 on T.L.C. same solvent) was found in the eluate, 175–300 ml after the dye marking the front. The arabinitol (R_F 0.40) was found in the 675–1000 ml fraction. Evaporation of the fraction containing arabinitol yielded a non-reducing sirup (1.4 g) $[\alpha]_D$ −7° (*c*, 5.8 in $CHCl_3$).

*2,4-Di-O-methyl-*L*-erythrose*

3,5-Di-*O*-methyl-L-arabinitol (527 mg, 2.93 mmoles) in water (200 ml) was treated with 0.08 *M* sodium periodate (50 ml). The oxidation was complete in 10 minutes and was worked up as described for its isomer.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The final periodate uptake was 1.04 moles per mole of pentitol. Purification on silica gel gave a colorless sirup (365 mg) $[\alpha]_D$ −61.4° (*c*, 4.85 in MeOH).

2,4-Dinitrophenylhydrazone of 2,4-di-O-methyl-L-erythrose

The hydrazone was prepared using the same quantities as those used in the preparation of its optical isomer. Upon recrystallization from ethyl acetate – petroleum ether (30–60°), it melted at 107–108°. Calculated for $C_{12}H_{16}O_7N_4$: N, 17.07; OCH_3, 18.90%. Found: N, 16.97; OCH_3, 19.08%.

1,2-Isopropylidene-D-xylofuranose

1,2-Isopropylidene-D-xylofuranose was prepared by the acid hydrolysis of 1,2:3,5-diisopropylidene-D-xylose. The product was recrystallized from ethyl acetate – petroleum ether (30–60°) (1:4) m.p. 67–69° $[\alpha]_D$ −21.9° (*c*, 3.15 in H_2O). Lit. (12), m.p. 41–43° $[\alpha]_D$ −19.0° (*c*, 2 in H_2O). Calculated for $C_9H_{14}O_5$: C, 50.52; H, 7.37%. Found: C, 50.68; H, 7.65%.

3,5-Di-O-methyl-1,2-isopropylidene-D-xylose

1,2-Isopropylidene-D-xylofuranose was methylated by the method of Kuhn *et al.* (13). The compound was isolated as a sirup, which was distilled under vacuum, and the fraction boiling at 80–82° (0.05 mm) was collected. The mobile liquid had a specific rotation $[\alpha]_D$ −57.3° (*c*, 5.2 in $CHCl_3$). Lit. (14), $[\alpha]_D$ −60° (*c*, 1.09 in $CHCl_3$).

3,5-Di-O-methyl-D-xylose

3,5-Di-*O*-methyl-1,2-isopropylidene-D-xylose (5 g) was dissolved in 25% aqueous acetic acid and heated on a steam bath for 5 hours after which time the optical rotation was constant. After evaporation a yellow sirup (2.1 g) remained which showed only one component (R_F 0.57) upon paper chromatography in butanone–water azeotrope, $[\alpha]_D$ 23.5° (*c*, 3.9 in H_2O). Lit. (14), $[\alpha]_D$ 25° (*c*, 1.13 in H_2O).

p-Bromophenylosazone of 3,5-Di-O-methyl-D-xylose

The osazone was prepared by the method of Applegarth, Dutton, and Tanaka (15). 3,5-Di-*O*-methyl-D-xylose (75 mg) and *p*-bromophenylhydrazine (280 mg) were dissolved in glacial acetic acid (4.3 ml). Water (2.2 ml) was added and the solution was heated 6 minutes on a steam bath and allowed to cool. After 2 hours at 5° the crystals were filtered and recrystallized from ethyl acetate – petroleum ether (30–60°) (1:7) m.p. 106.5–107.5°. Lit. (5), m.p. 107–108°.

3,5-Di-O-methyl-D-xylitol (1,3-Di-O-methyl-L-xylitol)

3,5-Di-*O*-methyl-D-xylose (390 mg) dissolved in water (15 ml) was treated with excess sodium borohydride (200 mg). The solution was left at room temperature overnight, and worked up in the manner described for the arabinitol. The sirup (330 mg) obtained showed no reducing properties $[\alpha]_D$ −5.4° (*c*, 6.6 in $CHCl_3$).

2,4-Di-O-methyl-D-threose

3,5-Di-*O*-methyl-D-xylitol (212 mg, 1.17 mmoles) in water (40 ml) was treated with 0.203 *M* periodic acid (10 ml). The oxidation was complete in 10 minutes and the final periodate uptake amounted to 0.91 moles per mole of pentitol. Workup was identical with that described earlier for the erythroses and a mobile sirup (124 mg) was obtained. Purification of this material on a silica gel column yielded crystalline (dimeric?) 2,4-di-*O*-methyl-D-threose. Recrystallization from ethyl acetate – petroleum ether (30–60°) (1:5) gave crystals melting at 114–116° $[\alpha]_D$ −14.8° (*c*, 1.17 in MeOH) showing no mutarotation after 24 hours. $[\alpha]_D$ −9° (3 min) → +0.9° (15 min) (*c*, 0.35 in 1 *N* H_2SO_4). Calculated for $C_6H_{12}O_4$: C, 48.64; H, 8.11; OCH_3, 41.89%. Found: C, 48.78; H, 8.22; OCH_3, 41.51%.

2,4-Dinitrophenylhydrazone of 2,4-di-O-methyl-D-threose

The hydrazone was prepared in the same manner and using the same quantities as for the 2,4-di-*O*-methyl erythroses. The derivative after recrystallization from ethyl acetate – petroleum ether melted at 148–149°. Calculated for $C_{12}H_{16}O_7N_4$: N, 17.07; OCH_3, 18.90%. Found: N, 17.26; OCH_3, 18.43%.

1,4,6-Tri-O-methyl-L-sorbose

1,4,6-Tri-*O*-methyl-L-sorbose was prepared by the method of Schlubach and Olters (6). The sirup showed only one component (R_F 0.72) upon paper chromatography in butanone–water azeotrope. $[\alpha]_D$ −1.85° → +3.16° (*c*, 7.2 in $CHCl_3$). Lit. (6), $[\alpha]_D$ 3.8° (*c*, 1.5 in $CHCl_3$).

Tri-O-methyl-hexitol (1,3,6-Tri-O-methyl-D-glucitol or 1,3,6-Tri-O-methyl-L-iditol)

1,4,6-Tri-*O*-methyl-L-sorbose (520 mg) in water (15 ml) was treated with excess sodium borohydride (1 g) and left overnight at room temperature. The methylated hexitols were isolated in the same manner as previously described. The resulting sirup showed only one major component (R_F 0.45) on silica gel thin-layer chromatography using butanone–water azeotrope. This component was isolated by chromatography on a silica gel column to give a sirup (280 mg) having a rotation $[\alpha]_D$ 5.6° (*c*, 1.5 in $CHCl_3$).

2,4-Di-O-methyl-L-threose

To the tri-*O*-methyl-hexitol (650 mg, 2.9 mmoles) dissolved in water (5 ml), 0.2 *M* sodium periodate (20 ml) was added. The oxidation was complete in 5 minutes with an uptake of 0.98 moles of periodate per

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

mole of hexitol. Recovery of the tetrose in the manner described above and subsequent purification on the silica gel column yielded a colorless sirup (370 mg) $[\alpha]_D$ −14.3° (*c*, 5.7 in MeOH). $[\alpha]_D$ −17° (5 min) → −3° (15 min) (*c*, 0.55 in 1 *N* H_2SO_4).

*2,4-Dinitrophenylhydrazone of 2,4-Di-O-methyl-*L*-threose*

The hydrazone was prepared using the same quantities as were used for preparing its optical isomer. The derivative, upon recrystallization from ethyl acetate – petroleum ether (30–60°), melted at 149–150°. Calculated for $C_{12}H_{16}O_7N_4$: N, 17.07; OCH_3, 18.90%. Found: N, 16.87; OCH_3, 19.16%.

ACKNOWLEDGMENTS

We are grateful to the National Research Council of Canada and the National Institute of Health (U. S. A.) for financial support and one of us (K. N. S.) thanks the Council for the award of a studentship. We are also indebted to Mr. A. Barlay and Mr. K. Gibney for technical assistance and to Mrs. A. Aldridge and Mrs. C. Jenkins for analyses.

ARSENIDES OF THE TRANSITION METALS

VII. THE PALLADIUM–ARSENIC SYSTEM[1]

G. S. SAINI,[2] L. D. CALVERT, R. D. HEYDING,[3] J. B. TAYLOR
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received October 4, 1963

ABSTRACT

In the Pd–As system the existence of seven intermediate phases, $PdAs_2$, α-Pd_2As, β-Pd_2As, Pd_5As_2, $Pd_{2.65}As$, Pd_3As, and Pd_5As has been established by X-ray diffraction and thermal analysis. Single crystals of β-Pd_2As and $PdAs_2$ have been grown by slow cooling from a temperature above the liquidus and of Pd_3As and Pd_5As by halide vapor transport. $PdAs_2$ is cubic, C2 (pyrite) structure, space group $Pa3(T_h^6)$, $a = 5.983\pm0.001$ Å. α-Pd_2As (stable below 455° C) is monoclinic, $a = 9.24\pm0.01$ Å, $b = 8.47\pm0.01$ Å, $c = 10.45\pm0.01$ Å, $\beta = 94°$. β-Pd_2As (stable above 455° C) has the revised C22 (Fe_2P) structure, space group $P\bar{6}2m$ (D_{3h}^3), $a = 6.650\pm0.003$ Å, $c = 3.583\pm0.003$ Å, $c/a = 0.5388$. Pd_5As_2 displays a form of polytypism and shows trigonal as well as hexagonal symmetry with different c parameters. $Pd_{2.65}As$ decomposes peritectically and its structure is unknown. Pd_3As has tetragonal $D0_e$ (Fe_3P) structure, space group $I\bar{4}(S_4^2)$; redetermined lattice constants are $a = 9.974\pm0.002$ Å, $c = 4.822\pm0.002$ Å, $c/a = 0.4834$. Pd_5As is C-face centered monoclinic, $a = 5.51_4\pm0.01$ Å, $b = 7.72_5\pm0.01$ Å, $c = 8.42_7\pm0.01$ Å, and $\beta = 99°\pm5'$.

The literature on the Pd–As system is very scanty. To our knowledge there are no reports on the formation and structure of palladium arsenides except an early study of $PdAs_2$ by Thomassen (1), short reports on Pd_3As by Schubert (2), Heyding and Calvert (3), and a recent note on Pd_2As (high temperature phase) by Schubert (4). In order to establish the existence and composition of the intermediate phases and to characterize them, an investigation of this system by X-ray diffraction and thermal analysis has been undertaken in this laboratory.

EXPERIMENTAL

The palladium sponge was supplied by Engelhard Industries and had a purity of 99.99% as determined spectrographically. It was used without further purification. Arsenic (99.999% purity) was obtained from Cominco. It was fractionally sublimed *in vacuo* at 450° C to remove oxide contaminant not recorded in the spectrographic analysis. Calculated quantities (5 to 10 g total) of palladium and arsenic were sealed in quartz ampoules at 10^{-5} mm Hg and heated at 700° C for 24 hours. The reaction between palladium and arsenic being highly exothermic, all specimens were found to have melted after the initial reaction. The products were removed, crushed, and resealed in quartz ampoules for a series of annealing periods ranging from 2 months at 300° C to 7 days at 850° C. After each annealing period the specimens were quenched in water and Debye–Scherrer patterns obtained in 11.46 cm Norelco cameras using Ni-filtered Cu radiation. Powder photographs were also obtained on a Guinier–deWolff focussing camera with As_2O_3 as an internal standard. The intensities of the powder diffraction lines were obtained by comparison with a logarithmic interval density scale. Single crystal photographs were taken on a precession camera using zirconium-filtered molybdenum radiation. Densities were determined pycnometrically using water except in the cases of β-Pd_2As and Pd_5As where single crystals were large enough to be measured on a Berman torsion balance using toluene as the immersion fluid.

Thermal analyses were performed on 3 g samples using vacuum-sealed thin-walled quartz ampoules. Seventeen samples ranging in composition from 24.4 at.% As to 66.7 at.% As were studied.

Single crystals were prepared by techniques involving either growth from the melt or vapor growth by halide transport. In the first case, a previously prepared polycrystalline specimen of the requisite composition was vacuum sealed in a quartz ampoule leaving a minimum of void space. Single crystals were

[1]*Issued as N.R.C. No. 7728.*

For personal use only.

obtained on slow cooling of the specimen from a temperature above the liquidus by lowering the ampoule through a suitable temperature gradient in a vertical furnace.

In the halide vapor transport experiments, the general reaction was of the type

$$Pd_xAs_{y(s)} + \text{halogen}_{(g)} \rightleftharpoons Pd\ \text{halide}_{(g)} + As_{(g)}.$$

Experiments were conducted with chlorine, bromine, and iodine but, within the range of conditions used, only chlorine was found to give successful transport reactions. The reaction tube was made of clear quartz, 35 cm long, 2 cm in diameter with 0.2 cm wall. A polycrystalline charge of required composition was contained in a fused alumina boat situated at one end of this tube. After evacuation to 10^{-4} mm Hg, dry chlorine was distilled into the tube to give a concentration of about 0.03 mg Cl_2/cc. The tube was sealed off and supported horizontally in a two-zone furnace. Temperatures were recorded on two chromel vs. alumel thermocouples attached to each end of the reaction tube. Manipulation of the temperature of the charge material and of the temperature gradient along the tube enabled crystals to be grown. Details of the exact procedure followed in individual cases and the results obtained are given under the relevant subheadings in the next section.

RESULTS AND DISCUSSION

The Phase Diagram

The results of the phase analytical studies are embodied in the phase diagram (Fig. 1) and may be summarized as below.

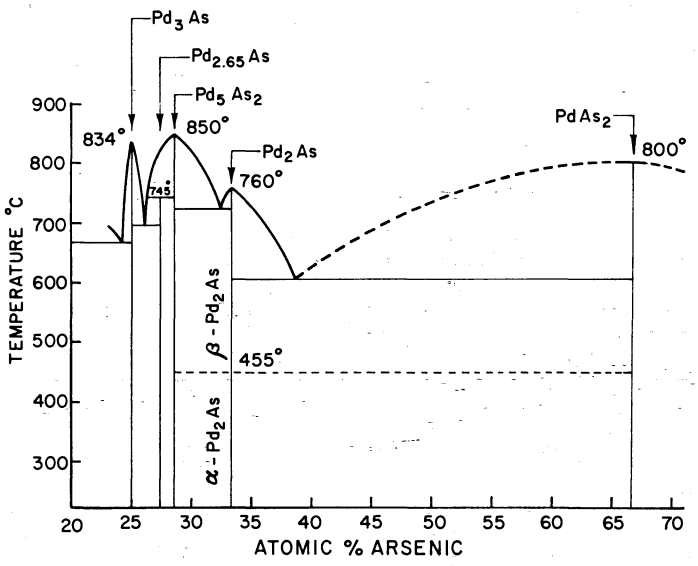

FIG. 1. Partial phase diagram of the system palladium–arsenic.

(i) In the Pd–As system, seven intermediate phases exist. They are Pd_5As, Pd_3As, $Pd_{2.65}As$, Pd_5As_2, α-Pd_2As, β-Pd_2As, and $PdAs_2$. (ii) The compound PdAs does not exist. This supports Thomassen's observation (1). (iii) The hexagonal β-Pd_2As phase transforms into the monoclinic α-Pd_2As phase when annealed at a temperature below 455° C. The transformation is extremely rapid and readily detectable on a thermal analysis cooling curve. (iv) $PdAs_2$, β-Pd_2As, Pd_5As_2, Pd_3As, and Pd_5As have congruent melting points whereas $Pd_{2.65}As$ undergoes peritectic decomposition above 745° C. (v) The formation of Pd_5As from the elements is very slow. The exact position of the liquidus curve in the region of Pd_5As was uncertain and results did not justify the inclusion of this portion of the phase diagram. The composition of this phase was deduced from the density and the unit cell volume as obtained by measurements on single crystals.

For personal use only.

The $PdAs_2$ Phase

From a study of powder photographs Thomassen (1) reported that $PdAs_2$ has the C2 (pyrite) structure; space group $Pa3(T_h^6)$; $a = 5.982$ Å. Heyding and Calvert (3) confirmed these observations and reported $a = 5.983 \pm 0.001$ Å. During attempts to grow single crystals of Pd_2As by slow cooling of melts of compositions Pd_2As, $Pd_{1.8}As$, and $Pd_{1.6}As$, a few well-developed rectangular crystals were observed in the matrix of a broken ingot of $Pd_{1.6}As$. When examined on the precession camera, these crystals were found to be $PdAs_2$; $a = 5.98_7 \pm 0.01$ Å; $U = 214.6$ Å^3; $Z = 4$; F.W. = 256.22; $D_x = 7.93$ g.cm^{-3} and $D_m = 7.62$ g.cm^{-3}.

The x parameter for the As atoms in the position 8*c* of the space group $Pa3$ (T_h^6) was determined to be 0.382 ± 0.004 from the ratios of the intensities of the observed reflections, {321}/{123}; {631}/{136}; {641}/{146}; and {421}/{124}. This is in good agreement with the value 0.38 found by Thomassen (5) for $PtSb_2$. The shortest interatomic distances (a taken as 5.984 Å) are: Pd to 6As = 2.49 Å; As to 1As = 2.45 Å; As to 3Pd = 2.49 Å.

The α-Pd_2As Phase

The low temperature α-Pd_2As phase was obtained by annealing a specimen of stoichiometric composition at 450° C. Debye–Scherrer photographs indicated α-Pd_2As to be of a low symmetry. All efforts to grow single crystals of this phase failed. Photographs obtained with a Guinier focussing camera, using As_2O_3 as internal standard (Table I) were indexed by Ito's method and subsequently reduced to a monoclinic cell; $a = 9.24 \pm 0.01$ Å, $b = 8.47 \pm 0.01$ Å, $c = 10.45 \pm 0.01$ Å, $\beta = 94°$; diffraction symbol $12/m1P\ldots$;

$U = 815.8$ Å^3; $Z = 18$; F.W. $= 287.71$; $D_x = 10.54$ g.cm^{-3}, and $D_m = 10.13$ g.cm^{-3}. The indexing was confirmed by using an I.B.M. digital computor.

It is to be noted that the indexing on a monoclinic cell is based on the presence of lines 3, 6, 10, and 11 in the powder pattern, which have been indexed as $\bar{1}02$, $\bar{2}01$, $\bar{2}02$, and 121, and $\bar{2}12$. In the absence of these lines the pattern can be indexed on an orthorhombic unit cell. However, careful consideration of all the available data indicates that these lines are unique to the α-Pd_2As phase and the assignment of the lower symmetry is regarded as essential.

The β-Pd_2As Phase

The high temperature Pd_2As phase is hexagonal with revised C22 (Fe_2P) structure; space group $P\bar{6}2m(D_{3h}^3)$; $a = 6.650\pm0.003$ Å, $c = 3.583\pm0.003$ Å, $c/a = 0.5388$; $U = 137.22$ Å^3; $Z = 3$; F.W. $= 287.71$; $D_x = 10.44$ g.cm^{-3}; $D_m = 10.33$ g.cm^{-3}.

Alloys with nominal compositions of $Pd_{2.0}As$ (two alloys, both single phase), $Pd_{2.1}As$ (one alloy, two phases β-Pd_2As + Pd_5As_2), and $Pd_{2.2}As$ (one alloy, two phases β-Pd_2As + Pd_5As_2) gave, for β-Pd_2As, lattice parameters which fell within the range of $a = 6.650\pm0.003$ Å, $c = 3.583\pm0.003$ Å, and $c/a = 0.5388\pm0.0007$ Å. A powder pattern of one $Pd_{2.0}As$ alloy indexed on the basis of $a = 6.651\pm0.002$ Å, $c = 3.582\pm0.002$ Å is listed in Table II. It was concluded from this that, at 700° C, β-Pd_2As has a negligible range of

TABLE II

composition on the metal-rich side. The homogeneity range on the arsenic-rich side of β-Pd_2As was not ascertained because the alloys rich in arsenic were not successfully quenched to give patterns of β-Pd_2As + $PdAs_2$. Invariably the patterns obtained were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

α-Pd_2As + $PdAs_2$. Three other alloys with a nominal composition of $Pd_{2.0}As$ and showing only a single phase pattern gave lattice parameters which ranged from $a = 6.652 \pm 0.002$ Å, $c = 3.576 \pm 0.002$ Å to $a = 6.642 \pm 0.002$ Å and $c = 3.600 \pm 0.002$ Å. These alloys were prepared by reannealing of crushed powders, and spectrographic analysis of a representative alloy showed no extra impurities. The origin of this variation is not certain.

Single crystals of β-Pd_2As were obtained by slow cooling from a temperature above the liquidus at stoichiometric composition. Crystal fragments for the precession camera were selected from the broken ingot. The zones recorded were $h0l$, $h1l$, $hk0$, and $hk1$. No systematic extinctions were observed. The intensities of $hk0$ and $h0l$ reflections compared very well with those obtained by Rundqvist and Jellinek (6) for Ni_6Si_2B and Fe_2P. Cell parameters determined from single crystal photographs are $a = 6.64_5 \pm 0.015$ Å, $c = 3.58_0 \pm 0.01$ Å, and $c/a = 0.5388$.

These results, obtained both by single crystal and powder diffraction studies are to be compared with values of $a = 6.62$ Å and $c = 3.60$ Å reported by Schubert in a recent note (4).

The Pd_5As_2 Phase

The specimen with 28.6 at.% As (Pd_5As_2) was extremely malleable and difficult to powder. It gave a rather complex powder pattern which seemed to be of a low symmetry. The phase has been characterized crystallographically by powder and single-crystal studies. The results indicate that it displays a form of polytypism and shows trigonal as well as hexagonal symmetry with a number of different c parameters. Detailed results will form the subject of a later communication in connection with the compounds of the type M_5X_2.

The $Pd_{2.65}As$ Phase

The Debye–Scherrer patterns show the presence of a phase between the compositions Pd_5As_2 and Pd_3As. The photographs of well-annealed specimens with 27.03 at.% As ($Pd_{2.7}As$) showed traces of diffraction lines from the Pd_3As phase, whilst those of specimens with 27.78 at.% As ($Pd_{2.6}As$) showed traces of diffraction lines from Pd_5As_2 in addition to the characteristic lines of the $Pd_{2.65}As$ phase. The specimen containing 27.4 at.% As ($Pd_{2.65}As$), which gave a single phase pattern, was, therefore, taken as representative. The pattern seems to be of a low symmetry. The compound undergoes peritectic decomposition at 745° C. Unsuccessful attempts were made to prepare single crystals of this phase by vapor transport and by slow cooling of a specimen in the two-phase region close to the stoichiometric composition on the palladium rich side. The powder pattern has not been indexed but is recorded in Table III.

The Pd_3As Phase

This phase was first reported in a short note by Schubert (2) and subsequently by Heyding and Calvert (3). Schubert reported the cell parameters to be $a = 9.98_6$ Å and $c = 4.83_6$ Å. Heyding and Calvert gave $a = 9.95_1 \pm 0.01$ Å and $c = 4.81_7 \pm 0.01$ Å based on an indexing of low-angle reflections only. A completely indexed powder pattern is given in Table IV and parameters have been calculated from measurements in the back reflection region. Pd_3As is body-centered tetragonal with the $D0_e$ (Fe_3P) structure; space group $I\bar{4}(S_4^2)$; $a = 9.974 \pm 0.002$ Å, $c = 4.822 \pm 0.002$ Å, $c/a = 0.4834$; $U = 479.7$ Å^3; $Z = 8$; F.W. = 394.11; $D_x = 10.91$ g.cm^{-3}, and $D_m = 10.88$ g.cm^{-3}.

In one of a series of experiments to grow single crystals of α-Pd_2As by vapor transport, a polycrystalline charge of composition Pd_2As was used. The tube was maintained at a

uniform temperature of 450° C for 4 weeks. Needle-shaped crystals about 0.2 mm long and faceted beads about 0.03 mm across were found to have grown on the inside of the boat. Both types of crystals were examined by Debye–Scherrer photographs and were found to be Pd_3As. The beads were examined by the precession method. Measurements of the photographs gave $a = 9.96_3 \pm 0.01$ Å, $c = 4.82_9 \pm 0.01$ Å.

The Pd_5As Phase

The powder patterns of well-annealed polycrystalline samples, prepared by the usual methods, were unsatisfactory for analysis. Invariably they were not single phase and lines unique to Pd_5As were not sharp. Accordingly attempts were made to grow single crystals by chloride vapor transport using an annealed polycrystalline charge containing 17 at.% Pd. This material was known to contain some Pd_3As. No crystals were obtained. As the failure of the experiment could be attributed to the particularly low decomposition pressure of the arsenide used, the experiment was repeated by using a charge of composition $Pd_{2.7}As$, which was suspected to have a relatively higher arsenic decomposition pressure. The charge was maintained at 500° C and the opposite end of the tube at 650° C for 6 days. Well-formed platelike crystals with skewed faces and having sides up to 1 mm and thickness about 0.05 mm were observed on the walls of the tube towards the hotter end. In addition there were also some needle-shaped crystals. Photographs of both types of crystals in a Debye–Scherrer camera showed them to be Pd_5As. Selected platelike crystals were examined by the precession method. Pd_5As is face centered monoclinic; $a = 5.51_4 \pm 0.01$ Å, $b = 7.72_5 \pm 0.01$ Å, $c = 8.42_7 \pm 0.01$ Å, and $\beta = 99° \pm 5'$; $U = 354.5$ Å^3; $Z = 4$; F.W. 606.91; $D_x = 11.37$ g.cm^{-3}, and $D_m = 11.33$ g.cm^{-3}. The zones studied were $hk0$, $hk1$, $0kl$, $1kl$, $h0l$, and $h1l$. The b axis was taken as unique. The only absent reflections were hkl with $h + k = 2n + 1$. The diffraction symbol is $12/m1C$ . . . and the space group may be any of the three: $C2/m(C_{2h}^3)$, $Cm(C_s^3)$, and $C2(C_2^3)$. The platelike crystals had the monoclinic b axis lying along the long diagonal of the well-developed parallelogram-shaped 001 face.

In the case of one crystal, the zone $1kl$ had the number of reflections along the c^* direction doubled, apparently corresponding to a doubled c axis; the $0kl$ zone had the expected reflections. This could be explained if the crystal was assumed to be twinned by a 180° rotation around the [100] direction. Three different crystals were examined to confirm the basic cell.

The empirical formula for Pd_5As was deduced from its cell volume, space group, observed density, and the approximately known chemical composition. Powder photographs indicate that the composition lies between Pd_6As and Pd_3As. The allowed space groups $C2/m$, Cm, and $C2$ require that the atoms occur in multiples of 2. Using a value of 20.4 Å^3 for the atomic volume of As and 13.2 Å^3 for the Pd, based on the observed cell volumes in Pd_3As, Pd_2As, and $PdAs_2$, we find, for the formula Pd_5As, a calculated volume of 346 Å^3 for four molecules in the unit cell. This agrees well with the observed unit cell volume 354.5 Å^3. The calculated density, 11.37 g.cm^{-3}, for four formula units of Pd_5As in the unit cell, is in good agreement with the observed density 11.33 g.cm^{-3}. No other atomic ratio in the required range fitted the observed data.

The monoclinic cell of Pd_5As resembles the monoclinic cells of the compounds $Co_{17}Th_2$ and $Fe_{17}Th_2$, which are based on the well-known $D2_d$ ($CaZn_5$) structure (7). There is also a striking resemblance between the pseudo-orthorhombic cell, which it is possible to choose for Pd_5As, namely $a = 7.72$ Å. $b = 16.64$ Å, $c = 5.51$ Å, and $\beta = 90°25'$, and the orthorhombic cell of PBr_5 with $a = 8.3$ Å, $b = 16.9$ Å, and $c = 5.6$ Å.

Efforts to obtain a smooth Debye–Scherrer pattern by crushing the single crystals failed because of their extreme malleability and, as mentioned above, it was found difficult to obtain a diffraction pattern of the pure Pd_5As phase from a well-annealed polycrystalline material of nominal composition Pd_5As. Some lines unique to Pd_3As pattern were always observed in this pattern. The principal lines of the Pd_5As pattern recorded in Table V, therefore, were obtained by subtracting all lines unique to Pd_3As with the exception of the obviously superimposed reflections.

TABLE V

ACKNOWLEDGMENTS

The authors are indebted to Mr. G. J. G. Despault, who prepared the samples; to Miss M. McLellan, who obtained the Debye–Scherrer patterns; and to Dr. F. R. Ahmed, who obtained the computor data relating to the α-Pd_2As phase.

NOTE ADDED IN PROOF: The paper by Ch. J. Raub and G. W. Webb (J. Less Common Metals, **5**, 271 (1963)) on the palladium–arsenic system has come to hand since submission of this manuscript. We have summarized Raub and Webb's results by plotting their thermal analysis points (triangles) together with ours (dots) in Fig. 2. Their inter-

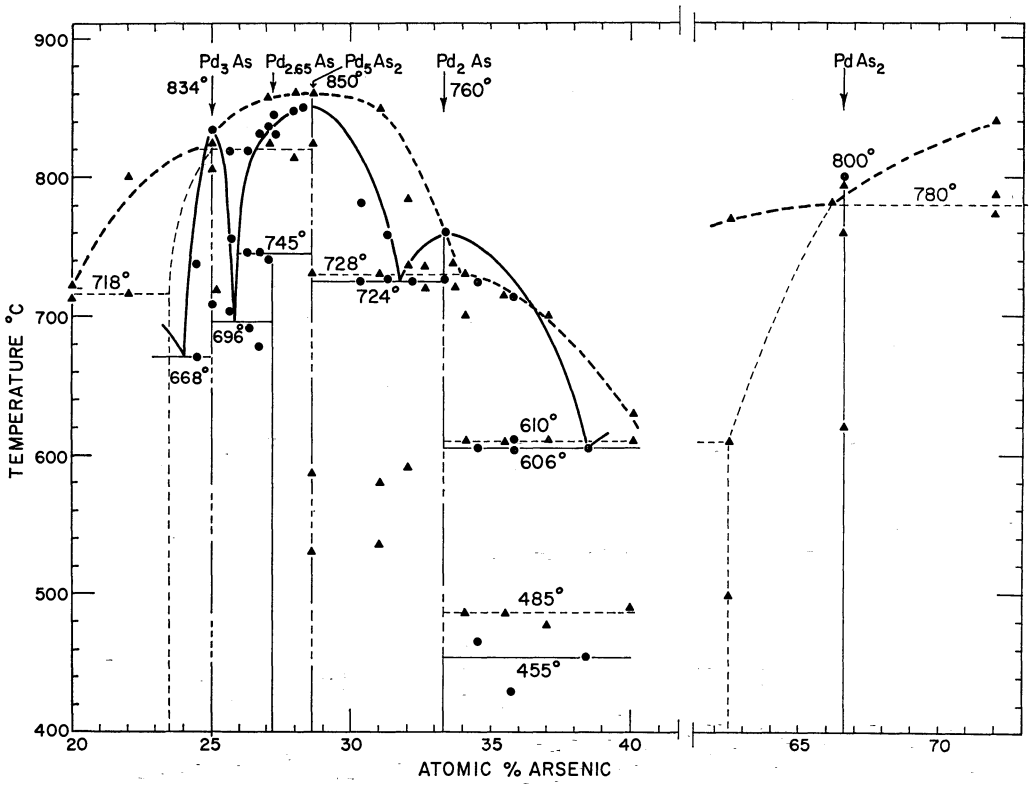

FIG. 2. Combined phase diagram for the system palladium–arsenic.

pretation is shown in dotted lines and ours in solid lines. There is a considerable measure of agreement in the actual observations but as the interpretations differ markedly, a few brief comments confined to the areas of significant difference appear necessary.

1. The phase tentatively designated Pd_7As by Raub and Webb is actually Pd_5As from our single crystal data.

2. Pd_3As is given by Raub and Webb as peritectically formed at 820° C. Since they did not detect the phase $Pd_{2.65}As$, their interpretation in this region is open to doubt. We did not obtain thermal data on samples of sufficiently low arsenic percentage to enable us to construct this area of the phase diagram with complete certainty.

3. Raub and Webb show Pd_2As being formed by a peritectic reaction 32° below the liquidus line. We have interpreted our results in terms of a congruent melting point 36° above the eutectic horizontal. Both interpretations are reasonably consistent with the observed data. We did grow crystals of β-Pd_2As (high temperature form) from a melt of stoichiometric composition, which would add support to the congruent melting interpretation.

PREPARATION AND CHARACTERIZATION OF CRYSTALS OF MX- AND MX_2-TYPE ARSENIDES OF NIOBIUM AND TANTALUM[1]

G. S. SAINI,[2] L. D. CALVERT, AND J. B. TAYLOR
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received October 19, 1963

ABSTRACT

Phase analytical work on the systems niobium–arsenic and tantalum–arsenic has established the existence of mono- and di-arsenides as the only phases on the arsenic-rich side of the composition 50 atomic % As. Single crystals of these phases were grown by halide vapor transport reactions. The monoarsenides are tetragonal and isostructural. The lattice parameters of NbAs are $a = 3.453 \pm 0.002$ Å, $c = 11.672 \pm 0.005$ Å and of TaAs, $a = 3.436 \pm 0.002$ Å, $c = 11.644 \pm 0.005$ Å. The diarsenides are isostructural and have a C-face centered monoclinic cell with $a = 9.354 \pm 0.002$ Å, $b = 3.381 \pm 0.002$ Å, $c = 7.799 \pm 0.002$ Å, $\beta = 119°26' \pm 5'$ for $NbAs_2$ and $a = 9.350 \pm 0.002$ Å, $b = 3.388 \pm 0.002$ Å, $c = 7.760 \pm 0.002$ Å, $\beta = 119°45' \pm 5'$ for $TaAs_2$.

The literature contains very little information on the systems Nb–As and Ta–As with the exception of early preparative work by Heinerth and Biltz (1) which claimed the isolation of $NbAs_{1.8}$ and $TaAs_{1.4}$.

Recent work by Brixner (2) on the diselenides and ditellurides of niobium and tantalum led to the successful growth of single crystals by halide vapor transport. The concept of vapor transport reactions first introduced by Schäfer (3) has also been applied to growth of other chalcogenides by Nitsche, Bölsterli, and Lichtensteiger (4). Our studies of the systems Ni–As and Pd–As have included the growth of single crystals of Ni_5As_2, Pd_5As, and Pd_3As using vapor transport reactions (5). These techniques have now been applied to the growth of niobium and tantalum arsenide crystals and this paper describes the preliminary phase analytical study, the subsequent single crystal preparations, and the determination of the lattice parameters.

EXPERIMENTAL

1. Phase Analysis

Niobium and tantalum were obtained as powders from A. D. Mackey and Johnson Matthey respectively. Both the elements were better than 99.7% pure with respect to the other. Both materials also contained up to 500 p.p.m. of iron. They were used without further purification. Arsenic was supplied by Cominco as "high purity arsenic" with a claimed spectrographic analysis better than 99.999%. It was fractionally sublimed *in vacuo* at 450° C to reduce oxide contaminant not accounted for in the analysis.

A number of 5-g samples were prepared by reacting calculated quantities of niobium or tantalum with 50 to 75 atomic percent arsenic in evacuated quartz ampoules at 700° C for 3 weeks. After this initial reaction period the samples were quenched, ground, divided into three parts, and resealed in quartz. These samples were then subjected to annealing treatments at 500°, 750°, and 1000° C for periods up to 4 months. As required, samples were quenched in water and Debye–Scherrer patterns obtained on 11.46-cm Norelco cameras using Ni-filtered copper radiation.

This examination revealed that within the composition range under examination there were two phases present in each system. These phases occurred at compositions corresponding to MX and MX_2. The patterns obtained in the case of the niobium arsenides were remarkably similar to the corresponding tantalum arsenide patterns. However, the thermal stability of NbAs differed from that of TaAs in that the NbAs pattern was obtained for all alloys of stoichiometric composition regardless of the thermal treatment. Some samples were held at 1700° C for a period of minutes and then quenched in air. They did not melt

For personal use only.

and still retained the NbAs structure. The TaAs samples, on the other hand, only showed the characteristic NbAs-type pattern when quenched from temperatures above 750° C. Below this temperature the pattern was of $TaAs_2$ together with a metal-rich phase. A somewhat similar metal-rich phase has also been observed in the Nb–As system and probably occurs at the composition Nb_3As but in contrast to the tantalum analogue it is unstable below 1000° C. Attempts to obtain good diffraction patterns or single crystals of these latter phases have not yet been successful so that no characterization is possible at this time.

2. Single Crystal Preparation

Growth of crystals from the melt was not attempted because of the high liquidus temperatures in this system. Direct growth from the vapor was not practicable either since there is no evidence that niobium and tantalum arsenides exist as molecular species in the vapor state. Halide vapor transport reactions using chlorine or bromine proved successful for growing small crystals of these arsenides. No transport was obtained with iodine. The general procedure has been described elsewhere (5) but in spite of a semiquantitative analysis given by Nitsche *et al.* concerning transport reactions in general, choice of temperatures for the charge and receiver is an empirical process because of lack of information on the thermodynamic functions involved. Accordingly the relevant parameters are recorded for each case although they may not define unique conditions necessary for crystal growth.

$NbAs_2$ and $TaAs_2$ crystals were grown in tubes 18 cm long and 1 cm bore using 0.25 mg/cc of chlorine or bromine. A charge of previously reacted polycrystalline diarsenide was held at 1000° C and the receiver end of the tube at 600 to 700° C. Lustrous black bladelike crystals grew at the cooler end, and after 2 days were about 3 mm long.

Experiments to grow NbAs and TaAs crystals using a charge of polycrystalline monoarsenide were unsuccessful. Previous experience with transport reactions in the palladium–arsenic system had indicated that the best results were always obtained when arsenic-rich phases were used as the charge material even when metal-rich crystals were required. Crystals of NbAs were finally grown from a charge of $NbAs_2$ using 0.2 mg/cc of bromine in the usual tube with the charge at 1000° C and the receiver at 760° C. After 20 hours the NbAs was obtained as small black polyhedra having a maximum dimension of 0.2 mm. These crystals were deposited at a temperature of about 850° C whilst further down the tube $NbAs_2$ blades appeared so that both phases were simultaneously present in the tube. Extension of the heating period resulted in complete disappearance of the monoarsenide phase. Parallel experiments in the tantalum system failed to yield TaAs crystals.

CRYSTALLOGRAPHY

The Monoarsenides

NbAs

Single crystals were examined on a precession camera using zirconium-filtered molybdenum radiation. The zones studied were $h0l$, $h1l$, $hk0$, $hk1$, and $hk2$. The only reflections present were hkl with $h + k + l = 2n$ and $00l$ with $l = 4n$. NbAs is tetragonal and the apparent observed symmetry is $4/mmm$ consistent with the space group $I4_122(D_4^{10})$. Cell parameters determined from the single crystal photographs are $a = 3.45 \pm 0.01$ Å, $c = 11.65 \pm 0.02$ Å. An indexed powder photograph obtained on an 11.46-cm Debye–Scherrer camera is given in Table I. The cell parameters obtained from this pattern are: $a = 3.453 \pm 0.002$ Å, $c = 11.672 \pm 0.005$ Å; from which we derive $c/a = 3.380$; $U = 139.2$ Å^3; $Z = 4$; F.W. = 167.83; $D_x = 8.01$ g cm^{-3}. The density measured on a Berman torsion balance using toluene as immersion fluid is 8.11 g cm^{-3}.

TaAs

An indexed powder photograph is given in Table II. TaAs is isostructural with NbAs; $a = 3.436 \pm 0.002$ Å, $c = 11.644 \pm 0.005$ Å, $c/a = 3.389$; $U = 137.5$ Å^3; $Z = 4$; F.W. = 255.87; $D_x = 12.36$ g cm^{-3}.

The monophosphides β-NbP and β-TaP were reported by Schönberg (6) as being $I4_122(D_6^{10})$ with 4Nb in 4(a) and 4P in 4(b). Rundqvist (7) suggests an alternative structure in the space group $I4_1(C_6^4)$ with 4Nb in 4(a), $z = 0$, and 4P in 4(a), $z = 0.42$. Rough estimates of our single crystal intensities are more consistent with Rundqvist's proposals than Schönberg's. Detailed structure factor calculations are required to resolve this point.

The Diarsenides

$NbAs_2$

The bladelike crystals were examined by the precession method. The zones studied were $hk0$, $hk1$, $hk2$, $h0l$, $h1l$, and $0kl$. The b-axis was taken as unique. The only absent reflections were hkl with $h + k = 2n + 1$. $NbAs_2$ is monoclinic, diffraction symbol $12/m\ 1\ C\ldots$, and the space group may be any of the three $C2/m(C_{2h}^3)$, $Cm(C_s^3)$, and $C2(C_2^3)$. One crystal was found to be elongated along the b-axis with 001 as the large flat face. Not all crystals had this orientation. The cell parameters determined from the precession photographs are $a = 9.36_5 \pm 0.02$ Å, $b = 3.38_3 \pm 0.01$ Å, $c = 7.80_9 \pm 0.02$ Å, $\beta = 119.25' \pm 5'$. The indexed powder pattern in Table IV was obtained on a Guinier

TABLE III

focussing camera using As_2O_3 as internal standard. Parameters determined from this pattern are $a = 9.354 \pm 0.002°$, $b = 3.381 \pm 0.002$ Å, $c = 7.799 \pm 0.002$ Å, $\beta = 119°26' \pm 5'$; from which $U = 214.8$ Å^3; $Z = 4$; F.W. = 242.75; $D_x = 7.50$ g cm^{-3}. The density measured pycnometrically using water is 7.01 g cm^{-3}.

$TaAs_2$

The diarsenides of niobium and tantalum are isostructural. An indexed powder pattern of $TaAs_2$ is given in Table IV. $TaAs_2$ is monoclinic, diffraction symbol $12/m\ 1\ C\ldots$, $a = 9.350 \pm 0.002$ Å, $b = 3.388 \pm 0.002$ Å, $c = 7.760 \pm 0.002$ Å, $\beta = 119°45' \pm 5'$; $U = 213.4$ Å; $Z = 4$; F.W. = 330.79; $D_x = 10.29$ g cm^{-3}; and $D_m = 9.21$ g cm^{-3} (pycnometric).

The monoclinic diarsenides $NbAs_2$ and $TaAs_2$ represent a new structure type in binary pnictides systems. The structure differs from that of the monoclinic diarsenides of the cobalt family (8).

THE HEARTWOOD EXTRACTIVES OF PINUS RESINOSA AIT.[1]

A. SATO[2] AND E. VON RUDLOFF
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received October 10, 1963

ABSTRACT

The acetone extract of red pine heartwood was found to contain mainly pinosylvin monomethyl ether, oleic, linoleic, dehydroabietic, and isopimaric acids, and triglycerides of unsaturated fatty acids. Smaller amounts of pinosylvin, β-sitosteryl esters, and benzoic acid were isolated. Palmitic, palmitoleic, stearic, linoleic, pimaric, sandaracopimaric, abietic, neoabietic, vanillic, and three unidentified acids, as well as pinocembrin, vanillin, and eleven trace components were recorded by gas–liquid chromatography. A small amount of steam volatile oil, which may have taxonomic significance, was isolated. α-Pinene, β-pinene, myrcene, limonene, γ-terpinene, terpinolene, camphor, *cis*-*p*-menthan-8-ol, terpinen-4-ol, and α-terpineol were tentatively identified.

Besides glucose and xylose, the methanol extract contained polylignan fractions similar to those which had been isolated previously from jack pine.

The North American red pine, *Pinus resinosa* Ait., a member of the subgenera diploxylon, is a medium-to-large tree found from the Atlantic Coast to southeastern Manitoba. Its thick sapwood is readily penetrated by creosote and the wood is therefore used extensively for poles and piling (1). Lindstedt and Misiorny (2) have shown that the heartwood phenols consist mainly of pinosylvin monomethyl ether and, by paper chromatography, have demonstrated the presence of pinosylvin, two unknowns (E and F), but could not confirm the presence of pinocembrin or pinobanksin. Levitin (3) reported the amount of ether extract in the heartwood and sapwood, and recently (4) demonstrated that knots contain a higher amount of α- and β-pinene than the sap or heartwood. However, a complete analysis of the heartwood extractives of this pine does not appear to have been carried out.

Recently, we reported on the total analysis of the heartwood extractives of jack pine (*Pinus banksiana* Lamb.) (5). The same chromatographic techniques and countercurrent distribution have now been applied to a similar analysis of those of the red pine. Equally satisfactory results have been obtained, except for the analysis of the phenolic fraction. The fractionation scheme is summarized in Fig. 1. The neutral components were saponified and the resulting alcohols and free fatty acids were analyzed by thin-layer (TLC) and gas–liquid (GLC) chromatography. The quantitative data obtained for the fatty acids are shown in Table I, and from these it follows that the neutral fraction is composed mainly of triglycerides of oleic and linoleic acids and smaller amounts of stearic, linolenic, palmitic, palmitoleic, and the two minor unidentified acids also found in jack pine heartwood (5). The free acids were separated from the phenolic constituents by countercurrent distribution, and were analyzed by GLC (see Table I) after conversion to the methyl esters. The same resin acid esters were recorded as had been found in jack pine heartwood (5), but the amounts (see Table I) of each differed. Also, approximately 40% fatty acid esters were recorded, showing that, in red pine, free fatty acids were a major constituent. Isopimaric and dehydroabietic were the main resin acids. Steam distillation of the acid fraction gave a small amount of benzoic acid, just as was obtained from jack pine wood (5).

Dehydroabietic	17.5	—
Abietic	10.5	—
Neoabietic	2.5	—

*Same relative retention times (RRT 0.53 and 0.73) as two unidentified components of the free acid mixture of jack pine (5).

Paper- or thin-layer chromatograms of the phenolic fraction streaked excessively and showed only the presence of pinosylvin monomethyl ether. This was the major constituent (at least 90%) of this fraction and crystalline pinosylvin monomethyl ether was isolated. TLC analysis of the mother liquors did not give useful data. Since Narasimhachari and von Rudloff (6) had shown that the methyl ethers of polyphenols, including flavonoids, may be separated by GLC, this method was investigated. However, Erdtman (7) as well as Lindstedt and co-workers (2, 8) have shown that in the heartwood of many pine species the monomethyl ethers of pinosylvin and flavanones may occur together with the parent polyphenol. Thus, GLC of the methylated phenol fraction could not be expected to give complete resolution of all components. Bentley *et al.* (9) have described successful

For personal use only.

GLC of polyols and saccharides in the form of their trimethylsilyl (TMS) ethers. These ethers are relatively volatile, fairly stable, and resistant to oxidation (10). Using a 15% SE-52 silicone polymer column, good peaks and resolution were obtained for the TMS derivatives of vanillin, vanillic acid, ferulic acid, and the pinosylvins (see Table II), but conversion of flavanones was not quantitative and double peaks were frequently recorded. However, the technique permitted qualitative analysis and the presence of pinosylvin, pinocembrin, vanillin, vanillic acid, and several unidentified trace constituents (see experimental) in red pine heartwood were demonstrated. The derivative of pinobanksin was not recorded. On the other hand, vanillin, vanillic acid, and the unidentified compounds were not found in the phenolic fraction from Jack pine heartwood.

The volatile oil was obtained only in very low yield. (see Fig. 1), and the amounts available were insufficient for the isolation of individual components. The GLC chromatogram, obtained from a temperature-programmed run on a 6 ft polyethylene glycol column, is shown in Fig. 2. At least 33 different compounds appear to be present and of these α-

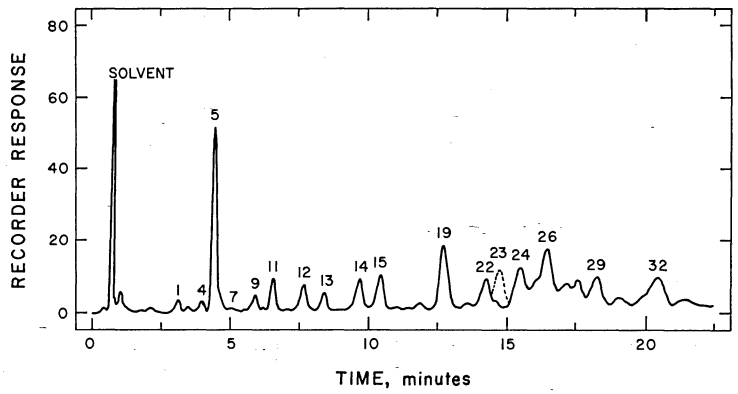

FIG. 2. Temperature-programmed chromatogram of the volatile oil from the heartwood of red pine as obtained on a 6 ft × 1/4 in. polyethylene glycol (Carbowax 20 M) column; 65 to 200° C, 120 ml helium/minute.

pinene (peak 4), β-pinene (peak 7), myrcene (peak 9), limonene (peak 11), γ-terpinene (peak 12), terpinolene (peak 13), camphor (peak 19), *cis*-*p*-menthan-8-ol (peak 22), terpinen-4-ol (peak 24), and α-terpineol (peak 26) were tentatively identified by retention characteristics. The major peak 5 does not appear to be a monoterpene (e.g. fenchene), since on Apiezon it had a considerably lower retention time than did these hydrocarbons. Peak 32 could be geraniol and peaks 14 and 15 are in the allo-ocimene range. When the oil was treated with diazomethane, peak 23 was recorded in significantly larger amounts (dotted lines in Fig. 2). This peak has the retention time of methyl benzoate. The chromatographic spectrum differs significantly from that of the oil of jack pine heartwood (5) and it appears likely that the volatile oil of pines may be used for taxonomic purposes. Swan (11) has recently applied this concept to a study of hybridization among West Coast pine species.

The methanol extract (see Fig. 1) was divided into water-soluble, acetone-soluble constituents, and a trace of ether-soluble material. The water-soluble portion was analyzed by paper chromatography and spots corresponding to glucose and xylose were detected. The acetone-soluble part was fractionated by precipitation from acetone or methanol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and three fractions having fairly sharp melting points were obtained. All had infrared spectra which were very similar to that of lariciresinol, and appeared to be similar to the polylignan fractions isolated from jack pine heartwood (5). Fraction A had m.p. 177–180° C, 10.6% methoxyl content, and a molecular weight of 1883. Fraction B melted at 164° C and fraction C at 145.5–150° C. During attempts to purify these fractions further it was noticed that the molecular weight increased. Thus, fraction A was found to have a molecular weight of 1790, which changed to 1883 upon re-precipitation. This was accompanied by a slight broadening of the melting point range, viz. from 178–180° C to 177–180° C. Nitrobenzene oxidation of these polylignan fractions gave mainly vanillin and some *p*-hydroxybenzaldehyde, showing that a guaiacyl residue is a typical feature of this group of compounds. Work is in progress to establish whether these compounds are true lignan polymers or rather simple lignin precursors, such as the guaiacyl glycerol dimers and trimers isolated by Freudenberg *et al.* (12, 13). In further work on the polylignans from Jack pine it was found that this group of compounds reacted with methanol during the extraction. This lends support to the surmise that a guaiacyl glycerol derivative is present, since the α-hydroxyl group of such compounds reacts readily with alcohols, phenols, and carbohydrates.

EXPERIMENTAL

Most of the experimental procedures and apparatus used were described previously (5). The wood was supplied by the Department of Mines and Natural Resources, Manitoba, and came from the Marchand district. The log was freed from bark and sapwood and milled in a hammer and a Wiley mill. The air-dried wood meal (3.0 kg) was extracted with acetone (10 liters) in a Soxhlet extractor for 30 to 36 hours. The solvent was removed by evaporation *in vacuo* in a rotary evaporator. The residual wood meal was similarly extracted with methanol or dioxane. Known crystalline compounds were identified by mixed melting point and comparison of infrared spectra.

Acetone Extract

The brown, viscous residue (152 g, 5.05%) from the acetone extraction was poured with stirring into ether (2 liters) and the small amount of precipitate (0.7 g) which formed was filtered off. The ethereal solution was extracted exhaustively with aqueous potassium hydroxide solution (5%) to remove all acids and phenols. After washing with water it was dried over sodium sulphate and the ether was removed to give the neutral constituents (15 g, 0.5%). The aqueous alkaline solution was acidified with dilute hydrochloric acid (10%) and extracted thoroughly with ether. The ethereal solution was dried and evaporated to dryness. The residual material (136 g, 4.5%) was resolved into free acids and free phenols by countercurrent distribution (5).

Neutrals

An aliquot (3 g) of the total neutral material was saponified and worked up in the usual manner to give the free alcohols (0.06 g) and acids (2.2 g). The latter were analyzed by GLC on a butanediol succinate (Craig) polyester column at 205° C and the results obtained are shown in Table I. The alcohols were analyzed by TLC when several terpenoid spots and a spot corresponding to β-sitosterol were recorded. The latter was obtained crystalline, m.p. 129–132° C, from the crude product by recrystallization from ethanol; the derived acetate had m.p. 122.5–124° C. Steam distillation of the filtrate gave a small amount of volatile product. Analysis by GLC (6 ft × 1/4 in. O.D.; 15% polyethylene glycol 20 M on Chromosorb W, 60–80 mesh) showed the presence of 10 peaks in the monoterpene range. The three major peaks (20 to 30% each) had the retention times of α-terpineol, terpinen-4-ol, and *cis*-*p*-menthan-8-ol respectively. These alcohols were presumably present in the free state, since they were also found in the steam volatile fraction (see below).

The aqueous residue from the above saponification was deionized with ion exchange resin and evaporated *in vacuo* to a viscous residue (0.8 g). This was acetylated and GLC analysis gave a single peak having the same retention time as triacetin.

Free Acids

An aliquot (5.0 g) of the total acids and phenols was subjected to countercurrent distribution (petrol, b.p. 40–60° C, and 75% aqueous ethanol saturated with each other, 20 transfers). Tubes 9 to 20 were combined to give the total free acids (3.0 g) and these were analyzed by GLC after conversion to the methyl esters. Since it was found that relatively large amounts of free fatty acids were present, the analyses were carried out on butanediol succinate polyester (at 205° C) as well as on the columns used previously for fractionation of the resin acid esters (5). The results obtained are summarized in Table I. Steam distillation of the free acid fraction gave a small amount of benzoic acid, m.p. 120–122° C.

For personal use only.

Free Phenols

Tubes 1 to 8 from the above experiment were analyzed separately by TLC but the chromatograms streaked excessively. The material was therefore combined and crystallization from aqueous ethanol and benzene gave pinosylvin monomethyl ether m.p. 119.5–121° C, undepressed in admixture with authentic material. An aliquot (30 mg) of the residue from the mother liquor was dissolved in dry pyridine (0.1 ml) and to this was added hexamethyl disilazane (0.1 ml) and trimethyl chlorosilane (0.1 ml). The mixture was shaken for a few minutes, allowed to stand for 5 minutes, and aliquots (10 to 40 μl) of the supernatant liquid were injected into the GLC apparatus. The column (3 ft × 1/4 in. O.C., 15% SE-52 silicone polymer on Chromosorb W, 60–80 mesh) was maintained at 160°, 192°, or 242° C to determine the presence of low- and high-boiling phenol ethers. Reference compounds were similarly converted to the TMS derivatives and the relative retention times (RRT) obtained are shown in Table II. The major component in the TMS-treated

†Found in red pine heartwood extractives.
‡Double peak.

phenol mixture was pinosylvin monomethyl ether and only small amounts of pinosylvin, pinocembrin, vanillin, and vanillic acid were recorded. In addition 11 trace components were recorded (RRT at 160° C 0.15; at 192° 0.53, 0.67, 1.08, 2.23, 2.98, 3.83, and 5.70; and at 242° 1.36, 2.68, and 2.89). Of these, the peak at RRT (at 242°) 1.36 may have been due to a resin acid. The presence of the relatively large amounts of pyridine in the injected aliquot resulted in a very large, tailing solvent peak, which tended to overlap (and distort) peaks of short retention times.

Column chromatography on silicic acid of the mother liquors gave a small fraction from which pinosylvin (m.p. 158.5–159.5° C) was obtained after recrystallization. None of the other components was obtained pure.

Steam-volatile Components

Fresh wood meal (100 g) was steam distilled for 2 hours and the distillate was taken up in ether. The ethereal solution was dried and the solvent carefully evaporated to give the volatile oil (0.08 g). The chromatogram obtained with a 5 μl aliquot on a 6 ft × 1/4 in. O.D. polyethylene glycol (Carbowax 20 M) column is shown in Fig. 2. The oil (10 μl) was treated with ethereal diazomethane solution. The chromatogram obtained with this product was similar to that obtained under the same conditions with the untreated oil, except that peak 23 was recorded in larger amounts (shown by the dotted lines in Fig. 2), and corresponded to methyl benzoate. Components were tentatively identified by comparison of RRT values with those of known compounds, using polyethylene glycol, Apiezon N, and polyester columns.

Ether-insoluble Material

TLC analysis of the ether-insoluble portion of the acetone extract (see above) gave two spots of R_f 0.00

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and R_f 0.15 ($CHCl_3$:HOAc; 9:1 v/v), which was the same as obtained from the polylignan fractions found in the methanol extract.

Methanol Extract

The residual wood meal (1.2 kg) after acetone extraction was extracted with methanol (5 liters) for 36 hours. The brown, sirupy residue (10 g, 0.8%) obtained after evaporation of the solvent was extracted with hot water (300 ml). The water-soluble portion (3.5 g) was analyzed by paper chromatography (Whatman No. 1; pyridine–butanol–water, 3:3:1 v/v) and two spots corresponding in color (aniline phthalate spray reagent) and R_f values to glucose (R_f 0.16) and xylose (R_f 0.27) were obtained.

The water-insoluble portion (6.4 g) was triturated with hot acetone and the soluble portion was separated. The solvent was evaporated and the residue (6.1 g) was taken up in a few milliliters methanol and dispersed into 2-butanone (200 ml). The resulting precipitate (0.40 g) was filtered off and had m.p. 178–180° C; OCH_3, 12.9%; molecular weight (osmometric, in acetone) 1790. The material was dissolved in dioxane and dispersed into water to give a precipitate, fraction A, with m.p. 177–180° C, $[\alpha]_D$ +1.0° (*c*, 1, dioxane). Found: C, 62.62; H, 6.17; N, 0.51; OCH_3, 10.63%; molecular weight, 1883. After some weeks, the material was no longer completely soluble in acetone or dioxane. On addition of ether to the above filtrate (methanol–butanone solution) fraction B (0.32 g), m.p. 164° C, $[\alpha]_D$ approx. 0° (*c*, 0.5, dioxane) was obtained. This fraction gave a crystalline acetate of m.p. 143–144° C.

The acetone-insoluble portion (0.3 g) was taken up in dioxane and dispersed into ether. The precipitate (0.01 g), fraction C, had m.p. 145.5–150° C.

Fractions A, B, and C had infrared spectra which resembled that of lariciresinol closely.

Nitrobenzene Oxidation

The compound (0.1 g), 2 *N* sodium hydroxide solution (6 ml), and freshly distilled nitrobenzene (0.4 ml) were placed in a stainless steel cylinder of 10 ml capacity (14). The mixture was then heated at 180° C ± 2° in an autoclave for 2 hours with rocking. After being cooled, the reaction mixture was transferred and the excess nitrobenzene was removed by continuous extraction with ether. The aqueous layer was acidified with dilute sulphuric acid (to pH 3) and extracted with ether. After it was dried over anhydrous sodium sulphate, the solvent was evaporated. The residue was taken up in pyridine, converted to the trimethyl silyl derivative, and analyzed by GLC on the SE-52 column (see above).

ACKNOWLEDGMENTS

We wish to thank Mr. M. Kaye, Extension Forester, Manitoba Department of Mines and Natural Resources, Winnipeg, for procuring the red pine log, and Mr. M. Granat for technical assistance. The microanalyses were carried out by Mr. M. Mazurek and infrared spectra were recorded by Mr. W. C. Haid.

THE THERMAL REVERSIBILITY OF THE MICHAEL REACTION

I. NITRILES[1]

Received August 12, 1963

ABSTRACT

Michael adducts of nitriles and α,β-unsaturated ketones have been found generally to undergo two or more kinds of thermal reversibility upon being heated to moderate temperatures. When the products are those from which the adduct was prepared, the dissociation is termed "normal," whereas the "abnormal" route gives an α,β-unsaturated nitrile and a methyl ketone. The scope and generality of the reversibility are described in three papers. The first deals with 31 ketonic nitriles, the second with nitroketones, and the last with diketones and acidic derivatives.

Allowing the materials to decompose thermally in the heated inlet of a mass spectrometer permits a direct study of thermal reaction mixtures and it affords data the interpretation of which gives an indication of the products present, many of which may not have been previously expected. Identification of products is confirmed by comparison of the mass spectra with those of reference compounds. Under favorable conditions, such products can be isolated from independent decomposition reactions and their identities further confirmed by classical chemical methods. Both operations have been done often enough to show the general application of the mass spectrometer for this purpose. Thus laborious laboratory separations may be avoided. In two instances the four major products from both paths were isolated, identified, and quantitatively determined.

Forty years ago, the senior author of this paper found that γ-benzoyl-α,β-diphenylbutyronitrile (I) (1), the adduct from benzyl cyanide and benzalacetophenone, dissociated on attempted distillation, and its components were identified in the distillate.

$$\begin{matrix} C_6H_5CHCH_2COC_6H_5 \\ | \\ C_6H_5CHCN \end{matrix} \rightleftarrows \begin{matrix} C_6H_5CH{=}CHCOC_6H_5 \\ + \\ C_6H_5CH_2CN \end{matrix}$$

I

Twenty years later, β,γ-diphenyl-γ-nitrobutyrophenone (II) was found to decompose when heated above its melting point; the products identified were benzalacetophenone, benzaldehyde, and nitric oxide (2).

$$\begin{matrix} C_6H_5CHCH_2COC_6H_5 \\ | \\ C_6H_5CHNO_2 \end{matrix} \rightarrow \begin{matrix} C_6H_5CH{=}CHCOC_6H_5 \\ + \\ C_6H_5CHO + NO + ? \end{matrix}$$

II

Although the reversibility of the Michael reaction in the presence of alkaline reagents is well known (3), there are very few recorded instances of the effect of heat upon the adducts. Those few described are all dicarbonyl compounds (see Part III). It seemed

advisable to postpone a study of the thermal reversibility of the Michael reaction until relatively simple but rapid qualitative and quantitative methods were available. Such tools have been employed in these Laboratories for some years in the form of the mass spectrometer and the gas chromatograph.

Summarizing the present work in three papers, it has been found that the thermal reversibility is dependent upon the number and kind of groups present. The degree of substitution, which has been varied from one to three aryl groups, has considerable effect. Cleavage, which is greatest and may occur in two ways when there are three aryl groups along the chain, is not detectable when there is but one such substituent; the results are intermediate with two aryls. In a given class, the nature of the functional groups is very important. For instance, 1,5-diketones (Part III) and delta ketonic nitriles (this paper) cleave the most easily and follow both paths; keto esters go both ways but less easily. γ-Nitroketones are thermally more stable; they can even be distilled with partial cleavage, which goes only one (normal) way. Cyano esters and diesters are relatively stable; the latter show slight decomposition, but not dissociation, on distillation. Ketonic acids are subject to a competing reaction—any Michael reversal is often undetectable by classical chemical methods.

The mass spectrometer is especially well suited for studying reaction mixtures from thermal decompositions because it furnishes mass numbers from which one can speculate usefully about the identity of the cleavage products, and which can provide positive identification when reference spectra are available. This paper discusses the behavior of nitriles, in particular, those of type I, of which a considerable variety are available.

Approximately 1 milligram of each substance studied was allowed to decompose in the glass and metal heated inlet (230°) system (9) of a mass spectrometer over a period of an hour while several spectra were recorded. Many of the reactions were rapid and there was little change in the spectral pattern during this time, indicating that an equilibrium state had been reached before making the first observation. The pattern changes during the hour were sufficient, however, to indicate that the spectra were those of mixtures. Careful measurement showed that the cracking patterns of the components, as identified, remained constant while the ratios of the several components changed with respect to each other during the period of observation. Factors such as rates of reaction, of volatilization, and of effusion through the leak, may account for the changes. For some slower decompositions, decrease in peak size for the original molecule was observed, accompanied by an increase in the pattern size of the products. Mass-spectral peaks which were judged to be probable parent peaks of undissociated molecule-ions formed the initial basis of speculation concerning the identity of components. Identifications were verified by subsequently comparing the entire spectral pattern with those of known reference compounds. Some of the identifications made by mass spectrometry were further confirmed by carrying out independent decompositions on a larger scale in the laboratory, followed by separation and identification by chemical means as well as by infrared and mass spectrometry.

The quantitative aspects of mass spectrometry are well known and might be applied to these studies. Since this work involved substances of widely different vapor pressures, it would have been necessary to establish the limits within which each substance would yield a linear relationship between amount present and peak intensity under the conditions of operation. The scope of the mass-spectrometric work was limited, therefore, to the qualitative identification of the reaction products, thereby establishing the modes of decomposition of the compounds studied. Once the identity of certain of the products was established by mass spectrometry, it was relatively simple to make quantitative

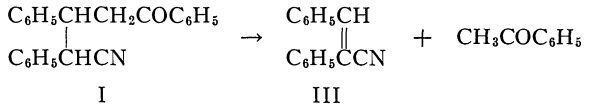
measurements on these components by gas chromatography on some of the reaction mixtures from decompositions carried out under laboratory conditions.

Both isomers of adduct I, when decomposed in the heated inlet of the mass spectrometer, yielded not only the expected chalcone and benzyl cyanide (1), but also α-phenylcinnamonitrile (III) and acetophenone, the products of a second mode of decomposition.



I III

The mass spectra also showed the presence of smaller amounts of other materials which we were unable to identify from the spectral peaks. There was no peak for the parent molecule-ion of either diastereomer of I. However, in a subsequent examination of the adducts, using an all-glass heated inlet to minimize thermal degradation, the mass spectra contained the peaks of the products plus the peaks of the undecomposed molecule, including a prominent peak at the mass of the parent molecule-ion. This finding shows that in the examination of these adducts under the original conditions, where no parent peaks of the adducts were found, the mass spectra represented only the reaction products.

Although the mass-spectrometric identifications were confirmed by comparison with reference spectra of known compounds, further proof was obtained to show that the adducts undergo thermal decomposition to yield the identical products. From an independent decomposition, carried out in the laboratory, the four reaction products were isolated and identified by classical methods.

In this paper the re-formation of the original components is called the "normal" reaction and the second mode of retrogression is termed "abnormal." Although presumably reversible, up to now it has not been possible to isolate any of the adduct I from the attempted Michael addition of these abnormal cleavage products, although from the infrared spectrum a small amount might be present.

It now became important to demonstrate the effect of the glass and metal surfaces of the mass spectrometer upon the reversibility of the Michael reaction at the temperature, 230°, of the heated inlet. Series of experiments in which the decompositions were carried out under several conditions in the laboratory were devised to clarify these and other points, using mainly adduct I. The amounts of benzyl cyanide and acetophenone were determined by gas chromatography, the total being taken as a measure of the retrogression. The results are collected in Table I. Quartz and steamed-out soft glass behaved essentially alike at 230°, giving the lowest value, which was used as the standard. At this temperature only normal dissociation occurred; but at 250° the abnormal reaction occurred. The latter was small in quartz, being only 1/10th that taking place in soft glass; hence it must be concluded that the abnormal retrogression is catalyzed to a much greater extent by the alkali present in the glass. This assumption is supported by the results in untreated soft glass at 250°; the normal reaction is of the same order, but the abnormal is doubled. This behavior also accounts for the failure to effect the synthesis of the Michael adduct from the products of the abnormal cleavage (the rate of the latter reaction must be greater than the rate of adduct formation). Retrogression in steamed-out Pyrex glass was, surprisingly, greater than that in soft glass, and approached that shown by metals (lead in the glass?). The metals tested were copper, stainless steel, Kovar alloy, and silver solder; all these are present in the heated inlet. The steel and Kovar were equal, but the silver solder was four times more effective. In the presence of copper, the

retrogression started 20° lower and took only two-thirds as long to run to completion. Doubling the time of heating gave only 4% more products, while raising the temperature by 20° increased them by 2.5 times. The reversal could be made complete by allowing the volatile products (nitrile and ketone) to distill (Table II). Quite surprisingly, the lower-

melting form was much less (one-sixth at 230°, one-fourth at 250°) active. However, the relative proportion of volatile products on distillation was considerably different, the abnormal component (acetophenone) being considerably less. It is concluded from these experiments that the materials used in constructing the heated inlet of the mass spectrometer do affect the rate of the decomposition reactions of these Michael adducts. In all cases the qualitative mass-spectrometric identifications were substantiated.

The thermal decomposition of 22 delta ketonic nitriles were studied in like manner, by allowing them to decompose in the heated inlet of the mass spectrometer. All identifications were confirmed by comparison with reference spectra, and most were further substantiated by classical methods. In addition to the product identification listed in Table III, in many instances there were other products not identified by their peaks in the spectra.

The effect of substitution was determined in a few instances. Nitrile adducts bearing substituents (IV: X, Z = H; Y = 4-Cl, 4-CH_3O, 3-NO_2, 4-NO_2, 4-NH_2) were selected. They all decomposed both normally and abnormally. In the confirming independent laboratory decompositions, gas-chromatographic analysis of the products showed that there was more retrogression of the first two than of the unsubstituted adduct. One type of adduct (IV: X = CH_3O; Y, Z = H) gave only the normal products (benzyl cyanide and 4′-methoxychalcone) from the confirming laboratory decomposition at 250°, yet in the mass spectrometer it showed some evidence of a small amount of abnormal dissociation. The mass spectrum of the phenyl analogue (IV: X = C_6H_5; Y, Z = H) showed only normal retrogression. The pair of diastereomers (IV: X, Z = H; Y = 4-NO_2) decomposed so badly in a large-scale laboratory decomposition that no useful quantitative results were obtained by gas chromatography.

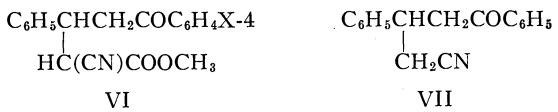
†Undecomposed molecule.

Both diastereomeric amides (adducts from *p*-nitrophenylacetamide) corresponding to IV (X, Z = H; Y = 4-NO_2; $CONH_2$ for CN) gave only normal retrogression as would be expected; this is due to the relative inactivity of the $CONH_2$ as compared to the CN in a Michael reaction.

From these very limited data it may be concluded that the nature of the addendum is the most important single factor in the thermal reversal. This conclusion is borne out by quantitatively observing the behavior of one of the methyl cyanoacetate adducts (VI) (4)—retrogression was 26% at a much lower temperature (195–215°) (Table I). The more highly substituted delta ketonic nitrile (V) (5) falls into line (5) since it gives both the normal products (benzaldesoxybenzoin and benzyl cyanide) and one abnormal product (α-phenylcinnamonitrile) in the mass spectrometer decomposition.



VI VII

For personal use only.

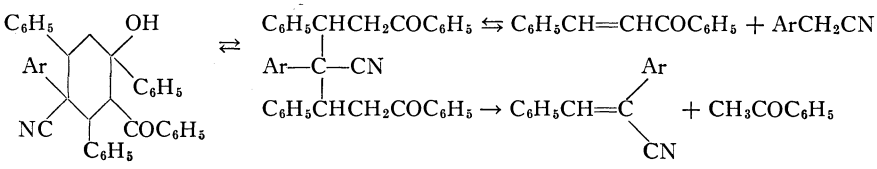
In order to learn the effect of fewer substituents along the chain, other ketonic nitriles were examined. γ-Benzoyl-β-phenylbutyronitrile (VII) (3) gave a parent peak of the undecomposed compound, as well as the normal product (chalcone) formed by loss of acetonitrile, and the abnormal products, cinnamonitrile and acetophenone. γ-Benzoylbutyronitrile (VIII) (6), having no substituents, shows no retrogression at all; this is in agreement with the fact that it distills unchanged. The mass spectrum appeared to be consistent with the structure of the undecomposed molecule, containing a parent peak at *m*/e 173 and a fragment ion peak at *m*/e 119 from cleavage of the bond β to the carbonyl. The largest peak was at *m*/e 105, the $C_6H_5\,CO^+$ ion. Two gamma ketonic nitriles (IX) which cannot give abnormal products were also examined; undecomposed molecules and chalcones were

VIII IX

found. In none of these last instances could the nitrile be identified because of undetermined contributions to the useful mass-spectral peaks by other components.

Two diastereomeric bromo derivatives (IV: X, Y = H; Z = Br) were also examined. The unsaturated compounds (chalcone, α-phenylcinnamonitrile), formed by both types of retrogression, were found. Benzyl cyanide was also identified, but there was no evidence as to the fate of the bromine. From the decomposition of the nitro derivative (IV: X = H; Y = NO_2; Z = Br), chalcone and *p*-nitrobenzyl cyanide, formed by normal retrogression only, were found. There was evidence for the liberation of nitric oxide also, but there were no products of abnormal decomposition. The identification of nitric oxide could not be confirmed in the mass spectrometer because of other possible sources of an NO^+ ion.

The trimolecular products, which are usually formed in small amounts in the preparation of Michael adducts from chalcones and nitriles, from their infrared absorption in the solid state, are now known to exist in the form of highly substituted cyclohexanols (X) (7). They are easily reversible by heat. The open-chain form (XI) (XI: Ar = C_6H_5, 4-$CH_3OC_6H_4$, 4-FC_6H_4) is obviously a Michael adduct, and is likewise reversible. The laboratory experiments again confirmed the mass-spectrometric identifications (1). The



X XI

only recognizable decomposition product from three non-cyclic trimolecular molecules of the type XII (8) was phenyl vinyl ketone, a normal retrogression product.

EXPERIMENTAL

Mass Spectrometry

The instrument was a 60° sector type, equipped with a 230° heated inlet system designed to accept readily samples of liquids or solids. The heated inlet (9) is constructed principally of Pyrex glass with some smaller exposed surfaces of stainless steel, Teflon, Kovar metal, silver solder, and platinum. Relatively large samples were introduced resulting, at least in some instances, in excess non-volatilized material, a condition which precludes quantitative treatment of the data.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Gas Chromatography

The gas-chromatographic separations were carried out in an 8 ft × 0.25 in. column packed with 25%, by weight, General Electric silicone gum rubber SE-30, on 80–100 mesh Celite 545. The column was thermostatted with boiling *p*-cymene and the flow rate was 50 ml of helium per minute. A Gow-Mac thermoconductivity cell, Model 9285, was used as the detector. The retention times observed were: methyl cyanoacetate, 2.23 minutes; acetophenone, 6.26 minutes; benzyl cyanide, 7.80 minutes; 4-chlorobenzyl cyanide, 18.8 minutes; 4-methoxybenzyl cyanide, 21.7 minutes; 4-methoxyacetophenone, 22.8 minutes.

Thermolyses

The specimens for gas chromatography were prepared as follows. One-gram samples of the adducts in vials were heated simultaneously in an oil bath at two temperatures (230°, 250°) for 20 minutes. Metal "catalysts" were included, as has been mentioned; the silver solder had the composition: 50% silver, 18% cadmium, 15.5% copper, and 10.5% zinc. The decomposition products were introduced into the chromatograph as ethyl acetate solutions; chalcone was not estimated since its amount would be equivalent to the benzyl cyanide.

The new soft-glass vials received a hot trisodium phosphate wash, followed by five rinses (in one instance, hydrochloric acid was used as a rinse, but the result was unchanged) and drying at 110°. Vials, steamed out for 10 minutes and dried at 110°, likewise gave a comparable result. In the instances in which all the volatiles were distilled, 5 g of adduct in a 25-ml Pyrex distilling flask was heated in an oil bath as long as distillate collected (Table I). The main features of the findings have already been mentioned.

Reagents and Chemical Reactions

The reagents used were Eastman chemicals except *p*-fluorobenzyl cyanide (10) and 4-aminobenzyl cyanide. The fluoro compound was quite acidic, requiring considerable sodium methoxide in the addition reaction before an alkaline test in moist litmus was obtained. Since Pschorr's procedure (11) (reduction of *p*-nitrobenzyl cyanide by tin and hydrochloric acid) gives a very pure aminonitrile in a high yield, this was followed. Selective catalytic reduction, using 10% palladium on charcoal, gave a very complex mixture.

Many of the adducts and reference compounds required in this and in the following papers were available from previous work. New 4-substituted-α-phenylcinnamonitriles were synthesized by the usual procedure using sodium methoxide, except for the 4-nitro, in which case Triton B was employed. For example, a mixture of 1.5 g of *p*-nitrobenzyl cyanide, 1 ml of benzaldehyde, and 10 ml of alcohol was heated to dissolve the solid, and five drops of Triton B were added. The initial magenta color quickly became greenish, the solvent boiled, and the solid product crystallized shortly. The yield was quantitative. The buff solid, m.p. 177–178°, was rinsed with methanol to remove most of the green color, and recrystallized from propyl alcohol.

The new delta ketonic nitriles of type I were prepared either in the continuous reactor (12), which gives more of the higher-melting isomer, or batchwise, using only a small amount of sodium methoxide as catalyst. The yield of crystalline mixed adduct was 85–87%; the sticky residue that did not crystallize appeared to be mainly the same adducts, according to infrared spectrometry. Only one of the two possible diastereomeric forms of the new adducts (IV: X, Z = H; 4-Y = F, Cl, OCH_3, 3-NO_2; Y, Z = H; X = C_6H_5) was isolated. Mixtures tended to oil out; the anisyl adduct crystallized readily from solutions if the latter were seeded with a little previously prepared sample. The 4-fluoro derivative did not separate from the oil for a month. Tedious fractional crystallizations from petroleum ether and also from methanol afforded no separation; in the previous instances it had been fortuitous with I, but very easy with IV (X, Z = H; Y = NO_2). The various crystalline fractions, which were mixtures of the diastereomeric forms, gave the correct elemental analyses. Since the differences were of degree rather than in kind, it was unnecessary to have both pure forms. A little trimolecular product (X) was separated during the first recrystallization of each of the adducts except the amino derivatives.

Both 4-amino adducts were obtained, however, one by addition and the other by selective catalytic reduction of the corresponding nitro adducts (13). The addition takes place (6 hours) at room temperature, after this mixture had been warmed enough to produce complete solution. Prolonged heating gives a complex mixture from which an impure amine can be isolated only with difficulty. In the catalytic reduction procedure, both adducts (m.p. 126° and 143°) gave 50% yields of the same amine, isomeric with the one produced on addition. The remainder of the product was an intractable yellow pitch. A solution of 32.5 g of nitro adduct in 370 ml of dioxane, containing 1 g of 10% palladium on charcoal, was shaken at room temperature and 60 p.s.i. of hydrogen until the theoretical amount was absorbed (24 hours). Most of the solvent was distilled. The residue was a sticky pitch in which a white solid had formed after 3 weeks. Methanol was added to facilitate manipulation, the solid was collected on a filter, and recrystallized.

The properties of the new substances are listed in Table IV.

All attempts to bring about formation of the Michael adducts (I) from the products of the abnormal dissociation (acetophenone and α-phenylcinnamonitrile) have so far been fruitless; conditions employed included changes in time, catalyst, and solvent. Either the cinnamonitrile, which crystallizes well from mixtures, or a sticky glue resulted. Occurrence of addition would have been indicated by the presence of the known adducts, detectable by infrared spectrometry, or the easily isolable trimolecular product (X),

or the known 2-oxo-1,2,3,4-tetrahydro-3,4,6-triphenylpyridine (1) which has a very brilliant blue fluorescence when exposed to ultraviolet light. The uncrystallizable glue from these attempts (as well as the residual oil from the normal preparation) always shows a blue fluorescence, but there was insufficient adduct to be isolated or detected by infrared spectrometry.

Tetrahydropyridine formation from delta ketonic nitriles under alkaline conditions (14) was successful with the latter only if they were not highly substituted. The triphenyl derivative (I), when treated in the same way, gives the trimolecular product (X) as previously determined (1) and now reconfirmed; the accompanying uncrystallizable portion does show a similar blue fluorescence.

ACKNOWLEDGMENT

The authors take pleasure in acknowledging the technical assistance of Dr. O. E. Schupp for the gas chromatography; of Mr. J. F. Stenberg and Mr. R. W. Ryan for the reactions under pressure; of Miss Thelma J. Davis and Mrs. L. C. Ketchum for the infrared determinations; of Mr. D. P. Maier for operation of the mass spectrometer; of Mr. D. F. Ketchum for the microanalyses; and of Dr. D. W. Stewart for many helpful suggestions.

THE THERMAL REVERSIBILITY OF THE MICHAEL REACTION

II. NITROKETONES AND RELATED COMPOUNDS[1]

C. F. H. ALLEN

Kodak Research Laboratories, Eastman Kodak Co., Rochester, New York

Received August 12, 1963

ABSTRACT

In continuation of the study of the thermal reversibility of Michael adducts, 13 γ-nitroketones were examined in the mass spectrometer, using the inlet heated at 230°. The presence of furans was indicated, arising from the intact molecule. Such remotely related substances would never have been envisaged had not the mass spectrum been available. In contrast to the behavior of delta ketonic nitriles (Part I) only normal retrogression was found. There were many secondary products resulting from extensive decomposition of the expected nitro addend. Not all the products can be isolated by classical procedures, but their presence is predictable, and can be shown by the use of the mass spectrometer. Nine simple nitro- and bromonitro-ethylenes, sensitive to heat alone, were unexpectedly stable in the heated inlet of the mass spectrometer, but did give rise to very small amounts of decomposition products. Phenyl- and 1-naphthyl-nitromethanes, which decomposed completely, gave comparable types of products. Most of these nitro compounds have previously been thermally treated by classical methods.

The γ-nitroketones used in this work are analogous to the δ-ketonic nitriles described in the previous paper (1), and were prepared similarly. In their behavior they differ from the latter in that the expected addend bearing the nitro group was never found, on account of its susceptibility to further degradation.

$$\begin{array}{lcll} C_6H_5CH{=}CHCOC_6H_4X\text{-}4 & & C_6H_5CHCH_2COC_6H_4X\text{-}4 & C_6H_5CH{=}CHCOC_6H_4X\text{-}4 \\ + C_6H_5CH_2NO_2 & \rightarrow & C_6H_5\underset{|}{C}HNO_2 \quad I & \rightarrow \quad + C_6H_5CHO + NO + ? \end{array}$$

In the first chemical investigation 20 years ago (2) three products of the thermal decomposition of I (X = H) were recorded; these were chalcone, benzaldehyde, and nitric oxide. In a renewed chemical investigation, after removal of the benzaldehyde as the 2,4-dinitrophenylhydrazone, benzonitrile, which has a very similar odor, remained; it was identified by infrared and mass spectra. Benzonitrile is present (3.5%) in the more volatile fractions of the thermolysis; however, as the temperature was raised, considerable water appeared along with the nitrile, as though both had resulted from the decomposition of some intermediate product. The latter could be benzaldoxime, a trace of which was found by gas chromatography; it was identified in the mass spectra of several of the fractions. That the nitrile arises from benzaldoxime was confirmed by following the course of the thermal decomposition of the pure oxime at 230° in the heated inlet of the mass spectrometer. The benzaldoxime peaks decreased with time, while those of the benzonitrile were simultaneously increasing. A small amount of benzoic acid was also isolated from the distilled products from I (X = H); this was not surprising, since it could arise by oxidation of the aldehyde by the nitric oxide, or by hydrolysis of the nitrile. When

the decomposition of this adduct I was examined in the mass spectrometer, by allowing the compound to decompose in the heated inlet, a considerable variety of products were identified (Table I). The ratios of the components changed during the 1-hour observation

period, while the cracking patterns of the components remained constant in all of the spectra. All of the identifications tabulated were confirmed by comparison with reference spectra, of known compounds unless otherwise noted. Adduct I gave 2,3,5-triphenylfuran, stilbene, chalcone, and nitric oxide; which presumably arise from the intact adduct. The furan and chalcone were estimated by gas chromatography. Many of the smaller molecules may be attributed to the very heat-sensitive phenylnitromethane, formed by retrogression. In this and in all other instances where nitric oxide is reported, its presence could not be confirmed by a reference mass spectrum because of the alternate possible source of an NO^+ ion fragment from most nitro compounds. However, nitric oxide was identified chemically as a product of the independent laboratory decomposition reaction

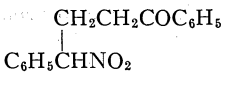
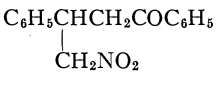
For personal use only.

of I. There was no definite indication of an abnormal dissociation, which would yield α-nitrostilbene and acetophenone. Both diastereomeric adducts behaved in a similar manner. γ-Bromo derivatives of I gave 3-bromo-2,4,5-triphenylfurans (2). At the time of the classical type of investigation the furan found was not even envisaged because of its seemingly remote relation to the bromonitro ketone; *it could have been predicted had a mass spectrometer been available*! The less highly arylated diphenyl-γ-nitroketone (II) (3) decomposed in the mass spectrometer inlet to yield diphenylfuran, vinyl phenyl ketone, nitric oxide, and a little acetophenone. Its isomer (III) gave chalcone and nitric oxide; none of the expected nitromethane was found, it being unstable under the experimental conditions.



II



III

The γ-bromo derivative of II gave 2,5-diphenylfuran and nitric oxide. This is at variance with the chemical finding (3) that heat alone gives rise to 3-bromo-2,5-diphenylfuran. Two γ-bromo derivatives corresponding to I gave complex mixtures, among which the previously detected chalcones and nitric oxide predominated, but in each instance there was some triarylfuran.

With a view to further elucidating these results, phenylnitromethane itself was examined in the mass spectrometer. It decomposed in the heated inlet, yielding a mass spectrum consistent with a mixture containing bibenzyl (1,2-diphenyl ethane), benzaldoxime, benzaldehyde, benzonitrile, benzene, nitric oxide, and an unknown giving a very small peak at mass 119, but no stilbene. Benzaldehyde, dibenzhydroxamic acid, nitric oxide, and water have been previously reported as products of thermolysis (4). Since phenylnitromethane is an unstable liquid that is not easily purified, α-naphthylnitromethane, which can be crystallized to constant melting point, was next examined. After exposure in the mass spectrometer at 230°, the analytically pure compound gave a spectral pattern corresponding to a mixture of dinaphthylethane, α-naphthaldehyde, α-naphthonitrile, naphthalene, nitric oxide, and an unknown giving a very small peak at mass 169. The *aci*-form, which is an oil, gave all the same products, plus a little α-naphthoic acid; however, there appeared to be more of the unknown and naphthonitrile. There was no α-naphthaldoxime, but a separate examination of this substance in the mass spectrometer at 230° revealed such a rapid decomposition to the unknown (169) and nitrile that its absence was not surprising. These results are analogous to and correspond with those found with the phenylnitromethane. Since there was no dinaphthylstilbene, it may indicate that the stilbene found on heating the adduct I probably arises from the latter structure rather than from the phenylnitromethane.

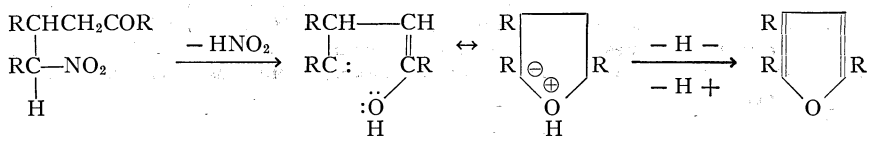
In view of these complex results, all the nine nitro- and bromo-nitroethylenes, available from the previous work (3), were examined in the mass spectrometer. Rather surprisingly, they were all relatively stable under the prevailing conditions, each giving a peak corresponding to the molecular weight of the original undecomposed molecule, with very little nitric oxide; there were peaks that could be attributed to the respective phenylacetylenes, although these were not confirmed. The changing ratio of these peaks with respect to the parent peak of the undecomposed molecule was accepted as proof that these peaks represented reaction products. This is in agreement with the chemical evidence; β-nitrostyrene can be distilled with some decomposition (b.p. 250–260°) (5). β-Bromo-β-nitro-α,α-diphenylethylene also showed a peak at its molecular weight, but partially decomposed to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

give some β,β-dibromo-α,α-diphenylethylene and tetraphenylethylene. β-Bromo-β-nitrostyrene showed the parent undecomposed molecule, plus 1,2-dibromostyrene and a monobromodiphenylethylene. β,β-Dibromo-α,α-diphenylethylene showed the parent molecule and tolane (diphenylacetylene). The latter and 1,2-dibromostyrene have been shown previously (2) by chemical methods.

DISCUSSION OF RESULTS

The formation of 2,3,5-triphenylfuran, which contains *all* the carbon atoms of the chalcone–phenylnitromethane adduct I indicates that it is not a retrogression product. In this instance, the yield of furan is low, whereas with the bromonitro ketones, the yield of bromofuran was very high; the difference is one of degree rather than kind. The adduct, either as such or in its *aci*-form, has lost nitrous acid, possibly to give the carbene (IV),[2] from which a hydride ion is removed under the prevailing oxidizing conditions. An alternate possibility, the direct displacement of nitrite ion by the free electron pair of the oxygen atom, seems less likely since the analogous cyano adduct (1) does not show a similar behavior, no furan being formed.[3]



IV

In the retrogression to chalcone and arylnitromethane, the behavior of the arylnitromethane can be summarized as shown in Chart I.

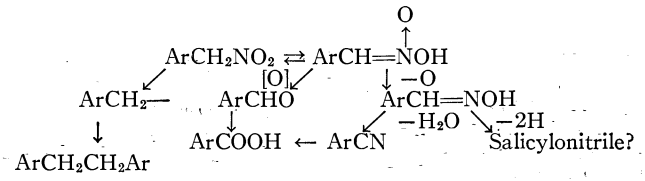


Chart I. Possible paths of decomposition of arylnitromethanes.

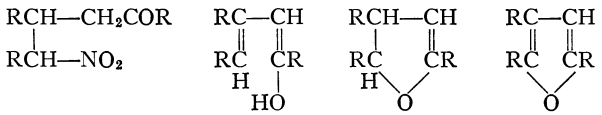
The unknown giving a peak of mass 119 could be benzonitrile oxide (6), benz[4,5]isoxazole (indoxazene), or its conversion product *o*-hydroxybenzonitrile (salicylonitrile) (7), all of molecular weight 119. The first two were excluded by comparison with mass spectra of authentic specimens. The unknown giving a peak at mass 169 could be a benzolog of any of the three; it is probably 2-hydroxy-1-naphthonitrile (8). Owing to the small size of the mass peaks, the identification of the hydroxynitriles (possible parent peaks at *m*/e119 and 169) is inconclusive; products corresponding to these molecular weights could not be isolated in the laboratory. The hydroxynitriles are probably formed as a result of the

[2]*The intermediate formation of a carbene, as proposed in an earlier paper (2), seems to have been overlooked by subsequent workers in the carbene field.*

[3]*The referee suggested an alternative mechanism, involving the beta-elimination of nitrous acid, and nucleophilic addition, followed by oxidation to the furan.*



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

known easy cleavage (7) of an indoxazene; the latter undoubtedly arises by formation of an additional ring which results from a dehydrogenation under the prevailing oxidizing conditions.

EXPERIMENTAL

The substances used for the thermolyses and the reference compounds were on hand from previous work[4] or were prepared by methods given in the literature, e.g., phenylnitromethane (9), 1-naphthylnitromethane (10), *o*-hydroxybenzonitrile (7), and 2-hydroxy-1-naphthonitrile (8).

Both stereomeric forms of the adduct (I) gave the same products, when heated for 0.5 hour *in vacuo* at 214–286°. Water appeared at 238°, and much unchanged adduct distilled; even at atmospheric pressure a little adduct comes over. This indicates that the nitroketones are more stable thermally that the cyanoketones (delta ketonic nitriles (1)). The evolved gas is nitric oxide (colorless, turns brown in air). The distillate from 5 g of adduct was collected in fractions for examination by gas chromatography; the percentages of the components given are totals. The main products were benzaldehyde (52%) and chalcone (35%). Lesser products were 2,3,5-triphenylfuran (19%), benzonitrile (3.5%), benzaldoxime (a trace), and benzoic acid. The benzaldehyde, benzaldoxime, and benzonitrile were chromatographed as before (1), the retention times being 3.87, 9.02, and 4.18 minutes, respectively. The chalcone and triphenylfuran were chromatographed in a Barber–Colman Model 10 Gas Chromatograph, containing the Lovelock ionization detector, with radium sulphate as the ionizing source. The conditions of the separation were as follows: the column contained 5%, by weight, of General Electric SE-30 silicone gum rubber on 80–100 mesh, acid-washed Celite 545. The column was 5 ft long, and was operated at 200° C with a flow rate of approximately 50 ml/minute. The retention times of chalcone and triphenylfuran were 0.48, 2.23 minutes, respectively.

Mass spectrometry.—The mass spectrometer used was described previously (1). The peaks found in the mass spectra and their identification by comparison of the entire pattern, with known reference compounds, are summarized in Table I.

ACKNOWLEDGMENTS

We are pleased to have had the assistance of Dr. O. E. Schupp for the gas chromatography; of Dr. J. F. Tinker for valuable mechanistic discussions; of Mr. D. Maier for operation of the mass spectrometer; and of Dr. D. W. Stewart for many helpful discussions.

THE THERMAL REVERSIBILITY OF THE MICHAEL REACTION

III. 1,5-DIKETONES AND ADDUCTS BEARING ACIDIC GROUPS[1]

C. F. H. ALLEN

Department of Chemistry, Rochester Institute of Technology, Rochester, New York

AND

G. P. HAPP

Kodak Research Laboratories, Eastman Kodak Co., Rochester, New York

Received August 12, 1963

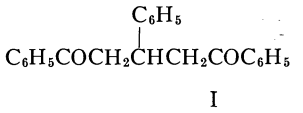
ABSTRACT

In this paper a number of known chemical facts obtained by classical methods are correlated with the mass spectra of compounds thermally decomposed in the heated inlet of the mass spectrometer. Of the 31 substances examined, 24 are dioxo compounds. Among them are the few and only Michael adducts previously known to undergo thermal reversal. Both normal and abnormal types of retrogression were found, but ketonic acids which could only regress normally, in a competing reaction, formed lactones by dehydration. A formally similar β-hydroxyketone dissociated both ways in a comparable manner. Esters were more stable than cyano ketones under the conditions employed.

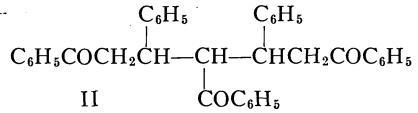
In two previous communications mass-spectrometric studies of the thermal reversibility of Michael adducts from nitriles (1) and nitroketones (2) have been described. This paper deals with diketones, adducts bearing acidic groups, and related substances.

Diketones

Many 1,5-dicarbonyl compounds belong to a class of substances now recognized as Michael adducts. The earliest representatives of this group were benzaldiacetophenone (1,3-dibenzoyl-2-phenylpropane (I) (3), dibenzaltriacetophenone (2,4-diphenyl-1,3,5-tribenzoylpentane (II) (3), which exists in two diastereomeric forms, and benzamaron (III) (4). Upon distillation, the first two were reported to give chalcone (benzalacetophenone) and acetophenone (3), while benzamaron (III) was reported to show retrogression to desoxybenzoin and benzaldesoxybenzoin (IV) (4).

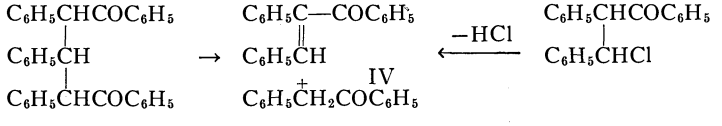


I



II

All mass-spectrometric identifications, unless otherwise noted, were established by comparison of the entire spectra of known reference compounds with those of the decomposition mixtures. Even for the compounds which appeared to decompose rapidly in the 230° heated inlet, the spectral changes during the period of observation showed changing ratios of components while the cracking pattern of each remained constant, lending further support to the identifications.



III IV V

[1]*Contribution No. 2293 from the Kodak Research Laboratories, Eastman Kodak Co., Rochester 50, New York, and the Department of Chemistry, Rochester Institute of Technology, Rochester 8, New York.*

As indicated in Table I, mass spectra obtained by thermal decomposition of these compounds in the heated spectrometer inlet showed spectral patterns of the same products that were reported in the earlier work (3, 4). A related adduct, β-chlorobenzyldesoxybenzoin (V) (5), yielded products identified by mass spectrometer as benzaldesoxybenzoin

(IV) and stilbene; the former is also obtained chemically by removing the elements of hydrogen chloride using alcoholic potassium acetate. Although stilbene has not been found in a chemical experiment, there is little doubt concerning its identification as a major product in the mass spectrometer inlet, where conditions are apparently more favorable for its production. While some stilbene might possibly be formed as a result of electron bombardment, at least a major part of it must have been formed thermally. In a subsequent study using an all-glass heated inlet, parent peaks at m/e 320 and 322 of V were present. During the 1-hour observation, their decay rate was noticeably different from that of the stilbene peaks, indicating that stilbene is present in the thermal reaction mixture.

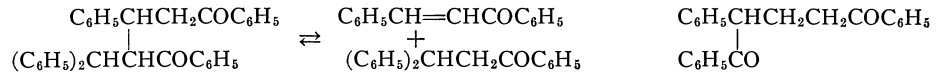
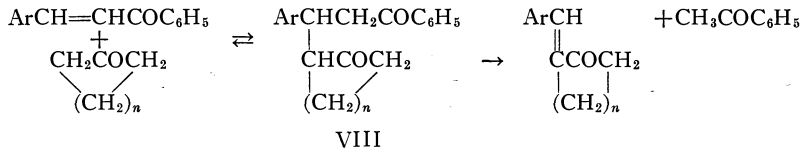
More recently discovered members of the first series are 1,1,3-triphenyl-2,4-dibenzoylbutane (VI) (6) and an isomer of I, 1,3-dibenzoyl-1-phenylpropane (VII) (7). Products identified from the mass spectrum indicate that VI dissociates as shown here. The diketone VII, however,



showed no appreciable thermal dissociation and the volatility of the substance was insufficient to yield a mass spectrum.

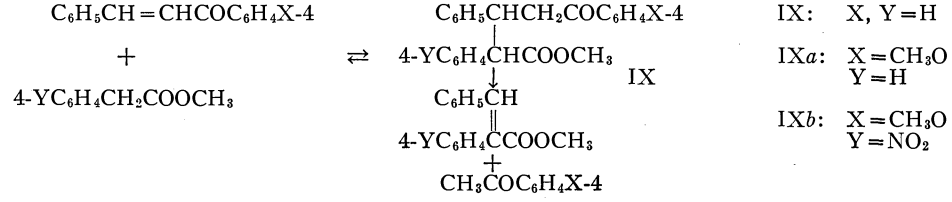
In his study of "semicyclic diketones" (VIII), Stobbe (8) observed that two of them distilled "partially decomposed" in two ways; in one (normal, see Part I (1)), the components were regenerated, but the other (abnormal) gave acetophenone and an arylideneketone. This was the first observed instance of an abnormal dissociation. In the present mass-spectrometric study of two members of the series (8, 9), the products which were identified indicated dissociation by both paths.



On distilling adducts from aliphatic aldehydes, Meerwein (10, 11) found that the components were regenerated (normal) except in two instances, which gave products from abnormal-type retrogression. These adducts were unavailable for mass spectral examination.

Esters

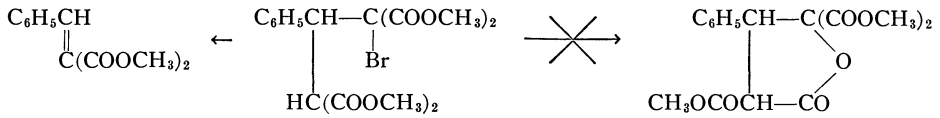
Michael adducts that are ketoesters (IX, IX*a*, IX*b* (12), X (13)) are much more thermally stable than cyanoketones (1). Mass peaks corresponding to the undecomposed molecule, as well as confirmed identification of products of both kinds of retrogression are found (Table I). It is concluded, as previously (1), from the very low intensity of the mass spectrum that the presence of a methoxy group in the para position of the chalcone residue greatly diminishes the tendency to dissociation (IX*a*, *b*).



Polyesters such as methyl α,γ-dicarbomethoxy-β-phenylglutarate (XI) gave a mass spectrum showing the presence of the undecomposed molecule, plus dimethyl benzalmalonate (XII) and dimethyl malonate.

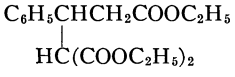
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Its α-bromo derivative (XIII) also gave predominantly the ester (XII). It is noteworthy that there was no evidence for the formation of a lactone (XIV) through loss of methyl bromide, a type of reaction that is so easily brought about in the laboratory (12).



XII XIII XIV

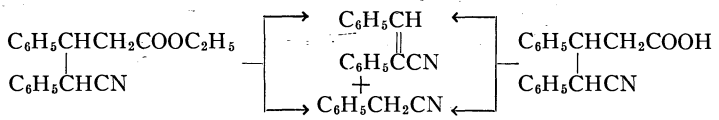
Michael's ester adduct (XV) (14) is stated to distill with decomposition at atmospheric pressure; we have found that the loss is a very small carbonaceous residue. In the heated inlet of the mass spectrometer, this ester is very stable; it showed neither type of retrogression.



XV

Cyanoester and Acid

In contrast to cyanoketones, ethyl γ-cyano-β,γ-diphenylbutyrate (XVI) (15) appears to be considerably more stable to heat, for the temperature has to be raised to 345° before appreciable dissociation is achieved. In a previously heated sample, examined by gas chromatography, we found 11% of benzyl cyanide, 8.6% of ethyl cinnamate (both products of normal dissociation), 12% of α-phenylcinnamonitrile (the abnormal cleavage product), and 42% of unchanged ester. In the mass spectrometer (inlet heated at 230°) only a slight reversal would be expected. In agreement there were small spectral peaks representing undecomposed molecule and the possible retrogression products, both normal and abnormal; these were too small to establish a confirmation although the patterns were reasonably consistent with those of benzyl cyanide and α-phenylcinnamonitrile. A large peak at mass 135 was not identified; it was *not* phenylacetamide, with which a direct comparison was made.



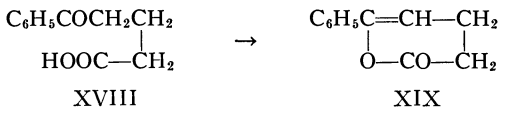
XVI XVII

When a sample of the corresponding acid (XVII) (16) was heated at 300° for 20 minutes, a trace of benzyl cyanide, but no styrene, was detected by gas chromatography. In the mass spectrometer, however, α-phenylcinnamonitrile and benzyl cyanide were indicated, with an unidentified peak at 104, which might have been from styrene, the known decarboxylation product of cinnamic acid. There was also some indication of undecomposed acid.

Ketonic Acids

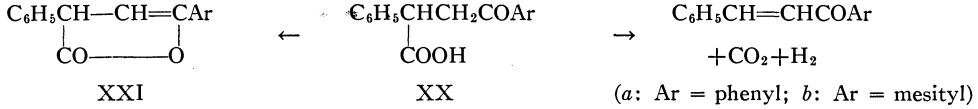
Gamma and delta ketonic acids are known to be readily dehydrated to unsaturated lactones by classical methods; this type of reaction would compete with any retrogression. The only delta ketonic acid (XVIII) examined in the mass spectrometer was very stable, being comparable to γ-benzoylbutyronitrile (1); the formation of a lactone (XIX) was indicated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



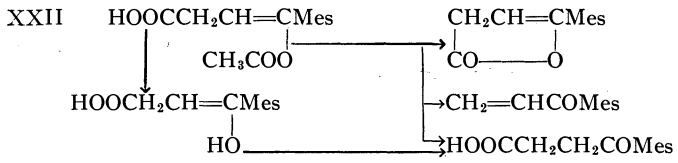
XVIII XIX

Gamma ketonic acids (XX) can be considered as Michael adducts formed by the addition of formic acid to α,β-unsaturated ketones. They can give only a normal retrogression to chalcones; this behavior, which cannot be readily realized by classical methods, was observed in the mass spectrometer. The expected formic acid undoubtedly decomposed to carbon dioxide and hydrogen. However, these acids can also cyclize by a loss of water to give the unsaturated crotonolactones (XXI), which were identified from the mass spectra; this reaction has also been demonstrated in the laboratory (17, 18).

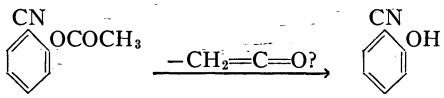


XXI XX (a: Ar = phenyl; b: Ar = mesityl)

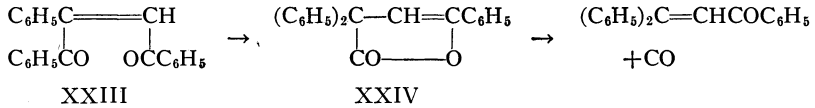
The closely related (β-acetoxy-β-mesitylvinyl) acetic acid (XXII) (18) gave a mass spectrum indicating the presence of β-mesitoylpropionic acid plus the corresponding lactone and mesityl vinyl ketone. The keto acid could result from the enol formed by a cleavage in the



acetate, with elimination of ketene. This behavior is supported by that of 2-acetoxybenzonitrile, which, we have found, gives 2-hydroxybenzonitrile under the same conditions.



The formation of the chalcone from the γ-ketonic acids (XX) was postulated earlier as being due to the elimination of formic acid. It could equally well result from a decarbonylation of the unsaturated crotonolactone (XXI). That unsaturated lactones can be decarbonylated to α,β-unsaturated ketones was shown many years ago by Japp (19) in his study of the unsaturated 1,4-diketone, α,β-dibenzoylstyrene (XXIII). The latter was first isomerized to 1,1,3-triphenylcrotonolactone (XXIV) which was then decarbonylated (19) to β-phenylchalcone.

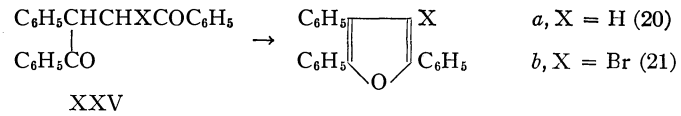


XXIII XXIV

These reactions were confirmed in the mass spectrometer, although the carbon monoxide was not identified.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

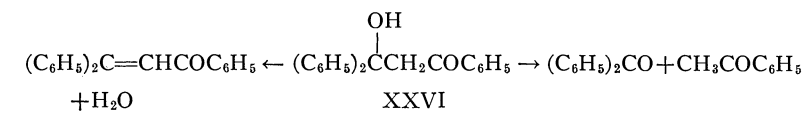
In contrast, saturated 1,4-diketones, which have only a formal similarity to Michael adducts, give mass peaks that indicate they are dehydrated to furans in the mass spectrometer inlet just as they are by classical methods.



a, X = H (20)
b, X = Br (21)

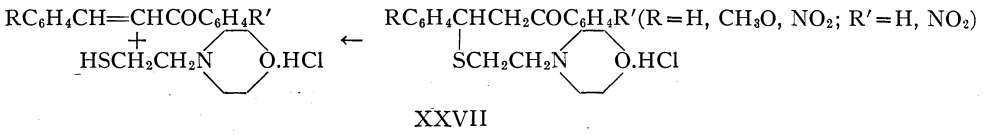
Related Compounds

Finally, two other series that have a formal similarity to the foregoing will be considered briefly. The first (XXVI) is the chalcone-type adduct, phenacylodiphenylcarbinol, which may be regarded as having been formed by the addition of water. In the mass spectrometer heated inlet, it dissociated by both possible paths. The same cleavages are brought about by laboratory reagents (22).



The loss of water corresponds to the normal retrogression shown by Michael adducts, whereas the alternate scission follows the abnormal path.

Finally, three Michael-type adducts (XXVII) (23), formed from β-morpholinoethylethanethiol and three chalcones, showed only normal dissociation as expected; the nonvolatile amine hydrochloride was not detected.



EXPERIMENTAL

The substances examined were available from previous work or were prepared by procedures already in the literature. The β-chlorobenzyldesoxybenzoin (V) was made by J. R. Byers, Jr. The acetoxybenzonitrile and salicylonitrile were readily obtained by published procedures (24). The crotonolactone (XXIV) was readily prepared in quantity by heating dibenzoylstyrene (19) but its subsequent conversion to the β-phenylchalcone was not very satisfactory; most of the lactone was recovered unchanged. This chalcone was obtained more easily by dehydration of the carbinol (XXVI) (22). In our hands, the yields of the acid (XVII) and of crystalline ester (XVI) were low, a large amount of a thick oil that had not crystallized in months being obtained.

Thermolyses.—When the ester (XVI) was heated in a Pyrex glass flask containing a "silver-solder catalyst," (1) there was no change until 300°, at which point a little volatile liquid condensed on the walls of the flask. No distillate appeared up to 345°; after 40 minutes, the now brown liquid was submitted to gas chromatography. In addition to the main components already mentioned, there were indications of a dozen others in very small amounts. The acid (XVII) was similarly heated at 300° for 20 minutes; it became brown. The residual solid, after recrystallization from acetic acid, melted at 226–227°. On treatment with alcoholic sodium hydroxide, followed by acid, a white solid, melting above 400°, was obtained. Since these were apparently not cleavage products they were not further investigated.

Gas Chromatography.—The samples were chromatographed on an 8-ft column of standard 6 mm O.D. glass containing 25%, by weight, of Dow Corning 200 silicone fluid on Celite (80–100 mesh) which had been previously washed with alcoholic potash and concentrated hydrochloric acid. The column was thermostated with boiling 1,2,4-trichlorobenzene (b.p. 218–219°). The detector was a Gow-Mac thermal conductivity cell, pretzel design, Model No. 9285. The carrier gas was helium at a flow rate of 50 ml per minute. The retention times were benzyl cyanide, 2.5 minutes; ethyl cinnamate, 8.9 minutes; α-phenylcinnamonitrile, 46.3 minutes; and the ester (XVI) approximately 103 minutes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Mass Spectrometry.—The mass spectrometer and its operation have already been described (1). The peaks found in the mass spectra and their identification, by comparison of the entire pattern with known reference compounds, are summarized in Table I. Unless otherwise indicated, identifications were based upon comparisons of the complete spectral patterns with those of authentic reference compounds.

ACKNOWLEDGMENTS

We are pleased to have had the assistance of Dr. O. E. Schupp for the gas chromatography; of Miss Thelma J. Davis for the infrared spectrometry; of Mr. D. Maier for operation of the mass spectrometer; and of Dr. D. W. Stewart for many helpful suggestions.

THE STABILITY OF THIOCOMPLEXES AND SOLUBILITY PRODUCTS OF METAL SULPHIDES

I. CADMIUM SULPHIDE

J. STE-MARIE, A. E. TORMA, AND A. O. GÜBELI
Department of Chemistry, Laval University, Quebec, Quebec

Received October 8, 1963

Abstract

The nature and stability of cadmium sulphide complexes in aqueous solutions have been investigated. The total concentration of the metal in solution was determined at constant temperature and ionic strength, and at various pH values, by a radioactive tracer technique.

Introduction

This work is part of a programme of study on the formation of complexes. A first paper (1) dealt with silver sulphide.

From the modern theory of complex compounds we know that many insoluble metal compounds may be formed through coordination of the metal ion with various ligands. These coordinate bonds are similar to those of mono- and poly-nuclear complexes in solution. Thus, a solution in equilibrium with a precipitate usually contains a number of complex ions besides the simple metal ions (2–5).

EXPERIMENTAL PART

The classical solubility product is a physicochemical constant, independent of the complex formation. Accordingly its value does not necessarily indicate the true solubility of a solid.

The values given in the literature for the second dissociation constant of H_2S differ considerably among themselves (6). Therefore we have decided to redetermine the constants k_1 and k_2 at ionic strength $\mu = 1.0$ and 25° C by means of pH titrations and potentiometric determinations of pAg vs. pH (Fig. 1).

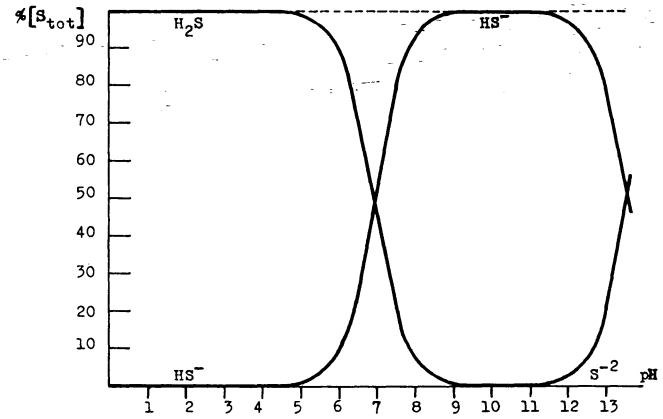

FIG. 1. Dissociated forms of H_2S.

$$[H_2S] \rightleftarrows [HS^-] + [H^+] \qquad pk_1 = 6.90 \pm 0.03 \qquad [1]$$

$$[HS^-] \rightleftarrows [S^{-2}] + [H^+] \qquad pk_2 = 13.48 \pm 0.16 \qquad [2]$$

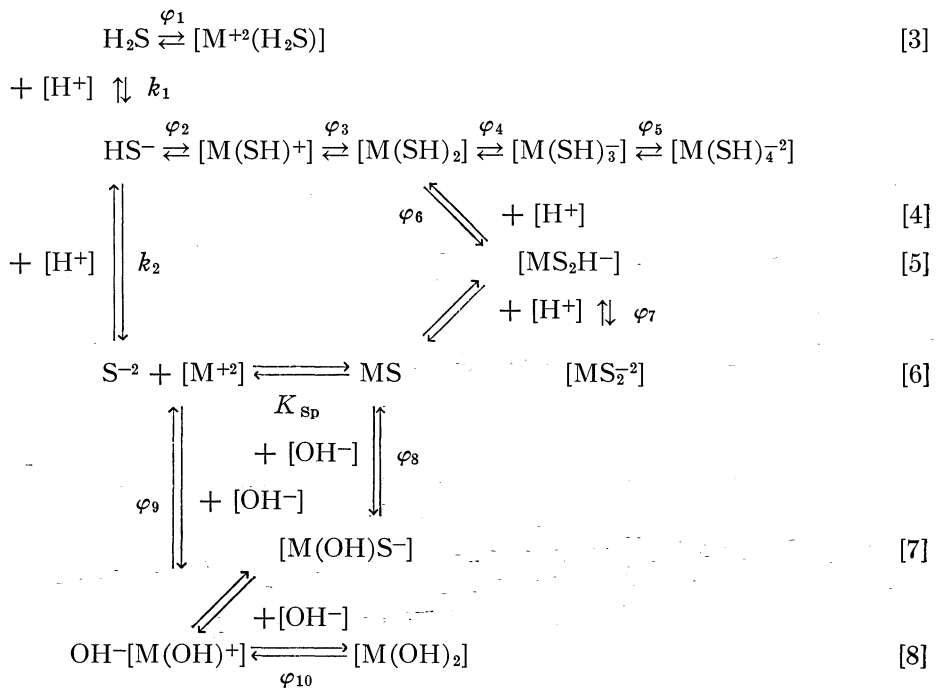
The total concentration of metal in aqueous solution, $[M]_{tot}$, in presence of an excess of sulphide ion may

only be measured by means of a radioactive tracer. These measurements were carried out at constant temperature and ionic strength $\mu = 1.0$ with sodium perchlorate. Buffers were chosen to avoid complex formation with the metal ion. All reagents, even distilled water, were prepared in absence of oxygen. A scintillation detector was used for radioactive determinations.

The following reagents were added to pure oxygen-free water to obtain the desired concentrations of cadmium (7): $CdSO_4$, 0.01 M (added tracer Cd^{115}); $NaClO_4$, up to ionic strength $\mu = 1.0$; Na_2S, 0.021 M; HCl, 0.04 M (decomposing the excess of Na_2S); buffer solutions 0.001–0.1 M (pH 1 to 2, $HClO_4$; pH 3 to 6, acetic acid + sodium acetate; pH 7 to 8, imidazole; pH 8 to 9, triethanolamine; pH 9 to 10.5, monoethanolamine; pH 10 to 12, piperidine; pH 12 to 14, NaOH).

THEORETICAL PART

From the experimental results it appears that the following diagram gives the best description of the formation of complexes.



The values of φ, to be determined from the experimental curve, represent the following equilibria:

$$\frac{[M^{+2}(H_2S)]}{[M^{+2}][H^+]^2[S^{-2}]} = \varphi_1 \quad [9] \qquad \frac{[M(SH)^+]}{[M^{+2}][H^+][S^{-2}]} = \varphi_2 \quad [10]$$

$$\frac{[M(SH)_2]}{[M^{+2}][H^+]^2[S^{-2}]^2} = \varphi_3 \quad [11] \qquad \frac{[M(SH)_3^-]}{[M^{+2}][H^+]^3[S^{-2}]^3} = \varphi_4 \quad [12]$$

$$\frac{[M(SH)_4]}{[M^{+2}][H^+]^4[S^{-2}]^4} = \varphi_5 \quad [13] \qquad \frac{[MS_2H^-]}{[M^{+2}][H^+][S^{-2}]^2} = \varphi_6 \quad [14]$$

$$\frac{[MS_2^{-2}]}{[M^{+2}][S^{-2}]^2} = \varphi_7 \quad [15] \qquad \frac{[M(OH)S]}{[M^{+2}][OH^-][S^{-2}]} = \varphi_8 \quad [16]$$

$$\frac{[M(OH)^+]}{[M^{+2}][OH^-]} = \varphi_9 \quad [17] \qquad \frac{[M(OH)_2]}{[M^{+2}][OH^-]^2} = \varphi_{10} \quad [18]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

From experimental determinations the following constants are known:

$$\frac{[H^+][HS^-]}{[H_2S]} = k_1, \qquad \frac{[H^+][S^{-2}]}{[HS^-]} = k_2, \tag{19}$$

$$[H^+][OH^-] = K_w, \text{ and } [M^{+2}][S^{-2}] = K_{sp}. \tag{20}$$

The $[S]_{tot}$ may be expressed by the following equation, when the sulphur, complexed with the small amounts of Cd in solution, is neglected:

$$[H_2S] + [HS^-] + [S^{-2}] = [S]_{tot} \tag{21}$$

and

$$[S^{-2}] = \frac{k_1k_2[S]_{tot}}{[H^+]^2 + k_1[H^+] + k_1k_2}. \tag{22}$$

$[S^{-2}]$ is a function of pH; as a function of $[S^{-2}]$, $[M^{+2}]$ is the same:

$$[M^{+2}] = \frac{K_{sp}}{[S]_{tot}}\left[\frac{[H^{+2}]}{k_1k_2} + \frac{[H^+]}{k_2} + 1\right] \tag{23}$$

We know that

$$[M^{+2}] + [M^{+2}(H_2S)] + [M(SH)^+] + [M(SH)_2] + [M(SH)_3^-] + [M(SH_4^{-2}] + [MS_2H^+] + [MS_2^{-2}] + [M(OH)S^-] + [M(OH)^+] + [M(OH)_2] = [M]_{tot} \tag{24}$$

and

$$[M^{+2}](1 + \varphi_1[H^+]^2[S^{-2}] + \varphi_2[H^+][S^{-2}] + \varphi_3[H^+]^2[S^{-2}]^2 + \varphi_4[H^+]^3[S^{-2}]^3 + \varphi_5[H^+]^4[S^{-2}]^4 + \varphi_6[H^+][S^{-2}]^2 + \varphi_7[S^{-2}]^2 + \varphi_8[OH^-][S^{-2}] + \varphi_9[OH^-] + \varphi_{10}[OH^-]^2) = [M]_{tot}. \tag{25}$$

Replacing

$$[M^{+2}] = \frac{K_{sp}}{[S^{-2}]} \text{ and } [OH^-] = \frac{K_w}{[H^+]}$$

we get

$$\frac{K_{sp}}{[S^{-2}]}\left(1 + \frac{\varphi_9K_w}{[H^+]} + \frac{\varphi_{10}K_w^2}{[H^+]^2} + [S^{-2}]\left[\varphi_1[H^+]^2 + \varphi_2[H^+] + \frac{\varphi_8K_w}{[H^+]}\right] + [S^{-2}]^2\left[\varphi_3[H^+]^2 + \varphi_6[H^+] + \varphi_7\right] + [S^{-2}]^3\left[\varphi_4[H^+]^3\right] + [S^{-2}]^4\left[\varphi_5[H^+]^4\right]\right) = [M]_{tot}. \tag{26}$$

In terms of pH the final equation becomes:

$$\frac{K_{sp}}{[S]_{tot}k_1k_2}\left[1 + \frac{K_w\varphi_9}{[H^+]} + \frac{K_w^2\varphi_{10}}{[H^+]^2}\right]\left[[H^+]^2 + k_1[H^+] + k_1k_2\right] + K_{sp}\left[\varphi_1[H^+]^2 + \varphi_2[H^+] + \frac{K_w\varphi_8}{[H^+]}\right] + K_{sp}[S]_{tot}k_1k_2\left[\frac{\varphi_3[H^+]^2 + \varphi_6[H^+] + \varphi_9}{[H^+]^2 + k_1[H^+] + k_1k_2}\right] + K_{sp}[S]_{tot}^2k_1^2k_2^2\left[\frac{\varphi_4[H^+]^3}{([H^+]^2 + k_1[H^+] + k_1k_2)^2}\right] + K_{sp}[S]_{tot}^3k_1^3k_2^3\left[\frac{\varphi_5[H^+]^4}{([H^+]^2 + k_1[H^+] + k_1k_2)^3}\right] = [M]_{tot}. \tag{27}$$

This takes into account all possible complexes in a fairly complex bivalent metal – sulphide system with a coordination number of four.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

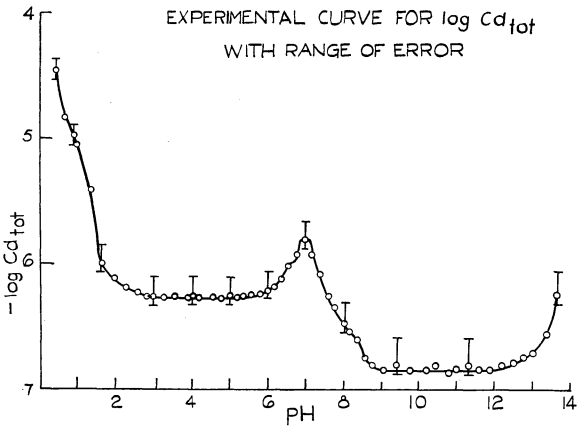


FIG. 2. Experimental curve for log Cd_{tot} with range of error.

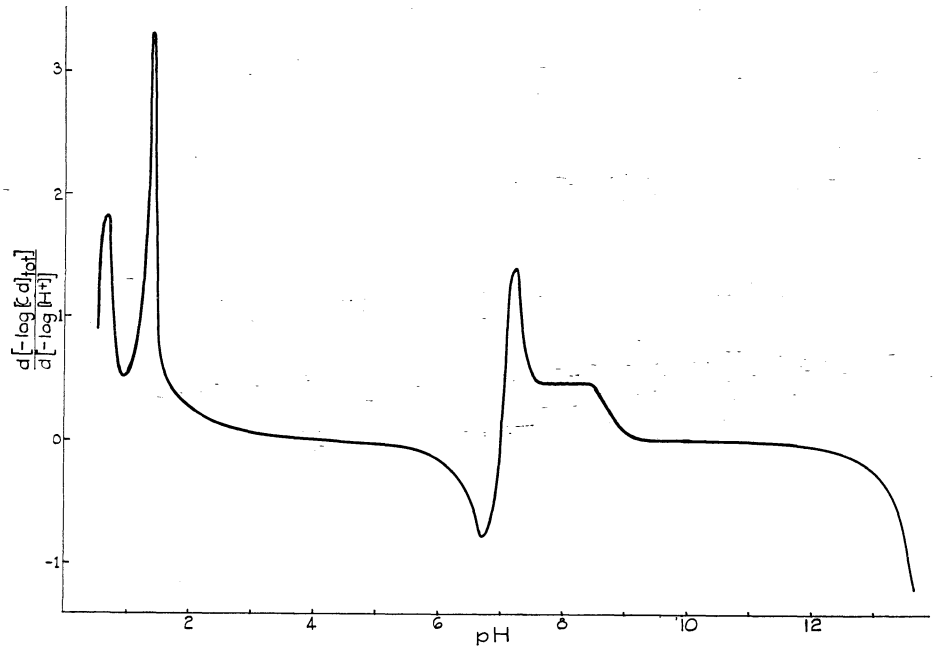

FIG. 3.

The experimental curve obtained from radioactivity measurements in equilibrated sulphide filtrates in presence of a known excess of sulphide ion is plotted vs. pH, i.e. $-\log [M]_{tot}$ vs. pH, and the experimental errors are calculated for each point of the curve (Fig. 2).

The first derivative of the experimental curve (Fig. 3) is used in the following treatment:

$$\frac{d(-\log [M]_{tot})}{d\text{pH}}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Mathematically:

$$\frac{d(-\log [M]_{tot})}{d(-\log [H^+])} = \frac{-d[M]_{tot}}{[M]_{tot}} \frac{-[H^+]}{d[H^+]} = \frac{[H^+]}{[M]_{tot}} \frac{d[M]_{tot}}{d[H^+]}$$

giving

$$\frac{d[M]_{tot}}{d[H^+]} = \frac{[M]_{tot}}{[H^+]} \frac{d(-\log [M]_{tot})}{d(-\log [H^+])}. \qquad [28]$$

The second term in equation [28] is known from experimental results (Figs. 2 and 3). The first term of this equation is also the first derivative of equation [27] vs. pH.

$$\frac{d(-\log [M]_{tot})[M]_{tot}}{d(-\log [H^+])[H^+]} = \frac{d[M]_{tot}}{d[H^+]} = \frac{K_{sp}}{d[H^+]} d\Bigg[[S^{-2}]^{-1}\left(1 + \frac{\varphi_9 K_w}{[H^+]} + \frac{\varphi_{10} K_w^2}{[H^+]^2}\right)$$
$$+ \varphi_1[H^+]^2 + \varphi_2[H^+] + \frac{\varphi_8 K_w}{[H^+]} + [S^{-2}](\varphi_3[H^+]^2 + \varphi_6[H^+] + \varphi_7)$$
$$+ [S^{-2}]^2(\varphi_4[H^+]^3) + [S^{-2}]^3(\varphi_5[H^+]^4)\Bigg]. \qquad [29]$$

Equation [29] may be written as a function of φ_1 to φ_{10} with the coefficients f_0 to f_{10} as a function of pH.

$$\frac{d(-\log [M]_{tot}}{d(-\log [H^+])K_{sp}} \frac{[M]_{tot}}{[H^+]}$$
$$= f_0 + f_1\varphi_1 + f_2\varphi_2 + f_3\varphi_3 + f_5\varphi_5 + f_6\varphi_6 + f_7\varphi_7 + f_8\varphi_8 + f_9\varphi_9 + f_{10}\varphi_{10}. \qquad [30]$$

The values of f are as follows.

$$f_0 = \frac{2[H^+] + k_1}{k_1k_2[S]_{tot}} \qquad f_1 = 2[H^+] \qquad f_2 = 1$$

$$f_3 = \frac{([H^+] + 2k_2)k_1[H^+][S^{-2}]}{[H^+]^2 + k_1[H^+] + k_1k_2}$$

$$f_4 = \frac{(3k_1k_2 + k_1[H^+] - [H^+]^2)[H^+]^2[S^{-2}]^2}{[H^+]^2 + k_1[H^+] + k_1k_2}$$

$$f_5 = \frac{(4k_1k_2 + k_1[H^+] - 2[H^+]^2)[H^+]^3[S^{-2}]^3}{[H^+]^2 + k_1[H^+] + k_1k_2}$$

$$f_6 = \frac{-([H^+]^2 - k_1k_2)[S^{-2}]}{[H^+]^2 + k_1[H^+] + k_1k_2} \qquad f_7 = \frac{-(2[H^+] + k_1)[S^{-2}]}{[H^+]^2 + k_1[H^+] + k_1k_2}$$

$$f_8 = -\frac{K_w}{[H^+]^2} \qquad f_9 = \frac{([H^+]^2 - k_1k_2)K_w}{k_1k_2[S]_{tot}[H^+]^2} \qquad f_{10} = \frac{(2k_2 + [H^+])K_w^2}{k_1k_2[S]_{tot}[H^+]^3} \qquad [31]$$

Fitting ten experimental values of the pH into equation [30] and solving gives zero, or vanishing values for the constants φ_1, φ_6, φ_7, φ_8, and φ_{10}, which correspond to the following complexes: $[Cd(H_2S)^{+2}]$, $[CdHS_2^-]$, $[CdS_2^{-2}]$, $[Cd(OH)S^-]$, and $[Cd(OH)_2]$. For the other constants we get the following values:

$$\varphi_2 = 10^{21.03},\ \varphi_3 = 10^{41.57},\ \varphi_4 = 10^{56.93},\ \varphi_5 = 10^{72.77},\ \varphi_9 = 10^{17.76}. \qquad [32]$$

By adding one more equation the solubility product may be calculated:

$$K_{sp} = [Cd^{+2}][S^{-2}] = 10^{-25.76}. \qquad [33]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The thermodynamic constant given by Rossini (8) is $10^{-26.16}$. We used our experimental result for K_{sp} to calculate the constants for complex formation. The value of K_W in 1.0 N $NaClO_4$ was determined to be $10^{-14.0}$.

The constants for complex formation are as follows.

$$\frac{[Cd(HS)^+]}{[Cd^{+2}][HS^-]} = k_2\varphi_2 = K_1 = 10^{7.55\pm0.16} \quad [34]$$

$$\frac{[Cd(HS)_2]}{[Cd(HS)^+][HS^-]} = \frac{k_2\varphi_3}{\varphi_2} = K_2 = 10^{7.06\pm0.16} \quad [35]$$

$$\frac{[Cd(HS)_3^-]}{[Cd(HS)_2][HS^-]} = k_2\frac{\varphi_4}{\varphi_3} = K_3 = 10^{1.88\pm0.2} \quad [36]$$

$$\frac{[Cd(HS)_4^{-2}]}{[Cd(HS)_3^-][HS^-]} = k_2\frac{\varphi_5}{\varphi_4} = K_4 = 10^{2.36\pm0.2} \quad [37]$$

$$\frac{[Cd(OH)^+]}{[Cd^{+2}][OH^-]} = \varphi_9 = K_5 = 10^{17.76\pm0.16} \quad [38]$$

DISCUSSION OF RESULTS

As mentioned above, the solubility product of cadmium sulphide does not give an idea of the actual solubility, particularly in presence of an excess of sulphide.

Depending on pH, with the same concentration of $[S]_{tot}$, $\mu = 1.0$ and at constant temperature, we find the data shown in Fig. 4.

In strongly acidic media (pH 0.5 to 1.0) Cd^{+2} is predominant and no formation of $[Cd(H_2S)^{+2}]$ is noted. In this region the solubility product may be calculated by taking into account the formation of Cd^{+2} and $[Cd(HS)^+]$ complexes.

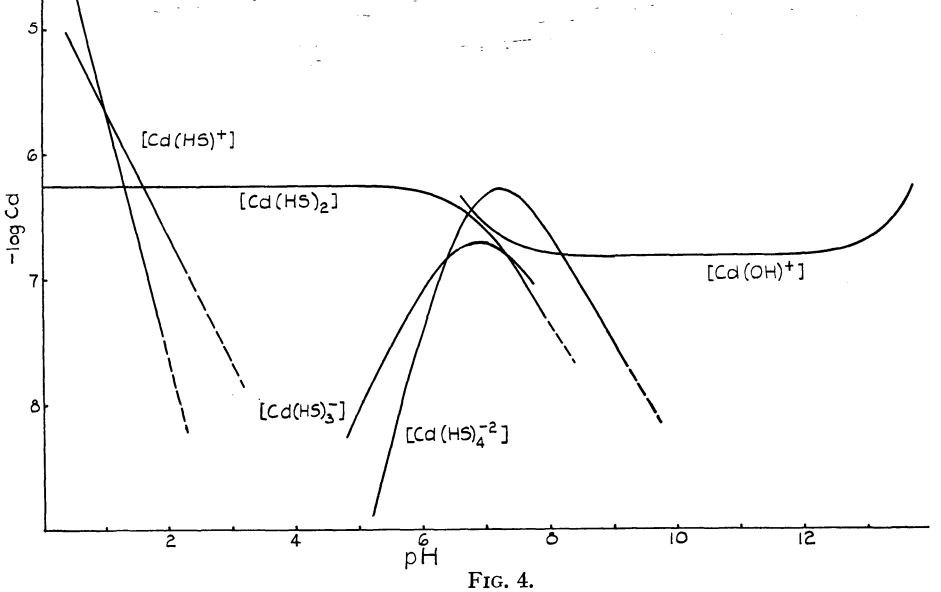

FIG. 4.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In acidic media (pH 1.0 to 3.0) $[Cd(HS)^+]$ is formed and is very stable, but as the concentration of HS^- increases rapidly other complexes become more important.

$[Cd(HS)_2]$ is also very stable and exists over a large pH range (pH 0 to 8.0). This complex is unaffected by pH. Equation [11] corresponds to the formation of $[Cd(HS)_2]$. With equation [20] and the modified form for this pH region of equation [22]:

$$[S^{-2}] = \frac{k_1 k_2 [S]_{tot}}{[H^+]^2}$$

we replace in equation [11] the factors of $[Cd^{+2}]$ and $[S^{-2}]$. We obtain $[Cd(HS)_2] = \varphi_3[Cd^{+2}][H^+]^2[S^{-2}]^2 = \varphi_3 K_{Sp}[H^+]^2[S^{-2}] = \varphi_3 K_{Sp}[S]_{tot} k_1 k_2$, which are constants.

The maximum solubility of cadmium sulphide is found at pH 6.89 where SH^- is present in the highest possible concentration. Now two complexes $[Cd(SH)_3^-]$ and $[Cd(SH)_4^{-2}]$ suddenly appear between pH 5.5 and 9.5.

These two complexes are not very stable and the first one may even be regarded as only an intermediate form. Other possible forms of thiocomplexes of cadmium do not exist.

In alkaline media only the hydroxy complex $[Cd(OH)^+]$ is present; its stability is high.

There are no data to be found in the literature on the stability of these thiocomplexes of cadmium.

ACKNOWLEDGMENT

The authors wish to express their sincere thanks to the National Research Council of Canada and to the Swiss National Foundation for generous grants.

ABSTRACT

A study of the effect of the addition of small amounts (<3.5%) of the halogenated compounds CCl_4, $CHCl_3$, and $CDCl_3$ on the radiolysis of cyclohexane has shown that processes other than radical scavenging occur. At the lowest concentrations of solute that it was practical to employ (0.004 *M*) cyclohexyl radicals were scavenged without a corresponding reduction in the hydrogen yield. At higher solute concentrations $G(H_2)$ was reduced by a physical process which did not involve the scavenging of thermal hydrogen atoms but did lead to chemical reaction involving the solute.

INTRODUCTION

The addition of small amounts of solutes to saturated hydrocarbons can cause a spectacular decrease in the yields of radiolysis products derived solely from the hydrocarbon. Explanations for this have been offered in terms of the known physical or chemical properties of the solutes. Hardwick (1) has interpreted the effect of many organic solutes on the hydrogen yields in terms of hydrogen atom scavenging. Holroyd (2), using ethylene as solute, has observed products which are formed by the addition of free radicals to the olefinic double bond. On the other hand, Hamill (3) has suggested that electron attachment to the solute may play an important part in changing the yields of products derived from the hydrocarbon. Our own work (4) with dilute solutions of benzene in cyclohexane led us to the conclusion that the major interaction was non-chemical and that, in this case, a physical interaction such as electron attachment or energy transfer, was occurring.

An identification of the interaction mechanism is only possible through a complete product analysis (and only then in favorable cases). In this study, carbon tetrachloride and chloroform were chosen as solutes in the hope that, since they are not hydrocarbons, all products derived from them could be readily separated and identified. Since these solutes do not contain π-bonds, product analysis would not be complicated by polymer formation. The use of isotopically substituted chloroform, $CDCl_3$, enabled us to measure the extent of hydrogen abstraction from chloroform.

We find that the yields of the liquid products derived solely from the hydrocarbon are reduced as a result of free radical reactions involving both solute and solvent. The yield of hydrogen, however, is reduced by another mechanism which involves a physical interaction between the solute and a precursor of molecular hydrogen (an excited molecule or an electron). This mechanism, which does not involve the scavenging of thermal hydrogen atoms, produces other free radicals which take part in subsequent reactions leading to liquid products.

EXPERIMENTAL

Materials

Cyclohexane (Fisher Spectranalyzed), carbon tetrachloride (Fisher Reagent Grade), chloroform (Fisher Spectranalyzed), and deuterated chloroform (Merck) were used as received. The non-deuterated chloroform

[1]*Issued as A.E.C.L. No. 1891.*

was found to contain about 0.2% carbon tetrachloride. This amount was shown to have negligible effect on the product yields since addition of comparable amounts of carbon tetrachloride did not alter these yields in any of the mixtures in which chloroform was the solute. The deuterated chloroform contained about 0.01% carbon tetrachloride and, again, further addition caused no appreciable difference in product yields.

Preparation and Irradiation of Samples

The degassed 20 ml samples were prepared as described previously (5). Solutions were made up in bulk and pipetted out as required. Two Co^{60} irradiation facilities were used with dose rates of 1.40×10^{19} ev/liter minute and 3.94×10^{20} ev/liter minute in cyclohexane as determined by the Fricke dosimeter. The samples were irradiated at 22° C to a total dose of 4.7×10^{22} ev/liter unless otherwise stated.

Product Analysis

Mass spectrometry showed that over 99% of the gas non-condensible at −196° C was hydrogen. Other gases in this fraction were therefore neither identified nor measured. Hydrogen isotopic analyses were performed on a C.E.C. 21–610 mass spectrometer.

Hydrogen chloride was estimated by measuring photometrically the chloride ion produced (6). Twenty-milliliter samples were irradiated under vacuum in specially designed cells which were then opened under a measured volume of doubly distilled water. Mercuric thiocyanate was added. The chloride ion displaced the thiocyanate ion, which subsequently reacted with added ferric perchlorate. The absorption of the colored complex formed was measured photometrically at 460 mμ. None of the reactants or major products of radiolysis of the various solutions used was found to produce chloride ions by hydrolysis and it was therefore assumed that all these ions came from hydrogen chloride.

All liquid products were analyzed by a combination of gas–liquid chromatography and mass spectrometry. Quantitative analysis was by gas–liquid chromatography. The columns used were as follows: for cyclohexene, a 1/4 in. by 16 ft 20% 123 tris(2-cyanoethoxy) propane column at 55° C; for bicyclohexyl, hexachloroethane, cyclohexyl chloride, trichloromethylcyclohexane, and dichloromethylcyclohexane, a 1/4 in. by 12 ft, 0.1% Apiezon-L grease on glass beads column at 100° C; for chloroform and carbon tetrachloride, a 1/4 in. by 8 ft, 20% Carbowax 6000 column at 60° C. Standard solutions of the products were interspersed with the unknowns for calibration purposes. No pure samples of the chlorinated methylcyclohexanes were available and the comparable chlorinated toluenes were therefore used as standards. This is justified since the sensitivity of the Beckman hydrogen flame detector used is practically the same for benzene and cyclohexane.

Product identification was by mass spectral analysis of the individual products trapped from the chromatographic effluent.

RESULTS

(a) Cyclohexane/Carbon Tetrachloride Mixtures

The principal products obtained in the radiolysis of pure cyclohexane are hydrogen, cyclohexene, and bicyclohexyl (5). These products are also formed in mixtures of cyclohexane and carbon tetrachloride but in yields which decrease with increasing solute contration as shown in Fig. 1. Since carbon tetrachloride reacted extremely rapidly during radiolysis, [$G(-CCl_4) \sim 30$], the yields of products at carbon tetrachloride concentrations less than 0.05 M were obtained by extrapolating to zero dose the results obtained at doses from 2×10^{21} to 1×10^{22} ev/liter. Above 0.05 M solute concentration, this extrapolation was unnecessary and the values shown are for doses of 4.7×10^{22} ev/liter.

Also shown in Fig. 1 is the variation of the yield of hexachloroethane with carbon tetrachloride concentration. This product also disappeared extremely rapidly during radiolysis and all the points shown were obtained by extrapolation to zero dose. Even so, the points for the lower solute concentrations involved long extrapolations and so represent minimum values only.

Figure 2 shows the yields of chloroform and cyclohexyl chloride together with the G value for the disappearance of carbon tetrachloride, all as a function of solute concentration. Once again the values at the lower solute concentrations were obtained by extrapolation to zero dose. Above 0.1 M carbon tetrachloride, the measurements of $G(-CCl_4)$ involved small differences in chromatographic peak heights and so the accuracy becomes less with increasing concentration.

The yield of the only other major liquid product, trichloromethylcyclohexane, was,

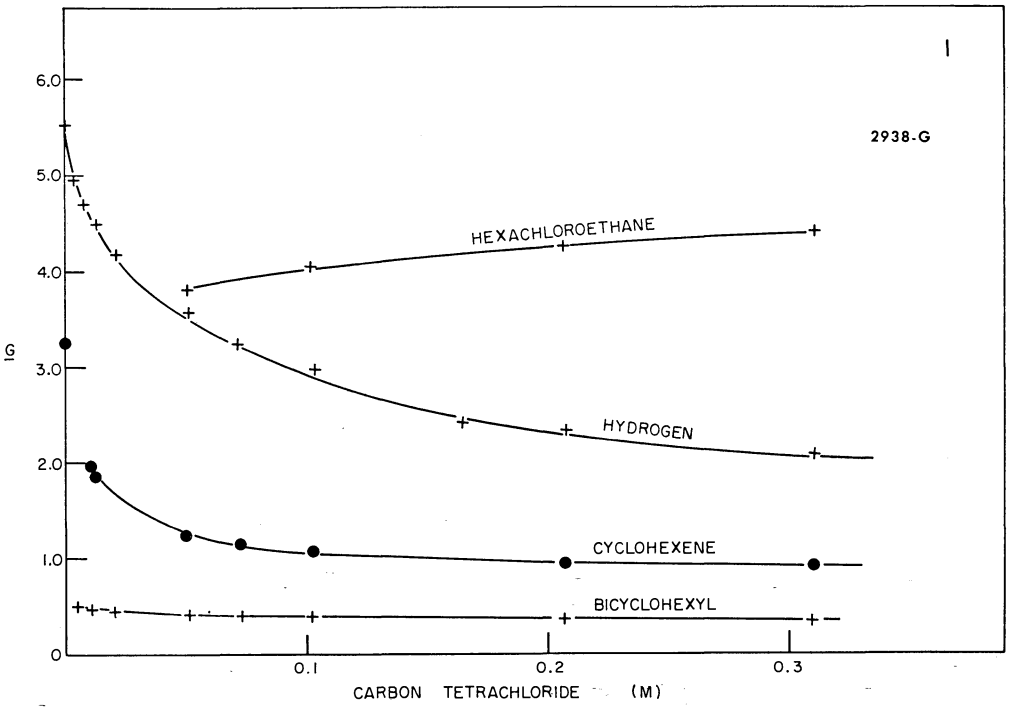

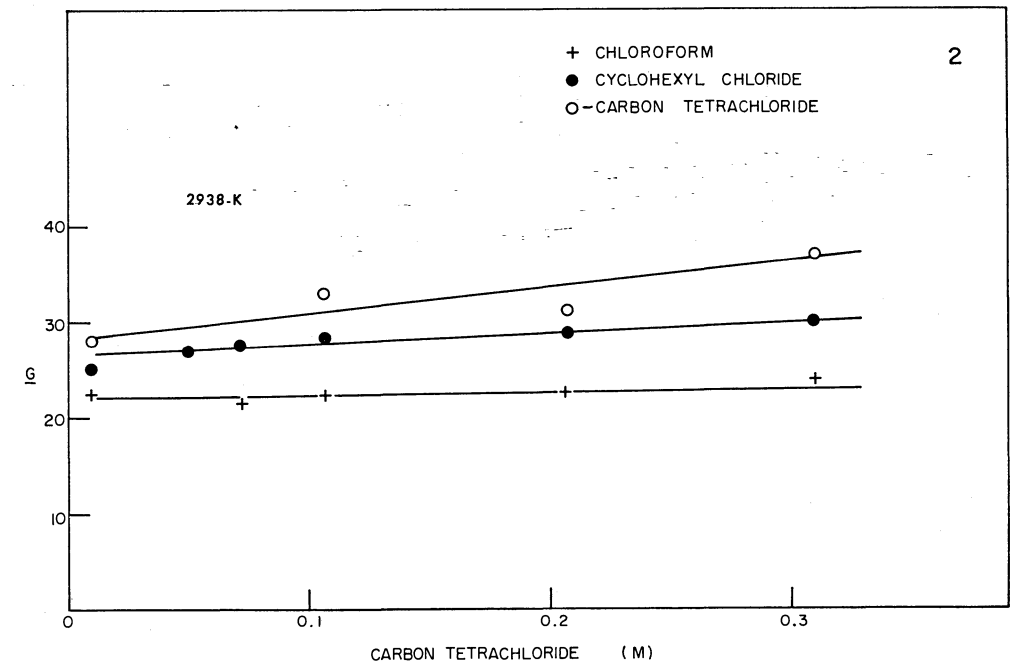

FIG. 1. G(hydrogen), G(cyclohexene), G(bicyclohexyl), and G(hexachloroethane) in C_6H_{12}/CCl_4 mixtures.
FIG. 2. G(cyclohexyl chloride), G(chloroform), and G(carbon tetrachloride) in C_6H_{12}/CCl_4 mixtures.

within experimental error, unchanged ($G = 0.65 \pm 0.03$) over the solute concentration range studied.

The yield of hydrogen chloride is shown in Fig. 3. There was no measurable variation in the yield with dose. While most of the carbon tetrachloride which reacts forms chloroform, this product also yields hydrogen chloride during radiolysis.

The yields of all products, with the exception of chloroform and cyclohexyl chloride, were invariant with dose rate. At 0.01 *M* carbon tetrachloride, *G*(chloroform) and *G*(cyclohexyl chloride) increased from values of around 23 at 3.94×10^{20} ev/liter minute to values of around 105 at 1.40×10^{19} ev/liter minute.

Cyclohexane/Chloroform Mixtures

Solutions of chloroform and deuterochloroform in cyclohexane were studied. At 0.01 *M* solute concentration, no variation of product yields with dose up to 4.7×10^{22} ev/liter was observed. Figure 4 shows that the decrease in $G(H_2)$ with increasing solute concentration is the same, within experimental error, for both solutes. For comparison, $G(H_2)$ in C_6H_{12}/CCl_4 solutions is shown. $G(H_2)$ decreases at the same rate for all three solutes up to about 0.04 *M*. Above this concentration, carbon tetrachloride is the most efficient in reducing the yield. In Figure 3, *G*(HCl) at different $CHCl_3$ concentrations is compared with *G*(HCl) at different CCl_4 concentrations. Up to 0.04 *M*, the values of *G*(HCl) are analogous to those for $G(H_2)$ in that, within experimental error, the yields are the same for both solutes. Above 0.04 *M*, the yield of HCl is greater with CCl_4 as solute. Deuterium chloride was not determined for the $C_6H_{12}/CDCl_3$ system but results similar to those for the $C_6H_{12}/CHCl_3$ system would be expected.

The variations in the yields of liquid products derived solely from cyclohexane are shown in Figs. 5 (cyclohexene) and 6 (bicyclohexyl) for both chloroform and deuterochloroform solutions and for carbon tetrachloride solutions. The yields of the chlorinated cyclohexanes (cyclohexyl chloride, dichloromethylcyclohexane, and trichloromethylcyclohexane) for the $C_6H_{12}/CHCl_3$ mixtures are shown in Fig. 7 whilst those for the corresponding compounds with $CDCl_3$ as solute are shown in Fig. 8. Trichloromethylcyclohexane was observed in such low yield ($G < 0.05$) in the latter system that its variation with solute concentration could not be determined with any accuracy. Monodeuteromethylene chloride ($CHDCl_2$) was identified and its yield was measured in the C_6H_{12}–$CDCl_3$ systems. Unfortunately, CH_2Cl_2 was not measured in the C_6H_{12}–$CHCl_3$ system.

DISCUSSION

In a previous paper (5) we showed that the yield of hydrogen in the radiolysis of pure cyclohexane is equivalent to the yields of liquid products, mainly cyclohexene and bicyclohexyl, which are formed from cyclohexane by loss of hydrogen. While, in the cases so far studied, solutes which reduce the hydrogen yield also reduce the yield of liquid products, it is not clearly established, if at all, whether these yield reductions are equivalent (4, 7).

In this discussion, we will show that at the lowest concentrations of the solutes, the total yield of liquid products is reduced to a much greater extent than the hydrogen yield. Further we will show that, while the products bicyclohexyl and cyclohexene may have, in part, a common precursor, there is a fraction of the cyclohexene yield which has another precursor. We will show that the large reduction in liquid product yields at low solute concentration is consistent with the scavenging of cyclohexyl radicals but that the reduction in hydrogen yield observed at higher concentrations is not explained by hydrogen

atom scavenging. The decrease in hydrogen yield is consistent with one or more types of physical interaction (e.g. energy transfer or electron capture) between the solvent and the solute.

We have divided this section into two parts: (*a*) a discussion of the liquid products from the irradiation of pure cyclohexane, their mechanism of formation, and the mode of interaction of their precursors with added solute; (*b*) the hydrogen yield, its variation with added solute, and the evidence we have obtained against the scavenging of thermalized hydrogen atoms by the solutes used.

(a) Liquid Products

(i) Cyclohexane/Carbon Tetrachloride

The high G values for the products cyclohexyl chloride and chloroform show that a chain reaction is occurring. A non-branching, radical chain reaction leading to the same major products has been initiated in the C_6H_{12}/CCl_4 system by the thermal decomposition of *n*-heptanoyl peroxide (8). The propagation steps of the radical chain were

$$\cdot CCl_3 + C_6H_{12} \rightarrow CHCl_3 + \cdot C_6H_{11}, \quad [1]$$

$$\cdot C_6H_{11} + CCl_4 \rightarrow C_6H_{11}Cl + \cdot CCl_3. \quad [2]$$

Chain termination was mainly by dimerization of trichloromethyl radicals to give hexachloroethane

$$\cdot CCl_3 + \cdot CCl_3 \rightarrow C_2Cl_6. \quad [3]$$

The similarity of these results to those for the radiolysis leads to the conclusion that the radiolytic products, chloroform, cyclohexyl chloride, and hexachloroethane are formed by the same reaction sequence.

Other chain termination products are possible besides hexachloroethane (equations 4, 5, and 6).

$$\cdot C_6H_{11} + \cdot C_6H_{11} \rightarrow (C_6H_{11})_2, \quad [4]$$

$$\cdot C_6H_{11} + \cdot C_6H_{11} \rightarrow C_6H_{10} + C_6H_{12}, \quad [5]$$

$$\cdot C_6H_{11} + \cdot CCl_3 \rightarrow C_6H_{11} \cdot CCl_3. \quad [6]$$

All these products are found. However, as Hardwick [9] has suggested, some or all of the yields of bicyclohexyl and cyclohexene at high concentrations of solute might be due to the reactions of radicals formed together in the same solvent cage.*

The experiments performed at the lower dose rate show that while the chain termination is not a function of dose rate, the chain length is. This is characteristic of a non-branching chain with termination by dimerization of radicals. The number of radicals involved in the termination stage (or stages) must therefore be equal to the number of initiating radicals. Unfortunately, the yield of hexachloroethane could not be measured accurately at the lowest CCl_4 concentrations and so a summation of radicals is not possible in this region.

From several pieces of evidence, it is clear that at the lowest solute concentration the initiating species must be the cyclohexyl radical, (*a*) the yields of bicyclohexyl and cyclohexene are decreased considerably even at the lowest concentrations while the yield of hydrogen is still close to its initial value (e.g. at 0.01 M CCl_4, $\Delta G(H_2) = 0.55$ whereas ΔG(bicyclohexyl) = 1.45 and ΔG(cyclohexene) = 1.30). At this solute concentration G(hexachloroethane) > 3.0. The decrease in hydrogen yield is far too small to account

**Ion–molecule reactions, as described by Williams (10) and Kevan and Libby (11), are other possible explanations for the residual yields. No solute has so far been described which, in reasonably low concentration, will reduce the yields of bicyclohexyl and cyclohexene to zero. In every case, some limiting yield is reached at ~0.3 M solute concentration when further addition of solute has negligible effect. In the present case, we have no means of distinguishing between products formed in a cage reaction and those formed as a result of chain termination.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

for the total number of radical groups in the termination products. (*b*) the yields of all possible chain termination products (with the exception of cyclohexene at the lower CCl_4 concentrations) show only small variations with solute concentration. The chain propagation products, cyclohexyl chloride and chloroform show a similar behavior and have high yields even at the lowest solute concentration employed.

Since all (>95%) the cyclohexyl radicals are scavenged at the lowest CCl_4 concentration an important conclusion can be drawn from Fig. 1. It is not until ~0.07 *M* CCl_4 that the yield of cyclohexene attains its limiting value. Part of the yield (~1 *G* unit) of cyclohexene which can be inhibited by CCl_4 cannot therefore arise from the disproportionation of cyclohexyl radicals.

If cyclohexyl radicals do disproportionate to give cyclohexene and cyclohexane, then the yield of cyclohexene is composed of three parts.

(i) That due to the disproportionation of radicals (~1.3 *G* units)

(ii) The yield of ~1 *G* unit mentioned above. This could arise from the unimolecular decomposition of some form of excited cyclohexane molecule (12).

(iii) The yield that cannot be inhibited by added solute (~0.9 *G* units).

If, however, there is no contribution to cyclohexene formation by mechanism (i) only two processes are present, the reduction in *G*(cyclohexene) to its limiting value being due to the inhibition of process (ii).

(ii) Cyclohexane/Chloroform

From Figs. 5 and 6 it is seen that (*a*) CCl_4 is much more efficient in reducing the yields of liquid products than either $CHCl_3$ or $CDCl_3$, (*b*) $CHCl_3$ is more efficient than $CDCl_3$, and (*c*) no observable chain reaction occurs in either chloroform system. But, Fig. 4 shows that up to 0.04 *M*, all three solutes reduce $G(H_2)$ to the same extent while at higher concentrations, CCl_4 is more efficient, $CHCl_3$ and $CDCl_3$ having the same efficiency. In all cases, however, the decrease in yield of liquid products is greater than the decrease in hydrogen yield. The mechanism by which the liquid products are reduced in yield cannot therefore be directly related to or correlated with the mechanism by which the hydrogen yield is reduced.

In the $C_6H_{12}/CHCl_3$ system, *G*(bicyclohexyl) does not reach its limiting value until ~0.15 *M* $CHCl_3$. In the case of $C_6H_{12}/CDCl_3$, this limiting value is not attained at the maximum solute concentration employed (0.22 *M*). Neither $CHCl_3$ nor $CDCl_3$ is therefore as efficient a radical scavenger as CCl_4. This is in agreement with chain transfer constants derived from polymerization studies in $CHCl_3$ and CCl_4 as solvents (13). Chain transfer with CCl_4 is at least an order of magnitude greater than for transfer with $CHCl_3$.

Evidence that chloroform is acting in part as a radical scavenger is provided by the relative product distributions. Free radicals preferentially attack the C—H bond in $CHCl_3$. However, with $CDCl_3$, C—D bond cleavage is reduced by a factor of 10 or more and a significant increase in C—Cl bond cleavage occurs (14). Figures 7 and 8 show that more $C_6H_{11}Cl$ is produced in $C_6H_{12}/CDCl_3$ than in $C_6H_{12}/CHCl_3$ even though the decreases in bicyclohexyl yields suggest the reverse. Scavenging by $CHCl_3$ will produce cyclohexane as well as cyclohexyl chloride.*

**Reaction [7] is the reverse of reaction [1] and so these reactions should more accurately be written as an equilibrium*

$$\cdot C_6H_{11} + CHCl_3 \overset{7}{\rightleftharpoons} C_6H_{12} + \cdot CCl_3$$

Although $\cdot CCl_3$ radicals (which take part in the chain reaction in the C_6H_{12}/CCl_4 system) are produced they do not in this system lead to an observable chain since reaction [1] simply regenerates chloroform and a cyclohexyl radical. This equilibrium decreases the net probability of reaction [7] and therefore facilitates the competing reaction [8].

$$\cdot C_6H_{11} + CHCl_3 \rightarrow C_6H_{12} + \cdot CCl_3, \quad [7]$$

$$\rightarrow C_6H_{11}Cl + \cdot CHCl_2. \quad [8]$$

With $CDCl_3$ little $C_6H_{11}D$ will be produced and the main reaction will be

$$\cdot C_6H_{11} + CDCl_3 \rightarrow C_6H_{11}Cl + \cdot CDCl_2. \quad [9]$$

Reference to other products show this to be the case. In the $C_6H_{12}/CHCl_3$ system we also obtain $C_6H_{11}CCl_3$ and $C_6H_{11}CHCl_2$, presumably by radical–radical additions:

$$\cdot C_6H_{11} + \cdot CCl_3 \rightarrow C_6H_{11}CCl_3, \quad [10]$$

$$\cdot C_6H_{11} + \cdot CHCl_2 \rightarrow C_6H_{11}CHCl_2. \quad [11]$$

In the $C_6H_{12}/CDCl_3$ system, $G(C_6H_{11}CCl_3)$ was immeasurably small. A radical–radical reaction would produce the large yields of $C_6H_{11}CDCl_2$

$$\cdot C_6H_{11} + \cdot CDCl_2 \rightarrow C_6H_{11}CDCl_2. \quad [12]$$

$CHDCl_2$ would be produced by hydrogen abstraction from C_6H_{12}:

$$\cdot CDCl_2 + C_6H_{12} \rightarrow CHDCl_2 + \cdot C_6H_{11}. \quad [13]$$

The yields of cyclohexene and bicyclohexyl in the $C_6H_{12}/CHCl_3$ system confirm once again that part of the inhibitable yield of cyclohexene cannot have the same precursors, namely cyclohexyl radicals, as bicyclohexyl. From Figs. 5 and 6, it is seen that although G(bicyclohexyl) attains its limiting value at $\sim$0.07 M $CHCl_3$, G(cyclohexene) is still above the limiting value found in the C_6H_{12}/CCl_4 system.

The Increased Radical Yield in C_6H_{12}/CCl_4 Mixtures

In a previous paper (4), we showed that the number of molecules of cyclohexane which react to form products is greater in pure cyclohexane than in cyclohexane containing small amounts of benzene. We interpreted this in terms of a physical interaction between the benzene and some form of excited cyclohexane, the benzene dissipating the energy gained in this process without decomposition. When carbon tetrachloride is used as solute, the converse is the case, more chemical reaction occurring than in pure cyclohexane. This excess of chemical reaction is shown by comparing the number of radicals found in chain termination products ($C_6H_{11}CCl_3$ and C_2Cl_6) to the number missing as calculated from the decrease in the yields of liquid products formed from cyclohexane alone. This summation of radicals (which is possible only at high solute concentrations) is shown in Table I. Each product molecule has been equated to two radicals. Some cyclohexene may, however, be formed by a first order process.

$$C_6H_{12} \rightarrow C_6H_{10} + H_2. \quad [14]$$

The quenching of this reaction by carbon tetrachloride could, however, lead to radical formation.

The yield of hydrogen chloride also demonstrates that, far from acting as a non-sacrificial protector, carbon tetrachloride enhances radiolytic reaction. It is customary to

TABLE I

The yields of "excess" radicals and hydrogen chloride in C_6H_{12}/CCl_4 mixtures

CCl_4, M	$2[\Delta G$(cyclohexene) $+ \Delta G$(bicyclohexyl) $+ \Delta G$(cyclohexyl-hexene-1)]	$2[G(C_2Cl_6) + G(C_6H_{11}CCl_3)]$	G (excess radicals)	G (excess HCl)

associate a 1:1 correlation between ΔG(hydrogen) and the G value for the reaction of an inhibitor, i.e. for every molecule of cyclohexane which is "protected", or every hydrogen atom which is scavenged, one molecule of solute is directly involved. If the solute is designated S then for H atom scavenging $\Delta G(H_2) = G(HS)$, or, if S takes part in an energy transfer process, $\Delta G(H_2) = G(S^*)$. We find that at low concentrations of $CHCl_3$ and CCl_4, hydrogen chloride (which could be formed by hydrogen atom scavenging or by some form of energy transfer) is not equivalent to $\Delta G(H_2)$ but is much greater. Figure 9

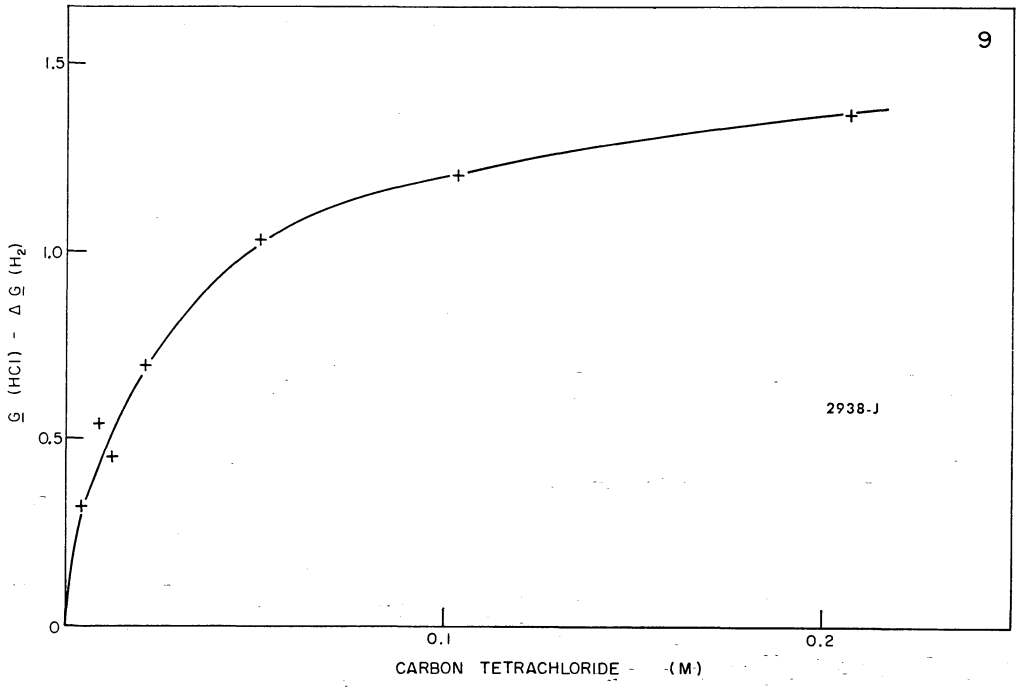

FIG. 9. The yield of hydrogen chloride that is in excess of that accounted for by the decrease in the yield of hydrogen (C_6H_{12}/CCl_4 mixtures).

shows that most of this excess HCl is produced at low solute concentration. The excess HCl formed at the highest solute concentrations is compared with G(excess radicals) in Table I.

The excess radicals are equivalent to the excess HCl. A sensitized decomposition must be occurring. Oster and Kallman (15) have suggested that a similar increase in radical production on the addition of carbon tetrachloride to benzene is due to an energy transfer mechanism. Molecules which, although excited by the incident radiation, do not normally yield products can hand on this excitation energy to the solute which then decomposes. A different interpretation for a similar phenomenon has been given by Nash and Hamill (16). They attribute the increase in $G(H_2)$ observed when hydrogen iodide is added to cyclohexane to an electron capture process.

(*b*) *Hydrogen*

We have shown that at low solute concentration, particularly in the case of CCl_4, cyclohexyl radicals can be scavenged without a corresponding large reduction in the hydrogen yield. It would be natural to assume that the decrease in hydrogen yield at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

higher solute concentrations is due to hydrogen atom scavenging. Our results do not support such a mechanism.

It has been demonstrated that CCl_4, $CHCl_3$, and $CDCl_3$ scavenge cyclohexyl radicals with different efficiencies. The hydrogen yields in the various systems do not reflect the same differing efficiencies. In particular, at concentrations of less than 0.04 M all three solutes show the same efficiency in reducing $G(H_2)$. It is just in this region that the largest differences in the rates of cyclohexyl radical scavenging are observed. One would also expect a difference for the reaction of any other free radicals, including hydrogen atoms. We therefore conclude that the reduction in hydrogen yield cannot be due to a scavenging process.

Hardwick (17) has interpreted the action of halogenated compounds on the hydrogen yield from the radiolysis of *n*-hexane in terms of hydrogen atom scavenging. The difference in limiting hydrogen yield at the highest concentrations of $CHCl_3$ and CCl_4 employed is explained as due to hydrogen abstraction from chloroform, i.e. with $CHCl_3$ we can have

$$\cdot H + CHCl_3 \rightarrow HCl + \cdot CHCl_2, \quad [15]$$

$$\cdot H + CHCl_3 \rightarrow H_2 + \cdot CCl_3, \quad [16]$$

but for CCl_4 only reaction (17) is possible.

$$\cdot H + CCl_4 \rightarrow HCl + \cdot CCl_3. \quad [17]$$

The value quoted for k_{16}/k_{15} is 0.14. We find for the systems $C_6H_{12}/CHCl_3$ and $C_6H_{12}/CDCl_3$ that $\Delta G(H_2)$ is the same at any given solute concentration. Using the above ratio of rate constants we have calculated the values of $G(HD)$ to be expected for given values of $\Delta G(H_2)$ in the $C_6H_{12}/CDCl_3$ system. These are shown in Table II together with

TABLE II

The decrease in hydrogen yield and the yield of HD in the system C_6H_{12}–$CDCl_3$

$CDCl_3$, M	$G(H_2)$	$G(HD)$ (measured)	$\Delta G(H_2)$	$G(HD)$ (calculated)
0.01	4.66	0.0013	0.89	0.12
0.05	3.64	0.0027	1.91	0.27
0.31	2.57	0.012	2.98	0.42

the experimentally determined values. As was to be expected, no D_2 was produced at these low solute concentrations. The decrease in total hydrogen yield, $\Delta G(H_2)$ at the same concentrations, is also tabulated.

The very large difference between these two sets of results (~a factor of 50) argue against the above hypothesis and hence against the presence of thermalized hydrogen atoms in the system.

Since the ionization potential of CCl_4 is ~1.5 ev greater than that for cyclohexane, charge exchange from the ground state of $C_6H_{12}^+$ cannot occur. Ion–molecule reactions as a major source of the inhibitable hydrogen are ruled out for the same reason. The effect must therefore be due to either an electron capture process or some form of energy transfer.

Van Dusen and Hamill (17) suggest that dissociative electron attachment is an important process in the radiation chemistry of liquid systems containing components that can readily attach slow electrons at low pressures in the gas phase. CCl_4 and $CHCl_3$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

are two such compounds. Lovelock (18) and Guarino, Ronayne, and Hamill (19), using different methods, showed that the affinity of CCl_4 for thermal electrons is greater than that of $CHCl_3$. Figure 4 shows that above 0.04 *M* solute, the relative decreases in hydrogen yield are as one would expect if thermal electron capture did occur. However, at low solute concentrations, both solutes decrease the hydrogen yield to the same extent and this is inconsistent with an electron capture mechanism.

From the results of experiments with very dilute solutions of iodine in cyclohexane, Schuler (20) suggested that solutes at low concentration can act as energy sinks and thus protect the solvent molecules although they may themselves decompose as a result of this absorption of energy. A similar conclusion was reached by us to explain the effect of dilute solutions of benzene on the radiolysis of cyclohexane (4). In the C_6H_{12}/CCl_4 system, any explanation for the decrease in the hydrogen yield must leave the total number of radicals unchanged. Both electron capture and energy transfer would do this if the participating CCl_4 molecules subsequently reacted. For example,

(i) energy transfer:

$$C_6H_{12}^* + CCl_4 \rightarrow C_6H_{12} + CCl_4^*, \quad [18]$$

$$CCl_4^* \rightarrow \cdot CCl_3 + \cdot Cl; \quad [19]$$

(ii) electron capture:

$$C_6H_{12} \rightarrow C_6H_{12}^+ + e, \quad [20]$$

$$e + CCl_4 \rightarrow CCl_4^- \rightarrow CCl_3 + Cl^-. \quad [21]$$

Recent work with hydrocarbons containing deuterated cyclohexane has also shown that explanations for reductions in $G(H_2)$ by added solutes must be formulated in terms of a non-chemical interaction (22).

From the complexity of the hydrogen yield curves (Fig. 4), it is not improbable that there is more than one mechanism operating to reduce the hydrogen yield.

ABSTRACT

Unlike sorbitan and glycerol monostearates, alkylphenol derivatives of polyoxytheylene appear to be monodisperse in benzene when the solutions were examined by vapor pressure lowering. In addition, the existence of micelles was not detected by light-scattering measurements in benzene with a few representative samples. In agreement with light-scattering data, the number average micellar weight in water decreased with increasing number of ethylene oxide units per molecule. A difference of about a factor of 8 between weight and number average molecular weight appears to exist for materials of similar composition.

INTRODUCTION

Nonionic detergents which derive their hydrophilic properties from ethylene oxide interact in aqueous solutions forming micelles above a critical concentration. The number of monomers clustering together to form micelles is dependent on the temperature (1, 2) and to some extent on the homogeneity of the polyoxyethylene chain lengths (3).

Although a linear relationship appears to exist between aggregation number (n) and the reciprocal of the average number of ethylene oxide units for compounds containing more than 10 such units (4,5), the micellar weight of surfactants of lower solubility rises sharply in water with decreasing numbers of hydrophilic groups (6). Thus departures from linearity occur that became particularly apparent at high ethylene oxide ratios when a wide range of ethylene oxide content is examined. Large differences in micellar weights were found between cryoscopic (7) and light-scattering measurements (8) of commercial isooctylphenol derivatives of nine ethylene oxide units. Since evidence for the existence of differences in number ($\bar{M}_n$) and weight ($\bar{M}_w$) average molecular weight appeared for other nonionic surface active agents in nonaqueous solvents (9, 10), it was of considerable interest to assess the solution properties of some alkylphenol derivatives of ethylene oxide in both aqueous and nonaqueous media.

In the present communication a number of octylphenol – ethylene oxide adducts (Tritons) were examined wherein the number of ethylene oxide units varied from 3 to 30 with the hydrophobic constituent of the molecule remaining constant. Two nonylphenols, Triton N128 and DowFax 9N9, were examined in benzene by vapor pressure lowering. Triton N128, DowFax 9N9, and Triton X-45 were also examined in benzene by light-scattering measurements and some vapor pressure measurements were carried out with DowFax 9N9 in alcohol. A variety of polyoxyethylated alkylphenols with cloud points above 50° C were examined in water using a vapor pressure "Osmometer".

A lauryl alcohol derivative of 23 (poly)oxyethylene units (Brij 35)* in which non-equilibrium states were found in water by light-scattering measurements (11) was examined in water and in benzene at 37° C and in alcohol at 44°. Some measurements were

[1]*Issued as N.R.C. No. 7700.*

carried out with solutions of methoxy polyoxyethylene glycols (Carbowax 350 and 750) in water and in dioxane at 35°.

EXPERIMENTAL

The nonionic surface-active agents were of industrial origin. The liquid materials were centrifuged to separate out insoluble matter, evacuated at room temperature to remove volatiles, and then stored under vacuum.

Solutions examined in benzene and in alcohol by vapor pressure lowering measurements and by light-scattering measurements in benzene at 25° C for Triton N128, Triton X-45, and DowFax 9N9 were prepared as described previously (10).

The aqueous solutions were prepared with conductivity water which was stored in thoroughly conditioned polythene bottles, and measurements made with a Mechrolab Vapor Pressure "Osmometer" Model 301 at 37° C using a probe adapted for aqueous systems. The apparatus was calibrated with solutions of reagent grade urea, sucrose, and mannitol. One solution syringe was used to diminish concentration errors due to evaporation. The solutions were measured in the order of increasing concentration.

Owing to aggregation of the nonionic detergents and the rather low readings due to the high latent heat of vaporization of water, it was necessary to carry out the measurements over a wide range of concentrations. Readings close to the calibrated range at low concentrations were obtained with solutions containing about 4 to 28% surface-active agent (grams of solute/100 g water). The solutions were shaken periodically and they were allowed to equilibrate at room temperature overnight. Because of the low sensitivity observed with water the required time to reach equilibrium was established by trial and error. Reproducible measurements were obtained by the following procedure.

The syringe containing an aliquot portion of the solution was allowed to stand about 20 minutes in the apparatus to reach ambient temperature, after which the solution thermistor was rinsed 8–10 times, then a drop of solution was deposited on the bead. Readings were taken every minute for 6 minutes. Three or four sets of measurements were taken for each solution. The average value after 5 minutes was used in calculating the apparent molecular weight at finite concentrations. The molar constant was obtained from a calibration curve relating the variation of $\Delta R/C$ versus ΔR.

The solutions assessed by static vapor pressure measurements employing a sensitive differential mercury micromanometer were prepared with rigorously deaired conductivity water. The amount of water used for making up the solutions was measured in a calibrated capillary tube. The amounts of solvent and solute used were in the range of 1 to 10 mg and 30 to 90 mg respectively.

The measurements were carried out as described previously for the organic solvents (10).

The methoxy polyoxyethylene glycols (Carbowax 350 and 750) were assessed by static vapor pressure determinations in water and dioxane at 35° C. The apparatus was modified to prevent the alternate condensation and evaporation of solvent on the solution cell while measurements were being taken (12). Carbowax 350 was distilled and the fraction boiling at 163° C at 2 mm Hg pressure was used. Carbowax 750 was used as received; however, a small portion of the material was distilled in a Späte tube under reduced pressure and used in a few experiments. The distillate was further evacuated at room temperature to remove light ends.

Dioxane was redistilled from and stored over CaH_2. It was used after being thoroughly deaired. The amount of dioxane used was measured in a calibrated capillary tube as described for the preparation of the aqueous solutions.

RESULTS AND DISCUSSION

The variation of the apparent molecular weight with solute concentration for a group of polyoxyethylated octylphenols in benzene at about 37° C is indicated in Fig. 1. Curves 1, 2, 3, 4, 5, and 6 were obtained for Triton X-35, X-45, X-102, X-165, X-205, and X-305 respectively (see Table I). The crosses (×) were obtained with the differential mercury micromanometer and the other points with the "Osmometer". The agreement between these two techniques is acceptable. The observed and the estimated molecular weights based on the composition data supplied by the manufacturers are also in fairly good agreement. The molecular weight of Triton X-305 is about 20% lower than the estimated value. This could be due to a higher heterogeneity of the substance. With the possible exception of Triton X-35 the apparent molecular weight versus concentration curves indicate that the solutions are monodisperse in benzene. Some departures from "ideal" behavior are indicated for the substances containing more than 12 to 13 ethylene oxide units (E.O.) The deviation becomes more pronounced with increasing ethylene oxide content. This

TABLE I

Summary of results indicated from vapor pressure measurements using the "Osmometer" on solutions of polyoxyethylated octyl- and nonyl-phenols in benzene at 37° C

	Av. No. E.O.	Mol. wt. estimated	Mol. wt. observed
Octylphenols			
Triton X-35	3	338	338
Triton X-45	5	426	442
Triton X-102	12–13	734–778	752
Triton X-165	16	910	910
Triton X-205	20	1086	1050
Triton X-305	30	1526	1290
Nonylphenols			
DowFax 9N9	9–10	616–660	655
Triton N128	12–13	748–792	770

suggests that polymer–solvent interaction increases with increased ethylene oxide units in benzene.

The results obtained for Triton N128 and DowFax 9N9 are summarized in Table II. The molecular weight of Triton N128 was about 10% higher at infinite dilution by static vapor pressure measurements than the value observed with the "Osmometer". The discrepancy between the two procedures was smaller in the case of DowFax 9N9. The differences are probably due to the different experimental conditions of the two procedures.

TABLE II

Molecular weights of Triton N128 in benzene and DowFax 9N9 in benzene and in alcohol by vapor pressure lowering measurements

Detergent	Solvent	% conc. range	Method	Mol. wt. indicated
Triton N-128	Benzene	1–10	"Osmometer"	770
		2–6	S.V.P.	860
DowFax 9N9	Benzene	1–7.5	"Osmometer"	655
	Benzene	2–6	S.V.P.	685
	Alcohol	1–8	"Osmometer"	630
	Alcohol	0.5–10.5	S.V.P.	660

While it is possible to work under very dry conditions under vacuum when employing the mercury micromanometer, it is impossible to do this when using the "Osmometer".

A slight negative deviation from Raoult's law was indicated for Triton N128. DowFax 9N9 behaved in an "ideal" way in benzene and in alcohol. Micelle formation with Triton N128, X-45, and DowFax 9N9 was not detected by light-scattering measurements in benzene at 25° C. This also suggests that benzene is a good solvent for these surface-active substances. The rise in apparent molecular weight with concentration for glyceryl and sorbitan monostearates in benzene (10) perhaps could be due to the influence of the lyophilic portion of the molecule which dimerizes in this solvent. The alcohol containing the same number of carbon atoms appears to be monodisperse. Since the hydrogen bond in carboxylic acids appears to be stronger than that in alcohols or in phenol, perhaps it has an influence on the solution properties of the esters. Association of polyoxyethylene glycol was not observed in benzene.

The variation of the apparent molecular weight with solute concentration for the octylphenol – and the nonylphenol – ethylene oxide adducts in water at 37° C using the "Osmometer" is shown in Fig. 2. The apparent $\bar{M}_n$ micellar weight and aggregation number (n) indicated for these substances are summarized in Table III. Curves 1, 2, 3, and 4 were obtained for Triton X-102, X-165, X-205, and X-305 respectively. Curves 5 and 6 represent the behavior of Triton N128 and DowFax 9N9 respectively. Each point in curve 5 is an average of three separate determinations conducted at different times at about the same concentration. The variation of the apparent molecular weight observed for each measurement lies within the vertical lines. The curves for the octylphenol series are of similar shape. As observed by ultracentrifugal measurements (3) over a narrower concentration range, the molecular weight above the critical micelle concentration (circa 0.01% for most members in distilled water) remains reasonably constant over a wide concentration range. With further solute concentration a decrease in apparent molecular weight occurred. A straight line through these experimental points, extrapolated to infinite dilution indicates a $\bar{M}_n$ micellar weight within 10% of that calculated from the results obtained at the lower concentrations. However, at the higher concentrations these solutions are very close to the gel range. Under these circumstances the extrapolation to zero concentration is of doubtful validity (13). The behavior of the nonylphenol – ethylene oxide adducts seems to be less dependent upon concentration. In every case, however, the micellar weight decreased with increasing number of ethylene oxide groups per molecule.

The lauryl alcohol derivative (Brij 35) behaved in much the same way as did the octylphenol series. The solutions were examined over a concentration range from about 5 to 23%. The apparent molecular weight of solutions of 5–10 weight% concentrations

TABLE III

The apparent $\bar{M}_n$ micellar weight and aggregation number (n) indicated from vapor pressure lowering measurements on aqueous solutions of polyoxyethylated nonionic detergents

	M_o benzene	No. E.O.	M_a	$\bar{M}_m$ calculated	n, calculated
Triton X-102	752	12.4	7000	7750	10.3
Triton X-165	910	16	5600	6500	7.1
Triton X-205	1050	19.2	5100	6170	5.9
Triton X-305	1290	24.7	4100	5370	4.2
Triton N128	770	12.5	5000	5800	7.5
DowFax 9N9	655	9.9	8000	8600	13
Brij. 35	1120	21.2	3800	4900	4.4

was about 3800±10%. It decreased to about 1800 at 20%. A value of 1120 was obtained when the substance was examined in alcohol over a concentration range of 1 to 10%. This is presumably the monomeric weight. Unlike DowFax 9N9, which behaved in an "ideal" way in alcohol over the same concentration region, Brij 35 showed a small discontinuity. The system was "ideal" from 1 to 4%. At about 5% the apparent molecular weight was 1020 and dropped to 960 at 10% concentration. These measurements fitted very closely a curve having a slight upward curvature and it converged to a value of 1120 at infinite dilution. The value calculated from the monomer composition is close to 1200. The solutions assessed in benzene with the "Osmometer" were concentration dependent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and the molecular weight at infinite dilution was in fairly good agreement with the value observed in alcohol.

The variation of the apparent molecular weight with solute concentration for the samples of methoxy polyoxyethylene glycol in water and in dioxane is shown in Fig. 3. Curves 1, 2,

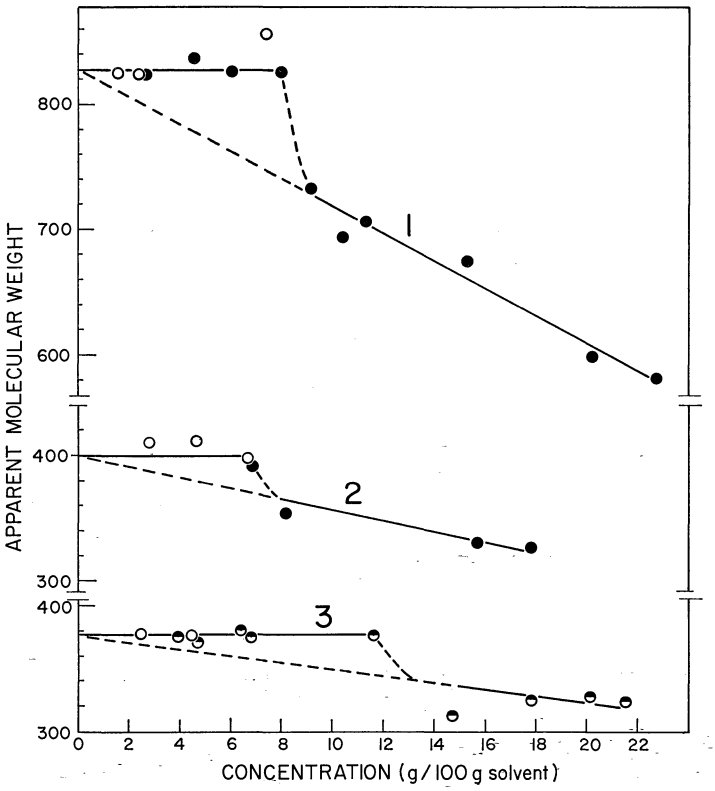

FIG. 3. Apparent molecular weight versus solute concentration for the samples of methoxy polyoxyethylene glycol in water and in dioxane (open circles) at about 35° C. Curve 1, Carbowax 750, curve 2, distilled fraction of Carbowax 750; and curve 3, Carbowax, 350.

and 3 were obtained for Carbowax 750, a distilled portion of the same material, and distilled Carbowax 350 respectively. The solutions behaved in an "ideal" fashion over a finite concentration range, then a sharp drop occurred in molecular weight. Subsequent determinations were dependent on concentration. However, a straight line joining these latter experimental points extrapolated to zero concentration yielded the same value for the molecular weight. The results obtained in dioxane (open circles) were in good agreement with those observed in water. It was not possible to cover a very wide concentration range with dioxane since the vapor pressure lowering was beyond the calibrated range of the apparatus.

The molecular weights of these nonionic substances are in reasonably close agreement with the value expected from the composition data supplied by the manufacturer. The reason for the break in the apparent molecular weight curves in aqueous systems even with the distilled materials is not too clear. It is quite possible that the polymer is not in a coiled configuration and, particularly, in the case of the octylphenol derivatives, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

micelles immobilize large quantities of water in addition to hydrogen bonding to the ether linkages. This immobilization gives rise to an abnormally high lowering of the vapor pressure owing to an increase in solute concentration; a lower apparent molecular weight results. If the surfactant were less soluble at the higher concentrations the vapor pressure of the solutions would remain virtually constant and a rise in apparent molecular weight would be observed.

The deviation could possibly be due to a slight amount of volatile precipitant sorbed on the polyoxyethylene chains. A similar phenomenon was observed previously with freshly prepared benzene solutions of a sample of polyvinyl acetate. When the solution was evaporated to dryness in a hard vacuum and a new solution was prepared under hermetically sealed conditions with fresh solvent, the effect disappeared and the molecular weight was dependent on concentration (14). Because the solution properties depend on delicately balanced lyophobic–lyophilic characteristics, small concentrations of extraneous materials can have an unexpectedly large influence.

Viscosity measurements on aqueous solutions of Carbowax 750 at 30° C indicated that the reduced viscosity increased slightly with concentration. At about 7% concentration, upward curvature became more pronounced. Although there was no evidence of a sharp break in the curve, it indicates that solvation contributes to the phenomenon. This agrees with previously reported work (15, 16).

The $\bar{M}_n$ micellar weight and aggregation number (n) for the lauryl alcohol derivative indicated by vapor pressure measurements in water is also shown in Table III. The aggregation numbers and the average number of ethylene oxide units in each substance was based on the molecular weight observed in benzene with the "Osmometer". The results suggest that considerable differences exist between $\bar{M}_n$ and $\bar{M}_w$ micellar weight in water for surface-active agents of similar composition. Owing to the negative temperature coefficient of solubility (1,2) these differences could be accentuated. The results observed by Gonick and McBain (7) support the molecular weights indicated from the colligative properties of the solutions.

It is quite possible that polydispersity of the micellar sizes, differences in molecular species, and the presence of soluble impurities could be contributing factors. The presence of electrolytes decreases $\bar{M}_n$ because of their contribution to the vapor pressure lowering but increases $\bar{M}_w$ by light-scattering measurements owing to probable "salting out" effects (4,5). Dust particles have very little effect on the colligative properties of the solutions, but these increased $\bar{M}_w$ by light-scattering measurements even after successive filtrations (17).

The variation of the aggregation number (n) with the reciprocal of the number of ethylene oxide units per mole of hydrophobe for the alkylphenols is shown in Fig. 4 by curve 1. The solid and open circles represent this property for the octyl- and nonyl-phenols respectively. Curve 2 indicates the concentration in which deviations from linearity occurred for the octylphenol series of surfactants. Although the data are too meager to attach too much significance to this, it could possibly indicate a transition in the properties of the solutions (18).

In good agreement with the $\bar{M}_w$ micellar weight obtained by light-scattering measurements (4,5), the $\bar{M}_n$ micellar weight indicated by curve 1 decreases with increasing ethylene oxide content. As found by Becher (4) the tendency to form large micelles decreases with increased solubility of the surfactant. Although most data obtained over a moderate range of ethylene oxide content can be fitted by a straight line which intercepts the 1/E.O. axis, it does not appear too unreasonable to fit a curved line over the same

INFRARED AND RAMAN SPECTRA OF CYANURIC FLUORIDE

JAMES E. GRIFFITHS AND DONALD E. IRISH*
Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey
Received October 4, 1963

ABSTRACT

Infrared spectra (250–2000 cm^{-1}) and Raman displacements ($\Delta\nu$ = 100–1800 cm^{-1}) with qualitative polarization measurements are reported for cyanuric fluoride. All of the active fundamentals are assigned on the basis of a planar D_{3h} model: a_1' = 1496, 999, 642; e' = 1617, 1424, 1087, 576, 378; a_2'' = 817, 436; e'' = 743 and 226 cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

The infrared and Raman spectra of cyanuric fluoride, $C_3N_3F_3$, have not been discussed previously, although an infrared spectrum of the liquid has been published without comment (1) and an attempt to assign four of the strongest infrared bands was made (2). The infrared spectrum of the basic structural unit, cyanogen fluoride, however, has been reported (3, 4, 5) and the three fundamentals were assigned.

Since cyanuric fluoride is a reactive compound and a potentially useful starting material for a variety of chemical reactions, a knowledge of its vibrational spectrum is desirable. Furthermore, chemical evidence favors a planar structure for this compound, but there has been no physical evidence presented up to this time. In this work, the infrared and Raman spectra are analyzed in terms of a planar D_{3h} model and all of the active fundamentals are assigned.

EXPERIMENTAL

The cyanuric fluoride was purchased from the Hynes Chemical Research Co., Durham, N.C. The sample was purified by fractional condensation and vaporization *in vacuo* until its vapor pressure was 21.8±0.2 mm at 0° (calc., 21.7±0.4 mm^2) and its molecular weight was 135.0 (calc., 135.0). A nuclear magnetic resonance spectrum measured at 56.4 Mc in $CFCl_3$ and in CF_3COOH showed single F^{19} resonance lines at +1760 c.p.s. upfield from $CFCl_3$ and at −2591 c.p.s. downfield from CF_3COOH. Therefore, there were no detectable fluorine-containing impurities.

The infrared spectrum was examined in the vapor and liquid states from 250 to 2000 cm^{-1} using a Perkin–Elmer Model 421 spectrophotometer which was equipped with a medium-far infrared grating interchange. Raman displacements (from the 4358 Å Hg line) were recorded photoelectrically with a Cary Model 81 spectrophotometer and the liquid sample was contained in a 0.7×27 cm glass tube. A light trap was incorporated into the tube to remove any spurious reflections and a sodium nitrite filter removed almost all undesirable mercury excitation lines. Frequencies reported in Table I are expected to be accurate to ±2 cm^{-1} and the individual spectra are shown in Figs. 1 (IR) and 2 (R). Qualitative polarization data were also obtained although the spectra themselves are not shown.

DISCUSSION

Of the possible models for $C_3N_3F_3$ the chemical evidence (1, 6) favors a symmetric ring structure which is expected to be planar (D_{3h} point group). The reduced representation of internal motion is $3A_1' + 2A_2' + 5E' + 2A_2'' + 2E''$. The A_1' (polarized) and E'' (depolarized) species are Raman active only and the A_2'' species are active only in the infrared. The E' type vibrations are active in both (Raman depolarized); whereas the A_2' species are inactive in both. The A_1', A_2', and E' type modes are of the in-plane type, whereas the A_2'' and E'' species represent out-of-plane motions. Therefore, in the vapor state infrared spectra, the unresolved rotational structure in the parallel A_2'' type absorption bands is expected to produce band contours which are similar to simple P, Q, and R

branches. Moreover, since I_A will likely be greater than I_B, the intensity of the observed Q branch will be more intense than that of the P or R branches (7). The fundamental frequencies are collected in Table II and the numbering system conforms to that of Herzberg.

VIBRATIONAL ASSIGNMENT

Three strong polarized bands at 1496, 999, and 642 cm^{-1} were observed in the Raman effect and are assigned to the three A_1' vibrations. The 1496 cm^{-1} band is assigned to the symmetric C–F stretching vibration. This leaves the two ring modes ν_2 and ν_3 for assignment to the bands at 999 and 642 cm^{-1}.

Two depolarized Raman lines, which are not observed in the gas phase infrared spectrum, are found at 743 and 226 cm^{-1}. These are assigned to the E'' type vibrations ν_{13} and ν_{14} and represent the C–F wagging and the out-of-plane ring modes respectively. The latter corresponds to the bands at 340 and 309 cm^{-1} in $C_3N_3H_3$ and $C_3N_3D_3$ respectively (8). The 226 cm^{-1} band is asymmetrical and a careful analysis shows the presence of a weak band whose center occurs at 244–253 cm^{-1}. This is assigned to $\nu_2-\nu_{13} = 256$ cm^{-1} (E''), and its comparable intensity relative to that of the sum band $\nu_2 + \nu_{13}$, might arise from a Fermi resonance with the $\nu_{14}(e'')$ fundamental.

The two infrared active but Raman inactive fundamentals of the A_2'' species occur at 817 and at 436 cm^{-1}. The first shows a well-defined PQR structure with a P–R separation of 16 cm^{-1}, but the contour of the second is poorly defined because of overlapping water vapor bands.

There remain the five fundamentals of the E' species to be assigned. Since these must be

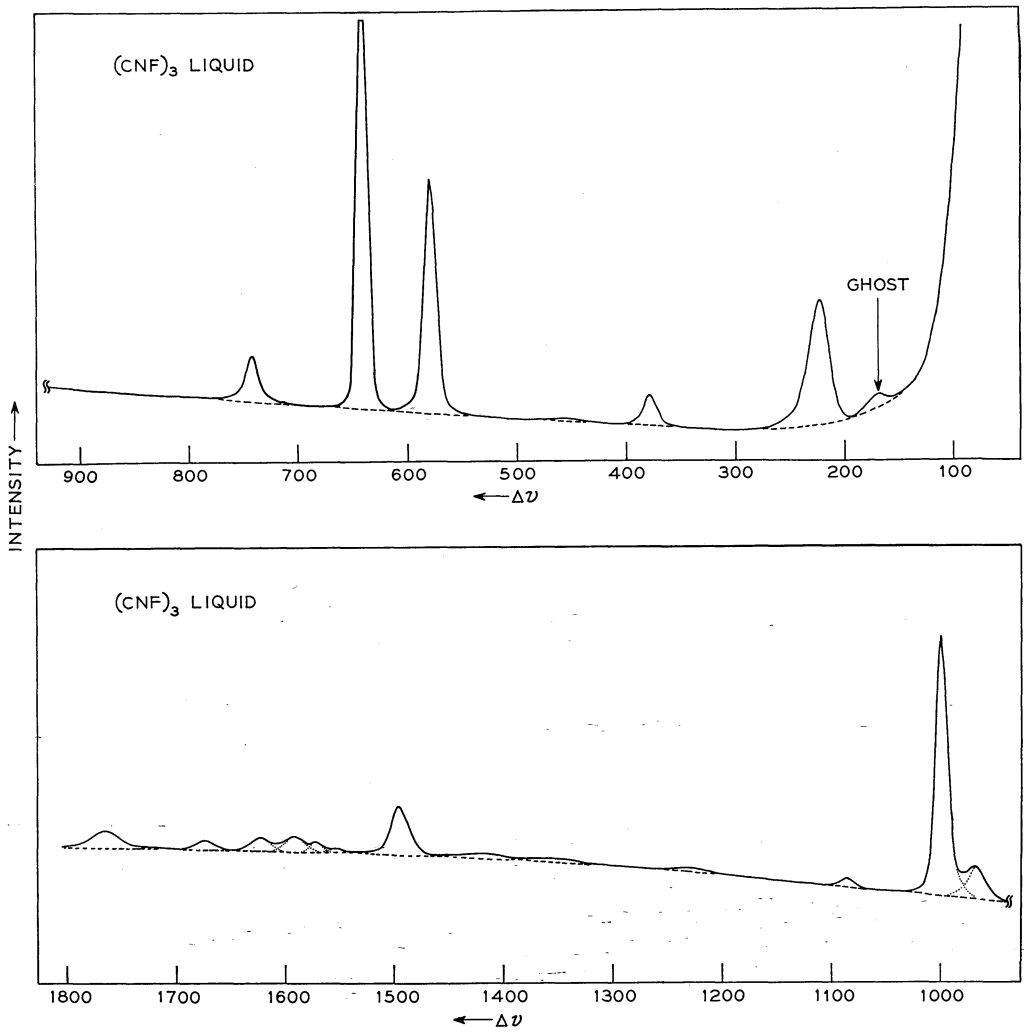

FIG. 2. Raman spectrum of cyanuric fluoride.

Raman and infrared active, the assignment of the bands at 1617, 1424, 1087, 578, and 378 cm^{-1} in the infrared (gas) and at 1622, 1418, 1087, 579, and 379 cm^{-1} in the Raman effect (liquid) is straightforward. The two highest frequencies represent the ring modes. The 1087 cm^{-1} band (strong in the infrared and weak in the Raman) obviously corresponds to the C–F stretching mode because of its proximity to the similar fundamental at 1078 cm^{-1} in FCN (5). There is no conclusive evidence for favoring the assignment of the 578 cm^{-1} band to the ring angle bend and the 378 cm^{-1} band to the C–F rocking mode (in-plane) over the opposite assignment. It does seem more likely, however, that the C–F rocking mode would be accompanied by a greater dipole moment change than in the case of the ring angle bending mode. Thus, the greater intensity of the 378 cm^{-1} band in the infrared when compared with the 578 cm^{-1} band supports the present assignment.

No information concerning the inactive fundamentals could be gleaned from the numerous combination and overtone bands. All but the very weak bands at 640 and 1303

13	743	E''	C–F wagging
14	226	Raman (depol.)	Out-of-plane ring mode

cm^{-1} could be explained in terms of the active fundamentals. These probably arise from unknown impurities.

Although the spectra are interpreted in terms of the planar D_{3h} model, there are two bands which at first seemed to contradict the interpretation. A very strong band at 1581 cm^{-1} in the infrared (1573 cm^{-1} in the Raman effect) could possibly arise if the molecule had a lower symmetry, thereby splitting the degeneracy of ν_6. On the other hand, the combination band $\nu_2 + \nu_9 = 1577$ cm^{-1} has the symmetry species (E') of ν_6 and occurs sufficiently close to ν_6 for its intensity to be greatly enhanced through a Fermi resonance interaction. The presence of a single F^{19} resonance in the nuclear magnetic resonance experiment is not proof of the planar structure either, for one could construct a structure of lower symmetry than D_{3h} in which the fluorine atoms were still equivalent. The fact that none of the other E' fundamentals appear to be split into doublets would favor the Fermi resonance interpretation offered above.

The second conflict with the D_{3h} model occurs with the ν_{13} (e'') mode which should be inactive in the infrared. It was not observed in the gas phase study (80 mm pressure) but it could be detected in the liquid phase spectrum. It can be argued, of course, that in the liquid phase the selection rules break down and, therefore, the ν_{13} fundamental might be observable. The problem can best be resolved by observing the infrared spectrum in the gas phase at elevated temperatures where the vapor pressure of the compound is higher, or by using a long path cell to see if $\nu_{13} = 743$ cm^{-1} is observable. The other point of interest is to see if $\nu_{14} = 224$ cm^{-1} (liquid phase) is present in the infrared spectrum. Nevertheless, the evidence presented in the paper strongly supports a planar structure for cyanuric fluoride.

ACKNOWLEDGMENTS

The authors are especially grateful to Miss D. M. Dodd and Mr. J. P. Luongo for the infrared spectra and to Mr. E. W. Anderson for the nuclear magnetic resonance data.

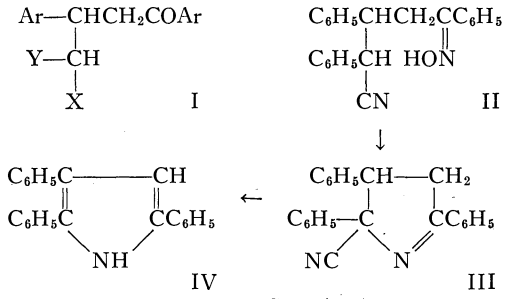
NOTES

A NEW SYNTHESIS OF ARYLPYRROLES

C. F. H. ALLEN

In connection with a routine examination of certain Michael adducts of type I in the mass spectrometer (1), the oxime (II) of a delta ketonic nitrile (2) was included. Entirely unexpectedly, it showed large peaks at masses 322 and 295. These are assumed to be the parent ions of two pyrroles (III, IV), thermal products, which could be accounted for by assuming successive losses of the elements of water and of hydrogen cyanide from the oxime.



Upon comparison, the complete mass spectral pattern in the mixture spectrum was found to be identical with that of an authentic specimen of 2,4,5-triphenylpyrrole. The latter only was isolable by classical methods, and was identified in the usual way.

The oxime (V) of the nitroketone (I, Ar, Y = C_6H_5, X = NO_2) (3), in an analogous manner, loses the elements of water and of nitrous acid; in this instance there is no suggestion of a dihydro derivative corresponding to III, the triphenylpyrrole (IV) being the main product. Similarly, the oximes of a diarylnitroketone (I, Ar = C_6H_5, X = H, Y = NO_2) (4) and of γ-benzoylbutyronitrile (5) give 2,4-diphenyl- and 2-phenyl-pyrrole, respectively. The pyrroles were not only indicated and identified by the use of the mass spectrometer, but triphenylpyrrole was isolated by classical methods upon attempted distillation of the oximes (II, V).

These series of reactions constitute a new synthesis of arylpyrroles.

ACKNOWLEDGMENT

I am indebted to Mr. Glenn P. Happ for the mass spectral data and interpretation.

THE SIGNS OF THE H′—C—H′ AND H′—C—O—H′ NUCLEAR MAGNETIC RESONANCE COUPLING CONSTANTS

F. HRUSKA,* T. SCHAEFER, AND C. A. REILLY

Buckingham and McLauchlan have recently shown that J_0(H′—H′) is definitely positive in *p*-nitrotoluene (1). It follows that $J(C^{13}—H)$ is also positive (1), thus vindicating the suggestion of Karplus (2). Then the work of Lauterbur and Kurland (3) shows that J(H′—C—C—H′) is positive, while the measurements of Anet (4) give J(H′—C—H′) as negative. Manatt *et al.* (5) have suggested that J(H′—P—C—H′) and J(H′—P—P—H′) are positive. From their data it follows that $J(P^{31}—H')$ is then also positive. However, Whitesides *et al.* (6) state that the latter coupling may be either positive or negative, which would mean that J(H′—P—C—H′) may be of either sign. Anderson, Freeman, and Reilly have shown that all the couplings in trivinylphosphine have the same sign (7). Presumably then, they are all positive, which means that $J(P^{31}—C—H')$ is positive. We show here that J(H′—C—H′) and J(H′—C—O—H′) are of opposite sign, an additional datum in the rapidly increasing knowledge of the signs of coupling constants.

2-Methyl-2-nitropropanediol-1,3 has magnetically nonequivalent methylene protons because the plane bisecting the HCH angle and perpendicular to the interproton axis is not a plane of symmetry of the molecule as a whole for any conformation (8, 9). Much of the shift is probably also due to differing conformer populations (9). In a saturated solution of this compound in water we find an AB quartet for the methylene protons with an AB shift of 0.23 p.p.m. and a magnitude of J(H′—C—H′) of 12.4 ± 0.2 c.p.s. No coupling to the hydroxyl protons was observed, no doubt as a result of rapid exchange of the latter protons with water molecules. A small broadening of the methyl and methylene protons indicated unresolved long-range couplings. A saturated solution of this compound in acetone gave rise to an ABC proton spectrum for the methylene and hydroxyl protons. The line widths were larger than in water solution indicating kinetic processes of some sort. A computer analysis by an iterative technique (10) yielded the parameters in Table I. The parameters with the vicinal couplings opposite in sign to the geminal

TABLE I

Chemical shifts relative to internal cyclohexane and proton coupling constants of 2-methyl-2-nitropropanediol-1,3 in acetone

Coupling constants (c.p.s.)	Chemical shift (p.p.m.)
$J(H'_A—C—H'_B) = \mp11.67\pm0.04$*	$H_A = -2.41$
$J(H'_A—C—O—H'_C) = \pm5.96\pm0.03$	$H_B = -2.57$

*R.M.S. deviations.

one gave a better fit to the observed spectrum than when the signs were the same. This was true for both the frequencies and intensities of the observed and calculated lines. The discussion in the first paragraph above means that the geminal coupling is negative and the H′—C—O—H′ vicinal couplings are positive, just as for H′—C—C—H′ couplings.

The geminal coupling differs from that in water as a solvent. A similar situation is discussed by Snyder (11). The two vicinal couplings are almost equal within experimental

error. It might appear that there is hydrogen-bonding to acetone; at any rate intramolecular hydrogen-bonding would appear to be absent (12). Temperature studies in a number of proton acceptors as well as in inert solvents are underway. It is hoped that these studies will yield information on the effect of the solvent on the geminal coupling, on the magnitude of the asymmetry shift (dependent on attaining sufficiently high temperatures in order to equalize conformational populations), on the magnitude of the cis and the trans vicinal couplings (dependent on attaining low enough temperatures), and on the magnitude of the hydrogen-bond shifts and enthalpies in the acceptor solvents.

EXPERIMENTAL

Proton magnetic resonance measurements were done on a Varian DP-60 high resolution N.M.R. spectrometer. Line separations were measured by the usual sideband technique using a Model 521 Hewlett–Packard Frequency Counter. The analysis was carried out on the IBM 7040 at the Shell Development Company.

ACKNOWLEDGMENTS

We are grateful to Dr. A. Unrau for a sample of 2-methyl-2-nitropropanediol-1,3. F. H. and T. S. thank the National Research Council for financial support.

THE REACTION OF N-BROMOSUCCINIMIDE WITH SOME ALKYL PYRIDINES

James P. Kutney, W. Cretney, T. Tabata, and M. Frank

In relation to another problem in our laboratory, it became necessary to prepare several bromoalkyl pyridines. Several methods are available for side chain halogenation in the pyridine series (1, 2) but, in general, these are not particularly attractive for the bromoalkyl series. It appeared that the most direct approach to this problem was to consider the reaction of N-bromosuccinimide (N.B.S.) with several alkyl pyridines. Previous work in the literature (3, 4) and our own experience with this reagent (5) encouraged further study.

When 4-ethylpyridine was reacted with N.B.S., it was found, as expected, that the nature of the reaction product was dependent on the relative amounts of brominating

THE REACTION OF N-BROMOSUCCINIMIDE WITH SOME ALKYL PYRIDINES

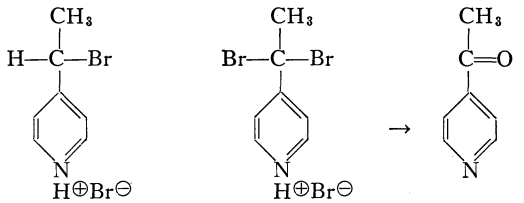
James P. Kutney, W. Cretney, T. Tabata, and M. Frank

In relation to another problem in our laboratory, it became necessary to prepare several bromoalkyl pyridines. Several methods are available for side chain halogenation in the pyridine series (1, 2) but, in general, these are not particularly attractive for the bromoalkyl series. It appeared that the most direct approach to this problem was to consider the reaction of N-bromosuccinimide (N.B.S.) with several alkyl pyridines. Previous work in the literature (3, 4) and our own experience with this reagent (5) encouraged further study.

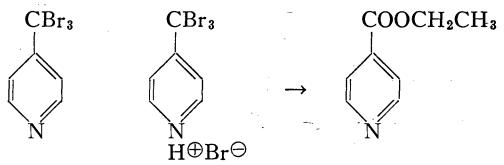
When 4-ethylpyridine was reacted with N.B.S., it was found, as expected, that the nature of the reaction product was dependent on the relative amounts of brominating

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

agent which were used in the reaction. As previously reported (5) utilization of a 1:1 molar ratio of 4-ethylpyridine to N.B.S. provides 4-(1-bromoethyl) pyridine as the major product whereas subsequent work reported here reveals that a 2:1 ratio of N.B.S. to 4-ethylpyridine provides 4-(1,1-dibromoethyl) pyridine in good yield. In both instances isolation and characterization of the products was carried out on the crystalline hydrobromides (I and II) since it is well known that halogenoalkyl pyridines of this type are unstable as the parent bases. At this point of the investigation it was clear to us that N.B.S. does indeed provide a simple and attractive method for the preparation of bromoalkyl pyridines particularly of type II since the yield of II was always good (about 70%) on the numerous occasions which we had to prepare this compound.



I II



IV III

Our attention was then directed at the methyl pyridine compounds with particular interest in the 4-methylpyridine series, since brominated derivatives in this series were also desirable. Hasegawa (3) had already shown that 2-methylpyridine reacts with N.B.S. to yield mono- and di-bromomethylpyridines as the products. On this basis, there seemed little reason to suppose that similar results should not be obtained from the 4-methyl series. Consequently 4-methylpyridine was reacted with N.B.S. according to the published procedure, and the product isolated as the hydrobromide salt. Subsequent analysis on this substance revealed, however, that neither the mono- nor di-bromoethylpyridines was formed but that the fully brominated, 4-tribromomethylpyridine, was actually being isolated as its salt (III). The n.m.r. spectrum of this salt indicated only two sets of multiplets—one set centered at 1.54 τ and the other centered at 1.19 τ, as expected for the α and β protons of the pyridine ring. Furthermore, the areas under these signals were equal and therefore provided good evidence for structure III. This latter structure was further confirmed when the parent base (IV) could be obtained as a stable, crystalline substance which analyzed well for $C_6H_4NBr_3$. The n.m.r. spectrum of 4-tribromomethylpyridine, in complete agreement with the assigned structure, indicated two sets of multiplets centered at 2.23 τ and 1.34 τ. The set at higher field (2.23 τ) was resolved into four peaks whereas the lower field set was broad and poorly resolved thereby approximating a doublet. The broadening of the latter signals is probably due to the nitrogen atom. A final confirmation of structure IV for the N.B.S. product was obtained from hydrolysis of the hydrobromide, III, which provided isonicotinic acid isolated and characterized as the ethyl ester.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

It must be emphasized at this point that although in all instances reported herein, the two sets of low field n.m.r. signals can be definitely assigned to α and β pairs of protons on the pyridine ring, it is not possible to assign with absolute certainty a particular set of signals to a particular pair of protons. It is clear that the bromoalkyl substituents at the γ position will have an appreciable, but unknown, effect on the chemical shift of the β protons.

These results indicated that 4-methylpyridine was more reactive toward the action of N.B.S. than 2-methylpyridine. To eliminate any doubt about this point we repeated the bromination of the 2-methyl compound under conditions *identical* with those used in the 4-methyl series and were able to confirm the results first reported by Hasegawa (3).

Finally, several attempts were made to brominate the methyl group in 3-methylpyridine under the above conditions but no bromo compounds could be obtained. On this basis it can be concluded that in the methylpyridine series, the rate of reactivity toward N.B.S. is 4-methyl > 2-methyl > 3-methyl.

Since 4-bromoalkylpyridines were readily available from the above work, a few preliminary experiments were carried out to determine whether some of these derivatives would be suitable intermediates for the preparation of pyridyl ketones which were desirable for another problem. Consequently, 4-(1,1-dibromoethyl) pyridine hydrobromide was reacted with aqueous sodium carbonate at the reflux temperature and, as expected, the product obtained in 41% yield was the known 4-acetylpyridine. The overall yield of 4-acetylpyridine from 4-ethylpyridine was 29% although it must be emphasized that sufficient experimentation was not carried out to develop optimum conditions for the alkaline hydrolysis of the brominated product. The overall yield in this two-step sequence could probably be improved and we feel that this approach does provide an attractive synthetic approach to pyridyl ketones.

EXPERIMENTAL

All melting points were determined on a Fischer–Johns apparatus and are uncorrected. The ultraviolet spectra were recorded in 95% ethyl alcohol on a Cary 11 recording spectrophotometer. Infrared spectra were recorded on a Perkin–Elmer model 21 spectrophotometer. The n.m.r. spectra were taken at 60 Mc/s on a Varian A60 instrument. The values are given in the Tiers τ scale with the signal of tetramethylsilane which was used as the internal standard, set at 10.0 τ units. Integration of areas under the signals was carried out in all cases and the number of protons is indicated in parentheses. The solvents used are indicated below. The analyses were performed by Dr. A. Bernhardt and his associates, Mulheim (Ruhr), Germany, and by Mrs. A. Aldridge, University of British Columbia.

4-(1,1-Dibromoethyl)-pyridine Hydrobromide (II)

A mixture of 4-ethylpyridine (6.5 g), N-bromosuccinimide (21.7 g), and benzoyl peroxide (1.0 g) in carbon tetrachloride (300 ml) was refluxed for 6 hours. The reaction mixture was allowed to stand at room temperature overnight, then filtered, and the filtrate was washed successively with 4% aqueous sodium hydroxide (100 ml), water (200 ml), 2% hydrobromic acid (50 ml), and finally dried over anhydrous magnesium sulphate. The carbon tetrachloride solution was then saturated with hydrogen bromide gas whereupon a white solid, mixed with an orange oil, separated. The solvent was carefully removed *in vacuo* at *room temperature* and the resulting paste was taken up in hot, absolute ethyl alcohol (50 ml). Upon cooling, the first crop (12.5 g) of product separated as long, white needles. A second crop (2.4 g) was obtained on further concentration of the solution. Several recrystallizations of a small portion of this product from ethyl alcohol – petroleum ether provided an analytical sample, m.p. 158–160° (with considerable decomposition); ultraviolet: λ_{max} 264 mμ (log ϵ 3.43), λ_{min} 249 mμ (log ϵ 3.37); n.m.r. signals ($CDCl_3$); intense singlet at 6.95 τ(CH_3—C, area = 3H), doublet centered at 1.56 τ(βH, area = 2H), doublet centered at 0.75 τ(αH, area = 2H). Found: C, 24.36; H, 2.54; N, 4.04; Br, 69.40. Calc. for $C_7H_8NBr_3$: C, 24.29; H, 2.33; N, 4.05; Br, 69.33.

4-Tribromomethylpyridine Hydrobromide (III)

A mixture of 4-methylpyridine (10 g), N-bromosuccinimide (44.3 g), and benzoyl peroxide (2.1 g) in carbon tetrachloride (300 ml) was refluxed with stirring. The reaction mixture darkened gradually until,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

after about 1½ hours, a vigorous exothermic reaction occurred and was accompanied by considerable tarring. The external source of heat was removed until this vigorous reaction had subsided and then applied again so that the total reflux period was 3 hours. The hot reaction mixture was filtered and the tarry residue which remained was washed with hot carbon tetrachloride and ether. All the washings were combined with the main filtrate and this solution was then concentrated *in vacuo* at *room temperature.* The orange-red oil which remained was extracted in the manner described by Hasegawa (3) in order to separate any mono- and di-bromomethyl derivatives which may be present.

Consequently this orange-red oil was treated with 20% hydrobromic acid (40 ml) and then diluted with water to a total volume of 400 ml. A small amount (1.04 g) of yellow solid material which had separated was removed by filtration. The acidic aqueous solution was extracted repeatedly with ether. The ether extract was dried over anhydrous magnesium sulphate, the drying agent removed by filtration, and the ether solution was then saturated with hydrogen bromide. Removal of the solvent *in vacuo* at *room temperature* provided 3.10 g of a white solid.

The remaining aqueous acidic solution was made weakly alkaline by the addition of sodium carbonate and extracted again with ether. After the ether extract was dried over anhydrous magnesium sulphate and the drying agent removed, the ether solution was saturated with hydrogen bromide. The solvent was then removed *in vacuo* at room temperature to provide 4.34 g of white solid. It was established that the three different crops of solid material (total of 8.84 g) melted in the same range (180–205°) and did in fact represent the same substance. Several recrystallizations from absolute ethyl alcohol provided an analytical sample, m.p. 204–206° (with decomposition); ultraviolet: λ_{max} 268 mμ (log ε 3.64), λ_{min} 254.5 mμ (log ε 4.02); n.m.r. signals (D_2O–acetone 2:1); multiplets centered at 1.19 τ and 1.54 τ (α and β protons, area = 4H). Found: C, 17.69; H, 1.34; N, 3.31; Br, 77.60. Calc. for $C_6H_5NBr_4$: C, 17.54; H, 1.22; N, 3.41; Br, 77.59.

4-Tribromomethylpyridine (IV)

The hydrobromide (III) (700 mg) was treated with anhydrous ether (25 ml) and anhydrous ammonia gas was then passed into the mixture until it was basic. The inorganic residue was removed by filtration and the ether removed *in vacuo* at *room temperature.* A brown residue (448 mg) which remained was divided into two equal portions and worked up as follows.

One portion was crystallized several times from petroleum ether to afford IV as colorless needles, m.p. 71–72°; ultraviolet: λ_{max} 269 mμ (log ε 3.37), λ_{min} 262 mμ (log ε 3.32); n.m.r. signals (CCl_4); multiplets centered at 1.34 τ and 2.23 τ (α and β protons, area = 4H). Found: C, 21.84; H, 1.22; N, 3.97; Br, 73.01. Calc. for $C_6H_4NBr_3$: C, 21.82; H, 1.21; N, 4.24; Br, 72.72.

The other portion was treated with an alcoholic solution of picric acid and the picrate which formed was then recrystallized from ethyl alcohol to provide an analytical sample, m.p. 162.5°–167°. Found: C, 25.98; H, 1.50; N, 9.85; O, 20.14; Br, 43.12. Calc. for $C_{12}H_7N_4O_7Br_3$: C, 25.80; H, 1.25; N, 10.00; O, 20.00; Br, 42.80.

Hydrolysis of 4-Tribromomethylpyridine Hydrobromide

4-Tribromomethylpyridine hydrobromide (1.1 g) was treated with 30% aqueous sulphuric acid (70 ml) and the mixture refluxed for 8 hours. After this time, the mixture was allowed to stand overnight at room temperature whereupon a portion (2.10 g) of a solid material had crystallized from the solution. Subsequent infrared comparison etc. established that the material was unreacted starting material.

The sulphuric acid solution was concentrated *in vacuo* at 100–130° to a volume of 25 ml and this concentrate was then treated with ammonia gas until the mixture was just slightly acidic. At this point, the mixture was essentially a solid paste and this was washed repeatedly with ethyl alcohol. The alcohol extract was reduced in volume to about 20 ml, concentrated sulphuric acid (2 ml) was added, and the whole mixture refluxed for 4 hours. After this time, about one-half of the solvent was removed *in vacuo* and the mixture was poured on ice, treated with concentrated ammonium hydroxide until basic and finally extracted with ether. The ether extract was dried over anhydrous magnesium sulphate, the solvents were removed carefully, and the residual liquid distilled to provide 521 mg of a liquid distilling at 125–130° (bath temp)/16 mm. This liquid product proved to be identical in every respect (infrared, ultraviolet, n.m.r.) with an authentic sample of ethyl isonicotinate prepared from isonicotinic acid. n.m.r. signals ($CDCl_3$); triplet centered at 8.59 τ(CH_3—, area = 3H), quartet centered at 5.58 τ(—CH_2—, area = 2H), doublets centered at 1.24 τ and 2.14 τ (α and β protons, area = 4H).

4-Acetylpyridine

A stirred mixture of 4-(1,1-dibromoethyl) pyridine hydrobromide (6 g), sodium carbonate (9 g), and water (30 ml) was refluxed over a period of 4 hours. The cooled reaction mixture was diluted with water and then extracted with ether. The ether extract was dried over anhydrous magnesium sulphate, the solvent *carefully removed*, and the dark red oil which remained was distilled to provide the known (6, 7) 4-acetylpyridine (1 g). n.m.r. signals (neat liquid); two sets of multiplets centered at 1.19 τ and 2.29 τ (α and β protons, area = 4H), a single peak at 7.35 τ (CH_3CO—, area = 3H). A crystalline oxime was prepared and its melting point (155°) was in good agreement with the literature value (8), m.p. 157–159°.

THE FLUORINATION OF CHROMIUM(VI) OXIDE AND POTASSIUM DICHROMATE

H. C. CLARK AND Y. N. SADANA

INTRODUCTION

The fluorination of metal oxides by bromine trifluoride frequently constitutes a useful method for the preparation of metal fluorides and oxyfluorides. However, considerable differences are observed in the ease with which such fluorinations occur. Some oxides (e.g. MgO, ZnO, MnO_2, Fe_2O_3) do not react or react only very slowly with bromine trifluoride. With other oxides (e.g. TiO_2, As_2O_3, SeO_2), complete replacement of the oxygen by fluorine occurs, together with oxidation of the metal to its highest state. In a few instances (e.g. V_2O_5), only partial replacement of oxygen takes place to give oxyfluorides. Chromium (VI) oxide is unique, in that reaction with bromine trifluoride (1) replaces two-thirds of the oxygen by fluorine and *reduction* of chromium occurs to Cr(V), the final product apparently being a thermally unstable addition compound of $CrOF_3$, with BrF_3. Also, it is interesting to notice the decreasing ease with which fluorination of the oxides occurs in the series TiO_2, V_2O_5, CrO_3, Fe_2O_3, although as yet no explanation can be given.

It seemed of interest to determine the ease and extent of fluorination of chromium(VI) oxide with other halogen fluorides, particularly bromine pentafluoride and chlorine trifluoride, since the higher fluorides CrF_5 and CrF_6, and an oxyfluoride such as $CrOF_4$ might well be formed. Since this work was completed, brief reports have appeared of the preparation by other methods of chromium hexafluoride (2), chromium pentafluoride, and chromium oxide tetrafluoride (3).

EXPERIMENTAL

The general manipulative and analytical techniques employed have been described elsewhere (4, 5); magnetic susceptibilities were determined with a Gouy magnetic balance (6), and X-ray powder photographs were taken on a General Electric unit with a camera of 14.4 cm diameter.

Reactions of Chromium(VI) Oxide

(i) With bromine trifluoride.—Excess bromine trifluoride was condensed onto a sample of chromium(VI) oxide in a silica vessel, and the reaction was allowed to take place at room temperature, with the evolution of gas and formation of a deep red solution. The excess bromine trifluoride was distilled off *in vacuo*, first

THE FLUORINATION OF CHROMIUM(VI) OXIDE AND POTASSIUM DICHROMATE

H. C. CLARK AND Y. N. SADANA

INTRODUCTION

The fluorination of metal oxides by bromine trifluoride frequently constitutes a useful method for the preparation of metal fluorides and oxyfluorides. However, considerable differences are observed in the ease with which such fluorinations occur. Some oxides (e.g. MgO, ZnO, MnO_2, Fe_2O_3) do not react or react only very slowly with bromine trifluoride. With other oxides (e.g. TiO_2, As_2O_3, SeO_2), complete replacement of the oxygen by fluorine occurs, together with oxidation of the metal to its highest state. In a few instances (e.g. V_2O_5), only partial replacement of oxygen takes place to give oxyfluorides. Chromium (VI) oxide is unique, in that reaction with bromine trifluoride (1) replaces two-thirds of the oxygen by fluorine and *reduction* of chromium occurs to Cr(V), the final product apparently being a thermally unstable addition compound of $CrOF_3$, with BrF_3. Also, it is interesting to notice the decreasing ease with which fluorination of the oxides occurs in the series TiO_2, V_2O_5, CrO_3, Fe_2O_3, although as yet no explanation can be given.

It seemed of interest to determine the ease and extent of fluorination of chromium(VI) oxide with other halogen fluorides, particularly bromine pentafluoride and chlorine trifluoride, since the higher fluorides CrF_5 and CrF_6, and an oxyfluoride such as $CrOF_4$ might well be formed. Since this work was completed, brief reports have appeared of the preparation by other methods of chromium hexafluoride (2), chromium pentafluoride, and chromium oxide tetrafluoride (3).

EXPERIMENTAL

The general manipulative and analytical techniques employed have been described elsewhere (4, 5); magnetic susceptibilities were determined with a Gouy magnetic balance (6), and X-ray powder photographs were taken on a General Electric unit with a camera of 14.4 cm diameter.

Reactions of Chromium(VI) Oxide

(i) With bromine trifluoride.—Excess bromine trifluoride was condensed onto a sample of chromium(VI) oxide in a silica vessel, and the reaction was allowed to take place at room temperature, with the evolution of gas and formation of a deep red solution. The excess bromine trifluoride was distilled off *in vacuo*, first

at room temperature and then at 100°. Chemical analyses of the red residue showed the presence of bromine and indicated an approximate composition $CrOF_3.0.25BrF_3$. Calc. for $CrOF_3.0.25BrF_3$: Cr, 32.7; F, 44.8. Found: Cr, 33.4; F, 44.5%. The molar magnetic susceptibility was 1715×10^{-6} c.g.s. units at 25°, giving $\mu_{eff.}$ a value of 2.02 Bohr magnetons (B.M.) corresponding to one unpaired electron. In a second similar experiment, the product was heated to 120° for 24 hours in an attempt to complete the removal of bromine trifluoride. The final product was a light-green powder characterized as $CrF_3.BrF_3$. Calc. for $CrF_3.BrF_3$: Cr, 21.1; F, 47.2. Found: Cr. 21.6; F, 48.5%. The molar susceptibility at 25° was 5682×10^{-6} c.g.s. units giving a magnetic moment of 3.67 B.M.

(ii) With bromine pentafluoride.—Excess pentafluoride was allowed to react with the oxide at room temperature, and when effervescence had ceased, the pentafluoride was removed under vacuum, first at 25° and then at 80°, leaving a red powder, $CrOF_3.0.25BrF_5$ Calc. for $CrOF_3.0.25BrF_5$: Cr, 30.6; F, 47.9; Br, 11.9. Found: Cr, 30.6; F, 47.7, 48.5; Br, 13.3%. This product, which reacted more rapidly with glass than did the bromine trifluoride product, had a molar susceptibility at 25° of 1443×10^{-6} c.g.s. units and an effective magnetic moment of 1.85 B.M.

(iii) With chlorine trifluoride in the liquid phase.—The reaction of chlorine trifluoride with chromium(VI) oxide was carried out as in *(i)* and *(ii)* at 12° (b.p. of ClF_3), the excess trifluoride being removed finally at 50° *in vacuo*. The orange-red product gave analytical results in agreement with $CrOF_3.0.30ClF_3$. Calc. for $CrOF_3.0.30ClF_3$: Cr, 34.1; F, 48.6. Found: Cr, 34.2; F, 48.0%. From the molar susceptibility at 25°, of 1418×10^{-6} c.g.s. units, the effective magnetic moment was calculated to be 1.83 B.M.

(iv) With chlorine trifluoride in the vapor phase.—Chlorine trifluoride gas was passed over chromium(VI) oxide which was contained in a nickel boat inside a silica tube heated to 120°. A dull-red volatile solid was swept with the excess trifluoride into the first of a series of traps connected to the silica tube. The passage of trifluoride was continued until all the oxide had reacted. Analysis of the dense red product, after the removal of excess trifluoride, agreed with the composition $CrOF_3.0.30ClF_3$. Calc. for $CrOF_3.0.30ClF_3$: Cr, 34.1; F, 48.6. Found: Cr, 34.5; F, 49.5%. Magnetic measurements at 25° gave $\chi_M = 1308\times10^{-6}$ c.g.s. units, and $\mu_{eff.} = 1.76$ B.M. This product differed considerably in color from that obtained from the liquid phase reaction, but when heated *in vacuo* at 75°, a phase transformation occurred with a considerable increase in volume from the dense red solid to the orange-red product. Chemical analyses confirmed that the composition was unchanged.

Reactions of Potassium Dichromate

(i) With bromine trifluoride.—The reaction was allowed to take place in a silica reaction vessel as described previously (1). Removal of bromine trifluoride at 100° gave a product of composition $KCrOF_4.0.5BrF_3$. Calc. for $KCrOF_4.0.5BrF_3$: Cr, 20.7. Found: Cr, 19.9%. The molar susceptibility at 25° was 1265×10^{-6} c.g.s. units, and susceptibility measurements over the range 85–298° K gave a value of +4° for θ (Weiss constant), and hence $\mu_{eff.}$ at 25° C was 1.73 B.M. When a sample of $KCrOF_4.0.5BrF_2$ was heated *in vacuo* at 160°, pure $KCrOF_4$ was obtained as previously reported (1). Both $KCrOF_4.0.5BrF_3$ and $KCrOF_4$ gave the same X-ray powder photograph which was indexed on an orthorhombic lattice with $a = 13.24$, $b = 10.31$, and $c = 8.32$ Å.

(ii) With bromine pentafluoride.—Potassium dichromate reacted readily with bromine pentafluoride at room temperature to give, after removal of excess pentafluoride, a product of composition $KCrOF_4.0.5BrF_5$. Calc. for $KCrOF_4.0.5BrF_5$: Cr, 19.2; F, 45.6. Found: Cr, 19.0; F, 44.5%. The molar susceptibility at 25° was 1237×10^{-6} c.g.s. units and $\mu_{eff.}$ had a value of 1.75 B.M. The excess bromine pentafluoride could be removed at 160° *in vacuo* to give pure $KCrOF_4$, identified by means of its X-ray diffraction powder photograph.

(iii) With chlorine trifluoride.—Similarly, liquid chlorine trifluoride reacted readily with potassium dichromate to give $KCrOF_4$, identified by its X-ray powder pattern.

DISCUSSION

In an extension of the work of Sharpe and Woolf (1) it has now been shown that chromium(VI) oxide reacts vigorously with bromine trifluoride, bromine pentafluoride, and chlorine trifluoride at or below room temperature to give products containing chromium(V). Our results indicate that these products have the approximate composition $CrOF_3.0.25$ (halogen fluoride), but it is not possible to determine whether this represents adduct formation, or just incomplete removal of solvating halogen fluoride. All attempts to remove the halogen fluoride completely leaving pure $CrOF_3$ were unsuccessful, and resulted in the formation of lower fluorides of chromium. The reaction of chromium(VI) oxide with chlorine trifluoride vapor also gave a product of composition $CrOF_3.0.25ClF_3$. This was a dull-red solid, which on heating at 75° appeared to transform without change in composition to an orange, less dense product, similar to that obtained from the reaction with *liquid* chlorine trifluoride.

These chromium oxytrifluoride products fumed in air giving chromyl fluoride, and were hydrolyzed vigorously by water giving Cr^{3+} and CrO_4^{2-} ions, in solution. They reacted with glass, even under vacuum, presumably because of the liberation of small quantities of halogen fluoride. Attempts to obtain X-ray diffraction powder photographs were all unsuccessful since reaction with the capillary (either silica or pyrex) always caused the capillary to explode during the exposure.

The fluorination of chromium(VI) oxide can therefore be summarized as follows. Sulphur tetrafluoride (7), selenium tetrafluoride (8), and iodine pentafluoride (9) cause displacement of only one-third of the oxygen to form chromyl fluoride, CrO_2F_2. Bromine tri- and penta-fluoride and chlorine trifluoride, which are more vigorous fluorinating agents, displace two-thirds of the oxygen to give the unstable oxytrifluoride, $CrOF_3$. It is perhaps surprising that none of these strong fluorinating agents produces the oxytetrafluoride, $CrOF_4$, which has recently been obtained (3) as a minor product from the direct fluorination of chromium metal.

Potassium dichromate, on fluorination with bromine trifluoride or pentafluoride, or chlorine trifluoride, gave potassium oxytetrafluorochromium(V), which has been previously reported (1). Again therefore, even the most vigorous fluorinating agents failed to remove oxygen completely, and again reduction to chromium(V) occurred. The compound $KCrOF_4$ is readily hydrolyzed in air, and is decomposed in water.

$$3KCrOF_4 + 5H_2O \rightarrow 3KF + CrF_3 + 2H_2CrO_4 + 6HF$$

The value of the Weiss constant, θ, for $KCrOF_4$ is $+4°$, which is remarkably low, particularly in comparison with the high θ values of 120° observed (4) for complex fluorides of V^{4+}, which is isoelectronic with Cr^{5+}. Unfortunately, no comparison can yet be made with other complex fluorides of chromium(V), and it may be that the low θ value in $KCrOF_4$ is associated with the presence of oxygen in the molecule.

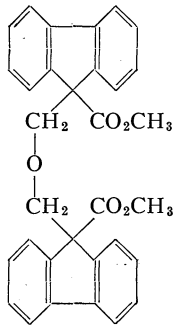
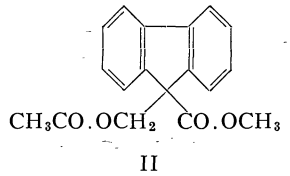
fluorene-9-carboxylate has shown exceptional reactivity (3) we examined its reaction with chloromethyl acetate. The major product, a sparingly soluble substance isolated in variable yield, proved to be I (4). The expected diester II was isolated in poor yield by chromatography. It seemed likely that the bis-fluorene I arose from α,α'-dichlorodimethyl ether and this was confirmed by both infrared spectroscopy and gas–liquid chromatographic analysis.

Although chloromethyl acetate has been used as a source of methylene for cellulose (5), in the Prins reaction (6) and in kinetic (7, 8) and mechanistic (9) studies, only Descude (10) amongst earlier workers seems to have noted the presence of α,α'-dichlorodimethyl ether. It has, however, been reported from the products of the reaction between benzoyl chloride and paraformaldehyde (11). We have now prepared and characterized pure chloromethyl acetate (see Experimental) from the reaction between paraformaldehyde and acetyl chloride (9). The dichlorodimethyl ether probably arises from water present in the paraformaldehyde, hydrolysis of part of the acetyl chloride liberating the necessary hydrogen chloride (c.f. the formation of α,α'-dichlorodimethyl ether from formaldehyde and hydrochloric and sulphuric acids (12)). Pure chloromethyl acetate is probably most easily prepared by photochlorination of methyl acetate (13, 14) since this method eliminates dichlorodimethyl ether as a likely contaminant.



I



II

EXPERIMENTAL

Chloromethyl acetate was prepared as described by Ulich and Adams (9) and fractionated under slightly reduced pressure using a 20×0.75 in. column packed with glass helices and fitted with a liquid dividing head. The first distillation at a reflux ratio of 10 to 1 gave ester of 97% purity. Refractionation using a reflux ratio of 30 to 1 gave pure chloromethyl acetate (30–40%), b.p. 95° at 729 mm (9, 15, 16): n_D^{20} 1.4102 (lit. n_D^{20} 1.409, (8*a*). Found: C, 33.32; H, 4.64; Cl, 32.43. Calc. for $C_3H_5ClO_2$: C, 33.29; H, 4.64; Cl, 32.66%. The infrared spectrum of a capillary film showed the following absorption peaks (cm^{-1}): 717 (vs), 818 (s), 936 (w), 986 (w), 1050 (vs), 1102 (w), 1209 (vs), 1263 (m), 1291 (w), 1341 (m), 1374 (s), 1443 (s), 1715 (w), 1764 (vs).

Before each distillation the apparatus was cleaned and dried by boiling acetyl chloride in the still pot. Polyformaldehyde was always deposited during the initial distillation of chloromethyl acetate and may have arisen from decomposition of the ester. Although some samples of crude ester contained as little as 8% dichlorodimethyl ether, product distilled through a Claisen head contained up to 45% of the ether.

Analysis of chloromethyl acetate fractions was carried out by gas–liquid chromatography, employing a 6 ft tube packed with 20% silicone oil on Hyflo and maintained at 20°. The carrier gas was argon. α,α'-Dichloromethyl ether showed a retention time of 0.86 relative to chloromethyl acetate (1.00). These results were checked by infrared spectroscopy, using the absorption peak shown by the ether at 915 cm^{-1}.

ÉTARD REACTION. IV. DEUTERIUM ISOTOPE EFFECT†

OWEN H. WHEELER

Evidence has been advanced (1) that the Étard oxidation of toluene with chromyl chloride proceeds by the rapid formation of a soluble π-complex, followed by the formation of the insoluble Étard complex. Stairs and Burns (2) carried out kinetic studies on this reaction which indicate that the insoluble complex is formed in two successive steps, each involving the replacement of one hydrogen atom. A consideration of the effect of solvent on the reaction (3) suggested that the activated complex is somewhat more polar than the starting materials. However, the reaction cannot be truly ionic since it is carried out in nonpolar solvents. In a recent study Gragerov and Ponomarchuk (4) found that, in the oxidation of α-monodeuterotoluene, the unreacted toluene and the benzaldehyde formed both contained an excess of deuterium. However, the reaction was carried out at reflux in carbon tetrachloride and much benzyl chloride was formed. This present study reports the oxidation of a mixture of toluene and α,α,α-trideuterotoluene with chromyl chloride in carbon disulphide at room temperature, under which conditions the minimum amount of chlorination occurs. Moreover, no complications arise as a result of the competition with hydrogen and deuterium in the same molecule (5).

EXPERIMENTAL

A mixture of distilled toluene (1.71 g) and α,α,α-trideuterotoluene (1.70 g) (Volk Radiochemical Co., 98%; infrared spectrum showed no C—D aromatic absorption (6)) in carbon disulphide (20 ml) was treated dropwise, with cooling to 0° in an ice bath, with distilled chromyl chloride (6.0 g, 0.55 equivalents) in carbon disulphide (10 ml) over 1/2 hour. The reaction was stirred at room temperature overnight and poured onto ice water containing sodium bisulphide. The organic phase was dried and most of the solvent removed through a 12 in. column packed with Fenske rings. The residue was fractionated through an 18 in. spinning-band column, giving toluene, b.p. 110–111°, 1.24 g (36%; 81% theory).

The deuterium analysis of the mixture before reaction was 16.60 atom%.

Deuterium analysis of recovered unreacted toluene was 24.40 atom%. If it is assumed that the reaction

ÉTARD REACTION. IV. DEUTERIUM ISOTOPE EFFECT†

OWEN H. WHEELER

Evidence has been advanced (1) that the Étard oxidation of toluene with chromyl chloride proceeds by the rapid formation of a soluble π-complex, followed by the formation of the insoluble Étard complex. Stairs and Burns (2) carried out kinetic studies on this reaction which indicate that the insoluble complex is formed in two successive steps, each involving the replacement of one hydrogen atom. A consideration of the effect of solvent on the reaction (3) suggested that the activated complex is somewhat more polar than the starting materials. However, the reaction cannot be truly ionic since it is carried out in nonpolar solvents. In a recent study Gragerov and Ponomarchuk (4) found that, in the oxidation of α-monodeuterotoluene, the unreacted toluene and the benzaldehyde formed both contained an excess of deuterium. However, the reaction was carried out at reflux in carbon tetrachloride and much benzyl chloride was formed. This present study reports the oxidation of a mixture of toluene and α,α,α-trideuterotoluene with chromyl chloride in carbon disulphide at room temperature, under which conditions the minimum amount of chlorination occurs. Moreover, no complications arise as a result of the competition with hydrogen and deuterium in the same molecule (5).

EXPERIMENTAL

A mixture of distilled toluene (1.71 g) and α,α,α-trideuterotoluene (1.70 g) (Volk Radiochemical Co., 98%; infrared spectrum showed no C—D aromatic absorption (6)) in carbon disulphide (20 ml) was treated dropwise, with cooling to 0° in an ice bath, with distilled chromyl chloride (6.0 g, 0.55 equivalents) in carbon disulphide (10 ml) over 1/2 hour. The reaction was stirred at room temperature overnight and poured onto ice water containing sodium bisulphide. The organic phase was dried and most of the solvent removed through a 12 in. column packed with Fenske rings. The residue was fractionated through an 18 in. spinning-band column, giving toluene, b.p. 110–111°, 1.24 g (36%; 81% theory).

The deuterium analysis of the mixture before reaction was 16.60 atom%.

Deuterium analysis of recovered unreacted toluene was 24.40 atom%. If it is assumed that the reaction

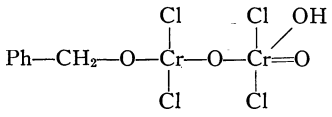
†*For Part III, see Can. J. Chem. 38, 2137 (1960).*

is first order in toluene (2), following Melander (7), then k_H/k_D = log (a_H/a^0_H/log (a_D/a^0_D), where a_H and a_D, and a^0_H and a^0_D are, respectively, the concentrations of unreacted toluene and deuterotoluene, and their initial concentrations. For 35% recovery k_H/k_D = 2.4. This value is approximate since the reaction is not strictly first order in toluene (2) and because of the error in measuring the yield of the reaction.

A second fraction, b.p. 150–155° (0.8 g), was treated with a solution of 2,4-dinitrophenylhydrazine in sulphuric acid and methanol and warmed to 50° for 10 minutes. The precipitate of benzaldehyde dinitrophenylhydrazone was chromatographed on alumina from benzene and recrystallized from ethyl acetate, m.p. 240–241° (lit. m.p. 238–239° (8)). The deuterium analysis was 0.2 atom%. It is not clear whether the exchange had taken place during workup or on formation of the derivative. The latter may be the case, since Gragerov and Ponomarchuk (4) report that the benzaldehyde recovered from the isolated Étard complex contains an excess of deuterium.

DISCUSSION

The maximum value k_H/k_D at 25° for carbon–hydrogen and carbon–deuterium bond breaking is 6.9 (7, 9). In many typical displacement reactions the observed value of k_H/k_D is much lower, although oxidation reactions in aqueous solution usually show high values for k_H/k_D (9). The value of this ratio in the present case indicates that the breaking of a carbon–hydrogen bond of the methyl group in toluene is the rate-determining step. This is in agreement with the suggestion that the replacement of the first hydrogen atom is the rate-determining step (2). A recent publication (10) indicates that the structure of the Étard complex is best represented by a formula (I) with tetra- and hexa-valent



I

chromium, and that the second hydrogen atom is removed by the cyclic attack of the divalent oxygen atom of this complex. This mechanism is consistent with the above findings. The kinetic deuterium isotope effect does not distinguish between hydride ion and hydrogen atom transfer (9), although the former is the more probable (10).

ACKNOWLEDGMENTS

The deuterium analyses were kindly determined by Dr. A. P. Wolf and Dr. D. Christman of the Department of Chemistry, Brookhaven National Laboratory. This work was carried out under contract No. AT (40-1)-1833 of the U.S. Atomic Energy Commission with the University of Puerto Rico.

THE EXTRACTION OF SCANDIUM BY MIXTURES OF OXINE AND NEUTRAL ORGANOPHOSPHORUS REAGENTS

P. G. MANNING[1] AND PRANOWO[2]

We have made a study of the two-phase liquid–liquid systems (Sc^{3+}–HCl–HX–TOPO–hexone and Sc^{3+}–HCl–HX–DBBP–hexone) at 25° C where HX is oxine, TOPO is trioctyl phosphine oxide, and DBBP is dibutyl butyl phosphonate. The experimental details, involving the use of "carrier-free" Sc^{46}, have been described in an earlier publication (1).

In 1.24×10^{-3} *M* HCl, scandium is present as the trivalent ion (2). When mixtures of oxine and the neutral extractants are used, the extraction stoichiometry may be formulated as

$$Sc_w^{3+} + nCl_w^- + (3-n)HX_o + mS_o = ScCl_nX_{3-n}S_{m_0} + (3-n)H_w^+,$$

where "w" and "o" designate water and organic phase species respectively, and S is the neutral organophosphorus extractant. The equilibrium constant is

$$[1] \qquad k = \frac{[ScCl_nX_{3-n}S_m]_0\,[H^+]^{3-n}}{[Sc^{3+}]\,[Cl^-]^n\,[HX^{3-n}]\,[S]^m}.$$

Since the distribution coefficient is, by definition,

$$[2] \qquad K = \frac{[Sc]_o}{[Sc]_w},$$

$$[3] \qquad \text{then } K = \frac{k[Cl^-]^n\,[HX]^{3-n}\,[S]^m}{[H^+]^{3-n}}.$$

It follows from equation (3) that a plot of log K against log [HX] has a slope of $3-n$, and from a plot of log K against log [S] we can estimate m.

That the reaction is synergic is evident from Fig. 1. The addition of 0.0050 *M* oxine to hexone solutions of TOPO or DBBP increases K by a factor of approximately 4. The extraction of Sc^{3+} by a 0.0050 *M* solution of oxine in hexone is small ($K < 10^{-4}$) by comparison, and can be ignored. The slopes of the plots indicate that $m = 2$. Also, when DBBP and TOPO are used individually, scandium extracts as the disolvate, in contrast to the lanthanides that extract as trisolvates (3, 4). The slopes of the plots of log K against log [HX], with [DBBP] = [TOPO] = 0.0010 *M*, show that $3-n = 2$, whence $n = 1$. The reaction stoichiometry is, therefore,

$$Sc_w^{3+} + Cl_w^- + 2HX_0 + 2S_0 = ScClX_2S_{2_0} + 2H_w^+.$$

The present extraction system differs from other synergic systems involving trivalent metals in that the supporting anion has replaced one of the chelating extractant molecules (1, 5, 6). Figures 1 and 2 show that TOPO and DBBP give similar synergic enhancements, whereas from a comparison of their electron donor properties, one would expect TOPO to be the more powerful synergistic agent. Experiments were then conducted with tributyl phosphate (TBP) to obtain further correlation between electron donor strength and degree

of synergic enhancement. TBP, however, failed to produce a synergic reaction. It is possible, therefore, that steric hindrance is an important factor in the present system; the weakest electron donor (TBP) being unable to overcome steric hindrance to coordination. In the case of DBBP and TOPO, steric hindrance and extractive power are balanced.

It is interesting to note, in the Sc^{3+}–HNO_3–thenoyltrifluoroacetone(HTTA)–DBBP–toluene system, that, because of steric obstruction, the extractable complex is $Sc(TTA)_3$–$(DBBP)_1$ (1). In the present investigation, extraction occurs via the formation of the complex $ScClX_2S_2$. Clearly, more work is required on the mechanism of synergism.

VAPOR PRESSURE MEASUREMENTS ON THE SYSTEM D_2O–H_2O. ANALYSIS OF D_2O–H_2O MIXTURES[1]

M. MAZUREK AND A. S. PERLIN

The difference in vapor pressure between a solution and the pure solvent is readily measured as the steady-state temperature difference (heat of vaporization) by use of thermally sensitive resistors (thermistors) (1). This thermometric type of measurement is now shown to be suitable also for examining some vapor pressure characteristics of mixtures of deuterium oxide and water, i.e., of two miscible liquids having substantially different vapor pressures (2, 3).

A commercial model (Mechrolab Inc., Mountain View, California) of a modified (1) thermoelectric osmometer (4, 5), developed for estimation of molecular weight, was used in these experiments. The general procedure was that devised for molecular weight estimations with this instrument. The measurement chamber (at 37° C) was saturated with water vapor and a drop of water was applied to the reference thermistor. A drop of deuterium oxide, or of a given deuterium oxide – water mixture, was applied to the sample thermistor, and resistance readings (ΔR) were then noted at chosen time intervals. The vapor pressure difference between pure deuterium oxide and water was found to be rather large in terms of the range of the instrument, and measurement of the equilibration process occurring with this system was not satisfactory. Much more satisfactory resistance readings were obtained with solutions of deuterium oxide at intermediate concentrations in water (5–20% deuterium oxide).

As shown in Fig. 1, the vapor pressure equilibrium process observed under these conditions follows an exponential law, the plot of log ΔR vs. time being linear. It is clear from these data that the concentration of deuterium oxide in the mixture initially can be related

VAPOR PRESSURE MEASUREMENTS ON THE SYSTEM D_2O–H_2O. ANALYSIS OF D_2O–H_2O MIXTURES[1]

M. MAZUREK AND A. S. PERLIN

The difference in vapor pressure between a solution and the pure solvent is readily measured as the steady-state temperature difference (heat of vaporization) by use of thermally sensitive resistors (thermistors) (1). This thermometric type of measurement is now shown to be suitable also for examining some vapor pressure characteristics of mixtures of deuterium oxide and water, i.e., of two miscible liquids having substantially different vapor pressures (2, 3).

A commercial model (Mechrolab Inc., Mountain View, California) of a modified (1) thermoelectric osmometer (4, 5), developed for estimation of molecular weight, was used in these experiments. The general procedure was that devised for molecular weight estimations with this instrument. The measurement chamber (at 37° C) was saturated with water vapor and a drop of water was applied to the reference thermistor. A drop of deuterium oxide, or of a given deuterium oxide – water mixture, was applied to the sample thermistor, and resistance readings (ΔR) were then noted at chosen time intervals. The vapor pressure difference between pure deuterium oxide and water was found to be rather large in terms of the range of the instrument, and measurement of the equilibration process occurring with this system was not satisfactory. Much more satisfactory resistance readings were obtained with solutions of deuterium oxide at intermediate concentrations in water (5–20% deuterium oxide).

As shown in Fig. 1, the vapor pressure equilibrium process observed under these conditions follows an exponential law, the plot of log ΔR vs. time being linear. It is clear from these data that the concentration of deuterium oxide in the mixture initially can be related

[1]*Issued as N.R.C. No. 7729.*

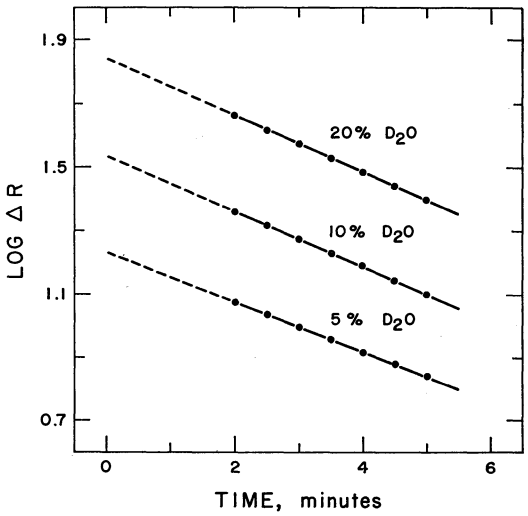

FIG. 1. Thermometric measurement of the vapor pressure equilibration process at 37° C in the system D_2O–H_2O for D_2O concentrations of 5, 10, and 20%; ΔR is a measure of the steady-state temperature difference as a function of resistance.

directly to the logarithm of ΔR at zero time. Hence, measurements of this type should afford a means for estimating the deuterium oxide content of mixtures of unknown composition, at least within the concentration range examined. The ΔR^* values obtained by extrapolation of plots (as in Fig. 1) to zero time were as follows: for 20% deuterium oxide, 68.80 ± 0.28 (average of five runs); for 10% deuterium oxide, 34.12 ± 0.15 (average of five runs); for 5% deuterium oxide, 16.94 ± 0.04 (average of three runs).

As far as we are aware, analyses of deuterium oxide – water mixtures have not been carried out in this way, although a sensitive manometric method based on vapor pressure lowering has been described by Puddington (3). Because of the simplicity and speed with which thermometric measurements may be made, and the small quantity of sample required, a method of this kind might offer specific advantages over some of the analytical procedures now available for heavy water analysis. The sensitivity and range of the measurement undoubtedly could be increased over those pertaining in the present study by suitable modification of the apparatus, most particularly, by use of a recorder in place of manual settings for obtaining ΔR values.

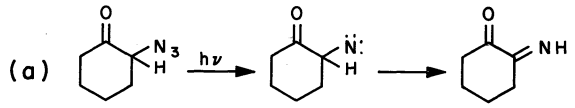
SOME REACTIONS OF ALICYCLIC α-AZIDOKETONES[1]

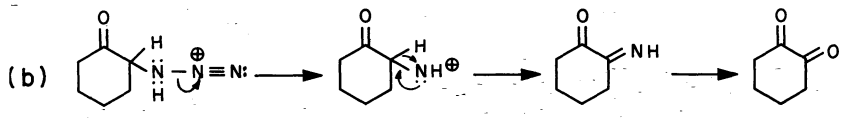
O. E. EDWARDS AND K. K. PURUSHOTHAMAN[2]

In connection with another problem we examined the preparation and reactions of two alicyclic α-azidoketones. Our initial object was a study of the photochemical decomposition of these compounds, but several factors forced a shift of emphasis to their acid- and base-catalyzed reactions.

The reaction of 2-chlorocyclohexanone and sodium azide in dimethylsulphoxide gave a good yield of yellow oil. This analyzed correctly for the 2-azidoketone and had intense absorption at 2110 cm^{-1} characteristic of an alkyl azide. However, it could not be distilled under reduced pressure without extensive decomposition and polymerization. Irradiation of a hexane solution of 2-azidocyclohexanone in a quartz vessel with ultraviolet light resulted in steady evolution of nitrogen. An oil deposited from the solution. This and the material remaining in the hexane after complete decomposition of the azide had absorption bands characteristic of an α-iminoketone (ν_{max} 3400 and 1670 cm^{-1}). However, the product could only partly be distilled under 15 mm pressure. It seemed that the expected (1) mode of reaction (equation *a*) was taking place, but that the iminoketone



was undergoing rapid polymerization. It appeared probable that acid catalysis would bring about a similar decomposition, as indicated in equation *b*, with the sensitive iminoketone now being rapidly hydrolyzed to the α-diketone. This indeed proved to be a smooth reaction leading in good yield to 1,2-cyclohexanedione. This very convenient



synthesis of the α-diketone is superior to the selenium dioxide oxidation or oximinoketone hydrolysis (2) methods for its preparation. A parallel acid-catalyzed conversion of cycloalkylazides to the corresponding ketones was described some time ago by Boyer and co-workers (3).

Attempts to prepare pure 2-azidocholestanone by the reaction of 2-α-bromocholestan-3-one with lithium azide in methanol or dimethylformamide or with sodium azide in dimethylsulphoxide were unsuccessful. A steady state concentration of the azidoketone was produced, as revealed by the infrared spectrum, but it was continuously being converted to a substance with ν_{max} 1655 cm^{-1}. After 1 hour at 50° in dimethylformamide containing excess lithium azide the bromoketone had been completely converted to the new compound. That this was the α-iminoketone I was shown by its hydrolysis to 2,3-cholestanedione, and by its reduction to a mixture rich in a 2-aminocholestan-3-ol which was characterized as its O,N-diacetate. The derived acetamido alcohol II was oxidized to 2-α-acetamidocholestane-3-one (III) (ν_{max} 1710 cm^{-1}, λ_{max} 279 mμ). Wolff-Kishner reduction of this gave a good yield of cholestane.[3]

[1]*Issued as N.R.C. No. 7701.*

[2]*National Research Council of Canada Postdoctoral Fellow.*

[3]*The elimination of α-substituents in this reaction is well known (4). The olefin which is first produced is often reduced to the hydrocarbon by diimide formed from the hydrazine present (5).*

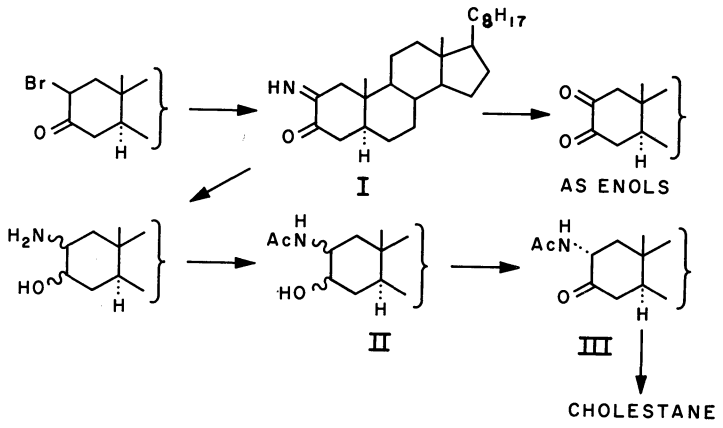
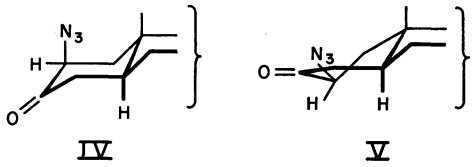
For personal use only.

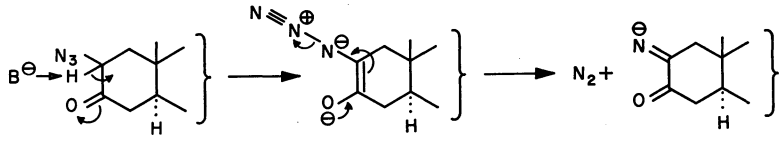


Boyer and Straw observed that thermal decomposition of phenacyl azides requires temperatures around 200° (6). The decomposition of liquid α-azidocyclohexanone began below 100°, but the compound was unchanged after several hours in boiling methanol or in dimethylformamide at 60° with or without added lithium bromide or lithium azide. Hence 2-azidocholestan-3-one is anomalously reactive. Investigation of its instability soon proved that it too was inert in methanol or dimethylformamide near 60°, or in these solvents containing lithium bromide. Clearly then, the observed decomposition during the preparative reaction is a lithium-azide-catalyzed process.

A conformational driving force for the accelerated decomposition of the azidocholestanone seems probable. Spectroscopic evidence (ν_{max}^{CO} 1720 cm^{-1} in chloroform) indicates that the parent bromoketone is 2-α-bromocholestane-3-one, with the bromine equatorial. Since the displacement of the bromine is probably a normal S_N2 reaction the azide should be 2-β-azidocholestane-3-one (IV). Since C-3 is trigonal, and the electrostatic repulsion between the carbonyl and azido groups seems low (2-azidocyclohexanone has an equatorial azido group) it is probable that the azido ketone adopts a ring A conformation closer to the half-boat V than the chair IV in order to help relieve the repulsive interaction of the azido group and the 10-methyl group.[4] This interaction seems the one factor which can



account for the rapid decomposition. We suggest that lithium azide acts as a generalized base aiding abstraction of the 2-hydrogen:



[4]*The azidoketone carbonyl appears as a shoulder on the low-wavelength side of the bromoketone carbonyl band in the infrared spectrum of a mixture of the two compounds. It is hence unlikely that the azidoketone has ring A as a boat with the azido group equatorial.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The repulsive interaction between the 10-methyl group and the azide group will be relieved in the enolate anion, thus providing the driving force for enolization by the weak base. The enolate ion must rapidly lose nitrogen to give the anion corresponding to the product.

The above reactions of α-azidoketones may provide valuable alternative routes to steroidal α-diketones (7, 8) and α-amino alcohols (9).

EXPERIMENTAL

2-Azidocyclohexanone

A solution of 2.05 g of sodium azide in 45 ml of dimethylsulphoxide was added to 1.45 g of 2-chlorocyclohexanone. The mixture was stirred at room temperature for 80 minutes. Water containing crushed ice was added, then the product extracted by three 25 ml portions of *n*-pentane. The combined extracts were washed with ice-cold water, dried, and the solvent removed *in vacuo*. The residual yellow oil polymerized if distillation was attempted under water pump pressure. The oil had $\nu_{max}^{CHCl_3}$ 2110 (—N_3) and 1722 cm^{-1} (C=O). Found: N, 29.82. Calc. for $C_6H_9N_3O$: N, 30.20.

A solution of 50 mg of 2-azidocyclohexanone in 20 ml of dimethylformamide was heated at 65°. Aliquots were periodically removed, diluted with water, and extracted with *n*-pentane. The intensity of the azide peak in the infrared spectrum remained unchanged during 1½ hours heating. When the solution was heated above this temperature, however, slow decomposition resulted.

Photolysis of 2-Azidocyclohexanone

The photolysis cell was 1 cm thick and 6.5 cm in diameter with quartz windows equipped with a side reservoir with cooling coil and circulation device. A solution of 750 mg of the azidoketone in 165 ml of cyclohexane was irradiated under nitrogen with a 140 watt Hanovia lamp while the temperature was maintained below 40°. A steady evolution of nitrogen ensued. The azide band at 2110 cm^{-1} had disappeared after 12 hours. The photolysis was interrupted at intervals to remove an oil which collected on the walls of the cell. This oil was soluble in methylene chloride, but the solution deposited polymer on standing. Both the oil and cyclohexane solution had infrared absorption at 3400 and 1670 cm^{-1}.

Acid-Catalyzed Decomposition of 2-Azidocyclohexanone

A mixture of 750 mg of 2-azidocyclohexanone and 15 ml of 10 *N* sulphuric acid was vigorously stirred a s the temperature was raised to 60°. Nitrogen evolution commenced. After 1 hour at 60–65° the oily drops of the azide had completely disappeared. The solution was cooled, saturated with sodium sulphate, and extracted three times with 50 ml portions of ether. The ether extracts were concentrated to 50 ml *in vacuo*, then extracted twice with 15 ml portions of ice-cold 10% potassium hydroxide solution. The aqueous layers were neutralized with cold 6 *N* hydrochloric acid and extracted thoroughly with ether. The dried ether solution was removed at 0° *in vacuo*, leaving 378 mg of 1,2-cyclohexanedione which crystallized from pentane; m.p. 38–40°, $\nu_{max}^{CHCl_3}$ 3500 cm^{-1} (OH), 1675 cm^{-1} (C=O), and 1650 cm^{-1} (C=C) corresponding to the enolic form; λ_{max} 266 mμ, ε 2460 shifted to 308 mμ in alkali. The dione formed a dioxime which melted at 187–188° after recrystallization from acetone. An aqueous solution of the dioxime gave a rose-red precipitate when a nickel sulphate solution was added.

Attempted Preparation of 2-Azidocholestanone

Numerous attempts were made to prepare pure 2-azidocholestanone by the action of alkali azides on 2-bromo(chloro)-cholestane-3-one, varying the solvent and temperature. Aliquots were removed from the reactions at intervals, the ether-extractable products isolated, and the infrared spectra examined. The azidoketone ($\nu_{max}^{CHCl_3}$ 2110 cm^{-1} and 1710 cm^{-1}) soon reached a steady state concentration while a second product steadily grew in concentration ($\nu_{max}^{CHCl_3}$ 1655 cm^{-1}). Of the three solvents used, dimethylformamide, dimethylsulphoxide, and methanol, the highest steady state concentration of azide was reached with the latter solvent, after 1 hour of refluxing. In a typical experiment 300 mg of 2-bromocholestan-3-one in 2 ml of chloroform was added to a solution of 300 mg of lithium azide in 25 ml of dry methanol. After 1 hour of refluxing the solvent was removed *in vacuo*, water added, and the products extracted into ether. After removal of the ether the extracted products were dissolved in benzene and the solution passed through a column of silica gel (20-fold ratio). The readily eluted material contained none of the by-product and had intense azide absorption. However, the product melted over a wide range and analysis for bromine indicated the presence of up to 50% of starting material. Attempts to further purify the azidoketone by chromatography on alumina were unsuccessful, hence this mixture was used to study the reactivity of the azidoketone.

The azide was not decomposed if a solution of 100 mg of the mixture in 10 ml of methanol or in 10 ml of methanol containing 100 mg of lithium bromide was refluxed for 1½ hours. It was also unchanged in a 3:7 mixture of chloroform and dimethylformamide after 2 hours at 50°.

2-Acetamidocholestan-3-ol Acetate

To a stirred solution of 3.8 g of 2-α-bromocholestan-3-one in 40 ml of dimethylformamide was added 3.8 g of lithium azide. The mixture was maintained at 50° for 1 hour then diluted with methanol and cooled to room temperature. Sodium borohydride (1.5 g) was added in small portions. After standing overnight the reaction mixture was diluted with water and thoroughly extracted with ether. The extracts were concentrated to 100 ml, then shaken with 3 *N* sulphuric acid. A sulphate which precipitated was collected by filtration and washed well with ether. It was then dissolved in 100 ml of hot ethanol, and the solution basified with alcoholic sodium hydroxide. The solvent was removed under reduced pressure, and the residue extracted with chloroform. The organic layer was washed with water and dried over anhydrous sodium sulphate. After removal of the solvent, 20 ml pyridine and 2 ml acetic anhydride were added and the contents left overnight. Pyridine was removed *in vacuo* and the residue taken up in ether. The fraction separated by the usual procedure was crystallized from alcohol to yield 2.6 g of 2-acetamidocholestanol acetate; m.p. 193–195°. $\nu_{max}^{CHCl_3}$ 3500 cm^{-1} (NH), 1722 cm^{-1} (ester), 1665 cm^{-1} (amide). Found: C, 76.74; H, 10.74; N, 2.94%. Calc. for $C_{31}H_{53}O_3N$: C, 76.33; H, 10.95; N, 2.87%.

2-Acetamidocholestan-3-ol

A solution of 2-acetamidocholestanol acetate (2 g) in 40 ml of alcohol was heated on a steam bath and 4 ml of 10% sodium hydroxide solution added to it. The contents were refluxed for 1 hour. The mixture was then concentrated to 25 ml and 20 ml water added. The resulting precipitate was washed with water and recrystallized from ethanol; m.p. 256°. Found: C, 78.16; H, 11.35%. Calc. for $C_{29}H_{51}O_2N$: C, 78.14; H, 11.53%.

2-α-Acetamidocholestan-3-one

One gram of chromic acid was added in small portions to 10 ml of pyridine at 0° C with vigorous shaking. When the formation of the complex was complete 1.5 g of 2-acetamidocholestanol dissolved in 30 ml pyridine was added slowly. The mixture was shaken overnight at room temperature and extracted with 1:1 benzene–hexane mixture. The organic layer was washed with acid and alkali and finally with water. After drying over sodium sulphate the solvent was removed. A chloroform solution of the product was passed through a column of grade III alumina (weight ratio 20:1). The readily eluted material finally crystallized from ether to give 2-α-acetamidocholestane-3-one, m.p. 184–186°, $\nu_{max}^{CHCl_3}$ 3370 cm^{-1}(NH), 1710 cm^{-1} (>C=O), and 1665 (—C(=O)—N<); λ_{max}^{EtOH} 279 mμ, ε 130. Found: C, 78.39; H, 11.09%. Calc. for $C_{29}H_{49}O_2N$: C, 78.5; H, 11.13%.

Wolff-Kishner Reduction

A mixture of 80 mg of 2-acetamidocholestan-3-one, 6 ml triethylene glycol, and 2 ml hydrazine was immersed in a bath at 110°. The temperature was gradually raised to 155–160° and maintained for 1 hour. Two grams of potassium hydroxide was now added and the water condenser replaced with an air condenser. The temperature was raised to 195–205° and kept at that temperature for 5 hours. The mixture was then cooled, diluted with water, and extracted with ether. The ether solution was washed with acid, with water, dried, and distilled. The 60 mg of residue was dissolved in pentane and the solution passed through a column of alumina (grade III). The eluate yielded 42 mg of a solid. Recrystallization from alcohol gave colorless plates, m.p. and mixed m.p. with cholestane 78–81.5°. Found: C, 86.81; H, 13.16. Calc. for $C_{27}H_{48}$: C, 87.02; H, 12.98%.

2,3-Secocholestan-2,3-dioic Acid

Four hundred milligrams of 2-α-bromo-5-α-cholestan-3-one was dissolved in 15 ml dimethyl formamide and 400 mg of lithium azide added. The mixture was heated at 50° for 1 hour, with shaking in nitrogen atmosphere. The contents were evaporated to dryness *in vacuo* and the residue taken up in 15 ml of 80% aqueous dioxane. Five milliliters of 1.5 *N* sulphuric acid was added and the mixture shaken at room temperature for 2 hours. The solution was concentrated to half its volume, diluted with water, extracted with ether. The residue (approx. 300 mg) obtained after the removal of the ether had $\lambda_{max}^{alcohol}$ 272 mμ which was shifted to 320 mμ in alkali (2).

Crude diketone (150 mg) was dissolved in 15 ml alcohol and a mixture of 1 ml hydrogen peroxide (30%) and 1 ml of 10% potassium hydroxide added. The mixture was heated on a steam bath. The same mixture of hydrogen peroxide and alkali was added twice more at 15 minute intervals. After 1 hour, the heating was stopped and the contents left overnight. After diluting with water the solution was extracted with ether to remove non-acidic materials. The clear aqueous layer was then acidified with 3 *N* sulphuric acid and ether-extracted. After washing with water the organic layer was dried over anhydrous sodium sulphate. Removal of solvent and crystallization of the residue from ethyl acetate gave 100 mg of the dicarboxylic acid, m.p. 193–194° (lit. m.p. 195° (2)). Found: C, 74.5; H, 10.29. Calc. for $C_{27}H_{46}O_4$: C, 74.61; H, 10.67%.

REACTIONS OF (i) ALUMINUM TERTIARY BUTOXIDE WITH ACETYL CHLORIDE AND (ii) ALUMINUM CHLORIDE WITH TERTIARY BUTYL ACETATE

R. C. MEHROTRA AND R. A. MISRA

Chemical Laboratories, University of Rajasthan, Jaipur, India

Received October 29, 1963

ABSTRACT

The reactions between aluminum tertiary butoxide and acetyl chloride have been studied. The addition of 1 mole of acetyl chloride to aluminum tertiary butoxide forms monochloride ditertiary butoxide, which, with another mole of acetyl chloride, appears to give the dichloride monotertiary butoxide derivatives. Further, these products appear to react with tertiary butyl acetate formed in the reaction itself, giving acetate derivatives. The above is confirmed by a detailed study of the reactions between aluminum chloride and tertiary butyl acetate, which have been found to result in the acetate derivatives. A plausible mechanism has been suggested.

Considerable work has been done on the reactions of acetyl chloride with the alkoxides of zirconium (1), titanium (2), and aluminum (3). In the cases of normal and secondary alkoxides, the reactions proceed in a straightforward manner yielding chloride alkoxides. For example, the reactions of aluminum isopropoxide with acetyl chloride can be represented by the following equation:

$$Al(OR)_3 + nCH_3COCl \rightarrow Al(OR)_{3-n}Cl_n + nCH_3COOR,$$

(where R = isopropyl radical and n = 1, 2, or 3).

However, for the three metals, their tertiary alkoxides showed a different behavior towards acetyl chloride. The reaction of the tertiary butoxides with acetyl chloride appeared to be quite facile up to the formation of the monochloride derivative, but further replacement appeared to be slow, a conclusion which was based on the determination of Cl:Al ratio in the product. A number of other physical and chemical properties (e.g., volatility (4), molecular complexity (5), reactivity with alcohols (4), and esters (6)) of the tertiary alkoxides in general, appeared to be explained easily on the steric hindrance caused in the molecule by the ramified alkyl groups. The same explanation was, therefore, offered (1, 3) for the comparative slowness of the reactions of the tertiary alkoxides with acetyl chloride. However, maximum steric hindrance should have been presented in the initial stages of the reaction between aluminum tertiary butoxide and acetyl chloride. The replacement of the first tertiary butoxide group by chloride should decrease the steric hindrance and aluminum monochloride ditertiary butoxide should react more readily with acetyl chloride. However, experimental results are just the opposite.

*The compound is sticky and appears to retain the solvent because of which the analyses are low. The reaction has, therefore, been repeated in *h*-hexane in place of benzene, which has been used as an inert solvent in all the other reactions and the effect of heat on the compound has been studied.

The first clue pointing to an entirely new explanation of the above facts was obtained in the reaction of silicon tetrachloride with tertiary butyl acetate, in which case silicon tetraacetate (7) was obtained in a quantitative yield at the room temperature. It was conjectured that in the present reactions also the aluminum chloride tertiary butoxide initially produced may react with the tertiary butyl acetate formed in the reaction itself, to yield the acetate derivative:

$$Al(OBu^t)_{3-n}Cl_n + xBu^tOOCCH_3 \rightarrow Al(OBu^t)_{3-n}(—OOCCH_3)_xCl_{(n-x)} + xBu^tCl,$$

(where $n = 1, 2,$ or 3
$x \leqslant n$).

The reactions of aluminum tertiary butoxide with acetyl chloride were, therefore, carried out in different molecular proportions, when the results shown in Table I were obtained.

A perusal of the data in Table I clearly indicates that monochloride ditertiary butoxide and dichloride monotertiary butoxide derivatives are formed initially by the reactions:

$$Al(OBu^t)_3 + CH_3COCl \rightarrow AlCl(OBu^t)_2 + Bu^tOOCCH_3,$$

$$AlCl(OBu^t)_2 + CH_3COCl \rightarrow AlCl_2(OBu^t) + Bu^tOOCCH_3.$$

However, the dichloride monotertiary butoxide appears to react with the tertiary butyl acetate produced in the reaction with the replacement of chloride groups by the acetoxy groups.

For testing the correctness of the above assumption, the reactions of aluminum trichloride with tertiary butyl acetate were carried out in different molar ratios, when the results shown in Table II were obtained.

A study of the data in Table II reveals that the reaction between aluminum chloride and tertiary butyl acetate is a straightforward reaction which can be represented by the following equation:

$$AlCl_3 + nBu^tOAc \rightarrow AlCl_{3-n}(OAc)_n + nBu^tCl + \text{heat},$$

(where $n = 1, 2,$ or 3).

The reaction at first is very vigorous and exothermic, and two of the chlorine atoms of aluminum trichloride are replaced with facility by the acyl group at room temperature. Later on the reaction becomes slow and the triacetate of aluminum is obtained only under refluxing conditions:

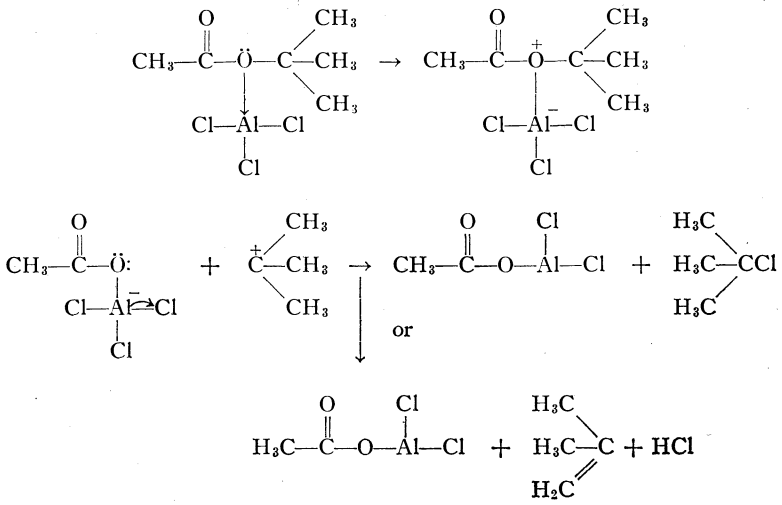
$$AlCl_3 + 3Bu^tOAc \xrightarrow[110^\circ C]{\text{reflux}} Al(OAc)_3 + 3Bu^tCl.$$

The reactions thus provide alternative routes for the synthesis of aluminum chloride acylates (8) and the triacetate (9), the existence of which was doubted for a long time and which were synthesized for the first time in these laboratories.

Possible Reaction Mechanism

The reaction between aluminum chloride and tertiary butyl acetate could be represented by the following probable mechanism :

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



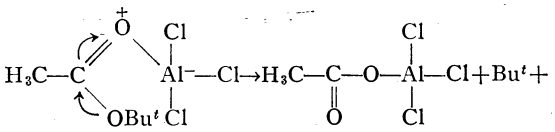
. . . and so on.

The facile manner of the reaction could be understood easily on the stability of tertiary butyl cations. As the chlorine is replaced in aluminum chloride by acetate groups, the electrophilic nature of the aluminum will decrease and can be expected to make the third stage of the reaction rather slow.

The above mechanism is similar to the alkyl fission mechanism suggested by Bunton, Comyns, and Wood (10) for the acid hydrolysis of tertiary butyl acetate:

$$(CH_3)_3COOCCH_3 + HO^{18}H \xrightarrow[HCl]{H_3O} (CH_3)_3CO^{18}H + CH_3COOH$$

In an infrared study of the ester – boron trichloride system, Lappert (11) found that the initial coordination occurs through the acyl oxygen of the ester. The above reaction mechanism will hold equally well in this case also:



. . . and so on.

However, the reactions of tertiary butyl acetate with the isopropoxides of aluminum (4) and zirconium (6) have been shown to give the corresponding tertiary butoxides and it would be difficult to explain this if the initial coordination were through the acyl oxygen.

EXPERIMENTAL

Apparatus

All-glass apparatus fitted with interchangeable standard joints was employed and adequate precautions were taken to exclude atmospheric moisture. Fractionations were carried out in a column packed with Raschig rings and fitted to a total condensation variable takeoff stillhead.

Materials

Aluminum tertiary butoxide was prepared with aluminum turnings and anhydrous tertiary butyl alcohol (12). It was sublimed (198–200° C at 1.0 mm) and analyzed before use. Found: Al, 10.9. Calc. for $Al(OBu^t)_3$: Al, 10.97%. Acetyl chloride (B.D.H./A.R.) was distilled (51–52° C) before use. Tertiary butyl alcohol was first dried over slaked lime and then on sodium tertiary butoxide and finally distilled (82.5° C). Benzene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(B.D.H.) was dried by refluxing it over sodium metal for 2 days and distilled. Finally it was dried azeotropically with ethanol. Anhydrous aluminum chloride (sublimed/E. Merck) was resublimed (180° C at 1.5 mm) and analyzed before use. Tertiary butyl acetate was prepared (13) by the action of acetic anhydride on tertiary butanol. After purification and drying over anhydrous potassium carbonate, it was fractionated (96–98° C) twice before use.

Analytical Method

Aluminum and chlorine were estimated as oxinate and silver chloride separately. Acetoxy group was estimated by titrating the weighed sample with $N/10$ caustic soda using phenolphthalein as indicator. It was initially tested by a large number of blank experiments that both aluminum trichloride as well as triacetate require 2.9 equivalents of caustic soda. Further, it was also found that the first drop of sodium hydroxide when added to tertiary butyl acetate and aluminum tertiary butoxide gives immediate color to phenolphthalein. This method of analysis giving the acetate groups is more accurate than elemental analyses.

I. Reaction between Aluminum Tertiary Butoxide and Acetyl Chloride in Benzene

To a solution of aluminum tertiary butoxide in dry benzene was added the calculated amount of acetyl chloride. No heat appeared to be evolved in 1:1 molar reactions and only a slight amount of heat was evolved in the other reactions. After the clear solution was shaken well and allowed to stand at room temperature for a number of hours or after it was refluxed at a bath temperature of nearly 90° C, the volatile fractions were removed at the room temperature under reduced pressure. A white powder was obtained in each case and the analyses of the various products obtained are given in Table I.

II. (a) Reactions of Anhydrous Aluminum Chloride and Tertiary Butyl Acetate in Benzene

The suspension of aluminum chloride in dry benzene was caused to react with tertiary butyl acetate in required amount for definite molar ratio. All the reactions were highly exothermic and were carried out in a cold bath (0–5° C). After the reaction mixture had been shaken and allowed to stand overnight, the volatile fractions were removed and then the product was dried under reduced pressure at room temperature. The final product was a white amorphous solid except in the 1:1 molar reaction, where it was a brownish sticky solid. The results of the analyses are tabulated in Table II.

II. (b) Reaction of Anhydrous Aluminum Chloride with Tertiary Butyl Acetate in Presence of n-Hexane (Molar Ratio 1:1)

In view of the sticky nature of the product in 1:1 molar reaction in benzene, the reaction was repeated in *n*-hexane. A suspension of aluminum chloride (2.92 g) in about 10 cc of *n*-hexane was treated with tertiary butyl acetate (2.56 g) in cold (0–5° C). An exothermic reaction occurred and after about 2 hours the volatile fractions were removed under reduced pressure, leaving a brown, viscous sticky solid. Yield 4.464 g. Found: Al, 14.0; Cl, 37.2; Cl:Al = 2; alkali eq., 2.97 moles. Calc. for $AlCl_2(OAc)$: Al, 17.3; Cl, 45.2%; alkali eq., 3.0 moles.

The above compound (3.60 g) when heated at about 50° C at 1.0 mm for 1 hour gave a brown color sticky solid (3.36 g) which, on analyses, gave: Al, 14.95; Cl, 37.8%; Cl:Al = 1.94; alkali eq., 2.95 moles.

This, on further heating (3.2 g) at 100° C 0.1 mm for 1 hour, gave a brown viscous solid (3.1 g). Found: Al, 15.4; Cl, 38.9%; Cl:Al = 1.91; alkali eq., 2.87 moles.

Further heating of the compound (2.91 g) at 120–130° C at a reduced pressure of 0.1 mm for 2 hours gave a brittle-brown solid (2.84 g). Found: Al, 16.6; Cl, 34.0%; Cl:Al = 1.6; alkali eq., 2.3 moles.

II. (c) Reaction between Aluminum Chloride and Excess of Tertiary Butyl Acetate without any Solvent

To avoid the hardening of the product formed in the reaction, a weighed amount of aluminum chloride was added cautiously, with shaking, to the flask containing tertiary butyl acetate in large excess. The reaction in each case was found vigorous and exothermic. The resulting mixture was shaken well, then kept overnight at room temperature or refluxed at about 110° C. The times of refluxing were varied with the conditions of the particular reaction. In every case, a white solid separated out from the clear solution. The supernatant liquid was decanted off and the product was freed from the volatile fractions under reduced pressure. The analyses of the various products are given in Table II.

THE pK_a OF PROTONATED α,β-UNSATURATED CARBOXYLIC ACIDS

T. S. SORENSEN
Department of Chemistry, University of Alberta, Calgary, Alberta
Received October 20, 1963

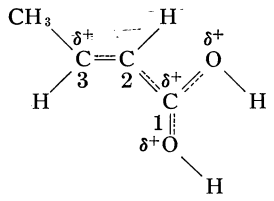
ABSTRACT

The pK_a of three, protonated α,β-unsaturated carboxylic acids have been determined from their ultraviolet absorption curves by using several of the well-known empirical methods. A detailed study of the absorption curves has been attempted in order to learn more about the "solvent effect" inherent in this spectral method of calculating pK_a values. Methyl substitution at the β-carbon of the acid results in large differences in the calculated pK_a.

The pK_a of protonated *o*- (1) and *p*-substituted (2) benzoic acids and of propionic (3) and acetic (4) acid have been reported. These values range from −6.2* to −8.6 for phthalic acid and *m*-nitrobenzoic acids (the extremes for substituted benzoic acids which have been measured), −6.4 for acetic acid and −7.3 for propionic acid.

The values for acetic and propionic acids are likely to be only approximate since the ultraviolet transition used in the measurement ($n \rightarrow \pi^*$) is weak and in the region of the spectrum where stray light and other effects can cause erroneous absorption. We have measured the complete accessible ultraviolet spectral curves for acrylic, crotonic, and β,β-dimethylacrylic acids in a wide range of sulphuric acid – water mixtures and have used these measurements to calculate the respective pK_a values by several different techniques. In addition, the roughly Gaussian shape of the spectral curves allows us to make an investigation of the "solvent effects" which appear as a serious complication in many pK_a determinations using ultraviolet spectroscopy to determine the concentration of the unprotonated and protonated species.

The structure of the protonated carboxyl group has been discussed by Stewart and Yates (2) and by Palmer and Urch (5) and is considered to have a symmetrical structure, e.g. I for protonated crotonic acid.



I

A pK_a value is a measure of the stability of the protonated form of a base relative to the unprotonated form, but since there is not likely to be much difference in energy between the unprotonated molecules, differences in pK_a can be attributed to differences in the stability of the protonated forms. It is to be expected that the substitution at carbon 3 of the oxonium ion I will cause some difference in the stability of this ion (tertiary > secondary > primary) but the magnitude is unknown.

Except for a very weak band ($n \rightarrow \pi^*$) which is hardly observable (6), the only accessible ultraviolet absorption in solutions of α,β-unsaturated acids is the intense $\pi \rightarrow \pi^*$

**All literature pK_a values are corrected by using the new H_0 scale in ref. 14.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

transition. This absorption band is very satisfactory for pK_a measurements except for acrylic acid where the λ_{max} in water is at 1940 Å, only some 100 Å above the cutoff point of the instrument and therefore subject to the usual inaccuracies. It has been reported (7) that Beer's law is not valid for the absorption spectra of certain α,β-unsaturated acids in ethanol solution. We have checked Beer's law for crotonic acid in 50% sulphuric acid and find that it holds well. The reported deviations are likely instrumental since these results were obtained with machines with effective cutoffs at 2100 Å.

We have made recovery and dilution experiments to verify that the spectrum we have recorded is not due to some irreversibly formed decomposition product. Solutions of β,β-dimethylacrylic acid underwent decomposition (decreasing ultraviolet absorption with time) with certain concentrations of sulphuric acid but no difficulty was encountered with crotonic and acrylic acids. We were able to obtain rough kinetics for this decomposition and to extrapolate the spectra to zero time.

RESULTS

The complete spectra for crotonic acid are shown in Fig. 1 plotted in wave numbers.

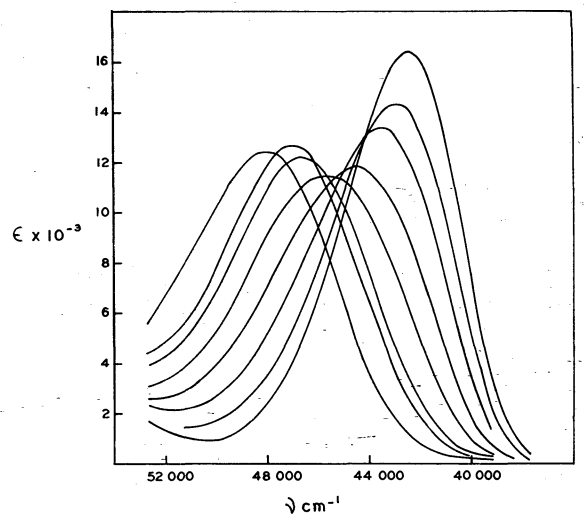


FIG. 1. Ultraviolet spectra of crotonic acid in aqueous sulphuric acid, % w/w sulphuric acid, curves from left to right, 0, 49.2, 58.9, 67.7, 73.2, 77.8, 82.2, 96.2.

The tabulated data for these curves (λ_{max}, ϵ_{max}, and $\Delta\nu$) as well as those for the other two acids are given in the Experimental section. A number of methods can be applied in using these curves to calculate pK_a values. Plots of ϵ_B vs. H_0 and ϵ_{BH^+} vs. H_0 all give sigmoid-shaped curves although the calculated pK_a in each case is not exactly the same. The procedure of Davis and Geissman (8), which has been most widely used, was applied to the absorption curves for each acid and is shown in Fig. 2 for crotonic acid. It is difficult to decide where the midpoint of the sigmoid curve is situated and in these cases Stewart and Granger (1) have shown that a plot of log $(\Delta D_{BH^+}-\Delta D)/(\Delta D-\Delta D_B)$ versus H_0 gives a straight line from which the pK_a can be directly located. We have also used this method to calculate the pK_a values. The remarkable thing about these plots is that they appear to be exact (a straight line is obtained) but the slope of the line is considerably less than unity.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

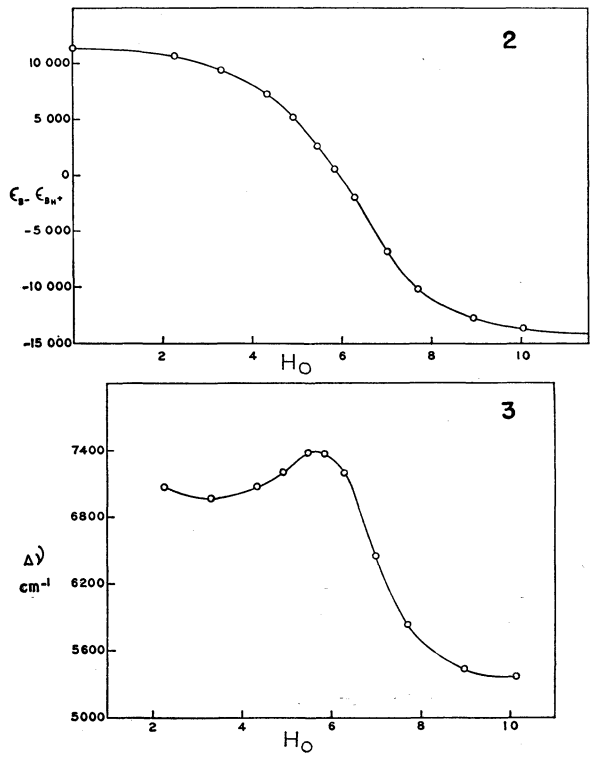

FIG. 2. pK_a calculation using the procedure of Davis and Geissman.

FIG. 3. A plot of the half-width, $\Delta\nu$, for the absorption curves of crotonic acid in aqueous sulphuric acid solutions, against the H_0 of these solutions.

Slopes of less than unity have been found for a number of other carbonyl compounds (9), so-called "non-Hammett bases". Finally the half-widths, $\Delta\nu$, of each curve, over the whole H_0 range, have been plotted against H_0 and, as shown in the following discussion, a rough pK_a can be calculated from this. The shape of this plot for crotonic acid is shown in Fig. 3. The calculated pK_a values, by each method, are collected in Table I along with the observed slopes determined by using the treatment of Stewart and Granger.

DISCUSSION

It is somewhat disturbing that qualitatively there is no real indication of two peaks in any of the complete absorption curves for β,β-dimethylacrylic and crotonic acids as shown in Fig. 1. Similar difficulties have been reported (10) in attempting to measure the pK_a of protonated anisole. The spectral curves of acrylic acid show somewhat better behavior (in that an approximate isobestic point is observed) but unfortunately we cannot measure the complete curves.

Vandenbelt and Henrich (11) have calculated the combined curves resulting from the mixing of two Gaussian curves, varying the separation of the curves and the ratio of the two in the combined curve. If the separation is small definite shoulders or inflection points are not obvious in the combined curve, e.g. if two identically shaped curves have a $\Delta\nu$ of 3 units and if the separation is 2 units, the combined curve also looks roughly Gaussian in shape. The $\Delta\nu$ of the combination curve is increased to 4 units, however, if the two

Stewart and Granger	−6.18	−7.55	−5.35
$\Delta\nu$ versus H_0	−5.8	−7.2*	−4.9
Slope	0.73	0.90	0.67

*Peak width at three-quarters peak height.

separate curves are of equal height. The presence of what appears to be a single peak need not cause any concern therefore except inasmuch as the component curves must be separated by amounts similar to those discussed above.

The curves for these α,β-unsaturated acids in aqueous sulphuric acid, where the H_0 of the solution is equal to the pK_a, must by definition be composed of equal parts of the curve due to the free base and that due to the protonated base. If a curve fitting is made, assuming constant ϵ_{max} and shape for the component curves, it can be shown that the λ_{max} for the absorption curve due to unprotonated acid shifts strongly to the red and that due to the protonated acid (with reference to the peak position at the pK_a point) also shifts, although less than the unprotonated species, to the red. The general theory (12) of solvent effects on $\pi \rightarrow \pi^*$ transitions of this type predicts that a red shift of the absorption curve of unknown magnitude should be observed for the unprotonated molecule but the protonated molecule, being a charged species, is expected to be rather insensitive to solvent polarity.

The red shift of the "free" carbonyl absorption peak has been noted by many workers in this field, beginning with Hammett (13). It has also been noted that the peak for the protonated carbonyl species shifts to the red with increasing acid concentration and also increases in intensity (1). In our spectral curves, the increase in intensity is paralleled by a decrease in $\Delta\nu$, so that the integrated intensity remains nearly constant.

If two identical Gaussian curves overlap strongly the combined curve will have a maximum $\Delta\nu$ when the two contributing curves are present in equal amounts. We have therefore plotted $\Delta\nu$ for the curves of Fig. 1 against H_0 and have calculated a pK_a by: (1) neglecting slight errors due to the different $\Delta\nu$ of the two contributing curves; (2) assuming that the shape of curves for the protonated and unprotonated base do not change with the H_0 of the solution; and (3) that within the 0.1–0.3 H_0 units involved, a plot of log BH^+/B versus H_0 is linear with unit slope so that in the case where ϵ_B is somewhat different from ϵ_{BH^+}, a pK_a can still be calculated. Since the individual curves must by definition be rising and falling very rapidly in the region of the pK_a, the assumptions which have been made do not have much effect on the value of the pK_a which is calculated. The pK_a values calculated in this manner agree fairly well (0.3–0.4 pK_a units lower) with those obtained by the Davis and Geissman method. This method of calculating pK_a values should be applicable to systems where the optical density of the absorption curves are decreasing rapidly with time, providing the time required to make the spectral measurements is fast relative to this decomposition and also that the decomposition products do not absorb themselves.

The calculated pK_a values are in the range reported for other carboxylic acids and a large difference, 1 pK_a unit, is observed between the successive members of this series. This would imply that the double bond is considerably delocalized by resonance with the

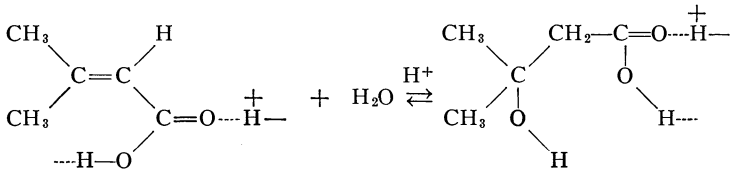
For personal use only.

protonated carboxyl group. This difference can be compared with the difference in pK_a between protonated benzoic acid (−7.65) and the *p*-methyl (−7.25) substituted acid.

The decomposition of β,β-dimethylacrylic acid was found to be catalyzed by ultraviolet light. In the absence of light the reaction, as measured by the decrease in ϵ_{max}, was found to be approximately first order and in all cases where there was appreciable reaction, a steady state was reached where no further decomposition occurred. At low H_0 values the rate of decomposition was slow but the position of the equilibrium was almost completely on the side of a non-absorbing species. As the concentration of sulphuric acid increases the rate of decomposition increases but the position of the equilibrium shifts in favor of the α,β-unsaturated acid. This decomposition can be satisfactorily explained as a simple hydration (equation I) since the hydrated species would have virtually no ultraviolet absorption.



Equation I

EXPERIMENTAL

Ultraviolet measurements were obtained from a Beckman DK-1 spectrophotometer which had been checked for accuracy of intensity and wavelength (down to 2200 Å). The stray light performance of this machine was investigated and this effect can cause errors in the region of the absorption curve near the cutoff point of the machine (1850–1950 Å). No correction has been applied but the curves for acrylic acid are the only ones appreciably affected. The scan speed was 100 Å/minute except where decomposition was occurring when a speed of 500 Å/minute was used. All peak maxima were rerun and an expanded scale was used in order to obtain maximum accuracy. The samples were not thermostated but the temperature did not vary much (22±2° C). The solutions were measured in 0.1 cm "suprasilica" cells, with a solvent blank in the reference cell of the same composition as that in the sample cell. A base-line correction was made where necessary by measuring spectra with only solvent in both cells. The curves for β,β-dimethylacrylic acid have been corrected back to zero time. The optical density of the absorption curve was determined at time intervals measured from the time of preparation of the solution. A rough check was made on curves where substantial decrease in optical density had occurred to make certain that no extraneous absorption was appearing. It was observed that decomposition was more rapid when the sample stayed in the cell compartment with ultraviolet light shining on it than when the sample was kept in the dark. Measurements were continued until a steady state was reached where no further decomposition occurred. The kinetics (as measured by the decrease in optical density in the dark) were approximately first order and the ϵ_{max} of the curves for this acid have been corrected. On fast scan, the time necessary to record most of the absorption (1 minute) is short compared to the decomposition rate. Some rough values for the kinetics of the decomposition are:

% Sulphuric acid	Half-life of decomposition, $T^{1/2}$ (min)	Equilibrium position, % α,β-unsaturated acid
63.76	ca. 90	Small
70.35	ca. 28	38
73.16	ca. 14	55
77.79	ca. 7	83

All curves were measured in duplicate and if the average error for the calculated ϵ_{max} was more than 2%, repeat measurements were made. Tabulated data from the absorption curves are collected in Table II.

Solutions were prepared by weighing out 0.3–0.5 mg of the carboxylic acid on a small glass boat, with a microbalance. This boat was added to the solvent previously made up to mark in a volumetric flask.

Aqueous sulphuric acid solutions were titrated against standard base. The Hammett acidity function H_0 for a given percentage of sulphuric acid was taken from the recent data of Jorgenson and Hartter (14).

100.0	16,150	2,355	5,380	10,500	2,175	—	13,200	2,436	—

The absorption spectra of these carboxylic acids in 100% sulphuric acid are not unusual except in the case of β,β-dimethylacrylic acid where the λ_{max} is at considerably shorter wavelengths than in 98% sulphuric acid. Evidently some other change has occurred in this solvent but we have not investigated this.

Unchanged carboxylic acid can be recovered from its concentrated sulphuric acid solutions. A more quantitative measurement of any decomposition was obtained by dilution experiments. Solutions of the carboxylic acids were prepared and the spectrum measured with 0.1 cm cells. This same solution was diluted 10-fold with ice and water and the spectrum (taken in 1 cm cells) was compared with that of the carboxylic acid in this medium (approximately 10% sulphuric acid). A quantitative recovery was calculated for crotonic acid; for β,β-dimethylacrylic and acrylic acids the recovery was better than 90%.

β,β-Dimethylacrylic and crotonic acids were recrystallized from water, m.p. 69–70° C and 72–73° C respectively. Acrylic acid was redistilled at reduced pressure and kept below 0° C.

POLYCONDENSED ANIONS OF THE TRANSITION METALS

LIGHT SCATTERING AND ULTRACENTRIFUGATION WITH SCHLIEREN AND INTERFERENCE OPTICS OF ALKALINE NIOBIUM(V) SOLUTIONS[1]

WILFRED H. NELSON[2] AND R. STUART TOBIAS
Department of Chemistry, University of Minnesota, Minneapolis

Received October 3, 1963

ABSTRACT

Alkaline aqueous niobium(V) solutions prepared by dissolving the salt $K_{14}Nb_{12}O_{37}\cdot 27H_2O$ were studied by means of light scattering and by equilibrium ultracentrifugation by using both schlieren and interference optics. All three experimental methods indicate that the degree of polymerization of the polycondensed niobate anion is no less than 5 and probably has the value 6. The centrifugation data indicate that only one polycondensed species exists in the solutions. The effective charge of the niobate anion appears to be reduced appreciably by the binding of potassium ions to a value of no greater than −2. The behavior of the solutions is very similar to that observed previously with alkaline tantalum(V) solutions, and it appears very likely that the hexameric anion $[HNb_6O_{19}]^{-7}$ found in niobate crystals also exists in aqueous solutions. The niobate is slightly protonated in comparison to the analogous tantalate. The stability of highly concentrated solutions containing this large polycondensed species is probably the result of the existence of a poly-ion with high symmetry which interacts only weakly with the solvent, water.

INTRODUCTION

Among the best known of the polycondensed inorganic compounds are those formed by the quinquevalent Group V-A and B elements. The polyphosphates in aqueous solution have been very thoroughly studied by modern physicochemical techniques (1). The picture with the V-A elements V, Nb, and Ta is certainly less clear. In the past, there have been many postulates concerning the structure of the polycondensed transition metal compounds based on the structures of the polyphosphates with analogous stoichiometry. With an increase in information on the stereochemistry of these transition metals, it became apparent that most of these analogies were false. Rather than exhibiting regular tetrahedral coordination with respect to oxygen, vanadium(V) occurs in badly distorted structures involving essentially five-coordination while niobium and tantalum seem to exhibit almost regular octahedral coordination.

Recently we completed a study of alkaline aqueous solutions of tantalum(V) prepared by dissolving the compound $K_8Ta_6O_{19}\cdot 16H_2O$ (2). This type of alkali metal tantalate appears to be unique in that it is the only example of a readily soluble tantalum oxy-compound (3). The measurements indicated that $K_8Ta_6O_{19}\cdot 16H_2O$ dissolves in water without appreciable changes in the degree of condensation of the polycondensed anion found in the crystals. X-Ray studies on single crystals of this tantalate have indicated that discrete anions are present which contain six tantalum atoms arranged at octahedral vertices (4). All of the experimental data indicated that the solutions were monodisperse and that the single polyanion had the stoichiometry $[Ta_6O_{19}]^{-8}$ or $[HTa_6O_{19}]^{-7}$.

Although quinquevalent niobium does not form a compound isostructural with $K_8Ta_6O_{19}\cdot 16H_2O$, a single crystal X-ray study of the compound $Na_{14}Nb_{12}O_{37}\cdot 32H_2O$

has indicated that this structure is also built up out of discrete anions with six niobium atoms arranged at octahedral vertices (5). The potassium niobate which seems to be most easily crystallized from aqueous solution apparently has the stoichiometry $K_{14}Nb_{12}O_{37}\cdot 27H_2O$ (6). In contrast to tantalum, which seems to crystallize in only the aforementioned type of alkali metal salt, niobium gives a series of soluble niobates differing but slightly in the ratio of alkali metal ion to niobium(V) (7). Recently a very thorough preparative study of the system K_2O–Nb_2O_5–H_2O has been carried out (8), and 10 different crystalline phases were identified.

By analogy with the alkaline tantalate solutions, it might be expected that solutions prepared by dissolving $K_{14}Nb_{12}O_{37}\cdot 27H_2O$ would also be monodisperse and contain a hexameric anion. Indeed, this has been suggested to be the case by Jander and Ertel (7) on the basis of measurements of the diffusion coefficient of the niobate species. On the other hand, these same authors had suggested earlier that tantalate solutions contained an anion with five tantalum atoms on the basis of analogous measurements (9). Recent work by Baker and Pope (10) has, however, shown that there is no theoretical or experimental basis for the assumed relation between diffusion coefficient and ionic weight used in the interpretation of Jander and Ertel's data (7, 9).

There is also definite evidence for differing behavior of the transition metals of the second and third long periods. Recent studies on sexavalent molybdenum have shown that the ions $[Mo_7O_{24}]^{-6}$, $[HMo_7O_{24}]^{-5}$, and $[H_2Mo_7O_{24}]^{-4}$ appear to exist in alkaline solutions (11, 12). In the case of tungsten, the anion $[HW_6O_{21}]^{-5}$ appears to be the main polycondensed species together with additionally protonated species with charges down to -2 (13, 14).

Rohmer and Guerchais using salt cryoscopy found a maximum degree of polymerization of 5 for niobate solutions and also concluded that the simple tetrahedral orthoniobate anion NbO_4^{-3} existed in strongly alkaline solutions (15). Although the basic theory of this experimental method has been known for 50 years there are some difficulties attending its use (16). Gridchina estimated the degree of polymerization to be 6 for solutions 2.5×10^{-3} to 2.5×10^{-2} M in niobium and 0.3 M in KOH using a dialysis method (17). Again this experimental method has proved to be erratic in the past, and there is no theoretical basis for the equation used in evaluating the data (18).

Since the studies on the tantalate solutions had indicated that the $[Ta_6O_{19}]^{-8}$ structure was a very stable one, it was decided to examine alkaline niobium solutions to see if there was any evidence for comparable stability of the analogous niobate anion. In the past, many problems have arisen in the study of such solutions, because it is now recognized that the theory used in the interpretation of the experiments was often inadequate. In recent years, there have been many refinements in the theory of multicomponent electrolyte solutions, and the use of sedimentation equilibrium in the ultracentrifuge with schlieren (19) and with interference optics (20) and the application of light scattering (21) for the study of relatively low weight inorganic polyions has been discussed. In order to make a detailed comparison of the experimental methods which all have the same thermodynamic basis, it was decided to undertake a study of the niobate solutions by all three techniques.

EXPERIMENTAL

Synthesis

Reagent grade Nb_2O_5 produced by H. C. Starch, A. G., was fused with KOH in a silver crucible to form the crude niobate. The cold melt was dissolved in a minimum amount of hot water, and the product was freed from the insoluble Ag_2O which resulted from attack on the crucible. Polyethylene vessels were used

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

throughout to avoid contamination by silicates. The partially purified product was precipitated by the addition of ethanol. This material was recrystallized several times from dilute KOH; and the crystals were dissolved in water and passed three times through a Millipore ultrafilter with a pore diameter of 4500 Å. Finally, pure crystals were precipitated with ethanol, collected on a glass frit under nitrogen, and dried in a vacuum desiccator. The infrared spectrum showed the final product to be free of ethanol and of carbonate. Niobium was determined by precipitation of the hydrous oxide from an aqueous solution of the salt with HCl. The precipitate was washed with 2% NH_4NO_3, ignited to constant weight at ca. 800° C and weighed as Nb_2O_5. Potassium was determined by precipitating the niobium with sulphuric acid, separating the hydrated Nb_2O_5 by filtration, evaporating the solution, and weighing the residue as K_2SO_4. Differential thermal and gravimetric analyses were run to determine the water of crystallization. The weight loss upon ignition was constant from 450° to 700°. Anal. Calc. for $K_{14}Nb_{12}O_{37}\cdot 27H_2O$: Nb 40.7, K 20.0, H_2O 17.8%. Found: Nb 40.7, K 19.9, H_2O 17.3%. Carbonate-free KOH solutions were prepared by precipitating carbonate with barium hydroxide and passing the solutions through the potassium form of Dowex-50W-X-8 to remove excess barium ions.

Infrared Spectra

The infrared spectrum of the potassium niobate was determined with both mineral oil mulls and KBr discs with a Perkin Elmer 21 spectrometer. The spectrum showed a sharp band at 852 cm^{-1} and broad absorption below 800 cm^{-1} with peaks at 760 and 720 cm^{-1}.

Light Scattering Measurements

The light scattering measurements were carried out as previously described (2, 22) with unpolarized 4358 Å light by using a Brice-Phoenix photometer. All measurements were made with 1 *M* KCl as the supporting electrolyte. Semioctagonal and cylindrical cells were used to determine the dissymmetry of scattering. The solutions were clarified by filtration through 0.10 μ Gelman ultrafilters in a stainless steel system under nitrogen pressure. Each sample was passed through the filter from 5 to 10 times and was discarded if any trend was observed in the turbidities from filtration to filtration. There was no measurable depolarization of the light scattered at 90°.

Sedimentation Equilibrium in the Ultracentrifuge

The experimental procedure was essentially that of Johnson and co-workers (23, 24). The centrifugations were carried out with a Spinco Model E ultracentrifuge using an Analytical "D" rotor. The optical systems standard with the instrument were used. Only one solution in a 12 mm cell was spun at a time. The temperature was controlled to 25±0.1° and the rotor speed to ±15 r.p.m. with accessories available for the centrifuge. All plates were read with a Bausch and Lomb microscope sliding scale comparator. The 5461 Å mercury line isolated with a Wratten 77A filter was used for all measurements. Density measurements were made with a 2 ml pycnometer. The data are summarized in Table I.

Schlieren Measurements

Schlieren patterns were taken at various bar angles between 60° and 85° and were recorded on Eastman Kodak I-N spectroscopic plates. Values of Z, the vertical displacement of the bar image caused by the refractive index gradient in the cell, were tabulated as a function of x, the radius from the center of rotation. Attainment of equilibrium was assured by observing images from day to day and noting the time at which no further change took place. Most of the runs had durations of from 40 to 70 hours. In addition to the centrifugation of the niobate in 1 *M* KCl, a background centrifugation was carried out on 1 *M* KCl. The difference between Z for the solution containing niobate + KCl and the Z for 1 *M* KCl gave Z^* from which the distribution of the polymeric niobate could be calculated.

Interference Optics

Interference optics have the advantage of permitting smaller amounts of solution to be used in the cell so that the distance from the meniscus to the cell bottom is reduced. As a result, equilibrium is much more rapidly attained. In addition, the precision in the determination of the refractive index gradient for a given run is considerably greater so that measurements can be made with more dilute solutions. The Rayleigh interference patterns were recorded on Eastman Kodak II-G spectroscopic plates with high green sensitivity. The plates were read by lining up the fringes, using the air reference fringes, and the distances between "vertical" fringes from the meniscus to the cell bottom were measured. From these measurements, the difference in refractive index between the solution and background compartments at different values of x can be calculated. In some cases, a series of photographs of the fringe pattern was taken throughout the run so that the position of a given fringe could be followed. From these data the absolute values of the refractive index differences at the various x values, n^*, could be obtained in the following way. From the movement of the fringes with time, the point where a given fringe at equilibrium would intersect the "reference fringe," i.e., the position of the fringe before sedimentation, could be noted. At this point the difference between the refractive indices of solution and background compartments is equal to the initial and known difference before sedimentation took place. Since the difference in refractive index between fringes is known, n^* values can be tabulated for the points corresponding to a fringe intersection with the "reference fringe." In most

[c]Bar angle.

cases, the values of n^* were obtained by an integrative procedure which only required values of the difference between the refractive index at the meniscus and at several values of x. The x values corresponded to points of intersection of the curved solution fringes with a reference fringe picked arbitrarily to pass through the meniscus and to intersect a curved fringe. Cell distortions for the interference cell were determined by centrifugations with both compartments filled with water, and fringe deviations from the horizontal were noted as a function of angular velocity. The distortions were found to be very small with our cell, and at speeds under 20,000 r.p.m. they never exceeded 0.1 fringe interval.

Since the solutions were alkaline, Kel-F single-sector and charcoal-filled Epon double-sector centerpieces rather than the usual aluminum-filled centerpieces were used with the usual quartz windows. The difference in refractive index between compartments corresponding to one fringe interval was determined with a capillary-type synthetic boundary cell and found to equal the value predicted from the instrument constants. Solution column thicknesses were determined by measuring the distance between the outer faces of the quartz windows with a micrometer and subtracting the known thicknesses of the quartz windows.

Unfortunately, it was necessary to vary the speed over a wide range as the concentration was varied in order to obtain good interference patterns in all cases.

Ion Exchange Measurements

Initial attempts to bind the anionic niobium(V) species to the hydroxide form of Dowex 2-X-8 were unsuccessful. Apparently the degree of cross-linking was too high to permit diffusion of the large niobate anion into the resin, and when the less highly cross-linked Dowex 2-X-4 was used, the niobate was bound quantitatively. The column was washed with distilled water, and the hydroxide ion in the eluate was titrated with standard acid. The equilibrium solution pH was measured with a Beckman H pH meter.

RESULTS

Light Scattering

Since the refractive index increments for the niobate solute were needed for both the light scattering and centrifugation with interference optics, these were obtained from measurements on solutions with known concentrations of KOH and KCl. The contributions of the latter two compounds to the gross Δn values could be calculated by using

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

known refractive index increments of KOH and KCl solutions, and these were subtracted from the gross Δn to give the Δn due to niobate. A plot of the Δn due to the niobate solute versus the niobate concentration is shown in Fig. 1 for the two wavelengths 4358

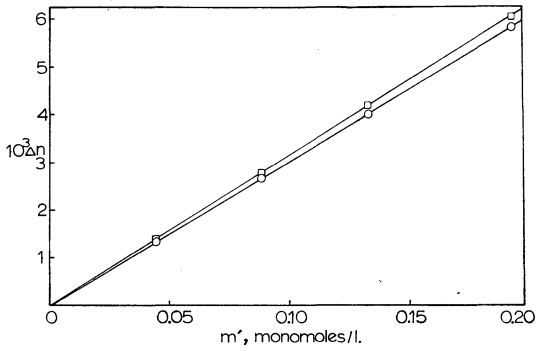

FIG. 1. Refractive index of the niobium(V) solutions as a function of concentration; □ 4358 Å, ○ 5461 Å.

and 5461 Å. The values for dn/dm' for the niobate in solutions 1 M in KCl were 0.0314 and 0.0301 l. monomole^{-1} at 4358 and 5461 Å respectively. The linearity of these plots tends to indicate that there are no condensation reactions leading to larger polycondensed species occurring as the concentration increases.

In order to verify that there were no significant contributions to the 90° scattering from colloidal particles, the angular dependence of the scattering was investigated from $\theta = 45$ to 135°. Typical data are illustrated in Fig. 2, which shows the normalized scattering

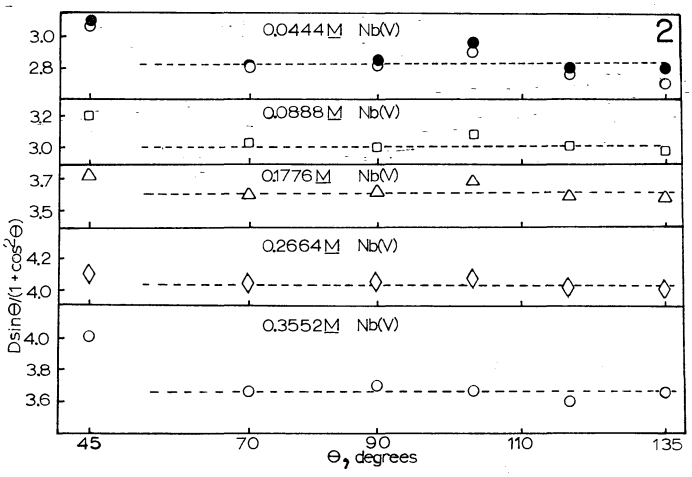

FIG. 2. Angular dependence of the light scattering of the niobate solutions.

envelope obtained by multiplying the observed galvanometer deflections by $\sin\theta/(1+\cos^2\theta)$. The 90° turbidities proved to be essentially the same as those obtained by extrapolation from larger angles.

The experimental turbidity data were used to compute the values of the deviation function (22) given in equation [1] for different values of the charge per monomer unit, Z'.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$$1/N_{z'} = \frac{\phi H'' \psi'^2 m'}{\tau^*} - \frac{Z'^2 m'}{2(m_3 + m_5)} \qquad [1]$$

Here, $N_{z'}$ is the number of monomer units (niobium atoms) contained in the polyanion, m' is the niobium concentration in monomoles per liter, ψ' is the value of dn/dm' for the monomeric scattering component, H' is a constant, ϕ is the volume fraction of solvent computed for 1 M KCl, and m_3 and m_5 are the concentrations of KCl and KOH respectively. The concentrations of KOH were sufficiently small in all of the solutions to be neglected.

In order to carry out these calculations, it is necessary to define a hypothetical "monomer" unit which contains one niobium atom and which has the proper stoichiometry. Since the compound $K_{14}Nb_{12}O_{37} \cdot 27H_2O$ used in preparing the solutions is obtained by crystallization from aqueous solution, the monomer unit is defined as $[K_{\bar{\nu}}H_{0.17}NbO_{3.17} + (1.17-\bar{\nu})K^+]$ with formula weight $M = 189.55$. In addition, the average value of the charge of the niobate species was determined from the ion exchange measurements coupled with pH measurements of the niobate solutions by using the relation $Z_{av} = ([OH]_{total} - [OH]_{eq})/[Nb]_{total}$. The values $Z_{av} = 0.111$, 0.112, and 0.113 were obtained from three separate determinations, and these are in fairly good agreement with the maximum value assumed above. In the definition of the monomer unit, the electrically neutral unit is written with $\bar{\nu}$ potassium ions to allow for a reduction in the effective average charge on the ion from the maximum value of -1.17. The monomeric *component* is then $K_{(1.17-\bar{\nu})}[K_{\bar{\nu}}H_{0.17}NbO_{3.17}] - (1.17-\bar{\nu})KCl/2$ with a formula weight $M' = M - Z'M_{KCl}/2$; $Z' = (1.17-\bar{\nu})$.

It is necessary to determine both the degree of polymerization, N, and the effective charge per monomer unit, Z', simultaneously from the experimental data (21). This was done graphically, and Fig. 3 shows $1/N_{z'}$ as a function of Z' with concentration as a

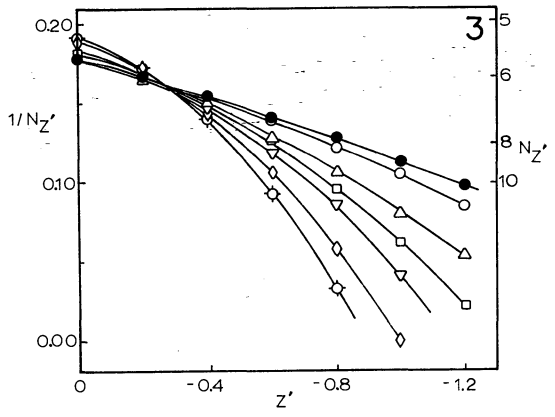

FIG. 3. Light scattering determination of $1/N_z$, as a function of Z' with concentration as parameter; special ○ 0.354 M, ◇ 0.266 M, ▽ 0.177 M, □ 0.133 M, △ 0.0888 M, ○ 00.0444 M, ● 0.0266 M Nb(V).

parameter. From the point of intersection of the curves, the value of N is obtained as ca. 6 and the charge per monomer unit $Z' = -0.3$. The data are very similar to those obtained for tantalate solutions and indicate that the polycondensed niobate species has the approximate formula $[HNb_6O_{19}]^{-7}$ and that the charge is reduced by the binding of potassium ions to ca. -2. It should be noted that the "effective" charge Z' determined

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

by light scattering measurements is generally lower than the value obtained, for example, from electrophoresis (25).

Ultracentrifugation

The schlieren data were evaluated in the usual manner (26). The components are defined as in the light scattering analysis, and N and Z' are the same. Once again a simultaneous determination of the degree of polymerization and the effective charge must be made. The experimental data $\ln Z^*/x(x)$ were plotted to determine graphically the value of $\underline{S}_e = d \ln (Z^*/x)/d(x^2)$. In all cases, essentially straight lines were obtained, and this indicates that the system is monodisperse. This is shown in Fig. 4 where the data are

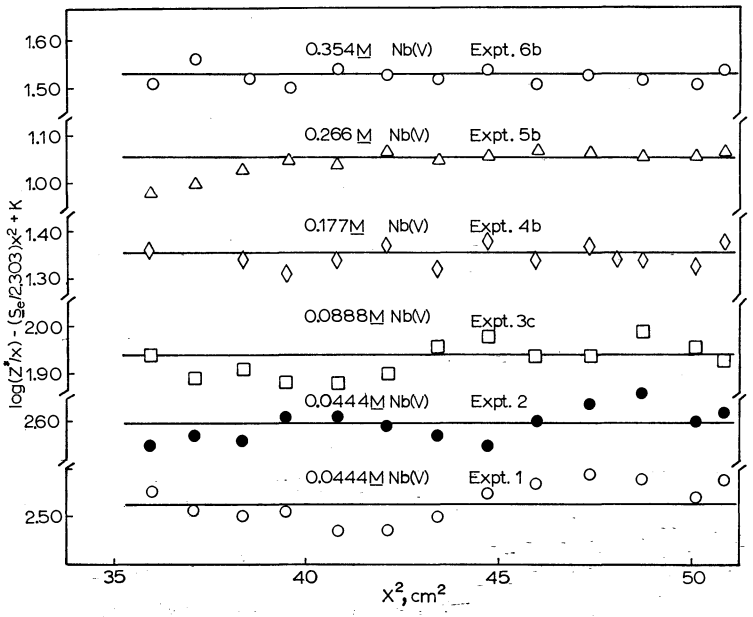

FIG. 4. Test of constancy of S_e for the schlieren ultracentrifugation data.

presented as the deviation functions $(\log Z^*/x) - \underline{S}_e x^2/2.303 + K$. Here K is an arbitrary constant used to normalize the values to ca. 1 to 2.

The degree of polymerization was calculated as a function of charge from equations [2] and [3].

$$d \ln m'/d(x^2) = S = S_e + \frac{\frac{Z'^2 m'}{2A'm_3}(S-\sigma)^2}{1 + \frac{Z'^2 m'\sigma}{2A'm_3}} \qquad [2]$$

$$N_{z'} = \frac{S}{A' - \frac{Z'^2 m'}{2m_3}(S-\sigma)} \qquad [3]$$

Here $A' = M'(1-\bar{\nu}'\rho)\omega^2/2RT$ where ρ is the solution density, ω is the angular velocity, and $\bar{\nu}' = (M\bar{V}_{\text{niobate}} - Z'M_{KCl}\bar{V}_{KCl}/2)/M'$. The apparent molal volume ϕ_{niobate} for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

niobate was determined to be essentially independent of concentration and had the value 27.5 ml, which was used for the partial molal volume $\bar{V}_{\text{niobate}}$. The value of $\sigma = d \ln m_3/d(x^2)$ was calculated from the relation $\sigma = M_{KCl}(1-\bar{\nu}_{KCl}\rho_{KCl})\omega^2/4RT$. The centrifugation data are tabulated in Table I, and Fig. 5 shows $1/N_{z'}$ as a function of Z' with con-

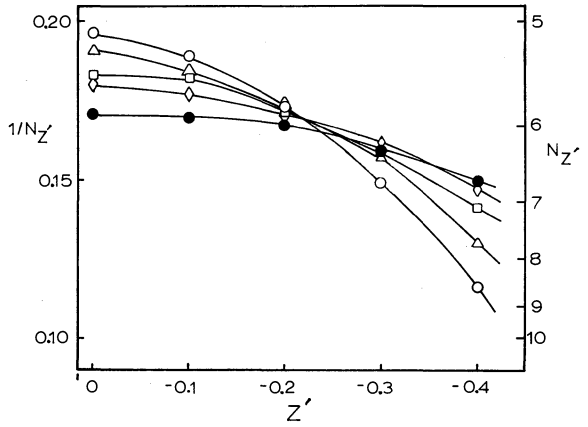

FIG. 5. Schlieren ultracentrifugation determination of $1/N_{z'}$ as a function of Z' with concentration as a parameter; ● 0.0444 M, ◇ 0.0888 M, □ 0.1776 M, △ 0.2664 M, ○ 0.3552 M Nb(V).

centration as the parameter for comparison with the light scattering data in Fig. 3. The results of the two different methods of determination are very similar, and the values $N = 5.8$ and $Z' = -0.2$ are obtained from the centrifugations.

The interference optics data were treated as suggested by Johnson, Scatchard, and Kraus (20). In general, the values of the refractive index differences between the solution and background compartments, n^*, as a function of the radius, x, were calculated by an integration procedure using equation (4) to compute the equilibrium value of n^* at the meniscus, n_α^*.

$$(\psi' m_0' + \psi_3 m_{3(0)} - \psi_3 m_{bg0}(x_\omega^2 - x_\alpha^2) = n_\alpha^*(x_\omega^2 - x_\alpha^2) + \int_\alpha^\omega (n^* - n_\alpha^*) d(x^2) \qquad [4]$$

Since the differences $(n^* - n_\alpha^*)$ were determined from the Rayleigh patterns, the value of n^* at the different points in the cell could then be calculated. Here $m_{3(0)}$ is the initial concentration of component 3, KCl, in the solution compartment and m_{bg0} is the initial concentration in the background compartment. Essentially the same values were obtained by this procedure as by following a fringe throughout the centrifugation. The refractive index data were then used to compute values of $\eta = Z'm'/2m_3$ by solving the quadratic equation [5] derived by Johnson *et al.*

$$(1-\eta^2)(1-\eta_0+\Delta)^2(n^*+\psi_3 m_{bg}^{\pm})^2 = m_{bg}^2(1-\eta_0^2)[2\psi'\eta/Z' + \psi_3]^2 \qquad [5]$$

Here η_0 is the initial value of η, $m_{bg}^{\pm}$ is a corrected background concentration to take into account the unsymmetrical location of the slits in the Spinco optical system, and $\Delta = (m_{bg0} - m_{BX0})/m_{30}$. The distribution of solutes is then obtained from equations [6] and [7].

$$m_3 = \frac{n^* + \psi_3 m_{bg}^{\pm}}{2(\psi'\eta/Z') + \psi_3} \qquad [6]$$

$$m' = 2m_3\eta/Z' \qquad [7]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The data ln m' and ln $(1+\eta)/(1-\eta)$ as functions of x^2 were fitted by a least squares procedure using equal weights to determine the slopes $S = d \ln m'/d(x^2)$ and $d \ln (1+\eta)/(1-\eta)/d(x^2)$. The values of the slope S were quite constant, and the precision of the measurement for a given run was considerably greater than in the case of the schlieren optics. The primary data are presented as the deviation function ln $n^* - \underline{S}(x^2)$ where $\underline{S} = d \ln n^*/d(x^2)$ in Fig. 6. Finally the values of the degree of polymerization as a function

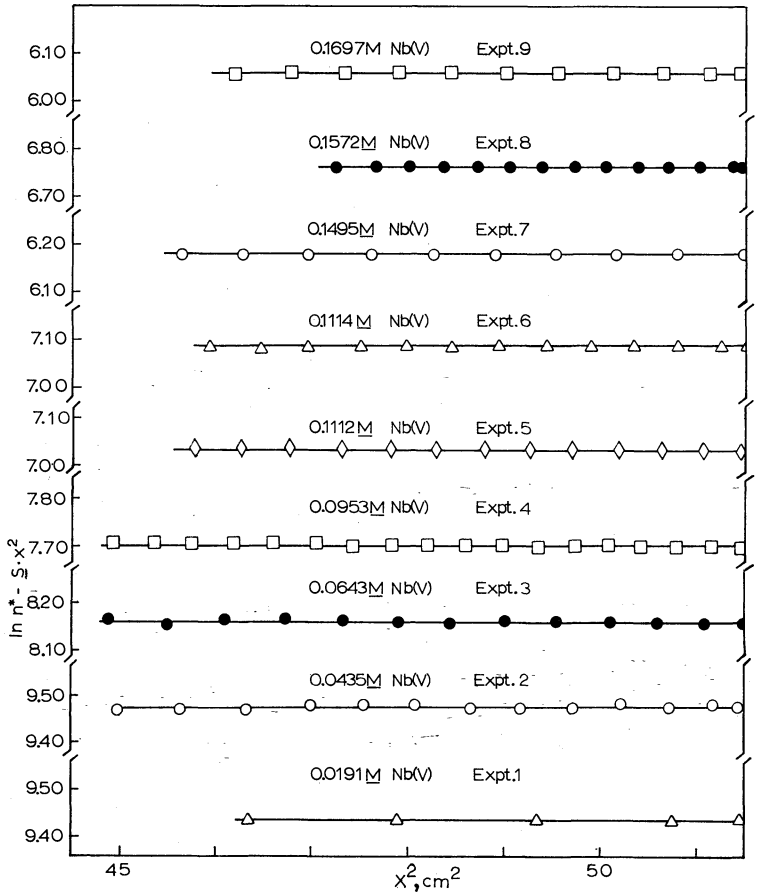

FIG. 6. Test of constancy of S for the interference optics centrifugation data.

of the charge were computed with equation [8].

$$N_{z'} = \frac{S}{A' - \frac{Z'}{2} d \ln [(1+\eta)(1-\eta)]/dx^2} \qquad [8]$$

The entire calculation was programmed in Fortran 60 for the Control Data Corporation 1604 computer at the University of Minnesota.[3] The data are tabulated in Table I and are again displayed in Fig. 7 as $1/N_{z'}$ as a function of Z' with concentration as the parameter for purposes of comparison with the light scattering and schlieren centrifugation

[3]*The complete deck listing, duplicate decks, and a flow sheet for this program ULTRACEN may be obtained by writing R.S.T.*

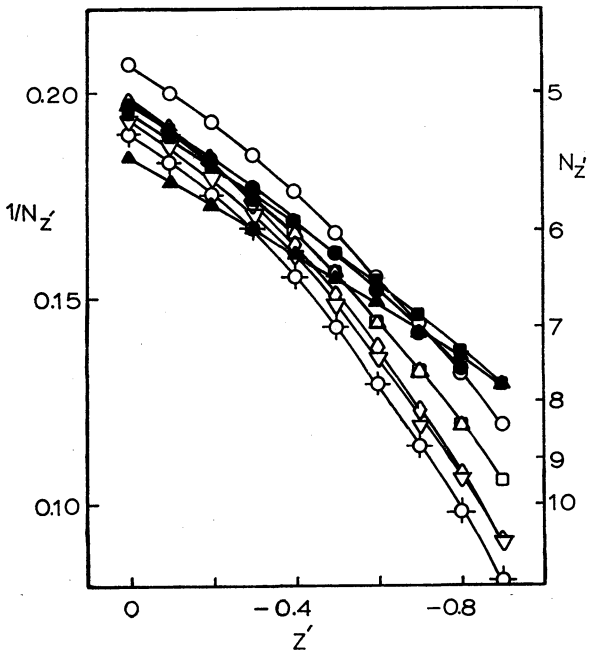

FIG. 7. Interference optics centrifugation determination of $1/N_{z'}$ as a function of Z' with concentration as a parameter; special ○ 0.1697 *M*, ◇ 0.1572 *M*, ▽ 0.1495 *M*, □ 0.1114 *M*, △ 0.1112 *M*, ○ 0.0953 *M*, ● 0.0643 *M*, ■ 0.0435 *M*, ▲ 0.0191 *M*, Nb(V).

data. Although the values of the slope S in the interference optics experiments could be determined much more accurately than the corresponding experimental quantity S_e in the schlieren experiments, the reproducibility of the $1/N_{z'}$ versus Z' curves was only fair. In some cases, the changes in S with concentration were not even in the correct direction. Part of the trouble may have been caused by the large changes in the speeds required in order to obtain good interference patterns as the concentration was changed, causing slightly different amounts of distortion of the cells. Distortions were, however, observed to be very slight. Pronounced experimental difficulties with leakage between the two solutions in the double compartment cell were also encountered initially. Although the curves are similar to those obtained by the other measurements and the degree of polymerization N has a value of ca. 5.4 and 5.8 at $Z' = -0.2$ and -0.3, respectively, it is considerably more difficult to determine the correct value of Z' from these measurements. When using interference optics, the measurements are also very susceptible to errors resulting from slight inaccuracies in the supporting electrolyte concentration in the two compartments. This is especially troublesome when working with dilute polymer solutions and high supporting electrolyte concentrations such as the 1 *M* KCl employed here.

DISCUSSION

The results obtained in these experiments are very similar to those obtained in the light scattering studies on alkaline tantalate solutions (2) which have also recently been confirmed by both schlieren and interference optics centrifugations (27). The agreement among the three experimental methods used here is also good, and in all probability the solute contains six niobium atoms and certainly no fewer than five. The data also indicate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

that there is but one polycondensed anion present in the solutions rather than a series of species with different degrees of polymerization. All things considered, it seems unlikely that such measurements as these can be considered accurate to better than about ±10%.

Although the light scattering measurements are intrinsically simpler from the experimental standpoint, the very large amount of time involved in removing large impurity particles by ultrafiltration makes the centrifugation experiments preferable. The light scattering results provide a valuable confirmation of the centrifugation data. In the derivation of the equations used in the analysis of both the light scattering and sedimentation equilibrium experiments, it is assumed that the polymeric solute is monodisperse, i.e., that a single poly-ion is present. In some of the centrifugations quite large concentration gradients are established, and it is conceivable that this could cause a gradation in the degree of polymerization from one end of the cell to the other with labile species. It is also quite likely that this would be detected from deviations in the linearity of the plots used to determine $\underline{S}_e$ and S. That this was not the case here is clearly shown by the data in Figs. 4 and 6. In addition with the centrifugation calculations, it is necessary to know the formula weight of the monomer unit. In general, the stoichiometry of the solute species will be known from independent measurements on the solute and (or) solution. In the case of the polycondensed species with oxygen bridges, these measurements often do not distinguish between a single oxo group and two hydroxo groups in a complex. With the polycondensed species formed from metals in high oxidation states but which have low net charges, the difference in M' between the oxo and the hydroxo complexes could be appreciable. This in turn affects the value of A' used in calculating the degree of polymerization, although the effect is partially compensated by the changes in the partial specific volume $\bar{v}'$. With light scattering measurements, no comparable assumption need be made. Since structural studies on crystals of the iso- and heteropolyions of the groups V and VI elements have generally indicated that these are built up of octahedra formed from the transition metal and six oxo groups, the dehydrated form of the niobate monomer unit, $(NbO_{3.17}]^{-1.33}$ was assumed as the basic unit. Since both the stoichiometry of the $K_{14}Nb_{12}O_{37}\cdot 27H_2O$ crystals and the value of the average charge per niobium atom determined from the ion-exchange measurements indicated that there was some protonation of the above unit, the anion monomer was taken as $[H_{0.17}NbO_{3.17}]^{-1.17}$.

In comparing the results of the study of the niobate species with the earlier work on tantalum (2), it is apparent that charge effects are slightly less pronounced with the niobate; and the value determined for the "effective" charge is also slightly lower with the niobate. This is qualitatively in accord with the stoichiometry of the crystals obtained from aqueous solution where the tantalate appears to be unprotonated as $[Ta_6O_{19}]^{-8}$ while the niobate is protonated to give $[HNb_6O_{19}]^{-7}$. It is also in accord with the determination of the average charge per niobium in solution from the ion exchange which gave the value 0.112. In general, the effective charge as determined from ultracentrifugation appears to be rather lower than the actual charge on the species as has been found to be the case from the light scattering analysis (25). Thus the species $[Bi_6(OH)_{12}]^{+6}$ has an effective charge of ca. +4 as determined by ultracentrifugation (20) and also by light scattering (22).

It seems very likely that the same structural unit which exists in the niobate and tantalate crystals, i.e., the polycondensed anions with cubic symmetry $[Nb_6O_{19}]^{-8}$ and $[Ta_6O_{19}]^{-8}$ respectively, also persist when these crystals are dissolved in water. The lack of any depolarization of the light scattered at 90° is in accord with the existence of a species with high symmetry. This structure is illustrated in Fig. 8. There certainly do not appear to be any larger condensed species present in the solutions. Large symmetrical

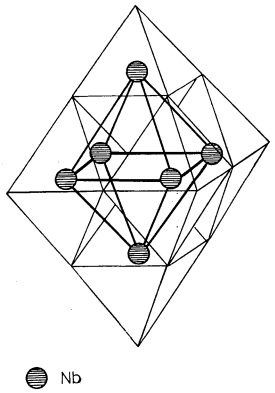

FIG. 8. Structure of the hexaniobate anion.

isopoly-ions such as these appear to behave much like the large heteropoly-ions such as the 12-tungstosilicate anion interacting only weakly with the solvent so that quite concentrated solutions can be obtained. The structural chemistry of niobium and tantalum is very different from that of phosphorus, and there is no evidence for the formation of chains and open ring structures.

The bonding in the hexatantalate anion has been discussed earlier (2), and it seems likely that pi-bonding to the six peripheral oxygens lowers the electron density at these oxygens, making them less susceptible to protonation or to functioning as bridges to give larger polycondensed species. The existence of the band in the infrared spectrum of crystalline $K_{14}Nb_{12}O_{37}\cdot 27H_2O$ at 852 cm^{-1} tends to indicate some metal–oxygen double bond character (27), although the vibration is at a considerably lower frequency than the band at 965 cm^{-1} found in $K_8Ta_6O_{19}\cdot 16H_2O$ or that at 906 cm^{-1} recently assigned to the Nb=O bond in $NbO(NO_3)_3$ (29). Bands attributed to niobium–oxygen double bonds are also found at 922 cm^{-1} in K_3NbOF_6 and at 927 cm^{-1} in $K_2NbOF_5\cdot H_2O$. The highest frequency band in $NbOCl_3$ is at 769 cm^{-1} and is attributed to Nb—O—Nb bridges.

It is interesting that the older semiempirical methods of determining the degrees of polymerization based on diffusion (7), dialysis (17), and salt cryoscopy (15) do appear to give approximately the correct values for the niobate. The latter method has essentially the same thermodynamic basis as the light scattering and equilibrium centrifugation measurements (16). It should also be pointed out that although the light scattering and centrifugation experiments may appear to give N and Z' quite precisely, very much depends on the behavior of the one or two most concentrated solutions. When charge effects are not pronounced, e.g. Figs. 3, 5, and 7, the determination of the intersection point depends largely on the most concentrated solutions, for the curves at concentrations $\leqslant 0.1\ M$ are all very similar. This also removes one of the main advantages of the measurements with interference optics, that of the use of low concentrations of the polymeric solute, since the value of Z' cannot then be easily determined. In some cases it has been necessary to assume values of Z' in order to interpret such measurements (20).

ACKNOWLEDGMENTS

The authors would like to express their appreciation to Professor Rufus Lumry for assistance in making the centrifugation measurements and to Mr. Norman Sweeney of

N,N-DIACETYLAMINES AS BY-PRODUCTS FROM THE ACETYLATION OF AMINES[1]

R. A. B. BANNARD
Defence Research Chemical Laboratories, Ottawa, Ontario
and
Department of Chemistry, University of Ottawa, Ottawa, Ontario

Received October 3, 1963

ABSTRACT

Acetylation of five alicyclic amines and isopropylamine with a large excess of acetic anhydride for 1 hour under reflux led to formation of appreciable yields (23–35%) of N,N-diacetylamines in addition to the anticipated N-acetylamines, except in the case of *cis*-2-aminocyclohexanol, which gave only the O,N-diacetyl derivative. The N-acetyl derivatives show an acetamido methyl proton resonance in their nuclear magnetic resonance spectra at 8.04–8.09 τ, whereas the N,N-diacetylamines show no absorption in this region but instead a resonance equivalent to six protons at 7.63–7.69 τ due to the N,N-diacetyl group. The infrared spectra of these compounds are consistent with the structures assigned on the basis of their n.m.r. spectra. Splitting of the amide carbonyl band was not generally observed in these compounds although two of the substances exhibited a minor band on the low frequency side of the main band which might be attributed to this cause.

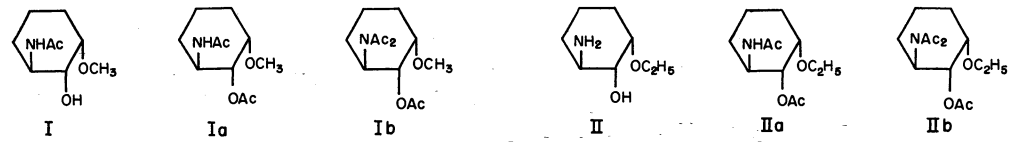
During the preparation of the acetyl derivatives of a series of 1-alkoxy-2-hydroxy-3-aminocyclohexanes for examination of their nuclear magnetic resonance (n.m.r.) spectra (1), it was found that treatment of 1α-methoxy-2α-hydroxy-3β-acetylaminocyclohexane (I) and 1α-ethoxy-2α-hydroxy-3β-aminocyclohexane (II) with a large excess of acetic anhydride under reflux for 1 hour gave appreciable yields (37–48%) of the O,N,N-triacetyl derivatives I*b* and II*b* in addition to the anticipated O,N-diacetyl compounds



I*a* and II*a*. The formation of N,N-diacylamines during uncatalyzed reaction between aromatic amines and aliphatic acid anhydrides is well known (2) but few examples of diacylation of aliphatic amines under similar conditions have been observed (see, however, ref. 3). This circumstance is somewhat surprising because the formation of diacylamines by the acid-catalyzed acylation of amines (4, 5) and the formation of imides by uncatalyzed (6) and acid-catalyzed (7, 8, 9) acylation of primary amides has been reported, and it does not seem unreasonable to expect the secondary amide resulting from monoacylation of an amine to undergo further acylation to at least some extent. It seemed possible, therefore, that under rather vigorous conditions by which I*b* and II*b* were formed—which were essentially the same as found by Sudborough (2) to produce significant amounts of N,N-diacyl aryl amines—other alicyclic and aliphatic amines would also yield diacetylamines as major by-products.

Accordingly, acetylation of the six amines shown in Chart I was examined under conditions identical with those used earlier (1) with compound II. The results given in Table I* show that with all but one of these compounds, namely, *cis*-2-aminocyclohexanol, such

[1]*Issued as D.R.C.L. Report No. 422.*

**Note: IIIa* = N-*Acetyl derivative of III; IIIb* = N,N-*diacetyl derivative of III, etc. Under these conditions hydroxyl groups were also acetylated.*

conditions lead to formation of 23–35% of the N,N-diacetyl derivative in addition to 76–65% of the normal N-acetyl compound. It is therefore concluded that acetylation of aliphatic and alicyclic as well as aromatic amines in this manner can be expected to yield significant amounts of the N,N-diacetylamines. In each instance, the N,N-diacetyl compound boiled at a lower temperature than the corresponding N-acetyl derivative, as might have been predicted from the lack of an available proton for intermolecular hydrogen bonding in the former.

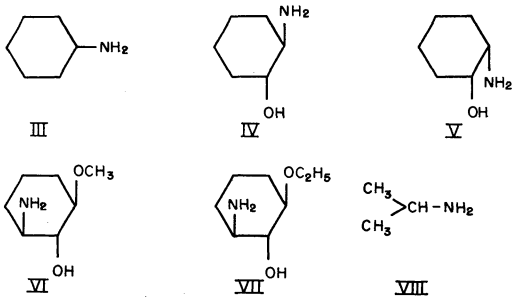


CHART I

In general, the total yield of N-acetylated compounds was 98% or higher† and thus no evidence of nitrile formation was obtained. This result contrasts with the results of Davidson and Skovronek (9), who observed the formation of large quantities of nitrile together with small amounts of imide by interaction of primary amides with acid anhydrides in the absence of acid catalysts. Consequently, the O-acetylation O → N migration mechanism advanced by these workers to explain their product distribution is not necessary to account for the products resulting from the present experiments, which are readily accommodated by the general mechanism for reaction of nucleophiles with anhydrides proposed by Denney and Greenbaum (10).

As in the case of compounds I*b* and II*b* described earlier (1), the structures of the N,N-diacetyl derivatives resulting from acetylation of compounds III to VIII were established from consideration of the n.m.r. and infrared spectra of the products.

In the n.m.r. data, which is summarized in Table II, all the N-acetyl derivatives exhibit a broad doublet at 3.17 to 4.20 τ, which disappears on deuteration by equilibration with deuterium oxide, and which owes its origin to the NH proton coupled with that attached to an adjacent carbon atom. The N,N-diacetyl compounds, on the other hand, show no resonance in this region. The N-acetyl derivatives show an acetamido methyl proton resonance at 8.04 to 8.09 τ, whereas the N,N-diacetyl compounds show no resonance in this region but instead exhibit resonance equivalent to six protons at 7.63 to 7.69 τ, which is assigned to the N,N-diacetyl group.

In the cyclohexane compounds, introduction of the second acetyl group on nitrogen causes the H_2 multiplet to shift to lower field by 0.7–0.9 p.p.m. and H_1 to shift to lower field by ca. 0.2 p.p.m., presumably due to the diamagnetic anisotropy of the newly introduced acetamido carbonyl group. It was reported earlier (1) that acetoxy-methyl protons in the equatorial orientation in cyclohexane derivatives show a resonance at 7.90 to 7.99. Reference to Table II makes it clear, however, that two ranges can be quoted for such

†*The one exception to this statement was provided by the first experiment of the series in which manipulative losses were much greater than in subsequent experiments.*

substituents, depending on whether the adjacent carbon atom bears an N-acetyl (7.90–7.96) or an N,N-diacetyl (7.97–8.04) group.

The $J_{1,2}$ and $J_{2,3}$ coupling constants of the N,N-diacetyl compounds were identical within experimental error with those found for the N-acetyl derivatives and the remarks made previously (1) with regard to the magnitude and variation of the coupling constants in relation to the Karplus equation (14) again apply.

Introduction of the second acetyl group into isopropylacetamide causes the resonance of the doublet due to the methyl protons of the isopropyl group to shift to lower field by 0.8 p.p.m. It thus appears that the large shift in the resonance of the multiplet due to a proton on the carbon atom adjacent to that bearing the acetamido group caused by introduction of the second acetyl group on nitrogen, which was observed in the 1,2,3-trisubstituted cyclohexanes, is also characteristic of acyclic amines.

The principal infrared absorption frequencies (exclusive of the C—H stretching region) observed for the N-acetyl- and N,N-diacetyl-amines in 0.05 *M* solution in carbon tetrachloride, together with their assignments (15, 16), are given in Table III. The N-acetyl derivatives show bands at ca. 3400 and 3300 cm^{-1} due to non-bonded and bonded N—H. The latter absorption disappeared in all cases on dilution, indicating that the bonding is of the inter- rather than the intra-molecular type (16, p. 517). The N,N-diacetyl compounds, on the other hand, exhibit no N—H absorption. The amide I absorption at 1680 ± 3 cm^{-1} in the N-acetyl compounds was shifted to 1699 ± 3 cm^{-1} in the N,N-diacetyl compounds in accordance with expectation for introduction of a second electrophilic substituent on the amide nitrogen (18). The amide II absorption at 1501 ± 4 cm^{-1} in the N-acetyl derivatives was absent from the N,N-diacetyl derivatives. All the compounds showed absorption at 1360–1370 cm^{-1} characteristic of the C—H bend in the acetyl methyl group (19). In agreement with this assignment, the intensity of this band increased as the degree of acetylation increased. Those compounds which contained O-acetyl groups showed absorption at 1218–1235 cm^{-1} (20) and at 1010–1049 cm^{-1} (17) due to C—O stretching modes of the acetate group. All these compounds gave a single prominent band at 1218–1235 cm^{-1}, which could be construed as evidence (20) that all the acetoxy groups are in the equatorial orientation, in agreement with the n.m.r. evidence derived from the substituent resonances and coupling constants reported earlier (1). It should be pointed out, however, that these bands are considerably broader than those given by equatorial acetoxy groups in steroids (20) and the appearance of shoulders near the band in several instances possibly detracts from the usefulness of this absorption for assignment of conformation to acetoxy groups in cyclohexane derivatives in the absence of other supporting evidence. The broadening of the band at 1218–1235 cm^{-1} and (or) the appearance of shoulders in some cases could owe its origin to a C–N amide III absorption which is sometimes found in this region (16, p. 220). Some evidence in support of this view was given by compounds III*a*, III*b*, VIII*a*, and VIII*b*, which contain no O-acetyl group yet exhibit medium to weak absorption at 1212–1240 cm^{-1}. Only the examination of a series of similar compounds in which the acetoxy groups have been shown unequivocally to occupy an axial orientation will clarify the usefulness of the acetoxy C—O absorption for assignment of conformation.

Several years ago Abramovitch (21) found that N,N-diacetyl compounds exhibit more than one carbonyl band in chloroform solution when examined at sufficiently slow chart speeds and narrow slit schedules. The effect was more noticeable in ca. 0.25 *M* solution than in ca. 0.05 *M* solution. Examination of the N,N-diacetyl compounds described herein in 0.05 *M* and 0.25 *M* solution in carbon tetrachloride at chart speeds as low as

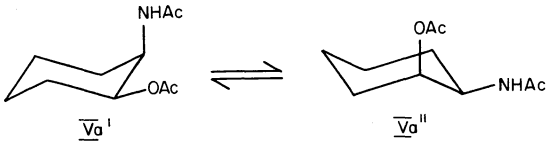
*Nolin and Jones (19).
†Jones and Herling (17).
‡Possibly due to C—N stretch in N-acetyl (amide III (16, p. 220)). s = Strong, m = medium, w = weak.

25 cm^{-1} per minute and a spectral slit width as low as 1.5 cm^{-1} (Perkin–Elmer model 421) did reveal the presence of very low intensity shoulders on the amide carbonyl band in some cases, but in only two compounds was the band resolved. It is therefore concluded that not all diacylamines exhibit multiplicity of amide carbonyl bands as reported earlier (21).

It was noted earlier that *cis*-2-acetamido-1-acetoxycyclohexane (V*a*) is the sole product resulting from the uncatalyzed reaction between *cis*-2-aminocyclohexanol and acetic anhydride. It was at first thought that this behavior might owe its origin to the circumstance that V*a* exists as an equilibrium mixture of conformers V*a*′ and V*a*″, in which the former predominates. If such were the case, the rate of formation of the O,N,N-triacetyl



Va′ Va″

derivative could be much slower than in the corresponding trans isomer in which both substituents are equatorial (22). However, extending the period of reflux on interaction of V with acetic anhydride by a factor of three produced no evidence for the presence of an O,N,N-triacetyl derivative by n.m.r. examination of the product and it was concluded that such an explanation is unsatisfactory. A second possible explanation for failure of the N,N-diacetyl compound to form from V*a* is that the proton attached to nitrogen in the latter is firmly held by intramolecular hydrogen bonding to the carbonyl oxygen of the acetoxy group. Although V*a* exhibited both non-bonded and bonded N—H vibrations at 3415 and 3320 cm^{-1} in 0.05 *M* solution in carbon tetrachloride, dilution caused the bonded vibration to disappear, indicating it to be of the inter- rather than the intramolecular type. Alternatively, it is suggested that further acetylation of the amide nitrogen may be prevented in V*a* by intramolecular interaction between the nitrogen atom and the cis ester carbonyl group. Such an interaction would not be expected to occur as readily in the trans derivative and for this reason di-N-acetylation may proceed in this case. No experimental evidence directly supporting this suggestion was obtained in the present study, however, and further work is planned to elaborate the reason for this difference in behavior between cis- and trans-1,2-aminocyclanols toward acetic anhydride.

EXPERIMENTAL[2,3]

trans-2-Aminocyclohexanol (IV)

trans-2-Aminocyclohexanol was prepared as described by Hawkins and Bannard (23).

cis-2-Aminocyclohexanol (V)

trans-2-Acetylaminocyclohexanol (IV*a*) (7.38 g, 0.047 mole) (12, 23) was added portionwise with mechanical stirring over a period of 15 minutes to thionyl chloride (42.4 g, 0.356 mole) at room temperature, contained in a three-necked flask equipped with a "trubore" stirrer and reflux condenser which was protected with a calcium chloride tube. The resultant light red solution was heated with stirring at 52–54° for a further 2½ hour, then poured into anhydrous ether (700 ml). The deep red oil which separated crystallized rapidly on standing at room temperature, changing in color to grayish-white. The ether was decanted, 10% hydrochloric acid (125 ml) was added, and the solution was heated under reflux for 5 hours. The solution was taken to dryness *in vacuo* and residual water was removed by azeotropic distillation with benzene and ethanol. The residue was recrystallized from ethanol, yielding 4.72 g (67.5%) of *cis*-2-aminocyclohexanol hydrochloride as colorless needles, m.p. 189–191°. McCasland *et al.* (12) report m.p. 189–190°. This method

[2]*All melting points and boiling points are uncorrected.*

of preparation is somewhat more efficient than the similar procedure starting from *trans*-2-benzoylaminocyclohexanol which was reported by Johnson and Schubert (24).

The above hydrochloride was converted to the free base by treatment with one equivalent of sodium hydroxide in ethanol, followed by evaporation to dryness *in vacuo* and extraction with ether. The crystalline material recovered by evaporation of the ether was heated at 60° at 0.001 mm pressure yielding *cis*-2-aminocyclohexanol as a colorless sublimate, m.p. 75.5–77.5°, in 91.4% yield. McCasland *et al.* (12) report m.p. 72°.

1-Alkoxy-2-hydroxy-3-aminocyclohexanes (I, II, VI, VII)

The preparation of these compounds was described previously by Bannard and Hawkins (25).

Acetylation of Amines

The acetylation and isolation procedures were the same for all the compounds examined. The acetylation of *trans*-2-aminocyclohexanol given below is typical.

trans-2-Aminocyclohexanol (3.45 g, 0.03 mole) was added at room temperature to acetic anhydride (79.5 g, 0.78 mole) contained in a round-bottomed flask equipped with a reflux condenser and calcium chloride tube. After the initial exothermic reaction had subsided, the colorless solution was heated under reflux for 1 hour and cooled to room temperature. The excess acetic anhydride was removed by distillation at room temperature at 6 mm pressure, whereupon the residue crystallized. The crystals were collected and washed with anhydrous ether, and the combined filtrate and washings were again evaporated to yield a second crop of crystals. These operations were repeated until no further crystals were obtained from the residual colorless oil. The crops of crystals were combined and recrystallized from anhydrous ether, yielding 3.79 g (63.5%) of *trans*-2-acetylamino-1-acetoxycyclohexane (IV*a*) as colorless platelets, m.p. 117.5–119° (see Table I). The oil fraction was transferred to a four-bulb Späth tube and distilled three times at 0.01 mm pressure at an air bath temperature of 78°, yielding 2.53 g (35.2%) of *trans*-2-diacetylamino-1-acetoxycyclohexane (IV*b*) as a colorless oil, n_D^{25} 1.4747.

The other preparations are summarized in Table I. It should be noted that in some of these the use of air bath temperatures much in excess of that required to barely cause the N,N-diacetyl derivatives to distill also caused the N-acetyl derivatives to sublime, necessitating further distillations to complete the separation. The separation of N-acetyl- and N,N-diacetyl-isopropylamine proved more difficult than that of the derivatives of the alicyclic amines and was accomplished by the use of an 18-inch Stedman column. The boiling points reported for the isopropylamine derivatives are thus true boiling points.

The proton magnetic resonance spectra were measured on a Varian V-4302 spectrometer operating at 60 Mc/second using a Varian V-4351 integrator for baseline stabilization. All solutions were 25% w/v in chloroform and were calibrated with reference to internal tetramethylsilane by the usual sideband technique.

Infrared spectra were measured in carbon tetrachloride (0.05 *M*) using a Perkin–Elmer model 21 double beam recording spectrometer. More dilute solutions (0.01–0.005 *M*) were used to examine hydrogen bonding effects. The 1600–1800 cm^{-1} region of the spectra of the N,N-diacetyl derivatives was re-examined for splitting of the amide carbonyl group using 0.05 *M* (0.1 mm cell) and 0.25 *M* (0.025 mm cell) solutions with both the Perkin–Elmer model 21 and model 421 spectrometers at a chart speed of ca. 25 cm^{-1} minutes.

ACKNOWLEDGMENTS

The author wishes to express his thanks to the Defence Research Board of Canada for granting him leave to participate in this work.

Thanks are also due to Dr. L. D. Hall for recording the n.m.r. spectra, to Mr. R. Lauzon for recording the infrared spectra, and to Professor B. Belleau, Professor F. A. L. Anet, and Dr. R. Norman Jones for the use of laboratory facilities and helpful discussions.

THE PHOTOLYSIS OF WATER VAPOR AND REACTIONS OF HYDROXYL RADICALS[1]

A. Y.-M. UNG[2] AND R. A. BACK

Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received August 17, 1963

ABSTRACT

The photolysis of water vapor at 1849 Å has been investigated as a possible source of hydroxyl radicals for kinetic studies. At temperatures from 23 to 350° C and pressures from 1.3 to 28 mm, H_2 and H_2O_2 were the only detectable products. Experiments with added oxygen indicated that O_2 may have been present as an intermediate at a very low steady-state concentration, although this is not certain. Possible mechanisms are discussed.

At temperatures from 200 to 350° C, carbon monoxide appeared to react quantitatively with the hydroxyl radicals produced in the photolysis of water by the reaction, $OH + CO \xrightarrow{k_{CO}} CO_2 + H$. Rates of this reaction relative to those of the reactions, $OH + H_2 \xrightarrow{k_{H2}} H_2O + H$, and $OH + D_2 \xrightarrow{k_{D2}} HDO + D$, were estimated from the decrement in the yield of CO_2 when H_2 or D_2 was added to the H_2O–CO system, and the following Arrhenius parameters were obtained:

$$E_{H_2} - E_{CO} = 4.0 \pm 0.3 \text{ kcal/mole}, \quad A_{H_2}/A_{CO} = 31 \pm 5,$$

$$E_{D_2} - E_{CO} = 6.4 \pm 0.3 \text{ kcal/mole}, \quad A_{D_2}/A_{CO} = 160 \pm 30,$$

$$E_{D_2} - E_{H_2} = 2.4 \pm 0.6 \text{ kcal/mole}, \quad A_{D_2}/A_{H_2} = 5 \pm 2.$$

At temperatures below 200° C, hydroxyl radicals were not completely converted to CO_2, as the yield of CO_2 increased to a maximum, then decreased again, with increasing pressure of CO. The mechanism of this system is complex, but probably involves secondary reactions of HCO or COOH radicals.

INTRODUCTION

Reactions of hydroxyl radicals in the gas phase at moderate temperatures have not been extensively studied; one reason for this is the lack of a good photochemical source of these radicals. Hydrogen peroxide, an obvious choice, does yield hydroxyl radicals upon photolysis at convenient wavelengths, but rapid reactions of the peroxide with radicals make the system, at moderate temperatures at least, rather complex (1). The photolysis of water vapor offers a possible alternative source of hydroxyl radicals. Its chief virtue lies in the high resistance of the water molecule, with an H—OH bond dissociation energy of 118 kcal, towards radical attack. This must be balanced against the inconvenience of working at wavelengths below about 1860 Å, where water begins to absorb light, and the possible complications of the concomitant production of hydrogen atoms in the photolysis process. A further experimental difficulty in the study of hydroxyl-radical reactions is that simple abstraction of hydrogen produces water, a product not easily measured in small amounts, and obviously impossible to measure if water is used as the radical source. One solution to this problem might be to use as a standard some reaction of hydroxyl that yields an easily measured product. Decrements in this product upon addition of a second reagent could then be used as a measure of the extent of reaction of the second reagent. The reaction, $OH + CO \rightarrow CO_2 + H$, seems particularly promising as such a reference standard (2, 3).

For personal use only.

In the present research, the photolysis of water vapor at 1849 Å was examined as a source of hydroxyl radicals; the use of the reaction of hydroxyl radicals with carbon monoxide as a reference standard was investigated; and, finally, relative rate constants of reactions of hydroxyl radicals with H_2, D_2, and CO were measured by this technique.

EXPERIMENTAL

The photolysis vessel was a quartz cylinder, 10 cm long and 5 cm in diameter, with plane windows of synthetic quartz (Suprasil) at the ends, and was mounted in an air thermostat. The light source was a mercury resonance lamp, similar to that described recently (4), but made from synthetic quartz. A common cylindrical housing enclosed both the lamp and the photolysis vessel, and was kept under a slight positive pressure of dry nitrogen to exclude air from the light path. The end of the housing that contained the lamp was made of brass, and was water-cooled to maintain a constant lamp temperature, while an intermediate section of the cylindrical housing was made of Pyrex to minimize heat transfer from the photolysis vessel.

Both the 2537 and the 1849 Å mercury resonance lines were emitted by the lamp, but all the reagent gases were transparent at 2537 Å. The 1849 Å line lies just within the sharply rising edge of the first absorption continuum of water (5). None of the other reagents (CO, H_2, D_2) absorb light in this region, and product concentrations were always too low to permit appreciable absorption at either 1849 or 2537 Å, so that the photolysis of water at 1849 Å should have been the only primary photolytic process of any importance.

The photolysis vessel was part of a circulatory system comprising the vessel, a glass paddlewheel pump, used to mix and circulate reagents, and two U-traps. One U-trap was mounted in a thermostatic bath which was used to maintain a suitable equilibrium vapor pressure of water in the system. Pressure was measured with a quartz-spiral gauge. The preparation line and reaction vessel were kept free of mercury, with access through suitable guard traps to a conventional gas analysis system.

In the experiments with water vapor alone, non-condensible gases were removed at −196° C by a diffusion-pump – Toepler-pump combination, measured in a gas burette, and analyzed by gas chromatography on an 8-ft, 5A molecular sieve column at 0° C, which gave good separation of H_2, N_2, O_2, and CO. Small amounts of oxygen were added in some experiments; this was done by adding air, so that the amount of oxygen originally added could be deduced from the nitrogen measured in the products. In the experiments in which large pressures of CO were added, CO and H_2 were transferred through a trap at −196° C, by a Toepler pump, into a trap at −220° C which condensed most of the CO. Controlled pumping on this latter trap (by expanding the non-condensed gases three times into a 500-cc volume) removed the hydrogen quantitatively, together with about a thousandfold excess of CO. This was transferred by a Toepler pump and analyzed by gas chromatography. In the same experiments, the trap originally at −196° C was warmed to −78° C and the CO_2 product was distilled off and measured in a gas burette. Mass spectrometric analysis confirmed that this fraction contained only CO_2. When the reaction mixture contained large pressures of H_2 or D_2, the non-condensible gases were pumped away at −196° C, and CO_2 was the only product measured.

Distilled water was used without special purification except for vigorous degassing and several bulb-to-bulb distillations. Blank experiments showed no measurable amounts of N_2, O_2, or CO_2. Carbon monoxide was Matheson C.P. grade from which traces of CO_2 were removed by passage through traps at −196°. This gas contained about 20 p.p.m. of O_2. In some experiments CO was purified by passing it over a potassium–sodium mixture deposited on glass wool, which reduced the oxygen content to less than 2 p.p.m. Hydrogen and deuterium were purified by passage through a hot palladium thimble. The deuterium contained 0.5% hydrogen.

RESULTS

Pure Water Vapor

A number of experiments were performed under a wide variety of conditions of light intensity, reaction time (7.5 to 150 minutes), pressure of water vapor (1.3 to 28 mm), and temperature (23 to 350° C). Hydrogen was the only non-condensible product detected in any of these experiments, although as little as 5×10^{-10} mole of oxygen would have been detectable on the gas chromatograms. Condensible products were not systematically analyzed, but did show a positive reaction to a permanganate test (6) for the hydrogen peroxide which is required by the stoichiometry if oxygen is not a product. Figure 1 shows the dependence of the hydrogen yield on irradiation time at two different light intensities. Table I shows the effect of pressure of water vapor on the hydrogen yield at 23° C with a light intensity corresponding to the lower curve in Fig. 1.

Water Vapor with Added Oxygen

To test the possibility that oxygen was a primary product of the photolysis, but disappeared by rapid secondary reactions, two series of experiments were performed. In the first, shown in Fig. 2, a constant quantity (7.5×10^{-8} moles) of oxygen was added initially,

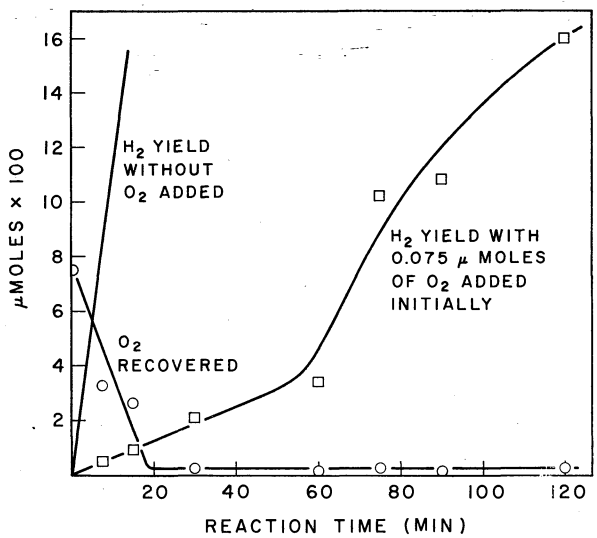

FIG. 2. The effect of 0.075 μmole of oxygen on the photolysis at 23° C and 19.8 mm pressure of water vapor.

and the hydrogen and oxygen measured after various times of irradiation. In the second series (Fig. 3), various amounts of oxygen were added initially, and hydrogen and oxygen determined after a constant reaction time of 75 minutes. Both series of experiments were performed at a temperature of 23° C and a pressure of water vapor of 19.8 mm.

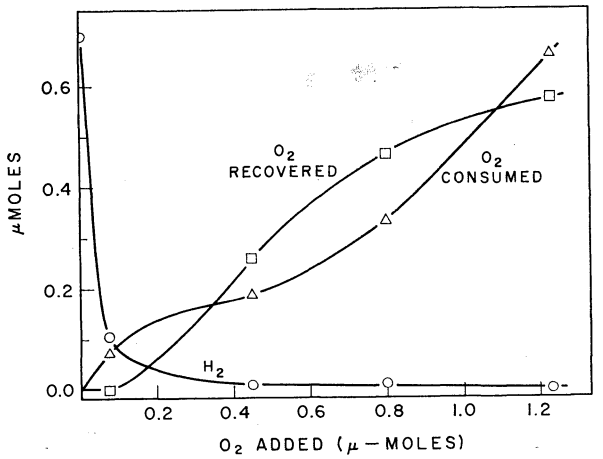

FIG. 3. The effect, at constant reaction time, of various amounts of oxygen on the photolysis at 23° C and 19.8 mm pressure of water vapor.

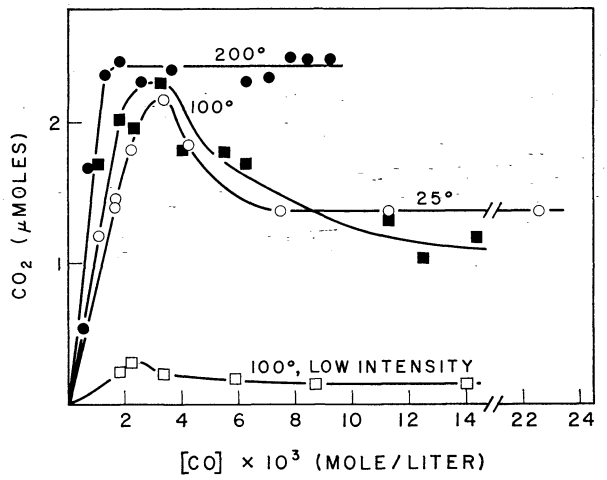

FIG. 4. The yield of CO_2 from the photolysis of water vapor in the presence of CO.

Water Vapor with Added Carbon Monoxide

In Fig. 4, yields of carbon dioxide at constant reaction time are plotted against concentration of carbon monoxide at temperatures of 25, 100, and 200° C. In all experiments at temperatures below 200° C, distinct maxima appear in these curves. At 200° C, and in several similar series of experiments (not shown) at temperatures ranging up to 350° C, the yield of carbon dioxide rose to a constant value, independent of carbon monoxide pressure, with no indication of any falling off from this value.

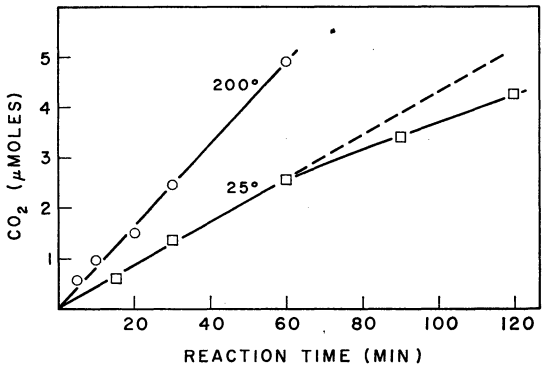

FIG. 5. The dependence on reaction time of the production of CO_2 from the photolysis of water vapor in the presence of about 220 mm of CO.

In Fig. 5, the yield of carbon dioxide at constant high pressure (~220 mm) of carbon monoxide is shown as a function of irradiation time at 25 and 200° C. At both temperatures the carbon dioxide yield was initially linear with time; at 25° C, at longer times, a decrease from the linear rate was observed. These data may be correlated with the curves in Fig. 4.

Hydrogen was a minor product in the experiments with added carbon monoxide. It was not measured systematically, as the analysis was complicated by the presence of hydrogen as a trace impurity in the carbon monoxide, but it was apparent that the yield of hydrogen was very low, less than a few percent of the CO_2.

Water Vapor with Added Carbon Monoxide and Hydrogen

At temperatures of 200° C and above, carbon monoxide appeared to act as a simple scavenger for hydroxyl radicals (Fig. 4), and the constant yield of carbon dioxide at high pressures of carbon monoxide should be a measure of the hydroxyl radicals produced in the photolysis. If, under these conditions, a second reagent such as hydrogen is added, the competition between the two reactions,

$$OH + CO \xrightarrow{k_{CO}} CO_2 + H,$$

$$OH + H_2 \xrightarrow{k_{H_2}} H_2O + H,$$

should lead to a reduced yield of carbon dioxide. The equation,

$$[(CO_2)_0 - CO_2]/CO_2 = (k_{H_2}/k_{CO})([H_2]/[CO]),$$

where $(CO_2)_0$ is the yield of CO_2 in the absence of H_2, should describe this competition. In Fig. 6 are shown typical plots of this equation at several temperatures, and representing a variety of irradiation times and carbon monoxide pressures. Tables II and III summarize the results obtained with the H_2–CO and D_2–CO systems respectively, including values of k_{H_2}/k_{CO} and k_{D_2}/k_{CO} derived from plots similar to those in Fig. 6.

DISCUSSION

The Primary Process in the Photolysis of Water Vapor

There is general agreement that the primary process in the photolysis of water vapor at wavelengths in the first continuum is

$$H_2O + h\nu \rightarrow H + OH \qquad [1]$$

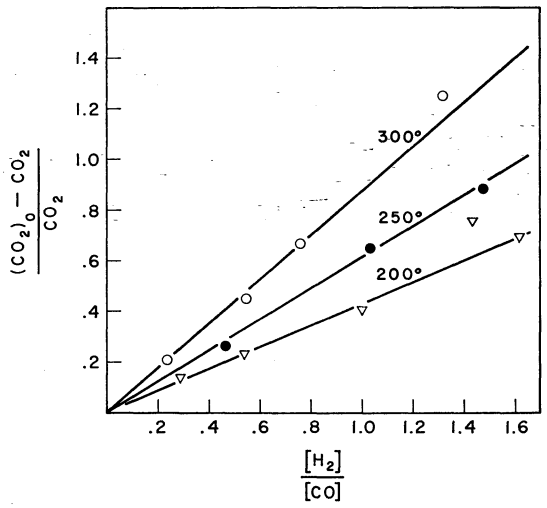

FIG. 6. The competition between the reactions of hydroxyl radicals with CO and H_2.

with both H and OH in their lowest electronic states (7, 8, 9). The present results confirm this conclusion. In particular, the reduction of the hydrogen yield to a negligible value by the addition of small quantities of oxygen (Fig. 3) definitely rules out the primary formation of molecular hydrogen.

Reactions in Pure Water Vapor

The simplest way to account for the absence of oxygen as a product is by the mechanism,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$$OH + OH + M \rightarrow H_2O_2 + M, \quad [2A]$$

$$OH + H + M \rightarrow H_2O + M, \quad [3A]$$

$$H + H + M \rightarrow H_2 + M, \quad [4]$$

where M is a third body, which has recently been suggested in the flash photolysis of water vapor at total pressures between 100 and 600 mm, in which the disappearance of hydroxyl radicals was observed to be termolecular (9). On the other hand, O_2 might have been formed in the present system, but reduced to an undetectably low steady-state concentration by rapid secondary reactions. The reaction,

$$OH + OH \rightarrow H_2O + O \quad [2B]$$

has been shown to predominate in a fast-flow system at about 1 mm total pressure (10, 11, 12). This is not incompatible with the flash photolysis results (9), as one would expect a gradual transition from reaction [2B] to [2A] as the pressure was increased. The pressures used in the present work lie between those used in the flash photolysis and in the fast-flow experiments, almost overlapping the latter. The abnormally high efficiency of water as a third body (9) may favor reaction [2A], so that a mixture of reactions [2A] and [2B], with [2A] probably predominant, might be expected in the present experiments.

In the low-pressure, fast-flow experiments (10, 11), concentrations of hydroxyl radicals were rather high (1 to 6 microns), and reaction [2B] was thought to be followed exclusively by the fast reaction,

$$O + OH \rightarrow O_2 + H. \quad [5]$$

In the present system, concentrations of hydroxyl were probably orders of magnitude lower, and reactions such as

$$O + O + M \rightarrow O_2 + M, \quad [6]$$

$$O + H + M \rightarrow OH + M, \quad [7]$$

$$O + HO_2 \rightarrow OH + O_2 \quad [8]$$

may also have been important, although reaction [5] should still have predominated.

Oxygen would have disappeared in the reaction,

$$H + O_2 + M \rightarrow HO_2 + M, \quad [9]$$

followed by

$$2HO_2 \rightarrow H_2O_2 + O_2, \quad [10]$$

$$H + HO_2 + M \rightarrow H_2O_2 + M, \quad [11]$$

$$H + HO_2 \rightarrow 2OH, \quad [12A]$$

$$H + HO_2 \rightarrow H_2 + O_2, \quad [12B]$$

$$OH + HO_2 \rightarrow H_2O + O_2, \quad [13]$$

and reaction [8]. If oxygen were formed in the photolysis of water vapor, this reaction sequence must have been fast enough to keep the steady-state concentration of oxygen below 2×10^{-9} moles per liter. It is impossible from the present results to say definitely whether or not oxygen was in fact an intermediate.

The dependence of hydrogen yield on irradiation time (Fig. 1) requires some comment. The fall-off from an initial linear dependence may be attributed to the loss of H, H_2, and H_2O_2 by secondary reactions,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$$H + H_2O_2 \rightarrow H_2O + OH, \quad [14A]$$

$$H + H_2O_2 \rightarrow H_2 + HO_2, \quad [14B]$$

$$OH + H_2O_2 \rightarrow H_2O + HO_2, \quad [15]$$

$$OH + H_2 \rightarrow H_2O + H. \quad [16]$$

Subsequent reactions of HO_2 radicals [9 to 13] might be expected to yield some oxygen, and it is perhaps significant that even in the experiments with the longest irradiation times, no oxygen was detected. However, reactions [11] and [12A] may well have predominated over [10] and [13], as H was probably much more abundant than HO_2 or OH. Reaction [12B] is an unknown quantity, and it is possible that production of oxygen from reactions of HO_2 was very inefficient. The experiments of Chen and Taylor, using much higher light intensities and conversions, and thus well on in the steady-state region whose approach is evident in Fig. 1, show that, ultimately, oxygen does appear as a major product in the photolysis of water vapor (8).

The dependence of the hydrogen yield on the pressure of water vapor (Table I) suggests that perhaps half the incident light was absorbed at the highest pressures used, which is quite compatible with published estimates of the extinction coefficient of water vapor (5). The observed dependence may be complicated by a dependence of the quantum yield of hydrogen on the absorbed light intensity and on the pressure of water vapor.

The initial quantum yield* of hydrogen in the photolysis of pure water vapor at 25° C was about 0.4. This is somewhat higher than might be expected from either a simple recombination mechanism or one involving oxygen as an intermediate. One possible source of extra hydrogen is the reaction of hydrogen atoms with trace impurities, as is thought to occur in the radiolysis of water vapor (13). The system is highly susceptible to such effects, which can compete effectively with the relatively slow termolecular combination reactions of hydrogen atoms.

Reactions in Water Vapor with Added Oxygen

Figure 2 shows that oxygen does indeed disappear rapidly when it is added to the photolysis system. The yield of hydrogen was initially much reduced by the presence of oxygen, but rose again as the oxygen was consumed. Small but measurable residues of O_2 scattered between about 1 and 3% of that added initially, were found after irradiation times of 30 minutes or longer. These residues may have arisen partly from O_2 remaining in the circulation system, and in several small sidearms attached to it, as the paddlewheel pump was not very efficient at low pressures. They may also have partly arisen from secondary reactions with H_2O_2 (mainly reaction [15] followed by [10]) which would set in earlier in the water–O_2 system than in pure water, and which could generate oxygen and so establish a low steady-state concentration of O_2, although the marked rise in hydrogen production between 50 and 90 minutes suggests that the oxygen concentration in the reaction vessel itself was still decreasing, probably to a very low value, even though the oxygen recovered was approximately constant from 30 minutes onwards. The rate of hydrogen production in Fig. 2 never reached the value found in the absence of oxygen, since by the time the oxygen concentration was sufficiently reduced, the same secondary reactions which led to the decreased hydrogen yield in pure water (Fig. 1) were coming into play.

The initial rate of disappearance of oxygen represented by the straight line drawn in Fig. 2 corresponds to a quantum yield* of 0.14. This gives an upper limit for the rate of

**Assuming a primary quantum yield (for reaction [1]) of unity, and a primary rate of formation of* OH *(and* H*) of* 2.8×10^{-8} *mole/minute as measured by the production of* CO_2 *by reaction with* CO *at 200° C.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

formation of oxygen in the photolysis of pure water vapor under similar conditions, in order for oxygen not to have accumulated, which is about half the quantum yield of 0.33 expected if all the hydroxyl radicals disappeared by reactions [2B] and [5], which consume 3 OH for each O_2 formed.

Reactions in Water Vapor with Added CO

By adding a sufficiently high pressure of carbon monoxide, it was hoped that hydroxyl radicals could be quantitatively converted to CO_2 by the reaction

$$OH + CO \rightarrow CO_2 + H. \quad [17]$$

Hydrogen atoms from reactions [1] and [17] might be expected to disappear by reactions such as

$$H + CO + M \rightarrow HCO + M, \quad [18]$$

$$H + HCO + M \rightarrow H_2CO + M, \quad [19A]$$

$$H + HCO \rightarrow H_2 + CO, \quad [19B]$$

$$2HCO \rightarrow H_2 + 2CO, \quad [20A]$$

$$2HCO \rightarrow H_2CO + CO, \quad [20B]$$

$$2HCO + M \rightarrow (HCO)_2 + M. \quad [20C]$$

The very low yield of hydrogen observed in this system suggests that reactions [19B] and [20A] were not important. At temperatures below 200° C, complete scavenging of hydroxyl radicals by reaction [17] was not achieved. As the CO pressure was increased, the yield of CO_2 rose to a maximum not far below the limiting value attained at high temperatures, decreased again, and finally became constant at about half its highest value. Two tentative explanations of this behavior may be offered. The first involves the reactions

$$OH + HCO \rightarrow H_2O + CO \quad [21A]$$

and

$$OH + HCO + M \rightarrow HCOOH + M, \quad [21B]$$

which consume hydroxyl radicals in competition with reaction [17]. Although reactions [17] and [18] are both nominally first order in CO pressure, CO can also act as a third body in reaction [18], so that with increasing CO pressure, the rate of formation of HCO, and hence its steady-state concentration, and the rates of reactions [21A] and [21B], will rise more rapidly than the rate of reaction [17]. This can account for a rise through a maximum and a subsequent decrease of the CO_2 yield. As the CO pressure is further increased, reaction [18] will eventually consume all the hydrogen atoms, and become independent of CO pressure. The dependence of reactions [17] and [21B] on further increase in the CO pressure could then lead to a constant yield of CO_2.

A second explanation is rather similar, and involves the COOH radical (14, 15). The formation of this radical again requires a stabilizing collision,

$$CO + OH + M \rightarrow COOH + M. \quad [22]$$

Loss of OH (or CO_2) by subsequent reactions such as

$$OH + COOH \rightarrow H_2O + CO_2, \quad [23]$$

$$2COOH \rightarrow HCOOH + CO_2, \quad [24]$$

and others involving HCO can equally well account for the observed dependence of the CO_2 yield on CO pressure, using arguments roughly analogous to those invoked for the HCO radical.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

A third rather similar mechanism involving HO_2 radicals formed by reaction [9] from the trace of oxygen impurity present in the carbon monoxide was ruled out by experiments with highly purified CO (less than 2 p.p.m. O_2), which showed no change in behavior.

With increasing temperature, both COOH and HCO radicals would tend to dissociate thermally, and the rate of reaction [17] would increase, leading finally to complete scavenging of hydroxyl radicals by CO. It is impossible from the present results to choose clearly between HCO and COOH as the more likely cause of the observed low-temperature behavior.

Loss of OH radicals by reaction with products such as HCOOH or H_2CO might also be invoked, and these probably account for the decrease in CO_2 yield at higher reaction times observed at 25° C (Fig. 5). However, all the data shown in Fig. 4 were obtained at reaction times in the linear portions of the curves in Fig. 5, so that reactions with products were probably unimportant. Partial removal of products such as HCOOH and H_2CO from the circulating reaction gases by solution in the liquid water present in the U-trap may have reduced product concentrations in the reaction vessel and minimized reaction with products.

Reactions in Water Vapor with Added CO, H_2, and D_2

Plots of the type shown in Fig. 6 appeared to give consistent values of relative rate constants over a considerable range of conditions, suggesting that above 200° C, the

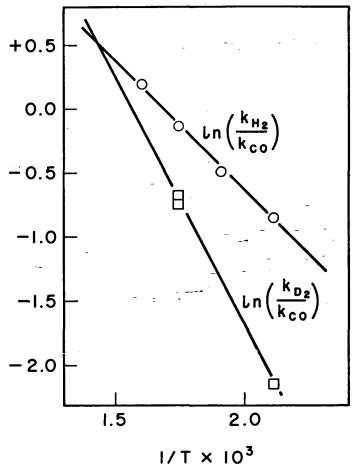

FIG. 7. Arrhenius plot of ratios of rate constants for the reactions of hydroxyl radicals with CO, H_2, and D_2.

simple mechanism suggested was obeyed. In Fig. 7 is shown an Arrhenius plot of the ratios k_{H_2}/k_{CO} and k_{D_2}/k_{CO}, from which the following parameters were derived:

$$E_{H_2} - E_{CO} = 4.0 \pm 0.3 \text{ kcal/mole},$$
$$A_{H_2}/A_{CO} = 31 \pm 5,$$
$$E_{D_2} - E_{CO} = 6.4 \pm 0.3 \text{ kcal/mole},$$
$$A_{D_2}/A_{CO} = 160 \pm 30,$$
$$E_{D_2} - E_{H_2} = 2.4 \pm 0.6 \text{ kcal/mole},$$
$$A_{D_2}/A_{H_2} = 5 \pm 2.$$

The limits of error suggested are rather arbitrary, and the values for the reaction with deuterium must be regarded as preliminary. The apparatus is presently being modified to permit operation at higher temperatures and thence to obtain more accurate Arrhenius parameters.

Avramenko and Lorentso (3), using a technique of doubtful accuracy, found $E_{CO} = 7$ kcal and $E_{H_2} = 10$. Both these values are supported by the measurements of Fenimore and Jones (16), and are in reasonable accord with our present estimate of $E_{H_2} - E_{CO} = 4$. Del Greco and Kaufman (10), however, have suggested that E_{H_2} must be closer to 6 kcal, which, combined with our data, gives $E_{CO} = 2$; the same value may be derived from $E_{CH_4} = 9$ kcal (17) (for the reaction of OH with CH_4) and $E_{CH_4} - E_{CO} = 7$ measured recently by Hoare (2). Thus E_{CO} would seem to lie somewhere between 7 and 2 kcal. There does seem to be general agreement that A_{CO} is markedly lower than typical values for hydrogen abstraction reactions; our value of $A_{H_2}/A_{CO} = 31$ may be compared with $P_{CH_4}/P_{CO} = 100$ (where P is a collision-theory steric factor) estimated by Hoare (2). Finally, a value of $k_{CO}/k_{H_2} = 15$ measured in aqueous solution at 20° C by Dainton and Hardwick (18) may be compared with a value of about 33 obtained by extrapolation of our present gas-phase data.

The isotope effect observed in the reaction of hydroxyl radicals with H_2 and D_2 in the present work is very close to that found for the parallel reactions of methyl radicals by Majury and Steacie (19), who reported $E_{D_2} - E_{H_2} = 2.5$ kcal and $A_{D_2}/A_{H_2} = 5$. It should be noted again that the present data for the reaction of hydroxyl with deuterium are very tentative.

TWO NEW PAPILIONACEOUS ALKALOIDS: ARGYROLOBINE AND (—)-APHYLLIDINE[1]

Y. TSUDA[2] AND LÉO MARION
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received August 19, 1963

ABSTRACT

Argyrolobium megarhizum Bol. has been found to contain a number of alkaloids, four of which have been well characterized. Two of these were identical with N-methylcytisine and cytisine respectively, while the other two were new. One of these proved to be the levorotatory enantiomorph of aphyllidine, while the other (the major alkaloid), $C_{15}H_{22}O_2N_2$, designated argyrolobine, was shown to be a hydroxyaphyllidine, and its absolute configuration derived by reduction to (−)-sparteine.

Argyrolobium megarhizum Bol. is a small shrub of the family Leguminosae which was collected at Bronkhorstspruit, Transvaal, South Africa.[3] The alcoholic extract of this plant has yielded several alkaloids, four of which have been characterized. Two of these have been found to be identical with N-methylcytisine and cytisine respectively, while the other two are new. N-Methylcytisine was characterized by the formation of its perchlorate, its picrate, and its hexahydro-deoxo derivative. Cytisine was identified as its high-melting picrate.

The first of the two new bases ($C_{15}H_{22}O_2N_2$) was the most abundant alkaloid and we propose to designate it argyrolobine (I). Its infrared spectrum showed it to contain a hydroxyl (3385 cm^{-1}) and a lactam carbonyl (1638 cm^{-1}). In the ultraviolet, a maximum (λ_{max} 239 mμ, ϵ 9400) was suggestive of a C=C—N—CO grouping (cf. aphyllidine, λ_{max} 240 mμ, ϵ 10,300). It formed a normal monohydrochloride, m.p. 170–172°, and a monomethiodide, m.p. 180°, and hence must be a monoacidic base. The n.m.r. spectrum of argyrolobine contained no signals attributable to an N-methyl or a C-methyl group, but contained a signal (δ 6.0) suggesting one olefinic proton.

Mild acetylation of argyrolobine produced a monoacetate, $C_{17}H_{24}O_3N_2$, m.p. 61°. The infrared spectrum of the acetate in chloroform solution showed no hydroxyl absorption, but bands at 1735 and 1225 cm^{-1} attributable to the acetyl group, and at 1650 cm^{-1} due to the lactam carbonyl, while its n.m.r. spectrum contained the signal (δ 2.02) of the acetate protons. The presence of a hydroxyl group in the alkaloid is thus confirmed.

The n.m.r. spectrum of the acetate also contained two signals at fields lower than δ ~4.0, each of which corresponded to one proton. The lower signal (δ 7.21) can be attributed to an olefinic proton situated on the second carbon away from the electron-attracting nitrogen, and since no other olefinic proton signal appeared in the region δ 5.0–7.0, the carbon adjacent to the nitrogen must be fully substituted (CH=C—N—CO). A complex signal centered at δ 4.82 could be attributed to the proton on the carbon bearing the acetoxy group which would indicate that the hydroxyl is secondary.

Although argyrolobine was difficult to hydrogenate in a neutral solvent, it smoothly absorbed 4 moles of hydrogen in hydrochloric acid solution in the presence of Adams' catalyst. The product was an oil, $[\alpha]_D$ −16°, which formed a picrate identified as

For personal use only.

(−)-sparteine dipicrate. The production of (−)-sparteine (II) involved the reduction of the lactam carbonyl, the double bond, and the hydrogenolysis of the hydroxyl; besides proving that argyrolobine possessed the sparteine structure, it showed that the hydroxyl must be present either in a carbinolamine grouping, or in an allylic position to the double bond. That it is the former, and not the latter, is shown by the action of lithium aluminum hydride on the base.

The action of lithium aluminum hydride on argyrolobine, as expected, also reduced the carbonyl and hydrogenolyzed the hydroxyl, giving rise to an unstable oil which in the infrared, in chloroform solution, showed a weak absorption band at 1620 cm^{-1} and in a liquid film showed bands at 1630 and 1650 cm^{-1}. The product, when hydrogenated catalytically, absorbed 1 mole of hydrogen and gave rise to (−)-sparteine, thus confirming the presence of one double bond. The unstable product of the reaction with lithium aluminum hydride, which is a dehydrosparteine, forms a crystalline perchlorate, m.p. 225–228°, showing in the infrared a sharp absorption band at 1677 cm^{-1} characteristic of the grouping $C{=}N^+$, and is therefore an imonium salt, thus confirming the location of the double bond, relative to a nitrogen, already indicated by the n.m.r. spectrum of the alkaloid.

These results suggest that argyrolobine is a hydroxyaphyllidine represented by structure I. Since sodium borohydride converted the perchlorate (m.p. 225–228°) to (−)-sparteine II, although the free base liberated from this salt was inert to lithium aluminum hydride, it follows that this free base arising from the action of lithium aluminum hydride on argyrolobine must be Δ^5-dehydrosparteine III, and its perchlorate $\Delta^{1(6)}$-dehydrosparteinium perchlorate (IV). The identity of the perchlorate was indeed confirmed by direct comparison (melting point of mixture, infrared spectra) with an authentic sample of $\Delta^{1(6)}$-dehydrosparteinium diperchlorate (1).

The hydroxyl group in argyrolobine could not occupy positions C-11, C-15, or C-17 (cf. formula I) for the following reasons: (*a*) argyrolobine could not be oxidized by manganese dioxide to a dilactam, (*b*) argyrolobine hydrochloride is not an imonium salt but a normal salt as shown by its infrared spectrum, and (*c*) argyrolobine is not affected by sodium borohydride.

That the hydroxyl is at C-2 was established by the pyrolysis of acetylargyrolobine (V). On distillation the acetyl-derivative lost the elements of acetic acid, and produced a colorless viscous oil which in the infrared showed absorption bands at 1650 and 1625 cm^{-1}, indicating a lactam carbonyl and unsaturation. The n.m.r. spectrum of the product contained three complex signals (δ 4.73, 5.12, 7.20), each corresponding to one proton, which can be assigned to olefinic protons. The ultraviolet spectrum of the pyro-compound (λ_{max} 252 mμ, ϵ 8300) when compared with that of argyrolobine (λ_{max} 239 mμ, ϵ 9400) reveals that the new double bond, introduced by elimination of acetic acid, has caused a bathochromic shift and, therefore, contributes to the original chromophore. That no skeletal rearrangement took place during pyrolysis was shown by catalytic hydrogenation of the pyro-compound followed by reduction with lithium aluminum hydride, which gave rise to (−)-sparteine. Thus the pyro-compound must be represented by VI or VII depending on whether or not the newly introduced double bond shifted into conjugation with that originally present. The formation of sparteine from VI also eliminates the possibility of structure VIII for argyrolobine since the acetyl derivatives of such a structure could not eliminate acetic acid with formation of a double bond without rearrangement.

Since the absolute configuration of (−)-sparteine is known (2), structure I represents both the structure and absolute configuration of argyrolobine.

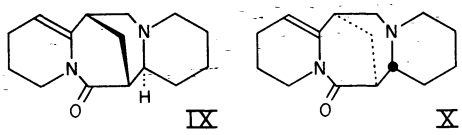
The second new alkaloid was isolated from the mother liquor of the crystallization of argyrolobine by chromatography on alumina and subsequent sublimation. It had the empirical formula $C_{15}H_{22}ON_2$, m.p. 101–106°, $[\alpha]_D$ −9.1° (EtOH). Its ultraviolet spectrum (λ_{max} 240 mμ, ε 12,000) is the same as that of aphyllidine and the infrared spectrum is superimposable on that of the latter. The melting point of the base in admixture with aphyllidine is lowered (63–67°) very appreciably. The alkaloid forms a hydrochloride, m.p. 228–230°, and picrolonate, m.p. 241–243° (decomp.), while the corresponding salts of aphyllidine melt at 235–236° and 235–237° respectively. When hydrogenated catalytically, the base absorbed 3 moles of hydrogen and gave rise to (−)-sparteine, whereas



aphyllidine, which is dextrorotatory, was hydrogenated to (+)-sparteine (3). Consequently, the new base is (−)-aphyllidine (IX) and its absolute configuration follows from that of (−)-sparteine (2). It is the enantiomorph of (+)-aphyllidine (X), and its isolation constitutes the first recorded natural occurrence of the levorotatory enantiomorph of this base.

Four more alkaloids were isolated as their salts, but in quantities insufficient to permit proper characterization.

EXPERIMENTAL

Separation of the Alkaloid

The crude, dried methanolic extract (670 g) from *Argyrolobium megarhizum* was stirred with warm 10% hydrochloric acid (2 l.) for 1 hour and filtered. The insoluble material on the filter was washed with water (1 l.) and the combined filtrate and washings extracted repeatedly with ether. The aqueous layer was made basic with sodium hydroxide and extracted with methylene chloride (4×1 l.). The extract was dried over sodium carbonate and evaporated to dryness. The residual brown gum (20.87 g) showed four spots (R_F 0.50, 0.42, 0.32, 0.16) on a paper chromatogram, in which 5% acetic acid – butanol was used as solvent. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

gum was dissolved in acetone and the solution, when allowed to stand, deposited a crop of crystals, 3.82 g (base A).

The acetone mother liquor was evaporated to dryness and the residue dissolved in 10% hydrochloric acid (500 ml), the solution washed with ether (discarded), neutralized with sodium bicarbonate, and repeatedly extracted with methylene chloride. This extract, on evaporation, left a brown residue (10.32 g) which crystallized on standing (base A and base B). The aqueous solution was made strongly basic with sodium hydroxide and extracted first with ether (yielding a colorless gum, 1.57 g, which crystallized on standing—mainly base A), and then with methylene chloride. This last extract, on evaporation, left a pale brown gum.

All the alkaline aqueous layers, which had been extracted, were combined, acidified with hydrochloric acid, and an aqueous solution of ammonium reineckate was added. The precipitated reineckate was collected by filtration, washed with water, and dried in air (ca. 50 g).

A second lot of the crude extract was worked up differently. The crude extract (100 g) in this case yielded 5 g of basic residue which was dissolved in 10% hydrochloric acid, washed with ether (discarded), made basic with sodium bicarbonate, and extracted with ether. This extract (extract I) yielded a gum, 1.0 g, on evaporation. The aqueous solution was further extracted with methylene chloride which on evaporation left a solid residue (3.4 g—extract II).

Sodium carbonate was added to the aqueous solution, which was extracted with methylene chloride. This extract (III) yielded a gum, 0.07 g. The aqueous solution was finally made strongly basic with sodium hydroxide and thoroughly extracted with methylene chloride (extract IV), which on evaporation left a gummy residue, 0.30 g.

Base A (Argyrolobine)

Base A formed colorless prisms from acetone, m.p. 168–169°. It could be sublimed unchanged at ca. 150° (air bath) and 10^{-3} mm, $[\alpha]_D$ +13.3° (*c*, 1.4 in $CHCl_3$). Found: C, 68.83; H, 8.30; N, 10.45. Calc. for $C_{15}H_{22}O_2N_2$: C, 68.67; H, 8.45; N, 10.68%. Infrared (in Nujol): 3385 (OH), 1638 cm^{-1} (lactam); in chloroform: 3450 (OH), 1620 cm^{-1} (lactam). Ultraviolet: λ_{max} 239 mμ, ϵ 9400. The base was unstable in chloroform solution, which discolored on standing.

Argyrolobine formed a hydrochloride crystallizing from methanol – ethyl acetate as colorless prisms, m.p. 170–172°. Found: C, 60.37; H, 7.63. Calc. for $C_{15}H_{22}O_2N_2.HCl$: C, 60.30; H, 7.76%. Infrared: 3450 (OH), 2360 (broad) (N^+H), 1640 cm^{-1} (lactam). It also gave rise to a methiodide crystallizing from methanol–ether, m.p. 180–183° (decomp.). Found: C, 45.77; H, 5.89. Calc. for $C_{15}H_{22}O_2N_2.CH_3I.H_2O$: C, 45.50; H, 6.44%.

Acetylargyrolobine

Argyrolobine (base A, 0.1 g) was kept overnight at room temperature in a mixture of pyridine (2 ml) and acetic anhydride (1 ml). The reaction mixture was poured into ice water, the solution made basic with potassium carbonate, and extracted with ether. The extract, dried and evaporated, left a colorless oil (0.11 g) which was dissolved in benzene and passed through a column of alumina. The benzene eluate contained the acetylargyrolobine which crystallized from *n*-hexane as colorless prisms, m.p. 61°. Found: C, 66.57; H, 7.70; N, 9.38. Calc. for $C_{17}H_{24}O_3N_2$: C, 67.08; H, 7.95; N, 9.20%. Infrared in chloroform: 1730 (acetyl carbonyl), 1650 cm^{-1} (lactam). The acetate when allowed to stand in the air gradually became discolored.

Hydrogenation of Argyrolobine

Argyrolobine (9.7 mg) was dissolved in 10% hydrochloric acid (6 ml) and hydrogenated at 23° over prereduced Adams' catalyst (35 mg). In the course of 3 hours, 3.4 ml of hydrogen was absorbed (~4.1 mole). The mixture was filtered, the filtrate alkalized with sodium hydroxide, and extracted with methylene chloride. The extract was dried over potassium carbonate and evaporated to dryness. It left a colorless oil which was distilled, b.p. 56–60° (air bath) at 10^{-2} mm, $[\alpha]_D$ −16° (*c*, 1.7 in EtOH). The oil formed a picrate which after recrystallization from methanol, melted at 208–209° either alone or in admixture with (−)-sparteine dipicrate. The infrared absorption spectra of the two were superimposable.

Reduction of Argyrolobine with $LiAlH_4$

Argyrolobine (0.16 g) and lithium aluminum hydride (0.16 g) in dioxane (20 ml) was heated under reflux for 20 hours. The mixture was cooled, a few drops of water added, followed by the addition of methylene chloride. The mixture was filtered, the filtrate dried over potassium carbonate, and evaporated under reduced pressure. There was left a colorless oil, 0.15 g, which could be distilled but with appreciable loss of material by resinification. The product was dissolved in 10% acetic acid and converted to the perchlorate by the addition of sodium perchlorate. The perchlorate thus obtained was recrystallized first from methanol and then from water from which it separated as colorless prisms, m.p. 225–228° (decomp.). Admixture with an authentic sample of $\Delta^{1(6)}$-dehydro(—)sparteinium diperchlorate (m.p. 237–238° (decomp.) (1)) did not depress the melting point. Hence the base itself was Δ^5-dehydrosparteine. Catalytic hydrogenation of this base in ethanol over platinum oxide yielded (−)-sparteine, isolated as its dipicrate.

$\Delta^{1(6)}$-Dehydrosparteinium diperchlorate in methanol was stirred for 30 minutes during which a methanolic solution of sodium borohydride was gradually added. The reaction, worked up as usual, gave an excellent yield of (−)-sparteine, isolated and characterized as its dipicrate. Argyrolobine and its hydrochloride were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

treated in a similar manner with sodium borohydride. In both cases unchanged argyrolobine was recovered in not less than 90% yield.

Pyrolysis of Acetylargyrolobine

Acetylargyrolobine (0.1 g) was distilled *in vacuo* (7×10^{-3} mm). The distillate collected at 130–150° (air bath) was redistilled under the same pressure. Most of the fraction (47 mg) distilled at 130–135° (air bath). The product failed to crystallize. Its infrared spectrum showed no acetate carbonyl absorption but contained bands 1650 and 1625 cm^{-1}. Ultraviolet: λ_{max} 252 mμ, ϵ 8300 (in 95% EtOH).

The pyro-compound (30 mg) dissolved in ethanol (10 ml) was hydrogenated over Adams' catalyst at room temperature for 20 hours. After removal of the catalyst by filtration, the solution was evaporated to dryness *in vacuo* and the residue (which showed an absorption band at 1620 cm^{-1} in the infrared) was heated under reflux in dioxane (5 ml) with excess lithium aluminum hydride for 10 hours. The reaction mixture, worked up as usual, yielded (−)-sparteine, characterized as its dipicrate, m.p. 208–210°, (melting point of mixture with authentic sample and comparison of infrared spectra).

Base B ((−)-Aphyllidine)

The residue obtained from extract I was dissolved in benzene and chromatographed on alumina. Elution with benzene gave a solid which was purified by sublimation at 90–100° (air bath) and 10^{-3} mm. The sublimate was crystallized from ether–hexane from which base B separated as colorless prisms, m.p. 101–106°, $[\alpha]_D$ −9.1° (*c*, 2.2 in EtOH). Ultraviolet: λ_{max} 240 mμ, ϵ 12,000. Found: C, 72.86; H, 8.24; N, 11.01. Calc. for $C_{15}H_{22}ON_2$: C, 73.13; H, 9.00; N, 11.37%. The infrared absorption spectrum was superimposable on that of (+)-aphyllidine.

The base formed a hydrochloride which separated from methanol–acetone–ether as colorless prisms, m.p. 228–230° (decomp.). The reported melting point (3) for (+)-aphyllidine hydrochloride is 235–237°. The base also formed a picrolonate crystallizing from methanol as yellow needles, m.p. 241–243° (decomp.). The literature (4) gives for (+)-aphyllidine picrolonate m.p. 235–236°.

Hydrogenation of (−)-Aphyllidine

(−)-Aphyllidine (base B, 17.1 mg) was hydrogenated over platinum oxide (42 mg) in 10% hydrochloric acid (5 ml) under the same conditions as argyrolobine. The absorption of hydrogen was 5.3 ml (~3.1 moles) in 5 hours. The product of the reaction, a colorless oil, had $[\alpha]_D$ −15°. It was isolated as the dipicrate, m.p. 203–205°. The melting point was unaltered in admixture with (−)-sparteine dipicrate. The identity was also confirmed by comparison of the infrared spectra which were exactly alike.

Base C (N-Methylcytisine)

The residue from extract II consisted of a mixture. Crystallization from acetone removed the argyrolobine present. The mother liquor was evaporated to dryness and the residue dissolved in benzene and chromatographed on alumina. Elution with benzene containing 1% of diethylamine gave first a small quantity of (−)-aphyllidine and then some argyrolobine. Further elution with benzene – methylene chloride (3:1) containing 1% of diethylamine yielded base C as an oil which was distilled at 80–120° (air bath) at 10^{-3} mm.

One-half of the distillate was neutralized with perchloric acid and the salt crystallized from methanol from which it separated as colorless needles, m.p. 274–275° (decomp.). Admixture with N-methylcytisine perchlorate (m.p. 282°) failed to depress the melting point, $[\alpha]_D$ −112° (*c*, 1.7 in H_2O). Found: C, 45.95; H, 5.55; N, 8.50. Calc. for $C_{12}H_{16}ON_2.HClO_4.\frac{1}{2}H_2O$: C, 45.94; H, 5.78; N, 8.93%. The infrared absorption spectrum of the salt was identical with that of N-methylcytisine.

The remaining half of the base in methanol was added to a saturated methanolic solution of picric acid. The precipitated picrate was crystallized several times from methanol and was obtained as yellow needles, m.p. 230–232°, either alone or in admixture with an authentic sample of N-methylcytisine picrate (5). The infrared absorption spectra of both picrates were superimposable.

Hydrogenation of N-Methylcytisine

N-Methylcytisine (base C) perchlorate (14.2 mg) was hydrogenated at 22° in 10% hydrochloric acid (7 ml) over prereduced Adams' catalyst (46 mg). In the course of 5 hours, 5.1 ml of hydrogen was taken up (~4.5 moles). The reaction mixture was filtered, the filtrate alkalized with sodium hydroxide, and repeatedly extracted with methylene chloride. The combined extract was dried over potassium carbonate and evaporated to dryness. It left a residual colorless oil (5 mg) (no lactam carbonyl absorption in the infrared) which was treated with picric acid. The picrate crystallized from methanol as yellow needles, m.p. 225–227° (decomp.). Found: C, 44.45; H, 4.32. Calc. for $C_{12}H_{22}N_2.(C_6H_3O_7N_3)_2$: C, 44.19; H, 4.32%.

Cytisine (Base D)

Extract IV was combined with the uncrystallized fractions from the separation by the first method described. The bases were subjected to fractional distillation at 10^{-2} – 7×10^{-3} mm. The following fractions were collected: I, b.p. ~120–130°; II, b.p. ~150°; III, b.p. ~180°; IV, b.p. ~200°. Fraction III was dissolved in acetone and added to an acetone solution of picric acid. The crystalline picrate was crystallized several times from acetone and then from methanol from which it separated as yellow prisms, wt. 15 mg, m.p. 285°

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(decomp.). The melting point was not altered by admixture with an authentic sample of cytisine picrate. The infrared absorption spectrum of the picrate and that of cytisine picrate were superimposable.

Throughout the fractional distillation, a sublimate came over which crystallized from acetone as colorless needles, m.p. 253–255° (decomp.).

Three other bases were isolated from the distillates as their hydrochlorides or perchlorates. The quantities recovered, however, were insufficient to allow proper characterization.

HIGH-FREQUENCY TITRATIONS

I. ARGENTIMETRIC DETERMINATION OF HALIDES AND THIOCYANATE IN METHANOL[1]

PETER GREY AND G. C. B. CAVE
Department of Chemistry, McGill University, Montreal, Quebec
Received August 1, 1963

ABSTRACT

A new method is proposed for the determination of milligram amounts of each halide present in a mixture of alkali-metal halides. In some mixtures, thiocyanate also may be determined. A methanol solution of the sample is titrated in a closed-type cell, with a standard solution of silver nitrate in methanol. By using high-frequency titrimetry, and an appropriate concentration of the halide solution, sharp end points were obtained for each halide. Because of solid solutions, the accuracy of the determination of individual halides in mixtures depended on the mole ratios of the halides; the errors found in the titration of various binary, ternary, and quaternary mixtures are reported. For some binary mixtures, the total amount of halide titrated in 120 ml of methanol was varied from 0.5 to 500 micromoles. At the lower concentrations, addition of a small amount of sodium nitrate sharpened the end point. At all concentrations of halide, an excessive amount of indifferent electrolyte essentially eliminated the end points. The alkali-metal halides gave more satisfactory titration graphs than did some other metal halides. The effects of variation in temperature, and of solvent evaporation were noted.

INTRODUCTION

The present work describes the high-frequency argentimetric titration of alkali-metal halides and thiocyanate in their mixtures dissolved in methanol. It was found that such titrations could also be performed in ethanol, in acetonitrile, and in acetone–water mixtures.

Volumetric methods for the halides usually are based on the use of silver nitrate as the titrant. In addition to the use of indicators to detect the end point, potentiometric and amperometric methods may be used (1). The potentiometric titration of halides in aqueous solutions of their mixtures was recently studied by Martin (2), and by Bowers *et al.* (3). The effect of using acetone–water mixtures instead of water in the amperometric determination of halides has been studied (4). Léon (5) determined by potentiometric titration the bromide and the thiocyanate contents of mixtures, in acetone.

High-frequency titrations have also been reported for the determination of chloride alone in aqueous solutions (6) and in other solvents (7), and for the determination of chloride and of sulphate present together in acetone–water solutions (8). Low-frequency conductometric titrations of single halides is practicable, but is not feasible for the individual determination of halides in mixtures, in aqueous solution, or in methanol.

EXPERIMENTAL

Apparatus

The Sargent Model V Oscillometer was used. It is a null-type instrument, with a fixed frequency of 5 megacycles per second. When higher sensitivity was needed, a Sargent cell compensator was coupled in the transmission line ahead of the sample cell. It is a variable inductor, whose reactance can be adjusted to the capacitance reactance due to the walls of the titration cell.

The titration cell was a capacitor in parallel with standard capacitors, to comprise the resonant circuit of the oscillometer's sine-wave oscillator. After each measured addition of titrant, the apparent capacitance

[1]*Presented in part at the Ninth Ottawa Symposium, Canadian Association for Applied Spectroscopy in conjunction with the Analytical Chemistry Division of the Chemical Institute of Canada, September 17–19, 1962.*

of the filled cell was measured by removing standard capacitances from the resonant circuit, until the frequency of the circuit was restored to its original value. This apparent capacitance is a function of the conductance and the dielectric constant of the solution. The principles of high-frequency titrimetry have been described by Reilley and McCurdy (9), and by Sherrick *et al.* (10).

For a titration cell, the closed-type macro cell supplied with the oscillometer was used. Its diameter was 50 mm, and the overall height was 165 mm. It had an outside-fitting ground-glass cap. For the present work, two holes, 9 mm in diameter, were drilled through this cap. A central hole was for the shaft of a polypropylene stirrer. The other hole was for the delivery tip of a buret. The shaft and the delivery tip were each fitted with a sliding washer of silicone rubber having a thin smear of silicone grease, to provide reasonably gas-tight seals at the two holes in the glass cap. A closed-type titration cell has also been used by Hitchcock and Elving, for non-aqueous titrations (11).

The solution for titration was contained in an annulus of 90-ml capacity, which constituted the lower half of the cell. The two outer cylindrical walls of this annulus each had a metal coating, to serve as the plates of the capacitor. Thus, solutions never were in contact with these plates.

A 50-ml buret was used, with its glass stopper lubricated with silicone grease. It had a special delivery tip. This tip was bent sharply at 90 degrees to give a horizontal section of about 8 cm, then sharply at 90 degrees to give a final vertical section of about 11 cm. Part of this 11-cm length projected into the titration cell. The orifice was immersed in the sample solution during stirring.

Burets and pipets were calibrated to deliver methanol.

Reagents

Standard solutions of silver nitrate, 10^{-4} N to 10^{-2} N, were prepared in pure methanol, from reagent-grade silver nitrate previously dried first at 110° C, then for 15 minutes at 255° C. They were standardized by high-frequency titrations, against reagent-grade sodium chloride dried at 550° C. This sodium chloride was the primary standard in the present investigation.

Standard solutions of sodium iodide, sodium bromide, sodium chloride, and potassium thiocyanate in methanol were prepared from dried reagent-grade salts. The iodide and thiocyanate were dried at 120° C, and the bromide at 550° C. The iodide, bromide, and thiocyanate solutions were standardized by high-frequency titrations against a previously standardized solution of silver nitrate.

Standard solutions of sodium nitrate in methanol were prepared from the reagent-grade salt previously dried at 120° C. These solutions were not standardized. Their halide content was found to be negligibly small, in the amounts used.

The methanol was absolute, reagent grade. Its water content was measured in accordance with the method of Willis and Miller (12) by using the infrared peak of water, at 1.950 μ and was found to be 0.03%.

The acetone was reagent grade. It contained about 5% of water, which was not removed.

The Titrimetric Procedure

A dry cell was inserted into the cell holder of the oscillometer. The instrument reading was then adjusted to zero by removing from the circuit a capacitance equal to that of the empty cell. Without removing the cell, the required aliquot of one of the standard solutions of halide in methanol was added by pipet. This aliquot was then diluted to 120±1 ml with methanol. This volume provided for satisfactory stirring, as well as bringing the level of the liquid well above the top of the condenser plates of the cell. The polypropylene stirrer was positioned, with its paddles 5 mm above the top of the condenser plates. The ground-glass cap was then slid down the stirrer shaft, into position. The filled buret was positioned. Finally, the two silicone-rubber washers were positioned at the holes in the cap.

The rate of stirring was not critical. It was adjusted so that the top of the vortex was about 25 mm above the still level of the liquid. The precipitated silver halide was then found not to settle.

After the original solution was stirred, the apparent capacitance due to the solution was measured, and recorded merely as "instrument divisions." A standard solution of silver nitrate in methanol was added in measured increments. After each such addition, the apparent capacitance due to the solution was read. The additions were continued past the end point. Stirring was continuous throughout the titration.

Apparent capacitance (as instrument divisions) was plotted against the volume of titrant added. In general, straight lines could be drawn through the points, and they intersected at the end point. Typical titration graphs are shown in Fig. 2 for the titration of methanol solutions of sodium halides by a standard solution of silver nitrate in methanol.

RESULTS AND DISCUSSION

The Effect of Temperature and Solvent Evaporation

The apparent capacitance due to an electrolyte solution in the titration cell is a function both of the dielectric constant of the solution, and of its conductance. The temperature coefficient of the dielectric constant will be negative, and that of the conductance will be

positive. Therefore, for a solution such as an alkali halide in methanol, the nett temperature coefficient of the apparent capacitance will change sign at some concentration of electrolyte. Measurements on a solution of sodium chloride in methanol confirmed this conclusion. A solution 5.5×10^{-5} M in sodium chloride showed a zero temperature coefficient; at higher concentrations the coefficient was negative.

On titrating stirred methanol solutions of alkali halides in a titration cell similar to the one described above but without the cover, solvent evaporation occurred, with concomitant lowering of the temperature of the solution. This cooling effect is shown in Fig. 1*a*.

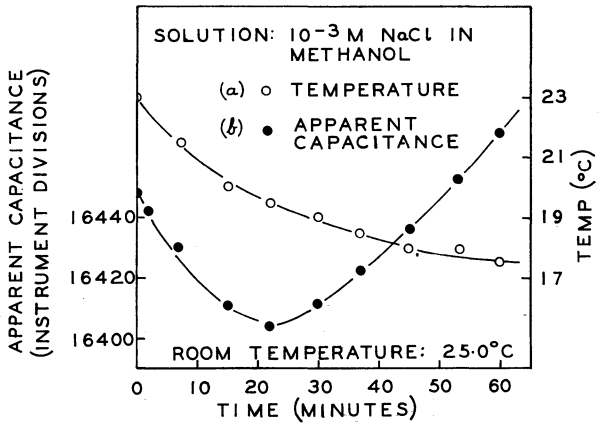

FIG. 1. Changes in temperature and in apparent capacitance due to solvent evaporation from a continuously stirred solution of NaCl in methanol, in an open cell.

The nett change in apparent capacitance due to this solvent evaporation is shown in Fig. 1*b*, as a function of the period of stirring. The curve is the resultant of two opposing effects; both are due to evaporation. The apparent capacitance for this solution has a negative temperature coefficient. The rate of fall of temperature of the solution declined with time. To the left of the minimum, the effect of the negative temperature coefficient predominated over the effect of the increase in concentration due to evaporation. Therefore the apparent capacitance declined. To the right of the minimum the increase in concentration was predominant.

Clearly the slope, and the degree of curvature of the arms of a titration graph will generally be affected by solvent evaporation from an open titration cell. Provided that stirring was continuous and at a reasonably constant rate, the titration graphs were found to be satisfactory for the detection of the end point. However, the slopes of the arms of these graphs varied with the rate of addition of titrant, and with the stirring program. The use of intermittent stirring, with unequal increments of titrant was found to produce anomalous kinks in the titration graphs. For example, when stirring was stopped between increments of titrant, then a change in the size of the increment during a titration produced a change in the slope of the titration graph. This effect was due to a change in the volume of methanol evaporated, per milliliter of titrant added.

Standardization of Solutions

Sodium chloride was the primary standard. The titrimetrically determined normalities of the silver nitrate, sodium iodide, sodium bromide, and potassium thiocyanate solutions were found to be within 1% of the values calculated from the weights of the pure salts

taken to prepare the standard solutions. In general, 1–10 mg of halide were taken for the high-frequency titration.

Titration of Single Halides

Typical titration graphs for single halides in methanol, titrated against silver nitrate in methanol are shown in Fig. 2.

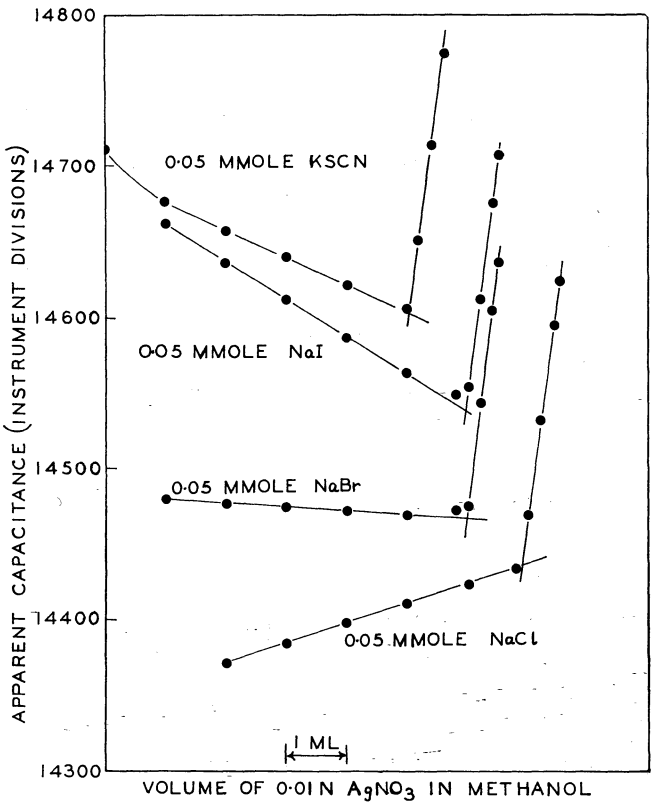

FIG. 2. Typical titration graphs of argentimetric titrations of single halides in methanol.

The slope of the lefthand branch of the graph was found to depend not only on the nature of the halide, but also on its concentration, and the concentration of indifferent electrolyte, such as sodium nitrate, present. These changes in slope will be explained in a subsequent communication.

The precision with which single halides can be titrated by using the proposed high-frequency method was found from replicate titrations; the standard deviations are given in Table I.

Determination of Halides and Thiocyanate in Mixtures

Binary, ternary, and even quaternary mixtures of halides and thiocyanate were satisfactorily titrated, and each component determined. However, the acuteness of the angles at the various end points was found to depend on the concentrations of the halides and thiocyanate present, and on the ionic strength of the methanol solutions. At extreme concentrations, low and high, the end points could not be recognized. The limits within

which titrations are feasible can be predicted, and are considered in a subsequent communication.

Typical examples of titrations are shown in Figs. 3 and 4.

Inspection of Fig. 3 shows that for the bromide–chloride mixture, the titration graph has decided curvature at the bromide end point, and practically none at the chloride end point. For a thiocyanate–chloride mixture, curvature was evident at the thiocyanate end point. The degree of curvature at an end point depends on the mixture. Moreover, curvature at the end point occurred when single halides were titrated (see Fig. 2).

In conventional low-frequency conductometric titrations in aqueous solutions, curvature at an end point is usual. This has been attributed to the solubility of the silver halide

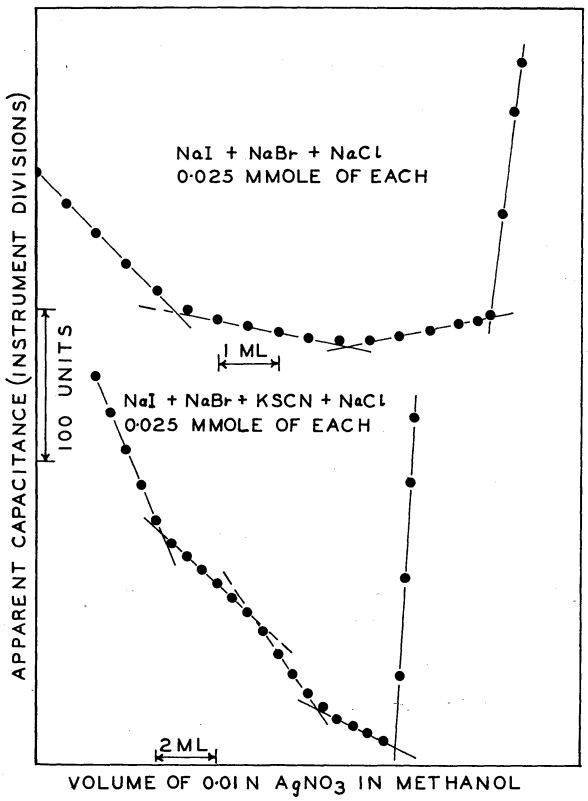

FIG. 4. Typical titration graphs of argentimetric titrations of mixtures of several halides in methanol.

(13), and to the adsorption of ions on the surface of the precipitate (14). In the present high-frequency titrations, the formation of solid solutions would be expected to contribute to curvature at an end point.

Replicate determinations of chloride and bromide in equimolar mixtures were made, in order to find the precision of the analyses as measured by the standard deviation. These results are in Table II. In addition to these replicate titrations, additional single or

duplicate titrations were made on assorted mixtures of halides and thiocyanate. The results are in Table III. Attention is drawn to the successful determination of chloride, bromide, iodide, and thiocyanate present together in an equimolar mixture.

In connection with these titrations of mixtures of halides and thiocyanate, as reported in Tables II to IV inclusive, the various solubility-product values are of interest. The pK values of the solubility products of AgCl, AgSCN, AgBr, and AgI in methanol at 25° C have been reported (15) to be, respectively, 13.05, 13.74, 15.24, and 18.22.

The Formation of Solid Solutions of Halides

The novel feature of the present communication is the detection of end points in argentimetric titrations of mixed halides in methanol; the purpose was not the reduction of errors due to the formation of solid solutions. However, several workers (13, 16–19) have studied the formation of solid solutions during the precipitation of halides from aqueous solutions. It was considered of interest to study precipitation from methanol solutions.

Argentimetric high-frequency titrations were carried out in replicate, on mixtures of sodium bromide and sodium chloride present together in various proportions. The results are in Table IV.

In all of the analyses reported in Tables II, III, and IV the end points were observable. However, not all titrations gave equally clear end points. The acuteness of the angle of intersection of two arms of a titration graph, that is, the sharpness of the end point, was found to depend on the total concentration of halide present.

Inspection of Table IV shows that solid solutions were formed in these chloride–bromide systems. The sign of the percentage difference between amount taken and amount found, given in column 6, changes at a point where the ratio of the initial concentration of chloride to that of bromide is less than unity. Flood (17), in considering the precipitation of chloride and bromide in aqueous mixtures, showed that this fact indicates the formation of heterogeneous solid solutions; the percentage differences should go through zero when the halide ratio is unity, if homogenous solid solutions are formed.

The data in Table III, and the relevant solubility products indicate that a thiocyanate–chloride mixture is the other binary mixture for which an argentimetric titration of each component is of limited use.

Range of Titratable Concentrations, and Effect of an Indifferent Electrolyte

When the apparent capacitance due to a solution is plotted against the logarithm of its concentration, a sigmoid curve is obtained. It has relatively flat arms parallel to the concentration axis, at high and low concentrations. Thus, there is a range of concentrations within which the concentration of a solution for titration must be kept, in order to ensure that the instrument will be sufficiently sensitive to changes in concentration to provide a definite break in the titration curve.

Each solute present in a solution contributes, by its conductance or by its dipole moment, to the apparent capacitance. The addition of an indifferent electrolyte, such as sodium nitrate, to a halide solution in methanol therefore increases this apparent capacitance. If too much of an indifferent electrolyte is present in the halide solution, then the response of the oscillometer will be along the upper, flat arm of the above-noted sigmoid curve. As a result, a break will not be evident in the titration graph obtained in the argentimetric titration of the halide. In general, the acuteness of the angle made by the arms of the titration graph will depend on the ionic strength of the solution. This was confirmed, and at about 0.01 M sodium nitrate, there was no break at the end point.

So far in the present report, the amount of alkali halide titrated in 120 ml of methanol has been 5–100 μmoles. However, up to 500 μmoles of sodium chloride and sodium bromide, alone and in their mixtures, were successfully titrated; the upper limit of

titratable concentration was not sought. Amounts down to 0.5 μmole of these two halides were also successfully titrated in their mixtures, provided that 50 μgrams or more of sodium nitrate were also present, and that the Sargent cell compensator was also used, at a setting of about 800 units.

Titration of Halides of Metals other than Alkali Metals

The titration graphs obtained for the alkali-metal halides consisted of linear branches, although in the immediate vicinity of the end points for some mixtures there was curvature. A few titrations were made of anhydrous strontium chloride, anhydrous cupric chloride, and ferric chloride hexahydrate, separately in methanol. Approximately 50 μmoles were titrated with 0.01 *N* silver nitrate in methanol. The titration graphs for strontium chloride and for cupric chloride are shown in Fig. 5; that for ferric chloride was too in-

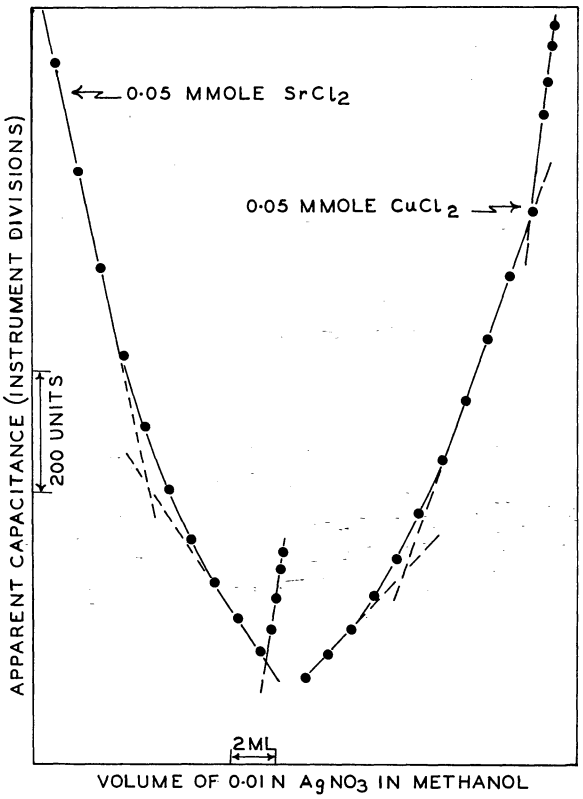

FIG. 5. Titration graphs of the argentimetric titration of strontium chloride and of cupric chloride in methanol.

definite to be useful. The second break in each graph corresponds to the stoichiometric end point. The first break, in the vicinity of which the graphs are curved, corresponds roughly to one-half the stoichiometric end point. However, it would be speculation to suppose that this first break indicates the presence of $CuCl^+$ and of $SrCl^+$.

The illustrated curvature in a titration graph, caused by the presence of a non-alkali metal, could obscure an end point when a mixture of halides is being titrated. Therefore, it may be necessary in analyses of mixtures of halides in which a non-alkali metal is present, to replace that metal by an alkali metal, prior to titration of the halides.

The presence of acid in the methanol solution of halide caused curvature in the branch of the titration graph that preceded the end point; the branch after the end point was linear. Such titration graphs are shown in Fig. 6, for several solutions that contained

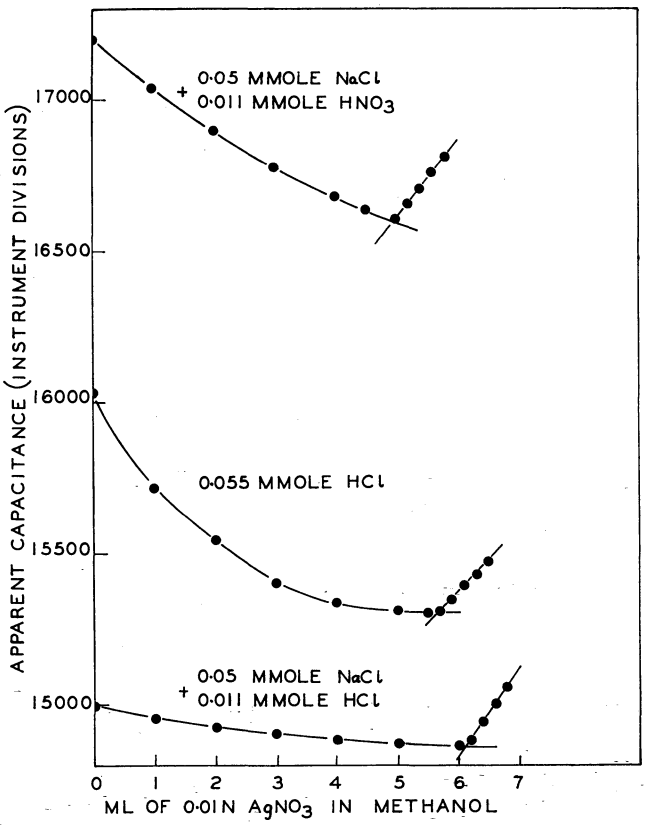

FIG. 6. The effect of acid on the titration graphs in the argentimetric determination of halide in methanol.

hydrochloric acid or nitric acid. As expected, nitric acid produced less curvature than did hydrochloric acid. To permit unequivocal titrations of mixtures of halides, it would seem advisable in general to neutralize almost all of the free acid present, prior to a titration.

ACKNOWLEDGMENTS

We are grateful to Mrs. Nurjahan Begum for obtaining the data in Table IV, to the National Research Council for financial support, and to the Province of Quebec for a scholarship to one of us (P. G.).

ABSTRACT

The hydrolysis of $(CH_3)_2SnCl_2$ has been studied in a medium 0.1 *M* in $(Na^+)Cl^-$ by a potentiometric titration technique. The complexes formed by the hydrolysis reactions together with their formation constants have been determined by analysis of the 394 data sets using a high speed digital computer. The data can be fitted equally well over the range pH 1.5 to 9 by the four formation constants for $(CH_3)_2SnOH^+$ ($\log {}^*\beta_{11} = -3.245\pm0.004$), $[(CH_3)_2SnOH]_2^{+2}$ ($\log {}^*\beta_{22} = -5.00\pm0.02$), $(CH_3)_2Sn(OH)_2$ ($\log {}^*\beta_{21} = -8.516\pm0.004$), and $[(CH_3)_2Sn]_4(OH)_6^{+2}$ ($\log {}^*\beta_{64} = -16.85\pm0.02$) or by the five constants for $(CH_3)_2SnOH^+$ ($\log {}^*\beta_{11} = -3.251\pm0.004$), $[(CH_3)_2SnOH]_2^{+2}$ ($\log {}^*\beta_{22} = -5.05\pm0.02$), $(CH_3)_2Sn(OH)_2$ ($\log {}^*\beta_{21} = -8.535\pm0.005$), $((CH_3)_2Sn)_2(OH)_3^+$ ($\log {}^*\beta_{32} = -9.81\pm0.01$), and $((CH_3)_2Sn)_3(OH)_4^{+2}$ ($\log {}^*\beta_{43} = -11.52\pm0.03$). Thus there is little question about the existence in the solutions of the simple monohydroxo complex and its dimer or of the neutral dihydroxide. Only very low concentrations of species containing more than four tin atoms can exist in aqueous solution. In addition, the data determined previously for the hydrolysis of $(CH_3)_2Sn(ClO_4)_2$ in a medium 3.0 *M* in $(Na^+)ClO_4^-$ have been refined by the least squares procedure. These 762 data sets can also be fitted equally well by the set of constants $\log {}^*\beta_{11} = -3.55\pm0.01$, $\log {}^*\beta_{22} = -4.52\pm0.01$, $\log {}^*\beta_{21} = -9.00\pm0.01$, and $\log {}^*\beta_{64} = -16.14\pm0.03$ or $\log {}^*\beta_{11} = -3.54\pm0.01$, $\log {}^*\beta_{22} = -4.60\pm0.02$, $\log {}^*\beta_{21} = -8.98\pm0.01$, $\log {}^*\beta_{32} = -9.76\pm0.06$, and $\log {}^*\beta_{43} = -10.40\pm0.05$. The tendency of dimethyltin dichloride to form polycondensed species in aqueous solution is slight, and there is no evidence for the formation of large rings or chains. The solid stannoxane which precipitates from chloride solution was studied by infrared and X-ray powder photography and is essentially the same as the compound obtained by reaction of $(CH_3)_2SnO$ and $(CH_3)_2SnCl_2$ in a 1:1 mole ratio in 95% ethanol. This corresponds to a slightly different product than that obtained by a 1:1 reaction of these compounds in benzene which gives $((CH_3)_2SnCl)_2O$. This is in accord with the observation that precipitation occurs only at a pH higher than that at which $((CH_3)_2SnOH)_2^{+2}$ has attained the maximum concentration, and hence precipitation is occasioned by the formation of larger polycondensed species. A comparison of the perchlorate and chloride data also indicates that the tendency to form polycondensed species is reduced by the presence of chloride ion. This is partially an ionic strength effect and partially a result of chloride complexing of the simple aquodimethyltin(IV) ion, and the first chloro-complexing constant was estimated to be 28 l. mole^{-1}.

INTRODUCTION

With the rise in interest in the synthesis of metalloxane polymers, numerous attempts have been made to synthesize tractable polyorganostannoxanes. Although it would appear by analogy with the organodihalosilanes that the dialkyltin dihalides could be used as starting materials in a hydrolytic polycondensation reaction, it was shown quite some time ago by Rochow and Seyferth (1) that this was not the case. The free energy change for the hydrolysis of dimethyltin dichloride is much less negative than for the hydrolysis of dimethyldichlorosilane, the hydrolysis is readily reversible, and large condensation polymers are not formed. It has also been established that dimethyltin dichloride undergoes extensive aquation in solution, and the equilibrium in [1] almost entirely favors the aquodimethyltin cation (2, 3). The value of n is presumed to be 2.

$$(CH_3)_2SnCl_2 + nH_2O = (CH_3)_2Sn(OH_2)_n + 2Cl^- \qquad [1]$$

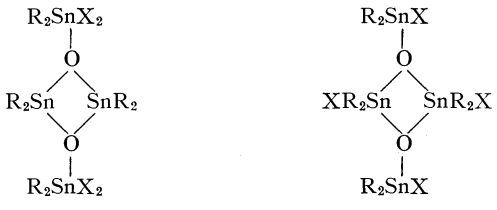
In the years intervening since these initial experiments, several attempts at other methods of synthesis of the polydialkylstannoxanes have been made. In general, these have been based on the direct reaction of dialkyltin oxides with the dialkyltin dihalides, since Harada showed that these reactions give low molecular weight polycondensation products (4, 5). In addition many attempts have been made to obtain useful materials by the cohydrolysis of organosilicon monomers with organotin monomers. Much of this work has been described in a recent review (6).

A short time ago, a study of the hydrolysis of the aquodimethyltin(IV) cation in a medium 3 *M* in sodium perchlorate was reported (7). It had been previously noted that the dimethyltin(IV) ion behaved, qualitatively, much like the tin(II) ion (8); and it had been shown some time ago that polynuclear hydrolysis products exist in hydrolyzed tin(II) solutions (9). Indeed, it was found that in addition to the simple conjugate base $(CH_3)_2SnOH^+$ appreciable concentrations of a binuclear species $((CH_3)_2Sn(OH))_2^{+2}$ were formed in the hydrolyzed dimethyltin perchlorate solutions. At even higher ratios of base to dimethyltin aquo ion, larger polynuclear complexes appeared to be formed together with the neutral hydroxide $(CH_3)_2Sn(OH)_2$; and the data were fitted in terms of equilibrium constants for the formation of $((CH_3)_2Sn)_2(OH)_3^+$ and $((CH_3)_2Sn)_3(OH)_4^{+2}$. When the total concentration of the dimethyltin was greater than about 5 m*M*, precipitation occurred at an $\bar{n}$ (average number of hydroxo groups bound per dimethyltin group) of ca. 1.4. Systematic deviations of the calculated $\bar{n}(\log [H^+])$ curves from the experimental data indicated that even larger polynuclear complexes were formed at $\bar{n}$ values slightly less than that at which precipitation occurred. In a few cases, the precipitate was filtered off from the solution and dried. This basic dimethyltin(IV) perchlorate burned violently in the open; and because of the potentially explosive nature of the compound, no further studies were made of it. It has been shown that the basic tin(II) nitrate is a rather violent explosive and is more heat- and impact-sensitive than lead azide (10).

Since most of the preparative studies on stannoxanes have been conducted with the halides and especially with the chlorides, it was decided to undertake a thorough study of the species present in solutions of dimethyltin dichloride. In such equilibrium studies, it is necessary to employ a rather high concentration of supporting electrolyte, and the medium 0.1 *M* NaCl was chosen. It was hoped that in comparison to the measurements in 3 *M* $NaClO_4$ the reduction in ionic strength would permit measurements to be made at higher concentrations in the region of extensive hydrolysis without precipitation occurring.

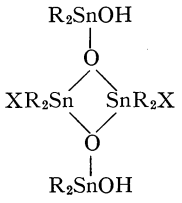
Tin 119 NMR studies on the hydrolysis intermediate with the stoichiometry $((CH_3)_2SnCl)_2O$ have indicated that the tin atoms are found with two different configurations. It was originally suggested that this compound was a tristannoxane (11), but further studies indicated that it was dimeric in benzene, and structures I and II were suggested



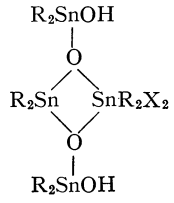
I II

(12). In addition, it has been reported that a single crystal X-ray study of tetramethyl-1, 3-bistrimethylsiloxydistannoxane shows that the tin and oxygen positions are those

suggested in structures I and II (13). Alleston *et al.* (12) also observed that compounds with the stoichiometry $R_4Sn_2X(OH)O$ are formed, and structures III and IV have been suggested for these.



III



IV

It was hoped that our studies on solutions of dimethyltin dichloride would shed more light on the processes by which these stannoxanes are formed during the hydrolysis. In addition, we have gained access to a Control Data Corporation 1604 computer since our original studies on perchlorate solutions were completed, and this permits us to subject all of our data to a much more rigorous evaluation.

EXPERIMENTAL

Solution Preparation

Solutions of dimethyltin dichloride were prepared by dissolving weighed amounts of $(CH_3)_2SnCl_2$ in distilled water. Hydrochloric acid was standardized against Na_2CO_3 and was added to the stock solution to give a hydrogen ion concentration of ca. 0.2 *M*. The $(CH_3)_2SnCl_2$ was obtained from M and T Chemicals, Inc., New York, and was recrystallized twice from benzene. Anal. Calculated: C 10.94, H 2.75. Found: C 10.94, H 2.82%.

Standard sodium hydrogen carbonate, sodium hydroxide, and sodium chloride solutions were prepared from reagent grade chemicals.

Apparatus and Procedure for Solution Measurements

The hydrogen ion concentration of the solutions was determined with the cell Ag|AgCl|100 m*M* NaCl satd. with AgCl||100 m*M* NaCl||*B* m*M* $[(CH_3)_2Sn]^{+2}$, *H* m*M* H^+, (100−2*B*−*H*) m*M* Na^+, 100 m*M* Cl^-|glass electrode. A Beckman type 40498 glass electrode was used. The glass electrode system was calibrated as a hydrogen ion concentration probe in the range $1.0 \leqslant pH \leqslant 4.0$ by measuring the cell e.m.f. during the titration of hydrochloric acid with sodium hydrogen carbonate and sodium hydroxide solutions. Deviations from ideal behavior are considerably more pronounced in dilute ionic media such as employed here than in the more concentrated media like 3 *M* $NaClO_4$. The potentials are described by the equation $E_g = E' + 59.15 \log [H^+]$. The quantity E' was fitted by least squares to an equation quadratic in $[H^+]$, $E' = E^0 - 0.524 [H^+] + 0.00204 [H^+]^2$; concentrations in m*M*. The apparatus and the general experimental procedure have been described earlier (7).

X-Ray Powder Patterns

All X-ray patterns were taken with a General Electric XRD-3 diffractometer using copper $K\alpha$ radiation.

Infrared Spectra

All infrared spectra were determined with a Perkin Elmer 21 spectrometer equipped with NaCl optics. The split mull technique was employed, using fluorocarbon from 4000 to 1325 cm^{-1} and Nujol from 1325 to 650 cm^{-1}.

Reaction of Dimethyltin Dichloride with Sodium Hydroxide

Ten grams of $(CH_3)_2SnCl_2$ was dissolved in 100 ml of 0.1 *M* NaCl, and NaOH solution was added until the mole ratio of $(CH_3)_2SnCl_2$ to NaOH was 1:1. The white precipitate which formed was filtered by suction, washed with water, and dried over $CaCl_2$. This product was only slightly soluble in benzene or ethanol. Anal. Calculated for $((CH_3)_2SnCl)_2O$: Sn 62.3, C 12.50, H 3.15. Calculated for $((CH_3)_2Sn)_3Cl_2O_2$: Sn 64.9, C 13.10, H 3.31%. Found: C 12.56, H 3.31. The infrared spectrum of the product showed absorption at 2980 and 2900 (C—H str.), 1410 (w. asym. methyl def.), 1197 (s) and 1193 (m) methyl def., at 960, and at 783 (s), 720, and 704 cm^{-1} (CH_3—Sn rock). There was no evidence for an O—H stretch.

Reaction of Dimethyltin Dichloride with Dimethyltin Oxide

A solution was prepared by dissolving 1.1 g of $(CH_3)_2SnCl_2$ in 300 ml of 95% ethanol and adding 0.83 g of $(CH_3)_2SnO$ to give a mole ratio of $(CH_3)_2SnCl_2$ to $(CH_3)_2SnO$ of 1:1. After heating for 3 hours on a hot plate, the unreacted $(CH_3)_2SnO$ was filtered off, the filtrate was evaporated to 100 ml, and the white product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

filtered by suction. This product was only slightly soluble in benzene. Anal. Found: Sn 63.1, C 12.78, H 3.18. The X-ray powder pattern for this compound was identical with that of the compound described above which had been precipitated from aqueous solution and also different from that of either of the starting materials. The infrared spectrum of the product showed absorption at 2980, 2900, 1410 (w), 1196 (s), 1193 (m), 968 (w), 780 (s), 720 (m), and 702 (m) cm^{-1}.

$(CH_3)_2SnCl_2$ and $(CH_3)_2SnO$ were reacted in a 1:1 mole ratio in hot benzene, and the product was separated after filtration and evaporation of a portion of the solvent. This compound was readily soluble in benzene. Anal. Found: Sn 62.3, C 12.68, H 3.14%. The infrared spectrum showed absorption at 2980, 2900, 1407 (w), 1200 (s), 1197 (m), 970 (w), 795 (s), and 725 (m) cm^{-1}.

The above reaction was also carried out in absolute ethanol, the hot solution was filtered after 15 minutes, and the product was obtained by evaporation of a part of the solvent. This product was also very soluble in benzene. The X-ray powder patterns of these last two compounds prepared under anhydrous conditions were identical and somewhat different from that of the first two compounds prepared in the presence of water. Anal. Found: Sn 63.3, C 12.84, H 3.19%. The infrared spectrum showed absorption at 2900, 1405 (w), 1200 (s), 1195 (m), 970 (w), 790 (s), and 725 (m) cm^{-1}.

TREATMENT OF DATA

Hydroxo Complexing

The nomenclature used in the description of the equilibrium constants is that of the Chemical Society Tables (14). The total dimethyltin dichloride concentration was held constant during the determination of the individual $\bar{n}(\log [H^+])_B$ curves. Here $\bar{n}$ is the average number of hydroxo groups bound (or protons transferred) per dimethyltin(IV) group in the solution, and B is the total dimethyltin dichloride concentration. Runs were made with 30.6, 20.4, 10.2, 5.1, and 2.55 mM $(CH_3)_2SnCl_2$. Duplicate runs were made with the three lowest concentrations. In contrast to the studies with the 3 M perchlorate medium (7), no precipitation was observed with $B \leqslant 20$ mM. The data are illustrated in Fig. 1. The general character of the curves is similar to that for the 3 M perchlorate

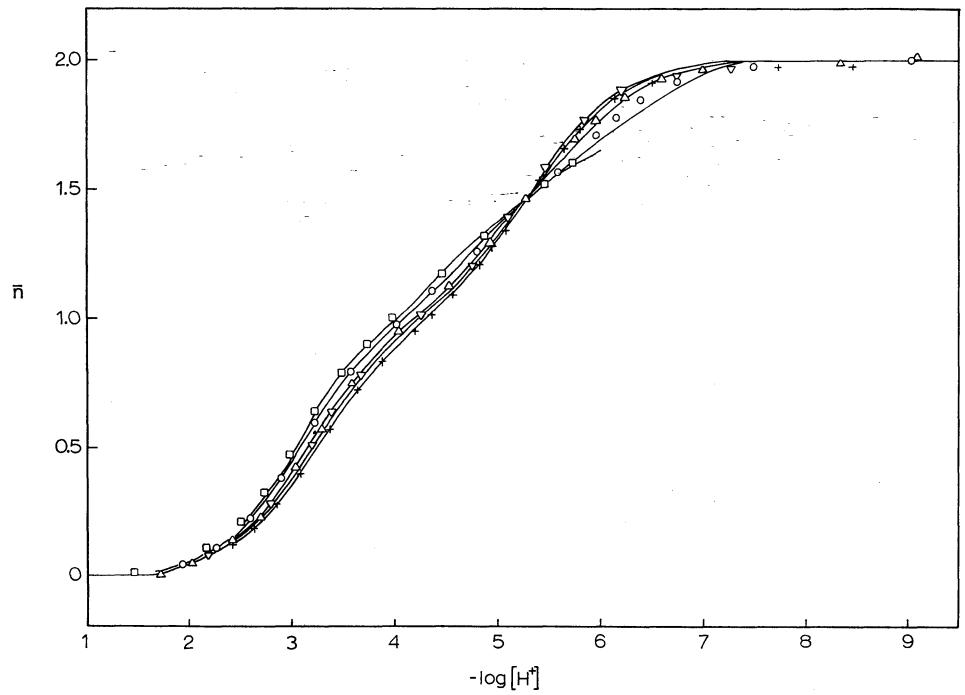


FIG. 1. Average number of protons transferred per dimethyltin(IV), $\bar{n}$, as a function of $-\log [H^+]$. Only about one-fifth of the data items are shown. □ 30.6 mM, ○ 20.4 mM, △ 10.2 mM, ▽ 5.1 mM, × 2.55 mM $(CH_3)_2SnCl_2$. Curves drawn with set of four constants (1, 1), (2, 2), (2, 1), (6, 4) given in Table I.

For personal use only.

medium, although it is immediately obvious that the dependence on the total dimethyltin ion concentration is much reduced. There is thus considerably less tendency to form polycondensed species in the chloride medium. The "isohydric" or crossover point (15) occurs at the same $\bar{n}$ value of 1.43, although the isohydric pH is shifted about 0.3 unit lower. This indicates that essentially the same species, aside from complexing by the medium ions, are formed in both the chloride and perchlorate solutions from pH 1 to 9.

Trial values for the equilibrium constants were obtained by curve fitting procedures. As has been observed for measurements in 3 M $NaClO_4$ (7) and in 0.1 M KNO_3 (16), the data up to $\bar{n} \leqslant 0.8$ could be fitted well in terms of two constants for the formation of $(CH_3)_2SnOH^+$ (1, 1) and the dimer $((CH_3)_2SnOH)_2^{+2}$ (2, 2). Trial values for $^*\beta_{11}$ and $^*\beta_{22}$, the equilibrium constants for reactions 2 and 3, were obtained by fitting the data $\log B(\log [H^+])_{\bar{n}}$ with normalized projection maps (7). The values $\log {}^*\beta_{11} = -3.2$ and $\log {}^*\beta_{22} = -4.9$ were obtained.

$$(CH_3)_2Sn^{+2} + H_2O = (CH_3)_2SnOH^+ + H^+ \quad [2]$$

$$2(CH_3)_2Sn^{+2} + 2H_2O = (CH_3)_2Sn(OH)_2Sn(CH_3)_2^{+2} + 2H^+ \quad [3]$$

At $\bar{n}$ values of from ca. 1 to 2, the predominant species is the uncharged dimethyltin dihydroxide. The trial value for the equilibrium constant $^*\beta_{21}$ for reaction 4 was obtained

$$(CH_3)_2Sn^{+2} + 2H_2O = (CH_3)_2Sn(OH)_2 + 2H^+ \quad [4]$$

from the value of $^*\beta_{11}$ estimated above and the $\bar{n}$ and $[H^+]$ values at the isohydric point according to the relation in [5]. The estimated value of $\log {}^*\beta_{21}$ was -8.6.

$$\bar{n}_{\text{mono}} = \frac{\beta_{11}[H^+]^{-1} + 2\beta_{21}[H^+]^{-2}}{1 + \beta_{11}[H^+]^{-1} + \beta_{21}[H^+]^{-2}} \quad [5]$$

It should be pointed out that since the measurements have been made in media with $NaClO_4$ or with NaCl as the supporting electrolyte, a concentration term such as $[(CH_3)_2SnOH^+]$ actually refers to the sum of the concentrations of several different structural entities, namely, to $\sum_x \sum_y \sum_z [(CH_3)_2SnOH(OH_2)_x(Na^+)_y(ClO_4)_z]^{+(y+1-z)}$ and $\sum_x \sum_y \sum_z [(CH_3)_2SnOH(OH_2)_x(Na^+)_y(Cl^-)_z]^{+(y+1-z)}$, respectively. In the case of measurements with perchlorate media, one generally assumes no appreciable complexing by the medium ions. On the other hand, with a chloride medium a measurable degree of complexing by chloride ions might be expected.

The data at the higher concentrations of the dimethyltin ion indicate that complexes larger than the dimer are formed at $\bar{n}$ values greater than ca. 0.8. In the earlier analysis of the perchlorate data (7), the data in this region were fitted fairly well by the inclusion of equilibrium constants for the formation of two additional species (3, 2) and (4, 3) formed according to equations 6 and 7. There was also some indication that the data

$$2(CH_3)_2Sn^{+2} + 3H_2O = ((CH_3)_2Sn)_2(OH)_3^+ + 3H^+ \quad [6]$$

$$3(CH_3)_2Sn^{+2} + 4H_2O = ((CH_3)_2Sn)_3(OH)_4^{+2} + 4H^+ \quad [7]$$

might also be fitted by adding an equilibrium constant for a (6, 4) complex formed according to equation 8 rather than by adding the constants for the (3, 2) and (4, 3) complexes. Because of the difficulty involved in the calculation of projection maps to try to fit the

$$4(CH_3)_2Sn^{+2} + 6H_2O = ((CH_3)_2Sn)_4(OH)_6^{+2} + 6H^+ \quad [8]$$

data in terms of the set of complexes (1, 1), (2, 2), (2, 1), and (6, 4), it was not feasible earlier to carry out a thorough test of this set of complexes using only a desk calculator.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The trial values of the constants for the (1, 1), (2, 2), and (2, 1) complexes together with estimated values for the higher constants were used as input to a least squares parameter refinement program for the CDC-1604 computer. Both the 394 chloride and 762 perchlorate data sets were refined. A brief description of some of the Fortran 60 programs used has been given (17). Initially the response surface (MAP Z) or "pit mapping" type of program (18) which adjusts the constants so as to minimize the sum of the squares of the residuals ($\bar{n}_{calcd} - \bar{n}_{exptl}$) was used. Subsequently, it was found that the Gauss method of least squares parameter refinement (19) was much faster, and a program (GAUSS Z) was written to carry out these calculations. This program was similar to the Gauss method program described earlier (17) with the exception that it also minimized the sum of the squares of the residuals in $\bar{n}$ as does MAP Z.[3] The advantage of the higher speed of the Gauss method refinement was quite important with the large numbers of data items involved in these refinements.

It was found that equally good fits to both the chloride and perchlorate data could be obtained with the two sets of complexes ((1, 1), (2, 2), (2, 1), (6, 4)) and ((1, 1), (2, 2), (2, 1), (3, 2), (4, 3)). A survey of the values obtained by the least squares refinement is given in Table I, which gives the constants, their standard errors, σ, and the standard

TABLE I

Survey of the refined values of the equilibrium constants for the dimethyltin(IV) hydrolysis

Medium	0.1 *M* (NaCl)		3 *M* (Na)ClO_4	
log $*\beta_{11}$	−3.251±0.004	−3.245±0.004	−3.54±0.01	−3.55±0.01
log $*\beta_{22}$	−5.05±0.02	−5.00±0.02	−4.60±0.02	−4.52±0.01
log $*\beta_{21}$	−8.535±0.005	−8.516±0.004	−8.98±0.01	−9.00±0.01

log $*K_{21}$	−5.284	−5.271	−5.44	−5.45
$\sigma_{\bar{n}}$	±0.015	±0.015	±0.035	±0.034

errors to the fit, $\sigma_{\bar{n}}$. Since there were 762 data items in the perchlorate set and 394 in the chloride set, tables of the t test of significance can be entered at an infinite number of degrees of freedom, so the errors at the 95% confidence limit are ±1.960 σ and at the 99% confidence limit are ±2.576 σ (20). Figures 2 and 3 give the least squares residuals ($\bar{n}_{calcd} - \bar{n}_{exptl}$) for the chloride data and the four- and five-parameter fits, respectively.

It is virtually certain that the same hydroxo complexes are formed in both the perchlorate and chloride media, and there is no question about the existence of the (1, 1), (2, 2), and (2, 1) complexes. Without these species, it is impossible to begin to reproduce the experimental data. There is some question about the nature of the larger complexes formed, since only a small fraction of the dimethyltin(IV) is distributed in these species except for a very short pH range before precipitation. As Dunsmore *et al.* (21) have pointed out, it is almost always possible to discern the principal complexes, and in general one tries to reproduce the small systematic deviations caused by additional complexes with the minimum number of additional parameters. Here it is difficult to choose between the fits with the sets of four and five parameters. Neither set reproduces the data ideally about the isohydric point. The variance to the fit is essentially the same with both sets.

The problem is that there is no independent way to determine the correct number of parameters, and there may be several additional complexes present in low concentrations just before the precipitation pH is reached.

Chloro-Complexing of the Aquodimethyltin(IV) Ion

The definite differences observed in the values of the equilibrium constants determined for the two different ionic media can be ascribed to two effects. The first is a result of definite chloro-complexing of the different dimethyltin(IV) species, while the second is a result of changes in activity coefficients due to all other factors. There is no indication in the literature of the magnitude of chloro-complexing of the aquodimethyltin(IV) ion except that it must be rather small. If one considers the difference in the values of log $*\beta_{11}$ in a 0.1 M KNO_3 medium (16, 17) (-3.13 ± 0.02) and in the 0.1 M NaCl medium (3.26 ±0.004) to be caused only by chloro-complexing, an estimate of the degree of complexing can be made. It seems logical to assume that the constant for the first chloro complex of the dipositive ion $(CH_3)_2Sn^{+2}$ should be much larger than for the first chloro complex of the unipositive ion $(CH_3)_2SnOH^+$. If this be true, then the following relation obtains.

$$\log *\beta'_{11} = \log *\beta_{11} - \log \alpha^0 \qquad [9]$$

Here, $*\beta'_{11}$ is the hydrolysis constant for the nitrate medium, $*\beta_{11}$ is for the chloride medium, and α^0 is the fraction of the unhydrolyzed dimethyltin(IV) in a 0.1 M chloride medium which is present as the free aquo ion. This gives an estimate of $\log \alpha^0 = -0.13$, $\alpha^0 = 0.74 = [(CH_3)_2Sn(OH_2)_n^{+2}]/[(CH_3)_2Sn^{+2}]_{total}$. Thus it appears that complexing of the dimethyltin ion by chloride ion is not extensive. With the assumption that chloro-complexing of the unipositive $(CH_3)_2SnOH^+$ is much less than that for the dipositive ion $(CH_3)_2Sn^{+2}$, the first chloro-complexing constant can be estimated to be $\beta_1 = \alpha^0/(1-\alpha^0)$ [Cl] = 28 l. mole^{-1}.

There are indications that the assumption that chloro-complexing of $(CH_3)_2SnOH^+$ is small is valid; for the constant for the dimerization of this complex according to equation [10], K_d, is approximately the same in the 0.1 M chloride medium ($\log K_d = 1.45$ to 1.48)

$$2(CH_3)_2SnOH^+ = (CH_3)_2Sn(OH)_2Sn(CH_3)_2^{+2} \qquad [10]$$

as it is in the 0.1 M nitrate medium ($\log K_d = 1.3$ to 1.6 (17)). Although it is questionable just how much reliance can be placed in the value of the first chloro-complexing constant, it appears to be of the right order of magnitude. For Sn^{+2}, the value for β_1 determined at 25° in a 3 M $NaClO_4$ medium is 15.1 l. mole^{-1} (22); this value should increase with a decrease in the ionic strength; and finally it would be expected that the value for $(CH_3)_2Sn^{+2}$ would be somewhat larger. Efforts made to determine the chloride complexing constants independently were without success. No bands attributable to halide complexing were found in the ultraviolet spectrum of solutions of dimethyltin dihalides with varying concentrations of the sodium halide. In addition, attempts were made to determine these constants by the method of ligand displacement with thio-Michler's ketone as a means of determining the concentration of the dimethyltin cation spectrophotometrically (23), but the solubility of the ketone in water proved to be too low.

Preparative Studies

The X-ray powder patterns for the two compounds prepared by precipitation from the aqueous solution of dimethyltin dichloride with NaOH and by the direct reaction of dimethyltin dichloride with dimethyltin oxide in 95% ethanol were identical and different from either of the starting materials. The analysis of these compounds indicates a slightly

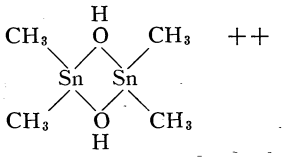
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

more hydrolyzed compound than $((CH_3)_2SnCl)_2O$. The patterns for the compounds prepared by direct reaction of the oxide and chloride in benzene or anhydrous ethanol were also identical but slightly different from that of the first compound. The latter compound was quite soluble in benzene, and it is apparently the one studied by Harada (4, 5) and by Alleston *et al.* (11, 12).

There was no evidence from the infrared spectrum that the compound precipitated from aqueous solution contained hydroxo groups after it had been dried over $CaCl_2$. It has, however, been reported that the hydroxo compounds such as $(CH_3)_4Sn_2Cl(OH)O$ dehydrate readily (12). In all cases, the infrared spectra were essentially that given by Brown, Okawara, and Rochow for $(CH_3)_4Sn_2Cl_2O$ (24). This spectrum differs from the oxide mainly in that the band due to the symmetrical methyl deformation at ca. 1200 cm^{-1} is split into two sharp bands in the oxide at 1206 and 1188 cm^{-1} while in the chlorostannoxanes the splitting is much less and the bands are at ca. 1200 and 1196 cm^{-1}.

DISCUSSION

When $(CH_3)_2SnCl_2$ is dissolved to give a dilute solution, almost all of the dimethyltin(IV) in the solution is found in the simple aquo ion. It seems likely that tin is essentially tetrahedrally coordinated in the solution and so the aquo ion is $(CH_3)_2Sn(OH_2)_2^{+2}$. In contrast to the hypothetical silicon analog, this ion is a rather weak aquo acid. If base is added to the solution, most of the aquodimethyltin(IV) is converted to the mono- and then to the neutral di-hydroxo complexes by simple proton transfer reactions. As the concentration of the dimethyltin ion is increased, more of the simple conjugate base $(CH_3)_2Sn(OH)(OH_2)^+$ is converted to the dimer which probably has the structure V. The



V

basic bridge structure indicated here has been shown to exist in the tetramethyl 1,3-trimethylsiloxydistannoxane (13). If oxygen–tin p_π–d_π bonding were appreciable, such a bridge with ca. 90° Sn—O—Sn angles would not be favored. Since the metal oxygen bonds are not nearly so strong with tin as with silicon, the bridging oxygens are protonated. Thus the stability of the di-μ-hydroxo bridges which satisfy the tetrahedral coordination of tin and hence inhibit the formation of long polycondensed chains is a result of the absence of substantial π bonding. If the hydrolysis is carried to $\bar{n}$ values of 1 and greater by increasing the pH, it should be possible to remove some of the protons on the bridging hydroxo groups. These oxygens could then function as donor atoms replacing water molecules in $(CH_3)_2Sn(OH)(OH_2)^+$ ions. If one proton in I were replaced by the monohydroxo complex, the (4, 3) complex $((CH_3)_2Sn)_3(OH)_4^{+2}$ would be produced while if both protons were replaced the (6, 4) complex $((CH_3)_2Sn)_4(OH)_6^{+2}$ would be produced. The latter complex corresponds to the intermediate described by Alleston *et al.* (12), III and IV. Since the variances to the fits given in Table I for hypotheses including the formation of each of these complexes were the same, there is no clear choice between them; and indeed it is quite possible that both are formed. Finally as the pH approaches 7, the simple monohydroxo complex is converted by a second proton transfer to the dihydroxo complex. Since the complexes are quite labile, this results in the depolymerization of the

and nitrate media compared to the value in 3 M $NaClO_4$ point up the tendency of the concentrated ionic media to stabilize charged polycondensed species.

The white solid which precipitates from the more concentrated solutions is very similar to the compound obtained by reaction of equimolar quantities of $(CH_3)_2SnCl_2$ and $(CH_3)_2SnO$ under anhydrous conditions, although it corresponds to a slightly more hydrolyzed intermediate than $((CH_3)_2SnCl)_2O$. Since no evidence for hydroxo groups was found, additional condensation may occur during the isolation of this product. This would be in accord with the lower solubility found for this product compared to that obtained by reaction in benzene.

The approximate value for the chloro-complexing constant for $(CH_3)_2Sn^{+2}$ was slightly greater than the comparable constant for Sn^{+2} just as it has been observed that the first proton transfer constant for $(CH_3)_2Sn^{+2}$ is slightly greater than the corresponding constant for Sn^{+2} (7). This is to be expected, for the pair of 5*s* electrons should lead to a weakening of the tin ligand bond in tin(II). The fact that these two ions have such similar values can be attributed to the distortions from spherical symmetry which occur with the tin(II) ion (25) which should lead to bonds of comparable strength to those of the dimethyltin(IV) ion.

THE EFFECT OF WATER VAPOR UPON THE DEHYDRATION OF $CaSO_4.2H_2O$

H. G. McAdie
Department of Physical Chemistry, Ontario Research Foundation, Toronto, Ontario
Received August 21, 1963

ABSTRACT

Kinetics of the two-stage dehydration of $CaSO_4.2H_2O$ have been examined under controlled water vapor pressures up to one atmosphere. For both stages water vapor initially accelerated the rate of dehydration and subsequently retarded it. Separate, temperature-dependent water vapor pressures were noted above which each stage could be suppressed.

The hemihydrate was clearly defined either as a change in the rate of weight loss during dehydration or, at higher water vapor pressures, as a fixed composition. The heat of solution of the hemihydrate increased linearly with the partial water vapor pressure present during its formation, but was independent of the formation temperature over the range studied. Activation energy and pre-exponential factor for the dihydrate → hemihydrate process also increased linearly with water vapor pressure. Hemihydrates produced at the extremes of water vapor pressure corresponded to the α- and β-modifications, as defined thermodynamically, and the production of a hemihydrate series with properties varying linearly from one extreme to the other is discussed.

The dehydration of calcium sulphate dihydrate (gypsum) has been studied for decades by many investigators, few of whom have made provision for controlling the partial water vapor pressure during dehydration. No systematic study of its kinetic influence has been reported, although Weiser and co-workers (1, 2) clearly demonstrated the importance of such isobaric studies to a proper understanding of the system.

Despite earlier controversy (3) the combination of evidence now available (1, 2, 4–8) has established the existence of the hemihydrate as the lower hydrate in the $CaSO_4$–H_2O system. However, the composition in terms of water of hydration can be variable over rather wide limits and has led to speculation that there may exist a zeolitic type of structure rather than that of a true hydrate. Clarification has recently been obtained from nuclear magnetic resonance results (5), showing the hemihydrate to contain definite crystal water as well as a variable quantity of relatively free water "occluded" within the crystal lattice. Two modifications of the hemihydrate are known, differing in thermodynamic properties (4), although being structurally quite similar (9, 10). Speculation that these differences reflect the degree of crystal lattice perfection has recently received support (6).

This paper will describe a systematic study of the influence of water vapor pressure upon the kinetics of the dehydration process and upon the thermodynamic properties of the hemihydrates obtained. Previous studies of these properties involved hemihydrates produced at the extreme conditions, i.e. under essentially anhydrous conditions or in an atmosphere saturated with water vapor, plus some commercial plasters produced under undefined partial water vapor pressures (4, 11). A later paper will discuss the influence of partial water vapor pressure upon such practical properties of the hemihydrate as gauging water requirement.

EXPERIMENTAL

Calcium sulphate dihydrate was precipitated slowly from equal volumes of 0.25 *M* calcium nitrate and sulphuric acid. The precipitate was filtered on sintered glass; washed with water, ethanol, ether; dried at 40° C for 1 hour; sieved; and the 60–80 mesh fraction retained. This material contained the theoretical water of crystallization, 20.93%, and appeared under the microscope to be polycrystalline.

For dehydration, 4-g samples were contained in a 3- to 4-mm annulus between two concentric 100-mesh copper gauze cylinders, 10 cm high and 4 cm o.d. The problem of vapor diffusion within the sample was greatly reduced by this arrangement and by the relatively large particle size of starting material. Using a constant initial weight, the reproducibility of *rate* of weight loss was found to be $\pm 1\%$.

The sample holder was suspended from an ordinary analytical balance by means of an iron–constantan duplex thermocouple wire, the junction being immersed within the powder mass. The dehydration was carried out in a vapor-jacketed cylindrical Pyrex oven in which the appropriate atmosphere was established by passing dry nitrogen directly or through water saturators maintained at the appropriate temperature. Heated lines were used to prevent condensation from the wet nitrogen stream and at flow rates of 50–100 cc min^{-1} the buoyancy correction was negligible.

The hemihydrate produced in each experiment was subsequently analyzed and the heat of solution in 2.0 *N* hydrochloric acid determined in a calorimeter described elsewhere (12). Debye–Scherrer powder patterns were obtained using CuK_α radiation with a nickel filter.

RESULTS

The fractional decomposition, α, was calculated in terms of the maximum possible water loss, so that

$$\alpha = (w_i - w_t)/(w_i - w_f)$$

where w_i = initial sample weight,
w_t = sample weight at any time t,
w_f = sample weight corresponding to complete water loss.

The two stages in the dehydration process:

I. $$CaSO_4.2H_2O\ (s) = CaSO_4.\tfrac{1}{2}H_2O\ (s) + 1\tfrac{1}{2}H_2O\ (v)$$

and

II. $$CaSO_4.\tfrac{1}{2}H_2O\ (s) = CaSO_4\ (s) + \tfrac{1}{2}H_2O\ (v)$$

were indicated in both fractional decomposition and sample temperature plots (Fig. 1), their respective rates being markedly influenced by the partial water vapor pressure (Figs. 2 and 3). Low partial water vapor pressures were found to catalyze both stages (Fig. 3), while further increase in water vapor pressure retarded stage II more rapidly than stage I. Above a definite water vapor pressure, dependent upon the dehydration temperature, no evidence of stage II was detected in the duration of the experiment, a higher water vapor pressure being required for suppression of stage I at the same temperature. Not all dehydration temperatures resulted in the clear-cut suppression of stage II indicated in Fig. 2. In some cases the sample was found to remain at the hemihydrate composition for a considerable period before commencing further loss of water. With increasing water vapor pressure, this induction period in stage II eventually increased to the point where no further reaction was observed. The induction period for stage I was relatively short, even at 1 atm of water vapor.

The calcium sulphate dihydrate used in this work was a polycrystalline material, having generally spherical-shaped particles, whose surface area was unknown except for the general estimate from screen-size data. In attempting to extract meaningful rate constants from the fractional decomposition plots several treatments were applied, including that of Spencer and Topley (13) for the case of rapid nucleation followed by rapid surface growth on spherical particles of known initial radius. The various treatments represented the data over a considerable range, but an equally extensive fit to the experimental points was obtained from the simple linear expression for a zero-order process

$$\alpha = kt.$$

Further, activation energies based on rate constants derived from these two treatments were virtually the same.

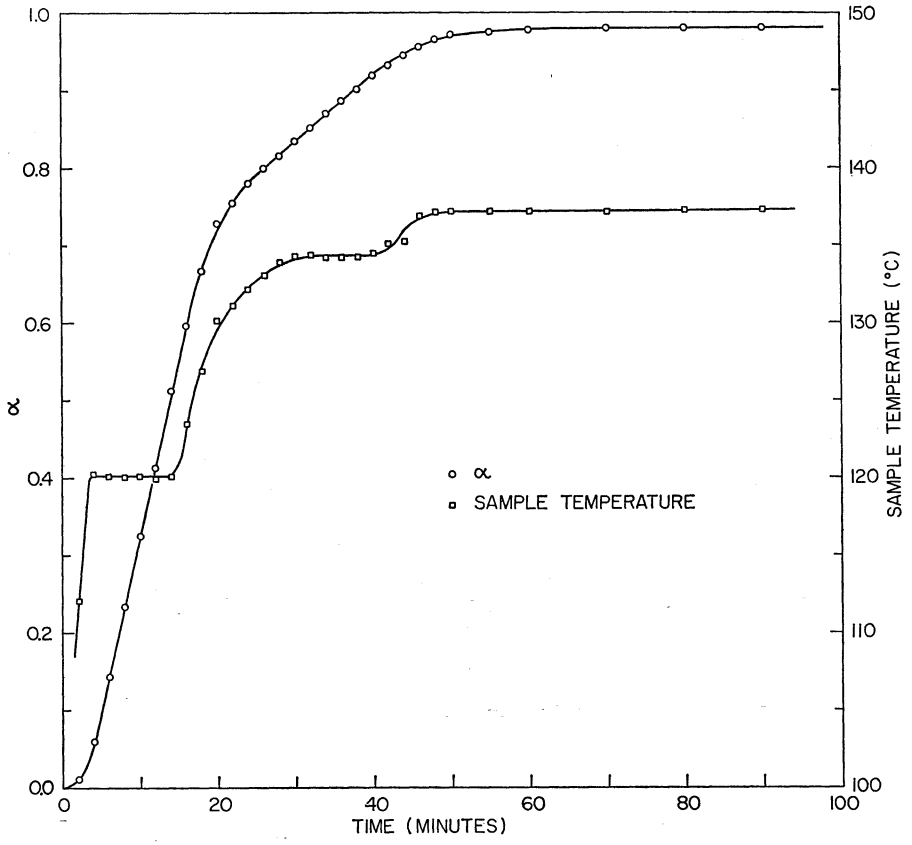

FIG. 1. Experimental fractional decomposition and sample temperature during dehydration at 139° C and 200 mm H_2O.

For simplicity, then, rate constants k_I and k_{II} were assigned for the two stages directly from the linear sections of the fractional decomposition plot, using the approach of Topley and Smith (14). These authors measured all rates at a definite fractional decomposition, and selected as *rate constant* the rate of weight loss at a given stage of decomposition divided by the original weight of the hydrate sample. Such a rate constant is empirical in nature, but has the merit of referring to a definite, although unknown, area of reaction interface and of largely standardizing any impedance effect of the product layer without eliminating it. For stage I, the rate constant and sample temperature were selected at $\alpha = 0.25$ and for stage II at $\alpha = 0.80$. Both these points lie on the respective temperature plateau for the two stages and within the linear regions of the α vs. t plots (Fig. 1), so that further normalization of the curves was unnecessary. The considerable range of dehydration over which the rate is constant indicates the "impedance" effect of the increasing product layer is not of great significance.

The plateau temperatures, T, as recorded by the thermocouple immersed in the sample mass, were considered to be representative of the overall reaction temperature. Care was taken to minimize differences due to packing of the sample and placement of the thermocouple.

The rate constants obtained, reaction temperatures, calculated activation energies, and Arrhenius pre-exponential factors are given in Tables I and II. Also included in Table

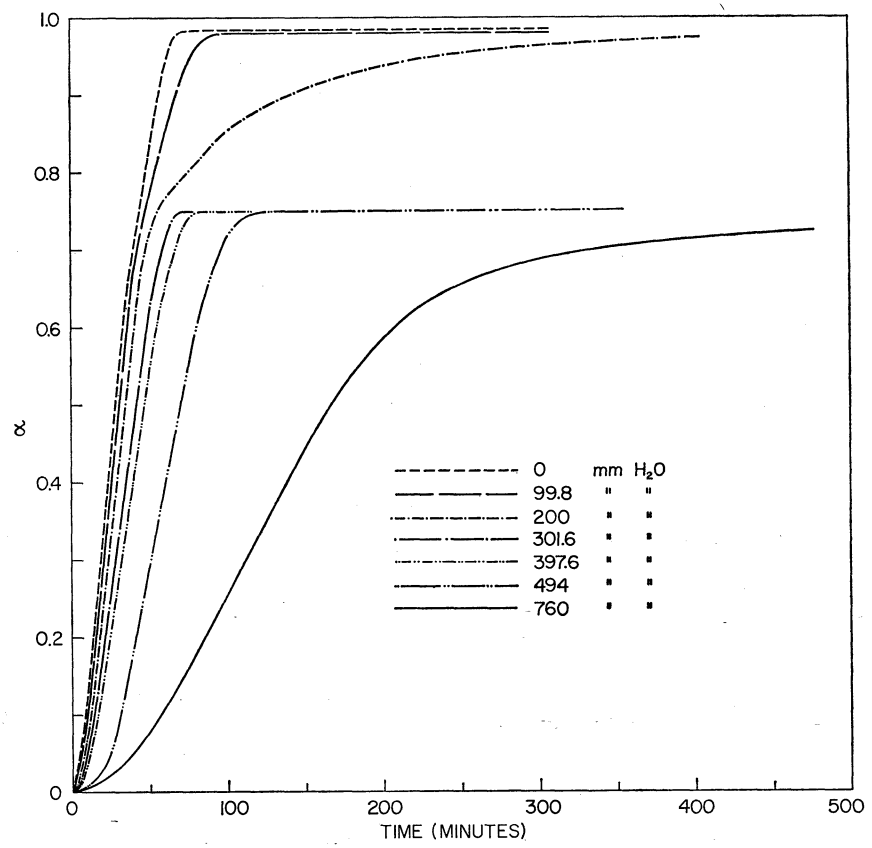

FIG. 2. Variation in fractional decomposition curves with ambient water vapor pressure during dehydration. Jacket temperature 124.3° C.

I are calorimetric heats of solution of the hemihydrates obtained at each partial water vapor pressure. The heat of solution of the hemihydrate was found to be independent of the temperature at which it was produced, over the range 100–140° C, provided the partial water vapor pressure in the system remained constant. In cases where dehydration ultimately resulted in the anhydrous calcium sulphate, a separate dehydration was performed later and the sample removed at a weight loss corresponding to the theoretical hemihydrate composition.

Debye–Scherrer patterns for calcium sulphate dihydrate and for hemihydrates produced under the two extremes of partial water vapor pressure, shown in Fig. 4, illustrate that no gross structural differences were found in the hemihydrates produced over the experimental range of water vapor pressures.

DISCUSSION

The dehydration of calcium sulphate dihydrate has been shown to begin by nucleation on the surface of the crystal at sites other than dislocations (15), followed by growth over the surface until discrete reaction areas overlap, propagation through the individual crystals also occurring along exfoliation planes (16). Representation of a considerable portion of the dehydration by the linear, zero-order relation found in the present work indicates this nucleation–propagation mechanism occurs on a substantially constant

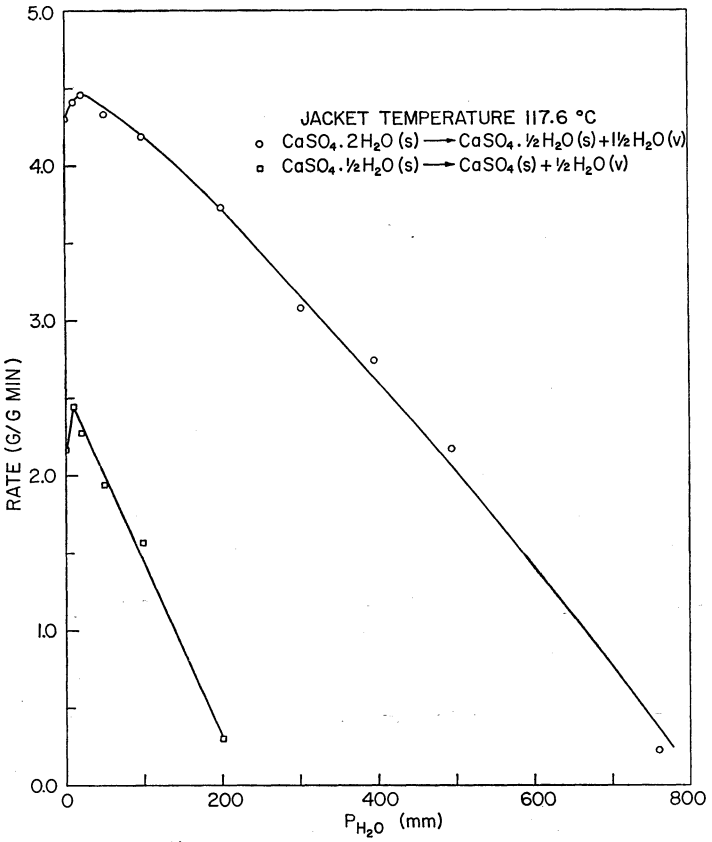

FIG. 3. Variation in dehydration rates with ambient water vapor pressure. Jacket temperature 117.6° C.

reaction interface where the effect of ingesting other potential nuclei may not be of great significance.

The principal effect of increasing partial water vapor pressure is to repress the rate of anhydrous calcium sulphate formation more rapidly than that of hemihydrate formation, as expected (4). Further, it has been shown kinetically that separate, temperature-dependent water vapor pressures exist above which each stage may be effectively suppressed. For example, for the process

$$CaSO_4.2H_2O\ (s) = \alpha\text{-}CaSO_4.\tfrac{1}{2}H_2O\ (s) + 1\tfrac{1}{2}H_2O\ (v),$$

$\Delta F°$ equals 0 at about 106° C (4). No measurable dehydration could be detected at 1 atm H_2O and 107.4° C, although a rate was measurable at 110.4° C under this water vapor pressure. A similar correlation between kinetic and thermodynamic results cannot be made for stage II since, as will be discussed below, the hemihydrate produced at the critical water vapor pressure for suppressing this stage is intermediate in thermodynamic properties between the α- and β-modifications reported (4).

Catalysis of both stages I and II by low water vapor pressures has been observed in other salt hydrate systems (17, 18), the magnitude of the pressures required in this work presumably being due to the less efficient transport of water molecules to and from the reaction site in processes at atmospheric pressure, compared to those carried out in

vacuum, and to the low surface area of the original materials. The regular decrease in rate with further increase in water vapor pressure may be associated with the increasing competition of the reverse reaction due to an increasing concentration of water molecules in the transition layer (18).

Heat of solution measurements have identified the hemihydrates produced at 0 and 760 mm H_2O to be the β- and α-modifications, as defined thermodynamically (4) and not on the basis of preparation (19). Despite a difference of only 0.5 kcal $mole^{-1}$ in heat of solution, the activation energy for formation of α-hemihydrate is some 20 kcal $mole^{-1}$ greater than that for β-hemihydrate. Heat of solution, activation energy, and pre-exponential factor were found to increase linearly with water vapor pressure (Fig. 5).

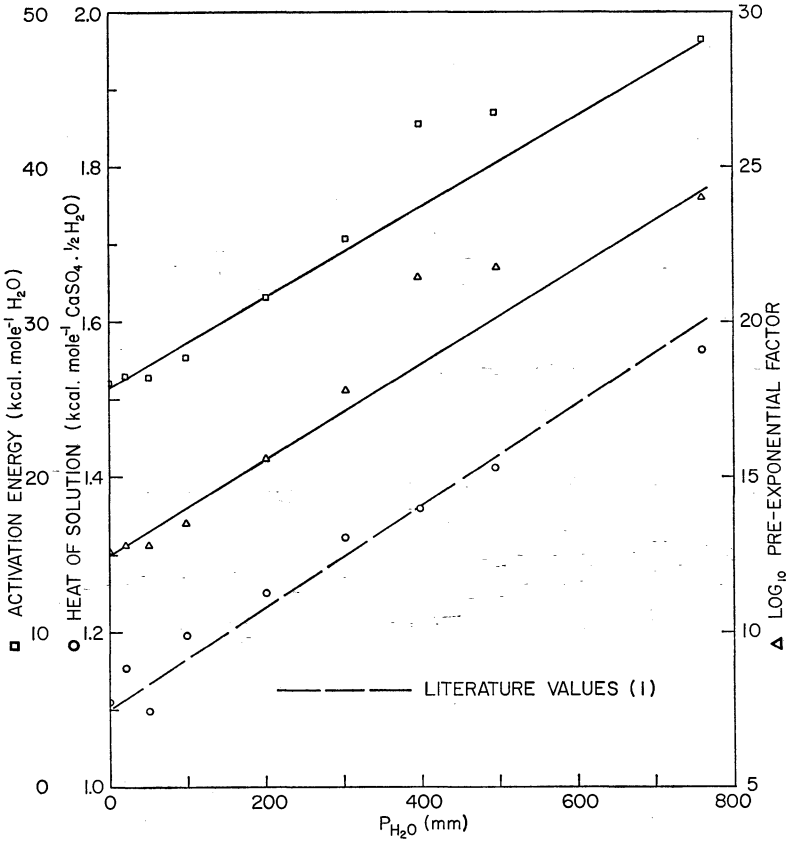

FIG. 5. Variation of kinetic and thermodynamic parameters for production of the hemihydrate with partial water vapor pressure during dehydration.

While a linear relationship between heat of solution and "relative amounts of α- and β-hemihydrate present in a plaster" (4) has been accepted, it has not previously been demonstrated that thermodynamic properties intermediate between these two modifications may be obtained by control of the partial water vapor pressure during dehydration. The possibility of such continuous variation had been suggested (3) on the basis of general considerations.

Some workers feel that differences in the heat of solution of hemihydrates are associated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with differences in specific surface, similar to the case for magnesium hydroxide (20). It is difficult to accept this viewpoint concerning the hemihydrate. This material exhibits a well-defined range of heats of solution, which would not be expected if these were dependent upon the specific surface which could be induced into the sample. Further, the same heat of solution can be obtained under widely differing methods of preparation. For example, hemihydrates have been produced in this laboratory by crystallization from boiling 50% nitric acid, and by dehydration under 760 mm water vapor pressure, both having the heat of solution reported for α-hemihydrate produced by autoclaving of lump gypsum under pressure followed by grinding (4). Although comparative surface area data are not available, it is difficult to conceive that such different preparative techniques would result in hemihydrates of sufficiently comparable specific surface to yield the same heat of solution. While changes in the rates of other transformations of calcium sulphate (21) may be attributed to differences in specific surface (3), no data are yet available to correlate specific surface with any thermodynamic properties of the hemihydrate. In one case (22) the concept of thermodynamically defined α- and β-modifications was discarded on the basis of heat of solution data outside the reported range (11). However, the lack of adequate description of the samples and calorimetric techniques involved leaves doubt about the purity of the hemihydrates employed.

It appears more reasonable that the range of thermodynamic properties found for hemihydrates reflects the overall order within the hemihydrate lattice, rather than its surface character. On this basis, not only does increasing water vapor pressure influence the kinetics of the dehydration process, it also influences the order with which the hemihydrate lattice is created at the reaction interface. It is significant that the determining factor is the partial pressure of water, not its relative pressure. Since the structure of the hemihydrate lattice (23) is comprised of continuous chains of successive calcium atoms and sulphate tetrahedra, these chains being arranged in bundles so that channels of about 3 Å diameter are formed wherein water molecules can be located, it is possible that at least two lattice features may be influenced by the water vapor pressure at the reaction interface:

(i) the packing of Ca–SO_4 chains with respect to one another, the overall order of these chains being higher in α-hemihydrate producing a higher "stacking order" (6);

(ii) the rotational orientation of a given SO_4 tetrahedron along the Ca–SO_4 chain with respect to succeeding SO_4 tetrahedra, the tetrahedra in the α-hemihydrate being more regularly oriented.

X-Ray evidence obtained in this work again found no gross differences in lattice features accompanying change in heat of solution. Morris (6) has recently demonstrated that any structural differences may be associated with degree of "stacking order" within the crystal, his results being consistent with earlier entropy calculations (4). The possibility of other types of defects in the ionic Ca–SO_4 chains cannot be excluded at the present time.

The continuous variation in thermodynamic properties and kinetic parameters with increasing water vapor pressure further supports the concept that the designations "α" and "β" represent merely the terminals of a hemihydrate series. The α- and β-hemihydrates are not necessarily separate entities which may be present in different proportions in a mixture (although such mixtures may be artificially prepared), but the designation of a hemihydrate as, say, 50% β-modification merely defines its properties as being the average of the two terminals. Because of the continuous variation in properties, depending upon partial water vapor pressure, it is reasonable that the inter- and intra-chain order is determined by conditions prevailing at the reaction interface. If the function of water

vapor were to promote further change in the lattice following passage of the reaction interface, such a process would presumably also be temperature-dependent and its extent, as determined by heat of solution, would not be constant over a temperature range at a constant water vapor pressure.

The anhydrous calcium sulphates obtained at the lower partial water vapor pressures were not studied extensively, because of difficulties in keeping them completely anhydrous (1, 2). The dehydration times and temperatures involved were such that formation of the insoluble form of anhydrous calcium sulphate was not favored. This was further evident from the fact that the water loss never equalled the theoretical value, although the starting dihydrate was found to contain this amount of water when dehydrated at 450° C. It is known (4) that a small fraction of water is retained by the anhydrous calcium sulphate lattice until its reversion to the insoluble modification at higher temperature, this rearrangement being sufficient to expel residual water.

AN INFRARED STUDY OF THE ADSORPTION OF AMMONIA ON POROUS VYCOR GLASS

N. W. CANT AND L. H. LITTLE
Department of Chemistry, University of Western Australia, Nedlands, Western Australia
Received October 4, 1963

ABSTRACT

The infrared spectrum of ammonia adsorbed on porous glass at 20° C and 150° C has been studied in the region 1450–4000 cm^{-1}. No absorption band due to the asymmetric bending mode of ammonia was observed but in the NH stretching region, bands occurred at 3280 cm^{-1}, 3320 cm^{-1}, 3365 cm^{-1}, and 3400 cm^{-1}. The bands at 3320 cm^{-1} and 3400 cm^{-1} were easily removed by evacuation and are due to ammonia molecules hydrogen bonded through the nitrogen atom to surface hydroxyl groups. The bands at 3280 cm^{-1} and 3365 cm^{-1} were not removed by evacuation even at 150° C and are due to ammonia molecules held to surface Lewis acid sites by the nitrogen lone-pair electrons. The site for this adsorption is not a surface hydroxyl group. These results are further evidence for the existence of the two adsorption sites proposed by Folman and Yates. Deuteration of the surface OH groups was easily accomplished with D_2O vapor at 300° C and the rate of hydrogen exchange between adsorbed ammonia molecules and surface OD groups was found to be rapid.

INTRODUCTION

The infrared spectrum of ammonia adsorbed on porous Vycor glass has been studied several times, most extensively by Folman and co-workers. They have correlated the infrared spectra (1, 2) with measurements on length changes (1, 3) and dielectric properties (4) of the adsorbent. Their results show that two sites with different kinetics of adsorption exist on evacuated porous glass: one is associated with residual hydroxyl groups and the other is assumed to be surface silicon or oxygen atoms. At room temperature, adsorption occurs principally on the surface OH groups by hydrogen bonding through the nitrogen atom of the ammonia molecule and this produces an initial contraction in the length of the glass. At higher temperatures a relatively larger number are adsorbed on the other sites and the initial contraction is not observed. Folman and Yates (2) were unable to distinguish spectroscopically between ammonia adsorbed on the two different sites although they reported that the characteristic stretching frequencies of ammonia did shift to lower values as the temperature was increased. In the present study it has been possible to resolve adsorption bands in the region 3250–3400 cm^{-1} due to two forms of adsorbed ammonia.

EXPERIMENTAL

In the present work, we used 0.1-mm thick porous glass in a cell with sodium chloride windows. This system has several advantages over that used by Folman wherein a 0.4-mm sample was placed in a silica cell. Measurements could be made of the bands that were due to the surface OH groups and residual water molecules both in the stretching and bending regions of the spectrum. Moreover, studies could be carried out at higher surface coverages and with greater spectral resolution when the thinner sample was employed.

Two types of infrared cells were used. One was similar to that used by Little, Sheppard, and Yates (5). For temperatures above 100° C a silica test tube of diameter 2.4 cm and length 15 cm was used. A ground glass joint at the upper end gave access for the sample and a simple external furnace was used for heating. For use in either cell the sample was supported in a metal holder and after evacuation in the furnace section of the cell it was carefully aligned in the infrared beam. All adsorption and desorption measurements were made without disturbing the alignment. The gasline was a conventional volumetric B.E.T. apparatus. Mercury levels could be read to ±0.005 cm by a cathetometer.

The samples of porous glass had the approximate dimensions 1 cm × 1 cm × 0.01 cm and weighed between 20 and 40 mg. They were cleaned by being heated to 450° C in air and outgassed at the same temperature.

For personal use only.

Deuteration was carried out by exposing evacuated samples to D_2O vapor at 300° C for 3 hours. Ammonia was obtained from cylinders and purified by bulb-to-bulb distillation.

After evacuation of the sample, doses of ammonia were admitted until the 3337 cm^{-1} band of the gas phase ammonia spectrum became appreciably intense (approximately 10 cm pressure). About 10 doses were admitted for each experiment and 30 minutes was allowed for equilibrium to be reached in each case. Desorption was carried out by successive expansions into the evacuated line. Finally the sample was evacuated and the spectrum of any residual ammonia recorded.

Because of small sample weights and large cell volumes it was possible to obtain only approximate isotherms for ammonia adsorbed on the samples during the course of spectral studies. More accurate adsorption–desorption isotherms were determined on a number of small pieces of the glass contained in a cell with a dead space of only 12 ml. This procedure introduced errors in that the exact temperature of the sample in the infrared cell could not be reproduced in the small cell because of the undetermined heating effect of the infrared beam. Comparison of the isotherms obtained in the two cells indicated that the temperature in the beam was possibly 20° C higher. This effect is shown in Fig. 1.

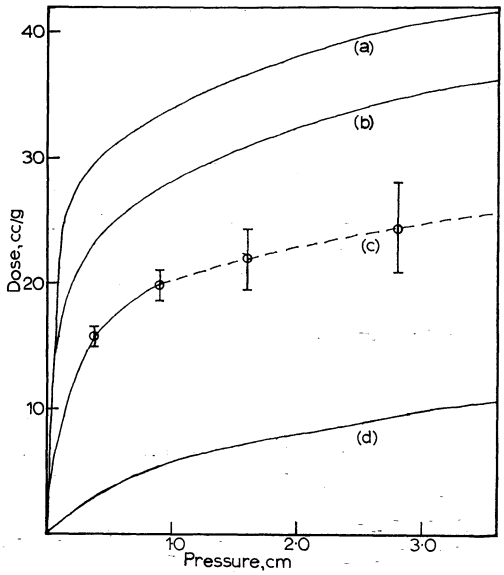

FIG. 1. Isotherms for ammonia adsorbed on porous Vycor glass at different temperatures (*a*) 13° C, (*b*) 20° C, (*c*) sample in infrared beam, (*d*) 150° C. The dotted section is extrapolated and the approximate error shown.

Spectra were recorded with a Perkin–Elmer Model 137G spectrophotometer which has only two scanning speeds, 350 cm^{-1}/minute and 110 cm^{-1}/minute. However, manual checks at particular wavelengths showed that the peak heights of bands were not affected by the finite scanning time at the slower scanning speed and this was used for all measurements. The error in determination of the optical densities is difficult to estimate but is probably less than ±5% for optical densities less than 1.0. Frequencies are accurate to ±5 cm^{-1}. Spectra as directly recorded were on the usual linear transmission scale. For comparison purposes they were replotted on a linear optical density scale at 50 cm^{-1} intervals and more closely for narrow bands.

The integrated molar intensity of the NH stretching modes of ammonia in carbon tetrachloride solution was measured for comparison with that of the surface species. The concentration of ammonia in carbon tetrachloride was determined by titration.

RESULTS

Figure 2 shows the spectra of representative doses of ammonia adsorbed on porous glass at temperatures of 20° C and 150° C and the effect of subsequent evacuation on the bands. The bands at 3665 cm^{-1} and 3730 cm^{-1} are due to surface hydroxyl groups, those from 3250–3400 cm^{-1} to NH stretching vibrations, and the broad band at 3000 cm^{-1} to OH groups hydrogen bonded to ammonia molecules. The optical densities of the NH bands

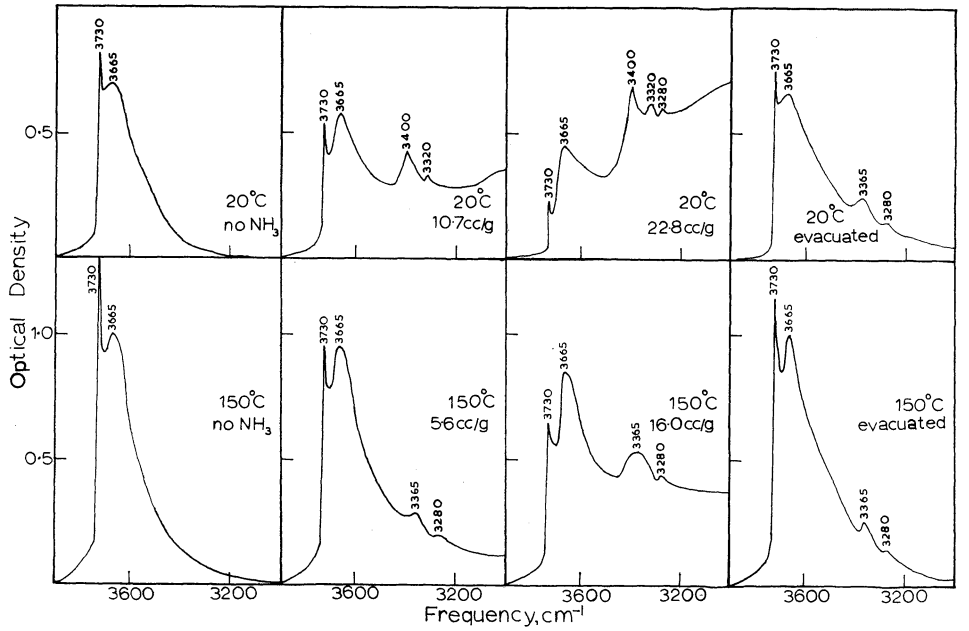

FIG. 2. The infrared spectrum from 4000 cm^{-1} to 3000 cm^{-1} of different amounts of ammonia adsorbed on 0.1-mm porous Vycor glass at 20° C and 150° C.

alone have been replotted in Fig. 3. The bands were graphically resolved from the background absorption. The peak optical densities of the main bands evident in Fig. 2 are plotted in Fig. 4 as a function of the dose of ammonia adsorbed. These doses of ammonia were estimated by measuring the equilibrium gas pressure over the sample in the infrared cell and then referring to the adsorption isotherms of Fig. 1 (*c*) and 1 (*d*) for the temperatures 20° C and 150° C respectively.

To investigate further the nature of the hydrogen bonding, the spectrum of ammonia adsorbed on deuterated porous glass was studied. Figures 5 (*a*) and 5 (*b*) are spectra of the evacuated glass before and after deuteration. The exchange was approximately 85% for both types of hydroxyl groups and may have been limited only by the purity of the D_2O used. After a dose of ammonia had been exposed to the sample for 1 hour, spectrum 5 (*c*) was obtained. Evacuation for 15 minutes at room temperature gave spectrum 5 (*d*).

A continuous absorption covering the region 1450–3000 cm^{-1} is a prominent feature of the spectrum of ammonia-covered Vycor glass. The optical density at any frequency in the region varies linearly with the amount of adsorbed ammonia. No band was observed in this region that could be assigned to the asymmetric NH bending mode of ammonia, which occurs at 1627 cm^{-1} in the gas phase spectrum.

DISCUSSION

Absorption Bands Due to the Evacuated Adsorbent

In the spectral region from 3500 cm^{-1} to 4000 cm^{-1}, two bands can be assigned to the adsorbent: a sharp symmetrical band at 3730 cm^{-1} to free surface hydroxyl groups; and a comparatively broad asymmetrical band with peak at approximately 3665 cm^{-1} to two adjacent hydroxyl groups hydrogen bonded to each other. The optical density of the 3730 cm^{-1} band was found to vary from 0.9 to 2.0 according to the individual sample and the

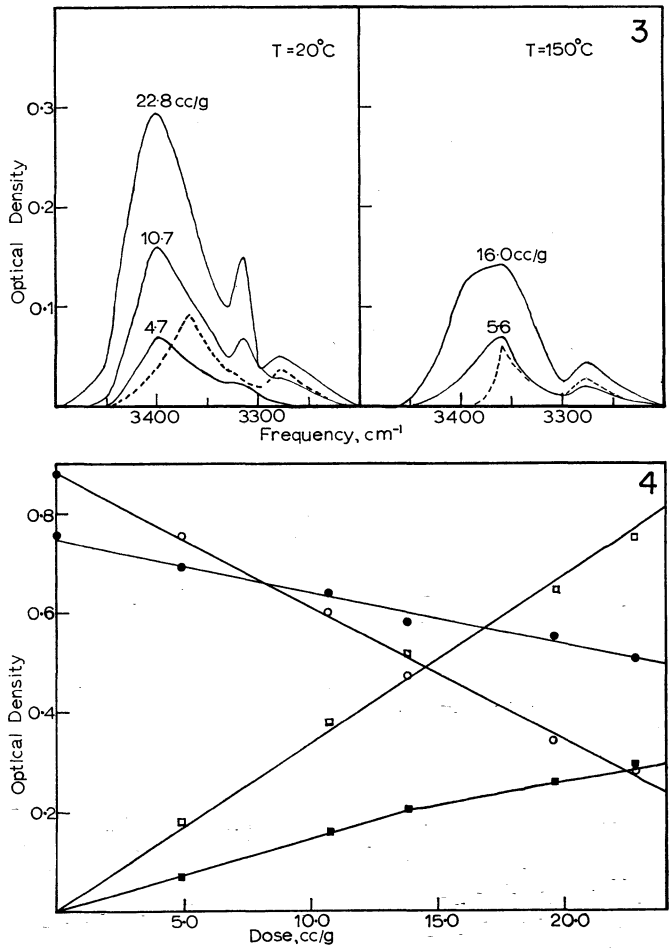

FIG. 3. The detailed structure of the infrared absorption bands of ammonia adsorbed on 0.1-mm porous Vycor glass at 20° C and 150° C. Evacuation after adsorption of the largest dose of ammonia gave the dotted spectra.

FIG. 4. Dependence of the intensities of the main absorption bands from 4000 cm^{-1} to 3000 cm^{-1} on the dose of ammonia adsorbed at 20° C: ○, 3730 cm^{-1}; ●, 3665 cm^{-1}; ■, 3400 cm^{-1}; □, 3000 cm^{-1}.

experimental conditions of evacuation. The final optical density depended more on the temperature than the time of evacuation. On the other hand variations of temperature in the range 400° C to 500° C produced only minor changes in the optical density of the hydrogen-bonded band, which was always between 0.8 and 1.0. These results are in general agreement with those published by Little and Mathieu (6) for the evacuation of similar samples, although intensities and band widths reported here are smaller for the same evacuation temperature. These variations are probably due to different sample preparations. The evacuated samples used here became slightly contaminated with hydrocarbons from the stopcock grease during the 24-hour period of the experiments.

Figures 5 (*a*) and 5 (*b*) show that both types of hydroxyl groups are easily exchanged for deuteroxyl groups. This agrees with the infrared studies of Benesi and Jones (7) on silica gel, although Pimentel *et al.* (8) found the rate of exchange to be much slower. The rate of exchange between adsorbed NH_3 and deuteroxyl groups was also very rapid as

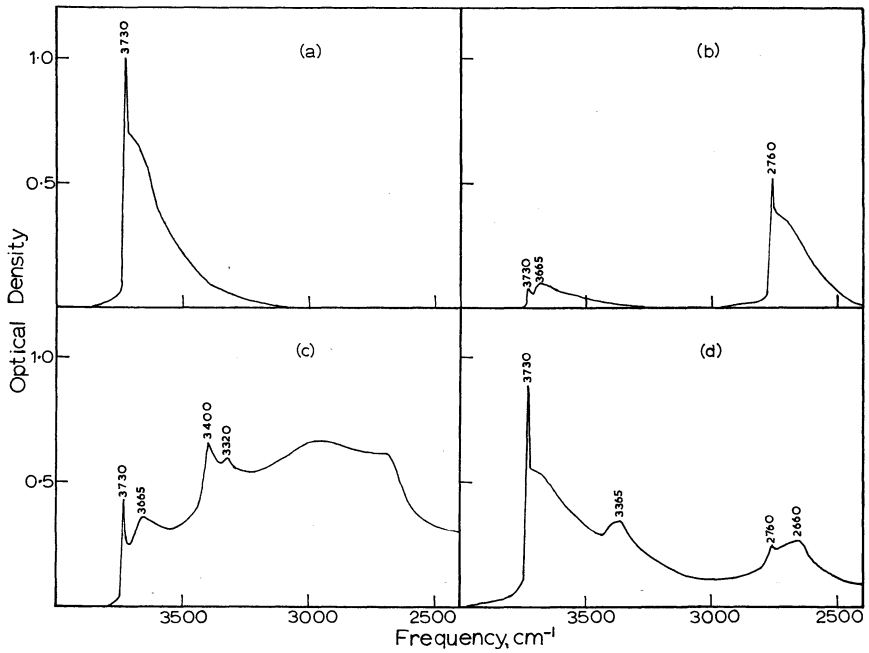

FIG. 5. The infrared spectrum of 0.1-mm porous Vycor glass at 20° C after (*a*) evacuation at 450° C, (*b*) subsequent deuteration at 300° C for 2 hours, (*c*) adsorption of approximately 20 cc/g of ammonia for 1 hour at 20° C on the deuterated sample, (*d*) subsequent evacuation at 20° C.

Figs. 5 (*c*) and 5 (*d*) show. Only weak OD bands were evident after 1 hour at room temperature; subsequent evacuation almost completely restored the original OH band.

When ammonia was adsorbed onto the porous glass the intensity of the free OH band at 3730 cm^{-1} decreased markedly, as is shown in Fig. 4. Those samples, for which the initial optical density of the band was less than 1.0, showed an approximately linear decrease with dosage. More intense bands could not be measured accurately. The slope of the line in Fig. 4 corresponding to the 3730 cm^{-1} band was unaffected by temperatures to 150° C. The optical density of the 3665 cm^{-1} band decreased much more slowly with increasing dosage of ammonia. In fact the observed decrease at this frequency may have been due to the decreased contribution from the free OH band, the wings of which overlap this band. Evacuation for 15 minutes at the temperature of the experiment restored the OH bands to almost the original intensity. These results show that free OH groups are better sites than hydrogen-bonded ones for the adsorption of ammonia and some, at least, of the ammonia is adsorbed on them at temperatures up to 150° C. Sidorov (9) found that the hydrogen-bonded hydroxyl groups on porous glass are better sites for the adsorption of water than free hydroxyl groups. It seems likely that the adsorption of ammonia and water proceeds by different means especially since Folman and Yates (10) found that water causes only expansions in the length of the glass.

Bands Due to Adsorbed Ammonia Molecules

Figure 4 shows that for the most intense NH band (3400 cm^{-1}), a graph of optical density against dosage is approximately linear. The marked flattening of the curve

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

reported by Folman and Yates (2) is not evident even though the surface coverage used here is much higher.

It was not possible to measure directly the amount of residual ammonia on a sample after evacuation. However, a comparison of the intensities of bands of residual ammonia on the sample was made after (*a*) adsorption of ammonia at 20° C and evacuation at 20° C and (*b*) adsorption of ammonia at 150° C followed by evacuation at 150° C. It was found that the intensities and frequencies (3280 cm^{-1} and 3365 cm^{-1}) were the same for both experiments. This result is consistent with the existence of a limited number of sites which will strongly adsorb the ammonia responsible for the 3280 cm^{-1} and 3365 cm^{-1} absorption bands (Figs. 2 and 3).

The main features of the observed spectra in the NH stretching region are summarized in Table I.

TABLE I

Frequencies and intensities of infrared bands due to ammonia adsorbed on 0.1 mm porous Vycor glass

Temperature	Dose, cc/g	Absorption bands			
20° C	10	3400 (0.15)*		3320 (0.06)	
	23	3400 (0.3)		3320 (0.15)	3280 (0.05)
After evacuation at 20° C			3365 (0.09)		3280 (0.04)
150° C	7		3365 (0.09)		3280 (0.04)
	16	3400 (0.13)	3365 (0.15)		3280 (0.04)
After evacuation at 150° C			3365 (0.07)		3280 (0.03)

*The values in parentheses are optical densities.

This table shows the existence of two types of ammonia on the porous glass—a comparatively weakly held species which gives absorption peaks at 3320 cm^{-1} and 3400 cm^{-1} and a more strongly held one with peaks at 3280 cm^{-1} and 3365 cm^{-1}. The close similarity between the two pairs of bands, as regards intensity ratios and frequency separations, indicates a mere difference in adsorption site and not a fundamental difference in the structure of the adsorbed species.

For comparison purposes a summary of the infrared absorptions of the NH groups of various molecules in the region 2800 cm^{-1} to 3600 cm^{-1} is presented in Table II.

There is no evidence for the presence of ammonium ions in the spectrum of ammonia adsorbed on porous glass and it can therefore be assumed that the adsorption is not on

TABLE II

Infrared absorption by NH groups of various molecules from 2800 cm^{-1} to 3600 cm^{-1}

For personal use only.

surface Bronsted acid sites, as was the case for some of the ammonia adsorbed on the silica–alumina cracking catalyst used by Mapes and Eischens (20).

The 3320 and 3400 cm^{-1} pair of bands most closely approximates those for ammonia dissolved in carbon tetrachloride and therefore interaction with the surface must be weak (no asymmetric bending vibration was evident in the spectrum of adsorbed ammonia and therefore the first overtone would not be expected to appear in this region of the spectrum). This pair of bands is easily removed by evacuation at room temperature and at the same time the broad hydrogen-bonded absorption at 3000 cm^{-1} disappears, to be replaced by bands identical in the OH stretching region with those of the sample before adsorption of ammonia. In view of this, the most likely assignment of the 3320 and 3400 cm^{-1} bands is to ammonia weakly held by hydrogen bonding to surface hydroxyl groups.

From comparison with the spectrum of the Lewis acid complex $F_3B{:}NH_3$ (Table II), it is suggested that the pair of bands at 3280 cm^{-1} and 3365 cm^{-1} are the stretching frequencies of ammonia bound to Lewis acid sites on the adsorbent by the nitrogen lone-pair electrons. These bands cannot be due to ammonia bound to either type of hydroxyl group since evacuation does not remove them but does remove all evidence of hydrogen bonding between ammonia and OH groups. Since the porous glass contained 3% of B_2O_3 and as it has been shown that the number of sites is limited, it is not impossible that this ammonia is adsorbed on the surface electron-deficient boron atoms themselves. It has been suggested (21) that surface aluminum atoms are active sites for the adsorption of olefinic hydrocarbons on porous Vycor.

Absorption Bands Due to Perturbed OH Groups

The integrated molar intensity of all bands due to adsorbed ammonia in the 3300–3400 cm^{-1} region is 4000 ± 1000 moles^{-1} liter cm^{-2} compared to 900 ± 200 moles^{-1} liter cm^{-2} for ammonia dissolved in carbon tetrachloride. It seems likely, therefore, that all adsorbed ammonia is contributing to the bands in this region and that it is unnecessary to assume that there is any contribution by hydrogen-bonded NH groups to the broad 3000 cm^{-1} band. The band must then be due to perturbed OH groups.

A graph of the optical density of this absorption band against dosage is linear at 20° C (Fig. 4) and also at 150° C. The slopes for the two temperatures are not markedly different, which is not in accord with the findings of Folman and Yates (2). In the present work and also in that of Folman and Yates (2) approximately 4 cc/g of ammonia remained on the glass after evacuation at 150° C and the optical density of the perturbed OH band (3000 cm^{-1}) was then zero.

Roev (22) and Basila (23) have suggested that the type of continuous absorption observed in the 1450–3000 cm^{-1} region arises from a photodesorption process, whereby the incident infrared radiation is responsible for the desorption of weakly held surface species.

A solution of sodium methoxide in methanol shows (24) a similar absorption over the frequency range accessible to study with this system (2050–2300 cm^{-1}). Here it is not possible for photodesorption to occur and it seems likely that a more satisfactory explanation for this phenomenon is forthcoming from the study of Zundel and Schwab (25) on a polystyrene – sulphonic acid – water system. The continuous absorption was shown to originate in the high exchange probability of a proton in such strongly hydrogen-bonded systems.

In the present study it is considered that the less strongly held ammonia (3320 and 3400 cm^{-1} bands) and surface hydroxyl groups are involved in hydrogen bonding. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

continuous absorption spectrum observed would be consistent with the rapid exchange of the surface hydroxyl proton with the ammonia. This view is supported by the rapid exchange between surface OD groups and adsorbed ammonia.

It is interesting to note that while the spectrum of the surface OH group is considerably perturbed to give the continuous absorption pattern, the spectrum of the adsorbed ammonia resembles that of ammonia in a nonpolar environment (Tables I and II). Perhaps it might have been reasonable to consider that the spectrum of this ammonia would have resembled more closely that of the ammonium ion.

ACKNOWLEDGMENTS

The porous glass used was a gift of Dr. M. E. Nordberg, of the Corning Glass Works, New York. One of us (N. W. C.) gratefully acknowledges the receipt of a Commonwealth Scientific and Industrial Research Organisation Senior Studentship.

ENERGY LEVELS OF TRIARYLMETHYL CARBONIUM IONS

E. K. NG AND F. C. ADAM
Department of Chemistry, University of Alberta, Calgary, Alberta

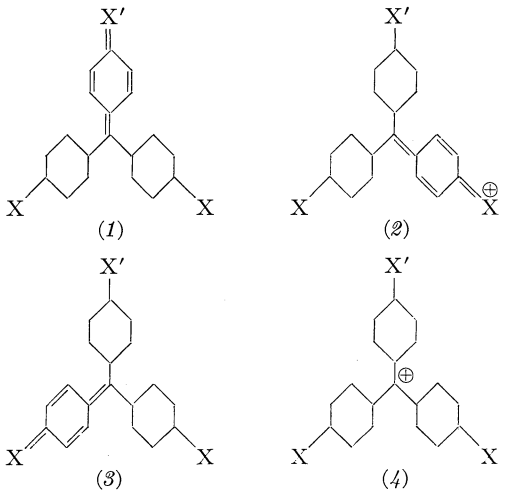
Received November 12, 1963

ABSTRACT

The near ultraviolet and visible spectra of the various phenyl-, *p*-biphenyl methyl carbonium ions have been investigated and the polarization of the absorptions relative to the fluorescence band have been determined. An assignment of the transitions is made, using as a basis simple molecular orbital calculations and the expectations based on the structure representation. These are compared to the assignments made in earlier researches. The calculated intensities are found to agree favorably with the observed values.

I. INTRODUCTION

The absorption spectra of various aryl hydrocarbon cations have been investigated with the end in view of comparing the transitions to those found in triaryl methane dyestuffs (1, 2, 3). The characteristics of the electronic state of the latter compounds are relatively well understood, and symmetry assignments have been made to these states by consideration of the properties of the various optical transitions. In this respect, the absorption energies, intensities, and the polarizations, related to a molecular fixed frame, are especially important. Most of the present work concerns the particular sequence of cations resulting from successive substitution of *p*-phenyl groups into the triphenylmethyl carbonium ion. This particular series of compounds has been studied by Chu and Weissman (4). We have essentially duplicated their results with the exception that particular attention has been paid to the polarizations of some of the weaker transitions of the spectrum. These are of critical importance in the final analysis of these systems, and their significance was apparently overlooked by the earlier authors. This has led us to a different assignment, but one which is more in accord with that of crystal violet and analogous dye compounds. Although the importance of these transitions of lesser intensity can be demonstrated by simple Huckel (HMO) calculations, the situation may be more easily visualized from consideration of the interaction between the four low-energy (N-state) species taken as equivalent to the paper structures (5).



For crystal violet, for instance, X′ = X = —N̈Me$_2$, so that structures (*1*) to (*3*) are related by the threefold axis of rotation. It can be shown by group theoretical arguments that interactions between these structures will give rise to four electronic states that may be described in terms of an arbitrary constant, c, by the following functions:

$$\psi_0 = (c/\sqrt{3})\ (1 + 2 + 3) + (1 - c^2)^{\frac{1}{2}}\ (4),$$
$$\psi_1 = (1/\sqrt{6})\ (2\,1 - 2 - 3),$$
$$\psi_2 = (1/\sqrt{2})\ (2 - 3),$$
$$\psi_3 = [(1-c^2)/3]^{\frac{1}{2}}\ (1 + 2 + 3) - c\ (4),$$

ψ_0 and ψ_3 are of the totally symmetric, A, representation and ψ_1 and ψ_2 are a degenerate pair, of symmetry E. Transitions between states of the representations E and A are allowed and in-plane while those between two states of the symmetric representation are allowed out-of-plane (i.e. parallel to the threefold axis, or "z" direction in the molecular frame). These considerations apply to any molecule with a threefold axis and are independent of twisting of the phenyl group, as long as the distortions are symmetrical. On the other hand, any perturbation which destroys this threefold axis of symmetry by preferential interaction with only one of the rings reduces the original molecular symmetry from D_3 or C_3 to C_2. If this preferential axis of perturbation is defined as the "y" axis, then the originally degenerate wave function will be split into symmetric (A) and antisymmetric (B) state wave functions with respect to this axis. Furthermore, all $A \leftrightarrow A$ intercombinations become allowed in-plane, and y-polarized, while the $A \leftrightarrow B$ combinations are also allowed, but x-polarized. Chemical substitution of one of the dimethylamino groups (i.e. X′ ≠ —N̈Me$_2$) is a perturbation of this sort, and to some reasonable order of approximation such substitution will affect only the energy of structure (*1*). The functions of symmetry B, because of the nodal plane in the axis of the perturbation, will, to the same approximation, be unaffected, experiencing only a relatively small and arbitrary shift in energy. Whether the symmetric states are lowered or raised in energy depends largely on whether the perturbation stabilizes or destabilizes structure (*1*). The situation is as depicted in Fig. 1. Both types of perturbations have been observed in the crystal violet series of dyes (2, 3).

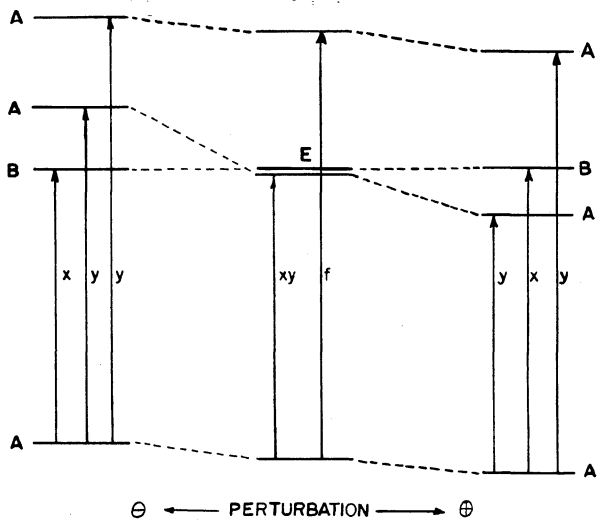


FIG. 1. Effect on energy level scheme of a y-axis perturbation on a trigonal molecule. "Stabilizing" perturbations are designated as positive.

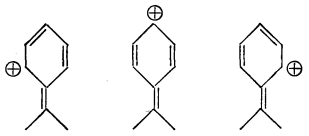
Experimentally, a pattern such as this is found; a low-energy intense transition ($\epsilon > 10^4$) being followed at higher energies by a weaker transition ($\epsilon < 10^3$). Considerations of HMO energies yield the same conclusions, with the same type of perturbation leading to the same prediction of the polarization axis for the long wavelength transition. Since the reverse of this particular transition is the only process occurring in fluorescence, it is possible to relate all absorptions to the single emission process. Absorptions are described as "parallel" or "perpendicular" to the fluorescence depending on whether the axis of polarization of the absorption is in the same direction or at right angles to the polarization axis of the emission. The key factor to the analysis is that the weak transition, when allowed in-plane, is always polarized "y", regardless of the particular perturbation affecting the molecule. Accordingly, this absorption is "parallel" with "stabilizing" perturbations, but is otherwise "perpendicular". These conclusions are perfectly general for trigonal molecules and should apply to the hydrocarbon cations, anions, and dye materials alike. In particular, the structure (*1*) for triphenyl methyl carbonium would be a composite of the ortho and para cation structures, each weighted about equally in the



final function. Furthermore, it would be expected that the biphenyl carbonium structures would be stabilized relative to the phenyl, since the composite function contains nine structures. The implication is that for monoxenyl diphenyl methyl carbonium (Mono), the degenerate state will be split and the function ψ_1, of symmetry A, will correspond to a state of lowered energy relative to that with the function of symmetry B, ψ_2. By comparison with Fig. 1, this corresponds to a stabilizing perturbation (to the right) so that the absorptions at increasing energy are polarized y, x, y. The absorptions will be accordingly described as $\|$, $\perp$, $\|$, relative to the fluorescence. On the other hand, dixenyl phenyl methyl (Di) carbonium may be considered as a perturbation of the symmetrical trixenyl carbonium (Tris). In this case, the substitution of biphenyl by phenyl results in destabilization, so that by analogy, the polarizations of the absorptions are in the order x, y, y, which will give $\|$, $\perp$, and $\perp$ absorptions respectively. It can be seen that it is the relative polarization of the third absorption band that is determined by the nature of perturbation. The converse is also true, that the determination of the polarization of this transition allows one to obtain the polarization of all other in-plane transitions.

II. EXPERIMENTAL

The absorption spectra of the mono-, di-, and tri-xenyl derivatives were taken by dissolving the corresponding carbinols in 10% sulphuric acid – 90% acetic acid mixtures at room temperature. These compounds sulphonated at varying rates in pure sulphuric acid but not in acetic – sulphuric acid mixtures. On the other hand, TPM carbonium ion was itself found to be very stable in sulphuric acid but did not result in complete conversion of the carbinol in the above mixture. Accordingly, the spectrum of the TPM ion was obtained in 95% sulphuric acid. The spectrum of each carbinol in acid is similar in essential details to those of the corresponding fluoroborate and perchlorate salts dissolved in various anhydrous solvents. A calibrated Beckman D.U. was used for all intensity measurements, and the transition moment magnitudes determined according to the formula,

$$[q(\text{Å})]^2 = 9.17\times10^{-4}\int \epsilon\, d \log \lambda.$$

Emission spectra and polarization ratios were determined from the carbonium ions dissolved in syrupy phosphoric acid at −130° C. The output of a Hanovia 1000-w mercury–xenon compact arc was passed through a Bausch and Lomb 250-mm monochrometer. The emergent beam was reflected from a stack of

quartz microscope cover slips at Brewster's angle in such a manner as to give a vertically oriented electric plane of polarization. The intensity of the beam was modulated at line frequency, since it is powered by alternating current. The fluorescence was detected at 90° to the propagation direction of the incident light, using a Du Mont K-1292 infrared sensitive photomultiplier tube. This fluorescence was observed through an adjustable Polaroid, which could be oriented to transmit either vertical or horizontal components of the electric vector of the fluorescence. Suitable Corning filters were used to further increase the spectral purity of the fluorescence. The power supply for the photomultiplier tube was a series of batteries, shielded so that pickup of spurious 60-cycle radiation was below the limits of detection as determined by a capacatively coupled Tetronix 805 oscilloscope on its most sensitive range ($\frac{1}{2}$ mv per cm). In this way any emission process of lifetime short enough to follow the modulated exciting light appears as a sinusoidal signal on the oscilloscope, with voltage amplitude proportional to the intensity of the emission. Two voltage readings corresponding to the vertical and horizontal settings of the analyzing Polaroid were taken. The ratio of these values is the polarization ratio "p", its value being between 1 and 3 for parallel processes, but between 1 and 0 for perpendicular absorptions. The results are set out in Table I, with energies quoted in kilokaisers, i.e. $cm^{-1} \times 10^{-3}$.

TABLE I

Spectral characteristics of the xenyl–phenyl carbonium ions

	40.0	—		

III. SYMMETRY ASSIGNMENTS

The transition energies, intensities, and polarizations for each of the ions have been calculated by the HMO method, and the values appear in Table II. Only those transitions of significant intensity in any of the x, y, or z directions, and those transitions predicted to have energies less than 40 kk are included, this last being the excitation energy of the B_{2u} transition of an isolated benzene molecule. No corrections have been made for overlap or non-planar distortions; nor have further improvements such as the ω-technique been employed (6). The value of $\beta = 26.3$ kk has been chosen for each cation except TPM where the value of $\beta = 24.0$ kk has been used. The observed energies are in each case those of the vertical transition, since it is clearly impossible to choose the 0–0 vibronic component in any consistent way for all of the transitions. The agreement between the observed and calculated quantities given in Table II is very good, although the calculated intensities are too large. This difficulty often obtains in HMO calculations and more refined techniques usually lower these values materially. It should be noticed that the second transition of Mono, relative to that of TPM, and the first transition of Di, relative to that of Tris, are predicted to lie at the same energy. This prediction is clearly borne out in the experimental results and is in accordance with observations made on other compounds of this type (7).

Within the framework of the experiments we have conducted, we have been able to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

reproduce all of the results of Chu and Weissman and at the same time experienced most of the difficulties that they mentioned in their paper. In particular, the fluorescence of TPM does not correlate with the absorption, and the fluorescence of Tris is not polarized during excitation of the long wavelength transitions. On the other hand excitation in the weak absorption band is perpendicularly polarized, a factor which would indicate that this transition is polarized in the z direction, as predicted by the group theoretical arguments and by the HMO calculations. Accordingly the transitions to degenerate states are assigned on the basis of intensity and of spectral energy, there being little doubt about the validity of this assumption. Even in the case of TPM this degeneracy has been lifted to some extent by some solvent or interionic interaction, so the observed band has two distinct maxima, and the upper states no longer lie at the same energy.

It is the question of the assignment of the Mono and the Di derivatives which brings disagreement with the earlier work and which is the main reason for this present research. Chu and Weissman have based their assignment on the assumption that localized excitation of the biphenyl rings was responsible for the absorption in the region of 2800 Å. They noted, first of all, that the net absorption at 2580 Å increased through the carbinol series TPM to Tris in a way proportional to the number of biphenyl rings. They then assumed that the increase in absorption in the 2800 Å region is due to similar process in the cation series. Secondly, the polarization ratio is observed to be larger (2) in the case of Mono than in the case of the Di compound (~1.2). For long axis polarized low-energy absorption in biphenyl, this leads to the assignment of the first excited states of both Mono and Di to the symmetric representation, A. This is at variance with the HMO calculations and the experimental results presented here for the lowest energy transitions. Reconsidering the 2800 Å region there is predicted by the HMO theory to be increasing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

absorption through the series of compounds. In the case of Mono, this is predominantly polarized parallel to the fluorescence. For the Di compound there is substantial overlapping of transitions of both polarizations, but the larger part of the absorption is predicted to be parallel. The polarization ratios would be expected to reflect these facts and Di would have a value reduced from that of Mono which would be expected to have a ratio typical of a solitary parallel transition. Accordingly, the measured polarization ratios have an alternative explanation, and it appears that the present assignment agrees in every detail with the experimental observations as well as with the expectations of the HMO and structure methods. At the same time there are fewer assumptions of a tentative nature.

IV. DISCUSSION

The critical factor in this determination, as in the case of the dye molecules, is that of the relative polarization of the low intensity band in the 300–400 mμ region of the spectrum. Similar transitions are found in the carbanion spectra of the hydrocarbon species. As far as the molecules of trigonal symmetry are concerned, it must be assumed that this transition gains intensity through slight distortions from the perfect symmetry. This might occur through non-totally symmetric vibrations, or through unsymmetrical perturbations in solution. The presence of such distortions and interactions are particularly evident in the case of TPM, where the loss of symmetry has resulted in a splitting of the degeneracy of the first excited states; there appear to be slight variations in this energy difference with the fluoroborate and perchlorate derivatives in various solvents, and the most reasonable explanation appears to be that the perturbations arise from a loose ion pairing. Crystal violet exhibits a similar tendency, and the perchlorate salt in non-polar solvents may exhibit as large a splitting as 2100 cm^{-1}. Nevertheless, the demonstration that these off-axis perturbations exist is not, in itself, sufficient to prove that the forbidden transition has gained sufficient intensity to correlate with the assignment. A considerably more valid test is to be found in some calculation where the assumed transition energy appears explicitly. In the structure representation a calculation of the transition intensities achieves this end in the following way. The first three term values for the molecule may be expressed in the Heisenburg form as a diagonal matrix,

$$\mathbf{E} = \begin{pmatrix} a & & \\ & 0 & \\ & & 0 \\ & & & b \end{pmatrix}$$

wherein a is the ground-state energy relative to the degenerate pair of states whose energy is arbitrarily taken as zero, b then is the energy of the normally inaccessible state, so that $(b-a)$ is the energy of the nominally symmetry forbidden transition. Using standard methods (3), it is possible to compute for the unperturbed molecule both $\mathbf{E}'$ and $\mathbf{S}^{-1}$ from the transformation equation,

$$\mathbf{E}' = \mathbf{S}^{-1}\,\mathbf{E}\,\mathbf{S}.$$

The intensities of the transitions are obtained from the square of the appropriate matrix element in the transition moment matrix, $\mathbf{X}$, resulting from the transformation,

$$\mathbf{X}' = \mathbf{S}\,\mathbf{X}\,\mathbf{S}^{-1},$$

where $\mathbf{X}'$ is, for instance, the dipole moment matrix for the structures in a specified

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

direction and $\mathbf{S}^{-1}$ is the same matrix as before. The elements in $\mathbf{X}'$ can be computed from the geometry and charge distribution of the structures. In particular,

$$\mathbf{X}' = \begin{pmatrix} 0 & 2.51 & \\ & & -2.51 \\ & & 0 \end{pmatrix}$$

for TPM, since it was assumed that the matrix is diagonal in the structure representation and that the ortho and para charged species contribute equally to each structure. The origin of the molecular frame is taken at the central carbon atom. Thus the calculated intensities depend upon $\mathbf{S}^{-1}$, which, in turn, depends upon the relative magnitudes of a and b. The magnitude of the forbidden band will always be zero, since $\mathbf{S}^{-1}$ incorporates the requirements of perfect symmetry. On the other hand, the intensities calculated for the intense bands will also reflect a faulty choice of b. The calculation of the transition moment lengths for the degenerate transitions for TPM and for Tris gives, in fact, the values 1.60 Å and 2.30 Å, which compare favorably with the experimentally determined values 1.64 Å and 2.50 Å respectively. By using the b values of transitions further in the ultraviolet, this agreement is lost. It should be noted that with the heterosubstituted dye molecules, the relative contributions of the ortho, para and extracyclic positive charge distributions are impossible to estimate a fortiori, so the required moments had to be determined empirically. This was not necessary in the present cases, a fact which lends credulity to the assumptions leading to formulation of $\mathbf{X}'$ as given above. It can be concluded that the use of structures results in a fairly accurate description of the charge distribution in the first few excited states of these carbonium ions.

Consideration of the matrix elements of $\mathbf{S}^{-1}$ of TPM leads to the conclusion that .043 units of electronic charge are distributed in each of the three phenyl rings. Unfortunately this is not in agreement with the estimates reached through nuclear magnetic resonance studies (8) which indicate that there is nearly twice this charge density on the ortho, meta, and para positions alone. Furthermore it would appear that the meta positions carry more positive charge than do ortho positions. This clearly contradicts the assumptions made above regarding the charge distribution within the rings. Roughly the same results are obtained for the carbanion of TPM (9). Using the suggested charge distribution as a basis for a calculation of the intensities of the optical transitions leads to much too high a value. On the other hand, proton chemical shifts are the resultant of many effects of both electrical and magnetic nature. As mentioned, there is good evidence that ion pairing exists with TPM salts in solution, and such association could in itself lead to considerable magnetic anisotropy. This would still be true if the counter ions undergo rapid exchange, in the time frame of n.m.r. measurements, but slow exchange as far as optical measurements are concerned (about 10^{-7} seconds in the present case). The possibility of rapid exchange may not be detectable by conductometric determinations (10) and could, in fact, account for some of the observed discrepancies. There is not much data available concerning the anisotropies associated with the highly charged central atom in TPM, and atomic contributions from this site might also modify the proton chemical shifts, but at the same time have relatively little effect on the charge distribution in the rings. Accordingly these purely magnetic effects would not necessarily show up in the optical spectra. Further investigations of other systems are under way in an effort to find the source of incongruity between the various measurements.

THERMOCHEMICAL STUDIES OF SOME ACRYLATE AND METHACRYLATE POLYMERIZATIONS IN EMULSION SYSTEMS

K. G. McCurdy and K. J. Laidler
The Department of Chemistry, University of Ottawa, Ottawa, Canada
Received October 3, 1963

ABSTRACT

With the use of a Tian–Calvet microcalorimeter, the heats of polymerization of a number of monomers have been measured in aqueous emulsion systems: the emulsifying agent was cetyltrimethylammonium bromide, and initiation was by Fenton's reagent ($Fe^{++} + H_2O_2$). The monomers employed were acrylic acid, methyl, ethyl, and butyl acrylates, 2-hydroxyethyl methacrylate, 2-hydroxypropyl methacrylate, methacrylic acid, and methyl, ethyl, butyl, and hexyl methacrylates. The heats of polymerization lie in the range from 13 to 19 kcal per mole, the experimental standard deviations being 40 to 110 cal per mole. A steady increase was observed for acrylic acid and its CH_3, C_2H_5, and C_4H_9 esters, and for methacrylic acid and its CH_3, C_2H_5, C_4H_9, and C_6H_{13} esters. This change is attributed to a steady increase in the proportion of head-to-head, tail-to-tail polymers, leading to a decrease in steric hindrance. Abnormally low heats observed with hydroxyethyl methacrylate and 2-hydroxypropyl methacrylate are attributed to the solvation of the monomer, less solvation being possible in the polymer as a result of shielding.

INTRODUCTION

During the past few years a considerable amount of attention has been devoted to heats of polymerization, including those of monosubstituted (CH_2=CHX) and 1,1-disubstituted (CH_2=CXY) ethylenes. Estimates of heats ($-\Delta H$) of polymerization on the basis of bond and group energies lead to values close to 20 kcal per mole (1). Heats of polymerization of the monosubstituted ethylenes agree with this value, but the disubstituted ethylenes have heats that are less by 3 to 9 kcal per mole. This difference has been attributed (2, 3) to the energy of repulsion between the neighboring side-units in the polymer formed. The vinyl polymers exist predominantly in the head-to-tail arrangement, and in polymers formed from 1,1-disubstituted monomers there is steric hindrance involving side-groups or neighboring monomer residues. Valuable support for this point of view has been obtained by Baxendale and Madaras (4) in a study of heats of copolymerization.

The work done so far has shown that the heats evolved in the polymerization of the methacrylates (1,1-disubstituted ethylenes, H_2C=C(CH_3)COOR) are significantly lower than with the acrylates (monosubstituted ethylenes, H_2C=CHCOOR). No systematic study of the effect of substituents has, however, been carried out on these compounds. This has been done in the present investigation, the object of which was to learn more about the magnitude of the effects of steric hindrance. The polymerizations were carried out in aqueous emulsions, the emulsifying agent being cetyltrimethylammonium bromide. Initiation was brought about by Fenton's reagent: this produces OH radicals,

$$Fe^{++} + H_2O_2 \rightarrow Fe^{+++} + OH^- + OH,$$

and these initiate polymerization by adding on to double bonds.

EXPERIMENTAL

Calorimetry

The heats of polymerization were measured using a Tian–Calvet microcalorimeter that has been described in previous publications from this laboratory (5, 6); the amplification and integration circuits have been

described in detail by Attree and co-workers (7). The instrument was calibrated electrically by passing a known current through a measured resistance for a definite period of time. As a check the heat of solution of anhydrous lithium sulphate was measured; the value obtained, -6.54 ± 0.10 kcal per mole, is in satisfactory agreement with the value of -6.61 kcal per mole reported in the N.B.S. tables (8). The calories reported in this paper are defined calories, equal to 4.1840 joules.

Materials

The monomers employed in this work were kindly supplied by the Rohm and Haas Company, and had been purified. They were all reported to be over 99% pure except for 2-hydroxyethyl methacrylate and 2-hydroxypropyl methacrylate, which were both 96.5% pure. When received, the monomers contained a few parts per million of inhibitor. Just prior to polymerization of a monomer the inhibitor was removed by distillation under reduced pressure of nitrogen. The middle fraction of the distillate was collected and kept under refrigeration until used.

The emulsifying agent, cetyltrimethylammonium bromide, was an Eastman Kodak product; it was purified by recrystallizing it twice from acetone. The ferrous sulphate and hydrogen peroxide were reagent-grade chemicals. The materials used in the volumetric determination of the monomers were Fisher Certified Reagents.

Reaction Cell Assembly

A special cell was designed for measuring the heats of polymerization, and is shown in Fig. 1. The function

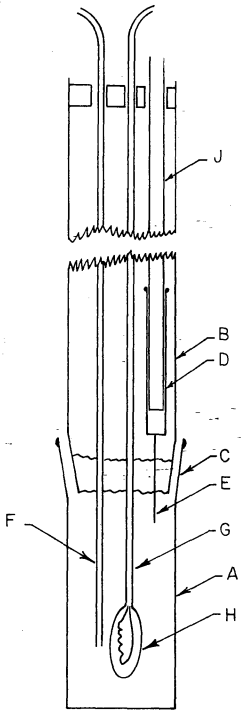

Fig. 1. The reaction cell assembly.

of the apparatus is to add the initiator to the reactants and to bring about gentle stirring. The cell A is constructed completely of glass, and it is connected to the upper part B by means of a 19/38 ground glass joint C. The monomer solution is contained in A, while the initiator is held in a 1-ml syringe, D. The syringe needle E passes through the ground glass joint, as does a small diameter glass tube F and a glass tube G carrying electrical leads; these are sealed in with epoxy resin, and the glass tube ends in a bulb H, which contains a calibrated resistor immersed in oil. This bulb is held submerged in the middle of the liquid in the reaction cell. The tube F is used for stirring, small regular alterations in pressure causing the liquid to oscillate through a short distance in the tube. The plunger of the syringe D was extended by a glass rod J that extended out of the top of the assembly; in this way the initiator solution could be injected into the reaction cell by merely depressing the plunger.

Experimental Procedure

The general procedure used for measuring heats of polymerization was as follows. The two syringes in the reaction assembly were loaded with the appropriate amount of hydrogen peroxide to give a 10^{-3} M solution after injection into 10 ml of solution in the reaction cell. An oxygen-free solution was prepared containing 1% of emulsifier and 10^{-2} N with respect to sulphuric acid and 10^{-3} M with respect to ferrous sulphate. Part of this solution (10 ml) was placed in one of the reaction cells, to be used as a blank. Monomer was introduced into the remainder of the solution and 10 ml of this placed in the other reaction cell. Both cells were allowed to stand in the calorimeter block long enough for thermal equilibrium to be attained. To initiate the polymerization in the cell containing monomer, the syringe plungers were then depressed. At the same time stirring was begun (and continued through the experiment) and the recording was started. When the reaction had essentially stopped, the heat evolved was estimated, and approximately the same quantity of electrical heat was developed in the reaction cell. At the conclusion of this calibration the exact heat evolved was calculated from the ratio of the two curve heights on the recorder that was connected to the integrator circuit.

Immediately after the completion of the calibration, the amount of monomer in the initial solution and in the final partially polymerized solution was determined by titration. The titration procedure was a modification of that described by Mitchell *et al.* (9). Ten milliliters of bromide solution was placed in each of three stoppered iodine-number flasks and the flasks were cooled in ice water. To one flask was added 5 ml of initial monomer solution and 5 ml of chloroform. Into a second flask was introduced the partially polymerized solution from the reaction cell, which was rinsed twice with 2 ml of water and twice with 2.5 ml of chloroform. The contents of the other reaction cell was introduced in a similar manner to the third flask. Each iodine-number flask was placed on an oscillating shaker immediately after the addition of the solution. The flasks were shaken for 1-hour periods, and then again chilled in the water. A 25-ml portion of a 10% KI solution was then added to each flask, which was then shaken. The solutions were then titrated with sodium thiosulphate solution until the chloroform layer was clear.

The amount of monomer polymerized can readily be shown to be given by

$$\text{no. moles polymerized} = \{N(Na_2S_2O_3)/2000\}\ (V_B - 2V_{mi} + V_{mp})$$

where $N(Na_2S_2O_3)$ is the normality of the thiosulphate solution, V_B is the titer of the blank, V_{mi} is the titer of the initial monomer solution, and V_{mp} is the titer of the partially polymerized solution. Duplicate titrations of monomer solutions were in agreement with each other to within 1%. Titrations on weighed quantities of monomer showed that gravimetric and volumetric determinations agreed to better than 1%.

Special checks were made to confirm that neither the initiation reaction nor the stirring contributed to the heat measured.

RESULTS

A number of measurements, at least five, were made on each monomer. The results obtained with 2-hydroxypropyl methacrylate are shown in Table I. Most of the measurements, including all of those in Table I, were made with a fixed initiator concentration and emulsifier concentration, namely 10^{-3} M initiator and 1.0% emulsifier. A number of measurements were made with different initiator and emulsifier concentrations, the range covered being from 0.5 to 2.0% emulsifier and 0.5×10^{-3} M to 4×10^{-3} M initiator. No effect on the heat was observed.

DISCUSSION

Comparison with Previous Results

Heats of polymerization have previously been reported for some of the monomers used in the present study. These heats relate to a number of different states of the monomer and polymer, and Dainton and Ivin (10) have suggested a notation, which is summarized in Table III, for these states. Table IV summarizes the results obtained by

TABLE III

Summary of standard states

various previous workers, our own values being shown in parentheses. Our values are best compared to the solution–solution values where available; they are measured at a different temperature (25.0° C) from those of previous studies, but the effect will be small.

The agreement between our results and those of other workers is good in some cases (acrylic acid and ethyl methacrylate) but not in others. In the case of methyl acrylate we agree with the lc value of Tong and Kenyon (11), but the ss value of Evans and Tyrrall (12) is considerably higher than ours. Their estimated error of 1 kcal, amounting to 5%, indicates a large degree of uncertainty in their results. Their value for methacrylic acid also differs considerably from ours, again being much higher. In the case of methyl methacrylate our value does not differ greatly from any of the several previous values, especially when the estimated errors are taken into account. The value of Tong and Kenyon (13) may be too low because they assumed complete polymerization.

The results of Joshi (23, 24), for bulk polymerization, were obtained at 74.5° C. They are in fair agreement for methyl methacrylate and *n*-butyl methacrylate, but differ significantly from previous results, and from the results of the present paper, for the two monomeric acids.

Interpretation of Results

Addition of a free radical to a monosubstituted or 1,1-disubstituted ethylene may occur in one of two different ways:

$$R— + H_2C{=}CXY \rightarrow R{-}CH_2{-}CXY—$$

$$R— + XYC{=}CH_2 \rightarrow R{-}CXY{-}CH_2—$$

The former process leads to a head-to-tail (HT) polymer, the latter to a head-to-head, tail-to-tail (HHTT) polymer. The relative rates of the two processes depend on the energies of the corresponding activated complexes, and the following two factors are of primary importance:

(1) In the radical R—CH_2—CXY— the substituents X and Y provide the possibility of resonance structures in which the unpaired electron resides on the radical, and this has the effect of stabilizing the radical. This resonance stabilization will also enter to some extent into the activated complex. No such resonance stabilization is possible in the case of the radical R—CXY—CH_2— or of its corresponding activated complex. This factor therefore favors the formation of HT polymers, and structural studies (14, 15, 16) in fact indicate that these are the most common.

(2) Steric effects, on the other hand, tend to favor the HHTT arrangement, as is shown schematically in Fig. 2. There is more steric interference in the case of an HT polymer than in an HHTT polymer, and this is also true in the case of the activated complexes. A polymer radical in which the odd electron is on the —CH_2— group (I and II in Fig. 2) will therefore prefer to add on to the —CH_2 end (I) rather than the —CXY end (II). Similarly a polymer radical with the odd electron on the CXY group will prefer to add on to the —CXY end of the monomer (IV) rather than to the —CH_2 end (III). As a result, the HHTT polymers tend to be preferred if there is much steric hindrance. In agreement with this, Marvel and Cowan (17) have shown that the monomers

For personal use only.

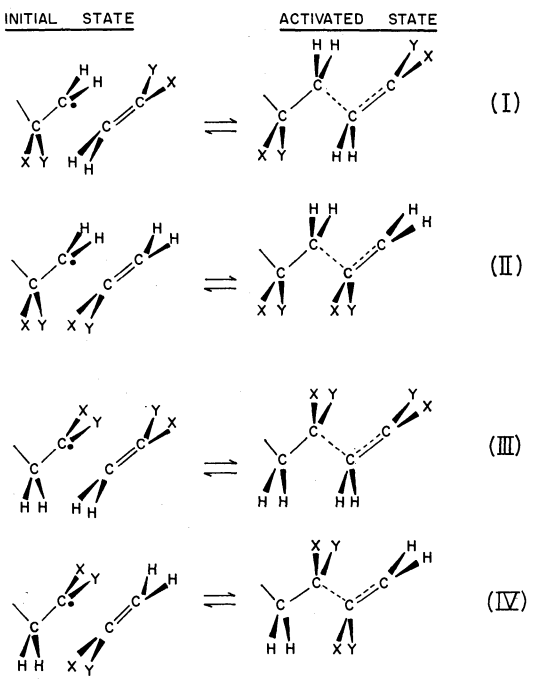

Fig. 2. Initial and activated states in polymerization.

where considerable steric effects are expected, lead predominantly to the HHTT arrangement.

These considerations lead naturally to an interpretation of the apparently paradoxical result that in both the acrylate and methacrylate series the change from methyl to ethyl to *n*-butyl leads to a steady increase in the heat of polymerization. It must be supposed that in these series the increasing steric hindrance leads to an increase in the proportion of HHTT polymer, so that in the products there is actually less hindrance with the more bulky substituents than with the smaller ones.

2-Hydroxyethyl methacrylate and 2-hydroxypropyl methacrylate both exhibit lower heats of polymerization than do the monomers having no hydroxyl groups. The difference seems too large to explain on the basis of changes in the bond strengths, or by steric hindrance, brought about by the hydroxyl groups. The most likely explanation appears to be that in solution the hydroxyl group in the monomer is solvated, but that in the polymer chain the hydroxyl groups are only partially solvated. The heats of solvation of alcohols are in the range from 2.5 to 4 kcal per mole, so that the effects observed could be explained if only part of the solvation shell is removed on polymerization.

It must be emphasized that since all of the effects discussed above are small, the explanations are necessarily tentative. Factors such as heats of emulsification of the monomers, or heats of wetting of the polymers, might also play a part.

RATES OF POLYMERIZATION OF ACRYLATES AND METHACRYLATES IN EMULSION SYSTEMS

K. G. McCurdy and K. J. Laidler
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received October 3, 1963

ABSTRACT

The microcalorimeter has been used to obtain rates of polymerization of a number of monomers in emulsion systems. The rates with the acrylates are consistently higher than those with the methacrylates, and this is attributed to less steric hindrance. Low rates found with monomers containing a hydroxyl group are explained as due to solvation in the initial state. In both the acrylates and methacrylates the rates go through a maximum as one goes up the series methyl: ethyl: butyl: hexyl. This is discussed in terms of inductive and steric effects.

INTRODUCTION

The preceding paper (1) describes a microcalorimetric study of a number of vinyl polymerizations in emulsion systems. Several investigators (2–6) have described procedures for determining rate constants on the basis of calorimetric measurements, and in particular Baumgartner and Duhaut (7) and Lueck, Beste, and Hall (8) have developed methods that are especially suitable for our technique using the Tian–Calvet microcalorimeter. Lovering and Laidler (9) have recently applied the Baumgartner–Duhaut procedure to the determination of alcohol–isocyanate rate constants. The method of Lueck, Beste, and Hall (8), which is very similar, applies specifically to the differential method, which is the one employed in the present work.

EVALUATION OF THE RATE CONSTANTS

Kinetics of Emulsion Polymerization

The kinetic laws applicable to emulsion polymerization have been worked out in detail, and the present brief account covers only the essential points. Soap solutions such as those used in the present work, in which cetyltrimethylammonium bromide is the emulsifying agent, have been shown by McBain (10) and Harkins (11, 12) to contain micelles consisting of layers of oriented soap molecules. When substances such as the monomers used in the present investigation are added to such a soap solution they are "solubilized", which means that some of the monomer penetrates the micelles. Some of the monomer also remains as suspended droplets in the aqueous phase.

Harkins (13) proposed that in emulsion systems there are two principal loci of polymerization. Initially, when there is not much polymer present, the micelles contain largely monomer, and because the radii of the micelles are much smaller than those of the droplets the micelles present a much larger interfacial area. Most of the polymerization therefore takes place in these micelles. The process is that the free radicals generated by the initiation in the aqueous phase are captured by the micelles, and that monomer is supplied to the growing radicals from the droplets in the surrounding solution. The micelles therefore grow larger and soon consist largely of polymer particles with soap adsorbed on them. After 2 to 3% of the monomer has been converted into polymer the micelles have in fact largely disappeared, and have been replaced by polymer particles. From this point on, therefore, the locus of polymerization is the polymer particles.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

A quantitative formulation of this theory was put forward by Smith and Ewart (14). Applied to the later phase of the process, when polymerization is occurring in the polymer particles, the number of which has become constant, the treatment may be outlined as follows. On the average there are 10^{14} particles per cubic centimeter and in a typical experiment 10^{13} radicals are produced per cubic centimeter per second; if all of these enter the polymer particles a particle will acquire a radical once in about 10 seconds on the average. Once a radical has entered a particle it proceeds to grow by adding monomer units at a rate equal to the rate constant for the propagation process, k_p, multiplied by the monomer concentration [M] in the particles.

If a radical enters a particle that already contains a radical it will at once combine with it, and from this it follows that at any time one-half of the polymer particles will contain one radical and the other half no radical. If N is the total number of polymer particles the rate of polymerization is therefore given by

$$[1] \qquad v_p = \tfrac{1}{2}k_p[\mathrm{M}]N.$$

This relationship has been confirmed (15–19) for a number of systems, and the k_p values derived are in reasonable agreement with those obtained in other ways. Relationships between the number, N, of particles and the concentrations of emulsifier and initiator have been derived by Smith and Ewart (14) and by Medvedev (20), whose model is a little different from that outlined above.

The essential point as far as the present investigation is concerned is that the monomer concentration is sufficiently low (0.2 M) that all of the monomer is solubilized. The monomer concentration in the particles is therefore proportional to the overall monomer concentration.

The experiments were all carried out at an emulsifier concentration of 1% and an initiator concentration of 10^{-3} M; this ensures constancy of the number N of particles. Since this number remains constant throughout a run the kinetics will be first-order.

THE THERMAL METHOD FOR DETERMINING RATE CONSTANTS

The principle of the method used has been described by Lovering and Laidler (9). It is sufficient here to note that the extent of reaction at time t is measured by the area of the e.m.f. vs. time curve up to that point, plus a contribution due to the loss of heat from the cell to the calorimeter block; this is determined by a separate measurement in which electrical heat is supplied to the cell.

In this way the amount reacted can be determined at various times, and the rate constant calculated in the usual way. This was carried out at various times, covering the initial part of the reaction, up to 50% completion. A graphical method was employed for obtaining the first-order rate constants.

RESULTS

Fig. 1 shows a typical plot used for the determination of a rate constant; it relates to experiment 1 (cf. Table I) for methyl methacrylate. Table I gives the rate constants calculated on the basis of a number of completely different experiments, under identical experimental conditions, for the polymerization of methyl methacrylate. The values are seen to be reasonably constant. Table I summarizes also the averaged rate constants, and standard deviations, for all of the polymerizations studied.

DISCUSSION

Comparison with Previous Results

Rate constants previously derived for the polymerizations of the monomers employed in the present work are derived from bulk polymerization studies; they are second-order

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

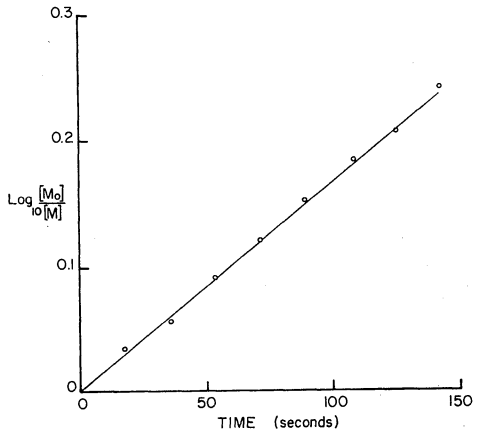

Fig. 1. A typical first-order plot, for the polymerization of methyl methacrylate.

TABLE I

Rate constants for the polymerization of methyl methacrylate and all compounds studied

Polymerization of methyl methacrylate		All polymerizations studied (T = 25° C)	
Expt. No.	Rate constant × 10^3 (sec^{-1})	Monomer	Rate constant × 10^3 (sec^{-1})
1	1.66	Methacrylic acid	2.15 ± 0.19
2	1.70	Methyl methacrylate	1.83 ± 0.28
3	1.68	Ethyl methacrylate	2.84 ± 0.28
4	1.72	*n*-Butyl methacrylate	2.66 ± 0.23
5	1.68	*n*-Hexyl methacrylate	1.35 ± 0.18
6	1.72	Acrylic acid	4.19 ± 0.43
7	1.68	Methyl acrylate	8.83 ± 0.60
8	1.70	Ethyl acrylate	12.64 ± 0.41
9	1.67	*n*-Butyl acrylate	9.62 ± 0.10
10	1.52	Hydroxyethyl methacrylate	1.24 ± 0.19
11	1.60	2-Hydroxypropyl methacrylate	1.97 ± 0.39

rate constants, and relate to those of the present work through N, the concentration of particles. The values agree provided that N is 10^{15} to 10^{16} particles per cc, and this is the value of N obtained in a number of investigations of emulsion polymerization (15–19, 21).

The previous kinetic studies of bulk polymerization are consistent with the results of the present work as far as general trends are concerned. Thus in the methacrylate series previous work shows the maximum in rate constant in going from methyl to butyl. Some previously obtained rate constants are:

methyl methacrylate at 24° C: 310 liter $mole^{-1}$ sec^{-1}, (22)

n-propyl methacrylate at 30° C: 467 liter $mole^{-1}$ sec^{-1}, (23)

n-butyl methacrylate at 30° C: 362 liter $mole^{-1}$ sec^{-1}. (24)

For the acrylates the only previously reported values are:

methyl acrylate at 30° C: 769 liter $mole^{-1}$ sec^{-1}, (25)

n-butyl acrylate at 25° C: 13 liter $mole^{-1}$ sec^{-1}. (26)

Our value (cf. Table I) for methyl acrylate is lower than that for *n*-butyl acrylate. There is evidence, however, that the previously reported value (25) for methyl acrylate is too high on account of autoacceleration (27).

Also, the previous value for *n*-butyl acrylate (26) is lower than that for *n*-butyl methacrylate (24), which is contrary to expectation on steric grounds.

For personal use only.

Interpretation of Results

The propagation rate constants are seen from Table I to be consistently higher for the acrylates than for the corresponding methacrylates. As discussed in the preceding paper (1), with reference to heats of polymerization, there is considerably less steric hindrance to polymerization in the case of the acrylates than in the methacrylates, and this may well explain the difference in rates.

In the acrylate series the rate constants increase from acrylic acid to methyl acrylate to ethyl acrylate, but then decrease on going to butyl acrylate. The behavior in the methacrylate series is similar: the apparent deviation for methacrylic acid and methyl methacrylate is within the experimental error. There is a decrease from ethyl to butyl to hexylmethacrylate. These trends can be explained in terms of inductive effects and steric effects. The increases in rates from methyl to ethyl are attributed to the greater electron-donating power of the ethyl group as compared with methyl. It would appear that the increased electron-donating power facilitates the opening of the double bond, and in this way increases the rate of addition of the monomer to the polymer radical. The steric difference between methyl and ethyl is probably unimportant.

In the series ethyl: butyl: hexyl the inductive effects will be very similar, and the steric effects will now become predominant, leading to a progressive decrease in rate. This steric effect is envisaged as simply arising from the physical size of the monomers; as this size is increased there is more interference between substituent groups, a bulky monomer having greater difficulty in approaching a polymer radical.

Hydroxyethyl methacrylate and 2-hydroxypropyl methacrylate both exhibit low rates of polymerization, and this is to be related to their low heats of polymerization (1). The monomers will be more solvated than the activated complexes, and the free energies of activation will therefore be higher than with the monomers not containing hydroxyl groups.

EXTRACELLULAR GLYCOLIPIDS OF RHODOTORULA SPECIES

THE ISOLATION AND SYNTHESIS OF 3-D-HYDROXYPALMITIC AND 3-D-HYDROXYSTEARIC ACIDS[1]

A. P. TULLOCH AND J. F. T. SPENCER
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received November 27, 1963

ABSTRACT

Several species of the red yeast *Rhodotorula* produce extracellular glycolipids which consist of a mixture of mannitol and pentitol esters of 3-D-hydroxypalmitic and 3-D-hydroxystearic acids. One molecule of the long chain acid is attached to each polyol molecule and most of the remaining hydroxyl groups including the one on the fatty acid are acetylated.

The formation of extracellular lipid by *Rhodotorula graminis* was reported by di Menna in 1958 (1). Later Deinema (2, 3) studied extracellular lipid production in *R. graminis* and in two strains of *R. glutinis*. She also investigated the composition of the lipids and found acetic acid, a number of known and unknown long-chain fatty acids, and polyols among the hydrolysis products. In an investigation of the production of extracellular lipids by yeasts which is being carried out in this laboratory (4), three species of *Rhodotorula*, which form such lipids, were isolated.

The composition of the lipids produced by these species and also that produced by *R. glutinis* CBS 4648, originally studied by Deinema, were investigated. The "oily" extracellular material, obtained when the yeasts were grown in shaken culture, was heavier than water and therefore was easily isolated. It was found to be a mixture of polyol esters, which was soluble in both methanol and hexane. However, on one occasion when *R. glutinis* strain 4648 was grown in fermentors the oil produced was only partly soluble in methanol, and could be separated by solvent distribution into polyol esters and triglycerides. The principal fatty acids of the latter were oleic and palmitic acids. It is probably this extracellular triglyceride which gave rise to the ordinary fatty acids found by Deinema (2, 3).

Acid methanolysis of the polyol esters gave free polyols, the methyl esters of hydroxy acids, and methyl acetate. The relative amounts of the first two groups of components corresponded approximately to a ratio of 1 molecule of fatty acid to 1 molecule of polyol. The polyols were analyzed as the acetates by gas liquid chromatography (GLC) and consisted of a mixture of D-mannitol, D-arabitol, and minor amounts of xylitol. The fatty acid ester portion was almost the same for each strain and was a mixture of 3-D-hydroxypalmitic (85%) and 3-D-hydroxystearic (15%) acids. The evidence for this conclusion is described below.

A mixture of palmitic and stearic acids was obtained by reduction of the hydroxy acids with red phosphorus and hydrogen iodide followed by zinc and hydrochloric acid, showing that the fatty acids contained unbranched carbon chains. This finding and the observation that the carbon numbers, on a silicone column, were 17.7 and 19.7, or almost two units greater than the carbon numbers of palmitic and stearic acids, suggested that

[1]*Issued as N.R.C. No. 7801.*

the fatty components were hydroxy acids (5, 6). The methyl esters were partly separated into C_{16} and C_{18} components by countercurrent distribution. The only isolatable product of chromic acid oxidation of the C_{16} ester was myristic acid, which indicated that the hydroxyl group was at position 3.

Further evidence for this was derived from the action of base on the original polyol esters and on the acetoxy ester, obtained by acetylation of the hydroxy ester. Treatment of the polyol ester with sodium methoxide solution, to effect methanolysis, produced an unsaturated C_{16} ester in addition to the hydroxy ester. The acid corresponding to this ester was found to be *trans*-2-hexadecenoic acid. This acid was also obtained by alkaline hydrolysis of the polyol ester or the C_{16} acetoxy ester. Linstead *et al.* (7) have shown that when β-acetoxy esters are treated with bases β-elimination of acetic acid occurs and an α,β-unsaturated acid is produced. The relative amounts of unsaturated and hydroxy acid obtained by alkali treatment of the polyol ester and of methyl 3-acetoxypalmitate were compared by GLC analysis. The relative amount of unsaturated acid yielded by the polyol ester was slightly lower than that yielded by the pure acetoxy ester indicating that in most, but not all, of the polyol ester molecules the 3-hydroxyl group was acetylated. The results showed that the 3-hydroxystearic acid was also mainly acetylated. Therefore in working with a lipid which contains a 3-acetoxy fatty acid grouping hydrolysis must be carried out in an acid medium. The previous workers (2, 3) employed alkaline hydrolysis and consequently obtained confusing results.

Racemic methyl 3-hydroxypalmitate was synthesized and compared with the ester obtained from the glycolipid. The carbon numbers, on the silicone column, were the same and the infrared spectra in carbon tetrachloride solution were indistinguishable. However, the infrared spectra, compared as Nujol mulls, were quite different. The 3-hydroxy esters and acids obtained from the glycolipid were quite strongly laevorotatory in chloroform, but in methanol the specific optical rotation was quite small, which is characteristic of 3-hydroxy fatty acids (8). The negative rotation suggests that the compounds have the D-configuration (9).

To establish the configuration and structure of the acids of the glycolipid 3-D-hydroxypalmitic and 3-D-hydroxystearic acids were synthesized from (+) methyl hydrogen β-acetoxyglutarate by the general method of Serck-Hanssen (8). The products were identical with those obtained from the yeast lipid.

It appears that these two particular 3-hydroxy acids have not been obtained from natural sources previously, but 3-D-hydroxymyristic acid has been isolated from *Escherichia coli* (10), 3-D-hydroxylauric acid from a metabolite of *Isaria cretacea* (11), and 3-D-hydroxycapric acid from a metabolite of *Pseudomonas aeruginosa* (12).

Approximately 3.5 molecules of acetic acid were obtained per molecule of glycolipid but the points of substitution of the acetic acid and fatty acid residues on the polyol were not investigated. The product is probably a complex mixture of isomers. The fatty acids and polyols of the intracellular lipids of three of the four strains were also analyzed. The composition of the polyol fraction is shown in Table I. The two lipids are quite different, the intracellular lipid being mostly triglycerides and the extracellular lipid a mixture of esters of 5 and 6 carbon polyols. Table II shows the composition of the fatty acid fractions. The two lipids obtained from *R. glutinis* strain 4648 closely resemble each other in fatty acid composition and strain 16A8 is also similar. However, the acids from *R. graminis* strain 6CB contain different relative amounts of palmitic and oleic acids. The composition of the cell fat of *R. graminis* di Menna has been reported (13) but differed from that of the strain used here in having a considerably lower oleic acid content.

Unidentified	0.5	2.7	2.1	0.2
Oil content %	—	71	64	74

EXPERIMENTAL

Melting points were determined using a Leitz hot-stage microscope. Optical rotations were measured at 25° C in a 1 dm tube.

Method of Oil Production

The yeasts were isolated from flowers obtained from several localities in Canada. On the basis of carbon assimilation tests (14) the yeasts were considered to be *R. glutinis* strain 16A8, *R. mucilaginosa* strain S6A1, and *R. graminis* strain 6CB. The last strain resembled *R. graminis* di Menna C.B.S. 2826 but differed from this culture in not assimilating cellobiose, L-arabinose, dulcitol, and salicin (J. F. T. Spencer and H. Phaff, unpublished work). The medium used consisted of glucose (4%), yeast extract (0.2%), potassium dihydrogen phosphate (0.1%), and magnesium sulphate heptahydrate (0.02%). Flasks containing 50 ml of medium were agitated on a Gump shaker having a radius of 1 in. at 230 r.p.m. for a period of 8–10 days. Three liter fermentors were used at 28° C, with an air flow of 1 liter/minute, a stirring speed of 400 r.p.m., and inoculated with 100 ml of 24-hour shaken culture. The yield of extracellular lipid was 1–2 g/liter. The cells and lipid were allowed to settle and the lipid was washed away from the cells with light petroleum, b.p. 60–80° C.

Gas–Liquid Chromatographic Analysis

The hydroxy fatty acid esters were analyzed by means of a silicone on celite column as previously described (5). Methyl 3-hydroxypalmitate and methyl 3-hydroxystearate had carbon numbers of 17.7 and 19.7 respectively. On this column methyl 2-hexadecenoate has a carbon number of 16.5 and is completely separated from methyl palmitate. On the other hand, methyl 9-hexadecenoate has a carbon number which is very slightly lower than that of methyl palmitate.

The separation of all the pentitol and hexitol acetates except for those of glucitol and galactitol was described by Jones and co-workers (15) using a column packing which consisted of a mixture of polyester and non-polar phases. In the present work an 8 ft × 3/16 in. copper column packed with 1:30 butanediol. succinate (16) on 40–60 mesh acid-washed firebrick was used. The oven temperature was 212° C and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

helium flow rate 60 ml/minute. This column partly separated glucitol and galactitol acetates and the retention times of the acetates relative to arabitol pentaacetate were as follows: ribitol 0.89, arabitol 1.00 (18 minutes), xylitol 1.24, mannitol 2.60, galactitol 2.97, glucitol 3.12. The column used by Jones and co-workers separated the acetates in the same order, except for the last two, and also effected a good separation of allitol, talitol, and iditol acetates from the other three. It is probable that the present column would separate all six hexitol acetates.

To separate and collect larger quantities of arabitol and mannitol acetates and fatty acid esters an 8 ft × 5/16 in. copper column with 1:6 silicone grease on acid-washed celite was used at 240° C, with injector at 290° C, and a flow rate of 60 ml helium/minute.

Composition of the Extracellular Lipids

The lipid had a molecular weight (osmometric in acetone) of 560, a saponification equivalent of 110.5, and gave 0.44 g of volatile acid (calculated as acetic acid) per gram of lipid. The volatile acid was analyzed by gas chromatography as the decyl ester (17) and acids of chain length longer than two carbon atoms were absent. The analyses do not correspond to a definite composition and the lipid is probably quite a complex mixture. It contains approximately 3 to 4 molecules of acetic acid for each lipid molecule.

Acid Methanolysis of the Extracellular Lipid

Lipid (11.56 g) was refluxed for 1 hour with 3% methanolic hydrogen chloride and the acid neutralized with silver carbonate. After filtration the volatile material was removed on a rotary evaporator and collected in a dry-ice trap. This fraction, which contained methyl acetate, was saponified and a portion of the salt obtained treated with S-benzyl thiouronium chloride to give S-benzyl thiouronium acetate with a melting point of 135–138° C, which was not depressed by an authentic sample.

Hydroxy fatty acid esters (5.30 g) were extracted from the residue, obtained after removing the methyl acetate, by stirring with ether. The polyols (3.18 g) remained and when analyzed by paper chromatography (*n*-butanol–ethanol–water 40:11:19 v/v) only pentitols and hexitols were found. When the polyols from *R. glutinis* strain 4648 were examined a portion was acetylated and separated in 35 mg batches by means of the preparative silicone column. D-Mannitol hexaacetate, so obtained, had $[\alpha]_D$ +32.0° (*c*, 1.0, $CHCl_3$) and melting point 120–123° C, after crystallization from ethanol. The mixed melting point with an authentic sample of D-mannitol hexaacetate was 122–124° C. D-Arabitol pentaacetate was crystallized from ethanol–hexane and had $[\alpha]_D$ +36.8° (*c*, 1.5, $CHCl_3$) and melting point 71–73° C. The mixed melting point was not depressed by an authentic sample.

Structure of the Hydroxy Fatty Acids

The composition of the hydroxy fatty acid methyl ester portion, as analyzed by GLC, was almost the same for the lipids from all the strains examined. Palmitic and stearic acids were very minor components (0.3% or less), the approximate composition was 3-hydroxypalmitate (85%), and 3-hydroxystearate (15%).

Mixed esters (10 mg) were refluxed overnight with 47% aqueous hydrogen iodide (5 ml) and red phosphorus (100 mg), the mixture poured into water, and the acids isolated. The saturated acids obtained by refluxing for 5 hours with concentrated hydrochloric acid (1 ml) and zinc dust (100 mg) were identified, by GLC, as palmitic and stearic acids. Hydroxy methyl esters (3 g) were distributed between 85% ethanol and light petroleum b.p. 40–60° C by 125 cycles of a modified E.C. Apparatus Co. fractionater with 100 tubes and 20 ml capacity each phase. Only a partial separation of the C_{16} and C_{18} esters was obtained. Tubes 52–70 contained methyl 3-hydroxypalmitate (1.3 g) and tubes 84–88 contained methyl 3-hydroxystearate (0.075 g). After crystallization from acetone, methyl 3-D-hydroxypalmitate had melting point 48–49° C and $[\alpha]_D$ −13.8° (*c*, 5.6, $CHCl_3$) and −0.3° (*c*, 7.1, MeOH). Calculated for $C_{17}H_{34}O_3$: C, 71.3%; H, 12.0%. Found: C, 71.2%; H, 11.9%. The peaks in the OH and carbonyl regions of the infrared spectra were as follows: 3380 (s), 3300 (s), 1735 (s), 1690 (s), (Nujol mull); 3550 (w), 1727 (s) cm^{-1}, (0.2% in carbon tetrachloride). Saponification of the methyl ester with potassium hydroxide (5% in 90% ethanol) at 60° C for 1 hour yielded 3-D-hydroxypalmitic acid which had melting point 78–79° C, after crystallization from acetone, and $[\alpha]_D$ −12.9° (*c*, 1.3, $CHCl_3$) and +2.1° (*c*, 6.8, MeOH). Calculated for $C_{16}H_{32}O_3$: C, 70.5%; H, 11.8%; neutral equivalent, 272.5. Found: C, 70.8%; H, 11.7%; neutral equivalent, 275.5.

The C_{18} fraction was crystallized from acetone and yielded methyl 3-D-hydroxystearate, m.p. 55.5–56.5° C; $[\alpha]_D$ −15.0° (*c*, 1.9, $CHCl_3$). Calculated for $C_{19}H_{38}O_3$: C, 72.6%; H, 12.2%. Found: C, 72.5%; H, 12.0%. The peaks in the infrared spectrum (Nujol mull) in the OH and carbonyl regions were 3380 (s), 3300 (s), 1735 (s), 1690 (s) cm^{-1}. Saponification yielded 3-D-hydroxystearic acid which had melting point 84–86° C, after crystallization from acetone and $[\alpha]_D$ −12.0° (*c*, 1.2, $CHCl_3$). Calculated for $C_{18}H_{36}O_3$: C, 71.95%; H, 12.1%. Found: C, 71.8%; H, 12.0%.

Chromic Acid Oxidation

Methyl 3-D-hydroxypalmitate (0.12 g) was oxidized overnight with 0.1 *N* chromium trioxide in acetic acid (50 ml); water was added, the excess oxidant reduced with sulphur dioxide and the product (0.1 g) extracted with ether. The product was converted to the methyl ester and purified by gas chromatography using the preparative silicone column at 200° C. Saponification and crystallization from hexane yielded myristic acid with melting point 53–54° C, which was not depressed by admixture with pure myristic acid.

Synthesis of the Hydroxy Esters

Racemic Methyl 3-Hydroxypalmitate

Methyl 3-oxopalmitate was prepared from myristoyl chloride (18) and hydrogenated over Raney nickel (19) to give methyl 3-hydroxypalmitate, m.p. 41–43° C. Calculated for $C_{17}H_{34}O_3$: C, 71.3%; H, 12.0%. Found: C, 71.4%; H, 11.8%. Infrared maxima in the OH and carbonyl regions were 3390 (m), 3570 (sh), 1730 (s), (Nujol mull); 3550 (w), 1727 (s) cm^{-1}, (0.2% in carbon tetrachloride.)

3-D-Hydroxypalmitic Acid

(+) Methyl hydrogen β-acetoxyglutarate (8) (1 g) and tridecanoic acid (3 g) were electrolyzed in 0.022 *N* sodium methoxide in methanol (30 ml) until the solution was just alkaline. After the solution was acidified with acetic acid, it was filtered from hydrocarbon by-products, part of the methanol was taken off, 3% methanolic hydrogen chloride added, and the mixture refluxed for 3 hours. Water was added and the product extracted with ether. The crude product (1.1 g) was chromatographed on silicic acid (60–200 mesh); elution with light petroleum (b.p. 60–80° C) containing 2% acetone gave a small amount of methyl tridecanoate followed by the desired hydroxy ester (0.45 g). Crystallization from acetone yielded methyl 3-D-hydroxypalmitate, m.p. 49–50° C, which was not depressed when mixed with the natural ester, $[\alpha]_D$ was −14.3° (*c*, 2.5, $CHCl_3$). Calculated for $C_{17}H_{34}O_3$: C, 71.3%; H, 12.0%. Found: C, 71.1%; H, 12.0%. The infrared spectrum (Nujol mull) and the X-ray powder photograph were indistinguishable from those of the natural product. 3-D-Hydroxypalmitic acid was obtained by saponification, and after crystallization from acetone had melting point 77–79° C and $[\alpha]_D$ −13.8° (*c*, 2.4, $CHCl_3$); the melting point was not depressed by admixture with natural acid. Calculated for $C_{16}H_{32}O_3$: C, 70.5%; H, 11.8%. Found: C, 70.5%; H, 12.0%.

3-D-Hydroxystearic Acid

Pentadecanoic acid was prepared by stepwise oxidation of 1-hexadecene in the same way as the preparation of heptadecanoic acid (5). (+) Methyl hydrogen β-acetoxyglutarate (1 g) was electrolyzed with pentadecanoic acid (3 g) and worked up as in the preparation of the C_{16} ester. After silicic acid chromatography methyl 3-D-hydroxystearate (0.47 g) was obtained and crystallized from light petroleum (b.p. 60–80° C). The melting point was 56.5–57.5° C, undepressed by admixture with the natural ester, and $[\alpha]_D$ was −12.9° (*c*, 4.1, $CHCl_3$). The infrared spectrum (Nujol mull) and the X-ray powder photograph were indistinguishable from those of the natural ester. Calculated for $C_{19}H_{38}O_3$: C, 71.6%; H, 12.2%. Found: C, 72.3%; H, 12.2%. Hydrolysis yielded 3-D-hydroxystearic acid which was crystallized from acetone and had melting point 83–85° C, which was not depressed by the natural acid; $[\alpha]_D$ was −12.2° (*c*, 1.4, $CHCl_3$). Calculated for $C_{18}H_{36}O_3$: C, 71.95%; H, 12.1%. Found: C, 71.9%; H, 12.1%.

Reaction of the Lipid and of Methyl 3-Acetoxypalmitate with Alkali

The glycolipid was treated with 0.022 *N* sodium methoxide in methanol both at room temperature and under reflux. The relative amounts of methyl 2-hexadecenoate, methyl 3-hydroxypalmitate, and methyl 3-acetoxypalmitate, found in the product by GLC, varied with the time and temperature of the reaction. Similar results were obtained starting with methyl 3-acetoxypalmitate. The latter was prepared by refluxing synthetic racemic methyl 3-hydroxypalmitate with 20 times its weight of acetic anhydride for 1 hour and removing the excess reagent. The acetate ester was distilled with boiling point 110–115° C (bath) at 0.05 mm. The following conditions were found to give the best yield of 2-hexadecenoic acid. Acetoxy ester (0.3 g) was added to boiling *M*/50 potassium hydroxide in methanol (100 ml) and refluxed for 1 hour, potassium hydroxide (0.5 g) in water (5 ml) was then added and the mixture refluxed for a further 30 minutes. Water was added followed by dilute hydrochloric acid and the acids extracted with ether. The product was extracted with light petroleum (b.p. 40–60° C) leaving insoluble 3-hydroxypalmitic acid (0.065 g). The extract was concentrated to 4 ml and cooled to −10° C and *trans*-2-hexadecenoic acid (0.080 g) was obtained with melting point 47–48° C. Reported melting point is 48.7–49° C (20).

Methyl 3-D-acetoxypalmitate (0.3 g) was prepared from the natural hydroxy acid and treated in the same way. GLC analysis of the methyl esters of the crude product showed that the ratio of 2-hexadecenoic acid to 3-hydroxypalmitic acid was 3.44:1. 2-Hexadecenoic acid (0.052 g) was isolated and the melting point and mixed melting point with the 2-hexadecenoic acid, prepared as above from synthetic racemic acetoxy ester was 46.5–47.5° C. The polyol ester from yeast was also treated with *M*/50 potassium hydroxide as described above and the ratio of 2-hexadecenoic acid to 3-hydroxypalmitic acid was 2.82:1.

The Polyols of the Extra- and Intra-cellular Lipids

The intracellular lipids were extracted from the dried yeast cells by the method used for rust spores (21). The lipids were treated with methanolic hydrogen chloride (3%), the acid neutralized with silver carbonate, the mixture filtered, and the methanol taken off. The fatty esters were extracted with ether and the remaining polyols were acetylated by heating at 100° C with a mixture of acetic anhydride and pyridine (1:1). The excess reagent was removed and the acetates were analyzed by GLC. The results are shown in Table I.

The Fatty Acid Composition of the Lipids Other than Polyol Esters

The methanol-insoluble extracellular lipid produced by *R. glutinis* CBS 4648 when grown in fermentors was separated from polar polyol esters by distribution between 90% methanol and light petroleum (b.p. 40–60° C) in four separatory funnels. Methyl esters were prepared from this lipid as before. The fatty acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

methyl esters were analyzed on silicone and polyester columns as previously described (21). The methyl esters from the above-mentioned extracellular triglycerides produced by *R. glutinis* CBS 4648 were oxidized with the permanganate–periodate reagent and the oxidation fragments analyzed (22). The results confirmed the assumption that the unsaturated fatty acids had the usual structures, and no evidence for the presence of isomeric acids was found. The esters of the other lipids were also assumed to have the usual structures. The results are summarized in Table II.

ACKNOWLEDGMENTS

The authors thank Mr. L. L. Hoffman and Mr. N. R. Gardner for technical assistance, Mr. M. Mazurek for the microanalyses, and Mr. W. C. Haid for the infrared spectra and the X-ray powder photographs.

PREPARATIONS OF DIALKYLAZOXYBENZENES AND THEIR DERIVATIVES[1]

BRIAN T. NEWBOLD AND DANIEL TONG
Department of Chemistry, University of Moncton, Moncton, New Brunswick
Received June 19, 1963

ABSTRACT

The three isomeric symmetrical dimethylazoxybenzenes have been prepared in very good yield by oxidation of the corresponding azobenzenes with peracetic acid. 2,2′- and 4,4′-Diethylazoxybenzenes have been synthesized by oxidation of the azobenzenes and reduction of the ethylnitrobenzenes. The diethylazoxybenzenes were also reduced to the corresponding azo- and hydrazo-benzene derivatives.

INTRODUCTION

Some work on the oxidation of mono- and di-methylazobenzenes has been reported in the chemical literature. For instance, 2- and 4-methylazobenzene have been oxidized by means of peracetic acid (1, 2) and the rates of oxidation of some dimethylazobenzenes with perbenzoic acid have been determined (3). One object of this work was to prepare dimethylazoxybenzenes from the azobenzenes by oxidation with hydrogen peroxide in glacial acetic acid.

Schultz reported in an earlier paper (4) that 2- and 4-nitroethylbenzenes are reduced to the corresponding diethylazobenzenes by zinc dust and sodium hydroxide, and recently Wheeler (5) has studied the polarographic reduction of these nitroethylbenzenes. In the present work, new diethylazoxybenzenes were prepared both from the nitroethylbenzenes by reduction with reducing sugars in alkaline medium, and from the diethylazobenzenes by oxidation with peracetic acid.

DISCUSSION

2,2′-, 3,3′-, and 4,4′-Dimethylazoxybenzenes were prepared in very good yield from the corresponding azobenzenes by oxidation with peracetic acid. Some results are shown in Table I. The 2,2′-dimethylazobenzene proved difficult to oxidize, a great excess of hydro-

gen peroxide being necessary to obtain the azoxybenzene in over 90% yield. The azo linkage in this case is sterically hindered by the methyl groups and this impedes oxidation. A similar effect was encountered previously with the oxidation of 2,2′-dichloroazobenzene (6, 7). Prolonged oxidation of the dimethylazobenzenes led in each case to decomposition and lower yields of the dimethylazoxybenzenes.

2,2′- and 4,4′-Diethylazoxybenzenes were also prepared from the corresponding azobenzenes by oxidation with hydrogen peroxide in glacial acetic acids and fair yields were achieved. The details are found in Table I. To prepare 2,2′-diethylazoxybenzene in over 60% yield, either an extended period of reaction or elevated temperature was necessary, and this can be attributed to steric hindrance by the bulky ethyl groups.

The diethylazoxybenzenes were synthesized also by reduction of the nitroethylbenzenes with reducing sugars. The sterically hindered 2-nitroethylbenzene was very difficult to reduce as expected. With dextrose, over 80% of the starting material was recovered, whereas when lactose was used more reduction occurred. In both cases, 2,2′-diethylazoxybenzene and 2-ethylaniline were obtained in very low yield. Attempts were also made to reduce 2-nitroethylbenzene with sodium arsenite in alkaline medium but these were not successful. Reductions of 4-nitroethylbenzene with dextrose or lactose gave low yields of 4,4′-diethylazoxybenzene. Some results are given in Table II.

TABLE II

†Methanol (25 ml).

The diethylazoxybenzenes described in this work were synthesized for the first time. The structure of 2,2′-diethylazoxybenzene was established by reduction to 2,2′-diethylhydrazobenzene and oxidation of the latter to the known 2,2′-diethylazobenzene. Confirmation of the structure was also achieved by reduction to 2-ethylaniline with stannous chloride. The structure of 4,4′-diethylazoxybenzene was determined by conversion to the known 4,4′-diethylazobenzene via the new hydrazobenzene.

The compounds 2,2′-diethylazo- and azoxy-benzene are of interest since the bulky ethyl groups should present steric hindrance to coplanarity and this effect can be detected by ultraviolet absorption spectroscopy. Badger and Buttery (8) showed by a model that 2,2′-dimethylazoxybenzene must be non-coplanar and observed a hypsochromic shift of about 20 mμ in the *K*-band (conjugation) of the ultraviolet spectrum on conversion of 2,2′-dimethylazobenzene to the azoxybenzene. Here conjugation is inhibited and the *K*-band should occur at shorter wavelength. Gore and Wheeler (9) have reported that the hypsochromic shift in the above case is 18 mμ. The ultraviolet spectra of 2,2′-diethylazo- and azoxy-benzene are compared in Fig. 1. The introduction of the oxygen atom into

For personal use only.

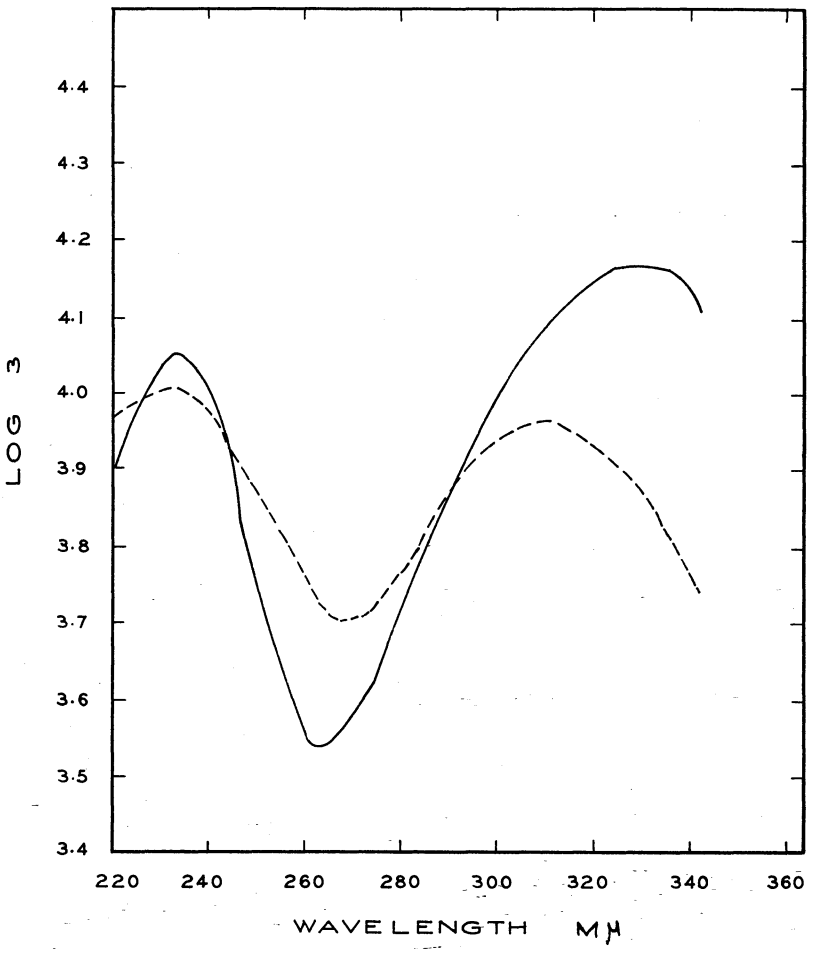

FIG. 1. Absorption spectra of 2,2′-diethylazobenzene (—) and 2,2′-diethylazoxybenzene (– – –).

2,2′-diethylazobenzene caused a hypsochromic shift of 21 mμ in the *K*-band due to inhibited conjugation. Spectral data for the diethylazoxybenzenes and their derivatives are given in Table III.

The ultraviolet spectrum of azobenzene has been shown to possess a *K*-band at 320 mμ (ε17,300) (10). In Table IV, the shifts and changes in intensity of the *K*-bands for dimethyl- and diethyl-azobenzenes are compared. The *K*-bands of the 2,2′-dialkylazobenzenes undergo bathochromic shifts accompanied by decreases in intensity. The results indicate that the more bulky ethyl group leads to increased steric hindrance to coplanarity. If it is assumed that the molecular extinction coefficient of the *K*-band of the 2,2′-disubstituted azobenzenes will be as high as that of the 4,4′-disubstituted derivatives in the absence of steric effects, then the degree of non-coplanarity or total deformation angle can be calculated using the method of Braude and Sondheimer (11). The deformation angle for 2,2′-diethylazobenzene is 33° compared to 23° for 2,2′-dimethylazobenzene as reported by Gore and Wheeler (10). The deformation angle should increase with the effective size of the substituent and such is the case here.

TABLE IV*

Shifts and intensity changes of the *K*-bands of dialkylazo- and azoxy-benzenes

Substituents	Azobenzenes		Azoxybenzenes	
	Shift, mμ	Intensity change	Shift, mμ	Intensity change
2,2′-Dimethyl-	+10	−900	−11	−3400
2,2′-Diethyl-	+10	−2500	−14	−5200
4,4′-Dimethyl-	+10	+2000	+ 7	+3600
4,4′-Diethyl-	+11	+3700	+11	+6200

*The results for the dimethylazo- and azoxy-benzenes are those of Gore and Wheeler (9, 10).

The *K*-band in the ultraviolet spectrum of azoxybenzene has been shown to occur at 323 mμ (ε 14,500) (9). The data in Table IV shows that the *K*-bands of 2,2′-dimethyl- and diethyl-azoxybenzene exhibit hypsochromic shifts together with decreases in intensity. There is, however, more pronounced steric hindrance to coplanarity in the 2,2′-diethyl-azoxybenzene. The deformation angle for the latter compound is 48° compared to 38° for the 2,2′-dimethylazoxybenzene (9). There is greater hindrance in the 2,2′-dialkylazoxy-benzenes than the azobenzenes due to the presence of the oxygen atom of the azoxy group. Moreover, our results show that for both the azoxy- and the azo-benzenes the replacement of the methyl groups by ethyl groups causes an increased distortion of 10° in the molecule. The total deformation angle is also increased by 15° for both 2,2′-di-methyl- and 2,2′-diethyl-azobenzene on passing to the corresponding azoxybenzene, due to the insertion of the coordinated oxygen atom.

Data concerning the *K*-bands of the ultraviolet spectra of the 4,4′-dialkylazo- and azoxy-benzenes is also given in Table IV. The *K*-band of both 4,4′-dimethyl- and diethyl-azobenzene showed a bathochromic shift and increased intensity. If the ethyl groups contribute equally to the polarization of the molecule, the results indicate that each ethyl group causes a bathochromic shift of 5.5 mμ, and an increase in intensity of 1850

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

compared to 5 mμ, and 1000 per methyl group. Similar results were obtained with 4,4′-dimethyl- and diethyl-azoxybenzenes, the increases in intensity of the *K*-bands being greater. These results show that for the 4,4′-dialkylazo- and azoxy-benzenes, the electron-releasing inductive effect of the alkyl groups is the important factor rather than the hyperconjugative effect.

The ultraviolet spectra of the diethylhydrazobenzenes possess two bands, a high intensity *E*-band at 245–250 mμ, and a low intensity band at about 285–300 mμ (Table III). Oxidation of the diethylhydrazobenzenes to the azobenzenes causes the latter band to disappear and a high intensity *K*-band to occur in the ultraviolet spectrum. The formation of the azo group is also shown by the appearance of a low intensity *R*-band in visible spectrum.

The diethylhydrazobenzenes showed quite different sensitivities to air oxidation. After it had been standing in air for several weeks the 2,2′-diethylhydrazobenzene turned pink but was only slightly oxidized. Furthermore, it was not completely oxidized to the azobenzene when boiled in alcoholic solution for 10 minutes. In contrast, 4,4′-diethylhydrazobenzene was extremely sensitive to oxidation, turning deep yellow when in contact with air for a few minutes and oxidizing to the azobenzene completely after 2 weeks.

The resistance of 2,2′-diethylhydrazobenzene to air oxidation can be accounted for by steric hindrance, whereas in 4,4′-diethylhydrazobenzene this effect is not operative. Recent results (12) have shown that the sterically hindered 2,2′-diethoxyhydrazobenzene can only be converted to the azobenzene by refluxing with peracetic acid.

EXPERIMENTAL*

Materials

The nitroethylbenzenes used in this work for reductions were commercially available samples.

Reductions of Nitroethylbenzenes

Since essentially the same procedures were used in all reductions carried out using the sugars and sodium arsenite, only one procedure for each method is described.

Reduction of 4-Nitroethylbenzene with Dextrose

4-Nitroethylbenzene 5.0 g (0.033 mole) was dissolved in methanol (25 ml), and sodium hydroxide 5.8 g (0.14 mole) in water (57 ml) was added. Dextrose 4.56 g (0.025 mole) was then added in portions and the mixture stirred vigorously and heated at 75° for 1 hour. The reaction mixture was steam distilled to give a distillate containing a yellow liquid. The distillate was acidified with hydrochloric acid and the yellow liquid separated off, dried, and purified by distillation to give recovered 4-nitroethylbenzene, b.p. 240° at 758 mm (lit. b.p. 245–246° at 760 mm) (13), yield, 18.2%. The acid layer was made alkaline with sodium hydroxide and allowed to stand overnight in the refrigerator, but no 4-ethylaniline separated out. The mixture in the flask after steam distillation contained an oily liquid which was extracted with ether to give a yellow extract. The latter was dried and removal of solvent left a reddish liquid, which was distilled under reduced pressure to give a deep yellow oil, b.p. 244° at 16 mm. When it had been cooled in the refrigerator, the oil solidified to give orange-yellow crystals, m.p. 16–17°. Anal. Calc. for $C_{16}H_{18}N_2O$: C, 75.56%; H, 7.13%; N, 11.01%. Found: C, 76.30%; H, 7.14%; N, 11.28%. The product was 4,4′-diethylazoxybenzene, yield, 5.6%. Infrared spectrum bands at: 3.08, 3.42, 3.50, 3.51, 3.61, 5.98, 6.28, 6.74, 6.90, 7.10, 7.60, 7.69, 7.88, 8.61, 8.98, 9.45, 9.51, 9.85, 10.32, 10.92, 11.82, and 14.78 μ.

In the reduction of 2-nitroethylbenzene, besides the azoxybenzene, some 2-ethylaniline was formed and identified by conversion to the acetyl derivative.

Reduction of 2-Nitroethylbenzene with Sodium Arsenite

2-Nitroethylbenzene 25.9 g (0.17 mole) was dissolved in methanol (65 ml), and sodium hydroxide 30.0 g (0.75 mole) in water (125 ml) was added. Then arsenic trioxide 29.7 g (0.15 mole) as a paste mixed with water (25 ml) was added in portions to the mixture, which had been heated to 60°. The reaction mixture was vigorously stirred throughout and the reaction carried out at 82° for 3 hours. Steam distillation gave recovered 2-nitroethylbenzene, in the acidified distillate, b.p. 223–225° at 756 mm (lit. b.p. 227–228° at 760 mm) (13), yield, 95.6%. No other products were isolated.

**All melting points are uncorrected.*

Preparations of Dialkylazobenzenes

The dimethylazobenzenes were prepared from the appropriate nitrotoluenes by reductions with zinc dust and sodium hydroxide. Reductions of 2- and 4-nitroethylbenzene by the method described by Schultz (4) gave 2,2′-diethylazobenzene, red needles, m.p. 45–46°. Anal. Calc. for $C_{16}H_{18}N_2$: N, 11.75%. Found: N, 11.66%. (Lit. m.p. 46.5° (4), and 4,4′-diethylazobenzene, orange needles, m.p. 59–60°.) Found: N, 11.47%. (Lit. m.p. 63° (4).)

Peracetic Acid Oxidations of Dialkylazobenzenes

Only one oxidation will be described since essentially the same procedure was employed in all cases.

Oxidation of 2,2′-Diethylazobenzene

2,2′-Diethylazobenzene (1.858 g) was dissolved in glacial acetic acid (50 ml) and 30% hydrogen peroxide (10 ml) added. The red solution was then refluxed for 30 minutes (at which time the color had turned to yellow) and poured into an excess of cold water. The mixture was cooled and extracted with ether to give a yellow extract, which was dried and the solvent removed. The residue, a deep yellow oil, was purified by distillation under reduced pressure, b.p. 168–169° at 2.7 mm. When cooled in the refrigerator, the oil solidified to give orange-yellow crystals, m.p. 12–13°. The product was 2,2′-diethylazoxybenzene, yield, 64.0%. Anal. Calc. for $C_{16}H_{18}N_2O$: C, 75.56%; H, 7.13%; N, 11.01%. Found: C, 75.62%; H, 7.16%; N, 10.91%. Infrared spectrum bands at: 3.35, 3.50, 3.51, 3.58, 6.34, 6.79, 6.90, 7.30, 7.60, 8.08, 8.43, 8.63, 8.75, 8.92, 9.20, 9.46, 9.69, 10.50, 10.80, 10.90, 11.80, 12.58, 12.91, and 14.91 μ.

In the peracetic acid oxidations of the dimethylazobenzenes, the azoxybenzene separated out as a yellow solid when the reaction solution was cooled after dilution and the product was recrystallized from aqueous ethanol.

Reductions of Diethylazoxybenzenes

2,2′-Diethylazoxybenzene

2,2′-Diethylazoxybenzene (1.313 g) was dissolved in a minimum of ethanol and 40% sodium hydroxide solution (4 ml) added, together with an excess of zinc dust. The mixture was refluxed for 1 hour (at which time all color had disappeared), decanted, and poured into an excess of cold water. A yellow product separated out when the mixture was allowed to stand. This product was washed with water and, to decolorize it, was dissolved in ethanol containing a little glacial acetic acid and warmed in the presence of a little zinc dust. The solution was then poured into cold water to precipitate the colorless product, m.p. 106–108°. Repeated recrystallizations from aqueous ethanol gave 2,2′-diethylhydrazobenzene, colorless needles, m.p. 108–108.5°, yield, 62.8%. Anal. Calc. for $C_{16}H_{20}N_2$: C, 79.95%; H, 8.38%; N, 11.66%. Found: C, 80.08%; H, 8.27%; N, 11.55%. Infrared spectrum bands at: 2.80, 3.30, 3.35, 3.40, 3.48, 6.28, 6.64, 6.71, 6.81, 6.92, 7.33, 7.61, 7.75, 8.05, 8.64, 8.95, 9.52, 9.75, 10.43, 10.68, 11.90, 12.64, 12.97, 13.30, and 14.92 μ. This compound slowly oxidizes in air when it has been left standing and takes on a pinkish color. After preparation it must be dried in a vacuum desiccator and stored there.

2,2′-Diethylazoxybenzene (0.5 g) was treated with an excess of stannous chloride dihydrate and concentrated hydrochloric acid for several minutes and the reaction mixture shaken and warmed. The latter was then cooled, diluted with water, and made alkaline. Ether extraction and removal of the solvent gave a dark yellow oil, which was 2-ethylaniline, the infrared spectrum being identical with that of an authentic sample. Acetylation with acetic anhydride also gave 2-ethylacetanilide (from ethanol), m.p. 108–109.5°, alone or with an authentic sample.

4,4′-Diethylazoxybenzene

4,4′-Diethylazoxybenzene (0.352 g) was dissolved in ethanol and 40% sodium hydroxide (1.5 ml) added, together with an excess of zinc dust. The reaction was carried out under a nitrogen atmosphere and the mixture warmed and shaken until all color disappeared. The solution was decanted into an excess of water, the nitrogen atmosphere being maintained throughout. When the solution had been shaken, a colorless product separated out and was collected by very rapid filtration. The substance was 4,4′-diethylhydrazobenzene, which immediately turned pale yellow, m.p. 87–89°, yield, 40.8%. Anal. Calc. for $C_{16}H_{20}N_2$: C, 79.95%; H, 8.38%; N, 11.66%. Found: C, 79.66%; H, 7.64%; N, 11.41%. Infrared spectrum bands at: 2.98, 3.30, 3.35, 3.40, 3.48, 6.20, 6.58, 6.70, 6.88, 7.10, 7.70, 8.02, 8.10, 8.52, 8.70, 9.00, 9.46, 11.78, 12.00, 12.10, 13.87, and 14.45 μ. This reduction, when carried out in air gives a product which turns deep yellow and must be decolorized with glacial acetic acid and zinc dust. 4,4′-Diethylhydrazobenzene oxidizes very rapidly in air and must be stored under a vacuum or nitrogen.

Reductions of Diethylazobenzenes

To 2,2′-diethylazobenzene (0.3 g) in a minimum of ethanol, 40% sodium hydroxide (1 ml) and excess zinc dust were added, and the mixture refluxed for 2 hours. Extraction, using the procedure described for the reduction of 2,2′-diethylazoxybenzene, gave 2,2′-diethylhydrazobenzene, m.p. 107–108°, identity confirmed by infrared spectral analysis.

Reduction of 4,4′-diethylazobenzene with sodium hydroxide and zinc dust using the method employed for the reduction of 4,4′-diethylazoxybenzene gave 4,4′-diethylhydrazobenzene, whose infrared spectrum was identical with that of an authentic sample.

Oxidations of Diethylhydrazobenzenes

2,2′-Diethylhydrazobenzene

2,2′-Diethylhydrazobenzene (0.15 g) was dissolved in ethanol and the solution boiled in air to the point of crystallization. The product was dissolved in ethanol again and the treatment repeated several times to give a mixture of red and colorless crystals. The red product was 2,2′-diethylazobenzene, m.p. 44–46° alone or with an authentic sample. The colorless product was 2,2′-diethylhydrazobenzene, m.p. 107–108° alone or with an authentic sample.

4,4′-Diethylhydrazobenzene

When 4,4′-diethylhydrazobenzene (0.09 g) was dissolved in ethanol and the solution was boiled for several minutes, an orange color developed. Evaporation produced orange crystals, m.p. 57–58°. Repeated recrystallizations from ethanol gave 4,4′-diethylazobenzene, orange needles, m.p. 60–61° alone or with an authentic sample.

4,4′-Diethylhydrazobenzene (0.05 g) was allowed to stand in air for several days and was oxidized to 4,4′-diethylazobenzene, m.p. 58–60° alone or with an authentic sample.

Spectra

The infrared spectra were recorded on a Perkin–Elmer Infracord model 137B spectrophotometer. The spectra of the diethylazoxybenzenes were obtained from liquid samples and those of the diethylhydrazobenzenes by the potassium bromide pellet technique. The other infrared spectra were recorded by employing Nujol mulls. The visible and ultraviolet spectra were determined on a Beckman model DK-2 ratio-recording spectrophotometer, using absolute ethanol as solvent.

ACKNOWLEDGMENT

The authors wish to express their profound gratitude to the National Research Council of Canada for a grant during the course of this work.

CATALYTIC HYDRODESULPHURIZATION OF THIOPHENE

V. THE HYDROTHIOPHENES. SELECTIVE POISONING AND ACIDITY OF THE CATALYST SURFACE[1, 2]

P. DESIKAN[3] AND C. H. AMBERG

Received August 15, 1963

ABSTRACT

The hydrogenolysis of tetrahydrothiophene over sulphided cobalt molybdate – alumina was shown to proceed in two ways. The main reaction was hydrodecyclization to *n*-butanethiol and conversion of the latter to butenes and butane; the second and less prominent reaction involved dehydrogenation to thiophene, which was also desulphurized. The overall desulphurization activity decreased in the order *n*-butanethiol > tetrahydrothiophene > 2,3-dihydrothiophene > thiophene. A better understanding of the dual catalytic nature of the catalyst resulted from selective poisoning experiments with H_2S, thiophene, methylthiophene, pyridine, and NH_3. The sites responsible for olefin hydrogenation were shown to have strong affinity for thiophenes, H_2S, and pyridine, as well as limited capacity to dehydrogenate thiolane and desulphurize thiophenes. Sites weakly electrophilic in character were also shown to be present on the catalyst surface. These could be poisoned only by ammonia or alkali and have been identified with the bulk of the desulphurization in the hydrogenolysis of thiophenes, hydrothiophenes, and thiol.

INTRODUCTION

During earlier investigations on thiophene hydrogenolysis (1) saturated derivatives still containing sulphur, such as tetrahydrothiophene and *n*-butanethiol, could not be detected as gas-phase intermediates over a sulphided cobalt molybdate catalyst under the conditions used. It was noted also (2) that in the conversion of thiolane (tetrahydrothiophene) over the catalyst a small amount of thiophene was present among the products in addition to the C_4 hydrocarbons. Essentially the same products had been observed earlier by Girelli, Helm, Thompson, Meyer, and Ball (3), who dehydrogenated thiolane both thermally and over several catalysts. Apparently, the hydrogen produced in the dehydrogenation served to decyclize the thiolane to the hydrocarbons through intermediate formation of *n*-butanethiol.

Previous experiments in this laboratory (1, 4) had also focussed attention on the selective effect of hydrogen sulphide on the desulphurization and hydrogenation activities of sulphided cobalt molybdate. There was enough evidence to suggest two different catalytic functions to be operative, and this included the possibility that one type of site was responsible for both. Sulphided chromia (5, 6) perhaps exemplifies such a case.

On all considerations, it seemed attractive to look into the reaction of thiolane over the catalyst in some detail. Primarily the reaction could be expected to show characteristics relevant to the hydrogenolysis of thiophene itself, the latter having been found among the products. Also, it was felt that a molecule like thiolane with a non-aromatic, saturated ring might react differently on a strong acid site which could polarize one of its carbon atoms, and on a much weaker site to which the lone pair of electrons on the sulphur atom might have affinity.

The hydrogenolysis of thiolene (2,3-dihydrothiophene) and *n*-butanethiol (representing the two routes by which thiolane decomposes thermally (3)) was also studied and the results compared with those for thiophene and thiolane.

[1]*Issued as N.R.C. No. 7755.*
[2]*For Parts I to IV see refs. 1, 5, 6, and 4.*
[3]*N.R.C. Postdoctoral Fellow 1961–63.*

Finally, selective poisoning techniques were employed to accentuate one or more steps involved in the hydrogenolysis reaction.

EXPERIMENTAL

The apparatus was the same as in Part IV of the series (4). The catalysts employed were all cobalt molybdate on alumina, sulphided before use: G_1, G_2, and G_3 were samples of Girdler catalyst G35A previously described (1), which differed merely in that G_1 had been used in earlier experiments and in that G_2 consisted of somewhat larger granules than our normal 32–65 mesh size. G_2 was used only in a few experiments with ammonia. A catalyst designated as HM was made to contain 1.3% Co and 6.1% Mo to equal the commercial sample in composition. In its preparation a batch of highly acidic alumina, made from aluminum isopropoxide by the method of Pines and Haag (7), was impregnated successively with aqueous ammonium molybdate and aqueous cobalt acetate and ignited after each impregnation. The blue powder so obtained was reduced and sulphided as usual at 400°. One-gram catalyst beds were employed throughout.

The thiolane and *n*-butanethiol used (Eastman) were found to be chromatographically pure. A sample of 2,3-dihydrothiophene was prepared by a slight modification of Sosnovsky's procedure (8, 9) and purified by preparative gas chromatography. The hydrocarbons used for reference were all Phillips research grade. Hydrogen from a cylinder was passed through a palladium catalyst and drying column to remove oxygen and water. The pyridine used in poisoning experiments contained a maximum of 20 p.p.m. of ammonia. A portion of this was purified by drying and repeated distillation through a Vigreux column. Research grade ammonia (Matheson) was passed over a drying column and used either as such or in admixture with hydrogen.

Hydrocarbon analysis was carried out using a propylene carbonate column (25 ft copper tube; 30% w/w on 30–48 mesh Chromosorb). Squalane and tricresyl phosphate (6 ft glass U-tubes; 20 and 28.6% w/w respectively on 30–48 mesh Chromosorb) were employed for separating the C_4 hydrocarbons from the sulphur-containing starting materials and intermediates.

RESULTS AND DISCUSSION

The main hydrocarbon products of the desulphurization of thiolane, predictably, were butenes and butane. Thiophene and *n*-butanethiol were found under certain conditions and will be discussed in detail below. Butadiene, which could be expected to be formed from thiophene (1), was probably hydrogenated too fast to be detected.

The distribution of the butene isomers obtained from thiolane over catalyst G_1 at 308° C is presented in Table I and compared with similar distributions from thiophene, butanethiol, and thiolene, as well as with the thermodynamic equilibrium values.

TABLE I

Distribution of *n*-butene isomers over catalyst G_1 at 308° C, using 2-μl pulses of C_4 sulphur compounds
H_2 flow rate: 50 cc/minute

	Thiophene	Thiolene	Thiolane	Butanethiol	Equilibrium calc. from (10)
1-Butene, %	19.5	17.8	17.7	16.0	14.0
trans-2-Butene, %	42.1	44.0	44.0	44.0	53.5
cis-2-Butene, %	38.4	38.2	38.3	40.0	32.5

It is apparent that *trans*-2-butene cannot be the initial mono-olefin formed from any of the four sulphur compounds considered. Both 1-butene and *cis*-2-butene are in excess of thermodynamic equilibrium and it is not possible to decide from the distribution alone which of these two isomers could have formed first. It has been shown in the case of thiophene over chromia catalyst that 1-butene is the initial isomer formed (1) presumably through 1,2-hydrogenation of butadiene. Vernon and Richardson (11) working with MoS_2 catalysts promoted with different amounts of cobalt also reported the initial formation of 1-butene. If, as will be pointed out, *n*-butanethiol is the principal gas phase

For personal use only.

intermediate in thiolane conversion, 1-butene can be expected to be the initial isomer in that case as well.

The amounts of C_4 hydrocarbons formed from 2-μl pulses of thiolane over catalyst G_1 at different temperatures, and the extent of their saturation, are presented in Table II

TABLE II

along with corresponding data for thiophene, thiolene, and butanethiol. In the runs marked with an asterisk, the pulses were injected 7 minutes after a 5-μl thiophene pulse. In the other runs, the catalyst had been flushed for at least 1 hour in H_2 at reaction temperature before introducing the pulse. The predosing with thiophene was carried out to determine whether it could act as a poison. Preliminary experiments had shown that two equal consecutive pulses of thiolane spaced at an interval of about 7 minutes gave approximately the same amount of C_4 product with nearly the same butene to butane ratio. On the other hand, if the thiolane pulse was injected ~7 minutes after an equivalent hydrogen sulphide pulse, some suppression of butane formation (olefin hydrogenation) was evident. This could mean that H_2S formed as a result of reaction is not able to compete successfully with thiolane for adsorption on the hydrogenation sites; if preadsorbed, however, it can suppress the hydrogenation of olefins. Eventual displacement of H_2S by the organosulphur compound is thought to be too slow to have any effect on the conversion of the pulse. Therefore in the experiments with thiophene-predosing (Table II) if there was any poisoning effect, it could be attributed to the thiophene rather than to the H_2S formed from it. If, as will be shown presently, the hydrogenation sites are strong acid sites, thiophene should at any rate adsorb more strongly on them than H_2S.

The table shows the normal effect of temperature on overall activity. Also, the conversion decreases in the order thiol > thiolane > thiolene > thiophene. Furthermore, on a clean catalyst both thiolane and thiol yield a larger amount of butane than does thiophene. Predosing with thiophene indeed suppresses the saturation appreciably except when thiophene is also the reactant. Since the H_2S originating from the thiophene can be assumed to be relatively ineffective (as in the case of thiolane), and the hydrocarbons are only weakly adsorbed (1), these observations clearly show that thiophene is strongly adsorbed on the hydrogenation sites; they also explain why the butane formed from thiophene is always less than that from thiolane. Predosing affects the desulphurization activities only to a slight extent, presumably because thiophene reacts on the

For personal use only.

desulphurization sites. Suppression of hydrogenation activity, which was in remarkably close agreement with the thiophene results, was also observed when 3-methylthiophene was used as a poison (98% reduced to 48% with an 8 minute 20 second interval between poison and reactant pulses).

Earlier experiments in this laboratory (1) implied that the main selective poison for butene hydrogenation in continuous flow desulphurization of thiophene over cobalt molybdate would be the H_2S which is being maintained at high levels of concentration. This view must now be modified to include the organosulphur compounds themselves which are able to compete as hydrogenation poisons.

The gas phase intermediates in thiolane hydrogenolysis were studied in some detail. As already mentioned, thiophene and *n*-butanethiol were found among the products of thiolane conversion. Using the squalane column for analysis it was observed that small amounts of the thiol could be obtained at temperatures below 270° and small amounts of thiophene above 300°. The amount of thiophene formed varied with the history of the catalyst. The older catalyst G_1 gave much less thiophene than did G_3. Assuming that the thiophene formed by dehydrogenation of thiolane reacted further with hydrogen at the same rate at which it would normally react in the absence of thiolane, it was possible to calculate the contribution of the thiophene route in the overall reaction. With 10-μl shots of thiolane at ~400°, the dehydrogenation route accounted for approximately 20% of the reaction over freshly sulphided G_3, 10% over G_1, and 15% over HM. Pyridine, ammonia, and H_2S all poisoned the dehydrogenation reversibly; some irreversible suppression of dehydrogenation activity was noticeable in catalysts that had been extensively used in desulphurization or after repeated poisoning with pyridine or ammonia. The strong (reversible) poisoning by H_2S was evident from continuous flow experiments on G_1 and HM when no thiophene could be detected among the products as a result of the steady H_2S level on the catalyst surface.

Thiophene was also formed in the hydrogenolysis of pulses of dihydrothiophene and the latter is therefore a possible intermediate in thiolane dehydrogenation. In fact, Girelli *et al.* (3) were able to detect dihydrothiophene by mass spectrometric analysis of the products of decomposition of thiolane; no success, however, was achieved in our attempts to detect it in the thiolane hydrogenolysis product. Liquid thiolene readily polymerizes, even under refrigeration, and loss by polymerization on the catalyst surface may well cause the disappearance of unreacted material in the course of hydrogenolysis. Other mechanisms might be operative, such as a relatively faster second dehydrogenation step to thiophene. It is difficult to decide between the two possibilities, considering the very small concentrations involved.

It should be emphasized, however, that in the conversion of thiolane, the maximum contribution of the thiophene route was only 20%, and that the principal intermediate, therefore, is *n*-butanethiol. If the hydrodecyclization step leading from thiolane to thiol had been very much faster than the removal of H_2S from the latter (see the rates for compounds I and IV, Fig. 1) the rates of hydrogenolysis of thiolane and thiol should have been much closer to each other. One may reasonably conclude that the decyclization is also a slow step with a significant contribution to the overall rate.

Earlier experiments with alkali modified specimens of Girdler G35A catalysts had revealed that with sufficient amount of alkali both the hydrogenation and the desulphurization activities for the hydrogenolysis of thiophene could be almost completely poisoned, indicating that practically all the catalytic sites involved in the reaction were acidic. The distinction between desulphurization sites and hydrogenation sites could then be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

one of relative acidities. To define this more clearly, pyridine was used to poison the hydrogenolysis of thiophene as well as of thiolane.

Most of the experiments were carried out with catalyst G_1 and pyridine containing a maximum of 20 p.p.m. ammonia. Later experiments with purified pyridine led us to expect that this impurity had negligible effect at least in reversible poisoning. A quantitative assessment of the effect of pyridine on the various steps of the reactions studied was hampered by two factors: (1) the presence of strong and weak types of adsorption leading to a single chromatographic peak with a sharp front and a diffuse tail and (2) a gradual irreversible modification of the catalyst.

A 5-μl pyridine sample was introduced on freshly sulphided G_1 at 367°, followed at various intervals by several pulses of 2 μl thiophene. Independently, without using an analytical column but employing the same temperature and hydrogen flow rate, we obtained an adsorption–desorption peak for 5 μl pyridine. The shape of the peak did not unequivocally suggest two types of adsorption, and could very well have been taken to signify fast adsorption and slow desorption. The amounts of pyridine which resided on the surface at the various time intervals during the poisoning of the thiophene reaction were calculated and are shown in Table III along with the corresponding poisoning effects.

TABLE III

22.0	0.31	83	21.9
28.4	0.18	77	21.2
Fresh catalyst	0.00	92	44.0

If the peak had been governed by adsorption on one kind of site, there should have been considerably more poisoning of butane formation at the 1.0-cc pyridine level (close to the maximum) than at the lower levels (representing the tail). The sharp portion of the peak therefore represents a weak adsorption–desorption mechanism on one type of site conceivably associated with the bulk of the desulphurization (Table III, col. 3). On the other hand, the tail is due to strong adsorption of pyridine on, and slow desorption from, sites which mainly catalyze butene hydrogenation (Table III, col. 4) and to a small extent also thiophene desulphurization. This latter fact may well be the origin of the slow recovery of desulphurization (col. 3): recovery should have been faster if desulphurization were to take place exclusively on weakly adsorbing sites. The association of the weakly adsorbing sites with desulphurization was confirmed by thiolane hydrogenolysis experiments using pulses mixed with different amounts of pyridine over catalyst G_1. These runs were spaced at intervals of over 1 hour, although a few thiolane pulses without pyridine were injected in between. The results are shown in Table IV. They distinguish sharply between the strong and immediate suppression of desulphurization and the somewhat weaker one of hydrogenation. Moreover, the persistence of the latter effect shows desorption of pyridine from the hydrogenation sites to be much slower than from the

For personal use only.

desulphurization sites. This is consistent with the hydrogenation sites being the more strongly acidic ones. A slow drift in the saturation values (e.g. 59 to 47%) was consistently noted after the first introduction of poison, but could not be explained. The original value of 90% was restored after about 1 hour.

The irreversible modification of G_1, briefly referred to earlier, became measurable after about 30 μl pyridine had passed over the catalyst. The most significant effect was that the catalyst (G_1) no longer produced thiophene from thiolane within the temperature range studied; the overall desulphurization and olefin hydrogenation activities, however, remained virtually unchanged.

To examine thiolane dehydrogenation further, poisoning experiments were carried out on fresh catalysts G_2 and G_3 using ammonia and purified pyridine, respectively. Successive injections of ammonia mixed with hydrogen on to 1.0 g of catalyst G_2 reduced the thiophene yield at 418° from 4.8% to 1.4% when about 0.4 cc of ammonia had been adsorbed (5 to 8 μl thiolane pulses). Further increase of ammonia increased the yield to 2.3%, probably because some of the more weakly acidic thiophene desulphurization sites were also getting poisoned. The original 4.8% yield could not be restored. Purified pyridine reduced thiophene yields at 402° on G_3 by about one-quarter of the value on fresh catalyst, when the cumulative amount of pyridine injected had reached 45 μl. The contribution of the thiophene route in the thiolane conversion fell from 20% to 15%. The fact that this decrease was less marked than with G_1 (10% to 0% with 30 μl of unpurified pyridine) can be attributed to the longer use of G_1 in desulphurization runs and (or) the higher purity of the second sample of pyridine. It is tempting to speculate on the mechanism by which dehydrogenation becomes irreversibly poisoned. One possibility might be that thiolane is adsorbed on the desulphurization sites and the bulk of the hydrogenation sites through the S-atom. In addition a small number of strong acid sites are capable of polarizing one of the C-atoms of thiolane, i.e. they are able to chemisorb thiolane by a dissociative mechanism, giving adsorbed carbonium and hydride ions. These sites, which are responsible for the limited dehydrogenation reaction, can be progressively and irreversibly neutralized by ammonia or pyridine.

The hydrogenolysis of *n*-butanethiol, which did not undergo any side reaction (e.g. dehydrogenation) in the temperature range under consideration, showed good selectivity in the effect of pyridine on its constituent steps. The results on catalyst G_3 at 247° are presented in Table V and once again indicate that H_2S elimination and butene hydrogenation take place on different sites.

In conclusion, we propose the following functional model of the catalyst surface as meeting all the requirements of the results described. The sulphided cobalt molybdate desulphurizes thiophene and thiolane with the use of only two types of sites, one very strongly acidic and the other having low affinity for electrons. The strong acid sites are

TABLE V

Effect of pyridine on *n*-butanethiol conversion
Catalyst G_3 at 247°; pulse size: 2 μl; H_2 flow: 50 cc/minute

Description of pulse	% Thiol converted to: total C_4	butane

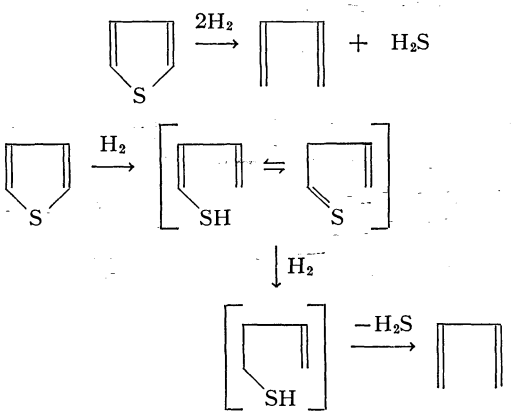
7 minutes after 5 μl pyridine pulse	58.3	18.2
40 minutes after 5 μl pyridine pulse	52.5	18.8

sufficiently electrophilic to interact with olefins and to hydrogenate them (see also ref. 4). Hydrogen sulphide, thiophene, and pyridine can be strongly adsorbed on them. Prior to irreversible modification by poisoning, these sites include a small number capable of dissociatively chemisorbing thiolane and dehydrogenating it. All the strong sites can also catalyze desulphurization to a limited extent when the compound to be desulphurized is sufficiently basic, i.e., when it has sufficiently high electron density at the surface-directed portion of the molecule.

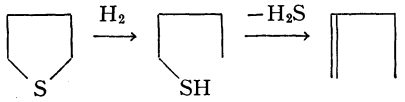
The weaker acid sites can be poisoned irreversibly only by a sufficiently strong base or alkali. These sites can be expected to desulphurize in two ways, either by adding H_2 across a C—S or C=S bond or by removing SH from a C—SH, forming an adsorbed carbonium ion. Thus starting from thiophene, one can obtain butadiene and H_2S either in one concerted action (*a*) or through several surface intermediates (*b*):



(*a*)

(*b*)

Decyclization of thiolane on the other hand leads to butanethiol, followed by H_2S removal:



The butadiene or butene if produced on the stronger acid sites will, without leaving the sites, get hydrogenated further. If formed on the weaker sites, they can desorb into the gas phase or migrate to the strong sites for saturation.

The major steps involved in the reaction scheme involving thiophene, the hydrothiophenes, butanethiol, and the C_4 hydrocarbons on the sulphided cobalt molybdate are

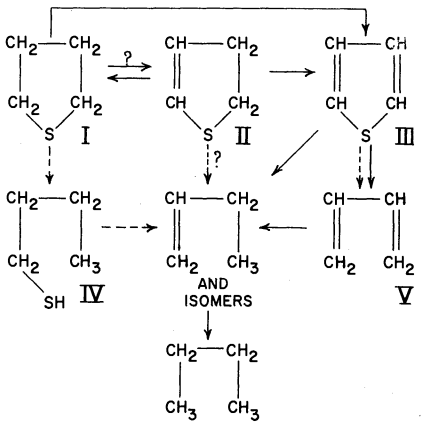

FIG. 1. Reaction scheme and the catalytic sites. ⟶ Strong acid site. ----→ Weaker site. ? = Route not definitely identified.
Approximate rates of conversion to butenes and butane for I to V at 280° C were found to be 24, 18, 16, 35, and 75 micromoles per gram catalyst per second, respectively.

featured in Fig. 1. Approximate rates of conversion to butenes and butane at 280° on a fresh catalyst are also given for the various starting materials and intermediates.

It is easily seen that the surface species involved in H_2S removal from a saturated C_4 mercaptan and the hydrodesulphurization of an olefinic mercaptan (which may be involved in thiophene hydrogenolysis) would be similar. It was therefore of interest to see whether the activation energy for continuous flow hydrogenolysis of thiolane was of the same order as for thiophene. Using low thiolane feed and high H_2 flow and a squalane column for analysis, continuous flow hydrogenolysis of thiolane was carried out over catalyst G_3 (before contacting with pyridine) in the temperature range 200 to 300°; the E value obtained was 23.6 ± 1.5 kcal, close to the value 24.4 ± 1.6 obtained earlier (4) for thiophene.

SECONDARY KINETIC ISOTOPE EFFECTS IN BIMOLECULAR NUCLEOPHILIC SUBSTITUTIONS

I. DEUTERIUM EFFECTS IN THE BUNTE SALT REACTION[1]

K. T. LEFFEK
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia
Received October 30, 1963

ABSTRACT

The secondary deuterium isotope effects have been measured for the reaction between sodium thiosulphate and α-deuterated methyl, ethyl, and *n*-propyl bromide, and also for β- and γ-deuterated *n*-propyl bromide, in aqueous ethanol solvent. The α-deuterium isotopic rate ratios (k_H/k_D) are all greater than unity. These unexpected results are discussed with respect to the suggested use of the α-deuterium isotope effect as a test of mechanism in nucleophilic substitutions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

There are many examples in the literature of changes in the rates of nucleophilic substitutions when some of the hydrogen atoms of the reactant, which are not directly involved in the reaction, are replaced by deuterium (1–5). However, nearly all of these examples pertain to S_N1-type solvolytic reactions. Of the bimolecular reactions studied, many are solvolyses in water which show regular changes of isotope effect with changes of alkyl group and the site deuterated (6–9); very few isotope effects have been measured in non-solvolytic S_N2 reactions (10, 11). It is not known whether the regularities found in the solvolytic reactions are general for all bimolecular substitutions; hence, the present investigation is part of a program of systematic study of secondary deuterium isotope effects in non-solvolytic bimolecular substitutions.

Since the known isotope effects in this type of substitution are small (11), it is necessary to choose reactions for study which allow the precise determination of their rate constants. The attack of thiosulphate ion on alkyl bromides, in 50% v/v ethanol–water solvent, to yield S-alkyl thiosulphates, known as Bunte salts (12), is one such group of reactions, and may be represented by the equation

[1] $$S_2O_3^{2-} + RBr \rightarrow RS_2O_3^- + Br^-.$$

The unreacted sodium thiosulphate can be estimated quite accurately by titration with standard iodine solution.

Hammett and co-workers (13, 14) made a careful investigation of this reaction in their study of the changes which occur in the enthalpy and entropy of activation with structure of the alkyl group. They used an acetate buffer to avoid decomposition of thiosulphate ion in an acidic medium which could result from solvolysis of the alkyl bromide to give hydrobromic acid and an alcohol (or ether). The rate of acetate ion attack on the alkyl bromide was found to be negligibly slow under the conditions of reaction. For the straight-chain alkyl bromides, the rate of solvolysis was too slow to necessitate correction of the observed rate constants of the thiosulphate reaction.

Subsequently, Bevan and Monk showed that Hammett's rate constants for the reaction of sodium thiosulphate with *n*-propyl bromide in 50% v/v ethanol–water solvent, calculated using stoichiometric molarities of thiosulphate, are not the true rate constants

[1]*Presented at the XIXth International Congress of Pure and Applied Chemistry, London, England, July 10–17, 1963.*

because sodium thiosulphate is incompletely dissociated in this solvent (15). Corrected rate constants measured by Bevan and Monk (16) gave the same activation energy but a higher Arrhenius frequency factor for the above reaction compared to those obtained by Hammett *et al.* However, since Hammett's discussion was based on comparisons between the activation parameters for different alkyl groups, his conclusions are not invalidated by the use of apparent rate constants. In the determination of secondary isotope effects the use of apparent rate constants is equally valid, as the correction factor used by Bevan and Monk is the same for normal and deuterated alkyl bromides and therefore would cancel in the ratio of the rates.

RESULTS AND DISCUSSION

Results of kinetic experiments on the reactions between sodium thiosulphate and methyl, ethyl, and *n*-propyl bromide and their α-deuterated analogues are given in Table I.

TABLE I

Secondary α-deuterium isotope effects for the reactions between alkyl bromides and sodium thiosulphate in 50% v/v ethanol–water at 25.00±0.05° C

Compound	No. runs	$10^4\, k_2 \pm$ Std. dev. (l./mole sec)	$k_H/k_D \pm$Std. dev.
Methyl bromide	5	872±7	
Methyl-d_3 bromide	3	846±6	$1.03_1 \pm 0.01$
Ethyl bromide	9	12.23±0.04	
Ethyl-1,1,d_2 bromide	3	11.45±0.10	$1.06_8 \pm 0.01$
n-Propyl bromide	11	6.03±0.04	
n-Propyl-1,1,d_2 bromide	4	5.61±0.05	$1.07_5 \pm 0.01$

These rate ratios are interesting as they constitute a critical test of the α-deuterium isotope effect as an indicator of mechanism of nucleophilic substitution.

At the time of their discovery α-deuterium isotope effects were recognized as a possible means of distinguishing between the S_N1 and S_N2 mechanisms (17, 18). The first evidence for this was given by Johnson and Lewis (11), who showed that whereas normal isotope effects ($k_H/k_D > 1$) are obtained with S_N1 reactions, inverse effects ($k_H/k_D < 1$) result for S_N2 reactions. Their examples of inverse effects were reactions of methyl-d_3 *p*-bromobenzenesulphonate, the methanol solvolysis ($k_H/k_D = 0.94$) and the non-solvolytic methoxide ion attack ($k_H/k_D = 0.96$).

An elegant demonstration of the correlation between α-deuterium isotope effect and mechanism for solvolytic reactions was given by Hartman and Robertson (19). A plot of secondary deuterium isotope effect, k_H/k_D, for methyl and deuterated methyl compounds solvolyzing in water, against the ratio $k_{2(OH^-)}/k_{1(H_2O)}$, the rate of attack by hydroxide ion to the rate of solvolysis by water, gave a good straight-line relationship. The latter ratio has been used as a diagnostic test of mechanism for many years (20) and it is generally accepted, although some criticism can be levelled against it (21). Thus it was assumed that k_H/k_D for α-deuteration indicated mechanism equally well.

The rate ratios for α-deuterated alkyl bromides for the Bunte salt reaction, listed in Table I, are all greater than unity, the opposite effect to that expected according to the mechanistic test outlined above and also the opposite effect to that obtained for the water solvolyses of these bromides, for which the rate ratios are less than one (6, 7). There is little doubt from the work of Hammett *et al.* (13, 14) that the Bunte salt reaction is a bimolecular nucleophilic substitution. Thus, one of two conclusions must be drawn—

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

either that the α-deuterium isotope effect is not a generally reliable indicator of mechanism, or that there is some special peculiarity in the Bunte salt reaction which makes it alone an exception to the rule. There are insufficient data in the literature at the present time to decide between these two possibilities on the basis of experimental evidence, but the lack of any gross peculiarity in the isotope effects observed for β- and γ-deuterated *n*-propyl bromide for the Bunte salt reaction, collated in Table II, and certain theoretical considerations, favor the first of the alternatives.

TABLE II

Secondary β- and γ-deuterium isotope effects for the reaction between *n*-propyl bromide and sodium thiosulphate in 50% v/v ethanol–water at 25.00±0.05° C

Compound	No. runs	$10^4\, k_2 \pm$ Std. dev. (l./mole sec)	$k_H/k_D \pm$Std. dev.
n-Propyl bromide	11	6.03±0.04	
n-Propyl-2,2,d_2 bromide	4	5.91±0.04	$1.02_1 \pm 0.009$
n-Propyl-3,3,3,d_3 bromide	3	6.09±0.01	$0.99_0 \pm 0.006$

Both the β- and γ-deuterium isotope effects for thiosulphate ion attack of *n*-propyl bromide, although very small, are of the same sign as those found for the same compounds solvolyzing in water. Thus the anomaly of the α-effect is not carried through to the rest of the molecule, although there is some change in the γ-effect towards unity.

Calculations made by Wolfberg, Seltzer, and Freund (22) lead them to the conclusion that secondary isotope effects are brought about by force field changes and only in a subsidiary manner by geometrical changes, between the initial and transition states. Thus, the geometry of the transition state will correlate with the secondary isotope effect only insofar as the force field change correlates with the geometrical change during the activation process. A comparison of force constants for sp^2 and sp^3 hybridized carbon–hydrogen bonds tabulated by Robertson and co-workers (7) showed that the direction of the change in force constant, when the molecular geometry is changed, is unpredictable. It may therefore be overly optimistic to expect the α-deuterium isotope effect to change in a systematic manner with the geometry of the transition state, i.e., with the mechanism, for all nucleophilic substitutions, despite the fact that it has been shown to do so in certain cases.

Even if the non-universality of the α-deuterium isotope effect test of mechanism is accepted, the problem remains to explain why the attack of thiosulphate ion on α-deuterated alkyl bromides gives significantly different rate ratios from those obtained for the same compounds solvolytically attacked by water. Pertinent to this problem is the question of the immediate source of these isotope effects. The rate changes may be brought about by a difference in the enthalpies of activation, a difference in the entropies of activation, or by a difference in both, between the normal and deuterated compounds. To separate the free energy of activation difference between two isotopic analogues into its enthalpy and entropy contributions, the rate ratio must be determined at several different temperatures. Meaningful results can be obtained only when the rate difference is quite large and the errors in the rate measurements are small. Unfortunately, the isotope effects observed for both the Bunte salt and the water solvolysis reactions are too small to allow this analysis to be made experimentally. Previous work (23), however, on the temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

dependence of the β-deuterium isotope effects in the water solvolysis of isopropyl compounds, in which the effects were shown to be entirely in the entropy of activation, demonstrates that it can no longer be assumed that all secondary deuterium isotope effects are enthalpy of activation effects. Recently a 12% inverse effect observed in the reactions of 2-methyl pyridine with methyl and deuterated methyl iodide, in benzene solvent, has also been found to be entirely an entropy of activation effect (24).

The immediate conclusion which may be drawn from the Bunte salt reaction isotope effects is that the α-deuterium effect test of mechanism is probably not completely reliable and should therefore be used with great care.

EXPERIMENTAL

Materials

The deuterated alkyl bromides, supplied by Merck and Co. Ltd., each had a minimum isotopic purity of 98%. The normal alkyl bromides were reagent grade chemicals and were dried and distilled immediately before the commencement of the kinetic measurements.

Anhydrous sodium thiosulphate was prepared from the hydrous salt using the method described by Vogel (25) and dried to constant weight at 115° C. This was used in the kinetic runs and also as a primary standard for the iodine solutions used in the titrations. Sodium acetate was dried over potassium hydroxide before use.

The solvent was prepared by mixing equal volumes of water and dry ethanol at 25.0° C. Absolute ethanol was dried according to the method of Lund and Bjerrum (26) and distilled. The exact composition of the solvent was established by density measurements: $d_4^{25} = 0.9229$, which corresponds to 44.05% ethanol, by weight.

Kinetic Method

Stock solutions of sodium acetate and sodium thiosulphate were prepared. The calculated volumes of these solutions and of solvent, all at the temperature of the thermostat, were mixed in a volumetric flask. A solution of appropriate concentration of alkyl bromide in the solvent was prepared, brought to thermostat temperature, and added to the reaction mixture. After rapid mixing a 5-ml sample was withdrawn and run into 50 ml of ice-cold water. The time of quenching was taken as the kinetic zero. Subsequent samples were withdrawn at appropriate intervals and each sample was analyzed by titration of the unreacted thiosulphate against a standardized iodine solution, using 1 ml of 1% starch solution as an indicator. Immediately after each 5-ml sample was withdrawn from the reaction flask a sufficient quantity of small glass ampoules was added to restore the air space above the solution to its original volume. By this procedure, steady rate constants were obtained from the integrated rate equation for a second order irreversible reaction.

Initial concentrations of approximately 0.05 *M* sodium thiosulphate and 0.025 *M* alkyl bromide were used for all the runs except those involving methyl bromide, for which the concentrations were reduced to 0.02 *M* and 0.01 *M* respectively. The sodium acetate buffer used for the ethyl and *n*-propyl bromide reactions was 0.020 *M*. Two illustrative runs are shown in Table III.

Each isotope effect was measured by carrying out runs with the protium and deuterium compounds simultaneously, which gave a constant check on the kinetic operations and ensured that any errors due to fluctuations in temperature would affect both compounds equally. The temperature of the thermostat was measured with a mercury-in-glass thermometer which had been compared with a standard thermometer certified by H. J. Elliott Ltd. (E-mil). The observed fluctuations in the bath temperature were less than 0.01° C, but the limit of accuracy of E-mil standardization was ±0.05° C. At least three pairs of runs were carried out with each deuterated compound.

As the second order rate constant for this reaction under the described conditions varies with the initial concentration of thiosulphate, presumably due to a medium effect (13), care was taken to ensure that the initial thiosulphate concentration did not vary from run to run sufficiently to introduce rate differences from this source. The magnitude of the medium effect was determined separately before the isotopic measurements, to be certain that this was feasible.

Since the rate constants did not show any variation from this source or from temperature fluctuations, the final rate ratios were calculated from the mean rate constant of all the runs carried out with each compound. The standard deviation in the rate ratio was computed from that calculated for k_H and k_D separately, according to the treatment by Crumpler and Yoe (27).

PYRIDINE N-OXIDE COMPLEXES OF ZIRCONYL, THORIUM, AND URANYL PERCHLORATES

P. RAMA MURTHY AND C. C. PATEL

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore, India

Received October 2, 1963

ABSTRACT

Pyridine N-oxide complexes having the composition $ZrO(Py.O)_6(ClO_4)_2$, $Th(Py.O)_8(ClO_4)_4$, and $UO_2(Py.O)_5(ClO_4)_2$ have been prepared. The infrared and electronic absorption spectra show that the bonding between the metal and pyridine N-oxide in the complexes has occurred by donation of the lone pair of *p*-electrons on oxygen to the metal, and that the π-bond character of NO group increases in the complexes as uranyl < thorium < zirconyl. The decrease in the vibrational structure of the UO_2^{2+} spectrum in the visible region indicates strong coordination of pyridine N-oxide to the uranyl group. The decomposition temperatures of zirconyl, thorium, and uranyl complexes are 307, 350, and 319° C respectively.

Recently Quagliano (1) *et al.* have prepared a number of metal complexes of pyridine N-oxide and determined their conductivity and magnetic susceptibilities. The same workers (2, 3) have also investigated the infrared spectra of these complexes. Carlin (4) has also prepared a number of pyridine N-oxide complexes of metal perchlorates and investigated their visible spectra.

The survey of the literature shows that the pyridine N-oxide complexes of IV A group metal perchlorates and of uranyl perchlorate have not been prepared before. The pyridine N-oxide complexes of zirconyl, thorium, and uranyl perchlorates were, therefore, prepared for the first time and some of their properties studied.

EXPERIMENTAL

Materials Employed

Pyridine N-oxide was prepared according to the method of Ochiai (5), purified by repeated vacuum distillations, and finally recrystallized from chloroform.

Zirconyl perchlorate dihydrate and thorium perchlorate tetrahydrate were prepared as reported earlier (6, 7).

Uranyl perchlorate hexahydrate was prepared by digesting uranyl nitrate hexahydrate with the calculated amount of perchloric acid and evaporating the mixture to dryness. Uranyl perchlorate formed was crystallized until free from nitrate ions.

Preparation of the Complexes

To 1 g of zirconyl perchlorate dihydrate in 20 ml of anhydrous ethanol, 2.5 g of pyridine N-oxide in 20 ml of ethanol was added. The solution was allowed to stand for 15 hours in the refrigerator and the crystals obtained were filtered, washed with ethanol, dried over phosphorus pentoxide under vacuum, and analyzed. Zirconium was estimated gravimetrically by precipitating the hydroxide with ammonium hydroxide and weighed as ignited oxide. Perchlorate was estimated by Kurz's method (8) by reducing the perchlorate with sodium nitrite at about 500° C and estimating the chloride formed by Volhard's method. Nitrogen was estimated by Duma's semimicro method. (Zr = 10.32, ClO_4 = 22.38, and N_2 = 9.48%. Calc. for $ZrO(Py.O)_6(ClO_4)_2$: Zr = 10.40, ClO_4 = 22.69, and N_2 = 9.58%.)

Crystals of the thorium complex were obtained immediately by mixing the reactants as above. The crystals were purified, dried as before, and analyzed in the same way as in the above case. (Th = 16.79, ClO_4 = 27.86, and N_2 = 7.99%. Calc. for $Th(Py.O)_8(ClO_4)_4$: Th = 16.68, ClO_4 = 28.45, and N_2 = 8.06%.)

In the case of uranyl complex, it was necessary to evaporate the solution almost to dryness to get the crystals of the complex. The crystals were purified, dried, and analyzed as before. (U = 24.85, ClO_4 = 20.85, and N_2 = 7.40%. Calc. for $UO_2(Py.O)_5(ClO_4)_2$: U = 25.10, ClO_4 = 21.06, and N_2 = 7.42%.)

Properties

Zirconyl and thorium pyridine N-oxide complexes were white while uranyl complex was bright yellow in color. All the complexes were non-hygroscopic, insoluble in non-polar solvents, and soluble in water,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

acetonitrile, and dimethyl formamide. When the complexes were heated, they exploded. To minimize the impact of explosion, the differential thermal analysis of the complexes were carried out by mixing the complexes with alumina in the ratio of 1:10. The DTA for zirconyl, thorium, and uranyl complexes gave a big exothermic peak at 307°, 350°, and 319° C respectively.

Infrared and Electronic Absorption Studies

The infrared spectra of the complexes were taken in Nujol mull with Perkin–Elmer infrared spectrophotometer model 21, equipped with sodium chloride optics. The infrared absorption frequencies of these complexes together with those of pyridine N-oxide (2) are given in Table I.

TABLE I

Electronic absorption spectra of the complexes in pure dry acetonitrile were taken with Hilger Uvispek spectrophotometer, model H 700, using 1 cm matched pair of quartz cells. The spectra are given in Figs. 1 and 2.

DISCUSSION

The three main vibration frequencies of pyridine N-oxide which are likely to be influenced on complex formation with metal ion are NO stretching vibration, NO bending vibration, and C–H out-of-plane vibration frequencies (3).

Shindo (9–11) has assigned the strong band at 1265 cm^{-1} to NO stretching vibration in the spectrum of pyridine N-oxide in carbon disulphide, while in the solid state the band occurs around 1243 cm^{-1}. The NO stretching frequency of the complexes in mull is lowered to below 1225 cm^{-1} (Table I). The decrease in the frequency is attributed to the change in the nature of the NO bond as a result of coordination. With the formation of M ← O bond, there is a decrease in the π-bond character of NO. The NO stretching vibrational frequencies of zirconyl, thorium, and uranyl complexes are at 1222, 1218, and 1207 cm^{-1}

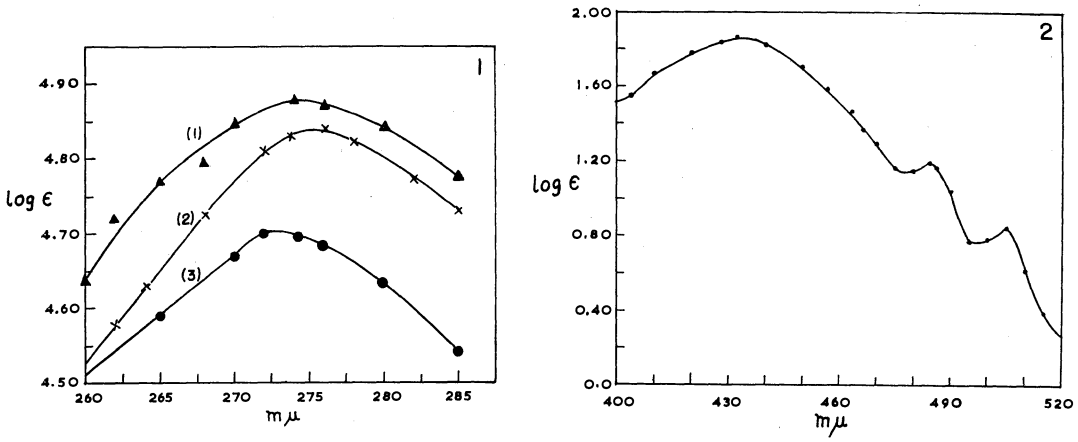

FIG. 1. Ultraviolet absorption spectra of (1) $Th(Py.O)_8(ClO_4)_4$, (2) $ZrO(Py.O)_6(ClO_4)_2$, and (3) $UO_2(Py.O)_5(ClO_4)_2$ in acetonitrile.
FIG. 2. Absorption spectra of uranyl pyridine N-oxide complex in acetonitrile in the visible region.

respectively, showing gradual decrease in the π-bond character of NO and consequent increase in the bond strength between the metal and the oxygen. Using these frequencies, the force constants calculated for the NO group in the complexes are 6.577, 6.531, and 6.398 millidynes per Å respectively. The decreasing order also follows the decreasing order of π-bond character of the NO group in the complexes.

The 840 cm^{-1} band in the spectrum of pyridine N-oxide has been assigned to NO bending vibration (2). Because of the coordination of oxygen atom of NO group to the metal atom, a noticeable shift of NO bending could be expected. However, a very slight shift of this vibration is observed in these complexes. The small shift is due to the two opposing effects. One, similar to that of coordinated water where bending vibration, δOH, is shifted to the higher frequency and the other, lowering in the frequency because of the decrease in π-bond character of the NO bond. If both these effects are practically equal, a very small shift in the frequency would result.

Kakiuti (3) and co-workers have assigned C–H out-of-plane vibrations at 741 (ν_{11}), 935 (ν_{10b}), 993 (ν_5), 846 (ν_{10a}), and 972 cm^{-1} (ν_{17a}) for pyridine N-oxide. In the complexes studied almost all vibrations except (ν_{11}) and (ν_{10b}) appear as weak shoulders, and all are considerably shifted to higher frequencies owing to the decrease in the electron density of the pyridine ring. This observation is in agreement with the findings of Kross (12).

All the remaining bands due to the pyridine ring are very little affected on complex formation and their assignments are made after the work of Kida (2). The in-plane ring vibration band of pyridine N-oxide around 1475 cm^{-1} has merged with the Nujol band. In the uranyl complex, the strong band at 907 cm^{-1} is due to the asymmetric stretching frequency and the 858 cm^{-1} weak band due to the symmetric stretching frequency of uranyl ion (13). The asymmetric vibration band is shifted to the lower frequency. A similar shift was observed by Comyns *et al.* (14) in uranyl acetylacetone complex. Such a shift is possible when the ligand groups are presumed to lie in or nearly in a plane perpendicular to the axial O–U–O direction (16). The force constant K_{eff}, and $r_{U-O(2)}$, $r_{U-O(1)}$ distances calculated for UO_2^{2+} group in the complex are 6.87 millidynes per Å and 1.74 Å and 1.72 Å respectively. The U–O distances are calculated using equations of Jones (15) and McGlynn (16) respectively. The broad strong band at 1085 cm^{-1} in all the three complexes is due to the degenerate stretching vibration of the perchlorate ion.

The electronic absorption of spectrum of pyridine N-oxide in *n*-heptane gives one intense band at 280 mμ and a weak band at about 320 mμ. The former band is assigned to $\pi \rightarrow \pi^*$ transition, and the latter to the $n \rightarrow \pi^*$ transition by Ito (17) *et al.* On complex formation the weak band at 320 mμ disappears while the band at 280 mμ shifts to lower wavelength around 275 mμ. This shows that the complex formation has taken place by donation of the lone pair of *p*-electrons on oxygen of the NO group to the metal atom, thus supporting the findings by the vibrational spectra. The absorption maximum in zirconyl, thorium, and uranyl complexes occurs at 276, 274, and 272 mμ respectively. This shows that π-electrons in the NO group are held in the following increasing strength: uranyl < thorium < zirconyl complex. This observation is in agreement with the decrease in NO stretching frequency. The intensity of the band around 275 mμ is roughly proportional to the number of pyridine N-oxide ligands attached to the metal atom.

In place of nearly 10 bands due to the free uranyl ion in solution, uranyl pyridine N-oxide complex gave only three weak bands in the visible region at 432 ($\epsilon = 71.88$), 484 ($\epsilon = 15.07$), and 505 mμ ($\epsilon = 6.955$) (Fig. 2). From their position and low intensity, the 432 and 484 mμ bands are the modified form of uranyl bands. The lowest intensity 505 mμ band may also be due to the uranyl ion, although it falls just outside the range of absorption usually observed in the spectrum of uranyl ions in solution. The decrease in the number of bands indicates the strong coordination between pyridine N-oxide and uranyl group.

From the number of pyridine N-oxide molecules in the metal complexes, the coordination number for both zirconium and uranium is seven and that for thorium is eight. In general, compounds with coordination number of seven are rare. However, both zirconium and uranium (18) exhibit coordination number of seven in complex ions $(ZrF_7)^{3-}$ and $(UO_2F_5)^{3-}$. The zirconyl complex with coordination number seven may be represented either as a face-centered octahedron (d^5sp hybridization) having the extra oxygen atom at the center of one face of the octahedron or as a trigonal prism with the extra oxygen at the center of one square face (face-centered trigonal prism with d^4sp^2 hybridization). The uranyl complex with coordination number seven may have pentagonal bipyramidal arrangement. In this case, two separate sets of hybrids are possible: d^2sp^2 to give five planar bonds and $d_{z^2}p_z$ or df to give the axial bonds (18). The arrangement may resemble that of $(UO_2F_5)^{3-}$ complex ion (19). Thorium complex with eight coordination number may have the square-antiprism structure with d^5p^3 hybridization as in the acetylacetonate complexes of Th(IV), U(IV), and Ce(IV) (20).

ACKNOWLEDGMENT

The authors are thankful to Professor M. R. A. Rao for his interest in the work.

REACTIONS OF DIETHYLBERYLLIUM AND DIETHYLBERYLLIUM TRIMETHYLAMINE WITH THE METHYLHYDRAZINES

NEIL R. FETTER
Chemistry Division, U. S. Naval Ordnance Laboratory, Corona, California

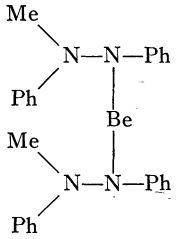
Received November 7, 1963

ABSTRACT

The reactions of Et_2Be and $Et_2Be{:}NMe_3$ with the methylhydrazines produce the following compounds: $Et_2Be{:}NMe_3$ and H_2NNMeH give $(EtBeMeNNH_2)_n$, Et_2Be and H_2NNMeH give $Be(MeNNH_2)_2$, Et_2Be and H_2NNMe_2 give $Be(HNNMe_2)_2$, Et_2Be and HMeNNMeH give $(EtBeMeNNMeH)_n$, $Et_2Be{:}NMe_3$ and $HMeNNMe_2$ give approximately 50% $Et_2Be{:}HMeNNMe_2$ and 50% $(EtBeMeNNMe_2)_n$, Et_2Be and $HMeNNMe_2$ give primarily $(EtBeMeNNMe_2)_n$, and Et_2Be and Me_2NNMe_2 give $(Et_2Be_2){:}Me_2NNMe_2$.

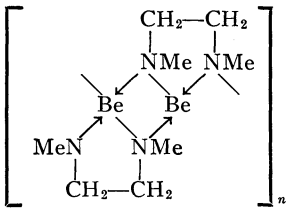
INTRODUCTION

The first preparation of an organo-beryllium–nitrogen compound was reported by Gilman and Schulze (1), who prepared



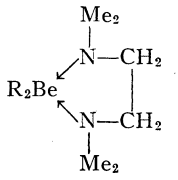
from the reaction of azobenzene and dimethylberyllium. Several years later this area of beryllium chemistry was extensively investigated by Coates and co-workers. They first reported the preparation of $Me_2Be{:}NMe_3$ and an unstable compound $(Me_2Be)_2{:}(NMe_3)_3$ (2). Also reported was the preparation of $(MeBeNMe_2)_3$ from the reaction of dimethyl beryllium and dimethylamine and the preparation of $Me_2Be{:}H_2NMe$, MeBe—NHMe, and $(MeBe—NHMe{:}Be{:}NMe)_y$ from dimethylberyllium and methylamine. Later Coates and Glockling (3) prepared $(i\text{Pr})_2Be{:}NMe_3$, $i\text{PrBeNMe}_2$, $Be(NMe_2)_2$, and $(BeNHMe_2)_n$ from reactions of diisopropylberyllium with trimethylamine and dimethylamine. These authors also prepared $(t\text{-Bu})_2Be{:}NMe_3$ by reaction of $(t\text{-Bu})_2Be{:}Et_2O$ with NMe_3 and $Be(NMe_2)_2$ by reaction of di-*t*-butylberyllium with dimethylamine (4).

Recently Coates and Green (5) have described the preparation and properties of two bipyridyl complexes, Et_2bipyBe and Ph_2bipyBe, and a series of ethylenediamine complexes with dimethylberyllium. A 1:1 adduct is formed between dimethylberyllium and N,N,N′,N′-tetramethylethylenediamine; N,N,N′-trimethylethylenediamine gave the dimer $(Me_2NCH_2CH_2NMe—BeMe)_2$: N,N′-dimethylethylenediamine produced a polymer with the structure



N,N-dimethylethylenediamine gave the dimer $(Me_2NCH_2CH_2NH—BeMe)_2$: and ethylenediamine reacted with dimethylberyllium to give a compound with the empirical formula $(C_2H_4N_2BeH_2)_x$.

The present work was undertaken to observe the behavior of diethylberyllium and its trimethylamine complex with several methylhydrazines. The hydrazines, in their reactions with beryllium alkyls, are chemically similar to the ethylenediamines, but sterically less flexible; hence, complexes involving these amines, which have nitrogen atoms that can be positioned to form the type



reported by Coates (5), are less likely to be found.

EXPERIMENTAL

Apparatus and Reagents

The compounds described below were prepared on a conventional glass high-vacuum system, which was equipped with a Toepler pump and calibrated volume for measurement of evolved gases. The products were handled in a nitrogen-filled dry box.

The methyl hydrazine (Matheson, Coleman and Bell), 1,1-dimethylhydrazine (Olin Mathieson Corp.), and tetramethylhydrazine (Metalectro Corp.) were vacuum distilled over CaH_2 before use. The 1,2-dimethylhydrazine was isolated from its dihydrochloride (K and K Laboratories) by treatment with liquid ammonia, and the trimethylhydrazine was prepared by the method of Class, Aston, and Oakwood (6). The diethylberyllium was prepared by the method of Gilman and Schulze (7), and the diethylberyllium trimethylamine was prepared by treatment of Et_2Be in heptane with a slight excess of NMe_3. The Et_2Be:NMe_3 was distilled under high vacuum before use. Solvents were reagent grade and were used without further purification except benzene, which was distilled over $LiAlH_4$ before use.

Molecular weight determinations were done cryoscopically in benzene with a Bender-Hobein apparatus, and infrared spectra were taken with NaCl cells on a Beckman IR-5 spectrophotometer. Elemental analyses were performed by the Schwarzkopf Microanalytical Laboratories, Woodside, New York. Nuclear magnetic resonance spectra were made on a Varian Associates Model V-4302 operating at 60 mc. Samples were 10–15% by weight in benzene solutions.

Reaction of Diethylberyllium Trimethylamine with Methylhydrazine

Onto 0.797 g (6.33 mmole) of Et_2Be:NMe_3, dissolved in 20 ml of *n*-octane, at −196° C was transferred 0.455 g (9.90 mmole) of H_2NNMeH. The mixture was allowed to warm to room temperature and stand for 2 hours. The evolved ethane was measured after the condensible substances were passed through a −100° C trap and into a calibrated volume by a Toepler pump. The reaction yielded 228 ml (10.2 mmole) of ethane and 61.5 ml (2.96 mmole) of trimethylamine.

Removal of the solvent via vacuum transfer left a powdery white solid which did not sublime or dissolve in hydrocarbons. Elemental analysis of the crude product gave results which agree with the formula $C_3H_7N_2Be$. Anal. Calc.: C, 43.44; H, 12.12; N, 33.70; Be, 10.84. Found: C, 42.55; H, 12.23; N, 33.05; Be, 10.70.

Methanolysis of 0.0963 g (1.16 mmole) of the crude product yielded 27.4 ml (1.20 mmole) of ethane. The infrared spectrum of the product has a strong N—H band at 3100 cm^{-1} and a weak NH_2 band at 1700 cm^{-1}.

Reaction of Diethylberyllium with Methylhydrazine

The above reaction was repeated with 0.831 g (12.1 mmole) of Et_2Be and 1.308 g (28.4 mmole) of H_2NNMeH. The reaction mixture stood at 25° C for 2 days after having reached room temperature. During this period 408 ml (18.2 mmole) of ethane evolved. After the solvent was removed there remained a powdery white solid which was sufficiently unstable that a sample for the C and H analysis exploded before results could be obtained. The Be and N analyses were in closest agreement with the formula $C_3H_7N_2Be$. Anal. Calc.: N, 33.70; Be, 10.84. Found: N, 36.98; Be, 10.97.

Methanolysis of 0.392 g (4.71 mmole) of the crude product, $C_3H_7N_2Be$, gave only 58.2 ml (2.60 mmole) of ethane. This material had infrared bands at the same wavelengths for N—H and NH_2 as the product obtained from the reaction of Et_2Be:NMe_3 with H_2NNMeH.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In another experiment, 0.473 g (7.07 mmole) of Et_2Be and 0.794 g (17.2 mmole) of H_2NNMeH were combined in 10 ml of nonane at −196° C. The mixture was warmed to room temperature and heated at 65° C for 14 hours. During this period 258.3 ml (11.5 mmole) of ethane was collected. The solvent and any unreacted H_2NNMeH were removed under vacuum and 0.1547 g (1.84 mmole $EtBeNMeNH_2$) of the powdery white product was treated with methanol, yielding 9.4 ml (0.42 mmole) of ethane. The ethane was 22.8 mole% of that calculated for 0.1547 g of $EtBeNMeNH_2$. The infrared spectrum of the product had an NH band at 3100 cm^{-1} and a weak NH_2 band at 1680 cm^{-1}.

Reaction of Diethylberyllium with 1,1-Dimethylhydrazine

By vacuum transfer, 1.347 g (22.5 mmole) of H_2NNMe_2 was placed on 0.540 g (8.05 mmole) of Et_2Be dissolved in 20 ml of *n*-octane at −196° C. The mixture was allowed to warm to room temperature, stand overnight, and was then heated at 50° C for 1 hour. A total of 341 ml (15.2 mmole) of ethane was recovered. After solvent and excess H_2NNMe_2 were removed under vacuum a light-yellow, gummy material remained. Since the crude product could not be distilled or sublimed, an elemental analysis of this material was obtained and the results agree with the formula $Be(HNNMe_2)_2$. Anal. Calc.: C, 37.70; H, 11.09; N, 44.05; Be, 7.08. Found: C, 37.58; H, 11.70; N, 43.85; Be, 7.03.

Methanolysis of approximately 0.5 g of crude product produced no ethane measured on a mercury manometer. The infrared spectrum of the product had no NH_2 band at 1700 cm^{-1}, but did have an N—H band at 3100 cm^{-1}. The reaction is: $Et_2Be + 2H_2NNMe_2 \rightarrow Be(HNNMe_2)_2 + 2C_2H_6$.

Reaction of Diethylberyllium with Trimethylhydrazine

Under vacuum, 1.248 g (15.5 mmole) of $HMeNNMe_2$ was transferred to a solution at −196° C containing 0.858 g (12.8 mmole) of Et_2Be and 20 ml of *n*-octane. The mixture was allowed to warm to room temperature and stand for 2 hours. During this period, 263 ml (11.8 mmole) of ethane evolved. The solvent was removed under vacuum to a −196° C trap and the clear fluid that remained was vacuum transferred (0.05 mm) at 25° C onto a −196° C cold surface. Approximately 15% of the crude product was collected in this manner and was a clear mobile liquid. The remainder of non-volatile material was a viscous fluid.

Elemental analysis of the volatile liquid gave results which agree with the formula $Et_2Be{:}HMeNNMe_2$. Anal. Calc.: C, 59.52; H, 14.27; N, 19.83; Be, 6.38. Found: C, 59.75; H, 13.95; N, 20.00; Be, 5.91.

There was not sufficient material to do a methanolysis. Elemental analysis of the non-volatile material gave results which agree with the formula $EtBe{-}NMeNMe_2$: Anal. Calc.: C, 54.01; H, 12.69; N, 25.20; Be, 8.10. Found: C, 54.86; H, 11.03; N, 25.30; Be, 8.06.

Methanolysis of 0.2027 g (1.82 mmole) of $EtBe{—}NMeNMe_2$ gave 35.7 ml (1.60 mmole) of ethane.

The above reaction was repeated with a 2:1 ratio of Et_2Be to $HMeNNMe_2$ in an attempt to prepare $Be(NMeNMe_2)_2$. In heptane, 0.585 g (8.73 mmole) of Et_2Be was added to 1.29 g (17.4 mmole) of $HMeNNMe_2$ at −196° C. The mixture was allowed to reach room temperature and was heated at 55° C for 4 hours. During this period 302 ml (13.5 mmole) of ethane was evolved. The solvent and any unreacted $HMeNNMe_2$ were removed at 25° C under vacuum, and the product that remained was a clear, viscous, non-volatile fluid.

Methanol hydrolysis of 0.2146 g of the product produced 33.2 ml (1.48 mmole) of ethane and the results of an elemental analysis suggest only a partial formation of $Be(NMeNMe_2)_2$ had occurred. Anal. Calc. for $Be(NMeNMe_2)_2$: C, 46.41; H, 11.68; N, 36.08; Be, 5.80. Calc. for $EtBe{—}NMeNMe_2$: C, 54.01; H, 12.69; N, 25.20; Be, 8.10. Found: C, 51.08; H, 12.25; N, 29.76; Be, 7.51.

The reactions of Et_2Be with $HMeNNMe_2$ may be summarized by the following equations:

$$(1)\ Et_2Be + HMeNNMe_2 \rightarrow Et_2Be{:}HMeNNMe_2$$

$$(2)\ Et_2Be{:}HMeNNMe_2 \rightarrow EtBe{—}NMeNMe_2 + C_2H_6$$

and presumably, if vigorous enough conditions are used,

$$(3)\ EtBe{—}NMeNMe_2 + HMeNNMe_2 \rightarrow Be(NMeNMe_2)_2 + C_2H_6.$$

Reaction of Diethylberyllium Trimethylamine with Trimethylhydrazine

The reaction of $Et_2Be{:}NMe_3$ with $HMeNNMe_2$ is essentially the same as the reaction with Et_2Be, except that a higher yield of $Et_2Be{:}HMeNNMe_2$ is obtained (approx. 50% by wt. of crude product). The reaction of 0.819 g (6.50 mmole) of $Et_2Be{:}NMe_3$ with 0.596 g (8.05 mmole) of $HMeNNMe_2$ in 15 ml of *n*-octane yielded 151 ml (6.72 mmole) of ethane during warming to 25° C over a period of 1 hour. The crude product that was obtained after solvent removal was vacuum transferred at 25° C onto a −78° C cold surface. Approximately 50% of this crude material transferred as a clear, mobile liquid. Its elemental analysis agreed with the formula $Et_2Be{:}HMeNNMe_2$. Anal. Calc.: C, 59.52; H, 14.27; N, 19.83; Be, 6.38. Found: C, 58.72; H, 13.07; N, 20.07; Be, 6.16.

Methanolysis of 0.0695 g (0.49 mmole) of $Et_2Be{:}HMeNNMe_2$ yielded 15.7 ml (0.70 mmole) of ethane. Elemental analysis of the non-volatile liquid gave results which agreed with the formula $EtBe{—}NMeNMe_2$: Anal. Calc.: C, 54.01; H, 12.69; N, 25.20; Be, 8.10. Found: C, 54.86; H, 11.03; N, 24.40; Be, 8.25.

Reaction of Diethylberyllium with 1,2-Dimethylhydrazine

Under vacuum, 1.384 g (23.1 mmole) of HMeNNMeH was transferred to a solution of 1.584 g (23.7

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

mmole) of Et_2Be and 15 ml of *n*-octane at −196° C. The mixture was allowed to warm to room temperature, the solvent was removed, and the crude product was then heated at 75° C for 3 hours. During this period, 620 ml (27.7 mmole) of ethane evolved leaving a non-volatile gummy yellow fluid product. Elemental analysis of this material gave results which agree with the formula EtBe—NMeNMeH. Anal. Calc.: C, 49.44; H, 12.45; N, 28.84; Be, 9.27. Found: C, 49.90; H, 11.66; N, 29.00; Be, 9.03.

Methanolysis of 0.3244 g (3.34 mmole) of EtBe—NMeNMeH yielded 68.7 ml (3.07 mmole) of ethane.* The infrared spectrum of the product had a strong NH band at 3120 cm^{-1}. The reaction is:

$$Et_2Be + HMeNNMeH \rightarrow EtBe—NMeNMeH + C_2H_6.$$

Reaction of Diethylberyllium with Tetramethylhydrazine

Under vacuum, 1.108 g (12.5 mmole) of tetramethylhydrazine was transferred to a solution at −196° C containing 0.748 g (11.1 mmole) of Et_2Be in 20 ml of octane. The reaction mixture was allowed to warm to room temperature and stand overnight. No gas evolution occurred. The solvent was removed under vacuum and the product that remained was a white crystalline solid (m.p. 84–87° C). Elemental analysis of the crude product gave results which agree with the formula $(Et_2Be)_2{:}Me_2NNMe_2$. Anal. Calc.: C, 64.80; H, 14.50; N, 12.60; Be, 8.10. Found: C, 64.46; H, 14.31; N, 12.35; Be, 8.31.

Methanolysis of 0.1980 g (0.893 mmole) of $(Et_2Be)_2{:}Me_2NNMe_2$ produced 87.3 ml (3.90 mmole) of ethane.

DISCUSSION

The reactions of Et_2Be and $Et_2Be{:}NMe_3$ with methylhydrazines follow the same general course observed for Me_3Al–hydrazine reactions (8). The following two general reactions, illustrated by the equations, show (1) the formation of a dative Be:N bond, and (2) the formation of a covalent Be—N bond by elimination of ethane:

$$(1)\ Et_2Be + HMeNNMe_2 \rightarrow Et_2Be{:}HMeNNMe_2$$

$$(2)\ Et_2Be{:}HMeNNMe_2 \rightarrow EtBe—NMeNMe_2 + C_2H_6.$$

The products obtained from these reactions suggest that steric effects may determine the number of ethyl groups which are substituted by a hydrazine. It was found that, at 50° C, 1,1-dimethylhydrazine readily reacts with diethylberyllium to give $Be(HNNMe_2)_2$, but trimethylhydrazine under similar conditions gave a compound which still contained 20.0% by weight of active ethyl (calc.: 26.1% for EtBe—$NMeNMe_2$). Also, 1,2-dimethylhydrazine gave only EtBe—NMeNMeH at 75° C. Even methylhydrazine, which forms $Be(MeNNH_2)_2$ upon reaction with diethylberyllium at 65° C, still does not replace all the active ethyl on Et_2Be. When treated with $Et_2Be{:}NMe_3$ at 25° C, methylhydrazine replaces one ethyl group and the resulting compound may have the formula EtBe—NHNHMe or EtBe—$NMeNH_2$.

From these results, it appears that the presence of a methyl group on a hydrazine nitrogen atom which also has an active hydrogen atom, in some manner limits the substitution of ethyl groups on diethylberyllium to one. It may be that the N-methyl group sufficiently hinders the close approach of another molecule of the same hydrazine that it cannot react with the remaining Be-ethyl. If this effect applies to all of the methylhydrazines, then it is possible to choose one of the two formulas indicated above for the Et_2Be—methylhydrazine monosubstituted reaction product. Since the compound contains an active Be-ethyl, then the Be—N bond must be at the nitrogen atom with the methyl group and the reaction may be written:

$$Et_2Be + H_2NNMeH \rightarrow EtBe—NMeNH_2 + C_2H_6.$$

This formula is supported by the infrared spectrum which exhibits an NH_2 absorption at 1700^{-1}.

**In some methanolyses the amount of ethane is less than the calculated amount. In this case, the polymeric nature of the product may prevent complete reaction, but in other cases no evident explanation is available.*

For personal use only.

The reaction between diethylberyllium and 2 moles of methylhydrazine may yield three products, $H_2NNMe—Be—MeNNH_2$, $MeHNNH—Be—MeNNH_2$, and $H_2NNMe—Be—MeNNH_2$; however, no attempt was made to determine which species were present.

Unlike $Me_3Al{:}Me_2NNMe_2$, which is a 1:1 complex (8), tetramethylhydrazine reacts with 2 molecules of diethylberyllium even though the molar ratio of reactants was 1:1. This reaction is the only one in this series in which two molecules of diethylberyllium were bonded to a hydrazine, although 1,1-dimethylhydrazine and trimethylhydrazine present possibilities for such datively bonded diethylberyllium. The fact that compounds

$$\begin{matrix} BeEt_2 & Et_2Be & BeEt_2 \\ \| & \| & \| \end{matrix}$$

such as $EtBe—NMeNMe_2$ and $Me_2NHN—BeNHNMe_2$ were not isolated may be the result of charge transfer from the nitrogen atom not covalently bonded to a beryllium atom. Such an effect may reduce the basicity of the nitrogen atoms sufficiently to prevent further complexing by diethylberyllium.

The n.m.r. spectrum of $(Et_2Be)_2{:}Me_2NNMe_2$ has a single sharp N—Me proton peak (τ = 8.11 p.p.m.) and a triplet–quartet characteristic of ethyl protons. Since the N—Me protons are identical, the structure of this complex is probably

$$\begin{matrix} & & Et_2Be \\ & & \| \\ Me_2N— & NMe_2, & \text{for the} \\ & \| & \\ & BeEt_2 & \end{matrix}$$

monomeric species.

The molecular weight data shown in Table I indicate that all of the compounds which are soluble in benzene are associated, but not in integral numbers.

TABLE I

Molecular weights of Et_2Be–methylhydrazine complexes

Compound	Molecular weight		Degree of association	Solution molality
	Found	Calc.		
$(Et_2Be)_2{:}Me_2NNMe_2$	315	222.4	1.42	.0271
	337		1.52	.0238
$EtBe—NMeNMe_2$	464	111.2	4.18	0.143
	464	111.2	4.18	0.107
$EtBe—NMeNMeH$*	1468	97.1	15.1	0.142
	772		7.95	0.216

*Poorly soluble in benzene.

The remaining compounds were insoluble in hydrocarbons. All of the products, except $(Et_2Be)_2{:}Me_2NNMe_2$, appeared to be highly associated or polymeric as indicated by molecular weight data, insolubility in hydrocarbons, low volatility, and very high melting temperatures (usually decomposition occurred before melting). Since all compounds but $Be(HNNMe_2)_2$ contained at least one beryllium–ethyl group, the polymers probably involve dative Be:N bonds between molecules as illustrated below using $EtBeNMeNH_2$ as an example:

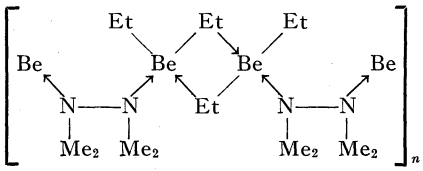
For personal use only.

or, in the case of $(Et_2Be)_2Me_2NNMe_2$, which is also associated, only ethyl bridging may be involved:



Since the n.m.r. of $(Et_2Be)_2Me_2NNMe_2$ has only one set of ethyl peaks it is assumed that exchange among the Be—ethyl bonds is rapid enough at room temperature to give only an average ethyl proton spectrum and the N—Me protons will be identical in either the monomer or associated molecule.

ACKNOWLEDGMENTS

The author wishes to acknowledge the valuable suggestions of Drs. Peter J. Slota and Charles P. Haber of the U. S. Naval Ordnance Laboratory, Corona, California, and to thank Mr. Donald W. Moore of the U. S. Naval Ordnance Test Station, China Lake, Calif. for the n.m.r. spectra.

ABSTRACT

Examination of the n.m.r. spectra of *cis*- and *trans*-1,2-diphenylcyclopentane and 3,4-diphenylcyclopentanone substituted in the para positions of both rings with methoxyl, methyl, and chloro substituents has shown that the previous explanation (1) of the effect of temperature on the n.m.r. spectra of 1,2-diphenylcyclopentane and 3,4-diphenylcyclopentanone (unsubstituted) was incorrect. The n.m.r. spectra provide no evidence of restriction of rotation of the aromatic rings of these compounds. An alternative explanation is offered.

Comparison of the spectra of the compounds above and those of *meso*- and *dl*-3,4-diphenyladipic esters with the para substituents mentioned leads to the observation that in the *dl*-adipates and the *cis*-cyclopentanes the position of absorption of the protons ortho to the central structure (H_R) is shifted to higher field compared to the corresponding meso or trans isomer by an amount ranging from 0.2 to 0.7 p.p.m. The protons ortho to the substituent X (H_X) are also shifted to higher field but by only about 0.1 p.p.m.

Shifts of the benzylic protons of the *trans*-cyclopentanes and cyclopentanones to higher field amount to 0.3–0.6 p.p.m. in agreement with previous work (1, 34). The corresponding shift of the benzylic protons of the *meso*-adipic esters is only 0.1–0.2 p.p.m. The methylene protons and the methyl ester protons of the *meso*-adipates are also shifted to higher field by about 0.3 and 0.2 p.p.m. respectively.

These shifts seem adequately explained in terms of ring current effects of the benzene rings and lead to the possibility of obtaining detailed information concerning the stereochemistry of such substances. They are of immediate value in making configurational assignments to related compounds.

INTRODUCTION

In the course of an investigation (1) of the steric interaction of cis phenyl groups (relative to trans) in the 1,2-diphenylcyclopentanes I and a number of other related compounds it was observed that the nuclear magnetic resonance spectrum of *cis*-I, either without any solvent or in carbon tetrachloride, at room temperature showed the absorption attributable to the aromatic protons as two incompletely resolved broad sets of absorptions. Similar behavior was shown by *cis*-3,4-diphenylcyclopentanone *cis*-II, but the corresponding trans isomers and either *cis*- or *trans*-1,2-diphenylcyclopropane showed the narrow absorption to be expected by analogy with the aromatic proton spectrum of toluene (2). The aromatic proton spectrum of the *cis*-diphenylcyclopentanes narrowed on heating. Thus, the aromatic proton spectrum of *cis*-I with a bandwidth at half-height of 25 c.p.s. at 60 Mc sec at 25° had a bandwidth at half-height of 5 c.p.s. at 182°. It was proposed that the origin of the broadening in the *cis*-diphenylcyclopentanes *cis*-I and *cis*-II was due to restricted rotation of the phenyl rings with consequent non-equivalence of the "inside" and "outside" hydrogens. The present investigation of derivatives of *cis*- and *trans*-I, substituted in the para position, was undertaken to simplify and to make possible a more rigorous interpretation of the spectra. It has from the outset shown that the proposed explanation of the n.m.r. spectra of compounds such as *cis*-I in terms of restricted rotation of the phenyl rings is erroneous.

EXPERIMENTAL[2]

Preparation of Materials

The compounds employed in the present investigation were either known compounds or close relatives of compounds which had already been prepared. Their physical properties and the syntheses employed are outlined in Table I. In addition to the para-substituted *cis*-1,2-diphenylcyclopentanes and *cis*-3,4-diphenylcyclopentanones originally sought a number of other compounds whose n.m.r. spectra are relevant to the present discussion are tabulated.

Nuclear Magnetic Resonance Spectral Determinations

Unless otherwise indicated n.m.r. spectra were obtained in deuterochloroform with tetramethylsilane as

*Purified by distillation after recovery from the oxime (which had been chromatographed on alumina and recrystallized from benzene: ligroin 1:2) by hydrolysis with 4 *N* sulphuric acid containing a small amount of formaldehyde.

†Found for the oxime after recrystallization from benzene: ligroin 1:4: C, 73.3; H, 7.1; N, 4.0. Calc. for $C_{19}H_{21}NO_3$: C, 73.3; H, 6.8; N, 4.5.

‡Found for the *cis*-ketone after distillation and recrystallization from methanol: C, 86.4; H, 7.9. Calc. for $C_{19}H_{20}O$: C, 86.3; H, 7.6.

§Found for the *trans*-ketone after recrystallization from methanol: C, 86.4; H, 7.6. Calc. for $C_{19}H_{20}O$: C, 86.3; H, 7.6.

‖Found for the *cis*-ketone after recrystallization from chloroform – petroleum ether: C, 66.9; H, 4.6; Cl, 23.2. Calc. $C_{17}H_{16}Cl_2O$: C, 66.9; H, 4.6; Cl, 23.2.

¶A melting point of 56.5–57.5° has been reported (20) for an isomer of which the stereochemistry was not assigned. Found for the *cis*-cyclopentane after distillation and recrystallization from aqueous ethanol: C, 80.7; H, 8.0. Calc. for $C_{19}H_{22}O_2$: C, 80.8; H, 7.9.

**Found for the *trans*-cyclopentane after crystallization from ligroin: C, 80.0; H, 7.7. Calc. for $C_{19}H_{22}O_2$: C, 80.8; H, 7.9.

††Hydrolysis of *trans*-III by 2 hours of refluxing with 10 ml of acetic acid and 50 ml of 47% hydriodic acid gave a 67% yield of what was presumably the dihydroxyphenyl derivative, m.p. 173°, (recrystallized from carbon tetrachloride). The n.m.r. spectrum was in agreement with this structure. However, even at 100° under vacuum it apparently did not lose solvent imbedded in the crystal because the carbon analysis was 3.4% below that expected. The compound dissolved in dilute sodium hydroxide solution and when the basic solution was treated with acetic anhydride there resulted the diacetyl compound, m.p. 124.5° (recrystallized from ethanol). Found: C, 74.1; H, 6.5. Calc. for $C_{21}H_{22}O_4$: C, 74.5; H, 6.6. Hydrolysis of cis-III in the same way gave what was probably the *cis*-dihydroxy- compound, m.p. 72–73°.

‡‡Found after purification by distillation: C, 90.6; H, 9.0. Calc. for $C_{19}H_{22}$: C, 91.1; H, 8.9.

§§Found after crystallization from aqueous methanol: C, 90.9; H, 8.8. Calc. for $C_{19}H_{22}$: C, 91.1; H, 8.9.

an internal standard with a Varian A-60 spectrometer. As a check on the reliability of the instrument in the aromatic region, the absorption due to a trace of chloroform present in the deuterochloroform when it could be observed was found to be 2.75±0.05 p.p.m. Although the position of absorption of the chloroform proton is notoriously subject to shifts due to the interaction with other species present it appears that the values reported for the aromatic protons are reliable to about ±3 c.p.s. The n.m.r. results reported in τ units (25) are presented in Tables II, III, and IV.

DISCUSSION

Aromatic Proton n.m.r. Spectra

As will be seen from the data in Table IIIA the spectrum of the *cis*-di-*p*-methoxyphenylcyclopentane *cis*-III in deuterochloroform showed a single aromatic proton absorption in sharp contrast to the unsubstituted compound *cis*-I, which showed a broad

*Although, strictly speaking, the spectra are those of an A_2B_2 type they approximate the spectra to be expected of two independent AB systems superimposed as has been observed in previous studies (29) of *p*-disubstituted benzenes. Accordingly when the AB quartette was observed J and δ were calculated from the equation (30) $(1-3) = (2-4) = \sqrt{[(\delta_B-\delta_A)^2+J^2_{AB}]}$. In all cases where the spectrum was of this type, J, estimated as the separation between peaks 1 and 2 or 3 and 4, was found to be 9±0.5 c.p.s.

Spectra were obtained with 10–25% solutions (generally 20% in deuterochloroform unless otherwise specified. Spectra obtained in acetone agreed well with those in deuterochloroform, in general, and data obtained in acetone will be presented in footnotes to the Tables when they are available.

†The correction was applied by adding or subtracting the error estimated from a comparison of the position of the peak due to chloroform present as an impurity in the deuterochloroform with that of pure chloroform (2, p. 8), τ 2.73. The corrected values appear to have somewhat better internal consistency but the major conclusions are unaffected by the correction.

‡Methyl *p*-hydroxyhydrocinnamate (20% in acetone) had H_X 3.15, H_R 2.85 τ.

§In acetone (7%) dimethyl *meso*-di-(*p*-hydroxyphenyl-adipate had H_X 3.18, H_R 2.82 τ.

‖In acetone (20% solution) *trans*-III had H_X 3.27 and H_R 2.95. The analogous dihydroxyphenyl compound (20% in acetone) had H_X 3.28, H_R 3.00.

¶The spectrum of a neat sample showed H_X 3.71, H_R 2.81.

**No correction was possible since the chloroform peak was obscured by the aromatic absorption.

††The *trans*-ketone was obtained by the ring closure employed for the other *trans*-ketones in very small amount and not purified fully. The spectrum was obtained with a 4.8% solution in deuterochloroform.

‡‡In carbon tetrachloride the values were H_X 2.84, H_R 2.96. Although the positions of H_X and H_R of *p*-chlorotoluene have not been reported in a form which would make possible direct comparison with the present values their difference of 0.113 with H_R at higher field (29) agrees with the values here.

cis-Di-(*p*-chlorophenyl)-cyclopentanone (*cis*-XI)	2.88	2.90	3.32	3.34	+0.28¶	+0.62¶

*The *J*'s had values from 8.5 to 9.0 c.p.s. Spectra were obtained with 10–25% solutions in deuterochloroform unless otherwise specified.

†8% solution in deuterochloroform. Dimethyl *dl*-(*p*-hydroxyphenyl)-adipate (15% solution in acetone) had H_A 3.11, H_B 3.25, for the aromatic proton absorption.

‡At −52° there was no noticeable change in the shape of the spectrum (determined by Mr. O. Norton) and $H_X = H_R$ was 3.37 (uncorrected). *cis*-3,4-(Dihydroxyphenyl)-cyclopentanone (20% acetone solution) had $H_X = H_R$ 3.37.

§A 16% solution of *cis*-III in acetone showed H_X and H_R at 3.23 and 3.43. In decalin (20% solution) at room temperature the corresponding values were 3.31 and 3.50. The separation between the peaks was essentially the same (12 c.p.s. between peaks 1 and 3) when the sample was heated to 180° as it was at room temperature (11 c.p.s. between peaks 1 and 3). The corresponding hydroxy compound had the aromatic chemical shifts at 3.33 and 3.45 in deuterochloroform and at 3.26 and 3.36 in acetone (20% solution). It will be noted that there is some possible ambiguity in making assignments of the H_X and H_R absorptions. They have been made here with the assumption that the H_X band is the lower one but without good justification.

‖A 20% solution of *cis*-IX in decalin showed H_X 3.25, H_R 3.37. On heating to 180° the two branches coalesced with $H_X = H_R$ 3.57. On recooling the AB quartette returned with H_X 3.11, H_R 3.27. The values of the chemical shifts in decalin were obtained with no calibration of the instrument in the region of interest and accordingly this result has only qualitative significance.

¶Since no corrected values could be obtained for the *meso-trans*-compounds, the uncorrected values were used throughout.

complex aromatic proton spectrum (1). (In acetone or decalin the aromatic proton spectrum of *cis*-III has the appearance of an AB spectrum (26) (doubled in this case) with a chemical shift between the A and B protons of 0.10–0.12 p.p.m.) This would seem at the outset not to be in accord with the previous postulation (1) of restricted rotation of the aromatic rings. In a further analysis of the n.m.r. data it is instructive first to consider together the spectra of those *p*-methoxy compounds which have only one phenyl ring and those which might be expected to have the maximum physical separation of the two phenyl rings and, hence, the minimum interaction of one phenyl ring with the other. Such a series, presented in Table IIA, includes, in addition to the compounds containing only one *p*-methoxyphenyl ring, the *meso*-dimethoxyphenyladipic ester (*meso*-IV) and the *trans*-dimethoxyphenylcyclopentane derivatives *trans*-III, *trans*-V, and *trans*-VI. The inclusion of the *meso*-adipic ester *meso*-IV is based on the somewhat intuitive premise to be discussed later that the predominate conformation is that (*meso*-A) with the aryl groups trans to each other, which places the CH_3OCOCH_2— groups trans to each other also. Each of these compounds had an aromatic proton spectrum which approximated the typical AB quartette as does *p*-methoxytoluene (27). The proton ortho to the substituent is designated by H_X; that ortho to the point of attachment of the molecule proper by H_R.

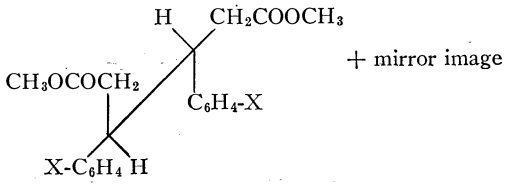
meso-A



dl-A

The data in Table IIA show the chemical shifts of the aromatic protons to be quite insensitive to changes in the carbon skeleton to which the benzene rings are attached. It can be seen further that the values for the two kinds of protons are scattered around the values of τ 3.20 and 2.95 for H_X and H_R obtained from the Varian Spectra Catalogue (27) for *p*-methoxytoluene. A similar situation exists in the *p*-methyl series (Table IIB) and also with the more limited and less dependable data available for the *p*-chloro series (Table IIC). Thus, the chemical shifts of H_X and H_R for the methyl compounds in Table IIB are sufficiently close to each other to appear as a single aromatic proton absorption close to the position of absorption (28) of *p*-methylisopropylbenzene.

In Table III are summarized the data for the aromatic proton spectra of the *dl*-diaryladipic esters and *cis*-diarylcyclopentane derivatives. The methoxy compounds (Table IIIA), in contrast to the meso–trans series, show, in deuterochloroform a single absorption attributable to both H_X and H_R. The methyl and chloro compounds (Tables IIIB and IIIC) have, as the aromatic proton spectrum, an AB quartette (28). As was the case with the series of Table II, the H_X (or H_R) values of the methoxy compounds (Table IIIA) are quite insensitive to the structural changes involved and this seems to be true also for the methyl compounds (Table IIIB) and chloro compounds (Table IIIC) although the data are rather limited. Most striking is the difference between the position of the H_X (or H_R) proton in the *dl*-cis series and that of the corresponding proton in the meso–trans

series. There is clearly a structural effect on the positions of the aromatic protons which is stereochemical in origin and which leads to a small shift to higher field (0.03–0.1 p.p.m.) of the H_X protons, in the *dl*–cis series and a somewhat larger shift (0.2–0.7 p.p.m.) again to higher field of the H_R protons. Although there is some indication that this difference is largest with the *p*-chloro compounds and smallest with the *p*-methyl the precision of the data is hardly adequate to justify any such correlation of the shift with the electrical effect of the substituent.

The shift to higher field of the aromatic protons of the compounds in the *dl*-cis series would seem to be primarily the result of the effect of the ring currents of each ring on the magnetic environment of the protons of the other adjacent to it. Such an effect was observed by Waugh and Fessenden (31) in their study of the paracyclophanes and in the series of *cis*-olefins and cyclic compounds (1, 30 p. 119 *ff.*) which led to the present investigation. It is of interest to compare the value of 0.57 p.p.m. for the shift to higher field relative to *p*-xylene of [2,2]paracyclophane (31) with the present data. Although it is not possible to make calculations with more than qualitative significance (32) because of the freedom to rotate of the phenyl rings in the diphenylcyclopentanes, inspection of molecular models makes it appear reasonable both that the shift of the paracyclophane should be comparable to those observed for H_R in the present examples and that shifts of H_R should be considerably larger than those of H_X.

The questions of the complexity and temperature dependence of the shape of the aromatic proton spectrum of the unsubstituted diphenylcyclopentane *cis*-I and the related diphenylcyclopentanone can now be considered. The results obtained with the *p*-substituted compounds just discussed explain readily the complexity of the spectra since the position of absorption of the ortho protons could be expected to be shifted more to higher field than the meta or para by the adjacent ring. Although the spectra of the unsubstituted compounds are too complex to permit assignments of chemical shift values to the ortho, meta, and para protons, the separation previously observed (1) between the centers of the two multiplets (0.2–0.3 p.p.m.) is of the order of magnitude expected from the study of the para-substituted relatives in Tables II and III.

A possibility which might be considered is that although rotation of the aromatic rings in the diphenyl compounds without para substituents is slow (on the n.m.r. time scale) it is accelerated by an electronic effect (which might alter the effective size of the π-electron cloud) of the para substituents. Substituents of the compounds studied include the methoxyl group with σ_{meta} negative, σ_{para} positive; the methyl group with σ_{meta} and σ_{para} both negative; and the chlorine atom with both σ_{meta} and σ_{para} positive. Since in none of these para-substituted compounds has there been complexity in the aromatic proton spectrum beyond that to be expected in molecules with freely rotating phenyl rings, such an explanation appears to be ruled out. As was noted in Table IIIA an attempt to slow the rotation of the *p*-methoxyphenyl rings of *cis*-III by cooling the solution to −52° made no significant change in the spectrum. It is anticipated that at lower temperatures or with appropriate ortho or meta substituents on the phenyl rings their rotation rates may be measured with n.m.r. techniques.

The most probable explanation of the narrowing at 180° (1)[3] of the phenyl proton spectrum in the cis compounds *cis*-I and *cis*-II appears to involve the non-coplanarity of the cyclopentane ring (33). Suppose, for example, that a solution of the *cis*-hydrocarbon *cis*-I contains at room temperature a mixture of molecules in two or more conformations

[3]*The examination of the n.m.r. spectrum of cis*-I *in decalin at room temperature and at 180° has been repeated with complete confirmation of the previous results (1).*

of the cyclopentane ring, which differ in the relative positions of the phenyl groups with respect to each other and which are in rapid equilibrium. The effective magnetic field at each H_R is then a weighted average which depends on the field at that proton in each of the conformations and on the equilibrium constant (*s*) describing the degree to which each conformation is populated. If the increase in temperature were to increase the populations of conformations in which the phenyl groups were most separated there would then be a preferential shift to lower field of the resonance position of the H_R protons and a corresponding narrowing of the proton resonance band.[4] This leads to the prediction that there should be a preferential shift to lower field of the H_R protons in the *cis*-1,2-diphenylcyclopentane derivatives. A compound which might be expected to show this effect most dramatically is the *para*-methyl compound *cis*-X, which was studied as a 20% solution in decalin. At room temperature as mentioned in the footnote to Table IIIB the AB quartette had a chemical shift between H_X and H_R of 0.12 p.p.m. At 180° the quartette had a single peak, in agreement with expectation. The *para*-methoxy compound *cis*-III (20% solution) in decalin failed to show a significant change in the shape of the aromatic proton spectrum. As was noted in Table IIIA, this substance, in contrast to its behavior in deuterochloroform, shows an AB quartette with a chemical shift between H_X and H_R of about 0.19 p.p.m. This separation did not change appreciably on heating. It seems clear that a detailed understanding of the temperature dependence of *cis*-diarylcyclopentanes awaits the accumulation of further experimental data. The difference between the spectra of deuterochloroform and acetone or decalin solutions in the cis series indicates that part of the chemical shift differences considered above between the cis–*dl* and trans–meso series is due to solvent interactions which are probably most serious with the deuterochloroform solutions (34).

Absorption of the Benzylic Protons

It was pointed out previously (1, 35) that a few *vic*-diphenylcyclic compounds and the stilbenes had a shift of the benzylic proton 0.32–0.50 p.p.m. to higher field in the trans isomer (in which the benzylic proton is cis to the phenyl ring on the adjacent carbon). In Tables IVB and IVC are presented data showing the benzylic proton absorptions of compounds now available. The value given is the center of the unresolved multiplet. Both the previous generalization relating configuration with benzylic proton absorption and the configurational assignments of the compounds in Tables IVB and IVC are confirmed with the benzylic protons of the trans isomers absorbing 0.44 ± 0.11 p.p.m. higher than the corresponding protons of the cis isomers.

Conformations of the Diphenyl Adipic Esters

It is of interest to compare more fully the n.m.r. spectra of the *meso*- and *dl*-adipic esters. At the outset it might be supposed that the staggered conformation in which the small hydrogen atom lies between the two larger groups on the adjacent carbon atom, as in *meso*- and *dl*-A, is the most populated one in each case. As a beginning then it is instructive to examine the positions of the proton resonances with the assumption that the meso isomers have the conformation *meso*-A, and that the *dl*-isomers have those shown as *dl*-A. On this basis it has already been noted (Table II) that the phenyl proton positions of the *meso*-adipic esters (with a dihedral angle of 180° between the bonds to the phenyl rings) are the same to within the present limits of the experimental measurement as those

[4]*Substantially this explanation was proposed by Dr. F. A. L. Anet, to whom we are indebted, in a letter written in April, 1962, before the results with the para-substituted compounds were available.*

of the *trans*-diarylcyclopentanones and cyclopentanes with a dihedral angle of 120°, neglecting the twisting of the five-membered ring.

The data in Table III might be interpreted as showing that the phenyl proton positions are not shifted quite as much to higher field in the *dl*-adipic esters (dihedral angle 60° as in conformation *dl*-IVA) as they are in the *cis*-cyclopentanes (dihedral angle nearly O°). The precision of these data is not sufficient to permit more than a suggestion that this difference may be real. In any case the trend is reasonable, the greatest shift to higher field occurring with the smallest dihedral angle between the bonds to the phenyl rings. If the postulated conformations *meso*-A and *dl*-A are interpreted literally with the benzylic proton on one carbon atom centered between the bonds to the phenyl and methylene groups on the adjacent carbon atom, then the spacial relationship of the benzylic proton to the two aromatic rings is the same in the two conformations and there should be no shift due to a change in the effect of ring currents on the proton's environment. Data in Table IVA show that this prediction is not verified. The benzylic protons in the meso series are consistently somewhat higher (0.14 ± 0.05 p.p.m.) than the corresponding protons in the *dl*-series.[5] An improved picture would take into account the possibility that the stabilities of conformations *meso*- and *dl*-A can be increased by distorting them slightly so that the proton is not equidistant from the two bonds opposite it, and also the probable existence of an appreciable fraction of the molecules in the other staggered conformations, as well as the non-planarity of the cyclopentane ring. This over-simplified picture is of value, however, in a consideration of the shifts of the methylene protons and ester methyl protons (Table IVA). It is seen that the meso isomers which had the H_R protons at lower field (relative to the *dl*) have both the methylene and methyl protons shifted to higher field. This is readily explained if conformations *meso*-A and *dl*-A are assumed to be the most important conformations, since in *meso*-A the methylene and methyl ester groups are above the face of the opposite benzene ring and therefore subject to a ring-current shift to higher field. In the *dl*-isomer (conformation *dl*-A) the phenyl groups are adjacent.

It seems clear that with more refined data, n.m.r. studies are capable of giving detailed structural information about positions of conformational equilibria in systems such as the diphenyladipic esters. Hyne (36) has reported such studies of the diastereoisomeric ephedrines. In any case the positions in the n.m.r. spectrum of the H_R protons together with the methylene and methyl protons appears to provide a reliable method of assigning configuration to compounds similar to those studied here.

ABSTRACT

The extraction equilibria in the system aqueous hydrochloric acid – uranyl chloride – undiluted tri-*n*-butoxyethyl phosphate, TBEP, were examined as a function of increasing uranyl concentration (0.44 to 4.41 *M*) in the initial aqueous solution, the acid content of the initial aqueous solution being kept constant at 6.76 *M*. The extraction behavior of TBEP is found to be different from that of tributyl phosphate. Evidence has been presented to show that the three ethereal oxygen atoms in the TBEP molecule are, under high organic phase loading conditions, available for participation in complexation. The hydrochloric acid promoted hydrolysis of TBEP and the instability toward light of the TBEP layer containing hydrochloric acid and uranium were also examined.

INTRODUCTION

Numerous papers (1–9) have been presented on the comparison of tri-*n*-butyl phosphate, TBP, with other neutral organophosphorus extractants. In the extraction of uranyl nitrate, the extraction ability of the phosphorus compounds usually increases in the order of phosphate $(RO)_3PO$, phosphonate $(RO)_2RPO$, phosphinate $(RO)R_2PO$, and phosphine oxide R_3PO. The explanation is that the alkoxy oxygen lowers the electron donor properties of the phosphoryl oxygen, which is the only coordination site in the extractants. It was thought, accordingly, that combination of three oxygen atoms (in addition to the three alkoxy oxygens) with the phosphoryl oxygen might lead to an inferior extractant in comparison with TBP. Tri-*n*-butoxyethyl phosphate, $(C_4H_9OC_2H_4O)_3PO$, TBEP, was chosen as the representative of this class of compounds, since it is commercially available in pure state.

A roughly comparable distribution ratio of uranyl nitrate by TBP and TBEP has been observed (1, 7) under otherwise identical conditions. Halpern, Kim, and Li (10) observed a weaker extraction by TBEP in comparison to TBP of micro quantities of zinc, indium, and uranyl chlorides from dilute hydrochloric acid solutions. To compare TBP and TBEP further, we felt that experiments have to be carried out under conditions of high organic loading. The extraction of uranyl chloride from concentrated hydrochloric acid was chosen, since the system for comparison, $HCl–UO_2Cl_2–TBP$, was recently investigated by two of the present authors (11) and others (12, 13).

Although there are no general considerations which make it possible to predict the effect of degree of hydration on the extraction ability of a given organophosphorus compound, Sidall (14) has reported that the order of affinity for water increases in the order of phosphate, phosphonate, phosphinate, and the same order is kept in the extraction ability. Usually the acid or metal salt entering the organic phase will remove one or more ester molecules as a water acceptor. This is certainly true for the nitrate systems, and is

[1]*This investigation was supported in part by the U.S. Atomic Energy Commission through Contract No. At-(30-1)-1922.*
[2]*On leave of absence from the Hebrew University.*

also true for systems containing uranyl chloride (11) and cobalt chloride (12). The unusually high degree of hydration of the HCl·TBEP complex (10), as compared to that of the corresponding HCl·TBP complex (15), places TBEP far ahead of TBP in the order of extraction capacity, which is not in agreement with the previous reasoning on the possible inferior effect of the ethereal oxygens on the extraction ability of TBEP. In order to resolve this question, experiments had to be carried out with high aqueous electrolyte concentration leading to saturation of the extractant and causing, consequently, an appreciable transfer of water to the organic phase. Since the presence of an inert diluent in the organic phase affects the hydration of both the extractant and the extracted solute, we have used undiluted TBEP throughout this study.

An additional emphasis has been placed in this study upon the chemical stability of the TBEP phase. Recently Kertes and Halpern (16, 17) reported on the hydrochloric acid promoted hydrolysis of TBP and the instability of the TBP layer containing both hydrochloric acid and uranyl chloride. They found that, when aqueous hydrochloric acid and TBP were mixed together and the equilibrium phases separated, after a few days the homogenous TBP phase became heterogenous; a second phase was formed. If the organic layer had been separated from the equilibrated aqueous phase containing both HCl and uranyl chloride, after a period of several days a solid appeared. The uranium (VI) initially present was photolytically reduced to uranium (IV) and the TBP hydrolyzed to alkyl phosphates, resulting in a greenish precipitate. In our studies with TBEP, we have observed similar phenomena, and the results of our study on the instability of TBEP are included in this paper.

EXPERIMENTAL

Materials

Samples of pure TBEP and uranyl chloride monohydrate were obtained from the Food Machinery and Chemical Corp., New York and S. W. Shattuck Chemical Co., Denver, Colo., respectively. A determination of the molecular weight by means of a vapor pressure osmometer showed that TBEP is at least 99% pure. The TBEP was washed with 1 *N* HCl, then with 1 *N* sodium hydroxide, and finally with water. In its general physical properties TBEP differs but little from TBP (18). The solubility of water in the phosphorus esters corresponds to the formation of a monohydrate for TBP, and to a TBEP:water mole ratio of 1:1.5. The latter value has been confirmed by equilibrating dry undiluted TBEP with water (10).

Procedure

The initial aqueous solutions were prepared by mixing calculated amounts of stock solutions of hydrochloric acid and uranyl chloride with water to give the desired initial concentrations. Undiluted TBEP was used as extractant throughout the experiments. After equilibration by shaking for 15 minutes and centrifugation, the TBEP phase was immediately diluted with a 1:2 water–ethanol mixture and then analyzed. The uranium content of the equilibrated aqueous phase was determined gravimetrically using 8-hydroxyquinoline. The amount of uranium extracted into the TBEP phase was calculated by difference from the total uranium content. The concentrations of hydrochloric acid in the equilibrium aqueous and TBEP layers were calculated by subtracting twice the uranium concentration values from the chloride values obtained by titrations using the Volhard method.

The conductivity of the equilibrium organic phases having the composition as listed in Table I has been measured by a procedure previously given (10). The water content of the organic layers was found by means of the Karl Fischer reagent using the dead-stop end-point method as determined with a Fisher titrimeter.

In experiments designed to study the degradation of TBEP, the procedure was essentially identical with that previously described (16), except that they were run at 60±0.4° C for periods ranging from 2 to 12 days. The concentrations of the acidic degradation products, H_2DBEP and HMBEP, in the organic phase were determined potentiometrically while the aqueous phase was analyzed for orthophosphoric acid spectrophotometrically (19).

RESULTS AND DISCUSSION

(A) Extraction of Uranyl Chloride

In this set of experiments the hydrochloric acid content of the initial aqueous solution

*Initial organic phase volume 5.0 ml (2.56 *M* TBEP).

was kept constant at 6.67 *M*, and the extraction by undiluted TBEP was examined as a function of increasing uranyl chloride concentration in the initial aqueous solution. The above initial HCl concentration was chosen to approach "saturation" of the extractant, leaving practically none of the extractant unreacted (10). Table I and Figs. 1–4 summarize the results obtained. Figures 1–3 include the results obtained with TBP (11) for comparison with TBEP. Since the volume change measurements were reproducible to ±0.05 ml, we believe that the values in Table I are accurate to ±3%. Figure 1 shows that there is very probably a change in the extraction mechanism at about 1 *M* uranyl chloride in the organic phase (as discussed previously for TBP (11)), coinciding with the intersection of the lines in Fig. 4. The latter corresponds to a TBEP:UO_2Cl_2 ratio of nearly 2. The

FIG. 4. Molarity of TBEP in the equilibrium organic phase (ordinate) vs. molarity of UO_2Cl_2 in the equilibrium organic phase (abscissa).

slope of the second part of the curve in Fig. 4 seems not to be incidental since by extrapolation to zero uranium content the molarity of undiluted TBEP, 2.56 *M*, is obtained. Figure 2 suggests that the acid content of the TBEP phase decreases up to about 1 *M* UO_2Cl_2 in the organic phase and increases afterwards. The line with a slope of 1.4 has its origin at zero concentrations of the solutes. Up to about 1 *M* UO_2Cl_2 in the organic phase, the concentration of HCl in TBEP is smaller than in TBP, both decreasing with increasing concentration of uranyl chloride. Beyond 1 *M* uranyl chloride, however, a different behavior is noted. The concentration of HCl in TBEP is now greater than that in TBP, and is increasing with increase in uranium concentration, while the concentration of HCl in TBP is still following the same trend. We would like to suggest that, up to the concentration of 1 *M* uranyl chloride, there is only one coordination site in TBEP, namely the phosphoryl oxygen, just as in TBP. At higher concentrations, however, the acid may be coordinated additionally to the ethereal oxygens in TBEP, hence the increase in the TBEP phase over TBP. This is confirmed in the comparison between TBEP and TBP in the extraction of water, as shown in Fig. 3. The same general trends are observed for the extraction of HCl in Fig. 2.

The most striking result for TBEP is that the extraction of uranium, acid, and water shows no indication of levelling off. This is in contrast to the behavior of neutral alkyl phosphates containing no ether linkage, but is in line with that of certain ethers (19). It has been observed that about 5.5 *M* UO_2Cl_2 and 6.67 *M* HCl in the aqueous phase result in complete miscibility with the undiluted TBEP, a phenomenon which has so far

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

been observed only for undiluted TBP with pure nitric acid (21) and anhydrous phosphoric acid (22).

When the aqueous HCl concentration is less than 2 *M* (corresponding to organic phase HCl concentration of less than 0.2 *M*), the extraction ability of TBEP for tracer amounts of Zn(II) and In(III) is less than that of TBP (10). In extraction from dilute aqueous solutions there is but one coordination site in TBEP, namely, the phosphoryl oxygen. Because of the presence of three additional oxygen atoms in TBEP, the electron donor strength of the phosphoryl oxygen becomes slightly weaker in TBEP than in TBP, and hence also the extraction ability. In extractions from concentrated aqueous solutions, however, three additional coordination sites (the ethereal oxygens) become available in TBEP. Since TBP still has only one coordination site, its total extraction capacity now becomes lower than that of TBEP.

Additional evidence for the formation of a compound with TBEP:UO_2Cl_2 ratio of 2 and for different extraction mechanisms involved is shown in Fig. 5, representing the resistance curve of the organic phase as a function of its UO_2Cl_2 content. The maximum resistance is observed at about 1 *M* UO_2Cl_2 in the TBEP phase (corresponding according to Fig. 4 to 2 *M* TBEP) and as more uranium goes into the organic phase, together with ever-increasing amounts of acid and water, the conductance of the organic phase increases. This behavior is very different from that of a TBP system under comparable conditions.

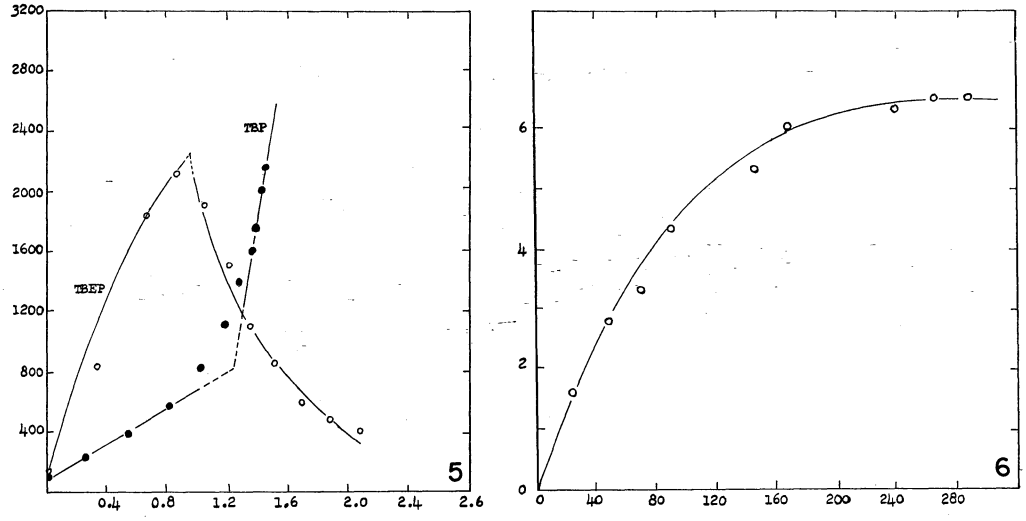

FIG. 5. Resistance in scale reading units of the equilibrium organic phase (ordinate) as a function of its UO_2Cl_2 content in molarity (abscissa).
FIG. 6. Volume decrease in ml at 60° of the equilibrium TBEP phase (ordinate) vs. ageing time in hours (abscissa).

(B) Hydrochloric Acid Promoted Degradation of TBEP

When equal volumes (15 ml) of undiluted TBEP and 12.1 *N* HCl were mixed at 60°, the result was that the organic layer increased in volume to 20.30 ml. Thereafter, as degradation of TBEP proceeded, the volume of the equilibrium organic phase decreased, reaching a constant volume of 14.00 ml after 238 hours at 60°; the liquid ejected from the organic layer was completely miscible with the aqueous layer. This decrease in volume as a function of time is plotted in Fig. 6. A separate experiment in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

which the aqueous phase was discarded after equilibration, while the TBEP phase was left standing in a thermostat at 60° for 205 hours, has shown that the ejected phase is an aqueous HCl solution of 6.13 *M* concentration. Qualitative experiments have shown that the phenomenon of an ejected layer also occurs when TBEP is equilibrated with as dilute a solution as 2 *M* HCl.

In a simple and formal analogy with the dealkylation of TBP (16), the corresponding degradation of TBEP may be represented as

$$\underset{\text{TBEP}}{(C_4H_9OC_2H_4O)_3PO} + HCl_{aq} \xrightarrow{k_1} \underset{\text{HDBEP}}{HO(C_4H_9OC_2H_4O)_2PO} + C_4H_9OC_2H_4Cl,$$

$$\text{HDBEP} + HCl_{aq} \xrightarrow{k_2} \underset{\text{H}_2\text{MBEP}}{(HO)_2(C_4H_9OC_2H_4O)PO} + C_4H_9OC_2H_4Cl,$$

$$H_2MBEP + HCl_{aq} \xrightarrow{k_3} H_3PO_{4aq} + C_4H_9OC_2H_4Cl.$$

The analytically determined values of the concentrations of the decomposition products are shown in Table II. The values of log unreacted TBEP plotted against the ageing

315	0.929	0.450	1.133	0.048

time gives a straight line only for the first four values tabulated. Assuming for these four values a first-order reaction, the rate constants represented by the equation $d[TBEP]/dt = k_1[TBEP]$ have been calculated. The four values: 4.6×10^{-3}, 5.4×10^{-3}, 5.6×10^{-3}, and 7.5×10^{-3} hour^{-1} show a trend, demonstrating that the rates of formation of HDBEP, H_2MBEP, and H_3PO_4 are dependent on other variables and that the rate of reaction is much more sensitive to these products than in the case of TBP. This evidence was sufficient to discourage further quantitative study of the degradation process.

This failure is not surprising in view of the presence of ethereal oxygens in TBEP. At higher temperatures the degradation of TBEP is more complicated, since the possibility of electrophilic attack by hydrogen ion on the ethereal oxygen increases, presumably by the higher dissociation of HCl in the organic phase at the higher temperature.

(C) Hydrolytic Degradation of TBEP and the Simultaneous Photolytic Reduction of Uranium (VI)

If TBEP is equilibrated with an aqueous solution of 1–4 *M* uranyl chloride in 7–8 *M* HCl and the loaded organic phase separated and stored in the dark, no transformation occurs. However, if it is left 2 days on open shelves, the organic solution, initially homogenous and yellow in color, develops a greenish tinge, characteristic of uranium (IV), and a greenish precipitate. The solid obtained is apparently non-hygroscopic and does not undergo oxidation at room temperature. The infrared spectrum, using KBr disc, shows strong absorption at 3350 cm^{-1} indicating free OH. Powder diffraction data were not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

definitive in establishing the nature of these compounds. Only diffuse powder lines were obtained characteristic of amorphous type substances.

The results of phosphorus and carbon analysis for the uranium (IV) compound are as follows: P, 8.2%; C, 31.2%. If no degradation occurred in TBEP, the C/P ratio would be 7.0; whereas if degradation to HDBEP and H_2MBEP occurred, the C/P ratios would be 4.6 and 2.3, respectively. The actually observed C/P ratio, 31.2/8.2, is 3.8, so that about two thirds of TBEP is degraded into HDBEP, and one third degraded into H_2MBEP.

ACKNOWLEDGMENTS

The authors wish to thank Drs. B. S. Fraenkel and Lionel Cohen for X-ray, and Dr. Anna Feilchenfeld, of the Hebrew University, for the infrared results.

THE CHEMISTRY OF ALUMINUM–NITROGEN COMPOUNDS

IV. THE REACTIONS OF Me_3Al AND $H_3Al{:}NMe_3$ WITH SEVERAL TERTIARY POLYAMINES

NEIL R. FETTER AND DONALD W. MOORE[1]

U.S. Naval Ordnance Laboratory, Corona, California

Received August 29, 1963

ABSTRACT

The reactions of Me_3Al with $Me_2N(CH_2)_3NMe_2$, $Me_2NCH_2CH{=}CHCH_2NMe_2$, $(CH_2)_6N_4$, and $(Me_2N)_2C{=}C(NMe_2)_2$ have yielded complexes with two molecules of Me_3Al per amine. The structures of these complexes are rationalized on the basis of a pentacoordinated aluminum atom with a linear N → Al ← N dative bond. The reactions of $H_3Al{:}NMe_3$ with these amines have produced a variety of products in which the amines appear to have undergone rearrangements. The complexes are 1:1 except the $(Me_2N)_2C{=}C(NMe_2)_2$ complex, which has 2 moles of H_3Al per amine.

INTRODUCTION

In this paper are presented further investigations into the proposal made recently (1) that ditertiary amines will form 2:1 complexes with trimethylaluminum whose nitrogen atoms are separated by more than two methylene groups and 1:1 complexes with one or no intervening methylene groups. In our last communication (1) it was stated that $Me_2NCH_2NMe_2$ formed a 1:1 complex while $Me_2N(CH_2)_2NMe_2$ formed a 2:1 complex. We are now reporting the results obtained from the reactions of Me_3Al with $Me_2N(CH_2)_3NMe_2$ and $Me_2NCH_2CH{=}CHCH_2NMe_2$. The latter amine was chosen not only because it contains four carbon atoms between the N—Me_2 groups, but also because we wished to see whether Me_3Al would react with the double bond. We have also treated $H_3Al{:}NMe_3$ with these amines.

The reactions of Me_3Al and $H_3Al{:}NMe_3$ with two unusual tertiary tetramines, namely, hexamethylenetetramine and *tetrakis*-dimethylaminoethylene, have been studied. The n.m.r. spectra of some of these complexes have revealed new structural possibilities for aluminum–nitrogen dative bonded complexes.

EXPERIMENTAL

Apparatus and Reagents

The experimental apparatus and procedures have been described in earlier publications (2, 3). The $Me_2N(CH_2)_3NMe_2$ and the $Me_2NCH_2CH{=}CHCH_2NMe_2$ were supplied by the Ames Laboratories of Milford, Conn., and were used without further purification. The hexamethylenetetramine was Eastman White Label grade and the $(Me_2N)_2C{=}C(NMe_2)_2$, generously donated by the Chemistry Division of the U.S. Naval Ordnance Test Station, was vacuum fractionated once before use. The trimethylaluminum was obtained from the Ethyl Corp., New York, N.Y., and the triethylaluminum was obtained from Texas Alkyls, Houston, Texas. Both of these materials were vacuum distilled before use. All solvents were reagent and were used without further treatment, except benzene which was distilled over CaH_2 and stored in a dry box.

The n.m.r. spectra were obtained with a Varian Associates Model V-4302 spectrometer operating at 60 Mc. Liquid compounds were diluted 10% with benzene and the solid compounds were dissolved in benzene to 15% by weight. All solutions were sealed under vacuum in 5 mm pyrex tubes. All spectra were taken at 30° C unless otherwise noted.

Cryoscopic molecular weight data were obtained in a Bender-Hobein apparatus employing benzene as a solvent. The samples were prepared in a dry box to eliminate moisture contamination. The elemental analyses were performed by the Schwarzkopf Microanalytical Laboratories of Woodside, N.Y.

All melting points are uncorrected.

[1]*Present address: U.S. Naval Ordnance Test Station, China Lake, California.*

Reaction of Trimethylaluminum with N,N,N′,N′-Tetramethylpropanediamine

By vacuum transfer, 2.79 g (21.4 mmole) of $Me_2N(CH_2)_3NMe_2$ was added to 1.54 g (21.4 mmole) of Me_3Al dissolved in 20 ml of *n*-heptane. The reaction was started at −196° C and completed at 25° C. During the warming period (30 minutes) a white precipitate formed and the solvent was then removed by vacuum transfer. The crude product was sublimed (0.05 mm) at 100° C. Elemental analysis of the sublimate (m.p. 158–168° C) agreed with the formula $C_{13}H_{36}N_2Al_2$. Anal. Calc.: C, 56.89; H, 13.22; N, 10.21; Al, 19.66. Found: C, 55.90; H, 12.90; N, 10.53; Al, 20.69.

Methanol hydrolysis of 0.187 g (0.683 mmole) of the sublimate gave 90.2 ml (4.02 mmole) of methane. Yield of sublimate was approximately 65 mole% based on Me_3Al.

Reaction of Aluminum Hydride Trimethylamine with N,N,N′,N′-Tetramethylpropanediamine

When the amine was used as a solvent, 15 g was condensed on 1.58 g (17.8 mmole) of $H_3Al{:}NMe_3$ at −196° C. The mixture was allowed to warm to room temperature, stand overnight, and was then heated at 80° C for 2 hours. During the heating, the $H_3Al{:}NMe_3$ dissolved in the amine and 243.0 ml (10.5 mmole) of NMe_3 evolved. The mixture was cooled to 25° C, the excess amine was removed via vacuum transfer, and the remaining white solid was sublimed at 80° C under 0.05 mm vacuum. Elemental analysis of the sublimate (m.p. 136–140° C) gave results in fair agreement with the formula $C_7H_{21}N_2Al$. Anal. Calc.: C, 52.14; H, 13.13; N, 17.38; Al, 16.73. Found: C, 51.19; H, 12.49; N, 17.37; Al, 15.55.

Methanol hydrolysis of 0.1224 g (0.760 mmole) of the sublimate gave 58.3 ml (2.60 mmole) of hydrogen. Yield of sublimate was 75 mole% based on $H_3Al{:}NMe_3$.

Reaction of Trimethylaluminum with N,N,N′,N′-Tetramethyl-2-butene-1,4-diamine

By vacuum transfer, 1.28 g (9.05 mmole) of $Me_2NCH_2CH{=}CHCH_2NMe_2$ was placed on a solution of 1.27 g (17.6 mmole) of Me_3Al and 20 ml of *n*-heptane at −196° C. When the components melted during the warming to room temperature, a flocculent precipitate formed. After reaching room temperature, the solvent was removed and the crude product was vacuum sublimed at 85° C (0.05 mm). Elemental analysis of the sublimate (m.p. 141–144° C) gave results which agreed with the formula $C_{14}H_{36}N_2Al_2$. Anal. Calc.: C, 58.71; H, 12.67; N, 9.78; Al, 18.83. Found: C, 58.55; H, 12.52; N, 9.75; Al, 18.49.

Methanol hydrolysis of 0.3327 g (1.14 mmole) of the sublimate gave 138.0 ml (5.93 mmole) of methane. Yield of sublimate was approximately 80 mole% based on Me_3Al.

Reaction of Aluminum Hydride Trimethylamine with N,N,N′,N′-Tetramethyl-2-butene-1,4-diamine

By vacuum transfer, 1.04 g (7.35 mmole) of $Me_2NCH_2CH{=}CHCH_2NMe_2$ was added to an *n*-octane solution at −196° C containing 1.52 g (17.0 mmole) of $H_3Al{:}NMe_3$. The mixture was warmed to room temperature and heated with stirring at 40° C for 2 hours. During this period, 18.1 ml (0.807 mmole) of hydrogen evolved and the trimethylamine was recovered as $H_3Al{:}(NMe_3)_2$. The solvent was removed and the crude product was vacuum sublimed at 105° C (0.05 mm). Elemental analysis of the white crystalline sublimate (m.p. 150–155° C) gave results which give closest agreement with the formula $C_9H_{23}N_2Al$. Anal. Calc.: C, 58.03; H, 12.44; N, 15.04; Al, 14.48. Found: C, 58.13; H, 12.49; N, 13.23; Al, 14.51.

Methanol hydrolysis of 0.2174 g (1.16 mmole) of the sublimate yielded 78.8 ml (3.52 mmole) of hydrogen. Yield of sublimate was approximately 50 mole% based on $Me_2NCH_2CH{=}CHCH_2NMe_2$.

Reaction of Trimethylaluminum with Hexamethylenetetramine

By vacuum transfer, 2.12 g (29.0 mmole) of Me_3Al was added to 20 ml of *n*-octane and 2.00 g (14.3 mmole) of $(CH_2)_6N_4$ at −196° C. The mixture was allowed to warm to room temperature and stand for 2 additional hours. At the end of this period the solvent was removed leaving behind a white solid. This material was vacuum sublimed at 90° C (0.05 mm) and elemental analysis of the resulting sublimate (m.p. 146–148° C) gave results which agreed with the formula $C_{12}H_{30}N_4Al_2$. Anal. Calc.: C, 50.69; H, 10.62; N, 19.69; Al, 18.99; Found: C, 50.74; H, 10.58; N, 19.90; Al, 18.87.

Methanol hydrolysis of 0.1785 g (0.625 mmole) of the sublimate gave 82.2 ml (3.67 mmole) of methane. Yield of sublimate was approximately 65% based on Me_3Al.

The above reaction was repeated employing a 4:1 starting ratio of Me_3Al (21.8 mmole) to $(CH_2)_6N_4$ (5.44 mmole), but the sublimate obtained melted at 225–228° C and its elemental analysis agreed with the formula $C_{11}H_{28}N_3Al_2$. Anal. Calc.: C, 51.54; H, 11.00; N, 16.39; Al, 21.07. Found: C, 51.55; H, 11.36; N, 16.39; Al, 21.54.

Methanol hydrolysis of 0.2417 g (0.945 mmole) of $(Me_3Al)_2{:}(CH_2)_5N_3$ yielded 128.2 ml (5.73 mmole) of methane. Yield was approximately 40% based on $(CH_2)_6N_4$. Both products were soluble in benzene.

Reaction of Aluminum Hydride Trimethylamine with Hexamethylenetetramine

A mixture containing 1.70 g (19.1 mmole) of $H_3Al{:}NMe_3$, 1.34 g (9.95 mmole) of $(CH_2)_6N_4$, 15 ml of nonane, and a stirring bar was stirred for 3 days at 25° C. During this period the granules of $(CH_2)_6N_4$ were reduced to a fine powder, and 119.0 ml (5.31 mmole) of NMe_3 evolved. The solvent and a small amount of $H_3Al{:}(NMe_3)_2$ were removed by vacuum transfer leaving a powdery white material. This material could not be vacuum sublimed up to 120° C and would not melt up to 200° C; at this temperature an aluminum mirror appeared on the melting point tube. Elemental analysis of the crude material gave results which agree

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

with the formula $C_6H_{15}N_3Al$. Anal. Calc.: C, 45.90; H, 9.63; N, 26.78; Al, 17.18. Found: C, 46.12; H, 10.26; N, 26.68; Al, 17.29.

Methanol hydrolysis of 0.3407 g (2.17 mmole) of $H_3Al:(CH_2)_6N_3$ yielded 159.2 ml (7.10 mmole) of hydrogen.

Reaction of Trimethylaluminum with Tetrakis-dimethylaminoethylene

By vacuum transfer, 1.91 g (9.60 mmole) of $(Me_2N)_2C{=}C(NMe_2)_2$ was added to 1.35 g (18.8 mmole) of Me_3Al dissolved in 20 ml of heptane at −196° C. The mixture was allowed to warm to room temperature and an immediate precipitation occurred when the components thawed. At room temperature (25°) the solvent was removed under vacuum and the remaining white solid was vacuum sublimed at 60° C (0.05 mm). Elemental analysis of the sublimate (m.p. 141–143° C) gave results which were in fair agreement with the formula $C_{16}H_{42}N_4Al_2$. Anal. Calc.: C, 55.78; H, 12.29; N, 16.27; Al, 15.66. Found: C, 56.75; H, 12.51; N, 16.33; Al, 14.60.

Methanol hydrolysis of 0.6810 g (1.98 mmole) of the sublimate gave 271.0 ml (12.0 mmole) of methane. Yield of sublimate was approximately 75 mole% based on $(Me_2N)_2C{=}C(NMe_2)_2$.

The sublimate was very soluble in benzene, but after standing a few minutes a dense phase separated from solution. The dense phase contained $C_{16}H_{42}N_4Al_2$ and benzene and the light layer contained only benzene. The n.m.r. spectrum of the dense layer is shown in Fig. 1.

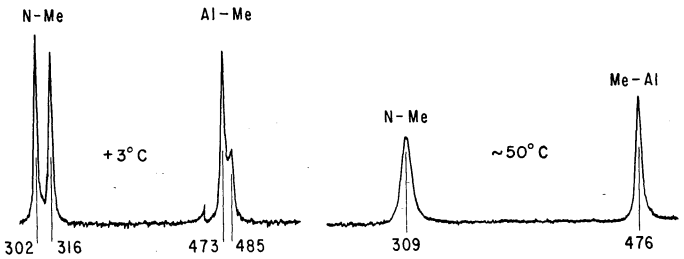

Fig. 1. Nuclear magnetic resonance spectrum of $(Me_3Al)_2{:}(Me_2N)_2C{=}C(NMe_2)_2$.

This compound was found to have another interesting property, namely, exposure of the solid or solutions to even a trace of dry oxygen produced an intense red color. It was also noted that dry solvents such as acetone and methanol developed this color. A benzene solution of 0.597 g (1.73 mmole) of compound was exposed to an atmosphere of dry oxygen for 3 days at 30° C. At the end of this period the material was a viscous red fluid and 58.0 ml (2.59 mmole) of O_2 had been absorbed. Elemental analysis of the oxidized compound gave results which agree most closely with the formula $C_6H_{14}NO_2Al$: Anal. Calc.: C, 45.27; H, 8.86; N, 8.80; O, 20.10; Al, 16.94. Found: C, 42.69; H, 9.35; N, 9.74; O, 20.13; Al, 18.09.

Methanol hydrolysis of 0.0874 g (0.550 mmole) of the oxidized material gave 25.9 ml (1.16 mmole) of methane. The infrared spectrum exhibits a strong absorption at 1690 cm^{-1} and two weaker bands at 912 cm^{-1} and 3420 cm^{-1}. The first of these suggests a $\diagdown\!\!\diagup C{=}O$ absorption and the latter appear to be —OH modes.

The reaction of Me_3Al with $(Me_2N)_2C{=}C(NMe_2)_2$ was repeated with a 4:1 starting ratio of reagents. Using the procedure described above, 1.25 g (6.27 mmole) of $(Me_2N)_2C{=}C(NMe_2)_2$ was mixed with 1.81 g (25.1 mmole) of Me_3Al in heptane. The solvent and any unreacted Me_3Al were removed and the crude product was vacuum sublimed at 95° C.

Elemental analysis of the sublimate (m.p. 58–68° C) gave results which agree most closely with the formula $C_{14}H_{36}N_4Al_2$: Anal. Calc.: C, 53.46; H, 11.54; N, 17.81; Al, 17.15. Found: C, 53.98; H, 11.88; N, 17.70; Al, 17.17.

Methanol hydrolysis of 0.3108 g (0.987 mmole) of the sublimate yielded 108.2 ml (4.85 mmole) of methane. The infrared spectrum exhibits a weak band at 1800 cm^{-1}, indicating the presence of ethylenic bonds.

Reaction of Aluminum Hydride Trimethylamine with Tetrakis-dimethylaminoethylene

This reaction is not as simple as the two described above. Some of the $H_3Al{:}NMe_3$ is consumed by the formation of $H_3Al{:}(NMe_3)_2$ and the elemental analysis of the sublimed product suggests some rearrangement may occur during sublimation.

When 20 ml of *n*-octane was used as the solvent, 3.25 g (16.3 mmole) of $(Me_2N)_2C{=}C(NMe_2)_2$ was transferred to a solution at −196° C containing 1.45 g (16.3 mmole) of $H_3Al{:}NMe_3$. The mixture was allowed to warm to room temperature and it was then heated at 40° C for 3 hours. No hydrogen or trimethylamine evolution was observed; however, considerable $H_3Al{:}(NMe_3)_2$ was present in the solvent removed from the mixture. Also the infrared spectrum of the solvent showed the presence of unreacted $(Me_2N)_2C{=}C(NMe_2)_2$. After removal of the solvent, $H_3Al{:}(NMe_3)_2$, and $(Me_2N)_2C{=}C(NMe_2)_2$, a white powdery material remained which was vacuum sublimed at 75° C. Sublimation at this temperature is slow, but, if the temperature is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

raised, discoloration of the crude product commences. Elemental analysis of the sublimate gave results which most closely fit the formula $C_{15}H_{40}N_4Al$. Anal. Calc.: C, 51.54; H, 12.21; N, 16.97; Al, 16.34. Found: C, 52.97; H, 12.04; N, 18.18; Al, 16.20.

Methanol hydrolysis of 0.2138 g (0.647 mmole $(H_3Al)_2C_{15}H_{34}N_4$) gave 108.0 ml (4.83 mmole) of hydrogen. Exposure to oxygen produced no color change.

RESULTS AND DISCUSSION

As can be seen from the experimental data presented, $Me_2N(CH_2)_3NMe_2$ and $Me_2NCH_2CH{=}CHCH_2NMe_2$ react with Me_3Al, to form the 2 to 1 complexes $Me_3Al{:}Me_2N(CH_2)_3NMe_2{:}AlMe_3$ and $Me_3Al{:}Me_2NCH_2CH{=}CHCH_2NMe_2{:}AlMe_3$. The double bond in the latter complex does not appear to be involved with the trimethylaluminum, because the n.m.r. spectrum shows both the Al—Me and N—Me protons as sharp single peaks and no other unusual proton bands for the amine. (N—Me, τ = 8.07 p.p.m.; Al—Me, τ = 10.46 p.p.m.).

TABLE I

Molecular weights of several Me_3Al – tertiary amine complexes

Compound	Molecular weight		Degree of association	Solution molality
	Found	Calc.		
1. $Me_3Al{:}Me_2NNMe_2$*	164	160.3	1.02	.0675
2. $Me_3Al{:}Me_2NCH_2NMe_2$	246	174.3	1.41	.0491
	232		1.33	.0505
3. $(Me_3Al)_2{:}Me_2N(CH_2)_2NMe_2$	359	260.4	1.38	.0690

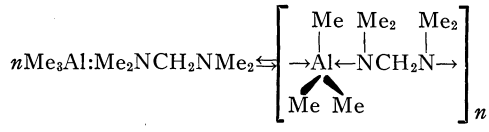
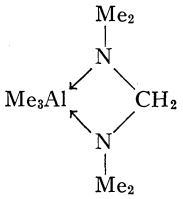
*Measured in cyclohexane.

The cryoscopic molecular weights of the trimethylaluminum–amine complexes from tetramethylhydrazine to N,N,N′,N′-tetramethyl-2-butene-1,4-diamine, where the intervening carbon atoms range from zero through four, are presented in Table I. It will be noted that with the exception of $Me_3Al{:}Me_2NNMe_2$, which appears to be monomeric, there is a trend toward monomeric character as the number of intervening carbon atoms increases. This pattern of association suggests that $Me_3Al{:}Me_2NCH_2NMe_2$ may be in rapid equilibrium with a species involving a pentacoordinated aluminum atom:



Such a scheme is a better rationalization of both n.m.r. and molecular weight data, than is the cyclic structure

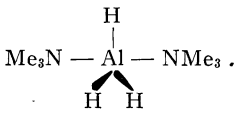


Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

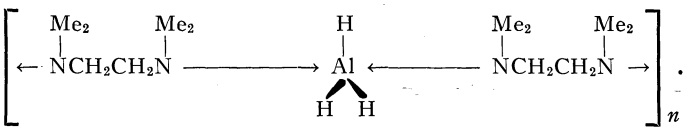
proposed earlier (1); however, the third complex in Table I must be associated in a different manner because there is a Me_3Al on each amino nitrogen atom. Within experimental error ($\pm 10\%$) the fourth, fifth, and sixth complexes are monomeric.

Although the analytical data are poorer, it appears that H_3Al forms only 1:1 complexes with $Me_2N(CH_2)_3NMe_2$ and $Me_2NCH_2CH{=}CHCH_2NMe_2$. These results fall into the pattern established for $Me_2NCH_2NMe_2$ and $Me_2N(CH_2)_2NMe_2$ complexes of AlH_3. All of these complexes are insoluble in hydrocarbons and it has been difficult to obtain n.m.r. and cryoscopic molecular weight data.

A clue to the possible structure of the polyamine complexes with aluminum hydride and trimethylaluminum has been provided by a recent publication of Heitsch, Nordman, and Parry (4), and by the preliminary data of Palenik (5). The former authors have reported that $H_3Al{:}(NM_3)_2$ in the crystal state is a monomer with a trigonal bipyramidal structure and a linear N—Al—N bond:

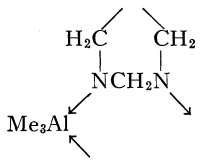


The work of Palenik indicates the complex $H_3Al{:}Me_2N(CH_2)_2NMe_2$ has a similar structure with a unit cell containing eight dimer units:



Since all the aluminum hydride – amine complexes are 1:1, the structure proposed for the aluminum hydride – N,N,N,′N′-tetramethylethylenediamine may be assumed to apply to the complexes with $Me_2NCH_2NMe_2$, $Me_2N(CH_2)_3NMe_2$, and $Me_2NCH_2CH{=}CHCH_2NMe_2$.

The trimethylaluminum complexes present a different problem because some are 1:1 and others are 2:1. The linear structure for $Me_3Al{:}Me_2NCH_2NMe_2$ has already been proposed above to rationalize both molecular weight and n.m.r. data. The n.m.r. spectrum of $(Me_3Al)_2{:}(CH_2)_6N_4$ may also be explained by considering hexamethylenetetramine to be similar to $Me_2NCH_2NMe_2$ or by considering it to be a series of $—CH_2NCH_2NCH_2—$ groups. If the Me_3Al molecules, which are datively bonded to the nitrogen atoms, are pentacoordinated and if the bonds are oscillating rapidly among all possible positions, then the n.m.r. spectrum in Fig. 2 and the 2:1 stoichiometry are compatible. The hexamethylenetetramine–trimethylaluminum complex may be illustrated as follows:



employing one-half of an amine molecule and one Me_3Al molecule. It should be noted that the monomeric molecular weight shown in Table I for this complex does not appear consistent with the bonding scheme proposed above and this discrepancy cannot be readily explained since the n.m.r. sample concentration was approximately 10 times greater than those used for the molecular weight determinations.

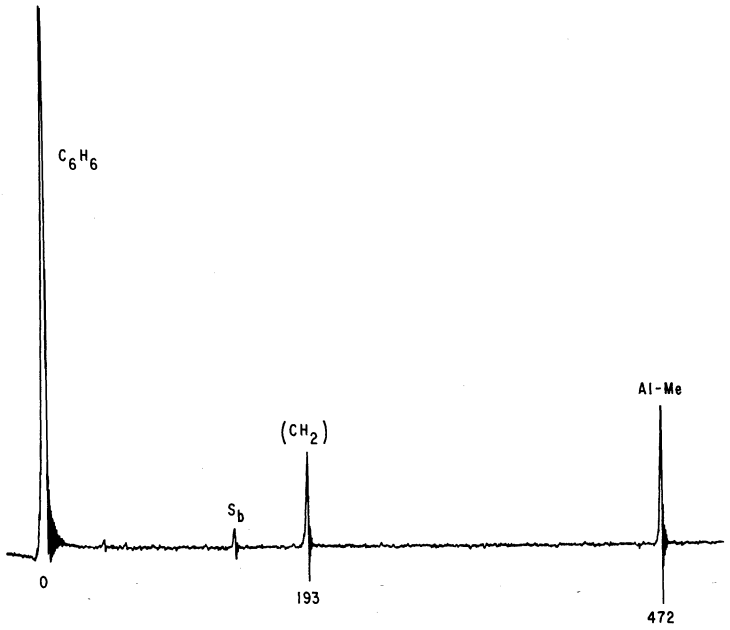

Fig. 2. Nuclear magnetic resonance spectrum of $(Me_3Al)_2{:}(CH_2)_6N_4$.

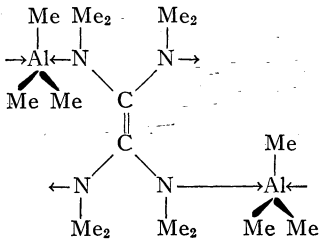
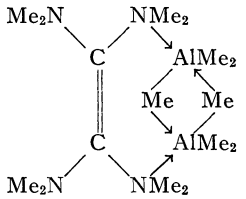
If *tetrakis*-dimethylaminoethylene is considered to be two $Me_2N—C—NMe_2$ groups connected by a double bond at the center carbon atoms, then the bonding proposed for $Me_3Al{:}Me_2NCH_2NMe_2$ could also apply to this complex. A structure of the type



would be consistent with the n.m.r. data at 50° C, for if all Al ← N dative bonds are equivalent, then all Al—Me protons are identical and so are all N—Me protons. The structure of the complex at 5° C may be

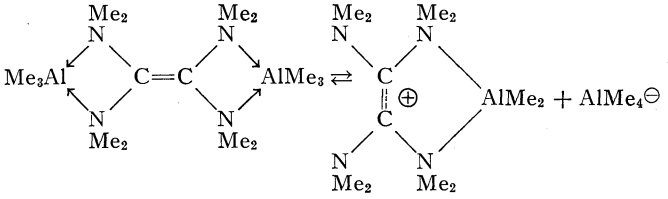


to give the proper number and area ratios to the n.m.r. peaks shown in Fig. 1.

Since n.m.r. is the only technique employed to characterize this complex, it should be noted that other structures are consistent with the observed spectra. An equilibrium

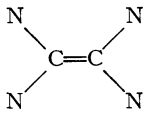
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

involving a species recently described by Wiberg and Buchler (6) for the boron trifluoride – *tetrakis*-dimethylaminoethylene complex would also fit the n.m.r. data:



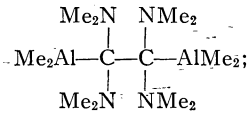
I

and they may also be explained by a structure similar to I in which the system is planar and each $AlMe_3$ molecule is situated above this plane over a pair of nitrogen atoms.



If such a bonding system were "frozen" the protons are in a position such that they may produce the n.m.r. spectrum observed at 5° C. As the Al ← N dative bond system "thaws" and bond rotation is possible, the N—Me protons become identical and so do the Al—Me protons. The selection of the correct structure may be possible from a single crystal X-ray examination.

An anomalous reaction was observed between Me_3Al and $(Me_2N)_2C{=}C(NMe_2)_2$ when the starting ratio of Me_3Al to amine was increased to 4 to 1. Although no methane or ethane was observed, the analysis of the sublimate indicated a formula in which a 2 to 1 complex had formed, but which contained two methyl groups less than that needed for the dative-bonded complex. The structure of such a compound could be



however, structural confirmation must await further study.

Although no n.m.r. spectrum of the aluminum hydride – *tetrakis*-dimethylaminoethylene complex could be made, the elemental analysis indicates a higher carbon content than is required for the simple 2 to 1 complex. Since hydrolysis shows only active hydrogen, the amine appears to have undergone a change which as yet has not been characterized. It should be noted that the aluminum hydride – N,N,N,′N′-tetramethyl-2-butene-1,4-diamine complex also has a high carbon value for the 1 to 1 complex. In this case hydrolysis also showed only active hydrogen. Again, it appears the amine may have undergone rearrangement.

The reaction of $H_3Al{:}NMe_3$ with hexamethylenetetramine appears to have disrupted the amine, because the elemental analysis, for a 1 to 1 complex, agrees best with a formula which is minus one nitrogen atom. The amine also appears to have changed when the starting ratio of Me_3Al to amine is raised to 4 to 1. In this case the analysis of the sublimed product agrees best with a formula which is short one methylene or methyl group and a nitrogen atom. Possible formulas may be $(Me_3Al)_2{:}(CH_2)_5N_3$ or $(Me_3Al){:}(Me_2Al—)(CH_2)_6N_3$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

This brief study of AlH_3 and Me_3Al amine complexes has posed a few questions which we hope to answer by further investigations. One of these is, why does AlH_3 form only 1 to 1 complexes with amines which are separated by as many as three or four carbon atoms whereas $AlMe_3$ forms 2 to 1 complexes? The linear bonding scheme proposed above would favor 1 to 1 complexing because of the apparent higher stability of the pentacoordinated aluminum atom. However, the fact that $H_3Al{:}NMe_3$ and Me_3Al are employed as starting compounds may have some influence upon the product formed. Repeating this series of reactions with $Me_3Al{:}NMe_3$ may cast some light on this problem. Also, repeating the reactions with bulkier aluminum alkyls may indicate whether steric effects have an influence on stoichiometry.

THE CONFORMATIONS IN SOLUTION OF *trans*-CYCLOHEXENE DIHALIDES AND *cis*- AND *trans*-1,2-CYCLOHEXANEDIOLS AND DERIVATIVES

R. U. LEMIEUX AND J. W. LOWN[1]

The Department of Chemistry, University of Alberta, Edmonton, Alberta

Received September 20, 1963

ABSTRACT

trans-1,4,4-Trideuteriocyclohexene dichloride, dibromide, and diiodide and the 1,4,4-trideuterio-*cis*- and *trans*-1,2-cyclohexanediols together with their *O*-acetyl, *O*-tosyl, and *O*-isopropylidene derivatives were synthesized. Their nuclear magnetic resonance (NMR) spectral parameters were obtained with a spectrometer operating at 100 Mc.p.s. and employing double irradiation to establish the chemical shifts and the signs of the coupling constants. The interpretation of the data according to expectations based on the Karplus relationship, for dihedral angles and coupling constants, support the conformational equilibria assigned to the *trans*-dichloride and *trans*-dibromide of cyclohexene on the basis of dipole moment measurements (previously published results). The results indicate that *trans*-cyclohexene diiodide exists to about 84% in the diaxial conformation. In the case of the 1,2-cis-disubstituted cyclohexanes, the occurrence of the signal for the 3-hydrogen in trans relation to the 2-hydrogen at lower field than its geminal 3-hydrogen is assigned to the deshielding influence on the 3-hydrogen when in axial orientation by an opposing axial oxygen at the 1-position. Support for this contention was obtained by determination of the chemical shifts of the geminal hydrogens at the 3- and 5-positions of the *cis*- and *trans*-4-*t*-butyl-2,2,6,6-tetradeuterio-1-methylcyclohexanols. The conformational equilibria indicated for the 1,2-diol, 1,2-diacetoxy, and 1,2-ditosyloxy trans derivatives of 1,4,4-trideuteriocyclohexane by NMR parameters obtained from the spectrum of the *O*-isopropylidene derivatives of the *trans*-diol allowed conclusions regarding the non-bonded interaction energies involved. The Karplus relation had to be adjusted to the form, $J_\phi = 14.7 \cos^2\phi - 0.2$ (0°–ϕ–90°) and $J_\phi = 11.2 \cos^2\phi - 0.2$ (90°–ϕ–180°), to accommodate the results. Solvent effects on conformation are noted. Also, the investigation provided further evidence for the opposite signs of the coupling constants for geminal and vicinal hydrogens. A consideration of the chemical shifts observed for a variety of derivatives of cyclohexanol appears to indicate that intramolecular shielding effects are better accounted for on the basis of neighboring atomic groupings than on the basis of individual chemical bonds.

Attempts have been made previously to study the conformational equilibria of the *trans*-cyclohexene dihalides in benzene solution by the measurement of dipole moments (1) and by observation of the chemical shifts of protons adjacent to the halogen atoms (2). Both of these methods suffer from disadvantages; in the first, it is impossible to estimate the molecular dipole in the diaxial conformation, i.e. of allowing for dipolar contributions from the cyclohexane skeleton (3). The second method requires the assumption that the usual orientational effects on chemical shifts apply (4, 5). This latter assumption, as it transpired, proved to be justified in the case of the *trans*-dihalides but could not have been foreseen and would not have applied to the series of *cis*-1,2-cyclohexane derivatives. Moreover, it would be impossible to study the conformational equilibrium of the diiodide by the dipole method since this compound exists in solution in chemical equilibrium with cyclohexene and iodine. A more attractive approach was to use nuclear magnetic resonance (NMR) spectroscopy to measure appropriate coupling constants. By preparing specifically deuterium-labelled cyclohexene, the NMR spectra of the dihalides could be simplified sufficiently to measure coupling constants which could then be related by the Karplus (6) expression to the corresponding dihedral angles. The actual shape of the molecules could then be examined. It was realized that the theoretical Karplus

[1]*University of Alberta, Postdoctoral Fellow, 1961–62.*

relation, which has been supported by experimental observations (7), has its own limitations (8, 9). However, it was thought to be of interest to show that the two procedures afforded consistent results. This was found to be the case and in addition the NMR coupling constant method gave information on the conformational equilibrium of the diiodide. The method also appeared to provide interesting new insight on ring distortions, conformational equilibria, solvent effects, and orientation effects on chemical shift in the case of the *cis*- and *trans*-1,2-cyclohexanediols and their *O*-acetyl, *O*-tosyl, *O*-*p*-toluenesulphonate, and *O*-isopropylidene derivatives.

1,4,4-Trideuteriocyclohexene was selected as a suitable starting material for the preparation of the corresponding *trans*-dihalides and *cis*- and *trans*-glycols. These afford spectra of the ABX type (10) arising from the protons at the 2,3,3-positions. It turned out that the paramagnetic shift of the substituent at the 2-position on the 2-proton was always sufficient to render the ABX approximation valid. Analysis of the ABX spectra then gave the conformationally averaged coupling constants J_{AX} and J_{BX} from which the dihedral angles could be deduced. Except for the diacetate, the trans compounds gave spectra in good approximation to the AMX type (11).

Cyclohexane-1,4-dione was reduced in tetrahydrofuran with lithium aluminum deuteride, and the resulting 1,4-dideuteriocyclohexane-1,4-diols were dehydrated over alumina (12) to provide 1,4-dideuterio-1,4-epoxycyclohexane, which produced virtually no detectable signal (at 4.6 p.p.m. from internal tetramethylsilane) in the NMR spectrum for hydrogens at the 1- and 4-positions. The maximum hydrogen content at these positions was estimated to be 5%. The epoxide was cleaved in 87% yield to the 1,4-dideuterio-*trans*-4-bromocyclohexanol using hydrogen bromide in diethyl ether at room temperature. Again the NMR spectrum was devoid of signals (at 3.7 and 4.1 p.p.m.) for hydrogens at the 1- and 4-positions. This reaction was found to be much cleaner than that involving the direct action of hydrogen chloride to the epoxide (12). The bromine atom was replaced by deuterium through very rapid deuterolysis in the presence of a palladium-on-charcoal catalyst in methanol containing sodium methoxide. It is noteworthy that no difference in the deuterium content of the product was observed when methanol-*O*-*d* was used as solvent. The resulting 1,4,4-trideuteriocyclohexanol showed no detectable absorption at the position in the NMR spectrum for the 1-hydrogen of cyclohexanol.

Recently, Premuzic and Reeves (13) described the preparation of 1,3,3-trideuteriocyclohexene by the conventional dehydration of 2,2,6,6-tetradeuteriocyclohexanol with orthophosphoric acid, but gave no indication of the extent of deuteration of the product. A similar trial dehydration of our 1,4,4-trideuteriocyclohexanol resulted in complete loss of deuterium by acid-catalyzed exchange, so that this method was abandoned in favor of base-catalyzed cleavage of the tosylate. The *O*-tosyl derivative of the alcohol was treated with potassium hydroxide in dry diethylene glycol to yield 1,4,4-trideuteriocyclohexene (I). Gas–liquid partition chromatography showed the presence of cyclohexene only and integration of the NMR spectrum showed the relative intensities of the ethylenic and methylenic hydrogens to be 1:5.8 (expected for I, 1:6). The spectrum (see Fig. 1) clearly required that the reductions in the intensities of the signals relative to those in cyclohexene be at the 1- and 4-positions. Compound I was converted to the dichloride and the dibromide by halogenations in benzene. The diiodide was prepared by mixing equimolar amounts of I and iodine at about −70°. On warming of the mixture to room temperature, the iodine had dissolved and the resulting mixture was taken up in benzene for the NMR experiment. The *cis*-diol was prepared by osmium tetraoxide oxidation in pyridine (14) and decomposition of the osmiate with sodium bisulphite (15).

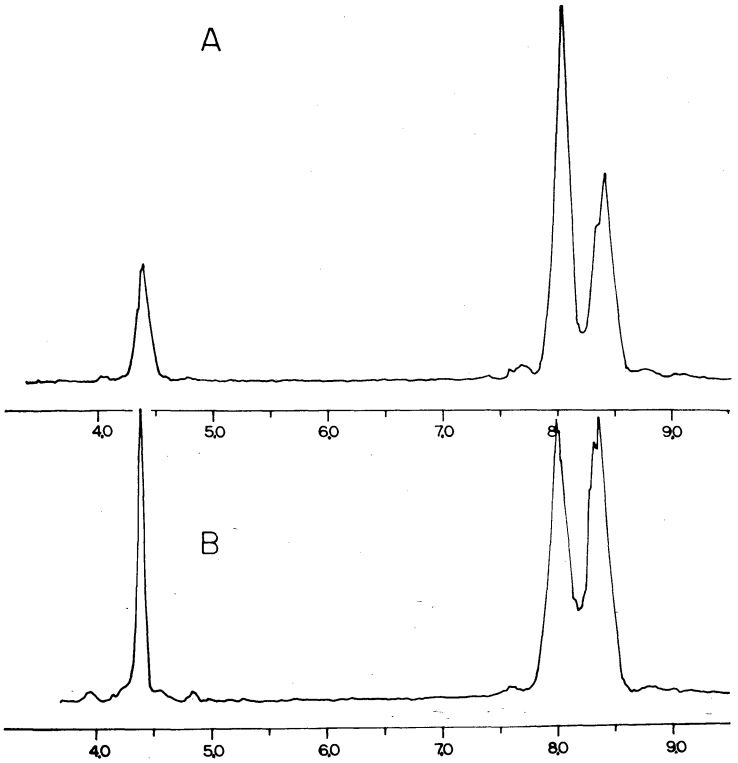

FIG. 1. (A) 1,4,4-Trideuteriocyclohexene. (B) Cyclohexene. Both 5% solutions in CCl_4 at 60 Mc.p.s. with tetramethylsilane (1%) as internal reference. The scale is in τ units.

Performic acid oxidation followed by hydrolysis gave the *trans*-diol (14). Each spectrum showed a clearly resolved triplet or quartet due to the X-proton (which was broadened by neighboring deuterium coupling) but a direct ABX analysis was not possible owing to the overlap of the AB signals by the equivalent protons at the 6-position. The ABX parameters could, however, be determined by the spin decoupling or double resonance method (16–19).

By this means it could be shown that the X-proton was coupled to two and only two other protons at higher field in the methylene envelope, thereby confirming the structures. By measuring the decoupling frequencies, the chemical shifts of the A- and B-protons could be found within two cycles per second. Spin decoupling has been used with considerable success in assigning relative signs of coupling constants in spectra which approximate to first order (16, 17). In view of the theoretical interest in the relative signs of the vicinal and geminal couplings (20–22), it was of interest to determine the relative signs of the coupling constants in these systems. This refinement had added advantages in that it provided an additional consistency check on the measured decoupling frequencies and allowed a rationalization of those experiments (see below) where anomalous double resonance effects occurred owing to a small AB chemical shift as described by Freeman (23). Also the method provided a reasonable estimate of the third coupling constant J_{AB} and so provided all the spectral parameters including the relative signs of the coupling constants. Thus, it was possible to derive better approximations to the true coupling constants and chemical shifts by iterative calculations of theoretical spectra. By using

For personal use only.

the values for the coupling constants and chemical shifts to predict the appearance of the experimentally observable X-part of the ABX spectrum at both 60 and 100 Mc.p.s., an additional check on the accuracy of the derived parameters was obtained.

Valuable qualitative information is obtained directly by this selective decoupling of the individual groups of A and B transitions in that one can tell from the appearance of a decoupled quartet which proton, high field or low field (B or A by definition), gives rise to the larger coupling.

Spin decoupling may be carried out with the integrator of the Varian 100 Mc.p.s. spectrometer (24). The observed frequency difference, Δw, which produces optimum decoupling is not exactly equal to the chemical shift difference of the two spin-decoupled nuclei. Anderson and Freeman (25) have shown that, for two sets of nuclei whose chemical shifts are w_A and w_X, the condition for optimum decoupling is given by the expression,

$$\Delta w = w_A - w_X - (\gamma H_2)^2/2(w_A - w_X),$$

where H_2 is the decoupling radio-frequency field strength and γ is the magnetogyric ratio of the proton. For nuclei with large relative chemical shifts such as are considered here the correction term $(\gamma H_2)^2/2(w_A - w_X)$ is small and $\Delta w \simeq (w_A - w_X)$. An estimate of the magnitude of the correction to be made in the least favorable case gave a value of 0.2 c.p.s., which was considered negligible.

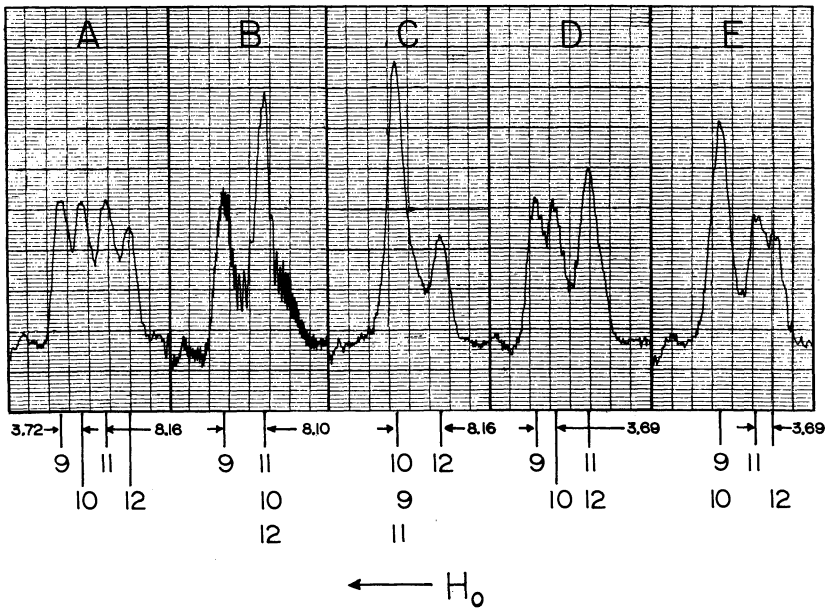

FIG. 2. The signal for the 2-hydrogen (X-part) of *trans*-1,4,4-trideuteriocyclohexene dichloride, taken at 100 Mc.p.s. in benzene at room temperature, showing the effects of double irradiation performed with first lower sideband. (A) Single resonance spectrum. (B) With double irradiation frequency at 239.8 c.p.s. (C) With double irradiation frequency at 223.7 c.p.s. (D) With double irradiation frequency at 179.8 c.p.s. (E) With double irradiation frequency at 160.8 c.p.s.

It was anticipated that the geminal coupling J_{AB} would be large, ca. 12 c.p.s., and experience showed that δ_{AB} was about 50 c.p.s. for the *trans*-dihalides at 100 Mc.p.s. Consequently, the general appearance of the ABX spectra would be three widely separated sets of quartets. For reference purposes, the 12 transitions are numbered with decreasing

For personal use only.

field from 1 to 12. The possibility arises of irradiating the branches of the A- and B-quartets selectively so that four decoupling frequencies are measured. The relative signs of the coupling constants may be deduced from the appearance of the decoupled multiplet (18). The determination of relative signs of coupling constants in this way is illustrated by the appearance of the X-proton quartet of the *trans*-dichloride in Fig. 2. It can be seen from Fig. 2 that when the largest decoupling frequency, which must necessarily correspond to the 1- and 2-transitions, is employed there resulted a collapse of lines 10 and 12. The next lowest decoupling frequency irradiates the 3- and 4-transitions and caused the collapse of lines 9 and 11. This showed that J_{AX} and J_{AB} are of opposite sign and also that J_{BX} is greater than J_{AX}. This result is in accordance with the usual orientational effects on chemical shifts in 6-membered rings (4). A similar experiment carried out by irradiating in the region of the A-nucleus confirmed that J_{AB} and J_{BX} are opposite in sign and that J_{AX} was the smaller constant. It thus followed that, as expected (20–23), the signs of the coupling constants for vicinal hydrogens were opposite to that for the geminal hydrogens.

It follows that the four decoupling frequencies observed will be given by the following expressions:—

Lines irradiated		Decoupling frequency (c.p.s.)	
1 and 2		$\delta_{BX} + \frac{J_{AB}}{2} + \frac{J_{AX}}{2}$	(1)
	B-quartet		
3 and 4		$\delta_{BX} - \frac{J_{AB}}{2} - \frac{J_{AX}}{2}$	(2)
5 and 6		$\delta_{AX} + \frac{J_{AB}}{2} + \frac{J_{BX}}{2}$	(3)
	A-quartet		
7 and 8		$\delta_{AX} - \frac{J_{AB}}{2} - \frac{J_{BX}}{2}$	(4)

where δ_{BX} etc. represent the chemical shifts in c.p.s. Therefore, the difference between expressions 1 and 2 equals $J_{AB}+J_{AX}$; similarly the difference between expressions 3 and 4 equals $J_{AB}+J_{AX}$. It can be shown that the calculated separations of the X-quartet are very insensitive to the magnitude of J_{AB}, therefore an estimate of J_{AB} could be obtained from the differences in decoupling frequencies by subtracting the corresponding spacings of the quartet measured at 100 Mc.p.s.

Thus, two estimates of J_{AB} are obtained from decoupling of the B- and A-protons, respectively. Now by substituting the approximate values of J_{AB}, J_{AX}, and J_{BX} in equations 1 to 4, values could be obtained for the positions of the four branch lines of the unperturbed AB-quartet, the simple AB analysis then furnished the chemical shifts of the A- and B-protons.

It is seen from Tables I and II that the chemical shifts of the A-, B-, and X-protons were usually large. However, for certain compounds, particularly the *trans*-diacetate and the *cis-O*-isopropylidene compounds, δ_{AB} was quite small. Consequently, transitions 3 and 4, and 5 and 6, of the ABX spectrum tended to overlap or at least be so close together that irradiation of transitions 5 and 6, for example, tended to perturb transitions 3 and 4 (26). Thus, no precise decoupling frequencies could be measured in this region of the spectrum. However, clear-cut spin decoupling was achieved at the outer regions, that is, by irradiation of transitions 1 and 2 of the B-proton and transitions 7 and 8 of the A-proton. The values for δ_A and δ_B were then derived by using the value for J_{AB} obtained

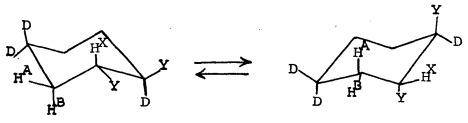
for the isomers. It was found that the calculated values for J_{AX} and J_{BX} were quite insensitive to the value of J_{AB} in the range 11 to 12 c.p.s.

$$nJ_{aa} + (1-n)J_{ee} = J_{BX} \quad (5)$$

$$nJ_{ae} + (1-n)J_{ea} = J_{AX} \quad (6)$$



II III

The NMR results obtained for the *trans*-dihalides allow the following conclusions to be drawn. With respect to their relative magnitudes, J_{AX} and J_{BX} represent the weighted averages of the coupling constants for the *cis*- and *trans*-hydrogens, respectively (equations 5 and 6). Judging from structurally closely related compounds wherein the halogens (Y) are axial, only the chair conformations II and III need be considered (27). Bender, Flowers, and Goering (1) have estimated by dipole moment studies that the fraction, n, in the diequatorial form (II) is 0.75 and 0.43 for the dichloride and dibromide, respectively. Substitution of these values for n and the appropriate values for J_{AX} and J_{BX}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

given in Table I into expressions 5 and 6 provides the values $J_{aa} = 10.2$, $J_{ee} = 2.04$, $J_{ae} = 3.74$, and $J_{ea} = 3.66$ c.p.s. These values are in excellent agreement with those to be expected (28) and thus provide confirmation of the significance attached to the dipole moment data. To the extent to which the results from the two methods are in agreement, the assumption that the cyclohexane skeleton makes a negligible contribution to the molecular dipole in the diaxial conformation is justified (1, 3).

Substitution of the above values for J_{aa} and J_{ee} and the value for J_{BX} obtained from the diiodide in equation 5 suggests that this compound exists in benzene at room temperature to an extent of about 84% in the conformation wherein both iodines are in axial orientation. Since the chemical shift for the A- and B-hydrogens (44 c.p.s.) is more than three times greater than J_{AB} the condition is met that the triplet is not degenerate and J_{AX} does equal J_{BX} (29). It is pertinent in this regard that the coupling constant of the 1-hydrogen with the vicinal hydrogens in a number of 2,6-disubstituted cyclohexyl iodides were found (30) to be of the magnitude (necessarily greater than the observed spacings, 9 and 2.5 c.p.s., for hydrogens in trans and gauche relations, respectively) expected on the basis of the present results.

It must be noted that the NMR data taken together with the dipole moment data can only indicate that the hydrogens at the 1- and 2-positions of the *trans*-1,2-dihalogenocyclohexanes are both well staggered with the hydrogens on the vicinal carbon atoms when the halogens are in axial orientation (III). It seems likely that the erection of the halogens into axial orientation to achieve conformation III will cause some distortion of the opposite side of the ring in the direction which will increase the internuclear distance between the halogens and the opposing axial hydrogens. This condition seems likely in view of the results, discussed below, obtained with the di-*O*-tosyl-*cis*-1,2-cyclohexanediol.

TABLE III

Effect of solvent on the conformational equilibria for *trans*-cyclohexene dihalides

Having established the close correspondence between the results obtained from the dipole moment and NMR studies, it would be predicted that the conformationally averaged spacings would be dependent on the dielectric constant of the solvent. The greater the dielectric constant the greater should be the population of the more polar diequatorial conformation (II). Accordingly, the spacings of the X-quartet for the dichloride and the dibromide dissolved in a number of solvents were determined at

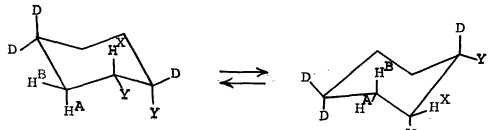
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

60 Mc.p.s. (Table III). Since it has been established that the spectra in benzene are close to the AMX type, the spacings can be expected to be approximately equal to J_{AX} and J_{BX}. On this basis, the values for the fraction n of the compounds in the diequatorial conformation II were estimated. It is seen that the quantitative prediction is borne out and illustrates the advantage of the NMR technique for the study of conformational equilibria in highly polar solvents (31).

An inspection of a conformational Barton model allows the conclusion that the dihedral angles defined by the 2-hydrogen of *O*-isopropylidene-*trans*-1,2-cyclohexanediol with the hydrogens at the 3-position are very close to 60° and 180°. Therefore it was concluded from the data in Table III that for this compound $J_{AX} = J_{60°} = 3.5$ c.p.s. and $J_{BX} = J_{180°} = 11.0$ c.p.s. These values are in excellent agreement with those observed by Anet for similar groupings in cyclohexane rings (28). The above value for $J_{60°}$ requires an upward displacement in this region of the original Karplus curve (6) by 1.65 c.p.s. A simple upward displacement of the whole curve would yield $J_{90°} = 1.37$ c.p.s., a value which is not acceptable in view of the evidence that $J_{90°}$ invariably is very small (6, 7, 32).

For the cis compounds listed in Table III, the observed coupling constants must represent the average coupling of the *cis*- and *trans*-3-hydrogens with the 2-hydrogen, respectively, in the two energetically equivalent chair conformations IV and V. Therefore,

$$J_{ae}+J_{ea} = 2J_{BX} \text{ and } J_{aa}+J_{ee} = 2J_{AX}.$$



IV V

In view of the near linearity of the Karplus curve in the vicinity of 60°, the sum $J_{ee}+J_{ea}$ should be near constant, and J_{aa}, being only slightly dependent upon dihedral angle in the region 170° to 180°, should have very nearly the same value for all the compounds. Therefore, assuming $J_{ae} = J_{60°} = 3.5$ c.p.s. and $J_{aa} = J_{180°} = 11.0$ c.p.s. it would be expected that for the cis compounds,

$$J_{AX}+J_{BX} = (J_{180°}+3J_{60°})/2 = 10.75 \text{ c.p.s.}$$

It is seen in Table II that the values found for $J_{AX}+J_{BX}$ are in excellent general agreement with this expectation. Evidence has been obtained that the cis compounds exist in solution in the chair forms (33). The slight difference between the shift for unbonded and bonded hydroxyl infrared frequency of 39 cm^{-1} for the *cis*-diol and 32 cm^{-1} for the trans isomer has been ascribed (34) to deformation of the cis compound from the perfect chair. The hydroxyl groups are said to be able to approach each other more readily in the *cis*- than in the *trans*-diol. A similar explanation has been advanced to explain the slightly greater reactivity of the *cis*-diol towards cleavage by lead tetraacetate (35).

Should the cis compounds exist in undistorted chair forms, one would expect $J_{AX} = 7.25$ c.p.s. and $J_{BX} = 3.5$ c.p.s. Indeed, values very close to these were found in the case of the *cis*-diacetate and of the *cis*-diol when dissolved in chloroform. However, the high value for $J_{BX} = 4.1$ c.p.s. and the low value for $J_{AX} = 6.7$ c.p.s. for the *cis*-diol when dissolved in deuterium oxide infer appreciable distortion of the chair for this compound in aqueous solution. The result, as expected, seems best explained on the basis of a dihedral angle of less than 60° for the oxygen atoms. However, it is to be noted that the distortion is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

probably related to the hydration of the hydroxyl groups rather than simple intramolecular hydrogen bonding since the distortion was not present for the compound dissolved in chloroform. Thus, the apparent ring distortion brought on by intramolecular hydrogen bonding when the compound is dissolved at high dilution in carbon tetrachloride (34) must be imposed on the molecule by the state of dilution which has rendered intermolecular hydrogen bonding unfavorable.

The value, 5.4 c.p.s., found for both J_{AX} and J_{BX} in the case of the *cis*-isopropylidene compound requires considerable distortion of the cyclohexane ring (36, 37). Because of unusually strong deuterium broadening of the signal, these coupling constants are not known to better than ± 0.2 c.p.s. Should expressions of the type proposed by Karplus allow an interpretation of these results, in view of the data contained in Table II and the above considerations regarding $J_{90°}$, the following expressions are indicated.

$$J_\phi = 14.7 \cos^2\phi - 0.2 \quad (0° \leq \phi \leq 90°), \tag{7}$$

and

$$J_\phi = 11.2 \cos^2\phi - 0.2 \quad (90° \leq \phi \leq 180°). \tag{8}$$

On this basis, with $\phi_{ae} = \phi_{ea} = 50°$, $\phi_{aa} = 170°$, and $\phi_{ee} = 70°$, the values $J_{AX} = J_{BX} = 5.9$ c.p.s. are obtained. Although these values are in reasonably close agreement with those determined experimentally, a somewhat greater distortion was anticipated on the basis of a conformational model.

The values for J_{AX} and J_{BX} found for the ditosylate appear to require $J_{ee} > J_{60°}$ and $J_{ea} < J_{60°}$. The only distortion apparent from a study of conformational models that can provide such a condition is that wherein the 3-, 4-, and 5-carbons have moved toward coplanarity with the 1-carbon (the position of the axial tosyloxy group). Such a distortion is plausible since it provides a relief of the congestion between the axial tosyloxy group and the opposing axial hydrogens.

The values of J_{BX} ($\simeq J_{aa}$) for the *trans*-diol when dissolved in chloroform and deuterium oxide require the compound to exist almost entirely in the diequatorial orientation in both solvents. This situation could not necessarily be anticipated from the published values for the non-bonded interaction energies involved. The experimentally determined free-energy differences between equatorial and axial hydroxyl groups in aprotic solvents have been estimated (3, p. 236) to be 0.5 (pyridine), 0.4 (carbon disulphide), and 1.0 (carbon tetrachloride) (28) kcal/mole. The differences (so-called A-values) seem greater in protic solvents (3, p. 236); 0.8 (75% aqueous acetic acid), 0.9 (water), 0.96 (isopropanol), 1.25 (deuterium oxide) (28). This change in A-value on change from aprotic to protic solvents has been assigned to solvation phenomena (38, 39). For the purpose of illustrating the present status of our appreciation of the conformation of the *trans*-diol, it is useful to assume average A-values for the hydroxyl group of 0.6 kcal/mole (aprotic solvent) and 1.0 kcal/mole (protic solvent). Only one value has been reported for the non-bonded interaction free energy of hydroxyl groups in gauche relation, namely, 0.35 kcal/mole (40) (we propose the term G-value for this type of non-bonded interaction free energy). On this basis, it was to be anticipated that the conformational equilibrium constant toward the diequatorial conformation (II) at ordinary temperatures for *trans*-1,2-cyclohexanediol should be about 4 for aprotic solvents and about 16 for protic solvents. These constants would require J_{BX} to have values of 9.5 and 10.7 c.p.s., respectively. The value of 9.5 c.p.s. is significantly lower than the experimentally determined value of 11.0 c.p.s. for the *trans*-diol dissolved in chloroform. Clearly, however, because of the possibility of intramolecular hydrogen bonding the G-value for hydroxyl groups can be expected

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

to be appreciably dependent on solvent. However, the values found for J_{AX} suggest that such intramolecular bonding effects are negligible at the concentrations required for the NMR experiments. That is, the values of 4.5 and 4.1 c.p.s. observed for J_{AX} reflect a distortion of the cyclohexane ring in the direction which will decrease the dihedral angle defined by the A- and X-hydrogens in the diequatorial conformation (II). This situation can only be achieved by the hydroxyl groups moving somewhat further apart than in the ideal chair form. On the basis of the expressions 7 and 8, only very slight distortions are necessary. Thus, for the *trans*-diol, a dihedral angle of about 58° is indicated for the A- and X-hydrogens when the solvent is either chloroform or water. Our results are best explained using the A-values for the hydroxyl group of 1.25 kcal/mole in deuterium oxide and 1.0 kcal/mole in carbon tetrachloride determined by Anet (28). This conclusion rests on the assumption that the non-bonded interaction energy between two hydroxyl groups in gauche relation (G-value) has the value of 0.35 kcal/mole estimated by Angyal and McHugh (40). The above noted distortions require a repulsion between the hydroxyl groups in the *trans*-diol. It does not seem likely that this repulsion can be substantially less than 0.35 kcal/mole.

A-values of 0.66 kcal/mole (28) and 0.7 kcal/mole (3, p. 236) have been reported for the acetoxy group. The values, $J_{AX} = 3.5$ c.p.s. and $J_{BX} = 10.9$ c.p.s., found for the *trans*-diacetate obviously require the compound to exist essentially only in the diequatorial orientation. Evidently, the G-value for acetoxy groups must be small. Setting this value at 0.35 kcal/mole (the value for the hydroxyl groups) and using an A-value of 0.7 kcal/mole, one would expect the compound to exist to an extent of 85% in the diequatorial orientation, in poor agreement with the NMR data. However, this G-value must be a maximum value in view of the correspondence of J_{AX} with $J_{60°}$. On the other hand, it is difficult to conceive why the A-value for the acetoxy group should be substantially less than for the hydroxyl group. We therefore arbitrarily propose that A- and G-values for the acetoxy groups of 1.0 and 0.2 c.p.s., respectively, are in best agreement with the present data. On this basis, the compound would exist to an extent, 95%, compatible with the NMR data ($J_{BX} = 10.7$ c.p.s.). The low G-value presumably could arise from attractive dipole–dipole interactions between the acetyl groups tending to offset the repulsive non-bonded interactions.

In the case of the *trans*-ditosylate, assuming $J_{aa} = 11.0$ c.p.s. and J_{ee} is in the range 2.6–3.5 c.p.s., since $J_{BX} = 7.9$ c.p.s., it would follow that 59% to 63% of the compound resides in the diequatorial conformation. There thus appears to be a considerably stronger repulsion between tosyloxy groups in *gauche*-orientation than in the case of acetoxy groups. On the basis of the reasonable assumption that the A-value of the tosyloxy group is the same as for the hydroxyl group in aprotic solvents, namely 1.0 kcal/mole, a G-value for the tosyloxy group of 1.8 kcal/mole is indicated. This high value is consistent with the conformational properties of the *trans*-dihalides and provided a basis for explaining the difficulty often experienced in attempts to completely tosylate carbohydrate structures.

It is seen in Table II that the A-protons of the cis compounds are more strongly coupled with the X-proton than are the B-protons. This difference in coupling must arise from the strong coupling to be expected between the 2- and 3-*trans*-hydrogens in conformation IV. Therefore, the A- and X-protons of the cis compounds must be in trans relation as shown in IV and V. The chemical shifts observed for the ring hydrogens of sugars and their derivatives were found to require the assignment of magnetic shielding of an axial hydrogen by an opposing, axially oriented C—O bond (41). On this basis, it

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

could be anticipated that the A-protons of the cis compounds are deshielded relative to the B-protons because of the occurrence of this diaxial arrangement involving the A-protons when in conformation IV. To better assess the magnetic shielding of axial C—O bonds relative to C—CH_3 bonds on opposing axial hydrogens, it was decided to examine the NMR spectra of the *cis*- and *trans*-4-*t*-butyl-2,2,6,6-tetradeuterio-1-methylcyclohexanols. In the case of the *trans*-isomer, wherein the hydroxyl is equatorial, and using carbon tetrachloride as solvent, a rough doublet of intensity 2 centered at 1.7 p.p.m. was assigned to the two equivalent equatorial hydrogens at the 3- and 5-positions. The signals for the geminal axial hydrogens on the basis of intensity measurements appeared to be about 1.0 p.p.m., a position in the field about half-way between the signals for the two kinds of *C*-methyl peaks in the molecule. This chemical shift between the geminal hydrogens at the 3- or 5-positions of about 0.70 p.p.m. is assumed to arise mainly from the diamagnetic anisotropy of the neighboring C—C bonds (42). On the other hand, the spectrum of the *cis*-isomer required both the axial and equatorial hydrogens at the 3- and 5-positions to produce their signal at about the same positions, 1.47 p.p.m. Thus, as expected, the axial hydroxyl has a deshielding effect on the opposing axial hydrogens. The signals for the axial and equatorial hydrogens at the 3- and 5-positions of *trans*-4-*t*-butyl-2,2,6,6-tetradeuteriocyclohexanol under the same conditions were at about 1.0 and 1.8 p.p.m., respectively. A comparison of these chemical shifts with those given above for the 1-*C*-methyl derivative (1.0 and 1.7 p.p.m., respectively) shows the influence of an axial C—CH_3 bond on the chemical shift of an opposing axial hydrogen to be much less than that of a C—OH bond. Since substantially the same results were obtained with pyridine as the solvent, it seems clear that the shielding effects noted are intramolecular in origin.

In conclusion, it is of interest to note that the chemical shifts of the ring hydrogens of cyclohexane and its derivatives appear best rationalized as a first rough approximation (±0.1 p.p.m.) through a consideration of the inductive effects of substituent groups and of the shielding effects from neighboring *groups of atoms* rather than individual chemical bonds. Tau values are used in the following discussion to simplify the presentation. Shielding effects were derived by inspection of the chemical shifts observed in the variety of compounds considered using the chemical shift of the equatorial hydrogens of cyclohexane 8.35 τ (43), as the reference point in the magnetic field. Using Anet's data (28),* the inductive effect of an hydroxyl group on the chemical shift of a hydrogen situated on the same carbon was set at -2.20 τ and on a vicinal carbon at -0.20 τ. Furthermore, the effect on the chemical shift of a hydrogen of projecting between H—C—H, H—C—OH, H—C—CH, and CH—C—OH groupings was estimated to be about 0.0, 0.0, 0.25, and 0.50 τ, respectively. Also, the effect on the chemical shift of an axial hydrogen of being opposed by an axial hydroxyl was set at 0.50 τ. On this basis, it would be anticipated that the equatorial hydrogens at the 2- and 6-positions of the *cis*- and *trans*-4-*t*-butylcyclohexanols and at the 3- and 6-positions of *trans*-1,2-cyclohexanediol would produce their signals at 8.15 τ. The chemical shifts actually observed were 8.23, 8.08, and 8.08 τ, respectively. The 1-hydrogen of *cis*-4-*t*-butylcyclohexanol would be expected to give its signal at 6.15 τ; the observed position was 6.06 τ. The calculations of the chemical shifts for these equatorial hydrogens involved only the inductive effects. However, the shielding effects of neighboring groups influence strongly the chemical shifts of axially oriented hydrogens. Thus, the chemical shifts for the axial hydrogens at the 2- and 6-positions of *trans*-4-*t*-

The authors wish to thank Professor Anet for providing them prior to publication with the chemical shifts of the ring hydrogens of the cis- and trans-4-t-butylcyclohexanols deuterated at the 3-, 4-, and 5-positions.

butylcyclohexanol and at the 3- and 6-positions of *trans*-1,2-cyclohexanediol would both be expected to be at 8.35 + 0.50 + 0.25 − 0.20 = 8.90 τ. The values observed are 8.88 and 8.77 τ, respectively. The position of the 1-hydrogen of *trans*-4-*t*-butylcyclohexanol would be expected at 8.35 + (2×0.25) − 2.20 = 6.65 τ, found 6.62 τ. The signal of the 1- (or 2-) hydrogen of *trans*-1,2-cyclohexanediol would be expected to occur at 8.35 + 0.50 + 0.25 − 2.20 − 0.20 = 6.70 τ, the chemical shift actually observed. In the case of the axial 2- or 6-hydrogens of *cis*-4-*t*-butylcyclohexanol, a chemical shift of 8.35 + (2×0.25) − 0.20 = 8.65 τ is expected. The shift found for this hydrogen was 8.63 τ. A consideration of the chemical shifts for the A-, B-, and X-hydrogens of *cis*-1,2-cyclohexanediol in equal populations of the conformations IV and V gave the following results. The A-hydrogen would be expected to produce its signal at 8.35 + 0.50 + 0.25 − 0.50 − 0.20 = 8.40 τ and at 8.35 − 0.20 = 8.15 τ in conformations IV and V, respectively. Thus, an averaged value of 8.28 τ would be expected which compared well with the observed value of 8.23 τ. In the case of the B-hydrogen, chemical shifts of 8.35 − 0.20 = 8.15 τ and 8.35 + (2×0.25) − 0.20 = 8.65 τ would be expected for conformations IV and V, respectively, with an averaged value of 8.40 τ. The value observed was 8.47 τ. Thus, the relative positions of the A- and B-hydrogens are rationalized. The X-hydrogen would be expected to produce its signal at 8.35 + (2×0.25) − 2.20 − 0.20 = 6.45 τ and 8.35 − 2.20 − 0.20 = 5.95 τ in the IV and V conformations, respectively. The average of these values 6.20 τ, is in good agreement with that observed, 6.25 τ. The agreement could be improved by the introduction of further parameters. However, such refinements would only obscure the main point of the discussion, which is to indicate that reasonably good agreement can be achieved by the addition of shielding effects arising from neighboring groups of atoms. This was not possible when only individual neighboring bonds were considered. The same situation was found to be the case in an attempt to rationalize the chemical shifts observed (4) for the ring hydrogens of isomeric benzene hexachlorides. Reasonable agreement was only obtained when shielding effects were assigned to H—C—Cl, H—C—CH, CH—C—Cl, and axial C—Cl groups in the manner described above for the alcohols.

EXPERIMENTAL

Nuclear Magnetic Resonance Spectra and Double Irradiation Experiments

Solutions, 5–10% (w/v), were prepared in suitable solvents containing 0.5% tetramethylsilane as internal reference. Spectra were first recorded conventionally at 60 Mc.p.s. on a Varian Associates A-60 spectrometer and at 100 Mc.p.s. on a Varian model H.R. 100 spectrometer and line positions calibrated in both cases by the sideband technique using a Hewlett-Packard audiofrequency oscillator model 200AB and electronic counter model 521C. It is possible to operate in the sideband mode by altering the modulation level and altering the audio phase by 90°. Ordinary absorption spectra differing only in sign are then obtained by using the upper or lower 2 kc.p.s. sideband (w_1). Additional field modulation at a variable frequency w_2 c.p.s. can make a portion of the residual rf power available for selective nuclear saturation in the w_1 sideband spectrum. In this way, proton–proton spin decoupling is obtained (24). When operating on the first lower w_1 sideband (which was used throughout these experiments) protons with chemical shifts at higher applied fields (the A- and B-protons) may be decoupled in turn from the X-proton by setting ($w_2 - w_1$) approximately equal to the chemical shifts δ_{AX} or δ_{BX}. Due care was taken to reduce the modulation amplitude so that the observed X-lines were not broadened by saturation. To confirm that successful decoupling had been accomplished, a check was made that the X-quartet or triplet regained its original shape as ($w_2 - w_1$) was increased beyond the optimum decoupling value. Several determinations were made of decoupling frequency for each substance and the results are summarized in Tables IV, V, and VI. In general, as seen from Table II, the agreement between the sums of the X-spacings and the calculated coupling constants ($J_{AX} + J_{BX}$) was as good as the measurement of the spacings (±0.2 c.p.s.). Judging from results with other compounds involving similar chemical shifts, the discrepancy in the case of the *trans*-diol in deuterium oxide must be the result of experimental errors and J_{AX} and J_{BX} likely have values closer to the values reflected by the X-spacings for this compound.

All melting points were determined in capillaries and are uncorrected.

trans-1,4,4-Trideuteriocyclohexene

A solution of 26 g of cyclohexane-1,4-dione (L. Lights and Co., purified by sublimation) in 100 ml of purified anhydrous tetrahydrofuran was added dropwise to a rapidly stirred suspension of 5 g of lithium aluminum deuteride (98%) in 100 ml of anhydrous tetrahydrofuran over a period of 1 hour. A considerable quantity of white insoluble complex separated and the mixture became very viscous. After complete addition of the dione the mixture was stirred at room temperature for 12 hours, cooled in ice, and treated cautiously with 20 ml of ice water with rapid stirring, followed by 100 ml of ice-cold 2 *N* sulphuric acid. The organic layer was removed and the aqueous layer saturated with sodium chloride and extracted three times with ether. The combined extract was dried over magnesium sulphate and filtered, and the solvents evaporated. The combined yield of *cis*- and *trans*-1,4-dideuteriocyclohexane-1,4-diols, obtained as a waxy solid from three similar preparations, was 70.5 g, 88%. The mixture of diols was used without further purification.

A mixture of 70 g of reagent aluminum oxide (which had been freshly roasted to drive off absorbed water, and cooled) and 70.5 g of *cis*- and *trans*-cyclohexane-1,4-diols was heated to 240–250° under a Vigreux column for 6 hours and the distillate collected. The organic layer of the distillate was removed and the aqueous layer extracted with ether (3×15 ml). The combined extract was dried over magnesium sulphate, filtered, and fractionated at atmospheric pressure through a spinning-band column. The 1,4-dideuterio-1,4-epoxycyclohexane distilled at 115° at 700 mm (b.p. for hydrogen analogue, 117–118° (12)). The yield was 12.05 g, 20.5%. Gas–liquid chromatographic analysis of the product on a silicone oil column at 80° showed the product to be pure. The NMR spectrum showed no detectable absorption at 4.66 p.p.m. from internal tetramethylsilane at the position expected for the hydrogens at the 1- and 4-positions.

A solution of hydrogen bromide in ether was prepared by passing the dry gas into ice cold anhydrous ether for ½ hour. The concentration of the hydrogen bromide was determined by titration. 1,4-Dideuterio-1,4-epoxycyclohexane (12 g, 0.12 *M*) was dissolved in 250 ml of the anhydrous ether solution of hydrogen bromide (0.18 *M*) and the mixture set aside in the dark at room temperature for 24 hours. The solution was refluxed for ½ hour, the solvent removed *in vacuo* and the residual pink oil purified by chromatography of silicic acid with light petroleum ether (b.p. 60–80°) as eluant. Evaporation of the eluate afforded 1,4-dideuterio-*trans*-4-bromocyclohexanol, 19 g (87%), as a white crystalline solid m.p. 80°. Rothstein (44) has described the preparation of the mixed cis- and trans-compounds.

1,4,4-Trideuteriocyclohexanol

In a typical experiment 2.03 g of 1,4-dideuterio-*trans*-4-bromocyclohexanol was dissolved in a solution of 0.307 g of sodium in 20 ml of anhydrous methanol. The bromide was subjected to rapid deuterolysis over 0.312 g of 5% palladium-on-charcoal with deuterium generated electrolytically from sodium deuteroxide solution. A rapid uptake of gas was observed and when no more deuterium was absorbed the solution was filtered through Celite. The methanol was removed by fractional distillation with a small spinning-band column. The residue was poured into brine and the mixture was extracted several times with ether. The combined extracts from several similar experiments were dried over magnesium sulphate, filtered, and

fractionated to yield 7.32 g (75% yield) of 1,4,4-trideuteriocyclohexanol as a colorless oil. Freshly recrystallized *p*-toluenesulphonyl chloride, 21 g, was added in portions with shaking to a solution of 7.32 g of 1,4,4-trideuteriocyclohexanol in 45 ml of anhydrous pyridine at −2°. The solution was shaken until all the chloride had dissolved, then allowed to warm to room temperature, and set aside for 3 hours. Two milliliters of water was added cautiously with shaking. After several minutes, the mixture was poured into 200 ml of water. On chilling, the precipitated oil crystallized. The product was purified by washing with water, drying, and recrystallizing from (1:2) ether/pentane. The white plates, 16 g (87%), melted at 44–45°, the melting point recorded (45) for cyclohexyl-*p*-toluenesulphonate. The 1,4,4-trideuteriocyclohexyl-*p*-toluenesulphonate, 5 g, was dissolved in a solution of 3 g of potassium hydroxide in 10 ml of redistilled diethylene glycol. The mixture was heated under conditions for distillation at 110° and the distillate was collected in a trap cooled in a mixture of solid carbon dioxide and acetone. The organic layer was removed from the distillate and dried over magnesium sulphate. Gas–liquid chromatographic analysis of the product showed it to be pure. The yield of 1,4,4-trideuteriocyclohexene was 1.3 g, 10%. Integration of the NMR spectrum showed the relative intensities of the ethylenic and methylenic hydrogens to be 1:5.8 (expected for I, 1:6). See Fig. 1.

1,4,4-Trideuteriocyclohexene-trans-1,2-dibromide in Benzene

A 4% (w/v) solution of bromine in cold dry benzene was prepared and a slight molar excess was added with stirring to a solution of 117.6 mg of 1,4,4-trideuteriocyclohexene in 1 ml of dry benzene until a permanent pink color remained. The excess bromine was dispelled with a stream of air, the solution passed down a short column of grade 1 alumina, and the eluate concentrated under a spinning-band column to a small volume. The solution was then made up to 1.0 ml with dry benzene containing 0.5% of tetramethylsilane for the NMR experiment.

1,4,4-Trideuteriocyclohexene-trans-1,2-dichloride in Benzene

A solution of 124.3 mg of 1,4,4-trideuteriocyclohexene in 1 ml of dry benzene was treated dropwise with stirring with a solution of chlorine in cold dry benzene. The course of the reaction was followed by NMR and the reaction was judged to be complete when the olefinic band disappeared. The excess chlorine was dispelled with a stream of air, the solution passed down a short column of grade 1 alumina, and the eluate concentrated under a spinning-band column to a small volume. The solution was then diluted to 1.0 ml with dry benzene containing 0.5% of tetramethylsilane for the NMR experiments.

1,4,4-Trideuteriocyclohexene-trans-1,2-diiodide in Benzene

Finely powdered iodine, 378 mg, in a vial was cooled in an acetone – solid carbon dioxide mixture and treated dropwise with 127 mg of 1,4,4-trideuteriocyclohexene. The iodine reacted immediately and a reddish-brown solution resulted. The mixture was allowed to reach room temperature, then made up to 1.0 ml with dry benzene containing 0.5% of tetramethylsilane. The solution was used immediately for the NMR experiments.

1,4,4-Trideuterio-cis-cyclohexene-1,2-diol

1,4,4-Trideuteriocyclohexene, 0.7 g, and 2 g of osmium tetraoxide in 30 ml of dry pyridine were mixed at 0° with rapid stirring (14). The mixture immediately set to a mass of brown crystals. After 30 minutes, the mixture was treated with a solution of sodium bisulphite in 60 ml of water and 40 ml of pyridine (15) and the mixture stirred until a clear orange solution was obtained. The solution was thoroughly extracted with chloroform and the extract was dried over magnesium sulphate. Evaporation of the filtered extract left a brown gum from which pure 1,4,4-trideuterio-*cis*-cyclohexane-1,2-diol was obtained as a white crystalline solid by sublimation at 70° and 1 mm pressure. The yield was 0.69 g (70%), m.p. 98° (46).

1,4,4-Trideuterio-trans-cyclohexane-1,2-diol

A solution of 1.44 g of 1,4,4-trideuteriocyclohexene in 5 ml of 98% formic acid was warmed to 45° and treated with 30% aqueous hydrogen peroxide (14) with stirring at a rate to maintain an internal temperature of 55–60°. The addition took 75 minutes. The solution was stirred at 60° for 1 hour, then subjected to steam distillation until 90 ml of distillate was collected. Evaporation of the residual aqueous solution *in vacuo* afforded a yellow gum which readily crystallized. The product, 1,4,4-trideuterio-*trans*-cyclohexane-1,2-diol, was dried and purified by sublimation at 70° and 1 mm pressure. The compound was obtained as a white crystalline solid, 1.30 g (65%), m.p. 101° (literature, m.p. 103.5° (46)).

1,4,4-Trideuterio-cis-cyclohexane-1,2-diol Di-p-toluenesulphonate

A solution of 0.10 g of 1,4,4-trideuterio-*cis*-cyclohexane-1,2-diol in 2 ml of dry pyridine at −5° was treated with 0.60 g of freshly recrystallized *p*-toluenesulphonyl chloride in portions with shaking. When all the reagent has been added, the solution was allowed to attain room temperature and was set aside for 3 hours. A few drops of water were added, and after several minutes the solution was poured into 4 volumes of water. The precipitated oil crystallized. The product was washed with water, dried, and purified by recrystallization from ethanol. The yield was 0.25 g (70%), m.p. 127° (literature (47) m.p. of hydrogen analogue 128.5–129.5°).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

1,4,4-Trideuterio-trans-cyclohexane-1,2-diol Di-p-toluenesulphonate

Similar treatment of 0.1 g of the *trans*-deuteriodiol with 0.6 g of *p*-toluenesulphonyl chloride afforded 0.2 g (55%), m.p. 105°, of the di-*p*-toluenesulphonate (literature (47) m.p. of hydrogen analogue 109°).

1,4,4-Trideuterio-cis-cyclohexane-1,2-diol Diacetate

1,4,4-Trideuterio-*cis*-cyclohexane-1,2-diol, 141 mg, was treated with 0.5 ml of acetic anhydride containing a trace of concentrated sulphuric acid as catalyst. The diol dissolved immediately with evolution of heat but the solution soon returned to room temperature and was set aside for an hour. The acid catalyst was neutralized with a little solid calcium carbonate and the filtered solution concentrated to a small volume *in vacuo*. The crude diacetate was purified by elution chromatography on acid-washed alumina using carbon tetrachloride. Evaporation of the eluant afforded diacetate as a colorless oil, 0.2 g (83%), which was characterized by comparison using gas–liquid partition chromatography with an authentic sample.

1,4,4-Trideuterio-trans-cyclohexane-1,2-diol Diacetate

Similar treatment of 0.143 g of the *trans*-trideuteriodiol with 0.5 ml of acetic anhydride and chromatographic purification provided the diacetate as a colorless oil, 0.2 g (82%), which was characterized by gas–liquid partition chromatography.

O-Isopropylidene-1,4,4-trideuterio-cis-cyclohexane-1,2-diol

A solution of 0.201 g of the trideuterio-*cis*-cyclohexane-1,2-diol in 8 ml of dry acetone and 8 ml of pentane containing 20 mg of *p*-toluenesulphonic acid was refluxed for 60 hours in a Dean-Stark apparatus (48). The residual solution was cooled and treated with 10 mg of solid sodium acetate. The filtered solution was concentrated to a small volume *in vacuo*. The residual oil was purified by elution chromatography on acid-washed alumina using carbon tetrachloride. Evaporation of the eluate afforded the isopropylidene derivative as a colorless oil, 0.15 g (56%). The product was shown to be pure by gas–liquid partition chromatography.

trans-O-Isopropylidene-1,4,4-trideuteriocyclohexane-1,2-diol

A solution of 78 mg of the trideuterio-*trans*-cyclohexane-1,2-diol and 9.65 mg of *p*-toluenesulphonic acid in a mixture of 15 ml of 2,2-dimethoxypropane and 5 ml of carbon tetrachloride was heated under reflux for 20 hours. The excess solvents were removed by distillation at atmospheric pressure until the residual volume was about 4 ml. The cooled yellow solution was poured down a silica gel chromatography column covered by a 1-in. section of alumina. The column was developed with carbon tetrachloride and 25-ml fractions of the eluant were collected and concentrated to a small volume by fractionational distillation. The fractions containing the desired product were detected by NMR spectroscopy and combined. The pure product was isolated by preparative gas–liquid partition chromatography on a silicone oil column at 90° and collected in tubes cooled by a mixture of acetone and solid carbon dioxide. The *trans-O*-isopropylidene-1,4,4-trideuteriocyclohexane-1,2-diol, 15 mg (14.5%), produced an NMR spectrum at 100 Mc.p.s. consistent with its structure. Also, it showed the same behavior on gas–liquid partition chromatography as an authentic sample (48).

4-t-Butyl-2,2,6,6-tetradeuteriocyclohexanone

A solution of 2.74 g of 4-*t*-butylcyclohexanone in a mixture of 10 ml of anhydrous dioxane and 7 ml of deuterium oxide containing a trace of sodium was sealed in a Carius tube and heated at 100° for 12 hours. The contents were than rapidly extracted with *n*-pentane. Evaporation of the *n*-pentane gave a yellow oil which was treated for a second time under the above conditions for deuterium exchange. The product was isolated by extraction and purified by sublimation. The yield was 2.05 g of a compound with the expected melting point and deuterium content (NMR analysis).

trans-4-t-Butyl-2,2,6,6-tetradeuteriocyclohexanol

The tetradeuterioketone was reduced with lithium aluminum hydride in ether and the product was isolated in the usual way. The crude product, m.p. 63–65°, was purified by chromatography as described by Winstein and Holness (49).

cis- and trans-4-t-Butyl-2,2,6,6-tetradeuterio-1-methylcyclohexanols

The tetradeuterioketone, 10 g, was reacted with methylmagnesium iodide in ether and the partially crystalline product, isolated in the usual manner, was chromatographed on grade 1 alumina using *n*-pentane – diethyl ether (1:2) for development. Two well-resolved fractions were obtained. The first fraction (cis-isomer) gave a white crystalline material, m.p. 70–71°, after recrystallization from Skellysolve B. The second fraction (*trans*-isomer) melted at 97–98° after recrystallization from ethyl acetate. This latter compound in carbon tetrachloride solution showed absorption in the infrared for intermolecularly hydrogen-bonded hydroxyl which was much more dependent on concentration than was the lower melting, faster moving (chromatogram) former compound. The configurational assignments were made on this basis.

ABSTRACT

Assuming a random distribution of solute molecules on substitutional sites of a cubic-close-packed solvent crystal, the probabilities have been calculated of finding single solute molecules and pairs of solute molecules in various degrees of isolation. The probabilities have been derived as a function of solute concentration and for distances corresponding to the separation of first, second, third, and fourth nearest neighbors.

INTRODUCTION

Following the use of the matrix isolation technique for the trapping and identification of unstable species, a number of investigations have been carried out in this laboratory (1) and others (2, 3) on the effect of the matrix environment on the spectra of the trapped species. The gross features of these spectra can usually be explained in terms of monomeric and polymeric solute molecules (4) but high resolution studies reveal a fine structure which requires a more elaborate explanation. The possibilities of hindered rotation (2) and multiple trapping sites (1, 3) have been put forward as explanations of this fine structure. We have found, however, that even these refinements are unable to account completely for the matrix spectra of water and the halogen acids obtained in this laboratory. In fact, the complexity of these spectra has suggested to us that other than nearest-neighbor solute molecule interactions may be significant; hence the calculations reported here.

Previous calculations on the statistics of isolation in matrices have been reported by Jackson (5) and Behringer (6). In both cases, however, only the probabilities for nearest neighbors were evaluated—our S_1 and D_1.

CALCULATIONS AND RESULTS

In all of the calculations it has been assumed that the solute molecules are randomly distributed throughout the crystal. Following the notation of Behringer the fractional concentration of solute molecules is designated p and the probabilities of finding isolated singlets, doublets, or triplets are denoted by the symbols S, D, and T respectively.

Since the matrices with which we are concerned are all cubic-close-packed at low temperatures, we have considered only this type of lattice. Probabilities for degrees of isolation out to distances corresponding to the fourth nearest neighbor were calculated (Fig. 1); the four different cases being denoted by subscripts. Thus, S_1 represents the probability of finding a solute molecule with no nearest neighbors. S_2 represents the probability of finding a solute molecule with no nearest or second nearest neighbors, and so on.

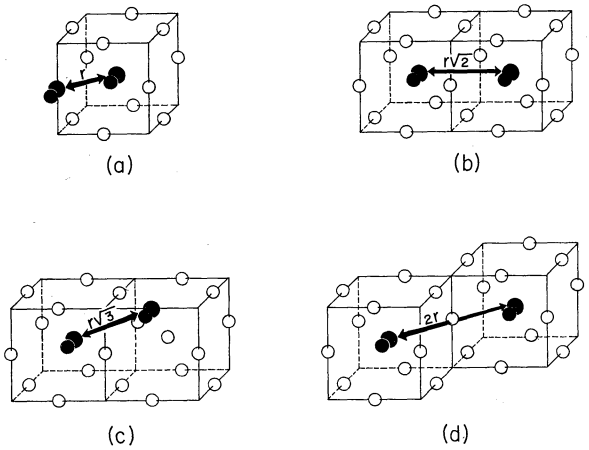

FIG. 1. Structure of a cubic-close-packed lattice showing the first, second, third, and fourth nearest neighbors.

The equations giving the probabilities of finding a single molecule in various degrees of isolation are as follows:

$$S_1 = (1-p)^{12} \qquad S_3 = (1-p)^{42}$$
$$S_2 = (1-p)^{18} \qquad S_4 = (1-p)^{54}$$

Values of S_1, S_2, S_3, and S_4 for matrix ratios between 10:1 and 1000:1 are listed in Table I

TABLE I

Probability of finding isolated single molecules in various degrees of isolation

p	S_1	S_2	S_3	S_4
0.00100	0.9881	0.9822	0.9588	0.9474
0.00125	0.9851	0.9777	0.9488	0.9347
0.00167	0.9801	0.9704	0.9322	0.9137
0.00200	0.9763	0.9646	0.9194	0.8975
0.00250	0.9704	0.9559	0.9002	0.8736
0.00333	0.9608	0.9417	0.8693	0.8352
0.00500	0.9416	0.9137	0.8102	0.7629
0.00667	0.9228	0.8865	0.7550	0.6967
0.01000	0.8864	0.8345	0.6557	0.5812
0.02000	0.7847	0.6951	0.4281	0.3359
0.05000	0.5404	0.3972	0.1160	0.0627
0.10000	0.2824	0.1501	0.0120	0.0034

and plotted in Fig. 2. It should be noted that these equations represent probabilities and not numbers of atoms as in Behringers calculations. They differ by a factor Np, where N is the number of lattice sites in the crystal.

The symbol D_1 denotes the probability of finding a pair of molecules a distance r apart (i.e. in nearest-neighbor positions), with no other molecules in nearest-neighbor positions to either of the pair. D_2 represents the probability of finding a pair of molecules a distance $\sqrt{2}r$ apart (i.e. in second nearest-neighbor positions), with no other molecules in nearest or second-nearest-neighbor positions to either of the pair, and so on.

The equations used in calculating these probabilities are as follows.

$$D_1 = 12p(1-p)^{18} \qquad D_3 = 24p(1-p)^{69}$$
$$D_2 = 6p(1-p)^{30} \qquad D_4 = 12p(1-p)^{90}.$$

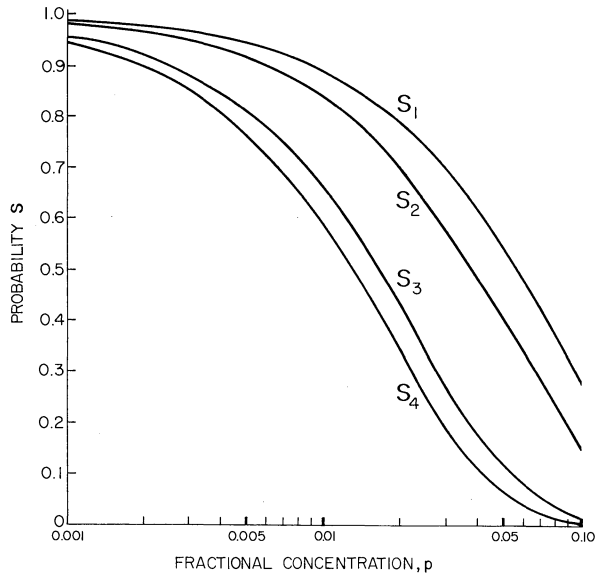

FIG. 2. Probability of finding isolated single molecules as a function of solute concentration, p.

The factors 12, 6, 24, and 12 arise from the number of first, second, third, and fourth nearest neighbors, respectively. These probabilities are listed in Table II and illustrated in Fig. 3.

The systematic classification of triple clusters is a much more difficult problem. It is apparent, however, that the additional factor, p, in the formulae, will reduce the probabilities to a negligibly small value in most cases. Thus, we did not feel a detailed analysis of the problem was worthwhile. On the other hand, when the number of possible arrangements of the triple cluster is large the probability may become of significant magnitude.

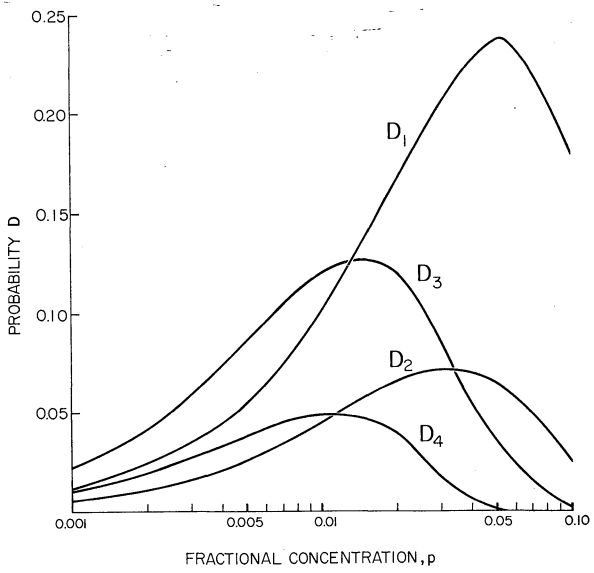

FIG. 3. Probability of finding isolated pairs of molecules as a function of solute concentration, p.

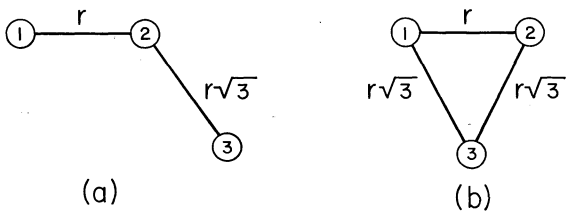

FIG. 4. Open (*a*) and closed (*b*) triple clusters.

A case in point is what we have designated a T_{A1}^3 cluster. The subscript A denotes an open cluster as defined by Behringer (Fig. 4) while the sub- and super-script numerals refer to the two shorter internuclear distances. Thus in a T_{A1}^3 cluster there is a pair of solute molecules in nearest-neighbor positions to each other with a third molecule at a distance of $\sqrt{3}r$ from one of the pair and a distance greater than $\sqrt{3}r$ from the other. None of the three has any molecules in nearest-neighbor positions except as specified above. With 168 possible arrangements, $T_{A1}^3 = 168p^2(1-p)^{28}$, this would appear to be the most probable triple cluster but the probability is still less than 10% (Table II). Behringer's triple cluster, which we would designate a T_{A1}^1, is considerably less probable, although there would appear to be a discrepancy in his calculations. Our calculations indicate a numerical factor of 12 in the formula, i.e. $T_{A1}^1 = 12p^2(1-p)^{23}[5(1-p)+2]$.

DISCUSSION

As expected the S probabilities decrease with increasing p, the falloff being greater the greater the degree of isolation stipulated. The D's, on the other hand, exhibit maxima in the region of $0.01 < p < 0.06$ because the isolation of the pair decreases as p increases. Furthermore, the magnitudes of the maxima are not simply a function of p but depend quite strongly on the number of coordinating positions at the required separation. Thus the probability of finding a D_3 double cluster is considerably higher than that for a D_2 or D_4 when p is less than 0.02. In principle, one could make use of this fact to ascertain the presence of double clusters in the matrix deposits but this conclusion must be accepted with some reservation in the light of practical considerations.

Some diffusion certainly occurs in the matrix during deposition, its extent depending

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

on the experimental conditions. In effect, this may be interpreted as a localized increase in the effective value of p. Thus our S probabilities must be considered as maximum values since an increase in p leads to a lower value of S. In the case of the D's the situation is more complicated. Because of the presence of the maxima, the sign of the change in D will depend on both the absolute value of p and the extent of diffusion. For p less than 0.01 a small change in p will lead to an increase in all of the D's calculated. For larger values of p each case must be considered separately. For $p=0.02$, for example, a small amount of diffusion would lead to an increase in D_1 and D_2 but a decrease in D_3 and D_4. The situation would be further obscured by the presence of solute molecules on other than substitutional sites.

The authors are grateful to the National Research Council of Canada and the University of British Columbia for financial support of this work and to the University of British Columbia computing center for assistance with the calculations.

RÉSUMÉ

Pour une distribution faite au hasard des molécules de solute sur les emplacements substitutionals d'une assemblage compacte cubique de molécules solvents, on a calculé les probabilités de trouver une molécule de solute unique ou en paires pour plusieurs degrés d'isolement. Les probabilités ont été derivées comme fonction de la concentration de la solute et pour les séparations des plus proche première, deuxième, troisième et quatrième voisines.

CARBOHYDRATES OF CENTROSEMA SEED. THE CONSTITUTION OF AN ARABINO GALACTAN. I[1]

A. M. UNRAU
Department of Plant Science, University of Manitoba, Winnipeg, Manitoba
Received January 19, 1963

ABSTRACT

Treatment of the water-soluble polysaccharides of *Centrosema plumari* seed with Fehling's solution resulted in the formation of a precipitate in major proportions. The polysaccharide forming a copper complex was composed of D-galactose (92.5%) and L-arabinose (7%). No change was observed in this ratio upon further treatment of the polysaccharide with Fehling's solution. Partial hydrolysis of the arabinogalactan liberated about 80% of the arabinose. Controlled periodate degradation (Smith degradation) indicated a complex branched structure with a preponderance of 1,4-glycosidic linkages. Methylation experiments also indicated a branched structure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

The isolation and a few characteristics of a galactan present in *Centrosema plumari* seed have been described in an earlier communication (1). Whereas it was previously found that extraction of the crushed seed with hot water yielded an amorphous polysaccharide composed primarily of D-galactose (92%) with lesser amounts of arabinose and mannose, the sample of seed used in this investigation gave a product which contained galactose and arabinose, but no mannose could be detected. It was therefore suspected that two or more related polysaccharides were present in the seed.

The use of complexing agents in the fractionation of polysaccharide mixtures has met with considerable success (2). Probably all galactomannans obtained from leguminous seeds form copper complexes. Neutral copper sulphate solutions, which contain the cation $Cu(OH_2)_4^{++}$ (3), precipitate yeast mannan and the *Lupinus albus* galactan. Alkaline copper sulphate solution, containing the anion $Cu(OH)_4^{--}$ (3), precipitates a greater range of gums and mucilages. It is believed that the same structural characteristics are required in the formation of polysaccharide copper complexes as are necessary for borate complex formation, namely, adjacent cis hydroxyls. In the case of the borate anion, $B(OH)_4^-$, it is believed that cross linkages are formed between two adjacent polymeric chains resulting in a three dimensional network (4, 5). The arabinogalactan with which this communication is concerned showed little or no evidence of forming a borate complex. Treatment of an aqueous solution with Fehling's solution gave a rigid gel. It was found that 80% of the original starting material formed a copper complex. Acid hydrolysis of this polysaccharide showed it to be composed of D-galactose (92.5%) and L-arabinose (7%). Results obtained from partial hydrolysis of the arabinogalactan showed that the greater proportion (80%) of arabinose units were released. This indicated that the arabinose residues were mainly present as nonreducing terminal furanosyl units, a structural feature which has been observed in a fairly large number of polysaccharides containing this pentose (2). A series of internal arabinofuranosyl units could also explain this result although such a structure is less likely.

The further investigation of the structure of the polysaccharide using the Smith degradation (6) largely confirmed the earlier findings (1), although some interior structural systems were found to be much more complex than was at first believed. The absence of

[1]*Contribution No. 74, Department of Plant Science, University of Manitoba.*

ethylene glycol in the mild acid hydrolyzate of the polyalcohol eventually obtained in the reaction sequence showed that few, if any, nonreducing terminal arabinopyranose units were present. The relatively large amount of glycerol (component 1) obtained when considered together with the preferential release of arabinose upon mild acid hydrolysis of the intact polysaccharide further indicated the presence of nonreducing terminal arabinofuranose units. Glycerol would also be formed from terminal as well as 1,6-linked galactopyranose residues and 1,5-linked arabinofuranose units. D-Threitol (component 2) obviously originated from 1,4-linked galactose units. The detection of arabinose (component 3) in the hydrolyzate indicated the presence of periodate-resistant internal arabinose units.

In addition to the above simple degradation compounds, a number of threityl glycosides were obtained which, when hydrolyzed, showed that some galactose and a minor quantity of arabinose units were linked in a manner rendering them immune to periodate cleavage. The simplest galactoside found was 2-O-β-D-galactopyranosyl-D-threitol (component 4), a β-linkage being assigned because of the low specific optical rotation. The structure was deduced from the fact that upon hydrolysis a 1:1 molar ratio of D-galactose and D-threitol was observed. Periodate oxidation of the glycoside followed by borohydride reduction and hydrolysis gave only glycerol (two molar proportions). The amount of formaldehyde released in the periodate oxidation of the glycoside indicated a molecular weight of 300 (7). The compound was readily hydrolyzed by β-D-galactosidase, thus further indicating a β-linkage; and yielded equimolar amounts of galactose and threitol. Methylation of the compound followed by hydrolysis gave crystalline 2,3,4,6-tetra-*O*-methyl-D-galactose. Direct reduction (BH_4) of a portion of the hydrolyzate followed by demethylation with 40% hydrobromic acid gave threitol, characterized as the solid *p*-nitrobenzoate, and galactitol in a 1:1 molar ratio. Treatment of the galactoside with *p*-nitrobenzoyl chloride in the usual fashion gave a powdery derivative which was rather insoluble in organic solvents except pyridine. Elemental analysis gave close to theoretical values for nitrogen.

Component 5 gave upon complete acid hydrolysis galactose, arabinose, and threitol in a 2:1:1 molar ratio. The quantity of formaldehyde released upon periodate oxidation indicated a molecular weight of 430 (7). Reduction of the polyaldehyde with borohydride and complete hydrolysis of the resulting polyalcohol gave galactose, threitol, and glycerol in a 2:3:4 molar ratio. A trace of arabinose was also detected. Part of the glycerol obviously arose from threitol residues. The presence of some galactose in the hydrolyzate indicated that a small number of these units were still linked in a manner rendering them immune to periodate attack. Practically all of the arabinose units were degraded to glycerol indicating that they were present as internal 1,4-linked units.

Paper electrophoretic analysis of component 5 showed the presence of two compounds. Compound 5A, which showed the lower mobility, constituted about 75% of the total. This material gave, upon hydrolysis, galactose and threitol in a 2:1 molar ratio. Periodate oxidation of 5A gave formaldehyde, the amount of which indicated a molecular weight of 440 (7). Borohydride reduction of the polyaldehyde and hydrolysis of the product gave galactose, glycerol, and threitol in a molar ratio of 1:4:1. These results indicated that 5A was composed of two oligosaccharides with the probable partial structures of (*a*) D-Gal*p*(1 → 4)-D-Gal*p*(1 → 2)-D-threitol and, (*b*) D-Gal*p*(1 → 3)-D-Gal*p*(1 → 2)-D-threitol. The specific optical rotation of 5A (−3°) indicated β-glycosidic linkages. Similar experimental procedures applied to 5B showed it to be composed of galactose, arabinose, and threitol (1:1:1 molar ratio). Periodate oxidation released formaldehyde, the amount of which indicated a molecular weight of 420 (7). Borohydride reduction of the polyaldehyde

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

followed by hydrolysis gave glycerol and a trace of arabinose. These results indicated that 5B was composed of two oligosaccharides with probable partial structures of (*a*) D-Gal*p*(1 → 4)-L-Arab*p*(1 → 2)-D-threitol and (*b*) D-Gal*p*(1 → 2 or 3)-L-Arab*p*(1 → 2)-D-threitol.

Component 6, which had a specific optical rotation of −4.6°, indicating the predominance of β-glycosidic linkages, gave, upon hydrolysis, galactose, arabinose, and threitol in a 3:1:1 molar ratio. Periodate oxidation gave formaldehyde, the amount of which indicated a molecular weight of 680. Hydrolysis of the reduced (BH_4) product gave galactose, arabinose, threitol, and glycerol in an approximate molar ratio of 2:1:4:4. The threitol arose from galactose residues while the original threityl residues were converted to glycerol by reduction of the aldehyde produced by periodate cleavage between C_3 and C_4. A 1,3-linkage would explain the survival of some galactose residues whereas both 1,3- and 1,2-linked arabinopyranosyl units would account for the survival of such pentose units.

Paper electrophoretic analysis of component 6 showed that it was heterogeneous. A substance with a somewhat greater mobility than the bulk of the material gave, upon complete hydrolysis, galactose and threitol in a molar ratio of 3:1. Periodate oxidation of this oligosaccharide gave formaldehyde, the amount of which indicated a molecular weight of 600. Borohydride reduction of the polyaldehyde and complete hydrolysis of the product gave galactose, threitol, and glycerol in a molar ratio of 1:3:4. The survival of a portion of galactose indicated the presence of two compounds with probable partial structures of (*a*) D-Gal*p*(1 → 4)-D-Gal*p*(1 → 4)-D-Gal*p*(1 → 2)-D-threitol, and (*b*) D-Gal*p*(1 → 4)-D-Gal*p*(1 → 3)-D-Gal*p*(1 → 2)-D-threitol. A few other structures with minor modifications could also fit the experimental results. The specific optical rotation (−6°) indicated β-glycosidic linkages.

Hydrolysis of the slower migrating material gave galactose, arabinose, and threitol in molar ratio of 2:2:1. Periodate oxidation of the material gave formaldehyde, the amount of which indicated a molecular weight of 700. Reduction (KBH_4) of the polyaldehyde and complete hydrolysis of the product gave galactose, arabinose, threitol, and glycerol in a 2:1:4:5 molar ratio. These results indicated considerably more structural complexity than was found for the previously discussed oligosaccharide-type fragments.

The results from experiments with the larger oligosaccharide fractions (components 7 and 8) suggested similar structural features. Component 7, which had a specific rotation of −7.5° indicating a dominance of β-glycosidic linkages, gave, upon complete hydrolysis, galactose, arabinose, and threitol in a 4:2:1 molar ratio. A molecular weight of about 1000 may be deduced from this result. Periodate oxidation gave formaldehyde, the amount of which suggested a molecular weight of about 1550. This result is at variance with that which was deduced from hydrolysis of the oligosaccharide. A possible structural unit to accommodate these observations would be a disubstituted D-threityl glycoside. Since a considerable quantity of formaldehyde was formed upon periodate oxidation of component 7, the greater proportion of oligosaccharide molecules contained the glycosyl-1,2-threitol structure. Borohydride reduction of the polyaldehyde and complete hydrolysis of the polyalcohol gave galactose, arabinose, threitol, and glycerol in a molar ratio of 2:1:2:10. A number of molecular arrangements might be suggested to accommodate these results. The relatively large quantity of glycerol formed by the above reaction sequence considered together with the smaller quantity of formaldehyde evolved suggests that the oligosaccharide originated from a highly branched segment of the original polysaccharide. In these segments must be present multiple-linked galactose units containing 1,3-glycosidic bonds and other combinations such as 1,2,4- and 1,2,3-linkages. To survive two successive

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

periodate treatments, the arabinose units must be protected by a series of linkages resisting periodate glycol cleavage. Whereas components 5 and 6 could be further resolved by paper electrophoresis, similar separation was not achieved with component 7.

Component 8, also having a negative specific optical rotation (−7.7°) and being the largest oligosaccharide on the basis of its lowest chromatographic mobility, gave galactose, arabinose, and threitol (5:3:1 molar ratio) upon hydrolysis. Periodate oxidation gave formaldehyde, the quantity of which indicated a molecular weight of approximately 1300. This value is in accord with the molecular weight which can be deduced from the molar proportion of threitol that was released upon hydrolysis. Borohydride reduction of the polyaldehyde and complete hydrolysis of the product gave galactose, arabinose, threitol, and glycerol in a molar ratio of 2:1:4:4. An attempted resolution of fraction 8 by paper electrophoresis was not successful.

The polysaccharide was fully methylated using the Howarth procedure (dimethyl sulphate and strong alkali) followed by extended treatment with Purdie reagents (silver oxide and methyl iodide). Hydrolysis of the alkylated polysaccharide with sulphuric acid (8) gave tetra-, tri-, and di-*O*-methyl sugars. No unmethylated sugar was found and only a trace of mono-*O*-methyl galactose was detected. The color reaction of the tetra-*O*-methyl hexose indicated the presence of tri-*O*-methyl arabinose. The mixture of sugars was resolved into tetra-, tri-, and di-*O*-methyl fractions by cellulose column chromatography (9) using the butanone–water azeotrope solvent (10). The weight of the three fractions indicated a molar ratio of tetra-:tri-:di-*O*-methyl hexose of 3:14:3.

2,3,4,6-Tetra-*O*-methyl-D-galactose and 2,3,5-tri-*O*-methyl-L-arabinose were identified as follows: the mixture was oxidized with bromine, the resulting acids were converted to their lactones, and these separated by vapor phase chromatography. 2,3,4,6-Tetra-*O*-methyl-D-galactono-δ-lactone and 2,3,5-tri-*O*-methyl-L-arabono-lactone both crystallized in the collection tubes. The molar ratio of tetramethyl galactose to trimethyl arabinose was 3:1.

The trimethyl fraction was separated by the following procedure. Treatment of the methyl glycosides with trityl chloride gave a water-insoluble trityl compound which was presumed to be methyl 2,3,4-tri-*O*-methyl-6-*O*-trityl-D-galactoside. Detritylation and hydrolysis gave crystalline 2,3,4-tri-*O*-methyl-D-galactose. The non-tritylated trimethyl galactosides were hydrolyzed and chromatographically resolved into 2,4,6-tri-*O*-methyl-D-galactose, which crystallized spontaneously, and 2,3,6-tri-*O*-methyl-D-galactose, the faster migrating sugar, which did not crystallize. The latter sugar was identified by degradation to 2,3-di-*O*-methyl-L-threose, which was reduced (BH_4) to the corresponding alcohol. Demethylation of the mixture of 2,3-di-*O*-methyl-L-threitol and monomethyl ethylene glycol gave the expected alcohols in a 1:1 molar ratio. Both were transformed to the solid *p*-nitrobenzoates. The molar ratio of 2,4,6-:2,3,6-:2,3,4-trimethyl hexoses was estimated to be 2:10:1. Although a small amount of dimethyl-L-arabinose was expected to be present with the trimethyl galactoses, apparently not enough was present to facilitate detection.

The dimethyl hexose fraction was analyzed in the following manner. Reduction (BH_4) and periodate oxidation gave two reducing sugars which were presumed to be 2,3-di-*O*-methyl-L-threose (arising from 2,3-di-*O*-methyl-D-galactose) and a dimethyl pentose believed to be 2,4-di-*O*-methyl-L-lyxose which would arise from 2,4-di-*O*-methyl-D-galactose. The two sugars were present in a 5:1 molar ratio. Reduction of the dimethyl tetrose and demethylation gave L-threitol, which was transformed to the solid *p*-nitrobenzoate.

The results from the Smith degradation and those from the methylation experiments are essentially in accord insofar as to show that the polysaccharide investigated has a rather complex structure. Although it was, with possibly one exception, difficult to characterize rigorously the fragments obtained in the Smith degradation, this procedure at least affords a possible opportunity to study in more detail the internal structural units which resist periodate cleavage. With this in mind, it appears that the Smith periodate degradation scheme should be the method of choice when complex or even simple polysaccharides are considered. Small amounts of undegraded sugar present after the more classical periodate degradation of a polysaccharide should not be disregarded since this observation likely has structural significance. The Smith degradation also presents the opportunity to isolate periodate-resistant backbones of certain polysaccharides which then can be studied in further detail. It is believed that the Smith degradation when applied to simple polysaccharides may yield results indicating a somewhat more complex structure.

EXPERIMENTAL

Paper chromatographic separation of compounds was carried out by the descending technique and the following solvent systems: A, butanol – acetic acid – water (12:5:3); B, ethyl acetate – pyridine – water (9:2:2); C, ethyl acetate – acetic acid – water (8:2:2); and D, butanone – water azeotrope (10). Electrophoretic examinations of oligosaccharide components were carried out using either Whatman No. 1 or 3MM paper and sodium borate buffer (0.07 *M*). Compounds were detected with *p*-anisidine trichloroacetate (11), ammoniacal silver nitrate (12) and periodate–permanganate (13) spray reagents. Evaporations were carried out under reduced pressure at 35 to 40° C. Melting points (uncorrected) were determined on a hot-stage apparatus. Optical rotations are equilibrium values unless otherwise stated.

Isolation of Arabinogalactan

Coarsely ground seed (200 g) of *Centrosema plumari* was covered with water and boiled for 1 hour. The slurry was cooled somewhat to facilitate handling and coarse solids removed by pouring the mixture through several layers of cheesecloth. The residue was resuspended twice more in boiling water and filtered as described. To the combined filtrates potassium borohydride (200 mg in 150 ml water) was added and after six hours at room temperature, sodium hydroxide was added to give a final alkali concentration of 7–8% (wt./vol.). The solution was boiled for several hours to decompose protein and then left overnight to allow sedimentation of suspended solids. Insoluble material was removed by centrifugation and the slightly opalescent acidified (acetic acid) supernatant poured with vigorous stirring into three volumes of ethanol. The precipitated polysaccharide was collected and dissolved in hot water. After three re-precipitations of the polysaccharide by addition of aqueous solutions to four volumes of ethanol, a nearly white amorphous product, $[\alpha]_D^{25}$ +11° (*c*, 1.0 in 0.5 *N* NaOH), was obtained in about 40% yield. Hydrolysis (reflux temperature for 7 hours) of a small portion (0.5 g) of the above product with *N* HCl (20 ml) gave a mixture of sugars identified by their characteristic chromatographic mobilities in solvents A, B, and C and reactions with the stated spray reagents. Galactose, arabinose, and xylose were found in a molar ratio, as determined by the phenol – sulphuric acid method (14), of 45:8:1.

Fractionation of Polysaccharide

(a) Passage through ion-exchange resin columns.—A solution (100 ml) of polysaccharide (0.3 g) was slowly passed successively through cation and anion exchange resin columns. The effluent was evaporated to dryness and the residue refluxed in *N* sulphuric acid for 8 hours. Galactose, arabinose, and xylose were identified chromatographically. The molecular proportion of each sugar was found to be unchanged when compared to the original preparation.

(b) Treatment with Fehling's solution.—A preliminary test showed that a precipitate resulted when Fehling's solution was added to a solution of the polysaccharide. To a portion (40 g) of polysaccharide suspended in water (300 ml), Fehling's solution (900 ml) was added, with vigorous stirring. The gel was collected, washed with Fehling's solution, and dissolved in dilute acetic acid. The solution was dialyzed against distilled water and the volume reduced to 300 ml. Fehling's solution (900 ml) was again added and the procedure repeated. After three treatments as described, the polysaccharide was precipitated twice from aqueous solution with ethanol. The product was finally precipitated from an aqueous solution (pH 7.5) in 4 volumes of ethanol containing 8-hydroxyquinoline. The precipitate was thoroughly washed with acetone to remove chelate and excess chelating agent. The polysaccharide in the form of a nearly white powder had $[\alpha]_D^{25}$ +13° (*c*, 1 in water). Complete hydrolysis of a portion (1.5 g) yielded galactose (92.5%) and arabinose (7.0%). The mixture of sugars was resolved on sheets of Whatman 3MM paper using solvent A. D-Galactose was obtained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

crystalline, m.p. and mixed m.p. 165–167° C, $[\alpha]_D^{25}$ +79.5° (*c*, 0.9 in water) and was converted by oxidation with nitric acid to mucic acid, m.p. and mixed m.p. 218–219° C. L-Arabinose was also obtained crystalline, m.p. and mixed m.p. 158–160°, $[\alpha]_D^{25}$ +104° (*c*, 0.4 in water).

Controlled Periodate Degradation of Arabinogalactan (Smith Degradation) (6)

To a quantity (4.45 g) of polysaccharide in water (120 ml) was added 0.5 *M* periodic acid (60 ml) and the solution stored at 5° C in the dark. Periodate uptake was determined periodically by the usual arsenite procedure. After 4 days, 0.82 moles of periodate per hexose unit had been consumed; after 6 days, 1.04 moles of periodate had been consumed per sugar residue with no change noted after 7, 8, and 9 days. Formaldehyde was determined (7) and on the assumption that two molecular proportions of formaldehyde are produced from a galactitol residue linked through C_4, the D.P. was estimated to be 285. Periodate and iodate were removed from the solution by precipitation with $BaCO_3$. To the filtrate containing the polyaldehyde was added KBH_4 (2.7 g) and the solution stored at room temperature for 24 hours. The solution was neutralized with dilute hydrochloric acid and evaporated to dryness. Borate was removed as methyl borate by several additions and evaporations (20° C) of 1% methanolic hydrogen chloride. The residue was dissolved in water, and the acidic solution (pH 2) left at room temperature for 6 hours, after which the solution was deionized using cation and anion exchange resins. Evaporation of the effluent gave a clear, syrupy product which was chromatographed using the three solvent systems and spray reagents mentioned earlier. At least eight components were detected, one of which reacted with *p*-anisidine trichloroacetate whereas the others were nonreducing in that they reacted only with Tollen's reagent. The mobilities (R_g) of the eight major components in solvent B were as shown below. A portion of the mixture was resolved using Whatman 3MM paper sheets and solvent B.

TABLE I

Chromatographic separation of compounds

Component	R_g	Weight (mg)
Glycerol (1)	2.92	465
D-Threitol (2)	1.82	445
L-Arabinose (3)	1.38	24
4	0.75	54
5	0.61	50
6	0.47	65
7	0.30	83
8	0.20	93

Characterization of Components

(a) Glycerol

The oily residue co-chromatographed with a known standard in the three solvent systems. To a portion (100 mg) of the compound in dry pyridine (4 ml) was added *p*-nitrobenzoyl chloride (5% molar excess) and the mixture heated at 70° for 1 hour. Excess aroyl halide was decomposed with water (1 ml) and saturated sodium bicarbonate (50 ml) added to the mixture with vigorous agitation. The precipitate was collected, thoroughly washed with water, and recrystallized from an ethanol:acetone mixture (1:1 v/v). The product, glycerol tri-*p*-nitrobenzoate, had m.p. and mixed m.p. 191–193° C.

(b) D-Threitol

The syrupy residue, $[\alpha]_D^{25}$ +4.5° (*c*, 8 in water), failed to crystallize. Treatment of a portion (100 mg) with 5% molar excess of *p*-nitrobenzoyl chloride in the manner described above gave the solid tetra-*p*-nitrobenzoate, m.p. 219–221° C. Calculated for $C_{32}H_{22}O_{16}N_4$:N, 7.92. Found: N, 7.88, 7.90.

(c) L-Arabinose

The syrup, $[\alpha]_D^{25}$ +103° (*c*, 0.2 in water), crystallized upon addition of a few seed crystals. The product had m.p. and mixed m.p. 158–160° C.

(d) Component 4

This nonreducing substance (54 mg), $[\alpha]_D^{25}$ −2° (approx.) (*c*, 1.8 in water) gave upon hydrolysis of a small portion (12 mg) galactose and threitol. The specific optical rotation changed in the course of hydrolysis from the stated value to approximately 36°. This upward shift constitutes strong evidence for a β-glycosidic linkage. The two constituents were determined using the phenol – sulphuric acid procedure (14) for the sugar and the periodate – chromotropic acid method for the polyol (7, 15). The molar ratio of galactose and threitol was found to be 1:1. The remainder of threityl galactoside (32 mg) was subjected to periodate oxidation (at 5° C) and formaldehyde determined. Approximately 3.4 mg formaldehyde was found from which a molecular weight of 290 was calculated for the compound, theory, 284. Periodate and iodate was precipitated with barium carbonate and the mixture filtered. Potassium borohydride (100 mg) was added to the filtrate and after 24 hours storage at room temperature, the solution was acidified with 2 *N* HCl,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

refluxed, and worked up as described previously. Only glycerol (13 mg characterized as the *p*-nitrobenzoate) was found. The amount of glycerol obtained showed that galactose and threitol were both converted to the polyol. Treatment of a small portion (3.5 mg) of the glycoside in water (10 ml) with β-D-galactosidase (2 mg) gave galactose and threitol (1:1 molar ratio). The reaction was completed in 30 minutes. To a further quantity (5 mg) of this substance in dry pyridine was added *p*-nitrobenzoyl chloride and the reaction mixture handled in the usual fashion. The powdery product, 18 mg, was very sparingly soluble in organic solvents except pyridine and melted at 175–180° C. Calculated for $C_{73}H_{41}O_{40}N_7$: N, 5.92. Found: N, 6.08, 6.01.

A small portion (12 mg) of component 4 was methylated by the Kuhn procedure (16), followed by extended methylation with methyl iodide and silver oxide. The final product, 14 mg, showed no OH absorption in the infrared spectrum. The syrup was hydrolyzed with sulphuric acid (8) and 2,3,4,6-tetra-*O*-methyl galactose identified by paper chromatography. Resolution of a portion of the hydrolyzate by paper chromatography led to recovery of a few crystals of the tetramethyl galactose, m.p. 71–73° C. The remaining portion of the hydrolyzate was reduced (KBH_4) and the reduced residue boiled for 45 minutes with concentrated hydrobromic acid. After removal of the acid by repeated evaporation with methanol, galactitol and threitol were identified chromatographically. The molar ratio of the alcohols was determined by the periodate – chromotropic acid procedure (7, 15) and found to be 1:1 as expected. The experimental results dictate that the identity and structure of the compound must be 2-O-β-D-galactopyranosyl-D-threitol.

(e) Component 5

This substance had $[\alpha]_D^{25}$ −2° (approx.) (*c*, 1.8 in water), and gave, upon complete hydrolysis (N H_2SO_4) of a portion (10 mg), galactose, arabinose, and threitol, in a molar ratio of about 2:1:1. Another aliquot (40 mg) of the material was treated with periodic acid as described above. The molecular weight computed from the quantity (2.79 mg) of formaldehyde evolved was 430. The polyaldehyde was reduced (KBH_4) in the usual manner. The polyalcohol gave upon complete hydrolysis galactose, threitol, and glycerol in a molar ratio of 2:3:4. Paper electrophoresis of component 5 showed two components which will be referred to as 5A and 5B. A quantity (65 mg) of the mixture was resolved by paper electrophoresis. Component 5A constituted about 75% of the total material recovered from the electrophoretograms (75% recovery). Hydrolysis of a portion (7 mg) of 5A gave galactose and threitol in a molar ratio of 2:1. Periodate oxidation of the remaining material (40 mg) gave formaldehyde, the quantity (2.69 mg) of which indicated a molecular weight of 445 for the compound. Reduction (KBH_4) of the polyaldehyde and complete hydrolysis of the product gave galactose, glycerol, and threitol in a molar ratio of 1:4:1. These results indicated that 5A was composed of two oligosaccharides with the probable partial structures of (*a*) D-Gal*p* (1 → 4)-D-Gal*p* (1 → 2)-D-threitol and (*b*) D-gal*p*(1 → 3)-D-Gal*p*(1 → 2)-D-threitol. The oligosaccharide fragments were present in about equal molar proportions. The specific optical rotation (−3°) indicated that the glycosidic linkages were of the β-configuration.

Component 5B was investigated in a manner similar to that used for 5A. Hydrolysis of a portion (5 mg) gave galactose, arabinose, and threitol in a molar ratio of 1:1:1. Periodate oxidation of the remaining material (10 mg) gave formaldehyde, the amount (0.72 mg) of which corresponded to a molecular weight of 417. Reduction of the polyaldehyde (KBH_4) and complete hydrolysis of the product gave glycerol and a trace of arabinose. These results indicated that 5B was composed of two oligosaccharides with the probable partial structures of (*a*) D-Gal*p*(1 → 4)-L-Arab*p*(1 → 2)-D-threitol and (*b*) D-Gal*p*(1 → 2 or 3)-L-Arab*p* (1 → 2)-D-threitol.

(f) Components 6, 7, and 8

These substances were analyzed in the manner described for components 4 and 5. Some of the results are summarized in Table II.

TABLE II

Characteristics, composition, and results from Smith degradation (6) of some oligosaccharide components

Component	$[\alpha]_D^{25}$	Molar ratio of galact:arab: threitol	Molar ratio of galact:arab: threitol:glycerol after IO^-_4 treatment
6	−4.6	3:1:1	2:1:4:4
7	−7.5	4:2:1	2:1:2:10
8	−7.7	5:3:1	2:1:4:4

Paper electrophoresis of component 6 indicated that it was composed of two compounds and possibly three. The resolution of this material was by no means as distinct as for component 5. A portion (approximately 20%) of component 6 showed a somewhat faster electrophoretic mobility under the particular conditions used (350 v, 1–1.5 ma/in. of paper, 36 hours). Hydrolysis of a portion (6.5 mg) of the fast moving fraction gave galactose and threitol in molar ratio of 3:1. Periodate oxidation of the remaining material

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(12 mg) gave formaldehyde, the amount (0.59 mg) of which indicated a molecular weight of 610. Reduction (KBH_4) of the polyaldehyde followed by complete hydrolysis of the polyalcohol gave galactose, threitol, and glycerol in a molar ratio of 1:3:4. The resistance of some galactose to periodate oxidation indicated the presence of at least two compounds with probable partial structures of (*a*) D-Gal*p*(1 → 4)-D-Gal*p*(1 → 4)-D-Gal*p*(1 → 2)-D-threitol and (*b*) D-Gal*p*(1 → 4)-D-Gal*p*(1 → 3)-D-Gal*p*(1 → 2)-D-threitol. The low specific optical rotation (−6°) indicated β-glycosidic linkages.

Hydrolysis of a portion (10 mg) of the slower moving material gave galactose, arabinose, and threitol in a molar ratio of 2:2:1. Periodate oxidation of the substance (60 mg) gave formaldehyde (1.25 mg) the amount of which indicated a molecular weight of 720. Reduction (KBH_4) of the polyaldehyde and complete hydrolysis of the product gave galactose, arabinose, threitol, and glycerol in a molar ratio of 2:1:4:5. These results indicated considerably more structural complexity.

Components 7 and 8 could not be resolved by electrophoresis and were not investigated further than indicated in Table II.

(g) Identification of Constituents of Oligosaccharide Hydrolyzates

The hydrolyzates from the individual oligosaccharides were combined and the constituents (galactose, arabinose, and threitol) separated using solvent C and Whatman 3MM paper. This procedure was adopted because of (*a*) the limited individual quantities involved and (*b*) the qualitative identity, as established by paper chromatography, of the individual oligosaccharide hydrolyzates. D-Galactose, 55 mg, was obtained crystalline after introduction of a few seed crystals and had m.p. and mixed m.p. 165–167° C. The original syrupy product had $[\alpha]_D^{25}$ +79° (*c*, 0.8 in water). Mucic acid, m.p. and mixed m.p. 218–219° C, was obtained upon oxidation of the sugar with nitric acid. L-Arabinose, 20 mg of syrupy material, $[\alpha]_D^{25}$ +101° (*c*, 0.4 in water), did not crystallize. The substance was reduced (KBH_4) to the corresponding alcohol, $[\alpha]_D^{25}$ −12.3° (*c*, 2.4 in water), and the final product, which was freed from borate, was acetylated with acetic anhydride and fused sodium acetate. The pentaacetate was obtained crystalline, m.p. and mixed m.p. 73–75° C.

(h) Identification of Constituents formed in Periodate Degradation of Oligosaccharides

The mixtures from components 5, 6, 7, and 8 were combined and resolved as described in the previous section. D-Galactose was isolated as a syrup (60 mg) which crystallized upon seeding, m.p. and mixed m.p. 165–167° C, $[\alpha]_D^{25}$ +80° (*c*, 0.6 in water). L-Arabinose was obtained as a syrup (30 mg), $[\alpha]_D^{25}$ +101° (*c*, 0.3 in water) and failed to crystallize. Reduction (KBH_4) of the sugar followed by acetylation gave the crystalline L-arabitol pentaacetate, m.p. and mixed m.p. 73–75° C. D-Threitol, obtained as a syrup (100 mg), $[\alpha]_D^{25}$ +4.4° (*c*, 2 in water), gave upon treatment with *p*-nitrobenzoyl chloride the corresponding *p*-nitrobenzoate, m.p. and mixed m.p. 219–220° C. Glycerol (180 mg), isolated as a mobile oil, gave upon treatment with *p*-nitrobenzoyl chloride the crystalline *p*-nitrobenzoate, m.p. and mixed m.p. 192–194° C.

Partial Acid Hydrolysis of Polysaccharide

A quantity (2.0 g) of arabinogalactan was suspended in cold 0.1 *N* HCl (200 ml). No change in viscosity was observed after the suspension had been left several days at room temperature. The solution was placed in a hot water bath (85° C) and after 1.5 hours, the relative viscosity had changed from 2.6 to about 1.2. The solution was cooled to 5° C and examined chromatographically using solvents A, B, and C. Arabinose, galactose, and a series of oligosaccharides were detected with *p*-anisidine trichloroacetate spray reagent. The relative amounts of arabinose, galactose, and oligosaccharide were determined by the phenol – sulphuric acid method (14). Approximately 80% of the arabinose present in the polysaccharide was removed by the above treatment. Increasing the acid concentration and refluxing the solution released the remaining arabinose. The relative quantities of each sugar were in accord with results obtained previously.

Methylation of Polysaccharide

To a sample (2.0 g) of borohydride-reduced polysaccharide in 30% sodium hydroxide (20 ml) was added simultaneously and with vigorous stirring five aliquots of dimethyl sulphate (30 ml) and 30% sodium hydroxide (30 ml). After the third addition, acetone was added to keep the partially methylated polysaccharide in solution. The polysaccharide was recovered from the acidified solution by extraction with chloroform and further methylated over extended time (two 72-hour treatments) with methyl iodide and silver oxide. The final product (2.5 g), a yellow glass, showed no OH^- absorption in the infrared spectrum. The alkylated polysaccharide was dissolved in 72% sulphuric acid (8), and after 45 minutes, the acidic solution diluted to about 2 *N* and boiled for 8 hours. The neutralized ($BaCO_3$) solution was evaporated to a syrup (1.8 g). Paper chromatography of the syrupy residue using butanone–water azeotrope (10) as solvent showed the presence of tetra-, tri-, and di-methyl hexose. The spot for tetramethyl galactose was multicolored, indicating the presence of 2,3,5-tri-*O*-methyl-L-arabinose. The components were separated by cellulose column chromatography (9) using butanone–water azeotrope (10) as irrigant. The weights of the components thus recovered were as follows.

Component		Weight (mg)
No. 1.	Tetramethyl fraction	244
No. 2.	Trimethyl fraction	1023
No. 3.	Dimethyl fraction	211
No. 4.	Monomethyl fraction	7

Analysis of Components

Component No. 1.—To the syrupy substance dissolved in water (15 ml) was added bromine and lead carbonate. The flask was wrapped in foil and the oxidation allowed to proceed for over 48 hours, after which time the solution was nonreducing. Excess bromine was removed by aeration, the insoluble inorganic lead salts filtered off and the filtrate passed through a cation exchange resin column to generate the free aldonic acids. The effluent was evaporated to a thick syrup which was, in turn, heated (water bath temperature 60° C) under vacuum to facilitate lactone formation. The mixture was resolved by vapor phase chromatography using a column (3 ft long, $\frac{1}{4}$ in. in diameter) packed with silanized chromosorb W coated with Versamid* (7%). With helium flow of 45 ml per minute and column temperature 155° C, the retention time of 2,3,5-tri-*O*-methyl-L-arabono-γ-lactone was 2 minutes. The compound crystallized spontaneously in the collection tube, m.p. 34° C, $[\alpha]_D^{22}$ −46° → −24° (*c*, 1.0 in water). These values are in agreement with those found in the literature (17). The retention time of 2,3,4,6-tetra-*O*-methyl-D-galactono-δ-lactone was 3.5 minutes, and it also crystallized spontaneously in the collection tube, m.p. 84–85° C, $[\alpha]_D^{22}$ +23° (*c*, 1.2 in water). Lit. (18) m.p. 84° C, $[\alpha]_D^{22}$ +22.6° (water). The molar ratio of tetramethyl galactose to trimethylarabinose was estimated using an integrator attachment and found to be 3:1.

Component No. 2.—The syrupy mixture was dissolved in methanol containing 1% hydrogen chloride and the solution refluxed until nonreducing. The solution was neutralized with silver carbonate, filtered, and evaporated. The syrup was dissolved in dry pyridine (10 ml) and trityl chloride added. The mixture was heated on a boiling water bath for 1 hour, cooled, and ice water added. The precipitate that formed was collected and dissolved in methanol (15 ml) containing hydrogen chloride. After the solution was warmed at 60° C for 30 minutes, water (150 ml) and lead carbonate were added. The insoluble material was removed by filtration and the filtrate evaporated. The residue was dissolved in 1 *N* H_2SO_4 and the solution boiled for 8 hours. Neutralization ($PbCO_3$) and evaporation of the solution gave a clear syrup (75 mg) which crystallized spontaneously. After recrystallization from ethyl acetate, the sugar had m.p. 82–84° C, $[\alpha]_D^{22}$ +152° → +117° (*c*, 0.5 in water). These values are in accord with those in the literature (19) for 2,3,4-tri-*O*-methyl-D-galactose.

The non-tritylated glycosides were hydrolyzed to the free sugars by boiling in 1 *N* H_2SO_4 for 8 hours. Paper chromatography indicated two sugars with R_f values similar to those reported (2) for 2,4,6- and 2,3,6-tri-*O*-methyl galactoses. The compounds were separated by cellulose column chromatography. The slower migrating sugar, 150 mg (2,4,6-tri-*O*-methyl galactose) crystallized spontaneously after evaporation of the solvent. After recrystallization from ethyl acetate, the sugar had m.p. 103–106° C, $[\alpha]_D^{22}$ +118 → +90° (*c*, 0.8 in water). These values are in good accord with reported values (20) for 2,4,6-tri-*O*-methyl-D-galactose. The faster migrating sugar, 750 mg, did not crystallize. The syrup had $[\alpha]_D^{22}$ +82° (*c*, 2 in water) indicative of 2,3,6-tri-*O*-methyl-D-galactose. A portion (500 mg) of the sugar was reduced with KBH_4 and the generated alcohol cleaved with periodate. No formaldehyde was evolved. Paper chromatography indicated the presence of a dimethyl tetrose, presumably 2,3-di-*O*-methyl-L-threose. A portion of the reaction mixture was freed from periodate and iodate and KBH_4 added. The reduced alcohols, presumably 2,3-di-*O*-methyl-L-threitol and monomethoxy ethylene glycol, were demethylated with hydrobromic acid to yield ethylene glycol and threitol. These products can only arise from 2,3,6-tri-*O*-methyl-D-galactose by the above reaction sequence. The two alcohols were resolved by paper chromatography using solvent A. Ethylene glycol (42 mg) was converted to the *p*-nitrobenzoate in the usual fashion, m.p. and mixed m.p. 140–142° C. L-Threitol (82 mg) $[\alpha]_D^{22}$ −4.4° (*c*, 4.1 in water) upon treatment with *p*-nitrobenzoyl chloride gave the tetra-*p*-nitrobenzoate, m.p. 220–221° C. Calculated for $C_{32}H_{22}O_{16}N_4$: N, 7.92. Found: N, 7.88, 7.93.

Component No. 3.—A portion (150 mg) of the syrup was dissolved in water and KBH_4 (180 mg) added. The product after removal of borate was oxidized with periodic acid at 5° C. Slightly less than 2 moles of periodate was consumed per mole of dimethyl hexitol. Periodate and iodate was removed by precipitation and the deionized solution evaporated. Paper chromatography of the product indicated the presence of a dimethyl tetrose as the major component with identical R_f value (0.79) as that obtained for 2,3-di-*O*-methyl-L-threose above. A slower-moving dimethyl pentose (R_g 0.5) was evident, presumably 2,4-di-*O*-methyl-L-lyxose. The components were resolved by column chromatography to give 2,3-di-*O*-methyl-L-threose, 65 mg, and 2,4-di-*O*-methyl-L-lyxose, 7 mg. A portion (40 mg) of the tetrose was reduced (KBH_4) and the dimethyl tetritol demethylated with hydrobromic acid. Removal of ionic material from the reaction mixture left L-threitol (22 mg), $[\alpha]_D^{22}$ −4.5° (*c*, 2.2 in water), which was identified chromatographically and as tetra-*p*-nitrobenzoyl-L-threitol, m.p. 219–221° C. The dimethyl pentose was not further investigated.

N.M.R. STUDIES OF BRIDGED RING SYSTEMS

II. UNUSUAL MAGNETIC DESHIELDING EFFECT ON THE BRIDGE METHYLENES OF NORBORNADIENE AND BENZONORBORNADIENE

K. TORI, Y. HATA, R. MUNEYUKI, Y. TAKANO, T. TSUJI, AND H. TANIDA

ABSTRACT

Proton magnetic resonance spectra of some norbornane derivatives having double bonds and (or) a benzene ring in the skeleton were studied. Differences in the chemical shifts between the bridge methylenes of norbornene and benzonorbornene and that of norbornane result from the diamagnetic anisotropy effect of a double bond or a benzene ring being in good agreement with the values calculated theoretically. However, in the norbornadiene derivatives which have two double bonds or one olefinic double bond with a benzene ring in a part of the skeleton, the signals of their bridge methylenes show extraordinarily larger downfield shifts by about 0.8 p.p.m. than those expected from the additive shielding due to each π-electron system. This anomaly is not observed in bicyclo[2.2.2]octane ring series. A large transannular interaction between two π-electron systems in that system would be a major contribution to the above anomaly.

INTRODUCTION

In the past few years a number of proton magnetic resonance (n.m.r.) spectra of bridged ring systems have been investigated, reporting the relations between the spin coupling constants of ring protons and the stereochemistry (1–10), various types of long-range spin couplings (3, 5, 6, 8–11), the establishment of the configuration of substituents by the evaluation of diamagnetic shielding effects of a double bond or a benzene ring (9, 12–15), and so forth (16–19). However, the substantial features of n.m.r. spectra of bicyclo[2.2.1]heptane derivatives have not received much attention. By the studies of various monohydroxyl derivatives of bicyclo[2.2.1]heptane, Musher (8) has recently reported that (i) a strikingly large difference in the magnetic shielding between an exo and an endo proton was observed, showing larger deshielding on the exo proton, and this difference can not be explained only by the diamagnetic anisotropy of the C—C bonds in the ring; that (ii) the coupling constants between each pair of adjacent protons, $J_{H_x-H_x}$ and $J_{H_n-H_n}$*, are not equal; and that (iii) fairly large long-range spin coupling constants were found. On the basis of these results, he suggested the presence of some π-characters in this ring system. In a previous paper (20), we also suggested the presence of this character on the basis of the increased *s*-character of the C—H bonds, which was reflected in the strikingly large values of carbon–hydrogen spin coupling constants $J_{C^{13}-H}$ obtained from the C^{13}-satellites (21) in the n.m.r. spectra of norbornane (I), norbornene (II), norbornadiene (III), benzonorbornene (IV), benzonorbornadiene (V), and quadricyclene (VI).

This paper deals with the spectra of the compounds of I–VI in comparison with those of bicyclo[2.2.2]octane derivatives, which are bicyclo[2.2.2]octene (VII), bicyclo[2.2.2]-octadiene (VIII), benzobicyclo[2.2.2]octene (IX), benzobicyclo[2.2.2]octadiene (X), and dibenzobicyclo[2.2.2]octadiene (XI). The diamagnetic shielding effects of a double bond (14, 22) or of a benzene ring (23) upon their bridge methylenes and (or) bridge ethylenes are estimated experimentally and are compared with the values theoretically

calculated (24, 25, 26). Particularly, an unusual deshielding effect on the bridge methylenes of III and V will be discussed.

RESULTS AND DISCUSSION

The chemical shifts of assignable protons in the n.m.r. spectra of bicyclo[2.2.1]heptane derivatives (I–VI) are shown in Table I, in comparison with those of bicyclo[2.2.2]octane derivatives (VII–XI). Figure 1 shows a part of the spectra of II and IV.

In general, the signals of these compounds were easily assignable, except for the chemical shifts of the protons on the bridge methylenes of II and IV, which were assigned according to the following way. The signals of protons on these bridge methylenes generally appear as an AB-type quartet, each of which is further split into a triplet by the bridgehead protons. Additional long-range spin couplings, if they appear, will be small (3, 8, 11). The geminal coupling constant of these bridge methylene protons is believed to be about 8 c.p.s., which is unusually small, by reference to this sort of the coupling constant in V (20). The differences in the chemical shifts between the protons H_x and H_n on the ethylene bridge of II and IV should be much larger than the value observed in I, because of the anisotropy effect of a double bond or a benzene ring. On the basis of the above idea and observed relative integrated areas of signals, we tentatively assigned signals of the bridge methylenes of II and IV, as shown in Fig. 1. The signals of the bridge methylene of V separately appear as an AB-type quartet, each of which is split into a triplet. The detailed assignments of this quartet to the H_{7s} or H_{7a} were achieved on reference to the data of some authentic C_7-derivatives (28). The protons on the bridge ethylenes of VII, IX, and X exhibit the complex signal patterns of an $A_2B_2X_2$ system and the determinations of their exact chemical shifts seemed difficult. However, they closely resemble the AB part of a usual ABX system. Therefore, approximate values of the chemical shifts were obtained according to the treatment of an ABX-type pattern (9). It is of interest to note the presence of a long-range spin coupling

$J_{7x-2(3)}$ (about 0.3 c.p.s.), being clearly observed on the C^{13}-satellites in the spectrum of III, in addition to the long-range spin couplings, J_{2x-6x} (J_{3x-5x}) and $J_{7n-5x(6x)}$, already observed by several workers (3, 8, 11).*,†

Shielding Effects of a Double Bond upon Bridge Methylenes

Much is now known about the appreciable anisotropy of the diamagnetic shielding effect of a double bond on neighboring protons in the presence of a strong field (22). By this effect, the signal of a proton which lies above the plane of the sp^2-bonds is shifted to upfield, whereas a downfield shift is experienced by the proton which lies in the sp^2-bond plane. Fraser (14) demonstrated these facts in comparison of the signals of the protons H_5 and H_6 on some C_5- or C_6-substituted norbornenes with those of the corresponding norbornanes.

The shift values of the signals of bridge methylenes or ethylenes due to an introduction of a double bond are summarized in Table II.‡ The introduction of a double bond into I induces a downfield shift of the H_{7x} signal by 0.13 p.p.m. and also an upfield shift of the

The coupling constants of the compounds I–VI were reported in the previous paper (20).

†*The long-range spin coupling $J_{7s-2(3)}$ (about 0.8 c.p.s.) is noticed clearly in some 7a-substituted derivatives of V (28).*

‡*It may be somewhat dubious to estimate the effect of a double bond by the difference in proton signal shifts between the saturated and the unsaturated compound because the introduction of a double bond produces a change in the conformation of a ring and consequently in the shielding effects of* C—C *bonds (29) and* C—H *bonds. The* C—H *bond anisotropy has recently been discussed to be not negligible (refer to Discussions of Faraday Soc. 34 (1962)). However, the relative position of a relevant proton on a bridge to the* C—C *bonds, which construct the ring of our compounds, will be almost unchanged with respect to the replacement of a single bond into a double bond. Accordingly, the above treatment will be generally valid.*

corresponding H_{7n} signal by 0.12 p.p.m. It is possible to explain quantitatively the difference in these shieldings (in p.p.m.) by using the following formula [A] of Nakagawa *et al.* (25) for the total shielding effect due to two π-electrons of a double bond:

$$\delta(\text{p.p.m.}) = \frac{\Delta\chi}{3}\left(\frac{1-3\cos^2\theta_1}{R_1^3} + \frac{1-3\cos^2\theta_2}{R_2^3}\right) \qquad [A]$$

where R is the distance from a carbon atom **C** of a double bond to an affected proton **H**, θ is the angle formed by the axis of a π-electron (z-axis) and the **C–H** line, as illustrated diagrammatically in Fig. 2, and the constant $\Delta\chi$ was determined empirically as about

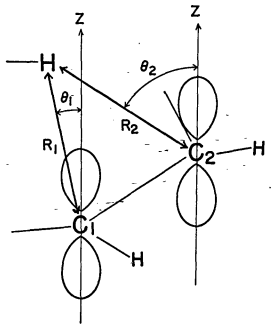

FIG. 2. A diagrammatic illustration of magnetic anisotropy of a double bond.

-10×10^{-30} cm³.* The values calculated from the equation [A] agree well with those observed, as listed in Table II. Molecular geometries were estimated by using the Barton model. The data on bicyclo[2.2.2]octane derivatives are also consistent with the calculated values, as seen from Table II. However, of particular interest is the fact that a further introduction of a double bond into the compounds II and IV already having a double bond or a benzene ring causes an extraordinary downfield shift of the bridge methylene signals, whereas this fact is not experienced in a series of bicyclo[2.2.2]octanes.

**The procedure of Nakagawa et al. (25), which is an application of McConnell's equation (30) and different from the others (14, 24), seemed to us best for obtaining the anisotropic effect of a double bond. A good example is the effects on the protons* $H_{5n}(H_{6n})$ *and* $H_{5x}(H_{6x})$ *in norbornane derivatives, which were obtained to be +0.04 and −0.14 p.p.m. experimentally by Fraser (14), and* $+0.04_7$ *and* -0.22_3 *p.p.m. by the present calculations, respectively.*

Shielding Effects of a Benzene Ring upon Bridge Methylenes

The shielding effect of a benzene ring on neighboring protons is well known as the ring current effect (23). The effects of a benzene ring are summarized in Table III in the same

TABLE III

†Derived from the spectral data on eleven bicyclo[2.2.2]octane derivatives, which were reported in ref. 9.

manner as those of a double bond were done. The theoretical shielding effect of a benzene ring can be easily calculated from the molecular geometry according to Johnson and Bovey's method (27). Table III also shows the values obtained from the calculations. Molecular geometries were estimated by using the Barton model. Upon the similar consideration to the case of a double bond, the introduction of a benzene ring into I produces downfield shifts of the H_{7a} and H_{7s} signals by 0.53 and 0.28 p.p.m., respectively. These shifts as well as those of the bicyclo[2.2.2]octane derivatives are comparable to the values obtained from calculations. The analogous interesting fact to the above is found in the case of a condensation of a benzene ring to the C_5- and C_6-positions of II, in which extraordinary downfield shifts appear in the H_{7a} and H_{7s} signals of V. There are not such indications in bicyclo[2.2.2]octane series.

Unusual Deshielding Effects upon Bridge Methylenes of Norbornadienes

If the additivity principle of magnetic shielding effects could be applied to the bicyclo-[2.2.1]heptane series, the bridge methylene signals of III should appear at about 8.8τ and that of V should be at about 8.4τ. However, their signals actually obtained show such a striking large downfield shift as about 0.8 p.p.m. from the expected positions. This fact could not be explained by the change of molecular geometries due to the introduction of two π-electron systems. Recently we proposed the increasing of *s*-character in all the C—H bonds of this ring system (20). Moreover, recent studies of ultraviolet absorption spectroscopy demonstrated a considerably larger transannular interaction between two double bonds of III, and its resonance integral value was estimated to be 0.385 β (SMO) by Wilcox *et al.* (31) and 0.74 eV (SCFMO) by Paldus and Koutecký (32). In contrast, the ultraviolet spectrum of VIII suggests that this kind of interaction is not so large as that of III (33). These findings were also supported by the measurements of the heats of hydrogenation of III and VIII (34).

A clear explanation for these unusual deshielding effects on the bridge methylenes of III and V may be difficult immediately. However, we suppose that this effect can result from a novel type of the magnetic shielding arising from a large transannular interaction between the π-electron systems, besides from the change in the diamagnetic anisotropy

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of C—C bonds of III and V with the "bent" of the bonds due to the more ring strain, as reflected in the increased $J_{C^{13}-H}$ values in the rings (20). The signal of the bridge methylene of VI also appears at a very low field as 7.98τ, as shown in Table I. The latter observation would be due to the change in the diamagnetic anisotropy of C—C bonds, as mentioned above, along with the possible small ring currents of two cyclopropyl rings (35).*

EXPERIMENTAL

All the spectra were observed on 10% (w/v) solutions in deuterochloroform with tetramethylsilane as an internal standard at room temperature, by using a Varian A-60 n.m.r. spectrometer, whose calibration was checked by Tiers and Hotchkiss' method (37). Accuracies of chemical shifts and coupling constants are within $\pm 0.02\ \tau$ and ± 0.03 c.p.s., respectively.

ACKNOWLEDGMENTS

The authors are indebted to Prof. N. Nakagawa, University of Electro-communications, for his helpful discussions on the diamagnetic anisotropy of a double bond, to Prof. C. A. Grob, Universität Basel, for the supply of an authentic sample of bicyclo[2.2.2]octadiene, and to Mr. M. Yamakawa, in this laboratory, for the information about its ultraviolet spectrum. They also acknowledge the encouragement of Drs. K. Takeda, T. Nakagawa, and K. Kitahōnoki in this laboratory.

THE KINETICS OF THE CHELATION OF NICKEL (II) AND 1,10-PHENANTHROLINE

P. F. BARRETT AND W. MACF. SMITH
Department of Chemistry, Queen's University, Kingston, Ontario
Received September 17, 1963

ABSTRACT

The kinetics of the formation of the bidentate monocomplex of 1,10-phenanthroline and nickel (II) have been examined spectrophotometrically at ionic strength 0.5 over the range of temperatures 8 to 37° C and over the range of hydrogen ion concentrations 0.01 to 0.30 molar. The kinetic behavior over the range of conditions is consistent with that found at 25° C by Margerum, Bystroff, and Banks. The limiting values for the second-order rate constant for the reaction at high acidities have been assessed and imply associated values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ of 9.5 kcal mol^{-1} and −5.3 e.u. respectively.

INTRODUCTION

The reaction between nickel (II) and 1,10-phenanthroline yields a bidentate monocomplex at a rate convenient for kinetic studies both in water and in certain mixed solvents. The kinetics of the reaction involving the formation of the complex was studied in detail by Margerum, Bystroff, and Banks (1) at 25° C. They showed that the second-order rate constant increased with acidity and approached a constant value at higher acidities.

Wilkins and Williams (2) and Ellis, Hogg, and Wilkins (3) estimated the rate of the acid-independent solvolysis of the monocomplex over a range of temperature through measurements on the rate of exchange of ^{63}Ni (II) which, they considered, was directly controlled by the rate of solvolysis.

The work described below assesses kinetic features of the acid-dependent formation of the monocomplex at constant ionic strength and over a range of temperatures and is part of a program to obtain comparable data about the kinetics of the formation of the bidentate complexes of nickel (II) and iron (III) and the effect of solvent composition on the reactions of nickel (II).

EXPERIMENTAL

Materials

Water used in preparing the solutions was triply distilled, the second distillation being from alkaline permanganate. Sodium perchlorate (anhydrous), perchloric acid (70%), and nickel (II) perchlorate were all reagent grade obtained from G. Frederick Smith Chemical Company. The pyridine method outlined by Vogel (4) was used in estimating the nickel content of solutions. Eastman reagent grade 1,10-phenanthroline was used and three different sample lots gave indistinguishable spectra and kinetic properties.

Methods and Apparatus

The reaction was followed spectrophotometrically with light of wavelength 310 mμ. Nickel (II) is essentially transparent at this wavelength for the conditions of this work and the difference in the extinction coefficients of the monocomplex and the monoprotonated phenanthrolium ion is nearly at a maximum. The data discussed below indicate that under the conditions of the kinetic studies over 99.9% of the phenanthroline is in the protonated form and over 98% of the total phenanthroline is complexed at equilibrium. Under these conditions the concentration of complex is proportional to the change in optical density.

All spectrophotometric measurements relating to kinetics and equilibria were made with a Beckman extended range DK-1 spectrophotometer using thermostated quartz cells of path length of 1 cm. The pH was determined with a Radiometer number 4 pH meter on thermostated samples. Standardization for the lower pH's was made with 0.050 molar potassium tetroxalate (5).

In a kinetic run, equal volumes (1.5 ml) of two solutions, one containing nickel (II) perchlorate, the other

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

phenanthroline, were mixed in the quartz absorption cell of the spectrophotometer by simultaneous ejection of the solutions from 2-ml syringes fitted with polythene tips directed in a way to ensure mixing. The two solutions were of identical ionic strength and had the same concentrations of perchloric acid. Solutions and pipettes were thermostated prior to the mixing operation. The value of the optical density at equilibrium along with the extinction coefficient of the complex (estimated as indicated below) was used to check the concentration of total phenanthroline using the assumption that substantially all of the phenanthroline was present as the monocomplex.

The Ionization Quotient of Phenanthrolium Ion

The interpretation of the kinetic data required a knowledge of the acid ionization quotient of the monoprotonated phenanthrolium ion. Margerum, Bystroff, and Banks (1) examined the equilibria involving the free and protonated forms. However, quantitative values for the acid ionization quotient of the monoprotonated species covering the range of our experimental conditions were not available and we have carried out measurements relating to the quotient at ionic strength 0.5 and temperatures from 13 to 37°. We have also assessed the extinction coefficient of the monocomplex ($NiPh^{++}$).

If Q_a represents the acid ionization quotient of the monoprotonated species then

$$\log ([Ph]/[HPh^+]) + \log a_{H^+} = \log Q_a\gamma_{H^+} \quad [1]$$

where [Ph] and $[HPh^+]$ represent concentrations of the free and monoprotonated 1,10-phenanthroline and γ_{H^+} is the activity coefficient of hydrogen ions. If the pH, indicated by the meter, were equal to $-\log a_{H^+}$ then $\log Q_a\gamma_{H^+}$ could be estimated. Also the plot of $[Ph]/[HPh^+]$ against the antilog of the pH would be a straight line.

We have estimated by spectrophotometric methods the ratio $[Ph]/[HPh^+]$ for solutions in the range of pH 4.9 to 5.5 and ionic strength 0.5 and find that the plot of $[Ph]/[HPh^+]$ against the antilog of the pH is indeed a straight line over this range. The extinction coefficients for the free base and the monoprotonated species were estimated from absorption measurements in solutions in the pH ranges 7.8 to 8.9 and 1.2 to 2.3. Values of $Q_a\gamma_{H^+}$ estimated from relation 1 are given in Table I. The associated standard deviations are about four percent of the values given. A value of 0.567×10^{-5} for 8° was obtained by extrapolation. These values of $Q_a\gamma_{H^+}$ along with measured pH values and equation [1] were used to estimate the ratio $[HPh^+]/[Ph]$ and $f = [Ph]/([HPh^+] + [Ph])$ for the solutions used in the kinetic experiments. Under all conditions more than 99% of the phenanthroline was in the monoprotonated form. It may be noted that the validity of the procedure depends on the measured estimate of the pH being proportional to $-\log a_{H^+}$ and the value of γ_{H^+} remaining constant.

The extinction coefficient of the $Ni(Ph)^{+2}$ complex at 310 mμ was determined using solutions of pH = 2.0, total phenanthroline concentrations in the range 0.15×10^{-3} to 1.0×10^{-3} molar and Ni (II) in about 10-fold excess. Under these conditions the optical density is proportional to the total concentration of phenanthroline, which indicates essentially complete complexing of this base. The slope of the plot of data obtained at temperature 25° C and ionic strength 0.5 indicated an extinction coefficient of 1338 l. mol^{-1} cm^{-1}. The overall changes in optical density under the conditions of the kinetic runs were consistent with this value and complete complexing of the phenanthroline to ±2%.

13.0	0.613
19.0	0.676
25.0	0.751
31.0	0.888
37.0	1.022
43.0	1.194

Interpretation of the Kinetic Data

For the solutions used in the kinetic runs and at λ 310 mμ the monobidentate complex and the monoprotonated phenanthroline are the only species contributing appreciably to optical density, and the concentration of monocomplex is proportional to the change in optical density which has occurred since zero time. If the reaction is first order in free phenanthroline and first order in Ni (II) ion, which is in large excess, then

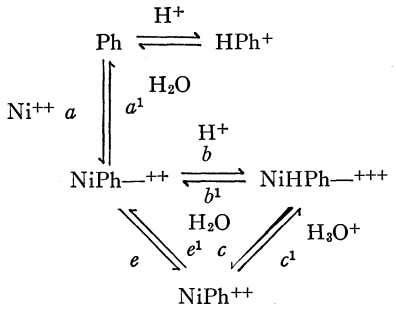
$$\text{constant} - \ln (D_\infty - D) = k_f f.M.t \quad [2]$$

where D_∞ and D are the optical densities of the reacting solution at equilibrium and time t, k_f is the second-order constant defined by (d/dt) [complex] $= k_f$ $[Ni^{++}]$ [Ph], f is the fraction of uncomplexed phenanthroline existing as the free base and M is the total concentration of Ni (II).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

A plot of ln $(D - D_\infty)$ against t should yield a straight line with slope $k_f.M.f.$ Data from our runs yield linear plots with the value of k_f depending on acidity and tending to a limit at higher acidities. This was noted by Margerum, Bystroff, and Banks (1), who suggested two mechanisms to account for this behavior.

In their mechanism I, indicated below, a labile intermediate NiPh—$^{++}$ (A) involving a single bond between phenanthroline and nickel ion is formed and this then forms a bidentate complex directly or via a path involving the protonated species NiHPh—$^{+++}$



a, a^1, b, etc. represent rate constants.

In their second mechanism the transient species A is formed directly as in mechanism I but in addition phenanthrolium ion (HPh^+) is involved in reaction with nickel to give the singly bonded and protonated intermediate (NiHPh—$^{++}$) which by proton loss yields the species A and this is the sole precursor to the final bidentate complex.

If the back reaction of the final product is neglected it can be shown that both mechanisms imply that at higher acidities the rate of formation of the bidentate complex can be expressed by

$$(d/dt)[\mathrm{NiPh}^{++}] = (m+[\mathrm{H}^+])/(p+n[\mathrm{H}^+])[\mathrm{Ni}^{++}][\mathrm{Ph}]$$

where m, p, and n are related to the rate constants of the various steps. If m is negligible relative to $[H^+]$ the effective rate constant (k_f) becomes $[H^+]/(p+n[H^+])$ and a plot of $1/k_f$ against $1/[H^+]$ would yield a straight line with intercept n. At very low acidities the rate constant is m/p, which on the basis of both mechanisms is equal to $ae/(a^1+e)$. On the basis of mechanism I $1/n$ is equal to a, the rate constant for the first step in the attachment of the ligand. (This corresponds to the condition approached at high acidity where the intermediate A is transformed to bidentate product by the acid-catalyzed path at a rate equal to that of the formation of A.) On the basis of mechanism II, $1/n = e \times K_e^1$ where K_e^1 is the formation constant for A from nickel (II) ion and free phenanthroline. (This corresponds to the condition where the intermediate A is maintained at equilibrium concentration through formation from phenanthrolium ion.)

RESULTS OF THE KINETIC MEASUREMENTS AND DISCUSSION

Measurements of rate were made over the range of temperatures and concentrations of acid shown in Table II. Concentrations of nickel (II) varied from 1×10^{-2} to 4×10^{-2} M and total phenanthroline from 0.6×10^{-4} to 1.3×10^{-4} M. Data from all runs yielded plots of log $(D_\infty - D)$ against time which were good straight lines with no significant dependence of the slope (and rate constants) on the initial concentration of either reactant at a given hydrogen ion concentration. The values of the rate constants (k_f) given in Table II are the means of values from six to eight runs carried out with different concentrations of nickel (II) and phenanthroline.

Plots of $1/k_f$ against $1/[H^+]$ for concentrations of hydrogen ion 0.04 molar and greater are given in Fig. 1 and indicate that data for higher acidities were consistent with a linear relationship. Values of n, p, and m were derived separately from values of the rate constants obtained from smoothed curves of k_f against $[H^+]$ through the experimental points and are given in Table III. The dispersion in the data for highest acidities at the temperatures 8° and 13° was considerable and the values of n, p, and m for these temperatures were obtained by ignoring the data for acid concentrations 0.2 and 0.3 molar.

Included in Fig. 1 are lines drawn in accord with the values of n and p of Table III, p indicating the slope of the plot of $1/k_f$ against $1/[H^+]$ at limiting high acidity. The values

37	1.34	1.0	3

for the constants n, p, and m are those which best summarize the experimental data but the values for p and more particularly for m have rather wide confidence limits. For example, for 19° C an increase in n of 4% along with an associated decrease in p of 15% and in m of 40% yield values for k_f which fit the smoothed experimental curves to about 3% of the value of k_f.

Our data for 25° C and those of Margerum, Bystroff, and Banks (1) are in fair agreement. Their value for n is 2.62×10^{-5} and ours is 2.25×10^{-5} mol $l.^{-1}$ sec. Their value for p is 2.58×10^{-6}, ours is 1.54×10^{-6} mol^2 $l.^{-2}$ sec. The difference in values for p is probably attributable to the influence of ionic strength on the rate characteristics of the acid dependent path.

Our values for m and p indicate a value of 2.7×10^3 l. mol^{-1} sec^{-1} for the rate constant for the overall acid independent reaction at 25° C. This may be compared with 4.1×10^3 l. mol^{-1} sec^{-1} derived from Ellis, Hogg, and Wilkins (3) value of 6.2×10^{-4} min^{-1} for the rate constant for dissociation and Margerum, Bystroff, and Banks value of 2.5×10^{-9} mole $liter^{-1}$ for the equilibrium constant for the dissociation. In view of the uncertainty associated with the value for equilibrium dissociation constant and our value for m the agreement between the values is satisfactory.

Our values for $1/n$ at various temperatures yield the values 9.5 ± 0.6 kcal mol^{-1} for $\Delta H^{\ddagger}$ and -5.3 ± 2.1 cal mol^{-1} $degree^{-1}$ for $\Delta S^{\ddagger}$. These values apply to the transition state involved in the formation of the unidentate intermediate A if mechanism I applies or to that involved in the formation of final bidentate complex relative to the same initial states of nickel (II) and phenanthroline if mechanism II applies. Although six or seven co-ordinate intermediates are conceivable (6), recent work by Eigen and co-workers (7) suggests that the transition state involving the smaller co-ordination number is more likely. It may be noted that the values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ quoted by Basolo and Pearson (8) for the acid-independent solvolysis and based on the data of Ellis, Hogg, and Wilkins (3) apply to the overall reaction and not necessarily to the rate-controlling step.

The work of Eigen and co-workers (7) involving relaxation techniques provides convincing evidence that the reaction between a metal ion and potential ligand involves two types of ion pairs as precursors to the unidentate complex, the immediate precursor being one in which the metal ion and ligand are separated by one molecule of water. This ion pair yields the complex with a first-order rate constant (k_{34}) which, in the case of most bivalent metal ions, is characteristic of the metal ion but nearly independent of the loosely associated ligand of the ion pair. If it is assumed that the concentrations of the two types of ion pairs are small relative to the concentrations of the free reactants then the overall second-order rate constant for complex formation should be $K_e k_{34}$ where K_e is the effective association equilibrium constant for the ion pair from which the complex is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

directly formed. Swift and Connick (9) have used N.M.R. relaxation methods to estimate the rate constant (k_1) for water exchange from the first co-ordination sphere of various cations and find values which are nearly proportional and close in magnitude to the values for k_{34} found by Eigen, e.g. for nickel (II) at 25° C k_1 is 2.7×10^4 seconds^{-1} and k_{34} for nickel (II) and sulphate ion is 1.5×10^4 seconds^{-1}. Both Eigen and Connick have emphasized the implication that the rate of association (anation) is controlled essentially by the rate of water loss from the metal ion and that the rate constant for this process for most bivalent ions is nearly independent of the nature of the neighboring ligand in the ion pair.

If mechanism I of Margerum and co-workers applies to the reaction of nickel (II) and *o*-phenanthroline at high acidity then $1/n$ is the rate constant for the formation of the unidentate intermediate A and is identifiable with $K_e k_{34}$. Eigen's value of 1.5×10^4 sec^{-1} for k_{34} along with a value of 4×10^4 mole^{-1} liter second^{-1} for $1/n$ imply that k_e is approximately 2.7 mole^{-1} liter, a value sufficiently small to lead to a relatively negligible concentration of ion pairs under our range of experimental conditions and consequently to a situation consistent with second-order kinetics. Using Swift and Connick's value for k' in place of Eigen's value for k_{34} leads to the same conclusions. Melson and Wilkins (10) have determined values ranging from 2.5×10^3 to 3.2×10^3 mole^{-1} liter second^{-1} for the overall association rate constant of nickel (II) with three uncharged unidentate ligands which had widely different association equilibrium constants. Davies and Smith (11) found a value of about 4×10^3 mole^{-1} liter second^{-1} for the reaction between nickel (II) and the singly charged thiocyanate ion. The significant excess of our value for $1/n$ (4×10^4) over those obtained by Melson and Wilkins may imply that $1/n$ is not measuring the rate constant for formation of A and that mechanism I does not operate. Melson and Wilkin's finding that the rate constants for association are essentially independent of ligand type, when considered in terms of Eigen's mechanism, implies that the effective association constant (K_e) for ion pair formation is almost independent of the equilibrium constant for complex formation. It follows that if mechanism I operated in a series of reactions involving nickel (II) with various ligands of the same charge, then there should be essential independence of rate constant on ligand type.

Mechanism II implies that at high acidity the concentration of intermediate A is maintained close to that for equilibrium with nickel (II) and phenanthroline via a path involving protonation and deprotonation and $1/n = K_e'k''$ where K_e' is the association constant for the unidentate species A and should be much more dependent on the nature of the ligand than is K_e. k'' is the first-order rate constant for formation of the bidentate complex from the unidentate intermediate A and could conceivably be less than k' (12). If the magnitude of k'' be assumed to be close to that for k', there is implied a value for K_e' which is comparable to K_e and consistent with a second-order rate law.

It appears then that the data for the nickel–phenanthroline reaction are quite consistent with both the data obtained and mechanisms proposed by Eigen and by Connick but taken alone do not permit decision to be made about the detailed nature of the acid-catalyzed mechanism. Our values for $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, while potentially significant, may not be usefully interpreted in the present state of knowledge about solvation in aqueous ionic solutions. It is, however, pertinent to note that a dependence of $1/n$ on K_e' and consequently on the nature of ligand is implied for a series of reactions proceeding by mechanism II and involving nickel (II) and various ligands. Ahmed and Wilkins (13, 14) provide data on the kinetics of the dissociation of complexes of nickel (II) with various aliphatic diamines which suggest a mechanism for association and dissociation similar to that applying to the phenanthroline complex. They find that the rate constant for the dissociation increases

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with acidity and tends to a constant value before increasing again at high acidities. They satisfactorily interpret their results on the basis of a mechanism which is essentially mechanism II. If their values for the dissociation rate constant at intermediate acidities be considered to indicate the limiting value for high acidities, then an estimate of $1/n$ should be obtained by multiplication of this dissociation rate constant and the equilibrium association constant. Values in the range 14×10^4 to 27×10^4 mole^{-1} liter second^{-1} are implied for a temperature of 0.6° C and ionic strength of 2.0. The high magnitude of $1/n$ relative to that anticipated for the rate constant for unidentate ligand formation (3×10^3) seems to support mechanism II while its relative independence on type of ligand suggests mechanism I. However, values for K_e' (for the unidentate intermediate) are not available and it is possible that the range of the values is small. It appears that more extended and accurate data relating to the acid dependence of the association rate constants for nickel (II) with a series of bidentate ligands which could have quite different association equilibrium constants for the unidentate intermediate might help assessment of the acid-catalyzed mechanisms.

N.M.R. SPECTRA OF TIN COMPOUNDS

II. Sn^{119} AND H^1 MAGNETIC RESONANCE SPECTRA OF HEXAMETHYLDITIN

H. C. CLARK, J. T. KWON, L. W. REEVES, AND E. J. WELLS

Received November 20, 1963

ABSTRACT

The H^1 and Sn^{119} resonances in hexamethylditin have been examined. A coupling constant $J = 4400 \pm 70$ c.p.s. is reported for Sn^{117}—Sn^{119} nuclei directly bonded. Comparison with some other heavy metal couplings is made. Changes in bond type of the Sn—C bond in hexamethylditin from tetrahedrally bonded tin compounds with no Sn—Sn bond is indicated by an anomalously low value for J_{Sn-C-H}.

INTRODUCTION

The proton resonance spectrum of hexamethylditin was first reported by Kaesz (1) but more recently discussed by Brown and Morgan (2). The latter workers have assigned the Sn^{119} and Sn^{117} satellites of hexamethylditin, octamethyltritin, and cyclic and linear polymethyltin compounds. Interpretation of the respective coupling constants from methyl protons to tin followed empirical assignment of *s* character in the tin–carbon bond after suggestions of earlier workers (3, 4). Other coupling constants involving magnetic tin nuclei have recently been reported by the present authors in methyltin derivatives (5). A correlation of coupling constants involving the group IV elements has been published by Reeves and Wells (6).

The purpose of the present work is to investigate the Sn^{119} magnetic resonance spectrum of hexamethylditin and to point out some further features of the H^1 spectrum. The classic work on Sn^{119} spectra in various compounds has been published by Lauterbur and Burke (7).

EXPERIMENTAL

Proton resonance spectra were obtained at 60 Mc using an A60 spectrometer with calibrating side bands. The side bands were produced by a Hewlett Packard 2000CD wide-range audio oscillator and measured with a Hewlett Packard 522B electronic counter. Sn^{119} magnetic resonance spectra were obtained at 15.37 Mc, with a Varian variable-frequency spectrometer model V4210A. Calibration of these spectra was achieved by using modulation side bands on the Li^7 resonance signal in lithium nitrate solution. The procedure for this calibration is as follows. The Sn^{119} resonance was obtained at 15.37 Mc and the field sweep conditions standardized. The sharp Li^7 resonance in dilute $LiNO_3$ solution was then recorded at the same value of H_0. For modulation frequencies much larger than the line width the recorded derivative of absorption signal consists of two absorption mode signals in opposite phase separated by twice the modulation frequency serving to calibrate the spectrum. It was not possible with the experimental conditions available to observe audio side bands on the Sn^{119} resonances. The Sn^{119} spectra appear as derivatives of the absorption spectrum because the main magnetic field was modulated by a 400-c.p.s. variable field.

The compound was prepared in the manner of Clark and Willis (8).

RESULTS AND DISCUSSION

The proton resonance spectrum of hexamethylditin is illustrated in Fig. 1(*a*) with the calibrating audio side bands included at ± 114.9 c.p.s. When the gain of the A60 instrument is increased by 20 times the observation of weak satellite resonances can be investigated as shown in Fig. 1(*b*). The proton resonance spectrum arises in the first approximation from the contribution of 10 molecular types. These are listed with their fractional abundances as follows: (1) $(CH_3)_3SnSn(CH_3)$—no magnetic tin nuclei—0.692;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

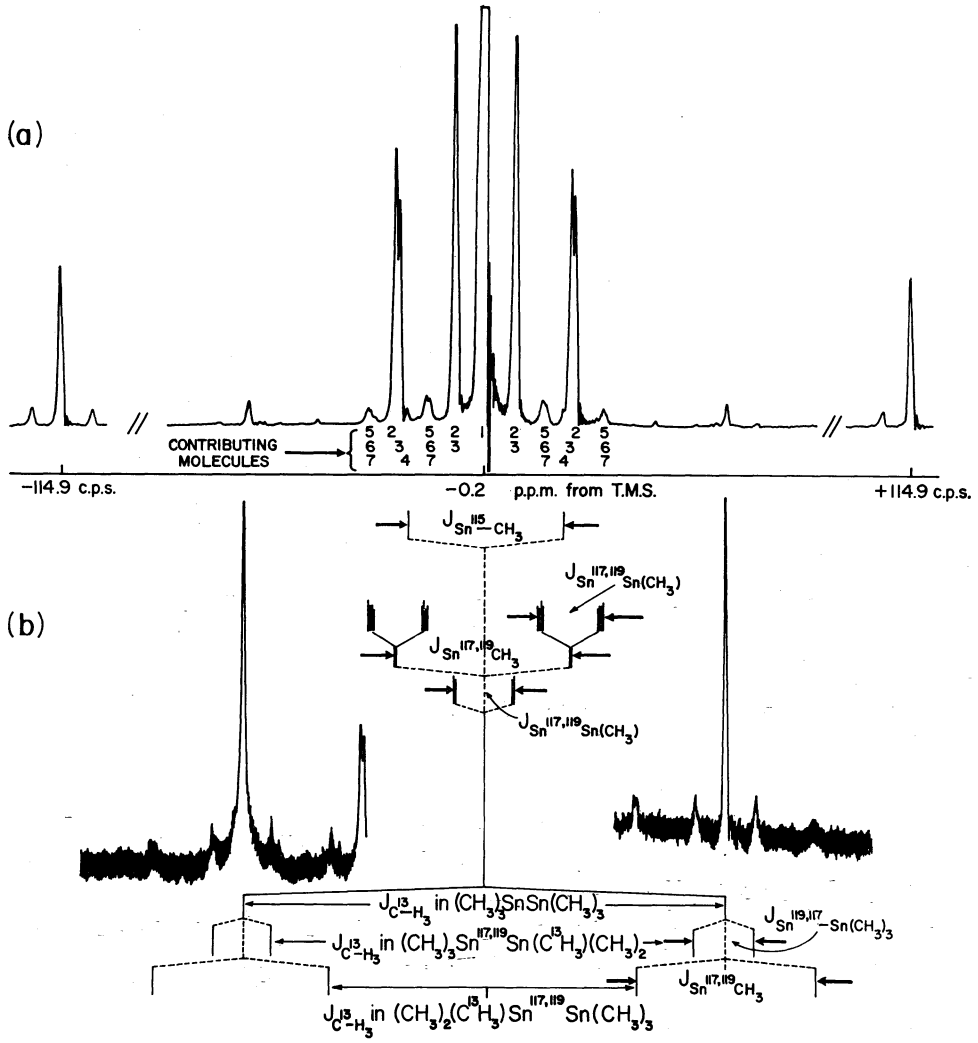

FIG. 1. (*a*) Spectrum of the H^1 resonance in hexamethylditin at low gain (60 Mc). (*b*) Spectrum of the H^1 resonance at 20 × amplitude of (*a*).

(2) $(CH_3)_3Sn^{119}Sn(CH_3)_3$ 0.144; (3) $(CH_3)_3Sn^{117}Sn(CH_3)_3$ 0.128; (4) $(CH_3)_3Sn^{115}Sn(CH_3)_3$ 7×10^{-3}; (5) $(CH_3)_3Sn^{119}Sn^{119}(CH_3)_3$ 7.5×10^{-3}; (6) $(CH_3)_3Sn^{117}Sn^{117}(CH_3)_3$ 5.9×10^{-3}; (7) $(CH_3)_3Sn^{117}Sn^{119}(CH_3)_3$ 0.013; (8) $(CH_3)_3Sn^{119}Sn^{115}(CH_3)_3$ 6×10^{-4}; (9) $(CH_3)_3Sn^{117}Sn^{115}(CH_3)_3$ 6×10^{-4}; (10) $(CH_3)_3Sn^{115}Sn^{115}(CH_3)_3$ 1.2×10^{-6}. Molecules 8, 9, and 10 are in such low abundance as to be unobservable. In Fig. 1 the main central resonance is due to molecules of type 1. The first satellites arise from molecules 2 and 3 and their separation corresponds to an averaged remote coupling, methyl protons to the distant Sn^{117} or Sn^{119}, i.e. $(CH_3)SnSn^{119,117}$. The methyl groups coupling to adjacent Sn^{117} and Sn^{119} are further separated from the central resonance and individually resolved. A resolution of the small abundance of molecules containing an Sn^{115} nucleus is clearly seen just inside the resonances due to adjacently coupled methyl protons (to Sn^{117}, Sn^{119}). The much weaker satellites on each side of these peaks are from the molecules 5, 6, and 7, containing two magnetic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

tin nuclei. The relative intensities of individual peaks of these multiplets are indicated below in Fig. 1(*b*) directly under the peaks in Fig. 1(*a*).

The main C^{13} satellites due to the 1.108% abundant isotope are clearly seen even at the low gain settings in spectrum 1(*a*). Examination of the spectrum in 1(*b*) shows peaks due to C^{13}—H^1 coupling in the molecules 2 and 3 and for both adjacent and remote methyl groups. Each of these weakest C^{13} satellites has an intensity $\sim 10^{-4}$ times that of the main resonance. The coupling constants which uniquely fit the observed spectrum are recorded in Table 1. The estimated error in these values is $\pm 0.25\%$.

TABLE 1

$J_{Sn^{115}-CH_3}$	= 42.9 c.p.s.	$J_{Sn^{119}-Sn-CH_3}$	= 16.3 c.p.s.
$J_{Sn^{117}-CH_3}$	= 47.0	$J_{C^{13}-H_3}$	= 128.9
$J_{Sn^{119}-CH_3}$	= 49.6	$J_{Sn^{117}-Sn^{119}}$	= 4400±70
$J_{Sn^{117}-Sn-CH_3}$	= 15.8	δ_{CH_3}	= −0.2 p.p.m.

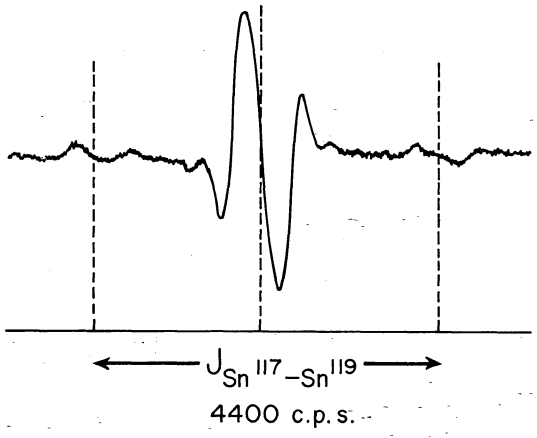

FIG. 2. Sn^{119} spectrum of hexamethylditin showing the coupling to Sn^{117} (15.37 Mc).

The Sn^{119} resonance spectrum is shown in Fig. 2. In order to observe the weak side-band resonances the modulation width exceeded the tin resonance width and the derivative of absorption signals are thus distorted. The weak satellite lines are due to molecules of type 7 in which two dissimilar isotopes Sn^{117}, Sn^{119} occur together. The separation of these two satellite lines is equal to $J_{Sn^{117}-Sn^{119}}$ (4400±70 c.p.s.). Spin-couplings between heavy metal atoms are quite rare in nuclear magnetic resonance and apart from a recent value of the Tl^{203}—Tl^{205} coupling constant of 2560 c.p.s. in the tetramer of thallous ethoxide there seems no other case reported (9). In this tetramer the coupling occurs through an intervening oxygen atom. A large platinum phosphorous coupling of 5700 c.p.s. has been reported in (10) $\{(EtO)_3P\}_2PtCl_2$ and in this case there is no intervening atom between the coupled nuclei. The electronic contribution to these coupling constants can be compared by dividing by the product $\gamma_N\gamma_N'$ where N and N′ are the two nuclear species involved. The result gives for the reduced coupling constants; Tl^{203}—O—Tl^{205} = 248 c.p.s. $\mu^{-1}.I$; Pt^{195}—P^{31} = 2080; Sn^{117}—Sn^{119} = 1062. The Pt^{195}—P^{31} coupling has the largest electronic contribution. We have shown that the coupling constant varies roughly as the square of the atomic numbers of coupled nuclei (6) in a given group of the periodic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

table. The large reduced coupling constants Sn^{117}—Sn^{119} and Pt^{195}—P^{31} are a reflection of the large atomic number of coupled nuclei.

The change in bond type of the Sn—C bond in hexamethylditin is well illustrated by examination of Fig. 3. This is a plot of $J_{C^{13}-H}$ in the methyl group for hexamethylditin,

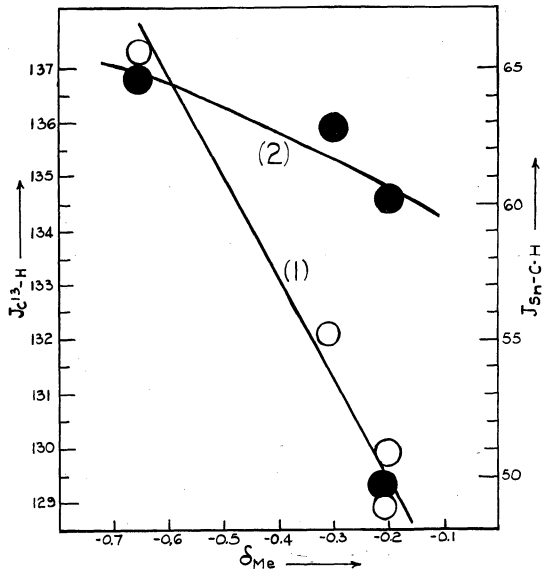

FIG. 3. Coupling constants $J_{Sn^{119}-C-H}$ and $J_{C^{13}-H}$ plotted as a function of δ_{Me} in methyl tin derivatives measured by us.

dimethyltin dihydride, dimethyltetrafluoroethyltin hydride, and dimethylditetrafluoroethyltin (5) against the chemical shift of the methyl protons. The values of $J_{C^{13}-H}$ versus chemical shift fall near a straight line—curve I—in the figure. The coupling constants J_{Sn-C-H} lie near a smooth curve except for the value in hexamethylditin, which is much lower than curve 2 in the figure. The Sn—Sn bond, therefore, considerably influences the Sn—C—H coupling constant and it is tempting to associate this with a reduced *s* character in the Sn—C bond and enhanced *s* character in the Sn—Sn bond.

NOTES

THE COVALENT CHARACTER OF ALKALI ALKOXIDES

M. S. BAINS[1]

Alkali metal alkoxides have been little studied (1) as is shown by a general lack of information regarding their structure and properties. Conductance measurements (2) show that dilute solutions of alkoxides of sodium are completely ionized in their parent alcohols. Use of these compounds as synthetic agents (3) in ionizing and polar media (4) appears to confirm the usual belief about their ionic character. Except for certain compounds of lithium, such as alkyls, alkali metals are assumed to form predominantly electrovalent compounds. It is only recently that a study of the crystal structure of lithium methoxide (5) has provided evidence that lithium–oxygen (Li–O) bond in this compound is approaching covalency.

Organic compounds of alkali metals such as alkoxides, amides, and mercaptides are important as catalysts or reagents in the reactions of organic carbonyl or unsaturated compounds (6–9). In view of this, the present work on alkali metal alkoxides was undertaken as a preliminary study of this neglected field by obtaining conditions of sublimation of pure compounds, by determining molecular weights cryoscopically, and by securing nuclear magnetic resonance spectra of the soluble alkali alkoxides.

Lithium *tert*-butoxide, according to present investigation, is found to be the most volatile lithium alkoxide amongst those studied, subliming at 110° C at 0.1 mm; lithium ethoxide is relatively less easily sublimed (155° C at 10^{-4} mm). Lithium isopropoxide sublimes under intermediate conditions, i.e. 170° C at 0.1 mm. It is also observed that, with increasing atomic number of the alkali metal, volatility decreases as, for example, potassium *tert*-butoxide which sublimes at 145° C at 10^{-4} mm. These data show that these compounds might be more covalent than hitherto supposed.

It is also found that pure lithium *tert*-butoxide and lithium iso-propoxide are soluble in benzene and in cyclohexane. Their molecular weights determined in these solvents show that lithium *tert*-butoxide is tetrameric in benzene and hexameric in cyclohexane over a fairly wide range of concentration. Lithium iso-propoxide is found to be undecameric in cyclohexane. The fact that the molecular weight of lithium *tert*-butoxide is lower in benzene suggests that the solvent plays some role in the dissolution of the compound. Cyclohexane has no π-electrons but benzene, by virtue of its sextet of π-electrons, may be expected to share in the covalency of the metal and thus lower its polymerization.

The determination of nuclear magnetic resonance spectra of the two soluble lithium alkoxides reveals their covalent metal–oxygen bond: the diamagnetic shielding of protons due to electrons is less than in the parent alcohol. For instance, the methyl protons in *tert*-butanol have a negative shift of -1.222 p.p.m. with respect to tetramethylsilane, while an even more negative shift is observed in the case of the tert-butoxide for the same protons (-1.527 p.p.m.). This indicates that metal–oxygen bond in lithium alkoxides is more covalent than the hydrogen–oxygen bond in alcohols. This may be explained by the fact that the electrons in the p–π orbitals of oxygen can be accepted by the empty p–π

[1]*National Research Council of Canada Postdoctoral Fellow, 1959–61.*

orbitals of lithium. This effect is probably augmented by the branching alkyl groups of the alkoxides on account of their enhanced +I effect and consequently the metal–oxygen bond is made more covalent by the so-called back-cordination. There is thus a decreased electronic shielding of the protons of the alkyl groups.

It is also possible to suggest as an alternative that steric requirements of the branched alkyl groups cause a weakening in the lattice forces of the crystalline compounds and this in addition to the +I effect may contribute toward the increased volatility of the more branched alkoxides.

EXPERIMENTAL

The desolvated alkoxides were sublimed at as low a temperature as possible and were handled in a dry box or under a continuous stream of dry nitrogen. The molecular weights were determined cryoscopically in both cyclohexane and benzene respectively.

The proton magnetic spectra were run at room temperature through a Varian 4300 B high-resolution spectrometer using frequency of 60 Mc/second. Tetramethylsilane sealed in a fine capillary was used as an external reference. Anhydrous carbon tetrachloride was employed as the solvent and the concentration of tert-butanol and lithium *tert*-butoxide were 11.9 and 3.6% weight/volume respectively.

The details of this work will be published in due course.

ON THE PORE STRUCTURE OF VYCOR GLASS

D. Basmadjian and K. P. Chu

The narrow pore size distribution believed to be present in porous Vycor glass makes it a suitable material for investigating basic properties of porous solids. Sorption isotherms of various gases on Vycor have been reported by Amberg and McIntosh (1) and Barrer and Barrie (2). The latter have, in addition, made extensive measurements of pure gas permeabilities in the Knudsen flow region. The sorption data have been used to evaluate the main structural parameters of the solid, yielding a B.E.T. area of about 120 m^2/g and a most probable pore radius of 28 Å obtained by application of the Kelvin equation to the desorption branch of the hysteresis loop (1). Using the pore size distribution derived in this manner and assuming a uniform cylindrical pore structure, Amberg and McIntosh

For personal use only.

(1) were then able to calculate a cumulative surface area in good agreement with the B.E.T. value. The cylindrical pore model proposed by these authors is, however, in conflict with the findings of subsequent investigators. de Boer, in a theoretical study (3), showed that the data of Amberg and McIntosh point to the existence of non uniform pores, the most likely shape being a cylindrical pore with globular *enlargements*. Barrer and Barrie (2) found that their measured permeabilities were about five times lower than those calculated on the basis of Knudsen flow through a cylindrical pore of 28 Å radius, even after correction for the percentage of solid in their plugs. Barrer and Gabor (4) attributed this to periodic *constrictions* in the pores, although similar low values could conceivably have resulted from a highly tortuous pore structure or a high percentage of blind pores.

Recent diffusion measurements made by us in the range 0.2–70 atm may serve to throw some fresh light on this discrepancy. A Corning brand Vycor glass (No. 7930, S = 120 m²/g, ϵ = 0.34) was used to measure counterdiffusion of hydrogen and nitrogen at constant pressure and in two directions perpendicular to each other. Details of the apparatus and

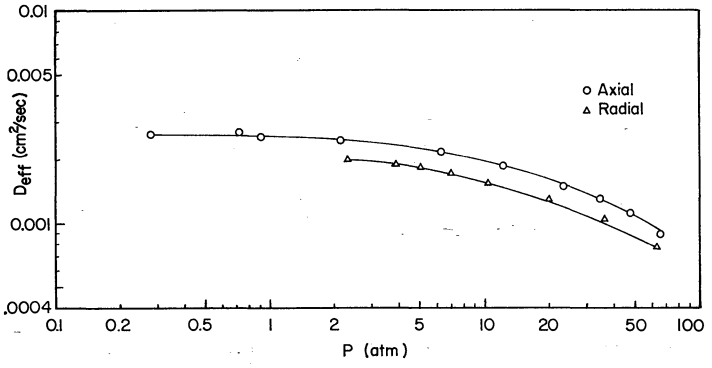

FIG. 1. Effective diffusivity of Vycor glass as a function of pressure.

procedure have been given elsewhere (5) and the results are plotted in Fig. 1. The pertinent equation for calculating effective diffusivities valid for both Knudsen and bulk diffusion as well as the transition zone has been derived by Scott and Dullien (6):

$$[1] \qquad \frac{N_A RTL}{P(y_{A_1}-y_{A_2})} = D_{eff} = \frac{(D_{AB})_{eff}}{(y_{A_1}-y_{A_2})\alpha} \ln \frac{1-\alpha y_{A_2}+(D_{AB}/D_{KA})_{eff}}{1-\alpha y_{A_1}+(D_{AB}/D_{KA})_{eff}}$$

At pressures up to about 5 atm, the data yield constant diffusivities, i.e. the material transport in this region is by Knudsen diffusion, which is independent of the total pressure and directly proportional to the average channel radius R_c. Under these conditions equation [1] reduces to the effective Knudsen diffusivity:

$$[2] \qquad D_{eff} = (D_{KA})_{eff} = \tfrac{2}{3} R_c \cdot v_A \cdot \epsilon \cdot X.$$

The tortuosity factor X accounts for any constrictions of the pore channel below the value R_c, the existence of blind pores, as well as the tortuous path of the pore.

At higher pressures, there is a gradual drop in diffusivity values, indicating a transition to bulk diffusion which is inversely proportional to pressure but independent of channel radius. In the limit, equation [1] reduces to the expression

$$[3] \qquad D_{eff} = (D_{AB})_{eff} = D_{AB} \cdot \epsilon \cdot X.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Substituting measured diffusivities in equations [1] and [2] and eliminating ϵX from equations [1–3], it is possible to evaluate the controlling pore radius R_c independent of any structural considerations and independent also of surface tension and other parameters which are required in the application of the Kelvin equation. The value of R_c obtained in this manner was 28 Å ±2 for both sets of measurements, and is in good agreement with the radius calculated from sorption data (1, 2). The corresponding tortuosities were 0.23 and 0.19. Thus, although Barrer and Barrie's tortuosity factor of 0.18 is essentially confirmed, the reason given by them to explain its small magnitude is not. The latter must instead be attributed to the tortuous pore path and (or) the existence of blind pores.

A possible pore structure which would yield the correct cumulative pore area and volume and be in agreement with the diffusion data as well as de Boer's pore model may be proposed. It would consist of randomly oriented pores with a tortuous path factor of $1/\sqrt{2} = 0.707$ proposed by Wheeler (7) and having globular enlargements part of whose volume would act as blind pores. Calculations have shown that a model of this type would require alternate sections of cylindrical pores ($R_c = 28$ Å, $L = 50$ Å) and spherical cavities ($R_s = 2R_c$). Further refinements of the model are at present not justified, but it may be pointed out that diffusion measurements of the type described may be usefully applied for the independent evaluation of controlling pore radii in similar solids.

NOMENCLATURE

A, B	Components in binary mixture.
D_{eff}	Effective diffusivity of a porous body, defined by equation [1], cm²/second.
$(D_{AB})_{eff}$	Effective diffusivity of a porous body in the bulk diffusion region, defined by equation [3], cm²/second.
$(D_{KA})_{eff}$	Effective diffusivity of a porous body in the Knudsen diffusion region, defined by equation [2], cm²/second.
D_{AB}	Bulk diffusion coefficient in free space, cm²/second.
L	Length of porous disk, cm, or cylindrical pore, Å.
M	Molecular weight.
N_A	Moles of component A diffusing per unit time and area of porous disk, g moles/second cm².
P	Pressure, atm.
R	Gas constant, atm cm³/g mole ° K.
R_c	Radius of cylindrical pore, cm.
R_s	Radius of spherical cavity, cm.
S	Surface area of porous solid, m²/g.
T	Temperature, ° K.
v_A	Average molecular velocity of component A, cm/second.
X	Tortuosity factor, dimensionless.
y_A	Mole fraction of component A, dimensionless.
α	$1+(N_A/N_B) = 1-(M_B/M_A)^{\frac{1}{2}}$.
ϵ	Porosity of material, cc/cc.

Subscripts 1 and 2 refer to the two ends of the porous disk.

Grateful acknowledgment is made for a National Research Council grant in support of this work.

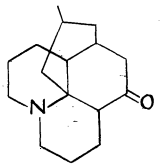
LYCOPODIUM ALKALOIDS. VI. THE NATURE OF ALKALOID L.9

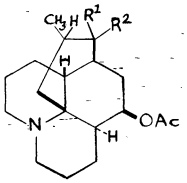
W. A. AYER, A. N. HOGG, AND A. C. SOPER

In 1943 Manske and Marion reported (1) the isolation of a basic substance, m.p. 122°, from *Lycopodium annotinum L.*, which they designated alkaloid L.9. At that time they stated that "alkaloid L.9 is probably a mixture but, owing to its exceptional behaviour, it has been deemed advisable to retain one designation only until more can be ascertained concerning its nature". Through the courtesy of R. H. Manske we have obtained a sample of "alkaloid L.9" and wish at this time to report on its composition.

Thin-layer chromatography (t.l.c.) over alumina revealed the presence of (at least) two components, one having the same R_f value as lycopodine (I), the other having a lower R_f value.



I



II, $R^1 = H$; $R^2 = OAc$
III, $R^1 = OH$; $R^2 = H$
IV, $R^1 = OAc$; $R^2 = H$

A mixture of lycopodine and "alkaloid L.9" also showed only two spots on t.l.c., suggesting that lycopodine (I) was a component of "alkaloid L.9". Since insufficient material was available for a preparative separation of the components we turned to mass spectrometry as a further aid to identification of the components. The mass spectrum of alkaloid L.9 displayed all the major ions expected for lycopodine (2, 3) and in addition showed weak peaks at m/e 349, 290, 289, and moderately intense peaks at m/e 234 and 174. The infrared spectrum of alkaloid L.9 suggested the presence of O-acetyl groups (1735, 1725, 1250, 1230 cm^{-1}) and thus it seemed reasonable to interpret the extra peaks in the mass spectrum in terms of the following sequence, since it is known (2, 3) that ions of type A and B are readily formed from *Lycopodium* alkaloids:

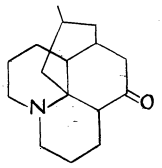
LYCOPODIUM ALKALOIDS. VI. THE NATURE OF ALKALOID L.9

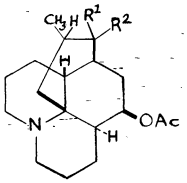
W. A. AYER, A. N. HOGG, AND A. C. SOPER

In 1943 Manske and Marion reported (1) the isolation of a basic substance, m.p. 122°, from *Lycopodium annotinum L.*, which they designated alkaloid L.9. At that time they stated that "alkaloid L.9 is probably a mixture but, owing to its exceptional behaviour, it has been deemed advisable to retain one designation only until more can be ascertained concerning its nature". Through the courtesy of R. H. Manske we have obtained a sample of "alkaloid L.9" and wish at this time to report on its composition.

Thin-layer chromatography (t.l.c.) over alumina revealed the presence of (at least) two components, one having the same R_f value as lycopodine (I), the other having a lower R_f value.

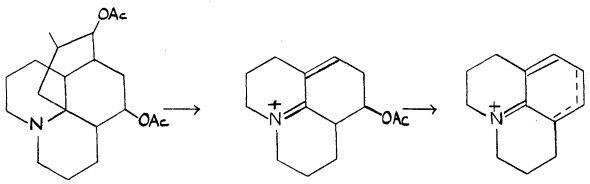


I



II, $R^1 = H$; $R^2 = OAc$
III, $R^1 = OH$; $R^2 = H$
IV, $R^1 = OAc$; $R^2 = H$

A mixture of lycopodine and "alkaloid L.9" also showed only two spots on t.l.c., suggesting that lycopodine (I) was a component of "alkaloid L.9". Since insufficient material was available for a preparative separation of the components we turned to mass spectrometry as a further aid to identification of the components. The mass spectrum of alkaloid L.9 displayed all the major ions expected for lycopodine (2, 3) and in addition showed weak peaks at m/e 349, 290, 289, and moderately intense peaks at m/e 234 and 174. The infrared spectrum of alkaloid L.9 suggested the presence of O-acetyl groups (1735, 1725, 1250, 1230 cm^{-1}) and thus it seemed reasonable to interpret the extra peaks in the mass spectrum in terms of the following sequence, since it is known (2, 3) that ions of type A and B are readily formed from *Lycopodium* alkaloids:



A B

m/e 349 m/e 234 m/e 174

The peaks at m/e 290 and 289 simply represent loss of OAc and HOAc from the molecular ion.

At this point it seemed that the naturally occurring O-acetylfawcettiine (II) (4) might represent the second component of alkaloid L.9. However, when a mixture of II and alkaloid L.9 was subjected to t.l.c. three distinct spots were obtained, O-acetylfawcettiine displaying a lower R_f value than either of the L.9 components. The C-8 epimer of O-acetylfawcettiine, O-acetyllofoline (IV), prepared by acetylation of lofoline (III) (5), was, however, indistinguishable by t.l.c. from the lower R_f component of alkaloid L.9. The mass spectrum of O-acetyllofoline showed the expected peaks (see above), the base peak appearing at m/e 174 (ion B). Crystallization of a 1:1 mixture of lycopodine and O-acetyllofoline from hexane yielded crystals, m.p. 121–122°, identical (mixed melting point, infrared spectrum, t.l.c. behavior) with authentic "alkaloid L.9", which is thus a molecular complex of these two substances. Recrystallization of the complex from either hexane or ether did not alter the melting point. It is interesting to note that the analytical results obtained earlier by Manske and Marion (1) agree well with the composition $C_{16}H_{25}ON \cdot C_{20}H_{31}O_4N$.

The natural occurrence of O-acetyllofoline (IV) has not been reported previously.

EXPERIMENTAL

The mass spectra were determined on a AEI MS2-H mass spectrometer at an ionizing potential of 70 ev and an ionizing current of 100 μa. Samples were introduced through a heated inlet system maintained at 150°. Thin-layer chromatograms were carried out on 0.25 mm layers of alumina G (Research Specialties Co., Richmond, Calif.) on glass plates using chloroform – 0.75% ethanol as the solvent system, and were developed with Dragendorff's reagent (6).

Alkaloid L.9

(*a*) A sample supplied by Dr. R. H. Manske melted at 121–122°. Infrared spectrum: ν_{max}^{nujol} 1735, 1725, 1698, 1250, 1230 cm^{-1}.

(*b*) O-Acetyllofoline (84 mg) and lycopodine (60 mg) were dissolved in a minimum volume of hot hexane. On cooling, colorless crystals (110 mg), m.p. 121–122°, separated. The melting point was not altered by recrystallization from either hexane or anhydrous ether. The material obtained in this way was identical (mixed melting point, infrared spectrum, t.l.c. behavior) with the authentic sample of alkaloid L.9.

O-Acetyllofoline

Lofoline (0.22 g) was dissolved in 1:1 acetic anhydride – pyridine (30 ml) and the solution kept at room temperature for 48 hours, then evaporated at the pump. The oily residue was dissolved in $CHCl_3$ and filtered through alumina (8 g). Evaporation of the solvent left a colorless viscous oil (0.22 g) which showed a single spot on t.l.c. A sample was purified by evaporative distillation under reduced pressure. Calc. for $C_{20}H_{31}O_4N$: molecular weight, 349. Found: molecular weight (mass spec.) 349. Infrared spectrum: $\nu_{max}^{CHCl_3}$ 1720–1730, 1225 cm^{-1}. Nuclear magnetic resonance spectrum (CCl_4): 4.92 τ (1H, triplet, C*H*OAc), 5.25 τ (1H, mult., C*H*OAc), 7.96 and 8.02 τ (6H, two OCOC*H*$_3$), 9.12 τ (3H, doublet, CHC*H*$_3$).

A sample of the base in acetone was converted to the perchlorate by addition of perchloric acid. After recrystallization from acetone–ether the salt melted at 272–273° (dec.). Calc. for $C_{20}H_{31}O_4N.HClO_4$: C, 53.40; H, 7.17; N, 3.11%. Found: C, 53.30; H, 7.06; N, 2.95%. Infrared spectrum: ν_{max}^{nujol} 3040 (—N$^+$H), 1737, 1722, 1235 cm^{-1} (OAc).

PROTON MAGNETIC RESONANCE ABSORPTION IN COPPER(II) STEARATE

R. F. GRANT

The magnetic moment of copper in copper(II) acetate is known to decrease as the temperature is lowered (1, 2). This anomalous effect has been explained by assuming that the copper ions are arranged in isolated pairs which interact strongly through exchange forces (3). X-Ray studies, supporting this explanation, have shown that copper(II) acetate monohydrate exists as a binuclear molecule $Cu_2(CH_3CO_2)_4 \cdot 2H_2O$ in which the copper ions are situated close together (4). By analogy, a similar structure has been suggested for copper(II) salts of higher fatty acids (5, 6), although a layer structure allowing a kind of antiferromagnetic interaction between the copper ions has also been proposed (7). This layer structure, which is supposedly characteristic of fatty acid salts (8), infers a cooperative effect between copper ions extending in planes throughout the crystal lattice. In such a structure, the interaction between the copper ions should decrease if the lattice expands with rising temperature and some correlation between motion of the hydrocarbon portion of the molecule and the magnetic moment might be expected. The following investigation of proton magnetic resonance absorption in copper(II) stearate shows no such correlation.

EXPERIMENTAL

The stearic acid used was Eastman Kodak white label grade, purified by repeated crystallization at −20° C in acetone. Copper(II) stearate was prepared by metathesis of potassium stearate in 70% ethanol with an aqueous solution of copper(II) sulphate at 60° C. The soap precipitate was allowed to settle overnight and was then washed repeatedly on a suction filter with distilled water and with aqueous ethanol. The product was dried in an air oven at 100° C and then heated to about 130° C under vacuum to render it more compact. Portions of this soap used in the proton magnetic resonance investigations were reheated under vacuum in sample tubes, dry nitrogen was admitted to the system, and the tubes were sealed off.

Copper(II) stearate has been reported to melt indefinitely to a clear blue liquid at 125° C (9). This was not observed, either for the samples which had been heated under vacuum or for new samples dried in air. On a Fisher–Johns melting block, some sample particles were observed to deform slightly around 120° C,

In such a structure, the interaction between the copper ions should decrease if the lattice expands with rising temperature and some correlation between motion of the hydrocarbon portion of the molecule and the magnetic moment might be expected. The following investigation of proton magnetic resonance absorption in copper(II) stearate shows no such correlation.

EXPERIMENTAL

The stearic acid used was Eastman Kodak white label grade, purified by repeated crystallization at −20° C in acetone. Copper(II) stearate was prepared by metathesis of potassium stearate in 70% ethanol with an aqueous solution of copper(II) sulphate at 60° C. The soap precipitate was allowed to settle overnight and was then washed repeatedly on a suction filter with distilled water and with aqueous ethanol. The product was dried in an air oven at 100° C and then heated to about 130° C under vacuum to render it more compact. Portions of this soap used in the proton magnetic resonance investigations were reheated under vacuum in sample tubes, dry nitrogen was admitted to the system, and the tubes were sealed off.

Copper(II) stearate has been reported to melt indefinitely to a clear blue liquid at 125° C (9). This was not observed, either for the samples which had been heated under vacuum or for new samples dried in air. On a Fisher–Johns melting block, some sample particles were observed to deform slightly around 120° C,

but most of the particles became glassy in appearance at 117–122° C and retained their shapes. At 250–252° C the sample particles appeared to melt and flow freely.

The nuclear magnetic resonance spectrometer and associated apparatus have been described previously (10).

Figure 1 shows the variations of the proton magnetic resonance absorption line width of copper(II) stearate as a function of temperature. The line width was taken as the separation, in gauss, of the points of maximum and minumum slope on the resonance line. Also shown in Fig. 1 are the corresponding variations of second moment with temperature. The second moments of the resonance lines were obtained by a graphical method (11) and were corrected for the effects of modulation (12). Between 116 and 120° C, in the vicinity of the reported melting point (9), the line width decreased to a value governed by the depth of modulation which was 0.3 gauss. The narrowed line retained broad wings of comparatively small amplitude, allowing a second moment of 0.9 gauss^2.

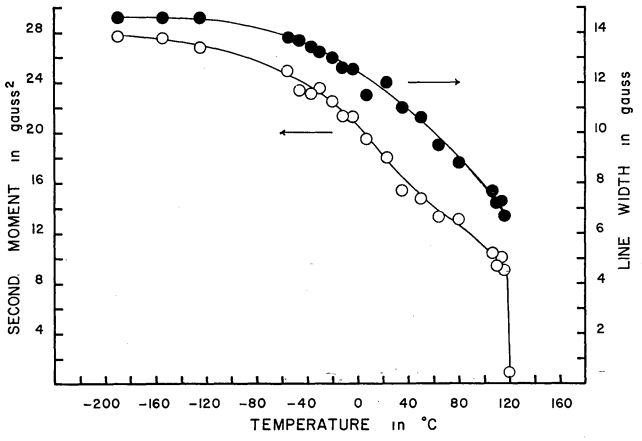

FIG. 1. Line width and second moment of copper(II) stearate as functions of temperature. Filled circles, line width; open circles, second moment.

DISCUSSION

Since details of the copper(II) stearate unit cell are not available, the rigid lattice second moment cannot be directly calculated. However, X-ray studies reporting long and short spacings (13) suggest that the hydrocarbon chain packing in copper(II) stearate may be similar to the chain packing in silver stearate. The crystal structure of silver stearate is well known (14) and a rigid lattice second moment of 28.3 gauss^2 has been calculated for it (15). This value is close to the experimental second moment of 27.7±0.5 gauss^2 obtained for copper(II) stearate at –190° C, and it is assumed that there is little molecular motion at this temperature. The contribution of the paramagnetic copper(II) ions to the second moment was calculated to be less than 0.1 gauss^2. The gradual decrease in the second moment of copper(II) stearate as the temperature is raised between –190° C and 116° C can be interpreted in terms of a torsional oscillation about the longitudinal axis of the hydrocarbon chain portion of the molecule (15). The effect of such motion on the second moment has been calculated for a silver stearate structure (15) and is assumed to be valid for copper(II) stearate. Torsional oscillation amplitudes can therefore be obtained from the copper(II) stearate results by using the second moment versus torsional oscillation curve calculated for silver stearate (15). The temperature dependence of the relative amplitude of torsional oscillation is shown in Fig. 2 along with the magnetic moment results of Martin and Waterman (6). A comparison of the two curves in Fig. 2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

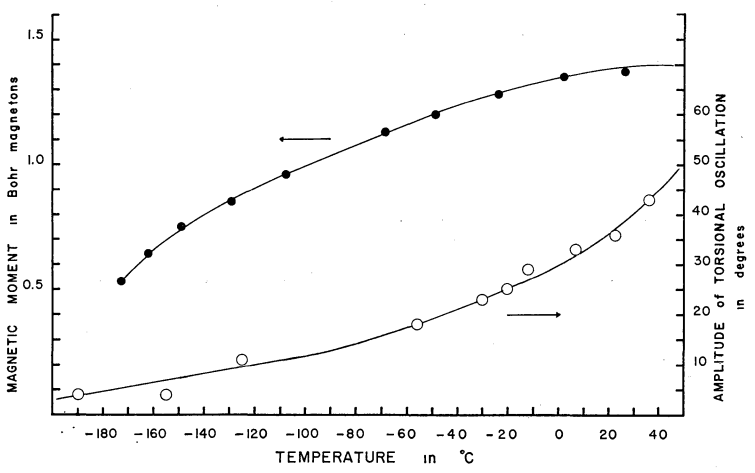

FIG. 2. The copper magnetic moment (6) and amplitude of torsional oscillation of the hydrocarbon chains in copper(II) stearate as functions of temperature. Filled circles, magnetic moment; open circles, torsional oscillation.

suggests that there is little correlation between hydrocarbon chain motion and change in the magnetic moment of the copper ion in copper(II) stearate.

The change in line width and second moment between 116 and 120° C seems to be related to a thermal transition previously reported as the melting point. Since copper(II) stearate does not become a freely flowing liquid until 250° C it is assumed that the melting point reported to occur around 125° C is a mesomorphic transition, perhaps similar in nature to one of the transitions known to occur in alkali metal soaps (15, 16). The second moment of 9.0 gauss^2 at 116° C for copper(II) stearate is slightly larger than the 8.1 gauss^2 predicted for complete rotation of the hydrocarbon chain about the long axis in the silver stearate structure (15). The narrow line at 120° C indicates that the hydrocarbon chain has become free to rotate about many axes, however, the finite second moment implies that the molecules are not free to diffuse through the lattice (17).

THE NUCLEAR MAGNETIC RESONANCE SPECTRA OF THE CARBOLINES

R. A. ABRAMOVITCH AND I. D. SPENSER

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

There is no report in the literature on the n.m.r. spectra of the parent fully aromatic carbolines. The spectra of α- (Fig. 1), β- (Fig. 2), and δ-carboline (Fig. 3) have now been measured using a Varian DP-60 instrument. Unfortunately, a sample of the γ-isomer was not available at this time. The spectra had to be determined on dimethyl sulphoxide solutions of the compounds due to their insolubility in the common solvents: the solvent peak was used as internal reference.[1] Solvent corrections have not been applied and a complete analysis of the spectra has not been attempted. A number of features are worth commenting upon, however.

A band (not shown) at 719 c.p.s. towards low field in the spectrum of β-carboline is due to the *ind*-N–H group. The single proton singlet at 555 c.p.s. is undoubtedly due to C_1–H and the doublet centered at 515 c.p.s. ($J_{3,4}$ 6 c.p.s.) to C_3–H. The signals for C_4–H (a pyridine β-proton) overlap with those of the phenyl protons at higher field. The corresponding assignments for δ-carboline appear to be almost as straightforward. The The *ind*-N–H proton gives rise to a line at 704 c.p.s. (not shown). A single-proton doublet ($J_{2,3}$ 4 c.p.s.) centered at 520 c.p.s. may be attributed to C_2–H (pyridine α-proton). At much higher resolution this may be seen to be a quartet ($J_{2,4}$ 1 c.p.s.) as expected. A second single-proton doublet ($J_{3,4}$ 8 c.p.s.), centered at 506 c.p.s., is probably due to C_4–H (pyridine γ-proton). The single-proton doublet (J 8 c.p.s.) at 480 c.p.s. may be due to C_3–H but this seems to be a somewhat low field for a pyridine β-proton absorption (though lines within the range 479–499 c.p.s. have been attributed to pyridine β-protons (1)), and one would have expected the resonance due to this proton to give rise to a quartet. It is more likely that this doublet is due to C_8–H (cf. the lines due to C_8–H in quinoline (2)) and that the lines for C_3–H overlap with those of the phenyl protons. It is of interest to note that, if the above assignments are correct, the signal corresponding to C_1–H in β-carboline is at a much lower field than that for C_3–H in β- and that for C_2–H in δ-carboline, and is certainly at a lower field than is expected for a pyridine α-proton (3). A similar situation is observed in isoquinoline (2). The electron-attracting character of the *ind*-*N* may well also play a role here. An analogous effect appears to exist in δ-carboline, where C_4–H (corresponding to a pyridine γ-proton) absorbs at a lower field than expected.

The interpretation of the α-carboline spectrum is more difficult and only tentative suggestions can be made at this time. The *ind*-N–H absorbs quite unexceptionally at 723 c.p.s. (not shown). Two lines appear at 519 and 511 c.p.s., respectively, each one having an area corresponding to one proton. A single-proton doublet (J 7 c.p.s.) is centered at 496 c.p.s. One of the bands at 519 and 511 c.p.s. is undoubtedly due to C_2–H, and it is then tempting to suggest that these peaks are caused by overlapping doublets due to C_2–H and C_4–H. C_3–H would be expected to give rise to a quartet due to coupling with two non-equivalent protons, so that the doublet at 496 c.p.s. may be due to C_8–H. No firm assignments can be made without further studies.

[1]*The signal of dimethyl sulphoxide is observed at 152.7±0.3 c.p.s. downfield from that of tetramethylsilane when the latter is dissolved in dimethyl sulphoxide.*

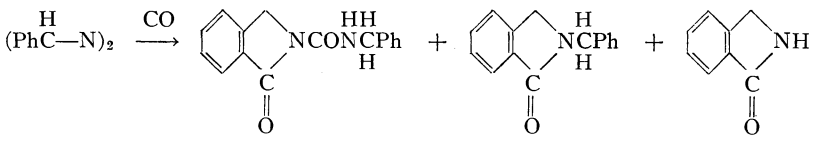
REACTION OF BENZALDEHYDE SEMICARBAZONE AND AZINE WITH CARBON MONOXIDE

ALEX ROSENTHAL AND S. MILLWARD

It has been reported previously (1) that benzophenone semicarbazones and benzophenone azine reacted with carbon monoxide in the presence of dicobalt octacarbonyl to yield phthalimidines. The work reported herein deals with an extension of a similar reaction to benzaldehyde semicarbazone and to benzaldehyde azine.

When benzaldehyde semicarbazone was treated with about 4000 p.s.i. of carbon monoxide at 235–245° in the presence of preformed dicobalt octacarbonyl, no cyclization took place but the substrate was converted in 63% yield into benzaldehyde azine. Under similar conditions, except at a lower temperature of 215–220°, the same substrate afforded a 54% yield of the same product. In addition to the azine, about 39% of an insoluble blue organocobalt complex (no catalyst was present after the reaction) and about 6% of bibenzyl were also produced. Presumably, the cyclization reaction did not take place because the catalyst was precipitated out of the reaction mixture. On the other hand, benzaldehyde azine incorporated carbon monoxide at 235–245° to yield 2-(N-benzylcarboxamido)phthalimidine (I), N-benzylphthalimidine (II), and phthalimidine (III) in 5%, 16%, and 13% yields, respectively. In the last experiment some of the catalyst was still present in the reaction mixture. As in the previous experiments, a trace quantity of bibenzyl was produced in addition to about 14% of an organocobalt complex. From the mixture of products which were separated by alumina chromatography, a substance (IV) was also isolated in 12% yield.



I II III

Structure (I) was deduced on the bases of its elemental analysis and a comparison of its infrared spectrum with that of 3-phenyl-2(N-benzhydrylcarboxamido)phthalimidine (1). Final confirmation of structure (I) was obtained by direct comparison of compound

Presented at the XIXth International Congress of Pure and Applied Chemistry, London, England, July, 1963.

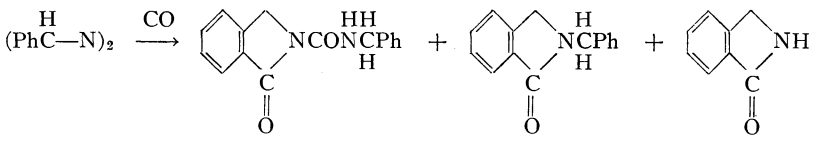
REACTION OF BENZALDEHYDE SEMICARBAZONE AND AZINE WITH CARBON MONOXIDE

ALEX ROSENTHAL AND S. MILLWARD

It has been reported previously (1) that benzophenone semicarbazones and benzophenone azine reacted with carbon monoxide in the presence of dicobalt octacarbonyl to yield phthalimidines. The work reported herein deals with an extension of a similar reaction to benzaldehyde semicarbazone and to benzaldehyde azine.

When benzaldehyde semicarbazone was treated with about 4000 p.s.i. of carbon monoxide at 235–245° in the presence of preformed dicobalt octacarbonyl, no cyclization took place but the substrate was converted in 63% yield into benzaldehyde azine. Under similar conditions, except at a lower temperature of 215–220°, the same substrate afforded a 54% yield of the same product. In addition to the azine, about 39% of an insoluble blue organocobalt complex (no catalyst was present after the reaction) and about 6% of bibenzyl were also produced. Presumably, the cyclization reaction did not take place because the catalyst was precipitated out of the reaction mixture. On the other hand, benzaldehyde azine incorporated carbon monoxide at 235–245° to yield 2-(N-benzylcarboxamido)phthalimidine (I), N-benzylphthalimidine (II), and phthalimidine (III) in 5%, 16%, and 13% yields, respectively. In the last experiment some of the catalyst was still present in the reaction mixture. As in the previous experiments, a trace quantity of bibenzyl was produced in addition to about 14% of an organocobalt complex. From the mixture of products which were separated by alumina chromatography, a substance (IV) was also isolated in 12% yield.



I II III

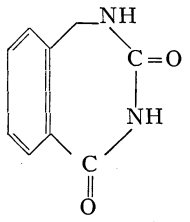
Structure (I) was deduced on the bases of its elemental analysis and a comparison of its infrared spectrum with that of 3-phenyl-2(N-benzhydrylcarboxamido)phthalimidine (1). Final confirmation of structure (I) was obtained by direct comparison of compound

Presented at the XIXth International Congress of Pure and Applied Chemistry, London, England, July, 1963.

(I) with an authentic sample of 2-(N-benzylcarboxamido)phthalimidine prepared by the condensation, under conditions previously described (2), of benzylisocyanate with phthalimidine.

The structure of compound (II) was established by direct comparison with an authentic sample of N-benzylphthalimidine prepared by the method of Murahashi and co-workers (3). Likewise, compound (III) was directly compared with an authentic sample of phthalimidine (4) and shown to be the same in melting point and infrared spectrum.

Compound (IV) had an empirical formula of $C_9H_8N_2O_2$. When heated with either concentrated sulphuric acid or concentrated sodium hydroxide, carbon dioxide and ammonia, respectively, were evolved. On the bases of elemental, infrared, and proton magnetic resonance analyses, its structure is tentatively suggested to be that represented by structure (IV). Infrared absorptions at 3380 and 3220 cm^{-1} indicated the presence of



IV

two different monosubstituted amide functions, the one at 3380 cm^{-1} being a non-bonded NH and the one at 3220 cm^{-1}, a bonded NH absorption. The CONHCO group showed a single bonded amide NH absorption in the 3200 cm^{-1} region similar to that of cyclic lactams (5). Absorptions at $\delta = 4.96$ and at about 7.6 in the nuclear magnetic resonance spectrum of compound (IV) were consistent with the presence of a benzylic methylene group and a fused benzene ring in the proposed formulation. As attempts to synthesize compound (IV) by unequivocal methods were without success, further work was abandoned.

EXPERIMENTAL

General Considerations

(*a*) The high-pressure equipment has been described previously (1).

(*b*) In every carbonylation experiment preformed dicobalt octacarbonyl (6) was used, and high purity carbon monoxide (containing 0.01% hydrogen) supplied by the Matheson Co., East Rutherford, N. J., was added to an initial pressure of about 2100 p.s.i. at room temperature.

(*c*) The aluminum oxide (calcined) "Analar" was procured from the British Drug Houses (Canada) Ltd., Toronto 14.

(*d*) All melting points were obtained on a Leitz heating stage and are uncorrected. The infrared analyses were done on a Perkin–Elmer spectrophotometer, Model 21, using a sodium chloride crystal. Microanalyses were done by Dr. A. Bernhardt, Mikroanalytisches Laboratorium, im Max-Planck Institut fur Kohlenforschung, Mülheim (Ruhr), Germany, and by Mrs. Aldridge of this Department. The n.m.r. spectra were obtained on a Varian A-60 instrument using tetramethylsilane as the internal standard (set at $\delta = 0$).

Carbonylation of Benzaldehyde Semicarbazone at 235–245°

To a mixture of 5.90 g of benzaldehyde semicarbazone (0.036 mole) in 45 ml of anhydrous, thiophene-free benzene were added 1.8 g of preformed dicobalt octacarbonyl and 2000 p.s.i. of carbon monoxide. The mixture was heated, with rocking, for 150 minutes at 235–245°. The reaction product consisted of 2.76 g of blue solid (A), and a brown liquid (free of catalyst) which, on evaporation under reduced pressure, yielded 3.50 g of a brown solid (B).

Benzaldehyde Azine (from Solid A)

The solid (A) was extracted with ethyl ether for 48 hours in a Soxhlet apparatus yielding 0.19 g of solid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

residue. Recrystallization of this residue from petroleum ether (b.p. 65–110°) yielded benzaldehyde azine. m.p. 90–92°. The mixed melting point of the latter substance and an authentic sample of benzaldehyde azine (7) was 90–92°. The infrared spectra of the two compounds were identical. Infrared spectrum of benzaldehyde azine (KBr); 3000 (w), 2920 (w), 1619 (m), 1570 (w), 1492 (w), 1446 (m), 1320 (w), 1305 (w), 1288 (w), 1210 (m), 1170 (w), 1070 (w), 1020 (w), 999 (w), 955 (m).

Separation of Substances in Solid B

A 0.87 g sample of solid B was dissolved in a minimum of benzene, and chromatographed on alumina using benzene as a developer. Bibenzyl (0.019 g, 2% yield) was eluted first, followed by benzaldehyde azine (0.569 g, 61% yield). Bibenzyl was compared with an authentic stock sample of bibenzyl and shown to be the same. Further elution of the column with benzene–ethanol (90:10) eluted about 0.03 g of solid which was crystallized from benzene, m.p. 214–215°. The substance was not analyzed because of the lack of material.

Carbonylation of Benzaldehyde Semicarbazone at 215–220°

Similarly, benzaldehyde semicarbazone (10 g) was carbonylated at 215–220° for 3 hours. The reaction product consisted of 5.47 g of blue solid and a brown liquid which afforded, on evaporation, 4.32 g of solid. The products were worked up as described in the 235–245° experiment yielding 6% of bibenzyl, 54% of benzaldehyde azine, and 39% of a blue insoluble complex.

Carbonylation of Benzaldehyde Azine at 235–245°

An amount of 8.20 g of benzaldehyde azine was carbonylated as described in the first experiment for 2.5 hours at 235–245°. The reaction product consisted of 2.28 g of a black solid (C) and a dark green solution which, upon evaporation under reduced pressure, gave 7.15 g of greenish black solid (D). The solid (C) was extracted with chloroform. Evaporation of the chloroform solution yielded a residue which was chromatographed on alumina to yield bibenzyl.

Separation of Substances in Solid (D)

A 2.28 g sample of material (D), dissolved in benzene, was chromatographed on an alumina column (130×60 mm diameter). The following developers were then added consecutively with elutions as indicated:

(1) 1100 ml of benzene eluted 0.372 g of oily material (E);
(2) 1300 ml of benzene yielded no material;
(3) 300 ml of benzene gave 0.449 g (16%) of white solid (II);
(4) 1600 ml of benzene–chloroform (3:1) eluted 0.12 g of solid;
(5) 550 ml of benzene–chloroform (3:1) eluted 0.187 g (6%) of solid;
(6) 1200 ml of benzene–chloroform (1:1) eluted a trace of material;
(7) 600 ml of chloroform eluted a trace of solid;
(8) 1000 ml of benzene–ethanol (4:1) eluted 0.45 g (13%) of solid (III);
(9) 2000 ml of ethanol–water (1:1) afforded 0.37 g (12%) of solid (IV).

Characterization of Fractions

2-(N-Benzylcarboxamido)phthalimidine (I)

Material (E) was rechromatographed on alumina. Petroleum ether (b.p. 30–60°) eluted bibenzyl (0.023 g, 1%). The column was then eluted with 800 ml of benzene – petroleum ether to afford 0.03 g of white solid. Benzene–chloroform (500 ml) removed 0.17 g (5%) of 2-(N-benzylcarboxamido)phthalimidine which was recrystallized from ethyl ether – petroleum ether (b.p. 30–60°), m.p. 127–128°. Infrared spectrum (KBr) of compound (I): 3290 (m), 3030 (w), 2940–2920 (w), 1710 (s), 1675 (m), 1613 (w), 1590 (w), 1533 (s), 1494 (w), 1470 (w), 1442 (m), 1369 (s), 1343 (w), 1324 (m), 1302 (m), 1258 (m), 1237 (w), 1216 (w), 1193 (w), 1155 (m), 1104 (w), 1078 (w), 754 (m), 737 (s), 693 (s).

Synthesis of Authentic 2-(N-Benzylcarboxamido)phthalimidine

Benzyl chloride (15 g) was first treated with silver cyanate (21.6 g) under reflux for about 10 minutes. Distillation of the product under reduced pressure yielded benzylisocyanate. The latter compound (0.07 g) was then condensed with phthalimidine (0.07 g) following the procedure previously described (8) to yield 0.095 g (68%) of a white solid which, after recrystallization from carbon tetrachloride – petroleum ether (b.p. 30–60°) gave white needles, m.p. 126–127°. The mixed melting point with compound (I) was 126–127°. The infrared spectra of the two substances were identical. Anal. Found: C, 72.12; H, 5.13; N, 10.17. Calc. for $C_{16}H_{14}N_2O_2$: C, 72.16; H, 5.30; N, 10.52.

2-Benzylphthalimidine (II)

Compound (II) was repurified by alumina chromatography and then recrystallized from petroleum ether (b.p. 30–60°), m.p. 90–91°. The mixed melting point of compound (II) and an authentic sample of N-benzylphthalimidine, prepared by the method of Murahashi and co-workers (3), was 90–91°. Infrared spectrum of compound (II) (KBr): 3020 (w), 2900 (w), 1667 (s), 1492 (w), 1466 (m), 1450 (m), 1436 (w), 1411 (m), 1354 (m), 1324 (w), 1315 (w), 1298 (w), 1284 (w), 1264 (m), 1219 (w), 1203 (m), 1180 (w), 1140 (w), 1070 (w), 968 (w), 926 (w), 855 (w), 764 (w), 735 (s). Anal. Found: C, 80.61; H, 5.97; N, 6.25. Calc. for $C_{15}H_{13}NO$: C, 80.67; H, 5.87; N, 6.27.

Phthalimidine (III)

Compound (III) dissolved in benzene–ethanol was treated with Norite, filtered, evaporated to dryness, and then recrystallized from benzene – petroleum ether (b.p. 30–60°), m.p. 154–155°. The mixed melting point of compound (III) with an authentic sample of phthalimidine prepared by the method of Graebe (4) was 154–155°. The infrared spectra of both substances were identical.

Substance (IV)

Substance (IV) was recrystallized from hot benzene, m.p. 255–256° (decomp.). Infrared spectrum (KBr): 3380 (s), 3220 (m), 3030 (w), 2900 (w), 1715 (s), 1664 (s), 1597 (s), 1580 (s), 1555 (m), 1470 (m), 1455 (m), 1391 (m), 1363 (s), 1320 (m), 1300 (m), 1219 (m), 1183 (w), 1154 (m), 1145 (m), 1082 (w), 922 (w), 820 (w), 800 (w), 761 (m), 730 (m), 677 (w). Nuclear magnetic resonance signals (given in δ units); (*a*) spectrum obtained in trifluoracetic anhydride; 4.96 (area = 2H), 7.55, 7.60, 7.79 (area = 4H), 7.90, 8.01 (area = 2H); (*b*) spectrum obtained in dimethylsulphoxide; 4.80 (area = 2H), 7.72 (area = 6H).

Compound (IV), when heated in concentrated sulphuric acid, evolved carbon dioxide, and, when heated with concentrated sodium hydroxide, yielded ammonia. Anal. Found: C, 61.55; H, 4.82; N, 15.78; O, 18.13. Calc. for $C_9H_8N_2O_2$: C, 61.35; H, 4.58; N, 15.91; O, 18.16.

1(7),8-*p*-MENTHADIENE EX PYROLYSIS OF β-PINENE

L. Steinbach, E. T. Theimer, and B. M. Mitzner

The mechanism postulated by Burwell (1) for the pyrolysis of β-pinene I, via a biradical II, predicts the formation of myrcene III, dipentene IV, and 1(7),8-*p*-menthadiene V. Although it is well known (for example, cf. ref. 2) that myrcene and dipentene are products of this pyrolysis, the formation of 1(7),8-*p*-menthadiene has not been reported.

We have found 1(7),8-*p*-menthadiene in an amount of about 5% among the products formed by the vapor-phase pyrolysis of β-pinene. The separation is a difficult one and thus V may easily have been overlooked by previous workers who did not have available refined gas chromatographic equipment.

This confirmation of the presence of 1(7),8-*p*-menthadiene in β-pinene pyrolyzate adds support to the pyrolysis mechanism of Burwell.

EXPERIMENTAL

Myrcene from the pyrolysis of commercial β-pinene (94%) was used for most of this work. To be absolutely certain that the 1(7),8-*p*-menthadiene was not an impurity in the starting β-pinene, a sample of β-pinene* (99% by gas chromatography) was pyrolyzed under the conditions of Goldblatt and Palkin (2). Here also 5% of 1(7),8-*p*-menthadiene was found in the pyrolyzate. Preparative gas chromatography was carried out using a VPC unit consisting of 10 ft × 1/2 in. O.D. × 7/16 in. I.D. copper tubing packed with 20% Carbowax 20 M on 60–80 mesh silane-treated Celite at a temperature of 120° C and an inlet pressure of 40 p.s.i. helium with a flow rate of 120 ml/minute. The 1(7),8-*p*-menthadiene eluted between myrcene and dipentene. Two passes were required to obtain pure V because of the closeness in elution time to dipentene and myrcene. The relative retention times of 1(7),8-*p*-menthadiene and dipentene are 0.95:1.00. The infrared spectrum of our V was the same as that reported by Webb and Bain (3). It was also the same as that of the 1(7),8-*p*-menthadiene formed (together with dipentene) by the pyrolysis of β-terpinyl acetate VI (4).

EXPERIMENTAL

Myrcene from the pyrolysis of commercial β-pinene (94%) was used for most of this work. To be absolutely certain that the 1(7),8-*p*-menthadiene was not an impurity in the starting β-pinene, a sample of β-pinene* (99% by gas chromatography) was pyrolyzed under the conditions of Goldblatt and Palkin (2). Here also 5% of 1(7),8-*p*-menthadiene was found in the pyrolyzate. Preparative gas chromatography was carried out using a VPC unit consisting of 10 ft × 1/2 in. O.D. × 7/16 in. I.D. copper tubing packed with 20% Carbowax 20 M on 60–80 mesh silane-treated Celite at a temperature of 120° C and an inlet pressure of 40 p.s.i. helium with a flow rate of 120 ml/minute. than that allowed these molecules in their normal, close-packed crystalline state, so that the gas molecules are permitted a greater than normal freedom of motion. These considerations combined with the results of an X-ray diffraction study led Von Stackelberg (1) to propose freedom of rotation for the SO_2 molecule in the SO_2 hydrate. Pauling (2), on the other hand, found the best agreement with the observed diffraction intensities for Cl_2 hydrate when the Cl_2 molecule was restricted to sterically favorable positions in the non-spherical cavity. The evidence to be presented here indicates that in the case of the SO_2 hydrate, the motion of the SO_2 molecules is similarly limited.

The frequencies of absorption from spectra obtained on a Perkin–Elmer 421 double beam grating spectrometer are listed in Table I. It can be seen that the spectrum of the

hydrate is, to a good approximation, simply the combined spectra of solid SO_2 and cubic ice. In the case of the SO_2 absorption the largest shift occurs for the ν_3 peak. This is in the direction of the value for the gas phase and may be attributed to the relative freedom of the SO_2 molecule in the hydrate compared with its environment in solid SO_2.

Of even more interest is the behavior of the absorption due to ν_3 when the temperature is varied. These spectra, shown in Fig. 1, were obtained on a Perkin–Elmer 112G spectrometer with slit widths sufficiently narrow to give a resolution of 1 cm^{-1} or better. The resolution was adequate, therefore, to resolve, at least partially, the J subbranches of a vibration–rotation band of a freely rotating SO_2 molecule (5). No such absorption is observed; however, there are two weak shoulders spaced approximately 10 cm^{-1} above and below the principal absorption peak at 1340 cm^{-1}. This is too large a separation for the energy levels of a free rotator but 10 cm^{-1} is a reasonable value for the first excited state of hindered rotatory or translatory motion. The decrease in intensity of the low frequency component with lowering of the temperature would result from depopulation of the upper level of the hindered rotator in the ground vibrational state.

The spectrum of the H_2O skeletal vibrations exhibits several points of interest. Not unexpectedly, because of the fairly large dipole moment of the SO_2 molecule, there is a substantial downward shift of the librational frequency to 780 cm^{-1}. On the other hand, the peak at 1600 cm^{-1} in cubic ice is shifted upward by some 40 cm^{-1} in the hydrate, confirming its assignment to ν_2 rather than $2\nu_R$ as has been suggested (6). The opposite shifts approximately cancel one another in the combination $\nu_2 + \nu_R$ to give a peak at 2220 cm^{-1}, almost the same frequency as in cubic ice.

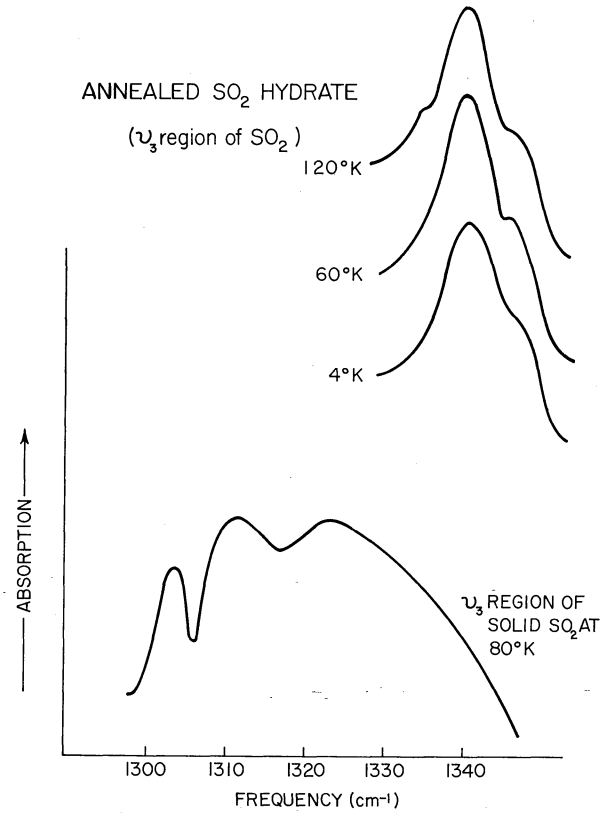

FIG. 1.

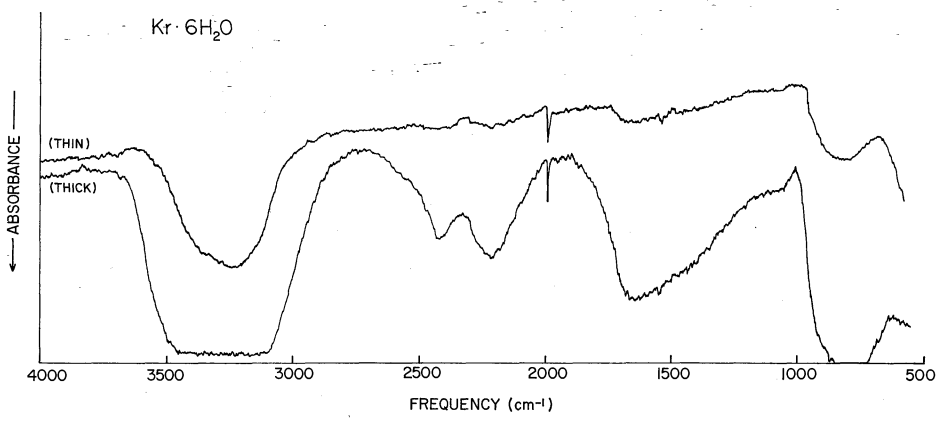

FIG. 2.

Another prominent feature of the H_2O skeletal spectrum is the peak at 2410 cm^{-1}. Absorption at this frequency has also been observed in the spectra of the H_2S and krypton hydrates (Fig. 2) hence it must be associated with the H_2O vibrations. Like the peak at 2220 cm^{-1}, the frequency of peak absorption is approximately the same in all of the

hydrates we have studied so that neither the 2220 cm^{-1} or 2410 cm^{-1} peaks are overtones of ν_R. There are several possible explanations for the absorption at 2410 cm^{-1} but none are very satisfying and, on the basis of the evidence presented, all are speculative. The two peaks at 2210 cm^{-1} and 2410 cm^{-1} could be assigned as components of $\nu_2 + \nu_R$ of different symmetry arising from correlation field splitting. None of the other vibrations exhibit such a splitting, however, and 200 cm^{-1} seems a rather large difference to explain in this way.

Alternatively, the two peaks in question may arise from combinations of ν_2 with two different librational frequencies ν_R and ν_R'. This implies a value of about 1000 cm^{-1} for the absorption due to ν_R' and no such absorption has been detected. In addition, it has been estimated (7) that the three librational frequencies in ice should not differ from one another by more than 10%. Unless severe distortion of the H_2O molecule occurs in the hydrate, and the spectra do not indicate this, one would expect the librational frequencies to be accidentally degenerate in the gas hydrate also. On the other hand, lack of activity of the fundamental, ν_R', certainly does not exclude activity of the combination $\nu_2 + \nu_R'$.

Obviously, more information is required before a reasonable interpretation can be made. We are hoping to obtain this information from a detailed study of the fundamentals and overtones of both the H_2O and D_2O hydrates.

EXPERIMENTAL

The general technique was to deposit the sample to be investigated on a cesium iodide window at 78° K and anneal it by raising the temperature to approximately 110° K before spectra were recorded. The samples were prepared initially by mixing gaseous SO_2 and H_2O in the correct stoichiometric ratio. This technique does not, however, assure a deposit of the correct stoichiometric ratio since inadequate mixing or fractionation during deposition may lead to a change in composition. To compensate for this the gas phase samples were prepared with an excess of one component when the spectrum of the other component was being observed. This method obviously leaves much to be desired and improved techniques are being devised.

For personal use only.

concentrations of benzene (<3%), the polymer consisted largely of cyclohexyl groups. This note presents further observations on the yield and constitution of the polymer which support these conclusions.

EXPERIMENTAL

Polymer was isolated from 100 ml samples of benzene–cyclohexane mixtures, irradiated to a dose of $\sim 1.6 \times 10^{23}$ ev/liter, by vacuum sublimation. This technique was suggested to us by Dr. J. G. Burr. The irradiated sample was initially frozen in liquid nitrogen; sublimation was carried out at ice temperature under vacuum, the receiver being cooled in liquid nitrogen. When about 95% of the solvent had been removed, the residue was transferred to a smaller weighed flask and the sublimation continued. After it was weighed, the polymer was redissolved in solvent and the unsublimed bicyclohexyl determined by gas liquid chromatography. Molecular weights were determined in benzene solutions with a Mechrolab vapor pressure osmometer. Yields and molecular weights were corrected for residual bicyclohexyl.

The 'benzene' content of the polymer was determined by a radiotracer technique using benzene C-14 obtained from Merck and Company (Canada). A 0.1 mc quantity of benzene-C_{14} was diluted with Phillips Research Grade benzene, treated with bromine to remove 1,3-cyclohexadiene (3), and distilled. The activity in the polymer was measured by scintillation counting of solutions containing the polymer (or an aliquot of the stock solutions), 1 ml of benzene, and 20 ml of liquid scintillator (Nuclear Enterprises WE-293), using a Packard Tri-Carb counting system.

RESULTS

Values of G(monomer → polymer) assuming a monomer molecular weight of 83(C_6H_{11}) are shown in Fig. 1 together with values of G(benzene in the polymer) determined from

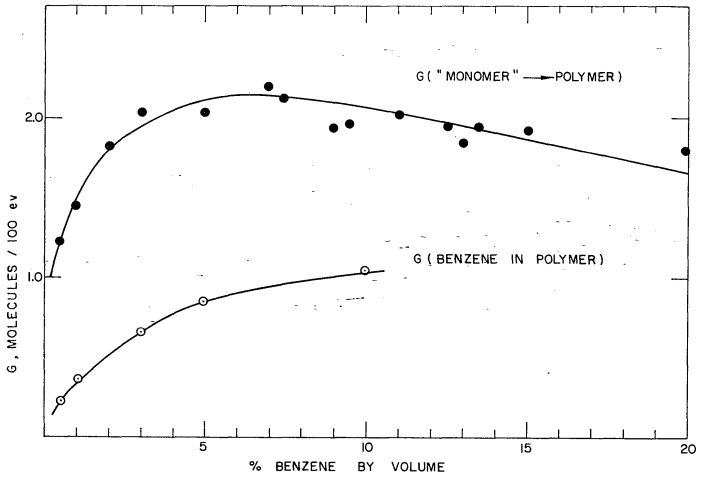

FIG. 1. Yield of polymer formed in the radiolysis of benzene–cyclohexane mixtures and the benzene content of the polymer.

the C-14 assay. The molecular weight of polymer over this concentration range is 335±15 with a trend towards increasing molecular weight at the higher benzene concentrations. Carbon–hydrogen analysis of polymer obtained from 3 and 10% benzene solutions gave compositions of $CH_{1.59}$ and $CH_{1.46}$, respectively. C_{24} hydrocarbons of this composition have molecular weights of 323 and 328. A C_{24} hydrocarbon containing three cyclohexyl residues and one benzene residue would contain 25% benzene; at 1% benzene the aromatic content of the polymer is 21% and it is clear that most of this polymer has this composition. At higher benzene concentrations, the polymer composition averages two cyclohexyl residues to two aromatic residues.

The molecular weight of the polymer shows a slight dose dependence increasing from 285 at a dose of 2×10^{22} ev/l. to 350 at 3.2×10^{22} ev/l., for solutions containing 1% benzene. While the polymer is, in the main, a C_{24} hydrocarbon it must contain amounts of C_{18} and C_{30} hydrocarbons which vary with dose. It appears that the benzene molecule attaches two and three cyclohexyl groups very readily but that the C_{24} hydrocarbon has a much lower, although not negligible affinity for attachment of a further cyclohexyl group. This variation in the molecular weight of the polymer with dose is similar to that reported by Barker and Hill (4) for the polymer formed in the radiolysis of cyclohexane at high doses. In their system, the polymer is a secondary product formed through cyclohexene, so that G(polymer) is initially very dose dependent. In our system, benzene, the nucleus for polymerization, is always present and G(polymer) varies only slightly with dose.

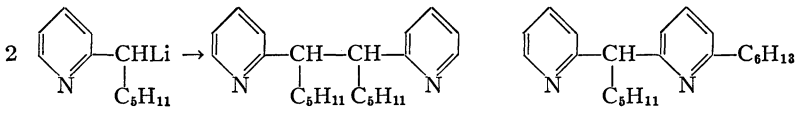
6,7-DI-2′-PYRIDYLDODECANE

J. T. EDWARD

Ziegler and Zeiser (1) found that *n*-butyllithium metalated α-picoline to α-picolyllithium, but added to 2-*n*-butylpyridine to give (in undisclosed yield) 2,6-di-*n*-butylpyridine. There was no report of significant metalation in the second reaction. Accordingly an attempt was made to prepare 2-*p*-anisyl-6-*n*-hexylpyridine by the reaction of *p*-anisyllithium with 2-*n*-hexylpyridine. The reaction mixture became red, indicating some metalation of the alkyl group (2) to give 1,2′-pyridyl-1-hexyllithium (I). After reaction of the organolithium compounds, the reaction mixture was stirred under dry air to oxidize dihydropyridine derivatives (3) and then worked up in the usual way (1). A fraction boiling at 155–160° at 0.5 mm was found to be made up of *p*,*p*′dianisyl (known to be produced by the air oxidation of *p*-anisyllithium (4)), a base $C_{22}H_{32}N_2$, and probably the desired 2-*p*-anisyl-6-*n*-hexylpyridine, although the last compound could not be obtained in an analytically pure state.



I II III

The base $C_{22}H_{32}N_2$ appeared to be 6,7-di-2′pyridyldodecane (II) produced by air oxidation of the metalation product I (cf. 4). Its ultraviolet absorption (λ_{max}^{EtOH} at 258, 260, 270 mμ; log ϵ_{max} 3.81, 3.86, 3.75) was closely similar to that of 2-alkylpyridines (5) showing that the two pyridine nuclei were linked through an insulating alkyl group,

The molecular weight of the polymer shows a slight dose dependence increasing from 285 at a dose of 2×10^{22} ev/l. to 350 at 3.2×10^{22} ev/l., for solutions containing 1% benzene. 6,7-DI-2′-PYRIDYLDODECANE

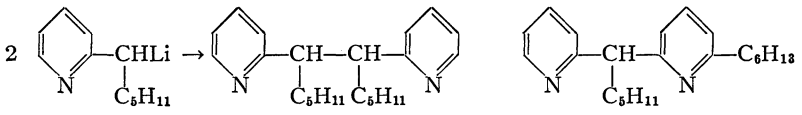
J. T. EDWARD

Ziegler and Zeiser (1) found that *n*-butyllithium metalated α-picoline to α-picolyllithium, but added to 2-*n*-butylpyridine to give (in undisclosed yield) 2,6-di-*n*-butylpyridine. There was no report of significant metalation in the second reaction. Accordingly an attempt was made to prepare 2-*p*-anisyl-6-*n*-hexylpyridine by the reaction of *p*-anisyllithium with 2-*n*-hexylpyridine. The reaction mixture became red, indicating some metalation of the alkyl group (2) to give 1,2′-pyridyl-1-hexyllithium (I). After reaction of the organolithium compounds, the reaction mixture was stirred under dry air to oxidize dihydropyridine derivatives (3) and then worked up in the usual way (1). A fraction boiling at 155–160° at 0.5 mm was found to be made up of *p*,*p*′dianisyl (known to be produced by the air oxidation of *p*-anisyllithium (4)), a base $C_{22}H_{32}N_2$, and probably the desired 2-*p*-anisyl-6-*n*-hexylpyridine, although the last compound could not be obtained in an analytically pure state.



I II III

The base $C_{22}H_{32}N_2$ appeared to be 6,7-di-2′pyridyldodecane (II) produced by air oxidation of the metalation product I (cf. 4). Its ultraviolet absorption (λ_{max}^{EtOH} at 258, 260, 270 mμ; log ϵ_{max} 3.81, 3.86, 3.75) was closely similar to that of 2-alkylpyridines (5) showing that the two pyridine nuclei were linked through an insulating alkyl group,

and not directly together (6). The nuclear magnetic resonance spectrum of the base in carbon tetrachloride (Table I) showed peaks at the positions (7) and having the areas expected for the structure II. It excluded the other possible structure III, formed by addition of I to 2-*n*-hexylpyridine, since such a compound would have only one α-pyridyl proton.

The present work makes it likely that not only methyl groups, but also other alkyl groups at the 2-position of pyridine are metalated by *n*-butyllithium.

EXPERIMENTAL

2-*n*-Hexylpyridine (81 g) in ether (100 ml) was added in 5 minutes to a stirred solution of *p*-anisyllithium, prepared from *p*-bromoanisole (93.5 g) and lithium (7.0 g) (3). After 50 minutes color test I (8) was only weakly positive, and dry air was passed over the stirred mixture for 18 hours. The mixture, worked up in the usual way, gave several basic fractions boiling below 115° (0.5 mm); these most probably consisted of 2-*n*-hexylpyridine and of 1-(2′-pyridyl)hexan-1-ol (from air oxidation of I), but did not give crystalline picrates or mercurichlorides, and were not investigated further. At 155° to 160° (0.5 mm) a yellow oil (19.5 g) distilled over; at higher temperatures only small amounts of reddish oils were obtained.

The yellow oil dissolved in concentrated hydrochloric acid, leaving a non-basic residue (0.1 g), m.p. 145–155°, which crystallized from ethanol as white flakes, m.p. 172–174°; melting point reported for *p*,*p*′-dianisyl, 172° (9). Calc. for $C_{14}H_{14}O_2$: OMe, 29.0%. Found: OMe, 28.0%. The solid gave a dark blue color with concentrated nitric acid, as reported for *p*,*p*′-dianisyl (9).

Neutralization of the hydrochloric acid solution afforded an oil, which on treatment with picric acid in ethanol gave a gummy solid. Washing with hot ethanol removed a gummy red impurity and left a crystalline solid (25 g, 5% yield), m.p. 145–147°. This was obtained on crystallization from methanol as yellow needles, m.p. 148–150°, analyzing as the *dipicrate* of II. Calc. for $C_{34}H_{38}O_{14}N_8$: C, 52.1; H, 4.9; N, 14.3%. Found: C, 52.4; H, 4.9; N, 14.4, 14.6%.

The free base, recovered from the dipicrate by treatment with sodium hydroxide solution, was redistilled to give a pale yellow oil, b.p. 215–217° (13 mm), d_{25}^{25} 0.9571, n_D^{25} 1.5163. Calc. for $C_{22}H_{32}N_2$: C, 81.5; H, 9.9; N, 8.6%. Mol. wt. 324.5. Found: C, 81.0; H, 10.1; N, 8.4%. Mol. wt. (Rast) 322. R_D calc. from constants of Vogel (10): 101.7. Found: 102.4.

The mother liquors and the red gum removed from the dipicrate were treated with sodium hydroxide to regenerate the free bases, which were taken up in ether and redistilled at reduced pressure. The yellow oil obtained appeared from analysis to be 2-*p*-anisyl-6-*n*-hexylpyridine ($C_{18}H_{23}NO$) contaminated with $C_{22}H_{32}N_2$. Calc. for 63% $C_{18}H_{23}NO$ + 37% $C_{22}H_{32}N_2$: OMe, 7.2; N, 6.13%. Found: OMe, 7.1, 7.4; N, 6.13%. All attempts to form a crystalline derivative (picrate, mercurichloride, hydrochloride, perchlorate, aurichloride, chloroplatinate) were fruitless.

ACKNOWLEDGMENTS

Grateful acknowledgment is made to Professor Henry Gilman, in whose laboratory the reaction was first investigated, for encouragement, Dr. C. Stammer for nuclear magnetic resonance studies, and the National Research Council for financial support.

NMR SPECTRA OF O,O-DIALKYLORGANOPHOSPHORUS ESTERS. P^{31} CHEMICAL SHIFTS BY HETERONUCLEAR SPIN DECOUPLING[1]

J. B. STOTHERS AND J. R. ROBINSON

Other studies required the synthesis of a family of organophosphorus esters (I–IV, below) which differ only in the atoms bonded directly to phosphorus:

$(RO)_2P(O)OAr$	$(RO)_2P(S)OAr$	$(RO)_2P(O)SAr$	$(RO)_2P(S)SAr$
I	II	III	IV

where R = CH_3 or C_2H_5 and Ar = C_6Cl_5.

These model compounds, representing the dialkylphosphate (I), phosphorothionate (II), phosphorothiolate (III), and phosphorodithioate (IV) systems, possess a common third ester group; the latter (pentachlorophenyl) was chosen partly to provide solid products, partly to allow a toxicological study of these highly chlorinated aromatic organophosphorus esters. The syntheses and chemical, physical, and toxicological properties will be reported elsewhere.

Because of the four differing chemical environments of the phosphorus nuclei, it seemed of interest to report on the variation in phosphorus chemical shifts. Such information is a useful complement to infrared spectra in confirming the structures of organophosphorus esters, particularly in differentiating P(S)O structures from their P(O)S isomers; many phosphorothionates possess no infrared absorption peak which is assignable to the P(S) group whereas, as shown below, the P^{31} chemical shift in these $(RO)_2P(S)OAr$ materials is quite different from that of the isomeric $(RO)_2P(O)SAr$ compounds. Also, these shift data can be applied generally over a wide range of organophosphorus esters since the values are not altered radically through changes in R and Ar by substitution. Moreover, these closely related model compounds provided a unique opportunity to compare, systematically, two methods of determining phosphorus chemical shifts, the direct P^{31} shift measurement and the indirect heteronuclear spin decoupling technique.

Although the H^1 and P^{31} NMR data for phosphorus esters exactly comparable to those for the present series have not been determined, extensive surveys of P^{31} chemical shift data now available (1–4) allow one to estimate these values for the phosphorus nuclei

in these compounds. On this basis, one would expect the shifts to occur in the order of increased shielding: $(RO)_2P(S)SAr$, $(RO)_2P(S)OAr$, $(RO)_2P(O)SAr$, $(RO)_2P(O)OAr$. The P^{31} data obtained at 15.1 Mc/sec are listed in Table I and the observed shifts follow

the expected trend. The principal disadvantage concerned with the direct determination of these data, however, is the low sensitivity of P^{31} nuclei to NMR experiments, ca. 6.6% of that for H^1 at the same field (5); if larger samples are available this can be overcome to some extent, but at the expense of high resolution results. In addition, a second complete transmitter–receiver unit is required for such measurements (for optimum results at 14.1 kgauss, a 24.3 Mc/sec source). In the present case, only small amounts of material were on hand and the additional radio-frequency unit available operated at 15.1 Mc/sec. These two features restricted the information from the P^{31} spectra to a determination of the chemical shifts only, since the fine structure due to P^{31}–H^1 spin coupling was not clearly resolved for these samples under such conditions.

Spin coupling data, however, are readily obtained from the proton spectra and, furthermore, the P^{31} chemical shifts also may be found by the technique of heteronuclear spin decoupling. The latter involves observation of the proton spectrum at 60 Mc/sec while simultaneously irradiating the P^{31} nucleus at its resonance frequency of 24.3 Mc/sec with a strong radio-frequency field which meets the requirement $\gamma H_2/2\pi \sim J$. The general method has been reviewed (6) and some examples of its application to chemical shift measurements have appeared for N^{14} (7–9) and C^{13} (10–12), but little use of the technique for H^1–P^{31} coupled systems has been reported. For these systems, the method presents a very important advantage to the chemist. Since the size of sample required for proton work is *much* less than that for P^{31} spectra, all of the NMR data could be obtained from a few milligrams of material. The results measured by the spin decoupling method compare well with those measured directly (see table), and the data are readily obtainable in a few minutes.

By its nature, the spin decoupling method for P^{31} chemical shift determinations requires the use of a secondary reference compound, and triethylphosphite was selected since the P^{31} chemical shift has been determined by many workers (2, 3, 4). Using the value −138.1 p.p.m. for $(EtO)_3P$, the rest of the data from the spin decoupling experiments were converted to the more common scale with 85% H_3PO_4 = 0 p.p.m. These results are listed in the table, together with the proton data for the series.

It can be noted that the methyl protons of the ethyl groups are spin coupled to the phosphorus nuclei with a coupling constant of ca. 1 cycle/sec. The magnitude of this interaction is not greatly affected by the substitution changes at the phosphorus nucleus, although there may be a small decrease for the substitution: $—OC_6Cl_5 \rightarrow SC_6Cl_5$. The stronger P^{31}–H^1 coupling (P–O–C–H), however, is clearly dependent on the substituents on phosphorus. In each case, replacement of an oxygen by sulphur increases the coupling constant, but the increase is larger for the thiono than for the thiolo grouping. This effect of sulphur on the coupling constant has been reported previously (e.g. 2, 13, 14) but the magnitude of the P^{31}–O–C–H^1 coupling constants is significantly larger than those noted in some reviews (1, 2). As indicated above, the P^{31} chemical shifts are close to those "expected" on the basis of previous work (2, 4), and the differences, which are due to the particular substituent groups, are not large enough to change the relative positions of the shifts.

In considering substitution effects upon the P^{31} chemical shift, a comparison of these data with those of Van Wazer *et al.* (4) gives an indication of the changes caused by fully chlorinating the benzene ring. For example, in substituting sulphur for oxygen in the aromatic ester linkage only, $(RO)_2P(O)OAr \rightarrow (RO)_2P(O)SAr$, there is little difference in effect between $Ar = C_6H_5$ and $Ar = C_6Cl_5$ as the replacement effects are −26 p.p.m. (4) and −25.8 p.p.m. (on the average) respectively. However, where sulphur replaces a phosphoryl oxygen only, $(RO)_2P(O)OAr \rightarrow (RO)_2P(S)OAr$, the chlorinated ring has a much greater effect, the corresponding data being −46 p.p.m. for $Ar = C_6H_5$ (4) and −70.5 p.p.m. in the present case. The substituent effects are seen to be approximately additive; for example, when both oxygen atoms are replaced by sulphur, $(RO)_2P(O)OC_6Cl_5 \rightarrow (RO)_2P(S)SC_6Cl_5$, the P^{31} chemical shift is changed by about 94 p.p.m. (average value) while addition of the two separate sulphur replacements gives a 96.3 p.p.m. replacement effect.

EXPERIMENTAL

The H^1 NMR spectra were determined with a Varian DP-60 spectrometer and were calibrated by the usual side-band technique with an audio oscillator whose output was continuously monitored with a Hewlett-Packard 522B frequency counter. The peak positions were determined relative to internal tetramethylsilane (TMS) and the precision is estimated to be within 0.05 p.p.m. for the chemical shifts and 0.05 cycle/sec for the coupling constants. The P^{31} spectra were obtained at 15.1 Mc/sec. Because of the relatively small amounts of material, rapid-passage dispersion mode operation afforded the better result. These peak positions were determined relative to an external 85% H_3PO_4 signal with an estimated accuracy of ±0.5 p.p.m. For both cases, the samples were 35–50% (w/w) solutions in deuterochloroform contained in 5 mm O.D. tubes.

The decoupling experiments were carried out using an NMR Specialties, Inc., Model SD-60 spin decoupler operating at a nominal frequency of 24.3 Mc/sec. Essentially this unit provides a signal whose frequency can be varied continuously. This is achieved by mixing the output of a variable frequency oscillator (VFO), operating close to 5.35 Mc/sec, with the output of a crystal oscillator at 18.95 Mc/sec to produce the required variable frequency near 24.3 Mc/sec. To monitor the output of the decoupler, the VFO output is mixed with that of a 5.30 Mc/sec crystal oscillator (an NMRS Model EC-60 counter adapter) and the difference frequency (in kc/sec) measured using the H-P 522B counter. After locating the desired region of the proton spectrum, for example, the methylene pattern for the ethyl derivatives, the variable 24.3 Mc/sec signal is changed until the approximate decoupling frequency is found. The proton spectrum of the methylene group becomes a simple quartet in the case of the ethyl derivatives, and the spectrum of the methylated compounds collapses to a singlet at the frequency required to decouple the P^{31} nucleus. The decoupler power is then reduced to determine this frequency more accurately, since the higher the power level used, the wider is the frequency range over which decoupling occurs. These operations can be conveniently carried out by following the spectral changes on the oscilloscope of the instrument. The counter reading for maximum decoupling (i.e., complete collapse of the pattern to a quartet) is noted. Similarly, the necessary frequency for each sample is obtained. Since operation in this way does not provide a check on the stability of the fixed oscillator, one can observe the frequency required for the reference sample between each determination, to test for a possible drift of the fixed frequency. The difference between the decoupling frequencies for two compounds provides a measure of the P^{31} chemical shift directly, if the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

shifts of the decoupled protons of the two compounds are identical. Otherwise, a correction for any change in the applied field required to observe the two proton patterns must be included. The frequency measurements are converted to a p.p.m. scale by division by 24.3, after which the correction (if any) may be taken into account. The estimated precision of the present results is ±0.5 p.p.m. Although higher precision could be obtained through the use of a stabilized VFO, e.g. an audio-modulated single side-band oscillator as the source, the large chemical shift differences for P^{31} nuclei do not require that the data be of the highest precision.

As an example of the method, the optimum decoupling frequency for the reference, triethyl phosphite, was found to give a counter reading of 15,585 cycles/sec, while the reading for $(EtO)_2P(S)OC_6Cl_5$ was 17,443 cycles/sec. This difference, 1858 cycles/sec (76.46 p.p.m.), represents the "apparent" chemical shift difference for the two P^{31} nuclei. Since the counter reading monitors only the VFO output relative to another crystal oscillator, the actual direction of change in the decoupler frequency (24.3 Mc/sec) must be established independently. In this case we know that the P^{31} nucleus of the sample absorbs at *higher* field than the reference and so the change in counter reading from reference to sample corresponds to a *lower* decoupling frequency for the sample. The phosphorous nuclei were decoupled at different applied fields and the apparent shift must be corrected for this change, 0.48 p.p.m. (i.e., the chemical shift difference between the proton absorptions used for the two decoupling experiments). In this case, the apparent separation is *larger* than the actual difference since the proton band used for the sample is at *lower* field than that for the reference. The P^{31} chemical shift for this sample is, therefore, 76.0 p.p.m. relative to $(EtO)_3P$ or −62.1 p.p.m. relative to 85% H_3PO_4. The remaining P^{31} shifts were calculated in a similar manner.

PROTON MAGNETIC RESONANCE AND THE STRUCTURE OF MALEIC HYDRAZIDE

Osamu Ohashi, Mitsuo Mashima,* and Masaji Kubo

There are three possible structures for maleic hydrazide (I). Miller (1) found that the compound exhibits acidic properties with a single pK_a value of 5.65. From this fact and comparison between the ultraviolet spectra of the compound and its derivatives in

*Saga University, Saga, Japan.

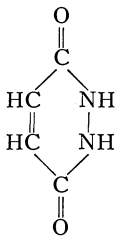
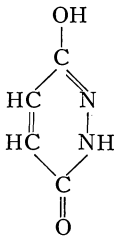
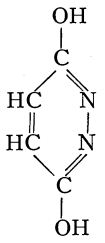
solutions at low and high pH's, Miller and White (2) concluded that maleic hydrazide exists as structure IB, i.e., 3-hydroxy-1,6-dihydropyridazin-6-one. One of the present



IA

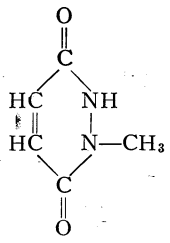


IB

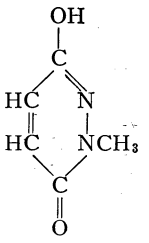


IC

authors (M.M.)(3) observed the infrared absorption of this compound in the rock-salt region. From the presence of absorption bands attributable to CO, NH, and OH groups, it was concluded that the molecules assume form IB in the crystalline state. On the other hand, Gompper and Altreuther (4) interpreted the n.m.r. spectrum of the compound in terms of form IA. However, Katritzky and Waring (5) criticized the interpretation by pointing out that fast exchange can render two or more protons equivalent in a tautomeric compound and therefore the molecules simulate a more symmetric structure. They further suggested that the dangers of misinterpretation can be avoided if proton resonance spectra of potentially tautomeric compounds are compared with those of methylated derivatives (6). Therefore, the present authors undertook to measure the n.m.r. spectra of this compound along with those of maleic methylhydrazide or 1-methyl-3-hydroxy-1,6-dihydropyridazin-6-one (II) for comparison.



IIA



IIB

EXPERIMENTAL

Materials

Maleic anhydride and hydrazine hydrate were heated in ethanol to obtain compound I, which was recrystallized from ethanol, m.p. 263° C (decomp.) (lit. (7) >260° C (decomp.)). Compound II was prepared by a method employed by Eichenberger *et al.* (8), m.p. 209–213° C (lit. (8) 210-211° C).

Apparatus and Experimental Procedure

The proton magnetic resonance spectra were recorded at room temperature with a JNM-3 high-resolution n.m.r. spectrometer from Japan Electron Optics Laboratory Company operating at 60 Mc/sec. Since the compounds under investigation are sparingly soluble in water and other common solvents, dimethylsulphoxide was used as a solvent with tetramethylsilane as an internal standard, the concentration being 11.3 and 8.4% for maleic hydrazide and the methyl derivative, respectively. To obtain definite spectra, it was of crucial importance to keep the samples free from moisture, because dimethylsulphoxide is very hygroscopic.

ASSIGNMENTS

The observed spectra are illustrated in Fig. 1. The spectrum of compound II consists of a sharp intense peak at −3.49 p.p.m., a group of four closely spaced lines centered at −6.99 p.p.m., and a broad absorption at −11.06 p.p.m. The strongest peak is attributable to N—CH_3 protons. The quartet is symmetric about its center with two central

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

lines of greater intensity than the outermost lines. The pattern of peak heights and line spacings is characteristic of a two-spin system of nonequivalent protons having J, the spin coupling constant, approximately equal to δ, the internal chemical shift (9). Therefore, the quartet is unequivocally assigned to protons in —CH=CH—. J, equal to the separation between an extreme resonance line and the neighboring line in the quartet, is calculated to be 9.8 c.p.s. The internal chemical shift δ is given by the geometric mean, 0.16_7 p.p.m. or $9._9$ c.p.s., of the frequency separation between the extreme lines and that between the central ones (9). The broad absorption on the low-field side is tentatively attributed to C—OH protons, a final decision being suspended until the detailed discussion is given below.

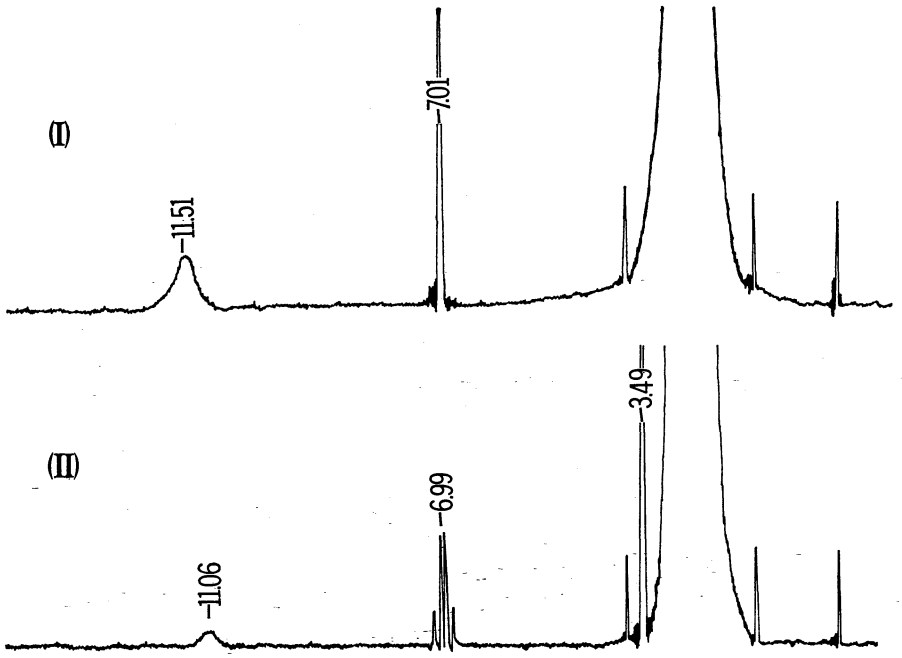


FIG. 1. Proton magnetic spectra of maleic hydrazide (I) and maleic methylhydrazide (II). In each spectrum, the strongest signal is due to dimethylsulphoxide, which was used as solvent. Satellites on either side of this peak are attributable to protons bonded to ^{13}C in solvent molecules. The signal of tetramethylsilane is at the highest field.

The compound I shows only two signals. One of them is a very sharp peak appearing at −7.01 p.p.m., in almost perfect agreement with the center of the aforementioned quartet at −6.99 p.p.m. Accordingly, it is attributable to —CH=CH— protons. The other signal is a broad one at −11.51 p.p.m. and corresponds to the broad absorption of compound II. It became broader and finally disappeared with increasing moisture content. Either the C—OH proton or the N—H proton or both must be responsible for this absorption. The problem is discussed in the succeeding section. The results of assignments are summarized in Table I.

DISCUSSION

The proton signal of $—CH_{(4)}=CH_{(5)}—$ in maleic hydrazide molecules is a singlet indicating that the two hydrogen atoms in a molecule are magnetically equivalent, whereas that of the methyl derivative is a quartet as expected from its chemical formula. In addition, only one line was observed for C—OH and N—H protons in maleic hydrazide. From these two facts, it is concluded that if the structure IB is correct as indicated

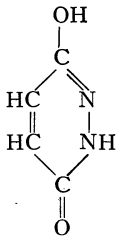
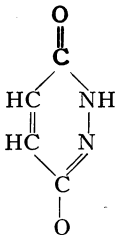
by ultraviolet and infrared spectroscopy, prototropic rearrangement takes place leading to keto–enol tautomerism between equivalent structures, IB and IB′, the lifetime of which



IB



IB′

is much shorter than the relaxation times of proton spin orientations in a magnetic field but is much longer than the lifetime of transitions in infrared vibrations (10). During the relatively longer observation time of n.m.r. measurements, protons bonded to oxygen at a particular time find themselves at another time near nitrogen, and vice versa. The intramolecular rearrangement possibly superposed on the intermolecular exchange of protons as well as the effect of the nuclear quadrupole moment of nitrogen gives rise to the broadening of the observed signal at −11.51 p.p.m. The same explanation can be made for the broad signal of compound II at −11.06 p.p.m. These signals are at a lower field than expected for ordinary non-exchanging N—H or O—H protons. This suggests the presence of intramolecular hydrogen bonds and (or) intermolecular interactions through hydrogen bonding between the N—H or O—H protons of the solute and the > S=O groups of solvent molecules. In summary, the n.m.r. spectra of maleic hydrazide and its methyl derivative are consistent with the results of ultraviolet and infrared spectroscopy and provide experimental support in favor of the conclusions reached by Katritzky and Waring (5).

CATALYTIC OXIDATION OF LEAD (II) ACETATE BY OZONE[1]

GARSON P. SHULMAN[2]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Lead tetraacetate is widely used as an oxidizing agent in organic chemistry. Only three methods for its preparation have been reported. A solution of red lead (Pb_3O_4) in acetic acid (preferably with acetic anhydride present to remove water) produces a mixture of lead (II) and lead (IV) acetates (1).

Oxidation of lead (II) acetate by chlorine gives a mixture of lead (II) chloride and lead (IV) acetate (2). These methods have been combined in the generally recommended laboratory procedure for preparation of lead tetraacetate, but because of lead chloride formation, the yield is inherently limited. An alternative preparation involves electrolysis of lead (II) acetate in acetic acid, giving hydrogen and lead (IV) acetate (3). During some experiments involving catalytic decomposition of ozone on metal oxide surfaces, appearance of lead tetraacetate in an acetic acid solution which came into contact with the catalyst suggested the feasibility of oxidizing lead (II) acetate directly with ozone. The initial experiment apparently involved oxidation of the lead (II) oxide followed by solution; a solution of lead (II) acetate (from lead (II) oxide) in acetic acid was not affected by ozone. A number of metal ions known to react with ozone and to form higher valent oxides with oxidation potentials greater than that required for a lead (II) to lead (IV) conversion (4) ($Pb^{++} + 2H_2O \rightarrow PbO_2 + 4H^+ + 2e^-[-1.46\ v]$) were selected and screened as potential catalysts (see Table I). Of these, cobalt appeared to be particularly effective.

Table II summarizes the results of a series of reactions on a small preparative scale. Addition of acetic anhydride to the solution is not necessary to prevent hydrolysis by water formed during the reaction. The rate of hydrolysis of lead tetraacetate in glacial acetic acid must therefore be slow compared to the rate of its preparation. However, failure to add the acetic anhydride markedly affects yield of lead tetraacetate.[3] Cobalt chloride gave a conversion of 11.6% per gram of ozone at 60°, the acetate 8.9% at 60°, and 14.1% at 25°. Changing the anion thus does not affect the catalytic activity greatly, but a marked increase as the temperature is lowered is apparent. The more efficient utilization of ozone at a lower temperature must be due to a decrease in the rate of the catalytic decomposition of ozone to oxygen, resulting in use of a greater share of the absorbed ozone for oxidation. The reaction of equimolar amounts of lead acetate and ozone gives a yield of 72%.

The mechanism of the catalysis is not clear. While it was originally postulated that trivalent cobalt would be capable of oxidizing lead to the tetravalent state, cobalt (III) is not reduced rapidly by lead (II) acetate. The green color of the solution persists for at least 12 hours without noticeable change when the ozonization is interrupted. Because of the inverse effect of temperature, it is most unlikely that oxygen atoms formed from decomposition of ozone are the reactive intermediate. Therefore, direct oxidation of lead

[1]*Presented at the A.C.S. Southwest Regional Meeting, Houston, Texas, December 1963.*
[2]*Present address: The Martin Company, Baltimore 3, Maryland.*
[3]*Hydrolysis of lead tetraacetate gives a brown precipitate (lead dioxide) and would be readily apparent. The water must therefore inhibit the catalytic oxidation.*

acetate by ozone must be catalyzed by cobalt ion (and to a lesser extent, by silver, bismuth, cerium, and manganese ions).

EXPERIMENTAL

Effect of Various Catalysts

Solutions of 0.50 g of yellow lead oxide, 2.5 ml of acetic anhydride, and a small crystal (10±1 mg) of catalyst were dissolved in 100 ml of acetic acid. Ozone was passed through the solution at a rate of about 65 mg/min for 5 minutes, with total unreacted ozone being measured by passing the off-gas stream through a potassium iodide trap, which was then titrated with thiosulphate. The acetic acid solutions were mixed with 8.0 g of potassium iodide, poured into water, filtered, and titrated with thiosulphate. Results are summarized in Table I.

Preparation of Lead Tetraacetate

A solution of yellow lead oxide, acetic anhydride, and a cobalt salt in 100 ml of acetic acid was treated with a 0.02 c.f.m. stream of ozonized oxygen containing approximately 60 mg/min of ozone. The ozone was produced using a Welsbach Model T-23 Ozonator. Repeated titration of the ozone stream during an 8-hour day showed that variation in ozone concentration was less than the uncertainty in the titration (2%) as long as instrument settings were unchanged. As a precaution, ozone concentration was determined before and after each reaction. Consumption of ozone was determined by connecting the outlet of the reaction vessel (a gas-washing bottle) to a potassium iodide trap periodically and titrating the iodine liberated in 1 minute. A smooth curve of rate of ozone uptake vs. time resulted. Total ozone uptake was determined from the area under the curve. The solid which formed was filtered, washed with benzene, and dried. An additional small crop of crystals was obtained by adding a mixture of benzene and hexane to the acetic acid. Yields were determined from the weight of the precipitate, since the filtrate then contained a negligible amount of lead tetraacetate, as shown by attempted iodimetric titration. Results are summarized in Table II.

REARRANGEMENT STUDIES WITH ^{14}C. XVIII. 2-PHENYL-2-^{14}C-ETHYL CHLORIDE FROM GAMMA-IRRADIATION OF 2-PHENYL-1-^{14}C-ETHYL CHLORIDE

C. C. LEE AND D. J. KROEGER[1]

The γ-irradiation of propyl halides (1–4) and butyl halides (5, 6) has been shown to result in isomerizations. These isomerizations have been postulated to take place by 1,2-halogen shifts (2, 3) or by 1,2-hydrogen shifts (5, 6). Using ^{14}C as tracer, isotope position rearrangements of the label from the C-1 to the C-2 positions have been observed in the γ-irradiation of 1-^{14}C-ethyl iodide (7), 2-phenyl-1-^{14}C-ethyl iodide (8), 2-phenyl-1-^{14}C-ethyl bromide (9), and 2-*p*-methoxyphenyl-1-^{14}C-ethyl bromide (9). The present communication reports observations on the ^{60}Co γ-induced rearrangement of 2-phenyl-1-^{14}C-ethyl chloride to 2-phenyl-2-^{14}C-ethyl chloride.

The reaction of 2-phenyl-1-^{14}C-ethanol with thionyl chloride in pyridine has been shown to give 2-phenyl-1-^{14}C-ethyl chloride (I) without rearrangement (10). This method of preparation of I was adopted with the modification that the reaction was carried out in benzene as solvent. The modified method led to less tendency for tar formation and high yields of I. Degradation of I so synthesized to benzoic acid showed the presence of 0.09% of the ^{14}C-activity in the C-2 position. In the subsequent studies on γ-induced rearrangements, corrections were made by subtracting this 0.09% of activity present in C-2 before irradiation.

Samples of I were irradiated and analyzed for total decomposition and for rearrangement to 2-phenyl-2-^{14}C-ethyl chloride as described previously for analogous studies with the bromide and iodide (8, 9). The results are shown in Table I. For the range of absorbed doses investigated, the extent of rearrangement increases with increasing dosage. The mean G_r resulting from γ-irradiation of I is 0.21 ± 0.02, which may be contrasted with G_r values of 0.30 ± 0.01 and 0.50 ± 0.05, respectively, for isotope position rearrangements upon γ-irradiation of 2-phenyl-1-^{14}C-ethyl bromide (9) and 2-phenyl-1-^{14}C-ethyl iodide (8).

The extent of decomposition of I also increases with increasing amount of radiation. Since these estimates of decomposition were calculated from small differences between large specific activities, the errors involved may be relatively high (8). If G_d for the first sample (Table I) were neglected, the mean G_d is about 4.5, which may be compared with G_d of about 2 for the irradiation of 2-phenyl-1-^{14}C-ethyl iodide (8).

It has already been pointed out (8) that formation of 2-phenyl-2-^{14}C-ethyl halide from γ-irradiation of 2-phenyl-1-^{14}C-ethyl halide could result neither from a 1,2-halogen shift nor from the addition of hydrogen halide to styrene produced during the irradiation.

*II is $C_6H_5CH_2CH_2COOH$; III is C_6H_5COOH.
†Measured by a liquid scintillation counter.
‡Corrected for the 0.09% of activity in III derived from the unirradiated sample.

These processes could lead to the structurally rearranged 1-phenyl-2-^{14}C-ethyl halide, but not the isotopically rearranged 2-phenyl-2-^{14}C-ethyl halide. The observed rearrangements (Table I) indicated the occurrence of a net 1,2-phenyl shift during radiolysis. If 1,2-shifts take place in the free radicals produced during irradiation, it would be of interest to investigate the effects of added iodine, a free radical scavenger (11), on the extent of γ-induced rearrangements.

Two 5-g samples of I containing 5% (by weight) of iodine were irradiated and then fractionated through a small helix-packed column. About one-half of the material was distilled and the remainder designated as the residue. Both the distillate and the residue from each sample were analyzed for rearrangement and total decomposition. The results are given in Table II. From this table, it can be seen that G_r for the distillate is about one-half as large as G_r for the residue (about 0.18 and 0.36). While the probable errors involved in the calculated G_d may be quite high, a trend is evident in that G_d for the distillate is approximately 0.3 while G_d for the residue is about 7. The small G_d for the distillate suggests that this fraction is relatively pure I while most of the decomposition products remain with the residue. In these experiments, there is a possibility of energy transfer from organic halide to dissolved iodine. No attempt is made in the current work to investigate this problem. If such an energy transfer were to take place, the dose absorbed by I would be lower, and the calculated G values would be higher than those given in Table II. Such a possible change in the absolute magnitudes of the G values, however, should not materially alter the qualitative conclusion that, relatively, G_r and G_d are apparently greater for the residue than for the distillate.

During irradiation of I in the presence of iodine, if 2-phenyl-1-^{14}C-ethyl and 2-phenyl-2-^{14}C-ethyl radicals were produced, both radicals could be scavenged by iodine. If the separation of 2-phenylethyl chloride and 2-phenylethyl iodide were complete, one might then expect no rearrangement in the distillate, which would be pure 2-phenylethyl chloride, and some rearrangement in the residue, which would contain some 2-phenylethyl chloride and all of the 2-phenylethyl iodide. Since the separation of 2-phenylethyl chloride from

2-phenylethyl iodide likely was not quantitative, the observed higher rearrangement in the residue may be regarded as in qualitative agreement with prediction.

The strength of the carbon–halogen bond, as indicated by bond dissociation energies, follows the order chloride > bromide > iodide (12). The G_r value from irradiation of 2-phenyl-1-^{14}C-ethyl chloride is less than that from the bromide, which, in turn, is less than that from the iodide. Such findings suggest that the extent of rearrangement may depend on the strength of the carbon–halogen bond, which could influence the readiness with which the 2-phenylethyl radical is formed during the irradiation. Another factor which may play a role is the relative magnitudes of the favorable energy balance in the dissociative electron attachment process for organic radical formation from radiolysis of organic halides. Feng (12) has estimated the order to be iodide > bromide > chloride, while Geissler and Willard (13) indicated that thermodynamically the process is most favorable for iodide and about the same for bromide and chloride. The observed G_r of about 0.5, 0.3, and 0.2, respectively, for 2-phenylethyl iodide, bromide, and chloride are in the order expected if the rearrangement involved formation of 2-phenylethyl radical by the dissociative electron attachment process.

EXPERIMENTAL

2-Phenyl-1-^{14}C-ethyl Chloride (I)

A solution of 10.1 g (0.082 moles) of 2-phenyl-1-^{14}C-ethanol (10) in 10 ml of benzene was added dropwise with stirring to a solution of 10.7 g (0.090 moles) of thionyl chloride and 2.0 ml of pyridine in 20 ml of benzene. Stirring was continued at room temperature for 1.5 hours and then the mixture was refluxed for 1 hour. The resulting solution was cooled in an ice bath and 20 ml of ice water was introduced. The benzene layer was separated and the aqueous layer was extracted with three 10-ml portions of benzene. The combined extract was washed with 10% sodium carbonate solution and with water and then dried over anhydrous potassium carbonate. After the benzene was removed by distillation, the residue was distilled under reduced pressure, giving 9.8 g (85%) of 2-phenyl-1-^{14}C-ethyl chloride, b.p. 77–78° C at 10 mm (lit. (10) b.p. 85–87° C at 17 mm). The material was diluted with ordinary 2-phenylethyl chloride and redistilled to give a uniform stock for irradiation studies.

Irradiation and Analyses for Decomposition and Rearrangement

The procedures were analogous to those used in previous studies (8, 9). Irradiation of I was continued for periods of up to about 5 months, the dose rates being of the order of 1.9 megarad/day. The irradiated halide was converted to a solid derivative, hydrocinnamic acid, which, in turn, was oxidized to benzoic acid. Based on isotopic dilution, the decrease in specific activity of the hydrocinnamic acid after irradiation measured the extent of decomposition. The ^{14}C-activity of the benzoic acid measured the amount of rearrangement.

INTRODUCTION

In Part I, a new method was proposed for the argentimetric titration of alkali-metal halides present in their mixtures in methanol. The sample volume was 120 ml. Amounts of halide down to about 0.5 micromole (μmole) could be determined.

In the present work, the same method was applied to mixtures of alkali-metal halides in about 6 ml of methanol. Amounts of halides of the order of a few micrograms were successfully determined.

EXPERIMENTAL

Apparatus

The Sargent Model V Oscillometer was used. A Sargent cell compensator was coupled in the transmission line ahead of the sample cell. It is a variable inductor, whose reactance can be adjusted to the capacitance reactance due to the walls of the titration cell.

For the titration vessel, a 10-ml closed-type cell supplied with the oscillometer was used. It was 15 mm in diameter, and 123 mm in height, constructed like the Sargent macrocell used in Part I, but with an annulus 65 mm deep that held only 5 ml of liquid. The outer walls of the annulus were metal plated, to provide a capacitor. In practice, 6 ml of solution were used for a titration. The standard taper 14/10 stopper supplied with the cell was replaced by a cover that consisted of a 25-mm square of silicone rubber, 4 mm thick. A thin smear of silicone grease on the underside of this square provided a reasonably gas-tight seal.

The solution was stirred with a small paddle-type stirrer, made from a flexible Teflon shaft, 3 mm in diameter, with a small polyethylene paddle inserted in a slot at the end. The shaft was rotated in a centrally cut hole in the silicone-rubber cover of the cell. The shaft was coupled to the stirring motor by a flexible cable. A Variac provided for changes in the stirring rate.

The titrant was dispensed into the cell solution from a 5-ml Koch microburet having 0.01-ml graduations. The stopcock had a Teflon plug. The tip supplied was detachable, having a standard No. 5 taper joint which also happened to fit the standard Luer joints of hypodermic needles. This tip was replaced by a lumbar puncture needle of standard gauge 22 G, and 3 in. in length, which had a standard Luer joint. In use, the needle was inserted through the silicone-rubber cover of the titration cell, to a depth such that its orifice was in the solution to be titrated, during stirring.

The microburet and the pipets were calibrated to deliver methanol.

Reagents

The reagents used were those described in Part I. A 0.01 N standard stock solution of silver nitrate was standardized by high-frequency titrimetry against sodium chloride (the primary standard). Standard stock solutions, 0.01 N in sodium chloride, sodium bromide, and sodium iodide in methanol were also prepared; the latter two solutions were standardized against the 0.01 N silver nitrate solution.

From these 0.01 N stock solutions, 10^{-4} N working solutions were prepared by dilution.

The Titrimetric Procedure

An aliquot of the halide solution in methanol was transferred to the titration cell, and the contents diluted to 6 ± 0.2 ml with absolute methanol. In some cases, particularly at very low concentrations of halide, an aliquot of a 5×10^{-4} N solution of sodium nitrate in methanol was added prior to the final dilution to 6 ml. The purpose was to raise the ionic strength of the solution to a point where the sensitivity of the instrument toward changes in concentrations was sufficient. In cases of such additions, titration blanks for halide in the sodium nitrate were always separately run.

The stirrer was then positioned so that the paddle was about 5 mm above the top of the cell electrodes. The tip of the buret needle was placed about 5 mm above the level of the still solution. The silicone-rubber cover was then pressed firmly to the top of the open cell, to form a seal by reason of the applied silicone grease. The rate of stirring was adjusted to cause the outer edge of the solution to rise about 1 cm in the cell.

The Sargent cell compensator was set at 640 dial units. This value gave the maximum instrumental sensitivity, while still keeping the oscillometer readings within the limits of variation of its standard capacitors, for the solutions titrated. Without the cell compensator, breaks were not obtained in the titration graphs for the microgram amounts of halide taken in the present work.

RESULTS AND DISCUSSION

Effect of Temperature

It was shown in Part I of this series that the apparent capacitance due to a solution is temperature dependent. Therefore, a closed-type cell was used in that work and in the present work. The use of only 6 ml of solution instead of the 120 ml used in the macro-titrations of Part I would make the cell solution more susceptible to changes in ambient temperature. Therefore the effect of temperature changes in the 10-ml cell used in the present work was studied. The results are in Table I. The apparent capacitance (as

TABLE I

The effect of temperature on the apparent capacitance due to methanol

2.25	22.0	30461	30	23.0	30379
4	21.0	30568	50	23.0	30378

instrument divisions) of the closed 10-ml titration cell containing 6 ml of methanol was measured at intervals over a 4-hour period. The decline in room temperature caused a rise in apparent capacitance. Evaporation could not have occurred to cause this change, since at 23° C a 2×10^{-5} *M* solution of sodium chloride in methanol gave no significant change in apparent capacitance over a 50-minute period of continuous stirring.

Titration of microgram amounts gave, in general, rather small changes in the slope of the titration graph, at the end point. Therefore, it is clearly necessary to carry out such titrations at a reasonably constant temperature. This is readily achieved. However, the slopes of the arms of the titration graph also were found to be temperature dependent; the lower the temperature, the more acute the angle of intersection. A change of a few degrees of temperature can produce this effect. The position of the end point was not shifted, in the few titrations performed to observe this effect.

Precision and Accuracy of the Micro Titrations

Replicate determinations on 0.1 μmole amounts of sodium chloride alone in 6 ml of methanol were made, to obtain an estimate of the standard deviation. The results are in Table II. Precision and accuracy are good.

Duplicate determinations were made on several mixtures of sodium bromide and sodium chloride. In addition, replicates ($N = 7$) were run on one such mixture to obtain an estimate of the standard deviation. Results are in Table II, and typical titration graphs are shown in Fig. 1. These results agree with those in Part I, where solid-solution formation was evident.

Lower Limits of Titratable Concentrations

Titrations were performed on various micro amounts of sodium chloride, sodium bromide, and sodium iodide, in 6 ml of methanol. The purpose was to find approximately

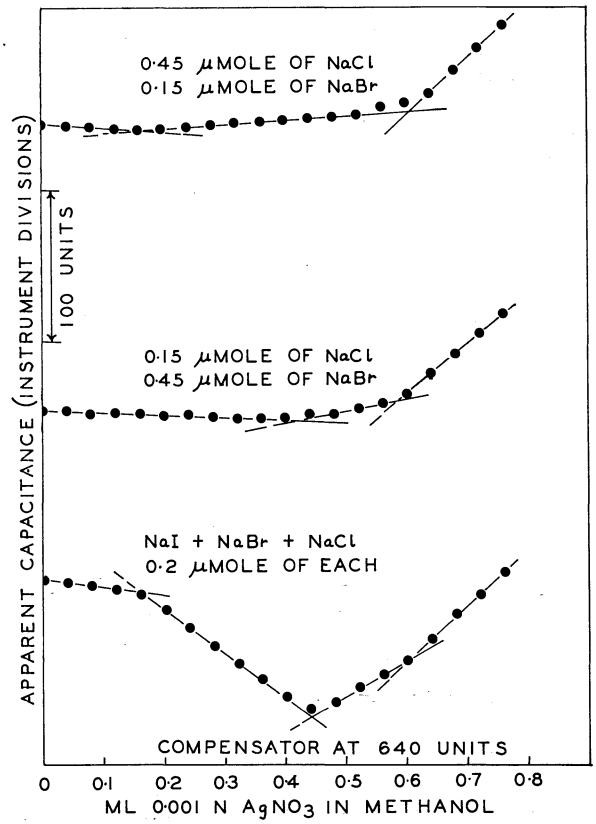

FIG. 1. Typical titration graphs of argentimetric titrations of mixtures of halides in methanol.

the lower limits of concentration, below which the angle of intersection of the arms of the titration graph became very small, and the precision of the titration poor. It is to be noted that these lower limits will be in part defined by the precision required.

In all of the titrations, the methanol was made approximately 2×10^{-5} M in sodium nitrate. This indifferent electrolyte sharpened the end point at the lowest concentrations of halide, but it is not a necessary additive at higher concentrations. The reason for its effectiveness will be given in a subsequent communication.

For the single halides, down to about 6 μg of sodium chloride could be titrated with accuracy and precision. Below that amount, precision became progressively less, although even at 3 μg the two linear arms of the titration graph intersected at about 4–5°, at the end point. At about 10 μg it was possible to dispense with the sodium nitrate. Down to about 10 μg of sodium bromide, and down to about 8–15 μg of sodium iodide were also satisfactorily titrated.

For binary mixtures of these halides, the lower limits were about 50% higher than the corresponding limits for the single halides. It is to be noted that for Table II, the amounts taken were in fact near the lower limits recommended here.

All three halides, present in a favorable ratio, were titrated satisfactorily in their ternary mixture, but the lower limits were about double those for the corresponding single halides. In Fig. 1 is shown a typical titration graph of such a ternary mixture.

VOLUME 42 MAY 1964 NUMBER 5

THE DECOMPOSITION OF SILYL PEROXIDES[1]

RICHARD R. HIATT[2]

Department of Chemistry, University of Toronto, Toronto, Ontario

Received November 25, 1963

ABSTRACT

The thermal decomposition of *tert*-butyl trimethylsilyl peroxide has been investigated and found to be sensitive to acid and base catalysis and to the nature of the solvent. In heptane and iso-octane the first-order rate constant could be expressed as $1.09\times10^{15}\ e^{-42300/RT}$ and in 1-octene as $3.90\times10^{15}\ e^{-42300/RT}$ (sec^{-1}). The half life at 203° C was about 1 hour. The reaction was faster in aromatic solvents; in chlorobenzene it was complicated by formation of HCl from the solvent.

Products of the reaction were acetone, *tert*-butyl alcohol and hexamethyldisiloxane.

INTRODUCTION

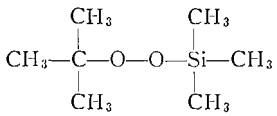
Although the silicon analogues of alkyl peroxides and hydroperoxides have been known for some time (1, 2), and it has been shown that these compounds can initiate free radical polymerizations (1), it has been only recently that careful kinetic studies on their homolytic decomposition have been initiated (3).

The orthodox explanation for the effect of substituents on the stability of the oxygen–oxygen bond concerns the ability of the attached groups to minimize the charge on the opposed dipoles of the two oxygen atoms (4). This argument, advanced to explain rates

$$R\overrightarrow{\ }O-O\overleftarrow{\ }R$$

of decomposition of a large number of substituted benzoyl peroxides, is probably always operative, even though other considerations may be, in some instances, more important (5).

A silicon atom should be particularly effective in delocalizing the electrons on an adjacent oxygen through $d\pi$–$p\pi$ bonding, and should confer stability to a silyl peroxide greater than that of its carbon analogue.* To determine the correctness of this hypothesis, a study of the thermal decomposition of *tert*-butyl trimethylsilyl peroxide (I) was instituted.



I

[1]*This work received financial assistance from the National Research Council of Canada.*

[2]*Present address: Stanford Research Institute, Menlo Park, California.*

**This has not proved to be the case for bis(trimethylsilyl)peroxide (2) or for triphenylsilyl hydroperoxide (3). But hydroperoxides are notorious for their susceptibility toward induced decomposition, and the seemingly unrealistic activation energy for thermal decomposition, in the former compound, of 6.3 kcal suggests that in neither case was the reaction under consideration the uncomplicated cleavage of the O—O bond.*

EXPERIMENTAL

tert-Butyl trimethylsilyl peroxide was prepared by the method of Buncel and Davies (1). Distillation at reduced pressure gave material which liberated 96–99% of the theoretical amount of iodine on titrations.

To titrate, the peroxide was added to a solution of 20% acetic acid –80% isopropyl alcohol. Solid sodium iodide was added and the mixture refluxed for 20 minutes, with subsequent titration of the liberated iodine by a standard solution of sodium thiosulphate.

Chlorobenzene, iso-octane, and *n*-heptane were Fisher Reagent Grade materials, used without further purification. Tetralin was freed from peroxides by washing with Fenton's reagent and distilling immediately prior to its use. 1-Octene, 99+% pure, was obtained from Phillips Petroleum Company.

Rates of reaction were measured using solutions 0.04 to 0.2 *M* in peroxide in the appropriate solvent. Solutions were degassed, decanted into ampoules, and sealed off under vacuum. After they were heated for various lengths of time in a constant temperature bath, the ampoules were opened and the contents titrated for remaining peroxide. Depending on the solvent, plots of log peroxide concentration vs. time were linear for 40 to 90% of the reaction.

Products of the decomposition were determined by vapor-phase chromatography, using the F & M Model 500. Columns of isodecylphthalate and on Carbowax 20 M, both on Chromosorb, were equally effective in separating the components.

RESULTS AND DISCUSSION

Like the analogous di-*tert*-butyl peroxide, *tert*-butyl trimethylsilyl peroxide gave clean unimolecular thermal decomposition in a number of solvents (Table I). A fivefold change

TABLE I

†Initial rate.

in the initial peroxide concentration showed, by its lack of effect on the rate constant, that free radical induced decomposition was not a complicating factor. The peroxide was also found to be unattacked by *tert*-butoxy radicals produced by the decomposition of di-*tert*-butyl peroxalate at 45° C. Similar conditions are found to destroy *tert*-butyl hydroperoxide (6) completely.

The products were those to be expected from subsequent reactions of *tert*-butoxy and trimethylsiloxy radicals. The high temperature necessary for the decomposition and the consequent formation of tars precluded a good material balance. In 1-octene there was considerable attack on the solvent to give low molecular weight polymer.

Hexamethyl disiloxane	0.18	0.21
Undistillable residue	8.22*	0.300*

*Grams.

tert-Butyl trimethylsilyl peroxide is remarkably stable, temperatures of 180–200° C being necessary to give conveniently measurable rates of decomposition. This is 60–70° warmer than is required for di-*tert*-butyl peroxide and is reflected in the activation energy for the reaction of 41 kcal compared with 38 kcal for the carbon analogue (7).

The marked effect of the solvent on the stability of the peroxide is, however, very unlike that of di-*tert*-butyl peroxide, which is relatively indifferent to its environment (8). Since the reaction, which appears to be unimolecular, goes faster in more polar solvents, it might be inferred that it is not homolytic at all but shows a heterolysis similar to those observed for some acyl peroxides (9).

Decomposition in Chlorobenzene

The initial decompositions were done in chlorobenzene, a solvent generally considered inert to free radicals. The difficulties encountered were twofold. The reaction became autocatalytic after about one half life, and the extent of decomposition became increasingly unreproducible as the reaction proceeded. Thus titration after several half lives of two ampoules which had contained identical amounts of peroxide at the beginning of the reaction might show peroxide titers differing by as much as 25%.

In the expectation that adventitious materials on the glass walls of individual ampoules were responsible, several methods of cleaning the glass before use were tried. In ampoules cleaned by steam, by concentrated sulphuric acid, by alcoholic potassium hydroxide, or fitted with quartz liners, the decomposition was faster than in uncleaned pyrex. Packing the ampoules with uncleaned pyrex wool did not enhance the rate appreciably but the onset of unreproducibility was hastened.

It is well known that silicon–oxygen bonds are subject to rapid solvolysis catalyzed by acid or base. The results suggested a reaction of the peroxide with water (formed by condensation of two molecules of trimethylsilanol) catalyzed by the glass walls or by other products of reaction.

$$(CH_3)_3Si{-}O{-}O{-}t\text{-Bu} + H_2O \rightarrow (CH_3)_3SiOH + t\text{-BuOOH}$$

As *tert*-butyl hydroperoxide would be rapidly decomposed at 180° C, the hydrolysis would be rate determining.

Saturation of the chlorobenzene solution with water, prior to reaction, had no effect. Other known products of the decomposition were then tested by adding amounts substantially in excess of those produced by the decomposing peroxide (3% by volume in chlorobenzene). The effect of added *tert*-butyl alcohol was negligible, but both acetone and hexamethyl disiloxane *retarded* the decomposition. Not only was the half life increased by about 20%, but the reaction could be carried to near completion with no evidence of autocatalysis, and duplicate ampoules gave identical titers at all stages. A mixed solvent of 3% 1-octene, 97% chlorobenzene gave similar results.

TABLE III

Decomposition in mixed solvents*
(97% chlorobenzene + 3% co-solvent†)

Co-solvent	T, ° C	$k_1 \times 10^5$ sec^{-1}
None	191.2	25.7
tert-Butyl alcohol	191.1	26.5
Acetone	191.0	19.2
tert-Butyl hydroperoxide	191.5	19.6
Hexamethyl disiloxane	191.5	17.9
1-Octene	193.1	12.6

*Initial peroxide concentration = 0.14 mole/l.
†By volume.

Clearly the known products of the reaction were not responsible for the autocatalysis, but that the product mixture did contain a powerful catalyst was demonstrated by using this medium as solvent for a new decomposition. This catalyst could be removed by washing the solution with dilute $NaHCO_3$ or its effect could be eliminated by adding 1-octene to the mixture. When the solvent for decomposition was composed of the reaction product solution plus 3% 1-octene, the reaction started out very rapidly but after several minutes slowed to the rate previously observed for a pure chlorobenzene–1-octene mixture.

That the miscreant product might be HCl was suggested by results of Hammond and co-workers (10), who showed that silyl radicals could displace chlorine atoms from chlorobenzene. On treatment with aqueous $AgNO_3$ the product mixture gave a positive test for chloride ion, and titration showed the presence of a minute amount of acid.

The supposition of HCl formation allows a ready explanation of the effect of acetone and of hexamethyl disiloxane, which are much more ready sources of hydrogen atom than is chlorobenzene. Thus trimethyl siloxy radicals would react preferentially with this material suppressing the formation of HCl. 1-Octene is effective not only in this way, but also is capable of reacting with HCl previously formed.

Heterolytic Decomposition

It was suggested (*vide supra*) that the effect of HCl was to catalyze a hydrolysis at the silicon atom. However, peroxides which undergo heterolytic cleavage of the O—O bond are also subject to acid catalysis. From the rate dependence on solvent character it seems likely that there is some contribution from this sort of reaction with *tert*-butyl

$$(CH_3)_3Si—O—O—t\text{-}Bu \rightarrow (CH_3)_3Si—O^- + t\text{-}Bu—O^+$$

trimethylsilyl peroxide. It is not to be expected that t-BuO$^+$ would be formed as such, but that a concerted shift of a methyl group to oxygen would have acetone as the detectable product. That the major product from the decomposition was found to be acetone is not significant, however, since *tert*-butoxy radicals formed at this temperature would be expected to cleave to give acetone also.

While the relative amounts of heterolytic and homolytic decomposition remain in doubt, an upper limit for the rate of homolysis has been established. That this is slower in all the solvents investigated than the similar reaction of di-*tert*-butyl peroxide is significant and leads to a confirmation of the original hypothesis.

THE INFLUENCE OF SUBSTITUENTS ON THE EASE AND DIRECTION OF RING OPENING IN THE $LiAlH_4$–$AlCl_3$ REDUCTIVE CLEAVAGE OF SUBSTITUTED 1,3-DIOXOLANES[1]

B. E. Leggetter and R. K. Brown
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received December 9, 1963

ABSTRACT

The room temperature hydrogenolysis by $LiAlH_4$–$AlCl_3$ of ether solutions of a number of 1,3-dioxolanes has been studied.

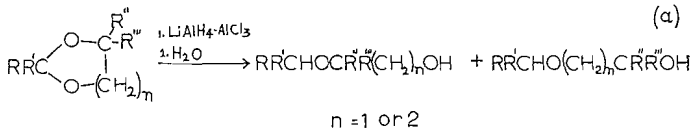
Electron donor substituents on the C_2 atom of the ring accelerate while electron acceptor substituents on C_2 retard the reductive ring cleavage. The same effect but to a lesser extent is observed when these substituents are attached to the C_4 or C_5 atom of the ring.

When electron donor substituents are attached to C_4, ring cleavage occurs predominantly at the C_2—O bond remote from the C_4 position. On the other hand, electron-withdrawing groups attached to C_4 give predominantly scission of the C_2—O bond closer to the C_4-substituted position. In contrast to this marked control over the direction of ring cleavage exhibited by substituents on C_4, those on C_2 generally have little or no effect on the direction of ring opening.

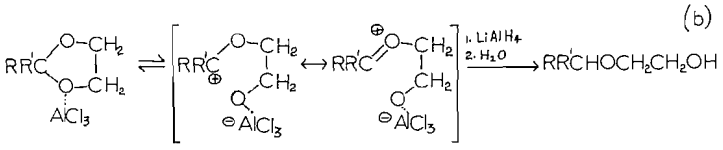
A mechanistic interpretation of the results is presented.

INTRODUCTION

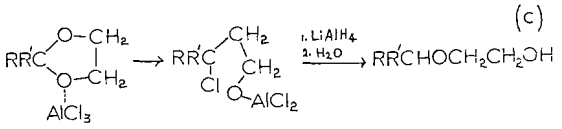
The stability of acetals and ketals towards lithium aluminum hydride permits their use as a means of protecting a ketone or aldehyde moiety during hydride reduction of other functional groups in a molecule (1). However, in the presence of acidic reagents such as anhydrous aluminum chloride or boron trifluoride, lithium aluminum hydride reductively cleaves the acetal or ketal to an ether (1–5). Eliel *et al.* (6) have recently examined the $LiAlH_4$–$AlCl_3$ hydrogenolysis of a number of cyclic acetals and ketals (1,3-dioxolanes and 1,3-dioxanes) and obtained a high yield of the corresponding hydroxyethers arising from the cleavage of either the C_2—O_1 or C_2—O_3 bond according to equation (*a*).



Two mechanisms for this reduction have been suggested (3). One involves hydride attack on the complex formed from the Lewis acid and the acetal, a complex which tends to form the stabilized oxocarbonium ion (equation (*b*)). The other requires prior formation of the α-haloether, which is then readily reduced (equation (*c*)).



[1]*Taken from the thesis of B. E. Leggetter, submitted to the Graduate School, University of Alberta, Edmonton, Alberta, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*



The latter mechanism was preferred for the reductive cleavage of *1,3-oxathiolanes* due to the observation that one of the oxathiolanes could be isomerized by $AlCl_3$ and also reduced by $AlCl_3$–$LiAlH_4$, whereas the same compound could be isomerized by BF_3 but could *not* be reduced by BF_3–$LiAlH_4$ (4, 7). However, since *1,3-dioxolanes* could be reduced by either $AlCl_3$–$LiAlH_4$, or BF_3–$LiAlH_4$, α-haloether formation was not considered necessary in the mechanism of hydrogenolysis of 1,3-dioxolanes (note 18, ref. (7)).

Recent work in this laboratory has shown that BF_3–$LiAlH_4$ *does* hydrogenolyze 1,3-oxathiolanes (8), hence invalidating the main supporting argument for the requirement of α-haloether formation in the reduction of oxathiolanes. The results of the work reported (8) favor the first mechanistic scheme (equation (*b*)) for Lewis acid – $LiAlH_4$ hydrogenolysis of both 1,3-dioxolanes and 1,3-oxathiolanes.

Pertinent to the mechanistic interpretation of acetal hydrogenolysis by $LiAlH_4$ and a Lewis acid is the work recently reported by Bonner and Saville (9), who have shown evidence for α-haloether formation in the reaction of boron trichloride with cyclic acetals of hexitols. But since the experimental conditions* used by Bonner and Saville differed considerably from those employed by Eliel and co-workers (6, 7) or by Leggetter and Brown (8), their results cannot be considered as proof of α-haloether formation in the aluminum chloride – lithium aluminum hydride reductions in *ether* solution.

During part of a program of study of the hydrogenolysis of acetals, interest arose concerning the effect of substituents on the ease and direction of ring opening in C_2- and C_4-substituted dioxolanes and the bearing this might have on the mechanistic interpretation of the hydrogenolysis in ether solution of cyclic acetals and ketals by lithium aluminum hydride in the presence of a Lewis acid. This paper reports some of the results obtained. Since it was discovered quite early in the course of this work that those compounds capable of cis–trans isomerism gave results which depended upon the relative proportion of cis and trans isomers in the mixture, such compounds were omitted from the present study. These will be reported upon in a later publication.

RESULTS AND DISCUSSION

Several 1,3-dioxolanes were prepared by standard methods (see Experimental). The choice of substituents on positions C_2 or C_4 of the dioxolane ring was somewhat limited by the availability of suitable starting materials, but was sufficient to provide a satisfactory range of electron-donating and electron-withdrawing groups. Compounds that were the expected products were synthesized by known routes or prepared originally and characterized.

These acetals and ketals were then dissolved in pure, dry diethyl ether containing an equimolar quantity of lithium aluminum hydride. To this stirred mixture at room temperature was then added slowly an ether solution of an equimolar amount of anhydrous aluminum chloride. The mixture was then allowed to stand, with continuous stirring, for

**Bonner and Saville used methylene chloride as solvent for both the acetals and the BCl_3. They then removed the solvent and excess BCl_3 from the reaction mixture. A solvent such as methylene chloride co-ordinates much less readily with Lewis acids than does diethyl ether, hence even normally stable 1,3-dithiolanes are isomerized by Lewis acids in methylene chloride solution (8). One would expect much more extensive reaction of the boron trichloride with acetals, particularly if the solvent methylene chloride is removed, as found by Bonner and Saville. These conditions might be expected to lead to α-haloether formation more readily than would our conditions.*

the requisite time. This was usually 90 minutes except in those cases where the reaction was slow or negligible. In such situations, reactions were allowed to continue for as long as 24 to 48 hours. Analysis by gas–liquid chromatography (g.l.c.) gave information concerning the extent and direction of reductive cleavage of the ring. Identification of products was made by comparison of the products with authentic compounds with respect to retention times, infrared analyses, n.m.r., and the usual boiling points or melting point. The total recovery of products was generally quite high. The products were found to be stable under reaction conditions. The results of these experiments are shown in Table I.

A number of general conclusions can be made from an examination of the data in Table I.

(i) The formyl acetals (experiments 1–6) are hydrogenolyzed with greater difficulty than are the C_2 alkylated or arylated isomers and homologues. For example, when 4,4-dimethyl-1,3-dioxolane (experiment 3) was reduced for a period of 24 hours, 16% of the product was unchanged starting material. On the other hand, the isomer 2,2-dimethyl-1,3-dioxolane, under the same conditions was completely hydrogenolyzed within 90 minutes (experiment 8). Again, no unreacted starting material was found when 2-phenyl-1,3-dioxolane was allowed to react for 60 minutes (experiment 12), whereas 60 hours of reaction yielded a product containing 25% of unreacted 4-phenyl-1,3-dioxolane (experiment 6). The pairs of experiments 4, 21 and 5, 20 further exemplify this point.

Generally a reaction period of 24 to 48 hours left a substantial quantity of the formyl acetal unchanged. The only exception is that of 4-methyl-1,3-dioxolane (experiment 2), which was reduced to the extent of about 90% within 90 minutes. This was checked at least four times to be certain of the results, and is the only case of a formyl acetal that in our experience was largely reduced in so short a period under our conditions.

The slow reaction of formyl acetals has also been observed by Abdun-Nur and Issidorides (5) during their reduction of acetals by a mixture of lithium aluminum hydride and boron trifluoride in ether.

(ii) A greater effect on the rate of reductive cleavage of the dioxolane ring is exerted by substituents on position C_2 than by the same substituents on any other of the ring carbon atoms. Thus 2,2-dimethyl-1,3-dioxolane (experiment 8) was completely hydrogenolyzed within 90 minutes, whereas 4,4-dimethyl-1,3-dioxolane (experiment 3) even after 24 hours of reduction yielded a product containing 16% of unreacted material. Experiments 6 and 12 as well as 4 and 9 further exemplify this observation.

(iii) Electron-donating substituents (methyl, phenyl) accelerate while electron-withdrawing groups (chloromethyl, dichloromethyl) retard or prevent reductive cleavage of acetals or ketals. This effect is much more pronounced when these substituents are on C_2 than on any other carbon atom of the ring. For example, due to the electron-withdrawing effect of the chlorine atom, 2-chloromethyl-1,3-dioxolane (experiment 9), when hydrogenolyzed for 48 hours, gave a product which was 86% unreacted material whereas the electron donor properties of the methyl group caused 2-methyl-1,3-dioxolane (experiment 7) to be completely converted to its reduction product within 60 minutes. That the same phenomenon occurs when such groups are attached to position C_4 rather than C_2 is shown by comparison of experiments 3 and 4. The two methyl groups in 4,4-dimethyl-1,3-dioxolane promote reaction sufficiently so that in 24 hours only 16% of the product is unreacted material. On the other hand, 4-chloromethyl-1,3-dioxolane is nearly three-fourths unchanged even after 48 hours of reduction. In the extreme case of 2,4-bis(chloromethyl)-1,3-dioxolane (experiment 18) practically no reduction occurred in 48 hours.

These observations (i–iii) are consistent with the view that the mechanism of reaction involves first the rapid reversible association of the Lewis acid with the acetal or ketal,

*These figures represent the fraction of the isolated reduction products that is primary or secondary (tertiary) alcohol.
†This represents the fraction of the total recovered material which is unreduced or unchanged.
‡This includes both reduced and unreduced material.
§Considerable loss occurred due to the high water solubility of compounds and to the volatility of the acetal.
‖The small amount of unreduced material (3%) is surprising, since both the phenyl group on C_2 and the *gem*-dimethyl group on C_4 enhance reduction. In experiment 12, the phenyl group on C_2 caused complete and rapid reduction.
¶In 90 minutes there was no sign of reduction. In 48 hours only small amount of reduction occurred. This was not examined thoroughly since isomerization of original acetal occurred and the two acetals are known to reduce at different rates.
**In experiments 4, 5, and 20 the primary alcohol reduction product was assumed to be respectively 3-chloro-2-methoxy-1-propanol, 3-isopropoxy-2-methoxy-1-propanol, and 2,3-diisopropoxy-1-propanol as expected. Due to the unavailability of a different synthetic route for their preparation, these were not made for comparison with the respective products of reductive cleavage. However, the isomers (the secondary or tertiary alcohols) were synthesized by known routes. Because of the invariable dual reduction path of all these dioxolanes, and since only two products were obtained, one of the pair being known, the assumption of the other structure is reasonable.

followed by a slow, rate-controlling cleavage of the ring to form the stabilized oxocarbonium ion which is then rapidly and irreversibly reduced (equation (*b*)). Groups which stabilize the oxocarbonium ion enhance the ring scission and hence the rate of reduction. Substituents R and R′ on C_2, because of their proximity to the incipient carbonium ion, exert a strong stabilizing or destabilizing influence on this ion, more so than do the same substituents on the other two more distant C_4 and C_5 atoms attached to oxygen.

The similarity between the results of the reductive cleavage of acetals and ketals and the rates of acid-catalyzed hydrolysis of substituted acetals (10) is quite striking. Kreevoy and Taft (10), in a study of the influence of substituents on the rates of acid-catalyzed hydrolysis of acetals and ketals of the type $RR'C(OR'')_2$ found that the rates paralleled the inductive order of the substituents R and R′. Electron donors accelerated while electron acceptors retarded the hydrolysis. The results supported their postulated mechanistic path of hydrolysis (equations (*d*) and (*e*)) in which the slow step of oxocarbonium ion formation is rate controlling.

We have made no kinetic study of the reductive cleavage of acetals or ketals, but a qualitative estimation of their relative ease of hydrogenolysis has been obtained by subjecting them to a competitive reduction. A mixture of two dioxolanes was treated with a limited amount of reducing agent so as to achieve about 10 to 15% of reduction. If the extent of reduction is limited in this way so that the concentration of the dioxolanes is practically constant, and if we adopt the reasonable assumption that the dioxolane molecule participates in the rate-determining step of the reaction, and also know that the reduction step is irreversible and that under our conditions very little or none of the product is lost by further reaction, then the ratio of the rates of reduction of the two dioxolanes will be directly proportional to the ratio of the amounts of reduction product of these dioxolanes. The total recovery of material was sufficiently good and the ratios sufficiently large to give a clear indication of the relative effects of the substituents on the ease of hydrogenolysis of the acetals or ketals. The results of these experiments are shown in Table II. From an examination of the results in Table II in conjunction with those in

TABLE II

The competitive reduction of 2-substituted -1,3-dioxolanes with lithium aluminum hydride and aluminum chloride*

Expt. No.	Mixtures of dioxolanes	Relative amounts of reduction products (mole %)	Total recovery, %	k_a/k_b
1 (*a*)	2-Phenyl-1,3-dioxolane	2-Benzyloxyethanol (89)	84	8
(*b*)	2,2-Dimethyl-1,3-dioxolane	2-Isopropoxyethanol (11)

(*b*)	2-Methyl-1,3-dioxolane	2-Ethoxyethanol (negligible)		
3 (*a*)	2,2-Dimethyl-1,3-dioxolane	2-Isopropoxyethanol†	77	>1
(*b*)	2-Methyl-1,3-dioxolane	2-Ethoxyethanol†		

*In ether solution; reaction time was about 30 minutes for each experiment. The extent of reduction was controlled by limiting the amount of reducing agent to obtain ~15% hydrogenolysis.
†Analysis of reduction products were performed by n.m.r., which indicated a large proportion of 2-isopropoxyethanol. No separation of the reduction products could be obtained by gas–liquid chromatography.

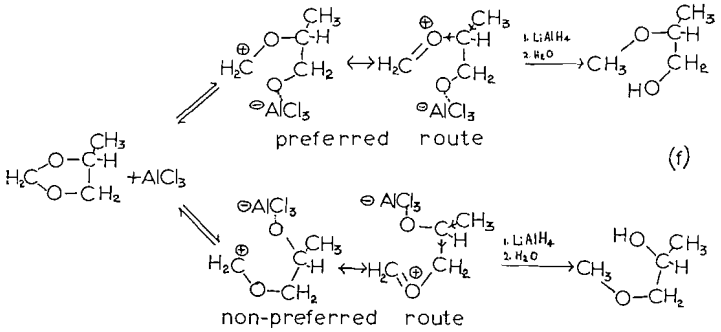
Table I, the groups can be arranged in the following order of their decreasing ability to enhance reductive cleavage of the dioxolane ring when they are attached to the C_2 position of the ring.

$$C_6H_5— > (CH_3)_2— > CH_3— > H— > ClCH_2— > Cl_2CH—$$

This order is in agreement with the stability of the correspondingly substituted carbonium ions.

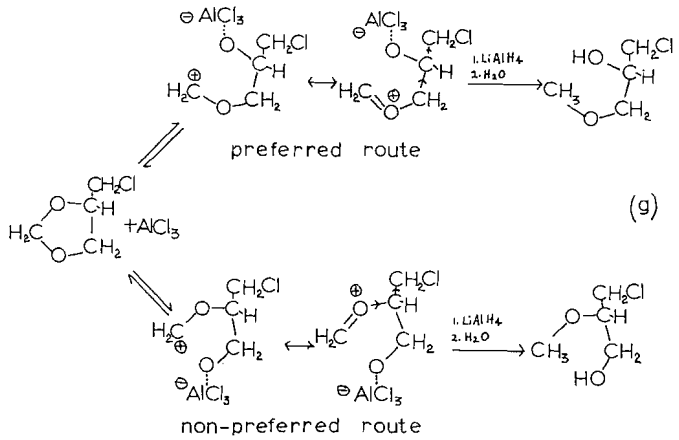
(iv) A further interesting observation obtained from a study of Table I is that *electron donor or acceptor substituents attached to carbon atoms C_4 or C_5 of the dioxolane ring exert a marked control over the direction of ring cleavage.* The results of the present work show that, by and large, substituents which by electron donation assist in the stabilization of the oxocarbonium ion will favor cleavage of the C_2—O bond remote from the substituted carbon atom, thus yielding a high preponderance of the primary alcohol. Eliel, Badding, and Rerick (6) found similar preferential direction of cleavage of a number of cyclic acetals. On the other hand, electron acceptor groups favor cleavage of the C_2—O bond closest to the C_4-substituted moiety, producing largely the secondary or tertiary alcohol. This is exemplified by 4-methyl-1,3-dioxolane (expt. 2) which, because of the presence of the electron-donating methyl group at C_4, gave 93% of the reduction product as

the primary alcohol, 2-methoxy-1-propanol and only 7% of the secondary alcohol, 1-methoxy-2-propanol (equation (*f*)).



Experiments 13, 14, and 17 also clearly illustrate this point. It is interesting to note that the phenyl group does not appear to exert as much control in this manner as do the alkyl groups (cf. experiments 6 and 16).

The reverse effect due to an electron-withdrawing substituent at C_4 is illustrated by the reduction of 4-chloromethyl-1,3-dioxolane (experiment 4), which, upon reduction, gave a product which consisted of 90% of the secondary alcohol, 1-chloro-3-methoxy-2-propanol, and only 10% of the primary alcohol, 3-chloro-2-methoxy-1-propanol (equation (*g*)).



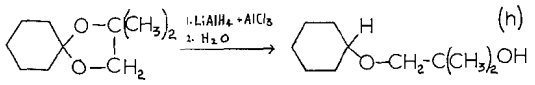
Experiments 5, 19, and 20 supply further illustrations of the effect of electron-withdrawing substituents on the direction of ring cleavage.

These observations are also consistent with the view that the formation of the oxocarbonium ion is the rate-controlling step. In equation (*f*) the preferred path of ring cleavage is that wherein the methyl substituent is closer to the incipient oxocarbonium ion and hence more effective in stabilizing the positive charge on this ion. In equation (*g*) the electron-withdrawing chloromethyl group destabilizes that oxocarbonium ion in which the chloromethyl group is closer to the site of positive charge. Hence the other ion is preferred. However, formation of both ions is retarded as compared with those containing an electron donor substituent at C_4 (equation (*f*)).

The only exception to the general statement of the observation noted in (*iv*) that electron-releasing groups show preferential cleavage of the C_2—O bond remote from the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

substituted C_4 atom is that provided by the compound 2,2,4,4-tetramethyl-1,3-dioxolane (experiment 15). Instead of forming largely the primary alcohol, 2-isopropoxy-2-methyl-1-propanol as expected on the basis of the above observations, there was obtained a greater than 90% yield of the tertiary alcohol, 1-isopropoxy-2-methyl-2-propanol. A similar anomaly has been pointed out by Eliel and co-workers (6), who found that the isobutylene ketal of cyclohexanone gave exclusively the tertiary alcohol (equation (*h*)) in sharp contrast to all their other C_4-substituted dioxolanes.

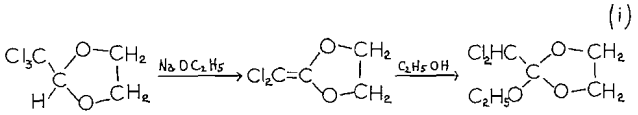


They suggested that this may be the result of either a different mechanism of hydrogenolysis or "a counterplay of polar and steric influences". A report of further investigations in our laboratory concerning this anomalous behavior will be given at a later date.

In contrast to the pronounced effect that C_4 substituents have on the direction of ring opening, those at the position C_2 have little or no effect in this regard. Apart from the peculiar ring cleavage found for 2,2,4,4-tetramethyl-1,3-dioxolane, the ineffectiveness of C_2 substituents is amply demonstrated by the examples found in Table I.

(v) The final observation of interest concerning the data in Table I is that of *the peculiar reduction experienced by 2-trichloromethyl-1,3-dioxolane* (experiment 11). The material recovered from this experiment, rather than being either the reduction product 2-β,β,β-trichloroethoxyethanol or the unchanged starting material, proved to be 2-dichloromethyl-1,3-dioxolane, which is stable to further reduction. Further work showed that the formation of the dichloro compound from the trichloro precursor could be achieved by the use of lithium aluminum hydride *alone*, although it is conceivable that aluminum chloride could in this case have been formed *in situ* during the course of the reaction.

A somewhat analogous result has recently been found by Ruske and Hartmann (11), who studied the action of strong bases such as sodium ethoxide upon the same dioxolane. These workers found that 2-trichloromethyl-1,3-dioxolane, upon treatment with an ethanolic solution of sodium ethoxide, afforded 2-dichloromethyl-2-ethoxy-1,3-dioxolane as indicated in equation (*i*). They postulated the prior elimination of hydrogen chloride from the trichloromethyl compound, followed by addition of the solvent ethanol to the intermediate 2-dichloromethylene-1,3-dioxolane. The elimination of hydrogen chloride in the first portion of the reaction was brought about by attack of base on the strongly acidic C_2 hydrogen atom, followed by departure of a chloride ion.



The same line of reasoning may very well hold true for the reaction found in the present instance. The basic character of lithium aluminum hydride could promote elimination of hydrogen chloride from the 2-trichloromethyl-1,3-dioxolane and the intermediate 2-dichloromethylene-1,3-dioxolane could then be reduced by the hydride. The reduction of double bonds upon treatment with lithium aluminum hydride is not without precedent. For instance, allyl alcohol has been reduced to 1-propanol (12) and ω-nitrostyrene to β-phenylethylamine (13).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The possibility of direct displacement of a chlorine ion of the trichloromethyl group by a hydride ion via an S_N2 substitution seems rather doubtful, since lithium aluminum hydride reduction of chloral hydrate yields β,β,β-trichloroethanol with the trichloromethyl group intact (14).

EXPERIMENTAL

All boiling points and melting points are uncorrected. Except where otherwise stated, g.l.c. analyses were done with a Burrell K-2 Kromo-Tog using a 2-meter column packed with 25% of carbowax 20M on Gas-Chrom P as the solid stationary phase. Helium at a flow-rate of approximately 80 ml per minute was the carrier gas. The column temperature was dependent upon the boiling point of the compounds being analyzed. All compounds were identified by comparison of their g.l.c. retention times and the infrared and n.m.r. spectra with those of authentic samples. Quantitative analyses were made by measuring the integrated areas of the peaks concerned. The areas were compared with those of peaks obtained by use of definite measured amounts of samples.

Infrared spectra were recorded on a Perkin–Elmer Model 221 instrument. Nuclear magnetic resonance spectra were obtained with a Varian Associates A-60 spectrometer.

Preparation or Source of 1,3-Dioxolanes

2-Methyl-1,3-dioxolane was prepared according to the method of Hibbert and Timm (15).

2-Phenyl-1,3-dioxolane was prepared in 57% yield by the method devised by Salmi (16), except that toluene rather than benzene was used as solvent, and a Dean–Stark water separator (17) was employed. B.p. 116° at 20 mm. Lit. b.p. 101° at 10 mm (18).

4,4-Dimethyl-2-phenyl-1,3-dioxolane was prepared from benzaldehyde and 2-methyl-1,2-propanediol in 70% yield by the above modification of the procedure described by Salmi (16). B.p. 85° at 5 mm; η_D^{25}, 1.5015. Calc. for $C_{11}H_{14}O_2$: C, 74.16; H, 7.87. Found: C, 74.26; H, 8.06.

The precursor, *2-methyl-1,2-propanediol*, was prepared as follows: a solution of ethyl α-hydroxyisobutyrate (19) (5.2 g, 0.4 mole) in 100 ml of dry ether was added dropwise to a stirred suspension of lithium aluminum hydride (15.2 g, 0.4 mole) in 500 ml of dry ether. After complete addition of the reagents, the reaction mixture was allowed to stand for 2 hours and then water was cautiously added to decompose any excess hydride and the aluminum complexes. The inorganic solid was then removed by filtration and the filtrate dried over anhydrous magnesium sulphate. Removal of the ether afforded the required product as an oil which was purified by distillation under reduced pressure. Yield, 25.2 g (70%) of material boiling at 55° at 3 mm. Lit. b.p. 79–80° at 12 mm (20).

4-Methyl-1,3-dioxolane.—A mixture of paraformaldehyde (33 g, 1.1 moles), 1,2-propanediol (76 g, 1.0 mole), anhydrous magnesium sulphate (30 g), and concentrated hydrochloric acid (2 ml) was refluxed 5 hours. The reaction mixture was then cooled and filtered free of solid. The filtrate was neutralized with Na_2CO_3, washed, and then dried over anhydrous magnesium sulphate, and finally fractionally distilled to give 55 g (65.5%) of material boiling at 82–83° at 700 mm. Lit. b.p. 88–89° at 755 mm (21).

4-Chloromethyl-1,3-dioxolane was prepared in 82% yield from paraformaldehyde and 3-chloro-1,2-propanediol (Eastman Kodak Co.) according to the preceding experimental conditions. B.p. 76° at 54 mm. Lit. b.p. 126° at 750 mm (22); cf. 146–147° at 745 mm (23).

4-Phenyl-1,3-dioxolane was prepared according to the preceding directions from paraformaldehyde and 1-phenyl-1,2-ethanediol (Eastman Kodak Co.). Yield 75%. B.p. 66° at 1.4 mm. Lit. b.p. 101° at 12 mm (22, 24).

4,4-Dimethyl-1,3-dioxolane was prepared as above in 51.5% yield starting with paraformaldehyde and 2-methyl-1,2-propanediol (see above) but using a reaction time of 20 minutes rather than 5 hours. B.p. 100–102° at 700 mm; η_D^{25}, 1.4004. Calc. for $C_5H_{10}O_2$: C, 58.82; H, 9.80. Found: C, 58.46; H, 10.06.

1,3-Dioxolane was prepared by a modification of the method advocated by Vogel (25). A mixture of 1,2-ethanediol (32 g, 0.5 mole), paraformaldehyde (20 g, 0.67 mole), anhydrous magnesium sulphate (20 g), and 2 ml of concentrated hydrochloric acid was heated at such a rate that the product was taken off through a 4-inch Vigreux column as it was formed. The product was collected, dried over anhydrous sodium carbonate, filtered, and then fractionally distilled giving the required material boiling at 71–73° at 700 mm. Lit. b.p. 75° at 760 mm (26).

2,2-Dimethyl-4-hydroxymethyl-1,3-dioxolane was prepared according to the directions given by Fischer and Pfahler (27). Yield, 80%. B.p. 95° at 24 mm. Lit. b.p. 82.5° at 11 mm (27).

2,2-Dimethyl-4-phenyl-1,3-dioxolane was synthesized in 79% yield by the method of Fischer and Pfahler (27) starting with acetone and 1-phenyl-1,2-ethanediol (Eastman Kodak Co.). B.p. 73° at 2 mm. Lit. b.p. 95–96° at 10 mm (28).

2,2,4-Trimethyl-1,3-dioxolane was prepared by the method of Fischer and Pfahler (27) starting with acetone and 1,2-propanediol (Eastman Kodak Co.). Yield, 33%. B.p. 99° at 700 mm. Lit. b.p. 98–99° at 760 mm (29).

4-Chloromethyl-2,2-dimethyl-1,3-dioxolane was prepared in 78% yield by the procedure of Fischer and

Pfahler (27) starting with 3-chloro-1,2-propanediol (Eastman Kodak Co.) and acetone. B.p. 78° at 40 mm. Lit. b.p. 45–50° at 10 mm (30); cf. 157° at 767 mm (27).

2,2-Dimethyl-1,3-dioxolane was prepared in 24% yield from acetone and 1,2-ethanediol using the procedure of Fischer and Pfahler (27). B.p. 89° at 700 mm. Lit. b.p. 92.5° at 760 mm (29).

2,4,4-Trimethyl-1,3-dioxolane was prepared by a modification of the method of Fischer and Pfahler (27). A mixture of paraldehyde (10 ml) and 2-methyl-1,2-propanediol (Eastman Kodak Co.) (8 g), 0.2 g of para-toluene-sulphonic acid, and 8 g of dry magnesium sulphate was kept in a refrigerator overnight, then filtered, and treated according to the procedure cited (27). Yield, 7.4 g (72%). B.p. 97–99° at 720 mm. Lit. b.p. 100.1° at 762 mm (31).

2,2,4,4-Tetramethyl-1,3-dioxolane.—This ketal was prepared by the acetal or ketal exchange reaction using a modification of the procedure described by McElvain and Curry (32).

The precursor, *2,2-dimethoxypropane*, was prepared in 41% yield by the method of Croxall *et al.* (33) starting with isopropyl acetate and methanol. B.p. 79–80° at 700 mm. Lit. b.p. 83° at 760 mm (34).

A mixture of 2,2-dimethoxypropane (7 g, 0.067 mole), 2-methyl-1,2-propanediol (see above) (6 g, 0.067 mole), and 0.05 g of *p*-toluenesulphonic acid was heated in a flask, equipped with a 4-inch Vigreux column, at such a rate that the methanol formed during the reaction slowly distilled over. When the theoretical amount of methanol had been removed, the residual oil was fractionally distilled to give 5.8 g (67%) of material boiling at 106° at 700 mm. Lit. b.p. 109–110° (35).

4-Isopropoxymethyl-1,3-dioxolane was prepared in 42% yield by the acetal exchange method described above, starting with 1-isopropoxy-2,3-propanediol and 1,1-diethoxymethane (Eastman Kodak Co.). B.p. 70° at 20 mm; n_D^{25}, 1.4201. Calc. for $C_7H_{14}O_3$: C, 57.53; H, 9.59. Found: C, 57.30; H, 9.49.

The precursor, *1-isopropoxy-2,3-propanediol*, was synthesized by acid-catalyzed hydrolysis of the corresponding epoxide by a modification of the method advocated by Lucas *et al.* (36). 1,2-Epoxy-3-isopropoxypropane (see above) (25 g, 0.22 mole) was added to a stirred mixture of water (40 ml) and concentrated sulphuric acid (2 ml) at 60°. During the addition, the temperature of the reaction mixture rose to 95° and was kept at this figure for 30 minutes following complete addition of the reagent. Solid sodium carbonate was then added to the cooled solution to neutralize the acid completely, and then the product was extracted with ether. When the ether extract was dried (Na_2CO_3) and the ether removed, an oil was obtained which was distilled under reduced pressure yielding 21.5 g (74%) of material boiling at 94° at 3.5 mm. Lit. b.p. 187–190° (37).

2,2-Dimethyl-4-isopropoxymethyl-1,3-dioxolane was made in 51% yield from 2,2-dimethoxypropane (Eastman Kodak Co. (33)) and 1-isopropoxy-2,3-propanediol (see above). B.p. 68° at 16 mm. Lit. b.p. 56–57° at 10 mm (28). The experimental procedure of McElvain and Curry (32), as modified for the preparation of 2,2,4,4-tetramethyl-1,3-dioxolane, was used for this preparation.

2-Chloromethyl-1,3-dioxolane was prepared in 63% yield from 1-chloro-2,2-dimethoxyethane (Eastman Kodak Co.) and 1,2-ethanediol using the above modification of McElvain and Curry's directions (32). B.p. 154–155° at 700 mm. Lit. b.p. 155–159° at 740 mm (32).

2-Dichloromethyl-1,3-dioxolane was prepared from 1,2-ethanediol and 1,1-dichloro-2,2-diethoxyethane using the above modification of McElvain and Curry's directions (32). B.p. 185° at 700 mm. Lit. b.p. 185–188° (38).

The precursor, *1,1-dichloro-2,2-diethoxyethane*, was made by a modification of the procedure described by Fritsch (39). Chlorine gas was bubbled through ethanol (100 ml) at 25° for 6 hours, after which time the lower layer of the reaction mixture was separated and mixed with 100 ml of ethanol. The resulting solution was treated with sodium carbonate (solid) and then poured into aqueous sodium carbonate solution. The oil that precipitated was taken up in ether and the ether extract then dried over anhydrous sodium carbonate. Removal of the ether afforded an oil which was fractionally distilled under reduced pressure to give 15 g of material boiling at 74–75° at 20 mm. Lit. b.p. 66–71° at 12 mm (40); cf. 178–185° (39).

2-Trichloromethyl-1,3-dioxolane was prepared as described by McElvain and Curry (32).

2,4-Bischloromethyl-1,3-dioxolane was prepared by the modification of McElvain and Curry's acetal exchange method (32), as described above for the preparation of 2,2,4,4-tetramethyl-1,3-dioxolane. From 45 g of chloroacetaldehyde diethylacetal (Eastman Kodak Co.) and 33 g of 3-chloro-1,2-propanediol (Eastman Kodak Co.) there was obtained 46 g (90%) of material boiling at 66° at 2 mm; 58–59° at 1.5 mm. Calc. for $C_5H_8Cl_2O_2$: C, 35.11; H, 4.72; Cl, 41.5. Found: C, 34.88; H, 4.29; Cl, 41.17; n_D^{24}, 1.4761.

Preparation or Source of Reduction Products

2-Ethoxyethanol and *ethylene glycol monomethyl ether* were obtained from Eastman Kodak Co.

2-Benzyloxyethanol was prepared by the procedure of Bennett and Hock (41) with the following modification. After the addition of the benzyl chloride, the mixture was heated at 120° for 2 hours, then cooled, and poured into water. The dried ether extract was then distilled. From benzyl chloride and 1,2-ethanediol there was obtained a 35% yield of the product boiling at 116° at 6 mm. Lit. b.p. 138° at 15 mm (42).

The following compounds were made by a modified version of the method described by Chitwood and Freure (43). After the epoxide had been added to the sodium alkoxide as directed by these authors, the solution was allowed to stand at 25° for 16 hours, then poured into cold water. The organic layer was separated, dried ($MgSO_4$), and distilled.

1-Methoxy-2-propanol.—B.p. 115–116° at 700 mm. Lit. b.p. 118–119° at 765 mm (44).

1-Isopropoxy-2-propanol.—B.p. 68° at 40 mm. Lit. b.p. 137–138° (45).

1-Chloro-3-isopropoxy-2-propanol.—This compound was prepared by a modification of the procedure described by Koelsch for the synthesis of derivatives of 2-propanol (46). 1-Chloro-2,3-epoxypropane (1 mole) (Matheson, Coleman, and Bell, Inc.) was added dropwise to 2-propanol (10 moles) to which three drops of concentrated sulphuric acid had been added. The temperature of the reaction mixture was maintained at 30° during the addition. The mixture stood for 3 hours and was then poured into saturated aqueous sodium carbonate solution. The organic layer was separated, dried (Na_2CO_3), and fractionally distilled. B.p. 80° at 6 mm. Lit. b.p. 87–87.5° at 20 mm (47).

The following compounds were prepared by this modified procedure of Koelsch:

1-Chloro-3-methoxy-2-propanol from 1-chloro-2,3-epoxypropane and methanol. B.p. 77° at 8 mm. Lit. b.p. 95° at 20 mm (46).

1-Isopropoxy-3-methoxy-2-propanol from methanol and 1,2-epoxy-3-isopropoxypropane (Eastman Kodak Co.). Yield, 65%. B.p. 97° at 30 mm. Lit. b.p. 202–203° (48).

1,3-Diisopropoxy-2-propanol from 2-propanol and 1,2-epoxy-3-isopropoxypropane. Yield, 46%. B.p. 101° at 20 mm. Lit. b.p. 74–75° at 2 mm (49).

2-Methoxy-1-propanol was prepared by the reduction of methyl α-methoxypropionate with lithium aluminum hydride according to standard procedure (14). B.p. 125° at 700 mm. Lit. b.p. 130° at 758 mm (44).

The *methyl α-chloropropionate* required to prepare methyl α-methoxypropionate (50) was made by heating under reflux for 3 hours 108.5 g (1 mole) of α-chloropropionic acid (Eastman Kodak Co.) with methanol (400 ml) containing 20 ml of concentrated sulphuric acid. The reaction mixture was cooled and poured into aqueous sodium carbonate and the organic layer removed. The organic layer was washed with sodium carbonate solution, dried (Na_2CO_3), and distilled to give 41 g (33%) of the ester boiling at 127–129° at 700 mm. Lit. b.p. 127–130° (50).

2-Isopropoxy-1,3-propanediol was made by lithium aluminum hydride reduction (14) of the mixed diester of isopropoxymalonic acid. B.p. 93° at 2 mm; η_D^{25}, 1.4430. Calc. for $C_6H_{14}O_3$: C, 53.73; H, 10.45. Found: C, 53.28; H, 10.11.

The mixed diester of isopropoxymalonic acid was prepared as follows: Isopropyl chloroacetate was made in 60% yield from 2-propanol and α-chloroacetic acid using the same procedure described above for the preparation of methyl α-chloropropionate. B.p. 68° at 23 mm. Lit. b.p. 150° (51).

The method of Nieman *et al.* (50) was used to prepare *isopropyl isopropoxyacetate* starting with sodium isopropoxide and isopropyl chloroacetate in 2-propanol. B.p. 65° at 8 mm. Calc. for $C_8H_{16}O_3$: C, 60.00; H, 10.11. Found: C, 60.13; H, 10.25. The isopropyl isopropoxyacetate (55 g, 0.34 mole) was treated with diethyl carbonate in the presence of sodium methoxide, according to the directions of Ames and Bowman (52), to form 30 g of the mixed diester of isopropoxymalonic acid boiling at 89° at 1.5 mm. Confirmation that this was indeed the diester of isopropoxymalonic acid was obtained by shaking a small portion of the diester with concentrated ammonium hydroxide. The diamide separated as a colorless solid. After crystallization from aqueous acetone it melted at 220–221°. Calc. for $C_6N_{12}N_2O_3$: C, 45.00; H, 7.50; N, 17.50. Found: C, 44.86; H, 7.42; N, 17.37.

2-Isopropoxy-1-propanol was prepared by the lithium aluminum hydride reduction (14) of isopropyl α-isopropoxypropionate. B.p. 141–142° at 700 mm. Lit. b.p. 143–144° (43).

The precursor, *isopropyl α-chloropropionate,* was made by the acid-catalyzed esterification of α-chloropropionic acid with 2-propanol using the procedure described for the preparation of methyl α-chloropropionate. Yield, 87%. B.p. 91° at 85 mm; η_D^{25}, 1.4127. Calc. for $C_6H_{11}ClO_2$: C, 47.85; H, 7.36; Cl, 23.57. Found: C, 47.65; H, 7.13; Cl, 23.64.

Using the procedure of Nieman *et al.* (50) *isopropyl α-isopropoxypropionate* was prepared from sodium isopropoxide and isopropyl α-chloropropionate in 2-propanol. B.p. 78° at 23 mm. Calc. for $C_9H_{18}O_3$: C, 62.07; H, 10.34. Found: C, 61.93; H, 10.15.

2-Methoxy-2-methyl-1-propanol was prepared in 82% yield by the reduction of α-methoxy isobutyric acid with lithium aluminum hydride (14). B.p. 137° at 700 mm. Lit. b.p. 141° (53).

The precursor *α-methoxyisobutyric acid* was prepared according to published directions (54) from 2-methyl-1,1,1-trichloro-2-propanol (Eastman Kodak Co.). Yield, 60%. B.p. 84–85° at 7 mm. Lit. b.p. 98–99° at 20 mm (54).

2-Ethoxy-2-methyl-1-propanol was prepared in 56% yield by standard lithium aluminum hydride reduction (14) of α-ethoxyisobutyric acid. B.p. 140° at 700 mm. Lit. b.p. 146–148° (53).

The precursor, *α-ethoxyisobutyric acid,* was prepared by the procedure of Weizmann *et al.* (54) in 36% yield from ethanol and 2-methyl-1,1,1-trichloro-2-propanol. B.p. 85–86° at 7 mm. Lit. b.p. 97° at 19 mm (54).

2-Isopropoxy-2-methyl-1-propanol was prepared in 53% yield by lithium aluminum hydride reduction (14) of α-isopropoxyisobutyric acid (54). B.p. 147–149° at 700 mm. Lit. b.p. 42–46° at 10 mm (55).

2-Benzyloxy-2-methyl-1-propanol was prepared in 78% yield by lithium aluminum hydride reduction (14) of α-benzyloxyisobutyric acid. B.p. 102° at 3.5 mm; η_D^{25}, 1.5088. Calc. for $C_{11}H_{16}O_2$: C, 73.33; H, 8.89. Found: C, 73.58; H, 8.90.

The *α-benzyloxyisobutyric acid* was prepared in 34% yield from benzyl alcohol and 2-methyl-1,1,1-trichloro-2-propanol by the method of Weizmann *et al.* (54) but with the modification that the reaction mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was heated at 100° for 2 hours rather than refluxed for the same length of time. B.p. 139° at 3 mm; η_D^{25}, 1.5048. Calc. for $C_{11}H_{14}O_3$: C, 68.04; H, 7.22. Found: C, 68.36; H, 7.02.

1-Methoxy-2-methyl-2-propanol was prepared by the method mentioned by Palomaa (56). Since no details were given by Palomaa, the procedure employed is described.

Ethyl methoxyacetate was prepared in 59% yield by the acid-catalyzed esterification of methoxyacetic acid (Eastman Kodak Co.) with ethanol. The procedure was the same as that described above for the preparation of methyl α-chloropropionate. B.p. 138–139° at 700 mm. Lit. b.p. 144° at 748 mm (57).

Ethyl methoxyacetate (19.7 g, 0.167 mole) was slowly added to an ethereal solution of methyl magnesium iodide prepared from methyl iodide (52.0 g, 0.37 mole) and magnesium (8.9 g, 0.37 mole) in 200 ml of ether. After the addition of the ester was completed, the reaction mixture was stirred for 3 hours, and then crushed ice was added to decompose the complex. After inorganic salts were removed by filtration, the ethereal solution was dried ($MgSO_4$). Removal of the ether gave an oil which was distilled, yielding 3.7 g (21%) of 1-methoxy-2-methyl-2-propanol. B.p. 112–115° at 700 mm. Lit. b.p. 116.6° (56).

1-Ethoxy-2-methyl-2-propanol was prepared by the method described above to synthesize 1-methoxy-2-methyl-2-propanol. From ethyl ethoxyacetate and methyl iodide there was obtained a 40% yield of the desired alcohol. B.p. 125° at 700 mm. Lit. b.p. 129–130° (53).

Ethyl ethoxyacetate was prepared in 62% yield from ethoxyacetic acid (Eastman Kodak Co.) and ethanol by the method described above for the preparation of methyl α-chloropropionate. B.p. 152–153°. Lit. b.p. 154° (58).

1-Isopropoxy-2-methyl-2-propanol was made in 37% yield from isopropyl isopropoxyacetate (see above) and methyl iodide by the procedure given for the preparation of 1-methoxy-2-methyl-2-propanol. B.p. 75° at 70 mm; η_D^{25}, 1.4055. Calc. for $C_7H_{16}O_2$: C, 63.64; H, 12.12. Found: C, 63.57; H, 12.14.

1-Benzyloxy-2-methyl-2-propanol was made in 46% yield from ethyl benzyloxyacetate and methyl iodide by the method described above for the synthesis of 1-methoxy-2-methyl-2-propanol. B.p. 106° at 6 mm; η_D^{25}, 1.4997. Calc. for $C_{11}H_{16}O_2$: C, 73.33; H, 8.89. Found: C, 73.70; H, 9.12.

Ethyl benzyloxyacetate was prepared in 23% yield from ethyl chloroacetate and sodium benzyloxide in benzyl alcohol by the procedure of Nieman *et al.* (50). B.p. 118–120° at 3 mm. Lit. b.p. 100–102° at 1 mm (59).

2-Methoxy-2-phenylethanol was made by acid-catalyzed methanolysis of 1,2-epoxyethylbenzene (Eastman Kodak Co.), as described by Reeve and Christoffel (60).

2-Isopropoxy-2-phenylethanol was prepared in 54% yield from 1,2-epoxyethylbenzene and 2-propanol using acid catalysis (60). B.p. 94° at 3 mm; η_D^{25}, 1.4982. Calc. for $C_{11}H_{16}O_2$: C, 73.33; H, 8.89. Found: C, 73.51; H, 8.72.

2-Methoxy-1-phenylethanol.—This was prepared by the base-catalyzed reaction between methanol and 1,2-epoxyethylbenzene, as described by Reeve and Christoffel (60). There was obtained 24 g (76%) of material boiling at 108–110° at 6 mm. Lit. b.p. 137–138° at 30 mm (60). This substance was found by g.l.c. to contain a small amount of the isomeric 2-methoxy-2-phenylethanol. This impurity was removed by solution of the product in skellysolve and addition of sodium metal (1.2 g). The precipitated sodium derivative was removed by passing the solution through a column of alumina using skellysolve as eluant. Removal of the solvent from the eluant afforded 2-methoxy-1-phenylethanol which g.l.c. showed to be >99% pure.

2-Isopropoxy-1-phenylethanol was made according to the method of Reeve and Christoffel (60) from 1,2-epoxyethylbenzene and sodium isopropoxide in 2-propanol. Yield, 24%. B.p. 93° at 3 mm; η_D^{25}, 1.4995. Calc. for $C_{11}H_{16}O_2$: C, 73.33; H, 8.89. Found: C, 73.14; H, 8.76.

2-β-Chloroethoxyethanol was prepared by the acid-catalyzed alcoholysis of 1,2-epoxyethane by β-chloroethanol using a modification of the method of epoxide solvolysis described by Lucas *et al.* (61).

1,2-Epoxyethane (8.89 g, 0.2 mole) was slowly added to β-chloroethanol (16 g, 0.2 mole) containing 1 ml of concentrated sulphuric acid. The resulting mixture was allowed to stand at 25° for 48 hours, then poured into a saturated aqueous solution of sodium carbonate. The product was extracted with ether, the ether extract dried (Na_2CO_3), and then freed of solvent. The residual oil upon fractional distillation at reduced pressure gave 2.8 g (11%) of 2-β-chloroethoxyethanol boiling at 70° at 3 mm. Lit. b.p. 180–185° (62).

1-Isopropoxy-2,3-propanediol.—This compound was prepared in 74% yield by the acid-catalyzed hydrolysis of 1,2-epoxy-3-isopropoxypropane (Eastman Kodak Co.) by a modification of the method described by Lucas *et al.* (61).

1,2-Epoxy-3-isopropoxypropane (25 g, 0.22 mole) was added to a stirred mixture of water (40 ml) and concentrated sulphuric acid (2 ml) at 60°. During the addition the temperature of the mixture rose to 95° where it was maintained for 30 minutes after complete addition of reagents. It was then cooled and solid sodium carbonate added to neutralize the acid. The ether extract was dried over anhydrous sodium carbonate. Removal of the ether and distillation of the oil under reduced pressure gave 21.4 g (74%) of material boiling at 94° at 3.5 mm. Lit. b.p. 187–190° (37).

3-Chloro-2-isopropoxy-1-propanol was not made by an independent route but was prepared and characterized as one of the products of the reduction of 4-chloromethyl-2,2-dimethyl-1,3-dioxolane by lithium aluminum hydride in the presence of aluminum chloride. For the details of the procedure see below.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

General Procedure for the Reduction of 1,3-Dioxolanes by Lithium Aluminum Hydride and Aluminum Chloride

A standard reduction procedure was employed throughout the course of this work. This is exemplified by the following description of the reduction of 2,2-dimethyl-4-phenyl-1,3-dioxolane. Anhydrous conditions were observed and maintained where necessary.

A quantity (18.0 g, 0.1 mole) of 2,2-dimethyl-4-phenyl-1,3-dioxolane was added to a stirred suspension of lithium aluminum hydride (3.9 g, 0.1 mole) in 300 ml of diethyl ether. The resulting suspension was stirred whilst a solution of aluminum chloride (13.35 g, 0.1 mole) was added in a dropwise manner. The reaction mixture was stirred for 1 hour after complete addition of the Lewis acid, which usually took about 10 minutes. Cold water was then added cautiously to decompose the aluminum complexes as well as the excess hydride. The inorganic material was removed by filtration and washed with ether. The combined ethereal filtrate and extract was dried ($MgSO_4$) and then freed from the bulk of the ether. The residual oil when analyzed by gas–liquid chromatography was found to be a mixture of 2-isopropoxy-2-phenylethanol (52%) and 2-isopropoxy-1-phenylethanol (48%), each identified by comparison with authentic samples of these compounds. The total product of the reduction distilled over the range 90–92° at 3 mm, yielding 14.7 g (81%) of material.

In many cases the mixture was actually separated by fractional distillation into unreacted dioxolane and the two isomeric hydroxyethers.

The Reduction of 4-Chloromethyl-2,2-dimethyl-1,3-dioxolane with Lithium Aluminum Hydride and Aluminum Chloride and the Resulting Preparation of 3-Chloro-2-isopropoxy-1-propanol

In this case the products of the reduction were separated and characterized due to the fact that one of the reduction products, 3-chloro-2-isopropoxy-1-propanol, was unavailable.

A quantity (40 g, 0.27 mole) of 4-chloromethyl-2,2-dimethyl-1,3-dioxolane was reduced according to the general procedure described above and afforded 36.0 g (86%) of crude reduction product after removal of the ether. G.l.c. analysis of this product showed it to be a mixture of two substances, 1-chloro-3-isopropoxy-2-propanol (95%) and 5% of a second material assumed to be the other possible reduction product, 3-chloro-2-isopropoxy-1-propanol.

These two products were separated by careful fractional distillation with a 12-inch column packed with glass helices. The first fraction (32.0 g) boiled at 114° at 72 mm and was shown to be 1-chloro-3-isopropoxy-2-propanol by comparison of its g.l.c. retention time as well as its n.m.r. and I.R. spectra with those of an authentic sample. The residue (4.0 g) from the fractionation was purified by passing it through a g.l.c. preparative column and collecting the effluent and then finally by distillation under reduced pressure. There was obtained 1.5 g of material boiling at 108° at 35 mm. The n.m.r. spectrum in carbon tetrachloride, with tetramethylsilane as reference, agreed with the structure designated as 3-chloro-2-isopropoxy-1-propanol. n_D^{25}, 1.4430. Calc. for $C_6H_{13}ClO_2$: C, 47.22; H, 8.52; Cl, 23.28. Found: C, 46.87; H, 8.39; Cl, 23.21.

In view of the invariable twofold direction of reduction of dioxolanes found for all previous cases, agreeing with the predicted products, and because of the above evidence, we are convinced that the compound dealt with is actually that designated. Final confirmation of course will have to await the unambiguous synthesis by another route.

Competitive Reduction of 2-Substituted 1,3-Dioxolanes

Equimolar quantities (0.025 mole) of two dioxolanes were dissolved in ether (300 ml) containing 0.05 mole of lithium aluminum hydride. To this stirred solution was added an ether solution of aluminum chloride (0.005 mole) over a period of 3 minutes and the mixture then stirred for 30 minutes. The extent of reduction could be controlled by the amount of Lewis acid added, since no further reduction occurred after the limited amount of aluminum chloride had been added even though there was originally sufficient lithium aluminum hydride to reduce most, if not all, of the dioxolane. Water was then cautiously added and the solution worked up and analyzed by g.l.c. as described in the general procedure.

ANOMALOUS RING CLEAVAGE DURING LITHIUM ALUMINUM HYDRIDE – ALUMINUM CHLORIDE REDUCTION OF 2,2,4,4-TETRAALKYLATED-1,3-DIOXOLANES[1]

B. E. LEGGETTER AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received December 6, 1963

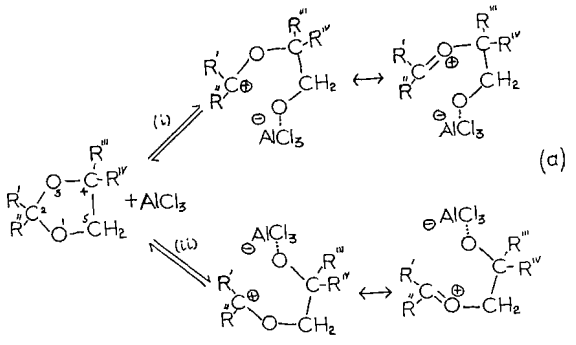
ABSTRACT

The anomalous reductive cleavage by $LiAlH_4$–$AlCl_3$ of 2,2,4,4-tetramethyl-1,3-dioxolane in ether solution has been examined. Evidence supports the view that this unexpected direction of ring cleavage is due to steric repression of the formation of the intermediate oxocarbonium ion leading to cleavage of the C_2—O_1 bond of the dioxolane ring.

INTRODUCTION

In a recent publication (1) it was shown that in the reductive ring cleavage of 1,3-dioxolanes with a mixture of lithium aluminum hydride and aluminum chloride in ether solution, substituents on C_4 of the dioxolane ring exerted a marked control over the direction of ring opening. Electron donor substituents attached to C_4 gave predominant cleavage of the C_2—O bond remote from C_4, while electron-attracting groups attached to C_4 resulted in a high proportion of cleavage at the C_2—O bond nearest to the C_4-substituted position. Substituents on C_2 of the 1,3-dioxolane ring system were found to have a negligible effect on the direction of reductive ring cleavage.

This effect was rationalized on the basis of the stabilizing or destabilizing effect that the C_4 substituents exerted on the two possible intermediate oxocarbonium ions, the formation of which was considered to be rate-determining (equation (*a*)). Electron donor substituents (R‴, R^{iv}) would stabilize to a greater extent the oxocarbonium ion shown



in equation (*a*), route (i), hence this ion would be predominant and reduction would follow largely this route. On the other hand, electron-withdrawing groups (R‴, R^{iv}) would preferentially destabilize the oxocarbonium ion shown in route (i) of equation (*a*), hence the formation of the ion indicated in route (ii) would be predominant and reductive cleavage would follow largely this path. Subsequent reduction to the hydroxy ether was considered to be fast, and found to be irreversible.

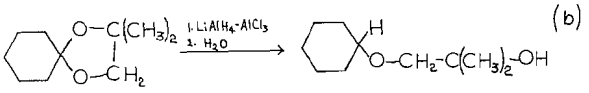
However, the cleavage of one compound encountered in this work (1), that of 2,2,4,4-tetramethyl-1,3-dioxolane, gave 94% of 1-isopropoxy-2-methyl-2-propanol and only 6% of the 2-isopropoxy-2-methyl-1-propanol. This was the reverse of what had been expected considering the results found for all the other cases examined. Its formation could not be rationalized within the framework of the postulated mechanistic pathways. A similar situation has been pointed out by Eliel and co-workers (2), who found that the isobutylene ketal of cyclohexanone gave exclusively the tertiary alcohol (equation (*b*)) in sharp contrast to the results found for all their other C_4-substituted 1,3-dioxolanes. They suggested that this anomaly might be the result of either a different mechanism of hydrogenolysis



from that occurring for the other examples studied, or a "counterplay of polar and steric influences".

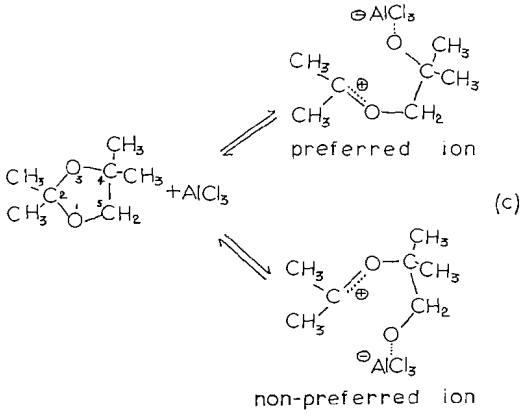
The purpose of this work was to examine this anomalous reductive cleavage in more detail and to provide an explanation for the results obtained.

RESULTS AND DISCUSSION

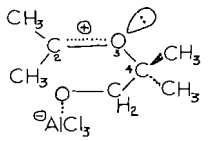
The reduction of 2,2,4,4-tetramethyl-1,3-dioxolane was repeated as described and the results found to be in agreement with those published (1).

Two explanations may be offered to account for this unexpected direction of ring cleavage. The first is that the steric strain, due to non-bonded repulsion of the four alkyl substituents at C_2 and C_4 positions, outweighs the polar influence normally controlling the direction of the ring opening. This view is supported by the fact that the corresponding 2,4,4-trimethyl-1,3-dioxolane and the 2,2,4-trimethyl-1,3-dioxolane both gave the predicted preferential cleavage at the C_2—O bond (equation (*a*), route (i)) to give the primary alcohols in the proportion of 90% and 82% respectively of the total reduction product (ref. (1), Table I). It thus appears that the fourth group plays a decisive role in the direction of ring opening.

The second explanation of the anomaly is that the oxocarbonium ion formation, necessary for the cleavage at C_2—O_1, is retarded by the steric influence of the substituents on C_2 and C_4, whereas similar steric retardation involving the formation of the alternate oxocarbonium ion does not occur (equation (*c*)).

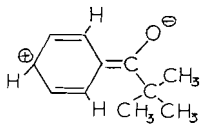


For the cleavage of the C_2—O_1 bond to occur, overlap of the p orbital of the O_3 atom with the developing empty p orbital of the C_2 atom must take place, resulting in the formation of the stabilized oxocarbonium ion. A requirement for effective overlap of these two p orbitals, and hence formation of the "double bond", is a configuration in which the C_2 atom with its two substituents, the oxygen atom with the lone pair in the sp^2 hybrid orbital *and* the C_4 atom are all coplanar as shown below.



This configuration would result in strong non-bonded interference between one of the two methyl substituents at C_2 and the substituents on the tertiary carbon, C_4. Thus a strain would occur during the formation of the oxocarbonium ion, tending to inhibit its development.

The literature contains a closely analogous case in the explanation offered to account for the anomalous rate of reduction of *t*-butyl phenyl ketone by sodium borohydride compared to the rates of reduction found for the homologous methyl, ethyl, and isopropyl phenyl ketones (3).* It was found that the order of the rates of reduction of the homologues was methyl phenyl ketone > ethyl phenyl ketone > isopropyl phenyl ketone as expected from steric and polar considerations. However, the *t*-butyl phenyl ketone was found to reduce at a rate faster than that of the methyl phenyl ketone. This was rationalized by the postulation that, due to steric repression, there was a much lower contribution of the resonance structure, such as that shown below, for the *t*-butyl compound than for each of the other homologues.



The difference between the two explanations suggested to account for the unexpected ring cleavage found in the present work is that the first requires steric *acceleration* of the cleavage of the C_2—O_3 bond, while the ease of cleavage of the C_2—O_1 bond is unaffected by the substituents on C_2 and C_4, other than by polar influences. On the other hand, the latter explanation requires that the cleavage of the C_2—O_1 bond be *retarded* by steric compression due to the four groups on C_2 and C_4, while the rate of cleavage of the C_2—O_3 bond is not changed other than by polar effects.

One can differentiate between these two routes by a study of the rate of reduction of 2,2,4,4,5,5-hexamethyl-1,3-dioxolane. If the first explanation is correct, then this dioxolane should cleave much more readily than does the 2,2-dimethyl-1,3-dioxolane where no steric strain between C_2 and C_4 substituents occurs. On the other hand, if the latter explanation is correct then the rate of reductive cleavage of the hexa-substituted dioxolane should be greatly retarded.

The ease of reduction has been examined and results show that the reduction of

**The referee has kindly pointed out that the heat of hydrogenation of cis-methyl-t-butylethylene provides a second analogy. This olefin is destabilized through steric strain by about 4.3 kcal/mole relative to the trans isomer. (R. B. Turner, D. E. Nettleton, Jr., and M. Perelman. J. Am. Chem. Soc. 80, 1430 (1958).)*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

2,2,4,4,5,5-hexamethyl-1,3-dioxolane is greatly retarded. After 1 hour of reduction, this compound was practically unchanged, and even after 48 hours of reduction 30% of the original dioxolane was recovered intact. Under identical conditions both 2,2-dimethyl-1,3-dioxolane and 2,2,4,4-tetramethyl-1,3-dioxolane were completely cleaved in less than 90 minutes (1). On the basis of these results, the second explanation is preferred.

EXPERIMENTAL

Analysis of products of the reduction was carried out by gas–liquid chromatography as described in the previous publication (1).

The reduction of the 1,3-dioxolanes were carried out according to the general procedure described by Leggetter and Brown (1).

2,2,4,4,5,5-Hexamethyl-1,3-dioxolane was prepared in 72% yield from 2,2-dimethoxypropane (1) and anhydrous pinacol using the ketal exchange procedure described by McElvain and Curry (4). B.p. 145–146° at 700 mm. Lit. b.p. 147.5–148.5° (5).

DEUTERIUM–HYDROGEN EXCHANGE BETWEEN WATER AND SILK FIBROIN

JOHN L. MORRISON
Department of Physical Chemistry, Ontario Research Foundation, Toronto, Ontario
Received November 13, 1963

ABSTRACT

A gravimetric method for measuring deuterium–hydrogen exchange between light and heavy waters and macromolecular solids has been applied to the fibrous protein, silk fibroin (*Bombyx mori*). The accessibility of the protein to water vapor can be estimated from the amount of exchange, and it appears to be related to the amorphous regions of the fiber. A comparison of the amount of exchange with the water monolayer content as obtained from the adsorption isotherm and the equilibrium evaporation technique suggests that the water molecules use the polar side chains of the amino acid residues as the sites of primary adsorption.

INTRODUCTION

Isotopic exchange studies are useful in elucidating the secondary and tertiary structures of proteins, celluloses, and other macromolecules. Usually, the isotopic exchange has been followed by indirect methods such as change in composition of the water (1, 2), infrared measurements (3–6), and tritium exchange (7, 8).

Three groups of workers (9–11) have measured the exchange directly by the change in dry weight of the macromolecular solid. All of them used a quartz spring balance, and two of them (9, 11) stated that they made measurements with a sample between 0.1 and 0.2 grams.

In this paper, a simpler gravimetric method of measuring deuterium–hydrogen exchange (12) is applied to a preliminary study of the reaction between light and heavy waters and the protein, silk fibroin (*Bombyx mori*).

EXPERIMENTAL

Materials

The silk fibroin, *B. mori*, was kindly supplied by Belding–Corticelli Limited, Montreal, as Japanese raw silk. It was degummed by the method of Drucker, Hainsworth, and Smith (13). The deuterium oxide was 99.7% pure (Atomic Energy of Canada, Limited).

Apparatus

The same type of glass reaction cell (14, 15) was used for both the exchange measurements and the sorption determinations. It consists of a thin-walled glass bulb, to hold about 5 g fibrous substance, a vacuum stopcock, and an inner ground-glass joint. It was readily removed for weighing. An oil manometer containing Apiezon oil B was used to measure the water vapor pressure. The reaction cell and the light and heavy water reservoirs were immersed in a thermostat at 24.8° C.

The assembly was evacuated by a mercury condensation pump and a rotary oil pump. A trap immersed in a dry ice – methyl cellosolve bath at −86° C was placed between the reaction cell and the mercury pump to avoid the back exchange inherent in the use of drying agents (2) and to prevent mercury from reaching the sample.

Drying Procedures

Fifty hours of continued evacuation at 25° C against a dry ice trap reduced the water content of silk fibroin to about 0.2% compared with the dryness obtained by a further 1 day evacuation at 70° C.

Subsequent evacuation of a 6-g sample of silk fibroin at 70° C for 15 days decreased the weight by about 1 mg. Lang and Mason (16) showed that the evacuation of cellulose at 70° for 24 hours achieved a water content not sensed by isotopic exchange as analyzed by a mass spectrograph.

However, when the silk sample was alternately wetted and dried by a cycle similar to that used in the heavy and light water dosing procedure, a significant weight loss amounting to 0.5 mg per cycle occurred (Fig. 1). The weight loss appeared to be largely independent of dose size or of time of drying at 70°, and only

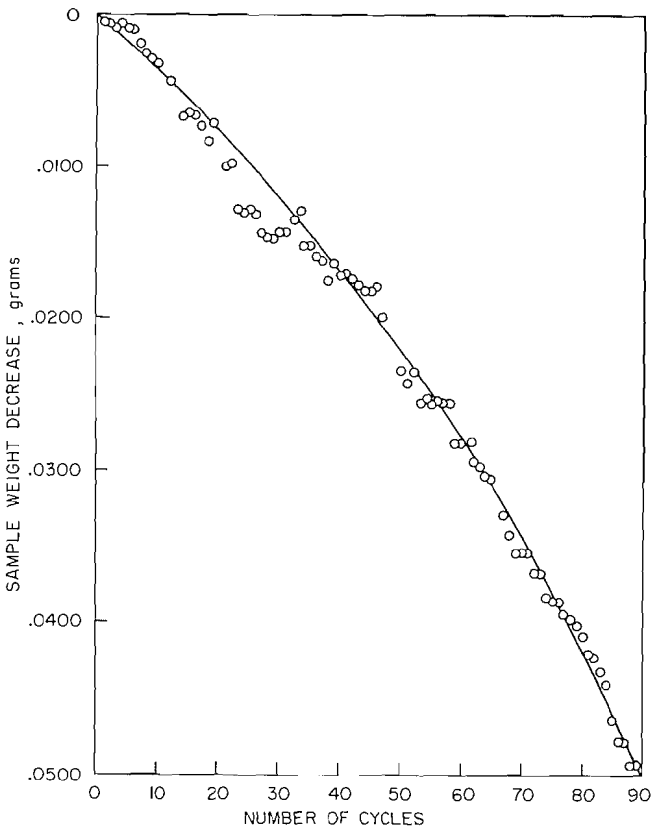

FIG. 1. Cyclic wetting and drying of 6.2 g silk fibroin. Cycles 1–14, 0.05 to 0.44 g H_2O dried 1 day at room temperature and 1 day at 70° C; cycles 15–89, increasing doses from 0.03 to 0.73 g, dried 12 hours at room temperature and 16 hours at 70°.

dependent on the number of wetting and drying cycles. A similar phenomenon has been observed for cellulose by Lang and Mason (8).

In view of an observation that drying at 50° C removed the last amounts of sorbed water as effectively as at 70° C, a number of exchange experiments were dried at the lower temperature. This partially avoided the possibility of thermal decomposition at 70° (17). In all cases, samples undergoing exchange were evacuated at room temperature for 12 to 24 hours before being raised to a higher temperature.

Sorption Characteristics

The adsorption–desorption isotherms of light water and the adsorption isotherm of heavy water on silk fibroin were determined by the same method as was used for cellulose (15). A maximally deuterated sample was used for the heavy water isotherm. Each point was the result of equilibration for at least 24 hours. The isotherms are given in Fig. 2.

From the adsorption isotherms, the B.E.T. monolayer contents (18) on a dry protein basis were found to be 4.47 and 4.98% for H_2O and D_2O, respectively. These values are exactly in their molar ratios.

An independent method for determining monolayer values, recently developed in this laboratory (19), was applied to silk fibroin. The method, an equilibrium evaporation technique, involves experimentally determining the rate of evaporation of water from a wet polymer sample under conditions approaching equilibrium. A completely wetted sample in a cell similar to that used in the other experiments is dried under vacuum through a capillary tube (0.85 mm diameter, 20.5 cm long) for 20 minutes, weighed, left to stand for 12 hours, and again evacuated for 20 minutes. This cycle is repeated until the sample is practically dry. Except for the time of weighing, the sample tube is continually thermostatted at 25.0° C. Figure 3 shows the drying rate below 26% water content. The break at about 5% water content is interpreted as the monolayer value. An even sharper break has been obtained for other polymers by using 24-hour waiting intervals between the evacuation periods.

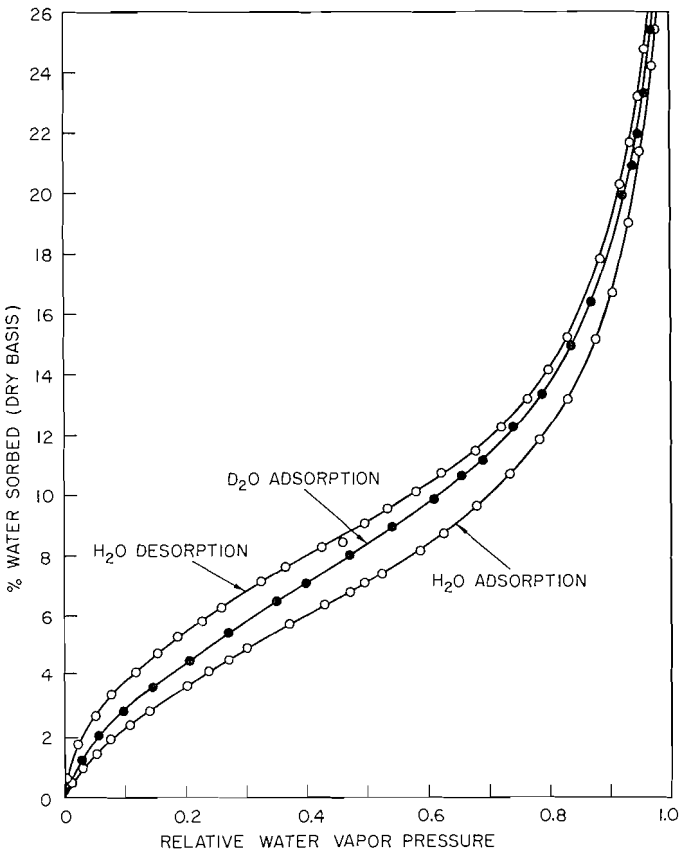

FIG. 2. Sorption isotherms at 24.8° C.

Since the evaporation rate method is a desorption process, it would be better to compare the break at 5% with the B.E.T. monolayer value calculated from the desorption rather than the adsorption branch of the isotherm. The desorption branch value was 5.4%.

Rapid Exchange Experiments

In one experiment 6.20 g silk fibroin were wetted with six doses (8, 9, 4, 9, 6.5, 5.5 g respectively) of heavy water. After 3 to 4 days contact, the sample was evacuated for 12 hours at 25° C and 16 hours at 50° C with each successive dose. By the end of the second cycle, the sample weight was within 6% of the total increase. The final weight increase was 1.04%. Then this sample was used for the heavy water isotherm determination.

Another sample of 5.35 g was similarly treated with five doses (5.7, 6.0, 5.3, 6.0, and 9.0 respectively) of heavy water. After the second cycle, the sample was within 10% of its total increase. The final increase was 1.06%.

This sample was back-exchanged with three doses (14, 13, 12.5 respectively) of light water and finally dried at 50° C when it had recovered exactly its original weight.

Slow Exchange Experiments

The 6.20 g sample was deuterated and protonated by a rate method already applied to insulin (12). Small doses of heavy water (0.142 g) and light water (0.127 g), the latter for the deuterated sample, were admitted to the sample through a capillary tube. After 10.5 minutes, the samples were evacuated for several hours at 24.8° C. The final drying of the first series was carried out at 70° C and of the second at 50° C. When the weight change appoached a maximum, between 15 and 22 doses, much larger doses were admitted to the sample, until the maximum degree of exchange was attained. The results are reported in Figs. 4 and 5.

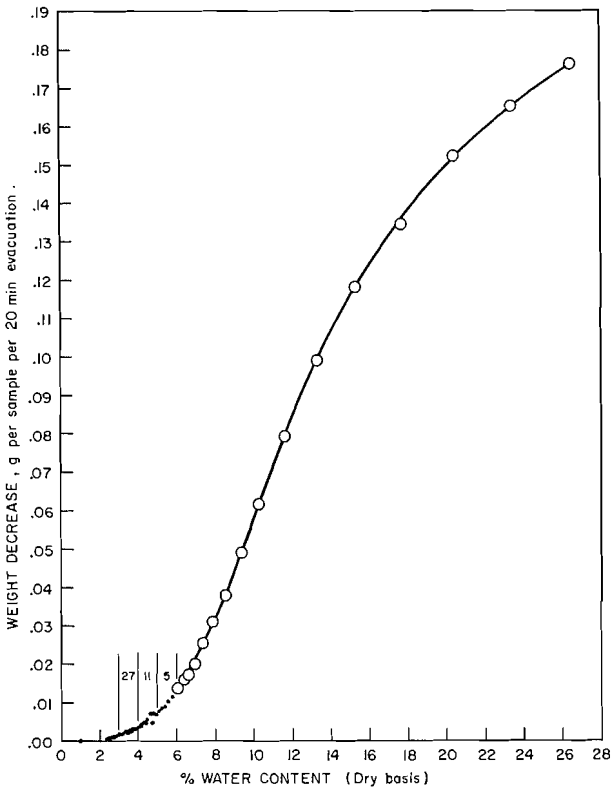

FIG. 3. Weight decreases by a highly wetted sample of silk fibroin (dry wt. = 5.35 g) on evacuation through a capillary tube. Each point represents the *change* in sample weight after 20 minutes evacuation. The numbers 5, 11, and 27 represent the number of 20-minute evacuations between 6 and 5, 5 and 4, and 4 and 3% water contents, respectively.

DISCUSSION

Assuming that the weight decrease in the cyclical wetting and drying (Fig. 1) is a loss in water, one can speculate about its origin. It does not appear to be ordinarily adsorbed water and it is not removed merely by continual heating. This difficultly removable water, which requires for its removal the perturbations of the solid set up by the cyclical wetting and drying process, may be intracrystalline water.

When a correction for the weight loss due to cyclical wetting and drying is applied to the deuteration and protonation curves given in Fig. 4, the two curves come closer together, but they do not coincide. That coincidence does not occur may be due to a number of factors (12). One possible explanation is that the cycling correction has been determined only for light water. Heavy water may have a drying effect arising from the entropy of mixing, that is, it is very hygroscopic. To test this hypothesis, one would carry out wetting and drying experiments with heavy water on a maximally deuterated sample.

The true value of the exchange rate probably lies somewhere between the deuteration and protonation curves of Figs. 4 and 5. In principle it need not be the mean between the two curves because of differences in such properties as zero-point energy.

The maximum value for the exchange, as given by the rapid exchange experiments, corresponds to an increase of 1.05% in the dry weight of the protein. In the slow experiments, with the drying at 50° C, Fig. 5, the mean of the two maxima is 1.0%. For slow

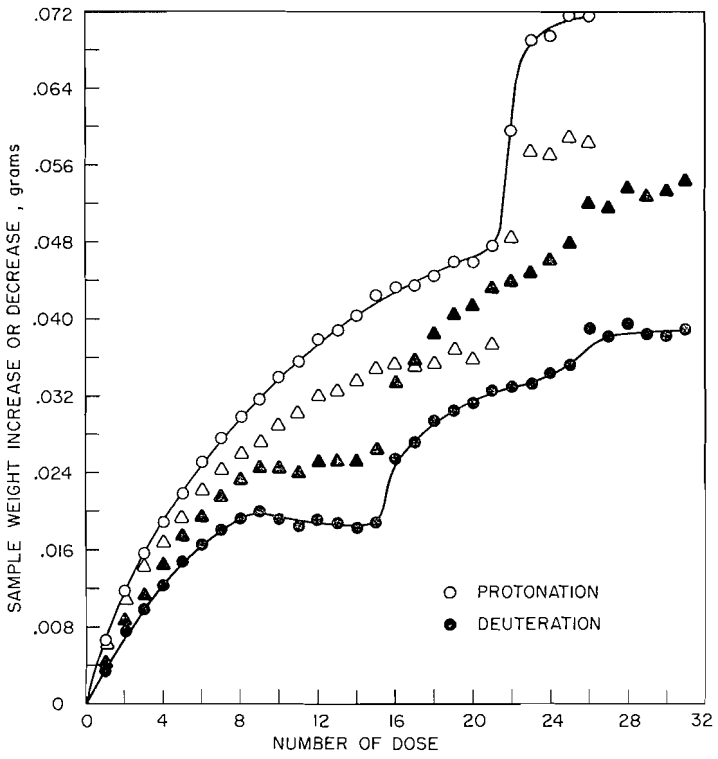

FIG. 4. Deuteration and protonation of 6.20 g silk fibroin by cyclic dosing with each final drying at 70° C. Deuteration: doses 1–12, 0.142 g D_2O for 10.5 minutes, then evacuation; doses 13 and 14, 0.142 g left overnight before evacuation; dose 15, 0.35 g, immediately evacuated; doses 16–23, 0.60 g evacuated after 64½ minutes; dose 24, 0.60 g left overnight; dose 25, 0.88 g left overnight; dose 26, 2.56 g left 2 days; dose 27, 3.04 g left 1 day; doses 28–31, 0.142 g D_2O left overnight. Protonation: doses 1–18, 0.127 g H_2O added for 10.5 minutes, then immediately evacuated; doses 19 and 20, 0.127 g left overnight; dose 21, 1.0 g left 3 days; doses 22–26, 6.5–8.4 g H_2O left several days before evacuation. The symbols ▲, △ are weight changes on deuteration and protonation respectively corrected for the weight losses as shown in Fig. 1.

experiments with the drying at 70°, Fig. 4, the means of the maxima are 0.89% uncorrected, and 0.92% corrected.

Deuterium–hydrogen exchange between water and proteins occurs with hydrogens attached principally to nitrogen and oxygen atoms. These occur on the peptide and other polar groups of the constituent amino acids. In the case of silk fibroin, the total exchangeable hydrogens make up about 1.58% of the weight of the protein. The present results show that 1.05% are exchangeable. The part of the fibroin which is accessible to deuterium–proton exchange is probably the amorphous part, the inaccessible region being the crystalline part (6).

The only experimental work on silk fibroin, *B. mori*, with which to compare the present results is that of Lucas and Smith (20). They separated the fibroin into two fractions by means of chymotrypsin digestion. They suggested that the fraction, CTL (40% of the total protein nitrogen), soluble in the enzyme digest consists of the amorphous region and that the soluble fraction, CTP (60%), is the crystalline region. From their Table II (20), the total exchangeable hydrogen in the soluble fraction is 0.67% of the total fibroin, made up of the hydrogens of 0.499 moles peptide nitrogen and 0.157 moles polar groups per

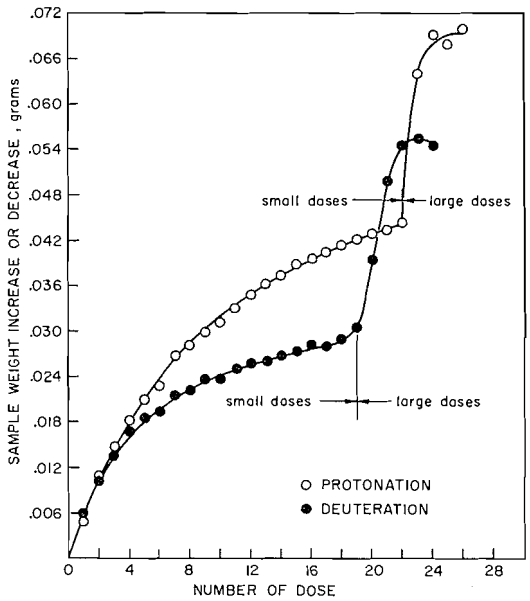

FIG. 5. Deuteration and protonation of 6.20 g silk fibroin by cyclic dosing with each final drying at 50° C. Deuteration: small doses 1–18, same as for 70° experiments; dose 19, same as 1–18 but left 1 day before evacuation; doses 20–24, 0.7, 5.1, 7.0, 6.6, and 9.4 g D_2O, respectively, evacuated after 2 days. Protonation: small doses 1–21, same as for 70° experiments; dose 22, same as dose 19 of deuteration; doses 23–26, 6.2, 6.0, 13.2, and 14.5 g H_2O, evacuated after 2–3 days.

100 g fibroin. On the basis of the present observations it would appear that chymotrypsin dissolves about two-thirds of the amount of fibroin accessible to water exchange. This is not surprising in view of the enormous difference in size between the chymotrypsin and water molecules.

The data of Lucas and Smith (20) can be used in a discussion of the mode of attachment of the water monolayer to the amorphous region. The deuterations and protonations are adsorption processes. The monolayer content on adsorption is 4.5% or 0.25 moles H_2O per 100 g fibroin. There are 1.05 moles exchangeable hydrogen in this amount of fibroin. Consequently water molecules could not be attached directly to all of the exchangeable hydrogens. Pauling (21) suggested that the water molecules are attached to the amino acid residues with polar side groups.

If water is accessible to all of the CTL and part of the CTP fractions of the fibroin, the number of polar side groups is 0.222 moles per 100 g fibroin, made up of 0.157 moles from the CTL and 0.065 from the CTP. The value 0.222 is somewhat less than the 0.25 moles H_2O in the monolayer. Two possible explanations may account for this discrepancy.

The fractional number of polar side groups in the part of the CTP accessible to water is assumed to be the same as that for the whole CTP, namely 0.17. In the case of the CTL, this fraction is 0.315. It is possible that the part of the CTP accessible to water has a greater proportion of polar side groups than the whole CTP.

Another explanation which may not be different from the first one is that there may be more polar side groups on the surfaces of the crystallites than inside them.

Finally, let us consider the fact that small doses of water reach an intermediate maximum in their exchange with silk fibroin. This is particularly clear in the experiments shown in Fig. 4. The levelling off, which is independent of time for the small doses, occurs

at between 0.5 and 0.6% exchange. Two alternative explanations are possible: either the accessibility to the amorphous region is determined by dose size or the amorphous region is completely accessible to any amount of water, and the exchangeable hydrogens exist in different energy levels. There is, of course, the possibility that both effects operate together.

The fact that the equilibrium evaporation rate curve (Fig. 2) can be entered at any point by wetting from the dry state to a moisture content a little higher than the desired entry point strongly suggests that the accessibility is independent of moisture content. It is more probable that the exchangeable hydrogens on each different group have their own equilibrium constant with respect to water.

Of the 1.05% exchangeable hydrogens about 0.23% are attached to polar side groups when the calculations are based on the amino acid contents of the two fractions of fibroin. However, comparison with the monolayer value of 0.25% suggests that the 0.23% may be underestimated. If 0.25 is taken as the percentage of exchangeable hydrogens on polar side groups and if an approximately equal number of peptide hydrogens occurring in the same amino acid residues is added, the total may account for the half more readily exchangeable hydrogens observed during deuteration. This would be consistent with the location of the water monolayer molecules on the polar side groups.

NEPHELOMETRIC DETERMINATION OF PALLADIUM WITH DI-2-THIENYLKETOXIME

WILLIAM J. HOLLAND AND LEO LEE
Department of Chemistry, University of Windsor, Windsor, Ontario
Received November 25, 1963

ABSTRACT

Di-2-thienylketoxime is used to determine 1 to 4 p.p.m. of palladium nephelometrically. Palladium (II) can be determined in the presence of a 30-fold excess of platinum. A sixfold excess of other platinum metals and gold do not interfere. No interference was found with other common cations or anions with the exception of cyanide.

INTRODUCTION

Of the several methods (1) generally recommended for the determination of microgram quantities of palladium, the most sensitive is that employing *p*-nitrosodiphenylamine as a colorimetric reagent. The reagent 2-thienyl-*trans*-aldoxime has been used for the gravimetric estimation of palladium (2). The nephelometric method described herein constitutes part of the results of an investigation into the use of thienylketoximes as analytical reagents. A previous paper (3) reported the reactions of di-2-thienylketoxime and the structure of the complexes formed with bivalent palladium. Di-2-thienylketoxime reacts with microgram quantities of palladium (II), as the chloride, in acid solution to form a suspension of a complex which could be determined nephelometrically. The method was investigated to determine such factors as optimum concentration of reagent, effect of time of standing, pH, temperature, stabilizing agents, and diverse ions.

EXPERIMENTAL

Reagents

Standard palladium solutions.—Reagent grade palladium (II) chloride was used. This material was analyzed gravimetrically with dimethylglyoxime and was found to contain 60.16% palladium. A palladium (II) stock solution was prepared by dissolving a weighed amount of the reagent in hydrochloric acid and diluting to a given volume. The palladium (II) standard solutions were prepared by appropriate dilution of aliquots of the stock solution with a buffer solution of pH 3.2.

Diverse ions.—Reagent grade chlorides were employed in the preparation of cation solutions and sodium salts were used for the anion solutions.

Stabilizing agent.—A 1% solution of U.S.P. grade gelatin was used.

Di-2-thienylketoxime.—The reagent was synthesized and purified by the method outlined in a previous publication (3). A 0.1% solution in ethanol was employed.

Generator solution.—This solution was prepared by suspending powdered pyrex glass in water. The procedure used in this preparation was that outlined by Fikman (4).

Buffer solution.—pH 3.2. Prepared from potassium acid phthalate and hydrochloric acid solutions.

Instruments.—A Fisher Nefluorophotometer was used for the nephelometric measurements and a Beckman Model G pH meter for the pH determinations.

Procedure

Standard solutions of palladium (II) buffered to pH 3.2 and of various concentrations (0.05 to 0.25 mg per 50 ml final dilution) were prepared by pipetting aliquots of the stock solution (0.1 mg per ml) into 100-ml volumetric flasks and diluting with the buffer. Exactly 25 ml of these solutions were pipetted into 50-ml volumetric flasks. To each flask was added 5 ml of the ketoxime solution and the mixture was allowed to stand for 1 hour. After addition of 5 ml of the gelatin solution and diluting to the mark the mixture was shaken vigorously for 2 minutes. The suspension prepared with the most concentrated of the palladium (II) solutions was transferred to a nephelometric cell and the percentage transmittancy scale set at 100%. The scale readings of the remaining suspensions were measured using the glass suspension as the generator solution. By plotting the scale readings against palladium (II) concentration a straight line was obtained over the range 0.05 to 0.20 mg per 50 ml final solution. The results of this plot are shown in Fig. 1.

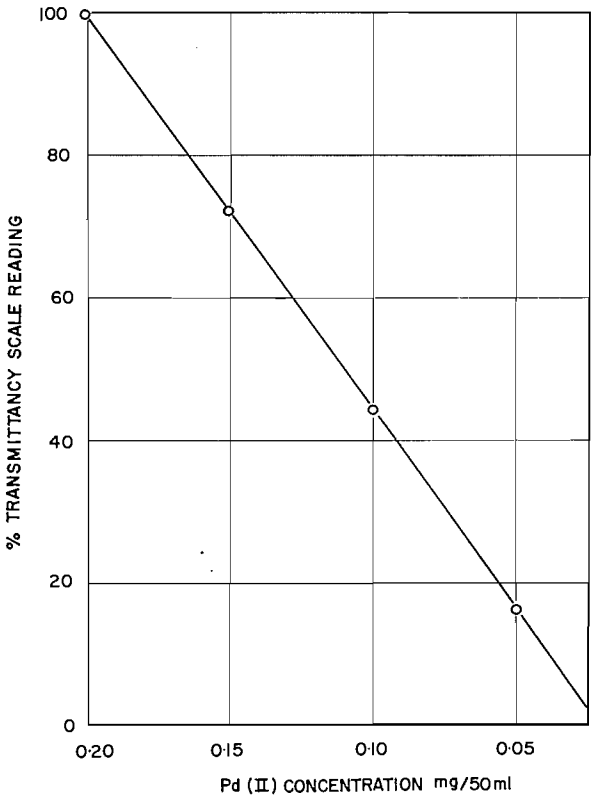

FIG. 1.

Effect of pH.—Constant scale readings were obtained for solutions containing 0.15 mg palladium (II) per 50 ml final dilution between pH 2.8 and 4.2. Solutions of pH less than 1.2 or higher than 4.5 gave very little turbidity. The greatest turbidities were produced between pH 1.5 and 2.5, but these were very sensitive to slight changes in pH. The solutions were adjusted to the desired pH by dropwise addition of 0.1 *N* hydrochloric acid or sodium hydroxide solutions. A diluted glass suspension solution was used as the reference standard.

Effect of time of standing.—The procedure described above was followed with a number of solutions of the same palladium (II) content varying the time allowed after the addition of the reagent and before the addition of the gelatin solution prior to measurement of the turbidity. Constant readings were obtained after 1 hour standing.

Effect of reagent concentration.—Results indicated that a 0.1% solution of the ketoxime was the most suitable concentration. Higher concentrations resulted in precipitation of the reagent with a consequent increase in turbidity. Lower concentrations gave decreasing turbidities.

Effect of ethanol concentration.—The total amount of reagent added to solutions having the same palladium (II) content was maintained constant while the amount of ethanol was varied. Constant readings were obtained when the final dilution contained 5 ml of ethanol per 50 ml. Higher alcohol contents resulted in decreasing turbidity while lesser amounts caused precipitation of the reagent.

Effect of variation of temperature.—Constant readings were obtained in the temperature range 20–25° C. Above 25° the turbidity decreased markedly.

Effect of diverse ions.—Suspensions were prepared for solutions containing the same concentration of palladium (II) to which had been added various amounts of other cations or anions. Readings were taken for the solutions and the results are given in Table I. These results indicate that no serious interference occurs with the ions investigated with the exception of cyanide.

Determination of known samples.—Known palladium (II) solutions were prepared and then concentrations determined using the procedure outlined and the calibration curve of Fig. 1. The results given in Table II show a recovery of at least 95%.

PRESSURE EFFECT AND MECHANISM IN THE ACID-CATALYZED HYDRATION OF PROPYLENE AND ISOBUTYLENE[1]

B. T. BALIGA[2] AND E. WHALLEY
Division of Applied Chemistry, National Research Council, Ottawa, Canada

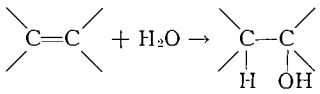
Received October 4, 1963

ABSTRACT

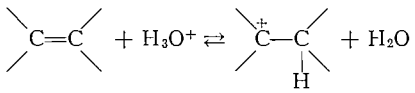
The effect of pressure up to 3 kbar on the rate of the acid-catalyzed hydration of propylene and isobutylene has been measured. The volumes of activation are: for propylene at 100° C $-9.6 \pm \sim 1.0$ cm^3 mole^{-1}, and for isobutylene at 35° C $-11.5 \pm \sim 1.0$ cm^3 mole^{-1}. The effect of temperature in the range 90–120° C on the rate of hydration of propylene at 100 bar was measured. At 100° C the Arrhenius energy is $27.1 \pm \sim 1.0$ kcal mole^{-1} and the entropy of activation is $-5.4 \pm \sim 2.5$ cal deg^{-1} mole^{-1}. Both the volumes and entropies of activation strongly indicate that a molecule of water is present in the transition states, which can therefore be represented as $[\text{olefin}.H^+.H_2O]^{\ddagger}$. There appears to be no strong evidence regarding the molecular structure of the transition states.

1. INTRODUCTION

The acid-catalyzed hydration of olefins in aqueous solution has been studied frequently



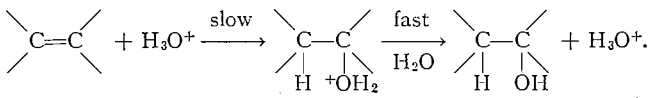
in the past few years, but the mechanism is still not entirely settled. The main direct evidence relating to the mechanism is as follows. The hydration of isobutylene (1, 2, 3) and many other tertiary olefins (4, 5, 6) is specifically acid-catalyzed, and so is catalyzed only by the solvated hydrogen ion. It is first order in hydrogen ion in dilute acid and first order in olefin. The transition states therefore contain one molecule of olefin, one proton, and perhaps one or more molecules of water. When the hydration of 2-methyl-2-butene is carried out (7) under conditions such that the *t*-amyl alcohol formed does not dehydrate appreciably, there is no exchange between the hydrogen of the unreacted olefin and the solvent. A pre-equilibrium proton transfer to form a carbonium ion does not



therefore occur since, if it did, then exchange of hydrogen with the solvent would occur. The lack of an acid-catalyzed isomerization of certain olefins under similar conditions (8) is further confirmation of this point.

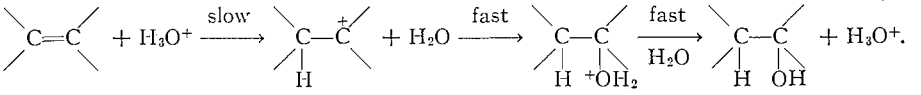
The foregoing evidence is reasonably direct. The main likely mechanisms that are consistent with it are as follows.

(*a*) A one-step addition of H_3O^+, perhaps via a cyclic transition state

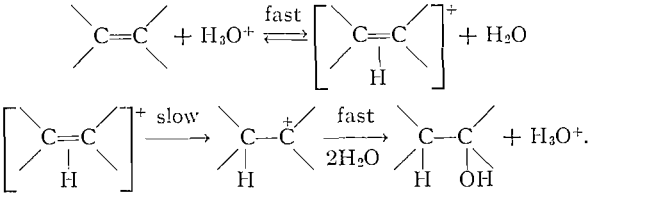


[1]*N.R.C. No. 7841.*
[2]*N.R.C. Postdoctoral Fellow 1962–4.*

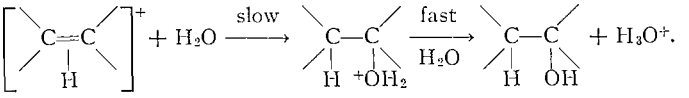
(*b*) A slow proton transfer followed by a rapid addition of a molecule of water



(*c*) A rapid pre-equilibrium protonation of the double bond of the olefin, followed by a slow unimolecular rearrangement to a carbonium ion which then reacts rapidly with water

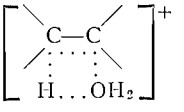


(*d*) A mechanism similar to (*c*) in which the double-bond-protonated olefin reacts slowly with a molecule of water

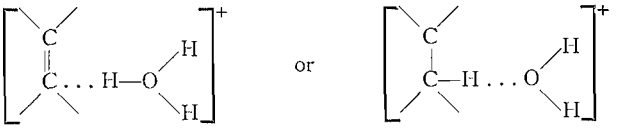


Mechanisms intermediate between these four can, of course, be envisaged. The mechanism could also be more complicated and involve several molecules of water in the transition state (see, for example, ref. 9). More complicated mechanisms will not be discussed here because there is no even moderately sound method at present of distinguishing between one and more than one molecule of water in the transition state.

There are no direct methods at present of distinguishing between mechanisms (*a*)–(*d*), and there is very little indirect evidence of useful weight. Mechanism (*c*) was suggested by Taft and co-workers (10) mainly because the rate of hydration of several olefins, including isobutylene, in concentrated acid is more nearly proportional to Hammett's acidity function h_0 than to the hydrogen-ion concentration. The Zucker-Hammett hypothesis, on which this conclusion was based, is now known to be invalid, and so this evidence has no weight. Other methods of determining the mechanism based on rates in concentrated acids seem to be hardly more soundly based. Kinetic solvent isotope effect studies have been reported on the hydration of some olefins. The ratio of the rates in H_2O and D_2O is close to unity (7) for the hydration of 2-methyl-2-butene and 1-methyl-1-cyclopentene, whereas it is 2.2 (11) for the addition of concentrated sulphuric acid to ethylene and 2.8 for hydration of propylene (12) in 90% aqueous formic acid. Willi (13) has argued that an isotope effect of near unity is consistent with a 4-centered transition state



whereas Bunton and Shiner (14) have suggested that an isotope effect of near unity favors either of the following transition states



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in which the H—O bond is either only slightly broken or almost completely broken. In short, the solvent deuterium isotope effect can be plausibly explained on the basis of any of the foregoing mechanisms and so does not at present distinguish between them. The dehydration of the *t*-butyl (15) and *t*-amyl alcohols (16) is much slower than the exchange of oxygen between the alcohol and the solvent. However, as it is not known whether oxygen exchange and dehydration go by related or unrelated mechanisms, the relevance of this evidence to the mechanism of dehydration of alcohols and the reverse reaction, the hydration of olefins, is not established. The entropy of activation should provide useful evidence, and indeed it has already been discussed (10) as eliminating mechanism (*b*) and favoring mechanism (*c*). However, as we shall discuss in more detail in Section 4, the analysis that this was based on is incomplete, and the conclusion drawn is probably erroneous.

Volumes of activation of acid-catalyzed reactions have in recent years proved useful for determining whether there is a molecule of water in the transition state (17). In the hope that useful information might be obtained about the acid-catalyzed hydration of propylene and isobutylene, the effect of pressure on the rates has been measured. The effect of temperature on the rate of hydration of propylene was not previously known and has also been measured.

2. EXPERIMENTAL METHODS

Materials

Propylene and isobutylene were Phillips Petroleum Co. research grade, *n*-heptane was Anachemia Chemicals Ltd. pure grade, and other chemicals were reagent grade.

Analysis of Alcohols

The hydrations were followed by estimating the alcohol produced. This was done by Shmulyakovskii's (18) method in which the alcohol is converted to the nitrite, and the nitrite is extracted into *n*-heptane and estimated spectrophotometrically. Five milliliters of the reaction mixture was added to 10 ml of *n*-heptane in a 60-ml separating funnel. Then 2 ml of 1 *N* HCl was added followed by 2 ml of 6% aqueous sodium nitrite. A stop-watch was started when the nitrite was added. The mixture was shaken for 2 minutes, allowed to settle for 2 minutes, and the aqueous layer discarded; 5 ml of 0.5 *N* ammonium carbonate solution was added and the mixture shaken for 1 minute. One minute later the optical density of the heptane layer was measured with a Beckman DU spectrophotometer using 1-cm silica cells. In a separate series of experiments the optical density was verified to be linear in the concentration of alcohol in the original solution in the range of concentration used in the kinetic experiments; the measurements are summarized in Fig. 1. The analysis for ethanol in concentrations that would be obtained by hydrating ethylene in aqueous solution was also tested as it is hoped to study this reaction in the future, and the results are included for convenience in Fig. 1.

Kinetic Measurements

The high-pressure techniques have been described previously (19, 20). Perchloric acid was used as catalyst. Because propylene and isobutylene are only slightly soluble in water, the reaction mixture was prepared by saturating aqueous perchloric acid at 0° C by bubbling the olefin through the solution by means of a sintered glass tube. The solution was taken up in the hypodermic syringe, and the pressure vessel was quickly assembled, put into the thermostat, and pressurized. The thermostat was maintained at 35.000±0.005° C for isobutylene and at 90.00, 100.00, 110.00, and 120.00°±0.015° C for propylene. The fall in temperature of the thermostat when the pressure vessel was put into it was quickly compensated by means of a 1-kw boost heater. To ensure temperature equilibrium, about 15 minutes was allowed for isobutylene and about 30 minutes for propylene before samples were taken. Propylene is much less soluble in water than isobutylene, and it is important to have the solution nearly saturated at 0° C. To reduce the loss of propylene, the syringe, pressure vessel, and mercury were precooled to ~0° C in a refrigerator, and the vessel was pressurized to ~100 bars immediately after assembly.

About six samples were taken during each run. Three samples were taken for the infinity reading after allowing the reaction to go to completion overnight, which was at least 10 half-lives.

To verify that no significant amount of olefin was present at equilibrium, two experiments were done. In the first, 0.5 *M* *t*-butanol in 1 *M* perchloric acid was kept overnight at 70° C and 50 bar. In the second, 0.034 *M* isopropanol in 1 *M* perchloric acid was kept overnight at 110° C and 100 bar. In both experiments there was no change in concentration of the alcohol within the reproducibility (± ~0.3%) of the measurements. There will be an even smaller amount of olefin present at higher pressures because alcohols dehydrate with an increase of volume.

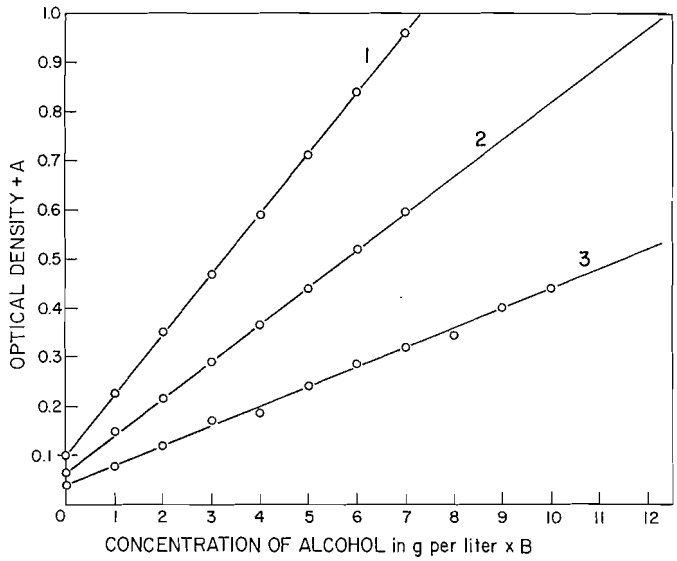

FIG. 1. Optical density of solutions of the alkyl nitrite in *n*-heptane against the original concentration of alcohol. Curve 1: isopropanol at 358 mμ, A = 0.1, B = 0.314. Curve 2: *t*-butanol at 382 mμ, A = 0.05, B = 0.186. Curve 3: ethanol at 357 mμ, A = 0, B = 0.315.

3. RESULTS

All runs were accurately first order in olefin, and the first-order rate constants k_1 were obtained graphically by plotting log $(D_\infty - D_t)$ against time t where D_∞ and D_t are the optical densities of the alkyl nitrite solution when the reaction had gone to completion and after time t respectively. The rate constants are accurate to about 3%. The second-order rate constants k_a were obtained by dividing the first-order constants by the concentration of hydrogen ion at the temperature and pressure of the experiment (21, 22). The results are summarized in Tables I and II.

The kinetics of the hydration of propylene in low concentrations of strong acid in water do not appear to have been studied previously. The measurements described above confirm that it is first order in olefin. It was shown to be first order in perchloric acid at 90° C and 100 bars by doing runs in 0.857 and 1.146 *M* perchloric acid, the results of which are summarized in Table I. The effect of temperature on the rate of hydration of propylene was also measured at temperatures from 90 to 120° C. These reactions were carried out

in the pressure vessel, as described above, and a pressure of 100 bars was used to ensure that the propylene did not come out of solution.

For comparison, previous results for $10^3 k_a$/l. mole^{-1} sec^{-1} for the hydration of isobutylene in dilute nitric acid at atmospheric pressure and 35° C are 1.41 (1) and 1.34 (3) compared with our 1.27 (Table II).

The rate constants as a function of pressure are shown in Fig. 2. The volumes of activation $\Delta V^{\ddagger}$ at zero pressure were obtained graphically by plotting mean volumes of activation $\Delta V^{\ddagger}_{mean}$ calculated between adjacent pressures p_1 and p_2 from the formula

$$\log_{10} \frac{k_a(p_2)}{k_a(p_1)} = -\frac{\Delta V^{\ddagger}_{mean}(p_2 - p_1)}{2.303RT}$$

against $(p_1+p_2)/2$, where $k_a(p_1)$ and $k_a(p_2)$ are the rate constants at the adjacent pressures p_1 and p_2, and extrapolating to zero pressure. For isobutylene

$$\Delta V^{\ddagger} = -11.5 \pm \sim 1.0 \text{ cm}^3 \text{ mole}^{-1} \text{ at } 35° \text{ C},$$

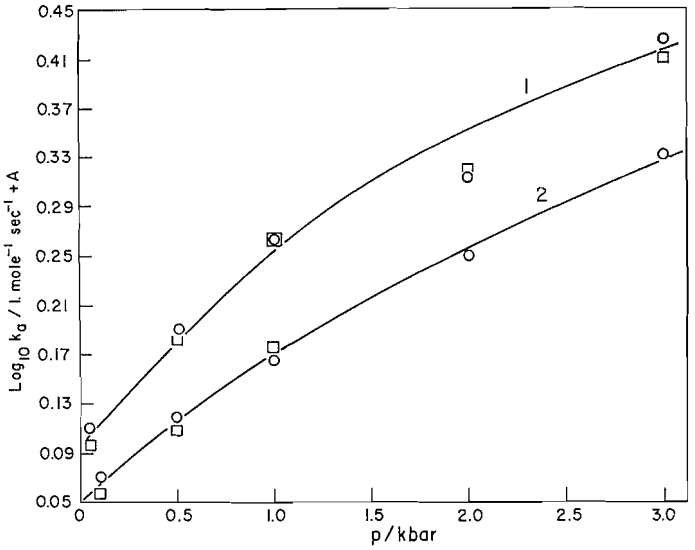

FIG. 2. Effect of pressure on the rate of the acid-catalyzed hydration of propylene and isobutylene catalyzed by aqueous perchloric acid. Curve 1: isobutylene at 35° C, A = 3. Curve 2: propylene at 100° C, A = 3.81.

and for propylene

$$\Delta V^{\ddagger} = -9.6 \pm \sim 1.0 \text{ cm}^3 \text{ mole}^{-1} \text{ at } 100^\circ \text{ C.}$$

An Arrhenius plot of the second-order constants for the hydration of propylene is given in Fig. 3. There appears to be a curvature, indicating that a change of mechanism may be

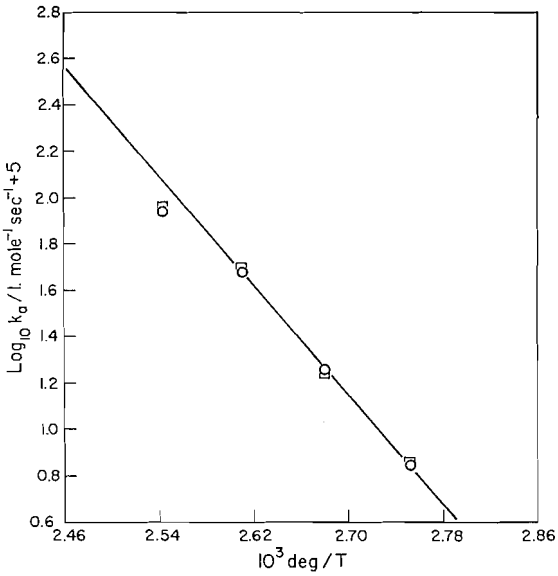

FIG. 3. Effect of temperature on the rate of the acid-catalyzed hydration of propylene at 100 bars.

occurring. However, no great weight should be put on this until the curvature is confirmed. The parameters at 100° C and 100 bars of the Arrhenius equation, obtained graphically from the line drawn in Fig. 3, are

$$E_A = 27.1 \pm \sim 1 \text{ kcal mole}^{-1},$$

$$\log_{10} A/\text{l. mole}^{-1} \text{ sec}^{-1} = 12.1,$$

and the entropy of activation $\Delta S^{\ddagger}$ [$= R \ln(A/\text{l. mole}^{-1})(h/ekT)$] is $-5.4 \pm \sim 2.5$ cal deg^{-1} mole^{-1}. The difference between these values and those for zero pressure or 1 bar will be quite inappreciable.

4. DISCUSSION

The volumes of activation for the acid-catalyzed hydration of propylene and isobutylene are $-9.6 \pm \sim 1.0$ cm^3 mole^{-1} at 100° C and $-11.5 \pm \sim 1.0$ cm^3 mole^{-1} at 35° C respectively. A volume greater than half the volume of a water molecule is therefore lost when the transition state is formed. Information about the mechanism can be extracted from this observation.

The transition states of the slow steps of the mechanisms listed in the Introduction can be divided into two groups according as the transition state is better represented as [olefin.H$^+$]‡ (mechanism (*c*)) or as [olefin.H$^+$.H$_2$O]‡ (mechanisms (*a*), (*b*), and (*d*)). If the formation of the transition state can be represented by

$$\text{olefin} + H_3O^+ \rightarrow [\text{olefin.H}^+]^{\ddagger} + H_2O, \qquad [1]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

there is no change in the number of molecules and probably little change in the electrostatic interaction with the solvent when the transition state is formed, and the change in the electrostatic interaction is more likely to be a decrease than an increase due to the larger size of the transition state than of H_3O^+. There is therefore probably little change in volume, or perhaps a slight increase, when the transition state is formed. On the other hand if the formation of the transition state can be represented by the reaction, or sequence of reactions represented by,

$$\text{olefin} + H_3O^+ \rightarrow [\text{olefin}.H^+.H_2O]^{\ddagger}, \qquad [2]$$

a molecule is lost by the conversion of a van der Waals bond into a partial valence bond. On theoretical and empirical grounds (17) this should be accompanied by a loss of volume of very roughly 10 cm^3 $mole^{-1}$. It seems clear therefore that the observed volumes of activation can be readily understood only if a molecule of water is bound into the transition state.

The entropies of activation support this conclusion. The entropy change for reaction [1] is roughly analogous to the entropy changes for the proton transfer reactions

$$R_3N + H_3O^+ \rightarrow R_3NH^+ + H_2O. \qquad [3]$$

The entropy changes for reactions [3] for a variety of substituents R have been collected (23). They are all positive and as high as 15 cal deg^{-1} $mole^{-1}$. While the analogy between reactions [1] and [3] is by no means perfect, it seems likely that the entropy change of reaction [1] is positive. The fact that the entropies of activation of all unimolecular acid-catalyzed (A-1) reactions that have been measured appear to be positive provides further empirical confirmation (17). Reaction [2] can be considered as the sum of reaction [1] and the reaction

$$[\text{olefin}.H^+]^{\ddagger} + H_2O \rightarrow [\text{olefin}.H^+.H_2O]^{\ddagger}.$$

The entropy change of this reaction is undoubtedly negative because of the loss of freedom of the water molecule, unless there is a considerable decrease in the electrostatic interaction with the solvent when the water molecule adds, which seems unlikely. The entropy change of reaction [2] is therefore the sum of a positive and a negative term, and the sign is at present unpredictable. We note, however, that a negative entropy of activation is predicted only if the transition state is $[\text{olefin}.H^+.H_2O]^{\ddagger}$. Empirically, all bimolecular acid-catalyzed (A-2) hydrolyses or hydrations in aqueous solution, in which the transition state can be represented as $[\text{substrate}.H^+.H_2O]^{\ddagger}$, have negative entropies of activation (17), which provides some confirmation for this view.

The entropy of activation for the hydration of propylene is $-5.4 \pm \sim 2.5$ cal deg^{-1} $mole^{-1}$ and of isobutylene is -7.7 cal deg^{-1} $mole^{-1}$ in the range 25–50° C (24). The negative values confirm the conclusion derived from the volumes of activation that the transition states have the composition $[\text{olefin}.H^+.H_2O]^{\ddagger}$, and mechanism (*c*), which has been widely held recently, can be eliminated with good assurance for propylene and isobutylene.

The structure of the transition states, as opposed to their compositions, i.e. whether the mechanisms are best represented as reactions [*a*], [*b*], [*d*], or otherwise, is a subtle question that cannot be answered at present. Several tertiary alcohols have been shown (15, 16) to exchange oxygen with the solvent by acid catalysis faster than they dehydrate. The volume of activation for the acid-catalyzed racemization of *sec*-butanol (25) indicates that the mechanism is best represented as the unimolecular decomposition of the protonated alcohol. It seems likely then that the oxygen exchange in tertiary alcohols occurs by the mechanism

$$ROH_2^+ \rightleftarrows R^+ + H_2O,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and that the carbonium ion reacts with water faster than it is deprotonated to form the olefin. The question whether the dehydration of the alcohol goes by the carbonium ion or by a different mechanism is unanswered by this evidence. Although it is often assumed that both exchange and dehydration go by the carbonium ion (16), there is no strong evidence that this is so.

The results reported in this paper do not, of course, throw any direct light on the mechanism of hydration of other olefins. They do, however, suggest that evidence based on the use of acidity functions should be re-examined. The most useful kinetic parameter for determining whether a molecule of water is bound into the transition state that has hitherto been widely measured is probably the entropy of activation. For many olefins it is negative, but only by a small amount (ref. 6 and this work). This indicates, on the basis of the arguments given above, that a molecule of water is bound into the transition states. However, as the entropies of activation are not far from zero, the evidence is not wholly convincing, and volumes of activation would be worth measuring.

ACKNOWLEDGMENTS

We are greatly indebted to Mr. A. Lavergne for help in maintaining the high-pressure apparatus.

THE METAL-CATALYZED AUTOXIDATION OF TETRALIN

III. CATALYSIS BY MANGANESE, COPPER, NICKEL, AND IRON[1]

Y. KAMIYA[2] AND K. U. INGOLD

Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received December 20, 1963

ABSTRACT

The catalysis of the autoxidation of tetralin by the decanoates of manganese, copper, nickel, and iron has been examined over a large concentration range at 50° C. With all four metals the oxidation rate approaches a limit at high catalyst concentrations but in each case this limit is smaller than the theoretical maximum rate of oxidation of pure tetralin (Y. Kamiya *et al.* Can. J. Chem. 41, 2020 (1963)). However, upon dilution with an inert solvent, such as chlorobenzene, or with the metal acetates, acetic acid, the theoretical maximum rate is attained. The low limiting rates in pure tetralin are apparently due to the low solubilities of the catalysts and are not due to chain termination by the catalysts.

INTRODUCTION

The previous papers in this series showed that the limiting rate of the cobalt-catalyzed autoxidation of tetralin in acetic acid (1) and of pure tetralin (2) at 50° C was due to the production of a steady-state concentration of hydroperoxide. The experimental limiting rate was in fairly good agreement with the theoretical predictions of Tobolsky (3). This work has now been extended to catalysis by manganese, copper, nickel, and iron since it is of considerable interest to compare and contrast the behavior of several metal oxidation catalysts. The four metals were examined as their decanoates in pure tetralin* and as their acetates in acetic acid. The experimental technique has been described previously (1, 2). All measurements were made at 50° C.

The kinetic scheme describing the production of a steady-state hydroperoxide concentration is given by (1, 4):

$$\mathrm{ROOH} + n\mathrm{M} \xrightarrow{k_1'} \text{radical} \xrightarrow{\mathrm{RH}} \mathrm{R}\cdot, \qquad [1\mathrm{D}]$$

$$\mathrm{R}\cdot + \mathrm{O_2} \xrightarrow{k_2} \mathrm{RO_2}\cdot, \qquad [2\mathrm{D}]$$

$$\mathrm{RO_2}\cdot + \mathrm{RH} \xrightarrow{k_3} \mathrm{ROOH} + \mathrm{R}\cdot, \qquad [3\mathrm{D}]$$

$$\mathrm{RO_2}\cdot + \mathrm{RO_2}\cdot \xrightarrow{k_5} \text{inactive products} + \mathrm{O_2}. \qquad [4\mathrm{D}]$$

When the rate of hydroperoxide decomposition is negligible compared with the rate of formation, the overall rate of oxidation is given by

$$\frac{-d[\mathrm{O_2}]}{dt} = k_3\left(\frac{k_1'}{2k_6}\right)^{1/2}[\mathrm{RH}][\mathrm{ROOH}]^{1/2}[\mathrm{M}]^{n/2}. \qquad [2]$$

As the hydroperoxide concentration increases with time its rate of decomposition will eventually equal its rate of formation. This steady-state concentration is given by

$$[\mathrm{ROOH}]_\infty = \frac{k_3^{\,2}[\mathrm{RH}]^2}{2k_1'k_6[\mathrm{M}]^n}, \qquad [3]$$

[1]*Issued as N.R.C. No. 7842.*

[2]*N.R.C. Postdoctoral Fellow 1962–64.*

**Cobalt decanoate was the most soluble cobalt fatty acid salt examined previously (2).*

and, therefore, the limiting rate of oxidation is given by

$$\left(\frac{-d[O_2]}{dt}\right)_\infty = \frac{k_3^2[RH]^2}{2k_6}. \qquad [4]$$

The limiting rate defined by this equation for pure tetralin at 50° C is 1.0×10^{-3} mole/l. sec (1).

Two papers on the cobalt-catalyzed autoxidation of tetralin that have been published very recently deserve some comment. The first paper by Cerny and Hajek deals with the oxidation in acetic acid (5). These authors conclude, on the basis of very inadequate data, that the Tobolsky theory of limiting rates (3) as outlined by Woodward and Mesrobian (4) is incorrect. They prefer to interpret their results in terms of Denisov's theory (6, 7), which assumes that the radical induced decomposition of hydroperoxide predominates over the metal-catalyzed decomposition. This assumption seems very unlikely to be true at the high catalyst concentrations where limiting rates occur, and, in fact, it leads to the incorrect prediction that $[ROOH]_\infty$ is independent of the catalyst concentration. Since this is obviously incorrect, Denisov introduces two more reactions,

$$RO_2\cdot + M \rightarrow X\cdot + P,$$
$$X\cdot + RH \rightarrow XH + R\cdot,$$

which have the effect of making $[ROOH]_\infty$ inversely proportional to the catalyst concentration at high levels of catalyst. Our own work (1) showed that the radical induced decomposition of hydroperoxide only has an important effect on $[ROOH]_\infty$ at low catalyst concentrations and that the Tobolsky mechanism gives a quantitative explanation of oxidation rates and $[ROOH]_\infty$ values at high catalyst concentrations.

The second paper by Tomiska deals with the oxidation of pure tetralin (8). The initial rate was found to vary with the catalyst concentration but to be independent of the initial peroxide concentration. It was therefore concluded that chain initiation was due to the production of radicals in a reaction between the catalyst and tetralin or between the catalyst and oxygen rather than to a reaction between catalyst and hydroperoxide. However, we have shown (2) that a much more likely explanation of this effect is that chain initiation occurs by the slow decomposition of a rapidly formed cobalt catalyst – hydroperoxide complex. Tomiska showed that the rate at later times in the oxidation depends on the peroxide concentration and is only slightly greater than that of the uncatalyzed oxidation. This provides excellent evidence for catalyst deactivation during the reaction (2).

RESULTS AND DISCUSSION

1. Pure Tetralin

Oxygen Absorption

The effect of manganous, cupric, nickelous, and ferric decanoate on the rate of autoxidation of tetralin at 50° C has been examined in the range of catalyst concentrations from 2×10^{-6} mole/l. to 1.0 mole/l., the exact range depending on the activity of the metal. The maximum rate of oxidation (ρ_m) has been plotted as a function of the metal catalyst concentration in Fig. 1. The data obtained previously for cobalt (2) have been included. All the metals show the same general characteristics. That is, at low concentrations ρ_m is proportional to $[\text{catalyst}]^{1/2}$ as required by equation 2 for catalysis by a monomer of the metal. At high concentrations ρ_m becomes independent of the catalyst concentration. However, certain features of these curves are specific to each metal and therefore each

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

metal is separately discussed below. Comparative data on the five metal catalysts have been collected together in Table I.

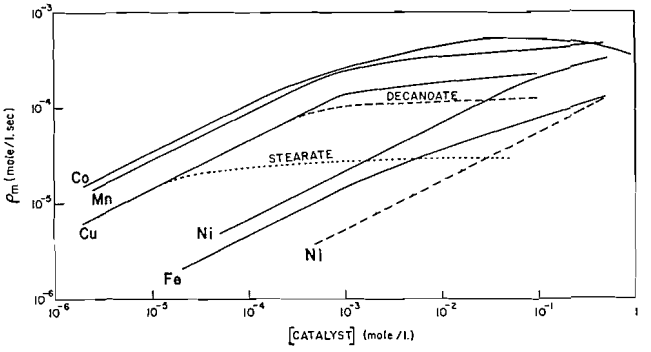

FIG. 1. The maximum rate of oxidation of tetralin as a function of metal decanoate concentration.

Manganese

A typical oxygen absorption curve is shown in Fig. 2 for a manganese decanoate concentration of 5×10^{-3} mole/l. This curve is quite different from those obtained with cobalt (2) and the other metals (see below) in that it shows a very pronounced induction period during which the rate of oxygen absorption is extremely small. The induction period depends on the initial hydroperoxide concentration ($[ROOH]_0$) since it can be readily increased or decreased by removing or adding hydroperoxide without materially affecting the main oxygen absorption curve except at very low manganese concentrations. That is, ρ_m is virtually independent of $[ROOH]_0$ at manganese concentrations above about 5×10^{-5} mole/l.

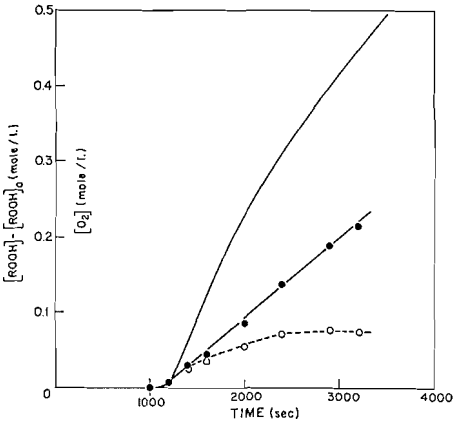

FIG. 2. Oxygen absorption and hydroperoxide formation with 5×10^{-3} mole/l. manganese decanoate. $[ROOH]_0 = 5\times10^{-4}$ mole/l. Measured $[ROOH]-[ROOH]_0$ ●. Calculated $[ROOH]-[ROOH]_0$ ○.

The induction period is roughly proportional to the manganese concentration divided by $[ROOH]_0$. When this ratio is 1.0 or less, the induction period is effectively eliminated, but it rises to about 1000 seconds for a ratio of 10 and to more than 10,000 seconds for a ratio of 100. These results suggest that divalent manganese is a powerful oxidation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

inhibitor that must be almost entirely converted to the trivalent state by reaction with a roughly equivalent amount of hydroperoxide before rapid oxidation can commence, i.e., during rapid oxidation $[Mn^{III}]$ must be $\gg [Mn^{II}]$. Towards the end of the induction period the brownish color of trivalent manganese can often be observed. Once the induction period is over, the maximum rate is reached very rapidly even at high manganese concentrations. The decrease in rate after the maximum generally results from the conversion of the catalyst to a much less active form during oxidation, i.e., the catalyst is deactivated.

The inhibiting property of manganous manganese has been observed previously in autoxidations (7, 9, 10) and can be attributed to chain termination by the catalyst. That is,

$$MnA_2 + RO_2\cdot \rightarrow ROOMnA_2 \qquad [8]$$

or, alternatively,

$$MnA_2 + RO_2\cdot \rightleftarrows ROOMnA_2, \qquad [8']$$

$$ROOMnA_2 + RO_2\cdot \rightarrow \text{inactive products.} \qquad [9]$$

Incidentally, this Mn^{III} chain termination product (and also $ROMnA_2$) may, for steric reasons, be a less active peroxide decomposition catalyst than is the usual form of Mn^{III}, which is produced by reaction of MnA_2 with ROOH, i.e., $HOMnA_2$.

Over a range of manganese concentrations from 1.0×10^{-3} to 4×10^{-1} mole/l., ρ_m rises steadily from 3×10^{-4} to 4.6×10^{-4} mole/l. sec. These rates are rather less than the limiting rate of 5.3×10^{-4} mole/l. sec obtained with cobalt in our earlier work (2) and are considerably less than the theoretical limit of 1.0×10^{-3} mole/l. sec. It was suggested previously that the cobalt ρ_m values should be corrected for three effects: (i) consumption or deactivation of the catalyst (with cobalt this correction was negligible at concentrations above 5×10^{-2} mole/l.); (ii) consumption of the tetralin in those cases where a considerable fraction of the tetralin was oxidized before the maximum rate was reached; (iii) dilution of the tetralin by the catalyst (a rather small correction even at high catalyst concentrations). When these three corrections were applied to the cobalt data a limiting rate of oxidation roughly equal to the theoretical limit was obtained. However, with manganese, the second and third corrections are of little importance and even the first is only 15–20%, compared with 40% for cobalt. The reason for the smaller correction with manganese is that the maximum rate is reached after very little oxygen has been absorbed and, therefore, after comparatively little manganese has been deactivated. The total correction to the measured rate at the highest manganese concentrations is about 20–25%, which is insufficient to raise the rate to its theoretical limiting value. This result does not appear to be due to chain termination by the catalyst. That is, the inclusion of reaction 8 in the normal chain sequence yields the following kinetic expressions:

$$[ROOH]_\infty = \frac{k_3^2[RH]^2 - k_3k_8[RH][Mn]}{2k_1' k_6[Mn]},$$

$$\left(\frac{-d[O_2]}{dt}\right)_\infty = \frac{k_3^2[RH]^2 - k_3k_8[RH][Mn]}{2k_6}.$$

Alternatively, the inclusion of reactions 8′ and 9 yields

$$[ROOH]_\infty = \frac{k_3^2[RH]^2}{2k_1'[Mn](k_6 + K_8' k_9[Mn])},$$

$$\left(\frac{-d[O_2]}{dt}\right)_\infty = \frac{k_3^2[RH]^2}{2k_6 + 2K_8' k_9[Mn]}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Both expressions predict a smaller limiting rate than that predicted by equation 4 but they also predict that as the manganese concentration is increased the rate will go through a maximum and then immediately decrease.* Since the limiting rate obtained with manganese is drawn out over a very large concentration range (i.e. 1×10^{-3} to 4×10^{-1} mole/l. [Mn]) it seems likely that chain termination by the catalyst is unimportant in determining its magnitude. On the other hand, ρ_m does decrease at manganese concentrations above 0.4 mole/l. (as did ρ_m for cobalt stearate) but not too much significance should probably be attached to rate data obtained in such viscous solutions (2). By and large, it seems probable that the low measured limiting rate is due to the rather low solubility of manganese decanoate in pure tetralin.

The chief evidence in favor of this view is provided by the fact that the measured and theoretical limiting rates become equal upon dilution of the tetralin with an inert solvent. This is shown in Fig. 3 in which ρ_m is plotted against the tetralin concentration at a manganese decanoate concentration of 5×10^{-2} mole/l. The tetralin has been diluted with chlorobenzene, dimethyl phthalate, and α-tetralone. In the last case, the rates have been corrected for the self-oxidation of the α-tetralone at this catalyst concentration (i.e., 6×10^{-5} mole/l. sec). The heavy line represents the theoretical limiting rate. It has a slope of 2.0 (i.e., an order of 2.0 in [RH], see equation 4) and reaches the theoretical rate of 1.0×10^{-3} mole/l. sec in pure tetralin. It can be seen that the experimental rates fall close to this theoretical line in dilute tetralin, i.e., the manganese-catalyzed reaction rate becomes roughly equal to the theoretical limiting rate and has the correct second-order dependence on tetralin concentration required by the Tobolsky theory (3). These dilution experiments provide the best test of this theory since the limiting rate will be reached at lower catalyst concentrations in dilute solution than is required in pure tetralin (2), i.e., the rate becomes less sensitive to catalyst solubilities in dilute tetralin solutions. In addition, the diluent may be a good solvent or dispersing agent for the catalyst, even water being satisfactory in this respect. For example, with 5×10^{-2} mole/l. manganese decanoate, the addition of 10% of water by volume raised the measured rate from 3.7×10^{-4} to 6.0×10^{-4} mole/l. (tetralin) sec. In contrast, organic acids inhibit the reaction. This is probably because they co-ordinate with the metal and are not readily displaced by the hydroperoxide. For example, with 4×10^{-3} mole/l. [Mn] the rate was decreased by a factor of 2.5 on the addition of 0.2 mole/l. of decanoic acid. A similar result was also obtained with copper and nickel under these conditions. On the other hand, decanoic acid increases the rate of the cobalt-catalyzed oxidation (2). In this last case the improved dispersion of the catalyst presumably outweighs any decrease in its activity resulting from association of the catalyst with the acid. Incidentally, the agreement between the measured and theoretical rates at low tetralin concentrations proves that the low limiting rate in pure tetralin is not due to a reaction between the catalyst and hydroperoxide to give non-radical products (rate constant k_1*,

$$\left(\frac{-d[O_2]}{dt}\right)_\infty = \frac{k_3^2[RH]^2}{2k_6}\frac{k_1'}{k_1'+k_1^*} \qquad (2)),$$

nor is it due to a decrease in the propagation rate constant such as might come about if a complex were formed between the chain carrying peroxy radicals and the metal catalyst.

A few experiments were performed with manganese stearate. The change in anion had

*Chain termination by reaction 8 will produce a very sharp decrease in the rate as the catalyst concentration is increased beyond a certain point, the rate reaching zero when $k_3[RH] = k_8[Mn]$ (see, for example, reference 11). Chain termination by reaction 9 will produce a slow and steady decrease in the rate.

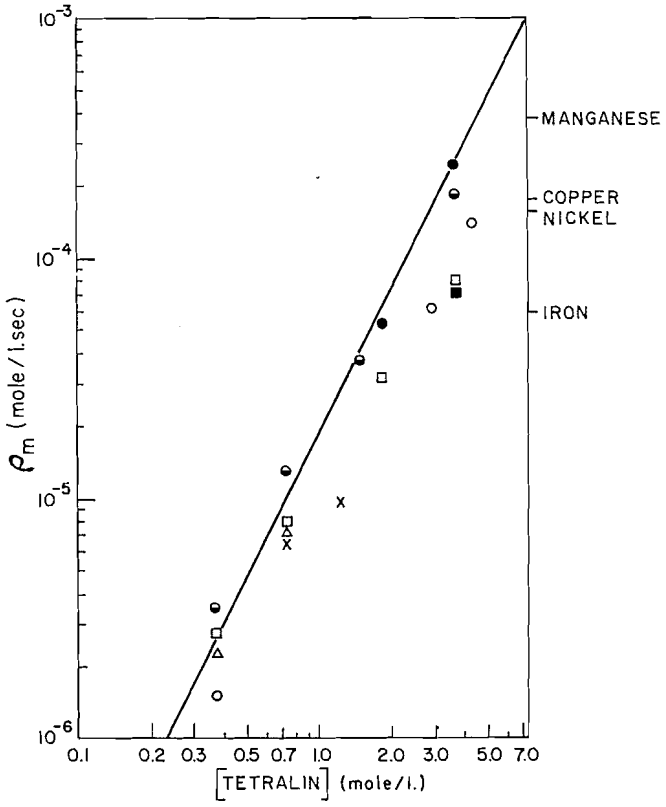

FIG. 3. The maximum rate as a function of tetralin concentration with 5×10^{-2} mole/l. of catalyst. Manganese decanoate diluted with chlorobenzene ○; with dimethyl phthalate ◒; with α-tetralone ●. Copper decanoate diluted with chlorobenzene □; with α-tetralone ■. Nickel decanoate diluted with chlorobenzene △. Ferric decanoate diluted with chlorobenzene ×. The line drawn on the figure represents the theoretical limiting rate.

little effect on the rates at low manganese concentrations but at 10^{-2} mole/l. the measured rate was slightly lower (2.9×10^{-4} mole/l. sec) than that found with the decanoate at this concentration (3.4×10^{-4} mole/l. sec). However, with the stearate the maximum rate was not reached until considerably more oxygen had been absorbed than with the decanoate case. Identical rates were obtained after the two measured rates were corrected for tetralin consumption.

The slow but steady increase in the rate at manganese concentrations above 10^{-3} mole/l. is probably due to catalysis by micelles and by solid, undispersed, catalyst. That is, the catalyst has a small but definite effect on the rate even when it is in an associated form (cf. 2, 9).

As was mentioned previously, manganese catalysts are deactivated during autoxidation. By analogy with cobalt (2), this deactivation probably occurs mainly in the chain-initiating step, the acidic products contributing only slightly to the deactivation. The extent of the deactivation will therefore be dependent on the amount of oxygen absorbed. The amount absorbed when the rate has fallen to half its maximum value ($[O_2]\rho_{m/2}$) has been plotted against the catalyst concentration in Fig. 4. The curve is similar to the one obtained previously with cobalt (2). At manganese concentrations below about 10^{-2}

For personal use only.

mole/l. the straight line is described by the equation,

$$[O_2]\rho_{m/2} = 7.3\,[Mn]^{1/2}\ \text{mole/l.} \qquad [8]$$

This equation gives a measure of the amount of oxygen required to deactivate a given amount of catalyst at a particular concentration (2). The constant in the corresponding equation for cobalt was 12.8 $\text{mole}^{1/2}\text{l.}^{-1/2}$.

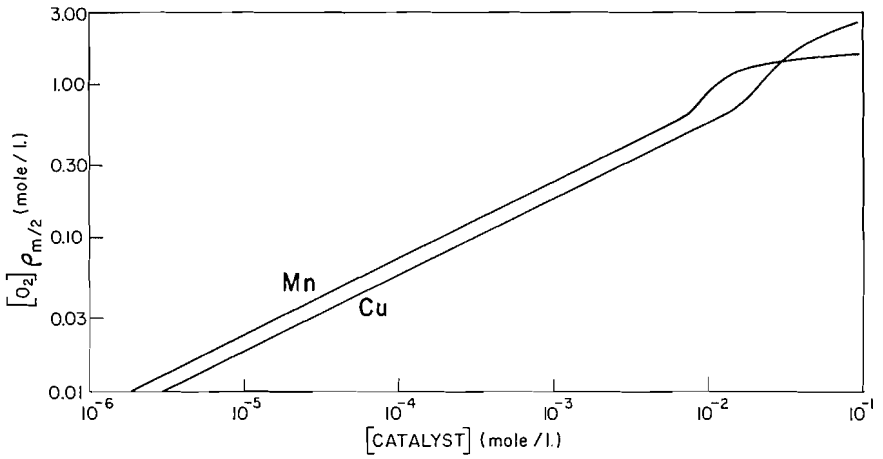

FIG. 4. Amount of oxygen absorbed when the rate reaches half its maximum value as a function of the catalyst concentration.

At manganese concentrations above 7×10^{-3} mole/l., $[O_2]\rho_{m/2}$ shows a sharp increase. This is followed by a levelling off and an approach to a constant value which has been shown to be due to consumption of the tetralin rather than to consumption of the catalyst (2). The theoretical limit of $[O_2]\rho_{m/2}$ is 2.2 mole/l. if it is assumed that each molecule of oxygen oxidizes 1 molecule of tetralin (2). At high catalyst concentrations, it is more probable that 2 molecules of oxygen oxidize 3 molecules of tetralin (1), in which case the limit will be 1.5 mole/l. With cobalt catalysts at concentrations above 2.5×10^{-2} mole/l., $[O_2]\rho_{m/2}$ reached a constant value of about 2.2–2.4 mole/l. This rather high value is probably connected with the fact that a significant fraction of the tetralin is oxidized before the maximum rate is reached (2). Since this does not occur with manganese decanoate it is not surprising to find that $[O_2]\rho_{m/2}$ appears to level off at 1.5–1.6 mole/l.

During autoxidation the deactivated manganese catalyst is precipitated. The precipitate from a 4.5 hour oxidation catalyzed by 10^{-3} mole/l. manganese decanoate contained 33.0% [Mn] by weight, 73% of the manganese being recovered (cf. analysis of a cobalt precipitate under similar conditions (2)). X-Ray examination of the precipitate in a focusing camera using monochromatic CuK_α radiation showed that it was completely amorphous and its infrared spectrum in a nujol mull contained only the broad bands corresponding to hydrogen-bonded hydroxyl groups.

As a result of catalyst deactivation it is quite difficult to obtain meaningful results at low concentrations. For example, the plot of ρ_m against [Mn] tends to show the same too-rapid decrease in rate as the manganese concentration is reduced as was observed previously with cobalt (2), i.e., the apparent order in [Mn] appears to increase as the manganese concentration is reduced. Similarly, in the $[O_2]\rho_{m/2}$ against [Mn] plot, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

experimental points show a positive deviation at low manganese concentrations and tend to a limit of about 0.02 mole/l. These deviations from the expected kinetics are more pronounced with manganese than with cobalt, possibly because it is more rapidly deactivated.* Thus, if the induction period is eliminated by the initial addition of hydroperoxide then a significant fraction of the manganese catalyst may be deactivated before any rate measurements are made. Alternatively, if no hydroperoxide is added, the same deactivating process will probably slowly occur during the induction period. In either case, the true manganese concentration will be less than its initial concentration at the point where the first rate measurements are made. However, at manganese concentrations below about 5×10^{-5} mole/l., there is an optimum initial hydroperoxide concentration which minimizes the effects of catalyst deactivation. For example, with 2.5×10^{-6} mole/l. [Mn] the following maximum rates were obtained: 2.6×10^{-6} mole/l. sec ($[ROOH]_0<10^{-5}$ mole/l.); 1.15×10^{-5} ($[ROOH]_0 = 5\times10^{-4}$); 5.8×10^{-6} ($[ROOH]_0 = 10^{-3}$); 4.6×10^{-6} ($[ROOH]_0 = 4\times10^{-3}$); 2.8×10^{-6} ($[ROOH]_0 = 3\times10^{-2}$).† These values can be compared with a rate of 1.4×10^{-5} mole/l. sec, which is obtained by extrapolation of the data in the concentration range from 5×10^{-5} to 1×10^{-3} mole/l. [Mn] where ρ_m is much less sensitive to $[ROOH]_0$ and has the expected dependence on the square root of the manganese concentration. Similarly, at 1×10^{-5} mole/l. [Mn] the extrapolated rate was 2.8×10^{-5} mole/l. sec, which can be compared with measured rates of 1.4×10^{-5} ($[ROOH]_0 = 5\times10^{-4}$ mole/l.); 2.3×10^{-5} ($[ROOH]_0 = 3.5\times10^{-3}$); and 1.7×10^{-5} ($[ROOH]_0 = 7\times10^{-2}$). It is obviously difficult to obtain true maximum rates at low manganese concentrations but, under optimum conditions, the results suggest that ρ_m is proportional to $[Mn]^{1/2}$ in the range from 2.5×10^{-6} to 1.0×10^{-3} mole/l. [Mn]. This implies that chain termination by the catalysts is unimportant at these low concentrations (9). At the optimum initial hydroperoxide concentration, the $[O_2]\rho_{m/2}$ points at low manganese concentrations also fall fairly close to the line obtained by extrapolation from higher concentrations.

The observation that the initial hydroperoxide concentration only increases ρ_m up to a certain limiting value implies that the rate-controlling chain-initiation reaction between manganese and hydroperoxide is not the simple bimolecular process suggested by reaction 1D. Instead, the rate-controlling step must involve the slow decomposition of a rapidly formed complex. By analogy with cobalt (2), this reaction can be written as:

$$ROOH + Mn^{III} \overset{\text{fast}}{\rightleftarrows} [ROOHMn^{III}] \overset{\text{slow}}{\rightarrow} RO_2\cdot + Mn^{II} + H^+. \qquad [1b']$$

By comparing relative rates of oxidation with different catalysts at the same concentration in the region where ρ_m is proportional to $[\text{catalyst}]^{1/2}$ but is independent of [ROOH] we can compare the rates of decomposition of the different catalyst–hydroperoxide complexes. That is, the rate of oxidation will be given by

$$\frac{-d[O_2]}{dt} = k_3\left(\frac{k_1'}{2k_6}\right)^{1/2}[RH][M]^{1/2}$$

where k_1' is the rate constant for decomposition of the ROOH–M complex. Since $(\rho_m)_{Mn}/(\rho_m)_{Co} = 0.83$ for the uncorrected rates, $(k_1')_{Mn}/(k_1')_{Co} = 0.69$. There is only a small error involved in using measured ρ_m values which have not been corrected for catalyst deactivation, etc.

*This would mean that, for a given extent of catalyst deactivation, smaller concentrations of catalyst-solubilizing oxidation products will be formed in the presence of manganese. Differences in measured and in extrapolated rates between cobalt and manganese at high concentrations may be due to this factor rather than to any intrinsic differences in the solubilities of their decanoates.

†In contrast, the rate tends to reach a limiting value as $[ROOH]_0$ is increased with the other metals (including cobalt (2)).

At manganese concentrations above about 2×10^{-2} mole/l. the rate of oxygen absorption frequently goes through two maxima, an effect which becomes more pronounced the higher the manganese concentration. An excellent example of this phenomenon is shown in Fig. 5. After correcting for tetralin consumption the two maximum rates are approximately equal. This suggests that the manganese decanoate in solution at the start of the reaction (solubilized by a large $[ROOH]_0$) is deactivated more rapidly than fresh catalyst can be dissolved into the solution. The rate therefore decreases after the first maximum. Subsequently, the oxidation products solubilize undissolved catalyst so that the concentration of active catalyst in solution rises and the rate goes through the second maximum. This effect was observed previously with cobalt stearate (the first cobalt salt studied (2)) at concentrations above 5×10^{-3} mole/l. provided the stearate was added to the reaction vessel as a solution and the solvent was then removed under vacuum. When the cobalt catalyst was added as a solid the double maxima were not observed. This phenomenon is presumably more noticeable with manganese because it is more rapidly deactivated than cobalt.

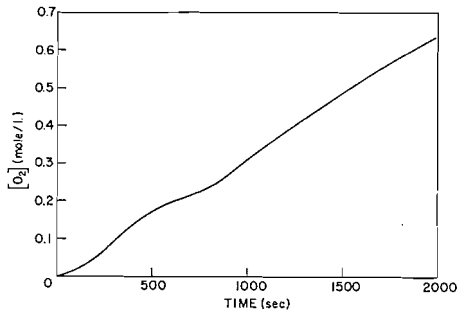

FIG. 5. Oxygen absorption at a manganese decanoate concentration of 0.3 mole/l., $[ROOH]_0 = 0.4$ mole/l.

TABLE I

Comparison of five metal decanoates as catalysts of tetralin autoxidation at 50° C

	Decanoate catalysts				
	Co^{II}	Mn^{II}	Cu^{II}	Ni^{II}	Fe^{III}
Largest measured ρ_m (mole/l. sec $\times 10^4$)	5.3	4.6	2.2	3.1	1.3
Largest corrected ρ_m (mole/l. sec $\times 10^4$)	10	5.7	3.0	4.3	1.8
$(k_1')_M/(k_1')_{Co}$	1.0	0.69	0.18	0.004	0.002
Kk_1' from $(-d[O_2]/dt)_\infty$ and $[ROOH]_\infty$(l./mole sec)	2.9	2.7	0.67	—	—
Kk_1' from direct measurement (l./mole sec)	5.0	3.5	0.33	0.002	—
$k_i/(2k_6)^{1/2}$ (l./mole sec)$^{1/2}$	0.31	0.19	0.14	—	—
$[O_2]\rho_{m/2}/[M]^{1/2}$ (mole/l.)$^{1/2}$	12.8	7.3	5.8	—	2.8

Copper

For initial hydroperoxide concentrations below about 5×10^{-2} mole/l. the maximum rate of oxidation rises steadily from 1.0×10^{-4} to 1.25×10^{-4} mole/l. sec over a range of copper decanoate concentrations from 10^{-3} to 10^{-1} mole/l. (see broken line in Fig. 1). The correction for catalyst deactivation is about 10% at copper concentrations below about 5×10^{-3} mole/l. At higher copper concentrations the correction for tetralin consumption becomes quite significant since appreciable oxidation has to occur before ρ_m is reached (cf. oxidation curves at high cobalt concentrations (2)). This correction amounts to about 40% at 0.1 mole/l. [Cu], giving a corrected ρ_m of about 1.8×10^{-4} mole/l. sec. However,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

this correction is very much smaller if $[ROOH]_0$ is increased to 0.3 mole/l. since the maximum rate now occurs nearly at the beginning of the reaction (see Fig. 6). Further increases in $[ROOH]_0$ only affect ρ_m at copper concentrations above about 10^{-2} mole/l. and even then the effect is quite small. For example, with 0.1 mole/l. [Cu], ρ_m is 1.8×10^{-4} mole/l. sec with 0.3 mole/l. $[ROOH]_0$ and is 2.2×10^{-4} mole/l. sec with 1.0 mole/l. $[ROOH]_0$. Incidentally, the only correction of any significance which has to be applied to these measured rates allows for the dilution of the tetralin by the added hydroperoxide.* The largest measured rates which were actually obtained are shown as the solid line in Fig. 1. They are roughly equal to the corrected rates obtained from the runs with low initial peroxide concentrations. These very large $[ROOH]_0$ values have no effect on ρ_m at low copper concentrations, i.e., ρ_m at 2×10^{-6} mole/l. [Cu] is the same for 0.04 and 0.3 mole/l. $[ROOH]_0$ (cf. cobalt (2)). At high copper concentrations one of the main functions of the added peroxide is probably to solubilize the catalyst. Water also has this effect, 10% by volume increasing the rate with 5×10^{-2} mole/l. [Cu] and 10^{-3} mole/l. $[ROOH]_0$ by about 15%. As with manganese, ρ_m decreases at very high copper concentrations (>0.3 mole/l.). A typical oxygen absorption curve is shown in Fig. 6.

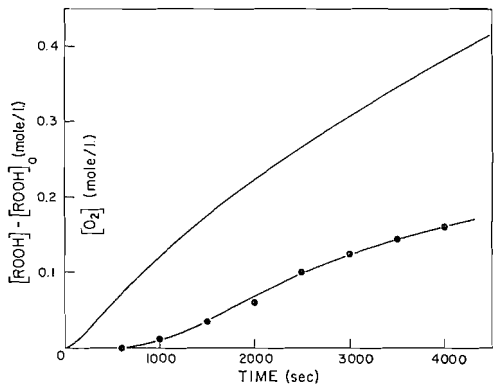

FIG. 6. Oxygen absorption and hydroperoxide formation with 5.0×10^{-3} mole/l. copper decanoate. $[ROOH]_0$ = 0.3 mole/l. Measured $[ROOH] - [ROOH]_0$ ●.

The steady rate obtained with copper stearate at an initial peroxide concentration of 0.04 mole/l. is much smaller than the rate obtained with the decanoate (see dotted line in Fig. 1). This is not unexpected if the rate is determined by the solubility of the catalyst. Increasing the initial peroxide concentration to 0.3 mole/l. at a copper stearate concentration of 10^{-2} mole/l. raised the rate to 1.35×10^{-4} mole/l. sec, which is not much less than the value found with the decanoate under these conditions. The effect of the added peroxide can probably be entirely explained by its solubilizing action on the stearate. However, the possibility that there is a smaller equilibrium constant for the formation of the peroxide–stearate catalyst complex than for the peroxide–decanoate catalyst complex cannot be completely ruled out.

Evidence that the limiting rate is determined by catalyst solubilities was again obtained by experiments in which the tetralin was diluted with an inert solvent. With 5×10^{-2} mole/l. of copper decanoate and 0.3 mole/l. $[ROOH]_0$† the experimental and theoretical rates are in excellent agreement at low tetralin concentrations (see Fig. 3).

**This is also true of the rates obtained with nickel and iron decanoates at high* $[ROOH]_0$.
†*The rate in pure tetralin is marked at this initial peroxide concentration in Fig. 3.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Catalyst deactivation again occurs mainly in the initiation reaction (see ref. 12) and therefore the amount of oxygen absorbed when the rate reaches half its maximum value is proportional to the square root of the catalyst concentration (Fig. 4), i.e., $[O_2]\rho_{m/2} = 5.8$ $[Cu]^{1/2}$ mole/l. The experimental ρ_m and $[O_2]\rho_{m/2}$ values at low copper concentrations are much less sensitive to the initial peroxide concentration than are the manganese values and they therefore show a more exact dependence on $[catalyst]^{1/2}$. At concentrations below 0.1 mole/l. the present results show none of the peculiarities which have been observed in some other autoxidation systems and which probably arise from chain termination by the copper catalyst (7, 10, 11, 13).

Nickel

Nickel decanoate appears to be rather more soluble than copper decanoate but it is a much less active catalyst. The ρ_m values depend on $[ROOH]_0$ over the entire concentration range rather than just at high concentrations, which suggests that the added hydroperoxide is not serving solely as a solubilizing agent for the catalyst. This is confirmed by the fact that with 5×10^{-3} mole/l. of nickel decanoate ρ_m is proportional to the square root of the initial peroxide concentration from 0.1 to 1.0 mole/l. $[ROOH]_0$ as required by equation (2) (see Fig. 7). In this $[ROOH]_0$ concentration range ρ_m occurs right at the beginning of the reaction (see Fig. 8). At lower $[ROOH]_0$ concentrations ρ_m is not reached until a significant amount of oxygen has been absorbed (Fig. 9). Therefore, ρ_m can no longer be expected to be proportional to $[ROOH]_0^{1/2}$, particularly in view of the fact that some of the nickel catalyst will have been deactivated by the time ρ_m is reached. At low $[ROOH]_0$, ρ_m actually decreases to a constant value, but the *initial* rates continue to be proportional to $[ROOH]_0^{1/2}$ (see Fig. 7).

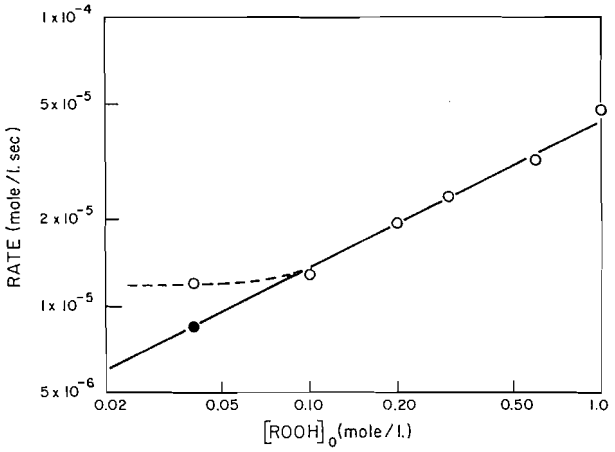

FIG. 7. Measured rates of oxidation with 5×10^{-3} mole/l. nickel decanoate as a function of $[ROOH]_0$. The rates have not been corrected for the diluting effect of the added peroxide. Key: initial rate ● ; maximum rate ○.

The dependence of the rate on $[ROOH]_0^{1/2}$ could arise if the nickel catalyst did not form a complex with the hydroperoxide prior to the formation of free radicals. However, this would make nickel quite different from the other metal catalysts. It therefore seems more reasonable to suppose that the equilibrium constant for the formation of the nickel–peroxide complex is rather smaller than the equilibrium constants for the other metals.

The solid line in Fig. 1 represents ρ_m values obtained with $[ROOH]_0 = 1.0$ mole/l. and

the dotted line ρ_m values obtained with $[ROOH]_0 \leqslant 4\times10^{-2}$ mole/l. Since ρ_m depends on $[ROOH]_0^{1/2}$ up to at least 1.0 mole/l. [peroxide] the rate constant for decomposition of the expected nickel-peroxide complex (k_1') cannot be compared with the rate constants for the other metals.

At low initial peroxide concentrations virtually all the absorbed oxygen appears as peroxide (see Fig. 9). This is presumably due to the low rate of chain initiation. That is, since the rate of chain termination is proportional to $[RO_2\cdot]^2$, the chain length will be very long and therefore a large amount of oxygen will be absorbed for every molecule of hydroperoxide decomposed. At the beginning of the reaction the low rate of chain initiation is due to the low peroxide concentration. Later, when the peroxide concentration has

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

built up, the rate of chain generation is still small because much of the catalyst will have been deactivated. In general, the amount of peroxide produced will become more nearly equal to the amount of oxygen absorbed as the activity of the catalyst, and hence the rate of radical production, decreases. Such decreases in catalyst activity can include a decrease in $[ROOH]_0$ (cf. peroxide formation in Figs. 8 and 9) as well as a change in the catalyst (cf. peroxide formation in Figs. 6 and 8*).

Dilution with chlorobenzene (0.3 mole/l. $[ROOH]_0$ for diluted tetralin) again suggests that the measured limiting rate is due to the low solubility of nickel decanoate in pure tetralin (see Fig. 3). The relation between $[O_2]\rho_{m/2}$ and the catalyst concentration depends on $[ROOH]_0$ because of the variation in chain length with $[ROOH]_0$. For example, at catalyst concentrations below about 5×10^{-2} mole/l., $[O_2]\rho_{m/2}/[Ni]^{1/2}\approx2.5$ (mole/l.)$^{1/2}$ at $[ROOH]_0 = 0.3$ mole/l. and ≈7.5 (mole/l.)$^{1/2}$ at $[ROOH]_0 = 4\times10^{-2}$ mole/l. Deactivation by acidic products is relatively unimportant (cf. ref. 14).

Iron

Ferric decanoate is a rather inactive catalyst that requires large initial peroxide concentrations to give the true maximum rates even at fairly low catalyst concentrations. For example, with 5×10^{-3} mole/l. $[FeDe_3]\rho_m$ is 2.3×10^{-5}, 2.1×10^{-5}, and 1.0×10^{-5} mole/l. sec at $[ROOH]_0$ values of 1.0, 0.3 (Fig. 10), and 0.1 mole/l., respectively. In the first two cases, although the rate is at its maximum value for only a very short time and for only a small degree of oxygen absorption, the subsequent decrease in the rate is very slow. This suggests that the catalyst may be quite rapidly converted to a slightly less active form that is very resistant to further deactivation. At lower initial peroxide concentrations, ρ_m is not reached until a fair amount of oxygen has been absorbed. The results suggest that the equilibrium constant for the formation of the catalyst–peroxide complex is slightly larger with iron than with nickel but is still much smaller than with the other three metals. The rate constant for decomposition of the complex is smaller with iron than with any of the other metals.

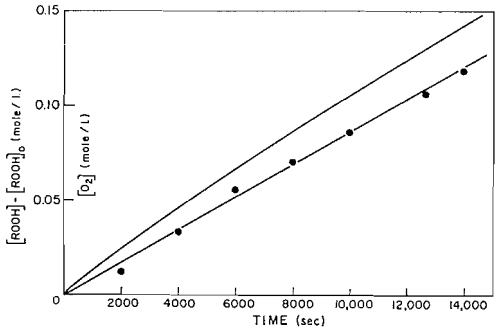

FIG. 10. Oxygen absorption and hydroperoxide formation with 5×10^{-3} mole/l. ferric decanoate. $[ROOH]_0 = 0.3$ mole/l. Measured $[ROOH] - [ROOH]_0$ ●.

At catalyst concentrations above 5×10^{-3} mole/l. ρ_m is noticeably larger with 1.0 mole/l. $[ROOH]_0$ than with 0.3 mole/l. For example, in the latter case ρ_m reaches a constant value of 5.4×10^{-5} mole/l. sec from 0.2 to 0.5 mole/l. $[FeDe_3]$. This limit is probably due both to the low solubility of the catalyst as well as to the fact that 0.3 mole/l. of peroxide will be insufficient to complex all the catalyst, i.e., the chain initiation rate will be dependent

**Similarly, with 5×10^{-3} mole/l. copper decanoate and 4×10^{-2} mole/l. $[ROOH]_0$ after 2500 sec, absorbed $[O_2] = 0.22$ mole/l., and $[ROOH] - [ROOH]_0 = 0.16$ mole/l. (cf. Fig. 9).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

on the peroxide concentration. Thus, with 1.0 mole/l. $[ROOH]_0$, the rate rises to 1.3×10^{-4} mole/l. sec at 0.5 mole/l. $[FeDe_3]$. The line in Fig. 1 represents ρ_m values obtained with $[ROOH]_0$ equal to 1.0 mole/l. at catalyst concentrations above 5×10^{-3} mole/l. At low catalyst concentrations it represents the values obtained with 0.3 mole/l. $[ROOH]_0$.

Dilution with chlorobenzene (0.3 mole/l. $[ROOH]_0$ for the diluted tetralin) indicates that ρ_m is controlled by catalyst solubility (Fig. 3). With high initial peroxide concentrations the amount of oxygen absorbed at the half maximum rate is given by, $[O_2]\rho_{m/2} = 2.8$ $[Fe]^{1/2}$ mole/l. in the range from 10^{-3} to 10^{-2} mole/l. $[FeDe_3]$. This very rapid deactivation may possibly be due to the production of phenolic inhibitors by the catalytic decomposition of tetralin hydroperoxide (cf. inhibiting action of ferric chloride on the autoxidation of cumene and tetralin (15)).

Hydroperoxide Formation

The formation of tetralin hydroperoxide in the presence of 5×10^{-3} mole/l. catalyst is shown in Figs. 2, 6, 8, 9, and 10. As was mentioned above, the amount of peroxide formed becomes more nearly equal to the amount of oxygen absorbed as the activity of the catalyst decreases. With the exception of copper, the amount of peroxide produced tends to increase steadily during the reaction, there being no steady-state concentration, i.e., no $[ROOH]_\infty$. This was also observed previously with cobalt and was attributed to the low solubility of the catalyst combined with its rapid deactivation (2). The exception, copper, apparently has a steady peroxide concentration equal to $[ROOH]_0$ in the region of the maximum rate at the beginning of the reaction, i.e., $[ROOH]_\infty = [ROOH]_0 = 0.3$ mole/l. Using this value of $[ROOH]_\infty$, the rate constant for chain initiation by copper decanoate in pure tetralin can be calculated from the ratio of equation 4 to equation 3, i.e.,

$$\left(\frac{-d[O_2]}{dt}\right)_\infty \Big/ [ROOH]_\infty = k[Cu]. \qquad [6]$$

Therefore, using the theoretical limiting rate rather than the measured limiting rate, $(k)_{Cu} = (Kk_1')_{Cu} = 0.67$ l./mole sec, where K is the equilibrium constant for the formation of the catalyst–hydroperoxide complex and k_1' is the rate constant for decomposition of this complex.

In our previous work with cobalt it was shown that the measured hydroperoxide concentration could be very roughly corrected to allow for catalyst deactivation by means of the equation relating $[O_2]\rho_{m/2}$ to the square root of the catalyst concentration (i.e. equation 8) and that this corrected peroxide concentration reached a roughly constant value (2). Upon applying the same type of correction to the manganese data, $[ROOH]-[ROOH]_0$ also reaches a steady value (see Fig. 2). However, the actual magnitude of this calculated $[ROOH]_\infty$ depends on the constant in equation 8 and therefore the validity of the results obtained by this method is open to some question. Nevertheless, it is interesting to obtain a rough measure of Kk_1' for manganese by this method for comparison with the directly measured value (see below). From the data in Fig. 2, $[ROOH]_\infty = 0.075$ mole/l., therefore $(Kk_1')_{Mn} = 2.7$ l./mole sec.

It is impossible to estimate $[ROOH]_\infty$ for nickel and iron at 5×10^{-3} mole/l. because they are such inactive catalysts that the kinetic conditions necessary for a constant peroxide concentration cannot exist. That is, with these catalysts at this concentration, $[ROOH]_\infty$ would be greater than its limiting value of 6 or 7 mole/l. for the pure peroxide. No attempt was made to obtain $[ROOH]_\infty$ values at higher catalyst concentrations because the catalysts would probably be only incompletely dissolved.

Hydroperoxide Decomposition

The rate of the metal–decanoate catalyzed decomposition of tetralin hydroperoxide in chlorobenzene has been measured. Estimation of the rate constant for this reaction is complicated by catalyst deactivation and low catalyst solubilities as well as by a radical induced peroxide decomposition process,

$$\text{radical} + \text{ROOH} \rightarrow \text{radical} + \text{products.} \qquad [i]$$

The rate of hydroperoxide decomposition is given by (2),

$$\frac{-d[\text{ROOH}]}{dt} \Big/ [\text{ROOH}][\text{M}] = Kk_1' + k_t \left(\frac{Kk_1'[\text{ROOH}]}{2k_6'[\text{M}]}\right)^{1/2}$$

and a plot of the lefthand side of this expression against $([\text{ROOH}]/[\text{M}])^{1/2}$ should give a straight line of intercept Kk_1'. A moderately good straight line was obtained with manganese decanoate over the range 1×10^{-4} to 6×10^{-4} mole/l. [Mn] and 1×10^{-2} to 6×10^{-2} mole/l. [ROOH]. The intercept was 3.5 ± 1.0 l./mole sec and the slope was 0.35 l./mole sec. The agreement between this value of Kk_1' and the value obtained indirectly from $[\text{ROOH}]_\infty$ at 5×10^{-3} mole/l. [Mn] provides some support for the assumptions implicit in calculating $[\text{ROOH}]_\infty$ from measured hydroperoxide concentrations. From the intercept and the slope $k_t/(2k_6)^{1/2}$ was calculated to be 0.19 (l./mole sec)$^{1/2}$, which is in moderately good agreement with a value of 0.31 (l./mole sec)$^{1/2}$ obtained in the same way from the cobalt data (2). At manganese concentrations above about 8×10^{-4} mole/l. the half-life for peroxide decomposition becomes virtually constant, which suggests that this concentration represents the limiting solubility of manganese decanoate in chlorobenzene at this temperature, i.e., this catalyst is about equally soluble in tetralin and chlorobenzene.

Copper decanoate is a much less active catalyst for peroxide decomposition than manganese or cobalt and the rate measurements were correspondingly less accurate. Over a range of copper concentrations from 6×10^{-4} to 5×10^{-3} mole/l. and with 1×10^{-2} mole/l. [ROOH], Kk_1' was found to be 0.33 l./mole sec and $k_t/(2k_6)^{1/2}$ was about 0.14 (l./mole sec)$^{1/2}$.

Nickel decanoate is so inactive that it was necessary to work with 5×10^{-2} to 2×10^{-1} mole/l. [Ni], which is probably beyond the limits of solubility of the catalyst in chlorobenzene. However, an approximate first-order dependence of the rate on the nickel concentration was obtained with 1×10^{-2} mole/l. [ROOH]. Neglecting any radical-induced decomposition, $Kk_1' \approx 2\times10^{-3}$ l./mole sec. No rate measurements could be made with ferric decanoate as the solutions were so strongly colored by the catalyst that the peroxide concentration could not be determined by iodometric titration.

2. Tetralin in Acetic Acid Solution

We have shown previously (1) that the kinetics applicable to the cobalt acetate catalyzed oxidation of tetralin in acetic acid are quite different from the kinetics of the cobalt decanoate catalyzed oxidation of pure tetralin and of tetralin in chlorobenzene. However, the limiting oxidation rate in acetic acid is still determined by the Tobolsky mechanism (3), i.e., it is determined by the condition that $d[\text{ROOH}]/dt = 0$ and it is therefore given by equation 4.

No attempt was made to check the overall kinetics in acetic acid for catalysis by manganous, cupric, nickelous, and ferric acetates. This was simply because these metals are all so very much less active than cobalt as catalysts for peroxide decomposition in acetic acid that a thorough kinetic treatment would be extremely tedious at the present

reaction temperature (50° C). For example, the half-life for the decomposition of 1×10^{-2} mole/l. of tetralin hydroperoxide in a 1:1 by volume acetic acid – benzene solvent mixture is more than 30,000 sec for catalysis by 2×10^{-2} mole/l. of manganese, copper, and nickel acetate.* In contrast, cobalt acetate at 1/10th of this concentration gives a half-life of 710 sec (1).

The variation in ρ_m with catalyst concentration for a 1:1 by volume mixture of tetralin and acetic acid is shown for all five acetates in Fig. 11. The rate only reaches its theoretical limit (which is 2.5×10^{-4} mole/l. sec under these conditions) with cobalt acetate. Manganous manganese is a powerful inhibitor in acetic acid just as it is in pure tetralin. To eliminate a very long induction period at least sufficient peroxide must be added at the start of the reaction to convert all the Mn^{II} to Mn^{III}. The experimental rates for iron, nickel, and copper acetate were also obtained under conditions where $[ROOH]_0 \geqslant$ [catalyst]. The results suggest that in acetic acid the active catalytic species for manganese, iron, and nickel are dimeric just as they are for cobalt (1, 4). The results with copper acetate suggest that although it is a moderately active catalyst it is extremely insoluble under these conditions.

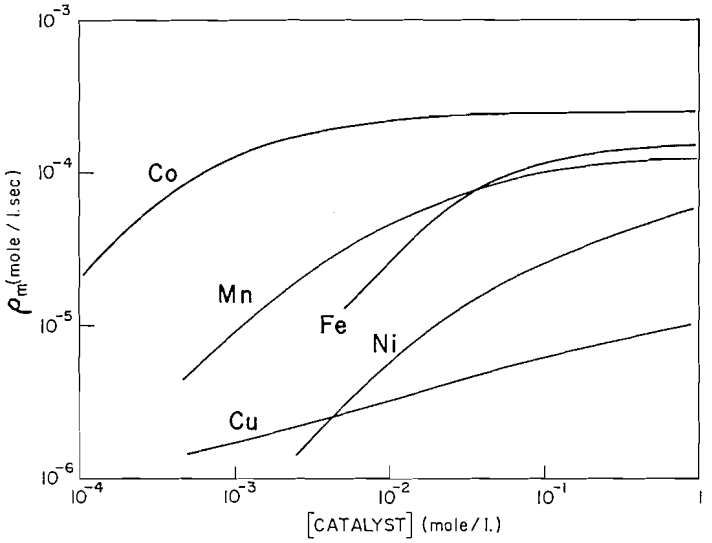

FIG. 11. The maximum rate of oxidation of a 1:1 by volume tetralin: acetic acid mixture as a function of the metal acetate concentration.

The theoretical rate upon dilution of the tetralin to 1.22 mole/l. is 2.8×10^{-5} mole/l. sec. The following rates were obtained with 0.5 mole/l. [catalyst] and 0.5 mole/l. $[ROOH]_0$ at this tetralin concentration. Manganese 2.9×10^{-5}, nickel 1.9×10^{-5}, and copper $\sim3\times10^{-6}$ mole/l. sec. Ferric acetate at 5×10^{-2} gave a rate of 2.8×10^{-5} mole/l. sec. These rates provide convincing evidence that, although manganese, iron, and nickel are less active catalysts than cobalt in acetic acid, they will nevertheless raise the rate to its theoretical limiting value in sufficiently dilute tetralin solutions. The very low rate obtained with copper is most probably due to the low solubility of the cuprous salt.

**Ferric acetate is too highly colored at this concentration for the peroxide to be determined by the usual iodometric procedure.*

CONCLUSIONS

In pure tetralin the maximum rate of oxidation is proportional to [catalyst]$^{1/2}$ at low metal catalyst concentrations and approaches a limiting value at high concentrations. This limit is controlled by a combination of the catalyst solubility and the condition that $d[\mathrm{ROOH}]/dt = 0$ as was originally proposed by Tobolsky. These two factors become readily apparent upon dilution of the tetralin with an inert solvent. There is no evidence that the magnitude of the limiting rate is in any way controlled by a chain-terminating process involving the catalyst, although such a process may effect the rates at very high catalyst concentrations (> 0.1 mole/l.). The catalysts are all deactivated during the oxidation and the rate of deactivation is proportional to the rate of initiation and, therefore, is also proportional to [catalyst]$^{1/2}$.

Finally, it should be noted that the specific order of catalytic activity of the different metals is obviously a function of the experimental conditions. That is, the curves in Fig. 1 represent rates obtained with large initial peroxide concentrations. If peroxide were not added at the beginning of the reaction, nickel and iron would appear to be much less active and manganese, in a short experiment, would appear to be totally inactive. Similarly, copper appears to be relatively much less active than the other metals in acetic acid solution compared with its activity in pure tetralin.

THE INHIBITED AUTOXIDATION OF STYRENE

PART IV. SOLVENT EFFECTS[1]

J. A. HOWARD AND K. U. INGOLD
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received November 20, 1963

ABSTRACT

The influence of solvents on the rate of the uninhibited oxidation of styrene can be roughly correlated with the dielectric constants of the solvents. It is suggested that the propagation reaction involves a dipolar transition state and that the magnitude of the solvent effects might be used to identify dipolar transition states in other oxidation reactions. The effect of solvents on the rate of oxidation of styrene inhibited by phenolic antioxidants is attributed to hydrogen bonding interactions between the phenolic hydroxyl group and the solvent. The magnitude of these interactions depends on the acidity of the phenol and on the degree of steric protection afforded the hydroxyl group by ortho-alkyl substituents.

INTRODUCTION

In recent years there has been a growing interest in the effect of the medium upon the rates of radical reactions. To gain a greater understanding of liquid phase oxidations and to continue our study on the inhibition of hydrocarbon autoxidation by phenols (1–4), we have examined the effect of a number of solvents on both the uninhibited and the inhibited autoxidation of styrene.*

The experimental technique has been described in previous papers in this series (1, 2, 3). The oxidation rates are generally reproducible to within $\pm 3\%$. All the work was done at 65° C.

RESULTS AND DISCUSSION

The Uninhibited Oxidation

The theoretical rate of the azo-bis-isobutyronitrile (AIBN) initiated oxidation of styrene is given by

$$P_0 = \rho_0 - (2e-1)k_1[I_2] = k_3[RH]\left(\frac{ek_1[I_2]}{k_5}\right)^{1/2}$$

where ρ_0 is the measured uninhibited rate, e is the efficiency of radical production by the initiator I_2, k_1 is its rate constant for decomposition, and k_3 and k_5 are the propagation and self-termination rate constants (1). RH represents the styrene. Experimentally it was found that $P_0 \propto [I_2]^{0.6}$ over a range of AIBN concentrations from 10^{-4} to 10^{-1} mole/l. (1). However, the data showed some curvature and it was suggested that the high order was due to a first-order chain terminating process occurring concurrently with the

[1]*Issued as N.R.C. No. 7815.*

**In some preliminary experiments on inhibited autoxidations the medium was changed by changing the oxidizable substrate rather than by adding a solvent to a given substrate. However, this proved to be rather unsatisfactory because completely saturated hydrocarbons (which might be expected to behave somewhat differently compared with alkyl aromatics and olefins) are so difficult to oxidize that high temperatures are required even with an initiator and the reactions are then autocatalytic. A second difficulty arises from the fact that the inhibitor may compete very efficiently for peroxy radicals relative to the hydrocarbon so that the inhibited rate is effectively zero. For example, the rate of oxidation of decalin at 100° C, initiated by 0.16 mole/l.[t-butylperbenzoate], is independent of the concentration of 2,6-di-t-butyl-4-methyl phenol over a range from 10^{-3} to 5×10^{-2} mole/l. The residual rate (1.6×10^{-6} mole/l. sec) is due to oxygen absorption by the initiator. Similar problems were encountered with n-decane and with 2,4,4-trimethyl pentane. More satisfactory results were obtained by using styrene as the oxidizable substrate and diluting it with excess inert solvent.*

normal bimolecular termination. The first-order process was considered to involve the reaction of a peroxy radical with a phenolic type inhibitor formed during the oxidation. Recently, it was suggested to us that the high order might be due to a wall effect (5) and it certainly would appear that some chains are terminated on the walls. That is, increasing the volume of styrene from the usual 5 ml to 25 ml increased the rate by 13% and decreasing the volume to 1 ml decreased the rate by 13%. However, the order in AIBN remained 0.6 for both the 1 ml and the 25 ml samples. It therefore seems quite probable that there are two first-order chain-terminating processes occurring during the uninhibited oxidation.

The rate of oxidation of a constant volume of styrene in the solvents listed in Table I is accurately first order in styrene over a concentration range from 0.42 to 1.75 mole/l. Deviations from first-order kinetics at higher styrene concentrations are positive for *n*-decane, CCl_4, *tert*-butylbenzene, etc., and are negative for acetonitrile, nitromethane, nitrobenzene, etc. The reaction is most nearly first order at all concentrations in chlorobenzene (see Table I). Because of the deviations at high styrene concentrations the oxidation rates were compared at 0.42 mole/l. styrene (1.0 ml styrene with 20 ml solvent).* The data in the various solvents are given in Table I at an AIBN concentration of 7×10^{-2} mole/l. The value given for pure styrene is the measured rate for 1.0 ml divided by 21 so that it is directly comparable with the other results. The values for toluene, *p*-xylene, and isopropanol have been corrected to allow for the self-oxidation of these solvents at this initiator concentration. They are probably less accurate than the rates obtained in solvents that resist oxidation. The reaction order with respect to $[I_2]$ was also determined in several solvents over a range of AIBN concentrations from 10^{-3} to 7×10^{-2} mole/l. The measured orders given in Table I are not too significant since with most solvents the curvature in the log (rate) against log $[I_2]$ plots is even greater than in pure styrene. However, these orders do emphasize the fact that specific correlations between the rates in different solvents and any physical properties, etc., of the solvents will depend to some extent on the AIBN concentration at which the rates are compared. As an extreme example, the rate in carbon tetrachloride becomes greater than the rate in *t*-butylbenzene at AIBN concentrations below 2×10^{-2} mole/l.

The rate constant, k_1, for the decomposition of AIBN in several solvents (determined by the rate of nitrogen evolution) is also given in Table I. In agreement with recent work (6, 7) it was found that k_1 is greater in aromatic than in aliphatic solvents.

Some values of ek_1 were determined by the induction period method of Boozer *et al.* (8) using the inhibitor 2,6-di-*t*-butyl-4-methylphenol (BMP) and the equation

$$ek_1 = n[\mathrm{BMP}]/2[I_2]t$$

where t represents the induction period, and the inhibitor stoichiometric factor, n, is assumed to have a value of 2.0. It can be seen from Table I that e appears to vary with the solvent and it is interesting to compare the present results with those reported previously by Hammond, Sen, and Boozer (6). These authors used the same inhibitor but worked with 2 ml of cumene in 4 ml of solvent at 62.5° C. Their values of e were 0.43 (CCl_4), 0.61 (benzene), 0.57 (chlorobenzene), 0.73 (nitrobenzene), and 0.73 (nitromethane). More recently, Hendry (9) has determined ek_1 in several solvents at 60° using BMP together with both cyclohexene and cumene as the substrate. His results indicate a similar variation in e with solvent together with some difference in ek_1 values between the two

*NOTE ADDED IN PROOF. *The effect of solvents on the rate of the AIBN initiated autoxidation of styrene (25% solvent – 75% styrene) at 50° C has been reported by R. Kerber (Z. Elektrochem. 63, 296 (1959)).*

substrates. In particular, with cyclohexene (but not with cumene) he found that e was about 1.2 in nitromethane (k_1 measured) and about 1.0 in acetonitrile (k_1 not measured). Since e cannot be greater than 1.0 it was suggested that these anomalously high values were due to the catalysis by polar solvents of a reaction between the hydroperoxide formed during the induction period and the phenol or its phenoxy radical. It was, in fact, shown that the addition of hydroperoxide at the start of a run in nitromethane reduced the induction period. However, it does not seem likely that such reactions would be of any importance with styrene since its polyperoxide is much less reactive than most hydroperoxides. This was readily shown to be the case, that is, the induction period of a styrene–nitromethane mixture (1:20 ml) was the same whether the inhibitor was added at the start of the reaction or after the absorption of an amount of oxygen roughly equal to that absorbed at the end of the normal induction period ($\sim$0.01 mole/l.). The apparent variation in e may perhaps be associated with the fact that BMP becomes a relatively less efficient inhibitor in solvents of high polarity, i.e., the styrene competes more favorably with the phenol for peroxy radicals (see following section). As a result, the effective inhibitor concentration will tend to be reduced in these solvents which will lead to a shorter induction period and hence to an apparent increase in e. At all events, there seems no reason to believe that e will vary appreciably with the solvent and an "average" value of 0.75 was therefore used in calculating P_0 and $k_3/k_5^{1/2}$ in all solvents. The rate constant, k_1, was taken to be 1.8×10^{-5} sec^{-1} in those solvents in which it was not measured.* It is clear, that the fairly large solvent effects recorded in Table I must be mainly due to the influence of the solvents on the $k_3/k_5^{1/2}$ ratio. Any correlation that exists between a physical property of the solvents and $k_3/k_5^{1/2}$ should, therefore, apply almost equally well as a correlation with ρ_0. The determination of e and k_1 in each solvent is therefore unnecessary except insofar as it confirms or improves such a correlation.

The importance of solvent effects on free radical abstraction reactions was first demonstrated by Russell for atomic chlorinations (10). It was shown that a π-complex was formed between the chlorine atom and most aromatic solvents with a consequent reduction in the reactivity of the chlorine atom compared with its reactivity in aliphatic solvents or nitrobenzene. The oxidation rates given in Table I cannot be correlated with Russell's chlorination data since they show a completely dissimilar pattern of solvent effects. It must therefore be concluded that peroxy radical – π complexes do not play a very important role in determining $k_3/k_5^{1/2}$ for styrene. A similar conclusion was reached by Hendry as a result of his study of the AIBN-initiated oxidation of cyclohexene and cumene in a number of solvents at 60° C (9). Hendry showed instead that the oxidation rate could be very roughly correlated with the dielectric constant (D) of the solvent by means of the function $(D-1)/(2D+1)$, which describes the bulk effect of solvents on dipole forming reactions.† That is, the rate constant k' for reaction in solution is given by (12),

$$\ln k' = \ln k_0' - \frac{1}{kT}\frac{D-1}{2D+1}\left[\frac{\mu_A^2}{a_A^3}+\frac{\mu_B^2}{a_B^3}-\frac{\mu_M^{\ddagger 2}}{a_M^{\ddagger 3}}\right]+\frac{\phi_A+\phi_B-\phi_M^{\ddagger}}{kT}$$

where k_0' is the specific rate constant in a solvent of unit dielectric constant and μ and a are the dipole moment and radius of the reactants (A and B) and the transition state

Fortunately, the exact values of e and k_1 are relatively unimportant in determining P_0 since the correction factor $(2e-1)k_1[I_2]$ is small in comparison with ρ_0. Moreover, they are also relatively unimportant in determining $k_3/k_5^{1/2}$ since $\sqrt{(ek_1)}$ is comparatively insensitive to changes in e or k_1.

†A similar correlation under very different experimental conditions has been obtained by Zaikov (11) for the oxidation of ethanol and methyl ethyl ketone in benzene.

($M^{\pm}$). ϕ is a correction factor for non-electrostatic forces between the solvent and the reactants and the solvent and the transition state (e.g. dipole–quadrupole forces, van der Waals forces, and other specific solvation effects). Provided the non-electrostatic terms are small enough to be neglected a plot of log k' against $(D-1)/(2D+1)$ should be linear. Deviations from linearity will probably be greatest in solvents of low dielectric constant where the non-electrostatic terms may become relatively important. The data in Table I is presented in terms of this equation in Fig. 1 where $\log_{10}(k_3/k_5^{1/2})$ has been plotted against $(D-1)/(2D+1)$ (the dielectric constant at 25° C having been used to calculate this function). The results show a rather more linear correlation than was obtained by Hendry with cyclohexene but there is still the same sharp increase in rate for the solvents of very high dielectric constant.

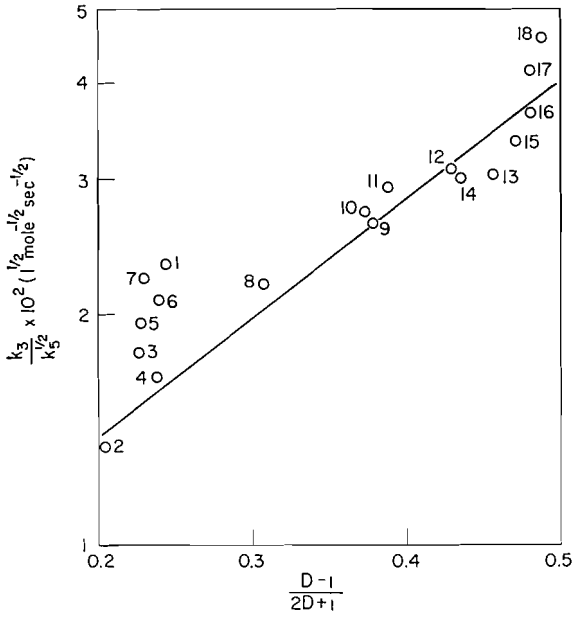

FIG. 1. Plot of $k_3/k_5^{1/2}$ for the uninhibited oxidation of styrene against the dielectric function, $(D-1)/(2D+1)$.

The rates of autoxidation of many organic substrates are extremely sensitive to trace impurities which may be either inhibitors or catalysts. Although considerable care was taken in drying and purifying the solvents used in this work, one can never be absolutely sure that a particular rate is a function of the solvent rather than of some impurity contained in it. A second factor that may produce deviations in Fig. 1 is that the pure solvent itself may become directly involved in the oxidation process, e.g. the decomposition of hydroperoxides to free radicals is accelerated in ketonic solvents (13). As would be expected, the greatest deviations of the experimental rates from the line in Fig. 1 occur in the solvents of low dielectric constant (CCl_4 and the alkyl aromatic solvents). These deviations probably arise from non-electrostatic forces, i.e., from specific solvation effects that can perhaps be attributed to the high polarizability of CCl_4 and of the π electrons of the aromatic ring.

The correlation between $\log_{10}(k_3/k_5^{1/2})$ and $(D-1)/(2D+1)$ is not significantly improved by multiplying this dielectric function by the ratio of the density (d, at 25° C) to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the molecular weight (M) of the solvent (compare, however, ref. 9), i.e., by plotting $\log_{10}(k_3/k_5^{1/2})$ against $d(D-1)/M(2D+1)$ (see Fig. 2). The factor d/M is introduced on the supposition that the radii of the reactants and of the transition state (the "a" terms in the previous equation) are not independent of the solvent but, instead, depend on its molar volume (14, 15). However, in this plot the aliphatic solvents (with the single exception of *t*-butanol, No. 14) now fall fairly close to one line, and all the aromatic solvents (including even nitrobenzene) fall close to a second steeper line, the two lines having roughly the same intercept on the rate axis. It seems reasonable to ascribe this separation of the aromatic solvents onto a separate line to a specific solvating effect of their π electron clouds.

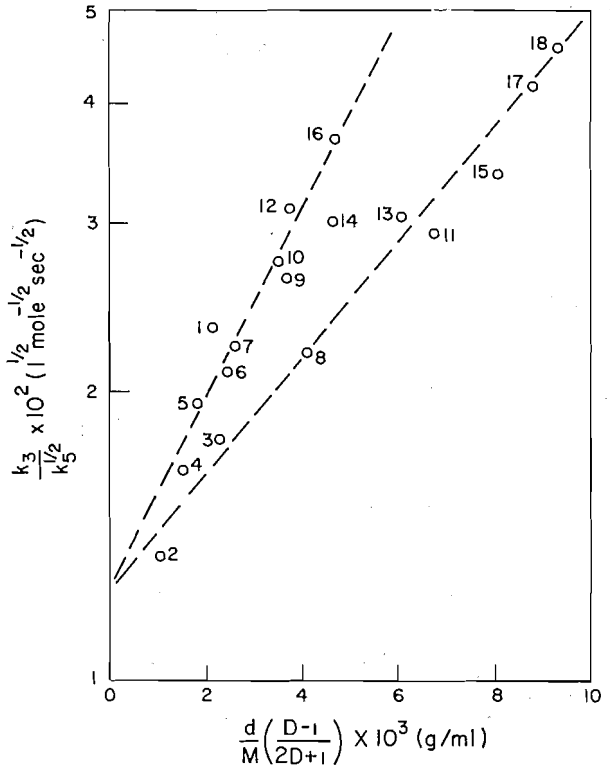

FIG. 2. Plot of $k_3/k_5^{1/2}$ for the uninhibited oxidation of styrene against the dielectric function, $d(D-1)/M(2D+1)$.

The increase of $\log_{10}(k_3/k_5^{1/2})$ with the dielectric function $(D-1)/(2D+1)$ suggests that the dipolar character of the transition state of the propagation reaction is greater than the dipolar character of the reactants,*

i.e., $$\frac{\mu_M^{\ddagger 2}}{a_M^{\ddagger 3}} > \left(\frac{\mu_A^2}{a_A^3}+\frac{\mu_B^2}{a_B^3}\right).$$

**This conclusion is based on the assumption that the increase in the dipolar character of the reactants in the propagation step on going through the transition state of this step outweighs any decrease in the dipolar character of two peroxy radicals which is produced in the transition state of the termination reaction. That is, either effect would cause the overall oxidation rate to increase with increasing solvent dielectric constant, but it is assumed that the former predominates over the latter.*

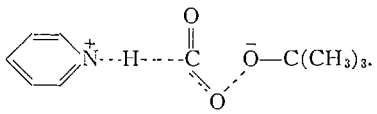
In this respect, therefore, the addition of a peroxy radical to styrene is similar to many free-radical hydrogen abstraction reactions from compounds of the type C_6H_5YH (2). It is particularly interesting to note that the rates in the hydroxylic solvents are correlated just about as well as the rates in the aprotic solvents since this is frequently not the case for reactions involving the formation of a dipolar transition state. Instead, hydroxylic solvents generally produce a greatly enhanced reactivity over that which would be expected on the basis of their dielectric constant. This is because the dielectric constant, which is a macroscopic quantity, is not a good measure of solvent-ionizing power. Several empirical methods of estimating solvating power have been suggested, including one based on the rates of solvolysis of *t*-butyl chloride in hydroxylic solvents (Y values (16)), one based on the rates of ionization of *p*-methoxyneophyl *p*-toluenesulphonate in aprotic solvents (log k_{ion} values (17)), another based on the position of the charge-transfer absorption maximum of pyridinium iodides (Z values (18)), and finally, one based on the product distribution in the cyclopentadiene – methyl acrylate addition reaction (Ω values (19)). All four of these measures of solvating power are linearly related to one another and all involve systems in which there is a rather large increase in the dipole on going from the initial state to the transition or final state. The dipoles in these systems must be stabilized by a direct interaction with hydroxylic solvents. Presumably this does not occur in the transition state of the styrene oxidation propagation reaction possibly because the amount of charge and of charge separation is very much less.

Rather convincing evidence that a dipolar transition state is involved in the oxidation of styrene is provided by a comparison of the present results with those reported by R. E. Pincock for the solvent effect on the rate of decomposition of *t*-butylperoxyformate (TBF) catalyzed by pyridine at 90° C (20). The position of attack of the base and the polarity of the transition state for this reaction can be represented by (20):



The transition state for this reaction involves a fairly large dipole so the linear relation between the logarithm of the rate constant for the TBF decomposition and log $k_3/k_5^{1/2}$ in the solvents common to both studies* (which unfortunately does not include any hydroxylic solvents) is quite gratifying (see Fig. 3).

In conclusion, we suggest that the relative magnitude of the solvent effects observed in the present work may provide a useful method of identifying dipolar transition states in other reactions.

The Inhibited Oxidation

In the presence of an inhibitor AH which completely suppresses the bimolecular self-termination reaction, the theoretical rate of oxidation is given by,

$$P = \rho - (2e-1)k_1[I_2] = \frac{ek_1k_3[RH][I_2]}{k_6[AH]}$$

where ρ is the measured inhibited rate and k_6 is the rate constant for abstraction of the active hydrogen from AH by a peroxy radical (1). It has been shown previously (3), that at moderately low concentrations of AH, P is exactly proportional to $[I_2]^{1\cdot0}/[AH]^{1\cdot0}$.†

*Point 2, refers to n-decane in our work and to n-heptane in Pincock's work.

†*At very low inhibitor concentrations the apparent order in* [AH] *decreases (even at a fixed* $[I_2]/[AH]$ *ratio) owing to the increasing importance of the self-termination reaction (1).*

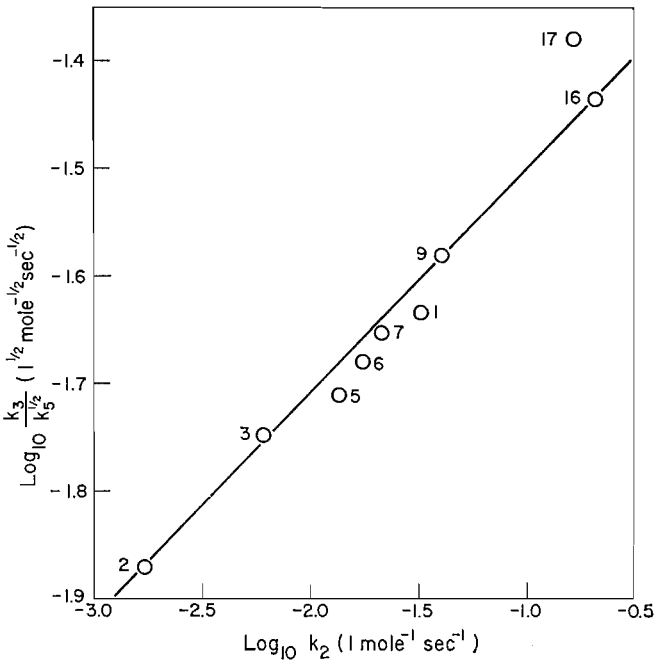

FIG. 3. Plot of $k_3/k_5^{1/2}$ for the uninhibited oxidation of styrene against the rate constant, k_2, for the pyridine-catalyzed decomposition of *t*-butylperoxyformate at 90° C.

This relationship has now been reconfirmed in several solvents at low styrene concentrations with BMP. It has also been confirmed that $P \propto [RH]^{1.0}$ in all the solvents examined at styrene concentrations below about 2.0 mole/l. The order is most nearly unity over the entire styrene concentration range in nitrobenzene (see Table II).

As the inhibitor concentration is raised, the apparent order in [AH] decreases but this is not due to chain transfer nor, in the case of BMP, is it due to intermolecular hydrogen bonding (3). The deviations from first-order kinetics occur at lower AH concentrations as the acidity of the phenolic inhibitor is increased* and as the steric protection afforded the hydroxyl group by ortho-alkyl substituents is decreased. Our initial results on the effect of solvents (particularly CH_3CN) on the rate of the BMP-inhibited oxidation immediately suggested that these kinetic peculiarities were due to complex formation between the phenols and the nitrile groups of the initiator. This is inherently probable in that, at high AH concentrations, $[I_2]$ must also be very large to obtain measurable oxidation rates.

The occurrence of non-hindered phenol–AIBN complexes was readily confirmed by examining the O–H stretching fundamental region in the infrared spectra of such mixtures in CCl_4 at room temperature. For 0.05 *M* phenol – 0.05 *M* AIBN mixtures the percentages of the phenol involved in a complex with AIBN (based on the decrease in the intensity of the free O–H band produced by the AIBN) were 33% for 3-chlorophenol, 20% for phenol, and 16% for 4-methoxyphenol. The difference in the frequencies of the free and bonded O–H band maxima ($\Delta\nu$ cm^{-1}) were 161 cm^{-1}, 138 cm^{-1}, and 137 cm^{-1} respectively, for these three phenols. It is obvious that the strength of the hydrogen bond increases with increasing acidity of the phenol and therefore parallels the kinetic deviations.

**This effect makes the determination of k_6 for phenols containing electron-withdrawing groups doubly difficult since these are also the weakest inhibitors.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Replacing the AIBN by 0.05 M acetonitrile (i.e. halving the number of CN groups) reduces the amount of ordinary phenol in hydrogen-bonding complexes to 12%. The hydrogen bond is probably slightly stronger since $\Delta\nu$ is 155 cm^{-1}.

The infrared evidence for complexing between BMP and AIBN is not quite so clear-cut but there seems to be no doubt that it occurs. For example, a 0.05 M BMP – 0.05 M AIBN mixture in CCl_4 shows a very weak band at about 3475 cm^{-1} ($\Delta\nu$ = 175 cm^{-1}) and a second weak band at about 3625 cm^{-1} ($\Delta\nu$ = 25 cm^{-1}) which is not properly resolved and is therefore most easily seen by running the mixture against a 0.05 M BMP solution in the reference beam. These bands can be compared with those at 3627 cm^{-1} (sharp) and 3479 cm^{-1} (broad) reported by Bellamy and Williams for BMP in acetonitrile (21). There appears to be a slight shift of the O–H band maxima to longer wavelengths in the presence of AIBN but the expected small decrease in the intensity of the free O–H band cannot be measured because this band is not properly resolved from the small band at 3625 cm^{-1}. Bands in similar positions were obtained on replacing the AIBN by 0.05 M acetonitrile. With 2,6-di-t-butyl-4-cyanophenol in place of BMP the two hydrogen-bonded bands with AIBN are two or three times as intense and occur at $\Delta\nu$ values of 40 cm^{-1} and 170 cm^{-1}.

These results certainly suggest that the kinetic peculiarities we have noted previously at high phenol concentrations are due to the formation of a complex which causes the inhibitor efficiency to decrease. Further confirmation is provided by the fact that the addition of 0.1% and 1.0% by volume of acetonitrile (i.e., 2×10^{-2} and 2×10^{-1} mole/l., respectively) to a 1.74 M styrene in decane solution raised the BMP-inhibited oxidation rates ([BMP] = 9.8×10^{-5} mole/l., [AIBN] = 4.8×10^{-4} mole/l.) by 13% and 37% respectively, over the rates calculated on a linear basis from the rates in n-decane and in acetonitrile.

The formation of complexes between phenols and AIBN which affected k_6 suggested that these complexes might also affect k_1. The results of nitrogen evolution measurements from 0.2 mole/l. [AIBN] in 5 ml styrene indicated that 0.3 mole/l. [BMP] had no effect on the rate, but that 0.8 mole/l. [phenol] increased the rate by 5–10%. Similar results were obtained in tetralin. The same accelerating effect on k_1 has also been observed by Godsay *et al.* with 4-chlorophenol (22). The magnitude of this effect is such that it can be neglected in calculating k_3/k_6 but it does suggest yet another reason for the non-linear kinetics exhibited by the acidic, unhindered phenols at high concentrations.

For the reasons outlined above, the effect of solvents on the inhibited oxidation of styrene was measured at low styrene concentrations (1.74 mole/l.), low initiator concentrations (4.8×10^{-4} mole/l.), and low inhibitor concentrations (9.8×10^{-5} mole/l.). To obtain measurable rates, these conditions sometimes necessitated the use of rather large samples (up to 100 ml). However, the correction factor $(2e-1)k_1[I_2]$ was always very small. The inhibitors examined were BMP, 2,4,6-trimethylphenol, 2-t-butyl-4-methylphenol, and 4-methylphenol, these representing four general classes of phenolic antioxidants (3). Two members within a class were also examined briefly, 2,6-di-t-butyl-4-cyanophenol (for which the initiator concentration was reduced to 1.0×10^{-4} mole/l.) and 2,6-di-t-butyl-4-methoxyphenol. The values of k_3/k_6 given in Table II have been calculated on the assumption e = 0.75 in all solvents.

The k_3/k_6 values for BMP are shown plotted against $(D-1)/(2D+1)$ in Fig. 4 and against $d(D-1)/M(2D+1)$ in Fig. 5. Although these values show a general increase with D both correlations are rather poor. That is, the alkyl aromatic solvents show large positive deviations in both figures and the solvents of high dielectric constant also show large positive deviations in Fig. 4. In addition, there is considerable random scatter in

Fig. 5. The other phenols give generally similar figures except that, in these cases, the k_3/k_6 values in the hydroxylic solvents (Nos. 11 and 14) are greatly enhanced relatively to the other solvents.

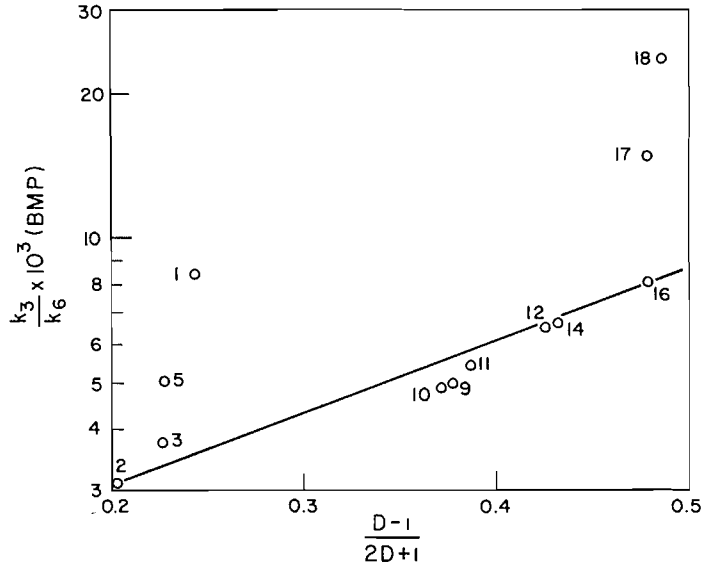

FIG. 4. Plot of k_3/k_6 for the BMP-inhibited oxidation of styrene against the dielectric function, $(D-1)/(2D+1)$.

The failure of the data to correlate with either dielectric function is not too surprising since dipolar transition states are involved in both the propagation reaction (k_3, see above) and in the termination reaction (k_6 (3)). The general increase in k_3/k_6 with D might suggest that the formation of the transition state for the propagation reaction involved the formation of a greater dipole than did the formation of the transition state for the termination

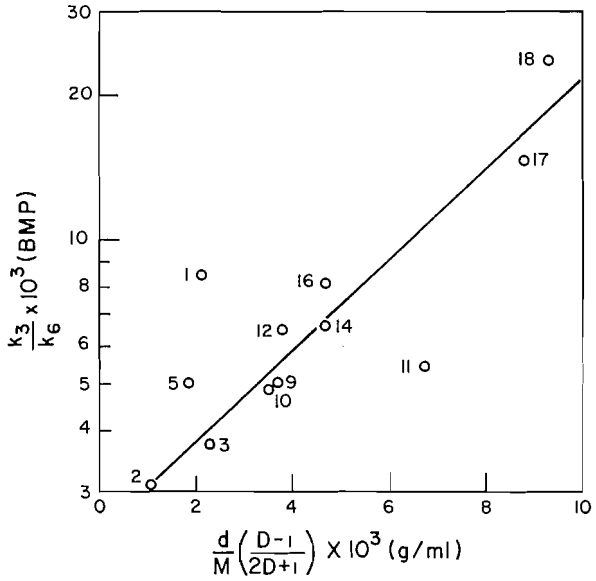

FIG. 5. Plot of k_3/k_6 for the BMP-inhibited oxidation of styrene against the dielectric function, $d(D-1)/M(2D+1)$.

reaction. However, it seems more likely that such purely dielectric effects on the transition state will tend to cancel out in the function k_3/k_6. Changes in this function probably reflect changes in k_6 which arise from hydrogen bonding interactions between the phenolic hydroxyl group and the solvent (cf. hydrogen abstraction from nitrophenols by the 2,4,6-tri-*t*-butyl phenoxy radical (23)). The frequency of the O–H fundamental stretching band (ν_m) in the different solvents gives a very rough relative measure of the strengths of the O–H···solvent interactions. Therefore, a plot of k_3/k_6 against ν_m should show a smooth relation between these two quantities. Since this is indeed the case (see Fig. 6), it strongly suggests that k_3/k_6 is determined by the strength of the hydrogen bond between the phenol and the solvent and that purely dielectric effects are largely cancelled out.

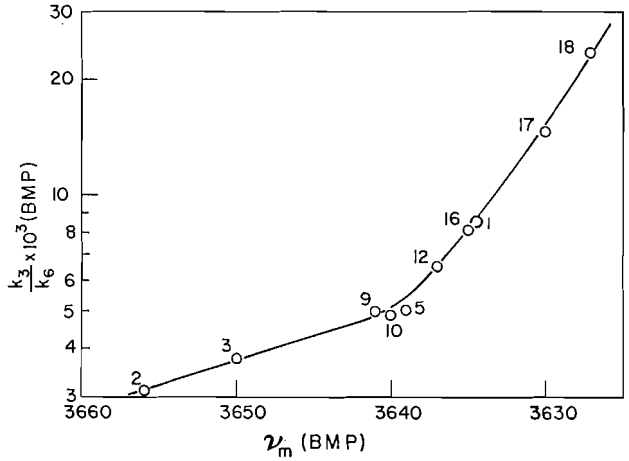

FIG. 6. Plot of k_3/k_6 for the BMP-inhibited oxidation of styrene against the frequency of the fundamental O–H stretching band maxima for BMP in the different solvents.

The k_3/k_6 values for the other three phenols have been plotted in Fig. 7 against k_3/k_6 for BMP. With the exception of the two hydroxylic solvents, there is an excellent linear correlation between the different sets of data. The lines in Fig. 7 all have a slope of about 1.5, which implies that 2,4,6-tri-methylphenol, 2-*t*-butyl-4-methylphenol, and 4-methylphenol are more susceptible than BMP to solvent effects, i.e. for a given change in solvent k_6 for any of these three phenols changes more than k_6 for BMP. This result is hardly surprising as these hydroxyl groups are sterically much more poorly protected than is the hydroxyl group in BMP. It is, however, rather surprising that all three are about equally susceptible to solvent effects as one might expect the partially hindered trimethylphenol to be intermediate in behavior between BMP and the other two non-hindered phenols. It seems clear that the relative inhibiting efficiencies of phenolic antioxidants belonging to any of these three general structural classes will be very nearly independent of the solvent or reactant system in which the efficiencies are determined. To judge by the results in *t*-butanol and acetic acid, this generalization may also apply roughly to hydroxylic solvents or reactants (compare, however, k_3/k_6 for trimethylphenol in *t*-butanol relative to the other *t*-butanol and acetic acid results). On the other hand, the efficiency, relative to the other phenols, of the highly hindered antioxidant BMP will show a strong solvent dependence. For example, BMP is a more efficient inhibitor than 4-methylphenol in nitromethane and acetonitrile but is less efficient in all the other non-hydroxylic solvents. It is much more efficient than 4-methylphenol in the two hydroxylic solvents.

The strength of O–H · · · solvent interactions increases as the phenolic hydrogen becomes more acidic (24). Relative inhibiting efficiencies in different solvents must therefore depend not only on the steric protection of the O–H group but also on the extent to which the phenol is substituted on the ring by electron donating or withdrawing groups.

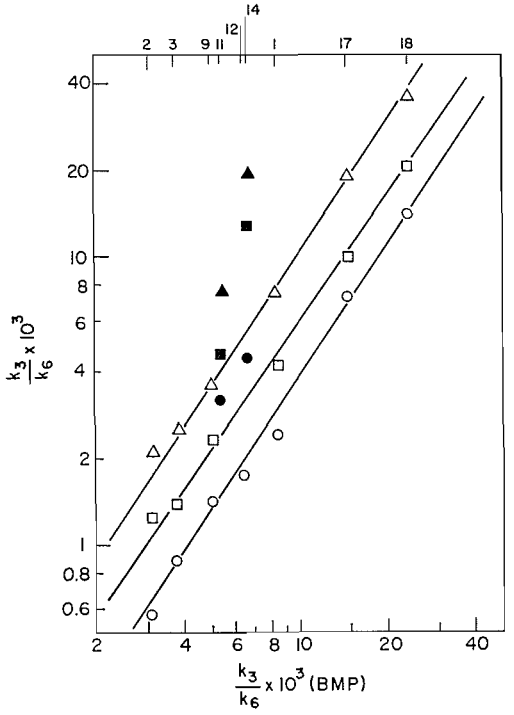

FIG. 7. Plot of k_3/k_6 for 2,4,6-trimethylphenol (○), 2-*t*-butyl-4-methylphenol (□), and 4-methylphenol (△) as a function of k_3/k_6 for BMP. The solid points represent the two hydroxylic solvents.

This effect was demonstrated by measuring the k_3/k_6 values for 2,6-di-*t*-butyl-4-methoxyphenol and 2,6-di-*t*-butyl-4-cyanophenol in *n*-decane (0.6 and 15.6×10^{-3}, respectively) and in acetonitrile (3.7 and 156×10^{-3}, respectively). The slopes of the lines obtained by plotting these values against k_3/k_6 for BMP were 0.95 for the 4-methoxy- and 1.23 for the 4-cyano-phenol. That is, the 4-methoxy derivative is less sensitive and the 4-cyano more sensitive than BMP to solvent effects.

The fact that the relative efficiencies of different classes of phenols are largely solvent independent suggests that since the efficiencies of the meta- and para-substituted phenols of a given class must be correlated in the Hammett equation by means of the σ^+ constants of the substituents in styrene (3), then similar correlations with σ^+ constants must exist in all other solvents.* Moreover, this fact suggests that the ρ factor in the Hammett equation should be nearly independent of the solvent. That is, there is no solvent effect on the type (i.e. σ or σ^+) of substituent constant correlation, nor should there be a significant solvent effect on the sensitivity of the reaction to polar influences (ρ).

In conclusion, the dependence of the relative inhibiting efficiencies of phenolic antioxidants on the solvent probably accounts for much of the conflicting data on relative efficiencies in the literature, i.e., different substrates were employed by different workers. The present work emphasizes that the most efficient inhibitor varies from system to system. The best inhibitor for a given substrate can, therefore, only be found by experimentally testing the more efficient inhibitors of each different structural class under the same conditions as the substrate will eventually be required to withstand in practice.

**In some earlier work from this laboratory (4) it was found that the induction periods produced by 2,6-di-t-butyl-4-substituted phenols in a saturated naphthenic hydrocarbon oil at 160° C were correlated by the σ constants of the 4-substituents. The present work shows that this correlation cannot be attributed to the low polarizability of this medium (cf. (2)). However, a variety of factors control the length of an induction period, particularly at 160° C, and the observed correlation may therefore not be directly related to the rate of reaction 6.*

GAS–LIQUID CHROMATOGRAPHY OF TERPENES

PART X. THE VOLATILE OILS OF THE LEAVES OF SITKA AND ENGELMANN SPRUCE[1]

E. VON RUDLOFF

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received December 9, 1963

ABSTRACT

The leaf oils from Sitka and Engelmann spruce were obtained in 0.36 and 0.094% yield respectively. The average percentage composition was determined by gas–liquid chromatography. Sitka spruce leaf oil was found to contain mainly *d*-myrcene (23.5%), *l*-piperitone (23.2%), and *d*-camphor (17.2%). Smaller amounts of 1,8-cineole, *l*-β-phellandrene, *p*-cymene, two aliphatic esters, *d*-bornyl acetate, *d*-borneol, and *d*-terpinen-4-ol were also isolated and several other esters appeared to be present in small amounts. Engelmann spruce leaf oil was found to contain mainly *cis*-hex-3-en-1-ol (18.5%), *d*-camphor (16.0%), *d*-bornyl acetate (8.6%), *d*-linalool (5.8%), and two unidentified compounds. Smaller amounts of myrcene, β-phellandrene, *p*-cymene, piperitone, and several sesquiterpenoids were also recorded. Tricyclene, α-pinene, camphene, β-pinene, 3-carene, limonene, γ-terpinene, and terpinolene were found in small amounts in both oils.

Phylogenetic relationships between the different spruces and other conifers are discussed.

INTRODUCTION

The volatile oils of many different species of eucalyptus (1) and pine wood (2) have been analyzed systematically, and Mirov (2) has discussed the relationship between the chemical composition of these oils and the taxonomic position of the plants. A systematic study of the volatile oils from the leaves of conifers does not appear to have been carried out, although Shaw (3, 4) has analyzed, by fractional distillation, the oils of four Canadian conifers and earlier Lehmann and Lynn (5) investigated those of a number of Washington conifers. In this series, oils from the leaves of several different conifers have been analyzed by gas–liquid chromatography (GLC) and the opinion was advanced (6) that certain of the oxygenated monoterpenes may have considerable taxonomic and phylogenetic value. In part V of this series (7) the analysis of the oils from black spruce (*Picea mariana* (Mill) B.S.P.), white spruce (*P. glauca* (Moench) Voss), and Colorado spruce (*P. pungens* Engelm.) was described. This communication deals with a similar analysis of the oils obtained from the foliage of Sitka spruce (*P. sitchensis* (Bong) Carr) and Engelmann spruce (*P. engelmanni* Parry).

In 1931, Lehmann and Lynn (5) analyzed the oil from Sitka spruce leaves and report the isolation of β-pinene, β-phellandrene, camphor, an α,β-unsaturated ketone and, after saponification, borneol and terpineol. The oil from Engelmann spruce leaves does not appear to have been investigated before.

EXPERIMENTAL

The same experimental procedures as described in the previous paper (6) were followed. Analytical chromatograms were run with 1 to 5 μl aliquots of the oils on 6 ft × ¼ in. O.D. columns having polyethylene glycol (Carbowax 20M, PEG; 15%), neopentyl glycol adipate (NGA; 15%) or polyethylene glycol adipate (PEGA; 15%) polyester, Apiezon N (A-N; 5%) or fluorinated silicone polymer (QF-1; 15%) as liquid phase, and Chromosorb W or Gaschrom P (60–80 mesh) as solid support. Isothermal runs were also carried out on a 10 foot × ¼ inch rapeseed oil (RO; 10%) and a 6 ft ethylene glycol bis-propionitrile (EGPN; 15%)

[1]*Issued as N.R.C. No. 7821.*

column. Preparative runs were carried out on a 20 ft × ⅜ in. O.D. PEG 20M (20%) column using the Aerograph Autoprep model 700 instrument. Infrared spectra (IR) were recorded as films between sodium chloride plates on a Perkin–Elmer model 21 double beam spectrophotometer. Optical rotations were determined as chloroform solutions at room temperature (23 to 27° C) unless otherwise indicated.

Relative retention times (RRT) of monoterpenes were measured relative to limonene and of oxygenated monoterpenes relative to camphor. The values recorded for most of the compounds encountered have been reported previously (6, 7). Those of *cis*-hex-3-en-1-ol (limonene = 1.00) were 0.17, 4.10, 0.41, 1.51, and 5.28 respectively on the A-N, PEG 20M, RO, NGA, and EGPN columns. Those of α-phellandrene were 0.83, 0.82, 0.86, 0.81, and 0.86, and those of β-phellandrene 0.97, 1.06, 1.05, 1.06, and 1.16 respectively. The RRT values (camphor = 1.00) of piperitone on the A-N, PEG 20M, and NGA columns were 2.02, 2.57, and 2.31 respectively.

Isolation of the Oils

Sitka spruce foliage (4.1 kg) from the Prince Rupert district, British Columbia, and water (25 liters) were mascerated in a Waring blendor and the mixture was steam-distilled for 4 to 5 hours. The volatile oil was extracted into a small volume of ether and this solution was washed with aqueous bicarbonate and water. After drying (Na_2SO_4), the ether was evaporated on a steam bath in a flask having a long neck (8). The residue (15.0 g, 0.36%) was a light yellow oil; n_D 1.4735, $[\alpha]_D$ +4.3° (undiluted).

Engelmann spruce (identified by cone morphology) leaves (3.3 kg) from Indian Head, Saskatchewan, were similarly treated to give a yellow oil (3.1 g, 0.094%) with n_D 1.4783 and $[\alpha]_D$ +11.0°.

Temperature-programmed runs (from 65° to 200° C) of each oil (3 μl aliquots) on the PEG 20M columns are shown in Figs. 1 and 2. The average percentage composition, as determined by area measurement (triangulation method) on a variety of analytical columns, is shown in Table I.

Isolation and Identification of Individual Components

Aliquots (50–100 μl) of the oil were injected repeatedly onto the 20-ft PEG column and each individual peak recorded (at 100 ma detector current) was collected in ice-cooled traps. Aliquots (1–2 μl) of each portion thus collected were chromatographed on the analytical columns to determine purity and RRT values. Where sufficient material was collected the IR spectrum, refractive index (at 25° C), and optical rotation was recorded. The following data were obtained for the oil from Sitka spruce leaves:

Peak 2: ester and α-pinene according to the IR spectrum and RRT data (1735–1715 cm^{-1}, no significant absorption at 1250–1200 cm^{-1}); $[\alpha]_D$ +54.8°.

Peak 3: ester and a little camphene (IR 1735–1715 cm^{-1}, RRT); $[\alpha]_D$ +11.6°; n_D 1.4700.

Peak 5: myrcene (IR, RRT) with slight contamination of peak 4 (β-pinene, RRT) and peak 6 (3-carene, RRT); $[\alpha]_D$ +19.3°; n_D 1.4668.

Peak 8: mainly β-phellandrene and 1;8-cineole (IR, RRT) and some contamination with peak 7 (limonene, RRT); $[\alpha]_D$ −18.2°; n_D 1.4661.

Peak 9: γ-terpinene (RRT).

Peak 10: mainly an ester (IR 1735 cm^{-1}) and some terpinolene (RRT); $[\alpha]_D$ +25.6°; n_D 1.4270.

Peak 11: *p*-cymene (RRT, u.v. spectrum).

Peak 12: unsaturated ester and ketone (IR 1732, 1715, weak 1635, and 885 cm^{-1}) (two unknowns, RRT); $[\alpha]_D$ +5.9°; n_D 1.4310.

Peak 18: camphor (IR, RRT); $[\alpha]_D$ +40.5°; m.p. 166–173° C.

Peaks 19 and 20: bornyl acetate and an unsaturated ketone (isopulegone ?) (IR 1735, 1715, 1638, 885 cm^{-1}); $[\alpha]_D$ +7.1°; n_D 1.4901.

Peaks 21 and 22: terpinen-4-ol and an unknown (IR, RRT); $[\alpha]_D$ +48.5°; n_D 1.4910.

Peaks 23 and 24: borneol and an unsaturated ketone (IR 1715, 1675, 1637, 887 cm^{-1}; RRT); $[\alpha]_D$ +69.2°; n_D 1.4890.

Peak 25: piperitone (IR, RRT); $[\alpha]_D$ −15.9°; n_D 1.4823.

Peak 26: C_{15} hydrocarbon (canadene ?) (IR, RRT).

When Sitka spruce oil (0.2 g) was saponified with alcoholic (80%) potassium hydroxide (2 *N*) solution the analytical chromatograms showed a considerable reduction of peaks 10, 12, 29, 32, and some reduction of peaks 2, 3, 19, and 33.

The amount of oil obtained from Engelmann spruce leaves was sufficient only for the isolation of the major constituents.

Peak 4: β-pinene (impure) (IR and RRT).

Peak 5: myrcene (IR and RRT); $[\alpha]_D$ +5°.

Peak 13: *cis*-hex-3-en-1-ol (IR and RRT); n_D 1.4823.

Peak 17: linalool (IR and RRT); $[\alpha]_D$ +10°.

Peak 18: camphor (IR and RRT); $[\alpha]_D$ +35°.

Peak 19: bornyl acetate (IR and RRT); $[\alpha]_D$ +20°.

Saponification removed peak 19 almost entirely.

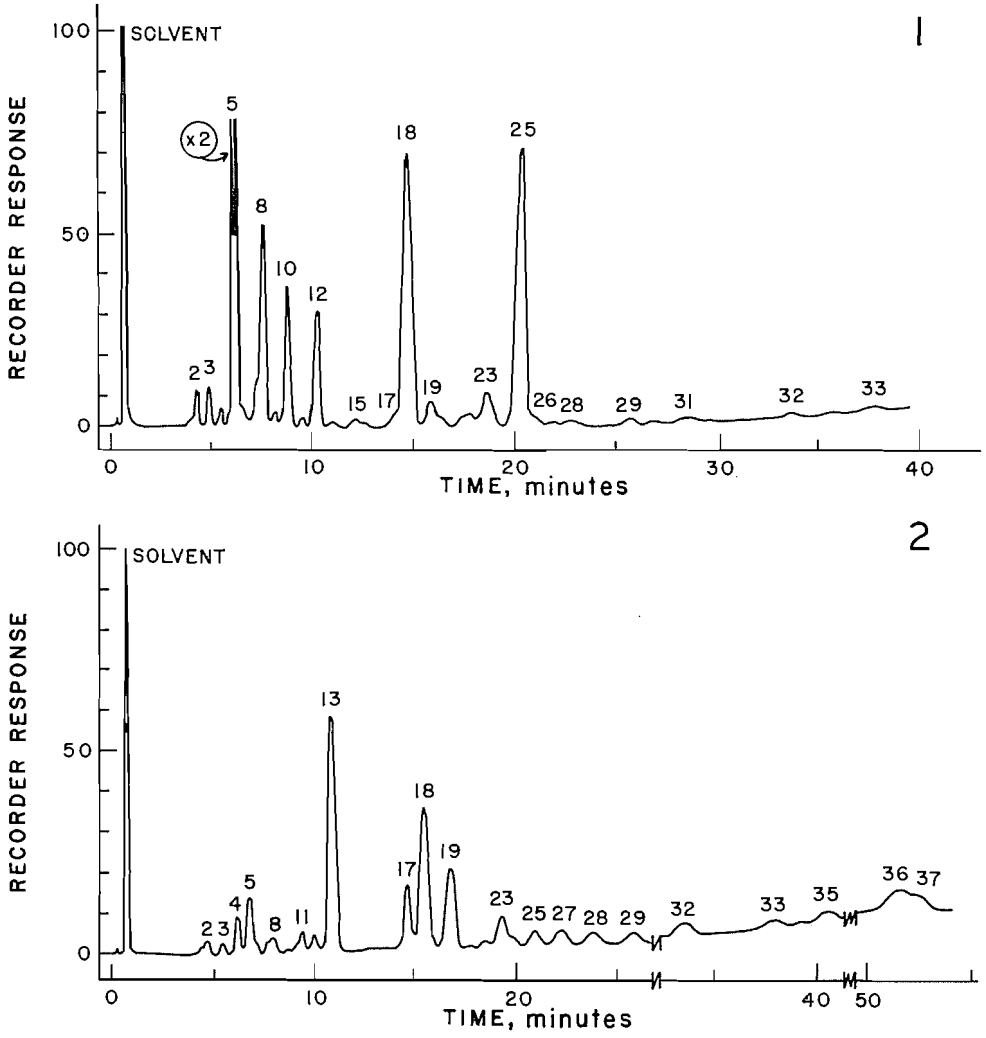

FIG. 1. Temperature-programmed chromatogram of the volatile oil from the leaves of Sitka spruce (see Table I for the peaks which have been identified).

FIG. 2. Temperature-programmed chromatogram of the volatile oil from the leaves of Engelmann spruce (see Table I for the peaks which have been identified).

RESULTS AND DISCUSSION

The oil from Sitka spruce leaves was obtained in comparatively good yield (0.36%), but that from Engelmann spruce leaves was rather poor (0.094%). Both oils were dextrorotatory and the refractive index was in the same range as that of other spruce leaf oils (6). Typical temperature-programmed chromatograms are shown in Figs. 1 and 2, and the average percentage composition of each oil in Table I. Both oils show significant qualitative and quantitative difference with respect to the composition of the oils from the leaves of black, white, and Colorado spruce (6).

The major constituents of Sitka spruce leaf oil were found to be *d*-myrcene, *l*-piperitone, and *d*-camphor. Piperitone appears to be the unidentified ketone (semicarbazone m.p.

†Contains an unidentified ester.

231–232° C) isolated by Lehmann and Lynn (5). Read and Smith (9) report that piperitone forms two semicarbazones with melting points 185° and 226° C respectively. The presence of fairly large amounts of 1;8-cineole and β-phellandrene and several non-terpenoid esters (peaks 2, 3, 10, and 12) is also noteworthy. RRT values of peaks 10 and 12 suggest that they are C_8 esters. They were not separated on an Apiezon N column, which suggests that they differ by a double bond. This is substantiated by their infrared spectra. However, neither compound was obtained in pure form, peak 10 being contaminated with terpinolene and peak 12 with a ketone. The retention time on the PEG column of peak 12 is similar to that of citronellal, but this aldehyde did not appear to be present. Lehmann and Lynn also report the isolation of borneol and terpineol from the saponified oil. Free borneol (peak 23*a*) and bornyl acetate (peak 19) were found in small amounts in this study, but α-terpineol (RRT same as peak 23*b*) or α-terpinyle acetate (RRT same as peak 24) were not detected. However, the saponified oil showed a reduction in the relative sizes of peaks 2, 3, 10, 12, 19, 29, 32, and 33 and it is possible that the later peaks are higher esters of α-terpineol. Sesquiterpenes were found only in very small amounts and only canadene, the cadinene isomer (4) found in other spruce leaf oils, was tentatively identified.

The leaf oil from Engelmann spruce was found to contain mainly *cis*-hex-3-en-1-ol (leaf alcohol) and camphor. Monoterpene hydrocarbons were present in relatively small amounts, β-pinene and myrcene being the most prominent members. The typical minor components, including tricyclene and β-phellandrene, were recorded, but 1;8-cineole was not found. Fairly large amounts of linalool and bornyl acetate were isolated and borneol, piperitone, and several unidentified higher boiling constituents were recorded in the 1 to 3 percentage range. Two prominent peaks (Nos. 36 and 37) were recorded in the sesquiterpene alcohol range, but attempts to correlate retention data with those of known compounds (cedrol, eudesmol, cadinols) failed to give conclusive data. Canadene was not recorded.

The presence of piperitone and large amounts of myrcene in the oil from Sitka spruce may have phylogenetic value. In this respect the presence of non-terpenoid esters (e.g. peak 10 and 12) and fairly large amounts of 1;8-cineole and β-phellandrene may also be significant. In Engelmann spruce leaves the formation of large amounts of *cis*-hex-3-en-1-ol, and perhaps also the large number and relatively high amounts of components in the sesquiterpene range, appears to be highly characteristic. *cis*-Hex-3-en-1-ol does not appear to have been isolated from spruce leaf oils before. Engelmann spruce is known to hybridize with white spruce and a distinct western variety of white spruce, *P. glauca* (Moench) Voss var. *albertiana* (S. Brown) Sarg., is recognized (10). Thus the presence of *cis*-hex-3-en-1-ol and major amounts of linalool in the leaf oil from Engelmann spruce may serve as a convenient taxonomic guide. This aspect will be studied further.

On comparing the composition of the oils from the leaves of spruces and other members of the family Pinaceae (11) with those from junipers (6) and cedars (12, 13) (fam. Cupressaceae) a phylogenetic pattern becomes discernible. The latter are characterized by the presence of monoterpenes of the thujane type (thujone, sabinol, sabinene, etc.). Oils from the members of the family Pinaceae contain bornyl acetate, borneol, and frequently camphor. Thus each botanical family has a closely related series of monoterpenes in common. It will be noted, that the oxygenated compounds are all substituted at carbon two of the cyclohexane ring (*p*-menthane nomenclature). Therefore, the finding of large amounts of piperitone, a C_3-substituted terpene, in the leaf oil of Sitka spruce is most remarkable. Its formation would require a separate biogenetic step.

Small amounts of many monoterpene hydrocarbons are found in the volatile oils of

plants from widely different genera. Yet, some of these occur in significant amounts and thus appear to be characteristic for a single family or species. For instance, large amounts of myrcene were found in the Sitka spruce leaf oil. Mirov (2) has shown that α- and β-pinene, as well as the phellandrenes are highly characteristic of pine wood oils. In junipers, sabinene is very prominent and thujene also appears to be a characteristic constituent. An extended study of volatile oils may, therefore, establish further phylogenetic relationships in this group of terpenes. As yet, the data on the sesquiterpenoid constituents are too fragmentary to allow any comparison. The fact that many peaks with different retention characteristics are recorded in this range would indicate that phylogenetic relationships exist. Improvements in the isolation and characterization of these minor constituents are being sought to obtain more conclusive data.

ACKNOWLEDGMENTS

The author wishes to thank Mr. P. J. Salisbury, plant pathologist, Indian Head Forest Nursery, Saskatchewan, for identifying and supplying the Engelmann spruce foliage, Dr. H. Worster, Columbia Cellulose Co., Prince Rupert, B.C., for sending the Sitka spruce leaves, and Mr. M. Granat for technical assistance. Infrared spectra were recorded by Mr. W. C. Haid.

COMPLEXES OF PLATINUM (0)

I. COMPLEXES WITH TRIPHENYLPHOSPHINE AND SUBSTITUTED PHENYLACETYLENES

A. D. ALLEN AND C. D. COOK[1]

Department of Chemistry, University of Toronto, Toronto, Ontario

Received December 4, 1963

ABSTRACT

Kinetic and equilibrium measurements have been made on the exchange of one arylacetylene for another of different structure in the compounds bis-triphenylphosphineacetylene-platinum (0). The rate of exchange is proportional to the concentration of the complex but is independent of the reagent. The complexes are stabilized by electron-withdrawing groups in the acetylene ligand. A mechanism for the reactions is proposed in which an intermediate $Pt(Ph_3)_2$ is formed which has a significant stability.

Compounds with the general formula $Pt(PPh_3)_2.ac$, where ac = acetylene or a substituted acetylene, were first prepared in 1957 by Chatt, Rowe, and Williams (1). These authors reported that the compounds are monomeric, that the acetylenic carbons are at least approximately in the same plane as the platinum and phosphorous atoms, and that the stability of the compounds is increased by the presence of alkyl, and even more so by aryl groups attached to the acetylenic carbons. The great stability of the compound formed with di-4-nitrophenylacetylene indicated that electron withdrawing substituents also stabilize the compounds.

We have prepared a series of compounds of this type containing monosubstituted phenylacetylenes and have attempted to determine the effect of the substituent on the properties of the free acetylene and on the stability of the complex formed. The relative stabilities of the various compounds have been determined by carrying out kinetic and equilibrium measurements on the exchange reaction in cyclohexane:

$$Pt(PPh_3)_2.ac + ac' \rightleftarrows Pt(PPh_3)_2.ac' + ac.$$

Use was made of the differences in optical absorption of the different complexes, so that by measuring the change in optical density with time at a selected wavelength the progress of the reaction and the position of equilibrium could be determined. Cyclohexane was chosen as the medium because spectra of solutions of the compounds in it do not change during the time necessary to carry out the experiments, and it is the most inert solvent that will sufficiently dissolve all the compounds.

EXPERIMENTAL

(1) Preparation and Characterization of Substituted Phenylacetylenes

The methods used for the preparations of the substituted phenylacetylenes, their physical properties, and infrared and nuclear magnetic resonance spectra have been reported elsewhere (2, 3).

(2) Preparation of Complexes

The following general method was used to prepare the complexes.* Hydrazine hydrate (100%, 2 ml) was added to a suspension of *cis*-bis(triphenylphosphine)dichloroplatinum (II) (2 g, 0.0025 mole) in 45 ml absolute ethanol. When the suspension was warmed to about 40°, the solid dissolved with slight effervescence. The yellow solution formed was filtered and the appropriate arylacetylene (0.004 mole), dissolved in 5 ml ethanol, was added. Precipitation of the complex generally began after about 30 minutes and was complete

[1]*Present address: Department of Chemistry, University College, London, England.*

**We are indebted to Dr. J. Chatt and Dr. G. A. Rowe, who provided us with details of this general method of preparation used in reference (1).*

when the suspension was left to stand overnight at room temperature. Recrystallization from benzene–methanol or methylene chloride – methanol gave the pure product. The compounds prepared in this way are listed in Table I.

TABLE I

Complex $[Pt(PPh_3)_2.ac]^0$ ac =	M.p. (decomp.)	Analysis Found % C	Found % H	Calc. % C	Calc. % H

(3) Solvent

Cyclohexane was dried by reflux over lithium aluminum hydride and fractionally distilled. Purity was checked by constancy of boiling point on changing to total reflux.

(4) Kinetic and Equilibrium Measurements

Absorption spectra of cyclohexane solutions of the complexes and the acetylenes were examined in the visible and near ultraviolet region of the spectrum. In the range 300–400 mμ it was usually possible to find a wavelength at which the free acetylenes were essentially transparent and the two complexes involved in a particular reaction to be studied had different extinction coefficients. The common feature of the spectra of these complexes is that they have an intense absorption below about 350 mμ and are more or less transparent at about 400 mμ. The absorption in between these two wavelengths depends on the substituent in the combined acetylene. Most of these systems showed a maximum change in absorbance at about 365 mμ, and many of the reactions were investigated at this wavelength.

Separate solutions of the complex and reagent acetylene in cyclohexane were prepared in a constant temperature (29±0.5°) room. Appropriate volumes of the reagents and solvent were mixed at zero time, and the mixture was rapidly transferred to the spectrophotometer cell. The cell temperature was maintained at 28.8 (±0.1)° by the use of aluminum block cell holder through which constant temperature water was circulated. The spectrophotometer (Bausch and Lomb 505) was set to run at constant wavelength and the recorder was started at zero time. The first reading was usually obtained within 1 minute of mixing. The change in absorbance with time was followed continuously for the first 10–20 minutes, and the final reading was checked after approximately 2 hours. In all cases both the forward and backward reactions were studied and only those which gave close agreement in the final equilibrium position were accepted. Details are given of the readings taken for a typical pair of reactions:

$$Pt(PPh_3)_2.C_6H_5C_2H + C_6H_5C_2C_6H_5 \rightleftarrows Pt(PPh_3)_2.C_6H_5C_2C_6H_5 + C_6H_5C_2H$$

Complex and reagent 1.00×10^{-4} *M* in cyclohexane. Wavelength 365 mμ. Temperature 28.8 (±0.1)°.

Forward reaction:								
Time (minutes)	1	2	3	4	6	8	10	∞
% *T*	70.8	68.8	67.5	66.3	64.3	63.1	62.2	60.5
Backward reaction:								
Time (minutes)	1	2.5	3	4	6	8	10	∞
% *T*	40.7	43.0	43.9	45.0	47.2	49.8	51.1	60.2

It was established that the optical densities are proportional to the concentrations of the two complexes in the solution, so that the equilibrium position can be calculated directly from the optical density at equilibrium. For the above reaction the concentration equilibrium constant, i.e.

$$[Pt(PPh_3)_2.C_6H_5C_2C_6H_5][C_6H_5C_2H]/[Pt(PPh_3)_2.C_6H_5C_2H][C_6H_5C_2C_6H_5],$$

has the value 0.25.

First-order rate coefficients were calculated by two methods: (*a*) from the rate of approach to equilibrium,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

using the equilibrium position to calculate the rate coefficient from the slope of the plot of log [complex] vs. time, and (*b*) from the initial slope of the first-order log plot based on the reaction going to completion. Good agreement was obtained in all cases.

Reactions were carried out in which the concentration of the reagent was varied, and also in which some of the acetylene contained in the complex was used in addition to the reagent acetylene.

DISCUSSION

Tables II, III, IV show the kinetic and equilibrium results obtained for several of these reactions, together with published data on the nuclear magnetic resonance spectra of the free acetylenes.

TABLE II

Table II shows the observed first-order rate coefficients for the reaction of the phenylacetylene complex with various substituted phenylacetylenes at several concentrations. It is clear that the rate is insensitive to the nature and concentration of the reagent. In Table III are shown similar first-order rate coefficients for the reaction of various substituted phenylacetylene complexes with phenylacetylene at several concentrations. Again the rate is independent of the concentration of the reagent, but it is apparent that

†First-order rate coefficient for complex containing substituted phenylacetylene, with phenylacetylene as reagent.
‡From ref. (3).

it depends markedly on the nature of the acetylene in the complex. The simplest interpretation of these results is that the rate-determining step involves the splitting of the complex into the free acetylene and an intermediate $Pt(Ph_3P)_2$, without the direct intervention of the reagent. Thus the rate coefficient is a measure of the ease of rupture of the metal–acetylene bond, and we see that the strongest bond is formed by the acetylene containing the strongly electron-withdrawing nitro group. The only complexes reacting more rapidly than the phenylacetylene complex are those containing the methoxy group in the ortho- or para-position, in which it is weakly electron-releasing.

Table IV shows these rate coefficients together with the equilibrium constants and τ values for the acetylenic hydrogen of the free acetylenes. It will be seen that, with minor variations, the equilibrium constants and rate coefficients follow the same pattern. By both measurements the nitro group strongly stabilizes these complexes. This means that the effect of the substituent is important in the region of the triple bond. Chemical shifts of the acetylenic hydrogen (3) follow the same sequence for substituents in the para- and meta-positions, showing clearly the change in electron density in the region of the hydrogen atom, and thus, presumably, in the triple bond. It is noteworthy that ortho substituents give much lower chemical shifts. The so-called "ortho effect" is well known in aromatic systems, and it is interesting that the ortho-substituted complexes do not show this effect, their stabilities being very similar to those containing analogous para-substituents.

It is clear that the bond between the triple bond and the metal atom has some double bond character, as originally proposed by Chatt *et al.* (1). The ability of the unsaturated system to accept electrons from the *d* orbitals of the metal atom plays an important part in the formation of the bond. An increase in the electron-accepting power of the ligand more than compensates for the decrease in donor properties caused by the presence of an electron-withdrawing substituent.

Also shown in Tables II and III is the effect on the reaction rate of adding to the mixture some of the acetylene which is also contained in the complex, e.g. addition of phenylacetylene to the reaction between the phenylacetylene complex and a substituted phenylacetylene. Two extreme cases are observed: (*a*) addition of a small amount of *p*-nitrophenylacetylene (to give a concentration of only 1/10th of that of the reagent) to the reaction between the *p*-nitrophenylacetylene complex and phenylacetylene produces a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

very marked reduction in the observed first order rate coefficient, from 1.6 to 0.25×10^{-4} sec^{-1}, and (*b*) addition of phenylacetylene to the reverse reaction in a concentration equal to that of the reagent *p*-nitrophenylacetylene produces an insignificant reduction in rate.

These observations are consistent with the formation of a relatively stable intermediate, $Pt(PPh_3)_2$, in the following reaction scheme (4):

$$Pt(Ph_3P)_2.ac \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} Pt(Ph_3P)_2 + ac,$$

$$Pt(Ph_3P)_2 + ac' \xrightarrow{k_2} Pt(Ph_3P)_2.ac'.$$

If we assume a steady state for the intermediate $Pt(Ph_3P)_2$, the rate expression for the initial forward reaction is:

$$v = k_1[Pt(Ph_3P)_2.ac] \Big/ \left(\frac{k_{-1}[ac]}{k_2[ac']}\right)+1.$$

At the beginning of a reaction in which the reagent ac′ is the only free acetylene present the term $k_{-1}[ac]$ is zero, and a simple first order expression is obtained, $v = k_1[Pt(PPh_3)_2.ac]$. The first-order rate coefficients given in the tables are derived from this expression for the initial part of the reaction. If some free acetylene ac is also added to the reaction mixture, at a concentration equal to ac′, the denominator at the beginning of the reaction becomes $(k_{-1}/k_2)+1$. The effect of this addition upon the observed first order rate coefficient will depend on the relative magnitudes of k_{-1} and k_2. If $Pt(PPh_3)$ is a reactive intermediate its reaction with the acetylene present will depend only on their relative concentrations. The nature of the acetylene will not be important, so that k_{-1} and k_2 will be approximately equal and very large. Their ratio will be close to unity and the denominator in the rate expression will be approximately equal to two. Thus, with a reactive intermediate and with equal concentrations of the two acetylenes, the rates of the forward and backward reactions of the intermediate will be approximately equal and the net forward rate will be about half of that observed in the absence of added ac, irrespective of the nature of ac. Our results show clearly that this is not the case.

If, however, the intermediate $Pt(PPh_3)_2$ is sufficiently stable the rate of its reaction may depend upon the acetylene involved. If, for example, the activation energy for the reaction of this intermediate with *p*-nitrophenylacetylene is substantially less than that for its reaction with phenylacetylene it will react selectively, at a faster rate, with the former reagent. In the reaction scheme above the rate coefficients k_{-1} and k_2 will depend on the acetylene involved, and the observed rate will depend upon the ratio of these coefficients. In the reaction between the *p*-nitrophenylacetylene complex and phenylacetylene, the coefficient k_{-1} appears to be very much greater than k_2, so that addition of small amounts of free *p*-nitrophenylacetylene strongly inhibit the overall rate of the forward reaction. Similarly, for the reverse reaction, addition of relatively large amounts of free phenylacetylene have a very small effect on the overall rate of reaction. With other combinations of acetylenes less extreme results are obtained, as shown in Tables II and III. The results obtained are consistent with the reasonable hypothesis that the activation energy for the reaction of the intermediate with an acetylene is directly related to the stability of the complex formed, i.e. it is lowest for the acetylene which forms the strongest complex.

It follows from this argument that the stability of diphosphine intermediate should be affected by the nature of the phosphine used. Work is in progress to determine the effect of substituted aryl phosphines on the stability of this intermediate.

ABSTRACT

The formation and stability of urea inclusion compounds of *n*-alkyl bromides and iodides were established from X-ray powder diffraction data. The stability of both homologous families is greater than would be expected from a consideration of the cross-sectional diameter of the molecules only. The procedure for isolating the complexes has been simplified.

INTRODUCTION

In preparation for studying the effect of radiation on the urea inclusion compounds of *n*-alkyl bromides and iodides it was necessary to demonstrate unequivocally that these compounds form urea inclusion compounds. A second objective was to ascertain the relative stability of these compounds and to determine which compounds were sufficiently stable to make reasonable candidates for a study of radiation effects.

DISCUSSION

It has been previously reported (1) that molecules such as organic acids and ketones are capable of forming urea inclusion compounds for shorter (unbranched) chains than the *n*-alkanes. These molecules which appear to be more effective in their ability to form urea inclusion compounds all contained a polarizable functional group containing pi bonding electrons. In a previous study the effect of fluorine in esters was tested (2). The results indicated that the influence of the fluorine was independent of any inductive effect resulting from the pronounced electronegativity of the halogen atom. In fact, the results could be explained by the larger atomic radius of fluorine (as compared with hydrogen) requiring a slightly greater number of methylene groups in the chain than that required for non-fluorinated esters to form a complex. Since the cross-sectional diameters of the *n*-alkyl bromides and iodides were 4.75 Å (previously reported (1) to form a urea complex) and 4.95 Å (not previously reported to form a complex) respectively, it was anticipated that both would form complexes since the maximum (3) cross section of a urea channel is 6 Å. At the same time it was anticipated that the shortest alkyl iodides and bromides (1) would require a somewhat greater number of methylene groups than the shortest alkane (4.6 Å in cross section) which would form a urea complex. It was surprising, therefore, to find that both the shortest *n*-alkyl bromide and iodide capable of forming a complex were shorter than the shortest *n*-alkane (*n*-octane) which would form a channel complex with urea by the method employed.

Since all the starting materials are liquids, the X-ray powder pattern of the crystalline products obtained after treatment with a urea–methanol solution must be either that of uncomplexed urea (tetragonal) or that of some new product. It is easy to distinguish

[1]*Holder of a U.S. Secretary of the Army Research and Study Fellowship at The Hebrew University of Jerusalem, 1962–1963.*

between these two since the spacing at 3.98–4.02 Å* is the most intense spacing characteristic of tetragonal (4) (uncomplexed) urea and the spacing at 4.10–4.11 (Table I) or 4.11–4.15 Å (Table II) is the most intense spacing characteristic of the (hexagonal) urea inclusion compound (4). From these spacings which indicate the relative concentration of free urea and the complex, it was concluded that *n*-heptylbromide is the shortest bromoalkane tested which unequivocally gives a complex (Table I). Table I contains all X-ray measurements for the *n*-alkyl bromide urea inclusion compounds. The *n*-heptylbromide complex is appreciably contaminated by free urea as indicated by a relative intensity of 0.19 at 3.98–4.02 Å. The complexes of 1-bromooctane and all higher homologues are free of urea (no interplanar spacing at 3.98–4.02 Å) and retain a maximum intensity for the complex of 1.00 at 4.10–4.11 Å.

The most surprising result was the appreciable formation of a complex by 1-iodopentane (Table II) as indicated by a relative intensity of 0.31 at 4.11–4.15 Å, characteristic of complex formation. The 3.98–4.02 Å spacing, characteristic of free urea, was very strong in the case of 1-iodopentane with a maximum relative intensity of 1.00 which indicated a high concentration of urea contaminating the complex. For 1-iodohexane the value fell to 0.33, and none of the higher homologues above 1-iodohexane showed a spacing at 4.00–4.02 Å (Table II).

The ease of complex formation decreases as the cross-sectional diameter of the molecule in the planar zigzag conformation increases over and above that of a *n*-hydrocarbon (5). This results in the fact that the shortest homologue able to form a complex in a family of compounds which has a high cross section requires a larger number of methylene groups and thus a longer chain to produce enough van der Waals forces for stable inclusion compound formation. For the 1-bromo and 1-iodoalkanes this behavior is reversed. For the cross-sectional diameters we find *n*-RI (5.0 Å) > *n*-RBr (4.8 Å) > *n*-RH (4.6 Å). Consequently, it would be expected that the alkyl iodide would require the longest and the alkane the shortest chain for the complex formation. Instead, the shortest homologue in the three series to form a complex under the same conditions is 1-iodopentane, 1-bromoheptane, and normal octane (4). The shorter chain length requirements for complex formation of the molecules of greater girth can be accounted for by the stabilization resulting from the polarizability of the carbon–halogen bond.

In all cases the most reliable criteria for the relative stability of the complexes was the amount of uncomplexed urea, as determined by the intensity of the strongest urea spacing around 4.00 Å. In the tables it is seen that this spacing decreases in intensity as we proceed to the higher homologues and rapidly disappears.

The formation of urea inclusion compounds of *n*-alkyl bromides was unequivocally identified by the following spacings which occurred in decreasing order of intensity: 4.10–4.11, 3.39–3.40, 2.62, 2.06, and 3.26–3.27 Å. Most of the other spacings are uniformly weak except the one at 3.53–3.57 Å, which is characteristic of both complexed and free urea. The 7.13–7.15 Å spacing which is characteristic of urea complexes is weak and not present in all the complexes (Table I).

Channel complex formation of the *n*-alkyl iodides was identified by the following spacings which occurred in decreasing order of intensity: 4.11–4.15, 3.39–3.40, 2.37–2.38, 2.05–2.06, and 7.13–7.21 Å. Again the spacing at 3.56–3.58 Å cannot be used as it is characteristic of both complexed and free urea (Table II).

To determine whether there is any advantage in washing the filtered crystalline

**The range of 3.98–4.02 Å is used to cover the maximum intensity urea spacing which occurs in Table I and III at 3.98–4.00 Å and Table II at 4.00–4.02 Å and will be used throughout the text.*

inclusion compounds with absolute ethanol, the complexes of the *n*-alkyl iodides were prepared in two ways, by simply filtering them (results Table II) or by filtration and washing with ethanol (results in Table III). No advantage could be found by including the washing step since it only reduced the yield of complex. The data in Tables II and III indicate the disappearance or diminution of some of the spacings characteristic of the complex for the washed inclusion compounds. Consequently, the washing step was omitted from the preparation of the 1-bromoalkane complexes.

EXPERIMENTAL

1-Bromo- and iodo-alkanes.—Pure compounds were obtained from the Gallard–Schlesinger Mfg. Corp., Long Island, N.Y.

Urea inclusion compounds.—To 4.5 ml of a urea–methanol solution (0.15 g urea/ml of methanol) in a screw-cap vial was added 30 drops of the alkyl halide. The vial was capped, shaken vigorously for 30 seconds, and allowed to stand for 3–4 hours at 29–30°. Then the compounds were kept at 4° for 24 hours. Crystals that formed were filtered by suction using a rubber sheet to cover the funnel, thereby reducing the possibility of contaminating the complex with free urea resulting from the evaporation of the mother liquor during filtration.

The inclusion compounds of Tables I, II, and III were prepared in the same way except that the inclusion compounds of Table III were washed with 10 ml of absolute ethanol at 4° during the filtration step.

X-ray powder diffraction measurements.—These measurements were made on a North American Phillips Co. X-Ray Diffractometer (Model 5001) which was equipped with a high angle goniometer and a proportional counter. CuK_α radiation was obtained by operating the Cu tube at 35 kv and 15 ma using a nickel filter and passing the radiation through a 1° slit. The goniometer scanning speed was 1°/minute. Samples were mounted on a roughened glass slide using a spatula and enough pressure to make the samples stick to the slide.

Cross-sectional diameters.—These measurements were made on scalar molecular models by a previously described procedure (6).

STUDIES IN THE PYRROLINE SERIES

III. SOME PYRROLINYLPYRROLES AND RELATED COMPOUNDS

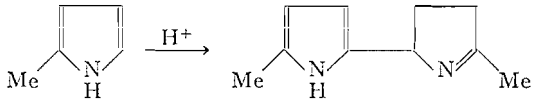
R. BONNETT, K. S. CHAN, AND I. A. D. GALE
Chemistry Department, University of British Columbia, Vancouver, British Columbia
and
Chemistry Department, Queen Mary College, London, England

Received November 12, 1963

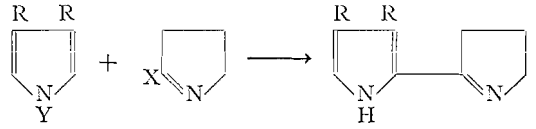
ABSTRACT

The addition of 5,5-dimethyl-1-pyrroline to pyrrole gives both the 1:1 adduct and the 2:1 adduct. The palladium-catalyzed dehydrogenation of 2,2′-pyrrolidinylpyrrole has been studied at various temperatures. In refluxing toluene the reaction proceeds satisfactorily to the pyrroline level, while in cymene the corresponding bipyrrole is produced. 1,2′-(1′-Pyrrolinyl)-pyrrole has been obtained from the reaction of 2-methoxy-1-pyrroline with pyrrole: on pyrolysis it yields 2,2′-(1′-pyrrolinyl)pyrrole. A similar sequence is observed with 3,4-dimethylpyrrole.

Compounds with two rings of the pyrrole type linked directly at α,α' positions have become of much interest recently with the formulation of vitamin B_{12} and prodigiosin as naturally occurring examples of this class. The most direct routes to such systems appear to be (i) dimerization of suitably substituted pyrroles, e.g. (1, 2):



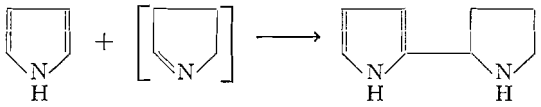
(ii) nucleophilic substitution at position 2 of a suitable 1-pyrroline:



R = Y = H; X = $OPOCl_2.HCl$ (ref. 3)

R = CH_3; Y = MgHal; X = OMe (ref. 2)

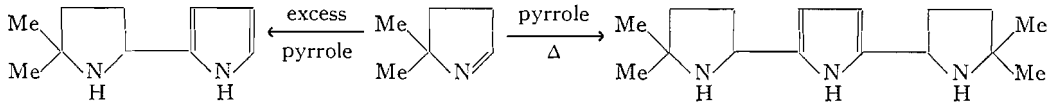
and (iii) the addition of a pyrrole to a 1-pyrroline (4):



The latter approach now has been investigated further, with particular attention being paid to the dehydrogenation of the resulting 2,2-pyrrolidinylpyrrole under various conditions.

The addition reaction itself was examined at the outset since it appeared likely that the addition of a further pyrroline nucleus to the pyrrolidinylpyrrole might occur. In the case of 1-pyrroline itself the 1:1 adduct is the only isolated product, and this is not surprising in view of the ready trimerization of 1-pyrroline, a process which could effectively limit the concentration of the monomer. 5,5-Dimethyl-1-pyrroline, which does not trimerize so

readily, has now been shown to yield both 1:1 and 2:1 adducts. The former adduct is isolated when the reaction medium contains a considerable excess of pyrrole.



I II

That compound II was in fact the 2:1 adduct was evident from the analysis of the base and that of its dipicrate, and from the equivalent of the base. The assignment of structure II was in accord with the ultraviolet spectrum (λ_{max} 223 mμ; log ϵ 4.04) and the infrared spectrum (two NH bands in dilute solution): 2,5-disubstitution was assigned on the basis of the known relative nucleophilicity of the pyrrole positions ($\alpha > \beta$) and received support from the proton magnetic resonance spectrum, which indicated only one type of aromatic proton (Table I).

TABLE I

Proton magnetic resonance spectra
(τ values, internal T.M.S., A60, $CDCl_3$)

*These values are somewhat lower than those quoted by Rapoport (3). We assign the ~6τ signal to the 5′ protons and the ~7τ signal to the 3′ protons rather than vice versa (cf. (9) and τ values given above for 4′ and 5′ protons in 3,3-dimethyl-2-phenyl-1-pyrroline).
†Singlets. Other values refer to the centers of broad or multiplet signals.

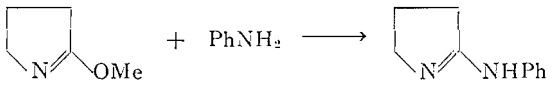
When the dehydrogenation of 2,2′-pyrrolidinylpyrrole was carried out in xylene (5) the major product was a base with a pK_a (aqueous ethanol) of 7.9, and evidently not 2,2′-bipyrrole. Analysis of the base indicated the formula $C_8H_{10}N_2$, which was supported further by the titration results. The ultraviolet spectrum indicated increased conjugation (λ_{max} 279 mμ; log ϵ 4.21) and, moreover, the band experienced a bathochromic shift on acidification of the solution (λ_{max} 318 mμ; log ϵ 4.41). Closely analogous behavior was shown by the Schiff base formed from pyrrole-2-aldehyde and methylamine (6). In ethanol this was found to have a band at 285 mμ (log ϵ 4.20) which shifted to 325 mμ (log ϵ 4.36) in acid solution. The infrared spectrum indicated the presence of the NH group: in addition, a band, which in the infrared of the base was at 1620 cm^{-1}, appeared in the spectrum of the perchlorate at 1655 cm^{-1} (Ar—C=N— → Ar—C=N$^+$H—). These results strongly supported the formulation of the base as 2,2′-(1′-pyrrolinyl)pyrrole III, and this structure was in accord with the proton magnetic resonance spectrum (Table I). After the completion of this work a similar conclusion was reported by Rapoport (3), who isolated 2-(4-aminobutyl)-pyrrole and 2,2′-bipyrrole in addition to the pyrroline. It is of interest that this pyrrylpyrroline (formulated as the Δ^2-tautomer) was reported much earlier (7)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

as the product of the conventional Cloke pyrroline synthesis. This report has recently been shown to be in error; the Cloke synthesis is not of general application to the pyrrylmagnesium halides and the isomer obtained earlier has been characterized as 2-(3-cyanopropyl)pyrrole (8).

Small-scale experiments (evaluated by paper chromatography) were carried out to obtain conditions which would give 2,2′-(1′-pyrrolinyl)pyrrole and the corresponding bipyrrole in satisfactory yields. The results (Table II, Experimental) suggested that the pyrroline oxidation level could be satisfactorily reached in refluxing toluene, while in refluxing cymene the 2,2′-bipyrrole was formed in moderate amount. On a preparative scale the pyrrylpyrroline has been obtained in 54% yield from the reaction in toluene.

The synthesis of 2,2′-(1′-pyrrolinyl)pyrrole has been approached in another way, following the observation that the cyclic iminoether 2-methoxy-1-pyrroline reacted readily with various anilines to give amidines such as IV, which, as would be expected, are strong



IV

bases (pK_a in aqueous ethanol 9.8 cf. p-$ClC_6H_4NHC(=NH)CH_3$ pK_a 9.5 (10)). It was of interest that pyrrole also reacted with the cyclic iminoether to give a white crystalline substance isomeric with compound III. This compound is assigned the novel structure V, although it is, in fact, a rather weak base (pK_a 5.4). The ultraviolet spectrum of the compound had a maximum at 245 mμ (log ϵ 4.15) which shifted to 252 mμ (log ϵ 4.24) on acidification. This absorption is comparable to that of 1-acetylpyrrole (λ_{max} 238.5 mμ; log ϵ 4.03 (11)), and the shift observed in acid is similar to that recorded for the base for which structure VI has been advanced (2). The infrared spectrum of base V had no prom-

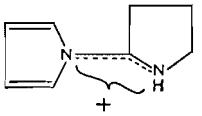
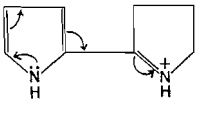
inent absorption in the NH region but did possess a band assignable to the C=N stretching mode at 1650 cm^{-1}. Further support for the proposed structure came from the n.m.r. spectrum (Table I), which had two groups of equally intense signals corresponding to the two types of aromatic protons in V; and from the fact that an analogous compound (n.m.r. spectrum: Table I) could be obtained, though in low yield, from the reaction of 3,4-dimethylpyrrole with 2-methoxy-1-pyrroline. Clearly, although compound V is formally an amidine, the lone pair on the pyrrolic nitrogen has aromatic commitments and cannot be readily involved in the cation VII. On the other hand, the 2,2′-compound (III) gives a



VII



VIII

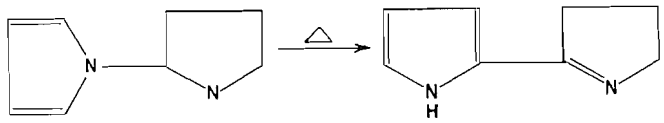
cation in which not only has protonation occurred on nitrogen but in which mesomerism may involve the entire π-system (VIII—arrows). Thus the 2,2′-compound is a much stronger base than the 1,2′-compound.

It is striking that the reaction of pyrrole and the cyclic iminoether appears to occur specifically at position 1 under the mild conditions employed; it should be noted (cf. reaction (ii)) that when various pyrrylmagnesium halides are used (2) reaction at carbon (rather than at nitrogen) prevails following the general experience (cf. 12) with magnesium salts of pyrroles. The migration of groups from nitrogen to carbon (especially α-carbon) under thermal stimulus is, however, a well-known reaction in pyrrole chemistry, and it was pertinent to observe whether or not the 1-pyrroline residue could survive such a process. Pyrolysis carried out in a stream of purified nitrogen was attended by much decomposition, but a 12% yield of 2,2′-(1′-pyrrolinyl)pyrrole was isolated, and paper chromatography indicated that 2,2′-bipyrrole was amongst the by-products of this novel pathway to the α,α' direct linkage.



V III

EXPERIMENTAL

The following equipment was used. Melting points: Fisher–Johns heated block. Infrared spectra: Perkin Elmer Infracord or Model 21. Vapor phase chromatography: Aerograph A-90-P. Proton magnetic resonance spectra: Varian A60. The pK_a values refer to the pH recorded at the half-neutralization point at 18° by a Doran pH meter previously standardized with aqueous buffer at pH 9.15. Analyses by Dr. A. Bernhardt, Mulheim.

Reaction of 5,5-Dimethyl-1-pyrroline with Pyrrole

(a) With a large excess of pyrrole.—The pyrroline (0.5 g) and pyrrole (8 g) were kept at 100° for 32 hours in a sealed tube. The pyrrole was removed (rotary evaporator) and the oily residue was sublimed at 95° at 1 mm. The white sublimate (0.27 g, 32%) had m.p. 39° when crystallized from hexane. It gave an orange picrate from ether, which, recrystallized from ethanol, melted at 155°. Found: C, 49.05; H, 5.0; N, 18.0. $C_{16}H_{19}N_5O_7$ requires C, 48.85; H, 4.9; N, 17.8%.

(b) 2,5-Bis-2′-(5′,5′-dimethylpyrrolidinyl)pyrrole (II).—The pyrroline (1 g) and pyrrole (2 g) were heated in a stoppered flask on a steam bath for 24 hours. Readily volatile material was removed on a rotary evaporator and the remaining oil was treated in benzene–hexane with charcoal to give 0.24 g (18%) of colorless prisms, m.p. 127–131°. Recrystallization from the same solvent raised the m.p. to 133°. Found: C, 73.8; H, 10.4; N, 15.8. $C_{16}H_{27}N_3$ requires C, 73.5; H, 10.4; N, 16.1%. $\nu_{max}^{CHCl_3}$ 3430, 3310, 1587, 1475 cm^{-1}. λ_{max}^{EtOH} 223 mμ; log ϵ 4.04. Titration in aqueous ethanol gave an equivalent of 134 (calc. 131). The *picrate*, prepared in moist ether and recrystallized from ethanol, had m.p. 213° (decomp.). Found: C, 46.8; H, 4.7; N, 17.5. $C_{28}H_{33}N_9O_{14}$ requires C, 46.7; H, 4.6; N, 17.5%.

Dehydrogenation of 2,2′-Pyrrolidinylpyrrole

(a) Trial experiments.—2,2′-Pyrrolidinylpyrrole (25 mg (4)) and 5% palladium on charcoal (25 mg) were refluxed in 10 ml of aromatic solvent (Table II) for 4½ hours. The hot solution was filtered (Celite) and the depth of color of the filtrate was observed. The solutions were examined by descending paper chromatography in two systems: (A) Whatman No. 1 with *n*-butanol – acetic acid – water (4:1:5—top phase) over 4½ hours and (B) aluminum oxide paper No. 288 (Schleicher and Schnell, Dassel) with *n*-butanol saturated with water over 15 hours. The spots were developed with iodine vapor. The relative intensities were estimated visually; they give a rough guide to the progress of the reactions as illustrated in Table II.

(b) Preparation of 2,2′-(1′-pyrrolinyl)pyrrole (III).—2,2′-Pyrrolidinyl pyrrole (250 mg) and 5% palladium on charcoal (250 mg) were refluxed in toluene (15 ml) for 4 hours. The hot solution was filtered (Celite) and the pad was washed with ether (45 ml). The filtrate was extracted with two portions of 0.5 *N* HCl (40 ml, 20 ml), and the separated aqueous extract was basified (NaOH) and re-extracted with ether (2×50

ml). The dried ethereal solution was concentrated to yield (at −10°) 132 mg (54%) of 2,2′-(1′-pyrrolinyl)pyrrole, m.p. 166°. Found: C, 71.1; H, 7.5; N, 20.9. $C_8H_{10}N_2$ requires C, 71.6; H, 7.5; N, 20.9%. $\nu_{max}^{CHCl_3}$ 3450 (sharp, free NH) 3300 (broad, hydrogen-bonded NH), 1620 cm^{-1} (Ar—C═N). In Nujol mull only H-bonded NH absorption was observed. λ_{max}^{EtOH} 279 mμ (log ε 4.21) with inflexion at 240 mμ (log ε 3.61); on acidification the maximum appeared at 318 mμ (log ε 4.41). Potentiometric titration in aqueous ethanol (50% ethanol) gave an apparent pK_a of 7.9 and an equivalent of 138 (calc. 134).

(c) Preparation of 2,2′-bipyrrole.—2,2′-Pyrrolidinylpyrrole (250 mg) and 5% palladium on charcoal (250 mg) were refluxed in *p*-cymene (5 ml), stirred with a slow stream of nitrogen for 3 hours. The cooled mixture was applied to a column (10×1.5 cm) of alumina (activity IV) in petrol and eluted with benzene. The eluate was tested from time to time with the Ehrlich reagent. Those fractions which gave a royal blue color were combined, reduced to a small volume, and diluted with petrol to give 47 mg (19%) of 2,2′-bipyrrole, m.p. 185°. Sublimation (100° at 0.5 mm) raised the m.p. to 187° (lit. 189–190° (3)).

Preparation of 1,2′-(1′-Pyrrolinyl)pyrrole (V)

2-Methoxy-1-pyrroline (2 g (2)) and pyrrole (4 g) were heated together in a sealed tube (40 hours, 100°). The excess pyrrole was removed (rotary evaporator) and the oily residue was sublimed to give 0.93 g (34%) of 1,2′-(1′-pyrrolinyl)pyrrole, m.p. 71°, after two crystallizations from 60–80° petroleum. Found: C, 71.8; H, 7.6; N, 20.8; mol. wt. (Rast) 126. $\nu_{max}^{CHCl_3}$ 1650, 1495, 1378 cm^{-1}. λ_{max}^{EtOH} 245 mμ (log ε 4.15); on acidification 252 mμ (log ε 4.24). Potentiometric titration in aqueous alcohol gave a pK_a value of 5.4 and an equivalent of 135.

Thermal Rearrangement of 1,2′-(1′-Pyrrolinyl)pyrrole

1,2′-(1′-Pyrrolinyl)pyrrole (0.7 g) was distilled in a stream of oxygen-free nitrogen through a column (20×1 cm) of glass beads (2–3 mm diameter, Hopkins and Williams Ltd.) at dull red heat. The crude product (0.46 g) solidified; it was triturated with methanol (0.5 ml) and the liquid withdrawn at the filter stick. The off-white solid remaining was crystallized (charcoal) from ether to give 69 mg of 2,2′-(1′-pyrrolinyl)pyrrole, m.p. and mixed m.p. 166°. A further 12 mg, m.p. 164°, was obtained from the mother liquors (total yield 12%). Paper chromatography (system A) of the mother liquors suggested the presence of 2,2′-bipyrrole (R_f 0.88).

3,4-Dimethyl-1,2′-(1′-pyrrolinyl)pyrrole

3,4-Dimethylpyrrole (1.72 g) and 2-methoxy-1-pyrroline (2 g of a 60% solution in benzene) were heated in a sealed tube (100°, 72 hours). Vapor phase chromatography showed the presence of a new compound (retention volume 620 ml; 5 foot Ucon Polar column at 210°; helium carrier) in addition to starting material. The lower boiling fraction was removed at reduced pressure, and the solid residue was crystallized from petroleum ether (60–80°; charcoal) to give 0.41 g (21%) of 3,4-dimethyl-1,2′-(1′-pyrrolinyl)pyrrole, m.p. 93–94° after two recrystallizations from petroleum. Found: C, 73.9; H, 8.7; N, 17.3. $C_{10}H_{14}N_2$ requires C, 74.0; H, 8.7; N, 17.3%. Electrometric titration in aqueous ethanol gave an equivalent of 152 (calc. 162) and a pK_a of 5.8. ν_{max}^{Nujol} 1650 cm^{-1}, no NH, λ_{max}^{EtOH} 258 mμ (log ε 4.15).

Pyrolysis of this compound as before gave a low yield of 3,4-dimethyl-2,2′-(1′-pyrrolinyl)pyrrole, m.p. 173–177°; after sublimation 178–178.5° (lit. 178–179° (2)).

2-Phenylamino-1-pyrroline (IV)

2-Methoxy-1-pyrroline (0.5 g) and aniline (0.5 g) were heated together in a sealed tube (90°, 5 days).

Readily volatile material was removed on a rotary evaporator, whereupon the residue solidified. It was crystallized (charcoal) from 60–80° petroleum to give 0.54 g (67%) of 2-phenylamino-1-pyrroline (tautomeric system) m.p. 115° (lit. 114–115°, (13)). Sublimation (95°, 1 mm) and recrystallization raised the melting point to 116–117°. Found: C, 74.9; H, 7.4; N, 17.3. $C_{10}H_{12}N_2$ requires C, 75.0; H, 7.55; N, 17.5%. Titration gave an apparent pK_a of 9.8 and an equivalent of 165 (calc. 160).

CO-ORDINATION COMPLEXES OF GROUP (IV) HALIDES

PREPARATION AND INFRARED SPECTRA OF THE CO-ORDINATION COMPOUNDS OF TITANIUM TETRACHLORIDE, TITANIUM TETRABROMIDE, ZIRCONIUM TETRACHLORIDE, TIN TETRACHLORIDE, AND BORON TRICHLORIDE WITH ETHYL CYANOACETATE AS LIGAND[1]

SUMER CHAND JAIN AND ROLAND RIVEST
Department of Chemistry, University of Montreal, Montreal, Quebec

Received December 4, 1963

ABSTRACT

Co-ordination compounds between ethyl cyanoacetate and boron trichloride, titanium tetrabromide, and tetrachlorides of titanium, zirconium, and tin have been prepared. The analytical results indicate that under similar experimental conditions, 1:1 addition compounds are obtained in each case. On the basis of infrared spectra it has been postulated that the compounds obtained are six-membered ring chelates, satisfying the most common co-ordination number six for the elements of group IV.

INTRODUCTION

In our previous work (1) on the co-ordination complexes of group (IV) halides with nitriles and dinitriles it has been postulated for some of the compounds that the central element had a co-ordination number five, or a co-ordination number six, where this co-ordination number six was reached through halide bridging. In the complexes with halogen-substituted esters (2) the formation of 1:1 addition complexes was explained on the basis of co-ordination number six for the central titanium atom where both the oxygen atoms of acid and ether groups were involved in co-ordination forming a four-membered-ring chelate. But at the same time the probability of co-ordination number five for titanium where only the carbonyl group was co-ordinated, could not be ruled out. Since titanium compounds having co-ordination number eight have been well established by Nyholm (3) and his co-workers, in the compounds of general formula $TiCl_4.2$ esters titanium can exhibit a co-ordination number six, if only the carbonyl groups act as donors, or it can exhibit a co-ordination number eight if both oxygens of the monoester molecule are involved in co-ordination.

To know more about the possible co-ordination numbers of titanium (IV), it was thought of interest to use a bidentate ligand where it was easy to detect the co-ordination of the two different donor elements and in which one could see what was happening to both donor groups when present on the same molecule. For this purpose ethyl cyanoacetate was chosen where it was possible to differentiate between the co-ordination effects of cyano and carbonyl groups through infrared spectroscopic studies. To investigate the respective influence on the stretching frequencies of the two donor groups when only one of them is involved in co-ordination, boron trichloride was chosen.

EXPERIMENTAL

Material and Manipulations

Boron trichloride obtained from the British Drug Houses Limited (in sealed capsules) was used without further purification. Ethyl cyanoacetate was obtained from Eastman Organic Chemicals through The Fisher Scientific Company and was dried over molecular sieves. The solvent carbon tetrachloride was made anhydrous by appropriate method. The group (IV) halides were purified as mentioned in previous publication (1).

[1]*Presented at the XXXI Congrès de l'Association Canadienne Française pour l'Avancement des Sciences, Québec, November 2, 1963.*

The group (IV) halides and their complexes are extremely sensitive to humidity. Therefore, all manipulations were carried out in a rigorously dried apparatus and handled in an anhydrous chamber, which was continuously flushed with dry nitrogen in a manner described in an earlier paper (4). The experimental methods and the methods of analysis for metal and halogens are essentially the same as described previously (4, 5). Boron was analyzed as boric acid after adding mannitol, and titrating with a standard NaOH solution to a phenolphthalein end point (6).

The spectrophotometric measurements were carried out on a Perkin–Elmer Infrared spectrophotometer, model 21, using sodium chloride prism. Samples were prepared as Nujol mulls.

Preparation of the Complexes

The preparation of these complexes was performed in carbon tetrachloride. In each case except for $SnCl_4$ and BCl_3, insoluble precipitates were obtained which were filtered, washed with the solvent, and dried under vacuum at room temperature. The following proportions of the reactants w/v % were used to obtain the respective compounds.

$TiCl_4.NCCH_2CO_2C_2H_5$.—To 20 ml of 25% solution of the ligand was added 20 ml of 42.25% solution of $TiCl_4$. The analytical and the infrared results of the product so obtained and its sublimate at low pressure were identical.

$2TiCl_4.NCCH_2CO_2C_2H_5$.—To 20 ml of 85% solution of $TiCl_4$ was added 10 ml of 10% solution of the ligand and the reaction allowed to go for 3 days.

$TiBr_4.NCCH_2CO_2C_2H_5$.—To 20 ml of 10% solution of the ligand was added 20 ml of 32.5% solution of $TiBr_4$.

$ZrCl_4.NCCH_2CO_2C_2H_5$.—Twenty milliliters of 15% solution of the ligand and 2 g of $ZrCl_4$ was allowed to react for about 1 week under continuous stirring.

$SnCl_4.NCCH_2CO_2C_2H_5$.—Ten milliliters of 10% solution of the ligand was added to 20 ml of 33.5% solution of $SnCl_4$. In this particular case no product was obtained in the beginning, but when the solution in the reaction flask was evaporated slowly, a white crystalline product separated from the mother liquor.

$BCl_3.NCCH_2CO_2C_2H_5$.—A 25 g capsule of BCl_3 was cooled to 0° C before breaking the seal and was then diluted with 15 ml cold CCl_4 in a reaction flask. To this solution 4 ml ligand was added drop by drop keeping the reaction flask at 0° C. The reaction mixture was then subjected to slow evaporation. The product so obtained and its sublimate at reduced pressure gave the same analytical results of boron and chlorine. The analytical results are included in Table I.

INFRARED SPECTRA AND DISCUSSION

It is well known that the carbonyl stretching frequency is lowered on co-ordination (2, 5). In previous published work it has been shown (2) that the magnitude of the negative shift is largely affected by the number and position of the chlorine atoms on the ester molecules used as ligands. Infrared observations as included in Table II show that the presence of the cyano group seems to have a similar electron pulling effect as the one noticed in the case of chlorine substituted esters, and thus reduces the donor ability of the oxygen of the carbonyl group. A negative bathochrome effect gives an indication that C=O group is involved in co-ordination. On the other hand a positive shift is observed for the C≡N stretching frequency. In our work (1) on the complexes of group IV halides with dinitrile series it was pointed out that on co-ordination the C≡N stretching frequency is increased. Coerver and Curran (7) working with mononitriles and $TiCl_4$, BCl_3, and $SnCl_4$ compounds reported a positive shift of the same order as obtained in the case of ethyl cyanoacetate complexes.

To investigate the relative influence on the stretching frequencies of the two donor groups when only one of them is involved in co-ordination, $BCl_3.NCCH_2COOEt$ was prepared. Though the boron trichloride compound was prepared in large excess of BCl_3 the analytical results confirmed the one to one composition. The infrared spectrum of this compound did not indicate any marked increase in the C≡N frequency while C=O and C′—O stretching frequencies showed marked negative shifts. This is an indication that co-ordination through the carbonyl group has no marked effect on the cyano stretching frequency of the ligand, but does influence the C′—O stretching frequency as shown in the boron trichloride complex.

Another point worth mentioning is that the infrared spectra of 1:1 ethyl cyanoacetate

complexes are similar to those of the complexes of halogenated esters with $TiCl_4$ in the regions attributed to C=O and C′—O absorption. This leads one to the conclusion that titanium in the compounds of halogenated esters exhibits a co-ordination number five in the 1:1 addition compounds, and a co-ordination number six in the 1:2 addition compounds. These two types of compounds may be assumed to have co-ordination through the carbonyl group only of the monoester molecule. The lowering of the C′—O band in the infrared spectra of these complexes might be due to the mutual interaction of the C=O and C′—O groups. Moreover, a similar lowering of C′—O stretching frequency in boron trichloride complex, where only the carbonyl group is co-ordinating, further supports our interpretation. If the above interpretation was not true then the central metal atom in the ethyl cyanoacetate complexes would have a co-ordination number seven, forming per molecule of complex two chelate rings of six and four atoms. This situation would put an extra strain on the ligand molecule and is to be rejected.

Then, it seems, that in the complexes with the group (IV) halides, where both the cyano and the carbonyl stretching frequencies are changed on co-ordination, six-membered ring chelates are formed. This interpretation is further supported if the melting points of $TiCl_4.NCCH_2COOEt$ (150–152° C) and that of $TiCl_4.CH_3COOEt$ (110–111° C) are compared. In the work with halogenated esters it was shown that with halogen substitution both the carbonyl shifts and the melting points of the compounds fall (2). But in the present case of cyanoacetate compound the carbonyl shift is smaller (85 cm^{-1}) than for the ethyl acetate compound (148 cm^{-1}) but at the same time the melting point is much higher. This would not be the case if co-ordination through C≡N group forming a more strongly co-ordinated and more stable chelated ring was not taking place. On the basis of the above discussion it is quite reasonable to presume that in the cyanoacetate complexes the central elements exhibit a co-ordination number 6, except for the complex with boron trichloride.

From the infrared spectra of all these complexes one can see that in the cases of $TiCl_4$, $TiBr_4$, and $ZrCl_4$ complexes there is not much dissociation as seen from the shifted carbonyl stretching frequencies. But the spectrum of $SnCl_4$ compound clearly shows two carbonyl peaks, one shifted due to co-ordination and the other one in the original region due to dissociation. The low melting point of $SnCl_4$ compound and its solubility in CCl_4 and CH_2Cl_2 in comparison to titanium and zirconium compounds indicate the weakness of tin tetrachloride as a Lewis acid against the tetrahalides of titanium and zirconium mentioned above. The stability of Ti and Zr compounds in question can further be seen by comparing the shifts in C≡N stretching frequency which is maximum in the case of $TiCl_4$ compound and least with $SnCl_4$ compound. The ipsochrome effect of the cyano group in the case of $SnCl_4$ and $ZrCl_4$ compound falls considerably as compared with $TiCl_4$ compound. The reason for this behavior may be attributed to the fact that the 4*d* orbitals of zirconium and tin are more diffused in space than the 3*d* orbitals of titanium and thus lead to weaker bonds.

To investigate the possibility of co-ordination number five of titanium in $TiCl_4$ complexes an experiment, taking very large excess of $TiCl_4$ and adding cyanoester to it in methylene chloride medium, was performed. The analytical results indicate the formation of a 2:1 compound. The infrared spectrum of this 2:1 addition compound clearly shows an increase of the cyano stretching frequency and a decrease of the carbonyl stretching C=O frequency, thereby indicating that out of the two $TiCl_4$ molecules one is involved in co-ordination through the carbonyl group and the other through the cyano group of the same ligand. As shown in Table I and Table II the melting points,

carbonyl, and cyano stretching frequencies of the 1:1 and 2:1 addition compounds of $TiCl_4$ and ethyl cyanoacetates are quite similar to each other. This observation is in accordance with our previous experience with similar complexes of dinitriles (1) where almost the same ipsochrome effect of the C≡N stretching frequency for both 1:1 and 2:1 complexes was observed. As it was postulated for the 2:1 complexes of dinitriles, the central element can exhibit co-ordination number five or six depending on the absence or presence of chlorine bridging.

SOMMAIRE

Des composés de co-ordination entre le cyanoacétate d'éthyle et le trichlorure de bore, le tétrabromure de titane et les tétrachlorures de titane, de zirconium et d'étain ont été préparés. Les résultats analytiques indiquent que, suivant des conditions expérimentales identiques des composés d'addition un à un sont obtenus. De plus, en se basant sur les spectres infrarouges, on peut proposer que les composés obtenus sont de chélates à six atomes où le nombre de co-ordination 6 des éléments du groupe (IV) est satisfait.

PHOTOCONDUCTION AND SEMICONDUCTION IN MONOCRYSTALS OF THE CHARGE-TRANSFER COMPLEX, PERYLENE–FLUORANIL*

H. KOKADO,† K. HASEGAWA,† AND W. G. SCHNEIDER
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received December 10, 1963

ABSTRACT

Single crystals of the perylene–fluoranil charge-transfer complex were found to be photoconductive throughout the near ultraviolet, visible, and near infrared spectral regions. The temperature dependence of the semiconduction and photoconduction are characterized by apparent activation energies of 0.73 ev and 0.12 ev, respectively. Conductivity parallel to the *c*-crystallographic axis (along which the complex units are stacked in columns) was found to be about threefold greater than that in the perpendicular direction. Attempts to measure carrier mobilities proved unsuccessful. The results suggest extrinsic carrier generation accompanied by pronounced carrier trapping processes.

INTRODUCTION

The electronic behavior of crystalline charge-transfer complexes of aromatic molecules is of particular interest. Because of the enhanced π-electron interaction in complexes of this type the electronic conductivity may be expected to exceed that observed in pure aromatic compounds. Complexes of polycyclic aromatic hydrocarbons with iodine have very high conductivities and small energy gaps (1, 2) together with a pronounced ESR absorption (3). The complexes, however, exhibited negligible photoconductivity. Polycrystalline samples of complexes formed by the anils (chloranil, bromanil, and iodoanil) with aromatic diamines have also been investigated (4, 5). These showed moderate conductivities with apparent activation energies in the range 0.2 to 0.8 ev, and a comparatively very weak ESR absorption (6, 7). Thus in contrast to the iodine complexes, the ground state of these complexes exhibits very little ionic character. A similar behavior was found for complexes of aromatic hydrocarbons with tetracyanoethylene (8). With few exceptions previous experimental measurements have been carried out with compressed powder samples of the complexes. Photoconductivity measurements of charge-transfer complexes have not been reported. The present paper describes an investigation of the semiconduction and photoconduction behavior of single crystals of the charge-transfer complex, perylene–fluoranil (2,3,5,6-tetra-fluoro-*p*-benzoquinone).

EXPERIMENTAL

Monocrystals of the complex, approximately 10×2×2 mm, were grown from a toluene solution of the component compounds. For best results it was found necessary to adjust the relative concentration of the solution to about a 50% excess in fluoranil, the more soluble component. The crystals, which are bluish-black in color, have a prismatic habit with well developed crystal faces. Chemical analysis confirmed a 1:1 stoichiometry for the complex. A crystal structure analysis, carried out by Dr. A. Hanson (9), showed the crystal to be monoclinic with unit cell, $a = 17.3$, $b = 7.49$, $c = 6.97$ Å, and $\beta = 90.4°$ C. The structure is thus very nearly orthorhombic, the crystals tending to be elongated along the *c*-direction. There are four molecules, i.e. two complex units, in the unit cell. In common with other C.T. complexes, the donor (perylene) and acceptor (fluoranil) molecules are alternately stacked in columns which are parallel to the *c*-axis. The perpendicular interplanar spacing between neighboring coparallel donor and acceptor molecules within the column is 3.27 Å.

Electrodes were applied to the crystal specimens by means of silver paste. Conductivity measurements were carried out by means of a four-probe method to be described elsewhere (10). It was established that

*National Research Council No. 7816.
†National Research Council Postdoctoral Fellow, 1961–63.

the presence of air or oxygen had no effect on the dark conductivity or photoconductivity. Accordingly the crystals were mounted in a cell and maintained in an atmosphere of dry air saturated with fluoranil vapor. These conditions were found desirable, since, due to the appreciable volatility of fluoranil, the surface of the crystal tended to deteriorate if the cell was evacuated over extended periods of time.

The spectral dependence of the photocurrent was measured with two silver paste electrodes, one on each end of the elongated crystal, and an area between the two electrodes was illuminated. The light source consisted of an Osram XBO–1001 xenon discharge lamp together with a Beckman DV monochromator. Currents were measured with a Keithley electrometer.

RESULTS AND DISCUSSION

Table I summarizes the results of the semiconductivity and photoconductivity measurements. The results exhibit the anticipated larger (approximately threefold) conductivity

TABLE I

	$\parallel c$-direction	$\perp c$-direction
Dark conductivity (Ω^{-1} cm^{-1})(20° C)	1.5×10^{-14}	5.0×10^{-15}
Semiconduction activation energy (ev)	0.73	0.73
Photoconductivity (Ω^{-1} cm ^{1})* (20° C)	3.0×10^{-12}	—
Photoconduction activation energy (ev)	0.12	—

*Measured with 100-watt tungsten lamp at 1 meter distance.

parallel to the c-axis relative to that in the ab plane. However, the relative magnitudes of the conductivity as well as the semiconduction activation energy are only slightly lower than those usually found in aromatic hydrocarbons (11). This implies that the ground state of the complex has relatively little ionic character. The relatively weak ESR absorption observed in crystals of the complex is consistent with this conclusion.*

The photoconductivity of the complex exhibits a characteristic temperature dependence with an apparent activation energy of 0.12 ev. This may be compared with the corresponding value of 0.17 ev observed in anthracene crystal photoconduction (12). The spectral dependence of the photoconductivity is illustrated in Fig. 1(*a*). Since even the thinnest crystals were virtually opaque to visible light a satisfactory absorption spectrum could not be obtained. Figure 1(*a*) shows the short-wavelength absorption spectrum of the complex measured as a Nujol mull. Under these conditions the charge-transfer band could not be satisfactorily measured. A charge-transfer band centered at 670 mμ was however observed in a toluene solution of the complex. From measurements on sublimed films a low-level absorption throughout the range from 700 to 1300 mμ was indicated. The absorption from 350 to 450 mμ arises mainly from the perylene component of the complex.

The photocurrent response shown in Fig. 1(*a*) has not been corrected for the intensity and dispersion of the light source. It is thus only an indication of spectral activity and not a measure of relative quantum efficiency. Photocurrents were detectable over the entire spectral range measured, 350 to 1500 mμ. The xenon lamp emits a number of strong lines in the near infrared region. Figure 1(*b*) shows for comparison the response of a PbS cell in the region 700 to 1300 mμ when used in place of the crystal complex. Also shown is the region from 350 to 700 mμ recorded by a conventional photocell. It can be seen that the complex exhibits a peak activity between 450 to 500 mμ, and a surprisingly broad activity in the infrared.

Although a true absorption edge or a photoconduction threshold could not be established, it is evidently less than 1 ev. Considering also the measured semiconduction activation energy of 0.73 ev, charge carrier generation would appear extrinsic in nature.

We are greatly indebted to Dr. A. Reddoch for carrying out the ESR measurements.

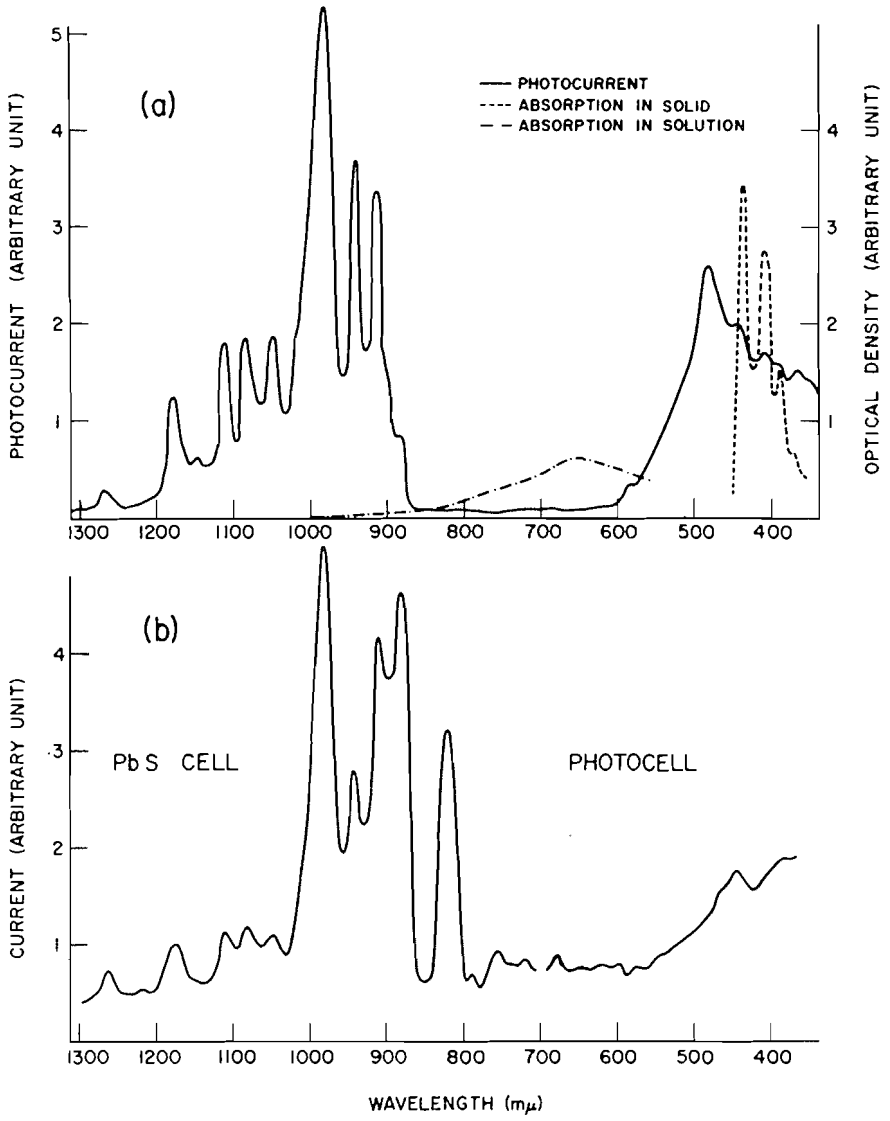

FIG. 1.

There is also evidence of strong carrier trapping effects. For example the photocurrent rise time and decay time are relatively long, particularly in the red and infrared regions, and, as is evident from Fig. 2, they also vary with wavelength. Contributions to the current due to thermal heating of the crystal by the illumination employed in these experiments is negligibly small.*

Attempts were made to determine carrier mobilities by measuring carrier transit times in the crystal of the complex using the microsecond light-flash technique (1, 3). The resulting photocurrent pulse exhibited a fairly rapid exponential decay, indicative of either

*Assuming all the radiant energy incident on the crystal is absorbed, and that no heat is lost, it is estimated the maximum temperature rise of the crystal is approximately 0.2° C per minute. On the other hand, on the basis of the known temperature dependence of the dark current, a temperature rise of 67° C would be required to thermally generate currents of the magnitude of those observed on illumination.

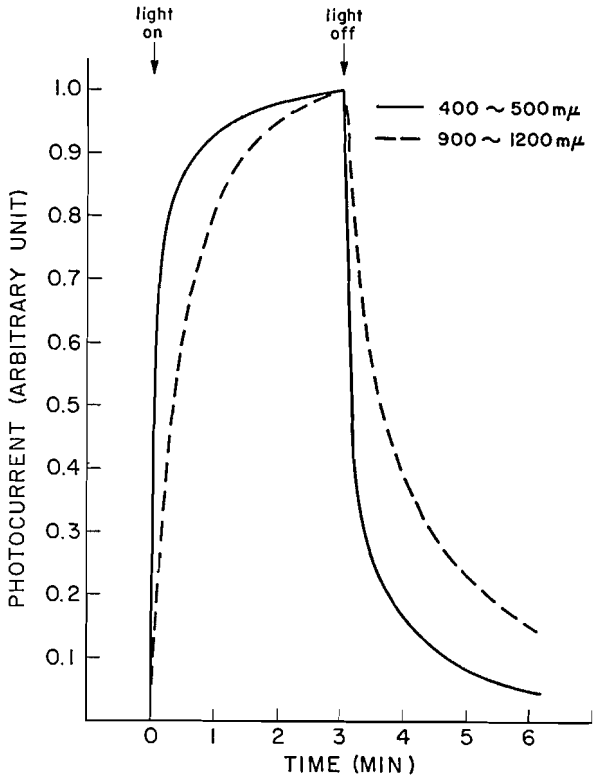

FIG. 2. Rise and decay of photocurrent in perylene–fluoranil monocrystal.

comparatively high mobilities, or of unusually short carrier lifetimes. Attempts to measure carrier transit times along the *c*-axis in crystals 1.0 to 1.5 cm long by the Haynes and Shockley method (14) also proved unsuccessful. This would appear to support the possibility that the carrier lifetime is reduced by trapping effects, although this point requires further investigation.

Preliminary measurements were also carried out on single crystal specimens of the complexes; perylene–chloranil, perylene–TCNQ (tetracyanoquinodimethan), and pyrene–chloranil. All of these crystals are blue-black in color and all proved to be photoconductive on illumination with a tungsten light source. However, in all cases the photoconductivity was somewhat less than that of the perylene–fluoranil complex.

THE GLUCOMANNAN OF BLUEBELL SEED (SCYLLA NONSCRIPTA L.)

J. L. THOMPSON[1] AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario
Received November 7, 1963

ABSTRACT

A glucomannan has been isolated from bluebell seeds. It is a linear polymer composed of D-glucopyranose and D-mannopyranose residues in the approximate ratio of 1:1.3. Methylation and periodate oxidation results support this structure. Acetolysis of the polysaccharide led to the isolation of cellobiose, 4-*O*-β-D-mannopyranosyl-D-glucose and 4-*O*-β-D-glucopyranosyl-D-mannose.

INTRODUCTION

It has been shown that seeds and food reserves of some plants of the family Liliaceae contain glucomannans (1). Proof of the presence of glucomannans in plant materials can be of taxonomic value, so that it was of interest to investigate the food reserve of other seeds from this family. Accordingly, the seeds of the English bluebell (*Scylla nonscripta* L.), a member of the Liliaceae, were examined. The powdered alcohol-extracted seeds were found to contain an alkali-soluble polysaccharide which formed an insoluble copper complex and which on hydrolysis yielded D-glucose and D-mannose in the ratio of 1:1.3.

The polysaccharide was obtained as a white powder which on drying rapidly became insoluble in all the common solvents. However, it was found possible to obtain a solution of the polymer in water by dissolving it in aqueous urea solution containing sodium hydroxide.

The methylated polymer on hydrolysis yielded mainly 2,3,6-tri-*O*-methyl-D-glucose and 2,3,6-tri-*O*-methyl-D-mannose which are not readily separated. Very small amounts of a 2,3,4,6-tetra-*O*-methyl hexose (tentatively identified as a D-glucose derivative) and di-*O*-methyl hexose (not identified) were also detected. No attempt was made to isolate the di-*O*-methyl fraction which was very small in amount. The apparent low methoxyl content (42.5%) (see experimental section) of the methylated polysaccharide indicates that it might not have been completely methylated. Experience has shown that end groups are methylated more rapidly than is the main body of the polysaccharide. It is unlikely that the yield of methylated end group is greatly underestimated. The oxidation by periodate of several preparations of polysaccharide was studied. In general it was observed that oxidation proceeded satisfactorily if it was carried out with 0.103 *M* periodate at 2° C or with 0.015 *M* periodate at room temperature. At the end of these experiments the consumption of periodate was approximately 1 mole (±0.05) per mole of hexose. The yield of formic acid corresponded to a chain length of 170–230 units. When the oxidation was made with 0.1 *M* periodate at room temperature overoxidation occurred. The periodate-oxidized polymer yielded no detectable hexose sugar after hydrolysis by acid, indicating the absence of 1,3-linked sugars. Acetolysis of the polymer afforded D-glucose, D-mannose, 4-*O*-β-D-glucopyranosyl-D-glucose (cellobiose), 4-*O*-β-D-mannopyranosyl-D-glucose, and 4-*O*-β-D-glucopyranosyl-D-mannose, all of which were obtained crystalline. 4-*O*-β-D-Mannopyranosyl-D-mannose was tentatively identified on the basis of chromatographic evidence.

The above results, the 2*b* type absorption shown by the polymer in the infrared and

[1]*Present address: Collège Militaire Royal de Saint-Jean, Saint-Jean, Québec.*

For personal use only.

its optical rotation (−24°) indicate that the polysaccharide is linear and is built up in the main of beta 1 → 4-linked D-glucopyranose and D-mannopyranose residues terminated at the non-reducing end by a D-glucopyranose residue and that it is very similar in structure to glucomannans which have been isolated from seeds and bulbs of other members of the family Liliaceae.

EXPERIMENTAL

Paper Chromatography

Paper chromatography was carried out by the descending method, using Whatman No. 1 paper. All paper chromatograms were sprayed with a solution of *p*-anisidine hydrochloride in butanol-1 (2% w/v) and then heated in an oven at about 120° to reveal the positions of the sugars. The solvent systems used for development were: (1) ethyl acetate : acetic acid : formic acid : water (18:3:1:4, v/v); (2) butanol-1:pyridine : water (10:3:3, v/v); (3) benzene:butanol-1:pyridine:water (1:5:3:3, v/v); (4) butanol-1:ethanol:water (3:1:1, v/v); and (5) butanol-1:ethanol:water (4:1:2, v/v).

Concentration of solutions was carried out under reduced pressure unless otherwise stated.

Preparation of Bluebell Polysaccharide

The seeds of the bluebell (*S. nonscripta* L.) were collected near High Wycombe, England, in August 1939. They were powdered in a mill and extracted exhaustively with methanol. The extracts, which contained a crystalline saponin-like material, were discarded. Several preliminary experiments were made in order to obtain the best yield of undegraded polysaccharide from the seeds. The following experimental procedure gave good results.

Preparation of the Polysaccharide (with Exclusion of Air–N_2 Atmosphere)

The dry methanol-extracted seeds (58.1 g) were extracted for 12 hours and then for 10 hours with cold water (750-ml portions) which was decanted and discarded. The seeds were then suspended in hot boiled-out water (1 l.) and homogenized in a Waring Blendor for 5 minutes. The mixture was stirred overnight (N_2 atmosphere) and centrifuged. The water contained only traces of polysaccharide and was discarded. The residue from the hot water extract was stirred overnight with sodium hydroxide (1 *N*, 1 l.) which had been prepared from oxygen-free water. The mixture was centrifuged and the extract was poured into ethanol (2 l.). The precipitate was collected and dissolved in sodium hydroxide (1 *N*, 400 ml). Fehling's solution (75 ml) was added slowly to the solution, which was vigorously stirred. The precipitated copper complex was collected and dispersed in water (400 ml). Dilute cold hydrochloric acid was then added until the complex had dissolved, the solution then had pH 4. The solution was poured into ethanol (1 l.) and the precipitate was collected and washed with ethanol, acetone, and then with ether, and dried over phosphoric oxide. (Yield 5.38 g.)

The residue from the previous extraction was extracted with a solution of urea (50 g) and sodium hydroxide (100 g) in water (1 l.) for 36 hours. The mixture was centrifuged and the clear solution was poured into ethanol (2 l.). The precipitate was extracted with sodium hydroxide (1 *N*, 200 ml) and after 1 hour the suspension was centrifuged. The soluble material (0.73 g) was isolated as the insoluble copper complex and the alkali-insoluble polysaccharide was obtained in 5.9% yield (3.43 g).

The residue from the above extraction was extracted for 3 days with a solution of sodium hydroxide (100 g) and urea (50 g) in water (1 l.). The mixture was centrifuged and the supernatant solution was poured into ethanol (2 l.). The precipitate was collected, washed with ethanol, acetone, and ether, and dried (A). The residual seeds were again extracted with urea and sodium hydroxide solution (as above) but for 4 days. The soluble material isolated as described above was combined with A. Total yield 29.55 g (50.9%). A final extraction of the seeds yielded a further 1.22 g of product. Total yield 40.31 g (69.5%). The major fraction (29.55 g above) was refractionated by dissolving it in water (1500 ml) containing urea (75 g) and sodium hydroxide (150 g). Fehling's solution (75 ml) was added and the precipitated copper complex was collected and converted to the dry polysaccharide (X) by the usual procedure. Yield 13.15 g (44.6%), $[\alpha]_D$, −24°±1° in sodium hydroxide (10%) and urea (5%) solution. A further addition of Fehling's solution yielded a second fraction (Y) (7.58 g, 25.7%) of $[\alpha]_D$ −15°±1° in sodium hydroxide (10%) and urea (5%) solution. Both polysaccharides X and Y showed type 2*b* absorption in the infrared, characteristic of β-linked glycopyranosides (3). Zone electrophoresis in 2 *N* potassium hydroxide solution on glass fiber strips showed one component only to be present in fraction X (4). All the fractions gave mannose and glucose on hydrolysis in a ratio varying from 1.3:1 to 1.0:1. Trace amounts of arabinose or xylose were detectable in some of the fractions.

Methylation of the Polysaccharide

A sample of the polysaccharide (2.1 g) was methylated twice by the Haworth procedure (5). After the first methylation the product separated as a solid, when the reaction mixture was heated to the boiling point. The methylated polymer was isolated by chloroform extraction of the solution after the second methylation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

This material was then further methylated twice by the Kuhn procedure (6(*a*)). The product (1.2 g) was extracted under reflux with mixtures of hexane and chloroform containing 100%, 95%, 90%, 80%, and 65% (v/v) in turn. The fraction which was soluble in 80% hexane (0.64 g) had $[\alpha]_D$ − 18° (*c*, 4.0 in chloroform) and OMe, 42.5% (mean of three determinations). The infrared spectrum of the sample in potassium bromide was compared with that of a disc of potassium bromide alone. No difference could be detected in the area of OH peak absorption. It was concluded that the low methoxyl values are due in the main to the presence of non-carbohydrate impurities and to the errors in the procedure for the determination of methoxyl. A sample of each of the 95%, 90%, 80%, and 65% hexane-soluble fractions on hydrolysis followed by paper chromatographic examination of the hydrolyzate (solvent 4) showed the apparent presence of one component which moved at the speed and gave the color reactions of a tri-*O*-methyl hexose.

Hydrolysis of the Methylated Glucomannan

The polysaccharide (604 mg, 80% hexane fraction) was dissolved in a mixture of water (12.5 ml) and sulphuric acid (16.7 ml), i.e. in 70% sulphuric acid (w/w) and the mixture was kept at room temperature for 12 hours. The solution was then diluted with water to 300 ml and boiled under reflux for 7 hours. This procedure minimizes demethylation (6(*b*)). The mixture of the syrupy sugars (524 mg) isolated in the usual way was separated on a column of cellulose, using butanol-1 half-saturated with water as irrigant. The effluent was collected portionwise and the sugars isolated in the usual way (7). The *first fraction* (ca. 1 mg) had $[\alpha]_D$ + 20° (*c*, 0.07 in water), moved at the speed of a tetra-*O*-methyl hexose, and on demethylation with boron trichloride (8) gave glucose, detected chromatographically (solvents 2 and 4). The paper chromatogram was run for 4 days to ensure a good separation between the sugars. The tri-*O*-methyl fraction (551 mg) was dissolved in methanolic hydrogen chloride (124 ml, 1% w/v) and the optical rotation of the solution (+ 23.6°) was followed until it became constant at − 5.7° in 20 hours. The hydrogen chloride was neutralized with silver carbonate and the sugars were isolated in the usual way. The syrup was fractionated on Whatman 3MM paper and the tri-*O*-methyl mannose fraction was thus separated from the methyl tri-*O*-methyl glucoside fraction (9).

The *tri-O-methylmannose* (93.9 mg) was characterized as the 1,4-di-*p*-nitrobenzoate of m.p. 187–188° and $[\alpha]_D$ +36°±2° (*c*, 1.0 in chloroform) (9), yield 61.3 mg from 80 mg syrup. De-*O*-methylation of the tri-*O*-methyl fraction with boron trichloride showed the presence (paper chromatography, solvent 4) of mannose only. On the other hand gas–liquid chromatographic analysis (10) of the derived glycosides showed the presence of a trace of the methyl 2,3,6-tri-*O*-methyl-D-glucosides.

The *tri-O-methylglucose fraction* (156 mg) contained none of the mannose isomer since de-*O*-methylation of a sample with boron trichloride yielded glucose only (detected chromatographically). The syrup was converted to the 1,4-di-*O*-*p*-nitrobenzoate in the usual way (9). The product (24 mg) was recrystallized from methanol and then had m.p. 189–190° and $[\alpha]_D$ −31°±2° (*c*, 0.83 in $CHCl_3$), in agreement with the constants recorded in the literature. The *di-O-methyl fraction* was very small indeed (from chromatographic evidence and from the yields of tri-*O*-methyl fraction isolated) and was not examined.

Periodate Oxidation of the Polysaccharide

A sample of the polysaccharide (36.3 mg), which was insoluble in water, was oxidized with periodate (25 ml, 0.015 *M*) in the usual way and the periodate consumption was determined spectrophotometrically (2). After 70 hours 0.9 mole of periodate per $C_6H_{10}O_5$ had been consumed. A second experiment, using a solution of the polysaccharide which had been dialyzed against distilled water, showed the uptake of 0.96 mole of periodate per $C_6H_{10}O_5$ in 137 hours. The determination of formic acid production was unsatisfactory when oxidation was carried out with 0.1 *M* periodate at room temperature. The periodate-oxidized polysaccharide after 70 hours of oxidation (see above) was dialyzed to remove inorganic salts and the residue when tested with Molisch reagent gave a faint positive test for hexoses. However, when the oxidized polysaccharide was hydrolyzed with hot sulphuric acid (0.1 *N*) and the hydrolyzate isolated and examined chromatographically, neither glucose nor mannose could be detected.

Acetolysis of the Polysaccharide

As a result of several experiments the following conditions were chosen for acetolysis of the polysaccharide. The material, polysaccharide X (5.0 g), was treated at 0° with a stirred mixture of ice-cold acetic anhydride (250 ml) and sulphuric acid (50 ml) for 30 minutes. After this time the mixture was allowed to come to room temperature when the polysaccharide slowly dissolved. After 6½ hours the mixture was poured with stirring into ice and water (ca. 1 l.). The derived acetates (9.8 g) were isolated by chloroform extraction in the usual fashion. They were de-*O*-acetylated by the Zemplen procedure (11) and fractionated first on a resin column (12) and then on sheets of Whatmann 3 MM paper, using solvent 4.

The following sugars were isolated and identified.

α-D-*Glucose* (98 mg) was isolated as the crystalline solid of m.p. 140–141° and $[\alpha]_D$ +48° (equilib.) (*c*, 1.14 in water). The infrared spectrum was indistinguishable from that of authentic α-D-glucose.

D-*Mannose* (46 mg) was a syrup from which D-mannose phenylhydrazone of m.p. 195–196° and $[\alpha]_D$ + 21±3° (*c*, 0.3 in pyridine) was prepared. The infrared spectrum of this compound was essentially the same as that of an authentic specimen.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Cellobiose (32 mg) after recrystallization from ethanol had $[\alpha]_D$ +29°±1° (*c*, 1.0 in water) and m.p. 230–232°. 4-*O*-β-D-Mannopyranosyl-D-glucose was detected (chromatographically, solvent 3) in the mother liquor and also in trace amounts in the infrared spectrum of the crystalline cellobiose fraction (above).

4-O-β-D-Mannopyranosyl-D-glucose (18 mg) had m.p. 170° and $[\alpha]_D$ +14°±1° (const.) (*c*, 1.07 in water) after recrystallization from ethanol. The infrared spectrum of the compound was in good agreement with that prepared from an authentic specimen.

4-O-β-D-Glucopyranosyl-D-mannose behaved as a single component chromatographically. Its rate of movement relative to cellobiose was 1.69 in solvent 3. It crystallized on nucleation with an authentic specimen and then had $[\alpha]_D$ +10° → +8.3° in 5 hours (*c*, 0.6 in water) (13) and m.p. 128–137°. Its infrared spectrum was indistinguishable from that of an authentic specimen.

The mannobiose fraction (16 mg) was chromatographically pure (solvent 3) and had the mobility of 4-*O*-β-D-mannopyranosyl-D-mannose but it could not be induced to crystallize (13).

THE RESPONSE TO 14 MEV NEUTRONS OF SOME CHEMICAL DOSIMETER SYSTEMS*

W. A. Armstrong and W. G. Humphreys
Defence Research Chemical Laboratories, Department of National Defence, Ottawa, Canada
Received October 28, 1963

ABSTRACT

The response to 14 Mev neutrons of 10^{-3} *M* ferrous sulphate – 0.4 *M* H_2SO_4, 10^{-4} *M* ceric sulphate – 0.4 *M* H_2SO_4, 10^{-3} *M* calcium benzoate, and 10^{-4} *M* terephthalic acid – 4×10^{-4} *M* NaOH solutions has been investigated. *G* values as follows:
G(Fe III) = 10.5 ± 0.2, *G*(Ce III) = 3.13 ± 0.06, *G*(salicylic acid) = 0.316 ± 0.006, and *G*(hydroxyterephthalic acid) = 0.474 ± 0.007. These results are compared with those obtained when the same solutions are irradiated with Co^{60} γ-rays. Although the response to 14 Mev neutrons is only about one half the response of Co^{60} γ-radiation, the calcium benzoate and the terephthalic acid systems can measure doses as low as 20 and 2 rads, respectively.

INTRODUCTION

The dosimetric properties of the aqueous calcium benzoate and terephthalic acid systems have been studied in this laboratory for X- and γ-radiations of various energies (1, 2, 3). In this paper the response of these as well as the ferrous sulphate and ceric sulphate systems to 14 Mev neutrons is described and compared with their response to Co^{60} γ-radiation.

EXPERIMENTAL

Materials

Triply distilled water (one distillation from alkaline $KMnO_4$ followed by distillation from dilute H_2SO_4) was used in all solutions and preparations. All chemicals were reagent grade unless otherwise stated. Irradiation vessels were cleaned in an HNO_3–H_2SO_4 mixture (1:3) and washed many times with once-, twice-, and thrice-distilled water. Finally steam from thrice-distilled water was passed through.

The purification of materials and the preparation of solutions used in the 10^{-3} *M* ferrous sulphate – 0.4 *M* H_2SO_4, 10^{-3} *M* calcium benzoate, and the 10^{-4} *M* terephthalic acid – 4×10^{-4} *M* NaOH dosimeter systems has been previously described (4, 2, 3).

The preparation of the 10^{-4} *M* ceric sulphate – 0.4 *M* H_2SO_4 system was similar to that recently reported (5) with one significant change. The dosimeter solution was electrolyzed to oxidize the cerous ions which are always present to some extent in ceric solutions. Solutions so treated could then be used for the measurement of doses as low as 1000 rads. The electrolysis was performed in a simple cell equipped with platinum electrodes and a U-shaped bridge filled with 0.4 *M* H_2SO_4. While being stirred with a glass-encased magnet, the solutions were electrolyzed overnight by means of a $3\frac{1}{2}$-volt dry cell which gave a current of about 0.2 ma through the system. This treatment had no apparent effect on the dosimetric properties of the system since electrolyzed and untreated solutions gave identical results when irradiated with doses of more than 5000 rads. Since the ceric sulphate dosimeter is extremely sensitive to the presence of trace impurities, fresh samples were electrolyzed each day and the cerous ion yield measured for a given Co^{60} γ-ray dose.

Standard 0.5-g sulphur tablets supplied by Atomic Energy of Canada Limited were used in the sulphur activation studies.

Analytical Techniques

The ferric ion yield in irradiated 10^{-3} *M* ferrous sulphate – 0.4 *M* H_2SO_4 solutions was determined by its optical absorption at 224 mμ using a molar extinction coefficient of 4565 at 25° with a temperature coefficient of 0.13% per ° C (6).

The amount of cerous ion formed in irradiated samples of 10^{-4} *M* ceric sulphate – 0.4 *M* H_2SO_4 was determined by comparing its fluorescence intensity with that of a standard cerous sulphate – 0.4 *M* H_2SO_4 solution. The measurements were made with an Aminco–Bowman spectrophotofluorometer using an exciting wavelength of 254 mμ and recording the fluorescence emitted at 350 mμ. Ceric ions reduce the cerous ion fluorescence presumably by absorbing some of the exciting and emitted light. It has been shown that *Q*,

**Issued as D.R.C.L. Report No. 426.*

the ratio of Ce III fluorescence in the absence and presence of Ce IV, may be determined from the equation $\log Q = 3750$ [Ce IV] (5), where the concentration of ceric ion is determined from its absorption at 320 mμ using the value of 5580 for the molar extinction coefficient (7). Hence the formula for calculating the concentration of cerous ion in an irradiated sample is

$$[\text{Ce III}] = [(F - B)/F_S].S.Q,$$

where F is the sample fluorescence, B the blank fluorescence of the unirradiated solution, F_S the fluorescence of the cerous sulphate standard, and S the concentration in g-ions per liter of cerous ion in the cerous sulphate standard.

The fluorometric methods for the determination of salicylic acid in irradiated 10^{-3} M calcium benzoate solutions and hydroxyterephthalic acid in irradiated 10^{-4} M terephthalic acid – 4×10^{-4} M NaOH solutions have been described elsewhere (2, 3).

The specific activity of the activated sulphur pellets was measured by the Radiation Dosimetry Branch of the Biology and Health Physics Division, Atomic Energy of Canada Limited.

Irradiation Techniques

Samples (5.0-ml) were irradiated in Vycor tubes about 10 cm long and having an O.D. of 1.5 cm and an I.D. of 1.3 cm. A small piece of "Saran" was wrapped over the mouth of each tube to keep out dust and to prevent evaporation.

Monoenergetic neutrons (14-Mev) were obtained from a 150 kv Cockroft–Walton accelerator by means of the $H^3(d,n)He^4$ reaction. Four sample tubes were mounted on an aluminum turntable which was bolted to the target assembly flange in such a way that the tubes could be rotated in front of and as close as possible to the target. The turntable was rotated at 60 r.p.m. and the average distance of each sample tube from the target during irradiation was about 4 cm. The average dose rate was approximately 13 rads/minute and total doses of about 2000 rads were usually given. Preliminary experiments showed that each of the four sample tubes received the same dose during an irradiation. Since the γ-ray contamination has been reported as less than 5% of the neutron dose (8), it was considered negligible. A Tullamore BF_3 counter was used to monitor the runs but it was not calibrated.

Co^{60} γ-irradiations were performed at a dose rate of 17 rads/minute with a 500-c source.

RESULTS

Sulphur Activation Studies

Standard sulphur tablets 1.134 cm in diameter, 0.322 cm thick, and weighing 0.509 g were irradiated in the same Vycor tubes as were used for the chemical systems. Each tube was marked with a diamond pencil at the 5.0 ml level and the distance to the bottom of the tube marked off in thirds. Four tablets were placed in each tube, one at the bottom and one at each mark, the intervening spaces being filled with sulphur powder. Two such tubes were irradiated together with two tubes each containing 5.0 ml of ferrous sulphate solution. From the average specific activity of the four tablets in each tube and the half life of P^{32} (14.3 days), the number of P^{32} atoms/mg formed at the time of irradiation was calculated. From the dimensions of the sulphur tablets, the weight of sulphur, as compacted in the tablets, equivalent to the 5.0-ml volume was determined. These calculations are outlined below:

$$\text{specific activity} = -dN/dt = N\lambda$$

where

$$N = \text{no. of } P^{32} \text{ atoms/mg}$$

and

$$\lambda = \text{the disintegration constant} = 0.0485 \text{ days}^{-1},$$

$$N_0 = Ne^{\lambda t},$$

where N_0 = no. P^{32} atoms/mg at the time of irradiation and t is the time when the activity was measured. Since the volume of a sulphur pellet is 0.325 cm^3, the number of pellets equivalent to 5.0 ml is 15.4 and the weight of sulphur is 7.83 g. Thus the total number of P^{32} atoms that would have been formed in a 5.0-ml irradiated volume is $7.83 \times 10^3 N_0$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and the neutron fluence, the term recommended by the International Commission on Radiological Units and Measurements (9), is

$$[(7.83\times10^{3}\ N_0)/\sigma\cdot S]\ \text{neutrons/cm}^2$$

where σ = the cross section for the reaction $S^{32}(n,p)P^{32}$

$= 0.248\times10^{-24}\ \text{cm}^2$ (10)

S = number of S^{32} atoms in 5.0 ml

$= (7.83/32)\times6.023\times10^{23}\times0.9506$ (95.06% of natural sulphur is S^{32}).

Randolph (11) has calculated that D, the ratio of dose rate to neutron flux density for 14 Mev neutrons interacting with water, is 0.449 Mev/(g-sec-flux). It follows that D', the ratio of dose to fluence, is 7.19×10^{-9} rads/neutrons cm^{-2}. Since about 72.3% of the dose absorbed in water is due to proton recoils (11) and, since the concentrations of elements other than hydrogen and oxygen are very small, it is assumed that the dose absorbed for a given neutron fluence in a sample of $10^{-3}\ M$ ferrous sulphate – 0.4 M H_2SO_4, $10^{-4}\ M$ ceric sulphate – 0.4 M H_2SO_4, $10^{-3}\ M$ calcium benzoate, or $10^{-4}\ M$ terephthalic acid – $4\times10^{-4}\ M$ NaOH is the same as that absorbed by a water sample exposed under similar conditions. The errors involved in this dose determination include an uncertainty of ±5% in the sulphur activation measurements and ±5% in the value of the $S^{32}(n,p)P^{32}$ cross section. Randolph (11) quotes a ±7.5% uncertainty on his value for D but states that the real error should be considerably less. Thus the total error in dose measurements is about ±15%.

In Table I the dose determined by this technique is compared with the yield of ferric

TABLE I

G(Fe III) for 14 Mev neutrons

N_0 (10^6 atom/mg)	Fluence (10^{11} n/cm^2)	Dose (rads)	(Fe III) (10^{-5} moles/l)	G(Fe III) (molecules/100 ev)
1.53	3.44	2480	2.64	10.3
1.49	3.36	2410	2.64	10.6
1.49	3.36	2420	2.63	10.5
1.47	3.30	2380	2.63	10.7

ions in a ferrous sulphate solution which was exposed simultaneously with a sulphur sample. The results give G(Fe III) = 10.5±0.2. It is realized that wall effects introduce an unknown error in the dose determinations. However, a comparison of fluence determinations and ferric ion yields in Vycor tubes of I.D. 0.9 cm with similar measurements in tubes of I.D. 2.3 cm indicate that the error due to proton leakage is small in comparison with other experimental errors.

Chemical Studies

G(Ce III) was determined using G(Fe III) reported above by comparing the concentration of cerous ions formed in $10^{-4}\ M$ ceric sulphate – 0.4 M H_2SO_4 with the concentration of ferric ions formed in $10^{-3}\ M$ ferrous sulphate – 0.4 M H_2SO_4 when two samples of each solution were irradiated together. The results listed in Table II give G(Ce III) = 3.13±0.06. G(salicylic acid) for $10^{-3}\ M$ calcium benzoate and G(hydroxyterephthalic acid) for $10^{-4}\ M$ terephthalic acid – $4\times10^{-4}\ M$ NaOH determined in a similar way were found to be 0.316±0.007 and 0.474±0.007, respectively (Tables III and IV). the errors involved in both the sulphur activation and chemical determinations it is felt that G(Fe III) is accurate to about $\pm 17\%$, G(Ce III) to $\pm 25\%$, G(salicylic acid) to $\pm 20\%$, and G(hydroxyterephthalic acid) to $\pm 20\%$.

The results of the Co^{60} γ-irradiation experiments are given in Table V. Each G value is

TABLE V

Comparison of G-values for 14 Mev neutrons and Co^{60} γ-rays

	Co^{60} γ	14 Mev neutrons	% Difference
G(Ce III)	2.63 ± 0.05	3.13 ± 0.06	19.0
G(Sal)	0.654 ± 0.011	0.316 ± 0.006	51.7
G(HTA)	0.988 ± 0.009	0.474 ± 0.007	52.0

the average of 10 results together with the standard deviation. The dose rate was determined with the ferrous sulphate dosimeter assuming G(Fe III) = 15.5 and applying the proper density corrections when the dose rate in calcium benzoate and terephthalic acid solutions was required.

As the response to 14 Mev neutrons of the benzoate and terephthalate systems is about one half as great as to Co^{60} γ-radiation, γ-ray contamination of 5% or less in the neutron

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

irradiations (8) might introduce significant errors in the measured G-values for neutrons of these systems. At present there is no way of accurately determining the amount of γ-ray contamination.

DISCUSSION

As a larger fraction of radicals react with each other at higher LET, the yield of ferrous ion oxidation decreases with an increase in LET. The value reported here of $G(\text{Fe III}) = 10.5$ for 14 Mev neutrons falls within the range of values given by Schuler and Allen (12) for deuterons of 8 to 20 Mev (G(Fe III) 9.7 to 11.5) and by Anderson and Hart (13) for protons of 4.8 to 10.6 Mev (G(Fe III) 9.27 to 10.88).

The response of the ceric sulphate system has been shown to be almost independent of LET for helium ions of 11 Mev to 33 Mev and deuterons of 8 Mev to 18 Mev (14) as well as for protons of 11 Mev to 23 Mev (15). Barr and Schuler (14) found G(Ce III) to be 2.33 for Co^{60} γ-radiation and 2.85 for radiations having an LET of about 1.2 ev/Å, the value reported for 14 Mev neutrons (8). More recently Hochanadel *et al.* (15) measured G(Ce III) to be 2.48 for Co^{60} γ-radiation and 2.95 for protons of 11 Mev to 23 Mev. In view of the experimental errors involved our corresponding values of 2.63 and 3.13 are considered to be in good agreement with those of Hochanadel.

The yields of salicylic acid from calcium benzoate solutions and hydroxyterephthalic acid from terephthalic acid solutions are much lower for 14 Mev neutrons than for Co^{60} γ-radiation. This is to be expected if reaction with OH radicals rather than H_2O_2 is the important step in the hydroxylation process since G_{OH} decreases while $G_{H_2O_2}$ increases with increasing LET. It is interesting to note that the radical yield G_{OH} decreases from 2.90 for Co^{60} γ-radiation (16) to 1.45 for 5.4 Mev protons (14), a change comparable to that in G(salicylic acid) and G(hydroxyterephthalic acid) for a similar change in LET.

Although the response of the benzoate and terephthalic acid systems to 14 Mev neutrons is only about one half the response to Co^{60} γ-radiation the extreme sensitivity of the fluorometric analytical technique makes possible the measurement of very low neutron doses. The lower limit of this method is determined by the blank fluorescence of the unirradiated solution. This is equivalent to 10 to 20 rads with the calcium benzoate system and 1 to 2 rads with the terephthalic acid system.

ACKNOWLEDGMENTS

The authors wish to thank Mr. F. G. Strain for constructing the aluminum turntable and for operating the neutron generator. The authors are also grateful to Dr. W. G. Cross, of the Radiation Dosimetry Branch, Biology and Health Physics Division, Atomic Energy of Canada Limited, for measuring the activity of the irradiated sulphur pellets as well as for much helpful advice.

PROTON MAGNETIC RESONANCE ABSORPTION IN HIGH TEMPERATURE PHASES OF ANHYDROUS SODIUM STEARATE

M. R. Barr and B. A. Dunell
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received November 18, 1963

ABSTRACT

Nuclear magnetic resonance spectra of anhydrous sodium stearate have been observed between 114° and 320° C. The observed changes in line width and second moment suggest a grouping of the mesomorphic phases into a waxy group in which a lattice structure is preserved for the polar ends of the molecules and a group consisting of the neat and liquid phases in which diffusion takes place freely.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

INTRODUCTION

The extent of motion of the paraffin chains in sodium stearate below 114° C has been investigated previously by nuclear magnetic resonance (1). At 113° C the second moment of 6.7 gauss^2 corresponds to an amount of motion comparable to complete reorientation about the long axis of the hydrocarbon chain or possibly to extensive torsional oscillation of the chain combined with some rocking motion of the long axis itself, the polar ends of the molecules remaining fixed in a rigid layer lattice. The so-called supercurd to subwaxy phase transition is seen in the n.m.r. study as an abrupt decrease in line width and second moment occurring at 114° C. Above this transition the line width recorded by the broad line spectrometer was governed by the depth of modulation used, and the higher temperature transitions between mesomorphic phases observed by other physical methods could not be found using the broad line n.m.r. spectrometer. The work reported here is an extension of the earlier work done in this laboratory to the investigation of the n.m.r. spectrum of higher temperature phases of anhydrous sodium stearate.

EXPERIMENTAL

The sodium stearate sample was the same as the one used in the earlier work (1). Spectra were run on a Varian V-4352 high resolution n.m.r. spectrometer operating at 40 Mc/second. A minimum of six spectra were recorded at each temperature, three sweeps up field and three down, either on a Leeds and Northrup Speedomax recorder or on a photograph of the spectral trace on a Dumont 304-AR oscilloscope. The sweep was calibrated at each temperature by imposing side bands from an audio oscillator on the spectrum. At each temperature the r.f. power level was adjusted to a point below the region of saturation of signal. Temperature control was achieved by passing heated air through dewared leads past the sample tube. The temperature was measured by two thermocouples, one in the air just upstream from the sample and one in the return air stream. Thermocouple readings were controlled to within ±0.5°. Uncertainty in the temperature of the sample is approximately ±1° C near 100° C and ±4° C near 300° C. Demand on machine time precluded the possibility of equilibrating the sample for longer than 2 hours at any particular temperature, except in the special cases of two well-defined transitions at 114° and 246° C, in the vicinity of which 5 hours was allowed for equilibration.

RESULTS

Example spectra for several temperatures are shown in Fig. 1. Width of line between points of maximum and minimum slope is essentially constant at 0.06 to 0.09 gauss between 114° and 246° C. One can see, however, that line shape changes considerably in this range as the wings of the curve become progressively less intense with increasing temperature. The line width at the point of half-maximum intensity $\Delta H_{\frac{1}{2}}$ gives a measure

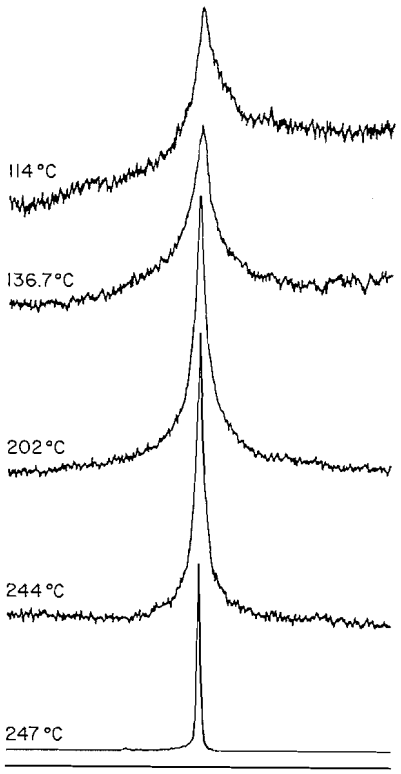

FIG. 1. Absorption spectra of sodium stearate at various temperatures between 110° and 250° C obtained from a high resolution spectrometer.

of this change in line shape and is plotted in Fig. 2 as a function of temperature. Uncertainty as to where to draw the base line because of instability due to noise and drift leads to variation of $\Delta H_{\frac{1}{2}}$ values of some 10% within a group of spectra run in succession at a particular temperature. Each point in Fig. 2 represents the average of such values for at least six spectra. Above 246° C the spectrum is effectively the same as that of water taken in the same field at room temperature.

The second moments which are plotted against temperature in Fig. 3 are also average values for at least six spectra at each temperature. Here, however, individual values are very sensitive to the position of the base line, and may vary by as much as 100% within a group of six spectra run in succession at a particular temperature. Values represented by the open circles are for spectra taken in a preliminary set of runs, and, although they were recorded at a slower sweep rate than the others, they are probably less accurate because the wings of the spectra were cut off by sweeping over an insufficient range of field. The faster sweep rate used in recording the second set of spectra (filled circles) gave a signal whose wings were less affected by noise and base-line drift. A third set of spectra, represented by triangles, shows much smaller second moments above 246° C than the other spectra do. This is thought to be caused by the third set of spectra being run in a more homogeneous field than the earlier spectra. Since we attribute significance only to the change in the second moment at 246° C, the variation from $2(10^{-5})$ to $5(10^{-4})$ gauss^2 above 246° is not important. At both ends of the temperature range 114° to

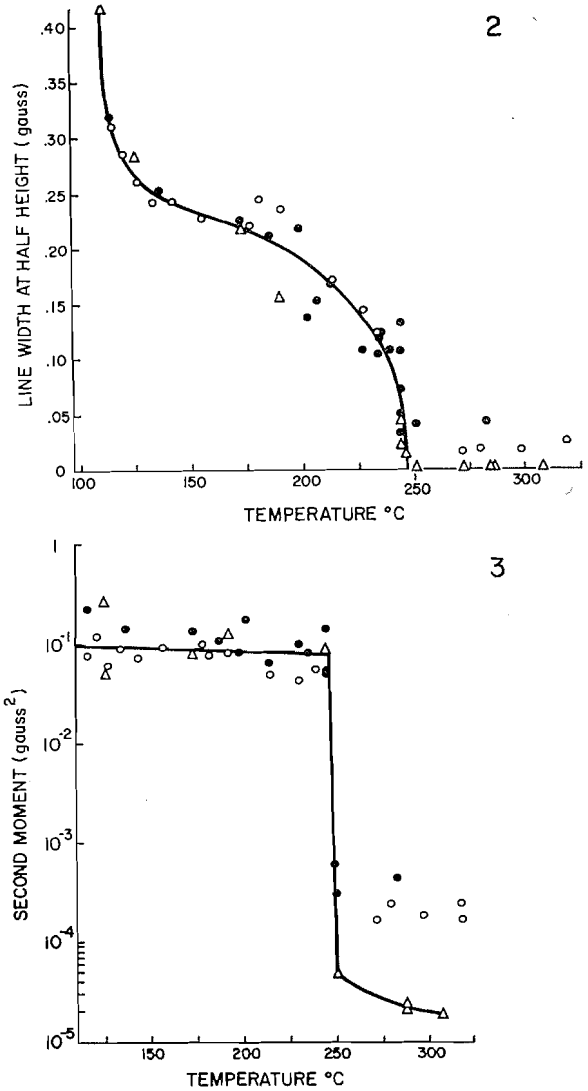

FIG. 2. Line width at half height as a function of temperature.
FIG. 3. Second moment as a function of temperature.

246° C, the observed second moments lie more or less between 0.25 and 0.05 gauss^2, so that there is no evidence of phase transition between these temperatures from second moments.

Above 245° C the second moment falls abruptly to an extremely small value.

DISCUSSION

The appearance at 114±1° C of a line which is narrow enough to observe by the high resolution technique agrees with the previously observed (1) n.m.r. transition at 114° C. From line width and second moment measurements we are led to group together the so-called subwaxy, waxy, superwaxy, and subneat phases (2) as being indistinguishable

one from another by this technique and characterized by very extensive motion of the hydrocarbon chains. The second moments of approximately 0.25 to 0.05 gauss^2 in the temperature range 114° C to 245° C, in which the group of waxy and subneat phases exists, show that the motion is much more extensive than mere rotation about the one long axis of the hydrocarbon chain. The motion is, however, probably restricted throughout this range by the constraining influence of the strongly interacting polar groups and only above 246±3° C where the second moment falls to a value of some 10^{-4} gauss^2 can the motion be said to be that characteristic of a liquid. The "neat" and isotropic liquid phases are not distinguished by this n.m.r. technique, and one might suppose that in the neat phase one is dealing with liquid character in two dimensions, or in which the hydrocarbon chains retain some semblance of parallel array even though rotation and twisting motions are extensive and diffusion takes place freely.

This n.m.r. interpretation supports the X-ray investigation of Skoulios and Luzzati (3), who classified the high temperature phases of sodium stearate into the same groups that we have made. The waxy phases and the subneat phase are understood in their work to form a group possessing a structure which consists of a set of parallel ribbons, indefinite in length, and packed in rectangular array. The polar groups fit end to end in the ribbons and the hydrocarbon chains, in a liquidlike state, fill the rest of the cell. They understand the neat phase to be a lamellar structure with a decidedly liquid character. The X-ray work, however, places the subneat to neat transition at 256° C, an assignment which agrees closely with those from the work of Vold (4) on density, 257° C, Puddington (5) on density, 259° C, Puddington (6) on light transmission, 258° C, and Ravich and Nechitaylo (7) on differential thermal analysis, 256° C. Vold's work on differential thermal analysis (8) gives this transition temperature as 238° C. The abruptness of the n.m.r. transition at 246° C appears to preclude the possibility that this is a non-co-operative transition which could be complete so far as n.m.r. is concerned at an unusually low temperature because of the comparatively low frequencies of molecular motion that are required to change the n.m.r. signal. The reason for the discrepancy between our subneat to neat transition temperature and that obtained from most other investigations is not understood.*

THE SYNTHESIS AND PROPERTIES OF THE ANHYDROUS HEXACHLOROZIRCONATES OF SODIUM AND POTASSIUM

R. L. Lister and S. N. Flengas
Department of Metallurgical Engineering, University of Toronto, Toronto, Ontario
Received December 30, 1963

ABSTRACT

The hexachlorozirconates of sodium and potassium have been produced in a closed system following the reaction:

$$ZrCl_{4(g)} + 2MCl_{(s)} = M_2ZrCl_{6(s)} \quad [1]$$

where M is Na and K, respectively. The zirconium tetrachloride was reacted at approximately 1 atm. pressure, and at temperatures of the alkali metal chloride between 425° C and 525° C. The densities, melting points, and the corresponding X-ray diffraction patterns for both compounds have been determined.

INTRODUCTION

Because of their high degree of thermal stability, alkali metal hexachlorozirconates offer interesting possibilities as a source of zirconium ions in the recovery of zirconium metal by fused salt electrolysis, especially since zirconium tetrachloride is so reactive.

Morozov *et al.* (1) have prepared sodium and potassium hexachlorozirconate by fusing calculated quantities of the salts in quartz tubes. However, no data on the composition and purity of the compounds thus prepared have been mentioned. Howell *et al.* (2), in their phase diagram study, have shown the compounds Na_2ZrCl_6 and K_2ZrCl_6 should exist, but have not isolated them.

The present investigation deals with the direct synthesis of sodium and potassium hexachlorozirconate by reacting gaseous zirconium tetrachloride with −325 mesh alkali metal chloride, a method similar to that employed in the direct synthesis of the hexachlorotitanates (3).

EXPERIMENTAL

The zirconium tetrachloride used was of commercial grade, Hafnium free, purified further by a triple distillation process. This was carried out by mixing zirconium tetrachloride with finely divided copper filings, preheating the mixture to 160° C to remove any oxychlorides of zirconium present (4), then vacuum distilling at 320° C. The condensed product was then redistilled twice, resulting in a very white zirconium tetrachloride, free of oxychlorides and impurities.

The alkali metal chlorides used were of reagent grade, purified further by vacuum degassing at about 400° C.

The sodium and potassium hexachlorozirconates were produced by the direct reaction,

$$2MCl_{(s)} + ZrCl_{4(g)} = M_2ZrCl_{6(s)}$$

where M is the sodium or potassium, respectively.

An excess of zirconium tetrachloride is placed in a pyrex boat which, in turn, is loaded into the pyrex reaction tube. A weighed amount of between 3 and 7 grams of −325 mesh alkali chloride salt is placed in another pyrex boat and loaded into the cell, as shown in Fig. 1. This step is carried out in a dry box to eliminate any contamination due to hydrolysis. The large end of the cell is then flame sealed and a constriction is made at E to minimize the thermal gradient in the cell. The entire cell is then evacuated through the vacuum outlet at F and simultaneously flamed to remove any traces of moisture in the tube. It is then vacuum sealed at F, and loaded into the furnace. The temperature of the zirconium tetrachloride is regulated to about 330° C, which corresponds to slightly less than 1 atmosphere pressure, while the alkali metal chlorides are heated to 475 ± 50° C.

After a minimum reaction time of 24 hours, the reaction cell is furnace cooled, removed from the furnace, opened at F in a dry box, and the reacted salt weighed to determine the amount of zirconium tetrachloride

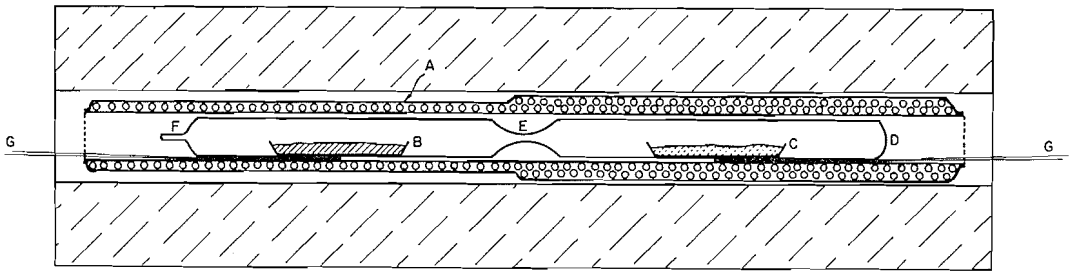

FIG. 1. Reaction apparatus: A, furnace windings; B, Pyrex boat containing purified zirconium tetrachloride; C, Pyrex boat containing alkali metal chloride salt; D, Pyrex reaction tube; E, constriction; F, vacuum-sealed outlet; G, temperature measuring thermocouples.

reacted with the alkali chloride originally placed in the boat. Thus, the exact composition of the reacted product could be easily determined.

RESULTS AND DISCUSSION

In all the preparations, approximately 3 to 7 grams of −325 mesh alkali metal chloride salt was used and the reaction time was at least 24 hours. The reaction temperature was not so critical as it was for the production of the chlorotitanates, but rather any temperature between 425 and 525° C could be readily used. The composition of the reaction products from six typical runs on both the sodium and potassium compounds are given in Table I.

Properties of the Hexachlorozirconates

At room temperature, both sodium and potassium hexachlorozirconate are a light grey color, while in the liquid state at about 25° C to 50° C above their melting points, the color observed is a reddish-orange in each case.

The melting points were determined by cooling curve techniques using the pure compounds in sealed quartz vessels. The melting point of Na_2ZrCl_6 was determined to be 646±1° C and that of K_2ZrCl_6 to be 799±2° C, which is in good agreement with those shown by Howell *et al.* (2) and Morozov *et al.* (1) in their respective phase diagram investigations.

With respect to their stability in air, the K_2ZrCl_6 appears to be slightly more stable than the Na_2ZrCl_6. Considering the hydrolyzed product to be $(MCl)_2ZrOCl_2.8H_2O$ (5), approximately 0.5% hydrolysis occurs in the initial hour, 6% in the first day, and 22%

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in the first week for the Na_2ZrCl_6, while 0.3% in the first hour, 4% in the first day, and 22% in the first week for the K_2ZrCl_6. As the hydrolysis occurred, the samples, which in both cases were approximately 6 grams, caked and finally turned to a pale green in color.

X-Ray information was gathered by taking diffractometer measurements on various batches of sodium and potassium hexachlorozirconates. Engel (6) has shown that Rb_2ZrCl_6 and Cs_2ZrCl_6 are of the *Fm3m* space group displaying the hexachloroplatinate structure. In this investigation, the K_2ZrCl_6 has been found to fall in this same group; however, the Na_2ZrCl_6 structure is not of this type and more work is required to solve the space grouping. Due to the hydrolysis of the materials diffractometer measurements were made on different samples, each being used for about 10 minutes only, corresponding to a 2θ value of about 10°.

The lattice parameter of the K_2ZrCl_6 has been determined to be 10.0818 ± 0.003 Å, and the corresponding density was found to be 2.48 g/cc based on four formulae units per cell. The experimental density, found by using reagent grade carbon tetrachloride in a standard density bottle, was 2.44 ± 0.01 g/cc for K_2ZrCl_6 and 2.43 ± 0.01 g/cc for the Na_2ZrCl_6.

Relative peak intensities and interplanar *d* spacings for the K_2ZrCl_6 are found in Table II. Also in Table II is included the 2θ diffraction angles and the relative intensities for the Na_2ZrCl_6.

Some physical properties of the hexachlorozirconates are summarized in Table II.

TABLE II

	A. K_2ZrCl_6		B. Na_2ZrCl_6

THE RELATIVE ACID STRENGTHS OF SUBSTITUTED PICRIC ACIDS[1]

JOHN W. ELDER[2] AND RAYMOND P. MARIELLA[3]
Department of Chemistry, Loyola University, Chicago, Illinois
Received November 26, 1963

ABSTRACT

The relative acidity of substituted picric acids has been determined using special non-aqueous titration techniques. Other organic and inorganic acids, whose acidities in water are well known, were also determined using this non-aqueous method. A correlation of the relative acidities of known acids in water with the relative acidities of these same acids, as measured under the non-aqueous conditions used, was excellent. Using this technique a single relative acidity scale was determined ranging from acids as strong as perchloric to acids as weak as acetic acid.

During recent work with substituted picric acids in reactions with amines and aromatic hydrocarbons (1, 2, 3) it became desirable to know the magnitude of the relative acidities of these acids.

The literature shows that considerable difficulties have been encountered in attempts to evaluate the acid strength of picric acids. The major difficulty is due to the fact that picric acid and its derivatives are too strong for the usual aqueous methods to give good results.

Bates and Schwarzenbach (4) determined the pK_a of picric acid spectrophotometrically in aqueous hydrochloric acid solutions. Because of picric acid's strong acidity, it was not possible to obtain a good value of the absorbance of a solution in which all the picric acid was in the non-ionized form. This difficulty was solved, in part, by selecting several likely values and determining the value that gave the most consistent pK_a values.

Spectrophotometric measurements by Davis *et al.* (5, 6), of methylpicric acid and dimethylpicric acid (7, 8) gave values of 0.81 and 1.38 respectively. Recent work by Davis and Paabo (9) gave the pK_a value of 0.33 for picric acid when measured spectrophotometrically in water containing hydrochloric acid. Attempts to determine the pK_a of picric acid by potentiometric titrations of picric acid and by spectrophotometric measurements of picric acid solutions in the near-saturation range did not yield satisfactory results (9).

The investigation of the acid strength of picric acid in *non-aqueous* solvents has been limited to conductometric measurements. Neale (10) determined the ionization constant of picric acid in acetone and in aqueous acetone solutions, obtaining a value of 10^{-6} in anhydrous acetone.

Goldschmidt (11) determined the dissociation constant of picric acid to be 1.75 times 10^{-4} in absolute methanol. MacInnes (12) using certain refinements in the determination of Λ_0, recalculated Goldschmidt's data to give a value for K of 1.84×10^{-4}.

In the present work several trials were made to find a suitable method to measure the acidities of the various picric acids. The spectral method of Davis *et al.* (5, 6) was applied to the determination of chloropicric acid, where it was found that the spectra of the unionized acid was not readily obtainable, since chloropicric acid was still ionized in 6 N hydrochloric acid. Selection of likely values of the absorbance of the non-ionized species gave values of pK_a ranging from 0.44 to 0.03, but no value gave particularly consistent results.

[1]*Taken in part from the Ph.D. dissertation of J. W. Elder.*

A method utilizing potentiometric measurements in a non-aqueous system was then adapted, in which the potential of the acetone solution of the acid, half neutralized with tetrabutyl ammonium hydroxide titrant, was taken as characteristic of the acid. The potential of the system was measured with a glass-modified calomel electrode pair. The use of such a non-aqueous potential system follows the methods developed by Heijde (13, 14, 15), Cundiff and Markunas (16, 17), Bruss and Wyld (18), and Fritz and Yamamura (19). The method of measuring the potential of the solution of half-neutralized acid rather than by the usual potentiometric titration method was necessitated by the long interval required before a steady potential value was reached.

The values obtained for the mid-equivalence points are listed in Table I.

TABLE I

Mid-equivalence potentials

	EMF (mv)	ΔEMF (mv)
Perchloric acid	733	243
Trinitrophloroglucinol (1st H)	610	120
Hydrochloric acid	582	92
Chloropicric acid	549	59
Bromopicric acid	542	52
Styphnic acid (1st H)	523	33
Iodopicric acid	509	19
Picric acid	490	—
Methoxypicric acid	467	−23
Ethylpicric acid	457	−33
Methylpicric acid	452	−38
Nitric acid	449	−41
Dimethylpicric acid	380	−110
t-Butylpicric acid	372	−118
Salicylic acid	72	−418
Trinitrophloroglucinol (2nd H)	−66	−556
Styphnic acid (2nd H)	−158	−648
Benzoic acid	−160	−650
Acetic acid	−223	−713

Included in Table I are also some other acids to test the theory. The magnitude of the relative acidities can be seen by comparing the Δ EMF column.

$$(\Delta\ \mathrm{EMF} = \mathrm{EMF}_x - \mathrm{EMF}_{p.a})$$

No value is given for sulphuric acid. Repeated attempts to obtain this value led to erratic results which it is believed are due to the dehydrating action of sulphuric acid on the surface of the electrode, or to the self-condensation of the solvent, caused by the sulphuric acid. The third dissociation of trinitrophloroglucinol could not be measured by our system, since this acidic hydrogen is so very weak.

It is best to consider these values (Table I) as only *relative* values, and no claim is made as to any absolute values. That there is a correlation between our values and those obtained in aqueous systems is seen in Fig. 1.

Figure 1 shows six acids, whose pK_a values are well known from aqueous work, plotted against the EMF values obtained from this work. A good linear relationship can be seen.

Our results agree with the theory that the presence of an increasing bulky group in the meta positions tends to decrease the coplanarity of the nitro groups with benzene ring, thus decreasing the resonance, and hence decreasing the acidity.

EXPERIMENTAL

Preparation of Tetrabutylammonium Hydroxide Titrant

Ten grams of tetrabutylammonium iodide (Eastman) and 6 g of purified silver oxide (Eastman) were vigorously agitated for 90 minutes in 25 ml of absolute methanol. The mixture was filtered through a fine sintered glass filter and diluted to 250 ml with absolute methanol, giving a solution about 0.1 *N*. The titrant was standardized against benzoic acid by potentiometric titration.

Potentials were measured with a Beckman Model G pH meter. A Beckman glass electrode (4990-80) and a Beckman fiber-type calomel electrode (1170) were used, the calomel electrode being modified by replacing the aqueous saturated potassium chloride solution with a potassium chloride saturated absolute methanol solution.

The picric acids were prepared (1, 3, 7, 8) and recrystallized at least three times from an appropriate solvent and dried under vacuum in a drying pistol.

Reagent grade acetone was used without purification.

Procedure for Determining the Potential of the Mid-equivalence Points

To 40 ml of acetone solution containing one-third millimole of acid, a volume of titrant was added that would exactly neutralize half of the acid. The solution was stirred and the glass and modified calomel electrodes inserted. Potential readings were taken until the potential became steady (about 20–30 minutes) and this potential was taken as being characteristic of the system. Between determinations the electrodes were removed from the solution, rinsed with acetone, wiped dry with soft tissue, and the glass electrode soaked in distilled water for 10 minutes. After this time the electrodes were again wiped with soft tissue, rinsed with acetone, and introduced into the next solutions (at least two determinations were made on all the acids reported). Duplicate determinations on any one acid usually did not vary by more than 2 mv.

SYNTHESIS OF MALTOBIOURONIC ACID (4-*O*-[α-D-GLUCOPYRANOSYLURONIC ACID]-D-GLUCOSE)

G. G. S. Dutton and K. N. Slessor
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received January 20, 1964

ABSTRACT

Benzyl β-maltobiouronic acid has been isolated from the catalytic oxidation of benzyl β-maltoside. Hydrogenolysis of the benzyl glycoside afforded maltobiouronic acid which was characterized as the methyl ester heptaacetate.

Benzyl hepta-*O*-acetyl-β-maltoside was synthesized from acetobromomaltose (1) and benzyl alcohol by the condensation method described by Helferich and Berger (2). Deacetylation with methanolic ammonia gave the crystalline benzyl β-maltoside (3). Catalytic oxidation (4) as described by Jayme and Demmig (5) in their synthesis of cellobiouronic acid gave a mixture of acidic sugars, which upon esterification with diazomethane and acetylation gave crystalline methyl (benzyl hexa-*O*-acetyl-β-maltosid)uronate. The methyl ester hexaacetate was obtained in 40% yield based on the benzyl β-maltoside consumed.

Saponification was achieved by warming with aqueous barium hydroxide to yield the barium (benzyl β-maltosid)uronate. Hydrogenolysis using palladium on barium sulphate (6), followed by acidification with Amberlite IR 120 (H^+) yielded maltobiouronic acid.

Borohydride reduction of a sample of the acid, followed by acid hydrolysis indicated only glucuronic acid and sorbitol upon paper chromatography. The structure of the synthetic uronic acid is therefore 4-*O*-α-D-glucopyranosyluronic acid-D-glucose.

Esterification of maltobiouronic acid with diazomethane, followed by acetylation with acetic anhydride in pyridine, yielded the crystalline methyl ester heptaacetate.

Future work on enzyme specificity will study the cleavage of this molecule into its constituent monosaccharides. In view of the wide distribution of α-linked glucose residues in the animal and plant kingdom, it is conceivable that maltobiouronic acid may be found in some future study of such polysaccharides.

EXPERIMENTAL

Evaporations were carried out under reduced pressure at a bath temperature of 40–45°. Optical rotations are equilibrium values measured on a Bendix–Ericson ETL-NPL Automatic Polarimeter (Type 143A) at 21±2°. Melting points quoted are uncorrected. Chromatograms were run by the descending technique in ethyl acetate : acetic acid : formic acid : water (18:3:1:4). Sugars were detected on chromatograms by the *p*-anisidine–trichloroacetate spray (7) for reducing sugars and periodate–permanganate spray (8) for non-reducing sugars.

Benzyl Hepta-O-acetyl-β-maltoside

To acetobromomaltose (16.6 g) prepared from maltose (10 g) by the method of Barczai-Martos and Korosy (1) was added freshly distilled benzyl alcohol (32 ml) and mercuric cyanide (6 g). The mixture was heated to 85° on a water bath and stirred vigorously for 45 minutes. The resulting solution was poured with stirring into ethanol (90 ml) and cooled to 5° for 3 hours. The crude product (10.5 g, 61% based on the acetobrom sugar) was collected by suction filtration. Recrystallization from ethanol yielded material melting at 124–125°. Lit. (3), m.p. 125°.

Benzyl β-Maltoside

Deacetylation of benzyl hepta-*O*-acetyl-β-maltoside was accomplished with methanol saturated with ammonia as described by Fischer and Kogl (3). Recrystallization from methanol – ethyl acetate gave the crystalline glycoside, m.p. 148–149°. Lit. (2), m.p. 147–148°.

Platinum Oxidation Catalyst

Modification of a method of Brown (9) facilitated the preparation of an active platinum catalyst. To carbon (10 g, Darco G-60), digested overnight in 6 *N* hydrochloric acid, washed free of chloride with distilled water and dried at 120° for 4 hours, a solution of chloroplatinic acid (5 g) in 50% aqueous ethanol (50 ml)was added. To this mixture, a solution of sodium borohydride (2.5 g) in ethanol (100 ml) was added slowly with stirring. After 5 minutes 6 *N* hydrochloric acid (10 ml) was added and the suspension suction filtered. The precipitate was washed free of chloride with distilled water and dried in vacuum over phosphorus pentoxide. The product (12 g) was pyrophoric and in later experiments drying was not carried out and the product was kept as a moist paste.

Catalytic Oxidation of Benzyl β-Maltoside

To a solution of benzyl β-maltoside (5 g) and sodium bicarbonate (1 g) in distilled water (100 ml) was added platinum catalyst (5 g). The mixture was maintained at 65° and magnetically stirred for 6 hours during which time a stream of oxygen was passed into the solution through a gas dispersion tube. After it had been cooled, the mixture was filtered through Celite, acidified with Amberlite IR 120 (H^+), and passed slowly through a column of Duolite A-4 (OH^-). The Duolite resin was washed with water (500 ml) and the combined eluates evaporated to recover unreacted benzyl β-maltoside (3–4 g). The Duolite resin was eluted with *N* NaOH (15 ml) and washed with water (100 ml), and the combined eluate acidified by passage through Amberlite IR 120 (H^+). The acid mixture obtained was evaporated to a brown sirup (1 g).

Methyl (Benzyl Hepta-O-acetyl-β-maltosid)uronate

To the acid mixture (1.5 g) dissolved in methanol (15 ml) excess diazomethane in ether was added. After 10 minutes the excess diazomethane was decomposed with glacial acetic acid, and the solution evaporated to a sirup. This material was acetylated in pyridine (20 ml) with acetic anhydride (50 ml) overnight. Recovery in the normal way yielded a sirup which crystallized. Recrystallization from ethanol or methanol yielded the methyl ester hexaacetate (0.8 g), m.p. 164–165°, $[\alpha]_D$ 33.8° (*c*, 2.04 in $CHCl_3$). Calculated for $C_{32}H_{46}O_{18}$: C, 53.95; H, 5.62%. Found: C, 53.80; H, 5.71%.

Barium (Benzyl β-maltosid)uronate

To a solution of the methyl ester hexaacetate (415 mg) in methanol (20 ml) a saturated aqueous barium hydroxide solution (40 ml) was added and the solution refluxed on a steam bath for 90 minutes. The solution was neutralized with carbon dioxide and filtered, and the precipitate washed with water (15 ml). The combined filtrates were acidified by passage through Amberlite IR 120 (H^+) and evaporated to a glassy solid. The solid was dissolved in water (2 ml) and neutralized with saturated aqueous barium hydroxide. The precipitate obtained upon the addition of ethanol (30 ml) was centrifuged, washed with ethanol (10 ml), and dried by solvent exchange with ether to give a white powder (300 mg) $[\alpha]_D$ 30° (*c*, 1.53 in H_2O).

Maltobiouronic Acid

A small scale experiment (8.25 mg of barium salt) was conducted in a Warburg type microhydrogenator. Hydrogenolysis was complete after 2 hours with the hydrogen uptake constant at 1.04 moles.

To a solution of the barium salt (202 mg) in water (10 ml) was added palladium oxide on barium sulphate catalyst (270 mg). The mixture was hydrogenolyzed at room temperature in a Paar apparatus at a pressure of 1 atmosphere. After 2 hours the mixture was filtered, the precipitate washed with water (10 ml), and the combined filtrates acidified by passage through Amberlite IR 120 (H^+) and evaporated to a sirup (138 mg). Freeze-drying yielded a product which analyzed as a monohydrate. After it was dried overnight *in vacuo* (0.02 mm) at 80°, the product had lost a weight equivalent to 1.2 moles of water. Upon drying at 100° for 36 hours a further 0.5 moles of water was lost. Drying was discontinued at this stage as the acid began to darken indicating decomposition. Neutralization equivalent: calc. for $C_{12}H_{22}O_{13}$, 374. Found: 367, $[\alpha]_D$ 116° (*c*, 2.52 in H_2O). Calc. for $C_{12}H_{22}O_{13}$ (monohydrate): C, 38.50; H, 5.88%. Found: C, 38.26; H, 5.76%. R_f 0.051, $R_{glucose}$ 0.33, $R_{maltose}$ 0.90 (EtOAc:AcOH:HCOOH:H_2O = 18:3:1:4).

Methyl (Hepta-O-acetyl-β-maltosid)uronate

To maltobiouronic acid (55 mg) in methanol (5 ml) was added excess diazomethane in ether, and after 10 minutes the solution was evaporated to dryness. Acetic anhydride (10 ml) and anhydrous sodium acetate (0.5 g) were added and the mixture heated on a steam bath for 2 hours. The mixture was poured into ice water and extracted into chloroform in the usual manner. Crystals (30 mg) were obtained which upon recrystallization from methanol melted at 197–198°. $[\alpha]_D$ 77° (*c*, 0.54 in $CHCl_3$). Calc. for $C_{27}H_{36}O_{19}$: C, 48.80; H, 5.42%. Found: C, 49.29; H, 5.53%.

Hydrogenolysis of methyl (benzyl hexa-*O*-acetyl-β-maltosid)uronate (145 mg) in glacial acetic acid (5 ml) with Pd/C catalyst (75 mg) for 10 hours at atmospheric pressure gave a material which upon acetylation as described above gave methyl (hepta-*O*-acetyl-β-maltosid)uronate (43 mg). Melting point and mixed melting point 197–198°.

Constitution of Maltobiouronic Acid

To maltobiouronic acid (6 mg) in water (5 ml) sodium borohydride (30 mg) was added. After 17 hours

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

at room temperature the solution was neutralized with acetic acid and evaporated to dryness. The sirup was evaporated with 3% HCl in methanol (3×5 ml) and the residue dissolved in water (5 ml), passed through Amberlite IR 120 (H^+), and evaporated to dryness. The resulting material was dissolved in *N* H_2SO_4 (3 ml) and hydrolyzed at 100° in a sealed tube overnight. Neutralization of the hydrolyzate with washed barium carbonate gave a filtrate which upon acidification by passing through Amberlite IR 120 (H^+) indicated only glucuronic acid and sorbitol upon paper chromatography.

ACKNOWLEDGMENTS

We are grateful to the National Research Council for financial support and one of us (K. N. S.) thanks the Council for the award of a studentship. We are also indebted to Mrs. C. Jenkins of this department and Dr. A. Bernhardt, Mulheim (Ruhr), Germany, for analyses.

THE SULPHURIC ACID SOLVENT SYSTEM

PART VI. THE BASICITIES OF COMPOUNDS CONTAINING SULPHUR–OXYGEN BONDS

S. K. Hall and E. A. Robinson
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario

Received December 6, 1963

ABSTRACT

Cryoscopic and conductimetric studies of a variety of compounds containing S—O bonds have shown that dimethyl sulphoxide behaves as a strong base in sulphuric acid whereas dialkyl sulphones behave as weak bases. In contrast diaryl sulphones and aryl sulphonic acids behave as non-electrolytes.

A correlation is established between the basicities of the alkyl sulphones, H_2SO_4, and the HSO_4^- ion, and their sulphur–oxygen stretching frequencies. This relation is used to predict the basicities of other compounds containing S—O bonds. In particular it is shown that the basicity of monomeric sulphur trioxide is similar to that of sulphuric acid, and sulphamide is shown to behave as a strong base in sulphuric acid, which implies protonation on a nitrogen atom rather than on oxygen, since the S—O stretching frequencies indicate only weakly basic behavior for O-protonation.

INTRODUCTION

Previous studies of sulphuric acid solutions of compounds containing sulphur–oxygen bonds have been largely confined to cryoscopic studies (1–6). However, the conductimetric behavior of a few solutes such as SO_2Cl_2 (7), methanesulphonic acid (8), and sulphur dioxide (9), has also been reported.

The earliest studies are due to Hantzsch (1), who studied the cryoscopic behavior of the sodium salts of benzene-, *m*-nitrobenzene-, and *p*-toluene-sulphonic acids. He allowed for solvolysis of the sulphonate anions to their parent acids

$$\text{e.g. } PhSO_3Na + H_2SO_4 = PhSO_3H + Na^+ + HSO_4^-,$$

and concluded that benzene- and *p*-nitrobenzene-sulphonic acids behave as non-electrolytes in sulphuric acid while *p*-toluenesulphonic acid behaves as a weak base. Gillespie (2) carried out similar measurements on solutions of diphenyl sulphone, sodium benzenesulphonate, and sodium *p*-toluenesulphonate in *slightly aqueous* sulphuric acid and concluded that diphenyl sulphone, benzenesulphonic acid, and *p*-toluenesulphonic acid behave as weak bases of the sulphuric acid solvent system ($C_6H_5SO_3H$, $K_b = 0.011$; $CH_3C_6H_4SO_3H$, $K_b + 0.016$).* However, it has been shown more recently that the use of slightly aqueous acid can lead to anomalous freezing point depressions (10, 11), due to salting-in or salting-out of the solute by the electrolyte $H_3O^+.HSO_4^-$, so that these results required re-examination.

In their initial work on the properties of anhydrous sulphuric acid as a non-aqueous solvent Gillespie, Hughes, and Ingold (3) found that SO_2Cl_2 behaves as a non-electrolyte in sulphuric acid. Their results also point to the probable behavior of dimethylsulphate as a non-electrolyte. Later conductivity measurements (7) confirmed the behavior of sulphuryl chloride as a non-electrolyte. Recently (8) the conductimetric behavior of methanesulphonic acid in H_2SO_4 was interpreted in terms of its behavior as either a non-electrolyte or as a *very* weakly ionized base.

Szmant and Brost (4) and Szmant and Lapinski (5) studied solutions of a variety of sulphones, sulphoxides, and sulphides but since they worked with very dilute solutions,

**For $B + H_2SO_4 = BH^+ + HSO_4^-$, $K_b = [BH^+][HSO_4^-]/[B]$.*

and did not correct their results for repression of the solvent self-dissociation, their conclusions, as Gillespie and Passerini have pointed out (6), are invalid.

The latest cryoscopic study of sulphuric acid solutions of some sulphones and sulphoxides is due to Gillespie and Passerini (6), who found that whereas 4-nitrodiphenyl sulphoxide, 4;4′-dinitrodiphenyl sulphoxide, and the corresponding sulphones give stable solutions, diphenyl sulphoxide is unstable in sulphuric acid and the freezing point depressions of its solutions increase with increase in time. This was attributed to protonation of the sulphoxide followed by its rapid sulphonation. Gillespie and Passerini give the following mean cryoscopic ν-factors: 4;4′-dinitrodiphenyl sulphoxide, 2.07; 4-nitrodiphenyl sulphone, 1.34; 4;4′-dinitrodiphenyl sulphoxide, 2.08; and 4;4′-dinitrodiphenyl sulphone, 1.28. Earlier measurements for the solute diphenyl sulphone (2) gave a mean ν-factor of 1.20. The results of these experiments were interpreted in terms of the behavior of aryl sulphoxides as strong bases and of aryl sulphones as weak bases.

One of the present authors has studied the conductimetric behavior of sulphur dioxide in 100% sulphuric acid (9). A slight increase in the electrical conductivity with increasing concentration of SO_2 was observed and was attributed to the behavior of SO_2 as a rather weak base.

In a following paper (12) we shall report the results of cryoscopic, conductimetric, and density measurements on solutions of some other solutes containing S—O bonds (CH_3SO_2F, CH_3SO_2Cl, $C_2H_5SO_2F$, $C_2H_5SO_2Cl$, and $CH_3SO_2.OCH_3$), which were found to behave as non-electrolytes. In this paper we give the results of a study of sulphuric acid solutions of (i) dimethyl sulphoxide, (ii) dimethyl-, diethyl-, di-*n*-propyl-, di-*n*-butyl-, tetramethylene-, diphenyl-, and 4;4′-dinitrodiphenyl-sulphones, (iii) the sodium salts of *p*-toluene-, and 2;4-dinitrobenzene-sulphonic acids, (iv) the monohydrate of *p*-toluene sulphonic acid, and (v) sulphamide.

EXPERIMENTAL

Commercial *dimethyl sulphoxide* (Baker Analysed Reagent) was purified by fractional distillation under reduced pressure (b.p. 55° at 5 mm mercury pressure); *dimethyl sulphone* (Crown Zellerbach Co.) by several recrystallizations from absolute alcohol (m.p. 109°); *n-propyl sulphone* (Eastman Kodak) by fractional crystallization from dry ether (m.p. 29.5°); and *n-butyl sulphone* (Eastman Kodak) by recrystallization from absolute ethanol (m.p. 44°). *Diethyl sulphone* was prepared from the corresponding sulphide by oxidation with ozone in chloroform solution. The product was recrystallized from dry ether (m.p. 73.5°). Pure *tetramethylene sulphone* was obtained by fractional distillation of a commercial product (Eastman Kodak) (b.p. 150° at 15 mm Hg pressure). *Diphenyl sulphone* (Eastman Kodak) was recrystallized from absolute ethanol (m.p. 128°). 4,4′-*Dinitrodiphenyl sulphone* was prepared from the corresponding sulphide by oxidation with an excess of 30% hydrogen peroxide in glacial acetic acid at 100°. It was recrystallized from glacial acetic acid (m.p. 251°).

Sulphuric acid of approximately 100% composition was prepared from analytical grade concentrated sulphuric acid and 30% oleum and the final adjustment to 100% composition carried either cryoscopically or conductimetrically as has been described before. The cells used in the determination of freezing point depressions and electrical conductivities have also been described previously (3, 13).

Cryoscopy

The freezing point depressions were obtained by the Beckmann method using solid stem mercury-in-glass thermometers for temperature measurements. The thermometers were graduated in 1/100° divisions and were calibrated against a platinum resistance thermometer. A supercooling correction, $ks\theta$, was applied to the observed freezing points where k is a constant, s the number of degrees of supercooling, and θ the freezing point depression (3). The affect of the heat capacity of the apparatus on the constant k was allowed for by determining its value experimentally, by comparing the freezing point depressions of solutions of $KHSO_4$ obtained in a particular cryoscope with the very accurate values obtained for this electrolyte by the method of equilibrium cryoscopy (14). An approximately constant amount of supercooling of about 2° was used throughout these experiments. A typical value of k obtained in this way is 0.016, which compares with the value of 0.012, which can be calculated theoretically (3), if the heat capacity of the apparatus is neglected.

No allowance for the non-ideality of the solutions was possible and cryoscopic ν'-factors were calculated from the equation

$$\nu' = \frac{\theta(1 + 0.002\,\theta)}{6.12\,m} - m_d/m,$$

where θ is the freezing point depression of a solution of molality m, calculated from the freezing point of hypothetical undissociated acid, (10.625°) (15), and m_d is the total concentration of species resulting from unrepressed self-dissociation present in a particular solution. Values of m_d were calculated from the tables given previously (15) via the degrees of ionization deduced from the conductivity measurements. This treatment assumes that the K_b values for sulphones do not change in magnitude in the temperature range 10–25°. This has been shown to be a valid assumption in the case of the weakly basic nitro compounds (17) and is also justified by the present results since the K_b values obtained in this way from cryoscopy at 10° are the same, within experimental error, as those obtained from the conductimetric measurements at 25°.

Conductivity Measurements

Electrical conductivity measurements were carried out at 25 ± 0.003° C. The method of calculating the degrees of ionization, γ, has been described previously (16). Acid–base conductimetric titrations were also carried out for the alkyl sulphones by adding small quantities of sulphone to an approximately 0.1 m solution of $H_2S_2O_7$ in H_2SO_4 and measuring the conductivity after each addition. The specific conductivities were plotted against $n_b/n_a{}^i$, the ratio of moles of added base to the number of moles of $H_2S_2O_7$ initially present, and the position of minimum conductivity, $r = (n_b/n_a{}^i)$ evaluated. The initial concentration of $H_2S_2O_7$ was found from the initial specific conductance. It has been shown previously that r is related to K_b, the ionization constant of the base, according to the equation

$$r = 0.56\,[1 + 0.018/K_b],$$

for an initially 0.1 m solution of $H_2S_2O_7$ (17).

Infrared Spectroscopy

Infrared spectroscopic measurements were carried out on 1–2% solutions of the sulphones in carbon tetrachloride, chloroform, or carbon disulphide, using a Perkin–Elmer 221 double beam spectrometer.

RESULTS

Cryoscopic and conductimetric measurements interpolated at round concentrations from the extensive original experimental data are shown in Table I, which also shows calculated cryoscopic ν-factors and conductimetric γ-values. In the case of those compounds which were found to behave as weak bases the basic ionization calculated from this data is shown in Table II. Figure 1 compares the conductivity curves for the sulphonic acid sodium salts and *p*-toluene sulphonic acid monohydrate with those of solutions of sodium hydrogen sulphate and water, respectively.

Dimethyl sulphoxide.—The observed ν'-factor is slightly greater than two, and the electrical conductivity measurements show that each molecule of solute ionizes to give one HSO_4^- ion, in agreement with complete protonation according to the equation

$$(CH_3)_2SO + H_2SO_4 = (CH_3)_2SOH^+ + HSO_4^-.$$

This result is consistent with those previously reported (6) for 4-nitrodiphenyl sulphoxide and 4;4′-dinitrodiphenyl sulphoxide.

Phenyl sulphones.—Both the cryoscopic and conductimetric measurements are consistent with the behavior of diphenyl sulphone and 4;4′-dinitrodiphenyl sulphone as non-electrolytes in sulphuric acid. These results do not agree with those of Gillespie (2). In the case of diphenyl sulphone the discrepancy is undoubtedly attributable to salting out of the sulphone by the slightly aqueous acid used by Gillespie. This could lead to an anomalously high ν'-factor. In the case of 4;4′-dinitrodiphenyl sulphone the discrepancy is more difficult to explain, since both the experiments of Gillespie and those presented in this paper were carried out in 100% sulphuric acid as solvent. However, our conductivity measurements confirm that both diphenyl sulphone and 4;4′-dinitrodiphenyl sulphone behave as non-electrolytes since the specific conductivities of solutions of both solutes fall below those of pure sulphuric acid.

*Initial molal concentration of $H_2S_2O_7$.
†Position of conductivity minimum.

Alkyl sulphones.—In the case of the alkyl sulphones all of the compounds studied were found to behave as weak electrolytes in sulphuric acid. The basic ionization constants, K_b, were calculated from both the cryoscopic and conductimetric results by the standard methods (5, 16). All the compounds were found to behave as relatively weak bases and their basicities decrease, reasonably, in the series $(CH_3)_2SO_2$, $(C_2H_5)_2SO_2$, $(n\text{-}C_3H_8)_2SO_2$, $(n\text{-}C_4H_{11})_2SO_2$. Tetramethylene sulphone was found to have approximately the same base strength as *n*-propyl sulphone.

To confirm the results of these measurements conductimetric acid–base titrations were carried out where each base was added to an approximately 0.1 *m* solution of the acid $H_2S_2O_7$. The results of these experiments are shown in Fig. 2 and Table II, and give values for the basic ionization constants in good agreement with those from cryoscopy and simple conductimetric studies (Table III).

Sodium salts of sulphonic acids.—Both sodium *p*-toluenesulphonate and sodium 2;4-dinitrobenzenesulphonate gave ν'-factors close to 3.0 and specific conductivities close to

FIG. 2. Conductimetric acid–base titrations at 25° C. A, $(CH_3)_2SO_2$; B, $(C_2H_5)_2SO_2$; C, $(n\text{-}C_3H_7)_2SO_2$; D, $(n\text{-}C_4H_9)_2SO_2$.

those of equimolar solutions of $NaHSO_4$, which is consistent with ionization according to, for example,

$$CH_3C_6H_4SO_3Na + H_2SO_4 = CH_3C_6H_4SO_3H + Na^+ + HSO_4^-.$$

Thus we conclude that these aryl sulphonic acids behave as non-electrolytes in sulphuric acid, which is consistent with the previously reported behavior of methanesulphonic acid (8).

p-Toluenesulphonic acid monohydrate.—It has previously been shown (18) that this compound is best regarded as the salt $H_3O^+.CH_3C_6H_4SO_3^-$. The freezing point depressions and electrical conductivities of its solutions in sulphuric acid are consistent with complete solvolysis of the *p*-toluenesulphonate ion to the parent acid, which then behaves

as a non-electrolyte. The results for the monohydrate are thus consistent with those for the sodium salt.

$$H_3O^+.CH_3.C_6H_4.SO_3^- + H_2SO_4 = H_3O^+ + HSO_4^- + CH_3C_6H_4.SO_3H$$

Sulphamide.—The ν'-factor of 1.9 and the electrical conductivity measurements (γ = 1.0) show that sulphamide probably behaves as a strong base in sulphuric acid.

DISCUSSION

In a following paper (12) we show that alkyl sulphonyl chlorides and fluorides and methylmethanesulphonate behave as non-electrolytes in sulphuric acid and it has been established previously that sulphuryl chloride, dimethyl sulphate, and methanesulphonic acid doubtless also behave as non-electrolytes. In this paper we have found that aryl-sulphonic acids and diaryl sulphones behave as non-electrolytes, dialkyl sulphones as rather weak bases, and dimethyl sulphoxide as a strong base. Previously on the basis of shifts in solvent bands in the infrared spectra Barnard, Fabian, and Koch (19), concluded that sulphoxides form stronger hydrogen bonds than do sulphones. They attributed this result to the greater basicity (polar character), of the S—O bonds in sulphoxides as compared to sulphones, and on the basis of the S—O bond stretching force constants they showed that indeed the S—O bonds in sulphoxides are weaker than those in sulphones. Recently correlations have been obtained between S—O bond lengths, force constants (i.e. stretching frequencies), and bond orders (20). It is thus of interest to attempt to correlate the basicities of compounds containing S—O bonds with the nature of these bonds as shown by, for example, the S—O stretching frequencies.

Tables III and IV show the S—O stretching frequencies of the compounds of interest to this paper. Some of them have been determined in this work while others have been taken from previous papers (18, 25). In the case of compounds containing an SO_2 group use is made of the "Lehmann average rule" (21) to obtain the "equivalent S—O stretching frequency" from the observed symmetric and asymmetric stretches [$\nu_{SO} = (\nu_{sym}+\nu_{asym})/2$]. Immediately it is clear that a decrease in ν_{SO} is paralleled by an increase in basicity.

The H_0 functions for aqueous sulphuric acid solutions have recently been redetermined by Jorgenson and Harrter (22), who found that, near to the composition 100% H_2SO_4, the H_0 function differs by -1.1 log units from the previous scale recommended by Paul and Long (27). It therefore seems reasonable to take H_0 for 100% sulphuric acid equal to -12.2 since Paul and Long give -11.1 for acid of this composition. pK_{BH^+} values

SO_2	1150	1334	1242	13.3	1×10^{-3}
SO_3	1069	1390	1283	15.2	2×10^{-5}
HSO_3F	1230	1445	1338	17.7	6×10^{-8}
HSO_3Cl	1209	1408	1308	16.3	1×10^{-6}
CH_3SO_3H	1174	1354	1264	14.3	1×10^{-4}

for the sulphones can be obtained by combining the expression $K_b = [BH^+][HSO_4^-]/[B]$ with the Hammett acidity function relationship

$$H_0 = pK_{BH^+} - \log [BH^+]/[B]$$

to give

$$H_0 = pK_{BH^+} - \log K_b - \log [HSO_4^-]$$

and since for acid of 100% composition $H_0 = -12.20$ and $[HSO_4^-] = 0.0178\ m$ at 25° C, (23) we obtain

$$pK_{BH^+} = -12.20 + \log K_b + 1.75,$$

or

$$pK_{BH^+} = -10.45 + \log K_b.$$

The pK_{BH^+} values calculated from this equation for the sulphones are shown in Table II. It should be emphasized that the values so obtained are relative to the H_0 function of 100% H_2SO_4, the value of which is based on indicator measurements on amine type bases. It is unlikely that the ratio f_{BH^+}/f_B (the ratio of activity coefficients for charged and uncharged base) will be the same for amines and for compounds containing S—O bonds so that the pK_{BH^+} scale derived here is quite arbitrary.

For the species H_2SO_4 and HSO_4^- the pK_{BH^+} values may be calculated directly from equation [1], since in the case of H_2SO_4 $[BH^+]/[B] = [H_3SO_4^+]/[H_2SO_4] = 0.0139/10.2 = 0.00136$, and for HSO_4^- $[BH^+]/[B] = [H_2SO_4]/[HSO_4^-] = 10.2/0.0178 = 573.3$ (23) (25° C).

pK_{BH^+} values are plotted against ν_{SO} in Fig. 3 and give a linear plot. A similar correlation of pK_{BH^+} with ν_{CO} of carbonyl compounds has been established previously by Stewart and Yates (24), who also found a linear relation. These authors also established a linear correlation between ν_{CO} and the Hammett σ functions of substituted aryl compounds. Recently Marziano, Montaudo, and Passerini (25) obtained similar relationships between ν_{SO} and the Hammett σ functions of substituted aryl sulphones.

Use can now be made of the correlation of pK_{BH^+} values and ν_{SO} to predict the basicities of other compounds containing S—O bonds. ν_{SO} and interpolated pK_{BH^+} and K_b values for a number of compounds are shown in Table IV. Since the ionization of a base with

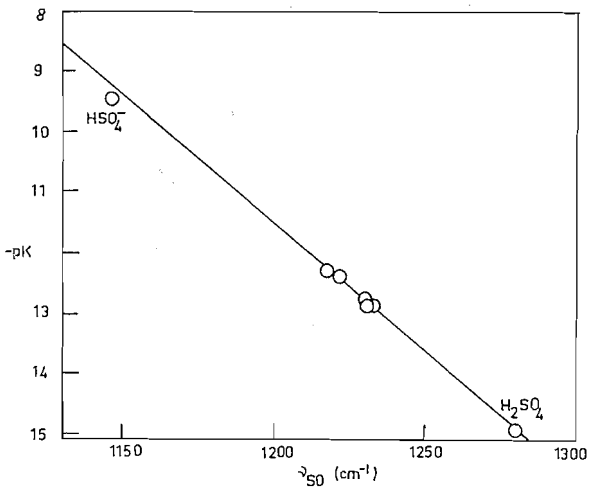

FIG. 3. Correlation of ν_{SO} with pK_{BH^+} values.

a K_b value $<1\times10^{-3}$ would be very difficult to detect experimentally it is quite reasonable that all the compounds less basic than tetramethylene sulphone would appear, from both cryoscopic and conductimetric measurements, to behave as non-electrolytes. Sulphur dioxide and diphenyl sulphone are just on the border line. Cryoscopically a small degree of ionization would be obscured by possible non-ideality effects.

Sulphur trioxide.—For monomeric sulphur trioxide the K_b value of 2×10^{-5} indicates a very weakly basic species, in fact the basicity is very similar to that of H_2SO_4 itself. Since SO_3 occurs only in negligibly small concentration in 95–100% H_2SO_4 it can be concluded that only negligible quantities of HSO_3^+ could be formed in these systems, which rules out the possibility of the participation of HSO_3^+ in sulphonations in these solvents.

Sulphamide.—For protonation on oxygen the S—O stretching frequencies lead us to expect only weakly basic behavior. However, sulphamide is found to behave as a strong base in H_2SO_4 solutions which implies that protonation must occur on a nitrogen atom. This conclusion is in agreement with that from the recent n.m.r. studies of Birchall and Gillespie (26), where N-protonation of sulphamide was found in solvent fluorosulphuric acid.

PERFLUOROALKYL ARSENICALS

PART IX. SOME REACTIONS OF COMPOUNDS CONTAINING As–As BONDS[1]

W. R. CULLEN AND N. K. HOTA
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received August 20, 1963

ABSTRACT

Arsenobenzene reacts with CF_3I to give $C_6H_5As(CF_3)_2$, $C_6H_5As(CF_3)I$, and $C_6H_5AsI_2$. $C_6H_5As(CF_3)I$ and AgCl yield $C_6H_5As(CF_3)Cl$. The compounds $CF_2=CFX$ react with $(CH_3)_2As—As(CH_3)_2$ under mild conditions to give 1:1 adducts $(CH_3)_2As—CF_2CFX—As(CH_3)_2$ (X = CF_3, Br). Some $(CH_3)_2As—CF=CF_2$ is produced when X = Br and is the major product when X = I. When X = F a 1:4 adduct $(CH_3)_2As—(CF_2CF_2)_4—As(CH_3)_2$ is probably formed on ultraviolet irradiation. $(CH_3)_2As—As(CH_3)_2$ reacts with $CF_3C{\equiv}CCF_3$ to give *cis* and *trans* $(CH_3)_2AsC(CF_3){=}C(CF_3)As(CH_3)_2$ and with $\overline{CF{=}CFCF_2CF_2}$ to give $(CH_3)_2AsF$ and $(CH_3)_2As—\overline{CF{=}CFCF_2CF_2}$.

DISCUSSION AND RESULTS

Compounds containing weak bonds such as As–As (1), P–P (1, 2, 3), and Sn–Sn (4, 5) are readily cleaved when treated with perfluoroalkyl iodides, for example,

$$(CH_3)_2As—As(CH_3)_2 + CF_3I \rightarrow (CH_3)_2AsCF_3 + IAs(CH_3)_2.$$

We have now found that the As–As bonds in arsenobenzene, better named hexaphenylcyclohexaarsine (6), undergo a similar reaction when heated with an excess of trifluoroiodomethane at 115°, or at lower temperatures when the reactants are exposed to ultraviolet radiation. The products are phenylbis(trifluoromethyl)arsine, iodophenyltrifluoromethylarsine, and diiodophenylarsine.

$$(C_6H_5As)_6 + CF_3I \rightarrow C_6H_5As(CF_3)_2 + C_6H_5As(CF_3)I + C_6H_5AsI_2$$

Similar products have been isolated from the thermal and photochemical reaction of tetraphenylcyclotetraphosphine with trifluoroiodomethane (2). In an attempt to extend this type of reaction to the preparation of more complex aryltrifluoromethylarsines, *p*-nitroarsenobenzene was heated to 100° with trifluoroiodomethane. After a few hours the reaction tube exploded. This result was reproducible.

Iodophenyltrifluoromethylarsine, a new compound, b.p. 136–137° (35 mm), 158° (65 mm), reacts with silver chloride to give the more volatile chloroarsine, b.p. 118° (65 mm). The iodoarsine does not react with methyl iodide in the presence of mercury to give the expected methylphenyltrifluoromethylarsine (7). However, coupling of the iodoarsine appears to take place to give a white solid diarsine which decomposes in air to benzenearsonic acid.

$$2\ C_6H_5(CF_3)AsI + Hg \rightarrow C_6H_5(CF_3)As—As(CF_3)C_6H_5 + HgI_2$$

Chlorophenyltrifluoromethylarsine reacts with bis(trifluoromethyl)arsine at 100° to give hydrogen chloride, tris(trifluoromethyl)arsine, tetrakis(trifluoromethyl)diarsine, and possibly chlorobis(trifluoromethyl)arsine. A white solid is also produced which decomposes to benzenearsonic acid on exposure to air. The formation of hydrogen chloride and an unstable solid suggests that the main reaction is a coupling one to produce a diarsine.

[1]*For a preliminary publication see W. R. Cullen, D. S. Dawson, N. K. Hota, and G. E. Styan. Chem. Ind. London, 983 (1963).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

However, analysis of the solid product indicates that it is mainly the symmetrical diarsine $(C_6H_5(CF_3)As)_2$ (Anal. Found: C, 36.6, H, 2.3%. Calc.: C, 37.9, H, 2.3%) rather than the unsymmetrical one $C_6H_5(CF_3)As—As(CF_3)_2$. Either diarsine could decompose to give benzenearsonic acid. The symmetrical diarsine could arise from reactions of the following sort (8).

$$C_6H_5(CF_3)AsCl + HAs(CF_3)_2 \rightarrow C_6H_5(CF_3)As—As(CF_3)_2 + HCl$$

$$- HCl \uparrow \downarrow + HCl$$

$$C_6H_5(CF_3)AsH + ClAs(CF_3)_2$$

$$(CF_3)_2AsH + ClAs(CF_3)_2 \rightleftarrows (CF_3)_2As—As(CF_3)_2 + HCl$$

$$C_6H_5(CF_3)AsH + ClAs(CF_3)C_6H_5 \rightleftarrows C_6H_5(CF_3)As—As(CF_3)C_6H_5 + HCl$$

Such a scheme would also explain the formation of tetrakis(trifluoromethyl)diarsine and chlorobis(trifluoromethyl)arsine. It does not, however, account for the presence of tris(trifluoromethyl)arsine in the reaction products.

There are a few examples known of the addition of olefins and acetylenes to compounds containing M–M bonds (M = P (9, 10), B (11), Sn (12), S (13)), for example

$$(CH_3)_2P—P(CH_3)_2 + C_2F_4 \rightarrow (CH_3)_2P—CF_2CF_2—P(CH_3)_2.$$

Cacodyl (tetramethyldiarsine) has now been found to react similarly with fluorine containing olefins and acetylenes. Thus when the diarsine is treated with excess hexafluoropropene under mild conditions, a 1:1 adduct, 1,2-bis(dimethylarsino)hexafluoropropane, is formed.

$$(CH_3)_2As—As(CH_3)_2 + CF_3CF=CF_2 \rightarrow (CH_3)_2As—CF(CF_3)CF_2—As(CH_3)_2$$

The adduct distills at 116–117° (50 mm) and is hydrolyzed by hot alkali to give 1,2,3,3,3,-pentafluoroprop-1-ene. The olefin is probably produced by HF elimination from the initially formed propane, which would contain two adjacent CHF groups (14).

$$(CH_3)_2As—C(CF_3)F—CF_2—As(CH_3)_2 \xrightarrow{NaOH} (CH_3)_2AsONa + CF_3CFH—CF_2H$$

$$CF_3CFH—CF_2H \longrightarrow CF_3CF=CFH + HF$$

Cacodyl also reacts easily with hexafluorobut-2-yne to give a 1:1 adduct 2,3-bis(dimethylarsino)hexafluorobut-2-ene, b.p. 42° (10^{-3} mm), 99° (17 mm).

$$(CH_3)_2As—As(CH_3)_2 + CF_3C\equiv CCF_3 \rightarrow (CH_3)_2As—C(CF_3)=C(CF_3)—As(CH_3)_2$$

The F^{19} nuclear magnetic resonance spectrum shows only two peaks of approximately equal intensity such as would be shown by an approximately equimolar mixture of the *cis* and *trans* forms of the adduct. The infrared spectrum of the adduct shows only a weak double-bond absorption at 1570 cm^{-1}. Hydrolysis gives a small amount of *trans*-1,1,1,4,4,4,-hexafluorobut-2-ene. The adduct reacts with mercuric chloride to give a complex of indefinite constitution. A similar adduct is obtained from hexamethylditin and hexafluorobut-2-yne on ultraviolet irradiation, although in this case the F^{19} n.m.r. spectrum has only one peak, indicating that only one isomer is formed (15). Grant (2) has found that the iodine catalyzed reaction of tetrakis(trifluoromethyl)diphosphine with acetylene gives a *trans* adduct.

$$(CF_3)_2P—P(CF_3)_2 + HC\equiv CH \rightarrow (CF_3)_2P—CH=CH—P(CF_3)_2$$

In the present investigation we have found that tetrakis(trifluoromethyl)-diphosphine and -diarsine do not react with hexafluorobut-2-yne at 100°. The nature and variety of

these addition reactions and their products makes it difficult to suggest a reaction mechanism without a much more detailed study; however, the *trans* orientation of one product and the 1:1 distribution of isomers in another seems to rule out a general four-center mechanism.

Cacodyl does not react immediately with tetrafluoroethylene at 20°, but, when the two are irradiated with ultraviolet light, reaction does occur. Trimethylarsine is produced in small amounts, but the main reaction product is an involatile, air-stable liquid which analysis indicates to be mainly the 1:4 adduct $(CH_3)_2As—(C_2F_4)_4—As(CH_3)_2$. The F^{19} n.m.r. spectrum supports this result. It shows three broad lines with chemical shifts of the magnitude expected for CF_2 groups in a chain (16). The relative areas of the peaks are 58:30:27, but because of overlap the ratio of the smaller peaks, 30:27, is not very accurate. However, their total relative area of 57 is reliable. These figures strongly indicate that the relative areas are in fact 2:1:1 or 4:2:2, the ratios which would be expected from the compound

$$(CH_3)_2As\cdot\overset{i}{C}F_2\cdot\overset{ii}{C}F_2\cdot(\overset{iii}{C_2F_4})_2\cdot\overset{ii}{C}F_2\cdot\overset{i}{C}F_2\cdot As(CH_3)_2$$

where the fluorines on carbon atoms i, ii, and iii would have different chemical shifts (16). Similar products have been obtained from the iodine-catalyzed reaction of tetrafluoroethylene with dimethyl disulphide (13).

$$(CH_3)_2S_2 + C_2F_4 \rightarrow CH_3S(C_2F_4)_nSCH_3$$

The reaction of cacodyl with hexafluorocyclobutene at 20° yields fluorodimethylarsine and the novel compound 1-dimethylarsinopentafluorocyclobutene, b.p. 125°, in good yield. The n.m.r. spectrum of this compound, which will be reported in detail later, is complex but contains three general regions of fluorine absorption as expected. The infrared spectrum shows a strong double-bond absorption at 1659 cm^{-1}. The method of preparation of the compound and the results described above suggest that the first product of the reaction is a 1:1 adduct which eliminates fluorodimethylarsine to give the cyclobutene derivative.

$$(CH_3)_2As—As(CH_3)_2 + \overline{CF{=}CF_2CF_2}\overline{CF_2} \rightarrow [(CH_3)_2As—\overline{CFCF_2CF_2}\overline{CF}—As(CH_3)_2]$$
$$\downarrow$$
$$FAs(CH_3)_2 + \overline{CF_2CF_2CF{=}C}—As(CH_3)_2$$

A similar reaction sequence has been suggested (17) to account for the formation of 1-alkyl-pentafluorocyclobutenes from the reaction of hexafluorocyclobutene with alkylmagnesium halides. The same cyclobutene derivative can be made by reacting hexafluorocyclobutene with the "Grignard reagent" made from dimethylarsine (18).

$$(CH_3)_2AsMgBr + \overline{CF{=}CFCF_2}\overline{CF_2} \rightarrow (CH_3)_2As—\overline{C{=}CFCF_2}\overline{CF_2} + MgBrF$$

A 1:1 adduct is probably formed when the diarsine reacts with bromotrifluoroethylene under mild conditions, although in this case analysis of the product 1-bromo-1,2-bis(dimethylarsino)trifluoroethane, b.p. 65° (10^{-3} mm), indicated it to be impure. The adduct slowly decomposes at 20° to give dimethyltrifluorovinylarsine and presumably bromodimethylarsine.

$$(CH_3)_2As—As(CH_3)_2 + CF_2{=}CFBr \rightarrow (CH_3)_2As—CF_2CFBr—As(CH_3)_2 \rightarrow$$
$$(CH_3)_2AsCF{=}CF_2 + (CH_3)_2AsBr$$

Both these decomposition products as well as fluorodimethylarsine, the dimer of bromotrifluoroethylene, and other unidentified fractions are also formed in the initial reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

to produce the adduct. Addition followed by elimination is probably the source of the dimethylperfluorovinylarsine and the bromodimethylarsine. In a similar way the reaction of bromotrifluoroethylene with tetrakis(trifluoromethyl)-diarsine and -diphosphine at 100° probably gives bis(trifluoromethyl)trifluorovinyl-arsine and -phosphine (19). Dimethyltrifluorovinylarsine is also produced when cacodyl and trifluoroiodoethylene interact at 20°. Iododimethylarsine and an unidentified volatile yellow solid are the other products. A stable adduct $(CH_3)_2As—(CF_2CFI)_n—As(CH_3)_2$ does not seem to be formed in this last reaction; the least volatile reaction products are air sensitive and the analytical data fit cacodyl better than any adduct of cacodyl with the olefin.

Dimethyltrifluoromethylarsine is produced when trifluoroiodomethane reacts with trimethylarsine (20) and with iododimethylarsine in the presence of mercury (1). It has now been found that trimethylarsine slowly interacts with trifluorovinyl bromide and iodide but does not give the expected dimethyltrifluorovinylarsine. This compound can, however, be prepared in low yield from the reaction of trifluorovinyl iodide with iododimethylarsine in the presence of mercury.

$$CF_2{=}CFI + Hg + IAs(CH_3)_2 \rightarrow CF_2{=}CFAs(CH_3)_2 + HgI_2$$

Trifluorovinyl bromide does not react with either iododimethylarsine or diiodomethylarsine in the presence of mercury. Since the vinyl bromide readily reacts with cacodyl yet does not react with iododimethylarsine and mercury, it seems that cacodyl itself is not a reactive intermediate in these coupling reactions. This conclusion is substantiated by the failure of hexafluorobut-2-yne to react with iododimethylarsine in the presence of mercury.

Dimethyltrifluorovinylarsine, b.p. 71°, is a colorless liquid slightly less volatile than trimethylarsine, b.p. 51°, and dimethyltrifluoromethylarsine, b.p. 58°. It is slowly hydrolyzed by hot alkali to trifluoroethylene, a result analogous to the slow hydrolysis of dimethyltrifluoromethylarsine to fluoroform (21). There appears to be a considerable difference in the hydrolytic stability of the easily hydrolyzed tris(trifluoromethyl)arsine and the stable tris(trifluorovinyl)arsine (22).

EXPERIMENTAL

Apparatus and Techniques

Most of the methods used in the present investigation have been described in earlier papers in this series. The F^{19} n.m.r. spectra were obtained using a Varian spectrometer operating at 56.4 Mc/sec. The spectra are reported relative to a trifluoroacetic acid external standard. A dinonylphthalate on firebrick column (12 ft) in an Aerograph instrument was used for vapor phase chromatographic separations. Helium was used as the carrier gas and the temperature of the column is indicated in the text. Starting materials were prepared by methods described in the literature.

Reaction of Arsenobenzene with Trifluoroiodomethane

(*a*) Arsenobenzene (10.0 g) and trifluoroiodomethane (18 g) did not react at 20° (3 days). However, reaction occurred at 115° (1 day) giving a dark-brown liquid product. Trifluoroiodomethane (5.4 g) was recovered, and the remaining contents of the reaction tube were distilled in a nitrogen atmosphere (65 mm) to give phenylbis(trifluoromethyl)arsine (8 g, 42% yield, b.p. 88°) of known infrared spectrum and a pale-yellow liquid shown by analysis to be *iodophenyltrifluoromethylarsine* (6.2 g, 27% yield, b.p. 158°). Anal. Found: C, 23.9; H, 1.54%. Calc. for $C_7H_5AsF_3I$: C, 24.2; H, 1.44%. The residue in the still pot (5.3 g) was largely diiodophenylarsine. The infrared spectrum of iodophenyltrifluoromethylarsine showed the following absorption bands (liquid film): 3055(w), 2230(vw), 1575(vw), 1482(m), 1435(m), 1330(m), 1302(w), 1252(m), 1185(s), 1110(broad vs), 1072(s), 1020(m), 997(m), 735(s), 725(m), 687(s) cm^{-1}.

(*b*) A similar reaction took place when arsenobenzene and trifluoroiodomethane were irradiated with ultraviolet light.

Reactions of Iodophenyltrifluoromethylarsine

(a) With silver chloride.—The arsine (3.4 g) and an excess of freshly prepared, dry silver chloride were shaken at 20° for 2 days. A colorless liquid, *chlorophenyltrifluoromethylarsine*, which was sufficiently volatile

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

to be taken into the vacuum system, was quantitatively produced. It distilled at 118° (65 mm) in a nitrogen atmosphere. Anal. Found: C, 33.0; H, 1.76; As, 28.9; Cl, 13.6%. Calc. for $C_7H_5AsClF_3$: C, 32.7; H, 1.93; As, 29.2; Cl, 13.8%. The infrared spectrum was almost identical with that of the iodoarsine.

(b) With iodomethane in the presence of mercury.—The arsine (6.2 g), iodomethane (13.4 g), and mercury (40 g) were shaken for 3 weeks at 20°. Iodomethane (13.3 g) was quantitatively recovered. A white solid in the reaction tube was extracted with benzene to give a solution which slowly deposited crystals of benzenearsonic acid. The acid was identified by means of its X-ray powder photograph.

Reaction of Chlorophenyltrifluoromethylarsine with Bis(trifluoromethyl)arsine

The chloroarsine (0.7 g) and bis(trifluoromethyl)arsine (0.812 g) were left at 100° for 7 days. Trap-to-trap distillation gave hydrogen chloride (0.043 g; mol. wt. 36.6), bis(trifluoromethyl)arsine (0.466 g), chlorophenyltrifluoromethylarsine (0.14 g), and a middle fraction which contained tris(trifluoromethyl)arsine, tetrakis(trifluoromethyl)diarsine, and possibly a trace of chlorobis(trifluoromethyl)arsine, all of known infrared spectra. A cream solid which was left in the reaction tube was highly unstable to air. Anal. Found: C, 36.5; H, 2.33%. The end product of the decomposition was benzenearsonic acid.

Reaction of Cacodyl with Hexafluoropropene

The diarsine (5.3 g) and the propene (16.0 g) were left at 20° for 13 days. A small amount (1.9 g) of a liquid, b.p. 36–38° (10^{-3}) mm, which fumed slightly in air was isolated. The infrared spectrum of this fraction showed the presence of C–F and As–CH_3 groups. All reactants and products were combined and heated to 50° (7 days). Distillation of the less volatile material in a nitrogen atmosphere at 50 mm gave 1.1 g of cacodyl, b.p. 78°; a middle fraction, b.p. 78–114°; and 1.6 g (18% yield) of *1,2-bis(dimethylarsino)-1,1,2,3,3,3-hexafluoropropane*, b.p. 114–116°. The last fraction still fumed in air, so air was bubbled through it until the fuming had ceased. An analytical sample, b.p. 116–117° (50 mm) was obtained from another distillation. Anal. Found: C, 23.2; H, 3.29; As, 41.6; F, 31.8%. Calc. for $C_7H_{12}As_2F_6$: C, 23.3; H, 3.33; As, 41.6; F, 31.7%. The infrared spectrum (liquid film) showed the following bands; 3005(w), 2915(w), 1670(w), 1418(m), 1277(s), 1265(s), 1195(broad, vs), 1142(s), 1158(broad, m), 999(w), 912(broad, m), 850(m), 798(w), 720(w) cm^{-1}. When the adduct (0.291 g) was heated (100°, 24 hours) with 8 ml of 10% aqueous sodium hydroxide, 0.034 g of 1,2,3,3,3-pentafluoroprop-1-ene, of known infrared spectrum (23), was produced.

Reaction of Cacodyl with Hexafluorocyclobutene

Cacodyl (5.0 g) and the butene (17.8 g) were left for 12 days at 20°. Apart from some white deposit on the glass all the contents of the tube were volatile. Trap-to-trap distillation isolated 1.149 g of fluorodimethylarsine, which attacked glass and which stopped in a trap cooled to −64°. Anal. Found: C, 18.2; H, 4.7%; mol. wt. 127; b.p. 66–68° (by distillation in a nitrogen atmosphere at 760 mm). Calc. for C_2H_6AsF: C, 19.4; H, 4.8%; mol. wt. 124; b.p. 75° (24). The most volatile fraction was perfluorocyclobutene (14.6 g), which contained some fluorodimethylarsine. The least volatile fraction (7.0 g) was distilled in a nitrogen atmosphere to give 0.52 g of fluorodimethylarsine, b.p. 70–75°, and 4.9 g (83% yield) of *1-dimethylarsinopentafluorocyclobutene*, b.p. 122–125°. An analytical sample, b.p. 125°, was obtained by redistillation. Anal. Found: C, 29.0; H, 2.41; As, 30.0; F, 38.0%. Calc. for $C_6H_6AsF_5$: C, 29.0; H, 2.42; As, 30.1; F, 38.4%. The infrared spectrum showed the following bands (liquid film): 3010(w), 2920(w), 2360(w), 2349(sh,w), 1695(s), 1424(w), 1397(s), 1374(m), 1275(vs), 1206(m), 1117(vs), 1104(s), 950(vs), 900(w), 865(m), 812(m) cm^{-1}.

Reaction of Cacodyl with Bromotrifluoroethylene

The diarsine (4.0 g) and bromotrifluoroethylene (16.5 g) were left for 7 days at 20°. Qualitative investigation showed that although some reaction had occurred considerable amounts of the diarsine were still present. The reactants were then heated to 50° (5 days). The volatile material was taken into the vacuum system leaving 4.3 g of a pale-yellow liquid in the reaction tube. Trap-to-trap distillation gave 13.5 g of bromotrifluoroethylene, 0.4 g of 1,2-dibromohexafluorocyclobutane (25), and 1.7 g of a mixture which was separated by vapor phase chromatography (v.p.c.) at 135° into fluorodimethylarsine (0.2 g; mol. wt. 121; calc. mol. wt. 124) of known infrared spectrum, bromodimethylarsine (0.4 g) of known retention time and infrared spectrum, and one other volatile fraction. This last fraction was a mixture of dimethyltrifluorovinylarsine and one other unidentified unsaturated compound.

The involatile reaction product distilled at 65° (10^{-3} mm) and analysis of the pale-yellow distillate suggested that it was an impure sample of 2-bromo-1,2-bis(dimethylarsino)-1,1,2-trifluoroethane. Anal. Found: C, 21.0; H, 3.47; As, 40.3; Br, 18.7; F, 16.9%. Calc. for $C_6H_{12}As_2BrF_3$: C, 19.4; H, 3.24; As, 40.4; Br, 21.6; F, 15.4%. The infrared spectrum showed the following bands (liquid film): 2985(m), 2905(m), 2800(w), 2330(w), 1723(m), 1705(m), 1420(m), 1290(m), 1265(m), 1152(m), 1110(m), 1067(s), 1015(m), 985(m), 904(m), 850(s), 825(m), 792(m), 682(m) cm^{-1}. An ethanolic solution of the adduct reacted with an ethanolic solution of mercuric chloride to give a white precipitate which was insoluble in boiling ethanol. An infrared spectrum of the solid showed the presence of C–H and the absence of C–F groups. The adduct slowly decomposed on standing at 20°, since some months after its preparation it was found to be volatile enough to be taken into the vacuum system where trap-to-trap distillation isolated slightly impure dimethyltrifluorovinylarsine.

Reaction of Cacodyl with Iodotrifluoroethylene

Cacodyl (1.7 g) and the ethylene (10.0 g) were left for 7 days at 20°. Trap-to-trap distillation gave iodotrifluoroethylene (8.9 g), a volatile unidentified yellow solid, iododimethylarsine, and dimethyltrifluorovinylarsine. These fractions could not be separated quantitatively. The trifluorovinylarsine was purified by v.p.c. (90°) to give 0.1 g of product. An involatile air-sensitive material which contained As–CH_3 and some C–F remained in the reaction tube. Anal. Found: C, 24.8; H, 4.9%.

Reaction of Cacodyl with Tetrafluoroethylene

When cacodyl (1.5 g) was exposed to the olefin at a pressure of 30 cm (20°) there was no drop in pressure. The diarsine (1.5 g) and the olefin (2.9 g) were irradiated in a sealed tube with ultraviolet light (24 hours), to give tetrafluoroethylene (0.4 g) and trimethylarsine (0.053 g) of known infrared spectra. The air-stable colorless involatile product (4.3 g) distilled at 10^{-3} mm in the range 110–125°. Elemental analysis of a middle cut, b.p. 120°, showed it to be probably a 1:4 addition product of the diarsine and the olefin, $(CH_3)_2As(CF_2CF_2)_4As(CH_3)_2$. Anal. Found: C, 23.2; H, 1.8; As, 22.7; F, 51.7%. Calc. for $C_{12}H_{12}As_2F_{16}$: C, 23.6; H, 1.97; As, 24.6; F, 49.9%. Two other cuts were taken and these analyzed as follows: C, 23.5; H, 2.4% (110–120°); C, 22.5; H, 1.6% (120–125°). The infrared spectra of the three fractions were very similar. The F^{19} n.m.r. spectrum of the third cut showed peaks at +2450, +2290, and +2240 c/s of relative area 58:30:27.

Reaction of Cacodyl with Hexafluorobut-2-yne

The acetylene (7.5 g) and the diarsine (5.0 g) reacted on warming to 20° to give a reddish-brown solution. The tube was left at 20° for 14 days. Hexafluorobut-2-yne (4.3 g) was the only volatile substance present in the tube. The involatile, air-stable reaction product distilled at 42° (10^{-3} mm) and at 99° (17 mm) and was identified as *2,3-bis(dimethylarsino)-1,1,1,3,3,3-hexafluorobut-2-ene*. Anal. Found: C, 26.0; H, 3.4; As, 40.2; F, 30.9%, mol. wt. 350. Calc. for $C_8H_{12}As_2F_6$: C, 25.8; H, 3.22; As, 40.3; F, 30.6%, mol. wt. 372. The infrared spectrum showed the following bands (liquid film): 2990(w), 2915(w), 1570(w), 1425(m), 1300(w), 1230(vs), 1175(sh,s), 1152(vs), 1135(vs), 897(w), 867(w), 852(w), 652(m) cm^{-1}. The F^{19} n.m.r. spectrum consisted of two peaks of nearly equal intensity at −1368 and −1483 c/s. The adduct (0.283 g) was hydrolyzed with 15% aqueous sodium hydroxide (5 days, 110°) to give a small amount (0.019 g) of *trans*-1,1,1,3,3,3-hexafluorobut-2-ene, of known infrared spectrum. The adduct had partially decomposed to a black solid and unidentified volatile products after 3 days at 150°. When ethanolic solutions of the adduct and mercuric chloride were mixed, a cream precipitate was obtained which was recrystallized from ethanol. Anal. Found: C, 11.5; H, 1.29; As, 12.7; Cl, 14.4; F, 10.7; Hg, 38.1%.

Reaction of Hexafluorobut-2-yne with Tetrakis(trifluoromethyl)-diarsine and -diphosphine

The arsine (1.53 g) and the acetylene (4.9 g) did not react after 7 days at 100° or, in a separate experiment, after 10 days at 150°. The acetylene (4.9 g) and the diarsine (1.50 g) were recovered. Similarly, the acetylene and the diphosphine did not react when heated to 100° for 2 days.

Reaction of Bromotrifluoroethylene with Iodoarsines in the Presence of Mercury

(*a*) Iododimethylarsine (25.7 g), mercury (250 g), and bromotrifluoroethylene (49.0 g) were shaken at 20° for 11 days. The only volatile substance present in the reaction tube was bromotrifluoroethylene (48.7 g).

(*b*) Diiodomethylarsine (18.9 g), mercury (200 g), and bromotrifluoroethylene (49.6 g) did not produce any trifluorovinylarsine after being shaken for 18 days at 20°. The weight of the ethylene recovered was 49.0 g.

Reaction of Iodotrifluoroethylene with Iododimethylarsine in the Presence of Mercury

Iododimethylarsine (24.2 g), mercury (240 g), and iodotrifluoroethylene (66 g) were shaken for 10 days at 20°. Iodotrifluoroethylene (64.4 g) was recovered and *dimethyltrifluorovinylarsine* (1.0 g) was produced. The arsine was identified by its molecular weight of 181 (calc. mol. wt. 186). An analytical sample was obtained by v.p.c. at 55°. Found: C, 26.0; H, 3.31; As, 40.3; F, 30.4%. Calc. for $C_4H_6AsF_3$: C, 25.8; H, 3.26; As, 40.4; F, 30.6%. Infrared spectrum (vapor): 3010(m), 2920(m), 1780(w), 1730(s), 1428(m), 1298(s), 1140(s), 1020(s), 897(m), 852(m), 715(m) cm^{-1}. The boiling point was found to be 71°, the latent heat of vaporization 8180 cal/mole, and Trouton's constant 23.8. When the arsine (0.086 g) was hydrolyzed by 15% aqueous sodium hydroxide (100°, 24 hours) trifluoroethylene (0.0094 g) was produced. Unreacted arsine was also isolated.

Reaction of Iododimethylarsine with Hexafluorobut-2-yne in the Presence of Mercury

Iododimethylarsine (21.0 g) and hexafluorobut-2-yne (30.0 g) did not react on being shaken for 7 days at 20° in the presence of 217 g of mercury. The butyne was recovered quantitatively.

Reaction of Trimethylarsine with Bromotrifluoroethylene and Iodotrifluoroethylene

Trimethylarsine (0.60 g) and bromotrifluoroethylene (6.5 g) were kept at 20° for 1 year. Trap-to-trap distillation of the volatile material recovered 6.4 g of bromotrifluoroethylene and 0.54 g of trimethylarsine. A small amount of unidentified brown solid remained in the reaction tube. The recovered arsine was left with 6.0 g of iodotrifluoroethylene for 14 days. Examination of the volatile contents of the reaction tube showed only the presence of starting materials. A small amount of dark solid remained in the reaction tube.

REARRANGEMENT STUDIES WITH ^{14}C

XIX. THE REACTION OF 2-PHENYL-1-^{14}C-ETHANOL WITH THIONYL CHLORIDE

C. C. Lee, D. J. Kroeger,[1] and D. P. Thornhill[2]

Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received January 8, 1964

ABSTRACT

The reaction of 2-phenyl-1-^{14}C-ethanol with thionyl chloride in pyridine, dioxane, toluene, or excess thionyl chloride as solvent gave 2-phenylethyl chloride showing, respectively, about 0, 15, 44, and 48% rearrangement of the ^{14}C-label from the C-1 to the C-2 positions. When reactions of 2-phenyl-1-^{14}C-ethanol or 2-*p*-anisyl-1-^{14}C-ethanol with thionyl chloride in dioxane or excess thionyl chloride were carried only to partial completion and the undecomposed chlorosulphites hydrolyzed by aqueous sodium hydroxide, the recovered alcohols showed only 0.1 to 0.5% isotope position rearrangement. This indicated a lack of return from ion-pairs to isotopically rearranged 2-arylethyl chlorosulphite and suggested that the first stage of ionization may involve ion-pairs with structures that will not result in rearrangement on return to covalent bonding, or that the first ion-pair may decompose faster than it can return to reactant. The possibility that rearrangements via rigidly oriented ion-pairs and via the concerted S_Ni' mechanism may represent the two extremes of a graded series is discussed. It is suggested that the relative contributions from the ion-pair and from the S_Ni' mechanisms will depend on the stability of the carbonium ion as well as on the nature of the reaction solvent.

As one approach in studying the ionic nature of reactions between alcohols and thionyl chloride, isotope position rearrangements in the thermal decomposition of 1-^{14}C-2-butyl chlorosulphite and in the reaction between 2-*p*-anisyl-1-^{14}C-ethanol and thionyl chloride, carried out in various solvents, have recently been investigated in this laboratory (1, 2). The results were explained by suggesting the involvement of carbonium ion – chlorosulphite ion-pairs. In 1954, Lee and Spinks (3) reported no isotope position rearrangement in the reaction of 2-phenyl-1-^{14}C-ethanol (I) with thionyl chloride in pyridine, while the reaction of I in excess thionyl chloride without pyridine resulted in extensive rearrangement (48–50%) to 2-phenyl-2-^{14}C-ethyl chloride. Since the use of dioxane or toluene as solvent could apparently affect the course of such reactions (1, 2, 4, 5), the present study extended the work of Lee and Spinks by carrying out the reaction of I with thionyl chloride in dioxane or toluene as solvent. Moreover, the possibility of returns from ion-pairs to covalent bonding was investigated. The reactions of I or 2-*p*-anisyl-1-^{14}C-ethanol (II) with thionyl chloride were interrupted before completion. The unreacted chlorosulphites were hydrolyzed and the recovered alcohols degraded to find whether isotope position rearrangements have or have not taken place.

RESULTS AND DISCUSSION

The reaction of 2-phenyl-1-^{14}C-ethanol (I) with thionyl chloride was carried out in pyridine, excess thionyl chloride, dioxane, or toluene as solvent. In some of these experiments, the dioxane or toluene contained about 1% dissolved hydrogen chloride. The 2-phenyl-*x*-^{14}C-ethyl chloride obtained in each case was converted to hydrocinnamic acid, which, in turn, was oxidized to benzoic acid. The activity in the benzoic acid was taken as a measure of the extent of rearrangement of the ^{14}C-label from the C-1 to the C-2 positions (3). The results are summarized in Table I.

TABLE I

Rearrangements in the reaction between 2-phenyl-1-^{14}C-ethanol and thionyl chloride

Solvent	^{14}C-Activity (c.p.m./mmole)*		% rearrangement
	Hydrocinnamic acid	Benzoic acid	
Pyridine	868,000	116	0.01
Pyridine	897,000	143	0.02
Thionyl chloride	826,000	401,000	48.5
Thionyl chloride	827,000	391,000	47.3
Dioxane	826,000	125,000	15.1
Dioxane	851,000	140,000	16.4
Dioxane	381,000	57,300	15.0
Dioxane	385,000	55,600	14.4
Dioxane + 1.3% HCl	521,000	81,500	15.6
Dioxane + 1.3% HCl	530,000	84,100	15.9
Toluene	888,000	391,000	44.0
Toluene	850,000	343,000	40.3
Toluene	379,000	170,000	44.9
Toluene	385,000	171,000	44.4
Toluene + 1.0% HCl	390,000	180,000	46.2
Toluene + 1.0% HCl	390,000	177,000	45.4

*Measured by a liquid scintillation counter.

The data obtained for the reactions carried out in pyridine or excess thionyl chloride confirmed the earlier findings of Lee and Spinks (3). That essentially no rearrangement was observed for the reaction in pyridine is as expected, an S_N2 process being operative when pyridine is present (3, 6). Reactions effected in dioxane and in toluene gave, respectively, about 15% and 44% rearrangement in the product. The inclusion of hydrogen chloride in the solvents dioxane and toluene was an attempt to ascertain the extent, if any, of involvement of a chain process, such as shown by equation [1],

[1] $$HCl + ROSOCl \rightarrow ClR + SO_2 + HCl,$$

a possibility suggested by Sharman and co-workers (5). The fact that neither the rearrangement nor the yield of 2-phenyl-*x*-^{14}C-ethyl chloride was significantly affected by the hydrogen chloride indicated that under the conditions of the present experiments, the presence of about 1% hydrogen chloride did not materially influence the course of these reactions.

If the rearrangements observed in the reactions of I with thionyl chloride effected in dioxane, toluene, or excess thionyl chloride were to involve carbonium ion – chlorosulphite ion-pairs, it would be of interest to investigate if any returns would occur from ion-pairs to covalent bonding to give rise to 2-phenyl-1-^{14}C-ethyl as well as 2-phenyl-2-^{14}C-ethyl chlorosulphites. Since rearrangements observed in the reaction of 2-*p*-anisyl-1-^{14}C-ethanol (II) with thionyl chloride were best explained in terms involving ion-pairs (2), possible returns in the reactions between thionyl chloride and I as well as II were studied. The alcohols, I or II, were added, with cooling, to excess thionyl chloride or thionyl chloride in dioxane and then allowed to stand at room temperature overnight. The resulting solutions of the corresponding chlorosulphites were refluxed for suitable lengths of time. The undecomposed fraction of chlorosulphite in each experiment was then hydrolyzed with aqueous sodium hydroxide to regenerate the alcohol, which was recovered, with the aid of inactive carrier, as the urethan. From the specific activities of the urethans derived from the original alcohol and from the diluted alcohol recovered after partial reaction, calculations based on isotopic dilution permitted an estimation of the extent of decomposition of the chlorosulphite. Each sample of recovered urethan was in turn

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

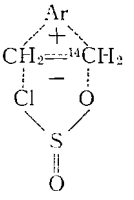
hydrolyzed back to the alcohol (7) and then oxidized to give benzoic acid or *p*-anisic acid. The ^{14}C-activities in these acids would measure the returns from ion-pairs to isotopically rearranged 2-phenyl-2-^{14}C-ethyl chlorosulphite or 2-*p*-anisyl-2-^{14}C-ethyl chlorosulphite. The results are summarized in Table II.

The possibility that the small amounts of rearrangement recorded in Table II might have arisen from hydrolysis of the reaction products, 2-phenyl-*x*-^{14}C-ethyl chloride or 2-*p*-anisyl-*x*-^{14}C-ethyl chloride, was investigated. The chlorosulphite from non-labeled 2-phenylethanol or 2-*p*-anisylethanol was subjected to partial decomposition. To the resulting material, some 2-phenyl-1-^{14}C-ethyl chloride or 2-*p*-anisyl-1-^{14}C-ethyl chloride was added and then the reaction mixture was treated with aqueous sodium hydroxide as before. The alcohols regenerated from the unreacted chlorosulphites gave urethans containing practically no radioactivity, indicating that the added labeled chlorides were not hydrolyzed under these conditions.

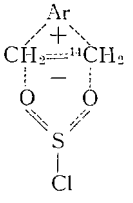
The data in Table II show that the extents of return from ion-pairs to isotopically rearranged 2-arylethyl chlorosulphite are very small, if any. These findings are in sharp contrast to the results obtained in the solvolyses of 2-phenyl-1-^{14}C-ethyl *p*-toluenesulphonate (8, 9) and 2-*p*-anisyl-1-^{14}C-ethyl *p*-toluenesulphonate (7). After partial solvolyses, the recovered sulphonates showed very significant amounts of isotope position rearrangements, indicating returns from nonclassical carbonium ion-*p*-toluenesulphonate ion-pairs to covalent bonding.

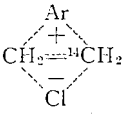
It has previously been pointed out (1) that the ionic nature of the thermal decomposition of alkyl chlorosulphites has been supported by studies on kinetics, stereochemistry, solvent effects, and rearrangements. The isotope position rearrangements observed in the present work (Table I) and in the reaction of II with thionyl chloride (2) may also involve carbonium ions. An ionic mechanism would be consistent with the estimated extents of reaction shown in Table II, which clearly indicate a faster decomposition of the chlorosulphite with a *p*-methoxyphenyl substituent than the one with a phenyl substituent. The lack of returns to rearranged 2-arylethyl chlorosulphites (Table II) could be explained by assuming that the first ion-pair formed may have classical structure III, or the first ion-pair may be rigidly oriented (1, 5) with the oxygen and chlorine atoms of the anion

$$ArCH_2{}^{14}CH_2{}^{+} \ldots\ldots\ldots OSOCl^{-}$$



III IV





V VI

oriented, respectively, towards C-1 and C-2 as shown in IV. Any return to covalent bonding from III or IV would not result in rearrangement. Another possible rigidly

TABLE II

Data from recovered alcohols after partial decomposition of the chlorosulphites from 2-phenyl-1-^{14}C-ethanol (I) and 2-*p*-anisyl-1-^{14}C-ethanol (II)

Reactant	Solvent	Reaction time at reflux temp.* (minutes)	% reacted		^{14}C-Activity (c.p.m./mmole)				% rearrangement	
					Recovered urethan		Oxidation product†			
			Run 1	Run 2	Run 1	Run 2	Run 1	Run 2	Run 1	Run 2
I	$SOCl_2$	90	32	28	1,070,000	1,080,000	1400	1400	0.1	0.1
I	$SOCl_2$	240	70		755,000		3020		0.4	
II	$SOCl_2$	8	56	53	1,520,000	1,550,000	4130	2970	0.3	0.2
II	$SOCl_2$	12	69	61	106,000	118,000	280	250	0.3	0.2
I	Dioxane	60	11		356,000		1490		0.4	
I	Dioxane	240	31		1,070,000		5150		0.5	
II	Dioxane	30	74	72	96,000	101,000	150	110	0.2	0.1

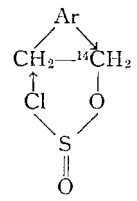
*The chlorosulphite solutions were prepared by adding I or II, with cooling, to $SOCl_2$ in the appropriate solvent and then allowed to stand overnight at room temperature. Decomposition of such solutions without any heating at reflux temperature followed by degradation of the recovered alcohols gave benzoic acid or *p*-anisic acid with less than 0.1% rearrangement.

†Benzoic acid or *p*-anisic acid from oxidation of I or II, respectively.

oriented ion-pair may have structure V. Return from V would lead to isotopically rearranged reactant; but this is excluded by the observed results. It might then be argued that ion-pair IV is also not involved in these reactions. However, Sharman and co-workers (5) have suggested that energetically IV is more favorable than V due to the greater polarizability of chlorine relative to oxygen. The decomposition of 1-^{14}C-allyl chlorosulphite to 3-^{14}C-allyl chloride was attributed by these workers (5) to an ion-pair oriented as in IV to the exclusion of one analogous to V. The anion of the first ion-pair formed in the reactions under study is "complex" and, as suggested by Cram (10), will collapse to a simple ion-pair, with structure VI or its equivalent, which will give rise to products having a maximum of 50% rearrangement. The results in Table II might also be explained by assuming that the first ion-pair could decompose to simple ion-pair VI faster than it could return to reactant (cf. ref. 11).

It is of interest to compare the rearrangement data recorded in Table I with those reported earlier (2) for analogous reactions between II and thionyl chloride. In the reaction of I with thionyl chloride, more rearrangement was noted with toluene than with dioxane as solvent (Table I). This behavior is similar to that observed in the thermal decomposition of 1-^{14}C-2-butyl chlorosulphite (1). On the other hand, in the reaction of II with thionyl chloride, more rearrangement was obtained when the reaction was carried out in dioxane than in toluene (2). For the reaction in dioxane, it was suggested (2) that because of the greater tendency of neighboring *p*-anisyl groups to form bridged ions, the carbonium ion moiety of the ion-pairs may have developed considerable nonclassical structure (such as IV, Ar = *p*-$CH_3OC_6H_4$) before being solvated by dioxane. The net result is a relatively large amount of rearrangement in the product. Since dioxane can apparently exert a specific solvent effect by solvating the carbonium ion as it displaces the chlorosulphite anion (4), the relatively lesser ability of neighboring hydrogen or phenyl to participate and displace dioxane would account for the smaller rearrangements in the products from reactions involving the 1-^{14}C-2-butyl and 2-phenyl-1-^{14}C-ethyl systems. The observed isotope position rearrangements of about 4% (1), 15% (Table I), and 44% (2), respectively, for the decomposition of the chlorosulphites from 1-^{14}C-2-butanol, 2-phenyl-1-^{14}C-ethanol (I), and 2-*p*-anisyl-1-^{14}C-ethanol (II) are in good qualitative agreement with this picture.

The observed rearrangements may also be explained by an S_Ni' mechanism as depicted by VII. In the reaction of II with thionyl chloride (2), the finding that the extents of rearrangement apparently followed the capability of the medium in supporting ionization



VII

suggested that ion-pairs rather than the largely covalent S_Ni' process may play the dominant role. Pegolotti and Young (12) have suggested for allylic rearrangements that the process via an intimate ion-pair analogous to IV and the S_Ni' mechanism analogous to VII may represent extremes of a graded series or a range of mechanisms. In the decomposition of the chlorosulphites from I or II in various solvents, the contribution from IV

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and VII will depend on both the stability of the carbonium ion and the nature of the solvent. Because of the greater carbonium ion stability, reaction of II with thionyl chloride may involve ionic characteristics even when effected in hydrocarbon solvents. In the present study, the rearrangements observed in the reaction of I with thionyl chloride may arise from intermediate ion-pairs when the chlorosulphite was decomposed in excess thionyl chloride or in dioxane. When the reaction was effected in toluene, the rearrangement was almost as high as that found for reaction in excess thionyl chloride. The contribution from the concerted, highly covalent S_Ni' process may be largely responsible for this fairly extensive amount of rearrangement when the reaction of I with thionyl chloride was carried out in toluene.

EXPERIMENTAL

The preparation of 2-phenyl-1-^{14}C-ethanol (I) and its reaction with thionyl chloride in pyridine were carried out essentially as described by Lee and Spinks (3).

Reaction in Excess Thionyl Chloride

To 30 ml of thionyl chloride, cooled in an ice bath, was added dropwise 3.0 ml of I. The mixture was stirred at room temperature for 3 hours and then refluxed for 24 hours. After cooling, 30 ml of ice-water was introduced and the resulting material was extracted several times with ether. The combined extract was washed successively with water, 10% sodium carbonate solution, and again water, and then dried over anhydrous sodium sulphate. After removal of the ether, the residue was distilled under reduced pressure, giving, for duplicate runs, 1.6 g (46%) and 1.4 g (40%) of 2-phenyl-*x*-^{14}C-ethyl chloride (VIII), b.p. 76–78° C at 10 mm (lit. (3) b.p. 85–87° C at 17 mm).

Reaction in Dioxane

A solution of 3.0 ml of I in 15 ml of dioxane was added dropwise at room temperature to a solution of 5.0 ml of thionyl chloride in 15 ml of dioxane. The resulting solution was stirred at room temperature for 24 hours and then refluxed for 48 hours. After cooling, ice-water was added and the mixture worked up as before. The yields of VIII for four similar runs were 1.2 g (34%), 1.4 g (40%), 1.8 g (51%), and 1.4 g (40%).

For the reaction in dioxane with hydrogen chloride present, gaseous hydrogen chloride was bubbled into dioxane and the increase in weight indicated that 1.3% hydrogen chloride was absorbed. Using this dioxane containing hydrogen chloride as solvent, the reaction was carried out exactly as described above. The yields of product VIII for duplicate runs were 1.3 g (37%) and 1.7 g (48%).

Reaction in Toluene

A solution of 3.0 ml of I in 15 ml of toluene was added dropwise to 5.0 ml of thionyl chloride in 15 ml of toluene, stirred at room temperature for 24 hours and then refluxed for 100 hours. The resulting solution was treated with ice-water and worked up as before to give, for dulpicate runs, 2.0 g (57%) and 1.8 g (51%) of product VIII.

Because of the prolonged refluxing, in order to avoid excessive decrease in volume, twice the amount of toluene (total volume of 60 ml) was used in two further experiments. The yields of chloride VIII obtained in these runs were 1.7 g (48%) and 1.2 g (34%).

For the reaction in toluene containing hydrogen chloride, gaseous hydrogen chloride was bubbled into toluene and the increase in weight indicated the presence of 1.0% hydrogen chloride. When the reaction of 3.0 ml of I with 5.0 ml of thionyl chloride in a total of 60 ml of toluene containing 1.0% hydrogen chloride was effected as described above, the yields of VIII for duplicate runs were 1.2 g (34%) and 1.5 g (42%).

Degradation of 2-Phenyl-x-^{14}C-ethyl Chloride (VIII)

The product, VIII, from each experiment was converted to a solid derivative, hydrocinnamic acid, which, in turn, was oxidized with alkaline potassium permanganate to give benzoic acid. The procedures have been described previously (3).

Partial Decomposition of the Chlorosulphites from 2-Phenyl-1-^{14}C-ethanol (I) and from 2-p-Anisyl-1-^{14}C-ethanol (II) in Dioxane

To a cooled and stirred solution of 3.0 ml of thionyl chloride in 50 ml of dioxane was added dropwise 3.0 g of alcohol I or II. The mixture was stoppered and allowed to stand overnight. The resulting solution, presumably containing the corresponding chlorosulphite of I or II, was refluxed for a suitable length of time (Table II) and then cooled in an ice bath. The undecomposed portion of chlorosulphite was hydrolyzed by the addition with stirring of 8.0 g of sodium hydroxide in 40 ml of water. One gram of inactive 2-phenylethanol or 2-*p*-anisylethanol was then introduced as carrier. The resulting mixture was extracted four times with ether, the combined extract washed with water, and then dried over anhydrous sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

sulphate. After removal of the ether, the residue was distilled under reduced pressure to give about 2 g of recovered alcohol.

The recovered, diluted alcohol, I or II, was heated for 5–10 minutes with phenyl isocyanate according to standard procedure to give the corresponding phenylurethans. Each sample of urethan was purified by repeated recrystallization from carbon tetrachloride – petroleum ether. The phenylurethan of I melted at 80° C (lit. (13), m.p. 79–80° C), and that of II melted at 128° C (lit. (7), m.p. 127–128° C).

Each sample of phenylurethan was hydrolyzed by treatment with alcoholic potassium hydroxide as described by Jenny and Winstein (7) and the resulting I or II was oxidized with alkaline potassium permanganate to give benzoic acid or *p*-anisic acid.

Partial Decomposition of the Chlorosulphites from I and from II in Excess Thionyl Chloride

To 50 ml of thionyl chloride, stirred and cooled in an ice bath, was added dropwise 3.0 g of alcohol I or II, and then stoppered and allowed to stand at room temperature overnight. The resulting solution was refluxed for a suitable length of time (Table II). Most of the excess thionyl chloride was removed at room temperature under reduced pressure. When the residual volume was about 3 ml, 40 ml of ether was added, and the solution treated with aqueous sodium hydroxide. One gram of inactive alcohol was introduced as carrier and the resulting mixture worked up in the same manner as described above.

Hydrolysis of Inactive Chlorosulphite in the Presence of Labeled Chloride

To ascertain whether 2-phenyl-1-^{14}C-ethyl chloride or 2-*p*-anisyl-1-^{14}C-ethyl chloride would undergo hydrolysis under the conditions by which unreacted chlorosulphite was hydrolyzed with aqueous sodium hydroxide, the chlorosulphite from inactive 2-phenylethanol or 2-*p*-anisylethanol in dioxane solution was refluxed to effect partial decomposition. Two grams of 2-phenyl-1-^{14}C-ethyl chloride or 2-*p*-anisyl-1-^{14}C-ethyl chloride was introduced into the reaction mixture and then the undecomposed chlorosulphite was hydrolyzed with aqueous sodium hydroxide. The regenerated alcohol, isolated as the phenylurethan as described above, contained practically no radioactivity, thus indicating that the labeled chlorides did not hydrolyze to the respective alcohols under these conditions.

The 2-phenyl-1-^{14}C-ethyl chloride used in this experiment was prepared from the reaction of I with thionyl chloride in pyridine. It is, however, known that reaction of II with thionyl chloride in pyridine gave a chloride product with about 0.5% rearrangement (2). 2-*p*-Anisyl-1-^{14}C-ethyl bromide has been prepared from the reaction of 2-*p*-anisyl-1-^{14}C-ethyl *p*-toluenesulphonate with anhydrous lithium bromide in dry acetone (14). An analogous attempt to obtain the chloride using lithium chloride in acetone failed, presumably because of the low solubility of lithium chloride in acetone. However, 2-*p*-anisyl-1-^{14}C-ethyl chloride without rearrangement was successfully prepared in 48% yield by refluxing for 3 hours a mixture of 19.0 g of 2-*p*-anisyl-1-^{14}C-ethyl *p*-toluenesulphonate and 8.0 g of anhydrous calcium chloride in 200 ml of dry acetone.

STUDIES ON THE THERMODYNAMICS AND CONDUCTANCES OF MOLTEN SALTS AND THEIR MIXTURES

PART I. THE DENSITIES AND MOLAR VOLUMES OF LITHIUM CHLORATE AND OF LITHIUM CHLORATE – LITHIUM NITRATE MIXTURES

A. N. Campbell and M. K. Nagarajan
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received October 24, 1963

ABSTRACT

The densities at different temperatures of pure molten lithium chlorate and of mixtures of lithium chlorate with lithium nitrate have been determined by a method of high precision. The change of molar volume with temperature has been interpreted in the light of possible structural changes in the melt.

In recent years a number of studies dealing with molten salts have been made. Since there is no adequate theory of the molten state, many of these studies have been quite speculative in nature. We confine ourselves in the present work to the presentation of some precise thermodynamic measurements on a particular binary fused salt system, the $LiClO_3$–$LiNO_3$ system, and results which can be inferred from these measurements. Because of the low melting points involved considerable improvement in experimental accuracy is possible over that obtained in work involving higher melting salt systems.

From a knowledge of the density and molar volume changes with temperature, information on the change in structure of the melt can be obtained. Some approximate relations between the molar volumes and the ionic character of a melt have been given by Drossbach (1).

EXPERIMENTAL

Lithium chlorate was prepared by a method originally suggested by Potilitzin (2) and by Kraus (3), and later modified by Campbell and Griffiths (4). The method involves the mixing of equimolar proportions of barium chlorate and lithium sulphate. The precipitated barium sulphate is filtered off and the clear solution titrated alternately with solutions of lithium nitrate and of barium chlorate until all excess over stoichiometric proportions is removed. The solution is then concentrated by vacuum distillation at about 60°. When the solution has attained a concentration of about 90% lithium chlorate, it is cooled in an ice-bath, when crystals of lithium chlorate separate out. The lithium chlorate crystals are removed by filtration and kept over sulphuric acid for a period of from 2 to 3 weeks. After the salt is sufficiently dry, it is ground to a fine powder in a dry-box. Final drying is then carried out under vacuum, evolved water being trapped in barium oxide. At various stages of this latter process, the melting point and specific conductance were determined, as criteria of dryness. Our final figure for the melting point of anhydrous lithium chlorate was 127.9° C. The specific conductance (electrical) was determined as 0.1148 ± 0.0002 ohm^{-1} cm^{-1} at 131.8°. The lithium nitrate used as addition material was a Fisher Reagent Grade material and it was not further purified except to dry it thoroughly.

The thermostat fluid used was Dow–Corning silicone fluid 550. The temperature was controlled by means of a Thyratron relay and did not vary more than ±0.1° at 130°.

The form of the dilatometers is shown in Fig. 1(*a*). They were made of pyrex glass and had a 1-mm bore capillary, 8 cm long. The capillaries were precision drilled and had a manufacturer's (Corning Glass) reported precision of ±0.002 mm. The slanted sidearm, terminating in a bulb, served as an overflow for the excess melt.

The dilatometers were calibrated with redistilled reagent grade mercury, at four temperatures. The meniscus level of the mercury column was adjusted to coincide with one of the stem marks, by means of a long hypodermic needle. The dilatometer and its contents were then weighed. This procedure was repeated for the remaining two of the three calibration marks. This calibration was carried out at four controlled temperatures. The plots of volume versus temperature, for each calibration mark, were essentially linear. The advantage of this method of calibration is that it does not require any correction for the expansion of the glass.

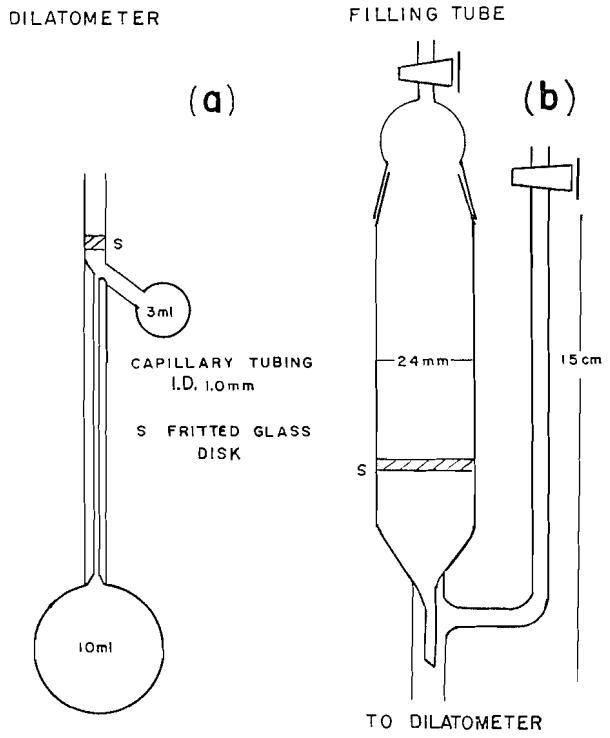

FIG. 1.

Because of the extreme hygroscopicity of lithium chlorate (it is as bad as phosphorus pentoxide) all operations with it have to be conducted in a completely moisture-free atmosphere. The transferring apparatus is shown in Fig. 1(*b*). This apparatus was sealed to the top of the dilatometer, as indicated in the diagram. The top compartment was loaded with anhydrous lithium chlorate, in a nitrogen-filled dry-box. The entire assembly was then evacuated and kept in a thermostat, at about 165°. As the lithium chlorate melted it flowed down and collected gradually in the bulb of the dilatometer, filling it without gas bubbles. When bulb and stem were full, excess lithium chlorate overflowed into the side bulb. In this way it was possible to fill the dilatometer to the desired level without having to add or remove material. The dilatometer was removed from the thermostat and sealed under vacuum at the constriction just above the smaller fritted glass disk. It was then weighed. This disk was very effective and is essential to the accuracy of all measurements with molten salts: it prevents any silt (arising from the decomposition of the thin layer of lithium chlorate during sealing) getting into the capillary bore. When we were dealing with mixtures of lithium chlorate and lithium nitrate, it was necessary to prepare the mixtures in advance and transfer the completely homogeneous melt to the transfer apparatus. All operations were carried out within the dry-box.

The filled dilatometer was now placed in the accurate thermostat. After the attainment of thermal equilibrium, the height of the liquid meniscus with reference to one of the three marks on the stem was determined with a microcathetometer. The distances between the marks were also measured at this temperature. From these data and the calibration graph, the volume of the liquid was obtained by interpolation. The procedure was repeated at intervals of about 2° over the range 130° to 170°. At constant temperature, the heights were reproducible to ±0.01 mm. The weight of the sample was obtained by breaking the dilatometer and weighing the broken pieces. Density measurements were made with pure lithium chlorate and four mixtures containing 0.108, 0.171, 0.227, and 0.292 mole fraction lithium nitrate.

A careful estimate of the overall precision of the method showed that the maximum possible error in the determination of density amounted to ±0.0002 g ml^{-1}.

RESULTS

Table I gives the densities and molar volumes of pure lithium chlorate and of the four mixtures, at different temperatures. When these values are plotted against temperature,

admirable straight lines are obtained, both for density and molar volume. The molar volume data were analyzed, by the method of least squares and using a Bendix computer, on the basis of the straight line equation, and this equation is reproduced at the bottom of each section of the table.

Isothermal cuts from the basic molar volume data were made, to show the dependence of molar volume on composition. The interpolations at arbitrarily chosen temperatures (390° K to 450° K at 10° intervals) were carried out on the computor. The values so obtained are given in Table II. The dependence of molar volume on the mole fraction of

lithium nitrate (n_2) at constant temperature satisfies the quadratic equation:

$$V = A_0 + A_1 n_2 + A_2 n_2^2$$

where A_0, A_1, and A_2 are constants. The data were fitted to a "best" curve by the method of least squares. The values of the constants, at different temperatures, are given in Table III.

TABLE III

Values of constants in the equation for the "Best" curve by the method of least squares ($V = A_0 + A_1 n_2 + A_2 n_2^2$)

The values of the coefficients of thermal expansion, α, were obtained from the equation $V = V_0(1+\alpha t)$; they are given in Table IV.

DISCUSSION

The dependence of the molar volume of molten lithium nitrate on temperature is given by the linear relation:

$$V = (35.503 + 0.0192\ T)\ \text{ml},$$

with an observed deviation of ±0.006 ml. It is generally agreed (5) that salts with non-spherical polyatomic anions, such as nitrates and chlorates, possess a more covalent

character than salts with spherical anions (e.g. chlorides, bromides, iodides). Klemm's rule (1) states that, in general, covalent melts possess higher molar volumes than ionic melts, owing to the weaker intermolecular forces in salts of the former type. For the same reason, the coefficient of expansion (α) is also generally higher in covalent melts than in ionic melts. The values of molar volume and of α for molten lithium chlorate suggest that the melt is probably more covalent than ionic in character but such a deduction is only approximate and requires further corroborative evidence.

We discuss the molar volume data for lithium chlorate – lithium nitrate mixtures according to an argument closely related to that developed by Papousek and Kucirek (6). All changes in molar volume of lithium chlorate – lithium nitrate mixtures are discussed relative to an assumed standard or reference state, in this case, 1 mole of pure lithium chlorate at its melting point (401.0° K). This assumption implies that the basic lattice of the reference state predominates over the entire region of temperature and composition involved, in other words, no major change or breakdown of the basic reference state lattice occurs in the region of investigation. The molar volume is considered to be a function of only two variables, viz. temperature and composition, i.e. $V = f(T,n_2)$, where n_2 is the mole fraction of lithium nitrate. The change in molar volume (dV) from the reference state is then defined by the complete differential

$$dV = (\partial V/\partial T)_{n_2}.dT + (\partial V/\partial n_2)_T.dn_2$$

where $(\partial V/\partial T)_{n_2}$ is the rate of change in molar volume with temperature at a fixed composition and $(\partial V/\partial n_2)_T$ is the rate of change of molar volume with composition at constant temperature, and dT and dn_2 are increments of temperature and composition.

The term $(\partial V/\partial T)_{n_2}$ is the thermal expansivity and the term $(\partial V/\partial n_2)_T$ is related to the partial molar volume $\bar{V}_2$ by the equation

$$(\partial V/\partial n_2)_T = \bar{V}_2.[n_T/(1-n_2)],$$

where n_T = total moles in the system. We think it instructive to separate these two quantities and to evaluate their respective effects on ΔV, the change in volume from the standard state, in this case pure molten lithium chlorate at its melting point.

Writing

$$V_T = (\partial V/\partial T)_{n_2}$$

$$V_n = (\partial V/\partial n_2)_T$$

the equation

$$\Delta V = \int_{T_0}^{T} V_T.dT + \int_{n_2=0}^{n_2=n_2} V_n.dn_2$$

450.0	−5.200	−7.257	−9.314	−11.370

The individual parts of the equation

$$\Delta V = \int_{T_0}^{T} V_T . dT + \int_{n_2=0}^{n_2=n_2} V_n . dn_2,$$

viz., the part due to temperature change, $\int V_T . dT$, and the part due to composition change, $\int V_n . dn_2$, of the total volume change, from the reference state, have been obtained by evaluating the integrals graphically, within appropriate limits. These parts are collected in Table VII and are shown graphically in Fig. 2, as functions of the composition of the melt. At low temperatures, and high concentrations of lithium nitrate, the change due to change of composition predominates. Thus, though the temperature effect is always positive above the reference temperature, the composition effect, which is presumably connected with interactions in the melt, contributes a large negative value, and the net effect is negative. It is noteworthy that the temperature effect increases considerably with increasing temperature and this may indicate a breakdown in the internal configurations.

RELATIVE RATES OF ABSTRACTION OF HYDROGEN FROM PROPANE AND *n*-BUTANE BY ATOMIC HYDROGEN

H. A. KAZMI[1] AND D. J. LE ROY
Department of Chemistry, University of Toronto, Toronto, Ontario
Received October 28, 1963

ABSTRACT

The activation energy for the abstraction of hydrogen from *n*-butane by atomic hydrogen was found to be approximately 1 kcal mole^{-1} smaller than for the analogous reaction with propane. The A factor is smaller by a factor of two. The A factors are discussed in terms of activated complex theory.

The recent determination in this laboratory (1) of the absolute value of the rate constant for the reaction

[1] $$H + C_3H_8 = H_2 + C_3H_7$$

has provided the opportunity for the determination, by relative methods, of the rate constants for other H atom reactions having comparable rates. In the present paper we report the results of experiments in which we determined the rate constant for reaction [2] relative to that for [1].

[2] $$H + n\text{-}C_4H_{10} = H_2 + C_4H_9$$

If H atoms are allowed to react with a mixture of propane and butane, and if the only reactions leading to propane and butane consumption are [1] and [2], and if neither compound is re-formed, then

[i] $$k_1/k_2 = \frac{\log [C_3H_8]_0/[C_3H_8]_t}{\log [C_4H_{10}]_0/[C_4H_{10}]_t}.$$

The experimental conditions used in the present work were similar to those used previously in studying the reaction with propane alone (1). The total concentration of hydrocarbons in the reaction vessel was approximately 10^{14} molecules cm^{-3}, while the H atom concentration was an order of magnitude greater. Since no products other than methane were found under these circumstances, it seems reasonable to assume that the use of [1] is valid.

The consumption of each hydrocarbon was measured relative to the concentration of an inert substance, carbon dioxide. The gases were analyzed by gas chromatography, using helium as the carrier gas and silica gel as the column material. Peak areas were measured with a planimeter, and are subject to an error of about 1%. The differing response factors for the detection of the three gases cancel out, permitting areas to be substituted for concentrations. The areas for the original gas mixture were in the proportion $C_3H_8:C_4H_{10}:CO_2::0.412:0.627:1$.

The results are shown in Fig. 1 in the form of an Arrhenius plot. Least squares treatment of the data yielded the expression

$$k_1/k_2 = (A_1/A_2) \exp - [(E_1 - E_2)/RT] = 2.0 \exp (-1.07 \times 10^3/RT).$$

[1]*Present address: Department of Chemistry, University of Peshawar, Peshawar, Pakistan.*

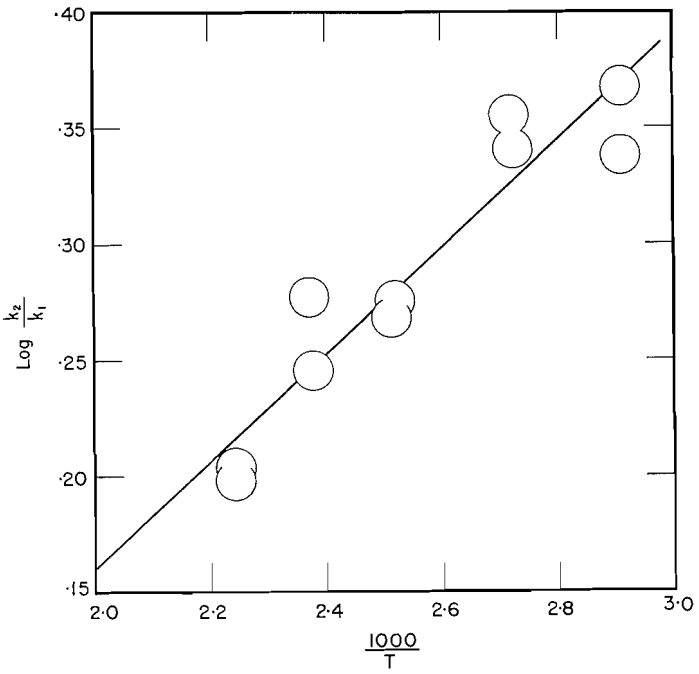

FIG. 1. Arrhenius plot of k_2/k_1.

Thus, utilizing the value $k_1 = 2.2\times10^{-10}$ exp $(-8.2\times10^3/RT)$ cm^3 molecule^{-1} sec^{-1} obtained previously (1), we find

$$k_2 = 1.1\times10^{-10} \exp(-7.1\times10^3/RT) \text{ cm}^3 \text{ molecule}^{-1} \text{ sec}^{-1}$$

$$\text{or } 6.6\times10^{13} \exp(-7.1\times10^3/RT) \text{ cm}^3 \text{ mole}^{-1} \text{ sec}^{-1}.$$

In the previous work, on reaction [1], the experimental evidence indicated that the reaction was predominantly with the secondary hydrogen atoms. It was not possible to draw any conclusion regarding this matter for reaction [2]. For the purpose of the following discussion, however, it will be assumed that only secondary hydrogen atoms are abstracted from *n*-butane.

DISCUSSION

Activated complex theory, in its original form (2), predicts that the A factor for a bimolecular reaction can be written in the form

[ii] $$A = \kappa e^2(kT/h) \exp(\Delta S^{\ddagger}/R),$$

in which $\Delta S^{\ddagger}$ refers to the molar entropy of formation of the activated complex from the reagents in the standard state of 1 mole cm^{-3}.

It has been pointed out a number of times, and most recently and convincingly by Schlag (3), that equation [ii] does not take into consideration the possibility of multiple paths. Account of this may be taken in two ways. One can disregard the external symmetry numbers of the reagents and the activated complex, defining $\Delta S^{\ddagger}$ on the basis that these are all unity, and then multiply the right-hand side of [ii] by n, the number of possible reaction paths; this would introduce a factor of two for reaction [1], four for reaction [2].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Alternatively, one can retain the actual external symmetry numbers in defining $\Delta S^{\ddagger}$ and multiply the right-hand side of [ii] by $n' = n/s$, where s is the product of the symmetry numbers of the reagents divided by the symmetry number of the complex. This would introduce a factor of unity for reaction [1], two for reaction [2].

In the case of reaction [2] it can be seen that the factor $n' = 2$ is required on *thermodynamic* grounds (if one is to retain the concept that the complex is in equilibrium with the reagents). Both the complex and the secondary butyl radicals formed from it must exist in two distinct forms, which are non-superimposable mirror images, say *d* and *l*. If C_d^* and C_l^* are the equilibrium concentrations of the two complexes then the forward rate of the reaction A + B = X + Y will be equal to $k^*C_d^* + k^*C_l^* = 2k^*K^*[A][B]$, where k^* is the unimolecular rate constant for the decomposition of either complex into products and K^* is the equilibrium constant for the formation of either complex from the reagents. Benson and Nangia (4) have preferred to consider this factor of two as an $R \ln 2$ term in the entropy of formation of the complex, arising from the entropy of mixing of the two forms of the complex.

If we define $\Delta S_{\text{II}}^{\ddagger}$ as the intrinsic internal contribution to the entropy of formation of the complex, omitting the translational and symmetry contributions, as well as that from the coordinate of decomposition, the corrected form of [ii] can be written:

[iii] $$A = \kappa n'(N^5h^4/8\pi^3ekT)^{1/2}\,\mu^{-3/2}(\sigma_a\sigma_b/\sigma^{\ddagger})\exp(\Delta S_{\text{II}}^{\ddagger}/R),$$

in which σ_a and σ_b refer to the two reactants and μ is the reduced molecular weight.

The square root term is only slightly dependent on temperature and it is convenient to calculate its value for 400° K, in the usual range of experimental values. Thus, at 400° K,

[iv] $$A = 2.02\times10^{13}n'\mu^{-3/2}(\sigma_a\sigma_b/\sigma^{\ddagger})\exp(\Delta S_{\text{II}}^{\ddagger}/R),$$

when κ is assumed to be unity.

In many instances the external symmetry numbers are known, or can be estimated with some degree of certainty, and hence the only unknowns are κ, which is usually assumed to be close to unity, and the factor $\exp(\Delta S_{\text{II}}^{\ddagger}/R)$. By making the assumption that the rotational contribution to $\Delta S_{\text{II}}^{\ddagger}$ is separable, and making reasonable assumptions about bond lengths and bond angles in the complex (5), the uncertainty in A can be reduced to that in the vibrational (and possibly electronic) contributions. For reactions in which a = H and b is a hydrocarbon, Bywater and Roberts (6) showed that rotation about the center of gravity contributed +2.3 e.u. to $\Delta S_{\text{II}}^{\ddagger}$ for methane, −0.1 e.u. for ethane, and a negligible amount for higher hydrocarbons. Internal rotations would have to be taken into account in certain instances, but in the case a = H (or even a = D) their contribution to $\Delta S_{\text{II}}^{\ddagger}$ would be quite small, except for possible changes in the symmetry numbers for internal rotations. In a series of reactions involving hydrogen abstraction from a paraffin by atomic hydrogen, one would therefore expect the relative values of the A factors to be determined almost exclusively by the relevant values of κ, n', μ, σ, and the vibrational contribution to $\Delta S_{\text{II}}^{\ddagger}$.

Herzberg's assumption (7) that propane has C_{2v} symmetry has recently been confirmed by Lide (8); it therefore has the symmetry number $\sigma = 2$. Presumably $\sigma^{\ddagger} = 1$. Using the value $A_1 = 1.3\times10^{14}$ cm^3 mole^{-1} sec^{-1} obtained in this laboratory (1), and assuming κ and n' to be equal to unity, we obtain the value $\Delta S_{\text{II}}^{\ddagger} = 6.8$ e.u. for reaction [1].

The complex has three more internal degrees of freedom than propane. One of these has been taken into account in the factor kT/h of equation [ii], namely the C–H_2 stretching vibration. By making the usual assumption that all frequencies except the doubly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

degenerate C–H–H bending and the H–H stretching are the same in the complex as in the propane molecule, it follows that the vibrational contribution to $\Delta S_{11}^{\pm}$ will arise from these new frequencies and the disappearance of one of the C–H frequencies on the secondary carbon of propane.

To affect A by as much as 10% any contribution to $\Delta S_{11}^{\pm}$ would have to be at least as large as 0.19 e.u.; from tables of Einstein functions it can be seen that this would necessitate a fundamental frequency of less than 1100 cm^{-1}. The loss of the C–H frequency will therefore have no effect. If we assume an H–H stretching frequency greater than 1100 cm^{-1} we are left with the doubly degenerate bending frequency as the only important contribution to $\Delta S_{11}^{\pm}$. To contribute 6.8 e.u. at 400° K it would have to have a value of 138 cm^{-1}.

From the result $A_2 = 6.6 \times 10^{13}$ $cm^3\,mole^{-1}\,sec^{-1}$ obtained from the present experiments, we calculate that $\Delta S_{11}^{\pm} = 4.2$ e.u. A statistical analysis of the results shows a probable error of 0.24 e.u. in the difference of 2.6 e.u. between the values of $\Delta S_{11}^{\pm}$ for reactions [1] and [2]. The difference is therefore significant. If, as before, the whole of $\Delta S_{11}^{\pm}$ is attributed to the doubly degenerate C–H–H bending frequency in the complex, then its value here must be 273 cm^{-1}, approximately twice that found for the complex C_3H_9.

The reason for the smaller value of $\Delta S_{11}^{\pm}$ for reaction [2] is not easily explained. However, the discrepancy is not unique to the abstraction of secondary hydrogen by atomic hydrogen. The observed ratio of the A factors, A_4/A_3, for secondary hydrogen abstraction from propane [3] and *n*-butane [4] by atomic chlorine (9) is 1.2_2; the value calculated from [iv], assuming $\Delta S_{11}^{\pm}$ to be the same for each reaction is 1.79, giving a discrepancy factor of 0.63. The effect is even larger for the abstraction of tertiary hydrogen from isobutane [5] and 2,3-dimethylbutane [6] by methyl radicals (10); the observed value of A_6/A_5 is 0.63; the calculated value is 1.8, yielding a discrepancy factor of 0.35. Since the present experiments give a discrepancy factor of 0.25 for A_2/A_1, one might conclude that the effect of adjacent hydrogen atoms on the C–H–X bending frequency is greatest when the abstracting radical X has the smallest mass, although the amount of supporting evidence is very limited.

FORMATION CROSS SECTIONS OF VARIOUS RADIONUCLIDES FROM Ni, Fe, Si, Mg, O, AND C FOR PROTONS OF ENERGIES BETWEEN 130 AND 400 MEV[1]

GARIMELLA V. S. RAYUDU
Department of Chemistry, Carnegie Institute of Technology, Pittsburgh 13, Pennsylvania
Received August 14, 1963

ABSTRACT

Formation cross sections of Co^{56}, Mn^{54}, Mn^{52}, Cr^{51}, V^{48}, P^{32}, and Be^{7} from Fe and Ni; of Na^{24}, Na^{22}, and Be^{7} from Si and Mg; and of Be^{7} from C and O have been measured for incident protons of energies between 130 and 400 Mev to assist in the interpretation of data on cosmic-ray-produced nuclides in iron and stone meteorites. Formation cross sections of Mn^{54}, Mn^{52}, Cr^{51}, V^{48}, and P^{32} are found to be a factor of 2 to 3 lower from Ni than from Fe, whereas those of Co^{56} are 20- to 50-fold higher than from Fe. Be^{7} cross sections from C are found to be almost the same as from O, within experimental uncertainties. Cross sections of Na^{24} and Na^{22} from Mg and Si are found to be relatively energy independent, whereas those of P^{32} and Be^{7} from Ni and Fe are found to increase rapidly with increasing energy. Some qualitative conclusions are drawn about the production of cosmogenic activities in meteorites.

INTRODUCTION

This paper describes the variation of formation cross sections of various product radionuclides when meteoritic elements (Ni, Fe, Si, Mg, O, and C) are irradiated by protons of energies between 130 and 400 Mev. In most of the previous studies of cross sections and excitation functions for high energy nuclear reactions, as described by Miller and Hudis (1), the main interest has been on the mechanism of the interactions. Such studies have acquired additional interest in connection with the study of cosmogenic activities in meteorites. Recently, several experiments have been done by Davis (2), Fireman and Zähringer (3), Honda and Lal (4, 5), Rayudu and Shedlovsky (6–12), and Rudstam *et al.* (13, 14) using targets, projectiles, and energies directly applicable to this problem. Ideally, one should have experimental excitation functions for all cosmogenic nuclides for protons of energies from threshold to several billion electron volts and for the important secondary particles (especially neutrons, π-mesons, and photons) of energies up to hundreds of million electron volts. In practice this is impossible, and one must be satisfied with representative data which will permit reasonably accurate interpolations, extrapolations, and theoretical calculations for the more important cases.

It is important to mention that α-particle-induced reaction cross sections in medium-weight elements are comparable to proton reaction cross sections in the 130–400 Mev energy region, as reported by Koterling (15), who bombarded Nb with protons and helium ions. In addition, Davis (2) bombarded Ni and Fe with 880 Mev α-particles, and the measured cross sections of $A^{37,39}$ agreed with proton-induced formation cross sections. Because cosmic rays consist of approximately 90% protons and 8% α-particles, measurements of proton excitation functions of several relatively short-lived radioactive products from meteoritic elements were undertaken.

EXPERIMENTAL PROCEDURE AND RESULTS

The target materials are listed in Table I. Silicon targets were sliced at Westinghouse Research Laboratories; half-inch square targets of the other elements were punched in this laboratory.

[1]*This work was supported by the U.S. Atomic Energy Commission.*

TABLE I

Target elements	Thickness (mg/cm²)	Chemical form
Ni	45	Metal foil
Fe	40	Metal foil
Si	120	Thin slice
Mg	22	Metal foil
C	75	Polyethylene (85% C)
C + O	75	Delrin (40% C and 53% O)[a]
Al	7	Metal foil (monitor)

[a]A polymer with the composition: —CH_2O— produced by Dupont Co., U.S.A.; supplied by Commercial Plastics Co., Pittsburgh 13, Pa., U.S.A.

Irradiations were carried out in the circulating beam of the Carnegie Institute of Technology Synchrocyclotron with proton energies between 130 and 400 Mev. The irradiation time varied between 8 and 12 minutes. The incident proton energy was varied by placing the target at different radial distances in the circulating beam. The energy spread was estimated to be about 10% at 130 and 208 Mev and 5% at 297 and 396 Mev. Fe, Ni, Mg, and Si targets were irradiated in maximum beam currents (as much as 1 microampere), whereas for the polyethylene and Delrin targets the beam currents were of the order of 0.1 microampere. All the cross sections were measured relative to the cross sections for the $Al^{27}(p,3pn)Na^{24}$ monitor, using 1-mil aluminum foils. The cross section values used in this work are 10, 9.3, 11, and 10.6 mb at 130, 208, 297, and 396 Mev respectively. For detailed discussion of the monitor cross sections see Gray (16) and Treytl (17). Na^{24} activity was measured from the monitor foil, using an end-window proportional counter.

Fe and Ni targets.—Fe and Ni targets were dissolved in aqua regia in the presence of Co, Mn, Cr, V, Ca, P, Na, and Be carriers. Chemical separation was started 2 to 3 days after the irradiation. The chemical separation procedure is summarized in the form of a flow sheet in Fig. 1. Fe was retained in the anion-exchange step, whereas Ni was decanted with the Na and Ca fraction. After the final purification, Co was electroplated. Mn was counted as MnO_2, V as $Pb(VO_3)_2$, Cr as $BaCrO_4$, Be as BeO, and P as $MgNH_4PO_4$. Yields were estimated by weighing finally mounted samples except in the case of V, for which the yield was estimated spectrophotometrically by the peroxide method.

Si, Mg, O, and C targets.—Be^7 from polyethylene and Delrin, and Na^{24}, Na^{22}, and Be^7 from Mg and Si were measured directly using a 2 in. × 2 in. NaI (Tl) scintillation crystal in conjunction with a 512-channel pulse-height analyzer.

The radiation characteristics of the nuclides measured are given in Table II. The measured cross sections are presented in Tables III, IV, and V. The total estimated uncertainties reported for various cross sections in Tables III, IV, and V include the errors and uncertainties involved in counting, chemical yield determination, beam monitoring, and saturation factor. In all cases, duplicate determinations agreed within 5 to 12%. Fifteen percent uncertainty was estimated for cross sections at energies of 208, 297 and 396 Mev. Higher uncertainties, up to 20%, are estimated for results at 130 Mev, because of low beam current. In the case of Be^7 from O, Mg, and Si, 20 to 25% uncertainties were estimated because of the difficulties in processing the data. From Mg and Si containing both Na^{22} and Be^7 activity, the intensity of the 480-kev Be^7 photopeak was estimated from the composite 480- and 511-kev photopeak by subtracting the Na^{22} contribution to the 511-kev photopeak (calculated from its corresponding 1280-kev peak). The multiplication factor used to calculate counts due to the 511-kev peak from the counts of the 1280-kev peak was determined by counting a pure Na^{22} source under similar conditions.

DISCUSSION

The formation cross sections of Co^{56} in Fe are in good agreement with the values of Treytl (17) and Koch (18), who studied $Ni^{64}(p,n)Cu^{64}$. P^{32} cross sections from Fe and Ni are in agreement with Gray's (16) P^{32} cross sections from Co, which are between the present values from Ni and Fe. Be^7 cross sections from C are almost the same, within experimental uncertainties, as from O. This observation is in agreement with Honda and Lal (4), who reported Be^7 cross sections from C and O at 225, 300, and 400 Mev. In Table V, Na^{24} cross sections were calculated from Mg on the basis of total mass and also on the basis of Mg^{25+26}. The latter calculations are justified in the case of Mg because the (p,2p) contribution could be as much as 20 mb according to Morrison (19), who determined the $Si^{30}(p,2p)Al^{29}$ cross sections in this energy region.

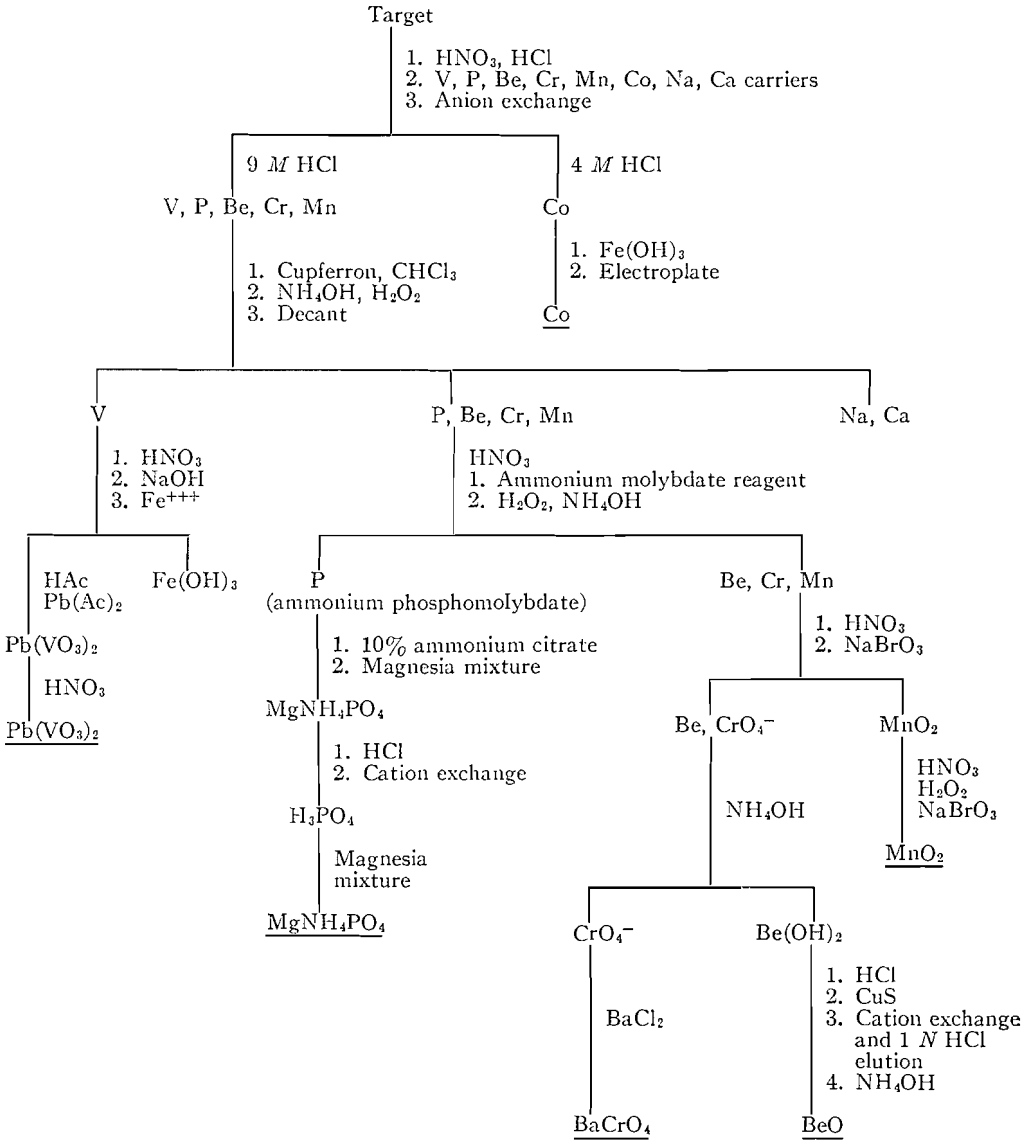

FIG. 1. Flow diagram of the chemical separation scheme for Fe or Ni targets.

From the cross sections reported in this work, some qualitative conclusions may be drawn about the production of cosmogenic activities in iron and stone meteorites.

Iron meteorites.—Production of cobalt activities from Ni is considerably higher than from Fe. High-energy products such as H^3, Be^7, Be^{10}, C^{14}, Na^{22}, Na^{24}, etc., have almost the same cross section from Fe as from Ni, whereas formation cross sections of low-energy products such as Mn^{54}, Mn^{52}, Cr^{51}, V^{48}, and P^{32} from Ni are found to be lower by a factor of 2 to 3 than from Fe. In the case of low-energy products, therefore, corrections are necessary, corresponding to Fe(~93%) and Ni(~7%) contents in meteorites.

TABLE II

Relevant properties of radionuclides measured

Nuclide[a]	Half-life[b]	Radiation measured (Mev)	Branch abundance	Type of cross section
		From Fe and Ni		
Co^{56}	77 day	β^+	0.18	I (independent)
Mn^{54}	310 day	0.850γ	1.00	I
Mn^{52}	5.7 day	β^+	0.33	C (cumulative)
Cr^{51}	27.8 day	0.320γ	0.10	C
V^{48}	16.1 day	β^+	0.56	C
P^{32}	14.3 day	β^-	1.00	I
Be^7	53 day	0.477γ	0.11	C
		From Si, Mg, O, and C		
Na^{24}	15 hour	2.75γ	1.00	I
Na^{22}	2.58 year	1.28γ	1.00	C
Be^7	53 day	0.477γ	0.11	C

[a]Co^{56} and P^{32} were measured using a methane flow-window proportional counter. Mn^{54}, Mn^{52}, Cr^{51}, V^{48}, $Na^{24,22}$, and Be^7 were measured using a 2 in.×2 in. NaI(Tl) scintillation crystal in conjunction with a 512-channel pulse-height analyzer.

TABLE III

Cross sections from iron (mb)

Proton energy (Mev)	Co^{56a}	Mn^{54}	Mn^{52}	Cr^{51}	V^{48b}	P^{32}	Be^7
130	4.25±0.85	38.2±7.6	68.6±10.3	30±6.0	5.87	0.020±0.004	0.175±0.035
208	2.26±0.34	27.7±4.2	49.0±7.4	22±3.00	6.40	0.086±0.013	0.313±0.047
297	1.50±0.22	21.4±3.2	33.7±5.1	25±3.75	8.50	0.320±0.050	0.47 ±0.071
396	0.89±0.13	18.63±2.8	24.2±4.0	25±3.75	9.50	0.61 ±0.092	0.57 ±0.086

[a]Cross sections based on 96.18% of the weight of Fe.
[b]Because up to 80–90% of the Cr^{48} had decayed by the time of separation, the V^{48} cross sections may be considered as lower limits for cumulative cross sections.

TABLE IV

Cross sections from nickel (mb)

Proton energy (Mev)	Co^{56}	Mn^{54}	Mn^{52}	Cr^{51}	V^{48}	P^{32}	Be^7
130	90	10.5±2.0	39.5±6.0	20.0±4.0	3.50	0.0070±0.0014	0.206±0.041
208	59	8.5±1.3	33.5±5.6	19.0±2.8	4.62	0.025 ±0.004	0.380±0.070
297	62	9.8±1.4	38.5±5.9	19.2±2.8	6.50	0.1330±0.020	0.594±0.090
396	45	6.95±1.0	28.0±4.3	18.0±2.7	7.50	0.2720±0.041	0.810±0.122

[a]Since 30% of the 6.4d Ni^{56} had decayed by the time of chemical separation, the cross sections may be considered as upper limits for independent formation.
[b]Since up to 80 to 90% of the Cr^{48} had decayed by the time of separation, the V^{48} cross sections may be considered as lower limits for cumulative cross sections.

Stone meteorites.—It is obvious that Fe contributes to the production of nuclides mainly in the region $15 \leqslant Z \leqslant 26$. It follows that the production of nuclides with low Z(Na^{22}, C^{14}, Be^{10}, H^3, etc.) by low-energy ($\leqslant$ 700 Mev) cosmic-ray protons comes from Si, Mg, and O rather than from Fe. Even at high energies (0.7 Bev–7 Bev), products in the region $1 \leqslant Z \leqslant 15$ are produced mainly from Si, Mg, and O rather than from Fe, because the Fe content is low in stones.

FIELD DEPENDENCE AND ANOMALOUS TEMPERATURE DEPENDENCE OF TAFEL SLOPES FOR PROCESSES OCCURRING AT HIGH ELECTROSTATIC FIELDS

M. J. DIGNAM
Department of Chemistry, University of Toronto, Toronto, Ontario
Received December 11, 1963

ABSTRACT

A consideration of the probability per unit time for the transport of a charged species over a potential barrier in the presence of a high external electrostatic field shows that the net activation energy for such a process is in general a complex function of the field strength. Both the field dependence and the anomalous temperature dependence of the Tafel slope for the steady-state anodic oxidation of Ta, Nb, and Al are accounted for quantitatively by a simple model according to which the field independent component of the potential energy function for displacement of a mobile charged species is assumed to resemble a Morse function. Accordingly, the steady-state anodic oxidation data for these metals may be represented within experimental error by only three empirical constants, the pre-exponential factor, the activation energy, and the Morse function distance parameter. If, in place of a Morse function, a parabolic or cosine potential energy function is assumed, less satisfactory agreement with the data is obtained. Although there is some doubt concerning the uniqueness of the Morse function in explaining the data, there is no doubt that the present considerations are able to account entirely for the anomalous Tafel slope behavior.

INTRODUCTION

The recent data of Young (1) on the anodic oxidation of tantalum shows an unmistakable field dependence of the Tafel slope $(\partial E/\partial \ln i)$ where E is the field strength in the oxide and i the current density. This dependence was accounted for quantitatively, over a range of temperatures, by an empirical equation of the form:

$$i = i_0 \exp\left[-(Q-\alpha E+\gamma E^2)kT\right] \qquad [1]$$

where Q, α, and γ are all positive constants. At the time equation [1] was first postulated, no theoretical justification for the quadratic term in the field, γE^2, was offered. Young (1) showed that it could not be justified by assuming a range or distribution of parameters associated with an amorphous film. Recently, Young (2) has suggested that the quadratic term may be explained in terms of an increase in the activation energy with increasing condenser pressure. As the condenser pressure is proportional to E^2, this explanation predicts a quadratic term of the correct sign.

Using Young's estimates of the magnitudes of the parameters involved, the predicted value of γ is only about 1/20 of the empirical value.* Admittedly, the estimate of the effect of pressure on the activation energy could be too small by a factor of 20. It is at least equally probable, however, that the influence of the condenser pressure is below the limit of detection. This is certainly the case for the actual estimate given by Young.

The purpose of the present paper is to show that a quadratic term of precisely the correct magnitude arises quite naturally from a more detailed analysis of ion transfer processes at high field strengths. The results obtained for the steady-state anodic oxidation of tantalum, niobium, and aluminum are compared with the theoretical predictions.

**As Young states (2) "a rule of thumb given by Jost is that, with materials such as AgCl, 100 atm are about equivalent to 1° C". Accordingly, $100\partial(Q'/kT)/\partial P \sim -\partial(Q'/kT)/\partial T$ where $Q' = Q + \Delta Q$ is the activation energy at a pressure P (in atm), $\Delta Q = 0$ when $P = 0$, and T is the temperature in °K. We also have P (atm) $= 1.2\times10^5[E\,(V/Å)]^2$ (2) so that since $\Delta Q \ll Q$ and $T \sim 300°$ K, $\Delta Q \sim 4Q[E(V/Å)]^2$ and hence $\gamma \sim 4Q = 8.6$ eÅ^{2}V^{-1} for $Q = 2.185$ ev (1). The empirical value for γ is 167.5 eÅ^{2}V^{-1} (1).*

THEORY

For generality, we shall not refer to any particular mechanism, but shall concern ourselves solely with the determination of the probability per unit time for a given charged species to cross a potential energy barrier. The results should be applicable to any high-field ionic transport process, whether it be anodic oxidation with metal–oxide interface control as suggested by Cabrera and Mott (3), anodic oxidation with transport of ions through the film rate controlling, or indeed conventional electrode processes such as hydrogen evolution.

The central problem, therefore, is to calculate the probability of an ion transfer process, p, in the presence of a very high field, E. To calculate this we must assume a form for the interaction potential between the ionic species in question and its immediate surroundings. Since we are concerned solely with highfield strengths, only the transfer probability in the direction assisted by the field need be considered. Accordingly, the potential energy function at zero applied field may be represented by $U_1'(\chi)$, where χ is the position variable chosen to increase in the ion transfer direction. It is now reasonable to suppose that the potential energy function in the presence of a field E will be given by:

$$U'(\chi,E) = U_0' + U_1'(\chi) - E\chi q \qquad [2]$$

where q is the absolute magnitude of the charge on the mobile species concerned and U_0' the usual arbitrary constant. In writing this equation, it is assumed that the interaction potential between the charged species and its surroundings is independent of the field (i.e. $\partial U'(\chi)/\partial E = 0$). If all of the bonding involved is purely ionic, this is probably a satisfactory approximation and we could proceed with equation [2] assuming quite properly that q is a constant. If covalent bonding is involved, however, q would in general be a function of both field strength and position. If q varies with field strength, it follows that $U_1'(\chi)$ would also vary with field strength for a given value of χ. In an attempt to generalize equation [2] to cover the cases where bonding has both ionic and covalent character, we shall consider the following equation:

$$U(\mu,E) = U_0 + U_1(\mu) - E\mu \qquad [3]$$

where μ is the product of the charge on the ionic species and its displacement from an arbitrary origin. It is worth noting initially that equations [2] and [3] are fundamentally identical if q is independent of χ and E. Furthermore, they differ only in the specific form of the functions U_1' and U_1 if μ is independent of field strength for fixed χ, provided that μ increases monotonically with χ over the region of interest. The difference between the equations arises, therefore, when μ is a function of E for fixed χ. For this case equation [2] implies that the potential interaction term, $U_1'(\chi)$, depends only on nuclear displacement, χ, which is clearly not valid, whereas equation [3] implies that the potential interaction term, $U_1(\mu)$, depends only on the charge displacement, μ, an assumption difficult to assess. Since an increase in μ for fixed χ (brought about by increasing E) should lead to a reduction in the bonding energy, the correction to equation [2] contained in equation [3] appears to be in the right direction. Whether or not it is of the correct magnitude, however, is not known. In the absence of detailed theoretical calculations, therefore, we must regard $U_1(\mu)$ as, in fact, a function of both E and μ. Fortunately, for realistic values of the current density for high field processes, the field can be varied only over a fairly narrow range (i.e. about $\pm 10\%$ from the mean value for anodic oxidation of the value metals). Therefore, provided $U_1(\mu)$ does not vary too rapidly with E for μ constant,

equation [3] should represent a fairly good approximation to the true behavior for field strengths in this range. We shall proceed on this assumption. The success ultimately achieved on this basis can be regarded either as evidence in support of equation [3], or as evidence that q is constant over the experimental range of field strengths.

For any given functional form for $U_1(\mu)$, it is now a simple matter to determine the net activation energy, $W(E)$, for the transfer process and hence the transfer probability, p, as a function of field. The values of μ corresponding to minima and maxima in $U(\mu,E)$, μ_0 and μ_m respectively, are obtained on solving the equation:

$$\partial U(\mu,E)/\partial\mu = 0. \qquad [4]$$

The net activation energy is then given by

$$W(E) = U(\mu_m,E) - U(\mu_0,E) \qquad [5]$$

and the transfer probability per unit time by

$$p(E) = \nu \exp [-W(E)/kT] \qquad [6]$$

where ν is the usual frequency term.

From equations [3] to [5] we may now derive the form of $W(E)$ for any reasonable representation of the potential energy function $U_1(\mu)$. If $U_1(\mu)$ contains enough disposable constants, agreement between the theoretical and empirical form of $W(E)$ can always be arranged. Such a procedure, however, has little to recommend it. We shall therefore restrict our attention to potential energy functions which involve only two disposable constants and are qualitatively of the correct form. In this way the three empirical constants of equation [1] (Q, α, and γ) will be replaced by only two independent constants, thus providing a fairly stringent test of the theory. Three obvious functions meeting these requirements are the parabolic function, the cosine function, and the Morse function. In the following sections each of these functions is considered in turn; the predictions derived from each are ultimately compared with experimental data.

"Clipped" Parabolic Potential

The simplest function one can choose to represent $U_1(\mu)$, which is qualitatively of the correct form, is the "clipped" parabolic function:

$$U_1(\mu) = \varphi(\mu/\mu^*)^2 \text{ for } \mu^* \geqslant \mu \geqslant 0 \qquad [7]$$

$$= \varphi \text{ for } \mu \geqslant \mu^*.$$

For this representation of $U_1(\mu)$, φ can be thought of as the zero field activation energy and μ^* the zero field charge-activation distance product, or "activation dipole". In view of the foregoing discussion concerning equation [3], these interpretations should not be taken too literally. It is preferable to consider φ and μ^* as extrapolated values, the extrapolation to $E = 0$ being based on experimental data at high fields only.

From equations [3], [4], and [7] we obtain:

$$[\partial U(\mu,E)]/\partial\mu = 0 = (2\varphi\mu/\mu^{*2}) - E \qquad [8]$$

from which $\mu_0 = E\mu^{*2}/2\varphi$. Since $\partial U_1(\mu)/\partial\mu$ has a discontinuity at $\mu = \mu^*$, μ_m cannot be obtained from equation [8], but is clearly given by $\mu_m = \mu^*$. We now have:

$$W(E) = \varphi - E\mu^*[1 - E\mu^*/4\varphi]. \qquad [9]$$

Before discussing this result, $W(E)$ will be calculated for a cosine and a Morse potential energy function.

Cosine Potential

Assuming the following cosine potential energy function

$$U_1(\mu) = (\varphi/2)[1-\cos \pi\mu/\mu^*] \qquad [10]$$

where both φ and μ^* have the same significance as for the parabolic potential, we can write:

$$[\partial U(\mu,E)]/\partial\mu = 0 = (\pi\varphi/2\mu^*) \sin (\pi\mu/\mu^*)-E$$

or

$$\sin \pi\mu/\mu^* = 2\mu^*E/\pi\varphi. \qquad [11]$$

Solving equation [11] for μ, the values for μ_0 and μ_m are given by the solutions which lie in the intervals $(0, \mu^*/2)$ and $(\mu^*/2, \mu^*)$ respectively. It therefore follows that:

$$U_1(\mu_0) = (\varphi/2)\left\{1-\left[1-\frac{4}{\pi^2}\left(\frac{\mu^*E}{\varphi}\right)^2\right]^{\frac{1}{2}}\right\} \qquad [12]$$

$$U_1(\mu_m) = (\varphi/2)\left\{1+\left[1-\frac{4}{\pi^2}\left(\frac{\mu^*E}{\varphi}\right)^2\right]^{\frac{1}{2}}\right\} \qquad [13]$$

and

$$\mu_0 = \frac{\mu^*}{\pi}\sin^{-1}\frac{2\mu^*E}{\pi\varphi} = \mu^*-\mu_m. \qquad [14]$$

Substituting these values into equations [3] and [5] we obtain

$$W(E) = \varphi\left[1-\frac{4}{\pi^2}\left(\frac{\mu^*E}{\varphi}\right)^2\right]^{\frac{1}{2}}-\mu^*E+\frac{2\mu^*E}{\pi}\sin^{-1}\frac{2\mu^*E}{\pi\varphi}. \qquad [15]$$

Expanding the square root term and the inverse sine function as power series in (μ^*E/φ) gives:

$$W(E) = \varphi-\mu^*E\left[1-\frac{2}{\pi^2}\frac{\mu^*E}{\varphi}-\frac{4}{3\pi^4}\left(\frac{\mu^*E}{\varphi}\right)^3 \cdots\right]$$

or

$$W(E) \simeq \varphi-\mu^*E\left[1-\frac{2}{\pi^2}\frac{\mu^*E}{\varphi}\right] \qquad [16]$$

for

$$\mu^*E/\varphi \lesssim 1.$$

Equation [16] is of the same form as that obtained for the parabolic potential energy function, the coefficient of E^2 being, however, somewhat smaller.

Morse Potential

Proceeding now with the Morse function, we have:

$$U_1(\mu) = \varphi[1-\exp(-\mu/\omega^*)]^2 \qquad [17]$$

where φ has approximately the same significance as for the other two potential functions. There is no very useful physical interpretation of ω^*, it being best regarded simply as a parameter with the same dimensions as μ. Proceeding as before, we have:

$$\frac{\partial v(\mu,E)}{\partial\mu} = 0 = \frac{2\varphi}{\omega^*}\left[1-\exp\left(-\frac{\mu}{\omega^*}\right)\right]\exp\left(-\frac{\mu}{\omega^*}\right)-E$$

or

$$\exp\left(-\frac{\mu}{\omega^*}\right) = \frac{1}{2}\left[1 \pm \left(1-\frac{2\omega^*E}{\varphi}\right)^{\frac{1}{2}}\right]. \qquad [18]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The two roots give values for μ_0 and μ_m which on substitution into equations [3] and [5] lead to the following equation:

$$W(E) = \varphi\left[1-\frac{2\omega^*E}{\varphi}\right]^{\frac{1}{2}}-\omega^*E\ln\left[\frac{1+(1-2\omega^*E/\varphi)^{\frac{1}{2}}}{1-(1-2\omega^*E/\varphi)^{\frac{1}{2}}}\right]. \quad [19]$$

Expanding the square root terms as power series in ω^*E/φ yields:

$$W(E) = [1-z-\tfrac{1}{2}z^2-\tfrac{1}{2}z^3\ldots]+\omega^*E\ln(z/2)$$
$$+\omega^*E\ln[(1+\tfrac{1}{2}z+\tfrac{1}{2}z^2.\ldots)/(1-\tfrac{1}{2}z-\tfrac{1}{4}z^2.\ldots)] \quad [20]$$

where $z = \omega^*E/\varphi$.

Expanding the second logarithm as a power series in z and collecting terms we obtain:

$$W(E) = \varphi-\omega^*E\left[1-\ln\frac{\omega^*E}{2\varphi}-\frac{\omega^*E}{2\varphi}-\left(\frac{\omega^*E}{2\varphi}\right)^2\ldots\right] \quad [21]$$

In order to arrange equation [21] in a form similar to equations [9] and [16] we shall make the following approximations:

$$(\omega^*E/2\varphi)^2 \lll 1$$

and

$$\ln\frac{\omega^*E}{2\varphi} = \ln\omega^*\left[\frac{\bar{E}+E-\bar{E}}{2\varphi}\right] = \ln\frac{\omega^*\bar{E}}{2\varphi}+\ln\left[1+\frac{E-\bar{E}}{\bar{E}}\right]$$
$$\simeq \ln\frac{\omega^*E}{2\varphi}+\frac{E}{\bar{E}}-1 \text{ for } \frac{E-\bar{E}}{\bar{E}} \ll 1$$

where $\bar{E}$ may be regarded as the mean value of the field strength for the set of measurements in question. Equation [21] then becomes

$$W(E) \simeq \varphi-\mu^*E\left[1-\frac{\mu^*E}{C\varphi}\right] \quad [22]$$

where

$$\mu^* = \omega^*\left[2-\ln\frac{\omega^*\bar{E}}{2\varphi}\right] \quad [23]$$

and

$$\frac{1}{C} = \left(\frac{\varphi}{\mu^*\bar{E}}\right)\frac{\omega^*}{\mu^*}+\frac{1}{2}\left(\frac{\omega^*}{\mu^*}\right)^2. \quad [24]$$

For comparison with experiment, it is desirable to obtain a single equation relating the experimental parameters φ, μ^*, C, and $\bar{E}$. Accordingly, from equation [24]:

$$\frac{\omega^*\bar{E}}{\varphi} = \left[1+\frac{2}{C}\left(\frac{\mu^*\bar{E}}{\varphi}\right)^2\right]^{\frac{1}{2}}-1. \quad [25]$$

Substituting this value for ω^* into equation [23] gives

$$y = \left[\left(1+\frac{2y^2}{C}\right)^{\frac{1}{2}}-1\right]\left\{2+\ln 2-\ln\left[\left(1+\frac{2y^2}{C}\right)^{\frac{1}{2}}-1\right]\right\} \quad [26]$$

where

$$y = \mu^*\bar{E}/\varphi.$$

From equation [26] y has been calculated for various values of y^2/C, from which corresponding values of $\mu^*\bar{E}/\varphi$ and C were obtained. The result of these calculations is shown

graphically in Fig. 1 along with the corresponding relations obtained for the parabolic and cosine potential energy functions. The points are experimental values, the calculations for which are discussed in a following section.

Summary

We may now summarize the results of the present section. The probability per unit time for a high field strength ion transfer process can be represented by the equation:

$$p(E) \simeq \nu \exp\left\{-\left[\varphi-\mu^*E\left(1-\frac{\mu^*E}{C\varphi}\right)\right]/kT\right\} \qquad [27]$$

where the three parameters φ, μ^*, and C are not independent constants but are related through the form of the potential energy function, as indicated in Fig. 1, making only two of them independent. If we assume for a given electrode process that the overall rate is controlled solely by the high field transfer of one kind of ionic species, then we may write

$$i = i_0 \exp\left\{-\left[\varphi-\mu^*E\left(1-\frac{\mu^*E}{C\varphi}\right)\right]/kT\right\}. \qquad [28]$$

The validity of this assumption in connection with the steady-state anodic oxidation of the valve metals will depend, of course, on the mechanism for the process. It will be valid for the Cabrera–Mott mechanism (3) and for the mechanism proposed recently by the author (4) but will not be strictly valid for the high field Frenkel defect model proposed by Bean, Fisher, and Vermilyea (5).

Equation [28] may also be applied to electrode reactions, such as hydrogen evolution from high overpotential metals, provided, of course, that the mechanism is consistent with the restrictive condition on this equation. For these processes, however, it is more

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

convenient to replace μ^*E in equation [28] by $q^*\psi$ where $q^* = \mu^*/\delta$, ψ is the absolute value of the potential drop across the Helmholtz double layer, and δ the width of the Helmholtz layer. The evaluation of ψ from experimental data and the correction for the field dependence of δ are by no means trivial problems. The application of the foregoing to the hydrogen evolution reaction will therefore be treated in a subsequent paper.

COMPARISON OF AVAILABLE EXPERIMENTAL DATA WITH THEORY

The only valve metals for which data of sufficient precision* are available to allow the parameters in equation [28] to be evaluated are Ta (1), Nb (6), Al (7), and Ti (8). Of these four the first three can be fitted to an equation of the form of [28] or [1] with C or γ positive. The behavior of Ti, however, is markedly different from the first three and, although the data may be fitted to an equation of the form of [1], γ is negative. Since the monoxide of titanium displays very large deviations from the stoichiometric composition (9), it is possible that effects arising from gross non-stoichiometry are responsible for the different anodic behavior of Ti.

The evaluations of the parameters for Ta, Nb, and Al are outlined in the following sections.

Tantalum

From analysis of extensive steady-state data for the anodic oxidation of tantalum in 0.1 N aqueous sulphuric acid, Young (1) calculated the following values for the constants in equation [1]:

$$i_0 = 10^{8.24} \text{ amp/cm}^2 \; Q = 2.185 \text{ ev}, \; \alpha = 34.98 \text{ e Å}, \; \gamma = 167.5 \text{ e Å}^2\text{v}^{-1}.$$

Comparing equations [1] and [27], we have

$$\varphi = Q, \; \mu^* = \alpha, \; C = \alpha^2/\gamma Q$$

from which $C = 3.33$. The mean field strength for the set of experiments from which the above parameters were calculated is about 0.056_5 v/Å $= \bar{E}$.

Niobium

For niobium, Young (6) found that the Tafel slope measured over the current density range 10^{-5} to 10^{-3} amp/cm^2 was, within experimental error, independent of temperature between 0° C and 70° C. This result may be expressed mathematically as follows

$$\partial^2 E/\partial(\ln i)\partial(1/T)] \simeq 0 \text{ for } \log i \simeq -4, \; T \simeq 273+35. \qquad [29]$$

Assuming that the current density is given by equation [27], we may solve for E and obtain

$$E = \frac{C\varphi}{2\mu^*}\left[1-\left(1-\frac{4}{C}-4\frac{kT}{C\varphi}\ln\frac{i}{i_0}\right)^{\frac{1}{2}}\right] \qquad [30]$$

from which

$$\frac{\partial E}{\partial(1/T)} = S = -\left[\frac{kT^2}{\mu^*}\ln\left(\frac{i}{i_0}\right)\right]\Big/\left[1-\frac{4}{C}-4\frac{kT}{C\varphi}\ln\left(\frac{i}{i_0}\right)\right]^{\frac{1}{2}}. \qquad [31]$$

Setting $$\partial S/\partial \ln i = 0$$

we obtain $$C = 4+2(kT/\varphi)\ln(i/i_0). \qquad [32]$$

**Data for metals which show a dependence of anodic oxidation parameters on film thickness have been excluded since additional complicating phenomena are clearly involved.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The reciprocal Tafel slope, β, will be defined as follows:

$$\beta = \frac{\partial \ln i}{\partial E} = \mu^*\left[1-\frac{2\mu^*E}{C\varphi}\right]/kT. \qquad [33]$$

Solving for C, μ^*, and $(\mu^*E/C\varphi)$ from equations [28], [31], [32], and [33], the following equations can be obtained:

$$C = 4\left[1+\left(\frac{1}{1+TE/S}\right)^2\right]^{-1} \qquad [34]$$

$$\mu^* = (1+TE/S)kT\beta \qquad [35]$$

$$\frac{\mu^*E}{C\varphi} = \frac{1}{2}\left[1+\frac{S}{TE}\right]^{-1}. \qquad [36]$$

Young determined five independent values for the slope of E versus $1/T$, the current density being 10^{-5}, 10^{-4}, and 10^{-3} amp/cm^2. Within experimental error, they were all the same, the mean value being 13.0 v Å^{-1} °K with a standard deviation of 1%. We shall assume that this represents the slope of the tangent, $S = \partial E/\partial(1/T)$, for the median condition (i.e. $T = 308°$ K and $\log i = -4$). Again, Young determined values for $\Delta E/\Delta \log i$ for i changing from 10^{-5} to 10^{-3} amp/cm^2 at eight different temperatures from 0° C to 70° C. They were found to be the same within experimental error, the mean value being represented in the expression $\Delta \ln i/\Delta E = 635$ Å/v with a standard deviation of 3%. Again we shall consider this as the slope of the tangent, $\beta = \partial \ln i/\partial E$, for the median conditions stated above. The median field value corresponding to $\log i = -4$ and $T = 308°$ K is, from Young's data, 0.0428 v/Å. Substituting these results into equations [34] to [36] the following values for the parameters are obtained:

$$C = 3.21,\ \mu^* = 34.0 \text{ e Å},\ \varphi = 1.80 \text{ ev}.$$

Using these values, i_0 can be calculated from equation [27] by setting $i = 10^{-4}$ for $E = 0.0428$ v/Å and $T = 308°$ K, obtaining $i_0 = 10^{7.61}$ amp/cm^2. From these constants, the data may be reproduced within the accuracy of the data.

Aluminum

Recently, measurements of the variation of the steady-state Tafel slope with field strength for the anodic oxidation of aluminum have been made in the author's laboratory (7). From these, the following values were calculated:

$$\mu^* = 23.5 \text{ e Å},\ C\varphi = 7.83 \text{ ev},\ i_0 \exp[-\varphi/kT] = 10^{-28.7}.$$

Unfortunately, at the present time measurements have been made at 25° C only, so that to obtain values for C and φ separately a value for i_0 of $10^{-8.0}$ amp/cm^2 was assumed. Since i_0 for tantalum and niobium differ by only a factor of 4, it is unlikely that i_0 for aluminum would differ from their geometric mean value by as much as a factor of 10. An error of about 3% would be introduced in C and φ by a factor of 10 error in i_0. The values for C and φ calculated in this way are 3.61 and 2.17 ev. The mean field strength for the set of experiments from which these constants were calculated was 0.085_0 v/Å $= \bar{E}$.

Discussion

The calculated values for C for these three systems are plotted against $\mu^*\bar{E}/\varphi$ in Fig. 1. The results are clearly in excellent accord with the theoretical curve calculated assuming

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

a Morse function potential energy surface. Accordingly, the Morse function parameter, ω^*, was determined from equation [25], the values for C and $(\mu^*\bar{E}/\varphi)$ used for the calculation being read from curve c of Fig. 1 at a position close to the experimental point in question. A summary of the results is presented in Table I.

TABLE I

Kinetic parameters for the steady-state anodic oxidation of Ta, Nb, and Al

Oxide	i_0 amp/cm²	φ ev	μ^* e Å	C	$\bar{E}$ v/Å	ω^* e Å
Ta_2O_5	$10^{8.21}$	2.18_5	34.9_8	3.33	0.056_5	7.8
Nb_2O_5	$10^{7.64}$	1.80	34.0	3.21	0.042_8	7.7
Al_2O_3	$10^{8.0*}$	2.17	23.5	3.61	0.085_0	5.7

*An assumed value based on the experimental values for Ta_2O_5 and Nb_2O_5.

A more precise calculation of the best value for ω^* would require a computer analysis of the data using equations [6] and [19] (or [21]) directly. Indeed, in view of the results, the proper conduction equation for these systems might well be:

$$i = i_0 \exp\left\{-\left[\varphi - \omega^* E\left(1 - \ln\frac{\omega^* E}{2\varphi} - \frac{\omega^* E}{2\varphi}\right)\right] \Big/ kT\right\} \qquad [37]$$

in accordance with equation [21].

Very accurate data over a wide range of field strengths (which would require obtaining data over a wide temperature range) would be needed for a more stringent test of the suitability of equation [37] and hence of the Morse function. There is no doubt, however, that the Morse function accounts for the quadratic term in the field in the net activation energy with an accuracy which is rather surprising.

It is worth noting that at low field strengths the Morse function cannot represent a satisfactory approximation to the true potential energy function since in the limit as $E \to 0$ the activation charge–distance product will become infinite. However, for the present valve metal systems, only the shape of the Morse function from about 0 to $2\omega^*$ is of any consequence, the shape of the potential energy curve beyond about $2\omega^*$ having no effect on the net activation energy for field strengths which give rise to measurable currents.

The very large values found for both μ^* and ω^* is deserving of some comment. The result is readily explained if the effective field strength assisting the ion transfer process includes an appreciable contribution from the electrostatic polarization of the oxide dielectric medium. A new mechanism based, in part, on this notion has been proposed recently by the author (4).

Preliminary attempts to interpret the anomalous temperature dependence of the Tafel slope for hydrogen evolution from Hg, observed by Bockris and Parsons (10), by assuming a Morse function potential for displacement of the proton from its hydration shell have been successful, the agreement between theory and experiment being comparable to that presented here for the valve metals. This data, along with other data for hydrogen evolution, will be discussed in a future publication.

VAPOR-PHASE RADIOLYSIS OF CYCLOHEXANE AND MIXTURES OF BENZENE AND CYCLOHEXANE[1]

J. BLACHFORD AND P. J. DYNE
Research Chemistry Branch, Atomic Energy of Canada Ltd., Chalk River, Ontario
Received January 10, 1964

ABSTRACT

The vapor-phase radiolysis of cyclohexane and benzene–cyclohexane mixtures has been studied with isotopic tracer techniques using C_6D_{12} and C_6D_6. Benzene does not quench the molecular detachment of hydrogen, $C_6D_{12} \rightsquigarrow D_2 + C_6D_{10}$, but interacts with the second-order processes giving HD in C_6D_{12}–C_6H_{12} mixtures. This interaction is not H-atom scavenging and an ionic mechanism is preferred. The radiolysis of all these systems is very different from their liquid-phase radiolysis.

The low radiolytic yields in liquid benzene–cyclohexane mixtures are a classic example of 'protection'. The interactions causing these low yields are physical; they do not involve the making or breaking of chemical bonds. This has been shown in two ways: by complete product analysis (1) and by techniques using isotopically labelled hydrocarbons (2). These isotopic techniques have revealed similar interactions in alkane mixtures (3) which are, however, absent in the vapor phase (4). As a result, we expect the vapor-phase radiolysis of benzene–cyclohexane mixtures to show marked differences from the liquid-phase radiolysis.

We have applied our isotopic techniques to the vapor-phase radiolysis. In the liquid, benzene quenches both the first-order process, which gives D_2 by molecular detachment from C_6D_{12}, and the second-order processes which give HD in C_6H_{12}–C_6D_{12} mixtures. In the vapor, however, the D_2 yield is reduced much more slowly than would be expected if H-atom scavenging were occurring and so we favor an ionic mechanism for this interaction. Physical interactions quenching the first-order processes are absent.

EXPERIMENTAL

Fisher 'Spectranalyzed' cyclohexane and benzene and Merck benzene-d_6 and benzene-free cyclohexane-d_{12} were used as received.

To minimize air contamination the sample vessels (volume about 330 ml) were evacuated to 5×10^{-6} mm Hg at 500° C for at least 24 hours before being filled and irradiated. Even so, the gaseous radiolytic products contained about 3% air. The vessels were sealed to a grease- and mercury-free preparation line; the sample (about 2 ml of liquid) was degassed by repeated freezing, pumping, and thawing and was then distilled into the irradiation vessel.

During irradiation in our Co^{60} source, the vessels were kept at a constant temperature (±2° C) in an electric furnace. Using the techniques already described (4), we found the dose rate to be 4.87×10^{15} ev/sec g cyclohexane; the dose in most experiments was 3.61×10^{19} ev/g organic vapor.

After irradiation the sample was frozen in liquid nitrogen; the gaseous products were pumped through two liquid-nitrogen traps and their volume measured with a McLeod gauge. This fraction, which contained mainly hydrogen and methane, was analyzed by mass spectrometry. A second fraction volatile at −112° C, consisting of C_2–C_4 hydrocarbons, was analyzed by gas chromatography on a silica-gel column.

The yields of the liquid products, cyclohexene, bicyclohexyl, and phenylcyclohexane, were determined by gas–liquid chromatography. Cyclohexene was separated on a 12-ft column packed with 20% 1,2,3-tris-(2-cyanoethoxy)propane on acid-washed firebrick. Bicyclohexyl and phenylcyclohexane were separated on a 6-ft column packed with silicone – gum rubber on firebrick.

RESULTS

C_6H_{12}–C_6D_{12} Mixtures

A mixture containing 4.77 mole % C_6D_{12} was used in all experiments. In dilute solutions we can define $G_1(D)$ as the number of molecules of D_2 per 100 ev absorbed in the deuterated hydrocarbon. It has previously been shown (2) that in dilute solutions D_2 arises from a first-order reaction in which both D atoms come from the same molecule. Similarly, $g(HD)$ is the number of molecules of HD per 100 ev absorbed in the deuterated hydrocarbon. This quantity is a measure of second-order reactions leading to hydrogen.

The values of G(total hydrogen), $g(HD)$, and $G_1(D)$ as a function of temperature are given in Fig. 1. Over the range 70–250° C the yields are independent of temperature, but the yields of total hydrogen and HD increase rapidly above 250° C. The temperature-independent values are given in Table I together with the values for the liquid-phase radiolysis (2).

TABLE I

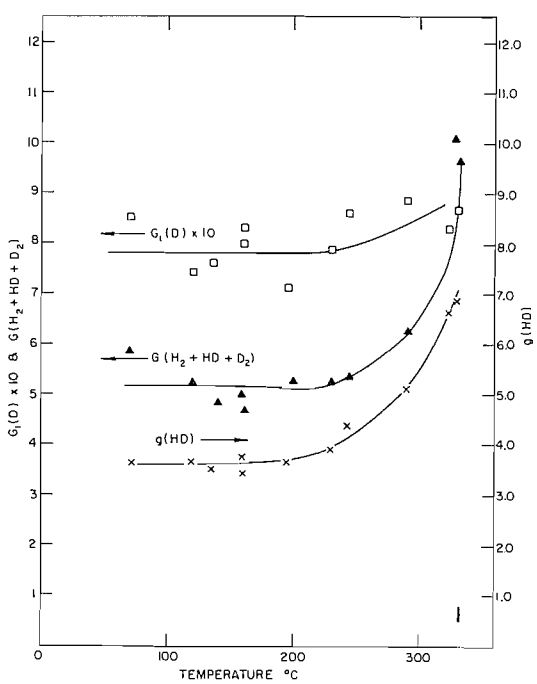
Product yields at 125° C are shown in Table II together with the vapor-phase α-radiolysis data of Ramaradhya and Freeman (5) and the liquid-phase data (γ-rays) of Dyne and Stone (6). The temperature dependence of the yields of bicyclohexyl, methane, and cyclohexene are shown in Fig. 2. From 70 to 235° C the yields of the first two products increase but little, while cyclohexene increases by a factor of two. The dose dependence of the hydrogen and cyclohexene yields is shown in Table III.

C_6H_{12}–C_6D_{12}–C_6H_6 Mixtures

The effect of benzene on the radiolytic yields in cyclohexane was examined by adding various amounts of benzene to a mixture of 4.77 mole % C_6D_{12} in C_6H_{12}. The dependence of the normalized yields of H_2, HD, and D_2 on temperature and benzene concentration is shown in Figs. 3*a*, *b*, and *c*. The normalizing factors are temperature-independent yields in Table I.



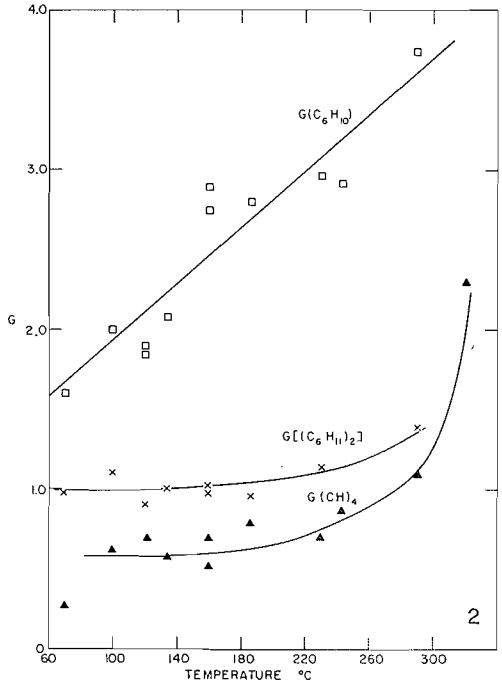


FIG. 1. The temperature variation of the yields of total hydrogen, HD, and D_2 (expressed as $G_1(D)$) in the radiolysis of C_6H_{12} with 4.77 mole % C_6D_{12}.

FIG. 2. The temperature variation in the yields of cyclohexene, bicyclohexyl, and methane in the gas-phase radiolysis of cyclohexane.

TABLE III

Dose dependence on the yields of hydrogen and cyclohexene

Dose, 10^{19} ev/g	Temperature, ° C	$G(H_2)$	$G(C_6H_{10})$
3.51	125	5.44	2.2
7.02	125	4.93	1.7
3.51	235	5.55	3.1
7.02	235	4.73	2.3

We shall compare all yields to those predicted by the mixture law which can be stated as follows (3). If G^0_M is the yield of M derived from a pure material A and X_A is the fraction of energy absorbed by A in a mixture, then the yield in the mixture is $G^0_M X_A$. In its simplest form this means that the yields are linear functions of composition.

No significant deviation from the mixture law is exhibited by $G(D_2)$ at any temperature. Both $G(H_2)$ and $G(HD)$ deviate from the mixture law at low temperatures. At higher temperatures the deviation is reduced and at 235° C the total hydrogen yield obeys the mixture law.

The effect of benzene on the other product yields at 125° C is shown in Fig. 4. Phenylcyclohexane is a significant product at low benzene concentration. As with hydrogen the effect of benzene on these yields is reduced at higher temperatures; the yield of phenylcyclohexane is also reduced.

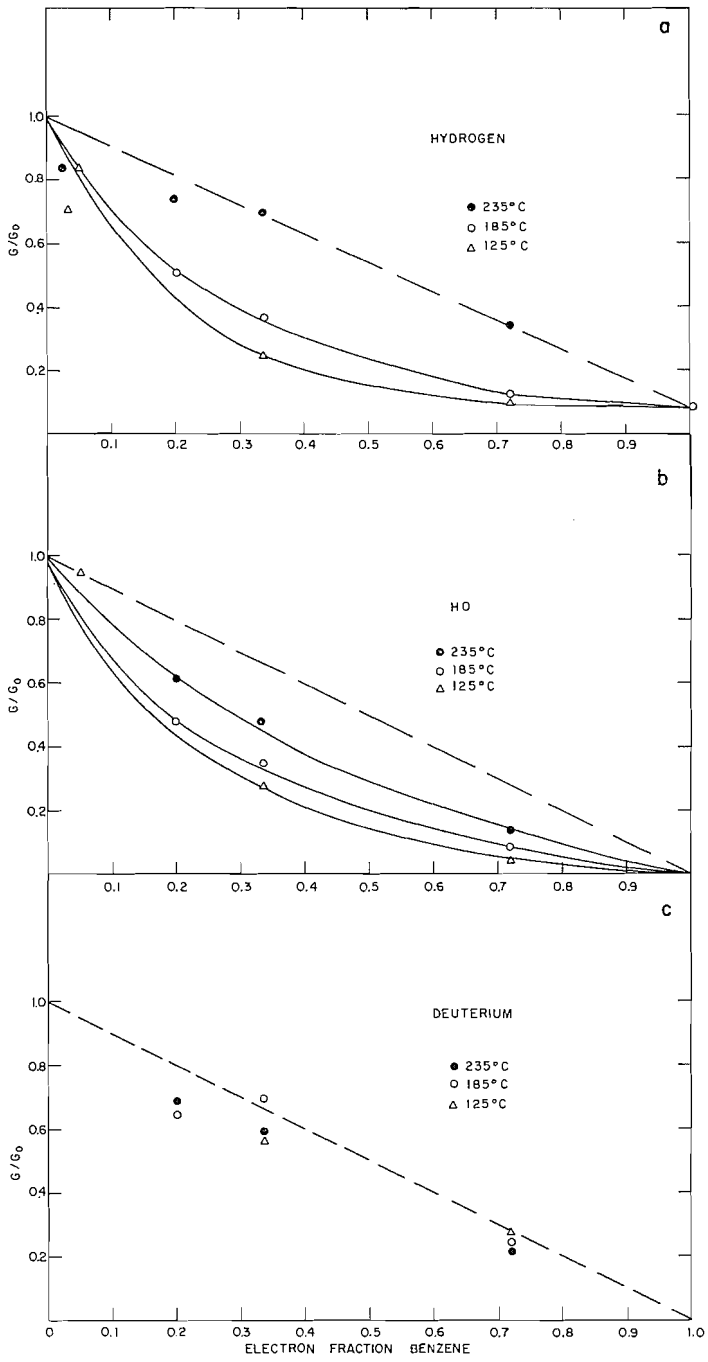

FIG. 3. The normalized yields of total hydrogen (3*a*), HD (3*b*), and D_2 (3*c*) in the radiolysis of mixtures of benzene with cyclohexane containing 4.77 mole % C_6D_{12}. The broken line represents the mixture law. The values of G_0 are, respectively, G (total hydrogen), g(HD), and G(D) as given in Table I.

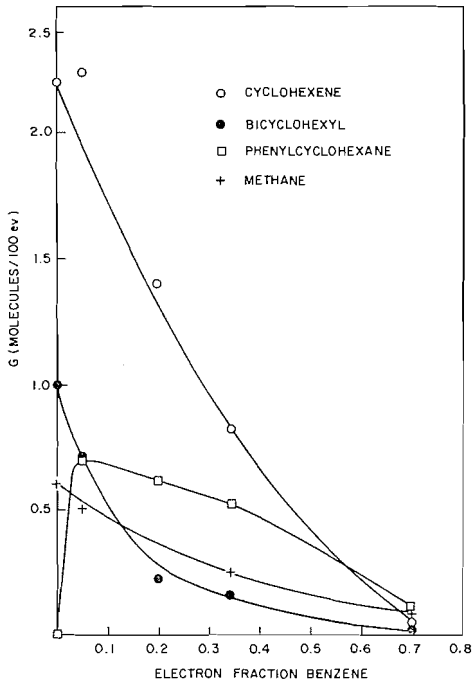

FIG. 4. Yields of cyclohexene, bicyclohexyl, phenylcyclohexane, and methane in benzene–cyclohexane mixtures at 125° C.

C_6H_{12}–C_6D_6 Mixtures

Benzene also takes part in second-order reactions which *produce* hydrogen. This is shown in the HD yields found in mixtures of 5 mole % C_6D_6 (Table IV). The high HD

TABLE IV

Isotopic composition of hydrogen from 5 mole % C_6D_6 in C_6H_{12}

Temperature, ° C	$G(H_2)$	G(HD)	$G(D_2)$	g(HD)
125	3.68	0.147	0.0049	2.92
235	4.52	0.278	0.0050	5.50

yield, comparable with that observed in similar C_6D_{12}–C_6H_{12} mixtures, shows that the efficiency of this reaction is comparable with the corresponding second-order reaction in the C_6H_{12}–C_6D_{12} system.

DISCUSSION

C_6H_{12}–C_6D_{12} Mixtures

We interpret the isotopic yields in terms of two reactions: a first-order molecular detachment and a second-order abstraction. If one writes $C_6H_{12} \equiv C_H$ and $C_6D_{12} \equiv C_D$, these may be written

$$C_H \rightsquigarrow H_2 + \ldots \quad [1]$$

$$C_H \rightsquigarrow X_H + \ldots \quad [2]$$

$$X_H + C_H \rightarrow H_2 + \ldots \quad [3]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where X_H is the reactive intermediate in the bimolecular process. In mixtures of C_H and C_D where $C_H \gg C_D$, D_2 is formed only by the analogue of [1]

$$C_D \rightsquigarrow D_2 + \ldots . \qquad [4]$$

The function $G_1(D)$ is a measure of reaction [4]. HD is formed by the analogues of [3]

$$X_H + C_D \rightarrow HD + \ldots \qquad [5]$$

$$X_D + C_H \rightarrow HD + \ldots . \qquad [6]$$

The function $g(HD)$ is a measure of the sum of reactions [5] and [6].

In the liquid we suppose that the first- and second-order processes have a common precursor, viz.

$$C_D \rightsquigarrow C_D^* \begin{cases} \nearrow D_2 + \text{products} \\ \searrow X_D + \text{products} \end{cases} \qquad [7]$$

since we find that, whatever the environment of the deuterated cyclohexane,

$$g(HD) \simeq A\, G_1(D) + B, \text{ where } A \simeq 4 \text{ and } B \simeq 1.5.$$

The gas-phase values of $g(HD)$ and $G_1(D)$ do not fit this equation. For $G_1(D) = 0.78$, this equation gives $g(HD) \sim 5$ which is significantly greater than the observed value of 3.6. This difference is discussed further in relation to the effect of benzene on $g(HD)$ and $G_1(D)$.

The negligible temperature coefficient of $G_1(D)$ is to be expected if it measures a true 'molecular' process such as reaction [4]. The small temperature dependence of the HD yield deserves comment. If one takes into account the scatter of the data, it appears that between 100 and 200° C $g(HD)$ increases by, at the most, 10%; a 20% increase would have been readily apparent. Part of the HD yield is formed in reaction [5], which is in competition with reaction [3]; this competition is likely to be temperature dependent. The rest of the HD comes from reaction [6], which (in dilute solutions of the deuterated hydrocarbon) is not involved in any competitive reactions. If reaction [6] contributed significantly to the HD yield, then the temperature dependence of reactions [3] and [5] would be masked. Wiberg (7) has estimated that the maximum effect due to the difference between C–H and C–D bond-dissociation energies would lower k_H/k_D ($\equiv k_3/k_5$) by about 25% between 100 and 200° C. If about half the HD yield came through reaction [6], then the observed, very small, temperature coefficient is in accord with Wiberg's estimate.

The sharp increase in the H_2 and HD yields above 250° C is similar to that observed in polyphenyls (8) at higher temperatures, >400° C. At these temperatures a radiation-induced pyrolysis is appearing which leads to further decomposition. As the aromatic hydrocarbons are thermally more stable than the aliphatic hydrocarbons, this induced pyrolysis appears at a higher temperature.

Product yields are tabulated in Table II for comparison with the α-radiolysis data at 108° C of Ramaradhya and Freeman (5). Back, Woodward, and McLauchlin (9) have already pointed out that $G(H_2)$ in the α-radiolysis of hydrocarbons is higher than that obtained in γ-radiolysis. These data show that even larger changes may be observed in the yields of higher molecular weight products.

For cyclohexene this comparison may be complicated by secondary reactions which lower the yield from the true 'initial' value at very low dose. These secondary reactions are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

shown in the increase in the cyclohexene yield between 100 and 220° C. This increased yield is not due to an increase in C–H bond breaking since $G(H_2)$ is temperature independent, nor is it due to an increase in radical disproportionation since bicyclohexyl (which would presumably be formed in the competing combination reaction) does not show a corresponding decrease. The increase in yield must be due to a reaction destroying cyclohexene and forming a polymer, whose efficiency decreases with an increase in temperature. Such a reaction will also cause $G(C_6H_{10})$ to decrease with dose (Table IV). Polymer formation is also shown, indirectly, by the poor hydrogen balance. The yields of hydrogen and molecules containing extra hydrogen relative to cyclohexane exceed the total yield of hydrogen-deficient molecules by about 7 G units. A similar inbalance was reported in Ref. (5).

The high yield of C_2, C_3, and C_4 hydrocarbons in the gas phase as compared with their small yields in the liquid phase has been discussed by Ramaradhya and Freeman (5) and by Kevan and Libby (10). Carbon–carbon bond breakage is strongly inhibited in condensed phases.

C_6H_6–C_6H_{12} Mixtures

From our measurements of $g(HD)$ and $G_1(D)$ in benzene–cyclohexane mixtures, we see that benzene does not interact with the first-order molecular-detachment process

$$C_D \rightsquigarrow C_D^* \rightarrow D_2 + \ldots .$$

The interaction of benzene with the second-order process

$$X_D + C_H \rightarrow HD + \text{products}$$

can be written

$$X_D, X_H + \text{benzene} \rightarrow \text{no hydrogen} \qquad [8]$$

Here we note that X_D and X_H could be any intermediates in the second-order process, and they are not, necessarily, the ones which react in the final steps, reaction [3] and/or [6].

Ramaradhya and Freeman (11) measured the total hydrogen yield in benzene–cyclohexane mixtures. When they used the H-atom scavenging mechanism

$$H + C_6H_{12} \rightarrow H_2 + C_6H_{11} \qquad [9]$$

$$H + C_6H_6 \rightarrow H_2 + C_6H_5 \qquad [10]$$

$$H + C_6H_6 \rightarrow C_6H_7 \rightarrow \text{no hydrogen} \qquad [11]$$

to interpret their results they found that reaction [10] had to have an unreasonably high efficiency (k_{10} was large). Because of this they rejected this mechanism. Our isotopic techniques also show that this analysis is invalid; there is another source of hydrogen—the unquenched molecular detachment. As reaction [10] is, in effect, a source of hydrogen, their kinetic analysis would express any other source of hydrogen as a high value of k_{10}.

In our opinion, an H-atom scavenging mechanism is unlikely because of the unreasonably low value required for k_{11}. If we assume that the contribution of the unquenched molecular-detachment process in C_6D_{12}–C_6H_{12}–C_6H_6 mixtures is equal to $G_1(D)$, 0.78, then from the hydrogen yield at 50% benzene we find $k_9/k_{11} \sim 0.16$. Now, Schiff and Steacie (12) found the collision yield for reaction [9] to be 1.4×10^{-7} and Allen, Melville, and Robb (13) found the collision yield of [11] to be 1.3×10^{-4} so that $k_9/k_{11} \sim 10^{-3}$ at 25° C. As our experiments were carried out at 125° C, the activation-energy difference would have to be ~12 kcal to reconcile these two values. The best estimate for the activation energy of reaction [9] is 8 kcals (12) and for reaction [11] is 4 kcal (14) giving ΔE

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$\sim$ 4 kcal. The observed ratio of k_9/k_{11} is therefore too large for the interaction to be attributed to hydrogen-atom scavenging. Our conclusion agrees with that of Ramaradhya and Freeman although our arguments differ.

As ionic reactions play an important part in the gas-phase radiolysis of hydrocarbons (15), it seems likely that X_D and X_H are ions and we suggest that they may be fragment (C_2–C_3) ions. Futrell (16) has proposed a mechanism for the radiolysis of *n*-hexane in which these fragment ions react rapidly with *n*-hexane in a hydride-ion transfer reaction to give fragment molecules or radicals and a $C_6H_{13}^+$ radical ion. This radical ion decomposes on capturing an electron to give a hydrogen atom and an olefin (or a biradical). A molecule of hydrogen is then formed by H abstraction by this H atom from a *n*-hexane molecule.

According to Borkowski and Ausloos (17), benzene does not take part so readily in hydride transfer reactions with fragment ions but forms addition complexes which decompose by other routes. In their studies benzene reduces the yields of products formed from fragment ions. Molecular elimination processes are unaffected and are, consequently, more prominent. Using Futrell's mechanism this interaction would affect the hydrogen yields in the same way; the molecular elimination would be favored, in agreement with our observations. As fragment ions are not formed in the liquid, benzene must, in this environment, reduce the hydrogen yield by a different mechanism.

The high yield of HD from dilute mixtures of C_6D_6 in C_6H_{12} shows that benzene contributes D atoms to the radiolysis almost as readily as does C_6D_{12}. A high HD yield is also observed in liquid C_6D_6–C_6H_{12} mixtures (18). It is unreasonable to attribute this to the abstraction

$$X_H + C_6D_6 \rightarrow HD + \ldots$$

because this requires the C–D bond in C_6D_6 to be essentially as reactive as the C–D bond in C_6D_{12}, whatever the nature of X_H. It is more reasonable to attribute the yield of HD to the reaction of an intermediate X_D', formed from C_6D_6

$$C_6D_6 \rightsquigarrow X_D' + \ldots, \qquad [12]$$

which can react with cyclohexane to give HD. Neglecting the possibility of energy transfer from cyclohexane to benzene then the yield of this reaction is equal to g(HD)—i.e. 3 molecules/100 ev absorbed in the benzene. This is, of course, much greater than $G(H_2)$ from pure benzene in the liquid or vapor. As the hydrogen yield in pure liquid benzene is much less than G(-benzene), it is not a proper measure of the radiation stability of benzene. While in pure benzene the intermediate X_H' gives a low hydrogen yield, it may react much more efficiently when the benzene is diluted with another hydrocarbon. A high yield of reaction [12] is not improbable and so it is not necessary to have efficient energy transfer from cyclohexane to benzene to give this high yield of HD.

The differences in the interactions in the gas and liquid eliminate any physical interaction with depends only on the electron-stopping power of the molecules. Such a mechanism has been proposed by Lamborn and Swallow (19). From calculations by Inokuti (20) of the excitation cross sections of π-electrons in aromatic molecules, they concluded that the electron-stopping power of benzene was considerably greater than that of cyclohexane. While their measurements of polymer yield in benzene–cyclohexane mixtures were consistent with Inokuti's estimates of the excitation cross sections, our gas-phase measurements are not; we find that one of the decomposition paths, the first-order decomposition is unaffected. The difference in stopping powers predicted by Lamborn and Swallow

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

should also be detectable by direct measurement. Recently, however, Rauth and Hutchinson (21) found the electron-stopping power of polystyrene and Formvar (polyvinyl formal, empirical composition $C_5H_8O_2$) to be identical, and no large effect of π-electron excitation was observed.

The differences in mechanism between the liquid- and vapor-phase are the most interesting part of this study. The common intermediate C_D* in reaction [7] is either not formed and the first- and second-order yields are not coupled, or else the lifetime and other properties of C_D* in the vapor differ from those in the liquid, so that (*a*) the HD/D_2 ratio (the branching ratio of [7]) is changed and (*b*) benzene cannot interact with it. While it is possible to devise *ad hoc* reasons for the properties of C_D* being changed, there is still no positive evidence for a common intermediate of the first- and second-order yields (C_D*) in the gas phase.

ACKNOWLEDGMENTS

It is a pleasure to thank Dr. D. R. Smith for his advice on experimental techniques and Dr. J. A. Stone for his candid criticisms of earlier drafts of this paper.

THE THEORY OF ULTRASONIC ABSORPTION: RELAXATION OF TWO INTERACTING REACTIONS

J. P. VALLEAU
Department of Chemistry, University of Toronto, Toronto, Ontario
Received October 9, 1963

ABSTRACT

The purpose of this paper is to extend the theory of ultrasonic absorption in fluids to the case of the relaxations of two interacting reactions. The linear theory of the absorption and dispersion of sound waves is developed in terms of a frequency-dependent viscosity coefficient. This coefficient is then evaluated for the familiar case of a single relaxing reaction and for the more complex case of two reactions interacting in an arbitrary way. The absorption and dispersion of the sound waves are related to familiar physical chemical quantities by explicit formulae, and non-ideality has been taken account of by the use of activity coefficients. Some discussion of the results is presented. The intention of this development is to make possible the extraction of physical chemical data from ultrasonic investigations of systems involving interacting equilibria, and such an application has been made in an accompanying paper.

1. INTRODUCTION

The viscosity of fluids leads to an absorption of sound waves, the classical absorption, calculated by Stokes (1) in 1845. To this may be added an absorption due to thermal conductivity (Kirchhoff (2), 1868). The latter measures a deviation from adiabaticity of the sound propagation, and is usually relatively small (except in liquid metals and He II). Subsequent interest has attached to the "relaxation absorption" caused by chemical and physical processes having time constants comparable with the period of the sound waves. From these absorptions it is possible to derive information about the rates and energetics of the processes responsible.

Until recently adequate account was not taken of the interaction between the simultaneous variations of pressure and temperature in the sound wave, an effect certain to be important in the case of chemical processes. This was rectified in 1958 (Davies and Lamb (3), and see Ref. (4), p. 138 ff.), giving a theory adequate for single processes in ideal solutions. More recently (Tamm (5), Eigen and Tamm (6)), activity coefficients have been introduced into the theory.

Work in our laboratory has focussed on ultrasonic absorption in electrolyte solutions, and we have been faced with the need to interpret relaxation processes occurring among simultaneous equilibria. An extension of the theoretical treatment was therefore necessary. A special case of the problem was treated by Eigen and Tamm (6), who considered an association reaction taking place in a number of steps, e.g.

$$A^+ + B^- \rightleftharpoons (AB)' \rightleftharpoons (AB)'' \rightleftharpoons AB,$$

the intermediates presumably being ion pairs separated by varying numbers of solvent layers. The authors solved this case by introducing a set of "normal coordinates", under the assumption that the rates of the various steps are (*a*) all well-separated, and (*b*) decrease from left to right. They believe that such an analysis is required to explain the famous and puzzling results on the sulphates of divalent metals.

In the present paper, we wish to develop the theory of sound absorption for the general case of any two interacting equilibria in non-ideal solutions and having arbitrary rate constants. This will be done only in the usual "linear" approximation.

It is well known that there are several possible starting points for ultrasonic theory, so that absorption may be regarded as due to a frequency-dependent viscosity, or to a heat capacity, or to a compressibility. We have chosen to develop the theory by introducing a "relaxation viscosity". Not only does this approach appear particularly simple, but it keeps ultrasonic theory within the "classical" mold established by Stokes. The classical viscous result appears, in fact, as an incidental product of the general theory. It seemed helpful to include, for completeness, a discussion of the case of a single relaxation process. A detailed example of the use of the results for simultaneous processes can be found in an accompanying paper (7).

2. GENERAL TREATMENT

Consider a fluid through which a plane wave passes in the x-direction. The fluid may be described by a local density ρ_l and a local hydrodynamic velocity u_x in the direction of propagation. The conservations of mass and momentum may be expressed, as usual, by the "continuity equation"

$$d\rho_l/dt+\rho_l(\partial u_x/\partial x) = 0, \qquad [1]$$

and the "equation of motion"

$$(1/\rho_l)(du_x/dt)+\partial p_{xx}/\partial x = 0. \qquad [2]$$

In these equations p_{xx} is the "longitudinal" pressure in the x-direction (more precisely, the x,x-component of the pressure tensor), and d/dt signifies the substantial time derivative: that is, it describes changes in an element of volume moving with the local hydrodynamic velocity.

As is well known, the classical sound absorption (1) is obtained from [1], [2] after inserting the viscous pressure tensor p_{xx}. We wish to modify the argument only by adding to the shear viscosity η and the bulk viscosity κ, a "relaxation viscosity" ξ due to slow dissipative processes. That is

$$p_{xx} = p_0-[(4/3)\eta+\kappa+\xi](\partial u_x/\partial x), \qquad [3]$$

where p_0 is the equilibrium hydrostatic pressure, determined by the instantaneous density and entropy of the fluid. The ξ term, unlike the η and κ terms, need not be in phase with the rate of expansion $\partial u_x/\partial x$, so we set

$$\xi = \xi_1-i\xi_2. \qquad [4]$$

We consider damped plane sine waves of circular frequency ω, when we may set

$$u_x = u_x' \exp\{i(\omega t-kx)\},$$
$$\rho_l = \rho+\rho' \exp\{i(\omega t-kx)\}, \qquad [5]$$

ρ being the density of the fluid. Then

$$k = (\omega/c)-i\alpha, \qquad [6]$$

in which c and α are the velocity and the amplitude absorption coefficient of the sound wave.

When [3] and [5] are inserted in [1] and [2] there results a pair of equations for ρ' and u_x'; these equations are linearized by dropping terms in $\rho'u_x'$. If the equations are to be satisfied for an arbitrary wave amplitude ρ', the determinant of their coefficients must vanish; i.e.

$$\left(\frac{k}{\omega}\right)^2\left\{\left(\frac{\partial p_0}{\partial \rho}\right)_s+\frac{i\omega}{\rho}\left(\frac{4}{3}\eta+\kappa+\xi\right)\right\} = 1. \qquad [7]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The linearization is valid when the absorption per wavelength, $\mu = 2\pi\alpha c/\omega$, is much less than unity; in view of this, and using [4] and [6], [7] may be rewritten

$$\alpha = (\omega^2/2\rho c^3)[(4/3)\eta+\kappa+\xi_1], \qquad [8]$$

$$c^2 = c_0{}^2+(\omega\xi_2/\rho), \qquad [9]$$

where c_0 is the classical sound velocity, $c_0 = \sqrt{(\partial p_0/\partial\rho)_s}$.

The first two terms of [8] give the viscous sound absorption (1). Since the contributions to α are, in the present approximation, additive, we need consider the viscous terms no more. In what follows we shall use α_r to refer to the final term, $\omega^2\xi_1/2\rho c^3$, by which we take account of "relaxation processes" in the fluid.

We now wish to obtain, for such processes, a description of the resulting hydrodynamic parameter ξ. We presume that the processes may be described by a number of "ordering parameters", z, y, etc., which have equilibrium values of $\bar{z}$, $\bar{y}$, etc. that may be regarded as determined by the specific volume and entropy of the fluid. Such ordering parameters might be, for example, the concentrations of certain substances taking part in chemical reactions, or the populations of certain vibrational levels of a particular molecular species. They will differ from their equilibrium values if they are involved in a process which does not proceed rapidly enough to maintain equilibrium during the fluctuations of temperature and pressure occurring in a sound wave. Then $-\xi(\partial u_x/\partial x)$ will describe, in view of [3], the deviation of the pressure due to the deviations $\Delta z = z-\bar{z}$, $\Delta y = y-\bar{y}$ etc., of the ordering parameters. We can write

$$-\xi(\partial u_x/\partial x) \equiv -(\xi/V)(dV/dt) = (\partial p/\partial z)_{s,v,y,\ldots}\Delta z+(\partial p/\partial y)_{s,v,z,\ldots}\Delta y+\ldots$$

or, putting $dV/dt = \dot{V}$,

$$\xi = -V\{(\partial p/\partial z)_{s,v,y,\ldots}(\Delta z/\dot{V})+(\partial p/\partial y)_{s,v,z,\ldots}(\Delta y/\dot{V})+\ldots\}, \qquad [10]$$

where V is the specific volume of the fluid. We make the assumption that the deviations Δz, Δy, etc. depend only on the magnitude and rate of the volume fluctuations $\dot{V}$, not on the geometry of the fluctuations; that is, ξ corresponds to a time-dependent bulk viscosity, not to a shear viscosity.

It only remains to evaluate the ratios $\Delta z/\dot{V}$, $\Delta y/\dot{V}$, etc. To do this we need the rate equations which govern changes in the parameters z, y, etc. Sufficiently close to equilibrium, these equations may always be written as linear relaxation equations:

$$dz/dt = -(\Delta z/\tau_z)-(\Delta y/\tau_z{}^y)-\ldots, \qquad [11]$$

$$dy/dt = -(\Delta z/\tau_y{}^z)-(\Delta y/\tau_y)-\ldots, \text{ etc.},$$

which define the relaxation times τ_z, $\tau_z{}^y$, $\tau_y{}^z$, τ_y, etc. In view of the definitions of Δz, Δy, etc., the relaxation times are those applying to constant entropy and volume ("$\tau_{s,v}$"; compare Ref. (10)). Naturally the above relaxation times are not all independent; there are only as many independent time constants as independent ordering parameters. We shall return to these matters.

The rate equations [11] may be combined with the identities

$$d\bar{z}/dt \equiv (\partial\bar{z}/\partial V)_s\dot{V}, \text{ etc.},$$

to give equations for the time variations of the deviations Δz, Δy, etc. For example

$$d\Delta z/dt \equiv (dz/dt)-(d\bar{z}/dt) = -(\Delta z/\tau_z)-(\Delta y/\tau_z{}^y)-\ldots-(\partial\bar{z}/\partial V)_s\dot{V}. \qquad [12]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

These equations, [12], may easily be solved for $\Delta z/\dot{V}$, $\Delta y/\dot{V}$, etc., and hence for ξ [10], α [8], and c [9]. It is sufficient to consider a sinusoidal density fluctuation, $\dot{V} \propto \exp(i\omega t)$. We shall not consider more than two interacting processes in this paper. The case of a single process is first discussed, and forms a useful introduction to the more complex case.

3. SINGLE RELAXING PROCESS

The deviation, Δz, of the single ordering parameter z, will not generally be in phase with the rate of expansion

$$\dot{V} = A \exp(i\omega t), \qquad [13]$$

and must be written

$$\Delta z = (B+iC) \exp(i\omega t). \qquad [14]$$

Equation [12] is then easily solved, and gives (with $\tau_z = \tau$)

$$\frac{\Delta z}{\dot{V}} = \frac{B+iC}{A} = -\left(\frac{\partial \bar{z}}{\partial v}\right)_s \frac{\tau(1-i\omega\tau)}{1+\omega^2\tau^2}. \qquad [15]$$

Thus ξ([4], [10]) takes the predicted form, $\xi_1 - i\xi_2$, and with [8] and [9] we obtain

$$\frac{\alpha_\tau}{\omega^2} = \frac{\xi_1}{2\rho c^3} = \frac{\tau V}{2\rho c^3(1+\omega^2\tau^2)} \left(\frac{\partial p}{\partial z}\right)_{s,v} \left(\frac{\partial \bar{z}}{\partial V}\right)_s, \qquad [16]$$

$$c^2 = c_0^2 + \frac{\omega\xi_2}{\rho} = c_0^2 + \frac{\omega^2\tau V}{\rho(1+\omega^2\tau^2)} \left(\frac{\partial p}{\partial z}\right)_{s,v} \left(\frac{\partial \bar{z}}{\partial V}\right)_s. \qquad [17]$$

In this simple case the absorption and the velocity dispersion are related, since $c \approx c_0$, by

$$c - c_0 \approx c^2\tau\alpha_\tau. \qquad [18]$$

One now wishes to relate the quantities $(\partial p/\partial z)_{s,v}$, $(\partial \bar{z}/\partial V)_s$, and τ more closely to the details of the process described by z. We are most interested in the case of a chemical process. Suppose therefore that z is the concentration of a substance Z taking part in a reaction which may in general be written, using an obvious notation,

$$\nu_z Z + \sum_i \nu_i X_i = 0. \qquad [19]$$

We may define a "stoichiometric quotient"

$$Q = z^{\nu_z} \prod_i x_i^{\nu_i}. \qquad [20]$$

When the system is at equilibrium $z = \bar{z}$, $x_i = \bar{x}_i$, and Q is given by

$$\bar{Q} = K/\bar{F}, \qquad [21]$$

where K is the thermodynamic equilibrium constant and F the quotient of the activity coefficients:

$$F = f_z^{\nu_z} \prod_i f_i^{\nu_i}. \qquad [22]$$

Then (cf. Appendix B)

$$\left(\frac{\partial \bar{z}}{\partial V}\right)_s = \frac{dz}{d\ln Q}\left(\frac{\partial \ln(K/\bar{F})}{\partial V}\right)_s = \frac{\frac{dz}{d\ln Q}\left\{\frac{\Delta H}{RT^2}\left(\frac{\partial T}{\partial V}\right)_s - \frac{\Delta V}{RT}\left(\frac{\partial p}{\partial V}\right)_s\right\}}{1+\frac{dz}{d\ln Q}\left(\frac{\partial \ln F}{\partial z}\right)_{p,T}}, \qquad [23]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where $\Delta H = \nu_z(\partial H/\partial z)_{p,T}$ and $\Delta V = \nu_z(\partial V/\partial z)_{p,T}$ are the enthalpy and volume change in the reaction [20]. It should be noted that we are assuming the activity coefficients to be determined by the temperature, pressure, and concentrations only. That is, we assume they adjust more quickly than the reactions under study; this will, of course, be true for most cases of practical interest (cf. (8)).

To evaluate the reaction quantity $(\partial p/\partial z)_{s,v}$ we first write the total differential

$$dp = (\partial p/\partial s)_{v,z}dS + (\partial p/\partial V)_{s,z}dV + (\partial p/\partial z)_{s,v}dz.$$

Then, considering a process at constant temperature and pressure, we easily find

$$\left(\frac{\partial p}{\partial z}\right)_{s,v} = -\frac{\left(\frac{\partial p}{\partial S}\right)_v \frac{\Delta S}{\nu_z} + \left(\frac{\partial p}{\partial V}\right)_s \frac{\Delta V}{\nu_z}}{1 - \left(\frac{\partial z}{\partial S}\right)_v \frac{\Delta S}{\nu_z} - \left(\frac{\partial z}{\partial V}\right)_s \frac{\Delta V}{\nu_z}}. \qquad [24]$$

This expression [24] repays some further thought. It is apparent that for our present purposes we may discard the second and third terms of the denominator, for they would lead to terms of higher order than are included in the present approximation; these terms would be of the fourth power in ΔH, ΔV, rather than the second. The reason for laboring the matter is that this denominator may be shown (cf. (9)) to be the ratio, $\tau_{s,v}/\tau_{p,t}$, of the relaxation time at fixed entropy and volume to that at fixed pressure and temperature. In what follows the distinction between such relaxation times will be ignored, since this is similarly consistent with the approximation.

Returning to [24], we note that $(\partial p/\partial S)_v \equiv -(\partial T/\partial V)_s$ and, at equilibrium, $\Delta H = T\Delta S$; thus, to the present approximation, we may set

$$\left(\frac{\partial p}{\partial z}\right)_{s,v} = \frac{1}{\nu_z}\left[\frac{\Delta H}{T}\left(\frac{\partial T}{\partial V}\right)_s - \Delta V\left(\frac{\partial p}{\partial V}\right)_s\right] \qquad [25]$$

$$= \frac{\rho^2 C_0^2}{\nu_z}\left[\Delta V - \frac{\Delta H}{C_p}\left(\frac{\partial V}{\partial T}\right)_p\right].$$

In writing the final form of [25] we imply that all extensive quantities and concentrations are expressed per unit mass of the system (so that $V\rho = 1$) and we have recalled that $c_0^2 = (\partial p/\partial \rho)_s$.

With the help of [23] and [25], and recalling that $c \approx c_0$, the absorption coefficient [16] may be written

$$\frac{\alpha_\tau}{\omega^2} = \frac{c - c_0}{\omega^2 c^2 \tau} = \frac{\tau\rho^2 c_0 (dz/d\ln Q)[\Delta V - (\Delta H/C_p)(\partial V/\partial T)_p]^2}{2RT\nu_z(1+\omega^2\tau^2)[1+(dz/d\ln Q)(\partial \ln F/\partial z)_{p,T}]}. \qquad [26]$$

The same result can be recovered from the equations of ref. (6), p. 101, 102.

The value of $(1/\nu_z)(dz/d\ln Q)$ follows from the definition [20] of Q, and is given (dropping unnecessary subscripts) in Appendix B, equation [B8]. In a similar way the relaxation time τ takes the form discussed in the appendix for a more general case. The activity coefficient derivatives $(\partial \ln F/\partial z)_{p,T}$ will generally prove difficult to estimate. Relevant data will not usually be available, and, since rather concentrated solutions are often required in ultrasonic work, theoretical estimates of activity coefficients will usually be unreliable. Sometimes $\bar{Q}$ is known as a function of the ionic strength I, and one might then make the rather gross approximation

$$\left(\frac{\partial \ln F}{\partial z}\right)_{p,T} \approx -\left(\frac{\partial \ln \bar{Q}}{\partial I}\right)_{p,T}\left(\frac{\partial I}{\partial z}\right);$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

this regards the activity coefficients as depending on concentration through the ionic strength only.

Vibrational relaxation involving a single excited level may be regarded as a special case of the above. If z is the population of the excited state, $Q = z/x$ is given at equilibrium by the Boltzmann factor $K = \exp(-h\nu/kt)$, and we may assume that $F \approx 1$ and $\Delta V \approx 0$. These simplifications lead to the usual result for such a case. Situations involving more than one vibrational level have been discussed by Beyer (10) and others (cf. ref. (4), pp. 90–138); they could be treated as special cases of interacting equilibria, to which subject we now turn.

4. TWO SIMULTANEOUS EQUILIBRIA

Where two ordering parameters y, z are required, it is necessary to solve two equations like [12], to obtain $\Delta y/\dot{V}$ and $\Delta z/\dot{V}$. This is easy but laborious. The results are put into [10] to obtain the "relaxation viscosity", $\xi = \xi_1 - i\xi_2$. Before doing this we indulge in a few preliminary considerations which somewhat simplify the procedure.

It is convenient (and always possible) to choose the concentrations y and z in such a way that each is included in only one of the stoichiometric quotients. That is, we can put (cf. [20], [22])

$$\begin{aligned} Q_y &= y^{\nu_y}\prod_i x_i^{\nu_i(y)}, & F_y &= f_y^{\nu_y}\prod_i f_i^{\nu_i(y)}, \\ Q_z &= z^{\nu_z}\prod_i x_i^{\nu_i(z)}, & F_z &= f_z^{\nu_z}\prod_i f_i^{\nu_i(z)}, \end{aligned} \qquad [27]$$

where $\nu_i(y)$, $\nu_i(z)$ are the stoichiometric numbers for X_i in the y and z reactions respectively. At equilibrium, $\bar{Q}_y\bar{F}_y = K_y$ and $\bar{Q}_z\bar{F}_z = K_z$ as before.

Although it is natural to define the four relaxation times τ_y, τ_y^z, τ_z^y, τ_z of [11], only two times can, of course, be independent. Both τ_y and τ_y^z, for example, depend (under [27]) on the rate constants, k_y, k_{-y} governing the y-reaction, but not on k_z, k_{-z}. In fact we may set

$$\tau_y = \mathscr{Y}\tau_y^z, \quad \tau_z = \mathscr{Z}\tau_z^y. \qquad [28]$$

The ratios $\mathscr{Y}$, $\mathscr{Z}$ prove to be very important; they are given in Appendix A, and it is pointed out that they are purely thermodynamic quantities.

We now solve for ξ, and using the definitions [28] we may write the result:

$$\begin{aligned} \frac{\xi_1}{V} = \frac{2\rho c^3\alpha_\tau}{\omega^2 V} = \Bigg\{ &\frac{\tau_y}{1-\mathscr{Y}\mathscr{Z}}\left(\frac{\partial\bar{y}}{\partial V}\right)_s\left[\left(\frac{\partial p}{\partial y}\right)_{s,v,z} - \mathscr{Z}\left(\frac{\partial p}{\partial z}\right)_{s,v,y}\right] \\ &+\left(\frac{\omega\tau_y}{1-\mathscr{Y}\mathscr{Z}}\right)^2\tau_z\left(\frac{\partial p}{\partial z}\right)_{s,v,y}\left[\left(\frac{\partial\bar{z}}{\partial V}\right)_s + \mathscr{Z}\left(\frac{\partial\bar{y}}{\partial V}\right)_s\right] + \text{similar terms with } y \text{ and} \\ &z \text{ interchanged}\Bigg\} \Big/ \left\{1+\frac{\omega^2[\tau_y^2+2\mathscr{Y}\mathscr{Z}\tau_y\tau_z+\tau_z^2]+\omega^4\tau_y^2\tau_z^2}{(1-\mathscr{Y}\mathscr{Z})^2}\right\} \end{aligned} \qquad [29]$$

$$\begin{aligned} \frac{\omega\xi_2}{V} = \rho^2(c^2-c_0^2) = \left(\frac{\omega}{1-\mathscr{Y}\mathscr{Z}}\right)^2\Bigg\{ &\tau_y\left[\tau_y\left(\frac{\partial\bar{y}}{\partial V}\right)_s\mathscr{Y}\tau_z\left(\frac{\partial\bar{z}}{\partial V}\right)_s\right]\left[\left(\frac{\partial p}{\partial y}\right)_{s,v,z} - \mathscr{Z}\left(\frac{\partial p}{\partial z}\right)_{s,v,z}\right] \\ &+\text{a similar term with } y \text{ and } z \text{ interchanged}\Bigg\} + \frac{\omega^4\tau_y^2\tau_z^2}{(1-\mathscr{Y}\mathscr{Z})^2}\left\{\left(\frac{\partial\bar{y}}{\partial V}\right)_s\left(\frac{\partial p}{\partial y}\right)_{s,v,y}\right. \\ &\left.+\left(\frac{\partial\bar{z}}{\partial V}\right)_s\left(\frac{\partial p}{\partial z}\right)_{s,v,y}\right\} \Big/ \left\{1+\frac{\omega^2[\tau_y^2+2\mathscr{Y}\mathscr{Z}\tau_y\tau_z+\tau_z^2]+\omega^4\tau_y^2\tau_z^2}{(1-\mathscr{Y}\mathscr{Z})^2}\right\}. \end{aligned} \qquad [30]$$

These expressions may be compared to [16], [17] of the former argument. Once again we wish to relate the result more closely to the details of the reactions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The reactions quantities $(\partial p/\partial y)_{s,v,z}$ and $(\partial_p/\partial z)_{s,v,y}$ may be found much as before ([24], [25]). To the relevant approximation they may be written

$$\left(\frac{\partial p}{\partial y}\right)_{s,v,z} = \frac{\rho^2 c_0^2}{\nu_y}\left[\Delta V_y - \frac{\Delta H_y}{C_p}\left(\frac{\partial V}{\partial T}\right)_p\right] = \frac{\rho^2 c_0^2}{\nu_y}\delta_y,$$

$$\left(\frac{\partial p}{\partial z}\right)_{s,v,y} = \frac{\rho^2 c_0^2}{\nu_z}\left[\Delta V_z - \frac{\Delta H_z}{C_p}\left(\frac{\partial V}{\partial T}\right)_p\right] = \frac{\rho^2 c_0^2}{\nu_z}\delta_z, \qquad [31]$$

where we have introduced the abbreviations δ_y, δ_z. The equilibrium quantities $(\partial\bar{y}/\partial V)_s$ and $(\partial\bar{z}/\partial V)_s$ are evaluated in Appendix B, where it is shown that

$$\left(\frac{\partial \bar{y}}{\partial V}\right)_s = \frac{\rho^2 c_0^2 (\partial y/\partial \ln Q_y)_z[\delta_y - (\nu_y/\nu_z)\mathscr{Z}\delta_z]}{RT(1-\mathscr{Y}\mathscr{Z})[1+(\partial y/\partial \ln Q_y)_z(\partial \ln F_y/\partial y)_{p,T,z}]}, \qquad [32]$$

$$\left(\frac{\partial \bar{z}}{\partial V}\right)_s = \frac{\rho^2 c_0^2 (\partial z/\partial \ln Q_z)_y[\delta_z - (\nu_z/\nu_y)\mathscr{Y}\delta_y]}{RT(1-\mathscr{Y}\mathscr{Z})[1+(\partial z/\partial \ln Q_z)_y(\partial \ln F_z/\partial z)_{p,T,y}]}.$$

With the help of [31] and [32], and recalling that $c \approx c_0$, we may rewrite α_r [29] and c [30] as follows:

$$\frac{\alpha_\tau}{\omega^2} = \frac{\rho^2 c_0}{2RT}\left\{\frac{\tau_y(\partial y/\partial \ln Q_y)_z[\delta_y - (\nu_y/\nu_z)\mathscr{Z}\delta_z]^2}{(1-\mathscr{Y}\mathscr{Z})^2\nu_y[1+(\partial y/\partial \ln Q_y)_z(\partial \ln F_y/\partial y)_{p,T,z}]}\right.$$

$$+\left(\frac{\omega\tau_y}{1-\mathscr{Y}\mathscr{Z}}\right)^2\frac{\tau_z(\partial z/\partial \ln Q_z)_y[\delta_z]^2}{\nu_z[1+(\partial z/\partial \ln Q_z)_y(\partial \ln F_z/\partial z)_{y,p,T}]} + \text{similar terms with } y \text{ and}$$

$$\left.z \text{ interchanged}\right\} \Big/ \left\{1+\frac{\omega^2[\tau_y^2+2\mathscr{Y}\mathscr{Z}\tau_y\tau_z+\tau_z^2]+\omega^4\tau_y^2\tau_z^2}{(1-\mathscr{Y}\mathscr{Z})^2}\right\}, \qquad [33]$$

$$\frac{c-c_0}{c_0^2} = \frac{\rho^2 c_0}{2RT(1-\mathscr{Y}\mathscr{Z})^3}\left\{\left[\frac{(\partial y/\partial \ln Q_y)_z}{\nu_y[1+(\partial y/\partial \ln Q_y)_z(\partial \ln F_y/\partial y)_{p,T,z}]}\right]\right.$$

$$\times\left[\omega^2\tau_y^2\left[\delta_y - \frac{\nu_y}{\nu_z}\mathscr{Z}\delta_z\right]^2 - \omega^2\tau_y\tau_z\frac{\nu_y}{\nu_z}\mathscr{Z}\left[\delta_y - \frac{\nu_y}{\nu_z}\mathscr{Z}\delta_z\right]\left[\delta_z - \frac{\nu_z}{\nu_y}\mathscr{Y}\delta_y\right]\right.$$

$$\left.\left.+\omega^4\tau_y^2\tau_z^2\delta_y\left[\delta_y - \frac{\nu_y}{\nu_z}\mathscr{Z}\delta_z\right]\right]\right\} + \text{a similar term with } y \text{ and}$$

$$\left.z \text{ interchanged}\right\} \Big/ \left\{1+\frac{\omega^2[\tau_y^2+2\mathscr{Y}\mathscr{Z}\tau_y\tau_z+\tau_z^2]+\omega^4\tau_y^2\tau_z^2}{(1-\mathscr{Y}\mathscr{Z})^2}\right\}. \qquad [34]$$

The absorption and dispersion are not so simply related as for a single relaxation [26]. In the appendices $\mathscr{Y}$, $\mathscr{Z}$, τ_y, τ_z, and the thermodynamic derivatives are related to more familiar quantities. With the help of [A1] and [B8] it can be shown that α_r and $(c-c_0)$ are necessarily positive.

5. DISCUSSION

A detailed example of the use of the results may be found elsewhere (7), but some general illustrative remarks may not be out of place here.

It will be convenient, for the purposes of this discussion, to abbreviate the thermodynamic expressions in [33], putting the equation in the form

$$\frac{\alpha_\tau}{\omega^2} = \frac{\tau_y A_{yz} + \tau_z A_{zy} + (\omega\tau_y/1-\mathscr{Y}\mathscr{Z})^2\tau_z B_z + (\omega\tau_z/1-\mathscr{Y}\mathscr{Z})^2\tau_y B_y}{1+\{\omega^2[\tau_y^2+2\mathscr{Y}\mathscr{Z}\tau_y\tau_z+\tau_z^2]+[\omega^4\tau_y^2\tau_z^2]\}/(1-\mathscr{Y}\mathscr{Z})^2}. \qquad [35]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

This general result [33], [35] is most easily surveyed in the special case $\tau_z \ll \tau_y$. There will then be two fairly distinct relaxation regions. These may be seen in Fig. 1, which shows the frequency dependence of the absorption per wavelength, $\mu_v = 2\pi\alpha_r c/\omega$, in such a case; τ_z is here $0.01\tau_y$. This and the subsequent figures refer to the same arbitrary choice of parameters: $\mathscr{Y} = \mathscr{Z} = 0.7$, $\nu_y = \nu_z = 1$, $B_y = B_z$, $\delta_y = \delta_z$. This may be regarded as a case of fairly strong interaction.

We would expect it to be a good approximation, when $\tau_z \ll \tau_y$, to discard the B_y term of [35]. At the same time the denominator will be well approximated, at all frequencies, by $(1+\omega^2\tau_y^2/(1-\mathscr{Y}\mathscr{Z})^2)(1+\omega^2\tau_z^2)$. These approximations lead us to express the absorption as the sum of two single relaxations, in the form

$$\frac{\alpha_r}{\omega^2} \approx \frac{\tau_y A_{yz}+\tau_z(A_{zy}-B_z)}{1+\omega^2\tau_y^2/(1-\mathscr{Y}\mathscr{Z})^2}+\frac{\tau_z B_z}{1+\omega^2\tau_z^2}. \qquad [36]$$

Very often there will be substantial cancellation of A_{zy} with B_z in this expression, so that we might write

$$\frac{\alpha_r}{\omega^2} \approx \frac{\tau_y A_{yz}}{1+\omega^2\tau_y^2/(1-\mathscr{Y}\mathscr{Z})^2}+\frac{\tau_z B_z}{1+\omega^2\tau_z^2}, \qquad [37]$$

which we shall call a "first approximation" to [35]. In the present case (Fig. 1) this is an excellent approximation, while the "second approximation" [36] is scarcely distinguishable from the complete result [33], [35]. They make a sharp contrast with what may be called the "zeroth approximation": i.e. the sum of single relaxations for the y and z processes, with no allowance for interaction. The zeroth approximation is given by

$$\frac{\alpha_r}{\omega^2} \approx \frac{\tau_y B_y}{1+\omega^2\tau_y^2}+\frac{\tau_z B_z}{1+\omega^2\tau_z^2}, \qquad [38]$$

and is shown by broken lines in the figures.

The failure of the zeroth approximation in the region of the low frequency relaxation is very striking. Not only the magnitude of the predicted absorption peak but also its position is grossly incorrect. In fact the characteristic time of the low frequency relaxation is $\tau_y/(1-\mathscr{Y}\mathscr{Z})$ rather than τ_y, as we may see from [36] and [37]; with the present parameters these times differ by a factor of two. This shift is helpful in that it always provides an "extra" separation of the two relaxation regions, but it means that estimates of $\mathscr{Y}$ and $\mathscr{Z}$ must be available if one is to extract precise kinetic data from the observed relaxation frequency (7). The low frequency absorption involves the energetics of both reactions, their interaction being expressed in the term $[\delta_y-(\nu_y/\nu_z)\mathscr{Z}\delta_z]^2$ of A_{yz} (cf. [33] and [35]). The small size of the peak in the present case is due to the near cancellation of δ_y by $\mathscr{Z}\delta_z$ in this squared bracket.

It is worth noting that these shortcomings of [38] persist even in the limit $\tau_z/\tau_y \to 0$, in which case no evidence of a high frequency absorption would be observable. They depend only on the *existence* of a fast interacting process, as expressed in non-zero values of $\mathscr{Y}$ and $\mathscr{Z}$. This fact implies that a certain caution should be used when interpreting the results even where there appears to be a simple single relaxation.

Evidently [38] is of no use in understanding multiple relaxation processes, while [36] and [37] will be satisfactory for most cases of well-separated relaxations. In Fig. 2 we turn to less well-separated relaxations, in this case $\tau_z = 0.1\tau_y$. The B_y term is no longer so very small, so that [36] and [37] will be somewhat low at the higher frequencies. At lower frequencies ($\omega\tau_y < 5$) [36] remains a good approximation: with the present parameters

For personal use only.

it is everywhere within 5%. It can be seen that the first approximation [37] is still a helpful one, but that it is beginning to break down. Where results like these occur experimentally it will be natural to extract chemical parameters from the ultrasonic data by a method of successive approximations, beginning with [37] (cf. (7)). These approximations will be better for cases of weaker interaction. Of course our earlier remarks about the inadequacy of [38] continue to apply.

In Fig. 3 we show the limiting case $\tau_z = \tau_y$. The approximate formulae [36] and [37] have no longer any relevance. The absorption curve is not that of a single relaxation, but slightly broader; rather precise measurements would be needed to display this, however. The high frequency part of the absorption approaches the zeroth approximation, as usual. The noticeable suppression and shift of the peak, as compared to that approximation, may

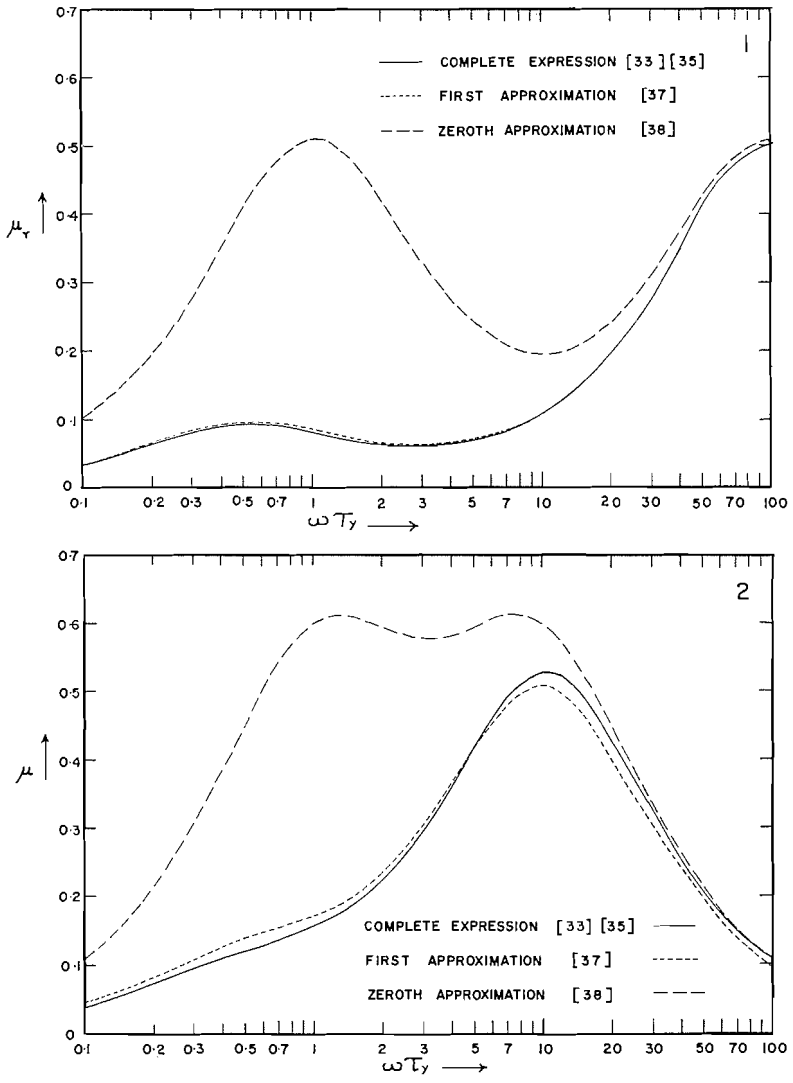

FIG. 1. $\tau_y/\tau_z = 100$.
FIG. 2. $\tau_y/\tau_z = 10$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

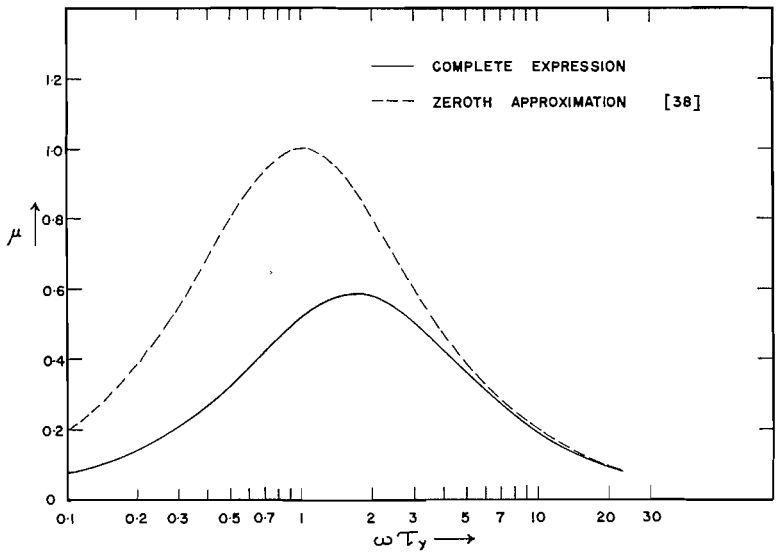

FIG. 3. $\tau_y/\tau_z = 1$.

be attributed to the small size of the low frequency terms A_{yz}, A_{zy}. This was ascribed earlier to the partial cancellation within the brackets $[\delta_y - (\nu_y/\nu_z)\mathscr{Z}\delta_z]$ and $[\delta_z - (\nu_z/\nu_y)\mathscr{Y}\delta_y]$. It should be mentioned that this interaction may have quite the opposite effect. Suppose that we take $\delta_z = -\delta_y$, leaving the other parameters unchanged. Now the terms within the brackets *augment* each other. When they are squared there results a large magnification of the low frequency terms, in contrast to the suppression shown in all the figures here. In the case $\tau_z = \tau_y$ (Fig. 3), for example, it will lead to an absorption peak much bigger than that of the zeroth approximation, and shifted to *lower* frequencies. The qualitative remarks we have made continue to apply, however.

The author appreciates the encouragement of Dr. W. G. Schneider, and the financial support of the National Research Council. He has had helpful discussions with Dr. M. J. Dignam and Mr. S. J. Turner.

APPENDIX A

The Relaxation Times

We consider first the ratios $\mathscr{Y} = \tau_y/\tau_y{}^z$ and $\mathscr{Z} = \tau_z/\tau_z{}^y$, [28]. Close to equilibrium the net rate of a chemical reaction is strictly proportional to the free energy charge, ΔG, of the reaction. This has been demonstrated by Manes, Hofer, and Weller, (11), for example, using purely thermodynamic arguments. It follows that

$$\mathscr{Y} = \frac{(\partial(\Delta G_y)/\partial z)_{y,T,p}}{(\partial(\Delta G_y)/\partial y)_{z,T,p}} = \frac{(\partial \ln Q_y/\partial z)_y + (\partial \ln F_y/\partial z)_{y,T,p}}{(\partial \ln Q_y/\partial y)_z + (\partial \ln F_y/\partial y)_{z,T,p}}, \qquad [A1]$$

$$\mathscr{Z} = \frac{(\partial(\Delta G_z)/\partial y)_{z,T,p}}{(\partial(\Delta G_z)/\partial z)_{y,T,p}} = \frac{(\partial \ln Q_z/\partial y)_z + (\partial \ln F_z/\partial y)_{z,T,p}}{(\partial \ln Q_z/\partial z)_y + (\partial \ln F_z/\partial z)_{y,T,p}}.$$

To take a different point of view, it can easily be shown that unless the ratios $\mathscr{Y}$, $\mathscr{Z}$ take the values shown, the absorption coefficient [33] will not be definitely positive. This would constitute a violation of the second law of thermodynamics, and is therefore a sufficient proof of the relations [A1].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The separate relaxation times are, of course, more difficult to manage. It is convenient to denote by N_y and D_y the numerator and denominator of the quotient Q_y [27]. For the rapid reactions studied by ultrasonic methods one may expect the simplest sort of reaction rate law, which may be written, assuming $\nu_y > 0$, in the form

$$dy/dt = -k_{-y}N_y + k_y D_y, \qquad [A2]$$

which defines rate constants k_{-y}, k_y. It is equally convenient, however, to write the somewhat more general rate law

$$dy/dt = P(-k_{-y}N_y^m + k_y D_y^m), \qquad [A3]$$

where m is any power and P an arbitrary positive function of concentration $P(y, z, x_i, \ldots\ldots)$. At equilibrium

$$dy/dt = 0 = \bar{P}(-\bar{k}_{-y}\bar{N}_y^m + \bar{k}_y\bar{D}_y^m). \qquad [A4]$$

Subtracting [A4] from [A3], and retaining only linear deviations from equilibrium, we obtain

$$\begin{aligned} dy/dt &= -\bar{k}_{-y}\bar{N}_y^m\bar{P}\{m\Delta \ln Q_y + \Delta \ln (k_{-y}/k_y)\} \\ &= -\bar{k}_{-y}\bar{N}_y^m\bar{P}\left\{\left[m\left(\frac{\partial \ln Q_y}{\partial y}\right)_z + \left(\frac{\partial \ln (k_{-y}/k_y)}{\partial y}\right)_{z,T,p}\right]\Delta y \right. \\ &\qquad \left. + \left[m\left(\frac{\partial \ln Q_y}{\partial z}\right)_y + \left(\frac{\partial \ln (k_{-y}/k_y)}{\partial z}\right)_{y,T,p}\right]\Delta z\right\}, \end{aligned} \qquad [A5]$$

which gives the relaxation times τ_y, $\tau_y{}^z$ by comparison with [11]. (For $\nu_y < 0$, the sign is, of course, changed in [A5].)

At equilibrium $(\bar{k}_{-y}/\bar{k}_y) = (\bar{F}_y/K_y)^m$; it is rather natural to identify (k_{-y}/k_y) with $(F_y/K_y)^m$ even away from equilibrium, and this assumption has often been made. It is physically very plausible that the two ratios are at least asymptotic at equilibrium. If this is assumed,

$$\begin{aligned} (\tau_y)^{-1} &= m\bar{k}_{-y}\bar{P}\bar{N}_y^m\left[\left(\frac{\partial \ln Q_y}{\partial y}\right)_z + \left(\frac{\partial \ln F_y}{\partial y}\right)_{z,T,p}\right], \\ (\tau_y{}^z)^{-1} &= m\bar{k}_{-y}\bar{P}\bar{N}_y^m\left[\left(\frac{\partial \ln Q_y}{\partial z}\right)_y + \left(\frac{\partial \ln F_y}{\partial z}\right)_{y,T,p}\right]. \end{aligned} \qquad [A6]$$

These expressions [A6] lead immediately to [A1]. It should be emphasized, however, that the relations [A1] are purely thermodynamic and do not depend on any kinetic assumption. Neither do they depend on the form of the rate law, and of course more general rate laws that [A3] are possible (cf. (11)).

APPENDIX B

The Thermodynamic Parameters

We begin by noting that

$$\left(\frac{\partial \bar{y}}{\partial V}\right)_s = \left(\frac{\partial y}{\partial \ln Q_y}\right)_z\left(\frac{\partial \ln (K_y/\bar{F}_y)}{\partial V}\right)_s + \left(\frac{\partial y}{\partial z}\right)_{Q_y}\left(\frac{\partial \bar{z}}{\partial V}\right)_s. \qquad [B1]$$

However, it is easy to show that

$$\left(\frac{\partial \ln (K_y/\bar{F}_y)}{\partial T}\right)_{p,y,z} = \frac{\Delta H_y}{RT^2},$$

$$\left(\frac{\partial \ln (K_y/\bar{F}_y)}{\partial p}\right)_{T,y,z} = -\frac{\Delta V_y}{RT},$$

so that we may write

$$\left(\frac{\partial \ln (K_y/\bar{F}_y)}{\partial V}\right)_s = \frac{\Delta H_y}{RT}\left(\frac{\partial T}{\partial V}\right)_s - \frac{\Delta V_y}{RT}\left(\frac{\partial p}{\partial V}\right)_s - \left(\frac{\partial \ln F_y}{\partial y}\right)_{p,T,z}\left(\frac{\partial \bar{y}}{\partial V}\right)_s - \left(\frac{\partial \ln F_y}{\partial z}\right)_{p,T,y}\left(\frac{\partial \bar{z}}{\partial V}\right)_s. \quad [B2]$$

It follows that

$$\left(\frac{\partial \bar{y}}{\partial V}\right)_s = \left(\frac{\partial y}{\partial \ln Q_y}\right)_z\left[\frac{\Delta H_y}{RT^2}\left(\frac{\partial T}{\partial V}\right)_s - \frac{\Delta V_y}{RT}\left(\frac{\partial p}{\partial V}\right)_s\right] + \left(\frac{\partial \bar{z}}{\partial V}\right)_s\left[\left(\frac{\partial y}{\partial z}\right)_{Q_y} - \left(\frac{\partial y}{\partial \ln Q_y}\right)_z\left(\frac{\partial \ln F_y}{\partial z}\right)_{p,T,y}\right] \Big/ 1 + \left(\frac{\partial y}{\partial \ln Q_y}\right)_z\left(\frac{\partial \ln F_y}{\partial y}\right)_{p,T,z}. \quad [B3]$$

When $(\partial y/\partial z)_{Q_y}$ is evaluated from the total differential (cf. [27])

$$d \ln Q_y = \left(\frac{\partial \ln Q_y}{\partial y}\right)_z dy + \left(\frac{\partial \ln Q_y}{\partial z}\right)_y dz, \quad [B4]$$

and the value [A1] of $\mathscr{Y}$ is noted, the result [B3] may be put (using the abbreviation $\delta_y = \Delta V_y - (\Delta H_y/C_p)(\partial V/\partial T)_p$, [31])

$$\left(\frac{\partial \bar{y}}{\partial V}\right)_s + \mathscr{Y}\left(\frac{\partial \bar{z}}{\partial V}\right)_s = \frac{\rho^2 c_0^2 \delta_y (\partial y/\partial \ln Q_y)_z}{RT[1+(\partial y/\partial \ln Q_y)_z(\partial \ln F_y/\partial y)_{p,T,z}]}. \quad [B5]$$

This equation and the corresponding equation for $(\partial \bar{z}/\partial V)_s + \mathscr{Z}(\partial \bar{y}/\partial V)_s$ may be solved for $(\partial \bar{y}/\partial V)_s$ and $(\partial \bar{z}/\partial V)_s$ separately. The result is

$$\left(\frac{\partial \bar{y}}{\partial V}\right)_s = \frac{\rho^2 c_0^2 [\delta_y - (\nu_y/\nu_z)\mathscr{Z}\delta_z](\partial y/\partial \ln Q_y)_z}{RT(1-\mathscr{Y}\mathscr{Z})[1+(\partial y/\partial \ln Q_y)_z(\partial \ln F_y/\partial y)_{p,T,z}]}. \quad [B6]$$

In writing [B6] use was made of the values [A1] of $\mathscr{Y}$ and $\mathscr{Z}$, and also of the relation

$$\nu_z\left[\left(\frac{\partial \ln Q_y}{\partial z}\right)_y + \left(\frac{\partial \ln F_y}{\partial z}\right)_{p,T,y}\right] = \nu_y\left[\left(\frac{\partial \ln Q_z}{\partial y}\right)_z + \left(\frac{\partial \ln F_z}{\partial y}\right)_{p,T,z}\right], \quad [B7]$$

which may be demonstrated with the help of the Gibbs-Duhem equation. The definitions [27] allow us to write

$$\nu_z\left(\frac{\partial \ln Q_z}{\partial z}\right)_y = \frac{\nu_z^2}{z} + \sum_i \frac{(\nu_i(z))^2}{x_i}, \quad [B8]$$

$$\nu_z\left(\frac{\partial \ln Q_y}{\partial z}\right)_y = \nu_y\left(\frac{\partial \ln Q_z}{\partial y}\right)_z = \sum_i \frac{\nu_i(y)\nu_i(z)}{x_i}. \quad [B9]$$

AN ULTRASONIC STUDY OF SOME OF THE COMPLEXING REACTIONS OF CHLORIDE WITH CADMIUM ION

J. P. VALLEAU AND S. J. TURNER
Department of Chemistry, University of Toronto, Toronto, Ontario

Received October 9, 1963

ABSTRACT

The ultrasonic absorptions of 0.25 *M* aqueous solutions of cadmium ions, containing various amounts of hydrochloric acid, have been measured by a pulse technique between 13 and 143 Mc/second at 16°, 25°, and 35° C. A relaxation occurs in this region, and it has been interpreted in terms of the interacting association reactions

$$CdCl_2 + Cl^- \rightleftharpoons CdCl_3^-$$
$$CdCl_3^- + Cl^- \rightleftharpoons CdCl_4^{2-}$$

An ultrasonic determination of the equilibrium quotient of the second of these reactions has been made, and the association and dissociation rate constants are reported for both reactions. In addition, the volume changes, ΔV, in the two reactions have been estimated, along with the activation energy for the dissociation of $CdCl_3^-$. The analysis breaks down at low ligand concentrations, and this is ascribed to the influence of a third interacting reaction.

1. INTRODUCTION

There has recently been increasing interest (1, 2, 3) in the use of ultrasonic absorption techniques of studying rapid chemical reactions near equilibrium. The magnitude and frequency dependence of the absorptions depend on the free energy, enthalpy, and volume changes in the reactions, as well as on the rate constants. In favorable cases both kinetic and thermodynamic data may therefore be extracted from ultrasonic experiments.

One of the attractions of the ultrasonic method is that when there occurs a series of interacting equilibria (as in complex ion formation), it is in principle possible to obtain kinetic and thermodynamic data for the separate reaction steps (4). In the present paper the chloride complexes of cadmium are studied from this viewpoint, making use of an extension (5) of ultrasonic theory to embrace relaxations involving two simultaneous equilibria.

In the cadmium–chloride system there occur the four association reactions

$$Cd^{2+} + Cl^- \rightleftharpoons CdCl^+, \qquad [1w]$$
$$CdCl^+ + Cl^- \rightleftharpoons CdCl_2, \qquad [1x]$$
$$CdCl_2 + Cl^- \rightleftharpoons CdCl_3^-, \qquad [1y]$$
$$CdCl_3^- + Cl^- \rightleftharpoons CdCl_4^{2-}. \qquad [1z]$$

The existence of higher complexes has occasionally been suggested, but there is no firm evidence of their existence at the solution concentrations in question. There have been several determinations of the first three stoichiometric equilibrium quotients $\bar{Q}_w$, $\bar{Q}_x$, $\bar{Q}_y$ (cf. (6, 7, 8, 9)), of which the most satisfactory appear to be those of Vanderzee and Dawson (7), who measured these quotients, and also the enthalpies (ΔH) of the three reactions as a function of ionic strength. There are also a number of values of $\bar{Q}_z$ in the literature (10, 11, 12, 13), but these differ very widely. A determination of the ultrasonic velocity, and thus of adiabatic compressibility, in cadmium chloride solutions has been made by Subrahmanyan (14) at 750 kc/second.

After describing our experimental measurements, we discuss what physical chemical information is obtainable from the results.

2. EXPERIMENTAL PROCEDURE

(a) Apparatus

The absorption and velocity of ultrasound in the range 13 to 143 Mc/second were determined by a pulse technique similar to that of Pinkerton (15). The sound wave was produced and detected by matched 13 Mc/second quartz crystals, using the circuit shown schematically in Fig. 1. The wave was transmitted into

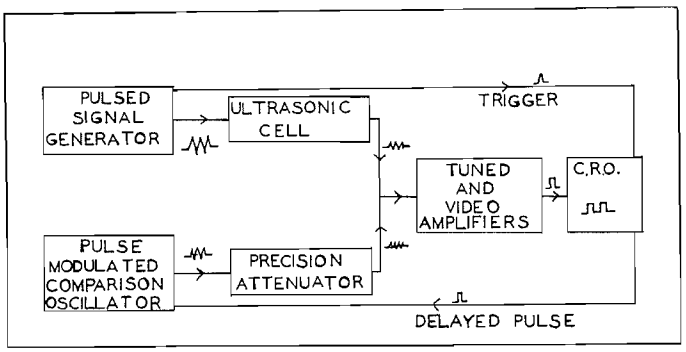

FIG. 1. Schematic circuit diagram of apparatus.

and out of the solution by fused quartz rods, one of which was driven by an accurate lead screw. The changes in ultrasonic attenuation on altering the path length in the solution were compared with electrical attenuation introduced into a comparison circuit by an Airborne Instruments piston attenuator (precision ±0.005 db per db).

The amplitude absorption coefficient α was thus determined for each solution at the five frequencies 13, 39, 65, 91, and 143 Mc/second. The velocity of the sound waves was determined by the interference of reflected pulses at short path lengths.

The precision of the absorption measurements is about 1%, and the estimated error below 3% (cf. (20)). The accuracy of the velocity measurements is estimated to be ±0.5%. Frequency was measured with a calibrated heterodyne frequency meter to within ±0.05%. The cell was thermostatted with a water jacket to within 0.1° C in a given run. The results reported in this paper are for 15.9±0.1° C, 24.7±0.3° C, and 35.1±0.1° C.

(b) Solutions

The solutions discussed in this paper were all 0.25 M in cadmium ion, but contained amounts of hydrochloric acid varying over a wide range (cf. Table I). Hydrochloric acid solutions were prepared by the dilution of Nichols or Baker and Adamson C.P. hydrochloric acid with distilled water, and were subsequently standardized by titrating against mercuric oxide (16). The solutions at 16° and 25° C were prepared by weighing Fisher certified $Cd(NO_3)_2 \cdot 4H_2O$ and adding the required amount of standard hydrochloric acid. The solutions at 35° C were prepared by dissolving weighed amounts of Fisher certified cadmium oxide in standard hydrochloric acid solutions.

The densities of the solutions at 25° C were measured to an accuracy of ±0.3% with hydrometers; the densities at 16° and 35° C were determined to an accuracy of ±0.01% with a specific gravity bottle. Using this data plots were made of density as a function of chloride concentration and from these plots the densities required in the calculations were obtained. Heat capacities and thermal expansion coefficients for the solutions could be estimated from data in the International Critical Tables, since the resulting uncertainties are of no significance.

(c) Determination of the Ultrasonic Parameters

In a single relaxation process the variation of the absorption α with the frequency f determines three constants, A, B, and f_c, according to the relation:

$$\alpha/f^2 = A/[1 + (f/f_c)^2] + B; \qquad [2]$$

f_c is the relaxation frequency. The ultrasonic absorption results on cadmium–chloride solutions were fitted to the expression [2] by the least squares method, using I.B.M. 7090 and 650 computers. The computers were programmed to give A, B, and the standard error $\sqrt{(s/n)}$ for trial values of f_c at 0.2 or 0.5 Mc/second intervals (where s is the sum of the squares of the deviations between the observed and fitted points and n is the number of experimental points).

It was observed that the values of A were quite insensitive to the values of f_c but that this was not so for B. It was of interest to demonstrate that a smooth curve of f_c against chloride ion concentration could be

obtained for values of f_c giving standard errors within the estimated experimental error. These "smoothed" values are given in Table I.* A comparison of the smoothed values with the best least squares values for B and f_c at 35° C is given in Fig. 3. In all cases the experimental results appeared to fit equation [2] very well (cf. Fig. 4), and it is on this basis that the remaining analysis in this paper is carried out.

A, B, and f_c at 25° C are shown in Fig. 2 as a function of hydrochloric acid concentration. It can be seen that both A and B exhibit maxima. Similar curves were obtained at 16° and 35° C. The peak in A is to be expected for a single relaxation process, but the peak in B is explained by the presence of a second, faster, relaxation process in the solution. B contains the classical viscous absorption and the so-called "structural

Only these derived parameters A, B, and f_c are reported here. We shall be glad to supply our absorption data at each frequency to anyone interested.

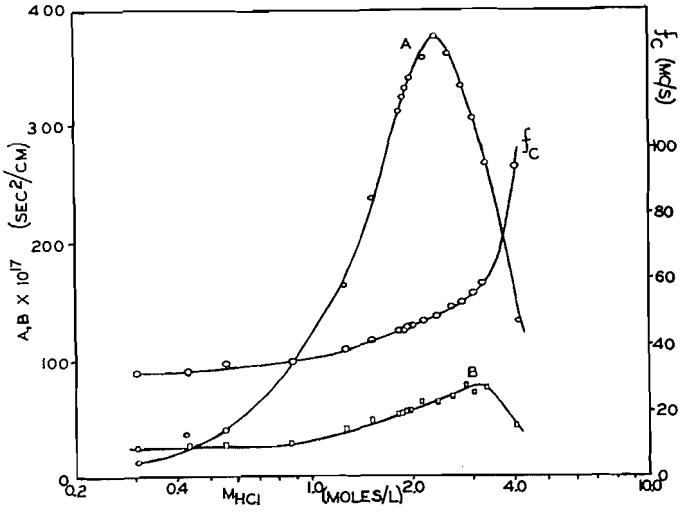

FIG. 2. Variation of A, B, and f_c with concentration of HCl at 25° C (0.25 M in $Cd(NO_3)_2$).

relaxation" of the solvent, plus the absorption of any processes too fast to relax at the frequencies studied. The theory and conclusions which follow are based on the existence of interacting chemical relaxation processes.

3. ANALYSIS OF THE RESULTS

We wish to assign the two peaks, in A and B, to two of the reactions [1]. It is possible to predict roughly the position to be expected for a peak due to a given reaction, and by comparison with such predictions the peaks in A and B have been assigned to reactions [1y] and [1z] respectively. This assignment seems quite unambiguous, for peaks due to [1w] or [1x] would occur at much lower ligand concentrations, below 1 M.

The situation may conveniently be described by the "ordering parameters" $y = [CdCl_2]$ and $z = [CdCl_4^{2-}]$. The general theory of absorption due to such a pair of reactions appears elsewhere (5), and it is shown that the absorption takes the form

$$\frac{\alpha}{\omega^2} = \frac{\alpha_b}{\omega^2} + \frac{\tau_y A_{yz} + \tau_z A_{zy} + (\omega\tau_y/1-\mathscr{Y}\mathscr{Z})^2\tau_z B_z + (\omega\tau_z/1-\mathscr{Y}\mathscr{Z})^2\tau_y B_y}{1+\{\omega^2[\tau_y^2+2\mathscr{Y}\mathscr{Z}\tau_y\tau_z+\tau_z^2]+\omega^4\tau_y^2\tau_z^2\}/(1-\mathscr{Y}\mathscr{Z})^2}, \quad [3]$$

where $\omega = 2\pi f$ and α_b is the absorption due to viscosity and other "background effects". The relaxation times τ_y, τ_z are defined by the rate laws

$$dy/dt = -(\Delta y + \mathscr{Y}\Delta z)/\tau_y, \; dz/dt = -(\Delta z + \mathscr{Z}\Delta y)/\tau_z, \quad [4]$$

where Δy and Δz are the deviations of the concentrations y and z from their equilibrium values. The quantities A_{yz}, A_{zy}, B_y, B_z, $\mathscr{Y}$ and $\mathscr{Z}$ are derived elsewhere (5); for example they may be written, for the above choice of parameters y, z.

$$A_{yz} = \frac{\rho^2 c(-\partial y/\partial \ln Q_y)_z(\delta_y + \mathscr{Z}\delta_z)^2}{2RT(1-\mathscr{Y}\mathscr{Z})^2[1+(\partial y/\partial \ln Q_y)_z(\partial \ln F_y/\partial y)_{p,T,z}]}, \quad [5]$$

$$B_z = \frac{\rho^2 c(\partial z/\partial \ln Q_z)_y \delta_z^2}{2RT[1+(\partial z/\partial \ln Q_z)_y(\partial \ln F_z/\partial z)_{p,T,y}]}, \quad [6]$$

$$\mathscr{Y} = \frac{(\partial y/\partial \ln Q_y)_z[1+(\partial z/\partial \ln Q_y)_y(\partial \ln F_y/\partial z)_{p,T,y}]}{(\partial z/\partial \ln Q_y)_y[1+(\partial y/\partial \ln Q_y)_z(\partial \ln F_y/\partial y)_{p,T,z}]}, \quad [7]$$

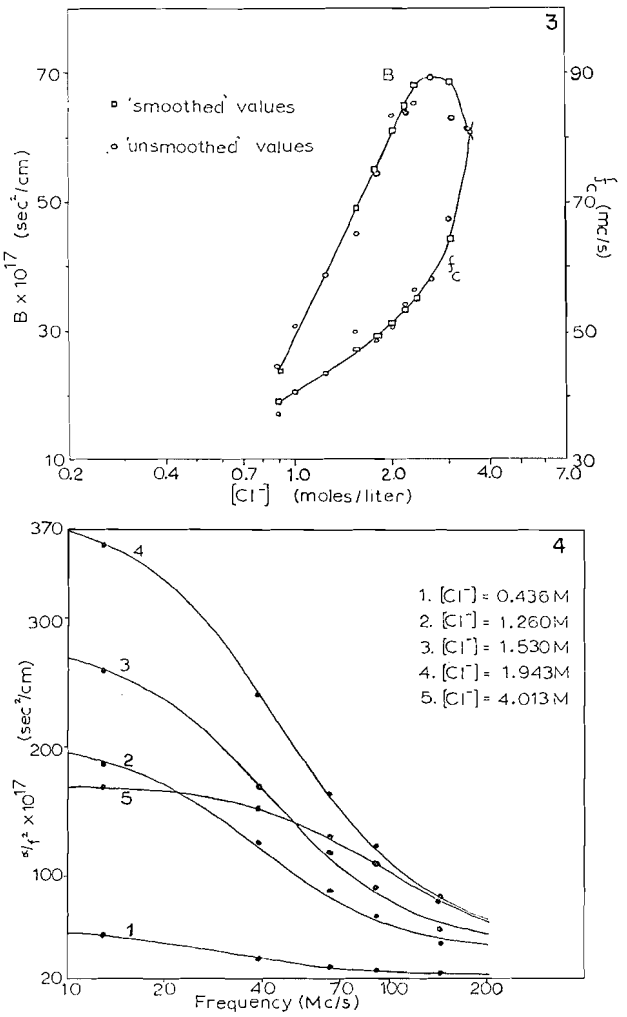

FIG. 3. Comparison of the "smoothed" and "unsmoothed" (best least squares) values for B and f_c at 35° C.

FIG. 4. Some typical fitted relaxation curves at 25° C, with the experimental values.

where

$$\delta_y = \Delta V_y - \left(\frac{\partial V}{\partial T}\right)_p \frac{\Delta H_y}{C_p}, \qquad \delta_z = \Delta V_z - \left(\frac{\partial V}{\partial T}\right)_p \frac{\Delta H_z}{C_p}. \qquad [8]$$

In these equations

ρ and V are the specific gravity and volume of the solution,

c is the sound velocity (cm/second),

C_p is the specific heat of the solution (cal/g deg),

Q_y, Q_z are the stoichiometric quotients for the reactions [1y] and [1z] (liters/mole) (ref. (5), eq. [20]),

F_y, F_z are the corresponding quotients of ionic activity coefficients for the two reactions (ref. (5), eq. [22]), and

ΔV_y, ΔH_y are the volume and enthalpy changes in the y-reaction [1y].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

It is understood that a derivative such as $(\partial z/\partial \ln Q_z)_y$ refers to fixed overall concentrations, and that in calculating the derivative we regard reaction [1y] as frozen (as indicated by the subscript), and need not take into account other reactions, such as [1w] and [1x], which are assumed not to be in interaction with the relaxing processes. In this case we obtain

$$\left(\frac{\partial y}{\partial \ln Q_y}\right)_z = \frac{-[CdCl_3^-]}{1+\bar{Q}_y([CdCl_2]+[Cl^-])}, \qquad [9]$$

$$\left(\frac{\partial z}{\partial \ln Q_z}\right)_y = \frac{[CdCl_4^{2-}]}{1+\bar{Q}_z([CdCl_3^-]+[Cl^-])},$$

$$\left(\frac{\partial y}{\partial \ln Q_z}\right)_z = -\left(\frac{\partial z}{\partial \ln Q_y}\right)_y = \frac{[CdCl_4^{2-}]}{\bar{Q}_z([CdCl_3^-]-[Cl^-])}.$$

Some simplification results from the fact that the observations can be fitted to single relaxation curves. Under this condition we can use the approximation $\omega\tau_z \ll 1$, $\omega\tau_z \ll \omega\tau_y$, when we get the approximate results (5)

$$A \approx \tau_y A_{yz}, \qquad [10]$$

$$B \approx \tau_z B_z + (\alpha_b/f^2),$$

$$1/(2\pi f_c) \equiv \tau_{\text{expt}} \approx \tau_y/(1-\mathscr{Y}\mathscr{Z}).$$

We have attempted to fit our experimental results to the complete expression [3] by a method of successive approximations, beginning with [10].

It will be recalled that the reported values of $\bar{Q}_z$ are widely discrepant. We therefore decided to extract a new value from our data. This is possible because the position and shape of the peak in $[B-(\alpha_b/f^2)] \approx \tau_z B_z$ ([6], [10]) depends primarily on $\bar{Q}_z$. Various trial values of $\bar{Q}_z$ were used, in conjunction with the data of Vanderzee and Dawson (7) on $\bar{Q}_w$, $\bar{Q}_x$ and $\bar{Q}_y$, to calculate, as a function of total halide concentration, a quantity proportional to $\tau z(\partial_z/\partial \ln Q_z)_y$ and thus to $[B-(\alpha_b/f^2)]$. The value of $\bar{Q}_z$ giving the most satisfactory agreement with the B curve was adopted as the best value for this quotient. (In doing this, (α_b/f^2) was given the values 29×10^{-17} (16° C), 21×10^{-17} (25° C), and 16×10^{-17} sec^2 cm^{-1} (35° C) as found in pure water. The absorption of 2.8 M hydrochloric acid solution without cadmium ion was found to be 23×10^{-17} sec^2 cm^{-1} at 25° C, showing that the error in using the above constant values for (α_b/f^2) was well within the estimated accuracy of B.) This should be regarded as an ultrasonic determination of $\bar{Q}_z$ for ionic strengths near three. At 25° C the value $\bar{Q}_z = 0.55$ thus determined agrees fairly well with two of those previously reported (10, 12). In the determination of $\bar{Q}_z$ at 16° and 35° C, it was necessary to know the values of $\bar{Q}_w$, $\bar{Q}_x$, $\bar{Q}_y$ for these temperatures, at various ionic strengths. These quantities were obtained by interpolation of the data of Vanderzee and Dawson (7), by means of plots of $\ln \bar{Q}$ vs. $1/T$ and of $\bar{Q}$ vs. ionic strength.

It should be emphasized that we have chosen only the best *constant* value of $\bar{Q}_z$, and have tacitly ignored, as well, any variation of δ_z or of the rate constants k_z, k_{-z} with concentration. In view of the experimental uncertainty in B, and especially of the imprecise estimate of α_b, it didn't appear justified to attempt more than this. We could, of course, have made our theoretical curve fit the experimental curve exactly by allowing $\bar{Q}_z$, or k_z, or both, to vary with the concentration. The fit based on constant parameters (Fig. 7) appears quite satisfactory, however, and is likely within the uncertainty in our estimate of $\tau_z B_z$ [9]. The very small reported variation of $\bar{Q}$ for $CdBr_3^- + Br^- \rightleftharpoons CdBr_4^{2-}$ (17) is also

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

encouraging with respect to our procedure. It appears, from our calculations using other trial values of $\bar{Q}_z$, that the uncertainty in the derived value of $\bar{Q}_z$ is about ± 0.2 liters/mole.

It should be mentioned that in the present analysis we have suppressed all the activity coefficient terms in the theoretical equations, on the following basis: the assumption that the activity coefficients depend on concentration through the ionic strength, I, only (so that $F_y = F_y(T, p, I)$, etc.) allows one to write*

$$(\partial \ln F_y/\partial y)_z = (\partial \ln F_y/\partial z)_y = (\partial \ln F_z/\partial y)_z = 0;$$

this follows from the fact that $(\partial I/\partial y)_z = 0$ (cf. ref. (5), eqs. [B7], [B9]). There is no useful data on F_z, but our constant value of $\bar{Q}_z$ is consistent, on the above assumption, with $(\partial \ln F_z/\partial z)_y = 0$, and we have accepted this value.

The analysis is now carried out as follows. From τ_{expt} we can calculate τ_y [10]. The experimental A values can then be compared with $\tau_y A_{yz}$ [10]; this gives us a trial value of $(\delta_y + \mathscr{Z}\delta_z)^2$ as a function of acid concentration. In order to proceed we need, however, values of δ_y and δ_z separately. There is no rigorous way of carrying out this separation, since both δ_y and δ_z could in principle vary arbitrarily with the concentration. If, on the other hand, δ_y and δ_z are independent of concentration, a plot of $|\delta_y + \mathscr{Z}\delta_z|$ against $\mathscr{Z}$ should be linear; in fact such a plot proves to be very closely linear except at the lowest chloride concentrations (cf. Fig. 5). The linear region extends through the concentration range of

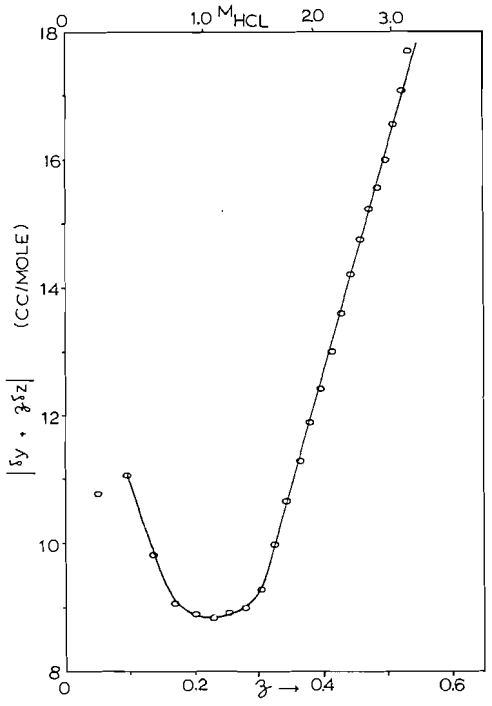

FIG. 5. $|\delta_y + \mathscr{Z}\delta_z|$ vs. $\mathscr{Z}$ at 25° C.

On the other hand, the same assumption allows one to calculate a small finite value for $(\partial \ln F_y/\partial z)_y$ from the reported variation of $\bar{Q}_y$ with ionic strength. Presumably the above assumption is (as one expected) at fault. Fortunately the terms remain so small that they can be neglected, however.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

both the A and the B peaks. The low concentration deviation will require a separate discussion later in the paper. From the linear plot we obtain trial values of δ_y and δ_z (these are of opposite signs and at 25° C their magnitudes are 1.4 and 36 cc/mole, respectively).

Using this value of δ_z, B_z [6] may be calculated. Comparison of this with $(B-\alpha_b/f^2)$ [10] gives a trial value for τ_z at each concentration. The set of trial values of δ_y, δ_z, and τ_z were then used to improve the approximation. With their help the corrections [3] to the first approximation [10] were calculated. These corrections are fortunately small, and allow a second cycle of determinations of δ_y, δ_z, and τ_z. The resulting values of $|\delta_y|$ and $|\delta_z|$ at 25° C are 1.8 and 36 cc/mole. The dissociation rate constant k_{-z} of $CdCl_4^{2-}$ [1z] was determined from τ_z according to the relation

$$\tau_z^{-1} = k_{-z}[1+\bar{Q}_z([CdCl_3^-]+[Cl^-])], \qquad [11]$$

which is equation [A6] of ref. (5) for the rate law

$$dz/dt = (d[CdCl_4^{2-}])/dt = -k_{-z}[CdCl_4^{2-}]+k_z[CdCl_3^-][Cl^-].$$

At 25° C its mean value was found to be 7.6×10^9 sec^{-1}. These values and the values obtained earlier were used to calculate the complete expressions for A and B, and at 25° C these are compared with experiment in Figs. 6 and 7; similar results were obtained at the other temperatures.

No dispersion could be observed in the velocity measurements at different frequencies. In fact the expected dispersion can be calculated from the absorption and was found to be within our experimental accuracy. Also no definite variation with concentration of HCl was found, the individual velocity determinations being scattered about the mean values given in Table II, with a maximum deviation of 0.7%.

	Mean = 4.1	−38				

4. DISCUSSION

The discrepancy (Figs. 5 and 6) in our fit of A at low ligand concentrations will be discussed presently. Meanwhile we shall comment only on the more extensive region for which our interpretation appears to be successful.

To carry out our analysis, we were forced to assume the constancy of δ_y and δ_z over a wide range of concentration. Happily this is consistent with our results, and indeed the linearity of $|\delta_y+\mathscr{Z}\delta_z|$ with $\mathscr{Z}$ would be highly fortuitous on any other assumption. The assumed constancy of $\bar{Q}_z$ is perhaps more worrying, although the resulting fit (Fig. 7) is probably within the uncertainty of our estimate of $\tau_z B_z$. There remains however some uncertainty in the constant value chosen—it may be in error by as much as 40%. The calculations have been repeated with the values $\bar{Q}_z = 0.3$ and 0.4, and from these calculations it appears that the uncertainty in $\bar{Q}_z$ leads to uncertainties of about ±3 cc/mole in

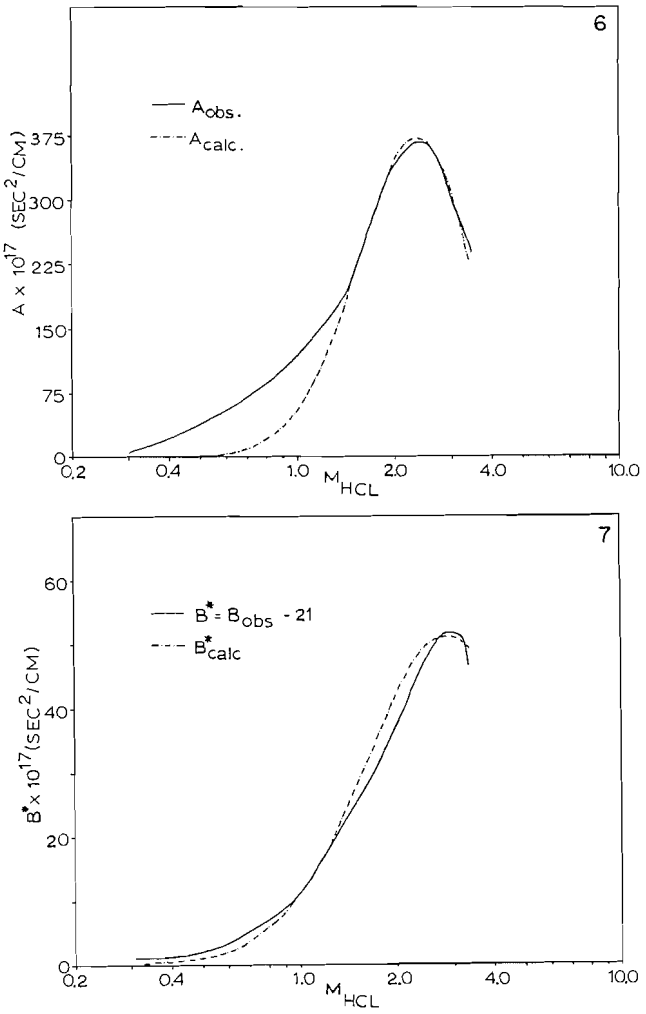

FIG. 6. Comparison of A_{obs} and A_{calc} at 25° C.
FIG. 7. Comparison of $B^* = [B_{obs} - (\alpha_b/f^2)]$ and B^*_{calc} at 25° C.

δ_y and ± 2 cc/mole in δ_z. There will be additional uncertainty in δ_y and δ_z due to errors in τ_y and the remaining $\bar{Q}$'s.

Since A_{yz} is proportional to $(\delta_y + \mathscr{Z}\delta_z)^2$ our plot (Fig. 5) allows us to determine only the magnitudes and the relative sign of δ_y and δ_z. However, one might expect ΔV_z and hence δ_z for the reaction [1z] to be negative, as discussed below. With the help of data from Vanderzee and Dawson (7) and Shchukaryev *et al.* (12) we can calculate the ΔH contributions to δ_y and δ_z [8], and thus extract ΔV for each reaction. Fortunately the ΔH contributions turn out to be small in both cases, and the resulting ΔV values are shown in Table II.

It is perhaps interesting to compare ΔV_z with that predicted by the empirical equations of Couture and Laidler (18). According to these authors the partial molal volume of monatomic anions may be represented by: $4 + 4.9\ r^3 - 14|z|$, where r is the crystallographic radius and z the charge. If we apply this expression to the present more complicated case it leads to:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$\Delta V_z = 4.9(r^3_{CdCl_4^{2-}} - r^3_{CdCl_3^-} - r^3_{Cl^-}) - 4.$$

Taking $r_{CdCl_4^{2-}} = r_{CdCl_3^-}$, this gives $\Delta V_z \approx -33$ cc/mole, quite close to our experimental value of -38 cc/mole. If, instead, we attempt to apply to the cadmium complex anions the expressions which the above authors (19) intended for oxyanions, it leads to a numerically smaller, but still negative, value for ΔV_z.

The experimental relaxation time [10] gives us the relaxation time τ_y of reaction [1y]. Since (cf. [11])

$$\tau_y^{-1} = k_{-y}[1+\bar{Q}_y([CdCl_2]+[Cl^-])],$$

we can derive the dissociation rate, k_{-y}, of $CdCl_3^-$, and then the association rate $k_y = \bar{Q}_y k_{-y}$. These rate constants and τ_y are given in Table III. It is interesting that the association rate k_y appears virtually constant, the variation of $\bar{Q}_y$ corresponding almost entirely to that of the dissociation rate; this is contrary to an expectation expressed elsewhere (1).

TABLE III

Derived rate parameters at selected ligand concentrations

	$k_y \times 10^{-8}$ (l. mole^{-1} sec^{-1})			$k_{-y} \times 10^{-8}$ (sec^{-1})			$\tau_y \times 10^9$ (sec)		
[Cl^-]	15.9° C	24.7° C	35.1° C	15.9° C	24.7° C	35.1° C	15.9° C	24.7° C	35.1° C
1.59	0.87	1.1	1.4	1.6	2.0	2.1	3.80	3.07	2.75
1.98	0.96	1.2	1.5	1.5	1.8	1.9	3.54	2.85	2.55
2.34	1.0	1.3	1.5	1.3	1.5	1.6	3.34	2.71	2.40
2.69	1.1	1.3	1.6	1.1	1.2	1.4	3.16	2.61	2.27
3.03	1.1	1.3	1.6	0.92	1.0	1.2	2.96	2.49	2.13
3.35	1.1	1.3	1.7	0.78	0.83	1.0	2.76	2.36	1.91

NOTE: The apparent activation energies for the association and dissociation reactions are 4.5 ± 0.8 kcal/mole and 2.3 ± 0.5 kcal/mole, respectively.

The activation energy for the dissociation reaction [1y] was determined from an Arrhenius plot to be 2.3 ± 0.5 kcal per mole. The linearity of these plots deteriorated at low chloride ion concentrations. This suggests that the relation [10] between τ_y and τ_{expt} may be breaking down at these concentrations. We shall later argue that this is probably due to the presence of a third relaxation process. Combining the above activation energy with the estimated heat of the reaction (7), we find that the activation energy of the association reaction is about 4.5 kcal per mole.

The method of extracting τ_y from the experimental data involves an uncertainty of about 8%. The accuracy of k_y or k_{-y} depends as well on the uncertainty of $\bar{Q}_y$ (7), giving an estimated uncertainty of about 15% in these rate constants. The corresponding figures for τ_z and for the rate constants k_{-z}, k_z are very difficult to estimate, but it appears they may amount to as much as 25% and 50% respectively.

We turn now to discussing the considerable discrepancy between the observed A curve at low concentrations and that predicted by parameters derived at higher concentrations; this discrepancy corresponds to the non-linear region of Fig. 5. The following explanations suggest themselves:

(*a*) a variation of δ_y or δ_z with low concentrations,
(*b*) errors in the $\bar{Q}$'s used in the calculations,
(*c*) a breakdown of the approximation $\tau_y \gg \tau_z$,
(*d*) the presence of a third interacting process.

The first two suggestions require implausibly large changes in the parameters involved,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

however. The implication of (*c*) is that our method of analyzing the results becomes inapplicable at low concentrations. If this were to be important, however, there should appear at least some region in which the relaxation curves were far from those of a single relaxation; nor do the results at higher concentrations suggest that any such calamity is to be expected, a factor of 30 remaining between τ_y and τ_z at [HCl] = 1.5.

We therefore turn to (*d*), the possibility of a third interacting process. Since the deviation occurs at low ligand concentrations, it is natural to suspect that the other complexing reactions [1*x*] or [1*w*], could be responsible, and in fact the deviation goes through a peak at [HCl] = 0.8, very close to the position to be expected for absorption due to reaction [1*x*]. There remains the very surprising fact that the relaxation appears to be single at each concentration. This could only happen if the relaxation time τ_x of the interacting process obeyed one of the following conditions:

(i) $\tau_x \gg \tau_y$, when the *x*-reaction would be frozen and make no contribution to the absorption.

(ii) $\tau_x \ll \tau_y$, when the *x*-reaction could influence the magnitude of A in the same way as we have seen the *z*-reaction to do. Against this, one would expect a peak in the B curve for such a case.

(iii) $\tau_x \approx \tau_y$ when (cf. (5)) it would be very difficult to distinguish the relaxation curve from that of a single relaxation.

The complete analysis of this third case requires a further extension of ultrasonic theory. One can see from the theory for two processes (5) that τ_x and τ_y would not be simply related to f_c in this case, and for that reason we have taken no kinetic data from our results below 1.5 M HCl. An attempt is being made to investigate the matter more thoroughly.

5. CONCLUSION

The experimental results have been interpreted in terms of the two interacting processes [1*y*] and [1*z*]. On this basis we have derived a variety of kinetic and thermodynamic information about these reactions, and this is summarized in Tables II and III.

It appears, however, that these results should be accepted with some caution, inasmuch as the analysis in terms of only two reactions is not satisfactory throughout the range of concentrations studied. It appears that the validity of the present interpretation can only be examined by carrying out a more complete analysis in terms of more than two processes. This is being attempted.

It is felt that the temperature variations in the derived values of the ΔV's, k_z, and k_{-z} are not significant, in view of the uncertainty in the determinations.

The relaxation we have observed is that of the third reaction, [1*y*], in the sense that it is controlled by the rates of this reaction. On the other hand, almost the whole of the magnitude of the absorption is "borrowed" from the fourth reaction [1*z*], due to the large size of ΔV_z compared to ΔV_y. This behavior lends weight to the warning given in a previous paper (5) concerning naive interpretations of apparently single relaxations. In the present case the absorption at [HCl] = 2.3 M, for example, if assigned to a simple relaxation of [1*y*] alone, would have led to the very different value $|\Delta V_y| = 13.5$ cc/mole.

THE PYROLYSIS OF TRIMETHYLINDIUM

M. G. JACKO[1] AND S. J. W. PRICE
Department of Chemistry, University of Windsor, Windsor, Ontario
Received December 12, 1963

ABSTRACT

The pyrolysis of trimethylindium has been studied in a toluene carrier flow system from 550° K to 781° K using total pressures from 6.0 to 33.5 mm. The progress of the reaction was followed by measuring the amount of methane, ethane, ethylene, propane, and ethylbenzene formed and in a number of cases by direct indium analysis. The decomposition occurs in three steps:

$$In(CH_3)_3 \rightarrow In(CH_3)_2 + CH_3 \quad [1]$$

$$In(CH_3)_2 \rightarrow In(CH_3) + CH_3 \quad [2]$$

$$In(CH_3) \rightarrow In + CH_3 \quad [3]$$

At all temperatures reaction [2] follows rapidly after reaction [1]. Reaction [3] occurs at a measurable rate only at temperatures sufficiently high that reactions [1] and [2] are completed in a very small fraction of the contact time. At lower temperatures the $InCH_3$ produced deposits in the reaction zone as a white film of $(InCH_3)_n$.

Both k_1 and k_3 decline rapidly if the toluene-to-alkyl ratio is decreased below 150. In an unseasoned vessel, the decomposition is markedly dependent on surface conditions. In the unpacked conditioned vessel the reaction is at least 89% homogeneous in the first bond region and 97% homogeneous in the third bond region. Both k_1 and k_3 depend on the total pressure in the system, the dependence of k_1 being very slight. A least squares analysis of the experimental results gives:

$$\log_{10} k_1\ (sec^{-1}) = 15.72 - (47{,}200/2.303RT)$$

$$\log_{10} k_3\ (sec^{-1}) = 10.91 - (38{,}700/2.303RT)$$

at 13.0 mm. E_1 may be directly related to $D[(CH_3)_2In—CH_3]$. A rough calculation based on unimolecular pressure effects indicates that $D[In—CH_3]$ is probably about 2 kcal/mole greater than E_3.

INTRODUCTION

No previous kinetic studies of the thermal decomposition of trimethylindium have been reported.

A study of the reaction of triisobutylindium with 1-decene at 150° C for 100 hours (1) yielded tridecylindium and 83% isobutylene. The tridecylindium broke down further to yield only 64% free indium metal plus 1/2 CH_2=CH—C_8H_{17} and 3/2 CH_3—CH_2—C_8H_{17}. The remaining indium was assumed to be in some polymeric form.

A kinetic study of the thermal decomposition of trimethylgallium has been reported (2). The rate constants obtained were extremely sensitive to the nature of the surface in the reaction zone. After a series of runs, the reaction zone became conditioned and reproducible results were obtained. The experimental results showed $D_1 = 59.5$ kcal/mole and $D_2 = 35.4$ kcal/mole. From a knowledge of the total bond energies, $D_3 = 77.5$ kcal/mole was calculated.

The thermal decomposition of trimethylindium is expected to be similar to that of trimethylgallium and the other neighboring methyl metallic alkyls that have been studied (3, 4, 5). The mean metal–carbon bond dissociation energy in trimethylindium has not been reported. However, from available data on the methyl compounds of groups II*b*, III*b*, IV*b*, and V*b*, a value for trimethylindium of $E = 41 \pm 3$ kcal/mole may be estimated.

EXPERIMENTAL

Materials

(*a*) Trimethylindium was prepared by refluxing indium metal with dimethylmercury in an atmosphere of dry nitrogen using mercuric chloride as catalyst (6). After 8 days the reaction flask was cooled to 0° C (vapor pressure of trimethylindium, 0.2 mm) and the unreacted dimethylmercury (vapor pressure, 17 mm) was distilled off. The crude trimethylindium was transferred to the main alkyl storage system where the remaining dimethylmercury was removed by repeated degassing at 0° C. The final product melted at 89.5° C and gave vapor pressure measurements consistent with literature values (6). It was stored under its own vapor pressure at −190° C.

(*b*) Toluene from sulphonic acid (Eastman Organic, X325) was dried by refluxing over sodium under vacuum and then degassed by bulb-to-bulb distillation.

Apparatus and Procedure

The experiments were carried out in a typical toluene carrier flow system in which the reaction zone was 195 cc. To test for surface effects the reaction vessel was packed with thin-walled quartz tubing of 2 mm O.D. The surface area in the reaction zone was increased by a factor of 10 and its volume reduced to 145 cc. Pressures were measured with a mercury-dioctylphthalate differential manometer designed to give a magnification of 10 to 1.

Trimethylindium was added to the carrier stream by a variable split-stream U-tube pickup system. Before a run, 0.1 to 0.2 gram of the alkyl was distilled from a weighed vessel into the U-tube and the vessel reweighed to determine the exact quantity used. The entire sample in the U-tube was used in the run. The period of alkyl injection was preceded by a 5- to 10-minute flow of toluene to stabilize flow conditions and was followed by a 5- to 10-minute flow of toluene to remove all volatile products from the reaction zone.

An acetone – dry ice trap removed unreacted trimethylindium, toluene, ethylbenzene, dibenzyl, and similar products. The remaining products were transferred by a diffusion pump to a trap at −100° C (acetone–toluene sludge) to remove traces of toluene and hydrocarbons higher than C_4. The remaining gaseous mixture was transferred past a non-return valve to a gas burette with the aid of a Toepler pump. After the gaseous mixture was measured, a sample was taken for chromatographic analysis.

Chromatographic analysis of the gaseous products was carried out using a 2-meter silica-gel column at 80° C with a helium flow rate of approximately 20 cc/min. The contents of the acetone – dry ice trap were analyzed using a 2-meter diisodecylphthalate on diatomaceous earth column at 130° C with a helium flow rate of 38.5 cc/min. This method is sensitive to better than 0.0002 parts ethylbenzene or xylenes in toluene. In the later stages, a Perkin–Elmer Model 800 gas chromatograph equipped with a 150-foot Golay column, 0.02 inch I.D. coated with poly(propylene glycol) was used. This increased the sensitivity of the analyses to better than 0.000002 parts ethylbenzene in toluene.

In 18 selected runs, the contents of the acetone – dry ice trap were analyzed for indium. Approximately 100 cc of concentrated hydrochloric acid (12 *N*) was added and the resultant mixture vigorously stirred and evaporated to 1 to 2 cc. The resulting indium trichloride solution was diluted to about 50 ml with distilled water, buffered with hexamethylenetetramine, and titrated with 0.02 *M* EDTA using xylenol orange as indicator (7). In 7 of these 18 runs, the indium content of the solid in the reaction zone was similarly analyzed.

RESULTS AND DISCUSSION

The experimental results are given in Tables I and II. They may be discussed in terms of the following mechanism:

$$In(CH_3)_3 \rightarrow In(CH_3)_2 + CH_3 \quad [1]$$

$$In(CH_3)_2 \rightarrow In(CH_3) + CH_3 \quad [2]$$

$$In(CH_3) \rightarrow In + CH_3 \quad [3]$$

$$n[In(CH_3)] \rightarrow [In(CH_3)]_n \quad [4]$$

$$CH_3 + C_6H_5{-}CH_3 \rightarrow C_6H_5{-}CH_2 + CH_4 \quad [a]$$

$$2CH_3 \rightarrow C_2H_6 \quad [r]$$

followed by the usual reactions of the benzyl radicals to produce dibenzyl or ethylbenzene. The abstraction reaction [*a*] is a composite reaction proceeding mainly as written but with a small percentage of abstraction from the ring. The ethylene and hydrogen observed in small amounts result from the reactions:

$$CH_3 + C_2H_6 \rightarrow C_2H_5 + CH_4 \quad [5]$$

$$C_2H_5 \rightarrow C_2H_4 + H \quad [6]$$

$$H + C_6H_5{-}CH_3 \rightarrow C_6H_5{-}CH_2 + H_2. \quad [7]$$

*Runs in an unconditioned vessel.

The values of $k_a/k_r^{1/2}$ given in Tables IA and IB have been calculated using the equation

$$k_a/k_r^{1/2} = \frac{[\text{moles } CH_4]}{[\text{moles } C_2H_6+C_2H_4]^{1/2}} \times \frac{1}{V^{1/2}t^{1/2}[\text{toluene}]}$$

where V = volume of reaction zone, and t = length of run.

If in the decomposition of a compound of the type $M(CH_3)_n$ we have

$$M(CH_3)_n \rightarrow M(CH_3)_{n-y} + yCH_3 \qquad [I]$$

occurring over a temperature range T_1 to T_2 while

$$M(CH_3)_{n-y} \rightarrow M(CH_3)_{n-y-z} + zCH_3 \qquad [II]$$

occurs appreciably only above T_2, we shall have a number of factors which will influence the value of $k_a/k_r^{1/2}$. First, in a flow reaction, the temperature increases as the reaction zone is approached, therefore when the temperature in the reaction zone T_3 is above T_2, reaction [I] will occur partly in the tube leading to the reaction zone and will be complete in some small fraction of this zone. This has a dual effect on $k_a/k_r^{1/2}$:

(i) reaction [I] is occurring at an average temperature above T_2 but below T_3, and

(ii) the volume over which reaction [I] occurs is no longer the total volume of the reaction zone.

The net effect is to hold the apparent observed value of $k_a/k_r^{1/2}$ approximately constant as T increases. Actually, the net effect might be a slight decrease except for the fact that reaction [II] is occurring over the entire reaction zone at T_3. Experimentally, for dimethylzinc,

$$Zn(CH_3)_2 \rightarrow ZnCH_3 + CH_3 \qquad [I]$$
$$ZnCH_3 \rightarrow Zn + CH_3 \qquad [II]$$

the ratio shows a slight decrease above T_2 (4). For trimethylgallium

$$Ga(CH_3)_3 \rightarrow Ga(CH_3)_2 + CH_3 \qquad [I]$$
$$Ga(CH_3)_2 \rightarrow Ga(CH_3) + CH_3 \qquad [II]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the ratio continues to rise slightly (2). In any case, a sharp break in the $k_a/k_r^{1/2}$ curve is observed.

The Arrhenius plot of $k_a/k_r^{1/2}$ for the present work is shown in Fig. 1. In this case, the characteristic break occurs at 67% theoretical yield of methyl radicals indicating that below 670° K reaction [2] follows rapidly after reaction [1], but reaction [3] does not occur to any appreciable extent. Rate constants below this temperature (k_1) have therefore

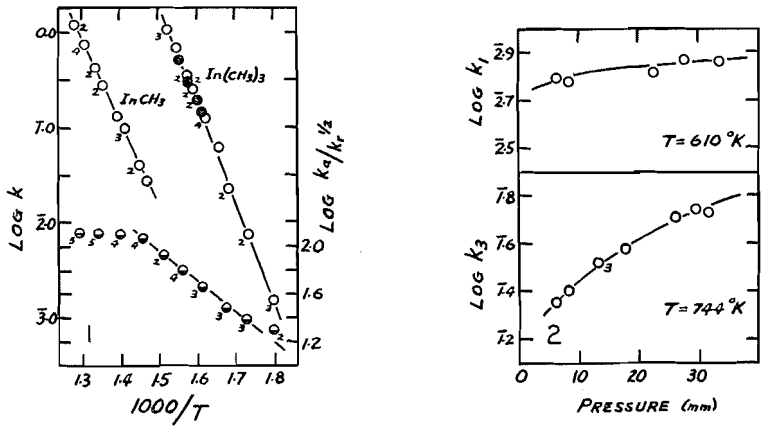

FIG. 1. Arrhenius plots for the pyrolysis of trimethyl- and methyl-indium and the reaction of methyl radicals with toluene. ○ rate constants based on gas analysis; ● rate constants based on metal analysis; ◒ log $k_a/k_r^{1/2}$. Subscripts denote the number of runs averaged to obtain the given point.

FIG. 2. Variation of k_1 and k_3 with pressure. Subscripts denote the number of runs averaged to obtain the given point.

been calculated assuming that two methyl radicals are released for each trimethylindium undergoing reaction. Above 680° K all of the trimethylindium is converted to methylindium plus two methyl radicals in a very small fraction of the contact time. Rate constants in this region (k_3) have therefore been calculated assuming that the fraction of the third bond ruptured is given by:

$$\frac{(\text{moles of methyl radicals}) - (2 \text{ moles trimethylindium})}{\text{moles of trimethylindium}}.$$

Although the break in the Arrhenius curve of $k_a/k_r^{1/2}$ is indicative of the process outlined, independent tests have been made to verify the mechanism.

(i) In 18 runs, the contents of the acetone – dry ice trap located at the outlet of the furnace were analyzed for indium. If reaction [4] is responsible for the removal of $In(CH_3)$, then above 670° K all the indium should be deposited in the reaction zone. Table II shows that over the entire third bond region only traces of indium reach the acetone – dry ice trap. Below this temperature the quantity of indium found in the trap was always in agreement with the proposed mechanism.

(ii) In 7 of the 18 runs listed in Table II a clean pyrex vessel was used. In each of these seven runs the indium content of the reaction zone was analyzed. The values of k_1 calculated assuming moles of indium in the reaction zone equal the moles of trimethylindium decomposed are shown in Fig. 1. The agreement with k_1 values in a seasoned vessel calculated assuming two methyl radicals released for each trimethylindium decomposed is excellent.

(iii) The rate constants for the reaction in a clean vessel based on gas analysis lie above the Arrhenius curve. The difference in extent of reaction based on metal analysis is a result of reaction on the unconditioned surface. The most probable surface reactions consistent with the experimental results are the surface decomposition of methylindium to give indium metal plus a methyl radical and the surface decomposition of trimethylindium. The first of these reactions leads to a decrease in the quantity of $(InCH_3)_n$ deposited in the reaction zone. Hence in an experiment in an unconditioned vessel in which 1.0 millimole of methylindium would have been deposited in the reaction zone in a conditioned vessel, addition of bromine vapor to the hot reaction vessel (637° K) while still under vacuum produced only 0.34 millimole of hydrogen bromide and a quantity of polymethylene qualitatively in agreement with the reaction

$$2nBr_2 + (InCH_3)_n \rightarrow nInBr_3 + n(CH_2) + nHBr$$

followed by the polymerization of the methylene radicals in cooler regions of the reaction vessel. The 0.66 millimole of methylindium apparently lost by surface decomposition was in good agreement with the additional methyl radicals detected in the gas analysis (0.58 millimole).

Starting with a clean vessel, both k_1 and k_3 decrease over several runs to a fixed minimum value in what is subsequently called a conditioned vessel. If air is admitted to the reaction vessel between runs, an additional two to three runs are required to recondition the surface of the reaction vessel. The percentage of heterogeneous reaction in the conditioned vessel was estimated by carrying out a series of runs in a packed vessel with a surface-to-volume ratio 12 times that of the unpacked vessel. Because of the large surface area, complete conditioning was probably not obtained, but after a series of runs k_1 was reduced to about 2.2 times its value in the unpacked vessel and k_3 to about 1.3 times its value in the unpacked vessel. Therefore, in the unpacked vessel used in this work, the reaction is at least 89% homogeneous in the first bond region and at least 97% homogeneous in the third bond region.

Both k_1 and k_3 depend on the total pressure in the system, although the dependence of k_1 is very slight (Fig. 2). The slight pressure dependence of k_1 is similar to that observed in the decomposition of trimethylgallium (2). As shown in Fig. 3, the pressure dependence

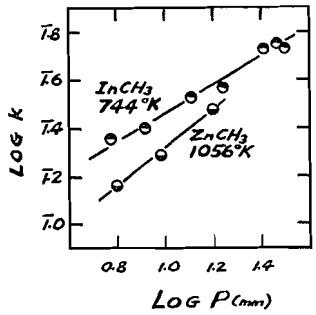

FIG. 3. Comparison of the effect of pressure on the rate of thermal decomposition of $InCH_3$ and $ZnCH_3$.

of the decomposition of methylindium is somewhat less than that of methylzinc (4). This is presumably due to the large temperature difference at which these decompositions occur.

The pressure dependence of $k_a/k_r^{1/2}$ is shown in Fig. 4. The fall-off with increasing

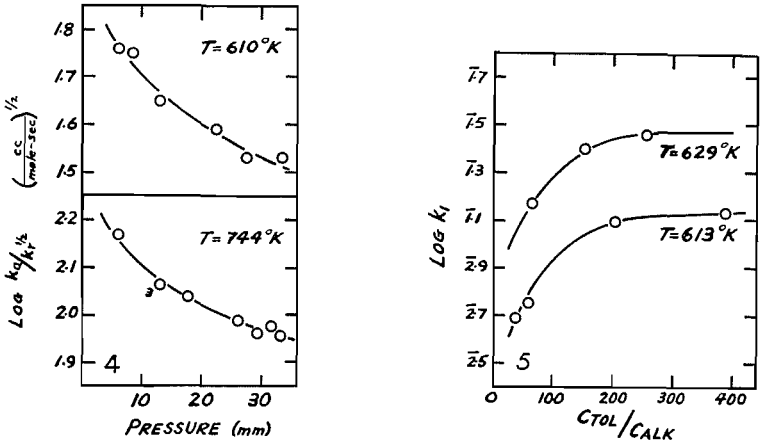

FIG. 4. Variation of $k_a/k_r^{1/2}$ with pressure at 610° K (first bond region) and 744° K (third bond region). Subscripts denote the number of runs averaged to obtain the given point.
FIG. 5. Variation of k_1 with the ratio of moles toluene to moles alkyl using fixed toluene concentrations.

pressure is similar to that previously observed (2–5) and may be attributed to the third body requirements of the methyl radical recombination reaction.

As shown in Fig. 5, the value of k_1 falls sharply when the toluene-to-alkyl ratio is decreased below 150. Values for k_3 are similarly affected. The Arrhenius curves shown in Fig. 1 were therefore plotted using only rate constants obtained in runs where the toluene-to-alkyl ratio was greater than 150. At 13.0 mm, the curves may be represented by:

$$\log_{10} k_1\ (\text{sec}^{-1}) = 15.72 - (47{,}200/2.303RT),$$

$$\log_{10} k_3\ (\text{sec}^{-1}) = 10.91 - (38{,}700/2.303RT).$$

The experimental evidence indicates that the activation energies may be approximately related to the bond strengths, although a rough estimate based on unimolecular pressure effects indicated that D_3 is about 2 kcal/mole greater than E_3. Thus $D[(CH_3)_2In—CH_3]$ equals 47.2 kcal/mole and $D[In—CH_3]$ equals 40.7 kcal/mole. The mean bond energy in trimethylindium is not known. However, comparison of neighboring methyl metallic alkyls indicate that $\bar{E}(In—CH_3)$ in trimethylindium is probably 41 ± 3 kcal/mole. Allowing limits of error of ±1 kcal/mole in D_1 and D_3 would give $D[CH_3In—CH_3]$ equal to 35 ± 5 kcal/mole, a value consistent with the proposed mechanism.

DISPLACEMENT OF C_4-HYDROCARBON MOLECULES ADSORBED ON PLATINUM[1]

S. AFFROSSMAN[2] AND R. J. CVETANOVIĆ
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received September 27, 1963

ABSTRACT

A special technique has been used in an attempt to determine the nature and the amount of the C_4-hydrocarbons desorbed by displacement with "poisons" (CO, CS_2) from the "active" sites of a platinum on asbestos hydrogenation catalyst. The "active" area of the catalyst determined in this way is found to decrease with increasing adsorption of the poison molecules, and is approximately related in the expected manner to the observed catalytic activity for butene hydrogenation. The likely nature of the adsorbed hydrocarbon species is discussed.

INTRODUCTION

Considerable progress has been made in recent years in the understanding of the mutually related processes of olefin hydrogenation, isomerization, and isotopic exchange on metallic catalysts (1). At the same time, a choice between the alternative mechanisms cannot be made with certainty and the overall situation in this respect is still far from being free from ambiguities. The present study has been carried out in an attempt to explore an experimental approach which would permit preferential detection of the molecules adsorbed on the "active" catalyst sites. A special technique has been employed using a flow system with gas chromatographic analysis at short intervals. Although it has been possible to carry out only an investigation of preliminary character, the technique appears capable of providing useful information and the results are therefore briefly reported here.

Removal of the molecules adsorbed in the course of the hydrogenation of butene on a platinized asbestos catalyst was attempted by displacement with catalyst poisons. For this purpose, use was made mainly of carbon monoxide and, to a smaller extent, of carbon disulphide. Since it has been shown that CO adsorbs only on metal surfaces and not on carrier (2, 3), the hydrocarbon molecules displaced from the surface by CO should also come only from the metal. As catalyst poisons have an immediate strong effect on the reaction rates, it may be assumed that initially they adsorb preferentially on active sites.

EXPERIMENTAL

Apparatus

The apparatus is shown schematically in Fig. 1. Greaseless stopcocks (Teflon needle valves, Fischer & Porter Co.) were used throughout. The reactor tube was attached to the system by small sections of Tygon tubing. The catalyst was held in place by clean glass wool. The gases coming from the reactor tube were split into two parts, one half going to a flowmeter and the other half to a gas sampling valve connected to a Perkin–Elmer 300 ft squalane capillary column and flame ionization detector. The back-pressure of carrier gas introduced into the system from the chromatography unit on rotating the gas sampling valve was thereby much reduced. The gas sampling valve was operated automatically by an air cylinder and timer, enabling the samples to be injected every minute into the nitrogen stream leading into the capillary column. The olefin used as reactant and the reaction products were all separated chromatographically within 1 minute. CS_2 was added to the system by allowing it to diffuse from the "poison tube" into the gas stream.

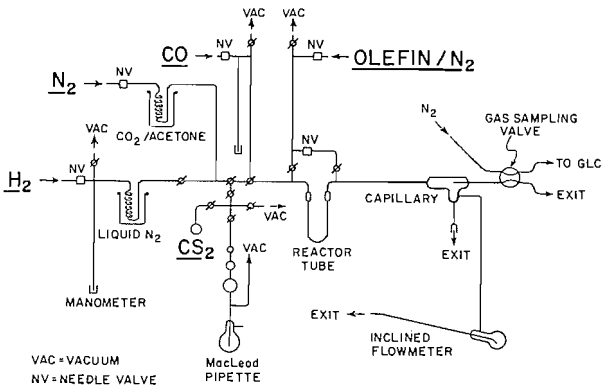

FIG. 1. Schematic diagram of the apparatus.

Materials

The catalyst was 5% Pt on asbestos (Matheson, Coleman & Bell Co.) and its weight was close to 0.03 g. Before each run, air was displaced from the apparatus by a stream of nitrogen. The catalyst was then pretreated with hydrogen for about 20 minutes before olefin was added. The BET surface area of the catalyst was close[3] to 11 m^2/g. Phillips research grade *trans*-butene-2 was used as reactant. A small amount of olefin was introduced into an empty cylinder and the pressure brought to 50 lb/in^2 with prepurified nitrogen. The gases were thoroughly mixed and this diluted olefin was used directly. In the experiments carried out, the partial pressure of olefin was varied from about 0.4 to 5 mm. The partial pressure of hydrogen was approximately 250 mm.

The nitrogen was a prepurified grade (Matheson Co.) and the only further treatment consisted of its passage through an acetone/CO_2 bath. Ultrapure hydrogen (Matheson Co.) was passed through a liquid nitrogen trap, and C.P. grade carbon monoxide (Matheson Co.) was used directly.

Procedure

After pretreating the catalyst with H_2, the olefin was introduced into the gas stream. Analysis of the products gave a measure of the activity of the catalyst as all runs were at one flow rate. Only *trans*-butene-2 and butane were detected when H_2 was present.

To measure the adsorption on the surface, the H_2 stream was first cut off; when no further reaction product was observed, the olefin stream was cut off as well. Only a N_2 stream remained at this stage, and the analysis showed only a decreasing amount of loosely held *trans*-butene-2. CO at a small partial pressure was then added continuously to the system. The following molecules were then observed: *trans*-butene-2, *cis*-butene-2, butane, butene-1. All except butane decreased rapidly in concentration with time. The effects of some alterations of this procedure will be indicated in the following section.

When CS_2 was used as a poison, a barely measurable amount was introduced into the "poison tube". The valve connecting this section to the main gas stream was then opened for a prescribed time: the amount of CS_2 diffusing into the gas stream was proportional to this time (as judged by its effect on the reaction).

It was found that CO was only a temporary poison but that CS_2, once adsorbed, was not easily removed.

RESULTS AND DISCUSSION

Most of the experiments were carried out at room temperature (25±2° C). The reaction was found to be first order in olefin and approximately zero order in H_2. This suggests that the rate-controlling process involves the adsorption of olefin at a low surface coverage on the active surface, as would be reasonable to expect at the very low olefin to hydrogen ratios used.

Table I shows the effect of altering the experimental conditions. Runs 1 and 2 provide evidence that during a reaction, in presence of H_2, the surface is only sparsely covered by olefin. In run 1, on cutting off H_2, adsorption of olefin immediately takes place. In run 2, passage of CO stops the reaction but does not displace any detectable quantity of olefin,

[3]*After outgassing for 17 hours at 0° C: 10.9 m^2/g; after outgassing for 36 hours at 125° C: 11.4 m^2/g. The areas are accurate to ±0.5 m^2/g. The authors are grateful to Mr. D. Kulawic for the surface area determinations.*

TABLE I

The effect of alterations in the experimental procedure (reaction of *trans*-butene-2 and H_2 in a N_2 carrier over Pt/asbestos at 0° C)

Run	Step 1: cut off	Step 2: cut off	Step 3: poison added	Molecules desorbed or adsorbed
1	H_2	—	—	Adsorption of olefin occurs
2	—	—	CO	None observed
3	H_2	—	CO	Butene-1 desorbed
4	H_2	Olefin	Small[a] CO	Butene-1 (mainly) desorbed
5	H_2	Olefin	Large[b] CO	Butene-1, *trans*-butene-2, *cis*-butene-2, butane, desorbed

[a]Approximately 1 ml (NTP) injected as a pulse.
[b]Approximately 1 ml (NTP) per minute, fed continuously until no further adsorption was detected.

in contrast to runs 3, 4, and 5. These last three runs show that only small amounts of CO are needed to poison the reaction, and that the olefin molecules adsorbed on cutting off H_2 give mainly butene-1 when displaced. Figure 2 shows the manner of desorption of the

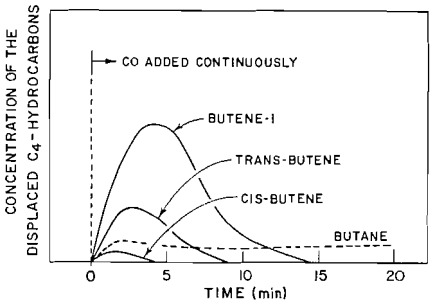

FIG. 2. Displacement of C_4-hydrocarbons from the catalyst by carbon monoxide. (The graph represents a typical example. Ordinate scale is in arbitrary units.)

butenes and butane as a result of displacement by CO (added continuously at a small partial pressure).

When carbon monoxide is added during a reaction, as in run 2 of Table I, it rapidly inhibits the reaction. It would therefore be expected that under conditions of present experiments the hydrocarbon molecules adsorbed on the active sites would be rapidly displaced from the catalyst. As shown in Fig. 2, the butenes desorb in the expected manner, but not the butane. Butane desorbs for a considerable time and when smaller partial pressures of CO are used, the rate of butane desorption decreases while the butenes are unaffected. The mechanism responsible for such behavior of butane is not clear[4] although there are indications that it does not contribute significantly to butene hydrogenation under reaction conditions.[5] For the latter, the butenes desorbed from the surface should

[4]*Perhaps slow displacement of the more strongly adsorbed butyl radicals is involved.*
[5]*When the catalyst is poisoned by injecting a small amount of* CS_2 *or* CO *into the hydrogen stream before the olefin is admitted, trans-butene-2 fed subsequently into the gas stream is not hydrogenated. Nevertheless, when the sequence of steps as in run 5 of Table I is then applied, butane is desorbed from the surface but not butene-1.*

provide an appropriate measure of the active surface of the catalyst. Since butene-1 forms the greater part of the butenes desorbed,[6] its amount could be used as an approximate indicator of the number of active sites.

The fact that butene-1, thermodynamically the least stable isomer, forms the major part of the desorbed butenes is of interest. A selective double-bond migration and a stereoselective formation of *cis*-2-butene have been repeatedly observed in recent years in the catalytic isomerization of *n*-butenes (4–10). Selective production of butene-1 is evidently also a part of the process of butene desorption by catalyst poisons under conditions of present experiments. Furthermore, isomerization of butene-2 to butene-1, i.e. double-bond migration, cannot involve in this case a concerted ("hydrogen switch") mechanism (9, 11), involving interaction of chemisorbed hydrogen atoms with the vapor phase or physically adsorbed molecules of butene which do not become chemisorbed at any time during the process.

It is also of interest that when butene-1 was substituted for *trans*-butene-2 as the initial reactant under otherwise identical conditions, the main olefin desorbed by displacement with CO was still butene-1. In terms of the Horiuti–Polanyi mechanism (1, p. 254) this would suggest that the "half-hydrogenated" species is the same in the two cases, perhaps the 2-adsorbed *n*-butane (i.e. the chemisorbed *sec*-butyl radical). If this is true, this species could give either butene-2 or butene-1 on desorption by CO displacement. That it gives predominantly the thermodynamically less stable butene-1 is perhaps due to the steric factors, since a vicinal H atom has to be donated to the surface prior to the re-formation of the double bond.

If there is a correlation between the active area of the catalyst and the amount of butene-1 desorbed by CO displacement, as suggested above, there should also be a proportionality between the latter and the catalyst activity.

The specific reaction rate is given by the equation

$$k = \frac{F}{V.A} \ln \frac{1}{1-Q} \qquad [1]$$

where F is the flow rate, V the reactor volume, A the active area of the catalyst, and Q the fraction of olefin reacted. This can be written in the form

$$\log u = 2 - \frac{k.V.A}{2.3\,F} \qquad [2]$$

where u is the percentage unchanged olefin. In this equation V is unknown but is constant for a given sample of catalyst. Therefore, at a constant flow rate,

$$\log u = 2 - k^*A. \qquad [3]$$

The percentage unchanged olefin, u, is obtained from the gas chromatographic analysis just before the H_2 is cut off. The active area, A, is assumed to be, to a good approximation, proportional to the amount of butene-1 desorbed on displacement with CO.

If the active area of a given sample of the catalyst can be varied by some means, equation [3] predicts linear dependence of $\log u$ on A. This, however, would be strictly true only for a homogeneous catalyst; if the sites are non-uniform and A decreases, for example, as a result of preferential deactivation of the sites of high activity (those on which the hydrogenation proceeds more rapidly) the expected plot would be concave to

[6]*Cis-butene-2 is formed in negligible amounts and trans-butene-2 could conceivably be desorbed also from the catalyst support and the reactor walls, since it is the original reactant.*

the ordinate. If, on the other hand, the sites of lower activity are initially deactivated preferentially, the plot would be convex to the ordinate. It should also be remembered that the effect of poisons on a surface is not necessarily only a pure blocking of sites (12, 13). Furthermore, the reaction conditions under which the activity is measured are not necessarily closely comparable with the conditions in the displacement experiments. The catalytic hydrogenation of olefins is of considerable kinetic complexity and, also, the H_2 content of a catalyst appears to affect its activity (14). In view of these difficulties, and the fact that measurements of this kind are experimentally exacting, only an approximate relation of the kind predicted by equation [3] may be hoped for.

The reaction was found to be slowly self-poisoning, leading to gradual decrease in catalyst activity. Decrease in activity could also be achieved by adding very small amounts of CS_2, and this was the main method used to reduce the active area of a catalyst sample.

Figure 3 shows some of the results obtained on decreasing the active area of the catalyst
